with styrene and substituted styrenes did occur, it was hampered by competing 5-*exo*-*trig* cyclizations, which took place upon the consecutive palladium-catalyzed alkenylation of the intermediate *o*-bromostyrene subunits on the central benzene ring.[5] This led to a variety of benzylideneindane and benzylindene by-products that were isomeric with and, therefore, not easily separable from the hexastyrylbenzenes.[6]

Both multiple coupling of vicinal oligohalobenzene derivatives[7] and the subsequent five-membered ring closing reactions[5] are favored only under modified Jeffery conditions[8] for the Heck reaction.[9] We were, therefore, intrigued to find out whether other types of palladium-catalyzed cross-coupling reactions, such as Suzuki[10] and Stille couplings,[11] might be feasable for preparing hexaalkenylbenzene derivatives.[12, 13]

Sixfold Suzuki alkenylation of hexabromobenzene (**1**) with **2a**, prepared by hydroboration of 3,3-dimethyl-1-butyne (*tert*-butylacetylene) with catecholborane,[14] under typical conditions ($[PdCl_2(PPh_3)_2]$, NaOH, toluene/THF 1/1) gave hexakis(3,3-dimethyl-1-butenyl)benzene (**3a**) as a colorless crystalline material [Eq. (1); Table 1]. Under the same conditions, reaction

a	*t*Bu	A	73
b	nC_7H_{15}	A/B	0[b]
c	Ad	C	6[c]

[a] A: $[PdCl_2(PPh_3)_2]$, NaOH, toluene/THF (1/1), 100 °C, 24 h; B: $[PdCl_2(dppf)]$, NaOH, toluene/DMF (1/1), 80 °C, 24 h; C: [*trans*-di(*μ*-acetato)bis[(di-*o*-tolylphosphano)benzyl]palladium(II)] [15], NaOH, toluene, 110 °C, 2 d; dppf = 1,1′-bis(diphenylphosphanyl)ferrocene. [b] Mixture of debrominated oligononenylbenzenes. [c] Additional 6% pentakis(adamantylethenyl)benzene.

of **1** with **2b** did not yield the sixfold coupling product **3b**, not even with $[Pd(dppf)Cl_2]$ as catalyst, which is known to accelerate reductive elimination in R_2Pd intermediates (R = alkyl, aryl).[16] Surprisingly, the bulky adamantyl derivative **2c** gave the highly congested **3c** (albeit in only 6% yield) when the palladacycle prepared from $Pd(OAc)_2$ and tris(*o*-tolyl)phosphane[15] was applied as the catalyst.

Since hydroboration of trimethylsilylacetylene (**4d**) with catecholborane led to a practically inseparable mixture of α- and β-(trimethylsilylethenyl)borole, the Suzuki coupling was not favorable for accessing the trimethylsilyl-substituted analog of **3a**. However, **5d**[17] could be readily prepared by hydrostannylation of **4d** (97% yield, *E*:*Z* = 9:1) and coupled to **1** six times in the presence of a palladacycle catalyst[15] to give hexakis(trimethylsilylethenyl)benzene (**3d**) in 41% yield (Table 2). This sixfold Stille coupling[11] was also successful with (*E*)-(2-*tert*-butylethenyl)tributylstannane, but the yield of **3a** (35%) was lower than for the sixfold Suzuki coupling.

Crystal structure analysis of **3a** and its trimethylsilyl analog **3d**[18] gave a clue as to why only these highly crowded molecules are formed in good yields. Both molecules exhibit approximate

[a] D: [*trans*-di(*μ*-acetato)bis[(di-*o*-tolylphosphano)benzyl]dipalladium(II) [15], toluene. [b] According to the ^1H NMR spectrum the crude product contained **3c** and pentakis[2-(1′-adamantyl)ethenyl]benzene; purification attempts failed.

C_6 symmetry in the crystal, and all six alkenyl groups are arranged on one side of the central ring like the blades of a propeller (Figure 1).[19] In **3a** the torsional angles of the six alkenyl groups out of the central plane vary from 47.2(4) to 57.2(3)°

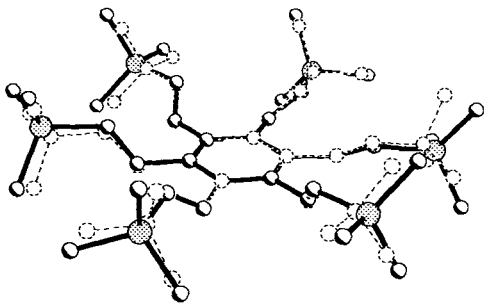

Figure 1. Crystal structures of **3a** and **3d** as superimposed ball-and-stick plots to show the differences; shaded balls represent Si atoms, and the rest carbon [18].

with an average of 51(3)°. In **3d** this angle is slightly smaller [44.3(4)–54.9(4), av 49(4)°], which is in accord with the longer bond length between the ethenyl C and Si atoms. The shortest nonbonding distances between hydrogen atoms on two adjacent *tert*-butyl or trimethylsilyl groups in **3a** and **3d** are around 2.5 and 2.6 Å, respectively, which are close to the sum of two van der Waals radii of hydrogen.[21] This suggests that an attractive van der Waals interaction might be operating as a self-organization principle during the six-step coupling sequence and, thus, favor the formation of the highly ordered molecules. The C_6-symmetrical arrangement of all six ethenyl groups around the ring is also a feature of the parent hexaethenylbenzene in the crystal;[12a] this indicates that there may be an additional π-stacking effect favoring the one-sided orientation. According to molecular mechanics calculations (MM2-ERW and MM3 programs) for **3a**, the *all-syn* conformation is 5.5 kcal mol^{-1} more favorable than one in which alternating groups are rotated above and below the ring.[22] With six *t*-butyl groups, **3a** adopts an interesting bowl shape, which may enable it to form host–guest complexes with appropriate substrates (Figure 2).

The major absorption in the UV spectrum of **3a** at λ = 262.3 nm (ε = 53600) is almost the same as that of the parent compound.[23] The oxidation potential E^0_{Ar} = 0.81 V vs. ferrocene/Fe^+ (corresponding to E^0_{Ar} = 1.21 V vs. NHE) as measured by cyclic voltammetry[24] is considerably lower than that of hexaethylbenzene.[25] Treatment of **3a** with $[Cr(NH_3)_3(CO)_3]$ in dioxane at 100 °C resulted in the bright yellow tricarbonylchromium complex **6** (62%).

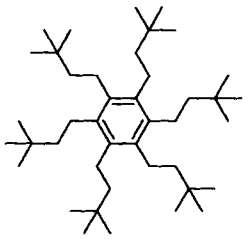
6



7

Catalytic hydrogenation of **3a** in hexane over Pd/C proceeds smoothly to hexakis(3,3-dimethylbutyl)benzene (**7**, 89% yield). This indicates that, at least in solution, the six unsaturated arms in **3a** have more conformational flexibility than the crystal structure suggests. Otherwise they could not be properly attached to the catalyst surface and accessible to the activated hydrogen molecules. Interestingly, **7** has approximate D_{3d} symmetry in the crystal, and the six saturated *tert*-butylethyl groups are alternatingly above and below the central plane (Figure 3).[19] This is typical for hexaalkylbenzene derivatives[1] and reproduced by molecular mechanics calculations, which indicate an energetic preference of 12.3 kcal mol^{-1} for this conformation over that with all groups on one side of the ring.[22] In the crystal **7** packs in columns, and the *tert*-butylethyl groups of each two adjacent molecules are staggered. Whether this leads to interesting charge-transfer phenomena in doped crystals remains to be seen.

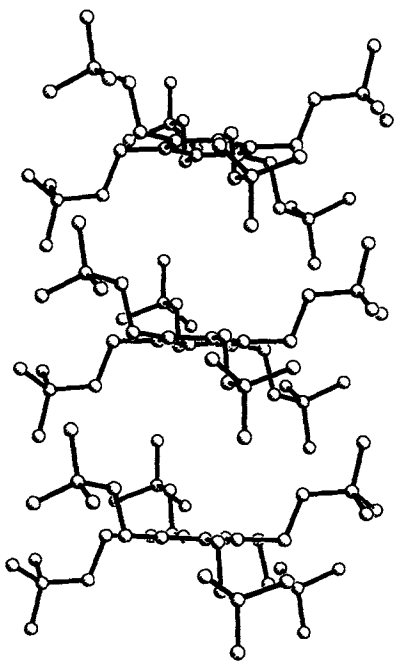


Figure 3. Structure of **7** and packing of the molecules in the crystal [19]; hydrogen atoms have been omitted.

Experimental Section

3a: A solution of **1** (1.00 g, 1.81 mmol) in a mixture of anhydrous toluene and anhydrous THF (50 mL each), which had been flushed with argon for 5 min, was treated with $[PdCl_2(PPh_3)_2]$ (0.36 g, 0.51 mmol), **2a** [14] (2.45 g, 12.1 mmol), and powdered NaOH (1.30 g, 32.5 mmol) and heated under an argon atmosphere at 100 °C for 24 h. After the mixture had cooled to room temperature, it was treated with 3 M NaOH (16 mL) and 30% hydrogen peroxide (2 mL) and stirred at room temperature for 1 h. The organic layer was then separated, washed with 3 M NaOH (5 × 10 mL), and dried ($MgSO_4$). The solvent was removed under reduced pressure, and the residue purified by chromatography on silica gel with pentane as eluent. Recrystallization from hexane/ethanol afforded **3a** (0.761 g, 73%) as colorless crystals, m.p. = 202 °C. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 6.47 (d, J = 16.5 Hz, 6H), 5.73 (d, J = 16.5 Hz, 6H), 1.18 (s, 54H); ^{13}C NMR (75.5 MHz, $CDCl_3$, additional DEPT): δ = 145.48 (+), 134.83 (C_{quat}), 124.72 (+), 33.79 (C_{quat}), 29.65 (+).

3d: Colorless solid, m.p. = 227–230 °C. ^{1}H NMR (250 MHz, $CDCl_3$): δ = 6.86 (d, J = 19.6 Hz, 6H), 5.63 (d, J = 19.6 Hz, 6H), 0.12 (s, 54H); ^{13}C NMR (75.5 MHz, $CDCl_3$, additional DEPT): δ = 143.91 (+), 137.05 (+), 135.79 (C_{quat}), −1.10 (+).

First Structural Characterization of a Benzophenone Ketyl Complex**

Zhaomin Hou,* Xueshun Jia, Mikio Hoshino, and Yasuo Wakatsuki

Although the formation of ketyls by one-electron reduction of ketones has been known for more than a hundred years,[1, 2] structurally characterized examples of this important class of highly reactive species remain very rare and are still limited solely to the fluorenone ketyl species that were recently isolated in our laboratories.[3] Isolation and structural characterization of new ketyl complexes continue to be of great importance and interest. Benzophenone ketyl is among the best known and most widely used ketyls.[1, 2, 4] Previous attempts to isolate a benzophenone ketyl species by utilization of low-valent titanium and lanthanide reducing agents were not successful.[4–6] Reaction of $[CpTiCl_2]$ with benzophenone in THF/ether was reported to give rapidly the corresponding pinacol-coupling product.[6] The use of a sterically demanding titanium(III) reductant such as $[Ti(OSitBu_3)_3]$ suppressed the pinacol-coupling reaction, but benzophenone dimerized by coupling of the *para*-carbon atom of a phenyl group with the carbonyl carbon of another molecule.[5f] Reactions of benzophenone with sterically demanding lanthanide reducing agents such as $[Ln(OAr_2(L)_n]$ (Ln = Sm, Yb; Ar = 2,6-tBu_2-4-MeC_6H_2); L = thf, hmpa),[3a, b] $[R_2Sm]$ (R = BH(3,5-dimethylpyrazolyl)$_3$),[7] or Ln/hmpa[3d] did not afford structurally characterizable benzophenone ketyl species either, but resulted in hydrogen abstraction in some cases, although many of these reducing agents have been successfully used for the isolation of fluorenone ketyl complexes.[3] All these results show that benzophenone ketyl species are extremely reactive and much more unstable than the corresponding fluorenone ketyl species. After the survey of several different types of reducing agents, we successfully isolated structurally characterizable benzophenone ketyl species by binding them to a calcium(II) ion containing hmpa ligands. In this communication, we report the isolation and structural characterization of a bis(benzophenone ketyl)calcium complex, which constitutes the first structurally characterized benzophenone ketyl complex, as well as the first structurally characterized complex of an alkaline earth metal with a ketyl.[8, 9] Its reaction with 2-propanol is also described.

In the presence of three equivalents of hexamethylphosphoric triamide (HMPA), reaction of fresh calcium chips with two equivalents of benzophenone in THF gradually gave a blue solution, which after filtration, concentration, and addition of hexane, afforded blue blocks of **1** in 77% yield of isolated product (Scheme 1). The UV/Vis ($\lambda = 635$ nm, $\varepsilon = 3.8 \times 10^3$ M^{-1} cm^{-1})[5c] and ESR ($g = 2.0028$) spectra of **1** in THF are very similar to those reported for the benzophenone ketyl species generated in situ.[5]

An X-ray analysis has shown that **1** is a bis(benzophenone ketyl)calcium(II) complex, which possesses a distorted trigonal-bipyramidal structure with one hmpa and two ketyl ligands in equatorial and two hmpa ligands in apical positions (Figure 1).[10] The two ketyl ligands form an O-Ca-O angle of 114.2(4)°, and the distance between the two radical carbon atoms (C(1) and C(14)) is 5.99 Å. The overall structure of **1** is similar to that of the calcium(II) aryloxide complex $[Ca(OAr)_2(thf)_3]$ (Ar = 2,6-tBu_2-4-MeC_6H_2).[11] The bond lengths of the Ca–O(ketyl) bonds in **1** (av 2.20(1) Å) are also similar to those of the Ca–OAr bonds in $[Ca(OAr)_2(thf)_3]$ (av 2.206(6) Å).[11, 12] The C–O bonds of the benzophenone ketyl ligands in **1** are significantly longer (av 1.31(2) Å) than that of free benzophenone (1.23(1) Å),[13] but comparable with those of fluorenone ketyls (1.27–1.31 Å).[3] As in fluorenone ketyls, the radical carbon atoms C(1) and C(14) in **1** are nearly coplanar with the atoms around them (d_{max} from the best least-squares plane smaller than 0.03 Å) and are still sp^2-hybridized. However, the planes defined by O(1)-C(1)-C(2)-C(8) and O(2)-C(14)-C(15)-C(21) are not coplanar with any of the phenyl rings. The dihedral angles formed by the O(1)-C(1)-C(2)-C(8) plane and the C(2)–C(7) and C(8)–C(13) phenyl rings are 16° and 30°, respectively, and those formed by the O(2)-C(14)-C(15)-C(21) plane and the C(15)–C(20) and C(21)–C(26) phenyl rings are 20° and 30°, respectively. This is in sharp contrast to fluorenone ketyl in which all the atoms lie in the same plane.[3] The lack of planarity in the whole benzophenone ketyl

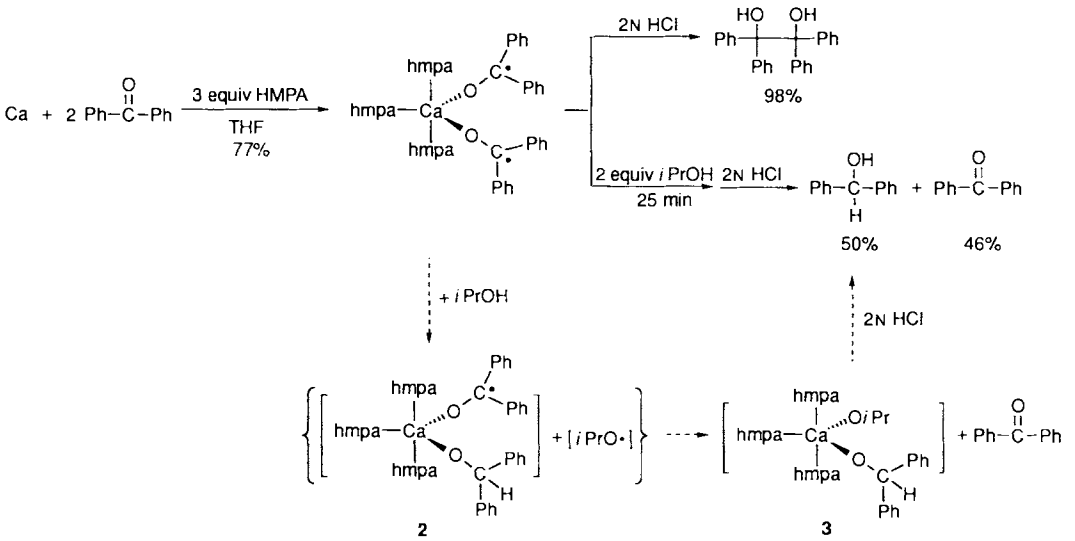

Scheme 1. Synthesis of **1** and mechanism of its reaction with 2-propanol.

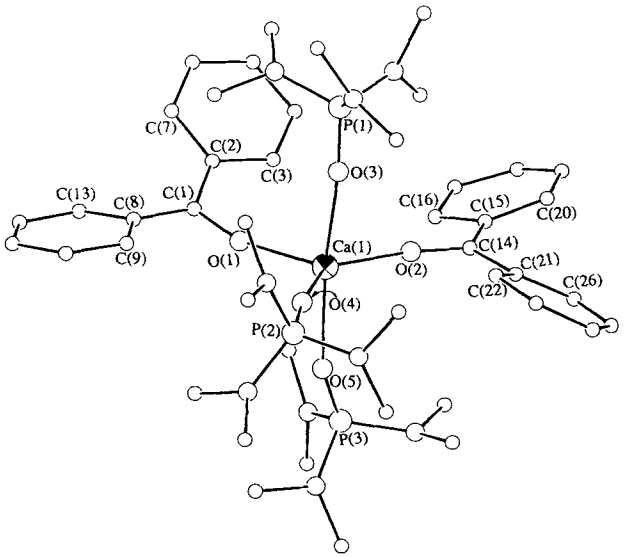

Figure 1. X-ray structure of **1**. Selected bond lengths (Å) and angles (°): Ca(1)–O(1) 2.187(9), Ca(1)–O(2) 2.206(10), Ca(1)–O(3) 2.315(9), Ca(1)–O(4) 2.286(8), Ca(1)–O(5) 2.314(10), O(1)–C(1) 1.31(1), O(2)–C(14) 1.31(2); O(1)-Ca(1)-O(2) 114.2(4), O(1)-Ca(1)-O(3) 95.0(4), O(1)-Ca(1)-O(4), 110.2(4), O(1)-Ca(1)-O(5) 94.5(4), O(2)-Ca(1)-O(3) 89.4(4), O(2)-Ca(1)-O(4) 135.6(4), O(2)-Ca(1)-O(5) 90.0(4), O(3)-Ca(1)-O(4) 86.2(3), O(3)-Ca(1)-O(5) 169.8(4), O(4)-Ca(1)-O(5) 87.1(4), Ca(1)-O(1)-C(1) 162.5(8), Ca(1)-O(2)-C(14) 160.0(10).

unit makes it difficult to stabilize the radical through $p_z-\pi$ orbital interactions with the phenyl groups, and thus explains why benzophenone ketyl is much more reactive than fluorenone ketyl.

Hydrolysis of **1** gave the coupling product, benzopinacol, almost quantitatively (Scheme 1). However, reaction of **1** with two equivalents of 2-propanol in THF followed by hydrolysis afforded benzhydrol and benzophenone in 50% and 46% yields, respectively (Scheme 1). This reaction could be explained by the mechanism shown in Scheme 1. Hydrogen radical abstraction by one of the two ketyls in **1** from 2-propanol[14] gives the ketyl/diphenylmethoxide **2** and the radical *i*PrO•. The subsequent rapid oxidation of the ketyl **2** by the inner-sphere radical *i*PrO• affords benzophenone and **3**, which yields benzhydrol after hydrolysis.

Experimental Section

Typical procedure for the synthesis of **1**: Under argon atmosphere, calcium chips (28 mg, 0.7 mmol) were stirred with CH_2I_2 (2 mol%) in THF (1 mL) for 2 h to activate the metal surface. Hexamethylphosphoric triamide (hmpa; 0.36 mL, 2.1 mmol) was then added by syringe. Addition of a THF solution of benzophenone (255 mg, 1.4 mmol) yielded a blue mixture within a few minutes. After being stirred at room temperature overnight, the blue solution was filtered and concentrated under reduced pressure. Addition of hexane precipitated the benzophenone ketyl complex **1** as blue blocks (510 mg, 0.54 mmol, 77% yield). Anal. calcd for $C_{44}H_{74}N_9O_5P_3Ca$: C 56.09, H 7.92, N 13.38; found: C 55.81, H 8.03, N 13.33.

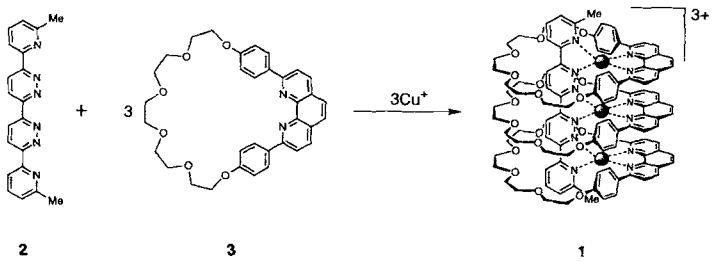
Multicomponent Self-Assembly: Generation and Crystal Structure of a Trimetallic [4]Pseudorotaxane

Paul N. W. Baxter, Hanadi Sleiman, Jean-Marie Lehn,* and Kari Rissanen

The generation of threaded molecular entities such as pseudorotaxanes, rotaxanes, and catenanes is currently the subject of considerable interest owing to the intriguing synthetic and structural issues posed by such systems.[1, 2] Recent developments in this field include potential applications for materials science and the design of supramolecular devices[3] such as novel polymer composites[4] and simple mechanical molecular processes.[5] In the case of rotaxanes initial synthetic strategies focused on statistical methods of preparation, but more recently supramolecular approaches utilizing intermolecular interactions—such as aromatic attractive forces,[2, 6] hydrogen bonding,[7] and metal ion coordination[2, 8]—have been found to be most efficient for threaded molecules. Rotaxanes and pseudorotaxanes that incorporate metal ions represent a particularly interesting class of supramolecular species that might display a rich variety of physicochemical properties such as redox, optical, and magnetic behavior. Metal ion directed threading may also be used for constructing linear arrays of metal ions with precisely defined interionic distances, for example, inorganic rack-type architectures.[9] This approach may additionally provide access to self-assembled pseudorotaxane racks that incorporate linear strings of metal ions in oxidation states not normally accessible in the presence of nonmacrocyclic ligand analogues due to dissociative instability.

We here report the high-yield formation (Scheme 1) and X-ray crystallographic investigation of the trinuclear [4]pseudorotaxane rack **1**. In previous work on metallorotaxanes incorporating linear oligobipyridines as the central unit,[10] the metal ions were alternately situated on opposite sides of the ligand rack in a *trans* conformation in the solid state. In contrast,



Scheme 1. Self-assembly of the tricopper pseudorotaxane [3]rack **1**.

2, which incorporates pyridazine metal ion bridging units, is expected to yield a pseudorotaxane rack in which the metal ions are situated on the same side, that is, an all *syn* relationship with shorter internuclear separations. This structural modification may increase electronic communication between the metal centers and render these systems more attractive candidates for molecular-device components.

Mixture of **2**, **3**, and $[Cu(MeCN)_4]PF_6$ in a 1:3:3 stoichiometric ratio in CH_2Cl_2/MeCN (1/1) resulted in the formation of **1** in greater than 80% yield. The rigid-rod ligand **2** and the macrocyclic ligand **3** were prepared as previously reported.[11, 12] The identity of the reaction product was established with ^1H and ^{13}C NMR spectroscopy, FAB-MS (Table 1), and X-ray crystallography. The ^1H NMR spectrum was particularly informative and showed **3** to be in two different chemical environments. For example, the *ortho* and *meta* phenyl-ring

Table 1. Physical and spectroscopic data for $\mathbf{1}(PF_6)_3$.

^1H NMR (CD_3NO_2, 500 MHz, 20 °C): $\delta = 9.212$ (d, J(H3′,H4′) = 9.3 Hz, **2**-H3′), 9.159 (d, J(H4′,H3′) = 9.3 Hz, **2**-H4′), 8.527 (d, J(H3,H4) = 8.1 Hz, **2**-H3), 8.192 (d, J(H4,H3) = J(H7,H8) = 8.3 Hz, $\mathbf{3}_{outer}$-H4/7), 8.153 (t, J(H3,H4,H5) = 7.9 Hz, **2**-H4), 8.096 (d, J(H4,H3) = J(H7,H8) = 8.4 Hz, $\mathbf{3}_{inner}$-H4/7), 7.908 (s, $\mathbf{3}_{inner}$-H5/6), 7.812 (s, $\mathbf{3}_{outer}$-H5/6), 7.498 (d, J(H3,H4) = J(H8,H7) = 8.3 Hz, $\mathbf{3}_{outer}$, H3/8), 7.444 (d, J(H5,H4) = 7.7 Hz, **2**-H5), 7.284 (d, J(H3,H4) = J(H8,H7) = 8.3 Hz, $\mathbf{3}_{inner}$-H3/8), 6.678 (d, J(*ortho*-H,*meta*-H) = 8.6 Hz, $\mathbf{3}_{outer}$-*ortho*-H), 6.422 (d, J(*ortho*-H,*meta*-H) = 8.7 Hz, $\mathbf{3}_{inner}$-*ortho*-H), 6.215 (d, J(*meta*-H,*ortho*-H) = 8.8 Hz, $\mathbf{3}_{inner}$-*meta*-H), 6.171 (d, J(*meta*-H,*ortho*-H) = 8.7 Hz, $\mathbf{3}_{outer}$-*meta*-H), 4.125–3.600 (m, $\mathbf{3}_{inner/outer}$-$H(CH_2)$), 1.711 (s, **2**-CH_3). Figure 1. Crystal structure of **1**. Left: Side view; the central ligand **2** is highlighted in black (hydrogen atoms of ligands **3** removed for clarity). Center: Ball-and-stick representation as viewed down the long axis of **2**; the inner macrocycle **3** is highlighted in black (all hydrogen atoms removed for clarity). Right: CPK representation, side view. Labeling of atoms in the structure on the left from bottom to top: Cu1 to Cu3, N_1 to N_6, C–C bonds C_6–C_7, C_{10}–C_{11}, and C_{14}–C_{15} between successive rings.

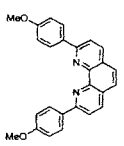
protons of **3**, which appeared as two doublets, were split into two groups in a 2:1 ratio. Also the signals corresponding to the phenanthroline-ring protons (H3,8; H4,7; H5,6) were each divided into two sets in a 2:1 ratio. This corresponds to two outer and one inner units of **3**. The *ortho* phenyl-ring protons of the inner ligand **3** experience the greatest shielding, as expected for protons buried deepest within the interior of **1**. The protons of **2** on the other hand appear as a set of five signals, which indicates that **2** is in a single chemical environment. This then provides a ligand ratio $\mathbf{2}$:$\mathbf{3}_{outer}$:$\mathbf{3}_{inner}$ of 1:2:1. The FAB-MS of a CH_2Cl_2 solution of the reaction product displayed three peaks at $m/z = 2520.6$, 2375.6, and 2230.6 corresponding to the cations $\{[Cu_3(\mathbf{2})(\mathbf{3})_3](PF_6)_2\}^+$, $\{[Cu_3(\mathbf{2})(\mathbf{3})_3](PF_6)\}^+$, and $\{[Cu_3(\mathbf{2})(\mathbf{3})_3]\}^+$. No peaks higher than $m/z = 2520.6$ were observed, but bands at lower values that are characteristic of partially dethreaded species were present.

An X-ray crystallographic investigation of **1** confirmed that its structure was that of a trinuclear [4]pseudorotaxane rack (Figure 1).[13] As defined by its van der Waals surface, the cation is approximately a cube of dimensions 16 × 16 × 15.5 Å. Three macrocyclic ligands **3** are threaded onto a single ligand **2**, which passes centrally through the internal cavity of each macrocycle. The array of three Cu^+ ions, each coordinated to **2** and a unit of **3**, is curved (Cu1-Cu2-Cu3 160.69°) as a result of the curvature of **2** itself.[16]

The pseudometallorotaxane **1** self-assembles by correct association of seven particles by a metal ion mediated threading of three units of **3** onto **2**. Ten aromatic edge-to-face and face-to-face attractive interactions also help to stabilize the resulting superstructure. Further evidence for the stability of **1** was provided by UV/Vis spectroscopic dilution experiments, which demonstrated that **1** showed no appreciable dethreading in ten days down to a concentration of 10^{-4} M in CH_2Cl_2. To establish whether it was possible to generate a rack of composition $[Cu_3(\mathbf{2})(\mathbf{4})_3](PF_6)_3$, a control experiment was performed in which **2**, **4**, and $[Cu(MeCN)_4]PF_6$ (1:3:3) were combined under conditions identical to those for the preparation of **1**. The ^1H NMR spectrum of the reaction mixture after 96 h showed it to consist of $[Cu(\mathbf{4})_2]^+$ and a complex mixture of species comprising **2**, **4**, and Cu^+. This demonstrates that pseudorotaxane self-assembly is essential for the formation of multinuclear Cu^I racks.



4

The successful generation of a trimetallic rack incorporating metal ions in close proximity has been achieved. This design principle should be extendable to the preparation of multimetallic racks that are inaccessible by sequential synthesis (although this is possible for ruthenium(II) [2]- and [3]racks)[9] or by self-assembly from mixtures of nonmacrocyclic ligand components. Metallopseudorotaxane racks such as **1** may display novel electro-, photo-, and surface chemical properties, and their incorporation into more complex supramolecular assemblies may be envisioned.

Experimental Section

CH_2Cl_2 (2 mL) was added with a syringe to a mixture of **2** (5.0 mg, 1.47×10^{-5} mol), **3** (25.0 mg, 4.41×10^{-5} mol), and $[Cu(MeCN)_4]PF_6$ (16.5 mg, 4.42×10^{-5} mol) under an argon atmosphere, and the dark brown solution stirred at ambient temperature for 3 h. MeCN (2 mL) was then added with a syringe, and the reaction mixture heated at 60 °C with stirring for a further 96 h. After the mixture had cooled to room temperature, all solvent was removed under vacuum, and the residue redissolved in CH_2Cl_2 (3 ml), filtered through a microporous filter, and the solvent again removed under vacuum to give a dark brown, glassy solid. A ^1H NMR spectrum (CD_3NO_2) of the product showed it to be $\mathbf{1}(PF_6)_3$ (≥80% yield) [17]. Final purification was achieved by recrystallization from $MeNO_2$/benzene by liquid–liquid diffusion. The crystals that formed over a three-month period were isolated by vacuum filtration, washed with benzene, and dried in the air and then at 90 °C/2×10^{-6} mm Hg for 48 h. Yield: 0.019 g (49%) $\mathbf{1}(PF_6)_3$ as small, dark brown-red cubes.

[13] Crystal structure data for $[\mathbf{1}(H_2O)](PF_6)_3 \cdot 3C_6H_6 \cdot CH_3NO_2$, $M_r = 2979.346$ (the crystallographically determined value for M_r was 2977.24, since the positions of the H atoms of the included water molecules could not be located or calculated), triclinic, space group $P\bar{1}$ (no. 2), $a = 18.239(3)$, $b = 19.766(2)$, $c = 20.572(2)$ Å, $\alpha = 69.53(1)$, $\beta = 83.85(1)$, $\gamma = 85.22(1)^\circ$, $V = 6915(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.433$ g cm^{-3}, $F(000) = 3079$, $T = 296 \pm 1$ K. Crystals of **1** were grown by slow diffusion of benzene into a CH_3NO_2 solution of the complex at 293 K. Data was collected on a crystal of dimensions $0.40 \times 0.40 \times 0.50$ mm (Enraf-Nonius CAD4 diffractometer, $\lambda(Mo_{K\alpha}) = 0.7107$ Å, graphite monochromator). Of 17515 collected reflections 16859 were unique ($R_{int} = 0.007$), $\omega/2\theta$-scan mode, $2\theta = 44^\circ$ (h: $0 \rightarrow 19$, k: $-20 \rightarrow 20$, l: $-21 \rightarrow 21$); 10912 reflections with $I > 3\sigma I$ were used for refinement. Lp and absorption corrections based on psi scans were applied, $\mu(Mo_{K\alpha}) = 0.585$ mm^{-1}. The structure was solved by direct methods (SHELXS) [14] and subjected to block-matrix refinement in seven blocks [15]. The H atoms were calculated at theoretical positions (C–H 1.0 Å, isotropic temperature factor 8.0 Å^2) and included in the final structure-factor calculations but not refined; F_0-parameter ratio = 6.09, final R value 0.055, $R_w = 0.064$ for 1793 parameters: $w = w'[1.0 - (\Delta F/6\sigma F)^2]^2$, where w' is the Chebychev polynomial for F_c with three coefficients (12.9, −2.42, and 10.4); $S = 1.15$, convergence, max. shift/error < 0.08. The final difference map displayed no electron density higher than 0.77 e Å^{-3}. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100241. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[16] The deviation of the array of three Cu^+ ions from linearity arises from the curvature of **2**, which in turn results from the summed effects of two types of distortions. Firstly, when viewed perpendicular to its mean plane, the six nitrogen atoms of **2** describe a shallow arc, which stems from the fact that the pyridazine ring is not a regular hexagon but contracted along the N=N bond. Secondly, the aromatic rings of **2** are bent and rotated with respect to each other through each interring bond, which causes **2** to adopt a twisted crescent shape when viewed along the ligand mean plane perpendicular to its long axis (torsion angles N1-C6-C7-N2 14.36, N3-C10-C11-N4 12.84, N5-C14-C15-N6 19.44°). A striking feature of the complex is the relative arrangement of the phenanthroline moieties along **2** (Figure 1b). The three phenanthrolines from **3** are not eclipsed, but substantially staggered with respect to each other (torsional angles D1-Cu1-Cu2-D2 35.56, D2-Cu2-Cu3-D3 76.90, D1-Cu1-Cu3-D3 39.07°; D1, D2, and D3 are the centroids of the central fused C_6 rings in the phenanthrolines coordinated to Cu1, Cu2, and Cu3 respectively). When viewed along the long axis of **2**, one outer (coordinated to Cu3) and the inner phenanthroline units lie on opposite sides of the mean plane through **2**, whereas the remaining outer phenanthroline sits approximately centrally. Due to the relatively short distances between the copper ions (Cu1–Cu2 3.597, Cu2–Cu3 4.268, Cu1–Cu3 7.753 Å), the phenyl rings of the three ligands **3** cannot lie simultaneously coplanar to **2**. The relative staggering of the macrocyclic ligands about **2** is therefore a possible way of minimizing steric congestion between the phenyl rings. The relative displacements of **3** additionally introduce five stabilizing face-to-face contacts between **2** and the phenyl rings of **3**, and a further two face-to-face and three edge-to-face interactions (that is, within 3.4 Å) between the phenyl rings themselves. The highly dissymmetric environment of **3** is however not observed in the ^{1}H NMR sprectrum of **1**, presumably because of averaging by rapid rotational oscillations at room temperature. The wide range of N(ligand **2**)-Cu-N(ligand **3**) bond angles (108.1(2)–134.9(2)°) indicates that the Cu^+ ions are located in a highly distorted tetrahedral coordination polyhedron, and results mainly from the staggering of ligands **3** along **2**. On the other hand, the Cu–N bond lengths (1.973(4)–2.169(4) Å) are unexceptional. A single water molecule is captured within the cation and hydrogen bonded to three of the oxygen atoms of the central macrocyclic ligand **3**, ($O(H_2O)$–O(**3**) 2.95–3.06 Å).

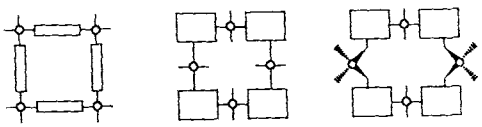
[17] Attempted further purification by column chromatography on silica gel or alumina with a variety of eluant systems resulted in rapid dethreading and extensive decomposition of $\mathbf{1}(PF_6)_3$.

Cyclic Metal Complexes of Nucleobases and Other Heterocycles: Molecular Boxes, Rectangles, and Hexagons**

Holger Rauter, Ilpo Mutikainen,* Merja Blomberg, Colin J. L. Lock, Pilar Amo-Ochoa, Eva Freisinger, Lucio Randaccio,* Ennio Zangrando, Elisabetta Chiarparin, and Bernhard Lippert*

In memory of Colin J. L. Lock

Spontaneous self-assembly of cyclic metal complexes with right angles at their corners ("molecular squares", "molecular boxes") represents an area of great current interest.[1–4] In general, the metal unit provides the right-angular component, whereas four bifunctional organic ligands, for example 4,4'-bipyridine, form the sides (Scheme 1a).[5] In principle, it is possible to reverse this situation by placing the organic ligands at the corners and the metal units along the edges.[6, 7] This leads to "squares" in the strict sense (Scheme 1b).[8] Use of six-membered heterocycles with angles of 120° at the ligands and linear metal units provides molecular hexagons instead of squares.



Scheme 1. Schematic representation of the basic structural types of molecular squares.

Variations of this principle with simultaneous use of different metal moities (such as *cis*-MX_2 and *trans*-MX_2 with M = Pt^{II}, Pd^{II}; X = NH_3, H_2O, NO_3^-, etc.) are also feasible (Scheme 1c). Here we report on relevant principles of this strategy utilizing the two nucleobases uracil (U) and 1-methylcytosine (1-MeC) as well as 2-aminopyridine (Hampy; Scheme 2).

We recently described a "molecular box" (open at the top and bottom) consisting of four Pt^{II}(en) units (en = 1,2-diaminoethane) and four bridging uracil nucleobases.[9] The cation **1** (UH_{-1} = monoanion from uracil) resembles calix[4]arenes as

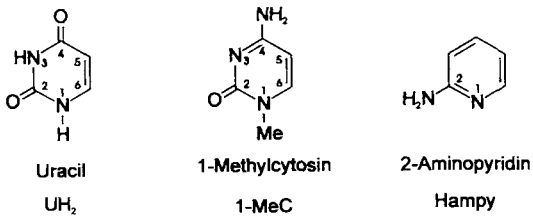
[**] This work is in memory of Prof. Dr. C. J. L. Lock (Laboratories of Inorganic Medicine, Chemistry and Pathology, McMaster University, Hamilton, Ontario L8S4M1, Canada) who contributed to it but passed away too early. We gratefully acknowledge financial support of the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and MURST and CNR (Rome, Italy). We thank Prof. Dr. W. S. Sheldrick and Mrs H. Mayer-Figge (Bochum, Germany) for their help with the structure determination of Pt_2Hg_6. This research was a part of HCM and COST projects.



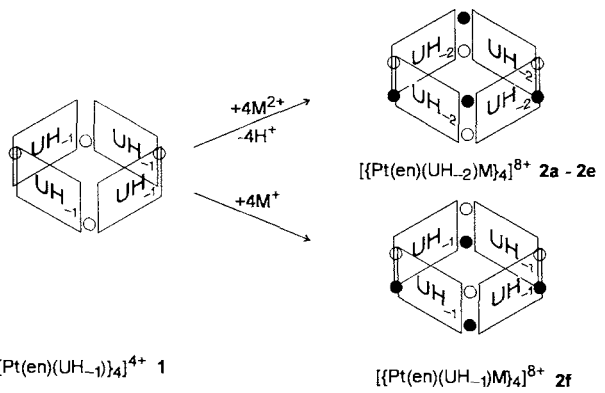
Scheme 2. The ligands uracil, 1-methylcytosine, and 2-aminopyridine.

far as its structure and solution dynamics are concerned. This analogy also includes the propensity of calix[4]arenes to complex metals.[10, 11] For example, after deprotonation of U to the uracil dianion (UH_{-2}), **1** binds additional divalent cations to yield octanuclear complexes **2** (M = *cis*-$Pt^{II}(NH_3)_2$ (**2a**), Pt^{II}(en) (**2b**), $Ni^{II}(H_2O)_3$ (**2c**), Pd^{II}(en) (**2d**), Cu^{II} (**2e**)). With M = Ag^{I}

$[\{Pt(en)(UH_{-1}\text{-}N1,N3)\}_4]^{4+}$ **1**

$[\{Pt(en)M(UH_{-2})\}_4]^{8+}$ **2a–2e**

$[\{Pt(en)Ag(UH_{-1})\}_4]^{8+}$ (**2f**) is obtained. In all of the octanuclear compounds the basic structure of the open box **1** is retained, but, instead of a single Pt^{II}(en) residue, two metal units (Pt^{II}(en) and M) represent the corners of the boxes (Scheme 3).



Scheme 3. Schematic representation of the molecular boxes **1** and **2**.

The complex cations were isolated as their nitrate salts, and crystals suitable for X-ray crystallography were obtained for **2a–2c** and **2f**. Although the octanuclear composition of the cation was established in all cases, a complete crystallographic analysis was only possible for **2a**.[12a] For **2b**,[12b] **2c**,[12c] and **2f**[9a] disorder of the NO_3^- anions and water molecules was so severe that, despite repeated attempts and data collection at low temperature, no satisfactory refinement was achieved.[12b,c]

The structure of the cation in **2a** is depicted in Figure 1. The basic feature of **1**, the 1,3-*alternate* arrangement of the four uracil nucleobases, is evident. The acidic protons of the UH_{-1} ligands in **1**, located between the O(2) and O(4) atoms of adjacent nucleobases, have been replaced with *cis*-$Pt^{II}(NH_3)_2$ units in **2a**. As a consequence, each uracil ring carries a metal ion at four positions (N(1), N(3), O(2), O(4)). Compared to the free base[13] and platinum complexes coordinated at N(1) and N(3),[9, 14] there are no significant changes in the ring geometry. The Pt(1)(en) units, which link the N(1) and N(3) positions, display normal geometries, as do the *cis*-$Pt^{II}(NH_3)_2$ moities. The Pt–Pt distances are Pt(1)–Pt(1c) 8.31, Pt(1)–Pt(2a) 7.51, Pt(1)–Pt(1b) 5.88, Pt(1)–Pt(2b) 4.75, and Pt(1)–Pt(2)

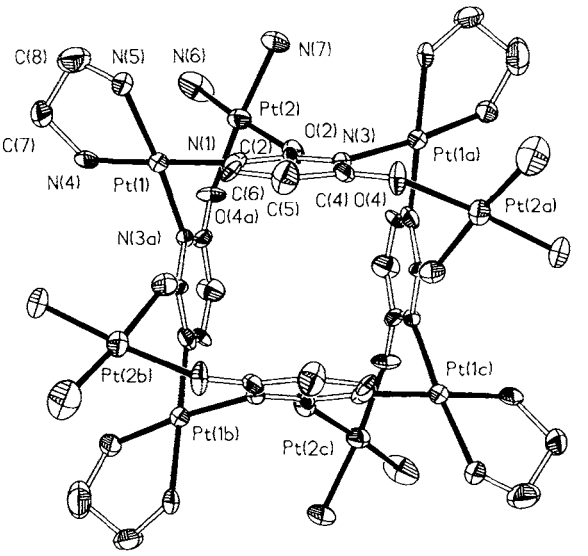


Figure 1. Crystal structure of the cation **2a** of the cyclic uracil complex $[\{Pt(en)\}_4(C_4H_2N_2O_2)_4\{Pt(NH_3)_2\}_4](NO_3)_4 \cdot 4H_2O$.

3.036(2) Å. Therefore, the shortest Pt–Pt separation is about 0.1 Å longer than that in related dinuclear complexes *cis*-$[Pt(a)_2L_2Pt(a)_2]^{2+}$ (a = NH_3; head-to-head orientation of bridging uracil nucleobases L).[15] The dihedral angle between the planes of the Pt(en) and *cis*-$Pt(NH_3)_2$ moities (Pt(1) and Pt(2)) is also rather large (40.9(6)°). Uracil rings at opposite sides of the box are not exactly parallel, which leads to different O(2)–O(2c) and C(5)–C(5c) distances (5.92 and 4.27 Å, respectively). Considering the spatial requirements of the π electron clouds of the uracil rings, the openings of the box at the top and bottom, which are rotated by 90° with respect to each other, are about 1×2.5 Å. There are no significant intermolecular Pt···Pt contacts, as frequently seen for dinuclear *cis*-$[Pt^{II}(a)_2L_2Pt^{II}(a)_2]^{2+}$ cations (L = UH_{-2} or cyclic amidate).[9, 16]

The composition of **2b** (M = Pt^{II}(en))[12b] is analogous to that of **2a**. Within the Pt_2 pairs, metal–metal separations differ slightly: 2.998(2) and 3.023(3) Å. The cations of the Pt_4Ni_4 compound **2c**[12c] is also of similar composition, but the Ni^{II} centers display distorted octahedral coordination spheres of five oxygen atoms (O(4), O(2), and three OH_2 groups) and a Pt atom. All four Pt–Ni distances within **2c** vary slightly (2.652(2)–2.700(5) Å). The structure of the Pt_4Ag_4 complex **2f** proves that the *cone* conformation can also be stabilized by metal ions and demonstrates that the 1,3-*alternate* → *cone* rearrangement can take place even in strongly acidic medium with the help of a suitable metal ion. Considering the close structural similarities of related di- and trinuclear PtM and Pt_2M complexes (M = Pt^{II}, Pd^{II}, Cu^{II}) with uracil nucleobases,[15] we propose that the compositions of the Pt_4Pd_4 and Pt_4Cu_4 cations **2d** and **2e** are analogous to those of **2a–2c**.

Cations **2a** and **2b** are inert in D_2O (see Experimental Section) and only decompose at pH* = 0. In the presence of excess NaCl, loss of the Pt units bound to O(4) and O(2) takes place over a period of several days at 40 °C. The cations react with excess CN^- within minutes to give **1** and $[Pt(CN)_4]^{2-}$. In a slow secondary reaction (1 d, 22 °C) an equilibration of 1,3-*alternate* and *cone* forms of **1** occurs (see *Experimental Section*). These findings confirm earlier observations that, despite the high thermodynamic stability of $[Pt(CN)_4]^{2-}$, N(3)-platinated uracil (and thymine) is inert with respect to CN^-.[17] Only those Pt residues bound to the exocyclic oxygens are readily displaced. The reaction $\mathbf{1} + 4M^{n+} \rightarrow \mathbf{2}$ can, therefore, be reversed; this fur-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3612-1297 $ 17.50+.50/0

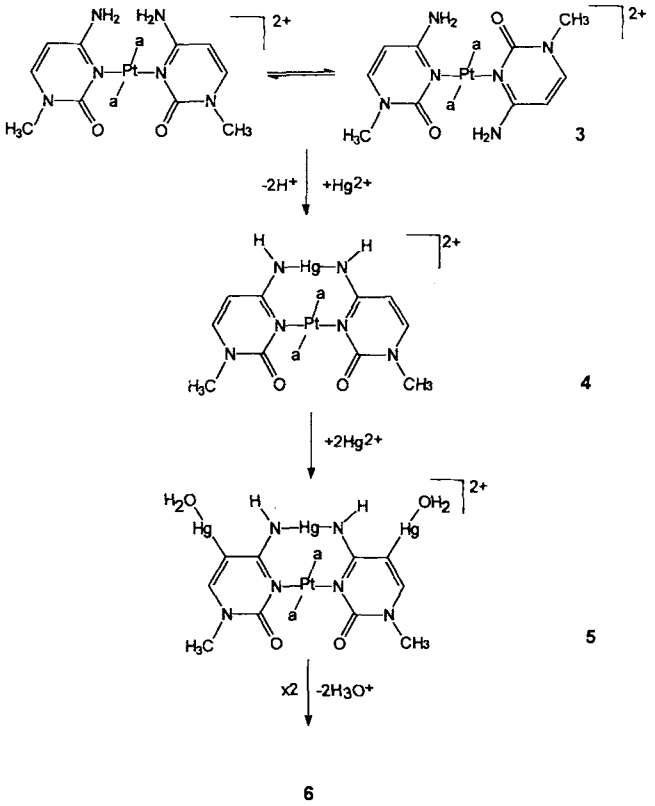
ther corroborates the analogy with the metal-coordinating properties of suitably modified calix[4]arenes.

The crystal structure determinations of **2a** and of its precursor **1** demonstrate that, irrespective of the 120° angle between the Pt–N1 and Pt–N3 vectors, molecular boxes are formed as long as the metal units are of *cis* geometry. As shown for **6**

$[\{Pt(CH_3NH_2)_2(1\text{-}MeCH_{-2})_2Hg_3(OH)\}_2](NO_3)_6 \cdot 4H_2O$ **6**

(1-$MeCH_{-2}$ = dianion of 1-MeC) *trans* geometry at the metal units leads to formation of a molecular hexagon (Scheme 4). To suppress formation of open-chain oligomers, fixation of the two cytosine nucleobases in **3**[18, 19] in a head-to-head arrangement is advantageous. This can be accomplished by metal binding at the deprotonated exocyclic amino groups[18] by, among others, Hg^{II}.[19]

Electrophilic attack of excess $Hg(NO_3)_2$ or $Hg(OAc)_2$ at the C5 positions of the two cytosine ligands in **4** leads, presumably via **5**, to **6** (Scheme 4). Metalation reactions at C5 are known for



Scheme 4. Synthesis of **6**.

free cytosine[20] and various uracil derivatives.[21] Following the formation of **6** by ^1H NMR spectroscopy indicates that reaction of the head-to-head rotamer[22] of **3** via an intermediate (**5**?) takes place with a drop in pH. Compound **6** was isolated from acidic solutions (pH = 1.8–3) and characterized by elemental analysis, X-ray crystal structure determination,[23] and NMR spectroscopy.

Figure 2 shows the structure and Figure 3 schematic views of the cyclic cation $[\{Pt(CH_3NH_2)_2(C_5H_3N_3O)_2Hg_3(OH)(NO_3)\}_2]^{4+}$ of **6**. The basic form of the centrosymmetric cation is that of a compressed hexagon (sides 7 and 5.5 Å) with four Hg^{II} and two Pt^{II} atoms at the edges, and four nucleobases and two OH groups representing the corners. Two additional Hg^{II}

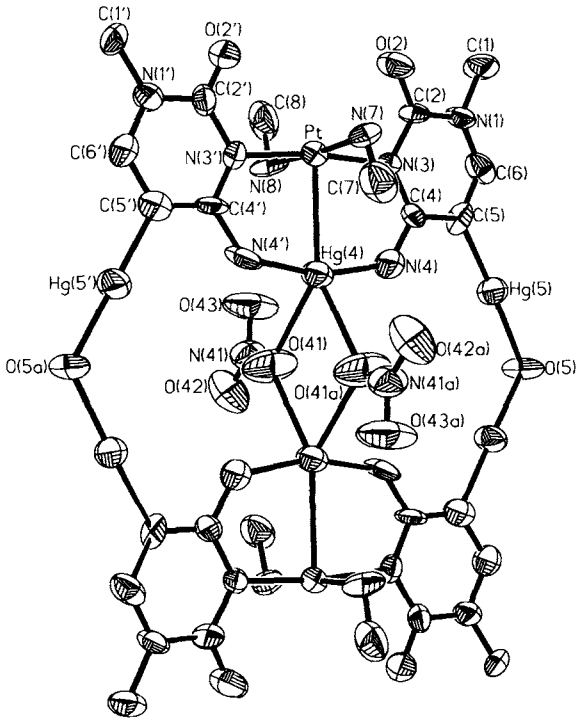


Figure 2. View of the cation $[\{Pt(CH_3NH_2)_2(C_5H_3N_3O)_2Hg_3(OH)(NO_3)\}_2]^{4+}$ in **6**. Selected bond lengths [Å] and angles [°]: Pt–N(3) 2.05(2), Pt–N(3') 2.07(2), Hg(4)–N(4) 2.08(2), Hg(4)–N(4') 2.08(2), C(5)–Hg(5) 2.05(2), Hg(5)–O(5) 2.09(1), C(5')–Hg(5') 2.04(2), Hg(5')–O(5') 2.06(1); N(3)-Pt-N(3') 172.8(5), N(4)-Hg(4)-N(4') 162.3(6), C(5)-Hg(5)-O(5) 175.0(6). For intermetallic distances see Figure 3.

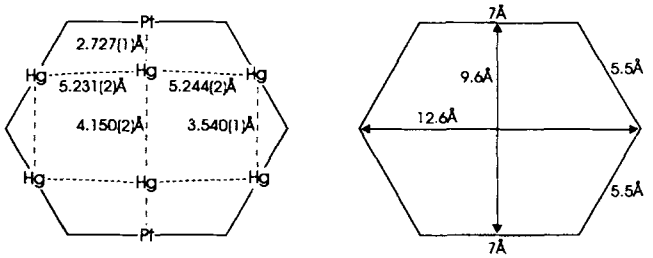

Figure 3. Dimensions and intermetallic distances in the cation of **6**.

ions, which bridge pairs of deprotonated exocyclic N(4) groups of the cytosine bases, are located along the Pt–Pt vector. All metal ions and OH groups are almost coplanar. The cation of **6** is made up of two units of **4**, which are linked by two Hg-OH-Hg units. Apart from the Pt–Hg(4) distances (2.727(1) Å in **6**, 2.785(1) Å in **4**) and the additional Hg(5) ions, there are no major differences between the structures of **4** and **6**. Even the NO_3^- groups bridging the dinuclear PtHg units in **6** are present.

In the crystal Pt_2Hg_6 cations form infinite, interlacing staircases. Thus the four O(2) oxygen atoms of the cytosine bases each form pairs of two hydrogen bonds with the amino protons of the CH_3NH_2 groups of the adjacent cations (O–N 2.85(2) and 2.89(2) Å). The intermolecular separation between the Pt ions is 4.929(2) Å. The steps in the second direction are formed by two intermolecular OH···OH hydrogen bonds (O(5)–O(5)' 2.773(23) Å) and four weak intermolecular Hg–ONO_2 bonds between the bridging nitrate groups and the Hg(5) or Hg(5') center of the adjacent cations (Hg–O 2.68(2)–2.94(2) Å). The Hg ions located at the sides of the hexagon exhibit different coordination geometries.

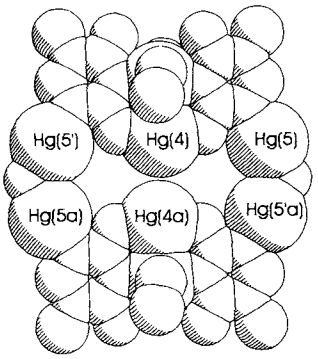

Figure 4. Space-filling model of the cation in **6**; bridging NO_3^- groups have been omitted.

A special structural feature of **6** is the arrangement of the six Hg^{II} ions (Figure 4). It is feasible that in solution, as in the solid state with weakly bonded nitrate anions and water molecules, interactions between the Lewis acidic Hg centers and nucleophiles occur, which could lead to specific substrate binding and catalysis.[26, 27] This arrangement bears some resemblance to the surface of a metal salt.[28]

Reaction of Hampy with first *trans*-$[Pt^{II}(CH_3NH_2)_2(H_2O)_2](NO_3)_2$ and then $[PdCl_4]^{2-}/AgNO_3$ leads to a species that can be considered as a hybrid between a rectangle and an open box containing both *trans*-MX_2 and *cis*-MX_2 units. Complex **9** was obtained from **7** upon reaction with $K_2[PdCl_4]$ and excess $AgNO_3$. Initially **7** reacts with K_2PdCl_4 with a drop in pH to give a poorly soluble orange product (**8**), which redissolves with red coloring upon addition of $AgNO_3$. Dark red cubes of **9**

trans-$[Pt(CH_3NH_2)_2(Hampy)_2](NO_3)_2$ **7**

$[\{Pt(CH_3NH_2)_2(ampy)_2\}_2Pd_4(NO_3)_6(H_2O)_2](NO_3)_2 \cdot 3.5H_2O$ **9**

crystallize from the solution. X-ray structure analysis[29] reveals that **9** consists of two crystallographically independent hexanuclear cations (A and B), nitrate anions, and water of crystallization. The two cations have a crystallographic C_2 axis, which passes through the two Pt centers in the case of A and is perpendicular to the Pt–Pt vector in B. Consequently, adjacent cations are mutually perpendicular in the crystal lattice. Cation A is depicted in Figure 5. Each *trans*-$[Pt(CH_3NH_2)_2]$ unit carries two coplanar aminopyridonate rings that are bound to Pt through the endocyclic ring N atoms and adopt, unlike in **7**, a head-to-head orientation. The two Pd_2 units each bridge the four deprotonated exocyclic amide nitrogen atoms to give a μ_3-η^2 coordination pattern for the ampy ligands.[31] All four Pd ions have *cis* geometries: the four remaining coordination sites are occupied by oxygen atoms (three from NO_3^- and one from H_2O). The resulting Pd_2N_2 rings are folded along the N···N vectors, which leads to short Pd–Pd distances (2.877(2) and 2.855(2) Å). In planar Pd_2N_2 rings, metal–metal distances are usually much longer (3.0633(9) Å).[32] The edges of the two cations are 4.07 (N1···N1') by 7.18 (N1···N4) (A) and 7.23 Å (B), respectively. Pt···Pt distances are 6.949(1) (A) and 6.990(1) Å (B), and the separations between the midpoints between the pairs of oppositely placed Pd_2 units are 6.276(1) (A) and 6.270(1) Å (B). In both cations the two $Pt(ampy)_2$ units are slightly twisted (Figure 6). The roughly coplanar orientation of the four NH protons of the exocyclic amide groups could be of interest with respect to receptor properties.

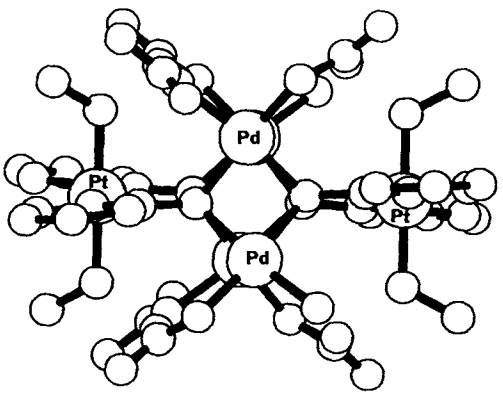

Figure 6. Side view of cation A in **9**. The two $Pt(ampy)_2$ units are slightly twisted with respect to each other.

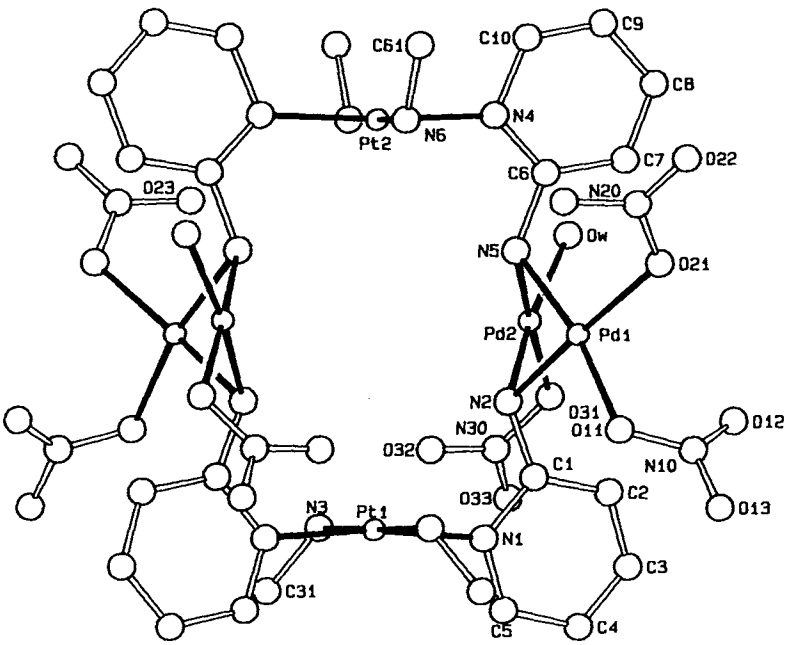

Figure 5. Structure of the crystallographically independent cation A in **9**. Selected bond lengths [Å] and angles [°]: Pt1–N1 2.04(1), Pt2–N4 2.01(2), Pd1–N2 2.03(2), Pd1–N5 2.03(1), Pd2–N2 2.07(1), Pd2–N5 2.08(1); N1-Pt1-N1' 172.0(6), N4-Pt2-N4' 175.1(7), Pd1-N2-Pd2 89.2(6), Pd1-N5-Pd2, 88.9(6), N2-Pd1-N5 77.4(6), N2-Pd2-N5 75.4(5).

Experimental Section

2: In a typical experiment, **1** (0.058 mmol) was dissolved in 15 mL of an aqueous solution of the respective metal salt ($Ni(NO_3)_2$, $Cu(NO_3)_2$, $AgNO_3$, *cis*-$[M(a)_2(H_2O)_2]^{2+}$ with $M = Pt^{II}$, Pd^{II}; four- to tenfold excess). The solution was concentrated under vacuum to about 5 mL and then exposed to air. The pH values of the solutions were typically between 1.5 and 2.5. In the case of the Ag compound **2f** the pH was adjusted to 0 with HNO_3. Within 2–7 d yellow (**2a**, **2b**, **2e**), green/yellow (**2c**), orange (**2d**), or colorless (**2f**) crystals formed, which were isolated by filtration, washed with a minimum amount of water, and dried in air. Yields 15–30%. Higher yields were not possible since further concentration resulted in cocrystallization of the metal-salt reagent. Satisfactory elemental analyses (C, H, N) were obtained for $[(C_2H_8N_2)_4(NH_3)_8Pt_8(C_4H_2N_2O_2)_4](NO_3)_8 \cdot 4H_2O$ (**2a**), $[(C_2H_8N_2)_8Pt_8(C_4H_2N_2O_2)_4](NO_3)_8 \cdot 4H_2O$ (**2b**), $[(C_2H_8N_2)_4Pt_4(C_4H_2N_2O_2)_4Ni_4(H_2O)_{12}](NO_3)_8 \cdot 1.5H_2O$ (**2c**), $[(C_2H_8N_2)_8Pt_4(C_4H_2N_2O_2)_4Pd_4](NO_3)_8$ (**2d**), $[(C_2H_8N_2)_4Pt_4(C_4H_2N_2O_2)_4Cu_4](NO_3)_8(H_2O)_8$ (**2e**), and $[(C_2H_8N_2)_4Pt_4(C_4H_3N_2O_2)_4Ag_4](NO_3)_8(H_2O)_4$ (**2f**).

2a: ^1H NMR (200 MHz, D_2O, TSP, pH* = 1.5–7): $\delta = 8.01$ (d, $J = 7.4$ Hz, H6), 5.90 (d, H5), 2.8 (en).

2b: ^1H NMR (200 MHz, D_2O, TSP, pH* = 1.5–7): $\delta = 7.95$ (d, $J = 7.4$ Hz, H6), 5.87 (d, H5), 2.7 (en). ^{195}Pt NMR (D_2O, pD = 4): $\delta = -2484$ (PtN_4), -1570 (Pt_2O_2); immediately after addition of CN^- (20 equiv per Pt atom, pD = 12): $\delta = -2613$ (**1**, PtN_4, 1,3-*alternate*), -4720 ($[Pt(CN)_4]^{2-}$); after 6–18 h: $\delta = -2613$ (**1**, PtN_4, 1,3-*alternate*), -2647 (**1**, PtN_4, *cone*), -4720 ($[Pt(CN)_4]^{2-}$). Assignment of the conformers of **1** by comparison of ^{195}Pt and ^1H NMR spectra [9a] of **1** in the presence of CN^- (pD = 8.2).

6: Method 1: $Hg(NO_3)_2$ (324 mg, 0.95 mmol) was added to a solution of *trans*-$[Pt(CH_3NH_2)_2(1\text{-}MeC)_2](NO_3)_2$ (**3**) [18] (200 mg, 0.32 mmol) in water (13 mL), and the solution stirred at 22 °C. After 7 h a colorless precipitate was isolated by filtration, washed with a minimum amount of H_2O and MeOH, and dried in the air. Colorless crystals of **6** form in the filtrate (pH = 2–2.5) within 3 d. The precipitate and the single crystals are identical (IR and ^1H NMR spectroscopy). Yield 223 mg (51%). Method 2: $Hg(NO_3)_2$ (53 mg, 0.15 mmol) was added to a solution of *trans*-$[Pt(CH_3NH_2)_2(1\text{-}MeC_{-1})_2Hg](NO_3)_2$ (**4**) [19] (64 mg, 0.07 mmol) in water (13 mL), and the solution stirred at 22 °C. Precipitation of **6** started after 4 h. The yield of the isolated product after 19 h is 18% and increases to that of Method 1 with higher concentrations (NMR). Elemental analysis data (C, H, N) agree with the composition determined by X-ray analysis. ^1H NMR (200 MHz, D_2O, NMe_4^+ internal standard, TSP) $\delta = 7.25$ (s, H(6); ^{199}Hg satellites: $^3J = 196$ Hz), 7.47, 7.56, 7.61 (three weak singlets; intensities increase with time and after addition of DNO_3 (pD = 1.7) at the expense of the signal at $\delta = 7.25$). ^{195}Pt NMR (D_2O, $[PtCl_6]^{2-}$): $\delta = -2195$.

7: Reaction of *trans*-$[Pt(CH_3NH_2)_2Cl_2]$ with Hampy (2 equiv) in the presence of $AgNO_3$ (2 equiv) in H_2O (pH = 7, 1 d, 50 °C), removal of AgCl and little Pt^0 by filtration, and crystallization results in colorless cubes of **7** in 84% yield. Satisfactory elemental analysis (C, H, N). ^{195}Pt NMR (42.95 MHz, $[PtCl_6]^{2-}$): $\delta = -2681$; ^1H NMR (200 MHz, D_2O, pD = 7, TSP): $\delta = 8.40$ (m, H6; ^{195}Pt satellites: $^3J \approx 34$ Hz), 7.66 (m, H4), 6.82 (m, H5, H3), 2.14 (s, CH_3; ^{195}Pt satellites: $^3J \approx 43$ Hz). Derivative **7′** was prepared analogously with $AgClO_4$ instead of $AgNO_3$. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3500 s, 3380 s, 3260, 3220, 3160 s, 1680 s, 1650 s, 1615 s, 1555 s, 1500 s, 1380 vs, 1310 m, 1220 m, 1140 m, 1060 m, 810 s, 650 m, 565 s, 510 m, 480 m. Crystal structure analyses of **7** and **7′** confirmed the compositions.

8: Compound **7** (0.5 mmol) was dissolved in H_2O (20 mL), and the pH value of the solution (6.3) adjusted to 12.2 with NaOH. $K_2[PdCl_4]$ (1 mmol) dissolved in water (5 mL) was added dropwise with stirring. Precipitation of red-orange **8** started immediately. The pH value of the solution, which dropped to 4, was repeatedly adjusted to 7 until it remained constant. After the solution had been stirred for 1 h at 22 °C, the precipitate was isolated by filtration, washed with water, and dried at 40 °C. Elemental analysis (C, H, N, Cl) approximately corresponded to $[Pt(CH_3NH_2)_2(C_5H_5N_2)_2(PdCl_2)_2]\cdot 4H_2O$. Yield 90%. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3530 s, b, 3280 s, 1680 s, 1660 s, 1610 s, 1520 s, 1490 s, 1330 m, 1230 m, 1250 m, 1150 m, 1140 m, 820 m, 500 m, 360 m, b.

9: Excess $AgNO_3$ (8–10 equiv) was added in small portions to a suspension of **8** (0.133 mmol) in H_2O (5 mL) until **8** had completely dissolved. The now dark red solution was filtered to remove AgCl and concentrated at 22 °C. Within two weeks, dark red cubes of **9** formed. Only the first fraction (10–15% yield) was not contaminated with $AgNO_3$ and other products. Elemental analysis (C, H, N) of a freshly isolated sample was in agreement with a septa- or octahydrate (Pt:Pd = 1:2 (scanning electron microscopy)). The X-ray structure analysis indicated six positions for water molecules, five of which display occupancies of only 0.5. ^{195}Pt NMR (D_2O): $\delta = -2594$; ^1H NMR (D_2O, pD = 3.7): $\delta = 9.09$ (d, 1H), 9.02 (d, 1H), 8.20 (t, 1H), 7.53 (t, 1H), 2.02 (s, 3H). The signals for the aromatic protons could not be unambiguous assigned, even with a ^1H–^1H COSY experiment; coupling constants were determined from the 2-D, *J*-resolved NMR spectrum ($^3J \approx 6-7$, $^4J \approx 1.3-1.4$ Hz); IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3500 s, vb, 3160 s, 1615 s, sp, 1565 s, sp, 1480 vs, 1440 vs, 1380 vs, 1270 vs, 1245 s, 1200 s, 1160 m, 1100, 1090 m, 1000 s, b, 850 m, 825 m, sp, 790 m; UV/Vis (H_2O): λ[nm] (ε[mol L^{-1} cm^{-1}]) = 218 (43790), 275 (sh), 300 (32720), 380 (6106), 437 (7514).

[5] The term "molecular square" [3] is somewhat misleading in that it ignores the three-dimensional structure (with the organic ligand perpendicular to the plane created by the metal ions). Therefore, the term "open box" is better.

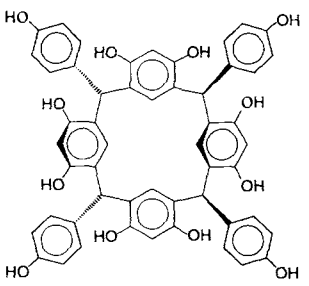
Quasi-Complete Solvation of Organic Molecules in the Crystalline State**

Alexander Shivanyuk, Erich F. Paulus, Volker Böhmer,* and Walter Vogt

The solvation of biologically important molecules with water has been intensively studied by X-ray diffraction. The structural information obtained from such studies provides valuable insights into the role of solute–solvent interactions for crucial processes like protein folding or DNA double helix formation.[1] Examples of crystal structures of more simple compounds like cyclodextrins[2] and calixarenes[3] containing many water molecules per unit cell are also known. In the latter case bilayers of the sulfonated calixarene anion held together by hydrophobic forces are separated by water-rich layers containing the cations. However, these structures, dubbed "organic clays", provide little or no information on the solvation of the single molecules in solution. Here we describe the quasi-complete solvation of resorcarene **1**[4, 5] by dimethyl sulfoxide (DMSO) and pyridine (Pyr) in the crystalline state.



1

Acid-catalyzed condensation of resorcinol with 4-hydroxybenzaldehyde in EtOH at room temperature led to a mixture[6] from which the *rctt* isomer **1**[7] could be isolated simply by repeated recrystallization. The rigidity of its macrocyclic skeleton completely excludes the formation of intramolecular hydrogen bonds between hydroxy groups, contrary to the *rccc* isomer.[8] We therefore expected that **1** would form supramolecular structures in the crystalline state, held together by intermolecular hydrogen bonds between different resorcarene molecules.[9]

Slow recrystallization of **1** from DMSO at room temperature (20–23 °C) gave colorless crystals of the composition **1**·18 DMSO which, although extremely unstable without solvent, were suitable for X-ray structure analysis.[10] These crystals (containing 62.2% DMSO) proved to be stable in the presence of the mother liquor at higher temperatures and could be completely redissolved only at 80–100 °C.

The resorcarene **1** indeed adopts the C_{2h} symmetrical chair conformation (Figure 1)[11] in which two opposite aryl rings of the macrocyclic framework are almost coplanar (the deviation

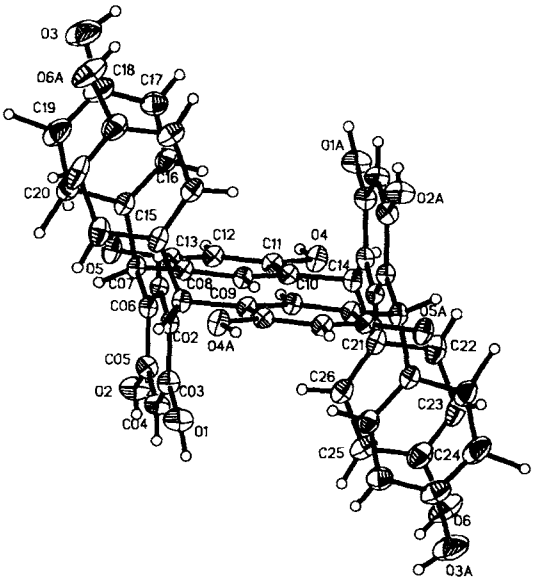


Figure 1. Molecular conformation and numbering scheme of resorcarene **1** (20% thermal elipsoids are shown).

between their planes is 0.35 Å) and two others are nearly perpendicular to this plane (dihedral angle: 85.9°) with their hydroxy groups pointing in opposite directions. (Since molecule **1** has a crystallographic inversion center, opposite aryl rings must be parallel.) The phenolic rings connected to the bridging carbon atoms assume the axial positions; two of them point up and two down leading to dihedral angles of 83.0 and 88.8° with the coplanar resorcinol rings. These pairs of *cis*-oriented phenolic rings are almost parallel (dihedral angle: 8.4°), and their hydroxy groups (O3H and O6AH) together with those of the vertically oriented resorcinol ring (O1H and O2H) form a polar "cap" of the molecule.

The distances between neighboring oxygen atoms of the resorcinol rings (O1–O4A = 4.00 and O2–O5 = 4.02 Å) and of the *cis*-oriented phenolic moieties (O6–O3A = 4.54 Å) are too long to allow intramolecular hydrogen bonding and therefore twelve intermolecular hydrogen bonds pointing in all directions are formed to twelve DMSO molecules. Six additional DMSO molecules fill voids in the crystal lattice (Figure 2). The distances between the oxygen atoms of hydroxy groups and the hydrogen-bonded DMSO molecules are between 2.58–2.81 Å. Both the shortest and the longest distances were found for the *para*-hydroxy groups O3H and O6H.

All 18 (nine crystallographically independent) DMSO molecules are located at definite positions; however, their sulfur atoms are disordered between two sites above and below the triangle formed by the oxygen and the two carbon atoms (Figure 2 top). The site occupation probabilities for those two positions could be exactly determined for each sulfur atom. They vary between 0.51 and 0.93. Four of them are within 0.51–0.57 (S1, S3, S6, S7), suggesting that there is almost no preference for any position. Values between 0.73 and 0.93 for S9, S8, S2, S4, and S5 demonstrate an increasing preference for one site.

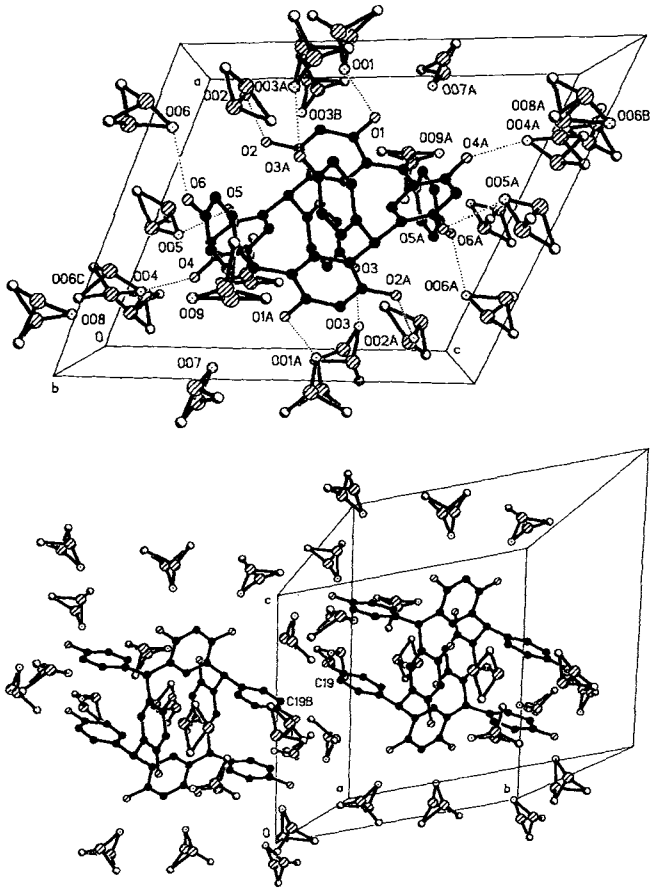

Figure 2. Packing and quasi-complete solvation of **1**·18 DMSO (hydrogen atoms are omitted and carbon atoms of **1** darkened for clarity). Top: The embedding of molecule **1** by DMSO seen along the crystallographic *b* axis. For each DMSO molecule the two positions of the sulfur atoms are shown. Hydrogen bond lengths [Å]: O1–O01 2.688(4), O2–O02 2.777(4), O3–O03 2.584(4), O4–O04 2,652(4), O5–O05 2.662(4), O6–O06 2.805(4). Bottom: "Corner-to-corner" contact between molecules of **1**; shortest intermolecular distance: C19–C19B 3.705(5) Å).

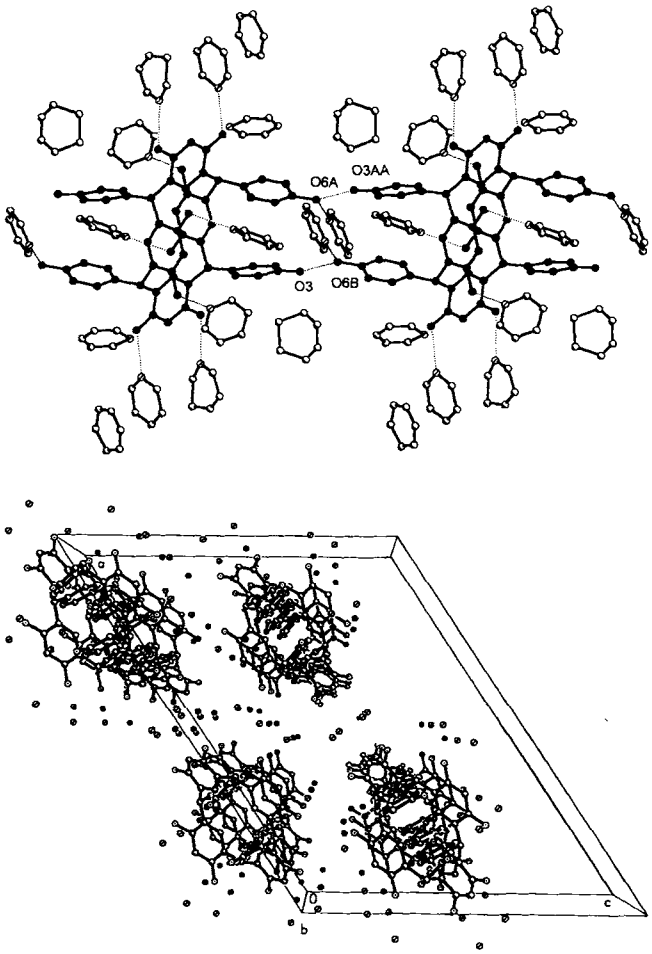

Figure 3. Crystal packing of **1**·14 Pyr. Top: Two molecules of **1** (darkened for clarity) from the infinite hydrogen-bonded column entirely wrapped by pyridine. The intermolecular hydrogen OH···OH···NC_5H_5 bonds are clearly shown (O3–O6B 2.78(1) Å, O6–N6 2.68(1) Å). Bottom: Hydrogen-bonded columns of **1** seen along their axes (only nitrogen atoms of pyridine molecules are shown for clarity).

The packing of **1**·18 DMSO can be also deduced from Figure 2. In the directions of the crystallographic axes *a* and *c* the molecules **1** are completely separated from each other by layers of DMSO, thus preventing any direct intermolecular contacts (Figure 2 top). Only the two carbon atoms C19 and C19A protrude out of this "solvent box" and form "corner-to-corner" van der Waals contacts between the molecules **1** along the axis *b* (Figure 2 bottom). The shortest intermolecular distance (C19–C19B = 3.70 Å) rules out any strong interaction also in this case.

In conclusion, the molecule **1** is almost entirely surrounded by solvent in the crystal and can be considered as "completely solvated", since hydrogen bonding gives by far the highest contribution to the solvation enthalpy. The volume of the unit cell ($V = 2949$ Å^3) corresponds to a concentration of 0.563 mol dm^{-3} for this "quasi-solution". In a slightly simplified description, the crystal of **1**·18 DMSO is formed by molecules **1** together with their first and most ordered solvation shell. The structural information described above can be compared, for instance, with molecular dynamics simulations for molecule **1** in solution.

Recrystallization of **1** from pyridine gave transparent, pink crystals (composition **1**·14 Pyr) that were of perfect size and shape for X-ray structure analysis (Figure 3),[10] although they were again quite unstable without the solvent. As in the previous case, the crystals were very stable in the presence of the mother liquor, and could be redissolved only by boiling.

The conformation of **1** in **1**·14 Pyr is almost the same as for the adduct **1**·18 DMSO. (root mean square = 0.083 Å for the macrocyclic skeleton). Of the fourteen (seven crystallographically independent) partly disordered pyridine molecules, ten are hydrogen bonded by ten hydroxy groups (N–O distances 2.68–2.78 Å). The remaining four, which fill voids in the crystal lattice, also assume definite positions, although in two cases the nitrogen atom cannot be located.

In contrast to **1**·18 DMSO the molecules of **1** are connected by two intermolecular hydrogen bonds that are formed on each side between the phenolic hydroxy groups O3H and O6H. One molecule of pyridine is involved as acceptor (O6H···Pyr) in this intermolecular contact, making O6H a strong acceptor for the intermolecular hydrogen bond O3-H···O6B-H. In this way, hydrogen-bonded molecules **1** are arranged to infinite columns, which are entirely wrapped (solvated) by layers of pyridine, and therefore, completely isolated from each other (Figure 3).

Highly solvated structures were observed also for resorcarenes prepared with 3- and 2-hydroxybenzaldehyde, showing the generality of the phenomenon described above. Intensive crys-

[4] Resorcarenes are readily synthesized in multigram quantities by acid-catalyzed condensation of resorcinol with different aldehydes. Among four possible stereoisomers only two are easily available, namely the *rccc* isomer that exists in a C_{4v} symmetrical *crown* conformation and the *rctt* isomer that assumes a C_{2h} symmetrical *chair* conformation. The *rccc* isomers having intramolecular cavities were widely used [5] for the complexation of polyols like sugars and steroids through an interplay of cooperative hydrogen bonds and CH-π interactions and for the construction of even more sophisticated receptors such as cavitands, carcerands, and hemicarcerands. However, the *rctt* isomers have not yet attracted much attention.

PS Ligands as Building Blocks of Chiral Dimetallatetrahedranes with a Common Vertex**

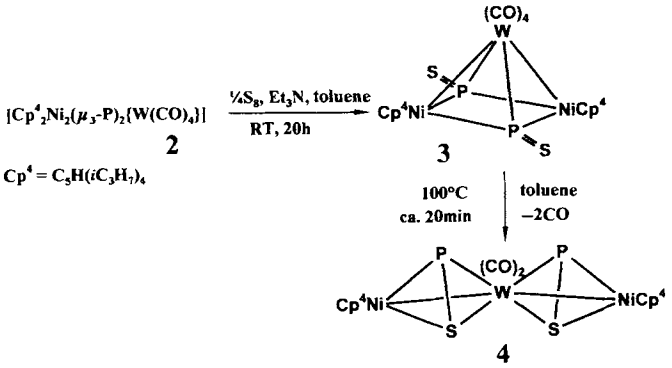
Otto J. Scherer,* Clemens Vondung, and Gotthelf Wolmershäuser

Dedicated to Professor Hans Bürger on the occasion of his 60th birthday

The preparation of the first complex with a PO ligand[1] was rapidly followed by several further examples.[2] A few isolated examples of compounds with a PS ligand were described earlier[3a, b] as well as more recently;[3c, d] however, to date **1** is the only crystallographically characterized example.[3d]

$[\{CpFe(CO)_2\}\{\mu\text{-}CO[CpFe(CO)]_2\}PS]$ **1**

The trinuclear complex **3** with two μ_3-P=S ligands can be obtained in good yields from **2**[1] (Scheme 1) by oxidation with S_8 at room temperature. When **3** is heated to 100 °C for about



Scheme 1.

20 min, the unusual cluster **4** is formed under CO elimination (^{31}P NMR, monitoring by IR). The two tetrahedra in **4**, which each contain four different framework atoms (two transition metals and two main group elements), are linked to each other through a common tungsten vertex. Complex **3**[4] forms red-

[+] Crystal structure analysis.

[**] This work was supported by the Fonds der Chemischen Industrie and by the Graduiertenkolleg "phosphorus chemistry as a link between different chemical disciplines".

brown crystals, and complex **4**[4] red crystals, the solubilities of which are moderate to good in hexane and good to very good in toluene.

The most important structural features in the tetragonal-pyramidal complex **3** are its μ_3-PS ligands (Figure 1). The P–S

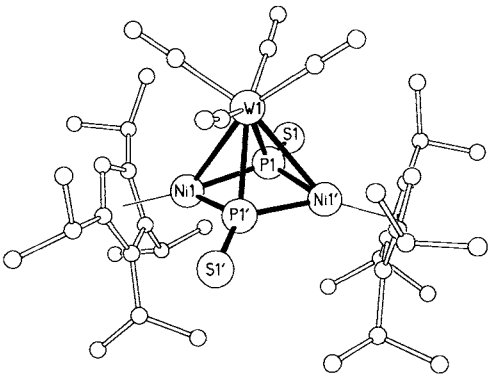

Figure 1. Crystal structure of **3** [5]. Selected bond lengths [Å] and angles [°]: Ni1–W1 2.8578(7), W1–P1 2.5219(13), Ni1–P1 2.1635(14), Ni1–P1′ 2.173(2), P1–S1 1.952(2), Ni1 ··· Ni1′ 3.37, P1 ··· P1′ 2.70; Ni1-P1-Ni1′ 102.04(6), P1-Ni1-P1′ 77.16(6), dihedral angle (Ni1-P1-P1′)/(Ni1′-P1-′P1) 192.1.

distance is 1.952(2) Å, which is almost identical with that for the P–S bonds in the triangulated dodecahedron compound $[Cp_4Fe_4(P_2S_2)_2]$;[6] the P–S bond length in **1** is 2.008 Å.[3d] For the PS radical, which was prepared by the discharge of a $PSCl_3$/helium mixture,[7a] a value of 1.8977 Å was established by laser spectroscopy; the theoretically[7b] calculated value is slightly larger.

A "simple" PS-side-on coordination was proposed for the compound **5** formed in the photolysis of **1**.[3d] The "five-membered ring middle deck" of **6**[8] consists of a P_3 and one PS ligand (d(P–S) = 2.023(5) Å).[8] The P–S distances in the tetrahedrane framework of **4** are as expected slightly longer than those in **3** (2.092(2) Å, Figure 2). The Ni–W (2.86 and 2.69 Å) and P–W distances (2.52 and 2.45 Å) in the tetragonal-pyramidal Ni_2P_2W framework of **3** are significantly longer than the respective distances in the tetrahedra of **4**; in contrast, the Ni–P bond lengths differ only slightly (**3**: 2.17, **4**: 2.20 Å).

$[\{CpFe(CO)\}(\mu\text{-}\eta^2\text{-PS})\{\mu\text{-CO}[CpFe(CO)]_2\}]$ **5**

$[Cp^*_2Mo_2\{\mu_3\text{-}\eta^3\text{:}\eta^3\text{-P}_3[Cr(CO)_5]\}(\mu\text{-}\eta^2\text{:}\eta^2\text{-PS})]$ **6**

With 54 valence electrons (VE) the μ_3-P=S complex **3** corresponds to a *nido* octahedron. The cluster **4** has 62 VE, which

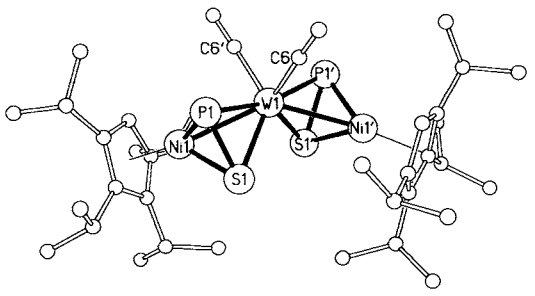

Figure 2. Crystal structure of **4** [5]. Selected bond lengths [Å] and angles [°]: Ni1–W1 2.6911(4), W1–P1 2.4506(11), W1–S1 2.4526(10), Ni1–S1 2.1837(12), Ni1–P1 2.2040(12), P1–S1 2.092(2); Ni1-W1-Ni1′ 137.87(2), P1-W1-P1′ 166.56(6), S1-W1-S1′ 94.58(5), C6-W1-C6′ 87.5(3).

according to the Wade–Mingos rules[9] is the number required for two tetrahedra sharing a common vertex; to our knowledge this structural type is very rare. Examples with two sandwichlike oriented three-membered rings $(M'L_n)_3$ with a common corner M occur in the $[M\{(M'L_n)_3\}_2]^{n+}$ class of substances;[10] in $[H_2Os_5(CO)_{14}(\mu_3\text{-}S)_2]$[11] the two Os triangles of the Os_5 bow tie substructure exhibit a dihedral angle of 56.3°. The triangular planes Ni1-P1-S1 and Ni1′-P1′-S1′ in the two tetrahedrane frameworks in **4** display an $(Ni1\text{-}P1\text{-}S1)_{centroid}$-W1-$(Ni1'\text{-}P1'\text{-}S1')_{centroid}$ angle of 138.5° and thus deviate significantly from a parallel orientation (Figure 2). Cluster **4**, which exists as a racemate in the crystal,[5] is to our knowledge the first compound in which two chiral tetrahedranes,[12] each containing two main group and two transition metal fragments, are additionally linked to each other through a common vertex. ^1H and ^{31}P NMR spectroscopic studies provided no evidence for an additional isomer of **4**.

Experimental Section

3: **2** (45 mg, 0.047 mmol), S_8 (3 mg, 0.0117 mmol), and triethylamine (0.8 mL) were added to toluene (10 mL) and stirred for 20 h at room temperature. The solution changed color from green to red-brown. After removal of the solvent under vacuum, the residue was taken up in a small amount of petroleum ether and transferred to a column (30 × 1.5 cm) packed with silica gel (activity grade II). A red-brown fraction was eluted with petroleum ether/toluene (5/1), from which **3** was obtained as a black-brown powder (38 mg, 77%). Recrystallization from hexane at −18 to 6 °C gave red-brown crystals

4: **3** (25 mg, 0.024 mmol), dissolved in toluene (15 mL), was warmed to 100 °C for about 20 min, and this caused the solution to change from red-brown to dark green (monitored by IR); work-up as for **3**. A dark, black-green fraction was eluted with petroleum ether/toluene (10/1) (column 15 × 0.6 cm), from which **4** (11 mg, 46%) was isolated as a black-green solid. Recrystallization from hexane at room temperature afforded dark red crystals.

[1] O. J. Scherer, J. Braun, P. Walther, G. Heckmann, G. Wolmershäuser, *Angew. Chem.* **1991**, *103*, 861–863; *Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 852–854. In the meantime we have established that **2** can be oxidized to the PO complex very simply with oxygen (see ref. [2c]). Experimental procedure: O_2 (0.2 bar, purity 99.8%) was passed through a tube (3 mm diameter) into a solution of **2** (45 mg, 0.047 mmol) in hexane (30 mL) for at least 1 min. The color of the solution changed from green to red brown. The solvent was removed under vacuum, and the residue was purified by column chromatography (silica gel, activity grade II, column 30 × 1.5 cm, petroleum ether/ether 7/1). $[Cp^4_2Ni_2(\mu_3\text{-}PO)_2\{W(CO)_4\}]$ (11 mg, 23.4%) was isolated from a dark red fraction; $\tilde{\nu}$(PO) = 1159 cm^{-1} (m, in hexane) and not—as in ref. [1]—1260 cm^{-1}.

Effective Low-Temperature Aromatization of Ethane over H-Galloaluminosilicate(MFI) Zeolites in the Presence of Higher Alkanes or Olefins**

Vasant R. Choudhary*, Anil K. Kinage, and Tushar V. Choudhary

Over the last seven to eight years, aromatization of lower alkanes (C_3 and C_4) over Ga-modified zeolites of type ZSM-5 has been widely investigated,[1–3] and commercial processes for aromatizing propane and higher alkanes have been developed.[1] Natural gas contains an appreciable amount of ethane (upto about 10 mol%). In addition, ethane can be produced in large quantities by oxidative coupling of methane, but, because of its low concentration, separation of ethane from the product stream by conventional means is difficult or uneconomical.[4] Ethane is also formed to an appreciable extent in the Cyclar LPG aromatization process as an undesirable by-product.[1] Its conversion into arenes would, therefore, be of great practical importance. However, because of its very low reactivity[5–7] and high thermodynamic barrier to aromatization,[6, 8] ethane can be converted and yields of arenes that are of practical significance obtained only at high temperatures (≥600 °C).[8] Conversion of ethane into arenes with high yield and selectivity at lower temperatures would not only be of scientific interest but also have a great impact on the natural gas conversion technology. Here we show that the thermodynamic barrier can be overcome and that the conversion and yield of arenes in the aromatization of ethane over H-galloalluminosilicate of ZSM-5 type (H-GaAlMFI) zeolite at lower temperatures (400–500 °C) can be increased manyfold (4–80×) by adding olefins or higher alkanes to the feed. Furthermore, we show that the ethane–ethylene conversion mechanism is changed in the presence of olefins or higher alkanes; the large enhancement in the reactivity of ethane results from a hydrogen-transfer reaction between ethane and higher (C_{3+}) olefins.

Results showing a large increase in the conversion of ethane by aromatization over H-GaAlMFI zeolite due to the presence of various additives A—such as ethylene, propylene, *n*-butylene, propane, and *n*-hexane—at different A/C_2H_6 mole ratios in the feed are presented in Table 1 and Figures 1 and 2. The increase

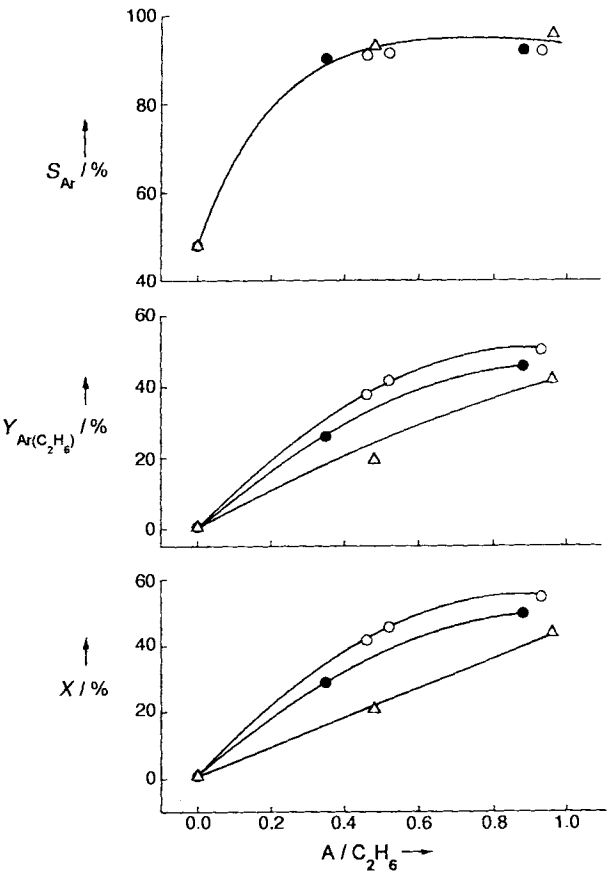

Figure 1. Enhancement in ethane conversion X and yield of arene based on ethane conversion ($Y_{Ar(C_2H_6)}$) over H-GaAlMFI zeolite at 500 °C in the presence of *n*-butylene (○), propylene (●), and ethylene (△) as additives in the feed at different A/C_2H_6 ratios. S_{Ar} = aromatics selectivity in the overall aromatization of ethane and additive; conversion of the olefin additives = 98±2%.

in ethane conversion is higher when the A/C_2H_6 ratio is larger and for additives containing a greater number of carbon atoms. It is interesting that arene selectivity in the simultaneous aromatization of ethane and any of the additives is higher than that in the aromatization of the additives in the absence of ethane (Table 1). The ethane conversions and yields of arenes (based on

[a] Yield of arene based on the ethane conversion X.

ethane conversion) obtained are much higher than those reported earlier (Table 2). The present results and their comparison with earlier ones[5, 8, 9] clearly show a highly beneficial effect for the addition of olefins or higher alkanes to the feed. Because of the additives, both the limitations—high thermodynamic barrier and very low reactivity of ethane for its aromatization at lower temperatures—are overcome.

The change in free energy (ΔG_r) for ethane aromatization, which is positive below 575 °C, approaches zero and becomes negative (even at lower temperatures, Table 3) with increasing concentrations of the additives. This makes the process thermodynamically more and more feasible. The increase in the ethane conversion with higher A/C_2H_6 ratio (Figure 1) and temperature (Figure 2) is consistent with the decrease in ΔG_r (Table 3).

Table 2. Earlier results of ethane aromatization over Ga-modified zeolites of type ZSM-5 without addition of alkenes or higher alkanes.

$3C_2H_6 + n\text{-}C_6H_{14} \rightarrow 2C_6H_6 + 10H_2$	0.33	–	−5.2	−15.8

The intrinsic reactivity of ethane is much lower than that of the higher alkanes.[5–7] The observed enhancement in the ethane reactivity due to the presence of C_3 and C_4 olefins results from their hydrogen-transfer reaction with ethane [Eq. (a)]. Since ethylene and propane or butane are much more reactive than ethane, they are further converted into arenes over the zeolite according to Equations (b) and (c).

$$C_2H_6 + C_nH_{2n} \longrightarrow C_2H_4 + C_nH_{2n+2} \quad (a)$$

$$C_nH_{2n+2} \longrightarrow C_nH_{2n} + H_2 \quad (b)$$

$$C_nH_{2n} \longrightarrow C_{6+} \text{ olefins} \longrightarrow \text{arenes} \quad (c)$$

However, the enhancement in the ethane conversion due to the presence of ethylene in the feed was expected due to the hydrogen-transfer reaction of its dimer butylene, which is formed by ethylene dimerization over the zeolite. In the case of higher-alkane addition, the enhancement also results from the hydrogen-transfer reaction of ethane with the olefin formed from the alkanes by dehydrogenation over the zeolite [Eq (b)], which is a bifunctional catalyst with both dehydrogenation and acid functions.

The reactivity of the olefins in the hydrogen-transfer reaction is higher for that with a larger number of carbon atoms.[10] Therefore, the observed larger enhancement due to the longer carbon chain in the additive and the higher A/C_2H_6 ratio (Figure 1) is consistent with the above-mentioned hypothesis. It is also consistent with the fact that the pentasil zeolites of ZSM-5-type show high activity for the hydrogen-transfer reaction between alkane and olefin, even at 400 °C.[10, 11]

A path and elementary reaction steps for ethane aromatization over the zeolite, which contains both Lewis (extraframework Ga sites) and Brønsted (zeolitic protons) acid sites, are proposed here for explaining the beneficial effect of the additive. In the absence of additive, dehydrogenation of ethane is expected to occur by interaction with the Lewis acid site G located close to the zeolitic proton; this is similar to that proposed for dehydrogenation of propane.[12–15] The steps involve C–H bond cleavage (which is facilitated in the presence of a proton) and abstraction of H^- by the Lewis acid site [Eq. (d)], regeneration of the Lewis acid site by interaction with the nearby proton and H_2 desorption [Eq. (e)], and finally desorption of ethylene by the release of proton from the carbonium ion [Eq. (f)].

$$C_2H_6 + G \rightleftharpoons C_2H_5^+ + GH^- \quad (d)$$

$$GH^- + H^+ \rightleftharpoons G + H_2 \quad (e)$$

$$C_2H_5^+ \rightleftharpoons C_2H_4 + H^+ \quad (f)$$

Because of the very low reactivity of ethane, the activation of ethane by reaction (d) is slow and, hence, limits its conversion. However, the enhancement in ethane conversion in the presence of higher (C_{3+}) olefins results from a change in the mechanism of ethane activation. First, the olefin is activated by interaction with a zeolitic proton to form a carbonium ion by the equilibrium reaction (g). The carbonium ion then undergoes a hydrogen-transfer reaction with ethane [Eq. (h)]. The ethyl carbonium ion undergoes reaction according to Equation (f) to form

$$C_nH_{2n} + H^+ \rightleftharpoons (C_nH_{2n+1})^+ \quad (g)$$

$$C_2H_6 + (C_nH_{2n+1})^+ \rightleftharpoons C_2H_5^+ + C_nH_{2n+2} \quad (h)$$

ethylene with the release of a proton. The activation of ethane according to Equation (h) is much faster than that by Equation (d). Because of its high reactivity, the higher alkane formed in reaction (h) is converted back into the olefin by reactions similar to that in the ethane–ethylene conversion in the absence of olefin additive [Eqs. (d)–(f)].

Ethylene and higher olefins are converted into arenes on the Brønsted acid sites by oligomerization [Eq (i), $N = 6–10$]. Successive dehydrogenation of the carbonium ions[16] by reaction (j) results in formation of the arenes, release of protons, and adsorbed H atoms that remain unchanged.

$$C_2H_4 \text{ or } (C_nH_{2n}) + C_2H_5^+ \text{ [or } (C_nH_{2n+1})^+] \rightleftharpoons (C_NH_{2N+1})^- \quad (i)$$

$$(C_NH_{2N+1})^+ \rightleftharpoons C_NH_{2N-6} \text{ (arenes)} + H^+ + 6H_{ad} \quad (j)$$

The desorption of H_{ad} atoms from the zeolite surface as molecular hydrogen, which controls the formation of aromatics and hence the aromatics selectivity,[17] is facilitated by their spillover to the Ga sites followed by recombinative desorption [Eqs. (k) and (l)].[16, 17] The very high arene selectivity observed

$$H_{ad} + G \rightleftharpoons H\text{–}G \quad (k)$$

$$2H\text{–}G \rightleftharpoons H_2 + 2G \quad (l)$$

is, therefore, attributed to the presence of well-dispersed nonframework Ga sites in the zeolite channels in a close vicinity of the zeolitic protons.

Since the aromatization of ethylene is exothermic and the ethane dehydrogenation or overall ethane aromatization is endothermic, there is a coupling of exothermic and endothermic reactions in the simultaneous aromatization of ethane and ethylene. This makes the process most energy efficient, which is similar to the case of the methane–syngas[18] and ethane–ethylene[19] conversion processes.

This investigation clearly shows that ethane, which has very low reactivity (compared to higher hydrocarbons), can be converted into arenes with high conversion, yield, selectivity, and productivity (because of the high space velocity) at low temperatures (400–500 °C) if enough olefins or higher alkanes are present in the feed. This concept would have great practical implications, particularly for the conversion of ethane from natural gas, which contains appreciable amount of higher hydrocarbons along with methane and ethane, and from the OCM (*o*xidative *c*oupling of *m*ethane) product stream, which contains comparable amounts of ethane and ethylene along with smaller amounts of higher hydrocarbons.

Experimental Section

H-GaAlMFI zeolite [framework (FW) Si/Ga 49.9, FW Si/Al 40.3, non-FW Ga 2.2 wt%, Na/(Al+Ga) 0.03, crystal shape spherical hexagonal, and crystal size 5.5 ± 1.5 μm] was prepared and characterized by methods described earlier [20]. The zeolite was pretreated in a flow of hydrogen (space velocity 1030 $cm^3 g^{-1} h^{-1}$) at 600 °C for 1 h and then in air for 0.5 h. The number of strong acid sites (in terms of the pyridine chemisorption at 400 °C) in the zeolite is 0.46 mmol g^{-1}. The ethane aromatization reaction over the zeolite was carried out under steady-state conditions at atmospheric pressure in a continuous-flow quartz reactor with a mixture of

ethane (33.3 mol%) and nitrogen, with or without any additive (higher alkanes or olefins), as the feed at a space velocity of $6100 \pm 100\ cm^3 g^{-1} h^{-1}$ with a square-pulse technique described earlier [21]. The space velocity was measured at 0 °C and 1 atm. Conversion X in %, S_{A_r} in %, and yield of arene based on ethane conversion ($Y_{Ar(C_2H_6)}$ in %) were determined as follows: $X = [\{(wt\%\ of\ reactant\ in\ the\ feed\ hydrocarbons) - (wt\%\ of\ reactant\ in\ the\ product\ hydrocarbons)\}/(wt\%\ of\ reactant\ in\ the\ feed\ hydrocarbons)] \times 100$; $S_{A_r} = [(wt\%\ of\ arenes\ in\ the\ hydrocarbon\ products)/\{100 - wt\%\ of\ reactant(s)\ in\ the\ hydrocarbon\ products\}] \times 100$; $Y_{Ar(C_2H_6)} = (X S_{A_r})/100$.

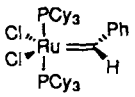
High-Yield Synthesis of [2]Catenanes by Intramolecular Ring-Closing Metathesis**

Bernhard Mohr, Marcus Weck, Jean-Pierre Sauvage,* and Robert H. Grubbs*

The development of effective approaches to interlocked molecular rings, catenanes, constitutes a great challenge in preparative chemistry,[1] especially in light of their role in DNA structure and related molecules of biological relevance.[2] Following the pioneering work of Schill and Wasserman,[3] template-directed strategies that used transition metal complexation,[4, 5] π-donor–acceptor interactions,[6] and hydrogen bonding[7] have not only made the synthesis of interlocking rings more accessible but have also allowed the introduction of various functional groups. In most cases, the cyclization reaction is restricted to the formation of ether and amide bonds or quaternary ammonium salts by an intermolecular pathway.

Ring-closing metathesis (RCM) has been established as an efficient approach to macrocyclic systems with intramolecular formation of carbon–carbon double bonds.[8, 9] The ruthenium benzylidene catalyst **1** (Cy = cyclohexyl) is particularly attractive in these reactions, due to its high activity and tolerance to an array of functional groups.[8, 10] Although RCM was initially applied in the synthesis of small five- to eight-membered rings,[11] this methodology has recently been extended to larger ring systems incorporating up to 38 atoms.[12]



1

The approach presented here utilizes a combination of a transition metal based template strategy and RCM to provide access to [2]catenanes (Figure 1). The building blocks are the 30-membered macrocycle **2**, bearing a 2,9-diphenyl-1,10-phenanthroline (dpp) bidentate chelate in its backbone, and the acyclic ligands **3** and **4**, in which the dpp moiety is symmetrically substituted with ethylene oxide groups with a terminal olefin (Scheme 1a).[13] The threaded complexes **5** and **6** were formed quantitatively by the reaction of **2** with a stoichiometric amount of $[Cu(MeCN)_4]PF_6$ in CH_2Cl_2/MeCN followed by addition of diolefins **3** and **4**, respectively. Analogously, the intertwined

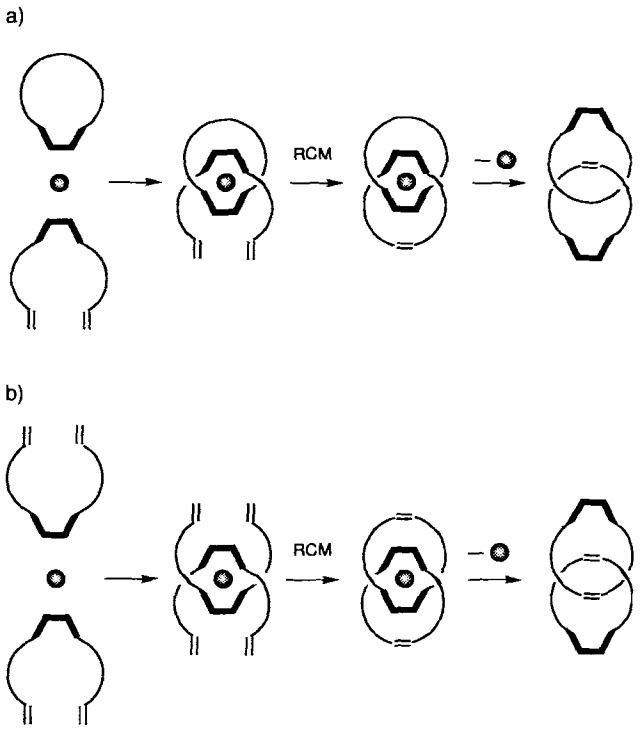


Figure 1. Schematic drawing of the approach utilizing a combination of a transition metal based template strategy and RCM to provide access to [2]catenanes: a) formation of a threaded complex followed by RCM and decomplexation; b) formation of an intertwined complex followed by twofold RCM and decomplexation. The black circle represents the transition metal ion.

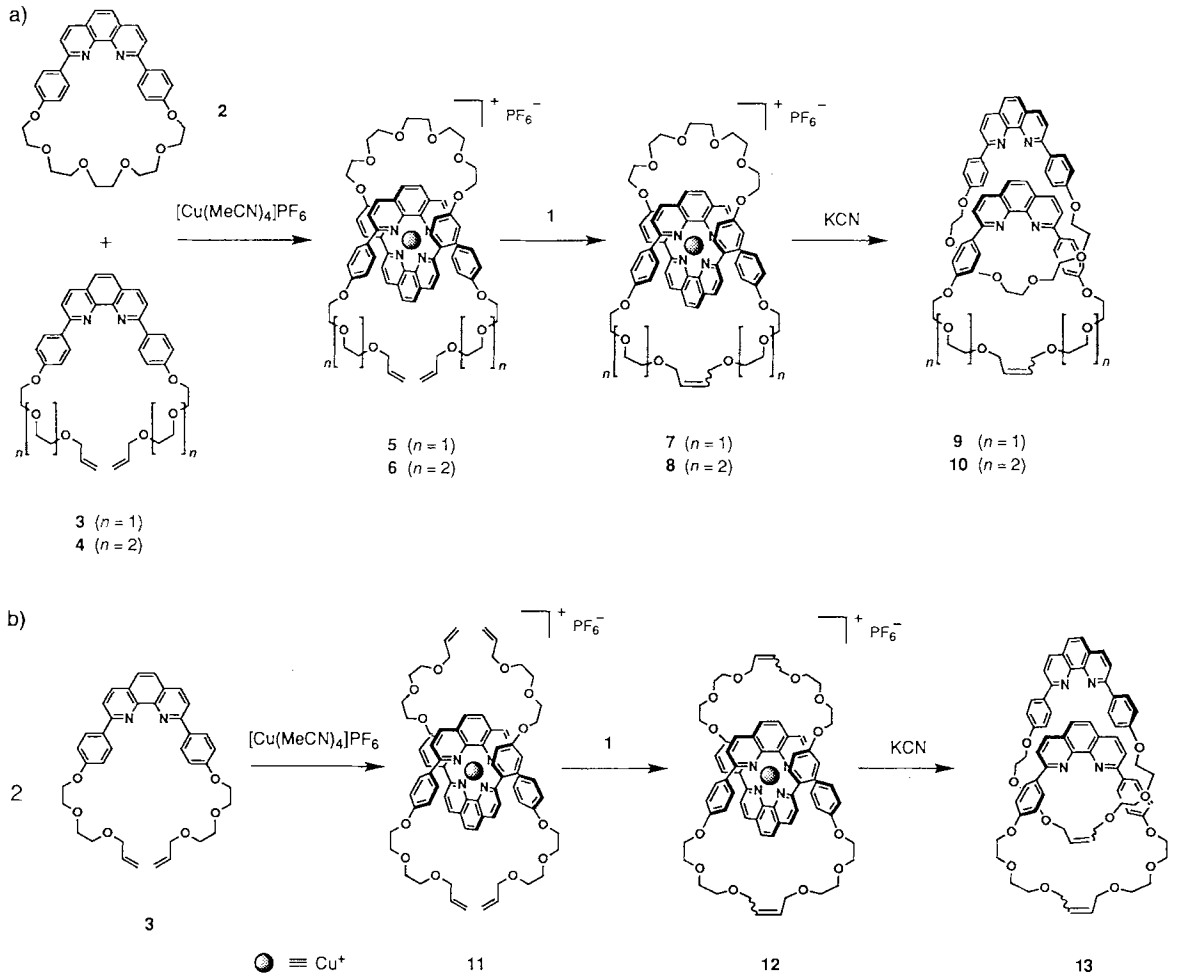

Scheme 1. Synthesis of the [2]catenanes **9**, **10**,and **13**. a) RCM of the threaded complexes **5** and **6** resulting in a 32- and 38-membered ring, respectively. b) RCM of the intertwined complex **11** resulting in two 32-membered rings.

complex **11** was obtained in quantitative yields by complexation of two equivalents of **3** with $[Cu(MeCN)_4]PF_6$ (Scheme 1b). Complexes **5**, **6**, and **11** were then subjected to intramolecular RCM with catalyst **1** to yield the corresponding catenates **7**, **8**, and **12** by formation of 32- (**7**, **12**) and 38-membered (**8**) rings. Twofold RCM of **11** led exclusively to the system with two interlocked rings; the twisted product (formed by the intramolecular reaction between the olefins of different ligands) did not form, as unequivocally concluded by ^1H NMR spectroscopy, FAB-MS (FAB = Fast Atom Bombardment), and the topology of the demetalated species. The yields obtained in these cyclization reactions (Table 1) exceed those for most other medium or even large rings, where hydrogen bonding,[8, 12] the presence of conformational constraints, or template effects[14] are present to facilitate RCM. We believe that the remarkable efficiency of this RCM reaction stems, at least in part, from a preorganization of the olefins due to electrostatic interactions between the oxygen atoms and the phenanthroline system,[15] in combination with a locked conformation of the phenyl rings (π donor) and phenanthroline system (π acceptor).[16] This is supported by the exclusive formation of the interlocked species in the RCM of **11** and the observation that RCM of the free ligands **3** and **4** proceeds in lower yields (73%). For all catenates, the energetically favored *trans* configuration at the double bond prevails.

Table 1. Results of the ring-closing metathesis and demetalation reaction.

Catenate	Yield[%][a]	*trans*/*cis*[b]	Catenand	Yield[%][a]
7	92	97/3	**9**	92
8	88	95/5	**10**	93
12	92	98/2	**13**	90

[a] Yield of isolated product. [b] Determined by integration of the ^1H NMR signals of the isomeric olefin protons.

Demetalation of the catenates **7**, **8**, and **12** with potassium cyanide in aqueous MeCN afforded the [2]catenands **9**, **10**, and **13** in almost quantitative yields (Scheme 1, Table 1). Their composition was confirmed by FAB-MS (see Figure 2 for **13**). All spectra display the characteristic pattern for catenated species, in particular the absence of peaks between the molecular ion peak and the peaks corresponding to the individual macrocycles.[17] The FAB-MS of **13** provides further proof for the exclusive formation of the interlocked species **12** in the RCM step.

In conclusion, RCM has been established as a highly efficient protocol for the synthesis of [2]catenanes by intramolecular cyclization. This methodology provides a versatile approach for the efficient synthesis of [*n*]catenanes, knots, and topologically related species.

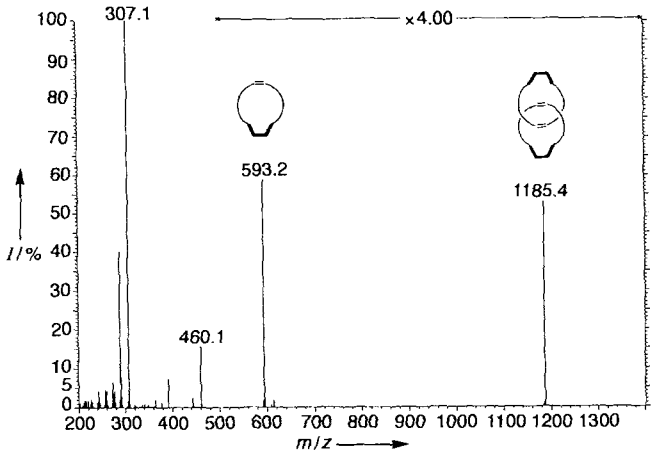

Figure 2. Positive FAB-MS spectrum of catenane **13** in a *p*-nitrobenzyl alcohol matrix (display from $m/z = 200$ to 1400; peaks at $m/z = 307.1$ and 460.1 result from the alcohol matrix). The peak at $m/z = 1185.4$ corresponds to [catenane $- H^+$], and at $m/z = 593.2$ to [macrocycle $- H^+$]. The absence of peaks between the molecular ion peak and the the peak corresponding to the individual macrocycle is characteristic for catenated species [16].

Experimental Section

General procedure for ruthenium benzylidene catalyzed RCM: Under exclusion from air and moisture, **1** (5 mol%) in CH_2Cl_2 was added to a 0.01 M solution of the diolefin (typically 200 to 900 mg) in CH_2Cl_2. After the mixture was stirred for 6 h at room temperature, additional catalyst (5 mol%) was added, and stirring continued for 6 h. The solvent was then removed under reduced pressure, and the crude reaction mixture purified by repeated column chromatography (silica gel, CH_2Cl_2/MeOH 96/4 v/v) to yield the [2]catenates as burgundy solids. All compounds were characterized by NMR spectrscopy, FAB-MS, and elemental analysis.

Azo-Dye Rotaxanes

Sally Anderson,* Tim D. W. Claridge, and Harry L. Anderson*

Azo dyes are the largest and most commercially important class of synthetic colorants.[1] Their interaction with cyclodextrins (CDs) has been investigated as a method of controlling their stability, solubility, and aggregation.[2] Rotaxane formation offers a way of converting these labile inclusion complexes into robust encapsulated chromophores, with the dye permanently protected inside the cavity of the CD. There seem to be no previous reports of rotaxanes of this type.[3] We have synthesized a range of water-soluble azo-dye rotaxanes using the hydrophobic effect to direct rotaxane formation (Scheme 1).[4]

When azobenzene diazonium salt **1a** is added to an aqueous solution of β-naphthol **2** in the presence of either α-CD **3a** or β-CD **3b** at 0–5 °C, the solution immediately turns deep purple. Paper chromatography reveals the formation of the fast-running rotaxanes **4a**⊂**3a** or **4a**⊂**3b**, respectively, as well as the less mobile non-rotaxanated dye **4a**, which is rather insoluble in water and can be separated from the rotaxanes by centrifugation. Rotaxanes **4a**⊂**3a** and **4a**⊂**3b** were purified by paper chromatography and recrystallization, and isolated in 12 and 15% yields, respectively. The tolidine diazonium salt **1b** also gave a

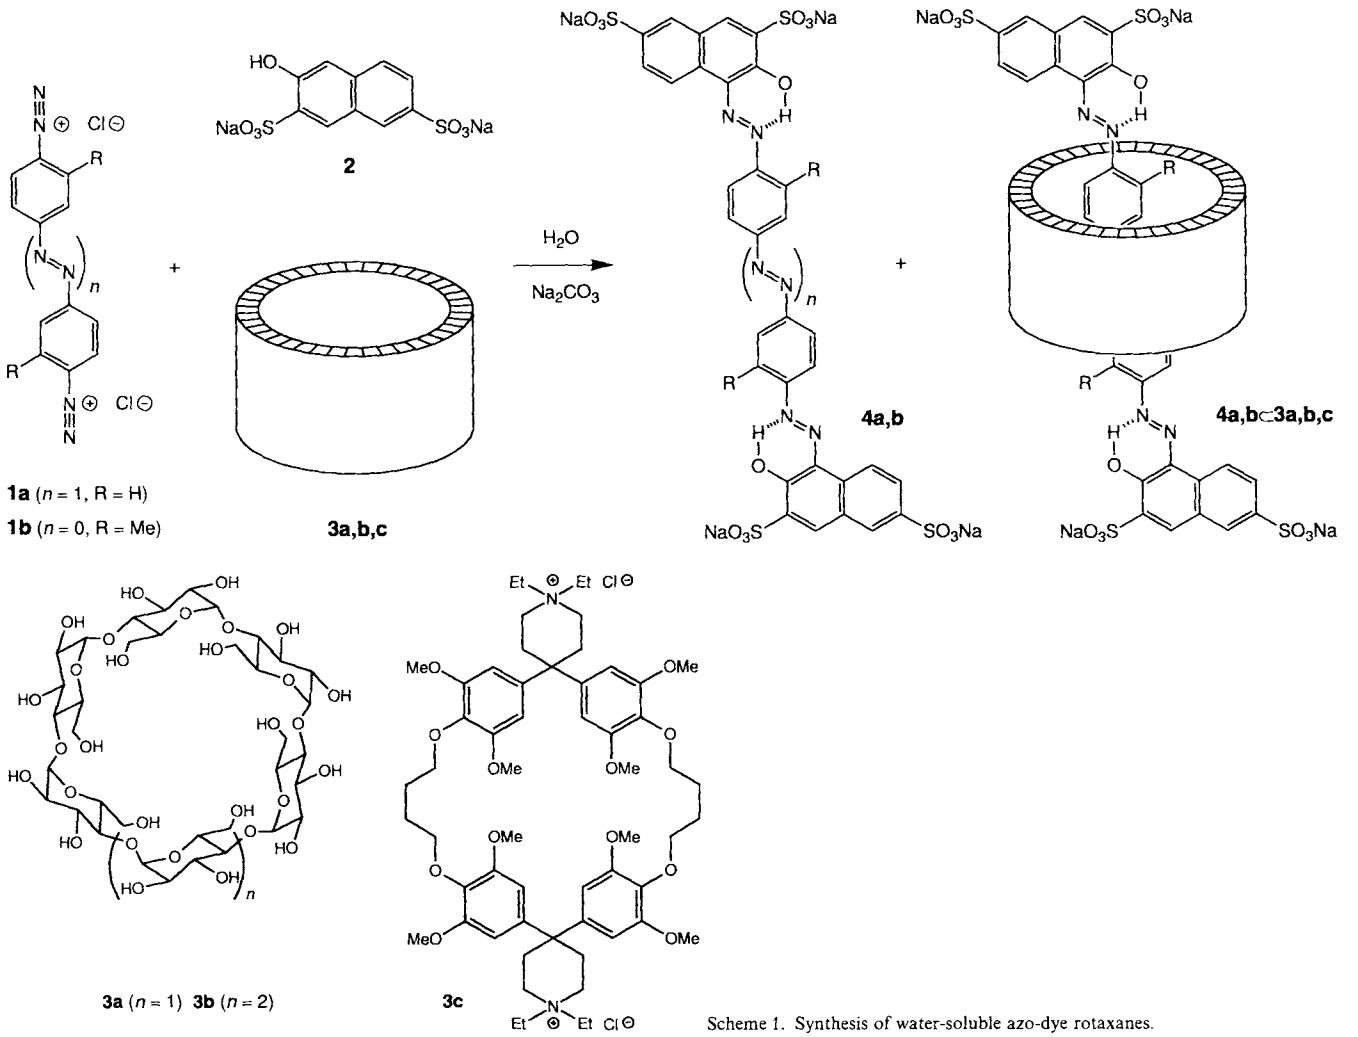


Scheme 1. Synthesis of water-soluble azo-dye rotaxanes.

rotaxane with **3b** when allowed to react with **2** under similar conditions, but it failed to give any rotaxane with **3a**. Diazonium salt **1b** is evidently too large to bind in the cavity of **3a**. Rotaxane **4b⊂3b** was isolated in 6% yield.

All three rotaxanes were fully characterized by ^{1}H and ^{13}C NMR spectroscopy and ESI-MS (Table 1).[5] In all mass spectra the most abundant molecular ion corresponds to the tetraanion formed by loss of four sodium cations. The NMR spectra show that the symmetry of the CD is imposed on the azo dye, making its two ends nonequivalent, whereas the symmetry of the CD is maintained, since it rotates rapidly around its guest on the NMR timescale. When ^{1}H NMR spectra are recorded in [D$_6$]DMSO, all the signals for hydroxyl groups are sharp and well-resolved. Two signals appear at about $\delta = 17$ due to the hydrogen-bonded phenolic OH groups at each end of the rotaxanes. The ^{1}H NMR spectrum of **4b⊂3b** was assigned by 1-D-NOESY and 2-D-COSY NMR techniques. Long-range weak NOEs are observed with 1-D double-pulsed field-gradient spin-echo (DPFGSE) NOESY experiments.[6] A separate and complementary set of NOEs is seen from each rim of the CD (Scheme 2). For example, the naphthalene proton H_A shows NOEs to hydroxyl protons OH-2 and OH-3 as well as to the proximate internal CD proton H-3, whereas H_A shows NOEs to OH-6 and H-6, which are situated on the opposite rim of the CD. Both protons $H_{G'}$ and H_I show NOEs to CD H-5 and H-3 on the inner surface of the CD. This shows that the central portion of the dye is encapsulated by the CD.

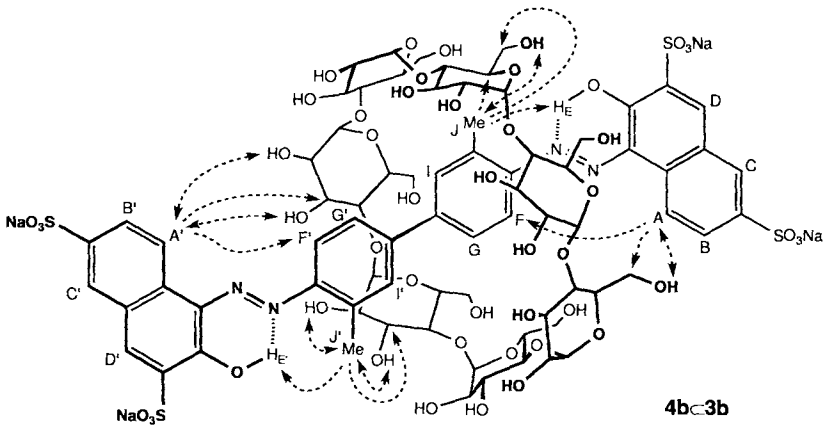
Table 1. Selected physical and spectroscopic data for **4a⊂3b**, **4a⊂3b**, and **4a** [a].

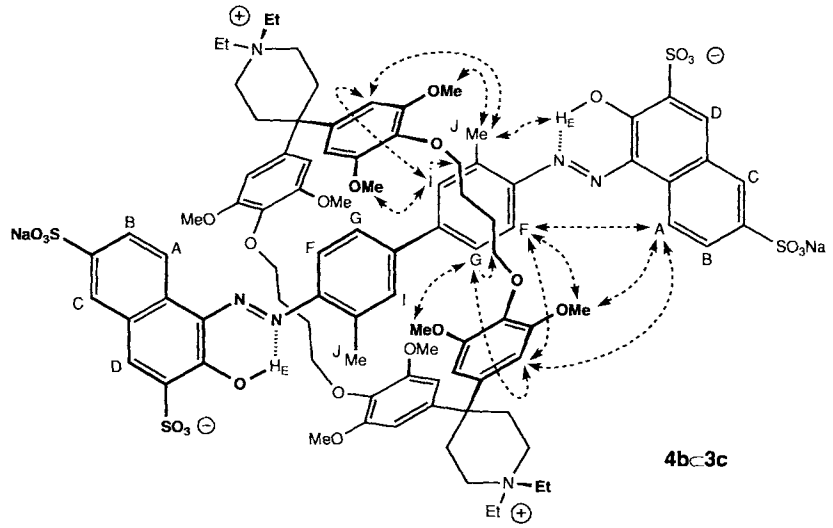
4a⊂3b: ^{1}H NMR: $\delta = 16.79$ (s, 1H; $H_{E'}$), 16.47 (s, 1H; H_E), 8.51 (d, $J = 8$ Hz, 1H; $H_{A'}$), 8.44 (d, $J = 8$ Hz, 1H; H_A), 8.28 (s, 1H; $H_{D/D'}$), 8.26 (s, 1H; $H_{D/D'}$), 8.14 (d, $J = 9$ Hz, 2H; $H_{G'}$), 8.02 (d, $J = 9$ Hz, 2H; H_G), 8.0–7.9 (m, 7H; $H_{C'}$, H_C, H_F, $H_{F'}$, $H_{B'}$), 7.87 (d, $J = 9$ Hz, 1H; H_B), 5.70 (d, $J = 7$ Hz, 7H; OH-2), 5.60 (brs, 7H; OH-3), 4.79 (d, $J = 3$ Hz, 7H; H-1), 4.49 (t, $J = 5$ Hz, 7H; OH-6), 3.7–3.1 (m, 42H; H-2, H-3, H-4, H-5, H-6); ^{13}C NMR: $\delta = 174.13$, 173.53, 150.37, 150.25, 146.94, 146.77, 144.81, 144.56, 141.14, 140.74, 139.80, 139.52, 133.29, 133.14, 130.87, 130.54, 128.35, 127.83, 126.77, 126.58, 125.76, 125.49, 124.57, 124.47, 122.22, 121.37, 118.06[b], 101.85, 81.11, 73.01, 72.39, 71.88, 59.61; UV/Vis: $\lambda_{max}(\lg\varepsilon) = 567$ nm (4.75); negative-ion ESI-MS: $m/z = 493.3$ $[M - 4Na^+ + H^+]^{4-}$, 658.1 $[M - 4Na^+ + H^+]^{3-}$, 987.7 $[M - 4Na^+ + 2H^+]^{2-}$, correct for $C_{74}H_{88}N_6Na_4O_{49}S_4$.

4a⊂3c: ^{1}H NMR: $\delta = 16.19$ (s, 2H; H_E), 8.32 (d, $J = 8$ Hz, 2H; H_A), 8.29 (s, 2H; H_D), 7.96 (s, 2H; H_C), 7.93 (d, $J = 8$ Hz, 2H; H_B), 6.99 (ABq, $J = 8$ Hz, 8H; $H_{F/G}$), 6.93 (s, 8H; cyclophane arenes), 3.64 (s, 24H; OMe), 3.5–2.6 (m, 32H; N^+CH_2, $N^+CH_2CH_2$, and OCH_2), 1.32 (m, 8H; OCH_2CH_2), 1.17 (t, $J = 7$ Hz, 12H; $N^+CH_2CH_3$); ^{13}C NMR: $\delta = 171.07$, 152.86[b], 149.67, 146.94, 144.66, 141.46, 138.14, 135.26, 132.43, 130.35, 127.08, 126.28, 125.74, 123.57, 120.53, 117.63, 104.01, 70.97[b], 55.86, 54.92, 42.68, 28.01, 25.05, 6.67; UV/Vis: $\lambda_{max}(\lg\varepsilon) = 567$ nm (4.82); negative-ion ESI-MS: $m/z = 920.4$ $[M - 2Na^+]^{2-}$, correct for $C_{90}H_{102}N_8Na_2O_{26}S_4$.

4a: ^{1}H NMR: $\delta = 16.18$ (s, 2H; H_E), 8.42 (d, $J = 8$ Hz, 2H; H_A), 8.26 (s, 2H; H_D), 8.06 (ABq, $J = 9$ Hz, 8H; H_G, H_F), 7.91 (brs, 2H; H_C), 7.83 (d, $J = 8$ Hz, 2H; H_B); UV/Vis: $\lambda_{max}(\lg\varepsilon) = 562$ nm (4.71); negative-ion ESI-MS: $m/z = 209.6$ $[M - 4Na^+]^{4-}$, 279.9 $[M - 4Na^+ + H^+]^{3-}$, 420.2 $[M - 4Na^+ + 2H^+]^{2-}$, correct for $C_{32}H_{18}N_6Na_4O_{14}S_4$.

[a] ^{1}H (500 MHz) and ^{13}C (125 MHz) NMR spectra were recorded in [D$_6$]DMSO, and UV/Vis spectra in DMSO unless otherwise stated. [b] Two coincident signals.





Scheme 2. Structures of **4b**⊂**3b** and **4b**⊂**3c** as well as some of the NOEs observed (double-headed arrows indicate NOEs in both directions).

We also synthesized azo-dye rotaxanes with cyclophane **3c**.[7] In the presence of **3c**, **1a** and **1b** couple with **2** to give rotaxanes **4a**⊂**3c** or **4b**⊂**3c** as the exclusive azo-dye product; no non-rotaxanated dye **4a** or **4b** is formed, although some by-products are produced due to dediazotization. The rotaxanes were isolated as their sodium salts in 46 and 40% yields, respectively. They precipitate from the reaction mixtures as $[\mathbf{4a}\subset\mathbf{3c}]^{2-}\cdot[\mathbf{3c}]^{2+}$ and $[\mathbf{4b}\subset\mathbf{3c}]^{2-}\cdot[\mathbf{3c}]^{2+}$ salts; they were filtered off and purified by column chromatography, then ion-exchanged to the sodium salts. The ^{1}H NMR spectra of these cyclophane rotaxanes are considerably simpler than those of their CD analogues due to both the higher symmetry of the cyclophane and to the cyclophane's aromatic ring current, which disperses the signals of the guest. For example, for **4b**⊂**3c** H_F, H_G, Me_J, and H_I are shifted upfield by $\Delta\delta = 0.90$, 2.08, 0.51, and 1.75, respectively, showing that these protons reside inside the cyclophane. DPFGSE NOESY experiments confirmed that the central portion of the dye is buried inside the cyclophane's cavity. Some of the observed NOEs are illustrated in Scheme 2.

We have shown that the hydrophobic effect can be used to direct the synthesis of azo-dye rotaxanes with both CD and cyclophane macrocycles. The cyclophane rotaxanes are formed in higher yield and are easier to characterize spectroscopically. All of these rotaxanes are more soluble (in most solvents) than the non-rotaxanated dyes. They also aggregate less than their non-rotaxanated analogues; for example, **4a** forms stable bimolecular aggregates in water ($K = 2\times10^3\,\mathrm{M}^{-1}$), whereas **4b**⊂**3b** does not ($K<20\,\mathrm{M}^{-1}$).[8] We plan to explore the effects of rotaxane encapsulation on the stability and photochemistry[9] of these dyes.

Experimental Section

4a⊂**3b:** $NaNO_2$ (41 mg, 0.59 mmol) was added to 4,4′-diaminoazobenzene (60 mg, 0.28 mmol) in aqueous HCl (0.1 M, 10 mL, 1.1 mmol) at 0–5 °C. The solution was stirred for 1 h, aqueous **3b** (11.4 mM, 70 mL, 0.80 mmol) added, and the mixture again stirred at 0–5 °C for 30 min. This solution was added to a mixture of **2** (200 mg, 0.56 mmol) and Na_2CO_3 (99 mg, 0.93 mmol) in water (8 mL) and stirred for 3 h at 20 °C. NaOAc (15 g) was added, and the mixture heated to 80 °C. The precipitate (**4a**) was separated from the supernatant by centrifugation. The product was then precipitated from the supernatant with acetone, washed with hot ethanol, dissolved in water, recrystallized by addition of ethanol, purified by chromatography on paper plates (Whatman 3MM) eluting with $MeCN/H_2O$ (1/1), and recrystallized from $DMSO/H_2O$ (1/1) by addition of acetone. Yield: 89 mg (15%).

4a⊂**3c:** $NaNO_2$ (20 mg, 0.29 mmol) was added to 4,4′-diaminoazobenzene (30 mg, 0.14 mmol) in aqueous HCl (0.19 M, 3 mL, 0.58 mmol) at 0–5 °C. The solution was stirred for 1 h, aqueous **3c** (21 mM, 20 mL, 0.42 mmol) added, and the mixture again stirred at 0–5 °C for 30 min. This solution was added to a mixture of **2** (98 mg, 0.28 mmol) and Na_2CO_3 (50 mg, 0.47 mmol) in water (2 mL) and stirred for 1 h. The solid was collected by centrifugation and purified by flash column chromatography on silica eluting with $MeOH/2\,\mathrm{M}\ NH_4CHO_2/MeNO_2$ (16/2/1). Concentration of the solution to 10% of its original volume resulted in precipitation of the rotaxane, which was isolated by filtration, washed with a minimum of water, and dried in vacuo at 100 °C/0.01 mm Hg to remove traces of ammonium formate. Cation exchange was carried out with Na^+ Dowex 50WX8-400 (10 g), and recrystallization from 1:1 $DMSO/H_2O$ by addition of ethanol. Yield: 122 mg (46%).

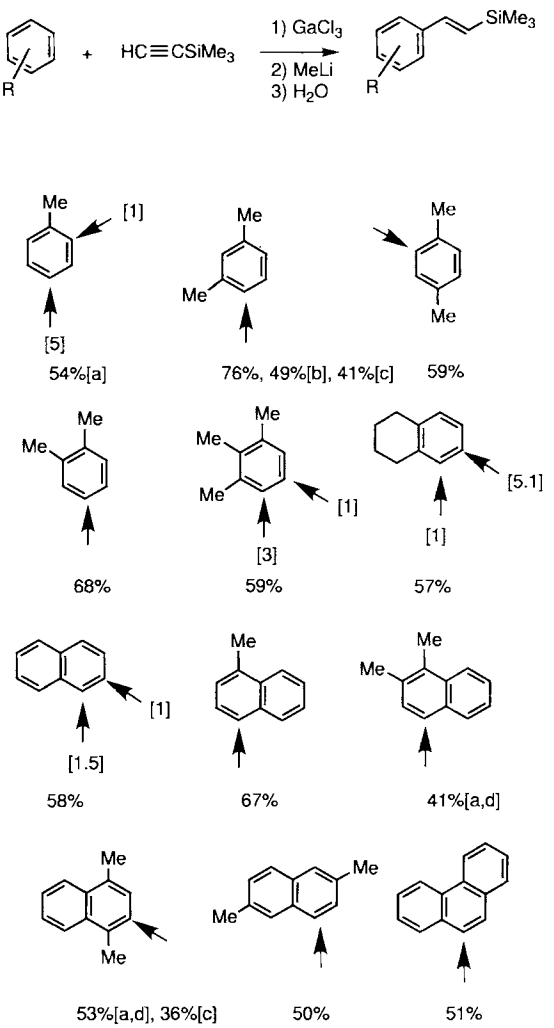
Friedel–Crafts β-Silylvinylations**

Masahiko Yamaguchi,* Yoshiyuki Kido, Akio Hayashi, and Masahiro Hirama

The Friedel–Crafts reaction is a fundamental method for converting aromatic C–H bonds to C–C bonds. Although Friedel–Crafts alkylations and acylations are often used in organic synthesis, the corresponding vinylations have not been successful. Attempts at vinylation using either ethyne or vinyl halides have given polymeric substances and 1,1-diarylethanes, even when the arenes are present in large excess.[1] This is due to the instability of the vinylated products under the reaction conditions. Even 2-propenylations gave very low yields, and formed various by-products.[2] Low efficiency in generating the electrophilic species may be another reason why the electrophilic vinylations failed. We report here the Friedel–Crafts (*E*)-β-silylvinylation of aromatic hydrocarbons promoted by $GaCl_3$. This reaction is a direct C_2-olefination of arenes[3] that proceeds via novel organogallium intermediates.

An aromatic hydrocarbon (1 equiv) and trimethylsilylacetylene (3 equiv) were treated with $GaCl_3$ (3 equiv) in a mixture of methylene chloride and methylcyclohexane at −78 °C. After 30 min, methyllithium (9 equiv) in ether was added, and the (*E*)-[(β-trimethylsilyl)vinyl]arene was obtained by aqueous workup (Scheme 1). The C–C bond was formed at the β-carbon atom of the silylacetylene, and the (*E*)-configuration of the product was determined by ^{1}H NMR spectroscopy. When only one equivalent of silylacetylene and $GaCl_3$ were used the yield was much lower. The regioselectivity of the aromatic substitution indicates an electrophilic mechanism,[4] and is consistent with the low reactivity of chlorobenzene, which can be used as solvent. Steric factors are also important. For example, 2,6-dimethylnaphthalene reacted at C-4 rather than at the most reactive position (C-1), and a considerable amount of 2-vinylated product was obtained from naphthalene. The electrophilic species involved in this reaction appears to be considerably



Scheme 1. $GaCl_3$-promoted β-silylvinylations of arenes. The reaction sites on the starting materials are marked with arrows; the relative regioselectivity in each case is given in square brackets. [a] Yield determined by gas chromatography. [b] Reaction in chlorobenzene. [c] Molar ratio $GaCl_3$:acetylene:arene = 1.0:1.0:1.0. [d] Molar ratio $GaCl_3$:acetylene:arene = 2.0:2.0:1.0.

bulky. Unlike previously reported Friedel–Crafts vinylations and alkenylations,[1, 2] this reaction does not require excess arene. Therefore, nonvolatile polycyclic arenes can be β-silylvinylated without the necessity to carry out the tedious separation of a large amount of unconverted starting materials. There was very little divinylation and isomer formation under the present reaction conditions. Triethylsilyl- and *tert*-butyldimethylsilylacetylene reacted analogously with *m*-xylene to give the corresponding products in yields of 54 and 52%, respectively. When 1-methylnaphthalene was treated with $GaCl_3$ and ethyne at −78 °C, the arene was consumed within 30 min to give a polymeric compound. Thus, the silyl group prevents the olefin group on the products from undergoing side reactions.

The (β-silylvinyl)arenes are useful synthetic intermediates for a variety of aromatic compounds (Scheme 2). For example, the trimethylsilyl group can be removed by trifluoroacetic acid to give the parent vinylarene, and epoxidation followed by treatment with an acid gives an arylacetaldehyde,[5] which can be reduced to an arylethanol.

The use of $GaCl_3$[6] in these β-silylvinylations is critical; other Lewis acids ($AlCl_3$, $GaBr_3$, $InCl_3$, $SnCl_4$, $SbCl_5$, SbF_5), protic acids (CF_3SO_3H, HCl), and heterogeneous acids (Na-Mont-

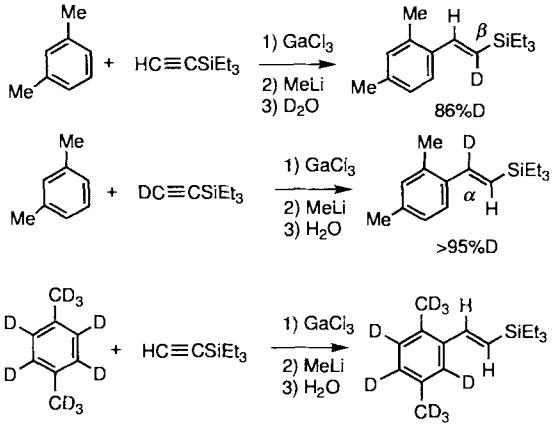
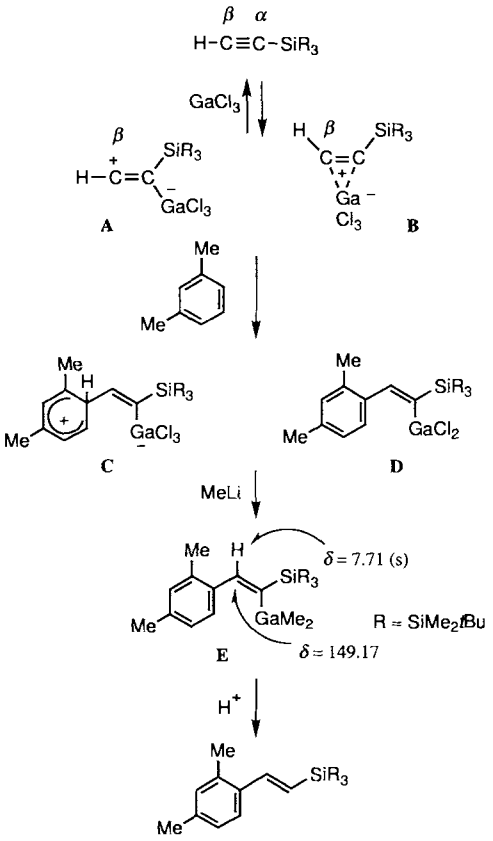
morillonite, Sn-Montmorillonite, Montmorillonite K10) were not effective. Methylene chloride and chlorobenzene are the preferred solvents, since they dissolve arenes at low temperatures. The methyllithium added prior to the aqueous quench can be replaced by methylmagnesium bromide or diethylzinc. However, the yields vary substantially with subtle changes in the workup procedures if the treatment with the organometallic compound is omitted. When D_2O was added after methyllithium, the (β-silylvinyl)arene was deuterated at the olefinic β-carbon atom (Scheme 3). Such deuteration did not take place when



Scheme 3. $GaCl_3$-promoted β-silylvinylations of arenes with deuterated starting materials or reagents.

the olefinic product was treated with methyllithium followed by D_2O either in the presence or in the absence of $GaCl_3$. These observations can be explained by formation of a (β-gallio-β-silylvinyl)arene. Methyllithium probably converts the $GaCl_n$ group to a $GaMe_n$ group, which facilitates the protonation of the organogallium intermediate. When a deuterated silylacetylene was used, the α-carbon atom was deuterated. The olefin group was not deuterated with [D_{10}]*p*-xylene as substrate.

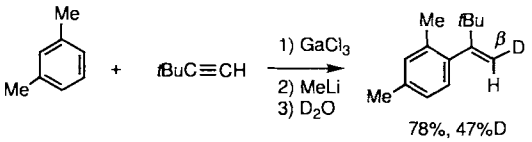
The high reactivity of the electrophilic vinylating reagent is clearly evident from the rapid reaction at a low temperature without the use of excess arenes. We assume that a $GaCl_3$-complexed silylacetylene is formed. The formation of a vinyl cation by protonation of the silylacetylene with $HGaCl_4$ does not explain the results of the deuteration experiments. Furthermore, the addition of 2,6-di(*tert*-butyl)-4-methylpyridine (0.3 equiv) did not interfere with the reaction. Therefore, the mechanism may be summarized as followed (Scheme 4): The activated silylacetylene, presumably either the open vinyl cation **A** or the bridged cation **B**, is attacked by *m*-xylene at the β-carbon atom. The resulting organogallium intermediate, the β-gallio-(β-silylvinyl)arenium cation **C** or the (β-gallio-β-silylvinyl)arene **D**,



Scheme 4. Proposed mechanism of the $GaCl_3$-promoted β-silylvinylation of *m*-xylene.

is then methylated, and the (β-silylvinyl)arene is obtained by protonation. The intermediate **E** was detected by NMR spectroscopy ([D_8]THF): the olefin proton appeared as a singlet at $\delta = 7.71$, which disappeared on the addition of water. Its (*Z*)-configuration was deduced by NOE studies.

$GaCl_3$ promotes alkenylation as well as β-silylvinylation. For instance, when *tert*-butylacetylene was treated with *m*-xylene and $GaCl_3$ followed by methyllithium and D_2O, a β-deuterated α-(*tert*-butyl)styrene derivative was obtained (Scheme 5). Since



Scheme 5. $GaCl_3$-promoted alkenylation of *m*-xylene with *tert*-butylacetylene.

the reaction with [D_{10}]*p*-xylene did not lead to deuteration of the olefin moiety, the mechanism of the alkenylation must be similar to that of the β-silylvinylation. The regioselectivity can be ascribed to the ability of the substituents to stabilize the cations in the electrophilic intermediates rather than to steric reasons. Stabilization of the β-cation by the silyl group[7] is substantial in the intermediate **A** and **B**, while the *tert*-butyl group stabilizes the α-cation. Notably, *trans*-addition occurred with *tert*-butylacetylene, and *cis*-addition with silylacetylene, although the origin of the stereoselectivity is unclear at present. Vinyl cations stabilized by a β-silicon group have attracted a great deal of interest over the last few years.[8] However, their reactivity, particularly C–C bond-forming reactions, has received little atten-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3612-1314 $ 17.50+.50/0

tion because of the very rapid desilylation to give acetylenic compounds. The electrophilic activation of silylacetylenes generally results in substitution.[7] It is therefore notable that the formation of a C–C bond at the β-silicon-stabilized vinyl cation can take place giving addition products. Thus, the chemistry of this extremely reactive electrophilic vinylating reagent promises to be very interesting.

In summary $GaCl_3$ promotes the C_2-olefination of aromatic hydrocarbons with silylacetylene via novel organogallium intermediates. Organogallium compounds have received much less attention in organic synthesis than organoaluminum compounds,[9] although both contain an element from group 13. Thus, the strong activation of π compounds by $GaCl_3$ is a new very promising approach to organogallium chemistry.

Experimental Section

Under an argon atmosphere, a 1.0 M stock solution of $GaCl_3$ in methylcyclohexane (3.0 mL) was added to a solution of *m*-xylene (107 mg, 1.0 mmol) in CH_2Cl_2 (10 mL) at −78 °C. Trimethylsilylacetylene (295 mg, 3.0 mmol) in methylcyclohexane (1.0 mL) was then added, and the mixture was stirred for 30 min. Methyllithium (1.4 M solution in diethyl ether, 6.5 mL) was added, and the mixture was stirred for another 30 min at −78 °C. Aqueous workup gave (*E*)-1-(2-trimethylsilylethenyl)-2,4-dimethylbenzene (155 mg, 76%).

Liquid-Crystal Templates for Nanostructured Metals**

George S. Attard,* Christine G. Göltner,* Judith M. Corker, Susanne Henke, and Richard H. Templer

A rapidly developing new trend in materials science is the transfer of structure from surfactant aggregates to inorganic solids.[1–3] In water, surfactants aggregate into micelles or, at higher concentrations, into lyotropic liquid-crystalline phases. Despite their beauty, lyotropic mesophases have so far not been utilized for their structure, but only for their properties (for example in shampoos), because these ordered aggregates readily undergo phase changes as a result of dynamic exchange processes.

Surfactant aggregates are, however, useful templates for the synthesis of inorganic nanostructures. For example, the synthesis of ordered mesoporous ceramic oxides involves the use of ionic surfactants as structure-directing additives in precipitation processes.[4] A more recent approach to mesoporous ceramic oxides makes use of lyotropic liquid crystals as structure-directing bulk media.[5] Here the sol–gel synthesis of inorganic ceramic oxides (for example silicates) is conducted in the aqueous domains of the microphase-separated medium; hence a cast of the liquid-crystalline phase is produced. In this way, different nanostructures have been obtained from the H_I, Ia3d, and L_x mesophase.[6] The generation of nanostructures from bulk lyotropic mesophases is not restricted to sol–gel processes such as the production of silicates; precipitation processes can also be carried out without loss of long-range order.[7] Pileni et al. have reported the generation of metal nanoparticles in surfactant solutions or lamellar lyotropic liquid crystals. Here metal particles are produced with a high degree of control over shape and size,[8] but the particle morphology cannot be correlated with the ordered structure of the liquid-crystalline phase.

Our aim was to apply the bulk liquid-crystal template method to the generation of ordered, porous metal nanostructures and to show that lyotropic liquid crystalline phases are versatile media for nanostructure design. A mesoporous metal can be expected to have advantages over classical metal colloids with respect to stability and handling. In particular we show that the reduction of platinum salts dissolved within the aqueous domains of a hexagonal (H_I) mesophase leads to platinum whose nanostructure is a cast of the liquid-crystalline phase architecture.

We employed hexachloroplatinic acid (HCPA) and ammonium tetrachloroplatinate (ATCP) as the platinum source. The lyotropic liquid-crystalline phases were prepared from $C_{16}(EO)_8$ (octaethyleneglycol monohexadecyl ether), because

this surfactant forms a wide hexagonal mesophase that is stable at room temperature.[9] The liquid-crystalline nature of the ternary mixtures of platinum salt, surfactant, and water was confirmed by polarized-light optical microscopy. HCPA was reduced by adding large pieces (>3 mm) of less noble metals (Fe, Zn, Mg) and allowing the mixture to stand at room temperature for 24 h, after which the mixture had become black. ATCP was reduced by bringing a ternary mixture of surfactant, water, and hydrazine hydrate (mixture A) into contact with a ternary system containing the metal salt (mixture B). Optical microscopy revealed that both mixtures A and B were hexagonal mesophases when brought into contact. Immediate reaction caused the system to turn black. To obtain platinum free from reagents (platinum salts, surfactant, and reducing agent), the solid products of the reaction were treated successively with acetone, water, 6 M hydrochloric acid, water, and acetone. Thermogravimetric analysis (TGA) of the resulting metal powders revealed that virtually all the surfactant could be removed by extraction, as a weight loss of 2% only was detected up to to 600 °C (in air). Scanning electron microscopy (SEM; see Figure 1, top) of the dried powder showed that the product comprised particles 90–500 nm in diameter.

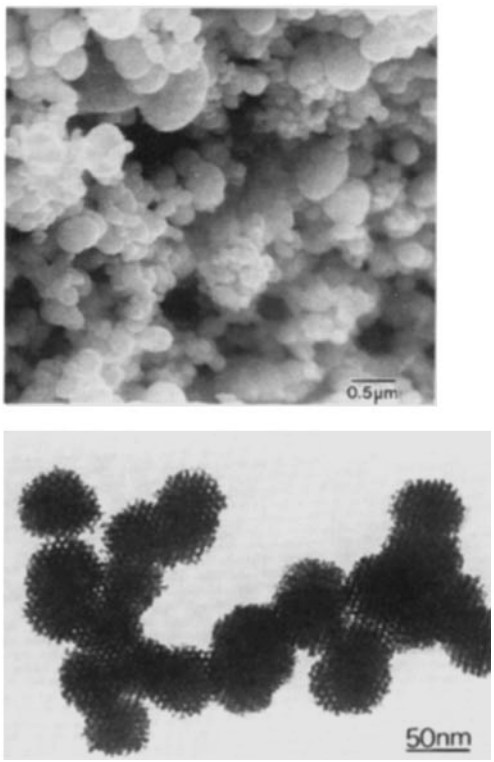

Figure 1. SEM image of a washed sample of mesoporous platinum (top) and TEM image of H_I-platinum (bottom). The material was suspended in acetone, sonicated for 5 min and applied to a carbon-coated copper grid.

Transmission electron microscopy (TEM; see Figure 1, bottom) revealed that these particles (termed H_I-Pt) have a hexagonal nanostructure consisting of cylindrical (30 Å diameter) pores separated by platinum walls 30 Å thick, with an average pore-to-pore distance of 60 Å. TEM studies of ultramicrotomed samples confirmed that this internal nanostructure was also present in larger particles. The wall thickness of the nanostructured metal H_I-Pt appears to be larger than that of the corresponding H_I-silica (where it is typically 12 Å).

X-ray diffractograms (Figure 2) of H_I-Pt show only one diffraction peak in the small-angle region, with a lattice parameter

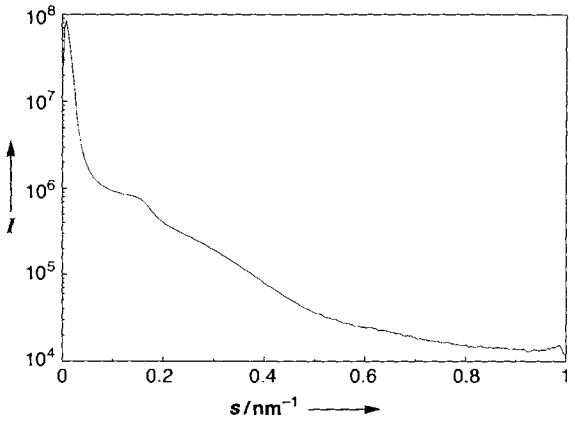

Figure 2. Small-angle X-ray diffractogram of H_I-platinum I = intensity (arbitrary units).

of 65 Å, which is in good agreement with the TEM results. The low-angle scattering and broadening of the diffraction peak indicates a degree of disorder, which is borne out by the TEM image. The presence of only one scattering peak in the diffractogram is probably due to a low degree of long-range order, which could be caused by nonuniform wall thickness. Wide-angle X-ray diffractograms showed the material to be polycrystalline with a face-centered cubic (fcc) structure.

The extended X-ray absorption fine structure (EXAFS[10]) data obtained for the platinum L_{III} edge of the nanostructured material (see Figure 3) are entirely consistent with the presence of pure platinum metal. Backscattering shells due to platinum are observed out to about 5.5 Å in the Fourier transform of the spectrum.

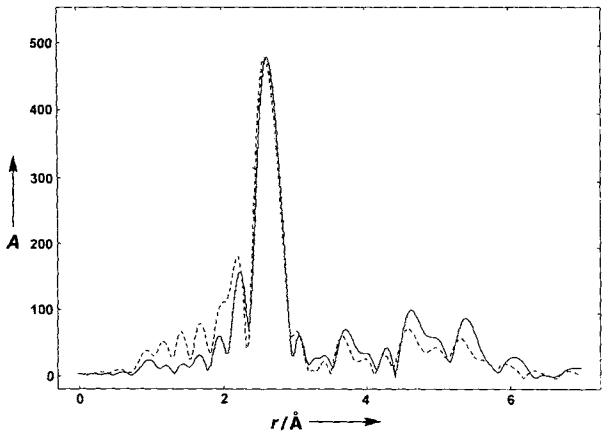

Figure 3. Comparison of the Fourier transforms of the L_{III} edge EXAFS for platinum foil (solid) and H_I-platinum. For clarity, the amplitude of the curve for platinum foil has been scaled down by a factor of 2.8. A = amplitude [13].

The absence of oxygen backscattering shells rules out the presence of platinum oxide. The best fit to the EXAFS data was achieved with four shells of platinum atoms at 2.75, 3.89, 4.79, and 5.47 Å (Table 1). These distances compare well with those observed for bulk platinum metal. Furthermore, the coordination numbers of 7, 3, 13, and 7 for the four shells indicate an fcc structure, which is in good agreement with the wide-angle X-ray diffraction results. The Fourier transforms of the EXAFS spectrum[11] for platinum foil and the nanostructured metal are almost identical, although a significantly lower amplitude is observed in the latter spectrum. The lower amplitude and the

	Pt	12	5.509(4)	0.0180(6)	

associated decrease in coordination numbers can be attributed to the presence of a high proportion of surface atoms. An additional effect of the larger number of surface atoms is an apparent shortening of the metal–metal bonds relative to those of the bulk metal.

A separate series of experiments employed lower surfactant concentrations in order to demonstrate that the structure of nanostructured H_I-Pt is a result of the liquid-crystalline phase acting as a template. Treating micellar solutions of $C_{16}(EO)_8$ [or cetyltrimethylammonium bromide (CTAB) as a cationic surfactant] and HCPA with iron as described above gave dense, unstructured particles. These results confirm that the template mechanism responsible for formation of M41S at low surfactant concentrations does not operate here.

The preparation of H_I-Pt is strongly dependent on the reducing agent. Hydrogenation (25 bar, 12 h) afforded only dendritic crystals, as revealed by TEM. Hydrogenation of the platinum salt is slower than reduction with iron or hydrazine and therefore allows the liquid-crystalline phase to reorganize, and large crystals to grow.

However, the confinement of the polar metal salt within the aqueous domains of the lyotropic phase does not imply that the same liquid-crystal template mechanism that is observed for the production of siliceous ceramic oxides[1,2] is responsible for the development of the metal nanostructure. The primary product of the reduction, a cluster of platinum(0) atoms, cannot be stabilized by the liquid-crystalline environment in the same way as the oligomeric silicic acid precursor of silica, which is able to undergo hydrogen bonding. Furthermore, a large reduction in the product's volume relative to that of the low-density (with respect to Pt) precursor ion, has to be accounted for. This is also the reason why no monolithic material is formed during the reduction. As the lyotropic phase nevertheless acts as a structure-directing medium, it seems reasonable to assume that the metal is stabilized at the interface between the hydrophobic and the hydrophilic domains of the microphase-separated environment. Reduction of the platinum salt affords small colloidal primary particles at this interface. Subsequently, these primary particles agglomerate and coalesce, until a wall thickness is reached at which the structure is mechanically stable. The proposed mechanism can also explain why only fast reduction is able to generate a metal nanostructure; only then can the nanostructure be generated before the LC phase is able to rearrange. Metal nanoparticles stabilized at this interface in micellar block copolymer solutions have been observed before.[13]

Our experiments demonstrate that lyotropic liquid-crystalline phases provide versatile reaction media for the synthesis of nanostructured mesoporous platinum. The inherent nanostructure of the porous material provides a high surface area, which is advantageous for catalytic applications. The large absolute particle size (relative to classical metal colloids) might allow for greater ease of catalyst without compromising the surface area. The combination of high surface area with a tailored nanoarchitecture consisting of regular pores and a continuous electron-conduction pathway would be expected to be advantageous in fuel cells, batteries, or sensors, whose performance is determined by mass transport and interfacial processes.

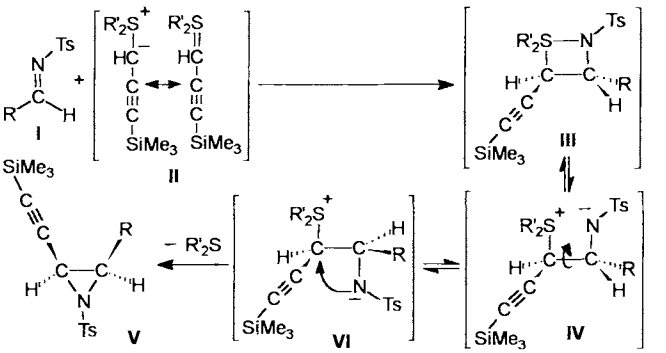
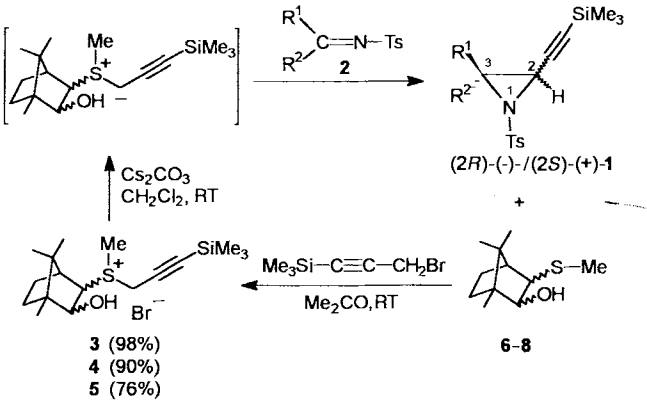
great challenge. By retrosynthetic analysis, there are two direct pathways for constructing the nitrogen-containing three-membered ring: reaction of a nitrene with a prochiral C=C bond[2-4] and of a carbene (or its equivalent carbanion or ylide) with a prochiral C=N bond.[5-7] In contrast to the extensively studied and overwhelmingly successful asymmetric epoxidation[8] and asymmetric cyclopropanation,[9] asymmetric aziridination is much less explored. Most examples appeared in the 1990s.[10] Evans et al.[2a] and Jacobsen et al.[2b] reported two excellent asymmetric aziridinations of a prochiral C=C bond with a nitrene in the presence of a chiral catalyst. Due to the intrinsic high reactivity of nitrenes, no aliphatic substrate was used in these reactions.[11] By the other route, Jacobsen et al.[5] realized the first asymmetric aziridination of a prochiral C=N bond with a carbene, and obtained a *cis/trans* mixture of chiral aziridines in low yields and moderate *ee* values. A substrate-controlled asymmetric aza-Darzens reaction with good *de* values was reported by Davis et al.[6a]. Very recently, Aggarwal et al.[12] disclosed an efficient, asymmetric benzylidene transfer to a prochiral C=N bond by a catalytic ylide aziridination. Optically active aziridines were also prepared by methylene transfer from $Me_2S^+CH_2^-$ or $Me_2S(O)^+CH_2^-$ to chiral sulfinimines.[6c-e] We found that the ylide pathway provides very efficient entry to vinylaziridines[13] and chiral epoxides.[14] For vinylaziridines, a mixture of *cis/trans* isomers was always obtained. After numerous investigations, exclusive *cis* selectivity was achieved by the reaction of *N*-sulfonylimines with propargylic sulfonium ylides under phase-transfer conditions. This may be explained by an intermediate formed by the [2+2] cycloaddition of the imine and the ylide (Scheme 1). This is similar to the epoxidation reaction of carbonyl compounds with propargylic telluronium ylides.[15] The high stereoselectivity enables as to realize a reagent-controlled asymmetric aziridination by a ylide route. We here disclose the preliminary results for preparing optically active acetylenylaziridines **1** in high yields and moderate to high *ee* values (Scheme 2).

Several results from the reaction of *N*-sulfonylimines **2** and sulfonium ylides—produced in situ from chiral sulfonium salts **3**, **4**, or **5**—under solid–liquid phase-transfer conditions are summarized in Table 1. This reaction proceeds smoothly with various kinds of substrates, including aryl- and heteroarylaldimines (reactions 4, 10, and 13), α,β-unsaturated



Scheme 1. Mechanism of the aziridination with propargylic sulfonium ylides. The [2+2] cycloaddition (**II** → **III**) is the rate-determining step. Due to steric hindrance, only the *trans* product forms.



Scheme 2. Asymmetric aziridination with chiral sulfonium propargylides (yields are given in parentheses). Compounds **6**–**8** were retrieved after the reaction; **3**, **6** *exo*-S, *exo*-OH; **4**, **7** *endo*-S, *endo*-OH; **5**, **8** *endo*-S, *exo*-OH.

aldimines (reaction 5), aliphatic aldimines (reactions 6, 7, 11, and 14), and even relatively unreactive ketimine (reaction 8). It is especially noteworthy that aziridination succeeded in aliphatic aldimine and ketimine systems, which is not possible with the nitrene or carbene methods (see above).

There is one example of a chiral, sulfide-catalyzed asymmetric ylide aziridination.[12] Although it gives high *ee* values and pro-

Table 1. Synthesis of chiral **1** by asymmetric aziridination of *N*-sulfonylimines **2** with sulfonium salts **3**, **4**, and **5**—derived from D-(+)-camphor—under phase-transfer conditions [a].

ceeds in a catalytic mode, it requires strict reaction conditions and suffers from low *trans/cis* selectivity ($\approx 3/1$). The present asymmetric aziridination is a stoichiometric reaction but may represent a promising general[16] and practical approach to optically active functionalized aziridines due to its compatibility to a wide range of substrates, high yields, and very mild reaction conditions. Furthermore, the ylide precursors (chiral sulfides) could be easily recovered in higher than 80% yields without loss of optical purity and reused. Though the *ee* value of the product is not very high (maximum 84.9%, reaction 6), it can be efficiently improved by a single recrystallization from *n*-hexane; this may offer a practical utility of these products. For example, the *ee* values of the products from reactions 3 and 4 can be increased from 69.5% to 96.6% and from 77.5% to 99.1% for yields of 58% and 52%, respectively. The opposite asymmetric induction was achieved with sulfonium salts containing *exo*-sulfido groups (**3**, reactions 1-8) to provide (2*R*)-(−)-aziridines and *endo*-sulfido groups[17] (**4** and **5**, reactions 9-14) to provide (2*S*)-(+)-aziridines. Chiral acetylenylaziridines are very difficult to prepare by the two direct approaches based on carbene, nitrene, or aza-Darzens reaction.[18]

Experimental Section

General procedure for aziridination: **2** (0.5 mmol), the chiral sulfonium salt **3**, **4**, or **5** (0.6 mmol), and Cs_2CO_3 (0.6 mmol) were mixed and stirred in CH_2Cl_2 (3 mL, reagent grade, used directly without drying) at room temperature in air. After the reaction was completed (TLC, 2–5 h), the reaction mixture was filtered through a short silica-gel column to remove inorganic salts. The filtrate was concentrated and purified by chromatography on a silica-gel column with petroleum ether(60–90 °C) and ethyl acetate (4:1) as the eluent to give pure (-)- or (+)- *N*-sulfonyl acetylenylaziridines **1**. Chiral sulfides **6**, **7**, or **8** were also recovered (>80% yields).

3, **4**, or **5**: A mixture of a chiral sulfide[14] **6**, **7**, or **8** (2.004 g, 10 mmol) and 3-trimethylsilylpropargyl bromide[19] (2.294 g, 12 mmol) in acetone (3 mL) was stirred at room temperature for 6–48 h. Most of acetone was removed under reduced pressure, and the residue collected by filtration, washed with dry ether (3 × 40 mL), and dried under vacuum at room temperature to give the desired sulfonium salt as a white solid. It was used directly without further purification.

Synthesis of Taxoid Ring Systems: AC → ABC Approach by Way of Intramolecular Alkylation**

Takashi Takahashi,* Hajime Iwamoto, Kensuke Nagashima, Tadashi Okabe, and Takayuki Doi

Taxol (**1**) is an attractive molecular target both in terms of its biological activity and its synthetic complexity, which includes a conformationally restricted ABCD ring system bearing many stereogenic centers with interesting functional groups.[1–3] We have focused on the development of a method for constructing the B ring of the taxoid system.[4] There are several methods for the preparation of medium-membered rings, however, it has been difficult to effect direct cyclization of eight-membered rings due to entropic and enthalpic effects.[5] This is especially true, if the conformation of the desired cyclic molecule is restricted in a highly strained conformation, such as in the taxoid system, thereby making the preparation of the ring from a strain-free acyclic compound even more difficult. We have previously reported several methods for overcoming this problem; for example, the contraction of large-membered ring molecules and the intramolecular alkylation of cyanohydrin ethers with alkyl iodides, tosylates, and allylic halides, efficiently form 10-

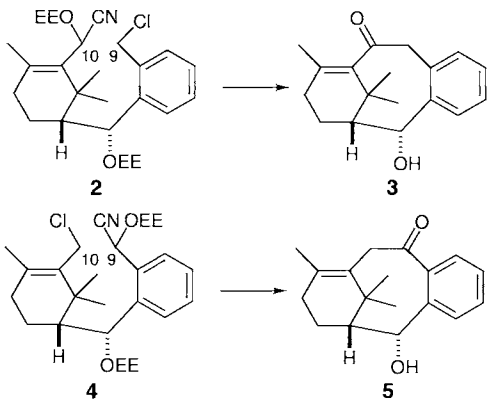
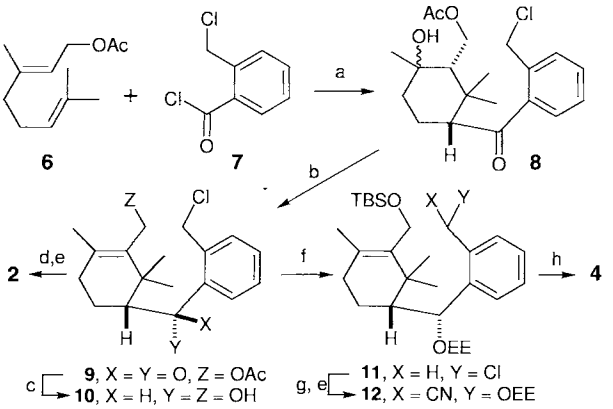
to 15-membered rings.[6, 7] Herein, we report the efficient formation of the eight-membered B ring of the taxoid system by the latter method.

Scheme 1 summarizes our initial study on the formation of the B ring of the taxoid system, in which the CD rings are



Scheme 1. Construction of the B ring in an aromatic taxoid system by intramolecular cyclization. EE = ethoxyethyl.

replaced with an aromatic ring. We planned to cyclize the B ring at positions C9 and C10 by applying an intramolecular cyanohydrin alkylation. In this respect, it was important to determine the feasibility of the alkylation of C10 in **2** by C9 and that of C9 in **4** by C10, which should lead to **3** and **5**, respectively. The syntheses of **2** and **4** are shown in Scheme 2. The

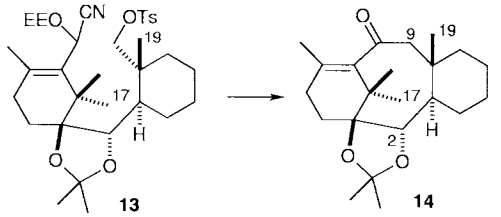


Scheme 2. a) $AlCl_3$, CH_2Cl_2, 0 °C, 5 h, 61%; b) $HC(OMe)_3$, *p*-TsOH, 25 °C, 5 h, 51% + 31% (isomer); c) diisobutyl aluminum hydride (DIBAL), CH_2Cl_2, −78 °C, 30 min, 91%; d) MnO_2, PhH, 25 °C, 44% (recovery of starting material: 40%); e) TMS(CN), [18]crown-6 KCN; 1N HCl, THF; *p*-TsOH, ethylvinyl ether (EVE), 84–88% in three steps; f) TBSCl, DMF, imidazole; PPTS, EVE, CH_2Cl_2-PhH, 91% (two steps); g) DMSO, $NaHCO_3$, 110 °C, 10 h, 77%; h) TBAF, THF; MsCl, NEt_3, CH_2Cl_2; LiCl, THF, 79% (two steps).

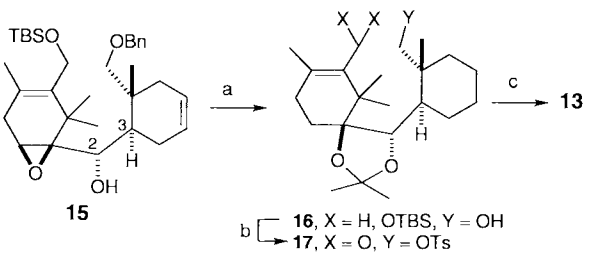
Friedel–Crafts reaction of geranyl acetate (**6**) with *ortho*-(chloromethyl)benzoyl chloride (**7**) gave a diastereomer mixture of **8** by acid-catalyzed olefin cyclization.[8] Dehydration of the tertiary alcohol in **8** provided tetrasubstituted alkene **9** in 51% yield, together with an *endo* isomeric alkene (30%). Stereoselective reduction of the ketone in **9** and deprotection of the acetate using DIBAL furnished diol **10** in 91% yield. Selective oxidation of the allylic alcohol gave the enal, which was converted to the protected cyanohydrin ether **2** in three steps (84% overall yield). The cyclization precursor **4** was also prepared from **10**: Selective protection of the primary alcohol of **10** with *tert*-butyldimethylsilyl chloride (TBSCl), followed by protection of the secondary alcohol with EVE gave **11** in 91% yield. Oxidation of **11** with DMSO afforded the aldehyde, which was converted to the protected cyanohydrin ether **12** as previously described. Deprotection of the TBS group in **12**, followed by chlorination afforded the cyclization precursor **4** in 79% overall yield.

The closure of the eight-membered ring in **2** and **4** was achieved by intramolecular alkylation (Scheme 1). Treatment of **2** or **4** with $LiN(SiMe_3)_2$ in THF at 80 °C immediately produced the cyclized products in 93 and 89% yields, respectively. The products underwent sequential hydrolysis with acid and base leading to the desired cyclic ketones **3** and **5** in 80% and 95% yields, respectively.[9] The structure of **3** was unambiguously determined by X-ray crystallographic analysis.[10] Thus, we have found that intramolecular alkylation of cyanohydrin ethers can form the eight-membered ring in both directions (C10 → C9, C9 → C10) leading to ABC taxoids with an aromatic C ring.

We then examined whether this method could be applied to the formation of taxoid system **14** with a nonaromatic C ring (Scheme 3). The cyclization of **13** must overcome the transannular interactions of the dimethyl groups (17-Me and 19-Me) which are close during the construction of the B ring. We prepared the cyclization precursor **13** as follows (Scheme 4): According to the reported method,[11, 12] the epoxide **15** was obtained by the coupling reaction of a vinyllithium species



Scheme 3. Construction of the B ring in a nonaromatic taxoid system by intramolecular cyclization.



Scheme 4. a) $LiAlH_4$, ether, 25 °C, 82%; isopropenyl methyl ether, camphorsulfonic acid (CSA), CH_2Cl_2, 0 °C, quant.; $Pd(OH)_2$, H_2, AcOEt, 25 °C, 16 h, 89%; b) TsCl, Py, 25 °C, 14 h, quant.; tetrabutylammonium fluoride (TBAF), THF, 25 °C, 18 h, 93%; tetrapropylammonium perruthenate (TPAP), 4-methylmorpholine *N*-oxide (NMO), 25 °C, 5 h, 76%; c) TMS(CN), [18]crown-6 KCN; 1N HCl, THF; *p*-TsOH, EVE, CH_2Cl_2, 59% (three steps).

corresponding the A ring moiety with *trans*-6-benzyloxylmethyl-6-methyl-3-cyclohexenecarboxaldehyde.[13] Reduction of **15** with $LiAlH_4$,[11] followed by protection of the resulting 1,2-diol, gave the corresponding acetonide, whose hydrogenation and concomitant deprotection of the benzyl ether furnished alcohol **16**. Tosylation of the neopentyl function in **16**, followed by deprotection of TBS provided the allylic alcohol, which was oxidized by TPAP[14] to afford enal **17** in 71% overall yield. The cyanohydrin ether **13** was prepared from **17** analogous to step

(e) in Scheme 2. Intramolecular alkylation of **13** proceeded in 70% yield by using $LiN(SiMe_3)_2$ in refluxing dioxane (Scheme 3). Treatment of the cyclized products with acid followed by base gave the desired cyclic enone **14** in 58% overall yield (based on **13**). The stereochemistry of **14** was fully consistent with the NMR data and was confirmed unequivocally by NOE difference spectroscopy.[15] It is noteworthy that the intramolecular alkylation using cyanohydrin anions overcame not only the transannular interactions in the formation of the taxoid B ring but also the steric hindrance in the alkylation at the neopentyl position.

In summary, we have demonstrated that the intramolecular alkylations of the cyanohydrin ethers are effective for the formation of the B ring of the taxoid systems with not only aromatic but also nonaromatic C rings.

Cofactor-Assisted Self-Cleavage in DNA Libraries with a 3′–5′-Phosphoramidate Bond**

Jens Burmeister, Günter von Kiedrowski,* and Andrew D. Ellington

Dedicated to Dr. Leslie E. Orgel on the occasion of his 70th birthday

The technique of directed molecular evolution[1] is a powerful tool in the emerging field of evolutive biotechnology. In vitro selections have been carried out to isolate RNA aptamers directed against various molecular targets[2] and to develop artificial ribozymes with stunning catalytic properties.[3] Preliminary results with DNA indicate that artificial deoxyribozymes exhibiting interesting catalytic functions can be achieved as well.[4] Directed molecular evolution may also prove useful in the search for an exponential self-replicating system based on oligodeoxynucleotide analogs.[5] Our objective was to select a 5′-aminooligodeoxynucleotide that can catalyze the carbodiimide-dependent condensation of the trideoxynucleotides CCGp and pCGG to yield the hexameric 3′–5′-pyrophosphate CCGppCGG.[6] Such an aminooligodeoxynucleotide could act as a nucleophilic catalyst, that is, a leaving group, for phosphoryl transfer (Figure 1). Similar transphosphorylations involving phosphoramidates and pyrophosphates occur in reactions catalyzed by T7-DNA ligase.[7]

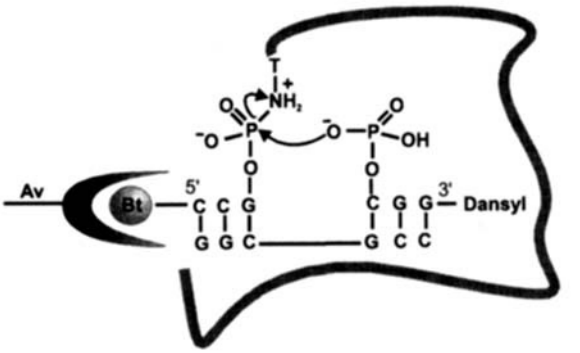

Figure 1. Schematic representation of the template-directed transphosphorylation reaction (Av = Avidine, Bt = Biotin).

To better understand the proposed transphosphorylation, we studied uncatalyzed reactions between N3-CCGpnT (**1**) and pCGG-dansyl (**2**) with HPLC (UV and fluorescence detection).[8] Even after long reaction times (up to two months) no fluorescent hexadeoxynucleotide N3-CCGppCGG-dansyl resulting from phosphoryl transfer could be detected. Hydrolysis of the 3′–5′-phosphoramidate bond (pn bond) was the only reaction observed, and the logarithm of the rate of hydrolysis is linearly dependent on the pH of the aqueous solvent. Between pH = 3 and 7,[9] the pseudo-first-order rate constants follow Equation (1).

$$\lg(k/h^{-1}) = 1.2 - 0.97 \times pH \qquad (1)$$

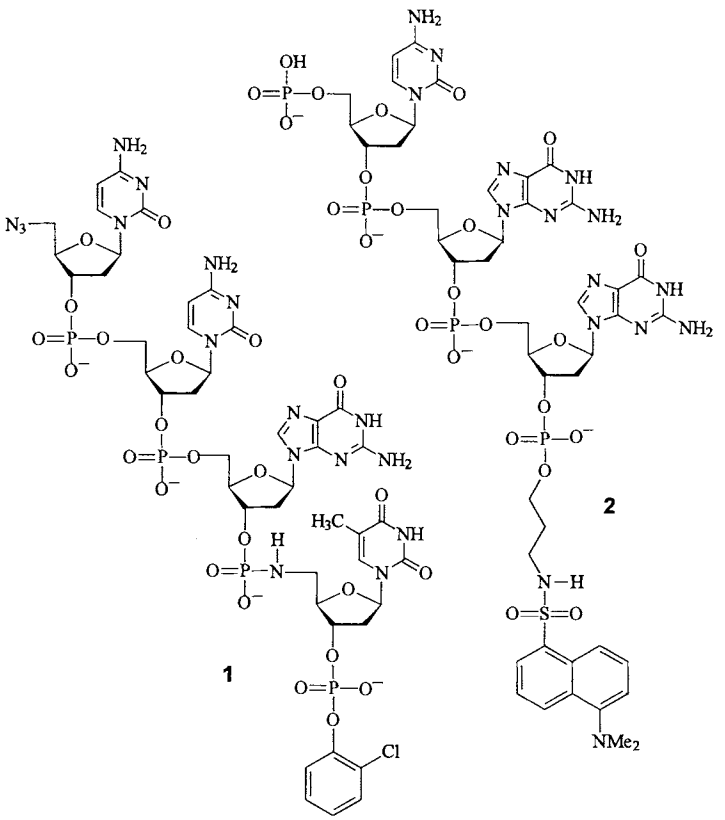
[**] This work was supported by the Deutsche Forschungsgemeinschaft and NATO. We thank D. Bartel for the generous gift of the N72-pool.



Based on these results, we expected to find nucleic-acid sequences that could catalyze cleavage of the pn bond and possibly enhance the rate of pyrophosphate ligation as well. For the in vitro selection studies we synthesized a modified primer bearing a 5′-terminal biotin moiety and an internal pn bond following the leader sequence CCG as well as an umodified primer for the second primer-binding site.[10] These primers were used to amplify a DNA pool containing 72 randomized positions embedded in two constant sequences by means of a polymerase chain reaction (PCR, Figure 2). Immobilization of the double-stranded pool on streptavidin-coated paramagnetic beads (Promega) and subsequent removal of the nonbiotinylated strand by denaturation resulted in a single-stranded DNA pool immobilized on the beads. The in vitro selection was performed on the beads by adding an excess of trimer **2** (5 μM) and the hexameric template CCGCGG (5 μM) in a magnesium-containing buffer with a high salt concentration. Prior to selection the mixture was warmed to 50 °C for 5 min to allow proper folding of the single-stranded pool and inclusion of **2** and the template.

In rounds 1–6, selection was performed for 30 h at room temperature. The 5′-aminooligomers released from the beads were amplified by PCR to form the starting pool for the next round. Starting with the seventh round we increased the stringency of selection to end up with an incubation time of 1 h in the tenth round. In addition, negative selection—that is, removal of those DNA sequences that were released from

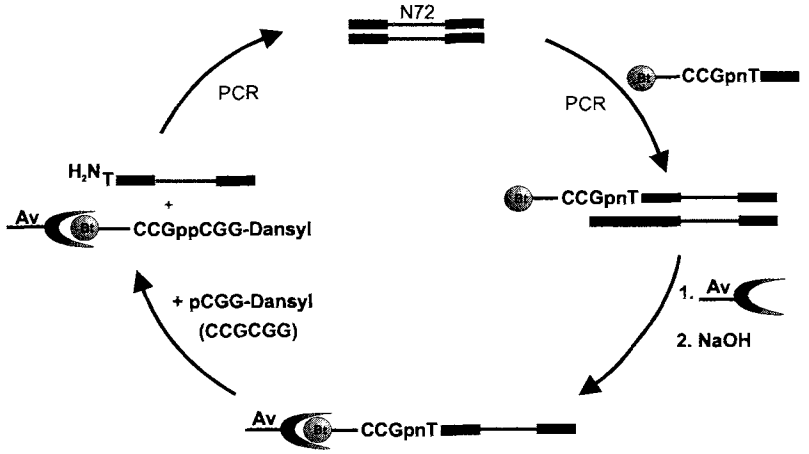


Figure 2. The selection cycle. The N72-pool had the following composition: 5′-GGAACACTATC-CGACTGGCACC-N72-CCTTGGTCATTAGGATCCCG-3′. Primers for PCR amplification: 5′-Bt-CCGpnTGGATCCTAA-TGACCAAGG-3′ (primer A) and 5′-AACACTATCCGACTGGCACC-3′ (primer B). PCR was performed in 30 individual reactions under the following conditions: primer A (80 pmol), primer B (80 pmol), $MgCl_2$ (300 nmol), dNTPs (40 nmol), template (100 ng), PCR buffer (20 μL, 10×; Promega), and Taq DNA-polymerase (0.05 U μL^{-1}) in 200 μL of solution. Gradient: 45 s at $T = 94$ °C, 1 min at $T = 52$ °C, 2 min at $T = 72$ °C, additional 5 min at $T = 72$ °C after 6 cycles. Immobilization was achieved by incubation of the lyophilized pool sequences for 20 min in PBS buffer (pH = 8, 0.690 M NaCl, 0.010 M KCl, 0.045 M Na_2HPO_4, 0.008 M KH_2PO_4) over streptavidin-coated (2 mg) paramagnetic beads (Promega). Denaturation was performed by incubation of the beads in 0.2 M NaOH for 15 min. For the selection the beads were incubated in 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer (0.1 M, sodium salt (pH = 6.1), 0.05 M $MgCl_2$, 0.50 M NaCl, 0.50 M KCl) with pCGG-dansyl (5 μM) and CCGCGG (5 μM) at $T = 23$ °C after an initial warming at $T = 50$ °C for 5 min. The released aminooligomers were precipitated with ethanol and subsequently amplified by PCR with *n* cycles with primer B and 5′-CGGGATCCTAATGACCAAGG-3′ (primer C) under the conditions described above.

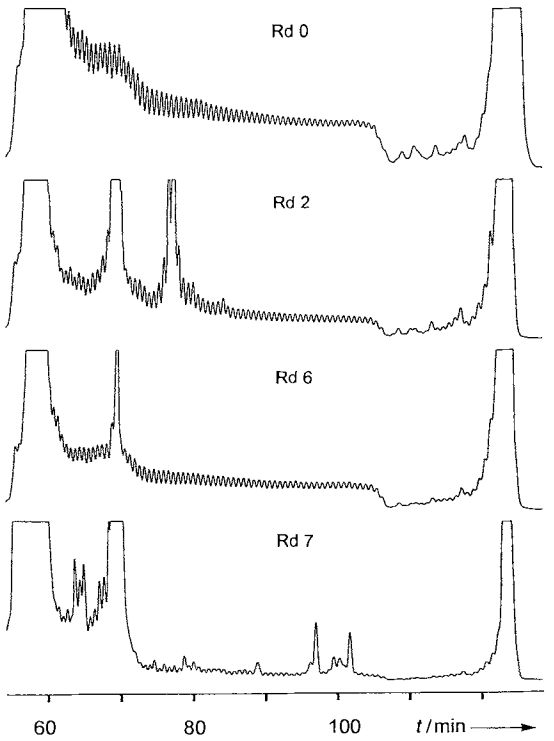

Figure 3. Analysis of pool diversity. DNA from each round (Rd) was amplified by PCR with the CY5-labeled primer 5′-CY5-CGGGATCCTAATGACCAAGG-3′ (primer D, Pharmacia) and primer B under the conditions described above (see legend for Figure 2). PCR products (4 μg) were digested with a combination of AluI, TaqI, and Tru9I (each 10 U enyzme in 10 mM Tris-HCl (pH = 7.9), 10 mM $MgCl_2$, 50 mM NaCl, and 1 mM 1,4-dimercapto-2,3-butanediol, DTT). Fragment analysis was performed on an ALFexpress automated sequencer (Pharmacia). The peak at 130 min corresponds to a full-length pool; the primer is detected at 58 min. The selected clone does not contain a restriction site, and the peak at 70 min probably corresponds to a Tru9I site in the second isolated clone randomized.

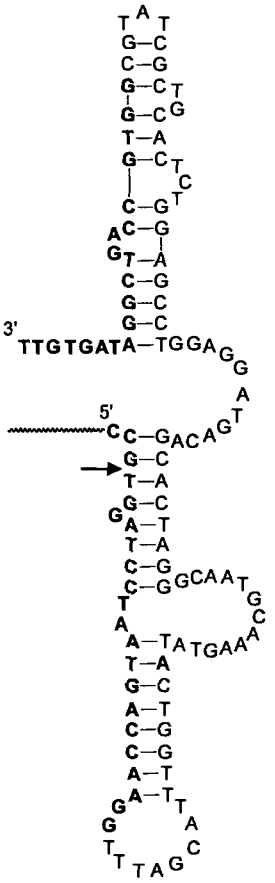

Figure 4. Proposed secondary structure for the selected clone as calculated by DNA *mfold* [15] for $T = 23\,^{\circ}C$. Primer sequences are written in boldface, and the arrow indicates the position of the pn bond. Cloning was performed with the TA-cloning kit (Invitrogen), and sequencing reactions were analyzed on an *A.L.Fexpress* automated sequencer (Pharmacia).

the beads by hydrolysis in the absence of **2** and the template—was used in rounds 7–10.[11] The progress of the in vitro selection was monitored with restriction digestion[3a] and bulk-pool sequencing.[12] Initial changes in sequence space were visible in the second round, and negative selection exhibited a dramatic influence on pool diversity (Figure 3). Our experience shows that an automated DNA sequencer is a useful tool for bulk-pool sequencing and restriction-digestion assays, as it allows rapid monitoring of the progress of an in vitro selection and can potentially quantify pool diversity.[13] Cloning and sequencing of PCR products from the last rounds revealed a single dominating clone in ten of eleven colonies.[14] The secondary structure calculated by the computer program DNA *mfold* from Zuker et al.[15] shows tight folding around the constant primer regions (Figure 4). To elucidate the catalytic activity in the selected pools, activity assays were performed on the beads as well as in solution. For solid-phase assays d-α-^{32}P-ATP was incorporated during PCR of the selected pools. Isotopic labeling facilitated the sensitive analysis of all column eluates with gel electrophoresis and autoradiography (Table 1).

The results indicate that 1) incubation of selected pools in the presence of **2** results in elution of 5′-aminooligomers that are not detectable during incubation of the initial pool under the same conditions, 2) the elution process does not depend on the presence of the hexadeoxynucleotide CCGCGG but rather on the sequence of the trimer, 3) the 5′-phosphate group of the trimer is essential, 4) phosphate itself does not assist cleavage, and 5) activity drops in the absence of magnesium.

We developed a solution phase assay to answer the question of whether the cleavage of 5′-aminooligomers results from hydrolysis of the pn bond or from phosphoryltransfer. It was necessary to extend the 5′ end of the DNA library to distinguish between the product of hydrolysis and the product of phosphoryl transfer with electrophoresis. Therefore, a modified primer was synthesized with the sequence ATGCTGCCGpnT instead of CCGpnT. Based on the proposed secondary structure of the selected clone (Figure 4), we concluded that this variation would not considerably disturb the system. Selected pools were amplified by PCR with the modified primer and a second primer containing a 5′-lengthener–terminator sequence.[16] Single-stranded DNA was purified with gel electrophoresis and subsequently radiolabeled with T4-polynucleotide kinase and γ-^{32}P-ATP. No ligation product could be detected upon incubation of the selected pools in the presence of **2** with and without hexamer. In contrast, a product whose length corresponds to that of the fragment formed by hydrolysis was observed.

We conclude that in vitro selection yielded a novel oligodeoxynucleotide that catalyzes the hydrolysis of an internal 3′–5′-phosphoramidate bond in the presence of the trideoxynucleotide **2** as a cofactor. Cofactor-assisted hydrolysis is at least three orders of magnitude faster than background hydrolysis when comparing the estimated pseudo-first-order rate constant with the kinetics of hydrolysizing model compound **1**.[17] Our present results underline the catalytic potential of DNA and give the first example of a cofactor-assisted deoxyribozyme.

[13] The pool diversity D is a statistical estimate that can be derived as the product of the positional diversities d_i for N positions according to $D = \prod_{i=1}^{N} d_i$. The positional diversity d_i can be estimated from the ratio of the peak integrals of the fragments $a_i:c_i:t_i:g_i$ in the normalized lanes by dividing the single integrals $x_{ij}(j = 1-4)$ by the largest of the four integrals x_{imax} and summing the quotients: $d_i = \sum_{j=1}^{4} x_{ij}/x_{jmax}$. For example, if the ratio $a_i:c_i:t_i:g_i$ is 100:0:0:0, x_{imax} is 100 and $d_i = 1$. For $a_i:c_i:t_i:g_i = 50:50:0:0$ $x_{imax} = 50$ and $d_i = 2$. In general the positional diversity d_i is a rational number between 1 and 4, and the pool diversity D is a rational number between 1 and 4^N.
[14] The second clone had the following sequence:
5′-CCGpnTGGATCCTAATGACCAAGGCATAGCCTTTTAATGGATC-CTCAGAAGGGGCTTGGTCCCGCCTGCGTCTAAACAACACGC-TACGGCTATTTCGGTGCCAGTCGGATAGTGTT-3′

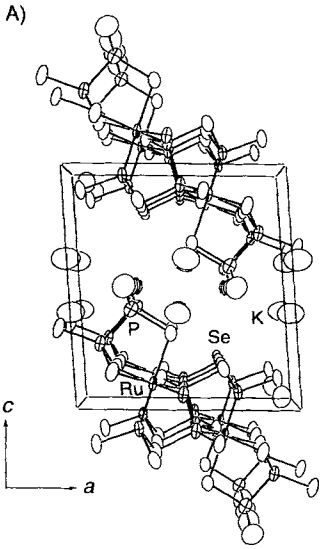
[17] At pH = 6 the pseudo-first-order rate constant for the hydrolysis of **1** is $k = 2 \times 10^{-5}\,h^{-1}$. Upon incubation of selected pools in the presence of **2** and the template at pH = 6, more than 50% hydrolyzed product was detected after 16 h. Under the assumption that the whole pool can be hydrolyzed we conclude that the catalyzed reaction is about three orders of magnitude faster than uncatalyzed hydrolysis.

$^1_\infty[P_3Se_4^-]$: A Novel Polyanion in $K_3RuP_5Se_{10}$; Formation of Ru–P Bonds in a Molten Polyselenophosphate Flux

Konstantinos Chondroudis and Mercouri G. Kanatzidis*

Recent advances in the polychalcophosphate flux technique has resulted in many novel quaternary chalcophosphate compounds.[1] The in situ fusion of A_2Q_x and P_2Q_5 (Q = S, Se), yields various $[P_yQ_z]^{n-}$ units. These highly anionic ligands, in the presence of metal ions, coordinate through the Q atoms in an astonishing number of ways forming new materials.[1] By fine-tuning the flux composition various ligands have been stabilized, such as $[PQ_4]^{3-}$, $[PSe_5]^{3-}$, $[P_2Q_6]^{4-}$, $[P_2Q_7]^{4-}$, and $[P_2Se_9]^{4-}$,[1-11] which have become the building blocks of various polymeric, solid-state, or even molecular structures.[8] Examples of compounds synthesized this way include $ABiP_2S_7$ (A = K,Rb),[2] $A_3M(PS_4)_2$ (A = Rb, Cs; M = Sb, Bi),[3] $A_2M_2P_2Se_6$ (A = K, Cs; M = Cu, Ag),[1] KMP_2Se_6 (M = Sb, Bi),[4] $Cs_8M_4(P_2Se_6)_5$ (M = Sb, Bi),[5] $APbPSe_4$,[6] $Rb_4Ti_2(P_2Se_9)_2(P_2Se_7)$,[7] $A_5Sn(PSe_5)_3$ (A = K, Rb),[8], $Rb_2AuP_2Se_6$,[9] $K_2UP_3Se_9$,[10] and $K(Ln)P_2Se_6$ (Ln = Y, La, Ce, Pr, Gd).[11] An inspection of the entire class of chalcophosphate compounds reveals a conspicuous absence of any ruthenium-containing members, even though several iron compounds are known. Furthermore, in all compounds the metal atoms form exclusively M–Q bonds. Given that Ru belongs to the noble metal group it seemed that the highly reactive polychalcogenide fluxes would serve as an excellent tool to access its chemistry. Here we report on the first structurally characterized ruthenium selenophosphate compound, $K_3RuP_5Se_{10}$, which surprisingly, shows a significant departure from the chemistry of any other metal studied in the P/Q systems.

$K_3RuP_5Se_{10}$[12] has an one-dimensional structure with Ru in the 2+ oxidation state (Figure 1). The compound contains



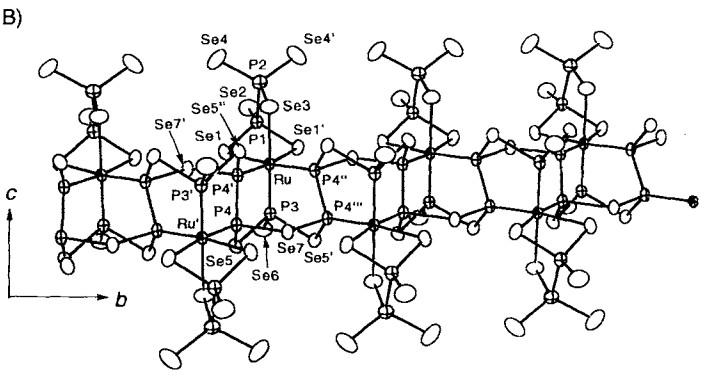


Figure 1. ORTEP representations of the unit cell viewed down the *b* axis (A) and of a section of the infinite $[Ru(P_2Se_6)(P_3Se_4)]^{3n-}_n$ chain with atom labeling (B). Selected distances [Å] and angles [°]: Ru–Se1 2.601(1), Ru–Se3 2.601(1), Ru–P3 2.288(3), Ru–P4′ 2.262(2), P1–Se1 2.202(2), P1–Se2 2.130(3), P1–P2 2.241(4), P2–Se3 2.240(3), P2–Se4 2.144(2), P3–Se5 2.326(2), P3–Se6 2.161(3), P4–Se5 2.240(2), P4–Se7 2.297(2), P4–P4′ 2.206(4); Se1-Ru-Se1′ 79.48(4), Se1-Ru-Se3 89.83(4), Se1-Ru-P4′ 92.23(5), Se1-Ru-P4″ 171.29(6), Se1-Ru-P3 91.346, angles around P range from 98.1(1) to 127.3(1)°.

$[P_2Se_6]^{4-}$ and $^1_\infty[P_3Se_4^-]$ ions and can thus be described as $K_3^+Ru^{2+}(P_2Se_6)^{4-}(P_3Se_4)^-$. Two unprecedented features in this compound are 1) the mixed P/Se coordination of the Ru centers and 2) the stabilization of a novel polymeric $^1_\infty[P_3Se_4^-]$ ion with P atoms in two different oxidation states (P^{2+}, P^{3+}), and which binds to Ru exclusively through P atoms. Hitherto in all the known polychalcophosphates, the $[P_yQ_z]^{n-}$ units coordinate to the metal centers through the negatively charged Q atoms (Q = S, Se). $K_3RuP_5Se_{10}$ is the first polychalcophosphate with bonding between the metal center and the P atoms of the $[P_yQ_z]^{n-}$ units. The strong preference of Ru^{2+} ions for binding to phosphorus is reminiscent of the coordination of ruthenium centers by phosphanes (R_3P) in organometallic complexes.

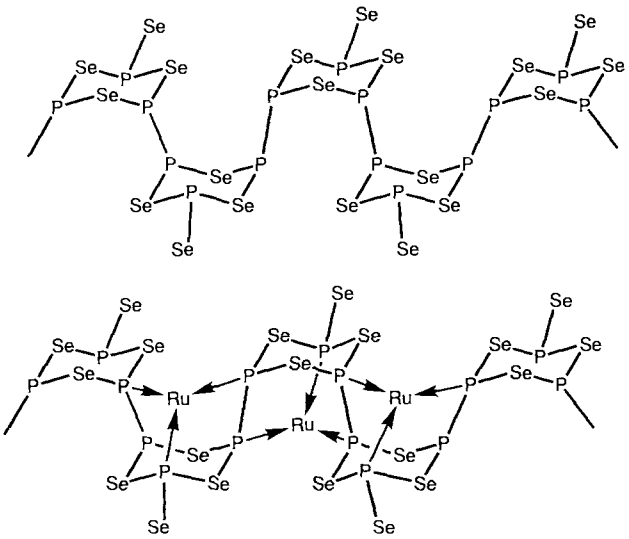
[**] This work was supported by the National Science Foundation DMR-9527347. The authors are grateful to the X-ray Crystallographic Laboratory of the University of Minnesota and to Dr. Victor G. Young Jr. for collecting the single-crystal X-ray data set.

The selection of phosphorus from a "sea" of selenide anions for bonding is remarkable and, at first unexpected. It can be rationalized by soft acid/soft base arguments, if we assign a softer basic character to the bound phosphorus centers than to the Se atoms of the $[P_2Se_6]^{4-}$ ions.

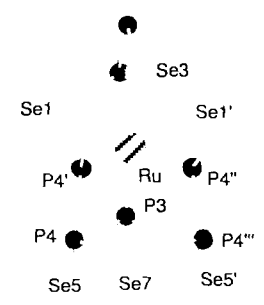
The $^1_\infty[Ru(P_2Se_6)(P_3Se_4)^-]$ chain structure is essentially based upon the $^1_\infty[P_3Se_4^-]$ unit, a novel, infinitely long, anionic ligand. Formally, it can be viewed as resulting from the polymerization of the cyclic $[P_3Se_4]$ unit (Scheme 1). The conformation of the



Scheme 1. The $^1_\infty[Ru(P_2Se_6)(P_3Se_4)^-]$ chain structure (bottom) in $K_3RuP_5Se_{10}$ based on the $^1_\infty[P_3Se_4^-]$ unit (top).

chain presents triangular binding pockets made of P atoms which accomodate the Ru centers. The formal oxidation states can be assigned as P^{2+} for the P–P bonded pair of atoms (e.g. P4) and P^{3+} for the remaining atom (e.g. P3). Both the P^{2+} and P^{3+} atoms in the chain are bound to Ru through their lone pairs of electrons. Therefore, they are electronically more similar to the phosphorus atoms in phosphane ligands which are so abundant in Ru coordination chemistry. The coordination sphere of Ru is completed by a tridentate $[P_2Se_6]^{4-}$ unit.

It is noteworthy, that the 2+ and 3+ oxidation states for P are among the lowest yet observed in chalcophosphate chemistry. The infinite "ladder" structure of the $^1_\infty[Ru(P_3Se_4)^+]$ unit that is formed by the coordination of the $^1_\infty[P_3Se_4^-]$ unit to the Ru centers is the backbone of the one-dimensional structure of $K_3RuP_5Se_{10}$ and propagates along [010]. The $^1_\infty[P_3Se_4^-]$ can be considered as an infinite chelating ligand which creates a cage structure around each Ru center. These cages are formed by the fusion of two five- and two six-membered rings and consists of one Ru, five P, and three Se atoms. Every Ru^{2+} center is in an octahedral coordination environment with three Se and three P atoms in a *fac* configuration (Scheme 2). The Ru–P bonds in $K_3RuP_5Se_{10}$ are very short [Ru–P(3) 2.288(3), Ru–P(4') 2.262(2) Å], and comparable only to the shortest distances found in some Ru phosphides



Scheme 2. Coordination sphere of Ru^{2+} in $K_3RuP_5Se_{10}$.

such as RuP_3,[13] and RuP_4,[14] and the shortest distances found in phosphane complexes such as *mer*-$[Ru(PEt_2Ph)_3Cl_3]^-$.[15]

The chains are separated by three, crystallographically independent, K cations (Figure 1). The ion K1 has an unusually high coordination environment with 11 Se atoms and one P atom in its coordination sphere; the average K1–Se distance is 3.59 Å and the K1–P distance is 3.526(4) Å. The K2 ion is eight-coordinate [av K2–Se 3.62 Å], and K3 is nine-coordinate with eight Se [av K3–Se 3.61 Å] and one P atom [K3–P 3.613(4) Å].

$K_3RuP_5Se_{10}$ melts incongruently at 661 °C yielding a mixture of amorphous $K_xP_ySe_z$ glass and residual $K_3RuP_5Se_{10}$. Some $RuSe_2$ or RuP_x should also be formed but they are either amorphous or in concentrations and particle sizes undetectable by our X-ray diffraction analysis. We have been unable to prepare $K_3RuP_5Se_{10}$ by a direct stoichiometric reaction for several days at 560 °C.

That metal centers can choose their own coordination sphere and even dictate the final structure of a compound is well known, but seldom in flux reaction chemistry do they play a prominent role in determining which ligand will form. This is mostly determined by the composition of the reactive flux, the reaction temperature, and the nature of the counterion. In $K_3RuP_5Se_{10}$ we observe an extreme case, in which the Ru exhibits a protagonistic role in stabilizing a ligand, which otherwise is unstable under the experimental conditions, to suit its coordination chemistry needs. The exclusively P-bound $[P_3Se_4]$ ligand with its low oxidation state phosphorus atoms seems tailor-made for binding to ruthenium centers.

Experimental Section

$K_3RuP_5Se_{10}$ was synthesized from a mixture of Ru (0.15 mmol), P_2Se_5 (0.45 mmol), K_2Se (0.225 mmol), and Se (1.5 mmol) that was sealed under vacuum in a Pyrex tube and heated to 490 °C for 10 d, and then cooled (2 °C per h) to 50 °C. The excess $K_xP_ySe_z$ flux was removed with DMF under N_2 atmosphere. The product was washed with tri-*n*-butylphosphane to remove residual elemental Se, and then with ether. Black, rodlike crystals were obtained (75% yield based on Ru). The crystals appear air- and water-stable. Semiquantitative microprobe analysis on single crystals gave $K_{2.8}RuP_{4.9}Se_{9.7}$ (average value from four analyses).

$R_2Si{=}P{-}SiR_2F$: 1,3-Sigmatropic Migration of Fluorine in a 2-Phospha-1,3-disilaallyl Derivative Capable of Conjugation and Its Conversion to Phosphadisilacyclopropanes**

Matthias Driess,* Stefan Rell, Hans Pritzkow, and Rudolf Janoschek*

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

Although stable compounds with isolated Si=E bonds (E = C, Si, N, P, As, S), which have an enormous synthetic potential at their disposal, have been prepared and even structurally characterized over the last few years,[1, 2] only very little is known about heteronuclear conjugated Si–E π systems, and nothing is known about corresponding homonuclear Si–Si π systems. Until now, only the 1,3-diphospha- and 1,3-diaza-2-silaallyl anionic derivatives **A**[3] and **B**[4] have been experimentally studied. We have been investigating the synthesis of stable conjugated Si–P π systems **C** (allyl, butadiene, and benzene analogues), whose stepwise formation can be achieved with salt-condensation reactions, as, for example, in the preparation of phosphasilenes (Si=P compounds).[2]

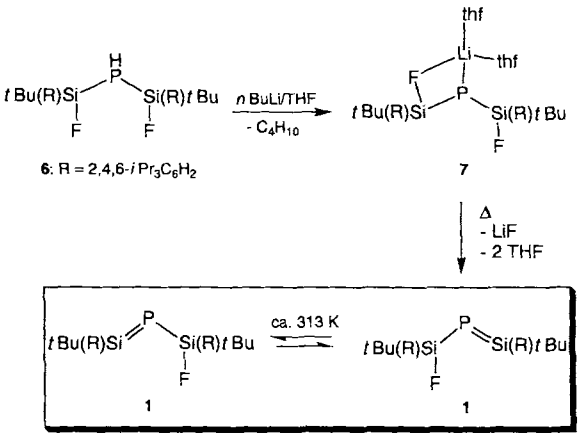
Here we report the first 2-phospha-1,3-disilaallyl fluoride derivative **1**, which undergoes a 1,3-sigmatropic shift (fluctional behavior) of the fluorine atom above 40 °C. Ab initio calculations on $H_2Si{=}P{-}SiH_2F$ are in agreement with this. Reduction of **1** with lithium leads to the elimination of LiF and, surprisingly, formation of the *P*-lithium phosphadisilacyclopropanide **2**. Compound **2**, which is most likely formed as a reactive intermediate via its valence isomer **5**, readily reacts to form neutral **3**.



The synthesis of **1** was carried out in a stepwise manner starting from the bulkily substituted bis(fluorosilyl)phosphane **6**,[5] which was converted to the lithium phosphanide **7** (a precursor of **1**) by reaction with lithium. The lithium center in **7** is coordinated by two THF molecules and is, as expected, dissociated in toluene at 25 °C (Table 1). The compound crystallized as a monomer and, surprisingly, enantiomerically pure in the space group $P2_12_12_1$ (Figure 1).[6]

The Li center is fourfold coordinated by two THF molecules, the phosphorus atom, and the fluorine atom. In contrast, the

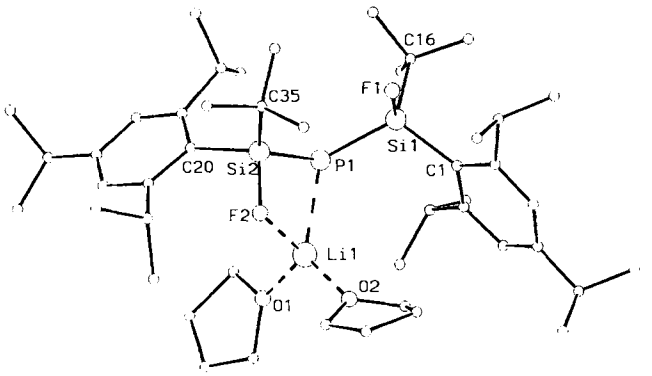

Figure 1. Crystal structure of 7. Selected distances [Å] and angles [°]: P1–Si1 2.199(2), P1–Si2 2.195(2), Si1–F1 1.619(3), Si2–F2 1.666(3), Li1–P1 2.538(9), Li1–F2 1.998(9), Li1–O1 1.955(10), Li1–O2 1.895(10), Si1–C1 1.914(4), Si2–C20 1.920(4), Si1–C16 1.918(5), Si2–C35 1.915(4); Si1-P1-Si2 113.56(7), Si1-P1-Li1 118.5(2), Si2-P1-Li1 74.5(2), F2-Li1-P1 81.1(3), P1-Si2-F2 99.9(1), P1-Si1-F1 110.4(1).

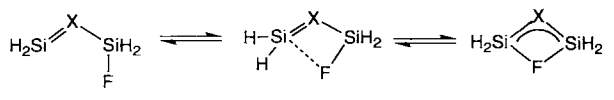
Li center in the analogous bis(di-*tert*-butylfluorosilyl)phosphanide[7] is not coordinated by the phosphorous atom, but by the two fluorine atoms in a chelating fashion. The substituents in **7** are apparently bulkier, and the observed arrangement provides efficient space filling. The Li1–F2 distance is 1.998(9) Å, and the Si2–F2 bond length (1.666(3) Å) is, as expected, longer than that of Si1–F1 (1.619(3) Å). However, this has no effect on the Si–P bond lengths (2.195 and 2.199(2) Å), which are in the range observed in related fluorosilylphosphanides.[8]

Heating a solution of **7** to 70 °C results in loss of LiF and formation of the desired 2-phospha-1,3-disilaallyl fluoride **1**, which crystallizes from hot toluene(!) as pale yellow cubes. The ^{31}P NMR spectrum of **1** (Table 1) shows a doublet ($\delta = -33.0$, $^2J(P,F) = 44$ Hz), which is at relatively high field for phosphasilenes. This indicates greater σ-donor character of the fluorodiorganosilyl group with respect to the triorganosilyl group.[2] All of the structures calculated by ab initio methods and the "thermally corrected" relative free energies were determined at the MP2/6-31G* level.[9] The calculated Si=P bond length in the parent compound **D** is 2.070 Å (Scheme 1), and the Si–P bond length in **D** is 2.235 Å. The crystal structure analysis of **1**,[6] which is unfortunately disordered in the crystal, gave similar distances. In addition, it showed that the fluorine atom is located in a position *trans* to the *tert*-butyl group. An isolated Si=P bond is present, and there are no intramolecular or intermolecular Si-F-Si contacts (Figure 2).



D **E** **F**

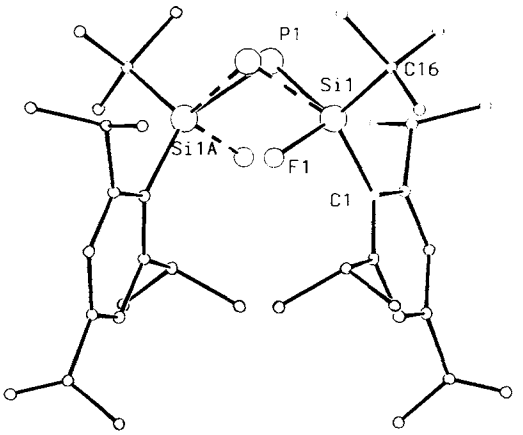

Figure 2. Crystal structure of **1**, which is disordered (two sites for both the P and F atoms). Selected distances [Å] and angles [°]: P1–Si1A 2.053(2), P1–Si1 2.207(2), Si1–F1 1.764(3), Si1–C16 1.895(4), Si1–C1 1.879(4); Si1A-P1-Si1 104.60(9), P1-Si1-F1 74.1(1), P1-Si1A-C16 105.4(1), P1-Si1A-C1 139.7(1), C1-Si1A-C16 114.1(2).

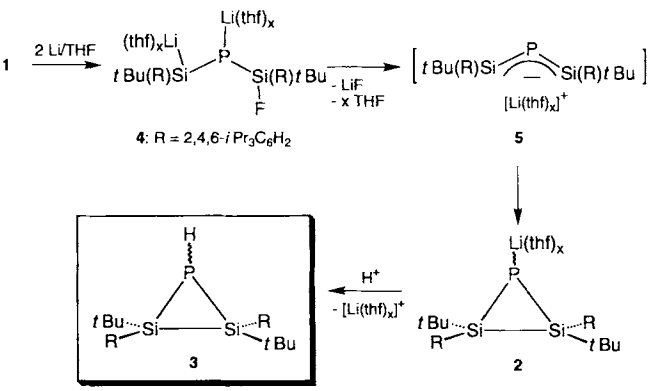
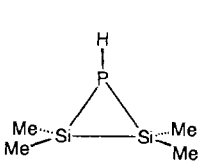
The ^1H NMR spectrum of **1** shows two types of anisochronic *tert*-butyl groups and aryl protons, and confirms that the isolated Si=P bond is retained in solution at 25 °C. Equilibration of the *tert*-butyl groups and thus fluctuation of the fluorine atom (suprafacial [1,3]-sigmatropic shift) is first observed at about 40 °C in [D_8]toluene. Therefore, this process has a Gibbs activation energy of about 16 kcal mol^{-1}. Until now, such fluctional behavior had only been observed in the silaethene $Me_2Si{=}C(SiMe_3)_2$.[10] We studied the reaction pathway of the [1,3]-fluorine shift in **D** with the fragments X = P (2-phospha-1,3-disilaallylfluoride) and X = CH (1,3-disilaallylfluoride) with ab initio calculations.[9] The transition state approximately corresponds to the expected structure **F**, with a symmetrically bridging fluorine atom between the silicon centers, only in the case of X = CH, whereas the transition state for X = P is described by **E** (Scheme 1). The experimentally verified migration of the methyl group of $Me_2Si{=}C(SiMe_3)_2$ occurs via a transition state with a structure analogous to that of **F** (as for **D** when X = CH).[10] For X = P, the calculated barrier of 14.7 kcal mol^{-1} agrees well with the experimental value of 16 kcal mol^{-1} for **1**. The barrier for $H_2Si = CH(SiH_2F)$, which is approximately 10 kcal mol^{-1} higher and results from the relatively high ring strain of **F**, is noteworthy.

We then carried out studies to investigate whether **1** could be converted to **4** by addition of lithium to the Si=P bond, and whether the lithium 1,3-disila-2-phosphaallyl anion **5** could be obtained by subsequent elimination of LiF. Addition of lithium to **1** does indeed occur at room temperature in THF, and **4** is formed as an extremely reactive intermediate.

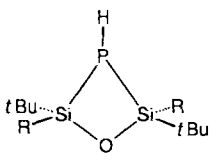


We were only recently able to prepare compounds of the type **4** from other phosphasilenes.[11] Because of its very high reactivity, it was only possible to characterize **4** by means of ^{31}P NMR spectroscopy, which shows a doublet at very high field ($\delta = -306$, $^2J(P,F) = 38$ Hz) at 25 °C (Table 1). However, gentle warming of **4** to 40 °C in THF or hexane initially leads to strongly basic **2** by elimination of LiF. This in turn is protonated (partially under the reaction conditions and completely upon work-up in anhydrous hexane) to form **3**. The hydrogen atom on the phosphorus atom in **3** originates from the THF ligands that initially solvate the lithium center in **2** and are then partially cleaved due to the strong basicity of the phosphanide (ether cleavage). The conversion of **4** into the ring compound **2** with elimination of LiF most likely occurs via **5**. The shift from **5** to **2** would be a particularly interesting parallel to the isomerization of bis(methylene)phosphoranes to phosphacyclopropanes.[12] Since the electrons in the HOMO of allyl anions are localized at the 1,3 positions and this structure is very unfavorable for the electropositive Si centers, the formation of a Si–Si bond proves very effective. In contrast, and as expected, no cyclization is observed for the "inverse" 1,3-diphospha-2-silaallyl anions **A** with more electronegative phosphorus atoms at the 1,3 positions.[3]

The composition of **3** was confirmed by mass spectrometry, and its structure determined by NMR spectroscopy (Table 1) and crystallography.[6] The ^{31}P NMR spectrum shows a doublet with ^{29}Si satellites at high field ($\delta = -325$), as expected for phosphasilacyclopropanes,[14] with a relatively small coupling constant of $^1J(P,H) = 161$ Hz. Furthermore, the $^1J(P,Si)$ coupling constant of 36 Hz is much smaller than that for other phosphacyclopropanes ($^1J(P,Si) = 72.5-121.7$ Hz).[13] The high degree of p character of the P–Si bonds apparently lowers ring strain. Geometry optimization of the derivative **3*** was carried out with the density-function method by Becke (B3LYP/6-31G*), and the ^{31}P and ^{29}Si NMR chemical shifts were calculated at the GIAO/6-311++G(2d,2p) level.[9] The $\delta(^{31}P)$ and $\delta(^{29}Si)$ values for **3*** (−344 and −48.4, respectively) agree well with the experimental values for **3** (−325 and −43.6/−44.5).



3*



8: R = 2,4,6-*i*Pr$_3$C$_6$H$_2$

The *two* doublet signals at high field ($\delta = -43.6$ and -44.5, $^1J(Si,P) = 36$ Hz) in the ^{29}Si NMR spectrum of **3** are characteristic for silacyclopropanes[14] and show unequivocally that the two silicon atoms are not chemically equivalent. These data are only consistent with the *trans* configuration of the *tert*-butyl groups on silicon and pyramidal coordination of the phosphorus atom, as confirmed by crystal-structure analysis (Figure 3).[6]

Until now, single crystals were only obtained of a mixture of **3** and the novel four-membered PSi_2O heterocycle **8** (ratio about 7:1). As a result of this "disorder", a discussion of the geometrical parameters is not meaningful. Surprisingly, **8** is formed as a side product (about 10 %, ^{31}P NMR) in the reaction of **1** with lithium in THF. The oxygen atom in **8** most likely originates from THF. We can exclude both unintentional entry of air and the presence of surface oxide/hydroxide on the lithium powder as possible sources of oxygen from control experiments. These

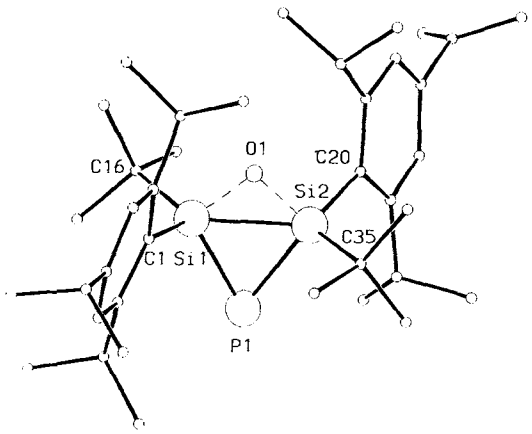


Figure 3. Overlap of the crystal structures of **3** and **8** (ratio about 7:1). Selected distances [Å] and angles [Å]: Si1–Si2 2.357(3), Si1–P1 2.292(3), Si2–P1 2.282(2), Si1–O1 1.56(2), Si2–O1 1.57(2); Si1-P1-Si2 62.04(8), P1-Si1-Si2 58.76(8), P1-Si2-Si1 59.20(7), C1-Si1-C16 114.7(2), C35-Si2-C20 115.0(2).

showed that **1** is inert to suspensions of Li_2O/LiOH in THF and that solutions of **3** and **8** do not react with oxygen in the air at room temperature.

The calculated Si–P (2.318 Å) and Si–Si (2.285 Å) distances as well as the endocyclic angles on phosphorus (59.06°) and silicon (60.47°) in **3*** show no principle differences to the corresponding experimental values of other heterodisilacyclopropanes with a Si_2X framework (X = O, S, Te, C, Ge, N, W).[14] In contrast, the calculated Si–Si distance in *P*-metallated phosphadisilacyclopropane derivatives of **3*** varies considerably depending on the nature of the metal center (s-, p-, and d-block metals), because the Si–Si bond can act as a σ and/or a π donor towards the metal centers. We are currently attempting to synthesize a heteroallyl π complex with the Si_2P framework.

Experimental Section

7: **6** (5.0 g, 7.74 mmol) in THF (50 mL) was allowed to react with *n*-BuLi (0.49 g, 7.74 mmol, 2.5 M solution in hexane) at −78 °C. The clear yellow solution was warmed slowly to 25 °C, and the solvent removed under vacuum (10^{-2} Torr). The residue was dissolved in a little hexane, and colorless, air-sensitive **7** crystallized at 25 °C. Yield: 5.3 g (6.6 mmol, 86 %).

1: **7** (5.3 g, 6.6 mmol) was stirred in toluene (50 mL) for 8 h at 70 °C. On cooling, poorly soluble **1** was obtained as extremely air-sensitive, pale yellow crystals. Yield: 3.7 g (5.9 mmol, 88 %).

3: **1** (2.0 g, 3.2 mmol) was stirred with Li powder (about 100 mg) in THF (30 mL) at 25 °C. Compound **4** was formed within 2–4 h (^{31}P NMR). The solvent was removed, and the yellow residue dissolved in hexane. Excess lithium powder was filtered off. The colorless solution was concentrated under reduced pressure (10^{-2} Torr) at 25 °C, and colorless crystals were formed (about 90 % **3** and 10 % **8**; ^{31}P NMR). Yield: 1.5 g (2.5 mmol, 78 %).

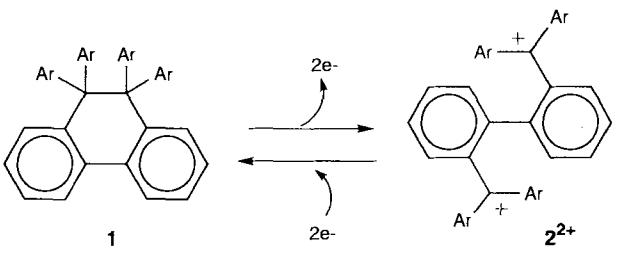
Hexaphenylethane Derivatives Exhibiting Novel Electrochromic Behavior**

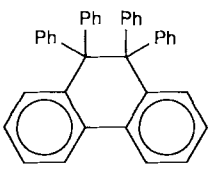
Takanori Suzuki,* Jun-ich Nishida, and Takashi Tsuji

9,9,10,10-Tetraphenyl-9,10-dihydrophenanthrene (**3**) is a stable molecule[1] whose central C–C bond is predicted to be the longest among "clamped" hexaphenylethane derivatives.[2] Although this weakened bond is resistant to homolytic rupture, the activation energy for its scission can be lowered by electron transfer,[3] especially when suitable substituents are introduced. Bearing this in mind, we have now designed a new redox system in which reversible C–C bond breaking and bond making occur upon two-electron transfer (Scheme 1). This system has the following interesting features: 1) the four dimethylamino and methoxy substituents in **1a** and **1b**, respectively, should facilitate the removal of electrons from these molecules, thereby activating the scissile bond; 2) the central bond in **1** like that in **3** is still expected to be sufficiently stable against homolysis taking into consideration that the aromatic substituents have little effect on the Gibbs activation energy of the homolytic cleavage $\Delta G^{\neq}_{homolysis}$ in 1,2-diarylethanes;[3,4] 3) the dications $\mathbf{2}^{2+}$ formed by the oxidation of **1** should be stabilized by delocalization of each positive charge over half of the molecule and due to the presence of the triarylmethylenium chromophores these cations are intensely colored; 4) the interconversions between **1** and $\mathbf{2}^{2+}$ should proceed very cleanly because they are intramolecular processes. Here we report the preparation, properties, and structures of these novel redox couples.

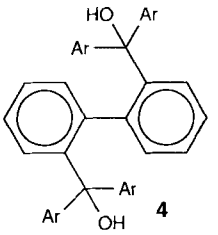


a: Ar = *p*-$Me_2NC_6H_4$; **b**: Ar = *p*-$MeOC_6H_4$

Scheme 1. Dynamic redox behavior of **1** and $\mathbf{2}^{2+}$.



3



4

The dication salts $\mathbf{2a}^{2+}(BF_4^-)_2$ and $\mathbf{2b}^{2+}(BF_4^-)_2$ were obtained in 98 and 93% yield by treating the diols **4a**[5] and **4b**, respectively, with HBF_4. Reduction of these salts with Mg in MeCN gave ethanes **1a** and **1b** as stable solids in 86 and 93% yield, respectuvely. On the other hand, oxidation of **1a** and **1b** with two equivalents of $(p\text{-}BrC_6H_4)_3N^{+\bullet}SbCl_6^-$ in CH_2Cl_2 led to the regeneration of the dications $\mathbf{2a}^{2+}$ and $\mathbf{2b}^{2+}$, which were isolated as $SbCl_6^-$ salts in 85 and 97% yield, respectively. The high-yield interconversions between **1** and $\mathbf{2}^{2+}$ indicate that they constitute "reversible" redox couples, although the bond breaking and making are induced by electron transfer.

The sharp contrast in the UV/Vis spectra of these couples is noteworthy. Ethanes **1** show absorption only in the UV region, whereas intense absorption bands in the visible region occur for the dications $\mathbf{2a}^{2+}$ [λ_{max} (MeCN): 661 (lgε 4.92), 604 nm (5.05)] and $\mathbf{2b}^{2+}$ [539 sh (4.72), 514 (4.87)]. Thus, electrochromic systems with color changes from colorless to deep blue and colorless to deep red could be constructed by using *p*-dimethylamino

and *p*-methoxy derivatives, respectively. Spectrophotometric monitoring of the electrochemical reduction of $\mathbf{2}^{2+}$ to **1** revealed the presence of several isosbestic points in both cases (Figure 1), indicating the quantitative conversion as well as the negligible steady-state concentration of the intermediary cation radicals.

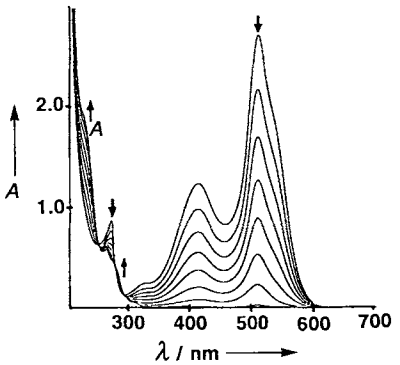

Figure 1. Change in UV/Vis spectrum of $\mathbf{2b}^{2+}(BF_4^-)_2$ (3.6×10^{-5} mol dm^{-3}, 2 mL) upon electrochemical reduction (10 μA) at 3 min intervals. The coulometric analysis indicates that the interconversion is a two-electron process.

Not only the color but also the geometry change drastically during the interconversion, as determined by the X-ray structure analyses.[6] While the biphenyl skeleton of **1b** is nearly planar (Figure 2a), the two molecular halves in $\mathbf{2a}^{2+}$ are twisted by 69° around the biphenyl axis; the distance between the two methylenium carbon atoms is 3.66(2) Å (Figure 2b). Such a dynamic change in structure causes the hysteretic redox properties of **1** and $\mathbf{2}^{2+}$ (Figure 3). Thus, **1a** and **1b** undergo electrochemical oxidation at peak potentials of +0.77 and +1.47 V vs. SCE in CH_2Cl_2, respectively. These processes are irreversible in the sense that the corresponding cathodic peaks were absent in the cyclic voltammograms (scan rate: 100–500 mV s^{-1}). Instead, new peaks appeared in the far cathodic region (−0.45 and +0.18 V, respectively), which were assigned to the reduction potentials of $\mathbf{2a}^{2+}$ and $\mathbf{2b}^{2+}$. This assignment was confirmed by separate measurements on $\mathbf{2}^{2+}(BF_4^-)_2$ salts under the same conditions. Again, quite similar hysteretic behavior was observed in the voltammograms of $\mathbf{2}^{2+}$, which showed new anodic peaks corresponding to the oxidation potentials of **1**.

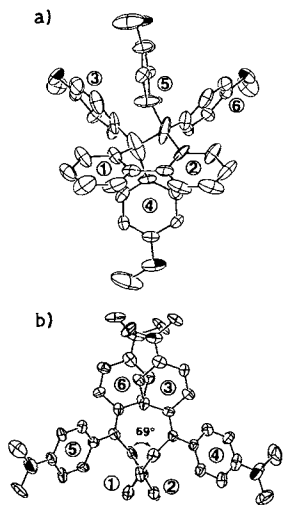

Figure 2. a) Molecular geometry of **1b** determined by X-ray structure analysis on the **1b**·THF solvate crystal. Two aryl groups (3 and 6) are equatorial and the other two (4 and 5) are axial substituents in the pseudo-half-chair six-membered ring. b) Molecular geometry of $\mathbf{2a}^{2+}$ determined by X-ray structure analysis on the $\mathbf{2a}^{2+}(SbCl_6^-)_2$ salt. The dication has pseudo-C_2 symmetry. Two aryl groups (3 and 6) overlap each other in a face-to-face manner (interplanar distance, 3.37 Å; dihedral angle 11.5°), indicating the π–π interaction between these rings.

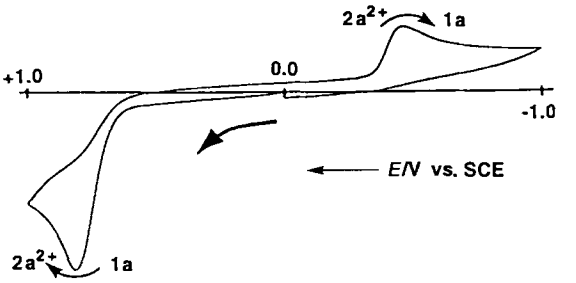

Figure 3. Cyclic voltammogram of **1a** in CH_2Cl_2 (0.1 M nBu$_4$NBF$_4$, Pt electrode, scan rate 500 mV s^{-1}). The reduction peak at −0.45 V was absent when the voltammogram was first scanned to the cathode.

Such separation of redox potentials is characteristic of "dynamic redox systems" that undergo reversible and drastic structural change during electron transfer, as in the present case.[7] In the region between the reduction potential and the oxidation potential, both the reduced form (**1**) and the oxidized form ($\mathbf{2}^{2+}$) can coexist in any ratio. By combining **1** with a suitable electron acceptor, it may be possible to apply this unique feature to the construction of novel redox-type photochromic systems in which the back reactions in the dark become endothermic due to the large shift of redox potentials.

Experimental Section

4b: The reaction of 4,4′-dimethoxybenzophenone and 2,2′-dilithiobiphenyl in THF afforded **4b** as a colorless powder in 47%. M.p. 226–228 °C; ^{1}H NMR (90 MHz, $CDCl_3$): δ = 6.97–7.13 (m, 10H), 6.71–6.89 (m, 12H), 6.05–6.15 (m, 2H), 4.35 (s, 2H), 3.82 (s, 6H), 3.78 (s, 6H).

$\mathbf{2}^{2+}(BF_4^-)_2$: To a solution of diol **4a** (5.65 g, 8.18 mmol) in THF (100 mL) was added 42% HBF_4 (2.60 mL, 17.4 mmol) over 10 min at 0 °C. After the mixture had been stirred for 18 h at room temperature, deep-blue microcrystals of $\mathbf{2a}^{2+}(BF_4^-)_2$ (6.64 g, 98%) were filtered, and washed with THF and ether, m.p. 316–317 °C (decomp); ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C): δ = 7.60 (br., 2H), 7.23 (ddd, J = 7.6, 7.6, 1.5 Hz, 2H), 7.17 (ddd, J = 7.6, 7.6, 1.5 Hz, 2H), 7.13 (br. AA′XX′, 4H), 7.05 (dd, J = 7.6, 1.5 Hz, 2H), 6.98 (dd, J = 7.6, 1.5 Hz, 2H), 6.92–7.02 (br., 6H), 6.77 (br. AA′XX′, 4H), 3.37 (s, 12H), 3.20 (s, 12H); ^{13}C NMR (100 MHz, CD_3CN): δ = 174.65, 158.21, 157.26, 143.86, 141.99, 140.38, 139.67, 133.93, 133.61, 131.29, 128.16, 128.04, 127.85, 114.81, 114.08, 41.50, 41.04; UV/Vis (MeCN): λ_{max} (lgε) = 661 (4.92), 604 (5.05), 431 (4.50), 408 (4.41), 319 nm (4.50). Diol **4b** was similarly treated with 42% HBF_4 in propionic anhydride, and $\mathbf{2b}^{2+}(BF_4^-)_2$ was obtained as a red powder in 93% yield, m.p. 200.5–202 °C (decomp); ^{13}C NMR (100 MHz, CD_3CN): δ = 192.63, 175.39, 172.50, 146.8 (br.), 144.39, 143.02, 140.93, 136.63, 134.48, 134.42, 134.04, 132.56, 128.62, 118.47, 117.71, 59.09, 58.20; UV/Vis (MeCN): λ_{max} (lgε) = 539 sh (4.72), 514 (4.87), 416 (4.54), 335 (3.83), 274 nm (4.36).

1: A suspension of $\mathbf{2b}^{2+}(BF_4^-)_2$ (173 mg, 0.222 mmol) and Mg turnings (740 mg, 30.4 mmol) in dry MeCN (10 mL) was stirred for 22 h at room temperature. The solvent was evaporated, and the residue was triturated with benzene. Chromatographic separation on Al_2O_3 (benzene) afforded **1b** (126 mg, 93%) as a colorless solid, m.p. 270–272 °C (decomp); ^{1}H NMR (400 MHz, $CDCl_3$, 50 °C): δ = 7.68 (dd, J = 7.8, 1.5 Hz, 2H), 7.23 (ddd, J = 7.8, 7.8, 1.5 Hz, 2H), 7.16 (dd, J = 7.8, 1.5 Hz, 2H), 7.11 (ddd, J = 7.8, 7.8, 1.5 Hz, 2H), 6.93 (br., 8H), 6.48 (br., 8H), 3.70 (s, 12H); UV/Vis (MeCN): λ_{max} (lgε) = 287 (4.13), 274 nm (4.25). Similarly **1a** was obtained as a colorless solid in 86% yield by Mg reduction of $\mathbf{2a}^{2+}(BF_4^-)_2$, m.p. 315–317 °C (decomp); ^{1}H NMR (400 MHz, $CDCl_3$, 50 °C): δ = 7.65 (dd, J = 7.8, 1.0 Hz, 2H), 7.21 (dd, J = 7.8, 1.0 Hz, 2H), 7.18 (ddd, J = 7.8, 7.8, 1.0 Hz, 2H), 7.07 (ddd, J = 7.8, 7.8, 1.0 Hz, 2H), 6.91 (br. AA′XX′, 8H), 6.31 (br. AA′XX′, 8H), 2.83 (s, 24H); UV/Vis (MeCN): λ_{max} (lgε) = 268 nm (4.87).

$\mathbf{2}^{2+}(SbCl_6^-)_2$: To a solution of **1a** (35 mg, 0.053 mmol) in CH_2Cl_2 (10 mL) was added (p-$BrC_6H_4)_3N^+SbCl_6^-$ (90 mg, 0.110 mmol), and the mixture was stirred for 1.5 h at room temperature. Deep blue precipitates of $\mathbf{2a}^{2+}(SbCl_6^-)_2$ (60 mg, 85%) were filtered, and washed with CH_2Cl_2, m.p. 300–320 °C (decomp). Similar oxidation of **1b** afforded $\mathbf{2b}^{2+}(SbCl_6^-)_2$ in 97% yield, m.p. 174.5–177 °C (decomp); ^{1}H NMR (400 MHz, CD_3CN, 24 °C): δ = 7.46 (ddd, J = 7.3, 7.3, 1.5 Hz, 2H), 7.41 (ddd, J = 7.3, 7.3, 1.5 Hz, 2H), 7.33 (dd, J = 7.3, 1.5 Hz, 2H), 7.23-7.33 (br. AA′XX′, 8H), 7.17 (dd, J = 7.3, 1.5 Hz, 2H), 7.09-7.15 (br. AA′XX′, 8H), 4.09 (br. s, 6H), 4.07 (br. s, 6H).

All the new compounds gave satisfactory analytical data, and IR and mass spectra.

Perfectly Staggered and Twisted Difluoromethylene Groups in Perfluoroalkyl Chains: Structure of M[$C_4F_9SO_2NSO_2C_4F_9$] (M = Na, K)**

Lixin Xue, Darryl D. DesMarteau,* and William T. Pennington*

In contrast to the perfectly all-staggered conformation observed for *n*-alkanes, the generally accepted structure of a perfluorinated *n*-alkane involves a helical conformation of the carbon backbone.[1] This is presumably due to the larger van der Waals radius of fluorine relative to that of hydrogen; rotation about the carbon–carbon chain bonds occurs to increase the distance between fluorine atoms on carbon atoms separated by one CF_3 group.[2]

Polytetrafluoroethylene possesses a helical structure at ambient conditions, but undergoes a solid–solid phase transition to a planar zigzag conformation under increased pressure.[3, 4] A similar transition occurs for perfluoro-*n*-alkanes, but at considerably lower pressure.[5] In a recent article it has been suggested that short perfluorinated carbon chains take on a planar zigzag structure rather than a helical one at ambient pressure, when closely packed on the surface of a substrate.[6] In that report, the structures of thin films of perfluorodecanoic acid deposited on glass were investigated by a combination of low-angle X-ray diffraction, X-ray grazing-incidence diffraction and molecular modeling. The compound was found to be present as two phases, and for both phases the best model had carbon chains that were untwisted. We have obtained more direct evidence, based on single-crystal X-ray diffraction analysis, of similar behavior for the perfluoro-*n*-alkyl side chains of the sodium salts **1**–**3** of bis[(perfluoroalkyl)sulfonyl] imides.

Na[$C_mF_{2m+1}SO_2NSO_2C_nF_{2n+1}$]

1, $m = n = 4$; **2**, $m = n = 6$; **3**, $m = 4$, $n = 6$

In this communication, we report the crystal structure of **1**,[7] a representative member of the series, and contrast its structure with that of a potassium derivative of **1** (compound **4**, $m = n = 4$).[8] A more thorough discussion of all of these compounds will appear later.[9]

The remarkable acidity of bis[(perfluoroalkyl)sulfonyl] imides[10, 11] is due, in part, to the resonance stabilization of the conjugate base anions of the acids. Extensive delocalization of charge over the SO_2-N-SO_2 framework allows these anions to serve as multidentate ligands that bond to multiple metal centers to maximize electrostatic interaction.[12] These interactions result in the formation of ionic hydrophilic regions and perfluoro hydrophobic regions, which typically associate into layers consisting of an ionic core and perfluoro surfaces.[13, 14] This behavior is observed in **1**; the sodium ion (Figure 1, left) interacts strongly with the nitrogen atom of the anion (interatomic distance 2.531(7) Å) and is chelated by a pair of sulfonyl oxygen atoms (Na1–O1b,O1c 2.331(5) Å) of an anion related by translation along the **b** axis to form ion-pair chains; chains related by inversion symmetry (1/2, 0, 0) are connected by additional interactions between the sodium ion and sulfonyl oxygen atoms (Na1–O2d,O2e 2.356(4) Å) to form layers, which stack along the *a* axis (Figure 1, right). Due to the strong interactions in-

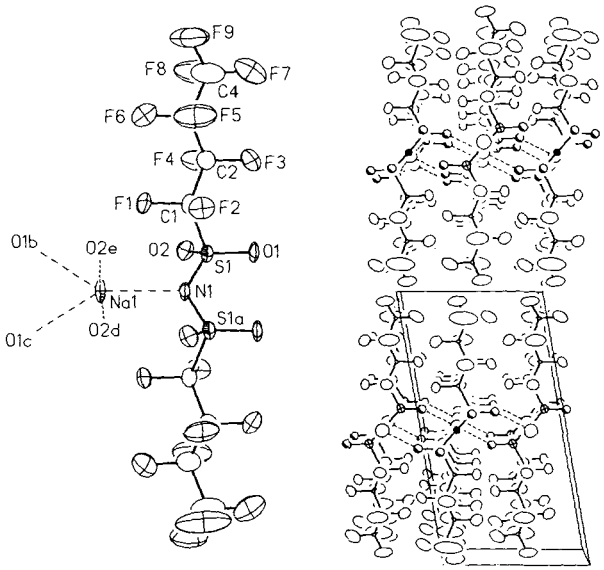

Figure 1. a) Left: Crystal structure of **1** *(thermal ellipsoids at 50% probability), showing the interionic contacts and the atom labeling scheme used. Atoms containing a lower case character in their labels were generated by the following symmetry operations: a) $1-x, y, 1/2-z$; b) $x, y-1, z$; c) $1-x, y-1, 1/2-z$; d) $1-x, -y, -z$; e) $x, -y, 1/2+z$. Right: crystal packing of* **1** *viewed down the b axis. The origin is the lower left rear corner; $+x$ is up, $+y$ is out and $+z$ is to the right. The sulfur atoms are represented as hatched ellipsoids, the sodium ions as large open circles, the fluorine atoms as boundary ellipsoids, the oxygen atoms as shaded circles, the nitrogen atoms as solid circles, and the carbon atoms as small open circles.*

volving the sodium ions, the perfluoroalkyl chains extending out from the hydrophilic core are too closely packed to allow helical twisting (Figure 2, left). The chains have a nearly ideal, planar, all-staggered conformation (range of largest F-C-C-F torsion angles along the chain range: 174.3–178.1°). By contrast, although the structure of **4** is also layered with an ionic core and perfluoroalkyl surfaces, the layers are much more complex. The perfluoroalkyl chains in **4** are more loosely packed on the hydrophilic core because of the significantly longer contacts to the potassium ions (K···O range: 2.624(12)–2.970(12) Å; average 2.8(1) Å). In contrast to those in **1**, many of these chains assume a twisted conformation (Figure 2, right)— the largest

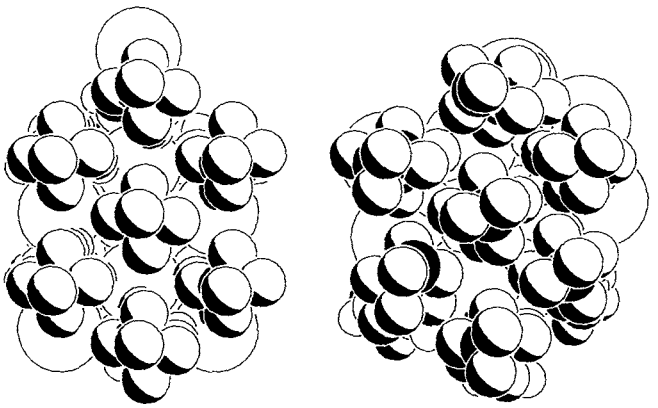

Figure 2. Left: space-filling drawing of **1** viewed normal to the layer. Right: space-filling drawing of **4** viewed normal to the layer.

F-C-C-F torsion angles along the chains range from 156.5 to 179.9°.[15] As with other compounds containing perfluoroalkyl groups, the repulsion between fluorine atoms is also alleviated by expansion of the C-C-C bond angle in the chain (average value of 117.8(8)° for **1** and 119(4)° for **4**).

Another interesting difference between the structures of **1** and **4** is the conformation of the anion. In **1**, it assumes a *trans* conformation—the two perfluoroalkyl chains extend to opposite sides of the hydrophilic core of the layer. In **4**, two of the anions in the asymmetric unit have a similar *trans* conformation, but the other two have *cis* conformation in which the perfluoroalkyl chains of a given anion extend away from the hydrophilic core to the same side of the layer. We have structurally characterized a wide variety of salts of the related anion $[CF_3SO_2NSO_2CF_3]^-$: this anion typically possesses a *cis* conformation when complexed to a cation, but more often has a *trans* conformation when uncomplexed.[16]

One of the interests in compounds such as those reported here is their potential usefulness as structural models for perfluorinated ionomeric membranes, which are important because of their outstanding performance in chlor-alkali and fuel cells.[17] These materials consist of three phases: a crystalline phase that results from ordered packing of the perfluorinated backbone, ionic regions typically referred to as clusters, which result from strong Coulombic associations of the polar side groups, and an amorphous phase.[18] Ion transport properties of these membranes critically depend on the clustering phenomenon. Many descriptions of clustering in hydrocarbon ionomers have been proposed, including a model consisting of spherical clusters in a paracrystalline lattice,[19] a shell core model,[20] and a lamellar model.[21] There is no consensus about which best describes clustering in hydrocarbon ionomers, and the situation in perfluorinated ionomers is even more complicated.[22] However, any model that successfully describes this phenomenon will have to take into account effects such as the steric restrictions imposed on and by the packing of the perfluorinated backbone of the polymer chain that are reported herein.

[2] However, as pointed out in reference [1], the rotation about the carbon–carbon bond that occurs is not sufficient to move a given fluorine atom to a point equidistant from the fluorines atoms on the next-but-one carbon atom. In addition to rotation, steric interaction between fluorine atoms is accommodated by expansion of the C-C-C bond angle.

Electrogenerated Chemiluminescence and Proton-Dependent Switching of Fluorescence: Functionalized Difluoroboradiaza-*s*-indacenes**

Matthias Kollmannsberger, Thomas Gareis, Stefan Heinl, Josef Breu, and Jörg Daub*

Dedicated to Fabian Gerson

Functional fluorescent dyes are of central importance as active components for light and electron transfer induced processes, mainly in the field of materials science and analysis.[1] Especially a combination of reversible electron transfer and of efficient light absorption/emission is essential for those processes playing the crucial role in photovoltaic/photoelectrochemical devices.[2] Due to their high absorption coefficients as well as high quantum yields of emission, difloroboradiaza-*s*-indacenes have very favorable photonic qualities.[3] To our knowledge, investigations concerning the electron transfer properties of these dyes have not yet been reported. In this communication we present tailor-made compounds that on one hand are highly fluorescent and on the other form stable radical cations and radical anions. The aim of these investigations is to obtain electrochemiluminescent compounds that can be incorporated as active components into organic light-emitting diodes (OLEDs).[4] During the course of this work we also synthesized a donor-substituted derivative whose fluorescence is quenched by photoinduced electron transfer.[5] This compound can be used for efficient proton-driven fluorescent switching.

Simple difluoroboradiaza-*s*-indacenes like **1** proved to be unsuitable for optoelectrochemical applications, because they do not form stable radical ions. To examine the possibility of stabilizing the radical ions by different substitution patterns at the chromophore, we synthesized compounds **2**–**4**. The synthesis started with pyrroles, which were condensed with appropriate aldehydes to form dipyrromethanes. These were then oxidized and treated with $BF_3 \cdot Et_2O$ to form the target compounds.[6]

For stabilizing the radical anions the *meso*-position of the indacene framework is of crucial importance, because of the expected strong spin localization at this carbon atom. In cyclic voltammetric (CV) experiments compound **1** shows an irreversible reduction, which under thin-layer conditions forms a chemically reversible cycle with a separation of the peak potentials of more than 900 mV. This shift of the reoxidation to significantly more positive potentials indicates a fast, subsequent chemical reaction of the primarily formed radical anions, presumably a dimerization at the *meso* position. If this position is blocked with phenyl substituents, the radical anions are stable under aprotic conditions. Spectroelectrochemical measurements show an absorption of the radical anions at 560–630 nm that is red shifted relative to that of the neutral compounds, whereas the spectrum of the reduction product of **1** lacks this characteristic peak and is therefore in agreement with a dimeric dianion species (Table 1). The values of the reduction potentials depend in a characteristic manner on the type of substituents and their position at the chromophore and thus can be varied in a defined way. The substituents in α-position to the nitrogen atom are increasingly electron-withdrawing from **2a** to **2c** and lead to a strong anodic shift of the reduction potentials, whereas comparing **2a** with **4b**, the presence of the additional electron-releasing ethyl groups at the β-position causes only a smaller cathodic shift (Table 1).

Stabilization of the radical cations can also be achieved by suitable substitution. Compound **1** cannot be oxidized at potentials accessible in common solvents. For a detectable electrochemical oxidation the electron density in the indacene ring has to be increased. This higher electron density, which is illustrated by the increasing values of the reduction potentials from **2c** to **2a**, runs parallel to the behavior upon oxidation. While **2c** like **1** cannot be oxidized, the radical cation of **2b** is unstable whereas **2a** can be oxidized at a lower potential and yields a stable radical cation. During oxidation the intense peak of the neutral compound decreases and a new absorption at shorter wavelengths (about 400 nm) appears.

The two reversible redox processes of **2a** are illustrated in Figure 1a. The difference of the potentials between the two redox processes is sufficiently high to populate excited singlet states upon recombination of radical cations and radical anions, which then emit photons. This electrogenerated chemiluminescence (ECL) matches the fluorescence spectrum obtained by photonic excitation (Figure 1b, for conditions see *Experimental Section*). The relatively narrow emission band and the stability of the radical ions makes this compound particularly interesting for applications in OLEDs.[7]

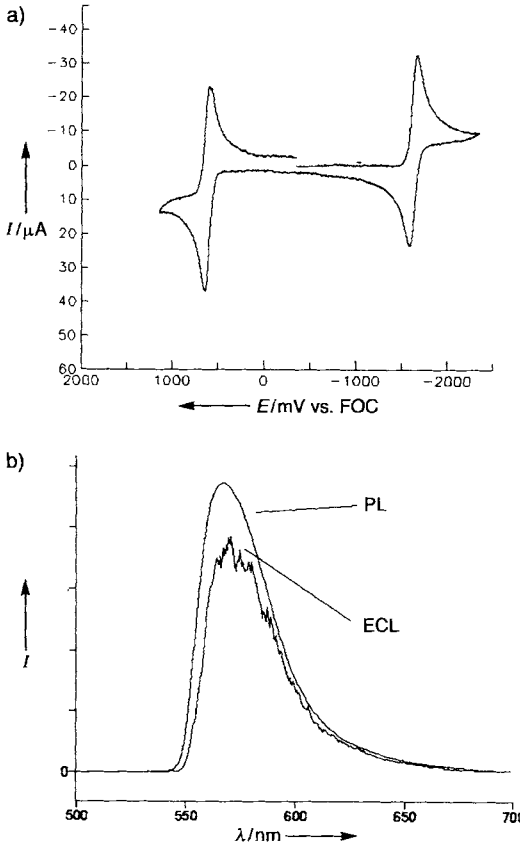

Figure 1. a) Cyclic voltammogram of **2a** in acetonitrile, scan rate 100 mVs^{-1}; b) comparison of the ECL spectrum of **2a** (bottom) with the photoluminescence at equal concentrations (top, excitation at 530 nm), both in CH_2Cl_2.

The attempt to stabilize the radical cations by donor substitution at the phenyl ring leads to an interesting result. The electron-accepting properties of the chromophore can be used for the construction of a proton-sensitive fluorescent switch. Compound **4a** shows practically no emission in its neutral state: fluorescence is probably quenched by an intramolecular electron transfer in the excited state from the dimethylamino group to the indacene chromophore.[8] Addition of trifluoroacetic acid protonates **4a**, and the bright green fluorescence typical of this class of compounds[3] appears (Figure 2). The ratios of the fluorescence quantum yields of the free base and of the protonated form in chloroform are about 1:200, whereas the UV spectra show only a slight difference. Owing to the complete quenching of the emission in the neutral form, this system should be suitable as a fluorescent pH-sensor.[9]

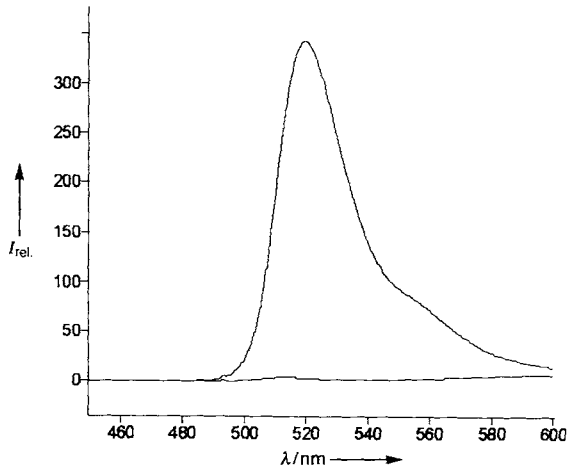

Figure 2. Fluorescence spectra of **4a** before (bottom) and after (top) protonation of the dimethylamino group with trifluoroacetic acid in $CHCl_3$ (excitation at 495 nm).

On- and off-switching of the fluorescence of **4a** is not based on a change of the electronic structure of the chromophore due to conjugation. The kind of interaction between the substituents at the phenyl ring and the chromophore is determined by the steric conditions at the bridging atom of the indacene framework, as shown by the X-ray structure of **3** (Figure 3).[10] The

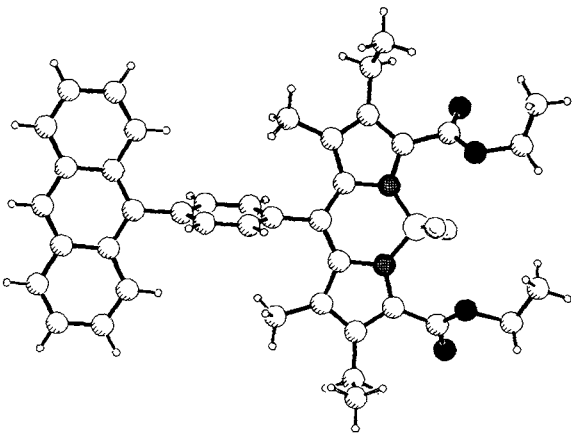

Figure 3. Crystal structure of **3**. The anthracene and the phenyl ring are twisted by 78°, the phenyl and the indacene ring by 75°.

twisting of the phenyl ring out of the plane of the indacene chromophore caused by the methyl groups interrupts the conjugation of the substructures. The UV spectrum of **3** is composed additively of the spectra of its subchromophores, which follows from a comparison with **2c**. Also **4a** and **4b** do not differ in their absorption maxima. In addition to the first reversible reduction signal, cyclic voltammetry of **3** shows a second irreversible re-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3612-1334 $ 17.50+.50/0

duction indicating destruction of the indacene structure. At an even higher negative potential reversible reduction of the phenylanthracene substructure can be observed. Apparently the substructures are electrochemically independent, too.

Cyclic voltammetry of **4a** indicated that the oxidation of the dimethylamino group appears between the oxidation and the reduction of the indacene framework. This suggests that the lone electron pair at the amino group is energetically located between the HOMO and the LUMO of the indacene chromophore. The oxidation potential of the protonated dimethylamino group is considerably higher than that of the free base and beyond the accessible potentials in acetonitrile, which is reflected in the CV upon protonation by the disappearance of this peak. This increase of the oxidation potential makes a nonradiative deactivation process like the one described above impossible. The oxidation of the indacene chromophore in the protonated form occurs at the same potential as in the neutral form, where it appears as the second oxidation step. Apparently the indacene chromophore is influenced inductively by a positive charge on the dimethylamino group in the same way no matter how the charge is created, by protonation or oxidation.

We have showed that by specific functionalization the electron donor and acceptor properties of the difluoroboradiaza-*s*-indacene chromophore can be directed in a way that leads to electrogenerated luminescence or proton-dependent fluorescence. Presently we aim to incorporate the described dye compounds as active components in OLEDs and to test analytical applications in sensor chemistry.

Experimental Section

Cyclic voltammetry: Solvent acetonitrile; potentials reported [mV] vs ferrocene (FOC) as internal standard. Experimental conditions: reversible half-wave potentials $E_{1/2}$, room temperature, scan rate 250 mVs^{-1}, platinum disc working electrode, Ag/AgCl pseudo-reference electrode, platinum counterelectrode, supporting electrolyte 0.1 M tetrabutylammonium hexafluorophosphate.

Spectroelectrochemistry: Solvent acetonitrile, transmission cell with a gold minigrid working electrode or reflection cell with a platinum disc working electrode.

Optical spectra: Concentrations 10^{-5} M to 10^{-6} M in chloroform filtered over basic alumina before use. Emission spectra are corrected.

ECL-measurements: The ECL spectrum was recorded by applying an alternating square wave with redox potentials determined by cyclic voltammetry (switching time 20 ms, solvent dichloromethane). Concentration: 10^{-3} M, supporting electrolyte: 0.1 M tetrabutylammonium hexafluorophosphate. The emission is red-shifted because of reabsorption in more highly concentrated solutions.

Protonation of a Linear Oxo-Bridged Diiron Unit without Rehybridization of the Bridging Oxygen: Structure of the (μ-Hydroxo)bis-(tetraphenylporphyrinato)iron(III) Cation**

Daniel R. Evans, Rajeev S. Mathur, Kristel Heerwegh, Christopher A. Reed,* and Zuowei Xie

The recognition that oxo- and hydroxo-bridged diiron active sites are widespread biological units has led to intense activity in defining their chemistry.[1] The transformation of an oxo to a hydroxo bridge is an obligatory or proposed step in the reaction pathways of a great variety of iron and copper redox enzymes, particularly the oxidases,[2] and is even a part of the more simple process of dioxygen binding in hemerythrin.[3] Structural responses, changes in spin coupling,[4] pK_a values, and rates of protonation[5] are all of particular interest. Structurally, singly bridged M-O-M units tend towards linearity because of π bonding and steric effects.[6] Upon protonation, they become more bent as the oxygen atom rehybridizes.[7] We now report a

diiron(III) complex in which this does not occur. Protonation of the nearly linear μ-oxo bridge in [(tpp)Fe–O–Fe(tpp)] (tpp = tetraphenylporphyrinate) leaves the bridge angle essentially unchanged. The resulting μ-hydroxo-bridged cation, $[(tpp)Fe–O(H)–Fe(tpp)]^+$, provides only the second known example of a diiron complex with a single hydroxo bridge unsupported by ancillary ligands.[7] Two additional features are notable. Antiferromagnetic coupling is greatly attenuated and the self-exchange rate of proton transfer for this strong acid is slow on the NMR timescale.

The synthesis of the hydroxo-bridged cation $[(tpp)Fe–O(H)–Fe(tpp)]^+$ by protonation of the μ-oxo precursor requires a strong Brønsted acid with a very weakly coordinating counterion. The inadequacy of anhydrous acids such as teflic acid ($HOTeF_5$) in this regard is illustrated by the formation of species with coordinated anions, such as $[Fe(OTeF_5)(tpp)]$.[8] The formation of bis(solvent) complexes such as $[Fe(H_2O)_2(tpp)][ClO_4]$ from aqueous perchloric acid[9] illustrates the additional problem of finding reaction conditions that exclude coordinating solvents. Current best choices for the least coordinating anion are hexahalo carboranes of the type $CB_{11}H_6X_6^-$ (X = Cl, Br, I),[10] and the tetraphenylborate ion with perfluorinated phenyl groups $[F_{20}\text{-}BPh_4]^-$.[11] For the case of the carborane anions, the isolable acids $[H_9O_4^+][CB_{11}H_6X_6^-]$[12] can be used to protonate [(tpp)Fe–O–Fe(tpp)] in haloarene solvents. Alternatively, strong Brønsted acidity is readily generated by hydrolysis of the strongly Lewis acidic "bare" $[Fe(tpp)]^+$ ion[13] in arene solvents. In practice, excellent yields of the μ-hydroxo dimer can be obtained by recrystallization of salts of this arene-solvated cation from toluene wetted with one equivalent of water. Single crystals suitable for high-quality X-ray diffraction were obtained with both the hexachloro carborane counterion to give **1** and with the $[F_{20}\text{-}BPh_4]^-$ counterion to give **2**.[14] Figure 1 shows a perspective view of the μ-hydroxo cation in **1**.

$[(tpp)Fe–O(H)–Fe(tpp)][CB_{11}H_6Cl_6]\cdot$toluene **1**

$[(tpp)Fe–O(H)–Fe(tpp)][F_{20}\text{-}BPh_4]\cdot 3$ toluene **2**

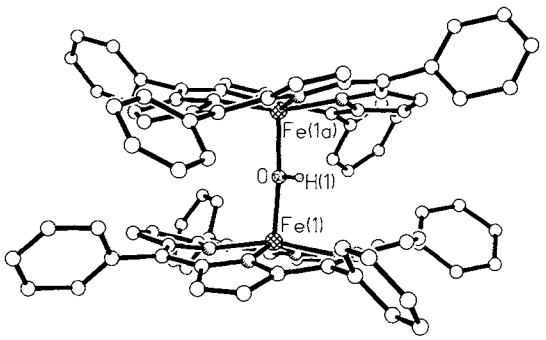

Figure 1. Perspective view of the μ-hydroxo-bridged cation $[(tpp)Fe–O(H)–Fe(tpp)]^+$ in the crystal structure of the $CB_{11}H_6Cl_6^-$ salt **1**.

The salient structural features of the μ-hydroxo cation from the two independent determinations are compared to those of the analogous μ-oxo compound in Table 1. Remarkably, the Fe–O–Fe bridge angle of 176.1(2)° in the μ-oxo dimer[15] is insignificantly changed by 3° upon protonation in **1** and is only 7° smaller in **2**. In the only other reported singly bridged μ-hydroxo iron(III) dimer, $[(oep)Fe–O(H)–Fe(oep)]^+$ (oep = octaethylporphyrinate), the Fe–O(H)–Fe angle is about 30° more acute (146.2(2)°).[7] The origin of this effect must be the steric bulkiness of the tpp phenyl rings. Although conformationally

[a] Average values. [b] pyr = pyrrole ring.

staggered (Figure 2), the porphyrin rings have little room to splay if a short Fe–O(H)–Fe linkage is to be maintained. In the corresponding manganese complex, the separation of the porphyrin rings is greater and the bridge angle is 160.4(8)°.[16] The Fe–O bond lengths undergo an expected extension from 1.759(1) Å in the μ-oxo complex to an average of 1.87(6) Å in the μ-hydroxo complex. Offsetting this, however, the out-of-plane displacements of the Fe atoms from the 24-membered porphyrin core (Fe···Ct_p) have contracted by 0.13–0.19 Å so that overall, the separation of the porphyrin planes is little changed. The change in iron atom displacement can be understood in terms of a change from a high to an admixed-intermediate spin state upon protonation. The shorter Fe–N and Fe···Ct_p distances of the hydroxo species (see Table 1), as well as the value for δ_{pyr} at −42 upfield in the ^{1}H NMR spectrum and large quadrupole splitting in the Mössbauer spectra ($\Delta E_q = 3.29 \pm 0.06$ mm s^{-1} for **1**) at room temperature, unambiguously identify the hydroxo spin state(s) as admixed-intermediate ($S = 3/2,5/2$).[17, 18] A suitable structural comparison is with other five-coordinate derivatives such as the perrhenate complex $[Fe(OReO_3)(tpp)]$, where an admixed-intermediate spin state is observed and the Fe–N and Fe···Ct_p distances are 2.059 and 0.48 Å, respectively.[19] The lower values of these parameters in **1** and **2** indicate somewhat more $S = 3/2$ spin character. Evidently, the hydroxo bridge provides a weaker axial ligand field than the oxo bridge. One consequence of the longer Fe–O bonds and the change of spin state is that the strong antiferromagnetic coupling in the μ-oxo dimer ($J \approx -135$ cm^{-1})[20] is attenuated to nearly zero in the μ-hydroxo species. The magnetic susceptibility data between 4 and 300 K for **1** and **2** yield plots of μ_{eff} versus temperature that do not contain points of inflection and have magnitudes very similar to monomeric admixed $S = 3/2, 5/2$ spin species. This places an upper limit of a few cm^{-1} on the magnitude of the magnetic coupling constant $|J|$.[21]

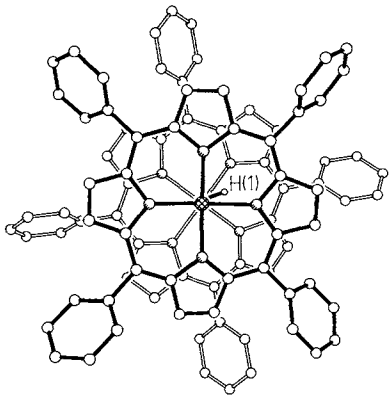

Figure 2. View of the μ-hydroxo-bridged cation $[(tpp)Fe–O(H)–Fe(tpp)]^+$ in **1** down the Fe–O(H)–Fe linkage. A similar staggered arrangement of the tpp rings and location of the H atom is seen in **2**.

The proton on the hydroxo bridge was located in both X-ray structure analyses with O–H distances of about 0.97 Å and Fe-O-H angles close to 90°. The location is apparently determined by steric considerations although weak hydrogen bond-

ing to the porphyrinato-N atoms may also play a role (N···H = 2.48–2.51 Å; Figure 2).

Trapped deeply in a hydrophobic environment and bonded to an unusually hybridized oxygen atom, the acidity of the μ-hydroxo proton is of both thermodynamic and kinetic interest. There is a conceptual parallel to acidic protons buried in protein structures. Obtaining a pK_a value in a suitable solvent for such measurements (e.g., CH_3CN, dimethyl sulfoxide (DMSO)) is complicated by the tendency of such solvents to act as ligands. The chemical shift of the ^2H NMR signal of the hydroxo group proton of **1** or **2** ($\delta = 11.6$) in bromobenzene solvent cannot be used as a criterion of acidity because of chemical shift contributions from the paramagnetism of iron. Nevertheless, the acidity can be bracketed by $H_9O_4^+$ in dry arene solvents (which protonates the μ-oxo conjugate base) and a two-phase arene/aqueous H^+ system. Addition of a drop of water to a solution of the μ-hydroxo species in bromobenzene causes deprotonation.

Kinetically, the lack of angular change at the oxygen atom upon protonation/deprotonation should contribute to a fast rate of proton transfer.[5] On the other hand, the iron atoms must move about 0.15 Å upon proton transfer and this will contribute to a slowing of the rate. Experimentally, there is no proton exchange between the μ-oxo and μ-hydroxo species on the ^1H NMR timescale. In [D_5]bromobenzene at 25 °C, separate pyrrole resonances are observed in a mixture of the two species and the chemical shifts are unchanged from those of single component measurements ($\delta = 13.8$ and -42, respectively). This probably reflects the steric impossibility of close approach of the protonated Fe–O(H)–Fe moiety to the unprotonated Fe–O–Fe moiety. Traces of smaller proton carriers such as hydronium ions, which must inevitably be present even in dried solvents, are apparently also ineffective at mediating proton exchange on the NMR timescale. This experiment suggests that the nature of the proton carrier and the accessibility of the base must be considered along with structural and electronic reorganizational barriers when rationalizing slow proton transfer rates. Given the interest currently being paid to proton transfer rates in bioinorganic chemistry,[22, 23] and the possibility that systems such as [(tpp)Fe–O(H)–Fe(tpp)]$^+$ may be useful in partitioning the various contributions to these rates, these aspects warrant more detailed study.

Tetraphosphasemibullvalene: First Valence Isomerizations in the Phosphaalkyne Cyclotetramer System**

Andreas Mack, Bernhard Breit, Thomas Wettling, Uwe Bergsträsser, Stefan Leininger, and Manfred Regitz*

Dedicated to Professor Michael Hanack on the occasion of his 65th birthday

Thermal or metal-induced cyclooligomerizations of phosphaalkynes in many cases provide a surprisingly simple access to polycyclic phosphorus–carbon cage compounds.[1, 2] The phosphaalkyne cyclotetramers have been investigated in most detail and are available in good yields by specific syntheses. Thus, for example, the tetraphosphacubane **1**,[3] the tetraphosphatricyclooctadiene **2**,[4] and the tetraphosphabarrelene **3**[5] may be considered as milestones along this road.

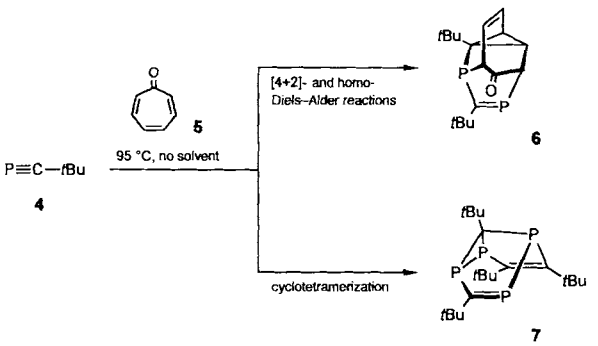
1 2 3

We now report on a new phosphaalkyne cyclotetramer, the tetraphosphasemibullvalene **7**. Although no valence isomerizations have yet been described for **1**–**3**, compound **7** can be both final and starting product for reactions of this type.

First evidence for the formation of the tetraphosphasemibullvalene **7** during the thermal cyclotetramerization of the phosphaalkynes **4** was surprisingly found in the reaction of **4** with tropone (**5**) at 95 °C, in which the diphosphatetracyclodienone **6** was formed by a sequence of Diels–Alder and homo-Diels–Alder reactions (Scheme 1).[6]



Scheme 1.

Work-up of the reaction mixture by column chromatography at −30 °C gave in addition to **6** the tetraphosphasemibullvalene **7** as an orange-red oil that was still contaminated with ≤5% (by ^{31}P NMR spectroscopy) of a further novel phosphaalkyne cyclotetramer. The latter was assigned the tetracyclic structure **13** on the basis of its NMR data (see Scheme 3).

The presence of tropone (**5**) has a significant but not yet understood influence on the course of the reaction. This is evident from the fact that the thermolysis of pure **4** at 95 °C[7] leads to the formation of a different cyclotetrameric distribution: after 8 h the main product is the tetraphosphatetracyclooctene **13**,[8] formed together with **7** and **12**[3c] in a ratio of 55:25:20 (by ^{31}P NMR spectroscopy).

Although semibullvalene itself undergoes a rapid, degenerate Cope rearrangement at −110 °C,[9] a Cope rearrangement for the tetraphosphasemibullvalene **7** cannot be detected even at room temperature. Higher temperatures cannot be used on account of thermal isomerization of **7** to furnish **12** (see Scheme 3). The constitution of **7** is confirmed by its NMR spectroscopic data. In the ^{31}P NMR spectrum the four phosphorus nuclei give rise to signals at $\delta = -49.0$ (P-7), −14.9 (P-1), 127.7 (P-4), and 332.0 (P-3); in the ^{13}C NMR spectrum the P=C and C=C units are characterized by signals at $\delta = 156.8$ (C-6), 170.5 (C-5), and 208.8 (C-2), while, as expected, the signal for C-8 is shifted markedly to high field ($\delta = 57.9$). The coupling patterns as well as the P,C coupling constants (Table 1) are in accord with the proposed structure.

Compound **7** reacts with [W(CO)$_5$·thf] by extrusion of tetrahydrofuran to furnish exclusively the dark-red complex **8** (Scheme 2), which is thermally more stable than the noncomplexed molecule. A skeletal rearrangement to afford the

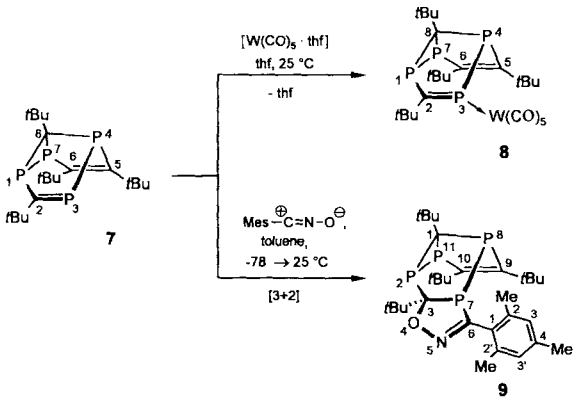
9: ^{1}H NMR (400 MHz): $\delta = 1.15$ (d, ^4J(P,H) = 2.0 Hz, 9H; C(CH$_3$)$_3$), 1.18, 1.38, 1.48 (each s, 9H; C(CH$_3$)$_3$), 2.04 (s, 3H; 4-CH$_3$), 2.52 (s, 6H; 2,2′-CH$_3$), 6.70 (s, 2H; 3,3′-CH$_3$); ^{13}C NMR (100.64 MHz): $\delta = 20.9$ (s; 4-*C*H$_3$), 22.0 (d, ^4J(P,C) = 5.7 Hz; 2,2′-*C*H$_3$), 29.0 (dd, ^3J(P,C) = 7.2 Hz (2×); C(*C*H$_3$)$_3$), 30.8 (s; C(*C*H$_3$)$_3$), 34.1 (dd, ^3J(P,C) = 14.0 Hz, ^4J(P,C) = 2.7 Hz; C(*C*H$_3$)$_3$), 34.4 (d, ^3J(P,C) = 13.6 Hz; C(*C*H$_3$)$_3$), 35.5 (m, *C*(CH$_3$)$_3$), 38.8, 38.9 (each s, *C*(CH$_3$)$_3$), 40.0 (dd, ^2J(P,C) = 21.9 and 17.8 Hz; *C*(CH$_3$)$_3$), 56.2 (ddd, ^1J(P,C) = 49.9 and 37.8 Hz (2×); C-1), 125.9 (dd, ^1J(P,C) = 71.2 and 53.8 Hz; C-3), 127.2 (d, ^2J(P,C) = 16.1 Hz; C-1 arom.), 129.6 (s; C-3,3′ arom.), 137.6 (s; C-2,2′ arom.), 138.3 (s; C-4 arom.), 150.2 (dd, ^1J(P,C) = 63.4 Hz, ^2J(P,C) = 15.2 Hz; C-10), 158.9 (dd, ^1J(P,C) = 48.2 Hz, ^2J(P,C) = 8.0 Hz; C-6), 164.3 (dd, ^1J(P,C) = 20.3 Hz, ^2J(P,C) = 9.3 Hz; C-9); ^{31}P NMR (161.98 MHz): $\delta = -2.8$ (ddd, ^1J(P,P) = 219.1 Hz, ^2J(P,P) = 16.3 and 9.1 Hz; P-2), 2.7 (dd, ^1J(P,P) = 219.1 Hz, ^2J(P,P) = 21.4 Hz; P-11), 62.5 (dd, ^1J(P,P) = 272.0 Hz, ^2J(P,P) = 9.1 Hz; P-7), 154.1 (ddd, ^1J(P,P) = 272.0 Hz, ^2J(P,P) = 21.4 and 16.3 Hz; P-8); MS (CI, 200 eV): *m*/*z* (%): 562 (2) [*M*$^+$ + H]; MS (EI, 70 eV): *m*/*z* (%): 561 (0.02) [*M*$^+$], 504 (2) [*M*$^+$ − *t*Bu], 416 (12) [*M*$^+$ − MesCN], 400 (5) [*M*$^+$ − MesCNO], 300 (2) [*M*$^+$ − MesCNO, −*t*BuCP], 262 (18) [*M*$^+$ − MesCNO, −(*t*BuC)$_2$], 169 (100) [P(*t*BuC)$_2^+$], 131 (11) [P$_2$(*t*BuC)$^+$], 119 (4) [Mes$^+$], 57 (51) [*t*Bu$^+$].

[a] NMR: Bruker AMX-400, ^{1}H and ^{13}C NMR in C_6D_6; ^{31}P NMR in C_6D_6 with 85% H_3PO_4 as external reference, all spectra recorded at $T = 25$ °C; MS: Finnigan MAT 90.



Scheme 2.

W(CO)$_5$ complex of the structure **12** does not occur either in the solid state or in solution. Coordination of the metal fragment at P-3, the signal of which is shifted only slightly to higher field ($\delta = 312.6$), is confirmed by the ^{183}W satellites [^1J(P,W) = 218.7 Hz] (for further NMR data, see Table 1).

Mesityl nitrile oxide undergoes rapid addition to the phosphaalkene unit of **7** in toluene to furnish the crystalline, polycyclic product **9** (Scheme 2), which is isolated in 92% yield after work-up by column chromatography. The NMR data unequivocally demonstrate the cycloaddition to the P–C double bond as well as the regiochemistry of the reaction. The signals for both reaction centers in **7** are shifted significantly to higher field: P-7 from $\delta = 332.0$ to $\delta = 62.5$, C-3 from $\delta = 208.8$ to $\delta = 125.9$. The unusual lowfield position of the signal for C-3 is reasonable when the oxygen of the dipole is bonded at this position. The remaining question of the stereochemistry of the cycloadduct **9** was resolved in favor of an *exo*-arrangement of the newly formed five-membered ring by a crystal structure analysis (Figure 1); an *endo* attack of the dipole is apparently prevented by the *tert*-butyl substituents at the C–C double bond. At the same time the structure of this novel phosphaalkyne cyclotetramer is confirmed.[10]

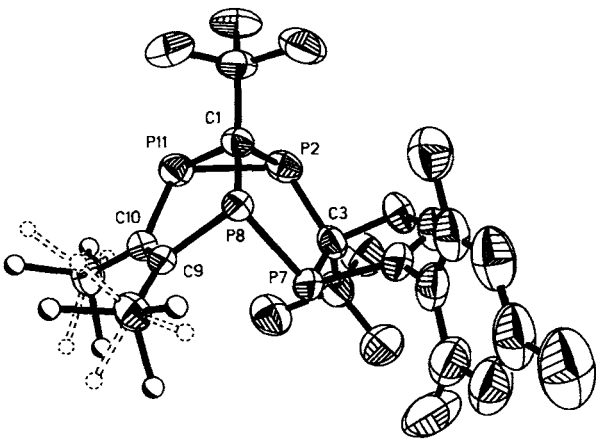


Figure 1. Structure of **9** in the crystal (XP-Plot, thermal ellipsoids drawn at 50% probability level). Selected bond lengths [Å] and angles [°]: P2–P11 2.2185(13), P7–P8 2.2095(12), P7–C3 1.865(3), P2–C3 1.892(3), P8–C9 1.869(3), P2–C1 1.855(3), P8–C1 1.845(3), P11–C1 1.836(3), P11–C10 1.851(3), C10–C9 1.357(4); C1-P2-P11 52.65(10), C1-P2-C3 103.49(14), C3-P2-P11 116.12(10), C1-P11-C10 100.21(14), C1-P11-P2 53.45(10), C10-P11-P2 115.66(11), P11-C1-P8 108.0(2), P11-C1-P2 73.89(12), P8-C1-P2 116.9(2).

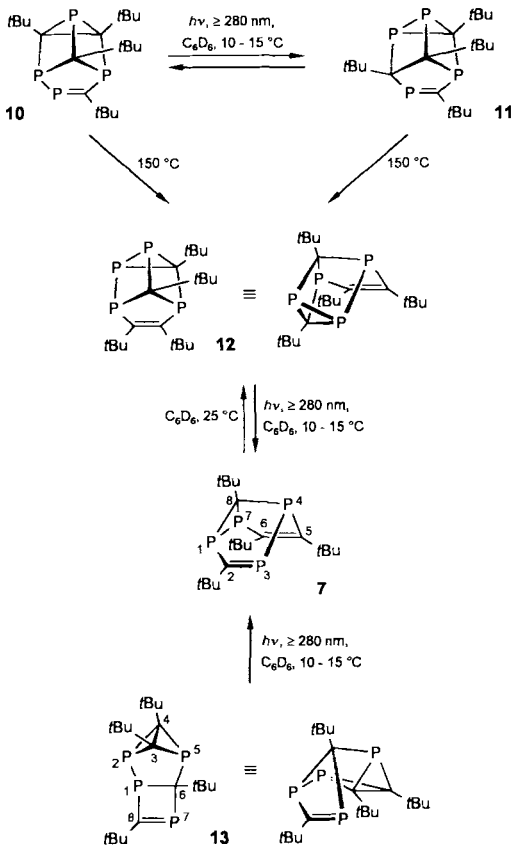
The P–C single bond lengths in the tricyclic phosphorus–carbon skeleton of **9** are between 1.836 and 1.892 Å (average value 1.856 Å) and thus in good agreement with those of other polycyclic compounds.[11] The P2–P11 bond length of 2.219 Å lies at the upper limit for diphosphiranes.[12] In accord with this, the angle P2-C1-P11 in the three-membered ring is larger (73.9°) and the angles C1-P11-P2 (53.5°) and C1-P2-P11 (52.7°) are smaller than those in other polycyclic systems containing a diphosphirane element.[13]

Valence isomerizations in phosphaalkyne cyclotetramer systems were previously unknown. We report here on reactions of this type that also make the tetraphosphasemibullvalene **7** accessible from the polycyclic systems **10**–**13** (Scheme 3).

The compounds **10** and **11** are known[13a,14] and coexist as a 1:1 equilibrium mixture (by ^{31}P NMR spectroscopy) upon irradiation of the one or the other in C_6D_6 (mercury high-pressure lamp Phillips, HPK 125W, Duran-50 filter). When each of the two isomers is heated separately at 150 °C, compound **12** (100 and 48%, respectively) is formed by a skeletal rearrangement; the latter product is also accessible directly from the thermal cyclotetramerization of the phosphaalkyne **4** at 180 °C.[3c] When **12** is photolyzed under the conditions mentioned for the equilibrium **10**⇌**11**, the valence isomer **7** is formed (up to 75%);



Scheme 3.

the reverse isomerization of **7** occurs relatively slowly at 25 °C in C_6D_6 (ca. 20% **12** after 7 d, both by ^{31}P NMR spectroscopy). Finally, **13** can undergo complete photochemical isomerization to furnish an isomeric mixture of **7** and **12** (80:20).

Experimental Section

7: In a 15-mL-pressure Schlenk tube, tropone (**5**) (0.14 g, 1.3 mmol) was added to phosphaalkyne **4** [15] and the two-phase system was heated with magnetic stirring under argon pressure (5 bar) for 17 h at 95 °C. After the mixture had cooled to 25 °C, unconverted phosphaalkyne **4** (2.15 g, 21.5 mmol) was recovered by condensation (0.003 mbar, received −192 °C). Column chromatography (1.4 × 30 cm) on silica gel (63–200 μm, baked for 16 h at 175 °C and 10^{-3} mbar and deactivated with 4% argon-saturated water) at −30 °C afforded the following in sequence: a) elution with *n*-pentane (500 mL) gave after evaporation of the solvent at 10^{-3} mbar/25 °C the orange-red, oily **7**. Yield: 32 mg (4.9%, with respect to converted **4**); stored at −25 °C; b) elution with *n*-pentane/diethyl ether 10/1 (50 mL) gave a dark orange-red, unidentified "polymer"; c) elution with *n*-pentane/diethyl ether 5/1 (70 mL) gave the pale yellow, oily tetracyclic product **6**.

8: Compound **7** (70 mg, 0.17 mmol) in tetrahydrofuran (5 mL) was added to a solution of [W(CO)$_5$·thf],[16] prepared by irradiation of [W(CO)$_6$] (92.3 mg, 0.26 mmol) in tetrahydrofuran (60 mL). After 17 h the solvent was evaporated at 25 °C/10^{-3} mbar, the oily residue was eluted with *n*-pentane (20 mL) and subjected to chromatography on silica gel (column: 1.8 × 37 cm) with *n*-pentane. Yield: 85.5 mg (69%) dark red oil, which could be crystallized from *n*-pentane at −80 °C. M.p. 8–13 °C (in thawing cold bath).

9: Mesityl nitrile oxide (40 mg, 0.25 mmol) in toluene (3 mL) was added dropwise with stirring at −78 °C to the tetraphosphasemibullvalene **7** (100 mg, 0.25 mmol) in toluene (3 mL), and the mixture was stirred for further 3 h at 25 °C. After evaporation (25 °C/10^{-3} mbar), dissolution in *n*-pentane (1.5 mL), and chromatography on silica gel (as described for **7**, but with water-cooling) the following were obtained in sequence: a) elution with *n*-pentane (80 mL) gave after evaporation about 5 mg of **12** formed by isomerization of **7**; identification by a comparison of the NMR spectrum with that of an authentic sample [3c]; b) elution with *n*-pentane/diethyl ether 25/1 (50 mL) gave the pale yellow cycloadduct **9**. Yield: 129 mg (92%), m.p. 123 °C (from *n*-pentane at −20 °C).

Rotational Spectroscopy of Mixtures of Trimethylamine and Fluorine: Identification of the Ion Pair $[(CH_3)_3NF]^+ \cdots F^-$ in the Gas Phase**

Hannelore I. Bloemink, Stephen A. Cooke, John H. Holloway, and A. C. Legon*

Reactions of elemental fluorine with organic compounds are notorious for their violence. They are assumed usually to proceed by a chain mechanism that is initiated by the facile homolytic dissociation of F_2 into atoms. The next step (propagation) is presumably the abstraction of an H atom from a CH_n group to give $\cdot CH_{n-1}$ and HF, which is strongly exothermic and makes the reaction difficult to control. Consequently, the products are often predominantly HF, CF_4, and carbon. The large value for the energy of heterolytic dissociation $F_2 = F^+ + F^-$ ($1370\ kJ\,mol^{-1}$)[1] means that reactions in the gas phase involving the F^+ ion are unlikely to be common. Are there reactions of F_2 in which heterolysis of the diatomic molecule needs to be invoked?

We report herein the identification and characterization of a complex formed by trimethylamine with F_2 in the gas phase. Interpretation of spectroscopic constants derived from analyses of the rotational spectra of three isotopomers leads to the conclusion that the observed species is best described as a Mulliken complex $[(CH_3)_3NF]^+ \cdots F^-$ of the inner type, that is, one in which the F^+ ion has been transferred from F_2 to the Lewis base. This is a surprising result, not only because of the reluctance of F_2 to dissociate heterolytically but also because, for all complexes $B \cdots F_2$ previously investigated ($B = NH_3$,[2] HCN,[3] CH_3CN,[4] H_2S,[5] and H_2O[6]), the interaction between the Lewis base and F_2 is very weak.

The rotational spectrum of the complex $[(CH_3)_3N, F_2]$ was observed by using a pulsed-nozzle, Fourier-transform microwave spectrometer[7] fitted with a fast-mixing nozzle.[8] This latter device consists of two concentric, nearly coterminal tubes and ensures that the two components (trimethylamine flowing continuously through the inner tube and F_2/Ar mixture pulsed down the outer tube) do not mix until they expand simultaneously into the evacuated Fabry–Pérot cavity of the spectrometer. The reasons why the fast-mixing nozzle is effective in inhibiting the production of F atoms, and therefore in precluding violent chain reactions of the type alluded to earlier, have been discussed elsewhere.[6]

The ground-state rotational spectrum of the isotopomer $[(CH_3)_3{}^{14}N, F_2]$ is characteristic of a symmetric-top molecule carrying a ^{14}N ($I = 1$) nucleus on the unique axis. Analysis of the ^{14}N nuclear quadrupole hyperfine structure in the $J = 2 \leftarrow 1$, $3 \leftarrow 2$, $4 \leftarrow 3$, and $5 \leftarrow 4$ transitions yielded the rotational constant B_0, the centrifugal distortion constants D_J and D_{JK}, and the ^{14}N-nuclear quadrupole coupling constant $\chi(^{14}N)$ (Table 1). A partially resolved substructure, arising from coupling of the various $I = 1/2$ (H and F) nuclei, together with the small magnitudes of $\chi(^{14}N)$ and D_{JK}, resulted in a complex and congested

Table 1. Ground-state spectroscopic constants of isotopomers of $[(CH_3)_3N, F_2]$.

	$[(CH_3)_3{}^{14}N,F_2]$	$[(CH_3)_3{}^{15}N,F_2]$	$[(CD_3)_3{}^{14}N,F_2]$ [a]	$(CH_3)_3{}^{14}N\cdots F_2$ [b]
B_0 [MHz]	1736.7453(7)	1731.9475(5)	1550.045(2)	1274.5
D_J [kHz]	0.288(13)	0.295(13)	0.21(3)	2.0
D_{JK} [kHz]	6.38(8)	6.16(5)	–	–
$\chi(^{14}N)$ [MHz]	−1.73(1)	–	–	≈ −5.0

[a] Only $K = 0$ transitions fitted to give B_0 and D_J. See text for discussion. [b] Values in this column are estimated for the weak binding model $(CH_3)_3N\cdots F_2$, as described in the text, but the species observed is the ion pair $[(CH_3)_3NF]^+\cdots F^-$. See text for discussion.

spectrum. For each ^{14}N nuclear quadrupole component, the center frequency of the partially resolved substructure was used in the analysis. The determined spectroscopic constants of $[(CH_3)_3{}^{15}N, F_2]$ and $[(CD_3)_3{}^{14}N,F_2]$ are also given in Table 1. For the latter isotopomer, the spectral complexity arising from the nine D ($I = 1$) quadrupolar nuclei precluded a detailed analysis and only the highest frequency component belonging to each $K = 0$ transition was fitted to give the reported B_0 and D_J values.

To establish the nature of the detected species $[(CH_3)_3N, F_2]$, we first compare its observed spectroscopic constants (Table 1) with those predicted from the model $(CH_3)_3N\cdots F_2$ of the complex in which the intermolecular binding is weak. The intermolecular stretching force constant k_σ for each $B\cdots F_2$ complex so far investigated[2–6] is small. For example, the largest value is $k_\sigma = 4.70(3)\ N m^{-1}$ for $H_3N\cdots F_2$ and this is similar in magnitude to those of $Rg\cdots HX$ complexes, where Rg is an inert gas atom.[9] The centrifugal distortion constant D_J for a weakly bound symmetric-top complex $B\cdots F_2$ composed of rigid, unperturbed subunits is related to k_σ by Equation (a),[10] where

$$D_J = (16\pi^2\mu B_0^3/k_\sigma)\{1 - (B_0/B_B) - (B_0/B_{F_2})\} \quad (a)$$

B_0, B_B, and B_{F_2} are rotational constants of the complex and the molecules B[11] and F_2,[12] respectively, and $\mu = m_B m_{F_2}/(m_B + m_{F_2})$. Using the estimated B_0 value for the weak binding model $(CH_3)_3N\cdots F_2$ from Table 1 and assuming $k_\sigma \approx 5\ N m^{-1}$, we obtain $D_J^{calcd} \approx 2.0$ kHz. The observed value of D_J is about seven times smaller and indicates that the detected complex is much more strongly bound than expected.

The value of $r(B\cdots F)$ for each $B\cdots F_2$ complex previously investigated[2–6] is close to the sum of the van der Waals radii $(\sigma(F) + \sigma(B))$ of F and the acceptor atom in B, a result also consistent with weak binding. If we assume $r(N\cdots F) = 2.65$ Å, (that is a distance slightly shorter than that of 2.71(1) Å in $H_3N\cdots F_2$[2]) and unperturbed geometries for $(CH_3)_3N$[11] and F_2,[12] we obtain the calculated value of B_0 recorded in Table 1 for the model $(CH_3)_3{}^{14}N\cdots F_2$. Comparison of the calculated value B_0^{calcd} and the observed value B_0 indicates that the complex has a much smaller moment of inertia than expected. Indeed, to fit B_0 with the weak binding model requires $r(N\cdots F) = 1.97$ Å, which is 0.9 Å shorter than $\sigma(N) + \sigma(F)$.

Additionally, the ^{14}N nuclear quadrupole coupling constant of the model complex $(CH_3)_3{}^{14}N\cdots F_2$ should be slightly less than the value of $\chi_0(^{14}N) = -5.502(3)$ MHz of the free molecule,[13] mainly as a result of the zero-point angular oscillation of the subunit $(CH_3)_3N$ in the complex. For example, the value $\chi(^{14}N) = -4.918(3)$ MHz was measured in the weakly bound complex $(CH_3)_3N\cdots HCCH$ ($k_\sigma = 5.86(2)\ N m^{-1}$),[14] and a similar value is expected for $(CH_3)_3N\cdots F_2$. The observed change $\Delta\chi = \chi(^{14}N) - \chi_0(^{14}N) = 3.77$ MHz is much larger (see Table 1).

Clearly, the comparisons of B_0, D_J, and $\chi(^{14}N)$ (Table 1) indicate that the detected complex is not the weakly bound species $(CH_3)_3N\cdots F_2$. However, the observed values can all be understood if we assume that the preponderant contribution to a valence-bond description of the complex is the ion pair $[(CH_3)_3NF]^+\cdots F^-$. Then k_σ would have a value appropriate to an ion pair. Typical values are $k_\sigma = 82$ and $67\ N m^{-1}$ for $[(CH_3)_3NH]^+\cdots Br^-$ and $[(CH_3)_3NH]^+\cdots I^-$, both obtained from D_J.[15] The version of Equation (a) relevant to the ion-pair structure $[(CH_3)_3NF]^+\cdots F^-$ is Equation (b), where B_+ is the

$$D_J = (16\pi^2\mu B_0^3/k_\sigma)\{1 - B_0/B_+\} \quad (b)$$

rotational constant of the cation and can be estimated to have the value 5035 MHz if the cation is modeled by placing F^+ on the C_3 axis of an unperturbed $(CH_3)_3N$ molecule at the distance $r(N-F) = 1.365$ Å, as in NF_3.[16] When $k_\sigma \approx 70\ N m^{-1}$ is used in Equation (b), the result is $D_J \approx 0.2$ kHz, which is much closer to the observed quantity than that estimated for $(CH_3)_3N\cdots F_2$ (see Table 1).

The difference $\Delta\chi(^{14}N) = \chi(^{14}N) - \chi_0(^{14}N) = 3.77$ MHz for $[(CH_3)_3{}^{14}N, F_2]$ is even larger than those observed in the vapor phase for the trimethylammonium halides $[(CH_3)_3N, HX]$, where X = Cl, Br, and I. The fractional contribution f of the ion-pair structure $[(CH_3)_3NH]^+\cdots X^-$ was estimated[15] from the X-nuclear quadrupole coupling constant for the complexes $[(CH_3)_3NH]^+\cdots X^-$, and Figure 1 shows a plot of $\Delta\chi(^{14}N)$ versus f for this series. The value of $\Delta\chi(^{14}N)$ for $[(CH_3)_3{}^{14}N, F_2]$ is shown as a horizontal dashed line in Figure 1 and corresponds to a f value of approximately 1. Hence, the $\Delta\chi(^{14}N)$ value is consistent with the observation of the ion pair $[(CH_3)_3NF]^+\cdots F^-$.

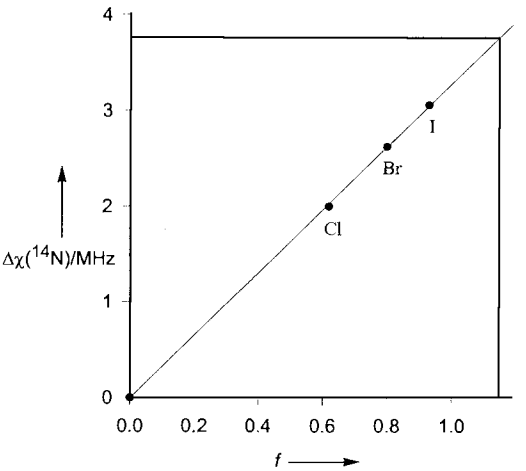

Figure 1. Plot of $\Delta\chi(^{14}N) = \chi(^{14}N) - \chi_0(^{14}N)$ against f (fractional ionic character) for some trimethylammonium halides. The horizontal dashed line indicates the value of $\Delta\chi(^{14}N)$ for $[(CH_3)_3N, F_2]$.

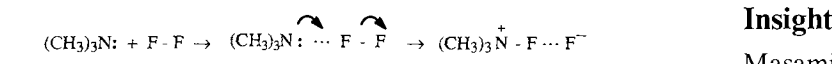
The ion pair $[(CH_3)_3NF]^+\cdots F^-$ should have a large electric dipole moment μ. Flygare et al.[17] demonstrated that a time-domain emission signal from a pulsed-nozzle, Fourier-transform microwave spectrometer passes through a maximum value as the input power P_{in} increases and that at the maximum $P_{in}^{1/2}\kappa\tau_p$ is a constant, where τ_p is the microwave pulse length and $\kappa = \langle J'K'F'|\mu|J''K''F''\rangle$ is the rotational transition moment. By comparing the P_{in} values that give maximum signals in transitions of $H_3N\cdots F_2$ and $[(CH_3)_3NF]^+\cdots F^-$, we find that the electric dipole moments of these two species are in the approxi-

mate ratio of 1:6. If the electric dipole moment μ for $H_3N\cdots F_2$ is assumed to be about 1.6 D (that is slightly in excess of that of the free NH_3), the implied electric dipole moment of $[(CH_3)_3NF]^+\cdots F^-$ is roughly 10 D.

Finally, the observed moments of inertia of the three isotopomers of the complex (Table 1) can be fitted to give the distances $r(N\cdots F_i)$ and $r(F_i\cdots F_o)$ (i = inner; o = outer) under the assumption that the geometry of the $(CH_3)_3N$ subunit is unchanged when F_2 approaches along the C_3 axis to produce $[(CH_3)_3NF]^+\cdots F^-$. The results of the least squares fit are $r(N\cdots F_i) = 1.29(4)$ Å and $r(F_i\cdots F_o) = 2.32(4)$ Å. Although the errors are large because these distances are highly correlated, it is significant that $r(N\cdots F_i)$ and $r(F_i\cdots F_o)$ are, respectively, similar to and much larger than the quantities $r(N-F) = 1.365$ Å in NF_3[16] and $r(F-F) = 1.41744(6)$ Å in F_2.[12] The bond lengths $r(N\cdots F_i)$ and $r(F_i\cdots F_o)$ are evidently also consistent with the conclusion from the other evidence adduced here: that is that F_2 is heterolyzed as it approaches the nitrogen atom along the C_3 axis of the $(CH_3)_3N$ unit to form a N–F bond and the ion pair $[(CH_3)_3NF]^+\cdots F^-$.

A possible mechanism for formation of the ion pair is shown in Scheme 1, in which the weak, outer complex (as observed for



Scheme 1.

$H_3N\cdots F_2$[2]) is formed first but nucleophilic attack on F_2 then occurs, accompanied by synchronous charge transfer. The present investigation is noncommittal about the existence of the outer complex at a minimum in the potential energy surface. The transfer of F^+ from F_2 to $(CH_3)_3N$ implies that the F^+ affinity (the analogue of proton affinity) of trimethylamine is large. We note that the mechanism in Scheme 1 is identical to that which would be written for formation of the isoelectronic molecule $(CH_3)_3CH_3\cdots F^-$ from trimethylamine and methyl fluoride.

Experimental Section

Rotational spectra of the complexes $[(CH_3)_3N, F_2]$ were observed by using a pulsed-nozzle, Fourier-transform microwave spectrometer [7] fitted with a fast-mixing nozzle [8]. A mixture of approximately 2% of fluorine (99.8% pure, Distillers M. G.) in argon was pulsed down the outer of the two concentric tubes that constitute the fast-mixing nozzle at a rate of 2 Hz from a stagnation pressure of 3 bar. Trimethylamine vapor (Aldrich) was flowed continuously from the inner (glass, 0.3 mm internal diameter) tube to yield a nominal pressure of 8×10^{-5} mbar in the evacuated Fabry–Pérot cavity of the spectrometer. Gas pulses produced in this way were rotationally polarized and the subsequent free induction decay at rotational transition frequencies collected and processed as described elsewhere [8]. Samples of [^{15}N]trimethylamine (99 atom%) and [D_9]trimethylamine (99.9 atom%) were supplied by CK Gas Products Ltd.

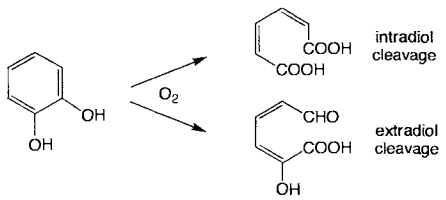
Biomimetic Extradiol Cleavage of Catechols: Insights into the Enzyme Mechanism**

Masami Ito and Lawrence Que, Jr.*

The catechol dioxygenases are a class of nonheme iron enzymes that catalyze the oxidative cleavage of catechols as part of nature's biodegradation pathway for aromatic molecules.[1] These enzymes can be divided into two subclasses: intradiol-cleaving enzymes, which break the catechol C1–C2 bond, and extradiol-cleaving enzymes, which break the C2–C3 bond (Scheme 1).[2, 3]



Scheme 1. The two modes of oxidative cleavage of catechols in nature.

The intradiol-cleaving enzymes require Fe^{III} and are the more extensively characterized. The persistence of the Fe^{III} oxidation state in the reaction cycle has led to a proposed mechanism in which the substrate catechol is activated by coordination to the Fe^{III} center for direct electrophilic attack by O_2.[4, 5] In contrast, the extradiol-cleaving enzymes, which typically require Fe^{II}, are proposed to utilize an oxygen activation mechanism,[2, 6] though this mechanism is not as well understood. Interestingly, extradiol-cleavage can also be elicited by catechol 1,2-dioxygenase with some substrate analogues,[7, 8] which demonstrates that even an Fe^{III} enzyme can carry out this chemistry.

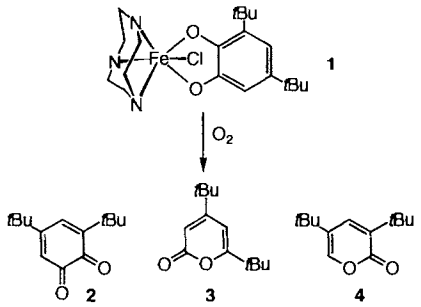
[**] This work was supported by a grant from the National Institutes of Health (GM-33162, L. Q.) and a fellowship from the Japan Society for the Promotion of Science (M. I.).

Biomimetic [Fe^{III}(L)dbc] complexes (L = tetradentate tripodal ligand; dbc = 3,5-di-*tert*-butylcatecholate dianion) react with O_2 to afford excellent yields of intradiol cleavage product.[5, 9] These complexes have played an important role in supporting and refining the novel substrate activation mechanism for intradiol cleavage. We have thus embarked on an analogous effort to elicit extradiol cleavage from a metal catecholate. Thus far, there are only two reported examples of extradiol cleavage by synthetic iron complexes. Funabiki et al. found that $FeCl_2$ in THF/H_2O cleaves $dbcH_2$ to extradiol cleavage products in 40% yield,[10] but the relevant reactive species was not identified. On the other hand, Dei et al. found that the complex [Fe^{III}(tacn)Cl(dbc)] (**1**, tacn = 1,4,7-triazacyclononane) afforded extradiol cleavage product upon exposure to O_2 in 35% yield.[11] Neither of these studies featured a systematic investigation that shed light on the extradiol cleavage mechanism. We have thus followed up on the study by Dei et al. and report in this paper conditions under which extradiol cleavage of the coordinated catecholate in **1** can be achieved quantitatively. Our observations provide the basis for a proposed mechanism for extradiol cleavage and the principles underlying the regioselectivity of catechol cleavage.

[Fe^{III}(tacn)Cl(dbc)] (**1**, Scheme 2) is a six-coordinate complex with a structure akin to that recently reported for [Fe^{III}(tacn)N_3(Cl_4cat)] (Cl_4catH_2, tetrachlorocatechol).[12] When exposed to O_2 in CH_3CN, **1** afforded three products: 3,5-di-*tert*-butylquinone (**2**) in 50% yield, and the two isomeric di-*tert*-butyl-2-pyrones (**3** and **4**) in 29% combined yield (Table 1). The pyrones **3** and **4** derive from the extradiol cleavage of dbc with insertion of one oxygen atom into either the C1–C6 or the C2–C3 bond followed by loss of CO.[10, 13, 14] In pyridine solvent the complex afforded a comparable yield of extradiol cleavage products, though the isomer ratio differs. In both cases 3,5-di-*tert*-butylmuconic acid anhydride, the intradiol cleavage product, was observed in only trace amounts, confirming the proclivity of this complex towards extradiol cleavage.



Scheme 2. The reaction of **1** with O_2 gives **2**–**4**.

Complex **1** differs from the [Fe(L)dbc] complexes that afford intradiol cleavage products in having a tridentate tacn ligand (instead of a tetradentate L) plus an additional chloride. Dei et al. have suggested that the presence of the labile chloride in **1** may be the essential factor for achieving extradiol cleavage.[11] We have thus investigated the reactivity properties of **1** in the presence of silver salts to remove the chloride (Table 1). No extradiol cleavage products were formed upon addition of an equivalent of AgOAc; instead about a 40% yield of quinone **2** was obtained in both CH_3CN and pyridine. However the use of $AgBF_4$ significantly favored the oxidative cleavage reaction; indeed, the conversion was 90% in pyridine. The contrasting effects of AgOAc and $AgBF_4$ on the oxidation of the coordinated catecholate suggest that the availability of a coordination site on the metal center plays a key role in the extradiol cleavage mechanism. Extradiol cleavage is inhibited in the presence of a coordinating anion such as acetate but favored in the presence of a noncoordinating anion such as BF_4.

Table 1. Product distributions for the reaction of complex **1** with O_2 [a].

Solvent	Reagent	**2**	**3**	**4**

	1 equiv $AgBF_4$, 20 equiv *N*-methylimidazole	trace	68	30
	1 equiv $AgBF_4$, 20 equiv 2,6-dimethylpyridine	trace	8	2

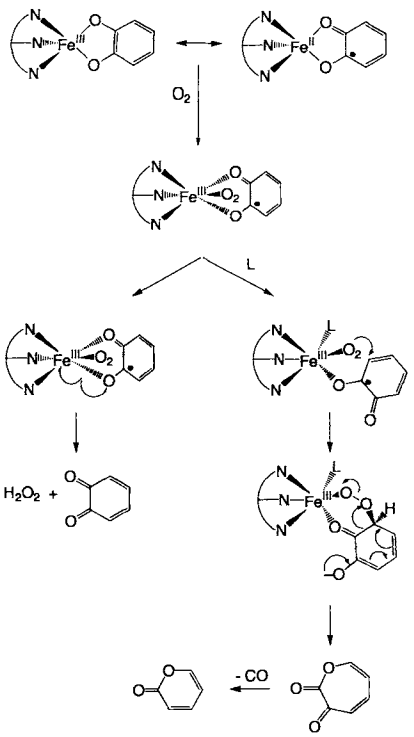
[a] Reaction time $t = 12$ h, ca. 25 °C. In all cases, only trace amounts (< 1% yield) of the intradiol cleavage product, 3,5-di-*tert*-butylmuconic anhydride, could be detected. Numbers reported are the average of three runs. For the reactions with low product yields, the balance is unchanged starting complex.

The reaction of **1** with O_2 was also investigated in CH_2Cl_2 to determine whether the coordinating solvents used thus far may play a role in extradiol cleavage. The major product observed in the presence of $AgBF_4$ was the quinone **2** (82% yield, Table 1). In the presence of $AgBF_4$ and 20 equiv pyridine, only trace amounts of quinone **2** were found, and the major products were the two isomeric pyrones **3** and **4** (78% yield). Under these conditions, ^{18}O labeling studies showed that the extradiol cleavage products formed had incorporated one atom of ^{18}O. The prominent ions at m/z 208 [M^+], 193 [$(M - CH_3)^+$], and 180 [$(M - CO)^+$] in the mass spectra of the two pyrone isomers shifted by two mass units in the corresponding ^{18}O-labeled products. Comparison of their intensities with the residual ^{16}O peaks indicated that the pyrone ring oxygen atoms of the products were approximately 90% labeled.

Interestingly, the use of stronger Lewis bases such as 2-methylpyridine, 4-methylpyridine, or N-methylimidazole afforded even higher conversions; indeed the latter two gave nearly quantitative (98%) extradiol cleavage of the bound catecholate, which suggests that coordination of this base to the metal center is an important feature of the mechanism. In accord with this observation, use of a sterically hindered pyridine such as 2,6-dimethylpyridine afforded a low yield of extradiol cleavage products. Thus, extradiol cleavage is elicited in the absence of chloride and in the presence of an additional coordinating aromatic nitrogen ligand.

The nearly quantitative extradiol cleavage elicited from the dbc complex **1** with tridentate tacn stands in striking contrast to the quantitative intradiol cleavage observed for the complexes with tetradentate ligands.[5, 9] This difference suggests that the key to the extradiol cleavage mechanism lies in the availability of a coordination site. While intradiol cleavage must involve the direct attack of an electrophilic O_2 molecule on the enediolate moiety of the coordinated catecholate,[4, 5] in extradiol cleavage

the initial C–O bond-forming step must occur at the carbon adjacent to the enediolate moiety. This distinct regiochemistry can only be achieved by a different mode of attack, which we propose to be that of a nucleophilic superoxide on an electrophilic site on the aromatic ring (Scheme 3). The superoxide would be generated from the binding of O_2 to the five-coordinate iron center.



Scheme 3. Proposed mechanism for the reaction of **1** with O_2. The first step, the freeing of a coordination site on cleavage of the chloride ligand from **1**, is not shown.

Such a mechanistic scheme raises an important question: how does O_2 bind to an Fe^{III} center? We propose that the Fe^{III}–catecholate complex is in resonance with its Fe^{II}–semiquinone form, as proposed for the intradiol cleavage mechanism.[5] The loss of the halide ligand from **1** enhances the covalency of the Fe^{III}–catecholate interaction, which increases the Fe^{II} character of the metal center. The availability of an iron coordination site allows O_2 to bind to the iron center, thereby forming an Fe^{III}–superoxide complex. In the absence of the added pyridine, electron transfer occurs between the semiquinone and the superoxide through the iron center to produce quinone, as observed in CH_2Cl_2. When present, the pyridine binds to the metal–O_2 adduct by displacing the more weakly bound carbonyl oxygen of the semiquinone. The conversion of the semiquinone into a monodentate ligand brings the bound superoxide in close proximity to a ring carbon adjacent to the enediol unit. The nucleophilic superoxide can then attack the ring at this carbon to effect a Michael addition on the dienone function; subsequent decomposition of the resultant peroxide affords the observed pyrone products. The regiospecificity of oxidative cleavage is thus determined by the nature of the dioxygen species that attacks the bound catechol: nucleophilic attack by superoxide for extradiol cleavage versus electrophilic attack by O_2 for intradiol cleavage.[5]

The emerging details of the active site of extradiol-cleaving dioxygenases derived from spectroscopy [6, 15] and X-ray crystallography,[16–18] show that the enzyme–substrate complex has a five-coordinate iron active site with a bidentate catecholate. This result supports the conclusions from our biomimetic studies.

Experimental Section

1 was synthesized as previously described [11]. The oxygenation reactions were carried out with 50 mg (0.1 mmol) of **1** in 10 mL solvent under O_2 over 12 h. The products were then extracted in ether and subjected to GC analysis (Hewlett Packard 5890 Series II gas chromatograph fitted with a J & W Scientific DB-1 column; injection temperature 250 °C; initial column temperature 200 °C for 1 min, then increasing at a rate of 2 °C min^{-1} to 260 °C, which was maintained for 10 min); retention times: 7.5 min for **3**, 8.4 min for **4**, 9.7 min for 3,5-di-*tert*-butylmuconic acid anhydride, and 10.8 min for **2**. The 3,5-isomer **4** was identified by independent synthesis [13]; the 4,6-isomer **3** exhibited similar NMR and mass spectra but could be distinguished from the 3,5-isomer by comparison of their GC retention times. Mass spectral analysis was carried out on a Hewlett-Packard Model 5989B mass spectrometer.

The Most Iodine-Rich Polyiodide Yet: Fc_3I_{29}**

Karl-Friedrich Tebbe* and Rita Buchem

Polyiodide ions of the general formula I_{2m+n}^{n-} (or $I_{1+2i+2l'/n}^{-}$, where i, l', and n are integers, $0 \le i, 0 < l' \le n$; n is the ionic charge, l' represents an independent series of compounds with the given ionic charge, i is a compound within such a series, and m the excess iodine) are generated by the addition of m iodine molecules and n iodide ions.[1] The number of known compounds with low or medium iodine content, particularly triiodides, is considerable: there are 329 entries in the crystallographic data bases.[2] On the other hand, the occurrence of iodine-rich compounds, which are distinguished by diverse cross-linking patterns, as the anions I_x^- for $x > 3$ (to date x = 8/2, 13/3, 5, 22/4, 12/2, 26/4, 7, 16/2, 9)[3] is increasingly rare because of decreased stability.

The ferrocenium ion $[(C_5H_5)_2Fe]^+$ or Fc^+ is capable of forming a series of crystalline polyiodides. Shortly after the discovery of ferrocene, the polyiodides FcI_x ($3 \le x \le 15$) were reported[4] although their structures, with the exception of the triiodide FcI_3, were not characterized. Surprisingly, the simple ferrocenium iodide FcI has not been found. FcI_3 can be described in the space group $R\bar{3}m$ with a rotational disorder of the cyclopentadienyl rings.[5]

We recently investigated the completely ordered heptaiodide FcI_7[6] as well as the hexadecaiodide Fc_2I_{16},[7] which has a stacking disorder of the cations. We report here the synthesis of presumably the most iodine-rich compound of this series, Fc_3I_{29}, whose iodine content with $I_{9.67}^-$ is even greater than that of the rare nonaiodide I_9^-.[8] Furthermore, the formula I_{29}^{3-} indicates that this compound is the first example from the series of ions I_{6i-1}^{3-}, which has a formal threefold charge, with $i = 5$. In contrast the series of ions I_{6i+1}^{3-} contains the known compounds $[Co(NH_3)_6]I_7$,[9] with $i = 1$ as well as $(Me_2Ph_2N)_3I_{13}$,[10] and $[\{Pb(phen)_2\}_2I]I_{13}$ with $i = 2$ (phen = 1,10-phenanthroline).[11] $FcI_{9.67}$ was obtained as single crystals from the reaction of FcI_3, synthesized by oxidation of ferrocene with iodine in ethanol, with excess iodine (molar ratio 1:45) in acetonitrile. The surface of the black, initially shiny polyhedrons quickly dulls in air due to loss of iodine. The composition was confirmed by elemental analysis,[12] and validated by comparing the X-ray powder diffractograms (Debye-Scherrer, $Cu_{K\alpha}$) with the diagram calculated from structural data.[13] The vibrational spectra are not meaningful, due to the high iodine content and the complicated network structure of the compound.[14] According to the crystal-structure analysis[15] the salt consists of complex cations and an anionic, three-dimensional network of iodine atoms, which exhibits typical structural features (Figure 1).

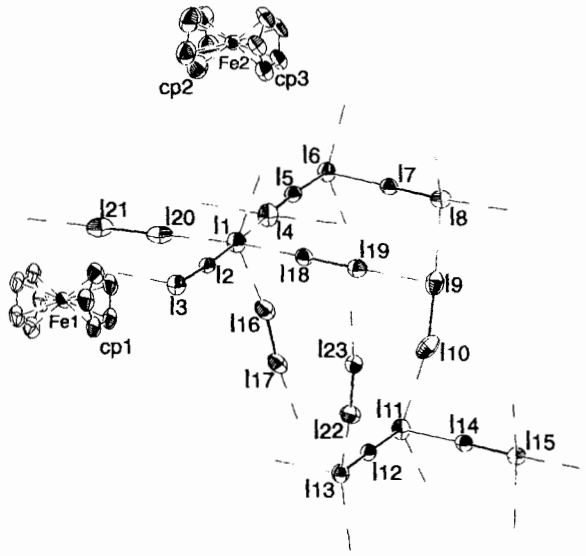

Figure 1. Fc_3I_{29}: ORTEP representation (with ellipsoids at the 50% probability level) of the structure with numbering scheme for the atoms. The hydrogen atoms of the cation have been omitted for clarity.

Bond lengths and angles within the anionic substructures of the polyiodides are often characteristic. For example, the distances of "extended" iodine molecules, which are mostly present in cross-linking iodine bridges, are 270 to 280 pm, whereas those of the stretched-symmetrical triiodide unit I_3^- are about 292 pm. A V-shaped pentaiodide unit I_5^- is often composed of a distorted triiodide ion and an iodine molecule, which are bonded with a distance of about 320 pm. Cross-linking secondary interactions[16] cover the range up to the van der Waals distance of 430 pm for the iodine atom with less sharp maxima at 340, 360, and 380 pm. The bond angles are preferentially around 90 and 180°, however, deviations can increase with longer bond lengths. Accordingly, the highly cross-linked polyiodide ion I_{29}^{3-} can be built up from triiodide and pentaiodide units as well as bridging iodine molecules.

The rather confusing structure of the anion is composed of iodine atoms that lie on and between the mirror planes with $y = 1/4$ and 3/4. In one mirror plane there is a $^1_\infty(I_5^-)$ chain that is built up of pentaiodide units (I11 to I15) and zigzags according to [100] (Figure 2a). This substructure is known for $(C_{10}H_{10}N)I_5$,[17] $(C_{20}H_{27}O_4N_2)I_5$,[18] and $(C_{34}H_{28}Br_2Fe_3)I_5$.[19] An iodine band $^1_\infty(I_{12}^{2-})$ with the composition of a dodecaiodide, which is built up in a manner similar to that of staggered dominos tiles, is parallel to the chain. This novel design contains a stretched asymmetrical triiodide ion (I1, I2, and I3), which is linked to the end of one leg (I4) of the V-shaped pentaiodide unit (I4 to I8). This produces a unique hook-shaped octaiodide unit that resembles an ice-hockey stick. Adjacent octaiodide hooks are bridged by two iodine molecules (I18–I19 and I20–I21) to form the novel dodecaiodide band. The pentaiodide chain is cross-linked over an iodine molecule (I22–I23) lying between the mirror planes to form a layer (Figure 2b). A further iodine bridge (I16–I17) lies between the mirror planes and connects the bands between I1 and I6 to form a layer parallel to that above. This produces the unique sixfold coordination at I1 (Figure 2c), which until now has only been reported for $^1_\infty[\{Ag([18]aneS_6)\}I_7]$ ([18]aneS$_6$ = 1,4,7,10,13,16-hexathiacyclooctadecane).[20] The chain and the band are joined together by a third iodine bridge (I9–I10) (Figure 2d) to form a three-dimensional network with the characteristics of an anionic cage structure $(I_5^- \cdot I_{12}^{2-})_{1/2} \cdot 3I_2$ or more precisely $[\{(I_5^-)_{1/2} \cdot I_2\} \cdot \{(I_{12}^{2-})_{1/2} \cdot I_2\} \cdot I_2]$. The completely ordered cations are intercalated within the cavities of the cage (Figure 3).

There are two crystallographically independent ferrocenium ions Fc^+ with point symmetry $\bar{1}$ and 1. Since the inversion center leads to a parallel arrangement of the two ligands, there is excellent convergence to D_{5d} symmetry. The ligands of the second cation, which is tilted towards the first by 14.70°, are almost parallel (deviation 1.52°). The ligands are in a staggered

arrangement with a twist of about 15°. The distances between the carbon atoms within the rings and to the iron atom are as expected. Less important interactions within the anionic substructure and with the cation exhibit distances of $d(I\cdots H)$ = 309, $d(I\cdots C)$ = 378, and $d(I\cdots I)$ = 405.7 pm. The displacement parameters of all the atoms appear to be normal.

Experimental Section

A mixture of FcI_3 (1.2 g, 2.1 mmol) and I_2 (11.2 g, 88 mmol) was dissolved in CH_3CN (≈80 mL) at 50–60 °C with stirring (3–4 h). After the solution had cooled to RT, and solvent was partially removed by evaporation, black polyhedrons were obtained (m.p. 352 K). The compound is soluble in nitromethane and acetone. Only the iodine-poorer phases, Fc_2I_{16} or FcI_7, are retrieved upon recrystallization.

o-Benzyne: Strained Alkyne or Cumulene?—NMR Characterization in a Molecular Container**

Ralf Warmuth*

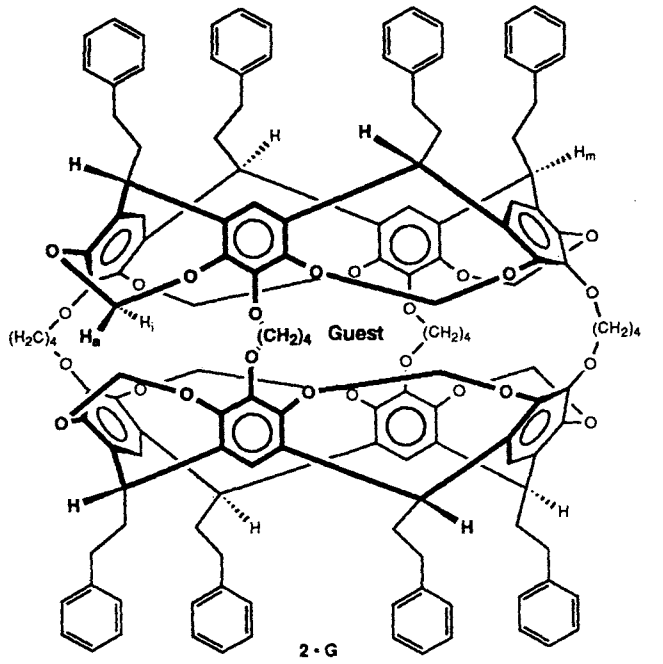
Since the concept of *o*-benzyne (**1**) as an unstable intermediate in nucleophilic aromatic substitutions was developed by Georg Wittig,[1] and its existence later proven indirectly with ^{14}C-labeling experiments by John D. Roberts and Diels–Alder trapping by Wittig,[2, 3] much effort has been made to characterize this highly reactive, short-lived species, which exists as a stable molecule only under cryogenic conditions in an inert gas matrix.[4] UV/Vis and IR spectra of **1** trapped below 77 K in an argon matrix and, most recently, a solid-state ^{13}C dipolar NMR spectrum of **1** at 20 K were recorded.[4f, 4g, 5, 6] However, detailed solution NMR spectroscopic characterization of **1** was not possible.

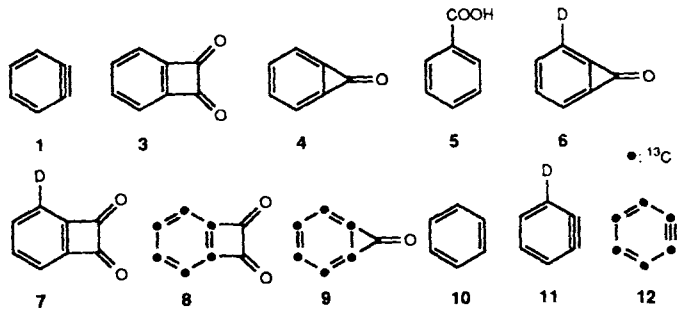
We made use of guest incarceration inside a molecular container to stabilize **1** in solution. The inner phase of molecular container compounds, developed and introduced to the scientific world by Donald J. Cram,[7] is particularly suitable for stabilizing reactive species. This was demonstrated by the generation of cyclobutadiene in the inner cavity of a hemicarcerand.[8] Protected by the surrounding host shell from self-destruction or reaction with reactants too large to enter the inner cavity through one of the host portals, cyclobutadiene was stable at room temperature and characterized in solution by ^{1}H NMR spectroscopy. Here we report the successful photochemical generation of **1** inside the known hemicarcerand **2**[9] as well as its ^{1}H and ^{13}C NMR spectra in solution.

We chose benzocyclobutenedione (**3**), whose photolysis has been studied at 77 K in an argon matrix,[4a, f, 10a, b] as the precursor to **1**. Upon illumination of **3** ($\lambda > 400$ nm) the highly strained benzocyclopropenone (**4**) is generated selectively.[10a, b] Simon et al. recorded ^{1}H and ^{13}C NMR spectra of **4** as a mixture with its decomposition products in [D$_6$]acetone at $-80\,^\circ$C.[10a] Upon further photolysis ($\lambda < 297$ nm) at 77 K **4** converts into **1**.[4f]

Hemicarcerand **2** was selected as the host for two reasons. Firstly, CPK model studies show that **2** has a cavity large enough to accommodate **3** but prevents **1** from exiting through one of the four equatorial host portals at ambient temperature. Secondly, the sharp decrease of the UV absorption of **2** above 275 nm allows photolysis of guest molecules at larger wavelengths.

Heating empty **2** in molten **3** at 145 °C in the absence of moisture gave the hemicarceplex **2**·**3** in 30–35% yield after column chromatographic separation from empty **2**.[11] Photolysis of a degassed solution of **2**·**3** in $CDCl_3$, sealed in a pyrex





NMR tube, at 77 K with ($\lambda > 400$ nm) gave **2**·**4** as the only product. This new hemicarceplex is stable at room temperature in solution. In water-saturated $CHCl_3$ at 25 °C, the incarcerated guest reacted very slowly within several days to form the benzoic acid hemicarceplex **2**·**5**, which was identified by comparison with an authentic sample.[12] Furthermore, **2**·**5** forms instantaneously upon contact of **2**·**4** with silica gel. This and the good agreement of the observed guest ^{13}C chemical shifts (Figure 1a and Table 1) with those published for free **4** at $-80\,^\circ$C strongly suggest that this new guest is **4**.[10a, b] The solid-state structure was confirmed by an X-ray crystal structure analysis.[10c] In general, guest ^{13}C signals are shifted upfield by about $\Delta\delta = 1$–4 upon incarceration, as seen by comparing the ^{13}C chemical shifts of free and incarcerated **3** (Figure 1b and Table 1).

The room-temperature ^{1}H NMR spectrum of **4** shows the expected AA′XX′ spin system for the guest protons (Figure 2). Assignment of the guest ^{1}H and ^{13}C NMR signals of **3** and **4** was possible with ^{1}H NMR spectra of deuterated **2**·**6** and **2**·**7** as well as heteronuclear ^{1}H–^{13}C COSY spectra of ^{13}C-enriched benzocyclobutenedione (**8**; 99% ^{13}C at C2, C2′, C3, C3′, C4, C4′) and its hemicarceplex **2**·**8**, and ^{13}C-enriched benzocyclopropenone hemicarceplex **2**·**9** (99% ^{13}C at carbon C2, C2′, C3, C3′, C4, C4′).[13]

To photochemically generate **1** from **4** encapsulated in hemicarcerand **2**, a solution of **2**·**4** in [D$_8$]THF (3 mM) was degassed, sealed in a quartz NMR tube, and irradiated at 77 K for 88 h with a 300 W xenon arc lamp, whose radiation was filtered through a water filter (15 cm) and an interference filter (maximum transmission of 17% at 280 nm; width at half maximum

[a] In $[D_8]THF$ at 25 °C. [b] In $[D_6]$acetone at −80 °C [10a]. [c] In $CDCl_3$ at 25 °C. [d] Simon et al. assigned δ of C2/C2′ to C3, C3′, δ of C3/C3′ to C4/C4′, and δ of C4/C4′ to C2/C2′ [10a].

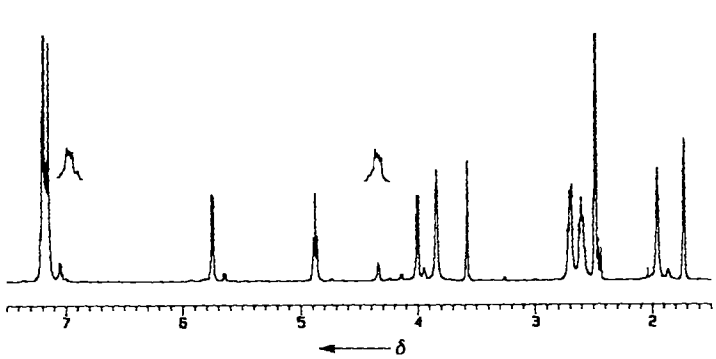

Figure 2. ^1H NMR spectrum (500.133 MHz, $[D_8]THF$; 25 °C) of the photolysis product of **2·3**.

intensity 10 ± 2 nm). Based on argon-matrix studies, photolysis of **4** under these conditions should lead to >95% **1**.[4f] The frozen sample was warmed to −97 °C for 2 min every 11 h to thoroughly mix the solution to maximize photo conversion. After photolysis the solution was warmed to −75 °C in the precooled probe of a 500 MHz NMR spectrometer, and its ^1H NMR spectrum recorded immediately (Figure 3a).

A second ^1H NMR spectrum was recorded 30 min later at −75 °C (Figure 3b), which clearly differs from the first. Additional spectra recorded still later showed no further change.

Figure 3. ^1H NMR spectra (500.133 MHz, $[D_8]THF$, −75 °C): a) a photolyzed solution of **2·4** immediately after warming from −196 °C to −75 °C; b) after 30 minutes at −75 °C; c) *o*-benzyne hemicarceplex **2·1**; d) benzene hemicarceplex **2·10**. Peaks marked with a black dot and an asterisk indicate the ^1H nuclei of incarcerated **1** and benzene, repectively.

Most likely **1** underwent reaction to form a new compound, which shows no carbonyl stretch between 1650–1900 cm^{-1} in the FT-IR spectrum and gives only one single FAB-MS peak for **2·1** at the expected mass ($[M+3] = 2327$). These results coupled with the absence of a FAB-MS signal for empty **2** (usually observed for hemicarceplexes of **2**) clearly demonstrate that **1** was formed and reacted with the host to form an addition product.[14]

These results clearly show that the ^1H NMR spectrum recorded at −75 °C (Figure 3a) is a superposition of the spectra of **2·1** and its hemicarcerand addition product. The spectrum of incarcerated **1** was obtained by spectral subtraction (Figure 3c). The proton signals assigned to **1** are at $\delta = 4.99$ and 4.31. The expected line pattern of the AA′MM′ spin system could not be verified due to strong line broadening. However, both signals were partially resolved in some runs and appear as doublets ($\Delta\delta = 5.20$ Hz). The strong line broadening, which is also observed for all proton signals of **2**, does not result from a triplet ground state for **1** but rather from the slow tumbling rate of **2·1** at low temperature. For comparison, the ^1H NMR spectrum of the benzene hemicarceplex **2·10** was recorded at the same temperature (Figure 3d). Both spectra show a remarkable similarity (comparable line shape and broadening) for the signals assigned

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3612-1348 $ 17.50+.50/0 Angew. Chem. Int. Ed. Engl. 1997, 36, No. 12

to **2**. The signal for incarcerated benzene at $\delta = 4.67$ appears between the two proton signals of **1**. The spin state of **1** was confirmed by EPR studies at $-100\,^{\circ}C$ in THF; no EPR signal for incarcerated **1** was observed. A singlet ground state has been predicted from the measured singlet–triplet gap of $E_{ST} = 37.7$ kcal mol^{-1}.[15]

Assignment of the signals for **1** was made with the ^{1}H NMR spectrum of deuterated **2**·**11**, which was generated photochemically from **2**·**6**. In this spectrum (not shown), an intensity ratio of 1:2 for the signals for **1** at $\delta = 4.99$ and 4.31 was observed. Hence, the first signal was assigned to H1/H1′, and the latter H2/H2′. The lifetime of **1** inside the hemicarcerand **2** at $-75\,^{\circ}C$ was determined from the decay of the intensity of the signal at $\delta = 4.99$. The rather short lifetime ($t_{1/2} = 205$ s) reflects the high reactivity of **1**.

Even stronger evidence for incarcerated **1** was obtained from its ^{13}C NMR spectrum. Preliminary experiments at lower temperature[14] show that the lifetime of **1** just above the melting point of [D$_8$]THF ($-108\,^{\circ}C$) is several hours, which is sufficient for recording a ^{13}C NMR spectrum. The ^{13}C-enriched incarcerated *o*-benzyne (99% ^{13}C at all positions) **2**·**12** was prepared from **2**·**9**. The ^{13}C NMR spectrum was recorded at $-98\,^{\circ}C$ in [D$_8$]THF. A pure ^{13}C NMR spectrum of $^{13}C_6$-**1** was obtained by subtracting the spectra of unphotolysed starting material **2**·**9** from the addition product between **12** and **2**, which formed during the accumulation (Figure 4).

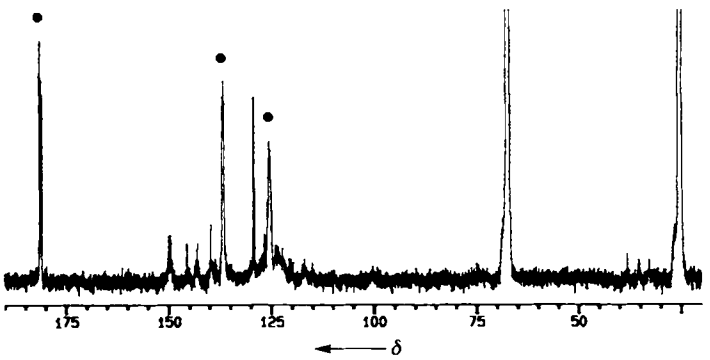

Figure 4. ^{13}C NMR spectrum (125.757 MHz, [D$_8$]THF, $-98\,^{\circ}C$) of the [$^{13}C_6$]1 hemicarceplex **2**·**12**. Carbon signals of incarcerated **12** are marked with a black dot.

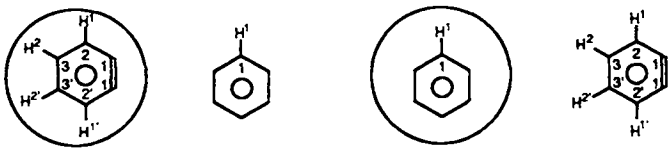
Three carbon signals for **1** were found, as expected for this AA′MM′XX′ spin system (Table 2). The exact assignment was made by line pattern analysis and confirmed by ^{1}H–^{13}C heteronuclear decoupling experiments.

We estimated the chemical shifts of free **1** in solution by assuming that the protons and carbon atoms of **1** and benzene, which are of similar shape and size, experience the same shielding by the surrounding host **2**. We further assumed that, on the time average, the two different protons in **1** must be located equally in the shielding area of the polar regions of **2**. The same must be true for the three different carbon atoms of **1**. Taking the chemical shift differences $\Delta\delta$(H) and $\Delta\delta$(C) of incarcerated benzene (**2**·**10**) as a measure for the host shielding and adding them to the observed chemical shifts of incarcerated **1** gives an estimate for the chemical shifts of free **1** in solution (Table 2). These predictions are tainted with uncertainty, since only empirical models for estimating host-shielding effects are available.

The chemical shifts of C2/C2′ and C3/C3′ are in the range of aromatic or olefinic nuclei; the signals for C2/C2′ are the most similar to those for benzene. The rather high chemical shift of

Table 2. ^{1}H and ^{13}C chemical shifts [δ_{exp}] of incarcerated guests in **2**·**1**, **2**·**10**, and of **10** as well as predicted chemical shifts [δ_{pred}] for free **1**.



2·**1** **10** **2**·**10** **1**

	δ_{exp}	δ_{exp}	δ_{exp} ($\Delta\delta$) [c]	δ_{pred} [d]
H1/H1′	4.99 [a]	7.34 [a]	4.64 (2.70) [a]	7.69 [a]
H2/H2′	4.31 [a]			7.01 [a]
C1/C1′	181.33 [b]	129.19 [b]	127.81 (1.38) [b]	182.71 [b]
C2/C2′	125.45 [b]			126.86 [b]
C3/C3′	136.80 [b]			138.18 [b]

[a] At $-75\,^{\circ}C$ in [D$_8$]THF. [b] At $-98\,^{\circ}C$ in [D$_8$]THF. [c] $\Delta\delta = \delta_{exp}$(**10**) $- \delta_{exp}$(**2**·**10**). [d] $\delta_{pred} = \delta_{exp}$(**2**·**1**) $+ \Delta\delta$.

C1/C1′ is in good accordance with the average of the three chemical shift tensor principle values $\delta_{calcd} = 193 \pm 15$ of matrix-isolated, ^{13}C-enriched **1** at 20 K in argon. The latter was determined by Grant et al.[6] by dipolar ^{13}C NMR spectroscopy. The difference might be partially due to the temperature difference, a medium effect, or the lower accuracy of the chemical shift tensors. However, the average of the three chemical shift tensors $\delta_{calcd} = 183$, obtained by Grant et al.[6] by DFT (density functional theory) calculations with the fully optimized MP2/TZ2P geometry of **1**, approximates very well our experimental value for incarcerated **1** and almost exactly duplicates the chemical shift predicted for free **1**. The good agreement of experimental and theoretical chemical shifts not only supports our prediction but also leaves little doubt that the observed spectrum is due to **2**·**1**.

The line pattern of all three multiplets was analyzed for information about the ^{13}C–^{13}C coupling constants. A modified version of the program MIMER[16] was used to simulate the spectrum. Due to the line broadening only the stronger one-bond couplings could be calculated with sufficient precision. Figure 5a–c shows the simulated best fit overlaid on the individual multiplets (see also Table 3).

The line frequencies of the calculated spectrum of **1** give excellent agreement with those of the experimental spectrum. However, some line intensities of the experimental spectrum, especially obvious in the multiplet for C1/C1′ (Figure 5a), deviate from the calculated intensities. This is possibly due to some

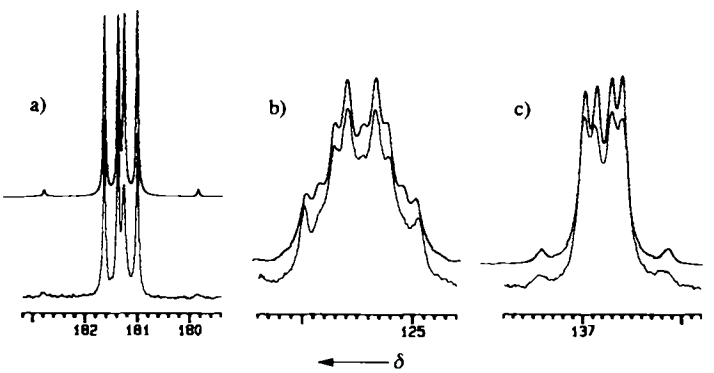


Figure 5. Part of a ^{13}C NMR spectrum (125.757 MHz, [D$_8$]THF, $-98\,^{\circ}C$) of **2**·**12**. The ^{13}C multiplets are given with the best fit (upper trace): a) C1/C1′, b) C2/C2′, and c) C3/C3′.

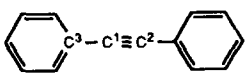
Table 3. $^{13}C-^{13}C$ coupling constants $^1J_{C,C}$ [Hz] of incarcerated [$^{13}C_6$]1 at −98 °C.

	C1–C1′	C1–C2/C1′–C2′	C2–C3/C2′–C3′	C3–C3′
$^1J_{C,C}$ [a]	177.9 (±0.7)	75.7 (±0.9)	50.9 (±0.8)	71.0 (±0.8)

[a] The 95%-confidence limits are given in parentheses.

interference effect between chemical shift anisotropy and dipole–dipole relaxation.[17]

The coupling constant $J_{C1,C1'}$ is in the frequency range expected for C–C triple bonds: for example, $J_{C1,C2} = 185$ Hz for diphenyl acetylene **13**, and $J_{C1,C2} = J_{C1',C2'}$ for **1** is smaller than the sp-C–sp^2-C coupling in **13** ($J_{C1,C3} = 91$ Hz).[18] We attribute the difference to the ring strain, which increases the p character of the hybridization of C1 and C1′ in **1** relative to **13**.



13

However, $^1J_{C3,C3'}$ is of the order of an olefinic bond (for example $^1J_{C3,C4} = 70.0$ Hz for *cis*-hexa-1,3-diene),[19] and $^1J_{C2,C3}$ and $^1J_{C2',C3'}$ are comparable with the coupling constants between two sp^2-hybridized carbon atoms connected through a single bond as in buta-1,3-diene ($J_{C2,C3} = 53.7$ Hz).[20] These comparisons and the fact that δ(C2,C3) = 170.3 for butatriene is only slightly smaller than the measured δ(C1/C1′) for **1** can be interpreted as follows: **1** has cumulenic character and is dominated by the mesomeric structure **1b**.[21]

1a **1b**

Such a hypothesis requires significant bond length alternation, which conflicts with recent ab initio calculations even at the highest level of theory.[6, 22] The problem is the lack of suitable model compounds for comparing their NMR spectra with those of **1** and the large uncertainty of structural predictions based on empirical correlations. The exact influence of the main factors that determine the value of the coupling constants is not fully understood.[23] However, the experimental NMR spectra of **1** reported here, in connection with ab initio methods that simulate the observed NMR spectrum with high precision, are valuable for making reliable predictions of the geometry and the electronic properties of this interesting molecule.[22g]

We have demonstrated that **1** can be stabilized in solution by incarceration in the unique protective inner cavity of a molecular container and characterized by NMR spectroscopy in solution. Additional compounds with highly strained multiple bonds and other reactive intermediates should be stabilized, and their structural and electronical properties examined.

The Anions $[W(CH_3)_7]^-$ and $[Re(CH_3)_8]^{2-}$ **

Valérie Pfennig, Neil Robertson, and Konrad Seppelt*

Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

The compounds $[W(CH_3)_6]$ and $[Re(CH_3)_6]$ were first prepared by G. Wilkinson et al.[1–5] Theoretical models predicted a nonoctahedral structure for six-coordinate d^0 complexes with pure σ ligands;[6–11] $[Zr(CH_3)_6]^{2-}$ has a trigonal prismatic

structure.[12] Recently the structures of $[W(CH_3)_6]$ and $[Re(CH_3)_6]$ were elucidated:[13] $[W(CH_3)_6]$ is a trigonal prism that is strongly distorted along the C_{3v} axis. It contains three long W–C bonds to methyl groups that form small angles with each other and three short W–C bonds to methyl groups that form large angles with each other. In contrast, crystalline $[Re(CH_3)_6]$ has an almost perfect trigonal-prismatic structure.

Recent theoretical calculations support the unusual structure of $[W(CH_3)_6]$.[14] It has also been established that $[Ta(CH_3)_5]$ is built like a square pyramid, and not like a trigonal bipyramid (as is $Sb(CH_3)_5$).[15, 16] Therefore, we wondered if d^0 complexes with pure σ ligands and coordination numbers larger than six would also show structural anomalies. Since neutral compounds of this type (for example $[Re(CH_3)_7]$) are apparently unknown, we looked for corresponding anions. G. Wilkinson et al. prepared $Li_2[W(CH_3)_8]$ and $Li_2[Re(CH_3)_8]$.[3–5] According to its ESR spectra, the $[Re(CH_3)_8]^{2-}$ anion probably has a square-antiprismatic structure.[17]

Our attempts to obtain a compound containing $[W(CH_3)_8]^{2-}$ failed. However, we could prepare salts of $[W(CH_3)_7]^-$ with various cations and investigate their structures by X-ray crystallography (Figure 1). $[W(CH_3)_7]^-$ is built like a capped octahedron. In the case of $[Li\{(CH_3)_3N\}][W(CH_3)_7]$ the C_{3v} structure is strictly obeyed because of the cubic crystal symmetry. The compounds appear as ion pairs with the lithium atom attached to the basal methyl groups; the W–C bonds to these methyl groups are markedly lengthened.

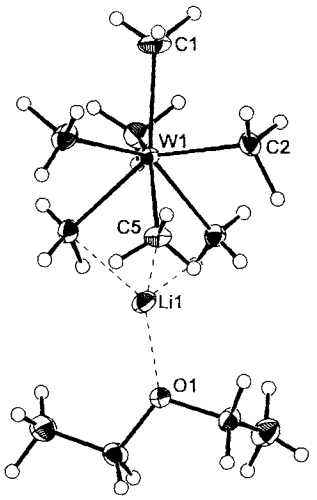

Figure 1. Crystal structure of $[Li(Et_2O)][W(CH_3)_7]$ at −153 °C (ORTEP, ellipsoids at 50% probability). Bond lengths [pm] and angles [°]: W–C1 218.4(6), W–C2 214.7(6), W–C3 215.8(5), W–C4 215.2(6), W–C5 227.8(5), W–C6 228.9(6) W–C7 228.2(5), Li–C5 212.4(11), Li–C6 213.5(11), Li–C7 216.4(11); C1-W-C2 81.2(3), C1-W-C3 80.9(3), C1-W-C4 80.3(3), C1-W-C5 132.2(3), C1-W-C6 132.5(3), C1-W-C7 131.5(3). The structure of the anion in $[Li\{(CH_3)_3N\}][W(CH_3)_7]$ is nearly identical. Bond lengths [pm] and angles [°]: $W-C_{apical}$ 216.9(13), $W-C_{equatorial}$ 215.4(6), $W-C_{basal}$ 228.3(5), $Li-C_{basal}$ 211.8(13); C_{apical}-W-C_{basal} 131.5(2), C_{apical}-W-$C_{equatorial}$ 80.2(2).

In the case of coordination number seven, the capped octahedron is the geometry with the least ligand-repulsion energy (followed by the capped trigonal prism and the pentagonal bipyramid) and is also found for $[WF_7]^-$ and $[MoF_7]^-$, independent of the type of cation.[18] Therefore, a structure anomaly due to the pure σ ligands is not observed for $[W(CH_3)_7]^-$. The building principle for similar main-group compounds is the pentagonal bipyramid (IF_7,[19, 20] $[TeF_7]^-$,[21, 22] $[ROTeF_6]^-$, $[(RO)_2TeF_5]^{2-}$, $[IOF_6]^-$[22]). The capped octahedral configuration of seven fluorine atoms is only observed in the presence of a "nonbonding" electron pair, such as in $[XeF_7]^-$.[23] $[Th(CH_3)_7]^-$, the sole homoleptic f-atom complex of this type, has also a capped octahedral structure.[24]

The structure of a mixed-substituted complex with tungsten(v) is also capped octahedral. Organometallic reactions with WF_6 are always difficult to control, although it is more stable and has lower oxidation power than WCl_6. The structure of $[WF(CH_3)_4(CH_3CN)_2]$ is shown in Figure 2. In accord with the ligand-repulsion model, the fluorine atom and the two acetonitrile ligands occupy positions that are characterized by longer bonds in $[WF_7]^-$ and $[W(CH_3)_7]^-$.

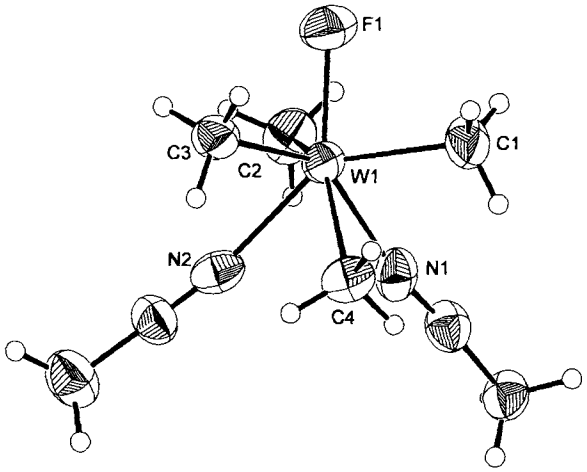

Figure 2. Crystal structure of $[WF(CH_3)_4(CH_3CN)_2]$ in $[WF(CH_3)_4(CH_3CN)_2]\cdot WF_6$ (ORTEP, ellipsoids at 50% probability). Bond lengths [pm] and angles [°]: W1–F1 189.0(10), W1–C1 210.4(19) W1–C2 212.8(19) W1–C3 212.8(18), W1–C4 225.5(16), W1–N1 220.7(16), W1–N2 217.0 (16); F1-W1-C1 78.8(7), F1-W1-C2 86.2(7), F1-W1-C3 79.3(7), F1-W1-C4 130.6(6), F1-W1-N1 137.4(5) F1-W1-N2 138.3(5).

Preparation and crystal growth of a compound with the $[Re(CH_3)_8]^{2-}$ anion is straightforward; apparently $[Re(CH_3)_6]$ is prepared via $[Re(CH_3)_8]^{2-}$. The structure of the deep red-brown compound $[Li(Et_2O)]_2[Re(CH_3)_8]$ is shown in Figures 3 and 4.

Disregarding the $[Li(Et_2O)]^+$ cations, which each cap four methyl groups, the structure of the anion is regular square antiprismatic, as predicted by G. Wilkinson et al. based on the ESR spectra.[17] This structure is also observed in the fluoro-anion $[ReF_8]^{2-}$,[25, 26] independent of the counterion, as well as in $[WF_8]^{2-}$, $[IF_8]^{2-}$, and $[XeF_8]^{2-}$.[26] The square antiprism seems to be the building principle for complexes with coordination number eight. Again, in contrast to $[W(CH_3)_6]$ and $[Re(CH_3)_6]$, no structure anomaly is observed.

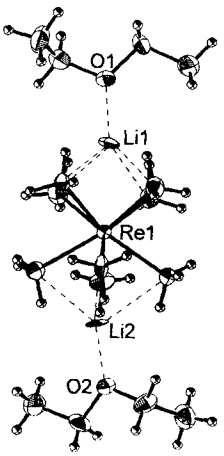

Figure 3. Crystal structure of $[Li(Et_2O)]_2[Re(CH_3)_8]$ (ORTEP, ellipsoids at 50% probability). Bond lengths [pm]: Re1–C1–8 223.1(14)–225.6(13), Li1–C5–8 233.9(24)–245.9(28), Li2–C1–4 233.5(25)–235.9(26).

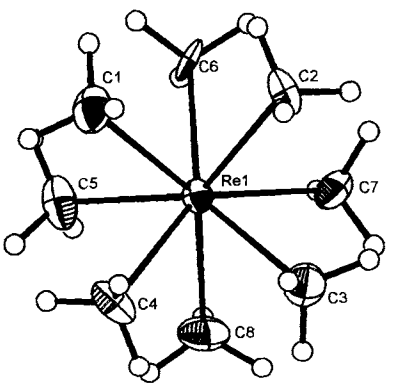

Figure 4. Structure of the $[Re(CH_3)_8]^{2-}$ anion in $[Li(Et_2O)]_2[Re(CH_3)_8]$ as viewed along the almost perfect S_8 axis (ORTEP, ellipsoids at 50% probability).

A preliminary bond-theory result is that the structures of $[M(CH_3)_7]^-$ and $[M(CH_3)_8]^{2-}$ are dominated by ligand repulsion. Furthermore, a 180° positioning of two ligands is avoided: in the case of $[W(CH_3)_7]^-$, the capped octahedron is favored over the pentagonal bipyramid. If the ligand sphere is less crowded, the principle of avoiding 180° orientations dominates: $[W(CH_3)_6]$ and $[Re(CH_3)_6]$ have C_{3v} structures, whereas $[Te(CH_3)_6]$ has an octahedral structure,[27] and $[Ta(CH_3)_5]$ has a C_{4v} structure, whereas $Sb(CH_3)_5$ has a D_{3h} structure. The root of this second principle can only be found by analysis of very precise ab initio calculations; these are not yet available for $[W(CH_3)_7]^-$ and $[Re(CH_3)_8]^{2-}$. Nevertheless, simplified models do exist. A ligand induces an extra electron density opposite to itself in the easily polarizable electron density of the heavy atoms W and Re. This prevents a second ligand from positioning there.[28] According to the Pauling bond theory s–d hybrid orbitals are not suitable for 180° ligand orientations, because s and d orbitals are gerade functions.[11]

In main-group chemistry an opposite principle is observed. Coordination geometries with ligand orientations of 180° are favored (trigonal bipyramid over tetragonal pyramid, octahedron over trigonal prism, and pentagonal bipyramid versus over capped octahedron). This is easily explained with the dominating p character of the central atom–ligand bonding.

Experimental Section

All procedures were carried out under argon or in vacuum in order to exclude, especially, oxygen. Solvents and Me_3N were dried by known procedures.

$[W(CH_3)_7]^-$: WCl_6 (500 g, 1.26 mmol) in isopentane (5 mL) was allowed to react in a Schlenk tube at −78 °C with trimethylaluminium (0.75 mL, 7,8 mmol) in isopentane (5 mL). The red solution was briefly warmed to room temperature and then cooled to −78 °C. Excess Me_3N was slowly added, and the voluminous adduct $Al(CH_3)_2Cl{\cdot}N(CH_3)_3$ removed by filtration at −77 °C. The solvent was removed in vacuo at −78 °C, and Et_2O (10 mL) added by condensation. CH_3Li (6 mL, 9.6 mmol, 1.6 M in Et_2O) was added dropwise; the solution turned yellow-brown. Removing solvent and adding isopentane yielded yellow platelets of $[Li(Et_2O)][W(CH_3)_7]$ upon cooling to −95 °C. Removing solvent at −10° and recrystallizing from isopentane at −95 °C afforded light yellow needles of $[Li\{(CH_3)_3N\}][W(CH_3)_7]$.

Crystal structure analyses: $[Li(Et_2O)][W(CH_3)_7]$: A suitable crystal ($0.2 \times 0.2 \times 0.2$ mm, yellow) was mounted at −120 °C under nitrogen on an Enraf Nonius CAD 4 four-circle diffractometer and measured at −153 °C; $a = 690.31(6)$, $b = 1274.92(8)$, $c = 1726.57(22)$ pm, $V = 1519.5(3) \times 10^6$ pm^3, space group $Pbc2_1$ (no. 29), $Z = 4$, $2\theta_{max} = 70°$, $Mo_{K\alpha}$, $\lambda = 71.063$ pm, ω scan. Of 3183 reflections measured, 3033 were independent and used for the calculation; Lorentzian-polarization and Ψ-scan absorption corrections, $\mu = 7.58$ mm^{-1}, min./max. correction = 0.91/0.99, no extinction correction. The structure was solved with SHELXS 86 [29] and refined with SHELXS 93 [30], 217 parameters, all atoms except hydrogen were treated anisotropically, $R_1 = 0.022$, $R_{w2} = 0.050$.

$[Li\{N(CH_3)_3\}][W(CH_3)_7]$: A suitable crystal ($0.3 \times 0.3 \times 0.3$, yellow) was mounted and measured as described above; $a = 1147.6(4)$ pm, $V = 1511.4(7) \times 10^6$ pm^3, −153 °C, space group $P2_13$ (no. 198), $Z = 4$, $2\theta_{max} = 52°$, $Mo_{K\alpha}$, $\lambda = 71.029$ pm, ω scan. Of 3439 reflections measured (including Friedel pairs), 994 were independent, and 961 reflections used for the calculation; Lorentzian-polarization and Ψ-scan absorption corrections, $\mu = 7.61$ min^{-1}, min./max. correction = 0.85/0.99, 71 parameters, all atoms except hydrogen were treated anisotropically, $R_1 = 0.021$, $R_{w2} = 0.044$.

$[WF(CH_3)_4(CH_3CN)_2]{\cdot}WF_6$: $Zn(CH_3)_2$ (100 mg 1.05 mmol) was dissolved in CH_3CN (2 mL) in a glass tube, and WF_6 (400 mg, 1.34 mmol) added by condensation. The solution was kept at room temperature. After 0.5 h the color was red, and large amounts of a brown deposit formed after 2 h, which were removed by centrifugation. Storing the mother liquor at −4 °C for weeks afforded yellow-brown crystals. ^{19}F NMR: $\delta = 144.3$. a suitable crystal ($0.2 \times 0.2 \times 0.2$ mm) was mounted and measured as described above; $a = 1185.5(5)$, $b = 1133.7(5)$, $c = 1202.0(5)$ pm, $\beta = 99.98(2)°$, $V = 1590.9 \times 10^6$ pm^3, −143 °C, space group $P2_1/n$ (no. 14), $Z = 4$, $2\theta_{max} = 50°$, $Mo_{K\alpha}$, 71.069 pm, ω scan. Of 2836 reflections measured, 2619 were independent and used for the calculation; Lorentzian-polarization and difabs absorption corrections [31], $\mu = 14.53$ mm^{-1}, max./min. correction = 0.79/0.99, 227 parameters, all atoms except hydrogen were treated anisotropically. $R_1 = 0.049$, $R_{w2} = 0.137$.

$[Li(Et_2O)]_2[Re(CH_3)_8]$: By varying the known procedure [5] $ReOCl_4$ (0.342 g) was dissolved in Et_2O (10 mL), and CH_3Li (6 mL, 9.6 mmol, 1.6 M in Et_2O) slowly added at −78 °C. The dark red solution turned orange-brown. The solvent was removed in vacuo at −10 °C, and the solid residue extracted with *n*-pentane at 0 °C. crystallization from the dark red solution occured at −18 °C. A suitable crystal ($0.3 \times 0.3 \times 0.3$ mm, brown) was measured as described above; $a = 1104.0(8)$, $b = 1958.2(8)$, $c = 1100.0(4)$, $\beta = 117.72(3)°$, $V = 2105.1(17)$, −153 °C, space group $P2_1/n$, $Z = 4$, $2\theta_{max} = 50°$, $Mo_{K\alpha}$, $\lambda = 70.069$ pm, ω-scan. Of 3245 reflections measured, 3040 were independent and used for the calculation; Lorentzian-polarization and Ψ-scan absorption corrections, $\mu = 5.77$ mm^{-1}, min./max. correction = 0.92/0.99, 323 parameters, all atoms except hydrogen were treated anisotropically, $R_1 = 0.047$, $R_{w2} = 0.113$.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100080. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Abstracts on CD-ROM—The New Age?

Crystal Structures. I: Patterns and Symmetry. By *M. O'Keeffe* and *B. G. Hyde*. Mineralogical Society of America, Washington, DC, 1996. 453 pp., hardcover $ 36.00.—ISBN 0-939950-40-5

The contents of this book are: "Preface and Note to the Reader" (6 pp.), "Symmetry in Two Dimensions" (27 pp.), "Three-Dimensional Point Groups" (30 pp.), "Three-Dimensional Space Groups" (41 pp.), "Lattice Geometry" (33 pp.), "Polyhedra and Tilings" (66 pp.), "Sphere and Cylinder Packings" (81 pp.), "Nets and Infinite Polyhedra" (92 pp.), Appendices (64 pp.), Book List (2 pp.), and Indices (7 pp.). The appendices as well as notes and exercises at the end of each of the chapters provide additional material for study. The scope of the book is narrower than the title would suggest. It deals with inorganic crystal structures of interest to the solid state chemist.

Crystallography has been too successful recently. If you can raise a few hundred thousand dollars you can buy a black box (an automatic single crystal diffractometer). At the push of a button most crystal structures can be solved without any deeper understanding of the scientific background involved. This results in a flood of published crystal structure data that tell us how atoms arrange in space. Unfortunately these data cannot be assimilated without (according to the preface) "...learning the methods appropriate to describing infinite periodic objects. These methods are generally unfamiliar to those who are not professional crystallographers (a fact that greatly hinders the development of solid state chemistry) and one of the aims of this book is to provide a usable introduction to them." The volume is meant by the authors "as a textbook for courses and as a general reference". The necessary basic tools of crystallography are introduced in the first four chapters. That covers the symmetry part of the subtitle. The remaining three chapters deal with the patterns of inorganic crystal structures, that is with polyhedra, tilings, packings, and nets, and they contain some new material. The short book list is well annotated, but even with the few references interspersed throughout the text it is insufficient as a guide for further study. One electronic data base is listed (Inorganic Crystal Structure Data) and is judged as rather imperfect, but still as excellent value for money. However, the equally important data base for metals, CRYSTMET, is omitted (a pity since intermetallics figure prominently in this volume). The incomplete indices are woefully inadequate and will unfortunately hamper the use of the volume as a general reference source. Thus, a notation is introduced for "coordination numbers" (p. vi), the term is used in the text (e.g., between pp. 208 and 255), but it is not entered in the subject index. The related topic of filling of interstices comes up in the text, but cannot be located via the subject index under "filling", "stuffing" or "interstices". The term "rutile" has four references in the index, but in fact shows up at least four more times (on pages vi, 82, 220, and 321).

The attempt to cover many aspects of basic crystallography and the tools of crystal chemistry within one book (the authors call this the "split personality" of the volume) means that both goals suffer from a lack of the space necessary for a thorough exposition. As a textbook for self-study by neophytes it seems to be too concise. It might be useful as ancillary reading in courses on solid state chemistry and the like. For experienced workers it will be fun, much appreciated, and very instructive in its last three chapters (which cover more than one half of the book). There they will find, after some searching (which should be entertaining in itself), many a nugget of information out of the rich store of the authors' knowledge. The fun part comes also from the idiosyncratic nature of the book and from the less-than-pompous language used by the authors ("why, for heaven's sake" on p. 270, when questioning the popular view on the reason for the occurrence of close packed structures). At its price, *Crystal Structures* is certainly a good buy.

Electronic Conference on Trends in Organic Chemistry, ECTOC 1. Edited by *H. S. Rzepa, C. Leach* and *J. M. Goodman*. Royal Society of Chemistry, London, 1996. CD-ROM £ 50.00.—ISBN 0-85404-899-5

So, the virtual conference has finally arrived. No more long trips to Tokyo, Rome, or Jerusalem to discuss new ideas with other scientists working in the same field. By using the Internet via a laptop we can now take part in conferences from the work-desk or even from home. Actually, of course, it has not quite reached that point yet, so do not worry. Although the expression "Electronic Conference" may at first conjure up an image of such a situation resulting from the use of new media, the reality is slightly different. As will become clear below, the purpose of an electronic conference is essentially to complement and report on an actual conference.

The growth of interest in electronic conferences in the last few years has largely been due to developments in the Internet, which has changed from being a text-orientated medium based on services such as e-mail, telnet, and ftp, to a multimedia network (the Worldwide Web, www). This transformation has opened up new possibilities for handling information, especially in the natural sciences. Lectures, posters, and discussion sessions taking place at a conference can now be recorded fully in electronic form, and transmitted without any loss of information in HTML format (hypertext markup language).

Three-dimensional molecular models embedded within the text can be moved and rotated on the monitor screen. Dynamic processes can be shown as animat-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

ed images, spectra can be compressed, stretched, or edited in other ways, and so on. By using the hypertext transfer protocol (HTTP), documents from any computer can be loaded onto the Internet, regardless of the operating system that they use or the computer platform. The only requirement for all these operations is that the client browser's plug-in is capable of recognizing the standardized data structure of the application concerned.

The first Electronic Conference on Trends in Organic Chemistry, ECTOC 1, was organized by one of the pioneers in the field of standardization of chemical information, Henry S. Rzepa of Imperial College, London, together with his colleague Christopher Leach, and Jonathan M. Goodman (Department of Chemistry, Cambridge University), and is published in a CD-ROM version by the Royal Society of Chemistry.

The conference proceedings consist of six "keynote papers" and 71 articles, which present recent results (up to mid-1995) in the areas of synthetic, mechanistic, and biological chemistry. The authors are from 13 countries. On reading the keynote papers one immediately appreciates the advantages of the HTML format. A mouse-click on one of the two-dimensional valence bond formulas that are displayed brings up a three-dimensional image of the molecule that can be rotated at will, an extremely useful facility for complicated structures. These 3D structures are filed as cartesian coordinates in the format of the Brookhaven Protein Database (*.pdb files).

Taking as an example the contribution "A New Synthetic Route to the Illudin and Pterosin Family of Sesquiterpenes", by Albert Padwa, Erin A. Curtis, and Vincent P. Sandanayaka (Department of Chemistry, Emory University, Atlanta), the key structure can be viewed from any direction and in many different representations (wire model, stick model, stick-and-ball model, space-filling model, etc.). The coordinates (from an X-ray crystallographic analysis) on which this is based are those of a precursor of illudin, which already has all the five benzene ring substituents of the later products, with the correct regiochemistry. Moreover, a novel feature of the HTTP approach is that one can then go on from this 3D presentation to edit the data. Once the coordinates from the X-ray data have been stored locally on the hard disk of one's PC, the way is clear for further data processing such as energy calculations.

In the contribution "Studying Perturbation Theory with Explorer EyeChem and VRML", by Guillermo A. Suner, Omer Casher, and Henry S. Rzepa, the imaging of structures is taken a step further. These authors have translated the semiempirical (AM1) calculated transition state structures for a large number of Diels–Alder reactions into the VRML format (virtual reality modeling language). This allows one to move around in the virtual space of the calculated structures and study the overlapping of the frontier orbitals. This technique opens up new perspectives, in the truest sense of the word, and has great possibilities for use in teaching.

Most of the other contributions use only HTML text and graphics in the GIF format. They range over many different areas of organic chemistry, from new syntheses of natural products and enantioselective catalytic reactions, via the chemistry of fullerenes (where, incidentally, pdb coordinates would have been ideal), to new nonlinear optical materials and to purely theoretical studies. The work includes a full list of contributions to the discussions of the individual presentations and a list of participants (with photographs in some cases), making altogether a very successful CD-ROM. Within the next five years we may witness the disappearance of the conventional printed "book of abstracts".

pH and Buffer Theory – A New Approach. (Series: Solution Chemistry, Vol. 1.) By *H. Rilbe*. John Wiley & Sons, Chichester, 1996. 192 pp., hardcover £ 40.00.—ISBN 0-471-96735-1

This subject has traditionally been a favorite area of research for Scandinavian chemists, and H. Rilbe is on familiar ground in this book. The author's claim to present a "new approach" refers essentially to a general procedure for treating all types of problems in this field. According to this, all the quantities that occur in pH and buffer theory, such as concentrations and equilibrium constants, are converted into dimensionless logarithmic numbers, so as to benefit from the well-known mathematical simplifications associated with the use of logarithmic relationships. Despite this, however, as the arguments are developed in greater depth the equations quickly become very complicated. Consequently the author's presentation comes over as rather dry and leaden on the whole, although that is partly due to the nature of the subject. Another disadvantage of the author's new approach is that, because of the special expressions that are used, one cannot simply begin reading at a chosen place in a chapter or section of interest; instead one must first search back in the book to work out the definitions. Many of the results have been published before by the author in specialist journals, and thus the book is a summary and consolidation of that work.

Chapter 1 begins by introducing the concepts of pH and the relevant equilibrium constants. For each of the aspects that are treated from a stoichiometric standpoint the author then goes on to discuss the thermodynamic relationships involved. Buffer solutions consisting of a single-proton weak acid combined with a strong base, or a weak base with a strong acid, are considered next. Here the reader meets the difficulty already mentioned above, as one needs to be familiar with the author's definitions in order to fully understand the curves that are shown.

Chapter 2 deals with two-proton protolytes and their salts with strong acids and bases. Here the ionic strength of buffer solutions is also considered.

In Chapter 3 the author guides the reader through the Scylla and Charybdis of mixtures of weak acids and weak bases, offering first an approximate solution to the problem and then a more rigorous analysis. Here, as in the other chapters, he mentions alternative approaches used by other authors and considers the strengths and weaknesses of the different methods.

Chapter 4 treats acids with three or more protons and their salts. Special attention is devoted to the differences between the K-values and how these affect the buffer properties. The main topic of Chapter 5 is the Debye–Hückel theory for strong electrolytes and its application to the calculation of activity coefficients. Chapter 6 is entirely devoted to the buffer properties of water and the associated titration curves. This is followed by a chapter on experimental methods for determining pK- and ΔpK-values and isoprotic (or isoelectric) points. Finally there is an appendix containing some computer programs for determining isoprotic points.

This book, written by a well-recognized expert in the field, is intended for the specialist rather than for the student, as indicated by the absence of exercise problems, and not least by its price. It takes up from the point where the usual introductions to quantitative analysis leave off, and assumes that one is already familiar with ordinary buffer theory. The question of whether one can begin to accept the nota-

tion used in the book is for the reader to decide. It remains to be seen to what extent the proposed new approach will be taken up in research and teaching.

Introduction to Theoretical Organic Chemistry and Molecular Modeling. By *W. B. Smith*. VCH Publishers, New York, 1996. 192 pp., hardcover DM 89.00.—ISBN 1-56081-937-5

Computer programs for quantum-chemical calculations are becoming increasingly user-friendly, and consequently chemists with limited theoretical knowledge are using them more and more often. It is all too easy for non-theoreticians to be misled by the suggestive power of the attractive graphics, so that they overvalue the information content of the results that the black box turns out with so little effort. For these users there are only three possible ways out of this dilemma: 1. leave well alone; 2. work in collaboration with colleagues; or 3. acquire the necessary theoretical knowledge by private study. This book by W. B. Smith is intended to help with the third alternative.

It is certainly a welcome development when an attempt is made to present theoretical organic chemistry at such a level that it can be understood by most non-specialists. Although there are many excellent books on the quantum-mechanical fundamentals of chemistry, few of these offer help in the practical application of theoretical methods. In accordance with the title of this book, the author's idea is first to introduce the reader to the theoretical fundamentals of quantum chemistry (qualitative MO theory), then in the second part (from Chapter 7 onward) to treat the most commonly used theoretical methods, and this approach is undoubtedly correct.

However, it must be said at the outset that neither the first nor the second part is suitable as a student textbook. The choice of subject matter and the strong emphasis placed on the Hückel theory give cause for concern. It is true that in a treatment of such a complex topic as this within a mere 192 pages, one has to be prepared to accept some compromises. Nevertheless, the mathematical derivations must be error-free, understandable, and entirely consistent. This book contains so many errors, loose and careless statements, and lapses from rigor in the physical arguments, that a newcomer to the subject is at risk of failing to follow the discussion or getting an incomplete picture. A few examples will illustrate this. The first is the derivation of the Schrödinger equation in a few steps on pages 2 and 3. The transition from classical mechanics to quantum mechanics is made, without further explanation, by replacing the momentum in the classical expression for the total energy by the corresponding quantum-mechanical operator, then multiplying the expression by a wave function which appears from nowhere. Arguments of this kind do not help towards an understanding of the quantum theory. The symbols used for variables are not always consistent. On page 3 the symbol ψ is used for the total wave-function, whereas on page 4 it represents the basis orbitals. Later we find that Ψ is used for molecular orbitals, whereas in the description of the SCF methods (p. 109) Ψ represents the total wave-function and ψ a molecular orbital. As the text contains no mention of the changes in meaning, the reader unfamiliar with the theory will inevitably be confused. In the mathematical formulas, vectors are never clearly distinguished as such, and operators and matrices only occasionally. The lack of care in the text also appears in statements that are difficult to understand or even misleading. On page 30 alone we find that a summation index is missing from each of the equations (2.17) to (2.22), a bracket is missing in the example of butadiene, and in Equation (2.22) the indices on the two sides of the equation do not agree. Often the symbols in the figures and equations do not correspond to those in the text; for example, on pages 32 and 33 the coefficients are denoted by 'a' in the figure but by a in the text, and on page 95 the symbol for the basis orbitals is ϕ in Equation (6.23) but φ in the text immediately below. On page 119 the method described here for minimizing the energy has little to do with the Newton–Raphson method to which the author refers. Also the general discussion about mathematical methods for energy minimization is scarcely understandable and will convey little to the reader. The explanation of CISD in Section 7.4 is simply incorrect. "CI-singles,doubles" is not, as stated here, a linear combination of the ground state Slater determinants and the first and second excited states.

There are also many mistakes in the non-mathematical part of the book. In Chapter 6 (pericyclic reactions, etc.) even the first reaction equation (6.1) defining pericyclic reactions is incorrect. In the Claisen rearrangement shown here, allylphenyl ether rearranges to give *o*-hydroxystyrene. In Equation (6.2) the second reaction arrow has below it *nv* instead of *hv*, and *hv* is missing from Equation (6.3). The claim that "... no stable ring systems containing an odd number of changes in β can exist ..." is presumably a guess. Again, it is incorrect and misleading to state (on page 91) that for a qualitative treatment of the stereochemistry of photochemical reactions it is unimportant whether a singlet or a triplet state is present. The list of errors and examples of slipshod writing could be continued.

The poor quality of the figures is evident even on first opening the book (the Möbius strip on p. 88 and the energy hypersurface on p. 150 are two interesting examples). Leaving aside esthetic considerations, many of the figures are not very suitable for explaining the matters to which they relate. For example, the connection between the orbital diagram (6.20) and the reaction equation (6.18) would only be apparent to a specialist.

Due to the large number of mistakes and examples of careless writing, the absence of any indications as to the previous knowledge assumed, and the disjointed and unclear style in which the arguments are presented, the reader unfamiliar with the subject is unlikely to learn much from the book. Moreover, the price seems unjustifiably high for a textbook of 192 pages. Perhaps the printing error on the first page—"testbook" in place of textbook—is no ordinary mistake but a Freudian slip.

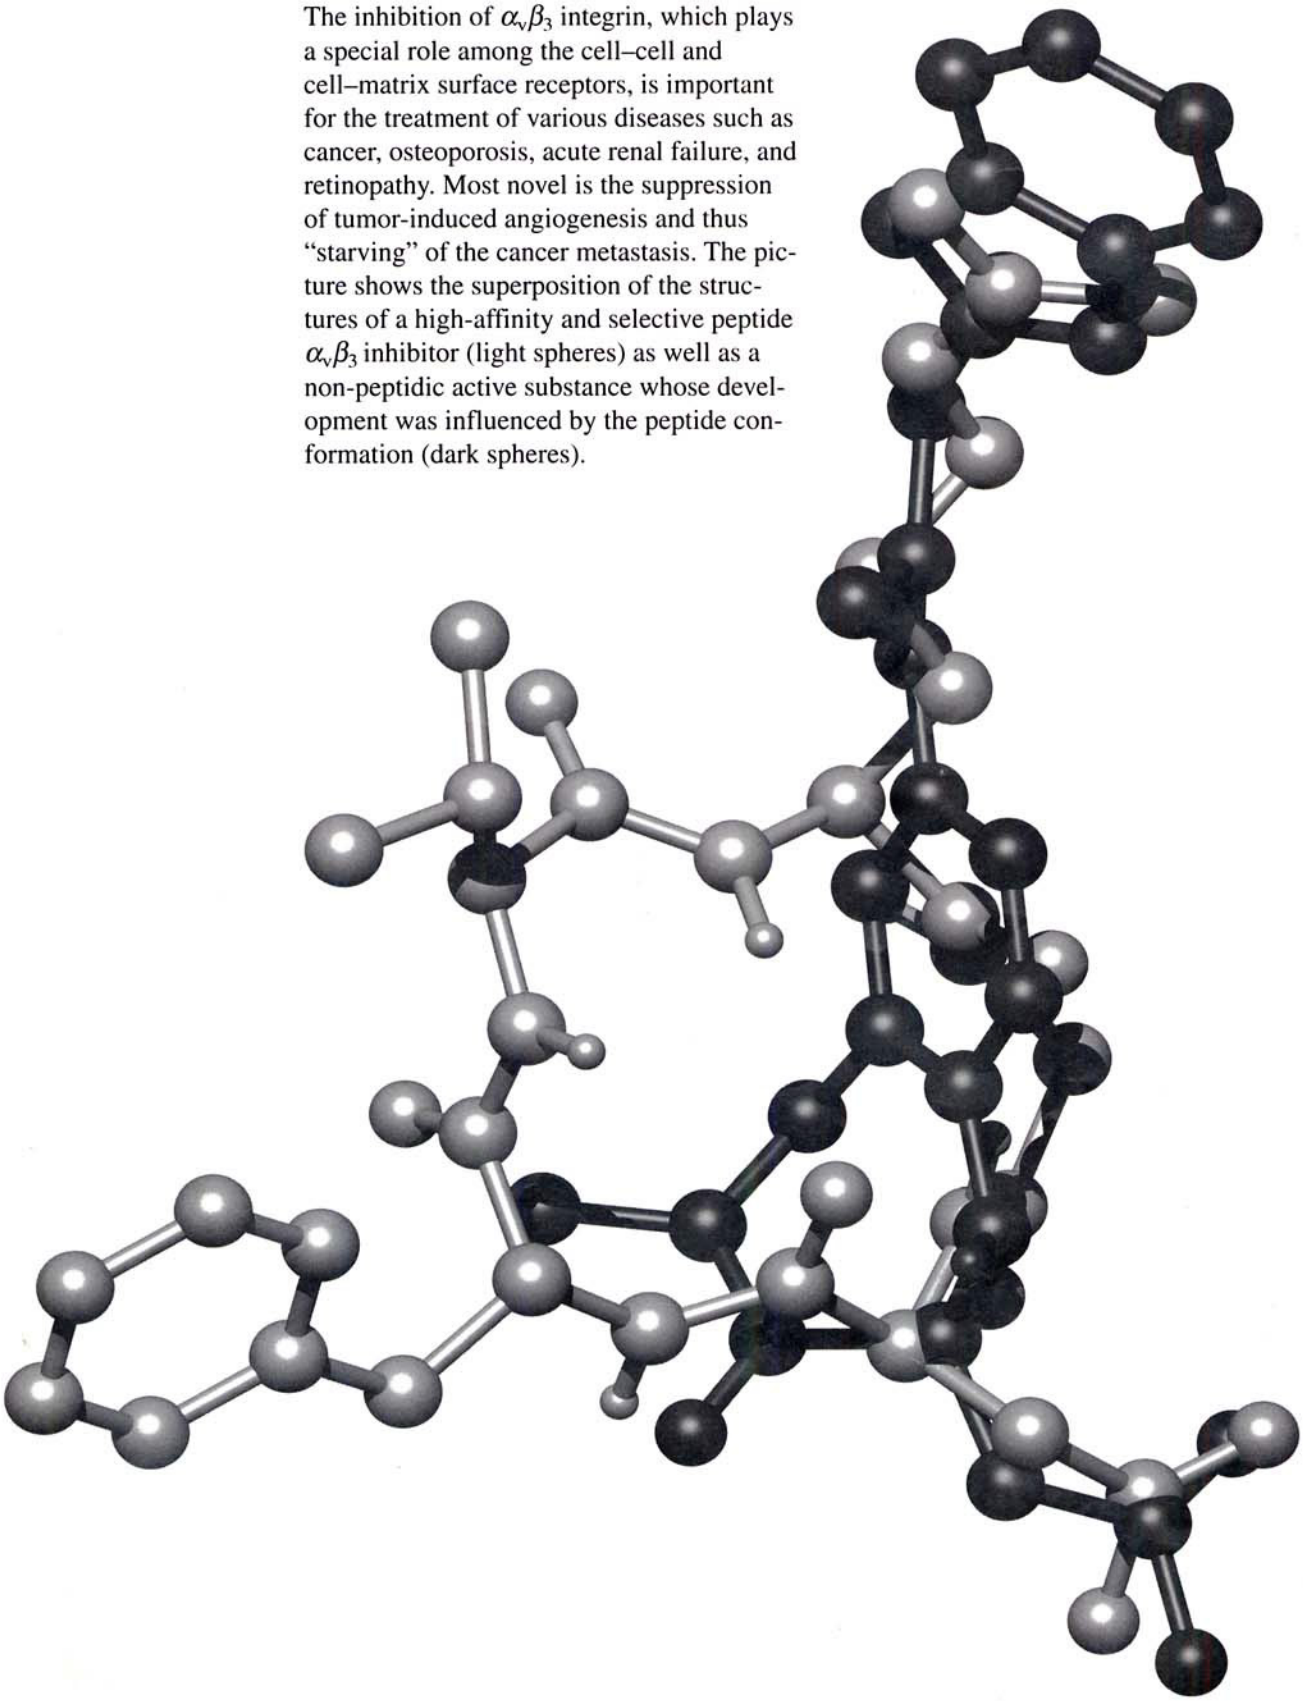
The inhibition of $\alpha_v\beta_3$ integrin, which plays a special role among the cell–cell and cell–matrix surface receptors, is important for the treatment of various diseases such as cancer, osteoporosis, acute renal failure, and retinopathy. Most novel is the suppression of tumor-induced angiogenesis and thus "starving" of the cancer metastasis. The picture shows the superposition of the structures of a high-affinity and selective peptide $\alpha_v\beta_3$ inhibitor (light spheres) as well as a non-peptidic active substance whose development was influenced by the peptide conformation (dark spheres).



Stereoisomeric Peptide Libraries and Peptidomimetics for Designing Selective Inhibitors of the $\alpha_V\beta_3$ Integrin for a New Cancer Therapy

Roland Haubner, Dirk Finsinger, and Horst Kessler*

Cell–cell and cell–matrix interactions play a major role in biology. An important class of surface receptors are the integrins, which exist in a number of subtypes and are involved in many biological processes, for example embryonic development, blood coagulation, osteoporosis, cancer, and regulation of the balance between proliferation and death (apoptosis) of a cell. Therefore, selective inhibition of specific integrin subtypes is of great pharmaceutical interest. It is possible to develop highly selective and active inhibitors of integrins, especially the $\alpha_V\beta_3$ subtype, by the novel procedure of spatial screening. The resulting $\alpha_V\beta_3$ antagonists exhibit activity in the nanomolar range and suppress tumor-induced angiogenesis (formation of new blood vessels). Tissues with intact blood vessels are not influenced. This opens a promising new way for cancer therapy.

1. Introduction

Physiological processes such as embryogenesis, cell differentiation, hemostasis, wound healing, and immune response are strongly influenced by cell–cell and cell–matrix interactions. Already in the early stage of embryonal development adhesion between cells, and between cells and the extracellular matrix, contribute to the determination of morphological development. Interaction of platelets with proteins of the extracellular matrix supports wound healing after injuries by forming blood clots, which stop bleeding.[1–5]

To maintain the efficiency of the immune system leukocytes have to move freely in the body to find infectuous organisms but must also be able to adhere to different cells and proteins of the extracellular matrix. This function is necessary to penetrate endothelial barriers and basal membranes, to reach the location of the infection, and to bind to cells presenting foreign antigenes. Different cell-adhesion receptors are involved in the interplay of adhesion and free mobility.[6, 7]

To get a feeling for the complexity of these processes one should recognize that the earliest signs of unicellular life on earth are more than two billion years old, whereas the first traces of multicellular life appeared only 600 milion years ago. A complicated network for the transfer of information, specialization, and functional interplay was necessary to organize this new form of life.[8] Recently it has been found that cell adhesion plays an important role in signal transduction and, thus, is involved in information transfer between cells.[9] However, binding of the cell to the extracellular matrix also signals into the cytoplasma and leads to the reorientation of the cytoskeleton as well as functional changes in cellular behavior,[10, 11] for example prevention of apoptosis[12–14] (progammed cell death) or stimulation of cell proliferation.

Elucidation of these interactions at the molecular level is an exciting yet, to a large extent, unknown chapter of modern cellular biology and medicine. Malfunctions in these highly complex regulatory processes between cellular adhesion and migration express themselves in pathological degeneration. For example, an uncontrolled coagulation of thrombocytes may cause stroke, emboly, or cardial infarction.[4, 15–18] During metastasis the tumor cells undergo a number of different adhesive interactions.[19, 20] In connection with osteoporosis[21–24] and several other diseases that involve uncontrolled formation of blood vessels[25–27]—such as arthritis, different malfunctions of the eye,[28] and tumor growth[29, 30]—a therapy by inhibition of adhesion has been discussed.

There are four major classes of receptors involved in cell–cell and cell–matrix interactions: cadherins, selectins, receptors of the immunoglobuline superfamily, and integrins. In the following chapter the integrins, in particular the $\alpha_V\beta_3$ receptor and its role in different diseases, are discussed. This is followed by a description of the development of selective antagonists using stereoisomeric libraries (spatial screening) and investigations on conformationally controlled structure–activity relationships (SAR). Finally the development of non-peptidic inhibitors is discussed.

2. The Integrins

Integrins are heterodimeric transmembrane glycoproteins consisting of an α and a β subunit. The larger α subunit (approximately 1100 residues) is often processed to form two disulfide-bridged chains of different length. The extracellular part of the α subunit is characterized by three to four regions near the N terminus that contain 12 to 15 amino acid residues capable of binding bivalent cations (Ca^{2+}, Mg^{2+}). These regions exhibit sequence homology to the EF hand, a calcium-binding motif found in other proteins such as calmodulin.[31] Five of the six octahedral binding sites in the EF hand are conserved in the integrin sequence.[32] Only glutamic acid 104 ($-Z$ in Scheme 1)[34] is replaced by a lipophilic amino acid residue that cannot interact with the metal ion. It is assumed that the Asp side chain of the RGD sequence (see below) occupies this binding site in the complex.[33]

		X	Y	Z	-y	-X	-Z

α_v:	346 -P-L-G-	D	L	D	Q	D	G	F-N-D-I-A-I-A-A-P-Y-
α_5:	357 -P-L-G-	D	L	D	Q	D	G	Y-N-D-V-A-I-G-A-P-F-

Scheme 1. Sequence comparison of the calmodulin (3CLN) EF-hand and three single calcium-binding repeating units of integrin α subunits [34].

X-ray structure investigations[35, 36] of the A domain of the α subunit also indicate the importance of the metal-binding sites for ligand binding. This is confirmed by observations[37–40] that show that integrins depend on the presence of bivalent metal ions and that addition of Mn^{2+} can increase the binding affinity of ligands.

The β subunit typically has about 800 amino acid residues, with the exception of β_4[41] (about 1750 amino acids). It contains four highly conserved cysteine-rich regions of 40 residues proximal to the transmembrane domain and a large loop at the N-terminus of the extracellular part. Both the α and β subunits contain a short transmembrane (20–30 residues) and an intracellular region (20–50 residues), and participate in ligand binding through contact regions next to the N-termini.[1, 42–45]

The C-terminus of the β subunit[2, 42] connects the integrin with actin filaments of the cytoskeleton[11] through intracellular proteins such as talin,[46] vinculin,[47, 48] and α-actinin.[49] This allows attachment of cells to the extracellular matrix as well as signal transduction into the cell (Figure 1).

There are many different integrins. Eight separate β and 15 α subunits are known (Scheme 2). Some α subunits (for example

Horst Kessler (right), born in 1940 in Suhl, Thüringen (Germany), studied chemistry in Leipzig and Tübingen, and finished his Ph.D. with Eugen Müller in preparative organic chemistry. In his habilitation (1969), he used NMR spectroscopy to find evidence for innermolecular mobility. In 1971 he became a full professor for organic chemistry at the Frankfurter Universität, and in 1989 moved to the Technische Universität München. He is a member of the Bayerische Akademie der Wissenschaften. In 1986 he received the Otto-Bayer-Preis, in 1988 the Max-Bergmann-Medaille für Peptidchemie, and 1997 the Emil-Fischer-Medaille from the Gesellschaft Deutscher Chemiker. He has been a guest professor in Halifax (Canada), Tokyo (Japan), Madison (USA), Haifa (Israel), and Austin (USA). His research interests include rational drug design on the basis of conformation, synthesis of peptides, sugars, and peptidomimetics, as well as development and application of NMR techniques and calculational methods for determination of peptides and proteins.

Roland Haubner (left), born in 1962 in Munich (Germany), studied chemistry from 1985 to 1991 as a recipient of the Bayerische Begabtenförderung at the Technische Universität München. He finished his Ph.D. with Horst Kessler in 1995 on the design, synthesis, and conformational analysis of high-affinity and selective $\alpha_v\beta_3$ antagonists. Since 1995 he has been developing new PET tracers for tumor diagnostic and therapy control at the Nuklearmedizinischen Klinik und Poliklinik des Klinikums at the Technische Universität München.

Dirk Finsinger (middle), born in 1968 in Munich, studied chemistry at the Technische Universität München. His Diplomarbeit in the research group of Horst Kessler dealt with the synthesis and structural characterization of thiopeptides. His current doctoral work concerns $\alpha_v\beta_3$-integrin antagonists and peptidomimetics.

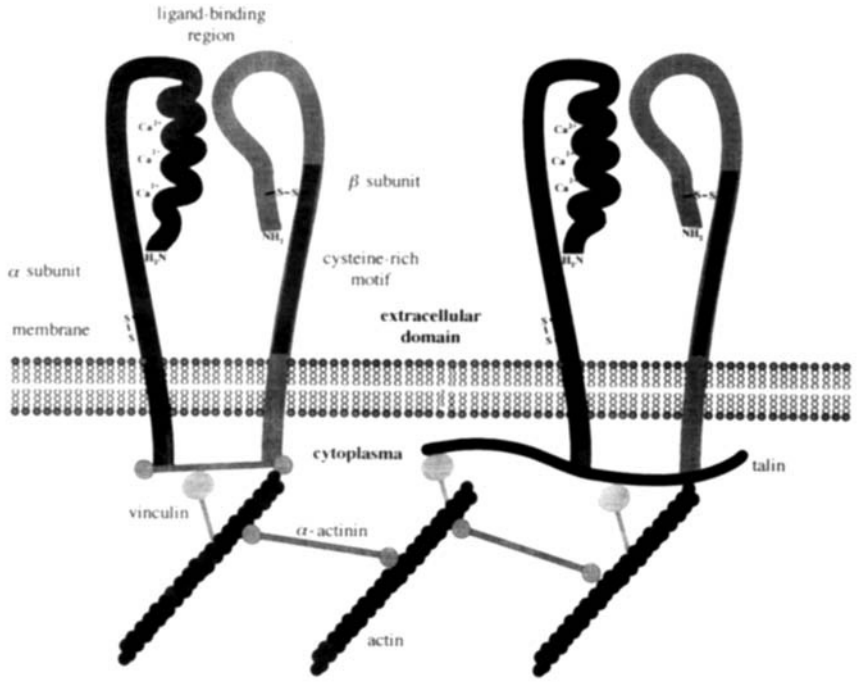

Figure 1. Schematic illustration of integrins and their interactions with proteins of the cytoskeleton.

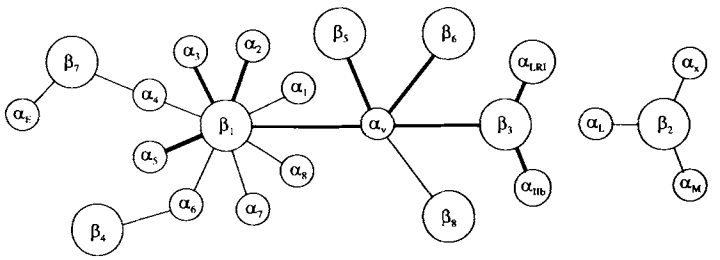

Scheme 2. The members of the distinct integrin subfamilies. Each integrin consists of an α and a β subunit (Figure 1). Different subtypes show distinct protein sequences. The bold lines indicate the integrins that bind their ligands through the RGD sequence.

α_V) can associate with a range of β subunits. The integrins are classified in three main families: β_1, β_2, and the β_3 subfamily.[2, 3, 6, 42]

The members of the widely distributed β_1-integrin family play a central role in tissue organization. They participate in the binding of different cells to extracellular matrix proteins in muscles, the nervous system, as well as the endothelial and epithelial layers, and are often found at the surface of leukocytes. Some β_1 integrins (for example $\alpha_1\beta_1$ and $\alpha_2\beta_1$) are expressed only after activation of the T lymphocytes by antigens, and, hence, are called very late activation antigens (VLA). They are important in inflammatory processes and control the localization of leukocytes after permeation of the endothelial layer.[2, 6, 50]

The β_2 integrins, also called leukocyte cell adhesion molecules (LeuCAM), are mainly found on leukocytes and microglia cells of neuronal tissue. Receptors of this type (Scheme 2) play an important role in the immune system.[2, 51, 52]

The family of β_3 integrins contains three receptors: the $\alpha_{IIb}\beta_3$ receptor ("platelet receptor"), the vitronectin receptor $\alpha_V\beta_3$, and the $\alpha_X\beta_3$ receptor[50] (which has not yet been fully characterized). The $\alpha_{IIb}\beta_3$ receptor,[53] also called GPIIb/IIIa, is probably the most investigated integrin receptor of the β_3 subfamily. Although it is expressed mainly on megakaryocyte-derived cells such as platelets, it was also found on melanoma cells.[54, 55] The $\alpha_{IIb}\beta_3$ receptor binds with different affinity to a great number of extracellular matrix proteins (for example fibrinogen, fibronectin, vitronectin, von Willebrand factor, and thrombospondin).[1, 2, 6, 56]

This receptor is involved in primary and secondary hemostasis. It allows aggregation of platelets at sites of vascular injuries by binding to the collagen filaments in the connective tissue at the lip of wounds. Aggregation of platelets by fibrinogen then forms a blood clot and seals the injured tissue. Defective formation of these clots may lead to embolies, stroke, or myocardinal infarction.[57–59]

The $\alpha_V\beta_3$ integrin is expressed on a considerably higher number of cell types than $\alpha_{IIb}\beta_3$.[60] Its function is discussed in the following.

3. The Role of $\alpha_V\beta_3$ Integrins in Diseases

The $\alpha_V\beta_3$ integrin, also known as the vitronectin receptor, can be found on almost all cells originating from the mesenchyme.[2] The complete amino acid sequence of the α_V subunit was obtained from cDNA studies,[61] and shows the typical structure for integrins as described in Section 2. It binds to a number of different ligands including the above-mentioned matrix proteins that also bind to $\alpha_{IIb}\beta_3$, tenascin, denaturated collagen type I, and osteopontin.[50] The vitronectin receptor is involved in many cell-adhesion processes. For example, it plays a role in angiogenesis,[25, 62] at different levels of tumor metastasis,[29] in phagocytosis of cells undergoing apoptosis,[63] in bone remodeling,[21, 23] and in acute renal failure.[101] There is also a relationship between $\alpha_V\beta_3$ integrin and the expression of the urokinase receptor (uPAR = urokinase-type plasminogen-activator receptor), which is involved in proteolytic processes, in metastatic melanoma cells.[64] Moreover, regulation of the integrin function by uPAR has been discussed.[65]

Tumor metastasis involves a number of different cell–cell and cell–matrix interactions (Figure 2), for example during release from the primary tumor, migration of tumor cells in the lymphatic system or blood vessels, anchoring in the capillary system of the target organ, and extravasation.[3, 66–70] Numerous investigations of integrin expression on tumor cells forming metastasis have demonstrated that those integrins that are responsible for stable contact in the tissue are down-regulated.[71–75] In contrast, those that are involved in migration are overexpressed. In particular $\alpha_V\beta_3$, which is responsible for binding to extracellular matrix proteins, is highly expressed on many tumor cells[76] such as osteosarcomas, neuroblastomas, carcinomas of the lung, breast, prostata, and bladder, as well as gliobastomas[77] and invasive melanomas.[78–80]

The formation of new capillary blood vessels from endothelial cells is essential to organ development, wound healing, and

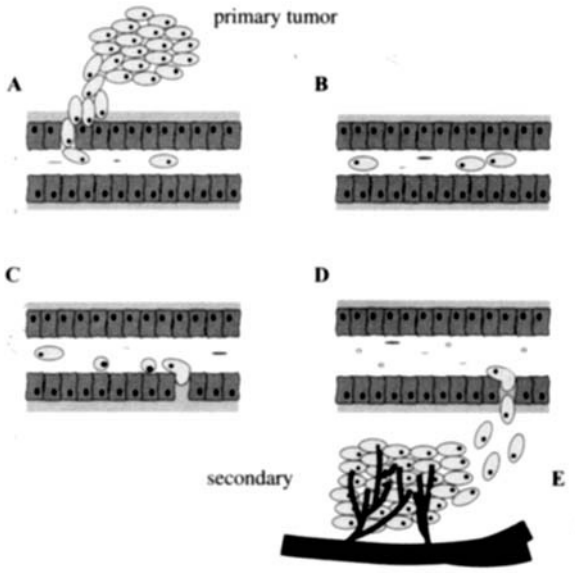

Figure 2. Metastatic cascade. A) Detachment of cancer cells from the primary tumor and invasion. B) Circulation in the blood or lymphatic system. C) Arrest in the venous or capillary bed. D) Extravasation. E) Development of metastatic colonies and tumor-induced angiogenesis.

inflammatory processes. The required adhesive events are strongly regulated; they are limited to affected cells, activated only for a relatively short period of time (several days), and suppressed completely afterwards. Cytokines and growth factors such as bFGF (basic fibroblast growth factor), VEGF (vascular endothelial growth factor), TNF-α (tumor-necrosis factor), and angiogenin activate the involved endothelial cells and regulate the formation of new capillaries.[81] The stimulated endothelial cells express proteases that decompose the basal membrane. This allows the endothelial cells to migrate into the tissue towards the stimulus.[29] The chemotactic and haptotactic behavior is controlled by cell-adhesion receptors.[82, 83] Moreover, it has been discussed[84] that lack of specific cell–matrix interactions induces an apoptotic signal in endothelial cells involved in angiogenesis and thus prevents neovascularization.

However, formation of new blood vessels is also involved in many diseases in which angiogenesis is misregulated. For example, in rheumatic arthritis the cartilage of joints is destroyed by invasion of new blood vessels. In diabetes blood vessels grow into the retina and the vitreous body (retinopathy), and lead to bleedings and, as a consequence, blindness.[26, 84]

The involvement of $\alpha_v\beta_3$ in neovascularization of the retina was demonstrated in a hypoxic-mouse model.[85] Expression of the $\alpha_v\beta_3$ and/or $\alpha_v\beta_5$ integrins can also be induced by growth factors.[86] In both cases the $\alpha_v\beta_3$-antagonistic peptides developed in our group (see below and ref. [87, 88]) drastically reduce capillary proliferation in retinal tissue.

Brooks et al.[82, 84] demonstrated that the integrin $\alpha_v\beta_3$ is present on cells of blood vessels of granulation tissue but not that of normal tissue. Expression of $\alpha_v\beta_3$ integrin is stimulated by angiogenetic factors such as bFGF and TNF-α.[89] Specific antibodies against $\alpha_v\beta_3$, for example LM 609 and our cyclic peptide *cyclo*(-Arg-Gly-Asp-D-Phe-Val-),[87] block the bFGF-induced angiogenesis but do not affect existing blood vessels. Tumors require angiogenesis to provide sufficient nutrition for the rapidly proliferating cancer cells.[26, 29, 90] Furthermore, the newly formed blood vessels are often used as a pathway for cancer cells to enter the blood circulation.

Tumor-induced angiogenesis is inhibited by the above-mentioned $\alpha_v\beta_3$ antagonists (Figure 3). For these experiments melanoma cell lines (human M21-L) that do not express $\alpha_v\beta_3$ integrins were chosen to demonstrate that blocking of angiogenesis can act directly through antagonism of cells of the blood vessels.[89] Investigations of human $\alpha_v\beta_3$ negative breast tumor tissue in a chimeric human/mouse model indicate reduction of tumor-supporting blood vessels and distinct reduction of tumor-cell proliferation by $\alpha_v\beta_3$-specific antibodies.[91] Therefore, blocking tumor-induced angiogenesis by inhibition of the $\alpha_v\beta_3$ receptor is an attractive target for fighting metastasis formation and tumor growth.[92]

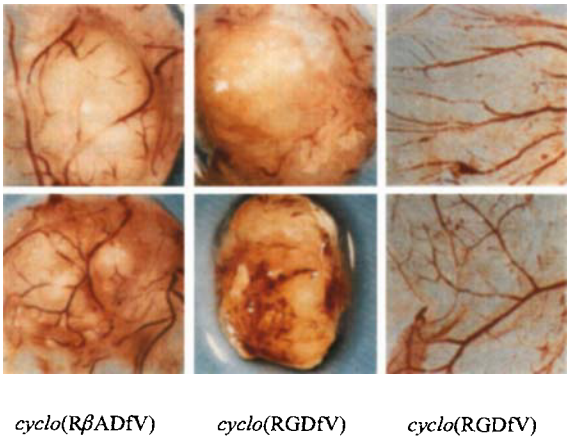

Figure 3. Inhibition of tumor-induced angiogenesis by *cyclo*(-RGDfV-)(middle). The picture on the left shows that the inactive peptide *cyclo*(-RβADfV-) with a similar amino acid sequence cannot inhibit angiogenesis of tumors implanted in chick embryos. The adjacent, normal CAM (chick chorioallantoic membrane) with blood vessels is not harmed by these peptides (right).

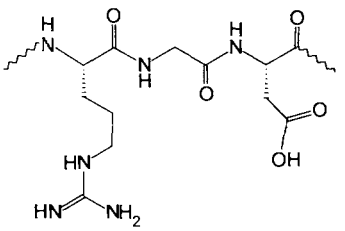
Another area where integrin-transmitted cell adhesion plays an important role is the turnover of bone mass. Docking of osteoclasts to extracellular bone-matrix proteins such as osteopontin or bone sialoprotein requires $\alpha_v\beta_3$ integrin.[93] This integrin is expressed in significant amounts on the cell surface of human osteoclasts as well as on those of rat or chicken.[94] In addition, in vitro studies with synthetic peptides containing the Arg-Gly-Asp sequence have demonstrated that bone resorption by isolated osteoclasts can be inhibited.[21, 95] The β_3-selective disintegrin echistatin exhibits the same effect on bone resorption in rats.[96] Therefore, $\alpha_v\beta_3$ antagonists also represent a promising therapeutic approach to preventing increased bone resorption.[24, 97]

Pathophysiological adhesion phenomena are also involved in acute renal failure. Isolated, detached necrotic endothelial cells cause ischemia in the tubular lumen.[98, 99] More recent investigations have found viable epithelial cells in the urine of kidney patients. This suggests that exfoliation of epithelial cells plays a role in the formation of vasoconstriction.[100] Analogous investigations have demonstrated that integrin receptors are involved in detachment of animal epithelial cells.[101, 102] Regeneration time after renal failure has been shortened drastically by directly injecting the peptidic $\alpha_v\beta_3$ antagonist *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) into the renal artery.[103, 104]

4. The RGD Sequence

Many extracellular matrix proteins are involved in interactions with integrins. For example, the basal membrane—the border between epithelial and connective tissue underneath—partially consists of these proteins.[105] Structure-forming collagen as well as the glycoproteins laminin[106,107] and fibronectin are found there.[108-112] Extracellular matrix proteins in the plasma that are involved in blood clotting are fibrinogen,[113,114] thrombospondin,[115,116] and the von Willebrand factor.[117,118] The glycoprotein vitronectin[119-121] is observed in plasma as well as in connective tissue. Osteopontin and bone sialoprotein, which are involved in osteoporosis,[23,122] and tenascin[123,124] are also ligands for the $\alpha_v\beta_3$ receptor. These extracellular matrix proteins contain different motifs that are potential cell-binding regions.[50] One of the most frequent cell-recognition motifs is the amino acid sequence Arg-Gly-Asp (RGD; Scheme 3), the "universal cell-recognition site"[1,6,44,119,125] (Table 1). Fibrinogen also binds to the $\alpha_{IIb}\beta_3$ receptor through the GGAKQAGDV sequence of the γ chain.[126]



Arg Gly Asp

Scheme 3. The RGD sequence.

The RGD sequence is the basis for the development of different antagonists, specifically for the prevention of platelet aggregation. However, antagonists based on this sequence can also be used to inhibit the $\alpha_v\beta_3$ receptor.

The reason for the high selectivity of certain integrins for distinct adhesion proteins, in spite of their common RGD-recognition site, is still not understood completely. Additional binding sites as well as different conformations of the RGD sequence in different proteins have been discussed.[1] We will demonstrate here that conformationally restricted peptides can show high receptor selectivity and affinity.

So far investigations on the conformation of natural matrix proteins have concentrated on fibronectin,[127] in particular the type III modules. The tenth type III module that contains the RGD sequence was studied by NMR spectroscopy[128,129] and X-ray crystallography.[130] An X-ray structure[124] from the third fibronectin type III domain of tenascin also exists. In both structures the RGD motif is located in a βII' turn between two β sheets extending from the protein core. It is assumed that this loop is flexible in solution, and, hence, it is not possible to draw a conclusion about its conformation on the integrin receptor. More recent X-ray[131] and NMR[132] investigations of a larger fibronectin segment (domains seven to ten) did not yield any additional information about the conformation of the RGD motif.

The RGD motif is also found in several snake venoms. Most of these disintegrins are toxins that interfere in the blood-coagulation cascade. They induce bleeding, which causes heart failure and circulatory collapse.[133] Disintegrins are efficient inhibitors of platelet aggregation.[50] Three-dimensional structures have been obtained for kistrin,[134,135] echistatin,[136-141] and flavoridin.[142] In addition, secondary structural elements are known in the case of albolabrin.[143] In all structures the RGD sequence is found at the apex of a flexible loop without a distinctly prefered conformation.

Dendroaspin,[144] also called mambin,[145] is found in snakes of the family *Elapidae* and also contains the RGD sequence. This is unusual, since the snakes of this family do not form hemotoxins but rather neurotoxins. Although dentroaspin exhibits a folding pattern typical for neurotoxins, it is not a neurotoxin. The RGD sequence, which is atypical for neurotoxins, is again located at the top of a flexible loop and allows inhibition of platelet aggregation similar to hemotoxins.

Polypeptides that inhibit blood coagulation are also found in leeches. Hirudin, for example, inhibits thrombin. On the other hand, ornatin and decorsin block binding of $\alpha_{IIb}\beta_3$ to fibrinogen and, thus, inhibit platelet aggregation. The RGD sequence in decorsin is also found in a loop region, but, in contrast to the structures mentioned above, this loop is well-defined. The RGD sequence exhibits an extended conformation in which the pharmacophoric groups are oriented in opposite directions. Since decorsin shows high affinity for $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$ integrins, we have to assume that the RGD sequence in this well-defined structure is still flexible enough to bind to both receptors.[146]

These structural studies indicate that the high activity of the disintegrins is based on the structural adaptability of the RGD sequence. Hence, the structures of these flexible compounds do not allow conclusions about the receptor-bound conformation, although knowledge of this conformation is necessary for rationally designing new bioactive compounds.

5. Design of Selective $\alpha_V\beta_3$-Integrin Antagonists

The development of antagonists for peptidic ligands normally starts with the search for the recognition site. In our case the active sequence was identified by sequence comparison of integrin-binding proteins.[147-149] Recently biologically or chemically synthesized peptide libraries were screened to obtain the same information. It was possible to confirm the RGD sequence by screening a phage-display library[150] and to identify adjacent amino acids that increase affinity for the receptor.[151] However, new developments focus on non-peptidic libraries to yield lead structures for drug development.[152]

At the beginning of our work the RGD sequence was known,[153] and it was clear that small modifications such as replacement of Asp with Glu or Gly with D-Ala or L-Ala result in total loss of binding activity.[154, 155] Therefore, our goal was to gain high activity and selectivity by fixing the spatial conformation.[156] Since the receptor-bound conformation, the "bioactive conformation", was not known, we synthesized stereoisomeric, constrained cyclic peptide libraries to define the optimal structure required for distinct receptor subtypes (spatial screening). We had already demonstrated that cyclization yields high affinity and selectivity if the conformation of the constrained structure is close to the bioactive conformation (matched case). This approach was also successful in the case of the RGD peptides.[157] Comparison of the activity of *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) with that of the linear sequences -D-Phe-Val-Arg-Gly-Asp-, -Val-Arg-Gly-Asp-D-Phe-, and -Arg-Gly-Asp-D-Phe-Val- exhibits drastically reduced activities and selectivities for the linear peptides (Scheme 4).

The use of cyclic peptides for the elucidation of the bioactive conformation and the generation of drug leads is now commonly accepted. However, cyclization may often fix a molecule in a conformation that is not bioactive. This results in a compound with drastically reduced activity (mismatched case). Searching for the best conformational restraints is still difficult and does not always lead to success.

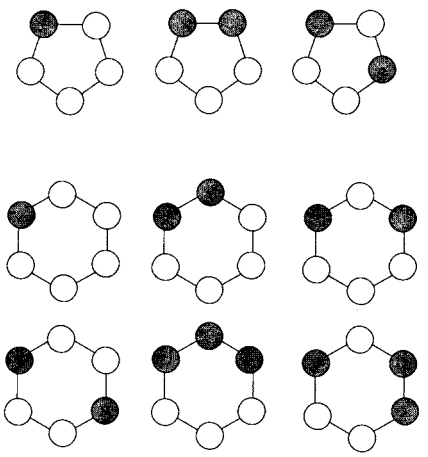
Scheme 4. Comparison of the activity (IC_{50} [μmol]) and selectivity (ratio of activity on the platelet and the vitronectin receptor) of the $\alpha_V\beta_3$-selective peptide *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) and its linear analogues. (Data for the linear peptides were provided by G. Hölzemann, Merck KGaA.)

5.1. Stereoisomeric Peptide Libraries

5.1.1. Choice of Basic Structures

A stereoisomeric peptide library has to lock the bioactive sequence in different conformations without changing its constitution. This is achieved with a rigid basic template such as a cyclic peptide, which should be as small as possible to induce sufficient restraints but large enough to include all pharmacophoric groups. Therefore, we chose cyclic penta- and hexapeptides, since larger cyclic peptides already exhibit greater flexibility.[158]

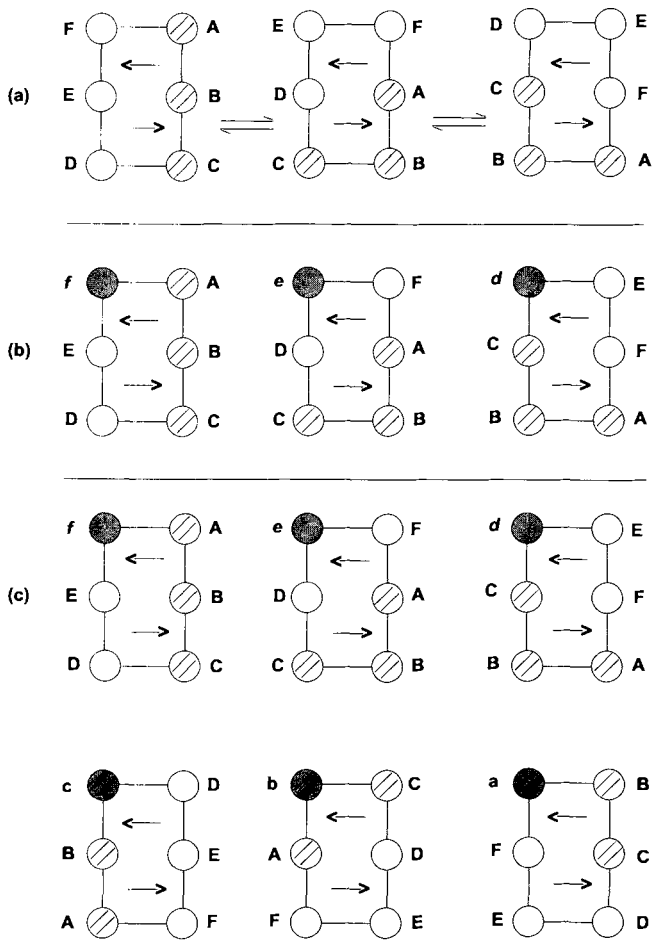
In the case of homodetic cyclic peptides the conformation is dominated by the chirality of the amino acid residues. Interactions of functional groups of the side chains with the peptide backbone— known, for example, for Ser and Thr in the *i* position of β turns[159] or for Asn[160]—as well as the influence of β branching are less important. We synthesized all possible cyclic penta- and hexapeptides with L-Ala and/or D-Ala and investigated their conformations in solution by NMR spectroscopy and molecular dynamics (MD) calculations (Scheme 5).[161] In addition, we introduced glycine (the only α amino acid without a side chain) and D- or L-Pro. Proline exhibits steric restraints of the ψ angle and keeps the ϕ angle between $+60$ and $-60°$.



Scheme 5. Cyclic penta- and hexapeptides consisting of D- (grey circle) and L-alanine. Cyclopeptides with more units of D-Ala than L-Ala, for example *cyclo*(L-Ala-D-Ala_4), are enantiomers of the shown compounds.

Some of the cyclic peptides prefer a single conformation, whereas others show evidence for fast equilibria of energetically similar conformations.[156] If one distinct conformation is preferred, often inappropriatly called a "rigid conformation", it can be used as a template for spatial screening. An example is given in the following:

Cyclic hexapeptides normally prefer a conformation with two β turns.[162] A cyclic hexapeptide containing only L-amino acids and a bioactive sequence ABC can adopt three different conformations in a fast equilibrium in which the sequence is found in different positions of the ring (Scheme 6a). However, a D-amino acid residue, especially D-Pro, strongly prefers the $i+1$ position of a βII′ turn. Therefore, we can now fix our ABC sequence in three different positions depending on which of the remaining



Scheme 6. Arrangement of an assumed bioactive amino acid sequence ABC (hatched circles) in cyclic hexapeptides. The arrows show the orientation of the hydrogen bonds in the β turns. a) The prefered β,β-conformation of hexapeptides allows a nearly equal population of three conformations if only L-amino acids are present. b) The bioactive sequence ABC is fixed in three different positions by a structure-inducing amino acid (D-Xaa or proline). c) Prefered conformations of six possible hexapeptides with an amino acid sequence ABCDEF with one D-amino acid each. The active sequence is shifted around the basis template by structural induction of the D-amino acid (grey circle) in the $i+1$ position of a βII′ turn.

three residues D, E, and F in the hexapeptide is D-configurated (Scheme 6b). We already used this method to design the bioactive conformation of the binding loop of tendamistat, an α-amylase inhibitor.[163, 164] If the bioactive conformation is not known one can synthesize six cyclic hexapeptides, each with D-configuration at one of the six amino acids. The D-amino acid residue prefers the above-mentioned distinct position and forces the essential sequence (ABC) into different spatial arrangements (Scheme 6c). The constitution, that is, all connectivities, remain constant in all six peptides. A correlation of their biological activities then identifies the required conformation.

5.1.2. *Stereoisomeric RGD Peptide Library*

In our search for selective and active inhibitors of integrins we started with the RGD sequence flanked by the hydrophobic amino acid phenylalanine at the C-terminus (based on sequence comparison of different natural RGD proteins). We synthesized different cyclic penta- and hexapeptides by systematically varying the chirality of the residues. We assume that in the first approximation the resulting conformations correspond to those of the equivalent alanine peptides. As shown in Figure 4, the conformations of *cyclo*(-D-Ala-Ala_4-) and *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) are in fact similar to a large extent. The cyclopeptide conformations are controlled by the amino acid residues D-Ala and D-Phe, respectively.

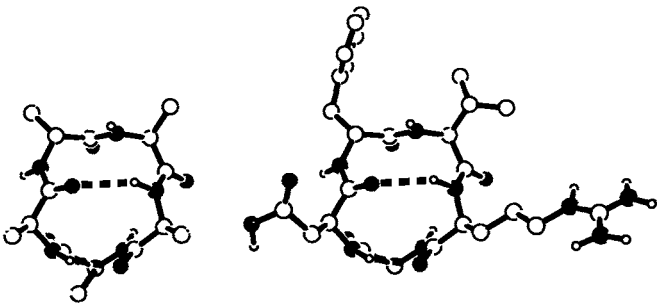


Figure 4. Conformations of *cyclo*(-D-Ala-Ala_4-) and *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) in DMSO; the time-averaged trajectory of a rMD simulation (restrained molecular dynamics) based on NMR data is shown.

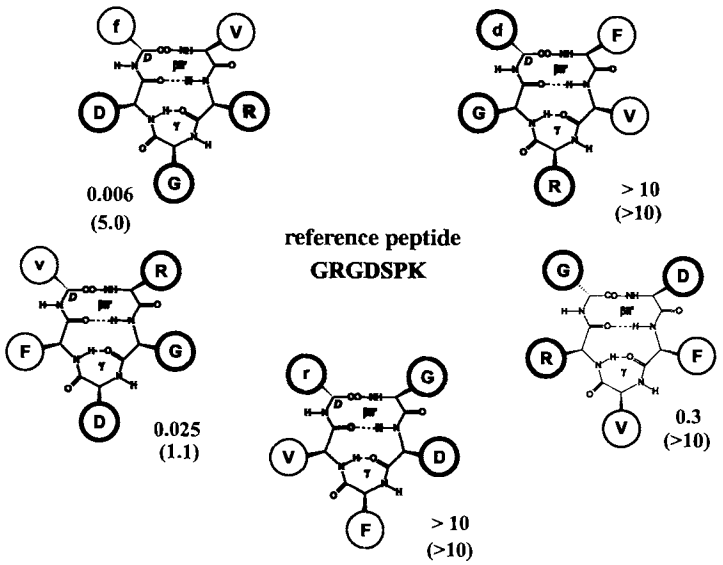
However, the glycine residue of the RGD sequence complicates the procedure, since glycine may serve as a D- or L-amino acid and allows greater flexibility due to the lack of steric hindrance from a side chain. Since the conformations of the RGD cyclic peptides were not completely predictable, we determined the structure by NMR spectroscopy in combination with distance geometry and/or molecular dynamics calculations.

Using this approach we indeed found cyclic hexapeptides with drastically increased affinity for the platelet receptor $\alpha_{IIb}\beta_3$.[157, 165] However, highly potent peptidic[166, 167] and non-peptidic[168–173] compounds for this receptor are already in clinical testing as antithrombolytica. In our most active hexapeptides[87] (for example *cyclo*(-Arg-Gly-Asp-D-Phe-Leu-Gly-) $IC_{50}(\alpha_{IIb}\beta_3/Fb) = 3\,\mu M$) the RGD sequence is located in a βII turn with C^{α}(Arg)–C^{α}(Asp) distances of about 560 pm and corresponding C^{β}(Arg)–C^{β}(Asp) distances of 700–780 pm. Peishoff et al.[174–176] observed comparable activities in homodetic proline-containing hexapeptides. In this case, the RGD sequence is in a similar kinked β turn. However, more active peptide analogues with IC_{50} values in the nanomolar range exhibit an extended conformation of the RGD sequence.[177–183] It is particularly interesting that some cyclic pentapeptides exhibit higher activities and selectivities for the $\alpha_v\beta_3$ integrin overexpressed on cancer cells (Scheme 7).[87]

Investigation of our stereoisomeric peptide library yielded two highly potent inhibitors of vitronectin binding to $\alpha_v\beta_3$: *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) and *cyclo*(-Arg-Gly-Asp-Phe-D-Val-).[165, 184] These pentapeptides prevent adhesion of different human cell lines (fibrosarcoma HT 1080, melanoma A 375, breast epithelial cells HBL 100)[87, 88, 184] and show IC_{50} values for the isolated, immobilized $\alpha_v\beta_3$ receptor in the nanomolar range.[165] This opens the possibility to affect tumor metastasis with this receptor selectively. Of particular interest was the inhibition of tumor-induced angiogenesis (see above). Furthermore, endothelial cells may receive an apoptotic signal from these cyclic pentapeptides. This can probably be attributed to

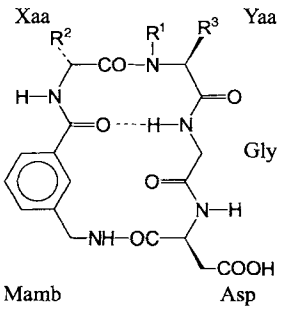


Scheme 7. Relative inhibition of cell adhesion, $Q = IC_{50}/IC_{50ref}$, by cyclic RGD pentapeptides. The values are based on the $\alpha_v\beta_3$ receptor; those referring to the platelet receptor ($\alpha_{IIb}\beta_3$) are given in parentheses. Lower values indicate higher biological activity (and lower concentration of the peptide that induces 50% inhibition).

the blocking of $\alpha_v\beta_3$ integrins, which prevents formation of focal adhesion points. All these properties qualify these peptides as promising candidates for a new class of anti-tumor drugs.[185-189]

5.1.3. Three-Dimensional Structure, Dynamics, and Retro-Inverso Peptides

Structure-activity studies have shown that high $\alpha_v\beta_3$ selectivity is obtained if glycine is in the $i+1$ position of a γ turn.[157] The sequence RGD has a strong kink in $\alpha_v\beta_3$-selective ligands whereas it is elongated in those selective for $\alpha_{IIb}\beta_3$. Usually the relative orientation of $C^\alpha-C^\beta$ bond vectors are considered to be the crucial parameter for describing the side-chain conformation of a peptide or protein (for example, the program CAVEAT[190] is based on this assumption). In cyclic pentapeptides these vectors for Asp and Arg point almost parallel to the same side of the ring. A similar arrangement is found for $\alpha_{IIb}\beta_3$-active peptides, but the distances between the C^α atoms of Arg and Asp (547 pm) and of the corresponding C^β atoms (668 pm) in $\alpha_v\beta_3$-selective compounds are significantly shorter.[191, 192]



Scheme 8. Constitution of the cyclopeptide *cyclo*(-Yaa-Gly-Asp-Mamb-Xaa-); Mamb = *meta*-aminomethylbenzoic acid.

Recently Bach et al.[191, 192] investigated different peptide analogues of the sequence *cyclo*(-Xaa-Yaa-Gly-Asp-Mamb-); Xaa = D-Ala, L-Ala, Aib, Pro, D-Abu; Yaa = *N*-Me-Arg, Arg; Mamb = *meta*-aminomethyl benzoic acid (Scheme 8). They demonstrated that peptides containing the sequence D-Xaa-*N*-Me-Arg are highly active $\alpha_{IIb}\beta_3$ antagonists, whereas the corresponding L-Xaa-Arg analogues are selective $\alpha_v\beta_3$ antagonists. The two structures differ mainly in the β loop formed by the dipeptide unit. The former compounds form a βII' turn with the D-amino acid residue in the $i+1$ position, and the latter a βI turn with the L-amino acid residue in the $i+1$ position. The βI-turn arrangement allows the formation of a γ turn about Gly similar to that discussed above with *cyclo*(-Arg-Gly-Asp-D-Phe-Val-). In close analogy to the cyclic pentapeptide[157] the C^β(Arg)$-C^\beta$(Asp) distance (630-660 pm) is smaller than that in the $\alpha_{IIb}\beta_3$ antagonist. In addition, Burgess et al.[193] observed a conformation with Gly in the $i+1$ position of a γ turn in the $\alpha_v\beta_3$-selective *cyclo*(-Arg-Gly-Asp-Arg-Gly-Asp-).

To elucidate the stereochemical requirements in more detail we synthesized almost all the stereoisomers of the pentapeptide *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) and its retrosequence *cyclo*(-Val-Phe-Asp-Gly-Arg-).[194] The use of the retrosequence is based on the observation of Prelog, Gerlach, and Owtschinnikow,[195, 196] who showed that a reverse amino acid sequence should be accompanied by an inversion of all amino acids to allow the side chains to adopt the same orientation as in the original peptide. Numerous publications describe this concept for obtaining enzymatic stability by partial substitution of natural sequences with retrosequences containing D-amino acids. Frequently this approach results in biologically active retro-inverso peptides.[194] However, it is easy to show that the assumption of similar conformation of retro-inverso peptides and their parent peptides is only valid if the backbone conformation is neglected.[194, 197] In fact, the retro-inverso compound of the highly potent *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) is four to five orders of magnitude less active (Figure 5). On the other hand, among the stereoisomeric retrosequences one compound shows surprisingly high activity, although the D-configuration of the Asp residue is normally accompanied by a total loss of affinity. Since this peptide shows high flexibility, we refrain from discussing its conformation. Nevertheless, there is considerable flexibility in the γ turn of *cyclo*(-Arg-Gly-Asp-D-Phe-Val-).[198]

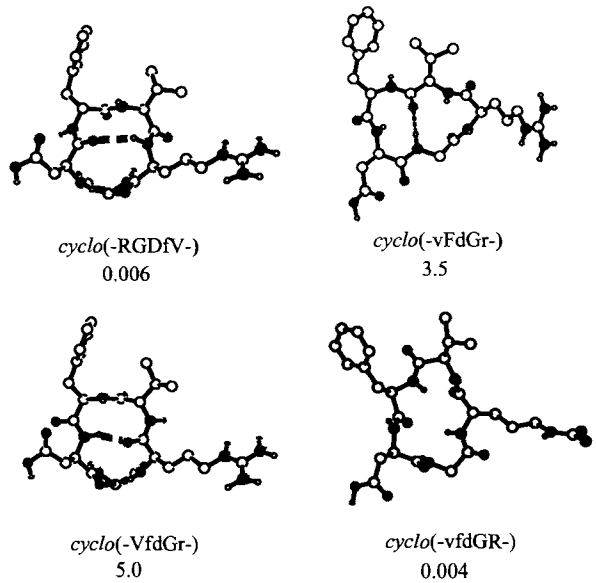


Figure 5. Steroisomers and retrostereoisomers of the pentapeptide *cyclo*(-RGDfV-). The relative inhibition of cell adhesion $Q = IC_{50}/IC_{50ref}$ (based on the linear reference peptide GRGDSPK) on the $\alpha_v\beta_3$-integrin receptor is given. Top left: parent peptide. Top right: retro-inverso peptide. Bottom left: retro-peptide with the same orientation of side chains, but opposite peptide-bond orientation. Bottom right: highly active retro-peptide (see Section 5.3.1).

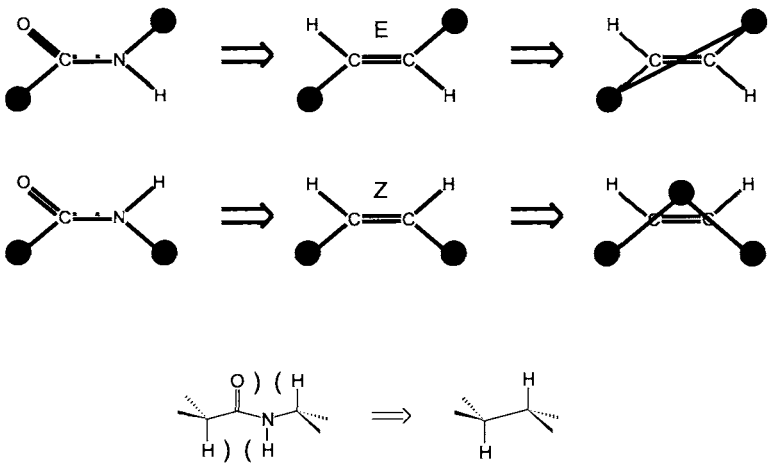
According to ensemble calculations especially the peptide bonds between Arg and Gly as well as between Gly and Asp exhibit different orientations in which the external geometry of the γ turn is more or less unchanged, but the internal hydrogen bridge of Asp–NH to Arg–CO is broken.[199]

The dynamics of cyclopentapeptide conformations can be explained with a model that reduces the cyclopentapeptide structure to the structure of a cyclopentane.[200] For that purpose, each *trans* peptide bond is transformed into a (*E*)-ethylene unit, and each *cis* peptide bond into a (*Z*)-ethylene unit. In the next step, according to Dunitz and Waser,[201] the (*E*)-ethylene unit is replaced by a "long" bond, and the (*Z*)-ethylene by a "phantom" CH_2 group. For a cyclic peptide with all-*trans* peptide bonds this results in the corresponding cycloalkane when only the α carbon atoms of the amino acids are considered as relevant. According to this concept, we expect to find a cyclic pentapeptide in an envelope conformation (four α carbons in one plane and one above or below), which shows rapid pseudorotation. This was indeed confirmed by X-ray crystallography.[202]

In a similar way the conformations of other cyclic peptides can be compared with those of cycloalkanes.[200, 231] As in cycloalkanes, 1,3-diaxial positions or ecliptic arrangements of the C^{α} atoms are avoided. This is surprizing at a first glance considering the large distance between α carbon atoms across the peptide bond. However, it can be explained by allylic strain, which is minimized in the arrangement shown in Scheme 9. This allows transmission of the steric effects at the α atoms across the peptide bonds (see also the discussion of conformational aspects of peptides in ref. [230]). In addition to this basic, sterically induced conformational behavior, hydrogen bonds may also play a role (although to a lesser degree[204]). We therefore expect that cyclopentapeptides adopt many low-energy conformations in fast equilibrium and cyclic hexapeptides, with all-*trans* peptide bonds, a cyclohexane-like conformation.



Scheme 9. Schematic illustration of the Dunitz–Waser concept and its application to amide bonds in peptides. Minimization of allylic strain leads to transmission of steric effects across the double bond.

5.2. Conformationally Controlled SAR

The peptides *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) and *cyclo*(-Arg-Gly-Asp-Phe-D-Val-) of the first generation were used to investigate the effect of the amino acids flanking the RGD sequence.[205, 206] These structure–activity studies were performed under conformational control;[207] the investigation of the influence of side-chain variation on biological activity was simultaneously accompanied by NMR spectroscopic structure determination to guarantee that the change in constitution did not change the conformation as well. Any change in biological activity can then be attributed to the change in side-chain functionality. The importance of this control was shown for the replacement of one of the amide bonds by thioamide or reduced amide bonds, which induces a total conformational change.[208] It is, therefore, not possible to decide if the drastic reduction in activity is due to the change in constitution or conformation (see below). A hydrophobic amino acid residue following the aspartic acid increases the affinity for the $\alpha_v\beta_3$ receptor, whereas the position preceeding the arginine residue can be varied without a reduction in affinity.

Mullen et al.[209] investigated a number of disulfide-bridged cyclic RGD peptides. The $\alpha_v\beta_3$-selective cyclic peptide Gly-Pen-Arg^{-2}-Ala^{-1}-Arg^{1}-Gly^{2}-Asp^{3}-Asp^{4}-Val^{5}-Cys-Ala exhibits a conformation in which the RGD sequence is involved in an undefined β turn adjacent to the Asp-Asp-Val sequence in a β sheet. It seems that here the RGD sequence is also in a bent conformation. In addition, a lipophilic β-branched amino acid next to the RGD sequence enhances the activity, although it is not in the same position as in the cyclic pentapeptides.

Screening of phage-display libraries for the sequence Cys-Xaa_6-Cys and Cys-Xaa_7-Cys confirm that the $\alpha_v\beta_3$ integrin has a hydrophobic binding pocket.[150] Several $\alpha_v\beta_3$-binding ligands contain Ser or Thr next to Asp followed by a hydrophobic amino acid residue such as Phe, Leu, or Ile. Phage-display libraries have also been used by Healy et al.[151] to screen for $\alpha_v\beta_3$ ligands. Although no unambiguous correlation between affinity and flanking residues could be derived from the qualitative data, sequences in which the RGD motif was flanked by two cystein residues bound most strongly. These results confirm that conformationally constrained peptides have a high affinity for the $\alpha_v\beta_3$ integrin if they can adopt a bent conformation as in a γ-turn arrangement.

5.3. Peptidomimetics

Substitution of one or more peptide bonds by thioamide groups, ketomethylene groups, or reduced peptide bonds and other modifications can be used to determine structural requirements for biological activity. This allows an investigation of the importance of distinct structural elements (for example a peptide bond in the active sequence) for receptor–ligand interactions. However, it is critical to confirm that the overall conformation of the peptide is not changed upon substitution. Only then can the observed effect be attributed to changes in constitution rather than changes in conformation.[207]

5.3.1. Influence of Peptide Bonds

There are different ways to investigate the importance of a distinct peptide bond for biological activity: for example, substitution by a peptide-bond isoster,[210] elimination of the amide

proton by N-alkylation,[211] or the use of retro–inverso peptides in which the orientation of the amide bond is inverted.[212] Replacement of the peptide bond between Asp and Gly by a thioamide[213, 214] (C(S)NH) and introduction of a reduced amide bond[208] (CH_2NH) between Phe and Val in the lead structure *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) led in both cases to a drastic reduction in affinity. However, it was not possible to assess whether this reduced activity is based on changes in the constitution of the cyclopeptide, because these modifications also induced conformational changes in the peptide backbone.[214]

Methylation of the different amide bonds in *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) results in five compounds. From this series, *cyclo*(-Arg-Gly-Asp-D-Phe-*N*-Me-Val-) exhibits high affinity as well as specificity.[189, 215] The other four cyclic peptides show only low affinity. N-Methylation induces structural changes in all five cyclic pentapeptides. For example, the *N*-Me-Val peptide exhibits a distinctly expanded βII′ loop centered around the N-methylated amide bond, which, however, does not influence the conformation of the RGD sequence. Conformational analysis for the other four peptides is not yet completed, and the reason for the reduced activity remains to be found.

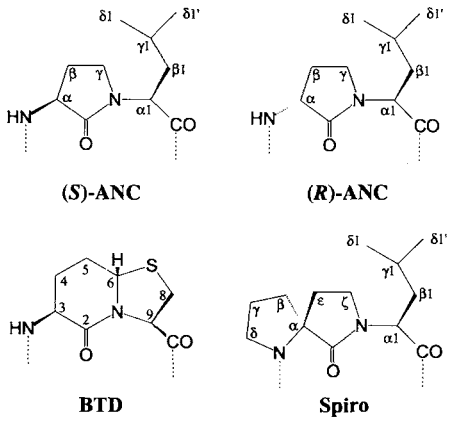
Investigation of the retro–inverso peptides demonstrated that at least one of the peptide bonds of the cyclic pentapeptide participates in binding to the receptor (see above and ref. [194, 214]). One of the stereoisomeric retro-peptides (*cyclo*-(-Val-D-Phe-D-Asp-Gly-D-Arg-)) adopts a conformation in which all side chains assume the same orientation as in the lead compound (Figure 5). Nevertheless, the activity of the retro-peptide was four orders of magnitude lower.[194] Since all amide bonds in the retro-peptide are inverted, the difference in activity has to be attributed to a nonoptimal orientation of at least one of the peptide bonds.

5.3.2. *Further Reduction in Flexibility*

Rational drug design requires a maximum of information about the structures of the ligand and the receptor as well as their interactions. If the three-dimensional structure of the receptor or the receptor–ligand complex is unknown, only indirect conclusions can be drawn based on the structure of the ligand. Therefore, rigid ligands are required for structure–activity studies.[156] Although cyclic pentapeptides are already relatively restricted in mobility,[157] the cyclic peptides described above show considerable conformational interconversions,[206, 216] especially in the γ-turn region.[198, 206] Ensemble calculations revealed that the two peptide bonds in the γ turn flip around the adjacent ϕ and ψ angles.[199, 217]

Turn mimetics[218, 219] were incorporated into the lead structure *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) to further reduce the flexibility of the pentapeptides.[220] Since structural changes in the RGD motif greatly influence the biological activity,[154, 155, 157] the mimetics were introduced in place of the D-Phe-Val dipeptide unit (Scheme 10). The mimetics were expected to stabilize the βII′ turn and simultaneously reduce flexibility in the γ-turn region.

Only the (*S*,*S*)-spiro-Pro-Leu moiety lead to the expected conformation with the turn mimetics in the $i+1$ and $i+2$ positions of the βII′ turn. The other peptide analogues *cyclo*(-Arg-Gly-Asp-(*S*)-ANC-), *cyclo*(-Arg-Gly-Asp-(*R*)-ANC-), and *cyclo*(-Arg-Gly-Asp-BTD-) contain the β-turn mimetics in the γ-turn region, and Gly is found in the $i+1$ position of a βII′ turn (the achiral Gly residue can act as D-amino acid residue). On the other hand, these investigations resulted in one of the most potent $\alpha_V\beta_3$ inhibitors, *cyclo*(-Arg-Gly-Asp-(*R*)-ANC-) with $IC_{50}(\alpha_V\beta_3/Vn) = 0.8$ nM.



Scheme 10. β-Turn mimetics. Building blocks shown were introduced into the β turn of the parent peptide *cyclo*(-RGDfV-) instead of the dipeptide -D-Phe-Val-.

Turn mimetics not only restrict flexibility but can also change the accessible conformational space. For this purpose 5-aminomethyl-2-thiophene acetic acid (Ate), a turn mimetic from Feigel et al.[221] was incorporated.[188, 222] In contrast to the D-Phe-Val unit this moiety provides seven atoms for the peptide backbone. The resulting cyclic peptide exhibited very high affinity ($IC_{50}(\alpha_V\beta_3/Vn) = 2$ nM) and specificity ($IC_{50}(\alpha_{IIb}\beta_3/Fb) = 3300$ nM) for $\alpha_V\beta_3$.

In many cases increased rigidity of the ligand reduces biological activity. This is often taken as an indication for the importance of molecular mobility in the binding process. In our opinion, the optimal fit is simply not reached in most of these rigid molecules. It should be possible to further increase the activity by more closely approximating the structure of the natural ligand. In most cases—an exception is, for example, the binding of cyclosporin to cyclophilin[223]—the biological activity is controlled by the *thermodynamic stability* of the receptor–ligand complex and not by the *kinetics of complex formation*. Hence, it is advisable to search for rigid molecules that present the pharmacophoric groups in an optimal spatial orientation to maximize biological activity.

6. Non-Peptidic $\alpha_V\beta_3$-Integrin Antagonists

The transition from peptidic lead structures to non-peptidic, orally administrable drugs is an important goal in medicinal chemistry. Peptides often have nonideal properties; for example, they are easily degraded in vivo by proteases. However, in the case of cyclic pentapeptides this was not an issue, since, due to the fixation in the cyclic structure, exo- and endopeptidases do not cleave these peptides. The stability is further increased with a retro–inverso peptide, as the high content of D-amino acids prevents cleavage. Aside from cyclization, introduction of peptidomimetics could also lead to higher proteolytic

stability. Another aspect to be considered in the development of pharmacologically active compounds is the rapid excretion of compounds with molecular weights of 500–1000. Depending on their hydrophilic–lipophilic profile, they are rapidly excreted through the kidney or the liver/bile pathway. Hence, small non-peptide molecules are usually prefered goals in the development of drugs. However, orally administrable drugs can also lead to problems due to individual differences in resorption rates by the gastrointestinal tract. In the case of life-threatening diseases intravenous, intraperitoneal, or subcutaneous injection is acceptable. Peptides may even be the drugs of choice, especially when extracellular receptors are targeted, and cellular membranes do not have to be passed.

The development of non-peptidic drugs can be successful if structure–activity studies of a stereoisomeric cyclic peptide library indicate which side-chain functionalities in a defined spatial orientation are essential for activity. Of course, other pharmacophors such as individual peptide bonds can also be incorporated in non-peptidic structures.

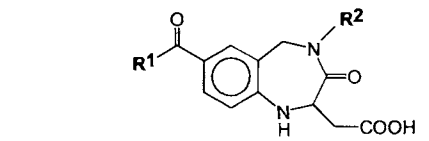
Investigations on the $\alpha_{IIb}\beta_3$ integrin have shown that the distance between the pharmacophors (the carboxyl group of Asp and the guanidino group of Arg) is crucial for activity and specificity.[224] This in principle allows an arbitrary choice of template to present these pharmacophors in the required spatial orientation. Direct de novo design is extremely difficult, even if the three-dimensional structure of the receptor is known. However, it is facilitated if the structure of a lead compound is known. For example, a suitable new non-peptidic template can be designed by studying the three-dimensional structure of a constrained peptide.[190] This should already have a reasonably rigid structure to guarantee selectivity by orienting the pharmacophors in distinct positions.

With the $\alpha_{IIb}\beta_3$-integrin inhibitors the transition from peptides to non-peptides has already been made, and there are several orally administrable integrin antagonists with sufficient activity and selectivity.[168, 173, 225] Most of these compounds contain an N-terminal guanidino or benzamidino group and a carboxyl group, which are separated by a defined distance.

Conformational investigations have shown that a cupped conformation for a potential template molecule is important for the correct presentation of the RGD sequence.[173, 177] This conformation mimics the peptidic loop. This conformation, as well as reduced flexibility, is achieved with substituted benzodiazepines, which present the RGD-like pharmacophors in the correct position.

The development of selective $\alpha_v\beta_3$ integrin antagonists has not yet advanced to a similar stage. Several compounds have been derived from the known $\alpha_{IIb}\beta_3$ selective benzodiazepines. The $\alpha_v\beta_3$ antagonists that should be employed as drugs for the treatment of osteoporosis were developed by varying the carboxyl and guanidino functional groups.[226, 227] This resulted in compounds that are active at the micromolar range. As shown in Scheme 11, variation in the guanidino group led to the largest increase in $\alpha_v\beta_3$ selectivity. Upon changing the benzamidine function into an aminopyridine, activity increased by one order of magnitude, and α_v selectivity raised by a factor of 300.

An important advancement was the recent introduction of the benzimidazole residue as an arginine mimic.[228] The resulting benzodiazepine derivative (Scheme 12) showed $\alpha_v\beta_3$ affinity in the nanomolar range, which was 15000 times higher than for $\alpha_{IIb}\beta_3$.



$\alpha_{IIb}\beta_3$ selective

R1	R2	μmol	$\alpha_v\beta_3/\alpha_{IIb}\beta_3$
		0.0028	–

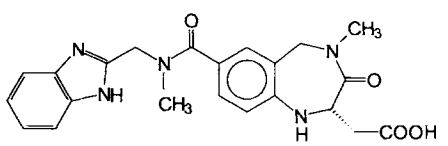
$\alpha_v\beta_3$ selective

R1	R2	μmol	$\alpha_{IIb}\beta_3/\alpha_v\beta_3$
	CH_3	1.50	3.4
	CH_3	9.18	12.0
	CH_3	0.15	1067

Scheme 11. Non-peptide $\alpha_v\beta_3$- and $\alpha_{IIb}\beta_3$-integrin antagonists with benzodiazepine structure. Activities (lower values indicate higher activities) and selectivities (quotient of activities) related to the isolated $\alpha_v\beta_3$ and $\alpha_{IIb}\beta_3$ receptors are given for selected compounds.

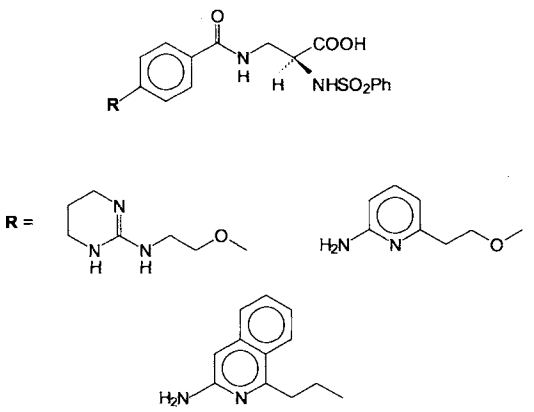
The superposition of the three-dimensional structures of the cyclic peptide *cyclo*(-Arg-Gly-Asp-D-Phe-Val-) and the 3-oxo-1,4-benzodiazepine derivative (see full-page picture on page 1374) shows that the distances between the arginine mimic and the carboxy group are very similar in both compounds.[229] This distance is distinctly shorter than in $\alpha_{IIb}\beta_3$ antagonists, which supports the hypothesis that the γ turn is crucial for $\alpha_v\beta_3$ antagonists.[88] A comparison of the functionalities of α_{IIb}- and α_v-



Scheme 12. Non-peptide $\alpha_v\beta_3$-integrin antagonists. Introduction of a benzimidazole side chain leads to activity in the nanomolar range: $IC_{50} = 0.002$ μmol ($\alpha_{IIb}\beta_3/\alpha_v\beta_3 = 15000$).

selective antagonists imply that a side-on interaction of two nitrogen atoms is important for strong binding to $\alpha_V\beta_3$.

Another class of $\alpha_V\beta_3$ antagonists is aimed at similar processes such as restenosis, osteoporosis, and tumor metastasis. These compounds are based on a *p*-hydroxybenzamide structure,[230] which allows a wide range of variation in the substituent R (Scheme 13).



Scheme 13. Non-peptide $\alpha_V\beta_3$-integrin antagonists with *para*-hydroxybenzoic acid amide structure. Biological data are not available.

The next step from non-peptidic, orally administrable, selective, highly potent $\alpha_V\beta_3$ antagonists to useful therapeutic agents appears feasible. Several of these compounds are already at the level of toxicological or clinical trials. This explains why they are mainly described in patents. It is difficult to directly compare their biological activities, bioavailabilities, and metabolic stabilities at the present stage.

7. Summary

Selective manipulation of cellular-adhesion processes should allow us to influence many physiological and pathological processes. The biochemistry of cell adhesion and signal transduction is currently of great interest. The approach described here represents a new way of identifying bioactive compounds in a semi-rational way, even if the three-dimensional structure of the receptor or the receptor–substrate complex is not known. Information derived by comparing protein sequences or from peptide libraries can be used to design a library of peptides in which the pharmacophors are presented in distinct, well-defined spatial orientations. This allows for an optimization of activity and specificity.

Compounds with high activity and selectivity for the integrin $\alpha_V\beta_3$ exhibit a shorter distance between carboxyl and guanidino groups than $\alpha_{IIb}\beta_3$ inhibitors. In peptidic structures this is achieved by a kinked conformation around glycine (γ turn). Moreover, a hydrophobic residue next to the RGD sequence is important for activity and selectivity. Bulky substitutions in the region of Gly are not tolerated.

The presented approach should also be applicable to other integrins to gain a more detailed understanding of the role of the different integrins in the organism. However, a prerequisite is the isolation of receptor subtypes for the biological assays. The cyclic pentapeptides and benzodiazepine derivatives, which have meanwhile been developed, are highly active and selective $\alpha_V\beta_3$ antagonists and may be used in the treatment of restinosis, osteoporosis, acute renal failure, and retinopathy as well as to inhibit cancer metastasis by blocking angiogenesis.

Many members of our group have been involved in these studies. We would especially like to emphasize the initial work of Dr. M. Gurrath and Dr. G. Müller. Also involved were (in alphabetic order) M. Dechantsreiter, Dr. A. Geyer, Dr. M. Kranz, Dr. E. Graf von Roedern, J. Schmitt, and Dr. J. Wermuth. For the initial biological investigations we thank Prof. R. Timpl (Max-Planck-Institut, Martinsried, Germany) and Prof. J. Engel (Biozentrum Basel, Switzerland). Since 1992 all work has been performed in close collaboration with Merck KGaA (Darmstadt, Germany). Our special thanks go to Dr. A. Jonczyk, Dr. S. L. Goodman and Dr. G. Hölzemann. The conformational studies were done by Prof. D. Mierke (now at Clarke University, Worcester, MA, USA), Dr. W. Schmitt, and R. Gratias. We also thank Dr. R. Geiger, Dr. J. Knolle, and Dr. W. König (Hoechst AG) for stimulating discussions. Financial support was provided by Merck KGaA (Darmstadt), the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. Nephrological studies were performed by Prof. M. S. Goligorski (Stoney Brook, NY, USA).

Received: December 20, 1996 [A 198 IE]

[217] The terms "rigid" and "flexible" are often used in conformational studies in an imprecise manner. Rotations around peptide bonds, defined by the ϕ and ψ angles, normally show a low energy barrier, which means that the rotations are not hindered. If one conformation is energetically prefered among the conformations typical for peptides, that is, it dominates the equilibrium, the term "the conformation" is used. If it is clearly dominant it is called the "rigid conformation".

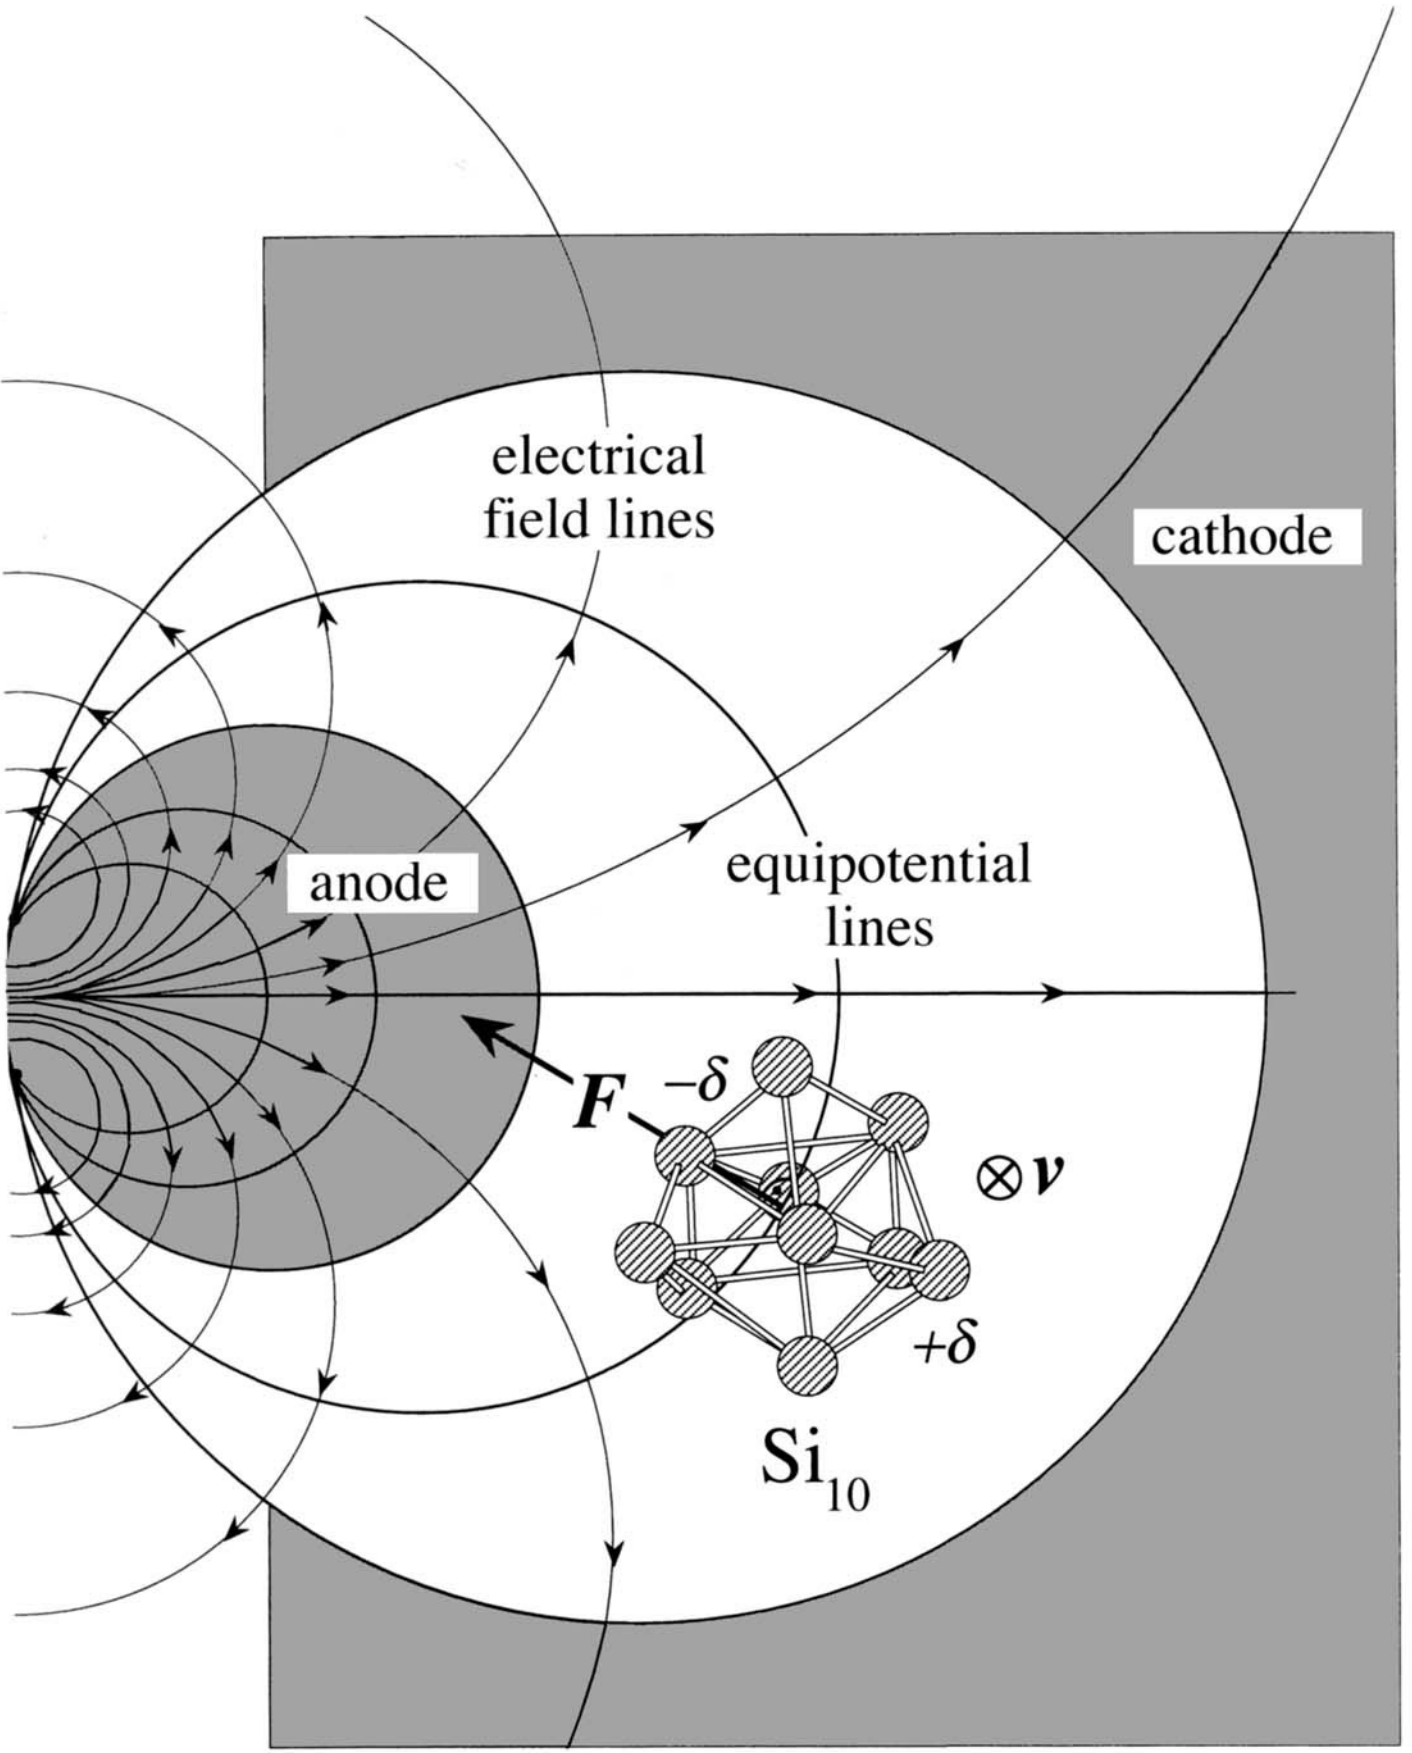
Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal*, and *Liebigs Annalen/Recueil*.



Schematic representation of a semiconductor cluster isolated in the molecular beam during the flight though an electric Stern–Gerlach field. The cluster flies with a velocity v parallel to the cylindrical bent electrode surfaces, which can be seen in the cross section. The field induces a dipole moment in the cluster that is proportional to the polarizability. Owing to the well-defined inhomogeneity of the field a somewhat larger force is exerted on the negative partial charge than on the positive. The resulting force $\boldsymbol{F}$ and the polarizability can be determined in the molecular beam experiment from the deflection of the cluster from the linear flight path.

Molecular Beam Studies on Semiconductor Clusters: Polarizabilities and Chemical Bonding

Jörg August Becker*

This article discusses experiments that measure polarizabilities, permanent dipole moments, and absorption spectra of semiconductor clusters such as Si_N, Ga_NAs_M, and Ge_NTe_M isolated in a molecular beam. The experiments show that the transition from the typical optoelectronic properties of macroscopic semiconductor crystals to the molecular properties of small polyhedral semiconductor molecules occurs in several steps. The bonding in nanometer-sized semiconductor colloids with approximately 10^3-10^5 atoms is similar to that in the solid state. The bonding orbitals of the semiconductor crystals, which extend over a nanometer range, are, however, somewhat more strongly localized in these clusters and are therefore already slightly modified. Over the size range from 10^3 to 10 atoms, a gradual transition occurs from localized solid-state-like bonds to molecule-like bonds. Interestingly, quantum size effects are found even in relatively small particles with about 10^2 atoms. These effects can be observed in the form of unusually small static polarizabilities of Si_N clusters or in the absorption bands of Ga_NAs_M clusters, which are strongly blue-shifted relative to those of the solid state. For smaller clusters, these effects disappear over the size range 10^2-10 atoms, which is manifested by an increasing red-shift of the absorption bands with decreasing cluster size.

Keywords: clusters · colloids · MO models · polarizability · semiconductors

1. Introduction

When a semiconductor crystal made of, for example, Si or GaAs, is divided into ever smaller pieces, one comes upon an interesting problem once the agglomeration numbers X in the fragments have been reduced to about 10^3. The average particle diameter D is then only about 3 nm, which can be estimated from the formula $R = X^{1/3}\bar{r}$ for a spherical particle of radius $R = D/2$ (r is the mean atomic radius in the solid state, Wigner–Seitz radii $\bar{r}_{Si} = 1.68$ Å, $\bar{r}_{GaAs} = 1.75$ Å). The nanometer-sized particles with $X > 10^3$ still contain enough atoms to maintain a bonding structure similar to that in the solid state, which can be observed in semiconductor colloids with an electron microscope.[1]

On the other hand, very small, ligand-free semiconductor particles having 5–10 atoms ($R < 0.4$ nm) exhibit typical molecular polyhedral structures, which have been demonstrated in a matrix for Si_6 and Si_7 by Raman spectroscopy and which are also found by ab initio calculations of quantum chemistry.[2] These structures differ significantly from the typical diamond or zinc blende structures of the solid. The quantum-chemical calculations[2] show that solid-state fragments such as the adamantane structure shown in Figure 1a are unstable for the Si_{10} cluster. Similarly, silicon cubane molecules,[3] which resemble a fragment of a simple cubic crystal (Figure 1b), can only be stabilized by means of ligands. According to quantum-chemical calculations, the adamantane structure shown in Figure 1a will relax into the structure of a tetracapped trigonal prism shown in Figure 1c,[2] thereby increasing its binding energy by 5 eV. These small polyhedral clusters are fairly well understood on a quantum-chemical level. There have even been calculations of isomeric structures (cf. Figure 1d) and their electronic properties.[2,4]

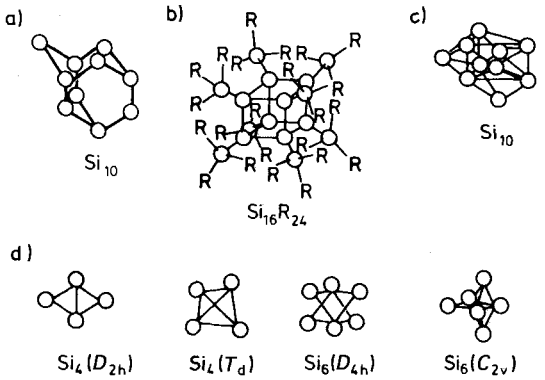


Figure 1. Possible structures for small Si clusters. a) Adamantane structure, b) silacubane molecule[3], c) quantum-chemically calculated structure of the free Si_{10} cluster [12], d) two isomeric structures of Si_4 and Si_6 [4].

The question remains, however, which changes occur in the chemical bonding[5] upon the transition from the solid-state-like semiconductor structures in particles with $X > 10^3$ to the molecule-like structures of small clusters with 5 to 10 atoms. This question does not arise for salt clusters[6] such as Na_NF_N or metal clusters such as Na_N, as the bonding in those species can be described in similar terms as the one in the solid state, even for very small aggregates. Salt clusters can be envisioned as packed anions and cations held together by Coulomb forces. In the case of metal clusters, the simplest model is a closest packing of atomic cores, bonded together by an electron gas. These two models can explain many properties of metal and salt clusters.[6, 7] In particular, properties of alkali metal clusters are often interpreted in terms of an electron gas model (jellium model).[7] For these clusters it is envisioned that the valence electrons are located within a hollow sphere of cluster radius R in which they move through an evenly distributed positive charge density.

According to the Mott criterium,[8] semiconductors can be transformed into metals even with small, doped electron or hole concentrations. In addition to the initially posed question on size-dependent bonding in semiconductor clusters, it is also necessary to deal with the influence of defect-type electrons on the chemical bonding. These effects will be discussed in this article with reference to the system $Ga_NAs_{N\pm1}$ as example.[8, 9]

Apart from the fundamental questions in chemistry about the chemical bonding, materials science also has an interest in small semiconductor particles. Because of the so-called size quantization effects, the optoelectronic and physical chemistry properties of semiconductor particles can be specifically varied based on the particle size. These effects can be observed in nanometer-sized semiconductor colloids,[1] and also play an important role for semiconductor crystallites.[11] A detailed and clear description of these size quantization effects can be found, for example, in the review article by H. Weller.[1]

The solid-state-like bonding in the semiconductor colloids allows optoelectronic excitations like those in the macroscopic semiconductor.[12a] The excitations lead from the valence band over the band gap $E_{G,F}$ into the conduction band and are often described as photochemical processes.[1, 12a, 13] During the excitation, a photon with the energy $\hbar\omega \geq E_{G,F}$ is absorbed and a positive as well as a negative particle is created. These particles are termed 'hole' (h) and 'electron' (e). The term 'hole' is meant to indicate that the positive charge is not localized on a certain atom, but that it can migrate through the crystal.[12a, 13] This migration of a positive charge is made possible by the exchange of bonding electrons between the atoms, which leads to the compensation of the positive charge on one atom and its reappearance on a neighboring atom. The electron–hole model is based on a theoretical study of the electron orbitals φ in crystalline solids by G. H. Wannier.[14] Even though this terminology may initially appear rather abstract, the electron–hole model allows the development of clear notions about the Wannier orbitals φ on the basis of known equations from physical chemistry. To this end, equations from electron spectroscopy and Born's theory of solvation are combined, because the properties of two charged particles in a dielectric medium (semiconductor) must be described. The orbital $\varphi(\boldsymbol{r})$ determines the probability density $|\varphi(\boldsymbol{r})|^2$ that the electron and hole are a distance $\boldsymbol{r}$ apart. As in electrolyte solutions, the Coulomb attraction is reduced by the polarizability of the medium.[12b, 13] This is also termed the shielding of the Coulomb potential due to the dielectric constant ε of the semiconductor. In addition, the relative motion of electron and hole are governed by a reduced effective mass m_{eff}, which is calculated, in analogy to the hydrogen problem known from gas-phase spectroscopy,[15] according to the formula $m_{eff} = m_{eff,e}m_{eff,h}/(m_{eff,e} + m_{eff,h})$. The terms $m_{eff,e}$ and $m_{eff,h}$ stand for the effective masses of electron and hole, respectively. An example is solid GaAs[16] with $E_{G,F} = 1.5$ eV, $\varepsilon = 11$, and the effective masses $m_{eff,e} = 0.07\, m_0$ and $m_{eff,h} = 0.5\, m_0$, where m_0 is the rest mass of the electron in a vacuum. As the mass of the hole is nearly ten times the mass of the electron, one can make the approximation that the electron moves towards a stationary hole and $m_{eff} \approx m_{eff,e} = 0.07\, m_0$.

Just as in the hydrogen problem, there are bound states in which the electron orbits a hole and the center of mass of the two particles moves in a straight line through the crystal. These so-called exciton states are therefore described by hydrogen-like orbital functions. The lowest excited electronic state in a semiconductor is expressed by a Wannier orbital function[13, 14] of the form $\varphi_1(\boldsymbol{r}) \propto \exp(-|\boldsymbol{r}|/a)$ with the exciton Bohr radius a [Eq. (1)].

$$a = \varepsilon\hbar^2/m_{eff}e^2 \qquad (1)$$

For GaAs the orbital radius of $a = 8$ nm obtained is very large, owing to the large dielectric constant and the small effective mass. If this orbital is supposed to fit into a small GaAs particle with a radius R of only a few nanometers, it must be compressed. The corresponding compression energy E_c must be

Jörg August Becker was born on September 15, 1962 in Kusel/Palatinate, Germany. After his studies at the Technische Universität Karlsruhe from 1982 to 1988 he completed his Diplom thesis on theoretical thermodynamics under the direction of G. Falk. He moved to Marburg to join the research group of F. Hensel and worked in the field of photoelectron spectroscopy. After completing his dissertation in 1991, he moved to the ETH Lausanne and worked, until 1993, with W. A. de Heer on Stern–Gerlach experiments on ferromagnetic metal clusters. Back in Marburg he began to study semiconductor clusters in molecular beams. In 1995 he completed his habilitation in physical chemistry and is currently Privatdozent. His area of research is the physical chemistry of inorganic clusters, colloids, and nanoparticles. He is particularly interested in the development of new techniques and the further development of existing experimental methods to examine the electronic, magnetic, and chemical properties of these particles.

accounted for in the excitation energy according to Equation (2). According to L. E. Brus[17] the compression energy

$$E_{\varphi 1} = E_{G,F} + E_c \tag{2}$$

can be approximated by $E_c = E_L + E_S$, where E_L [Eq. 3]

$$E_L = \frac{\pi\hbar^2}{2R^2}\frac{1}{m_{eff}} \tag{3}$$

represents the localization energy and E_S the solvation energy of the electron–hole pair in the dielectric medium. The latter is of the magnitude $E_S \approx -e^2/\varepsilon R$.[17,18] The high dielectric constant of GaAs means that the solvation energy is negligibly small in Equation (2), while the small effective mass leads to very high localization energies [Eq. (3)]. One could say that in colloids additional compression work has to be performed to form the electron–hole pairs. This pressure–volume work forms the basis for the size quantization effects. It causes the lowest electronic excitation energy $E_{\varphi 1}$ of a colloid to increase according to Equations (2) and (3) with decreasing particle radius R.

The constants ε, $m_{eff,e}$ and $m_{eff,h}$ are only at first glance electrical and mechanical in nature. In fact, they describe material properties that can be derived from the chemical bonding in the semiconductor with, for example, Hückel theory.[19a] This description makes it possible to understand many electronic properties of macroscopic semiconductors as well as the size quantization effects in the colloids with solid-state-like structures. However, now a question from physical chemistry arises. The concept of a macroscopic crystalline medium for the electron–hole excitations is based on a solid-state bonding model, which has to be replaced somehow with a model for a more molecular-type bonding upon decreasing cluster size. The electron–hole excitations have to disappear over the size range 10^3–10 atoms and be replaced by molecular-type electronic excitations. This example clearly shows that the changes in the chemical bonding lead to significant changes in the electronic properties of the semiconductor cluster. From a physical chemistry viewpoint, a description is therefore needed in which the chemical bonding does not yield a prescribed, fixed medium for the electronic excitations, but in which the bonding can be treated as an additional degree of freedom. This degree of freedom should manifest itself in such a way as to change the constants ε and m_{eff} into variables for the new description. Corresponding changes should occur when the solid-state-like chemical bonding is altered over the range 10^3–10 atoms. In this context, it must be considered, which molecular electronic properties of the clusters are reflected in the macroscopic electronic properties ε and m_{eff}.

I will first discuss the dielectric constant ε.[12d] Alternatively, one can use the electric susceptibility $\chi = (\varepsilon - 1)/4\pi$. Both properties can be generalized for a solid body in alternating electric fields. The frequency dependence of the dielectric function $\varepsilon(\omega)$ reflects in particular the band gap $E_{G,F}$ of the semiconductor. For frequencies $\omega < E_{G,F}/\hbar$, $\varepsilon(\omega)$ is constant and begins to increase when $\omega \approx E_{G,F}/\hbar$, similar to the electric conductivity $\sigma(\omega)$, which vanishes for $\omega < E_{G,F}/\hbar$ and increases above $\omega = E_{G,F}/\hbar$.[16] It is not useful to define the conductivity or susceptibility of a small semiconductor particle with fewer than 10^3 atoms. In addition, it would be impossible to measure these properties for clusters in the same way as for the solid state. An isolated semiconductor particle with only 10^2 atoms does not allow the attachment of metal contacts for conductivity measurements without significantly disturbing the chemical bonds within the entire cluster. The electrical polarizability $\alpha(\omega)$ however, does represent a suitable molecular property that can take on the role of $\chi(\omega)$ in clusters and can be measured without physically touching the semiconductor cluster. This can be explained by using the example of a small molecular semiconductor cluster such as Si_3. One envisions the effects on a cluster of a static homogeneous electric field of field strength $\boldsymbol{E}_0$, which is generated by two external electrodes far removed from the cluster. The effect of field-induced changes in the valence electron density $\rho(r)$ of a Si_3 cluster is depicted in Figure 2.[20] The changes in the valence electron density caused by the electric field $\boldsymbol{E}_0$ can be attributed to the shifts of the twelve valence electrons in the chemical bonds of Si_3. The thus created dipole moment $\boldsymbol{\mu}$ depends in the first approximation in a linear fashion on the strength of the applied electric field $\boldsymbol{E}_0$ according to $\boldsymbol{\mu} = \hat{\alpha}\boldsymbol{E}_0$, where the matrix $\hat{\alpha}$ stands for the static polarizability of the cluster. The polarizability matrix $\hat{\alpha}$ can be diagonalized by a suitable choice of coordinate system. The polarizability of a cluster is therefore most readily expressed by its primary axis polarizabilities α_{xx}, α_{yy}, and α_{zz}. For many questions in physical chemistry, the mean polarizability $\alpha_C = (\alpha_{xx} + \alpha_{yy} + \alpha_{zz})/3$ is of interest, as it determines the mean induced dipole moment of statistically oriented clusters. On average, a dipole moment of the value $\mu = \alpha_C|\boldsymbol{E}_0|$ is induced in the direction of the applied field. In the description of the experiments I will show that this dipole moment can be measured for a given field and that the polarizability of a cluster can thus be determined. This measurement therefore allows conclusions about the charge shifts in the cluster, rather like in the study of the dielectric polarization of a solid. As the charge cannot flow through the cluster via contacts, however, this method does not yield information analogous to the conductivity $\sigma(\omega)$. A parameter already a little closer to a conductivity measurement is obtained when the cluster is exposed to a high-frequency alternating electric field. The charge in the cluster is then moved back and forth, and direct contacts to the cluster become unnecessary. For a field that alternates with the periodic frequency ω, a corresponding expression $\mu_\omega = \alpha_C(\omega)\boldsymbol{E}_\omega$ can be found relating the amplitude of the field $\boldsymbol{E}_\omega$ to the amplitude of the dipole moment μ_ω. The proportionality constant $\alpha_C(\omega)$ is called the frequency-dependent or dynamic polarizability of the cluster and is closely related to the absorption spectrum of the cluster.

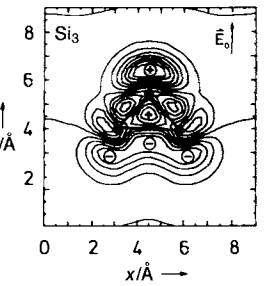

Figure 2. Contour diagram of the field-induced changes in the valence electron density ρ of the Si_3 cluster [20].

These analogies between the dielectric constant $\varepsilon(\omega)$ of a solid and the polarizability $\alpha_C(\omega)$ of a cluster can be expanded into a unified physical chemistry description of clusters and solids by reducing these two physical quantities to a common property of the chemical bonding. I will demonstrate that within a molecular orbital model the polarizability $\alpha(\omega)$ of a cluster comprises the sum of the contributions of the separate bonds in the cluster.

The average of these polarizabilities therefore describes, on one hand, the mean bond polarizability $\bar{\alpha}_B$ of the molecular cluster, and on the other hand, through the Clausius–Mosotti relation [Eq. (4)] the dielectric constant ε of the solid and of solid-like colloids in which the chemical bonds are present with the density $\hat{n}_B$.

$$\left(\frac{\varepsilon-1}{\varepsilon+2}\right)=\frac{4\pi\hat{n}_B}{3}\bar{\alpha}_B \qquad (4)$$

There is no physical chemistry approach as elegant as the Clausius–Mosotti relation for the reduction of the effective mass to a property of the chemical bonding in clusters and solids. The phenomenological description using the effective mass of the electron[12c] takes into account not only the kinetic energy of the conducting electron but also the quantum-chemical interactions with other electrons and the atomic cores in the zinc blende structure of the GaAs crystal. From the standpoint of physical chemistry, the small effective electron mass $m_{eff} = 0.07\, m_0$ implies that the conducting electrons in the semiconductor are present in a chemical environment in which they have a very low inertia and, hence, a high mobility. In this manner, the chemical environment affects the localization energy [Eq. (3)]. As it is possible to retain the concept of an electron in a chemical environment for clusters, the effective mass could be perceived as a characteristic of this environment by defining it by means of the localization energy according to $m_{eff} = \pi\hbar^2/2R^2E_L$. This is also useful from the standpoint of molecular theory, because Equation (3), in a similar form, applies approximately to the model of an electron in a spherical potential well when the effective mass m_{eff} is replaced by the rest mass m_0 of an electron in a vacuum. It is known that the model of an electron in a box can serve as a model for many molecules.[21] It should therefore also be applicable to the polyhedral structures of small semiconductor clusters, as these represent approximately spherical cages in which the molecular orbitals form. This simple picture is in accordance with quantum-chemical ab initio calculations for the clusters Ga_2As_3 and Ga_3As_2.[22] According to these calculations, in Ga_2As_3 (D_{3h}) there is a radical electron located in a molecular orbital inside the trigonal bipyramidal cage. This result is consistent with ESR signals of matrix-isolated Ga_NAs_M clusters, which have been assigned to the radical electron in Ga_2As_3.[23] Even though the electron localization model [Eq. (3)] can only yield a rough description of the molecule-like structures, it should be possible to apply it to the analysis of the critical changes during the transition from molecular to solid-state-like bonding. These changes should be rather large, as it can be assumed that, upon a decrease in the particle radius R, the parameter m_{eff} will change from its solid-state value of $m_{eff,F} = 0.07\, m_0$ into the electron rest mass m_0, an increase of more than one order of magnitude.

To study the questions posed here, a suitable experimental method is required to create semiconductor clusters containing 5 to 10^3 atoms and to measure the polarizability as well as the absorption spectrum as a function of cluster size. In the size range of interest of fewer than 10^3 atoms ($R < 1.7$ nm for GaAs or Si), colloid-chemical methods[1] only generate samples with a broad particle size distribution. The size determination for colloids containing fewer than 10^2 atoms with high-resolution electron microscopy is no longer feasible. The controlled stepwise preparation of ligand-stabilized clusters with 10, 12, 13,... atoms[1] by molecular chemistry is also exceedingly difficult. In addition, the bonding in clusters with fewer than 10^2 atoms is significantly affected by the presence of ligands. We have therefore modified molecular beam methods of metal cluster physics[7] to generate very intense molecular beams composed of ligand-free Si_N or Ga_NAs_M clusters with between 5 and 10^3 atoms and to allow their subsequent study. In these beams, the polarizabilities and the absorption spectra of the semiconductor clusters can be measured under collision-free conditions. The experiments are performed in combination with mass spectrometry, thus permitting the size-selective study of properties of isolated clusters. In this article, initial results are reported for polarizabilities and absorption spectra for clusters of 5 to typically 10^2 atoms. Size-selective measurements on clusters in the range of 10^2–10^3 atoms will have to await further developments of experimental techniques.

It should be noted that we were able to utilize the invaluable work of other research groups on colloids and small clusters already at the outset of this study.[24–26] In particular, we chose the system Ga_NAs_M for the spectroscopic studies, because the absorption spectra of GaAs colloids[25] and of the GaAs molecule[26] are known. In addition, the ionization potentials,[27] electron affinities,[28] and quantum-chemical structural calculations[29] of small Ga_NAs_M clusters have been reported.

2. Isolated Semiconductor Clusters: Preparation, Experiments and Physical Chemistry Models

The molecular beam technique offers an opportunity to study clusters under collision-free conditions.[7, 30] The semiconductor clusters are generated by laser evaporation of semiconductor crystals in a helium atmosphere.[27] The appropriate cluster source is located in the high-vacuum chamber (A) of the molecular beam apparatus, which is shown schematically in Figure 3. The sketch of the Marburg cluster source is shown in Figure 4.

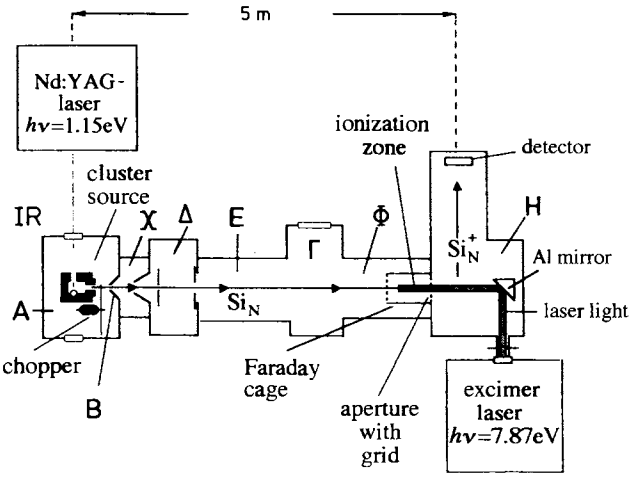

Figure 3. Schematic representation of the cluster beam apparatus. A = vacuum chamber, B = skimmer, X, Δ = differential pressure stages, E, Φ = flight tubes, Γ = experimentation chamber, H = mass spectrometry chamber.

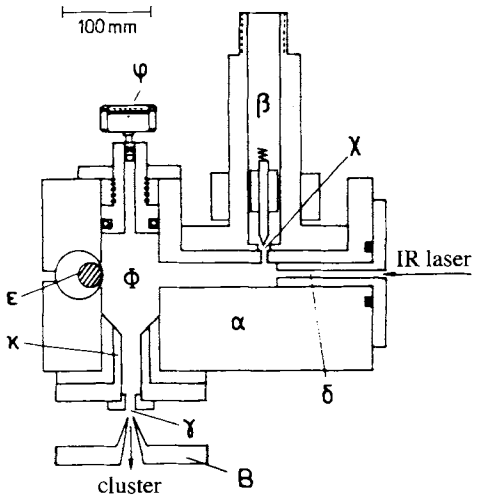

Figure 4. Molecular beam source for intense, pulsed beams of semiconductor clusters. α = housing, β = magnetic valve, χ = valve channel, δ = light introduction channel, γ = nozzle, ε = semiconductor rod, ϕ = condensation region, φ = pressure sensor, κ = nozzle channel, and B = skimmer. For operation, see text.

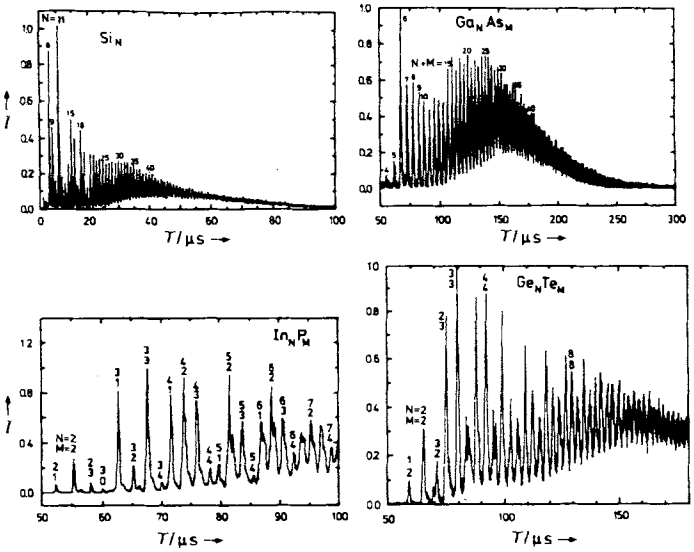

Figure 5. Mass spectra of semiconductor clusters prepared by pulsed laser evaporation of Si, GaAs, InP, and GeTe crystals in a stream of helium. The time of flight T in the flight tube of the mass spectrometer allows the calculation of the cluster mass ($M_C \propto T^2$), which in turn allows the determination of cluster sizes $X = N+M$ and compositions $N:M$.

In the housing (α), the helium carrier gas can enter the source through the pulsed magnetic valve (β) and the valve channel (χ). The pulsed IR laser beam, entering through the light introduction channel (δ), evaporates a little of the material from the slowly rotating semiconductor rod (ε). The short IR laser pulse, typically 15 ns long, contains a high pulse energy of typically 1 J and evaporates about 10^{-8} mol of the semiconductor material. In region (ϕ), the vapor condenses in the helium atmosphere ($p_{He} \approx 10$ mbar) to form clusters. The He density in the source can be monitored with the pressure sensor (φ), and the cluster distribution in the beam can be optimized. The clusters, dispersed in the carrier gas, flow through the nozzle channel (κ), leave the source through the nozzle (γ), and expand together with the helium into the vacuum chamber (A) (cf. Figure 3). The thus generated cluster beam passes through the first skimmer (B) and enters the differential pressure stages (X) and (Δ). It then passes through the flight tubes (E) and (Φ) as well as through the chamber (Γ), where the clusters can be studied under collision-free conditions. The clusters then pass into the chamber (H), where they are detected by a time-of-flight mass spectrometer. Typical mass spectra of semiconductor clusters are depicted in Figure 5. The time of flight T of the clusters in the flight tube of the mass spectrometer, a measure for the cluster mass M_C, is plotted on the x axis. The velocity v of the clusters and their residence time τ in the cluster source can be measured by using a rotating chopper. Typically one finds values of $v = 400-1200\ m\,s^{-1}$ and $\tau = 700-1200\ \mu s$.

2.1. Measurement of Permanent and Induced Dipole Moments in Molecular Beams

The dipole moment $\boldsymbol{\mu}$ of a particle isolated in a molecular beam can be determined through the force exerted on it by an inhomogeneous static electric field $\boldsymbol{E}_0$ (see Figure 6).[9, 10, 31, 32] The force that acts upon the cluster in an inhomogeneous electric field with z component $(\boldsymbol{E}_0)_z$ and corresponding field gradient $\partial(\boldsymbol{E}_0)_z/\partial z$ is given by $(\boldsymbol{F})_z = \mu\partial(\boldsymbol{E}_0)_z/\partial z$.[31] In order to examine this force, a collimated cluster beam is passed through an inhomogeneous electric field and the deflection of the beam due to the field's effect is measured after a given length of flight. The experimental setup of the deflection plates is schematically shown in Figure 6a. The clusters pass through the inhomogeneous electric field, which is located between the two bent brass

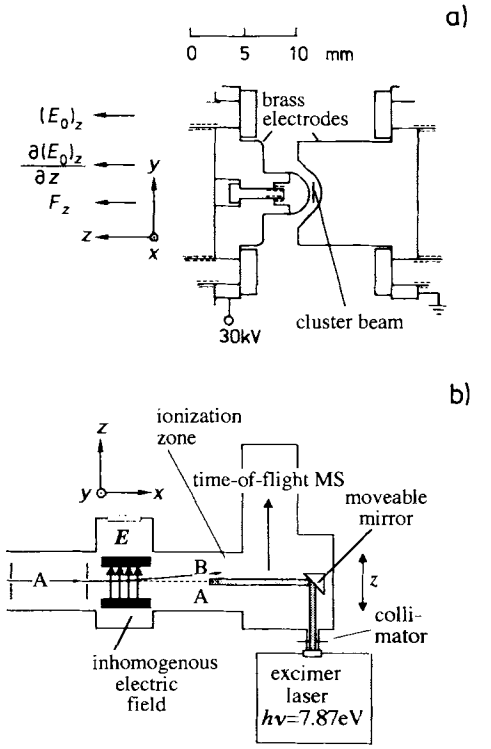

Figure 6. Experimental set-up of the apparatus for the measurement of static polarizabilities. a) Configuration of the high-voltage electrodes for the generation of the inhomogeneous electric deflection field. b) The clusters fly along beam A and are diverted in the inhomogeneous field E to direction B. The resulting beam B is sampled by the collimated ionization laser beam.

electrodes. The typical potential difference between the two electrodes is 30 kV. The deflections of the cluster beam generated in this way can be studied with a collimated pulsed ionization laser beam ($\lambda = 157$ nm, that is, a photon energy of $\hbar\omega = 7.89$ eV). The collimated ionization laser beam is directed into the Faraday cage of the mass spectrometer by means of an aluminum mirror. In the Faraday cage, the ionization of the clusters can occur in the absence of potentially interfering stray electric fields. The mirror can be moved along the z direction by step motors (Figure 6b). The UV laser beam can thus be shifted perpendicular to the molecular beam in the ionization zone. In this way, the cluster beam can be probed with laser light. The number of ionized clusters of a given size observed in the mass spectrum is proportional to their density in the sampled volume element of the Faraday cage. The mass spectra for the individual sampling positions are recorded with a multichannel analyzer and then stored. During the subsequent analysis, the intensity of a given mass can be determined for a given sampling position z. This way, an intensity profile can be measured for all cluster sizes. For particles with a permanent dipole moment, the two possible orientations of the dipole moment (parallel and antiparallel to the field) lead to a broadening of the molecular beam and, hence, to a decrease in the intensity along the beam axis.[9] Figure 7a demonstrates this effect for a Ge_2Te cluster. This

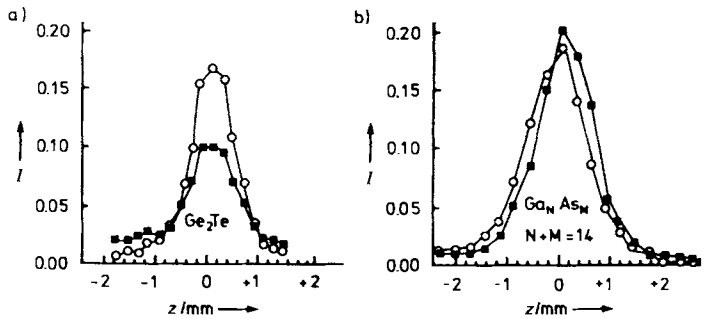

Figure 7. a) Comparison of a typical intensity profile of the undeflected beam A of Ge_2Te clusters with the field $\boldsymbol{E}$ turned off (circles) with that of the deflected beam B with the field $\boldsymbol{E}$ turned on (squares) (cf. Figure 6). b) The corresponding comparison for Ga_NAs_M clusters with $N+M=14$ and $N \approx M$. The sampling position z is varied by moving the Al mirror shown in Figure 6b.

broadening allows the determination of the permanent dipole moment of a cluster on using certain simplifying assumptions about the rotation of the cluster.[9, 33] The dipole moments obtained thus for Ge_2Te is $\mu = (1.4 \pm 0.2)$ Debye and for Ge_2Te_2 is $\mu = (1.1 \pm 0.1)$ D. This indicates C_{2v} symmetry for both Ge_2Te and Ge_2Te_2. In contrast to Ge_2Te and Ge_2Te_2, no measurable dipole moment is found for $GeTe_2$. This indicates that $GeTe_2$ possesses a linear structure, like its homologue CO_2. These symmetry considerations are supported by infrared spectra of Si_2S_2, a homologue of Ge_2Te_2, in a matrix[34] and recent quantum-chemical calculations of structures and dipole moments of small Ge_NTe_M clusters.[35] For those readers interested in theoretical quantum chemistry it should be noted that high-resolution molecular beam experiments to measure dipole moments of molecules are not only suitable for the study of molecular symmetries. These days, they are again employed to test the validity of more general symmetry principles in the theory of the electron.[36]

No effects attributable to permanent dipole moments are found for all larger Ge_NTe_M clusters studied ($4 < N + M < 25$). The same is true for the Ga_NAs_M and Si_N clusters studied.[9, 10] In this case, a shift of the molecular beam profile shown in Figure 7b for Ga_NAs_M clusters with $N+M=14$ and $N \approx M$ is observed. Due to the free rotation of the particles in the molecular beam, this experiment permits the measurement of the induced dipole moment $\boldsymbol{\mu} = \alpha_C(\boldsymbol{E}_0)_z$ and thereby the mean polarizability α_C of the clusters.

2.1.1. *Polarizability, Chemical Bonding, and Radical Electrons in Ga_NAs_M Clusters*

For Ga_NAs_M clusters, the polarizabilities were studied as a function of the cluster size $X = N+M$. To each cluster size $N+M$ observed in the mass spectrum in Figure 5 belongs a distribution of $N:M$ compositions with a maximum at $N \approx M$. Figure 8 shows that the mean polarizability per atom $\bar{\alpha}_C = \alpha_C/X$ exhibits regular oscillations as a function of the cluster size X.

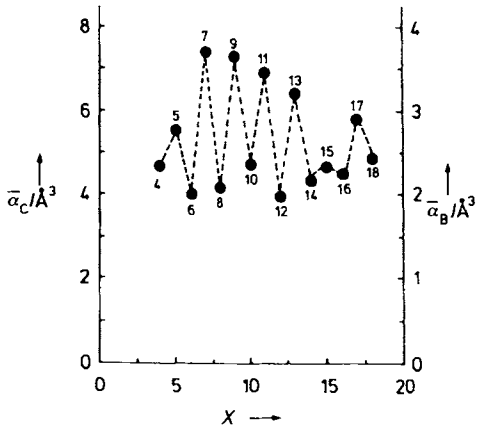

Figure 8. Measured polarizability for Ga_NAs_M clusters given as polarizability per atom $\bar{\alpha}_C$ (left ordinate) and as mean bond polarizability $\bar{\alpha}_B$ (right ordinate) as a function of the cluster size X.

The polarizability of clusters of an odd value for X is significantly larger than for those clusters with an even value for X. The values observed for odd-numbered clusters are rather high and are otherwise only found for typical metal clusters such as Na_N or K_N.[7, 37] The high polarizabilities for clusters with odd X values also affect the van der Waals forces between the Ga_NAs_M clusters and the inert gas atoms.[38] Similar odd–even effects have been observed for the ionization potentials (IPs)[27] and the electron affinities[28] of Ga_NAs_M clusters. One finds high ionization barriers for clusters with even X and low ones for odd X, and vice versa for the electron affinities. Figure 9 shows a simple MO scheme that explains this effect. The cluster Ga_3As_4 possesses an odd number of valence electrons and thus has an open-shell system of valence electrons. The unpaired (radical) electron also explains the high polarizabilities of these clusters. This electron is readily polarizable as it is not confined to a bond with another electron. It turns out, however, that even the contribution of the bonding electrons to the polarizability is affect-

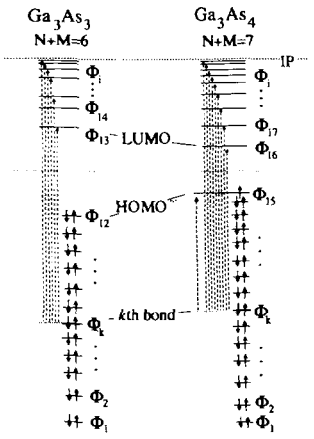

Figure 9. MO model for Ga_NAs_M clusters. Each occupied MO Φ_k can be assigned a bond or radical electron polarizability. The value of this bond or radical electron polarizability is calculated from the dipole-allowed transitions (dashed arrows), which lead from the occupied MO Φ_k into the higher-lying MOs Φ_i.

ed by the radical electron. This statement is supported by the correlation between polarizability and the chemical bonding. This correlation can be formulated with the MO model shown in Figure 9. Corrections to this approach, as well as the quantitative theoretical analysis of polarizabilities will not be discussed here, as they belong to the domain of theoretical quantum chemistry.[39]

From a chemical standpoint, the following model is appropriate: A Ga_NAs_M cluster with an even number of valence electrons $3N+5M$ (such as Ga_3As_3 in Figure 9) has $s=(3N+5M)/2$ ground-state MOs $\Phi_1, \Phi_2, \ldots, \Phi_k, \ldots, \Phi_s$ and infinitely many excited-state MOs $\Phi_{s+1}, \Phi_{s+2}, \ldots, \Phi_i, \ldots$. The energy of the cluster is calculated by adding the corresponding MO energies $E_1 \le E_2 \le E_3 \le \ldots$ according to $E = n_1E_1 + n_2E_2 + \ldots$, where $n_1, n_2, n_3, \ldots$ represent the occupation of the MOs $\Phi_1, \Phi_2, \Phi_3, \ldots$. In any given electronic state of a cluster, the occupation number n_t ($t = 1, 2, 3, \ldots$) takes on one of the values 0, 1, or 2. In the ground-state configuration of the cluster, shown on the left in Figure 9, the occupation numbers of the ground-state MOs are $n_k = 2$ and those of the excited-state MOs $n_i = 0$. Configurations for electronically excited states can be generated from this ground state by moving an electron from a ground-state MO Φ_k into an excited-state MO Φ_i (that is, by the transition $\Phi_k \rightarrow \Phi_i$). Such one-electron transitions can be used to generate all excited states (configurations) of the cluster from the ground state.

In the context of this description, the occupation of a ground-state MO Φ_k by $n_k = 2$ electrons means that a chemical bond is formed that stabilizes the cluster. The ground-state energy of the cluster can thereby be taken as the sum $E = 2E_1 + 2E_2 + \ldots + 2E_s$ of the energies $2E_k$ of all chemical bonds in the cluster. On this basis, the polarizability of a cluster can be correlated with its chemical bonds. One envisions that the chemical bonds are polarized in the z direction by the action of an infinitesimally small electric field $d(\boldsymbol{E}_0)_z$. The force of this applied electric field then leads to a small probability that the bonding electrons occupy the excited-state MOs Φ_i. This would lead to a change in the electron density in the bonds. If the transition dipole moment $M_{ki} = \int \Phi_k^* \hat{\mu}_z \Phi_i d\tau$ is not equal to zero, this change in the electron density generates an induced dipole moment and thereby a polarization of the bond. The basis for this polarization is that a change of $d(\boldsymbol{\mu})_z = \alpha d(\boldsymbol{E}_0)_z$ in the induced dipole moment $(\boldsymbol{\mu})_z$ leads to a reduction of the ground-state energy E by an amount $dE = d\boldsymbol{\mu}_z(\boldsymbol{E}_{0z})$. When this energy gain is integrated, one obtains for the decrease in the ground-state energy $\Delta E = -\alpha_C(\boldsymbol{E}_0)_z^2/2$. Hence, the polarizability is related to the second derivative of the ground-state energy with respect to the electric field $(\boldsymbol{E}_0)_z$ by the formula $\alpha_C = -d^2E/d(\boldsymbol{E}_0)_z^2$. As the energy E of the cluster comprises the sum of the energies $2E_k$ of its chemical bonds, the polarizability, too, is composed of the sum $\alpha_C = \alpha_1 + \alpha_2 + \ldots + \alpha_s$ of the polarizabilities of its constituent chemical bonds $\alpha_k = 2d^2E_k/d(\boldsymbol{E}_0)_z$. The additivity of the bond polarizabilities does not mean, however, that the bonds are independent of each other. Each chemical bond is situated within the chemical environment of the other bonds. This means that each bond can only be polarized by small electron shifts into unoccupied MOs, while shifts of electrons into the occupied MOs of the other bonds are forbidden by the Pauli principle. Quantum theory has a surprisingly simple formalism with which to describe this behavior. Using quantum-mechanical perturbation theory,[5] one can derive the formula for the bond polarizability: $\alpha_k = \sum_{i=s+1}^{\infty} 4|M_{ki}|^2/(E_i - E_k)$.[40] The summation takes into account all transitions $\Phi_k \rightarrow \Phi_i$, which can contribute to the polarization of the bond, because $M_{ki} \neq 0$. Usually one replaces the transition dipole moments M_{ki} by the oscillator strengths $f_{ki} = 2|M_{ki}|^2 m_0(E_i - E_k)/e^2\hbar^2$ known from spectroscopy, where m_0 is the rest mass of the electron in a vacuum. One thus obtains the formula (5),

$$\alpha_k = \sum_{i=s+1}^{\infty} 2\frac{e^2\hbar^2}{m_0}\frac{f_{ki}}{(E_i - E_k)^2} \qquad (5)$$

which describes the close relationship between spectroscopic properties of the cluster and the polarizable chemical bonds it contains. Every single bond polarizability α_k can therefore be correlated with excited-state MOs Φ_i, which are connected to the bonding MO Φ_k by dipole-allowed transitions ($f_{ki} > 0$). These transitions are shown schematically (dashed arrows) in Figure 9 for a selected bonding MO Φ_k. Each of these transitions contributes to the bond polarizability. Transitions into the ionization continuum need to be taken into account as well.

For clusters with an odd number of valence electrons, one obtains $s - 1 = ((3N+5M) - 1)/2$ bond polarizabilities and the polarizability $\alpha_s = \sum_{i=s+1}^{\infty} e^2\hbar^2 f_{si}/(E_i - E_s)^2 m_0$ of the radical electron. This additional polarizability of the radical electron is not the sole unusual characteristic of the open-shell clusters. The open shell allows the additional transitions $\Phi_k \rightarrow \Phi_s$ into the singly occupied HOMO. These transitions increase the bond polarizabilities by the amount $\Delta\alpha_k = (e^2\hbar^2/m_0)f_{ks}/(E_s - E_k)^2$.

For closed-shell clusters, the polarizabilities per atom shown in Figure 8 can be converted into mean bond polarizabilities by simply calculating the polarizability per electron pair, that is, $\bar{\alpha}_B = \alpha_C/((3N+5M)/2) \approx \alpha_C/2(N+M)$. Figure 8 indicates that the bond polarizability for closed-shell clusters is about 2.3 Å^3. If the radical electron is formally considered "half" a bond, the mean bond polarizability for open-shell clusters typically increases by 1 Å^3. This makes clear how a single defect electron can affect the chemical bonds and change a semiconductor cluster with up to 18 atoms into a metal-like cluster.[40] This is probably due to the strong shielding of the Coulomb potentials by the readily polarizable radical electron. The electrons are then not as strongly localized at the atomic cores or between atomic centers. Consequently, the bond polarizabilities increase, which in turn causes a further weakening of the Coulomb potentials. This transition from more strongly localized cova-

lent bonding to more delocalized metallic bonding yields the proper conditions for the earlier mentioned electron gas model (jellium model)[7] for metal clusters. It is, however, unrealistic to expect a perfect Coulomb shielding and free electron movement with the electron rest mass in a vacuum m_0. In fact, a correction is necessary for the alkali metals and is achieved by introducing an effective electron mass. The sequence of values for the alkali metals is enlightening. For Li $m_{eff}/m_0 = 1.33$, for Na 0.965, for K 0.86, for Rb 0.78, and for Cs 0.73: that is, for Na m_{eff} is approximately equal to m_0. A more detailed analysis[41,42] shows this to be due to a coincidental compensation of several effects. Nevertheless, Na_N clusters are considered ideal model systems for metal clusters, as solid state and cluster physicists[7,12] are more interested in the motion of electrons in fixed chemical environments. The main task of a description for physical chemistry must be to treat the cluster-size dependence of the chemical bonding as an additional variable and to study the consequences of this treatment on the electronic properties of the clusters. Hückel theory is a suitable starting point for this task. It can be employed effectively to describe orbital interactions of solid-state-like[19b,43,44] and molecular[45] chemical bonds.

2.1.2. *Bond Polarizabilities in Solid Si and Si_N Clusters with $N \approx 100$ Atoms*

Figure 10 shows the polarizabilities per atom $\bar{\alpha}_C = \alpha_C/N$ measured for silicon clusters. It is apparent that the bond polarizabilities of clusters with $N+M \approx 100$ are significantly smaller

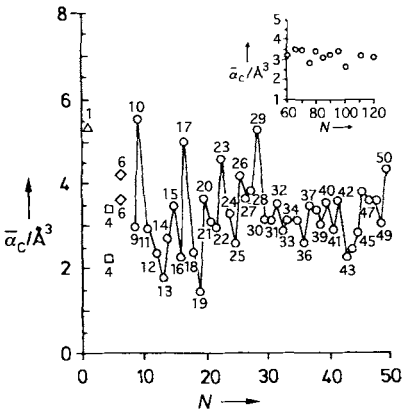

Figure 10. Polarizabilities per atom $\bar{\alpha}_C$ of Si_N clusters (circles). Inset: values for large Si_N clusters. Squares and diamonds: polarizabilities calculated from theory according to Rubio et al. [4] for the two isomers of Si_4 and Si_6 from Figure 1d). The two upper values belong to D_{2h} and D_{4h} symmetry of the two clusters Si_4 and Si_6, respectively. Triangle: theoretical values for the atom [31].

than those found for the solid state. The mean bond polarizability $\bar{\alpha}_{B,C}$ in the cluster is determined by dividing the experimentally found polarizability by the number of bonds present. The bond polarizabilities of large silicon clusters with $N \approx 100$ and $R \approx 0.8$ nm lie around 1.6 Å^3 and are therefore significantly smaller than the bond polarizability $\bar{\alpha}_{B,F} = 1.85$ Å^3 of the chemical bonds in the solid state, which can be calculated from the Clausius–Mosotti relationship [Eq. (4)] and the dielectric constant $\varepsilon = 12$. On first glance, it could be assumed that the changed bond polarizability mirrors the transition from the solid-state-like bonding structure to a more molecular bonding. A more detailed consideration, however, shows that this conclusion must be somewhat modified. The simple spatial confinement of a solid-state-like network of chemical bonds is sufficient to explain the observed bond polarizability: first one considers how the dielectric properties of a semiconductor can be derived from its chemical bonds. The electric susceptibility χ of a solid is defined by the linear relationship $\boldsymbol{P} = (\chi/4\pi)\boldsymbol{E}$ between the induced dipole density $\boldsymbol{P}$ and the electric field strength $\boldsymbol{E}$.[12d] The induced dipole moments stem from the polarizable chemical bonds between the semiconductor atoms. To quantify this bond polarization,[19c] each bond between two neighboring Si atoms μ and ν is assigned a valence bond orbital (VB) $\boldsymbol{\Phi}_k = (\phi_\mu + \phi_\nu)/\sqrt{2}$, which is formed by two overlapping sp^3 hybrid orbitals ϕ_ν and ϕ_μ. The antibonding orbital (VAB) is constructed analogously as $\boldsymbol{\Phi}_i = (\phi_\mu - \phi_\nu)/\sqrt{2}$. For each of the $s = 2N$ valence bonds between pairs of atoms in the crystal one thus obtains one VB and one VAB. The s VBs $\boldsymbol{\Phi}_1, \boldsymbol{\Phi}_2, \ldots, \boldsymbol{\Phi}_s$ and s VABs $\boldsymbol{\Phi}_{s+1}, \boldsymbol{\Phi}_{s+2}, \ldots, \boldsymbol{\Phi}_{2s}$ form a basis for an approximate description of the bonding in the solid state. If the overlap of the VB of one bond with the VBs and VABs of all other bonds is neglected, the bond polarizability is only described by the two electrons in the VB in question and their transitions into the VAB. In this purely local description, the VBs all have the same energy $E_1 = E_2 = \ldots = E_s$, as do the VABs ($E_{s+1} = E_{s+2} \ldots = E_{2s}$). The difference between the VAB and VB energies, which stems from the orbital interaction of the two sp^3 orbitals ϕ_ν and ϕ_μ, is termed $2E_{B,loc}$. With this approximation for the chemical bond, an expression for the static electric susceptibility can be derived,[19d] which can be written as $\chi_{B,loc}(0) = \hat{n}_B e^2 g^2/6E_{B,loc}$. Here, $\hat{n}_B$ stands for the density of the bonds, and g for the lattice constant. For silicon, the values obtained are $E_{B,loc} = 2.98$ eV, $g = 2.35$ Å^3, $\hat{n}_B = 1 \times 10^{23}$ cm^{-3}, and $\chi_{B,loc} = 0.45$; that is, $\varepsilon_{loc} = 1 + 4\pi\chi_{B,loc} = 6.58$.[19e] The value calculated thus for $\varepsilon_{B,loc} = 6.58$ is much smaller than the experimental value (12). Apparently, a more detailed theoretical treatment of this problem is required. The next best approximation takes into account the transitions and orbital interactions between VB and neighboring VABs. Within perturbation theory, the VB–VAB interaction with adjacent and once-removed bonds must be considered. One thus calculates a new corrected, partially delocalized VB, that has been termed an extended bond orbital.[19f] The occupation probability density for this partially delocalized VB is shown schematically in Figure 11a. The partial delocalization is reflected in a sort of corona, which has formed around the center of the bond. In the same fashion, one can obtain a corrected extended VAB. The calculation of these corrections requires a quantum-mechanical perturbation calculation and yields a correction factor for the susceptibility. In solid-state theory, this factor is usually represented by a number $\gamma^2 > 1$. I will use the same nomenclature and correlate the high experimental susceptibility of silicon with the partial delocalization of the chemical bonding in the solid. The susceptibility can be written as $\chi_{B,deloc} = \gamma^2_{deloc}\hat{n}_B e^2 g^2/6E_{B,loc}$, where the number γ^2_{deloc} acts as the correction factor. For silicon, the values for the experimental dielectric constant $\varepsilon = 12$ and $\varepsilon_{loc} = 6.6$ leads to a value for γ_{deloc} of $((\varepsilon-1)/(\varepsilon_{loc}-1))^{1/2} = 1.4$. For other semicon-

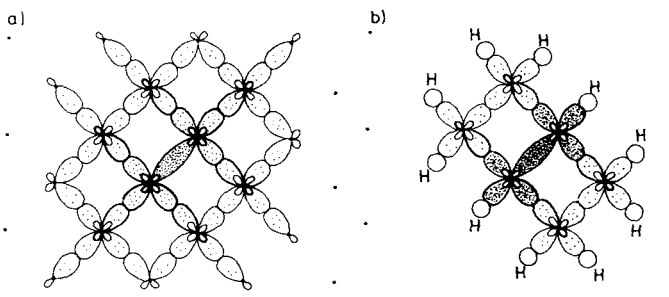

Figure 11. a) Schematic representation of the environment of a Si–Si bond in the solid state. The density of the dots represents the probability of locating the bonding electrons at any given point. These electrons can also occupy the VABs of neighboring bonds. The corresponding probability for an immediately neighboring VAB is about 3%, and still about 1% for a once-removed VAB. b) The extent of the chemical bond is significantly reduced in nanocrystallites.

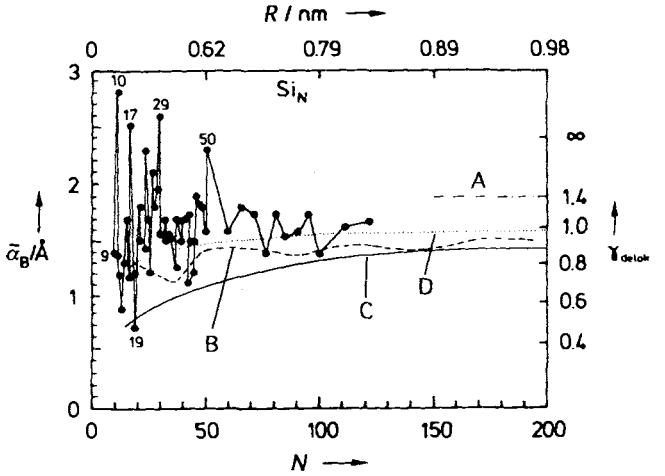

Figure 12. Comparison of the mean bond polarizabilities $\bar{\alpha}_B$ of free Si_N clusters (black dots) with the value for the solid state according to ref. [4] (A, ·····) and the theoretical results for the nanocrystallites: Hückel theory [46] (B, – – –), quantum well model I [48] (—), and quantum well model II [49] (· · · · ·).

ductors, the values fall typically within the range between $\gamma_{deloc} = 1.13$ for diamond and 1.85 for indium antimonide.[19c] These values imply a weaker delocalization for the bonding in diamond and a more strongly delocalized bonding in indium antimonide. The polarizability $\bar{\alpha}_{B,F}$ is connected to the dielectric constant by the expression of Clausius and Mosotti [Eq. (4)]. The value $\varepsilon = 12$ (that is, $\gamma_{deloc} = 1.4$) corresponds to a mean bond polarizability of $\bar{\alpha}_{B,F} = 1.85$ Å^3. The value for $\bar{\alpha}_{B,F,loc}$ of 1.61 Å^3 (valid for $\varepsilon = 6.58$, which represents the idealized, purely localized bonding with $\gamma_{deloc} = 1.0$) is correspondingly smaller. Interestingly, this value is in very good agreement with the experimental value $\bar{\alpha}_{B,F,loc} = 1.6$ Å^3 found for large clusters of $N \approx 100$ atoms. This agreement can be understood within the framework of the concepts of chemical bonds and their polarizabilities that have been developed here, as the partial delocalization of the chemical bonds must decrease together with the cluster size. This situation can be visualized by imagining a cluster that has been "cut" out of the solid-state bonding structure shown in Figure 11a. As simplification the broken local Si–Si bonds are taken to be saturated, for example with H atoms, to stabilize the structure. This is shown schematically in Figure 11 b. In this way, a small Si_NH_M crystallite has been generated.[46] The average number of nearest and next-nearest neighboring Si–Si bonds is reduced in this crystallite relative to the solid state. Consequently the delocalization parameter is reduced from the solid-state value of $\gamma_{deloc} = 1.4$ to, in extreme cases, $\gamma_{deloc} = 1.0$ in the cluster. Exactly this modification for the cluster explains the approximate agreement between $\bar{\alpha}_{B,C}$ and $\bar{\alpha}_{B,F,loc}$. The same result is obtained from a detailed Hückel calculation for Si_NH_M nanocrystallites.[46] The corresponding bond polarizabilities are shown in Figure 12. It is clear that they agree well with the experimental results for the large silicon clusters and that they correspond to a delocalization parameter γ_{deloc} of about 1.0 in our simple bonding model.

It is important to note that the changes in the bond polarizability discussed above are correlated to the known size quantization effect in the absorption spectrum. Those readers versed in the electrodynamics of continua will realize that this correlation stems from the Kramers–Kronig theorem,[12b] which relates static and dynamic polarizabilities or susceptibilities. For the experimental scientist it is helpful to develop this correlation with reference to an actual model. In the solid state, the energies $E(\boldsymbol{k})$ of the electron wave MOs having the wave vector $\boldsymbol{k}$ are so close to each other that one does not speak of energy levels but of energy bands.[44] In semiconductors, all valence band MOs are occupied by two electrons, while the conduction band MOs are empty (Figure 13a). The lower edge of the conduction band $E_c(\boldsymbol{k})$ is separated from the upper edge of the valence band $E_v(\boldsymbol{k})$

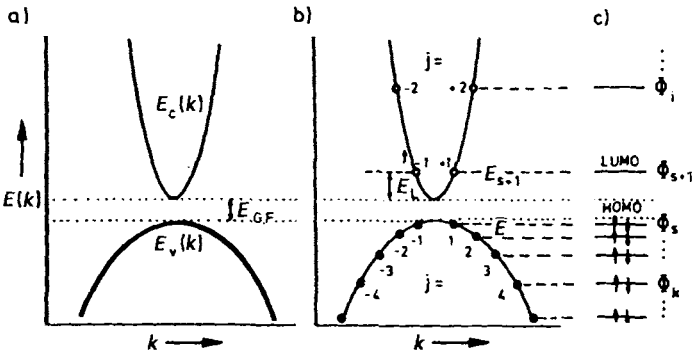

Figure 13. a) Two-band model of an infinitely extended semiconductor with conduction $E_c(k)$ and valence bands $E_v(k)$. b) Simple model for the quantization of the radial wave vector k and the energies for a spherical semiconductor cluster. One can associate each discrete value of k_j with standing spherical waves of radial wavelengths $\lambda_j = 2\pi/k_j$, which represent the MOs in c).

by the band gap (HOMO–LUMO gap), $E_{G,F}$. In solid state theory, an approximate expression for the course of a band in an isotropic semiconductor can be obtained by expanding the function $E(k) = E(|\boldsymbol{k}|)$ into a Taylor series according to Equation (6) for the magnitude of the wave vector $\boldsymbol{k} = |\boldsymbol{k}|$ around

$$E(k) = E(k)_{k=0} + (1/2!)(\partial^2 E(\boldsymbol{k})/\partial k^2)_{k=0} k^2 + \ldots \quad (6)$$

$k = 0$ and terminating the series after the quadratic term. The curvature of the band at $k = 0$ defines an effective mass. The curvature of the conduction band defines the electron mass $m_{eff,e} = \hbar^2/|\partial^2 E_c(\boldsymbol{k})/\partial \boldsymbol{k}^2|_{k=0}$, while that of the valence band defines the mass of the hole $m_{eff,h} = \hbar^2/|\partial^2 E_v(\boldsymbol{k})/\partial \boldsymbol{k}^2|_{k=0}$. On use of the two-band model, the static susceptibility of the semi-

conductor can be calculated according to D. R. Penn.[47] The electric susceptibility of the solid is expressed as $\chi = 2\hbar^2 e^2 \hat{n}_B / m_0 E^2_{G,Penn}$ and is therefore indirectly proportional to the square of the excitation energy $E_{G,Penn}$ required to generate excited electron waves within the semiconductor. The band gap $E_{G,Penn}$ can be empirically determined by the energy $\hbar\omega_{G,Penn}$, which describes the center of the absorption spectrum of the Si crystal.[47] This approach takes into account that the complicated band structure of the semiconductor is approximated by only two bands. For silicon, the literature cites values for $E_{G,Penn}$ of 4.7 eV, significantly above the regular band gap for Si of $E_{G,F} = 1.2$ eV. It is possible to transfer the two-band model for the electric susceptibility of semiconductors to clusters as well.[48] To do this, one envisions the electron waves in a spherical potential well of radius R and with infinitely high walls. The wave functions are standing spherical waves, which have a node at the edge of the potential well and vanish outside this edge. This is possible only for certain discrete values for the radial wave vector $\boldsymbol{k}_j = j\pi/2R$ where $j = \pm 1, \pm 2, \pm 3, \ldots$, and those energies $E(\boldsymbol{k}_j)$ that are marked by dots or circles in Figure 13b. An exact three-dimensional analysis[17] of the state with $j = 1$ in the conduction band yields the localization energy E_L of Equation (3). The corresponding MO scheme in Figure 13c shows, in addition, that with increasing localization energy E_L, the difference in energy $E_{G,C} = E_{s+1} - E_s$ between the HOMO $\boldsymbol{\Phi}_s$ and the LUMO $\boldsymbol{\Phi}_{s+1}$ also increases as R decreases (that is, as k_1 increases). This energy difference can become significantly bigger than the solid-state value of $E_{G,F}$. The susceptibility therefore decreases sharply with a decrease in R (see quantum well model I in Figure 12). This tendency causes a blue shift of the absorption edge as $R \rightarrow 0$ and a decrease in the static bond polarizability according to Clausius and Mosotti [Eq. (4)]. The decrease in the susceptibility caused by the localization of the molecular orbitals in the potential well is also observed in a more detailed model (cf. quantum well model II in Figure 13).[49]

The size quantization effect in the bond polarizabilities observed in the molecular beam is also of technological interest as it affects the defect conductivity in nanostructured semiconductors.[46, 49] For this reason it is particularly important for the electrochemistry during etching of semiconductor structures, for example in the electrochemical preparation of nanostructured porous silicon.[50]

2.1.3 *Small Si_N Clusters with Individual Bond Polarizabilities*

In the case of smaller clusters, other effects on the bond polarizabilities become noticeable. The polarizabilities of these clusters are very specifically dependent on the cluster size and cannot be correlated with size quantization effects. In particular, these polarizabilities can also not be related to those of diamond-like structures. This statement is supported by quantum-chemical calculations for the clusters Si_4 and Si_6.[4] The polarizabilities for the two pairs of isomers shown in Figure 1d were calculated. The values obtained thus for the polarizabilities are included in Figure 10 and fit well into the curve for the measured values for $N > 8$. This shows how sensitively the polarizability depends on the chemical bonding in the cluster. The chemical bonding must change with the cluster size to stabilize the individual geometric structure for each new cluster size. As the size quantization effects in the static polarizability vanish with decreasing cluster size, it is interesting to study the corresponding change in the absorption spectra of the clusters. These experiments were performed on Ga_NAs_M clusters,[51, 52] because the corresponding cluster beams exhibit an unusually high intensity stability.

2.2. Absorption Spectroscopy of Isolated Semiconductor Clusters

The absorption spectra reflect the eigenvibrations of the dipole moment, which can be excited by the oscillating electric field of light. If the excitation frequency satisfies the condition $\hbar\omega = E_i - E_k$ for a dipole-allowed transition $\boldsymbol{\Phi}_k \rightarrow \boldsymbol{\Phi}_i$, the induced dipole moment vibrates in resonance with the oscillating electric field. One can imagine that every chemical bond has a specific, frequency-dependent polarizability $\alpha_k(\omega)$, which determines how strongly the bond can be polarized by the excitation frequency ω. Similar arguments are valid for the radical electron polarizability of open-shell clusters. However, with clusters a problem arises: even the absorption of a single quantum of light leads to a photodissociation.[24, 51, 52] This problem is related to the fact that the electronic transition occurs from a bonding into an antibonding orbital, which therefore destabilizes the cluster. The deflections of the cluster fragments (B and C in Figure 14) that are generated in such a photoinduced dissociation are very large, due to the kinetic energy released. As the probability of the fragments' reaching the narrow detection zone is negligible, only a weakening of the cluster signal along the beam axis is observed. However, this photodissociation enables size-selective absorption spectroscopy on the clusters under study.

2.2.1. *Absorption Spectra and Radical Electrons in Small Ga_NAs_M Clusters*

Figure 14 shows the experimental setup for the measurement of the photon absorption cross sections. The absorption of a photon leads to the photodissociation of the cluster. The cluster fragments B and C depart from the beam axis A upon dissociation, and an attenuation of the original intensity in the mass

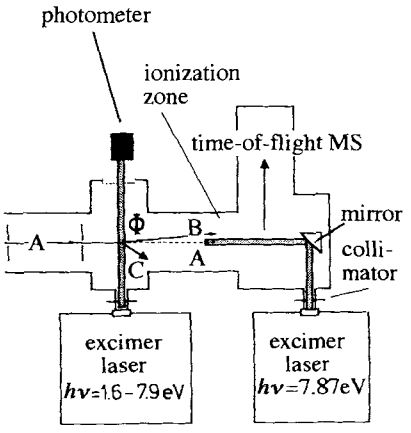

Figure 14. Experimental set-up for the measurement of absolute absorption cross sections of Ga_NAs_M clusters. The clusters fly along path A, fragment into the pieces B and C after absorption of a photon and miss the collimated ionization laser beam.

spectrum is observed when the excitation laser is turned on. This effect allows the determination of the absolute cross section $\sigma_{abs}(X)$ for the photodissociation of a cluster of size X. First the cluster beam intensities $I(X)$ and $I_0(X)$ are determined for the experiment with and without incident laser light. According to the quantum theory of absorption processes,[43, 51] the absolute cross section is calculated according to $\sigma_{abs} = (1 - I(X)/I_0(X))/\Phi$. The photon flux Φ in the interaction zone can be measured by photometer (Figure 14). The five absorption energies $\hbar\omega = 1.6, 3.5, 4.0, 5.0, 6.4$ eV are accessible in this experiment. For a photon energy of $\hbar\omega = 6.4$ eV, the photoionization cross section must be taken into account as well. This can be done by turning off the ionization laser and counting the cluster cations generated by the excitation laser. The measured photoionization yields for the isolated clusters can be a factor of 100 higher than those found for the solid state.[51] In contrast, the fluorescence yields are very low. The fluorescence of a range of clusters with between 3 and about 100 atoms was examined as a possible third reaction pathway.[51, 52] The fluorescence yields in the entire wavelength region from 400 to 900 nm are smaller than 3% and therefore much smaller than that found for GaAs crystals, which show yields of up to 99%. They are also significantly smaller than the yields for semiconductor colloids[1] and ligand-stabilized polyhedral semiconductor molecules.[53] The different chemical bonding in the isolated semiconductor clusters apparently permits a nonradiative relaxation. This conclusion is also supported by theoretically calculated potential curve schemes for electronically excited states of very small semiconductor clusters such as In_2Sb.[54]

The absorption cross sections per atom $\bar{\sigma}_{abs,C} = \sigma_{abs}/X$ for small clusters are depicted in Figure 15a for three cluster sizes and for a range of discrete photon energies. The dipole-allowed transitions shown in Figure 9, which contribute to the bond and radical electron polarizability, become noticeable in these absorption spectra. It is striking that the intensity of the absorption changes significantly with the cluster size. One observes that the absorption by the radical electron for all clusters with $X = 5$ to 11 (shown in Figure 15 for 5–7) is enhanced over the entire energy range. There are no bands in the spectra, however, that could be directly assigned to the radical electron. Such bands can be observed, for example, in salt clusters with an excess electron, such as $Na_{N+1}F_N$.[6] This leads us back to the concept, developed in Section 2.1.1, that the radical electron in the Ga_NAs_M clusters can effect a transition to a more metallike bonding. In this metallic bonding, the radical electron polarizability α_s does not only contribute directly to the polarizability of the cluster, but also enhances the bond polarizabilities α_k by increasing the corresponding oscillator strengths f_{ki} according Equation (5).

2.2.2. Optical HOMO-LUMO Band Gaps of Large Ga_NAs_M Clusters with About 80 Atoms and of Colloids

Figure 15b shows the absorption spectrum of Ga_NAs_M clusters with 80 atoms. For comparison, a spectrum calculated from the solid-state dielectric constant $\varepsilon(\omega)$ with Mie theory is shown as well.[51, 52] It is apparent that the increase in the absorption is blue-shifted relative to the edge expected from the solid, as expected from the size quantization effect (cf. Figure 13). For

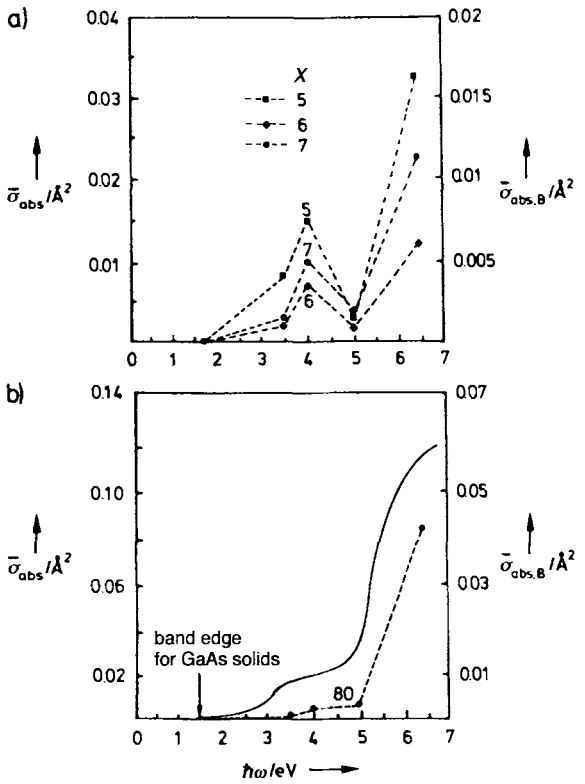

Figure 15. Mean UV/Vis absorption cross sections per atom $\bar{\sigma}_{abs}$ and per bond $\bar{\sigma}_{abs,B}$ for three small Ga_NAs_M clusters ($X = N+M$) (a) and for large clusters with $X = 80$ atoms (circles and dashed line). For comparison, the absorption spectrum of a solid-state-like GaAs sphere composed of 80 atoms, as calculated with Mie theory [51], is shown as well (solid line).

semiconductor colloids it is customary to estimate an effective optical HOMO–LUMO gap $E_{G,C}$ from optical spectra and plot it as a function of the colloid diameter, in order to quantify the observed blue shifts. The result of such an estimate of the effective optical HOMO–LUMO energy is plotted in Figure 16 for isolated clusters, GaAs colloids,[25] and for a GaAs molecule.[26] The detailed analysis is given in reference [51]. For the small clusters with a radical electron, one observes a reduced effective HOMO–LUMO gap. The theoretical calculations[22] mentioned earlier yield excited states for the clusters Ga_2As_3 and

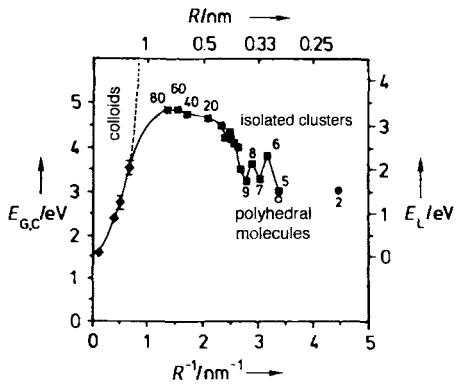

Figure 16. The size $E_{G,C}$ of the effective optical HOMO–LUMO band gap of Ga_NAs_M clusters as function of the cluster size $X = N+M$. The parabolic curve (dashed line) for the band gap energy according to the quantum well model by L. E. Brus [17] is shown for comparison. The calculated value for Ga_2As_3 [22], as discussed in the text, is also shown (circle at $X = 5$).

Ga_3As_2 with D_{3h} symmetry between 0.3 and 2.9 eV above the ground-state energy. In this calculation the most intense transition for Ga_2As_3,[22] for example, is found at $\hbar\omega = 2.8$ eV. One observes that the estimated effective optical HOMO–LUMO gap for $X = 5$ agrees fairly well with the theoretical value[22] for the intense transition at $\hbar\omega = 2.8$ eV.

The localization model [Eq. (3)] describes the results for larger colloids very well, when the solid-state value for the effective mass m_{eff} of $0.07\,m_0$ is used. For smaller particles, there are deviations from the simple localization model. Based on the usual Hückel models with size-independent parameters the HOMO–LUMO gap of a solid-state-like colloid is expected to rise steadily due to the decrease of the average bonding coordinates with a decrease in the radius R. Even though the HOMO–LUMO gaps of the larger clusters follow the values found for colloids fairly well, for clusters with less than 60 atoms the opposite behavior is observed. Hence, the Hückel parameters, and dependent on them the chemical bonding, must change markedly with the cluster size.

2.2.3. Optical HOMO–LUMO Band Gaps and the Transition from Solid-State-Like to Molecular Clusters

It has already been shown that the effective mass of the electrons in a solid can be viewed as a property of the chemical bonding. An approximate expression for the effective mass for electrons in the conduction band is given by the Hückel theory of the solid state[19a] [Eq. (7), in which the influence of the bond

$$m_{eff} = [1 + (2\gamma^2_{deloc} m_0 g^2 E^2_{B,loc}/\hbar^2 E_{L,F})]^{-1} m_0 \qquad (7)$$

polarity has been neglected as it is not relevant to the discussion below]. The formula shows that the effective mass can only be a constant for very large crystallites. It was shown when static polarizabilities were discussed that the solid-state-like bonding is already slightly modified by localization in the cluster. According to the bonding model developed in Section 2.1.2, a decrease in the radius R causes the parameter γ_{deloc} to change from the solid-state value γ_{deloc} for GaAs of 1.6 to 1.0. This slight change in the solid-state-like chemical bonding alone can lead, according to Equation (7), to a change in the effective mass upon a decrease in the cluster radius R. It is therefore useful to study how the effective mass m_{eff} in Equation (3) must be modified to yield agreement with experimental results. It must also be noted that with decreasing cluster radius R, the two-band model in Figure 13 is no longer valid in its strict theoretical solid-state definition. The values for the wave vector k_j become too large to be accounted for by the quadratic term of the Taylor series [Eq. (6)]. Thus, the effective mass of the electron can no longer be defined as the curvature of the conduction band $E_c(k)$ of a solid. Based on the foregoing discussion, however, we are particularly interested whether the concept of a localization energy can be maintained for small clusters by interpreting Equation (3) in the context of the quantum-chemical model of an electron in a box. The result of the adaptation of Equation (3) to fit the experimental results in Figure 16 is shown in Figure 17. The effective mass remains initially constant at the value for the solid state and then slowly increases with decreasing cluster radius R. For the smallest clusters, the effective mass m_{eff} reaches the value of the rest mass of the electron in a vacuum m_0. In the microscopic range, $m_{eff} \approx m_0$, as was initially assumed based on the polyhedral structures present. In the transitional range, m_{eff} follows a simple exponential expression [Eq. (8), where

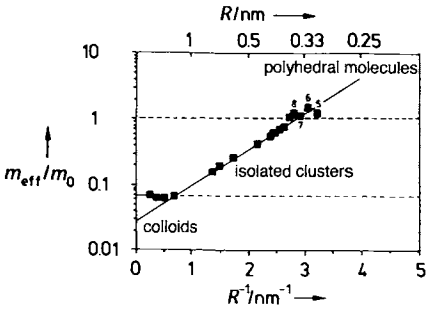

Figure 17. Effective mass based on the analysis of the experimental data of the effective optical HOMO–LUMO band gap $E_{G,C}$.

$$m_{eff} = m_U \exp(R_U/R) \qquad (8)$$

$m_U = 0.033\,m_0$ represents a characteristic mass and $R_U = 1.24$ nm a characteristic length] with a high degree of accuracy.

Based on these considerations it can be seen how the size quantization effects disappear together with the solid-state-like bonds. A small effective mass of the electron causes the most distinct size quantization effects for nanoparticles, based on Equations (2) and (3), and then leads to very significant changes in the smaller clusters so that the HOMO–LUMO gap can decrease to reach typical molecular values. A small effective mass is guaranteed by extended chemical bonds and strong orbital interactions in the semiconductor, that is, by large values of γ_{deloc} and $E_{B,loc}$. This forms the basis for the strongly increasing energy of the excited-state MOs upon increasing localization in the nanometer-sized clusters. This high localization energy cannot leave the chemical bonding unaffected as excited-state MOs and ground-state MOs are inexorably linked by quantum theory. This becomes particularly clear by the description in terms of extended VBs and VABs (see Section 2.2.1). In Hückel theory, the extended VABs take on the role of the Wannier orbitals φ.[19f,g] It was shown in Section 2.1.2 that not only the Wannier orbitals φ or the extended VABs in the cluster become localized, but that the localization also applies to the extended VB orbitals. This description makes it particularly clear that the spatial extent of an excited-state orbital is directly linked by quantum theory to the ground-state orbitals. When the excited-state orbital becomes more localized, the chemical bond is affected as well. The modification of the chemical bonding by the localization is already noticeable in the bond polarizabilities of nanometer-sized silicon clusters. Once sizes fall below the nanometer range, these modifications become so strong that the chemical bonding in its original form becomes unstable and different types of bonding arise. Quantum-mechanical simulations[55] on Si_N clusters with 20 to 45 atoms, for example, yield spherical structures (Figure 18) that resemble neither the solid-state-like structures of colloids nor the simple polyhedral structures of small clusters. They therefore support the concept developed here.

The high localization energy of the excited-state MOs can be reduced by changes in the chemical bonding upon a decrease in

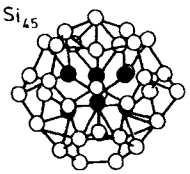

Figure 18. Suggested structure for a cluster composed of 45 silicon atoms [55]. For clarity, atoms in the interior of the cluster are depicted in black, while those on the surface are shown in white.

cluster size. This can be observed in the form of a red shift for the smaller clusters of 10 to 60 atoms (Figure 16). The strong decrease of the localization energy and the disappearance of the size quantization effects have been formally connected with the exponential increase of the effective mass. This enables a smooth transition $m_{eff} \rightarrow m_0$ with decreasing R in the relatively small interval $1.7\ nm > R > 0.4\ nm$.

3. Summary

The results of the experiments and the physical chemistry considerations can be graphically depicted by the diagram shown in Figure 19. It shows a comparison between the characteristic orbital radius a according to Equation (1) and the cluster

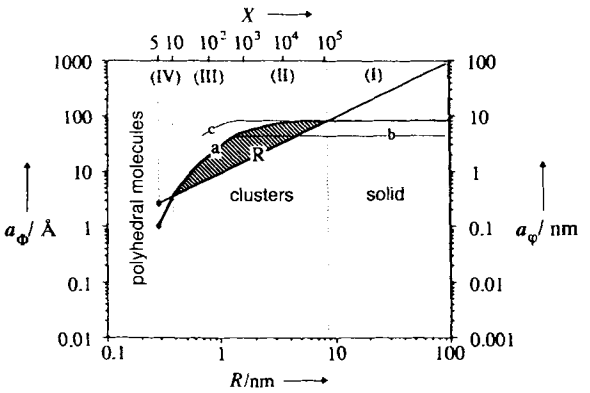

Figure 19. a) The characteristic electron orbital radius a as a function of the reciprocal cluster radius R. The corrections discussed in the text for the size dependence of the effective mass according to Figure 17 and of the dielectric constant as outlined in Section 2.1.2 were taken into account in Equation (1). For comparison, curve c shows the dependence of the Bohr radius on changes in the effective mass alone for the values $\varepsilon = \varepsilon_\infty = 11$, whereas curve b shows the corresponding effect for $\varepsilon = \varepsilon_{\infty,bulk} = 5$. In the transitional range between molecule and solid state structures, $a < R$ (hatched region), and size quantization effects occur. On the left edge, a takes on the typical extent of an excited-state orbital Φ (about 1–3 Å). On the right edge, as expected from its definition, a approaches the exciton Bohr radius of the Wannier orbital φ_1 (approximately 8 nm).

radius R for the GaAs system. In region (I), where $X > 10^5$ ($R > 8$ nm), the typical partially delocalized bonds of the macroscopic semiconductor with $\gamma_{deloc} = 1.6$ are found. This bonding yields the solid-state values $m_{eff} = 0.07\ m_0$ and $\varepsilon = 11$. One obtains $a < R$ and, hence, no significant localization energy E_L. This changes upon moving to region (II) where $10^5 > X > 10^3$ ($8\ nm > R > 1.7\ nm$). The extended chemical bonds of the semiconductor are slightly modified by localization in the cluster. The delocalization parameter γ_{deloc} decreases from right to left in region (II) from $\gamma_{deloc} = 1.6$ to about 1.0. This causes a decrease of ε from 11 to about 5. Although the solvation energy E_S in Equation (3) increases by a factor 11/5, it remains negligible with respect to the localization energy E_L. The effective mass remains at its solid-state value of $m_{eff} = 0.07\ m_0$. Under these conditions, one finds particularly strong size quantization effects, as $a \gg R$. This implies a large localization energy because the orbitals φ must be strongly compressed to fit into the cluster. In region (III), where $10^3 > X > 10$ ($1.7\ nm > R > 0.4\ nm$), the transition from the localized, solid-state-like bonding to a molecule-type bonding takes place. This leads to the exponential growth [Eq. (8)] of $m_{eff} = 0.07\ m_0$ to $m_{eff} \approx m_0$. The chemical environment of the excited electron changes so strongly, that the inertia of the electron increases by an order of magnitude, while the localization energy decreases correspondingly. One can envision a more electrophilic chemical environment for the electron, which is in agreement with the observed increase in electron affinity.[28] This change in the chemical environment accompanies an exponential decrease of the orbital radius a, so that for $X \approx 10$ ($R = 0.4$ nm), the orbital radius a [Eq. (1)] again becomes smaller than R, and size quantization effects disappear in region (IV) for polyhedral molecules with $10 > X \geq 5$. In this manner, it becomes possible to understand the transformation of the Wannier orbitals φ of the crystalline semiconductor into the excited-state molecular orbitals Φ in the polyhedral semiconductor clusters.

I wish to thank Prof. Dr. F. Hensel for his generous support of my work and for many discussions about chemical bonding in metals and semiconductors. Prof. W. A. de Heer is acknowledged for my time with him at the ETH Lausanne, where I learned about metal clusters. I thank Prof. Dr. H. Weller for the discussions about quantum size effects. I am particularly indebted to my students Dr. M. Weibels, Dr. J. Woenckhaus, Dr. R. Schäfer, S. Schlecht, S. Pokrant, my post-doctoral fellows Dr. E. Marceca, Dr. M. Sakurai, Dr. T. Hihara, as well as to our technician A. Rödig for their numerous contributions to the work presented here. The Deutsche Forschungsgemeinschaft (DFG) is acknowledged for a research stipend and the support of our work (SFB 383 'Disorder in Solids on Mesoscopic Scales' and the project 'Specific Phenomena in the Chemistry of Si'). The Fonds der Chemischen Industrie is also acknowledged for support. The Wacker-Chemitronic company (Burghausen) is acknowledged for the gift of a silicon crystal. I also thank the Klein & Becker company (Idar-Oberstein) for the free preparation of high-precision ceramic and crystal structural units.

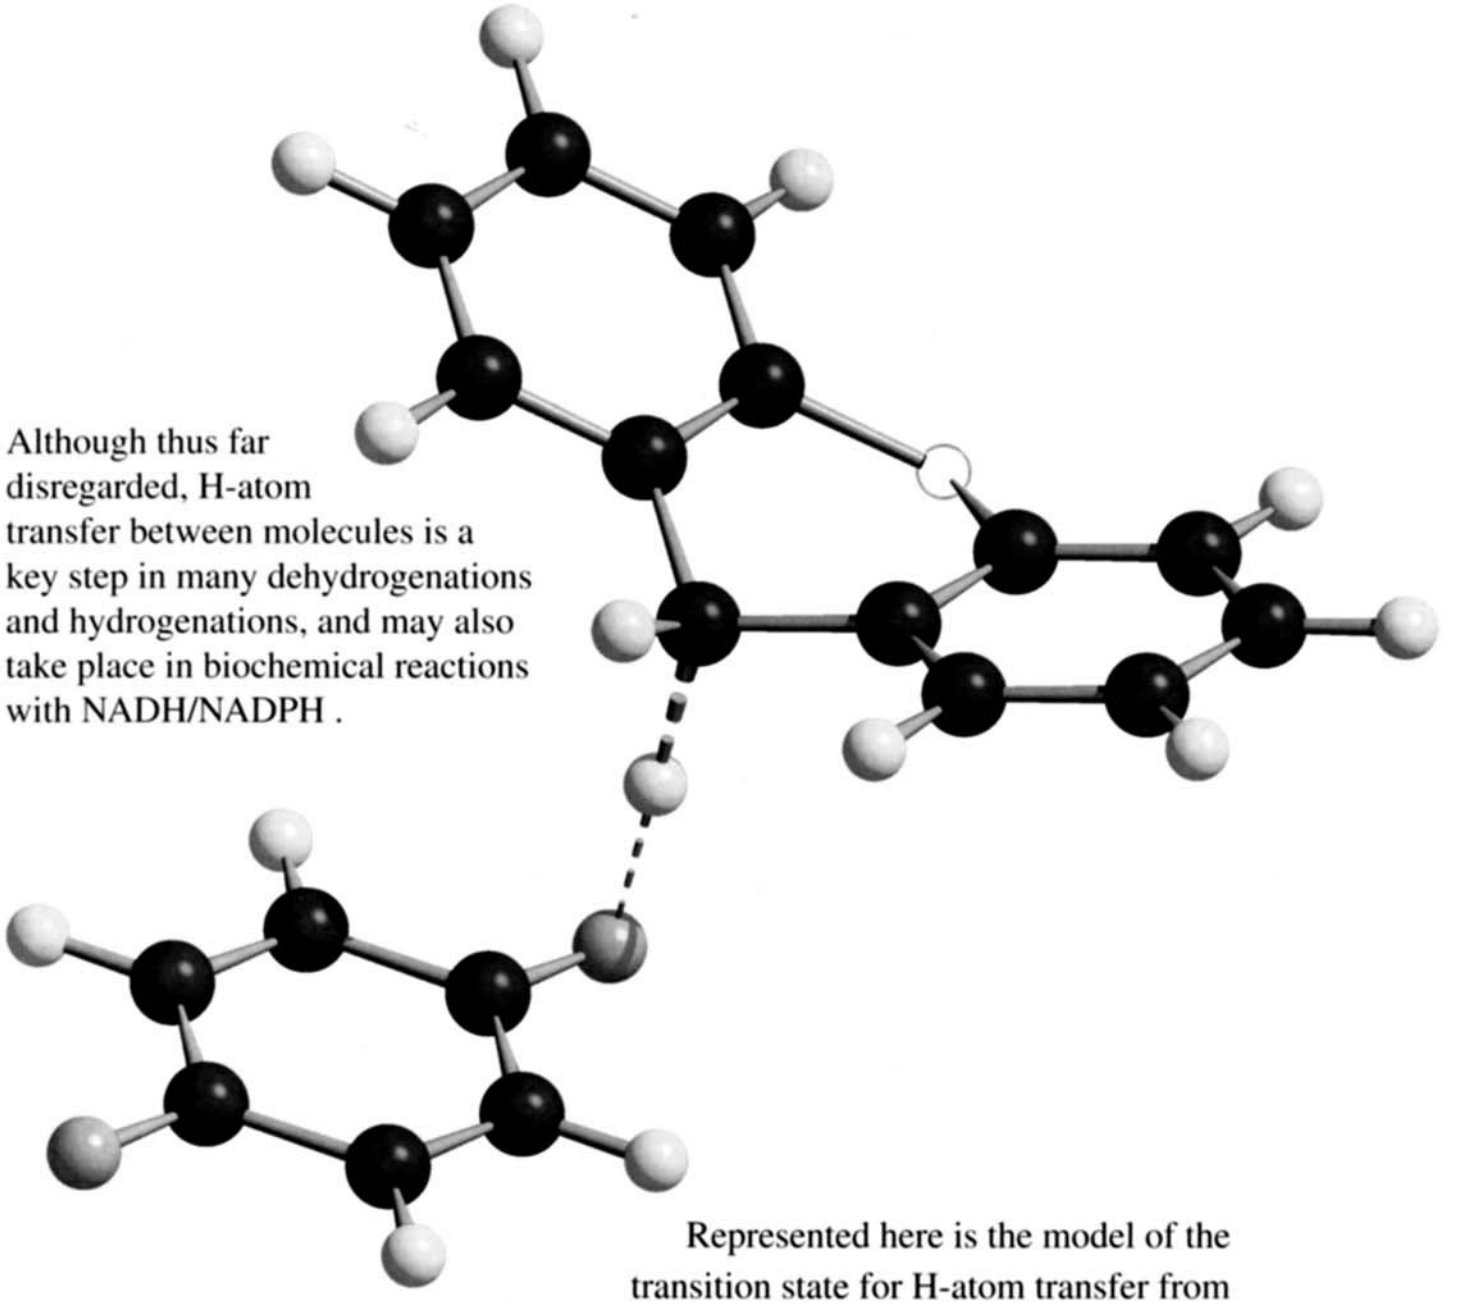
Although thus far disregarded, H-atom transfer between molecules is a key step in many dehydrogenations and hydrogenations, and may also take place in biochemical reactions with NADH/NADPH .



Represented here is the model of the transition state for H-atom transfer from 9,10-dihydroanthracene (X = CH_2), xanthene (X = O), or acridan (X = NH) to benzoquinone [Eq. (1)].

Uncatalyzed Transfer Hydrogenation and Transfer Hydrogenolysis: Two Novel Types of Hydrogen-Transfer Reactions

Christoph Rüchardt,* Matthias Gerst, and Jochen Ebenhoch

Dedicated to Professor Paul D. Bartlett on the occasion of his 90th birthday

Uncatalyzed transfer hydrogenations are H_2-transfer reactions in which donors that contain weakly bound hydrogen atoms undergo an H-atom transfer (retrodisproportionation) onto an acceptor containing unsaturated bonds such as C=C, C=O, C=N, N=N, or N=O. Transfer hydrogenolyses are reactions in which σ bonds are cleaved upon addition of H_2. These hydrogenations are terminated by H• transfer; they do not follow a radical-chain mechanism. The initial steps of both types of reactions, H-atom transfer, complement the bimolecular formation of 1,4-diradicals from alkenes or heteroalkenes within the scope of bimolecular radical formations (Molecule-Induced Radical Formation, MIRF). The title reactions play an important role in coal liquefaction, aromatization reactions with nitroarenes or quinones, and possibly biochemical dehydrogenations. This review focuses on mechanistic studies, structure–reactivity relationships, and current applications of these reactions.

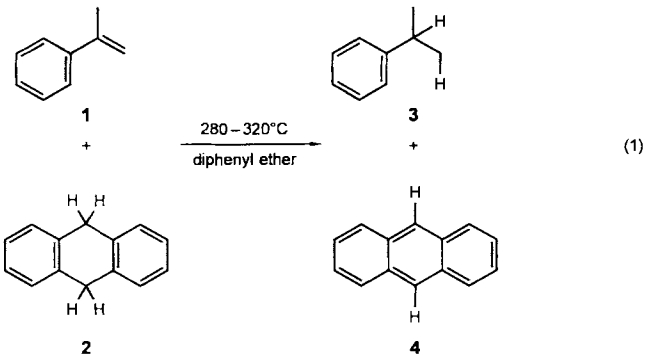
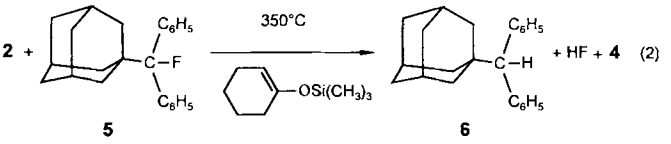
1. Introduction

In early 1992 while studying homolytic, thermal C–C cleavage reactions,[1, 2] we observed two unknown reactions, uncatalyzed transfer hydrogenation (1) and transfer hydrogenolysis (2). Both reactions are characterized by almost quantitative hydrogen transfer from 9,10-dihydroanthracene (DHA, **2**) to the respective substrate.



(1)

Whereas in reaction (1)[3] hydrogen is added across the π bond of α-methylstyrene (**1**), in reaction (2) a novel type of



(2)

hydrogenolytic cleavage of a C–F bond leads to the formation of HF.[4] Control experiments to determine the thermal stability of **2** showed that it remains stable under the reaction conditions. Therefore, reactions (1) and (2) do not proceed by elimination and addition of elemental hydrogen,[5] but by a different pathway.

2. Transfer Hydrogenation

2.1. Mechanism

Various mechanistic possibilities exist for the uncatalyzed transfer hydrogenation (1) of α-methylstyrene (**1**, ≈0.1 M) with DHA (**2**, ≈1.0 M). In analogy to the dyotropic transfer reactions,[6, 7] the three pericyclic mechanisms (3)–(5) are theoreti-

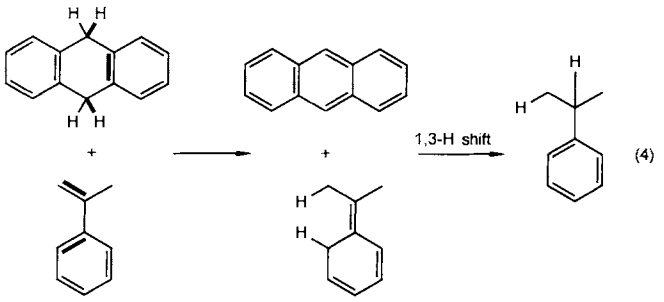
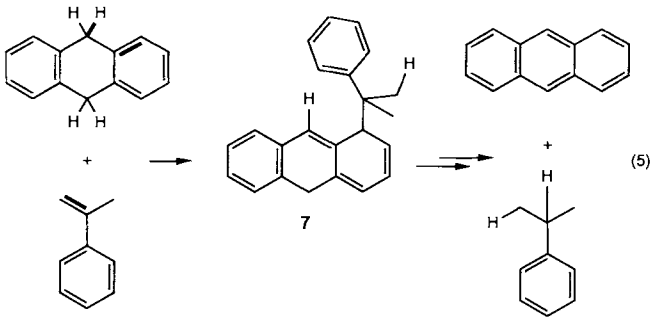
cally possible.[6] The bonds involved in these pericyclic processes are accentuated in Equations (3)–(5).



$[_{\sigma}2_s + {}_{\pi}2_s + {}_{\sigma}2_s + {}_{\pi}4_s]$-type



$[_{\sigma}2_s + {}_{\pi}2_s + {}_{\sigma}2_s]$-type (ene reaction)

According to the Woodward–Hoffmann rules, thermal reaction (3) between the ${}_{\pi}2_s$-bond of **1** and the $[_{\sigma}2_s + {}_{\pi}2_s + {}_{\sigma}2_s]$ bonds of **2** is symmetry forbidden. Reaction (4) between the ${}_{\pi}4_s$ bonds of **1** and the $[_{\sigma}2_s + {}_{\pi}2_s + {}_{\sigma}2_s]$ bonds of **2** is disfavored by approximately 15 kcal mol^{-1} compared to a multistep process and, therefore, does not need to be considered.[6, 8] The third pericyclic possibility is the ene reaction (5); **2** represents the ene component, and **1** functions as the enophile. Participation of a benzoidal C=C π bond postulated for this reaction type has not yet been observed. Furthermore, **1** is not a good enophile.[9] Since no ene products **7** were detected, it can be assumed that under the applied reaction conditions a rapid secondary reaction follows in which **7** undergoes quantitative homolytic decomposition to the 2-phenyl-2-propyl radical (**8**) and the 9-hydroanthryl radical (**9**), followed by their disproportionation. Enthalpically, the ene reaction should be disfavored over the retrodisproportionation.[9] As shown in control experiments methyl groups in positions 1, 4, 5, and 8 of **2** have only a small effect on the activation parameters such as, in particular, the entropy of activation.[10] This is atypical for the ene reaction, which is notoriously sensitive towards steric effects.[9] Consequently, the ene reaction can be ruled out as well.

It is also possible that the hydrogen transfer proceeds by a two-step mechanism, either as hydride transfer (6), which was first proposed by Braude and Linstead et al. for quinone dehydrogenations[11] and appears to be commonly accepted,[12] or as a radical retrodisproportionation (7) by transfer of an H atom leading to the formation of **8** and **9**.[3] The latter reaction pathway, which we prefer as a working hypothesis,[3] has occasionally been proposed for reactions for coal liquefaction[13] as well as the initiating step of chain reactions.[14, 15] However, it

C. Rüchardt

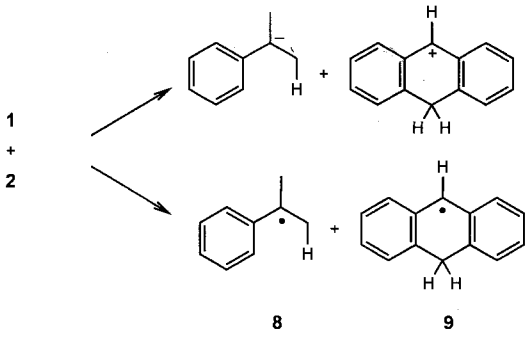
M. Gerst

J. Ebenhoch

Christoph Rüchardt, born in 1929, studied chemistry at the Universität München and the University of Georgia (M. S. degree), and completed his Ph.D. under Professor R. Huisgen in 1956 with studies on aliphatic diazoesters. Afterwards, he spent two years as a postdoctoral fellow at Harvard University with Professor P. D. Bartlett and at the California Institute of Technology with Professor J. D. Roberts. In 1963 he completed his habilitation studying radical-rearrangement reactions at the Universität München. In 1968 he accepted a position at the Universität Münster, and in 1972 at the Universität Freiburg, where he was rector from 1987 to 1991. His research interests include reaction mechanisms, in particular radical chemistry. He received the Adolf-von-Baeyer-Denkmünze from the Gesellschaft Deutscher Chemiker in 1983. He is a member of several academies and a recipient of the Bundesverdienstkreuz 1. Klasse.

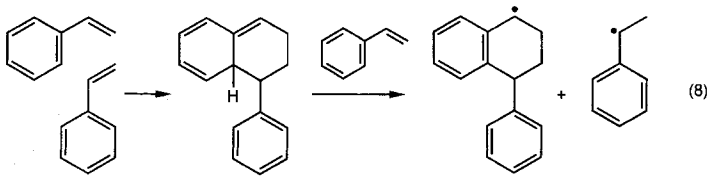
Matthias Gerst, born in 1965, studied chemistry at the Universität Heidelberg and the Universität Freiburg, and received his Ph.D. in 1994 under Professor C. Rüchardt with the thesis Retrodisproportionation—A Novel Method of Radical Formation. In 1991 he worked at the Max-Planck-Institute für Polymerforschung in Mainz, and in 1992 joined the Kunststofflaboratorium at BASF AG. He has received stipends from the Fritzter-Meer-Stiftung, the Fonds der Chemischen Industrie, and the Verband der Chemischen Industrie as well as a prize from the Stifteverband fyr die Deutsche Wissenschaft and the Goedecke research award.

Jochen Ebenhoch, born in 1966, studied chemistry at the Universität Tübingen and the Universität Freiburg, and received his Ph.D. in 1996 under Professor C. Rüchardt with the thesis Transfer-Hydrogenations with 9,10-Dihydroanthracene. He joined Wacker-Chemie, GmbH in 1997.



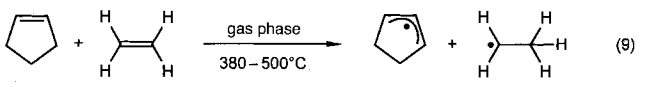
has not been experimentally proven nor defined in its application range. This reaction constitutes the reverse reaction of the disproportionation of two radicals, and, in contrast to the reverse reaction of the radical dimerization, thermal bond dissociation;[1] it is hardly known as an elemental reaction. For this reason, we prefer the name "retrodisproportionation" for this reaction over "molecular disproportionation", as it has been occasionally called.[16] The reaction is an example of the bimolecular radical-formation reactions that Pryor[16] referred to as "Molecule-Induced Homolysis", and others as "Molecule-Induced Radical Formation" (MIRF).[17]

This new reaction type in which weakly bound alkane hydrogen atoms are transferred to alkenes became primarily known by the spontaneous initiation of styrene polymerization (8) in



(8)

the absence of an initiator.[14] Retrodisproportionations have also been proposed for other reactions[18] such as the disproportionation of **2** and 2-ethylanthracene[19] or as the initiating reaction of the addition of alkanes to alkenes at elevated temperatures (ane reaction).[15] A reaction of great importance is the H-atom transfer of transition metal hydrides to alkenes, as first shown by Halpern et al.[20] Benson convincingly interpreted the transfer hydrogenation of ethene with cyclopentene at 380–500 °C in the gas phase as a two-step process with retrodisproportionation (9) as the initial step.[21] This suggestion was sup-



(9)

ported by the good agreement of the enthalpy of activation of $\Delta H^{\neq} = 42.8\ \mathrm{kcal\,mol^{-1}}$ with the thermochemically calculated reaction enthalpy ΔH_R of the first step (thermochemical kinetics),[21] as well as the entropy of activation $\Delta S^{\neq} = -15\ \mathrm{cal\,K^{-1}\,mol^{-1}}$. The calculated reaction enthalpy of $44.9\ \mathrm{kcal\,mol^{-1}}$ determined by Benson for reaction (9) from thermochemical data increases to $53.4\ \mathrm{kcal\,mol^{-1}}$ when the new, commonly accepted C–H bond energies and radical-stabilization energies are considered.[21c] Strictly speaking, the enthalpies must be compared at the same temperature. This surprising discrepancy of approximately $8\ \mathrm{kcal\,mol^{-1}}$ between ΔH^0 and $\Delta H^{\neq}$, and particularly the observation that $\Delta H^0 > \Delta H^{\neq}$, appear contradictory and do not seem to be consistent with the requirements of thermochemical kinetics.[21b] However, upon closer examination, and this is a direct result of our mechanistic studies of the retrodisproportionations, this observation becomes less contradictory.

A further point of discussion is whether the oxidation reactions of *tert*-benzylic hydrogen atoms with chromic acid,[22a] chromyl chloride,[22b] and permanganate[22c] or enzymatic H-activations[22b, d, e] can be included in this category from a mechanistic point of view. The relationship between the termination reactions of free radicals (dimerization and disproportionation) and the radical-forming reactions (homolytic bond dissociation and retrodisproportionation) is discussed here with the example of two ethyl radicals.[23]

The high rate constants of the dimerization and disproportionation steps, which are partially determined by the rate of diffusion of the reactants, influence the lifetime of free radicals. For the most part it is assumed that these termination reactions proceed without requiring any enthalpy of activation $\Delta H^{\neq}$.[25] This means that for the homolytic bond dissociation on the one hand and the retrodisproportionation on the other, the enthalpy of activation $\Delta H^{\neq}$ should be equal to the reaction enthalpy ΔH_R. The dotted line in Figure 1 B depicts the reaction coordinate of enthalpy ΔH in the case of two ethyl radicals. Entropically, the two radical-forming reactions are fundamentally different, because the change in number of particles is not the same for both reactions. This is demonstrated in Figure 1 A with the entropic reaction coordinate ΔS. In both reactions a radical pair is primarily formed; the dissociation of butane has a positive, and the retrodisproportionation a negative entropy. The dissociation of the radical pair to form free ethyl radicals proceeds with $\Delta S = +25\ \mathrm{cal\,K^{-1}\,mol^{-1}}$. The entropic reaction coordinate can also be reversed, starting with the ethyl radicals in the direction of the dimerization and disproportionation. Thus, it is apparent that the selectivity of the dimerization/disproportionation is generally controlled by entropy.[1, 24] For entropic reasons, the reaction coordinate of the free enthalpy ΔG (Figure 1 B) contains local maxima (transition states) for both the dimerization and the disproportionation, the geometric coordinates of which correlate to the entropy minimum.[24b] In principle the experimental enthalpies of activation $\Delta H^{\neq}$ of both termination reactions of alkyl radicals can be smaller than the respective reaction enthalpies ΔH_R.[26]

In the uncatalyzed transfer hydrogenation (1) of **1** ($\approx$0.1 M) with **2** ($\approx$1.0 M), which proceeds in greater than 98% yield at 280–300 °C (1),[27] retrodisproportionation (10) is very selectively followed by two known radical reaction steps. These include H transfer onto the cumyl radical **8** and disproportionation of two hydroanthryl radicals **9** (reactions (11) and (12) in Scheme 1).

Since these experiments are performed above the ceiling temperature, polymerization does not occur. The selectivity is dictated by the presence of the well-stabilized radicals **9**.[28] The reaction order with respect to **1** and **2** was one; therefore, the reaction does not represent a chain reaction with **9** as the chain carrier.[27] Moreover, increasing the concentration of **9** by

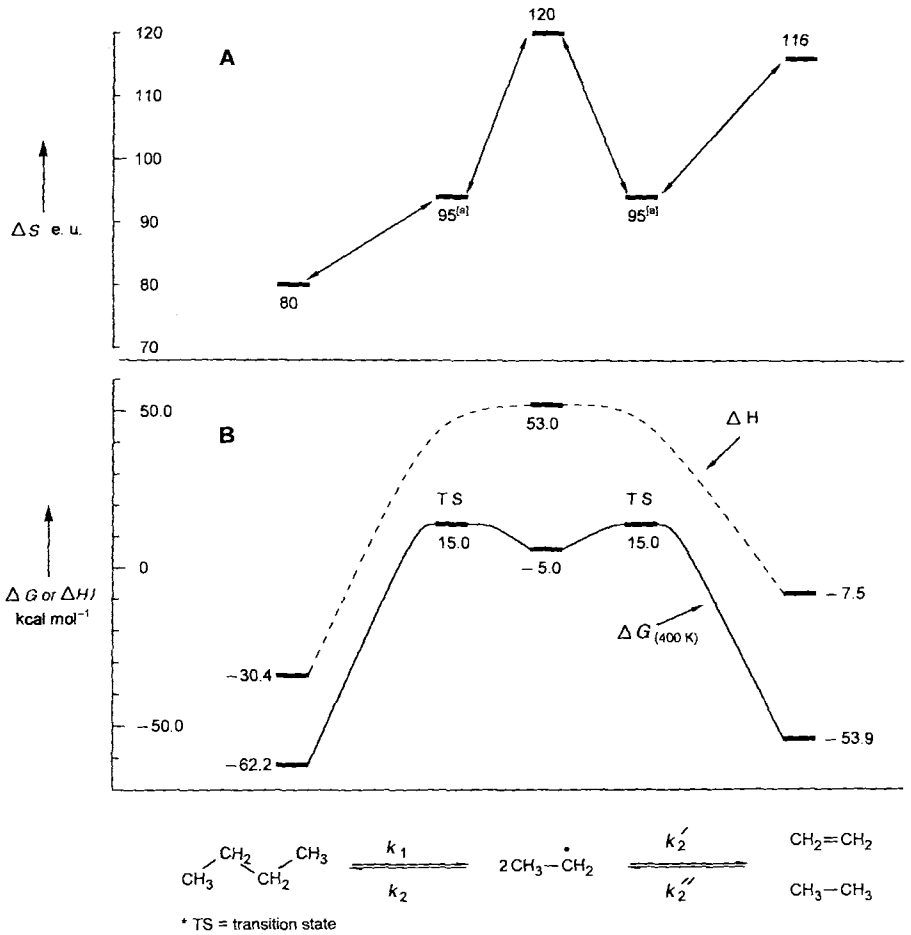


Figure 1. Reaction coordinate of entropy S (A) and of enthalpy H and free enthalpy G_{400K} (B) for the dimerization and disproportionation of ethyl radicals and the dissociation of butane, respectively, as well as the retrodisproportionation of ethane and ethene (calculated values) [23]; TS = transition state of radical-pair formation, e. u.: entropy units = 4.184 $JK^{-1}mol^{-1}$). [a] No conclusion should be drawn from this Figure concerning the selectivity of radical dimerization over disproportionation.

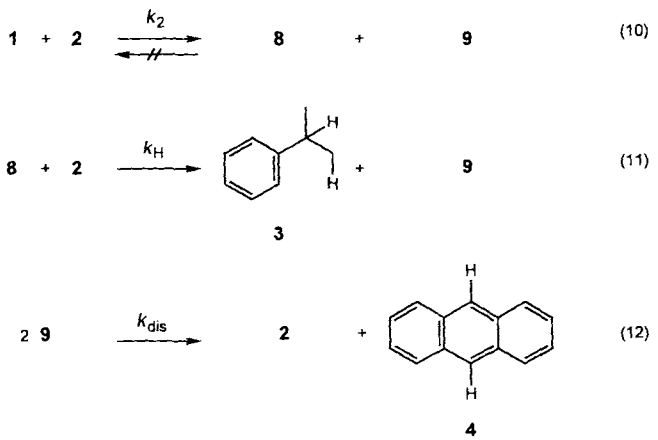


Scheme 1. Reaction mechanism of the retrodisproportionation of **1** (1.0 M) with **2** (1.0 M). The reaction was investigated in diphenyl ether at 270–320 °C.

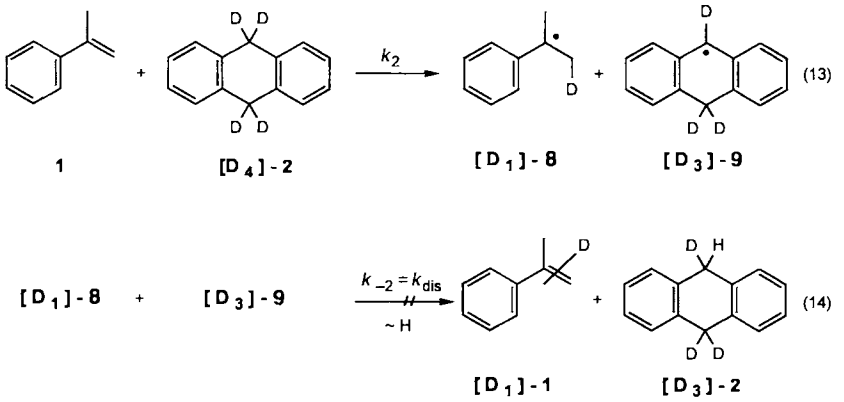
adding either bifluorene[3] or anthracene (**4**)[19] did not result in a rate acceleration as expected for a chain reaction. Consequently, transfer hydrogenation proceeds stoichiometrically.

With 9,9,10,10-tetradeutero-9,10-dihydroanthracene ([D_4]-**2**) the H transfer with rate constant k_2 could be identified as the rate-determining step. [D_2]-cumene ([D_2]-**3**) was exclusively formed. When the reaction was stopped after approximately 80% conversion, no deuterium could be detected in the remaining **1**.[27] This observation proves that the retrodisproportionation is irreversible under these reaction conditions, and k_2 alone is rate-determining.[29]

Treating **1** with a tenfold excess of an equimolar mixture of **2** and [D_4]-**2** not only formed cumene (**3**, 48%) and [D_2]-**3** (11%) but also [D_1]-cumene ([D_1]-**3**, 41%) after 20% conversion (Scheme 2). Incompatible with the above-mentioned pericyclic mechanisms, this result is consistent with a radical mechanism. Accordingly, [D_1]-**3** was formed either from the cumyl radicals **8** with [D_4]-**2** as the radical scavenger or from [D_1]-**8** with **2** as the radical scavenger. Nondeuterated as well as mono- and dideuterated anthracene were identified as further reaction products, which excludes the possibility that **2** transfers both H atoms consecutively in one radical pair. At 300 °C, the primary kinetic isotope effect is $k_{2(H)}/k_{2(D)} = 2.1$ (see Table 4). Figure 1 B suggests that the transition state of the retrodisproportionation does not geometrically correlate to the free radicals or the radical pair, although the respective enthalpies of activation and reaction must be very similar. The H atom to be transferred is located between the participating C atoms; due to the small enthalpy difference between the radical pair and the transition state (TS, Figure 1 B) its exact location cannot be determined.[30] This explains that a primary kinetic isotope effect was determined with a value close to the highest possible expectation value, and, furthermore, that a linear alignment of the C−H···C axis should be expected.[30]

The difference of the enthalpies of activation $\delta\Delta H^{\neq}$ for the transfer hydrogenation and the transfer deuteration was experimentally determined to be 1.0 kcal mol^{-1} (see Table 4 and ref. [27]). With this value and an approximation equation the maximum kinetic isotope effect at 300 °C can be calculated to be $k_{2(H)}/k_{2(D)} = 2.7$,[31a] which correlates well with the experimental value. The activation parameters of the transfer hydrogenation and the transfer deuteration of **1** by **2** or [D_4]-**2** (see Table 4) provide the temperature dependency of the isotope effect. As expected the isotope effect of 2.5 at 250 °C is slightly higher than that of 2.2 at 350 °C.

Using approximately 20 rate constants k_2 for the reaction of **1** with **2** in a temperature range 250 to 320 °C, the activation parameters were calculated to be $\Delta H^{\neq} = 31.8$ kcal mol^{-1}, $\Delta S^{\neq} = -21.5$ cal $K^{-1}mol^{-1}$, and $\Delta G^{\neq}_{300\,°C} = 44.1$ kcal mol^{-1} (see Table 4).[3, 31b] The negative entropy of activation is in



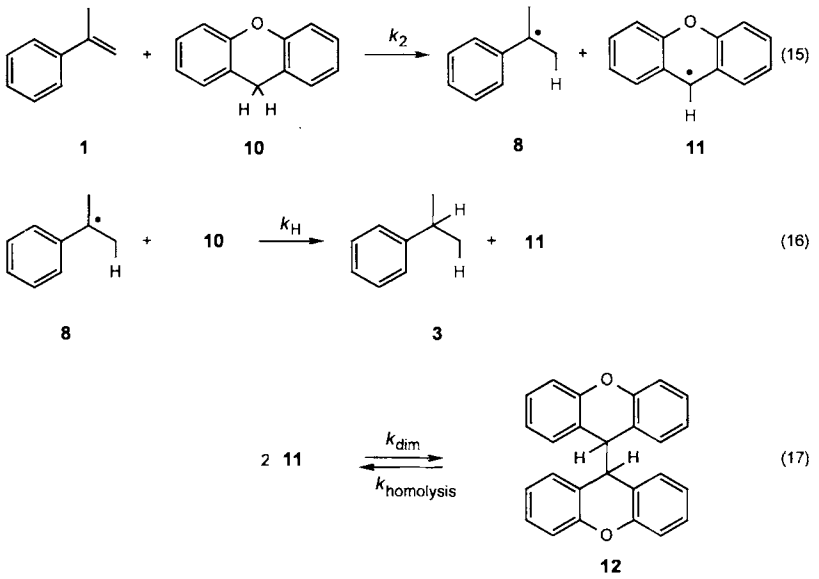
Scheme 2. Deuteration experiment as an analytical probe for the reverse reaction (v_{-2}).

agreement with the prediction of a second-order reaction. The enthalpy of activation of 31.8 kcal mol^{-1} agrees fairly well with the reaction enthalpy of $\Delta H_R = 38.7$ kcal mol^{-1} (298 K; see Table 4),[32] but this is another example of the above-mentioned unexpected phenomenon that ΔH^0 is larger than $\Delta H^{\neq}$. This supports the rate-determining character of H transfer from **2** to **1** as well as the postulated radical mechanism. The unexpected observation that $\Delta H^{\neq}$is smaller than ΔH_R, which was confirmed to varying extent in most of the retrodisproportionation reactions investigated to date (see also ref. [2a]), has also been verified for the thermolysis of bibenzyl[32d] and is consistent with the influence of entropy on the location of the transition states ($\Delta G^{\neq}$; Figure 1, Section 2.2.3). This phenomenon is probably partly due to the fact that the thermochemical reaction enthalpies were calculated for the gas phase at 25 °C, whereas the activation enthalpies were measured in solution at elevated temperatures. The equilibration of **2** and **4**, which was observed earlier by Stein et al.,[19] also follows an H-transfer mechanism and apparently does not have an impact on the reaction kinetics.

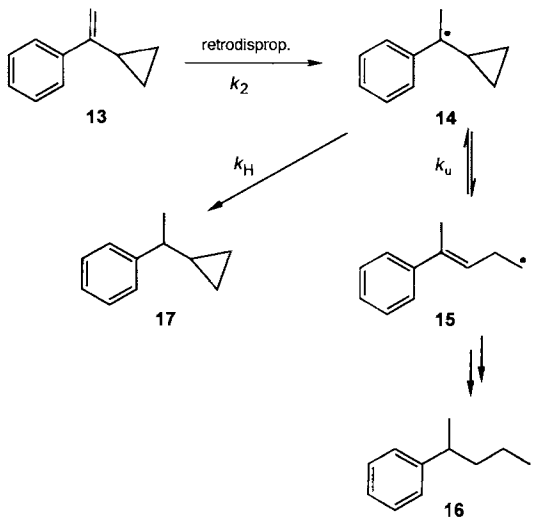
Attempts to prove the existence of a radical by ESR spectroscopy under the same reaction conditions remained unsuccessful. Due to the high rate constant of disproportionation (12), the stationary concentration of radicals **9** is apparently too low for this method. However, the ESR experiment was successful with xanthene (**10**) as the H donor (reaction (15) in Scheme 3),[33] since the xanthyl radicals **11** are unable to disproportionate.

At 280–310 °C, **1** was also hydrogenated by **10** to give cumene (**3**) in nearly quantitative yield, leading to the formation of dimer **12**, which in the given temperature range is in equilibrium with radicals **11** [Eq. (17)].[34] The stong ESR signal of **11** can therefore be observed throughout the entire reaction. The relatively high concentration of **11** is also responsible for the fact that retrodisproportionation (15) is partially reversible. This can be shown by incorporating deuterium into **1** with 9,9′-[D_2]-xanthene ([D_2]-**10**) in diphenyl ether. The deuterium content in **1** increases from 1% after 10% conversion to 13% after 64% conversion. Deuterium incorporation can be totally suppressed with the effective H donor tetraline as the solvent without significantly affecting the rate of reaction. Without **10** no hydrogenation of **1** occurs under these conditions.

To prove the existence of the radicals formed from the H acceptor, we performed a qualitative radical-clock experiment[35, 36] with α-cyclopropylstyrene (**13**) as the model compound (Scheme 4).[37] Due to the thermolability of **13**, the reaction temperature was not allowed to exceed 230 °C; therefore, we used the H donor 7*H*-benz[*de*]anthracene (**30**), which is more reactive than **2**. The intermediate radical **14** was indirectly identified



Scheme 3. Retrodisproportionation of **1** with xanthene (**10**).



Scheme 4. Radical-clock experiment to identify the intermediate radicals of the H acceptor in the retrodisproportionation.

by the presence of the typical secondary product **16**.[36] 1-(Phenylethyl)cyclopropane (**17**) was formed as an H-trapping product.

Typical radical side and secondary reactions can also be observed in the transfer hydrogenation of **1** with *cis*-9,10-dimethyl-9,10-dihydroanthracene (*cis*-**18**).[38] Figure 2 shows product

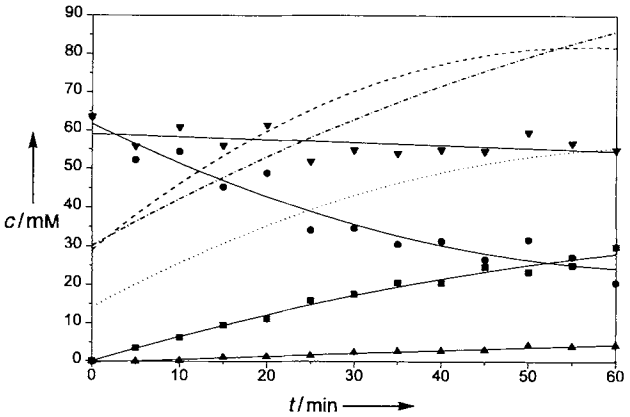


Figure 2. Transfer hydrogenation of α-methylstyrene (**1**, 0.1 M) with *cis*-9,10-dimethyl-9,10-dihydroanthracene (*cis*-**18**, 1.0 M) in diphenyl ether at 320 °C; ● **1**, ■ cumene (**3**), ▲ 2-phenylbutane (**19**), ··· *trans*-9,10-dimethyl-9,10-dihydroanthracene (*trans*-**18**), - - - - - 9-methylanthracene (**20**), — 9,10-dimethylanthracene (**21**), ▼ mass balance (total of **1**, **3**, and **19**)

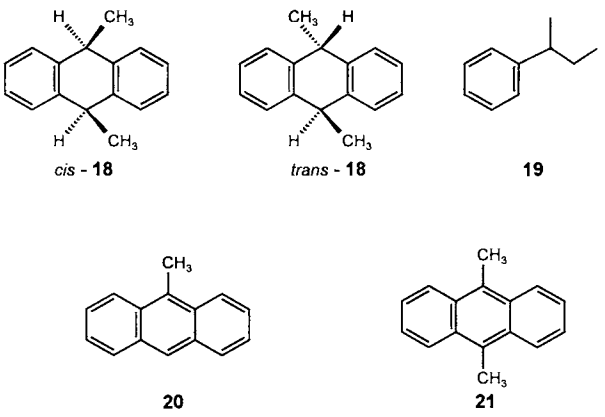
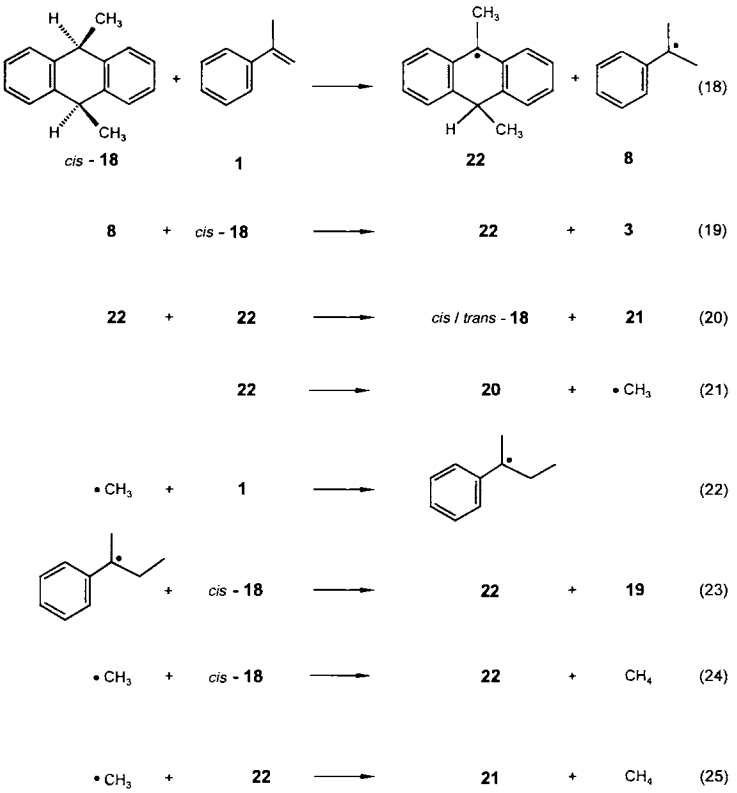
formation as a function of reaction time. As the concentration of **1** decreases, the concentration of **3** and *sec*-butylbenzene (**19**) increases with a fairly constant mass balance. In addition, more than stoichiometric amounts of *trans*-**18**, 9-methylanthracene (**20**), and 9,10-dimethylanthracene (**21**) were formed. This result



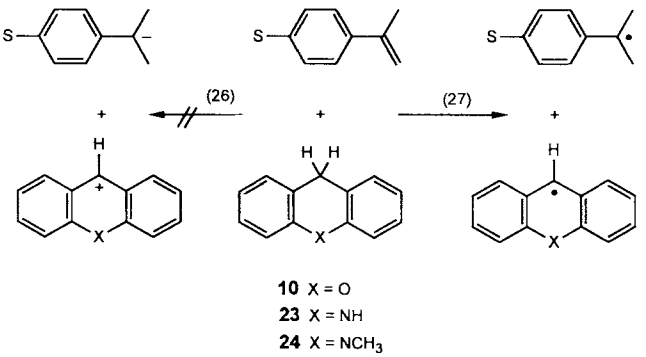
confirms a radical reaction mechanism. 9,10-dimethyl-9-hydroanthryl radicals (**22**), which formed during initial retrodisproportionation (18) in Scheme 5 and subsequent formation of **3** by H transfer [Eq. (19)], either disproportionate by reaction (20) to form **21** and *cis*/*trans*-**18** or suffer loss of methyl radicals by reaction (21) to give **20**. By adding onto **1** [Eq. (22)] the latter are responsible for the formation of *sec*-butylbenzene [**19**, Eq. (23)]. They also trigger a short radical chain reaction [Eqs. (21), (24)], which explains the overstoichiometric formation of radicals **22**, and thus products *trans*-**18**, **20**, and **21**.

To differentiate between a hydride transfer[11] and an H-atom transfer (retrodisproportionation), polar substituent[39] and solvent effects[40] were investigated with respect to the reaction kinetics. The reactivity difference between **2**, **10**, and acridan



Scheme 5. Interpretation of the reaction of *cis*-9,10-dimethyl-9,10-dihydroanthracene (*cis*-**18**) and **1** at 310 °C in diphenyl ether.

(**23**)[39] in the transfer hydrogenation of **1** was small (Table 1), as is expected for the rate-determining retrodisproportionation (27) but not for the hydride-transfer step (26). Due to par-



ticipation of the oxonium and ammonium structures $\mathbf{10}^+$ and $\mathbf{23}^+$ the reactivity should significantly increase in the order $\mathbf{2} < \mathbf{10} < \mathbf{23}$ for a hydride-transfer mechanism.[41]

[a] In pyridine.

The influence of solvent polarity on the transfer hydrogenation of **1** was determined for eight different H donors (Table 3).[3] The solvent pair *N*-methylacetamide (NMA) and diphenyl ether (DPE) were compared preferably but not exclusively, because the dielectric constant for NMA is available for the temperature range used and differs significantly from that of DPE.[40] The ratio of the rate constants k_2(NMA)/k_2(DPE)varies only slightly within the range 0.7 to 1.4, which also contradicts a hydride-transfer mechanism.

Table 3. Solvent effects of the retrodisproportionation of H donors (see Figure 3) with α-methylstyrene (**1**) in diphenyl ether (DPE) and the more polar *N*-methylacetamide (NMA) [40, 44].

H Donor	T [°C]	k_{rel} [a]

xanthene [b] **10**	300	0.7
fluorene **28**	300	1.4
phenalene [c] **29**	250	1.1
[7*H*]benz[*de*]anthracene [d] **30**	250	1.1
1,4-dihydronaphthaline **31**	290	0.9
1,2-dihydronaphthaline **32**	350	0.9
acridan [e] **23**	280	1.3

[a] $k_{rel} = k$(NMA)/k(DPE); for the E_T values of the solvents see ref. [45]. [b] $k_{rel} = 1.2$ in *tert*-butylbenzene; $k_{rel} = 0.6$ in benzonitrile. [c] $k_{rel} = 1.5$ in *o*-dichlorobenzene. [d] $k_{rel} = 1.2$ in *o*-dichlorobenzene. [E] k(NMA)/k(pyridine) = 1.3; k(triglyme)/k(pyridine) = 1.0.

2.2 Relationship between Structure and Reactivity

The reactivity of the transfer hydrogenation is determined by both an enthalpic and an entropic term. Whereas the entropic factor is difficult to estimate and is further complicated by the phenomenon of an isokinetic relationship (see Section 2.2.3.), a direct relationship between the enthalpy of activation $\Delta H^{\neq}$ and the reaction enthalpy ΔH_R is expected and found according to Benson et al.[21] Based on the discussion above, it cannot be expected that both of these enthalpies are identical, but rather that $\Delta H^{\neq}$ is about 5 kcal mol^{-1} smaller than ΔH_R. However, it can be expected that the change of both parameters follows the same trend and, furthermore, that they correlate with one another.

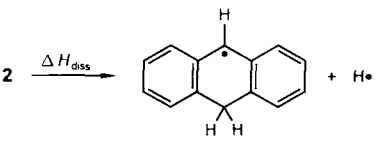
Equation (a) can be formulated with the standard enthalpies of formation ΔH_f^0(g) of the starting materials **1** and **2** as well as the products **8** and **9**;[32] ΔH_R represents the reaction enthalpy at 25 °C.[21b]

$$\Delta H^{\neq} \approx \Delta H_R = \Delta H_f^0(g)[\mathbf{8}] + \Delta H_f^0(g)[\mathbf{9}] - \Delta H_f^0(g)[\mathbf{1}] - \Delta H_f^0(g)[\mathbf{2}] \quad (a)$$

For any given H donor/H acceptor pair, the corresponding standard enthalpies of formation ΔH_f^0(g) can be used to calculate the reaction enthalpies ΔH_R of the respective retrodisproportionation. It is also possible to derive a relationship [Eq. (b)]

$$\Delta H_{diss}(C{-}H) = \Delta H_f^0(g)[H^{\bullet}] + \Delta H_f^0(g)[\mathbf{9}] - \Delta H_f^0(g)[\mathbf{2}] \quad (b)$$

between the reaction enthalpy ΔH_R or the experimental enthalpy of activation $\Delta H^{\neq}$ and the C–H bond enthalpy ΔH_{diss}(C–H) of the H donor (see reaction (28)). The term $(\Delta H_f^0(g)[\mathbf{9}] - \Delta H_f^0(g)[\mathbf{2}])$ is also present in Equation (a). Under the assump-



9

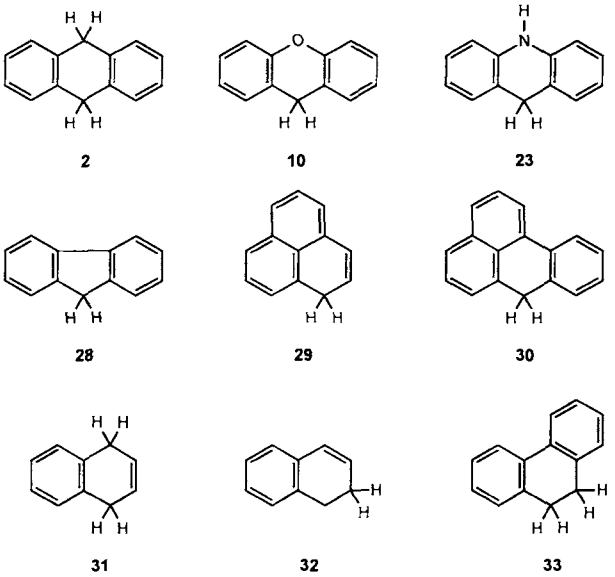
tion that $\Delta H^{\neq} \approx \Delta H_R$, combining Equations (a) and (b) allows one to derive a relationship between the C–H bond enthalpies ΔH_{diss}(C–H) of the H donors and the enthalpies of activation $\Delta H^{\neq}$ of the transfer hydrogenation with, for instance, **1** [Eq. (c)].

$$\begin{aligned}\Delta H_{diss}(C-H) &\approx \Delta H^{\neq} + \Delta H_f^0(g)[H^{\cdot}] + \Delta H_f^0(g)[\mathbf{1}] - \Delta H_f^0(g)[\mathbf{8}] \\ &\approx \Delta H^{\neq} + 52.1 + 28.5^{[46]} - 36.3^{[32]} \\ &\approx \Delta H^{\neq} + 44.3\ \text{kcal mol}^{-1}\end{aligned} \quad (c)$$

Thus, the C–H bond enthalpies ΔH_{diss}(C–H) can be approximated from the enthalpies of activation for the transfer hydrogenation and vice versa. Moreover, the influence of the H donor on the reactivity of the retrodisproportionation can be predicted prior to the experiment (Section 2.2.1). Predictions with respect to the reactivity can also be made from the difference in the enthalpies of formation of the H acceptor (for example **1**) and the radicals formed by H addition (for example **8**, Section 2.2.2). All this forms the basis for a discussion of the relationship between structure and reactivity of a given system.

2.2.1. Variation of the H Donor

To establish the influence of the H donor on the reactivity of the retrodisproportionation with α-methylstyrene (**1**) as the H acceptor, a series of compounds with especially low C–H bond enthalpies ΔH_{diss}(C–H) was chosen (Scheme 6).[50] Mech-

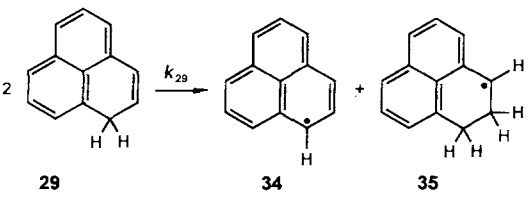


Scheme 6. H donors that react with **1** under retrodisproportionation [50] (for bond enthalpies ΔH_{diss}(C–H) see Table 4).

anistic studies were performed for each compound to confirm the radical mechanism.[48,49] In the case of the H donors xanthene (**10**), phenalene (**29**), and 7*H*-benz[*de*]anthracene (**30**), the initially formed H-donor radicals were detected by ESR spectroscopy.[33]

Among the selected H donors **10**, **29**, **30**, fluorene (**28**), and anthrone (**44**) represent special substrates, since the radicals formed by cleavage of the C–H bonds cannot disproportionate but instead only dimerize. Compared to **2**, this particular behavior can lead to a different kinetic situation if the dimer forms a dissociation equilibrium with the radicals under high-temperature conditions (200–350 °C).[34,49] In this case, the retrodisproportionation step becomes reversible, as shown by isotopic-labeling experiments. If the extent of the reversibility is small (< 10%), it can be accounted for with a kinetic correction factor.[27,49] However, it would be better in such cases to use an H-donor solvent such as mesitylene, *sec*-butylbenzene, or tetraline to trap the radicals formed in equilibrium. Even if the rate constants k_{obs} thereby change slightly, better activation parameters are obtained, since the extent of reversibility is apparently temperature-dependent.

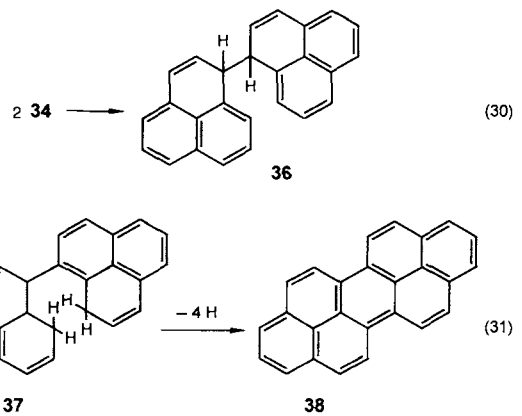
Since the H donors **29** and 1,2-dihydronaphthalene (**32**) contain styrene-like double bonds, they can also function as H acceptors, giving them the ability to function both as an H acceptor and as an H donor.[48] This phenomenon was especially apparent with **29**,[51,48] the methylene group of which has an especially low C–H bond enthalpy (ΔH_{diss}(C–H) = 74.0 kcal mol^{-1}; Table 4). Retrodisproportionation (29) of two



(29)

molecules of **29** led to the formation of the phenalenyl radical **34** and the dihydrophenalenyl radical **35**. This step might be responsible for the exceptionally fast autoxidation of **29** at 25 °C as well as its thermolability at temperatures above approximately 180 °C.[51]

To ensure that these radicals do not react to form known complex products such as dibenzo[*cd*,*lm*]perylene (peropyrene, **38**),[51] **2** is added in excess as a radical scavenger to the reaction



(30)

(31)

of **29** with **1**.[48] In this case, **2** serves exclusively as a radical trap in reactions (33), (35), and (36) in Scheme 7 and does not compete as a H donor. The conversion–time plots in Figure 3 show that under the given reaction conditions **1** and **29** react almost quantitatively to **3** or dihydrophenalene (**39**).

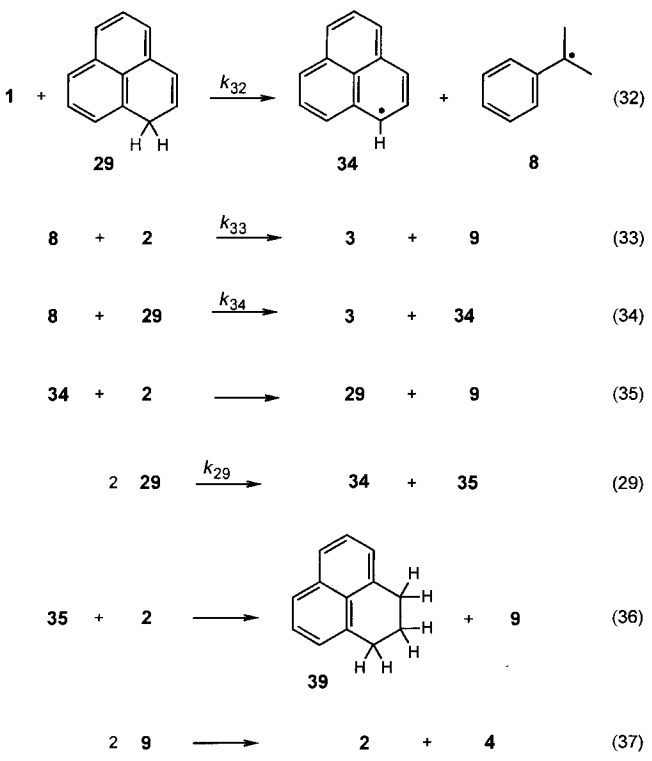

Scheme 7. Transfer hydrogenation of **1** with **2** and phenalene (**29**) as the catalyst.

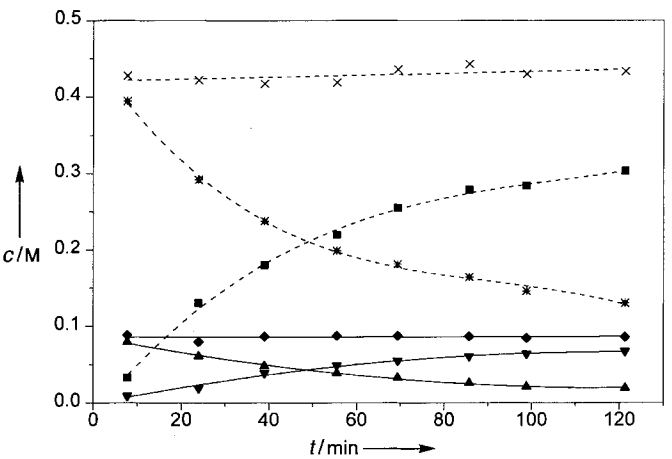

Figure 3. Conversion–time plot for the reaction of phenalene (**29**, c = 0.41 M) with α-methylstyrene (**1**, c = 0.08 M) at 227 °C in diphenyl ether. 9,10-Dihydroanthracene (**2**, 2.00 M) was added as a radical trap; ▲ **1**, ▼ **3**, ◆ **1**+**3**, * **29**, ■ **39**, × **29**+**39**.

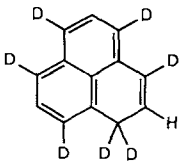
Kinetic analysis allows one to determine both the rate constants k_{32} [Eq. (32)] and k_{29} [Eq. (33)] in the same experiment and to calculate the activation parameters from their temperature dependencies.[48] An interesting aspect of the phenalene kinetics is the fact that when **2** is added as a radical trap phenalene is reformed from the phenalenyl radicals **34** [Eq. (35)], which were detected by ESR spectroscopy. Thus, **29**

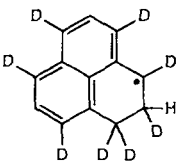
is a promotor of the transfer hydrogenation of **1** with **2**.[52] However, in reaction (29) phenalene is continuously converted so that the promotor concentration continues to decrease, and **29** is ultimately consumed.

The occurrence of the cycle (32)–(35) can be proven with [D_4]-**2**. Reactions (33) and (34) require that, in this case, **3** remains undeuterated or becomes monodeuterated but not dideuterated. At the same time, however, six or seven D atoms per molecule of **29** or **39** are being accepted in the cycle (32), (34), and (35) since the phenalenyl radical **34** contains six equivalent positions for the delocalization of the single electron.[48]

The irreversibility of reaction (29) was proven with [D_7]-phenalene ([D_7]-**29**) and [D_4]-**2**.[48] In the transfer hydrogenation of **1**, no additional deuterium was incorporated into [D_7]-**29** after 90% conversion. This observation suggests that radical [D_8]-**35**, which is formed in the reaction of [D_7]-**29** with itself,



[D_7]-29



[D_8]-35

does not disproportionate back to form **29**, because then hydrogen would preferably be cleaved in this process and lead to the formation of [D_8]-**29**. Instead, [D_2]-**3**, [D_9]-**39**, and [D_2]-**4** are formed exclusively. In addition, some incorporation of deuterium (about 4–8%) could be detected in unchanged **1**, which suggests that the reverse reaction in Equation (32) does occur to a slight extent.[53] In contrast, 7*H*-Benz[*de*]anthracene (**30**) is a promotor of the transfer hydrogenation that is not consumed in the reaction (see Table 4, ΔH_{diss}(C–H) = 76.0 kcal mol^{-1}),[54] because it does not contain any styrene-like double bonds as does **29** (Figure 4).[36]

This phenomenon of acceleration by promotors containing weak C–H bonds[36, 48] appears to be an important concept

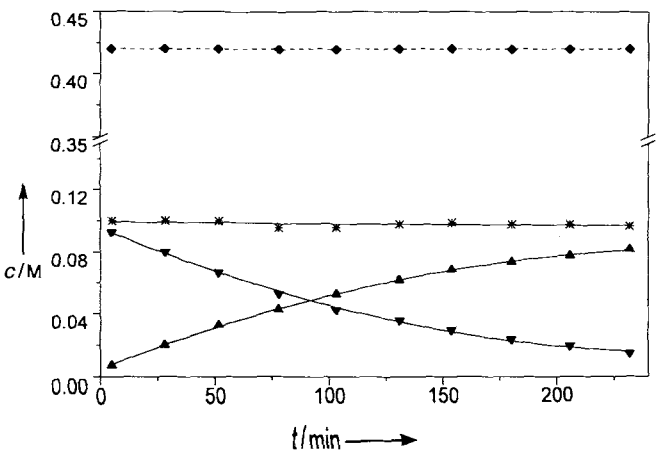


Figure 4. Conversion–time plot for the transfer hydrogenation of α-methylstyrene (**1**, c = 0.08 M) with 9,10-dihydroanthracene (**2**, 2.00 M) at 230 °C in diphenyl ether in the presence of 7*H*-benz[*de*]anthracene (**23**, 0.43 M) as a promotor; ▼ **1**, ▲ **3**, * **1** + **3**, ♦ **30**.

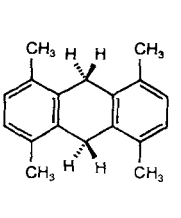
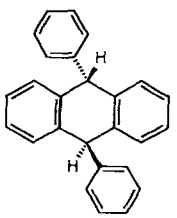
in coal liquefaction.[5, 13, 55] Coal, similar to phenalene structures, contains both the acceptor and donor components necessary for retrodisproportionations, and a mixture of hydroaromatic hydrocarbons is typically used in the liquefaction process. Catalysis of C–H activation by activated carbon described by Dockner[55c] can probably be explained also with this phenomenon.

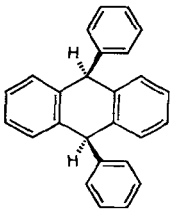
The H donors fluorene (**28**),[56] 1,4-dihydronaphthalene (**31**),[27] and 1,2-dihydronaphthalene (**32**)[27] shown in Scheme 6 could also be investigated quantitatively in the retrodisproportionation with **1**. The transfer hydrogenation of **1** can also be performed in good yields with 9,10-dihydrophenanthrene (**33**) at approximately 350 °C; however, due to unwanted side reactions, the kinetic behavior of this reaction is not reliable. This can probably be attributed to the high C–H bond energy of **33** (90 kcal mol^{-1}). In the case of **32**, the same phenomenon occurred as for **29** (that of simultaneous donor and acceptor functionality). Therefore, the corresponding rate constants of both the hydrogenation of **32** and of the H transfer onto **1** as well as their activation parameters were simultaneously accessible at the same time (see Table 4).[27, 57–61] The substituted 9,10-dihydroanthracene derivatives **18**, **40**–**43** were used for investigating steric effects of the H donors in the retrodisproportionation with **1** (see Table 4).[38]



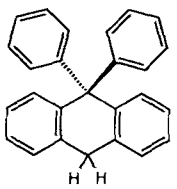
40



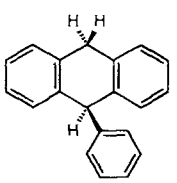
trans-**41**



cis-**41**



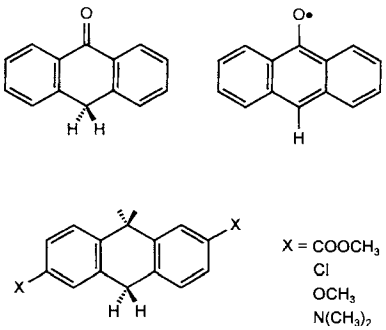
42



43

In the transfer hydrogenation with **41** and **42**, but not with **43**, a phenyl radical is cleaved from the initially formed substituted 9-hydroanthryl radical; this radical either phenylates with the solvent diphenyl ether or is hydrogenated to form benzene. In either case, the mass balance is greater than 95%. Surprisingly, only small differences in the rate constant k_2 can be detected in the retrodisproportionation with **1**. With 1,4,5,8-tetramethyl-9,10-dihydroanthracene (**40**) and *trans*-9,10-diphenyl-9,10-dihydroanthracene (*trans*-**41**), for instance, an acceleration relative to the reaction with **2** can be observed (k_{rel}(300 °C) = 3.1 and 2.2, respectively), whereas the other substrates react more slowly (k_{rel}(300 °C) = 2).[38] However, the activation parameters (see Table 4) are significantly different from each other (Section 2.2.3.). Steric effects in the donor molecule apparently have almost no effect on H transfer.

Although the reactivity $\Delta G^{\neq}$ of anthrone (**44**) is very similar to that of DHA, the corresponding components $\Delta H^{\neq}$ and $\Delta S^{\neq}$ differ significantly.[56] The concentration of **44** remains constant during the transfer hydrogenation since it acts as a promotor, similar to **29**. The radicals **45** are quenched by the solvent tetraline to yield **44**. In the transfer hydrogenation of **1** with the substituted dihydroanthracenes **46**, only a minor substituent effect[38] could be observed, which suggests that polar effects do not have an impact on the rate of reaction.[62]



When trying to evaluate the Benson hypothesis[21] $\Delta H^{\neq} \approx \Delta H_R$ for the retrodisproportionation step using the results listed in Table 4, it can be seen that for all examples $\Delta H^{\neq}$ is 3–9 kcal mol^{-1} lower than the independently thermochemically calculated reaction enthalpies ΔH_R. This discrepancy allows the conclusion that, due to the influence of entropy, the maximum free enthalpy $\Delta G^{\neq}$ on the reaction coordinate (transition state) does not coincide with the radical products, but occurs earlier in the reaction (Figure 5).

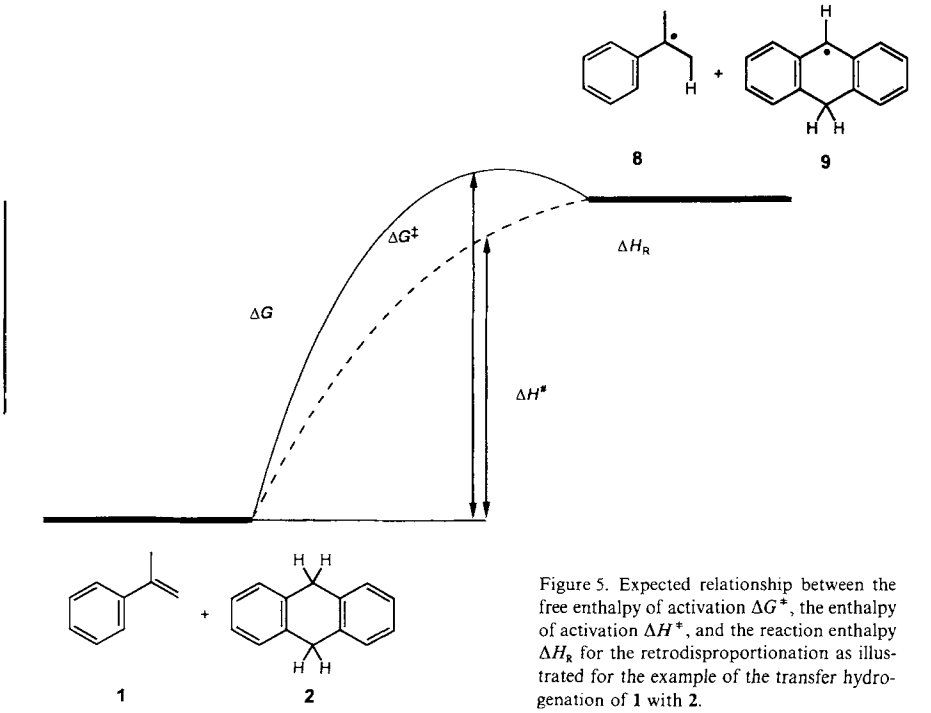


Figure 5. Expected relationship between the free enthalpy of activation $\Delta G^{\neq}$, the enthalpy of activation $\Delta H^{\neq}$, and the reaction enthalpy ΔH_R for the retrodisproportionation as illustrated for the example of the transfer hydrogenation of **1** with **2**.

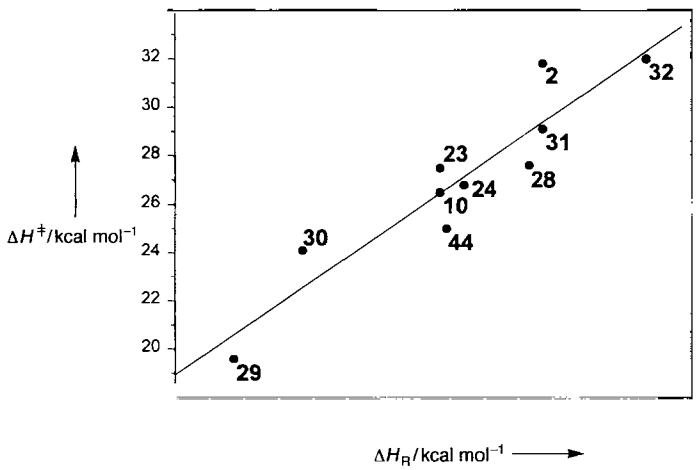
(indicating that H-atom transfer from the donor to the acceptor is approximately halfway completed in the transition state. The plot of the experimental enthalpy of activation $\Delta H^{\neq}$ against the reaction enthalpy of the retrodisproportionation step for a series of H donors (Figure 6) shows that a linear correlation



exists; the spread of the data is within experimental error. Qualitatively, the Benson criterion[21] appears fulfilled: the two parameters $\Delta H^{\neq}$ and ΔH_R follow the same trend upon structure variations. However, it should be kept in mind that ΔH_R^0 was determined in the gas phase at 25 °C, and $\Delta H^{\neq}$ in the liquid phase at higher temperatures.

The validity of Equation (c) can be demonstrated in a similar way. A linear relationship also results when the C–H bond enthalpies calculated according to Equation (c) are plotted against the thermochemical, experimentally determined or calculated bond enthalpies listed in Table 4 (Figure 7). These correlations strongly confirm that transfer of the H atom in the retrodisproportionation occurs in the rate-determining step of

2.2.2. Variation of the Olefinic H Acceptor

A variety of C=C bonds are prone to retrodisproportionation. The class of double bonds successfully investigated to date include those conjugated to double bonds, aromatic systems, or hetero double bonds (that is, C=O,[68, 70] N=O,[69a, b] and nitro

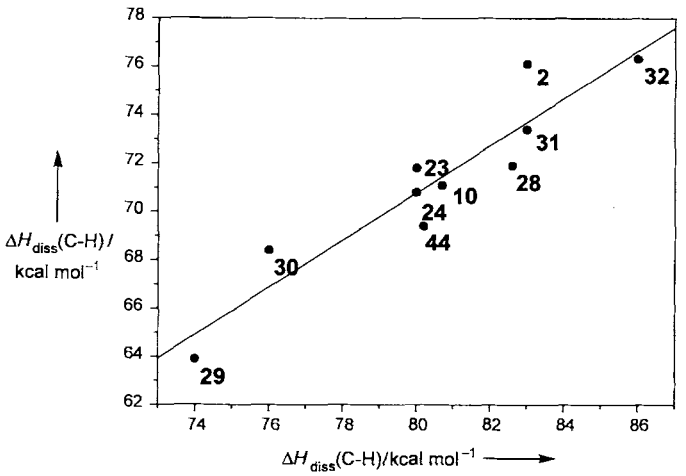


Figure 7. Correlation between the C–H bond enthalpies calculated from Equation (c) and the independently determined values from Table 4 (in kcal mol^{-1}); ΔH_{diss}(C–H) on the abscissa: from Table 4; ΔH_{diss}(C–H) on the ordinate: from Equation (c).

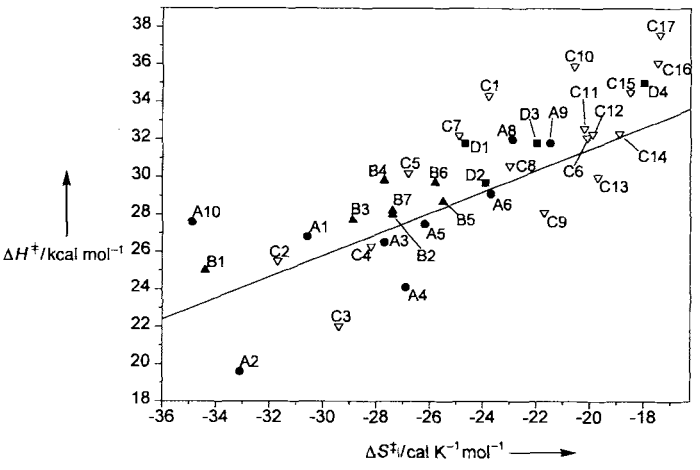

Figure 8. Correlation between the enthalpy of activation $\Delta H^{\ddagger}$ and the entropies of activation $\Delta S^{\ddagger}$ for retrodisproportionation reactions. Series A (unsubstituted H donors with **1**): A1: **10**, A2: **29**, A3: **24**, A4: **30**, A5: **23**, A6: **31**, A7: **33**, A8: **32**, A9: **2**, A10: **28**; series B (substituted dihydroanthracene derivatives with **1**): B1: **44**, B2: *cis*-**41**, B3: **43**, B4: **42**, B5: **40**, B6: *cis*-**18**, B7: *trans*-**41**; series C (H acceptors with a C=C bond and **2** as the H donor): C1: **50**, C2: **47**, C3: **55**, C4: **62**, C5: **49**, C6: **54**, C7: **51**, C8: **53**, C9: **66**, C10: **65**, C11: **57**, C12: **58**, C13: **56**, C14: **63**, C15: **48**, C16: **59**, C17: **64**; series D (additional H acceptors such as dienes and trienes with **2**): D1: **69**, D2: **67**, D:3 **68**, D4: **32**.

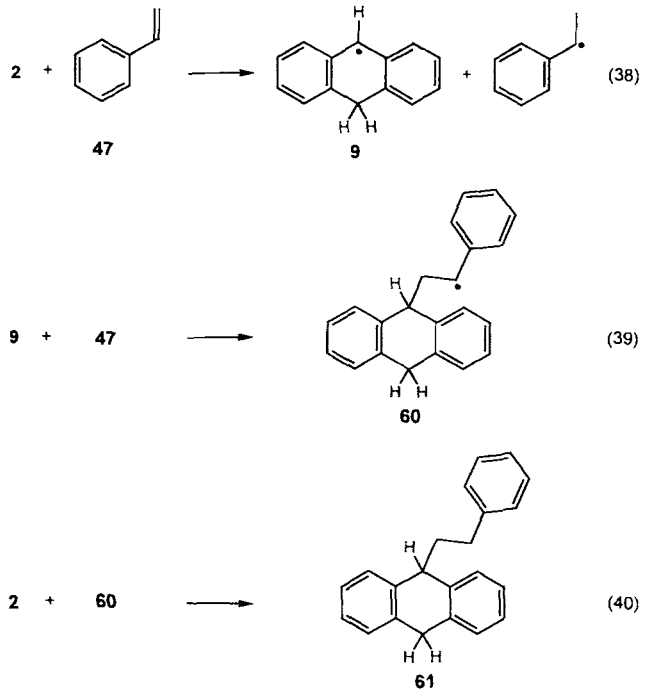
groups[69a, b]). Table 5 summarizes the kinetic and thermodynamic data for the retrodisproportionation of various H acceptors containing C=C bonds in the reaction with 9,10-dihydroanthracene (**2**).[36, 70]

This data shows that the reactivity ($\Delta G^{\ddagger}$ or k_{rel} in Table 5) varies only slightly with drastic structural variations of the H acceptor (maximum value of k_{rel}:2700 for **55**:**64**). For the series of H acceptors in Table 5 the reaction enthalpy $\Delta H^{\ddagger}$ is generally about 5–10 kcal mol^{-1} lower than the reaction enthalpy ΔH_R of the retrodisproportionation step. However, there is a close correlation between these two parameters. In some examples the deviation is significantly larger (in particular for **47**, **51**, **62**, **56**, and **66**). It is possible that the kinetic analysis in these examples is affected by side reactions such as reversibility or the ane reaction. Side reactions can result in errors when calculating the components $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ of the enthalpy of activation $\Delta G^{\ddagger}$ and create the false impression of an isokinetic relationship. Such a relationship can indeed be observed for the data in Tables 4 and 5. The reaction acceleration expected from the enthalpy data is reduced by entropy effects. Since the enthalpies of activation $\Delta H^{\ddagger}$ listed in Table 4 correlate well with the C–H bond enthalpies of the H donors (Figure 7), which deems them reliable, the isokinetic relationship (Figure 8) cannot be the exclusive result of side reactions and the experimental errors caused by them. To exclude any potential effects of this kind, the structure–reactivity relationship will be discussed under consideration of $\Delta H^{\ddagger}$.

An increase in the size of the α-alkyl substituent in the α-alkylstyrenes **1**, **48**–**50** decreases the rate only by a factor of 17. However, a clear trend cannot be determined with the enthalpies of activation $\Delta H^{\ddagger}$. The nontwisted alkenes **53**–**54** react at only a slightly faster rate.[74] 2,6-Dimethylstyrene (**51**) reacts 17 times slower than styrene (**47**), and the enthalpy of activation of **51** is 6 ± 2 kcal mol^{-1} larger than that of **47**. In the reaction of **47** with **2** [Eq. (38)] it was possible for the first time to detect the secondary product **61** [Eq. (40)] of the addition of the 9-hydroanthryl radical **9** onto the double bond of the H acceptor [Eq. (39), Scheme 8]. This product will hereafter be referred to as the ane product, as this reaction was already described earlier as the ane reaction.[15]



Scheme 8. Formation of the ane product **61** in the reaction of styrene (**47**) with **2**.

The formation of the ane product was later observed with other H acceptors[70] including acenaphthylene (**62**, 5%), phenylacetylene (**70**, >95%), diphenylacetylene (**71**, >30%),

[a] Solvent diphenyl ether (DPE); volume expansion was considered in all cases; a reverse reaction with rate k_{-1} was not detected. [b] Autohydrogenation of 1,2-dihydronaphthalene, which acts as both the H donor and the H acceptor. [c] The reaction enthalpies ΔH_R were calculated from the enthalpies of formation of the reaction partners. Except for the values shown in Table 5 for ΔH_f^0(g) of the H acceptors and the radicals fomed from them, the following values were used: ΔH_f^0(g)[**2**] = 38.2 kcal mol^{-1}, ΔH_f^0(g)[**9**] = 69.1 kcal mol^{-1}, see ref. [63, 64]. [d] Based on calorimetric measurements, see ref. [65, 70]. [e] Based on MM2-ERW force field calculations, see ref. [70]. [f] Whenever data was available from both force-field calculations and determinations of combustion enthalpies, the latter was preferably used to calculate ΔH_R. [g] See ref. [3, 48, 63]. [h] See ref. [70]. [i] Estimated from the enthalpy of formation ΔH_f^0(g) for 9-ethylidenefluorene as well as strain-free increments, see ref. [70]. [k] Based on ΔH_f^0(g) for **57** using the ΔH_f^0(g) difference of 80.0 kcal mol^{-1} obtained from AM1 calculations [66]. [l] Adduct radical formed from the H acceptor by H transfer. [m] Based on MM2-82 force-field calculations, see ref. [70]. [n] From ΔH_f^0(g) for acenaphthene (37.3 kcal mol^{-1})[65] and the estimated BDE for acenaphthene of 81.8 kcal mol^{-1} [70]. [o] Based on the resonance stabilization energy (RSE) for the 1-tetralyl radical (≈8.4 kcal mol^{-1}) and the 1,2-dihydro-2-naphthyl radical (≈13 kcal mol^{-1}). [p] Ref. [2b]. [q] The force-field method was calibrated [70] for 9-alkyl-9-fluorenyl radicals with the RSE of the 9-methyl-9-fluorenyl radical (15.3 kcal mol^{-1}) [2b]. [r] Based on ΔH_f^0(g) (9-methyl-9-fluorenyl radical) as well as strain-free increments [70]. [s] See ref. [72]. [t] The enthalpies of formation ΔH_f^0(g) of the radicals were calculated from the enthalpies of formation of the hydrogenation products and the RSE of the radicals. The following values were assumed for the latter: RSE(3-cyclohexen-1-yl) ≈ RSE(3-cyclohepten-1-yl) = −13.3 kcal mol^{-1} and RSE(3,5-cycloheptadien-1-yl) = −17.3 kcal mol^{-1}; see also ref. [73]. [u] With respect to *N*-methylacetamide (NMA) [45]: Solvent effect = k_{obs}(DPE)/k_{obs}(NMA). [v] $k_{rel} = k$(DPE)/k(benzonitrile), see also ref. [40]. [w] Kinetic isotope effect for the reaction with [D_4]-**2**. [x] $k_{rel} = k/k$(**1**).

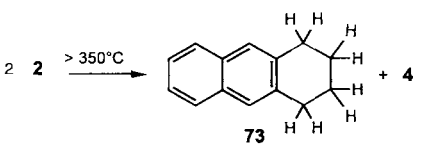
and 1,1-bis(*p*-tolyl)allene (**72**, 50%). No kinetic data is available for the latter three cases, because the portion of the ane product is too high.

When the sterically demanding H donor 1,4,5,8-tetramethyl-9,10-dihydroanthracene (**40**) was employed, transfer hydrogenation of **47** is not accompanied by the ane reaction, so that a kinetic analysis is feasible.[70] Steric effects of α-alkyl groups influence the rate of the reaction only to a minor extent. The difference in $\Delta H^{\neq}$ for the reaction of **2** with **1** (31.8 kcal mol^{-1}) and 1,1-diphenylethene (**63**) (32.3 kcal mol^{-1}) is also surprisingly low, which can probably be attributed to the strong distortion of **63** ($\alpha = 43.5$[75]). The high reactivity of the dibenzofulvenes **55**–**58** can be explained with an increased π-electron ground-state energy of fulvenes[76] as well as with the planarity of the formed radicals.[34]

If the carbon atom that is attacked during H transfer is substituted, the rate of the transfer hydrogenation decreases, and the enthalpy of activation increases, as is known for radical addition

reactions onto alkenes.[77] This becomes very obvious in the transition from dibenzofulvene (**55**, $\Delta H^{\neq} = 22.0\ \mathrm{kcal\,mol^{-1}}$) to 9-ethylidenefluorene (**56**, $\Delta H^{\neq} = 30.0\ \mathrm{kcal\,mol^{-1}}$) and 9-isopropylidenefluorene (**57**, $\Delta H^{\neq} = 32.6\ \mathrm{kcal\,mol^{-1}}$; Table 5). This trend is presumably caused by the steric shielding of the reaction center at the attacked β-C atom, as well as by the stabilization of the C=C bond in the ground state by additional alkyl substituents. The latter effect can be observed very clearly when phenyl substituents are introduced in the β position as, for instance, in *trans*-stilbene (**64**, $\Delta H^{\neq} = 37.6\ \mathrm{kcal\,mol^{-1}}$). The slight increase in reactivity with triphenylethene (**65**, $\Delta H^{\neq} = 35.9\ \mathrm{kcal\,mol^{-1}}$) is probably also caused by distortion. The β-substituent effect is also evident in the relatively high enthalpies of activation for indene (**59**, $\Delta H^{\neq} = 36.1\ \mathrm{kcal\,mol^{-1}}$) and 1,2-dihydronaphthalene (**60**, $\Delta H^{\neq} = 35.8\ \mathrm{kcal\,mol^{-1}}$). The high reactivity of acenaphthylene (**62**, $\Delta H^{\neq} = 26.3\ \mathrm{kcal\,mol^{-1}}$) is not only caused by the increased radical stabilization in the naphthalene system,[78] but also by the *cis* stereochemistry of the double bond. At 300 °C, *trans*-crotylbenzene reacts approximately ten times slower than **1**.

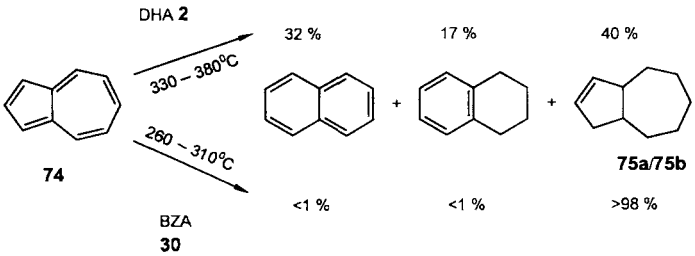
Neither the rate constants nor the activation parameters change significantly when both methyl groups in **57** are replaced with two cyano groups to give 9-fluorenylidenemalononitrile (**58**). This observation is consistent only with a radical reaction mechanism and indicates a slightly polarized transition state. The solvent effect of 0.91 established for **57** at 300 °C in the transition from diphenyl ether to *N*-methylacetamide supports this hypothesis even though dibenzofulvenes possess notable dipolar character.[76] This character is probably strongly reduced in **58**, since both the dicyanomethylene and the fluorenylidene substituents can stabilize anionic but not cationic charges. Therefore, no decrease in the rate of reaction is observed by conjugation in the ground state. It is noteworthy that **57** and **58** are the only tetrasubstituted alkenes to date for which kinetic data have been established for the H-transfer reaction. Although tetraphenylethene reacts with **2** to yield the dihydro product, even at 380 °C, the reaction is very slow, and side reactions such as the decomposition of 9,10-dihydroanthracene (**2**) to tetrahydroanthracene [**73**, Eq. (41)] are so pronounced that activation parameters could not be obtained.[79]



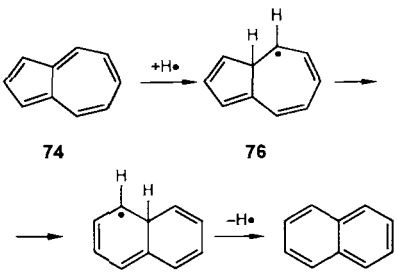
(41)

H acceptors containing conjugated C=C bonds such as 1,3-cyclohexadiene (**67**), cycloheptadiene (**68**), and cycloheptatriene (**69**)[36] are also subject to retrodisproportionation with **2** as the H donor (Table 5). Once again, $\Delta H^{\neq}$ and ΔH_R correlate within the expected values, and the other common criteria support a radical mechanism of the transfer hydrogenation.

Especially interesting is the transfer hydrogenation of azulene (**74**). Under mild conditions at 260–310 °C with **30** as the H donor, a mixture consisting of two isomeric octahydroazulenes is formed in almost quantitative yield (Scheme 9).[38b] However, when this reaction is performed at 330–380 °C and with **2** as the H donor, only 40% of the isomeric octahydroazulenes **75a**/**75b** is obtained along with 32% naphthalene and 17% tetraline. Azulene (**74**) by itself is stable under these reaction conditions. These observations support the mechanism of the thermal azulene–naphthalene rearrangement (42) at 400 °C as proposed by Scott et al.[80] Accordingly, the H-atom adducts of azulene are responsible for the isomerization. The purely



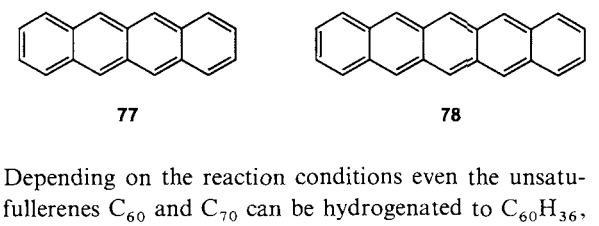
Scheme 9. Product distribution of the transfer hydrogenation of azulene (**78**) with DHA (**2**) at 330–380 °C, and with BZA (**30**) at 260–310 °C in diphenyl ether [38]; **75a,b**: two constitutional isomers.

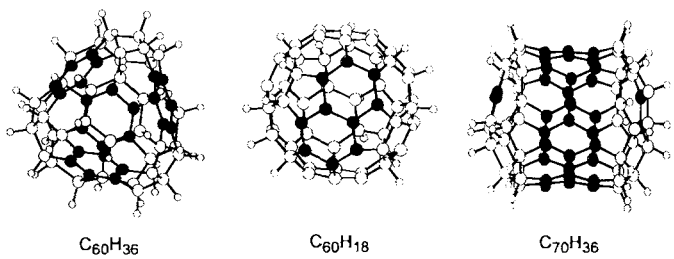


(42)

thermal azulene–naphthalene rearrangement suffers from the fact that no suitable H donor is available. Therefore, the rearrangement occurs in the presence of **2** or **30** at milder reaction conditions. The different course of reaction upon the use of **2** or **30** can be explained by the high donor reactivity of the latter upon trapping of the intermediate radical **76**.

Among aromatic π systems the rate of reaction with **2** increases in the order anthracene (**4**),[19] tetracene (**77**),[71] and pentacene (**78**) to form the corresponding dihydro derivatives. Depending on the reaction conditions even the unsaturated fullerenes C_{60} and C_{70} can be hydrogenated to $C_{60}H_{36}$, $C_{60}H_{18}$, or $C_{70}H_{36}$ (Scheme 10).[81]





Scheme 10. Proposed structures for $C_{60}H_{36}$, $C_{60}H_{18}$, and $C_{70}H_{36}$. The sp^2-hybridized carbon atoms are partially filled for a better overview [80, 81].

Upon heating to 550 °C, the isolated hydrogenated fullerenes eliminate hydrogen to reform the parent fullerenes. This observation prompted investigations targeted towards the use of fullerenes as H-transfer promotors.[82]

2.2.3. Isokinetic Relationship

Comparison of the activation parameters of the investigated H donor/H acceptor pairs upon variation of the H donor and H acceptor clearly showed a parallel course of the enthalpy of activation $\Delta H^{\neq}$ and the entropy of activation $\Delta S^{\neq}$, which is a general trend. Smaller values of $\Delta H^{\neq}$ are accompanied by smaller values of $\Delta S^{\neq}$ and vice versa. Therefore, the entropy of activation $\Delta S^{\neq}$ acts as an antagonist to the enthalpy of activation $\Delta H^{\neq}$ when ranking the reactivities of the rate constants. Such a correlation between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for a given series of reactions is referred to as an "isokinetic relationship",[83] and is shown in Figure 8 for the results from Tables 4 and 5 (see also ref. [22b]). The slope of the best-fit curve β (in K) is the isokinetic temperature [Eq. (d)].[84] The value of β represents the tem-

$$\Delta H^{\neq} = \Delta H_0^{\neq} + \beta \Delta S^{\neq} \qquad \text{(d)}$$

perature at which all reactions of a given series should occur with the same rate constant. The isokinetic relationship can also be deduced from the temperature dependency of the rate constants of the various H-transfer reactions.[36] For the retrodisproportionation reactions shown in Figure 8 β is greater than 1000 K, which indicates that all the reactions presented here proceed at temperatures significantly below the isokinetic temperature.

In many cases it cannot be unambiguously determined if an isokinetic relationship is indeed significant. Statistical uncertainties of a kinetic analysis[84, 85] and systematic errors can create the impression of such a relationship, since, according to the Eyring relationship, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are interdependent parameters. In the current series of experiments, the statistical experimental errors of $\Delta H^{\neq}$ (2–3 kcal mol^{-1}) are small compared to the expanded range of the isokinetic relationship ($\Delta H^{\neq}$ = 19.6 kcal mol^{-1} for A2 and 37.6 kcal mol^{-1} for C17 in Figure 8). Systematic errors, especially the reversibility of the retrodisproportionation step, were also excluded when possible. The significance of the $\Delta H^{\neq}$ values are supported by their good correlation to the reaction enthalpies ΔH_R or the C–H bond enthalpies, respectively, in Figures 7 and 8.

A structure variation of the starting materials that causes a more pronounced interaction in the transition state ($\Delta G^{\neq}$) leading to a decrease in $\Delta H^{\neq}$ probably results in a shorter C–H–C distance in the transition state and, thus, in a parallel decrease in $\Delta S^{\neq}$.[83b] The main portion of the entropy loss occurs upon formation of the activation complex from the starting materials and, therefore, depends on the varying attraction of the starting materials in the activation complex (ΔS_0 activation complex) as well as on the requirements for the orientation of the starting materials to each other during the formation of the activation complex. The transition state is loacted between the activation complex and the radical pair on the ΔG reaction coordinate (Figure 1). The H-atom transfer occurs in this section under formation of the radical pair, which should be located close to the maximum of ΔG. The strong variation of $\Delta S^{\neq}$ within the reaction series suggests that the structures of the transition states vary depending on the starting materials. According to the Hammond principle, the smaller the reaction enthalpy of the retrodisproportionation step, the shorter the C–H–C distance in the transition state and the lower the entropy could be (Figure 9).

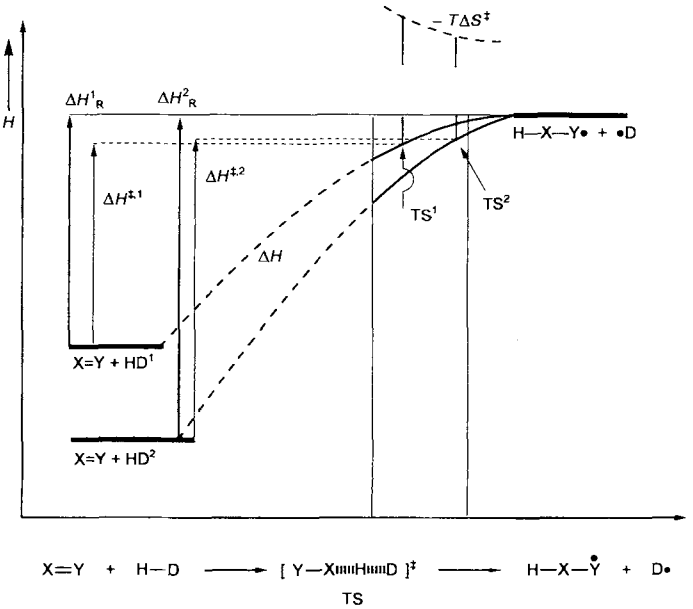


Figure 9. Shift of the transition state TS along the reaction coordinate for reactions with various reaction enthalpies; starting materials: X=Y and H–D; free radicals: H–X–Y• and D•.

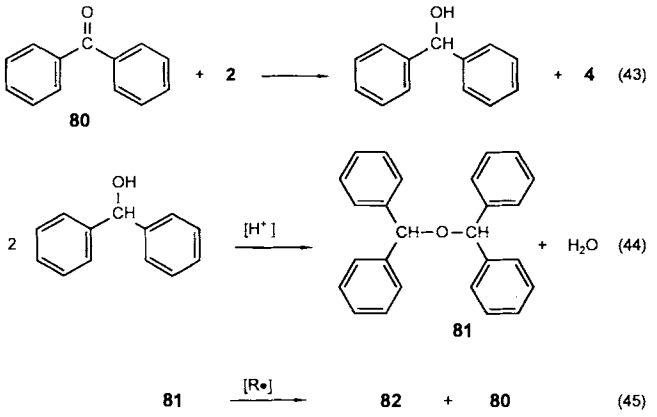
Accordingly, $\Delta S^{\neq}$ would decrease parallel to $\Delta H^{\neq}$ or ΔH_R (for a similar demonstration see also ref. [86]). The fact that the actual H transfer takes place in the transition state ($\Delta G^{\neq} = \Delta G_{max}$) when the radical formation has not yet been completed explains the observation of H/D isotope effects close to the theoretical maximum on the reaction rates. It also becomes apparent why the measured enthalpy of activation $\Delta H^{\neq}$ is generally smaller than the reaction enthalpy ΔH_R.

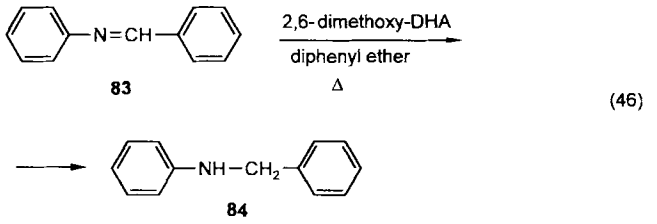
2.2.4. Transfer Hydrogenations of C=X and X=X

Retrodisproportionation is not limited to H acceptors containing C=C bonds. However, carbonyl groups are less reactive, probably due to their high bond enthalpies. α,β-Unsaturated carbonyl compounds were selectively hydrogenated at the C=C bond,[56c] whereas ketones were only slowly hydrogenated under the same reaction conditions (activated charcoal, white mineral oil).[56c] The reduction of fluorenone (**79**) with DHA and other H donors to form fluorene (**28**) occured only above 400 °C.[68] The reduction of benzophenone (**80**) with tetraline starts with a radical transfer hydrogenation [see Eq. (43) in Scheme 11]; benzhydryl ether (**81**) is presumably formed in a secondary reaction [Eq. (44)] and further reduced to diphenylmethane (**82**) in a radical-chain reaction [Eq. (45)].[68] The complex nature of this reaction could be confirmed in our laboratory.[87]



Scheme 11. Transfer hydrogenation of benzophenone with DHA (2).

The C=N bond in benzylideneaniline (**83**) could be readily hydrogenated to *N*-benzylaniline (**84**) upon heating with **2** or, for example, with 2,6-dimethoxy-9,10-dihydroanthracene to 280–320 °C in diphenyl ether [Eq. (46)]. Activation data and



kinetic isotope effects (Table 6) again support an initial retrodisproportionation with subsequent H transfer in which, according to AM1 calculations, the hydrogen primarily adds onto the nitrogen and not the carbon atom.[36c]

Table 6. Kinetic and thermodynamic data for the transfer hydrogenation of H acceptors containing C=X bonds with H donors in diphenyl ether (DPE). X = heteroatom.

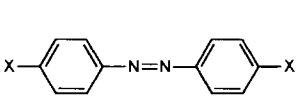
85g [69c]	**2**	40.2±0.5	28.0±0.5	−21.2±1.0

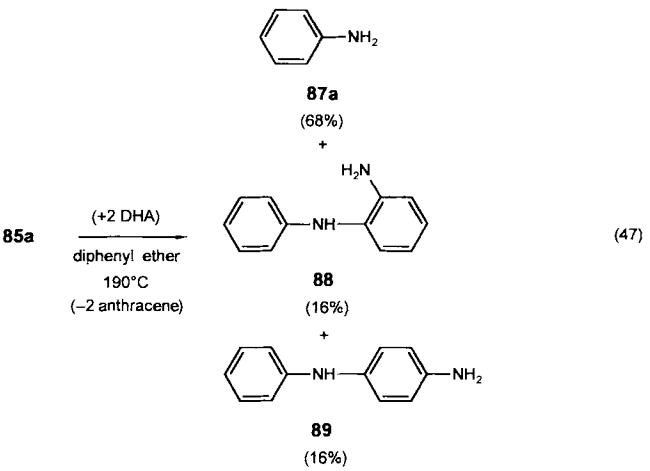
[a] 2,6-Dimethoxy-9,10-dihydroanthracene. [b] Solvent effect [45] k_{obs}(NMA)/k_{obs}(DPE) = 2.2 (**85a**, 200 °C); k_{obs}(benzonitrile)/k_{obs}(DPE) = 2.9 (**83**, 300 °C). [c] k_H/k_D = 1.4 (**83**, 300 °C; 4.7 (**85a**, 220 °C).

At temperatures between 190 °C and 250 °C, azobenzene (**85a**) and the substituted azobenzenes **85b–g** (50 mM) also react



X = H **85a** X = Cl **85e**
X = CH_3 **85b** X = Br **85f**
X = *t*Bu **85c** X = NH_2 **85g**
X = OCH_3 **85d**

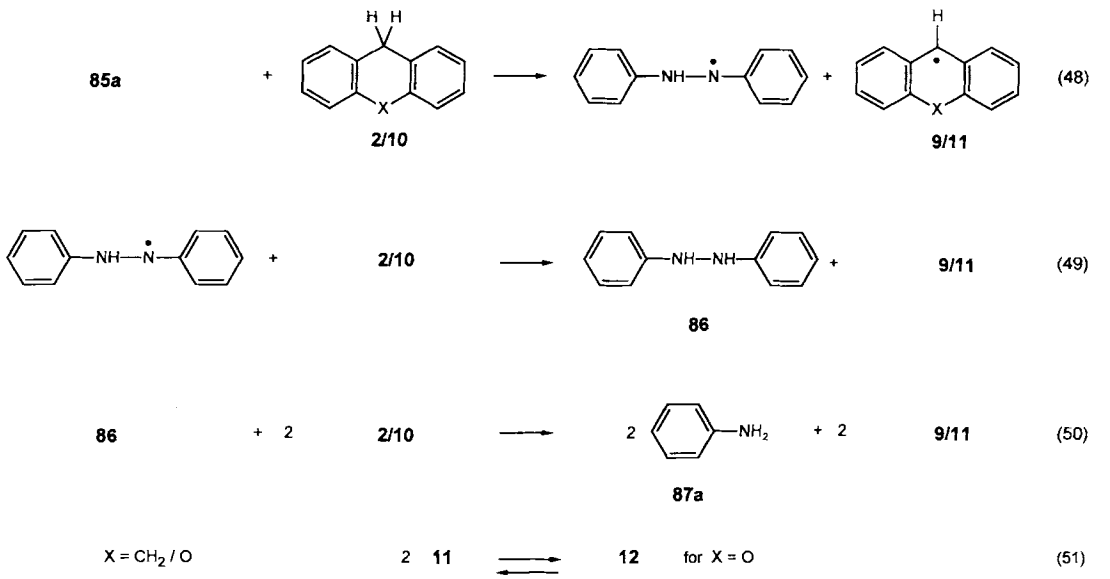
with **2** (1.0 M) in diphenyl ether.[69c, 88] Hydrazobenzene (**86**) could be detected by gas chromatography as an intermediate in the reaction of **85a**, ultimately leading to the formation of 68% aniline (**87a**) and 32% of a 1:1 mixture of *o*- and *p*-semidine [**88** and **89**, Eq. (47)].



The yield of semidine decreases with higher temperatures. The yields of tetraline or *N*-methylacetamide are very similar. The reaction with *p*,*p*′-dimethylazobenzene (**85b**) at 220 °C in diphenyl ether led to the formation of *p*-toluidine (**87b**, 76%) and the corresponding *o*-semidine **88b** (20%). Similar ratios were found with **85c–f**. In contrast, *p*-phenylenediamine was formed exclusively in the transfer hydrogenation of **85g**. When performing the transfer hydrogenation of **85a** with xanthene (**10**) at 250 °C in diphenyl ether, 75% **87a**, 15% **88**/**89**, and 88% of bixanthene (**12**) formed. Dimer formation indicates the intermediate existence of the 9-xanthyl radicals **11** in the hydrazobenzene formation [see Eq. (48), (49) in Scheme 12]. Under the latter reaction conditions, **11** could also be detected by ESR spectroscopy with high resolution.

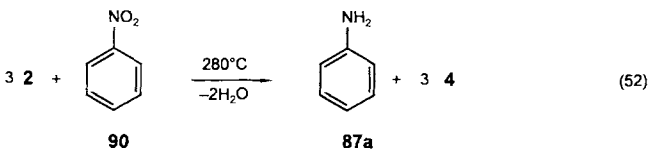
It remains unclear whether the formation of **87a** is caused by thermolysis of **86**[89] or by transfer hydrogenation [Eq. (50)]. The activation parameters for the azobenzene reduction determined by kinetic measurements confirm that the retrodisproportionation step (48) with X = O, CH_2 is rate-determining (Table 6). However, it is still not proven if this step is partially reversible under the given reaction conditions. The reaction enthalpy of 33 kcal mol^{-1} estimated from thermodynamic data at 25 °C for the retrodisproportionation of **2** (X = CH_2) with **85a** [Eq. (48)][90] corresponds well to the enthalpy of activation of 26 kcal mol^{-1} determined at 190–250 °C. Indications for a radical retrodisproportionation step, but against a possible hydride-transfer mechanism, are the small reactivity difference between **2** and **10**, (Table 6) and the small solvent effect on the rate of the transfer hydrogenation of **85a** with **2** (k(NMA)/k(DPE) = 2.2 at 200 °C).[69c] The solvent effect, which is of the same order of magnitude as for the reaction of **2** with **1**, supports a similar reaction mechanism, as does the isotope effect of k_H/k_D = 4.7 at 220 °C (Table 6).

Transfer hydrogenation of **85a** with **2** can also be considered as a dehydrogenation reaction under aromatization of **2** to anthracene (**4**). This possibility raises the question whether the



Scheme 12. Transfer hydrogenation of azobenzene (**85a**) with xanthene (**10**; X = O) or dihydroanthracene (**2**; X = CH_2) as the H donor.

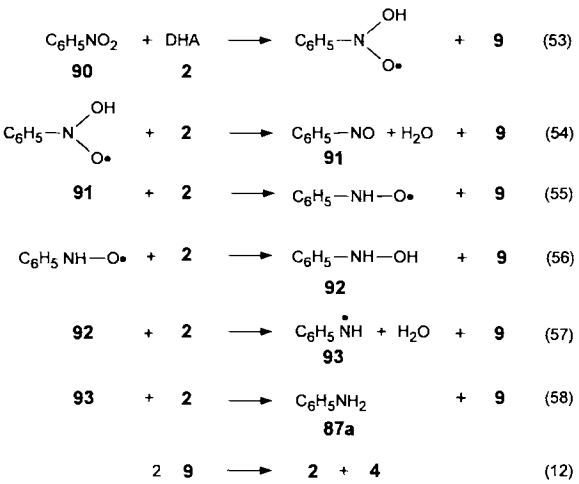
stepwise H-atom transfer discussed here is mechanistically feasible for dehydrogenation reactions in general,[91] either supplementary or alternatively to the common hypothesis of a direct hydride or electron transfer.[91b] Prompted by this issue, we investigated transfer hydrogenations with aromatic nitro[91c] and nitroso compounds[91d] as well as with quinones.[11, 12] Nitrobenzene (**90**) was quantitatively reduced to aniline (**87a**) upon heating to 230–280 °C with excess **2** or **10** [Eq. (52)].[69]



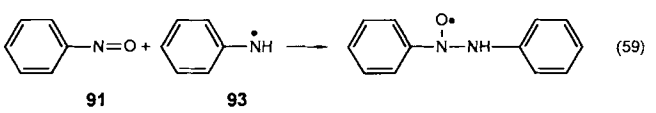
para-Substitution of **90** with methoxy, methyl, or cyano groups increased the rate of reduction with **2** by a factor up to a maximum of 7. Polar solvents do not have a significant or unambiguous influence on the rate of reduction (half-lives $t_{1/2}$; *N*-methylacetamide:diphenyl ether:*o*-dichlorobenzene:benzonitrile 2:14:56:52). The slightly increased substituent and solvent effect compared to the reaction of **2** with **1** is probably caused by the higher electronegativity of the H acceptor **90**. The kinetic isotope effect, which was determined with $[D_4]$-**2** was 2.4 (280 °C) in diphenyl ether. The reactions exhibit first-order kinetics with respect to **90**, but not precisely with respect to the H donor. This is presumably caused by the multistep process [see Eqs. (53)–(55) in Scheme 13] in which various NO radicals occur as intermediates, which can make the reaction more complicated. The experiments were therefore performed under conditions of pseudo-first-order kinetics.[69] Retrodisproportionation or an H-atom transfer is again proposed as the initial step.

Xanthene (**10**) is less reactive than **2**, which is also in contradiction to a direct hydride-transfer mechanism.[69] The observation of the strong ESR signal for the 9-xanthyl radicals **11** during the reaction supports the retrodisproportionation step. The formation of 9,9-bixanthene (**12**) as the major product shows that the radical formation does not constitute a side reaction.

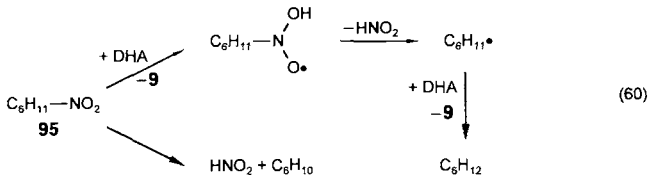
Nitrosobenzene (**91**) was quantitatively converted into aniline (**87a**) and anthracene (**4**) when exposed to **2** at temperatures as low as 210 °C; azoxybenzene (**94**) and presumably phenylhydroxylamine (**92**) occur as intermediates (Scheme 13).[69b] The phenylaminyl radicals **93** were apparently trapped by excess **91**, as in spin-trapping experiments [Eq. (59)].



Scheme 13. Mechanism of the transfer hydrogenation of nitrobenzene (**90**) with DHA (**2**).



The aliphatic nitrocyclohexane (**95**) was also reduced with **2** at 280 °C to a mixture of cyclohexene and cyclohexane [Eq. (60)].[92a] The *syn* elimination of HNO_2 appears to compete with the reduction. 1- and 2-Nitroadamantane were reduced to

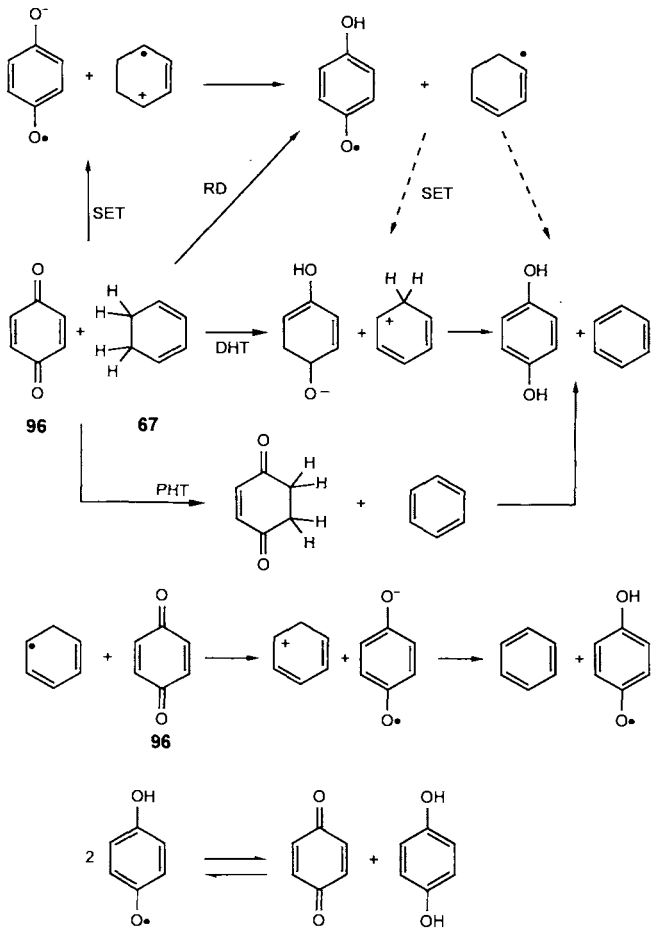


(60)

adamantane at 300 °C without any elimination.[92b] However, the homolytic cleavage of the $C-NO_2$ bond competes with the retrodisproportionation.[92a]

Reduction of phenylhydroxylamine as the intermediate [Eq. (57) in Scheme 13] presumably represents a different, novel step of a bimolecular radical formation, namely transfer hydrogenolysis (Section 3). Interest in the uncatalyzed transfer hydrogenation of nitro compounds focuses predominately on the elucidation of the reaction mechanism (retrodisproportionation versus hydride transfer) of the dehydrogenation and aromatization of cyclic alkenes by nitro compounds as, for instance, occurs in the Skraup, Doebner–Miller, or Bischler–Napieralski syntheses of quinolines.[69]

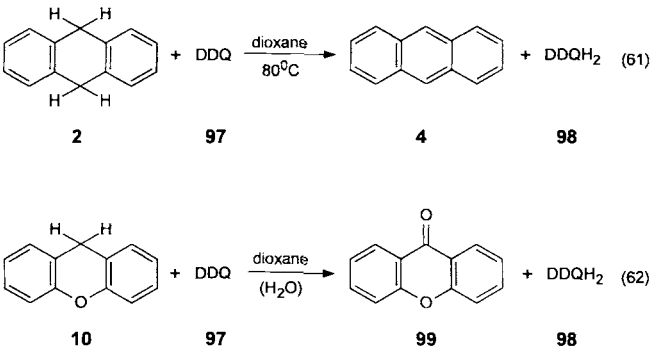
Quinones are also suitable dehydrogenation agents for the aromatization of partially hydrogenated aromatic or heteroaromatic compounds.[11, 12, 93] Scheme 14 illustrates the various mechanisms discussed for this reaction (for an overview see ref. [11, 12, 94]).



Scheme 14. Alternative pathways for the quinone dehydrogenation; single-electron transfer (SET), pericyclic H-atom transfer (PHT), direct hydride transfer (DHT), retrodisproportionation (RD).

When comparing the redox potentials of **96** and **67**, and furthermore considering the experimental enthalpy of activation $\Delta H^{\neq}$, it can be concluded that a single-electron transfer (SET) is contradictory to a dehydrogenation reaction.[94] Pericyclic H-transfer reactions (PHT) were eliminated by stereochemical isotopic labeling experiments and thermochemical arguments.[12, 94] Based on kinetic H/D isotope effects, exclusion of a radical chain mechanism, and sporadic evidence for carbenium-ion intermediates,[12] the direct hydride transfer (DHT), which was postulated by Linstead, Braude et al.,[11] is favored. However, these arguments also support a primary H-atom transfer (retrodisproportionation, RD) without any chain-reaction character, possibly followed by an electron transfer or a disproportionation. This possibility is supported by the fact that the hypothesis of increased reaction rates in polar solvents has not been convincingly proven.[12]

At 80 ° in nondried dioxane, **2** and **10** react with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ, **97**) at very similar rates and in a second-order reaction to give anthracene (**4**) or xanthone (**99**), respectively in almost quantitative yield [Eqs. (61) and (62) in Scheme 15).[94]



Scheme 15. Dehydrogenations of DHA (**2**) and xanthene (**10**) by DDQ (**97**).

In methanol, 18% of 9-methoxyxanthene was formed from **10** as well as 82% of **99**. Although this clearly proves the existence of the 9-xanthylium ion **100** as an intermediate, it does not provide any information as to its mechanism of formation. In the reaction of 3,5,3′,5′-tetra-*tert*-butyldiphenoquinone with xanthene in diphenyl ether at 260 °C, 35% of bixanthene (**12**) was formed, thus proving the formation of the 9-xanthyl radicals **11**.[94b] Kinetic investigations of the solvent dependency of the reaction rate were used to distinguish between the two alternatives presented in Scheme 14. The results in Table 7 show a minimal solvent effect, which is in sharp contrast to the expectations for the ionization process of the hydride transfer[40, 41] but correlates well with a primary retrodisproportionation.

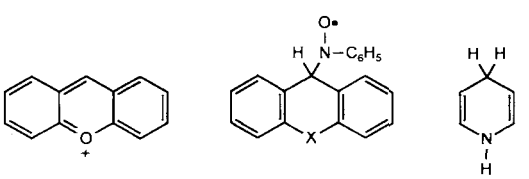


Table 7. Dehydrogenation of 9,10-dihydroanthracene (**2**, 7.2×10^{-2} M) and xanthene (**10**, 6.6×10^{-2}–1.1×10^{-1} M) by DDQ (**97**, 1.5–6.6×10^{-3} M) in various solvents at 25–65 °C.

Solvent		$E_T(30)$ [a] [kcal mol^{-1}]	k_{rel} [M^{-1} s^{-1}]	$\Delta G^{\neq}$ (25 °C) [kcal mol^{-1}]		$\Delta S^{\neq}$ [cal K^{-1} mol^{-1}]

7	acetic acid	51.7	3.8 [d]	17.7	9.6	−27.2
8	dioxane [e]	36.0	0.13 [b]			

[a] $E_T(30)$ parameter from ref. [40]. [b] Relative rate k_{rel} at 50 °C. [c] 9,9′,10,10′-D_4-Dihydroanthracene ([D_4]-**2**). [d] At 25 °C; $k_2(\mathbf{10})/k_2(\mathbf{2}) = 16\pm1$ at 25 °C. [e] 9,9-D_2-Xanthene ([D_2]-**10**).

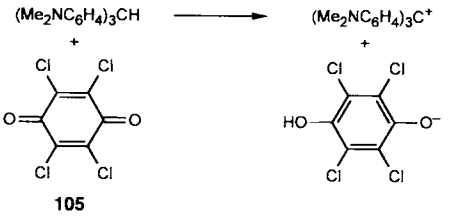
The very similar rate constants of **2** and **10** are remarkable and can be explained with a primary radical formation in the 9-position (**9** and **11**, respectively), but not with the formation of carbenium ions. The oxonium stabilization of **100** should significantly accelerate the rate of reaction.[41]

Also noteworthy are the relatively low values for $\Delta H^{\neq}$ and $\Delta S^{\neq}$, which are in agreement with the isokinetic relationship established for retrodisproportionation reactions with alkenes. Unfortunately, no reliable thermodynamic data is available for the reaction enthalpies ΔH_R of this step; however, initial calculated values suggest that ΔH_R has a higher value than $\Delta H^{\neq}$.

The kinetic isotope effect $k_H/k_D = 8.0\pm0.3$ for **2** and **10** with DDQ (**97**) in dioxane at 50 °C is also astonishingly high. This value, which reaches the theoretic maximum, shows that the hydrogen transfer is completed approximately in the middle of the transition state on the ΔG reaction coordinate. This can be explained in the same way as the retrodisproportionation reactions mentioned above, however, a tunnel effect appears feasible as well.[94b, 97] Although all attempts to detect radical intermediates by ESR spectroscopy or chemically induced dynamic nuclear polarization (CIDNP)[95] failed, spin-trapping experiments with nitrosobenzene (**91**) were successful. In the reactions of DDQ with both DHA and xanthene, ESR spectra of the known adduct radicals **101** and **102** could be unequivocally identified.[94] No comparable signal could be detected without the addition of DDQ under otherwise identical reaction conditions.

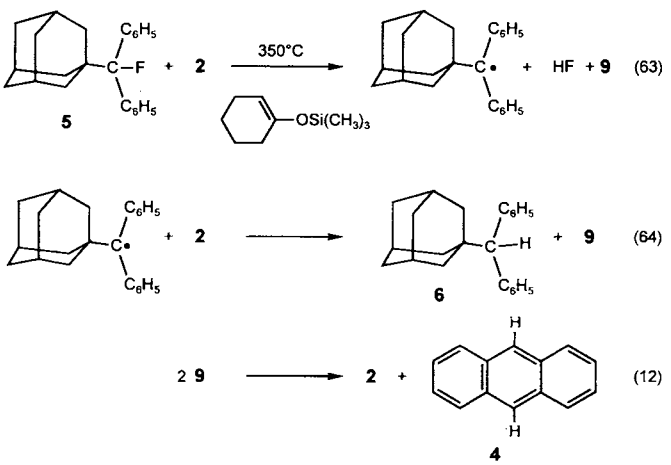
The results discussed here[94] support an H-atom transfer mechanism for the quinone dehydrogenation. It is still unclear which secondary steps shown in Scheme 14 apply for the given reaction conditions. A fascinating issue is the behavior of 1,4-dihydropyridine (**103**), acridan (**23**), and *N*-methylacridan (**24**) in the reaction with quinones, since it is relevant for the mechanism of the biochemical hydride transfer with NADH or $FADH_2$.[96] Primary H-atom transfer has never been seriously considered.[96, 97] Acridan (**23**) reacts very rapidly with DDQ in acetonitrile at 40 °C to yield acridine (**104**) quantitatively.[94, 98, 99] A spin-trapping experiment with **91** provided a well-resolved ESR spectrum. Additional experiments will have to underline the significance of these results.

A related reaction, the oxidation of leuco crystal violett by chloranil (**105**) to provide cations of crystal violett was reported.[99b] The kinetics ($\Delta H^{\neq} = 8.1\pm0.5$ kcal mol^{-1}, $\Delta S^{\neq} = -19$ cal K^{-1} mol^{-1}) and the observed solvent, isotope, and pressure effects are better compatible with rate-determining H-atom transfer than the proposed electron-proton-electron transfer.[99b] The expectation that the quinone/acridan reaction also has a very low enthalpy and entropy of activation would strongly support an enzymatic mechanism in which the $\Delta S^{\neq}$ barrier is overcome in the substrate–enzyme complex (entropy protection).



3. Transfer Hydrogenolysis

A novel type of bimolecular radical formation was found with the transfer hydrogenolysis and investigated quantitatively in the reaction of 1-adamantyldiphenylmethyl fluoride (**5**) with **2** [see Eq. (63) in Scheme 16 and Eq. (2)].[4] The reaction of **5** with



Scheme 16. Mechanism of the transfer hydrogenolysis of 1-adamantyldiphenylmethyl fluoride (**5**) with DHA (**2**) [4].

2 (tenfold molar excess) was observed between 330 °C and 375 °C with 1-(trimethylsiloxy)cyclohexene as the solvent and an efficient HF trap. The reaction products included 1-adamantyldiphenylmethane (**6**, >95% yield) as well as anthracene (**4**), cyclohexanone, and trimethylsilyl fluoride.

No example exists in the literature[4, 16, 17] for the first step (63) of this reaction sequence. The following reaction steps (64) and (12) represent a known H-trapping reaction and disproportionation. Under the given conditions, the reaction proceeds stoichiometrically rather than by a chain mechanism. The reaction mechanism illustrated in Scheme 16 was supported by selecting xanthene (**10**) and 7*H*-benz[*de*]anthracene (**30**) as H donors. In these experiments, the intermediate 9-xanthyl rad-

icals **11** and the 7*H*-benz[*de*]anthryl radicals, respectively, were detected by ESR spectroscopy with high intensity and resolution.[4] Similar to the experiments on the retrodisproportionation with **2** as the H donor, the corresponding 9-hydroanthryl radicals **9** cannot be proven by ESR due to the rapid disproportionation [Eq. (12)]. Comparison of the experimental enthalpy of activation $\Delta H^{\neq}$ with the reaction enthalpy ΔH_R (see Section 2.2) is in agreement with the postulated radical mechanism (Table 8). The comparison allows the conclusion that the transition state of this reaction is also located very close to the radicals. Deuteration experiments with [D_4]-**2** identified H transfer as the rate-determining step ($k_H/k_D(373\,^{\circ}C) = 2.4$). The reverse reaction with rate v_{-2} as a termolecular process is kinetically disfavored, hence it can be disregarded.[4]

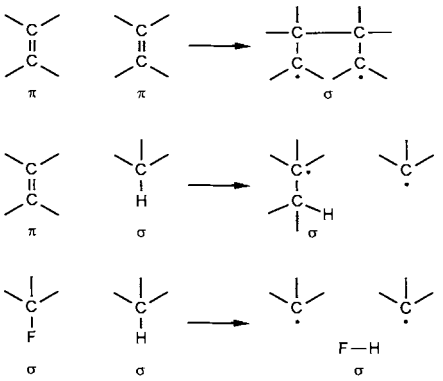
Table 8. Kinetic and thermodynamic data for the bimolecular radical formation of 1-adamantyldiphenylmethyl fluoride (**5**) by 9,10-dihydroanthracene (**2**) [4].

$\Delta H^{\neq}$ [kcal mol^{-1}]	$\Delta S^{\neq}$ [cal K^{-1} mol^{-1}]	$\Delta G^{\neq}_{300\,K}$ [kcal mol^{-1}]	ΔH_R [kcal mol^{-1}]
37.2±0.5	−18.8±0.8	48.0±0.5	48.1±2.2

Additional experiments on the transfer hydrogenolysis showed that, in addition to triphenylfluoromethane, diphenylfluoromethane, and benzyl fluoride, 1-adamantyldiphenyl chloride also reacts with **2** with H transfer. The driving force of the transfer hydrogenolysis with fluorides is clearly the high bond enthalpy of hydrogen fluoride (136 kcal mol^{-1}).[4]

4. Summary and Outlook

Retrodisproportionation and transfer hydrogenolysis represent novel methods for forming radicals. Mechanistic investigations led to systematic and broad structural variations from which quantitative relationships were recognized and formulated, thus making retrodisproportionation very versatile. Both reactions can be classified as bimolecular radical-formation reactions of the known tetramethylene concept,[14e] which includes the intramolecular variation of the Bergman cyclization of enediynes (Scheme 17).[100]



Scheme 17. Classification of bimolecular, molecule-induced radical-formation reactions: a) tetramethylene concept (that is, reaction of $F_2C{=}CF_2$ with styrene (**47**)) [14e]; b) retrodisproportionation (reaction of **1** with **2**); c) transfer hydrogenolysis (reduction of a benzylhydryl fluoride with **2**).

Instead of the established H donors containing C–H bonds, it should be feasible to employ additional H donors including, for instance, O–H, S–H, Si–H, or metal–H groups[20] as a source of H in the systematic variation of starting materials for retrodisproportionation and transfer hydrogenolysis. It is possible that some catalytic hydrogenations that proceed in the presence of metals or metal complexes with the intermediacy of metal hydrides involve retrodisproportionations.[20, 52] Broad variations are also likely for H acceptors beyond the systems known to date (conjugated or isolated olefins, ketones, polycyano alkenes, quinones, alcohols, nitro and nitroso groups, aromatic compounds, fluorides, and chlorides), which should be investigated more precisely and completely, and new systems should also be the focus of future investigations (aldehydes, ketenes, and S=O groups). Moreover, future mechanistic studies should be targeted to test, underline, or supplement the examples of retrodisproportionations that have been postulated but only qualitatively investigated.[101]

We wish to thank the following colleages who participated in the investigations reported in this review and who, both experimentally and conceptually, contributed significantly to the success of this research: Dr. Margot Nölke, Dr. Friedrich Keller, Dr. Frank Schaffer, Dipl.-Chem. Michael Cöllen, Dipl.-Chem. Christoph Höfler, Dipl.-Chem. Heike Friebolin, Dipl.-Chem. Jens Morgenthaler, Dipl.-Chem. Rolf Roers, Dipl.-Chem. Frank Wurche, and Peter Kapferer. Furthermore, we wish to thank Dr. S. P. Verevkin (thermochemistry), Dr. Manfred Keller (crystal-structure analysis), Dr. Dieter Hunkler (NMR spectroscopy), and Dr. Jürgen Wörth (mass spectrometry) and their co-workers for numerous extensive analytical investigations. Special thanks go to Dr. Hans-Dieter Beckhaus for continuous discussions and competent support (ESR spectroscopy, calculational methods, thermochemistry) as well as for a critical reading of this manuscript. We would also like to thank Prof. Dr. A. G. Davies (London) and Prof. Dr. A. L. J. Beckwith (Canberra) for many stimulating discussions and ideas. We gratefully acknowledge financial support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

[8] The enthalpy of activation for the reaction of 2-butene with butadiene, a $[_\sigma 2_s + _\pi 2_s + _\sigma 2_s + _\pi 4_s]$-type reaction, was calculated to be 45 kcal mol^{-1}.[6] As it should be higher for the transfer-hydrogenation of **1** with **2**, since the aromaticity of **1** would be given up in this pericyclic reaction, it should be excluded as a mechanistic possibility. The enthalpy of activation $\Delta H^{\neq}$ of the transfer hydrogenation of **1** and **2** was experimentally determined to be 31.8 kcal mol^{-1}, approximately 15 kcal mol^{-1} lower than that of a pericyclic process.

[9] a) H. M. R. Hoffmann, *Angew. Chem.* **1969**, *89*, 597–618; *Angew. Chem. Int. Ed. Engl.* **1969**, *8*, 556–577; b) B. B. Sinder, *Acc. Chem. Res.* **1980**, *13*, 426; E. C. Keung, H. Alper, *J. Chem. Educ.* **1972**, *49*, 97; c) R. Loncharich, K. N. Houk, *J. Am. Chem. Soc.* **1987**, *109*, 6947–6952; the enthalpy of activation $\Delta H^{\neq}$ and the entropy of activation $\Delta S^{\neq}$ for the ene reaction of ethene or formaldehyde with propene are $\Delta H^{\neq} = 21.4$ kcal mol^{-1} and $\Delta S^{\neq} = -43.0$ e.u., and $\Delta H^{\neq} = 26.4$ kcal mol^{-1} and $\Delta S^{\neq} = -40.1$ e.u., respectively; the enthalpies of activation $\Delta H^{\neq}$ for the reactions of ethene with *cis*- and *trans*-2-butene are $\Delta H^{\neq} = 37.0$ kcal mol^{-1} and 36.5 kcal mol^{-1}, respectively. The entropies of activation for intermolecular ene reactions are generally between -32 and -40 e.u., and approximately -20 e.u. for intramolecular ene reactions. However, the enthalpy of activation for an ene reaction of **1** with **2** should have higher values, since the aromaticity of **2** would be perturbed.

[10] The entropy of activation changes by 4 ± 2 cal K^{-1} mol^{-1} when **40** is used as the H donor instead of **2** (see Table 4).

[31] a) The isotope effect is temperature dependent: R. W. Hoffmann, *Aufklärung von Reaktionsmechanismen*, Thieme, Stuttgart, **1976**, p. 62, Table 10. The entropies of activation of the transfer hydrogenation and the transfer deuteration have approximately the same value (see Table 4). b) The kinetics were determined with the ampoule technique under pseudo-first-order conditions (minimum of tenfold molar excess of **2** over **1**) and also accounting for the volume expansion of the reaction medium.

[32] The standard enthalpies of formation ΔH_f^0(g) for the radicals R$^{\bullet}$ were calculated according to Equation (b) in Section 2.2 from the C–H bond dissociation enthalpies ΔH_{diss}(R–H), which result from the radical stabilization enthalpies RSE(R$^{\bullet}$): ΔH_{diss}(R–H) = ΔH_{diss}(Alkyl–H) – RSE(R$^{\bullet}$). ΔH_{diss}(Alkyl–H) were used as the reference values: ΔH_{diss}[H–CH(CH$_3$)$_2$] = 98.6 [32a] and ΔH_{diss}[H–(CH$_3$)$_3$] = 95.8 [32b, c] kcal mol^{-1}. By definition, simple alkyl radicals have RSE = 0. The values for RSE(R$^{\bullet}$) were deduced from experimentally determined ΔH_{diss}(R–C) [1, 2]; among others, RSE = 10.7 [32d] for the benzyl radical and RSE = 8.4 kcal mol^{-1} [32e] for the cumyl radical. a) J. Berkowitz, G. B. Ellison, D. Gutman, *J. Phys. Chem.* **1994**, *98*, 2744–2765; b) W. Tsang, *J. Am. Chem. Soc.* **1985**, *107*, 2872–2880; see also ref. [21c]; c) J. J Russell, J. A. Seetula, R. [49] See ref. [31b]. Special calculation methods were used in some cases [3, 27]. The activation parameters were measured in a temperature range of at least 40 K.

[50] 1,4-Cyclohexadiene and 1,3-cyclohexadiene could also be employed as H donors with **1**. Quantitative investigations were complicated by the thermolability of 1,4-cyclohexadiene with isomerization to the 1,3-isomer, and, in the case of 1,3-cyclohexadiene, by the retrodisproportionation of two molecules, which yielded several by-products that were not further identified: S. W. Benson, R. Shaw, *J. Am. Chem. Soc.* **1967**, *89*, 5351–5354; G. R. DeMaré, G. Huybrechts, M. Toth, *J. Chem. Soc. Perkin Trans. 2* **1972**, 1256–1258; D. K. Agrafiotis, H. S. Rzepa, *J. Chem. Soc. Chem. Commun.* **1987**, 902–904; G. Huybrechts, B. V. Mele, *Int. J. Chem. Kin.* **1985**, *17*, 709–711).

[51] a) I. Murate, *Top. Nonbenzenoid Aromat. Chem.* **1973**, *1*, 159–190; b) D. H. Reid, *Quart. Rev.* **1965**, *19*, 274–302; c) W. Broser, H. Kurreck, S. Oestreich-Janzen, G. Schlömp, H.-J. Fey, B. Kirste, *Tetrahedron* **1979**, *35*, 1159–1166; d) J. E. Bennett, *Proc. Chem. Soc.* **1961**, 144–145; e) P. B. Sogo, M. Nakazaki, M. Calvin, *J. Chem. Phys.* **1957**, *26*, 1343–1345.

[52] Strictly speaking the promotor function, which can be referred to as catalysis, can presumably also be performed by other compounds that display weak C–H bond enthalpies ΔH_{diss} or by transition metal/H derivatives. The latter play an important role in the transition metal catalyzed transfer hydrogenation: a) T. E. Nalesnik, J. H. Freudenberger, M. Orchin, *J. Organomet. Chem.* **1981**, *221*, 193–197; b) R. L. Sweany, S. C. Butler, J. Halpern, *ibid.* **1981**, *213*, 487–492; c) R. L. Sweany, J. Halpern, *J. Am. Chem. Soc.* **1977**, *99*, 8335–8337; d) J. Halpern, *Pure Appl. Chem.* **1979**, *51*, 2171–2182; see also ref. [20, 35c].

[53] With a computer program the quantitative determination of deuterium incorporation into **1** by GC-MS analysis as a function of the conversion rate allows for the calculation of the percentage of the reverse reaction with rate k_{-32} of the formed 2-phenyl-2-propyl radicals **8** [27]. From these measurements, a correction factor F was introduced with which the experimental rate constants k'_{32} were multiplied to obtain the actual, slightly higher rate constants k_{32} [27]. The effect of disproportionation (for example v_{-32}) also occurs with other H donors and is usually small, so that the rate constants of the retrodisproportionation and particularly the activation parameters change only to a minor extent (see Table 4).

Functional Organic Analogues of Zeolites Based on Metal–Organic Coordination Frameworks**

Christoph Janiak*

Dedicated to Professor Roald Hoffmann on the occasion of his 60th birthday

Supramolecular chemistry has reached a stage at which it is possible to select molecular building blocks that will assemble into structures with specific and desired network topologies, so that a rational design of molecular solids with potentially interesting properties is possible.[1] Recent efforts are being undertaken to generate three-dimensional (3-D) organic and metal–organic porous frameworks by the molecular building block approach. Of special interest is the search for stable microporous organic networks that exhibit reversible guest exchange and possibly selective catalytic activity. So far, no practical uses have emerged, but hopes are running high, and potential applications appear very promising. Construction of inner cavities and channels that are mainly surrounded by organic components is attractive, since the shape, size, and function of the cavity then become designable.[2] There is much interest in tailoring the geometry and the hydrophilic and hydrophobic character of the pores.[3] However, the key feature is not only the incorporation of guest molecules but also their reversible exchange. Here the present state of research concerning this crucial aspect is summarized.

Research on intercalation has concentrated largely on nanoporous inorganic materials such as aluminosilicates (zeolites), aluminophosphates, pillared clays, and graphite—all of which have been known for a long time.[4] Porous solids such as zeolites, which can now be "engineered" to some extent, are already important materials and find widespread application in adsorption (molecular sieves), shape- and size-selective heterogeneous catalysis, and ion exchange. An important aspect of zeolites is their structural stability, which allows guest concentrations to range from zero (empty host) to a maximum value (saturation).[5]

The goal in the search for organic porous frameworks is not simply to mimic inorganic materials such as zeolites by using different building blocks. Some of the properties of organic compounds, such as low thermal stability and low Lewis acidity, are inherently different. Instead it is thought that organic networks should complement the inorganic ones since they exhibit properties that are not displayed by zeolites (for example chirality). The term "zeolite analogues" in connection with organic frameworks is not meant to imply that the full functionality of zeolites should be reproduced, rather it refers to the molecular-sieve character of zeolites, reversible guest removal, and the stability of the host framework in the absence of guest molecules.

Various research projects are currently concerned with the construction of channeled organic, metal–organic, and inorganic solids with a chemical architecture and, possibly, a catalytic activity that differ from those of zeolites. One approach involves porous metal organophosphates and organophosphonates in which the organic groups cover the internal surfaces.[3, 6, 7] Another variant combines the porous framework of zeolites with the catalytic activity of transition metal complexes by encapsulating molecular transition metal complexes in the pores of zeolites. Such an immobilization of metal complexes in a zeolite matrix should mimic the active center of enzymes.[8] A particularly intriguing strategy is to use covalent coordinative bonds and organic or inorganic ligands as links between metal ions. Different metal ions, various coordination geometries (such as octahedral, tetrahedral, or square planar), and numerous ligands provide a wide range of possibilities for connecting metal ions together to construct metal–organic frameworks. Covalent metal–organic lattices offer several possible advantages over their purely organic counterparts, including greater mechanical strength and the presence of catalytically active transition metals. An attractive feature of inorganic complexes is the availability of 90° joints for constructing a polymeric framework with macrocyclic boxes[9] as well as a potentially interesting interplay of hydrophobic and hydrophilic regions and interactions.[10] The synthesis or self-organization of these coordination polymers is achieved by combining the appropriate metal salt and a tailored ligand in a suitable solvent. The reaction proceeds under mild conditions, often spontaneously. The metal centers in a coordination polymer may be thought of as an assembling and templating species for the organic (ligand) groups.

A large number of static metal–ligand frameworks and host–guest structures are known, but a reversible guest exchange or chemical transformations of the guest inside a coordination-

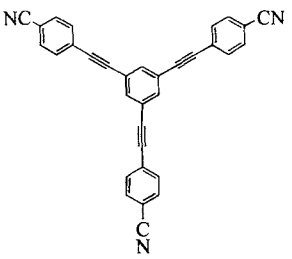
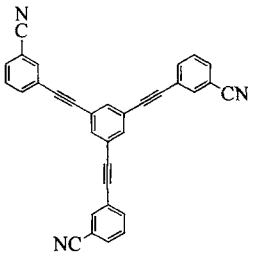
polymer framework has been described for only a few. Layered materials with channels perpendicular to the layers, such as in the first five examples, appear to be most promising as functional organic analogues of zeolites. The structural descriptions seldom include a detailed picture of the host–guest interactions, in part due to disorder. Only the building blocks will be illustrated here; for the often complicated 3-D networks see the original literature. The solid-state structure of $[Ag(TEB)CF_3SO_3]\cdot 2C_6H_6$ [(TEB = 1,3,5-tris(4-ethynylbenzonitrile)benzene, **1**) exhibits hexagonal 15 Å channels,[11] which are created in spite of the interpenetration of six independent 3-D networks. The crystals are porous to benzene exchange; storage in C_6D_6 led to the formation of the deuterosolvate, as monitored by NMR spectroscopy. Dissolution and reformation of the lattice does not occur, as shown by X-ray powder diffractometry (XRPD).[12]

The silver triflate complex with the related tridentate ligand 1,3,5-tris(3-ethynylbenzonitrile)benzene (**2**) forms a 2-D coordi-



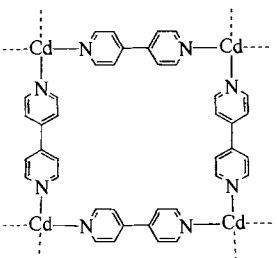
1



2

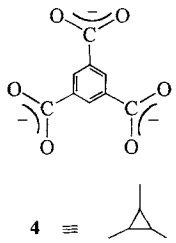
nation network that incorporates benzene molecules in channels running oblique to the layer plane. Of the 16 benzene molecules in the unit cell, four are lost reversibly at 110 °C (thermogravimetric analysis) without loss of crystallinity or a phase transition of the host structure, as shown by the optical transparency and XRPD. The remaining 12 benzene molecules are lost in a solid-to-solid phase transition at 145 °C, but even here subsequent cooling of the sample under a benzene atmosphere leads to the reabsorption of benzene and restoration of the original solid phase.[13]

The organic linkages can also be of smaller size, for example 4,4′-bipyridine groups. The 2-D square-network material $^2_\infty\{[Cd(4,4'\text{-bipyridine})_2](NO_3)_2\}$ (**3**), which contains microchannels perpendicular to the layers (Cd ··· Cd 11.8 Å), readily incorporates aromatic guests with high shape selectivity and catalyzes cyanosilylation of aldehydes.[2]

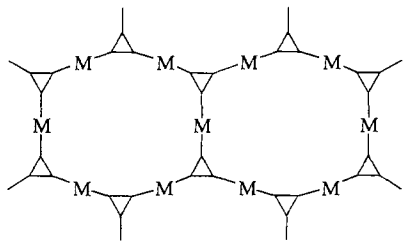


3

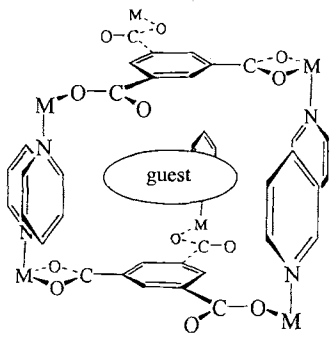
A porous solid of formula $M_3(BTC)_2\cdot H_2O$, which reversibly and repeatedly binds water without destruction of the framework, is obtained from divalent metal ions (such as Co^{2+}, Ni^{2+}, and Zn^{2+}) and 1,3,5-benzenetricarboxylic acid (BTC, **4**).[14] Inclusion of ammonia into the solid was also demonstrated, whereas larger molecules and those without a reactive electron lone pair were prevented from entering the channels. The 2-D metal–ligand assembly **5** with 1-D channels was proposed for the porous solid.[15] The same metal–BTC building block, but with two additional pyridine ligands at the metal center, gives the layer structure **6** in which the pyridine ligands act as



4



5



6

spacers between the layers. In the resulting 7×10 Å[11] rectangular channels, aromatic guests are accomodated and can be reversibly removed. According to optical microscopy, the single crystals retain their morphology and crystallinity upon loss of the guests. IR spectroscopy showed that aromatic molecule such as benzene, nitrobenzene, cyanobenzene, and chlorobenzene are selectively absorbed from mixtures with nonaromatic compounds. The crystal lattice is thermally stable up to 350 °C.[15]

An earlier study already showed that formation of a fully covalently interconnected 2-D or 3-D metal–organic network or coordination polymer is not a prerequisite for porosity and reversible guest exchange. The layered β-structure composed of discrete octahedral $[Ni(NCS)_2(4\text{-methylpyridine})_4]$ complexes forms inclusion compounds with aromatic guests and retains its porosity in the absence of the guest molecules. Thermodynamic and kinetic data for the uptake of different guests were collected, and sorption equilibria in systems containing two competing guests studied.[16] Furthermore, this and the next example illustrate that zeolite-type behavior of metal–organic host lattices was occasionally observed prior to the recent surge in interest: A partly reversible intercalation of ferrocene in the 3-D network of $^3_\infty[Fe^{III}(\mu\text{-CN}-SnMe_3-NC)_3]$ was described almost ten years ago. It was also demonstrated by XRPD that ferrocene can diffuse through the 6.8×6.8 Å[11] channels of the analogous network of $^3_\infty[Co^{III}(\mu\text{-CN}-SnMe_3-NC)_3]$(**7**).[17]

Not only neutral guest molecules but also lattice counterions can be removed: Crystals of $[Cu^I(\mathbf{8})]BF_4\cdot x C_6H_5NO_2$ were shown by IR spectroscopy to undergo anion exchange with PF_6^-. The metal–ligand moiety forms a diamond-related framework with no interpenetration and very large adamantane-like

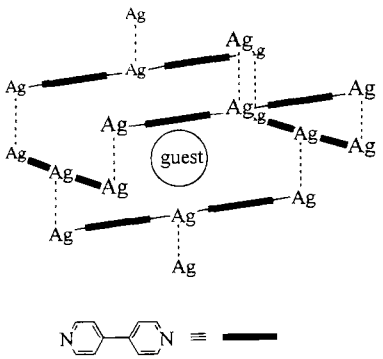
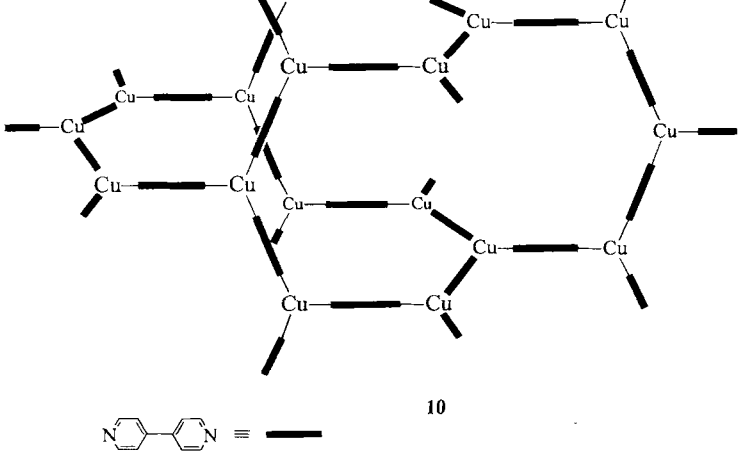
8

cavities[18] of about 1500 Å^3 (estimated from the space diagonals). The structure of [Ag(4,4′-bipyridine)NO_3] contains extended linear silver–ligand chains, which are cross-linked by Ag···Ag contacts (**9**) to give extended 23 × 6 Å[11] channels, in



9

spite of the interpenetration of three different frameworks.[19] These channels are occupied by the nitrate "guests", which can undergo reversible exchange with PF_6^-, MoO_4^{2-}, BF_4^-, and SO_4^{2-} (monitored by IR spectroscopy and XRPD). The 4,4′-bipyridine ligand also connects Cu^I centers in a trigonal-planar geometry and thereby allows formation of the open framework **10** in [Cu(4,4′-bipyridine)$_{1.5}NO_3(H_2O)_{1.25}$]. Since six of these



10

frameworks interpenetrate each other but do not fill all the available voids, that rectangular channels (8 × 6 and 4 × 5 Å[11]) remain. These channels are occupied by the nitrate anions, which according to IR spectroscopy and elemental analysis undergo exchange with SO_4^{2-} and BF_4^-.[20]

In the layered porous structure of $Na_2[PhMe_3N][Cr(C_2O_4)_3]_2Cl \cdot 5H_2O$, partial removal of the cationic templates ($PhMe_3N^+$) by cation exchange at room temperature and complete removal by thermal methods are apparently possible without loss of crystallinity. The $[Na_2Cr(C_2O_4)_3]^-$ moiety forms cylindrical pores of approximately 7 Å diameter and 3 Å[11] depth.[21]

From the examples given it becomes clear that nitrogen- and CN-containing ligands (nitriles) feature prominently as the organic building blocks. Building blocks for coordination networks are most often rigid bridging ligands, either linear or disk-shaped trigonal-planar; flexible ligands are used less often. Porphyrins and phthalocyanines have also been suggested as building blocks for microporous networks because of their relative rigidity and large size as well as their ready incorporation of a wide range of metal centers.[22]

Organic zeolite analogues promise a new range of applications, for example in pharmaceutical manufacture, molecular sieves, and sensors. A fascinating aspect is the potential to control the host–guest chemistry of the framework by tailoring the building blocks by including binding properties of functional organic groups that are not available in inorganic zeolites. One could imagine incorporating enantiomerically pure chiral groups to obtain microporous materials for enantiomer separation, chiral synthesis, and product-specific catalysis.[21, 23] However, before these ambitious goals can be achieved certain hurdles must be overcome. The basic problems of inclusion crystals based on an organic host lattice are that they tend to lose their crystallinity and undergo collapse of the void spaces on removal of the (reinforcing) guest molecules from the pores.[22] Furthermore, the guest may be entrapped in a clathrasil-like fashion inside the framework of the host without the possibility of diffusing through the lattice.[1] Nature tends to avoid vacuum, and identical copies interpenetrate to fill space are obtained rather than a single network.[24] Interpenetration, which arises from the necessity to fill the empty spaces inside the large cages, is the rule rather than the exception in these species. Seldom do the interpenetrating networks create large cavities.[25]

The design and synthesis of new polymeric framework materials containing cavities capable of taking up molecular substructures in a shape- and/or size-selective manner is a continuing challenge. Selective incorporation of metal ions as integral components of such frameworks offers additional factors (electron transfer) that can be exploited in stimulating substrate reactivity. The area of coordination polymers, which can also be seen as a meeting ground for the subdisciplines of molecular and solid-state inorganic chemistry, brings together synthetic techniques and analytical methods for designing and investigating extended structures with specific physical properties by low-temperature reactions.[7]

Harmony and Dissonance in the Concert of Proton Motions

Richard L. Schowen*

The motion of a proton between donor and acceptor atoms is one of the simplest chemical reactions, and an overall reaction involving two such motions within the same molecular array represents the simplest case in which to consider the coupling of two chemical processes; do they occur simultaneously in time (concertedly) or serially in time (in a stepwise manner)?[1] Reactions in which multiple (often two) proton-transfer events among electronegative atoms such as O, N, and S accompany bonding changes in a framework of atoms heavier than H are of interest in biology as well as chemistry, for example in the action of enzymes[2] and in tautomerization reactions in nucleic-acid base pairs.[3] Several recent studies have begun to illuminate the manner in which the molecular choice between concerted and stepwise motion of the protons is made.

The history of this subject began some time ago. In 1952 Swain and Brown[4] showed that reagents with both proton-donor and proton-acceptor sites can accelerate with extraordinary power reactions that require both proton donation and proton removal. They denoted the phenomenon polyfunctional catalysis, which is exemplified by the catalysis of an elementary ring-opening step in the mutarotation of glucose (or its 2,3,4,6-tetramethyl derivative) by 2-pyridone. The ring-opening reaction of glucose derivatives involves more than the motion of the two protons. The internal C—O σ bond of the pyranose ring is cleaved, and a π bond added to the external C—O σ bond. If the formation and fission of C—O bonds (heavy-atom reorganization) were coupled to the transfer of the protons between the glucose molecule and the catalyst (which need not be true),[2] such a reaction could proceed by any of three pathways from reactant state **1** to product state **3**, which can take place via the activated complex **2** and the intermediate compounds **4** and **5**.

In reactions through **4** and **5**, the motions of the two protons between their bonding partners occur in a stepwise manner via two transition states that come before and after the intermediates along the reaction pathway. In a reaction through **2** the motions are concerted, and there is no intermediate. Swain and Brown concluded from the extraordinary catalytic activity of bifunctional compounds that the concerted pathway was preferred. This follows from the fact that 2-pyridone would function only as a very weak general base in the reaction leading to **4** and only as a very weak general acid in the reaction leading to **5**. Only in transition state **2** for the concerted reaction is the cooperative acid–base enhancement characteristic of bifunctional catalysts capable of expression. Rony and co-workers[5]

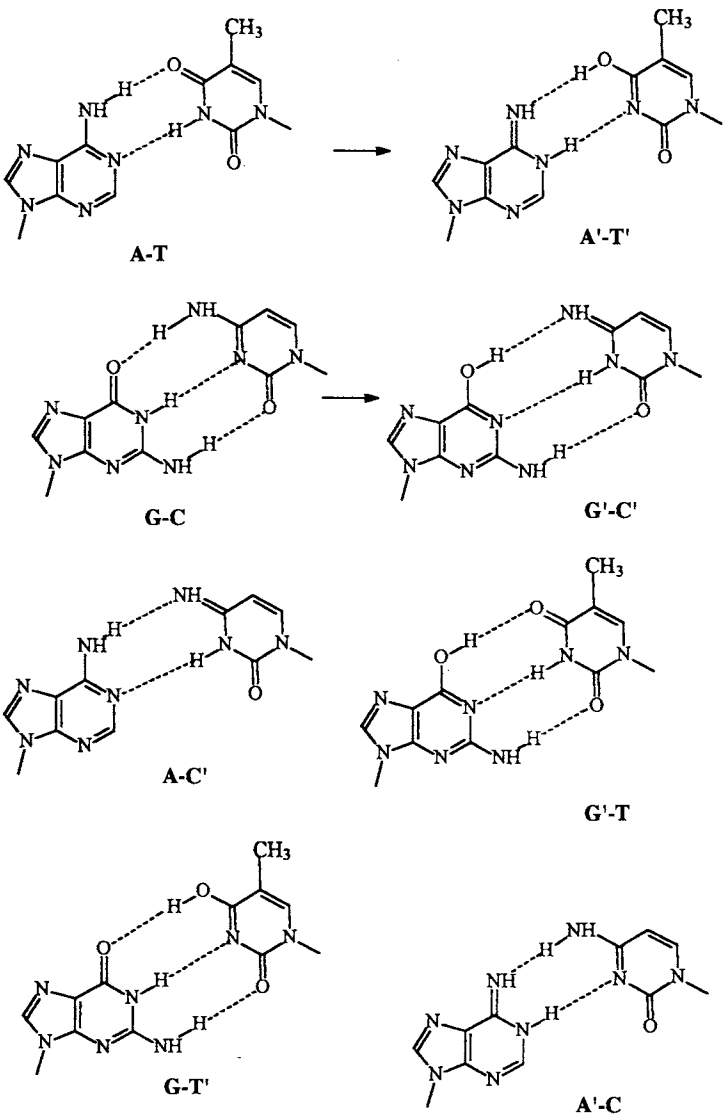
later showed that all highly effective bifunctional catalysts are indeed tautomeric catalysts, that is, they possess two tautomeric forms of similar energy (such as 2-pyridone and 2-hydroxypyridine) between which they interconvert in the course of bifunctional catalysis.

In 1953, the year following Swain and Brown's discovery of polyfunctional catalysis, Watson and Crick[6] proposed the best-known hydrogen-bonding scheme in all of modern science (Scheme 1). The Watson–Crick pattern that selectively binds pairs of nucleic-acid bases within the double-helical DNA structure provides for specific molecular recognition between deoxyadenylate (A) and deoxythymidylate (T) in a double hydrogen bond complex, and between deoxyguanylate (G) and deoxycytidylate (C) in a triple hydrogen bond complex. This enforces the security of the genetic code in DNA and the fidelity of the genetic code in its replication into DNA, its transcription into RNA, and its translation into a protein sequence. Watson and Crick also initiated a series of proposals, recently reviewed by Goodman[3] and by Douhal et al.,[7] according to which tautomerization within the hydrogen-bonded pairs could give rise to base pairs incorrectly matched in terms of the genetic code (see Scheme 1). Such tautomers might therefore produce genetic mutations through misreading of the DNA code during transcription into RNA or misreading of its RNA transcript during translation into a protein structure.

Like the ring-opening reaction of glucose, cooperative base-pair tautomerization in nucleic acids involves components of both proton transfer and heavy-atom reorganization. The fairly large-scale heavy-atom reorganization in glucose ring opening involves fission of a C–O σ bond and formation of a C–O π bond, whereas base-pair tautomerization produces more modest interconversions of wholly or partially single and double bonds between heavy atoms within the framework of the paired bases.

The question of whether double proton transfer in the glucose example is concerted or stepwise was addressed definitively in 1982 by Engdahl et al.[8] They measured the rate constant for mutarotation of tetramethylglucose catalyzed by 2-pyridone in benzene; the samples of sugar and catalyst had definite fractions n of deuterium replacing the protium at the two proton-bridging sites. This test for simultaneous or sequential bonding changes at two transition-state protonic sites by variation of the degree of deuteration is known as the proton-inventory ap-

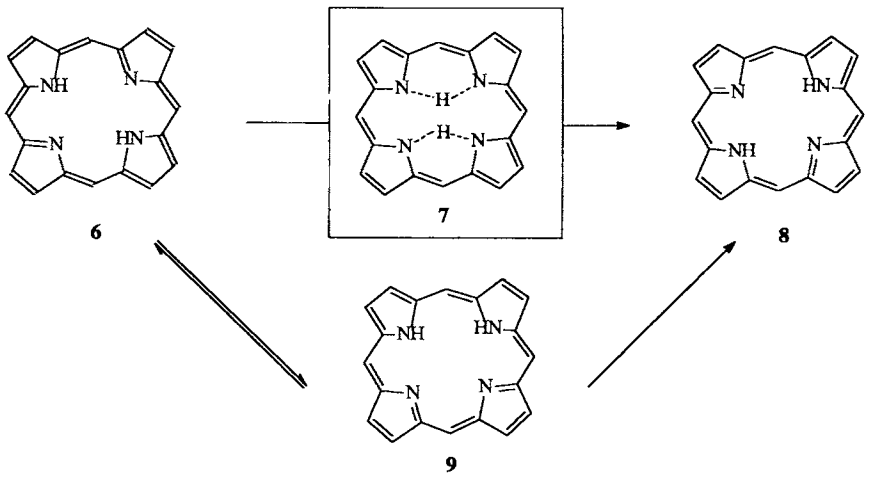


Scheme 1. Hydrogen bonding between Watson–Crick base pairs: A recognizes T (and vice versa) by the two hydrogen bond pattern (first row, left), G recognizes C (and vice versa) by the three hydrogen bond pattern (second row, left). Double proton exchange within A–T pairs can generate the tautomeric forms A′ and T′ (first row right), and double proton transfer within G–C pairs can generate the tautomeric forms G′ and C′ (second row, right). The lower half of the Scheme shows how misreading is possible by such tautomerizations. Each of the "wrong" tautomers A′, T′, G′, and C′ can successfully recognize and base pair with a "wrong" partner (C, G, T, and A, respectively).

proach.[9] A rate constant is measured as a function of the atom fraction of deuterium n in exchangeable positions from $n = 0$ (pure protium label) to $n = 1$ (pure deuterium label). A linear $k_n(n)$ indicates that the isotope effect arises from bonding changes at a single transition-state site (as in the transition states leading to or from the intermediates **4** and **5**), whereas a quadratic dependence indicates simultaneous bonding changes at two sites, as in the concerted reaction via transition state **2**. Engdahl and co-workers found a quadratic dependence with the isotope effect of about 4 arising from effects of about 2 at each of the transition-state sites. This confirms the Swain–Brown conclusion of concerted double proton transfer.

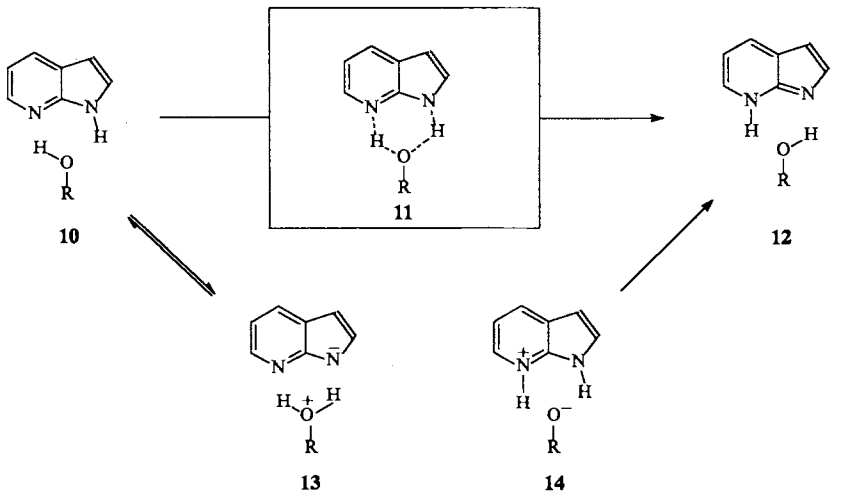
Another related isotope-effect approach to the coupling of proton motions was taken by Limbach and co-workers. From the 1970s to the present time they have been developing NMR methods for characterizing multiple hydrogen-transfer processes among tautomeric species, and have thereby elucidated the detailed dynamics of numerous tautomerization reactions in the liquid and solid states.

In very recent work, Braun and co-workers[10] examined the degenerate tautomerization of porphyrin molecules (**6**⇌**8**). This



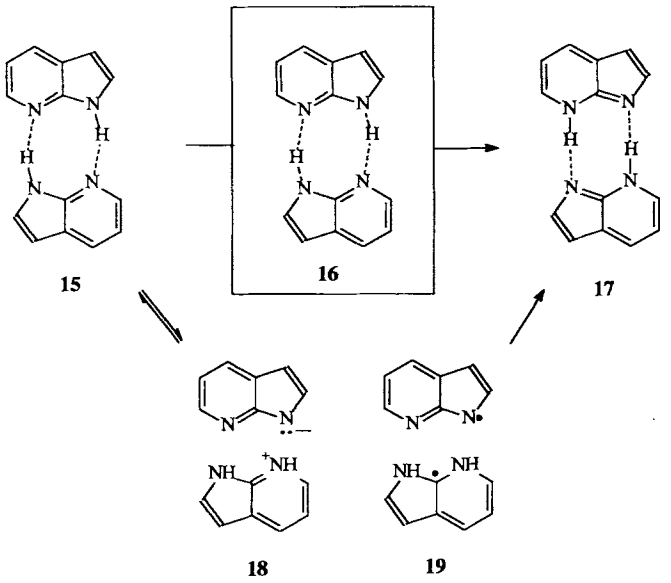
reaction may occur by simultaneous, concerted motion of the two hydrons through transition state **7**, or by two successive, stepwise motions through the "*cis* intermediate" **9**. By lineshape analysis of the ^1H, ^2H, and ^3H NMR signals of porphyrins separately labeled with the three isotopes of hydrogen (naturally necessitating precautions with the highly tritiated material), rate constants for the degenerate rearrangement of porphyrin by double proton transfer were obtained for proton and deuteron motions between 100 and 350 K as well as triton motions between 237 and 350 K. Rates and isotope effects are similar in organic solvents and in the polycrystalline state. At 298 K in dimethylformamide (DMF), the isotope effect k_{HH}/k_{DD} for simultaneous deuterium labeling at both positions is 11. The symmetry of this degenerate-rearrangement system requires the isotope effects at the two sites to be equal. If the two motions were occurring concertedly k_{HH}/k_{DD} would be equal to $(k_H/k_D)^2$, where k_H/k_D is the isotope effect at a single site. The single-site isotope effect k_{HD}/k_{DD} is then predicted to be 3.3. If the two hydrons instead move in succession, the *cis* intermediate **9** must form and then decompose through transition states of equal Gibbs free energy (because the rearrangement is degenerate). In such a case $k_{HH} = k_H$ and $k_{DD} = k_D$. In the singly deuterated species, either hydron may move first (with rate constant k_H for H or k_D for D) to generate the singly labeled intermediate. A fraction of the intermediate thus formed will proceed to product by motion of the hydron that did not previously move. The rate constant for this fraction will therefore be given by $[k_D/(k_H + k_D)]$ if H moved first and by $[k_H/(k_H + k_D)]$ if D moved first. Therefore $k_{HD} = 2k_Hk_D/(k_H + k_D)$ and k_{HD}/k_{DD} will approach 2 as k_H becomes much larger than k_D. In fact Braun et al. find that k_{HD}/k_{DD} is approximately 2 at 298 K. This is just as expected for the stepwise process, because k_H is 11 times greater than k_D on this model. This result indicates that the porphyrin rearrangement occurs by a stepwise mechanism through the low-concentration, kinetically insignificant intermediate **9**.

Along still another independent route of investigation, Petrich and his collaborators[11] examined the tautomerization of 7-azaindole in MeOH and EtOH (**10**⇌**12**). This chromophore forms the side chain of 7-azatryptophan, an unnatural amino acid introduced and applied by Petrich et al. to a wide variety of problems in peptide and protein dynamics.[12] The tautomerization of 7-azaindole occurs readily in the excited state and constitutes the major route of nonradiative relaxation; the rate constant can be measured by fluorescence decay. Compared to the rate constant for reaction in MeOH and EtOH, the decay rate constant is decreased by a factor of about 2.7 for reaction in MeOD or EtOD (since exchange at the N–H position is fast, 7-azaindole will also be deuterated in the deuterated solvents). The tautomerization reaction, which is surely mediated by at least one molecule of solvent, might occur by concerted transfer of the two hydrons through transition state **11** or by independent, stepwise hydron motions through intermediates



13 or **14** or both. Petrich and co-workers examined the question of concertedness in the double proton transfer by means of a proton-inventory experiment. The rate constant decreases as a quadratic function of the atom fraction of deuterium in the solvent, showing that the overall solvent isotope effect of 2.7 arises from roughly equal isotope effects of 1.6–1.7 at two sites in a single transition state such as **11**. These two sites are therefore likely to be the N–H(D) site of 7-azaindole and the O–H(D) site of the alcohol molecule mediating the tautomerization through a single transition state with concerted motion of the two protons. The alcohol molecule is thus functioning as a bifunctional catalyst.

The isomerization of excited 7-azaindole molecules also occurs in the hydrogen-bonded dimer (**15**⇌**17**), with each monomer serving as both substrate and bifunctional catalyst for the tautomerization.[13] The reaction may occur through a single transition state **16** for a concerted pathway or in a stepwise manner through intermediates such as **18** or **19**. Douhal et al.[7] examined the mechanism for this reaction in the gas



phase. They prepared dimers in a molecular beam with definite quantities of excess vibrational energy and electronically excited them with an initial 60-femtosecond laser pulse at 305–310 nm. After variable periods of up to 20 picoseconds a second pulse at 620 nm ionized the excited molecules, and the ions were drawn into the analyzer of a time-of-flight mass spectrometer. The ion signal decreased with time because the ionization cross section of the tautomer-product dimer was smaller than that of the initial 7-azaindole dimer. Furthermore, the signal decreased as a biexponential function of time, showing that an intermediate compound (of intermediate ionization cross section) formed in significant amounts in the course of the tautomerization reaction. At an excess vibrational energy of 1 kcal mol^{-1} the kinetic isotope effect $k_{HH}/k_{DD} = 10$ for the initial fast phase of the reaction and 12 for the second slower phase. This suggests that proton transfer occurs in both phases of the reaction. The most reasonable model is that single proton transfer generates the intermediate ion pair **18** or radical pair **19** or both in kinetically signficant amounts. The second proton then transfers to form the product. Thus, the gas-phase tautomerization of 7-azaindole occurs in a stepwise manner through a relatively stable intermediate.

Table 1 summarizes the results of these four studies on the question of concerted versus stepwise reaction pathways for double proton transfer accompanied by heavy-atom reorganization. The gamut of possible outcomes is observed: two reactions exhibit concerted mechanisms, one reaction occurs along a stepwise route through a high-energy, kinetically insignificant intermediate, and one reaction follows a stepwise pathway through an observable, accumulating intermediate.

It seems likely that these initially perplexing findings are in fact an expression of a principle we owe to William P. Jencks, which was summarized in 1980 in an article[14] entitled "When is an intermediate not an intermediate? Enforced mechanisms of general acid–base catalyzed, carbocation, carbanion, and ligand exchange reactions". The essence of Jencks's concept is that if an intermediate compound along a stepwise route must have a very high-energy structure, then it is likely that a lower-energy structure will be possible for the concerted-reaction transition state. If this is the case, the reaction will naturally proceed along the concerted route, a choice that Jencks describes as "enforced" by the high energy required for the alternative, stepwise process. Each of the cases we have considered obeys Jencks's principle.

The two examples that exhibit concerted mechanisms would require high-energy species as intermediates. In the mutarotation of glucose the instability of intermediates **4** and **5** enforces a concerted reaction through the transition state **2**. Similarly, in the alcohol-mediated tautomerization of 7-azaindole, the oxonium moiety of **13** and the alkoxide moiety of **14** confer instability

Table 1. Summary of the favored reaction pathways and potential intermediates for double proton transfer reactions.

Reaction	Concertedness: evidence	Potential intermediate
mutarotation of tetramethylglucose with 2-pyridone as catalyst in benzene	concerted: quadratic proton inventory indicates simultaneous bonding changes at two protonic sites	conjugate acid–base pairs for singly protonated–deprotonated sugar and catalyst (**4**·**5**)
porphyrin isomerization in DMF	stepwise: double-label isotope effect of 11, single-label isotope effect of 2 (see text)	*cis*-porphyrin **9**; steady-state intermediate not accumulating in kinetically significant amounts
alcohol-mediated isomerization of excited 7-azaindole in MeOH or EtOH	concerted: quadratic proton inventory indicates simultaneous bonding changes at two protonic sites	conjugate acid–base pairs for singly protonated–deprotonated substrate and catalyst (**13**,**14**)
isomerization of dimeric excited 7-azaindole in the gas phase	stepwise: intermediate accumulates in kinetically significant amounts; large isotope effects for both formation and decomposition of intermediate	presumably ion pair **18** or radical pair **19** or both

 © *VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997* *0570-0833/97/3613-1437 $ 17.50+.50/0*

even if the conjugate acid and conjugate base of 7-azaindole should be relatively stable. In both cases, the high energy of the required intermediates along the potential stepwise pathway may be considered to enforce reaction by the concerted route.

The two reactions that exhibit stepwise mechanisms, as required by the Jencks principle, can employ intermediate structures that may be of some stability. The porphyrin isomerization can pass through the intermediate **9**, which maintains the cyclic conjugation of the porphyrin system. Although the energy of this intermediate is lower than that of the potential transition state **7** for the concerted reaction, the intermediate is nevertheless sufficiently unstable that it returns to the reactant state or proceeds to the product state with such rapidity that it fails to accumulate and cannot be detected in the NMR experiment. However, in the gas-phase tautomerization reaction of the electronically excited 7-azaindole dimer, the stability of the intermediate state **18**/**19** is so great that it not only surpasses the stability of the potential transition state **16** for the concerted reaction but also accumulates during the reaction, rendering the kinetics biphasic. The stability of the intermediate species in the gas phase, if its correct representation is the ion pair **18**, may seem paradoxical in comparison to the instability of intermediates **13** and **14** in the polar liquid phase. However, both ionic moieties of **18** are stabilized by charge delocalization (unlike the oxonium moiety of **13** and the alkoxide moiety of **14**), and the stability of the complex may also benefit from the polarizability of the two relatively large partners. Furthermore, intramolecular electron transfer may occur readily to generate the radical pair **19**, which could be the accumulating form of the intermediate even if a minor population of **18** is the reaction-pathway intermediate that arises from reactants and generates products.

The reactions of Table 1 occur in widely different media ranging from the gas phase through benzene to DMF and alkanols. The molecular choices made in each of the cases (concerted reactions in benzene and alkanols, stepwise reactions in the gas phase and DMF) cannot be understood in terms of coarse generalizations but instead require a more refined consideration of the structure of the intermediate and its interaction with the medium. The power of Jencks's principle thus transcends the facile simplicity of traditional thinking.

A question that has not been treated here, but will be addressed elsewhere, concerns the means by which the hydrons achieve translocation, whether along the concerted or stepwise pathway. For example, is quantum tunneling involved; or, is the hydron motion coupled into the reaction coordinate for heavy-atom reorganization? Whatever the answer to this question, the main molecular selection between concerted and stepwise pathways appears to follow from Jencks's principle of avoiding high-energy intermediates.

Chemical order achieved from chaos: when a mixture of three different bis(catechol-amide) ligands is allowed to react with $[Ga(acac)_3]$, a highly ordered system emerges.

No mixed-ligand oligomers are observed in solution; only the discrete $[Ga_2L_3]^{6-}$-triple helical complexes form. More about this system is described by Raymond et al. on the next page.

Supramolecular Self-Recognition and Self-Assembly in Gallium(III) Catecholamide Triple Helices**

Dana L. Caulder and Kenneth N. Raymond*

Supramolecular chemistry has been described as a type of molecular information science:[1] a supramolecular assembly is manufactured from the information stored in preprogrammed molecular components. In nature there are numerous examples of highly symmetric supramolecular clusters, including the 24 subunit protein ferritin (pure rotation group *O*) and the 60 subunit coat of the human rhinovirus (pure rotation group *I*).[2, 3] In an analogous process, a few metal–ligand interactions can be used in place of the many, but weaker, interactions that drive the formation of natural molecular clusters. Recently the synthesis of some highly symmetric supramolecular architectures have been reported,[4–7] and we have described a rational design of such structures based on the incommensurate coordination numbers of interacting sites of the cluster.[4, 8]

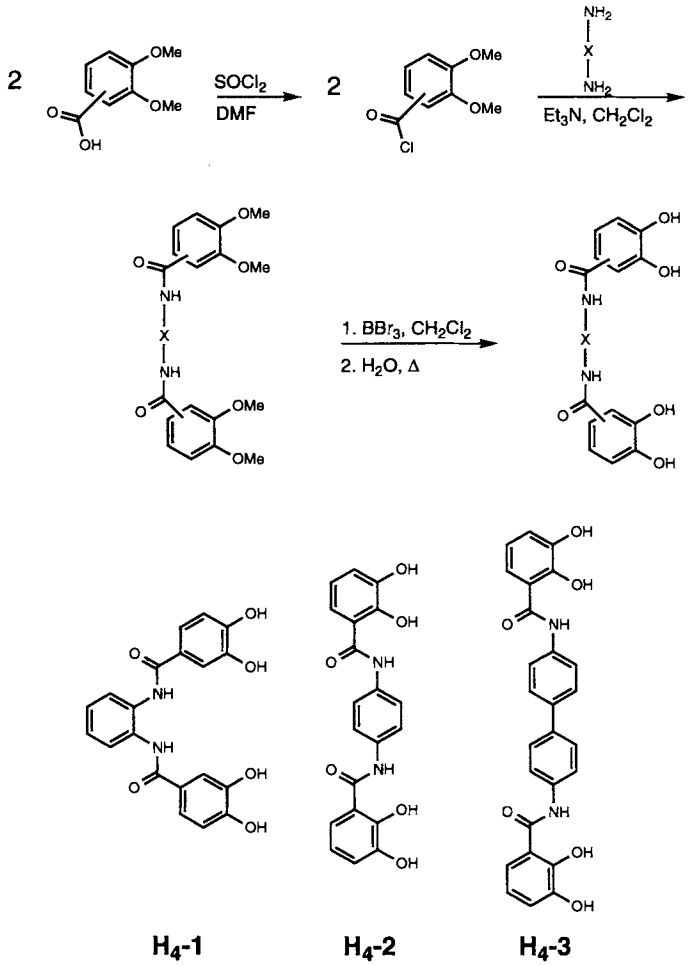
The triple helix formed by two metal centers is one of the simplest assemblies of this type. There are numerous examples of synthetic complexes with helical motifs incorporating bipyridine and benzimidazol ligands.[1, 9–11] More recently there have been examples of helical complexes with oxygen donor ligands, including catechol.[12–14] The exclusive formation of a predesigned cluster requires ligand rigidity, kinetically labile metal–ligand interactions, and thermodynamic stability. These features drive the formation of the thermodynamically favored cluster over the large number of other intermediate polymers. The complexes of catecholamides with Ga^{III} satisfy these requirements.[15, 16]

In a rational design of these self-assembling supramolecular clusters, a series of three bis(catecholamide) ligands (H_4-**1**–H_4-**3**) has been synthesized according to Scheme 1. Molecular mechanics calculations show that for all ligands the chiral helicate is lower in energy than the *meso*-$[M_2L_3]$ cluster.[17, 18] The synthesis of ligand H_4-**2** and the X-ray crystal structures of the gallium complexes of two derivatized versions of this ligand have been reported previously and confirm the helix structure.[12]

It was intended that the information stored in these rigid bis(catecholamide) ligand systems be used to overcome the intrinsic disorder of mixtures in order to produce a highly ordered system of complexes in solution. As will be shown, this has been achieved.

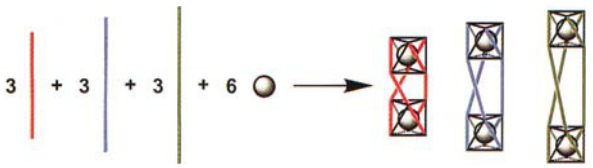
The three ligands H_4-**1**–H_4-**3** were designed to increase the metal–metal distance systematically in the dinuclear helicates, the goal being to probe the effect that size has on the ability of the helicates to form by self-assembly. So far a size limit has not been reached. When three equivalents of any ligand (H_4-**1**–H_4-**3**) are allowed to react with two equivalents of $[M(acac)_3]$ (M = Fe^{III}, Al^{III}, Ga^{III}; acac = acetylacetonate) and KOH in methanol at room temperature, the $K_6[M_2L_3]$ triple helical complexes can be isolated in high yield (70–80%) [Eq. (a)].

$$3\,LH_4 + 2\,[Ga(acac)_3] \xrightarrow[CH_3OH]{KOH} K_6[Ga_2L_3] \qquad \text{(a)}$$



Scheme 1. Synthesis of H_4-**1**–H_4-**3**.

When the complexes are prepared in the presence of excess ligand, there is no disruption of the formation of the $[M_2L_3]$ clusters. The ^1H NMR spectrum in all cases shows two sets of peaks, one for the complex and one for the excess ligand. This cooperativity ultimately facilitates the synthesis of controlled mixtures of complexes. Remarkably, when mixtures of any two or all three of the ligands (H_4-**1**–H_4-**3**) are allowed to react with $[Ga(acac)_3]$ under the conditions described above, only complexes containing one type of ligand form (Scheme 2). No



Scheme 2. Schematic representation of self-recognition of ligands in gallium catecholamide triple helices. Rods represent ligands of varying lengths and spheres represent Ga^{III} ions. Only the discrete complexes containing one type of ligand form in solution. No mixed or oligomeric species are observed.

oligomeric mixed-ligand species are observed in solution with ^1H NMR spectroscopy or with electrospray mass spectrometry (ES-MS). The ^1H NMR spectrum of the resulting solution shows a 1:1:1 mixture of the $K_6[Ga_2(\mathbf{1})_3]$, $K_6[Ga_2(\mathbf{2})_3]$, and $K_6[Ga_2(\mathbf{3})_3]$ helical complexes (Figure 1). This can be confirmed by comparing the resulting spectrum to a simulated spectrum

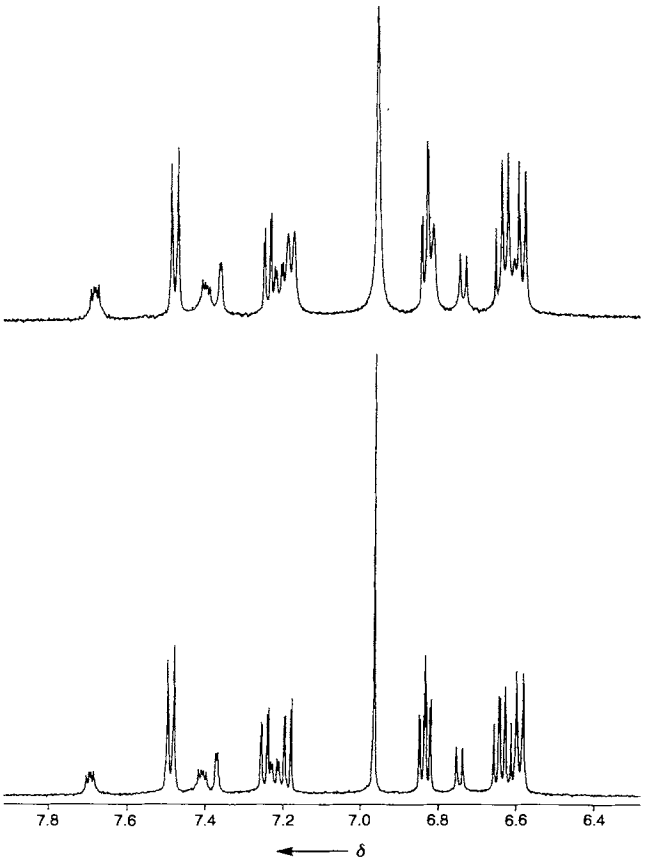

Figure 1. Bottom: ^{1}H NMR spectrum (5% K_2HPO_4, D_2O, pD = 9.2, 300 MHz) of a 3:3:3:2 mixture of **1**, **2**, **3** and [Ga(acac)$_3$] after workup. Top: simulation spectrum obtained by adding the spectra of the individually isolated gallium complexes of **1**, **2**, and **3**. No oligomeric species are observed in solution.

obtained by adding the spectra of the individual complexes. Positive-ion ES-MS (100% CH_3OH) also supports this conclusion, as no peaks from oligomeric mixed ligand species are found; only the $[Ga_2L_3]^{6-}$ complexes are observed.[19]

The driving force for the observed self-recognition is largely a concentration effect. In a closed coordination polymer (that is, all metal sites are coordinated by three catecholamide functionalities) for a simple system with one metal and one ligand, equilibrium (b) can be written. The equilibrium constant for this

$$n[M_2L_3] = [M_2L_3]_n \qquad (b)$$

equation should be approximately 1. Only if the polymer is significantly insoluble will the reaction be driven further to the right, but these species are highly charged and very soluble. Thus if $n = 4$ and the original concentration of the cluster is 2×10^{-3} M, then the polymer concentration will be approximately 10^{-11} M. This entropic driving force is also present with more complicated mixtures of ligands: the formation of mixed-ligand oligimers remains disfavored.

These ligand designs are unique, because the rigidity and different distances between the coordinating functionalities makes it geometrically impossible to form a mixed ligand $[M_2L_2L'_1]^{6-}$ complex. This steric factor makes closed polymers unattainable. Inevitably, there will be metal sites not coordinated by a catecholamide. For each mole of gallium ions coordinated by only two catecholamide functionalities, over 10 kcal of free energy is lost.[15, 16] Thus, fragments with uncoordinated ends are disfavored and removed in the equilibration of species.

In this work, a series of rigid bis(bidentate) catecholamide ligands has been designed and synthesized to form triple helicates with trivalent metal ions. As a consequence of the predesigned rigid geometry between the ligands' coordinating sites and the positive cooperativity displayed in the formation of the triple helicate systems, highly ordered systems are produced from a complex mixture of closely similar ligands upon addition of metal. Reaction of a mixture of the three bis(catecholamide) ligands (H_4-**1**–H_4-**3**) with [Ga(acac)$_3$] in methanol and KOH at room temperature yields only the individual complexes $K_6[Ga_2(\mathbf{1})_3]$, $K_6[Ga_2(\mathbf{2})_3]$, and $K_6[Ga_2(\mathbf{3})_3]$, according to both ^{1}H NMR and electrospray mass spectrometry. While similar self-recognition has been observed with mixtures of bipyridine-type ligands that differ in the number of metal coordination sites,[20] this demonstrates for the first time that molecular resolution can be achieved based solely on the distance between two metal coordination sites, cleanly separating as many as three ligand components.

Experimental Section

A solution of the appropriate diamine (3.0 mmol) and Et_3N (12 mmol) in CH_2Cl_2 (50 mL) was added dropwise to a stirred solution of the dimethoxybenzoyl chloride [21] (6.2 mmol) in CH_2Cl_2 (100 mL) at 0°C. The reaction mixture was stirred at room temperature for 2 h and then washed with distilled water, 2 N NaOH, and 2 N HCl. The CH_2Cl_2 layer was separated off, dried over $MgSO_4$, and filtered. Upon evaporation of the solvent, the methyl-protected ligands were all isolated in 85–95% yields.

BBr_3 (38 mmol) was added by syringe to a stirred solution of the methyl-protected ligand (3.1 mmol) in CH_2Cl_2 (100 mL) at −78°C. The reaction mixture was stirred at room temperature for 48 h. The volatiles were removed under vacuum, and the remaining orange-yellow solid was stirred in distilled water at 100°C. After 4 h the resulting white precipitate was collected by filtration, washed with absolute ethanol and diethyl ether, and dried under vacuum at 70°C for 12 h to yield the ligands (all in 80–95% yield). All ligands were characterized by ^{1}H NMR spectroscopy, mass spectrometry, and elemental analysis (C, H, N).

Under nitrogen, the ligand H_4L (0.39 mmol) was stirred in methanol (30 mL). A solution of KOH (0.497 N, 0.79 mmol) in methanol was added by pipet, and the reaction mixture was stirred until the ligand dissolved completely. [Ga(acac)$_3$] (0.26 mmol) was then added, and the reaction mixture was stirred at room temperature for 4 h. The volatiles were removed under vacuum, and the residue washed with acetone (2 × 10 mL). The resulting off-white residue was characterized as the $K_6[Ga_2L_3]$ complex. The complexes darken upon exposure to air.

$K_6[Ga_2(\mathbf{1})_3]$: ^{1}H NMR ([D$_6$]DMSO, 400 MHz): δ = 9.14 (s, 6H, NH), 7.76 (m, 6H), 7.26 (s, 6H), 7.10 (m, 6H), 6.99 (d, J = 7.6 Hz, 6H), 6.27 (d, J = 8.0 Hz, 6H); ^{1}H NMR (5% K_2HPO_4 in D_2O, 500 MHz): δ = 7.69 (dd, J = 3.6, 5.9 Hz, 6H), 7.40 (dd, J = 3.5, 5.9 Hz, 6H), 7.37 (d, J = 2.2 Hz, 6H), 7.21 (dd, J = 2.3, 8.1 Hz, 6H), 6.74 (d, J = 8.1, 6H). Positive-ion ES-MS: m/z: 1542[MK$^+$], 1526 [MNa$^+$], 1504 [MH$^+$] (1503 calcd. for $M = K_6Ga_2C_{60}H_{36}N_6O_{18}$).

$K_6[Ga_2(\mathbf{2})_3]$: ^{1}H NMR (5% K_2HPO_4 in D_2O, 500 MHz): δ = 7.18 (d, J = 7.8 Hz, 6H), 6.96 (s, 12H), 6.82 (d, J = 7.2 Hz, 6H), 6.62 (t, J = 7.8 Hz. 6H). Additional data as previously reported in Ref. [12].

$K_6[Ga_2(\mathbf{3})_3]$: ^{1}H NMR ([D$_6$]DMSO, 400 MHz): δ = 9.62 (s, 6H), 7.48 (d, J = 8.0 Hz, 12H), 6.83 (dd, J = 1.6, 8.0 Hz, 6H), 6.31 (dd, J = 1.6, 7.2 Hz, 6H), 6.15 (t, J = 7.2 Hz, 6H), 6.15 (d, J = 8.0 Hz, 12H); ^{1}H NMR (5% K_2HPO_4 in D_2O, 500 MHz) δ = 7.48 (d, J = 8.5 Hz, 12H), 7.25 (dd, J = 1.6, 8.2 Hz, 6H), 6.84 (dd, J = 1.6, 7.5 Hz, 6H), 6.64 (t, J = 7.9 Hz, 6H), 6.59 (d, J = 8.6, 12H); positive-ion ES-MS: m/z: 1770 [MK$^+$], 1753[MNa$^+$], 1732[MH$^+$] (1731 calcd. for $M = K_6Ga_2C_{78}H_{48}N_6O_{18}$).

A Bridged Porphyrinato(thiolato)iron(III) Complex as a Model of the Active Center of the Cytochrome P-450 Isozyme

Heinrich Volz* and Martin Holzbecher

Dedicated to Professor Leopold Horner on the occasion of his 85th birthday

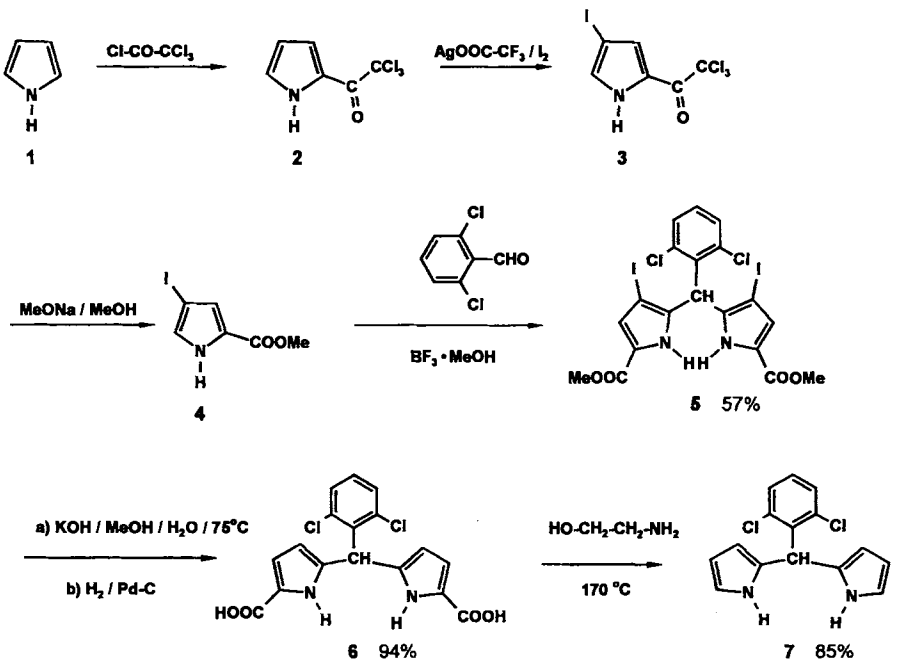
The ubiquitous cytochrome P-450 isozymes are heme–thiolate enzymes, which function as oxygen-activating components in monooxygenase systems. They play a vital role both in the construction and destruction of cellular substances, catalyze the oxidative metabolism of lipophilic xenobiotics,[1] activate vitamins, and convert a range of chemical compounds into carcinogens in the course of chemical cancerogenesis.[2] Under anaerobic conditions O donors such as ROOH, RCO_3H, IO_4^-, ClO_3^-, and PhIO can be used in place of oxygen.[3]

According to crystal structure investigations of the isozyme cytochrome $P\text{-}450_{CAM}$[4] the heme group is embedded in a hydrophobic environment between the helices L and I. The heme group provides the largest hydrophobic surface for interaction with the substrate. The fifth ligand L_5 is the thiolate group of cysteine 357, which is situated in a hydrophobic pocket constructed from the amino acids Phe 350–Leu 358–Gln 360. The Fe–S bond is thus shielded to a large extent from the environment. Removal of the thiolate ligand leads to loss of monooxygenase activity.[5] Chloroperoxidase[6] and NO synthase[7] are also heme–thiolate enzymes. The chemoselectivity of these enzymes is also controlled by the heme–thiolate group.

Due to the very high molecular weight of the cytochrome P-450 isozyme (at least 45 kDa), an exact description of the mechanism of the oxidation of substrates and the nature of the iron-containing intermediates is difficult. One possible method that might cast some light on this problem is the study of chemically produced model compounds containing iron porphyrins, which resemble the natural product. To ensure that the thiolate models cannot lead to S oxidation or allow the production of μ-oxo or μ-peroxo complexes, not only the Fe–S bond but also the opposite side of the porphyrin molecule must be effectively shielded by hydrophobic groups. None of the thiolate model compounds yet described fulfills both these criteria.[8] Except for the model described by Hirobe and co-workers, these compounds were therefore not used for oxidation with O donors.[9]

We report here the synthesis of the bridged porphyrinato(thiolato)iron(III) complex **16** as a model of the active center of the cytochrome P-450 isozyme. Complex **16** was prepared from pyrrole **1** and 1,6-dibromohexane **8** in an 18-step convergent synthesis.

Pyrrole **1** was converted by known methods,[10] via 2-trichloroacetylpyrrole (**2**) and 2-chloroacetyl-4-iodopyrrole (**3**), into 2-methoxycarbonyl-4-iodopyrrole (**4**) (Scheme 1). The iodo substituent serves as protection against electrophilic attack at the 4-position in the subsequent reaction. Compound **4** is then treated with 2,6-dichlorobenzaldehyde in the presence of $BF_3 \cdot MeOH$ (20% BF_3 in MeOH) to give the dipyrromethane **5** in 57% yield. Alkaline hydrolysis of the ester followed by hydrogenolytic cleavage of the C–I bond produced the dicarboxylic acid **6** in 94% yield. This was then decarboxylated



Scheme 1. Synthesis of 5-(2,6-dichlorophenyl)dipyrromethane (7).

[*] Prof. Dr. H. Volz, Dr. M. Holzbecher

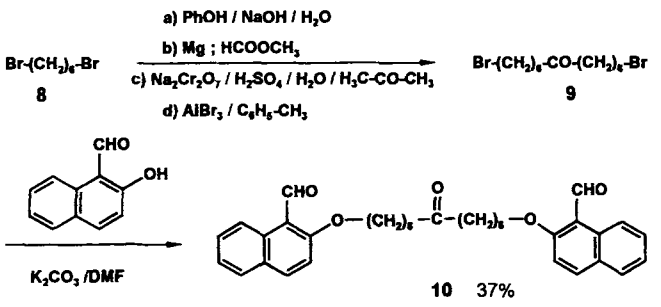
Richard-Willstätter-Allee, D-76128 Karlsruhe (Germany)
Fax: Int. code +(721)69-8529

to 5-(2,6-dichlorophenyl)dipyrromethane (**7**) by heating in ethanolamine[11] (170 °C, 1.5 h).

1,6-Dibromohexane (**8**) was converted into 1,13-dibromotridecan-7-one (**9**) in four steps (Scheme 2), in analogy to the method described for 1,4-dibromobutane.[12] This was then treated with 2-hydroxy-1-naphthalenecarbaldehyde to give the dialdehyde **10**.



Scheme 2. Synthesis of the dialdehyde **10**.

The coupling reaction of **7** and **10** catalyzed by BF_3–methanol and the subsequent oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) yielded the porphyrinophane **11** in 16% yield (Scheme 3). Reduction of the carbonyl group in **11** with $NaBH_4$ led to **12**, which was converted into the bromide **13** by reaction with CBr_4/Ph_3P/pyridine/THF.[13] This reacted with potassium thioacetate to give the thioester **14**.[8b] Metalation of **14** to yield the iron complex **15** was achieved with $FeBr_2$/lutidine,[14] and finally reaction with $NaOCH_3$ in $MeOH/CHCl_3$ produced the bridged porphyrinato(thiolato)iron(III) complex (**16**) in 77% yield. This crystallized together with a molecule of methanol, which is coordinated to the iron atom (Soret band at 415 nm). The methanol could be removed

17: UV/Vis (DMSO): λ_{max} ($\varepsilon \times 10^{-3}$) = 376 (41.6), 463 (97.1), 517 (10), 555 (10.8), 609 cm^{-1} (7.6).

by drying under extreme conditions, which moved the Soret band to 399 nm (blue shift). Addition of methanol restored the original spectrum. Reduction of **15** with the $Na_2S_2O_4$-[18]crown-6 complex **18**[15] in DMSO, cleavage of the thioester with the DMSO monoanion DIMSYL-Na, and introduction of CO into the solution yielded the CO complex **17**, which displays a split Soret band (376 nm, 463 nm; hyperporphyrin). The cause of the blue- and red-shifted Soret bands in carboxycytochrome P-450 and CO-porphyrinato(thiolato)iron(II) model compounds is a charge transfer transition from an occupied p orbital on the thiolate sulfur atom (lone electron pair) to the porphyrin $e_g(\pi^*)$ orbital and the strong interaction of this transition with the transitions $a_{1u}(\pi)$,$a_{2u}(\pi) \rightarrow e_g(\pi^*)$ of the porphyrin.[16] Charge transfer transitions are quite strongly solvent dependent;[17] this is probably the reason for the slight red shift of the long wavelength Soret bands of the CO–porphyrinato(thiolato) model compounds in DMSO upon the addition of base[8a, 8e] relative to carboxycytochrome P-450.

As can be seen from molecular modeling studies[18] of **16**, the chloro substituents and the phane chain shield the thiolate group effectively from attack by oxidants (O donors). On the other side of the molecule the chloro and naphthyl substituents hinder the formation of μ-oxo and μ-peroxo complexes (Figure 1).

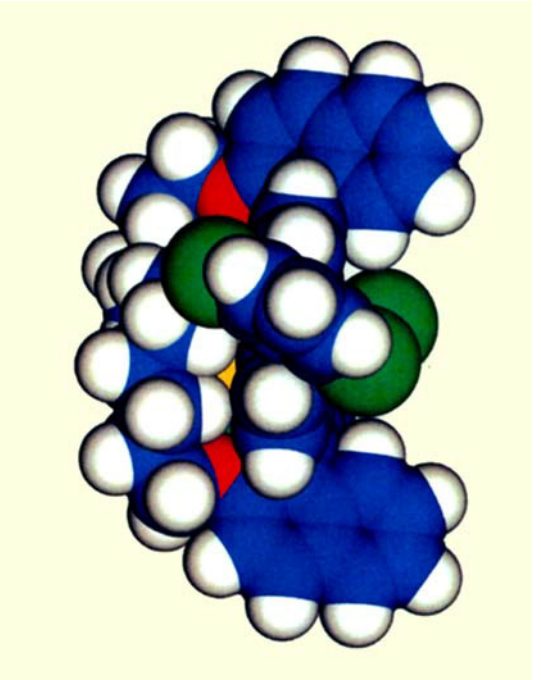

Fig. 1. Space-filling model of the porphyrinato(thiolato)iron(III) complex **16**.

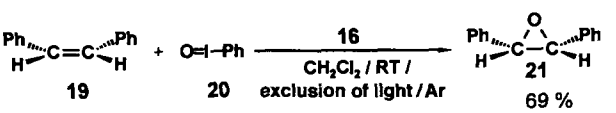
Measurement of the magnetic susceptibility of **16** yields a magnetic moment μ_{eff} of 4.7 μ_B. This value is significantly smaller than the value of 5.9 μ_B expected for a high spin porphyrinatoiron(III) complex (S = 5/2) and substantially larger than that of a low spin porphyrinatoiron(III) complex (S = 1/2), where a value of 1.73 μ_B is expected. The ^{1}H NMR spectrum of **16** displays two broad signals, each of intensity 4H, at δ = 83 and 69, which we ascribe to the porphyrin protons. The porphyrin protons are not equivalent due to the unsymmetrical disposition of the phane chain and the orientation of the thiolate ligand.



Scheme 4. Epoxidation of *cis*-stilbene to *cis*-stilbene oxide by iodosylbenzene catalyzed by **16**.

The reaction of *cis*-stilbene (**19**) with iodosylbenzene (**20**) as O donor and **16** as catalyst (room temperature, dichloromethane, exclusion of light) led to the formation of *cis*-stilbene oxide (**21**) as the single reaction product in 69% yield. This is in agreement with the conclusions drawn from molecular modeling studies and demonstrates how effectively the thiolate ligand is shielded from direct attack by the O donor iodosylbenzene.

Experimental Section

16: To a solution of **15** (92 mg, 0.072 mmol) in chloroform/methanol 1/2 (80 mL) was added 1 M $NaOCH_3/CH_3OH$ (2 mL, 2 mmol). This was held at reflux for 4 h under argon in the dark. After removal of the solvent and drying, the residue was purified by preparative thin layer chromatography (neutral Al_2O_3, CH_2Cl_2, exclusion of light; R_f of **16** is about 1). After drying at 40 °C/10^{-2} Torr, 64 mg of **16** was obtained (0.056 mmol, 77%).

17: All reactions were carried out in a glove box under argon. Iron complex **15** (0.56 mg, 4×10^{-7} mol) and crown complex **18** (16 mg, 21.2×10^{-6} mol) were dissolved in DMSO (4 mL) and allowed to react for 30 min. After the addition of a DIMSYLNa solution (31.44 mg NaH) and a further 30 min reaction, the volume of the solution was increased to 20 mL, and CO was bubbled through the solution.

Epoxidation of *cis*-stilbene (under argon with light exclusion): *cis*-stilbene (450 mg, 2.5 mmol), **16** (28.8 mg, 0.025 mmol), and iodosylbenzene (55 mg, 0.25 mmol) were stirred in CH_2Cl_2 (6 mL) for 5 h at room temperature. After removal of the solvent (30 °C, 300 mbar), the residue was taken up in 200 mL *n*-pentane, and the catalyst removed by filtration (25–30% **16** was recovered unchanged); the solvent was then removed (30 °C, 300 mbar). Quantitative analysis of the reaction products was carried out by ^1H NMR spectroscopy with 4-chlorotoluene as internal standard.

Self-Assembly of Supramolecular Polyoxometalates: The Compact, Water-Soluble Heteropolytungstate Anion $[As^{III}_{12}Ce^{III}_{16}(H_2O)_{36}W_{148}O_{524}]^{76-}$ **

Knut Wassermann, Michael H. Dickman, and Michael T. Pope*

Dedicated to the memory of GTP (1959–1996)

The hundreds of known examples of polyoxoanions of vanadium, molybdenum, and tungsten comprise a class of inorganic complexes of unrivaled versatility and structural variation, and have applications in many fields of science.[1] Very commonly these species have structures incorporating 6, 12, or 18 metal atoms and one or more other "heteroatoms" in positive oxidation states. The Keggin tungstophosphate $[PW_{12}O_{40}]^{3-}$ is a familiar example.

There are indications that much larger polyoxometalate anions might be synthesized. The structures of complexes such as $[Mo_{36}O_{112}(H_2O)_{18}]^{8-}$[2] and $[H_7P_8W_{48}O_{148}]^{33-}$[3] incorporate smaller known polyoxoanion units ($[Mo_7O_{24}]^{6-}$ and $[H_2P_2W_{12}O_{48}]^{12-}$ respectively), and more recently a class of mixed-valent, nitrosyl-containing polymolybdates with 57 molybdenum atoms per anion has been identified and characterized.[4] Following a general polymerization–reduction–polymerization protocol that has proved to be appropriate for the latter species, Müller et al. have succeeded in synthesizing a spectacular cyclic ("big wheel") anion with 154 molybdenum atoms.[5]

We now report that polyoxometalates with 148 tungsten atoms per anion can be easily and efficiently synthesized by straightforward "self assembly" processes in aqueous solution. The title anion **1** has been isolated as an ammonium salt in a yield of roughly 35%. The new compounds are by far the largest and heaviest discrete polyoxotungstates known. Other somewhat smaller compounds with 29 and 40 tungsten atoms have also been characterized and will be reported elsewhere.[6]

The structure of **1** is illustrated in bond, polyhedral, and space-filling representations in Figures 1–3. The anion has virtual D_{2d} symmetry and incorporates twelve B-α $[As^{III}W_9O_{33}]^{9-}$ and four $[W_5O_{18}]^{6-}$ groups. The AsW_9 units are augmented by additional tungsten and cerium atoms and are linked into a *folded* cyclic structure by pairs of edge-shared WO_6 octahedra.

The anion **1** may therefore be formulated as shown below.

$[Ce_{16}(H_2O)_{36}(B\text{-}\alpha\text{-}AsW_9O_{33})_{12}(WO_2)_4(W_2O_6)_8(W_5CeO_{18})_4]^{76-}$ **1**

Details of the structural motifs are shown in Figure 4. As revealed by the space-filling representation (Figure 3) the folded structure is very compact with no large central cavity as found for Mo_{154} and other polyoxoanions of comparable size, such as $[H_7P_8W_{48}O_{148}]^{33-}$. The structure analysis suggests that the central core of **1** contains four ammonium cations and/or water molecules. In the crystal, the disc-shaped anions (diameter ap-

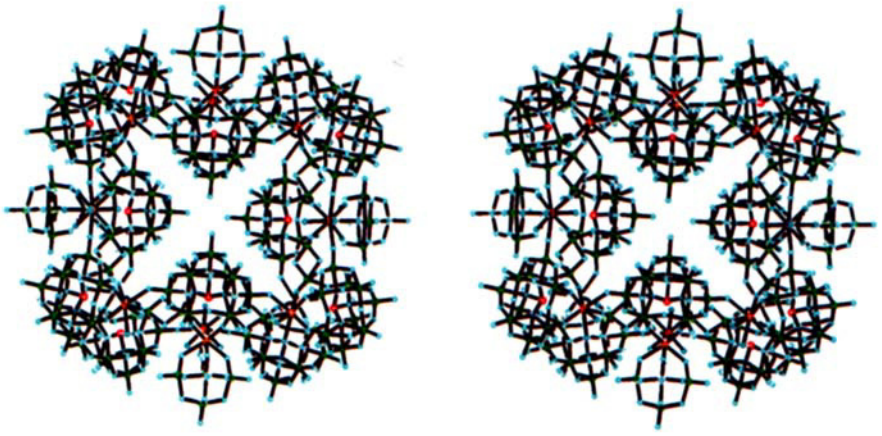

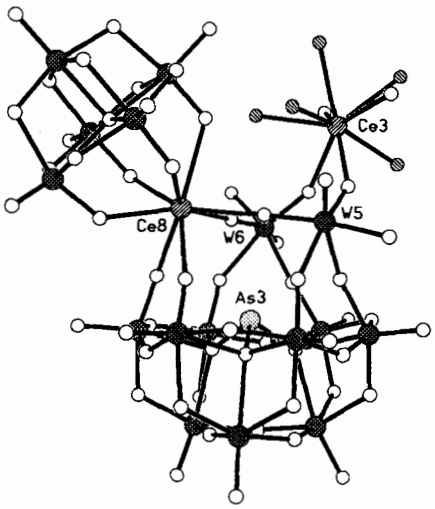

Figure 1. Stereoview of 1. Atoms are drawn with an arbitrary radius (green = W, orange = Ce, red = As, pale blue = O, dark blue = H_2O ligands).

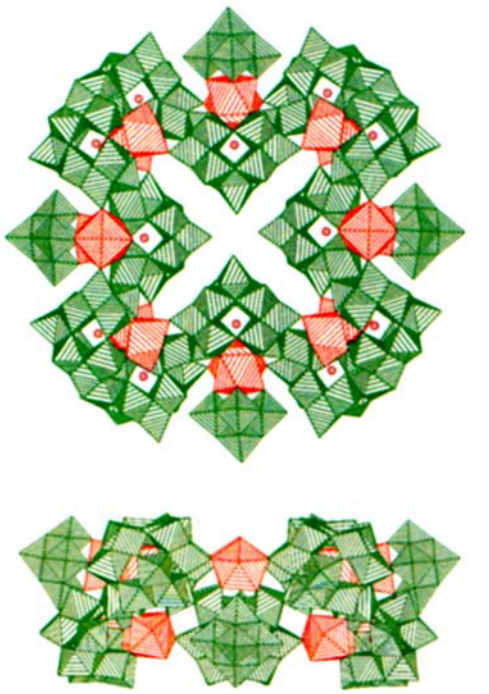

Figure 2. Polyhedral representation of 1. Top: View from the top, that is, down the unique C_2 axis of the D_{2d} molecular point group; the other two C_2 axes lie diagonally in the plane of the paper. Bottom: Side view, looking down the axis of a CeW_5 group, that is, along the bisector of the angle between the two C_2 axes (green = WO_6 octahedra, orange = CeO_x polyhedra, red = As atoms).

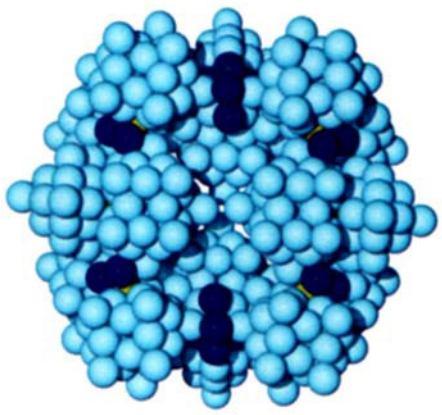

Figure 3. Space-filling view of 1 (blue = oxo oxygens, violet = water molecules coordinated to Ce; some of the Ce atoms (yellow) are visible).

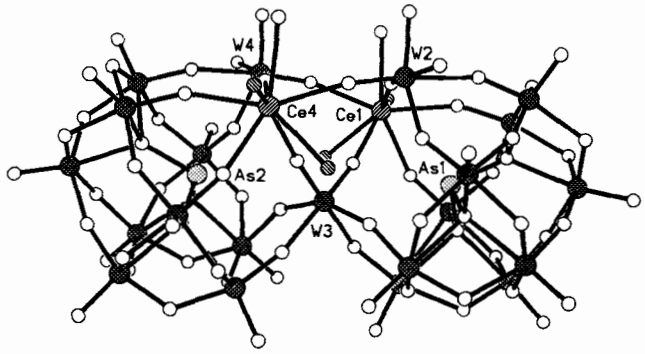

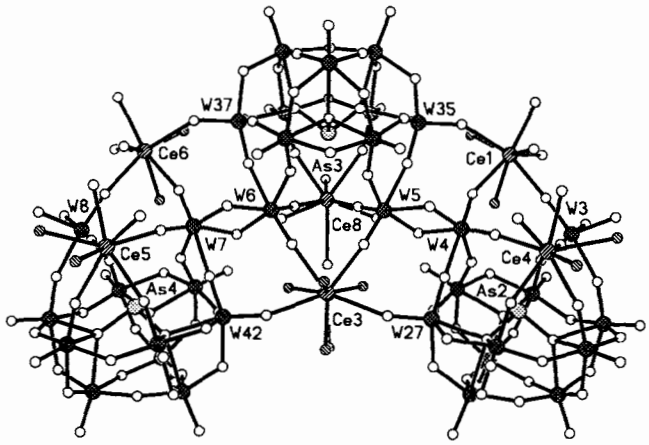

Figure 4. Details of the structure of 1 showing environments of the Ce atoms (small unnumbered hatched circles = water molecules coordinated to Ce atoms; open circles = oxygen atoms bridging Ce and W atoms. Top: Linkage of W_5 and augmented AsW_9 units through Ce8 (type *a*). Middle: Linkage of two augmented AsW_9 units through Ce1 and Ce4 (both type *b*). Bottom: Position of quadruply bridging Ce3 (type *c*). In this view the W_5 unit attached to Ce8 has been omitted for clarity.

proximately 4 nm; thickness approximately 1.8 nm) form parallel stacks along the *c* axis (see Figure 5).

There are three structural types of Ce atoms in the anion: four of type *a* are sandwiched between a W_5 and an augmented AsW_9 group (Figure 4a); eight of type *b* are shared between two AsW_9 units (Figure 4b); four of type *c* bridge three AsW_9 units (Figure 4c). Types *a* and *b* are eight-coordinate (square antiprism) and *c* is nine-coordinate (monocapped square antiprism). The Ce···Ce distances range from about 5.6 to 8.1 Å. The *b* and *c* type cerium atoms carry two and five terminal aqua ligands

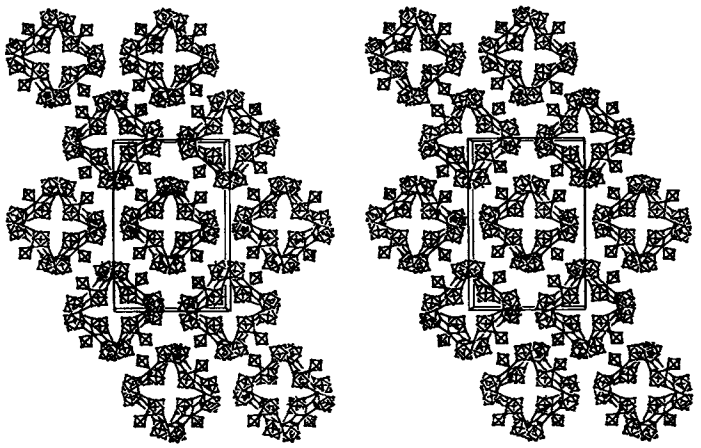

Figure 5. Stereoview of the crystal packing of **1** viewed down the crystallographic *c* axis. The *a* axis is horizontal. Only the heavy-atom skeleton is shown; lines do not represent bonds. Anions are stacked in an eclipsed fashion down the *c* axis. Alternate rows of these stacks across the *a* axis are offset by one-half of a unit cell along *c*.

respectively (see Figure 3) and offer sites for further derivatization of the heteropolyanion.

The ammonium salt of **1** can be recrystallized from water (for crystal packing structure see Figure 5) and is soluble enough to permit the observation of a well-resolved ^{183}W NMR spectrum in D_2O solution. Based on the crystal structure and assuming overall D_{2d} symmetry in solution, 21 resonances are expected, 16 of relative intensity 2 and 5 of intensity 1. Thanks to the paramagnetic Ce^{III} atoms, the spectrum (recorded at 12.5 MHz on a Bruker AM300 spectrometer) is well-dispersed: 18 of these lines are observed between $\delta = +320$ and -200. The spectrum of the diamagnetic lanthanum analogue of **1** is more congested with at least 15 lines between $\delta = -60$ and -260. Further measurements on a higher field spectrometer are planned.

That **1** can be prepared in fair yield by reaction of the stoichiometric quantities of monotungstate, arsenite, cerium cations, and protons in aqueous solution attests to its remarkable thermodynamic stability. Since the oxidation states of the components are unambiguous (As^{III}, Ce^{III}, W^{VI}), the overall anionic charge can be computed to be -76. Elemental analysis suggests that this charge is compensated by ammonium and sodium cations in the crystal, although the precision of the analysis cannot rule out the possibility of some protonation (either of the anion or of one or more lattice water molecules). The (unprotonated) anionic charge corresponds to a charge density of -0.51 per tungsten and is similar to that observed for water-stable Keggin anions such as $[H_2W_{12}O_{40}]^{6-}$ and $[Co^{II}W_{12}O_{40}]^{6-}$. Like these Keggin species, **1** is stable in solution at pH 6.5. The pH stability limits for **1** and its other physical and chemical properties are currently under investigation.

The new anion is an example of a potentially large class of isostructural heteropolyanions and may well prove to be as ubiquitous in supramolecular polyoxometalate chemistry as is the Keggin anion for "smaller" heteropolyanions. We have synthesized and collected a data set for the isomorphous lanthanum(III) derivative, and there is little doubt that other lanthanides, actinides, and other high-coordination-number cations such as Zr^{4+} can be incorporated into this structure. Moreover, since B-type XW_9O_{33} groups with $X = Sb^{III}$, Bi^{III}, Se^{IV}, and Te^{IV} are observed in other heteropolyanion structures, these could well act as building blocks for analogues of **1**. Although the two major building blocks, XW_9 and W_5 groups, are both observed in other tungstocerate heteropolyanions,[6, 7] anion **1** is a rare example where both groups are present in the same anion. To our knowledge, the only precedent for this structural feature is the tungstoeuropate $[Eu_3(H_2O)_3(SbW_9O_{33})(W_5O_{18})_3]^{18-}$ described by Yamase et al.[8]

Experimental Section

Crystals of the ammonium salt of **1** were isolated from several synthetic procedures. The following is one of the more direct approaches: $Na_2WO_4 \cdot 2H_2O$ (33.0 g, 100 mmol) and As_2O_3 (0.8 g, 4.05 mmol) were dissolved in 70 mL of boiling water. The pH of the solution was decreased from 9.0 to 7.1 by the addition of 6 M HCl (15.4 mL, 115 mmol). After 10 min a solution of $Ce(NO_3)_3 \cdot 6H_2O$ (4.69 g, 10.8 mmol) in 1.0 M acetic acid (18 mL) was added with a pipette to the vigorously stirred hot (90 °C) starting solution. The color changed to orange, and the pH decreased to 5.9. The mixture was heated for 30 min at 90 °C in a water-bath. Addition of a warm (70 °C) solution of NH_4Cl (40 g, 748 mmol) in water (150 mL) to the still hot (90 °C) transparent solution yielded a yellow-orange precipitate (about 33 g), which was recrystallized from 80 mL of warm water (70 °C, resultant pH 6.2). The recrystallized material consisted of long orange needles and a yellowish powder. The solution was stirred with a spatula so that the needles gathered at the bottom of the beaker before the milky solution was decanted. Once the precipitate in the decantate had settled, the clear supernatant (several portions of a few mL each) was poured onto the needles to extract any remaining yellowish fine powder by decantation before the needles were finally filtered off (about 17.0 g). Recrystallization of the needles from 20 mL water at 75 °C (pH 6.6) gave 10.0 g (yield: 36%) of the pure title compound. The lanthanum analogue of **1** was prepared in essentially the same way from lanthanum nitrate.

Elemental analysis calcd. (found) for $(NH_4)_{70}Na_6[(H_2O)_{36}Ce_{12}(B\text{-}\alpha\text{-}AsW_9O_{33})_{12}(WO_2)_4(W_2O_6)_8(W_5CeO_{18})_4] \cdot 175H_2O$: N 2.23 (2.17), Na 0.31 (0.30), Ce 5.10 (5.27), As 2.05 (1.82), W 61.93 (61.73), H_2O 8.65 (8.47)%. IR (KBr disk) in metal–oxygen stretching region: 950 (s), 850 (vs), 785 (vs), 700 (vs), 617 (s) cm^{-1}. Crystal structure analysis: crystal dimensions 0.28 mm × 0.28 mm × 0.36 mm, mounted under oil (to prevent water loss) on a glass fiber; $T = 173(2)$ K (nitrogen stream); Siemens SMART CCD single-crystal diffractometer equipped with a Mo anode and graphite monochromator ($\lambda = 0.71073$ Å). A hemisphere of data was collected out to a $2\theta_{max}$ value of 46° (99.65% coverage, 5.12 average redundancy); ω scans; Lorentzian and polarization corrections, empirical absorption correction based on measured intensities of equivalent reflections at different ϕ and ω values ($\mu = 22.196$ mm^{-1}; min/max transmission 0.00026/0.00644); total reflections collected: 157456; independent reflections: 54241; R(int) = 0.103, R(sig) = 0.069. Space group *Pnn*2; $a = 38.993(2)$, $b = 57.926(3)$, $c = 18.0842(11)$ Å, $V = 40847(4)$ Å^3, $Z = 2$; $\rho_{calcd} = 3.432$ $Mg\,m^{-3}$; structure solution by direct methods, refinement against $|F^2|$ over all reflections, $R_1 = 0.104$ for 49746 independent reflections with $I > 2\sigma(I)$ and 2275 parameters, $Rw_2 = 0.270$ for all reflections; highest residual electron density 4.15 e Å^3. Software used: Siemens SMART, SAINT, SHELXTL [9]. No hydrogen atoms were included. It was not possible to distinguish between H_2O and NH_4^+ due to disorder and the presence of heavy scatterers. Bond valence sum calculations [10] did not clearly indicate any protonated oxygens in the anion other than the water coordinated to cerium. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-406326.

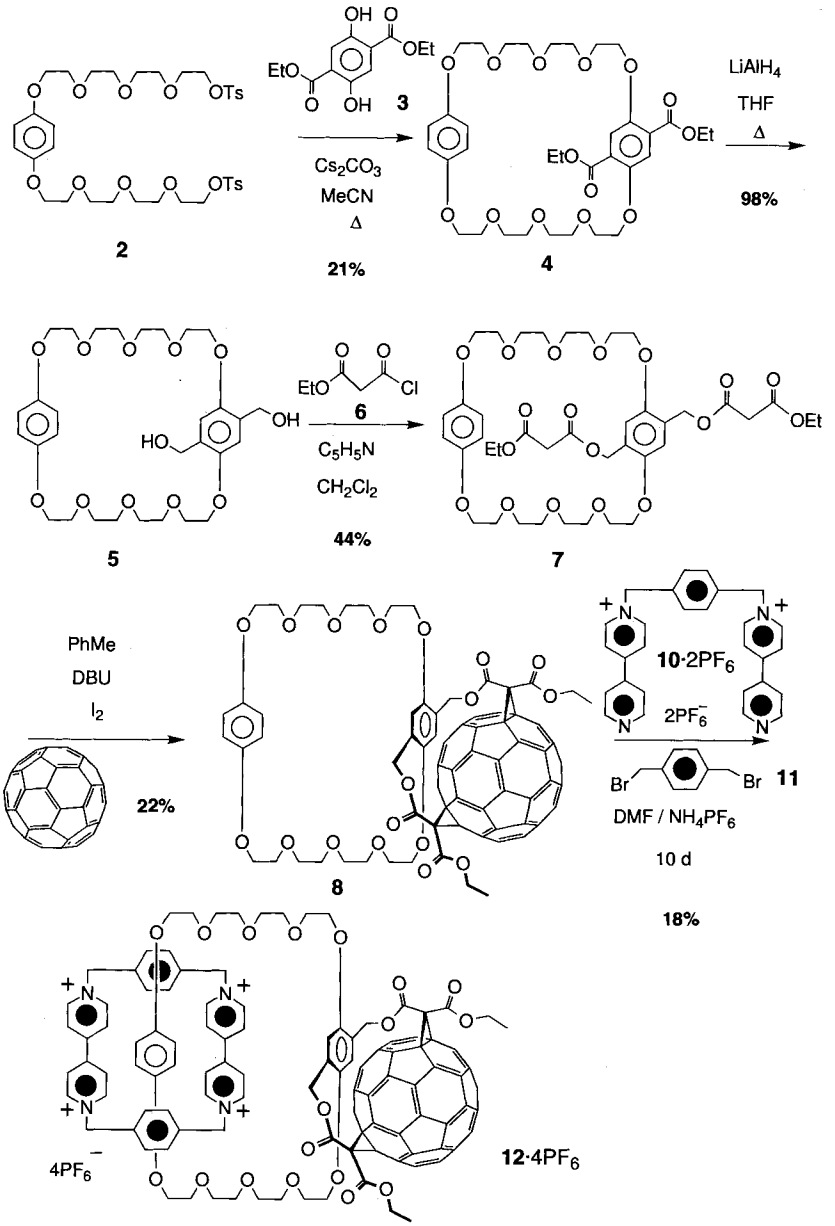
Self-Assembly of the First Fullerene-Containing [2]Catenane**

Peter R. Ashton, François Diederich,* Marcos Gómez-López, Jean-François Nierengarten, Jon A. Preece, Françisco M. Raymo, and J. Fraser Stoddart*

Since fullerenes[1] became available[2] in macroscopic quantities during the 1990s, a wide range of chemical transformations involving these novel carbon allotropes have been developed.[3] In the last few years chemists have also exploited noncovalent bonding interactions to self-assemble[4] a number of interlocked molecules—principally catenanes and rotaxanes[5]—that display fascinating topological features.[6] The unique electronic properties of C_{60}, for example its strong electron-accepting capabilities,[3] make it an attractive candidate for incorporation into rotaxanes[7] and catenanes. We now report the self-assembly of the first C_{60}-containing catenane, thus signaling completion of the initial merger between these two contemporary areas of chemistry. Recently the Zürich wing of this collaborative venture described[8] a regio- and diastereoselective bisfunctionalization of C_{60} based on cyclization of the carbon sphere with bis(malonate) derivatives in a double Bingel[9] addition. Here we underline the versatility of this method by fusing bis(*p*-phenylene)-[34]crown-10 (**1**), which has two π electron rich hydroquinone rings, to C_{60} in a regioselective manner. Thereafter, we describe the template-directed formation of cyclobis(paraquat-*p*-phenylene)[10] around the C_{60}-appended macrocyclic polyether to give the [2]catenane, an exotic molecular compound featuring an unusual topology and sporting undeniable aesthetic appeal.

For attachment to C_{60} by a double Bingel addition, the [34]crown-10 bismalonate **7** was prepared (Scheme 1). Macrocyclization (Cs_2CO_3, MeCN) of the bis(tosylate) **2** with the hydroquinone derivative **3** to produce **4** followed by reduction



Scheme 1. Regioselective synthesis of the fullerene-containing crown ether **8** and its subsequent self-assembly into the [2]catenane $12{\cdot}4PF_6$.

[**] This research was supported by the Swiss National Science Foundation, the Engineering and Physical Sciences Research Council in the United Kingdom, and by a predoctoral fellowship to M. G.-L. from the Eusko Jaurlaritza Unibersitate, Hizkuntza, eta Ikerketa Saila in the Basque Country, Spain. We thank Dr. M. Sebova and Dr. N. Spencer for carrying out the NMR spectroscopic measurements.

($LiAlH_4$, THF) yielded diol **5**, which was allowed to react with ethyl malonyl chloride (**6**) in the presence of pyridine to give **7**.[11] The subsequent reaction of **7** with C_{60} (I_2, 1,8-diazabicyclo[5.4.0]unde-7-ene (DBU), PhMe; Scheme 1) yielded regioselectively the macrocyclic *trans-4*-bis(adduct)[8,12] **8** in 22% yield.

The relative position of the two cyclopropane rings on the C_{60} surface in **8** was established from its ^1H and ^{13}C NMR ($CDCl_3$, 298 K) and UV/Vis spectra (CH_2Cl_2).[8,12,13] Although the intensity of the UV/Vis absorbance band of **8** is high, bands of similar intensities have been reported[12b] for other bis(adducts) of C_{60}.

Whereas the corresponding C_{60} *trans-4*-bis(adduct) produced[8] by addition of the simple, *p*-xylylene-tethered bis(ethyl malonate) [*p*-$(EtOCOCH_2CO_2CH_2)_2C_6H_4$] has C_s symmetry, and is therefore achiral, bridging of the fullerene sphere in **8** by the 2,5-disubstituted hydroquinone ring of the [34]crown-10 macrocycle introduces an element of planar chirality into the molecule, necessarily conferring upon it C_1 symmetry. As a consequence, the two sets of benzylic methylene groups, and the two protons within each group, are both, in a pairwise sense, diastereotopic, giving rise to four doublets ($J = 11$ Hz) in the 300 MHz ^1H NMR spectrum at $\delta = 4.59$, 5.30, 5.71, and 6.45. In contrast, all four benzylic methylene protons in the rapidly racemizing C_2 symmetrical enantiomers of **7** appear as the expected singlet at $\delta = 5.52$. The 125 MHz ^{13}C NMR spectrum of **8** uncovered 51 of 60 resonances expected for the fullerene C atoms. Molecular-modeling studies[14] on **8** revealed that the proximal (with respect to the carbon sphere) hydroquinone ring in **8** and one of the hexagons on the C_{60} surface undergo a nearly perfect parallel stacking at a distance of approximately 3.5 Å, implying the existence of donor(D)–acceptor(A) interactions[15] between the two rings.

Next we explored whether the fullerene-appended crown ether **8**,[16] which resembles closely **1** in its receptor portion, can act as a host for the π electron deficient guest **9**·$2PF_6$, the bis(hexafluorophosphate) salt of paraquat (*N*,*N*′-dimethyl-4,4′-bipyridinium dication).[17] In Me_2CO **1** forms a 1:1 complex ($K_a = 730\ L\,mol^{-1}$, $\Delta G° = -3.9$ kcal mol^{-1})[17] with **9**·$2PF_6$, wherein the π electron deficient bipyridinium unit is threaded through the cavity of the crown ether with its two π electron rich hydroquinone rings. On account of the low solubility of **8** in both Me_2CO and MeCN—two solvents commonly used to study this type of complexation—its affinity for **9**·$2PF_6$ was determined in $CD_3CN/CDCl_3$ (1/1). Evaluation of the complexation-induced upfield changes in chemical shift of the hydroquinone ring protons in ^1H NMR binding titrations (298 K)[18] yielded $K_a = 60 \pm 11\ L\,mol^{-1}$ ($\Delta G° = -2.44 \pm 0.1$ kcal mol^{-1}) for the 1:1 complex formed between **8** and **9**·$2PF_6$. Despite the more favorable solvent, this K_a value is considerably lower than that measured[17] for the corresponding complex with **1**. However, the ^1H NMR spectroscopic data suggest a similar, pseudorotaxane-like inclusion mode of complexation for both associations. It is not unlikely that donor–acceptor interactions between the proximal hydroquinone ring and C_{60}, as suggested by the modeling, could decrease the stabilizing donor–acceptor interactions between bound host and guest. As a result of the strong electronic absorptions of the fullerene appendage, the magnitude of the latter interactions could not be evaluated by UV/Vis spectroscopy.

Despite the low K_a value for **8**·**9**·$2PF_6$, self-assembly of the C_{60}-containing [2]catenane **12**·$4PF_6$ was attempted. A solution of **8**, the bis(pyridylpyridinium) salt **10**·$2PF_6$, *p*-xylylene dibromide (**11**), and an excess of NH_4PF_6 in DMF was stirred at 293 K for 10 d (Scheme 1). A brownish-red solid was isolated in

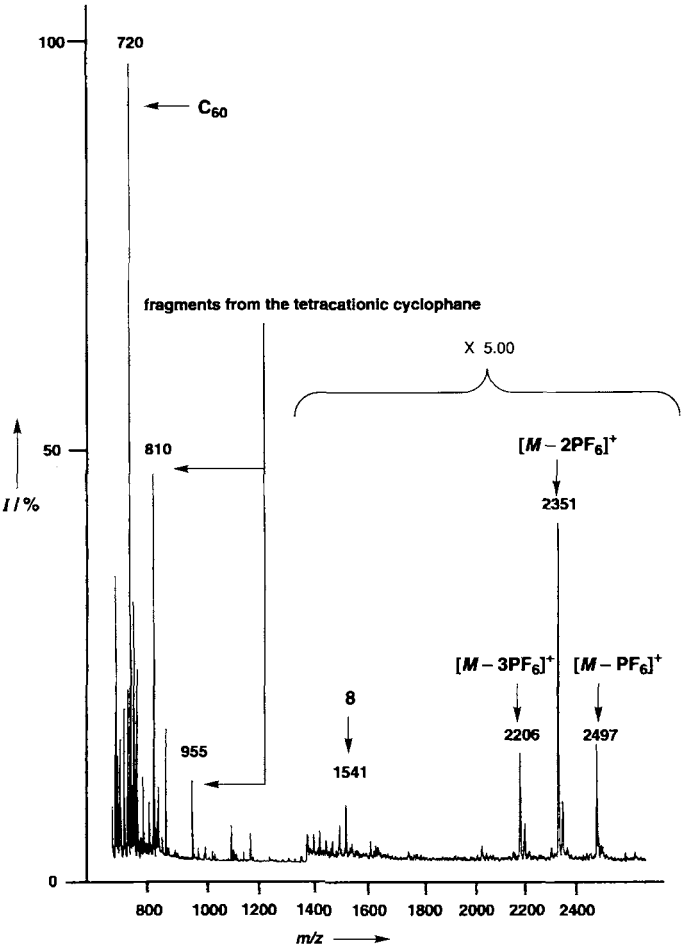

Figure 1. LSI mass spectrum of the fullerene-containing [2]catenane **12**·$4PF_6$. The *m*/*z* region from 1400 to 2600 is expanded five times for clarity.

18% yield and identified as **12**·$4PF_6$. Liquid secondary ion mass spectrometry (LSI-MS) revealed a fragmentation pattern characteristic of a catenane (Figure 1).[19] The spectrum showed peaks at $m/z = 2497$, 2351, and 2206, corresponding to the pseudomolecular ions originating from the losses of one, two, and three PF_6^- counterions from **12**·$4PF_6$, respectively. Furthermore, peaks at $m/z = 1541$, 810, and 720 arising from fragmentation of the [2]catenane were also observed: The peak at $m/z = 1541$ corresponded to the free fullerene-appended crown ether component, and the peak at $m/z = 810$ to the molecular ion of the cyclobis(paraquat-*p*-phenylene) component minus two PF_6^- counterions. A strong peak for the C_{60} fragment at $m/z = 720$ was also detected.

The ^1H NMR spectrum of **12**·$4PF_6$ (300 MHz, 298 K; Figure 2) provided further evidence for the existence of an interlocked molecular structure. A broad singlet at $\delta = 8.90$ and a broadened doublet at $\delta = 7.68$ correspond to the eight α- and eight β-bipyridinium protons, respectively, of the tetracationic cyclophane component. A singlet at $\delta = 7.79$ and a multiplet centered on $\delta = 5.67$, which integrate for eight protons, correspond to the protons on the xylyl spacers and the "corner" methylene protons, respectively, of this same component. The aromatic protons on the substituted hydroquinone ring appear as two singlets at $\delta = 6.23$ and 6.01. No signals are detected in the aromatic region for the unsubstituted hydroquinone ring. In the case of **8**, these protons resonate as a singlet at $\delta = 6.74$. However, when the hydroquinone ring is included within the

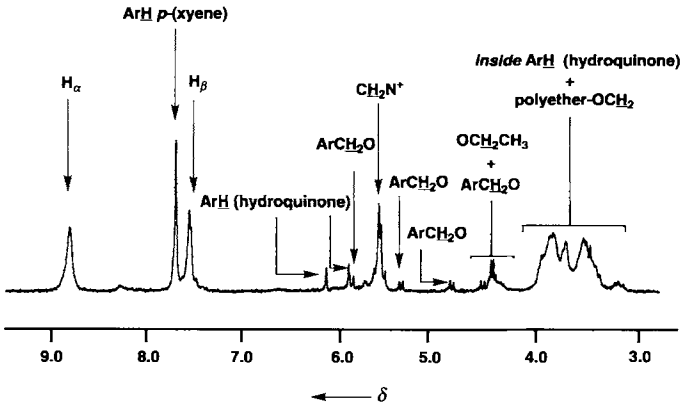

Figure 2. Section of the ^{1}H NMR spectrum (300 MHz, CD_3CN, room temperature) of **12**·4PF_6.

cavity of the cyclobis(paraquat-*p*-phenylene), its protons are shielded dramatically and shifted upfield into the region of the polyether protons.[20] Four different geminally coupled doublets are still observed at δ = 5.98, 5.45, 4.94, and 4.60 for the two pairs of *p*-(OCOCCH_2)$_2$$C_6H_4$ protons residing in diastereoisomeric environments.

Intramolecular D-A-D-A stacks involving π electron rich hydroquinone rings and π electron deficient bipyridinium units are well documented for a series of [2]catenanes.[21] However, in the case of **12**·4PF_6, the proximal substituted hydroquinone ring also acts as a π electron rich *exo* donor and undergoes additional interactions with the electron-accepting C_{60} moiety. This extra interaction builds an unprecedented intramolecular A-D-A-D-A stack into a [2]catenane, as portrayed by the space-filling molecular model of this intriguing **12**$^{4+}$ tetracation (Figure 3).

In this investigation two different branches of contemporary chemistry have been brought together to produce, by relatively new synthetic procedures including self-assembly,[4] a molecular compound that is a combination of two topologically nontrivial molecules[22]—that is, they cannot be represented by planar graphs—a macrocyclic C_{60} bis(adduct) and a catenane. The electrochemical and photophysical properties of **12**·4PF_6 are now under investigation.

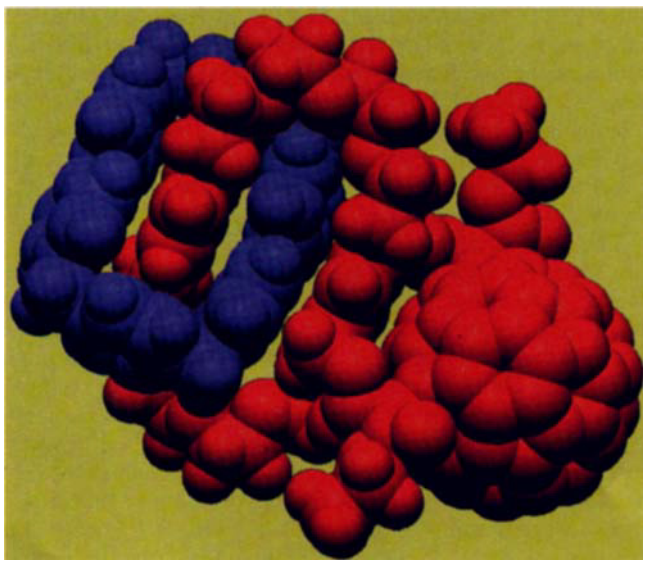

Figure 3. Molecular model of **12**$^{4+}$ revealing the intramolecular five-fold A-D-A-D-A stack.

Experimental Section

8: A solution of C_{60} (300 mg, 0.416 mmol), **7** (343 mg, 0.416 mmol), and I_2 (211 mg, 0.832 mmol) in PhMe (600 mL) was stirred under N_2. DBU (379 mg, 2.50 mmol) was added, and an instant color change from deep purple to wine red observed. The mixture was stirred overnight under N_2 before it was filtered through a plug (SiO_2) with PhMe to collect unchanged C_{60} (purple) and then with CH_2Cl_2/MeOH (98/2) to collect the product (red) of the double Bingel reaction. The solvent was removed in vacuo, and the product purified by column chromatography (SiO_2; CH_2Cl_2/MeOH, 99/1 then 98/2) to yield **8** as a brownish-red, glassy product (140 mg, 22%). IR (KBr): $\tilde{\nu}$ = 2871, 1744, 1506, 1453, 1421, 1364, 1239, 1104, 1062, 927, 862, 827, 735, 705 cm^{-1}; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 280 (155000), 365 (62500), 417 (sh, 35000), 472 (25000), 635 (5000), 701 nm (3200); ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ = 1.50–1.55 (two coincident triplets, J = 7.1 Hz, 6H), 3.62–3.85 (m, 28H), 3.97–3.98 (m, 4H), 4.56–4.58 (m, 4H), 4.59 (d, J = 11 Hz, 1H), 5.30 (d, J = 11 Hz, 1H), 5.71 (d, J = 11 Hz, 1H), 6.45 (d, J = 11 Hz, 1H), 6.51 (s, 1H), 6.74 (s, 4H), 6.79 (s, 1H); ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C): δ = 14.2, 14.3, 49.2, 49.4, 62.5, 63.5, 64.3, 68.2, 68.8, 69.2, 69.4, 69.5, 69.8, 70.4, 70.7, 70.8, 70.8, 70.9, 70.9, 72.5, 115.5, 116.2, 116.6, 125.2, 126.3, 128.0, 129.8, 131.0, 140.6, 140.8, 141.0, 141.2, 141.3, 141.4, 141.4, 141.5, 141.6, 141.9, 142.1, 142.2, 142.2, 142.7, 142.8, 142.8, 143.1, 143.2, 144.3, 144.4, 144.6, 144.8, 144.8, 145.0, 145.1, 145.1, 145.2, 145.2, 145.3, 145.3, 145.4, 145.9, 146.1, 146.3, 146.5, 146.8, 147.0, 147.0, 147.9, 148.1, 148.2, 148.4, 151.2, 152.3, 153.1, 153.1, 163.6, 164.1, 164.2, 164.3; FAB-MS (*m*-nitrobenzyl alcohol): m/z = 1541 [M + H]$^+$, 720 [C_{60}]$^+$; elemental analysis calcd for $C_{100}H_{52}O_{18}$·0.7CH_2Cl_2: C 75.55, H 3.36; found: C 75.34, H 3.70.

12·4PF_6: A solution of **8** (70 mg, 0.045 mmol), **10**·2PF_6 (32 mg, 0.045 mmol), **11** (12 mg, 0.045 mmol), and NH_4PF_6 (100 mg, 0.61 mmol) in dry DMF (10 mL) was stirred under N_2 for 10 d. The solvent was removed in vacuo to yield a brown oil, which was taken up in CH_2Cl_2 (100 mL) to produce a brownish-red precipitate and a deep red solution. The precipitate was isolated by filtration and washed with CH_2Cl_2 (50 mL), distilled H_2O (50 mL), and hot distilled H_2O (50 mL). The remaining solid was dissolved in MeCN (5 mL) and iPr_2O (about 1 mL) introduced by vapor diffusion. A white precipitate formed and was removed by filtration. Et_2O was added dropwise to the solution in MeCN until a suspension was formed. The suspension was centrifuged, and the brownish-red solution decanted. The product was purified by column chromatography (SiO_2; saturated solution of NH_4PF_6 in CH_3COCH_3). The solvent was removed in vacuo, and the remaining solid thoroughly washed with H_2O to yield **12**·4PF_6 as a brownish-red solid (20 mg, 18%). IR (NaCl): $\tilde{\nu}$ = 3327, 3135, 3048, 2920, 1743, 1636, 1508, 1404, 1232, 832, 790, 739 cm^{-1}; UV/Vis (MeCN): λ_{max} (ε) = 280 (88420), 325 (50000), 421 (21050), 463 (9200), 636 nm (3700); ^{1}H NMR (300 MHz, CD_3CN, 25 °C): δ = 1.43–1.44 (m, 6H), 3.40–4.05 (m, 36H), 4.44–4.52 (m, 4H), 4.60 (d, J = 11 Hz, 1H), 4.94 (d, J = 11 Hz, 1H), 5.45 (d, J = 11 Hz, 1H), 5.62-5.73 (m, 8H), 5.98 (d, J = 11 Hz, 1H), 6.01 (s, 1H), 6.23 (s, 1H), 7.68 (d, J = 5.9 Hz, 8H), 7.79 (s, 8H), 8.90 (br s, 8H); ^{13}C NMR (125 MHz, CD_3CN, 25 °C): δ = 14.6, 29.8, 30.0, 32.2, 62.5, 64.7, 65.8, 67.8, 69.4, 70.0, 70.2, 70.4, 70.5, 70.7, 70.9, 71.5, 71.9, 72.0, 113.0, 116.4, 117.2, 125.8, 126.3, 127.7, 128.6, 129.3, 130.4, 130.6, 131.2, 132.9, 133.1, 137.6, 139.9, 140.1, 141.1, 141.5, 141.8, 142.1, 142.2, 142.4, 142.9, 143.0, 143.2, 143.6, 143.9, 144.8, 145.2, 145.3, 145.8, 146.1, 146.3, 146.7, 147.2, 147.3, 147.6, 147.9, 148.1, 149.1, 151.2, 152.0, 164.3, 164.6, 164.7, 164.9; LSI-MS: m/z = 2642 [M + H]$^+$, 2497 [M − PF_6]$^+$, 2351 [M − 2PF_6]$^+$, 2206 [M − 3PF_6]$^+$, 1541 [**8**]$^+$, 810 [cyclobis(paraquat-*p*-phenylene) − 2PF_6]$^+$, 720 [C_{60}]$^+$.

[15] The [2]catenane **12**·4PF$_6$ was constructed within the input mode of Macromodel 5.0 (F. Mahamadi, N. G. K. Richards, W. C. Guida, R. Liskamp, M. Lipton, D. Caufield, G. Chang, T. Hendrickson, W. C. Still, *J. Comp. Chem.* **1990**, *11*, 440–467). The geometry was subsequently optimized by energy minimization with the Polak–Ribiere Conjugate-Gradient (PRCG) method, the AMBER* force field, and the Generalized Born Surface-Accessible (GB/SA) solvation model for H_2O. The global minimum was searched for by molecular dynamics with stepwise simulated annealing performed in one step of 10 ps, followed by two steps of 20 ps in conjunction with the PRCG method, the AMBER* force field, and the GB/SA for H_2O. The simulated temperature was decreased from 300 to 150 and finally to 50 K; a bath constant of 5.0 ps was applied at all steps. The time step was maintained at 1.5 fs in the first two steps and increased to 2.0 fs in the final step.

Carbohydrate Nanotubes**

Giuseppe Gattuso, Stephan Menzer, Sergey A. Nepogodiev, J. Fraser Stoddart,* and David J. Williams*

Large cyclic oligosaccharides, which can be defined as compounds incorporating more than eight monosaccharide residues in their macrorings and often possessing internal cavities of nanometer dimensions, are accessible from both natural sources[1] and from total chemical syntheses.[2] However, on account of the difficulties associated with either a) the isolation of the pure natural products or semi-synthetic compounds, or b) their availabilities in reasonable quantities from chemical syntheses, the physicochemical properties of the solid-state structures and superstructures of these large cyclic oligosaccharides have been somewhat superficially studied. It is only recently, for example, that the higher cyclodextrin (CD) homologs δ-CD,[3] ε-CD,[4] and η-CD[5] have been obtained as sufficiently pure samples to be subjected to such detailed investigations. This situation contrasts sharply with the extensive studies that have been carried out on the chief members of the CD family composed of six, seven and eight α-(1 → 4)-linked D-glucopyranose residues, namely α-CD, β-CD, and γ-CD, respectively. These compounds, as well as numerous inclusion complexes, have been throughly characterized in the solid state by X-ray and neutron diffraction methods[6] and solid-state NMR spectroscopy.[7] Amongst the large cyclic oligosaccharides, crystallographic data are available only for δ-CD[8] and ε-CD.[4] Previously, we synthesized[9, 10] a series of novel CD analogs composed of alternating D- and L-rhamnopyranose (**R**) and D- and L-mannopyranose (**M**) residues, including the first examples (**RR** and **MM** series) of achiral cyclic oligosaccharides and the largest (so far) synthetic cyclic oligosaccharide **5-RR** built up of 14 alternating D- and L-rhamnopyranose residues. The crystal structures of **1-MM** (α-CD analog) as well as **2-RM** and **2-RR** (γ-CD analogs) have been reported.[9, 10]

	n	R^1	R^2
1-MM	3	CH_2OH	CH_2OH
1-RM	3	Me	CH_2OH
2-RM	4	Me	CH_2OH
1-RR	3	Me	Me
2-RR	4	Me	Me
3-RR	5	Me	Me
4-RR	6	Me	Me
5-RR	7	Me	Me

X-ray crystallography reveals that, in the solid state, the cyclic octasaccharide **2-RR**[10] assembles in infinite stacks to form nanotubes of approximately 1 nm in diameter in a manner similar to that exhibited[9] by the octasaccharide **2-RM**. This stack-

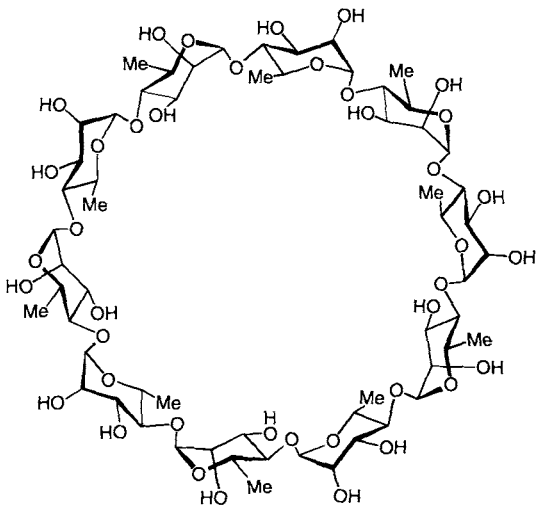
[**] Synthetic Cyclic Oligosaccharides, Part 3. Part 2: ref. [10b].

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1451 $ 17.50+.50/0

ing motif is closely reminiscent of the nanotubes formed by cyclic peptides composed of alternating D and L amino acids reported by Ghadiri and co-workers.[11] However, the contrast between the regular superstructures sustained by these highly symmetrical cyclic oligosaccharides and the more disordered packing exemplified by the larger members of the CD family—namely γ-CD,[12, 6c] δ-CD,[8] and ε-CD[4]—is striking. Here we report the results of X-ray crystallographic investigations on **3-RR**. This achiral cyclic decasaccharide displays quite a remarkable structure and superstructure in the solid state.



3-RR

The X-ray analysis[13] of a crystal produced by vapor diffusion of Me_2CO into an aqueous solution of the cyclic decasaccharide **3-RR** reveals a structure comprising two crystallographically independent, C_i-symmetrical macrocycles **A** and **B** (Figure 1). The two cyclic decasaccharide molecules have similar geometries, and each exhibits departures from ideal S_{10} symmetry. In **A** the radii of the polygon formed by the ten glycosidic oxygen atoms are 6.53 to 7.23 Å, whereas in **B** they are in the range of 6.73 to 7.21 Å. Although the planes of the α-D- and α-L-rhamnopyranosyl residues (those containing C2, C3, C5, and the ring O atom) are inclined approximately orthogonally to the mean plane of the macroring, as defined by the ten glycosidic oxygen atoms, they exhibit a distinct alternating pattern of inward and outward tilt angles that range between 77° and 81° in **A** and 76° and 85° in **B** (Figure 1b). The overall regularity of the molecular geometry is demonstrated by the conformation of the pseudo-ten-membered ring (Figure 2) formed by the ten glycosidic oxygen atoms, which adopts an approximately "all-*gauche*" geometry with alternating torsional twists of about ±76° about each O–O "linkage".

Inspection of the packing of the **A**- and **B**-type molecules shows each of them to be arranged in an approximately close-packed hexagonal array that extends in the crystallographic *b* and *c* directions (Figure 3). Adjacent molecules in both the *b* and *c* directions are offset by the thickness of about half a ring. However, there are no intermolecular hydrogen bonds in either case. In the *a* direction, the **A**- and **B**-type molecules form a slightly sheared alternating stack creating a nanotube-like arrangement (Figure 4). The mean interplanar separation between **A**- and **B**-type molecules is about 7.4 Å. A particular point of interest is that, within each stack, the **A**- and **B**-type molecules are not in register. Furthermore, and probably more

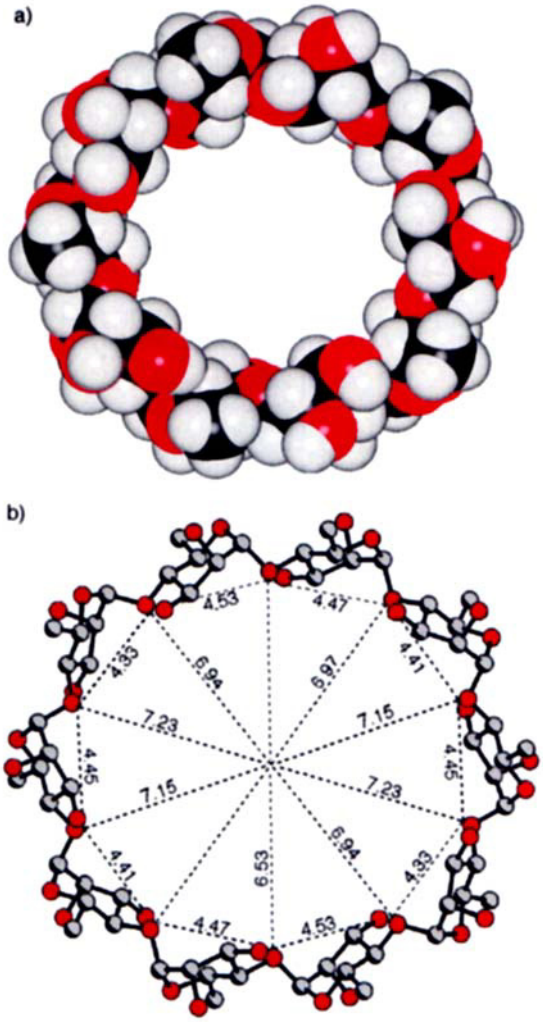


Figure 1. a) Space-filling and b) ball-and-stick representations of the C_i-symmetrical solid-state structure of **3-RR** (only molecule **A** is shown). The numbers beside the dashed lines indicate the distances [Å] between adjacent pairs of glycosydic oxygen atoms and their radial distances from the center of the cyclic decasaccharide. a) Red = O atoms; gray = C atoms; white = H atoms. b) Red = O atoms; shaded circles = C atoms.

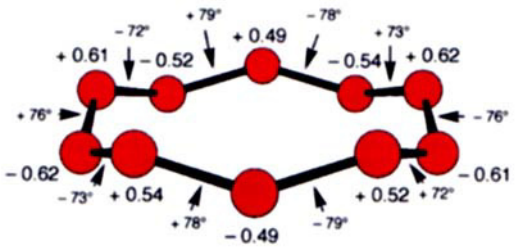

Figure 2. Polygon formed by the ten glycosidic oxygen atoms (red balls) of **3-RR** (only molecule **A** is shown). The distances [Å] from the mean plane of the molecule are shown in black beside each oxygen atom, and the "torsional angles" beside each bond.

significantly, they have different cyclic sequences for the glycosidic bonds between the α-D- and α-L-rhamnopyranosyl residues; that is, the sequence is clockwise in **A**, and counterclockwise in **B**. This disrotatory stacking is in contrast with the conrotatory arrangement present in **2-RM**[9] and **2-RR**,[10] where the molecules in each stack are in register with each other. There are no hydrogen bonds between the macrorings within each stack. Included Me_2CO and H_2O molecules lie both within and between the channels formed by the cyclic decasaccharide molecules.

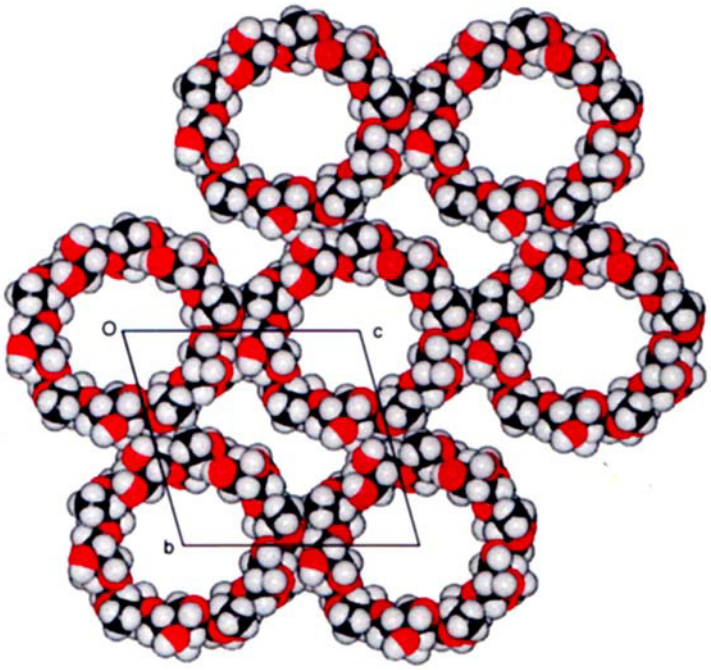

Figure 3. Distorted, close-packed hexagonal array of **3-RR** molecules (only molecule **A** is shown). Red = O atoms; grey = C atoms; white = H atoms.

Since **3-RR** crystallizes in the form of nanotubes with an internal diameter of about 1.3 nm, it adds to the two examples of cyclic octasaccharides already reported (namely, **2-RM** and **2-RR**)[9, 10] which sustain this intriguing superstructure in the solid state. Given the fact that these compounds share with the naturally occurring CDs an ability[10] to form inclusion complexes with other molecules, they could find themselves enjoying many biomedically-directed and materials-oriented applications in the future.

[13] Crystal data for **3-RR**: $C_{60}H_{100}O_{40}\cdot 6\,Me_2CO\cdot 10\,H_2O$, $M_r = 1990.0$, triclinic, space group $P\bar{1}$, $a = 15.130(6)$, $b = 19.077(5)$, $c = 20.017(5)$ Å, $\alpha = 72.74(2)$, $\beta = 87.60(3)$, $\gamma = 88.60(3)°$, $V = 5513(3)$ Å^3, $Z = 2$ (two independent molecules, each with crystallographic C_i symmetry), $\rho_{calcd} = 1.20$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 8.76$ cm^{-1}, $\lambda = 1.54178$ Å, $F(000) = 2144$. Crystal dimensions $0.33 \times 0.13 \times 0.07$ mm (plate-shaped prism), Siemens P4/RA diffractometer with $Cu_{K\alpha}$ radiation (graphite monochromated), ω scans. $T = 178$ K. The crys-

tal slowly desolvated during data collection. Of 7686 independent reflections measured ($2\theta \leq 100°$) 4846 had $I_o > (2\sigma I_o)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors, but not for absorption. The structure was solved by direct methods. The Me_2CO solvent molecules were disordered over seven partially occupied positions, and the H_2O molecules over 13 positions. Hydrogen atoms within the macroring were located from ΔF maps and refined applying distance constraints with riding isotropic thermal parameters, $U(H) = 1.2\,U_{eq}(C,O)$. Anisotropic refinement of all the exocyclic atoms of the sugar moieties, the full-weight H_2O molecules and six of the Me_2CO molecules; the remainder were held isotropic. $R_1 = 0.141$ and $wR_2 = 0.379$ based on F^2. All computations were carried out with the SHELXTL 5.03 package. The crystallographic data (excluding structure factors) for the structure reported in this paper has been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100130. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

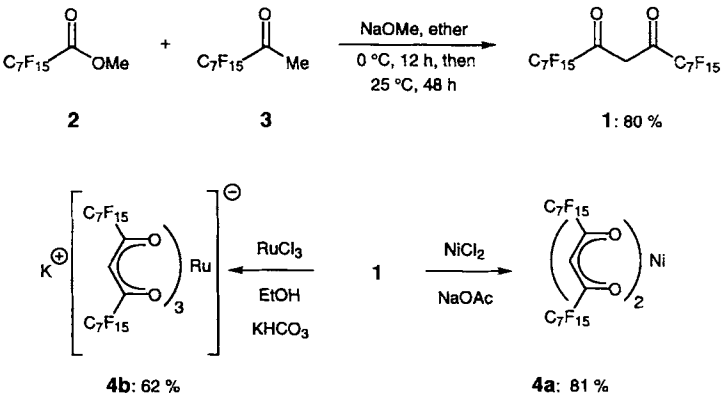
Transition Metal Catalyzed Oxidations in Perfluorinated Solvents**

Ingo Klement, Henning Lütjens, and Paul Knochel*

Perfluorinated hydrocarbons are chemically inert compounds that have found useful applications, especially as artificial blood substitutes.[1] As a consequence of their low tendency to undergo van der Waals interactions, they solubilize well a range of gases[2] and are immiscible with many organic solvents at room temperature. However, a good miscibility with some organic solvents is observed at higher temperature.[3] These properties, which were used first for synthetic applications by Horváth and Rabai,[3] make perfluorinated hydrocarbons ideal solvents for organic reactions in which gases serve as one reactant.[3,4]

Furthermore, the temperature dependence of the miscibility of perfluorinated solvents with organic solvents can be advantageously used for enhancing the reaction rate by obtaining a monophasic system during the reaction. By cooling down the mixture at the end of the reaction, a biphasic system is formed, which allows easy separation of the reaction products and recovery of the perfluorinated solvent (Scheme 1). Recently, we have used perfluorinated solvents for oxidizing organometallic compounds, such as organozinc derivatives, to give polyfunctional hydroperoxides.[5] Under these conditions, organoboranes could be oxidized stereoselectively with oxygen to give alcohols.[6] Herein, we report a new practical method for the biphasic oxidation of aldehydes, sulfides, or olefins to give carboxylic acids, sulfoxides or sulfones, and epoxides, respectively, in good to excellent yields, which uses a transition metal catalyst (Ni, Ru) bearing perfluorinated ligands. These chemical processes combine an efficient direct oxidation with oxygen with a small or negligible leaching of the metal salts in the organic phase and a trivial product isolation by phase separation. An excellent chemoselectivity was obtained in the case of the epoxide synthesis.

The required perfluorinated ligand, the 1,3-diketone **1**, was prepared by the condensation[7] of the methyl ester **2** with the methyl ketone **3** in the presence of NaOMe (1 equiv) in diethyl ether (0 °C, 12 h, then 25 °C, 48 h, 80% yield). The reaction of the perfluorinated 1,3-diketone **1** with the appropriate metal salt MCl_2 (M = Ni, Ru) in the presence of a base furnishes the desired complexes **4a** and **4b** in 81 and 62% yield, respectively. These were readily soluble in perfluorinated solvents (Scheme 2) leading to green and purple solutions, respectively.



Scheme 2. Preparation of the perfluorinated complexes **4a** and **4b**.

Thus, treatment of an aldehyde of type **5** with oxygen in a monophasic solvent system (toluene/perfluorinated decalin) at 64 °C in the presence of the nickel catalyst **4a** (3 mol%) furnishes the corresponding carboxylic acid of type **6** in yields of 71–87% (Scheme 3). The reaction tolerates several functional groups (ester, chloride, tetraisopropylsilyl(TIPS)-ether) and proceeds as well with aromatic as with aliphatic aldehydes.[8]

No leaching of the catalyst is observed (Figure 1) and the catalytic system can be easily recovered (by phase separation) and reused again as shown in the case of *p*-chlorobenzaldehyde (**5a**). The yield of the reaction was still 70% after six reaction cycles (Scheme 4). Similarly, this catalytic system can be used for the oxidation of sulfides **7** to sulfoxides **8** and sulfones **9** (Figure 1, Scheme 5). The reaction required the presence of isobutyraldehyde;[9] the optimum quantities are 1.6 equiv for the oxidation to sulfoxides and 5 equiv for the oxidation to sulfones.

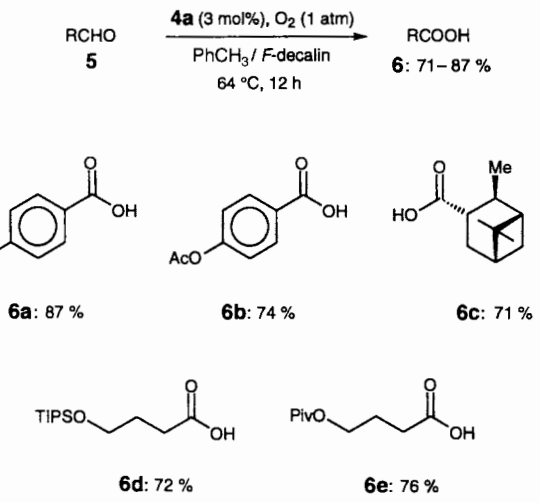

Scheme 3. Oxidation of the aldehydes **6** by oxygen with **4a** as catalyst (*F*-decalin = perfluorodecalin, TIPS = tetraisopropylsilyl).

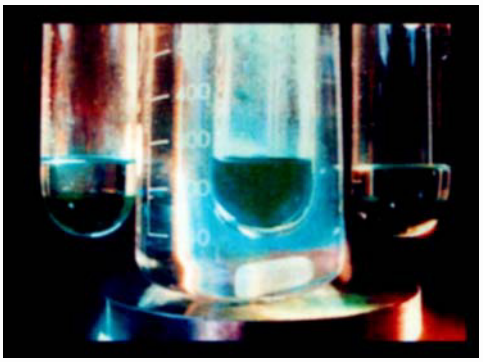

Figure 1. Oxidation of sulfides to sulfoxides in toluene/$C_8F_{17}Br$. Left: Biphasic system before the reaction. Center: Monophasic system during the reaction. Right: Biphasic system after reaction.

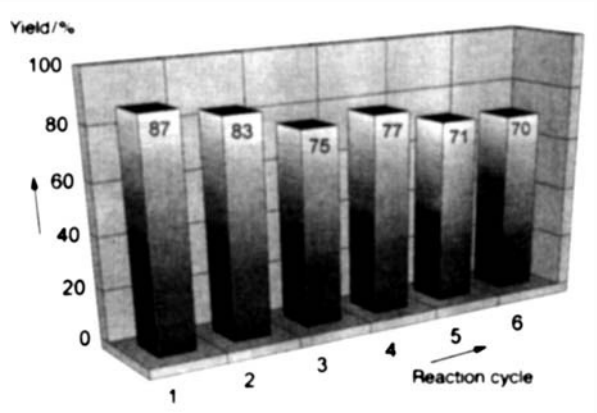
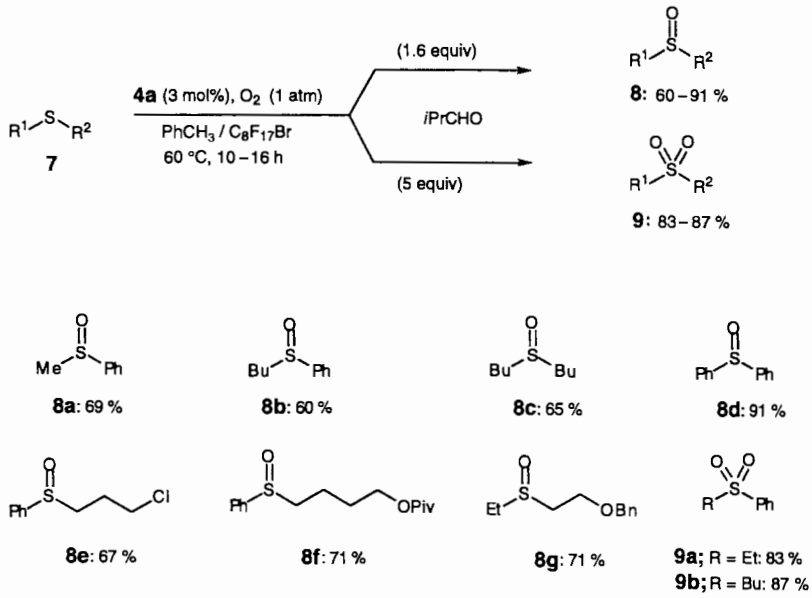


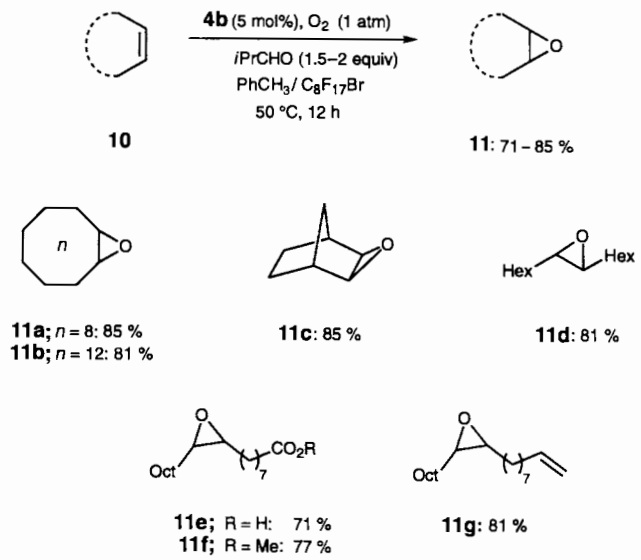
Scheme 4. Oxidation of *p*-chlorobenzaldehyde (**5a**) to give the corresponding acid **6a** (six reaction cycles with reuse of the catalyst **4a**).

Finally, whereas the nickel catalytic system is not suitable for the oxidation of olefins, we found that the ruthenium catalyst **4b** (5 mol%) allows the epoxidation of disubstituted olefins of type **10** to epoxides **11** in toluene/$C_8F_{17}Br$. The actual catalyst is a more oxidized ruthenium species, which is formed in situ and leads to a brown solution. Remarkably, only disubstituted olefins are selectively converted in good yields to the corresponding epoxide under the reaction conditions, as shown in the case of the preparation of the unsaturated epoxide **11g** (Scheme 6). Several functional groups (ester, carboxylic acid)



Scheme 5. Oxidation of sulfides **7**.

are tolerated in these epoxidations. The brown solution of the perfluorinated phase containing the catalyst can be used several times leading to similar yields in the epoxidation. A negligible leaching of the catalyst is observed[10] making this oxidation system suitable for large-scale reactions.[11, 12]



Scheme 6. Oxidation of disubstituted olefins **10**.

In summary, we have described a new metal-catalyzed oxidation method that uses perfluorinated solvents. The easy separation, nonleaching of the metal catalyst, and reuse of the catalyst make this procedure potentially interesting for industrial applications.

Experimental Section

Typical procedure for the preparation of *p*-chlorobenzoic acid (**6a**). A 150 mL Schlenk flask was charged with **4a** (250 mg, 0.15 mmol, 3 mol%) and perfluorodecalin (5 mL). A solution of *p*-chlorobenzaldehyde (0.70 g, 5 mmol) in toluene (5 mL) was added and the resulting emulsion was saturated with oxygen (15 min of bubbling at room temperature). The reaction mixture was warmed to 64 °C and the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1455 $ 17.50+.50/0

green solution was vigorously stirred under an oxygen overpressure (ca. 1 bar, 12 h). After allowing the mixture to cool to room temperature, phase separation of the solvent system occurred immediately. The precipitated *p*-chlorobenzoic acid (**6a**) was filtered off and recrystallized from acetonitrile affording a white solid (0.68 g, 4.3 mmol, 87% yield, mp 240–243 °C). The green perfluorinated phase containing the catalyst was separated from toluene and can be used for further experiments.

Preparation of cyclooctene oxide (**11a**). A 25 mL flask was charged with a solution of the ruthenium catalyst **4b** (640 mg, 0.25 mmol, 5 mol%) in 1-bromoperfluorooctane (2.5 mL) and a solution of cyclooctene (550 mg, 5 mmol) and isobutyraldehyde (720 mg, 10 mmol) in toluene. The biphasic system was warmed to 50 °C affording a single phase and was stirred at that temperature for 5 h under an oxygen atmosphere (oxygen balloon). The reaction mixture was cooled to 0 °C, and the phases separated. The brown perfluorinated phase containing the catalyst was separated and can be reused for further experiments. The organic phase was washed with 2M aqueous NaOH in order to remove the acid formed as by-product. The toluene was evaporated and the product was purified by flash chromatography on silica gel (eluent: hexanes/*t*BuOMe 10:1) yielding cyclooctene oxide (**11a**) (517 mg, 4.1 mmol, 82%).

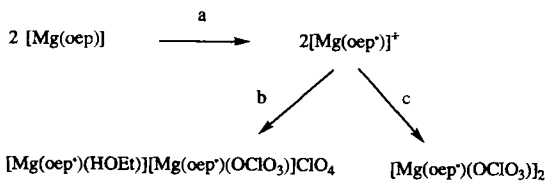
Inter-Ring Interactions in Dimers of Magnesium π-Cation Radicals: Control by Solvent Polarity**

Kristin E. Brancato-Buentello and W. Robert Scheidt*

An important property of metalloporphyrins is the facile oxidation of the macrocyclic ligand to yield π-cation radicals, which are important in both biological oxidation chemistry and photosynthesis. Such species have been known in solution for almost three decades.[1, 2] Temperature-dependent electronic spectra indicate that sterically unhindered π-cation radicals dimerize.[2, 3] Fajer et al.[2] also noted the importance of solvent for changes in the spectra of $[Mg(oep^{\bullet})]^{+}$ (H_2oep = octaethylporphyrin) in CH_2Cl_2 and MeOH. Fuhrhop et al.[3] showed that formation of the $[Zn(oep^{\bullet})]^{+}$ radical dimer was stabilized by solvents of increasing polarity. We have been concerned with the characterization of metalloporphyrin π-cation radicals, in particular their inter-ring and spin–spin interactions. In 1989 we reported the structure of the first sterically nonbulky derivative of a π-cation radical, $[\{Zn(OH_2)(oep^{\bullet})\}_2]^{2+}$, which forms a strongly coupled, virtually eclipsed cofacial dimer with an interplanar porphyrin-ring spacing of 3.31 Å.[4] The dimers show an unprecedented complete overlap of the two π-cation radical rings in the solid state, which was subsequently found in eight other derivatives.[5]

$[Mg(oep^{\bullet})]ClO_4$ is unusual in that it displays relatively high solubility in toluene/CH_2Cl_2 (4/1). We were thus able to prepare X-ray quality single crystals of $[Mg(oep^{\bullet})]ClO_4$ derivatives from two solvent systems (Scheme 1). Both **1**[8] and **2** are dimeric in



Scheme 1. Formation of dimers of π-cation radicals: a) oxidation with thianthrenium perchlorate [6] (1:1.05) in CH_2Cl_2; crystallization from b) $CH_2Cl_2/CHCl_3$ (5/1) and hexane or c) toluene/CH_2Cl_2 (4/1) and hexane. Dried solvents and flame-dried glassware must be used throughout to avoid acid-catalyzed demetalation [7].

the solid state, but their inter-ring interactions are dramatically different.[9] The structures, along with concentration-dependent electronic spectra, shed light on the effects of solvent (polarity) on the formation of radical-cation dimers.

Side and plan views of one of the identical dimeric units of **1** and that of **2** are presented in Figures 1 and 2. The π–π interaction between the rings is apparent. The two porphyrin rings of the cofacial dimer of **1** are directly above each other with no lateral shift between them. This is true for both dimeric units of **1**, even though there is no required crystallographic symmetry.

[**] This work was supported by the U. S. National Institutes of Health (GM-38401). K. E. B. thanks the J. Peter Grace Foundation for a doctoral fellowship.

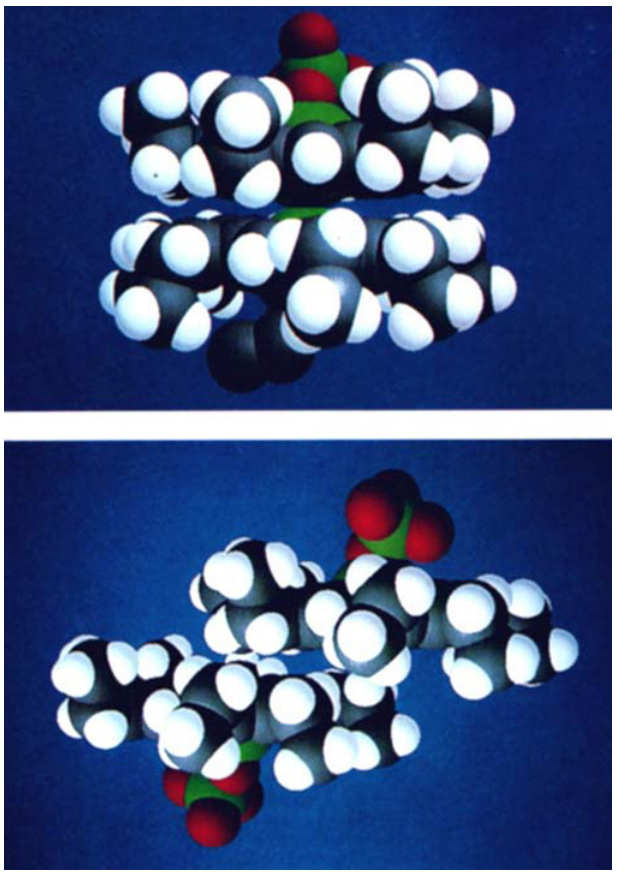

Figure 1. Space-filling diagrams showing side-on views of dimers **1** (top) and **2** (bottom), and the substantial differences in core overlaps. The interplanar spacing in **1** is 3.21 Å, and the lateral shift effectively 0 Å. In **2** the interplanar spacing is 3.46 Å, and the lateral shift 6.27 Å.

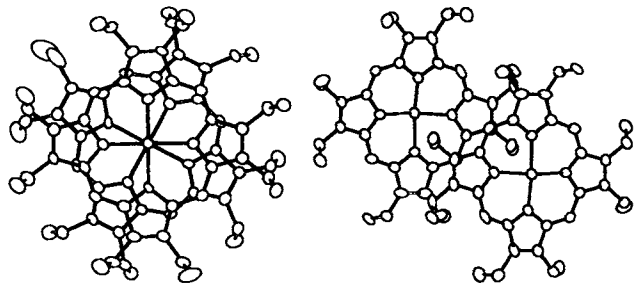

Figure 2. Plan views of the crystal structures of **1** (left) and **2** (right).

The strong interaction is consistent with a lateral shift of about 0 Å and is a feature of all previously characterized dimeric octaethylporphyrin π-cation radicals,[5] all of which were crystallized from polar solvents. The orientation of the ethyl groups in radical **1**, which all point outwards from the center, is also a characteristic feature.

The two rings of radical **2** show an apparently weaker interaction with a large lateral shift of 6.27 Å. Consistent with this, each porphyrin has four ethyl groups pointing "up" and four pointing "down" in an orientation that minimizes the inter-ring ethyl–ethyl interactions. Scheidt and Lee[11] surveyed the inter-ring geometry for all structurally characterized neutral porphyrin dimers with sterically unhindered peripheral substituents. They noted that the observed lateral shifts tend to cluster around specific values rather than displaying a continuous distribution. The lateral shift of **2** is in the range observed for the group Scheidt and Lee classified as "weak", whereas the lateral shift of about 0 Å for **1** is much smaller than that for the group they classified as "strong" (lateral shifts of 1.5 Å). However, the lateral shifts in **1** are similar to those seen in a number of other $[\{M(oep^{\bullet})\}_2]^{2+}$ dimers.[5]

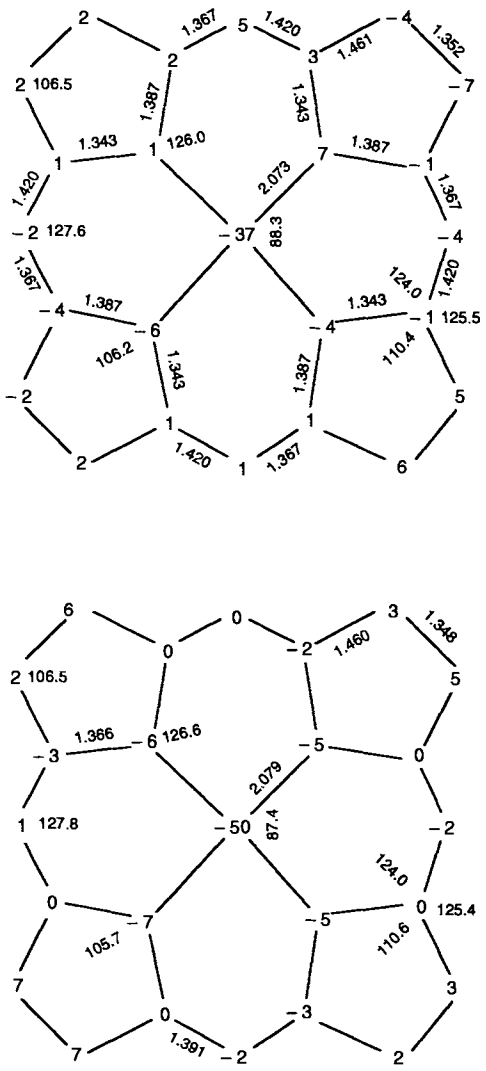
All other structural features of **1** and **2** are consistent with significant differences in the inter-ring interactions in the two derivatives. The twist angle of 28.3° in **1** leads to a number of close inter-ring atomic contacts in the inner 16-membered porphyrin ring. The closest inter-ring contacts are between α-C atoms and between α-C atoms and methine C atoms. The perpendicular displacements of each atom from the 24-atom mean planes of **1** are small. Interestingly, the deviations are such that the close interatomic separations are slightly smaller than they would be if the cores were precisely planar. The two rings interlock like puzzle pieces to allow more intimate interactions. The other independent dimer in **1** shows exactly the same phenomenon with a twist angle of 28.2° and similar core conformational features. Edge-over-edge overlap in **2** is small, and the two cores, each with modest C_{4v} doming, also dome away from each other. Both features are consistent with a weak inter-ring interaction.

An alternating long–short bond-length pattern is observed in the inner 16-membered rings of **1**. The same pattern is evident in each of the four independent rings (Scheme 2).This unusual pattern was first observed in $[\{Zn(OH_2)(oep^{\bullet})\}_2]^{2+}$[4] and has subsequently been seen in a number of other dimers of π-cation radicals.[5b,c] The basis for this unusual phenomenon is not certain but appears to be associated with strongly overlapping π-cation rings. Bond lengths in the weaker dimer **2** show the normal porphyrin delocalization pattern.

Differences in the inter-ring interactions of **1** and **2** are also reflected in the geometry of the coordination groups. The axial Mg–O distances ($\bar{d}$ = 2.039(15) Å and 2.046(4) Å, respectively) fall well within the broad range seen in other five-coordinate Mg derivatives (Mg–O 2.012–2.078 Å). The mean Mg–N_p bond length in **1** is 2.073(2) Å, slightly shorter than that found in other five-coordinate Mg porphyrins (2.083–2.096 Å)[13] but within the limits observed for six-coordinate Mg porphyrins (2.068–2.078 Å).[14] The mean Mg–N_p bond length of 2.079(3) Å in **2** is slightly longer. A larger difference is found in the out-of-plane displacement of the metal. For **1** the average of 0.34(4) Å is somewhat low for five-coordinate Mg porphyrin (0.39–0.52 Å),[13] whereas the 0.50 Å displacement in **2** lies within this range. The shorter-than-normal Mg–N_p bond lengths and the smaller Mg-atom displacement of **1** are the result of the very tight face-to-face interaction,[15] whereas the weaker π–π interaction in **2** leads to the normal geometry of the five-coordinate Mg center in the porphyrin.

The dramatically different solid-state structures of **1** and **2** are reflected in significant differences in the electronic spectra of $[Mg(oep^{\bullet})]^+$ in CH_2Cl_2 and toluene/CH_2Cl_2 (4/1). At high concentration a broad, concentration-dependent, near-IR band is seen in both CH_2Cl_2 (954 nm) and toluene/CH_2Cl_2 (ca. 912 nm). These bands are similar to that arising from dimerization.[2] Most important are the striking solvent- and concentration-dependent features in the UV/Vis region. The spectra generally show the normal features for formation of π-cation radicals[1–3,12]: weaker, blue-shifted, broadened Soret bands and red-shifted, substantially broadened visible (α and β) bands along with the appearance of a new band in the visible region at about λ = 660 nm, which is characteristic of the magnesium π-cation derivative.[17]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1457 $ 17.50+.50/0



Scheme 2. Diagram of the formal porphinato cores in **1** (top) and **2** (bottom) with averaged values of bond lengths and angles. For **1** these averages are taken over the four independent rings. The values of the averaged bond distances for the inner 16-membered rings are displayed four times to illustrate the alternating bond pattern; all other averaged values are displayed only once. Also displayed are the perpendicular atomic displacements, in units of 0.01 Å, of each atom from the 24-atom mean plane of the core. Positive values of displacement are toward the center of the other ring. One of the four independent rings is shown for **1**. Estimated standard deviations for individual C–C or C–N bonds are 0.008 Å for **1** and 0.007 Å for **2**, and 0.6° and 0.5° for their angles, respectively.

Figure 3a shows the general concentration-dependent spectral changes in CH_2Cl_2 in the Soret region. At the lowest concentration shown there are bands at 394 and 408 nm; the latter is more prominent at still lower concentrations. The intensity of the band at 394 nm increases monotonically with increasing concentration at the expense of the band at 408 nm. Other blue-shifted features (shoulders at 322, 355, and 379 nm) also become more prominent. Figure 3b shows the concentration-dependent spectral changes that occur in toluene/CH_2Cl_2 (4/1). Again there is a 410 nm Soret band, whose relative intensity decreases in favor of a band at 397 nm , accompanied by other blue-shifted shoulders. Even at the highest concentrations the blue-shifted Soret band and other components are not as completely developed as in CH_2Cl_2. The blue-shifted band envelopes exhibit strong similarities in the shapes and intensities of the shoulders. However, the concentration dependence is more complex in toluene/CH_2Cl_2. The ratio of intensities of the bands at 397 and

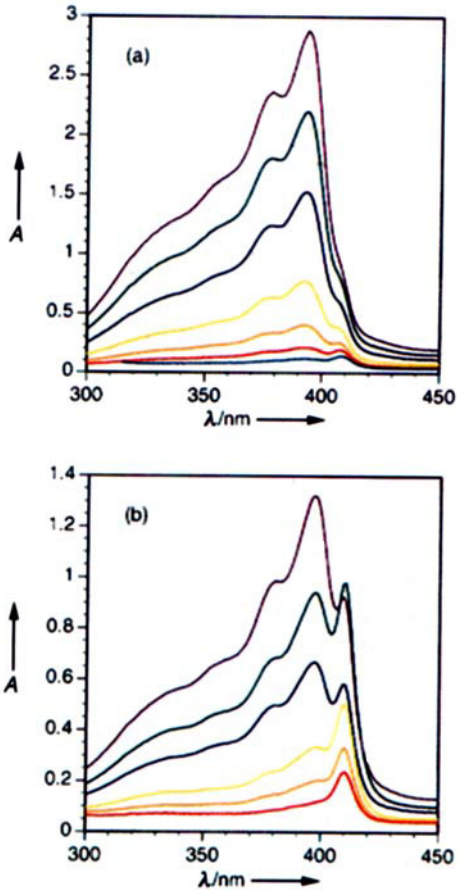


Figure 3. Electronic spectra of $[Mg(oep^{\cdot})]^+$ in a) CH_2Cl_2 and b) toluene/CH_2Cl_2. Concentrations in both solvent systems are (top to bottom) 3.00×10^{-4} M, 2.25×10^{-4} M, 1.50×10^{-4} M, 7.50×10^{-5} M, 3.75×10^{-5} M, and 1.88×10^{-5} M. The lowest concentration in a) is 9.38×10^{-6} M.

410 nm first increases, then decreases, and finally increase again. In CH_2Cl_2 the ratio of the bands at 394 and 408 nm increases monotonically.

The 408/410 nm band at low concentration almost certainly corresponds to the monomeric $[Mg(oep^{\cdot})]^+$ species, whereas the 394/397 nm Soret and other strongly blue-shifted features must correspond to the formation of an aggregated, tightly interacting dimeric species in which the in-plane x and y directions are distinct.[18] The nearly identical blue-shifted features in the two solvents suggests the presence of similar limiting species. The intensities clearly indicate differences in relative proportions in the two solvents: monomeric species are favored in toluene/CH_2Cl_2, and the species yielding the blue-shifted spectra in CH_2Cl_2. However, the presence of a significant amount of a third component, for which the intenstiy of the spectral band increases and then decreases with increasing concentration, is only seen in toluene/CH_2Cl_2. Since this (third) species appears with increasing solute concentration, it is clearly at least dimeric.

We interpret the spectral differences to be the result of differences in dimerization equilibrium constants and in the nature of the (dimeric) species in the two solvents. The differences for the two solvent systems are as expected if dimerization is more strongly favored in polar solvents, as is the case in the zinc system.[3] Although the exact nature of the solution species cannot be deduced solely from the electronic spectra, the data clearly suggest significantly different solution species in the two solvents. The dimeric solid-state structures obtained from the two solvents suggest possible structures in solution. The species yielding the strongly blue-shifted spectra could have a structure

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1458 $ 17.50+.50/0

similar to **1**, whereas the other dimeric species in toluene/CH_2Cl_2 may be associated with a species similar to **2**.

We have reported the first solid-state analysis of five-coordinate $[Mg(oep^{\bullet})]^+$ π-cation radicals. Two distinct dimeric species have been characterized in which the inter-ring overlap is controlled by crystallization from solvents of different polarity: high polarity leads to a tightly coupled cofacial dimer, and lower polarity to a more weakly coupled cofacial dimer. The concentration- and solvent-dependent differences in the UV/Vis spectra parallel the findings in the solid state.

[8] The EtOH molecule coordinated to Mg in crystals of **1** results from from the stabilizer in commercial $CHCl_3$. Despite the importance of the EtOH in obtaining crystals, it has minimal effects on the spectra of a solution in CH_2Cl_2 at the small concentrations of the crystallization experiment.
[9] Compound **1** crystallized from $CH_2Cl_2/CHCl_3$ (ca. 5/1) layered with hexanes, and **2** from toluene/CH_2Cl_2 (4/1). A pink-purple crystal of **1** ($0.13\times0.20\times0.60$ mm) and a dark purple crystal of **2** ($0.017\times0.06\times0.17$ mm) were analyzed on an Enraf-Nonius FAST area-detector diffractometer with a Mo rotating-anode source ($\lambda = 0.71073$ Å) by procedures that were described previously (W. R. Scheidt, I. Turowska-Tyrk, *Inorg. Chem.* **1994**, *33*, 1314–1318). Crystal data for **1**: $a = 12.176(1)$, $b = 21.657(5)$, $c = 29.302(8)$ Å, $\beta = 99.94(1)^\circ$, monoclinic, $P2_1$, $V = 7610.9(3)$ Å^3, $Z = 4$ (dimers), $\rho_{calcd} = 1.291$ g cm^{-3}, $2\theta_{max} = 27.06^\circ$. Crystal data for **2**: $a = 10.280(4)$, $b = 11.681(3)$, $c = 13.939(6)$ Å, $\alpha = 83.93(2)^\circ$, $\beta = 83.63(3)^\circ$, $\gamma = 78.18(3)^\circ$, triclinic, $P\bar{1}$, $V = 1622.2(10)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.344$ g cm^{-3}, $2\theta_{max} = 29.73^\circ$. All measurements were made at 124 ± 2 K. Data were corrected for Lorentzian, polarization, and absorption factors (relative transmission coefficients = 1.00–0.729 for **1** and 1.00–0.565 for **2**). Both structures were solved by direct methods (SHELXS) [10a] and refined against F^2 with SHELXL-93 [10b]. All data collected were used, and all porphyrin hydrogen atoms were idealized with the standard SHELXL-93 methods. **1**: $R_1 = 0.0746$ for 17417 observed reflections ($F_o \geq 4.0\sigma(F_o)$). $wR_2 = 0.2099$ for 24123 total unique data (1884 variables refined) including negative F^2 (residual electron density = 0.76 and -0.45 e Å^{-3}). **2**: $R_1 = 0.1030$ for 3993 observed data, $wR_2 = 0.2912$ for 8081 unique data (463 variables; residual electron density = 0.63 and -0.71 e Å^{-3}). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100099. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Ferromagnetic Coupling in the Bis(μ-end-on-azido)iron(III) Dinuclear Complex Anion of $[Fe^{II}(bpym)_3]_2[Fe_2^{III}(N_3)_{10}]\cdot 2H_2O$**

Giovanni De Munno,* Teresa Poerio, Guillaume Viau, Miguel Julve,* and Francesc Lloret

The design of new polynuclear species exhibiting ferromagnetic coupling is one of the major challenges in magnetochemistry.[1] Three strategies have been proposed for obtaining these compounds,[2] which make use of the 1) required or 2) accidental orthogonality of the magnetic orbitals and 3) spin-polarization effects. The second case depends on structural parameters that are difficult to control during synthesis. The di-μ-hydroxo-bridged copper(II) complexes are the best example for this: Magnetic coupling is ferromagnetic for angles θ at the hydroxo bridge of less than 97.5° and antiferromagnetic for θ larger than 97.5°.[3] The remarkable ability of the end-on bridging azide ion to stabilize the triplet state in dinuclear complexes of divalent transition metal ions of the first row[4–7] is another example of accidental orthogonality. The magnitude of the ferromagnetic coupling varies between +200 (Cu^{II})[4b] and +2.4 cm^{-1} (Mn^{II}).[7]

We recently synthesized new honeycomb layered materials of formula $[M_2(bpym)(N_3)_4]$ (M = Mn^{II}, Fe^{II}, Co^{II}; bpym = 2,2′-bipyrimidine), which exhibit alternating ferro- (through double end-on azido) and antiferromagnetic (through bis(chelating) bpym) interactions.[8, 9] In our attempts to synthesize the iron(II) derivative **2**, single crystals of **1** were obtained after partial oxidation by atmospheric oxygen. Complex **1** was characterized by IR spectroscopy, variable-temperature magnetic measurements, and X-ray structural analysis.

$[Fe^{II}(bpym)_3][Fe_2^{III}(N_3)_{10}]\cdot 2H_2O$ **1**

$[Fe_2(bpym)(N_3)_4]$ **2**

The crystal structure of **1** consists of centrosymmetric double end-on azido-bridged iron(III) dinuclear anions with monodentate azide groups as terminal ligands (Figure 1, top), mononuclear tris(2,2′-bipyrimidine)iron(II) cations (Figure 1, bottom), and water molecules.

Each iron atom in the anion has a distorted octahedral coordination sphere. The metal to bridging azide bond lengths (av 2.179(5) Å) are significantly longer than those involving the metal center and the terminal azide groups (av 2.031(5) Å), as expected. The latter value compares well with that of 2.023(8) Å in the mononuclear iron(III) complex $(Et_4N)[Fe\{HB(3,5\text{-}Me_2pz)_3\}(N_3)_3]$[10] ($HB(3,5\text{-}Me_2pz)_3$ = hydrotris(3,5-dimethyl-1-pyrazolyl)borate) but is somewhat longer than the Fe–N(axial azide) bond length (1.925(7) Å) in the porphyrin iron(III) complex $[Fe(TPP)(N_3)(py)]$[11] (TPP = tetraphenylporphirinate). The occurrence of high-spin (**1** and the pyrazolylborate

Selected bond lengths [Å] and angles [°] with standard deviations in parentheses: Fe(2)–N(13) 2.027(5), Fe(2)–N(16) 2.043(5), Fe(2)–N(19) 2.039(6), Fe(2)–N(22) 2.195(5), Fe(2)–N(22a) 2.164(5), Fe(2)–N(25) 2.017(6); N(13)-Fe(2)-N(16) 90.4(2), N(13)-Fe(2)-N(19) 87.7(2), N(13)-Fe(2)-N(22) 91.7(2), N(13)-Fe(2)-N(22a) 89.9(2), N(13)-Fe(2)-N(25) 176.8(2), N(16)-Fe(2)-N(19) 101.0(2), N(16)-Fe(2)-N(22) 89.8(2), N(16)-Fe(2)-N(22a) 163.8(2), N(16)-Fe(2)-N(25) 91.4(2), N(19)-Fe(2)-N(22), 169.2(2), N(19)-Fe(2)-N(22a) 95.2(2), N(19)-Fe(2)-N(25) 89.4(2), N(22)-Fe(2)-N(22a) 74.0(2), N(22)-Fe(2)-N(25) 90.9(2), N(22a)-Fe(2)-N(25) 89.1(2), Fe(2)-N(22)-Fe(2a),106.0(2); symmetry operation a) $1-x, 1-y, 1-z$. Bottom: Perspective view of the mononuclear cation $[Fe(bpym)]^{2+}$ in **1**. Selected bond lengths [Å] and angles [°] with standard deviations in parentheses: Fe(1)–N(1), 1.971(4), Fe(1)–N(3) 1.971(4), Fe(1)–N(5) 1.976(4), Fe(1)–N(7) 1.971(4), Fe(1)–N(9) 1.965(4), Fe(1)–N(11) 1.977(4); N(1)-Fe(1)-N(3) 81.2(2), N(1)-Fe(1)-N(11) 173.8(2), N(1)-Fe(1)-N(5) 95.8(2), N(1)-Fe(1)-N(7) 91.8(2), N(1)-Fe(1)-N(9) 94.4(2), N(3)-Fe(1)-N(11) 94.1(2), N(3)-Fe(1)-N(5) 174.1(2), N(3)-Fe(1)-N(7) 93.5(2), N(3)-Fe(1)-N(9) 92.1(2), N(5)-Fe(1)-N(11) 89.2(2), N(5)-Fe(1)-N(7) 81.5(2), N(5)-Fe(1)-N(9) 93.2(2), N(7)-Fe(1)-N(9) 172.2(1), N(7)-Fe(1)-N(11) 92.5(2), N(9)-Fe(1)-N(11) 81.7(2).

compound) and low-spin (porphyrinato complex) iron(II) accounts for the shortening of the Fe–N (terminal azide) bond length in the last-mentioned compound of this series of six-coordinate iron(III) complexes. The largest deviation from the best equatorial plane around Fe(2)—defined by N(19), N(16), N(22), and N(22a)—is 0.003 Å for N(16) and only 0.007 Å for the iron center. An inversion center is present, and the Fe(2)-N(22)-Fe(2a)-N(22a) skeleton is planar. The intradimer metal–metal separation is 3.481(1) Å, and the N(22)-Fe(2)-N(22a) and Fe(2)-N(22)-Fe(2a) bond angles are 74.0(2) and 106.0(2)°. These values are very close to those reported for the high-spin dinuclear bis(μ-end-on-azido)manganese(II) complex $[Mn_2(terpy)_2(N_3)_4]\cdot 2H_2O$[7] (terpy = 2,2′:6′,2″-terpyridine). The Fe-N-N angles of the terminally bound azide groups range from 120.0(5) (N(19)) to 145.6(6)° (N(25)). The former value is typical for azido-containing metal complexes, but the latter is not; this is probably related to the short internal N(25)–N(26) and N(26)–N(27) azide bonds (1.069(9) and 1.118(13) Å, respectively). Both the bridging and terminal azido ligands are quasi-linear, and the value of the N-N-N angle varies between 178.1(7) and 175.1(6)°.

The iron atom of the tris(chelated) iron(II) unit $[Fe(bpym)_3]^{2+}$ also exhibits a distorted octahedral FeN_6 surrounding with an average Fe–N bond length of 1.972(4) Å. This value compares well with that reported for **3**[12] (1.970(5) Å) and is in the range

$[Fe(bpym)_3](ClO_4)_2\cdot 0.25H_2O$ **3**

observed for low-spin tris(chelated) iron(II) complexes.[13] The shortest separation between low- and high-spin iron centers is 7.887(2) Å for Fe(1)···Fe(2c) or Fe(2)···Fe(1c) (symmetry operation c): $1-x, -y, 1-z$), whereas that between the low-spin iron atoms is 8.069(2) Å for Fe(1)···Fe(1b) (symmetry operation b): $-x, -y, 1-z$).

The temperature dependence of $\chi_M T$, where χ_M is the magnetic susceptibility per formula unit, in the temperature range 4.2–298 K is shown in Figure 2. χ_M was measured at an applied

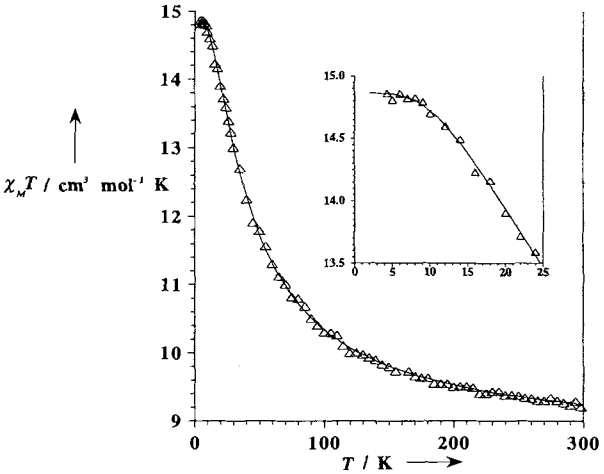

Figure 2. Plot of $\chi_M T$ versus T for complex **1**. Triangles: experimental data; line: best-fit curve (see text). The inset shows the plateau of $\chi_M T$ in the low-temperature region.

magnetic field H of 1.5 T above 50 K and 0.25 T below this temperature to avoid saturation effects. At room temperature $\chi_M T$ is 9.25 $cm^3 mol^{-1} K$, which is somewhat higher than that expected for two magnetically isolated $S = 5/2$ sextuplets. It continuously increases on cooling and reaches a plateau at $T \leq 6$ K with a maximum value of 14.86 $cm^3 mol^{-1} K$. This curve is characteristic of significant ferromagnetic coupling between two sextuplets, whereby the plateau at lower temperature corresponds to the exclusive thermal population of the low-lying $S = 5$ spin state. The fact that no further decrease occurs down to 4.2 K indicates that the zero-field splitting and/or the intermolecular magnetic interactions are very small. Therefore, the magnetic data of **1** were analyzed with the appropriate van Vleck equation for the magnetic susceptibility of a high-spin Fe^{III} dimer with the Hamiltonian operator $\hat{H} = -J\hat{S}_A\cdot\hat{S}_B$, where J is the magnetic coupling parameter and $S_A = S_B = 5/2$ (local spins). Least-squares fitting leads to $J = 4.80\ cm^{-1}$, $g = 1.99$, and $R = 1.1 \times 10^{-4}$ (R = agreement factor = $\sum_i[(\chi_m T)_{obs}(i) - (\chi_m T)_{calcd}(i)]^2/\sum_i[(\chi_M T)_{obs}(i)]^2$). The variation of the magnetization M with the field H at 4.4 K (Figure 3) follows

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1460 $ 17.50+.50/0 Angew. Chem. Int. Ed. Engl. 1997, 36, No. 13/14

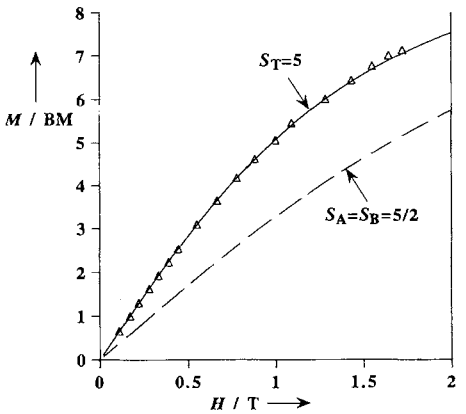

Figure 3. Dependence of the magnetization M of complex **1** on the field strength H at 4.4 K. Triangles: experimental data; solid line: Brillouin function for a spin of $S = 5$ with $g = 1.99$; dotted line: Brillouin function for two noninteracting local spins $S_A = S_B = 5/2$.

the Brillouin function for a spin of $S = 5$ with $g = 1.99$. The curve lies well above that for two independent local spins $S = 5/2$. The value of J is twice that reported for the parent bis(μ-end-on-azido)manganese(II) dimer $[Mn_2(terpy)_2(N_3)_4]\cdot 2H_2O$.[7] Because the angles at the azido bridge are similar (106.0(2)° in **1** and 104.6(1)° in the manganese(II) complex), the fact that the magnetically active 3d orbitals of Fe^{III} are lower in energy than those of Mn^{II}, and thus closer to the symmetry-adapted HOMOs of the bridging azide ligand, accounts for the greater ferromagnetic coupling in **1**. Further examples of iron(III) complexes with this structural type are needed to characterize the influence of the angle at the azido bridge on the nature and magnitude of the magnetic coupling.

Experimental Section

1: On attempting to prepare **2** by the diffusion technique described [9], polyhedral red-brown single crystals of **1** formed by slow oxidation (atmospheric oxygen) of aqueous solutions containing iron(II) chloride, bpym, and sodium azide. In the IR spectrum of **1** the $\nu_{as}(N_3)$ stretching mode appears as a very strong split band at 2040 and 2060 cm^{-1}, which is consistent with the presence of both end-on and terminal azide ligands. The ring-stretching mode of bpym appears as a quasi-symmetric doublet at 1570 and 1545 cm^{-1}, as observed in other complexes containing chelating bpym.

X-ray structure analysis of **1**: Siemens R3mV automatic diffractometer, $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, graphite monochromator, 295 K. Lorentzian, polarization, and ψ-scan absorption corrections [14] were made. Data collection, solution, and refinement: ω-2θ, standard Patterson methods with subsequent Fourier recycling (SHELXTL-PLUS program) [15]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of the water molecules were located on a ΔF map and refined with constraints. The hydrogen atoms of the bpym ligand were set in calculated positions and refined as riding atoms. They were all refined isotropically. Final geometrical calculations and graphical manipulations were performed with the PARST program [16] and the XP utility of the SHELX-PLUS system, respectively. $C_{48}H_{40}Fe_4N_{54}O_2$ ($M_r = 1628.7$), monoclinic, space group $P2_1/c$, $a = 10.644(2)$, $b = 15.026(3)$, $c = 20.549(6)$ Å, $\beta = 99.86°$, $V = 3238.0(13)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.671$ g cm^{-3}, $\mu = 9.67$ cm^{-1}, $F(000) = 1652$, $3 < 2\theta < 54°$, crystal size $0.31 \times 0.27 \times 0.22$ mm. 7126 unique reflections, and 3939 assumed as observed with $I \geq 3\sigma(I)$, 487 parameters, $R = 0.050$, $R_w = 0.053$, and $s = 1.426$ with $w^{-1} = \sigma^2(F_o) + 0.0008(F_o)^2$. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100168. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

Towards Artificial DNA-Repair Enzymes: Incorporation of a Flavin Amino Acid into DNA-Binding Oligopeptides**

Thomas Carell* and Jens Butenandt

UV irradiation of cells causes the formation of cyclobutane pyrimidine dimers by $[2\pi + 2\pi]$ cycloaddition of two pyrimidine bases that are adjacent to one another in the DNA double helix.[1, 2] To counteract the resulting lethal loss of genetic information, all organisms have developed sophisticated DNA-repair mechanisms to remove these DNA lesions and to restore the integrity of the genome.[3] Investigation of the inherited lethal disease *Xeroderma pigmentosum* revealed that insufficient DNA-repair capacities are directly involved in tumor genesis.[4, 5] DNA photolyases are ancient repair enzymes that are capable of specifically recognizing cyclobutane pyrimidine dimers, possibly by flipping the pyrimidine dimers out of the DNA double helix into a cage-like active site.[6] The enzymes

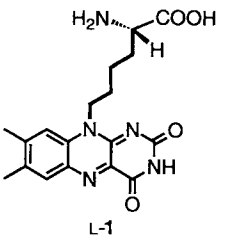
[**] This work was supported by the Swiss National Science Foundation, a Liebig fellowship from the Stiftung Stipendien-Fonds des Verbandes der Chemischen Industrie to T. C., and a doctoral fellowship from the Boehringer Ingelheim Fonds to J. B. We thank ASTA Medica and BASF AG for generous gifts of FMOC-protected amino acids (ASTA) as well as protected nucleotides and solid support for the oligonucleotide synthesis (BASF). We are very grateful to Prof. F. Diederich for generously supporting this research.

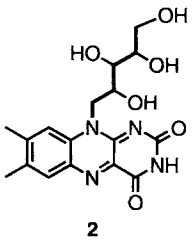
utilize multiple light-driven energy- and electron-transfer steps for repairing the dimer lesion. Initially, excitation of a flavin semiquinone ($FADH^{\bullet}$) yields the reduced flavin cofactor ($FADH^-$) by an electron transfer from Trp^{306}, which is more than 13 Å away from the flavin.[6] A second light-driven electron transfer from the $FADH^-$ to the bound cyclobutane pyrimidine dimer initiates monomerization (repair) of the dimer lesion. In addition to $FADH^-$ all known microbial photolyases contain a second cofactor (either a 8-hydroxy-5-deazaflavin or a methenyltetrahydrofolate), which acts as a photo antenna and transmits the required excitation energy to the flavin moiety.[6, 7]

To learn about these energy- and electron-transfer steps, we started a research program aimed at preparing small cofactor-containing model proteins that form stable and structurally well-defined complexes with DNA. These model proteins should allow rapid synthetic modification, for example incorporation of unnatural amino acids at various sites.

DNA-binding oligopeptides possessing the sequence of the DNA-binding domain of the helix-loop-helix transcription factors MyoD[8, 9] were prepared by solid-phase peptide synthesis. The DNA-repair function was included in these DNA-binding proteins by incorporation of the flavin amino acid L-**1**.[10] These



L-**1**

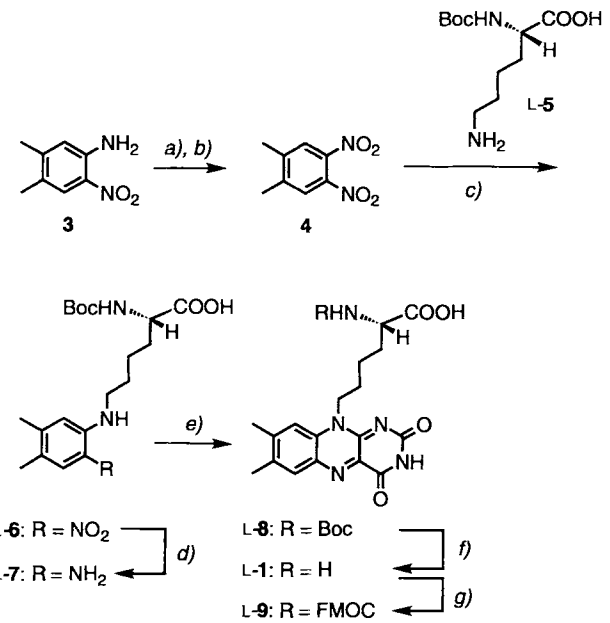


2

cofactor-modified oligopeptides were investigated for their ability to repair cyclobutane pyrimidine dimers in single-stranded DNA. A well-defined oligonucleotide containing a synthetic dimer lesion[11] was synthesized to enable quantification of the repair reaction and allow HPLC monitoring of potential side products that have been observed by irradiation of DNA in the presence of riboflavin **2**.[12]

Synthesis of L-**1** was achieved in gram quantities by the route outlined in Scheme 1. In the first two steps 4,5-dimethyl-2-nitroaniline (**3**) was oxidized with Caro's acid and hydrogen peroxide/nitric acid to yield dinitro dimethyl benzene (**4**).[13] Reaction of **4** with the chiral building block *N*-α-Boc-L-lysin (L-**5**), which was chosen with an unprotected carboxylic acid to minimize base-induced racemization at the chiral α-CH center during the *ipso*-substitution reaction, afforded nitroaniline L-**6**. The reaction conditions were varied to further reduce the risk of racemization; optimal results were finally obtained with potassium acetate as the base in water/ethanol/*n*-butanol (1/1/2). Catalytic hydrogenation of L-**6** afforded the amino acid L-**7**, which was then treated with alloxane monohydrate to yield the Boc-protected flavin amino acid L-**8**.[14] Deprotection of L-**8** and reaction of the resulting unprotected flavin amino acid L-**1** with 9-fluorenylmethoxycarbonyl-*N*-hydroxysuccinimide (FMOC-OSu) and sodium hydrogen carbonate afforded the FMOC-protected L-flavin amino acid L-**9** in an overall yield of 25%.

To determine the enantiomeric purity of L-**1**, the corresponding D-amino acid D-**1** was prepared by the same procedure from the D-lysine building block D-**5**. The racemate was obtained by



Scheme 1. Synthesis of the flavin amino acid L-**1** and the FMOC-protected amino acid L-**9**: a) H_2SO_5, room temperature (RT), 80%; b) H_2O_2, HNO_3, RT, 85%; c) KOAc, H_2O, EtOH, *n*BuOH, 80 °C, 3 d, 60%; d) H_2, Pd/C, quant; e) HOAc, $B(OH)_3$, alloxane, RT, 65%; f) TFA, RT, quant; g) FMOC-OSu, $NaCO_3$, 95%.

mixing both enantiomers. Separation of the enantiomers was accomplished by thin-layer ligand-exchange chromatography on reverse phase CHIRALPLATES.[15] A dilution experiment, in which decreasing amounts of D-**1** were added to the corresponding L-form, and subsequent scanning of the obtained TLCs established that as little as 1% D-amino acid is detectable. Since the synthetic material L-**1** yields only one spot, it was synthesized with greater than 99:1 enantiomeric purity.

A standard manual FMOC solid-phase synthesis protocol with a Rink-Amide MBHA resin as the solid support was modified for the synthesis of the oligopeptides depicted in Figure 1.[16] The X-ray crystal structure of the helix-loop-helix transcription factor MyoD complexed with double-stranded DNA was analyzed for an initial design of the flavin peptides.[17] The side chain of Leu^{121} at the C-terminal end of the basic domain points towards the major groove; Leu^{121} was therefore replaced by L-**1**. The solid-phase synthesis of the flavin oligopeptide **P1** was performed in analogy to **P2**, which does not contain flavin. However, due to the slower coupling rates of L-**9** the coupling time for this amino acid was extended from 25 to 45 min, and the coupling repeated three times with a threefold excess of L-**9**. Capping procedures (for example acetic anhydride/Hünig's base), often performed after an elongation step, were omitted when possible after incorporation of the flavin amino acid. Cleavage of the final peptide from the solid support and removal of the side-chain protection groups required larger quantities of the scavengers triisopropyl silane (2 vol%) and, in the case of the cysteine-containing peptide **P3**, ethanedithiol (2 vol%) to obtain the flavin oligopeptides **P1** and **P3** in yields and with a purity comparable to those of the non-flavin peptide **P2**.

All peptides were purified by preparative reverse-phase HPLC and characterized by analytical HPLC as well as electrospray and laser-ionization mass spectrometry.[18] The UV/Vis spectrum of the flavin peptides feature the typical flavin absorption bands around 450 and 360 nm. The fluorescence spectra show the flavin fluorescence band at 550 nm.

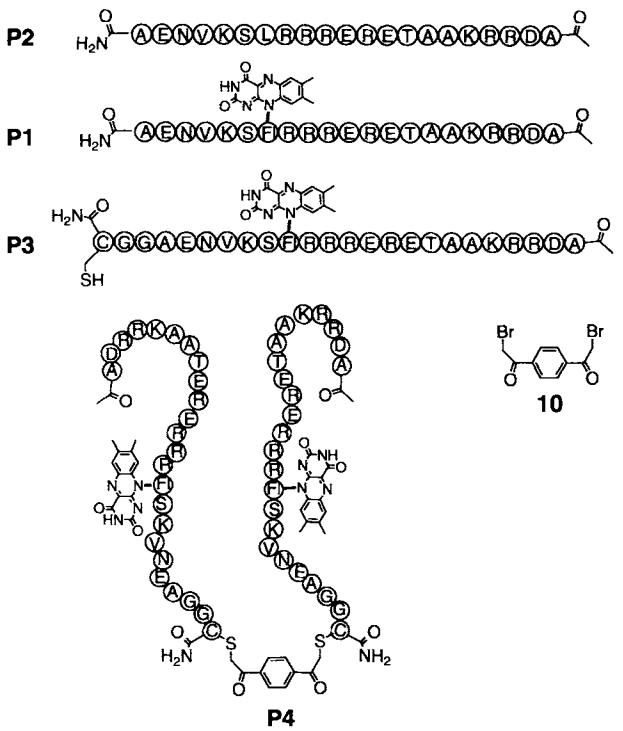

Figure 1. Sequences of the synthesized oligopeptide **P2** and the flavin-containing oligopeptides **P1** and **P3**. Presentation of the template **10** and the linked dimeric oligopeptide **P4**. Peptides were synthesized manually on Rink-Amide MBHA support (FMOC chemistry) with a HOBt/HBTU coupling protocol.

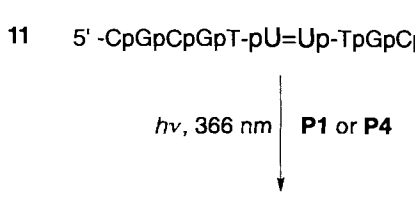
Maximizing the DNA-binding properties requires dimerization of the basic oligopeptides, for example, by linking the two peptides to a given template.[19] Such dimerized oligopeptides mimic the general feature of helix-loop-helix proteins to fold into an α-helical conformation and form stable, structurally well-defined complexes with their DNA targets.[19] To see if the novel flavin peptides are amenable to the required dimerization procedure, peptide **P3**, which possesses a Cys-Gly-Gly handle at the C-terminus, was synthesized.[19] The peptide was treated with the bis(bromo)acetyl benzene template **10**[20] under exclusion of oxygen (Figure 1) to yield a new peptide species, which was isolated by preparative reverse-phase HPLC.[18] The electro-spray mass spectrum confirmed the formation of template-linked **P4**.

To investigate if the flavin moiety within the transcription-factor fragments is a functional unit that can perform clean DNA repair, **P1** and **P4** were added to a solution containing the synthetic oligonucleotide **11**[11] (Scheme 2). The solutions were degassed with nitrogen and irradiated at 4 °C with daylight or with light of 366 nm. Ethylene diamine tetraacetic acid (EDTA)



Scheme 2. Repair of the synthetic oligonucleotide **11**. A lesion model compound (U=U) of the cyclobutane uracil dimer was incorporated into a specific site [11]. *The oligonucleotide product* **12** *of the reaction was independently synthesized and* co-injected to ensure that **12** was cleanly formed.

was added to the reaction buffer to photoreduce the isoalloxazin moiety. This resulted in the in situ conversion of the flavin into the fully reduced species, which is active in photolyases. We found that **P1** is able to *completely* convert the lesion-containing **11** into the repaired oligonucleotide **12**. The irradiation times required for the complete conversion varied from one to several hours, depending on the concentration of both peptides and the oligonucleotide substrate as well as on the ion strength of the reaction buffer. This indicates that a close association between the reaction partners, presumably based on interactions between the phosphodiester and arginine or lysine, is of crucial importance. However, the formed associates are still unstructured, since similar transcription-factor elements require double-stranded DNA for the formation of structurally well-defined complexes.[21]

Nevertheless, the repaired oligonucleotide **12** is cleanly formed upon irradiation without the appearance of cleaved DNA side products, which are generally obtained after irradiation of DNA in the presence of oxidized riboflavin.[12] The results of a long irradiation experiment are depicted in Figure 2 (10 μM **11** and 20 μM **P1**). Approximately 75% conversion of the starting material **11** into **12** was recorded after 6 h of irradiation. Further irradiation resulted in almost complete conversion into **12**. Independent syntheses of **12**[11] and co-injection confirmed that the new HPLC peak belongs to **12**.

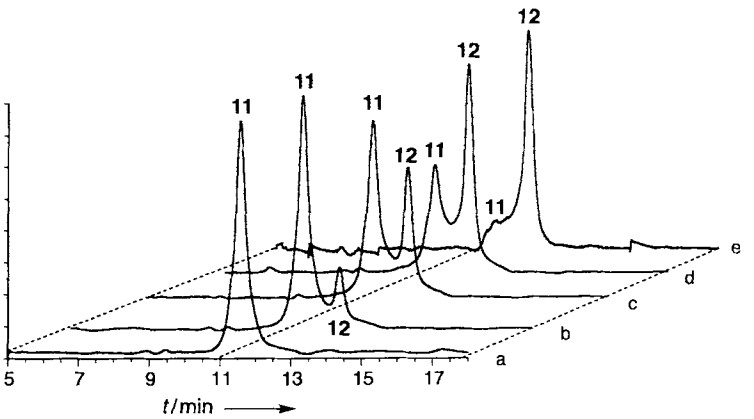


Figure 2. HPL chromatograms (a: 0 h; b: 1 h; c: 3 h, d: 6 h, e: 14 h) measured during the irradiation of a solution of oligonucleotide **11** (10 μM) in reaction buffer (12.5 mM Tris, 5 mM EDTA, 6 mM NaOH, pH 7.8) at 4 °C in the presence of **P1** (20 μM). Column: Lichrosphere C18, 100 Å, 0.4 × 250 mm. Mobile phase A: H_2O, 0.1 M NEt_3·HOAc. Mobile phase B: 80% CH_3CN, 20% H_2O, 0.1 M NEt_3·HOAc. Gradient: 0–30% B in 30 min. Injection volume: 20 μL.

Preliminary irradiation experiments with **P4** indicate that this dimeric oligopeptide performs the DNA-repair reaction faster than **P1**, even at lower substoichiometric concentrations (1–2 μM peptide, 10 μM DNA). Irradiation of DNA solutions containing either riboflavin or **P1** in the absence of EDTA caused decomposition of the oligonucleotide instead of repair. No repair was observed in the absence of the flavin peptide, in the presence of non-flavin-containing **P2**, or in the presence of reduced riboflavin under otherwise identical conditions (EDTA and damaged DNA in buffer solution). These control experiments prove that the prepared flavin-derived transcription-factor fragments **P1** and **P4** can perform primitive DNA repair. So far, reversion of pyrimidine dimers within a DNA strand has been reported with the electron-donating tripeptide Lys-Trp-Lys. Here, a maximum of 60% conversion was obtained, since the photo repair required a harmful wavelength of less than 300 nm.[22] More recently, diimine(9,10-phenanthrenequinone)-

rhodium complexes were reported to catalyze the repair of thymine dimers by electron abstraction from the DNA.[23] Therefore, the flavin oligopeptides represent the first compounds that can completely repair damaged oligonucleotides by simulating the light-driven electron-donating repair process of DNA photolyases.[24]

We have shown that the enantiomerically pure flavin-α-amino acid L-**1** is readily available in large quantities. The building block can be incorporated into oligopeptides by a slightly modified FMOC peptide synthesis protocol, and the peptides obtained are amenable to a dimerization procedure.[25, 26] Most importantly, the flavin peptides are able to cleanly repair a oligonucleotide containing a synthetic pyrimidine-dimer lesion. These results offer the possibility of constructing small, artificial DNA-binding and cofactor-containing proteins, which may help to elucidate the requirements for efficient energy- and electron-transfer reactions at the interface between proteins and DNA.

Solid-Phase Synthesis of the CD52 Glycopeptide Carrying an N-Linked Core Pentasaccharide Structure**

Zhong-Wu Guo, Yuko Nakahara, Yoshiaki Nakahara,* and Tomoya Ogawa*

With the increased understanding of the biological functions of glycoproteins as recognition signals for various phenomena,[1] the synthesis of glycopeptides and glycoproteins has become the focus of numerous research efforts.[2] Among the various methods that have been developed for synthesizing glycopeptides or fragments of glycoproteins, solid-phase synthesis has proven to be most suitable for larger oligomers. Thus, this method has been applied to synthesize *O*-[3] and *N*-glycopeptides,[4] usually by using acetylated oligosaccharides as building blocks. However, all reported syntheses have thus far employed relatively simple oligosaccharide moieties, whereas naturally occurring glycoproteins may contain rather compli-

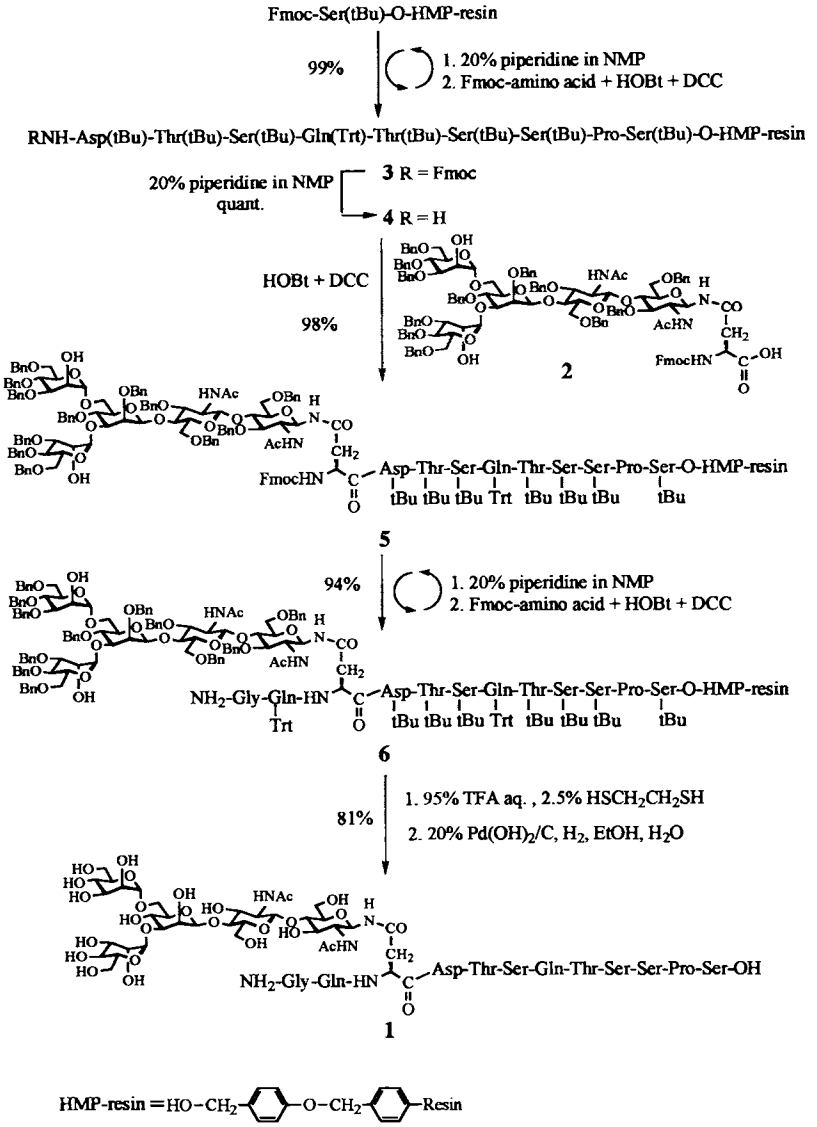
[**] This work was financially supported by the Special Coordination Funds of the Science and Technology Agency of the Japanese Government and partly by the CREST program of the Japan Science and Technology Corporation. Z.-W. Guo is grateful for a RIKEN Fellowship and thanks Dr. Y. Ito for many helpful discussions. We thank Dr. S. Kurono and N. Dohmae for ESI-MS and MALDI-TOF mass spectral measurements, Dr. J. Uzawa and his staff for NMR measurements, and Ms. A. Takahashi for technical assistance.

cated oligosaccharide structures. Recently, we disclosed the synthesis of an *N*-glycopeptide with a core pentasaccharide, in which the glycoasparagine building block was synthesized with the fluorenylmethoxycarbonyl (Fmoc) method and used in solution to construct a tripeptide sequence of human chorionic gonadotropin (hCG).[5] We have now chosen to apply solid-phase synthetic methods to generating the glycopeptide part (**1**) of the CD52 antigen containing an N-linked core pentasaccharide structure.

The CD52 antigen, a GPI-anchored glycoprotein, is expressed on virtually all human lymphocytes. Monoclonal antibodies against this antigen are potent effectors of complement-mediated lysis and have been widely used in vivo and in vitro for the control of graft versus host disease and for the prevention of bone marrow transplant rejection.[6] Structural studies on the CD52 antigen revealed that it is a remarkable glycoprotein; its peptide chain is extremely short and consists of only 12 amino acid residues making it the shortest cell-surface glycoprotein known to date.[6b] The peptide structure contains only one *N*-glycosylation site and no *O*-glycosylation site, which makes it an ideal synthetic target and also a simple model for pursuing strategic studies on glycopeptide synthesis and for studying the influences of N-linked oligosaccharides on both conformation and biological functions of a glycopeptide.

For the synthesis of target compound **1**, we employed a strategy (Scheme 1) that was based on solid-phase synthesis with Fmoc-amino acids and a benzyl-protected oligosaccharide.[3u, 5] The use of the benzyl group as protective group for oligosaccharides has several advantages. First, benzylated sugars are highly reactive in glycosylation reactions, which is clearly significant for the synthesis of complex oligosaccharides. Second, the stability of benzyl groups towards basic conditions eliminates the possible side reactions during the elongation of the peptide chain, such as potential acyl exchange between acylated sugar moieties and N-terminal groups of the peptide. Third, benzyl groups can be removed easily under mild conditions, for example by catalytic hydrogenlysis. In addition, the use of benzyl protective groups can be advantageous when the synthetic target contains sialic acid.[7] Therefore, starting from D-mannose and 2-amino-2-deoxy-D-glucose, we first prepared the Asn-linked core pentasaccharide with benzyl protective groups (**2**) according to a slightly modified version of a reported procedure.[5] The peptide fragment Asp^4–Ser^{12} linked to HMP-resin (**3**) was constructed on a serine-preloaded HMP-resin with an automatic synthesizer using the supplied program and standard Fmoc method on a 0.25-mmol scale with an efficiency of 99% (monitored by ninhydrin reaction). The coupling reactions were performed by using dicyclohexyl carbodiimide/hydroxybenzotriazole (DCC/HOBt) as the activating agent in *N*-methylpyrrolidone (NMP). The amino acid side chain functionalities were protected with *tert*-butyl and trityl (Trt) groups. Deprotection of the N-terminal in **3** with 20% piperidine in NMP gave **4** (quantitative yield), which was then coupled with the Asn-linked pentasaccharide **2** manually: the mixture of **2** (2.4 equiv) activated by DCC/HOBt (2.8 equiv) and **4** (1.0 equiv) suspended in NMP was shaken on a vortex mixer overnight. This gave the glycosylated peptide fragment linked to the resin (**5**) in 98% yield. Compound **5** was applied to the automatic synthesizer again and the peptide chain elongation was carried out on a 0.1-mmol scale by using the supplied program to give **6** (94 wt%). The glycopeptide was released from the resin by treating the loaded resin **6** with a 95% aqueous trifluoroacetic acid (TFA) solution containing 2.5% 1,2-ethanedithiol; under these conditions the protective groups on the amino acid residues were also removed concomitantly. According to HPLC and MS studies, the product mixture contained only a minor quantity (< 2%) of glycopeptide carrying a degraded sugar chain, but a substantial amount of partially debenzylated glycopeptides with complete sugar chain, including mono-, di-, and tridebenzylated derivatives (according to mass spectra). After simple separation of the product mixture by high-performance gel filtration, the fractions containing the fully benzylated glycoprotein as well as its mono-, di-, and tridebenzylated derivatives were completely debenzylated by hydrogenolysis using 20% $Pd(OH)_2$ on charcoal in 50% aqueous ethanol (four days). High-performance gel filtration of the product afforded the expected glycopeptide **1**



Scheme 1. Solid-phase synthesis of the glycopeptide part (**1**) of the CD52 antigen. The copolymer from 4-[4-(hydroxymethyl)phenoxymethyl]styrene and 1% divinylbenzene was used as resin.

(81% based on **6**, ≥95% purity by NMR) as a white solid,[8] which was then purifed further by reversed-phase HPLC (C18 column).

In conclusion, we have described the solid-phase synthesis of the part structure **1** of the CD52 antigen, which represents the first synthesis of an intact natural glycopeptide sequence carrying an N-linked core pentasaccharide. The results revealed that the benzylated pentasaccharide moiety does not influence the efficiencies of peptide coupling reactions in solid-phase synthesis and that the benzylated sugar moiety is sufficiently stable under the acidic conditions used to release the glycopeptide chain from the supporting resin, thus, smoothing the way to the synthesis of more complex glycopeptides containing complicated sugar structures.

Computational Binding Studies of Orthogonal Cyclosporin-Cyclophilin Pairs**

Albert C. Pierce and William L. Jorgensen*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

Gene therapy holds great promise for the treatment of inherited disorders, and much research is being devoted to the development of effective gene delivery systems. Control of the dosage of the gene product is a critical issue that has been addressed recently by Schreiber, Crabtree, and co-workers.[1] Their elegant method for regulation of transgenes features activation of a cellular process by association of two proteins upon the addition of a single drug molecule (Figure 1). In particular, if these proteins are the DNA binding and promoter domains of a transcriptional activator, gene expression can be induced. The receptors are chimeric proteins that include domains to bind nonoverlapping regions of the drug molecule. In the initial work, the drug-binding domains have been immunophilins such as cyclophilin (CyP) or FKBP12, with a synthetic dimer of an associated immunosuppressant drug as the chemical inducer of dimerization (CID).[1] This construct has been used successfully to provide protein synthesis both in vitro[1] and in vivo.[1c, 1d, 2] Gene expression levels may be controlled by varying the timing and quantity of drug administration.

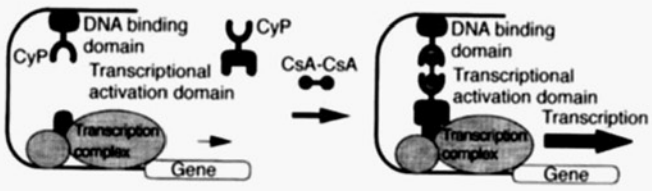

Figure 1. A typical CID scheme for regulation of protein synthesis

However, a potential problem stems from the fact that the immunophilins are expressed at high levels in many cell types.

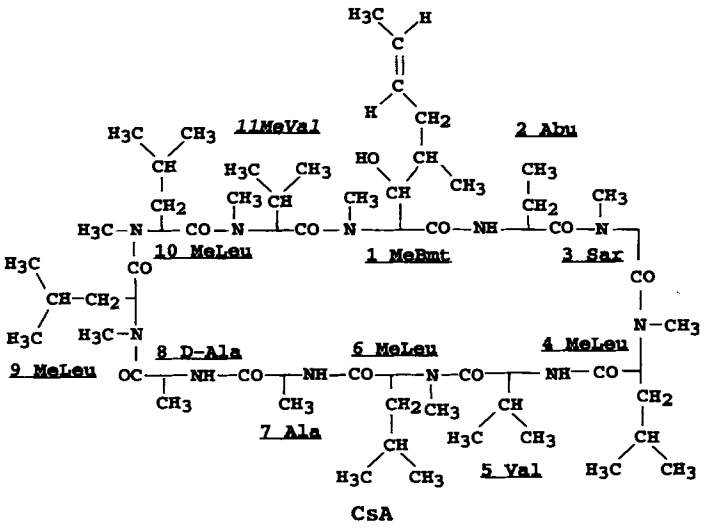
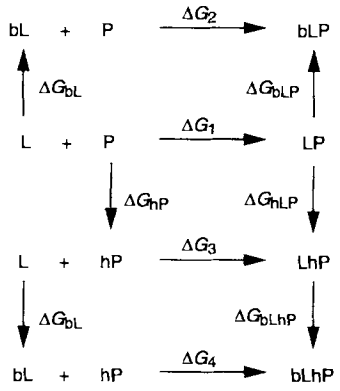
Consequently, the drug may be absorbed by immunophilins throughout the organism with the formation of unproductive protein complexes. A solution has been provided with the idea of orthogonal receptor–ligand pairs.[3] Specifically, Schreiber and co-workers have modified cyclosporin A (CsA) with a steric



CsA

"bump"; the MeVal11 residue of the cyclic undecapeptide was changed to MeIle, which was shown to drastically reduce the binding to wild type CyP. Mutants of CyP were then expressed with accommodating "holes", such as the mutation of Phe113 to Ala (F113A), which largely restored the binding.[3] Thus, problems with drug dilution can be eliminated and, furthermore, the bumped drugs will not have the undesired property of being immunosuppressant like their parents.

Herein we demonstrate how computational methods can participate in the design and structural understanding of orthogonal receptor–ligand pairs. The thermodynamic problem centers on the free energies of binding ΔG_1–ΔG_4 for the four protein–ligand complexes in Scheme 1. These correspond to binding the reference ligand (L) and bumped ligand (bL) to the original protein (P) and holed protein (hP). Experimentally, the free energies of binding are related to the observed association constants by $\Delta G_i = -RT\ln K_i$. Then, important for comparisons are the differences $\Delta G_2 - \Delta G_1$ (the effect of the bump on binding to the original protein), $\Delta G_4 - \Delta G_1$ (the restoration of binding with the bump–hole pair), $\Delta G_3 - \Delta G_1$ (the effect of the hole



Scheme 1. Thermodynamic cycles for the study of orthogonal receptor–ligand pairs. L: reference ligand; P: original protein; bL: bumped ligand; hP: holed protein. The FEP calculations are performed for the processes with vertical arrows.

on binding the reference ligand), and $\Delta G_4 - \Delta G_3$ (the effect of the bump on binding to the holed protein). A viable bump–hole pair requires $\Delta G_2 - \Delta G_1 \gg 0$ and it is also desirable for $\Delta G_4 - \Delta G_1 \leq 0$; that is, the bump destroys the binding and the hole restores it. The latter condition would benefit from $\Delta G_3 - \Delta G_1 < 0$ and $\Delta G_4 - \Delta G_3 < 0$. Computationally, these differences are available from computer simulations using free-energy perturbation (FEP) methods.[4] It is expeditious to perform the vertical perturbations indicated in Scheme 1, where, for example, ΔG_{bL} and ΔG_{bLP} represent the free energy changes for bumping the isolated ligand and the reference protein–ligand complex, and from the thermodynamic cycle $\Delta G_2 - \Delta G_1 = \Delta G_{bLP} - \Delta G_{bL}$.

As an initial application, the aforementioned MeVal11 to MeIle11 bump for cyclosporin A and the Phe113 to Ala113 hole for cyclophilin have been considered. The ensemble configurations were generated with Monte Carlo (MC) sampling in internal coordinates as implemented in the program MCPRO.[5] Along with a study of complexes of trypsin with benzamidines,[6] these are the first reports of MC/FEP calculations for proteins. Molecular dynamics has been the standard sampling procedure for proteins; however, encouragement for trying Monte Carlo simulations has come from recent comparisons of the efficiencies of MD and MC procedures for confomational sampling[7] and from prior successes with MC/FEP calculations for organic host–guest complexes.[4, 8] The AMBER/OPLS force field was used with all atoms except for hydrogen atoms on saturated carbon atoms.[9] The nonstandard amino acids in CsA could all be described with available parameters for amides and hydrocarbons. Initial protein coordinates were based on the crystal structures of free human cyclophilin A[10] and the CsA–CyP complex.[11] For the bumping of unbound CsA, two structures were used in two separate perturbations. One structure was obtained by neutron diffraction from a crystal grown in an ethanol/oil mixture,[12] and the other was extracted from the CsA–CyP structure, which NMR studies have suggested is closer to the conformation in aqueous solution.[13] All initial structures were energy-minimized for 250–1000 steepest descent steps using a distance-dependent dielectric constant with the program AMBER.[14] For efficient treatment of the protein systems, only 107 of 165 residues within about 18 Å of the perturbed MeVal of CsA were included in the MC simulations. For CsA, the bond lengths were held fixed except for one ring-closure bond, while all bond angles and dihedral angles were sampled. For the proteins, all bond lengths were fixed, while side-chain bond angles and torsion angles except those in aryl rings were sampled for residues with any atom less than 9.5 Å from MeVal11 of CsA. The protein backbone was fixed after the energy-minimizations. Though this simplification follows from the limited backbone movement found in MD/FEP calculations of typical durations especially for small perturbations such as Val → Ile, full sampling is desirable for optimal accuracy. Presently, the structures of CsA and the protein side chains are flexible and can adjust to the addition of the bump and the hole.

Each system was solvated with an 18-Å radius sphere of TIP3P water molecules[15] based on the center of the CsA ring unbound or on the α-carbon atom of MeVal11 bound. After deletion of those water molecules with serious steric conflicts, 748 water molecules remained for the unbound system and ≈450 for the proteins and complexes. The perturbations were run at 20 °C with 9-Å radius spherical, residue-based cutoffs for all nonbonded interactions. The first window for each FEP calculation was equilibrated for 5×10^6 configurations and the final structure from each window served as the starting structure for the next window. After 3×10^6 configurations of equilibra-

tion, averaging was performed for at least 3×10^6 configurations until an additional 10^6 configurations changed the ΔG of the window by less than 0.02 kcal mol^{-1}. Most windows required $4 \times 10^6 - 6 \times 10^6$ configurations of averaging, though a few took up to 11×10^6 configurations. In all, 18–26 individual MC simulations (windows) were used for each of the five unique perturbations corresponding to the vertical arrows in Scheme 1. The resultant free energy curves are smooth (see Figures 2 and 3) and

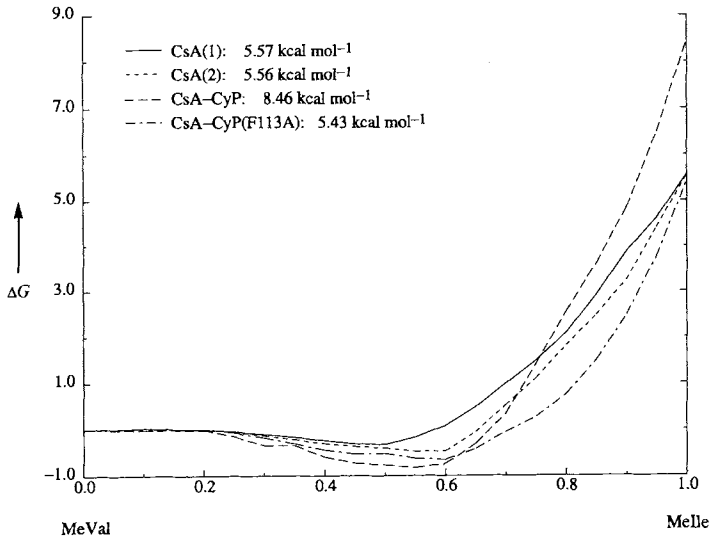


Figure 2. Computed free energy ΔG curves [kcal mol^{-1}] for the mutations of CsA to MeIle11 CsA under different conditions. The two curves for unbound CsA correspond to the two different starting geometries described in the text. The mutation was also performed with CsA bound to the protein CyP and to the mutant protein CyP(F113A). λ is the scaling parameter for the mutations.

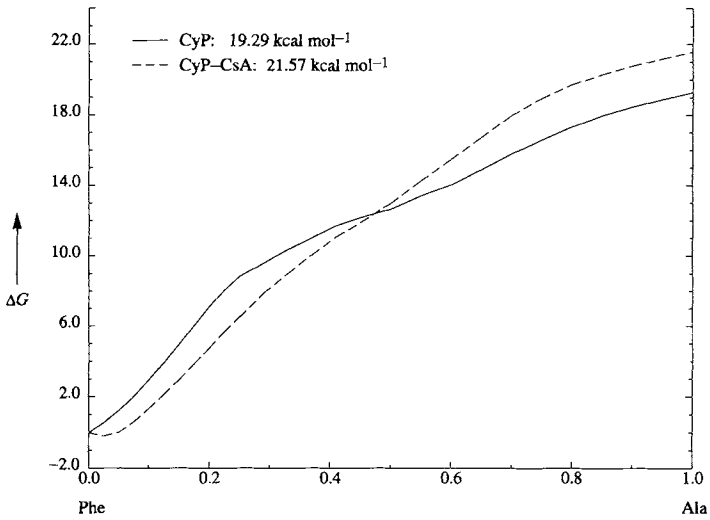

Figure 3. Computed free energy curves ΔG [kcal mol^{-1}] for the mutations of Phe113 to Ala in free cyclophilin (CyP) and in the CyP–CsA complex.

Table 1. Computed and experimental free energy differences ΔG [kcal mol^{-1}] for the processes in Scheme 1, where L = CsA, bL = MeIle11 CsA, P = CyP, and hP = CyP (F113A).

$\Delta\Delta G$	Exp. [a]	Calcd [b]
$\Delta G_2 - \Delta G_1 = \Delta G_{bLP} - \Delta G_{bL}$	>3.7	2.9±0.2
$\Delta G_4 - \Delta G_1 = \Delta G_{hLP} + \Delta G_{bLhP} - \Delta G_{bL} - \Delta G_{hP}$	1.4±0.1	2.1±0.3
$\Delta G_3 - \Delta G_1 = \Delta G_{hLP} - \Delta G_{hP}$	1.4±0.2	2.3±0.3
$\Delta G_4 - \Delta G_3 = \Delta G_{bLhP} - \Delta G_{bL}$	0.0±0.2	−0.1±0.2

[a] Ref. [3]. [b] This work.

the computed free energy differences are compared with the experimental values in Table 1. The statistical uncertainties ($\pm 1\sigma$) for the computed quantities were obtained from the fluctuations in separate averages over batches of 2×10^5 configurations. A similar protocol was applied for complexes of trypsin; high precision was also achieved including hystereses of approximately 0.3 kcal mol^{-1} for perturbations around closed cycles with three inhibitors, that is, A → B → C → A.[6]

In Figure 2, it can be seen that the net ΔG_{bL} value for the bumping of unbound CsA does not depend on which initial CsA structure was used. The Phe to Ala mutations (Figure 3) are quite large for FEP calculations; however, the MC calculations proceeded with good precision. The individual numerical results depend on the way the perturbation is performed and include contributions from, for example, the changes in intramolecular nonbonded interactions as a group is grown. The numbers become meaningful when taken as differences between bound and unbound states (see Scheme 1). It may also be noted that there is no problem at the endpoints of MC/FEP calculations when atoms appear or disappear since the forces, which can become infinite in MD simulations, are not used for MC simulations. The computed free energy differences compare favorably with the experimental results (Table 1). There are no qualitative errors and the average quantitative error is less than 1 kcal mol^{-1}. The bump is computed to substantially destabilize the complex with CyP ($\Delta G_2 - \Delta G_1$), while it has negligible effect on complexation with the holed protein ($\Delta G_4 - \Delta G_3$). The restoration of binding for the bump–hole pair, $\Delta G_4 - \Delta G_1$, is predicted to be 0.7 kcal mol^{-1} less favorable than observed.

Given the reasonable thermodynamic results, the structures from the simulations were analyzed to determine the origin of the difference of about 3 kcal mol^{-1} between the effect of the MeVal11 to MeIle11 bump on complexation for CyP and the F113A mutant. Analysis of dihedral angle distributions did not show any striking differences in conformational sampling for the ligand or protein side chains. Hydrogen-bond analyses also failed to show any salient advantage for one protein over the other. In the crystal structure, there are four hydrogen bonds between CsA and CyP: MeBmt1-O···Gln63 HN$^{\varepsilon}$, Abu2-HN···Asn102-O, MeLeu9-O···Trp121-HN$^{\varepsilon}$, MeLeu10-O···Arg55-HN$^{\eta}$. During the simulations, residues 1–3 of CsA showed considerable structural variations. The first hydrogen bond is lengthened substantially in all complexes, while the second one is also lengthened when the mutations are near the MeIle11 endpoint. However, this occurred for both proteins, so it should not provide preferential binding.

Finally, steric interactions were analyzed by determining the average distances between C$^{\delta}$ of the MeIle11 and all binding-site atoms in both proteins over 10^6 configurations. These distances were then used to calculate the average Lennard-Jones interaction energy for each pair. The most unfavorable interactions in the two binding sites are shown in Figure 4. For the wild-type protein, C$^{\delta}$ of MeIle has unfavorable interactions with C$^{\zeta}$ of Phe60, C$^{\gamma}$ of Met61, and C$^{\varepsilon}$ and C$^{\delta}$ of Phe113 (Figure 4 top); the average Lennard-Jones interactions are repulsive by 0.5–0.8 kcal mol^{-1}, and the average C–C distances are 3.3–3.5 Å. Thus, although in the original[3] and recent[16] studies only F113A and F113G mutants have been considered to provide holes for bumping MeVal11, the present results identify Phe60 and Met61 as additional candidates for size reduction. The

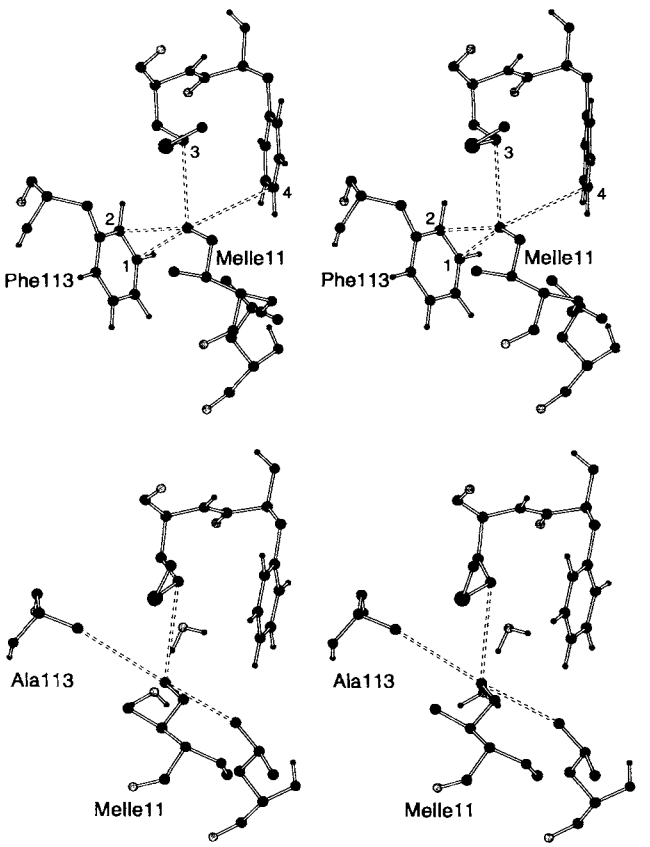

Figure 4. Stereoview of the four (top) and the three most unfavorable contacts (bottom) between the Melle11-C^{δ} atom and the binding site of CyP, and between the Melle11-C^{δ} atom and the binding site of the F113A mutant of CyP, respectively. The average values for the indicated distances and the corresponding Lennard-Jones interaction energies for the C^{δ}–CyP interaction are: to Phe113: 3.42 Å, +0.49 kcal mol^{-1} and 3.39 Å, +0.58 kcal mol^{-1}; to Met61: 3.54 Å, +0.63 kcal mol^{-1}; to Phe60: 3.33 Å, +0.84 kcal mol^{-1}; and for the C^{δ}–CyP(F113A) interaction are: to Ala113: 3.91 Å, 0.00 kcal mol^{-1}; to Met61: 3.92 Å, −0.05 kcal mol^{-1}; to Leu122: 3.80 Å, 0.14 kcal mol^{-1}.

F113A hole is larger than optimal,[3, 16] so less severe mutations are worth exploring. Turning to the F113A mutant, C^{δ} of Melle11 is now accommodated with no detrimental interactions (Figure 4 bottom). The shortest C–C contacts are 3.8–3.9 Å, and the average interaction energies are near zero. It is notable that two water molecules help fill the vacated space in the binding site of the F113A mutant. This makes the complex tolerant of the overly large hole, even in a hydrophobic pocket such as that of CyP.

The five mutations performed here provided a detailed thermodynamic and structural description of a bump–hole pair. The calculations reproduced well the observed relative binding energies, and analysis of the generated structures confirmed the steric origin of the binding differences and suggested alternative protein mutations. Though even closer quantitative accord may be expected with further enhanced sampling and use of the OPLS-AA force field,[17] these initial MC/FEP results establish the methodology as a promising tool for studying protein–ligand binding including the design and understanding of orthogonal receptor–ligand pairs.

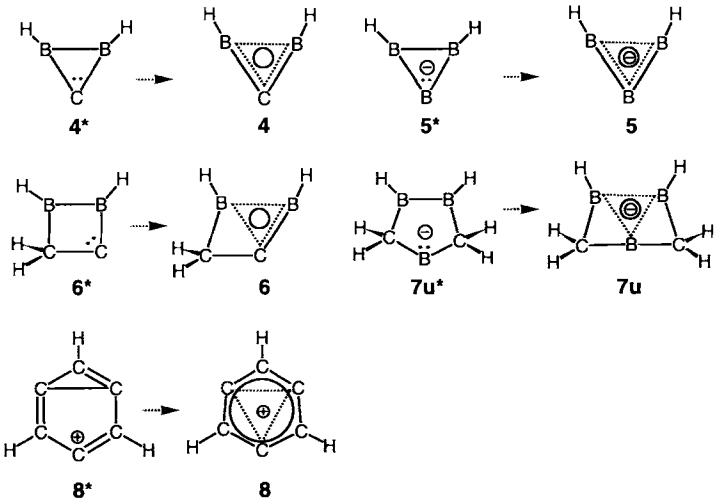
tions for the parent compound **7u**, is the key to understanding the electronic structure of **7a,u** and related compounds.

Based on ab initio calculations and NBO analyses[7] we explained the electronic structures of carbene **4**[8] and borenate ion **5**[9] as follows.[10] In the classical representations **4*** and **5***, the electron pairs prefer the p orbitals of the carbene and borenate centers, respectively, over the hybrid orbital in the molecular plane. This "inverse" occupation allows the formation of a three-center two-electron (3c–2e) π bond involving the empty p orbitals of the neighboring B–B moiety. In addition, the formally empty hybrid orbital in **4*** and **5*** participates in a 3c–2e σ bond with the B–B σ electrons (Scheme 2).[11]



4* **4** **5*** **5**

6* **6** **7u*** **7u**

8* **8**

Scheme 2. Electronic structure of double-aromatic compounds according to theoretical investigations. An asterisk designates formal Lewis representations without π and σ delocalization, a dashed triangle a 3c–2e σ bond, and a solid circle a 3c–2e π bond (for **4**–**7**) or a 6c–6e π bond (for **8**).

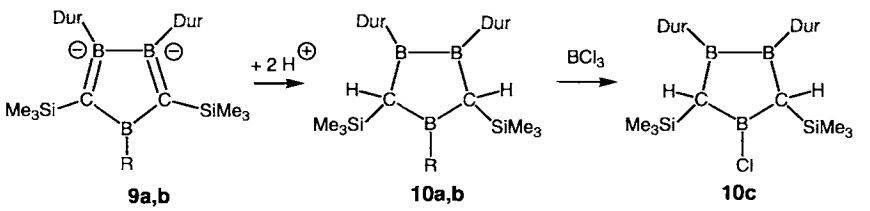
Molecules with two orthogonal systems of $(4n+2)$ electrons, first described for the 3,5-dehydrophenyl cation **8**, are called doubly aromatic.[6] Derivatives of **6**, the monohomo form of **4**, are known.[8, 10] The substituted **7a** reported here is based on **7u**, the bishomo form of **5**.

An NBO analysis[7] justifies the description of **7u** with both BBB 3c–2e σ and π bonds. Along with **4**–**6** and **8**,[6] **7u** belongs to the class of doubly aromatic. The aromaticity of **7u** is demonstrated by the large magnetic-susceptibility anisotropy (> 30.3 ppm cgs) and the substantial diamagnetic-susceptibility exaltation (−18.7 ppm cgs according to Equation (1), CSGT-SCF/6-31+G*//MP2(FU)/6-31G*). The stabilization (MP2(FU)/6-31G*+0.94 ZPE) of **7u** due to the 3c–2e bonding is estimated from Equation (1) to be 92 kcal mol^{-1}.[12] The computed energy of a classical borenate geometry, arbitrarily fixed to that of **10u**, is 90 kcal mol^{-1} higher than that of **7u**. The stabilization energy for **6** computed from Equation (2) is 93.7 kcal mol^{-1}. Borenate **7u** and the nonclassical carbene **6** are stabilized just as strongly as the Arduengo-carbene prototype **1a** [Equation (3)].[13]

The classical representation **7u*** suggests that 1,2,4-triboracyclopentanes should be suitable starting materials for synthesizing derivatives of **7u**. We recently reported doubly deprotonated 1,2,4-triboracyclopentanes, the 1,2-diborata-4-boracyclopentadienes **9a,b**.[14] These dianions can be protonated by HCl in ether to give **10a,b**; surprisingly, **9a** gives only one stereoisomer **10a** with *cis* trimethylsilyl groups.[15] Compound **10a** can be converted into **10c** by reaction with BCl_3 at 0 °C (Scheme 3).

The constitution of **10a–c** is confirmed by their NMR data (Table 1) and by crystal structures for **10b,c**.[16] Attempts to optimize the geometry of the dianion of **10d**[12] converged to **7u**; the chloride ion dissociated spontaneously (Scheme 4).

Therefore, we synthesized a derivative of **7u** by reducing **10c** in THF or diethyl ether at 0 °C with lithium. This gave a rather uniform reaction product that crystallized from diethyl ether. The chemical shifts of the framework atoms ($\delta^{11}B = 24$ (2B) and 21 (1B), $\delta^{13}C = 2.1$) agree satisfactorily with the values computed for **7u** at the GIAO-MP2/tzp level[17] (25.2 (2B) and 31.4 (1B), −19.2 (C)) when substituent effects are considered. The framework carbon atoms of the new product are shielded relative to those of **10c** by at least $\Delta\delta = 58$, a remarkable effect for tetracoordinate C atoms. We calculated $\Delta\delta = 54.1$ for the corresponding difference between **10d** and **7u**.[18] Based on these results, the reduction product of **10c** is a lithium salt of anion **7a**.



9a,b **10a,b** **10c**

Scheme 3. Protonation of **9a,b** to **10a,b**; **10a** can react further to **10c**. Dur = 2,3,5,6-tetramethylphenyl, **a**: R = OMe, **b**: R = $N(SiMe_3)_2$.

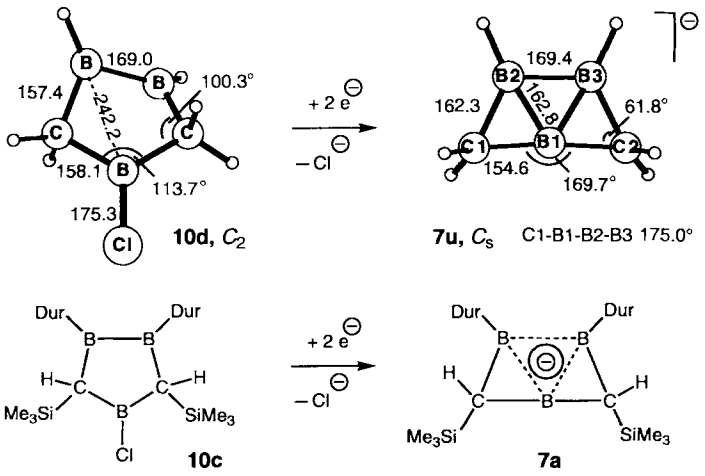
Table 1. Selected physical and spectropscopic properties of **7a**·Li(THF)$_3$·Et$_2$O and **10a–c**.

7a·Li(THF)$_3$·Et$_2$O: yellow solid, m.p. 164 °C, yield 50%. ^{1}H NMR (500 MHz, [D$_8$]THF, −80 °C): δ = −0.14 (s, 18H, SiMe$_3$), 0.14 (s, 2H, H–CB$_2$), 1.13 (t, 6H, Et$_2$O), 1.79 (t, br, 12H, THF), 1.93, 1.97, 1.99, 2.14 (each s, each 6H, *o*- and *m*-CH$_3$), 3.36 (q, 4H, Et$_2$O), 3.64 (t, br, 12H, THF), 6.37 (s, 2H, *p*-H); ^{13}C NMR (125 MHz, ^{11}B-decoupled, [D$_8$]THF, −80 °C): δ = 2.0 (q, 6C, SiMe$_3$), 2.1 (d, br, 2C, ^1J(C,H) = 125.1 Hz, HCB$_2$), 15.6 (t, 2C, Et$_2$O), 19.5, 20.8, 20.9, 22.7 (each q, each 2C, *o*- and *m*-CH$_3$), 26.0 (t, 2C, THF), 66.2 (t, 2C, Et$_2$O), 67.9 (t, 2C, THF), 126.2 (d, 2C, *p*-C), 129.9, 130.0, 133.5, 133.8 (each s, each 2C, *o*- and *m*-C), 153.5 (s, 2C, *i*-C); ^{11}B NMR (96 MHz, [D$_8$]THF, 25 °C): δ = 24; ^{11}B NMR (96 MHz, Et$_2$O, 25 °C): δ = 22, 24 (ratio 1:2).

10a: yellow solid, m.p. 138 °C, yield 92%. ^{1}H NMR (300 MHz, CDCl$_3$, 25 °C): δ = 0.28 (s, 18H, SiMe$_3$), 1.88, 2.19, 2.23 (each s, total 24H, *o*- and *m*-CH$_3$), 2.33 (s, 2H, HCB$_2$), 3.98 (s, 3H, OCH$_3$), 6.87 (s, 2H, *p*-H); ^{13}C NMR (75 MHz, CDCl$_3$, 25 °C): δ = 3.22 (6C, SiMe$_3$), 19.0, 19.5, 21.3 (total 8C, *o*- and *m*- CH$_3$), 49.8 (2C, br., HCB$_2$), 55.0 (1C, OCH$_3$), 129.5, 129.8, 132.6, 132.9 (total 10C, *o*-, *m*- and *p*-C), 149.6 (br, 2C, *i*-C); ^{11}B NMR (96 MHz, CDCl$_3$ 25 °C): δ = 53, 94 (ratio 1:2).

10b: yellow-fluorescing solid, m.p. 156 °C, yield 38%. ^{1}H NMR (300 MHz, CDCl$_3$, 25 °C): δ = 0.30, 0.50 (each s, each 18 H, SiMe$_3$), 2.05, 2.21 (each s, each 12H, *o*- and *m*-CH$_3$), 3.13 (s, 2H, HCB$_2$), 6.89 (s, 2H, *p*-H); ^{13}C NMR (75 MHz, CDCl$_3$, 25 °C): δ = 4.5, 6.7 (each q, each 6C, SiMe$_3$), 19.4, 20.0, 20.3, 21.7 (each q, total 8C, *o*- and *m*- CH$_3$), 60.1 (d, 2C, ^1J(C,H) = 99.7 Hz, CB$_2$), 130.4, 131.8, 132.8 (total 10C, *o*-, *m*- and *p*-C), 149.0 (s, br, 2C, *i*-C); ^{11}B NMR (96 MHz, CDCl$_3$ 25 °C): δ = 59, 91 (ratio 1:2).

10c: yellow-fluorescing solid, m.p. 130–134 °C, yield 72%. ^{1}H NMR (500 MHz, CDCl$_3$, −30 C): δ = 0.22 (each s, each 18H, SiMe$_3$), 1.78, 2.10, 2.15, 2.16 (each s, each 6H, *o*- and *m*-CH$_3$), 2.73 (s, 2H, HCB$_2$), 6.83 (s, 2H, *p*-H); ^{13}C NMR (125 MHz, CDCl$_3$, −30 °C): δ = 2.8 (q, 6C, SiMe$_3$), 19.0, 19.5, 20.0, 21.4 (each q, each 2C, *o*- and *m*-CH$_3$), 60.5 (d, 2C, ^1J(C,H) = 102.2 Hz), 129.7 (d, 2C, *p*-C, ^1J(C,H) = 148.3 Hz), 129.4, 129.5, 132.6, 133.0 (each s, each 2C, *o*- and *m*-C), 148.0 (s, 2C, *i*-C); ^{11}B NMR (96 MHz, CDCl$_3$, 25 °C): δ = 74, 94 (ratio 1:2).



Scheme 4. Calculated formation and synthesis of bishomotriboriranides.

The definitive proof came from an X-ray structure analysis: Figure 1 shows the structure of an ion pair of this salt in the crystal.[19] The Li^+ counterion in **7a** is coordinated to one diethyl ether molecule and three THF molecules. Anion **7a** has a distorted, trapezoidal geometry with very short transannular B–B distances of 165(1) pm (predicted computationally to be 162.8 pm for **7u**).[20] The boron atoms in **7a** are nearly planar tetracoordinate: B2 and B3 deviate from the best plane of their neighbors by 4.1 and 5.9 pm, respectively, and B1 by 12.5 pm. Cation **8**[6] has three planar-tetracoordinate carbon atoms.

The borenate ion **7a**, the first carbene analogue of boron characterized in solution and in the solid state, gains its stability from 3c–2e π and σ bonding involving the borenate center and the neighboring B–B unit. Bishomotriboriranides **7** are double-aromatic compounds like the homodiboriranylidenes **6**, which

[3] We suggest the name "borenate ion" for carbene analogues of boron in analogy to "nitrenium ion" for carbene analogues of nitrogen. Upon addition of a cation R^+, a nitrene N–R forms a nitrenium ion R_2N^+, and a borene B–R becomes a borenate ion BR_2^- by adding an anion R^-.

[18] GIAO-SCF/6-31G* gives 20.8 (2B), 22.2 (1B), and −19.6 (C) for **7u** and 94.1 (2B), 73.0 (1B), and 34.5 (C) for **10d**.
[19] X-ray structure analysis for **7a**·Li(THF)$_3$·Et$_2$O ($C_{44}H_{80}B_3LiO_4Si_2$): A yellow crystal (ca. 0.4 × 0.2 × 0.2 mm^3) was investigated on a four-circle diffractometer (CAD4, Enraf–Nonius) with $Cu_{K\alpha}$ radiation (λ = 154.178 pm) at −60 °C. Orthorhombic, space group $P2_12_12_1$, $Z = 4$, a = 1179.6(1), b = 1931.3(1), c = 2193.7(5) pm, $V = 4997.4(12) \times 10^{-30}$ m^3, ρ_{calcd} = 1.022 g cm^{-3}. A total of 4148 independent reflections were collected with $\omega/2\theta$ scans for $2\theta = 120°$ and subjected to LP and semi-empirical absorption corrections (Ψ scans, μ = 9.04 cm^{-1}, min./max. transmission = 0.83/0.87). The structure was solved by direct methods and refined with full matrix against the F^2 data. All heavy atoms were refined with anisotropic temperature factors. All hydrogen atoms were considered riding at idealized positions in groups with common isotropic temperature factors set to 1.2 and 1.5 times (methyl groups) the U_{eq} of the corresponding carbon atom. One THF molecule showed 1:1 disorder over two alternative orientations; high anisotropic distortion parameters indicate high flexibility or disorder in the cation and for several other groups, and reduce the accuracy of the structure determination: wR_2 = 0.2298 and R = 0.073 for 2331 observed reflections ($F_o > 4\sigma(F)$), max. residual electron density 0.28 e Å^{-3}. A Flack Parameter x = −0.07(8) proves that the correct enantiomer has been refined. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100161. Rapid Synthesis of the Enantiomers of *myo*-Inositol-1,3,4,5-tetrakisphosphate by Direct Chiral Desymmetrization of *myo*-Inositol Orthoformate**

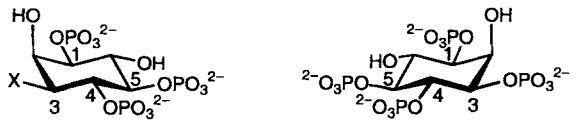
Andrew M. Riley, Mary F. Mahon, and Barry V. L. Potter*

D-*myo*-Inositol-1,4,5-trisphosphate (Ins(1,4,5)P_3, **1**) functions as an intracellular second messenger by eliciting the release of Ca^{2+} from non-mitochondrial stores in stimulated cells.[1] In mammalian tissues phosphorylation of Ins(1,4,5)P_3 at position 3 of the inositol ring by a highly specific cytosolic 3-kinase generates D-*myo*-inositol-1,3,4,5-tetrakisphosphate (D-Ins(1,3,4,5)P_4, **2a**), a molecule whose significance is much less



1 X = OH
2a X = OPO_3^{2-}
2b

well understood. Although binding sites for Ins(1,3,4,5)P_4 have been identified in a wide range of tissues,[2] the cellular function of Ins(1,3,4,5)P_4 remains unknown. Considerable interest has therefore followed the recent identification of an Ins(1,3,4,5)P_4-binding protein, which was purified from platelets, as a member of a family of GTPase activating proteins (GAP).[3] The high affinity of this protein (now designated GAP1^{IP4BP}) for Ins(1,3,4,5)P_4, and its extreme specificity for the 1,3,4,5 configuration of phosphate groups[4] suggest that it may be an Ins(1,3,4,5)P_4 receptor. Very recently it was reported that the interaction of Ins(1,3,4,5)P_4 with the pleckstrin homology (PH) domain of Bruton's tyrosine kinase (Btk) may be involved in B-cell activation and development.[5] Mutations in the Btk PH domain causing human X-linked agammaglobulinaemia (XLA) are associated with dramatically reduced Ins(1,3,4,5)P_4-binding activity.

The spreading interest in Ins(1,3,4,5)P_4 has created a need for an economical and rapid route to pure synthetic material.[6] Although several syntheses of D-Ins(1,3,4,5)P_4 have been published,[7] many are long or require the use of enzymes. Furthermore, the unnatural enantiomer L-Ins(1,3,4,5)P_4 (**2b**; alternative name D-Ins(1,3,5,6)P_4), for which there is only one reported synthesis,[7a] is increasingly being used as a biological tool in studies of D-Ins(1,3,4,5)P_4.[4a, 8] Here we describe a rapid and potentially useful large-scale route to both enantiomers of Ins(1,3,4,5)P_4 by desymmetrization of the well-known *myo*-inositol orthoformate **3**[9] (Scheme 1).

Table 1. Selected physical and spectroscopic data for **4a,b** and **2a,b**.

4a: $R_f = 0.32$ (CH_2Cl_2/ethyl acetate 3/1); $[\alpha]_D^{20} = -15.5$ ($c = 1$ in $CHCl_3$), $[\alpha]_D^{20} = -20.5$ ($c = 1$ in DMF). Crystallization from ethyl acetate/hexane, m.p. > 235 °C; elemental analysis calcd for $C_{27}H_{34}O_{12}$ (550.56): C 58.90, H 6.22; found: C 58.7, H 6.23; ^{1}H NMR (400 MHz, $CDCl_3$, TMS): $\delta = 1.00$, 1.03, 1.09, 1.10, 1.12, 1.14 (6s, 18H, camph-CH_3), 1.65–1.75 (m, 2H, camph-CH_2), 1.92–2.03 (m, 2H, camph-CH_2), 2.06–2.18 (m, 2H, camph-CH_2), 2.41–2.56 (m, 2H, camph-CH_2), 3.29 (d, $J = 6.8$ Hz, 1H, D_2O exchange, 4-OH), 4.36 (dddd, appears as dq, J = ca. 4, 2, 2, 2 Hz, 1H, C-3-H), 4.43 (dddd, appears as dq, J = ca. 4, 2, 2, 2 Hz, 1H, C-1-H), 4.55 (dddd, appears as tt, J = ca. 4, 4, 2, 2 Hz, 1H, C-5-H), 4.65–4.70 (br m, 1H, C-4-H), 5.30 (ddd, appears as partially resolved dt, J = ca. 2, 2, 1 Hz, 1H, C-2-H), 5.54 (d, $J = 0.98$ Hz, 1H, O_3CH), 5.63 (ddd, appears as dt, J = ca. 4, 4, 1.5 Hz, 1H, C-6-H); positive-ion FAB-MS: *m/z* (%) = 1101 (100) $[2M+H]^+$, 551 (80) $[M+H]^+$.

4b: $R_f = 0.23$ (CH_2Cl_2/ethyl acetate 3/1); $[\alpha]_D^{25} = +7.5$ ($c = 1$ in DMF). Crystallization from DMF/H_2O or 2-propanol, m.p. > 270 °C (decomp); elemental analysis calcd for $C_{27}H_{34}O_{12}$ (550.56): C 58.90, H 6.22; found: C 58.6, H 6.31; ^{1}H NMR (400 MHz, [D$_7$]DMF, TMS): $\delta = 0.95$, 0.96, 1.06, 1.08, 1.16, 1.17 (6s, 18H, camph-CH_3), 1.57–1.67 (m, 2H, camph-CH_2), 1.91–1.98 (m, 1H, camph-CH_2), 2.01–2.15 (m, 3H, camph-CH_2), 2.52–2.60 (m, 2H, camph-CH_2), 4.32–4.37 (m, 1H, C-1-H), 4.51–4.55 (m, 1H, C-5-H), 4.56–4.61 (m, 2H, C-3-H and C-6-H), 5.47–5.51 (m, 1H, C-2-H), 5.55–5.60 (m, 1H, C-4-H), 5.74 (d, $J = 0.91$ Hz, 1H, O_3CH), 6.21 (d, 1H, $J = 3.36$ Hz, D_2O exchange, C-6-OH); positive-ion FAB-MS: *m/z* (%) = 1101 (55) $[2M+H]^+$, 551 (100) $[M+H]^+$.

Optical rotations (cyclohexylammonium salts): **2a**: $[\alpha]_D^{22} = -2.5$ ($c = 2$ in H_2O), ref. [7a]; $[\alpha]_D^{25} = -2.5$ ($c = 1$ in H_2O); **2b**: $[\alpha]_D^{22} = 2.5$ ($c = 2$ in H_2O), ref. [7a]; $[\alpha]_D^{25} = 2.6$ ($c = 1$ in H_2O). All NMR data agree with the published values [7a, d].

Reaction of symmetrical **3** with 2.0 equivalents of (1*S*)-(−)-camphanic acid chloride gave two diastereoisomeric bis(camphanate) esters **4a** and **4b**, which were separated by flash chromatography and isolated as crystalline solids (Scheme 1, Table 1). A single-crystal X-ray crystallographic study of the less polar diastereoisomer[10] showed this compound to be 1D-2,6-di-*O*-[(−)-ω-camphanoyl]-*myo*-inositol orthoformate (**4a**, Figure 1). Diastereoisomer **4a** is therefore a synthetic precursor to D-Ins(1,3,4,5)P_4, whereas **4b** leads to L-Ins(1,3,4,5)P_4. It was possible to establish reaction conditions (see *Experimental Section*) that minimized production of the unwanted 2-monocamphanate and 2,4,6-tris(camphanate)s. Interestingly, under these conditions the reaction showed considerable diastereoselectivity in favor of **4a**, which allowed it to be isolated in up to 60% yield by careful chromatography. The more polar product **4b** was isolated in about 20% yield, and none of the possible side product 4,6-bis(camphanate) was detected.

Acid hydrolysis of the orthoformate protecting group from **4a** and **4b** gave tetraols **5a** and **5b**. Since these crystallized as hydrates, it was important that they were dried in vacuo at 60 °C before the next step. Phosphitylation with bis (benzyloxy) - *N,N* - diisopropylaminophosphine/1*H*-tetrazole followed by oxidation of the phosphites with *m*-CPBA gave the fully protected tetrakisphosphates **6a** and **6b**. As at the preced-

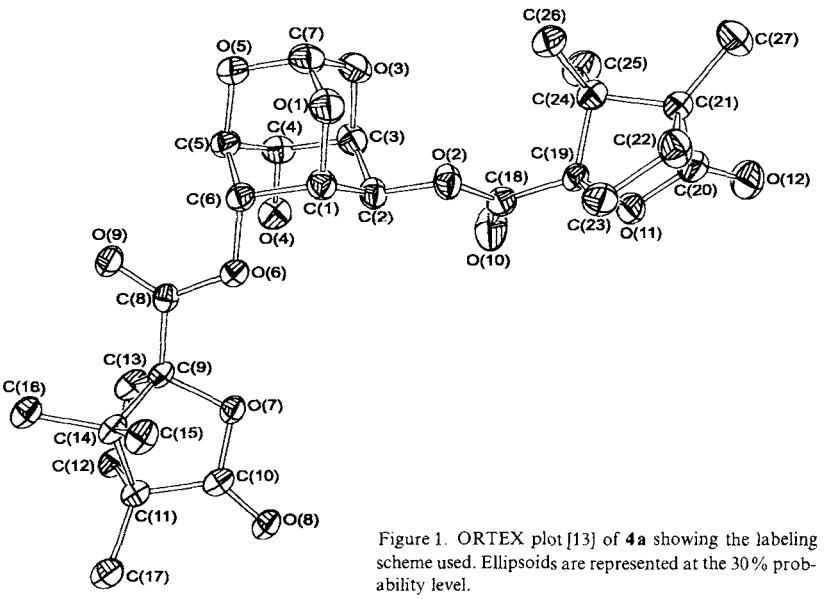

Figure 1. ORTEX plot [13] of **4a** showing the labeling scheme used. Ellipsoids are represented at the 30% probability level.

ing stages, any diastereoisomer contamination of **6a** or **6b** would be apparent from an examination of the camphanate methyl resonances in the ^{1}H NMR spectra. At no stage was any such contamination seen. A two-step deprotection strategy involving removal of the benzyl protecting groups on phosphates by hydrogenolysis and then cleavage of camphanate esters in a concentrated solution of ammonia at 60 °C was effective with no migration of phosphate groups.[11] Tetrakis(phosphate)s **2a** and **2b** could then be isolated on a gram scale as the cyclohexylammonium[7a] or potassium[7d] salts in overall yields of 60–70% from **4a** and **4b**. The structures of **2a** and **2b** were confirmed by ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy as well as high-resolution FAB-MS. We recently used bulk material prepared in this fashion to investigate the submolecular acid–base properties of Ins(1,3,4,5)P_4 by ^{31}P NMR titration experiments.[12] Alternatively, ion-exchange chromatography on Q-Sepharose Fast-Flow gave the pure tetrakisphosphates as their triethylammonium salts. A sample of **2a** was identical to biologically-derived D-Ins(1,3,4,5)P_4 with respect to its interaction with GAP1^{IP4BP}.

In conclusion, we describe rapid access to pure synthetic D- and L-Ins(1,3,4,5)P_4 from readily available starting materials by simultaneously using camphanate esters as desymmetrizing auxiliaries and protecting groups. This strategy should have wider applicability in the inositol phosphate field. Furthermore, the technique is capable of providing D-Ins(1,3,4,5)P_4 in quantities that will now be required for crystallographic and NMR studies of its interaction with the rapidly expanding range of Ins(1,3,4,5)P_4-binding proteins.

Experimental Section

4a, b: To a stirred suspension of **3** (2.00 g, 10.5 mmol) in dry CH_2Cl_2 (40 mL) at 0 °C were added Et_3N (3.3 mL, 23.7 mmol) and a catalytic amount of 4-dimethylaminopyridine (80 mg). A solution of (1*S*)-(−)-camphanic acid chloride (4.55 g, 21.0 mmol) in dry CH_2Cl_2 (10 mL) was added dropwise under an N_2 atmosphere at 0 °C. The cooling bath was removed after 30 min, and stirring continued for a further 30 min. After this time almost no solid remained, and TLC (CH_2Cl_2/ethyl acetate 3/1) showed two major products at $R_f = 0.32$ and 0.23. The solvents were removed in vacuo, and the residue was purified by flash chromatography (CH_2Cl_2/ethyl acetate 4/1) to give first **4a** (3.46 g, 6.28 mmol, 60% yield) and then **4b** (1.35 g, 2.45 mmol, 23% yield).

2a, b: A solution of **6a** or **6b** in MeOH/H_2O (19/1) was stirred vigorously with 10% Pd/C under an atmosphere of H_2 at room temperature overnight. The catalyst was removed by filtration, and the solvents in vacuo. The residue was dissolved in a concentrated solution of aq ammonia, and the solution stirred at 60 °C in a sealed Pyrex autoclavable bottle for 6 h. The solution was allowed to cool and then concentrated under reduced pressure. The residue was dissolved in deionized water, and the camphanamide removed by washing with CH_2Cl_2 (3 ×) followed by Et_2O. Purification by ion-exchange chromatography on Q-Sepharose Fast-Flow eluting with a gradient of triethylammonium bicarbonate buffer (pH 8, 0–1 M) gave the pure triethylammonium salts of **2a** or **2b**, which eluted at 730–850 mM buffer. For larger-scale production treatment with Dowex 50 H^+ resin gave solutions of the free acids of **2a** or **2b**, which were washed again with CH_2Cl_2 and Et_2O, and then converted into either the cyclohexylammonium [7a] or potassium [7d] salts in quantitative yield from **6a** or **6b**.

[10] Crystal structure analysis of **4a**: Suitable crystals were grown by slow crystallization from 2-propanol (approximate crystal dimensions 0.3 × 0.3 × 0.3 mm): $C_{27}H_{34}O_{12}$, $M_r = 550.54$, monoclinic, $a = 6.755(1)$, $b = 31.139(2)$, $c = 7.035(1)$ Å, $\beta = 117.80(1)^\circ$, $V = 1309.0(3)$ Å^3, space group $P2_1$, $Z = 2$, $\rho_{calcd} = 1.397$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.110$ mm^{-1}, $F(000) = 584$. Measurements were made at 293(2) K on a CAD4 automatic four-circle diffractometer in the range $2.61 < \theta < 21.93^\circ$. Data (1795 reflections) were corrected for Lorentzian and polarization but not for absorption effects. In the final least-squares cycles all atoms were allowed to vibrate anisotropically. Except for H1A, which was located in the penultimate difference Fourier and refined at a distance of 0.96 Å from O4, hydrogen atoms were included at calculated positions where relevant. The supramolecular structure contains a hydrogen-bonding feature. The structure was solved with SHELX86 and refined with SHELX93: based on 1326 with $F_o > 4\sigma(F_o)$ $R1 = 0.0318$ and $wR2 = 0.0755$; GOF = 1.029; max./min. residual densities 0.185/ − 0.175 e Å^{-3}. The asymmetric unit (Figure 1) and the labeling scheme were produced with ORTEX. Final fractional atomic coordinates, anisotropic temperature factors, and bond distances and angles are available as supplementary data. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100275. Copies of the data can be obtained free of charge on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[11] An earlier strategy involving phosphitylation with bis(cyanoethyloxy)-*N*,*N*-diisopropylaminophosphine/1*H*-tetrazole and oxidation as before followed by a one-step deprotection with aqueous ammonia was not satisfactory. It gave rise to slight but detectable migration of phosphate groups at the deprotection stage.

A New Cationic Domino Process to (±)-Uleine

Monika H. Schmitt and Siegfried Blechert*

Dedicated to Professor Ekkehard Winterfeldt on the occasion of his 65th birthday

Domino processes play an important role in organic synthesis,[1] and cation-induced processes are of great significance in both organic synthesis and biosynthesis. Herein we report on a new cationic cascade reaction (Scheme 1), which we have applied to the stereoselective synthesis of uleine. The introduced process might also be very interesting for the construction of strychnos alkaloids.

Several syntheses have been described for the alkaloids of the uleine group such as uleine (**2**), which like the strychnos alkaloids has an azocino[4,3-*b*]indole skeleton.[2] However, most concepts that employ a carbocyclization in a late step (either by formation of the C-1/C-9a or C-4/C-4a bond) lead to 3-*epi*-com-

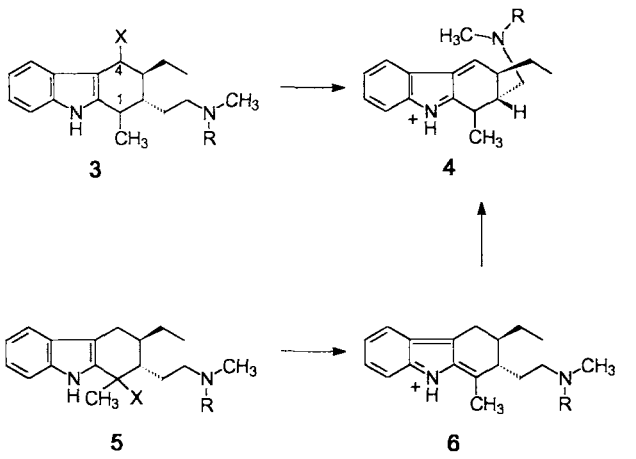
Scheme 1. Cation-induced transformations of **1** to uleine (**2**).

pounds. Therefore, for the synthesis of uleine (**2**) we envisaged a heterocyclization from the side opposite the ethyl group to form the piperidine ring. Ring closure should occur via an iminium ion of type **4** (Scheme 2) and should lead to the desired configuration at C-3. Cations of type **4** should be readily available by cleaving a suitable leaving group X from **3**, as described

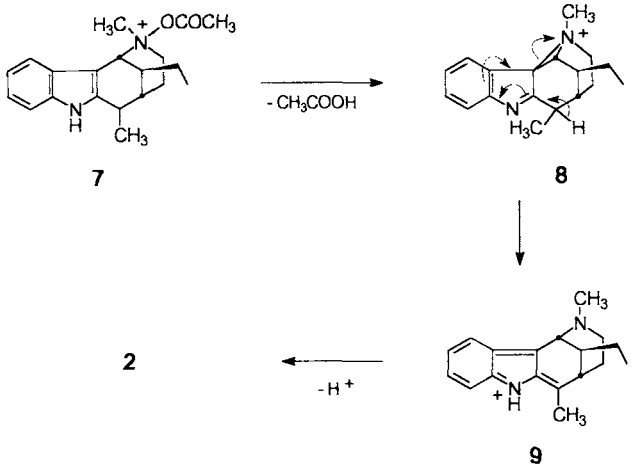


3 4 5 6

Scheme 2. Proposed routes to the vinylic iminium salt **4**.

in syntheses of similar systems.[3] We assumed that this iminium ion could also be formed by a leaving group on C-1 (uleine nomenclature). The cation **6** generated from **5** could undergo isomerization to the thermodynamically favored product **4** by a deprotonation–protonation sequence faster than addition of a nucleophile. In our concept, a positive charge generated on C-1 would activate position C-4 for nucleophilic attack. To the best of our knowledge a reaction like this has not yet been described in indole chemistry. However, the heterocyclization would give a 1,13-dihydrouleine. To construct the double bond, we planned a new cation-induced process. The *N*-acyloxyammonium ion **7** resulting from the heterocyclization step should be a suitable precursor for this reaction (Scheme 3). Because of the short distance between C-4a and the nitrogen atom of the piperidine ring and the convenient orientation of the π electrons to this nitrogen, an intramolecular substitution reaction could lead to **8**, containing a three-membered ring and an imine group. Tautomerization of **8** to **9** and subsequent removal of a proton to the vinylindole, would lead to uleine (**2**). Whereas, during the first reaction step, a carbocation on the "southern part of the molecule" should lead to a reaction in the "northern part", a cationic nitrogen center in the "northern area" should form the C-1/C-13 double bond. Generation of the ammonium ion **7** by the above-mentioned cyclization reaction serves to connect both processes.

This concept, which may seem speculative at first glance, proved viable. Thus, the *O*-acylated hydroxylamine derivative **1**, which was used as a mixture of two diastereomeres with regard to the configuration at C-1, was allowed to react with formic acid at room temperature to give uleine (**2**) in high yield (Scheme 1). The spectroscopic data of **2** are in agreement those



7 8 2 9

Scheme 3. Proposed mechanism for the formation of the C-1/C-13 double bond in **2** from the *N*-acyloxyammonium ion **7**.

of the natural product.[4] The structure was confirmed by comparison with an authentic sample. On the basis of our findings we propose the mechanism given in Schemes 2 and 3 for the synthesis of uleine; however, as of yet we have no definite proof. We tried to monitor the reaction by NMR spectroscopy, but we could not detect any clearly definable intermediates. Instead of tertiary alcohol **1**, the *exo*-methylene compound resulting from the removal of H_2O can be employed. We have prepared 1,13-dihydrouleine-N_b-oxide form **2** by hydrogenation with palladium and barium sulfate and subsequent conversion with *m*-chloroperbenzoic acid; its reaction with acetyl chloride at low temperature was then monitored by NMR spectroscopy. Salt **7**-Cl was formed at $-40\,^{\circ}C$ and transformed into uleine at $-30\,^{\circ}C$. Unfortunately, intermediates could not be confirmed. Several attempts at gaining indications of radical processes also proved unsuccessful. The transformation **7** → **2** is much faster than the overall process. The formation of the aziridinium ion could not be verified, but seems reasonable to us on the basis of results obtained form experiments with the *N*-acylated cationic uleine-*N*-oxide. Ions of type **7** with a double bond between C-1 and C-13 give products of a nucleophilic addition to C-13.

The devised domino process consists of the following steps: formation of a benzyl cation, multistep tautomerizations, cyclization to the piperidine derivative, formation of a three-membered ring, fragmentation, and tautomerization.

The synthesis of **1** is described in Scheme 4; each compound was fully characterized. Starting from cyclohexenone **10**, Michael addition followed by conversion of the enolate by alkylation,[5] and treatment with sodium hydride and ethylformiate yield the *trans*-configurated hydroxymethylene compound **11** in good yield.[6] A Japp–Klingemann reaction and subsequent Fischer indole synthesis give rise to the tetrahydrocarbazole **12**.[7] Unfortunately, the *trans* configuration is partially affected during the course of the Fischer indole synthesis. A complete isomerization to **12** is achieved by treatment with sodium methanolate in methanol after a reaction time of 1–2 weeks at room temperature. Evidently, the competing deprotonation of the acidic NH proton and the slight CH acidity of the vinylogous amide delay the isomerization to the thermodynamically favored *trans* product **12**. The subsequent oxidative cleavage of the double bond with a catalytic amount of osmium tetroxide and sodium periodate leads to the aldehyde, which reacts without further purification with *N*-methylhydroxylamine to give hydroxylamine **13** under reductive conditions (sodium cyanoborohydride) at pH 6. The formation of the tetrahydro-

carbazole derivative **1** is achieved by the addition of methyllithium to the carbonyl function, and O-acetylization of the hydroxylamine group.[9] The conversion of **13** to uleine (**2**) can be performed in good yields without chromatographic purification of the intermediates. The novel cascade reaction allows the application of the readily obtained *trans* configuration of the tetrahydrocarbazole **13** for a concise and stereoselective synthesis of uleine. This example demonstrates once more that the application of domino processes can open more efficient and shorter synthetic pathways.

Experimental Section

2: Tetrahydrocarbazole **1** (68.8 mg, 0.2 mmol) was dissolved in formic acid (5 mL) and left at room temperature for 15 min. The solvent was evaporated under reduced pressure and the crude product was purified by preparative thin-layer chromatography (silical gel, CH_2Cl_2/MeOH, 95/5 under NH_3 atmosphere) to give (±)-uleine (**2**) (54 mg, 95%).

Relative Migratory Aptitude of Substituents and Stereochemistry of Dyotropic Ring Enlargements of β-Lactones

Johann Mulzer,* Karsten Hoyer, and Anke Müller-Fahrnow

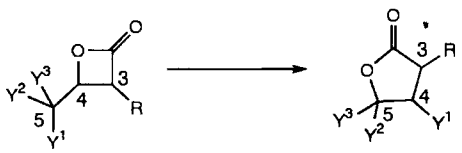
Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

In a dyotropic reaction of type 1 two substituents change their positions relative to a C–C single bond (Scheme 1).[1] The mutual 1,2 shift is reversible if there is no significant energy

Scheme 1.

difference between the two tautomers. In the case of a concerted mechanism the shift follows a *syn* or *anti* stereochemistry. The latter is characterized by an inversion at C1 and C2. If, on the other hand, the 1,2 shift proceeds by a stepwise mechanism, there is no compulsory correlation between the configurations of the two centers. Apart from the stereochemistry the migratory aptitude of the substituents is a point of issue about which practically nothing is known so far.

We report here on the dyotropic ring enlargement of β-lactones to γ-lactones. These rearrangements are irreversible due to ring-strain relief (Scheme 2) and proceed by inversion at C4.[2]



Scheme 2.

The relative migratory aptitude can be determined by placing different substituents Y^1, Y^2, and Y^3 at C5 of the β-lactone. We examined substituents with σ- (Y = alkyl), π- (Y = phenyl), and *n*- (Y = OR) donor qualities. In the last case the reaction resembles a semipinacol rearrangement.[3] The stereochemistry of the rearrangement with respect to the C4–C5 axis was studied with C3 as a stereochemical reference. The reaction can proceed by the concerted mechanism **A** or the stepwise-ionic mechanism **B** (Scheme 3).[2, 4, 5]

If mechanism **A** is involved the reaction should exclusively form γ-lactone **2** by a twofold inversion at C4 and C5. Conversely, in mechanism B a cationic species **Z-1** is generated, which may form **Z-2** by rotation about the C4–C5 axis. Intermediates **Z-1** and **Z-2** can cyclize to the epimeric γ-lactones **2** and **3**, respectively.[2] The experimental data are summarized in Table 1.

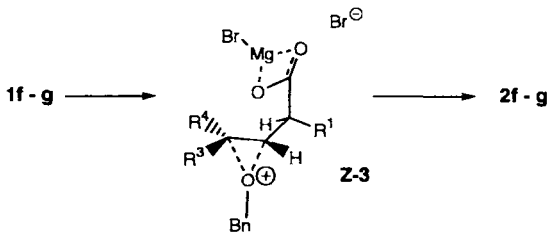
OBn	Et	Me	**h**	>99	<1	>99

[a] $R^3 = (H_3C)_2C{=}CHCH_2CH_2$.

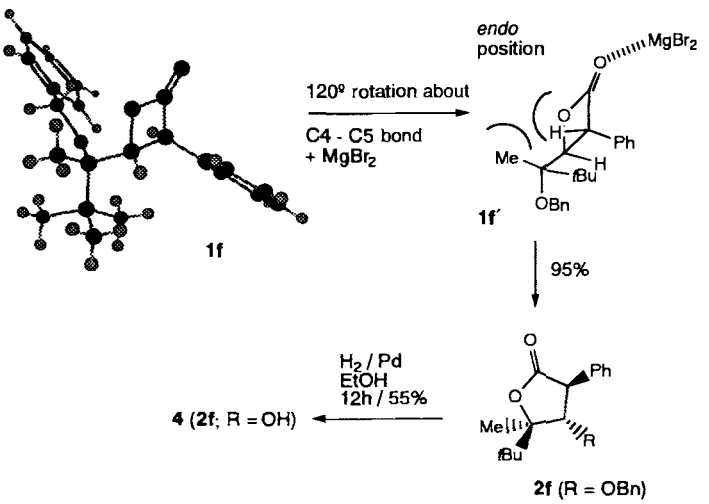
The highest migratory aptitude was observed for the phenyl group. Ring enlargement of the β-lactones **1a** and **1b** furnished the γ-lactones **2a** and **3a** or **2b** and **3b**, respectively, in practically identical ratios. This indicates that these rearrangements proceed via **Z-1**- and **Z-2**-type intermediates, which are in a fast equilibrium (Scheme 3). As ring closure of **Z-1** and **Z-2** to the corresponding γ-lactones is slower than the rotation about C4–C5, the ratio of products **2** and **3** reflects the composition of the **Z-1**⇌**Z-2** equilibrium. The rearrangement of **1c–e** also involves **Z-1** species; however, since they have secondary carbenium centers they are short-lived, and rotation about C4–C5 and ring closure are of comparable rates. In these cases the steric strain in **Z-1** determines the stereochemical pathway. If the bulky substituent (Me) is in the hindered *endo* position (R^4), as is the case for the rearrangement of **1d**, the tendency towards rotation about C4–C5 is much higher than in the case of **1c**, in which the methyl group adopts the more favorable *exo* position (R^3). This is reflected in the ratio of the products (97:3 for **2c:3c** and 85:15 for **2d:3d**, Table 1). Apparently a maximum of one rotation is allowed prior to ring closure, and phenonium species are not involved.

After the phenyl group, alkoxy substituents show the highest migratory aptitude. Within the limits of detection the rearrangement of the β-lactones **1f–h** produces the γ-lactones **2f–h** with perfect stereoselectivity. This indicates formation of the oxonium intermediate **Z-3**, which suppresses any rotation around the C4–C5 axis (Scheme 4). Diastereoselective dyotropic shifts of nitrogen residues have been reported.[8]



Scheme 4.

Single crystal X-ray diffraction studies of **1a–f** gave important information about the conformations around the C4–C5 axis. Assuming that the solid-state conformation remains unchanged after formation of the magnesium bromide complex in solution, the migrating substituent in **1a–e** already occupies the stereoelectronically "correct" position antiperiplanar to the C–O bond of the β-lactone. This means that in these cases the ground state and the reactive conformation are identical. Conversely, rotation about C4–C5 has to take place in **1f** to obtain the reactive conformation **1f'**, in which the Me group adopts the unfavorable *endo* position (Scheme 5).[11] For such rotations a barrier of less than 8 kJ mol^{-1} is required according to AM1-calculations, and the validity of the Curtin–Hammett principle can be assumed. This means that the ground-state conformation of β-lactones has no influence on the diastereomer ratio of the resulting γ-lactones.[12, 13]



Scheme 5.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1477 $ 17.50+.50/0

In conclusion, dyotropic β-lactone–γ-lactone ring enlargement follows the nonconcerted mechanism **B**; the migratory aptitudes of the substituents are in the order π-donor > *n*-donor > σ-donor substituent. Migration of π-donor (and possibly also of σ-donor) substituents proceeds via intermediate **Z-1**, whose lifetime depends on carbenium stabilization. The migration of *n*-donor (oxygen) substituents involves a bridged oxonium species **Z-3**. In all rearrangements an inversion at C4 is observed without exception. The stereochemical course of the reaction is better clarified,[1] and its preparative value lies in the stereocontrolled formation of three contiguous stereogenic centers in the γ-lactones **2c, e–h**.

[6] The synthesis of the β-lactones proceeded by carboxy-group activation with phenylsulfonyl chloride as described [9·10]. The diastereomeric β- and γ-lactones were separated by HPLC under normal-phase conditions with a Nucleosil (5–7 μm) stationary phase and *n*-hexane/ethyl-acetate as eluent.

[7] For ring enlargement the β-lactones were dissolved in anhydrous diethyl ether (10^{-1}–10^{-2} mmol mL^{-1}) and treated with 1.0 equiv of a 3.2 M solution of $MgBr_2$ in diethyl ether with ice cooling and stirring. After 12–60 h at 25–30 °C the reactions were quenched with water, and the diastereomeric γ-lactones isolated from the ether phase [2]. Cross-check experiments showed that γ-lactones **3a–e** remained unchanged under the reaction conditions.

Imidazol-2-ylidene: Generation of a Missing Carbene and Its Dication by Neutralization–Reionization and Charge-Stripping Mass Spectrometry**

Graham A. McGibbon, Christoph Heinemann, David J. Lavorato, and Helmut Schwarz*

Dedicated to Professor Zvi Rappoport on the occasion of his 60th birthday

There are many simple molecules that have been studied by quantum chemical methods sufficiently often and thoroughly enough that they take on an aura of familiarity but nevertheless still manage to elude experimental observation. Among the most famous of these is O=C=C=O.[1] A more recent candidate is imidazol-2-ylidene **1**, the parent compound of a carbene family with members that proved stable enough to be isolated.[2] Although imidazolylidenes have been studied for over three decades,[3] the theoretical scrutiny of **1** has recently intensified.[4] While computational investigations have concentrated on **1**, to-date all the aminocarbenes[2, 4d–f, 5] and related compounds[4d, 6] observed in condensed phases possess non-hydrogen substituents on the nitrogen atoms. Unsubstituted aminocarbenes have been reported in the gas phase,[7] for example the acyclic carbenes H_2N-C-NH_2 and H_2N-C-OH as well as the heterocyclic tautomers of oxazole, pyridine, and thiazole were prepared and characterized by using neutralization–reionization mass spectrometry (NRMS).[8] The latter method is particularly suitable for the identification of molecules that are susceptible to intermolecular isomerization but relatively stable toward unimolecular rearrangement since the experiments are performed on solitary gaseous species. This approach may be a route to **1** and to imidazol-4-ylidene **2**, the 1,2-hydrogen shift isomers of imidazole **3**. Earlier computations predicted that neutral **1** and **3** are separated by a substantial tautomerization barrier as are their radical cations.[4h, 9] Similarly, our hybrid Hartree–Fock/density functional theory calculations (Becke3LYP/6-31G**)[10] indicate that a barrier of 36 kcal mol^{-1} restricts the exothermic (50 kcal mol^{-1}) isomerization **2** → **3** and that the apparently isoenergetic ions $\mathbf{2}^{\bullet+}$ and $\mathbf{3}^{\bullet+}$ are separated by a barrier of 56 kcal mol^{-1}.[11] In light of this, it would seem that **1** and **2** are targets suitable for generation and characterization by NRMS if precursor molecules can be found (Scheme 1).

It was presumed that the ion $\mathbf{1}^{\bullet+}$ could be generated analogously to previous gas phase syntheses of carbene radical cations by dissociative electron ionization (EI) of an appropriately substituted imidazole. Indeed, the readily available imidazole-2-carboxaldehyde **I** seemed a good initial choice since it has

spectrometry.[12] The tandem mass spectrometry experiments[13] described here were performed by using the VG Analytical ZAB-R instrument at McMaster University[14] and the modified VG ZAB/HF/AMD mass spectrometer at the TU Berlin.[15]

A careful comparison of the data from the collision-induced dissociation (CID) mass spectra in Table 1 and the charge-stripping (CS) mass spectra in Table 2 reveals that two new m/z 68 $[C_3H_4N_2]^{\bullet+}$ ions, distinguishable from imidazole do exist. At first glance, the tabulated data from the CID mass spectra do not seem greatly different, which is perhaps not surprising in light of the structural similarity of the isomers and their complicated fragmentation pathways.[12] Nevertheless, the spectrum

12	1	1	0	0	1	1

[a] Intensities based on peak heights normalized to $\Sigma = 100$. Peaks containing metastable contributions have been omitted.

(a) from precursor **I** is distinguished by an intense peak at m/z 42 (see Figure 1) that is attributed to the loss of acetylene and thus taken as a strong indication of the carbene ion structure $\mathbf{1}^{\bullet+}$. This process has been shown to occur for the closely related thiazol-2-ylidene radical cation[7e] and we surmise that in this case ionized diimide $HN{=}C{=}NH^{\bullet+}$ is the product ion. However, attempts to demonstrate this experimentally are thwarted by the fact that isomeric CH_2N_2 radical cations are very difficult to distinguish.[16] In any case, intense signals at m/z 42 are not expected from $\mathbf{2}^{\bullet+}$ and they are not present in the CID mass spectrum of the imidazole radical cation. Indeed, the m/z 68 ions from both **II** and imidazole are similar in the respect that there is almost no signal to be seen at m/z 42 and in terms of the relative abundance of the other fragments in their CID mass spectra; however, there are some notable differences between the two spectra: a considerably enhanced (5% of total CID intensity) fragment peak at m/z 29 and a weak peak at m/z 16 is observed only in the spectrum of the ions from **II**, which is an indication that these ions have a structure different from $\mathbf{1}^{\bullet+}$ or $\mathbf{3}^{\bullet+}$.

The existence of $\mathbf{1}^{\bullet+}$ and $\mathbf{2}^{\bullet+}$ is further endorsed by the CS mass spectral data in Table 2. Quite different intensity ratios for the dications at m/z 68/67/66 are observed in all three spectra and in contrast to $\mathbf{3}^{\bullet+}$ the CS peaks are much more intense than the CID peaks for both of

Table 2. Data from the charge-stripping mass spectra of m/z 68 $[C_3H_4N_2]^{\bullet+}$ ions generated from **I**, **II**, and imidazole [a].

[a] Relative abundance are from peak heights. [b] NR/CS refers to dications formed from neutralized ions (see text). [c] Charge-stripping efficiency as measured by the peak height ratio of m/z 68 relative to that of the nearby m/z 39 in the CID mass spectrum.

the new ions. The larger susceptibility of the ions $\mathbf{1}^{\bullet+}$ and especially $\mathbf{2}^{\bullet+}$ to charge-stripping is typical for ylide ions as compared to mundane isomers.[17] The differences in the CS and CID mass spectra of the three isomers show that ions $\mathbf{1}^{\bullet+}$ and $\mathbf{2}^{\bullet+}$ do not easily isomerize to $\mathbf{3}^{\bullet+}$. Given that the fragmentation mechanisms of even the well-known ion $\mathbf{3}^{\bullet+}$ are still largely speculative,[12] we avoid dwelling further on these differences. Thus, the three isomers can be differentiated by CID and CS mass spectrometry, therefore, it still remains to be demonstrated that the corresponding neutral molecules are stable in NRMS experiments.[18]

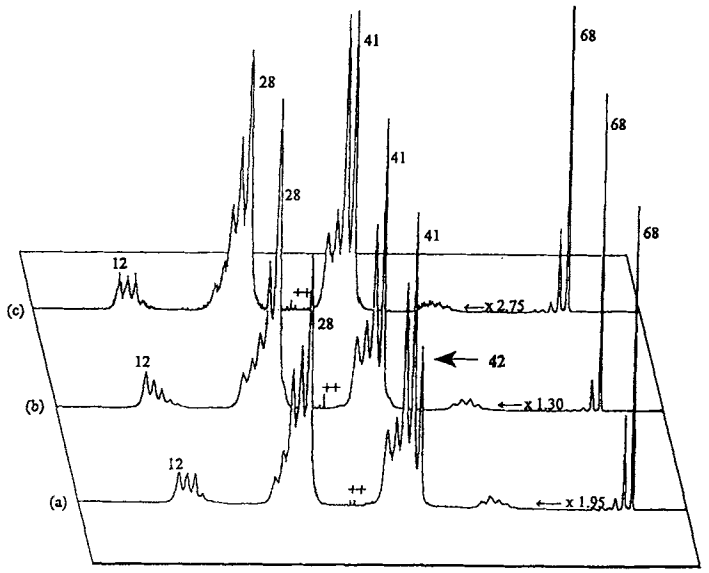

Figure 1. NR mass spectra of the m/z 68 ions generated from (a) ionized imidazole-2-carboxaldehyde **I**, (b) ionized precursor **II**, and (c) ionized imidazole.

When the individual NR mass spectra of distinguishable isomers match their respective CID mass spectra in appearance and contain observable recovery ion signals it is easy to conclude that the neutral molecules are stable. On this basis, the existence of **1** is strongly suggested since its NR mass spectrum (Figure 1 (a)) contains both the signature peak at m/z 42, and as the base peak, the recovery signal at m/z 68. The evidence is less clear-cut for **2** because the relative intensities of the peaks in the NR mass spectrum are not quite the same as in the CID mass spectrum. Note, however, that the m/z 12–16 cluster patterns are unique and the weak but observable dication peaks denoted + + in Figure 1 are very informative. The relative abundance of the dication at m/z 68 is once again most noticeable for $\mathbf{2}^{\bullet+}$ and the largest peak that is attributed to a dication at m/z 67 is again generated by $\mathbf{3}^{\bullet+}$. To probe the existence of **2** and **1** in more detail, we investigated the collision-induced dissociation behavior of the reionized species with m/z 68 (see Figure 1). This type of experiment (NR/CID)[18] requires a multisector mass spectrometer and high sensitivity.[7, 15]

To assist direct comparisons of the m/z 68 ions their NR/CID and CID mass spectra have been tabulated together in Table 1. An inspection quickly reveals the similarity of the NR/CID to the CID mass spectra for the three sets of ions, especially in regard to the key peaks at m/z 42 and 29. Scrutiny of the NR/CID mass spectra reveals that the m/z 40 peaks are likely diminished because of extensive fragmentation into smaller ions, which probably reflects a change to a higher internal energy distribution in the radical cations themselves after NR.[7b] This is consistent with the increased dissociation observed for the dications produced by charge-stripping of the m/z 68 ions (see the NR/CS mass spectra in Table 2). Taking this into account, the CS efficiencies of the recovery ions and of the ions not subjected to NR are comparable. These facts lead us to the conclusion that a significant portion of the neutral molecules **1** and **2** are able to survive structurally intact during the microsecond transit time between the neutralization and reionization cells in NRMS experiments.

In summary, the existence of imidazol-2-ylidene **1** and imidazol-4-ylidene **2**, their radical cations, and dications have been demonstrated through tandem mass spectrometry experiments.

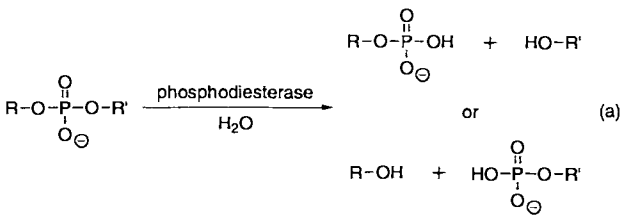
[18] In NRMS experiments 8 or 10 keV m/z 68 $[C_3H_4N_2]^{\bullet+}$ ions were mass-selected (by B with the ZAB-R or B_1E_1 with the ZAB/HF/AMD) and then subjected to neutralizing collisions with *N*,*N*-dimethylaniline or xenon vapor present in a small gas cell located in the field-free region. Afterward, any remaining ions were removed from the beam by deflection with a positively charged electrode so that only a beam of fast moving neutral species entered a second gas cell, therein being (dissociatively) reionized by collisions with oxygen molecules. For a NR mass spectrum, the survivor and fragment ions were analyzed by using the next available sector (B_2 in Berlin or E_1 at McMaster). Alternatively, when the recovery ions (m/z 68) were selectively transmitted by the sector and then passed through another oxygen-filled collision cell (70% transmission) the resulting CID products could be analyzed by using the last sector. The NR/CID mass spectrum so obtained is characteristic of only the species surviving neutralization and reionization. Mass spectra of doubly charged ions (NR/CS) were also obtained in the same manner. Comparative collision-induced dissociation (CID) and charge-stripping (CS) experiments were performed with the deflector electrode switched off.

Fluorescence Reporters for Phosphodiesterase Activity**

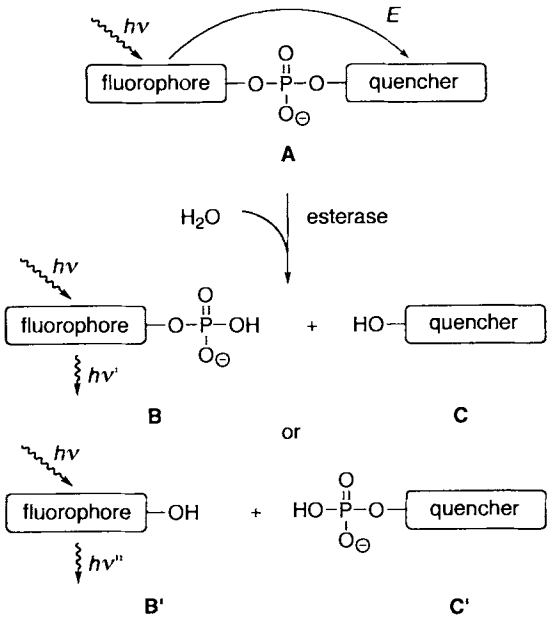
Albrecht Berkessel* and Rainer Riedl

Phosphodiesterases catalyze the hydrolysis of phosphodiester bonds [Eq. (a)].[1] Their most important biological substrates



are the nucleic acids. The manipulation of genetic material ("genetic engineering") hinges on the sequence-specific cleavage of DNA by the restriction enzymes,[2] which are isolated from natural sources and, consequently, invariable with respect to their catalytic parameters and particularly their base-recognition properties (number and type of the bases recognized). Due to the extreme importance of this class of enzymes in biochemistry and biotechnology, numerous attempts have been made to design "artificial phosphodiesterases".[3] Independent of the catalytic mechanism of these systems, highly sensitive assays are needed for detecting phosphodiesterase activity. So far, UV/Vis-spectroscopical quantification of nitrophenols liberated from the corresponding phosphodiesters or ^{31}P NMR spectroscopy were used in most cases. We found it worthwhile to design a simple and much more sensitive fluorescence probe for detecting phosphodiesterase activity. Due to the high sensitivity of fluorescence assays, we reasoned that with such probes phosphodiesterase activity might also be detected in complex mixtures of biological or synthetic origin.

The mechanism of our reporter molecules is shown in Scheme 1. In compound **A**, a fluorophore and a fluorescence



Scheme 1. Mechanism of the fluorescence reporters.

quencher are held in close proximity. The absorption spectrum of the quencher and the emission spectrum of the fluorophore should match as well as possible.[4] Upon irradiation of the fluorophore, rapid energy transfer to the quencher takes place. Therefore, this intact phosphodiester does not fluoresce.[4]

After hydrolysis of the phosphodiester group, the cleavage products **B** and **C** (or **B'** and **C'**) can diffuse away from one another, and the fluorescence is no longer quenched intramolecularly.[4] We synthesized two such fluorescence reporters, namely the phosphodiesters **1** and **2**. In these compounds a naph-

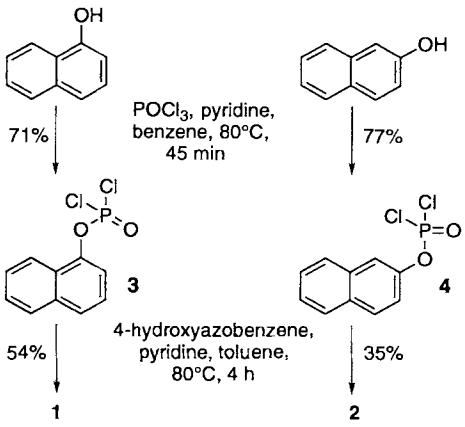
thalene residue acts as the fluorophore, and an azobenzene moiety as the quencher. Since 4-hydroxyazobenzene (pK_s = 8.20)[5] is a better leaving group than 1-naphthol (pK_s = 9.37)[6] or 2-naphthol (pK_s = 9.49),[6] hydrolysis of **1** and **2** should result in formation of 4-hydroxyazobenzene and the corresponding naphthyl phosphates. We here report the synthesis of **1** and **2** and the activation of their fluorescence by hydrolysis.

As shown in Scheme 2 the preparation of **1** und **2** starts with the reaction of 1- or 2-naphthol with phosphoryl chloride.[7] In



Scheme 2. Synthesis of the phosphodiesters **1** and **2**.

the second step, the azobenzene moiety is introduced. UV/Vis spectra of **1** and **2** show absorption bands for the naphthalene and azobenzene moieties (maxima at shorter and longer wavelength, respectively; Figure 1). Irradiation of the naphthalene absorption band results in virtually no fluorescence.[8]

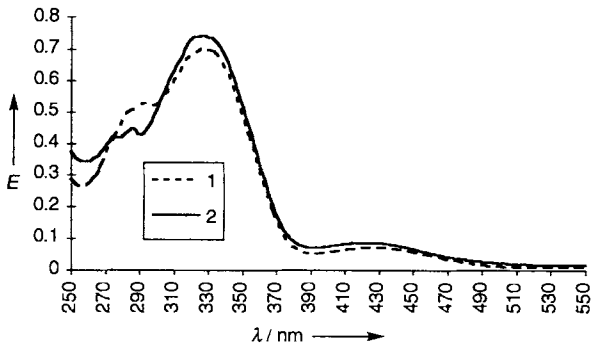


Figure 1. UV/Vis spectra of the fluorescence reporters **1** and **2** ($c = 5.0 \times 10^{-5}$ M) in AMPSO buffer (0.1 M, pH 8.8), $T = 25$ °C.

Addition of a phosphodiesterase, for example phosphodiesterase I from crotalus atrox venom,[9] to a solution of **1** in AMPSO buffer[10] results in a rapid increase in the fluorescence intensity (Figure 2). The shape of the fluorescence spectrum is identical to that of an equimolar mixture of 1-naphthyl phosphate and 4-hydroxyazobenzene. However, the intensity of the control mixture is not reached in the enzyme-catalyzed hydrolysis of **1**. Even more remarkably, the fluorescence intensity starts to decrease after about 4 h.

This unexpected observation results from a minor phosphatase activity in the commercially available enzyme preparation.[9] HPLC analysis revealed that 1-naphthyl phosphate initially liberated from **1** slowly degrades to 1-naphthol. Unlike

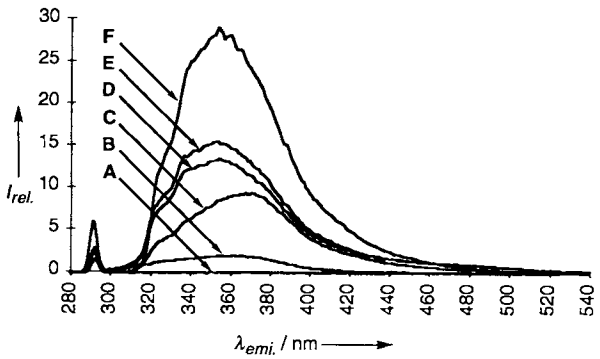

Figure 2. Fluorescence spectra of a 5.0×10^{-5} M solution of **1** in AMPSO buffer (0.1 M, pH 8.8), $T = 37$ °C, $V = 1.5$ mL. A: without enzyme; B: after addition of 0.05 u phosphodiesterase I (crotalus atrox venom); C: 30 min after addition of the enzyme; D: 360 min after addition of the enzyme; E: 240 min after addition of the enzyme; F: for comparison, 5.0×10^{-5} M 1-naphthyl phosphate $+ 5.0 \times 10^{-5}$ M 4-hydoxyazobenzene.

1-naphthyl phosphate, 1-naphthol is known[6] to show practically no fluorescence in aqueous solution at 357 nm. When we employed another commercially available[11] phosphodiesterase I (from bovine intestinal mucosa), 1-naphthyl phosphate could not be found at all as the primary hydrolysis product of **1**. HPLC analysis of the (nonfluorescent) reaction mixtures revealed immediate further degradation to 1-naphthol.

With this in mind, we subjected the 2-naphthol derivative **2** to hydrolysis catalyzed by phosphodiesterase I (from bovine intestinal mucosa). In contrast to 1-naphthol, 2-naphthol is known[6] to fluoresce strongly in aqueous solution. The results are summarized in Figure 3. Addition of the enzyme to a solu-

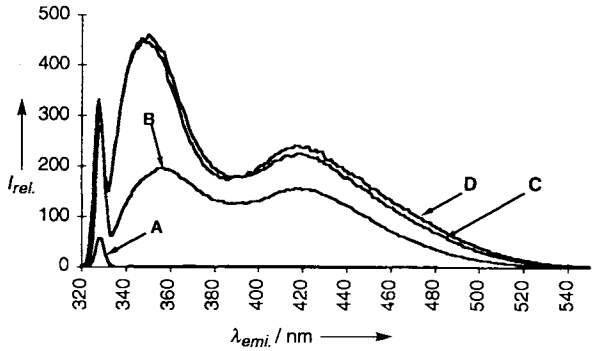

Figure 3. Fluorescence spectra of a 5.0×10^{-5} M solution of **2** in AMPSO buffer (0.1 M, pH 8.8), $T = 37$ °C, $V = 1.5$ mL. A: without enzyme; B: 40 min after addition of 0.05 u phosphodiesterase I (bovine intestinal mucosa); C: 4 h after addition of the enzyme (end of reaction); D: for comparison, 5.0×10^{-5} M 2-naphthol $+ 5.0 \times 10^{-5}$ M 4-hydoxyazobenzene

tion of **2** in AMPSO buffer[10] produced a rapid increase in the fluorescence intensity, which asymptotically approached that of an equimolar mixture of 2-naphthol and 4-hydroxyazobenzene (Figure 3). HPLC analysis of the reaction mixtures confirmed the formation of 4-hydroxyazobenzene and the secondary hydrolysis product 2-naphthol. Hydrolysis of **2** induced an at least thousandfold increase of the fluorescence intensity![12] Furthermore, the progress of the reaction was also indicated by the yellow color of the 4-hydroxyazobenzene formed (strictly speaking, of the phenolate anion, $\lambda_{max} = 421$ nm). A plot of the initial velocities versus the enzyme concentrations (addition of

0.025–0.1 u) confirmed the expected linear relationship (not shown, three experiments, $\rho = 0.9984$).

The fluorescence reporters **1** and **2** are highly sensitive probes for detecting phosphodiesterase activity. Their use as test substrates not only allows detection of phosphodiesterase activity, but also phosphatase activity.

Experimental Section

1-Naphthyl phosphoryl chloride (**3**) and 2-naphthyl phosphoryl chloride (**4**) were prepared according to ref. [7].

1: Under nitrogen **3** (2.63 g, 10.1 mmol) and 4-hydroxyazobenzene (2.00 g, 10.1 mmol, 1.0 equiv) were dissolved in abs toluene (150 mL) with heating, and abs pyridine (3.19 g, 40.4 mmol, 4.0 equiv) was added dropwise within 30 min. Stirring was continued for 4 h at 80 °C and overnight at RT. The precipitated pyridinium hydrochloride was removed by filtration, and the filtrate concentrated on a rotary evaporator to about 20 mL. The remaining oil was dissolved in pyridine/water (1/1, 20.0 mL), and the solution stirred at RT for 1 h. Afterwards 10% aqueous K_2CO_3 (100 mL) and chloroform (100 mL) were added. The biphasic mixture was shaken vigorously to induce the precipitation of the potassium salt of **1**. After 3 h the precipitate was isolated by filtration and taken up in boiling water (150 mL). The red extract was again filtered, and the filtrate adjusted to pH 1 with concd HCl. The orange precipitate was isolated by filtration and recrystallized from acetone to afford **1** as an orange crystalline powder (2.22 g, 54%).

M.p. 167 °C (acetone); IR (KBr): $\tilde{\nu} = 1222$ [s, ν(P=O)], 1204 [s, ν(C–O)], 1046, 989 [both s, ν(P–O)], 564 cm^{-1} [s, δ(P-O-Ar)]; ^1H NMR (300 MHz, [D$_6$]DMSO): $\delta = 7.34–7.51$ (m, 4H, aryl H), 7.51–7.64 (m, 5H, aryl H), 7.70–7.78 (m, 1H, aryl H), 7.81–8.00 (m, 5H, aryl H), 8.03–8.13 (m, 1H, aryl H), 11.20 (br s, 1H, OH); ^{13}C NMR (75 MHz, [D$_6$]DMSO): $\delta = 115.10$ (d, ^3J(C,P) = 2.82 Hz, aryl CH), 121.00 (d, ^3J(C,P) = 5.08 Hz, aryl CH), 121.70 (d, aryl CH), 122.64 (d, aryl CH), 124.32 (d, aryl CH), 124.38 (d, aryl CH), 125.97 (d, ^4J(C,P) = 1.70 Hz, aryl CH), 126.32 (s, ^3J(C,P) = 6.21 Hz, aryl C), 126.44 (d, aryl CH), 126.81 (d, aryl CH), 127.87 (d, aryl CH), 129.60 (d, aryl CH), 131.55 (d, aryl CH), 134.47 (s, aryl C), 147.16 (s, ^2J(C,P) = 7.35 Hz, aryl C), 148.64 (s, aryl C), 152.06 (s, aryl C), 153.96 (s, ^2J(C,P) = 6.78 Hz, aryl C); ^{31}P NMR (80 MHz, [D$_6$]DMSO): $\delta = -11.68$; LDI-MS: m/z (%) = 403.4 (100) [M^- – H], 298 (5) [$C_{16}H_{11}O_4P^-$], 197.1 (12) [$C_{12}H_9N_2O^-$], 142.9 (50) [$C_{10}H_7O^-$]; UV/Vis (H_2O): λ_{max} (ε) = 417 (1322), 330 (14910), 290 (9385), 220 nm (54300); elemental analysis calcd for $C_{22}H_{17}N_2O_4P$ (404.36): C 65.35, H 4.24, N 6.93, P 7.66; found: C 65.23, H 4.37, N 6.88, P 7.61.

2: Analogous to the preparation of **1**, abs pyridine (7.14 g, 90.4 mmol, 4.0 equiv) was added to a solution of **4** (5.90 g, 22.6 mmol) and 4-hydroxyazobenzene (4.49 g, 22.6 mmol, 1.0 equiv) in abs toluene (300 mL). The mixture was heated to 80 °C for 4 h and stirred overnight at RT. The precipitated pyridinium hydrochloride was removed by filtration, and the solvent removed on a rotary evaporator. The oily residue was stirred with pyridine/water (1/1, 20.0 mL) for 1 h at RT. The solution was then adjusted to pH 1 by adding concd HCl. A deep-red precipitate formed overnight, which was isolated by filtration and recrystallized from acetone to afford **2** as orange platelets (3.22 g, 35%).

M.p. 146 °C (acetone); FT-IR (KBr): $\tilde{\nu} = 1228$ [s, ν(P=O)], 1208 [s, ν(C–O)], 976, 946 [both s, ν(P–O)], 551 cm^{-1} [m, δ(P-O-Ar)]; ^1H NMR (300 MHz, [D$_6$]DMSO): $\delta = 5.05$ (br s, 1H, OH), 7.32–7.51 (m, 5H, aryl H), 7.52–7.63 (m, 3H, aryl H), 7.68–7.73 (br s, 1H, aryl H), 7.78–7.94 (m, 7H, aryl H); ^{13}C NMR (50 MHz, [D$_6$]DMSO): $\delta = 115.79$ (d, ^3J(C,P) = 4.58 Hz, aryl CH), 120.77 (d, ^3J(C,P) = 4.57 Hz, aryl CH), 121.08 (d, ^3J(C,P) = 5.34 Hz, aryl CH), 122.56 (d, aryl CH), 124.20 (d, aryl CH), 124.90 (d, aryl CH), 126.59 (d, aryl CH), 127.28 (d, aryl CH), 127.69 (d, aryl CH), 129.34 (d, aryl CH), 129.58 (d, aryl CH), 129.93 (s, aryl C), 131.32 (d, aryl C), 133.81 (s, aryl C), 147.91 (s, aryl C), 150.21 (s, ^2J(C,P) = 6.87 Hz, aryl C), 152.11 (s, aryl C), 155.38 (s, ^2J(C,P) = 6.87 Hz, aryl C); ^{31}P NMR (80 MHz, [D$_6$]DMSO): $\delta = -11.98$; LDI-MS: m/z (%) = 403.6 (100) [M^- – H], 298.4 (7) [$C_{16}H_{11}O_4P^-$], 197.4 (7) [$C_{12}H_9N_2O^-$]; UV/Vis (H_2O): λ_{max} (ε) = 419 (1195), 329 (15280), 286 (7480), 276 (6735), 220 nm (63090); elemental analysis calcd for $C_{22}H_{17}N_2O_4P$ (404.36): C 65.35, H 4.24, N 6.93, P 7.66; found: C 65.24, H 4.23, N 6.91, P 7.68. Hydrolyses were carried with a variable-temperature Shimadzu RF-5000 recording spectrofluorophotometer equipped with a 150 W xenon lamp.

[8] When **2** was subjected to hydrolysis, $\lambda_{exc.} = 326$ nm was used since at this wavelength there is basically no fluorescence of the enzyme, and the fluorescence intensity of 2-naphthol is not significantly lower than that at $\lambda_{exc.} = 290$ nm. In the case of **1**, $\lambda_{exc.}$ had to be 290 nm since at this excitation wavelength the fluorescence intensity of 1-naphthyl phosphate is much higher than that at $\lambda_{exc.} = 326$ nm.

[9] Phosphodiesterase I (from crotalus atrox venom), Sigma. Definition of activity by the suppliers: 1 u hydrolyzes 1.0 μmol of bis(*p*-nitrophenyl)phosphate per min at pH 8.8 and 37 °C. Concerning the phosphodiesterase activity, the suppliers state 0.16 u mg^{-1} protein at pH 8.8 and 37 °C. The phosphatase activity is specified as less than 0.001 u mg^{-1} protein at pH 10.4 and 37 °C (substrate: *p*-nitrophenyl phosphate).

[10] AMPSO: 3-[(1,1-dimethyl-2-hydroxyethyl)amino]-2-hydroxypropanesulfonic acid.

[11] a) Phosphodiesterase I (from bovine intestinal mucosa), Sigma. Definition of activity by the suppliers: 1 u hydrolyzes 1.0 μmol of bis(*p*-nitrophenyl) phosphate per minute at pH 8.8 and 37 °C. The suppliers state "non-specific phosphatase activity" for enzyme preparation. b) In a control experiment the rapid dephosphorylation of 1- and 2-naphthyl phosphate could be shown by HPLC.

[12] Fluorescence intensity at 357 nm at the end of the reaction/fluorescence intensity at 357 nm before addition of enzyme. A higher intensity of excitation should result in an even higher increase in fluorescence intensity.

N-Bromoacetamide—A New Nitrogen Source for the Catalytic Asymmetric Aminohydroxylation of Olefins**

Milan Bruncko, Gunther Schlingloff, and K. Barry Sharpless*

The β-amino alcohol moiety is one of the most abundant structural units in biologically active compounds. Recent developments by us[1] and others[2] have led to viable metal-catalyzed routes for its asymmetric synthesis. In our recently discovered asymmetric aminohydroxylation (AA),[1] olefins are converted to nonracemic protected amino alcohols *in a single step* by using catalytic amounts of osmium(VIII) and cinchona alkaloid derivatives (Scheme 1), by a process which closely mirrors the well-established asymmetric dihydroxylation of olefins (AD).[3] We have now found conditions that allow amides to join sulfon-

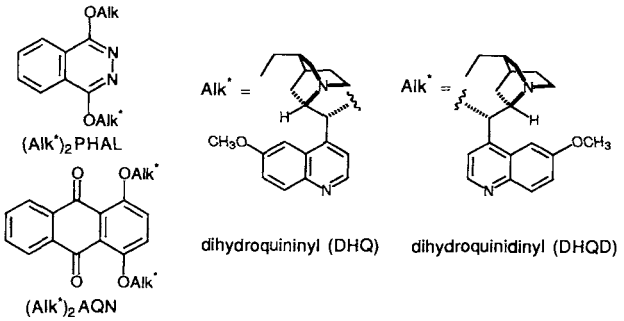
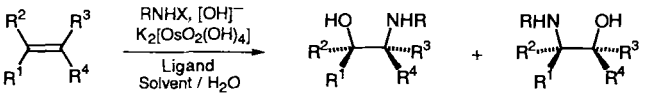


Scheme 1.

amides[1a-c] and carbamates[1d] as the nitrogen donor in this transformation.

Alkali metal salts of *N*-chloro carboxamides are well-known for their proclivity to undergo Hofmann rearrangement.[4] However, we were pleased to find that this competing reaction could be completely supressed by operating at 4 °C and using the more stable *N*-bromo derivative.[5] In the presence of 4 mol% of potassium osmate dihydrate and 5 mol% of the second generation alkaloid ligands,[3] a variety of olefins reacted smoothly with 1.1 equivalents of the oxidant/nitrogen donor to give the vicinal amino alcohols in good yield and with high enantiomeric excess (Scheme 2).

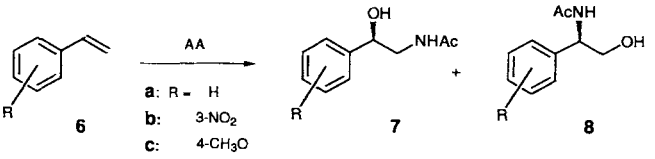


Scheme 2.

For each olefin class given in Table 1, the reaction parameters were optimized in terms of ligand, solvent, base,[6] and base/oxidant ratio, respectively. Both product enantiomers can be obtained by using either "pseudoenantiomers" of the alkaloid ligands.[3] A major advantage of this system is that only a stoichiometric amount of oxidant is needed (cf. reference [1]), which greatly simplifies isolation and purification of the product. In fact, use of excess of oxidant does not improve the reaction in any way.

As in the sulfonamide- and carbamate-based transformations,[1] cinnamates are among the best substrates (Table 1, entries 1–3).[7] While *cis*-stilbene gave mostly diol, *trans*-stilbene afforded the *threo*-amino alcohol **4** in 50% yield (together with 10% diol) and high enantiomeric excess (Table 1, entry 4). Ethyl acrylate gave rise to the isoserine derivative **5** as the major regioisomer detected by ^{1}H NMR spectroscopy (isoserine/serine > 20:1, Table 1, entry 5).

With styrenes **6** as substrates (Scheme 3), the regioselectivity is highly dependent on the choice of solvent *and* ligand. For example, alcoholic solvents resulted in a slight preference (**8**/**7** = 1.1–2.5:1) for introduction of the nitrogen substituent at the benzylic position (regioisomer **8**, Table 2), whereas acetonitrile significantly favored the other regioisomer (**7**) (**7**/**8** =



Scheme 3.

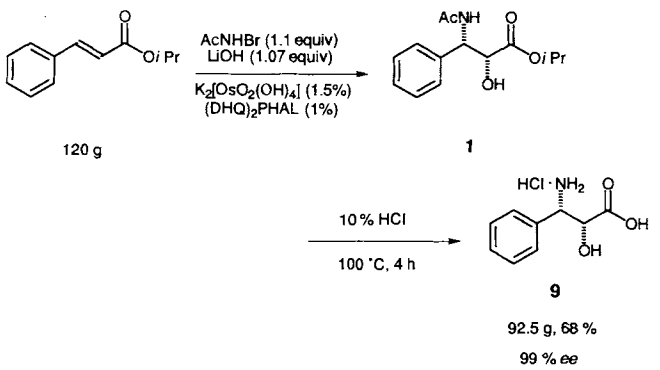
2–13:1). In most cases, the benzylic amides were formed with higher asymmetric induction (**8**, 85–96% *ee*) than the benzylic alcohols (**7**, 62–94% *ee*), but poor regioselectivity was observed when phthalazine ligands were used. However, our recently introduced anthraquinone (AQN) ligands (see Scheme 1)[8] were much more effective, leading to good regioselectivities with this olefin class (Table 2, entries 3, 6, 9). The AA protocols now enable selective synthesis of either of the regioisomeric β-amino alcohols derived from styryl olefins. The phenyl glycinols **8** are obtained by using the carbamate AA/phthalazine ligand combination,[9] *and* the adrenaline-type regioisomers **7** are preferentially derived by using the acetamide AA/anthraquinone ligand combination.[10] Irrespective of the regiochemical outcome, the facial selectivity of these acetamide AA reactions agrees with the face selectivity rule for the AD.[3, 11] Thus, dihydroquinine-derived ligands (DHQ class) give rise to oxidation from the α face of the olefin, whereas the diastereomeric dihydroquinidine (DHQD) ligands effect attack on the β face of the double bond.

With this efficient new process in hand, we focused on its application for a large-scale synthesis of (2*R*,3*S*)-3-phenylisoserine,[12] a precursor for the side chains of the anticancer drugs Taxol and Taxotere. A 630-fold scale-up of our standard one mmol recipe was undertaken with a somewhat lower catalyst loading (1.5 mol% osmate salt and 1 mol% $(DHQ)_2PHAL$), which did not affect the outcome of the catalysis.[13] The AA product was isolated by crystallization of the crude reaction mixture from ethyl acetate/hexane, and a second crop from diethyl ether. Subsequent hydrolysis furnished the enantiomerically pure amino alcohol as the hydrochloride salt **9** in 68% yield over two steps (Scheme 4).[12]

In summary, this third modification of the AA describes the use of *N*-bromoacetamide as the nitrogen source. In the case of styrenes, the regiochemistry of amino alcohol formation is reversed from that delivered by the carbamate version of the AA.[1d, 9] An efficient large-scale synthesis of enantiomerically pure 3-phenylisoserine highlights the prodical potential of this latest advance in the osmium-catalyzed asymmetric aminohydroxylation process.



Scheme 4. Large-scale synthesis based on the acetamide-AA.

Experimental Section

General procedure (described for isopropyl cinnamate) [12]: In 3 mL of an aqueous solution of $LiOH \cdot H_2O$ (42.8 mg, 1.02 mmol), $K_2[OsO_2(OH)_4]$ (14.7 mg, 0.04 mmol, 4 mol%) was dissolved with stirring. After addition of *t*BuOH (6 mL), $(DHQ)_2PHAL$ (39 mg, 0.05 mmol, 5 mol%) was added and the mixture was stirred for 10 min to give a clear solution. Water (6 mL) was added subsequently, and the mixture was immersed in a cooling bath set to 4 °C. After addition of isopropyl cinnamate (190 mg, 1 mmol), *N*-bromoacetamide [5] (151.8 mg, 1.1 mmol) was added in one portion (which resulted in an immediate color change to green) and the mixture was vigorously stirred at the same temperature. The reaction was monitored by TLC and pH control (full conversion is indicated when the mixture reaches pH 7). After 20 h the reaction mixture was treated with Na_2SO_3 (0.5 g) and, after stirring at room temperature for 30 min, ethyl acetate (5 mL) was added. The organic layer was separated, and the water layer was extracted with ethyl acetate (3 × 10 mL). The combined organic extracts were washed with brine (5 mL), and dried over $MgSO_4$. After evaporation of the solvent, the crude product was purified by chromatography on silica gel (hexanes/ethyl acetate 1/1) to give 215 mg (81% yield, 99% *ee*) of isopropyl (2*R*,3*S*)-3-(acetylamino)-2-hydroxy-3-phenylpropanoate (**1**).

Modifications of the above procedure: see Table 1. For styryl olefins (Table 2), 1.0 equiv KOH and a 1:1 solvent/water ratio (15 mL) was employed. For reactions with anthraquinone-based ligands, $(DHQD)_2AQN$ (42.8 mg, 0.05 mmol, 5 mol%) was used instead of the PHAL ligand.

Large-scale synthesis of (2R,3S)-3-phenylisoserine hydrochloride (**9**): The above general procedure was followed by using isopropyl cinnamate (120.0 g, 0.631 mol, not corrected for purity, 96%, Lancaster), *t*BuOH (3.79 L), water (5.68 L), *N*-bromoacetamide (99.71 g, 0.694 mol, 96% pure upon titration) [5], $LiOH \cdot H_2O$ (28.32 g, 1.07 equiv, 0.675 mol) [6], $(DHQ)_2PHAL$ (4.914 g, 6.31 mmol, 1 mol%), and $K_2[OsO_2(OH)_4]$ (3.486 g, 9.08 mmol, 1.5 mol%). Reaction time: 4 h. To separate the ligand after completion of the reaction, the crude product was taken up in ethyl acetate (500 mL) and passed through a 11-cm sintered glass funnel covered with a 2.5-cm layer of silica gel. Product purification was accomplished by recrystallization from ethyl acetate/hexane 1:2 (4 mL g^{-1}). A second crop of material was obtained by trituration of the previously evaporated mother liquor with Et_2O (100 mL) and subsequent filtration. Yield 119.5 g (71% yield, 99% *ee*). Hydrolysis of this material (10% HCl, reflux, 4 h, followed by concentration and filtration) [12b] provided 92.5 g (68% over two steps) enantiomerically pure (2*R*,3*S*) **9** (m.p. 224–226 °C, $[\alpha] = -14.9$ ($c = 0.55$ in 6 N HCl, ref. −14.8) [14]; correct elemental analysis.

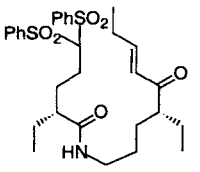
[5] a) *N*-bromoacetamide is commercially available (e.g. from Lancaster), but it should be recrystallized ($CHCl_3$/hexane 1/1) before use. We recommend preparation by a published procedure: E. P. Oliveto, C. Gerold, *Organic Syntheses Collective Volume IV*, 104–105. The purity of this oxidant was checked by acid–base titration: C. Bachand, H. Driguez, J. M. Paton, D. Touchard, J. Lessard, *J. Org. Chem.* **1974**, *39*, 3136–3138. b) S. C. Virgil in *Encyclopedia of Reagents for Organic Synthesis, Vol. 1* (Ed.: L. A. Paquette), Wiley, New York, **1995**, p. 691.

[6] Since the base/oxidant ratio should not exceed 1:1, the amount of hydroxide resulting from the initial oxidation of $K_2[OsO_2(OH)_4]$ to Os^{VIII}, releasing two equivalents of base, was taken into account.

[7] The use of isopropyl cinnamates instead of the methyl esters is preferable in terms of greater stability towards hydrolysis and enhanced regioselectivity under the reaction conditions. As in the case of compounds **1** and **2**, which are quite soluble in the reaction medium, the use of more than 50% (v/v) water may result in slightly increased regioselectivities.



3

[8] H. Becker, K. B. Sharpless, *Angew. Chem.* **1996**, *108*, 447–449; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 448–451: Corrigendum: The Experimental Procedure in this paper should include the following: "Asymmetric dihydoxylations of entries 1–8, and 16 in Tables 1 and 2 were run under buffered conditions in which the reaction is performed as desribed except that $NaHCO_3$ (252 mg, 3 mmol) was added at the beginning of the reaction". Also, in the syntheses of the ligands $(DHQD)_2AQN$ and $(DHQ)_2AQN$, it should be noted that the dihydroquinidine and dihydroquinine were dried over P_2O_5 under vacuum before use. Both $(DHQ)_2AQN$ and $(DHQD)_2AQN$ are commercially available (Aldrich); an improved synthesis will be reported elsewhere.

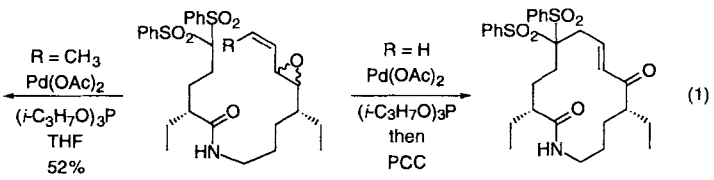
Palladium-Catalyzed Additions of Alkenyl Epoxides to Pronucleophiles: A Synthesis of the Macrolactam Aglycone of Fluviricin B1**

Barry M. Trost,* Marco A. Ceschi, and Burkhard König

The additions of alkenyl epoxides with pronucleophiles catalyzed by palladium constitutes a promising approach for constructing complex molecules.[1–3] However, the facility by which the palladium catalysts effect epoxide rearrangements,[4] which are intramolecular processes, makes their intermolecular capture a challenge. Macrocyclizations, which resemble intermolecular reactions, illustrate the delicate balance [Eq. (1)].



(1)

1a, R = H
1b, R = CH_3

2

Whereas, the simple vinyl epoxide **1a** cyclized smoothly to form the 14-membered ring **2**, addition of a methyl group at the terminus completely suppressed cyclization and led to isomerization of this alkenyl epoxide to the enone **3**.

The importance of such terminally substituted alkenyl epoxides stems from their use for chirality transfer to control relative configurations of distal centers. We therefore studied the characteristics of the pronucleophiles that would allow reaction with alkenyl epoxides, in order to provide a synthesis of the aglycone of fluviricin B1[5, 6] that exemplified their use in controlling stereochemistry of distal centers.

To explore the effect of substitution on the palladium-catalyzed addition of pronucleophiles to alkenyl epoxides, we chose the propenyl derivative **4** [Eq. (2)]. The unsubstituted bis(sul-

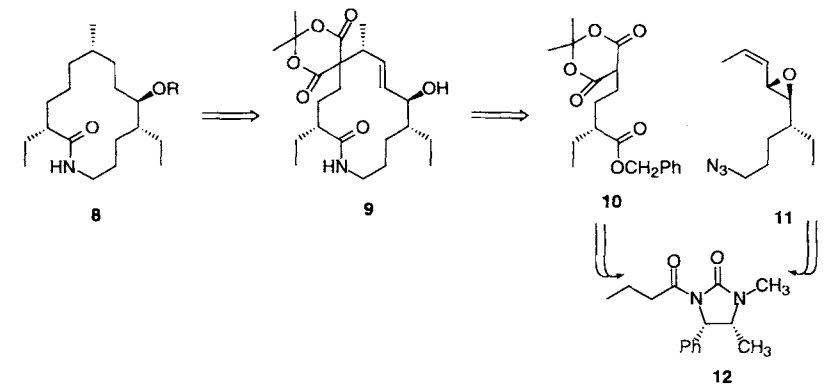
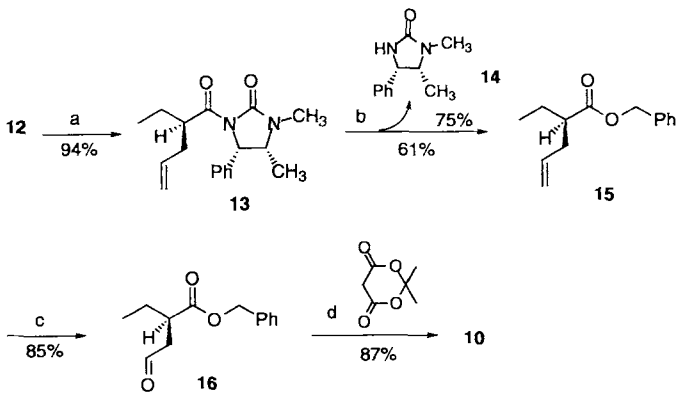
fone) **5a** as pronucleophile reacted smoothly to give the desired alkylation product **6a**[7] ([$(Ph_3P)_4Pd$], THF, reflux, 62%), whereas the monoalkylated derivative **5b** gave none of its corresponding dialkylated derivative **6b**. The unsubstituted ketosulfone **5c** underwent smooth alkylation to afford **6c**[7] ([$(dba)_3Pd_2]\cdot CHCl_3$, **7**, THF, reflux, 55%). More significantly, the substituted cyanosulfone **5d** also participated quite well, yielding the monoalkylated product **6d**[7] ($Pd(OAc)_2$, (i-$C_3H_7O)_3P$, THF, reflux, 55%). The best reaction involved use of a substituted Meldrum's acid (**5e**) as the pronucleophile: alkylation proceeded at room temperature to form the alkylated product **6e**[7] ($Pd(OAc)_2$, (i-$C_3H_7O)_3P$, THF, room temperature, 75%). In each of these cases NMR analysis reveals only one diastereomer, indicating good control of chirality transfer by the palladium catalyst.

We therefore chose to use Meldrum's acid as the pronucleophile for the synthesis of fluviricin B1 aglycone **8** as outlined in Scheme 1. This target is representative of the fluviricins (macrolactams active against influenza A virus as well as against pathogenic fungi). To use the concept of stereochemical relay via π-allylpalladium species to create the proper configuration at C-5, we required macrocycle **9** as synthetic precursor: bis-decarboxylation and reduction would create **8**. Splitting **9** into **10** and **11** yields two fragments that can both be synthesized from the imidazolidinone **12**, as revealed in Schemes 2 and 3.



Scheme 1. Retrosynthetic analysis of fluviricin B_1 (**8**, R = H).



Scheme 2. Asymmetric synthesis of the pronucleophile **10**. a) Lithium diisopropylamide (LDA), THF, −78 °C, $H_2C{=}CHCH_2Br$; b) $PhCH_2OH$, n-C_4H_9Li, THF, 0 °C; c) O_3, CH_2Cl_2, −78 °C, then Ph_3P; d) NaTeH ($NaBH_4$ + Te), C_2H_5OH, piperidine, HOAc, −30 °C → room temperature.

The stable imidazolidinone **12** was chosen as the chiral auxiliary because of its ease of access from ephedrine and its excellent diastereoselectivity in alkylations.[8] The alkylations to form **13**[7] and **17**[7] gave only one diastereomer detectable by NMR spectroscopy (>95% *de*). Either deacylation with lithium benzyloxide to **15**[7] or, remarkably, reduction with $LiAlH_4$ returned the chiral auxiliary **14**[7] in good yields. The monosubstituted Meldrum's acid **10** was best prepared by reductive alkylation of aldehyde **16** with sodium hydrogen telluride, generated in situ, under Knoevenagel conditions.[9]

For the azide half, direct reduction of **17** to aldehyde **19** could be accomplished with diisobutylaluminum hydride (DIBAL-H), but significant racemization accompanied the reduction—consequently, the two-step sequence via alcohol **18** was preferable. Asymmetric epoxidation[10] of the olefination product **20b** required larger amounts of catalyst for good yields, which suggests a low turnover number. On the other hand, only a single diastereomeric epoxide (**21a**) was observed. Olefination of the aldehyde **21b** under standard conditions gave a 7:1 (*Z*):(*E*) ratio of alkenes.

The key Pd-catalyzed alkylation employed a precatalyst generated by mixing [$(dba)_3Pd_2\cdot CHCl_3$] (1.5 mol%) and phosphite **7** (20 mol%) in THF. Sequential addition of equimolar quantities of the alkenyl epoxide **11** and Meldrum's acid **10** gave, after 12 h at room temperature, a 75% yield of the alkylation product **22** (Scheme 4) as a single diastereomer. Thus, chirality transfer occurred completely within experimental error. The assignment of the stereochemistry derived from mechanistic considerations[11] and the successful completion of the total synthesis.

Numerous attempts to effect both alkene hydrogenation and hydrogenolysis of the benzyl ester and azide proved futile. On the other hand, hydrogenolysis of the latter two functionalities did occur with ammonium formate in the presence of Pd/C;[12] though various protocols for the subsequent macrolactamization of the amino acid to give **23** failed, including the use of the Yamaguchi reagent,[13] bromotripyrrolidinophosphonium hexafluorophosphate[14] successfully effected macrolactamization in what may be a generally applicable procedure. The initial

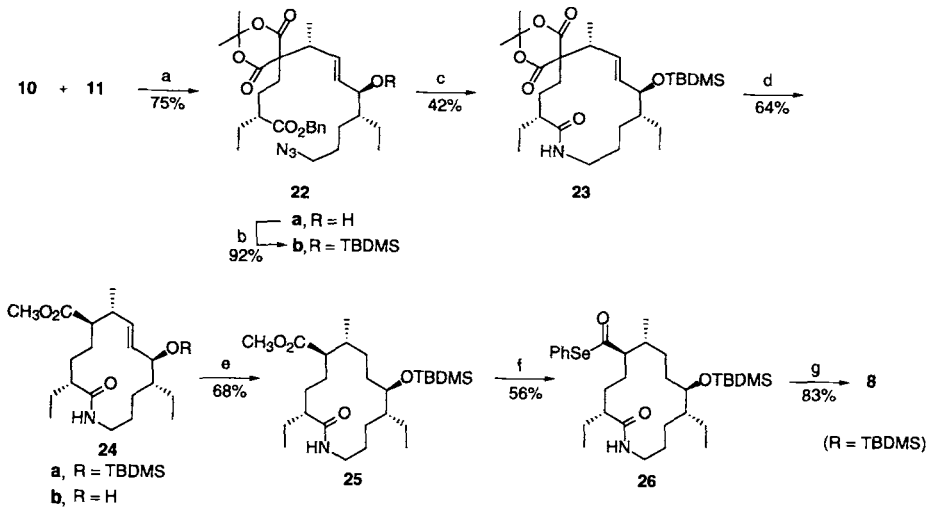

Scheme 4. Synthesis of the fluviricin B_1 aglycon **8**, R = TBDMS. a) See text; b) $TBDMSOSO_2CF_3$, 2,6-lutidine, CH_2Cl_2, 0 °C; c) 1.5% Pd/C, HCO_2NH_4, H_2O, 4 kbar, room temperature, 2. PyBroP, $(iC_3H_7)_2NC_2H_5$, 4-dimethylaminopyridine (DMAP), $PhCH_3$, 83 °C; d) LiOH, CH_3OH, H_2O, 4 kbar, room temperature, then DMSO, 120 °C; e) tetra-*n*-butylammonium fluoride (TBAF), THF, 0 → 40 °C, H_2 (1 atm), 10% Pd/C, C_2H_5OH, room temperature; $TBDMSOSO_2CF_3$, 2,6-lutidine, CH_2Cl_2, 0 °C; f) LiOH, KCN, CH_3OH, H_2O, THF, room temperature; $PhOP(O)Cl_2$, $(C_2H_5)_3N$, THF, 0 °C, then PhSeH, $(C_2H_5)_3N$, THF, 0 °C; g) $(C_4H_9)_3SnH$, azobisisobutyronitrile (AIBN), xylene, 175 °C.

decarboxylation gave a single diastereomeric monoester (**24a**, assigned based upon molecular modeling).[15] The double bond in silyl ether **24a** proved resistant to hydrogenation; however, allyl alcohol **24b** was reduced smoothly to give **25** after resilylation. Inability to form the ester from *N*-hydroxypyridine-2-thione[15] led to an alternative to decarboxylation for the removal of the remaining ester.[16] The acyl selenide **26** underwent a smooth decarbonylation[17] to the silyl ether of fluviricin B1, which was identical in every respect to an authentic sample (for physical data see Table 1). The monosilyl ether **8** (R = TBDMS) has previously been desilylated to fluviricin B1 aglycone **8** (R = H).

This reaction of terminally substituted vinyl epoxides provides a useful approach to chirality transfer. The selection of the pronucleophile is more critical than for unsubstituted vinyl epoxides. For a trisubstituted anion, steric hindrance appears to be the dominating influence as illustrated by the success of cyano-stabilized anions or those derived from Meldrum's acid. The stereochemical memory derives from its temporary storage as the π-allylpalladium species [Eq. (3)]. In this way, vicinal stereochemistry readily translates into 1,4-stereochemistry. The synthesis of the aglycone of the fluviricin family illustrates the utility of this methodology. The sequence also demonstrates some of the unusual properties of this ring system. The difficulty in hydrolyzing and decarboxylating the Meldrum's acid unit and in hydrogenating of the double bond illustrate two interesting aspects. In addition, the functionality present allows access to analogues. This convergent strategy in which the two halves are joined by a palladium-catalyzed alkylation and an amide formation may prove to be generally useful.

The Surprising Crystal Packing of Chlorinefluoride**

Roland Boese,* A. Daniel Boese, Dieter Bläser, Michail Yu. Antipin, Arkadi Ellern, and Konrad Seppelt

Dedicated to Professor Günter Schmid on the occasion of his 60th birthday

Interhalogen compounds are of special interest both from the synthetic and the theoretical standpoint. They are widely used as very strong oxidizing agents, and some of them, for example halogen fluorides, are typical amphoteric systems that exhibit Lewis acid Lewis base interactions in the liquid and solid states.[1, 2] As ions or neutral species they have become important objects of numerous structural investigations as they serve as model compounds in the studies of the chemical bond.[3, 4] Thus, the molecular structures of XF_3, XF_5 (X = Cl, Br, I), and some other polyhalogens are often considered as typical examples for the application of the VSEPR (Valence Shell Electron Pair Repulsion) model for describing molecular geometry.[4]

Strong intermolecular interactions between the halogen atoms (F···Cl, F···Br) were found in the crystals of neutral halogen fluorides, for example in the two polymorphic modifications of ClF_3[5] and BrF_3.[6] However, no short F···F contacts were observed in these structures. In most cases fluorine atoms act as bridging atoms, or do not participate in the intermolecular (interionic) interactions.

In general, X-ray diffraction studies of neutral interhalogen compounds are rather rare, because most of them are reactive and low-melting compounds, which causes difficulties in obtaining single crystals. Nevertheless, these studies are of great interest because they provide access to important information about the electronic nature of the intermolecular interactions between halogen atoms.

We report herein the molecular and crystal structure of the simplest interhalogen compound, chlorine monofluoride, ClF, at −188 °C. To the best of our knowledge, the solid-state structure of ClF is the only structure of the well-known family of halogen monofluorides that has ever been determined. There are a few objective reasons for this. Halogen monofluorides have very low melting and boiling points (e.g. ClF: −155.6 and −100.1 °C, respectively), and together with their very high oxidizing activity and moisture sensitivity this makes these compounds extremely difficult to handle. For example, ClF reacts readily with glass, so its storage and crystal growth in the usual thin-walled glass capillaries from the melt is very difficult. Furthermore, the crystallization point, which is essentially lower than the melting point, is almost at the limit of liquid nitrogen low-temperature devices for single-crystal diffractometers. All this was considered as a challenge to our developments in crystallization and low-temperature techniques. For the crystal packing of ClF we expected something similar to that observed for α-,[7] β-ICl[8] or IBr,[9] that is zigzag or herringbone patterns, governed by the intermolecular dipole interactions, with chlorine atoms surrounded by one or more fluorine atoms.

Surprisingly, the X-ray data show that in the crystal individual ClF molecules form infinite planar ribbons along the screw axis (space group $P2_1/c$), which are characterized by very short intermolecular Cl···Cl contacts (3.070(1) Å) between neighboring molecules (Figure 1). The ribbon planes are inclined to

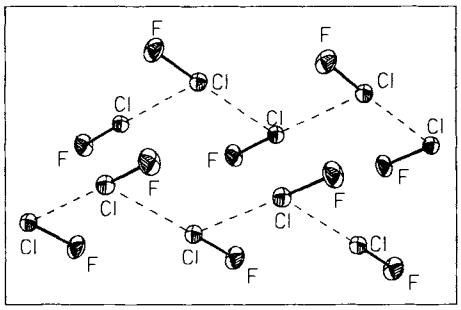

Figure 1. Perspective view of the crystal structure of ClF (ellipsoid plot (50%)), showing two rows of molecules, arranged along the screw axis.

the *a*, *b*, and *c* crystal axes by 74.7, 90, and 179.6°, respectively, and along the *c* axis they are antiparallel. In the ribbon the Cl atoms are arranged in a zigzag fashion, so each atom participates in two (symmetry equivalent) Cl···Cl contacts; the Cl···Cl···Cl angle is 87.5(1)°. One contact is directed along the prolongation of the F–Cl bond (the F–Cl···Cl angle is 178.8(1)°), and the other one is perpendicular to the same F–Cl bond (the corresponding angle is 93.5(1)°) (Figure 2). Between the ribbons there are only F···F contacts for which the shortest distance is 2.92 Å, which is a normal value for a van der Waals interaction.[10]

To our knowledge, the Cl···Cl contacts in the crystal of ClF are the shortest among the known Cl···Cl intermolecular distances in molecular crystals. In a recent study[10] a value of 3.50 Å is assumed as a typical distance for Cl···Cl contacts. In

Scuseria (Rice University, Houston, Texas) for his interest in the work and for providing computational recources.

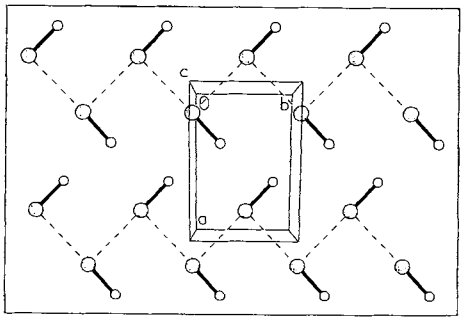

Figure 2. Packing of chlorinefluorine and the unit cell with a view down the c axis; the shaded spheres represent the chlorine atoms, the open circles the fluorine atoms.

solid chlorine, however, the intermolecular distances are 3.294(1) Å (see below).[11] The evidently strong intermolecular interactions in ClF in the solid state do not influence the Cl–F bond length of 1.628(1) Å very much, since the identical value was also obtained for ClF in the gas phase by a microwave study.[12]

We also[13] calculated the ClF monomer at MP2, B3LYP, and CCSD(T) levels of theory[14] using the 6-311 + G* basis set, which gave ClF distances of 1.673, 1.680, and 1.686 Å, respectively. These values are essentially longer than the experimentally determined data; on the other hand, the value calculated at the HF level (1.588 Å[13]) is much closer.

An approximate estimation of this distance with the Schomaker–Stevenson formula $d = R(x) + R(Y) - (0.095)\Delta(EN)$,[15] where R denotes the atomic covalent radii from the homohalogen dimers (0.710 Å for F, and 0.995 Å for Cl), and $\Delta(EN)$ is the electronegativity difference (equal to 1.0 for the pair F and Cl), results in a Cl–F distance of 1.610 Å. Taking into account that the bond lengths obtained by the X-ray method are usually longer than the data obtained in the gas phase, it is reasonable to suggest that the real internuclear Cl–F distance in the crystal should be slightly longer than 1.628 Å.

An interesting feature of the ClF crystal structure is its rather close similarity to that of chlorine,[11] where each Cl atom also forms two short intermolecular Cl···Cl contacts (3.294 Å) with nearly the same orientation as in ClF. The crystal structure of Cl_2 has planar, endless layers parallel to (100). In both structures there are zigzag chains of Cl···Cl···Cl interactions, but in ClF these chains are separated by F atoms thereby forming ribbons, whereas in Cl_2 the neighboring chains belong to one layer. The reason for this difference may be related with the inability of the F atoms to participate in bonding F···F interactions. The packing pattern in ClF also resembles that in 1,4-dichlorbenzene,[16] which exhibits T-shaped intermolecular Cl···Cl contacts. According to experimental[17] and theoretical[18] studies, the noble gas atoms in argon complexes of ClF were likewise found perpendicular to the F–Cl axis. From the molecular orbital point of view such an interaction may be regarded as involving bonding between a lone pair orbital of one Cl atom and an antibonding σ orbital of the F–Cl bond of a neighboring molecule. Modern theory on interatomic interactions, based on Bader's topological analysis of the total electron density distribution of a molecular system, describes this kind of "closed-shell interaction" as an interaction between the electron charge concentration (CC) and charge depletion (CD) areas in the electron valence shell of the interacting atoms.[19] Corresponding CC and CD areas may be related with the Lewis model of acid–base interactions, and these areas may be visualized in the Laplacian of the electron density $-\nabla^2\rho$.[20, 21]

Laplacian maps of the charge density were found to be very useful in analysis of the nature of the chemical bonds in terms of topological characteristics of the total electron density. Electron density distributions in crystals can be constructed with high accuracy from X-ray diffraction data and by using multipole models of the nonspherical atoms in the crystal (see reference [22] and references therein). In the present work we used the Hansen and Coppens multipole model[23] and the XD package programs[21] for the construction of an experimental electron density distribution in the ClF crystal and the calculation of some topological and other properties. Least-squares refinements of diffraction data with this model resulted in a strong decrease of R indexes ($R = 0.032$ and $Rw = 0.028$), and quite realistic values of multipole parameters. Values of $q(Cl) = +0.14$ and $q(F) = -0.14$ for the atomic charges, and a dipole moment of 1.2 D were calculated from the X-ray data. These values are in good agreement with the suggested polarity of ClF (Cl^+F^-, see discussions in references [24,25]), and with the experimental value of the molecular dipole moment (0.88 D[26]) as well as that obtained from theoretical calculations (1.01 D and 0.84 D in the HF and CI approximations[27, 28]).

The experimental map of the Laplacian of the electron density ($-\nabla^2\rho$) in the crystal of ClF in the plane of the interacting molecules is shown in Figure 3. It is clear that in the vicinity of

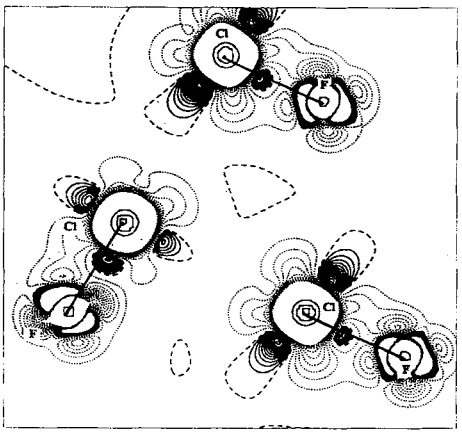

Figure 3. Laplacian of the electron density $-\nabla^2\rho(r)$ in the plane of three molecules of ClF, positive contour lines at 1, 2, 4, 6, 8... e Å^{-5} distances, zero contour lines dashed, and negative contour lines dotted.

Cl atoms the negative values of the Laplacian operator are concentrated not only in F–Cl bonds, but also in the directions perpendicular to these bonds. These peaks of the negative value of the Laplacian operator may be related with the charge concentration areas in the valence shell of the Cl atom. Each of these charge concentration peaks is directed to the neighboring Cl atoms where the Laplacian map indicates a corresponding charge depletion area along the prolongated F–Cl line. Thus, each Cl atom participates in two interactions between a Lewis base and a Lewis acid. A very similar Laplacian map, indicating the same type of interatomic interactions in the crystal, was obtained in the theoretical calculation of the topological charge density characteristics and Laplacian of the electron density in solid chlorine and its dimer.[28] For ClF (this work), the Cl_2 dimer, and Cl_2 in the crystal (see reference [28]), the (3, −1) bond critical points were found in the middles of the shortened intermolecular Cl···Cl distances (3.07 Å in ClF, 3.294 Å in solid Cl_2, and 3.37 Å in the Cl_2 dimer). The total electron density ρ and its Laplacian in these bond critical points are similar:

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1490 $ 17.50+.50/0

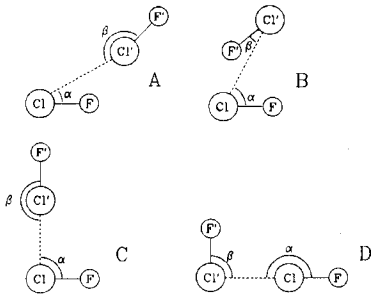

Figure 4. Orientation and angles of the ClF dimer calculated with different ab initio methods (stationary points each confirmed by frequency calculations): MP2: $\alpha = 30.7$, $\beta = 164.1°$ (A); $\alpha = 68.3$, $\beta = 10.9°$ (B); $\alpha = 179.2$, $\beta = 88.8°$ (D). B3LYP: $\alpha = 34.1$, $\beta = 160.1°$ (A); $\alpha = 177.9$, $\beta = 100.1°$ (D). CCSD(T): $\alpha = 31.2$, $\beta = 163.6°$ (A); $\alpha = 179.7$, $\beta = 85.0°$ (D) (no further angle scanning).

ρ: 0.135, 0.062, and 0.045 e Å^{-5} in ClF, Cl_2 crystal, and Cl_2 dimer, respectively; $-\nabla^2\rho$: 1.06, 0.805, and 0.713 e Å^{-5}, respectively, and the difference between the corresponding values are explained by the shortening of the Cl···Cl distances.

An ab initio energy surface scan was performed for the ClF dimer by using the 6-311 + G* basis set. The FCl···Cl′ angle α (Figure 4) was increased systematically from 0 to 180° with full optimization of the Cl···Cl′F′ angle β as well as the intra- and intermolecular distances. At the HF level of theory only one energetic minimum was detected for the linear arrangement ($\alpha = 0$, $\beta = 180°$), at the MP2 level three energy minima (A, B, and C or D, where C and D are equivalent), and with the B3LYP and the CCSD(T) method, two minima (A, D) were located. Configuration A represents the global energy minimum for all methods that include electron correlation.[29] A and B are mainly based on dipole interactions. However, the energy difference between configuration A and C (or D) decreases from 5.0 to 3.8 (MP2), 3.4 to 2.2 (B3LYP), and 4.8 to 3.8 kJ mol^{-1} (BSSE corrected).[30] The energy minimum for configuration B seems to be an artifact of basis set effects.[32] The intramolecular distances in the dimer vary from 1.672 to 1.676 (MP2), 1.676 to 1.686 Å (B3LYP), and the largest difference between both molecules ClF and Cl′F′ is represented in configuration C, in which the longer distance occurs for Cl′–F′ (reversed for D). This configuration also has the shortest Cl···Cl′ distance: 3.405 (MP2), 3.187 Å (B3LYP) and reflects the situation as found in the crystal lattice with the Cl lone pair of electrons donating into the antibonding σ-MO of Cl′–F′, thus causing a lengthening of the Cl′–F′ distance.

Although the global energy minimum of the ClF dimer was found for conformation A in the theoretical study of the dimer, the T-shaped conformation (C, D) also has a minimum which is energetically close to A, but is favored in the infinite ribbons of the crystal lattice. This demonstrates the stability of the Cl···Cl···Cl synthon.[32] The nature of the Cl···Cl interaction[33] in this polar molecule represents a cornerstone in the discussion of elliptical,[34] displaced spherical[35] van der Waals interactions. Alternatively, in simple terms, some positive charge is found in the prolongation of the F–Cl bond and some negative charge perpendicular to the bond at the chlorine atom, which holds the molecules together.

Experimental Section

Chlorine monofluoride was synthesized from ClF_3 and Cl_2 by using standard procedures [36], and purified by several low-temperature vacuum distillations in a stainless steel vacuum line. The pure ClF was kept and transported in a monel vessel with a special valve. On cooling with liquid nitrogen, a small amount of the compound was condensed several times into a thin-walled quartz capillary (diameter 0.3 mm), in order to passivate the inner surface. After the capillary had been filled, it was transferred to the diffractometer without interrupting the cooling process (to avoid bursting of the capillary) with the help of a special device, described previously elsewhere [37]. The single crystal was grown at −188 °C by applying the in situ crystallization technique using a miniature zone-melting method with an IR laser beam producing a molten zone in the capillary (Siemens-Challenge System) [38]. The data collection and structure determination were undertaken in the usual way at the same temperature [39].

[29] Approximately the same conformation for a ClF dimer was found in an SCF ab initio study: A. D. Buckingham, P. W. Fowler, *Can. J. Chem.* **1985**, *63*, 2018–2025.
[30] The basis set superposition error (BSSE) was determined by the counterpoise method which is essential for weakly bound complexes, see M Gutowski, J. G. C. M. van Duijneveldt-van de Rijdt, J. H. van Lenthe, F. B. van Duijneveldt, *J. Chem. Phys.* **1993**, *98*, 4728–4737.

[31] This is evident from the fact that the energy increases from 43 to 4.9 kJ mol^{-1} for configuration B by inclusion of the BSSE and even results in an endothermic binding energy for the dimer. The binding energies for configuration A and C(D) are −4.8 and −1.0 (MP2), −4.0 and 1.8 (B3LYP) and −4.4 and −0.6 kJ mol^{-1} for CCSD(T).

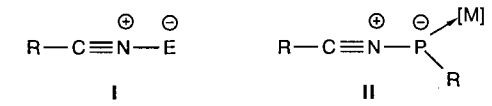
[39] Crystal system: monoclinic, space group $P2_1/c$, $Z = 4$, at −188 °C, a = 6378(1), b = 4.247(1), c = 6.425(1) Å, β = 104.55(3)°, V = 168.5(1) Å^3, ρ_{calcd} = 2.147 g cm^{-3}, μ = 1.73 mm^{-1}. Diffractometer Nicolet-Siemens R3m/V, $Mo_{K\alpha}$ radiation, graphite monochromator, λ = 0.7107 Å. A total number of 3747 reflections in the 2θ interval 2–90° were measured by using the Wyckoff scan technique (a half sphere of the reciprocal space in the interval 2θ = 2–60°, and two independent octants in the interval 2θ = 60–90°). During data collection some misalignment of the single crystal was observed (probably because of icing of the capillary at the low temperature) that resulted in relatively large variations of the intensities of the check reflections and high R_{int} value after averaging the equivalents (R_{int} = 0.130). Therefore, only one independent part of the total data set (one octant, 2θ = 2–75°) with 765 independent observable ($F_o > 4.0\sigma(F)$) reflections was used in further calculations. The structure was solved and refined (on F) in the anisotropic approximation (SHELXTL Plus programs Version 4.2) to R = 0.0357, Rw = 0.0401, and GOF = 1.73. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-406442.

Formation of 2*H*-1,2-Azaphosphole Tungsten Complexes by Trapping Reactions of Nitrilium Phosphane Ylide Complexes**

Rainer Streubel,* Hendrik Wilkens, Annette Ostrowski, Christoph Neumann, Frank Ruthe, and Peter G. Jones

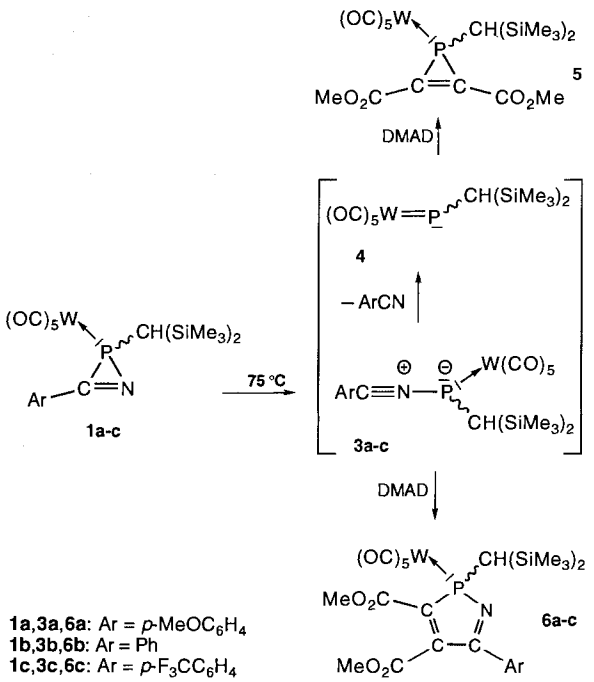
Dedicated to Professor Gottfried Huttner on the occasion of his 60th birthday

Nitrile oxides[1a] and nitrile imines[1a, 2] (**I**, E = O and E = NR, respectively; Scheme 1) are of great importance in heterocycle syntheses because of their versatility in 1,3-dipolar cycloadditions;[3] the properties of stable members of these classes of compounds have been thoroughly investigated. The synthesis of these 1,3-dipoles is usually based on readily available acyclic precursors.[1a, 2] Nitrile sulfides[4] (**I**, E = S) have until now only been identified by UV/IR spectroscopy[5] in inert matrices (e.g. PVC) at low temperature or as reactive intermediates by trapping reactions.[4] As far as we are aware, neither nitrilium phosphane ylides[6] (**I**, E = PR), nor their η^1 complexes (**II**), nor corresponding η^1 complexes of the above-mentioned nitrogen ylides are known. Our previous investigations of the thermal decomposition of a 2*H*-azaphosphirene tungsten complex in the presence of trapping reagents such as carbonyl,[7] phosphaacetylene,[8] or acetylene derivatives,[7, 9] provided evidence solely for the formation of a terminal phosphanediyl tungsten complex as a transient intermediate.[10] Here we report the synthesis and structural characterization of tungsten complexes of the novel 2*H*-1,2-azaphospholes,[11] which we explain on the basis of trapping reactions of transient nitrilium phosphane ylide tungsten complexes with dimethylacetylenedicarboxylate (DMAD; **2**).



Scheme 1. Propargylic resonance structures of various nitrile ylides **I** and nitrilium phosphane ylide complexes **II** (R = alkyl, aryl; [M] = metal complex fragment).

The thermal decomposition of 2*H*-azaphosphirene tungsten complexes **1a**[12] and **1b**, **c**[13] in toluene at 75 °C in the presence of DMAD (**2**) forms the 1*H*-phosphirene tungsten complex[9] **5** as the main product, and also the 2*H*-1,2-azaphosphole tungsten complexes **6a–c** and the corresponding aryl nitriles[14] (Scheme 2). The complexes are isolated by low-temperature chromatography and crystallization. The suggested structures of the complexes **6a–c** are based on solution NMR and IR spectroscopic and MS data (Table 1), and confirmed in the case of **6b** in the solid-state by X-ray structure analysis.[15]



Scheme 2. Postulated reaction course for the formation of the three- and five-membered rings of the complexes **5** and **6a–c**, respectively.

As reaction mechanism we propose a thermal opening of the three-membered ring to form the ylidic complexes **3a–c**, which then decompose to the terminal phosphanediyl tungsten complex **4** and the respective aryl nitrile, and subsequent ring-form-

[**] Chemistry of 2*H*-azaphosphirene complexes, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 5: Ref. [10].

Table 1. Selected NMR [a] and IR spectroscopic and MS data for **6a–c** [b].

6a: $^{13}C\{^1H\}$ NMR: δ = 2.7 (d, ^3J(P,C) = 2.0 Hz, $SiMe_3$), 3.3 (d, ^3J(P,C) = 2.6 Hz, $SiMe_3$), 19.2 (s, CH), 52.8 (s, OMe), 53.3 (s, OMe), 55.5 (s, $C_6C_4OCH_3$), 114.3 (s, *o*-Ph), 126.9 (d, ^3J(P,C) = 17.2 Hz, *i*-Ph), 130.5 (s, *m*-Ph), 143.1 (d, J(P,C) = 26.5 Hz), 161.5 (d, J(P,C) = 1.6 Hz), 162.7 (s, *p*-Ph), 162.9 (d, J(P,C) = 2.2 Hz), 165.7 (d, J(P,C) = 14.3 Hz), 166.2 (d, J(P,C) = 11.6 Hz), 196.8 (d, ^2J(P,C) = 6.6 Hz, *cis*-CO), 198.4 (d, ^2J(P,C) = 22.9 Hz, *trans*-CO); ^{31}P NMR: δ = 101.0 (s, ^1J(P,^{183}W) = 238.4 Hz); IR (KBr, $\tilde{\nu}$(C=O) region): $\tilde{\nu}$ = 2072 m, 1948 vs, 1919 s, 1741 m, 1724 m cm^{-1}; MS (EI, 70 eV, ^{184}W): *m/z*: 789 [M^+].

6b: $^{13}C\{^1H\}$ NMR: δ = 2.6 (d, ^3J(P,C) = 1.9 Hz, $SiMe_3$), 3.2 (d, ^3J(P,C) = 2.4 Hz, $SiMe_3$), 18.9 (s, CH), 53.0 (s, OMe), 53.2 (s, OMe), 128.4 (s, *o*-Ph), 128.8 (s, *m*-Ph), 131.7 (s, *p*-Ph), 134.4 (d, ^3J(P,C) = 16.6 Hz, *i*-Ph), 142.7 (d, J(P,C) = 25.9 Hz), 162.0 (d, J(P,C) = 1.4 Hz), 162.7 (d, J(P,C) = 13.1 Hz), 165.1 (d, J(P,C) = 14.2 Hz), 167.2 (d, J(P,C) = 11.5 Hz), 196.7 (d, ^2J(P,C) = 6.5 Hz, *cis*-CO), 198.0 (d, ^2J(P,C) = 23.1 Hz, *trans*-CO); $^{31}P\{^1H\}$ NMR: δ = 102.8 (s, ^1J(P,^{183}W) = 237.9 Hz); IR (KBr, $\tilde{\nu}$(C=O) region): $\tilde{\nu}$ = 2073 s, 1992 m, 1953 vs, 1926 vs, 1914 vs, 1745 s, 1719 s cm^{-1}; MS (EI, 70 eV, ^{184}W): *m/z*: 759 [M^+].

6c: $^{13}C\{^1H\}$ NMR: δ = 2.7 (s, $SiMe_3$), 3.2 (s, $SiMe_3$), 18.9 (s, CH), 53.0 (s, OMe), 53.4 (s, OMe), 123.7 (q, ^1J(C,F) = 272.6 Hz, CF_3), 125.9 (q, ^3J(C,F) = 3.7 Hz, *m*-Ph), 128.8 (s, *o*-Ph), 133.2 (q, ^2J(C,F) = 33.1 Hz, *p*-Ph), 137.6 (d, ^3J(P,C) = 17.0 Hz, *i*-Ph), 141.4 (d, J(P,C) = 25.1 Hz), 162.7 (d, J(P,C) = 13.2 Hz), 163.3 (d, J(P,C) = 4.1 Hz), 164.7 (d, J(P,C) = 13.9 Hz), 166.0 (d, J(P,C) = 10.7 Hz), 196.5 (dd, ^2J(P,C) = 6.5, ^1J(C,^{183}W) = 127.2 Hz, *cis*-CO), 197.6 (d, ^2J(P,C) = 23.0 Hz, *trans*-CO); $^{31}P\{^1H\}$ NMR: δ = 104.9 (s, ^1J(P,^{183}W) = 237.4 Hz); IR (KBr, $\tilde{\nu}$(C=O) region): $\tilde{\nu}$ = 2075 s, 1994 m, 1950–1914 vs (br.), 1741 s, 1725 s cm^{-1}; MS (EI, 70 eV, ^{184}W); *m/z*: 827 [M^+].

[a] In $CDCl_3$ at 25 °C; ^{13}C NMR: 50.3, ^{31}P NMR: 81.0 MHz. The deuterated solvents were used as internal and 85% H_3PO_4 as external standards. [b] Satisfactory C,H elemental analyses were obtained for **6a–c**.

ing reaction of the reactive intermediates **3a–c** and **4** with DMAD (**2**). This is based on the following findings. 1) The three-membered heterocycles cannot be converted to five-membered heterocycles by warming the complexes in solution in the presence of the corresponding aryl nitrile (**5** → **6a–c**), but neither can a ring contraction by extrusion of aryl nitrile (**6a–c** → **5**) be observed. 2) The relative amount of 2*H*-1,2-azaphosphole complex formed depends on the electronic influence of the *para* aryl substituents, in a way that can be interpreted in terms of increased reactivity and/or lifetime of the reactive intermediates **3a–c**; similar results have been obtained for *para*-substituted aryl nitrile sulfides.[16] The complexes **6a–c** display ^{31}P resonance signals in the range δ = 102–105 and characteristic ^{13}C chemical shifts of the carbon atoms of the five-membered rings in the range δ = 135–168;[17, 18] the magnitudes of the ^1J(^{31}P,^{183}W) coupling constants are about 238 Hz (cf. Table 1).

As also observed for 1*H*-pyrazoles[18] or η^1-phosphole complexes,[19] a notable feature of the molecular structure of complex **6b** in the crystal (Figure 1) is the planar five-membered ring. The bond lengths indicate localized double bonds; the C–N double bond (129.1(6) pm) is shorter than that in 1*H*-pyrazoles,[18] 2*H*-1,2,3-diazaphospholes,[11] or a 1,2,3,4-diazadiphosphole.[20] The phosphorus center displays a distorted tetrahedral coordination; the W–P bond length is 250.45(12) pm. Further investigations of the formation and reactivity of the 2*H*-1,2-azaphosphole tungsten complexes **6a–c** are currently in progress.

Experimental Section

6a–c: **1a** (1.62 g, 2.5 mmol), **1b** (1.54 g, 2.5 mmol), or **1c** (1.71 g, 2.5 mmol) was dissolved in toluene (7.5 mL). After addition of DMAD **2** (0.5 mL, ca. 5 mmol) the reaction mixture was stirred for 2 h (**6c**: 3 h) at 75 °C. When the reaction was complete (as monitored by ^{31}P NMR spectroscopy), the solution was evaporated to dryness in vacuo (ca. 0.1 mbar), and the residue subjected to low-temperature column chromatography on silica (– 20 °C, hexane/diethyl ether 97.5/2.5). The eluates were evaporated to dryness in vacuo (ca. 0.1 mbar), and the residues recrystallized from pentane.

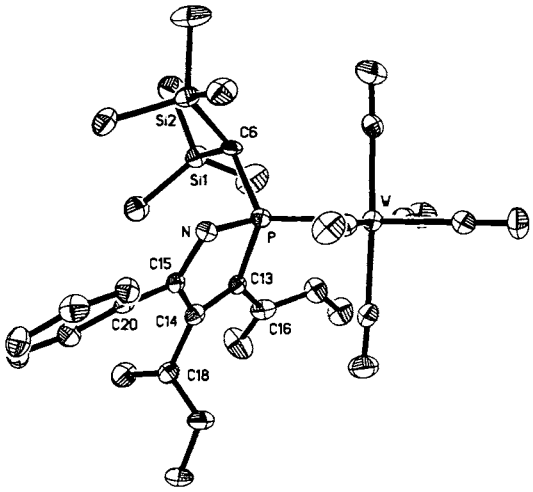

Figure 1. Molecular structure of complex **6b** in the crystal (ellipsoids represent 50% probability levels; hydrogen atoms omitted for clarity). Selected bond lengths [pm] and angles [°]: P–N 171.1(4), N–C15 129.1(6), C15–C14 149.7(6), C14–C13 134.3(6), C13–P 184.3(4); N-P-C13 91.8(2), P-C13-C14 108.2(3), C13-C14-C15 112.1(4), C14-C15-N 115.1(4), C15-N-P 112.7(3).

[6] To denote the zwitterionic form of the triatomic central framework of the compounds of type **I** with E = PR, and to draw attention to the relationship with other nitrogen ylides (the nitrile oxides, sulfides, and ylides), we propose the term nitrilium phosphane ylides. In recent publications we used the term phosphanitrile ylide for this reactive intermediate. Although confusion with $\sigma^3\lambda^5$-phosphanitriles (R_3PN), introduced by G. Bertrand, does not appear too evident, we decided in favor of the new term.

Palladium-Catalyzed Amidocarbonylation—A New, Efficient Synthesis of *N*-Acyl Amino Acids**

Matthias Beller,* Markus Eckert, Frank Vollmüller, Sandra Bogdanovic, and Holger Geissler

Industrial interest in racemic *N*-acyl amino acids has led to a broad range of applications such as chelating agents, detergents, and lubrication agents for boring machines.[1] In addition, enantiomerically pure, nonnatural amino acids are important in medical chemistry as components in peptidomimetics.[2] Asymmetric synthesis of amino acid derivatives has been studied intensively in recent years,[3] but none of the known processes has yet found industrial application. The development of technically feasible multicomponent reactions with low-cost starting materials will become even more important in the future.[4] An example of a successful, efficient, three-component reaction for the synthesis of *N*-acyl-α-amino acids from aldehydes, amides, and carbon monoxide, amidocarbonylation (W-3-CR), was first described by H. Wakamatsu in 1971.[5] Amidocarbonylation is an economic improvement on the classical synthesis methods and more environmentally friendly, since low-cost starting materials can be used and the production of stoichiometric amounts of side products is avoided. For the past 25 years, amidocarbonylation has been catalyzed solely by cobalt carbonyl complexes, but harsh reaction conditions and insufficiently active catalysts often lead to poor product selectivity, which has prevented technical exploitation of the reaction.

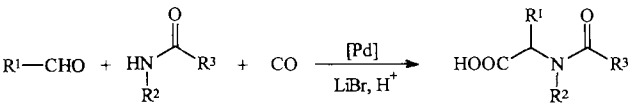
Despite the well-known reasons why only cobalt carbonyl complexes should be effective,[6] we now present amidocarbonylation reactions which have been successfully catalyzed by palladium and which show significant advantages over the cobalt system (Scheme 1).



Scheme 1. Palladium-catalyzed amidocarbonylation; R^1, R^2, R^3 = H, aryl, or alkyl; [Pd] = $PdBr_2$ or $[Pd(PPh_3)_2Br_2]$, for example.

We investigated the reaction of isovaleraldehyde with acetamide and carbon monoxide in the present of different metal complexes as part of a project aimed at developing new amidocarbonylation catalysts.[7] Palladium(II) halides proved to be fundamentally capable of catalyzing the reaction in the presence of two equivalents of triphenylphosphane. Subsequently, comprehensive screening was carried out to determine the characteristic reaction parameters for palladium-catalyzed amidocarbonylation (Table 1). Surprisingly, the presence of halide ions is essential for the reaction (Table 1, no. 2, 4 and 5). The order of activity (I > Br > Cl) correlates qualitatively with the C–X bond energy. A synergistic effect, doubling the rate of reaction without lowering the selectivity, was observed when a strong acid (for example H_2SO_4) was added as a cocatalyst (Table 1, no. 6). *N*-methylpyrrolidone (NMP) was found to be a particularly suitable solvent for the palladium-catalyzed amidocarbonylation reaction. Other aprotic solvents such as *N*,*N*′-dimethylformamide (DMF), *N*,*N*-dimethylacetamide (DMAc), and dioxane can also be used. A temperature and pressure study revealed that no further improvement in the reaction rate was achieved by increasing the temperature above 130 °C and the pressure above 60 bar CO.

Table 1. Selected palladium-catalyzed amidocarbonylation experiments [a].

No.	T [°C]	t [h]	Cat. [mol %]	LiBr [mol %]	H_2SO_4 [mol %]	Yield [%] [d]

9 [b]	120	60	0.25	35	1	99

[a] Isovaleraldehyde and acetamide (25.0 mL each of 1 M solutions in *N*-methylpyrrolidone) were treated with carbon monoxide. [b] The catalyst dibromobis(triphenylphosphane)palladium(II), was prepared in situ; 60 bar CO pressure. [c] The catalyst was palladium(II) bromide; 10 bar CO pressure. [d] Yield of isolated product.

With the new catalysts, it is now possible to carry out amidocarbonylation under the very mild conditions of 80 °C and 10 bar CO (Table 1, no. 7). Both palladium(II) (e.g., $PdBr_2$, $PdCl_2$) and palladium(0) (e.g., $[Pd_2(dba)_3]$ where dba = 1,5-diphenyl-1,4-pentadien-3-one, $[Pd(PPh_3)_4]$) compounds could be used as catalyst precursors. Palladium(II) bromide was shown to be particularly effective. This catalyst gave the highest ever turnover number (TON) of 25000 (mol product per mol Pd-cat.)

and the best-yet turnover frequency (TOF) of over 400 (mol product per mol Pd-cat. per hour) for an amidocarbonylation reaction (Table 1, no. 8).

The aldehyde and the amide components of the reaction were varied in order to illustrate the broad range of possibilities presented by the palladium-catalyzed amidocarbonylation (Table 2). Of particular interest are the good or very good yields

Table 2. Synthesis of *N*-acyl-α-amino acids by palladium-catalyzed amidocarbonylation [a].

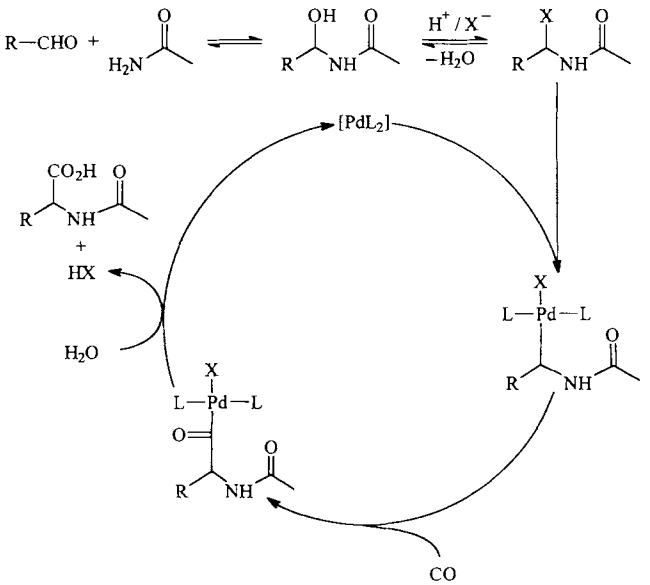
[a] Aldehyde and amide (25.0 mL each of 1 M solutions in *N*-methylpyrrolidone), 0.25 mol% dibromobis(triphenylphosphine)palladium(II), 1 mol% H_2SO_4, and 35 mol% LiBr were treated with 60 bar CO at 120 °C for 12 h. [b] Yield of isolated product.

obtained for *N*-acylarylglycine derivatives such as *N*-acetylphenylglycine (**5**)and *N*-acetyl-*p*-methoxyphenylglycine (**6**), and *N*-benzoyl-α-amino acid derivatives such as *N*-benzoylleucine (**4**), *N*-benzoylglycine (**8**), and *N*-benzoylphenylalanine (**9**). It was not previously possible to synthesize either of these groups of substances by cobalt-catalyzed amidocarbonylation![8] New synthesis strategies have therefore become available for the production of non-natural arylglycines, which are currently of great interest as components of antibiotics such as vancomycin.[9] Equally impressive are the reactions of *N*-methylamides in one-stage palladium-catalyzed amidocarbonylations to yield *N*-acetyl-*N*-methylleucine (**2**) and the sarcosine *N*-lauroyl-*N*-methylglycine (**7**). In contrast, the equivalent cobalt-catalyzed reaction, requires a two-stage synthesis procedure.[10]

Although in-depth mechanistic investigations have not yet been carried out, preliminary results show that the key steps in the palladium-catalyzed amidocarbonylation reaction mechanism are different from those in the cobalt-catalyzed reaction.[6, 11] The amidocarbonylation of benzaldehyde derivatives in the presence of palladium shows that the enamide intermediate, which is frequently discussed for the cobalt-catalyzed reaction mechanism, does not necessarily form during palladium-catalyzed reactions. The strong influence of halide and acid additives as well as the fact that both palladium(0) and palladium(II) compounds can be used as catalyst precursors add to the plausibility of the mechanism postulated in Scheme 2. Reaction



Scheme 2. Postulated mechanism for the palladium-catalyzed amidocarbonylation.

of the aldehyde with the amide leads, via a series of pre-equilibria, to the formation of an *N*-acyl hemiamidal intermediate which, after subsequent nucleophillic substitution, forms an α-haloamide. Oxidative addition inserts the Pd^0 species into the halogen–carbon bond of the α-haloamide to produce a (1-amidoalkyl)halopalladium(II) complex. After CO insertion the alkylpalladium species transforms into the corresponding acyl complex. Reductive elimination and hydrolysis of the acyl complex leads to the formation of the *N*-acyl-α-amino acid, and both the halide ion and the palladium(0) species revert to their original state. The proposed mechanism shows that amidocarbonylation takes place in the presence of CO only when catalyzed by palladium, whereas hydrogen (e.g. in synthesis gas) is also generally necessary for catalyst activation when cobalt catalysts are used. This result is a clear simplification in the process design with palladium catalysts particularly with respect to a possible continuous amidocarbonylation process.

The disadvantages of the cobalt-catalyzed amidocarbonylation, such as low catalyst activity and drastic reaction conditions, are overcome by the use of our palladium catalysts. In addition, important gaps in the range of application of this reaction have been filled. We now have catalysts available for the palladium-catalyzed amidocarbonylation reaction that can be controlled by the ligand sphere. Further investigations will show whether asymmetric amidocarbonylation can also be achieved.

Experimental Section

A 300 mL stirred reactor (No. 4561 from the Parr Company) with a magnet-driven propeller stirrer was used for the high-pressure reactions. General procedure: 25.0 mL each of 1 M solutions of the aldehyde and the amide in *N*-methylpyrrolidone (NMP), 0.25 mol% $[(PPh_3)_2PdBr_2]$, 1 mol% H_2SO_4, and

35 mol% LiBr were allowed to react under 60 bar CO at 120 °C for 12 h. The volatile components were removed under high vacuum, and the residue was taken up in a saturated aqueous solution of $NaHCO_3$ and then washed with chloroform and ethyl acetate. The aqueous phase was adjusted to pH 2 with phosphoric acid and extracted with ethyl acetate. The organic phases were then combined and dried over magnesium sulphate, and the solvent was removed under vacuum. The product was recrystallized from a suitable solvent mixture. All isolated compounds were characterized by means of NMR and IR spectroscopy and mass spectrometry. The purity of the products, as measured by HPLC, was >98%.

β-Silyl Diorganozinc Compounds— A New Class of Useful Zinc Reagents**

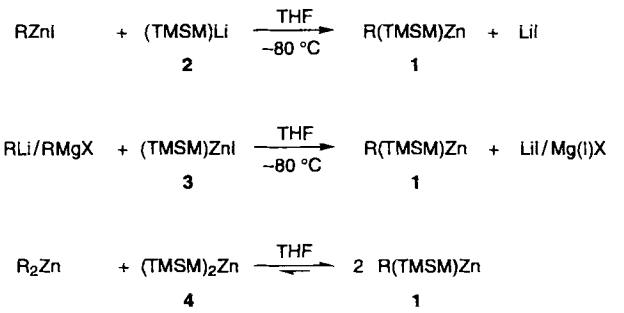
Stefan Berger, Falk Langer, Christian Lutz, Paul Knochel,* T. Andrew Mobley, and C. Kishan Reddy

Organozinc halides (RZnX) are useful organometallic intermediates for organic synthesis.[1] They are readily prepared by the direct insertion of zinc into organic halides,[2] display an exceptional functional group tolerance, and show a high reactivity toward a range of electrophiles in the presence of an appropriate transition metal catalyst.[1] Diorganozinc reagents (R_2Zn) have a significantly higher reactivity, but more importantly, they undergo highly enantioselective asymmetric additions to aldehydes to afford polyfunctional secondary alcohols.[3]

The drawback for some of these reactions[4] is that only one R group of R_2Zn is transferred. This disadvantage is especially disturbing in the case of the asymmetric addition to aldehydes when a highly functionalized, valuable R group has to be transferred, since a large excess of diorganozinc (2–3 equiv) is usually required to obtain high conversion and high enantioselectivity. Herein, we report a general solution to this problem with novel mixed β-silyl diorganozinc reagents.

Recently, Bertz et al. have shown that mixed cuprates RR'CuLi–LiX (R' is a nontransferable Me_3SiCH_2 (TMSM) group) are thermally stable but highly reactive.[5] This new class of copper reagents proves to be synthetically very useful in allowing the performance of 1,4-additions and acylations in high yields.[5] Stimulated by this work, we found that it is possible to prepare mixed diorganozinc compounds of the type R(TMSM)Zn (**1**) and to use them for Michael additions and enantioselective additions to aldehydes. The new zinc reagents **1** can be prepared by three methods: 1) by the reaction of (TMSM)Li (**2**) with an organozinc iodide, 2) by the reaction of (TMSM)ZnI (**3**) with an organolithium or -magnesium reagent, or 3) by the reaction of $(TMSM)_2Zn$ (**4**)[6] with a dialkylzinc compound (Scheme 1).

This last preparation is especially useful, because it allows the preparation of salt-free diorganozinc compounds **1**. This is of



Scheme 1. Preparation of the β-silyl organozinc compounds **1**.

prime importance for achieving high enantioselectivities in the asymmetric addition of diorganozinc compounds to aldehydes. The equilibrium between R_2Zn and R(TMSM)Zn as well as the evidence supporting the existence of the mixed diorganozinc compound **1** was studied in more detail with modern NMR techniques. The mixing of nearly equimolar amounts of $i Pr_2Zn$ and $(TMSM)_2Zn$ (**4**) ($\delta(CH_2) = -0.93$ and $\delta(CH_2) = -3.0$) in a ratio of 47:53 in [D_8]THF at $-20\,^{\circ}C$ leads to the appearance of a new set of signals attributed to the mixed species *i*Pr(TMSM)Zn (**1a**) ($\delta(CH_2) = -0.99$ and $\delta(CH_2) = -3.7$). New resonances for the *i*Pr and TMS groups were also observed. The ratio between remaining **4**, $i Pr_2Zn$, and the mixed species **1a**, determined by integration of the methylene groups of the TMSM of **4** and **1a**, was 20:15:65, from which an equilibrium constant of $K_{eq} = 14$ can be calculated. To confirm the structure of **1a**, we have acquired a gradient-selected, heteronuclear, multiple bond-coherence (HMBC) spectrum.[7] In this experiment we observed a cross-peak between the methylene protons of **1a** and the α-carbon (*CH*) of the *i*Pr groups, which suggests that both substituents are covalently bound to the same zinc center.[8] By mixing a primary diorganozinc compound (Et_2Zn) with **4**, a similar result was obtained. However, the exchange between Et(TMSM)Zn (**1b**) and $(TMSM)_2Zn$ (**4**) was fast on the NMR time scale at room temperature in contrast to that between *i*Pr(TMSM)Zn (**1a**) and **4**.

The thermal behavior of **1a** and **1b** were studied by variable temperature NMR spectroscopy. In addition to a dependence of the chemical shift on temperature, an exchange process between the three species, **1b**, Et_2Zn, and **4**, in solution was observed. The spectra for the methylene region of the TMSM groups at several temperatures are shown in Figure 1. For the methylene resonances of **1b** and **4** ($\Delta\nu = 42.3$ Hz), the coalescence temperature T_c is 305 K for the sample shown (1.4 M of **1b** in [D_8]THF) with the observed rate constant at the coalescence temperature for exchange $k = 94\ s^{-1}$ and $\Delta G^{\neq} = 63.2\ kJ\,mol^{-1}$.

In contrast, a 1.0 M solution of *i*Pr(TMSM)Zn (**1a**) has a T_c of 333 K ($\Delta\tilde{\nu} = 46.5$ Hz).[9] A dependence of the exchange rate on concentration was observed upon dilution of the concentrated sample of **1a** by a factor of 4. This resulted in a T_c which was greater than the boiling point of the solvent for the NMR spectroscopy (THF). Although the rate of exchange for the case of a primary alkylzinc derivative [EtZn(TMSM) **1b**] is faster than the rate of a secondary alkylzinc compound [*i*Pr(TMSM)Zn **1a**], the rates of exchange for both **1a** and **1b** are substantially faster than the observed rate of reaction with organic substrates.

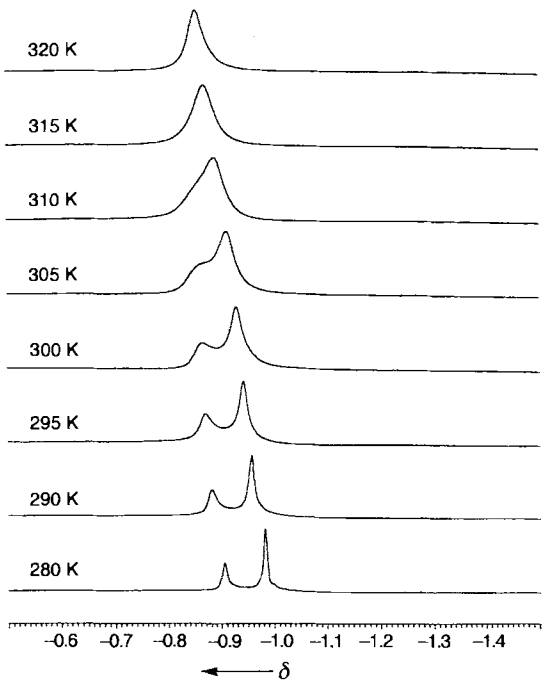

Figure 1. ^1H NMR spectra (500 MHz) for the region of methylene protons of the TMSM groups of **1b** and **4**.

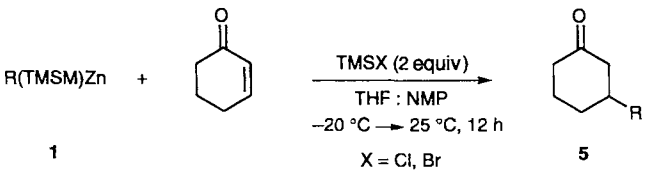
Recently, we have shown that diorganozinc compounds R_2Zn add to various Michael acceptors in THF/*N*-methylpyrrolidone (NMP) (2:1).[4] As only one group R is transferred in these reactions, one R group wasted. We found that the mixed zinc reagents **1** react readily with a typical enone like cyclohexenone to afford the 1,4-addition product **5** and that this 1,4-addition requires only about 1.2 equivalents of the mixed zinc reagent **1** (Scheme 2, Experimental Section, and Table 1). The use of TMSBr[10] to promote the Michael addition instead of TMSCl gives higher yields in all cases (Table 1).



Scheme 2. Michael additions of **1** to enones.

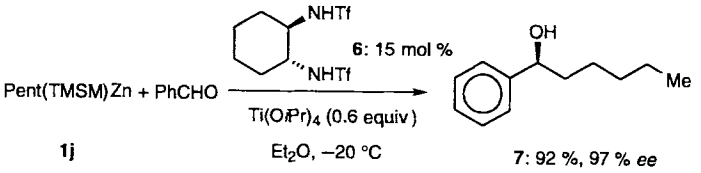
Table 1. Michael addition of R(TMSM)Zn (**1**) to cyclohexenone in THF/NMP in the presence of TMSBr (or TMSCl).

Entry	R	Zinc reagent **1**	Product **5**	Yield [%][a, b]
1	*c*-Hex	**1c**	**5a**	83 (76)
2	Bu	**1d**	**5b**	69 (52)
3	Ph	**1e**	**5c**	82 (45)
4	*p*-MeO-C_6H_4	**1f**	**5d**	87
5		**1g**	**5e**	84
6	$PivO(CH_2)_5$	**1h**	**5f**	52 (70)[c]
7	$EtO_2C(CH_2)_3$	**1i**	**5g**	49

[a] Yields of isolated analytically pure products. [b] Yields in parentheses refer to the reaction performed in the presence of TMSCl. [c] Yield obtained for the preparation of **1h** by mixing $(PivO(CH_2)_5)_2Zn$ with **4** (1:1) and performing the reaction in the presence of TMSBr.

The addition of a functionalized primary zinc compound such as **1h** is best performed by preparing this mixed zinc derivative with method (3) by mixing equimolar amounts of $(TMSM)_2Zn$ (**4**) and $(PivO(CH_2)_5)_2Zn$ and performing the reaction in the presence of TMSBr (Table 1, entry 6). Remarkably, the enantioselective addition of a mixed zinc reagent to benzaldehyde can also be performed. Thus, mixing $Pent_2Zn$ with **4** provides the mixed zinc species Pent(TMSM)Zn (**1j**, 1.8 equiv). Its addition to benzaldehyde (1 equiv) in the presence of (1*R*·2*R*)-1,2-bis(trifluoromethanesulfonamido)cyclohexane (**6**, 15 mol%)[3c] and $Ti(OiPr)_4$ (0.6 equiv) at $-20\,^{\circ}C$ for 9 h gives the desired chiral alcohol **7** in 92% yield and 97% *ee*. The new procedure requires significantly less zinc reagent (1.8 pentyl groups compared to 4–6 pentyl groups for previously described reaction conditions[3]) and opens the way to the enantioselective transfer of highly valuable R groups to aldehydes (Scheme 3).

In summary we have developed three methods to prepare mixed β-silyl diorganozinc compounds (**1**). These novel zinc reagents were characterized by NMR studies. The TMSM



Scheme 3. Enantioselective addition of Pent(TMSM)Zn (**1j**) to benzaldehyde.

group plays the role of nontransferable ligand. The zinc reagents **1** undergo efficient 1,4-additions in NMP/THF solvent mixtures and substantially improve the highly enantioselective addition to aldehydes.

Experimental Section

Typical procedure for the 1,4-addition of **1** to enones (example of **5a**): **1c** (1.0 equiv), prepared by the reaction of *c*-HexZnI with (TMSM)Li (−80 °C to −30 °C, 0.5 h), was treated at −20 °C in THF/NMP (2:1) with cyclohexenone (about 0.7–0.8 equiv) for 5 h in the presence of trimethylsilyl chloride (TMSCl, 2.0 equiv) or TMSBr (2.0 equiv). The yield of **5a** was 76% and 83%, respectively.

Example of **5c**: A dried and argon-flushed, three-necked, 50 mL flask was charged with TMSMZnI (12 mmol, prepared by zinc insertion from TMSMI (2.5 g, 12 mmol) and zinc dust (2.6 g, 40 mmol)) in THF (6 mL). Phenyllithium (12 mmol) was slowly added at −50 °C, followed after 30 min of stirring by NMP (2 mL), cyclohexenone (0.75 g, 8 mmol), and TMSBr (2.4 g, 16 mmol) at −50 °C. The reaction mixture was allowed to warm slowly to room temperature and then stirred for 12 h. After diluting with THF (20 mL), quenching with HCl solution (10%, 20 mL) and stirring for 15 min, the reaction mixture was worked up as usual. The crude product was purified by flash chromatography (hexanes/ diethyl ether 9:1) to yield pure **5c** (1.15 g, 82%) as a colorless oil. For less reactive aryl or primary alkyl (TMSM)zinc, the reaction mixture was stirred at 25 °C for 12 h.

Typical procedure for the enantioselective addition of **1** to an aldehyde (example of the preparation of **7**): A dried and argon-flushed 50 mL Schlenk flask was charged with (1*R*,2*R*)-1,2-bis(trifluoromethanesulfonamido)cyclohexane (**6**, 0.38 mmol, 15 mol%), $Ti(OiPr)_4$ (0.45 mL, 1.5 mmol, 0.6 equiv), and diethyl ether (3 mL). This catalyst solution was cooled to −20 °C. Meanwhile $Pent_2Zn$ (0.45 g, 2.1 mmol, 0.9 equiv) and $TMSM_2Zn$ (0.56 g, 2.3 mmol, 0.9 equiv) were mixed at 25 °C in another Schlenk flask. The resulting Pent(TMSM)Zn **1j** (1.8 equiv) was slowly added to the catalyst **6**. After 10 min, benzaldehyde (0.26 g, 2.45 mmol, 1 equiv) was added. The reaction mixture was stirred at −20 °C for 9 h and worked up as usual. The crude product was purified by flash chromatography (hexanes/diethyl ether 2:1) to yield analytically pure **7** (0.40 g, 92%) with 97% *ee* (HPLC, Daicel, Chiracel OD, heptane/isopropyl alcohol 97:3). α_D^{20} −36.4 (*c* = 4.2, $CHCl_3$).

[8] The corresponding cross-peak between the α-proton of the *i*Pr group and the α-carbon of the TMSM group was not observable due to coupling of the α-proton with the *i*Pr methyl groups. Attempts to acquire a selectively decoupled HMBC spectrum failed to reveal the weak couplings across the zinc center.

[9] Due to the chemical shift dependence on temperature, Δν changes as a function of temperature. Values for Δν at the coalescence temperatures were extrapolated for both the ethyl (**1b**) and isopropyl (**1a**) groups from low temperature chemical shift data. Since Δν is quite similar in the primary and secondary cases, the observed difference in fluxional behavior arises from a difference in chemical behavior.

Gas-Phase Reaction of Tetraborane(10) with Allene: The Fluxional *arachno*-1-Carbapentaborane(10) Isomeric System and Derivatives 1,2- and 1,3-Me_2-1-CB_4H_8; Analogies in 1-CB_4H_{10}, MeB_5H_{10}, and $B_5H_{10}^-$**

Mark A. Fox, Robert Greatrex,* Matthias Hofmann, Paul von R. Schleyer,* and Robert E. Williams

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

Unsaturated compounds such as alkynes,[1, 2] alkenes,[3, 4] and enynes[5] react in the gas phase with boranes, for example B_4H_{10}, to give a variety of remarkable products, often in which the C–C bonds have been cleaved.[6] We now report the identification of a fluxional monocarbapentaborane isomeric system, *arachno*-1,3- (**1a**) and *arachno*-1,2-Me_2-1-CB_4H_8 (**1b**) from the quenched reaction of B_4H_{10} with $H_2C{=}C{=}CH_2$ (Scheme 1). Whereas this reaction is also a superior synthetic route to the *arachno*-carbapentaborane 1-Me-2,5-μ-CH_2-1-CB_4H_7 (**2a**),[1] there was no sign of the basket-like ethanotetraborane derivative 2,4-$(MeCHCH_2)B_4H_8$ (**3**), which is the main product under hot–cold conditions.[7] The present investigation also clarifies earlier findings on the isoelectronic compounds CB_4H_{10}[8, 9] and $B_5H_{10}^-$.[9, 10]

In 1973 Matteson and Mattschei obtained a compound, believed to be CB_4H_{10} (m/z = 65, $M-1$),[8] by the reduction of tris(dichloroboryl)methane with lithium borohydride. Although noting an "infra red spectrum somewhat resembling that of pentaborane(11)", the authors did not assign a structure. In 1976 Williams predicted that the *arachno* constitution **4** should be preferred for CB_4H_{10} (the parent compound of **1a** and **1b**, see Figure 1).[9] Although in the *absence* of bridge-

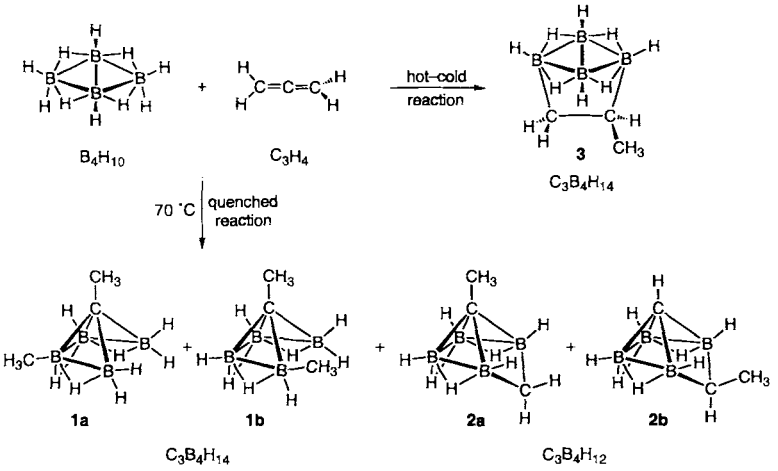

Scheme 1.

hydrogen competition carbon usually prefers a lower coordination site, 1-CB_4H_{10} (**4**) should be more favorable than alternative configurations (see below) because of the optimal locations of the three bridging hydrogen atoms.[9] About the same time Shore et al.[10] reported that isoelectronic $B_5H_{10}^-$ was produced by the reaction of hydride (KH) with pentaborane(11), and from the reaction of B_6H_{12} with NH_3. Although no structure was suggested,[10] an *arachno* arrangement like **4** also seems likely. The fluxional processes that take place in these systems are related to observations by Osborne et al. on the methylpentaborane(11) isomers.[11]

The NMR data[12] of **1** reveal two methyl groups, one attached to carbon and one to boron, and are consistent with the presence of five fluxional hydrogen atoms and single nonfluxional *exo*-terminal hydrogen atoms on three of the four boron atoms. This suggests a rapidly interconverting mixture of isomers **1a** and **1b** (see Figure 2). The mass spectrum gave a parent peak at $m/z = 93$ (corresponding to $C_3B_4H_{13}^+$, $M-1$), which, with the other experimental findings, points to a $C_3B_4H_{14}$ constitution. This was unexpected!

The rate-determining step in the reaction of B_4H_{10} with many unsaturated hydrocarbons is known to involve thermolysis, that is, elimination of H_2 to give B_4H_8 as the reactive species.[13] Addition of B_4H_8 to allene, C_3H_4, would lead to **2a** or **2b**, $C_3B_4H_{12}$. However, the formation of **1**, $C_3B_4H_{14}$, suggests that hydroboration of allene with B_4H_{10} can occur concurrently! Formally, **3** might also be formed by addition of B_4H_{10} to allene. In contrast to **1a**, **1b**, **2a**, and **2b**, **3** has C-C-C connectivity and is considerably higher in energy than **1a** (13.1 kcal mol^{-1}).

We now report the use of the ab initio/IGLO/NMR method[14] to establish the structures of **1**, CB_4H_{10}, and $B_5H_{10}^-$, and to investigate their exchange mechanisms. Relative energies as well as ^{11}B and ^{13}C NMR chemical shifts (IGLO/DZ//MP2(fc)/6 – 31G*)[15] computed[16] for the *arachno* parent compound **4** and possible isomers of its dimethyl derivative are given in Figures 1 and 2, respectively.[17] Since the computed energy of the *endo*-methyl isomer **1c** is significantly higher than that of **1a** or **1b** (Figure 2), it is not an important component in the system. (The bridging methylene groups in **2a** and **2b** are necessarily forced to be *endo*.) Experimental ^{11}B NMR chemical shifts of **1** do not compare favorably with averaged values computed for **1a** or **1b** (see Table 1). However, assuming a rapid equilibrium, averaging over **1a** and **1b** gives values closer to those from experiment. Isomer **1a** is lower in energy than **1b** and should be present to a greater extent in the mixture. Data, for example, for a 4:1 weighted average for **1a**:**1b** provide convincing support for the proposed structures.

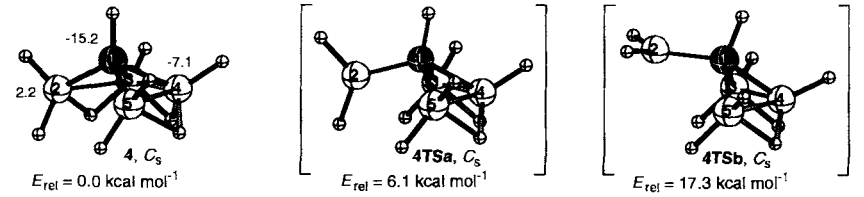

Figure 1. Computed relative energies and geometric parameters for CB_4H_{10} structures **4**, **4TSa**, and **4TSb** as well as IGLO/DZ chemical shifts for minimum **4**.

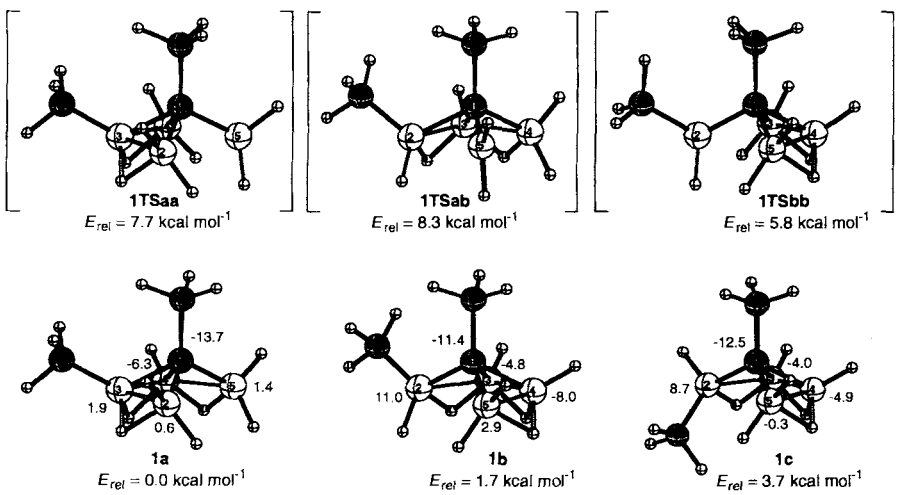

Figure 2. Computed relative energies and geometric parameters for various Me_2-1-CB_4H_8 structures as well as IGLO/DZ chemical shifts for minima **1a–c**.

With the parent compound **4** (see Figure 1) we first localized transition structures involved in the exchange of bridging and *endo* hydrogen atoms (**4TSa**, E_{rel} = 6.1 kcal mol^{-1}) as well as the exchange of *endo* and *exo* hydrogen atoms (**4TSb**, E_{rel} = 17.3 kcal mol^{-1}). In both **4TSa** and **4TSb**, a boryl group is formed at B2, and the B2–B3 bridging hydrogen becomes a terminal hydrogen atom at B3. A small rotation of the $B2H_2$ group about the C1–B2 bond leads from **4** (torsional angle H-C1-B2-H = 11.5°) to **4TSa** (H-C1-B2-H 0°) but preserves the *exo*/*endo* character. The favorably oriented (formally empty) p orbital at B2 in **4TSa** hyperconjugates effectively. In **4TSb**, $B2H_2$ is perpendicular to the plane of symmetry. The hyperconjugation in **4TSb** is not effective, and the relative energy of **4TSb** is 11.2 kcal mol^{-1} higher than that of **4TSa**. Accordingly, scrambling

Table 1. Comparison of the computed ^{11}B NMR chemical shifts for 1,3- (**1a**) and 1,2-Me_2-1-CB_4H_8 (**1b**) with the experimentally observed values.

Boron atom	**1a**	**1b**	**1a**:**1b** [a] 50:50	**1a**:**1b** [a] 80:20	exp. [b]
BMe	1.9	11.0	6.5	3.7	6.6
2BH [c]	−2.85	−0.95	−1.9	−2.4	−1.3
1BH	1.4	−8.0	−3.3	−0.5	1.6

[a] Average of the shifts for the relevant boron atom(s) in **1a** and **1b**, weighted as indicated. [b] In $CDCl_3$ at 298 K referenced externally to $BF_3 \cdot OEt_2$ ($\delta = 0.0$; see ref. [12]). [c] Average of the shifts for the boron atoms adjacent to the BMe group.

of bridge and *endo* but not of *exo* hydrogen atoms is observed for the dimethyl derivatives **1a** and **1b**. Indeed, the transition states for the degenerate rearrangements of **1a** (**1TSaa**) and **1b** (**1TSbb**) and for the conversion of **1a** into **1b** (**1TSab**, Figure 2) have relative energies comparable to that of **4TSa**. In contrast, a structure corresponding to C1,B4-dimethyl substituted **4TSb** has a much higher computed energy of 20.0 kcal mol^{-1}.

Further computations on CB_4H_{10} isomers confirm the benefits of favorable hydrogen bridging. Attempts to optimize 2- and 3-carbapentaboranes resulted in structures higher in energy than **4**.[18] The mass spectrometrically observed $CB_4H_9^+$ ion[8] has a stable B_5H_9-like *nido* structure. The same is true for the $C_3B_4H_{13}^+$ ion, which incorporates CH_3C and *exo*-CH_3B groups.

Pentaborane(11), the borane isoelectronic with **4**, is isostructural except for the additional hydrogen atom oscillating rapidly between the B1/B2 and B1/B5 bridging positions.[19] As further hydrogen scrambling does not take place, B_5H_{11} appears to have effective C_s symmetry on the NMR time scale. Consequently, the methyl derivative exists as a mixture of isomers, assigned 2-*exo*- and 3-*exo*-MeB_5H_{10}, in a temperature-dependent equilibrium.[11] A ratio of 1:2 was found from the ^{11}B NMR spectrum at −35 °C, and $\Delta H^0 = 300 \pm 30$ cal mol^{-1} was derived for a neat sample. As for the monocarboranes **1a** and **1b**, the most stable isomer has a Me-substituted basal boron atom, which is not part of the opened edge (B2/B5). According to our computations the stability of the MeB_5H_{10} isomers decreases in the order 4- ($E_{rel} = 0.0$ kcal mol^{-1}), 5-*exo*- (0.57), 2-*exo*- (0.71), 3- (0.81), 1- (2.30), 2-*endo*- (3.17), and 5-*endo*-MeB_5H_{10} (3.18).

Deprotonation of B_5H_{11} gives the fluxional $B_5H_{10}^-$ ion, for which average ^{11}B NMR chemical shifts of $\delta = -13.2$ (4B) and −52.0 (1B) were reported.[10] Structural and energetic features of the $B_5H_{10}^-$ minimum **5a** (isostructural with **4**) and transition structures **5TSa** and **5TSb** (corresponding to **4TSa** and **4TSb**, respectively, Figure 3), are analogous to those for the CB_4H_{10} system (Figure 1). However, the boron atom B1 in the apical position allows a B1−B2 hydrogen bridge. Consequently there are additional low-in-energy *arachno*-$B_5H_{10}^-$ minima: for example, **5b**, with unbridged B2−B3, and **5c**, without the B3−B4 hydrogen bridge, have energies of −0.05 and 6.3 kcal mol^{-1} relative to **5a** (MP2(fc)/6-31G* + 0.93 ZPE).[20] Barriers for the **5a**–**c** interconversion (via **5TSab**, **5TSbc**, and **5TScc**) are low, like those for the degenerate rearrangement of **5a** via **5TSa**. Averaging the individual ^{11}B NMR chemical shifts to effective C_{4v} symmetry gives $\delta = -4.2$ (4B), −57.4 (1B) for **5a** and

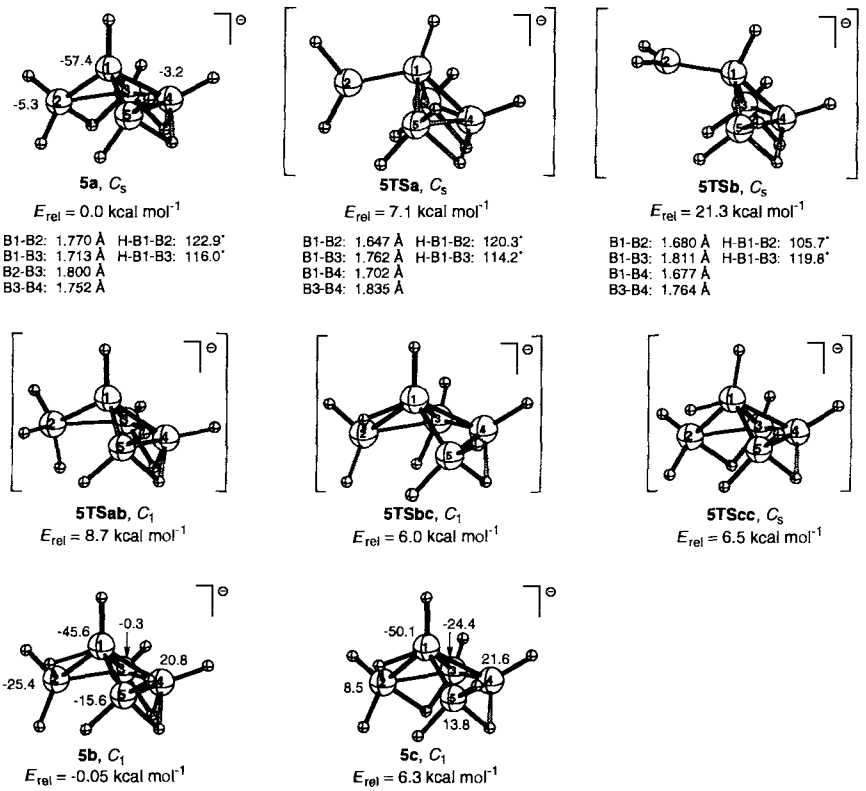

Figure 3. Computed relative energies and geometric parameters for various $B_5H_{10}^-$ structures as well as IGLO/DZ chemical shifts for minima **5a**–**c**.

−5.1 (4B), −45.6 (1B) for **5b**. The experimental NMR data should correspond to an average between **5a** and **5b**, since both have almost the same energy. The average value $\delta = -51.5$ (1B) agrees well with the experimental value of −52.0,[10] but the (4B) data do not match the reported −13.2. However, this was a typographical error;[21] the correct experimental value $\delta = -3.2$ (4B)[21] agrees well with the value of −4.5 derived theoretically. This supports the conclusion that both $B_5H_{10}^-$ structures **5a** and **5b** are present in solution.

We have isolated the smallest *arachno*-carbaborane, dimethyl-1-carbapentaborane(10), and characterized it as a mixture of rapidly interconverting isomers 1,3-Me_2-1-CB_4H_8 (**1a**) and 1,2-Me_2-1-CB_4H_8 (**1b**). The formation can be explained as the hydroboration reaction of B_4H_{10} with allene without thermolysis of the former. *Endo*-bridge hydrogen scrambling is facile due to hyperconjugative stabilization of the boryl groups that are present in the transition states. The same is true for the parent compound 1-CB_4H_{10}. Isoelectronic $B_5H_{10}^-$ is also fluxional, and the isomers with varying hydrogen-bridge positions have almost the same energy.

Experimental Section

In a typical experiment B_4H_{10} (0.5 mmol) and $H_2C{=}C{=}CH_2$ were heated for 35 min at 70 °C in a 1-L Pyrex bulb, and the reaction was quenched by pumping the volatiles into a trap immersed in liquid nitrogen. Low-temperature distillation of the combined volatiles from several reactions yielded a fraction with a main cut-off at $m/z = 92$. NMR spectroscopy showed it to consist predominantly of the methylene-bridged species **2a**, together with very small amounts of the minor isomer 2,5-μ-MeCH-1-CB_4H_8 (**2b**) and the new arachno species **1**. When this mixture was warmed to room temperature, **2** decomposed leaving **1** unchanged. Subsequent refractionation yielded a sample of **1** in an overall yield of 1% (cut-off $m/z = 93$). It is stable indefinitely at room temperature both in chloroform and in toluene.

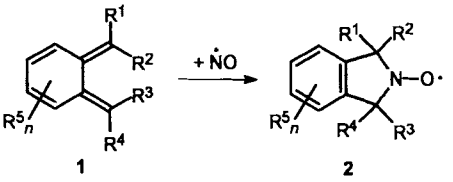
A Novel Method for Detecting Nitric Oxide (NO) by Formation of Fluorescent Products Based on Cheletropic Spin Traps

Michael Bätz, Hans-Gert Korth,* and Reiner Sustmann*

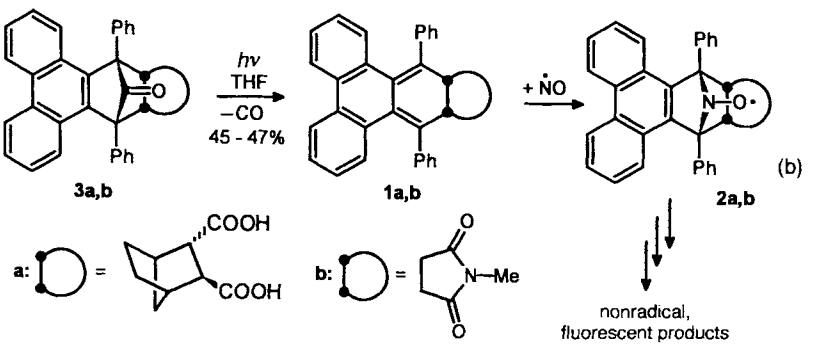
Nitrogen monoxide is an important intra- and intercellular signal molecule.[1] In recent years we have developed specific methods for detecting NO on the basis of "NOCTs" (*N*itric *O*xide *C*heletropic *T*raps, **1**), which transform NO by a formal cheletropic reaction into cyclic nitroxide radicals that can be monitored by EPR spectroscopy.[2]

This method has been successfully applied in investigations of the cytotoxicity of NO[3] and other aspects of the chemistry of NO.[2b] However, a general disadvantage of applying nitroxide radicals in biological environments lies in their markedly reduced lifetime due to facile reductive degradation to hydroxylamine derivatives.[4] We report here on a novel method based on the NOCT concept that uses fluorescence spectroscopy as a sensitive probe for detecting the trapped nitric oxide. We take advantage of the fact that aromatic π systems that are formed by reaction of NO with suitably selected NOCTs [Eq. (a)] exhibit



(a)

fluorescence properties. Therefore, the sensitivity is significantly increased over that of EPR spectroscopy, and the limited lifetime of the initially formed nitroxide radicals beneficially used.[5] In analogy to our current synthetic strategy, the stable cyclic *o*-quinodimethane derivatives **1**[6] were prepared as prototypes for FNOCTs [*F*luorescence *N*itric *O*xide *C*heletropic *T*raps; Eq. (b)].



(b)

Phencyclone[7] reacts with norbornene-2,3-(*E*)-dicarboxylic acid and *N*-methylmaleinimide to yield the bridged ketones **3a** (84%, m.p. 282 °C) and **3b** (50%, m.p. 297–298 °C), respective-

ly.[8] Compounds **3a** and **3b** are converted by photolysis ($\lambda = 300$ nm) into **1a** and **1b** (yields of isolated products 47% and 45%, respectively).[8] The *o*-quinodimethane derivatives **1a** and **1b** are stable at room temperature in the presence of oxygen and do not decay by reactions typical for *o*-quinodimethanes.[2] The two carboxyl groups confer sufficient solubility to **1a** in buffer solution at physiological pH.

The UV/Vis spectra of **1a** (Figure 1, curve a) and **1b** are characterized by broad absorption bands at λ_{max} (ε) = 450 nm (8300;

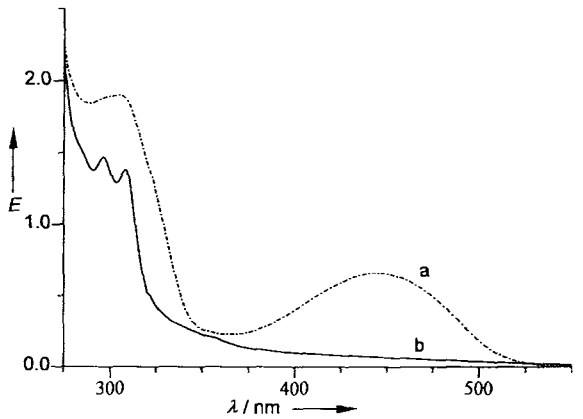

Figure 1. a) UV/Vis spectrum of **1a** (10^{-4} M) in phosphate buffer pH 7.4. b) Spectrum of a) after addition of NO (final concentration 5×10^{-4} M).

in phosphate buffer pH 7.4) and λ_{max} (ε) = 384 nm (8700; in THF), respectively, as is typical for *o*-quinodimethanes. This band is no longer detected immediately after addition of an excess of NO (in the same solvent; Figure 1, curve b). Instead, nitroxide radicals **2a** (Figure 2) and **2b** can be identified

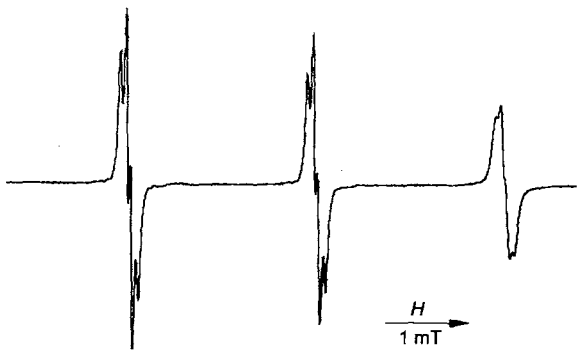

Figure 2. EPR Spectrum (9.4 GHz) of **2a** in THF at 20 °C.

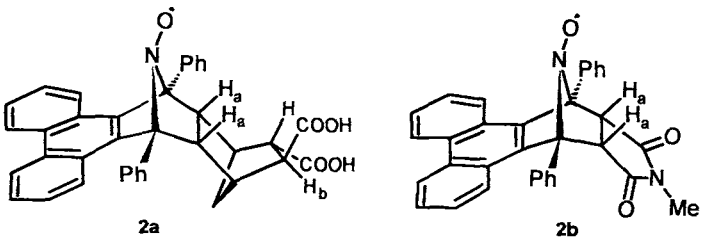
by EPR spectroscopy. Based on the hyperfine splitting patterns, we assign the structures displayed in Scheme 1 to the nitroxides.

Radicals **2a** and **2b** are not very persistent and decay to nonradical products. Kinetic analysis of the time evolution of the EPR signals at 20 °C yields a half-life of about 40 min for **2a** in a buffer at pH 7.4. The lifetime of **2b** in THF is approximately five times longer.

The rate of reaction of **1a** and **1b** with NO was determined with the stopped-flow technique by following the decay of the UV/Vis absorptions at $\lambda = 450$ and 384 nm, respectively. The reaction of **1a** in phosphate buffer at pH 7.4 occurs at a rate constant of $k(\mathbf{1a}+\mathrm{NO}) = (60 \pm 8)\,\mathrm{M}^{-1}\mathrm{s}^{-1}$ at 20 °C, and that of **1b** in benzene at $k(\mathbf{1b}+\mathrm{NO}) = (134 \pm 12)\,\mathrm{M}^{-1}\mathrm{s}^{-1}$.



Scheme 1. Structures of **2a** and **2b** determined from ESR parameters.

Solutions of **1a** and **1b** show only a weak fluorescence at an excitation wavelength of 315 nm (Figure 3). However, upon addition of excess NO to a solution of the FNOCTs (5×10^{-5} M), the characteristic fluorescence of the phenanthrene skeleton is observed immediately.[11] The intensity of the fluorescence increases slowly with time to reach a plateau value after several hours (about 16 h for **2a** and 26 h for **2b**; Figure 3).

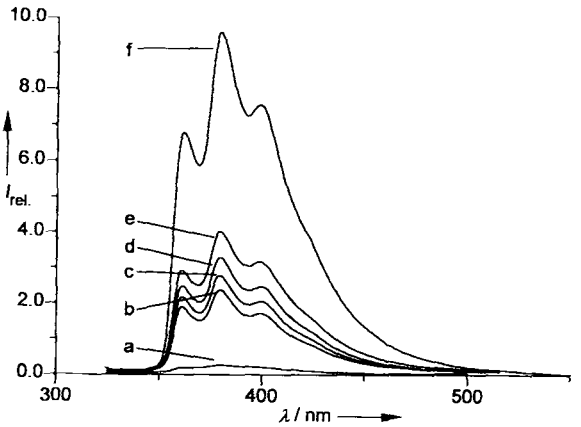


Figure 3. Fluorescence spectra of **1a** (5×10^{-5} M, phosphate buffer pH 7.4), a) before and b) 1 min, c) 35 min, d) 52 min, e) 78 min, and f) 960 min after addition of NO (final concentration 2×10^{-4} M). Excitation wavelength: 315 nm.

The time profile of the increase in fluorescence intensity correlates with the decrease in the EPR signals, that is, with the decay of the nitroxide radicals **3a** and **3b** to produce nonradical products with an intact phenanthrene fluorophore.[12] However, nitroxides can be fluorescence quenchers[13] and diminish their own fluorescence. With regard to developing a practical method for detecting NO, the fluorescence-quenching properties as well as the reduced lifetime of the nitroxides lead to a protocol by which, after formation of the nitroxide, addition of a suitable reducing agent instantaneously produces the maximum intensity of the fluorescence. Since **1a** was developed especially for biological applications, we selected ascorbic acid, which is ubiquitous in cell systems, as the reducing agent. Figure 4 demonstrates the rapid increase in fluorescence intensity to a maximum value after addition of excess ascorbic acid. Similar behavior is found for other "physiological" reductants such as glucose or Fe^{2+}.

The two FNOCTs presented here exhibit the high sensitivity towards NO necessary for biological applications. In addition to trapping from aqueous and nonaqueous nanomolar solutions of NO, good fluorescence spectra were obtained with **1a** ($c = 10^{-5}$ M) from a solution (10 nM, buffer, pH 7.4) of the NO donor compound "spermine NONOate".[14] (At these concentrations EPR signals of **2a** could no longer be detected.) The fluorescence intensity showed a strictly linear ($r^2 = 0.993$, 95%

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1502 $ 17.50+.50/0

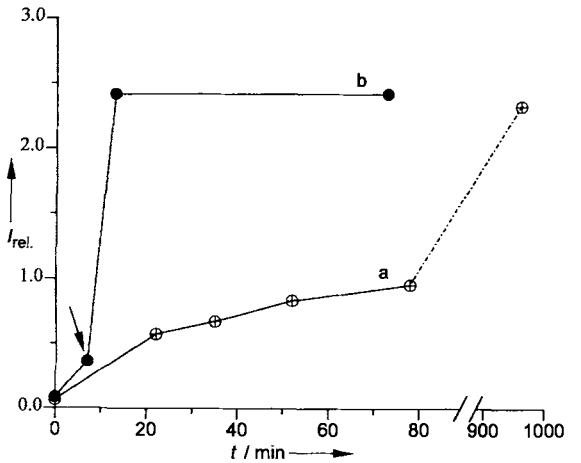

Figure 4. Time profile of the fluorescence intensity at 380 nm. a) After reaction of **1a** with NO. b) After addition of ascorbic acid (10^{-3} M). The arrow indicates when ascorbic acid was added.

confidence interval) dependency on the NO concentration between 2 nM and 4 μM.

The inertness of our FNOCTs towards reactive compounds commonly found in cell systems, in particular the "reactive oxygen species", is of special importance for their application. The influence of some typical cell ingredients on the lifetime of **1a** was tested: Figure 5 shows that the reaction with NO is by far the fastest. Compound **1a** is largely insensitive towards the buffer solution, the whole of the cell culture, glucose, superoxide, or Fe^{2+}. A slow reaction occurs with hydrogen peroxide. The Fenton system Fe^{2+}/H_2O_2, which generates OH radicals, exerts a less pronounced effect than H_2O_2 alone.

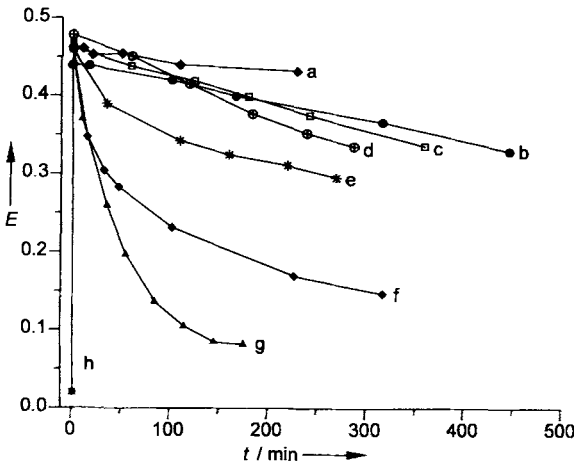

Figure 5. Time profile of the UV/Vis absorption ($\lambda = 450$ nm) of **1a** (1×10^{-4} M, phosphate buffer pH 7.4) in a) a cell culture of rat-liver endothelium cells, b) in pure phosphate buffer, and in presence of c) glucose (9×10^{-4} M), d) O_2^- (3×10^{-3} M), e) Fe^{2+} (7×10^{-4} M), f) $Fe^{2+} + H_2O_2$ (4×10^{-4} M; 1×10^{-3} M), g) H_2O_2 (2×10^{-3} M), and h) NO (2×10^{-4} M).

Our FNOCTs allow monitoring of the formation and decay of NO in chemical and biological systems with three complementary spectroscopic methods: UV/Vis, EPR, and fluorescence spectroscopy. The latter is particularly useful for the very low levels of NO found in biological environments. Synthetic modification of the *o*-quinodimethane backbone should lead to a family of custom-tailored NO traps for analyzing small amounts of NO in chemical and biochemical systems.

[8] Compounds **1a**, **1b**, **3a**, and **3b** were fully characterized by spectroscopic methods (^{1}H and ^{13}C NMR, IR, UV/Vis), mass spectrometry, and elemental analysis.

[9] The EPR spectra were completely reproduced by simulation with the following hyperfine splittings: **2a**: $a(^{14}N) = 2.284$, $a(H) = 0.077$ (2 H), $a(H) = 0.048$ mT (1 H), $g = 2.00622$; **2b**: $a(^{14}N) = 2.261$, $a(H) = 0.09$ (2 H), $a(H) = 0.027$ (3 H), $a(^{14}N_{Imid}) = 0.05$ mT, $g = 2.00628$. The magnitude of the ^{14}N splitting constants is characteristic for bridged nitroxide radicals [10]. Due to their orientation with respect to the radical center we assume that the *exo*-oriented hydrogen atoms H_a and proton H_b are responsible for the additional hyperfine splitting for **2a**, and the H_a protons, the nitrogen atom of the imide group, and the *N*-methyl group for **2b**.

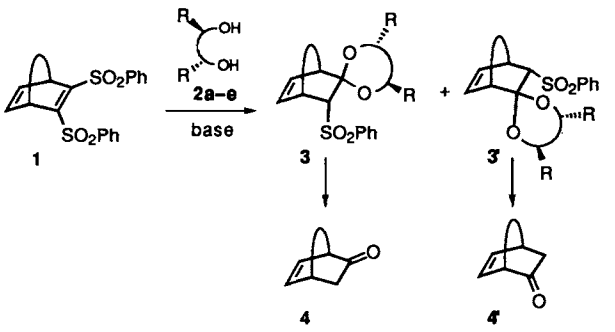
Total Enantiotopic Discrimination between Carbon Atoms of a Double Bond in the Reaction of Diolates with *meso*-Bis(phenylsulfonyl)alkenes—Synthesis of Enantiopure Ketones**

Sergio Cossu,* Ottorino De Lucchi,* and Paolo Pasetto

Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

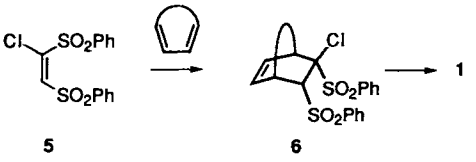
Enantiotopic discrimination of two functional groups in a *meso* compound is a well-established and convenient procedure for preparing enantiopure compounds, which avoids separation and disposal of the unwanted enantiomer.[1] This method, sometimes referred to as the "*meso* trick", is usually applied to diesters or other pairs of enantiotopic functional groups, and is often performed with enzymes.[2] The enantiotopic discrimination of two adjacent carbon atoms is very rare, and, other than the alkyllithium-based rearrangement of *meso* epoxides,[3] there are almost no cases in which such an extreme case of the *meso* trick was applied to an alkene.[4] Here we show that alkenes that are doubly substituted with phenylsulfonyl groups in *meso* compounds undergo reaction with the salts of alcohols and diols to afford totally dissymmetrical compounds in quantitative yields. This represents an enantiotopic discrimination[4] of the carbon atoms of a double bond. The reaction affords diastereo- and enantiopure ketones that are difficult to prepare by conventional routes, and can be utilized in the synthesis of numerous natural products,[5] antibiotics,[6] and drugs used in cancer[7] and AIDS therapy.[8]

The synthetic sequence consists of the reaction of a bis(phenylsulfonyl)alkene **1** with a chiral diol **2** followed by hydrolysis and reductive desulfonylation [Eq. (1)]. Since the reaction is totally stereoselective and affords one only of the possible diastereoisomers (**3**), a single enantiomeric ketone **4** is obtained.



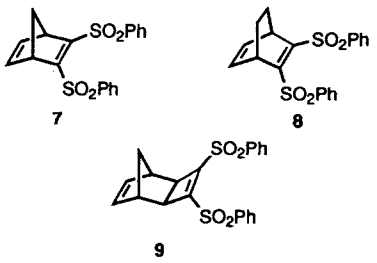
(1)

Starting **1** are readily prepared by cycloaddition of bis(phenylsulfonyl)acetylene with dienes.[9] Because this acetylene is not very stable, (*Z*)-1-chloro-1,2-bis(phenylsulfonyl)ethylene (**5**) may be used as its synthetic equivalent in the Diels–Alder reaction [Eq. (2)].[10] There are also several other routes available for preparing **1**.[11] The derivatives of **1** used in the present study

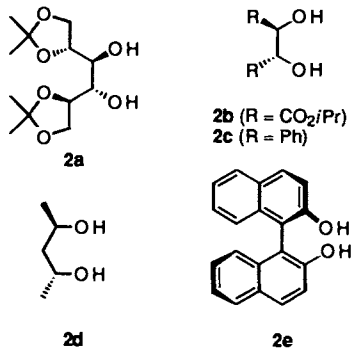


(2)

are the polycycles **7**–**9**,[12] which were chosen as representatives of the [2.2.1], [2.2.2], and cyclobutene systems.



The diols used represent the classes of 1,2- (**2a**–**c**) and 1,3-diols (**2d**) with substituents of different size as well as the atropisomers 1,1'-binaphthalene-2,2'-diol (**2e**). They all possess a C_2-symmetry axis, which avoids partition of the products into further diastereoisomers. Reaction of the sodium salts of **2a**–**e** (prepared by treatment with NaH in THF) with **7**–**9** leads to the ketals **10**–**12** (Table 1).



The bis(phenylsulfonyl)alkene **7** was considered as the standard substrate for testing the behavior of the different diols. Best results were obtained with (*R*,*R*)-(+)-1,2-diphenyl-1,2-ethanediol (**2c**) and **2e**, which both gave a single diastereoisomer (entries 3 and 5 in Table 1). Diol **2c** was used for desymmetrization of **8** and **9** because of the higher crystallinity of the adducts and simplicity in detecting the two diastereoisomers by NMR spectropscopy. With no exceptions **2c** gave the single diastereoisomers **11c** and **12c** (entries 7 and 9); that is, total C=C discrimination was accomplished in all cases. Diols derived from mannitol and tartaric acid **2a** and **2b** gave poorer results (entries 1, 2, and 6) with formation of both diastereoisomers. However, no attempts were made to separate the diastereoisomers. (2*R*,4*R*)-(−)-Pentanediol (**2d**) also showed little selectivity with substrates **7** and **8** (entries 4 and 8).

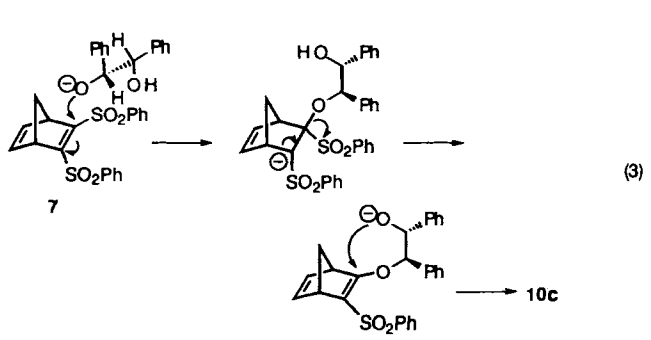
Table 1. Yields, diastereomeric ratios, and optical activity for the products of the reaction of **7**–**9** with diols **2a**–**e**.

Entry	Substrate	Diol	Product	Yield [%]	Diastereomeric ratio [a]	Optical activity [d]
1	**7**	**2a**	**10a**	97	85:15	
2		**2b**	**10b**	93	70:30	
3		**2c**	**10c**	88	[c]	+112.9 (1.7)
4		**2d**	**10d**	92	60:40	
5		**2e** [b]	**10e**	92	[c]	
6	**8**	**2a**	**11a**	72	50:50	
7		**2c**	**11c**	96	[c]	+87.9 (1.6)
8		**2d**	**11d**	90	50:50	
9	**9**	**2c**	**12c**	92	[c]	+82.2 (1.4)

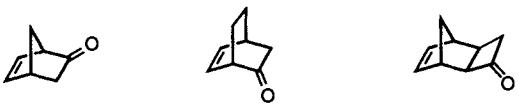
[a] Determined by ^{1}H NMR spectroscopy at 200 MHz. [b] Used as a racemic mixture. [c] Only one diastereomer was obtained. [d] The concentration c is given in parentheses; the measurements were conducted in $CHCl_3$.

The stereochemistry of **10c**, **11c**, and **12c** was determined by X-ray crystallography.[13] The mechanism of formation for **10c** from **7** and **2c** requires attack of the alcoholate functionality at the vinyl carbon atom α to the sulfonyl group, elimination, and addition [Eq. (3)]. Assuming that the approach of the reagent occurs from the *exo* face of the alkene, as is usually observed in norbornenes,[14] the least encumbered trajectory is the one shown in which the phenyl group points upwards, and the alkyl chain to the side. After elimination of the phenylsulfinate anion, a second nucleophilic addition takes place to provide the observed product. The sulfonyl group in **10c** is in the *endo* position, which is in accordance with the *exo* rule of attack of the proton onto the anion.[14] The latter stereoisomer appears to be the kinetic product, because if an excess of base is present epimerization occurs with formation of only the *exo* phenylsulfonyl isomer. Similar reasoning also accounts for the stereochemistry observed for **11c** and **12c**. However, in these cases attack of the alcoholate on **8** and **9** occurs from the *endo* face, as generally observed for these systems.[15]



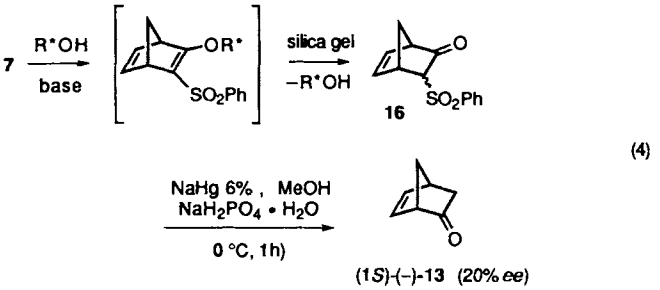
(3)

Diastereopure **10c**, **11c**, and **12c** can be hydrolyzed (Nafion H in toluene at reflux, 5 h) and desulfonylated (NaHg 6% in MeOH/$NaH_2PO_4 \cdot H_2O$, 0 °C, 2 h) to give the enantiomerically pure ketones **13**–**15**[16] in 75-90% yields with the absolute configuration shown. Deacetalization of **10c** affords



mixtures of epimers at the carbon atom α to the sulfonyl group in **16**. This scrambling apparently does not affect the enantiopurity of **13**–**15**. The α-sulfonyl ketones are also of synthetic interest and can be subjected to alkylation and further selective operations that are not dependent on the sterochemistry of the sulfone.[17] The deacetalization–desulfonylation sequence can be reversed to accomplish reductive desulfonylation[18] before hydrolysis. However, desulfonylation of α-sulfonyl ketones is easier and can be carried out with milder reducing agents.[19]

The step that is relevant for the stereochemistry of the products is the initial attack by the diolate ion on **1**. Once the alkene carbon has been chosen by the chiral diol, desymmetrization is virtually accomplished. On this basis, any monofunctionalized chiral alcoholate ion can provide desymmetrization through the enolether and, thus, the ketone. Indeed, reaction of **7** with the lithium salt of (1*R*,2*S*,5*R*)-(−)-menthol (obtained from *n*BuLi and menthol in THF) directly gives **16** in 80% yield [Eq. (4)]



(4)

after column chromatography on silica gel. The sufonyl ketone **16** is reduced to (1*S*)-(−)-**13** with NaHg (6% in MeOH/$NaH_2PO_4 \cdot H_2O$, 0 °C, 1 h, 20% *ee*, 80% yield). This reduces the entire operation to just two steps and allows easy recovery of the chiral auxiliary.

Although this latter protocol is rapid and effective, it produces ketones with lower optical purity since it does not allow a check of the enantiomeric purity of the ketone at the diasteromeric level. We are presently defining other enantiopure alcohols capable of maximum selectivity and studying other stereoselective transformations of these and other bis(phenylsulfonyl)alkenes.

A Straightforward Solid-Phase Synthesis of Cyclic Oligodeoxyribonucleotides**

ElMostafa Alazzouzi, Nuria Escaja, Anna Grandas, and Enrique Pedroso*

Nuclease-resistant oligonucleotides have received much attention due to their potential use in antisense or antigene therapeutics.[1] Cyclic oligonucleotides (CONs) have an intrinsic resistance to degradation by exonucleases, the most active nucleases. CONs can be used as efficient templates for DNA and T7-RNA polymerases to obtain multiple copies of their sequences by the rolling-circle mechanism[2] and are excellent models for studying structures of nucleic acids.[3] In addition, some CON sequences show interesting biological properties.[4]

The synthesis of CONs is a challenging case of macrocycle formation, since each nucleotide unit contributes six atoms to the cyclic backbone. Owing to the competition between inter- and intramolecular reactions, only relatively small sequences (2- to 8-mer) have been obtained by chemical ligation of partially protected oligonucleotides in dilute solutions.[5] Larger cyclic structures (24-mer or more) have only been successfully prepared by template-directed cyclization, chemically or enzymatically, of unprotected oligonucleotides.[6] The template sequence may be either a segment of the CON, as in the ligation of nicked dumbbells,[6a] or a second oligonucleotide molecule that forms a duplex[6b] or a triplex[6c] with the linear precursor of the CON. The main drawbacks of most of these template-assisted procedures[6a,c] are that the sequence of the affordable CONs is restricted and that a lower limit is imposed on their size by the need for efficient hybridization and adequate base pairing with the template sequences.

To our knowledge, the advantages of automated solid-phase methods have been successfully used by only one group for preparing CONs.[7] In their approach, the exocyclic amino group of cytosine is attached to the solid support, where both chain elongation and cyclization are carried out. The largest sequence obtained, which of course has to contain at least one cytosine residue, is a hexadecamer in 1% yield. This shows the difficulty of the synthetic goal.

The solid-phase synthesis described here allows facile obtention of small to medium-sized CONs with no restrictions on sequence. The procedure takes advantage of two main characteristics of the solid-phase methodology: pseudo-dilution conditions for cyclization [8] and ready elimination of by-products by simple filtration.

The synthesis starts with the anchoring of the 3′-terminal nucleotide to the solid matrix through the new bifunctional linker 3-chloro-4-hydroxyphenylacetic acid (**1**, Figure 1). To obtain a homogeneously derivatized resin it is advisable to couple the nucleotide to the linker and then to anchor the resulting product to the support. Thus, the reaction between the 2,4,5-trichlorophenyl ester derivative of linker **2** and a nucleoside phosphoramidite in the presence of tetrazole followed by oxidation gives the nucleotide-linker **3** (B = T, C^{Bz}, A^{Bz}, G^{iBu}). Aminomethyl-polystyrene-*co*-1%-divinylbenzene or a poly-

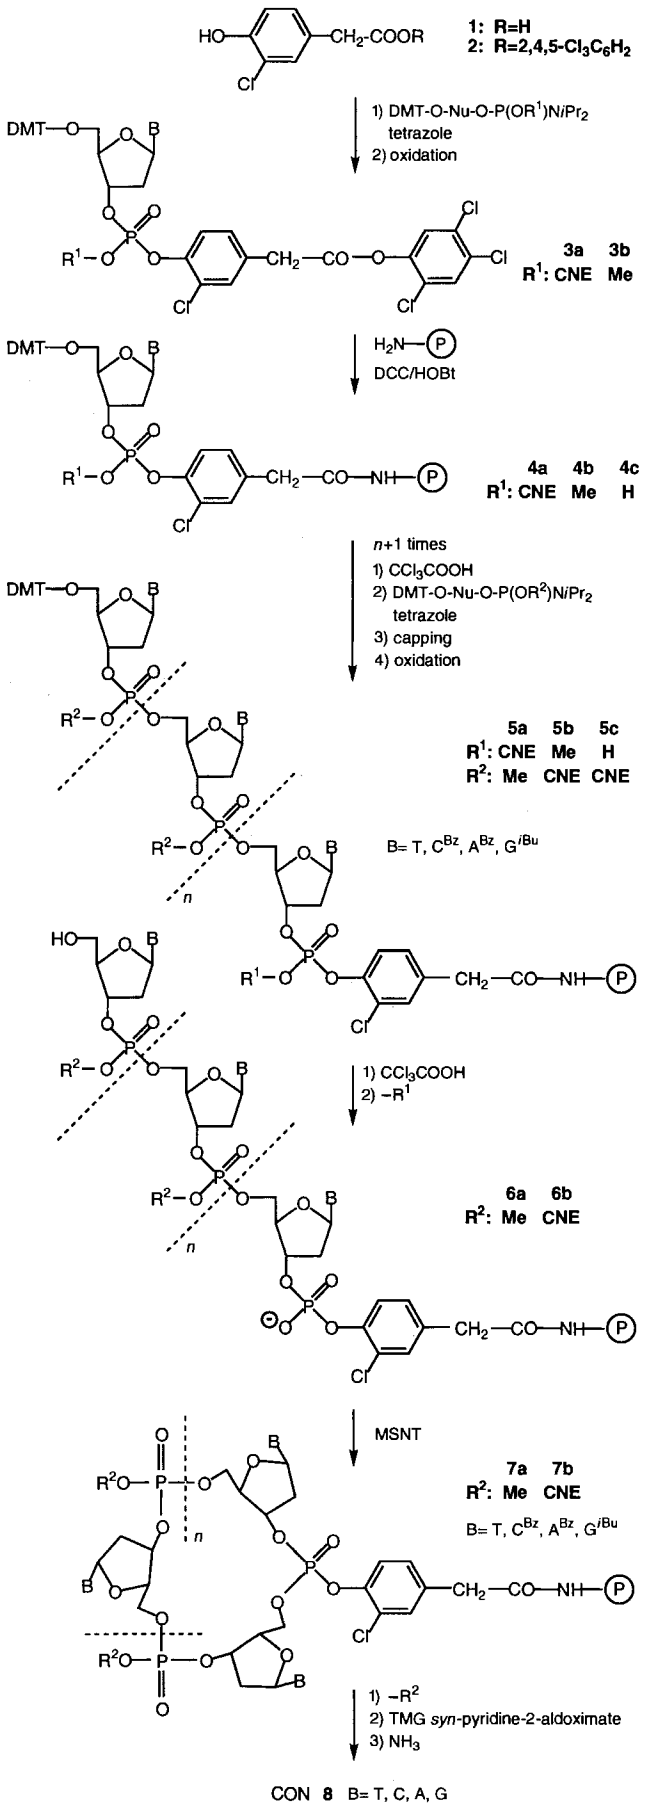

Figure 1. Synthesis of cyclic oligodeoxyribonucleotides.

ethyleneglycol-polystyrene copolymer (TentaGel-NH_2 resin) were used as solid supports, to which 6-aminohexanoic acid can be incorporated as a spacer in order to increase the flexibility of the oligonucleotide chain and facilitate the cyclization and cleavage reactions. Coupling of **3** to the amino-derivatized support affords the nucleotide-resin **4**, whose purity can be assesed by gel-phase ^{31}P NMR spectroscopy.[9] Assembly of oligonucleotide chain **5** takes place from **4** by the standard phosphite triester approach with CNE- or methylphosphoramidites of 5′-O-DMT-nucleosides (CNE = 2-cyanoethyl, DMT = dimethoxytriphenylmethyl). Removal of the 5′-OH and 3′-terminal phosphate protecting groups (if the latter was not previously removed) allows cyclization of the partially deprotected oligonucleotide **6** on the support. Finally, deprotection and cleavage of **7** affords CON **8**.

The synthetic method relies on an appropriate choice of three phosphate protecting groups. An *o*-chlorophenyl group permanently protects the 3′-terminal phosphate and anchors the oligonucleotide to the resin. This 3′-phosphate moiety is also protected with a semipermanent group R^1, which has to be selectively removed for the regioselective cyclization to take place. The remaining phosphates of the oligonucleotide chain are protected with a permanent group R^2. Various combinations of R^1 and R^2 were explored with fairly similar results. Either R^1 = CNE (**4a**), and the elongation is carried out with Me-amidites to afford **5a**, or R^1 = Me (**4b**), and CNE-amidites are used for assembling **5b**. Studies with model compounds showed that none of these approaches is completely orthogonal, since R^2 groups are partially eliminated under the conditions used for removing the semipermanent group R^1 in **5a** or **5b**. Therefore, an alternative approach was designed in which the CNE group is removed from **4a** to afford **4c**, and chain assembly to **5c** is carried out with CNE-phosphoramidites. UV monitoring of the DMT cations released in the deprotection steps shows that chain elongation proceeds normally regardless of the protecting scheme used (about 98% average yield of coupling).

Cyclization of **6** is carried out with 1-mesitylenesulfonyl-3-nitro-1,2,4-triazole (MSNT, 0.1 M in pyridine, 12–24 h). The CON **8** is obtained from **7** after deprotection of the phosphates ($PhSH/Et_3N$ if R^2 = Me or Et_3N/pyridine if R^2 = CNE), cleavage from the resin with tetramethylguanidinium *syn*-pyridine-2-aldoximate (0.1 M in dioxane/water for at least 8 h), and deprotection of the nucleoases with concentrated ammonia. After gel filtration over Sephadex G-10 or G-25, the crude CONs are analyzed, purified, and characterized with standard techniques. The sequences of some of the synthesized CONs, from dinucleotides to a 32-mer, are shown below.

d⟨pTT⟩; d⟨pGG⟩; d⟨pAG⟩; d⟨pTTT⟩; d⟨pTTTTTT⟩

d⟨pTCATTCAT⟩; d⟨p^{Br}UCAT^{Br}UCAT⟩

d⟨pTCATATCTATAT⟩; d⟨pACGCTATGCGAT⟩

d⟨pTTTCTTGCTTGATTTA⟩; d⟨pTTCACATTTTCACATT⟩

d⟨pAGGTTGGTATGGTTGGAT⟩

d⟨pTGTCGTTCGCCTTGGAGTTCTACT⟩

d⟨pTCGTCGCTTGCGCCGTTCGGAGCTTGCTACGT⟩

Yields of the crude products depend on the size of the CON and range from 40–50% for the smallest molecules (up to an 8-mer) to 4% for the largest 32-mer. The best yields were generally obtained with the TentaGel matrix, the nucleotide resin **4c**, and CNE-phosphoramidites. A positive common feature of the

HPLC profiles of all the crude oligonucleotides is a major peak (typically more than 80–90% of the total integrated area) accompanied by some small impurities. The reason for such elevated purity is that the noncyclized chains, which are anchored to the support through a phosphate diester bond, are not cleaved from the resin upon oximate treatment, whereas the cyclic molecules linked through a phosphate triester are easily removed. Furthermore, neither the capped sequences nor the polymeric products formed by interchain reactions during cyclization are detached from the polymer. As a result, the main impurities that accompany the CON on the solid support are separated in the filtration step following oximate treatment.

This reasoning accounts for the homogeneity of the crude products but also provides an argument for the cyclic character of the isolated oligonucleotides (major peaks). Moreover, their structures have been confirmed by two enzymatic digestion analyses. Complete degradation with snake-venom phosphodiesterase and alkaline phosphatase gives the expected ratio of nucleosides. On the other hand, the synthesized CONs show an increased resistance to degradation with calf-spleen phosphodiesterase under standard conditions, which is complete for the smallest sequences (up to a 12-mer) but decreases as the size of the molecule increases.[10] Most of the CONs were also analyzed by mass spectrometry, either negative electrospray or MALDI-TOF or both, and show the expected mass.

This simple procedure yields fairly pure products and, with regard to size, allows the limit under which template approaches are no longer efficient to be reached. The method is also amenable to scale-up, and, in fact, some products have been prepared on milligram scales for structural and biological studies.

Experimental Section

2: A solution of **1** (4 g) in AcOEt (130 mL) was slowly added to a solution of 2,4,5-trichlorophenol (4.7 g) and dicyclohexylcarbodiimide (DCC, 4.9 g) in CH_2Cl_2 (22 mL), and the reaction mixture stirred overnight. The filtrate was washed with aqueous $NaHCO_3$ and dried, and the solvent removed under vacuum. The resulting oil was purified by chromatography over silica gel eluting with hexanes and increasing amounts of CH_2Cl_2. After precipitation with hexanes 2.8 g of **2** were isolated (34% yield): m.p. = 78 °C; ^{1}H NMR (200 MHz, $CDCl_3$): δ = 7.53, 7.26 (Cl_3Ar), 7.35 (d), 7.20 (dd), 7.03 (d, ClAr), 5.60 (OH), 3.82 (CH_2); EI-MS: m/z = 366.

3. A solution of tetrazole (0.23 mmol) in dry CH_3CN (0.7 mL) was stirred with 5′-*O*-DMT-nucleoside phosphoramidite (0.23 mmol) and **2** (0.21 mmol) dissolved in CH_2Cl_2 (1.7 mL) under an argon atmosphere for 1 h. *t*BuOOH (0.24 mL, 3 M in toluene) was added, and 10 min later the reaction mixture diluted with CH_2Cl_2 and washed with water. The organic phase was dried, concentrated, and precipitated over hexanes. The products were isolated as white foams (65–75% yield) and used without further purification. ^{31}P NMR ($CDCl_3$): δ = ca. −7.8(**3a**), ca. −10.5 (**3b**).

4. The amino support (ca. 1 mmol NH_2 groups) was treated with *N*-Fmoc-6-aminohexanoic acid, 1-hydroxybenzotriazole (HOBt), and DCC (0.25 equiv each for PS and 1 equiv each for TentaGel) in a mixture of CH_2Cl_2/DMF (7/1) for 2 h. The unchanged amino groups were acetylated, and the Fmoc group was removed (50% piperidine in DMF). This resin (200 mg) was treated with **3**, DCC, and HOBt (1–2 equiv each based on the NH_2 groups) in CH_2Cl_2/DMF (4/1, 2 mL) for 2 h. Resins with a substitution degree ranging from 50 to 120 μmol DMT g^{-1} were obtained. The remaining amino groups were acetylated before chain elongation.

[10] Thanks are given to one of the referees for suggesting that a more definitive enzymatic assay for determining the circularity would be to carry out a partial degradation of the CONs with an endonuclease, since a cyclic product will initially produce linear oligonucleotides of homogeneous length [6c].

The First 1,3-Distanna-2-platina-[3]ferrocenophane and the Pt^0-Catalyzed Addition of 1,1,2,2-Tetramethyl-1,2-distanna-[2]ferrocenophane to C≡C Bonds**

Max Herberhold,* Udo Steffl, Wolfgang Milius, and Bernd Wrackmeyer

Dedicated to Professor Cornelius G. Kreiter on the occasion of his 60th birthday

The metal-catalyzed distannylation of the C≡C bond has been known for some time.[1] The reactions were carried out mainly in the presence of $[Pd(PPh_3)_4]$ as a catalyst;[2] however, potential intermediates such as *cis*-$[(R_3Sn)_2M(PPh_3)_2]$ (M = Pd, Pt) were neither structurally characterized nor isolated. So far, a structure was proposed on the basis of ^{1}H NMR and IR data for just one platinum complex with R = Me,[3] but the reactivity towards alkynes was not studied. A somewhat better characterized platinum complex, *cis*-$[(Ph_3Sn)_2Pt(dppe)]$, with $Ph_2PCH_2CH_2PPh_2$ (dppe) instead of the two PPh_3 ligands, was

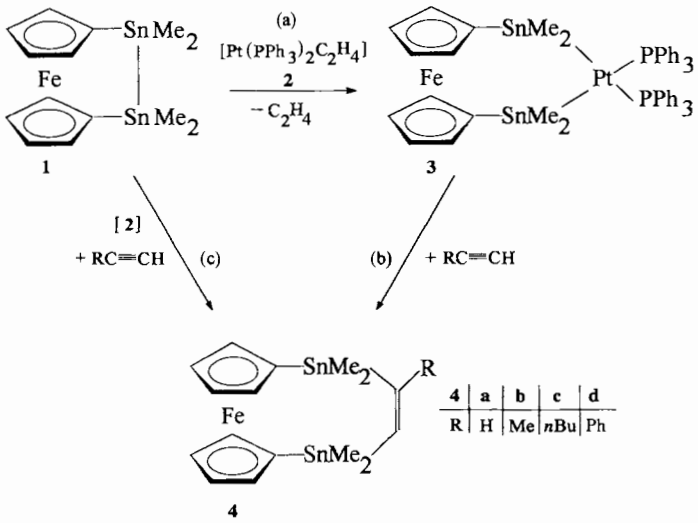
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

investigated by multinuclear NMR spectroscopy,[4] but information about reactions with alkynes is not available.

We have recently reported on the synthesis and molecular structure of the 1,2-distanna-[2]ferrocenophane **1**[5] for which considerable potential in the synthesis of novel ferrocenophanes can be expected.[6, 7] Here we show that **1** reacts smoothly with $[Pt(PPh_3)_2C_2H_4]$ **2** to give the 1,3-distanna-2-platina[3]ferrocenophane **3** by oxidative addition accompanied by liberation of ethene (Scheme 1, route (a)). The molecular structure of **3** is



Scheme 1. Synthetic routes to **4a–d**.

shown in Figure 1.[8] A related complex, 1,3-digerma-2-platina-[3]ferrocenophane $Fe(C_5H_4GeMe_2)_2[Pt(dppe)]$, has just recently been reported.[9]

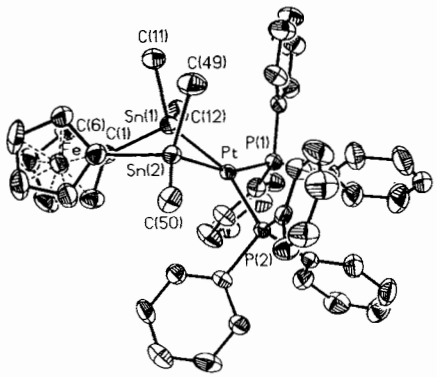


Figure 1. Molecular structure of **3**. Selected bond lengths [pm] and angles [°]: Sn(1)–Pt 264.4(1), Sn(2)–Pt 264.5(1), Sn(1)–C(1) 215.7(7), Sn(2)–C(6) 216.0(7), Sn–C(CH_3) (av) 217.0, P(1)–Pt 230.8(2), P(2)–Pt 229.9(2); Pt-Sn(1)-C(1) 112.7(2), Pt-Sn(2)-C(6) 122.7(2), Sn(1)-Pt-Sn(2) 82.3(1), Sn(1)-Pt-P(1) 88.1(1), Sn(1)-Pt-P(2) 162.9(1), Sn(2)-Pt-P(1) 160.2(1), Sn(2)-Pt-P(2) 89.2(1), P(1)-Pt-P(2) 104.2(1).

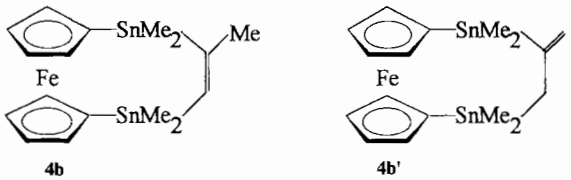
The platinum atom resides at the center of a distorted square plane of ligands; the planes P(1)-Pt-P(2) and Sn(1)-Pt-Sn(2) form an angle of 20.7°. A few examples of complexes showing such a distortion are known, for example *cis*-$[(Et_3P)_2Pt(GeMe_2Cl)_2]$.[10] However, the majority of *cis*-$[(R_3P)_2Pt(R)_2]$ complexes possess an undistorted planar coordination geometry.[11] In **3** the almost parallel cyclopentadienyl rings (tilt angle $\alpha = 2.3°$) deviate considerably from the ecliptic arrangement (twist angle $\tau = 17°$). The Sn(1)-C(1) and Sn(2)-C(6) bonds are slightly inclined from the cyclopentadienyl ring planes towards the Fe–Pt axis ($\beta = 2.2$ and 4°, respectively).

NMR spectra of **3** in solution (25 °C; CD_2Cl_2, see Experimental Section) indicate an intramolecular dynamic process (energy of activation:[12] $\Delta G^{\neq} = 41.8 \pm 2$ kJ mol^{-1}), resulting in fast site exchange of the PPh_3 ligands in *cis* and *trans* positions with respect to a particular tin atom. This is evident from the averaged coupling constant $|^2J(^{119}Sn,^{31}P)| = 680.0$ Hz in both the ^{31}P and ^{119}Sn NMR spectra. At −40 °C the $^{117/119}Sn$ satellites corresponding to $^2J(^{119}Sn,^{31}P)_{trans} = -1574.5$ Hz and $^2J(^{119}Sn,^{31}P)_{cis} = +206$ Hz are well resolved, and the comparison with the mean value proves that their signs are opposite, in agreement with the data for $[(Ph_3Sn)_2Pt(dppe)]$,[4] which, however, appears to have a rigid structure in solution. In the case of **3**, rotation of the $Pt(PPh_3)_2$ fragment about an axis bisecting an imaginary line connecting the two tin atoms can be assumed.

The dynamic properties of complexes of type **3**, observed here for the first time,[13] imply labile Pt–Sn bonds into which unsaturated units such as C≡C bonds can easily be inserted. This leads to transfer of the Sn Sn fragment, starting either from **3** in stoichiometric reactions or from **1** by using a catalytic amount of **2**. Both reactions (Scheme 1, routes (b) and (c)) give new 1,4-distanna-[4]ferrocenophanes **4** in good yield. In the case of propyne, a 1:1 mixture of **4b** and **4b′** is obtained. The Pd^0-catalyzed addition of Sn_2Me_6 to propyne affords selectively the product analogous to **4b′**.[2f] Compound **1** does not react with



alkynes in the absence of **2**. Our attemps to add **1** to alkynes[2] in the presence of $[Pd(PPh_3)_4]$ were not successful, and we did not observe formation of the palladium complex analogous to **3**. The structure of the complexes **4** in solution follows unambiguously from the consistent set of NMR data (see Experimental Section).

The reaction between **1** and **2** enabled us to determine structural and dynamic properties of **3**, the first 1,3-distanna-2-platina[3]ferrocenophane, and the first fully characterized intermediate of a metal-catalyzed distannylation reaction. The novel 1,4-distanna[4]ferrocenophanes **4** are attractive compounds for further transformations because of their reactive Sn–C bonds.

Experimental Section

3: A solution of **1** (0.11 g, 0.22 mmol) in diethyl ether (10 mL) was slowly added to **2** (0.16 g, 0.22 mmol) in toluene (10 mL), and the mixture was stirred at room temperature for 12 h. After about 10 min a yellow product precipitated. Decanting, washing with toluene and diethyl ether, and drying gave **3** (0.19 g, 69.5%) as a yellow crystalline solid (m.p. 185 °C, decomp). ^1H NMR (CD_2Cl_2, 500 MHz, $[J(^{195}Pt,^1H)]$, $(J(^{119}Sn,^1H))$, $\{J(^{31}P,^1H)\}$): $\delta = -0.41$ (s, 12H, Me_2Sn, [6.6], (44.3)), 4.02 (m, 4H, 2,5-H, (7.6)), 4.15 (m, 4H, 3,4-H), 7.09–7.42 (m, 30H, C_6H_5); ^{13}C NMR (CD_2Cl_2, 125.8 MHz, $[J(^{195}Pt,^{13}C)]$, $(J(^{119}Sn,^{13}C))$, $\{J(^{31}P,^{13}C)\}$): $\delta = -3.0$ (Me_2Sn, [57.1], (211.7), {15.7}), 79.3 (C-1, [96.0], {4.8}), 75.4 (C-2,5, [9.5], (38.6)), 69.6 (C-3,4, [6.0], (29.1)), 128.4 (C-1), 134.3 (C-2,6, [23.0], {12.9}), 128.1 (C-3,5, [1.8], {10.1}), 129.9 (C-4); ^{31}P NMR (CD_2Cl_2, 101.2 MHz, 25 °C, $[J(^{195}Pt^{31}P)]$, $(J(^{119}Sn^{31}P))$: $\delta = 31.6$ ([2627.9],(680.0)); ^{119}Sn NMR (CD_2Cl_2, 93.3 MHz, $[J(^{195}Pt^{119}Sn)]$, $(J(^{119}Sn^{117}Sn))$: $\delta = 27.5$ ([9056], (350.0)); ^{195}Pt NMR (CD_2Cl_2, 107.1 MHz, $[J(^{195}Pt^{31}P)]$): $\delta = -762.3$ ([2640]).

4: General procedure, starting from **3**: The respective alkyne was added to a solution of **3** (0.12 g, 0.1 mmol) in THF (30 mL) and the mixture was heated for several hours at 65 °C. The solvent was removed in vacuo and the residue dissolved in

hexane. After filtration and evaporation of the hexane, chromatography on silica with hexane as eluant gave **4a–d** as orange oils.

4: General procedure, starting from **1**: A solution of **1** (0.12 g, 0.25 mmol), alkyne (0.3 mmol), and **2** (0.01 equiv.) in THF (30 mL) was heated to reflux for 72 h, workup as described above gave **4c,d**.

4a: EI MS: *m/z* (%) 508 (100) [M^+]. ^{1}H NMR (C_6D_6, 500 MHz, ($J(^{119}Sn,^1H)$): $\delta = 0.29$ (s, 12H, Me_2Sn, (54.9)), 4.06 (m, 4H, 2,5-H, (10.6)), 4.25 (m, 4H, 3,4-H, (6.1)), 7.43 (s, 2H, HC = CH, (131.8),(204.6)); ^{13}C NMR (C_6D_6, 125.8 MHz, ($J(^{119}Sn^{13}C)$): $\delta = -8.0$ (Me_2Sn, (356.2)), 66.7 (C-1, (499.7), (2.0)), 71.5 (C-3,4, (41.1)), 74.7 (C-2,5, (52.8)), 154.9 (C=C, (528.2), (31.7)); ^{119}Sn NMR (C_6D_6, 93.3 MHz, ($J(^{119}Sn^{117}Sn)$): $\delta = -71.7$ ((444.2)).

Synthesis, Structure, and Reactivity of $[Cp_2Ti(HBcat)(PMe_3)]$: A Monoborane σ Complex**

Clare N. Muhoro and John F. Hartwig*

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

Transition metal σ complexes contain an intermolecular coordination of an H–H, Si–H, or C–H bond to a transition metal center.[1–6] Dihydrogen and silane σ complexes have been isolated, but alkane σ complexes have only been detected in solution by isotopic-labeling and kinetic isotope effect measurements.[7] Until our recent report of a bis(borane) σ complex,[8] there was no direct structural information on any X–H σ complexes (X is a first-row element such as B, C, N, or O). Species with intramolecular C–H bond coordination, frequently called "agostic" complexes, have been the best models. We now report the synthesis, characterization, and reactivity of $[Cp_2Ti(PMe_3)(HBR_2)]$, a set of remarkably simple monoborane σ complexes that demonstrate the stability of borane σ complexes in the absence of any potential B–B interaction that may have stabilized the bis(borane) complex.[8]

The reaction of $[Cp_2Ti(PMe_3)_2]$ and $[Cp_2Ti(HBcat)_2]$ at 0 °C in toluene [Eq. (a)] generated a maroon solution containing

$$[Cp_2Ti(PMe_3)_2] + [Cp_2Ti(HBcat)_2] \xrightarrow[0°C,\ 1.5h]{C_7H_8} \underset{\mathbf{1}}{2\,[Cp_2Ti(HBcat)(PMe_3)]} \qquad (a)$$

$[Cp_2Ti(PMe_3)(HBcat)]$(**1**) in 75% yield (^{1}H NMR spectroscopy with an internal standard). Cooling the solution of **1** in toluene to -30 °C led to the precipitation of **1** in 47% yield as spectroscopically pure material, which was further purified by recrystallization from toluene. Complex **1** was stable as a solid under

inert conditions at room temperature for several hours, but decomposed slowly over this time period in solution.

$[Cp_2Ti(PMe_3)(HBcat)]$ was characterized by detailed NMR studies to determine the bonding mode of the borane. Three possible structures are shown in Scheme 1. The ^{11}B NMR spectrum of **1** contained a signal at $\delta = 64.2$, which is outside of the region for borane Lewis acid–base complexes. The $^{31}P\{^1H\}$ NMR spectrum showed a singlet at $\delta = 29.3$, and the ^1H NMR spectrum a broad peak at $\delta = -9.8$, which is assigned to the borane hydrogen atom and confirmed by deuterium labeling. Typically, *cis*-boryl hydride complexes such as $[Cp_2W(H)(Bcat)]$[9] display sharp hydride signals with no broadening due to nuclear interactions through the metal center. Furthermore, hydrides of d^0-titanium complexes resonate at far lower field than that of **1**. The signal for the hydride in $[Cp^*_2TiH_2]$ appears at $\delta = 0.28$[10, 11] and that of $[(tBu_3OSi)_2(tBu_3SiNH)TiH]$ at $\delta = 8.62$.[12] A doublet at $\delta = 5.02$ ($J(H,P) = 3.0$ Hz) was observed for the Cp ligands of **1**. A single broad band at 1650 cm^{-1} was found in the IR spectrum of **1** between two bands observed previously for $[Cp_2Ti(HBcat)_2]$. The deuterated analog $[D_1]$-**1** showed no signal in this region and displayed a band at the appropriate value of 1184 cm^{-1}.

Scheme 1. Three potential structures for **1**.

Decoupling experiments revealed the connectivity of **1**. A sharp signal at $\delta = -9.8$ appeared in the $^1H\{^{11}B\}$ NMR spectrum. This contrasted the broad signal for the hydride resonance and demonstrated the presence of a B–H interaction. A sharp singlet for the cyclopentadienyl ligands was observed in the $^1H\{^{31}P\}$ NMR spectrum of **1**, demonstrating that the Cp doublet in the coupled ^1H NMR spectrum was due to phosphorus coupling as a result of PMe_3 coordination to titanium. The ^{11}B NMR chemical shift and the decoupling data are clearly inconsistent with structure **A**. In this case, structures **B** and **C** are distinguishable by the hydride chemical shift and the effect of ^{11}B decoupling on the line shape of the hydride signal. The difference in line shape between the ^1H and $^1H\{^{11}B\}$ NMR spectra demonstrates the presence of a B–H interaction, and the high-field chemical shift indicates Ti^{II} rather than Ti^{IV}.[13] The most appropriate structural description of **1** is therefore **C**.

An X-ray structure of the fluoro derivative **2** was obtained (Figure 1).[10] It is informative to make comparisons between the structure of this compound and that of $[Cp_2Ti(HBcat)_2]$ (**3**).[8] The Ti–B bond length in **2** (2.267(6) Å) is slightly shorter than that in **3** (2.335(5) Å), but is too long for a metallocene–boryl complex. The Ti–B distance in **2** is about 0.1 Å longer than the W–B distance in $[Cp_2W(BR_2)]$ complexes, despite the fact that W is 0.1 Å larger in size, and is similar to the M–B distances in Cp_2Nb and Cp_2Ta complexes, despite the fact that the Cp_2M covalent radii are 0.1 Å greater.[9, 13–21] The B–H bond length in **2** (1.35(5) Å) is longer than that in **3** (1.25(3) Å), although the difference is close to the estimated standard deviations. The Ti–H bond in **2** (1.61(5) Å) is shorter than in **3** (1.74(4) Å); again the difference may not be significant. The B-Ti-H angle in **2** is only 36(2)° and similar to the 33(1)° angle in **3**, consistent with B–H bonding in both complexes. The H-Ti-Si angle in the related $[Cp_2Ti(H_2SiPh_2)(PMe_3)]$ is 44(2)°.[22] The trends in bond length can be explained by the greater electron density on the phosphane-containing **2** than on the bis(borane) complex **3**, and perhaps by the slightly greater electrophilicity of the monofluoroborane in **2**. As a result of the increased electron density at Ti, **2** appears to be more of a full oxidative addition product than **3**. However, the decoupling data, the hydride chemical shift, the long Ti–B distance, and the small H-Ti-B angle strongly suggest that the borane has not undergone full oxidative addition in **2**.

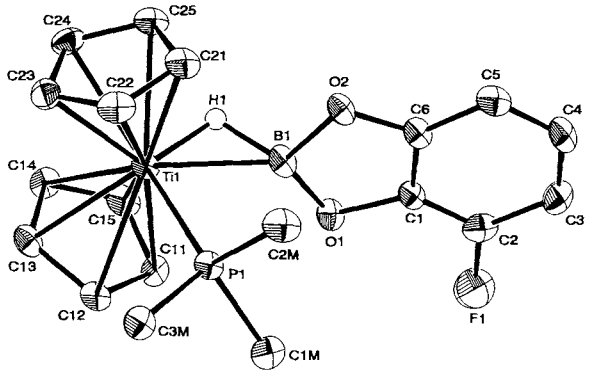

Figure 1. ORTEP drawing of **2**. Selected bond lengths [Å] and angles [°]: Ti–B 2.267(6), Ti–H 1.61(5), B–H 1.35(5), Ti–P2.522(2); B-Ti-P 74.64(14), B-Ti-H 36(2), Ti-B-H 44(2).

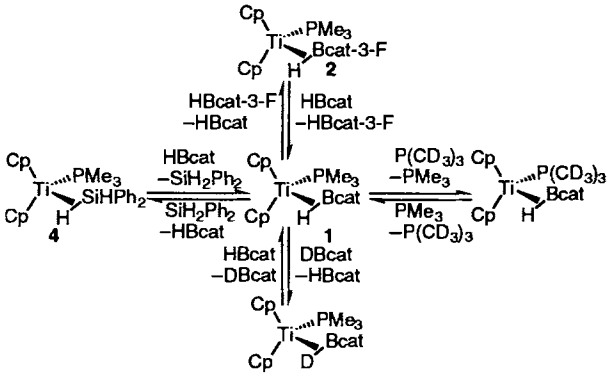
The chemistry of **1** was characterized by ligand-substitution reactions and addition of catecholborane across multiple bonds (Scheme 2). Reaction of triethylamine with **1** under a nitrogen atmosphere led to the displacement of catecholborane and formation of the corresponding Lewis acid–base adduct (87%) along with the titanocene dinitrogen complex $[Cp_2Ti(PMe_3)N_2]$ (23.6%).[23] Exposure of **1** to CO (2 atm) produced $[Cp_2Ti(CO)_2]$ (88%) and free catecholborane (64%). Compound **1** rapidly hydroborated *N*-methylbenzylidineamine in quantitative yield at room temperature and, furthermore, diphenylacetylene to form the vinyl boronate ester in 61% yield. In both reactions the titanium products appear to be paramagnetic and have not yet been identified.

Scheme 2. Reactivity of **1**.

Compound **1** underwent the borane and phosphane displacement reactions shown in Scheme 3: 1) [D_9]Trimethylphosphane reacted with **1** to generate a mixture of **1** and its deuterated analog [$Cp_2Ti(HBcat)\{P(CD_3)_3\}$]. 2) Addition of 3-fluorocatecholborane to **1** produced a mixture of **2** and **1**. 3) *B*-Deuteriocatecholborane reacted with **1** to form a mixture of **1** and



Scheme 3. Ligand-displacement equilibria for **1**.

[D_1]-**1**. 4) A similar exchange with diphenylsilane allowed comparison of the stability of **1** with that of a related titanium complex. Compound **1** reacted with diphenylsilane to form small amounts of the known [$Cp_2Ti(H_2SiPh_2)(PMe_3)$] (**4**).[22] In the reverse reaction **4** reacted with catecholborane to form **1** as the dominant species and to leave small amounts of unchanged **4**. There is clearly an equilibrium between **1** + silane and **4** + borane. This equilibrium favors the formation of **1**, but has not been measured quantitatively.

A previous theoretical study of **3** showed an important backbonding interaction from the metal into the borane p orbital, which is the LUMO.[8] A similar interaction may exist in **1**. The catecholborane LUMO is clearly different from the C–H σ^* LUMO of an alkane, but its symmetry is similar to that of an arene LUMO. It is therefore possible that arene σ complexes have structures resembling **1**. Further theoretical and experimental studies on these unusual borane σ complexes are required to better understand their structures and reactivity.

Experimental Section

1: [$Cp_2Ti(PMe_3)_2$] (395 mg, 1.20 mmol) and [$Cp_2Ti(HBcat)_2$] (500 mg, 1.20 mmol) were weighed into a sidearm flask, which was then cooled to $-30\,^{\circ}C$ and charged with cold toluene (3 mL). This solution was stirred for 90 min at $0\,^{\circ}C$. The resulting dark maroon solution was then kept at $-30\,^{\circ}C$ for 2 d, after which a dark pink solid precipitated from solution. The dark maroon supernatant was removed, and the solid dried in vacuo (46.4% yield). Further purification was achieved by recrystallization from highly concentrated solutions of **1** in toluene at $-30\,^{\circ}C$. ^1H NMR (300 MHz, [D_6]benzene, $20\,^{\circ}C$, TMS): $\delta = 7.09$ (m, 2H, CH), 6.79 (m, 2H, CH), 5.02 (d, $J(H,P) = 3.0$ Hz, Cp), 0.75 (d, $J(H,P) = 6.3$ Hz, CH_3), -9.8 (br. s, 1H, BH); ^{11}B NMR (96.38 MHz, [D_8]toluene, $20\,^{\circ}C$, $BF_3 \cdot OEt_2$): $\delta = 64.2$. $^{31}P\{^1H\}$ NMR (121.65 MHz, [D_8]toluene, $20\,^{\circ}C$, 85% H_3PO_4): $\delta = 29.3$; $^{13}C\{^1H\}$ NMR (75.48 MHz, [D_8]toluene, $-5\,^{\circ}C$, TMS) $\delta = 153.09, 120.69, 110.10, 96.69, 20.39$; IR (Nujol): $\tilde{\nu}_{BH} = 1650\ cm^{-1}$.

[10] Crystal data for **2** ($T = 153$ K, $Mo_{K\alpha}$ rays, $\lambda = 0.71073$ Å): triclinic, $P\bar{1}$, $Z = 2$, $V = 918.91(2)$ Å^3, $\rho_{calcd} = 1.417\ g\,cm^{-3}$, $2\theta_{max} = 45°$, scan width of 0.3° in ω, of 3724 reflections 2329 were independent, $I > 2\sigma(I)$, 256 parameters, residual electron density $= 1.059\ e\,Å^{-3}$. Data corrected for Lorentzian-polarization and absorption factors (SADABS program, $\mu \times r = 0.10$, 0.564 (min) and 0.928 (max)). The structure was solved and refined with the Siemens SHELXTL (version 5.0) Software Package. Final anisotropic full-matrix least-squares refinement on F^2 converged at $R1 = 0.0638$, $wR2 = 0.1631$, and GOF = 1.024. The hydrogen atoms were located and refined isotropically. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100125. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

cyclo-Sb_5^{5-}: A New, Highly Charged Zintl Anion, Stabilized as an Ion Complex in the Ammoniate $[Li(NH_3)_4]_3[Li_2(NH_3)_2Sb_5] \cdot 2NH_3$

Nikolaus Korber* and Frank Richter

Dedicated to Professor Hans Georg von Schnering

There are two generally adopted approaches towards the isolation of the homoatomic polyanions of groups 14 to 16 known as Zintl anions.[1] They are obtained either by excision of preformed structural units from congruently dissolving solids (e.g. As_{11}^{3-} [2] from K_3As_{11} or Rb_3As_{11}) and by extraction of alloys (e.g. Sn_9^{4-} [3] from $NaSn_{2.5}$), or by direct reaction of an electropositive metal with the main group metal in a suitable solvent. In the past, the constitution and properties of many Zintl

anions could be elucidated, especially by Corbett, by complexing the alkali metal counterions with cryptands and thus stabilizing the isolated polyanions in the corresponding salts.[4] However, the second method is the original one which dates back to Zintl and co-workers, who monitored the reduction of metals with sodium in liquid NH_3 by using potentiometric titrations, and gained indications of the polyanions which were subsequently named after him.[5] The characterization of salts like $[Na(NH_3)_n^+]_3Sb_7^{3-}$, which could be crystallized from these solutions, proved to be impossible with the techniques then available due to the high NH_3-decomposition pressure of these compounds. Probably for this reason, in later investigations of Zintl anions the solvent NH_3, which is the most suitable one for the direct reduction, was avoided, and ethylenediamine, in particular, was used instead, which automatically favored the excision and extraction routes. It is not clear though, whether the results thus obtained can be used to account for the observations made by Zintl and co-workers in every case; the alternative use of the chelating solvent ethylenediamine as well as the application of cryptands constitute major interferences with the systems investigated. In addition, several of the anions listed by Zintl et al. such as Sb_3^{3-} have still not been observed.[4, 5]

The methods available nowadays for performing X-ray structure analysis at low temperature allow the characterization even of very unstable ammoniates;[6] thus, it appeared appropriate to investigate the structures of the products formed by the direct reaction route. As a first example, the reactions of lithium with amorphous red phosphorus, arsenic, and antimony were chosen. The special advantage of lithium, in this context, is the relative stability of the ammine complex $[Li(NH_3)_4]^+$ (as compared to the very unstable ammine complexes of the remaining alkali metals), which is isoelectronic to the tetramethylammonium ion often used for isolating large anions.[7] In fact, the solution of lithium in liquid ammonia may be better interpreted as a solution of the "expanded metal" $Li(NH_3)_4$,[8] which forms the respective voluminous cation by oxidation, and which thus represents a simple analogy to the unknown "$N(CH_3)_4$".

The reaction of lithium with excess red phosphorus in liquid ammonia yields the compound $[Li(NH_3)_4]_4P_{14}$,[9] which contains the P_{14}^{4-} ion already synthesized by Hönle et al. by a different route.[10] The analogous reaction for arsenic yields $[Li(NH_3)_4]_3As_7 \cdot NH_3$,[11] which contains the known nortricyclane cage As_7^{3-} ion.[12] Both products form exclusively if the appropriate molar ratio is applied.

In contrast, the reaction of lithium with antimony gave a surprising result: even when high excesses of antimony are used, the product formed only contained an Li:Sb ratio of 1:1. The X-ray structure analysis[13] established the composition $Li_5Sb_5 \cdot 16\,NH_3$ for the dark red crystals, which form quantitatively if the corresponding stoichiometry is used. A better formulation, which reflects the different structural roles of the ammonia molecules, is $[Li(NH_3)_4]_3[Li_2(NH_3)_2Sb_5] \cdot 2\,NH_3$ (**1**). The main building blocks are $[Li_2(NH_3)_2Sb_5]^{3-}$ ion complexes (Figure 1), which are separated in the solid by $[Li(NH_3)_4]^+$ complexes that serve as counterion and by additional ammonia of crystallization (Figure 2). The ion complex consists of a novel *cyclo*-Sb_5^{5-} ion in an envelope conformation, which is capped by lithium cations on both sides of the ring. Each of the two lithium cations has three close contacts to antimony ($\bar{d}$(Li–Sb) = 2.82 Å); a roughly tetrahedral environment for these cations is achieved by two additionally bound ammonia molecules. This special coordination of the Sb_5 ring makes it possible to study the influence of the cations on the Sb–Sb bonds: the bonds between Sb(2), which is coordinated by two lithium cations, and its homoatomic neighbors are significantly longer (2.875 and 2.910 Å) than the mean length of the remaining Sb–Sb bonds (2.820 Å). This result agrees with the previously found bond-lengthening in polyphosphides caused by interactions with capping alkali metal cations.[14]

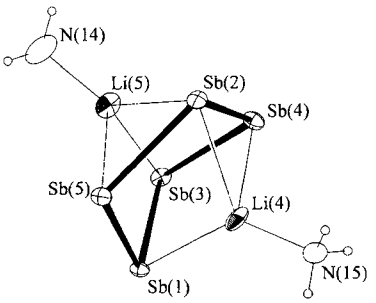

Figure 1. $[Li_2(NH_3)_2Sb_5]^{3-}$ in the crystal structure of **1** (ORTEP, 50% probability). Selected bond lengths [Å] and angles [°]: Sb(1)–Sb(5) 2.8059(10), Sb(1)–Sb(3) 2.8318(9), Sb(2)–Sb(4) 2.8751(12), Sb(2)–Sb(5) 2.9103(10), Sb(3)–Sb(4) 2.8212(12), Sb(1)–Li(4) 2.77(2), Sb(2)–Li(5) 2.80(2), Sb(2)–Li(4) 2.84(2), Sb(3)–Li(5) 2.84(2), Sb(4)–Li(4) 2.83(2), Sb(4)–Li(5) 3.28(2), Sb(5)–Li(5) 2.84(2), Sb(5)–Li(4) 3.05(2), N(14)–Li(5) 1.99(2), N(15)–Li(4) 2.02(2); Sb(5)-Sb(1)-Sb(3) 96.52(3), Sb(4)-Sb(2)-Sb(5) 101.41(3), Sb(4)-Sb(3)-Sb(1) 95.55(3), Sb(3)-Sb(4)-Sb(2) 101.97(3), Sb(1)-Sb(5)-Sb(2) 103.35(3)

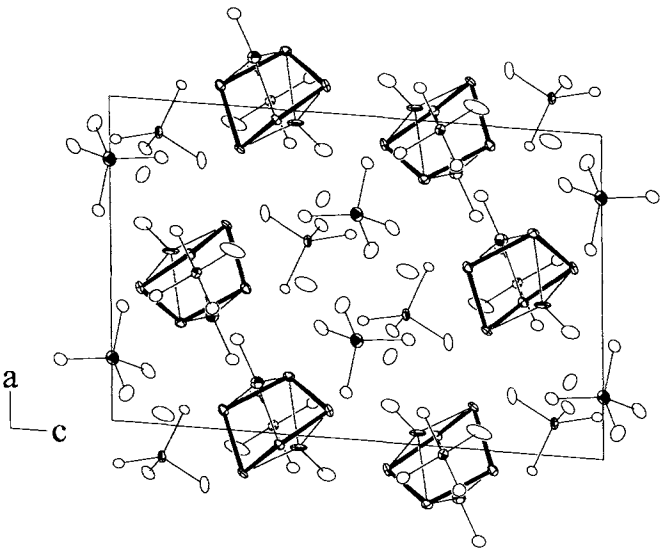

Figure 2. Projection of a unit cell of **1** in the direction [010] (ORTEP, 50% probability, designation of atom type analogous to that in Figure 1).

The dual structural role of the lithium cations in **1** demonstrates the advantages of the direct reduction with lithium in liquid ammonia for the isolation of Zintl anions: the cation coordinates directly to the highly charged anion and reduces its charge density to a value compatible with a ionic solid of this kind, and it also serves as a voluminous, noncoordinating counterion in the ammine complex $[Li(NH_3)_4]^+$, which separates the Zintl anions from each other. A cryptand fitting for lithium cations would remove the cations of the ion complex as well; a compound built from totally isolated Sb_5^{5-} and five cryptand counterions, however, would not result in a stable solid judging from past experiences. Consequently, up to now only Sb_{11}^{3-},[15] Sb_7^{3-},[16] and Sb_4^{2-}[16] were known as homoatomic antimony anions, obtained with the help of cryptands, all of which have a significantly lower charge density than Sb_5^{5-}. Group 15 cycloanions with one negative charge per atom are extremely rare, in contrast to the corresponding chains (e.g. in M^ISb, M^I = Na–Cs[17]). The most convincing example is *cyclo*-P_6^{6-} in

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1513 $ 17.50+.50/0

Th_7P_{11},[18] while the sometimes mentioned rings Sb_4^{4-} and Bi_4^{4-} (both planar!) in $Ca_{11}Sb_{10}$ and $Ca_{11}Bi_{10}$,[19] respectively, as well as P_6^{6-} in InP_3[20] are all very much borderline cases with respect to the Zintl–Klemm–Busmann concept. More common are the respective homoatomic rings in transition metal complexes like $[Cp^*Fe(P_5)Ir_2(Co)(Cp^*)_2]$ (*cyclo*-P_5 in envelope conformation)[21] or in organo-substituted molecules like $[As(CH_3)]_5$.[22] The probably most impressive analogy to Sb_5^{5-} is found in the up to now totally singular anion $[As_8Nb]^{3-}$, which was prepared by von Schnering et al.[23] This anion contains a crown-shaped As_8^{8-} ring, the high formal charge of which is reduced by an encapsulated niobium ion.

In summary, our return to the original method of creating Zintl anions demonstrates with this first result that the possible structural diversity of homoatomic polyanions of group 15 is still not fully explored. In particular, highly charged anions, which cannot be isolated with the previously used methods, may now be obtained by the direct reduction in liquid ammonia as ion complexes and immediately characterized as ammoniates. Perhaps this approach will even be applicable for Sb_3^{3-}, which was detected by Zintl et al. in the Na-Sb-NH_3 system.[5]

Experimental Section

All manipulations were carried out under dry argon in all-glass vessels that were dried in vacuo. A piece of Li (0.011 g, 1.60 mmol; scraped off a larger block in the glove-box; Alfa), and Sb (0.195 g, 1.60 mmol; Aldrich, 99.8%), which had been dried in vacuo for three days, were placed in a Schlenk tube. NH_3 (ca. 20 mL), which had been stored over Na, was condensed into the Schlenk tube using an ethanol bath at $-78\,^{\circ}C$. The mixture was kept at $-40\,^{\circ}C$ for 10 days. The color of the solution changed from blue to deep red after one day; red crystals of **1** precipitated directly from the solution and were mounted for the X-ray structure analysis as described previously [6]. After the removal of NH_3, an X-ray amorphous, homogeneous black product of the composition LiSb remained, which retained the shape of the original crystalline ammoniate.

Probing Nanocavities with Proton-Transfer Fluorescence**

Abderrazzak Douhal,* Francisco Amat-Guerri, and A. Ulises Acuña*

The ability of cyclodextrins (CD) to encapsulate functional compounds such as emitting dyes has led to intensive studies of their inclusion complexes.[1–7] In these species proton transfer,[8, 9] energy transfer,[4, 5] and bond rotation[10] can give rise to new molecular forms of the sequestered dye with different physicochemical properties. Here we describe the light-induced tautomerism of a fluorophore encapsulated by α-, β-, or γ-CD, for which both proton transfer and conformational changes cause spectral shifts that are directly related to the size of the CD cavity. The color change of the fluorescence provides a simple way of exploring and quantifying subtle details of the induced fit and cavity diameter.

The guest 2-(2′-hydroxyphenyl)imidazo[1,2-*a*]pyridine (HPIP) is a heterocyclic dye with two groups able for forming an intramolecular hydrogen bond (**1**, Scheme 1). UV irradiation of **1** in solvents with which it does not interact induces an electronic reorganization in the excited state that provides the driving force for the shift of the proton involved in the hydrogen bond.[11] The resulting phototautomer fluorescences around 600 nm;[11] the band appears at 535 nm in a solid matrix (a thin film of poly(methyl methacrylate) (PMMA)). The fluorescence in the solid phase is due to **2**, the photoproduct of the proton-transfer reaction. In liquid media **2** gives rise to the red-emitting species **3**. In hydrogen-bonding media such as water, the spectral evidence favors solvated structures such as **4**, which emit in the near-UV region, because the intramolecular proton-transfer

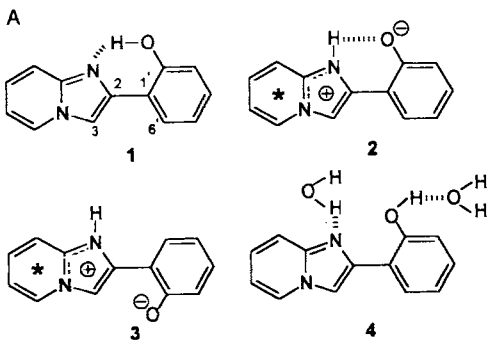
[**] This work was supported by the Dirección General de Investigación Cientifica y Tecnica of Spain (project no. PB93-0126).

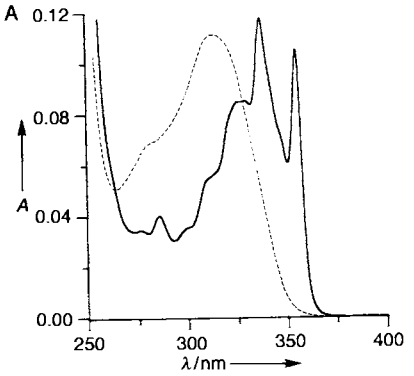


Scheme 1. A) Molecular structures of the different forms of HPIP; **2** and **3** are proton-transfer phototautomers of **1**. B) Structures of α-, β-, and γ-CD; *d* is the interior diameter.

photoreaction is prevented. The fluorescence of **4** (390 nm) and that of **3** (600 nm)[11] in liquid media, together with the weak solubility of HPIP in water and the hydrophobicity of the internal cavity of CDs, provide the experimental basis for monitoring the sequestration of the dye from water by CD and the subsequent processes.

Figure 1A shows the absorption spectra of HPIP in a nonpolar solvent (methylcyclohexane) and in water. We first investigated the influence of β-CD on the fluorescence spectrum of HPIP in water. An emission band at 550 nm grows upon addition of β-CD (Figure 1B), whereas the intensity of the fluorescence band at 390 nm decreases. The band at 550 nm can be easily understood by recalling the spectral behavior of HPIP in liquid and solid media. It is, accordingly, assigned to **2**, a proton-transfer phototautomer of **1** sequestered within the torus-shaped cavity of CD. To exclude other alternatives, such as nonencapsulating interactions, the effect of maltoheptose (MA) on the emission spectrum of HPIP in water was also analyzed. MA is a linear oligosaccharide with seven glucose units but without the characteristic conical shape of β-CD. Addition of MA (Figure 1C) only results in a slight broadening of the band at 390 nm; the yellow band observed in the presence of β-CD is indeed due to the entrapped dye. The emission band at 550 nm is very similar to that observed in dioxane,[11] and, therefore, the ground-state conformation of the entrapped dye should be close to **1**. The species emitting at 390 nm in the presence of β-CD should have a ground-state geometry similar to that of **4** according to the similarity between its excitation spectrum and the absorption spectrum of the dye in water.

A Benesi–Hildebrand (BH) plot[12] of the change in the fluorescence intensity at 550 nm as a function of β-CD concentration supports a 1:2 complex of the guest **1** with the cyclic sugar (apparent inclusion constant $K_a = 1.0 \times 10^5\ M^{-2}$; Figure 2A). This reflects the tendency of β-CD to form dimers[2, 3, 7] with a large hydrophobic cavity (Scheme 2). These complexes can be readily crystallized, and the fluorescence spectrum of the dried crystals consists of a single band at 550 nm, which is similar to that in the PMMA matrix (535 nm). Since the emission at



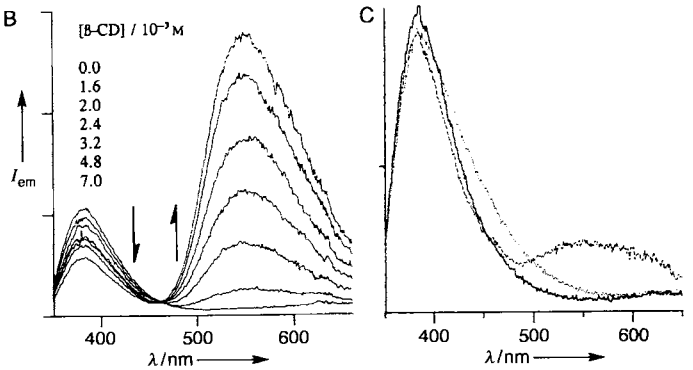


Figure 1. A) Normalized UV/Vis absorption spectra of HPIP in methylcyclohexane (solid line) and water (dashed line). *A* = absorbance. B) Fluorescence spectra (λ_{ex} = 340 nm) of HPIP (10^{-6} M) in water upon addition of β-CD. C) Fluorescence spectra (λ_{ex} = 340 nm, 300 K, pH(water) = 6.3) of HPIP in water (solid line), water plus β-CD (dashed line), and water plus maltoheptose (3×10^{-3} M; dotted line). I_{em} = intensity of the emission.

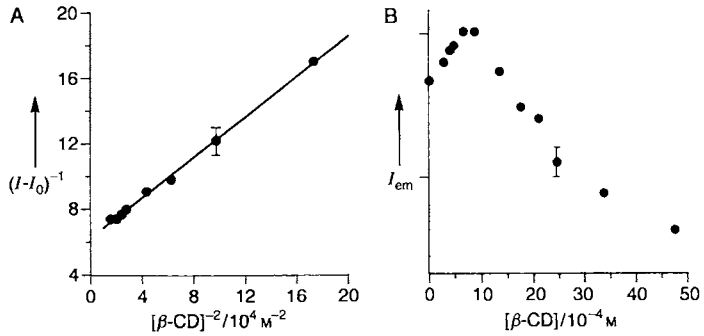

Figure 2. A) BH plot (for a 1:2 complex) of the changes in the fluorescence intensity *I* at 550 nm due to the formation of HPIP/β-CD complexes. I_0 is the fluorescence intensity in the absence of β-CD. B) Changes in the fluorescence intensity I_{em} at 390 nm upon addition of β-CD.

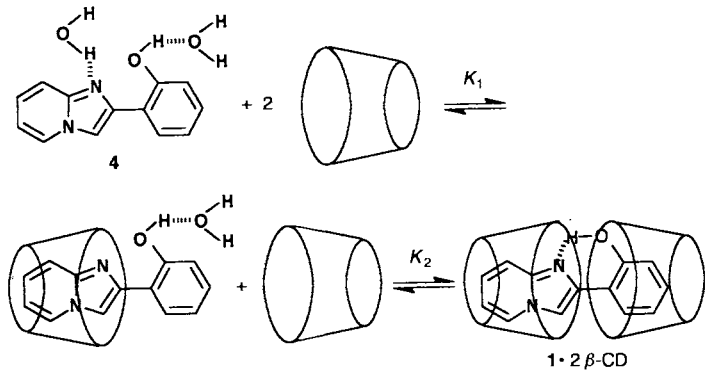

Scheme 2. Schematic view of the fitting of **4** into a β-CD cavity and the subsequent conversion into **1** in the 1:2 inclusion complex.

390 nm is absent in the crystals, the intramolecular hydrogen bond of the dye within the complex is not perturbed by the cyclic oligosaccharide host.

The dye-trapping process in aqueous solution can also be monitored by the biphasic behavior of the fluorescence intensity at 390 nm as a function of β-CD concentration. Thus, at low concentrations of β-CD the intensity of this band initially increases (Figure 2B) due to protection of the emitting fluorophore by β-CD. This trend is reversed and the intensity starts to decline upon further increase of the oligosaccharide concentration, with the simultaneous appearance of the band at 550 nm, as noted above. The BH analysis of the initial change of the intensity at 390 nm yields a 1:1 stoichiometry and a binding constant $K_1 = 500\ \text{M}^{-1}$ The equilibrium constant K_2 of the 1:2 final assembly is then $K_a(\text{apparent})/K_1 = 200\ \text{M}^{-1}$. The construction of the 1:2 assembly starts with inclusion of **4** within the hydrophobic cavity of a single β-CD molecule to form initially a 1:1 complex (see Scheme 2). Subsequent encounter of this species with a second β-CD molecule allows the binding of the two macrocycles through intermolecular hydrogen bonds and formation of the intramolecular OH···N bond, which is characteristic of HPIP in non-hydrogen-bonding environments,[11] with a partial twisting about the C2–C1′ single bond. Formation of the first inclusion complex occurs very quickly (within seconds), whereas that of the final 1:2 assembly proceeds much more slowly (within hours) and depends markedly on relative concentrations and temperature. The values of K_1 and K_2 suggest that the main driving interactions of the inclusion processes are not totally hydrophobic.[7]

UV irradiation of encapsulated **1** leads to excited **2**. The relaxation of this species to **3** by twisting about the C2–C1′ bond is restricted by the cavity formed by the two β-CD molecules (largest diameter 7.8 Å, length ca. 16 Å).[13] Therefore, formation of **3** cannot occur, and the emission must come from **2** or a very similar rotamer. The steady-state fluorescence anisotropy $\langle r \rangle$ of the band at 550 nm for the β-CD complex is 0.253 ± 0.005, which is close to that observed in PMMA ($\langle r \rangle = 0.335 \pm 0.008$ at 510 nm), where rotation is not possible. This indicates that little reorientation occurs during the lifetime (4.0 ns) of the excited phototautomer.

The spectral properties of HPIP sequestered by α- and γ-CD, which have different cavity sizes (see Scheme 1), agree with these. Thus, the maxima of the proton-transfer fluorescence bands of the α-, β-, and γ-CD inclusion complexes appear at 500, 550, and 570 nm, respectively. The red shift is due to increased twisting around the C2–C1′ bond in **2** and is, therefore, a simple and direct measure of the size (diameter) of the encapsulating cavity. Indeed, it reveals the involvement of single-bond rotation in a transient state. Recent ab initio calculations on a similar molecule are in accordance with this type of rotational process in the proton-transfer cycle.[13] Due to the dimensions of the dye (ca. $5.5 \times 11.7\ \text{Å}^2$), the cavity of the α-CD complex should provide the most constraining environment. However, since the proton motion in **1** is a direct process that takes place along the intramolecular hydrogen bond of the dye,[11, 13–15] its rate would not be substantially perturbed by these geometric restrictions. Thus the size of the bimolecular CD cavity only affects the electronic energy gap of the emitting phototautomers.

The blue to green-yellow fluorescence changes of aqueous solutions of HPIP in the presence of CDs have been found to be simply and directly related to the topology of hydrophobic cavities at the subnanometer level and to the assembly/disassembly of hydrogen-bond networks. Hence, this dye is a molecular probe for these phenomena, and we are currently investigating its use as a sensor for microdomains in biological membranes.

Sigmatropic Shifts in Allene Oxide Rearrangements: First General Route to [3,4] Shifts in Aliphatic Systems**

Ihsan Erden,* Fu-Pei Xu, and Wei-Guo Cao

In our initial report on thermal isomerizations of saturated fulvene endoperoxides we provided the first evidence for allene oxide and cyclopropanone intermediates by means of inter- and intramolecular trapping reactions.[1] The intermediacy of allene oxides was subsequently corroborated by isolation and characterization of a stable derivative of **3** ($R^1 = t\text{Bu}$, $R^2 = \text{H}$),[2] and the mechanism of the fulvene endoperoxide/allene oxide isomerization fully elucidated (Scheme 1). We also reported synthetic applications of this rearrangement employing acid-trapping reactions[3] and intramolecular vinylcyclopropanone/cyclopentenone cyclizations.[4]

In the course of our studies on related intramolecular trapping reactions we uncovered a new facet of the endoperoxide/allene oxide methodology. Placement of a 3-butenyl group at the exocyclic double bond in the fulvene precursor and thermolysis of the corresponding saturated endoperoxide **5** in CCl_4 at 60–80 °C results in a [3,4]-sigmatropic shift of the 3-butenyl group to give the 5-oxo-6-heptenal derivatives **8.**

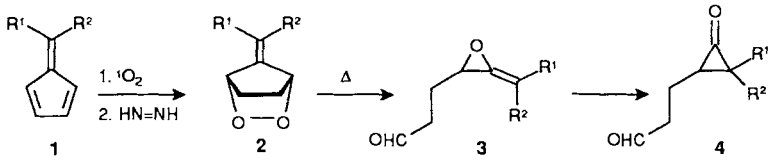


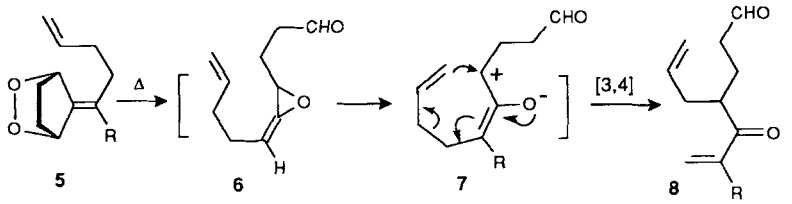
Scheme 1. Mechanism for the thermal rearrangement of saturated fulvene endoperoxides.

[3,4] Shifts were first observed by Schmid and co-workers in 1,4-cyclohexadienol/benzene rearrangements alongside competing [1,2] and [3,3] shifts.[5] Based on their failed attempts to extend these rearrangements to acyclic analogs Schmid et al. concluded that "the chances that in acyclic systems aliphatic [3s,4s] rearrangements could occur are slim".[6] Except for one isolated case, examples of [3,4]-sigmatropic shifts in aliphatic compounds are virtually unknown.[7] Dewar's prediction[8] that this type of [3,4] shift would proceed with ease if suitable systems were accessible has now been borne out in the experiments described.

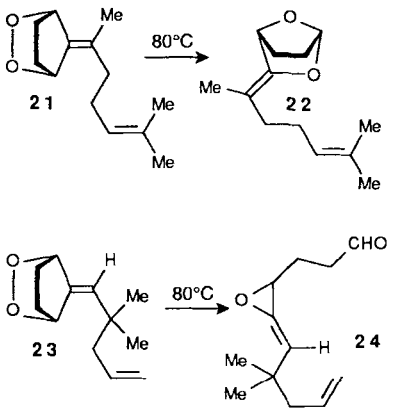
Table 1[9] depicts several examples of [3,4] shifts in endoperoxides. A mechanism consistent with our results involves initial formation of the allene oxide **6**, which undergoes a [3,4] shift via the oxyallyl intermediate **7** (Scheme 2). In certain cases, and in particular with endoperoxides derived from 4-enals, intramolecular 1,3-dipolar cycloaddition[1-3] of the allene oxide/oxyallyl intermediate onto the aldehyde moiety effectively competes with the [3,4] pathway; this manifests itself in the relatively low yields of isolated [3,4]-shift products in those systems. Although we have not yet systematically explored the scope and limitations of these rearrangements, preliminary results indicate that steric hindrance in the side chain of the starting endoperoxide impedes attainment of the proper transition geometry in **7** for the [3,4]-shift pathway. In the two examples studied that exhibit no tendency for the [3,4] shift due to steric crowding at the butenyl terminus, as in **21**, or the α-carbon atom, as in **23**, the alternative intramolecular 1,3-dipolar cycloaddition dominates. In the case of **23** brief thermolysis at 80 °C allowed observation of the stable allene oxide **24** by NMR spectroscopy (Scheme 3).

Table 1. [3,4]-Sigmatropic shifts in thermal decompositions of saturated fulvene endoperoxides.

Endoperoxide	Product	Yield
 **9**	 **15**	45%
 **10**	 **16**	55%
 **11**	 **17**	52%
 **12**	 **18**	83%
 **13**	 **19**	85%
 **14**	 **20**	79%

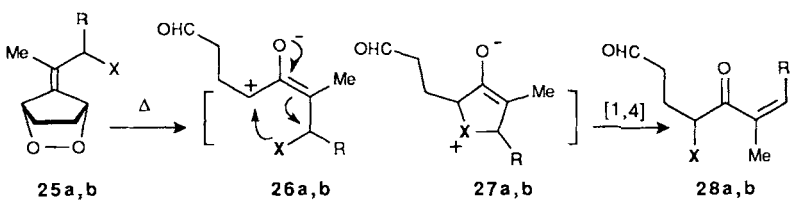


Scheme 2. Mechanism for [3,4]-sigmatropic shifts in allene oxides.



Scheme 3. Thermal rearrangements of sterically constrained systems not exhibiting [3,4] shifts.

Though a stepwise ionic or radical mechanism via cyclic intermediates might be possible for these [3,4] shifts, we favor the concerted pathway,[11-14] which is isoelectronic with its well-known [3,3] counterpart and thermally allowed by the Woodward–Hoffmann orbital-symmetry rules. In a related process, placing groups with migratory aptitude (for example SMe or Cl) at the 6-position of the starting fulvene[9b] resulted in [1,4]-sigmatropic shifts (Scheme 4). Here a stepwise mechanism involving a cyclic intermediate (**27a,b**) appears equally feasible.



a, X = Cl, R = H (52%); **b**, X = SMe, R = Me (78%)

Scheme 4. [1,4] Shifts in allene oxides with heteroatoms.

The fulvene endoperoxide approach to allene oxides has opened the door to discovering mechanistically interesting rearrangements and synthetically useful reactions. Currently we are probing the possibility of [3,4] shifts with heteroatom variants (O, S, Se) as well as other rearrangements and intramolecular trapping reactions of functionalized allene oxide intermediates.

Synthesis and Gas-Phase Structure of Perfluoro(2,4-dimethyl-3-oxa-2,4-diazapentane), $(CF_3)_2N-O-N(CF_3)_2$

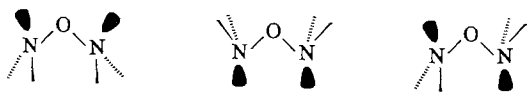
Stefan Reinemann, Rolf Minkwitz, and Heinz Oberhammer*

Although *n*-alkanes are highly stable molecules, saturated straight-chain compounds composed of other elements of the first row of the periodic table are increasingly unstable. Straight-chain molecules with more than two oxygen or nitrogen atoms could be isolated as stable species only in the presence of perfluoroalkyl groups such as CF_3. Molecular structures of bis(trifluoromethyl)trioxide, $CF_3O-O-OCF_3$,[1] and hexakis(trifluoromethyl)tetrazane, $(CF_3)_2N-NCF_3-NCF_3-N(CF_3)_2$,[2] have been reported. Their structures are influenced primarily by the interaction between electron lone pairs of adjacent atoms, which prefer a perpendicular orientation with respect to each other. In the trioxide, which possesses a C-O-O-O dihedral angle of 96(4)°, each of the two oxygen lone pairs $n_\pi(O)$ and $n_\sigma(O)$ is perpendicular to the respective lone pair of the adjacent oxygen atom. The p-shaped lone pairs of adjacent nitrogen atoms in the tetrazane are also perpendicular to each other (N-N-N-N 95(1)°). Due to their low chemical stability saturated straight-chain species composed of oxygen and nitrogen atoms are almost unknown, and no molecular structure of a compound of the type $R_2N-O-NR_2$ has yet been reported. Also in this case CF_3 groups have a strongly stabilizing effect. Perfluoro(2,4-dimethyl-3-oxa-2,4-diazapentane),[3] $(CF_3)_2N-O-N(CF_3)_2$ (**1**), was first synthesized over 30 years ago and characterized by IR, UV, and ^{19}F NMR spectroscopy as well as mass spectrometry.[4] We report here a new synthesis of **1** and its gas-phase structure.

In contrast to Haszeldine and Tipping,[4] who prepared **1** by combining the radicals $(CF_3)_2NO$ and $(CF_3)_2N$, we used OF_2 as the oxygen-carrying fluorination agent. In the presence of CsF as catalyst, OF_2 reacts with CF_3NCF_2 in the temperature range $-75/+25\,^{\circ}C$ nearly quantitatively to give **1** [Eq. (1)].[5]

$$2\,CF_3NCF_2 + OF_2 \xrightarrow{CsF\,(-70/+25\,^{\circ}C)} (CF_3)_2N-O-N(CF_3)_2 \quad \mathbf{1} \qquad (1)$$

Depending on the orientation of the electron lone pairs on the two nitrogen atoms, molecules of type $R_2N-O-NR_2$ can adopt different conformations (Scheme 1). In structure I the



I (ap,ap) II (sp,sp) III (ap,sp)

Scheme 1.

two n(N) lone pairs are antiperiplanar with respect to the opposite O–N bonds (C_{2v} symmetry), in structure II synperiplanar (C_{2v} symmetry), and in structure III one n(N) shows antiperiplanar and the other one synperiplanar orientation (C_s symmetry). In all cases the nitrogen lone pairs are perpendicular to the p-shaped lone pair of oxygen ($n_\pi(O)$) and parallel to $n_\sigma(O)$. Structures with synclinal or anticlinal orientations of the nitrogen lone pairs (C_2 symmetry) are also feasible. No experimental structures of compounds of this kind have yet been reported. Ab initio calculations (MP2/6-31G**) on the model compound $H_2N-O-NH_2$ predict structure III to be the most stable conformer.[6]

The molecular structure of **1** was determined by gas electron diffraction (GED).[7] The radial distribution function (RDF), derived by Fourier transformation of the molecular electron diffraction intensities, is presented in Figure 1. The experimental RDF is reproduced satisfactorily only with structure II, in which both n(N) lone pairs are oriented synperiplanar with respect to the opposite O–N bonds. The geometric parameters were obtained by least-squares fitting of the molecular intensities. Local C_{3v} symmetry was assumed for the CF_3 groups with

a possible tilt angle (tilt (CF_3)) in the CNC plane between the C_3 axis and the vector along N–C. The orientation of the CF_3 groups was described by a torsional angle of $\tau(CF_3)$ about the N–C bonds. For $\tau(CF_3) = 0°$ each CF_3 group exactly staggers the opposite N–C bond. The least-squares analysis results in a very small value for $\tau(CF_3)$ of 1.8(34)°, and it is not possible to determine whether adjacent CF_3 groups are rotated in the same or opposite directions. In the latter case the two $(CF_3)_2N$ entities possess local C_s symmetry, and the overall molecular symmetry is C_{2v}.

The results of this structural analysis are collected in Table 1, and the molecular model is shown in Figure 2. The fit of the

Table 1. Selected bond lengths [pm] and angles [°] from the electron diffraction analysis of **1** [a].

[a] Error limits are 3σ values and refer to the last digit. [b] Tilt angle in the CNC plane between the C_3 axis of the CF_3 group and the vector along O–N. [c] Torsional angle of the CF_3 groups about O–N bonds. For $\tau = 0°$ each CF_3 staggers the opposite N–C bond.

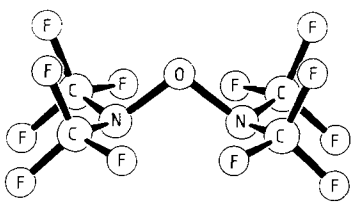

Figure 2. Molecular structure of **1**.

experimental intensities becomes worse when the two $(CF_3)_2N$ entities are rotated about the O–N bonds by more than 5°; that is, when the overall symmetry is reduced from C_{2v} to C_2. Attempts to fit the molecular intensities with structures I or III result in poor agreement, and, furthermore, in F···F or F···N contacts between the two $(CF_3)_2N$ entities of about 200 pm or shorter. Therefore, these conformations can be excluded.

The conformation determined for **1** (structure II) is different from that predicted for the model compound $H_2N–O–NH_2$ (structure III), primarily because of different steric requirements of the substituents. Replacement of H atoms by CF_3 groups leads to a strong destabilization of structures I and III due to steric repulsion between fluorine atoms and between fluorine and nitrogen atoms. The O–N bonds in **1** (146.2(8) pm) are longer than those in $(CF_3)_2N–OH$ (140(3) pm),[8] $(CF_3)_2N–OCH_3$ (142.4(28) pm),[9] or $(CF_3)_2N–ONO$ (141.0(15) pm)[10] but shorter than $O–N(sp^2)$ bonds in $O_2N–O–NO_2$ (149.2(4) pm)[11] or $(CF_3)_2NO–NO$ (157.2(21) pm). Despite the repulsion that is expected between the two nitrogen lone pairs in the *syn* orientation and between fluorine atoms of the two $(CF_3)_2N$ entities, the N–O–N angle (105.2(26)°) and the N···N nonbonded distance (232 pm) are remarkably small.

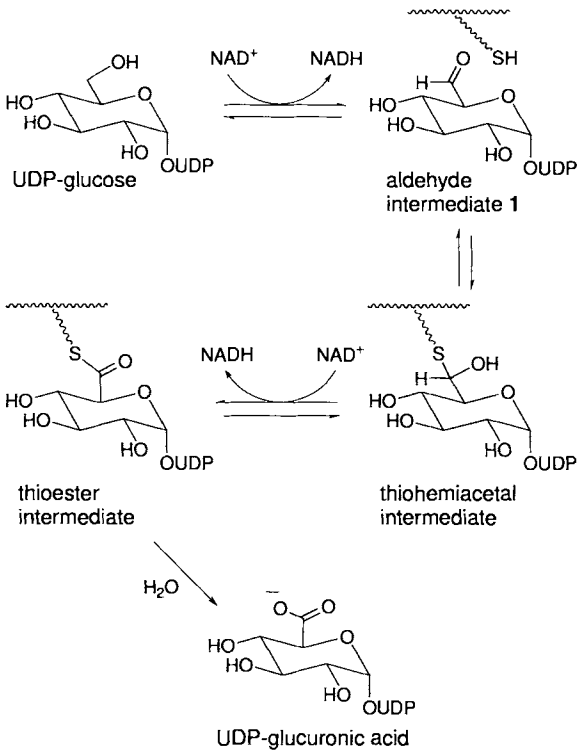
Uridine Diphospho-α-D-*gluco*-hexodialdose: Synthesis and Kinetic Competence in the Reaction Catalyzed by UDP-Glucose Dehydrogenase**

Robert E. Campbell and Martin E. Tanner*

UDP-glucose dehydrogenase catalyzes the irreversible NAD^+-dependent oxidation of UDP-glucose to UDP-glucuronic acid (Scheme 1).[1] In mammals the product of this reaction is used in the liver to tag waste metabolites for excretion,[2] and in the biosynthesis of glycosaminoglycans such as heparin[3] and hyaluronic acid.[4] In many strains of pathogenic bacteria, such as group A streptococci[5] and *Streptococcus pneumoniae* type 3,[6] it provides glucuronic acid, which is used in the construction of an antiphagocytic capsule. This capsule allows the bacteria to evade the immune system of the host and is thus responsible for their virulence.[7–9]

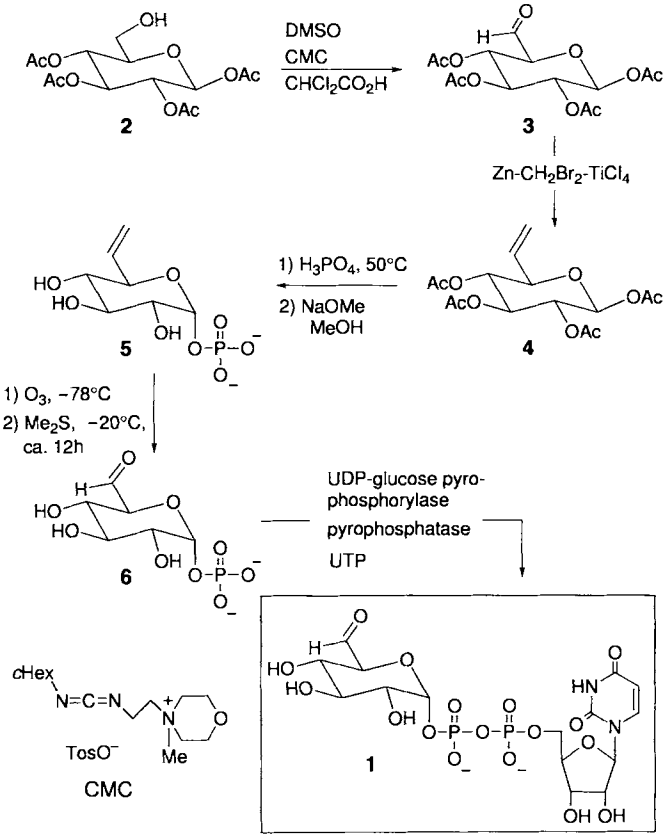


Scheme 1. Proposed mechanism for the reaction catalyzed by UDP-glucose dehydrogenase.

UDP-glucose dehydrogenase belongs to a small class of enzymes that are capable of carrying out the twofold oxidation of an alcohol to an acid without the release of an aldehyde intermediate.[1] The putative intermediate, uridine diphospho-α-D-*gluco*-hexodialdose (**1**), has therefore never been detected nor trapped with carbonyl-modifying reagents.[10–12] In previous work on the bovine liver enzyme it was suggested that the aldehyde is not an actual intermediate in the reaction and that the alcohol is converted directly to an enzyme-linked imine, which is held through a lysine side chain.[13] This is somewhat at odds with a report that only one solvent-derived oxygen atom is found in the product acid.[14] If an imine intermediate was formed one would expect both carboxylate oxygen atoms to come from solvent. In order to support the notion that **1** it is a tightly bound intermediate, we have synthesized it and measured the kinetic parameters that describe its oxidation by the enzyme.

Earlier work reported that **1** can be obtained from UDP-glucose with UDP-galactose 4-epimerase and galactose oxidase.[11, 13] This procedure tended only to work on a very small scale and required large amounts of expensive enzymes. Furthermore, the procedure neccesarily yielded an inseparable mixture of epimers at the C4 position, and no spectroscopic characterization of the product or indication of purity was reported. Therefore, we chose to carry out the stepwise synthesis of **1**.

A relatively recent paper by Müller and Schmidt[15] outlining the preparation of a dTDP-ketosugar prompted us to use an alkene as a protecting group for the sensitive aldehyde functionality (Scheme 2). The synthesis begins with an oxidation at C6 of the known tetraacetylated glucose **2**.[16] It is well documented



Scheme 2. Stepwise synthesis of **1** with an alkene as a protecting group for the sensitive aldehyde functionality.

that a facile β-elimination reaction occurs to give the α,β-unsaturated enone in these systems;[17] however, a Moffat oxidation is mild enough to minimize this elimination in related compounds.[18] The water-soluble coupling reagent CMC was used in place of *N*,*N*′-dicyclohexylcarbodiimide because the resulting urea derivative can easily be removed by extraction. We thus prepared aldehyde **3** and immediately used it without complete

purification. The alkene was introduced with Lombardo's reagent,[19] and **4** isolated in an overall yield of 12% based on **2** (Table 1). The α-phosphate was prepared by a modified MacDonald reaction[20] in neat phosphoric acid at 50 °C. No β-anomer was detected. The acetyl groups were removed with sodium methoxide to give **5** in 39% yield. Deprotection of **5** to give **6** was achieved by ozonolysis at −78 °C followed by an overnight treatment with dimethylsufide at −20 °C. Aldehyde **6** was used directly in an enzymatic coupling reaction with UTP, UDP-glucose pyrophosphorylase, and pyrophosphatase.[21] It was expected that **6** could replace the normal substrate glucose-α-1-phosphate in the coupling reaction, since the steric differences between them are slight. Indeed, following the reaction with ion-paired reverse-phase HPLC[22] indicated that one equivalent of UTP was cleanly converted into **1**. The product was surprisingly stable and could be isolated in 44% yield (based on **5**) by a combination of anion-exchange (DE-52 resin) and size-exclusion (Bio-Gel P-2) chromatographies. The aldehydic proton appears as a doublet at $\delta = 5.17$ in the ^{1}H NMR spectrum taken in D_2O (Figure 1, Table 1). This indicates that more than 95% of the aldehyde is present as a hydrate.[23]

Table 1. Selected physical data for **1**, **4**, and **5**.

[a] High-resolution liquid secondary-ion mass spectrometry: negative-ion mode in a glycerin matrix.

Treatment of aldehyde **1** with a saturating amount of NAD^+ (500 μM) and the *Streptococcus pyogenes* UDP-glucose dehydrogenase[10] resulted in the quantitative production of UDP-glucuronic acid and NADH, as analyzed by ion-paired reverse-phase HPLC.[22] The kinetics and stoichiometry of the reaction were followed by monitoring NADH formation with UV spectroscopy at $\lambda = 340$ nm. For each molecule of **1** that was oxidized, one molecule of NADH was generated. The oxidation of **1** at 30 °C and pH 8.7 followed Michaelis–Menten kinetics with $k_{cat} = 1.0\ s^{-1}$ and $K_M = 14\ \mu M$.[24, 25] These compare well with values obtained for UDP-glucose measured under identical conditions ($k_{cat} = 1.2\ s^{-1}$ and $K_M = 14\ \mu M$).[10, 25] The agreement in the k_{cat} values indicates that the aldehyde is kinetically competent to be an intermediate in the normal reaction pathway.

We envision two possibilities for the oxidation process. The enzyme may catalyze the oxidation of only the minor, unhydrated form of the aldehyde present in solution, leaving the hydrated form to bind nonproductively in a competitive manner. Alternatively, the enzyme may operate on the hydrated form and catalyze its dehydration prior to oxidation. It seems unlikely that the oxidation proceeds directly through the hydrate, since mounting evidence[10, 26, 27] suggests that the second oxidation proceeds via a thioester intermediate in a manner analogous to the reaction catalyzed by glyceraldehyde 3-phosphate dehydrogenase.[28, 29] The bound aldehyde is likely in equilibrium with a covalently bound thiohemiacetal intermediate that is attached to an active-site cysteine residue (see Scheme 1).

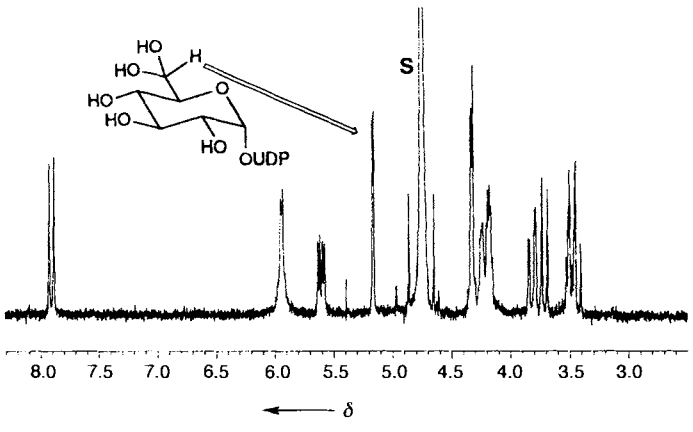

Figure 1. 200 MHz ^{1}H NMR spectrum of the hydrated form of **1** in D_2O. "S" indicates the signal for residual protiated solvent.

Activity of 2′,5′-Linked RNA in the Template-Directed Oligomerization of Mononucleotides**

Thazha P. Prakash, Christopher Roberts, and Christopher Switzer*

The ability of 2′,5′-linked nucleic acids to encode genetic information has been a matter of both experimental and theoretical interest. Whether 2′,5′-linked nucleic acids form helices had been debated[1] until relatively recently, when 2′,5′-linked oligonucleotides were found to associate.[2] A related issue is the possibility of forming chimeric helices. It has long been known that 2′,5′-linked oligoadenylate forms a triplex with natural oligouridylate.[3] This phenomenon has since been extended to other sequences and structures.[4] These findings raise the possibility of genetic-information transfer with 2′,5′-linked RNA or natural RNA with 2′,5′-linkage defects. Within the context of an enzymatic reaction, Lorsch et al.[5] demonstrated that reverse transcriptase reads through an RNA template bearing a 2′-linkage defect. In the context of non-enzymatic reactions, the ability of isomeric RNA to serve as a template was recently confirmed using the complex mixture of linear and cyclic 2′,5′-linked oligocytidylates that result from clay-catalyzed condensation of activated 5′-CMP.[6] Here we report the first mononucleotide oligomerizations allowing direct comparisons to be made between the properties of natural and 2′,5′-linked RNA templates.

Figure 1. Oligonucleotides used in this study. Double-underlined letters are 2′,5′-linked RNA. Single-underlined letters are 3′,5′-linked RNA. Italicized letters are 3′,5′-linked DNA.

Oligonucleotides used to explore template-directed synthesis are given in Figure 1. A schematic illustration of the template-directed reaction investigated in this work is given in Figure 2. The templates are modelled on hairpin-templates reported by Wu and Orgel.[7] As noted below and in earlier work,[7] incorporation of DNA into the stem and loop of the templates enables assay of product phosphodiester linkages (3′,5′ versus 2′,5′) with RNase. To assess whether the DNA stem perturbs the conformation of the 2′,5′-linked RNA tract in template **1**, the CD spectra of **1** and a standard for the RNA tract alone, 2′,5′-C_{12}, were compared. The standard gave an A-helix spectrum, and **1** a spectrum consistent with the superposition of B-helix and A-helix spectra. These observations are consistent with the RNA tract in **1** maintaining its conformational integrity.

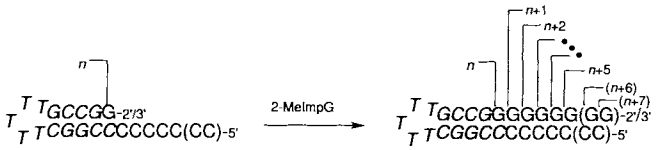

Figure 2. General scheme by which the reaction between templates **1**–**4** (Figure 1) and 2-MeImpG occurs. The GMP units sequentially add to the 2′/3′-terminus of the template (G^n). G^{n+5} is the full-length product for templates **1** and **2**, and G^{n+7} for templates **3** and **4**.

Initially the effect of different divalent metal ions on oligomerization of the 2-methylimidazolide of guanosine-5′-phosphate (2-MeImpG) was explored with templates **1** and **2** (Table 1). By far, the most effective divalent metal ion in promoting oligomerization with the 2′,5′-linked RNA bearing template **1** was magnesium. Magnesium ion was also most effective in promoting oligomerization with the 3′,5′-linked RNA template **2**, but other metal ions were also effective (notably mercury, zinc, and lead). It is not yet clear why 2′,5′-linked RNA is most active in the presence of Mg^{2+}, although it may be that the metal ion orders activated nucleotides on the template in a kinetically significant way. A representative autoradiogram showing oligomerization products obtained after eight days with **1** is given in Figure 3. On the basis of time-dependent data and comparison with the product of **2** (data not shown), the predominant product in lane 2 appears to result from incorporation of four ribonucleotides. To ensure that the observed reactions were indeed template dependent, **1** and **2** were incubated with 2-MeImpA. With this monomer no more than 10% of

Table 1. Oligomerization with templates **1** and **2** and different metal ions (100 mM in all cases) for eight days. Percentages refer to the amount of starting template remaining unconsumed by oligomerization. See the legend to Figure 3 for further details.

Metal ion	Template 1 [%]	Template 2 [%]
$MgCl_2$	27.4	1.44
$HgCl_2$	84.5	18.4
$ZnCl_2$	73.8	36.7
$CoCl_2$	76.6	61.4
$MnCl_2$	80.1	92.4
$UrO_2(NO_3)_2$	76.6	58.2
$Pb(NO_3)_2$	71.3	43.7
$Ni(NO_3)_2$	80.7	75.4

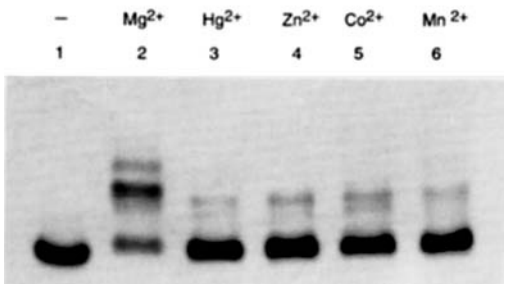

Figure 3. Autoradiogram of the products formed upon oligomerization of 2-MeImpG with template **1** in the presence of 100 mM divalent metal ion after eight days. All oligomerizations were conducted under the general conditions described by Wu and Orgel [7].

either template was consumed after eight days, and there were no multiple adducts.

The time dependence of oligomerization was investigated for all templates in Figure 1. These data are shown for **3** and **4** (Figure 4) after ten days and one day of incubation, respectively.

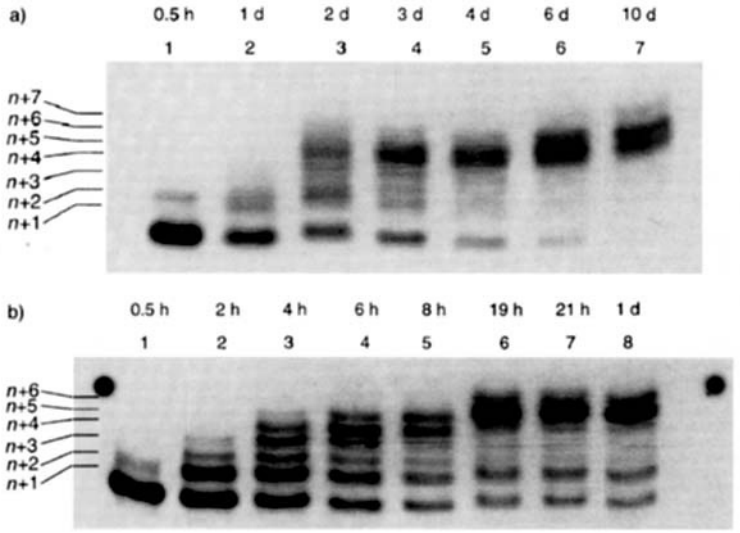

Figure 4. Results of the oligomerization of 2-MeImpG with templates **3** (a) and **4** (b) in the presence of $MgCl_2$. For each lane the time after which the reaction products were analyzed is given.

The half-lives for disappearance of templates **1**–**4** are 59, 3.4, 23, and 0.83 hours, respectively. Therefore, **3** is 28 times less efficient than 3′,5′-linked **4**, and 2′,5′-linked **1** is 17 times less efficient than 3′,5′-linked **2**. This suggests that templates **1** and **3** have roughly similar activities. 2′,5′-Linkages might well have been expected to interfere with oligomerization more dramatically, especially in **3**, which bears alternating linkages. Indeed, this is why **3** was synthesized with a more extended template region than in **1** (7-mer versus 5-mer).

Product digestions were performed with RNase T1.[7] This enzyme cleaves adjacent to *ribo*-G residues if, and only if, they are linked by a 3′,5′-phosphodiester bond. The products contain 3′-phosphate and free 5′-OH groups of the formerly adjacent nucleotides. In the present case, exhaustive RNase T1 digestion of an oligomerization product serves as an assay for the type of linkage formed between the 2′-/3′-terminal *ribo*-G residue in the hairpin templates (G^n) and the guanylate incorporated immediately adjacent to it in the product (G^{n+1}). As shown in Figure 5, lane 4, digestion of the products from 3′,5′-linked **2** yields a single major band with some faint slower-moving bands. This is consistent with the overwhelming formation of a 3′,5′-internucleotide linkage between G^n and G^{n+1} by the reaction of **2** with 2-MeImpG. As depicted in Figure 6, lanes 4–6, similar digestion of the products from 2′,5′-linked **1** yields two bands of approximately equivalent intensity. This is consistent with formation of almost equal amounts of 2′,5′- and 3′,5′-phosphodiester bonds between G^n and G^{n+1} in the oligomerization products from **1**.

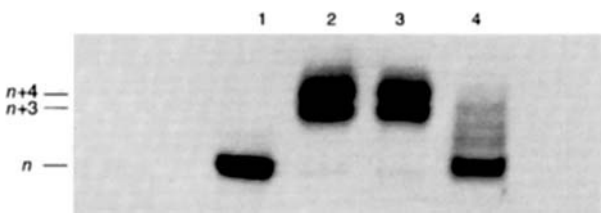

Figure 5. Digestion of the product from template **2** with RNase T_1 according to [7]. Lane 1: template **2**; lane 2: oligomerization product; lane 3: oligomerization product and buffer; lane 4: oligomerization product, buffer, and RNase T_1.

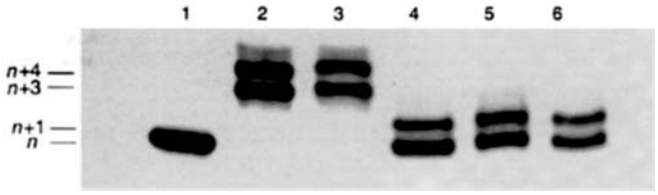

Figure 6. Digestion of the product from template **1** with RNase T_1. Lane 1: template **1**; lane 2: oligomerization product; lane 3: oligomerization product and buffer; lanes 4–6: oligomerization product, buffer, and RNase T_1 after 6, 12, and 24 hours, respectively.

In general, 2′,5′-linked RNA is more susceptible to hydrolysis than its 3′,5′-linked counterpart in a right-handed helix.[8] As noted here, diminished activity in template-directed synthesis is a further disadvantage of the 2′,5′-linkage. Consequently, there is a clear basis for supposing 3′,5′-linked oligonucleotides[9] are better adapted for the abiotic transfer of genetic information. However, there are few models for the *non-template-directed* prebiotic formation of 3′,5′-linked oligonucleotides.[10] This problem is less acute for 2′,5′-linked oligomers.[6, 11] Despite their susceptibility to hydrolysis, the present work suggests that latitude exists for the survival of 2′,5′-linked RNA. Thus, given a prebiotic bias towards non-template-directed formation of 2′,5′-linked oligomers, template-directed reactions with 2′,5′-linked RNA may have been unavoidabe to an extent. Since isomeric linkages are not per se an obstacle to template copying, 2′,5′-linked RNA (or RNA with mixed linkages) could have made a positive contribution to the evolution of modern nucleic acids.

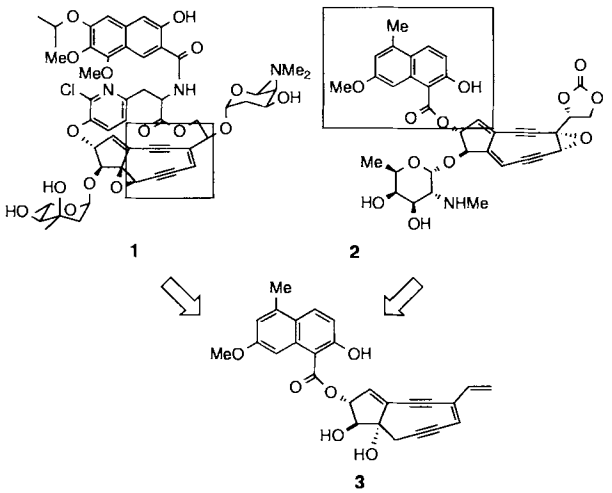
Synthesis of Nine-Membered, Masked Enediyne Analogues with DNA Intercalators and Its DNA Cleaving Activities**

Takashi Takahashi,* Hiroshi Tanaka, Haruo Yamada, Takuyuki Matsumoto, and Yukio Sugiura

Kedarcidin (KD)[1] and neocarzinostatin (NCS)[2] are members of a new class of highly potent antitumor chromoproteins whose biological activities stem from the ability of their labile nine-membered ring chromophores KD-chr (**1**) and NCS-chr (**2**) to cleave DNA via biradical intermediates. We have reported a facile approach to the nine-membered masked enediynes as analogues of **1**[3] and **2**[4] by a transannular [2,3] Wittig rearrangement. In attempts to improve the DNA cleaving activity, a number of hybrid molecules that contain a DNA-cleaving part and a DNA binder have been reported.[5] The base-[6] and sequence-[7]specificities in the cleavage of DNA by **2** have been attributed to the specific intercalation of the naphthoic acid group. However, in the cycloaromatization of **2**, intramolecular 1,5-hydrogen transfer would reduce the efficiency of double strand cleavage by quenching one of the biradical species.[8] Therefore, combination of the nine-membered KD analogue with the DNA intercalator of the NCS-chr would be expected to produce a new artificial DNA-cleaving molecule that has both high DNA-cleaving activity and base- and sequence-selectivity. In this communication, we report the synthesis and DNA-cleaving activity of the hybrid **3** possessing the KD-type DNA-cleaving moiety and the DNA intercalator of NCS-chr (Scheme 1).



Scheme 1. Design of hybrid enediyne analogue **3**.

The masked enediyne analogues **7** were designed as a potential precursor for the KD-chr analogue **3**. Phthalic acid servers as a suitable "trigger" for controlling the stability of **7b** and generating the nine-membered enediyne **3**, which would produce the biradical species in the DNA-cleaving experiment.[9]

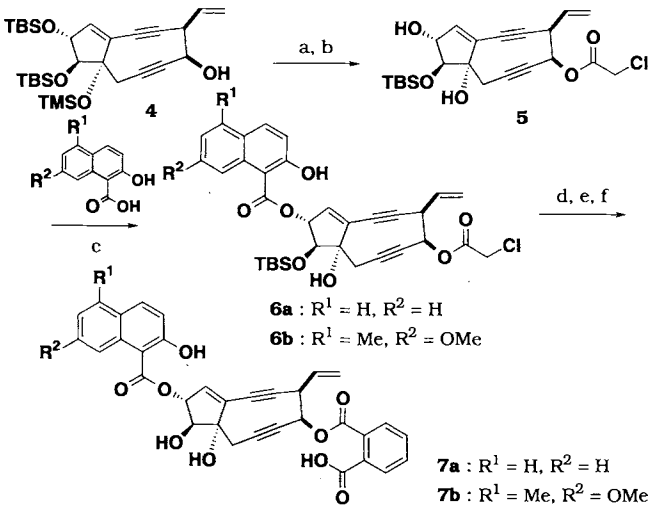
[**] This work was supported by the Ministry of Education, Science, and Culture, Japan (Grant-in-Aid for Scientific Research on Priority Area No. 06240104).

The nine-membered masked enediynes **7a** and **7b** were synthesized in six steps starting from the nine-membered diyne **4** (Scheme 2).[9] Protection of the propargyl alcohol in **5** with chloroacetyl chloride at 0 °C, followed by selective removal of



Scheme 2. Synthesis of hybrids **7a** and **7b**. a) Chloroacetyl chloride, pyridine, CH_2Cl_2; b) aqueous HF/CH_3CN (5/95), 0 °C, 76% from **4**; c) 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, CH_2Cl_2, 78%; d) aqueous NH_3, MeOH, 0 °C; e) phthalic anhydride, pyridine, DMAP, CH_2Cl_2; f) aqueous HF/CH_3CN (5/95), room temperature, **7a**: 16% from **6a**, **7b**: 24% from **5**.

the tertiary trimethylsilyl (TMS) and allylic *tert*-butyldimethylsilyl (TBS) groups with aqueous HF in CH_3CN gave diol **5** in 76% overall yield. Initially, synthesis of the model hybrid **7a** was examined. Treatment of the diol **4** with 2-hydroxy-1-naphthoic acid and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide gave ester **6a** in 78% yield. Selective removal of chloroacetyl group in **6a** with aqueous NH_3 in MeOH and treatment of the resulting alcohol with phthalic anhydride in the presence of 4-dimethylaminopyridine (DMAP) gave the diester. Deprotection by cleaving the TBS group with aqueous HF in CH_3CN afforded the desired hybrid analogue **7a**[10] in 16% overall yield from **6a**. The NCS-KD hybrid **7b** was prepared essentially as described above. The diol **5** was treated with 2-hydroxy-7-methoxy-5-methylnaphthoic acid, prepared from 5-methyl-1,3-cyclohexadione according to Hirama et al.'s procedure,[11] to give the naphthoate **6b**. The resulting ester **6b** was transformed into the **7b**[12] in 24% yield from **5**.

The DNA-cleaving activities of the hybrids **7a**, **7b**, and **8** (the triol lacking the naphthoic acid)[9] were examined under the conditions shown in Figure 1. Supercoiled pBR322 DNA was incubated with **7a** and **7b** at various concentrations (10–100 μM) in 10% MeOH in 20 mM Tris–HCl buffer (pH 7.5, Tris = tris(hydroxymethyl)aminomethane) at 37 °C for 18 h in the absence of thiol. Agarose gel electrophoresis of the DNA exposed to **7a** is shown in Figure 2 . These results clearly show that the introduction of the DNA intercalator (naphthoic acid) improved the DNA-cleaving activities of **7a** and **7b** to about ten times that of triol **8**. Remarkably, both **7a** and **7b** caused DNA cleavage with the formation of Form III even at 10 and 20 μM concentrations, respectively. The DNA-cleaving activities of the hybrid analogues **7a** and **7b** are outstanding relative to the reported enediyne analogues.[5] Studies on DNA cleavage of the 3′-labeled pBR322 fragment by **7a** and **7b** were carried out; no sequence-specificity was observed.

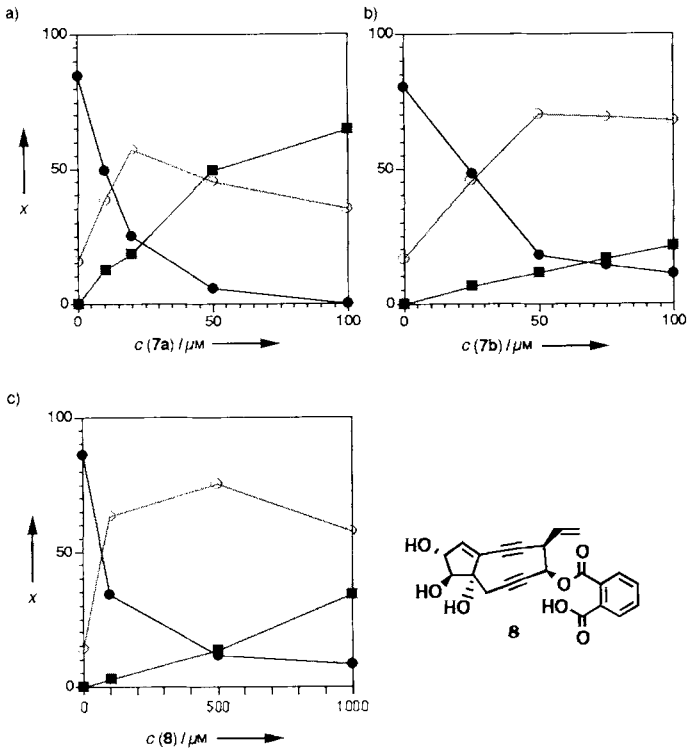


Figure 1. Percentages of the topological forms of pBR322-DNA Form I (superhelix (●)), Form II (circular DNA with one strand broken ○), and Form III (linear DNA (■)) after treatment with **7a** (a), **7b** (b), and **8** (c) at different concentrations. Reaction conditions: 10% MeOH, 20 mM Tris–HCl buffer (pH 7.5), 37 °C.

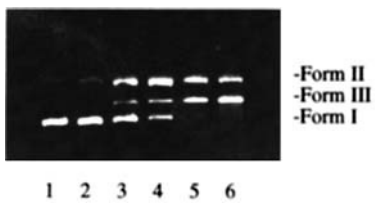

Figure 2. Dependence of the DNA-cleaving activity of **7a** on concentration: bands obtained on agarose gel by electrophoretic analysis after DNA strand cleavage. Lane 1: intact DNA; lane 2: control; lanes 3–6: fragments after DNA cleavage with 10, 20, 50, and 100 μM of **7a**.

The hybrid–DNA complex was modeled according to Schreiber et al.'s procedure[13] with the program MacroModel[14] (Figure 3). The model was developed by manually intercalating the diradical hybrid **9** (formed by activation) between A_4 and A_5 in the ten base-pair double-stranded DNA (poly-(dA-dT)). The complex was subjected to substructure minimization with the AMBER* (united atom) force field. The modeling study suggests that the hybrid analogue **3** can adopt the required conformation to facilitate double strand cleavage of DNA. The C3 radical approaches to within 3.1 Å of the C4′ hydrogen atom of A_6, and the C6 radical is also close to the C4′ hydrogen atom of T_4 (3.8 Å).

In summary, we have succeeded in designing and synthesizing nine-membered KD analogues possessing an intercalated naphthoic acid group. The biological properties of the designed analogues may provide a potential lead for the further development of DNA-cleaving molecules. Introduction of a DNA recognition site to improve base- and site-selectivities is under investigation.

Synthesis and Catalytic Activity of Dendritic Diphosphane Metal Complexes

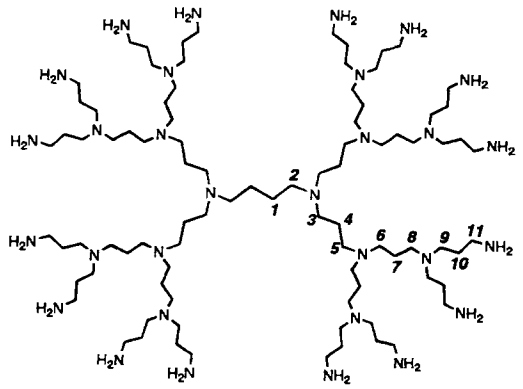
Manfred T. Reetz,* Gunther Lohmer, and Renate Schwickardi

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

The synthesis of dendrimers with defined inner and outer structural elements provides access to macromolecular materials having special properties and functions[1] that are, in principle, also useful for applications in catalysis. Although a number of metal-containing dendrimers have been described,[1, 2] they were rarely prepared for use as catalysts.[3–5] As recently delineated by van Koten et al., such catalysts can be considered to be at the interface between homogeneous and heterogeneous catalysis.[3] In the most favorable case they combine the advantages of both classes of catalysts, namely, the existence of a specific number of structurally defined, catalytically active metal centers as in traditional homogeneous catalysis as well as the possibility of simple separation and reuse of the catalyst as in heterogeneous catalysis. However, recycling has not yet been achieved for any dendritic metal catalyst.

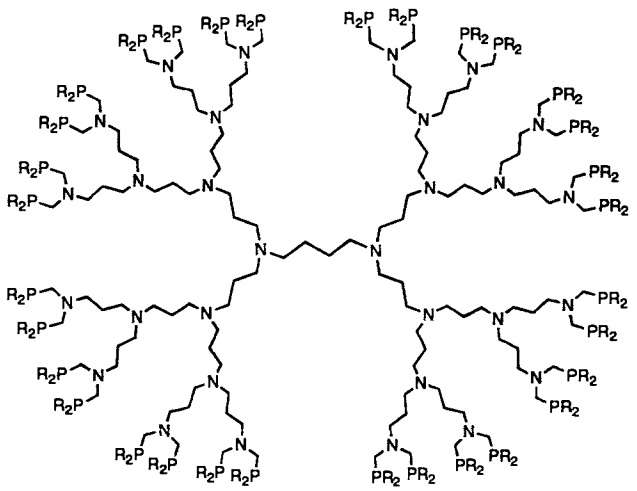
We now report on 1) a simple synthesis of dendritic diphosphanes, 2) the preparation of the corresponding metal and bimetal complexes, 3) their application in catalysis, and 4) modes of recycling the dendritic metal catalysts.

The starting point of our synthesis is the DAB-based (DAB = 1,4-diaminobutane) polyamino dendrimer DAB-dendr-$(NH_2)_{16}$ (**1**), which can be prepared according to the method



1

$CH_2O/HPPh_2$



2 (R = C_6H_5)

of Vögtle et al.,[6] and which is now commercially available.[7] Double phosphinomethylation of each of the 16 primary amino endgroups, a reliable reaction type in simple cases,[8] was effected in essentially quantitative yield upon use of Ph_2PCH_2OH prepared in situ from CH_2O and $HPPh_2$. The reaction affords the dendrimer DAB-dendr-$[N(CH_2PPh_2)_2]_{16}$[9] (**2**), which has a molecular weight[10] of 8029; it was characterized by elemental

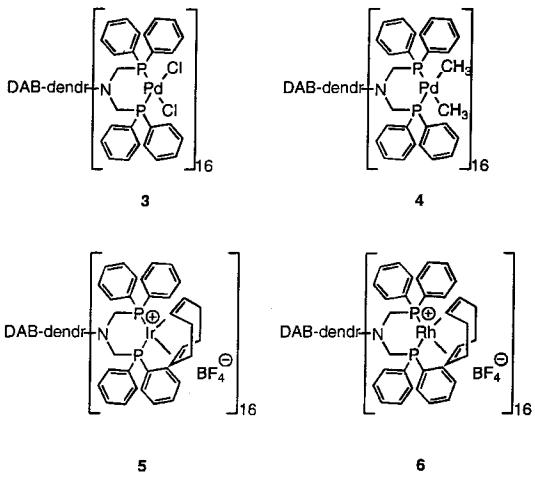
analysis as well as IR and NMR spectroscopy. For example, during the course of the reaction the NH bands in the IR spectrum disappeared completely. The ^{13}C NMR spectra of **1** and **2** are also instructive (Figure 1). In particular, the signals at $\delta = +30.6$ and $+40.3$, corresponding to the C10 and C11

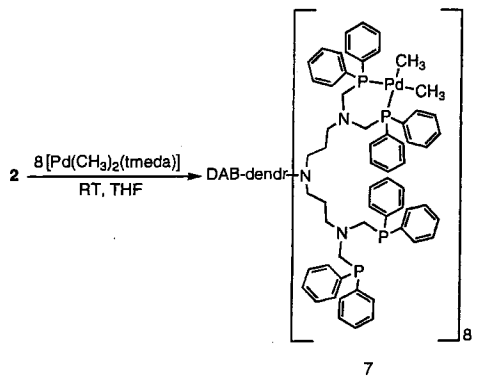
Figure 1. Portions of the ^{13}C NMR spectra of **1** (top) and of **2** (bottom).

atoms of **1**, are no longer visible in the spectrum of the phosphinomethylated compound **2**, which is a clear indication of a quantitative reaction mode. The completeness of the double phosphinomethylation is also evident by inspection of the ^{31}P NMR spectrum of **2**. It shows a sharp signal at $\delta = -28.0$ and resembles the spectrum of the parent compound n-C_3H_7-$N(CH_2PPh_2)_2$ ($\delta = -27.8$).

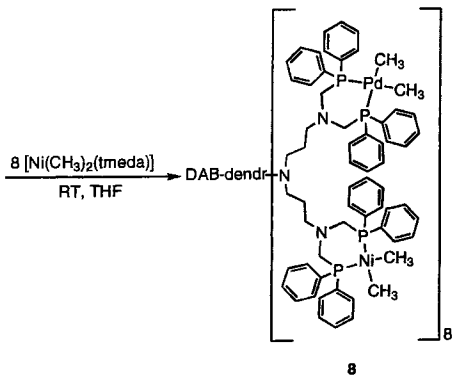
The dendrimer **2** with 16 bidentate ligands on the outer surface provides the possibility of specific complexation with a variety of transition metals, and loading can be complete or partial. In an initial series of experiments complete metal loading forming the metal-containing dendrimers **3**–**6** was readily accomplished under standard reactions with $[PdCl_2(PhCN)_2]$, $[Pd(CH_3)_2(tmeda)]$, $[Ir(cod)_2BF_4]$ and $[Rh(cod)_2BF_4]$. For the purpose of characterization, correct elemental analyses and particularly NMR spectroscopy were useful, especially as NMR data of the corresponding metal complexes of the parent compound n-$C_3H_7N(CH_2PPh_2)_2$ were available for comparison: the ^{31}P NMR data of the model compounds and of the dendrimers do not differ significantly ($\delta = +8.3$ for **3** and $+8.5$ for $[n$-C_3H_7-$N(CH_2PPh_2)_2PdCl_2]$; $+3.3$ for **4** and $+3.9$ for $[n$-C_3H_7-$N(CH_2PPh_2)_2Pd(CH_3)_2]$; $+7.6$ (d, $J_{P,Rh} = 141$ Hz) for **6** and $+7.8$ (d, $J_{P,Rh} = 141$ Hz) for $[n$-$C_3H_7N(CH_2PPh_2)_2$-$Rh(cod)BF_4]$).



To prepare bimetallic complexes, dendrimer **2** was first loaded with $[Pd(CH_3)_2(tmeda)]$ to 50%. Due to the statistical distribution of the metal, the formation of a single defined product **7** is unlikely. The ^{31}P NMR spectrum of the crude product shows two sharp signals at $\delta = -27.8$ and $+3.5$ for the metal-free and the metal-containing ligands, respectively. Upon reacting the material with $[Ni(CH_3)_2(tmeda)]$, bimetallic dendrimers **8** were obtained. The ^{31}P NMR spectrum reveals two signals at $\delta = +3.5$ and $+18.5$.

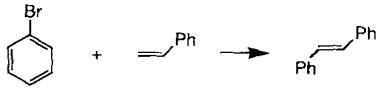


7



8

Initial experiments to test the metal-containing dendrimers in catalysis were successful, for example, in the Heck reaction[11] of bromobenzene **9** and styrene **10** with formation of stilbene **11**.

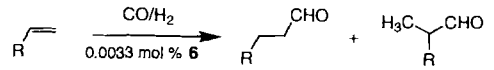


9 **10** **11**

Reactants **9** and **10** were dissolved in dimethylformamide (DMF) and heated for 3 h at 130 °C in the presence of sodium acetate as base and complex **4** (0.125 mol% corresponding to 2 mol% "Pd-monomer") as catalyst. The insoluble inorganic components were filtered from the reaction mixture, and the clear solution was diluted with diethyl ether. Addition of this relatively unpolar solvent caused essentially complete precipitation (>98%) of a Pd-containing dendrimer, the precise structure of which has not been determined.[12] The analysis of the reaction mixture by gas chromatography showed the presence of **11** (89%) and 1,1-diphenylethylene (11%) at a conversion of 85–90%. The isolated Pd-containing dendrimer was used in the same reaction once more and displayed comparable catalytic activity (91% **11** and 9% 1,1-diphenylethylene, conversion 77%). The catalytic activity of the precatalyst **7** having 50% Pd-loading was similar.

In the few previously known cases of catalysis with dendritic metal complexes, catalytic activity was shown to be slightly or significantly lower than that of the corresponding monomeric parent compounds.[3,4] In contrast, we observed in our system a significantly higher activity (typically, turnover numbers (TON) of 50 for **4** versus 16 for the parent compound $[RN(CH_2PPh_2)_2Pd(CH_3)_2]$, R = n-C_3H_7 or C_6H_5). This is attributable to the higher thermal stability of the dendritic complexes. Thus, in the case of **4** and **7** practically no undesired formation of elemental Pd was observed. In contrast, the Pd complexes of the parent compounds undergo partial decomposition with formation of Pd precipitates.

Finally, in preliminary experiments the hydroformylation[13] of 1-octene **12** was tested. Use of 0.0033 mol% (0.052 mol% "Pd-monomer") of the Rh-containing dendrimer **6** and a small excess (5%) of the free ligand **2** gave a smooth reaction with quantitative formation of the aldehydes **13** and **14** in a ratio of



14 R = C_6H_{13} **15** **16**

60:40 (turnover frequency (TOF) = 360 h^{-1}). These data are similar to the values obtained upon using the parent compounds $[PhN(CH_2PPh_2)_2Rh(cod)BF_4]$ or $[n\text{-}C_3H_7N(CH_2PPh_2)_2Rh(cod)BF_4]$ (TOF = 240 h^{-1}; n/iso = 62:38 and TOF = 185 h^{-1}; n/iso = 61:39, respectively).[14] Although an efficient method for recycling the very small amounts of the dendritic catalyst still needs to be developed, several options are evident. The use of membrane reactors[15] is a perspective that is also of interest for the other metal-containing dendritic catalysts described herein.

The strategy that we have developed for the synthesis of dendritic diphosphanes opens a general way to prepare transition-metal-containing dendrimers for use in catalysis. Thus, dendrimer **1** was treated analogously with CH_2O/HP($cyclo$-$C_6H_{11})_2$ or CH_2O/$HP(C_2H_5)_2$ to provide the corresponding dendrimers with 16 outer cyclohexyl- or ethyl-substituted diphosphane units. The corresponding $[Pd(CH_3)_2]$ and $[Rh(cod)BF_4]$ complexes were also prepared analogously and are currently the subject of further investigations, as are diphosphane-metal complexes of the commercially available polyamino-dendrimer DAB-dendr-$(NH_2)_{64}$[7] having 64 outer amino groups.

Experimental Section

Synthesis of dendrimer **2**: Under an inert atmosphere the mixture of paraformaldehyde (0.213 g, 7.09 mmol) and diphenylphosphane (1.35 mL, 7.76 mmol) in methanol (5 mL) was heated at 65–70 °C for 10 min. The reaction mixture was cooled to room temperature and treated with a solution of **1** (0.336 g, 0.20 mmol; 3.19 mmol with respect to the amino endgroups) in methanol (3 mL). After 0.5 h stirring at room temperature, toluene (15 mL) was added, and the clear yellow solution heated at 65 °C for 0.5 h. To ensure complete reaction, the mixture was stirred for an additional 12 h at room temperature. The volume of the reaction mixture was concentrated under reduced pressure to about 3 mL, and methanol (10 mL) was added. The product precipitated in the form of a glassy colorless solid, which was dried under high vacuum for 10 h at 60–65 °C. Yield: 1.53 g (>96%). IR (KBr): $\tilde{\nu}$[cm^{-1}] = 3068 (phenyl), 3050 (phenyl), 2941 (NCH_2), 2793 (NCH_2), 1484 (phenyl), 1479 (phenyl), 1432 (phenyl), 739 (phenyl), 693 (phenyl). ^1H NMR (400 MHz, $CDCl_3$): δ = 1.45 (m, 60H, $NCH_2CH_2CH_2N$, $NCH_2CH_2CH_2CH_2N$), 2.18 (m, 52H, $CH_2NCH_2CH_2$), 2.34 (m, 32H, $NCH_2CH_2CH_2NCH_2P$), 2.80 (m, 32H, CH_2NCH_2P), 3.54 (m, 64H, NCH_2P), 7.20 (m, 192H, phenyl), 7.37 (m, 128H, phenyl). $^{13}C\{^1H\}$ NMR (101 MHz, $CDCl_3$): δ = 23.99 (s, *C10*), 24.26 (s, *C4/7*), 24.70 (s, *C1*), 51.77 (s, *C9*), 51.97 (s, *C8*), 52.47 (s, *C5/6*), 52.68 (s, *C3*), 54.67 (t, $^3J(C,P)$ = 9.5 Hz, *C11*), 58.78 (dd, $^1J(C,P)$ = 14.1 Hz, $^3J(C,P)$ = 8.6 Hz, NCH_2P), 128.29 (m, phenyl), 133.03 (d, $J(C,P)$ = 18.2 Hz, phenyl), 138.28 (d, $J(C,P)$ = 13.3 Hz, phenyl). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): δ = −28.01 (s); elemental analysis calcd. for $C_{504}H_{560}N_{30}P_{32}$: C 75.39, H 7.03, N 5.23, P 12.34; found: C 75.18, H 6.91, N 5.24, P 12.59.

[12] Mechanistically it can be assumed that the Pd complex **4** as precatalyst undergoes a thermally induced, ethane-producing reductive elimination with formation of the corresponding 14-electron chelate [16]. This adds oxidatively to bromobenzene **9**, thereby initiating the Heck reaction. On completion of the reaction, the ^{31}P NMR spectrum of the separated solid material in [D_8]DMF shows a single signal at $\delta = +23$ as a sharp singlet. It is possibly an anionic Pd species [17].

Isolation of the Quinone Mono *O,S*-Acetal Intermediates of the Aromatic Pummerer-Type Rearrangement of *p*-Sulfinylphenols with 1-Ethoxyvinyl Esters**

Yasuyuki Kita,* Yoshifumi Takeda, Masato Matsugi, Kiyosei Iio, Kentoku Gotanda, Kenji Murata, and Shuji Akai

Treatment of aliphatic sulfoxides with acid anhydrides leads to a Pummerer rearrangement to give *O,S*-acetals. Because these products can be readily hydrolyzed to carbonyl compounds, these reactions have been widely utilized in a variety of organic syntheses (Scheme 1a).[1] On the other hand, similar reactions of aromatic sulfoxides have not been extensively explored. Pummerer-type rearrangements of *p*-sulfinylphenols **1** would be an effective method for the preparation of *p*-quinones **2** via the *O,S*-acetals **B** and would also be interesting from a mechanistic standpoint (Scheme 1b). King and Jung et al. have reported related studies on the reaction of acid anhydrides with 3,5-dimethyl-4-(methylsulfinyl)phenol[2] and with 4-methyl-2-(arylsulfinyl)phenols.[3,4] The main products in these reactions were obtained through conjugate addition of nucleophiles to the sulfonium ions (like **A**), while the *O,S*-acetals (like **B**) were obtained in very low yield[2] and only in very few cases.[4]

At the same time as the publications by Jung et al.,[3,4] we reported the Pummerer-type rearrangement of fully substituted *p*-sulfinylphenols **1** using trifluoroacetic anhydride (TFAA) as an effective method for preparation of *p*-quinones **2**.[5] We then extended this method to the *o*-unsubstituted *p*-sulfinylphenols **1** using TFAA and allyltrimethylsilane[6] and also to the silyl ethers of **1**, which enabled us to carry out the selective preparation of dihydroquinones.[7] Our results are noteworthy because they show novel *ipso*-substitution of sulfur functional groups into oxygen functional groups on phenol rings.

Although all of these reactions are certainly thought to proceed via the quinone mono *O,S*-acetals **B**, we were never able to isolate or even identify such acetal intermediates by spectroscopy. Difficulties in isolating **B** have been described previously[2–4] are probably due to the use of acid anhydrides as the initiator because acids or counteranions generated from the reagents would readily react with **B**.

Isolation of the acetal **B** is attractive from the view point of the utility of these compounds as useful synthons as well as the support of our proposed reaction mechanism. Here, we report the first isolation of the *O,S*-acetals **3** by employing 1-ethoxyvinyl esters **2a,b** for the Pummerer-type rearrangement of *p*-sulfinylphenols **1**.[8,9] Selective transformation of **3** into the quinones **4** and the dihydroquinone **6** was also achieved. This success is attributed to the fact that the reactions with the ketene acetal reagents **2**[10] can be carried out under nearly neutral conditions, thereby releasing neutral and stable ethyl acetate as a single side product.

We initially examined the Pummerer-type reaction of tetramethyl-4-(phenylsulfinyl)phenol (**1a**) using 1-ethoxyvinyl acetate (**2a**) (5 equiv) under various conditions. The reaction in dry MeCN or dry toluene without a catalyst proceeded very slowly and required a high temperature or a long reaction time, resulting in the formation of several products but not the *O,S*-acetal **3a**. On the other hand, use of a catalytic amount of *p*-toluenesulfonic acid (*p*-TsOH) in dry toluene sufficiently accelerated the reaction, so that **3a** could be isolated in 69% yield after stirring at 60 °C for 1 h (Table 1). This result is completely different from that obtained by a similar treatment of **1a** with acetic anhydride and a catalytic amount of *p*-TsOH in toluene at refluxing temperature: this reaction afforded the corresponding

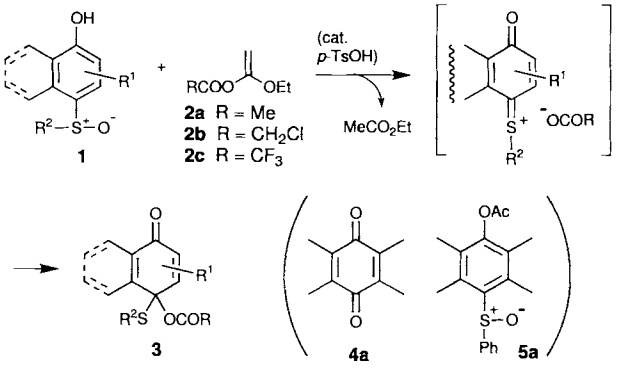
acetate **5a** quantitatively, which did not react further with **2a**. Use of the chloroacetate **2b** instead of **2a** gave the acetal **3b** in 81% yield. In contrast, the more reactive trifluoroacetate **2c** did not give the *O,S*-acetal **3** but the benzoquinone **4a** (40% yield). The reactions with 1-ethoxyvinyl benzoate (R = Ph) and the *p*-nitrobenzoate (R = *p*-$NO_2C_6H_4$) were slow and gave low yields of **4a** (Scheme 2). Thus, the chloroacetate **2b** was found to be a suitable reagent for preparation of the *O,S*-acetal **3**.



Scheme 2. Reaction of the *p*-sulfinylphenol **1** with the 1-ethoxyvinyl esters **2a–c**.

The reactions of various types of *p*-sulfinylphenols **1b–g** and naphthols **1h–j** with **2a,b** were carried out in an analogous manner to that applied for the preparation of **3a,b**, and the results are summarized in Table 1. The reactions were usually complete at room temperature or at 60 °C within several hours. Quenching the reaction mixture with Et_3N or K_2CO_3 followed by concentration and quick purification by chromatography on SiO_2 enabled us to isolate the products **3** in moderate to high yields. The compounds were identified by spectroscopy and can be stored under a nitrogen atmosphere in a refrigerator. Usually, **2b** provided **3** in higher yields. Both aliphatic and aromatic sulfinyl groups could be employed for this transformation. Allyl, ester, and hydroxyl groups are compatible with these reactions (entries 9–11). The formation of the *o*-unsubstituted products **3f,g** was also achieved in good yields (entries 6,7).

Table 1. Reactions of the *p*-sulfinylphenols **1a–j** with the 1-ethoxyvinyl esters **2a,b** to give the *O,S*-acetals **3a–l**[a].

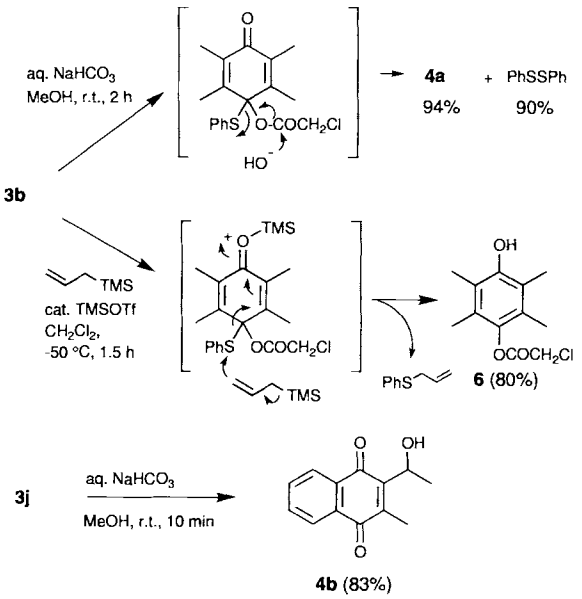
[a] *p*-TsOH (0.01–0.05 equiv) in toluene. For a typical procedure see the *Experimental Section*. [b] Obtained as a 1:1 mixture of two diastereomers.

Treatment of **3b** with aqueous $NaHCO_3$ in MeOH at room temperature caused selective saponification of the chloroacetate and the concomitant elimination of the phenylthio group to give the corresponding quinone **4a** and the disulfide PhSSPh in 94 and 90% yield, respectively. On the other hand, **3b** reacted with allyltrimethylsilane in the presence of a catalytic amount of trimethylsilyl trifluoromethanesulfonate (TMSOTf) to afford an 80% yield of the dihydroquinone **6** and allyl phenyl sulfide. Mild alkaline treatment of **3j** led to the rapid formation of quinone **4b** in 83% yield (Scheme 3). Thus, selective conversion of **3** to both quinones and dihydroquinones was achieved by the choice of the reaction conditions, which also supports the reaction mechanism for our previously reported preparation of quinones and dihydroquinones from *p*-sulfinylphenol derivatives.[5–7]



Scheme 3. Conversion of the *O,S*-acetals **3b** and **3j** to the quinones **4a** and **4b** and the dihydroquinone **6**.

The present results are of particular interest from the view point of the direct preparation of quinone monoacetals from aromatic compounds under *nonoxidative* conditions.[11] Extended studies on the utilization of the products **3** as versatile synthons are now under investigation.

Experimental Section

Typical procedure for the reaction of the *p*-sulfinylphenol **1** and 1-ethoxyvinyl esters **2a,b**: Under a nitrogen atmosphere, **2b** (0.82 g, 5.0 mmol) [9c, 10] and anhydrous *p*-toluenesulfonic acid (9 mg, 0.05 mmol) were successively added to a suspension of the *p*-sulfinylphenol **1a** (0.27 g, 1.0 mmol) in dry toluene (30 mL). The reaction mixture was stirred at 60 °C for 1 h and cooled to room temperature. Triethylamine (0.007 mL) was added and the reaction mixture was concentrated in vacuo. The residue was purified by SiO_2-flash column chromatography (hexane/ethyl acetate 8/1) to give the quinone mono *O,S*-acetal **3b**: pale yellow crystals (yield 81%); m.p. 132–133 °C (hexane/ethyl acetate); IR (KBr): $\tilde{\nu}$ = 1776, 1662, 1630 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$): δ = 1.64 (s, 6H), 2.01 (s, 6H), 4.16 (s, 2H), 7.01 (d,

$J = 7.5$ Hz, 2H), 7.21 (t, $J = 7.5$ Hz, 2H), 7.38 (t, $J = 7.5$ Hz, 1 H); MS (EI, 70 eV): m/z (%): 352 (0.6) [$M^+ + 2$], 350 (1.6) [M^+], 165 (100), 110 (57); HRMS calcd for $C_{18}H_{19}{}^{35}ClO_3S$ (M): 350.0742, found: 350.0727; elemental analysis: calcd C 61.62, H 5.46; found: C 61.61, H 5.32.

[8] We have elucidated a highly enantioselective Pummerer-type reaction of chiral, nonracemic aliphatic sulfoxides using *O*-silylated ketene acetals [1d], although the enantiomeric excesses for the reported asymmetric Pummerer reaction induced by acid anhydrides were low [1]. This method was efficiently applied to the asymmetric Pummerer-type cyclization of chiral, nonracemic sulfoxides and to the biomimetic conversion of Arnstein tripeptide analogs into optically active *cis* β-lactams. This synthesis resembles penicillin biosynthesis [9a]. Similar highly enantioselective Pummerer-type reactions of chiral, nonracemic aliphatic sulfoxides induced by a variety of 1-ethoxyvinyl esters including **2a,b** also gave α-acyloxy sulfides [9b,c].

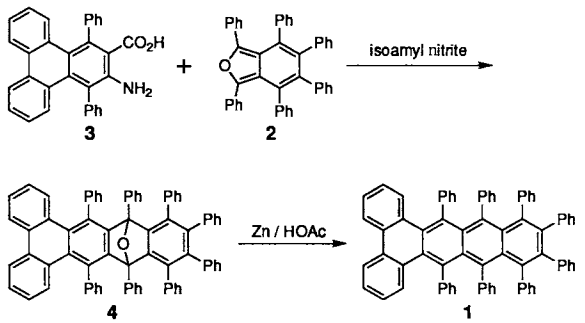
An Extraordinarily Twisted Polycyclic Aromatic Hydrocarbon**

Xiaoxin Qiao, Douglas M. Ho, and Robert A. Pascal, Jr.*

Among the most aesthetically pleasing chemical structures are polycyclic aromatic hydrocarbons (PAHs) that exhibit helical distortions from planarity.[1] In recent years a variety of longitudinally twisted PAHs and PAH derivatives—essentially twisted aromatic ribbons—have been prepared by the substitution of normally planar PAHs with bulky substituents.[2, 3] Thus, for example, anthracene is a planar molecule, but decaphenylanthracene exhibits an end-to-end twist of 63°.[3] In no case, however, has the overall twist of such a molecule exceeded 70°,[4] and we wondered what would be the properties of a PAH in which the twist exceeded 90°. We now report the synthesis and crystallographic characterization of 9,10,11,12,13,14,15,16-octaphenyldibenzo[*a,c*]naphthacene (**1**), a PAH with an extraordinary end-to-end twist of 105°.

The synthesis of **1** is similar to that of decaphenylanthracene;[3] the critical step is the addition of a highly substituted aryne to hexaphenylisobenzofuran[3, 5] (**2**) (Scheme 1). Thus,



Scheme 1.

the anthranilic acid **3**[2d] was diazotized in the presence of **2**, and the resulting oxide **4** was deoxygenated with zinc in acetic acid to yield compound **1** in 1.6% overall yield. Both the cycloaddition of the aryne with isobenzofuran (15% yield) and the deoxygenation (11%) suffer from severe steric hindrance, which accounts for the low yield in an otherwise simple procedure.

Compound **1** is an orange solid that is readily soluble in a wide variety of organic solvents, in contrast with many PAHs. Orange prisms were obtained from ethanol, and X-ray structure analysis unambiguously established the structure of **1** (Figure 1).[6] The molecule lies on a crystallographic C_2 axis, thus its site symmetry is equal to its expected molecular symmetry. The central naphthacene moiety is a smoothly twisted aromatic ribbon in which the terminal bonds [C(1)–C(1′) and C(13)-C(13′)] are rotated by 105.4(8)° with respect to each other. However, the distortion is evenly distributed among the four benzene rings of the naphthacene, which contribute twists of 26.1(8)°, 28.7(8)°, 28.6(8)°, and 21.9(8)°, thus enabling good conjugation to be maintained within the aromatic π system. Indeed, the UV spectrum of **1**, with absorption maxima at 496, 470, and 364 nm, retains most of the features found in the spectrum of the parent hydrocarbon, dibenzo[*a,c*]naphthacene,[9] but shifted by about 50 nm to the red.

Compound **1** is very stable in the solid state. Crystals heated to 400 °C in an open capillary appear unchanged (apart from some cracking) by visual inspection and mass spectrometric and thin-layer chromatograpic analyses. Concentrated solutions of **1** appear to undergo slow decomposition at room temperature, but the factors governing this process are unclear. However, a dilute solution of **1** (1.8×10^{-5} M in dimethyl sulfoxide), monitored spectrophotometrically, was indefinitely stable at 50 °C even in the presence of air and added HCl, and an NMR sample (1.6×10^{-3} M in $CDCl_3$) showed no decomposition after one week at room temperature.

The preparation of **1** establishes a new record for the twisting of an aromatic π-electron system, and its end-to-end twist of

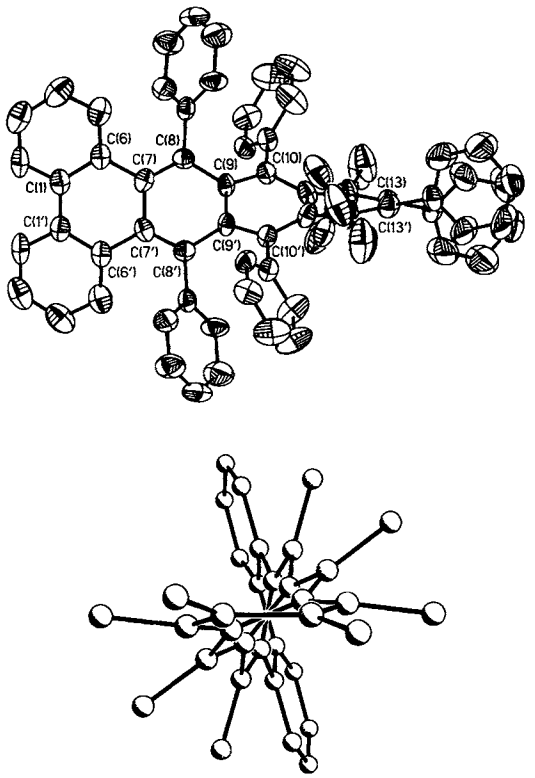

Figure 1. Molecular structure of compound **1** (thermal ellipsoids are drawn at the 50% probability level, hydrogen atoms have been omitted for clarity, and only the *ipso*-carbon atoms of the phenyl rings are shown in the lower illustration).

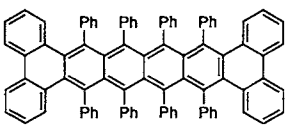
105° is more than 1.5 times as great as that observed in any previous PAH.[10] Looking to the future, two such molecules, fused to appropriate acenes to form a ring, would be sufficient to form a polycyclic aromatic Mobius strip. In addition, AM1 calculations,[12] which yield a geometry for **1** that is in excellent agreement with the X-ray structure, indicate that the hexacene **5** should have a twist of 178°. Such compounds are no longer unreasonable synthetic goals!



5

Experimental Section

1: A solution of **3** (0.530 g, 1.21 mmol) in 1,2-dichloroethane (80 mL) was added dropwise to a solution of **2** (1.10 g, 1.92 mmol) and isoamyl nitrite (0.5 mL) in 1,2-dichloroethane (55 mL) at reflux under argon. After 1 h, the solution was cooled, and ethanol (12 mL) and 1% NaOH (40 mL) were added. The resulting mixture was extracted with $CHCl_3$ (200 mL), and the organic extract was washed with saturated $NaHCO_3$, dried over $MgSO_4$, and concentrated to dryness. The residue was fractionated by column chromatography (silica gel; 1:1 hexanes:CH_2Cl_2, then 1:2 hexanes:CH_2Cl_2) to yield compound **4** as an off-white solid (0.174 g); ^{1}H NMR (500 MHz, $CDCl_3$): δ = 6.60–6.76 (m, 18H), 6.80 (d, J = 8 Hz, 6H), 6.86–7.03 (m, 16H), 7.09 (t, J = 8 Hz, 2H), 7.35 (t, J = 8 Hz, 2H), 7.42 (d, J = 8 Hz, 2H), 8.37 (d, J = 8 Hz, 2H); FAB MS: m/z (%) 953 (M^+ + H, 46), 849 (49), 662 (99), 575 (100). Without further purification, this material was treated with a large excess of activated Zn dust (0.3 g) in glacial acetic acid (50 mL) at reflux for 5 h. The mixture was filtered hot, and after cooling, water was added to the filtrate. The resulting orange precipitate was collected by filtration and rinsed with water. After drying, the solid was subjected to preparative TLC (silica gel; 2:1 hexanes:CH_2Cl_2) to give pure **1** as an orange solid (18.6 mg, 0.020 mmol, 1.6% yield): M.p. >400 °C; ^{1}H NMR (500 MHz, $CDCl_3$): δ = 6.19 (d, J = 8 Hz, 2H), 6.26 (t, J = 7 Hz, 2H), 6.37 (m, 4H), 6.49 (m, 12 H), 6.61–6.84 (m, 18H), 6.92 (m, 4H), 7.06 (t, J = 7 Hz, 2H), 7.20 (t, J = 8 Hz, 2H), 8.02 (d, J = 8 Hz, 2H); IR (KBr): $\tilde{\nu}$ = 3078, 3055, 3022, 1600, 1493, 1442 cm^{-1}; UV ($CHCl_3$): λ_{max} (lg ε) = 496 (3.69), 470 (3.78), 446 (sh, 3.68), 364 (4.78), 352 (sh, 4.69); FAB MS: m/z (%) 937 (M^+ + H, 100), 460 (31).

[6] An orange needle of **1**, cut to 0.06·0.08·0.40 mm, was used for the X-ray diffraction studies. Crystal data: $C_{74}H_{48}$, M = 937.12, orthorhombic, *Pbcn*, a = 16.562(2), b = 17.796(2), c = 17.641(2) Å, V = 5199.6(10) Å^3, Z = 4, ρ_{calcd} = 1.197 Mg m^{-3}. Intensity measurements were made by using graphite-monochromated $Mo_{K\alpha}$ radiation (λ = 0.71073 Å) at 298 K on a Siemens P4 diffractometer. A total of 4260 reflections were measured ($3° \le 2\theta \le 45°$, ω scan mode), of which 3406 were unique (R_{int} = 0.057), and 831 have $I > 2\sigma(I)$. Corrections were made for Lorentzian polarization but not for absorption or extinction. The structure was solved by direct methods (SHELXTL [7]) and refined by full-matrix least-squares on F^2 (SHELXL-93 [8]). All non-hydrogen atoms were refined with anisotropic displacement coefficients, and hydrogen atoms were included with a riding model and isotropic displacement coefficients [U(H) = 1.2U(C)]. The refinements converged to $R(F)$ = 0.047, $wR(F^2)$ = 0.032, and S = 1.07 for 831 reflections with $I > 2\sigma(I)$, and $R(F)$ = 0.237, $wR(F^2)$ = 0.049, and S = 0.67 for 3406 unique reflections and 334 variables. The residual electron density ranged from −0.15 to 0.17 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100115. [10] An enantiomerically pure sample of compound **1** might be expected to show exceptional optical activity. No attempt has been made to resolve **1**; however, the 500 MHz ^{1}H NMR spectrum of **1** in the chiral solvent mixture *d*-trifluoromethylbenzyl alcohol/deuterochloroform (1/2) is broadened, but not cleanly split into enantiomeric subspectra, suggesting that it may have a significant barrier to racemization. Previously prepared longitudinally twisted aromatic polycycles show evidence of great conformational flexibility, possess only modest barriers to racemization, and none has been successfully resolved [2b, 3, 11].

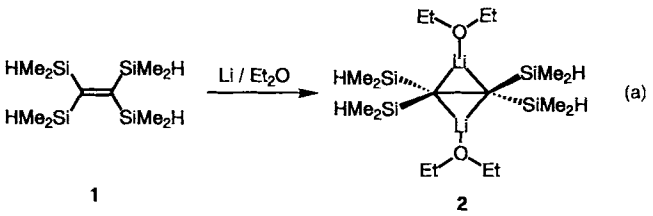
1,1,2,2-Tetrakis(dimethylsilyl)-1,2-ethanediyldilithium-bis(diethyl ether): Observation of a SiH–Li Agostic Interaction**

Akira Sekiguchi,* Masaaki Ichinohe, Masae Takahashi, Chizuko Kabuto, and Hideki Sakurai*

Si–H···M (M = alkali metal) agostic interactions attract considerable interest in view of the structure and bonding of organo alkali metal compounds, in particular the organolithium compounds.[1] The interaction between SiH and the lithium cation has so far only been predicted by the theoretical study of SiH_3Li.[2] The inverted C_{3v} structure is calculated to be 2.4 kcal mol^{-1} more stable than the tetrahedral C_{3v} isomer. However, the only experimental example of a SiH–Na interaction is in an oligomeric sodium alcoholate.[3]

Ab initio calculations on $LiCH_2CH_2Li$ suggest that a *trans* structure with partial or symmetrical lithium bridging is most stable, whereas the eclipsed conformation is much higher in energy than the *trans*-bridged planar structure.[4] Indeed, experimental studies of the planar or twisted lithium doubly bridged structures of ethylene dianion dilithium derivatives have been reported.[5, 6] In order to disclose SiH–Li interactions, we synthesized tetrakis(dimethylsilyl)ethylene (**1**),[7] which provides **2** upon reduction with lithium metal in ether. Here we report structural and spectroscopic evidence for a SiH–Li agostic interaction.

Reaction of **1** with excess lithium metal in dry, oxygen-free diethyl ether at ambient temperature led to a yellow solution of the dilithium derivative of **1** [Eq. (a)]. The solvent was removed



(a)

1 **2**

in vacuo, and dry, degassed pentane introduced by vacuum transfer. Crystallization from pentane afforded air- and moisture-sensitive, yellow crystals of **2**.

The structure of **2** was determined by X-ray crystallography (Figure 1).[8] The two lithium cations are bonded to two anionic

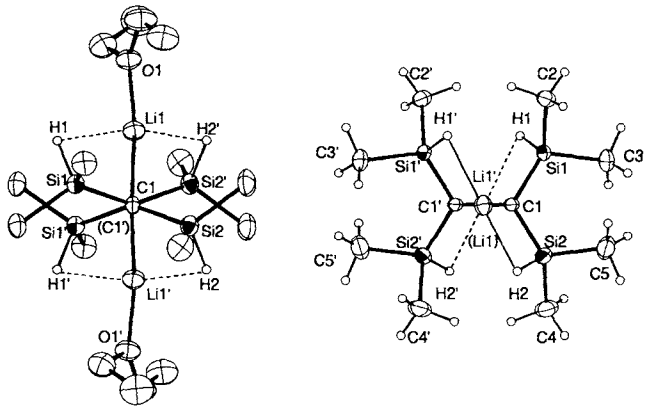


Figure 1. ORTEP representations of the crystal structure of **1a**. Left: view along the C1–C1′ bond (hydrogen atoms of CH_3 and Et_2O moieties omitted for clarity); right: top view (Et_2O omitted for clarity). Selected bond lengths [Å] and angles [°]: C1–C1′ 1.597(5), C1–Si1 1.818(4), C1–Si2 1.815(4), C1–Li1 2.125(9), C1–Li1′ 2.128(9), O1–Li1 1.908(9); Si1-C1-Si2 121.2(2), Si1-C1-C1′ 119.2(2), Si2-C1-C1′ 119.7(2), C1-Li1-C1′ 44.1(2), Li1-C1-C1′ 68.0(3), Li1-C1-Li1′ 135.9(3), Si1-C1-Si2/Si1′-C1′-Si2′ 41.0.

carbon atoms as well as to a diethyl ether moiety to produce a lithium doubly bridged structure. The central C1–C1′ bond of **2** (1.597(5) Å) is significantly longer than that of the precursor **1** (1.367(9) Å). In contrast, the Si–C(sp_2) bonds of **2** (1.818(4) and 1.815(4) Å) are shorter than those of **1** (1.901(7) Å). The dihedral angle between the Si1-C1-Si2 and Si1′-C1′-Si2′ planes is 41.0°, which is remarkably enlarged even though **1** is completely planar and gear-meshed.[7] Of particular interest are the rather short Li–H(Si) distances; the lithium–hydrogen atomic distances are 2.25(4) Å for Li1–H1 and 2.14(4) Å for Li1–H2′. These are in the range (2.00(5)–2.33(5) Å) found for Li···H–C interactions in the cyclohexyllithium hexamer.[9] Apparently the highly twisted structure of **2** can be attributed to the interaction of the hydrogen atom on the silicon atom with the lithium cations.

The SiH–Li interaction found in crystalline **2** is also observed by NMR and IR spectroscopy in solution. The NMR data are consistent with the doubly bridged structure; the signal for the anionic carbon atoms at $\delta = 14.6$ appears as a quintet due to coupling with two ^{6}Li nuclei ($I = 1$). The ^{29}Si NMR signal at $\delta = -19.7$ is shifted downfield with respect to that of **1** ($\delta = -24.4$). This is quite unusual,[10] since the ^{29}Si NMR signal of tetrakis(trialkylsilyl)ethylene dianions, which do not contain Si–H bonds, are shifted upfield.[5b–e] The ^{6}Li NMR signal of **2** is a quintet at $\delta = 0.10$ ($J = 0.49$ Hz). The splitting of the ^{6}Li signal is caused by coupling with four SiH protons, which suggests a flipping along the central C–C bond in solution. The most striking feature of **2** is the unusually small one-bond coupling (^1J(Si,H) = 141 Hz). Hydrosilanes generally display a value in the range of 160–200 Hz.[11] For example, ^1J(Si,H) = 181 Hz for **1**. The small value for **2** suggests significant SiH–Li interaction. In fact, the infrared spectrum of **2** in hexane exhibits a broad Si–H stretching band at 1937 cm^{-1}, which is at lower frequency than that for **1** (2145, 2103 cm^{-1}).

The SiH–Li interaction is also supported by a theoretical calculation of **3**. The structure of **3** with the SiH–Li interaction

$[(H_3Si)_2C{=}C(SiH_3)_2][Li(H_2O)]_2$ **3**

is calculated to be 3.93 kcal mol^{-1} more stable than the planar one without this interaction.[12] The central C–C bond is twisted by 35° due to the SiH–Li interaction. The calculated structural parameters for **3** are very similar to those experimentally

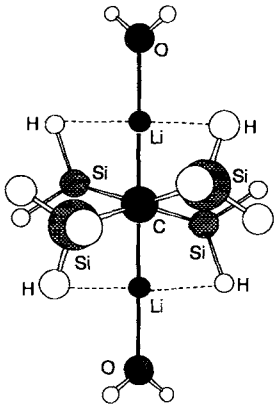

Figure 2. Optimized structure of **3** at the HF/6-31+G* level as viewed along the C–C bond. Selected bond lengths [Å] and angles [°]: C–C 1.581, C–Si 1.828, C–Li 2.105, O–Li 1.933; Si-C-Si 119.3, Si-C-C 120.4, C-Li-C 44.0, Li-C-C 67.9, Li-C-Li 136.0, Si-C-Si/Si-C-Si 35.

observed in **2** (Figure 2). The Li–H(Si) distance in **3** (2.360 Å) compares well to that in **2**.

The experimental and computational results clearly provide evidence for a SiH–Li agostic interaction. The dilithium dianion with Si–H bonds undergoes twisting due to the SiH–Li agostic interaction caused by the polarity of the $Si^{\delta+}-H^{\delta-}$ bond.[2]

Experimental Section

2: Crystalline **1** (76 mg, 0.29 mmol) and lithium metal (10 mg, 1.4 mmol) were added to a Schlenk tube with a magnetic stirrer. Degassed, dry, oxygen-free diethyl ether (≈1 mL) was introduced by vacuum transfer, and the mixture stirred at room temperature to give a yellow solution of the dianion within 1 h. The solvent was removed in vacuo, and degassed pentane introduced by vacuum transfer. The lithium metal was removed, and the solution concentrated and cooled to afford yellow crystals of **2** in quantitative yields. ^{1}H NMR ([D$_8$]toluene, TMS): $\delta = 0.45$ (d, $J = 4.0$ Hz, 24H, $SiMe_2$), 1.12 (t, $J = 7.0$ Hz, 12H, CH_3CH_2O), 3.30 (q, $J = 7.0$ Hz, 8H, CH_3CH_2O), 4.50 (br. s, 4H, SiH); ^{13}C{^{1}H} NMR ([D$_8$]toluene, TMS): $\delta = 6.3$ ($SiMe_2$), 14.6 (quint, $J(^{13}C,^6Li) = 2.3$ Hz, CLi), 15.7 (CH_3CH_2O), 66.0 (CH_3CH_2O); ^{29}Si{^{1}H} NMR ([D$_8$]toluene, TMS): $\delta = -19.7$; ^{6}Li{^{1}H} NMR ([D$_8$]toluene, LiCl in MeOH, external): $\delta = 0.10$ (quint, $J(^6Li,^1HSi) = 0.49$ Hz).

[8] A single crystal (0.25 × 0.30 × 0.40 mm) of **2** was sealed in a capillary glass tube, and diffraction data collected at 150 K on a Rigaku Denki AFC-5R diffractometer with a rotating anode (45 kV, 200 mA) employing graphite-monochromatized $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å). A total of 3247 reflections ($3 < 2\theta < 55°$) were collected. Crystal data for $C_{18}H_{48}Li_2O_2Si_4$ ($M_r = 422.80$): $a = 18.551(7)$, $b = 9.890(8)$, $c = 17.183(6)$ Å, $\beta = 113.61(2)°$, $V = 2889(3)$ Å^3, monoclinic, space group $C2/c$, $Z = 4$, $\rho_{calcd} = 0.972$ g cm^{-3}. The positions of the hydrogen atoms connected to silicon atoms were determined by a difference Fourier calculation, and those of the other hydrogen atoms calculated. When the hydrogen atoms were included in the refinement, the final R factor converged at 0.0698 ($R_w = 0.0717$) for 2114 reflections with $F_o > 3\sigma(F_o)$. Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-59427.

[10] The GIAO calculations of **3** at the HF/6-31 + G* level suggest that the SiH–Li interaction causes the ^{29}Si NMR signal to shift downfield by $\Delta\delta = 5.62$, and the ^{6}Li NMR signal to shift upfield by $\Delta\delta = 0.46$ with respect to the corresponding signals for the planar structure without this interaction. The calculated Si–H frequency for the twisted structure of **3** is 1925 cm^{-1} (DFT/6-31 + G*). These predictions are fully consistent with the experimental observations.

[11] E. A. Williams, J. D. Cargioli in *Annual Reports on NMR Spectroscopy, Vol. 9* (Ed.: G. A. Webb), Academic Press, New York, **1979**, p. 221.

[12] The twisted structure **A** with the SiH–Li interaction is calculated to be more stable than planar **B** by 3.93 kcal mol^{-1} (**A** −1405.3569491 a.u., **B** −1405.3506778 a.u.), 3.51 kcal mol^{-1} (**A** −1405.346044 a.u., **B** −1405.3404548 a.u.), and 6.06 kcal mol^{-1} (**A** −1406.3602892 a.u., **B** −1406.350628 a.u) at the HF/6-31+G*, HF/6-31G*, and MP2/6-31G* levels, respectively.

Coordination-Mediated Optical Resolution of Carboxylic Acids with *O,O′*-Dibenzoyltartaric Acid**

András Mravik,* Zsolt Böcskei, Zoltán Katona, Imre Markovits, and Elemér Fogassy

Racemic carboxylic acids are generally resolved by optically active bases from natural or synthetic sources. Some of the naturally occurring amines (brucine, strychnine) are extremely toxic and available only in one enantiomeric form.

In contrast, tartaric acid and its derivatives are relatively cheap, nontoxic resolving agents that are available in both enantiomeric forms, even on a large scale. Although derivatives of unnatural tartaric acid are more expensive than the enantiomers, the stereoisomers of *O,O′*-dibenzoyltartaric acid can be produced by preferential crystallization at the same cost on a fully synthetic basis.[1] We report here new applications of *O,O′*-dibenzoyltartaric acid, which is used for the resolution of bases, as a resolving agent *for carboxylic acids*. Conversion of *O,O′*-dibenzoyltartaric acid into its neutral calcium salt (**2**) results in a compound of basic character that can form salts with acids. In fact, **2** readily reacts with enantiomers of suitable acids **1** to form crystallizing, mixed calcium salts **3**; this provides excellent resolution of the acids (Scheme 1).

A coordinating group attached to the chiral center has an important role in crystallization and, furthermore, in the discrimination of the enantiomers. The resolving agent **2** itself forms a bulky crystalline mass upon separation that cannot be removed by filtration. However, it readily dissolves in hot ethanol or methanol, in which it can be prepared in situ by heating dibenzoyltartaric acid and calcium oxide.

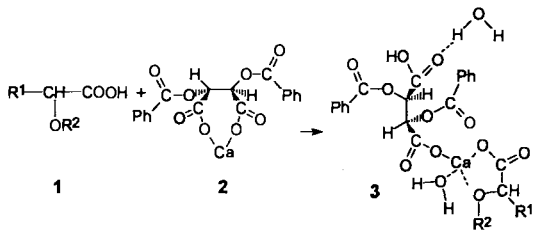
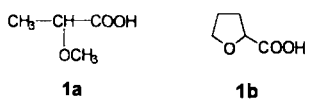


Scheme 1. Formation of a mixed calcium salt upon resolution of carboxylic acids with dibenzoyltartaric acid.

Racemic acids **1a** or **1b** and then water were added to the hot solution of **2** in the suitable alcohol. On cooling (or seeding) salts **3a** and **3b** began to separate. Thus, **1a** was resolved in aqueous ethanol, and pure (*R*)-(+)-**1a**-**2** ((*R*)-**3a**) was obtained in 51% yield after three recrystallizations (ethanol/water and methanol/water). The acid (*R*)-(+)-**1a** liberated from this salt showed a specific rotation of $[\alpha]_D^{23} = +74.5$ ($c = 1$ in methanol), $[\alpha]_D^{23} = +71.5$ (neat). (Traditional resolution of **1a** with (*S*)-(−)-1-phenylethylamine required five recrystallizations from benzene and gave a salt (63%) from which (*S*)-**1a** was obtained with $[\alpha]_D^{23} = -70.5$ (neat).[2]) Accordingly, (*S*)-(−)-**1b**-**2** ((*S*)-**3b**) was obtained (methanol/water) in 89% yield after one recrystallization, and the acid (*S*)-(−)-**1b** had $[\alpha]_D^{23} = -34.1$ ($c = 1$ in chloroform). Resolution of **1b** with brucine afforded the brucine salt (crystallization from ethyl acetate followed by two recrystallizations from acetonitrile) in 51% yield, and the isolated (*R*)-(+)-**1b** had $[\alpha]_D^{23} = +30.4$ ($c = 1.01$ in chloroform).[3] Yields were calculated based on half of the starting racemic acids.



1a

1b

X-ray crystal structure analyses were carried out on (*S*)-**3b**[4] and (*R*)-**3a** to investigate the interactions controlling the optical resolution (in particular the role of coordination around the calcium atom). The molecular structure of (*S*)-**3b** is shown in Figure 1. Tetrahydrofuroic acid (**1b**) has (*S*)-(−) configuration.

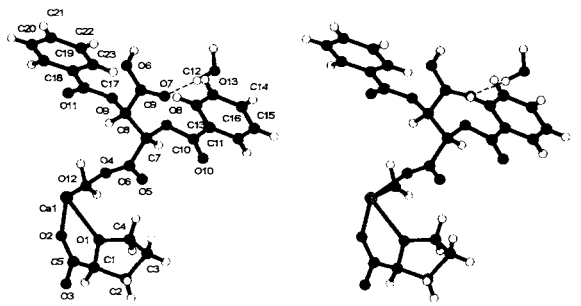


Figure 1. Stereoview of the crystal structure of (*S*)-**3b**.

A stereoview of the packing in (*S*)-**3b** is given in Figure 2. The crystal structure of (*S*)-**3b** (Figure 1) is made up of alternating hydrophobic layers, composed of the phenyl moieties of the benzoyl groups, and hydrophilic layers, composed of the Ca^{2+} ions and their coordinating ligands. The hydrophylic layers can be further divided into alternating stripes of hydrogen bonds and Ca^{2+}-coordination polyhedrons (Figure 2). The bond lengths and angles demonstrate that the coordination geometry at Ca^{2+} is distorted trigonal bipyramidal (Ca^{2+}—O 2.27–2.50 Å). The tetrahydrofurane carboxylate (THFC) ion is

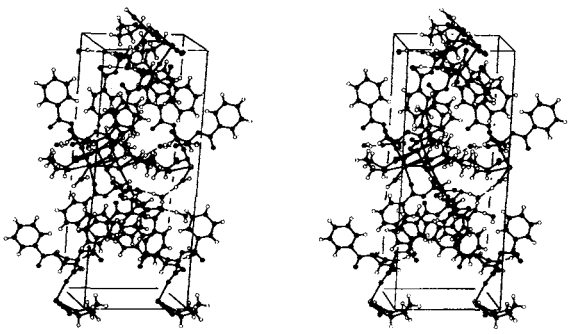

Figure 2. Stereoview of the packing of (*S*)-**3b**.

a bis(bidentate) ligand: Its carboxylate group is a bidentate Ca^{2+}-binding unit (O2···O3 nonbonding distance 2.18 Å), and one of the carboxylate oxygen atoms (O2) and the ring ether oxygen atom (O1; O1···O2 nonbonding distance 2.66 Å) form another bidentate moiety. The equatorial positions of the trigonal bipyramid are occupied by the two bidentate ligands of the THFC moiety as well as the oxygen atom O12 from water. One of the two oxygen atoms of the carboxylate groups (O2) simultaneously coordinates to two neighboring Ca^{2+} ions to form an endless Ca-O-Ca-O chain through the crystal lattice. The axial positions of the bipyramid are occupied by the carbonyl oxygen atoms of one of the two benzoyl groups (O11) and of the deprotonated carboxylate group (O4). Since the ligands at the axial positions are less bulky they are substantially closer to the Ca^{2+} ions than the equatorial ligands. The hydrogen-bonding system of the crystal also shows interesting features. The tartaric acid moieties are arranged in a head-to-tail fashion by hydrogen bonds between deprotonated and protonated carboxylate groups. Two stripes of Ca^{2+} bipyramids are interconnected by several hydrogen bonds mediated by water molecules.

Due to the crowded structure of these mixed salts, the scope of the method is limited to relatively small racemic acids. The alkyl ether functionality seems to be essential. α-Chloro acids do not form mixed salts, whereas α-hydroxy acids, due to the low solubility of their calcium complexes, separated as their simple calcium salts under the above conditions.

Because of these limitations we directed our interest to the resolution of simple derivatives of carboxylic acids (for example esters). The preparative-scale separation of an ester from the resolving acid can be easily accomplished, whereas problems might be encountered in certain cases upon separation of a free acid.

Hydroxy acids represent an important class of chiral compounds. We developed a simple, generally applicable method for resolving hydroxy acid esters (**5**, see Table 1 for examples). As the esters lack an acid functionality, salt formation should be entirely replaced by coordination bonds. The acidic calcium salt of *O*,*O*′-dibenzoyltartaric acid $Ca(HL_0)_2$ (**4**) readily coordinates hydroxy acid esters to form crystalline complex salts[5] of the general formula **6** (see Table 1).[6] This phe-

$$[Ca(L)_{n1}(A_1)_{na}(A_2)_{nw}](HL_0)_2 \quad \mathbf{6}$$

nomenon serves as a basis for the resolution of hydroxy esters, since selection between the enantiomers of **5** occurs during crystallization. In the formula for **6** L stands for **5**, and A_1 and A_2 stand for auxiliary ligands (A_1 is generally a simple ester such as ethyl or propyl acetate, and A_2 water). The complex salts formed can be divided into three major types. Type I: $n_1 = 2$; no auxiliary ligand is cocomplexed, but water may be present.

Table 1. Complex salts **6** obtained upon resolution of **5a,b** with (2*R*,3*R*)-*O*,*O*'-dibenzoyltartaric acid.

5b	CH_3	CH_3	II	EA	1	2	68	22(*S*)
5b	CH_3	C_2H_5	II	PA	1	2	63	38(*R*)

[a] EA: ethyl acetate, EP: ethyl propionate, PA: propyl acetate. [b] The number of cocomplexed auxiliary esters. [c] The number of water molecules in the complex. [d] Yield of the complex salt based on half of the starting racemic **5**. [e] Enantiomeric excess and configuration (in parentheses) of **5** obtained from the complex were determined by comparing the specific rotation value and the sign of rotation to those of the pure enantiomer. [f] Yield of the salt is based on the amount of the (*S*)-enantiomer present in the starting mixture. [g] Starting from a mixture with 76%(*S*) *ee*.

Type II: $n_1 = 1$; auxiliary ligands (generally both A_1 and A_2 when A_1 is a simple ester) are cocomplexed. Cocomplexation can be advantageous considering the remarkable influence of A_1 on the enantiomeric composition of L.[7] Type II is characteristic for medium-sized hydroxy esters. Type III: $n_1 = 1$; only water molecules are cocomplexed. This classification is valid for air-dried salts.

These methods present new aspects of optical resolution. Normally, the resolving agent should be selected to achieve better resolution. Using this second method, however, the efficiency of the resolution and, in certain cases, the configuration of the enantiomer obtained can be controlled by varying the ester function and/or the applied auxiliary ligands.

[4] Single crystals of (*S*)-**3b** were grown by slow concentration of a solution in methanol/water. A stereoview of (*S*)-**3b** is shown in Figure 1. $M_r = 548.50$, orthorhombic, space group $P2_12_12_1$, $a = 11.074(10)$, $b = 27.149(3)$, $c = 8.220(5)$ Å, $V = 2472(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.474$ g cm^{-3}, $\mu = 2.806$ mm^{-1}. Data were collected on a colorless crystal (0.70 × 0.30 × 0.25 mm) at room temperature with a Rigaku AFC6S diffractometer; $\omega/2\theta$ scans with a ω scan rate of 8° min^{-1} and a scan width of $(0.89 + 0.30 \tan\theta)°$ with graphite-monochromated $Cu_{K\alpha}$ radiation. Lattice parameters were determined by least squares using 25 reflections with $46.2 < 2\theta < 55.0°$. Three standards monitored every 150 reflections indicated no significant decay. A full set of Friedel mates was collected for a total of 10292 reflections ($\theta_{max} = 75.77°$; $13 \geq h \geq -1$, $34 \geq k \geq -34$, $10 \geq l \geq -10$) of which 5109 were unique with $R_{merge} = 0.082$ (without Friedel mates). The structure was solved with the TEXSAN package (Molecular Structure Co., TEXSAN. Single Crystal Structure Analysis Package, The Woodlands, TX 77381, USA, **1992**) and refined with SHELXL-93 (G. M. Sheldrick, SHELXL-93, Program for the Refinement of Crystal Structures, University of Göttingen, **1993**) against F^2 with all unique reflections (2788 had intensities higher than $2\sigma(I)$). All non-hydrogen atoms were refined anisotropically. Most hydrogen atoms were generated based on geometrical evidence with X–H bond lengths dependant on the chemical nature of X. Some hydrogen-atom positions (for example those belonging to the two water molecules) were taken from difference-Fourier calculations and reinforced by forming hydrogen bonds with proper geometry. $R1 = 0.0602$, $wR2 = 0.1369$, GOF = 1.095 for those reflections with $I > 2\sigma(I)$. The Flack parameter $x = 0.01(2)$ confirms the absolute configuration (H. D. Flack, *Acta Crystallogr. Sect. A* **1983**, *39*, 876–881). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100266. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[5] The previously prepared acidic calcium salt or dibenzoyltartaric acid and calcium oxide were dissolved in hot ethanol, and the racemic ester was added. In some cases crystallization can be carried out from this solution, but more frequently from a solvent mixture made by adding further solvents (such as acetone, toluene, or ethyl acetate). However, most of the complexes were separated from an ester-type solvent after the ethanol was removed by evaporation.

[6] Characterized by thermoanalytical methods (TGA, EGD), elemental analysis, and ICP-AES. The structure of the complex formed with two molecules of methyl mandelate was determined by X-ray crystallography (A. Mravik, Z. Böcskei, Z. Katona, I. Markovits, G. Pokol, D. K. Menyhárd, E. Fogassy, *Chem. Commun.* **1996**, 1983–1984.) In some cases partial decomposition occurs at slightly elevated temperatures or even at room temperature. Measurements were performed on air-dried samples, which may contain 0.5–2% of volatile impurities. Furthermore, the relatively high molecular weight may cause uncertainty in the results.

[7] The resolution of ethyl mandelate in the presence of various simple esters of C_2–C_4 alcohols afforded complex salts in which the *ee* values of the ethyl mandelate were in the range of 31–78%.

A Hydrogen-Bonding Receptor That Binds Urea with High Affinity**

Thomas W. Bell* and Zheng Hou

Urea is an important target for molecular recognition studies, both from fundamental and practical points of view. It is a small molecule having hydrogen-bonding sites of well-defined geometry. The urea moiety is present in numerous biologically relevant compounds, including barbiturates, biotin, citrulline, cytosine, thymine, uracil, and uric acid. As an end product of nitrogen metabolism, urea is found in the human blood stream in concentrations between 2 and 8 mM and is excreted in urine. The blood urea nitrogen (BUN) level is a primary indicator of kidney function[1] and compounds having high affinity for urea are potentially useful in clinical chemistry. We have synthesized an artificial receptor that fully satisfies the hydrogen-bonding capacity of urea. The resulting complex is stable even in pure DMSO, from which it can be isolated by crystallization.

The novel receptor **1** nearly encircles urea from the "bottom," that is from the side opposite the carbonyl group, as shown by the schematic structure **I** in Figure 1a. Like previously reported

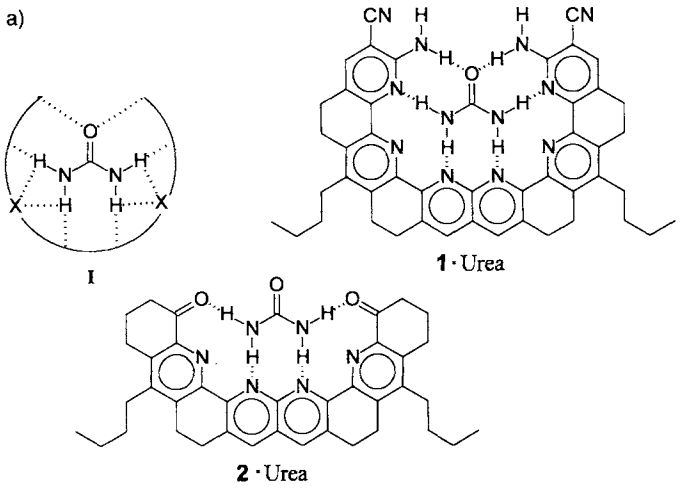
receptor **2**,[2] **1** is capable of forming four hydrogen bonds with the amino groups of urea; the complex is apparently stabilized further by secondary electrostatic interactions between these hydrogen atoms and the nitrogen atoms of the spacer pyridine rings, as indicated by dotted lines to X in **I**. Receptor **1** also incorporates two amino groups that can form hydrogen bonds with the two remaining hydrogen-bond acceptor sites of urea, the nonbonded electron pairs of the oxygen atom. Other known hydrogen-bonding receptors bind urea or urea derivatives from the "top" end, through the carbonyl group, as shown in schematic structure **II** (Figure 1b). Complexes of type **III**[3] and



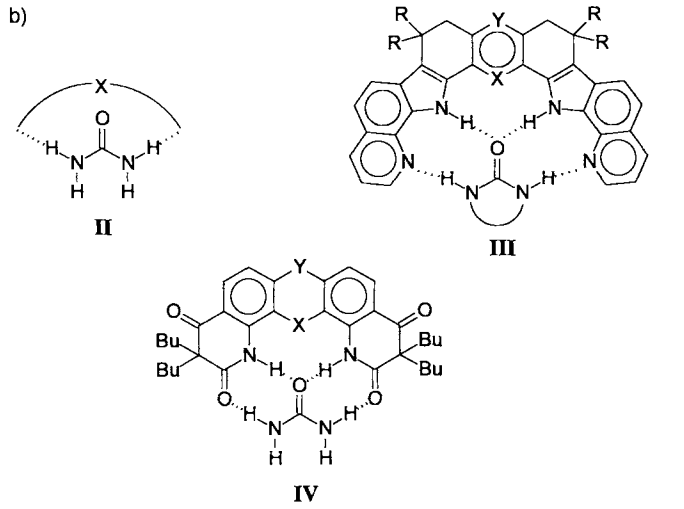


Figure 1. Representation of **1**·urea and other previously reported complexes in which hydrogen-bonding receptors bind urea a) from the bottom, that is opposite the C=O group, or b) from the top.

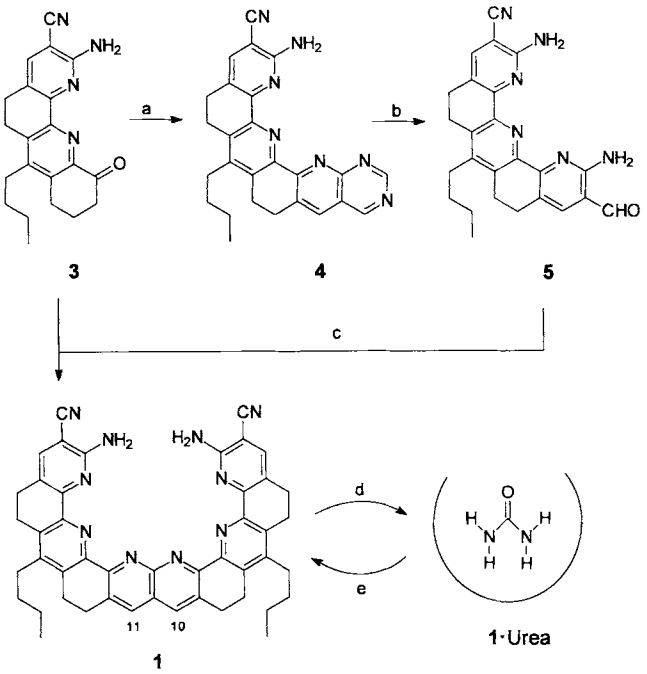
IV[4] bind only four of the six possible sites of urea; they lack acceptors for the two remaining NH donor groups. Therefore, we speculated that **1** would be much more selective toward urea relative to *N*-alkyl ureas. Macrocyclic polyethers capable of encircling urea are known,[5] but they do not have the high degree of conformational preorganization present in fused-ring receptors.

The choice of target structure **1** for synthesis was influenced by the known hydrogen-bond donor ability of the *o*-aminonitrile functionality[6] and the availability of the oxoaminonitrile **3**[6a] as a synthetic intermediate (Scheme 1). Friedländer condensation of **3** with 4-amino-1,3-pyrimidine-5-carboxaldehyde[7] gave **4**, which was hydrolyzed under standard conditions to give **5**, which contains both *o*-aminonitrile and *o*-aminoaldehyde functionalities. Condensation of **5** with a second equivalent of **3** was carried out in methanol/toluene, then excess urea was added to the hot reaction mixture. Cooling resulted in precipitation of receptor **1** as the complex **1**·urea, which was triturated with methanol and recrystallized from DMSO. While this complex is stable in hot DMSO, boiling in water causes the urea-free receptor to precipitate. Pure **1** was then obtained in good yield by recrystallization from dichloromethane/ethanol.[8]



Scheme 1. Synthesis of receptor **1** and of complex **1**·urea. a) 4-Amino-1,3-pyrimidine-5-carboxaldehyde [7], KOH, CH_3OH/toluene (3/2 (v/v)), reflux, 24 h (61%); b) 0.2N HCl, reflux, 14 h (95%); c) 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), CH_3OH/toluene (6/5 (v/v)), reflux, 28 h; d) urea, DMSO, reflux, 12 h, recrystallized from DMSO (77% from **5**); e) H_2O, reflux, 4 h, recrystallized from CH_2Cl_2/ethanol (15/8 (v/v); 87%) [8].

Cocrystallization of **1** and urea from DMSO is one of several experimental results that supports the proposed formation of a 1:1 complex (**1**·urea). The IR spectrum of this complex displays a peak at 1655 cm^{-1}, corresponding to the hydrogen-bonded C=O group of urea.[5a] Binding studies in solution were limited by the low solubilities of **1** and **1**·urea in most solvents, but in a 1/1 (v/v) mixture of $CDCl_3$ and $[D_6]$DMSO a significant shift of the ^{1}H NMR signals for the naphthyridine protons (H10, H11) in the receptor is observed on complexation. This resonance signal served as a marker in titration experiments involving incremental addition of urea to a 1 mM solution of **1** in this solvent system. Figure 2a compares the resulting ^{1}H NMR shifts with a curve calculated[9] for a stability constant of $8 \times 10^3\ M^{-1}$. The assumptions in this calculation were tested by recording the ^{1}H NMR spectra of **1**·urea and **1** at various concentrations. The results are plotted in Figure 2b in comparison with the curve calculated with the parameters obtained from fitting the titration curve. Dilution causes the host resonances to shift slightly downfield rather than upfield, indicating that 1:1 binding is not the only equilibrium of importance. Aggregation of urea-free **1** is also suggested by the concentration dependence of the position of the H10,H11 signals in the 0.4–3.6 mM concentration range (Figure 2b, triangles).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1537 $ 17.50+.50/0

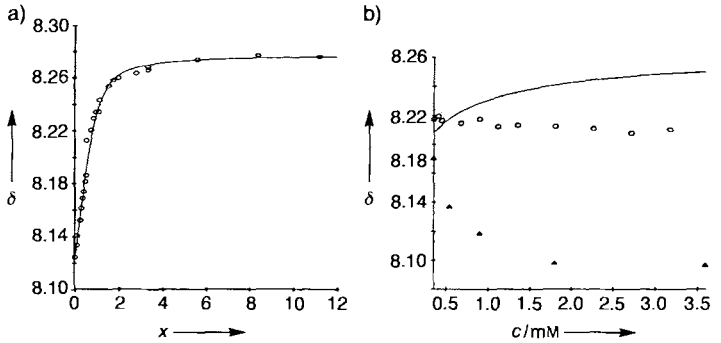


Figure 2. a) Plot of the ^{1}H NMR chemical shifts obtained for the protons H10 and H11 during the titration of a 1.07 mM solution of receptor **1** with urea ($CDCl_3$/[D_6]DMSO 1/1 (v/v), 298 K), together with the calculated curve ($K_s = 7600\,M^{-1}$)[9]. x = c(urea)/c(**1**). b) Concentration dependence of the ^{1}H NMR chemical shifts of the protons H10 and H11 for **1** (triangles) and **1**·urea (circles) in comparison with the calculated curve ($K_s = 7600\,M^{-1}$) [9].

The UV/Vis absorptions of polycyclic receptors similar to **1** undergo bathochromic shifts upon complexation of planar guests,[2a] so the effects of added urea or alkylated urea derivatives on the spectrum of **1** were compared (Figure 3). The addition of at least one equivalent of urea to a solution of receptor **1** in 1:1 $CHCl_3$/DMSO causes a shift of the longest wavelength absorption maximum from 394 nm to 410 nm (Figure 3b). *N*-Butylurea has a much smaller effect on the absorption spectrum of **1** (Figure 3b), whereas *N*,*N*′-dimethylurea and *N*,*N*-dimethylurea have negligible effects (Figures 3c,d). UV/Vis titration experiments were then conducted in which urea was added to a 22 μM solution of **1** in 1:1 $CHCl_3$/DMSO; the resulting absorbances at 410 nm are plotted in Figure 4. The stability constant of $1.4 \pm 0.2 \times 10^4\,M^{-1}$ calculated from this data[10] is larger than that obtained from NMR titration results, apparently due to suppression of competing equilibria at lower receptor concentration.

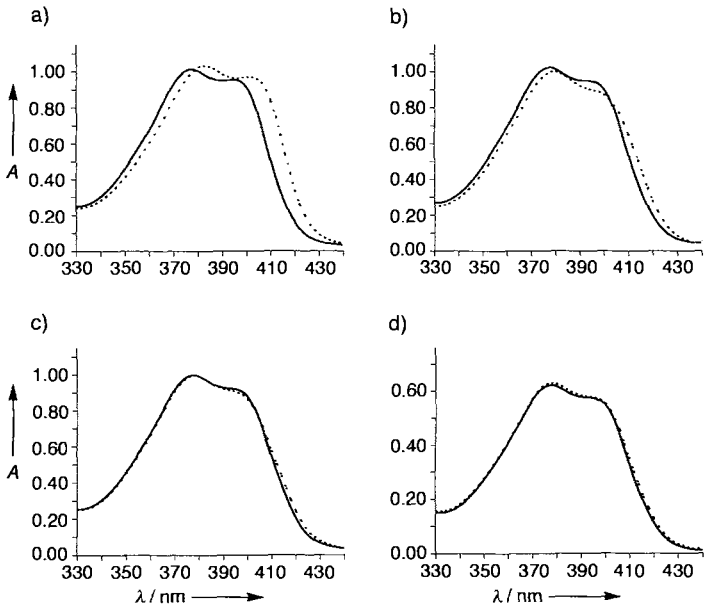

Figure 3. UV/Vis absorption spectra of receptor **1** (34.8 μM) in 1/1 (v/v) $CHCl_3$/DMSO (298 K) before (solid line) and after (dotted line) addition of a) excess urea, b) *N*-butylurea, c) *N*,*N*′-dimethylurea, or d) *N*,*N*-dimethylurea. In d) the concentration of **1** was 20.8 μM. A = absorbance.

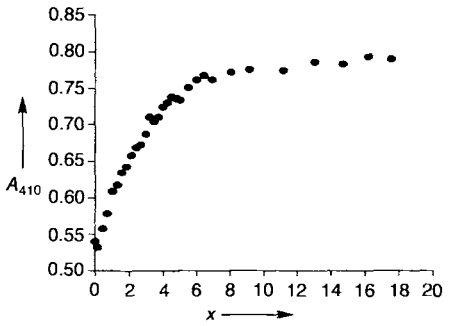

Figure 4. Absorbance changes at 410 nm during titration of receptor **1** (22.4 μM) with urea in 1/1 (v/v) $CHCl_3$/DMSO (298 K). x = c(urea)/c(**1**).

Compound **1** is the highest affinity receptor capable of binding urea solely with hydrogen bonds. Direct comparison between **1** and a uranyl complex that also forms a strong complex with urea[5c] cannot be made without performing complexation experiments under similar conditions. The observed combination of binding strength and selectivity makes **1** an attractive candidate for structural modification aimed at development of reagents and sensors[2a, 11] for urea analysis.

New Technology for the Synthesis of Vancomycin-Type Biaryl Ring Systems**

K. C. Nicolaou,* Xin-Jie Chu, Joshi M. Ramanjulu, Swaminathan Natarajan, Stefan Bräse, Frank Rübsam, and Christopher N. C. Boddy

Dedicated to Professor Samuel J. Danishefsky on the occasion of his 60th birthday

Due to their effective action against drug-resistant bacterial strains, the vancomycin antibiotics[1] are currently receiving unprecedented attention from chemists,[2] biologists, and clinicians.[3] As a target molecule, vancomycin[4] (**1**, Figure 1) presents several synthetic challenges, amongst which the construction of the 12-membered biaryl ring system stands, perhaps, as the most formidable. It is, therefore, not surprising that to date only one report[2a] exists for its construction. In this communication, we describe a new method for the construction of the biaryl ring system of vancomycin, which is direct and involves mild conditions. The application of the present Ni^0-mediated[5] C–C coupling strategy to the synthesis of model systems **5** and **12–14** demonstrates its generality and scope and holds promise for a solution to the vancomycin problem itself.

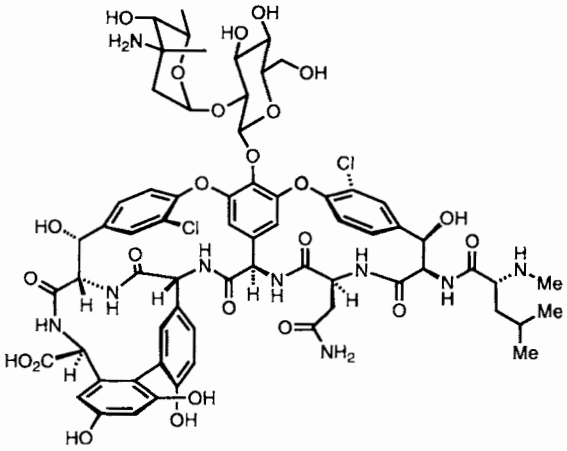

Figure 1. Molecular structure of vancomycin (**1**).

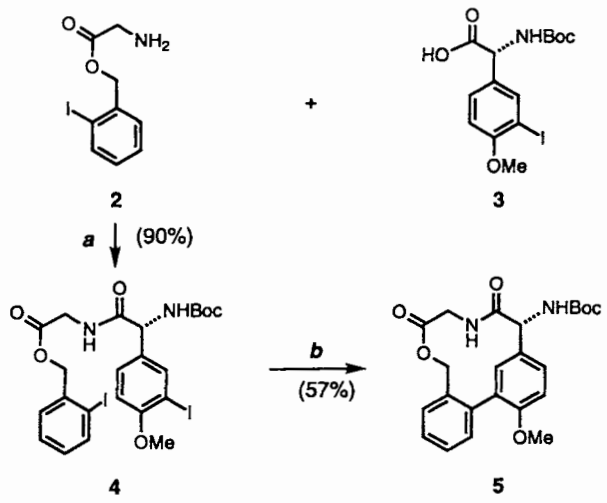
Scheme 1 summarizes the chemistry for the construction of the vancomycin model system **5**, which contains the 12-membered peptide ring. Coupling of fragments **2**[6] and **3**[6] with EDC as the coupling reagent in the presence of HOBT provided the targeted precursor **4** in 90% yield. The crucial cyclization reaction was carried out at 50 °C with tetrakis(triphenylphosphane)nickel [$(Ph_3P)_4Ni$] generated in situ in DMF (16 h) to afford the vancomycin model system **5** as a mixture of atropisomers (57% total yield). In thin-layer chromatography (TLC), compound **5** behaved as a single compound, but in the ^1H NMR spectrum ($CDCl_3$, 500 MHz, 25 °C) it exhibited splitting and broadness of signals characteristic of slow interconversion of its two atropisomers. On heating to 50 °C, the spectrum sharpened considerably, as expected (Table 1).



Scheme 1. Synthesis of vancomycin model system **5**: a) 1.5 equiv of EDC, 1.5 equiv of HOBT, DMF, 0 °C, 10 h; b) 1.8 equiv of $(Ph_3P)_2NiCl_2$, 1.8 equiv of Zn, 3.6 equiv of Ph_3P, DMF (0.002 M), 55 °C, 16 h. EDC = 1-(3-dimethylamino-propyl)-3-ethylcarbodiimide hydrochloride; HOBT = 1-hydroxybenzotriazole; Boc = *tert*-butoxycarbonyl, DMF = *N*,*N*-dimethylformamide.

Encouraged by this result we then attempted the construction of the more advanced systems **12–14**, which are closely related to vancomycin (Scheme 2). The required precursors **9–11**

Table 1. Selected physical properties of compounds **5**, **14a**, and **14b**.

5 (mixture of atropisomers): $R_f = 0.50$ [silica gel, 50% EtOAc in hexanes]; $[\alpha]_D^{25}$ −3.1 ($c = 0.13$ in CH_2Cl_2); IR (film): $\tilde{\nu}_{max} = 3289, 2924, 2851, 1726, 1689, 1647, 1527, 1454, 1371, 1298, 1240, 1110\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$) $\delta = 1.42$ (s, 9H, *t*Bu), 3.79 (s, 3H, OMe), 4.24–4.41 (m, 3H, H_1, H_4), 5.07–5.18 (m, 2H, H_7), 5.43 (bs, 1H, BocNH), 6.91 (d, $J = 4.5$ Hz, 1H, Ar_AH_c), 7.21 (bs, 1H, H_3), 7.35–7.43 (m, 6H, $Ar_AH_{a,b}$, Ar_B); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 171.8, 171.2, 168.9, 168.4, 168.1, 167.8, 156.3, 156.2, 155.7, 155.5, 140.7, 140.4, 132.8, 132.7, 131.6, 131.5, 130.7, 130.5, 129.9, 128.6, 128.51, 128.4, 127.9, 127.6, 127.4, 127.3, 127.1, 123.7, 110.4, 107.4, 80.3, 67.0, 65.9, 56.7, 55.6, 55.5, 52.2, 42.7, 42.3, 29.6, 29.5, 28.2, 28.1, 28.0$; HRMS (FAB) calcd for $C_{23}H_{26}N_2O_6Cs$ ($M+Cs^+$) 559.0845; found 559.0828.

14a: $R_f = 0.20$ [silica, 2.5% MeOH in $CHCl_3$]; $[\alpha]_D^{25}$ −45.7 ($c = 0.37$ in CH_2Cl_2); IR (film): $\tilde{\nu}_{max}$ 3320, 2924, 1673, 1611, 1585, 1501, 1366, 1324, 1256, 1157, 1110, 1063 cm^{-1}; ^1H NMR (600 MHz, $CDCl_3$): $\delta = 1.34$ (s, 9H, *t*Bu), 3.28–3.30 (m, 1H, H_7), 3.63 (s, 6H, OMe), 3.64–3.66 (m, 1H, H_4), 3.72 (s, 3H, OMe), 3.74–3.76 (m, 1H, H_4), 3.84–3.86 (m, 1H, H_7), 4.81 (br s, 1H, H_1), 6.56 (d, $J = 2.2$ Hz, 1H, H Ar_BH_a), 6.58 (d, $J = 2.2$ Hz, 1H, Ar_BH_b), 6.85 (br s, 1H, BocNH), 6.95 (d, $J = 8.3$ Hz, 1H, Ar_AH_c), 7.08 (br s, 1H, Ar_AH_d), 7.30 (dd, $J = 8.3$, 2.1 Hz, 1H, Ar_AH_b), 7.40 (br s, 1H, N_6H), 7.82 (t, $J = 6.6$ Hz, 1H, N_3H); ^{13}C NMR (150 MHz, [D_6]DMSO) $\delta = 172.1, 170.4, 167.5, 159.5, 158.1, 156.7, 137.4, 132.9, 129.9, 127.7, 124.1, 120.8, 110.8, 107.9, 97.9, 78.3, 59.7, 55.7, 55.5, 55.3, 43.7, 43.3, 28.1$; HRMS (FAB) calcd for $C_{25}H_{31}N_3O_7Na$ ($M+Na^+$) 508.2060; found: 508.2067. **14b**: $R_f = 0.25$ [silica, 2.5% MeOH in $CHCl_3$]; $[\alpha]_D^{25}$ −18.1 ($c = 0.63$ in CH_2Cl_2); IR (film): $\tilde{\nu}_{max}$ 3314, 2924, 2853, 1677, 1581, 1504, 1459, 1366, 1320, 1262, 1160, 1110 cm^{-1}; ^1H NMR (600 MHz, [D_6]DMSO): $\delta = 1.32$ (s, 9H, *t*Bu), 3.67 (s, 3H, OMe), 3.68–3.70 (m, 1H, H_4), 3.74 (s, 3H, OMe), 3.82–3.86 (m, 1H, H_4), 3.81 (s, 3H, OMe), 4.13–4.24 (m, 2H, H_7), 5.12–5.13 (m, 1H, H_1), 6.50 (s, 2H, $Ar_BH_{a,b}$), 6.98 (d, $J = 8.6$ Hz, 1H, Ar_AH_c), 7.18 (s, 1H, Ar_AH_a), 7.36–7.38 (m, 2H, BocNH, Ar_AH_b), 8.29 (br s, 1H, N_6H), 8.57 (br s, 1H, N_3H); ^{13}C NMR (150 MHz, [D_6]DMSO) $\delta = 171.1, 168.9, 160.8, 158.4, 156.4, 155.3, 142.3, 130.2, 130.1, 129.8, 128.2, 127.8, 111.0, 105.4, 97.4, 78.7, 57.6, 56.5, 55.5, 55.1, 47.8, 42.4, 28.1$; HRMS (FAB) calcd for $C_{25}H_{31}N_3O_7Na$ ($M+Na^+$) 508.2060; found 508.2069.

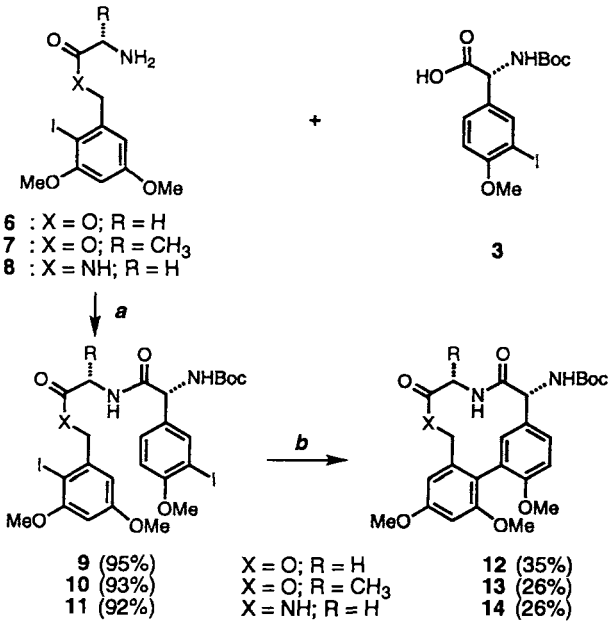

Scheme 2. Synthesis of vancomycin model systems **12**–**14**: a) 1.2 equiv of **3**, 1.3 equiv of EDC, 2.2 equiv of Et_3N, DMF, 0 °C, 12 h; b) 1.8 equiv of $(Ph_3P)_2NiCl_2$, 1.8 equiv of Zn, 3.6 equiv of Ph_3P, DMF (0.002 M), 55 °C, 16 h.

were synthesized in high yield (90–95%) by peptide coupling of the appropiate amino fragment (**6**–**8**)[6] with carboxylic acid **3**. Exposure of depsipeptides **9** and **10** with Ni^0 under the conditions of Scheme 1 gave the cyclized systems **12** and **13** in 35% and 26% yield, respectively, along with the reduced products **15** (43%) and **16** (29%) (Figure 2). Apparently, a

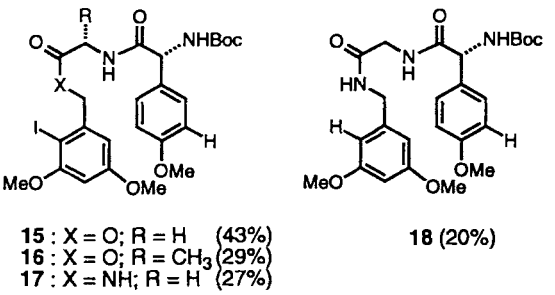

Figure 2. Reduced products from the Ni^0-mediated cyclizations of **9**–**11**.

higher degree of substitution on one of the aromatic rings slows down the intramolecular reaction, allowing the formation of reduced products. Finally, peptide **11**, upon treatment with Ni^0, resulted in the formation of biaryl system **14** in 26% yield as a mixture of two atropisomers. The two isomers (**14a** and **14b**) were separated by preparative layer chromatography [silica gel, 2.5% MeOH in $CHCl_3$, $R_f = 0.20$ (**14a**) and 0.25 (**14b**)]. NOESY experiments enabled assignment of the major atropisomer (**14a**) as indicated in Figure 3. It is noteworthy that the unnatural atropisomer **14a** prevailed as the major product in this cyclization reaction. However, removal of the methyl groups from the trimethoxybiaryl moieties of **14a** and **14b** is expected to facilitate their interconversion, as previously observed for a similar system.[2a]

The formation of dimers was also observed in all cases described above (MS, ^1H NMR). Further dilution of the reaction mixture disfavored dimerization, but increased the amount of

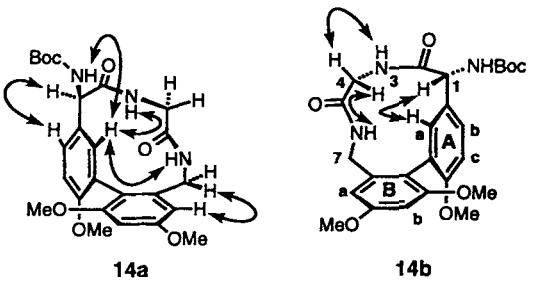

Figure 3. Structural assignment of atropisomers **14a** and **14b** based on NOESY experiments.

reduced by-products. Work is currently in progress for further optimization of these reactions and for the invention of new ones for the purposes of efficiently constructing this challenging biaryl system.

In conclusion, a mild method for the construction of the rigid 12-membered biaryl ring system of the vancomycin antibiotics has been developed. Its application to the total synthesis of natural and designed members of this class of compounds for biological studies may prove fruitful.

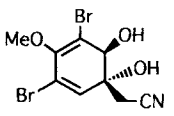
Selective Inhibition of Receptor Tyrosine Kinases by Synthetic Analogues of Aeroplysinin**

Herbert Waldmann,* Klaus Hinterding, Peter Herrlich,* Hans Jobst Rahmsdorf, and Axel Knebel

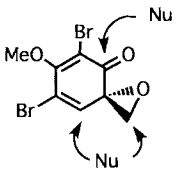
Various transmembrane receptors—for example the receptors of insulin-like growth factor (IGFR), nerve growth factor (NGFR), epidermal growth factor (EGFR), and platelet-derived growth factor (PDGFR)—phosphorylate themselves on tyrosine residues in response to the binding of extracellular ligands. Thereby these receptor tyrosine kinases (RTKs) gain the ability to trigger various intracellular signaling cascades by which cell growth, proliferation, and other genetic programs are regulated.[1] Dysregulation may contribute to the generation of various diseases. For instance, enhanced activity of RTKs can promote tumor growth and has been implicated in carcinogenesis and as participant in the development of proliferative diseases such as psoriasis.[2] Therefore, these signal-transducting proteins are considered as promising targets for drug development. In addition, such drugs are likely to be useful in dissecting signaling pathways.[2, 3] Essential to the use of a RTK inhibitor in biological studies is its efficacy both in vitro and in vivo.

Whereas most compounds developed so far display IC_{50} values in the low micromolar range[2-6]—the tyrphostins[2a, b, 6] are most often used—more efficient inhibitors were recently reported.[5, 6] As these values leave substantial room for improvement, identification of new and alternative classes of RTK inhibitors is of great importance to bioorganic and medicinal chemistry.

Aeroplysinin **1**, a highly functionalized marine natural product, is cytotoxic against human breast cancer cells and inhibits the EGFR receptor in an in vitro test system.[7] Its structure differs significantly from that of the RTK inhibitors reported so far, which are almost exclusively aromatic compounds; **1** might therefore serve as a promising lead for the development of a new class of these biologically active substances. However,



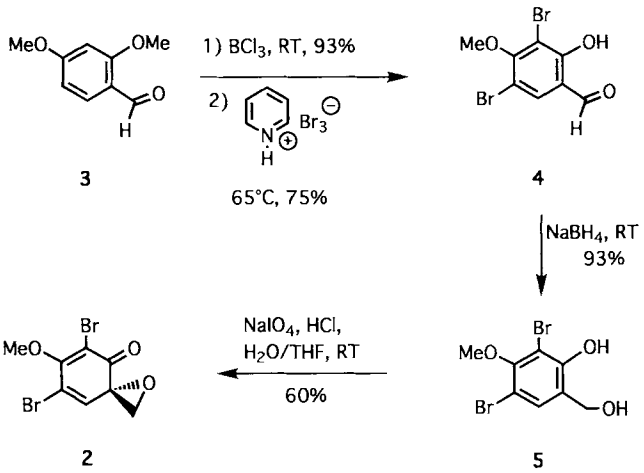
1



2

compounds with structural similarity to **1** have not been investigated, and data on the efficiency of **1** in vivo are lacking. To fill this gap we studied the EGFR-inhibiting activity of **1**[8] in a whole-cell assay system (see below) in which it, however, was not at all active. Since this lack of inhibition in vivo most probably has to be attributed to the inability of **1** to pass through the plasma membrane (the kinase domain of RTKs is on the cytosolic face of the membrane) due to the presence of a polar *trans*-diol unit, we designed the aeroplysinin analogue **2** as a possible RTK inhibitor for which higher membrane permeability and an enhanced inhibitory effect could be expected. In **2** the vicinal diol unit and the β-cyano alcohol are replaced by an α-spiroepoxy ketone. Thus **2** should be significantly more lipophilic than **1** and prone to nucleophilic attack at the epoxide and/or the vinylogous ketone functionality. This would lead to efficient inactivation of the receptor by covalent modification of nucleophiles in the binding site.

Ketone **2** was synthesized in a four-step sequence from the readily available aldehyde **3**[9] (Scheme 1). The methoxy group *ortho* to the aldehyde group of **3** was regioselectively cleaved by treatment with BCl_3, and the resulting phenol converted into the dibromo compound **4** with the pyridiniumhydrobromide/bromine complex.[10] Reduction of the aldehyde functionality of **4** generated the benzyl alcohol **5**, which was oxidized to **2** by a Becker–Adler oxidation.[11]



Scheme 1. Synthesis of the spiroepoxy aeroplysinin analogue **2**.

To investigate if **2** inhibits RTKs in vivo the inhibition of the receptor tyrosine kinase of the epidermal growth factor was studied first. In the assay system used, immortalized rat-1-HER cells[12] (rat fibroblasts that overexpress the human EGF receptor) were incubated with varying concentrations of inhibitor for five minutes followed by addition of EGFR to induce phosphorylation of unblocked receptor. The cells were subsequently lysed, and the proteins resolved by electrophoresis (SDS-PAGE). The extent of tyrosine phosphorylation of the EGFR was determined by phosphotyrosine immunoblotting (Figure 1).[13]

The results were very promising: **2** inhibited the kinase activity of the EGF receptor with an IC_{50} value of 10 μM (see Table 1). Preincubation of the cells for just a few minutes was sufficient to induce this effect; under the conditions of our assay inhibition of the RTK with tyrphostins required preincubation of the cells for at least several hours. These findings prove substantial in vivo activity of **2** and its sufficient lipophilicity. In a first attempt to determine whether **2** is receptor-subtype specific, the inhibition of the PDGF receptor was investigated by subjecting NIH-3T3-β-PDGFR cells to the assay conditions described above.[14] Ketone **2** did not inhibit this RTK up to a concentration of 100 μM, indicating pronounced subtype specifity.

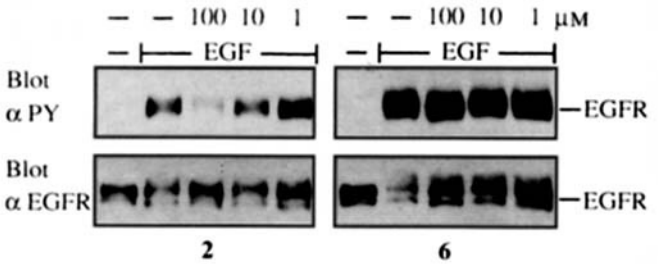

Figure 1. Determination of the IC_{50} values for the inhibition of the EGFR by immunoblotting of phosphotyrosin (αPY) and EGFR (αEGFR) to confirm that equal amounts of proteins were loaded. The aeroplysinin analogue **2**, but not *iso*-aeroplysinin **6**, inhibits the EGF-induced increase of EGF-receptor tyrosine phosphorylation in rat-1-HER cells (representative experiment). The numbers 100, 10, and 1 μM in the first row show the concentration of inhibitor for the corresponding incubation.

To delineate which structural properties are responsible for the RTK-inhibitory activity of **2**, several analogues of the spiroepoxy ketone were synthesized and investigated as possible inhibitors of the EGF and PDGF receptors in the in vivo assay systems described above. Table 1 demonstrate that neither aeroplysinin **1**[8] nor its isomer *iso*-aeroplysinin[7b] **6** inhibit the EGF or the PDGF RTK in vivo at concentrations up to 100 μM. The analogue **7**—in which the epoxide is opened, but the resulting tertiary alcohol is masked as ester—also inhibits the EGF receptor although it is less efficient than **2**. Likewise, **7** does not block the kinase activity of the PDGF receptor at all. Enhancing the polarity by saponifying the acetate (**7** → **8**) yielded a compound that is inactive under the assay conditions. This is probably due to its reduced ability to sufficiently pass through the plasma membrane of the cells within the time of assay. Interestingly the aromatic aldehydes **9**, which does not embody a methoxy group, and **4** also inhibited the EGFR (entries 6 and 7) albeit less efficiently than **2**. Furthermore, **9**, but not the methoxyaldehyde **4**, inhibited the PDGFR with an IC_{50} value of 30 μM. On the other hand neither aldehyde **3** (entry 8) nor alcohol **5** (entry 9) are inhibitors. These findings taken together suggest that the presence of the bromine atoms, probably to effect lipophilicity, and an electrophilic group are required for inhibitory activity. The nature of the electrophilic group may vary.

Table 1. Inhibition of the EGF and the PDGF receptor tyrosine kinases by aeroplysinin analogs in an in vivo assay system (see text for the description of the assay) [a].

Entry	Compound		Inhibition of the EGF receptor IC_{50} [μM]	Inhibition of the PDGF receptor IC_{50} [μM]
1		**1**	inactive	inactive
2		**6**	inactive	inactive
3		**2**	10	inactive
4		**7**	55	inactive
5		**8**	inactive	inactive
6		**4**	35	inactive
7		**9**	120	30
8		**3**	inactive	inactive
9		**5**	inactive	inactive

[a] Concentration at which 50% of the enzymatic activity are inhibited; "inactive" = no inhibition at <100 μM inhibitor concentration.

In conclusion we have demonstrated that α-substituted cyclohexadienones such as **2** and **7** as well as structurally related compounds inhibit RTKs. They display a marked in vivo activity and appreciable receptor-subtype specificity. Analogues of the natural product **1** are thus interesting lead compounds for the development of new drugs and tools in bioorganic and medicinal chemistry, that is, for the dissection of signal transduction pathways and the introduction of new tyrosine kinase inhibitors into medical use.

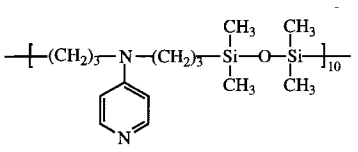
Ion-Induced Specificity Change in Polymer-Catalyzed Solvolyses of *p*-Nitrophenyl Alkanoates**

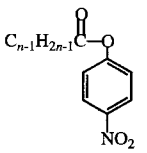
Guang-Jia Wang and Wilmer K. Fife*

Electrostatic interactions are considered to be major contributors to protein structure and specificity of enzyme catalysis.[1] However, few investigations have explored the control of substrate specificity of enzymes with ions of different sizes and charge densities. The control of substrate specificity in enzyme catalysis by use of organic solvents is well established.[1-3] Aggregation of amphiphilic polymers in water and water/organic solvent mixtures is well-known to lead to complex supramolecular structures with multiple morphologies.[4, 5] Upon decreasing the number of generations, the aggregate morphology of polystyrene with poly(propylenimine) dendrimers in aqueous solution has been shown to change from spherical micelles through micellar rods to vesicles.[6] The same morphological changes have also been found for polystyrene-b-poly(acrylic acid) (PS-b-PAA) as poly(acrylic acid) content decreases.[7] All of these studies[4-7] suggest that an increase in hydrophobic effects of amphiphilic macromolecules upon an increase in ratio of hydrophobic to hydrophilic monomers leads to such changes of aggregate morphology. Consistent with the notion that ion-induced hydrophobic effects control aggregate morphology of amphiphiles, the morphology of aggregates of PS-b-PAA, polystyrene-b-poly(ethylene oxide) (PS-b-PEO), and PS-b-poly(4-vinylpyridinium methyl iodide) in water/organic solvent mixtures can also be changed from spheres to rods, and to vesicles by addition of salting-out agents such as NaCl and $CaCl_2$.[8]

Polymers functionalized with the 4-(dialkylamino)pyridine group have been regarded as useful model systems for investigating the origins of enzymic efficiency and selectivity.[9-12] We have reported that macromolecule **1** containing the 4-(dialkylamino)pyridine functionality and a bis(trimethylene)disiloxane backbone as a nucleophilic catalyst exhibits enzyme-like substrate selectivity for the solvolysis of **2** in aqueous and methanol/water solutions.[10, 13, 14] To our knowledge, ion-induced substrate specificity changes have not been reported previously for catalytic ester solvolysis.



1



2

(n = 2, 4, 6, 8, 10, 12, 14, 16, 18)

We present here ion-induced substrate specificity changes in the **1**-catalyzed solvolysis of **2** (n = 2, 4, 6, 8, 10, 12, 14, 16, 18) in aqueous and methanol/water solutions. These results encourage more precise modeling studies of the molecular origins of catalytic efficiency and specificity in biological and chemical catalysis. Macromolecule **1** is an amphiphilic polymer that contains distinct hydrophilic and hydrophobic regions, and it dynamically associates to form macromolecular aggregates by self-assembly in aqueous or methanol/water solution.[9-11] The rate enhancements for **1**-catalyzed solvolysis of **2** have been attributed to hydrophobic association between catalyst and substrate in the reaction medium.[9-13] We have investigated the solvolysis of **2** (n = 2, 4, 6, 8, 10, 12, 14, 16, 18) catalyzed by **1** in different reaction media composed of solvent and added salts at pH 8.0 and 30 °C. Initial findings indicate that the solubility of **1** in 0.05 M aqueous tris(hydroxymethyl)methylammonium (Tris) buffer solution shows a more than tenfold increase over that in pure water as a result of salting-in effects of tris(hydroxymethyl)methylammonium ion from the Tris buffer system.[15-18] In 0.05 M aqueous phosphate or borate buffer solutions, the solubility of **1** is similar to that in pure water, and aqueous solutions of **1** show appreciable turbidity when the concentration of **1** is increased beyond 2.5×10^{-5} unit mol L^{-1}. However, a solution of **1** at 2.5×10^{-4} unit mol L^{-1} in 0.05 M aqueous Tris buffer solution remains clear even after standing for prolonged periods. These results suggest that changes of aggregate morphology of **1** at 2.5×10^{-5} unit mol L^{-1} from vesicles to rods or spheres apparently accompany changes of reaction medium from aqueous phosphate or borate to Tris buffer solutions.[7, 19]

We have measured the pseudo-first-order rate constants for **1**-catalyzed hydrolysis of **2** in 0.05 M aqueous Tris, phosphate, or borate buffer solutions (Figure 1). Without **1**, the hydrolysis rates of **2** (n = 2, 4, 6, 8, 10, 12, 14, 16) are very slow and no substrate selectivity is obtained in aqueous Tris, phosphate, or borate buffer solutions. In the presence of **1** the hydrolysis rates of **2** (n = 2, 4, 6, 8, 10, 12, 14, 16) are also very slow and differ from each other by only small factors in aqueous phosphate or borate buffer solutions, indicating that no appreciable catalysis is occurring in these systems. Increasing the alkanoate chain length in **2** causes small decreases in the hydrolysis rate and no substrate specificity is found for these systems (Table 1) in conformity with results from aqueous buffer solutions that contain

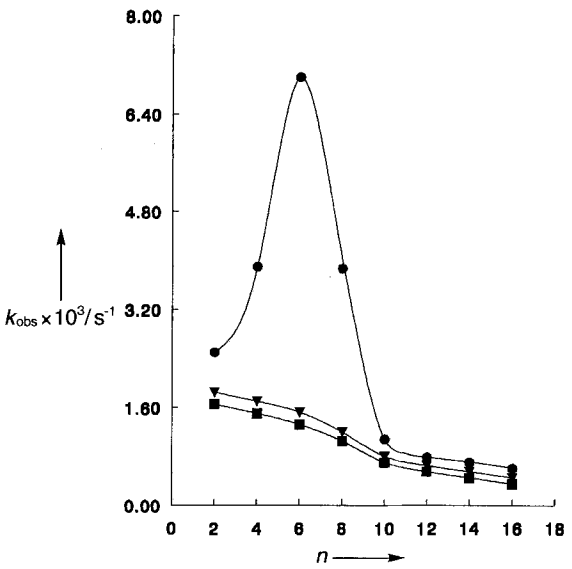


Figure 1. Pseudo-first-order rate constants (k_{obs}) for the hydrolysis of **2** (n = 2, 4, 6, 8, 10, 12, 14, 16, 5.0×10^{-5} M) catalyzed by 2.5×10^{-5} unit mol L^{-1} **1** as a function of alkanoate chain length n in 0.05 M aqueous buffer solution at pH 8.0 and 30 °C: ●: Tris buffer, ▼: phosphate buffer, ■: borate buffer.

Table 1. Summary of the effect of added salt concetration on the substrate specificity of 1-catalyzed solvolysis of **2** (n = 2, 4, 6, 8, 10, 12, 14, 16, 18) in aqueous and methanol/water solutions at 30 °C.

Reaction medium	Salt	c[M]	Substrate specificity
aqueous solution[a]	Tris buffer	0.05	**2** ($n = 6$)
	phosphate buffer	0.05	no
	borate buffer	0.05	no
methanol/water[b]	NaCl	0.00	**2** ($n = 14$)
	NaCl	0.01	**2** ($n = 14$)
	NaCl	0.10	**2** ($n = 14$)
	NaCl	0.25	**2** ($n = 12$)
	NaCl	0.50	**2** ($n = 12$)
	NaCl	1.00	**2** ($n = 12$)

[a] **1** (2.5×10^{-5} unit mol L^{-1}), pH 8.0. [b] **1** (5.0×10^{-6} unit mol L^{-1}), methanol/aqueous buffer (1:1, v/v; 0.05 M $H_2PO_4^-/HPO_4^{2-}$), pH 8.0.

no catalyst. However, in aqueous Tris buffer solution the rates for **1**-catalyzed hydrolysis of **2** (n = 2, 4, 6, 8) are much faster than those in aqueous phosphate or borate buffer solutions. Of added importance, macromolecule **1** demonstrates the same substrate preference for **2** (n = 6) that is observed with cholesterol esterase for the same hydrolysis reaction.[20] Under conditions where tenfold excess substrate is used in kinetic studies, the catalytic effectiveness of **1** is maintained to complete reaction.

We have also measured the effects of salting-out agent NaCl on substrate specificity for **1**-catalyzed solvolysis of **2** in 1:1 (v/v) methanol/water solution (Figure 2). Without NaCl,

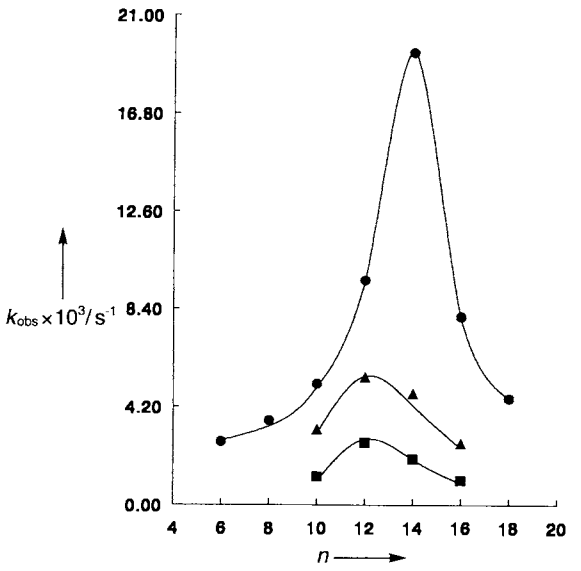

Figure 2. Effects of NaCl concentration on pseudo-first-order rate constants (k_{obs}) for the solvolysis of **2** (n = 6, 8, 10, 12, 14, 16, 18, 5.0×10^{-5} M) catalyzed by 5.0×10^{-6} unit mol L^{-1} **1** as a function of alkanoate chain length n in methanol/aqueous buffer (1:1, v/v; 0.05 M $H_2PO_4^-/HPO_4^{2-}$, pH 8.0) solution at 30 °C: ●: no NaCl; ▲: 0.25 M NaCl, ■: 1.00 M NaCl.

macromolecule **1** exhibits substrate specificity for **2** (n = 14). The solvolysis rate for **2** (n = 10, 12, 14, 16) decreases as the concentration of NaCl is increased from 0 to 1.00 M. Surprisingly, the substrate specificity is found to change from **2** (n = 14) to **2** (n = 12) when the concentration of NaCl is increased beyond 0.25 M (Table 1). Furthermore, we find that as the concentration of NaCl is increased to more than 1.00 M, the solutions of **1** at 5.0×10^{-6} unit mol L^{-1} become opalescent in 1:1 methanol/water solution. Apparently the aggregate morphology of **1** in 1:1 (v/v) methanol/water solution changes from spheres or rods to vesicles as the concentration of NaCl is increased from 0 to 1.00 M.[8, 19] We suggest that salting-out effects of NaCl induce changes of aggregate morphology of **1** in 1:1 (v/v) methanol/water solution from spheres or rods to vesicles,[15–18] while salting-in effects of the tris(hydroxymethyl)methylammonium ion induce changes of aggregate morphology of **1** in aqueous solution from vesicles to rods or spheres.[15–18] This is based on observations that added salts change aggregate morphology of small-molecule and macromolecular amphiphiles.[8, 21, 22]

Recently Zhang and Eisenberg have reported that the stretching of the hydrophobic chains in macromolecular amphiphiles is greatest in spherical micellar aggregates and decreases as the aggregate morphology changes from spheres to rods, and decreases further as vesicles are formed.[7, 19] The spherical aggregates tend to provide the strongest hydrophobic binding for lipophilic substrates in the reaction medium. We suggest that the changes of substrate specificity induced by NaCl may be attributed to changes in morphology of aggregates of **1** in 1:1 (v/v) methanol/water solution. Changes of aggregate morphology of **1** from spheres to rods or vesicles should accompany decreased hydrophobic binding for the substrates and decreased dependence of formation of complexes involving **1** and **2** on the hydrophobicity of the substrate. The substrate specificity change from **2** (n = 14) to **2** (n = 12) may result from NaCl driving a sphere to rod transition in aggregate morphology of **1** leading to hydrophobic binding that is optimum for **2** (n = 12) in 1:1 (v/v) methanol/water solution. This may be the origin of the molecular discrimination described by the term hydrophobic interactions at active sites of enzymes and catalysts for biological and chemical reactions. The behavior of **1** in aqueous Tris buffer solution may also be ascribed to spherical aggregates of **1** formed in response to the salting-in effects of tris(hydroxymethyl)methylammonium ion that contribute to efficient reaction within **1**·**2** complexes for **2** (n = 6) in aqueous solution.

These results provide the first instance in which the substrate specificity of catalytic ester solvolysis is seen to respond to the structural characteristics of aggregates of catalyst in the reaction medium, and illustrate a new approach to the control of chemical reactivity and aggregate morphology of amphiphilic macromolecules that can be useful in understanding the fundamental basis of controlling substrate specificity at the molecular level in biological and chemical catalysis. The kinetic behavior of our model system is quite similar to that of natural acyl-transfer enzymes such as chymotrypsin and cholesterol esterase for transfer of structural elements in cellular processes.

Experimental Section

Kinetic measurements: The cuvette was filled with 2.5 mL of a fresh solution containing catalyst in 0.05 M aqueous buffer solutions at pH 8.0 and the solution was equilibrated for 10 min at 30 °C in the thermostated cell compartment of a Hewlett-Packard Model 8450 spectrophotometer. The fresh catalyst solutions containing sodium chloride were prepared in methanol/aqueous buffer (1:1, v/v, 0.05 M $H_2PO_4^-/HPO_4^{2-}$, pH 8.0) solution. A stock solution (5 μL) of *p*-nitrophenyl alkanoates (2.5×10^{-2} M) in dioxane was added by microsyringe. The reaction mixture was quickly mixed by shaking and the absorbance at 400 nm was recorded as a function of time. The reactions were performed for four-to-five half-lives and the pseudo-first-order rate constants (k_{obs}) were obtained as slopes of plots of $\ln[A_\infty/(A_\infty - A_t)]$ against time, where A_∞ and A_t are the absorbance at infinite time and time t, respectively. The first-order rate constants (k_{obs}) represent the average of three runs and experimental error is less than 5%.

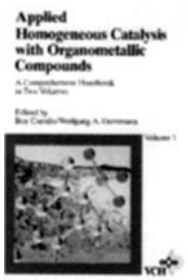
The Success Story of Organometallic Chemistry!

Applied Homogeneous Catalysis with Organometallic Compounds. A Comprehensive Handbook. (Volumes 1 and 2). Edited by *B. Cornils* and *W. A. Herrmann*. VCH Verlagsgesellschaft, Weinheim, 1996. Vol. 1, 571 pp.; Vol. 2, 675 pp.; hardcover, two-volume set DM 748.00.—ISBN 3-527-29286-1

This handbook could be considered as the fourth component of a tetralogy on transition metal chemistry. The first three are: the classic *Principles and Applications of Organotransition Metal Chemistry*, by J. P. Collman, L. S. Hegedus, J. R. Norton, and R. G. Finke (University Science Books, Mill Valley, **1987**), the second edition of *Comprehensive Organometallic Chemistry*, edited by the late G. Wilkinson, F. G. A. Stone, and E. W. Abel (Pergamon Press, Oxford, **1996**), and *Organometallics in Synthesis. A Manual*, edited by M. Schlosser (Wiley, Chichester, **1994**). The book under review fills the gaps left by the now outdated Collman's treatment of catalytic organometallic processes and the impressive 14-volume *Encyclopedia of Organometallic Chemistry*, which contains very little on homogeneous catalysis.



As pointed out by the editors, homogeneous catalysis is the success story of organometallic chemistry. The collaboration of an industrial research scientist and a university chemist provides an authoritative editorship for a comprehensive presentation of homogeneous catalysis in both basic and industrial aspects. The editors have assembled a team of 97 well-known authors from academia (48) and industry (49) who work in this field. The book comprises only four chapters, the central ones dealing with proven catalytic processes ("Applied Homogeneous Catalysis", Chapter 2, 542 pp.) and exploratory research ("Recent Developments in Homogeneous Catalysis", Chapter 3, 590 pp.).

In the introduction the editors give a brief account of the history of homogeneous catalysis and make the usual comparisons with heterogeneous catalysis. They stress the importance of cyclical changes in the relative popularity of the two types of catalysis as a result of progress in basic discoveries and process technologies, and changes in market requirements and feedstock availabilities, effects which are further developed in Chapter 2. They also sketch the attempts to create a symbiosis between the two types of catalysis, either at the molecular level (organometallic surface science) or at the macroscopic level (*n*-phase processes), aspects which inspire some parts of Chapter 3.

In Chapter 2 all the basic transformations using transition metal species are arranged according to either reaction types (hydrogenation, oxidation, hydrosilylation, hydroamination, asymmetric synthesis) or reactants (carbon monoxide and synthesis gas, unsaturated compounds, hydrogen cyanide, hydrocarbons).

Reactions with carbon monoxide (184 pp.) are discussed in detail by C. D. Frohning and Ch. W. Kohlpaintner (hydroformylation) and by a panel consisting mostly of industrial experts (synthesis of lower acids, carbonylation of benzyl and aryl moieties, amidocarbonylation, and oxidative carbonylation). This section provides an updated and concise survey of a domain where homogeneous catalysis has had some of its main successes. The discussions of reaction kinetics and mechanisms, commercial applications, and recent developments give the reader good insights into biphasic hydroformylation and methanol carbonylation to acetic acid, acetic anhydride, and methyl carbonate.

Reactions of unsaturated hydrocarbons are described by a panel of 16 contributors (including L. Böhm, Y. Chauvin, E. Drent, W. Kaminsky, R. Taube, and G. Wilke) who cover most of the field in 154 pages. Dimerization, codimerization, oligomerization, cyclooligomerization, polymerization of alkenes, of alkynes, and of 1,3-dienes and the corresponding cross-reactions are discussed, including industrial applications. This review of the "-ization" reactions is completed by an excellent survey of the alternating copolymerization of alkenes and carbon monoxide and a description of telomerization of olefins, although this is limited to the manufacture of 1-octanol. Finally, metathesis is reviewed, although too briefly and with little information on ring-opening polymerization.

The treatment of oxidations is mainly concernd with conversion of olefins to carbonyl compounds and with acetoxylations and other reactions promoted or catalyzed by palladium (37 pp., R. Jira), with details of the Wacker–Hoechst processes and a brief contribution on formation of aliphatic carboxylic acids via aldehyde oxidation (6 pp.), as well as reactions with aryl- and alkyl-substituted aromatic compounds (35 pp., R. W. Fischer and F. Röhrscheid). A short review (13 pp., R. A. Sheldon) on the synthesis of oxiranes with emphasis on developments for organic synthesis, especially for chiral compounds, completes this section (91 pp.), which is important because of the high selectivities towards oxygenates achieved in commercial homogeneous catalytic processes.

The shorter contributions to Chapter 2 focus primarily on recent advances in practical homogeneous catalysis. The most instructive of these is the one by R. Noyori and S. Hashiguchi, which illustrates the use of chiral molecular catalysts for the synthesis of bioactive molecules. Examples of the use of monodentate P, or more commonly bidentate N–N, N–O, P–P, P–N, and P–O ligands for the preparation of terpenes (Takasago), profens, pyrethroids, prostaglandins, secondary alcohols, amino alcohols, amino acids (Monsanto–Searle), and carbapenems (Takasago) are covered in 19 pages. The section on reactions with hydrogen cyanide also provides examples of asym-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

metric hydrocyanation of olefins (K. Huthmacher and S. Krill, 20 pp.). The contribution on hydrosilylation and related reactions of silicon compounds (B. Marcicniec, 20 pp.) emphasizes the recent advances in dehydrogenative coupling of hydrosilanes and disproportionation of silicon-containing olefins. Finally, the lack of efficient catalysts for olefin hydroamination as reported by R. Taube (14 pp.) clearly demonstrates that homogeneous catalysis is still facing many challenges.

In Chapter 3, Volume 2, some of these challenges are discussed in the three parts devoted to development of methods (195 pp.), special catalysts and processes (224 pp.), and special products (173 pp.).

One may consider three main areas in the first section: catalyst recovery, understanding and modeling of catalytic activity, and catalytic C–C coupling reactions. Several contributions deal with the major drawback of homogeneous catalysis: catalyst recovery. Immobilization by aqueous catalysts (B. Cornils and W. A. Herrmann, 26 pp.), heterogenization by other immiscible phases (I. T. Horváth, 5 pp.), and immobilization using supports (P. Panster and S. Wieland, 19 pp.) are discussed in terms of advantages and disadvantages for industrial applications, the best example cited being the Ruhrchemie–Rhône–Poulenc two-phase hydroformylation of propene. Ligand-stabilized clusters and colloids (G. Schmid, 8 pp.) and re-immobilized catalysts (H. Bahrmann, 10 pp.) are suggested as other approaches; these introduce new technological problems for which membrane separation offers a possible solution. The understanding and modeling of catalytic activity is covered in surveys of catalytic engineering aspects (M. Baerns and P. Claus, 15 pp.) and molecular modeling (R. Klein and R. Schmid, 18 pp.). An introduction to parahydrogen labeling as a new analytical method in homogeneous catalysis (J. Bargon, 12 pp.) is also described, as an example of the development of special in-situ techniques for mechanistic studies. Finally, introductions to organometallic surface science (J.-M. Basset and G. P. Nicolai, 12 pp.), to Fischer–Tropsch synthesis (W. A. Herrmann, 16 pp.), and to multicomponent or multifunctional catalysts (D. Hesse, 13 pp.) may indicate new routes to be explored, especially at the frontier between homogeneous and heterogeneous catalysis. Catalytic C–C coupling reactions are examined from three major aspects which already provide useful applications in organic synthesis. The Heck reaction and its variants (Blaser, Jeffery, Bozell, Milstein, intramolecular ...) are concisely summarized (W. A. Herrmann, 21 pp.), together with recent improvements using palladacycles and heterocyclic-carbene complexes of palladium. A brief report on aryl–aryl coupling, Grignard cross-coupling, and phenol coupling is also provided (W. A. Herrmann, 6 pp.). Finally, recent developments in catalytic cyclopropanation (A. F. Noels and A. Demonceau, 15 pp.) mainly concern enantioselective catalysts based on copper and rhodium.

The second section of Chapter 3 covers several aspects that are not easy to classify. Some undoubtedly correspond to methods or catalysts, others to reactants or processes. In the first group are: phase-transfer catalysis and related systems (Y. Goldberg and H. Alper, 22 p.) describing mainly oxidation, carbonylation, and Heck-type reactions under phase-transfer conditions; membrane reactors (U. Kragl, C. Dreisbach, and Ch. Wandrey, 12 pp.), where membranes act as catalysts or physical barriers for bulky components such as colloids, dendrimeric structures, etc.; homogeneous electrocatalysis (D. Astruc, 14 pp.) and photocatalysis (A. Heumann and M. Chanon, 15 pp.), where electrons or photons very often participate only in the formation of the catalytic species from the precursors. In the second group dealing with catalysts, the review on biocatalysis and enzyme-analogous processes (K. Drauz, H. Waldmann, and B. Sauerbrei, 34 pp.), in addition to a survey of the uses of hydrolases, dehydrogenases, aldolases, and transferases, offers examples of commercial applications which can be compared with abiotic catalysts. A summary of the potential uses of template or host–guest relationships (F. Vögtle, R. Hoss, and M. Händel, 22 pp.) completes this contribution by introducing new concepts for homogeneous catalysis, with supramolecular control of the interactions between the catalytically active site and the reactants. The use of rare earth compounds (R. Anwander, 27 pp.) and metallocenes (F. Küber, 10 pp.) concludes this second group: the authors demonstrate that both Group 4 chiral metallocenes and organolanthanides have unique stereoelectronic properties for efficient reactions forming carbon–carbon bonds (oligomerization and polymerization, Diels–Alder reactions, aldolization, etc.) and carbon–heteroelement bonds (hydrosilylation, hydroamination, epoxidation, etc.). In the third group, specific reactants are considered, using aldehydes and keto compounds for olefin formation (W. A. Herrmann, 9 and 5 pp. respectively). The analogy between the Wittig reaction and the olefination of aldehydes with diazo compounds mediated by molybdenum and rhenium compounds is first discussed; the catalytic McMurry coupling is considered as an additional example of how to go from a stoichiometric process to a catalytic one by appropriate choice of the components involved in the mediating system. Finally, in the fourth group, specific catalytic processes such as homologation, isomerization, the water-gas shift reaction, and hydrodesulfuration processes are considered. Homologation of methanol (H. Bahrmann, 13 pp.), with comments on technical applications, completes the treatment of carbonylations (Chapter 2). The contribution on double-bond isomerization of olefins (W. A. Herrmann, 12 pp.), with special attention to reaction mechanisms, introduces recent applications such as asymmetric isomerization. The water-gas shift reaction (W. A. Herrmann, 7 pp.) is briefly described in view of its involvement in several carbonylation processes and its interest for the catalytic synthesis of isocyanates and urethanes. Hydrogenation and hydrogenolysis of thiophenic compounds (C. Bianchini and A. Meli, 11 pp.) are described in the context of attempts to design a homogeneous process for hydrodesulfuration, a reaction of great importance in petroleum refining.

The third section of Chapter 3 is also a collection of short reviews on topics similar to those of the preceding part; they roughly correspond to specific processes, reactions, and molecules. In the first group one finds enantioselective synthesis and reactions in homogeneous systems. The very thorough contribution by H.-U. Blaser, B. Pugin, and F. Spindler (33 pp.) complements the approach of R. Noyori and S. Hashiguchi by considering the technical application of homogeneous enantioselective catalysts for additions to C=C, C=O, and C=N groups. Some examples of step-growth and chain-growth polymerizations are given by B. M. Novak (10 pp.), with special attention to ROMP processes. A brief account of biomembrane hydrogenations with water-soluble hydrogenation catalysts (L. Vigh and F. Joó, 7 pp.) provides a good example of exotic applications of homogeneous catalysts.

In the second group, other areas of application are described, with specific reactions leading to special products. These reactions are related to carbon monoxide chemistry, coupling of unsaturated compounds, oxidations, and C–H bond activation. Reductive carbonylation of nitro compounds (R. Sundermann and H. J. Scholl, 9 pp.) is presented, with a pessimistic assessment of prospects for indus-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1548 $ 17.50+.50/0

trial production. The Pauson–Khand synthesis of cyclopentenones (V. Rautenstrauch, 10 pp.) also seems to be of doubtful value for commercial applications. The review on hydrovinylation (P. W. Jolly and G. Wilke, 25 pp.) details the catalysts, substrates, and mechanisms for this reaction, whose asymmetric counterpart would be relevant for the synthesis of bioactive molecules. Also coming from Mülheim/Ruhr is an exhaustive survey of the cyclooligomerization of alkynes (H. Bönnemann and W. Brijoux, 17 pp.), describing the formation of five- and six-membered heterocycles and six- and eight-membered carbocycles. The synthesis of diols via catalytic dihydroxylation (M. Beller and K. B. Sharpless, 16 pp.) is discussed mainly in its asymmetric version, which is of possible industrial interest for the preparation of intermediates for pharmacologically active compounds. Finally, activation of C–H bonds is discussed in two reports. New approaches to C–H activation of alkanes (A. Sen, 12 pp.) draw attention to the effectiveness of electrophilic pathways in promoting activation and functionalization of the least reactive members of the hydrocarbon family. On the other hand, intramolecular C–H carbenoid insertion offers new possibilities for the catalytic synthesis of cyclic hydrocarbons from diazoalkanes (W. A. Herrmann, 7 pp.), the challenge now being to achieve enantioselective cyclizations.

In the third group, specific molecules are considered. The use of carbon dioxide as a C_1 building block (E. Dinjus and R. Fornika, 25 pp.) is discussed, with special attention to the use of supercritical conditions which are essential for the efficient production of formic acid and dimethylformamide. The description of a new catalytic synthesis of methacrylates from propyne (E. Drent et al., 13 pp.) represents an additional example of proper design of a catalyst for highly efficient methoxycarbonylation reactions. Molecular design is also the basis of a discussion on the preparation of acrolein and acrylonitrile (W. A. Herrmann, 8 pp.).

Chapter 4, "Epilogue", focusses on the numerous scientific and industrial problems which remain to be solved, and which have been made clear to the reader in many of the conclusions reached in the general and specific reviews included in Chapters 2 and 3. The message is that there is a need for better integration of theoretical chemistry, chemical kinetics, and chemical engineering, and for stronger relationships between groups working on homogeneous and heterogeneous catalysis.

Anyone who already has some knowledge of molecular transition metal chemistry will find this book extremely useful in providing a thorough account of the state of the art in homogeneous catalysis, both in its accomplishments (Chapter 2) and current trends (Chapter 3). The organization of Chapter 3 is rather open to criticism, as it does not have a clear structure. Nevertheless, this chapter provides a series of essays which complement the topics developed in Chapter 2 and open new perspectives. The reader wishing to study topics in greater depth has access to over 5000 literature references, with some from 1996 (and 1997!). Very few errors could be found, the most noticeable one being the citation of Reppe's work on hydroxycarbonylation (p. 146), which was published in *Liebigs Annalen der Chemie*, not in *Annales de Chimie* (a computer-generated error?). This reviewer was also pleased to find on page 199 a new spelling of his name! Some drawings are incomplete, for example structure **2** on page 961. Lastly, there is a detailed index which will help in searching the literature on the basis of molecules, reactions, or processes.

To summarize, this handbook is well justified in view of the immense growth of interest in homogeneous catalysis since the "roaring sixties", and the continuing role of the subject in highlighting new fundamental problems and in presenting chemical technology with new challenges. Despite its price, it should be available in every laboratory concerned with the future of catalysis and, certainly, of organic chemistry.

Comprehensive Organic Functional Group Transformations. Volumes 1–7. Editors-in-chief: *A. R. Katritzky, O. Meth-Cohn* and *C. W. Rees*. Pergamon/Elsevier, Oxford, 1995. approx. 7800 pp., hardcover $ 4437.25.—ISBN 0-08-040604-1

As stated in the first sentence of the introduction, the objective of this monumental work is to cover the enormous field of organic synthesis by describing methods for introducing or modifying functional groups. For this huge task the editors have chosen a structural form (said to have been conceived over a glass or two of wine in a London club) that is simple, convenient, and easily memorized by the user. In this system the experimental information is arranged according to the number of attached heteroatoms, the formal valency ("coordination") of the carbon atom under consideration, the position in the Periodic Table of the heteroatom(s) directly bonded to that carbon atom, and the principle of the latest entry. Accordingly, the six main text volumes are as follows: Volume 1. Carbon atoms with no attached heteroatom; Volume 2. Carbon atoms with one heteroatom attached by a single bond; Volume 3. Carbon atoms with one heteroatom attached by a multiple bond; Volume 4. Carbon atoms with two singly bonded heteroatoms; Volume 5: Carbon atoms with two attached heteroatoms, at least one being multiply bonded; Volume 6. Carbon atoms with three and four attached heteroatoms. Volume 7 consists of an author index and a subject index for all the above volumes.

A work of this nature and size cannot be reviewed in the same way as, for example, a monograph or textbook. It can only be evaluated after working with it on practical tasks. Therefore we have concentrated here on the two volumes, namely Volumes 2 and 5, that we have already used. Our presumption that similar conclusions would apply to the other four seems well justified in view of the scientific reputations and competence of the individual authors.

In accordance with the above scheme of organization, Volume 2 begins with alkyl derivatives, followed by a second part on aryl and vinyl compounds, and finally a third part on functionalized alkynes (the unsubstituted alkynes are covered in Vol. 1).

The first 30 pages contain a concise, but complete, survey of methods for synthesizing alkyl halides. Alcohols and ethers are then treated similarly, including methods for asymmetric syntheses. This is followed by three very long chapters on the synthesis of sulfur, selenium, and tellurium compounds, and a further one on alkyl derivatives containing nitrogen or other elements of Group 5. Part 1 ends with the synthesis of alkyl-boron and alkyl-silicon compounds and an excellent chapter of 50 pages on the synthesis of organometallic alkyl compounds. This includes useful tables of Grignard reagents and titanium alkyls with methods for preparing them, so that the reader can quickly review the various possibilities.

Part 2 begins with the synthesis of vinyl and aryl halides, followed by enols, phenols, thiols, and their ethers. The important aryl- and vinyl-substituted compounds with nitrogen or phosphorus as heteroatoms are then treated at length (130 pp.). A chapter on the synthesis of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1549 $ 17.50+.50/0

organometallic compounds concludes Part 2.

The third and final part, consisting of nearly 90 pages, deals with the synthesis of functionalized acetylenes. As well as derivatives with halogens, nitrogen, or phosphorus as heteroatoms, followed by metal acetylides, some unusual functionalities are also included, for example in the synthesis of alkynols, the less stable tautomeric form of ketenes.

Most of the synthetic methods described are illustrated by describing at least one practical example. Each chapter is accompanied by a comprehensive bibliography giving the reader quick access to original publications and laboratory recipes.

Volume 5 is concerned with carbon compounds containing two heteroatoms, one of which has a multiple bond. In accordance with the overall scheme of this work, Part 1 covers compound classes containing a C=O group. The first few chapters deal with methods for synthesizing carboxylic acids and their derivatives: acid halides, carboxylic acids, esters, thiocarboxylic acids and derivatives, and carboxylic acid amides. The methods are classified according to their degree of general applicability, the degree of functionalization of the carboxylic acid derivative, and the types of synthetic strategies that can be used (reactions without change of oxidation state, addition reactions, oxidations). A disadvantage of this treatment is that it includes no information about the preparation of carboxylic acids from reagents such as auxiliary-bound amides, which are nowadays an essential part of the synthetic chemist's armory. The chapter by Mulzer is a concise and informative description of methods for selective esterification and lactonization, such as those based on activation of carboxyl or hydroxyl groups, and also includes addition reactions of chiral esters. Two further chapters cover synthetic routes to amides, including lactams and *N*-heterosubstituted amides. The methods, treated according to the degree of substitution of the carboxylic acid moiety, include acylation of amines, hydrolysis methods, rearrangements, and *N*-functionalization reactions. Transition-metal-catalyzed methods for synthesizing amides and lactams are also described, as too are methods based on α-oxidation of amines. Part 1 ends with synthetic routes to acylsilanes, acylgermanes, and acyl-metal compounds.

Part 2 of this volume deals with compounds containing a fragment of the form X = C–Y. Six chapters are devoted to thiono derivatives of carboxylic acids and their selenium and tellurium analogs. These are followed by a further six chapters that concentrate on routes to iminoacyl compounds (imidoyl halides, iminoethers, amidines, and α-heterodiazo compounds. Next are three chapters on the synthesis of compounds containing a carbon–heteroelement multiple bond with a second heterosubstituent at the α-position. The first of these are α-heterosubstituted phosphoranes, which are followed by α-heterosubstituted silenes, germenes, and borenes. This part ends with a detailed survey of methods for preparing Fischer carbene complexes and analogous compounds.

Part 3 is devoted to carbonic acid derivatives with sp-hybridized carbon. Synthetic strategies for preparing isocyanates, isothiocyanates, carbodiimides, cyanates, thiocyanates, cyanamides, and organometallocyanides are described in detail. Some more unusual compound classes are also included, such as silaketenes, other metallaketenes, and phosphaalkynes.

In these two volumes the editors have admirably fulfilled their purpose of providing a route into the literature for the chemist seeking synthetic methods for a particular functional group. This is helped by the clear systematic arrangement mentioned above and by the comprehensive subject index. Nevertheless, when we come to consider the index volume (Vol. 7), we can no longer avoid asking the question: "Is it still appropriate nowadays for a literature survey of this kind to be published in book form?". With regard to Volume 7 itself, the answer must be: "No". If this index volume had been replaced by a diskette, the saving in weight would have been 2.9 kg, and the required shelf space would have been reduced by 6.7 cm. However, for the main text volumes (which are, of course, more important), the question cannot be answered so simply. With these one is likely to gain at least as much from chance discoveries, when looking for something else or leafing through at random, as from focussed searches. But here again one must ask whether, in the electronic age, publishers should not hold these undoubtedly very useful compilations in the form of in-house data bases that can be updated, and offer them to users in that form. This would, at least in principle, avoid the problem that, owing to the long time needed to complete a large book project of this kind, parts of it are already outdated by the time the work is published. The effects of this time delay can be clearly seen in the bibliography, as the numbers of references fall off noticeably after 1992; for example, in Volume 5 we find over 250 citations from 1992, about 150 from 1993, less than 100 from 1994, and only 23 from 1995.

In reviews of works of this kind, it is usual to end with a verdict to the effect that no library with pretensions of being scientific can afford not to buy the work in question. However, one must also ask how the money for it can be found, at a time when more and more primary journals are having to be axed from libraries' order lists (and when the few that remain are often no longer put into bindings). In any case, it is difficult to avoid the impression that the enormous numbers of comprehensive series, encyclopedias, and lexicons appearing in the last few years could be rather like the barrage of rockets and loud bangs that comes just before the end of a firework display: one can more or less dismiss the idea that such a tour de force is about to be repeated (perhaps even in an extended form).

Arrhenius: From Ionic Theory to the Greenhouse Effect. (Series: Uppsala Studies in the History of Science, Volume 23.) By *E. Crawford.* Watson Publishing International, Canton, MA, 1996. XIII, 320 pp., hardcover $ 49.95.—ISBN 0-88135-166-0

According to Swedish-born historian and sociologist of science Elisabeth Crawford, senior research fellow at the Centre National de la Recherche Scientifique (CNRS) and member of the Institute for the History of Science at the Louis Pasteur University, Strasbourg, France, scientists can be divided into three categories: "'truly great men'...whose work revolutionized the scientific worldview", "'great men'...who left their mark on an entire discipline", and "those who do not fit any particular category because their work spreads over several disciplines or is carried out on the boundaries of two or more disciplines." Arrhenius, Sweden's most prominent scientist and the best-known internationally since Berzelius, belongs to the interdisciplinary category.

Book-length biographies which perpetuate the myths advanced by Arrhenius himself exist in German (Ernst Riesenfeld [Arrhenius's brother-in-law], *Svante Arrhenius*, Akademische Verlagsgesellschaft, Leipzig, **1931**) and in Russian (Yurii I. Solov'ev, *Svante Arrhenius*

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3613-1550 $ 17.50+.50/0

(1859–1927), Nauka, Moscow, **1990**). Crawford's biography, seven years in the making and the first in English, recreates Arrhenius's three major scientific fields, or "projects" as she prefers to call them: (1) his work in electrochemistry and physical chemistry, including specifically his most creative achievement, the theory of electrolytic dissociation, for which he was awarded the 1903 Nobel Prize in Chemistry, although he regarded himself as a physicist; (2) his cosmic physics, in which he was the first to show a quantitative link between changes in atmospheric carbon dioxide and the earth's temperature and climate and to propose a model for what is now called the "greenhouse effect"; and (3) his application of the quantitative methods of physical chemistry to biology, thus creating immunochemistry, a field which he named. Each project was shaped by different national-cultural and social contexts and occupied him for roughly a decade. Thus (1) took place in Sweden and Latvia during the 1880s, (2) in Sweden during the 1890s, and (3) belongs to German chemistry, biology, and medicine during first decade of the twentieth century. Thus Arrhenius's crossing of disciplinary boundaries was to some extent coincidental with crossing national ones. Arrhenius's important work in cosmology (volcanoes and earthquakes, auroras, magnetic storms, solar spots and flares, and the development of galaxies and nebulae), though not dealt with in the detail accorded to the three projects, is not neglected, particularly his triumph of science popularization, *Världarnas utveckling* (English translation: *Worlds in the Making*, 1908; German translation: *Werden der Welten*, 1908), which was a simplified and abbreviated version of his unsuccessful *Lehrbuch der kosmischen Physik* (1903).

According to Crawford, Arrhenius' penchant to undertake such different projects was related to his love of ideas and of controversy. His love of ideas was the major source of inspiration for his scientific achievements, which arose not from experimental work but from his imagination and wide reading of old and new scientific literature. Not being tied to a single "investigative pathway" predetermined by instrumentation or experimental materials, he was able to roam at will through those fields of science that had not yet been compartmentalized into specialties. His unusual ideas and their startling results involved him in considerable polemics, but his love of controversy, which he shared with many of his contemporaries, involved him in more conflicts than these ideas seemed to warrant. These polemics are best known to most modern chemists in his fight, together with his fellow "ionists" Wilhelm Ostwald and Jacobus Henricus van't Hoff, for the acceptance of his electrolytic dissociation theory and the emerging field of physical chemistry in Europe and the United States. However, he sought out opponents to attack even when their objections did not merit his attention. His adversarial tactics, which persisted into his middle age and became part of his scientific style, marked the last major battle of his scientific life—his conflict with Paul Ehrlich concerning toxin–antitoxin reactions, which set the agenda for several years of theoretical and experimental work.

Because of Arrhenius's adversarial view of science, Crawford was forced to find the true facts behind the highly personal and colorful but self-serving and propagandistic accounts that he gave of his battles. Thus she "decided at the outset to discount Arrhenius's own versions of events unless corroborated by other sources." For example, his claim that his ionic theory was contained in his dissertation of 1884 (whereas it did not appear until 1887, in his celebrated article in the first volume of the newly founded *Zeitschrift für physikalische Chemie*), has become part of the lore of the history of science. Crawford attributes Arrhenius's propensity for such myth-making to what his son Olof, an agricultural botanist and soil scientist, called "a wound that never healed"—the humiliation that he felt he had suffered in 1884 when the "Uppsala physicists" did not award his dissertation the highest grade, thus denying him a docentship at Uppsala.

During the late 1970s Crawford carried out the first study of the background to the awarding of the Nobel Prizes in physics and chemistry, using the recently opened archives at the Royal Swedish Academy of Sciences (*The Beginnings of the Nobel Institution: The Science Prizes, 1901–1915*, Cambridge University Press, Cambridge, **1984**; and with John L. Heilbron and Rebecca Ullrich, *The Nobel Population 1901–1937*, Office for History of Science and Technology, University of California, Berkeley, **1987**). Arrhenius had been the key figure in the creation of the Nobel Institution, and she consulted these archives and others in Sweden, Germany, Denmark, and the United States, as well as Arrhenius's extensive correspondence with scientists around the world and the primary and secondary literature. She documents in detail Arrhenius's using his influential position to block the Nobel Prize of Walther Nernst, his former friend but later Ehrlich's ally, for a decade and a half.

Crawford consistently views Arrhenius's work in the context in which it arose. For example, she provides an entire chapter, "Sweden in the 1890s", as background for his work in cosmic physics. Although she does not neglect the events in Arrhenius's personal life, her emphasis is on their relationship to his career. His brief, unhappy first marriage, to his private assistant Sofia Rudbeck, a chemistry graduate of Uppsala University, who typified the new emancipated woman, "*die Nordische Frau*", by whom he had a son, is dealt with in about a half dozen pages, while his second, longer, and happy marriage, to Maria (Maja) Johansson, by whom he had three children, is relegated to one sentence and a one-sentence footnote. In contrast, Crawford devotes a full page to Maria's brother and Arrhenius's friend, Johan Erik Johansson, Professor of Physiology (1900–1927) at the Karolinska Institute. Thus her carefully documented book containing references as late as 1994 is better characterized as a scientific rather than a personal biography. It should fulfill her hope of furthering "the comprehension of a little-understood scientist who exerted an important influence on the development of the sciences in the late nineteenth and early twentieth centuries."

Dawn of the Fullerenes: Conjecture and Experiment (Nobel Lecture)**

Robert F. Curl*

Conjecture

Several individuals in widely separated parts of the world had envisioned the class of carbon cage compounds we now know as the fullerenes, in particular C_{60}, long before we began our work. The earliest reference in the area appears to be the somewhat whimsical proposal by Jones that giant carbon cage molecules, which we would now call giant fullerenes, might be synthesized by introducing defects in the graphitic sheet to allow them to curve and close.[1] He believed that such molecules should exhibit unique properties, such as having a very low density. He realized some time later that the required defects would be pentagons.[2]

Apparently the first person to imagine the truncated icosahedron isomer of C_{60} shown in Figure 1 was Osawa.[3, 4] Osawa conceived of the C_{60} structure while meditating on the structure of corannulene ($C_{20}H_{10}$), which has a central pentagon of carbon atoms surrounded by five hexagons, when he glanced at his son's soccer ball (football) and recognized the same pattern. Shortly thereafter a Hückel treatment of the π electrons was carried out in the Soviet Union[5] and repeated independently some years later in the USA as part of a larger article.[6] The Hückel calculation was repeated again by Haymet in his discussion of the stability of the molecule.[7]

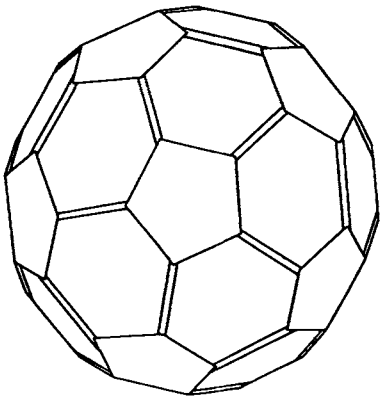

Figure 1. Truncated icosahedron C_{60} with the dominant Kekulé structure.

The synthetic organic chemist Orville Chapman took the challenge of the synthesis of truncated icosahedron C_{60} seriously in the early 1980s, obtained funding from the National Science Foundation for this purpose, and set to work with several graduate students on its total synthesis.[8] This project is indeed a tremendous challenge to the conventional methods of organic synthesis, and to date no such total synthesis of C_{60} has been completed.

These conjectures concerning C_{60} were based upon good chemical intuition backed up by approximate quantum chemical calculations. The conclusion of these conjectures was that truncated icosahedron C_{60} would be a chemically stable compound that, once prepared, could be handled much as any common substance.

Experiment

When we started our experiments on carbon clusters in late August 1985, we were completely ignorant of the conjectures just related. The purposes of our carbon-cluster project were to determine whether the sort of carbon chain compounds such as HC_7N found[9, 10] by radioastronomy in the interstellar medium could be synthesized by mixing carbon vapor with a suitable reagent such as ammonia and to find the conditions needed for a study of the low-temperature electronic spectra of carbon chain compounds using resonance-enhanced two-photon ionization. The spectroscopic work on carbon chains was motivated by the proposal made by Douglas[11] that electronic absorptions of long-chain carbon molecules, C_n ($n = 5-15$), are the source of the diffuse interstellar bands.[12] The work on formation of carbon chain compounds was ultimately published,[13, 14] but the carbon chain spectroscopy was never really begun.

I won't review in detail here the experiments we carried out in August and September of 1985 which resulted in our proposal[15] that truncated icosahedron C_{60} (buckminsterfullerene) is formed spontaneously in condensing carbon vapor. Accounts of this have been given[16, 17] by two of the five people involved and in two books on the discovery of the fullerenes.[8, 18] The authors of these books consulted all five of us and, in my opinion, made the best effort possible to use the recollections of those involved to recreate these events.

However, in order to understand what we did it is necessary to learn something about the apparatus[19–21] invented by Richard Smalley to investigate compounds and clusters formed from refractory elements. He and his students used it to investigate the high-resolution electronic spectra of a number of metal dimers,[20–23] copper trimer,[24] and SiC_2.[25] In 1984 Frank Tittel, Smalley, and I with our students began investigating semiconductor clusters using this apparatus.

The heart of the experiment is the laser vaporization supersonic molecular beam source. The source went through several design variations primarily to accommodate the physical form of the available sample material to be vaporized. For these experiments, it was a disk-vaporization source because the semiconductor samples that we had been investigating were more readily available in sheet form. Figure 2 shows a cross-section of

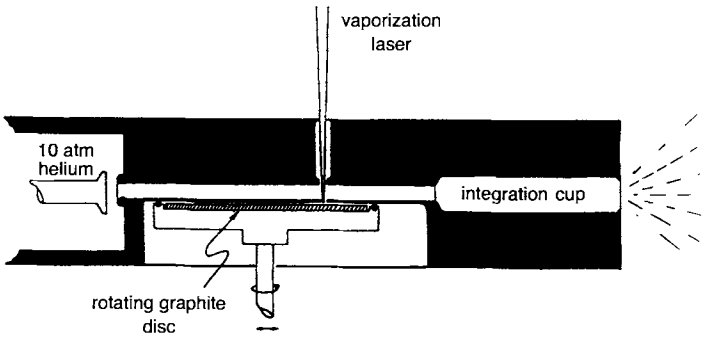

Figure 2. Laser-vaporization source for producing molecular beams of clusters of refractory materials. The integration cup can be removed. For the carbon experiments the target is a graphite disk which is rotated slowly to provide a fresh vaporization surface. The vaporization laser, a 5-ns pulse at 532 nm of about 30–40 mJ, is focused onto the surface of the graphite. The pulsed nozzle passes helium over this vaporization zone.

this pulsed molecular beam source. In operation the solenoid-actuated pulsed valve was fired to release through the 1-mm orifice a pulse of He gas over the sample lasting somewhat less than a millisecond. The backing pressure could be as high as 10 atm. At some point during the gas pulse, usually near its middle, the Q-switched frequency-doubled vaporization laser was fired generating a 5-ns-long pulse of green light (532 nm) with an energy of roughly 30–40 mJ. This laser was focused onto the rotating–translating graphite disk (to avoid digging pits into the sample) vaporizing a plume of carbon vapor into the gas stream. Multiphoton ionization and the subsequent heating of the resulting plasma limited the amount of material vaporized in a single shot and ensured that the species initially contained in it were atoms or very small molecules, such as C_2 and C_3.

Robert F. Curl, Jr. was born in 1933 in Alice, Texas (USA). He received his Ph.D. in chemistry in 1957 at the University of California, Berkeley (USA). After conducting research at Harvard University for one year he went to Rice University, where he has been a professor since 1967.

The material vaporized was caught up in the helium gas flow, mixed with it, and cooled by it. The cooling vapor then began to condense into clusters. The extent of clustering could be varied by changing the backing pressure, the timing of the firing of the vaporization laser with respect to the center of the gas pulse, and the length and geometry of the channel downstream from the vaporization point. In the configuration shown in Figure 2 an integration cup has been added to the end of the gas channel to provide more time for clustering and reaction before supersonic expansion.

After clustering, the gas pulse was expanded supersonically through a nozzle into a large vacuum chamber (Figure 3). Be-

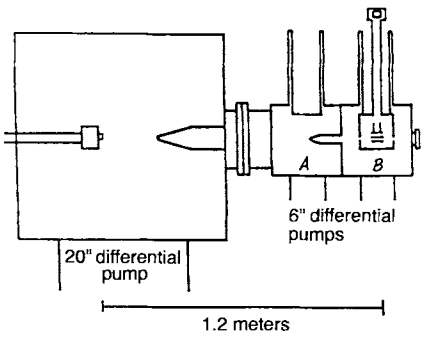

Figure 3. Molecular-beam photoionization time-of-flight (TOF) mass spectrometer.

cause this expansion is essentially an adiabatic reversible expansion, the temperature of the species in the gas drops from somewhat above room temperature to a few Kelvin. After a few dozen expansion-nozzle diameters, collisions between particles in the expansion jet cease resulting in a gas stream with a narrow, highly directional velocity distribution. The resulting jet of cold clusters can be skimmed into a molecular beam and interrogated by mass spectrometry. Mass spectrometric detection labels the species by mass, which is a particularly important consideration in the study of clusters, where a wide distribution of cluster sizes is always found. In addition, mass spectrometric detection provides high sensitivity and permits extensive control of the trajectory of the cluster ions. Consequently, a variety of methods for manipulating and probing the cluster ions were developed and used in this work. These more sophisticated methods will be described later at the appropriate point. For the present, we focus on the simplest mass spectrometry.

For mass spectrometric detection, the skimmer at the end of the large chamber forms a molecular beam from the portion of the jet moving directly away from the nozzle. This beam is passed through a differential pumping chamber and another skimmer and thence between the plates of the ion-extraction field. In the most usual experiments this field is a DC field, and ions are produced by a pulsed ionization laser (normally an ArF 193-nm excimer laser, 6.4 eV, pulse length about 10 ns). Once produced the ions are accelerated by the DC field into the drift tube of a time-of-flight (TOF) mass spectrometer. Because all ions of unit charge receive the same energy, ions of greater mass reach a final velocity that is less than that of ions of lesser mass. Therefore, the mass of the ion in the acceleration region is determined by its time of arrival at the ion detector. By plotting the ion-detector signal versus arrival time, a mass spectrum of the

cluster distribution is obtained. Often these cluster distributions are quite colorful exhibiting "magic number" cluster sizes, where a peak is more prominent than its neighbors by a factor of perhaps 2. Figure 4 shows a cluster distribution for carbon similar to that obtained previously by Rohlfing, Cox, and Kaldor in essentially the same apparatus.[26] In the Rohlfing, Cox, and Kaldor distribution C_{11}^+, C_{15}^+, C_{19}^+, and C_{60}^+ might be called magic numbers. The discovery of the fullerenes began when we found that under the right conditions, C_{60}^+ could become a super magic number that is far more prominent than its neighbors.

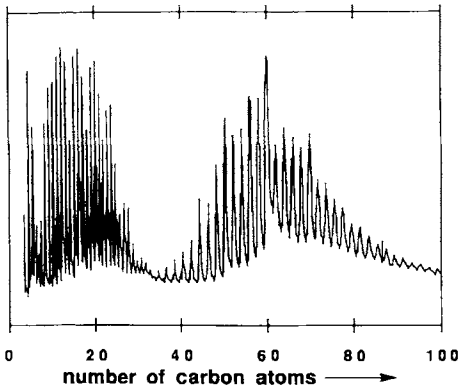

Figure 4. Carbon-cluster distribution observed under mild clustering conditions. This distribution is similar to that obtained by Rohlfing, Cox, and Kaldor; reprinted with permission [26].

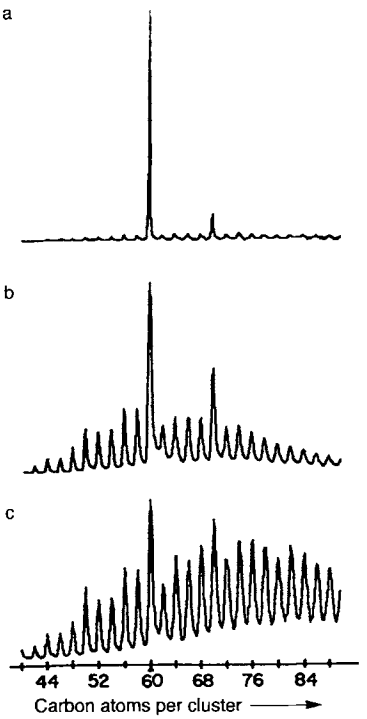

Figure 5. Series of mass spectra of the C_{60} mass region showing C_{60} peaks growing in intensity. Panel a: full helium backing pressure with integration cup. Panel b: full helium backing pressure with vaporization in the center of the gas pulse, no integration cup. Panel c: low helium backing pressure, no integration cup.

When the carbon system was investigated in September 1985, major fluctuations in the prominence of the C_{60} peak compelled us to examine this mass region more carefully under a variety of clustering conditions. It was found that the relative prominence of the C_{60} mass peak could vary from roughly twice the intensity of its nearest neighbors to about 50 times the intensity of its nearest neighbors. This led us to propose[15] that the very prominent C_{60} cluster we had observed has a closed, highly symmetric, carbon cage structure in the form of a truncated icosahedron. Since our inspiration to look for a spherical cage structure came from the geodesic domes of R. Buckminster Fuller, we dubbed this molecule buckminsterfullerene.

The buckminsterfullerene proposal rested on the single experimental observation that carbon vapor condensation conditions could be found where the intensity of the mass spectrum peak of C_{60} in the carbon-cluster beam was many times the intensity of any of its near neighbors in mass, as shown in Figure 5a. Was this proposal a lucky guess, or is this single observation taken in context sufficient to prove that the prominent C_{60} peak in Figure 5 is the truncated icosahedron isomer shown in Figure 1? Our claim has always been that the situation is much closer to proof than conjecture.

Note in Figure 5 that the relative prominence of C_{60} depends upon the clustering conditions. The C_{60} peak becomes more prominent when more time is given for high-temperature (room-temperature and above) collisions between the carbon clusters. This immediately indicates that whatever isomer(s) of C_{60} are responsible for its prominence must be "survivors" that are relatively impervious to chemical attack.

There are probably millions of plausible isomers of C_{60} that differ in chemical connectivity. Most of these millions of C_{60} isomers will be obviously chemically reactive with dangling carbon bonds and, thus, unable to survive chemical attack. The role of chemical attack is manifested in the fact that in all three distributions in Figure 5 only even carbon clusters are observed, in contrast to observations not shown here but shown in Figure 4 of the region below 25 carbon atoms where both even and odd clusters are observed with comparable intensities. It is possible to find clustering conditions where both even and odd carbon clusters are observed with comparable intensity near C_{60}; these conditions correspond to much less time for chemical reaction than for any of the mass spectra shown in Figure 5. Figure 6 (control) shows a distribution intermediate between Rohlfing, Cox, and Kaldor's and those observed with nearly equal intensity odd clusters. Thus, even in Figure 5c the observation of only clusters with even carbon numbers is evidence that already all the clusters in the region must have some special structures that are less susceptible to chemical attack than a typical dangling bond isomer. The obvious explanation from our present viewpoint is that these clusters are all closed carbon cage structures (fullerenes) also. In September 1985 we recognized, without the fullerene concept, that the even cluster distribution probably reflected isomers of reduced reactivity compared with the odd clusters.

Thus we believed that the very prominent C_{60} peak in Figure 5a could only be explained by a single isomer of C_{60} that is remarkably impervious to chemical attack. A readily imaginable alternative explanation would be in terms of a C_{60} isomer that is much easier to photoionize than its neighbors by the 6.4-eV ArF ionization laser employed. However, this explanation ignores the clear increase of the prominence in the C_{60} signal when more time is allowed for chemical reaction. Thus,

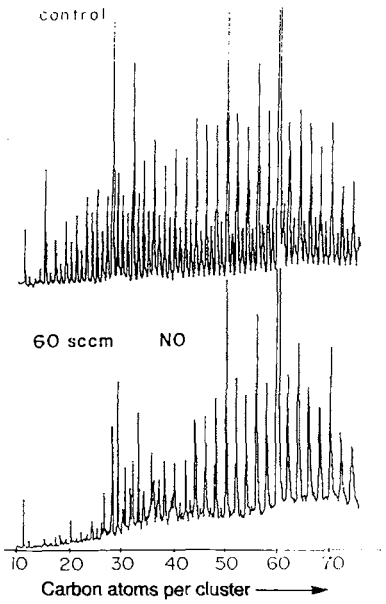

Figure 6. Reaction of carbon clusters with NO. Top: control mass spectrum obtained without added NO. Bottom: roughly 1 Torr of NO was added to the gas stream in the fast-flow reaction tube. It is clear that the odd clusters react with NO. The various products of these reactions are not resolved, but contribute to the elevated baseline.

an explanation for the prominence of C_{60} based on its easier photoionization does not take into account the obvious reduced chemical reactivity of C_{60} compared with its neighbors. Further evidence against an explanation based upon photoionization efficiency was obtained in later experiments, which demonstrated a similar prominence of C_{60}^+ upon photoionization with a 7.9-eV F_2 excimer laser.[27]

The truncated icosahedron form of C_{60} is clearly a special structure, which should be chemically very stable. It has no dangling bonds with the valences of every atom satisfied. The pattern of double and single bonds depicted in Figure 1 is just one of 12500 possible Kekulé structures[28] (but it has proved to be the dominant one). By symmetry every atom is equivalent, so there is no specific point of chemical attack. Strain is introduced in curving the intrinsically planar system of double bonds into a spherical shape, but the strain is symmetrically and uniformly distributed over the molecule thereby again avoiding a weak point for chemical attack. There is obviously no other structure with this high degree of symmetry, and very little reason to fear that another structure could be found that offers this unique combination of advantages. For these reasons, and even though it seems very counterintuitive for this high-symmetry, low-entropy molecule to form out of the chaos of carbon vapor condensing at high temperature, we have never really considered the assignment of the prominent C_{60} peak in the mass spectrum to the buckminsterfullerene structure to be a guess.

In science, more proof is always demanded. Later experiments[27, 29] demonstrated that the special prominence of C_{60} was not the result of some special preference for the C_{60}^+ ion upon photofragmentation, and that C_{60} can be made specially prominent in both the residual cations and anions (a residual ion being an ion that is formed in the vaporization plasma and survives the expansion process).

Conjecture—The Fullerene Hypothesis

We soon learned from Haymet's paper[7] of Euler's rule[30] stating that a solid figure with any even number n of 24 or more vertices could be constructed with 12 pentagons and $(n - 20)/2$ hexagons. This immediately provides an explanation in terms of such carbon cage molecules of the even cluster distribution that appears at carbon numbers above 30 in the mass spectrum, as these molecules would have no dangling bonds and would thus be relatively unreactive. These spheroidal carbon cage molecules consisting only of pentagons and hexagons were given the generic name of fullerenes.

However, in contrast with the truncated icosahedron explanation for the prominent C_{60} peak, this conclusion has always seemed to me to be much more conjecture, however plausible. The next few years of our lives were devoted to testing experimentally this fullerene hypothesis and finding that it passed every test.

Experiment—Reactivity and Photofragmentation

It is possible to inject chemical reagent gases into the cluster stream prior to the expansion and then to observe reaction-product ions in the mass spectrum.[31, 32] A reaction tube was added to the end of the cluster source and various reagents such as NO, SO_2, NH_3, H_2, CO, and O_2 were injected into the gas stream.[33] It was possible to obtain a mass distribution without added reagent that showed both odd and even carbon-number peaks with the odd carbon-number peaks about half the intensity of the even ones. When a reagent such as NO or SO_2 was added, the odd carbon-number peaks disappeared, but the even carbon-number peaks with 40 atoms or more remained unreactive as would be expected if they were fullerenes having no dangling bonds. The distributions observed in this experiment are shown in Figure 6. Note that the odd clusters which are believed to have dangling chemical bonds are much more reactive than the even clusters.

A series of photofragmentation experiments were carried out on the carbon cluster ions hypothesized to be fullerenes using a tandem time-of-flight mass spectrometer.[34] The apparatus is shown in Figure 7. In these experiments, a single carbon-cluster ion was mass selected and then interrogated by a photofragmentation laser as shown in the apparatus detail in Figure 8. It was then accelerated into a second TOF drift region, and the mass of its ionic fragments determined. The photofragmentation pattern of C_{60}^+ is shown in Figure 9. As can be seen, the fragmentation pattern corresponds to the loss of an even number of carbon atoms down to C_{32}^+ where it changes abruptly to produce ions containing about 20 atoms. We believe that C_{60}^+ is losing an even number of carbon atoms in a few-step process with the fullerene cage of the ion reclosing upon loss of the neutral even-number fragment. The abrupt change in pattern at C_{32}^+ takes place because the strained small fullerene can no longer close upon carbon loss, and instead a large neutral fragment is shaken off when the strain energy is suddenly released upon opening the cage.

The energies of many of the fullerenes have been calculated at the STO – 3G/SCF level of theory by Scuseria[35] and are

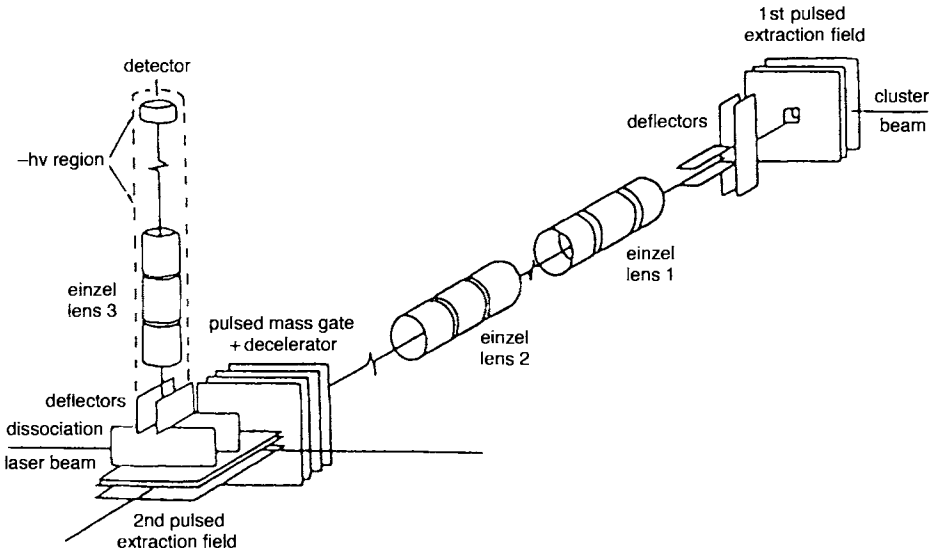

Figure 7. Tandem TOF mass spectrometer. The molecular beam containing residual ions from the vaporization plasma enters the extraction region of the primary mass spectrometer where a 2000-V pulse is applied across the grids. The deflectors remove the molecular-beam velocity. The einzel lenses focus the ion beam. Ions are selected by the mass gate, fragmented by the laser, and analyzed by the second TOF mass spectrometer.

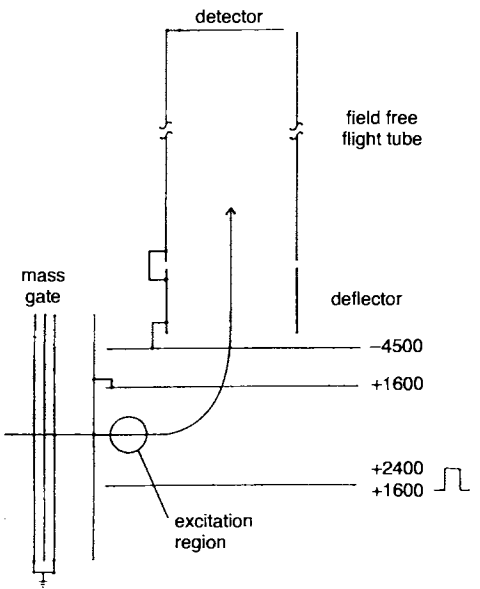

Figure 8. Detail of the photofragmentation region of the tandem TOF apparatus showing the mass gate, laser-excitation region, extraction optics, and flight tube.

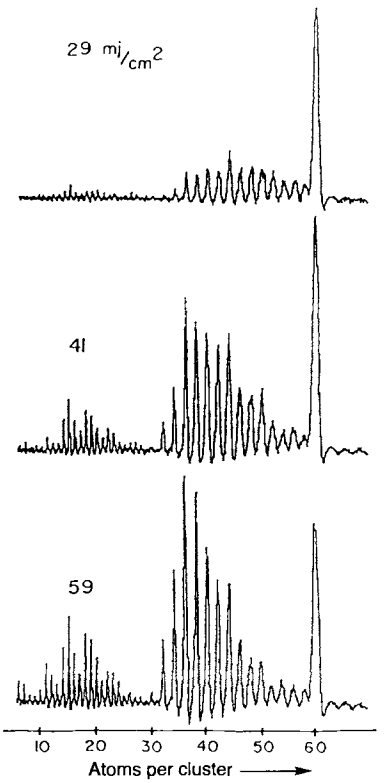

Figure 9. Photofragmentation pattern of C_{60}^+ showing loss of an even number of carbon atoms and break off at C_{32}^+.

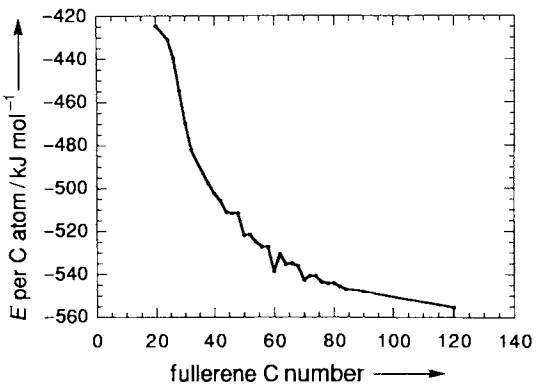

Figure 10. Energy per carbon atom relative to atomic C as a function of fullerene cluster size at the STO – 3G/SCF level at the MM3-optimized geometry for the lowest-energy fullerene structure for each size; based on calculations of R. L. Murry et al. [35].

shown in Figure 10. It should be noted that for fullerenes of size C_{28} and larger there is more than one fullerene structure for a given number of carbon atoms.[36] For example, there are 1812 fullerene isomers (that is, cages containing 12 pentagons and 20 hexagons) of C_{60} alone.[37, 38] The energies plotted in Figure 10 are for the lowest-energy fullerene isomers found. Truncated icosahedron C_{60} and D_{5h}-symmetrical C_{70}, which are respectively the lowest-energy fullerene isomers of 60 and 70 carbon atoms, are local minima in the energy curve, and this can be strikingly seen in these energetics. We label the buckminsterfullerene isomer of C_{60}, C_{60}^{BF}.

When these energies are combined with the bond dissociation energy of C_2 of 6.21 eV,[39] the overall energy change in fragmentation can be calculated. Thus the overall energy change for Equation (1) is $\Delta E = 0.7$ eV, while for the loss from C_{60}^{BF}, $\Delta E = 11.2$ eV [Eq. (2)]. The activation barrier for the fragmentation of C_{60} cannot be less than the fragmentation energy of 11.2 eV. In order to have substantial fragmentation of C_{60}^{BF+} in the few μs available in Figure 9, I estimate that about 100 eV must be deposited into the C_{60}^{BF} ion.

$$C_{62} \longrightarrow C_{60}^{BF} + C_2 \quad (1)$$

$$C_{60}^{BF} \longrightarrow C_{58} + C_2 \quad (2)$$

If the activation barriers to fragmentation follow the energetics, one would expect that the special stability of C_{60} would be apparent in the fragmentation pattern. Figure 11 shows frag-

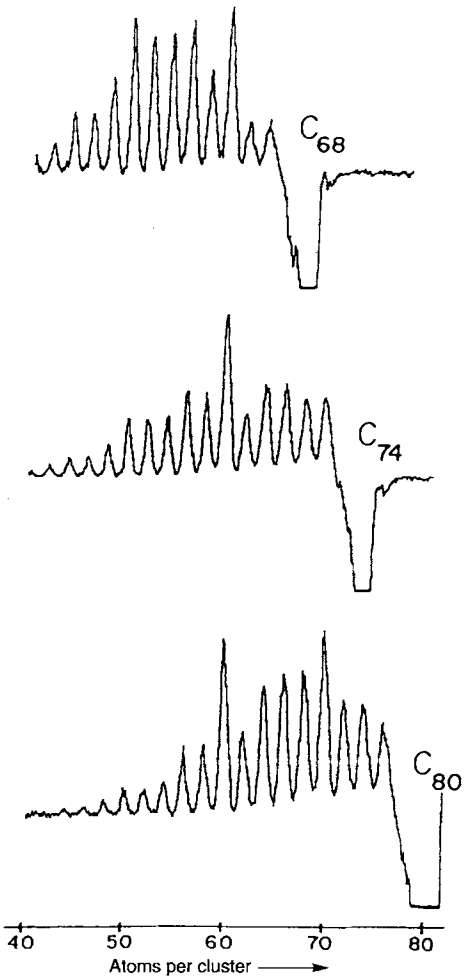

Figure 11. ArF-fragmented (15 mJ cm^{-2}), large, even carbon clusters. There is no difference in the fragmentation pattern of the large clusters. C_{60} and C_{70} are slightly favored.

mentation of some larger clusters when the sample is irradiated just before the acceleration region of the second TOF, as shown in Figure 8. Only a few μs are available for fragmentation after irradiation and before acceleration and analysis, and C_{60} and C_{70} are only slightly special fragments. However, if the irradiation is carried out in the *first* TOF extraction region just before extraction and the ions which have the right TOF for the initial species of Figure 12 are permitted through the mass gate, the pattern is much different. Here the sequence is that the large ion is irradiated and accelerated before it fragments; it then has time to fragment all the way to the second extraction region, which corresponds to a time of about 120 μs.

In Figure 12 it is clearly seen that C_{60} is quite prominent. The original ion is less energetic than is the case of the short-term fragmentation, and thus the fragmentation pattern is much more sensitive to the fragmentation energetics. The relationship between the long-time fragmentations of Figure 12, where C_{60}^+ is very prominent, to the short-time fragmentations of Figure 11, where C_{60}^+ is less prominent, can be explained if one assumes that the activation barriers to ring rearrangements on the surface of the fullerene ions are much less than the activation barrier to fragmentation of a typical fullerene ion.

Assume that a fragmentation which leads to a C_{60}^+ fullerene takes place. It is unlikely that this C_{60} ion has the buckminsterfullerene structure. Probably several rerrangements of this ion must take place before the especially stable C_{60}^{BF} structure is found. When long-time fragmentation is investigated, there is sufficient time for a number of lower activation energy ring-rearrangement processes to take place before fragmentation, because the energy deposited in the original ion is relatively small compared with the short-time fragmentation energy. These ring rearrangements find the low-energy buckminsterfullerene structure, which is very hard to fragment. With the short-time fragmentation far more energy is deposited in the original ion, and fragmentation occurs before the low-energy buckminsterfullerene structure is found.

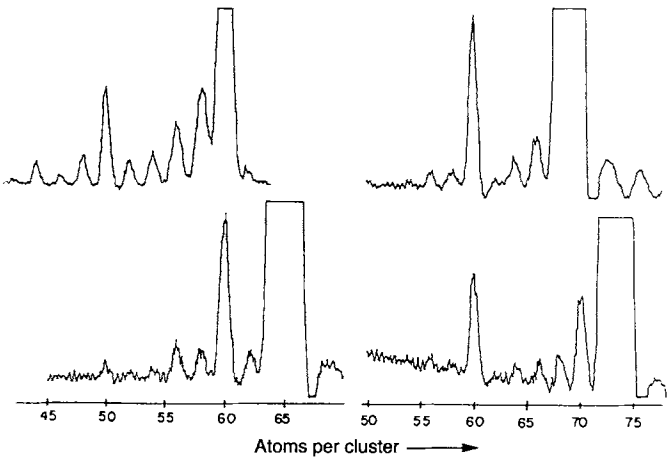

Figure 12. Metastable TOF mass spectra for 60-, 66-, 70-, and 74-atom clusters. The clusters were irradiated 1 μs before the first extraction pulse with ArF (15 mJ cm^{-2}). The ions were mass gated at the time appropriate to the parent ions listed above and analyzed in the second TOF mass spectrometer. The travel time to the second mass spectrometer was approximately 120 μs. The special prominence of C_{60} and C_{70} is clear.

Figures 9, 11, and 12 taken together provide striking evidence that cations being examined are structurally related to each other and to C_{60}^{BF}. It appears that fragmentation takes place with the preservation of the cage structure until the break-off point at C_{32} is reached.

Conjecture—The Existence of Endohedral Complexes

The fullerenes are hollow. Buckminsterfullerene has a cavity almost 4 Å in diameter that is capable of holding any atom of the periodic table. It seemed to us that it might be possible to introduce a foreign atom into the central cavity to produce an endohedral adduct. We recognized that bulk samples of such materials, if they could be obtained, might have many unusual and potentially useful properties. For this narrative, the important point is that such an endrohedral atom would be difficult to dislodge.

Experiment—Endohedral Metallofullerenes and "Shrink Wrapping"

Success in forming adducts with a single lanthanum atom was almost immediately achieved.[40] In these experiments, a low-density graphite disk was soaked in a water solution of $LaCl_3$,

dried, and used as target for laser vaporization. The mass spectrum at low-ionization laser fluence showed many peaks from both pure carbon and carbon–lanthanum adducts, but when the ionization laser power was turned up somewhat so that the least stable species would photofragment, all bare cluster peaks except for C_{60} and C_{70} disappeared, but clusters with one lanthanum atom at every even carbon number remained. There were no clusters remaining with more than one La atom. Thus, under laser fluences capable of destroying the less stable carbon clusters, one and only one lanthanum atom stuck. This is a strong indication that the lanthanum atom is inside the cage.

It was found that endohedral metallofullerenes containing the alkali metal atoms K and Cs could be readily formed. This led to a unique way to test the fullerene hypothesis by "shrink-wrapping". A series of photofragmentation experiments were carried out in a fourier transform ion cyclotron resonance cell on $C_{60}K^+$ and $C_{60}Cs^+$.[41] A supersonic beam of cluster ions is prepared as described above and injected into the ion cyclotron resonance cell where they can be trapped for several minutes. By applying a range of radio frequencies to the cell, the orbits of almost all ions but the desired one ($C_{60}K^+$ or $C_{60}Cs^+$) can be excited thereby driving the unwanted ions from the cell. Photofragmentation experiments can then be carried out on the remaining ions.

From our previous experiments on photofragmentation and $C_{60}La^+$, we expected that at low laser fluences the ions would lose C_2, C_4, and C_6 while retaining the metal. If the metal is in the cage as proposed, the cage will become increasingly strained upon loss of neutral carbon because it is shrinking down upon the resistant metal core. A point will be reached where the cage will break releasing the metal. This point will depend upon the size of the metal ion and will therefore be reached for larger clusters in the case of $C_{60}Cs^+$ than in the case of $C_{60}K^+$. Furthermore, the cage breaking point can be roughly estimated from the van der Waals radii of the alkali metal ion and the carbon atoms. Figure 13 shows the photofragmentation results. The even-carbon loss breaks off for $C_{60}K^+$ at $C_{44}K^+$ and for $C_{60}Cs^+$ at $C_{48}Cs^+$, which agrees well with predictions from the van der Waals radii. We can conceive of no explanation for these observations other than that we were observing fragmentation of endohedral fullerene complexes.

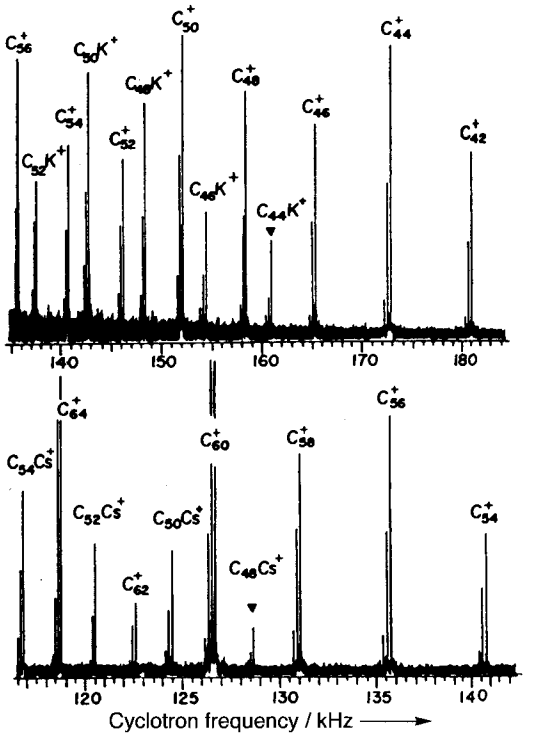

Figure 13. The low-mass portion of the fragment ions produced by intense laser excitation of $C_{60}K^+$ (A) and $C_{60}Cs^+$ (B) in the FT-ICR trap. The clusters containing carbon only seen in these spectra arise from fragmentation of empty fullerene ions simultaneously trapped with the metal species.

Conjecture—C_{70} has D_{5h} Symmetry

In almost all mass spectrometer carbon-cluster distributions where C_{60}^+ (or C_{60}^-) is prominent, C_{70}^+ (or C_{70}^-) is usually the next most prominent ion in the C_{40}–C_{90} mass range. Therefore it is likely to have a somewhat special structure. A plausible guess for the structure of C_{70} seemed to be one in which a band of five hexagons was added around the equator of C_{60}.[40] To form such a structure (Figure 14) choose an orientation of C_{60} so that pentagons are at the north and south poles; then cut the C–C bonds connecting the northern and southern hemispheres, separate them, rotate one hemisphere by a 1/10 turn with respect to the other, and add a string of 10 carbon atoms at the equator to rejoin the two hemispheres.

Both the structures of C_{60}, buckminsterfullerene, and D_{5h} C_{70} have no abutting pentagons. Haymet suggested that such connected rings would be destabilizing.[7] Shortly thereafter,

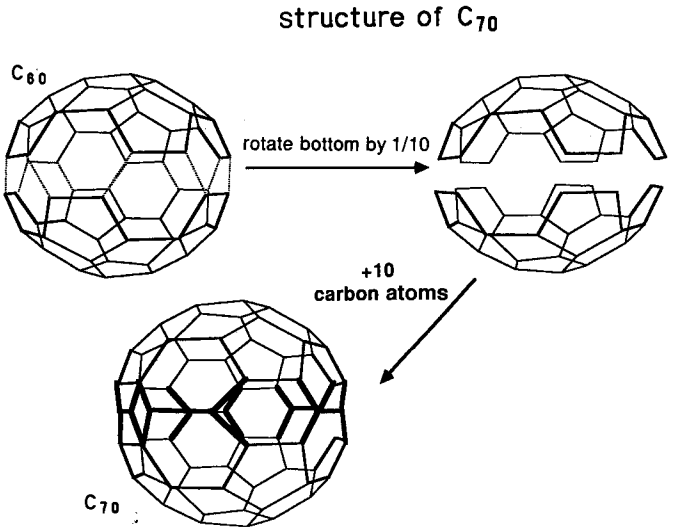

Figure 14. Relationship of the proposed structure of C_{70} to that of C_{60} (buckminsterfullerene).

Schmalz et al. pointed out that abutting pentagons necessarily involve destabilizing, antiaromatic, eight-atom, conjugated π electron circuits around the ring; this makes structures with abutting pentagons less stable.[42] Both Kroto[43] and Schmalz et al.[44] proposed that D_{5h} C_{70} is the smallest cage structure larger than C_{60}^{BF} without abutting pentagons. Both reported that they had made a diligent, but not exhaustive, search of structures between C_{60} and C_{70} for isolated pentagon cages. Subsequently, Liu et al. were able to prove this conjecture.[45] Kroto showed that the "magic number" mass spectrometer peaks containing fewer than 60 carbon atoms corresponded to structures

with the minimum number of abutting pentagons.[43] These considerations became the "isolated pentagon rule", which states that in the stable fullerenes the pentagons are isolated.

Although it was strongly supported by these theoretical considerations, the conjecture that the structure of C_{70} has D_{5h} symmetry could never be verified experimentally by molecular-beam mass spectrometry. The proof of this structure had to wait until the production[46] of macroscopic mixtures of C_{60} and C_{70} permitted the separation of C_{60} and C_{70} and the observation of the ^{13}C NMR spectrum of C_{70}.[47]

Conjecture—C_{60} Might Be the Carrier of the Diffuse Interstellar Bands

Not all conjectures can be expected to be correct. When we wrote our initial paper on C_{60}, we were inspired with wildly imaginative thoughts about the potential significance of the spontaneous formation of this remarkable molecule in all areas of chemistry and astrophysics.[15] Since we had been thinking of carbon chain molecules as possible carriers of the diffuse interstellar bands (DIBs),[11] it was natural to consider C_{60} as offering a potential explanation of the DIBs, and we proposed that as a possibility.

C_{60} seemed an attractive candidate for several reasons. First, any molecular carrier of the DIBs must be large enough so that it is not dissociated by absorbing photons of energies of up to 13.6 eV. In a large molecule such as C_{60}, when a photon is absorbed, internal conversion rapidly brings the molecule back to its ground electronic state. If there is more energy available in the photon than is needed for unimolecular dissociation, then dissociation competes with vibrational reradiation of the excess energy in the infrared. With a dissociation threshold of 11 eV and so many vibrational modes, unimolecular decay even with 13.6 eV of excitation is a very slow process and loses completely to infrared reradiation. Second, there are not many DIBs known, and, therefore, any proposed carrier must give only a few bands and should not be one of a large class of equally attractive candidates. The high symmetry of C_{60} suggests only a few bands, and, while there is a fullerene family, C_{60} is often uniquely prominent. Any carrier should consist of the more cosmically abundant elements. Lastly, the diffuseness of the bands could come from mixing of the spectroscopically active excited electronic state with ground- or lower-state levels. Subsequent to our original proposal, it became obvious that C_{60} would be likely to be photoionized or to react with H atoms so that C_{60}^+ and slightly hydrogenated derivatives of C_{60} would be more attractive.[48-50]

Experiment

Eventually it proved possible to obtain a portion of the visible electronic spectra of C_{60} and C_{70} using resonant two photon ionization,[51] and these spectra demonstrated conclusively that neither neutral C_{60} nor neutral C_{70} have absorptions that correspond to the known diffuse interstellar lines in the same region. These observations alone do not rule out C_{60}^+ or perhaps protonated C_{60} derivatives as carriers of the DIBs; however, the matrix-isolation spectrum of C_{60}^+ seems to rule it out as a DIB carrier.[52, 67]

Conjecture—Soot is Formed From Spiraling Icosahedral Carbon Shells

The control of soot formation is of enormous practical value; consequently, the nature of soot and the processes involved in its formation have been extensively studied, and this remains an active research field. Since soot consists primarily of carbon, we naturally thought about whether the chemistry involved in fullerene formation might be also applicable to soot formation. The combustion environment principally differs from condensing carbon vapor in that large quantities of hydrogen are present in combustion. Indeed, almost as many H atoms as C atoms are present in combustion soot. Combustion soot is considered to be regions of layered sheets of large polycyclic aromatic hydrocarbons joined by disorganized regions.

It seemed to us that the fullerenes were forming in a process where small carbon clusters such as C_2 and C_3 were adding to a growing, curving sheet of five- and six-membered rings. Curvature and ultimate closure into fullerenes was brought about by some sort of ring-rearrangement process that let the carbon cluster find its lowest-energy, least reactive forms. The growth of polycyclic hydrocarbons (PAH) in soot formation was thought to be by the creation of a reactive carbon atom on the periphery by H-atom abstraction from a peripheral C—H bond followed by acetylene addition to the reactive center, followed by ring closure with H-atom elimination.[53] The similarity between the process we imagined for fullerene formation and the PAH-growth process in combustion-soot formation seemed striking to us. The main difference seemed likely to be that hydrogen on the edges might interfere with the fullerene-closure processes leading to imperfect cages. Perhaps a soot particle was the result of such imperfect growth and would resemble a spiraling fullerenic shell. Thus we proposed that a soot particle would be based upon a spiraling icosahedral shell similar to the structure shown in Figure 15.

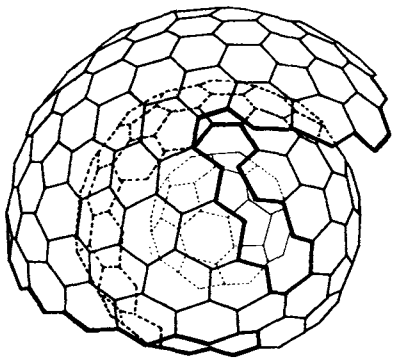

Figure 15. Spiraling icosahedral shell model of a growing soot particle. It has almost completed its second shell of growth.

Experiment

This suggestion was met with disfavor by some members of the soot community.[54-56] However, it did result in searches for fullerenes in flames by some of the leading combustion and soot scientists. Thus Homann found C_{50}^+, C_{60}^+, and C_{70}^+ prominently in hydrocarbon flames.[57] He suggested that soot particles might be supports for fullerene growth.[58] More recently

he has proposed more elaborate and detailed models for fullerene formation[59] and its relation to soot.[60] After C_{60} and C_{70} became available in bulk, soot scientists began looking for these species in combustion soots with success.[61, 62] Under optimal conditions the yield of C_{60} plus C_{70} was as much as 20% of the soot and up to 0.5% of the carbon fed making flames a practical preparation scheme for fullerenes.[63] Quite recently, electron microscope examination of nanostructures in flame soots has revealed the whole range of fullerenic structures: fullerenes, nanotubes, and the nested fullerenes resembling Russian dolls.[64] These observations are strong evidence that carbon has a strong propensity to form these structures in chemically quite different environments where elemental carbon forms are produced.

Thus some very special chemistry does not appear to be needed for fullerene formation. Howard has proposed a detailed kinetic scheme for the formation of C_{60} and C_{70} in flames, which parallels the standard mechanism for the formation of polyaromatic hydrocarbons, which are considered to be the soot precursors.[65] Nevertheless, fullerene formation and soot formation remain to him clearly distinct processes.

The soot community remains united in the belief that, while soot might produce fullerenes as an offshoot, soot formation is a different process from fullerene formation and that soot is primarily composed of PAHs and that there is no evidence for spiraling icosahedral shells. It should be noted that it is known that more than half of the soluble PAH inventory of flames contain five-membered rings and therefore curvature.[66] Whether the curvature introduced by such five-membered rings plays any role in the formation of soot particles remains an interesting, open question.

Conclusion

In science conjecture drives both experiment and theory for it is only by forming conjectures (hypotheses) that we can make the direction of our experiments and theories informed. If such and such is true, then I should be able to do this experiment and look for this particular result or I should be able to find this theoretical formulation. Conversely, experiment and theory drive conjecture. One makes a startling observation or has a sudden insight and begins to speculate on its significance and implications and to draw possible conclusions (conjecture).

However, not all conjectures are equally valid or useful. Thus the conjecture that C_{60} might be related to the diffuse interstellar bands was and remains wildly speculative. It has been one of my favorite speculations,[50] because it has many things going for it: Carbon is injected into the medium, and C_{60} forms spontaneously in condensing carbon under the right conditions; C_{60} is unique, its compounds are limited in number, and only a few species should be involved in the DIBs; C_{60}^+ could survive the UV present in the interstellar medium; the diffuseness of the bands could come from mixing of the spectroscopically active excited electronic state with ground- or lower-state levels. However, conjectures should be judged by the accumulation of evidence that supports and contradicts them. To date, there has been plentiful contradictory evidence for the C_{60} connection to the DIBs and no supporting evidence. Primarily, this conjecture has the fatal defect that it has stimulated little productive science.

The conjecture that soot may consist of spiraling spheroidal shells of carbon belongs in a slightly different category. It was based upon a hypothesis, which was somewhat vague at the time, about how fullerenes may form. Thus, it was not a wild idea in that there was some support for the speculation. In my opinion, the conjecture that soot consists of spiraling spheroidal shells is probably wrong. However, I think it likely that there is some more subtle connection between the curvature introduced by five-membered rings and soot formation. Regardless of its validity, this conjecture has turned out to be extremely valuable, because it got the soot community, in some cases somewhat grumpily, thinking about the formation of fullerenes and other carbon morphologies in flames. As a result, fullerenes were found in flames and soot. It appears that all the new carbon morphologies can be produced in flames.[64]

Turning to the central theme, the conjecture of Jones[1, 2] that carbon cage compounds might have interesting properties, and the conjecture of Osawa[3] and several others that C_{60} would be a stable, chemically interesting molecule are examples of conjectures which are correct and valuable, but which by themselves cannot be made useful. There was no way, or no easy way (remember Chapman), to proceed to further work based on the conjecture.

On the other hand, the conjecture that a new whole class of carbon cage compounds, the fullerenes, are formed spontaneously in condensing carbon vapor has led to sweeping consequences. At the time, this hypothesis seemed to be the only logical explanation of the observed carbon mass spectra distributions, but it was not self-evident. As we have seen, we tested this conjecture in a variety of experiments, which always provided evidence supporting the conjecture. This pattern of repeated confirmation of expected consequences is what is expected for a correct hypothesis. In the long run, the fullerene hypothesis has proved to be spectacularly correct and it has provided the basis for a whole new branch of organic chemistry.

Finally, I believe that the conjecture that started it all, namely that truncated icosahedron C_{60} forms spontaneously in condensing carbon, scarcely belongs in the category of conjecture. The three mass spectra in Figure 5, when coupled with the conditions under which they were obtained, demand that the species responsible for the prominent peak at C_{60} must be singularly different and chemically relatively unreactive. The human mind can conceive of no other isomer of C_{60} that better fits this requirement.

Richard Smalley and Harold Kroto are my corecipients of the Nobel prize. I must point out that we do not and cannot claim this discovery is ours alone. James Heath and Sean O'Brien have equal claim to this discovery. In addition, there are several others who were major participants in this research at an early stage: Yuan Liu, Qing-Ling Zhang, and Frank Tittel. The work of F. D. Weiss and J. L. Elkind on the shrink wrap experiments is appreciated.

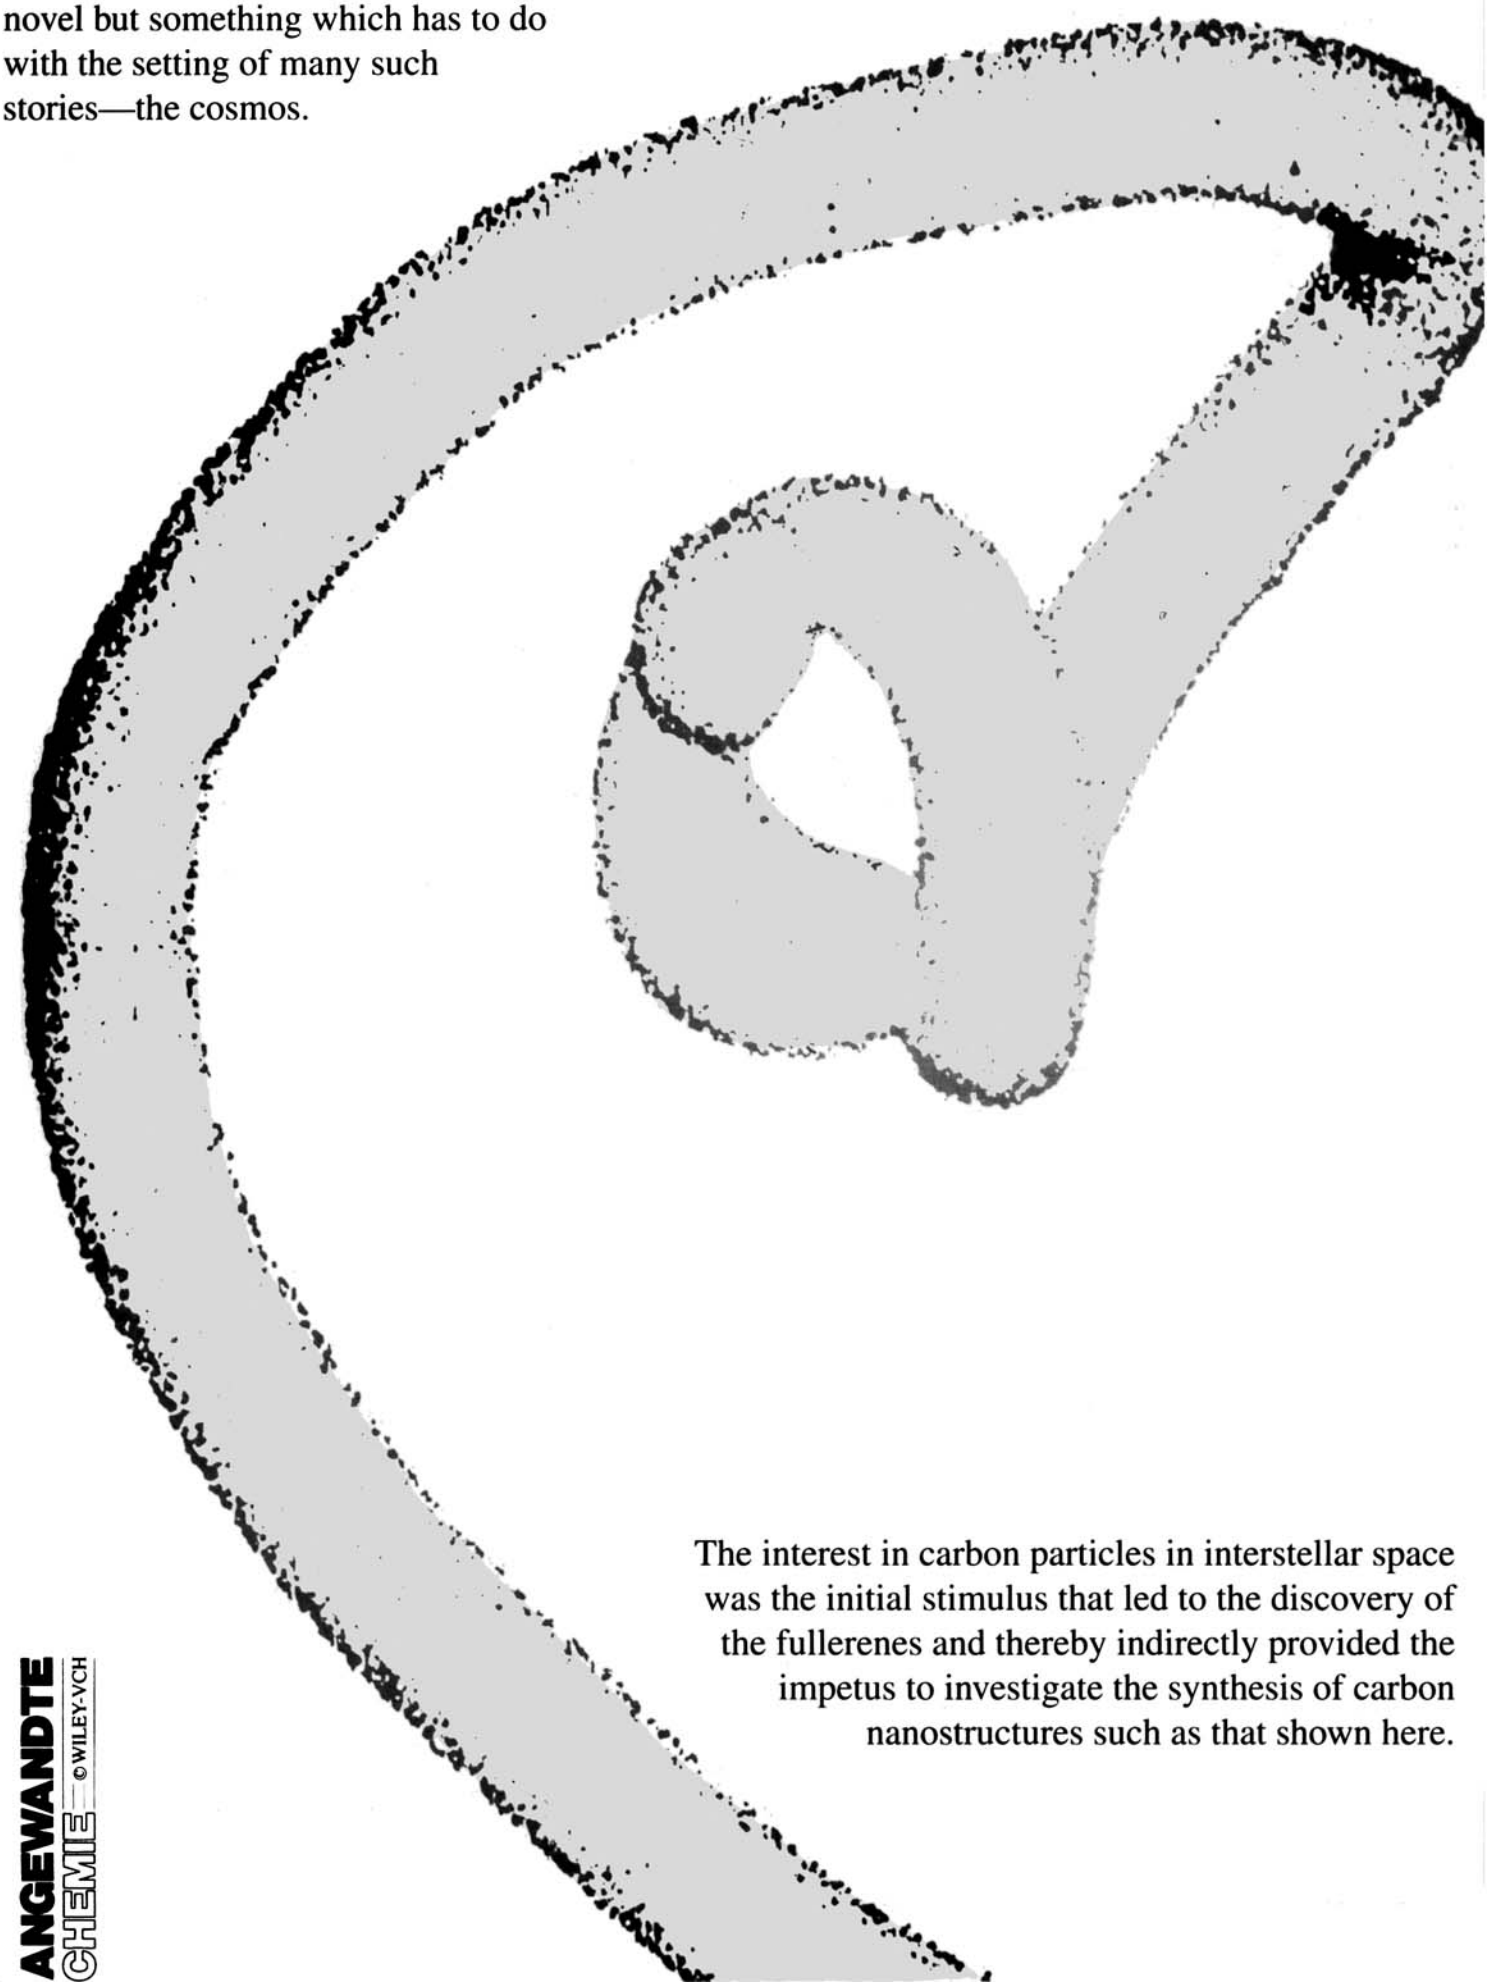
Not a creature from a science-fiction novel but something which has to do with the setting of many such stories—the cosmos.



The interest in carbon particles in interstellar space was the initial stimulus that led to the discovery of the fullerenes and thereby indirectly provided the impetus to investigate the synthesis of carbon nanostructures such as that shown here.

Harold Kroto*

Introduction: A Summary of the Key Phases in the Birth of the Fullerenes

The story of the discovery C_{60} buckminsterfullerene (Figure 1) and the birth of fullerene science consists of several disparate strands which came together over ten days in September 1985. During this period of feverish activity, working with Jim Heath, Sean O'Brien, Yuan Liu, Bob Curl, and Rick Smalley at Rice University in Texas, evidence was found that a C_{60} molecule self-assembled spontaneously from a hot nucleating carbon plasma.[1] The molecule had however a prehistory: The earliest paper that describes the C_{60} molecule is to be found in Kagaku (in Japanese) where Eiji Osawa in 1970 suggested that it should be stable[2] and the following year discussed its possible aromatic properties in more detail in a book with Yoshida.[3] Bochvar and Gal'pern published a theoretical study in 1973.[4, 5] Somewhat earlier in 1966 David Jones had conjectured that if pentagonal disclinations could be introduced among the hexagons in a graphene sheet, the sheet would close into a hollow balloon.[6, 7] We however did not know about this prehistory and none of us had ever heard of such a molecule or thought about it.

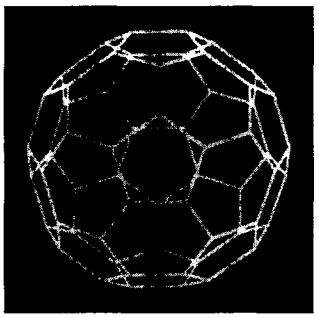

Figure 1. C_{60} buckminsterfullerene [1].

In retrospect, as far as I was concerned, I seem to have been fascinated by various peculiar aspects of carbon chemistry for much of my research career. With the perspective of hindsight my involvement can be split into five phases: At Sussex, in the late 1960s, David Walton and I initiated a synthetic/spectroscopic study (Phase I) which led directly—in the mid 1970s—to some unexpected discoveries (with colleagues at Sussex and NRC Ottawa, Canada) of long carbon chain molecules in the interstellar medium (Phase II). At about this time Don Huffman and Wolfgang Krätschmer were developing laboratory experiments which focused on the composition of the particulate carbon material which occupies the same interstellar regions—indeed the agents which caused the scattering in the dark regions and observed some intriguing new unexplainable features in the 220 nm region of their laboratory data. Also at about this time Richard Smalley was developing a range of advanced chemical physics techniques, which culminated in an ingenious apparatus that enabled small clusters of *refractory* materials to be created and probed for the first time. This was the pulsed supersonic nozzle–laser vaporization apparatus.[8] It is my view that the raison d'etre of this machine was to discover C_{60}.

It was the marriage of ideas resulting from the discoveries of carbon chains in space with the recognition that the cluster beam technique might offer laboratory support for their circumstellar origin that in 1985 resulted in the serendipitous discovery that the C_{60} molecule not only existed but that it self-assembled (Phase III).[1, 9] After this revelation it still remained for unequivocal proof of the soccerball structure to be obtained (Phase IV). Several groups made important contributions: 1) Theoreticians, who had a field day and came up with some results that ultimately proved crucial for the extraction,[10, 9] 2) the Rice group (initially in collaboration with Sussex)[11, 12, 9], 3) the Sussex Group,[13, 9] 4) the IBM group,[14] and last but not least 5) the Heidelberg/Tucson group who succeeded in the first extraction of macroscopic quantities of C_{60}.[15–17] It was this fantastic breakthrough that has made the explosive growth of fullerene science possible (Phase V). The advance made by Krätschmer and Huffman and their students is one of the most beautiful pieces of fundamental science.

In any complex story, the events can only be understood by reference to the complete set of personal subjective accounts of the participants—even purportedly objective accounts must be treated with skepticism.[18] In this case *all* the scientists—including research students—played crucial roles in the story. This article describes parts of the story to which Sussex researchers made contributions. There have now been numerous accounts ranging from the personal articles[19–22] as well as books by Baggott,[23] Aldersey-Williams,[24] Krätschmer and Schuster,[25] Dettman,[26] and Ball.[27] An excellent text focusing on the chemistry of C_{60} is that by Hirsch.[28] Several compendia have been published—some edited by or with Sussex researchers include one with a historical perspective,[29] a second from the viewpoint of carbon materials and physics,[30] and a third which concentrates on fullerene chemistry.[31] It should also be recognized that the discovery of C_{60} led to a further amazing ad-

vance—this was the discovery by Iijima that carbon nanotubes also form at the same time as C_{60}.[32]

The story of C_{60} also cannot be recounted without reference to its beauty which results from the incredible symmetry. Another important aspect of the molecule's aura lies in the name buckminsterfullerene,[33] and the direct association it has with the geodesic domes designed by Buckminster Fuller.[34–36] It invests this elegant molecule with a charisma that has fascinated scientists, delighted lay people, and has infected children with a new enthusiasm for science, and in particular it has given chemistry a new lease of life.[37]

Prologue: Symmetry, the Key to the Theory of Everything

Symmetry appears to be fundamental to our perception of the physical world and it also plays a major role in our attempts to explain everything about it. As far as structural symmetry is concerned it goes back to ancient times, as indicated by the (pre-)Platonic structures exhibited in the Ashmolean Museum in Oxford.[38, 39] The most famous examples are of course to be found in "The Timaeus" where in the section relating to "The Elements" Plato says: "In the first place it is clear to everyone(!) that fire, earth, water, and air are bodies and all bodies are solids"(!!).[40] Plato goes on to discuss chemistry in terms of these elements and associates them with the four Platonic solids (only four at that time—until Hippasus discovered the fifth—the dodecahedron).

Although this may at first sight seem like a somewhat naive philosophy it indicates a very deep understanding of the way Nature actually functions. A curiously close contempory analogue of this ancient assumption is to be found in the historially important article by Van Vleck[41] on which almost all of modern molecular spectroscopy is based: Van Vleck says:

> "Practically everyone(!) knows that the components of total angular momentum (NB the angular momentum operator is usually denoted by the symbol $\boldsymbol{J}$ and the associated quantum number by j) of the molecule relative to the axes X,Y,Z fixed in space satisfy the commutation relation of the form
>
> $$J_X J_Y - J_Y J_X = \mathrm{i}J_Z \quad (1)$$
>
> Klein discovered the rather surprising fact that when total angular momentum is referred to axes mounted in the molecule which we will denote by x,y,z the sign of i in the commutation relation is reversed ie
>
> $$J_x J_y - J_y J_x = -iJ_z" \quad (2)$$

Does practically everyone know this?—I wondered whether to check this claim out by asking everyone on the main street in Brighton whether they did. I hardly knew—or more accurately—really understood the first relation, let alone the second. However, I did know that angular momentum was quantized and governed by the fundamental relations (3) and (4), which means that J has $2j+1$ possible orientations, and which indicates that when a transition occurs, j may only change by one unit or on occasion remain unchanged.

$$<j|\boldsymbol{J}^2|j> = \hbar^2 j(j+1) \quad (3)$$

$$M_j = -j \ldots +j \quad (4)$$

$$\Delta j = 0, \pm 1 \quad (5)$$

I knew that the row structure of Mendeleev's periodic table could be explained on the basis of these quantum properties of angular momentum, in particular the fact that a system with angular momentum j possesses $2j+1$ quantized orientations. I decided I ought to understand these and under the tutelage of Jon Hougen and Jim Watson I dived into the *Theory of Atomic Spectra* by Condon and Shortley.[42] There can surely be no more elegant printed page in the sciences or the arts than page 60 of this book (Figure 2), where Dirac's proof of the $\Delta j = \pm 1$ selection rule (it is noncommittal on $\Delta j = 0$) is presented—a perfect example of elegant and powerful use of roman typeface. One only has to look at this page to know that it must be important. As far as I was concerned it planted the desire to understand the embedded theory—the effort was (for me) considerable, but worth it and remains one of the most intellectually rewarding tasks I have undertaken. Having finally grasped the implications of these relations, I ended up writing a book called *Molecular Rotation Spectra*,[43] which deals with the way the angular momentum relations govern the rotational dynamics of molecules.

The geometric pattern of the periodic table (Figure 3) is an implicit result of the angular momentum description of atoms and electrons (together with a few odds and ends(!) such as the Pauli exclusion principle). Any intelligent life on another planet that had developed an understanding of chemistry would almost certainly recognize it. The electron angular momentum wavefunctions are described in terms of spherical harmonics—known by mathematicians long before 1925 when quantum mechanics was created and thus these symmetric mathematical functions lend an elegant beauty to the abstract description of rotational/orbital motion of atoms, molecules and, of course, electrons. Thus, we discover that symmetry principles underpin the elegant quantum mechanical description of atoms and mol-

Harold W. Kroto was born in 1939 in Wisbech, Cambridgeshire, UK. He studied at the University of Sheffield from 1958 to 1964 and received his PhD for his research in the electronic spectroscopy of free radicals with R. N. Dixon. After three years of postdoctoral research at the National Research Council in Ottawa and Bell Laboratories, he started his acedemic career in 1967 at the University of Sussex in Brighton, where he still works. In 1985 he became Professor of Chemistry there and in 1991 Royal Society Research Professor. His research interests include the spectroscopy of unstable species, carbon and metal clusters, and microparticles, as well as interstellar molecules and circumstellar dust. Graphic design is his other passion. In 1995 he was knighted for his services to chemistry.

60 ANGULAR MOMENTUM 83

Another important fact which follows immediately from 12²6 is that the scalar product of any two vectors* which satisfy this commutation rule with respect to $\boldsymbol{J}$ will commute with J_x, J_y, J_z, and hence with $\boldsymbol{J}^2$:

$$[\boldsymbol{J}, \boldsymbol{T}_1\cdot\boldsymbol{T}_2]=0, \quad [\boldsymbol{J}^2, \boldsymbol{T}_1\cdot\boldsymbol{T}_2]=0. \tag{4}$$

This is independent of whether $\boldsymbol{T}_1$ commutes with $\boldsymbol{T}_2$ or not.

We shall now consider the problem of obtaining the matrices of T_x, T_y, T_z in a representation in which $\boldsymbol{J}^2$, J_z, and a set A of observables which commute with $\boldsymbol{J}$ are diagonal. We shall first obtain a selection rule on j, i.e. a condition on $j'-j$ necessary for the non-vanishing of a matrix component connecting the states j and j'. This we may do by a method outlined by Dirac (p. 158).

Using the relation 12²6, we find that

$$\begin{aligned}[\boldsymbol{J}^2, \boldsymbol{T}]&=\boldsymbol{J}\cdot[\boldsymbol{J}, \boldsymbol{T}]-[\boldsymbol{T},\boldsymbol{J}]\cdot\boldsymbol{J}=-i\hbar(\boldsymbol{J}\cdot\boldsymbol{T}\times\mathfrak{J}-\boldsymbol{T}\times\mathfrak{J}\cdot\boldsymbol{J})\\&=-i\hbar(\boldsymbol{J}\times\boldsymbol{T}-\boldsymbol{T}\times\boldsymbol{J})=-2i\hbar(\boldsymbol{J}\times\boldsymbol{T}-i\hbar\boldsymbol{T}).\end{aligned}$$

From this we have

$$\begin{aligned}[\boldsymbol{J}^2,[\boldsymbol{J}^2, \boldsymbol{T}]]&=-2i\hbar[\boldsymbol{J}^2,(\boldsymbol{J}\times\boldsymbol{T}-i\hbar\boldsymbol{T})]=-2i\hbar\{\boldsymbol{J}\times[\boldsymbol{J}^2, \boldsymbol{T}]-i\hbar[\boldsymbol{J}^2, \boldsymbol{T}]\}\\&=-2i\hbar\{-2i\hbar\boldsymbol{J}\times(\boldsymbol{J}\times\boldsymbol{T}-i\hbar\boldsymbol{T})-i\hbar(\boldsymbol{J}^2\boldsymbol{T}-\boldsymbol{T}\boldsymbol{J}^2)\}\\&=2\hbar^2(\boldsymbol{J}^2\boldsymbol{T}+\boldsymbol{T}\boldsymbol{J}^2)-4\hbar^2\boldsymbol{J}(\boldsymbol{J}\cdot\boldsymbol{T}),\end{aligned}$$

using 12²11a to expand $\boldsymbol{J}\times(\boldsymbol{J}\times\boldsymbol{T})$. But

$$[\boldsymbol{J}^2,[\boldsymbol{J}^2, \boldsymbol{T}]]\equiv[\boldsymbol{J}^2,(\boldsymbol{J}^2\boldsymbol{T}-\boldsymbol{T}\boldsymbol{J}^2)]\equiv\boldsymbol{J}^4\boldsymbol{T}-2\boldsymbol{J}^2\boldsymbol{T}\boldsymbol{J}^2+\boldsymbol{T}\boldsymbol{J}^4.$$

Hence

$$\boldsymbol{J}^4\boldsymbol{T}-2\boldsymbol{J}^2\boldsymbol{T}\boldsymbol{J}^2+\boldsymbol{T}\boldsymbol{J}^4=2\hbar^2(\boldsymbol{J}^2\boldsymbol{T}+\boldsymbol{T}\boldsymbol{J}^2)-4\hbar^2\boldsymbol{J}(\boldsymbol{J}\cdot\boldsymbol{T}). \tag{5}$$

Take the matrix component of this equation referring to the states $\alpha\, j\, m$ and $\alpha'\, j'\, m'$, where $j'\neq j$. Since $\boldsymbol{J}\cdot\boldsymbol{T}$ commutes with $\boldsymbol{J}$ [by (4)], this component will vanish for the last term in the equation. From the rest we obtain:

$$\begin{aligned}\hbar^4[j^2(j+1)^2-2j(j+1)j'(j'+1)+j'^2(j'+1)^2](\alpha j m|\boldsymbol{T}|\alpha' j' m')\\=2\hbar^4[j(j+1)+j'(j'+1)](\alpha j m|\boldsymbol{T}|\alpha' j' m').\end{aligned}$$

The bracket on the left is

$$[j(j+1)-j'(j'+1)]^2=(j-j')^2(j+j'+1)^2,$$

while

$$2[j(j+1)+j'(j'+1)]=(j+j'+1)^2+(j-j')^2-1.$$

Hence

$$[(j-j')^2(j+j'+1)^2-(j+j'+1)^2-(j-j')^2+1](\alpha j m|\boldsymbol{T}|\alpha' j' m')=0,$$

or

$$[(j+j'+1)^2-1][(j-j')^2-1](\alpha j m|\boldsymbol{T}|\alpha' j' m')=0. \qquad (j\neq j')$$

In order to obtain a non-vanishing matrix component one of the brackets must vanish. The first cannot since $j'\neq j$ and $j, j'\geq 0$. The second vanishes only when $j'-j=\pm 1$. Hence for a non-vanishing matrix component we must have

$$j'-j=0, \pm 1. \tag{6}$$

* An important special instance of this is the square of such a vector.

Figure 2. Page 60 of Condon and Shortley's book [42] in which Dirac's elegant derivation of the fundamental selection rule for j, the angular momentum quantum number, is given (published by permission of Cambridge University Press). These relations not only describe a beautiful example of the way Nature behaves but also are an exquisite example of man's mathematical invention to describe the behavior, as well as an elegant example of typeface which visually evokes a powerful feeling for the underlying abstract concept. Buried deep in this derivation are fundamental laws of symmetry that govern the way in which light interacts with matter. These relations govern the origin of the sunlight falling on this page, the modulation of that light by the page and the print on it, as well as the way in which the receptors in your eye detect the reflected light and transforms it into perceived images in your brain. By the way, it may be worth noting that not only does this paper consist mainly of carbon but so also does the ink.

ecules in an abstract picture in which statics and dynamics are paradoxically conflated in a way that often leaves us hovering on the boundary between abstract mathematical understanding and literal physical misunderstanding. It is the existence of similar abstract aspects of symmetry that has invested the C_{60} molecule with a charismatic quality that few other molecules possess.

Phase I: Carbon, Still Crazy After All These Years

Carbon is really peculiar—in fact, the fact that there is enough carbon around in the universe to allow enough biology to occur and result in the human race at all is due to peculiarities

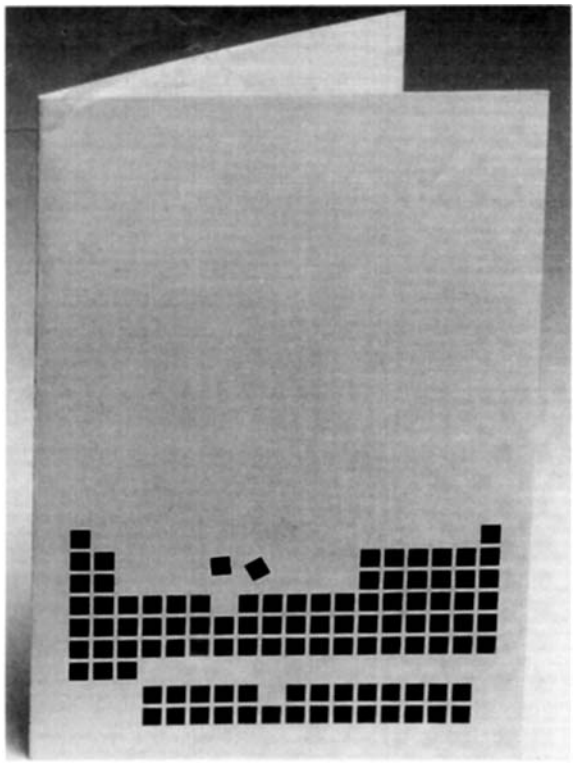

Figure 3. This item was designed by the author for a conference. It is left to the reader to deduce the topic of the conference and also the nature of item depicted. The answers may be in *The Hitchhiker's Guide to the Galaxy*.

in the nuclear chemistry of carbon. The "molecular" chemistry of carbon is no less peculiar. Even if we discount the whole of organic chemistry, the inorganic chemistry of carbon is also amazing. I worked with carbon-containing species right from the start when I was a graduate student with Richard Dixon at Sheffield. My first (successful) research project was a study of the electronic spectrum of the diatomic free radical CBr in which we also explored the intrinsic nature of the bond that the carbon atom formed with halogens.[44] Even more interesting was a preliminary (aborted) study of the fascinating molecule carbon suboxide OCCCO. The most interesting aspect of this molecule was the fact that it did not seem to know whether it wanted to be a linear or bent. The triatomic molecule C_3 was no less odd, exhibiting similar structural schizophrenia. The identification of C_3 in comets and flames, in the elegant historical study by Alec Douglas,[45] was a landmark in spectroscopy which added to the ubiquitous charismatic attraction of carbon species on earth as well as in space.

When I arrived at Sussex in 1967, after two years at NRC (Ottawa) and a year at Bell Labs (Murray Hill) I set up a microwave spectroscopy research program which aimed at the creation of new molecules that contained multiple bonds between carbon and various second or third row atoms,[46] for example sulfur (C=S, C=Se), phosphorus (C=P, C=P), and Si (C=Si). At this time the so-called double bond rule—*multiple bonds involving non first-row elements should not exist*—appeared to have some validity. However the stability of CS_2 indicated that the embargo was not total. Most importantly, as far as I was concerned, I became fascinated (while a postdoc at NRC in Canada) by the molecule HC≡P which Gier had made

in 1961.[47] I became convinced that the existence of this molecule (which incidently was produced spontaneously by a carbon arc in phosphine(!)) implied the existence of derivatives such as ClC≡P and $CH_3C{\equiv}P$. I also wondered whether these species could be used as synthons to create organic phosphorus cycloaddition products (analogues of the nitrogen heterocyclic compounds) as well as metal complexes that parallel those of the metal–nitrile complexes.

The first new molecules that we (Barry Landsberg, Krini Georgiou, Roger Suffolk, and myself) created possessed carbon–sulfur double bonds,[46] such as $CH_3CH{=}S$ (thioacetaldehyde), $CH_2{=}C{=}S$ (thioketene), and $CH_2{=}CH{-}CH{=}S$ (thioacrolein). They were created by thermolysis of custom-synthesized precursors and analyzed by both microwave and photoelectron spectroscopy. After the success with sulfur, it seemed that the same techniques might also work for phosphorus and, encouraged by Gier's HC≡P result of some dozen years previously, we tried it—and it worked like a dream![46]

With my Sussex colleague John Nixon, together with Nigel Simmons and Nick Westwood, Osamu Ohashi, Keichi Ohno and James Burkett St Laurent we produced a whole range of these species. With Colin Kirby and Terry Cooper we also produced some elegant boron–sulfur XB=S analogues.[46] $CH_2{=}PH$ was my favourite as it was the first (and simplest) molecule with a carbon–phosphorus double bond. Our first paper on $CH_2{=}PH$, $CH_2{=}PCl$, and $CF_2{=}PH$[48] and the paper by Becker, also on the creation of C=P-containing species,[49] appeared almost simultaneously. Our successful creation of $CH_3C{\equiv}P$[50] was almost equally exciting as it was the first analogue of HC≡P. It still seems amazing that Gier's 1961 result had not been recognized sooner by anyone else as a clear sign that a whole new class of compounds was just waiting to be discovered. The creation and structural determination of species such as $CH_2{=}PH$ and $CH_2{=}PCl$ (Figure 4), as well as

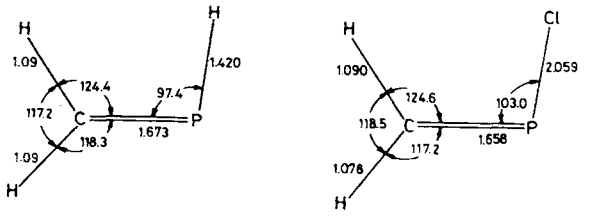

Figure 4. The structures of the first phosphaalkenes created, $CH_2{=}PH$ and $CH_2{=}PCl$, as determined by microwave spectroscopy [46, 48].

$CH_3C{\equiv}P$ and other related species, were (for me) some of our most exciting advances.[46] Since these papers were published these compounds, which we call phosphaethenes and phosphaethynes, have become the basis of some most fruitful fields of new chemistry. However, we never got to grips with the carbon–silicon double bond—a problem solved by others—as our interests led in other directions.

During this time (around 1970) my colleague David Walton was perfecting techniques for synthesizing very long linear chains of carbon atoms.[51–53] These molecules appeared like perfect test-beds for the quantum mechanical study of the dynamics of bending and rotation in simple linear systems. In 1972, as luck would have it, David and I proposed a project for the Chemistry by Thesis (CT) course at Sussex which aimed at probing such structural and dynamic behavior of moderately long carbon chains. The CT course had been initiated by Colin Eaborn[54] as a new approach to undergraduate teaching in which a BSc degree could be obtained on the basis of a thesis which the student would write on a research topic carried out under the supervision of two tutors from different chemistry disciplines (for example synthetic chemistry and spectroscopy). The course recognized that the traditional examination approach to the assessment of a student's ability—and in particular future capability—was an artificial and often unsatisfactory guide.

The course was unique to Sussex and produced a long stream of highly accomplished graduates with remarkably few who did not do well on the course. It *was* one of the numerous outstanding success stories of Chemistry at Sussex. I highlight *"was"* because the course has now been legislated out of existence by the combined efforts of Health and Safety Executive officials, lawyers, and misguided university administrators. This is an archetypal example of how a disparate mix of uncorrelated antagonists—each focused on individual goals with no perception of the true overall consequences can achieve negative results. A similar mix of advisors and officials in the secondary education sector has all but eliminated any real chemistry from the UK school curriculum. Today, students with any real chemical facility are virtually an extinct species.

Andrew Alexander was the outstanding student catalyst of the research project that aimed at the synthesis of a range of polyynes in particular HC_5N and their analysis by IR, NMR, and in particular microwave spectroscopy.[55, 46] In fact it was Alex's keeness in the first place that got the project going and his enthusiasm for the work, in the second place, which played a key role in its success. The start of the Sussex role in the story of C_{60} is really to be found in this project. It was the epitome of basic research and in these times when the mania for applied research is rampant, it is hard to imagine one less likely to gain support. There is little doubt in my mind that, had this project not been initiated, we at Sussex would not have been involved in the discovery of C_{60}.

HC_5N was the first molecule to be studied at Sussex on the newly arrived Hewlett Packard microwave spectrometer in 1974. This superb instrument enabled the rotational spectra of molecules to be measured with such ease (relative to the home-built instruments that existed in most microwave laboratories at the time). The machine enabled us to concentrate almost all our attention on the demanding chemistry involved in producing new species without worrying about how to optimize the detection parameters. There is no doubt that much of the work we did during the 1970s would have been essentially impossible without this amazing instrument.

Phase II: A Tale of Cold Black Giant Clouds and Warm Red Giant Stars

About the same time that we were creating the long-chain carbon molecules in the laboratory at Sussex, a veritable Pandora's box of molecules had been opened up by Townes and

co-workers[56] who discovered ammonia in the Orion constellation. After this discovery microwavers and radioastronomers joined forces and showed that the vast dark clouds which lie between the stars (Figure 5) harbor scores of molecules

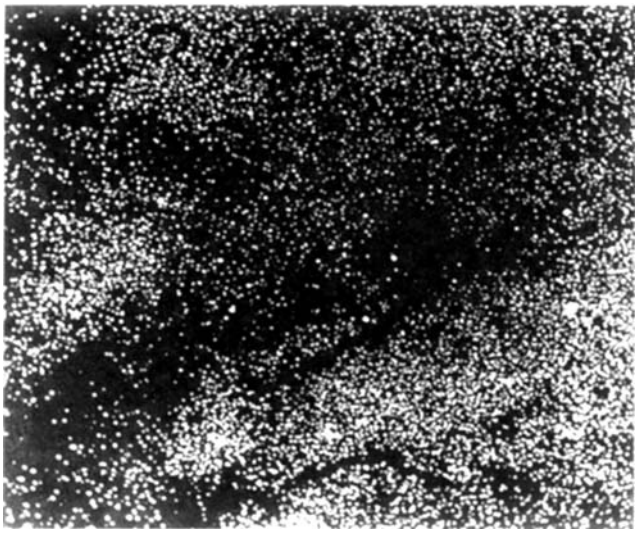

Figure 5. The dark clouds in Taurus from Barnards 1927 survey, *Atlas of Selected Regions of the Milky Way*, (Eds.: E. B. Frost, R Calvert) Carnegie Institute of Washington, **1927**. Heiles Cloud 2 is the dark area in the left-hand bottom corner.

(methanol, carbon monoxide, formaldehyde, ethanol, hydrogen cyanide, formic acid, formamide, etc)—all the molecules the galaxy could possibly need for a primordial pot of prebiotic soup.[57] Furthermore, they were all identified by the detection of their microwave rotational emission spectra using radiotelescopes. Cyanoethyne (or cyanoacetylene to we older guys) HC_3N was also detected[58] and when we made HC_5N I began to wonder whether it might also be present in interstellar space. It seemed like a very long shot at the time because an abundance *rule-of-thumb* had materialized, based on a rough correlation of available empirical data, that suggested that an additional carbon atom would reduce the abundance by approximately a factor of ten, and two extra atoms implied that HC_5N should be down by a factor of 100 from HC_3N and this meant that it would be undetectable. However my view is never to assume anything is right until it has been tested experimentally because, as often as not, assumptions are wrong and even when they are not something unexpected and interesting often happens.

However, the strong bond between laboratory spectroscopy and astrophysics, which goes back at least to Newton's time and perhaps even to antiquity, was again giving birth to yet another major new field—in this case *interstellar astrochemistry*. Molecular radioastronomy was the crucial medium in uncovering the hordes of molecules—indeed it has now shown that the molecules play a crucial role in the collapse of the clouds to form stars. As gravitational attraction causes the interstellar gas clouds to collapse and heat up, rotational transitions (mainly of CO) leak radio energy out allowing further cloud collapse to occur, ultimately to such high pressures and temperatures that new stars and planets can form.

I wrote to my friend Takeshi Oka (we had both been postdoctoral fellows at NRC during the "Golden Years" when NRC had been the outstanding National Research facility) and asked him whether he was interested in searching for HC_5N in space—he turned out to be as keen as I was. Together with NRC astronomers, Lorne Avery, Norm Broten, and John MacLeod, the molecule was detected in the giant molecular cloud SgrB2 towards the galactic center.[59] The discovery was really a surprise because the molecule turned out to be much more abundant than expected—one more example of why one should never let a theoretical assumption deter one from carrying out an experiment.

The next question was clear—was HC_7N present? David Walton worked out a synthesis and Colin Kirby set about the demanding task of synthesizing it and measuring the rotational frequencies.[60] After making it in the laboratory and searching for it in a dark cloud in Taurus (Figure 5) by using the 46-m radio dish in Algonquin Park, Canada, we found that it too was present (Figure 6)[61, 62, 57]—it scarcely seemed possible. This

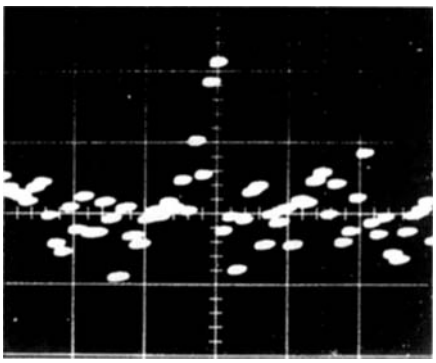

Figure 6. A photograph of the first oscilloscope trace of the radio signal emitted by interstellar HC_7N in Heiles's Cloud 2 in the constellation of Taurus (see Figure 5).

family of molecules was making total nonsense of the abundance *rule-of-thumb* that almost all other families of molecules appeared to follow. Then, just as we at Sussex were about to attempt the daunting task of synthesizing HC_9N, Takeshi found a clever way of estimating its rotational frequencies by extrapolation from the known frequencies of the set HC_nN ($n = 1,3,5,7$);[63] and we detected it as well.[64] These were then the longest and heaviest molecules conclusively detected in space—and still remain so nearly 20 years later. From these discoveries it became clear that there was a problem: The ion–molecule reaction theories of Klemperer, Herbst, Dalgarno, and Black,[65, 66] which accounted almost perfectly for almost all the other species observed were just not able to account for the high abundances such long carbon chains. It seemed to me that some alternative source was needed and fortunately a possible answer started to appear. As time progressed cool red giant carbon stars, such as the fascinating object IRC +10216,[67] were found to be pumping the chain molecules out into the interstellar medium.

Phase III: Ten Days in September 1985

During the early 1980s Robert Curl visited my laboratory at Sussex and invited me to come to Rice University in Houston at

some time in the future. During Easter 1984, just after attending the conference on molecular structure that Jim Boggs organized biennialy in Austin, I took up the invitation and visited Rice. Apart from this superb conference another good reason for going to Texas is that there are excellent "Half-Priced Bookstores" in Austin, Houston, and Dallas. When I arrived in Houston, Bob was enthusing about a very recent result that Rick Smalley and his group had just obtained. They had shown that SiC_2 was triangular[68]—a fascinating result. The way in which the Si had avoided forming a classical double bond in this species, at a stroke, explained why we had had so much difficulty observing molecules with Si=C bonds. It also fitted in nicely with the flexibility of C_3 and OC_3O which I had studied years before. I went over to Rick's laboratory where he enthusiastically described how his cluster beam machine worked. He explained how a pulsed laser, focused on a metal disc vaporized material to produce atoms which were swept up by pulses of helium which caused clustering and concomitant cooling. Then by, expansion through a nozzle into a vacuum, they are cooled further and by skimming into a pulsed beam which is analyzed by a time-of-flight mass spectrometer the cluster mass distributions can be ascertained. As Rick described the mode of operation, it reminded me of previous work on carbon clusters, particularly by Hintenberger and co-workers,[69] and I began to wonder whether, by substituting the metal target disc by a graphite one, the plasma produced by the laser might simulate the circumstellar shell of the cool red giant carbon stars such as IRC +10216 and produce the carbon chains. This would give strong support for the stellar solution to the chain problem and provide an important alternative mechanism to the ion–molecule schemes.

As that day wore on, I thought more-and-more about the idea and became more-and-more convinced that Rick's apparatus was the key to proving a circumstellar source of the chains. Furthermore the detection of the spectrum of SiC_2 suggested that the apparatus might be able to confirm the conjecture of Alec Douglas[70] that the carbon chains might be carriers of the diffuse interstellar bands (DIBs).[71] The DIBs are interstellar spectroscopic features that have puzzled astronomers and spectroscopists since the 1930s. That night I described these ideas to Bob who was keen to collaborate—particularly on the second much more difficult DIB problem. In the event, in August 1985, Bob called me at my home in the UK to say that my experiments were to be carried out at Rice imminently and asked whether I was interested in coming to Houston. I didn't need to be asked twice—I dropped everything and within three days I was in Houston.

As soon as I arrived I gave a concentrated two–three hour seminar on all aspects of interstellar molecules and their spectra. I met Jim Heath, Yuan Liu, and Sean O'Brien, the key students with whom I was to work intimately for the amazing ten-day period from September 1st to 10th, 1985. Jim Heath and I struck an instant rapport partly because we are both addicted to books and enjoy browsing in bookstores. So after long stints on the apparatus (Ap2 as Rick affectionately called his second generation cluster beam machine) Jim and I would occasionally play hooky to visit Houston book stores. We would invariably end up, often accompanied by Carmen (Jim's wife) and Sean, late in the night at the House of Pies—a Houston 24-hour coffee bar which served outstanding Dutch apple pie. Apparently (according to a recent TV program on the history of the PC) the founders of COMPAQ hatched their company at the House of Pies.

The experiments began on September 1st, and the good news is that they were successful. Almost immediately we detected the linear molecules with five to nine carbon atoms that we had observed in space,[72] and thus we got the evidence needed for the idea that the chains could easily have originated in red giant stars. The bad news is that an interloper was present. As the results emerged, our attention was quickly attracted by the precocious antics of this uninvited guest. It had 60 carbon atoms and was accompanied by a more diminutive but still fairly prominent partner with 70 carbon atoms. These characters actually had already appeared in a publication some twelve months previously by Rohlfing, Cox, and Kaldor in 1984,[73] and another group, Bloomfield et al. had also been probing their properties.[74] I had actually read the Exxon paper in some detail at the time it appeared because it described almost exactly the experiments I had proposed to the Rice group a few months previously. I had not however been moved to rub 60 brain cells together to devine what might be going on and apparently neither had anyone else. The Exxon group had made the discovery that a new family of carbon clusters with more than 30 atoms existed which appeared only to be even-numbered. Though C_{60} was definitely more prominent than its neighbors, it was not sufficiently prominent to attract any particular attention, and was certainly not dominant as it was after Jim and Sean had finally finished with it.

The stongest peak in the range between 30–100 C atoms of the mass spectrum was usually the peak for C_{60} and it was used to tee up the experimental parameters for these larger species. During these studies, conditions were discovered that gave a distribution in which C_{60} was completely off-scale (Figure 7).

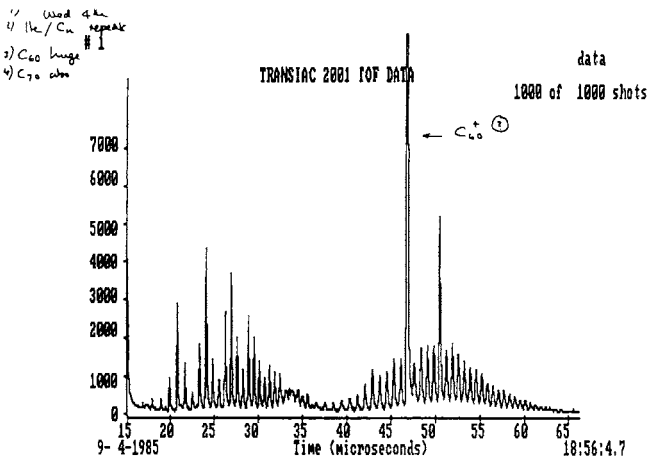

Figure 7. Annotated time-of-flight (TOF) mass spectrum of carbon clusters produced on Wednesday, September 4th, 1985 the day on which the dominance of the C_{60} signal was first recorded (see Figure 8a).

This observation was made on Wednesday, September 4th and our reactions were written up in the lab notebook by the graduate students (Figure 8). Two days later, on Friday, a group meeting took place at which Jim and Sean offered to work over the weekend to optimize conditions. Sean worked that evening

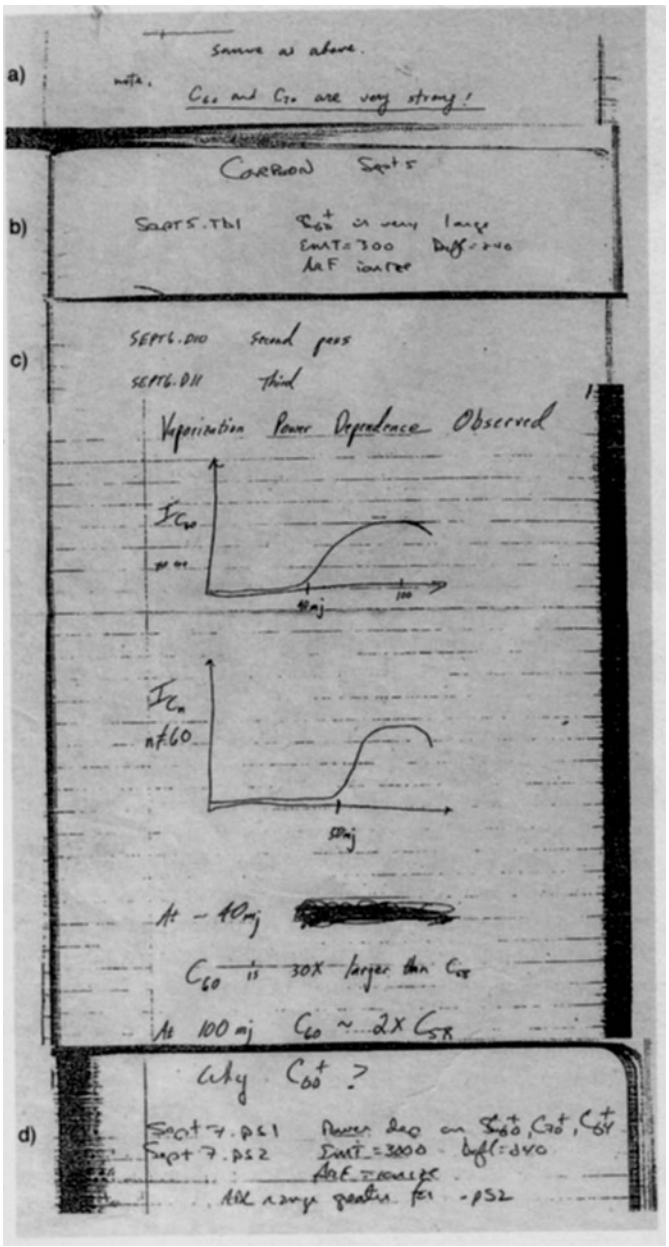

Figure 8. Entries by Heath, Liu, and O'Brien in the Rice Cluster Laboratory Notebook from the period September 4–7, 1985 when key experiments were carried out at Rice University. a) September 4th; b) September 5th; c) September 6th; d) September 7th.

and Jim took over the next day and worked all weekend on the problem of optimizing the signal. By Sunday evening (September 8th) the result was the spectrum shown in Figure 9 which exhibited almost nothing but the C_{60}; with C_{70} as a somewhat smaller but still prominent chaperone.

As C_{60} and its sidekick became the prime focus of our attentions, I began to call these peculiar *wadges* of carbon the Lone Ranger and Tonto or sometimes Don Quixote and Sancho Panza. Our deliberations came to a climax during discussions on Monday, September 9th. C_{60} appeared to be really quite unreactive, a behavior difficult to reconcile with a flat hexagonal graphene sheet—the most obvious first thought that would occur to anyone—which must have some 20 or more dangling bonds. After all, the chains had ends (two) and they added on two H atoms; thus a 60-atom flat hexagonal graphene sheet

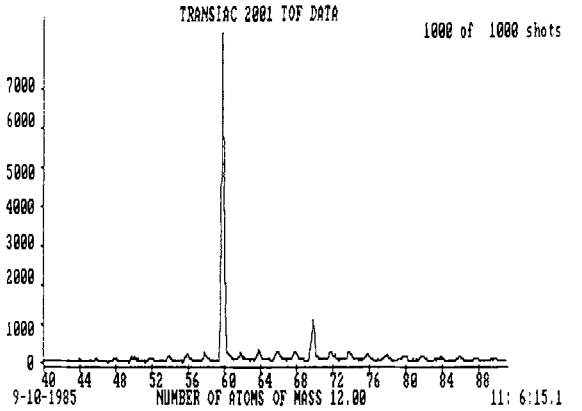

Figure 9. Time-of-flight mass spectrum of carbon clusters under the optimum conditions for the observation of a dominant C_{60} signal obtained by Jim Heath on Monday, September 9th, 1985.

should add on approximately 20 or more H atoms, but it did not. As we sought a solution, we discussed many possible structures that might explain the perplexing results.

Gradually a consensus developed that what might have happened was that flat hexagonal sheets had either formed or ablated from the surface of the graphite disc and closed into a cage, so eliminating the reactive edge. The closed hexagonal cage idea reminded me of a visit with my family to Expo67 in Montreal where Buckminster Fuller's dome had dominated the horizon. It particularly called to mind an image of the dome in an issue of Graphis magazine[75] devoted to the exhibition (Figure 10).

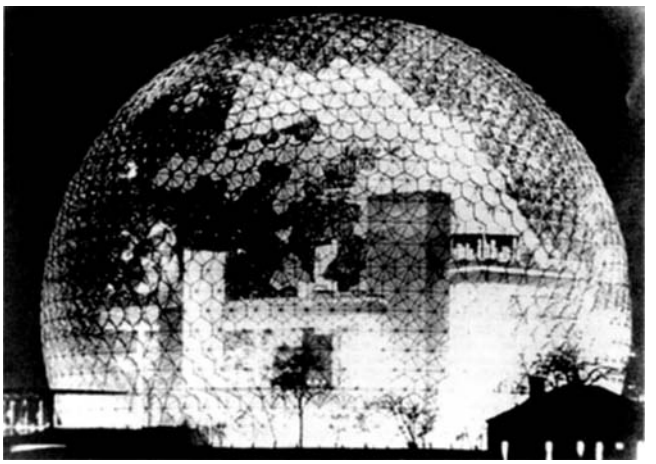

Figure 10. Photograph taken by Michel Proulx of the Geodesic Dome designed by Buckminster Fuller for the U. S. exhibit at EXPO67 in Montreal [75]. One of the pentagons necessary for closure is discernable in this photograph. The variation in the strut lengths of the hexagons in the vicinity of the pentagon, necessary to achieve a relatively smooth round surface, can also be discerned.

Rick went to the Rice Library and extracted a book about Buckminster Fuller and his inventions.[35] I also recalled a "stardome" skymap (Figure 11a), which I had built for my children some years before. I remembered that the stardome had not only hexagons but also pentagons and wondered, as Bob and I went home for lunch, whether I should call my wife at home back in England to check whether or not it had 60 vertices. As I was scheduled to leave for the UK the next day, I invited the team out for dinner at a Mexican Restaurant to celebrate the exciting

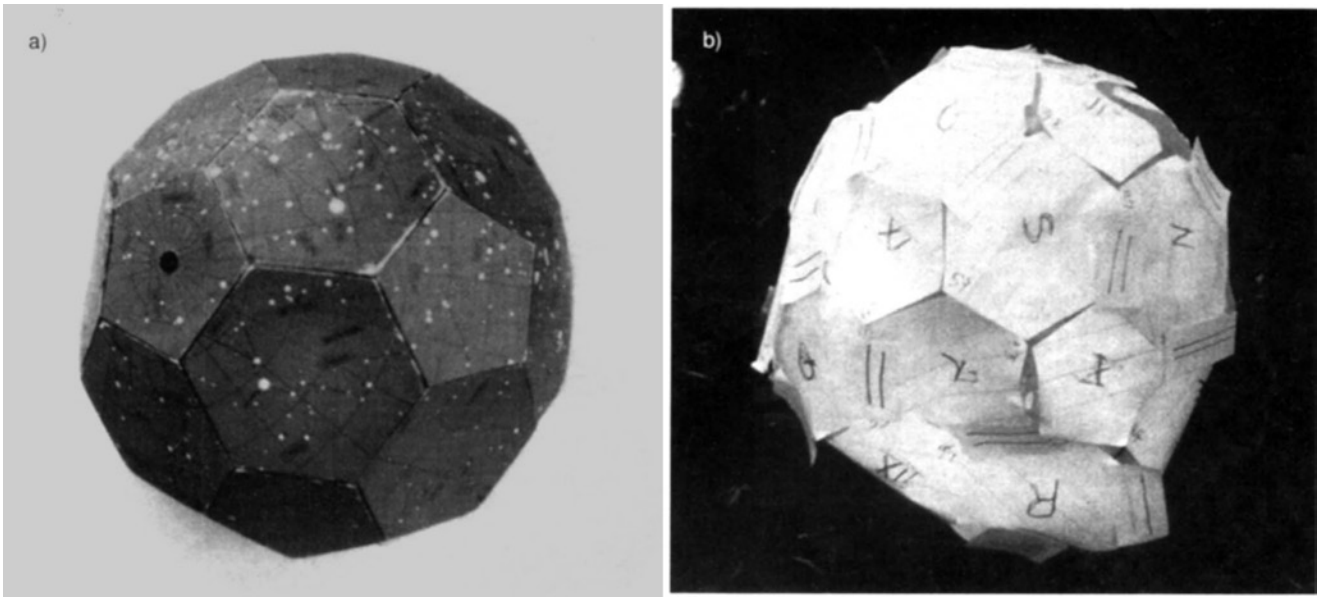

Figure 11. The two card models that played key roles in the positing of the truncated icosahedral structure of C_{60}. a) Stardome map of the sky (Buckminster Fuller patented t-icosahedral, and other polyhedral world-map projections); b) prototype C_{60} made by Smalley. Both models are truncated icosahedra with 60 vertices, 12 pentagonal and 20 hexagonal faces.

discovery. Needless to say we spent all the time at the restaurant trying to solve the puzzle.

That evening/night Rick experimented with sheets of hexagons, Jim together with Carmen experimented with toothpicks and jelly beans, and Bob and I discussed the stardome solution again. Rick could not make any progress until he remembered our discussion of the pentagons in the stardome.[19] Rick discovered that the structure started to curve into a saucer shape as soon as pentagons were included among the hexagons and finally closed as he added a twelfth pentagon. The next morning, when he revealed his paper model (Figure 11b), I remember being ecstatic. It was beautiful and looked just like the stardome (Figure 11a) as I remembered it. It is of course a truncated icosahedron and the fact that it turned out to be a football too was most appropriate. After all, the whole discovery story is an archetypal example of team effort. I remember thinking that the molecule was so beautiful that it just had to be right—and anyway even if it were not, everybody would surely love it, which they did—eventually! My suggestion that we call the molecule buckminsterfullerene (the -ene ending fitted perfectly) was, after some discussion, accepted and we sent off the paper to Nature—the date of receipt was September 13th (note: the experiments had started on September 1st).

Phase IV: Little Fullerenes, Giant Fullerenes, Red Solutions, and One-Line Solutions, or—How to Play Football Without Knowing the Rules

We decided to probe the consequences of the C_{60} discovery and experiments were initiated at Rice.[76] Jim Heath, Sean O'Brien, Yuang Liu, and Qing Ling Zhang were among the most heavily involved students. A series of experiments was also initiated at Sussex: With Tony Stace, a cluster beam machine was constructed by a highly dedicated set of students (Simon Balm, Richard Hallett, and Wahab Allaf) and we thus started to probe cluster behavior in general. With the aid of support from British Gas (through Steve Wood) we also started to probe the implications of our discovery for combustion.

One of the most charismatic things about C_{60}, and one which continually lay simmering in the back of my mind, was the fact that all the carbon atoms in C_{60} are equivalent and so the ^{13}C NMR spectrum should consist of but a single elegant line. However, how could one make enough to measure it?. That was a daunting task and I must admit that whenever my thoughts drifted onto this subject they invariably ended with the conclusion that one day some young, ingenious, upstart, synthetic organic chemist would surely observe it first. I certainly never entertained much hope of observing the line at Sussex and so it was not really an objective. It is important to understand how impossible such a task appeared at that time. My attitude to the research was to probe those aspects of the C_{60} discovery which particularly puzzled me and let the research flow whichever way it would.

A few days after the discovery I arrived back in Europe and announced our discovery and our conjectured structure at a conference in Riccione. Julie August, a former student now working at Nottingham, told Martyn Poliakoff of the discovery and he sent me a zerox copy of the idea that David Jones had had in 1966.[6, 7] Writing under the pseudonym of Daedalus in the Ariadne column of the *New Scientist* David had proposed the amazingly imaginative idea that large carbon balloons might be feasible. We also discovered that C_{60} itself had already been proposed by Osawa in a Japanese article 15 years earlier[2] and in a book with Yoshida.[3] Not only that, Bochvar and Gal'pern had even carried out a Hückel calculation and published the pattern of the molecular orbitals.[4, 5] We also discovered that Orville Chapman at UCLA (University of California at Los Angeles) had initiated a program aimed at the synthesis of the molecule (private communication). In retrospect it is rather peculiar that this charismatic molecule had not attracted the atten-

tion of the chemistry community earlier. Jones, in his articles[6, 7] introduced me to D'arcy Thompson's book *On Growth and Form*[77] and pointed out that Euler's law indicated that no sheet of hexagons could close. If however 12 pentagons were introduced into a hexagonal sheet of any size it would close. Almost everybody (who knows any organic chemistry!) knows that unsaturated molecules with adjacent pentagonal rings are extremely unstable. Thus from Jones' article it became immediately obvious that as 5×12 is 60, C_{60} had to be the smallest cage able to close without abutting pentagons. Thus the secret of C_{60}'s stability was beautifully simple. It lay in the accommodation of the two requirements: Euler's 12-pentagon closure principle and the chemical stability conferred by pentagon nonadjacency. I consider these two points to be the "2+2" of fullerene stability. Schmalz, Seitz, Klein, and Hite, using circuit theory, placed these principles on a firm theoretical basis.[78] The C_{70} peak was, as mentioned previously, also prominent and Rick found an elegant and a plausible structure, in which two C_{30} hemispherical halves were separated by a ring of ten extra C atoms. This structure was proposed in the paper describing the crucially important discovery, which Jim Heath made, that atoms (such as La) could be put inside the cage.[79] This discovery (and its refinements), that endohedral complexes could form, was perhaps the strongest empirical observation supporting the cage proposal prior to extraction in 1990.

During some moments of musing over these two stability criteria I began to wonder about the identity of the next cage (after C_{60}) that might be able to close without abutting pentagons. I started to play around with a model of C_{60} by adding atoms and before I had made much headway it suddenly struck me that perhaps closure could not occur again until C_{70} (Figure 12)—if that were the case it would explain—at a stroke—the

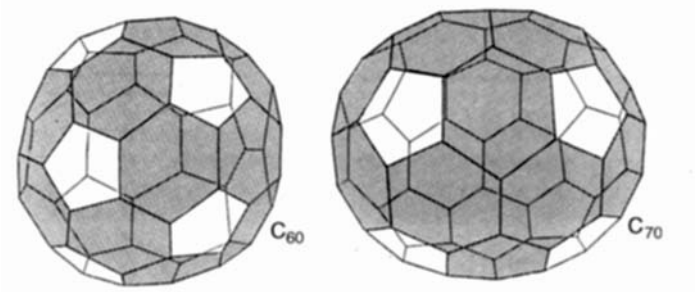

Figure 12. For species with less than 72 atoms these two structures are the only ones which can be constructed without abutting pentagons. Thus on the basis of the *pentagon isolation principle* [80,81] and geodesic considerations, C_{60} and C_{70} are predicted to be the first and second fullerene magic numbers, respectively. This result provided the simplest and most convincing circumstantial evidence in support of the closed cage concept prior to extraction.

prominence of C_{70}. That seemed to me a most unexpected and certainly not a very obvious result. Furthermore, there a subtle circular argument appeared—if it were true, closure demanded that C_{70} be strong and that would be, for me, by far the most convincing support for the fullerene proposal and I knew that there was not a hope-in-hell of an alternative explanation of *both* the 60 *and* 70 magic numbers. From that moment on I was certain that one day we would be proven right.

A call to the Galveston group to see whether they could prove the conjecture was in order. To my absolute delight Tom Schmalz told me that they had already shown that cages with 62, 64, and 66 atoms could not close without abutting pentagons and that the analysis on 68-atom cages was in mid-stream at that very moment. Thus the *pentagon isolation rule*, which governs general fullerene stability, was born.[80, 81] Another thought struck me during the phone call with Schmalz. I remembered that C_{50} was often a magic number in some of our experiments and suggested that they might check whether the 50-atom cage might be the smallest cage to close without *triplets* of abutting pentagons. Schmalz et al showed this to be the case too.[81] I wondered about a result that Sean had obtained.[82] He had found that laser irradiation of C_{60} caused it to fragment by reducing the size of the clusters more-or-less sequentially by even numbers from 60 to 58 to 56 etc... all the way down to 32. After 32 further irradiation blew the cluster into small fragments. I tried to push the pentagon multiplet isolation idea to quartets in the hope that it would explain the C_{32} result but to my amazement and delight an elegant C_{28} structure[80] formed in my hands (Figure 13). This reminded me of a result that had

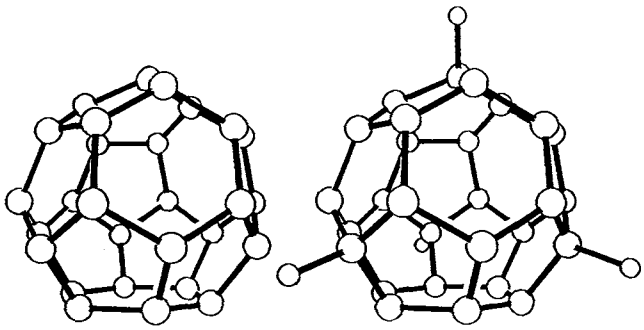

Figure 13. The tetrahedral small fullerene C_{28} (left) and the tetrahydrogenated derivative, $C_{28}H_4$ (right), which is expected to exhibit some stability [80].

puzzled us for some time—in some of our runs the 28-carbon-atom signal sometimes rivalled that of C_{60}. It also struck me that this species should be a sort of superatom cluster analogue of the carbon atom with effective tetravalency suggesting that an elegant tetrahedral $C_{28}H_4$ derivative (Figure 13) might actually be a stable molecule.[80] Indeed in some Exxon data,[83] I found just the mass spectrum distribution which confirmed that the isolation principle could be generalized to include various sizes of multiplets and account for magic numbers of smaller cages down to C_{20}.[80, 13] It not only exhibited magic numbers at 60, 50 and 28 but it stopped abruptly at 24. From Patrick Fowler I had learned that no cage could be constructed with 22 atoms.[84] Thus, there appeared to be "semistable" fullerenes (at least in beams) down to C_{20} which were predictable (Figure 14) on the basis of the cage closure concept. What more "proof" could one possibly want for the whole fullerene concept? None.

Then one day I decided that we should build our own Buckminster Fuller domes, or rather molecular models of the giant fullerenes[85] and ordered 10000 cabon atoms (molecular model atoms and bonds). Ken McKay, armed with Goldberg's paper[86] and Coxeter's book[87] set about building C_{240}, C_{540} and later C_{960} and C_{1500} with icosahedral symmetry. When Ken came in with the model of C_{540} it was beautiful but I could not quite understand its shape—the model was not round like Buck-

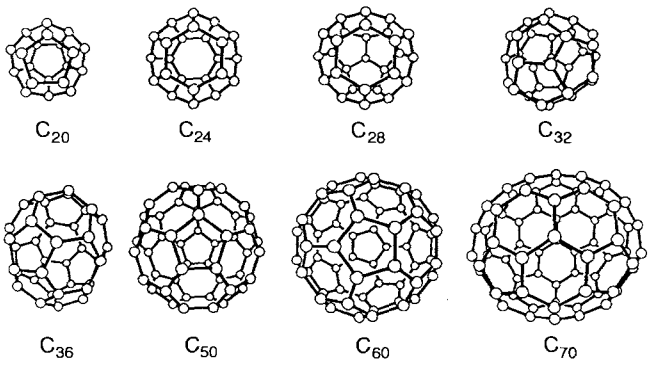

Figure 14. A set of fullerenes between C_{20} and C_{70} some of which are magic and others which are predicted to be "semi"-magic [80, 81].

minster Fuller's Montreal dome but had clear icosahedral tendancies (Figure 15).[90] Indeed Ken's model had cusps focused at the 12 pentagons and from a distance had a definite polygonal outline. Then we realized that the structure explained some very interesting results that Sumio Iijima had obtained in 1980.[89]

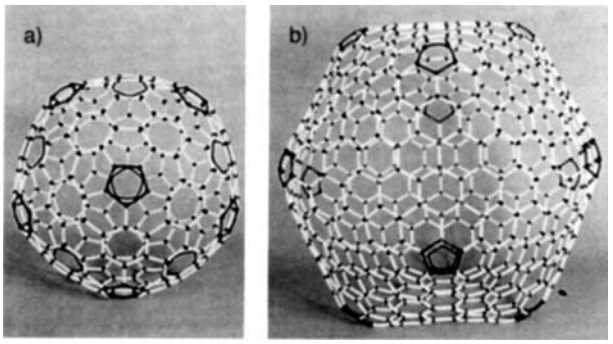

Figure 15. Photographs of molecular models of the giant fullerenes C_{240} (left) and C_{540} (right). The models turned out to possess icosahedral shapes rather than perfectly spheroidal ones similar to the geodesic domes. Each of these structures can be considered as an initially flat hexagonal network that has warped into a closed monosurface (of icosahedral symmetry) by 12 pentagonal disclinations which give rise to the cusps. The structures provided the first prediction of faceting in closed cage carbon species such as giant fullerenes and nanotubes.

He had observed concentric shell onionlike carbon particles by transmission electron microscopy. Superficially many of Iijima's particles appeared to be round, as one might assume if they were nanoscale geodesic domes. However because of this assumption I had glossed over some crucial subtle features in the micrographs—the outlines were not quite as round as they superficially appeared—they were actually polygonal.[13, 88] In fact as we looked more carefully at the infrastructure of Buckminster Fuller's domes we realized that the strut lengths in the vicinity of the pentagons had been adjusted to give them a smooth spheroidal shape (Figure 10). Thus the C_{60} discovery had led to an elegant explanation of a previously unexplained result. It showed that a cage with an icosahedral shape could be constructed *entirely* from sp^2 carbon atoms. Thus 12 pentagonal disclinations—a minimal number of defects by comparison with those found in any normal crystals—would convert a perfectly flat graphene sheet of any size into a closed cage.

There is a rather nice lesson to be drawn from this advance: There had been no premeditated research aim, the original reason for constructing the giant fullerene model was solely for the intrinsic interest and pleasure of building an elegant structure—and yet it revealed an unexpected result. The result had important consequences—for instance it was the first study of the way that the inclusion of pentagons influences the curvature of a graphene sheet—a result that was to find particular use later when elongated giant fullerenes (nanotubes) were discovered. On occasion I would wonder about our cage proposal, reassess each and every observation: 60 and 70 should be magic numbers; 50 and 28 were also explainable magic numbers; there was no clear evidence of C_{22}; the icosahedral shape of the giant fullerenes could be explained; Jim had observed metal complexes that behaved as though they were endohedral;[79] Sean had found that C_2 units were ejected,[82] and there were other supporting experimental results.[12, 19] It all fitted perfectly—there was no way we could be wrong.

I thought we should probe the Iijima result and see whether C_{60} might reveal some clues about the round particles in general. This was based on the idea we had proposed[90] that the mechanism of C_{60} production might be related to soot formation. We were able to acquire an old carbon arc evaporating unit and drill a hole in the base plate to admit He. Ken McKay monitored the structure of the carbon deposit by scanning electron microscopy as a function of He pressure. The idea was that as the He pressure increased C_{60} formation might be initiated and this would be accompanied by the creation of round carbon particles. A change in the deposit did occur as the pressure rose above 50 microns (5×10^{-2} Torr).[20] The next step *seemed* obvious—to monitor the possible production of C_{60}. However I made a fatal error. I assumed that if C_{60} were created in the arc, it would only be in minuscule quantities and only the most sensitive of detection techniques available (mass spectrometry) would work. I then tried, for the next two years (unsuccessfully), to obtain the financial support for quadrupole mass spectrometer.

I was still trying, with Geoff Cloke, to get a mass spectrometer when we learned of a study by Krätschmer, Fostiropoulos, and Huffman who had detected four IR bands (Figure 16; exactly as

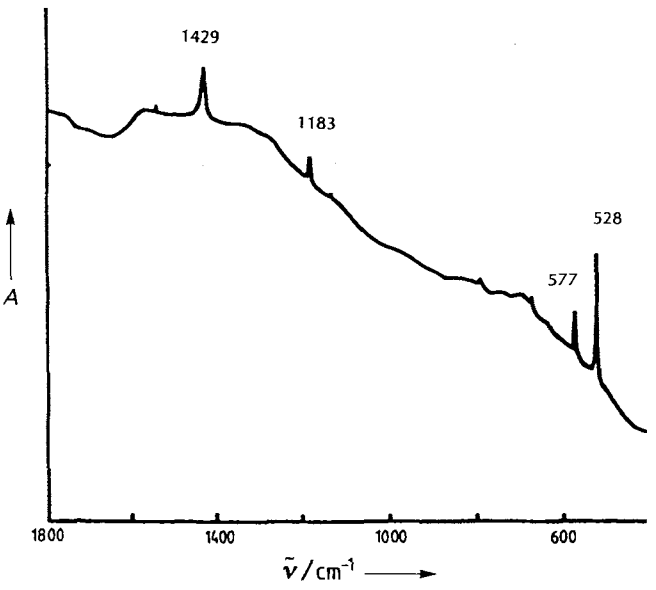

Figure 16. The four historic IR bands observed by Krätschmer, Lamb, Fostiropoulos, and Huffman, taken from reference [16].

predicted theoretically[91–93]) in a carbon deposit made in exactly the same way as ours.[16] If this were correct then their deposit (and ours also!!!) must contain at least 1% C_{60}. I could not believe it—and yet there were four sharp frequencies in the pure carbon deposit—what on earth could they be. I decided to check out this incredible (in its literal meaning) result and proposed it as as a third year project for Amit Sarkar (an undergraduate) to work with Jonathan Hare (graduate student) to see whether they could repeat it—and they did!!![20] It is difficult, today, to explain just how difficult it was to accept the Krätschmer et al. observations but it is important, for an understanding of how science advances, to try. How could C_{60} have remained undetected until the end of the 20th century if it could be produced in such a yield by this seemingly simple approach?

We then tried to see whether the deposit gave a mass spectrum and Ala'a Abdul Sada obtained a signal at m/z 720 (Figure 17 and 18a)—it still seemed impossible. I was still very suspicious,

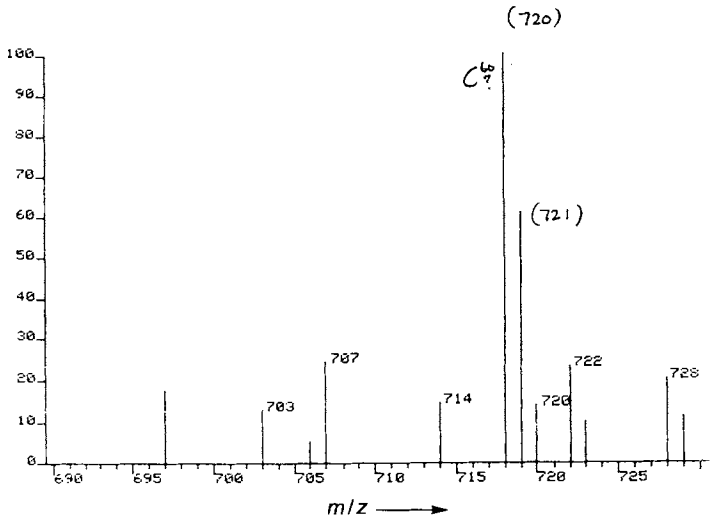

Figure 17. Fast atom bombardment (FAB) mass spectrum of a deposit of arc-processed soot obtained on July 23rd, 1990 at Sussex by Ala'a Abdul-Sada. The machine calibration is out by 2 amu; however, the isotope pattern was convincing as the peaks are close to the intensity ratio 1.0:0.66:0.22 as expected for $^{12}C_{60}$:$^{12}C_{59}{}^{13}C$:$^{12}C_{58}{}^{13}C_2$.

especially as I knew that C_{60} can be formed readily during the mass spectrometric sampling process. The mass spectrometer then broke down (Figure 18a)! Over the years we had often discussed the likely physical properties of C_{60}—some thought it would be a high melting point solid, others thought it would be a liquid or even a gas. On a Friday evening August 3rd Jonathan decided, with the unblinkered optimism that only the young possess, to test whether the species would dissolve in benzene (Figure 18b), and amazingly it produced a red solution which he placed on my desk on Monday morning (August 6th) (Figures 19 and 18c). Jonathan seemed to have no difficulty in accepting that it was C_{60} as is indicated by the fact that he called it C_{60}^{B} (see Figure 18), which was our shorthand notation for buckminsterfullerene. On the Thursday some of the solution was concentrated to see whether a deposit could be obtained which would yield a stronger signal at m/z 720—but it didn't (Figure 18d). This was exactly the right experiment and actually

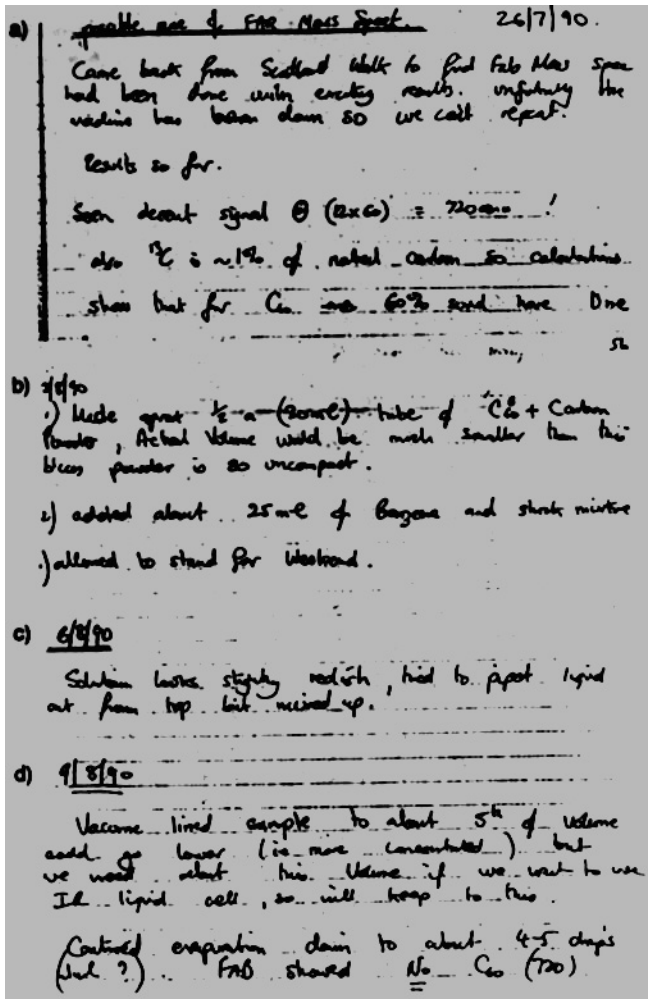

Figure 18. Entries by Jonathan Hare in his laboratory notebook: a) July 26th, 1990, b) August 3rd, 1990, c) August 6th, 1990, d) August 9th, 1990.

Figure 19. Original "reddish" extract obtained by Jonathan Hare on Monday, September 6th, 1990.

a rather difficult one for technical reasons and would almost certainly have worked the next time—*had there been one(!)*.

The next day, disaster struck—I had a call from *Nature*; Philip Ball asked whether I would referee a new paper by Krätschmer et al. When the manuscript arrived by fax at around 12 noon it was a bombshell. Krätschmer et al. had also obtained a red(!!!!) solution and what is more their solution had yielded

crystals (Figure 20), which X-ray analysis conclusively indicated consisted of arrays of spheroidal molecules exactly the right size to be C_{60}. There was absolutely no doubt about it—Wolfgang Krätschmer, Lowell Lamb, Kostas Fostiropoulos, and Don Huffman had done it.[15] It was only at that moment that I suddenly realized that we had been in a race and—we had been

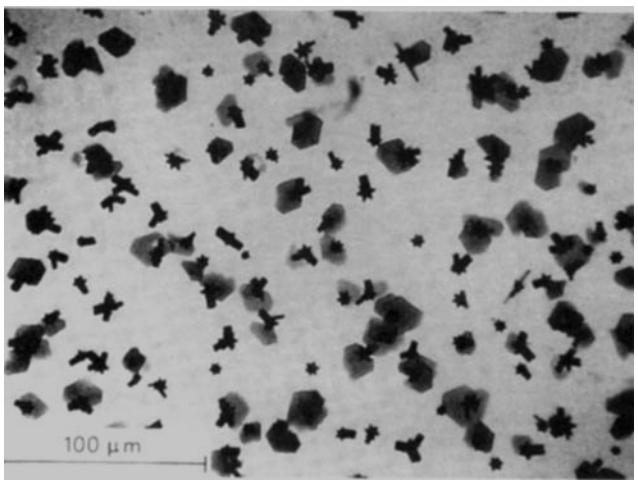

Figure 20. The astounding photograph of crystals of pure carbon which Krätschmer, Lamb, Fostiropoulos, and Huffman obtained during their breakthrough in extraction [15]. Photograph supplied by Wolfgang Krätschmer.

pipped at the post. I considered committing suicide—but decided to go for lunch instead. Over lunch I read and reread this fantastic manuscript and I doubt whether I shall ever have an experience like it again. It was a very strange mix of alternating feelings: First, exhileration from being proven right, and then disappointment from having come so close to proving it ourselves. Immediately after lunch I called Philip Ball back and told him to accept the paper immediately.

But what to do now, it was difficult to think at all let alone make any sensible decisions. However as the afternoon wore on it gradually dawned on me that although *almost* everything was lost—it was not quite all. Krätschmer et al. had analyzed their material by X-ray crystallography and not by NMR spectroscopy. So, the much-coveted single NMR line was still waiting to be observed. Thus I realized that there was just a single crumb of comfort left, but what a tasty morsel it would be and we should be able to observe it. (The NMR shift should also indicate just how aromatic the molecule was or was not. Of course the meaning of aromaticity for a species that cannot undergo substitution is debatable!) After all Jonathan had extracted the precious red solution on the Monday, four days before the extraction manuscript arrived on the Friday and we also had the confirmatory 720 amu mass spectrum. So we already had material in our hands and we were the only ones apart from Krätschmer and colleagues who had. We could also take immense intellectual satisfaction at having extracted the red solution before the arrival of the paper of Krätschmer and colleagues. I suppose that that should be enough for a scientist—but of course it never is.

In 1982 Krätschmer and Huffman had observed puzzling UV absorption features, while studying carbon dust produced by a carbon arc to simulate interstellar dust in the laboratory and measure the optical spectrum. After the publication of our discovery, and theoretical predictions of the UV spectrum such as those by Rosen and co-workers[94, 95] and others[9, 10] they conjectured that the features might be due to C_{60}. They then set about testing their idea by searching for the four telltale IR lines which theory suggested the molecule should exhibit,[91–93] (see Figure 16). When they found them they went on to make C_{60} from pure ^{13}C and show that the isotope shifts were perfectly consistent with their conjecture.[17] They then extracted crystals (Figure 20) and proved their conjecture conclusively. I look upon the conjecture that they had made C_{60} in 1982 together with the decision to test it by analyzing their deposit by IR spectroscopy as one of the most prescient pieces of science I have ever come across and as time has progressed I have come to appreciate it more and more. The role played by spectroscopy—in both the initial UV observation and in particular the crucial telltale IR fingerprinting is an archetypal example of the way spectroscopy can be used to solve important problems, in this case an historically significant one as well. To my mind there is no more amazing discovery than that there is a form of pure carbon that is soluble and the image of the carbon crystals of Krätschmer et al. (Figure 20) has to be one of the most sublime images of 20th century chemistry.

During the tea-break that afternoon I showed the paper to my colleagues. Roger Taylor, offered to help us to get the one-line solution and immediately tried to extract as much material as he could from Jonathan who was somewhat reluctant to part with the small amount of the precious material that he had. Roger then made a key discovery, he found that the red solution could be chromatographically resolved into two components, one was red and the other a beautiful delicate magenta. (Chromatography has since become the accepted way to separate all the members of the fullerene family.)

Would NMR analysis show the single line? Tony Avent who operated the NMR spectrometer produced a two(?)-line spectrum from the magenta material (Figure 21). One was a magnificent strong line, but it was benzene—quite a well-known compound. The second was a puny little blip in the base line—but Tony reckoned it was C_{60}—and he was right. To us it was the most beautiful little blip one could ever imagine. After further refinement the single line was observed as a strong signal (Figure 22a). The icing on the cake was the red material which gave five NMR lines—exactly what was expected for C_{70}[96] (Figure 22).

Thus, in summary, Krätschmer, Lamb, Fostiropoulos, and Huffman had indeed extracted C_{60} and at Sussex we had come a *very* close second. However Jonathan had extracted a red solution and Ala'a had detected a mass spectrum independently and before the Heidelberg/Tucson (*Nature*) manuscript had arrived. After this Roger had discovered the chromatographic separation of the fullerenes. Tony had detected the much coveted single line (Meijer and Bethune at IBM were also close and with Johnson also observed a single-line NMR spectrum[97]). As a certain English football manager, noted for his "eloquence", in adversity would say—"The lads dun good!"

So in September 1990 some 20 years after the molecule was conceived by Osawa and five years after we had discovered that it could self-assemble, Krätschmer et al. had extracted it and fullerene science was well and truly on its way.

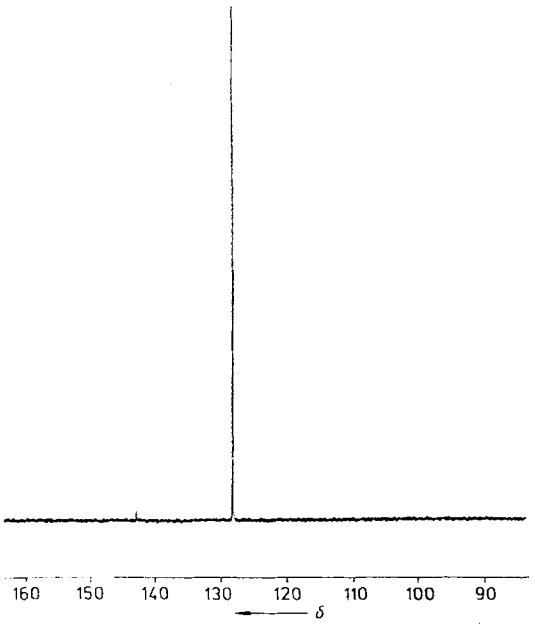

Figure 21. The first NMR trace in which the C_{60} resonance (at $\delta = 143$) was first identified (just!). The strong line at $\delta = 128$ is (rather appropriately) the resonance of benzene. The spectrum was recorded at the University of Sussex on an AMX-500 spectrometer.

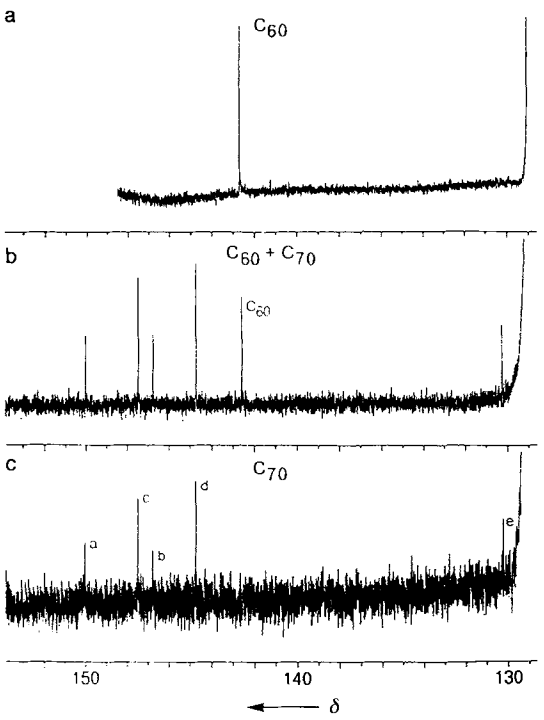

Figure 22. ^{13}C NMR spectra obtained from chromatographically purified samples of soluble material extracted from arc-processed graphite. a) Spectrum of purified C_{60} (magenta fraction), b) spectrum of mixed sample, c) spectrum of purified C_{70} (red fraction) showing five lines as expected for the symmetric egg-shaped molecule (see Figure 12).

Phase V: The New Round World of Fullerene Chemistry, Physics, and Materials Science

After the extraction breakthrough in 1990, the field of fullerene research exploded and now some thousand papers a year are published in the field. Several new research projects, designed to explore the chemical and physical behavior of the fullerenes were launched at Sussex. With Roger Taylor and David Walton fullerene synthetic chemistry became a primary aim.[98] Roger Taylor and others pioneered the extraction of higher fullerenes C_{76}, C_{78}, etc.[31] Spectroscopic studies were carried out with John Dennis and Jonathan Hare and also in collaboration with Sydney Leach and colleagues in Meudon/Orsay. Halogenation studies have turned out to be particularly important and Paul Birkett was able to show that $C_{60}Cl_6$ (Figure 23) can form.[98] These observations which may be considerd to be the fullerene equivalent of *ortho*, *meta*, and *para* direction in benzene have been followed by the creation of some key acylated derivatives. Adam Darwish has probed a wide range of reactions in particular hydrogenation and hydroxylation reactions. Interesting mixed crystalline compounds involving ferrocene and phosphorus have been made and structurally characterized by Jonathan Crane, Wyn Locke, and Peter Hitchcock.[98] Further chemical properties of C_{60} as a synthon, including for instance cycloaddition and metal complexation reactions, have been investigated by Mohammed Meidine, Brian O'Donovan, and Martin van Wijnkoop and solubilization methods have been developed by Huang Shaoming. Colin Crowley and Andy Caffyn have been investigating thermolytic routes to C_{60}. Fragmentation behavior is also being investigated with Perdita Barran, Steve Firth, and Tony Stace (in collaboration with Eleanor Cambell of the Max-Born-Institut in Berlin). These studies followed on from the work of Simon Balm, Richard Hallet, Ken McKay and Wahab Allaf. Cold fluorescence studies are being carried out with Reg Colin, Pierre Coheur, Steve Firth, Michele Carlier (in Brussels), and Eleanor Cambell (in Berlin).

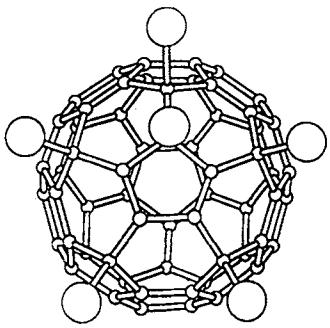

Figure 23. The structure of $C_{60}Cl_6$ [98].

A solid-state chemistry program has been initiated by Kosmas Prassides in which fascinating solid-state dynamics and phase behavior[99] as well as superconducting properties of the metal intercalation complexes have been probed.[100] With Fred Wudl's group, the elegant azafullerenes are under detailed investigation.[101]

On the nanotechnology front some fascinating advances have been made.[102] Collaboration with Morinobu Endo of Shinshu University in Japan has opened up several new avenues in the creation of nanostuctures by pyrolytic methods and possible nanotube growth mechanisms. With Mauricio Terrones, Wen Kuang Hsu, and Jon Hare, studies of the fascinating way that nanostructure creation is governed by metal cluster catalysts are being investigated (with Umberto Terrones in Mexico). Related investigations of these promising routes to nanoscale materials are under way with Thomas Müller, Doug Reid, and Nicole Grobert. Wen Kuang Hsu has observed the amazing result that nanotubes can be obtained by electrolysis.[101] Just as exciting as the new carbon structures are the boron nitride nanotubes. Some of this nanotechnology work is being carried out in collab-

oration with Tony Cheetham and Xing Ping Zhang at UCSB (University of California at Stony Brook) and Laurence Dunne at the University of the South Bank. All in all the way ahead looks exciting as is exemplified by the nanstructure shown in Figure 24, which appears very much like an extra who has escaped from the set of the film Alien II.

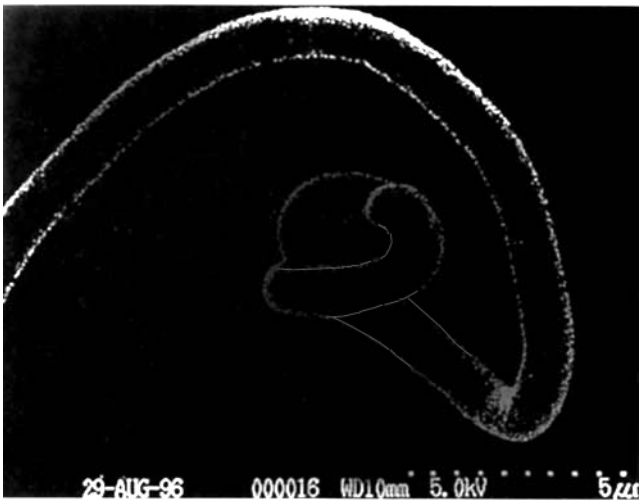

Figure 24. Thermolytically created carbon nanostructure.

Epilogue: The Cosmic and Microcosmic Charisma of the Soccerball

One cannot end any account of the discovery of C_{60} without noting that it has the same structure as a football (or soccerball) and that this led to its original conception. Thus it seems fitting to reproduce (Figure 25)[3] the image from the book by Osawa and Yoshida and point out that much of the world now plays football (or soccer). Furthermore a large number of researchers are studying the peculiar behavior of the ball on a microcosmic scale. Last but not least we should note that, perhaps, the molecules most delightful property lies in the inherent charisma[3,7] which arises from its elegantly simple and highly symmetric structure that is quite unlike any other. It is this charisma that has stimulated delight and fascination for chemistry in young and old alike. Perhaps no image captures the most important quality of C_{60} better than the photograph depicted in Figure 26. It says it all.

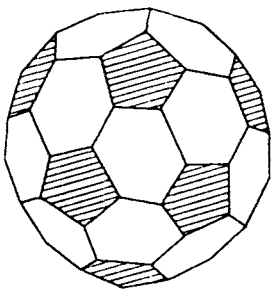

Figure 25. The first image of C_{60} ever published (Osawa and Yoshida [2,3] (taken from ref. [3]).

There are many people to whom I owe deep debts of gratitude in addition to the students, colleagues, and friends who appear in the above text. I thank in particular those students who were not directly involved with C_{60} related studies because much of their work formed a basis to which many ideas may be tenuously traced. The support over the years has come from several sources, mainly the The School of Chemistry and Molecular Sciences of the University of Sussex, SRC, SERC, EPSRC, NATO, The Royal Society, BP (John Cadogan), ICI/Zeneca (Peter Doyle, Mike Hutchinson, Neil Winterton), British Gas, and BOC (Steve Wood), and Alfred Bader.

Discovering the Fullerenes (Nobel Lecture)**

Richard E. Smalley*

It is a thrill for me to be here today and to be the first of three speakers discussing the wonders of the fullerenes, an infinite new class of carbon molecules. My colleagues in this famous photograph (Figure 1) are also thrilled to be here in Stockholm this week to see "Bucky get the Prize". This picture was taken

Figure 1. Photograph of the research group that discovered the fullerenes at Rice University in September of 1985. Standing: Curl, Kneeling in front, left to right: O'Brien, Smalley, Kroto, and Heath.

on September 11, 1985, the day before we sent off the manuscript describing the discovery of C_{60} to the editorial offices of *Nature*[1] (and only a few days after the discovery itself). Every one of the people in that photograph was critically involved in the discovery (with the exception of the one woman walking in the back – we still don't know who that mystery woman was), so you can understand that there is also some sadness in our hearts today. While the chemistry prize this year is for the discovery of the fullerenes, it is given to individuals, and this individual honor can be shared by no more than three. The Nobel committee has done as well as they possibly can with this problem. We understand. But the sadness remains.

On the other hand, there are positive aspects to the limit of three. For example, I have asked what happens in those years when there is only one person receiving an award in physics or chemistry. I was told that you just get one lecture for that prize. Now that I am beginning to appreciate the full impact of having a long lecture from each of the three winners this year in each of the two fields, physics and chemistry, all on the same day and in the same room, I can see that one must set limits somewhere.

This discovery was one of the most spiritual experiences that any of us in the original team of five have ever experienced. The main message of my talk today is that this spiritual experience, this discovery of what Nature has in store for us with carbon, is still ongoing. So the title of my talk is not "The Discovery of the Fullerenes" but rather "Discovering the Fullerenes". Fullerene researchers worldwide are still engaged in this process of discovery.

The sense in which we are still in this process has to do with what the true essence of the 1985 fullerene discovery actually turned out to be. After all, the five people in that happy photograph (Figure 1), brilliant as they all are, were not the ones who first conceived the truncated icosahedron. That was done several thousand years ago. Archimedes gets the credit for it, although one may reasonably suspect that icosahedra had been truncated long before Archimedes. Nor were we the first people to conceive that if you replaced the vertices of that pattern with carbon atoms, and let the carbon do what it wanted to do, that would be an interesting chemical object. That honor had already gone more than a decade before our discovery to E. G. Osawa,[2, 3] the Japanese physical organic chemist who had perceived that carbon in that structure would be aromatic and would therefore probably be stable. And a large part of this honor had been earned even before that by David Jones,[4] who in a wonderfully imaginative piece had conceived closed spheroidal cages made of graphene sheets somehow folded around. A little later, Jones realized that a pentagon would serve nicely as the required defect in an otherwise hexagonal lattice to produce a complex curvature.[5] The notion that C_{60} would be a closed shell molecule with a very large HOMO–LUMO gap, which is a well-appreciated signature of chemical stability, fell to Bochvar, Gal'pern,[6] and Stankevich[7] who actually did the relevant Hückel calculations in Russia well over a decade before we ever got into the game.

The conception of carbon being stable in the form of a truncated icosahedron really wasn't the discovery that is being honored this week. If that were, then Archimedes, Osawa, Jones, and/or one or more of these insightful Soviet scientists should

have gotten the prize. Instead, the discovery that garnered the Nobel Prize was the realization that carbon makes the truncated icosahedral molecule, and larger geodesic cages, all by itself. Carbon has wired within it, as part of its birthright every since the beginning of this universe, the genius for spontaneously assembling into fullerenes. We now realize that all you need to do to generate billions of billions of these objects of such wonderful symmetry is just to make a vapor of carbon atoms and to let them condense in helium. Now we are still in the process of discovering all of the other consequences of the genius that is wired into carbon atoms. It isn't just a talent to make balls. It can also make tubes such as the short section shown in Figure 2.

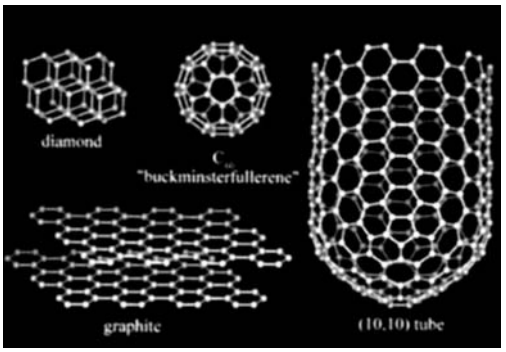

Figure 2. Four perfect crystalline forms of carbon: diamond, graphite, C_{60}, and a short length of a (10,10) fullerene nanotube showing the hemi-C_{240} end cap.

Nearly all of us have long been familiar with the earlier known forms of pure carbon: diamond and graphite. Diamond, for all it's great beauty, is not nearly as interesting as the hexagonal plane of graphite. It is not nearly as interesting because we live in a three-dimensional (3D) space, and in diamond each atom is surrounded in all three directions in space by a full coordination. Consequently, it is very difficult for an atom inside the diamond lattice to be confronted with anything else in this 3D world because all directions are already taken up. In contrast, the carbon atoms in a single hexagonal sheet of graphite (a "graphene" sheet) are completely naked above and below. In a 3D world this is not easy. I do not think we ever really thought enough about how special this is. Here you have one atom in the periodic table, which can be so statisfied with just three nearest neighbors in two dimensions, that it is largely immune to further bonding. Even if you offer it another atom to bond with from above the sheet—even a single bare carbon atom, for the matter—the only result is a mild chemisorption that with a little heat is easily undone, leaving the graphene sheet intact. Carbon has this genius of making a chemically stable two-dimensional, one-atom-thick membrane in a three-dimensional world. And that, I believe, is going to be very important in the future of chemistry and technology in general.

What we have discovered is that if you just form a vapor of carbon atoms and let them condense slowly while keeping the temperature high enough so that as the intermediate species grow they can do what it is in their nature to do, there is a path where the bulk of all the reactive kinetics follows that goes to make spheroidal fullerenes. Now it turns out that in addition to this most symmetric of all possible molecules, C_{60}, and the other fullerene balls, it is possible by adding a few percent of other atoms (nickel and cobalt) to trick the carbon into making tubes. Of all possible tubes there is one tube that is special.[8] It is the tube shown in Figure 2, the (10,10) tube. We are beginning to understand that what causes this tube to be the most favorite of all tubes is also wired within the instruction set of what it means to be a carbon atom. The propensity for bonding that causes C_{60} to be the end point of 30–40% of all the reactive kinetics, leads as well to this (10,10) tube. This detour on the road that otherwise leads to spheroidal fullerenes is taken if you somehow (with cobalt or nickel atoms) frustrate the ability of the open edge to curve in and close. The metal atoms prevent by local annealing the addition of the seventh, eighth, ninth pentagons, and insure by judicious choice of temperature and reaction rate that the growing tublet can anneal to its most energetically favored form.

The object shown in Figure 3 depicts one of the more fascinating new opportunities in the future of the fullerenes. It is a short

Figure 3. Derivatized section of a (10,10) fullerene nanotube with one end open.

piece of the (10,10) tube with chemically derivitized ends. One end is closed with a hemifullerene dome (actually one half of a very special fullerene, icosahedral C_{240}). The other end is intentionally left open. Since the closed end contains pentagons and is accordingly more reactive than the smooth, all-hexagon side of the nanotubes, there are techniques such as boiling in nitric acid[9] for eating the closed ends off of these tubes. We also know that if you take such a tube and put it in an oven and heat it to 1200 °C, it will spontaneously close back again. These ends, regardless of whether they are closed or open, are directly amenable to the formation of excellent C–O, C–N, or C–C covalent bonds[10] to attach nearly any molecule, enzyme, membrane, or surface to the end of the tube. You could attach one or several such objects (let's call them A) to the upper end and some other objects on the bottom (B). What is so stunning about this molecule, unlike any other molecule we have ever had before in chemistry, is that with this object "A" and "B" will communicate with each other by true metallic transport along the tube. The (10,10) tube is a quantum waveguide for electrons.

The band structure of graphene, the individual flat sheet of graphite, is that of a zero gap semiconductor. The valence band and conduction band meet at a point at the end of the Brillouin zone. There is a node in the density of states at Fermi energy,

and accordingly it is not a very good conductor. In my youth on first hearing that graphite was a poor conductor—more like lead than gold—I had thought that the problem must be due to some sort of original sin that the carbon had made. The valence electrons of carbon tended to be localized, and were not freely able to move from one carbon atom to another through an extended sheet. In fact that is not the problem. The π electrons are perfectly itinerant in the graphene sheet, just as they are perfectly itinerant in the aromatic ring of benzene. In fact, it is the freedom of the electrons to move around the ring that gives the special chemical stability to aromatic molecules. The trouble with the electrical conductivity is that when you calculate the band structure of the hexagonal graphene sheet, by symmetry, there is a node in the density of states at the Fermi energy. Even if you were somehow able to replace every one of the carbon atoms in the hexagonal lattice with a gold atom, the band structure would still look the same. It is the symmetry of the hexagonal lattice that is the problem, not the itinerancy of the π electrons of carbon.

But now we realize that there is one (but only one) answer to this problem of making a metal out of pure carbon. If you take the graphene sheet and cut out a thin strip, curl it along it's length to form a long cylinder, and seal up the dangling bonds together to form the (10,10) tube (Figure 2), the very symmetry that had been your enemy in preventing metallic behavior from the flat lattice, now becomes your friend. The symmetry of this tubular hexagonal lattice now insists that there will be two bands that cross at the Fermi energy, approximately two thirds of the way across the Brillouin Zone, (Figure 4). In addition, the

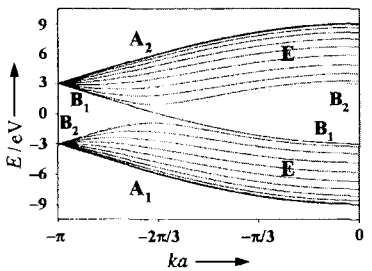

Figure 4. Electronic band structure of a (10,10) fullerene nanotube calculated with tight binding methods, using zone-folding from the band structure of an infinite two-dimensional graphene sheet [59]. The two bands that cross the Fermi energy at $ka = 2\pi/3$ have different symmetry, and guarantee that the tube will be a metallic conductor. k = crystal momentum, a = unit cell length.

cohesive rigidity of the σ-bond framework of the graphene sheet prevents the metallic π electrons from engendering a Peierls instability that normally plagues all such one-dimensional conductors.[11] The (10,10) fullerene tube, and all (n,n) tubes in general, will be a molecular wire that is simultaneously a good metallic conductor, and a good molecule, maintaining its structure and conductivity even when exposed to air and water in the real world.

I believe that in the future of chemistry, we are likely to see a vast new set of metallic fullerene molecules such as that shown in Figure 3 readily available from chemical supply houses. Imagine what the impact could be. Essentially, every technology you have ever heard of where electrons move from here to there, has the potential to be revolutionized by the availability of molecular wires made up of carbon. Organic chemists will start building devices. Molecular electronics could become reality.

This is where the fullerenes appear to be leading at the moment. One does not get a feeling that we are over with this discovery process yet. There may be many more wondrous properties of this one little atom in the periodic table than we have yet to appreciate.

Still there was a particular discovery that we celebrate this week. There was something about September of 1985. What was that? How did that happen? Since that original discovery we have been involved in a little bit of what I like to call the archeology of the buckyball: looking back in the written and oral history trying to decide what the roots of the fullerene discovery were. This discovery is principally about the way that carbon condenses, it's genius for forming clusters.

It has long been known that the carbon has a special ability to cluster in the gas phase at high temperatures. Unlike every other refractory element in the periodic table, the vapor of carbon in equilibrium with its solid at temperatures in the 3000–4000 K range is dominated by clusters, C_n, with substantial abundance of species as high as C_{15}. The first evidence of this extends back to early research on nuclear fission products by Hahn and Strassman in Germany.[12] They noticed that carbon cluster ions up to C_{15}^+ were produced in a high frequency arc with a graphite electrode, the arc being used for elemental analysis by mass spectrometry;[13] similar observations were made in the US about this same time in research associated with the Manhattan Project during the second world war.[14] By the early 1950s it was clear that there were sufficient numbers of small carbon clusters at equilibrium in the vapor to have a major affect on the measurement[15, 16] of the heat of formation of C(gas), one of the most important constants in chemical thermodynamics. In 1959 Pitzer and Clementi[17, 18] made the first serious quantum calculations of the structures responsible for this behavior in the vapor up to about 20 atoms, and concluded that they had the form of linear chains for C_2 up to about C_{10}, and above that they took the form of monocyclic rings—little 'Hula Hoops' of pure carbon.

Although it was not commented on at the time, this is quite a remarkable result. Here carbon is able to make clusters that are so stable that they are the dominant species—substantially more abundant than C_1—in the gas phase even at a temperature of 3000–4000 K, and they do this with only a coordination number of two! All other refractory elements such as platinum, tungsten, or tantalum achieve their high cohesive energy by a close packing arrangement within the bulk crystal or liquid, with coordination number of 8 to 12. Even though the clusters of these metals in the gas phase also adopt compact structures,[19] arranging as many atoms around each other in three dimensions as possible, they still do not have a sufficiently high cohesive energy to be abundant in the equilibrium vapor. Instead the vapor of these metals is almost completely monatomic. Above 1000 K the vapor in equilibrium with pure condensed phase of every element in the periodic table—except carbon—is dominantly either monatomic or diatomic. But here is carbon making so many of these large clusters that it throws off the measures of heat of formation, and in a show of chemical bonding *chutzpah*, doing this with two of it's three available dimensions for bonding "tied behind its back."

Looking back now at the data available in the literature on gas phase clusters of pure carbon up to mid 1984, it is clear that there was no suggestion in the experiments of anything more interesting going on than these one-dimensional clusters.[20, 21] All the data appeared to be well-explained by the model of linear chains and monocyclic rings, and the cluster abundance dropped off so severely by the time the clusters were in the mid-twenty-atom size that no one was led to speculate what would happen as the clusters grew larger. In light of what we now know about the fullerenes, this would have been a very fruitful line of speculation. After all, at some point as the clusters grew larger they would certainly have to start trying structures that were two- or three-dimensional. What would these look like? Consideration of the dangling bond energies could reasonably have led to the speculation that graphene sheets would form but curl up to closed cages.

But, as far as we can determine, no such speculation ever occurred. While in the mid 60's Jones[4] had the notion that graphene sheets could curl up to make "hollow molecules," Osawa[2] had already conjured up the notion of carbon in a soccer ball structure in early 1970, and Gal'pern[6] had completed the first of many Hückel calculations showing that it would be a closed shell molecule with a large HOMO–LUMO gap in 1973, but no one ever suggested these objects could form spontaneously in a condensing carbon vapor. The mystery of the buckyball was never so much that it would be a stable molecule once formed. After all, it violates no rules of organic chemistry. The secret laying there to be discovered is that part of carbon's "birth right" is the genius to form a chemically passive two-dimensional surface, to self-assemble fullerenes in general, and C_{60} in particular and in sensationally high yield, out of the chaos of a carbon vapor at thousands of degrees.

To trigger this realization, new data turned out to be necessary. Data on what happened when you allowed a carbon vapor to become supersaturated, allowed it to begin to condense, and the small clusters that were in equilibrium with the solid began to grow larger. That data had to wait for the invention of a new technique, something that would enable one to study the properties of carbon clusters in detail as they grow through the size range of 40 to 100 atoms where the dimensionality of the bonding does, in fact, increase from 1 to 2. It had to wait for the laser-vaporization cluster beam methods of the 1980s.

The laser-vaporization supersonic cluster beam technique was originally developed at Rice University in 1980–1981 as a means of studying clusters of virtually any element in the periodic table, including highly refractory metals[22–26] and semiconductors such as silicon[27] and gallium arsenide.[28] The objective of this line of research was to explore the behavior of matter intermediate in size between atoms and bulk crystals. It grew out of decades of development of atomic and molecular beams, and in particular the development of seeded supersonic molecular beams as a means of "freezing out" the vast number of rotational and vibrational excitations which otherwise preclude detailed study of polyatomic molecules.[29–32] In addition to enabling the study of common chemically stable polyatomic molecules, it was possible to generate supercold van der Waals clusters of these molecules with each other, and with other species, including at these ultralow temperatures even helium.[33] By the use of intense pulsed laser irradiation within the supersonic nozzle it was possible to study highly reactive fragments of molecules, free radicals.[34] Extension of the supersonic beam technique to seeded beams of refractory atoms and clusters was a direct outgrowth of this early work on free radicals.

Once beams of refractory clusters were available, a vast new area of research was opened, for each cluster may be thought of as a nanoscale crystalline particle that has a surface (in fact, most of it is surface). Supersonic metal cluster beams thereby provided a route to a new sort of surface science.[35] In my research group at Rice we were very heavily engaged in developing this new science. We developed and applied new methods for studying the electronic structure of the clusters by one- and two-photon laser photoionization with time-of-flight mass spectral detection,[25, 36, 37] photodissociation, and photodepletion spectroscopy,[38–40] and ultraviolet photoelectron spectroscopy.[41] In order to study the surface of the nanoscale clusters, we developed techniques using a fast flow reactor attached to the end of the supersonic nozzle.[42–44] We developed a variety of methods involving charged ions of the clusters levitated in a magnetic field and probed by ion cyclotron resonance spectroscopy,[45–47] etc. The early 1980s were a very busy, very fruitful time in this research group at Rice University, and much was learned.

The laser vaporization supersonic beam source and the associated probe techniques that we developed to study the 2–200 atom metal and semiconductor clusters was effectively a new sort of microscope. It allowed one to "see" something of the nature of nanoscopic aggregates of atoms in a way that was entirely new, and very poignant. Whatever we measured for the cluster in the supersonic beam, we knew that it was the true property of the cluster traveling free in space. We developed the technique in order to bring a sort of intellectual tension to surface science: to make measurements so fundamental that theorists stayed awake at night trying to understand them. Although we had no notion of it at the time we were engaged in this enterprise in the early 1980s, we were building the instrument and the line of research that would discover the fullerenes. All one had to do is put carbon in this new "microscope", adjust the focus a little, and "see" the fullerenes revealed plainly for the first time.

As it happened, we at Rice were not the first to put carbon into the new microscope. In 1984 a group headed by Andrew Kaldor at Exxon used such an apparatus (actually one that had been designed and built at Rice) in a study of carbon clusters that was motivated by the desire to study coke buildup on reforming catalyst. Now, in a famous mass spectrum reproduced here as Figure 5, carbon clusters were evident extending out beyond 100 atoms,[48] and it was immediately clear that a whole new world of interesting carbon clusters could exist that had never been seen before.

Three distinct regions characterized the mass spectrum: first the small clusters, containing fewer than 25 atoms, consisting of the chains and monocyclic rings[49] so well known from the earlier studies; second a new region between about 25 and 35 atoms in which few species of any sort were observed—a region that the Rice group came to call the "forbidden zone"; and, third, an even-numbered clusters distribution extending from the high 30s to well over 150 atoms. By early 1984 the laser-vaporization supersonic cluster beam technique had been

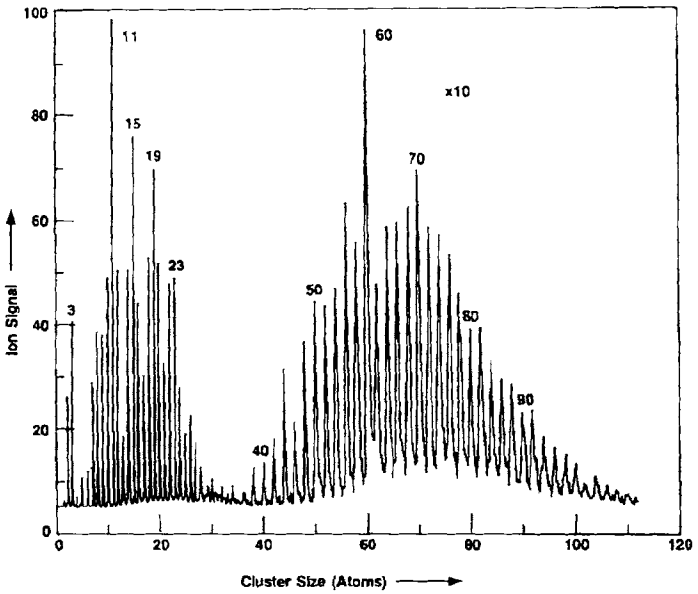

Figure 5. Mass spectrum of carbon clusters in a supersonic beam produced by laser vaporization of a carbon target in a pulsed supersonic nozzle operating with a helium carrier gas. The wide distribution of even-numbered carbon clusters starting near C_{40} and extending to over C_{100} is due the fullerenes. This was the first published experiment that revealed the fullerene cluster distribution, although it was not appreciated as such at the time. Reproduced with permission of the authors [48].

used to study clusters broadly throughout the periodic table, and many "magic number" cluster distributions had been found and studied,[35] but nothing remotely like this even-numbered distribution of carbon had ever been seen for any other element. Today this is still true: carbon is unique.

The even-numbered distribution seen by the Exxon group was due to the fullerenes. I suspect the members of that original group at Exxon still regret that they did not consider in more depth why the peak for C_{60} appeared to be about 20% more intense than its neighbors. But to be fair, at the time neither did we. This result of the Exxon group was widely known in the burgeoning metal and semiconductor cluster research world by the summer of 1984. I saw the result at a meeting, and discussed it with Andy Kaldor at some length. Bob Curl saw it. Harry Kroto saw it. Wolfgang Krätschmer and Donald Huffman saw it. None of us stopped to think just what might be the reason C_{60} was a little more prominent than the other even numbered clusters. It did not stand out sufficiently above its neighbors to attract notice. As it turned out, the Exxon group simply had not "focussed" the new cluster beam microscope carefully enough.

At nearly the same time another research group, including one of my former graduate students, Michael Geusic, had built a supersonic cluster beam apparatus as well, and was engaged in early experiments with mass-selected semiconductor cluster ions.[50] Having heard about the Exxon work, they put carbon in the apparatus, also observed the mysterious even-numbered large cluster distribution, and even selected out C_{60}^+ for a photofragmentation experiment. But they, too, failed to experiment sufficiently with the nozzle conditions to appreciate the potential preeminence of C_{60}.

The necessary "focussing" of the new supersonic cluster beam "microscope" was finally performed in my laboratory at Rice in the September of 1985.[1, 51] Now the supremacy of C_{60}, was made clear. In thinking about what this all meant, we finally saw that C_{60} must be a closed spheroidal cage. No other explanation was consistent with the observed facts. The realization that all the even-numbered carbon cluster distribution was due to carbon in the form of hollow geodesic domes—fullerenes—came within a month, as a result of reactivity studies of these clusters[52] using the fast flow reactor on the end of the supersonic nozzle. Soccer ball C_{60} quickly became a sort of "Rosetta Stone" leading to the discovery of a new world geodesic structures of pure carbon built on the nanometer scale.

This discovery episode has by now been so extensively covered in articles,[53, 54] monographs,[55, 56] and television documentaries, that there is little reason to repeat the details here. We succeeded where two other groups had failed for at least two reasons. First, we had evolved a better version of the "microscope". We had been the group to develop the supersonic cluster beam technique in the first place, and we were still leading the subsequent development and elaboration of its capabilities. The original apparatus, known affectionately by the students as "AP2" (Figure 6), was able to handle much larger gas flows,

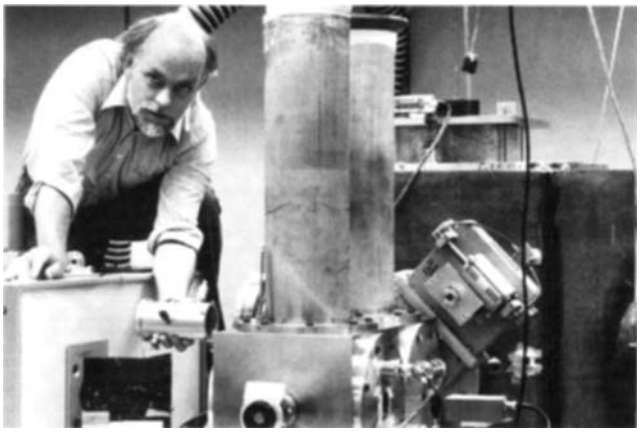

Figure 6. Photograph of the author climbing around on the top of a section of AP2, the supersonic laser-vaporization cluster beam apparatus that enabled the discovery of C_{60} and the fullerenes in the fall of 1985.

and had a more advanced supersonic nozzle design than the machines of either of the other groups. Particularly important was the development of the rotating disc design for the cluster beam source that we had just recently completed for our semiconductor cluster work with silicon, germanium,[27] and gallium arsenide.[28] As part of this project, it was necessary to anneal the semiconductor clusters in the supersonic nozzle source as much as possible. To simplify interpretation we need conditions so that the most energetically stable geometrical form would dominate the cluster distribution. For this reason the nozzle was fitted with a variety of down-stream flow restrictors to form what we called the "integrating cup" (Figure 7).

It was our experience with the extra "chemical cooking" achieved by this device that made us appreciate that it was cluster chemistry that differentiated C_{60} from the others. The relative absence of further up-clustering reactions was, we realized, what ultimately made the C_{60} peak stand out over 50 times more intensely than any other. And it was in thinking about how 60 carbon atoms could possibly avoid reactive edges, that we were led to the conclusion that C_{60} is a truncated icosahedron.

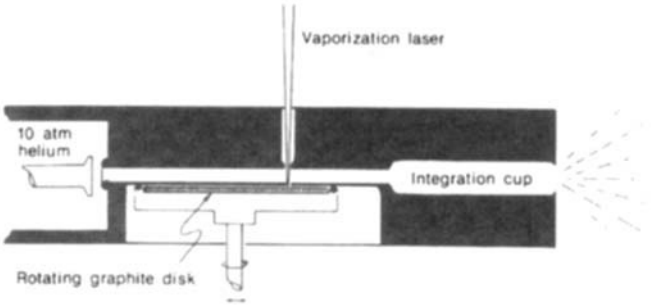

Figure 7. Schematic cross-sectional drawing of the supersonic laser-vaporization nozzle source used in the discovery of the fullerenes. Note the section labeled "integrating cup". Cluster "cooking" reactions in this zone were responsible for the C_{60} cluster becoming over 50 times more intense than any other cluster in the nearby size range. These up-clustering reactions with small carbon chains and rings reacted away nearly all clusters except for C_{60}, which because of its perfect symmetry survived.

The second reason I believe we succeeded was, in a word, karma. With Bob Curl in our collaboration on semiconductor clusters, we had evolved one of the most intellectually demanding and penetrating styles of research I have ever witnessed in any research group. Sean O'Brien had evolved just the right version of the cluster nozzle to handle the difficulties of dealing with semiconductor discs, and Jim Heath had developed an amazing talent for making "science happen" on the machine. When Harry Kroto came, his intensity and scientific background blended in perfectly. Working with the students mostly in late afternoons and at night, and in daily marathon conversations with me, he kept the focus of our minds on the results coming out of AP2, under the hot hands of Heath and O'Brien. One way or another, over the years, each member of the team had paid the dues required to deserve to be there for the discovery of the fullerenes during those wonderful days in September 1985.

Contrary to most written accounts, I do not believe the discovery of the fullerenes had much to do with questions of astrophyiscs, such as the mechanism of formation of interstellar carbon molecules. While this was certainly what brought Kroto to Texas, and this was without contest the reason we first put carbon into AP2 in preparation for his visit, in the end the connection of this line of research[57, 58] to the fullerene discovery was casual, not causal. The discovery of C_{60} and the fullerenes would have been made by AP2 or some other such instrument within a year or two in any event. Two other groups had already put carbon in a supersonic cluster beam machine for reasons that were much more mundane. At Exxon, as mentioned earlier, their principal concern was to understand carbon buildup on catalysts, while at AT & T Bell Laboratories the motivation derived from their long-term interest in semiconductors and the nanometer scale.

The notion that the discovery of the fullerenes came out of research into the nature of certain molecules in space is highly appealing to scientists. It is hard to think of any line of research that is less likely than interstellar chemistry to have some practical, technological impact back here on Earth. So if fullerenes turn out to lead to the technological wonders that some people (like me) believe are in our future, then perhaps one can argue that *any* research project could get lucky too, no matter how irrelevant to worldly problems it may currently seem. I have argued this way in the past, and I still believe there is some sense to it—but only a little. In fact, the fullerenes were discovered as a result of decades of research and development of methods to study first atoms, then polyatomic molecules, and ultimately nanometer-scale aggregates. It was well-funded research that at nearly every stage was justified by its perceived relevance to real world technological problems. To a great extent, many of these earlier bets as to the worldly significance of fundamental research actually paid off.

While it is fun to think about the wonderful role of serendipity in the story, one should also spend a bit of time comprehending the inevitability of the discovery as well. The only character of true genius in the story is carbon. Fullerenes are made wherever carbon condenses. It just took us a little while to find out.

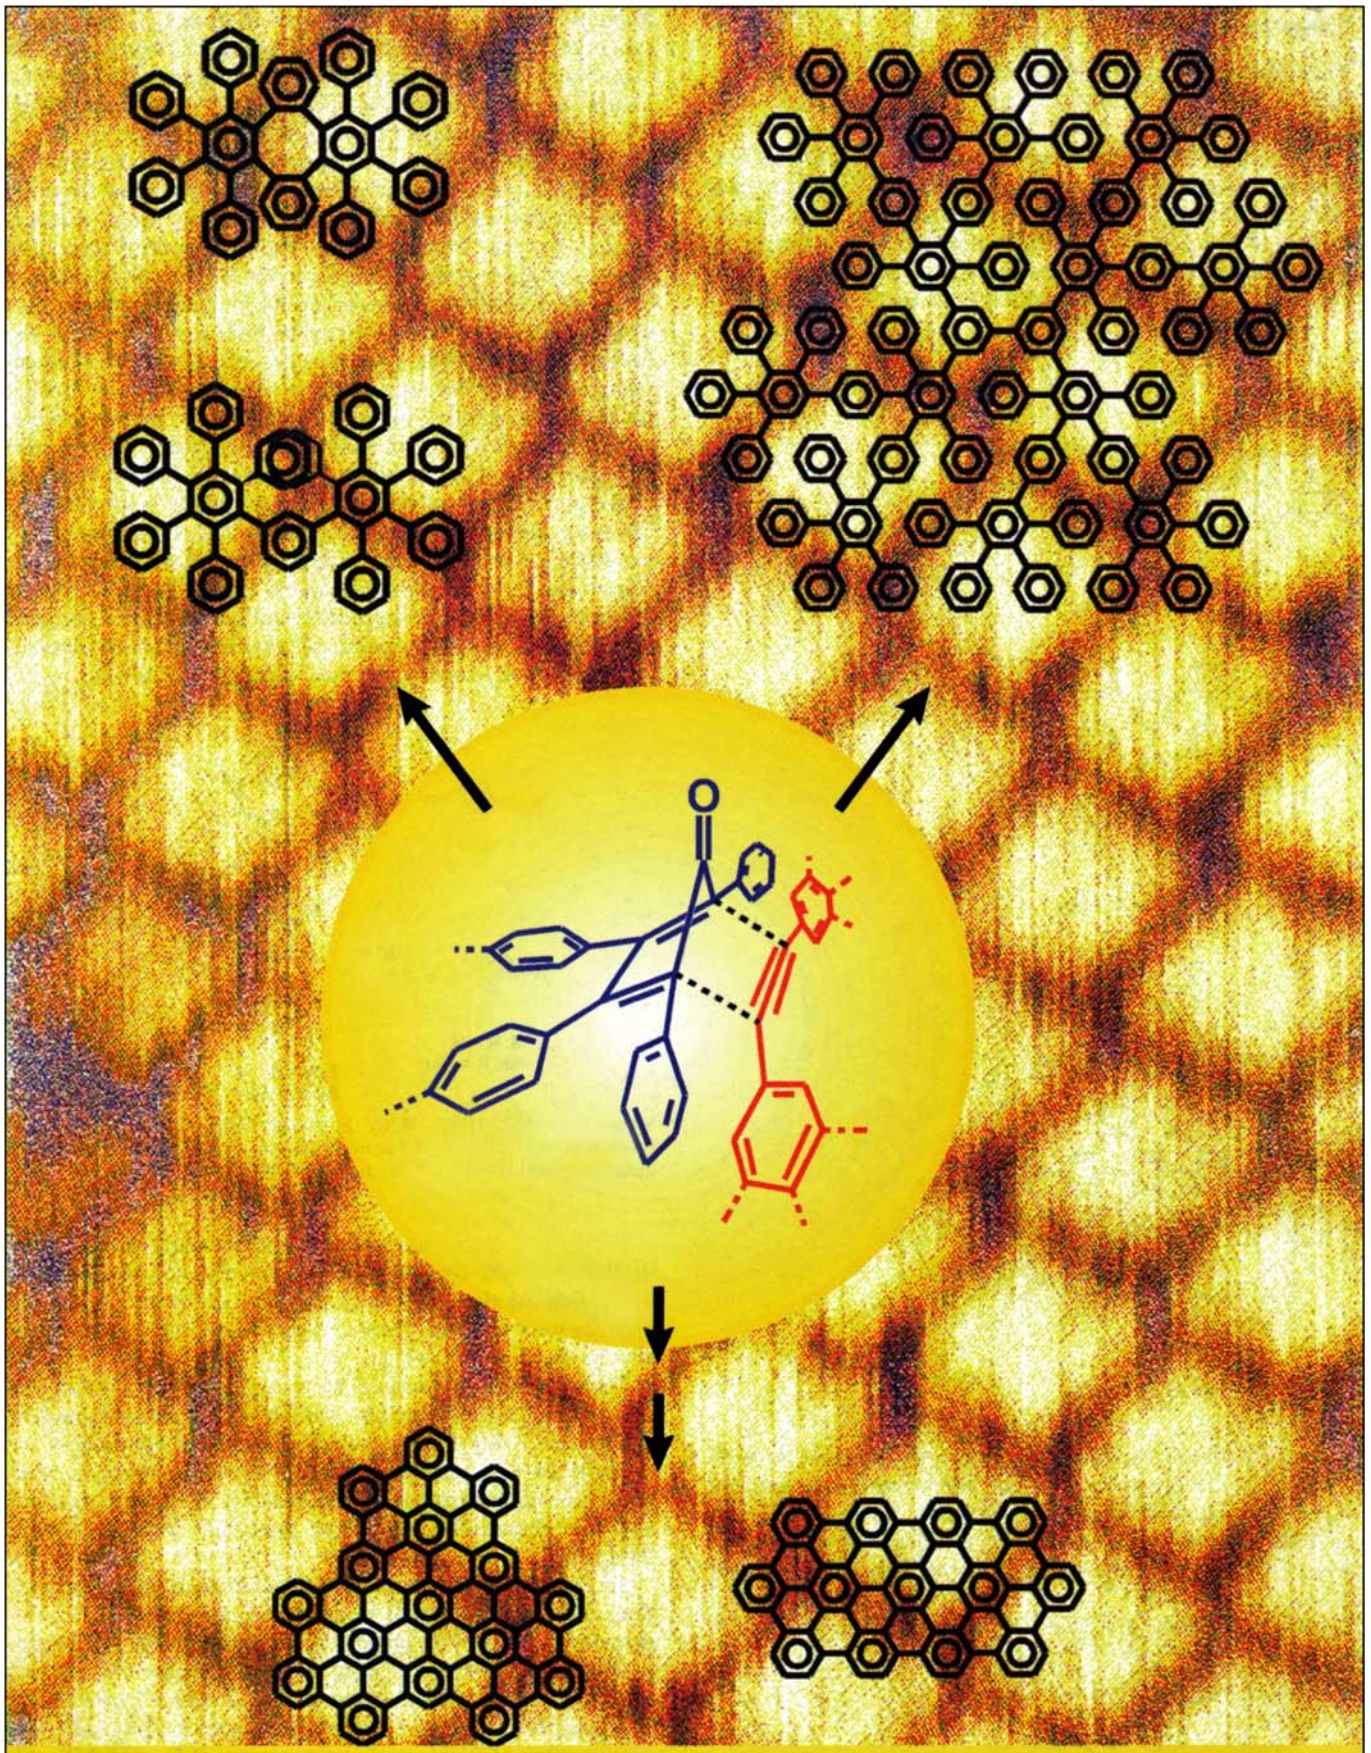
Deposition of Data from X-Ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

Prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data base, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data bases will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data base within two working days after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

This is now the uniform procedure for manuscripts submitted to the journals *Advanced Materials, Angewandte Chemie, Chemische Berichte/Recueil, Chemistry—A European Journal*, and *Liebigs Annalen/Recueil*.



Diphenylacetylene derivatives react with tetraphenylcyclopentadienone to form oligo- and polyphenylenes (top) as well as polycyclic arenes (bottom). Background: An STM image (R. Strohmaier, Stuttgart) of a polycylic arene synthesized by this method. K. Müllen et al. report more on this "graphite chemistry" on the following pages.

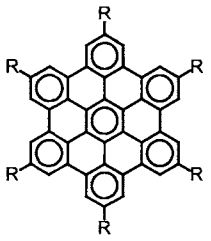
From Hexa-*peri*-hexabenzocoronene to "Superacenes"**

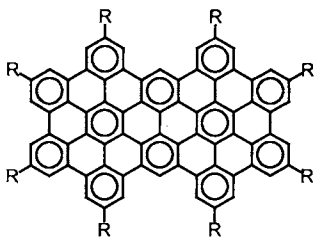
Vivekanantan S. Iyer, Mike Wehmeier, J. Diedrich Brand, Menno A. Keegstra, and Klaus Müllen*

We recently synthesized soluble derivatives of hexa-*peri*-hexabenzocoronene (**1**) by cyclodehydrogenation.[1] Compounds such as **1** are building blocks for supramolecular architectures; thus **1a** shows a stable discotic mesophase with a hexagonal superstructure over a wide temperature range[2] and forms monomolecular layers on suitable substrates.[1]

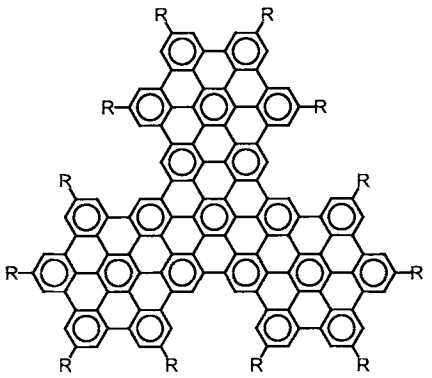


1: R = H

1a: R = *n*-$C_{12}H_{25}$



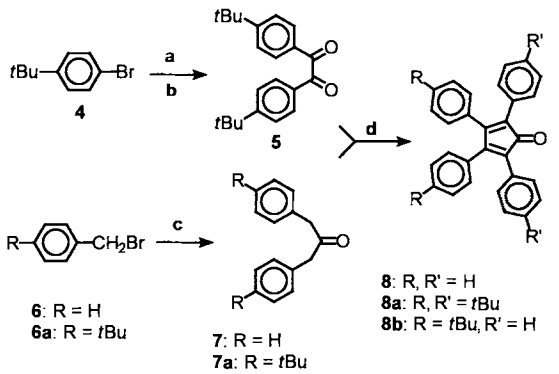
2: R = H, **2a**: R = *t*Bu



3: R = H, **3a**: R = *t*Bu

A key question concerns the change in the two- and three-dimensional superstructures upon further increasing the size and varying the periphery of the disc molecules. Their shape is particularly important when attempting to achieve densely packed layers on surfaces.[3] Here we outline a general synthetic strategy and disclose the syntheses of some extremely large polycyclic aromatic hydrocarbons (PAHs) derived from **1**. If, from a design point of view, one considers the hexagonal structure of **1** as "superbenzene", fusion reactions of **1** can lead to various homologues such as "supernaphthalene" (**2**), "supertriphenylene" (**3**), or the "phenalenyl" framework **17**.[4]

Our synthesis of PAHs is based on two steps: 1) construction of a soluble polyphenylene precursor of well-defined structure with a close spatial arrangement of the phenyl rings, which is similar to the framework of the target molecule, and 2) planarization of this precursor to the PAH by intramolecuar cyclodehydrogenation. Whereas cyclotrimerization of substituted diphenylacetylenes is restricted to PAH precursors with sixfold symmetry,[6] Diels–Alder reaction of tetraphenylcyclopentadienones with diarylacetylenes is a well-established method for the construction of polyaryl compounds.[7] By this process, each Diels–Alder reaction (followed by extrusion of CO) adds five phenyl rings to an existing alkyne in a one-pot reaction. Therefore, the task of designing the precursor is simplified to choosing the right alkyne. It appears that the known **10**[10] would be a suitable precursor to **2**. Alkyl substitution is a key step towards the synthesis of soluble PAHs. The 1,2-diketone synthesis by Mueller-Westerhoff[8] and our improved synthesis of 1,3-diarylacetones[9] expedite the synthesis of alkyl-substituted tetraphenylcyclopentadienones (Scheme 1, Table 1).



Scheme 1. a) *n*BuLi/THF/ −78 °C; b) 1,4-dimethylpiperazine-2,3-dione, 60% (two steps); c) $[Fe(CO)_5]$ (0.5 equiv)/NaOH/CH_2Cl_2/H_2O/5 mol% dodecyltrimethylammonium bromide, 65%; d) KOH/EtOH/reflux/3 h, 90–95%.

Diels–Alder reaction of alkyne **9** with two equivalents of **8** or **8a** resulted in the corresponding polyphenylene compounds **10** and **10a**, respectively, in nearly quantitative yields. Similarly, **12** and **12a** were obtained from triyne **11** and three equivalents of **8** or **8b** (Scheme 2, Table 1).

Triyne **15** was synthesized by trimerization of 3-bromoacetophenone (**13**; commercially available) with tetrachlorosilane in ethanol[11] followed by palladium-catalyzed coupling of tribromide **14** with phenylacetylene. Diels–Alder reaction of **15** with three equivalents of **8** or **8a** resulted in the precursors **16** and **16a**, respectively, in greater than 90% yield (Scheme 3, Table 1).

Similar to our results from the cyclodehydrogenation reactions of hexaarylbenzenes to give derivatives of **1**,[1,12] cyclodehydrogenation of the unsubstituted precursors **12** and **16** proceeded smoothly with copper(II) trifluoromethane sulfonate and aluminum(III) chloride to give the desired planar PAHs **17** and **3**, respectively (Scheme 4), which were identified by laser-desorption time-of-flight mass spectrometry (LD-TOF-MS; **17**: $M^+ = 1183\ g\,mol^{-1}$; **3**: $M^+ = 1633\ g\,mol^{-1}$). Cyclodehydrogenation of **10** with copper(II) chloride and aluminum(III) chlo-

Scheme 4. a) $CuCl_2$/$AlCl_3$/25 °C/CS_2, 1 d; *t*BuLi (excess), H_2O, >90%; b) $FeCl_3$/CH_2Cl_2/2–3 h, 30% (**2a**), 50% (**3a**), >80% (**17a**); c) copper(II) trifluoromethane sulfonate/$AlCl_3$/25 °C/CS_2/14 d, >90%.

ed **2** was again identified by LD-TOF-MS ($M^+ = 891\ g\,mol^{-1}$). Extensive attempts to dissolve (in high-boiling solvents or ionic liquids)[13] or sublime (under ultra-high vacuum)[14] the cyclized planar compounds for purification were unsuccessful.

To obtain soluble analogues of **2**, **3**, and **17** we prepared the *tert*-butyl precursors **10a**, **16a**, and **12a**. The latter was derived from cyclopentadienone **8b**, and **10a** and **16a** from **8a**. Cyclizations of all precursors were carried out with iron(III) chloride as the oxidizing agent. Due to the HCl formed in the course of the reaction, the expected products were invariably obtained together with chlorinated, cyclized products. Nevertheless, it was possible to isolate the non-chlorinated, fully cyclized products from these mixtures. Compound **2a** was isolated from the reaction mixture after reductive work-up (treatment with water/methanol followed by 5% aqueous Na_2SO_3) and multiple precipitation from dichloromethane (yield about 30%). Likewise, **3a** was isolated in about 50% yield.

Whereas **2a** and **3a** are slightly soluble in many solvents, **17a** is insoluble. Presumably the six *tert*-butyl groups are not enough to solubilize this large, planar PAH. UV spectra of **2a** and **3a**, recorded in tetrachloroethane, are characterized by broad absorptions from 320–500 tailing to 530 nm (Figure 1). Attempts

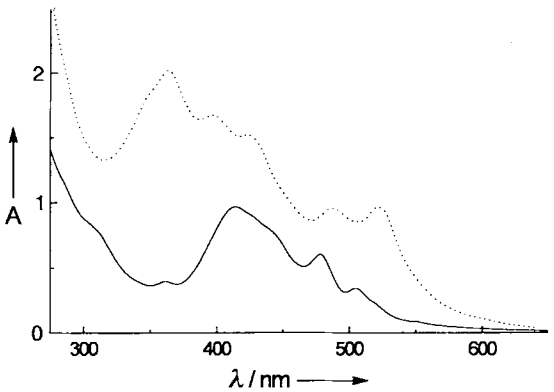

Figure 1. Absorption spectra of **2a** (solid line) and **3a** (dotted line) recorded in 1,1,2,2-tetrachloroethane.

to measure ^1H NMR spectra of **2a** and **3a** are hampered by poor solubility in a wide range of deuterated solvents. For example, **2a** has a solubility of less than 0.1 mg per 10 mL in [D_4]*o*-dichlorobenzene at 150 °C.[16]

Using the design principles presented in the introduction it is possible to envisage even larger PAH structures such as the hexagonal C_{222} hydrocarbon **21**. However, this extension meets with problems due to the lack of appropriate methods for structural proof. Triyne **18** undergoes Diels–Alder reaction with two equivalents of tetraphenylcyclopentadienone in diphenyl ether at 190° exclusively at the outer, sterically less encumbered acetylene units to give **19** (yield 66%; Scheme 5). In spite of the voluminous pentaphenyl substituents at the triple bond of **19**, its cyclotrimerization in dioxane proceeds smoothly to form **20** in 71% yield.

The soluble, fully characterized hydrocarbon **20**, which contains 37 benzene rings, serves as a precursor for the C_{222} graphite unit **21**. Treatment of **20** with aluminum(III) chloride and copper triflate in carbon disulfide affords a black solid, which is insoluble in all common solvents. Monitoring the intramolecular cyclodehydrogenation by LD-TOF-MS reflects the loss of hydrogen atoms by the formation of a broad signal in the mass range expected for **21**. However, signal broadening

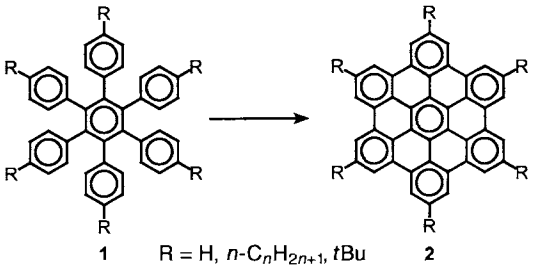
[16] Many other high-boiling solvents were tried, but the highest solubility (which was not enough to obtain a ^1H NMR spectrum) was observed for [D_4]*o*-dichlorobenzene.

Polycyclic Aromatic Hydrocarbons by Cyclodehydrogenation and Skeletal Rearrangement of Oligophenylenes**

Markus Müller, Vivekanantan S. Iyer, Christian Kübel, Volker Enkelmann, and Klaus Müllen*

Polycyclic aromatic hydrocarbons (PAHs) are becoming increasingly important in the areas of molecular electronics and optoelectronics. They are also of theoretical interest as models for graphite.[1, 2] We showed that the oxidative cyclodehydrogenation of oligophenylene precursors, for example the cyclization of hexaphenylbenzene (HPhB, **1**) to hexa-*peri*-hexabenzocoronene (HBC, **2**; Scheme 1), can serve as a mild method for

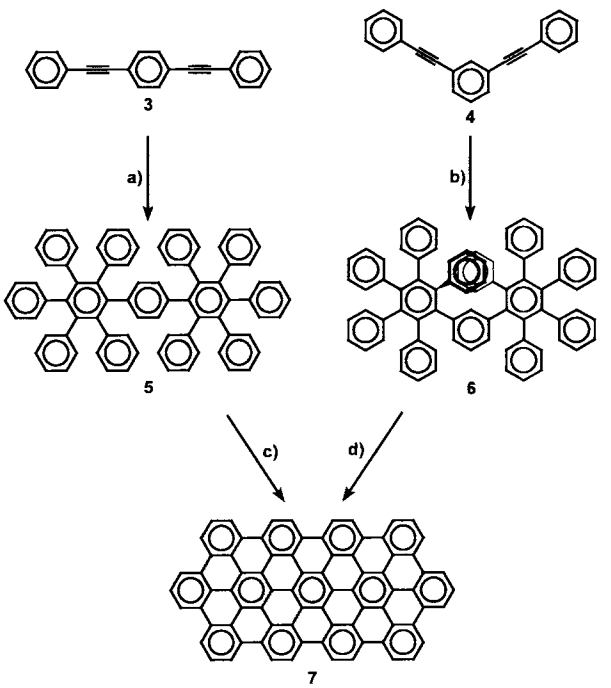


Scheme 1. Oxidative cyclodehydrogenation of hexaphenylbenzene (HPhB, **1**) to hexa-*peri*-hexabenzocoronone (HBC, **2**).

the synthesis of PAHs in high yields.[3, 4] In this case the oligophenylenes must render planarization to PAHs possible by elimination of hydrogen and formation of C–C bonds.

The work reported here involves oligophenylenes in which planarization is hindered by spatial superposition of phenyl units or by strained rings other than six-membered rings. For the intramolecular cyclodehydrogenation, surprisingly smooth skeletal rearrangements can lead to planar PAHs from "non-planarizable" oligophenylenes by removal of steric strain.

The oligophenylene derivative **6**, which is a positional isomer of oligophenylene **5**,[5] was obtained from 1,3-di(phenylethynyl)benzene (**4**) by double Diels–Alder addition with 1,2,3,4-tetraphenylcyclopenta-1,3-dienone (tetracyclone) and extrusion of carbon monoxide (Scheme 2). The crystal structure of **6** (Figure 1) shows clearly the spatial superposition of the two phenyl units directed towards the center of the molecule.[6]



Scheme 2. a) and b) 1,2,3,4-Tetraphenylcyclopenta-1,3-dienone 220 °C/Ph_2O/2 d; a) 97%, b) 95%; c) and d) copper(II) triflate or $CuCl_2$, respectively/$AlCl_3$/RT/CS_2/2 d/quantitative yield.

Martin for recording the LD-TOF mass spectra, and Prof. F.-G. Klärner and Dipl.-Chem. M. Kamieth for assistance with the MM3* and AM1 calculations. V. S. I. thanks the Max-Planck-Gesellschaft, and C. K. the Fonds der Chemischen Industrie for a scholarship.

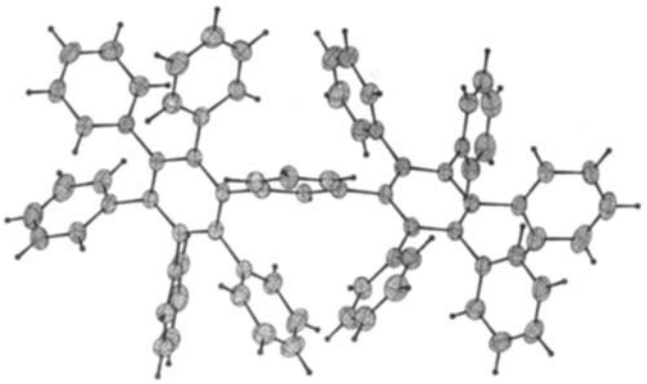

Figure 1. Crystal structure of **6**.

The polybenzenoid $C_{78}H_{26}$ hydrocarbon **7** is formed, as expected, when **5** is subjected to the mild reaction conditions of cyclodehydrogenation with copper(II) salts and aluminum(III) chloride. The quantitative yield of **7** could be demonstrated by laser-desorption time-of-flight mass spectrometry (LD-TOF-MS). Analogous cyclodehydrogenation of the *meta*-oligophenylene **6** could, in principal, permit formation of polyaromatic species with helical chirality (Figure 2).[7]

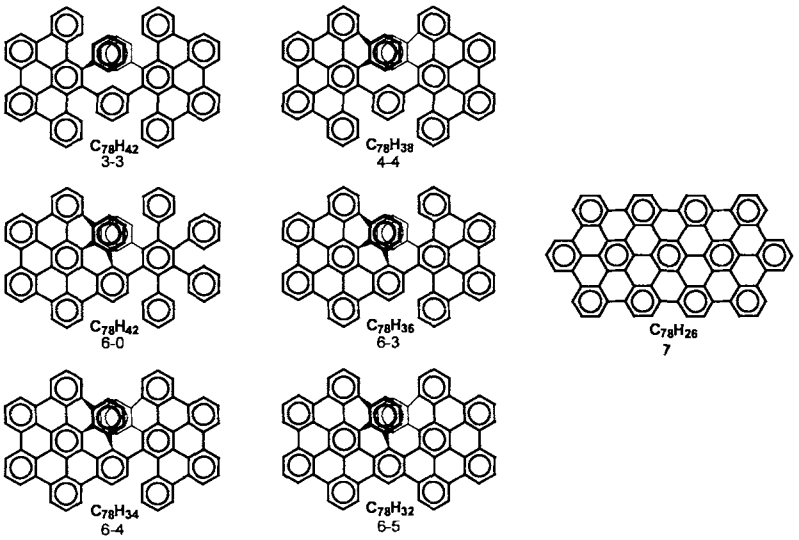
Semiempirical AM1 calculations[8] show that the products with partially cyclized hexaphenylbenzene subunits (HPhB, see **1**), which are bridged by a *meta*-phenylene structure, are higher in energy than the more extensively dehydrogenated, helical $C_{78}H_{32}$(6-5) derivative (Figure 2). (To describe the various dehdrogenation steps the number of newly formed C–C bonds is given for each of the HPhB subunits of the central, *meta*-substitued phenylene bridge, in addition to the empirical formula.) It is remarkable that **6** experiences a considerable energetic stabilization only through the complete cyclization of one HPhB subunit to HBC, whereas the partial cyclodehydrogenation of both HPhB subunits of **6** leads to products that are higher in energy.

Experiment shows that during the cyclization a quantitative 1,2-phenyl shift occurs at the central *meta*-substituted benzene ring of **6** (Figure 1) leading to formation of planar **7**, which is 30 kcal mol^{-1} more stable.[8] Although only 11 new bonds should be formed by the formation of a helical "graphite subsection" $C_{78}H_{32}$(6-5), loss of 28 hydrogen atoms with formation of 14 new C–C bonds can be demonstrated by LD-TOF-MS. Comparison of the IR spectra of the various cyclodehydrogenation products of **5** and **6** shows that the identical $C_{78}H_{26}$ hydrocarbon is involved in both cases.

By analogy to the synthesis of **6**, the doubly *meta*-bridged oligophenylene derivative **9** was obtained from the phenylethynyl compound **8** by triple Diels–Alder reaction with tetracyclone (Scheme 3). In contrast to **6**, compound **9** cannot be converted into a uniform, thermodynamically favored, planar product by cyclodehydrogenation. Consequently, intermolecular superposition of phenyl groups and fragmentation take place, which lead to formation of hydrocarbons **2** (R = H), **7**, and **13** as shown by mass spectrometry.

Octaphenyltetraphenylene **12** (Figure 3), which was synthesized as an oligopheneylene precursor with pronounced twisting, is formed from the highly strained phenylethynyl precursor **10**[9] by double Diels–Alder addition with tetracyclone (Scheme 4). Although **10** has been described as thermally unstable,[9] the double [4+2]cycloaddition could be carried out at 150 °C over 12 h in 95% yield. The crystal structure of **12** shows the boat conformation of the central eight-membered ring.[6] A molecule of carbon disulfide is deposited in the resulting cavity, as described for other tetraphenylene derivatives.[10]

Various products are formed during oxidative cyclodehydrogenation of tetraphenylene **12** depending on the temperature of reaction: copper(II) chloride/aluminum(III) chloride in carbon disulfide (30 °C) effects the quantitative cleavage of 12 hydrogen



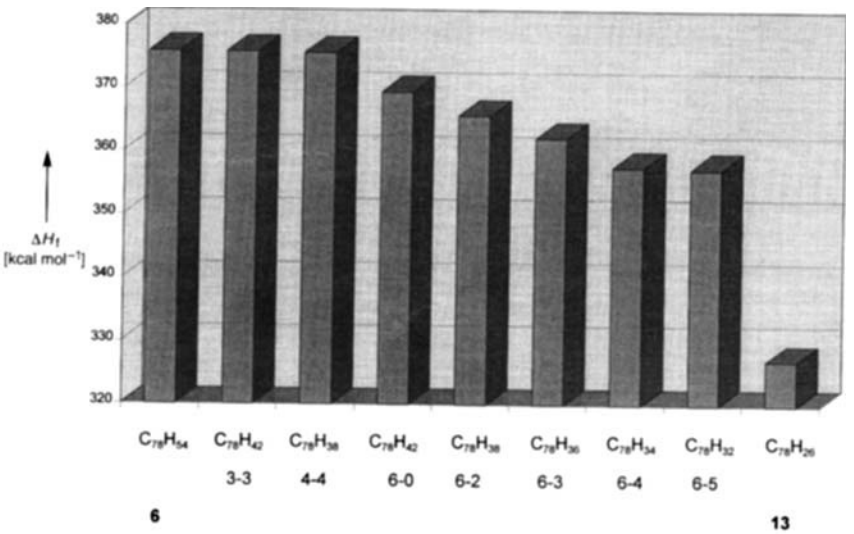


Figure 2. Theoretical cyclization products of **6** together with their relative energies [8]. To describe the various dehdrogenation steps the number of newly formed C–C bonds is given for each of the HPhB subunits of the central, *meta*-substitued phenylene bridge, in addition to the empirical formula.

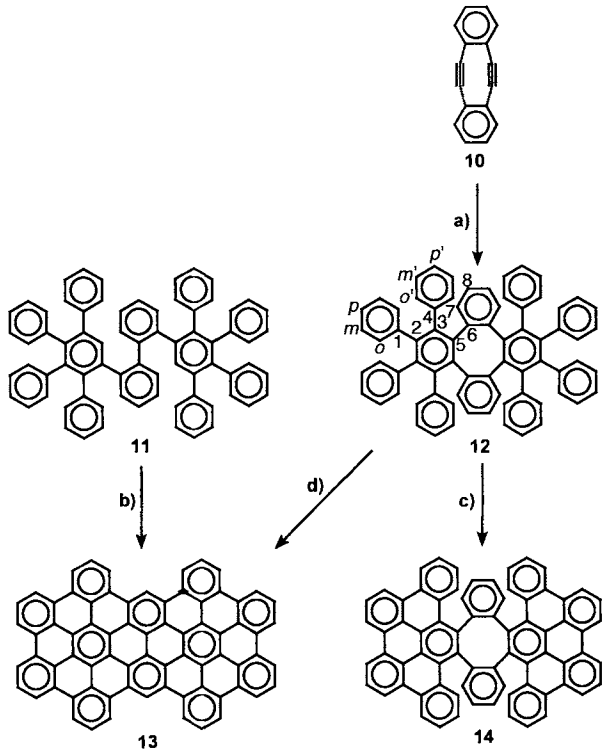
13: MS (LD-TOF): *m/z* (%) = 890 (100) [M^+] (calibrated with C_{60} and C_{70}); IR (KBr): $\tilde{\nu}$ = 2948, 2924, 1585, 1466, 1361, 1198, 1055, 865, 801, 746 cm^{-1}; m.p. > 300 °C.



Scheme 4. a) 1,2,3,4-Tetraphenylcyclopenta-1,3-dienone/150 °C/Ph_2O/12 h/95%; b) 1) $CuCl_2/AlCl_3$/140 °C/1,1,2,2-tetrachloroethane/2 d; 2) *t*BuLi in hexane/45 °C/1 d; yield for the two steps 80%; c) $CuCl_2/AlCl_3$/30 °C/CS_2/1 d; d) $CuCl_2/AlCl_3$/80 °C/1,1,2,2-tetrachloroethane/12 h/quantitative yield.

atoms with formation of six new C–C bonds, as demonstrated by field-desorption (FD) and LD-TOF-MS. Apparently **14** is the cyclodehydrogenation product, although this could not be examined by NMR spectroscopy because of low solubility.

Cyclodehydrogenation of **12** at 80 °C in 1,1,2,2-tetrachloroethane took place quite differently. According to LD-TOF-MS 22 hydrogen atoms were removed, and 11 new bonds formed (quantitative yield). This can be explained by assuming that the central tetraphenylene unit of **12** undergoes rearrangement to a dibenzopyrene structure, together with a subsequent, complete planarization of the remaining, peripheral phenyl substituents (Scheme 4, step d).

Cyclization of oligophenylene **11**[5] with copper(II) salts, which was carried out to test this assumption, leads to the anticipated polybenzenoid $C_{72}H_{26}$ hydrocarbon **13** in 98% yield according to mass spectrometry.[11] Again, comparison of the IR spectra of the corresponding cyclodehydrogenation products of **11** and **12** showed that the same $C_{72}H_{26}$ hydrocarbon **13** is involved in both cases.

The rearrangements presented here provide evidence that the driving force for intramolecular cyclodehydrogenation is the considerable gain in energy of the planar PAHs compared to the more energetic oligopheneylene precursors or partially cyclized products. We shall shortly report on the synthesis of nonplanar PAHs formed by intramolecular cyclodehydrogenation with simultaneous formation of five-membered rings.

[8] Complete geometry optimization of the molecules was carried out by using the MM3* force field in the program Macromodel 5.0 before calculating the heat of formation. Depending on the symmetry of the molecules 6–72 conformers, obtained by torsion about the central *meta*-phenylene unit by 20°, were used as starting geometries. The conformers obtained from the MM3* calculations were used as starting geometries for geometry optimization with subsequent determination of the heat of formation using AM1 calculations with the program SPARTAN. With the force-field method and the semiempirical calculations one obtains conformers with almost identical geometry. Only in the case of $C_{78}H_{42}$(6-0) does the torsional angle for the central *meta*-phenylene bond deviate by 20°.

Transition Metal Catalysis in Fluorous Media: Practical Application of a New Immobilization Principle to Rhodium-Catalyzed Hydroboration**

Jerrick J. J. Juliette, István T. Horváth,* and J. A. Gladysz*

Catalysis pervades the incessant quest for new or improved chemical transformations. Two of the most active frontiers entail 1) nontraditional reaction media, and 2) new catalyst-immobilization or recovery strategies to facilitate reuse.[1] A conceptually new protocol, fluorous biphase catalysis, was developed in our laboratories.[2] As detailed elsewhere,[2, 3] this involves modifying catalysts with fluoroalkyl groups or "pony tails" such as $(CH_2)_y(CF_2)_xCF_3$ ($x \geq 5$). These confer high affinities for fluorous media,[2c] and the $(CH_2)_y$ spacers insulate the active sites from the electron-withdrawing fluorines. Many organic solvents give bilayers with fluorous solvents, with some systems becoming miscible above room temperature. As a result, reactions may be conducted under either biphasic or monophasic conditions. Upon workup, appropriately derivatized catalysts remain immobilized in the fluorous layer.

Although applications of fluorous biphase chemistry are rapidly appearing from many laboratories, most feature stoichiometric quantities of the fluorinated species.[4, 5] We sought to showcase this protocol in a laboratory-scale catalytic reaction of utility in fine-chemical synthesis. Our attention was drawn to the transition metal catalyzed hydroboration of alkenes, for which a variety of complexes can be employed (for example $[RhClL_3]$, $[M(cod)(L)(L')]^+$ (cod = 1,5-cyclooctadiene), $[PdCl_2L_2]$, and $[Cp_2Ti(CO)_2]$).[6, 7] However, the resulting organoboranes can be flammable and inconvenient to purify, and catalysts are destroyed by the customary oxidations to alcohol products (H_2O_2/NaOH). Therefore, we set out to prepare and evaluate a fluorous analog of Wilkinson's catalyst, $[RhCl(PPh_3)_3]$, that would be recoverable prior to any oxidation. Indeed, this strategy affords an easily recycled hydroboration catalyst that is effective at 25–40 °C and loadings of 0.01–0.25 mol%, and gives turnover numbers (TON) as high as 8500.

To synthesize the catalyst (Scheme 1) a yellow-orange solution of $[\{RhCl(cod)\}_2]$ in toluene and a colorless solution of the fluorous phosphane $P[CH_2CH_2(CF_2)_5CF_3]_3$[2] in $CF_3C_6F_{11}$ were stirred at room temperature (molar ratio 1:6). The upper toluene phase became colorless, and the $CF_3C_6F_{11}$ phase became orange. The latter was isolated, and solvent removed to give **1** as an analytically pure, orange powder in 94% yield.

$[RhCl\{P[CH_2CH_2(CF_2)_5CF_3]_3\}_3]$ **1**

DSC showed a melting point at 90 °C but no significant decomposition below 300 °C. Complex **1** is evocative of a "Teflon greaseball" and, accordingly, very soluble in $CF_3C_6F_{11}$ and $CF_3C_6H_5$,[5a] insoluble in hexane, benzene, toluene, ether,

2	0.702	83	785
3	0.688	81	770

Total TON = 2431

Scheme 1. Fluorous biphase rhodium-catalyzed hydroboration.

$CHCl_3$, and CH_2Cl_2, and very slightly soluble in THF and acetone. For comparison, $[RhCl(PPh_3)_3]$ is insoluble in $CF_3C_6F_{11}$ and hexane, very slightly soluble in $CF_3C_6H_5$, slightly soluble in acetone, and soluble in benzene, toluene, ether, $CHCl_3$, CH_2Cl_2, and THF.

Next, alkenes and freshly distilled catecholborane (**2**) were combined in the presence of **1**. Exploratory runs with solvent mixtures ($CF_3C_6F_{11}$/THF or toluene) were sucessful. However, reactions were more rapidly and economically effected without a nonfluorous solvent. A stock solution of **1** (0.500 mL, 1.79 mM, 8.94×10^{-4} mmol, 0.10 mol%) in $CF_3C_6F_{11}$ was added to a 1:1 mixture of norbornene and **2** (0.849 mmol, 950 equiv based on Rh). The heterogeneous sample was kept for 1 h at 40 °C, and extracted with C_6D_6 (2×0.5 mL; room temperature). Then Ph_3SiMe was added to the extract; NMR analysis showed 0.765 mmol of the organoborane **3** (Scheme 1; 90%, TON 854). The $CF_3C_6F_{11}$ mother liquor was added to a second sample of norbornene and **2** (950 equiv). Identical reaction and workup gave a solution containing 0.702 mmol of **3** (83%, TON 785)in C_6D_6. A third cycle gave similar data for a combined TON of 2431 (Scheme 1). Comparable results were obtained with other alkenes. Hence, there is a very high degree of catalyst recovery.[8]

Preparative syntheses of alcohols were attempted. Thus, norbornene and **2** (1:1; 2.55 mmol) and a solution of **1** in $CF_3C_6F_{11}$ (0.03 mol%) were combined as described above. The sample was kept for 6 h at 40 °C and then extracted with THF (3×1 mL). Oxidative workup (H_2O_2/NaOH) gave *exo*-norborneol in 76% yield (TON 2170). Similar reactions were conducted with a variety of monosubstituted, disubstituted, and trisubstituted alkenes as summarized in Table 1. Some THF was added to dissolve the only solid reactant, *trans*-stilbene. With one exception reaction times ranged from 1–16 h; no special efforts were made to optimize catalyst loadings (0.03–0.25 mol%) or isolated yields (92–76%). In most cases, only one alcohol regioisomer or diastereomer was detected. These were identical to products from uncatalyzed reactions, which are commonly conducted at 100 °C.[9] However, both styrenes gave mixtures of regioisomers. The regioselectivities in rhodium-catalyzed hydroborations of styrenes can vary, and catalyst purity has been shown to be a critical factor.[6d, e] The ratios in Table 1 have been reproduced many times with different samples of **1** and **2**.[8c]

To investigate the feasibility of still higher TON values and lower catalyst loadings, the reaction of norbornene, **2**, and **1** was repeated with a 9650:9650:1 molar ratio (0.01 mol% **1**). After

40 h workup gave *exo*-norborneol in 88% yield, which corresponds to a TON of 8492! Furthermore, as shown by the last two examples in Table 1, **1** catalyzed the addition of **2** to alkynes. These reactions were more rapid (0.5 h)[9] and gave much more stable organoboranes, which were isolated directly (89–95%). Only one regioisomer was detected. Finally, various control and comparative experiments were conducted. For example, norbornene and styrene give no detectable reaction with **2** in the absence of **1**. A single extraction with benzene or THF (1/1 v/v $CF_3C_6F_{11}$) recovers greater than 90% of the organoborane product from the $CF_3C_6F_{11}$ medium. Also, $[ClRh(PPh_3)_3]$ catalyzes the reaction of norbornene and **2** under homogeneous conditions in C_6D_6 at 40 °C at a somewhat faster rate than **1** under the heterogeneous conditions of Scheme 1. There is the attendant question of fluorous-phase versus interfacial catalysis, and studies that address these and related issues are in progress.

The protocols described offer many advantages over existing methodologies for metal-catalyzed hydroborations. Even more importantly, they demonstrate the practicality and utility of a new, more environmentally friendly approach to laboratory-scale catalytic reactions. A number of extensions can be readily visualized. For example, the organoboranes generated in Scheme 1 and Table 1 undergo various types of metal-catalyzed carbon–carbon bond forming reactions.[10] Thus, there are intriguing possibilities for liquid-phase combinatorial syntheses involving a sequence of fluorous catalysts.[11] Complex **1** also catalyzes other transformations such as hydrogenations, hydrosilylations, and hydroacylations.[12] Parallel mechanistic studies have established unique selectivity patterns for oxidative additions in $CF_3C_6F_{11}$.[13] Finally, this constitutes a highly attractive approach to enantioselective catalysis, which often involves expensive metals and ligands.

Experimental Section

1: A flask was charged with $P[CH_2CH_2(CF_2)_5CF_3]_3$ (0.643 g, 0.600 mmol) and $CF_3C_6F_{11}$ (1 mL) under N_2. Then a solution of $[\{RhCl(cod)\}_2]$ (0.049 g, 0.0994 mmol) in toluene (1 mL) was added with stirring. After 14 h the orange $CF_3C_6F_{11}$ layer was isolated and dried under vacuum to give **1** as a bright orange solid (0.620 g, 0.186 mmol, 94%). Elemental analysis calcd for $C_{72}H_{36}ClF_{117}P_3Rh$: C 25.77, H 1.08; found: C 25.85, H 1.09; ^1H NMR ($CF_3C_6F_{11}$, external C_6D_6 lock): $\delta = 2.20$ (br, 6H), 1.90 (br, 6H); $^{31}P\{^1H\}$ NMR ($CF_3C_6F_{11}$, external C_6D_6 lock): 12.9 (dd, J(P,Rh) = 136.1, J(P,P) = 39 Hz), 29.3 (dt, J(P,Rh) = 186, J(P,P) = 39 Hz).

Representative reaction: A flask was charged with norbornene (0.240 g, 2.55 mmol), **2** (0.270 mL, 0.306 g, 2.55 mmol), and a solution of **1** in $CF_3C_6F_{11}$ (0.500 mL, 1.79×10^{-3} M) under N_2. The mixture was kept at 40 °C for 6 h, cooled to room temperature, and extracted with THF (3 × 1 mL). Solvent was removed under vacuum at 0 °C to give a white solid. Then ethanol/THF (5 mL, 1/1 v/v) and NaOH (5 mL, 2 M in H_2O) were added. The mixture was cooled to 0 °C, and 30% H_2O_2 (0.5 mL, 4.4 mmol) added dropwise with stirring. After 0.5 h the mixture was warmed and extracted with ether (3 × 10 mL). The extract was washed with NaOH (10 mL, 0.5 M in H_2O), H_2O (15 mL), and brine (15 mL), and dried over $MgSO_4$. Solvent was removed by rotary evaporation to give *exo*-norborneol as a white solid (0.182 g, 1.94 mmol, 76%; TON = 2167). NMR spectra matched those reported [9].

Synthesis, Structure, and Oxidative Additions of a Fluorous Analogue of Vaska's Complex, *trans*-$[IrCl(CO)\{P[CH_2CH_2(CF_2)_5CF_3]_3\}_2]$—Altered Reactivity in Fluorocarbons and Implications for Catalysis**

Marie-Andrée Guillevic, Atta M. Arif, István T. Horváth,* and J. A. Gladysz*

Although homogeneous transition metal catalysts are employed in vast numbers of bench-scale and commodity chemical transformations, there remain critical needs for improved catalyst-recovery methodologies, as well as higher or new types of selectivities.[1] Towards these ends, a conceptually new protocol, fluorous biphase catalysis, has been developed in our laboratories.[2] This entails derivatizing catalysts with fluoroalkyl groups or "pony tails" such as $(CH_2)_y(CF_2)_xCF_3$, which provide high solubility in fluorous media.[2, 3] Electronic properties can be tuned by varying the $(CH_2)_y$ spacer. Many combinations of fluorous and organic solvents give bilayers, enabling facile catalyst–product separation.

We have prepared fluorous rhodium catalysts that effect a variety of transformations and have many desirable attributes.[2, 3] Novel fluorous reagents are being developed in

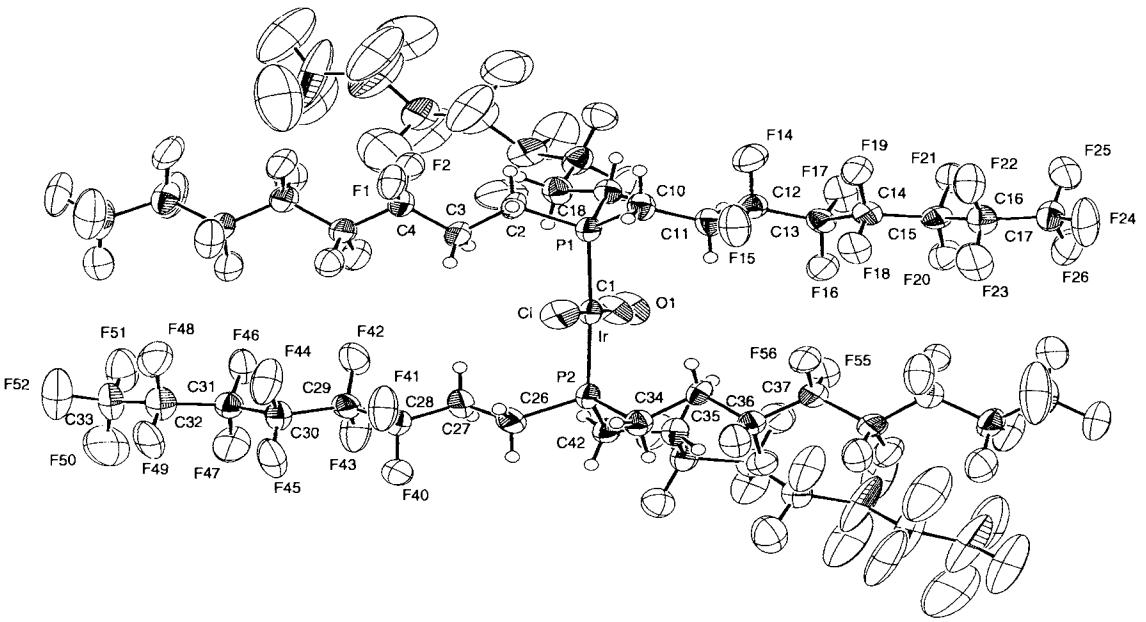

Figure 1. Molecular structure of **2**. For clarity the fluorine atoms are represented by unshaded ellipsoids, and atoms are completely numbered for only two of the $CH_2CH_2(CF_2)_5CF_3$ chains. Selected bond lengths [Å] and angles [°]: Ir–P1 2.307(2), Ir–P2 2.311(2), Ir–Cl 2.361(2), Ir–C1 1.783(7); P1-Ir-P2 172.18(6), P1-Ir-Cl 85.72(7), Cl-Ir-P2 86.46(7), P1-Ir-C1 94.4(3), Cl-Ir-C1 179.3(3), P2-Ir-C1 93.4(3).

other laboratories.[4] However, a number of fundamentally important underlying issues have yet to be addressed. For example, how are the structures of compounds with multiple pony tails best visualized? Can significant changes in selectivities occur in fluorous solvents? How is the reactivity of oxygen, which is exceptionally soluble in fluorous media, affected? Hence, we turned our attention to iridium relatives of the rhodium catalysts, seeking to make use of the large body of mechanistic and structural data involving Vaska's complex, *trans*-[IrCl(CO)-$(PPh_3)_2$] (**1**), and close congeners.[5]

$[\{IrCl(cod)\}_2]$ (cod = 1,5-cyclooctadiene) and the fluorous phosphane $P[CH_2CH_2(CF_2)_5CF_3]_3$[2] were combined in hexane/CH_2Cl_2 under CO (1 atm; see Scheme 1).[6] Workup gave **2** as an air-stable light-yellow powder in 97% yield.[7] A similar procedure with the analogous non-fluorinated phosphane $P[(CH_2)_7CH_3]_3$ gave **3** as a yellow oil in 84% yield. Complex **2**

trans-$[IrCl(CO)\{P[CH_2CH_2(CF_2)_5CF_3]_3\}_2]$ **2**

trans-$[IrCl(CO)\{P[(CH_2)_7CH_3]_3\}_2]$ **3**

is very soluble in $CF_3C_6F_{11}$, acetone, ether, and THF, but insoluble in hexane, CH_2Cl_2, and $CHCl_3$. In contrast, **3** is insoluble in $CF_3C_6F_{11}$, but soluble in all common organic solvents. Surprisingly, unlike **3** and the many fluorous phosphane complexes we have prepared to date, **2** crystallizes (yellow prisms, ether/pentane). DSC analysis (−100 to 350 °C) showed thermal decomposition above 200 °C, but only one phase transition (melting, 75 °C).

Figure 1 shows an ORTEP representation of the crystal structure of **2**.[7b] The metrical parameters are similar to those of other structurally characterized *trans*-$[IrCl(CO)(PR_3)_2]$ complexes.[8] However, data for such a perfluoroalkyl-rich species, of any composition, had previously not been available.[9] Perfluoroalkane conformations are of special interest in that *n*-C_4F_{10} exhibits three minima with C-C-C-C torsion angles of about 166, 95, and 54° (*anti*, *ortho*, and *gauche*, respectively).[10] However, the $CF_2CF_2CF_2CF_{2-3}$ segments in **2** display only the most stable *anti* conformations (torsion angles 161.7(6)–176.9(1.3)°, av 169.0(3.4)°).

The crystal structure also shows distinctive packing features. Four chains (commencing at C2, C10, C26, and C34) are essentially parallel and coplanar, defining a raft of approximately 21 × 6 Å. The two remaining chains (commencing at C18 and C42) extend on a common side of the raft. These feature *gauche* $\mathbf{CH}_2CF_2CF_2CF_2$ units and CF_2CF_3 endgroups that have larger thermal ellipsoids (20% disorder). The lattice consists of stacks of molecules, in which the rafts are paired back-to-back (Figure 2). Thus, every third layer consists of four out-of-plane

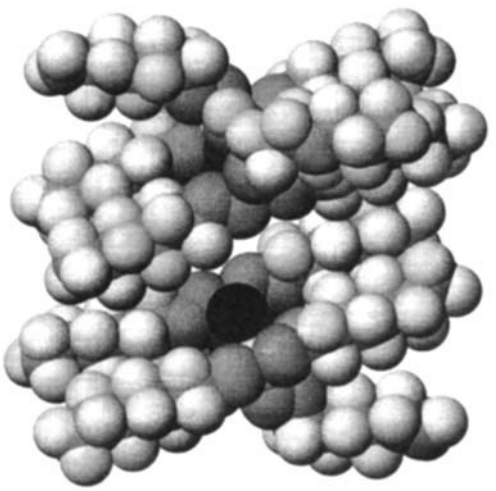

Figure 2. Packing of two molecules of **2**; non-hydrogen atoms are given at the van der Waals radii (fluorine atoms light, chlorine atoms dark). The crystal lattice consists of stacks of this repeat unit.

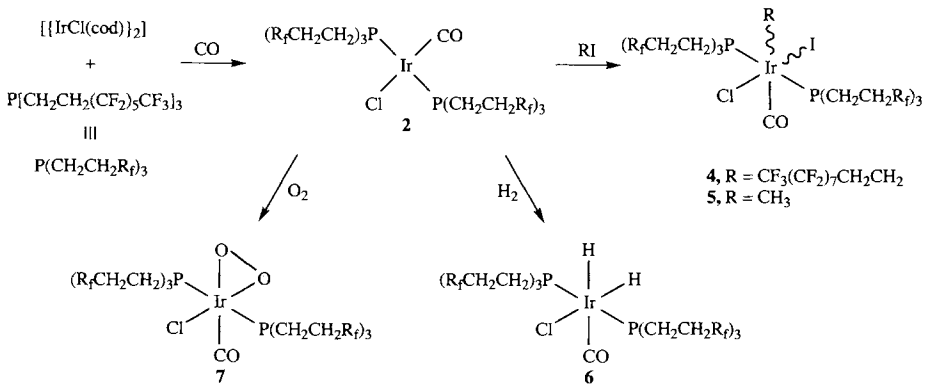
chains and is less densely packed. This arrangement maximizes the number of parallel perfluoroalkyl chains in every direction, in accord with the "like-dissolves-like" paradigm. However, the separations are somewhat greater than the sum of the van der Waals radii.

Reactions of **2** that model key steps in catalysis were investigated. Oxidative addition of CH_3I to **1** involves an S_N2-like

mechanism and a cationic iridium intermediate, even in benzene.[5b, 11] We thought that such pathways should be disfavored in nonpolar fluorous media. Therefore, **2** was first treated with the fluorous iodide $CF_3(CF_2)_7CH_2CH_2I$ (2 equiv) in $CF_3C_6F_{11}$ (homogeneous conditions) under anaerobic conditions. After 1 h workup gave the expected alkyl complex **4** as an analytically pure yellow oil in 84% yield (Scheme 1).[7] The ^{31}P NMR spectrum of **4** showed three peaks (73:19:8), which were presumed to represent geometric isomers. A similar reaction with CH_3I (4 equiv) in $CF_3C_6F_{11}$ (homogeneous conditions) gave the corresponding methyl complex **5** in 70% yield and greater than 97% isomeric purity. However, completion required 72 h.



Scheme 1. Synthesis and reactivity of **2**, a fluorous analog of Vaska's complex.

Competition experiments were conducted. When **2**, $CF_3(CF_2)_7CH_2CH_2I$, and CH_3I were combined in a 1:3:3 molar ratio, only **4** formed (^1H and ^{31}P NMR). This rate trend is inconsistent with a common S_N2-like mechanism.[12] We thought it likely that one or both substrates react by a free radical chain pathway, which is well documented for **1** and secondary or tertiary alkyl halides.[13] Accordingly, **4** formed much more slowly in the dark, and much more rapidly following brief irradiation. A reaction of **2**, $CF_3(CF_2)_7CH_2CH_2I$, and CH_3I was conducted in the presence of the free-radical trap duroquinone (2:6:6:3 molar ratio; heterogeneous conditions). After 72 h, only **2** and a small amount of a previously unobserved species were detected (95:5, ^{31}P NMR). The rate of reaction of **1** and CH_3I in CH_2Cl_2 is unaffected by duroquinone and galvinoxyl.[13] Hence, the polar addition mechanism appears to be completely shut down in fluorous solvents.

Attention was turned to nonpolar substrates that add to **1** by concerted mechanisms. First, a solution of **2** in $CF_3C_6F_{11}$ was treated with H_2 (1 atm).[14] After 2.5 h workup gave the dihydride complex **6** (Scheme 1) as a spectroscopically homogeneous yellow oil in 82% yield. Two ^1H NMR signals for the hydride ligands and one ^{31}P NMR signal was observed, which is consistent with the isomer shown. Second, a similar reaction was conducted with O_2 (1 atm).[15] In view of the high solubility of oxygen in fluorous solvents, rapid addition was expected. However, the oxygen complex **7** (Scheme 1) slowly formed over the course of 72 h. Workup gave a yellow oil in 67% yield.

To help interpret this result, side-by-side reactions of **2** in $CF_3C_6F_{11}$ and in THF (both 0.006 M) with O_2 (2 atm) were periodically monitored by ^{31}P NMR spectroscopy. The first went to 20% completion after 25 h, whereas the second to 24 and 92% after 3 and 18.5 h, respectively. Hence, the fluorous solvent actually retards oxygenation, suggesting that (relative to THF) the reactants are stabilized more than the transition state. Identical experiments with **1**–**3** in THF established the order of reactivity as **3** > **1** > **2** (1.5 h: 80, 41, and 6%; 3.0 h: 95, 68, and 24%, respectively). This parallels the electron density on iridium, as approximated by the IR ν_{CO} values (Nujol: 1942, 1952, and 1975 cm^{-1}, respectively). The latter also show that the $(CH_2)_2$ spacers in **2** do not completely insulate the iridium from the electronegative fluorine atoms.[16]

These data show that oxidative-addition rates of both polar and nonpolar substrates can be strongly affected by fluorous media. This in turn provides a foundation for the design of catalysts with fundamentally new selectivities. For example, fluorous solvents should disfavor the pivotal CH_3I addition in the rhodium-catalyzed, iodide-promoted conversion of methanol and carbon monoxide into acetic acid.[17] The absence of any intra- or intermolecular carbon–fluorine bond activation reactions involving **2** is also noteworthy.[18]

Experimental Section

2: A Schlenk flask was charged with [{IrCl(cod)}$_2$] (0.069 g, 0.10 mmol), and hexane/CH_2Cl_2 (50/50, 10 mL) and P[$CH_2CH_2(CF_2)_5CF_3$]$_3$ (0.440 g, 0.412 mmol) were added with stirring. After 10 min CO (1 atm) was added, and after 15 min the volatile components were removed under vacuum. Ether was added (10 mL), the sample filtered, and solvent removed by rotary evaporation. The light yellow powder **2** was dried under vacuum (0.479 g, 0.199 mmol, 97%), m.p. 75 °C. Elemental analysis calcd for $C_{49}H_{24}ClF_{78}IrOP_2$: C 24.52, H 1.01; found: C 24.46, H 1.07; IR ($CF_3C_6F_{11}$): $\tilde{\nu}_{CO}$ [cm^{-1}] = 1975 s; ^1H NMR (acetone): δ = 2.80 (m, 6 CH_2); 2.71 (m, 6 CH_2); $^{31}P\{^1H\}$ NMR (acetone): δ = 22.52 (s).

4: A Schlenk flask was charged with **2** (0.100 g, 0.0416 mmol), and $CF_3C_6F_{11}$ (3 mL) and $CF_3(CF_2)_7CH_2CH_2I$ (0.047 g, 0.082 mmol) were added with stirring. After 1 h the volatile components were removed under vacuum. The residue was washed with CH_2Cl_2 (5 mL), dissolved in ether/pentane (50/50, 10 mL), and purified by chromatography (silica gel). Solvent was removed from a yellow band to give **4** as a yellow oil (0.100 g, 0.033 mmol, 84%). Elemental analysis calcd for $C_{56}H_{28}ClF_{95}IIrOP_2$: C 23.83, H 0.95; found: C 23.95, H 1.01; IR ($CF_3C_6F_{11}$): $\tilde{\nu}_{CO}$ [cm^{-1}] = 2035 s; ^1H NMR ($CF_3C_6F_{11}$): δ = 3.0–2.4 (m, 6 PCH_2CH_2), 2.3–2.0 (m, $IrCH_2CH_2$); $^{31}P\{^1H\}$ NMR ($CF_3C_6F_{11}$): δ = −30.50 (s, 73%), −21.35 (s, 8%), −20.23 (s, 19%).

7: A Schlenk flask was charged with **2** (0.058 g, 0.024 mmol), and $CF_3C_6F_{11}$ (4 mL) and O_2 (1 atm) were added with stirring. After 3 d the volatile components were removed under vacuum. Ether was added (10 mL), the sample filtered, and solvent removed to give **7** as a yellow oil (0.039 g, 0.016 mmol, 67%). Elemental analysis calcd for $C_{49}H_{24}ClF_{78}IrO_3P_2$: C 24.20, H 0.99; found: C 24.70, H 1.20; IR ($CF_3C_6F_{11}$): $\tilde{\nu}_{CO}$ [cm^{-1}] = 2021 s, $\tilde{\nu}_{OO}$ [cm^{-1}] = 864 m; ^1H NMR (acetone): δ = 2.82–2.66 (m, 6 PCH_2CH_2); $^{31}P\{^1H\}$ NMR (acetone): δ = 1.59 (s).

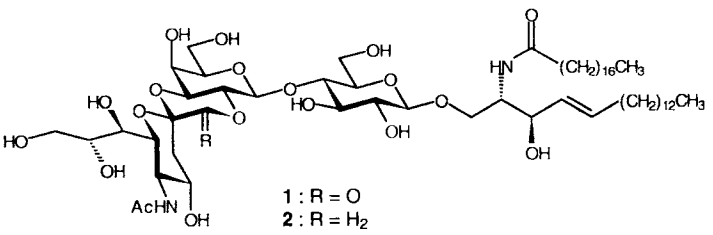
Synthesis of a Novel Stable GM_3-Lactone Analogue as Hapten for a Possible Immunization against Cancer**

Lutz F. Tietze* and Holger Keim

Dedicated to Professor Waldemar Adam on the occasion of his 60th birthday

In addition to proteins and lipids, carbohydrates—of which gangliosides constitute a large part—are essential elements of the cell surface. They are anchored to the lipid bilayer of the membrane with their ceramide portion, and the carbohydrate moiety is exposed to the outside. Gangliosides play an important role in cell–cell and cell–matrix recognition and are relevant for cellular growth since they interact with many growth receptors, for example the epidermal growth factor receptor.[1] The GM_3 ganglioside is the smallest and most widespread ganglioside in human and animal tissue. It has been found in brain and nerve cells as well as in the membranes of melanoma and liver carcinoma cells in increased concentrations.[2] However, immunization experiments with monoclonal antibodies indicate that the actual tumor-associated antigen is not the GM_3 ganglioside itself but its lactone form **1**.[3] Consequently, a greatly increased density of the GM_3 lactone was discovered in melanoma cells. Furthermore, the existence of a threshold at which the antibody recognizes the cell has been shown.[4] The GM_3 ganglioside lactone[4] and lactam[5] hitherto used to obtain antibodies are unstable towards hydrolysis under physiological conditions. Therefore, there is much interest in developing hydrolysis-resistant analogues of **1** and, thus, making a defined immunogen available for immunization. Here we describe the synthesis of the hydrolysis-stable GM_3 ganglioside lactone analogue **2** containing an ether group.



For the synthesis of **2** the cyclization of trisaccharide **3**[6]—with free hydroxy groups at C2′ and C4′ which is selectively built up from glucose, galactose and neuraminic acid by known procedures—with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in dichloromethane to yield the C2′-Gal lactone **5** was initially attempted (Scheme 1). However, reaction of the free hydroxy groups led to both possible lactone isomers in 86% yield as a nonseparable mixture in a ratio of 1.7:1. Conversely, the acid-catalyzed reaction of the partially deprotected trisaccharide **4**, which was already described for the isolated GM_3 ganglioside,[7] provided the desired GM_3 ganglioside lactone **5** in 57% yield.

To transform **5** into analogue **9** it was first peracetylated to give **6**; subsequent reduction of the lactone functionality led to lactol **7**, which was converted into thiohemiacetal **8**. Hydrogenolytic cleavage of the thiol moiety completed the sequence. The Red-Al derivative Na[$AlH(OCH_2CH_2OCH_3)_2$-OEt][8] proved to be the best reagent for reducing the carboxy functionality to afford **7** in 80% yield with conservation of the acetyl groups. Reaction with diisobutylaluminium hydride (DIBAL) mostly led to deacylated products; $LiBH_4$ and $NaBH_4$ yielded the corresponding, undesired diols as main products, as expected.

Conversion of the hemiacetal of **7** into the ether functionality of **9** proved extremely difficult, mainly due to the low reactivity of the hydroxy group, and almost led to failure of the entire project. The glycosidic bond at C1 was cleaved in all attempts to reductively remove the hydroxy group directly, for example with triethylsilane and boron trifluoride etherate. The obvious transformation into an *O,S*-acetal also failed initially. Activation of the hydroxy group by conversion into the acetate or trichloroacetimidate by standard procedures was achieved in very high yields. However, during the subsequent reaction with

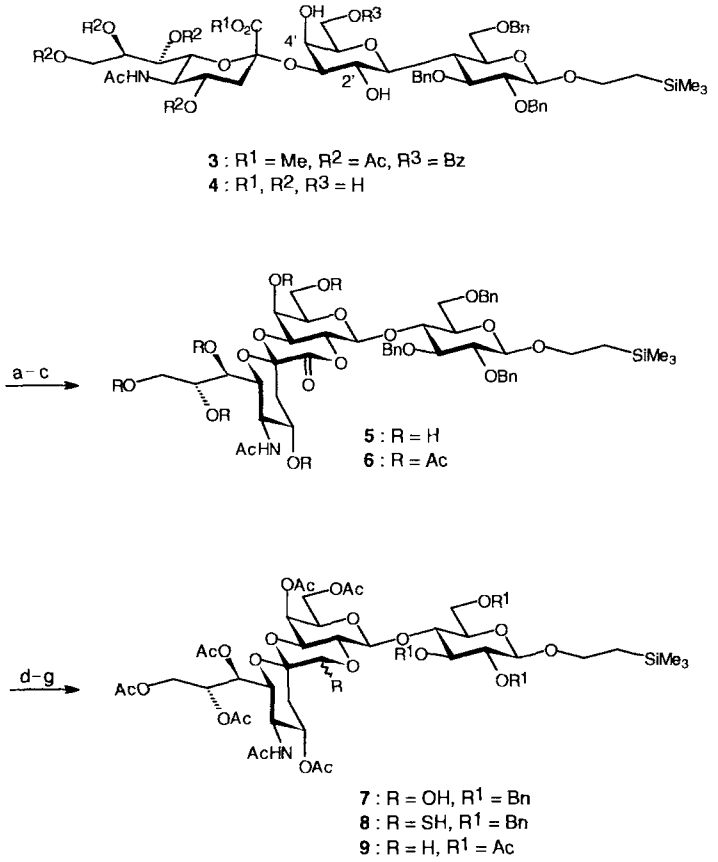
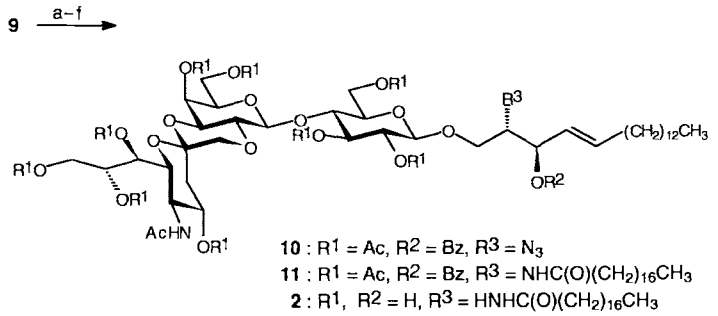


Scheme 1. a) NaOMe, MeOH, 30 h, room temperature (RT); b) HOAc, 3 d, RT, 57% (two steps); c) Ac_2O, pyridine, 4-(dimethylamino)pyridine (DMAP), 14 h, RT, 94%; d) $Na[AlH(CH_2OEt)_2OEt]$, toluene, −55 °C, 1 h, 80%; e) $(PyS)_2$ (5 equiv), nBu_3P (5 equiv), CH_2Cl_2, 3 d, RT, 6 h reflux, 71%; f) Raney nickel, EtOH, H_2 (1 atm), 30 h, RT; g) Ac_2O, pyridine, DMAP, CH_2Cl_2, 14 h, RT, 85% (two steps).

thiophenol in the presence of boron trifluoride etherate or trimethylsilyl triflate (TMSOTf), a competitive reaction took place at C1 of the glucose unit leading to the dithiophenyl glycosides. Only reaction with five equivalents each of bis(pyridinium) disulfide and *n*-tributylphosphane[9] resulted in the desired transformation of the lactol. Remarkably, the free thiohemiacetal **8** was obtained in 71% yield as a result of overreduction instead of the expected *S*-pyridyl derivative.

Subsequent conversion into the acetyl-protected GM_3-lactone analogue **9** was achieved by hydrogenation with H_2 and Raney nickel and concomitant cleavage of the benzyl groups in an excellent yield of 85%. The presence of the ether **9** was proven with NMR spectroscopy by $^1H-^1H$ correlation experiments. Two doublets at $\delta = 3.44$ and 3.89 ($^2J(H,H) = 11.5$ Hz) can be assigned to the two geminal protons at C1″.



Scheme 2. a) CF_3COOH/CH_2Cl_2 (2/1), 30 min, RT; b) CCl_3CN (30 equiv), DBU, CH_2Cl_2, 1 h, 0 °C, 93% (two steps); c) CH_2Cl_2, azido sphingosine (3 equiv), $BF_3 \cdot Et_2O$ (3 equiv), 4-Å molecular sieves, 1 h, −40 °C, 66%; d) NEt_3 (5 equiv), PhSH (5 equiv), $(PhS)_2Sn$, CH_2Cl_2 (5 equiv), 4 h, RT; e) stearic acid (5 equiv), EDC (5 equiv), CH_2Cl_2, 2 h, RT, 73% (two steps); f) NaOMe, MeOH, 20 h, RT, 77%.

To convert **9** into the complete GM_3 ganglioside lactone analogue **2**, the protecting group at C1 was removed by reaction with trifluoroacetic acid in dichloromethane (Scheme 2). Unfortunately, epimerization took place at C2 of the neuraminic acid to an extent of 17% and led to the thermodynamically more stable β anomer, which fortunately was easily removed by chromatography (silica gel) at the stage of **10**. The two anomers could be distinguished by their ^1H NMR signals for 3″-H_{eq} at $\delta = 2.50$ for the α anomer and 1.96 for the β anomer. Lewis acids such as boron trifluoride etherate or zinc chloride employed to cleave the C1 protecting group effected almost complete epimerization; no reaction took place with tetrabutyl ammonium fluoride.

For the further transformation into the ganglioside **10**, reaction of the hydroxy group at C1 was carried out to lead to the trichloroacetimidate. Subsequent glycosylation with azido sphingosine at −40 °C in dichloromethane, catalyzed with boron trifluoride etherate, afforded the sphingosine derivative **10** in two hours. No further epimerization was observed under these reaction conditions. Reduction of the azido group in **10** to the corresponding amine was effected in good yields with $NHEt_3^+[(PhS)_3Sn]^-$.[12] Once again many reagents were tested—such as triphenylphosphane, 1,3-propanedithiol, and H_2S—but all led to poorer results. In the final steps of the synthesis of the free GM_3-lactone analogue **2**, the amine reacted with stearic acid upon addition of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) to provide ceramide **11**, which was deprotected by solvolysis with sodium methanolate in methanol.

In cooperation with the Abteilung für Hämotologie und Onkologie as well as the Abteilung für Immunologie at the Universität Göttingen we are currently testing the biological activity of **2**. We are also forming conjugates with bovine serum albumin (BSA) and the keyhole-limpet hemocyanin (KLH), which are used for immunization.

Self-Assembly of a Mesogenic Polyamide: Induction and Significant Stabilization of a Liquid-Crystalline Phase through Complexation of a Phenylbenzoic Acid with a Polymer Backbone Derived from 2,6-Bis(amino)pyridine Units**

Takashi Kato,* Yasuo Kubota, Toshiyuki Uryu, and Seiji Ujiie

The use of specific interactions for the design and preparation of molecular materials such as liquid crystals has attracted attention because of their potential as dynamically functional molecular systems.[1] For liquid-crystalline polymers, specific intermolecular forces such as hydrogen bonding,[1-4] ionic,[5] and charge transfer interactions[6] have been used for several years for the formation of mesogenic structures. Thus, for instance, the first hydrogen-bonded supramolecular mesogenic polymer, which consists of different and independent molecular components, was prepared from a stilbazole and a polyacrylate containing a benzoic acid group in the side chain.[2] Two bifunctional complementary components were used for the formation of the first main-chain supramolecular mesogenic polymer.[3] Since then, a wide variety of hydrogen-bonded supramolecular polymers that exhibit mesomorphic behavior have been prepared by self-assembly processes.[4] Recently we have shown that 2,6-bis(acylamino)pyridine can be used as a molecular component for supramolecular liquid-crystalline materials through the formation of double hydrogen bonds.[7] These complexes exhibit only monotropic mesophases with relatively narrow temperature ranges. Aminopyridines have been used frequently as versatile molecular units for the control of molecular aggregation.[3, 8]

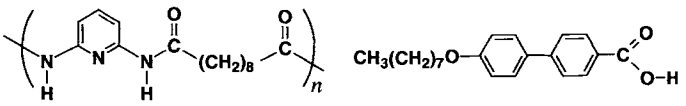
[**] This work was supported by the Ministry of Education, Science, Sports, and Culture (Grant-in-Aid for Scientific Research in Priority Areas of "New Polymers and Their Nano-Organized Systems" (No. 277/08246101) for T. K.).

Our aim is to obtain a nylon with heterocyclic units in the backbone that is capable of molecular recognition and self-organization through the incorporation of the bifunctional pyridine, and we report here on a novel form of self-assembly of a main-chain polymer, which leads to a greatly stabilized mesophase through complexation of a phenylbenzoic acid with a 2,6-bis(amino)pyridine unit in the polymer backbone. The 2,6-bis(amino)pyridine unit was incorporated into a polymer main chain to enable the polymer to recognize hydrogen-bonding molecules on its backbone. Polyamide **1** was prepared by low-temperature polycondensation of 2,6-bis(amino)pyridine and sebacoyl chloride in solution. The polymer is nonmesogenic. On heating the polymer, glass and melting transitions were observed at 118 and 222 °C, respectively. 4-(4'-(Octyloxy)phenyl)benzoic acid (**2**) exhibits a smectic C phase between 179 and 250 °C, and a subsequent nematic phase up to 259 °C.



1 **2**

We expected that **1** and **2** would form a supramolecular complex.[7, 8] The 1:1 complex from **1** and **2** (equimolar amounts of aminopyridine and carboxylic acid moieties) was prepared by direct mixing in the molten state. Microscope studies and differential scanning calorimetry (DSC) measurements gave no indications of transition behavior for each of the single components, rather the complex behaved as one single macromolecular component. The complex exhibited a melting transition at 212 °C. After melting, birefringence, which suggests the existence of a mesophase, was observed under a polarizing microscope. Significantly, the mesophase was stable up to 350 °C; thereafter, the polymer slowly decomposed. The results of X-ray diffraction measurements for the complex support the existence of the mesophase. Figure 1 shows X-ray diffraction patterns of the crystalline state (A) and of the mesomorphic state (B). The peak due to the layer spacing at 31.5 Å and several peaks in the

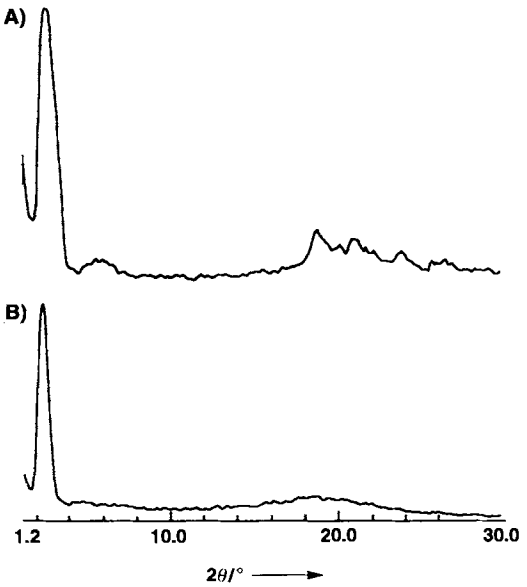


Figure 1. X-ray diffraction patterns of the complex formed from **1** and **2** at 100 °C (A) and at 290 °C (B).

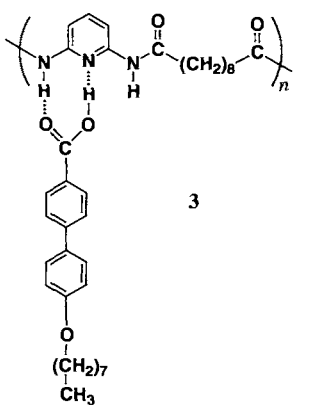
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3615-1617 $ 17.50+.50/0

wide-angle region are observed at 100 °C (Figure 1A). The X-ray pattern at 290 °C consists of one sharp peak due to the layer spacing at 35.9 Å and one diffused halo at 4.6 Å (Figure 1B). This liquid-crystalline molecular arrangement with a layer spacing of 35.9 Å is still observed even at 350 °C, where birefringence is also clearly evident. In contrast, the single component **2** becomes isotropic at 259 °C, and polyamide **1** is completely nonmesomorphic. These results suggest that a supramolecular liquid-crystalline polyamide of type **3** is formed and that a thermally stabilized mesophase of a smectic A molecular arrangement has been induced by the self-assembly. The length of the mesogenic part from the pyridyl unit to the end of the octyl group is estimated to be 26.0 Å by molecular modeling. A proposed molecular arrangement of the molecules in the liquid-crystalline phase is shown in Figure 2.



3

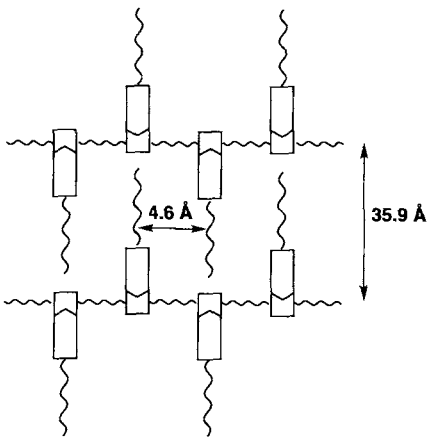


Figure 2. Schematic representation of the molecular arrangement of the supramolecular polymer complex from **1** and **2** in the liquid-crystalline state.

This polymeric structure consisting of **1** and **2** is quite unique for liquid-crystallline polymers because the mesogenic core unit is laterally connected and the structure is not simply classified into main-chain and side-chain types. Moreover, the overall structure of the supramolecular mesogenic part containing the lateral amide groups is neither simple rod nor disc shape. For a low molecular weight complex that has a similar structure but contains two rings (the biphenyl unit is replaced by a benzene ring), only a monotropic smectic B phase was observed below 100 °C,[7b] while the mesophase is observed up to 350 °C for the complex from **1** and **2**. The formation of the three-ring mesogen by the supramolecular assembly and the incorporation of the mesogen into the polyamide backbone have greatly contributed to the stabilization of the mesophase. For aromatic polyamides, high melting temperatures or no melting transitions are often encountered due to the stacking of the aromatic rings and the formation of hydrogen-bonding networks between the amide units. These interactions might also contribute to the stabilization of the mesophase. Recently a thermotropic mesogenic polyester containing a lateral pyridyl substituent was prepared to obtain hydrogen-bonded mesomorphic polymer blends;[9] however, in the present case the polymer backbone contains pyridyl groups, which, in turn, directly become part of the mesogen. The complex reported here belongs to a novel class of supramolecular mesogenic polymers, which is derived from a polyamide capable of molecular recognition on its backbone through the formation of hydrogen bonds.

Experimental Section

1: A solution of sebacoyl chloride (2.19 g, 9.16 mmol) in dry dimethylacetamide (DMAc) (5.0 mL) was added dropwise to a solution of 2,6-bis(amino)pyridine (1.00 g, 9.16 mmol) dissolved in the mixture of dry DMAc (30 mL) and LiCl (1.5 g) under argon atmosphere at room temperature. The reaction mixture was stirred for 24 h and then poured into 400 mL of acetone. The precipitate was filtered and washed with aqueous 5% Na_2CO_3, water, and finally acetone. The product was dried under vacuum at 70 °C for 24 h. Yield: 1.30 g (52%); m.p. 222 °C; $[\eta] = 0.27$ (in DMF at 30 °C). ^{1}H NMR (270 MHz, [D$_7$]DMF, 60 °C): $\delta = 9.85$ (2H; NH), 7.83 (2H; ArH *meta* to N), 7.72 (1H; ArH *para* to N), 2.47 (4H; $COCH_2$), 1.67 (4H; $COCH_2CH_2$), 1.34 (8H; $CO(CH_2)_2CH_2CH_2$); ^{13}C NMR (67.5 MHz, [D$_7$]DMF, 60 °C): $\delta = 172.9$ (CO), 151.7, 140.3, 109.3 (pyridine-C). 37.3, 25.9 (CH_2 groups). Two peaks due to the alkanediyl spacer overlapped with the peaks of DMF.

Complexation: An equimolar amount of the pyridyl unit of **1** and compound **2** was mixed and complexed in the isotropic molten state under an argon atmosphere. The sample was rapidly cooled to room temperature and used for the measurements.

Characterization: DSC thermograms were obtained on a Mettler DSC 30 apparatus at a heating rate of 10 K min^{-1} under a nitrogen atmosphere. For the polymeric materials, the temperature of the maxima of the melting endotherms and the middle point of the glass transition were taken as the transition temperatures. A polarizing microscope (Olympus BH2) equipped with a Mettler FP82HT hot stage was used for visual observation of the sample. X-ray diffraction measurements were carried out on a Rigaku X-ray Rad 2B system using Ni-filtered $Cu_{K\alpha}$ radiation. Samples placed on a Mettler FP 52 hot stage were used for the X-ray measurement.

$Co_2(O_3P-CH_2-PO_3)\cdot H_2O$: A Novel Microporous Diphosphonate with an Inorganic Framework and Hydrocarbon-Lined Hydrophobic Channels**

Douglas L. Lohse and Slavi C. Sevov*

Microporous materials are of great importance as molecular sieves, catalysts, ion-exchangers, and sensor materials.[1] Extensive exploration of new systems and new methods of synthesis has led to discoveries of novel materials with controlled pore sizes, better acidity, and better thermal stability. Nevertheless, despite the large number of different microporous compounds, all of them, with only two exceptions, have hydrophilic channels. The two exceptions are the methylphosphonates of aluminum and copper.[2] Such phosphonates and diphosphonates of the transition as well as main group metals have also received much attention during the last few years.[3-6] These are built of inorganic layers or chains that are either "coated" by the phosphonate and are held together by weak intermolecular forces,[3] or are linked covalently through diphosphonate groups.[4, 5] Many of the diphosphonates[5] and one monophosphonate, an aminoethylphosphonate,[6] mimic open-framework structures with hydrophobic channels but their "frameworks" contain organic interchain or interlayer links. The Al- and Cu-methylphosphonates are the only phosphonates that are microporous, have three-dimensional inorganic-only backbones, that is composed of a metal-oxygen-phosphorus network, and contain hydrophobic channels.[2]

We describe here the synthesis and structural characterization of the first microporous diphosphonate with an inorganic backbone and hydrophobic channels. The channels in the inorganic framework have hydrophobic walls built from methylene groups. The title compound was originally made in a hydrothermal synthesis designed to produce cobalt boro(methylene)diphosphonate analogues to the recently synthesized microporous cobalt borophosphate $CoB_2P_3O_{12}(OH)\cdot(enH_2)$ (en = ethylenediamine).[7] The reaction mixture contained $Co(NH_3)_6Cl_3$, boric acid, ethylenediamine, boron trifluoride-ethylamine complex, and methylenediphosphonic acid (instead of phosphoric acid). However, the reaction produced very fine flakelike crystallites of the sky-blue compound $Co_2(O_3P-CH_2-PO_3)\cdot H_2O$. In order to grow larger single crystals we repeated the synthesis but with some of the product of previous reactions added to a very dilute mixture of the starting materials.

The structure of the compound was determined by single-crystal X-ray diffraction. The monoclinic structure is of the open-framework type with channels running along the c axis (Figure 1). It contains one tetrahedrally coordinated (Co1) and two octahedrally coordinated (Co2 and Co3) cobalt atoms (Figure 2). The octahedrally coordinated Co2 (O1, O2, O2, O3, O4, O6) and Co3 centers (O1, O1, O3, O3, O5, O5) share edges and form zigzag chains running along the b axis (in out-of-phase fashion). Each Co3 octahedron shares two parallel edges with two Co2 octahedra (O1, O3), while each Co2 octahedron shares two oblique edges with one Co2 octahedron (2 × O2) and one Co3 octahedron. In addition, the Co2 octahedra share a corner

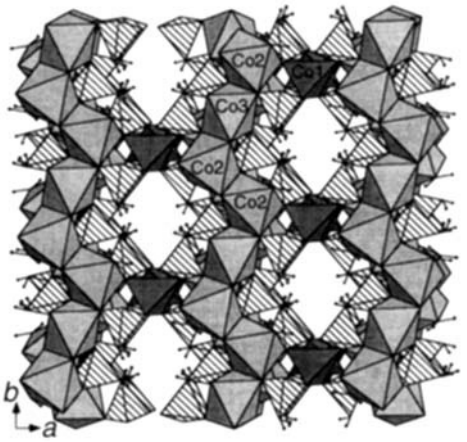

Figure 1. A view of the structure of $Co_2(O_3P-CH_2-PO_3)\cdot H_2O$ along the c axis of the monoclinic unit cell. The CoO_6 octahedra and the CoO_4 tetrahedra are shaded in light and dark gray, respectively. The tetrahedra of the O_3PC groups with a common C atom are striped. The C-H bonds of the CH_2 groups that form the walls of the hydrophobic channels are shown as well. Zigzag chains of octahedra run along the b axis; the chains are linked in sheets by the cobalt tetrahedra (see text).

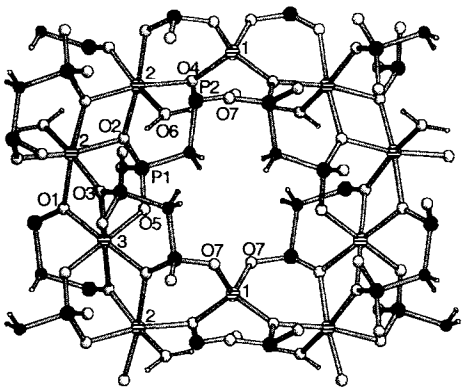

Figure 2. A detailed view of the channels along the c axis (the b axis runs vertical in the figure): C: black, P: dark gray, Co: striped, O: light gray, H: smallest circles. The "rectangular" shape of the channels is defined by CH_2 groups (the short dimension) and oxygen atoms (the long dimension). The water molecules coordinated to Co2 are also shown. The cobalt atoms are indicated by their numbers only. Pertinent (average) bond lengths [Å]: Co1-O(4×) 1.978, Co2-O(6×) 2.106, Co3-O(6×) 2.102, P1-O(3×) 1.524, P2-O(3×) 1.534, C-P(2×) 1.808, O6-H(2×) 1.00, C-H(2×) 1.02.

with the Co1 tetrahedron (O4). The remaining sixth vertex of the Co2 octahedron (O6) is occupied by a water molecule, while the two remaining vertices of the Co3 octahedron (2 × O5) are occupied by oxygen atoms from phosphonate groups. The Co1 tetrahedra link the zigzag chains at places of close approach (Figure 1) by sharing two of their vertices (2 × O4) with two Co2 octahedra from two different chains and form sheets of cobalt polyhedra (Figure 3). The remaining two vertices of the Co1 tetrahedron are occupied by atoms from phosphonate groups. The sheets of Co polyhedra are joined together to form a three-dimensional framework by oxygen-phosphorus-oxygen bonding (Figure 3); that is an inorganic-only network (backbone) is constructed. The P1 tetrahedron shares oxygen corners with two Co2 and one Co3 octahedra (O2 and O5, respectively) from one sheet, and with one Co2 and one Co3 octahedra (O1) from the adjacent one. The P2 tetrahedron shares its oxygen corners with one Co2 and one Co3 octahedra (O3) and a Co1 tetrahedron (O7) from one sheet, and with a Co2 octahedron and a Co1 tetrahedron (O4) from another one. Thus, the network of cobalt, phosphorus, and oxygen is linked quite tightly through covalent bonds.

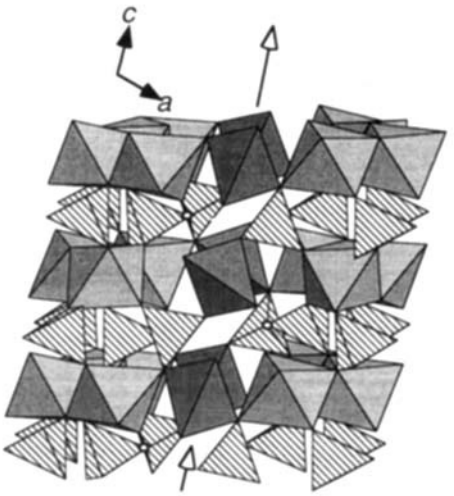

Figure 3. A view of the structure along the *b* axis showing how the layers of CoO_4 tetrahedra (dark gray) and CoO_6 octahedra (light gray) are linked by O–P–O bonds (the striped tetrahedra are of O_3PC) to give a three-dimensional inorganic framework. The carbon atoms are denoted by open circles. The open-head arrows show the general direction of the channels.

The Co–O distances are 1.963(5) and 1.992(5) Å in the tetrahedron, and range from 2.033(6) to 2.196(5) Å in the octahedra (the shortest distance is to the water molecule), all well within the expected limits. The two O_3PC tetrahedra of $[O_3P-CH_2-PO_3]^{4-}$ share the carbon atom of the methylene group; the P-C-P angle is 116.3(4)°. (The corresponding P-C-H and H-C-H angles are within the range of 101 to 116°, but as expected the uncertainties are much larger.) The P–O distances (1.513(5)–1.554(5) Å) and the two P–C distances (1.821(8) and 1.796(8) Å) are normal for phosphonates. Four of the seven different oxygen atoms are bonded to three neighboring atoms (O1, O2, O3, O4), two are bonded to two neighboring atoms (O5, O7), and one is the oxygen atom of the water molecule (O6), which is coordinated to Co2. The short distances between the oxygen atom of the water molecule and the two oxygen atoms bonded to two neighbors (2.646(9) and 2.719(9) Å for O6–O5 and O6–O7, respectively) indicate hydrogen bonding between these atoms.

The cross section of the channels has the shape of a quite elongated rectangle (Figures 1 and 2) with a short dimension of about 4.3 Å defined primarily by the methylene groups (the distance is measured from methylene group to methylene group). The compound can be considered as an inorganic microporous compound that has channels lined with hydrophobic CH_2 groups. Pointing towards the channels are also the two-bonded oxygen atoms O5 and O7, and the oxygen atom of the water molecule O6. They are located quite far from the center of the channels, about 3.5, 3.1 and 3.1 Å, respectively, and define the longer dimension of the latter. This unique arrangement of hydrophobic and hydrophilic units covering the walls of the channels may provide interesting absorption capabilities for small flat molecules with hydrophobic (hydrocarbon bodies) and hydrophilic (functional groups) regions.

Elemental analysis for carbon and hydrogen (M-H-W Laboratories) gave 4.8 and 1.19 wt%, respectively (the calculated values are 3.9 and 1.29 wt%, respectively). A diffuse reflectance spectrum of the compound shows strong absorption band in the region of 500–650 nm. Thermogravimetric measurements showed weight loss of about 4.5% above 350 °C, which is consistent with loss of most of the water in the structure (calculated value 5.8 wt%). This was confirmed by the IR spectra of the sample taken before and after the dehydration. The spectrum recorded before the heating clearly shows the characteristic P–O, C–H, and water bands in the regions 1000–1200, 2800–3000, and 3200–3600 cm^{-1}, respectively, but no water band can be seen in the IR spectrum recorded after the treatment.

The structure of the compound remains unchanged up to about 500 °C according to its X-ray diffraction pattern. The Guinier powder patterns taken of such heated samples showed relatively good crystallinity, and matched very well the powder pattern calculated from the refined structure of the compound before the dehydration. The lines were indexed with the same structure type, and the lattice parameters were only slightly smaller than those of the original unit cell. This clearly indicates that the framework of the structure remained intact at these temperatures. This, combined with the fact that the water molecules can be driven out of the structure, presumably through the channels, indicates that these channels can accommodate molecules at least the size of the water molecule. The dehydration process is irreversible and this is most likely due to the hydrophobicity of the channels.

We have shown that hydrophobic microporous compounds made of metal diphosphonates are accessible. The inorganic framework guarantees the relatively high thermal stability of the compound. The pore sizes are smaller than those in conventional microporous compounds but should be appropriate for small, flat, and hydrophobic molecules with sizes comparable to that of the water molecule such as ethylene and even benzene. Similar compounds with larger openings may be accessible by the use of appropriate hydrophobic templates in the synthesis.

Experimental Section

$Co_2(O_3PCH_2PO_3)\cdot H_2O$ was initially synthesized from a mixture of $Co(NH_3)_6Cl_3$, boric acid, methylenediphosphonic acid, ethylenediamine, $BF_3\cdot CH_3CH_2NH_2$ (all from Aldrich), and water in a molar ratio of 0.25:1:1:1:1: 50 (in an attempt to make a cobalt borophosphonate with an open-framework structure). After homogenization the mixture was loaded in teflon-lined autoclaves and heated at 190 °C for four days. Very fine blue flakes, the only solid product, were recovered and washed with water. It was determined that there was no boron in the product but the rest of the formula was not clear at this stage. A second reaction using HF instead of the boron trifluoride and without boric acid gave the same product but the flakes were again too small for single-crystal X-ray diffraction. In order to grow larger crystals, the washed product of the previous two reactions was added to a very dilute mixture of the starting materials ($Co(NH_3)_6Cl_3$, methylenediphosphonic acid, ethylenediamine, HF, and water in a molar ratio of 0.25:1:1:1:200). The idea was to use the small flakes as nuclei for larger crystals. The product had much larger crystallites indeed, and they were used for single-crystal X-ray strcuture analysis. Lastly, after the crystal structure and the stoichiometry of the compound had been determined, it was synthesized rationally from a mixture of $CoCO_3\cdot H_2O$, methylenediphosphonic acid, HF and water in a molar ratio of 2:1:1:50. The compound formed readily in high yields in acidic conditions.

Structure determination: Data were collected from a single crystal (0.1 × 0.05 × 0.01 mm) on a CAD4 single-crystal diffractometer with monochromated $Mo_{K\alpha}$ radiation at 21 °C (ω-2θ scans, $2\theta_{max} = 50°$, a hemisphere of $\pm h, k, \pm l$ was collected, 2322 measured and 1164 independent reflections with $R_{av} = 0.07$). After corrections for Lorentz and polarization effects the data set was consistent with the *C2/c* and *Cc* space groups. The Wilson plot suggested the centrosymmetric one and *C2/c* was chosen. Direct methods revealed the positions of the three cobalt and two phosphorus atoms. Subsequent least-squares refinement on F^2 followed by difference Fourier maps (using SHELXTL V5.0 package) revealed the positions of the remaining oxygen and carbon atoms. The four hydrogen atoms were refined by restraining their positions within a range of allowed O–H and C–H distances. The refinement of the cobalt, phosphorus, and oxygen atoms with anisotropic thermal parameters, and the carbon and hydrogen atoms with isotropic ones converged with $R1/wR2 = 0.0456/0.1028$ for 906 independent reflections with $I > 2\sigma_I$ and 122 parameters. (*Crystal data*: $Co_2(O_3PCH_2PO_3)\cdot H_2O$, *monoclinic*, *C2/c*, $a = 18.820(4)$, $b = 8.246(2)$, $c = 8.916(2)$ Å, $\beta = 106.68(3)°$, $V = 1325.4(5)$ Å^3 from Guinier data with Si as an internal standard and $Cu_{K\alpha 1}$ radiation, $Z = 8$, $\rho_{calcd} = 3.085$ g cm^{-3}, $\mu = 54.81$ cm^{-1}, residual electron density = + 0.85/ − 0.94 e Å^{-3} at 1.14/1.27 Å from Co3/Co1; crystal data for a sample heated at 480 °C for two days: monoclinic, *C2/c*, $a = 18.67(1)$, $b = 8.159(3)$, $c = 8.665(7)$ Å, $\beta = 106.29(3)°$ $V = 1267(1)$ Å^3 from Guinier data with Si as an internal standard and $Cu_{K\alpha 1}$ radiation). Enantioselective Diels–Alder Approach to Angucyclinones from (*S*)-2-(*p*-Tolylsulfinyl)-1,4-naphthoquinone and Substituted Racemic Vinylcyclohexenes**

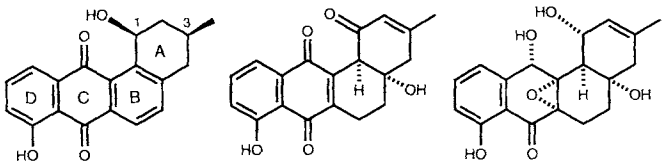
M. Carmen Carreño,* Antonio Urbano, and Jean Fischer

Angucyclines are a large group of naturally occurring quinones of microbial origin[1] that display a broad range of biological activities.[2] This family of antibiotics shares a benz[*a*]-anthracene framework of decaketide origin,[3] as well as a methyl group at C3 and an oxygen functionality at C1. The main structural differences among the members are found in the aromatic or hydroaromatic nature of the A and/or B rings. Some examples of angucyclinone antibiotics are (+)-emycin A, SF 2315A, and SF 2315B.



These challenging structures and their diverse biological activities have stimulated many synthetic studies of these compounds,[4] including several total syntheses.[5] The most general strategy employed for the regioselective construction of the angular tetracyclic core was the Diels–Alder reaction between a substituted naphthoquinone and a vinylcyclohexene. Efficient asymmetric syntheses were achieved by Sulikowski et al.[5d,e] from appropriately functionalized chiral dienes obtained from (−)-quinic acid, and by Larsen et al.,[5f] who used a chiral catalyst in the cycloaddition step that allowed kinetic resolution of the diene partner. To our knowledge no chiral dienophile has yet been used in asymmetric angucyclinone syntheses.

We studied the dienophilic behavior of enantiomerically pure sulfinyl quinones,[6] and found a high ability of the sulfoxide to control the regiochemistry, *endo* selectivity, and π-facial selectivity of cycloadditions with a wide range of dienes. We established the domino[7] Diels–Alder reaction/pyrolytic sulfoxide elimination as a general one-pot strategy to enantiomerically pure polycyclic dihydroquinones. This sequence could be applied to the synthesis of angucyclinones provided that substituted vinylcyclohexenes such as **2** (Scheme 1) reacted in a diastereoselective manner. We here report the first enantioselective approach to angucyclinones in which the homochiral sulfinyl quinone **1** is used to discriminate between both faces of a racemic vinylcyclohexene with a bulky alkoxy substituent at the allylic position.

A first test of this possibility was the ready reaction of (+)-**1**[8] with (±)-3-vinyl-2-cyclohexenol (**2a**;[9] Scheme 1). We isolated **3a** (28%) and **4** (51%) by flash chromatography. The stereochemistry of **3a**, which resulted from spontaneous pyrolysis of the sulfoxide in the initially formed adduct, fulfilled the expectations based on previous work with semicyclic dienes.[5c,f,10] Anthraquinone **4** was derived from **3a** in a fragmentation process[4a,5a,c] probably promoted by the free hydroxyl group and favored by the long reaction time required (3 d). The enantiomeric excess and absolute configuration of **3a** could not be determined at this stage due to its facile transformation into **4** under the experimental conditions necessary for preparing the corresponding Mosher esters.[11] To avoid the formation of **4** we thought of preparing a more stable derivative of **3a** en route to the angucyclinone functionality. Thus, treatment of **3a** with *m*-chloro peroxybenzoic acid (*m*-CPBA) afforded epoxide **5a** (90%) by the exclusive attack of the oxidant from the α face (*cis* to H12b).[12] The Mosher esters[11] of **5a** confirmed the absolute configurations shown in Scheme 1 for **3a** and **5a**. Nevertheless, the observed *ee* of 50% for **5a**[13] reflected low selectivity in the cycloaddition step.

The lability of **3a** and the low diastereoselectivity obtained with hydroxydiene **2a** prompted us to check a bulkier alkoxy substituent on the diene moiety to better differentiate the diene

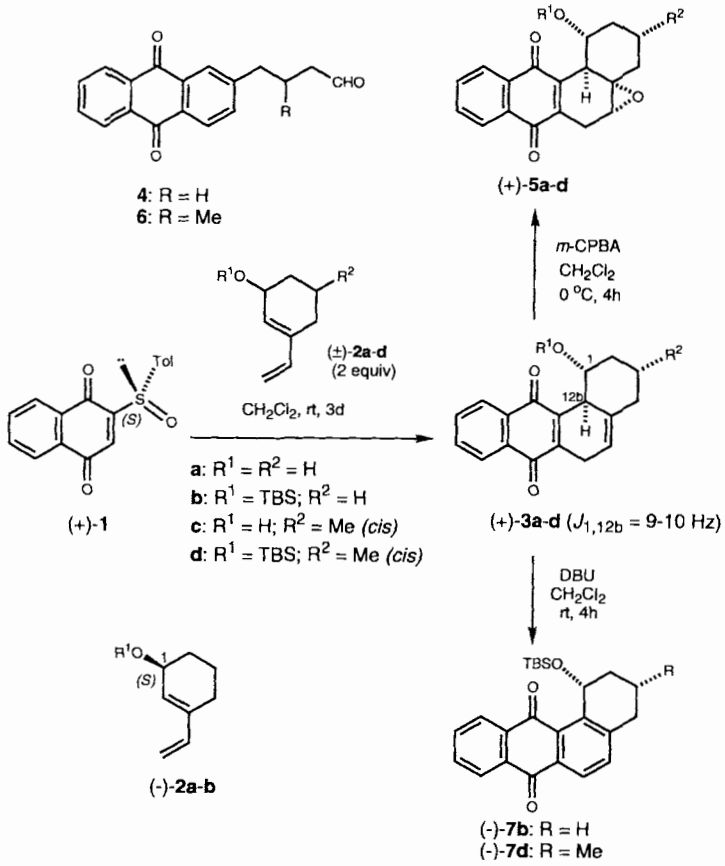

Scheme 1. DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene; TBS = *tert*-butyldimethylsilyl; RT = room temperature.

faces.[9] The Diels–Alder reaction of (+)-**1** with (±)-1-*tert*-butyldimethylsilyloxy-3-vinylcyclohex-2-ene (**2b**)[9] afforded **3b** (75%) as the exclusive reaction product (Table 1) together with unchanged diene. After flash chromatography we could recover 40% of optically active (−)-**2b** ($[\alpha]_D^{20} = -38$, $c = 1$ in $CHCl_3$), showing that kinetic resolution had occurred during the cycloaddition. The *ee* value of greater than 97% for **3b**[14] indicated excellent diastereoselectivity for the Diels–Alder reaction between (+)-**1** and **2b**. The *m*-CPBA epoxidation of **3b** again gave the sole epoxide **5b** (90%). In contrast, desilylation of recovered (−)-**2b** with TBAF afforded diene (−)-**2a** ($[\alpha]_D^{20} = -47$, $c = 1$ in $CHCl_3$) whose Mosher esters showed an *ee* value of 50% and *(S)* configuration at C1 (Scheme 1).

To extend these positive results and open an easy access to the substituted A ring of several angucyclinones, we investigated the behavior of dienes *cis*-**2c** and *cis*-**2d** with a methyl group at C5. Cycloaddition of (+)-**1** with (±)-5-methyl-3-vinylcyclohex-2-enol (**2c**)[15] afforded **3c** (26%) and **6** (50%) after flash chromatography. The *m*-CPBA oxidation of **3c** gave epoxide **5c** (82%) whose Mosher esters[11] again showed the absolute configuration depicted in Scheme 1 and 50% diastereoselectivity for the initial cycloaddition.[13] On the other hand, (±)-1-*tert*-butyldimethylsilyloxy-5-methyl-3-vinylcyclohex-2-ene (**2d**), obtained from **2c**[15] (*tert*-butyldimethylsilyl chloride (TBSCl), imidazole, *N*,*N*-dimethylformamide (DMF), 87%), reacted with (+)-**1** to yield exclusively **3d** (73%), whose epoxidation afforded **5d** (86%, *ee* > 97%).[14] This high enantiomeric excess indicated total stereocontrol in both the Diels–Alder reaction and epoxidation. Moreover, the absolute configuration of **5d** was confirmed by X-ray diffraction.[16] Enantiomerically pure epoxides **5b** and **5d** could be useful synthetic intermediates for the synthesis of antibiotics SF 2315A and SF 2315B that are lacking a hydroxy group at the C8 position.

7d: M.p. 125–126 °C; $[\alpha]_D^{20} = -59.0$ ($c = 0.1$ in $CHCl_3$); ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 8.20$ (m, 2H), 8.19 (d, $J = 7.9$ Hz, 1H), 7.74 (m, 2H), 7.46 (d, $J = 7.9$ Hz, 1H), 6.37 (t, $J = 5.9$ Hz, 1H), 2.86 (dd, $J = 10.8$, 15.5 Hz, 1H), 2.74 (dd, $J = 5.1$, 15.5 Hz, 1H), 2.19 (ddt, $J = 1.5$, 13.3, 5.9 Hz, 1H), 2.0–1.8 (m, 1H), 1.56 (ddd, $J = 6.2$, 8.7, 13.3 Hz, 1H), 1.18 (d, $J = 6.6$ Hz, 3H), 0.77 (s, 9H), 0.17 (s, 3H), −0.04 (s, 3H); ^{13}C NMR (50 MHz, $CDCl_3$): $\delta = 185.9$, 183.4, 148.1, 142.8, 135.4, 133.9, 133.6, 133.3, 133.2, 132.7, 131.8, 127.3, 126.5, 126.5, 66.3, 40.8, 39.0, 26.9, 26.0, 23.1, 18.1, −4.2, −4.5.

The approach to the anthraquinonic skeleton of (−)-emycin A required the aromatization of B ring of **3b** and **3d** without affecting the stereogenic moiety. Therefore, treatment of **3b** or **3d** with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in CH_2Cl_2 at room temperature[17] afforded anthraquinones **7b** (62%, *ee* > 97%)[14] and **7d** (58%, *ee* > 97%),[14] respectively.

According to the model proposed for (*S*)-*p*-tolylsulfinylquinone cycloadditions[6b–d] and the known behavior of dienes such as **2**,[5c,f,10] the absolute configuration of the new stereogenic centers should result from the matched *endo* approach of (*R*)-**2** from the face containing the less sterically demanding pseudoaxial substituent at the allylic position and towards the face of the quinone with the lone electron pair at sulfur in the s-*trans* conformation of **1** (Scheme 1).

We have reported the first asymmetric approach to the tetracyclic skeleton of angucyclinones from a chiral dienophile. The sulfinyl group on the quinonic framework promoted a double induction in Diels–Alder cycloadditions leading to efficient kinetic resolution of (±)-**2**. Further studies on the latter process and total syntheses of angucyclinones are in progress.

[12] The relative configuration was established by comparison with a similar intermediate prepared by Sulikowski [5d] in the total synthesis of SF 2315A.
[13] When the cycloaddition was carried out in water the reaction was faster (completed in 12 h at room temperature) but with a lower enantiomeric excess (20%).
[14] The enantiomeric excesses were evaluated by ^{1}H NMR spectroscopy using chiral lanthanide shift reagents: [Eu(tfc)$_3$] for **3b** and **5d**, and [Yb(hfc)$_3$] for **7b** and **7d**. The required racemic compounds were obtained from racemic quinone **1** [8].
[15] S. J. Hecker, C. H. Heathcock, *J. Org. Chem.* **1985**, *50*, 5159–5166.
[16] The absolute structure was determined by comparing refinements of both configurations, and confirmed by refining Flack's *x* parameter (G. Bernardinelli, H. D. Flack, *Acta Crystallogr. Sect. A* **1987**, *43*, 75–78). Crystallographic data (excluding structure factors) for (+)-**5d** have been deposited with the Cambridge Crystallographic Data Centre as suplementary publication no. CCDC-100127. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).
[17] These results contradict those reported by Sulikowski et al. [4g], who described no reaction for a similar system with DBU in benzene at 0 °C.

Evidence for a Stepwise Addition of Carbenes to Strained Double Bonds: Reactions of Dihalocarbenes with Cyclopropenes**

Jürgen Weber and Udo H. Brinker*

Dedicated to Professor William von Eggers Doering on the occasion of his 80th birthday

The most thoroughly investigated pathway of carbene stabilization is addition to carbon–carbon double bonds. Early studies by Skell and Woodworth[1] consider the singlet carbene addition a one-step process in which two new bonds are formed simultaneously. Even though the addition of singlet carbenes is concerted, it cannot be synchronous according to orbital symmetry considerations.[2] Jones et al.[3] suggested that the concept of nucleophilicity and electrophilicity, as applied to intermolecular additions of carbenes to alkenes, can be interpreted as the different contributions of the highest occupied and lowest unoccupied molecular orbitals (HOMOs and LUMOs). For instance, during the electrophilic attack of a dihalocarbene, charge is transferred from the olefin's HOMO to the empty p orbital of the carbene (LUMO). Calculations of activated complexes[4] for addition of dihalocarbenes to simple olefins support this direction of charge transfer. These calculations also show a shorter distance from the carbene carbon to one of the carbon atoms of the double bond.

Although addition of photochemically generated monohalocarbenes to 1,2-dimethylcyclobutene was postulated to proceed via zwitterions,[5] no conclusive evidence of their intermediacy[6] was provided.[7] We present here evidence that charge transfer during reactions of dihalocarbenes with differently substituted cyclopropenes leads to polarization of the activated complex or even to an intermediate dipolar species with complete charge separation.

Only few dihalocarbene reactions with cyclopropenes are known.[8] With the exception of perfluoro-1,3-dimethylbicyclo[1.1.0]butane,[9] geminal dihalobicyclobutanes, the addition products of dihalocarbenes, have never been isolated or unambiguously identified by spectroscopy. Instead cyclobutenes, probably formed by cationic cyclopropylallyl (CCA) rearrangements,[10] were found as the only products.

We initially reported that, for the first time, 2,3-diaryl-1,1-dihalo-1,3-butadienes were formed along with 1,3-diaryl-2,3-dihalocyclo-1-butenes by the reactions of dihalocarbenes (:CF_2, :CCl_2, :CBr_2, :CFCl, :CFBr) with 1,2-diarylcyclopropenes (Scheme 1).[11] We now present evidence for a step-wise addition of dihalocarbenes to strained double bonds of cyclopropenes. For the mechanistic studies of the formation of butadienes and cyclobutenes, three different aryl substituents were utilized. In the reactions of 1,2-diphenylcyclopropene (**1**) with dichlorocarbene, the ratios of the products, that is, of butadienes **2**[12] to cyclobutenes **5**,[12] were nearly independent of the method of carbene generation (Table 1).[13] This indicates that the same

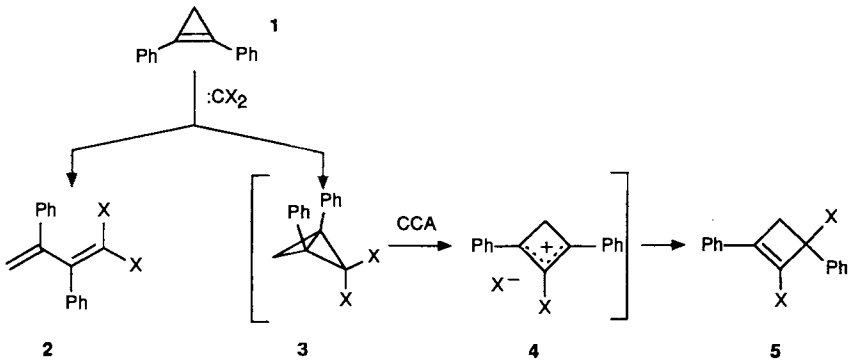


Scheme 1. Dihalocarbene addition to cyclopropene **1**: formation of 1,3-butadiene **2** and cyclobutene **5**.

Table 1. Ratios of cyclobutene **5a** to butadiene **2a** for reactions of cyclopropene **1** with the dichlorocarbene from different carbene sources.

Method	*T*	**5a**:**2a**	Yield [%] [c]
Doering–Hoffmann [13a]	−45 °C → 0 °C	79:21	20
ultrasound [a] [13b]	20 °C → 40 °C	87:13	70
Seyferth [b] [13c]	80 °C	80:20	79

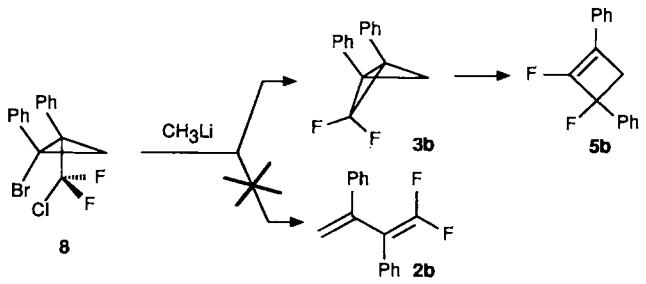
[a] Catalytic phase transfer method under ultrasound conditions. [b] $PhHgCCl_2Br$. [c] 2-Chloro-1,3-diphenylcyclobut-1-en-3-ol, the hydrolysis product from **5a**, was isolated.

reactive species, that is, a dichlorocarbene(oid), was involved in the formation of both products.

Cyclobutenes **5** may be derived from intermediate bicyclobutanes **3**. Cleavage of the central bond and loss of one halide in **3** leads to the stabilized homoaromatic cyclobutenyl cation **4**. Trapping of **4** by the halide gives **5** (Figure 1). In contrast, three different pathways can be suggested for the formation of butadienes **2** (Scheme 2).

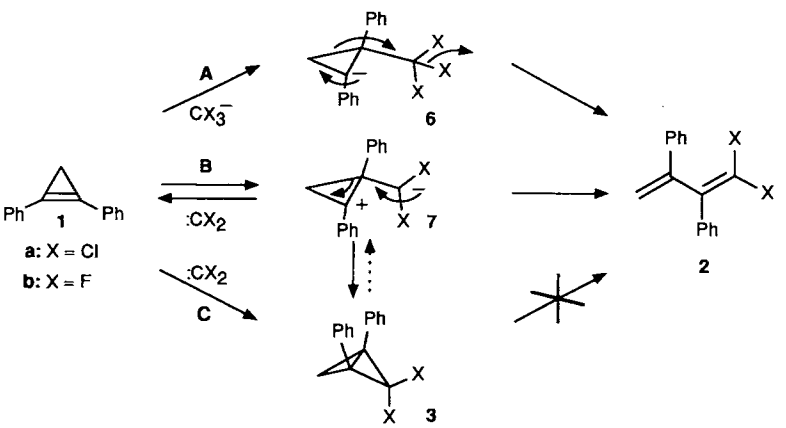
Butadienes **2** were formed when different conditions are applied for carbene generation, even at temperatures as low as −45 °C. This renders pathway C unlikely, because various substituted bicyclobutanes,[14] including several 1,3-diphenylbicyclobutanes,[15] are thermally stable at room temperature. Furthermore, attempts at an independent preparation of bicyclobutane **3b** exclude pathway C. *cis*-1-Bromo-2-chlorodifluoromethyl-1,2-diphenylcyclopropane (**8**)[12,16–18] was chosen as the precursor to **3b**. When **8** was allowed to react with methyllithium, only difluorocyclobutene **5b**, the formal CCA-rearrangement product of bicyclobutane **3b**, was found (Scheme 3). No evidence of difluorobutadiene **2b** was present. The only plausible way to explain the formation of **5b** is through **3b**. In contrast, the reaction of difluorocarbene with cyclopropene **1** affords only **2b** and no cyclobutene **5b**. That means, if **3b** were an intermediate, the formation of **5b** would also be expected.

Intermediates **6** and **7** (Scheme 2) may result from reactions of **1** with a trihalomethyl anion or a dihalocarbene (pathways A and B), respectively. However, the product ratios of the isomeric butadienes **13a** to **13b**[12] and **14a** to **14b**[12] obtained from dichlorocarbene additions to the asymmetrically substituted cyclopropenes **9**[12] and **10**[12,19], respectively, bearing an electron-withdrawing or electron-donating substituent at the *para* position of one of the phenylsubstituents support an electrophilic attack of the carbene (Scheme 2, pathway B). In contrast, butadienes **13b** and **14a**, which were expected to be the major isomers by nucleophilic attack of the trichloromethyl anion (pathway A), due to better stabilization of the negative charge, were found in lower amounts. Furthermore, direct generation of dichlorocarbene from phenyl(bromodichloromethyl)mercury without involvement of a trichloromethyl anion gave a butadiene to cyclobutene ratio of 20:80 when allowed to react with **1**. This ratio is nearly identical, within experimental error, to the ratios obtained by other methods of carbene generation (Table 1). Therefore, pathway A is not operative.

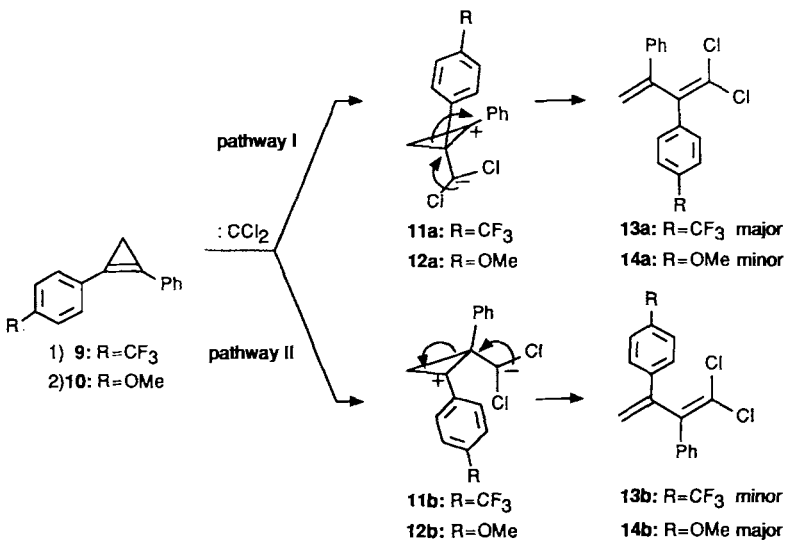


Scheme 3. Formation of cyclobutene **5b** by the ring-closing reaction of **8**.

Electrophilic attack of dichlorocarbene at the double bonds of **9** and **10** mainly gave **13a** and **14b**, which are derived from **11a** and **12b**, the intermediates that offer better charge stabilization (Scheme 4). Pathway I is more favorable for cyclopropene **9**, which has an electron-withdrawing trifluoromethyl substituent, due to better stabilization of the positive charge by the unsubstituted phenyl ring. On the other hand, for the reaction of **10** pathway II provides the better stabilization of the positive charge in **12b** through the electron-donating methoxy substituent. Comparison of the product ratios for both the butadienes substituted with *p*-methoxyphenyl or *p*-trifluoromethylphenyl shows a complete reversal of the ratios. This supports the proposed mechanism involving dipolar intermediates such as **7** (Scheme 2), **11**, and **12** (Scheme 4).[20,21] For simplicity, however, fully developed charges (zwitterions) have been depicted to explain the behavior of the reactants, even though the extent of polarization has not yet been established. Furthermore,



Scheme 2. Three possible reaction pathways to dihalobutadienes **2**.



Scheme 4. Electrophilic attack of dihalocarbenes on cyclopropenes **9** and **10** followed by rearrangement. Ratios of the butadienes: a) Doering–Hoffmann method: **13a**:**13b** = 74:26 and **14a**:**14b** = 29:71; b) catalytic phase transfer method under ultrasound conditions: **13a**:**13b** = 69:31 and **14a**:**14b** = 30:70.

the reaction of **1** with dichlorocarbene gave an increased ratio of up to 50:50 of butadiene **2** to four-membered ring compounds[22] when performed in the more polar solvent acetonitrile. This also provides strong evidence for the involvement of a polar intermediate similar to **7** (Figure 2) in the addition of dichlorocarbene to the strained double bond of **1**.

The data from this study indicate that the butadienes in the reactions of cyclopropenes **1**, **9**, and **10** with dichlorocarbene are derived from zwitterionic species, whereas the cyclobutenes result from a CCA rearrangement of the intermediate geminal dihalobicyclobutanes.

[16] We thank Professor R. Boese, Universität Essen, Germany, for the X-ray structure determinination of **8**. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-179. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223)336-033; e-mail: deposit@chemcrys.cam.ac.uk).

[17] Tetrahalocyclopropane **8** was synthesized from commercially available chlorodifluoroacetic acid: Treatment with sodium hydroxide gave the corresponding sodium salt, which reacted with phenylmagnesium bromide to afford chlorodifluoromethyl ketone [18] in 87% yield. Wittig reaction with methylenetriphenylphosphonium bromide produced α-(chlorodifluoromethyl)styrene (yield 71%). Addition of bromophenylcarbene, generated from treatment of benzal bromide with potassium *tert*-butoxide, afforded **8** and its *trans* isomer in very low yields. The isomers were purified in multiple steps and finally separated by HPLC.

[18] T. Ando, F. Namigata, M. Kataoka, K. Yachida, W. Funasaka, *Bull. Chem. Soc.* **1967**, *40*, 1275.

[19] The ratio of aryl-substituted butadienes to cyclobutenes was also found to be approximately 20:80, which is in good agreement with the previously determined ratio of **2** to **5**.

[20] Dipolar resonance structures have been proposed as intermediates in dihalocarbene additions to alkenes: P. S. Skell, A. Y. Garner, *J. Am. Chem. Soc.* **1956**, *78*, 5430; W. von E. Doering, W. A. Henderson, Jr., *J. Am. Chem. Soc.* **1958**, *80*, 5274.

[21] The strain energy probably has a major influence on the reaction of a dihalocarbene with cyclopropene **1**. Due to release of olefinic strain, an intermediate zwitterion should be lower in energy than **1**. Stabilization of the transition state can be achieved through ring opening and complete release of strain in the cyclopropane ring with concomitant formation of conjugated double bonds. On the other hand, ring closure of **7** to a geminal dichlorobicyclobutane leads to an initial increase in strain energy. However, once the bicyclic compound **3** has been formed, the CCA rearrangement inevitably proceeds, thereby releasing substantial amounts of strain energy.

[22] In addition to cyclobutene **5**, the coupling products *meso*- and (*R,S*)-2,2′-dichloro-1,1′,3,3′-tetraphenylbi[cyclobut-1-en-3-yl] were isolated.

Magnetization Studies of the Reduced Active Form of the Catalase from *Thermus thermophilus*

Lilian Jacquamet, Isabelle Michaud-Soret, Noëlle Debaecker-Petit, Vladimir V. Barynin, Jean-Luc Zimmermann, and Jean-Marc Latour*

Manganese-containing catalases[1, 2] are found in various bacteria such as *Thermus thermophilus* and *Lactobacillus plantarum*. Structural[3] and spectroscopic[4–6] evidence indicate that the enzyme from *T. thermophilus* possesses a dimanganese active site, which exists in four different redox forms. Mechanistic studies[7] have concluded that during catalysis the dimanganese center shuttles between a $Mn^{II}Mn^{II}$ and a $Mn^{III}Mn^{III}$ form. In vitro, mixed-valent forms $Mn^{II}Mn^{III}$ and $Mn^{III}Mn^{IV}$ can be generated. The latter two forms and the phosphate complex of the reduced enzyme exhibit characteristic EPR spectra, which have been extensively studied.[4–6] In particular, the temperature dependence of the EPR spectra has been used to estimate the magnetic exchange interaction J ($\mathcal{H} = -2J\boldsymbol{S}_1\boldsymbol{S}_2$) between the two manganese ions. This J value depends on the nature of the groups bridging these ions and therefore structural information may be derived from its estimation. A comparison of these values with those of structurally characterized model compounds supports the presence of a bis(μ-oxo)$Mn^{III}Mn^{IV}$ and a (μ-hydroxo)$Mn^{II}Mn^{III}$ unit in the two mixed-valent states.[5] Less conclusive results were obtained for the reduced catalase. For the phosphate derivative of the *T. thermophilus* enzyme, Khangulov et al. obtained a value of $J = -5.6\ cm^{-1}$ for the exchange interaction.[6] This value is intermediate between those observed for (μ-aqua)bis(μ-carboxylato)$Mn^{II}Mn^{II}$ centers ($-2.5\ cm^{-1} < J < -1.5\ cm^{-1}$)[8, 9] and for (μ-hydroxo)bis(μ-carboxylato)$Mn^{II}Mn^{II}$ centers ($J \approx -9\ cm^{-1}$).[10] No structural information is available for the unliganded $Mn^{II}Mn^{II}$ active form which does not have an EPR spectrum sufficiently resolved to investigate the temperature dependence.

In order to obtain structural information on the unliganded catalytically active site and on the phosphate complex of $Mn^{II}Mn^{II}$ catalase from *T. thermophilus*, we studied the field and temperature dependence of the saturation magnetization.[11] This technique is particularly suitable for evaluating the exchange interaction in dinuclear centers[12] and allowed us to get the first structural information on the active reduced state. From magnetostructural correlations we propose a (μ-aqua)(μ-carboxylato) bridging pattern in the unliganded $Mn^{II}Mn^{II}$ form of the enzyme. The same bridges are present in the phosphate derivative and the addition of a bridging phosphate is most consistent with all magnetic and biochemical observations—a fact that may have important mechanistic implications.

Figure 1 presents the magnetic properties of the reduced catalase in D_2O (curve a) and in a deuterated phosphate buffer

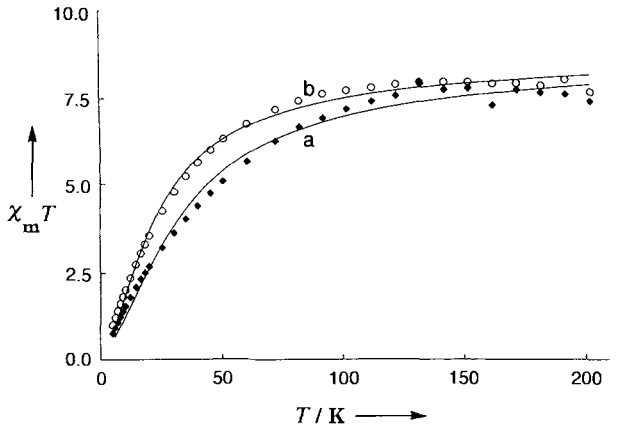

Figure 1. Temperature dependence of the product of the magnetic susceptibility and temperature (expressed in $cm^3 K mol^{-1}$) for unliganded catalase (a) and its phosphate derivative (b). Data collected at 5 Tesla. The solid lines are the theoretical curves corresponding to the best fit parameters (see text).

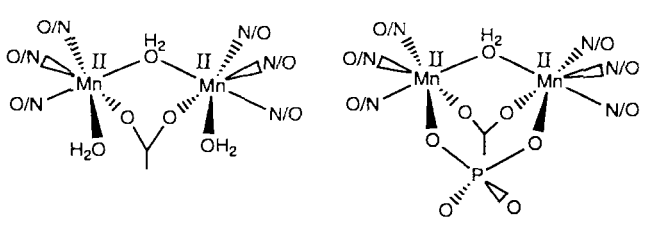
(curve b) as the temperature dependence of the product of the molar susceptibility and temperature. The two forms of the enzyme behave very similarly. At 200 K, $\chi_m T$ reaches about $8\ cm^3 K mol^{-1}$, a value consistent with two uncoupled spins $S = 5/2$. The product $\chi_m T$ decreases slightly over the domain between 200 and 60 K and then more strongly to become lower than $1\ cm^3 K mol^{-1}$ at 5 K. The data of both catalase forms were fitted with the Heisenberg exchange hamiltonian ($\mathcal{H} = -2J\boldsymbol{S}_1\boldsymbol{S}_2$); this gave exchange interactions J of $-2.4(2)\ cm^{-1}$ for the unliganded enzyme and $-1.7(2)\ cm^{-1}$ for the phosphate derivative. These values are very similar to each other; nevertheless, they are significantly different. Data on model systems[8, 9, 13] show that J values around $-2\ cm^{-1}$ are associated with dimanganese(II) units bridged by a water molecule and two carboxylate groups. It must be noted, however, that the number of carboxylate groups is not likely to have a strong effect on the J value provided that at least one carboxylate group is present. Thus, in contrast to EPR experiments, the magnetization data undoubtedly favor the presence of an aqua bridge in the reduced states of the enzyme.

Owing to the low absolute values of the exchange interaction it is difficult to derive firm conclusions on the phosphate binding mode. However, the decrease of $|J|$ in the presence of phosphate is in agreement with the formation of a phosphate bridge. Indeed, several examples are known in iron chemistry,[15] where introduction of a phosphate bridge in addition to or in place of a carboxylate bridge causes a decrease of the exchange interaction. The case of the diiron enzyme purple acid phosphatase (uteroferrin)[16] is enlightening in this respect. Another piece of supporting evidence for a bridging phosphate comes from our observation that phosphate binding protects the reduced center from oxidation by air or hydrogen peroxide.

The structural implications of these findings are depicted in Scheme 1. In the reduced enzyme the two manganese ions are bridged by a water molecule and one or two carboxylate groups. The presence of one or two carboxylate bridges is equally feasible. To form a bridge, the phosphate group should occupy two adjacent coordination sites of the dimanganese center. Since these sites are required for a concerted interaction of dioxygen or peroxide with the dimanganese center, a bridging phosphate would explain its inhibitory effect on the catalase reaction and the stabilization of the reduced state toward dioxygen. In turn this suggests that a single carboxylate bridge is present and that the two *syn* coordination sites of the dimanganese center are occupied by easily exchangeable ligands, namely water molecules.



Scheme 1. Structure of the unliganded reduced catalase from *T. thermophilus* (left) and its phosphate derivative (right).

Experimental Section

All samples were checked by UV/Vis and EPR spectroscopy, which allow the traces of $Mn^{II}Mn^{III}$, $Mn^{III}Mn^{III}$, and $Mn^{III}Mn^{IV}$ forms to be quantified. [Cu(edta)] was used as EPR standard. The manganese content was measured by ICP analysis and the enzyme concentration determined as in the literature [7]. After concentration to 130–150 μL in a deuterated buffer, the samples were deaerated on a manifold argon/vacuum line and 115 μL were transferred into a quartz sample bucket within a glove box. The samples were then frozen in liquid nitrogen and introduced in the magnetometer. Two samples (0.34 mM and 2.9 mM) of the phosphate derivative were prepared by hydroxylamine reduction [7] of oxidized catalase in 10 mM phosphate buffer at pH 6.8 followed by three dilution/concentration cycles against 100 mM phosphate buffer at pH 6.8. Two samples (0.21 mM and 2.15 mM) of the unliganded form were obtained from the phosphate derivative by dilution/concentration cycles against D_2O followed by overnight incubation within a glove box and concentration.

Magnetization experiments (Figure 1) were performed with a SQUID magnetometer SHE 500 at six different fields in the range 0.5–5 Tesla in the temperature domain from 5 to 200 K on the two samples. The data were analyzed according to the procedure outlined by Day [11]. In this treatment the diamagnetic contribution of the protein is eliminated with the ferromagnetic contamination of the quartz sample holder. Owing to the extremely small field dependence of the magnetization the susceptibility data were fitted with the equation derived from the Heisenberg hamiltonian $\mathcal{H} = -2J\boldsymbol{S}_1\boldsymbol{S}_2$ appropriate for a pair of spins $S = 5/2$. The data were corrected for the presence of a small amount (sample 1: 0.5%; sample 2: 5%) of strongly antiferromagnetically coupled mixed-valent species ($S = 1/2$). The g values were fixed at 2.0.

[12] In EPR experiments the exchange interaction is evaluated after deconvolution of the temperature-dependent experimental EPR spectra into those of the excited $S = 1$ and $S = 2$ states which allows the population of these states to be estimated and eventually fitted to the Heisenberg spin exchange equation. Owing to the larger temperature domain (ca. 200 K vs ca. 40 K) and the fact that the susceptibility is directly evaluated without an additional mathematical procedure, the magnetization techniques furnish a more reliable estimate of the magnetic exchange interaction.

[13] Owing to its d^5 configuration the manganese(II) ion is isotropic and not very sensitive to geometrical factors. Therefore it is quite unlikely that such factors can reduce the magnetic exchange coupling mediated by a hydroxo bridge. In this respect, it is worth noting that J was also evaluated to be $-9\ cm^{-1}$ in an (μ-hydroxo)bis(μ-carboxylato)$Mn^{II}Mn^{III}$ complex [14].

Perfluoroalkyl-Substituted Arylphosphanes as Ligands for Homogeneous Catalysis in Supercritical Carbon Dioxide**

Sabine Kainz, Daniel Koch, Wolfgang Baumann, and Walter Leitner*

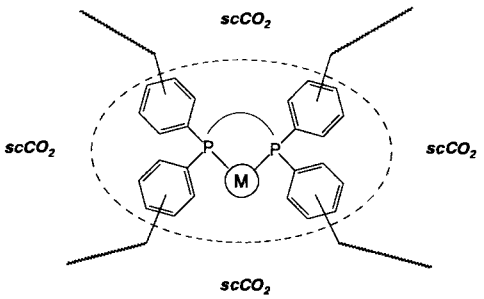
In memory of Sir Geoffrey Wilkinson

Carbon dioxide in the supercritical state ($scCO_2$) is an interesting reaction medium that has recently been established for application in homogeneous catalysis with transition metal complexes.[1] Compared to conventional organic solvents, $scCO_2$ provides a nontoxic and ecologically benign alternative. Furthermore, $scCO_2$ is highly miscible with many gaseous reactants, thus avoiding rate limitations by diffusion processes, as is often encountered with gas/liquid-phase reactions. A possible increase in selectivity and activity through special solvent effects in the supercritical medium has also been discussed. Finally, since the solvent properties of $scCO_2$ can be tuned by variation of pressure and temperature,[2] selective separation directly from the reaction mixture seems possible.

Ironically, the solvent properties of $scCO_2$ have up to now represented the major obstacle for its wide application as a reaction medium in homogeneous catalysis. In a first approximation $scCO_2$ possesses solvent properties comparable to those of saturated hydrocarbons; this leads to severe limitations for the choice of catalysts. Especially complexes containing arylphosphane ligands (such as Ph_3P, $Ph_2P(CH_2)_nPPh_2$, 4,5-bis[(diphenylphosphanyl)methyl]-2,2-dimethyl-1,3-dioxolan (Diop), 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl (Binap)), which have proven extremely useful in homogeneous catalysis, are often insufficiently soluble in $scCO_2$.[3] The use of complexes containing these ligands is therefore restricted to exceptional cases, for example when the substrate can act as a cosolvent.[4]

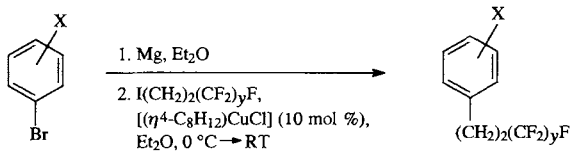
To increase the solubility of transition metal catalysts in $scCO_2$, Burk and Tumas used the lipophilic, fluorinated anion $[B\{3,5\text{-}(F_3C)_2C_6H_3\}_4]^-$ (BAr_f) for ionic catalysts with alkylphosphane ligands.[5] Jessop and Noyori suggested addition of perfluorinated alkyl alcohols to the reaction mixture for neutral complexes with Binap-type arylphosphanes.[3b] Both methods lead only to a moderate increase in solubility. The solubilizer is not directly bound to the reaction center, which results only in a weak, nonpermanent interaction. The use of the BAr_f anion is further restricted to ionic compounds, and application of additives is of course not desirable for practical reasons.

We have now developed a generally applicable methodology to increase the solubility of arylphosphanes and their metal complexes in $scCO_2$ without changing their catalytic properties. The concept is outlined in Scheme 1 for complexes containing a bidentate chelating phosphane ligand. The solubilizers (waved lines) are directly fixed at the aryl moiety in a way that keeps structural and electronic changes with respect to the unsubstituted parent complexes to a minimum. Long perfluoroalkyl chains $R = (CH_2)_2(CF_2)_yF$ ($y = 6, 8$) were chosen as solubilizers.[6]



Scheme 1. Concept for the use of bis(arylphosphanes) as ligands in homogeneous catalysis in $scCO_2$. The side chains (waved lines) in the periphery of the ligands help to dissolve the insoluble parent compounds in $scCO_2$ without changing the electronic or structural properties at the catalytically active center (dashed oval).

The aryl bromides **2a–d**, which are key building blocks for the synthesis of the previously unknown arylphosphanes, were obtained by Cu^I-catalyzed coupling of the mono Grignard reagents from dibromides **1a–c** with commercially available iodides $I(CH_2)_2(CF_2)_yF$ ($y = 6, 8$; Scheme 2). Subsequent lithiation of **2a–d** and reaction with 1,2-bis(dichlorophosphino)ethane in Et_2O gave the new phosphanes **3a–d**. In a similar manner, **4** and **5** were prepared from **2b** with PCl_3 and **2c** with $(Et_2N)PCl_2/HCl$, respectively (Scheme 3).[7, 8]



1a, X = 2-Br
1b, X = 3-Br
1c, X = 4-Br

2a, X = 2-Br, $y = 6$
2b, X = 3-Br, $y = 6$
2c, X = 4-Br, $y = 6$
2d, X = 4-Br, $y = 8$

Scheme 2. Synthesis of perfluoroalkyl-substituted aryl bromides **2a–d**.

Phosphane **5** represents a perfluoroalkyl-substituted derivative of Ph_2PCl, a starting material for the synthesis of a large variety of bis(arylphosphanes) and phosphinites including many chiral ligands. Phosphane **4** is an analogue of Ph_3P (TPP), probably the most widely used phosphane ligand in homogeneous catalysis. Phosphanes **3a–d** are derived from the well-known ligand $Ph_2P(CH_2)_2PPh_2$ (dppe). Similar to the unsubstituted

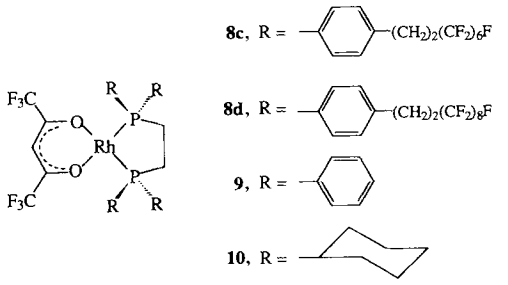
The significant enhancement of the solubility of arylphosphane complexes in $scCO_2$ upon substitution with perfluoroalkyl side chains was quantified by UV/Vis spectroscopy of saturated solutions of the colored rhodium hexafluoroacetylacetonate complexes **8**–**10**.[9, 10] The unsubstituted bis(arylphosphane) complex [Rh(hfacac)(dppe)] (**9**) is insoluble in pure $scCO_2$, even at high densities of the supercritical phase; neither a coloration of $scCO_2$ nor an absorption in the UV/Vis spectrum is observed. As expected the cyclohexyl analogue **10** is sparingly soluble. Although the supercritical phase is colorless at relatively low density ($\rho = 0.55\,g\,mL^{-1}$), it shows the typical[9b] absorption for complexes of type [Rh(hfacac)(P_2)]; the concentration was estimated to be $1.1 \times 10^{-5}\,mol\,L^{-1}$.[9] Under



identical conditions, **8c**,**d** yield bright orange solutions with saturation concentration of $6.3 \times 10^{-5}\,mol\,L^{-1}$ (**8c**) and $7.5 \times 10^{-5}\,mol\,L^{-1}$ (**8d**), which is 5 and 7 times higher, respectively, than that of **10** (Figure 1).

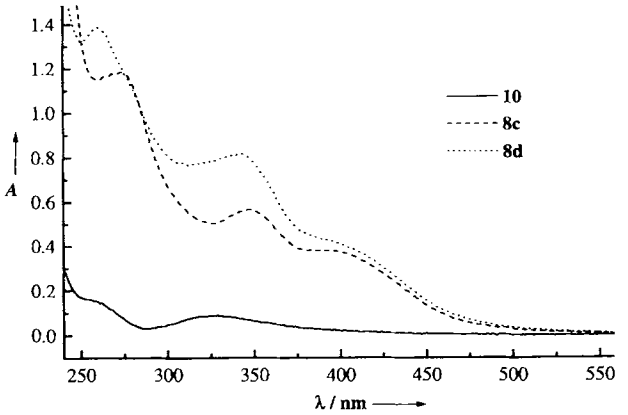


Figure 1. UV/Vis spectra of **8c**,**d** and [Rh(hfacac){$Cy_2P(CH_2)_2PCy_2$}] (**10**; Cy = cyclohexyl) in $scCO_2$ ($T = (45 \pm 5)\,°C$, $p = (90 \pm 5)$ bar, $\rho = 0.55\,g\,mL^{-1}$).

Increasing the density of the supercritical phase naturally enhances the solubility of **8**.[2] For instance, 158 mg of **8c** dissolved completely in the high-pressure cell ($V = 17.3$ mL) at a density of $\rho = 0.75\,mL^{-1}$ to yield a concentration of $4.4 \times 10^{-3}\,mol\,L^{-1}$. The solubility of **8c** in $scCO_2$ is thus at least 150 times higher than that of the alkylphosphane complex [Rh((*R*,*R*)-Et-Duphos)(η^4-C_8H_{12})][BAr_f] ((*R*,*R*)-Et-Duphos = (−)-1,2-bis[(2*R*,5*R*)-2,5-diethylphospholano]benzene), for which Burk and Tumas determined a maximum solubility of $0.03 \times 10^{-3}\,mol\,L^{-1}$ at much higher density ($T = 50\,°C$, $p = 345$ bar, $\rho = 0.89\,g\,mL^{-1}$).[5] Therefore, introduction of the perfluoroalkyl side chain not only transforms the insoluble parent compound **9** into the $scCO_2$-soluble **8**, but also results in solubilities exceeding those of known soluble catalysts by at least two orders of magnitude.

The chemical shift δ of the ^{103}Rh nucleus is a sensitive probe for structural and electronic variation at the metal center of complexes [Rh(hfacac)(P_2)].[9] The change of only a few ppm to lower field observed for the signal for **8b**–**d** compared to that for unsubstituted parent compound **9** ($\delta = 438$) shows that, as anticipated, the two CH_2 groups separate the strong electron-withdrawing effect of the long perfluorinated chains effectively from the aryl moiety (Table 1).[6a] In the case of **8a** the large perfluorinated chains in the *ortho* positions most likely lead to appreciable distortion of the coordination geometry at the rhodium center, resulting in a significant shift to lower field of $\Delta\delta \approx 270$ with respect to that of **9**.[9] This interpretation is supported by temperature-dependent ^1H and ^{31}P NMR spectra of **8a** as well as preliminary molecular modeling calculations. A simultaneous electronic influence cannot be fully excluded.

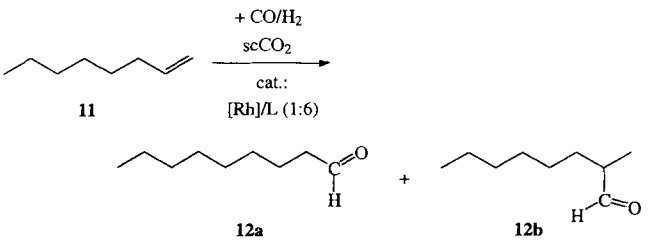
Finally, the potential of the perfluoralkyl-substituted arylphosphanes for homogeneous catalysis in $scCO_2$ was established with the rhodium-catalyzed hydroformylation of 1-octene (**11**) to isomeric aldehydes **12a,b** (Scheme 4).[11, 12] The



L = PPh_3 (26 % conversion) 3.5 : 1
L = **4** (92 % conversion) 4.6 : 1

Scheme 4. Rhodium-catalyzed ([Rh] = [Rh(hfacac)(η^4-C_8H_{12})]) hydroformylation of 1-octene (**11**) to nonanal (**12a**) and 2-methyloctanal (**12b**) in $scCO_2$ [12]; see text for reaction conditions.

catalytic system Rh/TPP, which is well established in organic solvents, was found to be unsuitable for application in $scCO_2$ owing to the insufficient solubility of the active species as suspected (colorless solution, 26% conversion, **12a**:**12b** = 3.5). On the other hand, a conversion of 92% and an *n*:*iso* ratio of **12a**:**12b** = 4.6 was obtained under identical but nonoptimized conditions with a catalyst formed in situ from [Rh(hfacac)(η^4-C_8H_{12})] and the TPP-analogue **4** (**11**:**4**:Rh = 200:6:1) at 60 °C and a total pressure of 220 bar ($p(CO) = p(H_2) = 30$ bar at room temperature). Side reactions such as hydrogenation or formation of further isomeric aldehydes were not observed. The intense yellow color of the homogeneous supercritical phase confirmed the solubility of the catalytically active species containing **4** during the whole course of reaction.

Our concept of homogeneous catalysis in $scCO_2$ relies on a straightforward and variable synthetic route to perfluoroalkyl substituted arylphosphanes. These ligands provide significantly higher solubility in $scCO_2$ compared to the insoluble parent compounds and to known soluble phosphane-containing catalysts. The solubilizers in the periphery of the ligand do not interfere with the electronic or structural properties of the coordinated metal center, provided that a suitable substitution pattern is maintained. Therefore, the well-known potential of arylphosphorus compounds as ligands for homogeneous catalysis is now available for applications in $scCO_2$.

[12] The experiments were carried out in a stainless-steel high-pressure reactor equipped with glass windows ($V = 20$ mL, $p_{max} = 300$ bar, $T_{max} = 120$ °C). The reactor was charged with the catalyst and **11** (1.50 mL, 9.60 mmol) under an inert atmosphere. The reactor was pressurized with a 1:1 mixture of CO and H_2 to 60 bar and then filled with CO_2 (13.6 g) using a compressor. After heating the reaction mixture to 60 °C for 19 h, samples were withdrawn and analyzed by GC and ^1H NMR spectroscopy.

Merocyanines as Extremely Bathochromically Absorbing Chromophores in the Halobacterial Membrane Protein Bacteriorhodopsin**

Dorothee Hoischen, Siegfried Steinmüller, Wolfgang Gärtner,* Volker Buss,* and Hans-Dieter Martin*

The binding of ligands to proteins can lead to significant changes in their physical and chemical properties. This is particularly apparent for photoisomerizable chromoproteins, for example the membrane protein bacteriorhodopsin (BR) of the halophilic archaebacterium *Halobacterium salinarium*, which contains retinal (**1**, see Scheme 1).[1, 2] Upon absorption of light, BR transports protons by a cyclic reaction sequence (the photocycle of BR lasts about 10 ms) into the outer medium, allowing

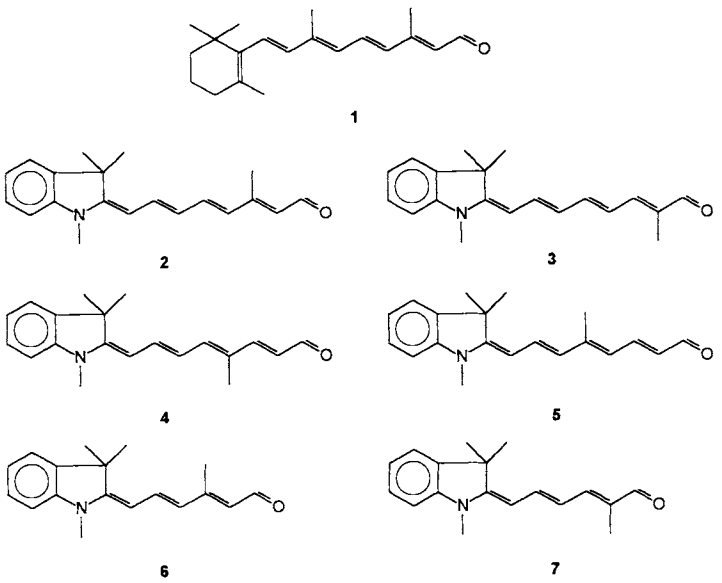


Scheme 1. Structural formulas of retinal (**1**) and the newly synthesized merocyanine dyes **2**–**7**.

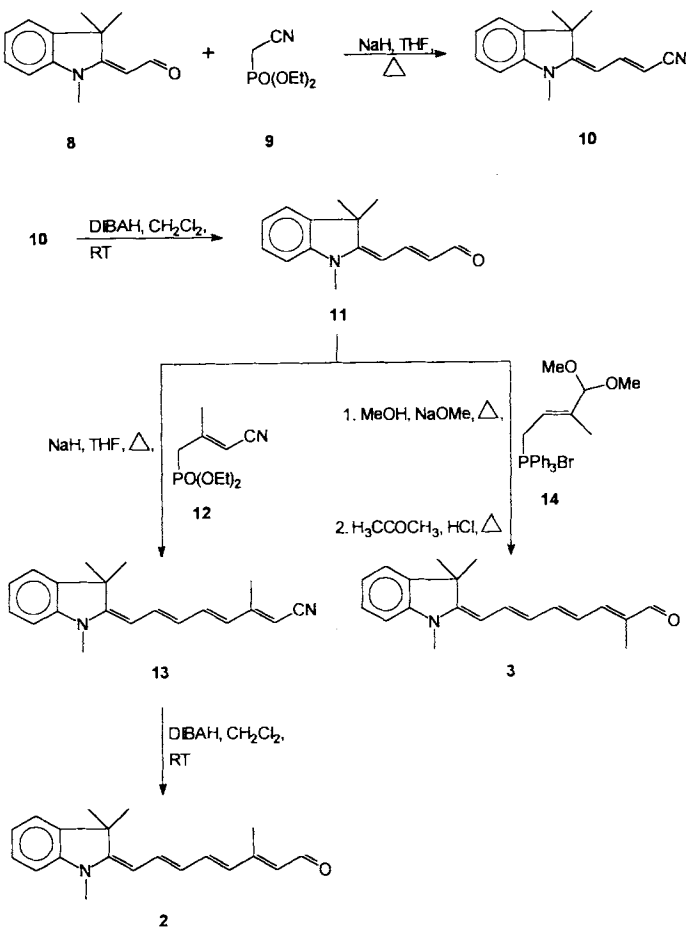
the energy thus stored to be employed for further metabolic processes. During the photocycle several intermediates with clearly discernable spectral properties are formed.[3] The structural changes that the chromophore and protein undergo can be followed by a variety of spectroscopic techniques.[2, 4, 5]

Covalent attachment of all-*trans* retinal to lysine 216 through a protonated Schiff base linkage causes a strong red shift of the absorption maximum (λ_{max} = 568 nm; protonated butylamine/retinal Schiff base in ethanol: λ_{max} = 440 nm). This energy difference is called the opsin shift (OS) and amounts to 5183 cm^{-1} for BR.[6]

Three increments that concertedly cause the red-shifted absorption of BR are currently being discussed:[2, 7] the positive charge of the Schiff base, the conformational changes of the chromophore resulting from incorporation into the binding pocket of the protein, and the influence of charged and polar amino acids in the chromophore environment. To study these influences when the π-electron system is strongly delocalized, we synthesized a series of novel merocyanine dyes (Scheme 1) and studied the spectroscopic properties of the new BR derivatives obtained by reconstitution with the protein (see also ref. [8, 9]). Due to the indolylidene end group these compounds should be converted into hemicyanine chromophores that show the expected absorption spectra upon formation of a protonated Schiff base.[10] The synthetic route to these novel compounds is given for the example of **2** and **3** in Scheme 2.

Upon incubation with chromophore-depleted BR (bacterio-opsin, BO) the merocyanine dyes generate BR derivatives exhibiting remarkably bathochromic, narrow-absorption bands with large absorption coefficients (Figure 1a, Table 1). UV/Vis spectra measured throughout the incubation of **2** with BO (Figure 1a) exhibit an isosbestic point, indicating a homogeneous reaction. The reconstitution apparently leads to a stable, covalent linkage between chromophore and protein, since the subsequently added retinal does not displace the merocyanine from the binding site (Figure 1b). Likewise, addition of any of the merocyanines to native BR does not result in red-shifted absorption bands (not shown).

The most apparent structural change between the novel dyes and native retinal (besides the different substitution pattern in some of the compounds) is the replacement of the cyclohexene



Scheme 2. Synthesis of **2** and **3** from **8**, which was kindly provided by BASF AG, Ludwigshafen, Germany (RT = room temperature). All intermediates and products exhibited the expected spectroscopic and chromatographic properties.

ring of retinal with an indolylidene group, which causes strongly red-shifted absorption maxima. Interestingly, BR derivatives also can be formed with compounds having a different methyl substitution pattern than retinal (**3**–**5**); only the correctly substituted compound forms a BR pigment upon truncation of the conjugated polyene chain (see **6** and **7** in Table 1).

A common feature of the new pigments is the formation of hypsochromic vibration band progressions.[11] The red-shifted absorption bands of the protonated Schiff bases of these compounds are already observable in ethanol and indicate a remarkable delocalization of the double bonds (see Table 1). Conse-

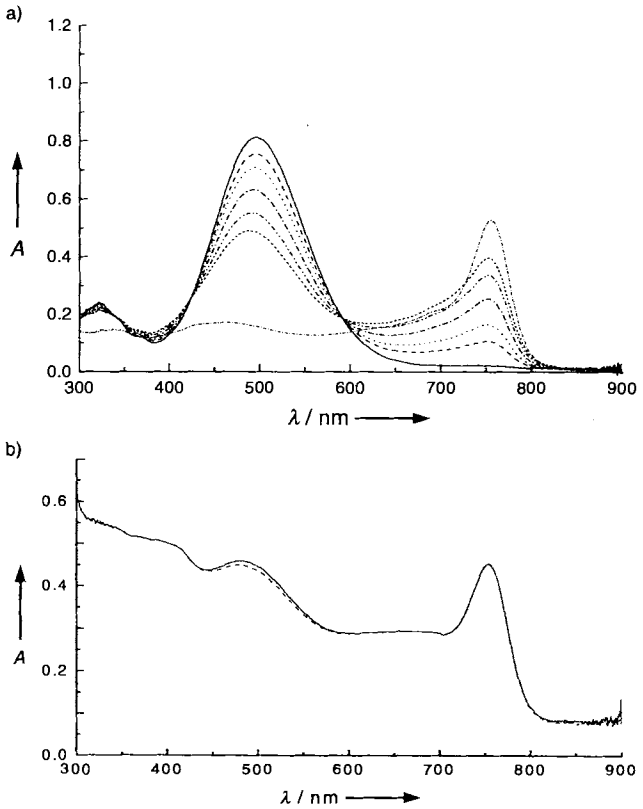

Figure 1. a) UV/Vis spectra of the reconstitution (at room temperature) of **2** with bleached bacteriorhodopsin (BO). The series of curves (growth of the absorption at 755 nm, and decrease of the absorption of the free chromophore at 500 nm) shows the course of the reconstitution starting with the spectrum recorded immediately after addition of the compound (——, λ_{max} = 500 nm) and after 40, 80, 120, 160, 200 min and 12 h (curve with largest absorption at 755 nm). The isosbestic point at about 590 nm is observed for at least 3 h and indicates a uniform reaction (incubation for 12 h—spectrum with maximal absorption at 755 nm—induces changes in the entire spectral range with loss of the isosbestic point). b) Spectrum on incubation of the fully reconstituted new pigment with all-*trans* retinal to demonstrate covalent incorporation of the merocyanine into the protein binding site.

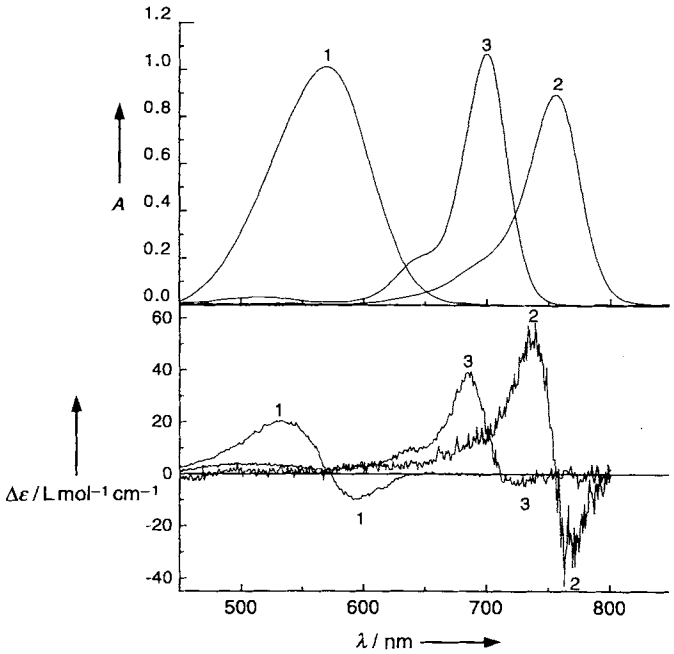

Figure 2. UV/Vis (top) and CD spectra (bottom) of BR derivatives containing **2** and **3** and the spectra of native BR (curve 1 in both panels).

quently, the influence of the protein environment on the position of the absorption maximum is only moderate, as is seen from the small values of the opsin shifts (on the order of about 900 cm^{-1}, except for **2**: 1770 cm^{-1}; see also Table 1).

Due to the strong fluorescence of the new BR pigments, direct proof of the presence of a protonated Schiff base could not be obtained from resonance Raman spectroscopy.[12] However, the CD spectra of the new BR derivatives (Figure 2) exhibit nonconservative, excitonic bands similar to those observed for native BR, and indicate incorporation of the dyes into the protein in a manner comparable to that of retinal. The CD spectra of all compounds (except for **7**, which does not react with the protein) are made up of a biphasic band with positive absorption at short and negative absorption at long wavelengths, and a cross-over wavelength identical to the absorption maximum in the UV/Vis spectrum. The nonconservative character of the CD spectra is also evident from the different $\Delta\varepsilon$ values of the extrema (Table 1). With the exception of compound **6**, the short-wavelength positive band is of greater intensity than the negative band; the ratio between them varies from 5:3 (**2**) to more than 10:3 (**3**). In line with the excitonic interpretation of the CD spectra of BR pigments,[13] all spectra can be separated into two contributions, that is, a monophasic positive contribution (negative in the case of **6**)—which correlates in shape and wavelength position with the absorption maximum, and is caused either by the chromophore that is incorporated into the protein in a twisted conformation or from chromophore–protein interactions—and a biphasic, conservative contribution resulting from the interaction between the chromophores.[14]

Laser flash induced study of the photochemical properties reveals a behavior remarkably different from that of BR. In the time range of about 100 ns to 10 ms, which covers all thermally driven kinetic processes of the BR photocycle (after photochemical generation of the intermediate K), no changes in the parent-state absorption could be detected for any of the cyanine compounds. However, the BR derivatives **4** and **5** undergo previously unreported light-induced, thermally controlled conformational changes (demonstrated for **4**, Figure 3). Narrow-band irradiation of the parent state (λ_{max} = 698 nm, curve 1) using an interference filter ($\lambda_{ex} = 654 \pm 10$ nm) for about ten minutes causes only a minimal change in the absorption for the range of absorption maximum (curve 2). A series of thermally driven conversions takes place after this photochemical reaction. On a

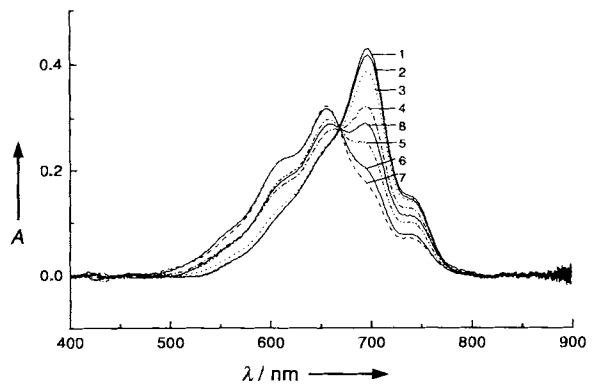

Figure 3. Photochemically induced reactions of the pigment formed from **4** and BO. Curve 1: absorption after complete reconstitution, prior to irradiation; curve 2: after irradiation for 10 min; curves 3–8: as for curve 2, but after 2, 4, 6, 7, 8, and 20 h, respectively, of incubation in the dark. Curve 8 already shows thermal reverse reaction.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1997 0570-0833/97/3615-1632 $ 17.50+.50/0

time scale of several hours, the absorption of the parent state at 698 nm declines in the dark with concomittant increase in the absorption at 654 nm (curves 3–7). This conversion exhibits an isosbestic point. Formation of the blue-shifted species does not go to completion, but is followed by an even slower process (which requires several days of incubation in the dark) by which the initial species that absorbs at 698 nm is partially restored (curve 8). These processes are definitely photo-induced; an identical sample that is not irradiated remains virtually unchanged after incubation in the dark for the same time period. This excludes thermal equilibration of present *E*,*Z* isomers as a possible origin of the observed absorption changes. As an explanation we propose a photoreaction with low quantum efficiency for these cyanine dyes that yields an isomer with nearly identical absorption properties as the parent state. This intermediate might adopt an unfavorable conformation in the binding site of the protein, thus inducing slow thermally driven reactions that generate a new species with hypsochromic absorption. This new form of the cyanine dye enters in an extremely slow kinetic equilibrium with the initial state. Further experiments to study photochemical reactions with significantly faster kinetics, as reported for other modified chromophores,[15–17] are in progress.

Anomalous Shift in the Fluorescence Spectra of a High-Generation Dendrimer in Nonpolar Solvents**

Chelladurai Devadoss, P. Bharathi, and Jeffrey S. Moore*

Charge-transfer (CT) states are characterized by broad, structureless absorption and emission spectra. The peak of the emission band is usually red-shifted (bathochromic shift) with increasing polarity of the medium.[1] This phenomenon of solvatochromism, that is the shift of emission maximum with the change in polarity of the medium, has been used to probe the microenvironment of micelles,[2] the extent of cure in epoxy resins,[3] the mobility of polymer backbones,[4] the morphology of poly(ethyleneglycol) matrices,[5] and the polarity and viscosity of various biological and other heterogeneous systems.[6] Fréchet et al. attached a solvatochromic chromophore, 4-(*N*-benzyl-*N*-methylamino)-1-nitrobenzene, to the focal point of polyether dendritic macromolecules and investigated solvatochromism as a function of generation.[7] They observed a dramatic change in the absorption maximum on going from third generation to fourth generation dendrimers in solvents of low polarity and correlated this transition with the transformation from an extended to a globular structure. Such a change in shape was consistent with their studies of intrinsic and melt viscosities of these materials.[8, 9] All of these observations and earlier molecular dynamics calculations from other groups[10] indicate that the higher generation dendrimers have compact, globular structure with a transition from an open extended form beyond a certain generation. We report here an anomalous spectral shift in the fluorescence maximum of a CT state in higher generation phenylacetylene dendrimers. In particular, large spectral shifts are observed in high generation monodendrons even in nonpolar hydrocarbon solvents in much the same way as those reported for other dendritic systems. We also show that this behavior is very dependent on dendrimer generation numbers. These findings suggest significant changes in the size and shape of these dendrimers beyond the fifth generation and the observations may have important implications for the design of dendritic molecules capable of undergoing long-range intramolecular electron transfer.

We have been studying the photoinduced electron transfer in a series of dendrimers (Scheme 1) using steady-state and time-resolved fluorescence spectroscopy. In these dendrimers, the *p*-dimethoxybenzene moiety at the focal point functions as the electron donor and the tolan segments of the dendrimer as the electron acceptors. In the lower generations (e.g. in **2**), the usual bathochromic shift with increasing polarity of the solvent is observed (see Figure 1a). However, in the higher generation dendrimers, an abnormal spectral shift in the fluorescence maximum is seen in nonpolar hydrocarbon solvents. This behavior is remarkably dependent on very subtle changes in the size and shape of the hydrocarbon molecules of the solvent. Specifically, in cyclohexane the fluorescence maximum of the fifth genera-

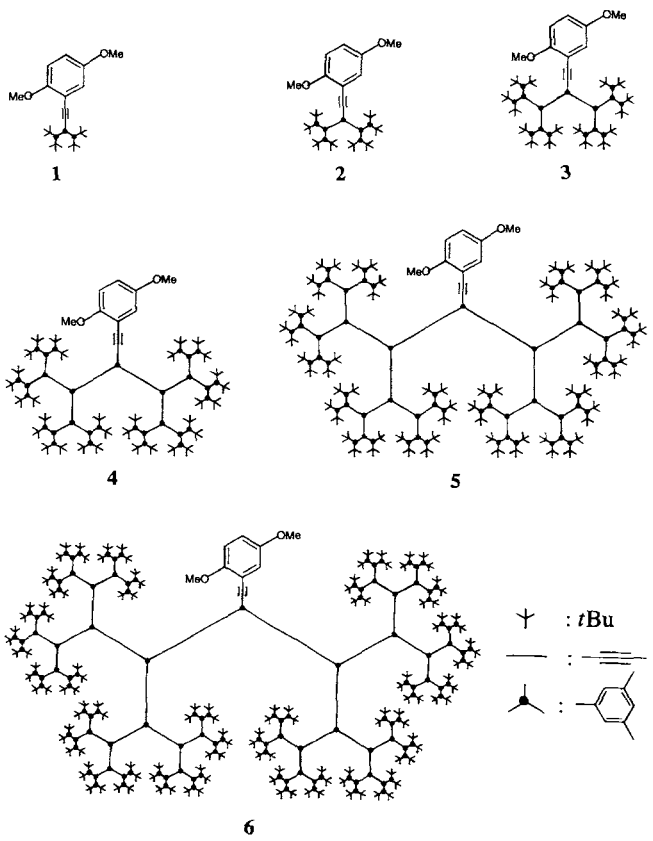

Scheme 1. Structures of the monodendrons capped with dimethoxybenzene at their focal points.

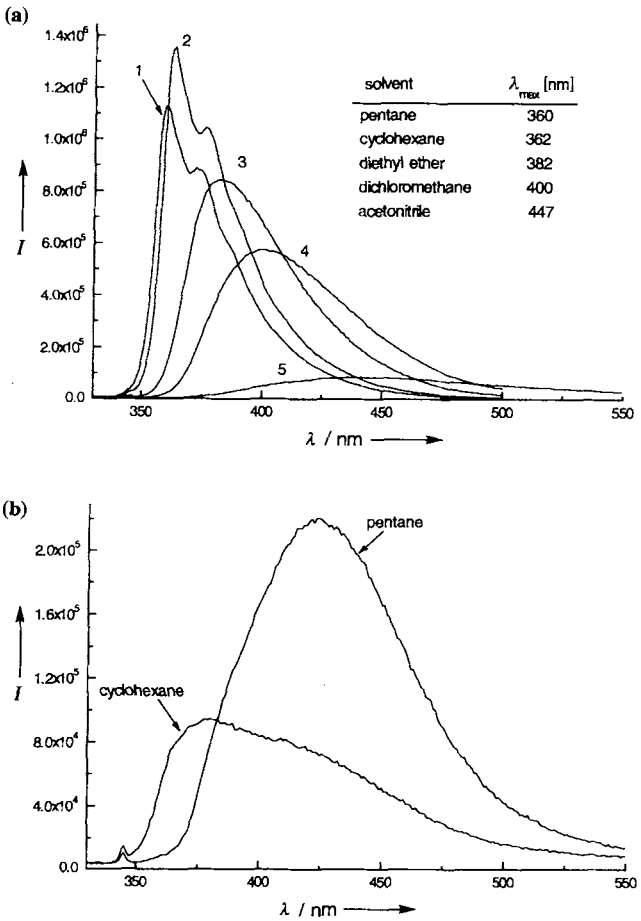

Figure 1. a) Fluorescence spectra of **2** in pentane (1), cyclohexane (2), diethyl ether (3), dichloromethane (4), and acetonitrile (5). b) Fluorescence spectra of the fifth generation (63mer) dendrimer **5** in cyclohexane and pentane. All the spectra were recorded with excitation at 310 nm and at a concentration such that they had the same absorbance at the excitation wavelength.

tion dendrimer (63mer, **5**) is 380 nm, whereas in pentane it is 421 nm (see Figure 1 b). To our knowledge, this is the first report of such a large spectral shift (41 nm) resulting from variations in the type of nonpolar solvent. Spectral parameters in other solvents are collected in Table 1. Control experiments with neat pentane and cyclohexane did not show any detectable emission upon excitation at 310 nm. The possibility of emission due to the presence of any adventitious impurities was ruled out by the matching of excitation and absorption spectra of the dendrimer. The solvents were tested for the presence of moisture using the Karl Fischer titration method and all were found to be dry (<35 ppm). It should be emphasized that the absorption spectra of this dendrimer in all nonpolar solvents are almost indistinguishable from the two-absorption maxima (293 and 310 nm) found with the tolan moiety. Moreover, this unusual behavior is observed only when the electron-donating dimethoxybenzene group is bound to the focal point (that is, when an unsubstituted phenyl group is attached to the focal point, the fluorescence maximum of the fifth generation dendrimer **5** is at 386 nm in pentane).

With increasing chain length of linear alkane solvents, the fluorescence maximum is blue-shifted (Table 1). The emission peak is at a shorter wavelength in cyclic hydrocarbon solvents than in linear ones. Moreover, branching shifts the fluorescence maximum to shorter wavelength. These results suggest that the size and shape of the solvent appears to play a major role in the magnitude of the spectral shift. There appears to be no correlation of this spectral shift with other physical parameters of the solvent like dielectric constant, viscosity, or solubility parameters.

The anomalous spectral shift is strongly dependent on dendrimer generation. As Figure 2 shows, the change in the peak of

Table 1. Fluorescence maximum λ_{max}^{fl} and quantum yield Φ_{fl} of **5** in various nonpolar solvents (dielectric constant ε, viscosity η).

Solvent	ε[a]	η[a] [10^{-3} Pa s]	λ_{max}^{fl} [nm]	Φ_{fl}
n-pentane	1.84	0.235	421	0.22
n-hexane	1.89	0.313	418	0.17
n-heptane	1.93	0.418	386	0.12
n-octane	1.95	0.545	373	0.12
cyclohexane	2.02	0.975	380	0.10
methylcyclohexane	2.02	0.734	373	0.10
methylcyclopentane	1.97[b]	0.473[b]	377	0.09
3-methylpentane	1.90	1.895	403	0.20
2,2-dimethylbutane	1.86[c]	0.33[c]	402	0.23

the CT emission in nonpolar solvents is minimal up to the 31mer. However, there is a sudden change for the 63mer in cyclohexane as well as in pentane. This observation is similar to that reported by Fréchet et al.[7] for their polyether dendrimers and by Tomalia[11] for the poly(amidoamine) (PAMAM) dendrimers. This change in fluorescence maximum may arise from the change in size and shape of the dendrimer in the higher generations, where the shape may be compact and globular, as proposed by Fréchet et al. and Tomalia.

The fluorescence maximum, according to the Lippert–Mataga relation,[12] is influenced by three factors; namely, the polar-

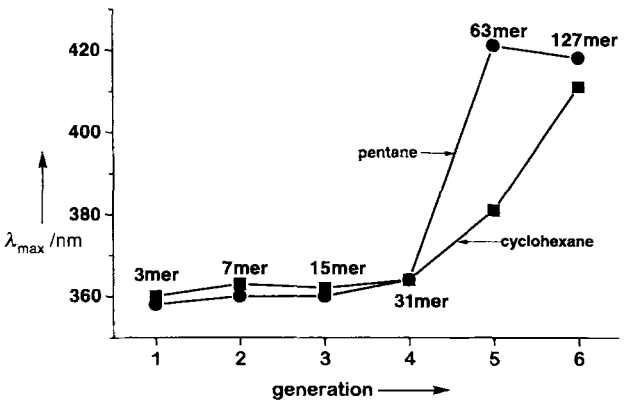

Figure 2. Plot of fluorescence maximum as a function of dendrimer generation in cyclohexane and in pentane.

ity of the solvent, the dipole moment of the CT state, and the radius of the Onsager cavity. Evidently, the polarity of the solvent does not play a major role in this spectral shift.[15] It is probable that the dipole moment of the CT state in pentane is larger than in cyclohexane due to larger distance of charge separation. This notion is supported by fluorescence lifetime measurements. The fluorescence decay of the 63mer in cyclohexane and pentane were multiexponential and the estimated lifetimes along with the percentage contributions can be described using a tri-exponential fitting function (in cyclohexane: τ[ns] (x[%]) = 11.0 (13.4), 3.1 (48.1), 0.75 (38.5); in pentane: 15.0 (61.5), 6.6 (29.7), 1.8 (8.8)). In pentane, the CT state has a longer lifetime than in cyclohexane (15 versus 11 ns), and the contribution from the long-lived component is larger. In cyclohexane, the major contributions are from short-lived components. Another possible explanation of the spectral shift is that the radius of the Onsager cavity for the dendrimer is larger in cyclohexane than in pentane. To probe for solvent-dependent size and shape changes of the dendrimer, small-angle scattering experiments (small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS)) are underway. The preliminary SANS results indicate that the radius of gyration of **5** is smaller in cyclohexane than in pentane.[19]

Experimental Section

Unless otherwise indicated, all starting materials were obtained from commercial suppliers (Aldrich, Lancaster, Fisher, Mallinckrodt, J. T. Baker, EM Science) and were used as received. Hexane, dichloromethane, and ethyl acetate were distilled before use. All air-sensitive reactions were carried out under nitrogen by using a vacuum line or in a dry box. All monodendrons were prepared by using previously reported procedures [20, 21]. All the compounds were purified by column chromatography and characterized by ^{1}H, ^{13}C NMR spectroscopy, gel permeation chromatography (GPC), high-performance liquid chromatography (HPLC), and mass spectrometry (EI or MALDI).

1: ^{1}H NMR (400 MHz, C_6D_6): δ = 7.82 (d, J = 1.5 Hz, 2H), 7.77 (t, J = 1.5 Hz, 1H), 7.63 (d, J = 1.9 Hz, 4H) 7.50 (t, J = 1.7 Hz, 2H), 7.17 (d, J = 2.9 Hz, 1H) 6.75 (dd, J = 8.9, 3.1 Hz, 1H), 6.42 (d, J = 9.0 Hz, 1H), 3.35 (s, 3H), 3.29 (s, 3H), 1.24 (s, 36H); MS (FAB): m/z calcd for $C_{48}H_{54}O_2$: 662.9; found: 663.3.

2: ^{1}H NMR (400 MHz, C_6D_6): δ = 7.83 (t, J = 1.5 Hz, 2H), 7.79 (d, J = 1.7 Hz, 2H), 7.75 (d, J = 1.7 Hz, 4H), 7.70 (d, J = 1.7 Hz, 8H), 7.62 (t, J = 1.5 Hz, 1H), 7.53 (t, J = 1.7 Hz, 4H),7.25 (d, J = 3.1 Hz, 1H) 6.77 (dd, J = 9.0, 3.2 Hz, 1H), 6.42 (d, J = 9.0 Hz, 1H), 3.38 (s, 3H), 3.29 (s, 3H), 1.24 (s, 72H); MS (FAB): m/z calcd for $C_{96}H_{102}O_2$: 1287.8; found: 1314.

3: ^{1}H NMR (400 MHz, C_6D_6): δ = 7.88 (d, J = 1.5 Hz, 2H), 7.84 (t, J = 1.4 Hz, 4H), 7.81 (d, J = 1.5 Hz, 8H), 7.74 (t, J = 1.5 Hz, 1H), 7.71–7.66 (m, 22H), 7.52 (t, J = 1.9 Hz, 8H), 7.24 (d, J = 3.2 Hz, 1H), 6.77 (dd, J = 9.0, 3.2 Hz, 1H), 6.42 (d, J = 9.1 Hz, 1H), 3.38 (s, 3H), 3.29 (s, 3H), 1.24 (s, 144H); MS (MALDI): m/z calcd for $C_{192}H_{198}O_2$: 2537.7; found: 2535.

4: ^{1}H NMR (400 MHz, C_6D_6) : δ = 7.88 (d, J = 1.5 Hz, 2H), 7.83 (t, J = 1.4 Hz, 8H), 7.81 (d, J = 1.5 Hz, 18H), 7.77 (d, J = 1.5 Hz, 4H), 7.74–7.71 (m, 9H), 7.71–7.66 (m, 36H), 7.52 (t, J = 2 Hz, 16H), 7.22 (d, J = 3.2 Hz, 1H), 6.73 (dd, J = 9.0, 3.1 Hz, 1H), 6.41 (d, J = 9.1 Hz, 1H), 3.38 (s, 3H), 3.28 (s, 3H), 1.24 (s, 288H); MS (MALDI): m/z calcd for $C_{384}H_{390}O_2$: 5037.3; found: 5246.5.

5: ^{1}H NMR (400 MHz, C_6D_6): δ = 7.95–7.65 (m, 157H), 7.52 (t, J = 1.5 Hz, 32H), 7.21 (d, J = 3.2 Hz, 1H), 6.75 (dd, J = 9.0, 3.1 Hz, 1H), 6.73 (dd, J = 9.0, 3.1 Hz, 1H), 6.44 (d, J = 9.1 Hz, 1H), 3.38 (s, 3H), 3.28 (s, 3H), 1.24 (s, 576H); MS (MALDI): m/z calcd for $C_{768}H_{764}O_2$: 10036; found: 10213.

6: MS (MALDI): m/z calcd for $C_{1534}H_{1541}O_2$: 20010; found: 20190.

Fluorescence spectroscopy: Steady-state fluorescence spectra were recorded on a Photon Technology International (PTI) QM-1 fluorometer. The absorbance of the solution for fluorescence measurements was around 0.1 at 310 nm, the excitation wavelength. Fluorescence and excitation spectra were corrected for the wavelength dependence of detector sensitivity and excitation source output. Fluorescence quantum yields were estimated with quinine sulfate in 0.1 N H_2SO_4 as the reference (Φ_{fl} = 0.55). The spectra were recorded by using a 1-cm path length quartz cuvette in the right angle geometry at room temperature. Fluorescence lifetimes were measured on a time-correlated single photon counting fluorimeter (Edinburgh Instruments, model OB9000). The excitation source was a hydrogen flash lamp operated at 40 kHz. The emission was detected at right angle to the excitation light with a Hamamatsu R955 photomultiplier tube (PMT) which was cooled to −22 °C. The response time of the PMT was 2.2 ns. A total of 10000 counts were at the maximum channel. The samples were excited at 310 nm and the decay was monitored at the emission maximum of the respective sample.

Columnar Liquid Crystals from Shape-Persistent Dendritic Molecules**

Douglas J. Pesak and Jeffrey S. Moore*

Dendritic molecules of well-defined structure offer special opportunities in materials chemistry.[1] In the area of self-organizing materials, correlations between molecular morphology and macroscopic symmetry are of fundamental as well as practical importance, yet this relationship is poorly understood at this time.[2] The morphology of perfectly branched dendrimers evolves from an open, extended form to a more globular shape, as generation increases.[3] Because of their globular shape, most higher generation dendrimers do not crystallize, although several reports have documented lyotropic and thermotropic liquid crystalline order. This intriguing behavior was first seen by Kim who observed lyotropic phases of hyperbranched[4] polyaramides in *N*-methylpyrrolidone (NMP) solutions.[5] Several groups have since discovered thermotropic liquid crystalline (LC) phases in dendritic materials. Percec et al. prepared a series of hyperbranched polymers based on flexible, branched mesogens that exhibited nematic LC phases resulting from the molecules ability to fold into anisotropic shapes.[6] The corresponding regular dendrimers were also found to be liquid crystalline.[7] Another type of dendritic architecture that displays liquid crystallinity involves functionalization of the periphery with mesogenic groups.[8] The flexibility of the dendritic interior in these systems allows the peripheral mesogens to acquire nematic organization. Recently, Percec et al. used benzylic ether monodendrons to prepare tapered mesogenic architectures functionalized with endo receptors or polymerizable groups at their focal points.[9] These molecules have been shown to organize into hexagonally packed columns in which a slice of the column (that is, one disc) is made of several of the wedge-shaped monodendrons. The monodendrons are suggested as being stacked in a face-to-face manner acting like the protein wedges found in the Tobacco Mosaic Virus. Another interesting recent report describes a "starlike" heptameric triphenylene derivative (a triphenylene mesogen substituted with six other triphenylene mesogens) which exhibited a discotic columnar mesophase.[10] However, the hexagonal cell edge in these materials corresponded to individual triphenylene mesogens rather than the star molecule as a whole (that is, registry of the entire molecule was not achieved).

Our group has been studying shape-persistent dendrimers,[11] which have the potential to behave like disk-shaped objects in early generations. Unlike previously reported liquid crystalline dendrimers, these molecules have the potential to be intrinsically mesogenic[12] and it is of interest to see how such behavior depends on dendrimer parameters like generation number and the type of peripheral group. Shape-persistent dendrimers may provide novel mesogenic architectures including the intriguing possibility of asymmetrically segregated columns and low-symmetry mesophases. This could be realized, for example, from a tridendron in which each of its monodendrons is terminated with three mutually incompatible segments (for example hydrocarbon, oligo(ethylene oxide), and fluorocarbon chains). Three-way demixing within the hexagonal columns might result in spontaneous symmetry reduction from *P6mm* to *P*3. Another architectural possibility unique to dendrimers would involve organizing donor and acceptor segments in concentric shells of a columnar structure. Such architectures may have unusual photoconducting properties (a molecular coaxial cable).[13] With these ideas in mind we developed a new series of columnar liquid crystalline dendrimers based on the stiff, triconnected phenylacetylene monomer.

Three generations of phenylacetylene tridendrons functionalized with isophthalic acid bis-(2-[2-(2-methoxy-ethoxy)-ethoxy]ethyl) esters on the periphery (tetramer **1**, decamer **2**, and 22mer **3**) were prepared by a convergent growth scheme.[14] All intermediates and final products were characterized by ^{1}H and ^{13}C NMR spectroscopy, mass spectrometry (FAB or MALDI[15]), and elemental analysis and shown to be devoid of significant amounts of impurities.[16] In marked contrast to the behavior of the *tert*-butyl capped dendrimers, which decompose without even undergoing a glass transition,[11a] these materials have a pastelike consistency at room temperature with **2** and **3** being more viscous than **1**. All three dendrimers show glass transition temperatures around $-55\,^{\circ}C$ (Figure 1). Two additional reversible transitions are observed for **1** and **2**, while dendrimer **3** exhibits only one reversible transition (isotropization). Molar enthalpies of isotropization increase with generation as expected (Table 1).[17]

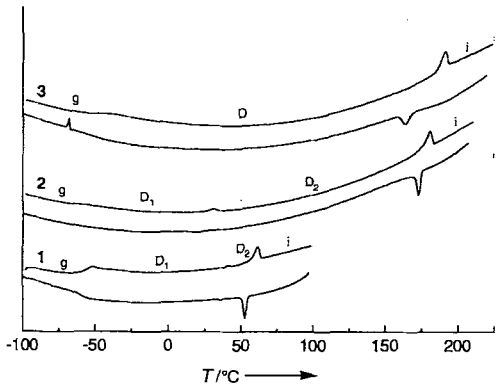

Figure 1. DSC traces recorded during the first cooling and the second heating cycle. The analyses were performed at heating and cooling rates of 20 K min^{-1}.

Optical microscopy between crossed polarizers reveals a birefringent texture up to the isotropization temperature for each dendrimer. Clearing points from both microscopy and differential scanning calorimetry (DSC) are given in Table 1. Slow cooling from the isotropic state on untreated glass reveals textures

Table 1. Transition temperatures [°C] of liquid-crystalline dendrimers **1**–**3**. Transition enthalpies [kJ mol^{-1}] are given in parentheses.

indicative of columnar discotic liquid crystalline phases. Micrographs of dendrimers **1**, **2**, and **3** are shown in Figure 2. Dendrimer **1** displays birefringent patterns of irregular shape along with homeotropically aligned regions shaped as six-pointed stars. A conoscopic image (Figure 2 top, inset) focused on a homeotropic region reveals that the material is uniaxial positive. This observation is consistent with aromatic rings whose normal axes are, on average, oriented parallel to the optic axis. It is interesting that these macroscopically aligned domains appear spontaneously on untreated glass without application of shear or other external forces.[9]

The second-generation dendrimer **2** shows birefringent "broken-fan" textures, while the third-generation dendrimer **3** shows two distinct features (Figure 2 middle and bottom, respectively). Birefringent fiberlike bundles make up most of the observable area of **3**. However, in certain regions, remarkable home-

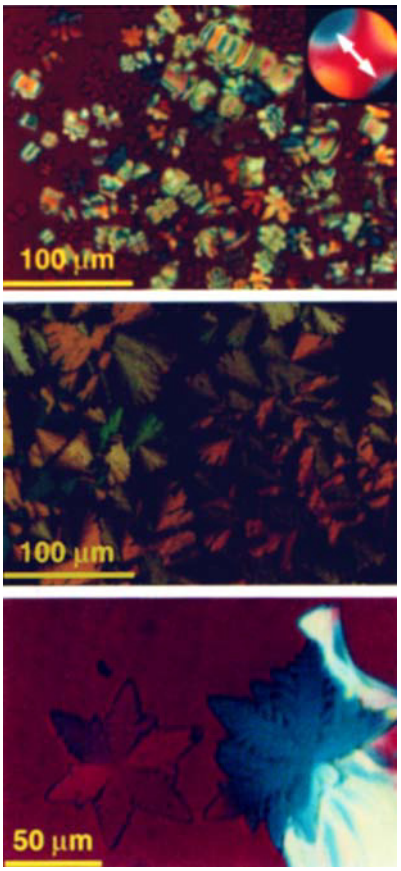

Figure 2. Optical micrographs of **1** at 65 °C (top), **2** at 196 °C (middle), and **3** at 197 °C (bottom) under crossed polarizers. All images were taken from samples slowly cooled from the isotropic melt on untreated glass slides (a cover slip was applied only to sample **3**). The inset (top right) shows a conoscopic image recorded on a homeotropically aligned domain with a quarter waveplate insert. The arrow indicates the direction of the waveplate.

otropically aligned dendritic hexagonal patterns appear that resemble snowflake morphologies. These domains are not crystalline solids as can be demonstrated by their ability to flow when sheared. Rheological studies will be required to fully characterize the fluid properties of the liquid crystilline phases. Preliminary studies on the next higher generation (46mer) indicate that it is amorphous.[18]

Wide-angle X-ray diffraction patterns of samples recorded at room temperature are shown in Figure 3 which correspond to

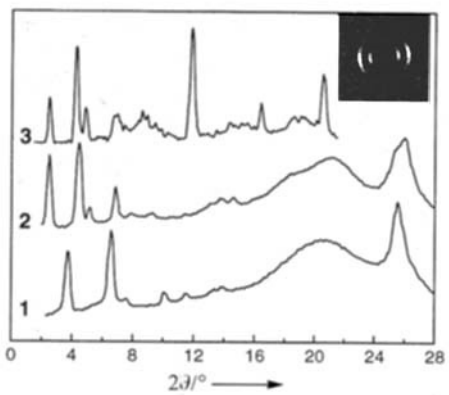

Figure 3. Wide-angle X-ray diffraction patterns of dendrimers **1**–**3** recorded at room temperature with $Cu_{K\alpha}$ X-ray radiation. The inset shows a Laue diffraction image of a melt-drawn fiber of **1**. The fiber axis is vertical.

the D_1 phases of **1** and **2**[19] and the D phase of **3**. The observed reflections can be indexed to hexagonal unit cells with a = 26.95 Å, 39.80 Å, and 41.65 Å, respectively (Table 2). These cell edges are consistent with the dimensions of **1**–**3** as calculated from molecular models (see below). The agreement between calculated and observed Bragg reflections is very good for **1** and **2**. However, for **3** the agreement is lower and additional data will be needed to rule out the possibility of lower symmetry.[20]

Table 2. Bragg reflections and corresponding calculated and observed d spacings [Å].

[a] All data recorded at room temperature with $Cu_{K\alpha}$ X-ray radiation. [b] Hexagonal unit cell assumed.

The sharpness of the diffraction data for **3** seems to indicate a remarkably high degree of order. Broad reflections with d spacings of approximately 3.5 Å are present in the diffraction patterns of both **1** and **2**. This is typical of van der Waals separation for π-stacked aromatic molecules. Molecular modeling suggests that both **1** and **2** can adopt completely planar conformations without experiencing unfavorable nonbonded contacts that would force the structure into a more globular shape.[21] For both **1** and **2**, the fraction of the hexagonal unit cell (c axis length of 3.5 Å) occupied by the molecule is about 0.60, consistent with that of typical liquids. In the case of **3**, however, molecular modeling suggests that a completely planar conformation is not possible. As such, one would expect the c axis length to increase to accommodate the increased thickness of the mesogen. Broad reflections are observed with d spacings of 4.3 (weak) and 7.5 Å (strong). A unit cell with a c axis length of 4.3 Å is much too small to accommodate a single molecule. The van der Waals volumes of one molecule occupies an unreasonable 93% of such a cell. In contrast, the van der Waals volumes of one molecule occupies 53% of a unit cell with a c axis length of 7.45 Å. This calculation leads us to believe the c axis elongates to accommodate the nonplanar structure. Although the X-ray diffraction data is consistent with a hexagonal lattice, we cannot rule out the possibility of other lower symmetry unit cells such as the orthorhombic or monoclinic lattices at this time. High-resolution X-ray data on oriented fibers will help resolve this issue. Preliminary diffraction data on a melt drawn fiber of **1** shows that the columnar axis aligns with the fiber direction as shown in the Laue image (Figure 3, inset).

The data presented here suggests that three generations of phenylacetylene tridendrons functionalized with isophthalic acid bis-(2-[2-(2-methoxy-ethoxy)-ethoxy]ethyl) esters on their peripheries exhibit liquid crystalline mesophases. Mesophase behavior is displayed over a wide temperature range (ca. 250 K for **2** and **3**). Optical microscopy and X-ray diffraction support a hexagonal columnar discotic phase. These compounds reveal an intriguing connection between molecular morphology and macroscopic organization. Further studies to probe the nature of the low-energy intermediate phase transitions of **1** and **2** are currently under way. We are also exploring the effect of unsym-

metrical peripheral group substitution on mesophase behavior in order to understand the factors which govern organization of phenylacetylene dendrimers with an interest toward the preparation of low-symmetry columnar phases.

[18] Preliminary microscopy studies under crossed polarizers of the fourth generation (46mer) show an initial birefringent texture. When heated, the sample shows a clearing point; however, upon cooling, no birefringent texture reforms down to room temperature. The original birefringence could be caused by mechanical stress within the sample. Differential scanning calorimetry (DSC) shows no observable phase transitions. X-ray diffraction shows only amorphous characteristics. This behavior should be viewed as preliminary since the MALDI mass spectrum reveals the presence of appreciable amounts of defective dendritic species which may affect possible mesophase behavior.

[19] While compound **2** does possess a phase transition at about 30 °C, it is unlikely that the X-ray diffraction data is a composite of two phases. DSC shows that a sample of **2** heated from room temperature does undergo this phase transition, thus X-ray diffraction data is of the D_1 phase.

[20] We have initially assigned D_1 (**1** and **2**) and D (**3**) to the ordered hexagonal discotic phase (D_{ho}) and D_2 to the disordered hexagonal discotic phase (D_{hd}). X-ray diffraction data of the D_2 phase is needed, however to verify the assignment. C. Destrade, H. H. Tinh, H. Gasparoux, J. Malthete, A. M. Levelut, *Mol. Cryst. Liq. Designing a Solid Catalyst for the Selective Low-Temperature Oxidation of Cyclohexane to Cyclohexanone**

Thomas Maschmeyer,* Richard D. Oldroyd, Gopinathan Sankar, John M. Thomas,* Ian J. Shannon, John A. Klepetko, Anthony F. Masters, James K. Beattie, and C. Richard A. Catlow

The catalytic activation, especially partial oxidation, of alkanes constitutes one of the major challenges of present-day chemistry; and the conversion of cyclohexane to cyclohexanone is among the principal target reactions since the latter is used as feedstock in several industrial processes including the production of nylon from ε-caprolactam and adipic acid. There have been numerous fundamental studies of the role of cobalt acetate as catalysts for such processes and[1] it is now recognized that cobalt(III) acetate exists as a number of distinct species,[2] both in solution and in the solid-state. Although stable alkylperoxo complexes of Co^{III} are formed in these systems there is also unmistakable evidence for free radicals such as $RO_2^{\bullet}$ and $RO^{\bullet}$ in the reaction, the occurrence of which is symptomatic of autooxidation. Homogeneous catalytic processes with $Co(OAc)_3$ suffer from the generation of significant quantities of unwanted by-products such as alkyl acetates, other ketones, cyclohexylidene diacetate, alkyl chlorides, and occasionally, cyclohexylmethanol.[1d, 3] To confer greater stability upon the homogeneous Co^{III} acetate catalyst it is also necessary to employ, for reasons that are not entirely understood, either acetic acid or trifluoro- (or trichloro-) acetic acid as solvent for the reactant mixture and bromides are often used as promoters.

With the aim of arriving at a cleaner, more efficient catalytic system for the production of cyclohexanone from cyclohexane, and also of gaining deeper insights into the nature of the catalytically active centers by in-situ EXAFS studies (EXAFS = extended X-ray absorption fine structure), we have designed a new catalyst that entails harnessing the advantages of homogeneous organometallic catalysis on the one hand and of a high-area, well-defined (MCM-41) mesoporous silica support on the other.[4]

Although there is still considerable debate[5] about the mechanism of the oxidation of cyclohexane in the presence of Co^{III}, Mn^{III}, and Ce^{IV} salts in acetic acid or other solvents, and even more about the nature of the active sites, our point of departure in this work is the earlier observation[6] that several oxo-centered trimeric cobalt(III) acetates (coordinated with pyridine)[7] exhibit much greater activity in selectively oxidizing the tertiary C–H bond in adamantane than their dimeric analogues.

We thank the CLRC for the synchrotron beam time and other facilities at Daresbury Laboratory. We also gratefully acknowledge assistance with the solid-state NMR spectroscopy by Dr. Abil Aliev and useful initial discussions with Dr. Fernando Rey.

Table 1. Catalyses with the cobalt complex **1** immobilized on MCM-41.

Catalyst support	Co [wt %]	Si:Co	t [h]	Conversion [%] [a]	TOF [b]	Selectivity [%] [c]	Cyclohexanone: cyclohexanol	Life time [h]
nonderivatized	0.376	210	4	3.7	89	85	0.6	< 48
			24	7.6	63	89	0.6	
MCM 41, glycine-functionalized through bromoalkyl tethers	0.201	300	4	4.3	352	84	0.9	> 96 [d]
			24	11.9	230	89	1.5	
			4 days	38.1	216	95	3.3	

[a] Cyclohexane (9.5 mL), TBHP (10 mL), and mesitylene (0.5 mL; internal standard) at 70 °C are required for 150 mg of catalyst. [b] In mol cyclohexane/(mol catalyst per hour). [c] Based on cyclohexanone and cyclohexanol. [d] The experiment was stopped after four days.

The apertures of the MCM-41 samples prepared by us[8] are close to 30 Å (determined by high-resolution scanning transmission electron microscopy and adsorption isotherms) and readily permits ingress of the monohydroxycobalt complex **1** (known

$[Co_3(\mu_3\text{-}O)(OAc)_5(\mu_2\text{-}OH)(py)_3]PF_6$ **1**

to substitute the hydroxyl group for other ligands)[9] which we selected for immobilization inside the channels of the MCM-41 mesoporous silica.[10] It is possible to employ various routes to effect immobilization; anchoring to the surface directly or using surfaces functionalized with, for example, alkylcarboxylic acids. Each of these routes yields a catalyst for the selective oxidation of cyclohexane to cylcohexanone. However, distinct differences are observed in their respective turnover frequencies (TOF), lifetimes, and selectivities (Table 1). The catalysis reported here was effected in an essentially solvent-free fashion: the sacrificial oxidant *tert*-butyl hydroperoxide (TBHP) and the reactant cyclohexane form a miscible liquid and each is consumed to yield cyclohexanone, cyclohexanol, other minor amounts of by-products (dicyclohexyl ether, dicyclohexyl peroxide, and *tert*-butyl cyclohexyl peroxide), and *tert*-butyl alcohol (from TBHP).[11]

In our first attempt at immobilization we reacted the cobalt complex **1** with partially dehydrated siliceous MCM-41. The EXAFS spectrum after immobilization showed that there was virtually no change in the structure of the cobalt complex, indicating either substitution of the bridging hydroxide by a surface silanol or physisorption brought about by interaction of the surface with the cationic cluster. Catalytic tests showed that after 24 h 7.6% of the available cyclohexane was converted with a selectivity of about 89% to cyclohexanol and cyclohexanone. The catalyst lifetime, however, was less than 48 h (Table 1).[12] This limited lifetime is most likely due to mobility of the cobalt clusters on the surface, giving rise to cluster–cluster and other unfavorable interactions at the interior surface as well as some leaching indicated by slight discoloration of the solution.

Working on the principle that immobilization at a carboxyl-functionalized surface (that is envisaging the replacement of the bridging hydroxyl by a carboxyl group) may produce a potentially more stable catalyst, we proceeded to functionalize the MCM-41 surfaces with a 3-bromopropyltrichlorosilane tether which we then derivatized by reaction with glycine. The virtual lack of solubility of glycine in solvents other than water means that the efficiency of the reaction between the amine part of the glycine and the bromoalkyl group could be expected to be low owing to the interaction of water with the amine.[13] However, this would as a side-effect provide a means to ensure a high dispersion of the cobalt complex which might aid stability (and, hence, longevity) by reducing possible interactions between cobalt clusters. Additionally, the nonderivatized bromoalkyl groups might act as a potential promoter echoing the use of bromide in commercial processes.

Catalytic tests established that after an initial TOF of around 352 mol cyclohexane/(mol catalyst per hour) a steady TOF of around 216 could be sustained for at least four days. The true heterogeneity of the catalyst was also examined by separating it by filtration and establishing that the filtrate displayed no further activity under the same reaction conditions. Additionally, no leaching could be detected (within experimental error) when comparing the elemental analysis results of the catalyst before and after reaction. No induction period could be observed (at a time resolution of 5 min); after an initial exponential behavior, the catalyst continued to produce cyclohexanone essentially in a linear fashion. At the outset more cyclohexanol than cyclohexanone is produced, but after about six hours cyclohexanone production is predominant, an equilibrium between cyclohexanol generation and consumption to form the ketone being reached after about 12 h (Figure 1).

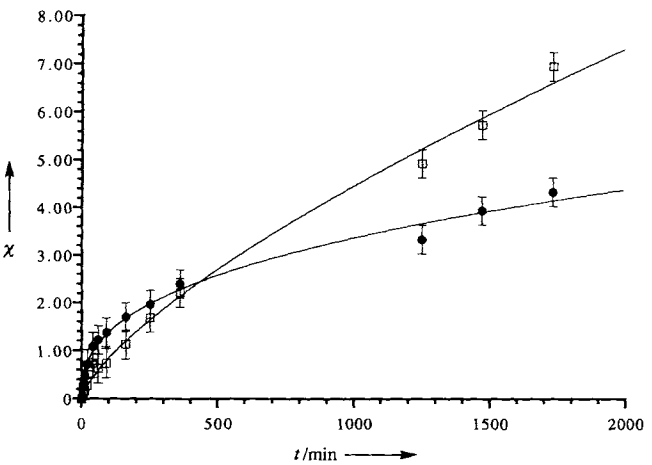

Figure 1. Plot of the percentage conversion x of cyclohexane into cyclohexanol (•) and cyclohexanone (□) against time t with 150 mg catalyst.

As expected, addition of extra TBHP after 12 h increased the oxidation rates, thus showing the potential for rate control (that is stabilization) by drip-feeding the reactants. Small amounts of the oxygenated by-products already mentioned (totalling no more than 5% of the converted cyclohexane) are also generated; however, this compares well with the 11% for the nonfunctionalized support. Hence, there is a clear advantage associated with the use of functionalized MCM-41 in terms of lifetime, TOF, and ultimate selectivity.[14] We believe this may be explained in terms of the improved isolation of the active centers achieved by the functionalization of the surface.

Additionally, in-situ X-ray absorption spectroscopy using synchrotron radiation[15a] (in what is to our knowledge the first report of such a type of experiment) enabled the detailed atomic

environment of the active cobalt complex to be determined both prior to and during the course of the solid–liquid heterogeneous catalysis at realistic temperatures under continuous flow using a novel liquid/solid cell.[15b] The liquid collected was analyzed by GC/MS to confirm catalytic activity at the point of measurement. Figure 2 shows the EXAFS spectrum (and associated Fourier transform) of the active catalyst and Table 2 contains the relevant structural parameters.

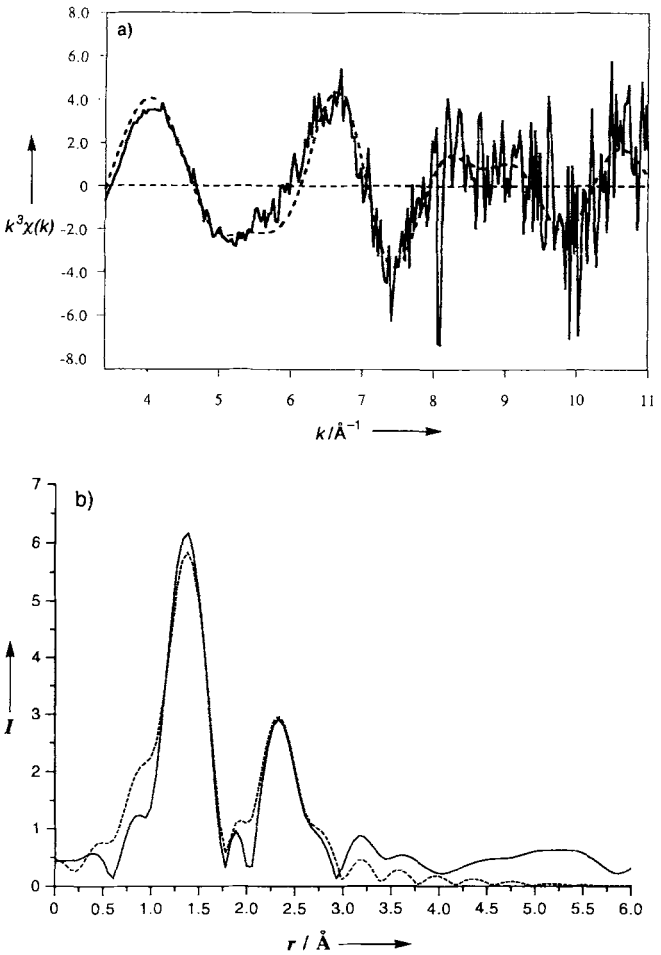

Figure 2. a) EXAFS of the active catalyst immobilized on glycine-functionalized MCM-41. b) Associated Fourier transform; solid line: experimental data, broken line: calculated data.

Upon reaction of **1** with the glycine-functionalized MCM-41, the asymmetric Co_3 unit rearranged into a symmetric one, that is the Co–Co distances changed from 2.80 Å and 3.17 Å to 3.13 Å for both Co–Co pairs (Table 2). This is readily explicable by postulating the replacement of the bridging OH group in **1** with the COOH group of the glycine tether, yielding essentially three equal coordination environments for the cobalt atoms. The structure of a homogeneous analogue has recently been determined by using single-crystal X-ray diffraction data and compares extremely well.[16]

Table 2. Local structural parameters of the complex **1** derived by Co K-edge EXAFS spectroscopy.

Cobalt cluster	Scatterer	N	r [Å]	σ^2 [Å^2]
before immobilization [a]	O [b]	6.00	1.90	0.002
	Co	0.66	2.80	0.003
	C	5.66	2.92	0.004
	Co	1.33	3.17	0.003
	O	3.33	3.26	0.004
before catalysis	O [b]	5.98	1.88	0.004
	C	6.04	2.82	0.002
	Co	1.63	3.13	0.004
	O	4.12	3.27	0.004
during catalysis	O [b]	5.37	1.87	0.007
	C	5.51	2.80	0.010
	Co	1.65	2.78	0.011
	O	3.02	3.07	0.010

[a] Deviation from distances derived from the crystal structure analysis are within experimental error (±0.03 Å). [b] Oxygen and nitrogen shells were averaged and treated as one shell.

Furthermore, in-situ EXAFS measurements during the catalysis of the glycine-immobilized catalyst revealed noteworthy structural changes (Scheme 1). The major feature is a contraction in the Co–Co distances from 3.13 Å to 2.84 Å, indicating a significant structural rearrangement in the complex. Dimitrou et al. have reported an oxo-centered trimeric cobalt acetate system that displays very similar Co–Co distances (average 2.81 Å) to the ones found in our active catalyst.[17] In their complex, however, three of the acetate groups have been displaced by bridging hydroxide groups, giving rise to the shorter distances. This may imply the presence of similarly bridging oxygen atoms in the catalytic species, which could arise from rearrangement of the μ_2-acetate groups due to the interactions with substrate molecules or, more likely, from the peroxide present in the reaction mixture (Scheme 1). The simultaneous presence of bridging hydroxide and some bridging peroxide or other organic oxide is consistent with the slightly higher than expected coordination number of the shell at 3.07 Å. For a trimer in which three of the acetate groups have been replaced by hydroxyl groups, only two oxygen atoms at around 3.1 Å would be expected; however, about three are observed. Since the distance to a carbon atom, for example in a bridging alkoxide group, is also about 3.1 Å, the larger coordination number may indicate the presence of such a species (Figure 3).

^{29}Si MAS NMR spectroscopy (MAS = magic angle spinning) revealed a significant perturbation in the ^{29}Si NMR spectrum of nonderivatized MCM-41 after immobilization of **1**, indicating a strong interaction between the complex and the surface. However, cross polarization (CP) MAS NMR spec-

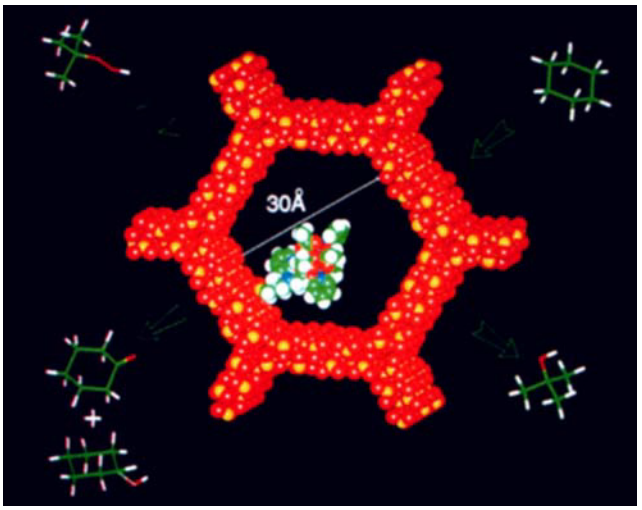

Figure 3. Proposed structure of the active catalyst (center) as well as the starting materials (top) and end products (bottom) of the oxidation of cyclohexane with *tert*-butyl hydroperoxide and Co^{III}-modified MCM41 as catalyst.

troscopy could not detect the presence of the cobalt acetate (the acetate resonances) for either catalyst, but this may well be due to a reduction of one of the diamagnetic Co^{III} centers to a paramagnetic Co^{II} center; a fact which could, incidentally, explain the fate of the PF_6^- ion.

The identification of the active trimeric cobalt allows not only further rational design of improved catalysts, but also provides a well-defined starting point for experimental and computational studies on the mechanism.

Experimental Section

Preparation of glycine-functionalized MCM-41: MCM-41 (1 g) was dehydrated under vacuum at 200 °C for 2 h and was then suspended in diethyl ether (30 mL). Me_2SiCl_2 (0.017 mL) was added and the suspension was left to stir for one hour. The solvent was then removed under vacuum. The solid was resuspended in dry chloroform (30 mL) and the suspension cooled in an isopropyl alcohol/liquid nitrogen slurry bath. $Cl_3Si(CH_2)_3Br$ (0.6 mL) was slowly added, and the mixture left to stir until it had warmed to room temperature. The resulting suspension was left to stir for a further 16 h. The solid was then separated by filtration, washed with chloroform (8 × 25 mL), suspended in 30 mL of an aqueous solution containing glycine (0.1 g) and stirred for 16 h after which it was separated by filtration, washed with water (150 mL) and then diethyl ether (100 mL).

Immobilization of 1: The same conditions were used for both supports (nonderivatized and glycine-derivatized MCM-41). The support (0.5 g) was suspended in a solution of **1** (50 mg) in dichloromethane (30 mL). The suspension was left to stir for 16 h after which the solid was separated by filtration and washed until the washings were colorless (usually around 200 mL dichloromethane). The catalysts were then washed by Soxhlet extraction in dichloromethane for 8 h.

EXAFS measurements: The EXAFS data were recorded at the Daresbury SRS facility on station 8.1 and analyzed with the XFIT (WIN95) and EXCUR V92 suites of programs [18]. The station was equipped with a Si(220) monochromator, and data were collected in fluorescence mode using a thirteen-element Canberra fluorescence detector. A powdered sample of each catalyst studied was pressed into a self-supporting wafer, and mounted into an in-situ reaction cell through which the reactant mixture (of cyclohexane and *tert*-butyl hydroperoxide) was passed by using a syringe driver. Heating to the required temperature was achieved by a jet of hot air directed onto the center of the sample. Details of the cell design have been published [15b]. Spectra were recorded both before and during the catalysis, in which the sample was heated to about 60 °C and the reactants were passed through the cell at a rate of 0.1 mL min^{-1} and the system allowed to stabilize for one hour before measurement (normal X-ray absorption spectroscopy, aquisition time per scan: 45 min). The reaction products were in all cases collected for subsequent analysis by GC/MS.

[11] a) This approach (results were calibrated by using mesitylene as internal standard) was deemed necessary for the in-situ X-ray absorption spectroscopy (XAS) experiments as the TOF using the flow system were anticipated to be low and appropriate chlorinated solvents interfere with the XAS measurements. b) Reaction conditions: TBHP (10 mL), cyclohexane (9.5 mL), mesitylene (0.5 mL; internal standard), catalyst (150 mg) stirred in a batch reactor at 70 °C under argon. Up to 20 aliquots of 0.1 mL were withdrawn for analysis during a catalysis run. The MCM-41 was initially exposed to a small amount of the reactive dichlorodimethylsilane with the aim of functionalizing the majority of the silanol groups on the external surface, assuming a faster rate of reaction for the external compared to the internal surface. Hence, to ensure that the catalyst was present predominantly on the inside of the MCM-41 channels, the MCM-41 was treated with the various alkyl tethers only after this pretreatment. This procedure has been shown by scanning transmission electron microscopy to yield the desired effect in related systems (unpublished results).

[12] The kinetic profile showed no detectable induction period at a resolution of 5 minute time steps and behaved in a typical exponential fashion.

[13] From the microanalysis the ratio of bromide tether to tethered cobalt is 100:1, NMR experiments aimed at trying to identify the glycine-derived tether were not sensitive enough to conclusively pick up the glycine-part, as can be expected at such low loadings.

[14] The increase in the selectivity of the catalyst system with time can be explained by the observation that the by-products dicyclohexyl peroxide and cyclohexyl *tert*-butyl peroxide might both decompose to cyclohexanone and that the by-products might react further, disappearing in the base-line. Due to the solvent-free conditions no full mass balance was attempted.

^{13}C and ^{139}La NMR Studies of $La_2@C_{80}$: First Evidence for Circular Motion of Metal Atoms in Endohedral Dimetallofullerenes**

Takeshi Akasaka,* Shigeru Nagase,* Kaoru Kobayashi, Markus Wälchli, Kazunori Yamamoto, Hideyuki Funasaka, Masahiro Kako, Tsutomu Hoshino, and Tomoki Erata

Endohedral metallofullerenes have attracted special interest as spherical molecules with novel properties that are not expected from empty fullerenes.[1] The higher fullerenes can even encapsulate two metal atoms inside the carbon cages to form soluble and relatively air-stable endohedral dimetallofullerenes. Because of the difficulty in producing pure samples in large quantities, experimental characterization of these species has been hindered. Important progress was marked by the successful isolation and purification of endohedral dimetallofullerenes such as $Sc_2@C_{84}$[2] and $La_2@C_{80}$[3] in macroscopic quantities. This has made it possible to investigate redox properties[3] and reactivity.[4] STM[5] and TEM[6] studies were also carried out in an attempt to confirm that two metal atoms are inside the fullerene cages.

Since there are many isomers for higher fullerenes, determination of cage structures and symmetries has long been of fundamental interest in disclosing the mechanism of growth. This has been a recent subject of theoretical[4, 7, 8] and experimental studies.[9, 10] Since its first observation in 1991[11] $La_2@C_{80}$ has been widely known as a representative and abundant dimetallofullerene. Despite several attempts, its cage structure and symmetry have not yet been experimentally confirmed. In addition, it is currently of increasing interest whether encapsulated metal atoms are rigidly attached to fullerene cages or move about freely. Although rotation of a molecule within a cage is of great help in designing functional molecular devices,[12] very little has been known about the dynamic behavior of metal atoms encapsulated inside carbon cages. Based on ^{13}C and ^{139}La NMR spectra of $La_2@C_{80}$, we now report its structural determination and the first experimental evidence for circular motion of two La atoms.

For the C_{80} fullerene there are seven distinct isomers (D_2, D_{5d}, C_{2v}, $C_{2v'}$, D_3, D_{5h}, and I_h) that satisfy the isolated-pentagon rule.[13] The isomer distribution has been an open question, since C_{80} was a "missing" fullerene between C_{60} and C_{96}. By isolating C_{80} and analyzing the observed ^{13}C NMR lines, however, it was verified that the D_2 isomer is most abundantly produced (>90%).[14] It seems plausible to assume that two La atoms are encapsulated inside the D_2 isomer. However, theoretical calculations[8] have shown that encapsulation of two La atoms inside the most unstable I_h cage (about 52 kcal mol^{-1} less stable than the D_2 isomer) is most favorable (63 kcal mol^{-1} more stable than encapsulation inside the D_2 isomer). This is because the I_h-symmetrical C_{80} has only two electrons in the fourfold degenerate HOMO and can accommodate six more electrons to form the stable, closed-shell electronic state of $(La^{3+})_2C_{80}^{6-}$ with a large HOMO–LUMO gap. The most stable endohedral structure optimized with the I_h cage is shown in Figure 1. It has D_{2h} symmetry; two La atoms are located equivalently on the C_2 axis facing the hexagonal rings of C_{80} with a long La–La distance of 3.655 Å.[8]

The ^{139}La NMR spectrum of $La_2@C_{80}$ measured at 296 K is shown in Figure 2. A single signal was observed at $\delta = -402.6$ with a linewidth of 113 Hz. This suggests that the two La atoms
