

Two of the fascinating characteristics of aerogels—highly porous materials made, for example, from SiO_2 and air—are demonstrated by these pictures: In their hydrophobic form the aerogels float on water for months, and under suitable conditions one obtains plates that are translucent even with a thickness of about 2 cm.

Aerogels—Airy Materials: Chemistry, Structure, and Properties

Nicola Hüsing* and Ulrich Schubert*

Aerogels are unique among solid materials. They have extremely low densities (up to 95% of their volume is air), large open pores, and a high inner surface area. This results in interesting physical properties, for example extremely low thermal conductivity and low sound velocity combined with high optical transparency. They are prepared from molecular precursors by sol–gel processing. The initially formed gels have a spongelike solid network filled with liquid. Special drying techniques must be applied to exchange the pore liquid with air while maintaining the filigrane solid network. Supercritical drying is most common. However, recently developed methods allow removal of the liquid in a classical way after chemical modification of the inner surface of the gels. The structure of the gel network, and thus the physical properties of aerogels, decisively depend on the choice of the precursors and the chemical reaction parameters for preparing the gels. Therefore, the later material properties are predetermined at the beginning of the preparation process. In this review, connections between the underlying sol–gel chemistry, the structure of the gels, and the resulting properties of the materials will be shown, which are the basis for a chemical "design" of aerogel properties.

1. Introduction

Whipped egg whites or solid bubble bath are closest in appearance to aerogels. In principle, the name says everything: the main component of this material is air which is surrounded by a very filigrane, solid network. This network can be constructed in a way that the resulting aerogels have a density that is only three times that of air.

If an aerogel is given to a chemist, a physicist, or a materials scientist, each of them would discover interesting properties which individually are also observed in other materials. For example, SiO_2 aerogels have a high transparency that is close to that of glass, a thermal conductivity corresponding to that of polystyrene or polyurethane foams, or very high specific surface areas, which are also found in charcoal. The unique feature of aerogels is the combination of these physical properties in one material which can have different chemical compositions. Important aspects for various applications are thus combined, for example, for heat insulation (Figure 1), optical applications, sensors, catalysts, or catalyst carriers.

What exactly is an aerogel? The term aerogel is not uniformly used in the literature, and there are two different definitions:

1) First, all materials prepared from wet gels (see below) by a special drying process, the supercritical drying technique, were called aerogels irrespective of their structural properties. With the development of new drying techniques (e.g., the possibility of drying under conventional conditions, see Section 3.3), this definition no longer appears appropriate.
2) According to the alternative definition, materials in which the typical structure of the pores and the network is largely maintained (which is not always the case for supercritical drying) while the pore liquid of a gel is replaced by air are called aerogels. However, it is not always clear to what extent the structure was maintained. Rearrangement and shrinkage in the gel body during drying are normal phenomena! In many publications attention is not paid to this issue.

In this review we will mainly follow the second definition, which better applies to the special properties of this class of materials. However, we do not generally exclude materials which correspond only to the first definition.

There are already some excellent reviews on aerogels,[1] most of which focus on physical properties or applications. Here, we want to present these fascinating materials from a more chemical point of view. Aerogels are an excellent example for how important chemistry is for the development of new materials. We want to use aerogels as an example to demonstrate that the intimate knowledge and understanding of the chemistry of precursors and the chemistry of the formation of the solid are indispensible for the deliberate optimization and tailoring of materials properties.

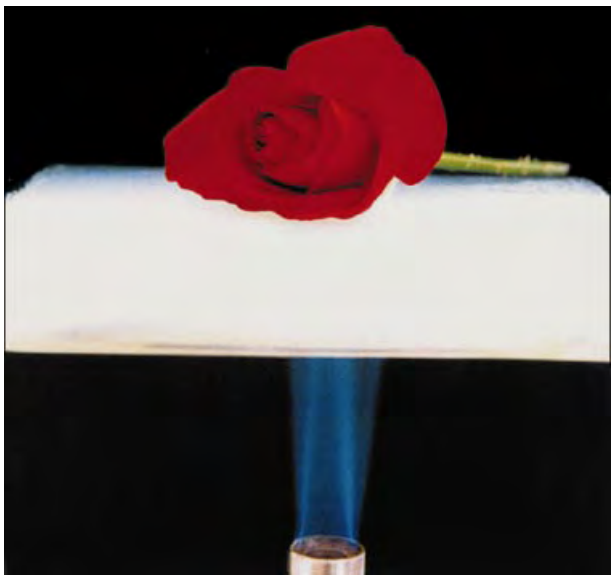

Figure 1. Aerogels have excellent insulating properties, as shown here for a silica aerogel tile.

Until recently, the chemical approach for developing materials with novel properties mainly consisted of preparing substances with a new chemical composition, that is, in an attempt to correlate the macroscopic properties and the chemical building blocks. The importance of the controlled synthesis of pore structures was only recently realized. A topical example is the family of mesoporous molecular sieves with regular channel systems (the M41S family).[2] Several emerging technologies depend on the development of engineered porous materials.[3] Nevertheless, deliberate tailoring of pores is still a major challenge in materials chemistry.

Materials are porous if they contain cavities, channels, or interstices that are deeper than they are wide.[4] The pores may be regularly arranged, as in molecular sieves. However, the more common situation is an irregular pore structure, as obtained by cross-linking of polymer chains, aggregation or agglomeration of small particles, or selective removal of elements of a solid (e.g. by etching or pyrolysis). The physical properties of a porous solid and its reactivity are effectively influenced by the kind, shape, and size of the pores. Some technical terms are defined in Table 1. The unique materials properties of aerogels result from the special arrangement of their solid network, which is schematically shown in Figure 2 for a SiO_2 aerogel.[6]

The structures of aerogels are characterized by well-accessible, cylindrical, branched mesopores. Other mesoporous materials are fumed silica, Vycor glass, carbon soot, or mesoporous molecular sieves. Among them, aerogels are

Table 1. Definition of terms used to characterize porous solids.

Term	Explanation
porosity	ratio of the pore volume to the volume occupied by the particles or powder
pore shape	ink-bottle, cylindrical, funnel, or slit-shaped
accessibility of the pores	closed, blind, or through pores
pore size,[5] dominating transport mechanisms	*micropores*: <2 nm, activated transport *mesopores*: 2–50 nm, Knudsen diffusion, surface diffusion along the pore walls, capillary transport *macropores*: >50 nm, molecular diffusion
density	skeletal density: density of the solid network bulk density: mass per total volume (volume = solid phase + closed pores + open pores)

N. Hüsing U. Schubert

Nicola Hüsing, born in Rheda-Wiedenbrück (Germany), received her Diplom in chemistry and in 1997 her Ph.D. at the Universität Würzburg (Germany). Her dissertaion was on the chemical modification of aerogels. Since 1994 she has been working as a research and teaching assistant at the Institut für Anorganische Chemie der Technischen Universität Wien (Austria). A research scholarship from the Deutschen Akademischen Austauschdienst allowed her to stay with Professor J. Zink at the University of California in Los Angeles (USA) for six months in 1996 to investigate enzymes trapped in inorganic gels. She was awarded an Erwin–Schrödinger scholarship of the Fonds zur Förderung der wissenschaftlichen Forschung for postdoctoral research in 1997/98 with Dr. J. Brinker at the Advanced Materials Laboratory in Albuquerque (USA) in the area of novel porous materials. In 1997 she received the Harry Kloepfer Aerosil Award, which was sponsored by the Degussa AG and awarded by the Gesellschaft Deutscher Chemiker. Her research interests are porous sol–gel materials.

Ulrich Schubert, born in Regensburg (Germany), studied chemistry at the Technische Hochschule München (Germany), and received his Ph.D. in 1974. His dissertation was on reactions of carbene complexes. After a postdoctoral year at Stanford University (USA) with Professor W. S. Johnson, he finished his Habilitation at the Technische Universität München in 1980 on the structural chemistry of metal complexes. From 1982 to 1994 he held the position of Associate Professor of Inorganic Chemistry at the Universität Würzburg. Since 1989 he also served in different positions at the Fraunhofer-Institut für Silikatforschung in Würzburg. In 1994 he was appointed ordinary Professor of Inorganic Chemistry at the Technische Universität Wien. The current research interests of his group center around applied fundamental research on sol–gel processes, the activation of silicon– and tin–element bonds by transition metal complexes, and the structural chemistry of molecular inorganic compounds.

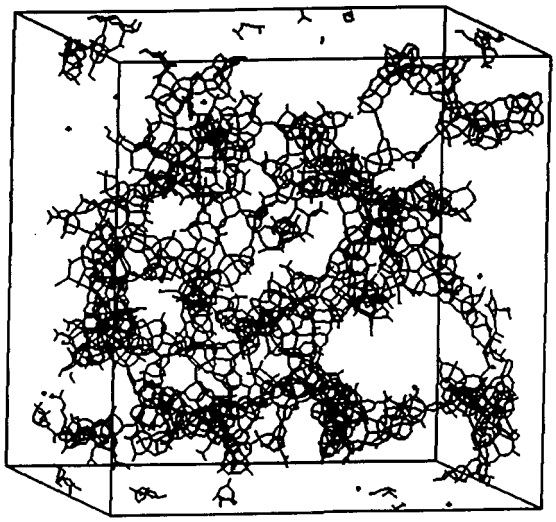

Figure 2. Schematic description of the structure of a silica aerogel (reproduced with friendly permission from ref. [6]).

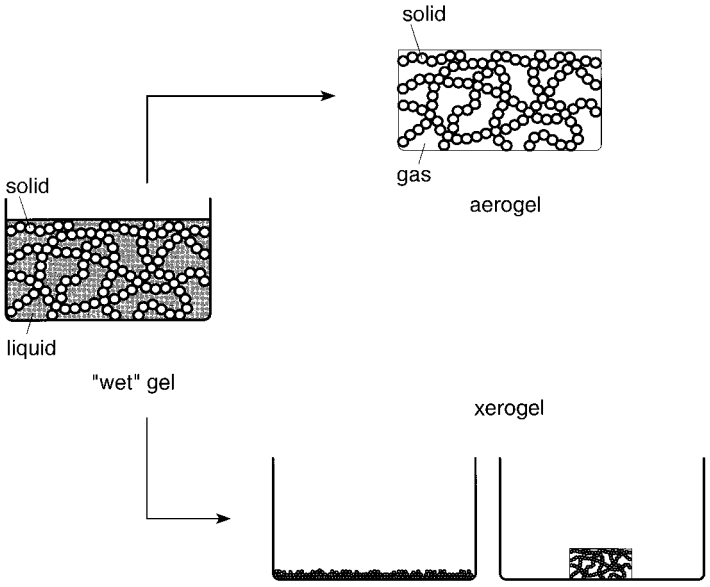

Figure 3. Shrinkage upon drying of a wet gel body to give an aerogel (top) and a xerogel (bottom) as a powder (left) and a monolith (right).

unique owing to their extremely high porosity (low density) and high specific surface area, and the possibility of making monoliths. Aerogels can also be obtained as granulates or powders. The bulk density of aerogels is in the range of 0.004 – 0.500 $g\,cm^{-3}$ owing to the high porosity (for comparison, the density of air is 0.00129 $g\,cm^{-3}$).

The pore structure of aerogels is formed by the controlled condensation of small (polymeric or colloidal) primary particles with a diameter of 1 – 3 nm, as discussed in detail in Section 2. Generation and aggregation of the particles is controlled by chemical processes, usually the sol – gel process, which has been extensively treated in books,[7, 8] conference proceedings,[9–11] and several reviews.[12, 13]

To begin, we want to explain some terms related to the sol – gel process which will be frequently used throughout this review. In a *sol* colloidal particles with diameters in the range of 1 – 1000 nm are dispersed in a liquid. A *gel* consists of a spongelike, three-dimensional solid network whose pores are filled with another substance (usually a liquid). When gels are prepared by hydrolysis and condensation of metal or semimetal alkoxides or other hydrolyzable metal compounds (through the sol stage), the pore liquid mainly consists of water and/or alcohols. The resulting ("wet") gels are therefore called *aquagels*, *hydrogels*, or *alcogels*. When the pore liquid is replaced by air without decisively altering the network structure or the volume of the gel body,[14] *aerogels* are obtained (or *cryogels* when the pore liquid is removed by freeze-drying). A *xerogel* is formed upon conventional drying of the wet gels, that is, by increase in temperature or decrease in pressure with concomitant large shrinkage (and mostly destruction) of the initially uniform gel body (Figure 3).

The large shrinkage of a gel body upon evaporation of the pore liquid is caused by capillary forces acting on the pore walls as the liquid retreats into the gel body. This results in the collapse of the filigrane, highly porous inorganic networks of the aquagels or alcogels. Therefore, other drying methods had to be developed to prepare aerogels (see Section 3). Kistler, who prepared the first aerogels in 1931, used the solvent in the supercritical state for drying.[15] The chemical composition of the gel networks included oxides of silicon, aluminum, tin, thorium, iron, and tungsten as well as organic compounds such as cellulose, cellulose nitrate, and gelatine. Therefore, the first publication on aerogels ended very optimistically: *"…and we see no reason why this list may not be extended indefinitely"*.

Despite the optimistic and encouraging prediction of Kistler, the application-oriented research and development of aerogels only started in the late 1960s, concomitant with the rapid development of the sol – gel process. They found their first application in particle detectors for high-energy physics (Çerenkov detectors). The continuing and steadily increasing interest, both in applied fundamental research and technical applications, is demonstrated by the increasing number of publications each year and the regular international symposia since 1985.[16]

2. Network Formation and Structure

Formation of the highly porous three-dimensional network is one of the key steps in the preparation of aerogels. It is remarkable that this can be achieved for inorganic, inorganic – organic, and purely organic systems under controlled conditions despite a typical solid content of only 1 – 15 vol %. Network formation is an excellent example for the influence of chemical parameters, in particular the kind of precursors and the reaction conditions, on the resulting microstructure. The microstructure, for their part, influences the macroscopic properties of the resulting solid. "Design" of the materials properties therefore requires mastering of the fundamental chemical processes. This is especially important for aerogels, because the network formed by wet chemical processes can be preserved nearly unchanged by the special drying techniques

(Section 3). Therefore, some possibilities for structural investigations should be mentioned at this point. In a simplifed manner we consider the structure of an aerogel, which is easier to investigate by physical methods, to be approximately equal to that of the corresponding wet gel. We thus want to link the chemical processes for the network formation with the structure of the (aero)gels.

The gathering of information on the structure of aerogels requires methods which cover the length scale from the lower nanometer (structure of the primary particles) to the micrometer range (linking of the particles).[17] No technique can provide the complete information, and a clearer picture only emerges by combining different methods. Some common methods for determining the structure of aerogels are listed in Table 2.

There are several other techniques for gaining structural information. For example, NMR spectroscopy was used to follow the evolution of the structure from the molecular precursors to the gel,[30] or to determine the pore diameters or fractal dimensions.[31] Mechanisms of the network formation can be derived from the fractality—that is, the self-similarity—of the structure.[32] Atomic force microscopy (AFM) was recently used to obtain information on the atomic structure at the surface.[33]

The irregular, branched three-dimensional gel network is usually formed by condensation of colloidal particles. There are two principal possibilities:

1. Solid gels are dissolved (peptized) and the obtained sols (colloids) then reaggregated under different conditions.
2. Sol particles are formed by chemical reactions from dissolved molecular precursors. Their condensation results in the formation of a gel. Most aerogel syntheses follow this route, with two variations:

a) Hydrolysis and subsequent condensation reactions are initiated starting from aqueous solutions of ionic precursors by changing the pH or the temperature.
b) Precursor molecules in an organic solvent are transformed into species capable of undergoing condensation. For example, the reaction of metal or semimetal alkoxide groups (E−OR) with water results in the formation of hydroxy groups (E−OH), which can then condense to form E-O-E units. Gel formation starting from multifunctional organic precursors proceeds similarly.

The production of inorganic and inorganic–organic aerogels is shown schematically in Figure 4. Some parameters are also listed with which the sol–gel process and therefore the properties of the resulting aerogels can be influenced and varied. Organic aerogels are produced similarly.

The solvent plays an important role in sol–gel processes. It not only serves to homogenize the precursors in the initial stage, but also influences the particle- and network-forming reactions to a very high degree due to its polarity and viscosity. In the preparation of aerogels it has an additional function, as shown in Figure 4. Since gelation results in only a marginal change in volume and the drying process during the aerogel production is performed (by definition) in a way that shrinking is minimal, the volume of the aerogel body (and thus its density) is determined by the volume of the reaction solution. Therefore, the density of aerogels is simply modified by varying the precursor concentration in the starting solution.

In principle, the structures of all covalently bonded gels are between those of colloidal and polymeric gels, which constitute the two extremes with regard to both the microstructure and the resulting properties (Figure 5). The three-dimensional network in both structural types is formed by connecting primary particles (clusters[34]). In colloidal gels, dense colloidal particles are interconnected like a string of pearls (Figure 5a). In polymer gels, linear or branched polymer chains are formed by condensation of small clusters (rings, cages) instead of dense particles (Figure 5b). There are several theoretical models for the aggregation of the clusters to three-dimensional networks.[7, 35]

Because the microstructure strongly depends on the preparation conditions, each aerogel has its own structural characteristics. It is difficult to compare different aerogels in spite of similar structural features. We therefore restrict ourselves in the following sections to discussing some basic concepts for network formation that are exemplarily for different chemical systems.

2.1. Inorganic Aerogels

Nearly all metal or semimetal oxides are known to form gels, and many served for the production of aerogels. A complete listing of all known inorganic aerogels would be beyond the scope of this review. For this reason, we restrict

Table 2. Typical methods for structurally characterizing aerogels and the structural information available from them.

Method	Structural information	Remarks/problems
N_2 adsorption and desorption according to Brunauer, Emmett and Teller (BET)[18]	specific surface area, distributions of pore radii,[19] interactions of adsorbents and adsorbates	only pores are detected which are accessible for N_2, structural changes by the N_2 pressure during the measurements results in falsification of the values for the pore radii[20]
helium pyknometry[21]	skeletal density	
mercury porosimetry[22]	pore volumina	compression of the network by the applied pressure instead of penetration of Hg into the matrix[23, 24]
electron microscopy [scanning, transmission, and scanning transmission electron microscopy (SEM, TEM, and STEM, respectively)]	particle sizes, form and arrangement of the particles (morphology)	sintering processes due to the high energy of the electron beam
light scattering (LS),[25] small-angle X-ray scattering (SAXS),[26, 27] small-angle neutron scattering (SANS)[28, 29]	particle and cluster sizes, fractal dimensions, surface area	inverse relation of the scattering vector and the structural dimension, information from the Angstroem to the micrometer range

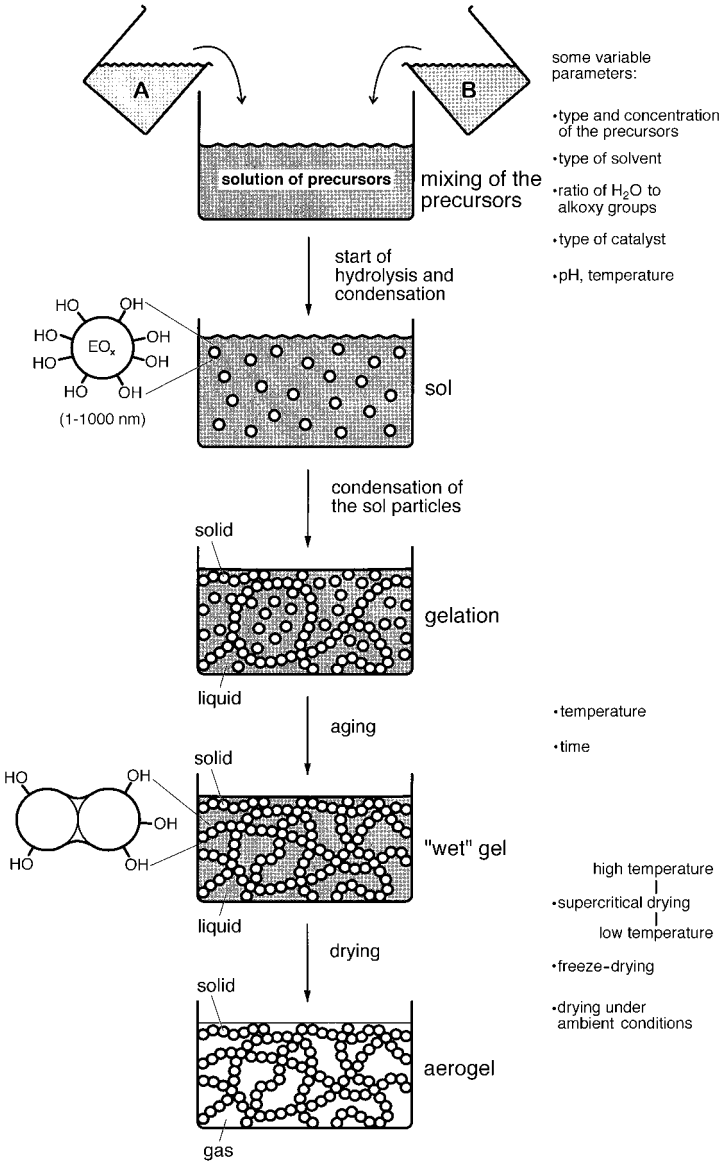

Figure 4. General scheme for preparing aerogels by sol–gel processing and some typical variable parameters.

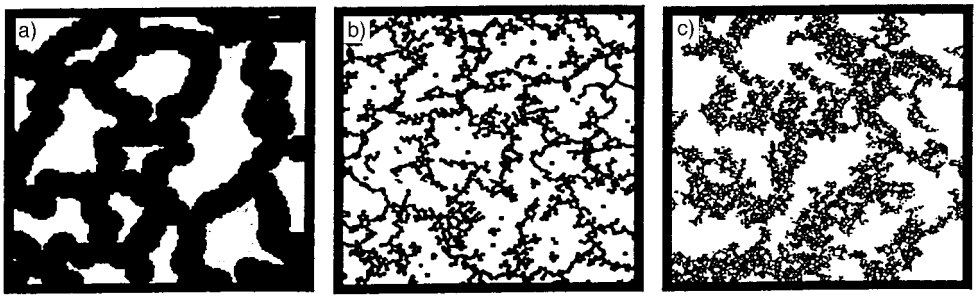

Figure 5. Two-dimensional structures of aerogels: a) colloidal, b) polymeric, and c) with a rough surface (see Section 2.1.1; reproduced with friendly permission from ref. [44]).

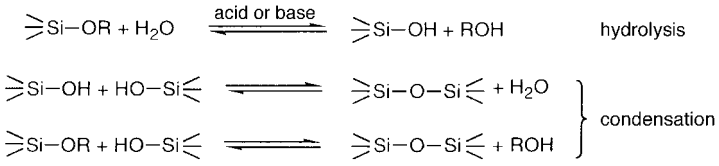
ourselves to some examples which we believe to be important or representative. A semantic aspect should be pointed out first. The term "SiO_2 gel" (correspondingly for other gels) is only used to characterize the type of inorganic skeleton. SiO_2 gels and aerogels often have the composition $SiO_x(OH)_y$ or, if they are prepared from alkoxides, $SiO_x(OH)_y(OR)_z$, where the values of y and z can be (but must not be) rather high. For example, in aerogels made from $Si(OMe)_4$ under basic conditions and then supercritically dried with methanol, 30% of the silicon atoms still carry a methoxy substituent ($z = 0.3$ in this case).[36]

2.1.1. SiO_2 Aerogels

Silica gels certainly belong to the best investigated materials in inorganic chemistry. Therefore, it is not surprising that Kistler used SiO_2 gels in 1931 for his first attempts to exchange the liquid in gels for air.[15] For this purpose he allowed water glass, an aqueous solution of sodium silicate, to react with hydrochloric acid [Eq. (1)].



$$\text{“}Na_2SiO_3\text{”} + 2\,HCl \xrightarrow{H_2O} [SiO_2 \cdot x\,H_2O] + 2\,NaCl \quad (1)$$

To convert the aquagels into aerogels he first had to remove the formed NaCl by several washing cycles. Then the water had to be exchanged for another solvent, because supercritical drying of the aquagels resulted in their complete peptization. Kistler showed impressivly that the liquid of the gels can be removed without destroying the gel structure. One of the reasons why it took 30 years for the aerogels to become interesting for industrial applications was certainly the time-consuming preparation, which took more than a week.

A decisive simplification and acceleration of the synthesis was achieved by Teichner et al. in the 1960s.[37] They dissolved tetramethoxysilane (TMOS) in methanol and added a defined amount of water to start the hydrolysis and condensation reactions [Eq. (2)]. The pore liquid now mainly consisted of

$$Si(OCH_3)_4 + H_2O \xrightarrow{CH_3OH} [SiO_2 \cdot H_2O/CH_3OH] \quad (2)$$

alcohol, and therefore the wet alcogels could be dried supercritically without the awkward solvent exchange. The chemical reactions during sol–gel processing of alkoxysilanes can be formally described by three equations (Scheme 1). Condensation already occurs even if not all of the OR groups are hydrolyzed. Small oligomers (clusters) are initially formed by the condensation reactions and then the sol particles which eventually form the oxidic gel network. However, all intermediate species still contain Si–OR and/or Si–OH groups. Hydrolysis therefore takes place parallel to condensation during all steps of the sol–gel process.

Scheme 1. Chemical reactions for the sol – gel process of alkoxysilanes.

Parameters which influence the hydrolysis and condensation and whose deliberate variation are used for "materials design" are, inter alia, the kind and concentration of the precursors, the relative concentration of the components in the precursor mixtures, the kind of the solvent, the ratio of H_2O to alkoxy groups, the temperature, and the pH value.

A variety of physical-chemical measurements and also some computer simulations were performed to determine the influence of these parameters on the network formation of SiO_2 aerogels.[16, 38–42] For example, Schaefer et al. showed with in situ SAXS experiments that variation of the mentioned parameters strongly influences the silicate structures on a length scale of 1 – 20 nm.[43] Schaefer and Keefer postulated kinetic models for the growth of gel networks based on SAXS data.[44, 45] Although probably not universal, they are currently the only basis for a preparative design of aerogel structures in the nanometer range. Two of the most important models are shown in Figure 6.

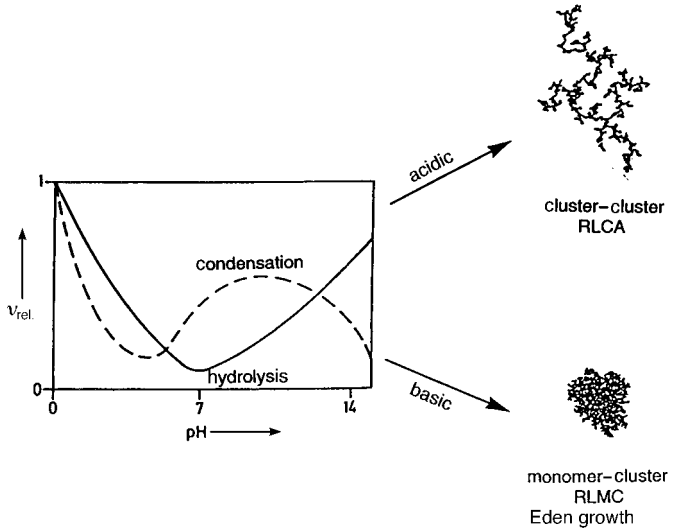


Figure 6. Dependency of the hydrolysis and condensation reaction on the pH, and derived models for kinetic growth of gel structures based on RLCA and RLMC growth (according to ref. [7, 35]). $v_{rel.}$ = relative rate of reaction.

The pH value is the decisive parameter for the relative rates of hydrolysis and condensation of tetraalkoxysilanes $Si(OR)_4$. Under acidic conditions (pH 2 – 5) hydrolysis is favored, and condensation is the rate-determining step. A great number of monomers or small oligomers with reactive Si–OH groups is simultaneously formed. Under these conditions, reactions at terminal silicon atoms are favored for electronic reasons. This results in polymerlike gels which are formed from chains with few branches; that is, small clusters condense to give a polymerlike network with small pores. This process is called reaction limited cluster aggregation (RLCA).

In contrast, hydrolysis is the rate-determining step under basic conditions. Due to a different mechanism, reaction at the central silicon atoms of an oligomer unit is favored. The resulting network is characterized by big particles and large pores ("colloidal" gels). Hydrolyzed species are immediately consumed because of the faster condensation. Condensation of clusters with each other is relatively unfavorable because it requires inversion of configuration at one of the silicon atoms involved in the reaction.[7] Therefore, the clusters grow mainly by condensation of monomers. This model is called reaction limited monomer cluster growth (RLMC) or Eden growth.[46, 47] It would ideally result in equally dense structures. However, for tetraalkoxysilanes this simple model must be slightly modified. Not all the four branching points are equal, because $Si(OR)_{4-x}(OH)_x$ is initially formed from $Si(OR)_4$ ("poisoned" Eden growth). Condensation is inhomogeneous owing to the presence of Si–OR groups at the growth front, and rough structures are obtained (see Figure 5c). Therefore, the kind of inorganic network formed upon condensation not only depends on the absolute rates of the individual reactions but also on the relative rates of hydrolysis and condensation.[48, 49]

The preparation of aerogels from polymeric gels is more difficult, because diffusion processes are strongly inhibited by the smaller pores. Complete removal of the pore liquid is therefore more difficult and results in greater shrinkage upon drying.[50] For this reason SiO_2 aerogels are usually prepared by base-catalyzed reaction of tetramethoxysilane (TMOS) or tetraethoxysilane (TEOS), usually with ammonia as the catalyst.

A modification of this procedure was developed by Brinker et al:[51] $Si(OR)_4$ is first prehydrolyzed with a small amount of water under acidic conditions. This results in the formation of small clusters of silicic acid. In a second step (which must not necessarily immediately follow the first) a defined amount of aqueous acid or base is added. Networks formed by this two-step procedure have a structure similar to that of the RLCA model; that is, they have polymeric character. The probable explanation is that the reactive clusters formed in the first step as structure-forming units are strongly responsible for the formation of the network, independent of the kind of catalyst used in the second step. The main difference caused by base or acid catalysis in the second step is the stiffness of the resulting network. The former results in a stiffening which stabilizes the gels. With this two-step procedure a more deliberate control of the microstructure and thus the particle and pore sizes of the SiO_2 gels is possible.

The group of Hrubesh used the two-step sol – gel process to vary the density of aerogels within a larger range.[52, 53] When aerogels are made by simple base- or acid-catalyzed reactions their density is restricted to 0.030 – 0.300 $g\,cm^{-3}$, because the alcohol formed during hydrolysis shifts the equilibrium towards species with alkoxy groups. This results in long gelation times. Tillotson and Hrubesh removed the alcohol by destillation after the first step and replaced it by an aprotic solvent (e.g. acetonitrile). Deliberate dilution, base-catalyzed hydrolysis of the remaining Si–OR groups, and condensation

of the SiO_2 particles resulted in the formation of a three-dimensional network and a solid with a density of only 0.004 g cm^{-3}.[53]

In principle, the work of Pajonk et al. is also based on a two-step procedure. They synthesized oligomeric polyethoxysiloxanes of a certain size from TEOS by adding an exact amount of water. These defined oligomers were then used as precursors for sol–gel processing to form the three-dimensional network.[54-56]

The preparative routes to SiO_2 aerogels described so far have one thing in common: an alkoxysilane was used as the precursor. For technical applications, in which large amounts of aerogels are needed, alkoxysilanes are too expensive. Therefore, BASF, Hoechst, and others use a procedure in which a solution of aqueous sodium silicate is ion-exchanged and then hydrolyzed under acidic conditions.[57, 58] For the production of Basogel, the aerogel product of BASF, a two step-procedure was applied. A solution of sodium silicate is mixed with sulfuric acid in the first step. Small hydrogel or aquagel droplets are formed by spraying. The metal salts are then extracted, and the water is exchanged for an organic solvent.[59] The gel droplets are then supercritically dried. The procedure of Hoechst and Nanopore, an American company, will be discussed with the drying methods.

Henkel patented a procedure in 1991 with which silicic acid is transfered into an organic solvent, and condensation is then performed under acidic, neutral or basic conditions. These wet gels are also potentially suited for producing aerogels.[60]

The transition from sol to gel is reached when a continuous network is formed (gel point). An extremely important aspect of the preparation of inorganic gels is that the chemical reactions are not finished with the formation of the gel network. First, the pore liquid is initially a sol. That is, it contains condensable particles or even monomers which slowly condense to the existing basic network. Second, there are structural rearrangements in the gel network for mainly two reasons. The gel network is originally still very flexible, and neighboring E–OH or E–OR groups can approach each other and undergo condensation ("aging"). Furthermore, hydrolysis and condensation are in principle reversible. Therefore, mass is dissolved from thermodynamically unfavorable regions, and the solutes condense to thermodynamically more favorable regions, in particular in pores, crevices, and particle necks ("Ostwald ripening"). This process results in the reduction of the net curvature, disappearance of small particles, and filling of small pores. Aging and ripening increase the stiffness of the gels (see Figure 4). This is an important aspect, particularly for aerogels, to which we will return when discussing the drying methods.

Because of the described differences in the structure of the primary particles and the network formation, which are caused by the different reaction mechanisms, the macroscopic properties of SiO_2 aerogels differ within a wide range. This is a very good example for the correlation between precursor chemistry and the properties of the final materials (see Section 5.1). "Typical" structural data therefore have only limited relevance. Nevertheless, some data for SiO_2 aerogels are listed in Table 3 to exemplify their properties.

Table 3. Important structural properties of SiO_2 aerogels

Property	Range	Typical value
bulk density [g cm^{-3}]	0.003 – 0.500	0.100
skeletal density [g cm^{-3}]	1.700 – 2.100	
porosity [%]	80 – 99.8	
mean pore diameter [nm]	20 – 150	
inner surface area [m^2 g^{-1}]	100 – 1600 [61]	600
refractive index	1.007 – 1.24	1.02
thermal conductivity λ (in air, 300 K) [W m^{-1} K^{-1}]	0.017 – 0.021	1.02
modulus of elasticity E [MPa]	0.002 – 100	1
sound velocity c_L [m s^{-1}]	< 20 to 800	100
acoustic impedance Z [kg m^{-2} s^{-1}]		10^4

2.1.2. Metal Oxide Aerogels

The principles for network formation of SiO_2 gels also hold for non-silicate inorganic gels. Aqueous solutions of salts or molecular precursors in organic solvents, again usually alkoxides, can be employed for sol–gel processing.

Metal alkoxides of, for example, titanium, zirconium, tin, or aluminum are much more reactive towards water than alkoxysilanes. This is due to the lower electronegativity and higher Lewis acidity as well as the possibility of increasing the coordination number. Table 4 lists some properties that are important for the reactivity of different tetravalent alkoxides. Reactivity in hydrolysis reactions decreases in the order $Si(OiPr)_4 <<< Sn(OiPr)_4$, $Ti(OiPr)_4 < Zr(OiPr)_4 < Ce(OiPr)_4$.

Table 4. Electronegativity EN, ionic radius r for the coordination number four, preferred coordination number CN, and the degree of coordinative unsaturation of the central atom (CN – N) for some tetravalent ($N = 4$) alkoxy compounds.[62]

Alkoxide	EN[a]	r [Å][63]	Preferred CN	CN – N
$Si(OiPr)_4$	1.74	0.40	4	0
$Sn(OiPr)_4$	1.72	0.69	6	2
$Ti(OiPr)_4$	1.32	0.56	6	2
$Zr(OiPr)_4$	1.22	0.73	7	3
$Ce(OiPr)_4$	1.08	1.02[b]	8	4

[a] Allred – Rochow electronegativities. [b] For the coordination number six.

The reactivity towards water is so high for many of these alkoxides that precipitates are spontaneously formed. Whereas the reactivity of alkoxysilanes has to be promoted by catalysts, the reaction rates of metal alkoxides must be moderated to obtain gels instead of precipitates. The most common method is the addition of acetic acid or acetylacetone to the precursor solution. This results in substitution of part of the alkoxy groups by acetate or acetylacetonate. Other chelating or bridging ligands can also be used. The new molecular compound $[M(OR)_y(L)_x]_n$ (L = bidentate anionic ligand, Figure 7) shows a different reactivity, structure, and functionality than the unsubstituted alkoxide $M(OR)_{y+x}$ as a function of the kind and number of the ligands.

Complexation allows the chemical design of the precursors, with which the properties of the sol–gel materials can be deliberately influenced. Not only are new building blocks introduced, but the average degree of condensation is also

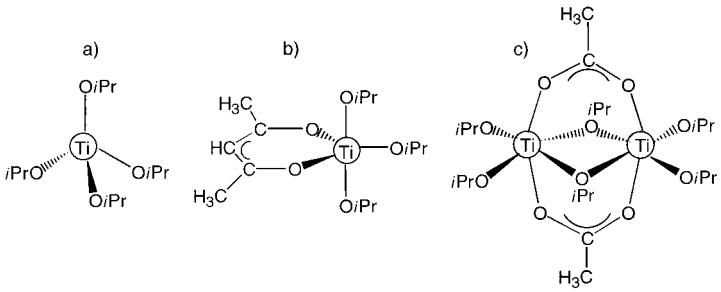

Figure 7. Molecular structure of a) $Ti(OiPr)_4$, b) the acetylacetonate derivative $[Ti(OiPr)_3(acac)]$, and c) the acetate derivative $[Ti(OiPr)_3(OAc)]_2$.

changed. Since the bidentate ligands are located at the surface of the oxo clusters, the size and structure of the primary particles can be engineered by deliberately varying the ratio of alkoxide to ligand.[64, 65]

Typical examples of metal oxide aerogels of some elements or combinations of elements will be discussed in the following. Compared to aerogels with a silicate network, only little work was done to elucidate their network formation and structure. One of the most important differences is the possibility of forming crystalline primary particles. As a general rule, the crystalline portion is favored by a large excess of water in the hydrolysis reaction.

Alumina

The preferred precursors for the synthesis of Al_2O_3 aerogels are $Al(OsBu)_3$ (ASB) and $Al(OtBu)_3$ (ATB). ASB has the advantage of being soluble in 2-butyl alcohol, whereas other aluminum alkoxides are insoluble in the corresponding alcohol. There are different possibilities for handling this problem.[66] The alkoxide can be dissolved in benzene followed by addition of pure water (two liquid phases are formed) or water dissolved in the corresponding alcohol. Alternatively, a dispersion of the alkoxide in the corresponding alcohol can be prepared, and water is added afterwards. Teichner et al investigated the basic chemistry of aluminum alkoxides in the context of preparing Al_2O_3 aerogels.[67–69] They found that one of the most important parameters is the relative amount of water, which allows control of the surface area, the pore volume, and the portion of crystalline (boehmite) and amorphous units in Al_2O_3 aerogels.

Mizushima and Hori prepared Al_2O_3 aerogels from ethylacetylacetonate-modified ASB.[70] They were able to interrupt the process at the sol stage owing to the better control of the hydrolysis and condensation reactions, to remove the solvent, and to modify the alumina particles. A hybrid network between alumina and organic units was prepared by cross-linking with, for example, hexamethylenediisocyanate (Figure 8), which has a lower density and a broader pore-radii distribution than an unmodified alumina aerogel.[71]

Markel et al. prepared Al_2O_3 aerogels by a different method.[72] They amalgamized the surface of metallic aluminum and then oxidized it with O_2. A layer of Al_2O_3 fibers oriented perpendicular to the metal surface was formed, which the authors called an aerogel.

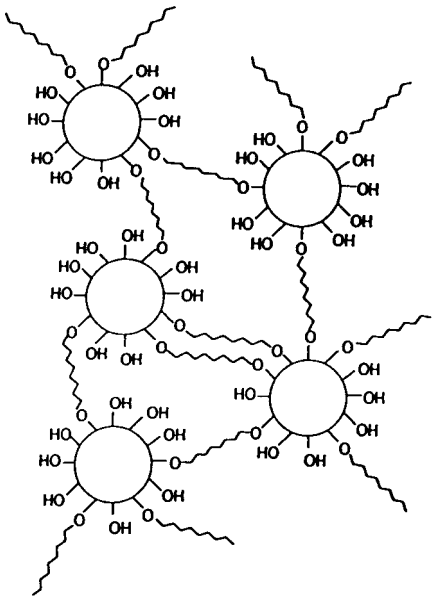

Figure 8. Schematic representation of an alumina gel cross-linked with hexamethylenediisocyanate (reproduced with friendly permission from ref. [71]). The large circles represent particles of hydroxylated alumina, and the snakelike lines $C(O)NH(CH_2)_6NHC(O)$ chains.

Titania and zirconia

The first TiO_2 and ZrO_2 aerogels were prepared by Teichner et al. as early as 1976.[67] Until today, the propoxides and butoxides of these metals are mainly used as precursors.[1f, 73–75]

TiO_2 aerogels can be prepared totally amorphous or with a network of anatase primary particles.[76] Zhu and Tomkiewicz were able to elucidate the microstructure and morphology over two length scales and three density regions by combining SAXS, SANS, N_2 sorption, and electron microscopy: the size and density of the nanoparticles (clusters) and the mesoparticles, and the bulk density of the whole network. Figure 9 schematically shows the network model derived from these measurements. Mesoparticles with a diameter of about 50 nm aggregate to give a three-dimensional network. They are formed by aggregation of the crystalline nanoparticles of about 5 nm in diameter.

As with the alumina gels, the amount of water added for hydrolysis is decisive for the structure of zirconia aerogel networks. Addition of substoichiometric amounts of water results in an amorphous network, whereas a structure composed of crystalline, monoclinic ZrO_2 particles is obtained with an excess of water.[1c, 67] Vesteghem et al. gelled $Zr(OnPr)_4$ in 1-propanol in the presence of acetic acid. The acetate ligand remained in the aerogel.[77]

Zeng et al. investigated the fractal dimension of amorphous and partially crystalline ZrO_2 aerogels.[78, 79] From the results of SAXS measurements (values for d_f [mass fractality] close to 2) they concluded that the aerogels have a branched, polymerlike fractal structure, which is analogous to that of the silicate systems investigated by Keefer and Schaefer,[45, 46] consisting of small primary particles with an average diameter of 5.2 nm (partially crystalline) or 2.5 nm (amorphous). Other one-component oxide aerogels are listed in Table 5.

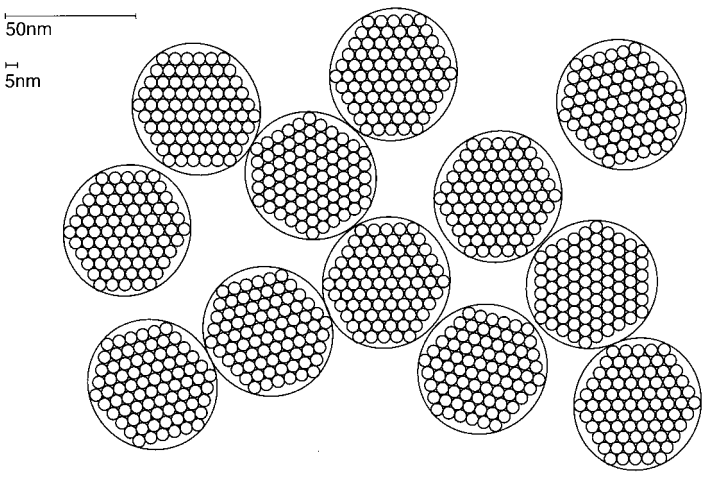

Figure 9. Schematic representation of the structure of partially crystalline TiO_2 aerogels (reproduced with friendly permission from ref. [76c]).

Table 5. Examples of purely inorganic aerogels, precursors for their preparation, and potential applications.

Aerogel	Precursor	Application
V_2O_5	$VO(OiPr)_3$,[80] $VO(OEt)_3$[81]	cathode in lithium batteries
Cr_2O_3	$Cr(NO_3)_3$,[82] $CrCl_3$,[83] $Cr(OAc)_3$[84, 85]	oxidizing properties, fluorination of hydrocarbons with HF
Fe_2O_3	$FeCl_3$,[82, 83] $[Fe(acac)_3]$[86–88]	
MoO_2	$[MoO_2(acac)_2]$[67, 89, 90]	electrocatalysis
Nb_2O_5	$Nb(OEt)_5$[91–94]	isomerizations, solid acids

Binary and ternary oxide aerogels

Compared to other methods for preparing multicomponent oxides, the sol–gel method offers the best control over the resulting properties of the materials by varying the processing parameters.[37, 89, 95, 96] When precursors that undergo hydrolysis and condensation at similar rates are combined, mixed metal oxides are obtained which are homogeneous at the molecular level. With increasing differences in the reaction rates, the microstructure of the product becomes more heterogeneous and phase separation may even occur. In particular, the "core-shell" phenomenon is observed. The faster reacting compound forms sol particles which are "coated" by the slower reacting component. There are several possibilities for avoiding this effect: The reaction rate of the faster reacting component can be moderated by the bidentate ligands discussed above. Alternatively, the slower reacting precursor can be prehydrolyzed, and the faster reacting component added afterwards.[97] The network in the thus prepared aerogels is analogous to that of the one-component oxide aerogels.

Typical binary or ternary systems consist of SiO_2, TiO_2, ZrO_2, or Al_2O_3 combined with NiO, CuO, ThO_2, PbO, or Fe_2O_3. A complete compilation is beyond the scope of this review. Some aerogels are exemplarily listed in Table 6. Mixed oxide aerogels for catalytic applications are summarized in reviews by Pajonk and Baiker.[1c, e]

The structural composition of Al_2O_3/SiO_2 (mullite) systems, prepared from the alkoxides in the presence of bidentate ligands, was thoroughly investigated by Heinrich et al.[101] The interpretation of the SAXS data again led to the postulation of a RLCA-related network. SiO_2 building blocks are partially incorporated into the alumina clusters and partially integrated onto the surface of these particles. The Si–OH groups at the surface of the clusters serve as condensation sites between the particles (Figure 10).

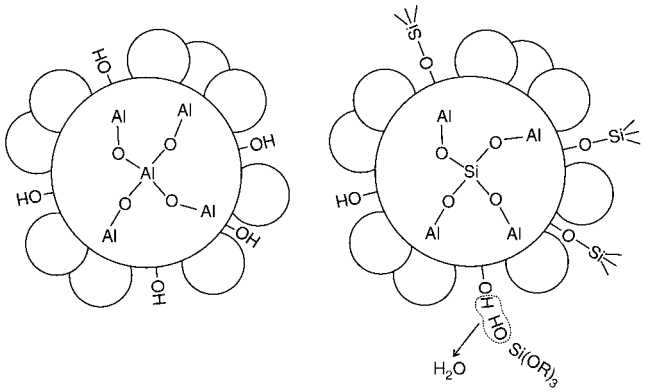

Figure 10. Schematic structure of alumina gel particles in the absence (left) and presence of alkoxysilanes (right). The circular segments at the outside of the particles represent the bidentate ligands (according to ref. [101]).

Several inorganic gels were investigated by X-ray diffraction (XRD). It was found that SiO_2 aerogels are always amorphous, whereas TiO_2, Al_2O_3, and ZrO_2 can also be partially crystalline as anatase, boehmite, or monoclinic ZrO_2.[67] In mixed oxide aerogels the SiO_2 and Al_2O_3 portions

PbO/Al_2O_3, PbO/ZrO_2	$Pb(OAc)_2 +$ ASB[104] and $Zr(OiPr)_4$[105]	nitroxidation of hydrocarbons to nitriles
BaO/Al_2O_3	$Ba[Al(OsBu)_4]_2 +$ ASB, Ba(1,3-butandiolate) + ASB[106]	car-exhaust catalysis
$x\,Li_2O/(1-x)\,B_2O_3$	$B(OBu)_3 + LiOMe$[107]	
$PbTiO_3$	$Pb(OAc)_2 + Ti(OiPr)_4$[108, 109]	model systems for piezoelectric lead zirconate/titanate (PZT) aerogels
$NiO/Al_2O_3/MgO$	$Ni(OAc)_2 +$ ASB $+ Mg(OMe)_2$	nitroxidation
$NiO/SiO_2/MgO$	$Ni(OAc)_2 + Si(OR)_4 + Mg(OMe)_2$[110]	
$2\,MgO/2\,Al_2O_3/5\,SiO_2$ (cordierite-like)	$Si(OEt)_4 +$ ASB $+ Mg(NO_3)_2$[77]	

are always amorphous.[87, 88, 110–112] However, crystalline aluminates are observed, for example $NiAl_2O_4$.

The structural data of some non-silicate aerogels are listed in Table 7. We want to emphasize again that this is only a selection, because particularly for these aerogels the structural parameters differ decisively with the preparation conditions.

Metals in Metal Oxide Aerogels

A second metal component in the gels must not necessarily yield a binary oxide aerogel. The use of alcohols for supercritical drying (see below) can, under the applied conditions, result in the conversion of easily reducible oxides into metals, because alcohols have reducing properties. Metal particles can also be generated by subsequently reducing the aerogels with hydrogen at high temperatures or by mixing hydrogen into the autoclave during supercritical drying.[118] Aerogels are particularly well suited as carriers for catalytically active metals because of their high porosity. Detailed discussions are found in reviews on aerogels as catalysts.[1c, e]

To incorporate metal components into the gel matrix, the formed aerogels can be impregnated with solutions of the corresponding metal salts (two-step process).[119, 120] Alternatively, suitable metal salts can be added to the precursor solution, which results in the incorporation of the metal compounds into the gel during sol–gel processing.[121] The first metal-containing aerogels, Pt/SiO_2 and Ni/SiO_2, were prepared by Foster and Keyes in this manner with water glass as the source of SiO_2.[82]

The number of examples of metal-doped aerogels and, correspondingly, the number of catalytic reactions in which these materials are employed increase every year. Table 8 gives a short selection.

2.2. Inorganic–Organic Hybrid Aerogels

Materials in which organic molecules or building blocks are combined with structural elements of ceramic materials have only been known for a short time. There are several reasons for modifying oxide aerogels with organic groups. Most importantly, the spectrum of properties of aerogels is widened or improved without influencing the existing positive properties, such as good heat insulation, transparency, and high surface area. For example, the hydrophobicity and the elastic properties of SiO_2 aerogels can be improved relative to unmodified SiO_2 aerogels by incorporating organic groups.[36, 129]

There are only limited possibilities for subsequently doping or modifying aerogels with organic compounds; they will be discussed in Section 4. A more general route is the integration of organic molecules or groups already during sol–gel processing. There are several options for doing this (Figure 11). Embedding molecules into gels without chemical bonding (Figure 11, top right) is achieved by dissolving the molecules in the precursor solution. The gel matrix is formed around them and traps them. Such doped wet gels can, in principle, be converted into aerogels, but the probability is very high that the organic groups are washed out during supercritical drying, which is usually used, and the associated rinsing processes. Bockhorst et al. were able to incorporate a fluorescent dye (POPOV) into the gel network. However, the extent of leaching during aging and drying was relatively high.[130] Although fullerenes C_{60} and C_{70} were also incorporated into SiO_2 aerogels, there is no information on how well the fullerenes are entrapped.[131]

Novak et al. investigated networks built analogously to those in Figure 11, top left (interpenetrating, but not con-

Table 7. Typical structural data of some non-silicate aerogels.

Aerogel	Density [g cm^{-3}]	Porosity [%]	Pore radii [nm]	BET surface area [m^2 g^{-1}]	Particle morphology [nm]

nected networks). The organic polymer was generated in situ during the sol–gel reaction by radical polymerization of a vinyl monomer. The aerogel obtained by supercritical drying with CO_2 consists of interpenetrating inorganic and organic networks (Figure 12).

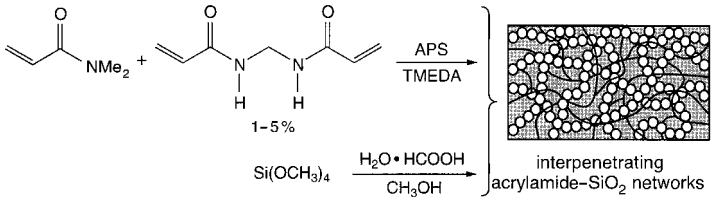

Figure 12. Formation of two interpenetrating networks (inorganic–organic) by simultaneous sol–gel reaction and polymerization of *N*,*N*-dimethylacrylamide (in the presence of *N*,*N*′-methylenebisacrylamide (APS = ammonium persulfate); according to ref. [132]).

Attempts to perform the sol–gel process in solutions of organic polymers usually failed, because the polymer was washed out during supercritical drying. The only success was observed with organic polymers capable of forming hydrogen bonds to the surface silanol groups of the inorganic matrix, such as poly(2-vinylpyridine).[132]

The more important modifications of aerogels are based on covalent bonding of the organic groups (Figure 11, bottom). In silicate systems precursors can be used in which the (functional) organic group is bonded through a hydrolytically stable Si–C link to the network-forming "inorganic" part of the molecule. Compounds of the type $R'Si(OR)_3$, in which R′ is the organic group modifying the inorganic gel, are usually employed. This kind of linkage is not possible for non-silicate systems because of the hydrolytic instability of M–C bonds. However, the organic groups can be introduced with bidentate ligands (Section 2.1.2). The preparation of organically modified xerogels is described in several reviews.[62, 133, 134]

In the remainder of this section we want to concentrate on organically modified SiO_2 aerogels, because these are best investigated. Schwertfeger et al. performed the sol–gel process with a mixture of a tetraalkoxysilane and an organically substituted trialkoxysilane $R'Si(OR)_3$ [Eq. (3)].[36, 129] The

$$x\,R'\text{–}Si(OR)_3 + (1-x)\,Si(OR)_4 + H_2O \xrightarrow{CH_3OH} [R'_x\text{–}SiO_{(2-0.5x)}\cdot H_2O/CH_3OH] \quad (3)$$

R′-substituted silanes (R′ = alkyl, aryl) condense in a kind of two-step process to the network formed from the tetraalkoxysilane under alkaline conditions, because the rate of hydrolysis and condensation of $R'Si(OR)_3$ is slower than that of the corresponding tetraalkoxysilane $Si(OR)_4$. Thus, they modify the inner surface without influencing the typical aerogel properties. The process is similar to the formation of the core-shell structures mentioned in Section 2.1.2. for the preparation of multicomponent oxide aerogels. This kind of network formation was verified by Hüsing et al. by Raman spectroscopy. The spectra clearly show that $Si(OR)_4$ hydrolyzes and condenses before $R'Si(OR)_3$. The R′-substituted silane units therefore condense to the then existing network much later (hours to days).[135, 136] These results are confirmed by NMR spectroscopic investigations, which additionally show the inverse trends for acid-catalyzed mixed sol–gel systems.

The integration of functional organic groups into the aerogel matrix allows further extension of the application spectrum of SiO_2 aerogels (for example, towards catalysts or sensors) because now the chemical properties can also be varied.[136–140] Figure 13 shows a selection of functional organic groups which were already

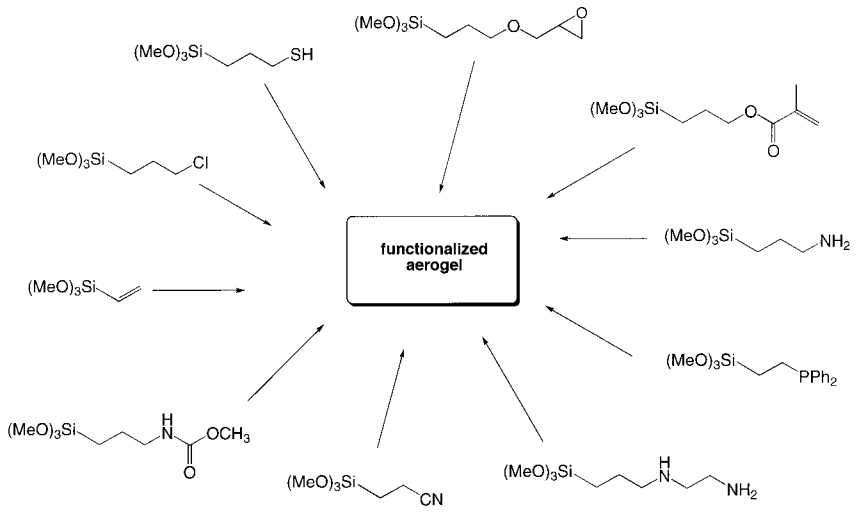

Figure 13. Silane precursors with organic substituents that were used for preparing functionalized aerogels.

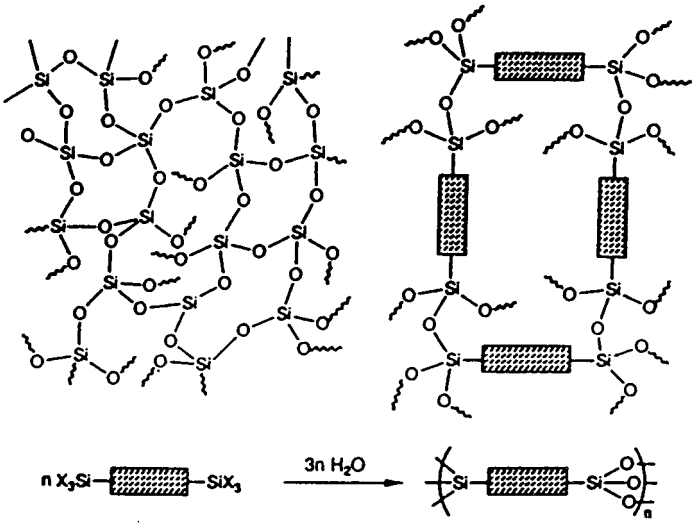
successfully incorporated into aerogels. A two-step sol–gel mechanism was also established for most of these groups. Surprisingly, structural variations (porosity, inner surface area) in the functionalized aerogels are not induced as much by the properties of the functional group than by indirect influences on the sol–gel process. The trialkoxysilane basically acts as a co-solvent in the first phase of the reaction. Therefore, the tetraalkoxysilane is more diluted at this stage (resulting in a decrease in the network density), and a larger amount of water and catalyst is available for its reaction (resulting in larger particles).[140]

In another approach, the morphology (pore sizes, surface) of the aerogels is not tailored by the reaction conditions of sol–gel processing but instead by linking of the $Si(OR)_3$ groups in the precursors. Organic groups of variable length (for example saturated or unsaturated hydrocarbon chains, or polyaryls) substituted with $Si(OR)_3$ groups at both ends are used. An inorganic oxidic network in which the hydrocarbon chains bridge the inorganic building blocks is formed during sol–gel processing (Figure 14).

Loy et al. used precursors of the type $(RO)_3Si(CH_2)_n$-$Si(OR)_3$ with $n = 2$, 6, 8, 10, 14 without adding $Si(OR)_4$ for sol–gel processing under both basic and acidic conditions. They showed that the length of the spacer n decisively influences the later aerogel structure.[141] Ethylene- and hexamethylene-modified gels are highly porous and have high specific surface areas (about 700 $m^2 g^{-1}$). The specific surface area decreases with increasing length of the spacer. The tetradecylmethyl-



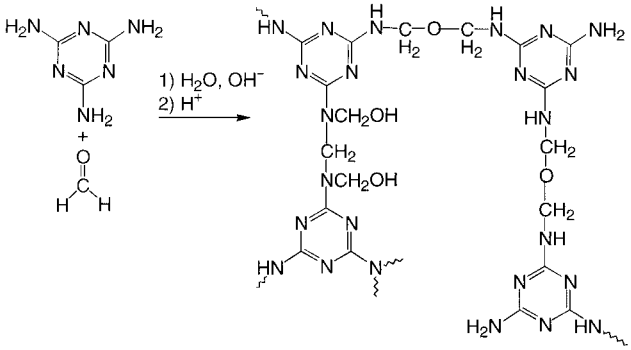


Figure 14. Schematic representation of silica gel (left) and inorganic–organic hybrid silsesquioxanes (right) as well as their syntheses (bottom, with drawings of the arenediyl, alkanediyl, and alkynediyl spacers; reproduced with friendly permission from ref. [141]).

ene-modified "aerogel" is nonporous, and SEM micrographs show a distinctly different morphology (whether this gel really is an aerogel is not discussed here, see Section 1).

2.3. Organic Aerogels

An interesting alternative to the inorganic aerogels was developed by Pekala et al. starting in 1987.[142] Purely organic aerogels were synthesized by polymerization of multifunctional organic monomers in dilute solution followed by supercritical drying.[143–145] Resorcinol/formaldehyde (RF) and melamine/formaldehyde (MF) were the first precursor mixtures for this organic sol–gel chemistry. Gelation was initiated by Na_2CO_3 or NaOH. The gels were then treated with dilute acid to increase the degree of cross-linking and, thus, to stabilize the network.

Resorcinol is a trifunctional monomer which can add up to three equivalents of formaldehyde. These substituted resorcinol derivatives then condense with formation of nanometer-sized clusters which then cross-link through groups at the surface (e.g. CH_2OH). For the polymerization of melamine with formaldehyde, either the monomers or MF polymers with low molecular mass can be used. Equation (4) shows the possible polymerization reactions.[146]

(4)

Topical developments in the area of organic aerogels are based on the polymerization of furfural with a phenolic Novolak resin (prepared by the reaction of phenol with formaldehyde) to give the "PF gels". A decisive advantage over RF or MF polymerization is that alcoholic solutions can be used, and the laborious solvent exchange before drying is avoided.[147]

The most important parameters for the synthesis of purely organic gels are the catalyst concentration and the pH of the solution. Their structure and properties—such as density, specific surface area, or particle and pore sizes—can be deliberately influenced by these variables.

Despite the structural differences originating from the different precursors, organic aerogels have some common properties. These include accessible pores with small diameters (≤ 50 nm), high specific surfaces (400–1000 $m^2 g^{-1}$), and a solid matrix which is formed from either connected colloidal particles or polymeric chains of about 10 nm in diameter.

RF and MF aerogels are built from linked colloidal particles formed during sol–gel processing. The size and number of the clusters strongly depends on the ratio of resorcinol to catalyst (R:C). Typical values are in the range of 50–300. High catalyst concentrations (for example R:C = 50) result in particles with diameters of 3–5 nm that are connected to each other through broad particle necks (polymeric gels). If the R:C ratio is increased, the particle are larger in diameter (11–14 nm) and cross-link like pearls on a string (colloidal gels). The structure of MF gels was investigated by Ruben by high-resolution transmission electron microscopy.[146] Table 9 shows some representative data for organic aerogels.

Table 9. Some typical structural data and properties of organic aerogels.

Parameter	RF aerogel	MF aerogel	PF aerogel[147]
density [g cm^{-3}]	0.03 – 0.06	0.10 – 0.80	0.10 – 0.25
surface area [m^2 g^{-1}]	350 – 900	875 – 1025	385
pore diameters [nm]	≤ 50	≤ 50	
particle morphology [nm]	3 – 20	2 – 10	irregular shape, ca. 10 nm
application	precursor for carbon aerogels	–	precursor for carbon aerogels
color	dark red, transparent	colorless, transparent	dark brown

Pekala and Schaefer tried to apply kinetic models for network formation, developed for inorganic gels, to organic RF aerogels.[148] However, no fractal character was found for these gels in SAXS experiments. Nanophase separation, both initiated and limited by the cross-linking, was discussed as an alternative explanation for the network formation.[3]

3. Drying Methods

Evaporation of the liquid from a wet gel is very complex, and different stages can be distinguished. At the first stage, the gel shrinks by the volume that was previously occupied by the liquid. The liquid flows from the interior of the gel body to its surface. If the network is compliant, as for gels derived from alkoxides, the gel deforms (Figure 15).

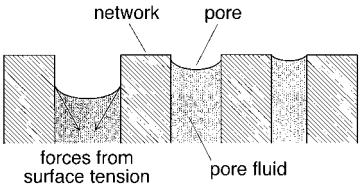

Figure 15. Representation of the contracting surface forces in pores of different size during drying. At the same pressure the curvature of all menisci in the pores is the same. For this reason the larger pores empty first (according to ref. [7]).

Upon shrinkage, OH groups at the inner surface approach and can react with each other. For example, new siloxane bridges are formed in SiO_2 gels. As drying proceeds the network becomes increasingly stiffer and the surface tension in the liquid rises correspondingly, because the pore radii become smaller. The second stage of the drying process begins when the surface tension is no longer capable of deforming the network and the gel body becomes too stiff for further shrinkage. This is the "critical point".[149] At this stage the tension in the gel becomes so large that the probability of cracking is at its highest. At the second stage of drying, the liquid/gas interface retreats into the gel body. Nevertheless, a contiguous funicular liquid film remains at the pore walls; that is, most of the liquid still evaporates from the exterior surface of the gel body. At the third stage of drying this film is raptured. Eventually only isolated pockets contain liquid, which can leave the network only by diffusion into the gas phase.[7, 150]

Two processes are important for the collapse of the network: First, the slower shrinkage of the network in the interior of the gel body results in a pressure gradient which causes cracks. Second, larger pores empty faster than smaller ones during drying; that is, if pores with different radii are present, the meniscus of the liquid drops faster in larger pores (see Figure 15). The walls between pores of different size are therefore subjected to uneven stress and crack.

The parameters influencing these capillary forces are well investigated, and strategies were developed to avoid cracking. Important options are, inter alia, the pore size (larger pores are more advantageous because the capillary force is inversely proportional to the pore radius),[151, 152] aging (the network becomes stiffer), or addition of tensides (reduction of the surface energy leads to a decrease in the capillary forces), organic templates, or drying-control chemical additives (DCCA).[153–157] Crack-free xerogels can be obtained by exact control of these parameters; however, large shrinkage cannot be avoided.

This situation is not sufficient for the production of aerogels. Methods have to be found to conserve the pore structure of the wet gels, that is, to avoid shrinkage. In the following sections possibilities are discussed with which the above-mentioned processes during drying and the occurrence of capillary forces can be avoided.

3.1. Supercritical Drying

In this procedure the solvent is put into the supercritical state, and therefore there are no liquid/gas interfaces in the pores during drying. The wet gel is placed in an autoclave and covered with additional solvent. Drying out of the samples (which would lead to the formation of cracks), is thus avoided, and the critical volume V_c is reached. After the autoclave is closed, the temperature is slowly raised resulting in an increase in pressure (pathway A in Figure 16). Both the

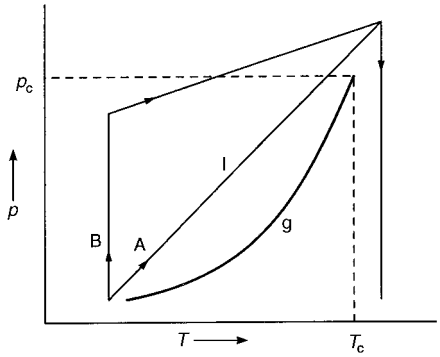

Figure 16. Schematic representation of the principle of supercritical drying. At the critical point (T_c, p_c) the densities of the liquid (l) and the gas (g) are equal. Supercritical drying can be performed along pathway A or B.

temperature and the pressure are adjusted to values above the critical point of the corresponding solvent (T_c, p_c) and kept there for a certain period of time. This ensures that the autoclave is completely filled with the supercritical fluid. The fluid is then slowly vented at constant temperature, which results in a drop in pressure. When ambient pressure is reached, the vessel is cooled to room temperature and then opened. Drying is often performed in a way that the vessel is prepressurized with nitrogen to avoid evaporation of the solvent (pathway B in Figure 16).[158] The phase boundary between the liquid and the gas must not be crossed during drying.

In principle, different organic solvents can be used for drying. The critical constants of the most common drying fluids are listed in Table 10. Supercritical drying is performed either "hot" (organic solvents) or "cold" (CO_2) depending on T_c.

Table 10. Critical constants for some solvents.

Solvent	T_c[°C]	p_c[Mpa]	V_c[cm^{3}mol^{-1}]
methanol	240	7.9	118
ethanol	243	6.3	167
acetone	235	4.7	209
2-propanol	235	4.7	
H_2O	374	22.1	56
CO_2	31	7.3	94
N_2O	37	7.3	97

3.1.1. Drying in Organic Solvents ("Hot")

The pore liquid, which is usually an alcohol or acetone owing to the preparation conditions, is used as the supercritical fluid. About 250 °C and 5–8 MPa are needed to put the solvent in the supercritical state. Problems arise from the combination of high temperatures and high pressure as well as the flammability of these solvents. In August 1984 the main gasket in the lid of a 3000-L pressure vessel for the production of 60×60 cm^2 aerogel tiles failed in a pilot plant in Lund (Sweden). More than 1000 liters of methanol were released, and a big explosion destroyed the whole building.[159]

In addition to the risks connected with supercritical drying in organic fluids, rearrangement reactions in the gel network are highly probable because of the high temperatures. For example, in SiO_2 aerogels a modification of the surface may occur upon conversion of Si–OH into Si–OR groups, or processes such as during aging and ripening of the gels are accelerated. Small pores are thus filled, and particle necks strengthened. As a consequence, the resulting aerogels have a lower specific surface area, a narrow pore-radii distribution (elimination of microporosity), and a stiffer network.[160–163] Organically modified aerogels are particularly sensitive to the high temperatures, and functional organic groups may be destroyed during drying.[164] Phase separation and loss of stoichiometry (SiO_2/B_2O_3, SiO_2/B_2O_5)[165] or crystallization (SiO_2/TiO_2)[166] may occur in multicomponent gels.[1e, 167]

3.1.2. Supercritical Drying with CO_2 ("Cold")

An alternative to drying in organic solvents is the use of liquid carbon dioxide.[168-170] This method was developed by biologists for electron microscopy[171] and has the advantage of a very low critical temperature at a moderate critical pressure. However, a time-consuming solvent exchange is necessary. The time required for exchanging the original pore liquid for liquid CO_2 is determined by the diffusion of carbon dioxide into the gel, and is therefore dependent on the dimensions of the gel body. Another requirement is the miscibility of the pore liquid with carbon dioxide. For example, water and CO_2 are immiscible, and therefore an intermediate solvent exchange (e.g. water for acetone) is necessary.[107]

Structural changes, as observed during supercritical drying with alcohols, take place to a minor extent with CO_2. Therefore, the network of the wet gel can be conserved almost unchanged.

A modification of this method and its application in a continuous plant in which CO_2 is recycled was described by van Bommel et al.[172, 173] Heating and cooling of the autoclave is avoided by exchanging the solvent with CO_2 that is already in the supercritical state.

Brodsky and Ko showed that deliberate structural changes can be induced in SiO_2/TiO_2, ZrO_2, and Nb_2O_5 aerogels by varying the temperature above T_c during supercritical drying with CO_2. For example, the ratio between crystalline and amorphous regions, which is important for catalytic applications, can thus be influenced.[174]

3.2. Freeze-Drying

Another possibility for avoiding phase boundaries between the liquid and gas phases during drying is freeze-drying. The pore liquid is frozen and then sublimed under vacuum.

Several attempts were made to use this method for producing aerogels.[175–177] However, aging periods have to be extended to stabilize the gel network, the solvent must be exchanged for another with a low expansion coefficient and a high pressure of sublimation, and low freezing temperatures should be achieved by addition of salts. Another disadvantage is that the network may be destroyed by crystallization of the solvent in the pores. Cryogels are therefore only obtained as powders.

3.3. Ambient-Pressure Drying

To make aerogels interesting for larger scale commercial applications, one must avoid the most expensive and risky part of the preparation: supercritical drying. Therefore, the interest in alternative ways for exchanging the pore liquid in the gels by air is very high. However, with the above-mentioned processes (Sections 3.1 and 3.2) during drying in mind, the intention already appears to face a contradiction.

The capillary forces exerted by the meniscus of the pore liquid and the pressure gradient upon the large shrinkage of the network are the main reasons for the collapse of the filigrane structure (see Section 3). To dry aerogels at ambient conditions (subcritical drying), one has to strengthen the network to avoid its collapse (irreversible shrinkage). Additionally or alternatively, the contact angle between the pore

liquid and the pore walls has to be influenced by deliberate modification of the inner surface and variation of the solvent to minimize the capillary forces.

Smith, Brinker, and Deshpande published the first synthesis of SiO_2 aerogels dried at ambient pressure in 1992.[178] In principle, their procedure involves a series of solvent-exchange processes and a modification of the inner surface.[179] The water/alcohol mixture in the pores of the gel is first exchanged for a water-free solvent, and the Si–OH groups at the surface are silylated (e.g. with chlorotrimethylsilane). The reactivity of the gel surface is thus reduced, and the surface hydrophobized. The actual drying process is performed after another solvent exchange. As expected, the gel shrinks strongly during evaporation of the solvent from the pores. However, no irreversible narrowing of the pores with formation of Si-O-Si bonds is possible because of the silylation. The gel therefore expands to nearly its original size after reaching the critical point. This is called the "spring-back effect". One of the prerequisites for this procedure is the strengthening of the network by exact control of the aging conditions. The network of the modified gels must be stable enough to tolerate a reversible shrinkage to 28% of its original volume![180]

Einarsrud et al. obtained similarly good results with another strategy.[181, 182] They increased the strength and stiffness of the network drastically by aging the wet gels in solutions of tetraalkoxysilanes in aqueous alcohols, and were thus able to avoid shrinkage during drying completely. The monomers added during aging mainly condense in the smallest pores and at the particle necks; the microporosity of the gels is thus lost. The gels can also be dried at ambient pressure between 20 and 180 °C because of the stiffer network.

The technique of ambient-pressure drying for preparing aerogels is still in its infancy, but is a highly topical area in which many research activities are concentrated. Since companies like Hoechst and Nanopore have taken over this method developed by Smith et al., a technically much simpler and therefore less expensive method is available. This makes the industrial application of aerogels economically interesting.[183]

4. Modification of Aerogels after Drying: Is There Chemistry after the Critical Point?

Chemical modifications are still possible even after drying. The intention of this section is to show some possibilities for improving or modifying the property profile of aerogels, in particular with respect to special applications. The examples show that this is another approach for chemically modifying aerogels which until now, however, was hardly used.

The subsequent doping of an aerogel host with active components appears attractive because of the high porosity of aerogels. However, follow-up treatment with a liquid phase is difficult because wet gels are formed again. As discussed in Section 2.1.2 aerogels can be doped with metals by impregnation with a suitable metal salt. The metal salt has to be introduced in alcoholic solution, and then the solvent has to be removed again in another supercritical drying step in order not to prevent destruction of the aerogel network.[122]

Another, more general possibility for subsequently modifying aerogels is their reaction with gaseous compounds. Early attempts were performed with gaseous dichlorodimethylsilane or other silylation reagents to remove the reactive silanol groups at the surface of the network and thus to hydrophobize the aerogel permanently.[184] There are now better possibilities for hydrophobation. However, doping with compounds from the gas phase is increasingly an attractive option. Even a homogeneous distribution in monoliths can be achieved.

Hunt et al. intensively investigated the reaction of aerogels with gaseous reactants, and called this method chemical vapor infiltration (CVI). Originally, the intention of this approach was to improve the thermal properties of aerogels by incorporation of carbon (see Section 5.2).[185–187] For this purpose, the aerogels were allowed to react with acetylene, methane, propane, xylol, or furfuryl alcohol in a stream of an inert gas at high temperatures. The temperatures necessary for pyrolysis depend on the gas and varied between 350 and 850 °C. The aerogels strongly favor decomposition of the organic compounds. Carbon is deposited as graphite on the inner surface of the aerogels, and even nanometer-sized carbon fibers, rings, and tubes were found.

The CVI method appears to be broadly applicable. Its potential is clearly visible for reactions in which new products are formed by chemical, thermal, or photolytic treatment. Cao et al. were able to prepare SiO_2/Si nanocomposites by decomposition of gaseous silanes (such as SiH_4 or $HSiCl_3$) in SiO_2 aerogels, which then showed photoluminescence upon irradiation with ultraviolet light.[188] Analogous reactions with ferrocene resulted in the deposition of iron particles in the aerogel matrix, which then displayed interesting magnetic properties.[188] Reaction of SiO_2 aerogels with $[W(CO)_6]$ and subsequent thermal decomposition of the metal carbonyl in the aerogel resulted in metallic tungsten particles. WN or WS_2 particles in aerogels were formed by follow-up treatment of the metal-doped aerogels with ammonia or sulfur. SiO_2 aerogels were analogously treated with gaseous $[Fe(CO)_5]$. Under an oxidizing atmosphere amorphous iron oxide/SiO_2 aerogels were formed, which were transformed into Fe_3O_4/SiO_2 (by reaction with additional $[Fe(CO)_5]$) or Fe_9S_{10}/SiO_2 aerogels (by reaction with H_2S).[189] Organic compounds can also be sublimed into the network through the gas phase as shown for a porphyrine derivative.[190]

Besides the treatment of aerogels with gaseous compounds, pyrolysis of organic groups which are part of the aerogel structure is another possibility for modifying aerogels. Schwertfeger et al. pyrolyzed the organic groups of inorganic–organic hybrid aerogels (see Section 2.2). They were thus able to coat the aerogel network with carbon nanostructures.[186a]

Pyrolysis reactions are most important for preparing carbon aerogels, which are of particular interest because they are the first electrically conducting aerogels.[191] They can be made by pyrolysis of resorcinol/formaldehyde or phenol/furfural aerogels under an inert atmosphere (1050 °C/N_2). Their structure and morphology basically corresponds to that of their precursors; that is, there are colloidal or polymeric gels (Table 11). The colloidal gels have spheric particles with

Table 11. Typical structural data of carbon aerogels.

skeletal density [g cm^{-3}]	2.06
density [g cm^{-3}]	0.05 – 0.80
specific surface area [m^2 g^{-1}]	600 – 800
pore size [nm]	< 50
particle morphology [nm]	3 – 20, amorphous
appearance	black, opaque

diameters of 12 – 15 nm which are loosely connected by graphitic ribbons. The polymeric gels have smaller particles (7 – 9 nm) connected by broad particle necks. Two factors mainly influence the properties of carbon aerogels: the ratio of precursor to catalyst during the preparation of the organic gels and the pyrolysis temperature.

5. Properties and Applications

SiO_2 aerogels are currently the aerogels with the highest potential for applications. They are not only the best investigated with regard to their preparation, structure, and properties, but can also be prepared with lower costs than other aerogels (cheaper precursors). There are already commercial applications. The development of the sol – gel process for non-silicate materials has recently boomed. One of the consequences is that the number of possibilities for varying aerogels becomes considerably larger. Non-silicate aerogels (see Section 2.1.2) increasingly play an important role, particularly in the search for new catalysts. In the case of organic aerogels, mainly their pyrolysis products (carbon aerogels) offer interesting new applications.

Since the main focus of this review is on the chemistry of aerogels, only a short overview on the properties of aerogels and the resulting applications will be given. Comprehensive information on these topics can be found in more physically oriented reviews.[1]

5.1. Optical Properties

The optical properties of SiO_2 aerogels and the derived inorganic – organic hybrid aerogels vary between transparent and translucent, depending on the preparation conditions. This means that the structure-forming units are smaller than the wavelength of visible light. However, inhomogeneities in the network in the nanometer range result in Rayleigh scattering. Therefore, aerogels appear yellowish under light and bluish against a dark background (see page 22). The portion of Rayleigh scattering correlates directly with the homogeneity of the gel network in the nanometer range. Objects that are viewed through an aerogel tile appear slightly blurred. Inhomogeneities in the micrometer range at the exterior surface of the aerogel body are responsible for this phenomenon.[192]

Numerous attempts were made to influence the optical properties of SiO_2 aerogels deliberately for their application in Çerenkov detectors (see below) or for transparent heat insulation. A transparency as high as possible is required for both applications. Initially, there were more physically oriented approaches to solving this problem, such as investigating the influence of the drying process, of water adsorbed to Si–OH groups, or of adsorbed organic components. It was found, for example, that supercritical drying with CO_2 results in more transparent materials than drying with organic fluids.[169, 193] Heating the aerogels also improves their transparency due to desorption of water and burning of organic components.[1d, 194]

However, these efforts are like putting the cart before the horse. Since scattering phenomena caused by inhomogeneities in the network are responsible for an insufficient transparency, it appears more logical to influence the transparency at its origin by optimizing the sol – gel parameters.[195, 196]

Russo and Hunt tried to quantify scattering in SiO_2 aerogels. They prepared aerogels from TMOS or TEOS under various conditions to determine the optimal precursor composition and gelation conditions.[196] They showed that transparency can be improved by lowering the concentration of water and the reaction temperature. Furthermore, base catalysis is more favorable, and aerogels prepared from TMOS show about nine times less scattering than the corresponding aerogels from TEOS. However, these are not necessarily general trends but instead specific statements for the investigated systems. The correlation of scattering measurements with other structural investigations (N_2 sorption according to Brunauer, Emmett, and Teller) was not successful.

Emmerling et al. investigated the pH dependence of the transparency of gels from TMOS. They showed that there are two distinct extinction minima (high transparency) at pH 1 and 13. They concluded from the correlation of these results with those from SAXS measurements that the particle diameter has to be kept small to improve the optical quality. Interestingly, the transparency was improved in this case when more than a stochiometric amount of water was used for hydrolysis and condensation.[197, 198] In subsequent work the same group correlated the transparencies of SiO_2 aerogels prepared in one step from TMOS, gels from water glass, and gels from the two-step synthesis with the nanostructure of their networks (SAXS, Ultra(U)-SAXS). Aerogels from water glass showed the lowest transparency because of the larger particles and the presence of sodium ions. The aerogels prepared in two steps were distinctly more transparent than gels prepared in one step, probably because smaller clusters are formed during the acid-catalyzed first step.[197]

The latter results were confirmed by Cao and Hunt.[199] They also showed that aerogels prepared by the two-step process (acid hydrolysis and subsequent base-catalyzed condensation) are more transparent than the corresponding aerogels prepared in one step (acid or base catalysis).

Çerenkov detectors

Çerenkov radiation is emitted by charged particles such as piones, muones, or protons if they move faster than light in a medium. A cone-shaped electromagnetic shock wave is formed, from which light is emitted. The velocity of the particles can be calculated from the cone angle. Since the speed of light depends on the refraction index of the medium,

media with different refraction indices were searched. SiO_2 aerogels with refraction indices between 1.007 and 1.024 offer a range not covered by the previously used compressed gases or liquids. Aerogels as solid materials additionally allow easier construction of the detectors and are therefore ideal materials for this application.[200, 201] They are now installed in several Çerenkov detectors worldwide, and the amount of aerogel tiles produced for this application is impressive. For example, 1000 liters of SiO_2 aerogels were produced by Henning for an experiment at the CERN in Geneva, and Poelz et al. equipped a detector (TASSO) at the German Electron Synchrotron (DESY) in Hamburg with 1700 liters of SiO_2 aerogel.[16a]

5.2. Thermal conductivity

The thermal conductivity of aerogels is extraordinarily low. It is made up of three components: thermal transportation by the gas phase, by the solid phase, and by radiation. Figure 17

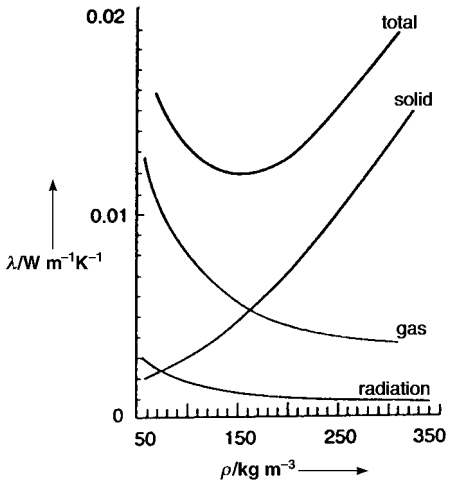

Figure 17. Composition of the thermal conductivity of aerogels: gas, solid, and radiation transport λ depending on the density ρ of the material (reproduced with friendly permission from ref. [200]).

schematically shows the contribution of these components depending on the bulk density. The solid conductivity clearly increases with increasing density, whereas the reverse is true for the gas and radiative transport. The minimum for the total thermal conductivity is at a density of about 0.150 $g\,cm^{-3}$.[200] Heat transport by the gas phase can be avoided by evacuation of the system. For example, an evacuated SiO_2 aerogel at about 300 K shows a thermal conductivity of only 0.010 $W\,m^{-1}\,K^{-1}$, compared to 0.020 $W\,m^{-1}\,K^{-1}$ in air.[202] This is not a special property of SiO_2 aerogels. Thermal conductivities as low as 0.012 $Wm^{-1}\,K^{-1}$ were measured for non-evacuated organic RF aerogels.[203]

Another possibility for reducing the thermal conductivity of SiO_2 aerogels is to reduce the radiative heat transport. This is more important at high temperatures, because the radiation maximum is then in a wavelength range in which SiO_2 does not sufficiently absorb (3–5 μm). Reduction of the thermal conductivity at these temperatures is possible by doping the aerogels with infrared opacifiers, such as carbon soot or TiO_2. These compounds can be mixed in a highly dispersed form to the precursor solution during sol–gel processing or to the sol.[203] Another possibility is the generation of carbon in the aerogel by pyrolysis of organic gases or covalently bonded organic groups of hybrid aerogels (see Section 4). The latter method leads to a particularly efficient decrease in the thermal conductivity (0.012 $W\,m^{-1}\,K^{-1}$ in air at 300 K), because the aerogel skeleton is partially covered with nanometer-sized carbon structures.[204] The improvement of heat-insulation properties is a continuing topic of intense research.[16]

Aerogels have the lowest thermal conductivities of all solids (Figure 18). There is no question that they belong to the best heat-insulation materials currently available. Additional ad-

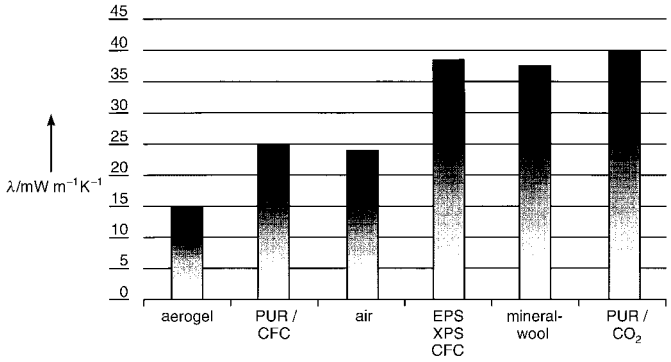

Figure 18. Comparison of the thermal insulation properties of some commercially available insulating materials. PUR: polyurethane foam, CFC: chlorofluorohydrocarbons; EPS, XPS: expanded and extruded polystyrene (reproduced with friendly permission from ref. [183]).

vantages are their nonflammability and transparency (see page 22 and Figure 1). However, a big problem for the insulation of windows is the production of large aerogel panels.[205] Conventional window systems cannot be equipped with the commonly prepared granulate, which is not transparent due to the roughness of its surface; they can only be used for "daylight windows" (for example bathroom, staircase, or ceiling windows). The scattering of the sunlight in the granulate layer is here rather advantageous, because a diffuse lighting of the rooms is achieved.

In addition to transparent thermal insulation, applications for a variety of other insulation problems are conceivable for which the transparency of the insulating material is not necessary, for example in cooling or heating systems and high-temperature batteries.[206, 207] Aerogels can also be utilized for the passive use of solar energy, for example for paneling house walls (Figure 19) or for coating solar-energy collectors.[208, 209] In the Cité Solaire in Ardon (Switzerland) a house was built using an aerogel granulate as a translucent insulating material. A layer of the transparent aerogel allows the penetration of the sun's radiation to the blackened wall, but not the escape of the heat generated there.[210]

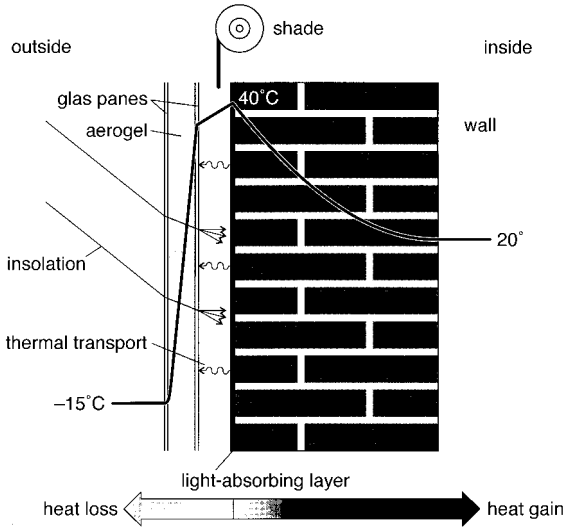

Figure 19. Concept for energy saving by passive use of the solar energy (reproduced with friendly permission from ref. [200]).

5.3. Hydrophobicity

One of the big problems of unmodified SiO_2 aerogels, in particular for technical use, is their long-term stability under a humid atmosphere. Owing to the large number of silanol groups on the inner surface of the material, adsorption and capillary condensation of water and eventually cracking of the gel body by the resulting capillary forces results. Approaches to hydrophobize aerogels permanently were therefore investigated quite early. The possibility of allowing an aerogel to react subsequently with a silylating reagent, such as chlorotrimethylsilane, has the disadvantage of a complicated processing procedure. This kind of modification is only possible by the gas phase (see Section 4).

Hydrophobation at the alkogel stage is time-consuming, since the diffusion rate of the silylating reagent into the pores is a limiting factor. However, this process is a key step in the prevailing ambient-pressure drying of aerogels (see Section 3.3); that is, aerogels prepared by this method are inherently hydrophobic.

Schwertfeger et al. prepared permanently hydrophobic aerogels with a one-step process using a mixture of a tetraalkoxysilane and an organically substituted trialkoxysilane for sol–gel processing (see Section 2.2).[36] They were able to prepare aerogels that floated on water for months (see full-page picture on page 22) while retaining the typical aerogel network.

5.4. Mechanical and Acoustic Properties

Mechanical properties have many aspects. Among others, rigidity, brittleness, and form stability as well as the method of investigation have to be considered. Although the rigidity of aerogels is low because of their structure and the brittleness of the SiO_2 particles, it is sufficient for most applications. The compressive strength of monolithic SiO_2 aerogels is between $0.15-0.30\ N\,mm^{-2}$, depending on the density, with an elastic compression of about 2–4%. The rigidity in vacuum is distinctly higher. The tensile strength is about $0.020\ N\,mm^{-2}$.[211]

One of the decisive parameters for the mechanical properties is the connection of the network in the nanometer range, which strongly depends on the preparation conditions. For example, aerogels prepared under acidic or neutral conditions are about twice as stiff as the corresponding samples prepared under base-catalyzed conditions.[212] Investigations of organically modified aerogels showed that the elastic properties of SiO_2 aerogels can also be improved by chemically modifying the precursors. Ultrasound measurements were used for these investigations. The longitudinal sound velocity is connected with one of the elastic constants (which correlates with the Youngs modulus), and the density of the aerogel. The reason for the improved elastic properties of hybrid aerogels is probably that the presence of alkyl or aryl groups at the surface of the secondary particles impairs stiffening of the particle necks by Ostwald ripening.[137]

Kramer et al. were able to prepare aerogels with very good elastic properties by cocondensation of flexible polydimethylsiloxanes (PDMS) with TEOS. An elastic compression of up to 30% was observed for aerogels into which 20 wt% of PDMS was incorporated.[213]

The particular network structure of aerogels results in impressive acoustic properties which, as mentioned above, correlate with the elastic properties.[214] The sound velocities in SiO_2 aerogels of $100-300\ m\,s^{-1}$ are among the lowest for inorganic solids (this is noteworthy when one considers that sound velocities of $5000\ m\,s^{-1}$ were measured in quartz glass).[215, 216]

The product of density and sound velocity is the acoustic impedance. Since both are low, SiO_2 aerogels have the lowest impedances of all solid materials ($Z = 10^4 - 10^5\ kg\,m^{-2}\,s^{-1}$). This allows interesting applications. For example, aerogels can be used as $\lambda/4$ layers for matching the high acoustic impedance of piezo ceramics to the low impedance of air. The efficiency of these devices is considerably increased by decreasing the reflexion losses at this interface.[217, 218]

5.5. Applications in Catalysis

All the advantages of sol–gel processing for preparing catalysts or catalyst supports—in particular the controllable dispersion of the active component and the possibility of deliberately influencing the microstructure—also apply for aerogels. Additionally, typical structural properties predestinate them for these applications: the extremely high inner surface (which is easily accessible because of the open porosity), the large pore volumes, the excellent temperature stability, and the high selectivities in catalytical processes. Nearly all oxides relevant for catalytical applications can be prepared as aerogels. This is also true for binary and ternary compositions, mixtures of metal oxides, or metal particles on oxide carriers. Furthermore, aerogels can be prepared as powders, granulates, or monolithes, either amorphous or with crystalline portions (see Section 2).

Despite these advantages, the use of aerogels in catalysis has only been increasingly investigated since 1974. The number of publications rises drastically every year. Considerable progress was achieved in solving problems originating from the low density and the low thermal conductivity, that is, pressure drops and bad heat dissipation in the catalyst bed. For example, heat-dissipating materials can be added, or the aerogels can be deposited already during their preparation (i.e. in the autoclave) on a carrier (such as Raschig rings, metal tubings, cordierite honeycombs, wire mesh screens, boiling stones, and others).[84]

It is impossible to list all the investigated systems here; they are summarized in more specialized reviews by Pajonk[1c] as well as Schneider and Baiker.[1e] The following incomplete selection is intended to give an impression of the numerous possibilities: nitroxidation of hydrocarbons to nitriles (NiO/Al_2O_3 with SiO_2 and MgO, PbO/ZrO_2),[105, 112] hydrogenation of nitrobenzene to aniline and of toluene to methylcyclohexane (Ni/SiO_2, Pd/Al_2O_3),[126] hydrogenation and hydrogenolysis after hydrogen "spillover" activation (ZrO_2, SiO_2, MgO, Al_2O_3),[219] isomerizations (Nb_2O_5, Nb_2O_5/SiO_2),[91, 92] Fischer–Tropsch syntheses (Fe_2O_3/Al_2O_3, Fe_2O_3/SiO_2),[102] polymerization of ethene or propene ($TiCl_4/Al_2O_3$),[220] deNO_x reactions ($Fe_2O_3/Cr_2O_3/Al_2O_3$, Pt/C),[143, 221] catalysis for combustion of car exhaust (Pd/Al_2O_3, Pt/Al_2O_3, $Pd/Al_2O_3/SiO_2$),[124, 222] and fluorinations (Cr_2O_3).[85]

5.6. Aerogel Films

Films (coatings) are one of the most important applications of sol–gel materials. Completely dense or partially densified films are prepared in most cases. However, there are numerous applications in which porous films are required. Aerogels with their high porosity and the resulting unique physical properties are highly interesting for such applications. Although aerogels can in principle also be prepared as films, supercritical drying is here a very delicate issue. Nevertheless, aerogel films were synthesized in some laboratories.[223, 224] The possibilities provided by ambient-pressure drying (see Section 3.3) eliminate the principal obstacles for preparing highly porous films.[225–227] The development and use of aerogel films is clearly just in its infancy.

Applications of aerogels as $\lambda/4$ layers for acoustic impedance matching or as catalytically active layers on carriers were already mentioned. Other examples for the application of aerogel films from the Lawrence Livermore National Laboratory in California are optical coatings for solar cells because of their low refractive index (aerogel films prepared for this purpose are subsequently fixed to the surface of the solar cell).[228] The currently used glass layers with high refractive indices can thereby be replaced by aerogels. More light reaches the active surface because of the lower Fresnel scattering losses. The efficiency of the solar cell is thus increased. Thermal applications are also interesting. For example, IR detectors can be coated to obtain a kind of shield against the heat radiating from the substrate.

Other applications for which aerogel films can compete with existing technologies are in microelectronics; here, the low dielectric constant of aerogels plays a particularly important role. With a value of lower than 2.0, they offer important progress in the velocity of electric curcuits. In addition, the dielectric constant is easily controlled because it is directly correlated with the porosity and thus the density of the materials.

This is only a short list of interesting possible applications for highly porous films. Many more will certainly emerge in the future.

5.7. Carbon Aerogels

Carbon aerogels are very well suited as electrode materials because of their low electric resistance ($< 40\ m\Omega\,cm$), their controllable pore-radii distribution (1–50 nm), and their high specific surface area. When a voltage is applied, a thin polarization layer with high capacity is formed on the large surface area. More charge can be stored than with conventional capacitors, because the surface area per volume is very high for aerogels. Compared with other materials (carbon powder or fibres), aerogels have the big advantage that they can be prepared as monoliths.[191]

5.8. Other Applications

Aerogels can be sintered at low temperatures and can therefore be processed to extremely pure and totally homogeneous glasses.[229, 230] The inner surface area and the porosity decrease during sintering. The pore structure can therefore be modified in a controlled way by partial sintering. This was used, for example, for producing gas filters with pores in the range of 20–100 nm.[231] Partially sintered aerogels can resist the tensions of a gas/liquid interface because their texture is strengthened during sintering. They can therefore be used for the storage, thickening, or transport of liquids, for example rocket fuels; in this case the low weight of aerogels is particularly advantageous.[1b]

There are no limits to the fantasy required to find other potential applications of aerogels. The concluding examples show that also exotic applications can be considered: SiO_2 aerogels are suitable as ecologically sound insecticides against pests in grain and seeds or on the ground, such as mites, ticks, cockroaches, or silver fish.[232,233] As a chemically inert dust with small particles and a high specific surface area, aerogels can remove the protecting lipide layer of insects by abrasion or adsorption. They are then killed by rapid loss of body liquid.

SiO_2 aerogels are currently one of the standard media for collecting cosmic dust,[234] and they are fixed on the outside of spacecrafts.[235] Aerogels have the advantage that they are extremely light with a unique mesostructure which is also transparent. This enables a "soft landing" of very fast extraterrestrial particles hitting with a velocity of more than $3\ km\,s^{-1}$, and also allows their later investigation by optical methods.

6. Final Remarks

The preparation of aerogels is "nanotechnology", because their unique optical, thermal, acoustic, and mechanical properties originate from the combination of a solid matrix (with a certain chemical composition) and nanometer-sized pores filled with air. We wanted to show in this review that there is a direct connection between the chemistry of the sol–gel process and the structure of the gels on one hand, and between the structure and the properties of the aerogels on the other. The choice of the precursors and the chemical reaction parameters already determines the physical properties of the final materials.

Physical research currently dominates the area of aerogels. The unique physical phenomena were and are intensively investigated, and are already well understood in many cases. In contrast, most aerogels are prepared empirically. Although the chemical principles are known, we are far away from a chemical "design" of aerogel properties and from an understanding of structure–property correlations. There is thus a wide field for applied chemical research. This is particularly true for the transfer of the physical effects investigated for simple systems, mostly SiO_2, to chemically more complex systems. Porous materials with totally new combinations of properties and applications can be expected by the combination of new chemical compositions with deliberately prepared micro- and nanostructures.

A big push forward can be expected in the next few years. The possibilities originating from ambient-pressure drying will provide strong impetus to preparative chemical research, because aerogels can now be prepared with standard laboratory equipment. The new drying methods have made the preparation process much "more chemical". There is now room for more extensive chemical modifications of the profile of properties of aerogels.

The new drying methods are also a big step forward from an economic point of view. Apart from special applications in which material costs only play a minor role, the rather high price of supercritically dried aerogels has hindered a broader range of applications. The most important area for the application of aerogels are all kinds of thermal and acoustic insulation. There is no doubt about the physical and ecological advantages (nontoxic, nonflammable, readily disposable) of SiO_2 aerogels over most other materials on the market. However, according to a study of the Austrian Academy of Science,[236] the period of amortization for aerogel insulation is relatively long when one considers the materials and energy streams over the whole preparation process (including the production of the precursors), even for favorable applications such as daylight elements. The new drying techniques will probably make the technical preparation much cheaper and will thus make aerogels more competitive.

Our own work was funded by the Bundesministerium für Wissenschaft und Forschung, Bonn (Germany), the Fonds zur Förderung der wissenschaftlichen Forschung, Vienna (Austria), and the Hoechst AG. We want to thank Professor J. Fricke (Physikalisches Institut der Universität Würzburg, Germany) and Professor P. Fratzl (Institut für Materialphysik der Universität Wien) and their co-workers as well as Professor W. Kiefer and Bernhard Riegel (Physicalisch-chemisches Institut der Universität Würzburg) for the very good cooperation and valuable discussions.

[14] It should be pointed out again that some shrinkage (changes in volume) during drying cannot always be avoided. Therefore, it is sometimes a question of judgement whether the resulting gels are considered to be aerogels.

[34] In the sol–gel literature and in this review, the term cluster does not mean the usual metal clusters, but instead the primary oligomeric species (primary particles) formed during sol–gel processing. Their structure can be chainlike, cyclic, or three-dimensional.

A New Model for Aluminophosphate Formation: Transformation of a Linear Chain Aluminophosphate to Chain, Layer, and Framework Structures

Scott Oliver, Alex Kuperman, and Geoffrey A. Ozin*

Self-assembly pathways of inorganic compounds to form microporous framework materials continues to be a topic under intense debate. The current view of the mode of formation of this class of materials is constantly evolving, and is in many cases different for each framework composition, which now spans most of the periodic table. For aluminophosphates, several models have been proposed, some of which are closely related to those of the aluminosilicates. In this review we discuss the contemporary models for the formation of aluminophosphates and a new model, developed in our laboratory, which accounts for the formation and structures of a family of one-dimensional (1D) chain, two-dimensional (2D) porous layer, and three-dimensional (3D) open-framework aluminophosphate materials. The building block for this model is a linear chain aluminophosphate, which is the first species to crystallize from the synthesis system. Structural, stereochemical, charge, and chemical information present in the chain precursor can be transcribed, under a particular set of experimental conditions, to allow the formation of other chain types through a hydrolysis–condensation self-assembly pathway. The sibling aluminophosphate chains can be crystallized from the system or condense further to more complex porous layer or open-framework aluminophosphate structures. Other solute species, such as aluminum oxide double octahedra or fluorinated aluminum species, can be incorporated into the final structures by a chain-encapsulation process. This construction paradigm represents a new way of rationalizing aluminophosphate structures and their formation.

Keywords: aluminum · phosphorus · solid-state chemistry · zeolite analogues

1. Introduction

The large number of synthetic and naturally-occurring inorganic layered and open-framework materials constitutes an important area of materials chemistry.[1–3] Within the domain of aluminophosphate compositions, a large number of synthetic microporous framework materials have been documented since their initial discovery by Flanigen et al.[4, 5] A series of aluminofluorophosphate layers[6, 7] and frameworks[8–12] has also been discovered in the last several years.

Aluminophosphate frameworks are built of alternating, corner-sharing phosphorus(v) oxide and aluminum(iii) oxide tetrahedra. In some materials aluminum can be four-, five-, and/or six-coordinate. While a number of dense-phase and small-pore aluminophosphates occur as natural minerals, the majority of known structure types are synthetic. Their preparation typically entails hydrothermal treatment of an aqueous gel containing templating amine or quaternary ammonium species. Some structures can only be obtained with a specific template, such as JDF-20,[13] which can only be synthesized with triethylamine as template. In contrast, others such as $AlPO_4$-5[14] can be made in the presence of any of more than twenty-three amines ($AlPO_4$-n denotes a porous aluminum phosphate framework). Many of the frameworks contain a single channel system, in which the walls of the channel comprise six-rings of T atoms (T = alternating Al and P centers, bridged by oxygen), analogous to the double-pyroxene chains of $AlPO_4$-tridymite.

Recently the number of reports on new chain[15–20] and layer[19–29] aluminophosphate structures has increased steadily. Many of these materials, including those obtained in our laboratory, are prepared by nonaqueous synthesis procedures.[15, 17–19, 21–23, 27] The discovery of these new materials has been attributed to the drastically different properties of a nonaqueous system compared to an aqueous system.[24, 30, 31] In spite of the large number of organic templates that may be employed in the synthesis of these new chain and layer aluminophosphates, the only established compositions for

layered structures to date are either $[Al_3P_4O_{16}]^{3-}$ or $Al_2P_3O_{12}H_x]^{(3-x)-}$ $(x = 1-2)$, where many of these inorganic layers possess the same architecture.

Similarly, there are only four known chain aluminophosphate structures containing tetrahedrally coordinated aluminum centers. Two are isostructural and of stoichiometry $[AlP_2O_8H_x]^{(3-x)-}$ $(x = 1, 2)$,[15,16] while the remaining two, UT-2[19] and UT-7[20] (University of Toronto, structure numbers 2 and 7), are isostructural and have the same formula, $[Al_3P_5O_{20}H]^{5-}$. The latter differ in their organic template species, namely cyclopentylammonium for UT-2 and cycloheptylammonium for UT-7. Two chain aluminophosphates are also known that contain exclusively octahedrally coordinated aluminum centers. The compound with a $[Al(H_2PO_4)_3]$ chain structure described by Kniep et al. was prepared by the evaporation of a concentrated, viscous solution,[17] while, more recently, Attfield et al. achieved the hydrothermal synthesis of an $[Al(PO_4)_2(OH)]^{4-}$ chain.[18]

A number of soluble aluminophosphate and aluminophosphonate monomeric complexes have also been reported; for instance, the tetramethylammonium salt of the trimeric diphosphatoaluminate complex was reported in 1969.[32] Cassidy et al. later isolated an $[Al_4(PO_4)_4]$ cubic complex from ethanol, in which each aluminum atom resides in an octahedral environment, connected to three phosphate ions of the cube corners and three ethoxy groups.[33] Kniep et al. also isolated a pentameric $[Al_2(H_2PO_4)_3](PO_4)$ cluster from a concentrated, viscous solution.[34] In 1996 Mason et al. prepared two different alkylaluminophosphate complexes, one of which contains a $Al_2O_4P_2$ four-ring. The other complex has a cubic $Al_4O_{12}P_4$ inorganic core, in which the nonbridging vertices of the aluminum and phosphorus tetrahedra are capped by *tert*-butyl and trimethylsiloxy groups, respectively.[35] Yang et al. also prepared a related cubic aluminophosphonate complex, in which the phosphorus centers carry terminal *tert*-butyl groups.[36] This research has also led to the discovery of related soluble phosphates and phosphonates containing boron[37,38] and gallium[39,40] centers.

In recent years significant progress has been made towards the development of mechanisms of formation of zeolites and aluminophosphate molecular sieves. Some models account for the final framework structures by postulating various building blocks, such as four-rings, six-rings, and other small secondary building units (SBUs; the primary building units are the simple monomeric polyhedra), similar to those believed to be involved in zeolite formation.[3a, 10] More recently, the role of the organic template has been discussed by Lewis et al.[41, 42] Their calculations were performed on aluminophosphate, metal-substituted aluminophosphate, and zeolite frameworks. Davis et al. have also made thermochemical calculations of both microporous and dense-phase aluminophosphates.[43] These results have led to a better understanding of the synthesis of aluminophosphate framework structures.

Other, older models are based on chain species that run through the structure parallel to the main channel system, such as the narsarsukite, double-crankshaft[44, 45] and triple-crankshaft chains.[46] Although these species can be identified in the frameworks, there is no direct evidence that they participate in the assembly process. Furthermore, double- or triple-crankshafts are rather complex and are difficult to envisage as stable species in solution. It has also been argued that pseudoboehmite is intercalated by polyphosphate, which forms an amorphous aluminophosphate layer either directly[47, 48] or via molecular species that are present in the aluminophosphate solution.[49, 50] The disordered layered material is proposed to undergo a solid-state transformation to give the crystalline framework. Chain tectons and models dealing with their transformation to give more complex chains or layers have not been reported. Only the mode of formation of 3D frameworks has been discussed previously.

S. Oliver

A. Kuperman

G. A. Ozin

Scott Oliver received his B.Sc. degree in chemistry from the University of Toronto in 1992 and recently completed his Ph.D. in inorganic materials chemistry in Professor Ozin's group. His thesis focussed on the solvothermal synthesis, characterization, and mode of formation of novel aluminophosphate materials. He is currently an NSERC postdoctoral fellow in Professor Whitesides' group at Harvard University.

Alex Kuperman graduated from the Moscow Institute of Fine Chemical Technology with an M.Sc. in Chemical Engineering. He received his Ph.D. in inorganic materials chemistry from the University of Toronto in Professor Ozin's group. He is now a Senior Specialist at the Dow Chemical Company in the Central R&D Catalysis Laboratory.

Geoffrey A. Ozin received his B.Sc. degree in chemistry from King's College, University of London in 1965 and his D. Phil. in inorganic chemistry from Oriel College, University of Oxford in 1967. From 1967 to 1969 he was an ICI Postdoctoral Fellow at Southampton University, before joining the chemistry faculty at the University of Toronto in 1969, where he is a full Professor. His field of specialization is interdisciplinary materials chemistry and his current research interests include nanochemistry chemistry, supramolecular chemistry, host–guest inclusion chemistry and biomimetic chemistry. He has published more than 400 articles in scientific journals and holds 10 patents.

The starting materials generally employed in the synthesis of aluminophosphates are phosphoric acid and an aluminum oxide in the form of pseudoboehmite or alkoxide.[3a] The mineralization of alumina by phosphoric acid is a well-documented process because of its relevance to soil science.[51, 52] Generally, phosphate ions form covalent bonds through bridging oxygen atoms to aluminum atoms by replacing hydroxide ions and breaking Al-O-Al linkages in the mineral. Through dissolution of the mineral structure, aluminophosphate molecular species are leached into the supernatant. Such species have been detected experimentally and their structure has been modeled.[53–58]

The next step in the formation of aluminophosphates is less clear. There is evidence that "aggregation polymers" exist for metal phosphates; the most studied are the aluminophosphate polymers in viscous gels.[59–63] These aggregation polymers are stable in acidic medium, and precipitate on rendering the medium alkaline.[60] The materials were found to be amorphous upon precipitation. The aggregation polymers have also been suggested as a "transition between the heteropoly acids and soluble complexes."[61] Chain species tend to form as the Al:P ratio of the solution is raised above 1:1;[61–63] for instance, Kniep et al. isolated large crystals of the $Al(H_2PO_4)_3$ chain structure by evaporation of a concentrated (Al:P = 1:5) solution.[17]

The stability of an unbranched chain aluminophosphate is also supported by the well-known fact that polyphosphates and ring metaphosphates avoid branching owing to the reduced negative charge of branching $PO_{2.5}$ groups over that of the negative PO_3^- groups of the chain, rendering branching points highly susceptible to removal by hydrolysis.[64] A similar tendency to avoid chain branching may occur for the aluminophosphates; thus, all higher molecular weight solution species may exist as nonbranched, 1D chains prior to their precipitation. This would also prevent the formation of condensed phosphates instead of aluminophosphate species. It is important to note that acidic starting conditions are also required for the synthesis of aluminophosphate molecular sieves; the pH value shifts into the range for alkaline compounds as the synthesis proceeds. Based on these observations, one can conclude that in the synthesis of aluminophosphates, it is initially necessary to build a concentration of aluminophosphate polymeric species in solution, which then self-assemble into various structures. Certainly, the work on aggregated aluminophosphate polymers clearly indicates that a polymeric aluminophosphate chain should be considered as the precursor in the formation of chain, layer, and framework aluminophosphates.

Here, we propose a new self-assembly model for the formation of aluminophosphates, in which a progenitor chain is introduced, which can account for the structures of 1D to 3D aluminophosphates and whose existence is supported by direct experimental evidence. Examples are given of the hydrolysis–condensation processes that can occur on the parent chain. These are only a few of the possible chain types that may be constructed in this way. We have also proposed a nomenclature scheme to denote a particular chain type, and it is hoped that this model will contribute to a greater understanding of the mode of formation of chain, layer, and framework aluminophosphates.

2. Discussion

2.1. The Parent Chain

The first structure that we obtained in our synthetic work using the tetraethylene glycol (TEG) solvent system was that of a 1D chain compound containing charge-balancing triethylammonium ions. This structure proved to be identical to that reported by Jones et al. when they used 2-butanol as solvent.[15] From the same TEG system we also obtained the anionic framework structure JDF-20, which contains triethylammonium ions in its channels; this had also been previously reported by Jones et al.[13] Inspection of the JDF-20 framework showed it to be composed of linear chains, which are linked to chains of a different type.[31] We proposed that the latter chain type was derived from hydrolysis and condensation of the linear aluminophosphate chain.[65] Arguably, the chain and JDF-20 structures co-crystallize and one phase grows in at the expense of the other.

Many other structures crystallize in the TEG–triethylamine system when water is used as an additive reagent.[24, 31] These new structures were also envisaged to be built of chain-building blocks derived from the parent chain. Structural studies of aluminophosphates prepared in other systems allow their architectures to be rationalized by similar chain-building blocks derived from the parent chain. We developed a scheme according to which many different types of chains can be formed by performing hydrolysis and condensation reactions on the parent chain.[65] However, the existence of this parent chain remained nebulous until one of the hypothetical crystal structures of this model was confirmed experimentally.[19, 20] Significantly, this 1D chain structure thermally transforms to give a 2D porous layer structure that we had previously isolated in the same synthesis system.[19] This appears to be one of the hitherto unrecognized assembly pathways for aluminophosphate layers and frameworks.

The parent chain is therefore the linear chain structure that crystallizes in the TEG–triethylamine system.[15] It consists of corner-sharing Al_2P_2 four-rings bridged at the aluminum(III) centers; two doubly bridging phosphates occur in each four-ring (Figure 1a). The parent chain only crystallizes for a specific set of templates, reagent concentrations, and reaction conditions, which explain its absence in other systems. The linear chain is likely the most stable polymeric aluminophosphate species. It has a simple structure, and contains only one type of aluminum(III) and phosphorus(V) site. The identical arrangement of orthogonally organized four-rings exists in other mixed oxides, such as the borosilicate chains of the mineral garrelsite,[3] and a zinc phosphate chain structure.[66] Importantly, the parent chain structure has also been isolated in an aqueous system, in which ethylenediamine was used as template.[16] This shows that the structure can also form in aqueous systems, which is an essential ingredient of the present model.

The tetrahedrally coordinated aluminum centers of the parent chain are fully coordinated to phosphate groups. This arrangement is similar to that found in homopolyoxo ions and heteropolyoxo ions. For example, the central aluminum atom in the Keggin ion is tetrahedrally coordinated, while the outer

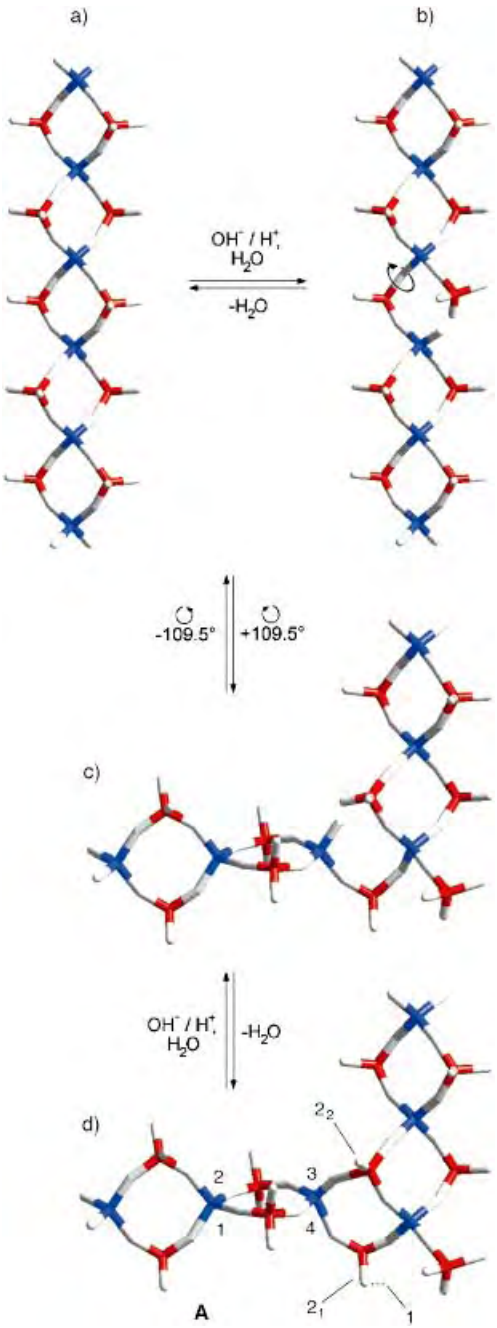

Figure 1. The transformation of the parent chain to give edge-sharing four-rings and terminal $P(O_{Al})(O)_3$ phosphate groups. All steps are reversible, as indicated by the equilibrium arrows. a) Parent chain. b) Ring-opening hydrolysis results in an AlOH group and a terminal phosphate group. c) Rotation about the remaining Al-O-P linkage of the chain brings the AlOH group in the vicinity of a POH group on the adjacent four-ring of the chain. d) Condensation and regeneration of the catalytic water molecule to define two edge-sharing four-rings (structure **A**; for numbering see text). Color scheme (same for all figures): Oxygen: white; phosphorus: red; aluminum: blue.

aluminum atoms are all octahedrally coordinated.[67] Similarly, phosphate groups display a tendency to doubly or triply bridge metal centers in inorganic chain structures, such as molybdenum phosphates[68–70] and vanadium phosphates[71] as well as in chain-building units of higher dimensionality structures.[72] The same is true for vanadium arsenates.[73] The preference of Al^{III} to be surrounded by four phosphate groups is also seen in molecular aluminophosphate complexes, in which one aluminum atom is coordinated to four phosphates groups.[74] It is possible that this type of monomeric unit is the precursor to the parent chain and is the species that is first mineralized from the starting materials.[74]

2.2. Chain-to-Chain Transformations

The parent linear chain is a metastable product that in solution can undergo dynamic hydrolysis of the Al–O and P–O bonds.[60–63] Even under predominantly nonaqueous conditions this will occur, as water will always be present in sufficient amounts. Depending on the pH, acid or base hydrolysis is expected to cleave the Al–O and P–O bonds, and terminal AlOH and POH groups are thereby formed (Figure 1b). Since polymeric aluminophosphate chains in solution are expected to be highly flexible, particularly at the elevated synthesis temperatures, rapid rotation and bending motions occur about the unhydrolyzed Al-O-P linkage (Figure 1b). Rotation would bring the AlOH and POH groups closer together (Figure 1c), allowing intra-chain condensation to occur with the loss of water (Figure 1d). In this way, two corner-sharing four-rings are transformed into two edge-sharing four-rings. Note that the reverse process is also likely, and is indicated by the equilibrium arrows for each step. A terminal phosphate group that is located at the aluminum atom common to the edge-sharing four-rings can remain on, or be cleaved off the chain by hydrolysis, allowing another degree of freedom for possible transformation pathways.

If the process shown in Figure 1 proceeds in the forward direction, the transformation is expected to continue down the chain backbone, for example, to the next four-ring of the parent chain. There are now several choices for the third four-ring to connect to the first two (Figure 2). Each Al-O-P linkage in the next four-ring, labeled 1 through 4 (see Figure 1d), has an equal chance of becoming hydrolyzed. Hydrolysis at sites 3 or 4 simply leads to an open-chain type (see below). If the ring is opened at site 1, rotation around the remaining oxygen bridge will bring the resulting AlOH group only within the proximity of the POH group also labeled 1. (Note that in Figure 1d, the POH group 1 is hidden behind the POH group 2_1.) The third four-ring thereby connects to form a new section in which the three edge-sharing four-rings define a "*cis*" conformation (Figure 2a).

Alternatively, for hydrolysis at site 2, rotation can bring the AlOH group close to one of two hydroxy groups, labeled 2_1 and 2_2 (Figure 2b and 2c, respectively). Rotation in one direction (i.e., $+109.5^\circ$) connects the chain onto phosphate group 2_1, and a section in which all the edge-sharing four-rings are "*trans*" to each other is formed (Figure 2b). Rotation in the other direction (i.e., -109.5°) results in condensation to phosphate group 2_2, and gives a "zigzag" chain section (Figure 2c). Subsequent four-ring "foldings" can be envisaged to continue down the chain, leading to an infinite chain with a new connectivity. For the "*trans*" chain, the process can continue down the chain without hindrance (Figure 3a). Similarly, the zigzag chain can readily be formed (Figure 3b). In the case of the "*cis*" chain, however, the chain must bend

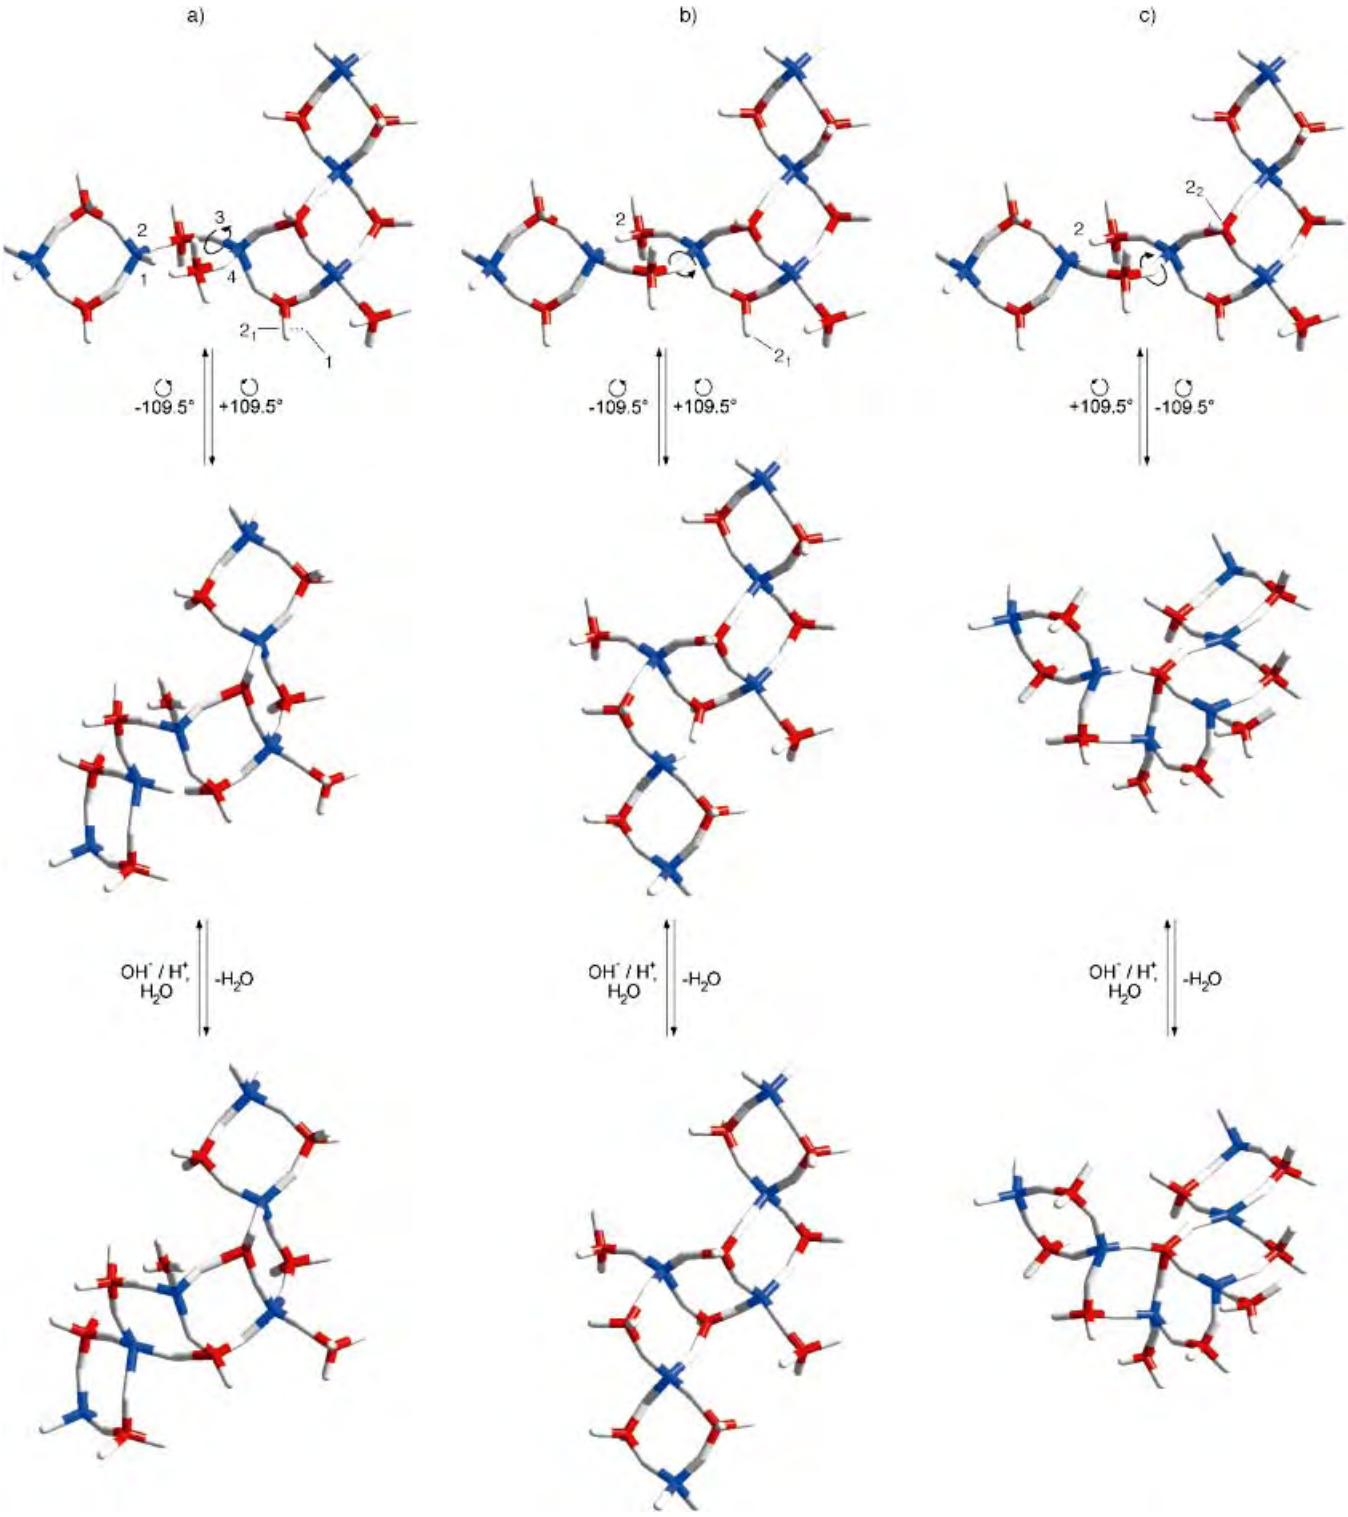

Figure 2. The next step in the transformation of the parent chain (after the formation of **A**) to form three edge-sharing four-rings. In each case the hydrolysis is followed by a rotation and a condensation. a) Formation of a "*cis*" section: ring-opening at position 1 and connection of the resulting AlOH group to the POH group 1. b) Formation of a "*trans*" section: ring-opening at position 2 and connection to the POH group 2_1. c) Formation of a "zigzag" section: ring-opening at position 2 and ring-closure at the POH group 2_2.

back in the opposite direction to avoid folding back onto itself. This leads to a chain with an alternating "*cis*–*trans*" arrangement (Figure 3c). An infinite connectivity scheme of this type would be equivalent to the double-crankshaft chain that has been previously described,[44, 45] except that in the present case, terminal phosphate groups are present on each aluminum atom. However, as will be seen, only small sections of the "*cis*–*trans*" chain type are necessary to rationalize aluminophosphate formation. With careful consideration of the means by which the ring-opening and ring-closing process propa-

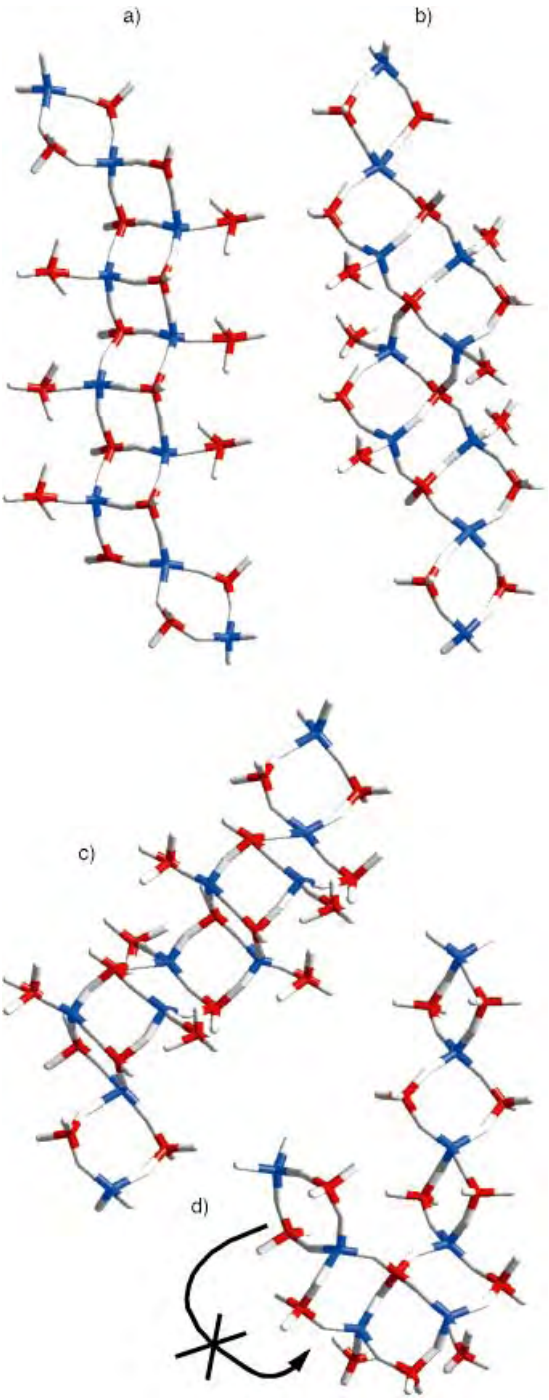

Figure 3. Extended sections of the chain types given in Figure 2. The terminal phosphate groups have been retained on each aluminum atom in these examples. The original connectivity on the end of the sections to the parent chain has also been shown for emphasis (as has been done for all the figures). a) A *trans* chain section, $(T_P)_7$; b) a zigzag chain section, $[Z(3,3)_P]_7$; c) an alternating *cis*–*trans* chain section, $(C_P)_7$; d) the zigzag chain given in Figure 2c. Hydrolysis of the next four-ring would not allow connection to the side necessary for a zigzag chain with two four-rings per leg. For nomenclature see Table 1.

gates down the axis of the parent chain, it becomes evident that for the zigzag chain, there must be an odd number of four-rings per leg (Figure 3d).

There are many other degrees of freedom for transformations of the parent chain by this process. For example, corner-sharing four-rings can be skipped in the process and remain intact (Figure 4a–e). Another example involves only ring-opening of the four-rings, resulting in an "open" chain intermediate as previously mentioned (Figure 4a). Further, each resulting chain type in principle represents an infinite family, since the different chain sections can be of any length, such as those shown in Figures 4b and 4c. Combinations of these processes can also occur on a single chain, allowing an unlimited number of mixed chain types; one example is shown in Figure 4e. The chains displayed in Figure 4 are but a few examples of the large number of possibilities. Additional intrachain condensation of a transformed chain can also occur, which results in, for example, phosphate-capped six-rings connected through four-rings (Figure 4f), or the connection of sections of five edge-sharing four-rings to sections of three corner-sharing four-rings (Figure 4g; this example will be important later). We will show that intrachain condensation and the formation of a chain with capped six-rings leads to many layer and framework aluminophosphates. Computer modeling studies show all chain types have high conformational stability. All tetrahedra remain only slightly distorted, as found in aluminophosphates, and bond angles and lengths need not be changed beyond their energetically accessible limits.[75]

With such a large number of possible chain types, we have introduced a nomenclature scheme, which is summarized in Table 1. Only the repeat unit of a particular chain need be described, and each section of the repeat unit is given a specific label for chain type, and a subscript for its length in terms of the number of aluminum atoms or four-rings. In this way, any chain type may be labeled. Examples of this nomenclature scheme are given throughout the figure captions.

Although the chain transformations can be viewed as a chain "zipping" process, it is more likely that they occur simultaneously or in short succession, along the entire length of the chain. It is possible that they happen during the short synthesis time scales that are sufficient for many aluminophosphate materials; for instance, the high-temperature or microwave synthesis of $AlPO_4$-5 only requires a few seconds.[76, 77] It should also be kept in mind that although chain transformations, such as those shown in Figures 1–4, seem complex, they only involve a very small number of operations per asymmetric unit.

The structure of polymeric UT-2, which we characterized in the TEG–cyclopentylamine system,[19] is in fact the chain structure shown in Figure 4g right. This is significant because we had previously hypothesized this chain to exist, and have now isolated what appears to be a "missing link" in the chain mechanism. As expected, the singly bridging, triply terminal $P(O_{Al})O_3$ phosphate groups reside on the edge-sharing four-rings of the *cis*–*trans* chain sections. The only other aluminophosphate crystal structure containing a singly bridging phosphate group is that of the monomeric $Al(PO_4)_4$ cluster previously mentioned.[74] It seems that a kinetic product has been trapped, in which the typically unstable terminal phosphate groups interact with those of other chains, thereby locking in the metastable structure. Even more surprising is that this structure, in which the chains are arranged into layers, undergoes a thermally induced solid-state transforma-

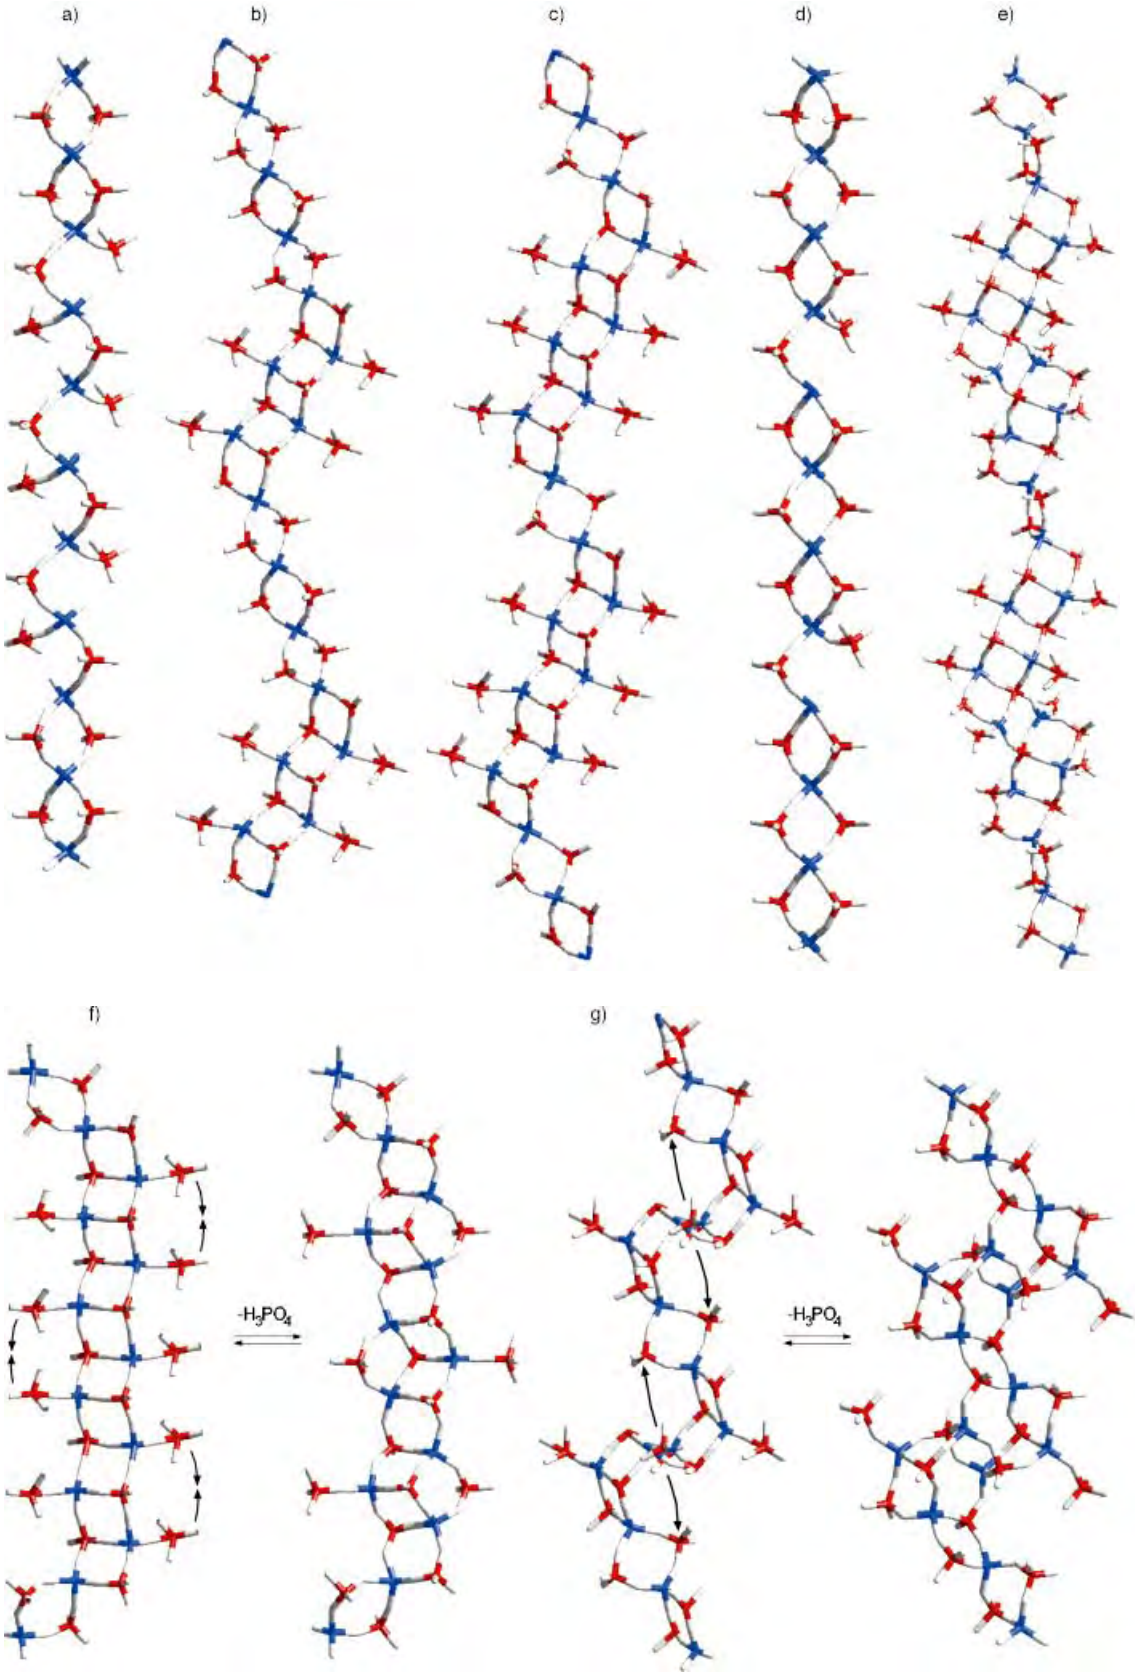

Figure 4. More examples of possible chain types; sections of varying length are displayed. a) A partially opened chain, $\diamond_2(O_P)_2$. b) A partial *trans* chain, $\diamond_5(T_P)_5$. c) Same as in b) but with sections of different length, $\diamond_3(T_P)_7$. d) Another partially opened chain, $\diamond_3(O_P)_1$. e) A chain containing three different sections, $\diamond_3(T_P)_5[Z(3,3)_P]_5$; f) Intrachain condensation of the *trans* chain ,$(T_P)_{10}$, results in a chain with edge-sharing four- and six-rings, in which the six-rings are capped by triply bridging phosphate groups alternating above and below the plane of the chain. g) Intrachain condensation of the C_p section of a partial *cis*–*trans* chain, $\diamond_3(C_P)_5$, with the parent chain section results in a new chain type, which we have characterized by X-ray crystallography.[19, 20] For nomenclature see Table 1.

Table 1. Nomenclature scheme for the description of the repeat units in aluminophosphate chains.

$\diamond_n$	Section of *n* corner-sharing four-rings of the unhydrolyzed parent chain
T_n	Section of *n* edge-sharing four-rings in a *trans* conformation
$(T_P)_n$	Section of *n* edge-sharing four-rings in a *trans* conformation, with terminal phosphate groups remaining on the aluminum centers
C_n	Section of *n* edge-sharing four-rings in a *cis*–*trans* conformation
$(C_P)_n$	Section of *n* edge-sharing four-rings in a *cis*–*trans* conformation, with terminal phosphates remaining on the aluminum centers
O_n	Section of *n* corner-sharing four-rings that have been ring-opened (and have lost their terminal phosphate groups)
$(O_P)_n$	Section of *n* corner-sharing four-rings that have been ring-opened, with terminal phosphate groups remaining on the aluminum centers
$[Z(a,b)]_n$	Section of *n* edge-sharing four-rings in a zigzag conformation; subsections of *a* and *b* four-rings per leg, respectively
$[Z(a,b)_P]_n$	Section of *n* edge-sharing four-rings in a zigzag conformation; subsections of *a* and *b* four-rings per leg, respectively, with terminal phosphate groups remaining on the aluminum centers

tion to the layered structure UT-3.[19] We had previously obtained UT-3 directly in the same synthetic system (i.e., in the presence of small amounts of water, which evidently catalyzed the transformation) and determined its structure by single-crystal X-ray diffraction.

We consider this unprecedented chain-to-layer transformation to be fundamentally important for comprehending the formation of aluminophosphates. The parent chain is initially hydrolyzed in solution, leading to the formation of other chain structure types. These chains are solvated and interact with alkylammonium ions, which keeps them apart in solution. The cationic templates reduce the chain–chain electrostatic repulsion, allowing them to crystallize from solution. Simple aggregation of the chains through ionic bonds to the template[15, 16, 18] or interchain hydrogen bonds[17, 19, 20] results in a chain structure, while chain condensation causes cross-linking and leads to a porous layer or open-framework structure. Rapid precipitation of the chains would result in an amorphous material that would appear to be layered by various experimental probes, but in reality contains layers of poorly arranged chains. Further heating of this phase would allow the chains to reconstruct, cross-link, and organize to form the final, crystalline structure. This would be consistent with, and account for, the various results and the typically fast precipitation rate of aluminophosphates that have been reported to date.[59–64] In the reconstruction process, the final structure is controlled by both the chain type and properties of the organic template. The templates are therefore only partly responsible for the resulting structure. This serves to elucidate the often unclear role of the template,[3a] and the template-dependent and template-independent trends that are observed for aluminophosphates.

The known solid-state transformations of aluminophosphate frameworks, such as that of VPI-5 to $AlPO_4$-8,[78, 79] $AlPO_4$-21 to $AlPO_4$-25,[44] and $AlPO_4$-C to $AlPO_4$-D,[45] as well as aluminophosphate minerals obtained through the solid-state transformation of other phases[80] provide supporting evidence for the present model. These transformations also involve hydrolysis–restructuring–condensation processes, and have been referred to as chain-to-chain transformations. Furthermore, they are chemically equivalent to the processes we propose, as well as to the UT-2 to UT-3 chain-to-layer transformation discussed above. In fact, solid-state transformations play a vital role in the formation of many chain, layered, and framework structures, as will be described in more detail below.

The chain model is also consistent with the P:Al ratios in aluminophosphates, which lie between 2.0 and 1.0 for most extended aluminophosphate structures. The largest value of 2 is only present in the parent linear chain. By hydrolytically cleaving the terminal phosphate groups from transformed chains (see Figures 4–10), the P:Al ratio is gradually reduced. The greater the degree of hydrolysis, the more phosphate groups that are removed, particularly in condensing to layers and frameworks. This accounts for the generally lower P:Al ratios in the higher dimensionality aluminophosphates.

Similarly, this accounts for the invariant, P:Al ratio of 1.0 for aluminophosphate frameworks. All aluminophosphates avoid direct Al-O-Al linkages between tetrahedral AlO_4 units; for zeolites this is known as Lowenstein's rule.[3] Recent calculations on the energy of formation of aluminophosphates show this rule to be both valid and strictly obeyed.[81] There are consequently no P-O-P linkages between the tetrahedral units in the nonmetal-substituted, aluminophosphate frameworks, and the P:Al ratio is 1.0. These rules are obeyed by the parent chain, which initiates the alternating Al and P centers. The maximum number of phosphate groups that may be removed from the chain by hydrolysis, while still maintaining an extended chain structure, is one of the two phosphate groups on each four-ring, thereby defining a minimum P:Al ratio of 1.0. Interestingly, in this respect the aggregation polymers of aluminophosphates prefer to form in solutions in which the P:Al ratio lies between 1 and 2.[61–63, 80] These also happen to be the ratios used for the synthesis of chain, layer, and framework aluminophosphates.

2.3. Chain-to-Layer and Chain-to-Layer-to-Framework Transformations

Having introduced the various chain types and the mode by which they form, we will now proceed to show structural examples of chain types and how they can account for the various architectures of aluminophosphate materials. The first example is that of the porous layer $AlPO_4$-5-like structure $[Al_3P_4O_{16}]^{3-} \cdot 3[R^+]$[22, 24, 27] (Figure 5). Intrachain condensation of $[Al_3P_4O_{16}]^{3-}$ chains of the type shown in Figure 5a forms a chain containing capped six-rings (Figure 5b), which snap together to create the two-dimensional net[82] (Figure 5c). The resemblance of the layer structure to $AlPO_4$-5 itself is not likely a coincidence. Removal of the caps and interlayer condensation would result in the $AlPO_4$-5 framework. However, the pathway given in Figure 5 does not necessarily have to be followed to obtain $AlPO_4$-5. Instead, the chains given in Figure 5a responsible for the $AlPO_4$-5 layer could bypass the layer "intermediate" and undergo

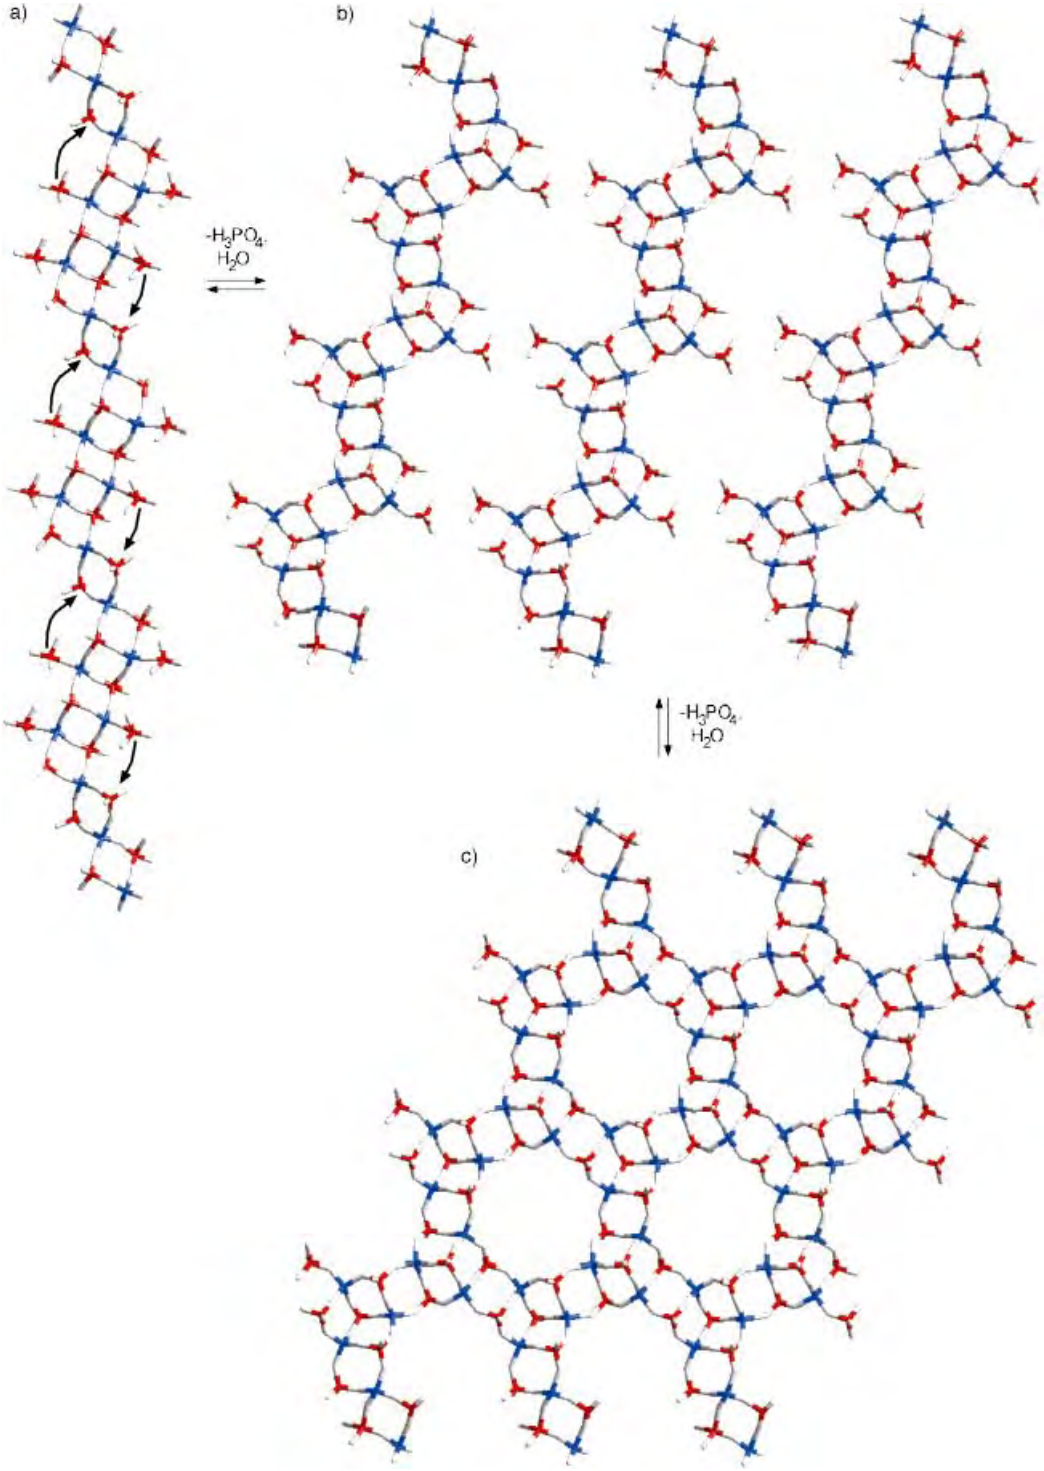

Figure 5. Formation of the capped $AlPO_4$-5-like layered structure. a) The partial *trans* chain, $\diamond_3(T_P)_7$. b) Intrachain condensation creates an array of edge-sharing four- and six-rings; phosphate caps on the six-rings alternate above and below the plane of the chain. c) Condensation of the chains to form the two-dimensional structure containing twelve-rings.

simultaneous chain-to-framework connection to create the framework, as will be shown for several frameworks below. The choice of the $AlPO_4$-5 layer or $AlPO_4$-5 framework as the end product is determined by parameters such as the synthesis conditions and template properties. Thermodynamically, the framework represents the more stable structure and is thus easy to isolate.[14] By contrast, the layer requires less vigorous reaction conditions to restrict hydrolysis and cross-linking processes.

In the context of the porous layer $AlPO_4$-5 structure (Figure 5c), two metal-substituted MAPO-*n* frameworks are worthy of mention.[14] The structure of MAPO-46 may be considered as two such capped layers arranged back-to-back, with the caps pointing in opposite directions. One layer is the

layered $AlPO_4$-5 structure, while the other contains six-rings in which, instead, the phosphorus centers of the six-rings are bound through their terminal oxygens to a capping metal atom. This "double-layer" in turn connects to its two neighboring double-layers through the respective phosphate and metal caps, to define the overall framework. The CoAPO-50 framework may also be considered to be constructed exclusively of layers with the $AlPO_4$-5 structure. In this case, the cobalt atoms cap the opposite side of the phosphate-capped six-rings, and connect to the phosphate caps of the next layer. While the predominance of the $AlPO_4$-5 framework architecture has been previously noted,[3, 41] it has not been pointed out that the capped $AlPO_4$-5 layer structure is also a predominant architecture among the $AlPO_4$-*n* structures. This underscores the importance of the chain shown in Figure 5a in the formation of $AlPO_4$-5 and related MAPO-*n* structures.

The result of another chain-to-layer transformation is the $[Al_3P_4O_{16}]^{3-}$ layer structure, which has been isolated in several nonaqueous systems.[20, 21, 25, 28] The $[Al_3P_4O_{16}]^{3-}$ chain, as was shown in Figure 4 f right, is formed from an "all-*trans*" chain by loss of terminal phosphate groups and intrachain condensation. Connection of the chains by further loss of phosphate groups forms the layered architecture, depicted in Figure 6. Interestingly, the layer arrangement of four-, six- and eight-rings is the same as that which occurs in the projection of the $AlPO_4$-12 structure along the *a* axis, with the exception that the the six-rings of the present layer are also capped by a triply bridging phosphate group.[14] As for the $AlPO_4$-5 layer, these layers can cross-link to form the $AlPO_4$-12 framework by removing the capping phosphate groups, or the starting chains (see Figure 4 f right) could by-pass the layer to directly form $AlPO_4$-12.

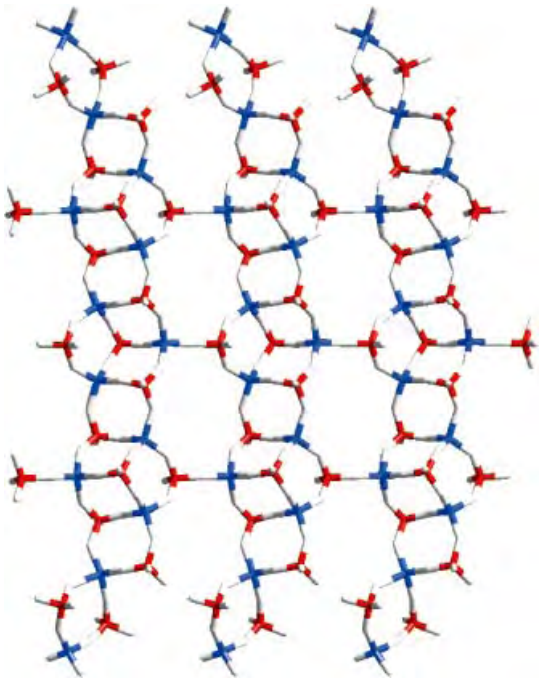

Figure 6. The $[Al_3P_4O_{16}]^{3-}$ layer from capped six-rings. Condensation of the chain given in Figure 4 f left with loss of terminal phosphate groups and water leads to the formation of a layer containing eight-rings.

2.4. Chain-to-Framework Transformations

An example of the connection of chains directly to a framework is shown in Figure 7. The formation of JDF-20 can be explained by the fusion of two simple types of chains,[31, 65] the parent chain (Figure 1 a), and the $[Al_4P_4O_{17}]^{2-}$ zigzag chain (Figure 3 b). The parent chain connects to two zigzag chains through six-rings (Figure 7 a). This building unit is arranged in a hexagonal array in the *ab* plane and thus defines the elliptical unidimensional channels of the framework, in which the units are connected through zigzag chains. Two sets of eight-ring channels perpendicular to the main channel are thereby created (Figure 7 b). The presence of parent and zigzag chains requires hydrolysis conditions that are less severe. This accounts for the fact that this material was only recently discovered in a predominantly nonaqueous triethylene glycol system. The ratio of parent $[AlP_2O_8H_2]^-$ chains to $[Al_2P_2O_{8.5}]^{2-}$ chains (the zigzag chains are one-half the length of the parent chain per asymmetric unit) in the structure is 1:2; their condensation affords a framework of the observed composition $[Al_5P_6O_{24}H]^{2-}$.

2.5. Chain Encapsulation

As two or more chain types can construct a new structure, it is expected that they can condense with other alumina or aluminophosphate solute species that coexist in the system. The coordination and aggregation state of aluminum(III) is known to be highly dependent on the pH value,[83, 84] as are those of the molecular aluminophosphates[57, 58] and aggregation polymers.[60–63] Such species might be incorporated between the chains under a particular set of synthesis conditions. This represents another degree of freedom for the chain model, and accounts for a number of other structure types.

One example is the aluminophosphate framework of tinsleyite (Figure 8 right). $AlPO_4$-tinsleyite[85] is exclusively built of octahedral AlO_6 and tetrahedral PO_4 units. Four vertices of the aluminum octahedra are occupied by the oxygen atoms of the neighboring phosphate groups. One third of the aluminum atoms have their coordination sphere completed by two terminal oxygen atoms (OH^-, H_2O), while the remaining two thirds achieve this as doubly oxygen-bridged pairs (Al-(μ_2-O)$_2$-Al). The structure of tinsleyite can be derived from the open chain given in Figure 8 left, which connects to aluminum(III)-based double octahedra (shown in the center of Figure 8) on either side of the chain. Octahedral coordination is favored for aluminum(III) under more acidic conditions.[83, 84] Thus, it is possible that under these conditions a chain aluminophosphate species contains octahedrally coordinated aluminum centers, as for the $[Al(H_2PO_4)_3]$ chain of Kniep et al.,[17] or that the aluminum coordination sphere changes from tetrahedral to octahedral by simply increasing its coordination with terminal water molecules. Aluminum(III) is known to partially exist as condensed oxo polyhedra, such as Al_2O_{10} dimers, in solution under acidic conditions.[83, 84] $AlPO_4$-tinsleyite therefore represents a chain-to-framework condensation in which a second species, in this case an alumina dimer, participates in the chain connection process.

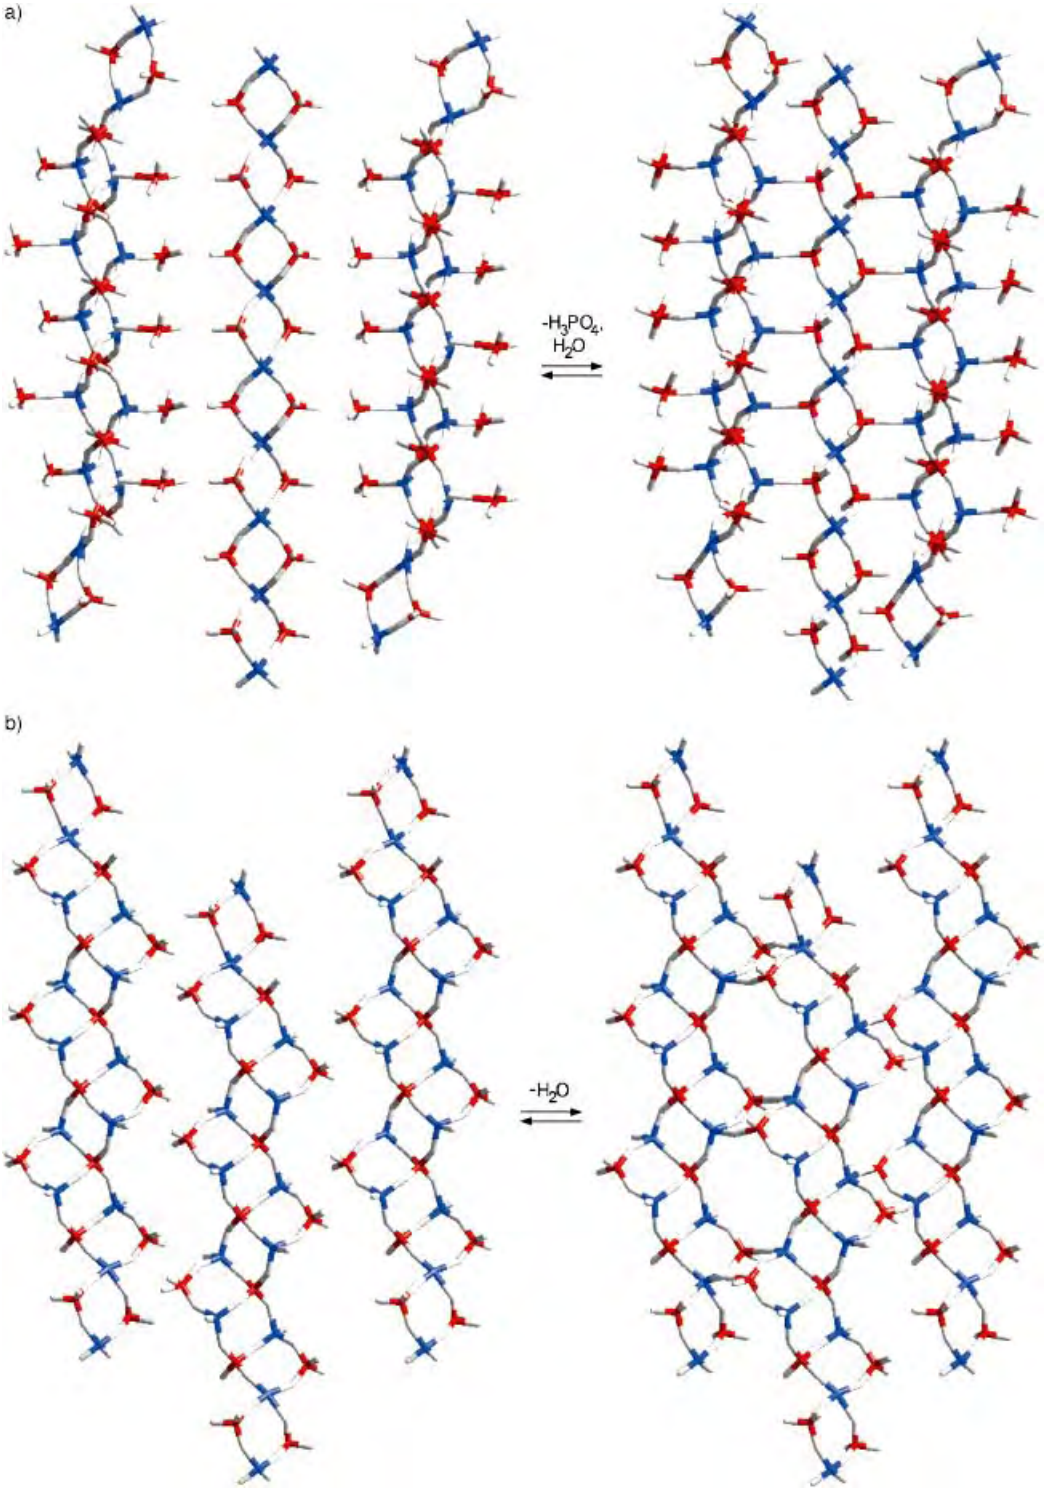

Figure 7. Chain condensation that leads to the framework topology of JDF-20. a) Two zigzag chains, $[Z(3,3)_P]_\infty$, connect to a parent chain, $\diamond_\infty$ and condense with formation of six-rings to give the building-block of the framework. Four such building blocks are arranged around the main channel of the structure: one on the top, one on the bottom, and one each side. b) The end-on view of three units from a), and the $[Z(3,3)]_\infty$ zigzag chains that reside on them; condensation of three of the zigzag chains leads to the formation of two independent eight-ring channels that intersect the main channels.

Another example of this kind of chain encapsulation is the recently reported framework of the aluminofluorophosphate UT-6.[12] This chabazite-like structure is related to $AlPO_4$-CHA (such as the $AlPO_4$-34, MAPO-34, MAPO-44 and MAPO-47 frameworks), in which one aluminum atom in each six-ring of the hexagonal prisms is replaced by an octahedrally coordinated aluminum atom, which connects to an octahedrally coordinated aluminum atom of an adjacent hexagonal prism through two bridging fluorine atoms. The UT-6 structure can be derived from the chain given in Figure 9a.

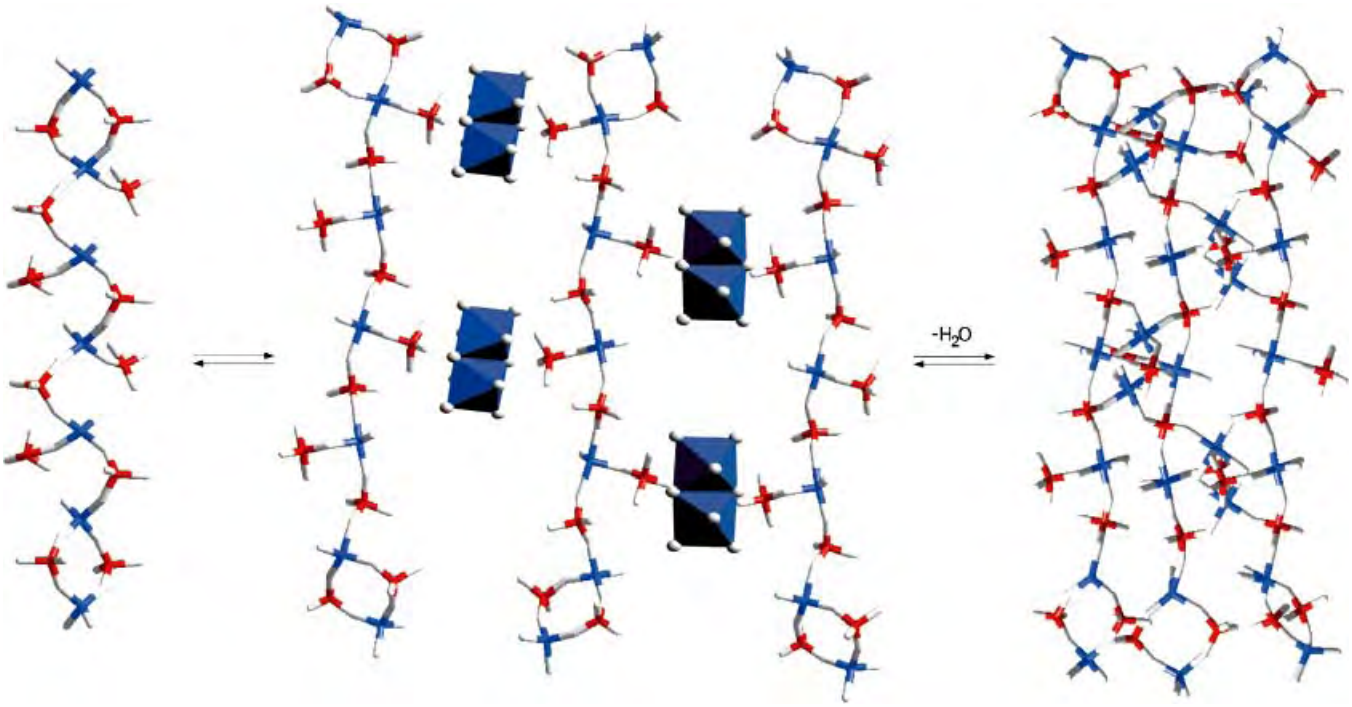

Figure 8. Model for the formation of the tinsleyite framework with its distorted eight-rings (right) from the open chain type, $(O_P)_\infty$ (left). The terminal phosphate groups extend outwards and reach above (center left) and below (center right) the Al_2O_{10} double-octahedra.

A plane of these chains surround one aluminum center of an adjacent plane of partially fluorinated (Al-(μ_2-F)$_2$-Al) double octahedra, to form the bottom six-ring of the hexagonal prism (depicted in yellow in Figure 9b). The other aluminum center of these double octahedra connects to the next layer of chains. Likewise, a plane of double octahedra above completes the upper six-ring of the hexagonal prism (not shown, but the second six-ring is depicted in pink, Figure 9c). In this way, a primitive array of hexagonal prisms is constructed that defines the framework of UT-6.

Significantly, the UT-6 structure thermally transforms in the solid state to $AlPO_4$-CHA, by removal of the bridging fluorine atoms and extra-framework template cations.[12] This is likely the mode by which the various polytypes of $AlPO_4$-CHA frameworks are formed. Initial condensation of the chains (Figure 9a) and Al_2O_{10} double-octahedra, followed by separation and dehydration of the double-octahedra to give tetrahedral centers, builds up the $AlPO_4$-CHA framework. Only with this knowledge of the UT-6 structure and its transformation is it possible to understand the origin of this framework. Similarly, it becomes possible to rationalize the formation of other aluminophosphate structures that would otherwise be very difficult to explain.

The final example, which also involves chain encapsulation of aluminum double-octahedra, is VPI-5. The chain proposed to be responsible for the formation of VPI-5 connects through aluminum double-octahedra to build up the structure of VPI-5, which contains 18-membered rings (Figure 10; the second octahedron of the dimer is not shown, but resides in the next layer). In this case, the alumina dimers separate but the octahedral coordination is retained; the fifth and sixth coordination sites of aluminum are occupied by terminal water molecules that reside in the main channel.[46] This mode of formation would account for the difficulty in synthesizing VPI-5,[49, 50] as one must first age the gel, and carefully control the pH. For the process given in Figure 10 to occur, one must first build up the more complex chain type given in Figure 10 left, as well as leach aluminum double-octahedra into the gel and encapsulate them with relatively labile terminal phosphate groups of the chain. Once this is achieved, nucleation of the material can begin.

The chain-assembly model has been developed by considering the relationships between crystal structures of various new aluminophosphate materials, which have been isolated by reaction profiling of nonaqueous synthesis systems. In many cases, the chain-to-layer and chain-to-framework transformations obscure the presence of the parent chain in the final structure of the product. This is evident in the UT-2 chain to UT-3 layer transformation.[19] Additionally, the chains responsible for the structures in most cases span the layer planes, which is also unique to the chain model. In this way, the complex arrangements of rings and channel systems of aluminophosphate frameworks can readily be understood. The dominance of particular chain precursors, such as that for $AlPO_4$-5 (Figure 5a), accounts for the large degree of template-independence observed for many aluminophosphate structures. The chain model only requires that the transformed sections of edge-sharing four-rings be three-to-five units long. This minimizes the number of chain hydrolysis steps of the parent linear chain.

2.6. Inorgano-Gene: The Progenitor Chain

Finally, it is interesting to consider that the paradigm shift presented in this review is in the same spirit as the emerging

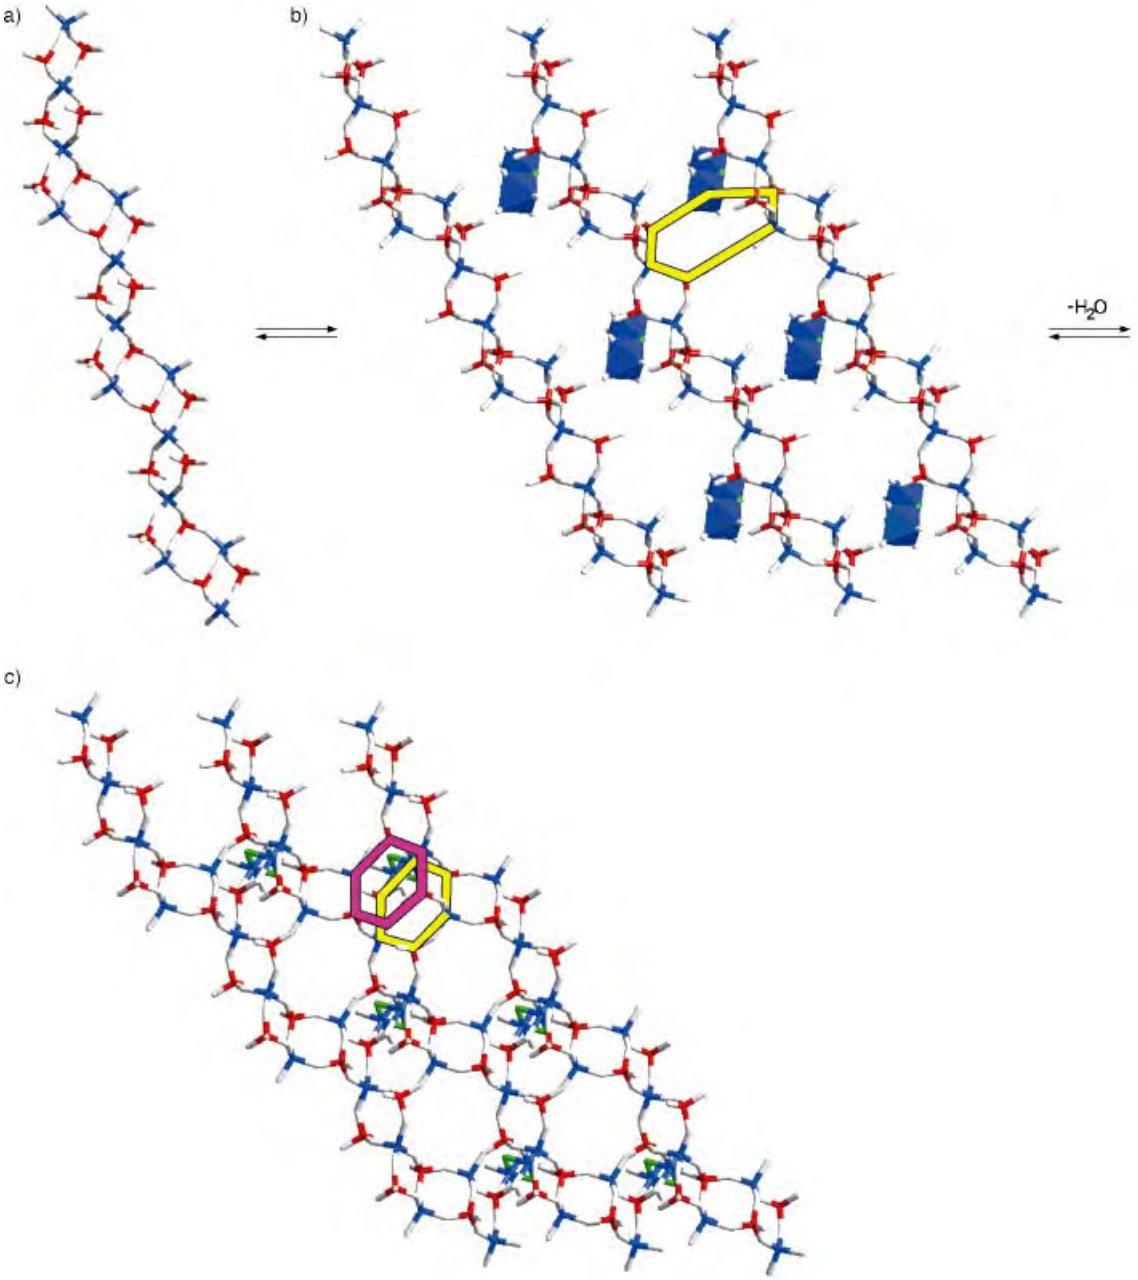

Figure 9. The build up of the UT-6 framework. a) $\diamond_3(T)_3$ chain. b) The chains surround the closer octahedron of the O_5Al-(μ_2-F)$_2$-AlO_5 dimeric units to form the bottom six-ring of the hexagonal prisms (yellow). (The $\diamond_3(T)_3$ chain has been slightly rotated to emphasize the shape that will become the hexagonal prisms). c) Condensation to the aluminum octahedra forms the bottom six-ring (yellow) and will connect in a like manner to the aluminum octahedra above the plane of the layer to form the other six-ring of the hexagonal prisms (pink). Fluorine atoms for UT-6 are shown in green.

biological view of materials chemistry and the description of inorganic materials with complex form.[86] The idea that inorganic materials have the capacity to store vast amounts of information is not new.[87] The thinking goes back to Schrödinger's aperiodic crystal description of the information-carrying genetic apparatus, and subsequently in another expression as the crystal abacus. In its more contemporary guise, the idea abounds in information storage materials found in, for example, records, tapes and discs. In the context of crystallography, Mackay first forwarded the proposal of an "inorganic gene" as a genetic algorithm in the search for the lowest energy configuration of a system of *N* atoms.[87]

In such a departure from the usual view of the aluminophosphate system, the structural, stereochemical, charge, and chemical information that is encoded in the chain can be transcribed to tectons based on an organic template and an aluminophosphate. In a synergistic co-assembly process these tectons will generate new and more complex structures, or "inorgano-phenotypes". Their survival in a particular synthesis is determined by the interplay of kinetic and thermodynamic factors, so that kinetic products are generated in local energy minima. Various hydrolysis "editing operations" of the parent linear chain can permute and alter the structure–directing information in the chain to produce

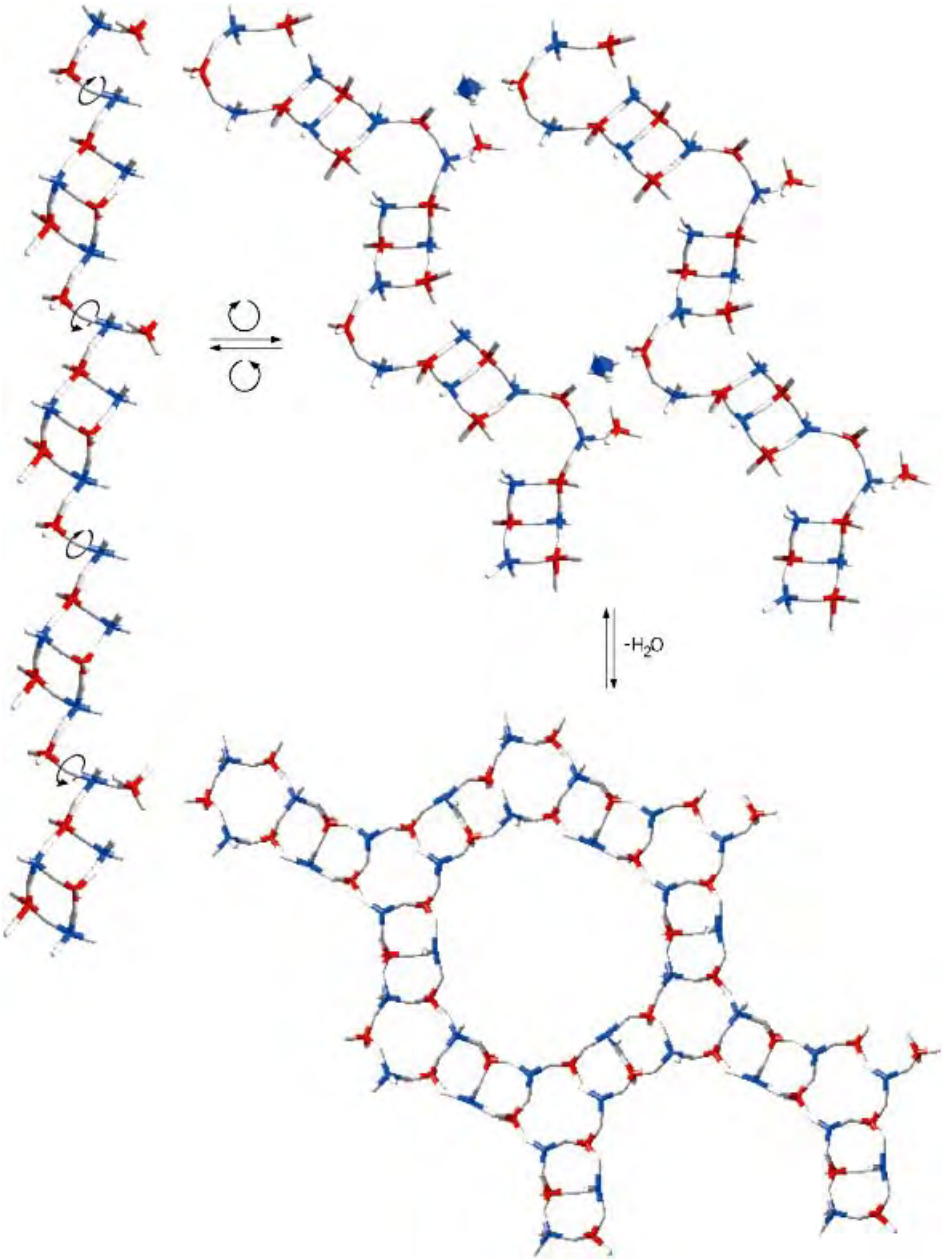

Figure 10. Direct formation of the VPI-5 framework, in which a capped VPI-5 layered "intermediate" of the type shown for $AlPO_4$-5 (Figure 5) is bypassed. Loss of phosphate groups from a chain type $(O_P)_2(T)_2$ gives the less symmetric chain type $(O)_2(T)_2(O)_1(O_P)_1(T)_2$ (left). Simple rotation around the linkages surround monomeric aluminum species with POH groups (center), and subsequent condensation leads to the framework topology.

condensed structures of varying dimensionality and degrees of "fitness."[87]

3. Summary and Outlook

The chain self-assembly model invokes a facile hydrolysis–condensation process of a metastable species that can be crystallized from the aluminophosphate synthesis system. Simple transformations of the parent chain can explain the wide variety of chain, porous layer, and open-framework structures found for aluminophosphates. Coupled hydrolysis and condensation reactions of the linear chain can produce a large number of other more complex chain structure types. Only a few selected examples of these are described herein. The amount of catalytic water in the system, which determines the amount of chain hydrolysis and thereby the resulting structure types. It should be possible to probe the aluminophosphate system and its structures in greater detail to further elucidate the chain self-assembly model. It is likely that new chain structures will be discovered that fit into the chain scheme presented. We hope that this chain model will allow for the rational design of new chain, layer, and framework structure types.

Financial assistance from the Natural Sciences and Engineering Research Council of Canada in support of this work is acknowledged. S. O. expresses his appreciation to the Ontario Graduate Scholarship program in partial support of his research. We thank Dr. Alan Lough of the Department of Chemistry, University of Toronto for single-crystal X-ray data collection and refinement of our series of aluminophosphate crystal structures and Dr. David Young for informative discussions.

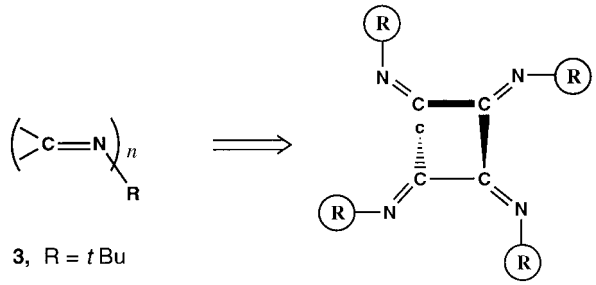
Helical Molecular Programming

Alan E. Rowan and Roeland J. M. Nolte*

The self-organization of molecules into helical and multiple helical architectures can be found throughout nature: from simple α-helical polypeptides and double-helical nucleic acids to more complex helical protein structures, microtubules, and the protein coating of the tobacco mosaic virus.[1] The overall architectural plans required are encoded within the molecular building blocks. Understanding the "programming language" developed and utilized by nature to construct helical structures is of fundamental importance. This knowledge will not only lead to a greater understanding of life, but will also enable the design and construction of new functional helical architectures. The most relevant parameters for controlling the architecture are the molecular size, topology, stereochemistry, and shape. Through processes of self-organization these parameters can be expressed at several hierarchical levels—molecular, macromolecular, and nanomolecular.



A simple example of molecular programming is the preorganized helical architecture of helicenes.[2] In hexahelicene **1** (Scheme 1) the structural information is encoded in the

1 **2**

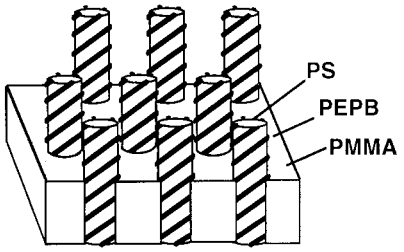
Scheme 1. Helicity at a molecular level: Helicene **1** and the oligomeric heteroarene **2** both form helical architectures owing to specific information encoded within the molecules.

geometry of the covalent bonds linking adjacent moieties which, in combination with steric interactions, forces the molecule to adopt a helical geometry. This simple expression of supramolecular helicity was recently further developed by the group of Lehn, who synthesized an achiral polyheterocyclic strand **2** (Scheme 2) which spontaneously organizes to from a two-turn helical structure.[3] This architecture arises as

3, R = *t* Bu

Scheme 2. Polymeric isocyanides **3** form helical rigid rods because of N=C–C=N torsions and steric interactions between the side groups.

a result of several encoded features: an alternating pyridine–pyrimidine sequence, linkage at specific positions, and the preference for a s-*trans* conformation of the single bonds between the alternating units. The resulting helix is adopted both in the solid state and in solution, and is one of the clearest demonstrations of preprogrammed molecular self-organization through specific intramolecular nonbonding interactions. In an alternative approach Moore et al. synthesized oligomers of *m*-phenylacetylene which also spontaneously arrange to give a helical geometry. In this example the helical organization can be readily controlled by solvent and temperature.[4]



The direct linking of aromatic moieties in a *meta* geometry can also give rise to helicity in larger oligomers and polymers. The crystal structure of *m*-deciphenyl revealed an apparently infinite helical chain in which there are five aromatic rings for each turn of the helix.[5] The predicted X-ray powder pattern of this compound, although only a small oligomer, is virtually identical to that of poly(*m*-phenylene) prepared by nickel-catalyzed coupling of *m*-dichlorobenzene. This implies that the larger macromolecule also adopts a similar helical arrangement. Helical polymers are themselves of increasing interest because of their wide variety of possible applications—for example in optical devices, as chiral separation columns, and as components in organic/inorganic hybrid materials. In polymer chemistry the expression of helicity has long been observed since the early work of Natta, Pino, and others.[6] In fact, most isotatic polymers exist as short-range helices in solution. These, however, are dynamic in nature and

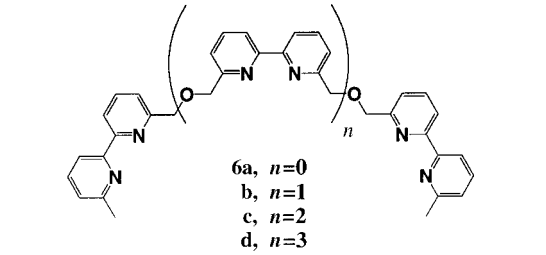
highly dependent on the solvent or slight changes in the polymer side chains. To date only a very limited number of stable, helical, synthetic macromolecules are known—for example polyisocyanides, poly(chloral), and poly(triphenylmethyl methacrylate). The helicity in polyisocyanides is determined by the torsional angle of the N=C–C=N bonds and the steric interactions of the side groups attached to the nitrogen atoms. Upon polymerization of *tert*-butyl isocyanide (**3**) two resolvable left- and right-handed helices were obtained (Scheme 2) with a turn at about every 3.9 units.[7] Unlike with helical biopolymers such as nucleic acids and proteins, the absence of chiral information in the basic building block leads in principle to an equal preference for either left- or right-handed helices. In practice, however, an enantiomeric excess of one helix can be obtained by using a chiral catalyst. The helical sense of the polymer can also be controlled by including chirality in the side group. Polymerization of homochiral isocyanides gives diasteroisomers in unequal amounts; polymerization of (*R*)-$(CH_3)_2CHCH_2CH(CH_3)NC$ preferentially gives a left-handed helix, whereas (*S*)-$CH_3CO_2CH_2$ $CH(CH_3)NC$ gives a right-handed helix. Takahashi et al. recently showed that by using a chiral isocyanide oligomer as an initiator subsequent polymerization with an achiral isocyanide monomeric unit gives a helical polymer with the same sense as the small oligomer.[8]

The subtlety of the parameters which induce chiral expression were clearly demonstrated by Green et al.[9] for polymeric isocyanates **4** (Scheme 3). These stiff helical polymers have no predetermined sense, and in long polymer chains helical reversals may occur. The cooperative stereochemistry of the side groups is so large that only a very small chiral bias in the monomeric unit is magnified and controls the helical sense of large portions of the macromolecule. Upon polymerization of a mixture of *R* and *S* enantiomers of **4a**—in which a 2% excess of the *R* enantiomer exists—the resulting polymer has similar chiral properties as the homochiral polymer made from enantiomerically pure (*R*)-**4a**. The chiral sense of the resulting polymer is determined by the major component. The reaction is so sensitive that even isotopic substitution of the side group results in a preference for one form (**4b**). This phenomenal positive cooperativity can be considered to be a form of molecular amplification. The two polymers discussed already possess a helical backbone whose helical preference can be modified by the size and stereochemistry of the side groups. The induction of helicity into nonhelical polymers is being studied in a very elegant way by Percec et al.[10] Inspired by the behavior of the tobacco mosaic virus, which induces a helical conformation in RNA, they synthesized a series of large, bulky "monodendron" side groups. When these large, tapered moieties are covalently attached to a polymer backbone, the conformation of the backbone is altered from a random coil to a helix. The size and shape encoded in the large side groups which pack on the outside of the polymer induce the chirality. The group of Stadler took one step further on the hierarchical ladder and synthesized a triblock copolymer: polystyrene(55)-*block*-polybutadiene(26)-*block*-poly(methyl methacrylate)(137) (**5**).[11] By a process of controlled phase separation this polymer forms an incredible self-organized system in which helices of polybutadiene microphases are wound around columns of polystyrene, which themselves are embedded in a matrix of poly(methyl methacrylate) (Scheme 4).

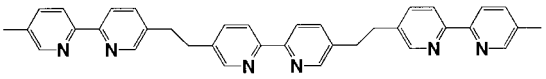
5

Scheme 4. Schematic representation of the self-organized architecture formed by phase separation of the triblock copolymer **5** (PS = polystyrene, PEPB = polybutadiene, PMMA = poly(methyl methacrylate)).

4a 4b



Scheme 3. The helical preference of polymeric isocyanates **4** can be controlled by isotopic substitution.



Intermolecular interactions between individual polymers chains can also lead to helical induction. Meijer and coworkers synthesized chiral, conjugated polythiophenes which show remarkable optical properties.[12] The helicity present in each polymer unit is only expressed upon cooling, when the polythiophene chains pack to form a helical aggregate. The helical sense of the assembled macromolecule can be easily controlled by varying the rate of cooling; rapid cooling gives one helical sense, and slow cooling the other. Another approach to the construction of chiral polymers was the elegant work by Ito et al., who prepared a variety of 2,3-quinoxalines from a chiral precursor.[13] The optical activity in these macromolecules could be easily tuned and results from the helicity in the backbone of the polymer and not the helical aggregated species.[14] An interesting recent development is the method for constructing double-helical polymer chains designed by Nozaki et al.[15] Condensation of (*S*)-1,1′-binapthyl-2,2′-dicarbonyl dichloride with biphenyl-2,2′,6,6′-tetrol generates oligomeric esters in which the chirality of the starting binapthyl is carried throughout the oligomer. Although only oligomers have been synthesized so far, polymeric chains can be expected to have interesting properties.

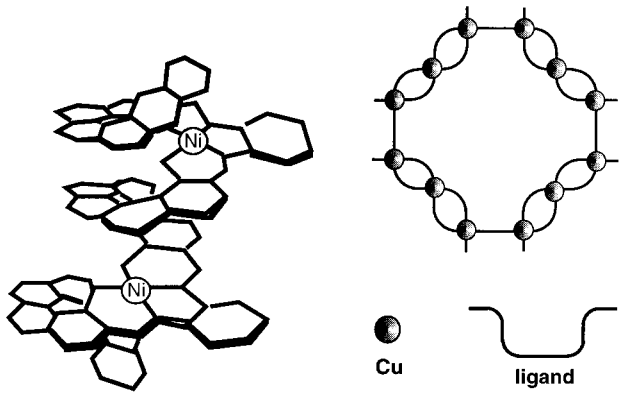
In nature numerous helical architectures result from self-assembly of small building blocks into larger molecular assemblages. This process of self-organization through noncovalent interactions is recognized as crucially important in the construction of biological systems. One approach to mimicking the helical arrays found in nature, in particular the double-stranded helix of DNA, has been the design and study

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0064 $ 17.50+.50/0

of metal–ligand complexes known as "helicates".[16] This area was investigated as early as the late 1970s by the group of Saenger, who constructed helical metal–polyether complexes,[17] but has rapidly expanded since the inspirational early work by Lehn and co-workers, who showed that oligobidentate ligands **6a** and **6b** (Scheme 5) form double-helical

7

Scheme 5. Oligopyridine ligands **6** and **7** self-assemble in the presence of metal ions to form a variety of helical arrays.



complexes.[18] These helicates possess many features seen for self-organizing biological systems. The binding of Cu^{I} ions is cooperative, and the oligoligands display self-selection. This means that for a mixture of ligands **6a**–**6d**, helical-forming species will only selectively bind a second ligand of the same size.[19] This phenomenon was described as "instructed system paradigm". Using this self-assembly to form a well-defined scaffold, Lehn et al. synthesized a helix with five copper ions and pendant nucleoside units, a "deoxyribonucleohelicate".[20] With possible applications as a complimentary ligand for the DNA double helix this nanometer-sized architecture highlights the possibilities for creating functional assemblies. The helical sense can also be controlled by a variety of means: introducing chirality in the oxymethylene linker,[21] using chiral bipyridine ligands,[22] or, as shown by Siegel et al., linking two strands of **6c** through a chiral spacer. The resulting helical sense of the copper–ligand helix is controlled by the chirality of the spacer at one end.[23]

The above-mentioned helical arrays can be considered as consisting of three basic components: a binding site, a metal, and a ligand linking this binding site to another. All three components can be programmed with specific information which spontaneously gives a defined final architecture upon mixing. The coordination preference of metal can be controlled by using the appropriate metal ions, and the ligand properties can be varied by altering the denticity (bidentate, tridentate). The spacer linking the ligand units must be sufficiently flexible to allow the molecule to wrap around but rigid enough to prevent the second binding site from coordinating to the first metal. The size and geometry of the spacer in part controls the pitch and also the sense of the resulting helix.

Using these structural parameters Williams et al. and Constable et al. demonstrated control over the resulting helical architectures by using different metal ions.[24] Upon adding Cu ions with a tetrahedral coordination geometry to a bidentate ligand a di-copper double helix is generated, whereas a triple helix is formed upon the addition of a metal ion with octahedral geometry. The latter, in which the metal centers are lanthanide ions, are currently being investigated as possible light-conversion devices.[25]

This process of spontaneous self-organization is also highly dependent on the data encoded within the ligand. Because of the 6,6′ linkage in ligands of type **6** (Scheme 5) octahedral metals cannot be accommodated due to steric hindrance if three strands were to bind to two metals; in the 4,4′ linkage in ligand **7** there would be no steric hindrance. When **6b** and **7** are mixed in the presence of Ni^{II} and Cu^{I} **6b** binds only to Cu and **7** only to Ni ions.[19] In the presence of Fe^{II} ions **7** forms an even more complex array. This bipyridine ligand self-assembles with the Fe^{II} ions around a chloride ion template to form a circular double-helicate architecture.[26]

Bell et al chose a slightly different approach to construct double-helical arrays.[27] Instead of using the coordination preference of the metal as a major driving force for assembly, a double helix was constructed by emphasizing the geometrical preference of the ligand. With a heterohelicene which already has a helical geometry enforced due to covalent bonds, it was demonstrated that with the correct ligand even Group 1 metal ions such as sodium may control the assembly of double-helical supermolecules. When sodium salts are added two types of double helices can be formed: one in which two helices wrap around one metal ion and one in which they wrap around two metal ions. Katz et al. took the combination of metals and helicene molecules a step further by constructing a helicene possessing a salicylaldehyde functionality at both ends. In combination with nickel acetate and a phenyldiamine ligand, a beautiful, helical, conjugated ladder polymer (**8**, Scheme 6) is formed.[28] The planarity of the "nickel salophene" connections not only results in a conjugated system but also induces the polymer to wind in just one direction.

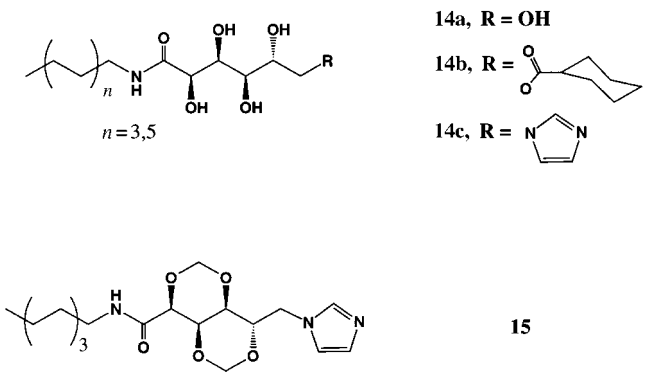
Scheme 6. Salicylaldehyde-functionalized helicenes complex nickel ions to form a helical polymeric assemblage (**8**). Schematic representation of the cyclic dodecacopper helicate from Lehn et al. which forms spontaneously in a preprogammed way.

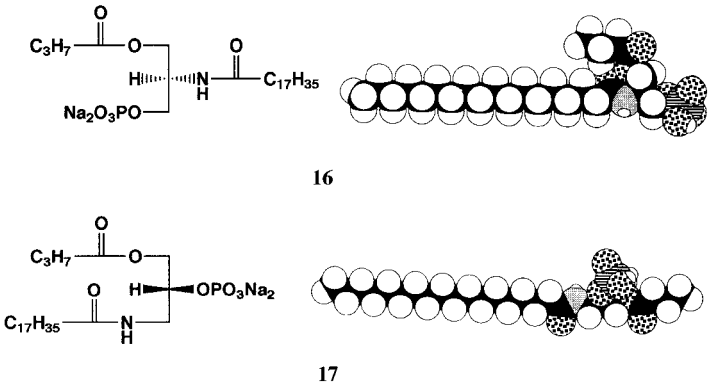
 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0065 $ 17.50+.50/0

Lehn et al. recently demonstrated that by using the molecular information encoded in the metal–ligand components it is possible to program the spontaneous assembly of even more highly complex, helical architectures. One of the most recent examples is the nanocyclic dodecanuclear Cu helicate **9**[29] (Scheme 6). In this assemblage twelve Cu ions and four multifunctional ligands spontaneously self-assembly in a two-step process to give a specific inorganic nanomolecule.

A variety of other approaches have also been investigated for the controlled construction of helical nanometer-sized architectures. The uracil and pyridine derivatives **10** and **11** based on tartaric acid assemble by complementarity of the base pairs to form helical superstructures. Species based on L-tartaric acid give right-handed helices, and those based on D-tartaric acid left-handed helices.[30] If a mixture of L-uracil and D-pyrimidine derivatives—or of D-uracil and L-pyrimidine derivatives—is used, no helicity is observed. Only configurationally compatible units assemble if all four possible species are mixed. This chiral resolution was also observed in the aggregation of chiral 1,2-diaminocyclohexanes by Hanessian et al.[31] When the (*R*,*R*) and (*S*,*S*) derivatives of **12a** were mixed with equimolar amounts of (*S*,*S*)-1,2-cyclohexanol **13**, two triple-helical supramolecular structures were generated (Scheme 7). The (*S*,*S*)-diamine of **12a** formed a homochiral left-handed helix with **13**, whereas **13** and the (*R*,*R*)-diamine of **12a** gave a heterochiral right-handed architecture. The group of Hanabusa modified the packing ability of *trans*-1,2-diaminocyclohexane by adding amide functionalities and long alkyl chains to give **12b**.[32] The (*R*,*R*) and (*S*,*S*) enantiomers of **12b** gelate in a variety of solvents to give right-and left-handed helical fibers, respectively, with a diameter of 40–70 nm. They result from cooperative, chiral self-organization.



Scheme 7. Chiral tartaric acid derivatives **10** and **11** self-assemble to helical architectures. (*R*,*R*)- and (*S*,*S*)-diaminecyclohexanes **12a** assemble with **13** to give helical arrays. Cyclohexanediamides **12b** aggregate through a network of hydrogen bonds and packing to form gels consisting of helical fibers.



The expression of molecular information at the macroscopic level by self-organization is a topic of great interest since it may lead to a more thorough understanding of the construction processes used by nature. The assembly of surfactants and amphiphilic molecules is of particular interest, as chirality within the individual molecule can be expressed in the suprastructure by the formation of helices and twisted bilayers. A wide variety of chiral amphiphiles based on amino acids (glutamate,[33] alanine[34]), phospholipids,[35] and carbohydrates[36] form chiral architectures. In the case of the glutamate derivatives the sense of the resultant helix is related to the molecular chirality: An L derivative of glutamate gives a right-handed helix, whereas a D enantiomer yields a left-handed helix. The encoded molecular data is expressed at the macroscopic level. The groups of Fuhrhop,[36] Pfannemüller,[37] and O'Brien[38] studied the assembly behavior of chiral amphiphiles—in particular gluconamides—which assemble to create micellar helical and multihelical superstructures. *N*-*n*-Octyl-D-gluconamide (**14a**, Scheme 8) forms ropelike architectures with a length to width ratio of up to 104. These structures are believed to consist of a helix of six intertwined micellar strands.[39] As in the glutamates the pure enantiomers form helices with enantiomorphology (i. e., in the case of **14a** only right-handed helices are formed), whereas racemic mixtures crystallize. The expression of chirality at the macroscopic level is a result of strong hydrogen bonds between adjacent molecules and efficient packing of the alkyl chains. The group of Nolte has varied the head group of these gluconamides (e. g. **14b**, **14c**) and found that the molecules self-assemble even in organic solvents to form organogels. Closer examination of these gels showed that they consist of well-defined micrometer-sized helical fibers.[40]

The self-assembly process required to form such highly complex nanomolecular architectures consists of numerous processes which are hierarchical in nature. Modified gluconamide **15** (Scheme 8), which possesses an imidazole head group, has also been fully investigated by Nolte et al. Although the hydrogen-bonding OH groups are protected, this molecule still readily self-assembles. In the presence of Cu^{II} ions **15** forms a 4:1 ligand–copper complex, which in turn self-assembles to generate a bilayer; in a stepwise fashion this further organizes to yield a nanometer-sized "molecular braid" consisting of four strands.[40] The sensitivity of the resultant architecture to the molecular geometry is highlighted by the phospholipid analogues **16** and **17** (Scheme 9).[41] Although both have an *R* configuration they are structurally different and give dramatically different expressions of chirality. Phospholipid **16** gives platelike aggregates, whereas **17** forms left-handed helical strands with a diameter of 22 nm, which themselves further assembly to give large ropelike architectures (Figure 1). The helicity is the

Scheme 8. *N*-*n*-Octyl-D-gluconamides **14** self-assemble in a variety of solvents to form complex intertwined architectures in which the chirality of the simple building blocks is expressed at a macromolecular level. Protected imidazole gluconamide **15** assembles in the presence of copper ions in a hierarchical fashion to give nanometer-sized molecular braids.

Scheme 9. Phospholipids **16** and **17** (and their space-filling representations).

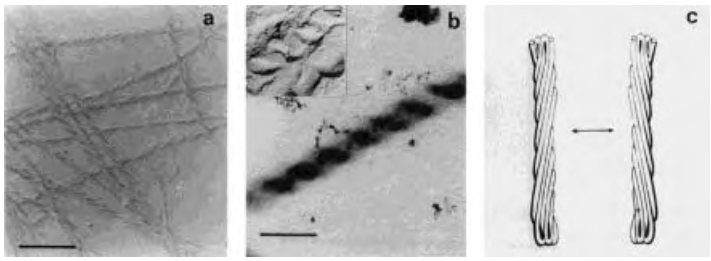

Figure 1. Electron micrographs of helices formed by **17** (2 wt %) in water (bar = 500 nm): a) left-handed helices (Pt shadowed), b) right-handed super helix (Pt shadowed; inset: image after freeze fracturing), c) schematic representation of supercoiled DNA.

result of the chirality within the molecular units and also the specific complementarity of intermolecular interactions, which carries this information through to the macroscopic level. Owing to its more linear shape **17** can pack more tightly, and hence the chiral molecular information is not lost upon self-assembly. The resultant nanomolecules themselves seem to be tunable by small changes in salt concentration or pH, which induces the left-handed helices to coil up and form large right-handed superhelices in a manner analogous to the formation of supercoiled DNA.[42]

Helicity in macromolecular and supramolecular systems can be obtained by a variety of methods. The principle of molecular programming is clearly demonstrated in the case of helicate structures resulting in the spontaneous self-assembly of, for example, large helical nanocycles. The rules governing the construction of helical nanosized arrays from amphiphlic building blocks are far more complex and are only now being elucidated. To mimic more closely the ability of nature to construct complex multicomponent helical architectures, a combination of many processes in a hierarchical assembly line will be required. The first steps in this direction are currently being taken. These helical assemblies and polymers are expected to have interesting physical and material properties, in particular as optical devices, that is, chiral light-emitting and nonlinear optical materials.[43] The ultimate goal is not just to mimic nature but to go a step further and be able to preprogram molecules to give not only specific architectures but also defined functionality.

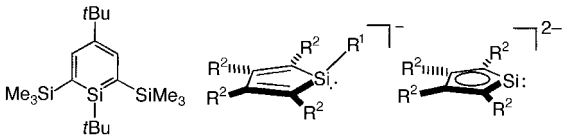
Conjugated π Systems with Heavy Main Group Elements— A Stable Neutral Silaarene and the First Tetrasilabutadiene**

Thomas Müller*



The question of conjugation and aromaticity in organosilicon compounds has recently attracted considerable interest. For instance, the influence of cyclic conjugation on the stability of aminosilylenes has aroused controversy.[1] However, even simple stable neutral silaarenes like derivatives of silabenzene have been elusive until very recently. This is in sharp contrast to the successful synthesis of kinetically stabilized silenes and 1-silaallenes.[2] In addition calculations predict for silabenzene a resonance stabilization of about 75% of that calculated for benzene.[3] Early fundamental investigations showed that silaarenes can be produced as short-lived intermediates in the gas phase or in the matrix at low temperatures and that they can be characterized by IR, UV, or PE spectroscopy.[4] None of these compounds could be however investigated in solution or even isolated in substance. Investigations by Märkl and co-workers[5] revealed the extraordinary reactivity of silaarenes. Even the with bulky groups substituted silabenzene **1** is at $-100^{\circ}C$ only of limited stability.

On the other hand the search for anionic silaarenes has been more successful during the last years. Almost simultaneously the groups of Boudjouk, Tilley, and West[6] reported the synthesis of silolyl anions **2**, analogues of the cyclopentadienyl anion, and silole dianions **3**. Surprisingly, the silicon in **2** is pyramidalized and the anions have localized C=C bonds. Cyclic conjugation with involvement of the silicon atom seems to play only a minor role in **2**. In contrast, silole dianions **3** as well as germole dianions[7] have delocalized π electron systems with almost identical CC bond lengths. The silicon atom in **3** is markedly deshielded relative to tetracoor-

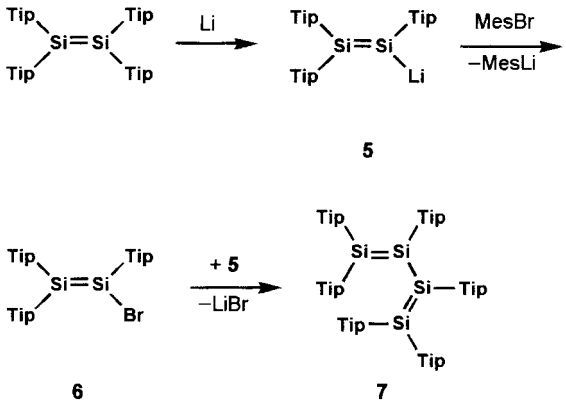
1 2 3

R^1 = alkyl, aryl, R_3Si; R^2 = Me, Et, Ph

dinated silicon atoms ($\delta(^{29}Si) = 64$, $R^2 = Ph$). Ab initio calculations for **3** ($R^2 = H$) and for its higher homologues suggest considerable resonance stabilization of the dianions, and the calculated magnetic properties give evidence for an aromatic ring current.[6c,d,7]

Another highlight of the experimental and theoretical studies in this area is the synthesis of a neutral silaarene stable at room temperature by the group of Tokitoh and Okazaki at Tokyo University. Like often in the chemistry of low-valent silicon, the sufficient protection from bimolecular reactions of the inherently stable target compound is also the key to success in this case. By taking advantage of the particular properties of the 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl (Tbt) protecting group the Tokyo group synthesized the 2-Tbt-2-silanaphthalene **4** by a HBr eliminiation in 80% yield as a colorless crystalline powder.[8] An X-ray analysis of the compound established the molecular structure and proved the planar environment of the silicon atom; the severe disorder of the 2-silanaphthalene ring in the crystal, however, prevents any discussion of structural details. The reported spectroscopic data are certainly unambiguous. The ^{29}Si NMR chemical shift ($\delta(^{29}Si) = 87.4$) is characteristic for sp^2-hybridized silicon in silenes and is in good agreement with calculated NMR chemical shifts for substituted 2-silanaphthalenes (e.g., $\delta(^{29}Si) = 94.3$ for 2-phenyl-2-silanaphthalene in which the phenyl group is fixed in a perpendicular conformation to the plane of the silanaphthalene in analogy to the Tbt-residue in **4**). Unequivocally, **4** posseses a Si=C bond, a finding which is supported by the chemical reactivity of **4**, which is typical for silenes.



(a)

4

What can be learned about aromaticity in this compound? Is the Si=C bond localized, or is the π bond part of a delocalized system similar to naphthalene? An indication for a delocalized structure are the $^1J_{Si,C}$ coupling constants to both neighboring carbon atoms ($^1J_{Si,C1} = 92$ Hz and $^1J_{Si,C3} = 76$ Hz), which are both clearly larger than expected for a Si–C bond (about 50 Hz). The value of the coupling constant suggests double-bond character for both Si–C bonds, although the comparison with coupling constants in silenes is problematic due to the very limited number of comparative values ($^1J_{Si=C}$: 83–85 Hz in $(Me_3Si)_2Si{=}C(OSiMe_3)R$[2a] and 104 Hz in a 1-silaallene).[2b] A clear geometrical indication for the delocalized structure of 2-silanaphthalenes is provided by DFT calculations. The calculated SiC1 and SiC3 distances in 2-silanaphthalene are intermediate between the Si=C bond length in silene and the Si–C bond length in methylsilane. This implies a bond order between 1 and 2 for both SiC bonds in **4**. The calculation of the Nucleus Independent Chemical Shift (NICS)[9] for 2-silanaphthalene, a method invented by Schleyer and co-workers for the quantification of the aromaticity of a compound, support the experimental evidence for the aromaticity of 2-silanaphthalene. The NICS indicates the magnetic shielding in the center of a cyclic molecule. Characteristicly NICSs are negative for aromatic compounds: for benzene a shielding of −9.7 ppm is calculated. The NICS calculated for 2-silanaphthalene is only slightly larger than that for naphthalene (−8.9 ppm for 2-silanaphthalene and −9.9 ppm for naphthalene). The experimental and theoretical results show concurrently that the aromaticity of naphthalene is only marginally reduced by the replacement of a ring carbon by a silicon atom.

These results give rise to the next question: to what extent is conjugation between Si=Si bonds possible? Recent studies by Weidenbruch and co-workers give a preliminary answer. They synthesized in a fascinating, simple reaction sequence the first tetrasilabutadiene stable at room temperature (**7**)[10]. The key

5

(b)

6 7

step to the synthesis of **7** is the metathesis reaction between a transitory disilene bromide **6** and a disilenyllithium compound **5**.

Tetrasilabutadiene **7** is kinetically exceptionally stabilized by six bulky 2,4,6-triisopropylphenyl (Tip) substituents. In the absence of air the compound melts without decomposition, and only at 267°C it is destroyed irreversibly! In the crystal **7** adopts a twisted s-*cis* conformation (C_2 symmetry) with a dihedral angle of 51° between the planes of the planar Si=Si bonds. Of interest are the SiSi distances in the molecule. The Si=Si bond lengths (217.5 pm) are 2–3 pm longer than isolated Si=Si bonds,[11] and the central Si–Si bond (232.1 pm) is relatively short, especially in view of the bulky Tip substituents. Due the limited published data, however, it is hard to distinguish whether this short central Si–Si bond is an indication of conjugation, as suggested by Weidenbruch et al. or is a result of the sp^2 hybridization of the silicon atoms in **7**. SiSi separations for $Si(sp^2)–Si(sp^3)$ bonds in disilenes scatter between 233.4 and 241.1 pm.[11] The UV spectra of a solution of **7** provides more clear evidence. The bathochromic shift of about 100 nm of the characteristic band of the π–π*

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0069 $ 17.50+.50/0

transition in disilenes in **7** indicates the conjugation between the Si=Si bonds in **7** in solution. A similar red shift is also found by comparison of the UV absorption of ethene and of 1,3 dienes with s-*cis* conformation.[12] Further investigations of the bonding situation in **7** are, however, certainly desirable to determine more precisely the interaction between the two Si=Si bonds.

With the isolation and characterization of these two substances another two dream molecules of the organosilicon chemists became reality. What is next on the agenda? Certainly, the synthesis of other silaarenes up to hexasilabenzene and its valence isomers will give us further important insights in the nature of chemical bonding in main group chemistry. At the moment, however, the quest for compounds with dicoordinated silicon seems to be a hotter topic. While stable silylenes have already gained entry into text books, the evidence for molecules with triply bonded silicon is rather scarce. Possible synthetic approaches to silaalkynes, disilaalkynes, and also 2-silaallenes are currently under intensive investigation in several groups.[13–15] Theoretically oriented papers have been published, which suggest possible synthetic pathways to these also thermodynamically very unstable compounds.[13] Suitable precursors for the generation of 2-silaallenes have been recently synthesized,[14] and the doubly bridged isomer of the disilaalkyne has been indentified spectroscopically in the gas phase and in the matrix.[15] Further highlights from the chemistry of low-valent silicon might therefore be expected for the near future.

Crystal Structure Solution of Hydrated High-Alumina Cement from X-ray Powder Diffraction Data**

Francesc Guirado,* Salvador Galí, Servando Chinchón, and Jordi Rius

The use of high-alumina cement (HAC; a quickly binding cement with a high aluminum oxide content) in concrete, precast, prestressed elements became highly controversial after the roofs of three educational buildings collapsed in the United Kingdom in 1973 and 1974. There were further incidents in other countries, and in 1990 an apartment building fell down in Barcelona, Spain. The relevant technical characteristics of HAC are better resistance to sulfates than Portland cements, good refractory properties, and above all a rapid gain in concrete strength which allows quick manufacture. However, a subsequent, complex evolution of this material—which is still not well understood—leads to the collapses.

The main phase present in HAC is $CaAl_2O_4$; additional components are Ca_2FeAlO_5, $Ca_{12}Al_{14}O_{33}$, and minor amounts of Ca_2AlSiO_7 and Ca_2SiO_4. After binding the cement with water (hydraulic reaction), $CaAl_2O_4$ gives raise to a metastable hexagonal phase currently but erroneously labeled as $CaAl_2O_4 \cdot 10H_2O$ (or CAH_{10}). Furthermore, some $Ca_2Al_2O_5 \cdot 8H_2O$ and an amorphous phase are present. The dominant crystalline phase in the paste (which determines the valuable cementitious properties), CAH_{10} slowly transforms into a new cubic phase with the hydrogarnet structure plus gibbsite and water. This unavoidable conversion is completed within several years; the rate depends on the humidity and the temperature. The effect of this rather slow conversion is an increase in concrete porosity and loss of strength. Chemical reactions facilitated by the porosity probably cause the continuous loss of strength, even after full conversion. Since 1990 a great deal of work has been undertaken in Catalonia to throw light on the extent of HAC pathology in buildings. It became apparent that the phase CAH_{10} was poorly characterized, and that the solution of its crystal structure would be of much practical importance in understanding the behavior of this phase in concrete.

We thank Prof. J. Rodriguez-Carvajal for providing facilities for the neutron-diffraction measurements and the Serveis Científico Tècnics (SCT) of the Universitat de Barcelona for technical support.

The hydration of $CaAl_2O_4$ below 20 °C yields an undetachable mixture of an amorphous and a crystalline phase with an overall composition of $CaAl_2O_4 \cdot nH_2O$ ($n \approx 5-8$). All attempts to isolate the crystalline phase were unsuccessful, and the relative proportions of the phases in the mixture as well as their individual compositions and water content remained unknown. These uncertainties could not be cleared up until the structure was refined. The poor quality of the crystalline material was an additional drawback and accounted for the fact that the crystal structure remained unsolved since Assarsson reported the existence of this phase in 1933.[1]

Nevertheless, several works have given partial information on the structure by using different techniques (^{27}Al NMR, IR, thermogravimetry (TG), and X-ray diffraction (XRD)).[2–5] According to the NMR data, the coordination at aluminum should be a slightly distorted octahedron of OH^- groups, and, by mimetism with gibbsite, the structure was believed to include rings of edge-sharing $Al(OH)_6$ octahedra. IR spectra of CAH_{10} revealed the presence of both H_2O and OH^- groups in the structure. Accurate kinetic analyses of the loss of water with increasing temperature, based on thermogravimetric and thermodiffractometric measurements, showed that a small amount of crystalline water is lost at about 94 °C without appreciable changes in the structure. This water was thought to be interlaminar. A subsequent, more important loss at about 126 °C produces the collapse of the crystalline portion.[6]

Since the unit-cell parameters of CAH_{10} were already known,[4] the integrated intensities could be extracted from the X-ray powder pattern with a modified LeBail method[7] using the whole-profile fitting program AJUST.[8] Inspection of the list of integrated intensities showed that reflections of type (*00l*) with $l = 2n+1$ were systematically absent, and reflections of type ($h-h\,l$) and ($h-2h\,l$) with $l = 2n+1$ were present. Accordingly, the allowed space groups are $P6_322$ (182), $P6_3/m$ (176), and $P6_3$ (173). Whereas space group $P6_322$ has Laue symmetry 6/*mmm*, $P6_3$/m and $P6_3$ belong to the Laue group 6/*m*. This means that reflections of type (*hkl*) and (*khl*) systematically overlap in $P6_3/m$ and $P6_3$. A first attempt to solve the structure in $P6_322$ was unsuccessful. Consequently, the structure was solved assuming $P6_3$ symmetry. The whole-profile fitting procedure with use of 6/*m* Laue symmetry yielded 30 resolved integrated intensities from a total of 158 reflections ($2\theta_{max} = 51.3°$, $d_{min} = 1.78$ Å). For the systematically overlapped reflections, equipartioned intensities were assumed.[9]

The structure was solved with the SUMF tangent formula (SUMF-TF)[10] implemented in the program XLENS.[11] The electron-density map with the best figures of merit is shown in Figure 1; inspection of this map revealed the positions of Ca^{2+} and OH^- ions as well as the water molecule bound to Ca^{2+}. Surprisingly, Al^{3+} did not appear in this map, so its position was deduced from crystallochemical considerations. The fact that the electron-density map obtained assuming $P6_3$ symmetry possesses a center of symmetry indicated that the true space group is $P6_3/m$.

The model derived from the electron-density map was introduced as the starting structure for the Rietveld refinement with the program FULLPROF.[12] A Pearson-VII function was selected to describe individual line profiles,

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0072 $ 17.50+.50/0

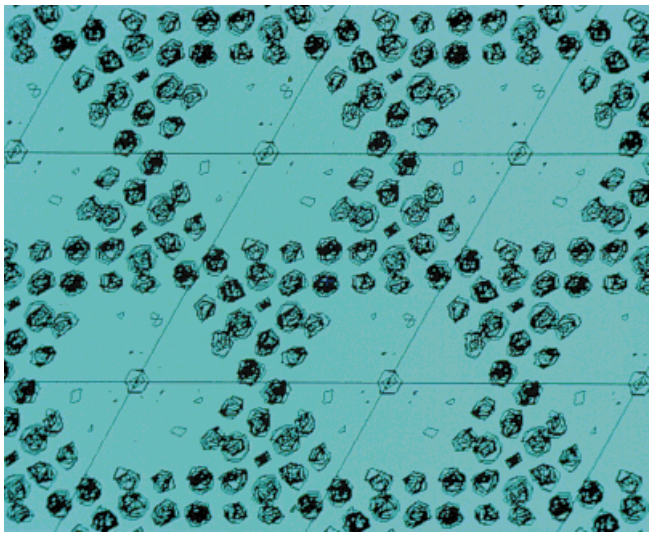

Figure 1. Electron-density map along [001] obtained by applying the SUMF-TF to the equipartioned intensities, which were extracted from the X-ray powder diffraction pattern with a resolution of up to 1.78 Å. One striking feature of this structure is the large channel parallel to the *c* axis, which can be seen clearly in this image. The graphic was produced with the FAN program.[20]

and possible angular variation of the mixing parameter was allowed. Peaks below 30° (2θ) were corrected for asymmetry following the model proposed by Berar and Baldinozzi.[13] The reflections with the 2θ intervals 5–9° and 70–100° were excluded from the refinement. Owing to the shortage of intensity data and the large number of atoms involved, geometrical restraints were applied to the cation–anion distances: $d_{Ca-O} = 2.468(7)$ Å (average distance for the coordination number eight) and $d_{Al-O} = 1.91(6)$ Å (average distance for coordination number six). The refinement converged to the conventional Rietveld residuals[14] $R_p = 16.7$, $R_{wp} = 18.0$, $R_B = 8.6$, and $\chi^2 = 3.5$. The result is shown in Figure 2. Table 1 gives the final atomic coordinates for CAH_{10}, which is better reformulated as $[CaAl_2(OH)_8(H_2O)_2] \cdot 1.84\,H_2O$.

The occupation parameters of the two "free" water molecules were refined after different isotropic temperature factors for groups of atoms were included in the refinement

The structure is based on ring-shaped units of three edge-sharing $Ca(OH)_6(H_2O)_2$ polyhedra at $z = 0.25$ which are laterally linked to the next units at $z = 0.75$ and $z = -0.25$ through two $Al(OH)_6$ octahedra. Each octahedron shares one edge with two Ca-containing polyhedra and one edge with two adjacent octahedra (Figure 3) to produce zig-zag chains of Al octahedra

Table 1. Refined atomic coordinates and isotropic temperature factors [Å^2] for $CaAl_2(OH)_8(H_2O)_2 \cdot 1.84\,H_2O$.

Atom	Wyckoff site	*x*	*y*	*z*	B_i	Occupation
Ca	6*h*	0.5185(7)	0.2791(8)	0.25	2.9(4)	1

O(2)	12*i*	0.403(1)	0.235(1)	0.039(2)	4.0(8)	1
O(3)	12*i*	0.521(1)	0.574(1)	0.072(2)	3.3(3)	1
O(4)	12*i*	0.330(1)	0.436(1)	0.090(2)	3.3(3)	1
O(5)	6*h*	0.663(1)	0.565(2)	0.25	3.3(3)	1
O(6)	6*h*	0.505(2)	0.428(2)	0.25	3.3(3)	1
O(7)	12*i*	0.000(3)	0.249(4)	0.921(3)	25(1)	0.71(7)
O(8)	6*h*	0.316(5)	0.567(3)	0.25	25(1)	0.42(4)

along the *c* axis. This peculiar atom connectivity gives rise to an extremely open structure with a large channel along *c* that is centered by the 6_3 screw axis. The balance of electrostatic valences for the oxygen centers of $CaAl_2(OH)_8(H_2O)_2$ estimated according to Allmann[15] is reproduced in Table 2. It allows recognition of the chemical role played by each oxygen atom. It can be seen that all oxygen atoms in the rigid part of the structure are in the form of hydroxy groups except for O(2), which belongs to a water molecule that is tightly bound to Ca^{2+}. The remainding water molecule in the structure is at partially occupied positions on the Ca units (O(8)) or inside the channel (O(7); see Table 1). The presence of water on the Ca units explains the slight shortening of the *c* axis by about 2% at 94 °C. The partial occupation as well as the abnormally high temperature factor of the water molecule in the channel suggest the possible existence of more disordered water molecules in the channel.

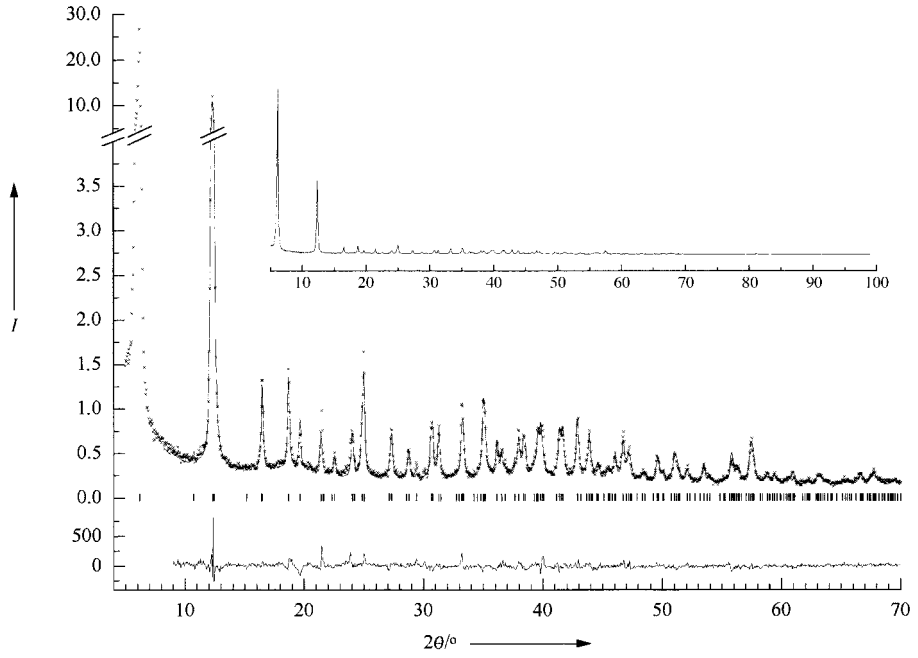

Figure 2. Calculated (inset) and experimentally observed (crosses) X-ray powder diffraction patterns of $[CaAl_2(OH)_8(H_2O)_2] \cdot 1.84\,H_2O$ as well as the difference profile (bottom). Intensity *I* is given in units of 10^{-3}. Measurement conditions: angle range 5–100° (2θ), step size 0.05° (2θ), counting time 15 s. An illumination correction was applied for reflections below 24° (2θ); the first diffraction line at very low angle could not be properly corrected and was excluded from the refinement. Reflections above 70° (2θ) were excluded as well. The short tick marks below the pattern give the positions of the Bragg reflections.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0073 $ 17.50+.50/0

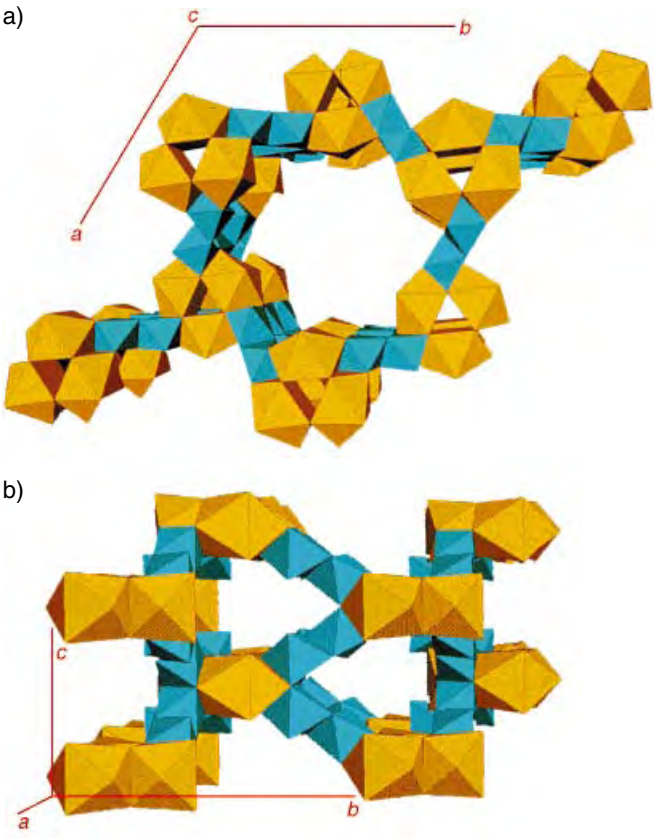

Figure 3. Structure of $[CaAl_2(OH)_8(H_2O)_2]\cdot 1.84\,H_2O$ as viewed a) along the *c* axis and b) along the *a* axis. Three-membered, ring-shaped units of polyhedra (yellow) with central Ca atoms are mutually connected to chains of octahedra (blue) with central Al atoms that run parallel to the *c* axis. The (free) water molecule not involved in the formation of the structure, which shows very high temperature factors, is located in three types of cavities. The most important is a tunnel parallel to the *c* axis, whose axis coincides with the symmetry axis 6_3 containing the O(7) water molecule (see Table 1). In b) the chains of Al-containing octahedra that are parallel to the *c* axis and the cavities parallel to the *a* axis can be observed. There are threefold intersecting tunnels at levels $z = 0.25$ and $z = 0.75$ (but rotated by 60°). The O(8) water molecule is inside these cavities.

The $Ca(OH)_6(H_2O)_2$ polyhedron is similar to the $Ca(OH)_8$ unit in hydrogarnet $(Ca_3Al_2(OH)_6)$[16, 17] and ettringite $(Ca_6(Al(OH)_6)_2(SO_4)_3\cdot 26\,H_2O)$.[18] The structure of the former is more compact, since each $Ca(OH)_8$ polyhedron shares four edges with four different $Ca(OH)_8$ and four more edges with four $Al(OH)_6$ polyhedra. These are in turn surrounded by six $Ca(OH)_8$ polyhedra. The slow conversion of the hexagonal phase into hydrogarnet and gibbsite (plus water) takes place with conservation of the first coordination shell—that is, without completely destroying the original structure. However, CAH_{10} is highly unstable in the presence of circulating water under atmospheric conditions, and quickly transforms into calcite and aluminum hydroxide.

The structural formula obtained from the refinement and given above can be converted into a conventional formula, namely $CaAl_2O_4\cdot 7.8\,H_2O$. This composition is very similar to the overall composition of the hydrated product (with crystalline and amorphous parts). Hence, the amorphous and crystalline portions have very similar compositions, a result that was not apparent when this work was initiated.

Table 2. Metal–oxygen bond lengths *L* [Å] and bond valences *v* (italics) of the oxygen atoms estimated according to Allmann;[15] $L(v) = L(1) - 2k \lg v$. The $L(1)$ and $2k$ values for Ca and Al are 1.896, 0.95 and 1.644, 0.88, respectively. The exchange of charge in the hydrogen bridges (Δe) is based on hydrogen-bond strengths according to Zachariasen.[18] The type of group that the oxygen atom belongs to is given in the last column. The coordination numbers for Al and Ca are 6 and 8, respectively.

Atom	Ca^{2+}	Al^{3+}	$\Sigma_c v$[a]	Δe	$\Sigma_c v_{corr}$	Type

[a] $\Sigma_c v$ = sum of bond valences for each anion. [b] $\Sigma_c v_{corr}$ = sum of bond valences for each anion after considering the H-bond charge exchange. [c] Two bonds per cation. [d] Two bonds per anion. [e] $\Sigma_A v$ = sum of bond valences for each cation. O(4)···O(2) 2.66(4) Å ≈ 0.28 valence units.

Experimental Section

The $CaAl_2O_4$ phase was obtained by heating an equimolar mixture of pure reactants Al_2O_3 and $CaCO_3$ at 1300 °C for 200 h. The progress of the reaction was periodically controlled by XRD. The final sintered product was finely ground and sieved through a 10-μ sieve. The optimal conditions were determined to be hydration of $CaAl_2O_4$ at 5 °C with excess water with periodic stirring. The final product was filtered, washed with acetone, and characterized by XRD. The X-ray powder diffraction pattern used for the structure solution and refinement was collected in reflection geometry on a high-resolution RIGAKU powder diffractometer equipped with a Cu rotating anode and a primary curved Ge(111) monochromator. Comparison with an additional pattern measured using a INEL X-ray PSD diffractometer with the sample enclosed in a glass capillary confirmed the absence of a preferred orientation in the flat sample.

To prepare a sample suitable for neutron diffraction, $CaAl_2O_4$ was hydrated with deuterated water as well. The results of neutron diffraction were very disappointing: Only few peaks emerged from an intense background, suggesting a high thermal and positional disorder of the deuterium atoms.

Self-Complementarity Achieved through Quadruple Hydrogen Bonding**

Felix H. Beijer, Huub Kooijman, Anthony L. Spek, Rint P. Sijbesma, and E. W. Meijer*

Hydrogen bonds are among the most useful interactions for encouraging molecules to self-assemble into well-defined aggregates.[1] The strength and selectivity of hydrogen bonds can be increased by introducing arrays of donor (D) and acceptor sites (A). Arrays of two and three hydrogen bonds have already been studied in detail, and their strength in $CHCl_3$ depends upon the particular arrangement of donor and acceptor sites. In triply hydrogen bonded complexes, for example, association constants vary from $K_a = 10^2 - 10^3$ M^{-1} for DAD–ADA pairs to $K_a = 10^5 - 10^6$ M^{-1} for DDD–AAA pairs.[2] Jorgensen[3] rationalized these differences as the result of secondary electrostatic interactions. Rules derived from this analysis are now widely used to design complementary host–guest systems characterized by high selectivity and recognition as well as strong binding.

However, for a number of applications ranging from container molecules[4] to supramolecular tubes,[5] self-complementarity is required. This is evidently found only in arrays with an even number of hydrogen bonds. Although examples exist of self-complementary arrays consisting of two hydrogen-bonding units,[6] arrays with four adjacent hydrogen-bonding sites are notably absent from the supramolecular literature.[7] Recently we reported the dimerization of a diacetyl diaminotriazine involving four hydrogen bonds with a dimerization constant K_{dim} of 35 M^{-1}.[8]

Here we show the generality of dimerization by way of the DADA sequence in readily available compounds, and present examples with unexpectedly high dimerization constants. Conceptually, the DADA arrays in compounds **1**–**6** are derived from DAD arrays in diaminotriazines or diaminopyrimidines that have been extended by an oxygen acceptor atom

from a *cis* amido or ureido group. The required *cis*-amide conformation in **1**, **2**, and **5** is favored by repulsion between the amide oxygen atom and nitrogen atoms in the heterocyclic ring, whereas an intramolecular hydrogen bond preorganizes the array in ureido derivatives **3**, **4**, and **6**.

Compounds **1**–**6** were prepared by acylation of diaminotriazine and diaminopyrimidine derivatives. The structures of **1**, **3**, **5**, and **6** were determined by single-crystal X-ray diffraction (Figure 1).[9] All four compounds form centrosymmetric dimers in the solid state, which are held together by four hydrogen bonds between self-complementary DADA arrays. The dimers of triazines **1** and **3** form infinite chains by double hydrogen bonding of the remaining N–H group to a triazine-ring nitrogen atom. An additional intramolecular hydrogen bond is present in ureido derivatives **3** and **6** from the ureido nitrogen atom to a ring nitrogen atom. Distances between hydrogen-bonded atoms are listed in Table 1. The DADA arrays in all four crystal structures deviate significantly from linearity. Thus, the oxygen atom does not fall on the line joining the nitrogen atoms in the array. As a result, the inner N–H···N hydrogen bonds are 0.30–0.49 Å longer than the outer N–H···O hydrogen bonds. Apparently, the enforced differences in bond lengths between N–H···O and N–H···N hydrogen bonds (which have similar equilibrium lengths)[10] does not prevent the formation of stable dimers.

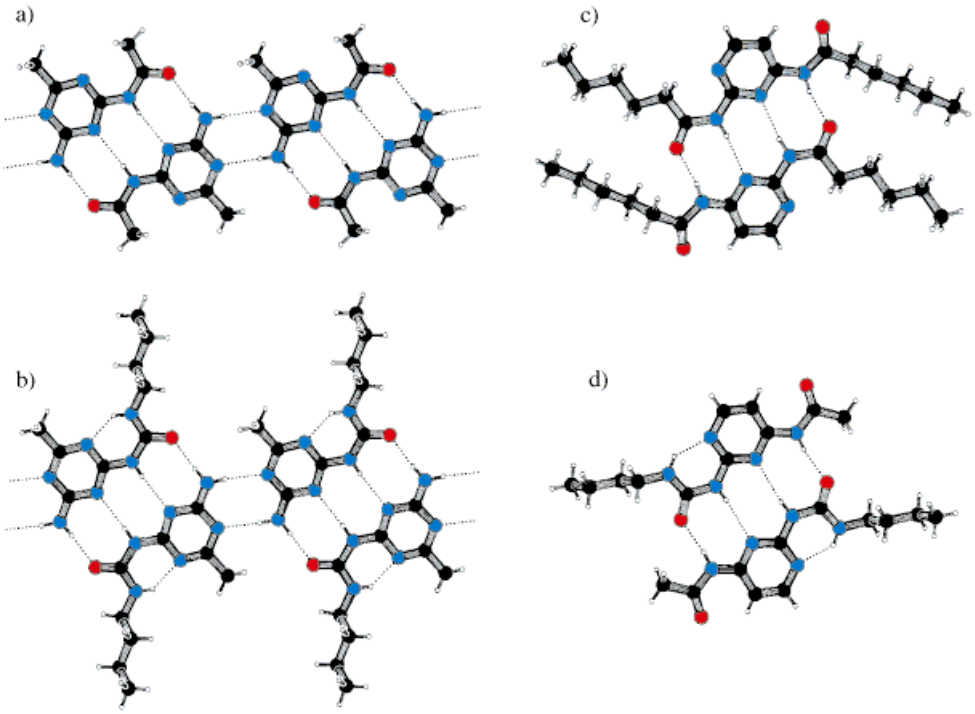

Figure 1. PLUTON representations of the structures of a) **1**, b) **3**, c) **5**, and d) **6**.

FT-IR spectra of solid samples and concentrated solutions of **2**, **4**, **5**, and **6** in chloroform are very similar both in the N–H region (3500–3170 cm^{-1}) and in the double-bond region (1750–1400 cm^{-1}), which indicates a similar complexation mode in the solid state and in solution. Dilution of the solutions in chloroform results in the appearance of the monomer IR spectrum. This permits derivation of both monomer and dimer absorptions, as well as the shifts that accompany complexation; all are typical for hydrogen bonding. Changes in the N–H stretching vibrations of **5** and **6** upon dimerization are very similar [$\Delta\nu = 167$ and 235 cm^{-1} (**5**) and 158 and 256 cm^{-1} (**6**)], which indicates that the hydrogen bonds themselves are similar.

^1H and ^{13}C NMR spectra taken both in chloroform and DMSO are in agreement only with the tautomeric form indicated in the structural formulas. In the ^1H NMR spectra of the soluble compounds **2**, **4**, **5**, and **6** the chemical shifts for the amide protons in chloroform are concentration-dependent. When the concentration is increased, the signals shift downfield, which indicates formation of a hydrogen-bonded complex. The concentration dependence of the N–H shifts can be simulated only with a model that assumes dimerization. Dimerization constants can be obtained from this model for **2**, **4**, and **5** (Table 2). The dimerization constant for **4** was determined to be $2.2 \times 10^4\,M^{-1}$ by evaluation of IR spectra at

various concentrations, whereas a value of $1.5 \times 10^4\,\text{M}^{-1}$ was obtained from NMR measurements. The dimerization constant of **6** is too high to be determined directly in $CDCl_3$. Limiting shift values for **6** in $CDCl_3$ containing 1, 2, 3, 4, and 5% methanol are identical, so these values can be used for extrapolation to pure $CDCl_3$. This results in an estimate for the dimerization constant in pure $CDCl_3$ of approximately $2 \times 10^5\,\text{M}^{-1}$.

The dimers of **2** and **4**–**6** in chloroform show remarkably different stabilities. Although all the dimers are stabilized by four intermolecular hydrogen bonds, the stabilities differ by as much as 17.5 kJ mol^{-1}. The most significant differences are observed between amide derivatives **2** and **5** on one hand, and ureido derivatives **4** and **6** on the other.

Sartorius and Schneider have recently proposed a simple free-energy relationship for the stability of multiply hydrogen bonded complexes in chloroform.[11] This is based on two increments: 7.9 kJ mol^{-1} for each hydrogen bond and $\pm$ 2.9 kJ mol^{-1} for each attractive or repulsive secondary electrostatic interaction. The increments were derived from association data for heterocyclic compounds with spatially fixed arrays. A dimerization constant of $310\,\text{M}^{-1}$ ($\Delta G^\circ_{\text{dim}} = -14.2$ kJ mol^{-1}) is predicted for a DADA array. The dimerization constants for amides **2** and **5** ($K_{\text{dim}} = 530$ and $170\,\text{M}^{-1}$, respectively) agree with the predictions, provided one takes into account the considerable degree of rotational freedom available. Most surprisingly, however, ureido derivatives **4** and **6** display stabilities that exceed the calculated values by 10.3 and 16.0 kJ mol^{-1}, respectively. The increased stability of the dimers from **4** and **6** relative to the dimers from **2** and **5** might be ascribed to preorganization of the DADA array provided by the intramolecular hydrogen bonds in these compounds, which fix the carbonyl groups in the plane of the ring. In both compounds a *cis* conformation for the amide groups and coplanarity with the aromatic ring are required for dimerization. Fixation of the amide in this conformation is unfavorable not only entropically, but also enthalpically.[12] Therefore, we propose that the higher stability of dimers of the ureido compounds compared to amido derivatives is caused by a combination of favorable entropic and enthalpic effects of the intramolecular hydrogen bonds of the ureido substituents. Although the difference in stability of dimers in the two series can indeed be explained this way, the argument does not account for the large deviations of the values for **4** and **6** from those calculated by Sartorius and Schneider;[11] this requires further investigation.

Self-complementary quadruply hydrogen bonded systems can be prepared very readily by acylation of DAD arrays, and the stabilities of the resulting dimers are anomalously high when the array is preorganized by intramolecular hydrogen bonds. Further elaboration of self-complementarity and preorganization by intramolecular hydrogen bonds, together with the application of four-point recognition in supramolecular chemistry, are the subjects of ongoing research.

Experimental Section

Dimerization studies in chloroform: Dimerization constants (K_{dim}) were obtained through ^{1}H NMR titrations, in which the shift of the N–H protons (as well as aromatic and CH_3 protons, where appropriate) was monitored as a function of concentration. At least ten data points in the 20–80% saturation range were measured, and dimerization constants were evaluated by nonlinear least-squares fitting of the data to the appropriate equation.[13] ^{1}H NMR titrations utilized $CDCl_3$ (Cambridge Isotope Laboratories, 99.8% D content, with TMS as internal reference). For the IR studies, freshly prepared anhydrous chloroform[8] was used.

1-6: Acetylaminotriazines **1** and **2** and ureidotriazines **3** and **4** were synthesized by heating the corresponding diaminotriazine in pyridine at reflux with excess acetic anhydride (15 min)[14] or excess butyl isocyanate (2 h). Cooling resulted in precipitation of pure **1** and **3**, and crystallization from DMF afforded crystals of sufficient quality for single-crystal X-ray analysis. Derivatives **2** and **4** were purified by precipitation in hexane or ethyl acetate and by column chromatography. Di(hexanoylamino)pyrimidine (**5**) was obtained by heating 2,4-diaminopyridine with hexanoic anhydride in pyridine at reflux for 2 h and crystallization from hexane/ethyl acetate. Crystals suitable for single-crystal X-ray analysis were obtained by evaporating a solution in hexane/dichloromethane under air. 2-Butylureido-4-acetylaminopyridine (**6**) was synthesized in two steps. Reaction of 2,4-diaminopyridine in warm THF with 1 equiv of butyl isocyanate afforded, after crystallization, pure 2-butylureido-4-aminopyridine. This was treated with 1 equiv of acetyl chloride in warm THF. Crystals suitable for single-crystal X-ray analysis were obtained by evaporating a solution in dichloromethane under air. All compounds provided satisfactory analyses. Full details regarding synthesis and characterization, together with a study of the observed association behavior, including bis-acylated derivatives, will be published elsewhere.

A Molecular Bowl with Metal Ion as Bottom: Reversible Inclusion of Organic Molecules in Cesium Ion Complexed Cucurbituril**

Dongmok Whang, Jungseok Heo, Joo Hyun Park, and Kimoon Kim*

Molecular containers,[1] rigid molecules with large cavities in which small molecules can be encapsulated, are of much interest because of their potential applications in separations, catalysis, sensors, and drug delivery. Although a number of molecular container systems have been studied only a few of them have demonstrated reversible encapsulation and release of their guests at ambient temperatures.[2, 3] We recently reported[4] a novel molecular container assembly based on cucurbituril (**1**),[5, 6] a macrocyclic cavitand with a hollow core of ≈ 5.5 Å diameter, which is accessible through two portals laced with carbonyl groups. In aqueous solution containing sodium ions, two Na^+ ions and their coordinated water molecules cover each portal of cucurbituril like a lid on a barrel.[4, 7] The "Na^+-lidded" cucurbituril can encapsulate small organic molecules such as THF and benzene. Moreover, the encapsulation and release of the guest molecules can be controlled by complexation and decomplexation of the sodium ions at the portals. Extending this work to cucurbiturils complexed to other alkali metal ions, we thought cesium-complexed cucurbituril would be particularly interesting because Cs^+, whose ionic radius is 1.81–2.02 Å seems to fit the portal better. Indeed, Cs^+-complexed cucurbiturils are drastically different from the Na^+-complexed cucurbiturils.[4] Here we report the cesium-complexed cucurbiturils, which uniquely behave like a "metal-ion-bottomed" molecular bowl.

1

Although cucurbituril is sparingly soluble in water it dissolves appreciably in cesium chloride solution ($\approx 5.9 \times 10^{-2}$ mol in 1.0 L of 0.2 M CsCl solution at room temperature) as it does in aqueous solutions of other alkaline metal salts. Slow diffusion of ethanol into cucurbituril dissolved in 0.2 M CsCl solution results in the formation of crystals of **2**. The X-ray crystal structure of **2** (Figure 1)[8] reveals that a cesium ion is coordinated to each portal of cucurbituril, but the structure is in sharp contrast to the sodium-complexed cucurbituril in which two sodium ions are coordinated to each portal of cucurbituril.[4] The cesium ion leans toward one side of the portal, being coordinated to only four carbonyl oxygen atoms

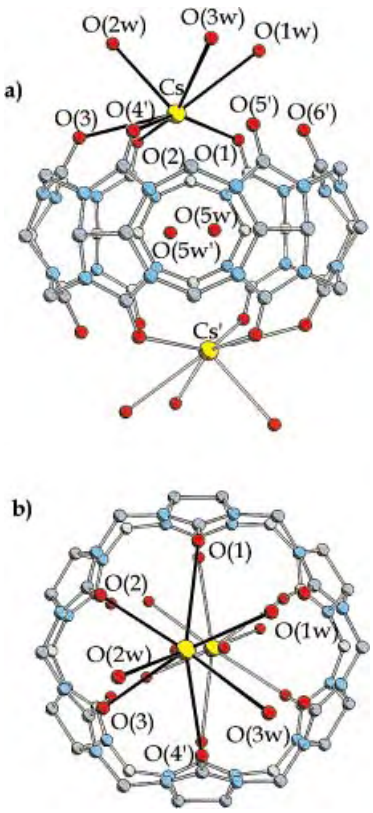

Figure 1. X-ray crystal structure of **2**: a) side view; b) top view. Color codes: Cs yellow, O red, N blue, C gray. Selected bond lengths [Å]: Cs–O(1) 3.378(6), Cs–O(2) 3.110(6), Cs–O(3) 3.100(6), Cs–O(4) 3.321(5), Cs–O(1w) 3.214(7), Cs–O(2w) 3.027(7), Cs–O(3w) 3.487(7).

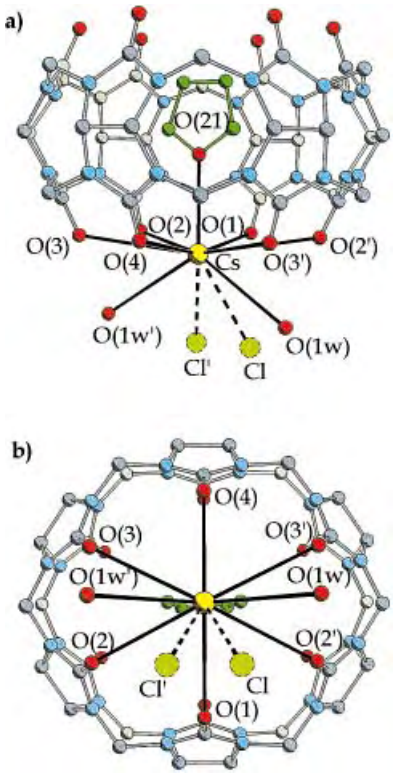
at the portal with Cs–O distances of 3.100(6) – 3.378(6) Å. Three water molecules O(1w) – O(3w) are also bound to the metal ion from outside with distances of 3.027(7) – 3.487(7) Å. The cesium ion is 0.684(2) Å above the mean plane of the six carbonyl oxygen atoms of the portal. This value is much smaller than the average displacement of the sodium ions (1.577(4) Å) from the six-oxygen plane of the portal in the sodium-complexed cucurbituril. The smaller displacement from the portal and larger ionic radius of the cesium ion make the size of the cavity in **2** considerably smaller than that in the sodium-complexed cucurbituril. This is illustrated by the fact that only one disordered water molecule resides in the cavity of **2** whereas three water molecules exist in the Na^+-lidded cucurbituril. We therefore expected that the cavity of the Cs^+-complexed cucurbituril is not large enough to accommodate a tetrahydrofuran (THF) molecule which can be encapsulated in the Na^+-complexed cucurbituril.

To our surprise, however, when THF was added to the cucurbituril in 0.4 M CsCl solution two sets of signals for THF were observed in the ^1H NMR spectrum, the second of which is shifted upfield from that assigned to the free THF molecules. This NMR spectrum supports inclusion of a THF molecule inside the cucurbituril dissolved in CsCl solution. The formation constant of this inclusion complex **3** is estimated to be $(1.1 \pm 0.1) \times 10^3\,M^{-1}$ at room temperature,[9] which is even larger than that in the sodium-complexed cucurbituril ($(5.1 \pm 0.5) \times 10^2\,M^{-1}$).[4] Thermodynamic parameters[10] associated with the inclusion phenomenon are quite different from those for the Na^+ case: $\Delta H^\circ = -9.8 \pm 1.0$ kcal mol^{-1} and $\Delta S^\circ = -19 \pm 2$ cal mol^{-1} K^{-1} (Cs^+) and $\Delta H^\circ = -5.8 \pm 0.6$ kcal mol^{-1} and $\Delta S^\circ = -7.4 \pm 0.7$ cal mol^{-1} K^{-1} (Na^+).[4] The apparent conflict of this observation with our earlier expectation prompted us to study the X-ray structure of the crystal of **3**.[8] As we suspected, the X-ray structure reveals a THF molecule encapsulated in the cucurbituril cavity. The structure of **3** is, however, quite different from that of **2**; in particular, only one cesium ion is bound to cucurbituril in **3** (Figure 2). This is in contrast to the Na^+-lidded cucurbituril, in



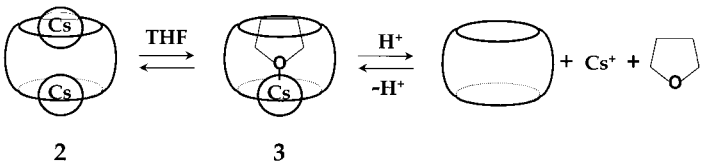


Figure 2. X-ray crystal structure of **3**: a) side view; b) top view. Color codes: Cs yellow, Cl greenish yellow, O red, N blue, C gray. The coordinated THF is highlighted in green. The coordinated Cl^- is disordered over two sites with half occupancy. Selected bond lengths [Å]: Cs–O(1) 3.250(7), Cs–O(2) 3.584(8), Cs–O(3) 3.574(6), Cs–O(4) 3.144(6), Cs–O(21) 2.934(10), Cs–O(1w) 3.591(10), Cs–Cl 3.365(3).

which the host structure of the complex that includes THF is nearly identical to that of the one free of the organic guest. In **3**, which is on a mirror plane in the crystal, the cesium ion is located at the center of the portal, which shows a severe ellipsoidal distortion. This distortion is manifested in the uneven distances between cesium and carbonyl oxygens at the portal: two of the six carbonyl oxygen atoms (O(1) and O(4)) are much closer to the metal center (Cs–O(1) = 3.250(7) Å, Cs(O(4) = 3.144(6) Å) than the four other carbonyl oxygens (Cs–O(2) = Cs–O(2′) = 3.584(8) Å; Cs–O(3) = Cs(O(3′) = 3.574(6) Å). The included THF molecule is coordinated to the metal ion (Cs–O(21) = 2.934(10) Å), and the molecular plane lies along the long axis of the ellipsoidal host molecule. Two water molecules and a disordered chloride ion are coordinated to the cesium ion from outside.[8]

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0079 $ 17.50+.50/0

The coordination of the guest THF to the cesium ion bottom of the molecular bowl may be responsible for the larger formation constant in the Cs^+-complexed cucurbituril than for the Na^+ analogue in which the encapsulated THF is not coordinated to the sodium ion lids. The larger enthalpy and entropy changes for the inclusion in the former than in the latter are also consistent with the coordination of the substrate. The fact that the inclusion complex formation constant for noncoordinating benzene in this Cs system is $2.1\,\text{M}^{-1}$, which is only 1/10 of that for the Na^+ case, also supports this explanation.

Reversible inclusion and release of the guest molecule in the cesium-complexed cucurbituril upon change in pH of the medium is observed as in the sodium-lidded cucurbituril.[4] Specifically, when trifluoroacetic acid is added to the solution containing the cesium-complexed cucurbituril and THF, the ^{1}H NMR signals for THF included in the cavity decrease, whereas those for free THF increase. Upon addition of about 300 equivalents of trifluoroacetic acid the signals for the bound THF essentially disappear. When the solution is neutralized again by adding Cs_2CO_3 the signals for the encapsulated THF are almost fully restored. A series of these observations suggests that the cesium ion coordinated to the portal is removed in strongly acidic solution due to the protonation of the carbonyl groups at the cucurbituril portals; consequently, the encapsulated THF molecule can escape from the cavity readily (Scheme 1). Neutralization of the

2 3

Scheme 1. Encapsulation and release of the THF guest molecule from the Cs-complexed cucrbituril host molecule.

solution restores the cesium ion bottom of the cucurbituril bowl and therefore also the ability to encapsulate THF.

In summary, we present a novel metal-ion-bottomed molecular bowl in which inclusion of a guest molecule can be reversibly controlled by the acidity of the medium. This work demonstrates the advantages of using metal ions as key control elements for reversible inclusion: 1) easy blocking and unblocking of portals and 2) coordination of encapsulated substrates. The latter provides additional guest selectivity of the inclusion process. Furthermore, the metal ion bottom may serve as a Lewis acid site for substrate activation and chemical catalysis. Work along this line is currently in progress.

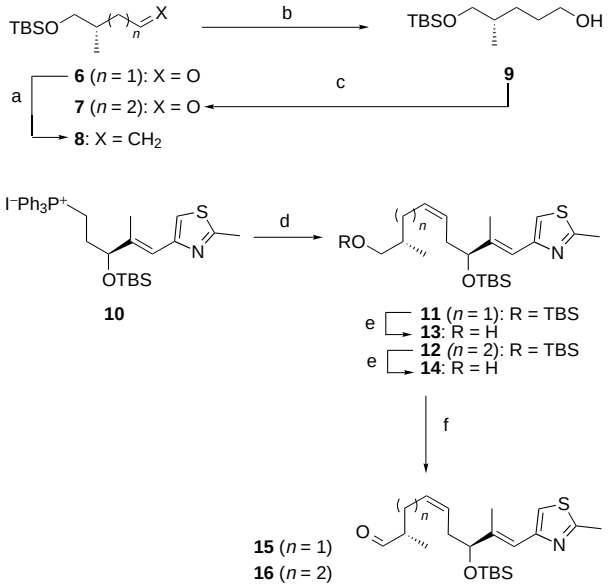
Probing the Ring Size of Epothilones: Total Synthesis of [14]-, [15]-, [17]-, and [18]Epothilones A**

K. C. Nicolaou,* Francisco Sarabia, Sacha Ninkovic, M. Ray V. Finlay, and Christopher N. C. Boddy

The discovery,[1] structural elucidation,[2] and biological activity[1–4] of the epothilones rapidly propelled them to the forefront of chemical[5] and biological research.[3, 4] Particularly exciting and stimulating was the recognition of their Taxol-like[6] mechanism of action[3] as antitumor agents and their ability to eradicate Taxol-resistant tumor cells.[4] Total syntheses of the 16-membered macrolactones epothilones A (**1**, Scheme 1),[7–11] B (**1** with a CH_3 group at C-12 instead of H),[10, 12, 13] and E (**1** with a CH_2OH group at C-21 instead of CH_3)[14] have been achieved, and many analogues[7–18] have already been synthesized and biologically investigated. From these studies, the epothilone pharmacophore has emerged as a well-defined and rather precise molecular structure tolerating only certain changes.[7–18] To probe the effect of the size of the macrocycle on its biological activity, we targeted the 14-, 15-, 17-, and 18-membered ring analogues of epothilone A (**1**), thus completing the [*n*]epothilone A series where $n = 1-5$ (Scheme 1). We report here on the successful total syntheses as well as the biological properties of these compounds (**2**–**5**).



Molecular modeling and molecular dynamics of [14]-, [15]-, [17]-, and [18]epothilones A led to the minimized structures shown in Figure 1 (see p. 82). These models revealed considerable structural distortions for the 14-, 15-, and 17-membered ring epothilones. In contrast the overall shape of [18]epothilone A was very similar to that of natural epothilone A ([16]epothilone A), heightening expectations for biological activity of the latter compound, if not for the others.

The charted route projected epoxidation of the C12–C13 double bond of the macrocycle as the final step and a convergent assembly of the epothilone skeleton by means of a Wittig reaction, an aldol condensation, and a macrolactonization.[8b, 10, 13] This strategy required fragments **6**, **7**, and **10**[10, 13] for the construction of the key intermediates **15** and **16**, which were needed for the 14- and 15-membered rings, respectively (see Scheme 2). A slightly different strategy for the synthesis of key building blocks **33** and **35**, needed for the 17- and 18-membered rings, respectively, was adopted, which required fragments **19**, **21**, and **22**[13] (see Scheme 3).

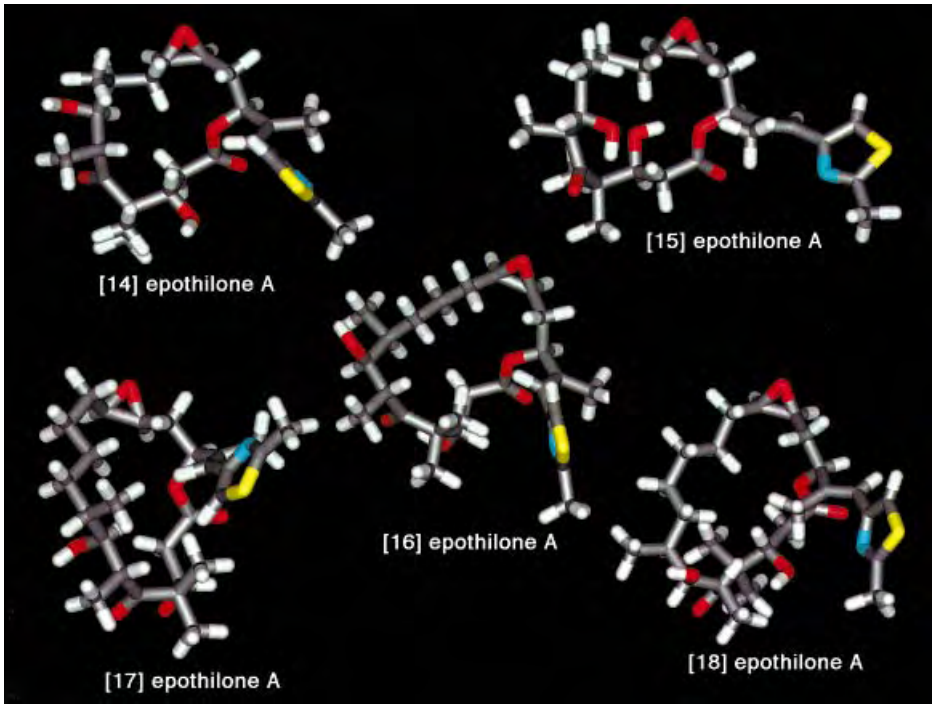
F.), and grants from Merck, DuPont-Merck, Schering Plough, Hoffmann La Roche, and Amgen are acknowledged.



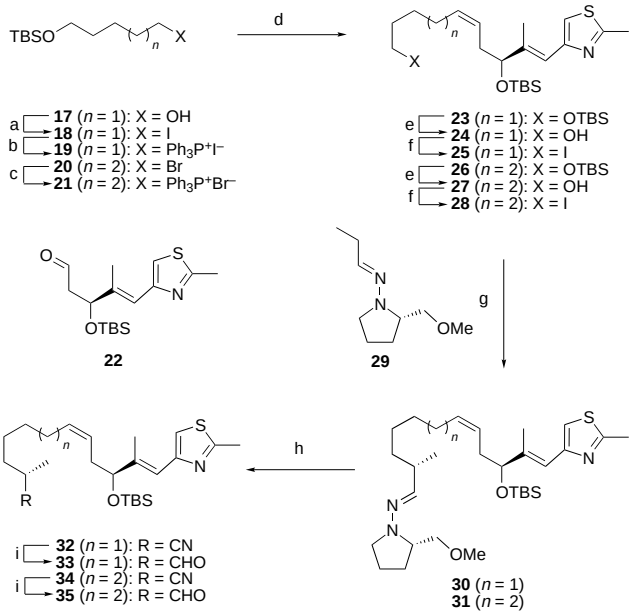


Figure 1. Computer-generated minimum-energy structures of [14]-, [15]-, [16]-, [17]-, and [18]epothilones A. Carbon = gray, hydrogen = white, oxygen = red, nitrogen = blue, sulfur = yellow. Molecular dynamics and minimization calculations (CV Force Field) were performed on a SGI Indigo-2 workstation using the program Insight II (Biosym Technologies Inc., San Diego, CA). Pictures were created with AVS software (AVS Inc., Waltham, MA) and locally developed modules running on a DEC Alpha 3000/500 with a Kubota Pacific Denali graphics card.

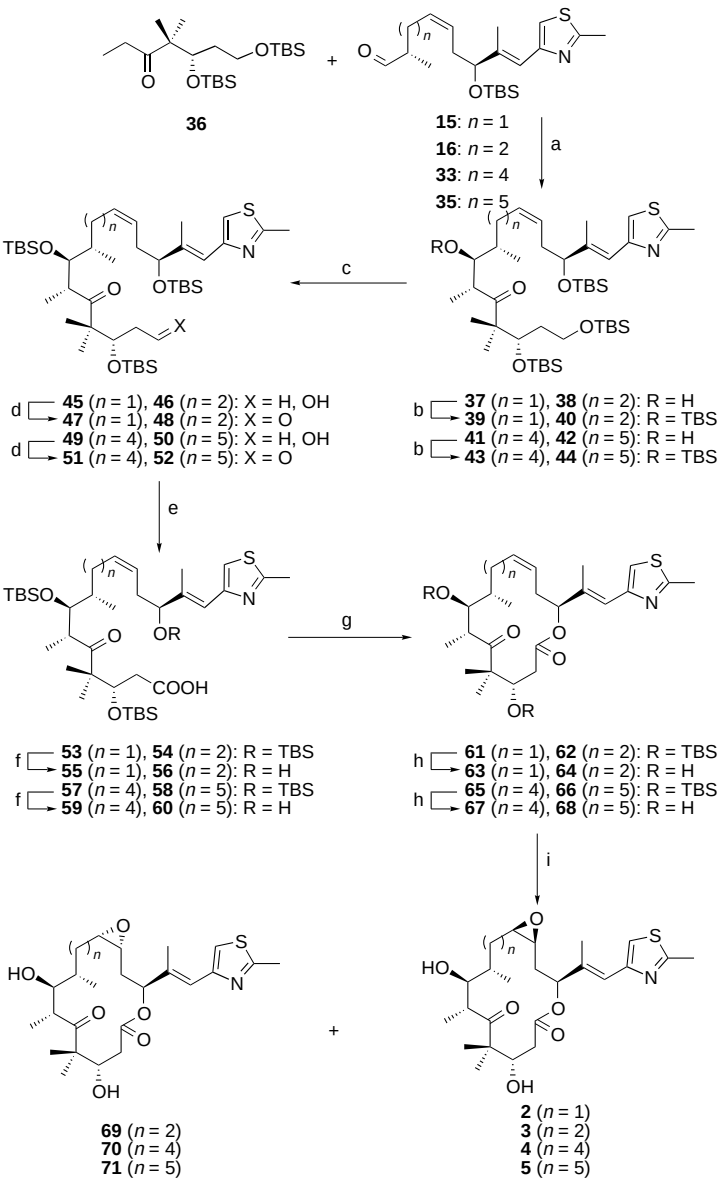
required aldehyde, **7**. Thus, olefination of **6**, hydroboration of the resulting olefin **8**, and oxidation of the formed primary alcohol **9** furnished the desired aldehyde **7** in excellent overall yield (Scheme 2). Each of these two aldehydes (**6** and **7**) was condensed separately with the ylide derived from phosphonium salt **10** (NaHMDS, THF) to afford the corresponding (*Z*) olefins (**11**, 77 % and **12**, 83 %) as the major geometrical isomer in each case (ca. 9:1 ratio). The silyl group was then selectively removed from the primary hydroxyl group by the action of CSA[20] leading to alcohols **13** (81 %) and **14** (61 %). Finally, oxidation of **13** and **14** with $SO_3 \cdot Py$ (DMSO/Et_3N) led to the targeted intermediates **15** and **16** in 81 and 84 % yield, respectively.



The reverse ylide – aldehyde condensation approach shown in Scheme 3 was utilized for the construction of advanced intermediates **33** and **35**. Thus, alcohol **17** was converted into iodide **18** by treatment with Ph_3P/I_2/imidazole (95 %) and thence to phosphonium salt **19** by heating with Ph_3P (neat, 100 °C, 97 %). A similar sequence was used to prepare phosphonium salt **21** from the bromide **20** as the intermediate. The ylides derived from **19** and **21** (NaHMDS, THF) were treated with aldehyde **22** to produce (*Z*) olefins **23** and **26** in 85 and 79 % yields, respectively, as the major isomers ($Z{:}E \approx$ 9:1). Each product, **23** and **26**, was selectively desilylated at the primary position with CSA, furnishing alcohols **24** (99 %) and **27** (95 %), respectively, and then converted into the corresponding iodides **25** (84 %) and **28** (98 %) by exposure to Ph_3P/I_2/imidazole. The iodides **25** and **28** were used to alkylate SAMP hydrazone **29** according to the method of Enders,[21] furnishing compounds **30** and **31** in 60 and 82 % yield, respectively. Each hydrazone (**30** and **31**) was converted into the corresponding nitrile[22] (**32**, 99 % and **34**, 96 %) by reaction with MMPP, and then into the desired aldehydes **33** (90 %) and **35** (81 %) by DIBAL reduction.

Scheme 3. Synthesis of aldehydes **33** and **35**. a) 1.5 equiv I_2, 3.0 equiv imidazole, 1.5 equiv Ph_3P, Et_2O/MeCN (3/1), 0 °C, 0.5 h, 95 %; b) 1.1 equiv Ph_3P, neat, 100 °C, 2 h, 97 %; c) 1.5 equiv Ph_3P, neat, 100 °C, 7 h, 99 %; d) 1.2 equiv **19** or **21**, 1.2 equiv NaHMDS, THF, 0 °C, 15 min; then 1.0 equiv **22**, 0 °C, 15 min, 85 % ($Z{:}E \approx$ 9:1) for **23**, 79 % ($Z{:}E \approx$ 9:1) for **26**; e) 1.0 equiv CSA added portionwise over 1 h, CH_2Cl_2/MeOH (1/1), 0 → 25 °C, 3 h, 99 % for **24**, 95 % for **27**; f) 1.5 equiv I_2, 3.0 equiv imidazole, 1.5 equiv Ph_3P, Et_2O/MeCN (3/1), 0 °C, 0.5 h, 84 % for **25**, 98 % for **28**; g) 1.5 equiv **29**, 1.5 equiv LDA, THF, 0 °C, 16 h; then 1.0 equiv **25** or **28** in THF, −100 → −20 °C, 10 h, 60 % for **30**, or 82 % for **31**; h) 2.5 equiv magnesium monoperoxyphthalate (MMPP), MeOH/phosphate buffer pH 7 (1/1), 0 °C, 1 h, 99 % for **32**, 96 % for **34**; i) 2.0 equiv DIBAL, toluene, −78 °C, 1 h, 90 % for **33**, 81 % for **35**. LDA = lithium diisopropylamide; DIBAL = diisobutylaluminum hydride.

Scheme 4 shows the coupling of the C1–C6 segment **36**[11] with fragments **15**, **16**, **33**, and **35**, and the elaboration of the products to the targeted epothilones. Thus, the (*Z*) enolate

Tf = triflate; TBAF = tetra-*n*-butylammonium fluoride; 4-DMAP = 4-dimethylaminopyridine.

generated from ketone **36** (LDA, THF, −78°C) reacted smoothly with aldehydes **15**, **16**, **33**, and **35** to afford compounds **37** (71%), **38** (72%), **41** (77%), and **42** (60%), respectively, together with their (6*S*,7*R*) diastereoisomers (see Scheme 4 for individual yields), which were removed by silica gel chromatography. These compounds were then silylated (TBSOTf/2,6-lutidine) leading to tetrasilyl ethers **39**, **40**, **43**, and **44** in 85–95% yield. Selective removal of the silyl group from the primary position with CSA led to alcohols **45**, **46**, **49**, and **50**, which were oxidized under Swern conditions [$(COCl)_2$/DMSO/Et_3N] to give the corresponding aldehydes (**47**, **48**, **51**, and **52**) in 85–99% yield. Further oxidation to the desired carboxylic acids (**53**, **54**, **57**, and **58**) was achieved by reaction with $NaClO_2$ (95–98% yield). The carboxylic acids were then selectively desilylated at C-15 by the action of TBAF[8b] producing hydroxy acids **55**, **56**, **59**, and **60** in 77–92% yield. Cyclization of **55**, **56**, **59**, and **60** was accomplished by the Yamaguchi method[23] as previously described for epothilones A and B[8b, 10, 13, 16] to furnish macrocyclic lactones **61**, **62**, **65**, and **66**, respectively, in yields ranging from 70 to 82% (Scheme 4). The silyl ethers were removed from **61**, **62**, **65**, and **66** by exposure to HF · Py in THF, leading to [14]-, [15]-, [17]- and [18]desoxyepothilones **63**, **64**, **67** and **68**, respectively (71–91% yield).

Epoxidation of [14]desoxyepothilone A (**63**) with methyl (trifluoromethyl)dioxirane[24] gave [14]epothilone A (**2**) essentially as a single product (52% yield), whereas epoxidation of the [15]desoxyepothilone A (**64**) under the same conditions led to a mixture of [15]epothilone A (**3**) and its diastereomeric epoxide **69** (70% yield, ca. 1:1 ratio). The [17]-membered macrolactone **67** furnished diastereomeric epoxides in a 6:1 ratio (97% combined yield) and the [18]-membered analogue provided products in a 2:1 ratio (79% total yield). In all cases the isomeric epoxides were separated by chromatography but their configurations have not yet been assigned.

Preliminary biological investigations with these compounds revealed significant tubulin polymerization activity for [18]desoxyepothilone A (**68**) (40% as compared to 72% for epothilone A and 53% for Taxol), but relatively weak activity for the two epimeric [18]epothilones A (**5** and **71**) and for all [14]-, [15]-, and [17]epothilones A (**63**, **64**, **67**, **2**–**4**, **69**, and **70**) in the filtration–colorimetric tubulin assay.[3] These results provide further support for the limited tolerance of the epothilone pharmacophore and its highly specific binding to the tubulin receptor. Further biological studies with **68** and related compounds are in progress.

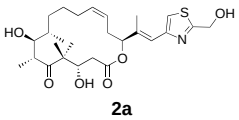
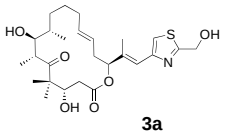
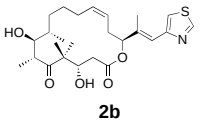
Total Synthesis of Epothilone E and Analogues with Modified Side Chains through the Stille Coupling Reaction**

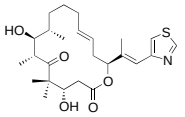
K. C. Nicolaou,* Yun He, Frank Roschangar, N. Paul King, Dionisios Vourloumis, and Tianhu Li

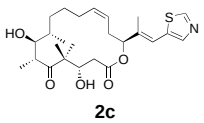
The epothilones are a growing class of naturally occurring antitumor agents[1–3] whose importance is clearly reflected in the increasing number of publications reporting on their total synthesis,[4–11] analogue construction,[4–16] and biological activity.[1, 3, 4, 5b, 8, 9, 12, 15–17] Here we report the first total synthesis of the naturally occurring epothilone E (**1**, Scheme 1)[16] in

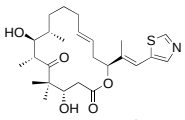


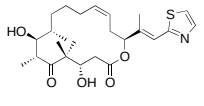


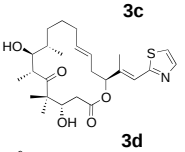


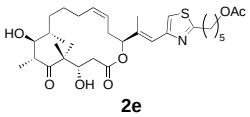


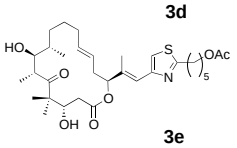


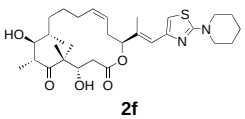


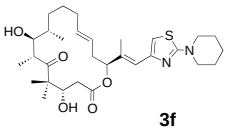


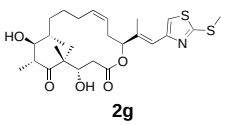


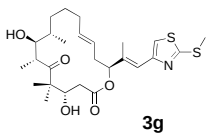


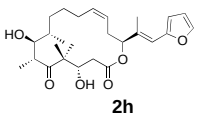


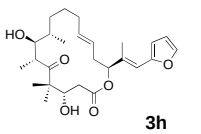


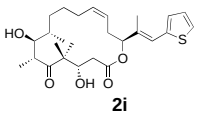


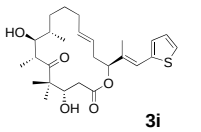


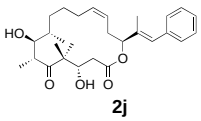


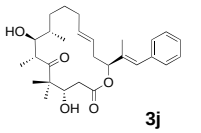


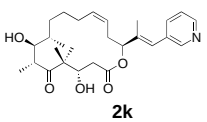


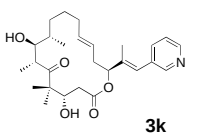












Scheme 1. Retrosynthetic analysis and strategy for the total synthesis of epothilone E (**1**) and analogues with modified side chains. (Ar) = aromatic moiety.

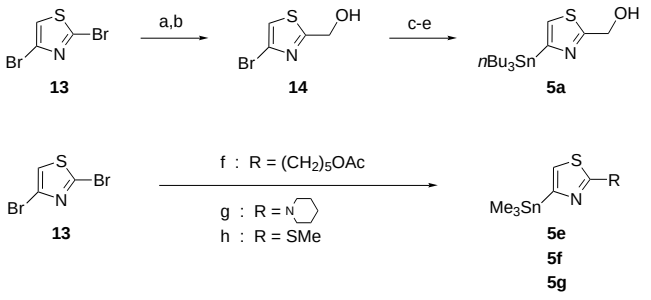
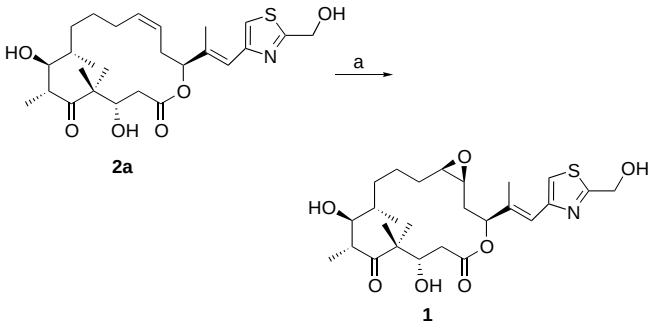
[a] See Scheme 2.



which an olefin metathesis reaction[4a, 5b, 6a, 7, 10, 13, 18, 19] is used to form the macrocycle and a Stille coupling[20] to construct the side chain. In addition, the developed strategy was applied to the synthesis of an analogue library containing a variety of aromatic systems in place of the 2-methylthiazole moiety of natural epothilone A (see Table 1). Scheme 1 outlines, in retrosynthetic format, the highly convergent metathesis/Stille coupling strategy towards epothilone E (**1**) and the new epothilones represented by structures **2** and **3**. The utilization of a common advanced intermediate (e.g. **4**) gives this Stille strategy a distinct advantage in delivering rapidly a plethora of side chain modified epothilone analogues for biological screening.

The epothilones shown in Table 1 were constructed as summarized in Scheme 2. Thus, alcohol **8**, prepared in 91% yield by addition of (+)-allyldiisopinocampheyl borane [(+)-Ipc_2B(allyl)] to the known aldehyde **6**,[21] was coupled with carboxylic acid **7**[10] (3:2 mixture with its C6,C7 diastereomer) with DCC and 4-DMAP to afford ester **9** (49% yield, after chromatographic separation from its C6,C7 diastereomer). Exposure of **9** to catalytic amounts of $[RuCl_2(=CHPh)(PCy_3)_2]$ in CH_2Cl_2 at ambient temperature resulted in a mixture of (*Z*) and (*E*) cycloolefins, which were chromatographically separated on silica gel (flash column, hexanes/ethyl acetate 9/1): **10** [R_f = 0.47, (hexanes/ethyl acetate 82/18), 35% yield]; **11** [R_f = 0.53, (hexanes/ethyl acetate 82/18), 30% yield]. Desilylation of **10** and **11** was then achieved with HF·Py in THF, leading to diols **4** (Table 2) (84%) and **12** (85%), respectively.

The required stannanes were either commercially available (**5h**, **i**), synthesized according to literature procedures (**5b–d**, **5j**, **k**),[22] or prepared by the sequences shown in Scheme 3. For the synthesis of epothilone E (**1**), dibromide **13**[23] was selectively metalated with *n*BuLi and then treated, in the presence of HMPA, with dimethylformamide (DMF); after reduction with $NaBH_4$ alcohol **14** was obtained in 63% overall yield. Protection of **14** as a silyl ether (TBSCl, imidazole, 96% yield) followed by a second metalation (*n*BuLi), exposure to nBu_3SnCl (85% yield), and desilylation with TBAF furnished stannane **5a** (95% yield). The synthesis of stannane **5e** required: 1) Sonogashira coupling of dibromide **13** with 4-pentyn-1-ol ($[Pd(PPh_3)_4]$/CuI, iPr_2NH, 70°C, 83% yield);[24] 2) chemoselective hydrogenation of the triple bond (cat. PtO_2/H_2, 100% yield); 3) acetate formation (Ac_2O, pyridine, 83% yield); and 4) reaction with $Me_3SnSnMe_3$/cat. $[Pd(PPh_3)_4]$ (toluene, 100°C, 93% yield). Stannane **5f** was prepared from dibromide **13** by reaction with piperidine (60°C, 100% yield), followed by palladium-catalyzed coupling with $Me_3SnSnMe_3$ ($[Pd(PPh_3)_4]$, toluene, 80°C, 100% yield). Similarly, **5g** was obtained from **13** by reaction with NaSMe (EtOH, 25°C, 94% yield) followed by the coupling (100% yield).



Scheme 2. Synthesis of intermediates **4** and **12** and desoxyepothilones **2** and **3**. a) 1.2 equiv (+)-Ipc$_2$B(allyl), Et$_2$O, −100°C, 0.5 h, 91%; b) 2.0 equiv **8**, 1.5 equiv DCC, 1.5 equiv 4-DMAP, toluene, 25°C, 12° h, 49% **9** and 33% of its (6*S*,7*R*) diastereomer; c) 10 mol% [RuCl$_2$(=CHPh)(PCy$_3$)$_2$], CH$_2$Cl$_2$, 25°C, 20 h, 35% **10** and 30% **11**; d) 10 equiv HF·Py, THF, 25°C, 30 h, **4** (84%); **12** (85%); e) procedure A: 1.5 equiv **5**, 10 mol% [Pd(PPh$_3$)$_4$], toluene, 100°C, 20 min; procedure B: 1.5 equiv **5**, 10 mol% [Pd(MeCN)$_2$Cl$_2$], DMF, 25°C, 10 h, see Table 1. TBS = *tert*-butyldimethylsilyl; DCC = dicyclohexylcarbodiimide; 4-DMAP = 4-dimethylaminopyridine; Py = pyridine.

Scheme 3. Preparation of stannanes **5a**, **5f**, **5g**, and **5e**. a) 1.1 equiv *n*BuLi, 1.2 equiv DMF, 1.1 equiv HMPA, −78→25°C, 2 h, 72%; b) 2.0 equiv NaBH$_4$, MeOH, 25°C, 20 min, 88%; c) 1.5 equiv TBSCl, 2.0 equiv imidazole, 25°C, 0.5 h, 96%; d) 1.2 equiv *n*BuLi, 1.2 equiv *n*Bu$_3$SnCl, −78→25°C, 2 h, 85%; e) 1.2 equiv TBAF, THF, 25°C, 20 min, 95%; f) 1. 2.0 equiv HCC(CH$_2$)$_3$OH, 0.05 equiv [Pd(PPh$_3$)$_4$], 0.1 equiv CuI, *i*Pr$_2$NH, 70°C, 2 h, 83%; 2. H$_2$, 0.1 equiv PtO$_2$, EtOH, 25°C, 4 h; 100%; 3. Ac$_2$O, pyridine, 25°C, 83%; 4. 10 equiv Me$_3$SnSnMe$_3$, 0.1 equiv [Pd(PPh$_3$)$_4$], toluene, 100°C, 3 h, 93%; g) 1. 10 equiv piperidine, 60°C, 6 h, 100%; 2. 10 equiv Me$_3$SnSnMe$_3$, 0.05 equiv [Pd(PPh$_3$)$_4$], toluene, 80°C, 3 h, 100%; h) 1. 3.0 equiv NaSMe, EtOH, 25°C, 2 h, 94%; 2. 10 equiv Me$_3$SnSnMe$_3$, 0.05 equiv [Pd(PPh$_3$)$_4$], toluene, 80°C, 3 h, 100%. HMPA = hexamethylphosphoramide; TBAF = tetra-*n*-butylammonium fluoride.

Attachment of the aromatic moieties onto the macrocyclic framework of vinyl iodides **4** and **12** was performed with the aromatic stannanes shown in Table 1 by means of palladium-catalyzed Stille couplings under conditions A ([Pd(PPh$_3$)$_4$], toluene, 100°C) or B ([Pd(MeCN)$_2$Cl$_2$], DMF, 25°C). Table 1 includes a selection of the synthesized epothilone A analogues, the coupling method, and the yields.

Epothilone E (**1**) (Table 2) was synthesized from its deoxy analogue **2a** (Table 2) by epoxidation with H$_2$O$_2$/KHCO$_3$/CH$_3$CN in methanol[13] as shown in Scheme 4 (65% yield, based on 50% conversion). Synthetic **1** exhibited identical ^{1}H and ^{13}C NMR spectra to those of the natural substance.[25] Epothilone E (**1**) exhibited 52% tubulin polymerization as compared to 76% for epothilone A, 98% for epothilone B, and 50% for Taxol in the filtration–colorimetric tubulin polymerization assay.[3]

Scheme 4. Synthesis of epothilone E (**1**). a) 33 equiv H$_2$O$_2$, 60 equiv CH$_3$CN, 9.0 equiv KHCO$_3$, MeOH, 25°C, 4 h, 65% (based on 50% conversion).

Table 2. Physical data for compounds **4**, **2a**, and **1**.

Novel, Highly Symmetrical Halogen-Centered Polynuclear Lanthanide Complexes: $[Cp_6Yb_6Cl_{13}]^-$ and $[Cp_{12}Sm_{12}Cl_{24}]$**

Winfried P. Kretschmer,* Jan H. Teuben, and Sergei I. Troyanov*

We recently discovered that numerous monocyclopentadienyllanthanide dihalides $[CpLnX_2(thf)_3]$ ($Cp = \eta^5$-C_5H_5) can be readily synthesized as very pure compounds in good yields by using trimethylsilylcyclopentadiene as the alkylating agent [Eq. (a)].[1] In contrast to the metathesis or synpropor-

$$Me_3SiCp + [LnX_3(thf)_n] \xrightarrow[2)\ thf]{1)\ toluene,\ -Me_3SiX,\ -thf} [CpLnX_2(thf)_3] \qquad (a)$$

Ln = La (X = Br, $n = 4$), Ce (Br, 4), Sm (Cl, 3), Yb (Cl, 3)]

tionation reactions reported to date, no coordination of a salt (LiCl, NaCl) nor the often observed multiple alkylation take place.[2,3]

The occurrence of distinct color changes during the synthesis (e.g. colorless →violet →orange in the case of ytterbium) indicated the presence of intermediates. Similar color changes were also observed earlier, in the synthesis of $[CpYbCl_2(thf)_3]$.[4] Recrystallization of the sparingly soluble residues, obtained after alkylation in toluene, led to compounds **1** and **2**, which contain very little or no THF, respectively. Single crystals of **1** and **2** could be reproducibly obtained by treating the THF adducts $[CpLnCl_2(thf)_3]$ (Ln = Sm, Yb) with hot toluene and simultaneous removal of the evolved tetrahydrofuran by distillation.

$[CpYbCl_2] \cdot {}^1/_3\,thf \cdot {}^2/_9\,toluene$ **1**

$[CpSmCl_2] \cdot {}^1/_6\,toluene$ **2**

Complex **1** exhibits an ionic structure, $[Cp_3Yb_3(\mu_3\text{-}Cl)_2(\mu\text{-}Cl)_3(thf)_3][Cp_6Yb_6(\mu_6\text{-}Cl)(\mu\text{-}Cl)_{12}] \cdot 2\,C_7H_8$, built up of trinuclear cations and hexanuclear anions (Figure 1).[5] The cation consists of an equilateral triangle of Yb atoms which are connected by doubly bridging Cl atoms over the edges ($\bar{d}$(Yb – Cl) 2.662 Å) and by triply bridging Cl atoms on either side of the triangular plane ($\bar{d}$(Yb – Cl) 2.764 Å). Three cyclopentadienyl ligands ($\bar{d}$(Yb – Cp_z) 2.29 Å) on one side of the plane and three THF ligands ($\bar{d}$(Yb – O) 2.25 Å) on the other side result in pseudooctahedral coordination for each Yb atom.[6] Thus, the cation can be assigned the quite common M_3X_{11} constitution.[7] The six Yb atoms of the anion in **1**

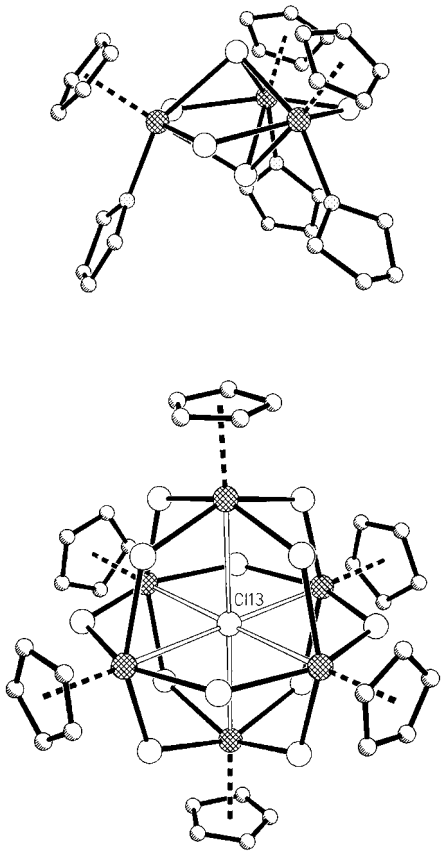

Figure 1. Crystal structure of the trinuclear cation $[Cp_3Yb_3Cl_5(thf)_3]^+$ (top) and the Cl-centered octahedral anion $[Cp_6Yb_6Cl_{13}]^-$ (bottom) of **1**.

delineate an almost regular octahedron, the edges of which are bridged by 12 Cl atoms with nearly equal Yb – Cl bond lengths of 2.61 – 2.67 Å. An additional Cl(13) atom with markedly longer Yb – Cl bond lengths of 3.14 – 3.28 Å lies at the center of the octahedron. The sixth coordination site of each Yb atom is occupied by a cyclopentadienyl ligand ($\bar{d}$(Yb – Cp_z) 2.29 Å). Thus, the anion exhibits uncommon high symmetry. In contrast, other hexanuclear complexes obtained from solutions, such as $[Cp^*_6Sm_6Se_{11}]$ ($Cp^* = \eta^5$-C_5Me_5) and $[\{Nd_3(\mu_3\text{-}OR)(\mu\text{-}OR)_3\}_2(OR)_3(\mu_6\text{-}Cl)]$ exhibit strongly distorted skeletons,[8,9] whereas the symmetrical octahedron in $[K(thf)_4]_2[Cp^s_6Yb_6I_8]$ ($Cp^s = \eta^5$-$C_5Me_4(SiMe_2$-tBu)) is not centered by a halogen and contains divalent Yb ions.[10]

An even greater degree of oligomerization than that attained in **1** is displayed by complex **2** $[Cp_{12}Sm_{12}(\mu_3\text{-}Cl)_{24}] \cdot 2\,C_7H_8$, which is built up from neutral molecules.[11] An X-ray crystal structure analysis showed that twelve $[CpSmCl_2]$ units are linked to produce the whole molecule, whereby the Sm atoms take up an icosahedral arrangement (Figure 2). The total molecular skeleton has 222 crystallographic symmetry with three twofold axes which intersect at the center of the molecule. As a result, only three Sm and six Cl atoms as well as three Cp ligands are crystallographically independent. Each Sm atom has a strongly distorted pentagonal-bipyramidal coordination sphere made up of six Cl atoms and one Cp ligand. Each Cl atom caps a triangle of samarium atoms, so that 20 Cl atoms form an "outer" pentagonal-dodecahedral

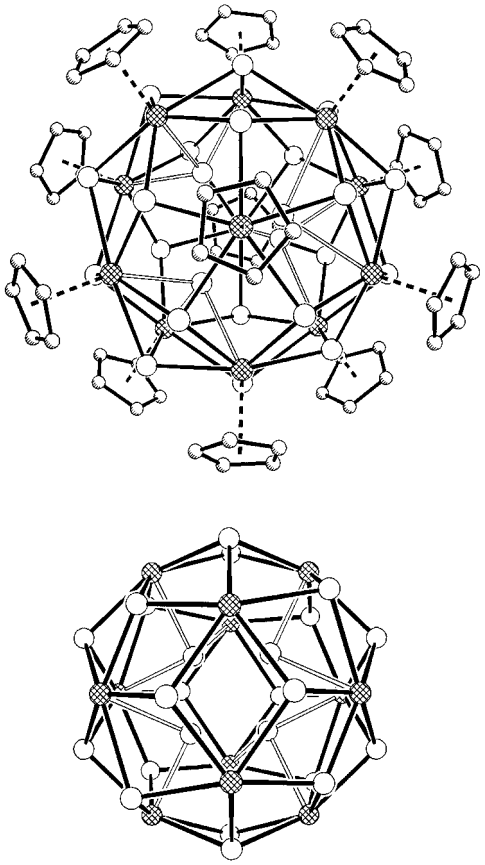

Figure 2. Top: Molecular structure of $[Cp_{12}Sm_{12}Cl_{24}]$ viewed along one of the six fivefold pseudoaxes. Bottom: Structure of the $Sm_{12}Cl_{24}^{-}$ skeleton of **2** with 20 outer and four inner Cl atoms viewed along one of the three twofold axes. The Sm atoms are represented as hatched circles, the Cl atoms as open circles, and the inner Sm–Cl bonds as double lines.

envelope (Sm–Cl_o distances in the range of 2.67–3.09 Å), and the other four Cl atoms form an "inner" tetrahedron(Cl_i–Cl_i 3.29 Å) at the center of the Sm icosahedron (Sm–Cl_i 2.95 Å). The arrangement of the 60 C atoms of the 12 Cp ligands ($\bar{d}$(Sm–Cp_z) 2.36 Å) corresponds to a truncated icosahedron, and is somewhat analogous to the C_{60} fullerene. The overall structure makes the Sm icosahedron unique—not only in lanthanide chemistry.

A comparison of the two complexes very effectively demonstrates the influence of the analogous reactivity of lanthanides with differing ionic radii on the structure. Thus, a pseudooctahedral environment (CN = 6) is a structural feature of monomeric $[CpLnCl_2(thf)_3]$ complexes, and is independent of the ionic radius.[12] If the bulky THF ligands are exchanged for the smaller μ-Cl atoms with a simultaneous elongation of the bond lengths, this leads to an increase in the coordination number from six to seven. This is the case in the analogous π-arene complexes $[(\eta^6\text{-arene})Ln(AlCl_4)_3]$, in all of which the Ln atom has a pentagonal-bipyramidal coordination sphere consisting of six μ-Cl atoms (between Ln and Al) and one arene ligand.[13] However, the coordination number seven can only be attained by the $[CpLnCl_2]$ complexes if each terminal Cl atom of the monomer becomes a μ_3-Cl atom in the oligomer. These conditions are excellently fulfilled in the Sm icosahedron, which, along with the pentagonal symmetry, also provides a cavity large enough to accommodate four Cl atoms. On the other hand, the smaller Yb ions ($r_{Yb} = 0.925$ Å, $r_{Sm} = 1.020$ Å for CN = 7)[14] prefer an octahedral Yb_6 arrangement with CN = 6.

The new compounds **1** and **2** prove very impressively, that in spite of analogous reactivity the lanthanides are capable of a rich and novel structural chemistry. It is expected that a systematic investigation of the removal of THF from the mononuclear monocyclopentadienyl compounds should lead to the isolation of new types of multinuclear complexes for the whole series of lanthanides.

Experimental Section

All the preparative work was carried out under an N_2 atmosphere.

1: A suspension of $[YbCl_3(thf)_3]$ (2.73 g, 5.5 mmol) and $C_5H_5SiMe_3$ (0.84 mL, 5 mmol) in toluene (50 mL) was heated at reflux for 24 h. After removal of the solvent under vacuum, the residue was washed with toluene until it was only slightly colored and then recrystallized from toluene. Slow cooling of the solution to room temperature gave violet prisms, which were filtered and dried under vacuum. Yield: 0.90 g (51 %). Elemental analysis $C_{71}H_{85}Cl_{18}O_3Yb_9$: calcd (found) C 26.80 (27.01), H 2.67 (2.78); IR (KBr, Nujol): $\tilde{\nu}$ [cm^{-1}] = 3097, 3081, 1688, 1681, 1673, 1651, 1038, 1012 (vs), 919, 854 (vs), 794 (vs), 788 (vs), 736, 694, 464.

2: A suspension of $[CpSmCl_2(thf)_3]$ (0.20 g, 0.4 mmol) in toluene (20 mL) was heated at reflux for 24 h with simultaneous removal of the solvent by distillation. The residue was repeatedly extracted with toluene (10 mL) at 80 °C until orange crystals formed. The liquid was decanted, and the crystals washed with a little toluene and dried under vacuum. Yield: 0.044 g (35 %).

Synthesis of the Trinaphthophenalenium Cation**

Masahiko Suenaga,* Yuji Miyahara, Nobujirou Shimizu, and Takahiko Inazu

The unique feature of odd-alternant hydrocarbons (i.e., polycyclic hydrocarbons with alternating double bonds and an odd number of carbon atoms), is the readily interconvertible redox triad (cation – radical – anion), which has been the subject of many experimental and theoretical studies. Recently we have disclosed a novel synthetic approach[1] to extended phenalenones as potential precursors of the corresponding odd-alternant hydrocarbons. Here we report the application of this method to the synthesis of the hitherto unknown trinaphthophenalenium cation **4**, a cation of a novel C_{3h}-symmetric odd-alternant hydrocarbon.

Treatment[2] of 7*H*-benzo[*hi*]chrysen-7-one (**1**)[3] with 7-methoxy-1-naphthyllithium (prepared from 7-methoxy-1-naphthyl iodide[4, 5] and *n*BuLi in ether at room temperature) and autooxidation of the resulting adduct in the usual workup afforded 6-(7-methoxy-1-naphthyl)-7*H*-benzo[*hi*]chrysen-7-one (**2**)[6] in 75% yield (Scheme 1). This molecule contains the necessary number of carbons for the construction of the desired trinaphthophenalene skeleton. The methoxy group was deliberately introduced to serve as an auxiliary in the following three key steps of the condensation to the target structure. First, it acts as an electron-donating group to make position 8 reactive enough to react with the central carbonyl group to give **3**. Second, it stabilizes the adjacent cationic center as shown in **3** to increase the chance for the ring-closing condensation with the facing benzene ring. Finally, it can leave as methanol to provide the trinaphthophenalenium cation **4**. Our system worked as beautifully as we had originally conceived.

The reaction proceeded in steps and we could isolate the intermediate **3** as a blue-violet solid after heating **2** in 30% HBr/HOAc at 95°C for 1 h. Although **3** was not fully characterized, the presence of 16 different aromatic protons and three methyl protons in the ^{1}H NMR spectrum supports the proposed structure. When the reaction temperature was increased to 110°C, the final transannular condensation occurred very smoothly to furnish trinaphthophenalenium trifluoroacetate **4** · CF_3COO as a dark violet solid (71% from **2**) after chromatographic purification (silica gel, CF_3COOH).

The characteristic absorption of **4** in acetonitrile ($\lambda_{max}(\varepsilon) =$ 568 (10400)) supports its extensively delocalized π system. The ^{1}H NMR spectrum[7] of **4** consists of four doublets at $\delta =$ 9.74, 9.42, 9.05, and 9.02 and one triplet at $\delta = 8.65$ in accord with the expected C_{3h} symmetry. The FAB mass spectrum (**4** in CF_3COOH/*m*-nitrobenzyl alcohol matrix) shows a peak for the trinaphthophenalenium cation at *m*/*z* 387.1172 (calcd for $C_{31}H_{15}$: 387.1174). As a measure of the thermodynamic stability of the trinaphthophenalenium cation, its pK_{R+} value was determined by spectrophotometric titration in buffered 50% aqueous acetonitrile. Although the titration curve was discontinuous[8] between pH 2.65 and 2.96, the preliminary pK_{R+} value was estimated to be roughly 4.2. Therefore, the stability of cation **4** is comparable to that of the tropylium ion ($pK_{R+} = 4.7$).

The electrochemical behavior of **4** was examined by cyclic voltammetry using a microelectrode (Table 1). Two quasi-reversible redox waves were observed. While the first reduction potential is much higher than that of phenalenium ion, the reverse is true with the second reduction potential. The electrochemical properties of the trinaphthophenalenium system are consistent with the results of semiempirical calculations.[11, 12] Thus, while the LUMO energy of cation **4** (−6.04 eV) is higher than that of phenalenium cation

Parallel Differentiated Recognition of Ketones and Acetals**

Jian-xie Chen and Junzo Otera*

Integration of multistep chemical reactions into one-pot reactions is of great significance from both economical and ecological points of view. A number of one-pot processes, which are named tandem, cascade, domino reactions, etc., have received much attention.[1–3] In these protocols, similar or different types of reactions are performed in sequence without isolating intermediates. This strategy is particularly elegant in that the preceding reaction creates the necessary functionality for the subsequent one. Accordingly, the relevant reaction sites are inherited from one step to the next. In practical synthesis, however, we often need to carry out chemical transformations on separate reaction sites within a molecule. Conventionally, such transformations have been executed in a stepwise, not a one-pot, manner. If the manifold reactions could be performed simultaneously (that is, in parallel), the process would be efficient and expeditious [Eq. (1)]. Here we wish to advance a new concept based on

(1)

such parallel (or horizontal) treatment rather than the conventional series (or vertical) strategy.

To arrive at the ultimate goal of parallel recognition [Eq. (1)], we require a new concept of chemoselectivity in which a mixture of substrates A and B reacts with a mixture of reagents X and Y to furnish products A–X and B–Y exclusively or predominantly over other possible products [Eq. (2)]. The requirement would be satisfied if product AX could be formed predominantly over BX in the competition reaction of substrates A and B with reagent X [Eq. (3)] and

$$\mathrm{A + B + X + Y \longrightarrow A\text{–}X + B\text{–}Y} \qquad (2)$$

$$\mathrm{A + B + X \longrightarrow A\text{–}X\ (+B\text{–}X)} \qquad (3)$$

$$\mathrm{A + B + Y \longrightarrow B\text{–}Y\ (+A\text{–}Y)} \qquad (4)$$

BY in preference to AY in the reaction with reagent Y [Eq. (4)]. To our knowledge, no such treatment has been put forth intentionally, although the analogous selectivity might have incidentally resulted from unintentional performances on rare occasions.[4]

For reaction (2) to occur efficiently the substrates A and B should be similar to each other in chemical reactivity, so that reactions (3) and (4) can proceed under the identical reaction conditions. They should simultaneously undergo different reactions irrespective of the other. The reagents X and Y also

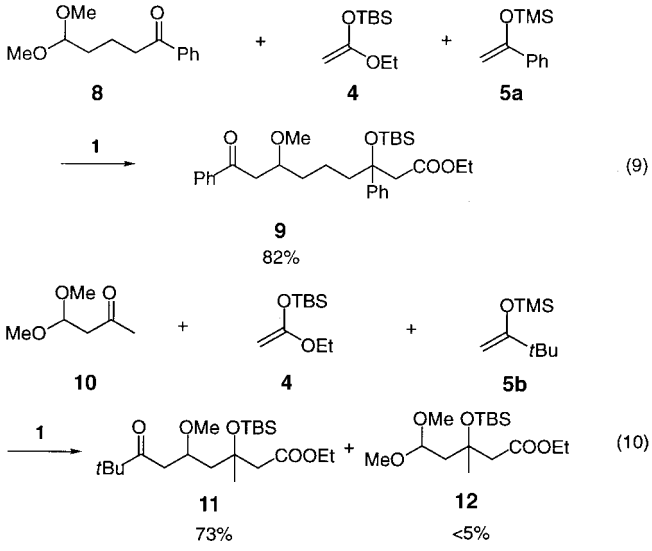
need to work in this way. In studies on synthetic applications of organotin Lewis acids we disclosed that bis(pentafluorophenyl)tin dibromide (**1**)[5] effects the Mukaiyama–aldol reaction of ketene silyl acetal **4** with ketones **2** quite smoothly [Eq. (5), TBS = *tert*-butyldimethylsilyl; Table 1]. These are the first examples, to our knowledge, in which ketones are successfully activated by an organotin Lewis acid. In addition, no reaction occurs with acetals **3** under the same reaction conditions. As a result, the competition reaction between acetophenone (**2a**) and benzaldehyde dimethyl acetal (**3a**) towards **4** furnishes ketone adduct **6a** exclusively (Eq. 6),[6] satisfying the condition for Equation (3). On the other hand, reaction of enol silyl ether **5a** derived from acetophenone led



to the totally opposite outcome, giving acetal aldolate **7a** exclusively [Eq. (7), TMS = trimethylsilyl],[7] satisfying the condition for Equation (4). With these results in hand, we treated a mixture of **2** and **3** with a mixture of **4** and **5** [Eq. (8)].[8] A clean reaction took place, and the catalyst indeed fulfilled a double role. As shown in Table 2, only the doublet **6** and **7** emerged, and no products derived from other combinations were detected at all.

Table 2. Chemospecific parallel reactions (8).

[a] Yields of **6** based on **4** and of **7** based on **3** were determined by gas chromatography. [b] 72% yield of isolated product. [c] 61% yield of isolated product.

This protocol was successfully applied to an intramolecular reaction. Keto acetals **8** and **10** were exposed to a mixture of enol silyl ethers **4** and **5** in the presence of **1** [Eqs. (9) and (10)].[9] As sole product **9**[10] was obtained in reaction (9), while reaction (10) provided a small amount of monoconverted product **12** in addition to major product **11**. Never-

theless, the complete parallel chemospecificity held in these cases as well.

We have already revealed the synthetic usefulness of weak Lewis acidity of organotin catalysts.[5, 11–13] It is the weak acidity of **1** that has enabled the parallel recognition. Its weak Lewis acidity is essential for detecting the subtle differences between ketone and acetal. Somewhat similar but actually different selectivity was found with a $Bu_2Sn(OTf)_2$ catalyst: Mukaiyama–aldol reaction of both **4** and **5** with acetal **3** took place smoothly but no reaction with ketone **2**.[11] Apparently, this catalyst succeeded in differentiating the substrates to some extent but failed to differentiate between reagents **4** and **5**. Moreover no preference for ketone over acetal was observed. This contrast well illuminates the unique activities of **1**.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0092 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 1/2

The intramolecular version is significant from a synthetic point of view, because it has potential as a new strategy for highly expeditious chemical processes. The following advantages are apparent for the parallel treatment: 1) No special elaboration on substrates is required. 2) Reactions that are commonly encountered in organic synthesis are employable. Needless to say, the carbonyl differentiation is not the only method suitable for this concept. 3) Conceivably, the scope will be expanded to a wider range where more than two parallel transformations are performed.

Promotion of multifold reactions by a single catalyst is of great importance. In some sequential reactions, catalysts work for more than one reaction,[14–18] yet each step involves a single reaction; hence, the catalysts are not required to promote several reactions simultaneously. On the other hand, the parallel recognition demands that the catalysts effect simultaneous reactions in a exclusive manner. Many catalysts, however, are available that can activate different types of reaction, and, accordingly, the concept of parallel recognition will find a variety of applications if the reaction conditions are suitably adjusted.

Experimental Section

General intermolecular parallel recognition: To a dichloromethane solution (3 mL) of **1** (31 mg, 0.05 mmol) was added a solution of ketone **2** (2.5 mmol) and acetal **3** (0.5 mmol) in dichloromethane (2 mL) at $-78^{\circ}C$. Then, a dichloromethane solution (2 mL) of **4** (0.5 mmol) and **5** (0.65 mmol) was added. The reaction mixture was stirred at this temperature for 4 h. Water (2 mL) was added to this solution. The reaction mixture was extracted with dichloromethane, and the extract washed with water and brine. The organic layer was dried (Na_2SO_4), and the solvent removed. The crude product thus obtained was analyzed by GLC.

Example of typical intramolecular parallel recognition: To a dichloromethane solution (5 mL) of **1** (122 mg, 0.2 mmol) and keto acetal **8** (122 mg, 0.55 mmol) was added a solution of **4** (101 mg, 0.5 mmol) and **5a** (384 mg, 2.0 mmol) in dichloromethane (2 mL) at $-78^{\circ}C$. The reaction mixture was stirred at this temperature for 7 h, after which water was added. The reaction mixture was extracted with dichloromethane, and the extract washed with water and brine. The organic layer was dried (Na_2SO_4), and the solvent removed. The residue was chromatographed on silica gel (eluent hexane/ethyl acetate 8/1) to give **9** (210 mg, 82 %). This compound was stirred in HF/CH_3CN solution at room temperature for 7 h. Usual workup and column chromatography quantitatively furnished the desilylated product (ethyl 8-benzoyl-3-hydroxy-7-methoxy-3-phenyloctanoate): ^1H NMR ($CDCl_3$): $\delta = 1.07$ (t, 3H, $J = 7.1$ Hz, CH_3), 1.42–1.82 (m, 6H, $3CH_2$), 2.77–3.24 (m, 4H, $2CH_2$), 3.25, 3.26 (1:1 mixture of diastereomers; s, 3H, OCH_3), 3.78 (m, 1H, CH), 4.00 (q, 2H, $J = 7.1$ Hz, CH_2), 4.40 (br., 1H, OH), 7.20–7.57 (m, $8H_{arom}$), 7.91 (m, $2H_{arom}$); ^{13}C NMR ($CDCl_3$): δ[19] = 13.85, 19.01 (19.07), 34.25 (34.35), 42.99 (43.06), 45.28 (45.33), 57.11, 60.62, 74.88, 77.28, 124.92, 126.67, 128.05 (128.08), 128.47, 132.98, 137.18, 145.15, 145.19, 172.77, 198.90; HRMS calcd for $C_{24}H_{31}O_5$ [$(M+1)^+$] 399.2171, found 399.2188; C,H analysis calcd. for $C_{24}H_{30}O_5$: C 72.34, H 7.59; found: C 72.39, H 7.34.

11: ^1H NMR[20] ($CDCl_3$): $\delta = 0.07$ (s, 3H, CH_3), 0.08 (s, 3H, CH_3), 0.83 (s, 9H, *t*Bu), 1.12 (s, 9H, *t*Bu), 1.24 (t, 3H, $J = 7.1$ Hz, CH_3), 1.43 (s, 3H, CH_3), 1.65–1.95 (m, 2H, CH_2), 2.51 (m, 2H, CH_2), 2.54–2.86 (m, 2H, CH_2), 3.24 (s, 3H, OCH_3), 3.89–3.93 (m, 1H, CH), 4.08 (q, 2H, $J = 7.1$ Hz, CH_2); ^{13}C NMR ($CDCl_3$): $\delta = -2.08$ (−1.96),[19] 14.16, 18.05, 25.75, 26.08, 27.40, 42.34, 44.30, 47.10, 48.57, 56.58, 60.08, 73.99, 74.46, 170.94, 214.16; HRMS: calcd for $C_{20}H_{39}O_5Si$ [$(M - CH_3)^+$] 387.2567, found 387.2558; C,H analysis calcd. for $C_{21}H_{42}O_5Si$: C 62.64, H 10.51; found: C62.87, H 10.68.

12: ^1H NMR ($CDCl_3$): $\delta = 0.09$ (s, 6H, CH_3), 0.84 (s, 9H, *t*Bu), 1.24 (t, 3H, $J = 7.1$ Hz, CH_3), 1.40 (s, 3H, CH_3), 1.87–2.01 (m, 2H, CH_2), 2.51 (m, 2H, CH_2), 3.28 (s, 6H, OCH_3), 4.09 (q, 2H, $J = 7.1$ Hz, CH_2), 4.61 (t, 1H, $J = 5.0$ Hz, CH); C,H analysis calcd. for $C_{16}H_{34}O_4Si$: C 57.45, H 10.24; found C 57.02, H, 9.89.

Phosphinic Acid Induced Reversal of Regioselectivity in Pd-Catalyzed Hydrophosphinylation of Alkynes with $Ph_2P(O)H$**

Li-Biao Han, Ruimao Hua, and Masato Tanaka*

One of the most attractive features of transition metal complex catalyzed addition to carbon–carbon multiple bonds is in the ease of fine-tuning the ligands for better regioselectivities. However, a sharp reversal of the selectivity by fine-tuning the ligand is not always an easy task, since the regioselectivity is usually inherent in the central metal of the catalyst.[1] We recently developed palladium-catalyzed additions of diphenylphosphane oxide to alkynes,[2] which allows efficient preparation of alkenylphosphane oxides of biological and synthetic value.[3] We now report a reversal of the regioselectivity: The selectivity of the addition of $Ph_2P(O)H$ to terminal alkynes, which normally forms (E)-β-adducts selectively,[2] switches in favor of α-adducts simply in the presence of just one drop of $Ph_2P(O)OH$ in the reaction mixture.

As previously reported,[2] when an equimolar mixture of diphenylphosphane oxide and 1-octyne in C_6D_6 was heated at 70 °C for 2 h in the presence of *cis*-$[Me_2Pd(PPhMe_2)_2]$ (5 mol% relative to the substrate), isomeric products **2a** and **1a** were formed in 75% total yield (NMR) in a ratio of 12:88 [Eq. (a)]. Surprisingly the regioselectivity was completely reversed when the same reaction was repeated in the presence of trace diphenylphosphinic acid. Therefore, the reaction in the presence of only 1 mol% of $Ph_2P(O)OH$ (relative to the substrate) resulted in 92% total yield and a **2a**:**1a** ratio of 79:21.[4] The regioselectivity for **2a** was further improved with an increased amount of $Ph_2P(O)OH$ to achieve nearly quantitative formation of the adducts in a ratio of 95:5 in the presence of 5 mol% of $Ph_2P(O)OH$. Besides the phosphinic acid, dibutyl phosphate (92%, **2a**:**1a** = 90:10) and phosphoric acid (89%, **2a**:**1a** = 85:15) also gave **2a** as the major product. However, a similar reversal did not result when hexamethyl phosphoramide (HMPA, 76%, **2a**:**1a** = 13:87), acetic acid (73%, **2a**:**1a** = 20:80), or benzoic acid (76%, **2a**:**1a** = 13:87) was employed.

As Table 1 suggests, the reactions catalyzed by palladium complexes with sterically less demanding and more basic phosphane ligands are more sensitively affected by $Ph_2P(O)OH$. In *cis*-$[PdMe_2(PPh_3)_2]$-catalyzed reactions, for instance, the **2a**:**1a** ratio of 9:91 in the absence of $Ph_2P(O)OH$ increased significantly, but without reversal of the regioselectivity, to 37:63 when 5 mol% of $Ph_2P(O)OH$ was added. On the other hand, as already described, addition of 5 mol% of $Ph_2P(O)OH$ to the *cis*-$[PdMe_2(PPhMe_2)_2]$-catalyzed reaction induced a reversal of the ratio from 12:88 to 95:5. In *cis*-$[PdMe_2(PPh_2Me)_2]$-catalyzed reactions neither decreasing the reaction temperature from 70 to 45 °C nor changing the solvent from benzene to THF affected the regioselectivity.

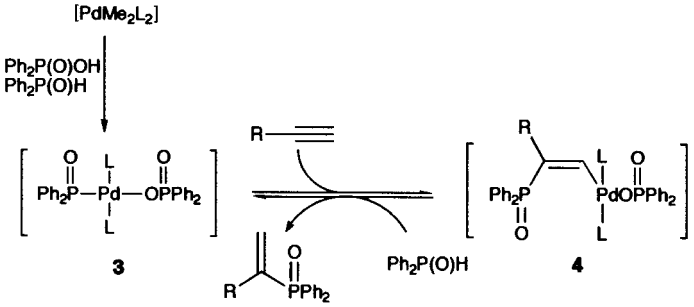

Table 1. Hydrophosphinylation of 1-octyne.[a]

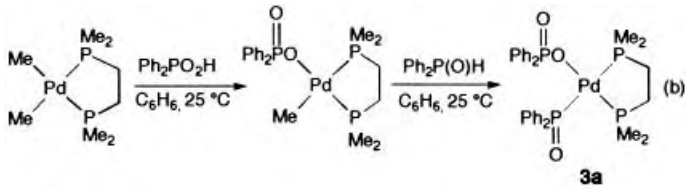
Catalyst	Conditions	Yield [%] with $Ph_2P(O)OH$ (**2a**:**1a**)[b]	Yield [%] without $Ph_2P(O)OH$ (**2a**:**1a**)[b]
$[Pd(PPh_3)_4]$	70 °C, 3 h	89 (33:67)	54 (8:92)
cis-$[PdMe_2(PPh_3)_2]$	70 °C, 3 h	73 (37:63)	43 (9:91)
cis-$[PdMe_2(PPh_2Me)_2]$	70 °C, 3 h	100 (84:16)	56 (10:90)[c]
cis-$[PdMe_2(PPhMe_2)_2]$	70 °C, 2 h	93 (95:5)	75 (12:88)
$[PdMe_2(PEt_3)_2]$[d]	70 °C, 2 h	95 (91:9)	51 (13:87)
$[PdMe_2(dmpe)]$[e]	100 °C, 6 h	93 (92:8)	0

[a] All reactions were conducted in a sealed NMR tube with equimolar amounts of $Ph_2P(O)H$ and 1-octyne (0.25 mmol) dissolved in C_6D_6 (0.5 mL) in the presence of 5 mol% of Pd catalyst. [b] In the presence of 5 mol% of $Ph_2P(O)OH$. The yields for the reactions with and without $Ph_2P(O)OH$ were determined by NMR spectroscopy. [c] Reaction time = 2.5 h. [d] *cis*:*trans* = 1:1. [e] dmpe = 1,2-bis(dimethylphosphino)ethane.

$Ph_2P(O)OH$ also enhances the catalytic activity. For example $[PdMe_2(dmpe)]$, which was nearly inactive in the absence of $Ph_2P(O)OH$, catalyzed the addition at 100 °C. Activities of other palladium–phosphane complexes were also boosted (see Table 1). A seemingly puzzling aspect is that even 1% of $Ph_2P(O)OH$ was sufficient to reverse the regioselectivity, despite a larger quantity (5%) of *cis*-$[Me_2Pd(PPhMe_2)_2]$ in the reaction system (see above). This is presumably due to a new palladium species that is formed upon addition of the phosphinic acid and is more catalytically active.

The present results strongly indicate that the OH group plays a crucial role in inducing the intriguing effect of $Ph_2P(O)OH$ (and related compounds).[5] We believe that the process shown in Scheme 1 is occurring: 1) generation of a new reactive Pd species **3**, 2) insertion of a C≡C unit into the Pd–$P(O)Ph_2$ bond (phosphinylpalladation) with formation of an alkenylpalladium species **4**, and 3) subsequent protonol-



Scheme 1. Proposed mechanism for the Pd-catalyzed hydrophosphinylation (L = PR_3).

ysis of **4** with $Ph_2P(O)H$[6] leading to the α-adduct with concomitant regeneration of **3**.[7] Protonolysis of a C–Pd bond in the generation of **3** from $[PdMe_2L_2]$ and its regeneration from **4** appears reasonable, since similar protonolyses with various acidic reagents are known.[8] We were able to confirm such reactions with $Ph_2P(O)H$ and $Ph_2P(O)OH$. When $[PdMe_2(PEt_3)_2]$ and $[Ph_2P(O)H]$ (4 equiv) were mixed in C_6D_6 at 25 °C, methane gas immediately evolved, and the colorless solution became pale yellow. The starting material $[PdMe_2(PEt_3)_2]$ disappeared within 0.5 h, and the ^{31}P NMR spectrum displayed signals for a new Pd complex in addition to those for remaining $Ph_2P(O)H$ ($\delta = 17.2$) and free PEt_3 ($\delta = -19.6$). Although the complex could not be isolated, the structure was assigned as $[PdMe\{P(O)Ph_2\}(PPh_2OH)(PEt_3)]$ on the basis of NMR data; the oxygen atoms are linked through an O-H-O hydrogen bond. Likewise, when $Ph_2P(O)OH$ was added to *trans*-$[PdMe_2(PEt_3)_2]$ (1 equiv) in benzene at 25 °C, evolution of methane gas was immediately observed, and a colorless oil of *trans*-$[PdMe\{OP(O)Ph_2\}(PEt_3)_2]$ produced quantitatively.[9] A similar reaction with *cis*-$[PdMe_2(dmpe)]$ allowed isolation of analytically pure *cis*-$[PdMe[OP(O)Ph_2](dmpe)]$ as a white solid. The resulting complex did not react further with excess $Ph_2P(O)OH$, even at 70 °C. Very interestingly, however, protonolysis of the complex with one equivalent of $Ph_2P(O)H$ proceeded readily at room temperature and *cis*-$[Pd\{Ph_2P(O)\}\{OP(O)Ph_2\}(dmpe)]$ (**3a**) was obtained as a white solid in good yield with liberation of another molecule of methane [Eq. (b)].[10] We were unable to detect intermediates formed by insertion of a C≡C unit into the Pd–$P(O)Ph_2$ bond in reactions of **3a** with acetylenes. In strong support of the proposed mechanism shown in Scheme 1, however, **3a** catalyzed the addition of $Ph_2P(O)H$ to 1-octyne at 100 °C in the absence of $Ph_2P(O)OH$; the adducts were obtained in 95% yield (NMR) with a **2a**:**1a** ratio of 90:10 after 10 h, which was in good agreement with the value observed for $[PdMe_2(dmpe)]$-catalyzed addition in the presence of $Ph_2P(O)OH$ (Table 1).

As shown in Table 2, this new recipe for hydrophosphinylation could be generally applied to various aliphatic and aromatic terminal alkynes to afford a variety of 1-alken-2-ylphosphane oxides regioselectively and in good yields. Functionalities such as amino, cyano, and hydroxyl groups were tolerated under the reaction conditions. As exemplified by entry 7, two phosphinyl groups could be efficiently introduced to both C–C triple bonds. Under the reaction conditions an olefinic bond is unreactive with respect to hydrophosphinylation. Accordingly, 1-ethynylcyclohexene (entry 8) underwent selective addition at the triple bond. As for the regioselectivity, the reaction of (trimethylsilyl)acetylene is an exception: Only the terminal carbon atom was phosphinylated, presumably owing to the steric hindrance at the internal carbon atom. Acetylenes with internal C≡C units also reacted, albeit somewhat slowly, to afford the corresponding products selectively. Worth noting from another synthetic viewpoint is that the reaction run in the presence of the phosphinic acid is very clean. On the other hand, reactions carried out without the phosphinic acid resulted in unidentified by-products, in particular at higher temperatures.[2] Applications of the current finding to other transition metal complex catalyzed additions are now under extensive study.

Table 2. Hydrophosphinylation of alkynes.[a]

Entry	Alkyne	Adduct	Yield [%] (**2**:**1**)[b]

10			81 [g]
11			94 [h]

[a] Conditions: equimolar amounts of $Ph_2P(O)H$ and alkyne in benzene (≈ 0.5 M), 3–4 mol% of *cis*-$[PdMe_2(PPhMe_2)_2]$, ≈ 5 mol% of $Ph_2P(O)OH$, 70 °C, 2–4 h. [b] Yields refer to isolated amounts after column chromatography or preparative gel permeation chromatography (GPC). The ratios of isomers were determined by ^1H NMR spectroscopy of the crude reaction mixture. [c] 1 atm CH≡CH, 70 °C, 5 h. [d] Amount of $Ph_2P(O)H$ used = 2.2 equiv. Regioselectivity > 95%. [e] *cis*-$[PdMe_2(PPh_2Me)_2]$ was used as the catalyst. [f] Only the *trans* isomer was formed. [g] Heated for 36 h. [h] Heated for 12 h.

Experimental Section

Catalytic additions of $Ph_2P(O)H$: Diphenylphosphane oxide (202 mg, 1.0 mmol), 1-octyne (110 mg, 1.0 mmol), diphenylphosphinic acid (11 mg, 5 mol%), and *cis*-[$PdMe_2(PPhMe_2)_2$] (12 mg, 3 mol%) were dissolved in dry benzene (2 mL) under argon. The solution was heated at 70 °C for 4 h and evaporated in vacuo to leave a pale yellow oil, which was purified by column chromatography (SiO_2, EtOAc/hexane 1/1) to give the adducts as a colorless oil in 92% combined yield (287 mg, 0.92 mmol, **2a**:**1a** = 95:5). The two regioisomers (**2a** and **1a**) could be isolated by preparative thin layer chromatography (PTLC; silica gel, hexane/EtOAc 2/3; **2a**: 250 mg, 80% yield; **1a**: 11 mg, 4% yield).

2a: Colorless oil. ^{1}H NMR (300 MHz, C_6D_6): δ = 7.77 – 7.83 (m, 4H), 7.05 – 7.16 (m, 6H), 5.60 (d, 1H, J(H,P) = 42.1 Hz), 5.55 (d, 1H, J(H,P) = 20.4 Hz), 2.30 – 2.38 (m, 2H), 1.39 – 1.49 (m, 2H), 1.01 – 1.21 (m, 6H), 0.80 (t, 3H, J = 6.8 Hz); ^{13}C NMR (C_6D_6, 75.5 MHz): δ = 145.8 (J(C,P) = 90.8 Hz), 133.4 (J(C,P) = 99.8 Hz), 132.2 (J(C,P) = 9.3 Hz), 131.5 (J(C,P) = 2.7 Hz), 128.5 (J(C,P) = 11.6 Hz), 127.8 (J(C,P) = 9.6 Hz), 32.6 (J(C,P) = 15.0 Hz), 31.9, 29.2, 28.7 (J(C,P) = 4.9 Hz), 22.9, 14.2; ^{31}P NMR (C_6D_6, 121.5 MHz): δ = 27.9; IR (neat/NaCl): $\tilde{\nu}$ = 3058, 2930, 2860, 1437, 1191, 1120, 940, 727, 696 cm^{-1}. HRMS calcd for $C_{20}H_{25}OP$: 312.1642, found: 312.1624.

1a: White solid, m.p. 68 – 69 °C. ^{1}H NMR (300 MHz, C_6D_6): δ = 7.78 – 7.85 (m, 4H), 7.05 – 7.08 (m, 6H), 6.87 – 7.01 (m, 1H), 6.11 (dd, 1H, J = 16.9, J(H,P) = 25.1 Hz), 1.87 – 1.91 (m, 2H), 1.09 – 1.21 (m, 8H), 0.82 (t, 3H, J = 6.8 Hz); ^{13}C NMR (C_6D_6, 75.5 MHz): δ = 152.2 (J(C,P) = 1.7 Hz), 135.4 (J(C,P) = 92.9 Hz), 131.6 (J(C,P) = 9.5 Hz), 131.3 (J(C,P) = 2.7 Hz), 128.5 (J(C,P) = 11.7 Hz), 123.1 (J(C,P) = 101.8 Hz), 34.6 (J(C,P) = 16.6 Hz), 31.8, 29.1, 28.1, 22.9, 14.2; ^{31}P NMR (C_6D_6, 121.5 MHz): δ = 18.9; IR (KBr): $\tilde{\nu}$ = 2962, 2928, 2856, 1632, 1439, 1185, 1122, 1002, 814, 745 cm^{-1}. HRMS calcd for $C_{20}H_{25}OP$: 312.1642, found: 312.1603.

cis-[PdMe[OP(O)Ph_2](dmpe)]: To a solution of *cis*-[$PdMe_2$(dmpe)] (17.2 mg, 0.06 mmol) in toluene/CH_2Cl_2 (1/1, 6 mL) was added $Ph_2P(O)OH$ (13 mg, 0.06 mmol) at room temperature under nitrogen. As the solid $Ph_2P(O)OH$ gradually dissolved, gas evolution from the solution was observed. A transparent colorless solution was obtained after 1 h at room temperature. Concentration of the solution to about half its volume in vacuo afforded a white precipitate of *cis*-[PdMe[OP(O)Ph_2](dmpe)] (28.6 mg, 0.058 mmol, 97% yield); m.p. 164 °C (decomp). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.26 – 7.94 (m, 10H), 1.74 (br s, 2H), 1.48 – 1.55 (m, 14H), 0.55 (dd, 3H, J(H,P) = 2.2, 8.2 Hz); ^{31}P NMR ($CDCl_3$, 121.5 MHz): δ = 37.2 (d, J(P,P) = 23.0 Hz), 22.6 (s), 21.4 (d, J(P,P) = 23.0 Hz); elemental analysis calcd for $C_{19}H_{29}O_2P_3Pd$: C 46.69, H 5.98; found: C 46.63, H 5.97.

3a: To a solution of *cis*-[$PdMe_2$(dmpe)] (116.4 mg, 0.406 mmol) in benzene (4 mL) was added $Ph_2P(O)OH$ (88.6 mg, 0.406 mmol) at room temperature under nitrogen. Gas evolution was observed immediately. After the mixture was stirred for 6 h at room temperature, a solution of $Ph_2P(O)H$ (82.1 mg, 0.406 mmol) in benzene (3 mL) was slowly added. The reaction mixture was stirred overnight to afford analytically pure **3a** as a white solid (255.1 mg, 0.378 mmol, 93%); m.p. 198 °C (decomp). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.16 – 7.80 (m, 20H), 1.80 (dd, 6H, J(H,P) = 1.8, 12.0 Hz), 1.71 – 1.83 (m, 4H), 1.56 (dd, 6H, J(H,P) = 3.5, 10.2 Hz); ^{31}P NMR ($CDCl_3$, 121.5 MHz): δ = 66.8 (d, J(P,P) = 467.8 Hz), 42.7 (d, J(P,P) = 33.4 Hz), 26.1 (d, J(P,P) = 9.2 Hz), 20.6 (ddd, J(P,P) = 9.2, 33.4, 467.8 Hz); elemental analysis calcd for $C_{30}H_{36}O_3P_4Pd$: C 53.39, H 5.38; found: C 53.57, H 5.68.

[4] In the absence of the catalyst, neither **1a** nor **2a** was obtained under the same conditions.

[5] The possibility of isomerization of **1a** to **2a** catalyzed by $Ph_2P(O)OH$ as the origin of the reversal is readily ruled out, since **1a** did not isomerize to **2a** when heated with $Ph_2P(O)OH$ (13 mol% relative to **1a**) in C_6D_6 at 70 °C for 4 h. Isomerization was also not observed when pure **1a** was added to the solution of the *cis*-[$PdMe_2(PPhMe_2)_2$]-catalyzed reaction of $Ph_2P(O)H$ with 1-octyne in the presence of 5 mol% of $Ph_2P(O)OH$ (Table 1) and reheated at 70 °C for 2 h.

[6] Secondary phosphane oxides exist in two tautomeric forms, P(=O)H and P–OH; the former is dominant in the equilibrium: a) W. J. Bailey, R. B. Fox, *J. Org. Chem.* **1963**, *28*, 531; b) W. J. Bailey, R. B. Fox, *ibid.* **1964**, *29*, 1013; c) L. A. Hamilton, P. S. Landis in *Organic Phosphorus Compounds*, *Vol. 4* (Eds.: G. M. Kosolapoff, L. Maier), Wiley, New York, **1972**, chap. 11.

[7] Hydrophosphinylation of alkynes in the absence of $Ph_2P(O)OH$ proceeds by hydropalladation; see ref. [2].

[9] The reaction of *cis*-[$PdMe_2(PEt_3)_2$] gave the same product. The complex did not react further with excess $Ph_2P(O)OH$ even upon heating at 70 °C for 2 h.

[10] Complex **3a** was similarly obtained when $Ph_2P(O)H$ was added first to [$PdMe_2$(dmpe)] followed by treatment with $Ph_2P(O)OH$.

Molecular Aluminophosphonate: Model Compound for the Isoelectronic Double-Six-Ring (D6R) Secondary Building Unit of Zeolites**

Yu Yang, Mrinalini G. Walawalkar, Jiri Pinkas, Herbert W. Roesky,* and Hans-Georg Schmidt

Dedicated to Professor Herbert D. Kaesz on the occasion of his 65th birthday

One of the main thrusts in the area of advanced materials has been the synthesis of phosphate materials of Al and Ga,[1–5] which can potentially serve as highly organized matrices of tunable pore size and shape. Since the first successful synthesis of aluminophosphate materials in 1982,[1] several groups have synthesized alumino- and gallophosphate materials by hydrothermal routes in the presence of structure-directing agents.[2–5] To understand the local structures of these complex materials, a few soluble model compounds were prepared which can also serve as secondary building

units (SBUs). In particular, we[6–8] and others[9–12] synthesized Group 13 phosphonates as soluble molecular compounds with a) a double-four-ring (D4R or 4–4) core structure with a $M_4O_{12}P_4$ central unit (M = Al, Ga) or b) stable eight-membered ring structures, which are conceived as intermediates during the formation of D4R structures. However, it has not yet been possible to obtain other larger assemblies which resemble the higher SBUs of zeolites. Here we report the first successful synthesis and molecular structure of an aluminophosphonate that is soluble in organic solvents and has an $Al_6O_{18}P_6$ central core which is identical to the double-six-ring (D6R or 6–6) building units found in zeolites.[13]

The reaction of *tert*-butylphosphonic acid[14] with equimolar quantities of $AlMe_3$ in THF/*n*-hexane yields a mixture of $[MeAlO_3PtBu]_6$ (**1**) and $[MeAlO_3PtBu]_4$ (**2**; Scheme 1).

Scheme 1. Synthesis of aluminophosphonates **1** and **2**.

Hexamer **1** is obtained as hexagonal single crystals from the reaction mixture by fractional crystallization at 4 °C. After removal of **1**, tetramer **2** was obtained from the mother liquor as an analytically pure solid. All our previous attempts to prepare aluminophosphonates from alkyl aluminum compounds containing bulky substituents invariably resulted in the tetrameric compound of the general formula $[RAlO_3PR']$.[6–8] In the present case, the smaller methyl substituent on aluminum allows isolation of hexameric **1** along with tetrameric **2**.

The constitution of **1** and **2** can be ascertained unequivocally from their elemental analyses, EI mass spectra, and NMR data. The base peaks observed in the EI mass spectra for **1** ($m/z = 1053$) and **2** ($m/z = 697$) each correspond to the loss of one methyl group. The chemical shift in the ^{31}P NMR spectrum of **2** ($\delta = 17.5$) is consistent with the value for the tetrameric aluminophosphonate $[i\text{BuAlO}_3P t\text{Bu}]_4$ (**3**, $\delta = 16.9$), which could be characterized as a molecular tetramer by single-crystal structure analysis.[6] The ^{31}P NMR signal of **1** ($\delta = 13.4$) is shifted upfield by $\Delta\delta = 4.1$ with respect to that of **2**. Likewise, in the ^1H NMR spectra there are minor differences in the chemical shifts for the methyl and *tert*-butyl protons of **1** and **2**.

The X-ray structure analysis[15] showed that **1** crystallizes in the centrosymmetric triclinic space group with half of the hexamer in the asymmetric unit. The molecular structure (Figure 1) resembles the D6R building units found in

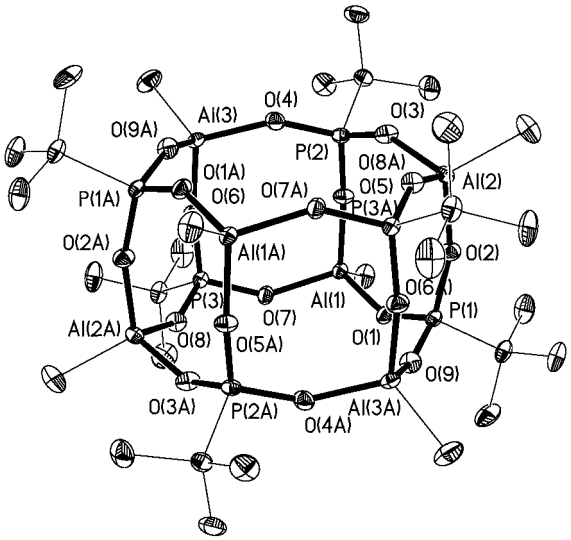

Figure 1. Molecular structure of **1** (thermal ellipsoids for the 20% probability level). Selected bond lengths [Å] and angles [°]: Al–O 1.747(2)–1.757(2) (av 1.752), P–O 1.511(2)–1.519(2) (av 1.515); P(1)-O(1)-Al(1) 149.3(1), P(1)-O(9)-Al(3A) 151.9(1), P(2)-O(3)-Al(2) 148.9(1), P(2)-O(4)-Al(3) 148.8(1), P(3)-O(7)-Al(1) 148.4(1), P(3)-O(8)-Al(2A) 151.2(1), P(1)-O(2)-Al(2) 162.5(1), P(2)-O(5)-Al(1) 166.4, P(3)-O(6)-Al(3) 163.0(1).

phosphate materials such as $AlPO_4$-5, CoAPO-5, CrAPO-5, and SAPO-5.[19]

The central core of the $Al_6O_{18}P_6$ polyhedron can be described as a cylindrical drum in the form of a hexagonal prism whose top and bottom faces are made up of twelve-membered $Al_3O_6P_3$ rings (including the oxygen atoms). The six remaining faces of this cylindrical drum are made up of $Al_2O_4P_2$ rings. All the twelve- and eight-membered rings exist in a crown conformation. The Al–O and P–O bonds within the molecule do not show any variation and are comparable to the corresponding values found for **3** (1.762 and 1.521 Å, respectively). All Al and P centers in the molecule largely have a tetrahedral geometry. The Al-O-P angles in the molecule fall into two different categories: The Al-O-P angles within the twelve-membered rings are much smaller (av 149.8°) than the six Al-O-P linkages that connect the two twelve-membered rings (av 164.0°).

Here we have shown that by tailoring the alkyl groups on aluminum and phosphorus, it is possible to generate bigger building units of aluminophosphate molecular sieves. By a proper balance of steric and electronic factors, it should be possible in the future to synthesize even larger SBUs such as D8R units. We plan to explore these possibilities.

Experimental Section

1 and **2**: A solution of *tert*-butylphosphonic acid (0.30 g, 2.17 mmol) in THF (20 mL) was added dropwise to an equimolar solution of $AlMe_3$ (2 M in hexane, 1.1 mL) in *n*-hexane (20 mL) at 0 °C. The reaction mixture was stirred at room temperature for 16 h and then concentrated to 20 mL in vacuo. The resulting solution was filtered and stored at 4 °C for two weeks to obtain hexagonal colorless crystals of **1** (0.041 g, 10.5%). The crystals, which were suitable for X-ray diffraction studies, were separated from the mother liquor by decantation. The mother liquor contained predominately **2** (0.185 g, 48.1%).

The Mechanism for Hydrogen Abstraction by n,π* Excited Singlet States: Evidence for Thermal Activation and Deactivation through a Conical Intersection**

Werner M. Nau,* Gerhard Greiner,* Julia Wall, Hermann Rau, Massimo Olivucci,* and Michael A. Robb

Salem's correlation diagram for hydrogen abstraction by n,π* excited chromophores,[1] most often depicted for the reaction between formaldehyde and methane, has become the classic textbook example for a theoretical rationalization of photochemical reactivity and for the contrast between the reactivity of singlet and triplet states. According to this diagram the hydrogen abstraction by triplet states proceeds smoothly and with unit efficiency, whereas for singlet states the system is predicted to "pause" at an avoided crossing and then to proceed either to the products or back to the reactants; this reduces the efficiency to below unity.[1,2] While the triplet reaction has received considerable experimental and theoretical attention, the distinct singlet mechanism has not been examined in detail.[3–6]

The intermolecular hydrogen abstraction of the n,π* excited singlet states of ketones is difficult to examine owing to short lifetimes and efficient intersystem crossing. This limitation warrants the choice of an alternative n,π* chromophore. The azoalkane 2,3-diazabicyclo[2.2.2]oct-2-ene (DBO) appeared to be the predestined experimental test case, since excited singlet DBO is very long-lived (up to 1 μs) and undergoes neither intersystem crossing[7] nor efficient photodecomposition (only about 2 %).[8] Moreover, excited singlet azoalkanes are efficiently quenched by C–H and O–H bonds of poor hydrogen donors such as chloroform or methanol.[9–11] This provides a fascinating case of a singlet hydrogen abstraction [Eq. (1)], which we have now elucidated in mechanistic detail. An unexpectedly low activation barrier and a large deuterium isotope effect are observed for chloroform as hydrogen donor. These findings are rationalized in terms of a thermally activated rather than a tunneling process.

(1)

Most importantly, the computed reaction pathway for hydrogen abstraction from C–H bonds by excited singlet azoalkanes involves decay at a conical intersection (i. e., a real surface crossing)[12,13] of the excited- and ground-state energy sheets (Figure 1) rather than the previously implicated

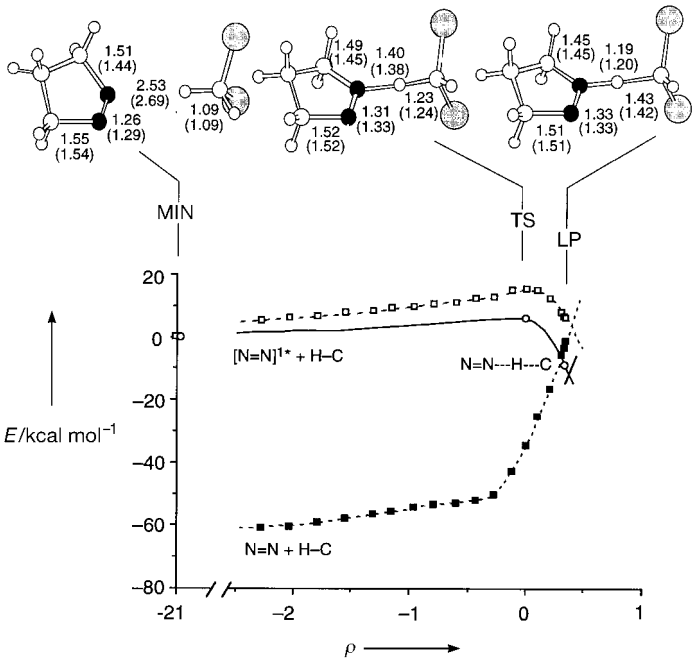

Figure 1. Energy profile along the S_1-(n,π*) reaction coordinate ρ [bohr (amu)$^{1/2}$] describing the hydrogen abstraction in the pyrazoline/CH_2Cl_2 system (see ref. [18] for computational details). Open and filled squares and the associated dashed lines indicate the relative CAS(8,7) energies of the S_1 and S_0 (CI values) states, respectively. Open circles and the solid line present the more accurate CAS(12,10)/PT2F energy profile for the S_1 state. The structures of MIN, TS, and LP [CAS(12,10) and (in parentheses) CAS(8,7) geometrical parameters in Å] document the geometrical progression along the reaction path. The LP point ($S_1 - S_0$ energy gap about 4 kcal mol^{-1}) is taken as representative of the conical intersection.

avoided crossing. The data lead us to propose a mechanism in which the deactivation of n,π* excited singlet azoalkanes is triggered by partial H abstraction from a solvent molecule loosely bound to a nitrogen center. In fact, the hydrogen abstraction on the excited-state surface is aborted at the conical intersection,[13] at which point the system must decay efficiently to the ground-state surface. The radiationless decay is experimentally manifested in low reaction quantum yields.

The decay rate of excited singlet DBO ($1/\tau$) can be analyzed as a composite of the rates of fluorescence (k_f), intramolecular radiationless deactivation (k_d), and intermolecular (solvent-induced) quenching (k_q)—that is, $1/\tau = k_f + k_d + k_q$. The gas-phase fluorescence lifetime[14,15] at ambient temperature (τ_0(DBO) = (930 ± 30) ns) is characteristic for conditions under which the latter process is absent ($1/\tau_0 = k_f + k_d$). In all common solvents, however, the fluorescence lifetime of DBO is shortened, whereas deuterated solvents display a smaller effect. Consequently, solvent-induced quenching (k_q) must be considered ($1/\tau = 1/\tau_0 + k_q$).

As previously corroborated by means of decomposition quantum yields,[9] most solvent-induced quenching of azoalkanes is chemically unproductive and results in radiationless deactivation; for DBO in nonprotic solvents the chemical reaction contributes less than 5%. Nevertheless, from the involvement of C–H bonds in the quenching process and the deuterium isotope effects we conclude that the solvent-induced deactivation must occur along the reaction coordinate for hydrogen abstraction, thus providing an example of an "aborted" hydrogen abstraction. This mechanistic interpretation of the experimental data is corroborated by our theoretical results (see Figure 1).

Chloroform as solvent was examined in experimental detail, since the observed quenching and isotope effects are amongst the largest (Table 1). The fluorescence lifetimes at ambient temperature (22–25 °C) were measured by three techniques (laser flash photolysis, single-photon counting, and streak camera detection) in different laboratories, and consistent results were obtained. The fluorescence quantum yields (Table 1) follow the same trend as the fluorescence lifetimes, and their ratio suggest a natural fluorescence lifetime (τ_n) of (1500 ± 300) ns, which is not significantly different from that in the gas phase (τ_n = (1700 ± 300) ns).[14] Most striking is that the fluorescence lifetime in chloroform is only (13 ± 1) ns, that is, nearly two orders of magnitude shorter than under conditions for which no intermolecular quenching applies (τ_0 = 930 ns). The use of the deuterated solvent ($CDCl_3$) increases the fluorescence lifetime by nearly one order of magnitude ((110 ± 5) ns). The calculated pseudo-unimolecular quenching rate constants k_q (Table 1) substantiate a deuterium isotope effect k_q(H)/k_q(D) of 8–11 at ambient temperature. This value exceeds the kinetic isotope effect expected from energy differences in C–H and C–D stretching vibrations alone (ca. 6), but lies at the upper limit when allowance for bending mode contributions is made (10).[16] This is the largest primary C–H/D isotope effect ever observed for an intermolecular photochemical hydrogen abstraction. For comparison, the isotope effects in the hydrogen abstraction by n,π* excited ketones range from 1–5.[3,4]

Table 1. Fluorescence lifetimes τ and quantum yields Φ for 2,3-diazabicyclo[2.2.2]oct-2-ene (DBO) as well as rate constants k_q and activation parameters for fluorescence quenching.

	Gas phase	$CHCl_3$	$CDCl_3$

The fluorescence lifetimes of DBO in $CHCl_3$ and $CDCl_3$ increase at lower temperatures and decrease upon heating, indicating a thermally activated process. The temperature dependence of the solvent-induced quenching ($k_q = 1/\tau - 1/\tau_0$)[17] was measured from -30 to $+50\,^{\circ}C$ by single-photon counting. The corresponding Arrhenius (Figure 2) or Eyring

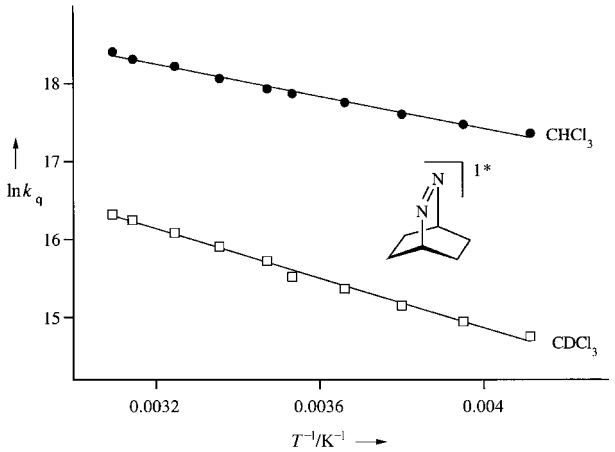

Figure 2. Arrhenius plots for the fluorescence quenching of DBO by $CHCl_3$ and $CDCl_3$ as solvents.

plots, which were linear in the examined temperature range ($r^2 > 0.99$), provide the activation parameters in Table 1. Most importantly, differences in the activation entropy ($\Delta S^{\neq}$) were insignificant, whereas the activation enthalpy ($\Delta H^{\neq}$) increased from 1.5 to 2.6 kcal mol^{-1} upon deuteration. This behavior suggests a classical kinetic isotope effect due to differences in the zero-point energy (ZPE).

The reaction pathway for the intermolecular hydrogen abstraction of an n,π* excited singlet azoalkane was established by ab initio methods.[18] A simpler model reaction, namely that between 1,2-diazacyclopent-1-ene (pyrazoline) and dichloromethane, was selected to allow the use of accurate but expensive computational methodology. It comprises the MCSCF calculation[19] and multireference Møller–Plesset perturbation theory (PT2F),[20] which provides excellent data when tested for other photochemical parameters of azoalkanes (Table 2), namely the 0–0 singlet excitation energy (GS MIN) and the activation energy for α-C–N bond cleavage (TS_α). The same level of theory successfully predicted virtually all experimental aspects of the solvent-induced deactivation of singlet excited azoalkanes, namely the low activation barriers, the isotope effects, and the high efficiency of radiationless deactivation at the expense of product formation.

The computed reaction pathway (see Figure 1) initiates at a loosely bound excited state complex (MIN) in which one of the two dichloromethane C–H bonds lies in the pyrazoline plane and points towards the nitrogen atom containing the "equatorial" unpaired electron; in this complex the geometry of pyrazoline corresponds to that of the isolated n,π* state. The reaction coordinate is initially dominated by the intermolecular distance. After shortening of the H–N distance from 2.5 to 1.6 Å the hydrogen transfer (i. e., simultaneous expansion of the C–H and contraction of the H–N distances) becomes important. Such motion is accompanied by expansion of the N–N bond and shortening of both C–N bonds of pyrazoline. After the transition state (TS) the energy decreases very rapidly. Remarkably, the reaction path does not end at a stationary point (as expected if the previously postulated avoided crossing took place)[1,9] but at a conical intersection (i.e., a singularity) between the excited- (S_1) and ground-state (S_0) potential energy surfaces. This intersection is located near the last calculated point (LP)[18] and about 6 kcal mol^{-1} below the initial complex and provides an extremely efficient channel for radiationless decay. Conceptually, the aborted hydrogen abstraction in Figure 1 presents an example of the minimum →transition state →conical intersection topology, which was documented for intramolecular photoreactions in polyenes and benzene.[13] In this particular topology, access to the radiationless decay channel is thermally controlled.

The energies (Table 2) and vibrational frequencies of the n,π* loosely bound complex and transition state provide a direct comparison of the computed (for the pyrazoline/CH_2Cl_2 model system) and experimentally measured (for DBO/$CHCl_3$) activation parameters. The computed activation enthalpy is 6.4 kcal mol^{-1} but becomes 2.9 kcal mol^{-1} when the ZPE correction is taken into account, and, thus, falls within 1.4 kcal mol^{-1} of the $\Delta H^{\neq}$ observed for the DBO/$CHCl_3$ system. The calculated activation enthalpy for monodeuterated dichloromethane is 0.95 kcal mol^{-1} higher as a consequence of ZPE differences, which is in good agreement with the experimental difference for chloroform (about 1.1 kcal mol^{-1}). Since the experimental and computed isotope effects are only manifested in enthalpic differences, tunneling does not seem to contribute significantly in the examined temperature range. Consequently, the photochemical hydrogen abstraction of excited singlet azoalkanes can be mecha-

Table 2. Calculated[a] and experimental energies for photochemical reactions of the S_1-(n,π*) state of pyrazoline/CH_2Cl_2, pyrazoline, and DBO.

nistically viewed as a thermally activated process, as previously established for many triplet ketones.[4,21]

In conclusion, the combined experimental and theoretical data for the solvent-induced quenching of n,π* excited singlet azoalkanes support a hydrogen abstraction in which a transition state is followed by a conical intersection as the reaction coordinate. This photochemical reaction mechanism should be general for n,π* singlet excited chromophores and provides an important rationale for their reactivity and efficiency in hydrogen abstractions.

[17] For the calculation of k_q the ambient-temperature value of τ_0 ((930 ± 30) ns, gas phase) was employed for all temperatures. Inclusion of the much smaller temperature dependence of τ_0, which implicitly includes any temperature dependence of k_f and k_d and the possible contribution due to photodecomposition, does not affect the activation parameters within the limits of statistical regression error. For comparison, the gas-phase lifetimes are 950 and 885 ns at −20 and 65 °C, respectively; that is, they are within the limits of error of or very close to the ambient value.
[18] All MCSCF geometry optimizations were carried out with a complete active space (CAS) including 12 electrons in 10 orbitals (CAS(12,10)). The CAS orbitals comprise the π and π* N=N orbitals, the four σ and σ* C–N orbitals, the two nitrogen lone pair orbitals of the pyrazoline fragment, and the σ and σ* orbitals of the reactive C–H bond of CH_2Cl_2. To improve the description of the H transfer the standard 6-31G* basis set (double-ζ + d-type polarization function for atoms of the first and seconds rows of the periodic system) was augmented with p-type polarization and s-type diffuse functions on the CH_2Cl_2 hydrogen atoms and with sp-type diffuse functions (included in Gaussian 94)[19b] on the nitrogen centers. To improve the energetics by including the effect of dynamic electron correlation, the S_1 energies of MIN, TS, and LP were recomputed using multireference Møller–Plesset perturbation theory with the PT2F method included in MOLCAS.[20] To reduce the computational cost we used a CAS(8,7) with the 6-31G* basis set for the reaction coordinate and frequency computations. This reduced CAS does not include the σ and σ* orbitals of the "short" C–N bond and the lone-pair orbital on the alternative N atom. CAS(8,7) produces optimized geometries of MIN, TS, and LP which differ only slightly from that of CAS(12,10) (see Figure 1, top). The reaction coordinate was determined with the IRC method available in Gaussian 94. The conical intersection is easily located by computing the reaction coordinate until degeneracy of S_1 and S_0 is achieved. This manifests itself in failure of the MCSCF calculation to converge owing to $S_1 - S_0$ near-degeneracy. The last reaction coordinate point before degeneracy (LP) is taken as representative of the conical intersection.

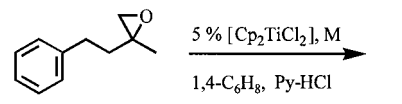
Catalytic, Highly Regio- and Chemoselective Generation of Radicals from Epoxides: Titanocene Dichloride as an Electron Transfer Catalyst in Transition Metal Catalyzed Radical Reactions**

Andreas Gansäuer,* Marianna Pierobon, and Harald Bluhm



During the last two decades the development of efficient chain reactions has led to an explosive growth in free radical chemistry.[1] Although the understanding of how substrate control determines the stereo- and chemoselectivity of these reactions has reached a high level,[2] to the best of our knowledge little is known about reagent-controlled, catalytic transformations of radicals not proceeding as chain reactions.[3] The advantage of this type of reaction is broader application because the influence of the substrate on the chemo- and stereoselectivity can ideally be overruled and the course of the reaction determined solely by the reagent in catalytic amounts. Therefore a reagent-controlled catalytic reaction would extend the synthetic utility of free radicals even further.

An interesting alternative to radical chain reactions is the reductive opening of epoxides by single electron transfer (SET) from titanocene chloride dimers.[4] The β-titanoxy radical thus formed can undergo the typical radical reactions. Epoxides can be prepared conveniently from a number of functional groups, for example olefins[5] and carbonyl compounds,[6] and can thus serve as radical precursors. An attractive feature of this reaction is that an alcohol is formed after hydrolysis rather than a hydrocarbon, as in the reactions of halides with stannanes.[7] However, both the electron transfer reagent precursor, titanocene dichloride, and the reductant, usually zinc powder, are employed in at least stoichiometric quantities. This is clearly disadvantageous when more complex titanocenes are used.[8] If the reaction could be conducted with a catalytic amount of titanocene, this problem would be solved, and the way would be paved for transition metal catalyzed radical reactions with the potential for efficient reagent control. To achieve this goal the titanocene alkoxide formed must be converted into a derivative of the alcohol or the alcohol itself and titanocene dichloride, the catalyst precursor. In situ reduction by the stoichiometric reductant would yield the redox-active titanium(III) complex[9] and complete the catalytic cycle.

Recently Fürstner et al. have devised efficient catalytic McMurry[10] and Nozaki–Hiyama couplings[11] by adding chlorotrimethylsilane to the reaction mixture. The metal alkoxides and oxides formed in the couplings are thus silylated and the catalytically active metal species are regenerated. This method is, however, not applicable to epoxides because silylated chlorohydrins would form by Lewis acid initiated ring opening. We reasoned that protonation of the titanium-bound oxygen atom should also allow efficient regeneration of the catalyst. For this purpose the acid must be strong enough for the protonation, but neither may the metal powder be oxidized nor the catalyst deactivated by complexation of the resulting base. Pyridinium hydrochlorides (Py-HCl) seemed to be appropriate based on their pK_a values[12] and were therefore tested as acids in the reaction

1

2 **3**

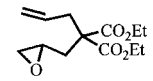
of **1** with cyclohexadiene as the hydrogen atom donor, a stoichiometric reductant, and 5 mol% titanocene dichloride (Table 1).

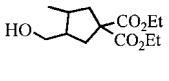
All of the pyridine hydrochlorides tested, except the bulky 2,6-di-*tert*-butylpyridine hydrochloride, led to conversion. 2,4,6-Trimethylpyridine hydrochloride (collidine hydrochloride) was the most efficient. In addition to the milder reaction conditions required, there are two more general advantages to having protonation as the key step in the catalytic cycle: 1. Protonations are amongst the fastest reactions. 2. 2,4,6-Collidine can be recovered simply by acid–base extraction or distillation; treatment with HCl then provides the hydrochloride. Hydrolysis of the silylated alcohols yields hexamethyldisiloxane, which cannot be reconverted to chlorotrimethylsilane in a straightforward manner. These advantages should become especially important in large-scale applications.

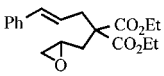
Table 1. Optimization of the reductive opening of epoxide **1** with 5 mol% [Cp_2TiCl_2] and 1,4-cyclohexadiene.

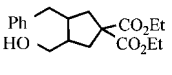
Hydrochloride	M	t[h]	**1**:**2**:**3**[a]
Py-HCl	Zn	35	28:32:26
2,4-Me_2Py-HCl	Zn	36	30:43:22
2,4,6-Me_3Py-HCl	Zn	36	15:71[b]:12
2,4,6-Me_3Py-HCl	Mn	16	0:88[b]:0.5

[a] Determined from the ^{1}H NMR spectrum of the crude mixture. [b] Yield of the isolated product.









In hydrogen atom abstraction reactions with 1,4-cyclohexadiene, manganese is superior to zinc as the stoichiometric reductant in two respects. When manganese is used, no chlorohydrin **3** is formed by Lewis acid initiated ring opening of the epoxides, and the reaction proceeds significantly faster. Apparently the zinc chloride formed in the reaction complexes the epoxide, prevents complete conversion into product, and allows the slow chloride-mediated ring opening to compete. Gratifyingly the much less Lewis-acidic manganese dichloride[11] does not interfer with the catalytic reaction and thus the products are obtained cleanly in a reasonable time. It should be noted that other metals such as aluminum[13] do not lead to fast reduction of titanocene dichloride and are therefore not suitable as stoichiometric reductants.

To explore the generality of the optimized reaction conditions a number of epoxides were tested in inter- and intramolecular C–C bond forming reactions and reductions (Table 2). Terminal, 1,1- and 1,2-disubstituted (*cis* and *trans*, entry 3), and trisubstituted epoxides give the desired products in good yields. It should be noted that deoxygenation of the epoxide was not detected for any substrate. The regioselectivity of the epoxide opening is opposite to that of S_N2 reactions and seems to be governed only by the stability of the radical formed. Therefore the radical is produced only on the more substituted carbon atom of the epoxide. The observed diastereoselectivities of the cyclizations are typical for radical reactions and their well-known conformational effects.

For the intermolecular addition of the radical to methyl acrylate, zinc was used as the stoichiometric reductant (entries 12 and 13). The lactones were isolated in 75–80% yield after 40 h but the corresponding chlorohydrins (roughly 5%) were also detected. The reaction was much slower with manganese. After 40 h the conversion was estimated at 15%. This is presumably due to deactivation of the titanium catalyst by the MeOH generated. Zinc chloride seems to be Lewis-acidic enough to complex MeOH and thus prevent catalyst deactivation. When manganese was employed in combination with zinc chloride, essentially the same results were obtained

as with zinc as reductant. This result supports the above-mentioned hypothesis of catalyst deactivation.

Since titanocene-mediated SET is the key step in the epoxide opening, a number of functional groups sensitive to electron transfer reagents such as samarium diiodide[14] were subjected to the optimized conditions. Gratifyingly benzyl ethers, chlorides, and even ketones (see Table 2, entry 10 for the competition experiment) are perfectly stable under the reaction conditions, and the corresponding products were isolated in good yields. Chlorides are not tolerated in radical chain reactions using tributylstannane (dehalogenation), and therefore the reaction described here allows a mild and highly chemoselective entry to radical chemistry.[7] Protecting groups that can migrate under basic conditions like pivalate (Piv), tosylate (Ts), and *tert*-butyldiphenylsilyl ether (OTBDPS) do not migrate even when it would be kinetically favorable, as in the case of the TBDPS ethers.[15] Also elimination of tosylate was not observed. Although these alcohols can also be obtained by hydroboration and oxidation, the method described here is superior because distant double bonds and ketones are not tolerated by the hydroboration protocol.[16] Also hydroboration of 2-methyl-1,11-dodecadiene takes place preferentially at the less substituted double bond and is therefore complementary to our reaction (entry 4).[17]

We have demonstrated that the reductive opening of epoxides with concommitant hydrogen atom abstraction and inter- or intramolecular C–C bond formation can be catalyzed efficiently and in a highly chemoselective manner by titanocene dichloride if manganese or zinc is used as the stoichiometric reductant and 2,4,6-collidine hydrochloride is used as an acid to protonate the titanium oxide and regenerate titanocene dichloride.

Experimental Section

All new compounds were characterized by the usual means. Preparation of cyclododecanol: A suspension of collidine hydrochloride (197 mg, 1.25 mmol), titanocene dichloride (12.4 mg, 0.05 mmol), manganese (60.0 mg, 1.1 mmol), 1,4-cyclohexadiene (0.425 mL, 4.5 mmol), and cyclododecene oxide (182 mg, 1.0 mmol) in THF (10 mL) was stirred at room temperature for 32 h. After extraction (5 mL 2 M HCl, 2×20 mL H_2O) and chromatography on silica gel (diethyl ether/petroleum ether 1/3) cyclododecanol (153 mg, 0.83 mmol) was obtained in 83 % yield.

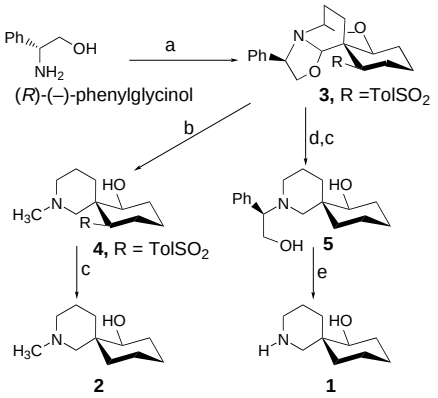
Expeditious Enantioselective Biomimetic Synthesis of the *Nitraria* Alkaloids (+)-Isonitramine and (−)-Sibirine

David François, Marie-Christine Lallemand, Mohamed Selkti, Alain Tomas, Nicole Kunesch,* and Henri-Philippe Husson*

Isonitramine **1** (Scheme 2) is a representative member of the *Nitraria* alkaloid family, for which considerable structural variety is encountered but in which a piperidine ring is an essential feature. We achieved the enantioselective syntheses of the spiropiperidine alkaloids (+)- and (−)-isonitramine,[1] and a number of other racemic[2] and asymmetric syntheses[3] have appeared. Some require numerous steps and have low overall yields. In a continuation of our work on the use of glutaraldehyde for constructing piperidine alkaloids,[4] we report here the most straightforward syntheses of natural sibirine (−)-**2** as well as isonitramines (+)-**1** and (−)-**1** from commercially available starting materials.

Despite the important achievements of Koomen et al.[2] in biomimetic approaches to synthesizing *Nitraria* alkaloids, some desirable objectives have not yet been attained. In particular, generation of a nonracemic chiral biogenetic intermediate with a suitable oxidation level remains an unsolved problem.

We previously showed[1] that the condensation of (*R*)-(−)-phenylglycinol with excess glutaraldehyde gives a tetracyclic compound containing the spiropiperidine skeleton of *Nitraria* alkaloids. However, six and eight additional steps are necessary to transform this precursor into (−)- and (+)-isonitramine, respectively. Such a reaction might form the basis of a biomimetic approach to synthesizing the title alkaloids. Since the first step of the reaction between (*R*)-(−)-phenylglycinol and glutaraldehyde is the formation of the enantiopure intermediate **A** (Scheme 1), we imagined that condensation of a second molecule of glutaraldehyde would afford aldehyde **B**, a chiral derivative of the piperideinoaldehyde **C** postulated by Koomen as a key intermediate in the biosynthesis of *Nitraria* alkaloids.[2]



Scheme 1. Mechanism for the formation of spirocompound **3**.

According to this biogenetic hypothesis, the crucial step is the reduction of the conjugated iminium system of **C** to a simple enamine. We reasoned that a stereocontrolled Michael addition of a convenient nucleophile to **B** should a) create a new stereogenic center which would further control the spirocyclization and b) allow elimination of the nucleophile by reductive cleavage.

We chose sodium *p*-toluenesulfinate as the nucleophile in the expectation that 1,4-addition to the α,β-unsaturated oxazolidine system of **D** would generate the desired enamine. Whereas the 1,4-addition of phenylsulfinate ion to α,β-unsaturated ketones is well documented, there are few examples of reaction with iminium salts. As far as conjugated iminium ions are concerned, we observed the only known case for a rearrangement in which a 1,4-addition occurred.[5]

The first step of our synthetic sequence was accomplished by condensation of (*R*)-(−)-phenylglycinol and glutaraldehyde (2.5 equiv) followed by addition of sodium *p*-toluenesulfinate. This resulted in the formation of the spirocompound **3** (51 % yield) as the major diastereomer, which was isolated by simple crystallization (Scheme 2) and characterized by X-ray structure analysis.[6]

Scheme 2. a) Aqueous glutaraldehyde (2.5 equiv), pH 3.5, $NaSO_2Tol$ (2.2 equiv), $ZnBr_2$, 3 h (51 %); b) W-2 Raney Ni, MeOH (reflux), 2 h (91 %); c) Na(Hg), anhydrous MeOH, anhydrous Na_2HPO_4, 24 h, −20 °C (95 %); d) $LiAlH_4$, Et_2O (82 %); e) $H_2/Pd(OH)_2/C$ 20 %, MeOH, 24 h (85 %).

The outcome of this highly efficient reaction suggests that **3** is the most thermodynamically stable compound resulting from a series of equilibration reactions. The possible control elements include a) diastereoselective 1,4-nucleophilic addition of $TolSO_2^-$ to the α,β-unsaturated oxazolidine system of **D**[7] and b) addition of the substituted enamine goup of **E** to the aldehyde group via a chairlike transition state in which the sulfone and the developing secondary alcohol are in a diequatorial arrangement, which provides stereocontrolled spiroaldolization.

Finally, natural sibirine (−)-**2** was obtained in a two-step procedure from **3** by hydrogenolysis/alkylation with Raney nickel in MeOH[8] followed by sulfone elimination (yield 86 %).[9] The synthesis of isonitramine (−)-**1** required reduction with $LiAlH_4$, sulfone elimination, and hydrogenolysis of the chiral N substituent (yield for three steps from **3** 66 %).[10] Natural isonitramine (+)-**1** could be obtained starting from

enantiomeric (*S*)-(+)-phenylglycinol. These results show the crucial role of the chiral phenylglycinol, which serves not only for the transfer of chirality but also for the stabilization of the intermediate iminium.

The nitramine alkaloids (derivatives of 2-azaspiro[5.5]undecan-7-ol) are structurally analogous to the neurotoxic histrionicotoxin alkaloids,[11] compounds which have a 1-azaspiro[5.5]undecan-8-ol skeleton with unsaturated lipophilic side chains. The introduction of such essential side chains on the nitramine skeleton is therefore of particular interest. Intermediate **3** opens the way to a variety of substitutions which can be made a) at the carbon atoms adjacent to the nitrogen of the piperidine ring by selective opening of the oxazolidine and/or 1,3-oxazine in an iminium ion and b) on the cyclohexane ring by the sulfone reactivity.

Experimental Section

All new compounds were characterized by 2D ^{1}H and ^{13}C NMR as well IR spectra, $[\alpha]_D$ values, simple and high-resolution mass spectrometry, or elemental analysis.

(*R*)-(−)-phenylglycinol (6.9 g, 50 mmol) was added to a solution of citric acid (24 g) in distilled water (200 mL). The mixture was stirred vigourously until complete dissolution of the phenylglycinol and then cooled to 0–5 °C in an ice/water bath. A 25% aqueous solution of glutaraldehyde (47 mL, 125 mmol) was added dropwise over 30 min, and then sodium *p*-toluenesulfinate (19.6 g, 110 mmol) was added simultaneously with CH_2Cl_2 (120 mL). The reaction mixture was stirred for 2 h at room temperature. The aqueous phase was neutralized with 5 N aqueous NaOH (80 mL) and extracted with CH_2Cl_2 (3 × 150 mL). The combined organic layers were concentrated under vacuum, diluted with MeOH (50 mL), and treated with $ZnBr_2$ (2 g, 8.9 mmol) over 12 h. Evaporation of the solvent gave an oily crude residue which crystallized from MeOH to give 11.19 g (51%) of **3** in two crops.

Preparation of Lithium Oligosiloxane Aluminates and Acid Strength of Hydroxy Groups in a Molecular Aluminum Oligosiloxane

Michael Veith,* Maria Jarczyk, and Volker Huch

Dedicated to Professor Manfred Weidenbruch on the occasion of his 60th birthday

As we recently reported, the molecular aluminum oligosiloxane **1**, which contains four aluminum atoms that are connected through OH bridges to form a ring, can be readily prepared in a one-step synthesis.[1] We observed that the hydrogen atoms of the OH groups are available for coordination with Lewis bases. Compound **1** can therefore be isolated as an adduct with three molecules of diethyl ether (a fourth is incorporated within the crystal lattice and does not

coordinate with a hydrogen atom). It can also be allowed to react with triethylamine to give a 2:1 adduct that may be described as an ion pair with the formula $[\{(Ph_2Si)_2O_3\}_4Al_4(OH)_2O_2]^{2-}(Et_3NH^+)_2$. It was a logical consequence for us to investigate the effect that various other Lewis bases with different steric requirements and basic strengths have on **1**. In addition, we wanted to study whether the Loewenstein rule (according to which the AlO_4 tetrahedra in such compounds are always separated by silicon atoms) is also applicable to molecular aluminum/silicon–oxygen compounds,[2] or whether the hydroxy compound **1** can be converted into a lithium derivative without rearrangement. Roesky et al. recently described a molecular sodium siloxoaluminate of the general formula $[\{Na(thf)\}_4][\{EtAlO_3SiR\}_4]$ in which the O_3R tetrahedra centered by aluminum and silicon atoms were indeed linked through oxygen vertices in an alternating fashion.[3]

Adduct $\mathbf{1}\cdot 4\,OEt_2$ reacts smoothly with pyridine (Py) under elimination of the diethyl ether molecule to give the pyridine adduct **2**[4] in almost quantitative yield (Scheme 1).The IR spectrum of crystalline **2** has a narrow band at 3630 cm^{-1}, and the ^{29}Si NMR spectrum has only one signal. Based on the integration of the ^1H NMR signals and the elemental analysis, **2** contains one pyridine molecule per OH group. A section of the structure of **2** as determined from the X-ray structure analysis[4] is shown in Figure 1. The molecule has $S_4(\bar{4})$ crystallographic symmetry with four pyridine molecules linked to the central $Al_4(OH)_4$ ring through bridging hydrogen bonds. The O–N distance of the linear N–H ··· O bridge is 2.548(3) Å; the adjacent Al atoms along with the N and O

atoms lie almost perfectly in a plane. In contrast to the triethylamine adduct (only two molecules per four OH groups) and the diethyl ether adduct (three molecules per four OH groups),[1] all OH groups in **2** are "coordinatively saturated". The fourfold incorporation of pyridine is attained in that half of the phenyl groups of the peripheral silyl groups are arranged parallel to each other and thus form a sandwich structure with the pyridine molecules (the average distance between the plane of the pyridine ring and the parallel phenyl

Scheme 1. Synthesis of compounds **2**–**4** from **1**.

groups is 3.6 Å, see Figure 2). The twofold symmetry of the $OSi(Ph)_2OSi(Ph)_2O$ handle is somewhat disturbed by the forced arrangement of the aryl groups. This manifests itself most clearly in the Si-O-Al angles of 154.4(1) and 166.6(1)°.

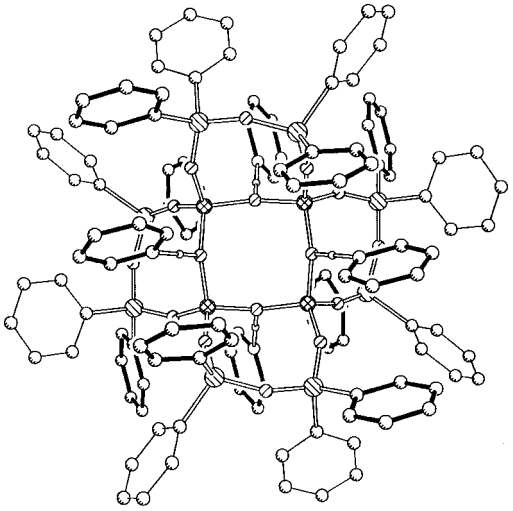

Figure 2. The parallel arrangement of the phenyl groups on the silicon atoms and the interstitial pyridine molecules in **2** (thick lines).

The Al–O(H) bond lengths are particularly informative with respect to the H···N interaction and the relative acidic strength of the OH groups. They are equal within the limits of the standard deviation (av 1.769(1) Å) and lie between the corresponding lengths in the adducts with diethyl ether (av 1.800 Å) and triethylamine (av 1.728 Å). In agreement with the pK_a values of diethyl ether (−3.0), pyridine (5.2), and triethylamine (10.8),[5] there is a correlation with the Al–O bond lengths; as expected, the strongest base effects the strongest attraction on the hydrogen atoms. This leads to a negative partial charge on the oxygen atoms and thus to a shortening of the Al–O bond. However, the lengths of the bridging hydrogen bonds (2.65 Å in $\mathbf{1}\cdot 4\,OEt_2$, 2.72 Å in the triethylamine adduct, and 2.55 Å in **2**) do not correlate with the base strengths. It appears that the steric requirements of the bases are reflected in these distances; pyridine clearly requires less space than diethyl ether or triethylamine. This is plausible when space-filling models of the molecules are considered.

With the reaction of $\mathbf{1}\cdot 4\,OEt_2$ with phenyllithium it is possible to replace all four hydrogen atoms of the hydroxy groups with lithium atoms[6] (Scheme 1). Product **3** reacts further with NH_3 in toluene; the formation of **4** is accompanied by the incorporation of two NH_3 molecules and the elimination of a diethyl ether molecule[7] (large molar amounts of NH_3 lead to mixtures of products, which could not yet be separated). The quantitative reaction can be inferred from the IR spectra of the reaction products: In the case of **3** no peaks between 3700 and 3150 cm^{-1} are found, and for **4** there is an intense peak at 3389 cm^{-1}, which can be attributed to the N–H vibrations of the NH_3 molecules coordinated to two lithium atoms (there is a signal at $\delta = -382.4$ in the ^{15}N NMR spectrum). X-ray structure analyses were performed on both compounds,[6, 7] the results of which are depicted in Figures 3 and 4.

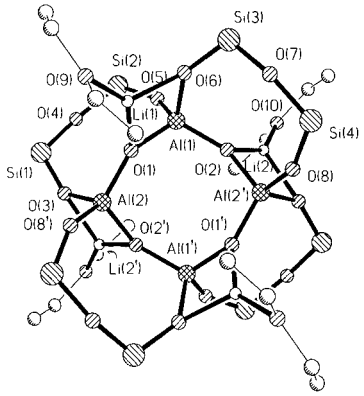

Figure 3. Section from the structure of **3** in the crystal (for clarity the phenyl groups on the silicon atoms are not shown). Selected bond lengths [Å] and angles [°]: Al(1)–O(2) 1.720(4), Al(1)–O(1) 1.729(4), Al(1)–O(5) 1.734(4), Al(1)–O(6) 1.799(4), Al(2)–O(1) 1.727(4), Al(2)–O(2′) 1.734(4), Al(2)–O(8′) 1.736(4), Al(2)–O(3) 1.786(4), Si(1)–O(3) 1.616(4), Si(1)–O(4) 1.618(5), Si(2)–O(5) 1.593(4), Si(2)–O(4) 1.631(5), Si(3)–O(6) 1.605(4), Si(3)–O(7) 1.617(5), Si(4)–O(8) 1.593(4), Si(4)–O(7) 1.630(5), O(1)–Li(1) 1.85(1), O(2)–Li(2) 1.84(1), O(3)–Li(2′) 2.03(1), O(6)–Li(1) 1.95(1), Li(1)–O(9) 1.91(1), Li(2)–O(10) 1.88(1); O(2)-Al(1)-O(1) 118.9(2), O(1)-Al(2)-O(2′) 116.4(2), Al(2)-O(1)-Al(1) 133.6(2), Al(1)-O(2)-Al(2′) 134.6(2).[8]

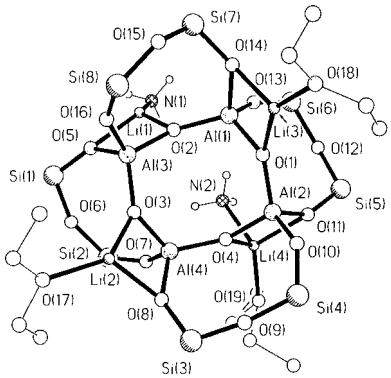

Figure 4. Section from the structure of **4** in the crystal that is analogous to that in Figure 3. Selected bond lengths [Å] and angles [°]: Al(1)–O(2) 1.715(3), Al(1)–O(13) 1.734(4), Al(1)–O(1) 1.746(3), Al(1)–O(14) 1.791(3), Al(2)–O(4) 1.733(3), Al(2)–O(1) 1.738(3), Al(2)–O(10) 1.748(3), Al(2)–O(11) 1.786(4), Al(3)–O(3) 1.727(3), Al(3)–O(2) 1.733(4), Al(3)–O(16) 1.743(4), Al(3)–O(5) 1.789(3), Al(4)–O(4) 1.714(3), Al(4)–O(3) 1.744(3), Al(4)–O(7) 1.757(3), Al(4)–O(8) 1.781(4), O(1)–Li(3) 1.85(1), O(2)–Li(1) 1.87(1), O(3)–Li(2) 1.85(1), O(4)–Li(4) 1.90(1), N(1)–Li(1) 2.00(1), N(2)–Li(4) 2.09(2); O(2)-Al(1)-O(1) 117.1(2), O(4)-Al(2)-O(1) 114.9(2), O(3)-Al(3)-O(2) 114.9(2), O(4)-Al(4)-O(3) 119.3(2), Al(2)-O(1)-Al(1) 127.1(2), Al(1)-O(2)-Al(3) 137.8(2), Al(3)-O(3)-Al(4) 128.5(2), Al(4)-O(4)-Al(2) 141.0(2).[8]

Compound **3** has the same central cyclic structural unit as **1**, but is supplemented by four annelated AlO_2Li rings. Each lithium atom is additionally connected to a diethyl ether ligand molecule, so that approximately trigonal-planar LiO_3 units are formed. Alternatively, the inner unit can also be described as consisting of four AlO_4 tetrahedra connected through common vertices with one edge of each tetrahedron being bridged by a lithium atom. The similarity to lithium aluminium silicates is also reflected by the formula $[\{Ph_2SiO\}_8][\{LiAlO_2\}_4]\cdot 4\,OEt_2$. The point symmetry of the molecule in the crystal is $C_2(2)$; however, the deviation from

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0107 $ 17.50+.50/0

$S_4(\bar{4})$ symmetry is only slight. Moreover, **3** crystallizes enantiomerically pure in a noncentrosymmetric space group. The Al–O bond lengths in the central Al_4O_4 ring alternate systematically according to whether the bond is situated within the AlO_2Li ring (av 1.732(3) Å) or outside it (av 1.723(3) Å). Otherwise, the distances are similar to those in the triethylamine adduct of **1**,[1] which suggests equivalent charge states on the oxygen atoms. Of all the Li–O distances, $Li–O(Al)_2$ is, as expected, the shortest (av 1.85(2) Å), followed by $Li–O(Et)_2$ (av 1.89(2) Å) and finally Li–O(Al,Si) (av 1.99(2) Å).

The fundamental structure of the framework of **4** is similar to that of **3**; the Al–O bond lengths of the central Al_4O_4 ring alternate also here. In contrast to the situation in **3**, the four lithium atoms are quite differently coordinated. Atoms Li(2) and Li(3) are coordinated by diethyl ether, which results in a slightly distorted trigonal-planar environment, whereas Li(1) is coordinated by an ammonia molecule, and Li(4) by both an ammonia and a diethyl ether molecule. Thus, Li(4) has the coordination number four. The asymmetrical ligand distribution leads to the point symmetry C_1 in the crystal. As in **3**, the shortest Li–O bond length is that between Li and O atoms of the central Al_4O_4 ring (1.846(9) – 1.865(9) Å). The $Li–O(Et_2)$ bond lengths (1.89(1) – 1.94(1) Å) are longer (as are Li–N bond lengths with 2.00(1) Å), and the Li–O(Al,Si) distances are the longest (2.01(1) – 2.03(1) Å). Due to the higher coordination number on Li(4), all bond lengths here are somewhat longer (e.g. Li(4)–N(2) 2.09(2) Å).

As shown unequivocally by the X-ray structure analyses of **3** and **4**, the fundamental framework is not altered by the incorporation of the lithium atoms into **1**. It thus appears that the Loewenstein rule does not apply for the molecular lithium oligosiloxane aluminates considered here. Their formation is apparently more "kinetically" than "thermodynamically controlled". Moreover, attack by bases occurs more readily than in the case of **1** (**3** contains four diethyl ether donors, and the corresponding adduct of **1** only three). The oxygen atoms of the $OSi(Ph)_2OSi(Ph)_2O$ handle readily coordinate to the lithium atoms, which leads to the observed cyclizations. It is expected that larger metal atoms would form coordinate bonds with even more oxygen atoms.

RNA – Aminoglycoside Interactions: Design, Synthesis, and Binding of "Amino-aminoglycosides" to RNA**

Hai Wang and Yitzhak Tor*

At the frontiers of RNA chemistry and biology stands the intriguing and largely unexplored area of RNA recognition. Despite the central role RNA plays in numerous biological processes, little is known about the interactions between small organic molecules and RNA biomolecules.[1, 2] The discovery that aminoglycoside antibiotics interact specifically with diverse RNA molecules—such as 16S ribosomal RNA,[3, 4] introns of group I,[5] and the hammerhead ribozymes[6]—and block the binding of the Rev protein[7] and Tat peptide[8] to their viral RNA targets attracted considerable interest and stimulated studies attempting to identify the elements involved in these recognition phenomena.[9, 10] The elucidation of general "recognition rules" for RNA – ligand interactions is essential for developing RNA binders of low molecular weight that target pivotal bacterial and viral RNA sites.

As aminoglycosides are highly functionalized polycationic oligosaccharides, interactions between their polar residues (amino and hydroxyl groups) and the RNA backbone and/or heterocyclic bases are likely to occur.[11] Since the amino groups are predominantly protonated at pH 7.0,[12] the overall charge density presented by the aminoglycosides toward the RNA host is likely to be important for RNA binding. The reported structure – activity relationships for natural aminoglycosides support this general view. Hence, aminoglycosides containing four amino groups show very little ability to bind RNA, whereas the most active derivatives contain five or six amino groups.[5–8] Although rather general, this view does not explain marked differences in RNA binding among related aminoglycoside antibiotics.[5, 7]

Here we focus on the importance of electrostatic interactions for binding between RNA and aminoglycoside, and address the following questions: 1. Will the ability of poor RNA binders (e. g. kanamycin A) to bind RNA be increased by incorporating an additional amino group into their structures? 2 Will the ability of the most active antibiotics (tobramycin and neomycin) to bind RNA be further increased by adding more amino groups? 3. Can a common recognition pattern be identified? We report here the design, synthesis, and ribozyme inhibitory activity of novel "amino-aminoglycosides" derived from kanamycin A, tobramycin, and neomycin B. We provide experimental evidence for the critical role of the overall charge of aminoglycosides in RNA binding and propose a general recognition model emphasizing the stereochemical display of the charged ammonium groups.

In designing amino-aminoglycosides three major factors had to be considered: 1. the modification site, 2. the degree of substitution of the amine and its basicity, and 3. synthetic accessibility. We recently synthesized and studied a series of systematically deoxygenated analogues of tobramycin. Preliminary results indicated that 6″-deoxytobramycin is comparable, yet slightly inferior, to tobramycin in its affinity to the hammerhead ribozyme.[13] This observation suggests that while the primary 6″-OH group might not be essential for RNA binding it is likely to be involved in RNA contact. Regarding the basicity of the amino groups, the primary aminomethyl groups ($-CH_2NH_2$) in various aminoglycosides are more basic (pK_a 8.6 – 9.0) than the other primary amines (pK_a 6.2 – 8.1).[12] Taken together with the relative ease of derivatizing a primary alcohol, we selected position 6″ in kanamycin A and tobramycin, and position 5″ in neomycin B as the modification sites.

The derivatives studied (Figure 1) include kanamycin A (**1**), 6″-amino-6″-deoxykanamycin A (**2**), kanamycin B (**3**), tobramycin (**4**), 6″-amino-6″-deoxytobramycin (**5**), neomycin B (**6**), and 5″-amino-5″-deoxyneomycin B (**7**). These represent aminoglycoside derivatives in which a single primary hydroxyl group is replaced by a primary amine while all other functional groups remain intact. A representative synthesis is illustrated in Scheme 1 for **5**. Tobramycin (**4**) was first protected as its Cbz derivative **8** and then tosylated at the primary 6″-hydroxyl group. The fully Cbz-protected monotosylate **9** was treated with sodium azide to afford **10**, which was then reduced to amine **11** with triphenylphosphane and an aqueous solution of sodium hydroxide. Catalytic hydrogenation afforded **5**. Similar transformations were utilized for synthesizing **2**[14] and **7**.[15]

The aminoglycosides and their amino derivatives were tested for their ability to inhibit the hammerhead ribozyme, a well-studied, small RNA enzyme.[6, 16] The effect of aminoglycoside derivatives on the cleavage rate of the hammerhead ribozyme was investigated at pH 7.3 under single-turnover conditions in the presence of Mg^{2+} and ribozyme at subsaturating concentrations. Figure 2 illustrates the results of a typical experiment, and Table 1 summarizes the pseudo-first-order rate constants obtained at different aminoglycoside concentrations.

Under our conditions the ribozyme cleaves its substrate at a rate of 0.075 min^{-1}. At a concentration of 100 μM, kanamycin A (**1**) slows the ribozyme down to about 75 % of this rate, whereas at 10 μM **1** does not inhibit the ribozyme at all. In contrast, at a concentration of 100 μM 6″-amino-6″-deoxykanamycin A (**2**) decreases the cleavage rate fivefold, which is similar to the effect induced by kanamycin B (**3**). This observation indicates that adding an amino group can convert a very poor RNA binder into a reasonably strong one. Modifying a stronger RNA binder such as tobramycin further enhances its affinity to RNA. Thus, at a concentration of 10 μM 6″-amino-6″-deoxytobramycin (**5**) decreases the ribozyme-cleavage rate fivefold more effectively than the parent tobramycin (**4**).

Neomycin B (**6**) is one of the strongest RNA binders. At a concentratin of 10 μM it shows strong inhibitory activity that is comparable to that of **2** at 100 μM. Replacing the 5″- primary

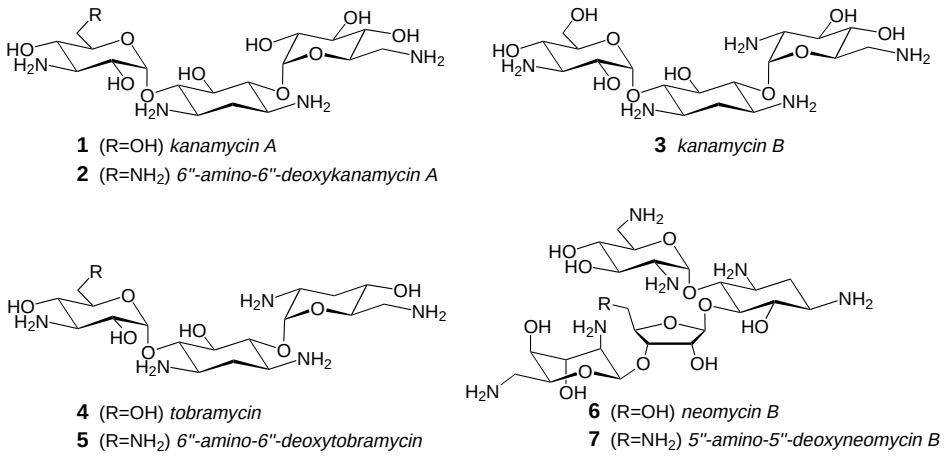

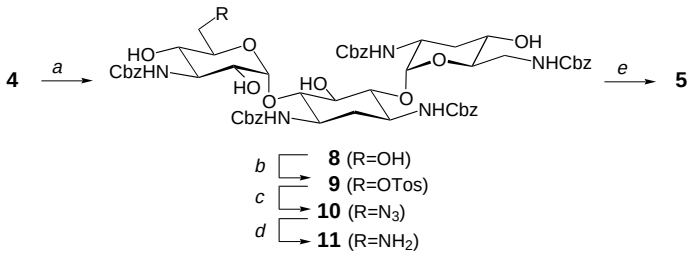

Figure 1. The structural formulas of the natural aminoglycosides and their amino derivatives studied in this work.

OH group with a primary NH_2 group leads to a novel aminoglycoside derivative **7** containing seven amino groups. At 10 μM **7** is an extremely potent inhibitor, and slows down the ribozyme by a factor of twenty-five. At 1 μM **7** slows down the hammerhead ribozyme twice as effectively as the parent neomycin B (**6**). These observations indicate that even the ability of the most active aminoglycosides to bind RNA can be further enhanced by increasing their overall charge.

The comparable ribozyme inhibitory activity of 6″-amino-6″-deoxykanamycin A (**2**) and kanamycin B (**3**) may not be coincidental. Both derivatives have five amino groups, albeit in different positions of the aminoglycosidic skeleton, and are likely to have a similar overall positive charge at a given pH. We propose that these aminoglycosides present a similar stereochemical array of positive charges. Thus, **2** is rotated around an imaginary pseudo-C_2 axis going through positions 2 and 5 in the central 2-deoxystreptamine ring so that the two central rings "overlap" (Figure 3). Amino groups 1 and 3 of **2** can overlap with amino groups 3 and 1 of **3**. The 3″-NH_2 group of **2** can take the position of the flexible 6′-NH_2 group in **3**, and the new 6″-NH_2 group in **2** can assume the position of the 2′-NH_2 group in **3**. In addition, 6′-NH_2 of **2** can occupy the position of 3″-NH_2 in **3**.[17] Taken together with the spherical shape of an ammonium group and its geometrical degeneracy, both derivatives can display a similar array of ammonium groups and charge densities toward the RNA skeleton (Figure 3).

Scheme 1. Synthesis of 6″-amino-6″-deoxytobramycin (**5**). Reagents and conditions: a) $PhCH_2OCOCl$, H_2O, Na_2CO_3, 90%; b) toluenesulfonyl chloride, pyridine, 4 °C, 52%; c) NaN_3, DMF, 80%; d) Ph_3P, THF, NaOH/H_2O; e) H_2, Pd/C, dioxane, H_2O, AcOH, 60% (for d+e).

Table 1. Inhibition of the hammerhead ribozyme by aminoglycoside derivatives.[a]

Derivative	k_2 [min^{-1}] 100 μM	10 μM	1 μM
none (control)		0.075	
kanamycin A (**1**)	0.058	–[b]	–[b]
6″-amino-6″-deoxykanamycin A (**2**)	0.018	0.050	–[b]
kanamycin B (**3**)	0.018	0.060	–[b]
tobramycin (**4**)	0.012	0.051	–[b]
6″-amino-6″-deoxytobramycin (**5**)	–[c]	0.011	–[b]
neomycin B (**6**)	–[c]	0.018	0.062
5″-amino-5″-deoxyneomycin B (**7**)	–[c]	0.003	0.030

[a] See Experimental Section for conditions. The values given are the average of three independent experiments, and the error is estimated to be 10%. [b] No inhibition is observed at this concentration. [c] Under these conditions the derivatives are too active, and complete inhibition is observed.

Previous studies showed that aminoglycoside antibiotics interact preferentially with the enzyme–substrate complex of the hammerhead ribozyme and inhibit the cleavage step.[6] The positively charged ammonium groups were suggested to displace critical Mg^{2+} ions.[18] Our results support this view and clearly demonstrate that the total number of amino groups in the aminoglycoside is correlated with inhibitory activity and RNA binding. Our aminoglycoside–RNA recognition model proposes a specific yet versatile three-dimensional projection of positively charged ammonium groups towards acceptor groups on the RNA binding site. This is in agreement with the results of recent NMR studies[10] and MD simulations[19] that suggest a three-dimensional electrostatic complementarity rather than highly specific contacts between aminoglycoside antibiotics and their RNA hosts.

Our studies have important implications for the design of RNA binders.[20] Such molecules will have to possess sufficient positive charges to bind electrostatically to the RNA target site. Competition with bound Mg^{2+} can be achieved by a strategic incorporation of ammonium groups with predetermined N–N distances and three-dimensional projection, and possibly by the incorporation of functional groups capable of coordinating Mg^{2+}. RNA binders of low molecular weight with higher efficacy and lower toxicity than aminoglycoside antibiotics may replace these drugs in clinical uses and may find novel applications as anti-viral agents.

Experimental Section

The syntheses of the aminoglycoside derivatives will be reported elsewhere.

The hammerhead ribozyme used was HH16, which contains the enzyme E16 and the ^{32}P-5′-labeled substrate S16.[6] Both E16 and S16 were prepared by in vitro transcription reactions of the corresponding synthetic DNA templates using T7 RNA polymerase. Ribozyme reaction conditions: 20 nM E16, trace ^{32}P-5′-labeled S16 ($\leq$ 1 nM), 7.5 mM $MgCl_2$, 50 mM Tris-HCl, and pH 7.3 with varying concentrations of aminoglycosides. The reactions were initiated by mixing equal volumes of preincubated solutions of the enzyme E16 and the labeled substrate S16. Aliquots were removed at various times and quenched by adding excess stop solution/loading buffer (8 M urea, 50 mM disodium ethylenediaminetetraactate (Na_2EDTA), pH 7.3, bromophenol blue, and xylene cyanol). The substrate and product were resolved on 20% polyacryamide/7 M urea gels, and the fraction cleaved was quantified using a Molecular Dynamics Phosphorimager with ImagQuant software. Plotting $\lg(1 - S/S_0)$ vs. time gives a straight line with a slope of $-k_2$ (Figure 2, right).

[17] Another approach is to compare the intramolecular $NH_3^+ \cdots NH_3^+$ distances in the minimized conformations of the two aminoglycoside derivatives. A similar set of distances (albeit for different pairs of ammonium groups) is obtained. This result supports the view that **2** and **3** display a comparable array of positive charges that are capable of competing with Mg^{2+} ions for binding to RNA.

Calix[5]arene-Based Molecular Vessels for Alkylammonium Ions**

Francoise Arnaud-Neu, Saowarux Fuangswasdi, Anna Notti, Sebastiano Pappalardo,* and Melchiorre F. Parisi

Dedicated to Professor Francesco Bottino on the occasion of his 70th birthday

	R
1a	H
1b	$(CH_2)_3CH(CH_3)_2$
1c	$(CH_2)_2OCH(CH_3)_2$
1d	$CH_2CO_2CH(CH_3)_2$
1e	$CH_2CO_2C(CH_3)_3$

Cation–π-electron interactions are known to play an important role in the recognition of positively charged guests by the electron-rich π-systems of natural[1] and synthetic hosts.[2] Calixarenes,[3] when suitably functionalized, can provide three-dimensional, rigid, π-rich cavities for the selective inclusion of organic cations in nonpolar media.[4] Recently we have shown that triether derivatives of (1,3)-*p*-*tert*-butylcalix[5]arene crown-6 are able to discriminate between linear and branched alkylammonium ions by means of *endo* complexation.[5] The low association constants (K_{ass} = 48–86 M^{-1}) observed for the selective inclusion of nBuNH$_3^+$ ions are probably related to the shape of the cavity of these host molecules (C_s symmetry) and their pronounced tendency to fill the cavity by canting a *tert*-butylphenyl residue inwards.[5]

To develop more powerful receptors, these calixarenes with distorted *cone* conformations should be replaced by compounds with an improved shape and preorganized, permanent *cone* conformations. Although the shape of the calix[5]arene cavity can, in principle, be tuned by changing the nature and bulkiness of substituents on both the upper and lower rims,[6] the presence of *tert*-butyl substituents on the upper rim is essential to keep the molecule in a *cone* conformation and ensure selective inclusion of RNH$_3^+$ ions. Therefore, structural modifications to the lower rim of *p*-*tert*-butylcalix[5]arene (**1a**) have been addressed. We have found that the attachment of long-chain pendant groups (bulkier than ethoxyethoxy)[7] on the lower rim of **1a**—by exhaustive alkylation with appropriate electrophiles—produces derivatives **1b**–**e**, which have a fixed and quite regular C_{5v} *cone* conformation. These receptors bind linear RNH$_3^+$ ions much more efficiently and selectively than the neutral synthetic host systems reported to date.

Host–guest binding affinities were investigated by ^{1}H NMR titration experiments of $CDCl_3/CD_3OD$ (9/1, v/v) solutions of **1b**–**e** with the four isomeric butylammonium picrate salts. Upon addition of increasing amounts of salts, the spectra consistently showed, from the first aliquot onwards, distinct sets of signals for the free and complexed species, indicating that exchange between the complexed and uncomplexed guests is slow on the NMR time scale. Consequently, the formation of 1:1 inclusion complexes was directly assessed by comparing the signal intensities of solutions containing equimolar amounts of host and guest. *endo* Complexation is unambiguously supported by the dramatic upfield shifts (complexation-induced shifts, CIS, up to $\Delta\delta$ = 4.1) of the resonances of the cavity-included alkyl chain of the guest. Due to the high preorganization of the host cavities prior to guest inclusion, the CIS of the receptors are lower ($\Delta\delta$ = 0.1–0.4).

The percentage of *endo* complexation for each butylammonium salt was determined by direct ^{1}H NMR analysis of equimolar solutions (5×10^{-3} M) of host and guest. Hosts **1b**–**e** show a remarkable affinity for the linear nBuNH$_3^+$ ion (68–95%) and a much lower affinity for the branched iBuNH$_3^+$ (6–38%) and sBuNH$_3^+$ (5–28%) ions. No interaction could be detected with the bulky tBuNH$_3^+$ ion, even when a large excess (10 equiv) of the salt was added under standard experimental conditions (15 min equilibration at 21°C before the spectrum was recorded). Furthermore, a direct NMR competition experiment has shown that when **1e** is mixed with equimolar mixtures of the four butylammonium picrates, only nBuNH$_3^+$ (95%) and iBuNH$_3^+$ (5%) ions undergo *endo* complexation. Owing to the high degree of *endo* complexation for the nBuNH$_3^+$ ion, relevant K_{ass} values could not be reliably assessed by ^{1}H NMR spectroscopy[8] and were determined in $CHCl_3$ saturated with water by using the picrate extraction method developed by Lein and Cram.[9]

The association constants of **1b**–**e** with the isomeric butylammonium picrates are summarized in Table 1. High lgK_{ass} values ($4.63 \le \lg K_{ass} \le 6.47$) are always found with the nBuNH$_3^+$ ion and receptors **1b**–**e**, while with the other branched cations and specifically with the tBuNH$_3^+$ ion they are significantly lower ($\lg K_{ass} \le 3.5$). For a given butylammonium picrate isomer, the stability of the complexes generally decreases in the following order: **1e** > **1b** > **1c** > **1d**. Accordingly, calix[5]arenes **1b** and **1e** appear to bind the nBuNH$_3^+$

Table 1. Association constants ($\lg K_{ass} \pm \sigma$) of isomeric BuNH$_3^+$ ions (picrate salts) with **1b**–**e**, obtained by UV spectroscopy.[a]

	nBuNH$_3^+$	iBuNH$_3^+$	sBuNH$_3^+$	tBuNH$_3^+$

ion more selectively than the other isomeric cations. For instance, the selectivity of **1e** for nBuNH$_3^+$ over tBuNH$_3^+$, expressed as the ratio $K_{ass}(n\text{BuNH}_3^+)/K_{ass}(t\text{BuNH}_3^+)$ approaches 10^3. This is, to the best of our knowledge, the highest selectivity so far observed for this pair of isomers. It is higher than the values reported for [18]crown-6[10] and calix[6]arene hexaesters[11] by about three and two orders of magnitude, respectively. Kubo et al. have recently reported a reversed selectivity for tBuNH$_3^+$ ions [$K_{ass}(t\text{BuNH}_3^+)/K_{ass}(n\text{BuNH}_3^+ = 11$] by a chromogenic 1,1′-binaphthyl-derived calix[4]crown. In this case complexation is presumed to involve the crown ether moiety and a phenolate group.[12]

Since the structural motif of nBuNH$_3^+$ is present in biologically important amines, calix[5]arenes **1b**–**e** can also act as biomimetic host systems. A screening with a number of α-amino acid methyl esters (including Phe-OMe · HCl, Arg-OMe · 2 HCl, Val-OMe · HCl) and small peptides has shown that receptors **1b** and **1e** form specifically 1:1 inclusion complexes only with N^{α}-Ac-Lys-OMe · HCl and Lys-Gly-OMe · 2 HCl. Noteworthy, in the latter the ε-butylenammonium group is recognized by the cavity and complexed in the presence of an unprotected α-ammonium group. In addition, the methyl ester hydrochlorides of the neurotransmitter γ-aminobutyric acid (GABA)[13] and the plasmin inhibitor ε-aminocaproic acid (ε-Ahx)[14] are also strongly included with degrees of complexation up to 80 % (Figure 1).

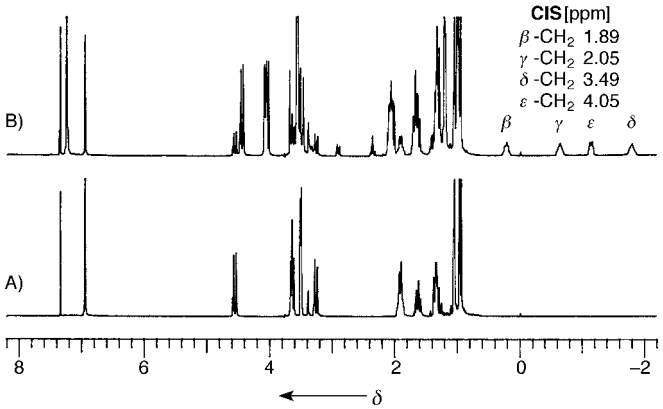

Figure 1. ^{1}H NMR spectra (300 MHz, $CDCl_3/CD_3OD$ 9/1, 21 °C) of receptor **1b** (A) and its 1:1 inclusion complex with ε-Ahx-OMe · HCl ([**1b**] = [ε-Ahx-OMe · HCl] = 5×10^{-3} M) showing characteristic CIS values for the included guest (B).

The calix[5]arene derivatives described here, which are frozen in a C_{5v}-symmetric *cone* conformation, are the most selective molecular receptors for linear alkylammonium ions reported to date. These receptors display an enzymelike selectivity[15] towards biologically important ammonium substrates. Enhancement of their efficacy as biomimetic host systems is currently in progress.

Experimental Section

1b: A stirred mixture of **1a**[16] (0.405 g, 0.50 mmol), isohexyl tosylate (1.923 g, 7.50 mmol), and anhydrous K_2CO_3 (1.037 g, 7.50 mmol) in dry CH_3CN (50 mL) was refluxed under N_2 for 16 h. After cooling, the precipitate was collected by filtration, washed with water, dried, and recrystallized from CH_3CN/CH_2Cl_2 to give **1b** in 72 % yield, m.p. 221–224 °C. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.94$ (d, $J = 6.6$ Hz, CHMe_2, 30 H), 1.03 (s, tBu, 45 H), 1.32 (m, $OCH_2CH_2CH_2$, 10 H), 1.60 (septet, $J = 6.6$ Hz, CHMe$_2$, 5 H), 1.89 (m, $OCH_2CH_2CH_2$, 10 H), 3.25, 4.54 (d, $J = 13.8$ Hz, $ArCH_2Ar$, 10 H), 3.63 (t, $J = 7.2$ Hz, $OCH_2CH_2CH_2$, 10 H), 6.92 (s, Ar H, 10 H); FAB MS (positive ion): m/z (%) 1248 [100, $(M + NH_4)^+$].

Calixarene **1c** was obtained analogously from **1a** and 2-isopropoxyethyl tosylate in 84 % yield, m.p. 180–185 °C (EtOH). ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.02$ (s, tBu, 45 H), 1.19 (d, $J = 6.1$ Hz, CHMe_2, 30 H), 3.26, 4.56 (d, $J = 13.8$ Hz, $ArCH_2Ar$, 10 H), 3.70 (septet, $J = 6.1$ Hz, CHMe$_2$, 5 H), 3.78–3.89 (m, OCH_2CH_2, 20 H), 6.88 (s, Ar H, 10 H); FAB MS (positive ion): m/z (%) 1258 [100, $(M + NH_4)^+$].

Calixarenes **1d** and **1e**[17] were prepared similarly by treating **1a** with the appropriate alkyl bromoacetate. After the reaction mixture had been heated for 24 h at reflux, the inorganic salts were filtered off and washed with $CHCl_3$. The combined organic layers were concentrated to dryness, and the oily residue (mostly the K^+ complex)[17] was treated with petroleum ether. KBr was filtered off and the solvent removed to afford the free calixarenes. **1d**: 70 % yield, m.p. 184-186 °C (hexane/CH_2Cl_2); ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.01$ (s, tBu, 45 H), 1.27 (d, $J = 6.2$ Hz, CHMe_2, 30 H), 3.35, 4.84 (d, $J = 14.5$ Hz, $ArCH_2Ar$, 10 H), 4.62 (s, $OCH_2C{=}O$, 10 H), 5.08 (septet, $J = 6.2$ Hz, CHMe$_2$, 5 H), 6.87 (s, Ar H, 10 H); FAB MS (positive ion): m/z (%) 1333 [100, $(M + Na)^+$]. The physical and spectral data of **1e** were identical to those in the literature.[16]

Controlling the Structure of Supramolecular Porphyrin Arrays**

Anthony K. Burrell,* David L. Officer,*
David C. W. Reid, and Kirstie Y. Wild

The importance of multichlorin assemblies in photosynthetic reaction centers and light-harvesting antenna complexes has inspired considerable interest in the synthesis of porphyrin arrays. Several synthetic strategies are employed for the assembly of multiporphyrin systems. A wide variety of porphyrin arrays of ever-increasing size have been constructed by the traditional methodology of covalently linking porphyrins.[1] More recently the incorporation of porphyrins into supramolecular assemblies has proven to be an attractive method for array formation. With careful choice of materials, the supramolecular structure of the array can be engineered. However, there is currently no porphyrin array system that can be "switched" from one ordered assembly to another. Here we report the first porphyrin system where the structure of the supramolecular assembly can be altered by a noninvasive technique such as photolysis.

With some notable exceptions,[2] the majority of the self-assembling porphyrin arrays are based upon metal – ligand interactions.[3] To a large extent this work has concentrated upon the coordination chemistry of *meso*-pyridyl porphyrins. Porphyrin assemblies prepared from *meso*-pyridyl porphyrins range from dimeric through to polymeric complexes.[3] Of particular interest are the ordered structures formed by a single component interacting with itself. The most common motif in this area is the use of pyridyl-functionalized metalloporphyrins; for example, the metal center of a zinc porphyrin will readily coordinate another ligand, such as pyridine. If the zinc porphyrin is also functionalized by a pyridine, the possibility for zinc – pyridine (inter-[4] or intramolecular[5]) interactions exist. The orientation of the pyridine functionality on the porphyrin macrocycle has a profound influence on the resulting superstructure, providing either dimeric[4f, 6] or oligomeric and polymeric[3j–l, 4] compounds. We have recently become interested in the formation of porphyrin arrays using coordination chemistry as a construction technique and the possibility that simple geometric changes, such as *cis/trans* alkene isomerization, would provide a method to control array superstructure.

As an introduction to this area we prepared the β-vinylpyridine functionalized porphyrin **1**. This compound can be obtained in 82% yield from the reaction of **2**[7] with 4-pyridinecarboxaldehyde (**3;** Scheme 1). The product isolated

Scheme 1. Synthesis of **1a** and **1b**.

is an isomeric mixture of *trans* **1a** (62%) and *cis* **1b** (20%) that can be separated by careful chromatography. The ^{1}H NMR spectra for both **1a** and **1b** are consistent with the structures reported. As expected **1a** is the more favored isomer, and solutions of **1b** convert into **1a** when heated in chloroform or if left exposed to light. Based on the X-ray

structure of a related compound,[1a] the porphyrin core, the olefin, and the pyridine ring of **1a** are presumed to be essentially planar, whereas simple molecular models indicate that it is not possible for the *cis* isomer **1b** to adopt a planar conformation. The effect the geometry of the alkene has on the reactivity of these porphyrins is most apparent when they are treated with Zn^{II}.

The reaction of **1a** with $Zn(OAc)_2$ results in the rapid insertion of Zn^{II} into the porphyrin core. Thin layer chromatography (TLC) of [Zn(**1a**)] did not yield a single spot as normally observed for metalloporphyrins. Instead [Zn(**1a**)] smears over a large portion of the TLC plate with almost every common eluent. The ^{1}H NMR spectrum of [Zn(**1a**)] is significantly changed from the spectrum observed for **1a**. The resonances of the pyridyl hydrogen atoms have shifted from $\delta = 7.11$ and 8.55 to 5.20 and 2.37, respectively, which is consistent with the coordination of the pyridine to a zinc porphyrin.[4] As it is not possible for this coordination to occur in an intramolecular fashion, the coordination must be intermolecular. This was confirmed by a single crystal X-ray analysis. The structure of [Zn(**1a**)] (Figure 1) consists of an

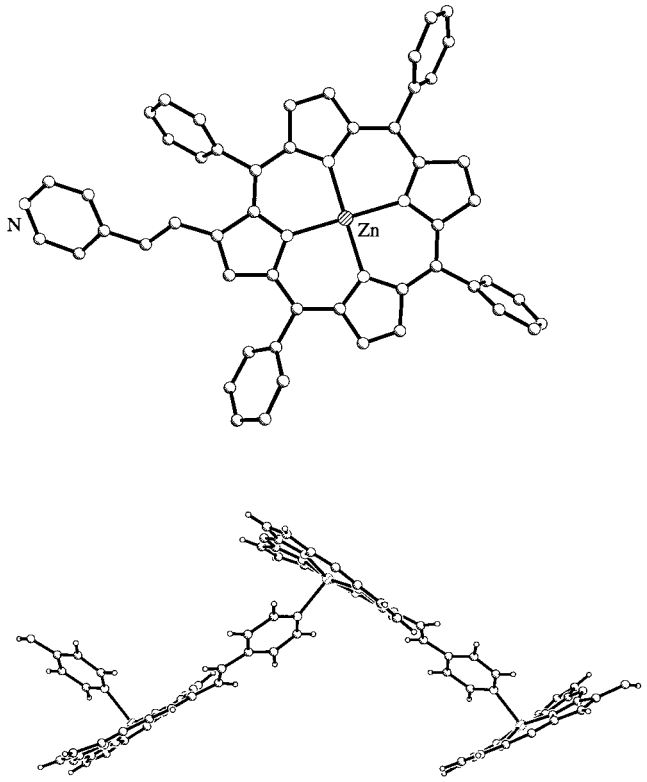

Figure 1. Molecular structure of a single molecule of [Zn(**1a**)] (top) and a section of the chain-like structure (bottom). The phenyl rings have been omitted from the second view for clarity.

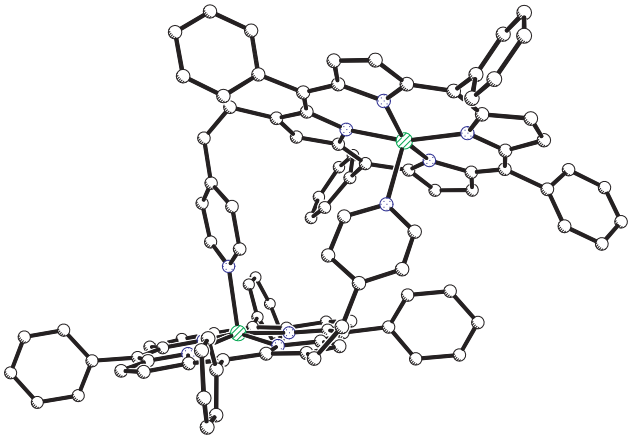
infinite chain of porphyrins.[8] The pyridine is tilted 30.2(4)° from the plane of the zinc porphyrin core. The nitrogen atom of each pyridine group is coordinated, as an axial ligand, to the zinc in an adjacent molecule, resulting in an infinite solid-state polymer. The axial pyridine is not completely orthogonal to the plane of the zinc porphyrin, but tilted at 64.6(6)°. In the solid state, a second structural feature is also present. Each of the porphyrin chains is stacked on another at an average porphyrin–porphyrin distance of 3.8 Å, to give sheets of corrugated chains.

The reaction of **1b** with $Zn(OAc)_2$ also results in the insertion of Zn^{II} into the macrocycle, but the nature of [Zn(**1b**)] is completely different from that of [Zn(**1a**)]. [Zn(**1b**)] runs as a single spot on TLC and is significantly less polar than either **1b** or [Zn(**1a**)]. The ^{1}H NMR spectrum indicates that the pyridine group is coordinated to a porphyrin-bound zinc[4] as the pyridyl protons have shifted from $\delta = 7.07$ and 8.24 in **1b** to 5.18 and 2.06, respectively, in [Zn(**1b**)]. Once again these large chemical shift changes can only be explained by the coordination of the pyridine moiety to the zinc center in a porphyrin core. Fast atom bombardment (FAB) mass spectrometry provided a molecular ion peak corresponding to the dimeric complex $[\{Zn(\mathbf{1b})\}_2]$. X-ray diffraction grade crystals were difficult to obtain, but crystallizations that included small amounts of anthracene resulted in crystals suitable for analysis. The complex $[\{Zn(\mathbf{1b})\}_2]$ crystallizes in the space group $C2/c$[9] and the structure, shown in Figure 2, clearly illustrates the dimeric nature. Each



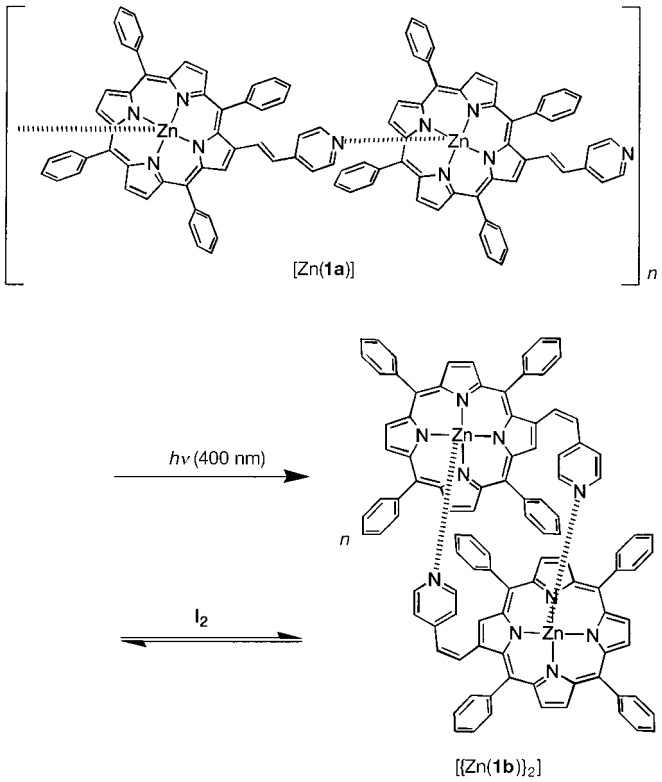


Figure 2. Molecular structure of $[\{Zn(\mathbf{1b})\}_2]$.

pyridine is coordinated to the zinc of the other porphyrin. The two porphyrin planes are tilted with respect to each other by 32(1)°. Presumably this distortion is to accommodate the geometrical requirements of the *cis* alkene linkage.

The chelation-like binding of the $[\{Zn(\mathbf{1b})\}_2]$ complex appears to result in a very stable complex, which is apparent from the strong molecular ion peak in the FAB mass spectrum. There is no evidence to indicate the presence of monomers. In contrast, the polymeric [Zn(**1a**)] appears to be quite dynamic in solution giving rise to an oligomeric mixture. The stability of the $[\{Zn(\mathbf{1b})\}_2]$ complex can be further demonstrated by the conversion of [Zn(**1a**)] (*trans*) into $[\{Zn(\mathbf{1b})\}_2]$ (*cis*) by irradiation with UV light, (Scheme 2). Other methods of isomerization have variable success. Thus, a mixture containing [Zn(**1a**)] and $[\{Zn(\mathbf{1b})\}_2]$ can be generated by treating pure solutions of either [Zn(**1a**)] or $[\{Zn(\mathbf{1b})\}_2]$ with iodine.

The alkene linkage in compounds **1a** and **1b** allows us to exert a control over the supramolecular structure of their derivatives. This is achieved by either beginning with the

appropriate *cis* or *trans* alkene as in traditional supramolecular chemistry or, more significantly, by converting the alkene, in the supramolecular complex, from *trans* to *cis* (or vice versa) and effectively switching from one supramolecular array to another. With this methodology it should be possible to control the molecular architecture of these supramolecular structures and thereby switch properties on or off as desired.

Experimental Section

1a and **1b**: A solution of **2** (135 mg, 0.146 mmol) and **3** (16 μL, 0.168 mmol) in CH_2Cl_2 (5 mL) was stirred at room temperature before 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (67 μL, 0.448 mmol) was added. After 15 min, the reaction mixture was subjected to chromatography (silica, CH_2Cl_2/ethyl acetate 19/1) to give a *cis/trans* mixture (about 1:3 by ^{1}H NMR) of products. A second careful separation on a flash column with the same eluent gave two major fractions. The first fraction can be recrystallized from CH_2Cl_2/methanol to give **1b** as a purple solid (21 mg, 20 %): ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = -2.70$ (br s, 2H; NH), 6.23 and 6.67 (2 d, both 1H, $^3J = 12.1$ Hz; H_{alkene}), 7.07 (d, 2H, $^3J = 5.8$ Hz; $H_{pyridyl}$), 7.58 – 7.82 (m, 12H; $H_{m,pPh}$), 8.09 (d, 2H, $^3J = 7.5$ Hz; H_{oPh}), 8.16 (d, 2H, $^3J = 7.5$ Hz; H_{oPh}), 8.21 – 8.27 (m, 6H; H_{oPh}, $H_{pyridyl}$), 8.47 (s, 1H; $H_{pyrrole}$), 8.77 – 8.85 (m, 6H; $H_{pyrrole}$); UV/Vis (CH_2Cl_2): $\lambda_{max} = 428$, 523, 563, 600, 657 nm. The second fraction contains **1a**, which is obtained as a purple solid after recrystallization from CH_2Cl_2/methanol (65 mg, 62 %): ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = -2.59$ (br s, 2H; NH), 7.11 (d, 2H, $^3J = 6.1$ Hz; $H_{pyridyl}$), 7.19 (s, 2H, H_{alkene}), 7.74 – 7.85 (m, 12H; $H_{m,pPh}$), 8.19 – 8.28 (m, 8H; H_{oPh}), 8.55 (d, 2H, $^3J = 6.1$ Hz; $H_{pyridyl}$), 8.74 – 8.85 (m, 6H; $H_{pyrrole}$), 9.02 (s, 1H; $H_{pyrrole}$); UV/Vis (CH_2Cl_2): $\lambda_{max} = 428$, 523, 563, 600, 657 nm. HR-MS calcd for $C_{51}H_{36}N_5$ (MH^+): 718.2971; found: 718.2947.

[Zn(**1a**)]: ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 2.37$ (br s, 2H; $H_{pyridyl}$), 5.20 (br s, 2H; $H_{pyridyl}$), 6.09 and 6.31 (2 d, both 1H, $^3J = 16.1$ Hz; H_{alkene}), 7.21 – 7.27 (m, 3H; $H_{m,pPh}$), 7.68 – 7.79 (m, 11H; $H_{o,m,pPh}$), 8.08 – 8.24 (m, 6H; H_{oPh}), 8.57 – 8.60 (m, 2H; $H_{pyrrole}$), 8.79 – 8.83 (m, 5H; $H_{pyrrole}$); UV/Vis (CH_2Cl_2): $\lambda_{max} = 433$, 558, 563, 621, 758 nm; HR-MS: calcd for $C_{51}H_{34}N_5{}^{64}Zn$ ($M+H)^+$: 780.2106; found: 780.2095 (monomeric fragment).

[{Zn(**1b**)}$_2$]: ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 2.06$ (d, 2H, $^3J = 6.1$ Hz; $H_{pyridyl}$), 5.18 (d, 2H, $^3J = 6.1$ Hz; $H_{pyridyl}$), 5.28 and 6.28 (2 d, both 1H, $^3J = 11.8$ Hz; H_{alkene}), 7.31 – 7.43 (m, 6H; $H_{m,pPh}$), 7.71 – 7.93 (m, 10H; $H_{o,m,pPh}$), 8.10 – 8.36 (m, 4H; H_{oPh}), 8.44 (d, 1H; $^3J = 4.6$ Hz; $H_{pyrrole}$), 8.67 – 8.81 (m, 2H; $H_{pyrrole}$), 8.94 and 8.99 (m(AB), 4H, $^3J = 4.6$ Hz; $H_{pyrrole}$); UV/Vis (CH_2Cl_2): $\lambda_{max} = 429$, 527, 564, 603 nm. HR-MS calcd for $C_{102}H_{70}N_{10}{}^{64}Zn_2$ ($M+4H)^+$: 1562.4368; found: 1562.4329.

Well-Defined Surface-Bonded Ruthenium Complexes with Molecular Nitrogen**

Hans Miessner* and Klaus Richter

Ruthenium is considered to possess great potential in the development of new catalysts for the ammonia synthesis. Indeed, recently a number of papers have reported the adsorption and the activation of nitrogen on ruthenium catalysts.[1]

The interaction of molecular nitrogen with supported transition metal catalysts is usually weak. By IR spectroscopy it was possible to confirm the adsorption of N_2 on ruthenium catalysts only at low temperatures (123 K),[2] or on certain supports (Al_2O_3, MgO).[3] Depending on the support, the promoter, and the pretreatment, the N_2 stretching vibrations were found in a wide range between 2214 and 1910 cm^{-1}.

Some reports have also covered the formation of dinitrogen–metal complexes in zeolites. For instance, monodinitrogen complexes with Cu^I ions have been identified in mordenite[4] and in ZSM-5.[5] We recently reported on the formation of well-defined surface-bonded rhodium complexes in dealuminated Y-zeolite (DAY),[6] which are stable up to 523 K in a nitrogen stream. The compounds were identified as the bis(dinitrogen) rhodium complex $[Rh^I(N_2)_2]^+$ and the mixed carbonyldinitrogen rhodium complex $[Rh^I(CO)N_2]^+$ and are probably located on cationic sites in the zeolite. In the present paper we show that ruthenium centers in zeolites also form defined surface-bonded compounds with molecular nitrogen. The chemistry of these compounds appears to be considerably more varied than that of the rhodium complexes.

The IR difference spectra obtained from a monocarbonyl ruthenium complex bonded to the DAY zeolite after treatment with a N_2/Ar gas mixture at 523 K are shown in Figure 1.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The complex was obtained by partial decarbonylation of a dicarbonyl ruthenium complex on the DAY zeolite, in a manner similar to that for the reactive monocarbonyl rhodium complex in Rh/DAY.[6] The negative band in the difference spectra at 2036 cm^{-1} and the positive bands in the carbonyl stretching region at 2083, 2023, 2016, 1997, and 1970 cm^{-1} clearly indicate that the monocarbonyl compound (2036 cm^{-1}) is replaced by other surface-bonded carbonyls, one of which is the starting dicarbonyl ruthenium reagent (2083 and 2016 cm^{-1}). At the same time, IR bands are clearly observed in the N_2 vibrational region at 2218, 2207, and 2173 cm^{-1}.

An analysis of the integrated band intensities from several experiments between 423 and 523 K and partial nitrogen pressures of 100–500 kPa indicated a correlation between the bands at 2218 and 2023 cm^{-1} on one hand, and between those at 2207 and 2173 cm^{-1} on the other (see Figure 1). Analogous

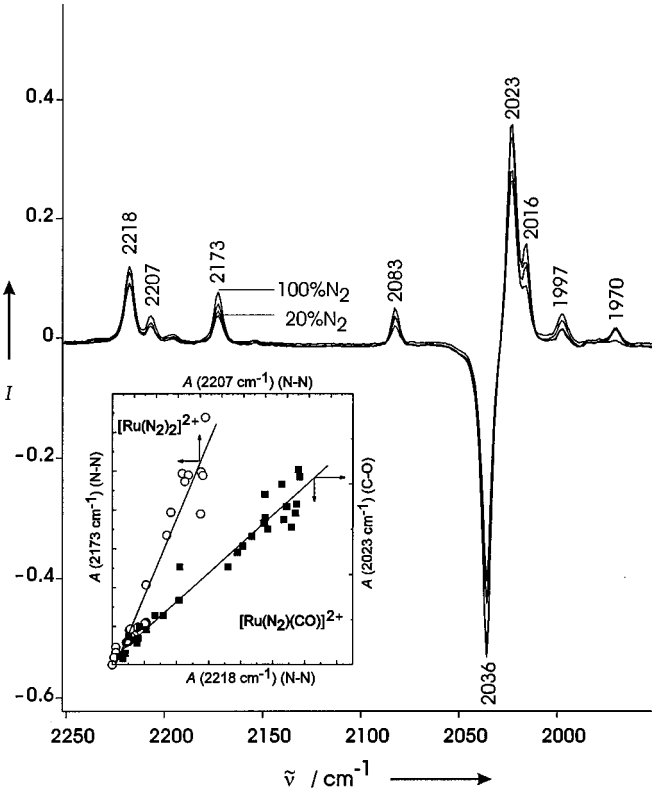

Figure 1. IR difference spectra (CO and N_2 vibration regions), recorded from the DAY-bonded monocarbonyl ruthenium complex after reaction with N_2/Ar at 523 K. The insert shows the correlation between the integrated intensities of the N_2 vibrations at 2207 and 2173 cm^{-1} (correlation coefficient $R^2=0.934$, $N=25$) and the N_2 vibration at 2218 cm^{-1} and the CO vibration at 2023 cm^{-1} ($R^2=0.957$, $N=30$). N = number of measurement values, A = absorption (arbitrary units).

to the results obtained with the Rh/DAY system,[6] the first band pair can be attributed to a carbonyldinitrogen ruthenium complex, and the second band pair to a bis(dinitrogen) ruthenium complex. The composition and the structure of the dinitrogen complexes were verified—similar to the manner employed in the Rh/DAY system[6]—from IR spectra recorded in the presence of ^{13}CO and $^{15}N_2$, and by force-field calculations. The formation of the dinitrogen complexes is reversible; the monocarbonyl is formed once again in the presence of hydrogen or in a pure argon stream at 523 K.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0117 $ 17.50+.50/0

As is the case for the pure carbonyl complexes on Ru/DAY, the carbonyl and dinitrogen bands of the dinitrogen ruthenium complexes occur at lower wavenumbers than those of the corresponding rhodium complexes. This indicates that stronger bonds are formed between the ruthenium centers and the ligands as a result of stronger π back bonding, but also that the nitrogen molecules are more strongly activated.

In contrast to the dinitrogen rhodium complexes, the IR spectra of the ruthenium complexes change significantly at low temperatures. Below 400 K new bands are observed at 2257, 2239, 2231, and 2205 cm^{-1}. The intensities of these bands increase at the expense of the bands at 2218, 2207, and 2173 cm^{-1}. The band at 2257 cm^{-1} correlates with a new carbonyl band at 2039 cm^{-1}, and studies performed with ^{13}CO and $^{15}N_2$ confirm the formation of a further monocarbonyldinitrogen compound. The structure of the complex evidently changes with temperature, due to, for example, differences in the bonding to the zeolite framework.

An additional significant difference to the rhodium system may also be related to the higher stability of the ruthenium–nitrogen bond. The dinitrogen rhodium complexes are very sensitive to traces of CO in the gas stream and are irreversibly transformed into the stable dicarbonyl rhodium compounds.[6] In contrast, the dinitrogen ruthenium complexes react with CO in the gas phase at temperatures below 350 K to form a further stable dinitrogen compound with an intense N_2 vibration band at 2231 cm^{-1}. Figure 2 shows the changes in the IR spectra in the regions of the N_2 and CO vibrations. In addition to a broad band at approximately 2130 cm^{-1} from physisorbed CO and carbonyl bands at 2152, 2081, and 2049 cm^{-1}, which may be attributed to a tricarbonyl ruthenium complex, there is an intense band at 2061 cm^{-1} and a weak band at 2129 cm^{-1}. The intensities of these bands change with that of the N_2 band at 2231 cm^{-1}, and we assigned them to a *trans*-dicarbonyldinitrogen ruthenium complex. A ligand exchange reaction with $^{15}N_2$ and ^{13}CO confirmed this assignment.

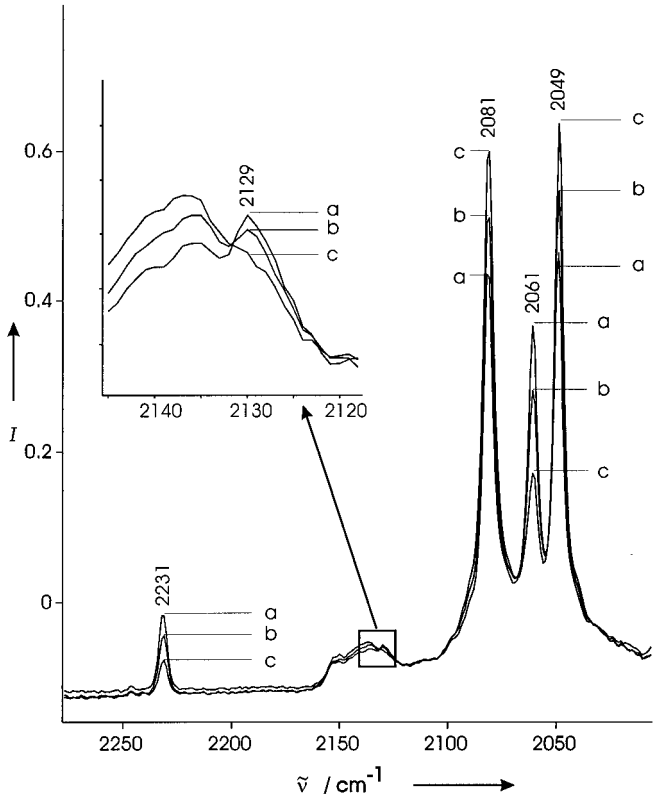

Figure 2. IR spectra in the CO and N_2 vibration regions in the presence of CO in the gas stream (5% CO/Ar:N_2 = 1:1) at 323 K (a), 343 K (b), and 363 K (c).

Table 1 provides an overview of the dinitrogen ruthenium complexes identified on the dealuminated DAY zeolite. As far as is presently known, the chemistry of molecular nitrogen and ruthenium compounds in dealuminated zeolites is considerably more diverse than that of rhodium compounds. Particularly remarkable is the higher bond strength of the molecular nitrogen to the ruthenium complexes compared to the rhodium complexes, and the associated weakening of the N≡N bond. Additional studies are required in order to show whether the nitrogen molecule can thus be sufficiently activated for further reactions such as, for example, protonation—the first step in a possible ammonia synthesis.

Table 1. N–N and C–O vibrational frequencies of the dinitrogen ruthenium complexes of the Ru/DAY system.

Species	T[K]	$\tilde{\nu}$[cm^{-1}] (N_2)	(CO)

Experimental Section

The DAY support used (Degussa, Germany) is a dealuminated Y zeolite with a Si:Al ratio ≥ 100:1. The sample Ru/DAY (1 wt. % Ru) was prepared by impregnation of the support with the necessary amount of $RuCl_3$ in ethanolic solution and then dried in air at 353 K. The remaining pretreatment was carried out in the IR cell and involved a carbonylation in a CO/Ar stream (5% CO) at 523 K and a partial decarbonylation in a H_2 stream at 523 K.

In order to study the effect of the residual chlorine still present after this treatment, a control experiment was carried out with $Ru_3(CO)_{12}$ as the ruthenium source. Identical results were obtained with the dinitrogen ruthenium complexes obtained this way.

The IR transmission studies were carried out with pressed samples made from the pure substance (self-supported wafers) in a special steel cell in which in situ measurements up to 673 K and 5000 kPa are possible. The small dead volume coupled with a suitable gas supply and mass flow-rate controllers (MKS) allowed rapid changes in gas composition. The high purity gases used (AGA Gas GmbH) were additionally purified with OXYSORB (Messer Griesheim GmbH). ^{13}CO (99%; Linde AG) and $^{15}N_2$ (98%; Chemotrade) were used for the isotope exchange reactions.

The IR spectra were recorded on a Perkin–Elmer Paragon 1000 FTIR spectrometer at a resolution of 2 cm^{-1}.

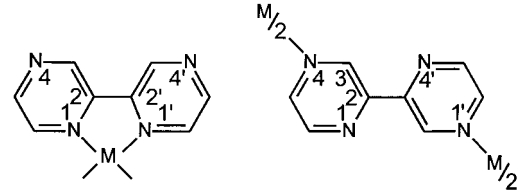
Molecular Triangle from enPt^{II} and 2,2′-Bipyrazine**



Ralf-Dieter Schnebeck, Lucio Randaccio,* Ennio Zangrando, and Bernhard Lippert*

Cyclic trimetallic complexes with metal–metal bonds[1] or bridging ligands[2,3] are known in large numbers (Scheme 1), but examples containing bridging heterocycles arranged approximately perpendicular to the metal triangle are relatively rare.[3] Here we report on a trinuclear Pt^{II} complex containing 2,2′-bipyrazine ligands (bpz) which fulfills the latter requirement and forms spontaneously in a self-assembly process. The compound is of interest with respect to the formation and stability of "molecular squares"[4] from 4,4′-bipyridine ligands and rectangular, square-planar metal units. However, the impression that combining these building blocks always leads to squares and rectangles is misleading. As first indicated by Fujita and co-workers,[5] *cis*-Pd^{II}en (en = ethylenediamine) can be used with 4,4′-bipy to form both molecular squares and triangles or both in a concentration-dependent equilibrium.

Scheme 1.

As demonstrated here, the heterocyclic ligand 2,2′-bipyrazine reacts with square-planar enM^{II} units (M = Pd or Pt) either with chelate or bridge formation (Scheme 2). In the first case bpz is practically coplanar with the coordination plane of M, whereas in the second case, following cyclization to the trinuclear complex, it is virtually perpendicular to the metal triangle. Compound **1** forms in 40% yield upon reaction of $[(en)Pd(H_2O)_2](NO_3)_2$ with bpz[6] and recrystallization of the crude product from water in the presence of $NaClO_4$. Figure 1 depicts the cation of **1**. The results of the X-ray structure determination[7–9] reveal that the N(1)-Pd-N(1′) angle of 80.7(1)° deviates markedly from 90° and is in the range found for related complexes containing 2,2′-bipyridine[10] or *o*-phenanthroline.[11] In the case of a Ru^{II} compound containing a chelating bpz ligand, this value is 78.92(6)°.[12] The geometry of the Pd(en) unit is normal.[13] Attempts to use cation **1** as a corner stone in the preparation of a molecular square in the true sense[14]—that is, cyclization through the 4 and 4′ positions via linear metal units—have been unsuccessful as yet. We assume that the low basicity[15] of these positions rather than the nonideal N(4)-Pd-N(4′) angle

Scheme 2.

Figure 1. Structure of cation of **1**. Selected bond lengths [Å] and angles [°]: Pd–N(1) 2.034(3), Pd–N(1′) 2.025(3), Pd–N(2) 2.026(3), Pd–N(3) 2.023(3); N(1)-Pd-N(1′) 80.7(1), N(1)-Pd-N(2) 98.8(1), N(1)-Pd-N(3) 178.2(1), N(1′)-Pd-N(2) 179.4(1), N(1′)-Pd-N(3) 97.6(1), N(2)-Pd-N(3) 83.0(1), N(4)-Pd-N(4′) 73.0(1).

(73.0(1)°) is responsible. However, we feel that metal units with a pronounced ability for π backdonation (e.g. Ru^{II})[16] might in principle be capable of forming such squares. There are many examples of complexes containing bridging pyrazine ligands[4e,f,17] for which similar criteria apply.

The Pt analogue of the cation in **1**, **1′**, was isolated as the nitrate salt and characterized by ^{1}H NMR spectroscopy. The sensitivity of crystals of **1′** has thus far prevented an X-ray crystal structure analysis.

A second Pt complex, which proved to be the cyclic species **2**, displays a markedly different ^{1}H NMR spectrum from **1′**. The cation of **2**[18] has C_2 symmetry (Figure 2). The three Pt

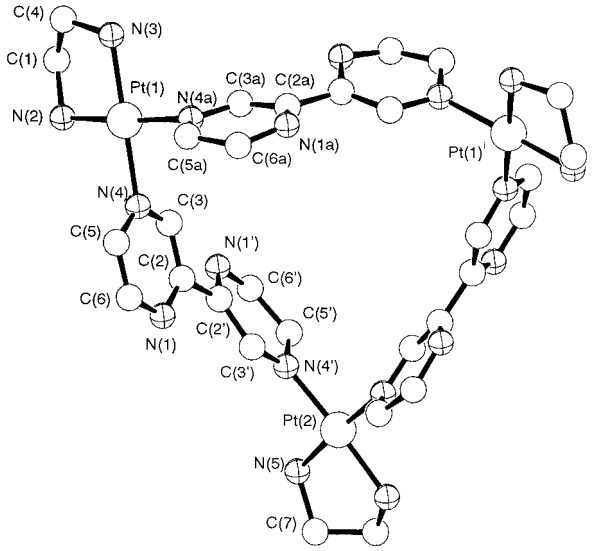

Figure 2. Structure of cation of **2**. Selected bond lengths [Å] and angles [°]: Pt(1)–N(4a) 2.017(13), Pt(1)–N(4) 2.075(14), Pt(1)–N(2) 1.97(2), Pt(1)–N(3) 2.043(13), Pt(2)–N(4′) 1.98(2), Pt(2)–N(5) 1.982(13); N(4a)-Pt(1)-N(4) 87.1(5), N(1)-Pt(1)-N(2) 175.5(5), N(4a)-Pt(1)-N(3) 93.8(5), N(4)-Pt(1)-N(2) 95.7(7), N(4)-Pt(1)-N(3) 178.6(7), N(2)-Pt(1)-N(3) 83.4(6), N(4′)-Pt(2)-N(4′)^i 93.3(9), N(5)-Pt-N(5)^i 84.6(7), N(4′)-Pt(2)-N(5) 91.1(6), N(4′)-Pt-N(5)^i 175.7(6).

atoms form an approximately equilateral triangle with Pt(1)–Pt(1)^i and Pt(1)–Pt(2) distances of 9.404(3) and 9.422(1) Å, respectively. The C_2 axis runs through Pt(2). In contrast to **1**, the bpz ligand in **2** is in a transoid orientation

$[\{(en)Pt(bpz)\}_3](NO_3)_6$ **2**

following rotation about the central C(2)–C(2′) bond. The three metal atoms are therefore linked through N(4) atoms. The N(4)-Pt-N(4′) angles at the Pt atoms are 87.1(5)° for Pt(1) and Pt(1)^i and 93.3(9)° for Pt(2).

The two pyrazine rings of each bpz ligand in **2** are markedly twisted with respect to each other (21 and 27°), which appears to be crucial for formation of the triangle. Considering the fact that similar twist angles have been observed for 2,2′-bipyridine in the gas phase and in solution,[19] it appears likely that formation of **2** and possibly even of the (en)Pd/4,4′-bipyridine triangle[5] is facilitated by this feature.

Formation of the chelate complex **1′** and of the molecular triangle **2** from $[(en)Pt(H_2O)_2]^{2+}$ and bpz apparently takes place from two different linkage isomers: bonding through N(1) for **1′** and through N(4) for **2**. Following the reactions with NMR spectroscopy (^{1}H, ^{195}Pt) confirms this assumption. In the ^{1}H NMR spectra the number of resonances decreases as the reactions proceed, as expected for formation of **1′** from $[(en)Pt(H_2O)(bpz\text{-}N(1))]^{2+}$ and of **2** from $[(en)Pt(H_2O)(bpz\text{-}N(4))]^{2+}$.

Based on model studies, it appears that the pyrazine rings of the bpz ligand in **2** can undergo rather facile rotation about the C(2)–C(2′) bond to produce different rotational isomers. The dynamics of this process and properties of the hydrophobic cavity of the cation of **2** with regard to possible host–guest interactions are subjects of ongoing work.

Experimental Section

1: (en)$PdCl_2$ (214 mg, 0.90 mmol) was suspended in water (30 mL) and stirred for 2 h at room temperature (RT) with $AgNO_3$ (297 mg, 1.75 mmol). After removal of AgCl by filtration and addition of bpz (138 mg, 0.87 mmol) to the filtrate, the mixture was stirred for 24 h at RT. The solution (pH 3.0) was then filtered and concentrated to 5 mL under vacuum. $NaClO_4$ (275 mg, 2.25 mmol) was then added to the yellow solution. Yellow **1** was obtained in 40% yield within two days at 4 °C. Satisfactory elemental analysis for $PdC_{10}H_{14}N_6O_8Cl_2$. ^{1}H NMR (200 MHz, D_2O, TSP): $\delta = 3.10$ (s, 4H, CH_2), 8.53 (dd, $^3J = 3.2$ Hz, $^5J = 1.1$ Hz, 2H, aromatic), 9.07 (d, $^3J = 3.2$ Hz, 2H, aromatic), 9.78 (d, $^5J = 0.9$ Hz, 2H, aromatic).

1′ and **2**: (en)$PtCl_2$ (325 mg, 0.99 mmol) was suspended in water (30 mL), $AgNO_3$ (323 mg, 1.90 mmol) added, and the mixture stirred for 1 h at 80 °C. After the mixture was cooled and AgCl removed by filtration, bpz (150 mg, 0.95 mmol) was added, and the mixture stirred for three days at 45 °C. The reaction mixture was filtered and concentrated to 5 mL under vacuum. $NaNO_3$ (170 mg, 2.0 mmol) was then added to the yellow solution (pH 4.5). Yellow $\mathbf{2} \cdot n\,H_2O$ was isolated in 35% yield after 6–10 d at 4 °C. Satisfactory elemental analysis for $Pt_3C_{30}H_{54}N_{24}O_{24}$) (for $n = 6$, the X-ray structure analysis gave $n = 4$). ^{1}H NMR (200 MHz, D_2O, TSP): $\delta = 2.85$ (s, 4H, CH_2), 8.84 (dd, $^3J = 3.2$ Hz, $^5J = 1.1$ Hz, 2H, aromatic), 9.10 (d, $^3J = 3.2$ Hz, 2H, aromatic), 9.33 (s, 2H, aromatic); ^{195}Pt NMR (43 MHz, D_2O): $\delta = -2753$ (PtN_4). Needles of **1′** are formed as a side product (5%) in the synthesis of **2** if the reaction time is shortened by two days and the reaction temperature kept at 25 °C. ^{1}H NMR (200 MHz, D_2O, TSP): $\delta = 2.88$ (s, 4H, CH_2), 8.90 (dd, $^3J = 3.2$ Hz, $^5J = 0.8$ Hz, 2H, aromatic), 9.15 (d, $^3J = 3.2$ Hz, 2H, aromatic), 9.79 (d, $^5J = 0.8$ Hz, 2H, aromatic); ^{195}Pt NMR (43 MHz, D_2O): $\delta = -2749$ (PtN_4).

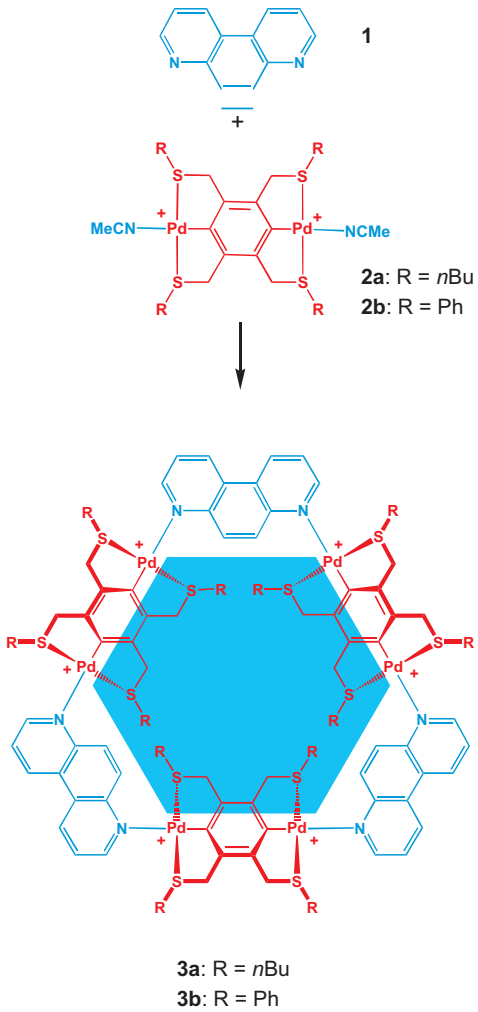
Supramolecular Arrays of 4,7-Phenanthroline Complexes: Self-Assembly of Molecular Pd_6 Hexagons**

Jeffrey R. Hall, Stephen J. Loeb,* George K. H. Shimizu, and Glenn P. A. Yap

The formation of supramolecular arrays of metal ions and ligands is favored by a metal-directed, self-assembly mechanism, which allows for high-yield synthesis under thermodynamic control.[1] Rigid complexes can be synthesized in which the overall structure is dictated by a combination of the binding constraints of the ligand and the geometrical requirements of the metal ions.[2] For example, tetranuclear squares were first prepared by combining the approximately 90° angles of a square-planar palladium complex with the linearly oriented donor atoms of 4,4′-bipyridine.[3] In a similar fashion, polypyridine ligands and metal ions have produced a fascinating variety of squares,[4] boxes,[3b, 5] helicates,[6] catenanes,[7] rotaxanes,[8] racks,[9] grids,[10] and ladders.[11]

To increase the scope of such assemblies, we have begun to explore the use of predesigned organometallic fragments as building blocks.[12] A similar strategy was recently employed to prepare dendrimers[13] as well as nanoscale squares[14] and hexagons.[15] Here we report the self-assembly of a rigid, cyclic structure that contains 4,7-phenanthroline (**1**) and the linear organopalladium complex fragments **2a** or **2b** as building blocks. Self-assembly of these complimentary molecular building blocks with angular requirements of 60 and 180° results in a six-component [3+3] cyclic array.



Complexes **2a** and **2b** are readily prepared by palladation of the thioether ligands 1,2,4,5-tetrakis(*n*-butylthiomethyl)benzene and 1,2,4,5-tetrakis(phenylthiomethyl)benzene, respectively, with two equivalents of $[Pd(MeCN)_4][BF_4]_2$ in acetonitrile. Combining equimolar amounts of **1** and **2a**$[BF_4]_2$ or **2b**$[BF_4]_2$ in an appropriate solvent (**2a**, CH_2Cl_2; **2b**, $(CH_3)_2CO$) resulted in quantitative formation of the hexanuclear complexes **3a** and **3b** (Scheme 1). These complexes can be isolated as BF_4^- salts in the form of air- and moisture-stable, pale yellow, microcrystalline solids; their solubility depends on the R group attached to the sulfur center.

The ^{1}H NMR spectra of **3a** and **3b** are consistent with highly symmetrical structures and show large coordination shifts for the phenanthroline ring protons, in the range from $\Delta\delta = 0.65$ for H1 and H10 to $\Delta\delta = 1.63$ for H5 and H6. Integration of the signals indicates a 1:1 ratio of organometallic complex fragment to 4,7-phenanthroline, and this is supported by elemental analyses. In attempts to observe intermediates in the self-assembly process, experiments involving stepwise addition of metal to ligand and ligand to metal were monitored by ^{1}H NMR spectroscopy. In no case were species other than the cyclic product and the component in excess

Scheme 1. Reaction of **1** with solvated **2a** and **2b** to give **3a** and **3b**, respectively (counterion BF_4^-).

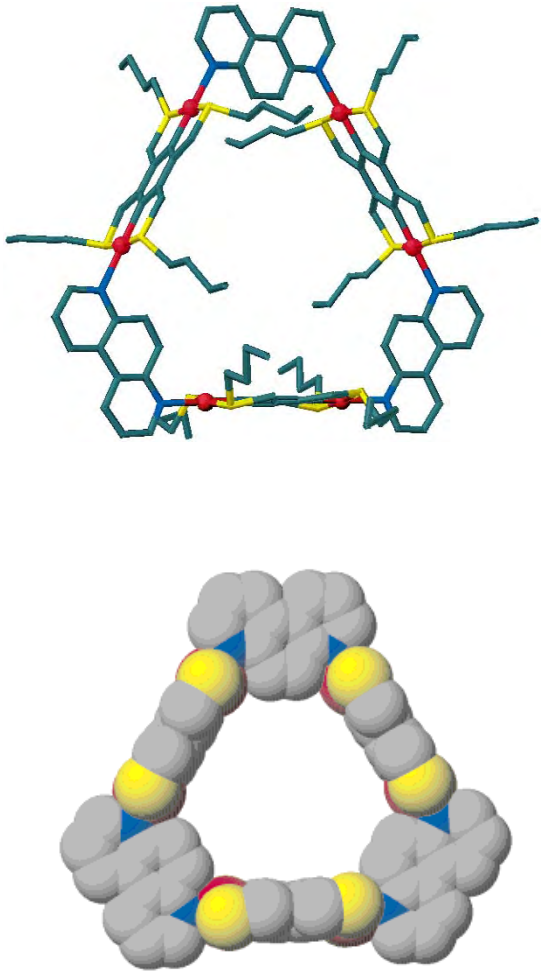

Figure 1. Crystal structure of **3a**. Top: Representation of the bonds in the framework (red = Pd, yellow = S, blue = N, gray = C). Bottom: space-filling representation (*n*Bu groups omitted for clarity).

observed. This is consistent with rapid formation of the thermodynamically favored cyclic product. An X-ray structural study of **3a** confirmed the postulated hexanuclear structure (Figure 1).[16]

As planned, the metalated aromatic units form three "walls" of the supramolecular array, and the 4,7-phenanthroline ligands form three corner pieces. The planes of the two different fragments are approximately perpendicular to each other. The Pd···Pd distances within the organopalladium unit average 6.83 Å, whereas the distance between two Pd atoms across the 4,7-phenanthroline ligand averages 7.80 Å. Since all six palladium atoms are constrained to lie in a single plane and the Pd-Pd-Pd angles are about 120° because of the geometrical requirements of the the phenanthroline bridges, the metal array approximates a Pd_6 hexagon. In overall dimensions, this rigid framework is about 2.0 nm in width, about 0.5 nm in depth (not including the *n*Bu groups), and contains a permanent cavity of approximately 1.2 nm in diameter.

In solution, two dynamic processes affect the line shape of the NMR signals of the benzylic protons: inversion at the sulfur center and rotation about the Pd–N bond. Variable-temperature ^{1}H NMR spectra of **3b** show that at elevated temperature (323 K, CD_2Cl_2) inversion at the sulfur center is rapid on the NMR time scale, but rotation about the Pd–N bond is restricted due to the steric requirements of the phenyl groups. This gives rise to an AB pattern at high temperature due to coupling of the benzylic protons which are constrained "inside" and "outside" of the cyclic structure. This is not observed for **3a**, which contains the smaller *n*Bu groups. The high-temperature spectrum of **3a** exhibits a single, sharp signal for the benzylic protons, which nonetheless provides evidence for the cyclic nature of this species in solution.

4,7-Phenanthroline is a simple, commercially available ligand that favors bridging over chelation and provides a rigid 60° corner for creating unique metal–ligand arrays. The self-assembly strategy allows the construction of large, rigid cavities, and this bodes well for the future development of metal-based receptors and nanoscale materials. An advantage of employing the organopalladium complex fragments described here is the readily variable substituent on the sulfur atom, which allows the physical properties to be modified. We are currently investigating the incorporation of R groups that make the product water-soluble so that solvophobic interactions inside the cavity become possible.

Experimental Section

3a: Equimolar solutions of 4,7-phenanthroline and **2a** were mixed in CH_2Cl_2 or acetone. The concentration range from 3.29 μM to 1.54 M was studied. The solvent was allowed to evaporate slowly. Pale yellow crystals were obtained from acetone, and microcrystalline powders from CH_2Cl_2. No further purification was required. In all cases, the yield of isolated product was greater than 90%. ^{1}H NMR (300 MHz, [D$_6$]acetone, 300 K): $\delta = 9.81$ (m, 12H, phen), 9.68 (m, 6H, phen), 8.28 (qt, 6H, phen), 4.69 (br s, 24H, Bz), 3.10 (br m, 24H, SCH_2), 1.63 (br m, 24H) 1.18 (br m, CH_2CH_3), 0.69 (br t, 36H, CH_3); FAB-MS: m/z = 965 $[M-3BF_4]^{3+}$; elemental analysis calcd for $C_{114}H_{156}B_6F_{24}N_6Pd_6S_{12}$: C 43.40, H 4.98, N 2.66; found: C 43.33, H 4.96, N 2.59.

3b: Equimolar solutions of 4,7-phenanthroline and **2b** were mixed in CH_2Cl_2, acetone, or MeOH. Neither the rate of addition nor the order of addition affected the product quality and yield. The concentration range from 3.17 μM to 1.54 M was studied. The solvent was allowed to evaporate slowly. Crystalline material was obtained from CH_2Cl_2, and microcrystalline powders from acetone and MeOH. No further purification was required. In all cases, the yield of isolated product was greater than 90%. ^{1}H NMR (300 MHz, CD_2Cl_2, 323 K): $\delta = 9.42$ (d, 6H, phen), 9.00 (br s, 6H, phen), 8.84 (br s, 6H, phen), 7.82 (qt, 6H, phen) 7.71 (m, 24H, SPh), 7.44 (m, 24H, SPh), 5.27 (dd, 24H, Bz); FAB-MS: $m/z = 1610$ $[M-2BF_4]^{2+}$. LSI-MS: $m/z = 1045$ $[M-3BF_4]^{3+}$; elemental analysis calcd for $C_{138}H_{108}B_6F_{24}N_6Pd_6S_{12}$: C 48.83, H 3.21, N 2.48; found: C 48.67, H 3.13, N 2.33.

[16] Crystal data[17] for **3b**$[BF_4]_6$: monoclinic, space group *C*2/*c*, $a = 26.8628(3)$, $b = 24.1205(2)$, $c = 28.4165(1)$ Å, $\beta = 113.504(1)^\circ$, $V = 16884.7(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.241$ g cm^{-3}, $2\theta_{max} = 42.0^\circ$, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), $T = 296$ K. A pale yellow, crystal ($0.2 \times 0.2 \times 0.3$ mm^3), grown by slow evaporation of a saturated solution in acetone, was sealed with the mother liquor in a thin-walled glass capillary. Of 8710 reflections measured, 7422 were observed ($I > 2\sigma(I)$) and integrated from frame data obtained from programmed hemisphere scan routine on a Siemens SMART CCD diffractometer. Decay (< 1%) was monitored by 50 standard data frames measured at the beginning and end of data collection. Systematic absences in the diffraction data and determined unit-cell parameters were consistent with *Cc* and *C2/c*. Solution in the centrosymmetric space group yielded chemically reasonable and computationally stable refinement results. Lorentzian and polarization corrections and a semi-empirical absorption correction, based on redundant data at varying effective azimuthal angles, were applied to the data ($\mu = 0.837$ cm^{-1}, min/max transmission = 0.3516/0.4663). The structure was solved by direct methods, completed by subsequent Fourier syntheses, and refined with full-matrix least-squares methods against F^2 to $R(F) = 0.1277$, $wR(F^2) = 0.3627$, $N_o/N_v = 8704/456$. The cation is located on a twofold axis. One of three symmetry-unique BF_4^- counterions was located and refined as a geometrically idealized rigid group. Attempts to model nine peaks with substantial electron density, remote from the cation and the located counterion, as disordered BF_4^- counterions or as chemically reasonable solvent molecules were unsuccessful. These peaks were assigned arbitrary carbon identities but replaced in calculations for intrinsic properties by the expected number of anions. Remaining peaks in the final difference map (max. 1.7 e Å^{-3}) were associated with the heavy atoms and considered to be artifacts arising from nonideal absorption corrections. The non-carbon and non-hydrogen atoms. as well as the phenyl ring carbon atoms of the cation were refined with anisotropic displacement coefficients. All other non-hydrogen atoms were refined isotropically. Hydrogen atoms were treated as idealized contributions. Scattering factors and anomalous dispersion coefficients are contained in the SHELXTL 5.03 program library (G. M. Sheldrick, Madison, WI).

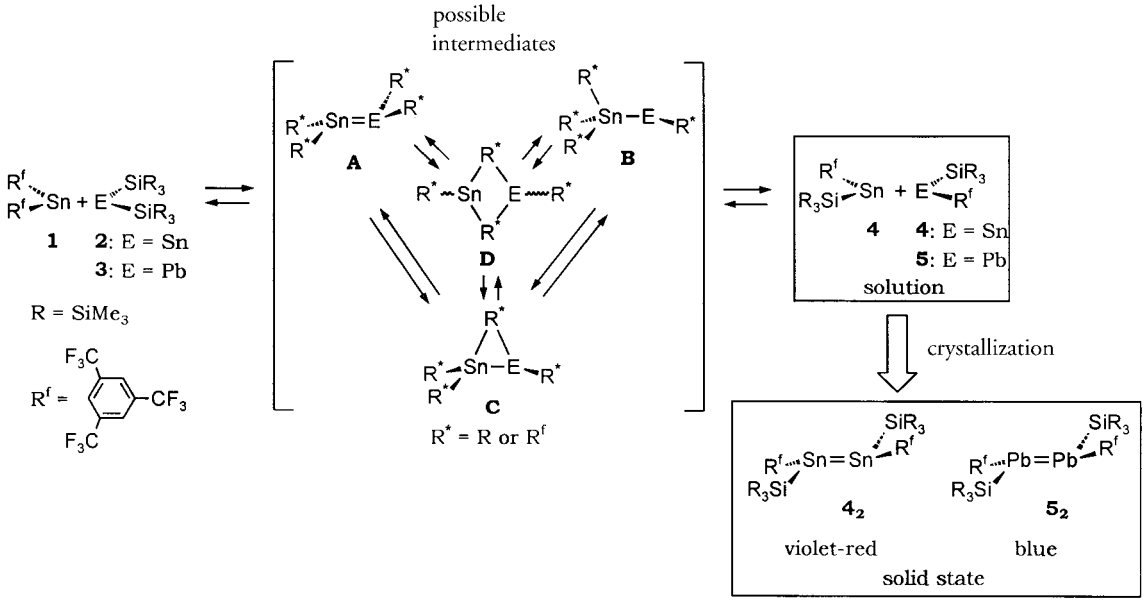
The Formation of Heteroleptic Carbene Homologues by Ligand Exchange—Synthesis of the First Plumbanediyl Dimer**



Karl W. Klinkhammer,* Thomas F. Fässler,* and Hansjörg Grützmacher*

Dedicated to Professor Manfred Weidenbruch on the occasion of his 60th birthday

Compounds of the heavier homologues of carbon containing double bonds ($R_2E{=}ER_2$, E = Si, Ge, Sn) differ strikingly from the corresponding alkenes, not only in their molecular structures but also in their chemical behavior. The type of bonding present in these molecules remains a very controversial subject.[1] The heaviest homologues, diplumbenes $R_2Pb{=}PbR_2$, were hitherto unknown. Plumbanediyls PbR_2 (also called plumbylenes), the constituent fragments homologous to carbenes, have, however, been isolated. They are monomeric even in the solid state, whereas the stannanediyls SnR_2 are known to dimerize in many cases, leading to the formation of distannenes $R_2Sn{=}SnR_2$.[2]

What happens if two carbene homologues, with differing dimerization tendencies, are mixed? Are mixed distannenes $R_2Sn{=}SnR'_2$ or even stannaplumbethenes $R_2Sn{=}PbR'_2$ accessible under such conditions? For our investigations we have chosen the stable monomeric stannanediyl [2,4,6-$(CF_3)_3C_6H_2]_2$Sn (**1**),[3] the distannene $[(Me_3Si)_3Si]_2Sn{=}Sn[Si(SiMe_3)_3]_2$ (**2_2**), and the plumbanediyl $[(Me_3Si)_3Si]_2$Pb (**3**).[4] In hydrocarbon solvents diyls **1**, **2**, and **3** exist as monomeric R_2E carbene analogues (E = Sn, Pb) in a singlet ground state. When equimolar solutions of **1** and **2** or **1** and **3** are mixed, the heteroleptic compounds **4** and **5**, respectively, are obtained (Scheme 1).

Fractional crystallization of the reaction mixtures in solution at $-60\,^{\circ}C$ led to thermochromic, needle-shaped crystals of the distannene **4_2**, which are violet-red at room temperature and brick-red at $-180\,^{\circ}C$, and blue prismatic crystals of the plumbanediyl dimer **5_2**. In both reactions a remarkable exchange of ligands has occurred with the result that each metal center E bears one 2,4,6-$(CF_3)_3C_6H_2$ and one $(Me_3Si)_3Si$ substituent. To our knowledge, a comparable rearrangement has been never observed in carbene or olefin chemistry but has been reported as a mechanism for the isomerization of disilenes, digermenes, and distannenes.[1] Although we have no spectroscopic evidence,[6] it is likely that the intermediates **A**–**D** play a crucial role in course of this rearrangement. Calculations showed that for R* = H and E = Sn or Pb, all E_2H_4 isomers correspond to local minima on the energy hypersurface following the order **A** < **B** < **C** < **D** of increasing stability within a narrow energy range.[6] In solution the dimers **4_2** and **5_2** dissociate into the monomers **4** and **5**. Note that no mixed Sn=Pb dimer was obtained from solutions containing **4** and **5** in accordance with calculated dimerization energies (Table 1) which show that the dismutation reaction as shown in Equation (a) is slightly exothermic.

Scheme 1.

$$2\,H_2Sn{=}PbH_2 \rightarrow H_2Sn{=}SnH_2 + H_2Pb{=}PbH_2 \qquad (a)$$

$$\Delta(\Delta E_{dim}) = -10\ kJ\,mol^{-1}$$

Pb=Pb	295	354	54.6	40.8	24	43
Sn=Pb	279	–	54.5(Sn) 49.3 (Pb)	–	55	–

[a] Calculation on Coupled-Cluster-Level.[9] [b] Data from very distorted distannenes were excluded.[1g] [c] Published data.[8]

Single-crystal X-ray diffraction experiments[7] performed at – 100 °C revealed that both compounds **4** and **5** crystallize as centrosymmetric *trans*-bent dimers $\mathbf{4}_2$ and $\mathbf{5}_2$ with idealized C_i symmetry (Figure 1). The experimentally determined tilt angles θ are 41.5° (E = Sn) and 40.8° (E = Pb). The Sn–Sn bond length in $\mathbf{4}_2$ [283.3(1) pm] is similar to the one in the distannene $\mathbf{2}_2$ [282 pm]. It is considerably longer, however, than the bond length in the distannene $R_2Sn{=}SnR_2$ [277 pm, $R = (Me_3Si)_2CH$, C_i symmetry][1f] and much shorter than the Sn–Sn distance in the stannanediyl dimer $R^f_2Sn{=}SnR^f_2$ [363 pm, R^f = 2,4,6-$(CF_3)_3C_6H_2$, C_i symmetry].[2b] The Pb–Pb bond length in $\mathbf{5}_2$ (353.7(1) pm) is long and exceeds the

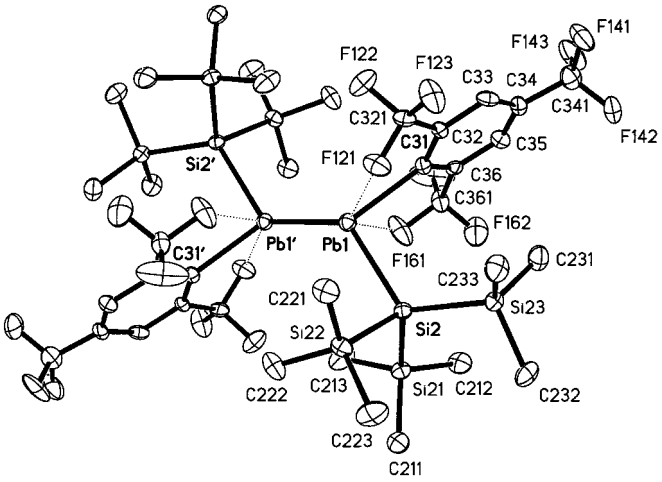

Figure 1. The structures of $\mathbf{4}_2$ and $\mathbf{5}_2$ in the crystal are very similar and only $\mathbf{5}_2$ is shown. Selected bond lengths [pm] and angles [°]: $\mathbf{4}_2$: Sn1–Sn1′ 283.3(1), Sn1–Si2 262.4(1), Sn1–C31 225.5(3); Si2-Sn1-Sn1′ 126.3(1), C31-Sn1-Sn1′ 107.8(1), Si2-Sn1-C31 103.8(1). $\mathbf{5}_2$: Pb1–Pb1′ 353.7(1), Pb1–Si2 270.5(2), Pb1–C31 236.9(7); Si2-Pb1-C31 96.7(2), Si2-Pb1-Pb1′ 124.82(5), C31-Pb1-Pb1′ 115.3(2).

calculated bond length in the parent compound $H_2Pb{=}PbH_2$ (295 pm) by about 50 pm. However, the potential curves for the tilt angles θ and the E–E distances in particular are very shallow.[8] In this case, the longer bonds and smaller tilt angles θ are a consequence of the steric demands of the substituents. The relatively short Pb–F contacts (276.7, 278.2 pm) in $\mathbf{5}_2$ also contribute to Pb–Pb bond elongation, an effect which is also present in $\mathbf{4}_2$ (Sn–F: 294.9, 295.6 pm) but to a lesser extent.[2b] The question arises whether the very long Pb–Pb distance is still consistent with the presence of a double bond.

In Table 1, theoretical[9] and experimental bonding parameters of the complete homologous series of unsaturated compounds of the type $R_2E{=}ER_2$ (E = C to Pb) are compared. While there is no acyclic olefin in which the carbon atoms deviate from planarity, and steric demands causes only slight bond elongation, the heavier homologues show increasing variations in bonds lengths and tilt angles θ with increasing main quantum number.

Frequently used indicators of the presence of double bonds such as *short bond lengths*, *planarity of the systems*, and *high dissociation energies* can be used to characterize "hard double bonds" like C=C bonds. According to these criteria no double bond is present in the plumbanediyl dimer $\mathbf{5}_2$. Several experimental results and extensive theoretical investigations in recent years,[1c] however, have shown that the application of these indicators to the (presumably) doubly-bonded dimers of the heavier carbene homologues is questionable. The presence of a double bond in compounds such as $\mathbf{5}_2$ cannot be confirmed with certainty until a more comprehensive and precise definition of a double bond than that given by the classical criteria becomes available.[10]

[4] Selected physical data: **4**: m.p. (decomp.) 150 °C; ^{1}H NMR (250.133 MHz, C_6D_6, 300 K): δ = 0.15 (CH_3), 7.88 (H_{arom}); ^{29}Si NMR (39.761 MHz, C_6D_6, 300 K): δ = – 5.5 [*Si*($SiMe_3$)$_3$], – 69.6 [Me_3*Si*)$_3$Si]; ^{19}F NMR (235.36 MHz, C_6D_6, 300 K): δ = – 60.5 [*ortho*-CF_3, $J(^{109/107}Sn,^{19}F)$ = 102 Hz, $^1J(^{19}F,^{13}C)$ = 275.8 Hz]; – 63.0 [*para*-CF_3, $^1J(^{19}F,^{13}C)$ = 273.3 Hz]; ^{119}Sn{^{1}H} NMR (74.631 MHz, C_6D_6, 300 K):

$\delta = 168$ ($W_{1/2} = 800$ Hz); UV/Vis (*n*-pentane): λ_{max} 540 nm. **5**: m.p. (decomp) approximately 90 °C; ^{1}H NMR (250.133 MHz, C_6D_6, 300 K): $\delta = 0.25$ (CH_3), 8.04 (H_{arom}); ^{19}F NMR (235.36 MHz, C_6D_6, 300 K): $\delta = -66.6$ [*ortho*-CF_3, $J(^{207}Pb,^{19}F) = 374$ Hz, $^1J(^{19}F,^{13}C) = 275.4$ Hz]; -62.8 [*para*-CF_3, $^1J(^{19}F,^{13}C) = 272.5$ Hz]; UV/Vis (*n*-pentane): λ 586 nm; 1025 nm. Both compounds gave correct elemental analyses.

[5] Temperature-dependent ^{119}Sn NMR measurements, which would give valuable information about rearrangement processes or about the presence of a monomer/dimer equilibrium, could not be performed up to now for several reasons, such as very long aquisition times, the thermal lability of $\mathbf{4}_2$ at temperatures above room temperature, and the low solubility in inert solvents at low temperatures.

[9] Calculations: Equilibrium structures of E_2H_4 were determined by CCD (Sn) and CCSD (Pb) calculations (Gaussian 94) with Stuttgart quasi-relativistic pseudopotentials [W. Kuechle, M. Dolg, H. Stoll, H. Preuss, *J. Chem. Phys.* **1991**, *74*, 1245] and extended basis sets for Sn and Pb: (4s4p2d)/[5s5p2d]; basis sets for H: (3s2p)/[4s2p] [T. H. Dunning, *J. Chem. Phys.* **1970**, *19*, 553]. The dimerization energies were calculated at the CCSD level and have been corrected with respect to basis set superposition errors (full Counterpoise method) and zero-point vibrations. The identification of local minima on the hypersurface was verified by frequency calculations [NIMAG = 0].

[10] The definition of a double bond by means of quantum mechanics is based on the presence of two electron pairs shared by two nuclei. It is independent of the topology or the inherent bond energy. Thus—within the framework of LCAO-MO approximation (LCAO = *L*inear *C*ombination of *A*tomic *O*rbitals)—methods such as NBO (NBO = *N*atural *B*ond *O*rbitals) or NLMO analyses (NLMO = *N*aturally *L*ocalized *M*olecular *O*rbitals) can be used [J. E. Carpenter, F. Weinhold, *J. Mol. Struct. Theochem* **1988**, *169*, 41]. A further valuable method outside this framework is the Electron Localization Function (ELF), which is a function of the kinetic energy of the electrons [B. Silvi, A. Savin, *Nature* **1994**, *371*, 683]. We will present a detailed quantum chemical analysis of the bonding in compounds such as $\mathbf{5}_2$ using these methods elsewhere.

Dynamic Error Correction in Autocatalytic Peptide Networks**

Kay Severin, David H. Lee, Jose A. Martinez, Michael Vieth, and M. Reza Ghadiri*

Life operates precariously in between two extremes: evolution requires new information to be generated through mistakes during the self-reproduction step, but at the same time living systems need to preserve their information against excessive accumulation of errors.[1] Here we describe autocatalytic peptide networks that stabilize themselves against errors by subjugating the mutant population for the synthesis of the wild-type peptide. The systems are based on three or four peptide fragments that undergo competitive condensation reactions in neutral aqueous solutions to produce the native sequence of a peptide replicator along with its mutant products. The peptide self-replication process is shown to respond to the spontaneous formation of errors—experimentally simulated by the background coupling reactions that yield the mutant peptides—by employing the mutant product(s) as catalyst(s) for the synthesis of the native replicator sequence. Detailed analyses have revealed that this novel mode of sequence selection arises as the result of self-organization into networks composed of two or three interconnected (auto)catalytic cycles. These networks are among the first examples of biopolymer-based nonlinear chemical systems in which catalytic and autocatalytic processes are cooperatively coupled.[2]

The present study describes an unprecedented response of a self-replicating peptide system to the spontaneous generation of mutations by self-organizing into networks of cooperative autocatalytic and catalytic cycles that upregulates the production of the native sequence. The system is based on the recently reported sequence of a peptide replicator[3] and is composed of a maximum of four peptide fragments: the native electrophilic **E** and nucleophilic **N** fragments and their single alanine mutants $\mathbf{E_{9A}}$ and $\mathbf{N_{26A}}$, respectively (Figure 1). These peptides undergo competitive ligation reactions to produce four products: the native sequence **T** along with the single mutant peptides $\mathbf{T_{9A}}$ and $\mathbf{T_{26A}}$ and the double mutant peptide $\mathbf{T_{9/26A}}$. Thus addition of the mutant fragments to the initial mixture simulates the spontaneous formation of errors during the self-replication process. Furthermore, the mutations were chosen to be conservative replacements for the native amino acid residues (alanine in place of valine 9 or leucine 26) in order to simulate the production of a mutant population with a closely related informational content,[4] previously termed quasi-species.[5]

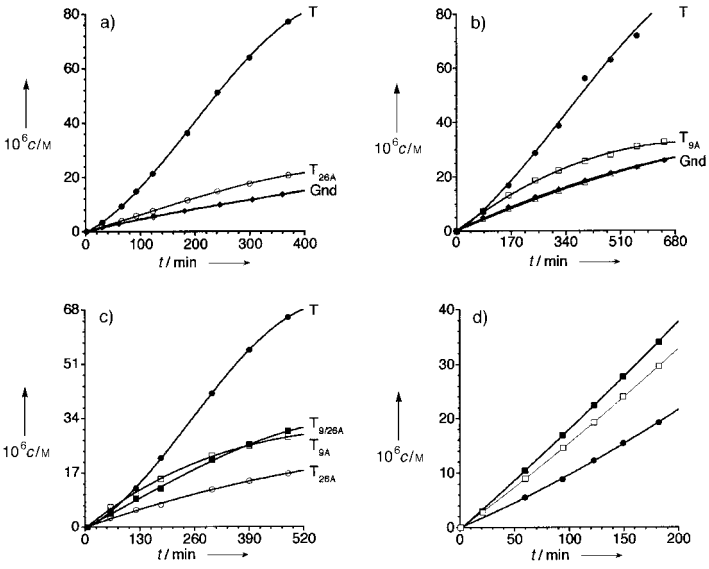

Figure 2. Product formation as a function of time. a) Reaction (1): **T** (●) and $\mathbf{T_{26A}}$ (○) and in the presence of 4 M Gnd **T** (◆) and $\mathbf{T_{26A}}$ (◇); b) reaction (2): **T** (●) and $\mathbf{T_{9A}}$ (□), and in the presence of 4 M Gnd **T** (◆) and $\mathbf{T_{9A}}$ (△); c) reaction (3): **T** (●), $\mathbf{T_{26A}}$ (○), $\mathbf{T_{9A}}$ (□), and $\mathbf{T_{9/26}}$ (■); d) reactions (8) and (9): **T** in the presence of 40 mM $\mathbf{T_{26A}}$ (□), 57 mM $\mathbf{T_{9A}}$ (■), or without any added template (●). It should be noted that the condensation of native fragments **N** and **E** is catalyzed by both single mutant products $\mathbf{T_{26A}}$ and $\mathbf{T_{9A}}$ [reactions (8) and (9) in d)], which leads to the pronounced selectivity for the native sequence **T** [reactions (1) – (3) in a) – c)].

Reaction mixtures composed of equimolar amounts of **E**, $\mathbf{N_{26A}}$, and **N** [Eq. (1)] or **E**, $\mathbf{E_{9A}}$, and **N** [Eq. (2)] in 4 M guanidinium (Gnd) solutions (pH 7.5) were shown to produce approximately equal amounts of the expected ligation products **T** and $\mathbf{T_{26A}}$ or **T** and $\mathbf{T_{9A}}$, respectively. This indicates a lack of kinetic preference for a specific ligation reaction under denaturing conditions. However, in the absence of denaturant, both reactions displayed pronounced preference for the production of the native peptide sequence **T** under neutral aqueous conditions (Figure 2a,b). A priori, the preferential production of the native peptide can be simply attributed to the known parabolic growth profile of the replicator sequence. Indeed, control experiments with equimolar amounts of **E** and $\mathbf{N_{26A}}$ [Eq. (4)] or $\mathbf{E_{9A}}$ and **N** [Eq. (5)] have shown that $\mathbf{T_{9A}}$ and $\mathbf{T_{26A}}$ are both incapable of catalyzing their own production. Therefore, the observed high selectivity in competitive ligation reactions can be attributed to a significant degree to the nonlinear growth profile of the peptide replicator[6] versus the linear background rate for the production of the mutants.

If one considers ternary complexes as the catalytically active intermediates,[3] for each reaction (1) and (2) there are two possible autocatalytic *and* two catalytic pathways that can lead to products formation (Figure 3). As suggested by the above experiments, pathways b and b′ for the autocatalytic production of the single mutant peptides $\mathbf{T_{9A}}$ and $\mathbf{T_{26A}}$ are not operative and the intermediate a is responsible for self-replication of the native sequence **T**. We therefore sought to examine the role of the remaining possible catalytic intermediates c, c′, d, and d′. Reactions composed of equimolar amounts of **E** and $\mathbf{N_{26A}}$ [Eq. (6)] or $\mathbf{E_{9A}}$ and **N** [Eq. (7)] do not

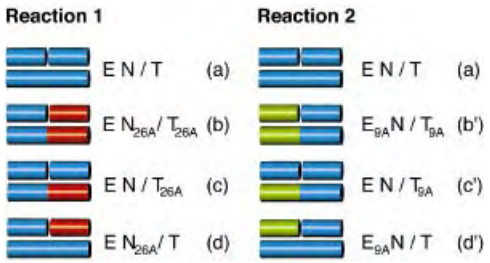

Figure 3. Schematic representation of plausible ternary intermediates for the autocatalytic (a, b, and b′) and catalytic (c, c′, d, and d′) production of ligation products in reactions (1) and (2). The ternary complexes are composed of an electrophilic peptide fragment (**E** or $\mathbf{E_{9A}}$), a nucleophilic peptide fragment (**N** or $\mathbf{N_{26A}}$), and the catalyst (**T**, $\mathbf{T_{9A}}$, or $\mathbf{T_{26A}}$). The different peptides are shown as colored cylinders to represent the α-helical configuration (native sequence: blue; E_{9A} and its corresponding T_{9A} segment: green; N_{26A} and its corresponding T_{26A} segment: red).

show any rate enhancements in the presence of added native peptide **T**. Therefore, the replicator sequence does not catalyze the formation of the mutant peptides, and pathways d and d′ are not operative. However, both single mutant peptides $\mathbf{T_{9A}}$ and $\mathbf{T_{26A}}$ catalyze the formation of the native sequence **T** [Eqs. (8) and (9), respectively; Figure 2d]. In fact, the catalytic efficiency of the mutant products for the production of the native sequence is approximately 75 % that of the native replicator sequence itself, as judged by the initial rate of product formation in the presence of similar amounts of added catalysts. The overall selectivity observed in reactions (1) and (2) is therefore the result of self-organized autocatlytic and catalytic cycles, which work in concert to favor the production of the native sequence **T** (Figure 4). It is

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0127 $ 17.50+.50/0

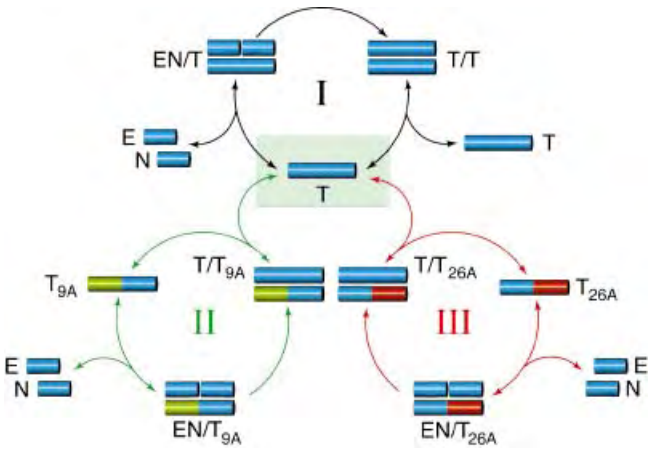

Figure 4. Peptide fragment condensations result in self-organized networks composed of two [cycles I and III or I and II for reactions (1) and (2), respectively] or three [reaction (3)] interconnected (auto)catalytic cycles with overall dynamic error-correcting properties. The mutant products $\mathbf{T_{9A}}$ (green-blue) and $\mathbf{T_{26A}}$ (red-blue) are infertile but catalyze the formation of the native replicator **T** (blue).

also interesting to note the asymmetry of the catalytic contribution: while the mutant peptides $\mathbf{T_{9A}}$ and $\mathbf{T_{26A}}$ are able to catalyze the formation of the native sequence **T**, **T** is "selfish" and does not accelerate the condensation of the mutant fragments. This unusual effect can be explained if one compares the stability of the intermediate ternary complex to the stability of the corresponding (self-inhibited) catalyst dimer. For reactions (6) and (7) the ternary complex is destabilized due to mutations in the hydrophobic core. Thus, the population of the intermediate is low, and no catalysis is observed. In Reactions (8) and (9), however, the mutation affects both the ternary complex and the catalyst dimer. The resulting increase in free catalyst concentration compensates for the reduced stability of the catalytic species.

The self-organized network persists also in reactions in which equimolar amounts of all four peptide fragments are employed [Eq. (3)]. In this case the double mutant product $\mathbf{T_{9/26A}}$ is not only infertile but also catalytically inactive [Eq. (10)]. Here the system is shown to self-organize into a network (*three* interconnected catalytic cycles), which displays a similar error-correction mechanism: each time a mutant product is formed, not only does it act as an efficient catalyst to generate several copies of the native sequence, but because these catalytic cycles are coupled to the native autocatalytic cycle, each new template produced in this way also serves to boost the production of the native sequence through the autocatalytic pathway (Figure 4). The net effect is significant upregulation in the production of the native peptide, leading to the selectivity observed in reactions (1) – (3) (Figure 2a – c).

The peptide-based systems described are the first examples of self-organized chemical networks that display characteristics essential for evolution: sequence-selective reproduction and dynamic error correction. Furthermore, these results suggest that short peptides are promising building blocks for complex nonlinear chemical systems, which may ultimately lead to the construction and understanding of molecular ecosystems.[7]

Experimental Section

All peptides were made by standard solid-phase peptide synthesis with *tert*-butyloxycarbonyl (Boc) chemistry. The electrophilic peptide fragments were synthesized as described previously.[3] The reactions were performed in 0.6 mL Eppendorf tubes. Temperature was maintained at 21.0($\pm$0.5)°C. A degassed, benzylthiol-saturated solution containing 3-(*N*-morpholino)-propane sulfonic acid (MOPS) buffer (pH 7.5), the nucleophilic peptide fragment(s) $\mathbf{N_x}$, and the internal standard 4-acetamidobenzoic acid (ABA) was incubated for 15 min. Reactions were initiated by adding a solution containing the electrophilic peptide fragment(s) $\mathbf{E_y}$ to give a total volume of 500 μL. Typically, the following final concentrations were employed: $\mathbf{N_x} = \mathbf{E_y} = 180 - 200\,\mu M$, MOPS = 140 μM, ABA = 100 μM. Peptide fragment condensations in the presence of Gnd ions (4 M) were performed as described above, except that MOPS buffer containing Gnd was used. Control experiments to probe (auto)catalytic contributions were performed with 15 – 40 mol % of the respective catalyst. All experiments were repeated twice. Samples (35 μL) were removed from the reaction vessel at various times, immediately quenched with 2% trifluoroacetic acid (70 μL), and stored at −78°C prior to HPLC analysis. Peptide concentrations were determined relative to the internal standard.

$(NH_4)_2Ge_7O_{15}$: A Microporous Material Containing GeO_4 and GeO_6 Polyhedra in Nine-Rings**

C. Cascales, E. Gutiérrez-Puebla, M. A. Monge,* and C. Ruíz-Valero

Crystalline microporous materials are widely used in the fields of catalysis, ion exchange, and adsorption. Since the first discovery of zeolites, many natural and synthetic zeolites,[1–7] silica polymorphs, aluminophosphate-based molecular sieves,[8–11] and microporous compounds built from MO_4 tetrahedra where the M centers are atoms other than aluminum or silicon[12] have been synthesized.

Like silicon, germanium atoms tend to be surrounded by a tetrahedron of oxygen atoms, which may join through shared corners to form larger units; in fact, some compounds of the two elements are isomorphous. However, in Ge zeotypes the structure of the framework can be formed by GeO_4 tetrahedra, GeO_6 octahedra, and sometimes even GeO_5 trigonal bipyramids.[13] For this reason it is surprising that few reports of microporous germanates exist in the literature. To our knowledge, the only fully characterized compounds are of the type $M_{3+x}H_{1-x}Ge_7O_{16}\cdot n\,H_2O$ (M = monovalent cation) with pharmacosiderite-type structure, obtained by ion exchange from the compounds $(NH_4)_3HGe_7O_{16}\cdot n\,H_2O$,[13–20] $[Ge_6O_{12}(OH)]^-[N(CH_3)_4]^+$[21] and $[Ge_{18}O_{38}(OH_4)]^{8-}[(C_2N_2H_{10})^{2+}]_4$.[22] All of them have the framework structure of zeolites and show many of their properties.

An extremely interesting question is whether different germanium dioxide frameworks can be obtained by changing the ratio of GeO_6 octahedra to GeO_4 tetrahedra while using the same template. In other words, can different phases be obtained inside the GeO_2/NH_4^+ system? In this paper we report the first results of our effort: the novel zeolite-like germanate, $(NH_4)_2Ge_7O_{15}$, containing octahedra and tetrahedra forming nine-rings, an arrangement that has never been observed before in microporous solids. Thus, this material could display new effects of shape selectivity in catalytic processes and offer unique properties as molecular sieves.

The title compound was synthesized hydrothermally from a reaction mixture containing GeO_2, $NH_4(OH)$, H_2O, and ethylene glycol in the molar ratio 1:0.6:30:12 on heating at 180°C for 14 days. The cubic and prismatic crystals observed in the resulting solid product were identified as $(NH_4)_3HGe_7O_{16}\cdot n\,H_2O$ and a new unknown phase, respectively. Figure 1 shows the X-ray diffraction patterns for both the cubic and the new microporous germanates.

A suitable single crystal of prismatic shape was selected and mounted in a diffractometer equipped with a CCD detector. The crystal structure (see Experimental Section) indicated that the composition is $(NH_4)_2Ge_7O_{15}$, in which six Ge atoms are tetrahedrally coordinated [range of Ge–O bond lengths 1.715(4)–1.782(4) Å; O-Ge-O bond angles 106.7(2)–116.1(2)°], and the remaining one is octahedrally coordinated to oxygen atoms [range Ge(4)–O bond lengths 1.863(4)–1.923(3) Å; bond angles between 86.2(2) and 93.8(2)°]. Therefore, in the unit cell there are 28 Ge atoms, 60 oxygen atoms, and 8 NH_4^+ ions.

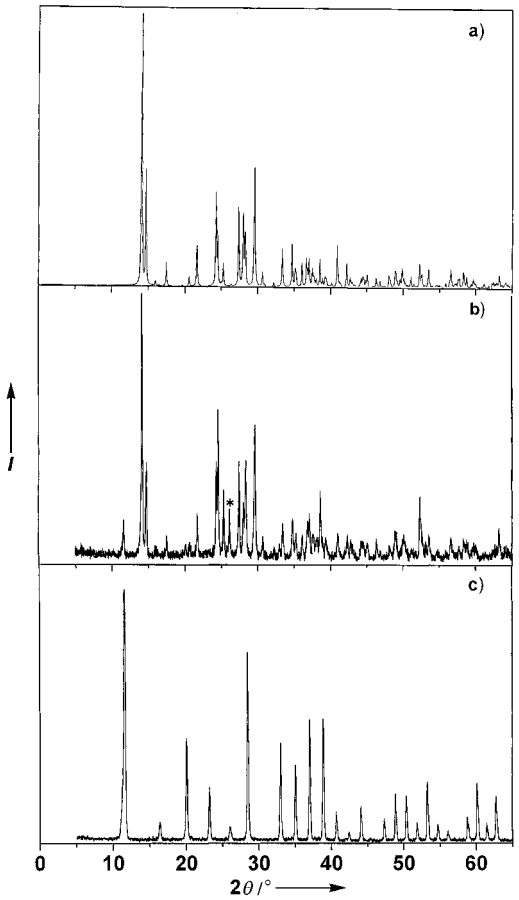

Figure 1. X-ray powder diagrams (XPD) a) calculated for $(NH_4)_2Ge_7O_{15}$ XPD from single-crystal structure data, b) recorded for the obtained material (* corresponds to the higher GeO_2 peak), and c) recorded for $(NH_4)_3HGe_7O_{16}\cdot 4\,H_2O$. I = intensity (arbitary units)

Tetrahedra and octahedra are linked by sharing corners in such a way that each tetrahedron is surrounded by one octahedron and three tetrahedra, and each octahedron is surrounded by six tetrahedra. The structure can be envisaged in terms of a two-dimensional sheet that is repeated to generate the full three-dimensional structure. This sheet is perpendicular to the c axes and is formed by nine-polyhedra rings (seven are tetrahedra and two are octahedra) in a 4Td-Oh-3Td-Oh sequence (Figure 2). This arrangement forces the formation of parallel double rings, which are held together through the octahedra and create some thickness to the layer. The shape of the ring is nearly a regular triangle.

This sheet, which is repeated by vertical translation along the stacking c direction, is bonded to the neighboring sheets located directly above and below through the only vertex of the tetrahedra not involved in connectivity inside the layer. As explained before, the octahedra are inside the sheet forming the double rings. This sort of packing gives rise to three types of channels, in all of which GeO_6 octahedra are

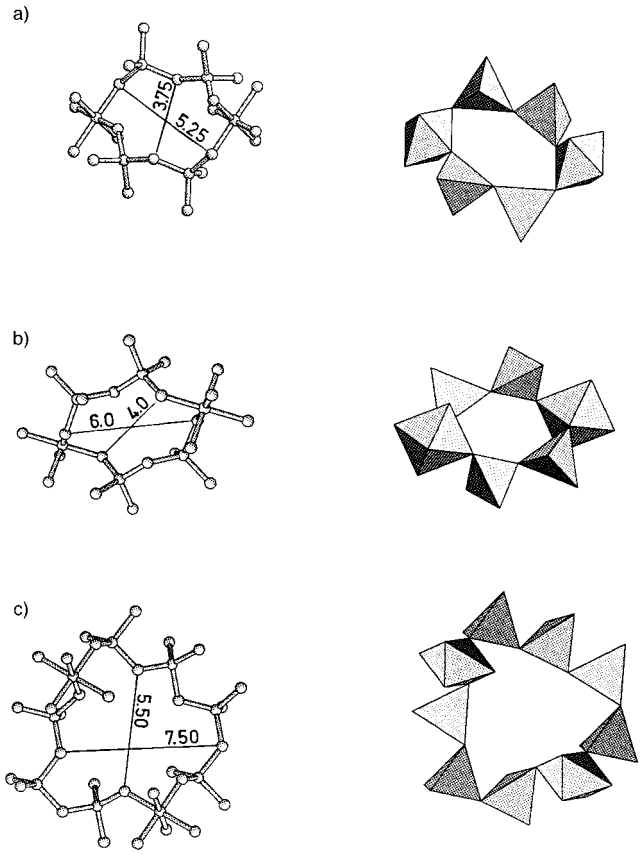

Figure 2. Ball-and-stick and polyhedral representations of the windows corresponding to the three different kinds of channels present in the structure of $(NH_4)_2Ge_7O_{15}$ along [110] (a), [010] (b), and [001] (c). Distances to the centers of atoms are given.

involved. The main channels are those that run in the *c* direction as a consequence of the stacking of the nine-rings. There are smaller hexagonal channels along [010] and [110] with a $2(GeO_4)$-(GeO_6)-$2(GeO_4)$-(GeO_6) sequence. Pore apertures and sizes are also shown in Figure 2.

Two NH_4^+ cations, whose positions are related by a inversion center, are guests in each cage along the main channels (Figure 3). Since every H atom was located in a difference synthesis and their coordinates refined with isotropic thermal parameters, the whole geometry around H bonds could be determined. The NH_4^+ cation is bonded to different oxygen atoms of the framework through the four hydrogen atoms; three of these atoms form bifurcated hydrogen bonds. The ranges of the N–H, N–O, and O–H bond lengths are 0.78(2)–1.05(1) Å, 2.631(5)–3.106(6) Å, and 1.82(1)–2.51(1) Å, respectively.

A comparison of the coordination polyhedra and their connectivities present in the cubic $(NH_4)_3HGe_7O_{16}\cdot n\,H_2O$ (structural type I), the $Ge_9O_{20}Na$ structure (structural type II),[23] and the new monoclinic $(NH_4)_2Ge_7O_{15}$ (structural type III) reveals a number of interesting features. Although the frameworks are always formed by GeO_4 tetrahedra and GeO_6 octahedra, the ratio GeO_4/GeO_6, which is 3/4 for I and 5/4 for II, is 6/1 in III. This composition avoids the formation of the Ge_4O_{16} cluster, which is present in I and II, and brings about the formation of tunnels of different sizes, creating a main

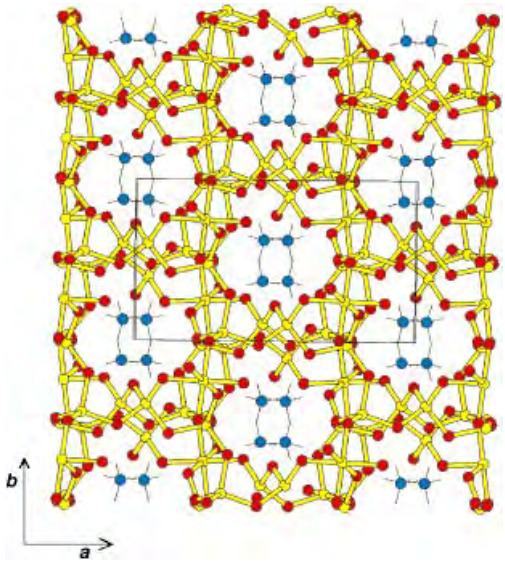

Figure 3. View along [001] of the structure of $(NH_4)_2Ge_7O_{15}$. The NH_4^+ ions are in blue.

channel and thus a preferential direction for ionic conductivity. In other tunnel-containing materials that are good ionic conductors[24] the amplitude of thermal vibration of the ions in the direction of the tunnels is associated with an unhindered motion of those cations and with high ionic conductivity. In this new germanate, although the NH_4^+ cations are involved in hydrogen bonds, the anisotropic thermal parameters of the N atom is especially large in the *c* direction (about twice as large: $U_{11} = 20(4)\times10^{-3}$, $U_{22} = 20(3)\times10^{-3}$, and $U_{33} = 44(4)\times10^{-3}$). Moreover, in the title compound the formal charge of the framework is compensated by two NH_4^+ cations per seven Ge atoms, which decreases the electrostatic interaction between the anion framework structure and the cations. In contrast, for the same number of Ge atoms in I, four cations are needed.

TGA-DTA (TGA = thermogravimetric analysis, DTA = differential thermal analysis) shows a 4% weight loss between 320 and 450°C, which is endothermic. This corresponds to the total decomposition of the $(NH_4)_2Ge_7O_{15}$ present in the sample (70% $(NH_4)_2Ge_7O_{15}$ and 30% GeO_2) by loss of one H_2O and two NH_3 molecules. Powder X-ray diffraction measurements show that the structure is maintained after heating to 312°C and collapses at 450°C to crystalline GeO_2.

As $(NH_4)_2Ge_7O_{15}$ is stable 100°C above the temperature limit for $(NH_4)_3HGe_7O_{16}\cdot n\,H_2O$,[16] we can obtain the monoclinic phase free of the cubic one by heating at 250°C for two hours. This material thus has an advantage for potential applications.

The charged framework of this material contains no Ge–OH group, which is present in analogous materials,[21–22] and therefore, besides potential use as a solid electrolyte, it might be possible to make this material acidic and thus catalytically active. Relative to silica molecular sieves and clathrates, this novel compound seems to have a unique structure: the interaction between GeO_4 and GeO_6 anion framework structure and the cations in the channels is weaker than the one between the tetrahedral anionic network of zeolites and their cations.

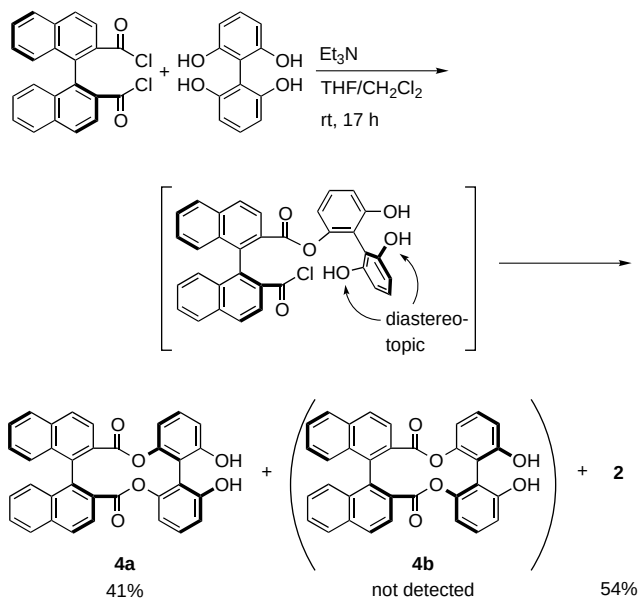
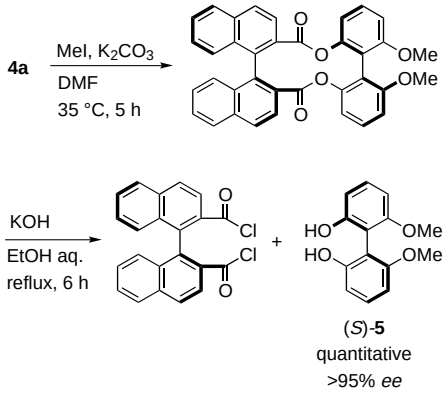
Double-Helical Oligo Esters: Chiral Twist of Two Aromatic Ester Chains

Kyoko Nozaki,* Takakiyo Terakawa, Hidemasa Takaya, and Tamejiro Hiyama

The double-helical structure is often found in nature, and artificial double-helical molecules are also of interest; for instance, in 1991 Lehn and co-workers prepared a double-helical structure by utilizing the coordination of nitrogen atoms of two chains to copper ions.[1] In another example, two chains are bound by hydrogen bonds of an oligopeptide.[2] However, in contrast to these approaches based on self-assembly, covalent bonds have been used less frequently in the synthesis of such molecules. Here we report the preparation of oligo esters **2** and **3**. In these molecules, biphenyl groups are sandwiched between two chiral binaphthyl groups. Through this "chiral twist", the originally achiral biphenyl groups are fixed in the same absolute configuration as the two binaphthyl groups on both ends. As a result, the two oligo ester chains in one molecule (green and red in **1** – **3**) are twisted to form a double-helical structure.[3]



For the synthesis of these compounds (*S*)-1,1′-binaphthyl-2,2′-dicarbonyl dichloride was initially treated with biphenyl-2,2′,6,6′-tetrol (Scheme 1), which gave the 1:1 coupling product **4a** and the 2:1 product **2** in 41% and 54% yield, respectively. It is noteworthy that **4a** was obtained as a single diastereomer although two diastereomers **4a** and **4b** could have formed. Biphenyl-2,2′,6,6′-tetrol itself is an achiral molecule. After the first esterification of the 2-hydroxy group, the two hydroxy groups at the 2′- and 6′-positions are diastereotopic. Thus the second esterification step proceeds exclusively at one of these two hydroxy groups.



The absolute configuration of the biphenyl group was determined by the following method: The two hydroxy groups of **4a** were protected as methyl ethers, and then the compound was hydrolyzed to give the 2,2′-dimethoxybiphenyl-6,6′-diol (**5**) and 1,1′-binaphthyl-2,2′-dicarboxylic acid (Scheme 2). The

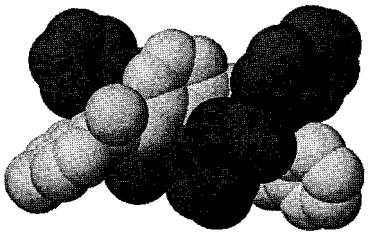
Scheme 1.

Scheme 2.

each other at their 2-positions to form a (*R*)-biphenyl group.[7, 8] In the 1:2 condensation product **2** (Scheme 1), one biphenyl group is sandwiched between the two binaphthyl groups. Only one diastereomer was formed. The absolute configuration of the central biphenyl group is assigned to be *S* on the basis of the above result. An optimized space-filling model of the oligo ester **2** is shown in Figure 1. In this model,



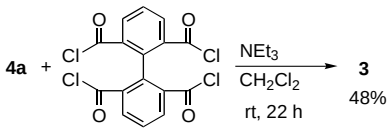


Figure 1. A model of **2** optimized with an MM2 force field (CAChe system). One ester chain, "naphthyl-C(=O)OC$_6$H$_3$OC(=O)C$_6$H$_3$-naphthyl", is depicted in light gray and the other in dark gray. The two chains form a double-helical structure.

two ester chains, whcih are depicted in light gray and dark gray in Figure 1, form the double-helical structure. The two chains are bound to each other by the covalent bond between the two benzene rings of each biaryl group.

The longer biphenyl ester **3** was synthesized from **4a** and biphenyl-2,2′,6,6′-tetracarbonyl tetrachloride (Scheme 3). Again, a single coupling product was obtained. The product

Scheme 3.

enantiomeic excess of **5** was determined to be $>95\,\%$ by HPLC on a chiral column. By comparison of the optical rotation value of **5** to that in the literature,[4] this compound was assigned the absolute configuration *S*. This indicates that the absolute configuration of the biphenyl group is controlled by that of the binaphthyl group. The 1,1′-binaphthyl-2,2′-dicarboxylic acid was recovered without racemization. Thus, the present method provides a novel synthetic route to optically active biphenyl compounds.[5]

The following experiments also suggest that the biphenyl group in such cyclic esters prefers to adopt the same absolute configuration as the binaphthyl group. The condensation of (*S*)-1,1′-binaphthyl-2,2′-diol with (*S*)-1,1′-binaphthyl-2,2′-dicarboxylic acid dichloride gave the cyclic ester **1** as a single product in 92 % yield, while a complex mixture of products was obtained from (*R*)-1,1′-binaphthyl-2,2′-diol and (*S*)-1,1′-binaphthyl-2,2′-dicarbonyl dichloride. In addition, Miyano and co-workers reported the asymmetric synthesis of a biphenyl group.[6] In their work, two benzoic acid derivatives were linked to (*R*)-1,1′-binaphthyl-2,2′-diol through ester bonds, and then the two phenyl groups were connected to was assigned as the aromatic oligo ester **3** with three *S* configured biphenyl groups and two binaphthyl groups.

The specific rotations of esters **1**–**3** $[\alpha]_D$ ($c = 1.00$ g 100 mL^{-1}) are shown in Table 1. The greater the number of biphenyl groups in the molecule, the more the specific rotation increases. This increase in specific rotation can be attributed to the double-helical structures of **1**–**3**. The CD absorption of the biaryl group at around 250–260 nm also increases in the series **1** → **2** → **3**. This is a further indication that all biphenyl groups in **3** are *S* configured. Unlike common

Table 1. Optical rotation and CD-spectroscopic data of the oligo esters **1**–**3**.

Ester	No. of biphenyl groups	$[\alpha]_D^{25}$	CD[c]	
			λ_{max}	ε_{max}
1	0	−553[a]	260	2
2	1	−589[a]	254	−131
3[d]	3	−821[b]	252	−286

[a] $c = 1.00$ in $CHCl_3$. [b] $c = 1.00$ in CH_2Cl_2. [c] 2.05×10^{-5} M in 1,4-dioxane. [d] Because of the low solubility of **3**, other solvents that were clear at <240 nm were not used.

macrocyclic compounds, the conformation of the cyclic oligo esters **2** and **3** is much more restricted because the binaphthyl groups are not allowed to rotate around the 1,1′ axis because of steric repulsion between the 8- and 8′-hydrogen atoms. Thus once the configuration of the biphenyl groups is regulated in **2** and **3**, the conformation of the whole molecule is restricted unequivocally except for the small changes in the torsion angles of the biaryl groups. Accordingly, a double-helical structure similar to that of **2** is suggested for **3**.

Experimental Section

2 and **4a**. A solution of biphenyl-2,2′,6,6′-tetrol (1.10 mmol) in THF[9] was added to a solution of the acid chloride derived from (*S*)-1,1′-binaphthyl-2,2′-dicarboxylic acid[10] (1.00 mmol) in CH_2Cl_2, and the resulting mixture was stirred at 20 °C for 22 h. Aqueous work-up followed by purification by silica-gel column chromatography (CH_2Cl_2/EtOAc, 9/1) gave **4a** (41 % yield) and **2** (54 % yield) as colorless solids. **4a**: Sublimed above 206.0 °C; ^{1}H NMR ($CDCl_3$): $\delta = 7.95-7.89$ (m, 4H), 7.81 (d, 2H, $J = 8.58$ Hz), 7.52 (t, 2H, $J = 6.93$ Hz), 7.30–7.03 (m, 6H), 6.79 (d, 2H, $J = 8.25$ Hz), 6.60 (d, 2H, $J = 8.25$ Hz); ^{13}C NMR ($CDCl_3$): $\delta = 166.76$, 154.16, 149.27, 136.95, 134.39, 133.01, 129.60, 129.49, 128.57, 128.17, 127.71, 127.53, 127.22, 124.56, 115.44, 113.98, 111.32. **2:** M.p. (CH_2Cl_2/hexane) 274.3–274.9 °C; ^{1}H NMR ($CDCl_3$): $\delta = 7.97-7.91$ (m, 8H), 7.81 (d, 4H, $J = 8.58$ Hz), 7.52 (t, 4H, $J = 6.93$ Hz), 7.31–7.24 (m, 4H), 7.05–6.99 (m, 6H), 6.75 (d, 4H, $J = 7.92$); ^{13}C NMR ($CDCl_3$): $\delta = 166.34$, 149.00, 136.35, 134.29, 132.96, 129.58, 128.57, 128.37, 128.18, 127.63, 127.42, 127.26, 124.56, 119.37, 116.17; HR-MS: *m*/*z* found for $[M+H]^+$: 831.1975; calcd.: 831.2017.

3: Biphenyl-2,2′,6,6′-tetracarboxylic acid[11] (0.21 mmol) was converted into the corresponding acid chloride and condensed with **4a** (0.41 mmol) in the presence of triethylamine (21 mmol). Work-up followed by purification by column chromatography (CH_2Cl_2) gave **3** (48 % yield) as fine needles: Sublimed above 470.0 °C. ^{1}H NMR (CD_2Cl_2): $\delta = 8.02-7.78$ (m, 16H), 7.58 (t, 4H, $J = 7.92$ Hz), 7.47 (t, 2H, $J = 8.24$ Hz), 7.32 (t, 4H, $J = 8.24$ Hz), 7.21–7.02 (m, 12H), 6.79 (d, 4H, $J = 8.25$ Hz); ^{13}C NMR (CD_2Cl_2): $\delta =$ 166.54, 165.35, 149.65, 149.14, 137.39, 136.80, 134.77, 133.46, 133.40, 131.75, 129.88, 129.04, 128.77, 128.68, 128.52, 128.21, 127.71, 127.65, 124.63, 120.39, 120.14, 116.33; HR-MS: *m*/*z* found for $[M+H]^+$: 1307.2607; calcd.: 1307.2548.

From Molecular to One-Dimensional Polychalcogenides: Preparation, Structure, and Reactivity of $NaNbS_6$, the First Ternary Alkali Metal Niobium Polychalcogenide Exhibiting Infinite Anionic Chains**

Wolfgang Bensch,* Christian Näther, and Peter Dürichen

The preparation of multinary transition metal chalcogenides in reactive alkali polychalcogenide melts at temperatures between 250 and 500 °C is a fast-growing area of inorganic solid state chemistry.[1,2] Owing to the relatively low reaction temperatures, compounds containing large Q_x^{2-} ions ($x > 1$) are accessible which cannot be obtained with classical high-temperature syntheses.

Recently we investigated new polychalcogenide compounds of niobium. There are only a few examples of such compounds prepared by the reactive flux method.[3] Systematic variation of the preparation conditions yielded several novel niobium chalcogenides, all containing molecular $[Nb_2Q_{11}]^{4-}$ subunits (Figure 1).[4–7] These units occur as isolated anions, as in $K_4Nb_2S_{11}$,[4] or are connected through terminal sulfur ligands, as in $Rb_6Nb_4S_{22}$ or $Cs_6Nb_4S_{22}$.[5] Incorporation of additional S_3^{2-} fragments, which are present under the preparation conditions, can lead to an expansion of the $[Nb_2Q_{11}]^{4-}$ subunits. In $K_4Nb_2S_{14}$[6] the S_3^{2-} ion acts as a terminal ligand, and in $K_6Nb_4S_{25}$[7] it connects two units to form the novel complex $[Nb_4S_{25}]^{6-}$ ion.

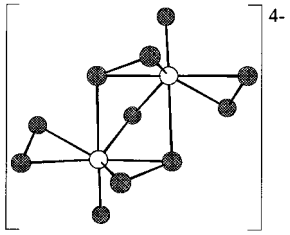

Figure 1. View of the $[Nb_2Q_{11}]^{4-}$ unit (Nb = ○, Q = ⊗).

By extending the synthetic conditions used for preparing the novel niobium compounds to sodium polysulfide melts, we succeeded in synthesizing transparent, orange-red needles.[8] All crystals investigated were grown together, and a twin refinement had to be performed.[9] Here we report on the synthesis, crystal structure, optical behavior, and reactivity of $NaNbS_6$, the first ternary niobium chalcogenide containing one-dimensional anionic polymeric chains.

The results of the structure determination revealed that a polymeric structure was formed, which is surprisingly not based on the above-mentioned $[Nb_2Q_{11}]^{4-}$ subunits. The structure of $NaNbS_6$ consists of $^1_\infty[NbS_6]^-$ chains running parallel to [001] (Figure 2a and b). These chains are separated by the Na^+ ions. The shortest interchain S–S contacts of 3.396(3) Å are only slightly shorter than the sum of the van der Waals radii (3.6 Å). Within the chains the Nb centers are ninefold coordinated by S atoms. The environment is best described as a pentagonal plane that contains one S_2 unit and three S atoms. Two S_2 units above and below this plane are twisted by about 90° to provide a $Nb(S_2)_3(S)_3$ polyhedron (Figure 2c). These polyhedra are condensed through three S atoms to one-dimensional chains. Every S_2^{2-} unit is coordinated to two Nb centers in a $\mu\eta^1\eta^2$ mode. The description of the title compound as $NaNb(S_2)_3$ leads to an assignment of the formal valences as Na^+, Nb^{5+}, and $(S_2)^{2-}$.

Alternatively, the environment at the Nb centers can be described as distorted trigonal prisms in which the basal planes are formed by the condensation of three S atoms. These prisms are joined through the trigonal faces to give rise to infinite columns parallel to [001]. Every corner of the prisms is occupied by a S atom of a S_2^{2-} ion. The environment of the Nb centers is completed by three S atoms of the S_2 dumbells, which are in turn directed towards the rectangular faces of the distorted prisms (Figure 2d). The Nb–S distances range from 2.501(2) to 2.713(2) Å (av 2.573(2) Å).

Bond-valence calculations according to Equation (1) developed by Pauling give Nb–S bond valences between 0.65 and 0.36, which are smaller than for a Nb–S single bond.

$$S_{ij} = \exp((r_0 - D_{ij})/b) \quad (1)$$

The chains are not strictly linear but slightly bent, as evidenced by the angle between three successive Nb atoms of 169.9°, and are better described as zigzag chains. The distance of 3.589(4) Å between adjacent Nb centers is about 0.7 Å larger than in metallic niobium and too long for Nb–Nb interactions. The S–S distances of 2.056(2) Å within the S_2^{2-} units are in the usual range. The Na centers are ninefold coordinated by S atoms with a mean Na–S distance of 3.090(4) Å. These values correspond to the sum of the ionic radii for Na^+ (1.24 Å) and S^{2-} ions (1.84 Å).[10]

The optical properties of $NaNbS_6$ were investigated with UV/Vis diffuse reflectance measurements.[11,12] The spectra showed a steep absorption edge, from which an optical band gap of about 2.3 eV is estimated (Figure 3). The orange-red color of the material as well as the value for the band gap corroborate the semiconducting nature. These findings are also in agreement with the oxidation states mentioned above.

The thermal behavior was studied by differential thermal analysis/thermogravimetry (DTA/TG) measurements.[13] The title compound is stable up to 400 °C. At 407 °C the onset of an endothermic peak together with a weight loss of 41 % indicates decomposition of the material**.** The weight loss can be attributed to the loss of four equivalents of sulfur.[14] The X-ray powder pattern of a decomposed sample obtained at 600 °C under vacuum could be indexed on the basis of a hexagonal cell of the intercalation compound Na_xNbS_2.[15] This result is also consistent with the atomic absorption spectrometry (AAS) analysis, which yields a composition of $NaNbS_2$ for the decomposed material. We note that the Nb centers in $NaNbS_2$ are in a trigonal-prismatic coordination of six S atoms. However, within the NbS_2 layers these prisms are joined by

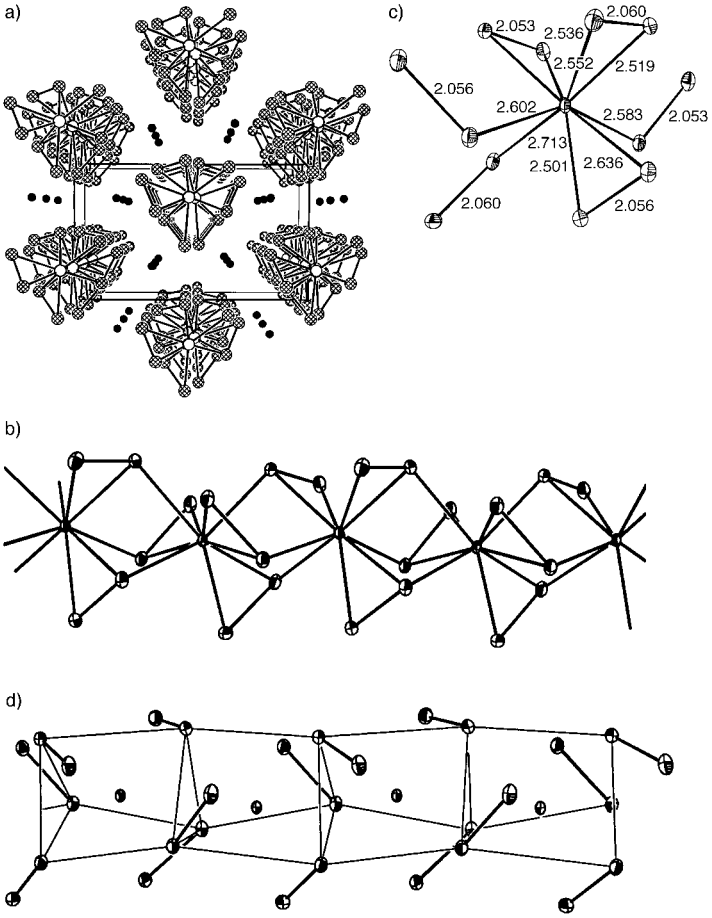

Figure 2. Crystal structure of $NaNbS_6$: a) view along the *c* axis (S = ⊗, Nb = ○, Na = ●); b) connection of the $NaNbS_6$ polyhedra; c) coordination sphere of the Nb centers with selected bond lengths [Å]; d) the NbS_6 trigonal prisms joined through common trigonal faces (thermal ellipsoids are drawn at the 50 % probability level).

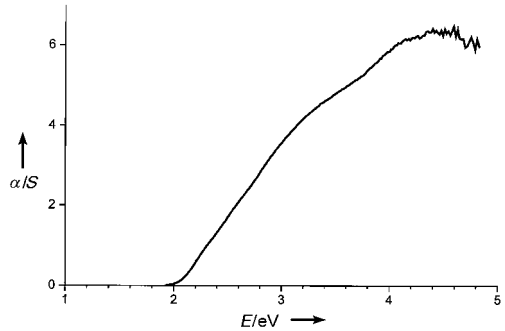

Figure 3. UV/Vis reflectance spectra of $NaNbS_6$ showing an optical band gap of 2.3 eV; α is the absorption coefficient, and S the scattering coefficient.

common edges. Hence, there is no simple relationship between the structures of the title compound and $NaNbS_2$.

The results presented clearly demonstrate the enormous synthetic potential of the reactive flux method. The mild reaction temperatures, at which the polychalcogenide building blocks are retained, together with a large pool of preparative data should enable the inorganic chemist to synthesize new compounds more predictably. This seems to be possible at least for the niobium compounds. In agreement with these assumptions we isolated the first chainlike niobium polyselenide using similar reaction conditions as for the sulfur compounds.[16] Again, its structure is based on $[Nb_2Q_{11}]^{4-}$ units connected through Se_2^{2-} and Se_3^{2-} ligands. It can be expected that many more new and interesting niobium compounds will be accessible by a systematic variation of the reaction conditions.

[8] Preparation of $NaNbS_6$: In a dry box Na_2S_3 (2.11 mmol) was mixed with niobium (1.06 mmol) and additional sulfur (4.22 mmol). Na_2S_3 was made by the reaction of stoichiometric amounts of sodium and sulfur in liquid ammonia under an argon atmosphere. The reactants were thoroughly ground together in a mortar and then transferred to a glass ampoule which was subsequently evacuated (10^{-3} mbar) and flame-sealed. The ampoule was heated to 350 °C within 5 h, held at this temperature for 6 d, and cooled to room temperature at a rate of 3 degrees per hour. By washing the resulting melt with DMF and diethyl ether, orange-red, transparent, fiberlike crystals of $NaNbS_6$ were isolated. The homogenity of the product was confirmed by powder X-ray diffraction. All reflections of the powder pattern could be indexed on the basis of $NaNbS_6$. $NaNbS_6$ is stable against air and water.
[9] Crystal structure determination of $NaNbS_6$ ($M_r = 308.26$), orange-red needles, crystal size: $0.05 \times 0.05 \times 1$ mm^3, $a = 7.451(2)$, $b = 12.743(2)$, $c = 7.151(2)$ Å, $\beta = 96.81(1)^\circ$, $V = 674.18$ Å^3 (RT), $\rho_{calcd} = 3.037$ g cm^{-3}, monoclinic, space group *Cc* (no. 15), $Z = 4$, STOE-AED-II four-circle diffractometer, $Mo_{K\alpha}$ radiation, $\mu = 3.58$ mm^{-1}, 1311 measured reflections in the range $3^\circ < 2\theta < 60^\circ$, 1249 independent reflections used for refinement, structure solution with direct methods (SHELXS-86), structure refinement against F^2 (SHELXL-93), 74 parameters, $w = 1/[\sigma^2(F_o^2) + (0.0235 \cdot P)^2 + 2.88P]$, R for 1224 $F_o > 4\sigma(F_o) = 0.0191$, w$R2$ for all 1249 data = 0.0547, GOF = 1.579, residual electron density: 0.56/ – 0.48 e Å^{-3}. Flack parameter: 0.08(7). All crystals investigated were grown together. For one crystal all 86 reflections found by searching the reciprocal space could be separated into two groups. The reflections in each of these two groups were successfully indexed on the basis of the same monoclinic *C*-centered cell. From the transformation matrix between both individuals, it was shown that all reflections *hk*0 as well as *hk*11 were overlapping. Therefore, a twin refinement with SHELXL-93 was performed. This led to a significantly improved model compared to those obtained only with the raw data (R for all reflections with $F_o > 4\sigma(F_o) = 0.0939$; w$R2 = 0.2887$; residual electron density: 11.60/ – 1.72 e Å^{-3}). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-407 708.

[11] UV/Vis diffuse reflectance measurements were carried out on a Leica Orthoplan microscope equipped with a Leica MPV-SP, an ICS quartz UV optic, and a xenon lamp as light source. The resolution was 1 nm, and $BaSO_4$ was used as standard for 100 % reflectance. Absorption data were calculated from the reflectance data using the Kubelka – Munk function.[12] The approximate band gap was determined as the intersection point between the energy axis and the line extrapolated from the linear part of the absorption edge in a $(F(R))^2$ plot.

Spin Polarization and Ferromagnetism in Two-Dimensional Sheetlike Cobalt(II) Polymers: $[Co(L)_2(NCS)_2]$ (L = Pyrimidine or Pyrazine)**

Francesc Lloret,* Giovanni De Munno,* Miguel Julve, Juan Cano, Rafael Ruiz, and Andrea Caneschi

The spin-polarization mechanism[1] describes how an unpaired electron on one atom polarizes the electron cloud on the adjacent atom in the opposite sense. This would result in an alternation of the spin density at atoms in a bridging unit, and consequently the sign of the magnetic exchange parameter J should alternate at each atom in the bridging unit. In this way, oligocarbenes or radicals linked through *m*-phenyl-

enes have been designed with a high-spin ground state and prepared.[2] However, since unpaired electrons have a strong tendency to react and to form covalent bonds, stable high-spin organic materials can be expected to be hard to prepare. In contrast, transition metal ions are very stable spin carriers, and in principle, they would be the best candidates for this purpose. Although the spin polarization was shown to be valid for some oxygen- or nitrogen-containing organic systems[3] as well as for some systems comprising paramagnetic transition metal ions and organic radicals,[4] the limits of its application are unclear, especially for coordination compounds containing transition metal ions as the only spin sources. In fact, the first reports on this topic are not conclusive because the magnetic interactions are weak, and a structural determination is lacking.[5]

In an attempt to verify the validity of the spin-polarization mechanism for these systems, we have prepared the sheetlike polymeric compounds $[CoL_2(NCS)_2]_n$ (**1**, L = pyrazine (pyz); **2**, L = pyrimidine (pym); Figure 1) and studied their variable-

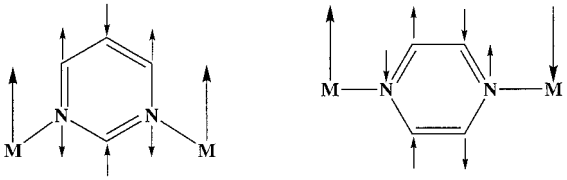

Figure 1. Representation of the spin polarization in pyrimidine (left) and pyrazine ligands (right) bound between two transition metal centers.

temperature magnetic properties. The monomeric complex $[Co(pyd)_4(NCS)_2]$ (**3**, pyd = pyridazine) has been also prepared, and its magnetic properties have been used as a reference for the magnetic behavior of the orbitally degenerate Co^{II} octahedral complex.

The crystal structure of **1**[6] and **2** consists of parallel sheets of square arrays of cobalt atoms bridged by bismonodentate pyz (**1**) or pym (**2**) groups (see Figure 1). A section of the sheetlike structure of **2** is shown in Figure 2. The thiocyanate groups occupy the axial positions. Cobalt is in a compressed octahedral environment with four long Co–N(L) bonds [2.210(1) and 2.261(2) Å for **1** and **2**, respectively] and two short Co–N(NCS) bonds [2.047(2) (**1**) and 2.026(3) Å (**2**)]. The metal atoms in **1** and **2** are on a 2/*m* site; that is, they lie on the inversion center at the intersection of a reflection plane and on a twofold axis perpendicular to it. Within each square of a layer the cobalt atoms lying diagonally opposite each other—Co(1)/Co(1g) and Co(1e)/Co(1f) [for **1** (g) at $x, 1+y, z$, (e) at $-0.5+x, 0.5+y, z$, and (f) at $0.5+x, 0.5+y, z$; for **2** (g) at $1+x, y, z$, (e) at $0.5+x, y, 0.5+z$, and (f) at $0.5+x, y, -0.5+z$]—are generated by a unit cell translation along the *x* and *z* axis for **2** (*x* and *y* axis for **1**). Therefore, the Co(1)···Co(1g) and Co(1e)···Co(1f) distances in **2** are the unit cell values of *a* (9.477(2) Å) and *c* (8.487(2) Å) [*b* (10.383(2) Å and *a* (10.049(2) Å in **1**]. The metal–metal separation through pym in **2** (6.361 Å) is significantly shorter

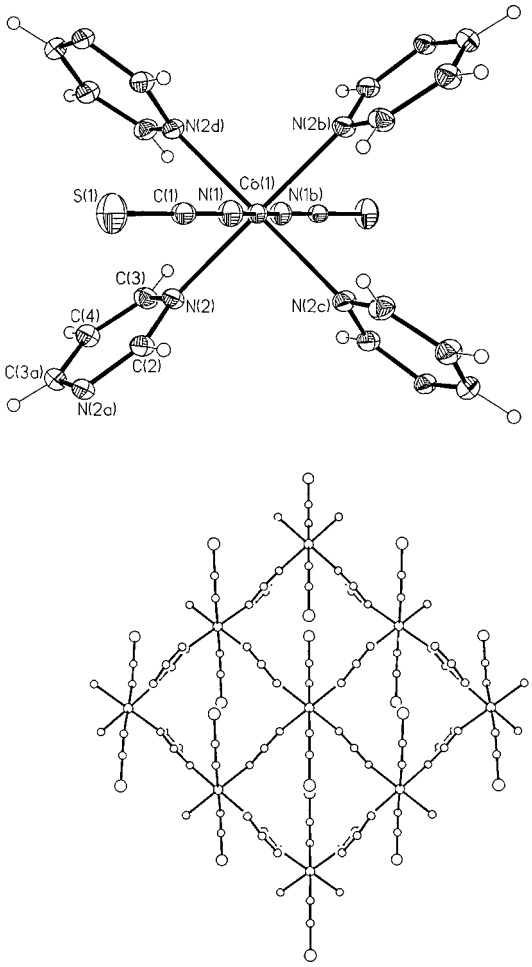

Figure 2. Section of the crystal structure of **2**. Top: Perspective view of the local coordination of the cobalt center (ellipsoids at the 30% probability level). Bottom: View of a sheet along the *xz* plane (hydrogen atoms have been omitted for clarity). Selected bond lengths [Å] and angles [°] with standard deviations in parentheses: Co(1)–N(1) 2.026(3), Co(1)–N(2) 2.261(2); N(1)-Co(1)-N(2) 89.9(1), N(2)-Co(1)-N(1b) 90.1(1), N(2)-Co(1)-N(2c) 91.6(1), N(2)-Co(1)-N(2d) 88.4(1) (generated by symmetry: (b) $-x, -y, -z$; (c) $x, -y, -z$; (d) $-x, y, z$).

than that through pyz in **1** (7.225 Å). Within a square unit of metal atoms in a sheet of **2**, the equatorial planes of opposite Co^{II} ions (constituted by four pyrimidine-nitrogen atoms) are coplanar, whereas the planes of neighboring metal ions form a dihedral angle of 80.7(1)°. The *xz* plane (sheet plane) forms dihedral angles of 40.4(1) and 90.0(1)° with these equatorial planes and with the mean plane of the pym ring, respectively. However, in the case of the related compound **1**, all the equatorial planes of the square unit (ligating atoms are pyrazine-N atoms) are coplanar, and the values of the dihedral angles between the sheet plane (*xy* plane) and the equatorial and mean pyz planes are much reduced [1.5(1) and 65.4(1)°, respectively]. Two adjacent sheets in **2** are separated by 8.487(2) Å (that is, a *b*/2 translation), and they are shifted with respect to the other in such a way that the cobalt atoms of one sheet are located above the centers of the square units of the next sheet. The distance between adjacent layers in **1** is 6.307 Å, and they are related by a translation of *a*/3 along the *x* axis. The shorter interlayer separation in **1** is due to the

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0136 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 1/2

greater interpenetration of the axial NCS groups between the sheets that it exhibits. This is impossible in the case of **2**, in which the square units are more puckered and the pym rings are perpendicular to the sheet plane.

The structure of **3** is made up of neutral $[Co(pyd)_4(SCN)_2]$ units (Figure 3). The cobalt is in a compressed octahedral

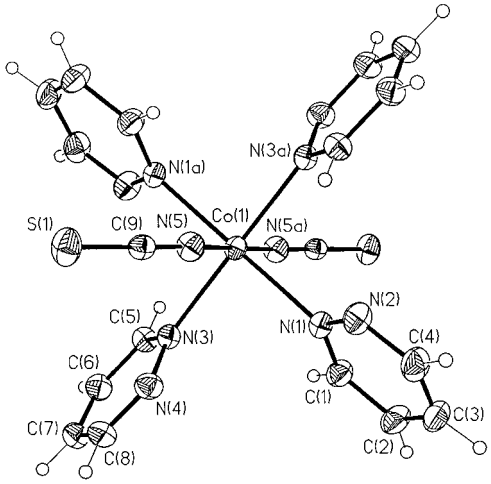

Figure 3. Perspective view of the structure of **3** with thermal ellipsoids at the 30% probability level. Selected bond lengths [Å] and angles [°] with standard deviations in parentheses: Co(1)–N(1) 2.199(2), Co(1)–N(3) 2.208(2), Co(1)–N(5) 2.057(2); N(1)-Co(1)-N(5) 92.9(1), N(1)-Co(1)-N(3) 89.0(1), N(5)-Co(1)-N(3) 90.1(1), N(5)-Co(1)-N(1a) 87.1(1), N(3)-Co(1)-N(1a) 91.0(1), N(3)-Co(1)-N(5a) 89.9(1) (generated by symmetry: (a) $0.5-x, 0.5-y, -z$).

environment with four long Co–N(pyd) bonds [2.199(2)–2.261(2) Å] in the equatorial plane and two short axial Co–(NCS) bonds [2.057(2) Å], as in **1** and **2**. The pyd ligands are planar, and the dihedral angle between the equatorial CoN_4 plane and the pyd ring planes are 50.3(1)° and 120.3(1)°. The shortest intermolecular metal–metal separation is 7.769(3) Å.

The magnetic behavior of **1**–**3** is shown in Figure 4. At room temperature, the $\chi_M T$ value (χ_M is the molar magnetic susceptibility per cobalt atom) is similar for all these

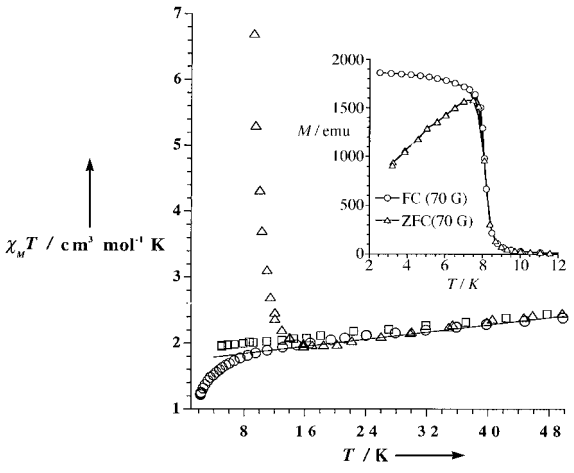

Figure 4. Dependence of the magnetic susceptibility $\chi_M T$ on temperature T for complexes **1** (○), **2** (△), and **3** (□). The inset shows the thermal dependence of the magnetization M in a field of 70 G for **2** after being cooled in an applied field (FC) or in zero field (ZFC).

compounds ($\chi_M T \approx 3.3$ cm³ K mol^{-1}), and it decreases upon cooling. This decrease is related to a spin–orbit coupling effect. In fact, their magnetic behavior can be theoretically modeled, in the temperature range 20–300 K, as monomeric octahedral Co^{II} complexes with λ (spin–orbit coupling parameter) $= -126$ cm^{-1} and κ (orbital reduction parameter) $= 0.75$ (solid line in Figure 4). Complex **3** still follows this theoretical behavior at low temperatures, whereas in the other two cases $\chi_M T$ increases (**2**) or decreases (**1**) rapidly, indicating the presence of ferro- (**2**) and antiferromagnetic (**1**) interactions.

The temperature dependence of the molar magnetization M for **2** was investigated under an applied magnetic field of $H = 70$ G (inset of Figure 4). When the sample was cooled within the field, the field-cooled magnetization showed an abrupt break at 8.2 K. After cooling the sample in zero field and then warming it within the field, the zero-field-cooled magnetization had a maximum just below 8.2 K. All these features are characteristic of a magnetically ordered state below 8.2 K. The ordering temperature T_c was also confirmed by the measurement of both the in-phase (χ') and out-of-phase (χ'') components of the *ac* magnetic susceptibility. The magnetic hysteresis loop for **2** measured at 2.3 K was characteristic of a soft magnet with a small coercive field of 120 G and a remnant magnetization of $0.25\ N\beta$.

The crystal structures of **1** and **2** are thus two important examples of how pyz and pym diazine ligands can spontaneously organize metal ions into a two-dimensional structure and also control the sign of the magnetic interaction in full agreement with the spin-polarization mechanism.

Experimental Section

Synthesis of **1** and **2**: These polymers were prepared in methanol (50 mL) by reaction stoichiometric amounts of $Co(NCS)_2$ and the appropriate diazine (2 mmol). Polymer **1** separates immediately as a polycrystalline orange powder, whereas pink octahedral single crystals of **2** were formed after a few days at room temperature. Prismatic single crystals of **1** were grown by the slow diffusion technique in an H-shaped tube.

Synthesis of **3**: Octahedral orange single crystals of **3** were obtained by slow evaporation (room temperature) of solutions of $Co(NCS)_2$ (1 mmol) and pyd (6 mmol) in methanol (50 mL).

Satisfactory elemental analysis (C,H,N) were obtained for **1**–**3**. Yield about 60%. Crystal structure analyses of **2** and **3**: Siemens R3m/V automatic diffractometer, $Mo_{K\alpha}$, $\lambda = 0.71073$ Å, graphite monochromator, 295 K; data collection, solution, and refinement: $\omega - 2\theta$ scan, standard Patterson methods with subsequent Fourier recycling, SHELXTL-PLUS.[7] **2** ($C_{10}H_8CoN_6S_2$): orthorhombic, space group *Cmca*, $a = 9.477(2)$, $b = 16.284(2)$, $c = 8.487(2)$ Å, $V = 1309.7(4)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.700$ g cm^{-3}, $3 < 2\theta < 55°$, crystal size $0.38 \times 0.21 \times 0.10$ mm; of 811 unique reflections, 661 were assumed observed with $I > 3\sigma(I)$; refinement of 51 variables with anisotropic thermal parameters for all non-hydrogen atoms gave $R = 0.028$, $R_w = 0.031$ and $S = 1.22$. **3** ($C_{18}H_{16}CoN_{10}S_2$): monoclinic, space group *C2c*, $a = 12.341(5)$, $b = 12.950(5)$, $c = 14.322(5)$ Å, $\beta = 109.21(3)°$, $V = 2161(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.523$ g cm^{-3}, $3 < 2\theta < 54°$, crystal size $0.42 \times 0.37 \times 0.32$ mm; of 2380 unique reflections, 1924 were assumed observed with $I > 3\sigma(I)$; refinement of 142 variables with anisotropic thermal parameters for all non-hydrogen atoms gave $R = 0.031$, $R_w = 0.038$ and $S = 1.23$. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data centre as supplementary publication no. CCDC-100411. Copies of the data can be obtained free of charge on application to

Synthetic *Shigella* Vaccines: A Carbohydrate – Protein Conjugate with Totally Synthetic Hexadecasaccharide Haptens**

Vince Pozsgay*

Carbohydrate-based antibacterial vaccines are among the most successful carbohydrate pharmaceuticals.[1] The basis of using carbohydrates as vaccine components is that the capsular polysaccharides (CPs) and the O-specific polysaccharides (O-SPs) on the surface of pathogenic bacteria are both essential virulence factors and protective antigens, and that serum antibodies raised against these polysaccharides may provide immunity by killing the inoculum.[1] This principle led to the development of CP vaccines against Pneumococci and other Gram-positive bacteria. The inability of polysaccharides to elicit protective levels of anti-carbohydrate antibodies in infants could be overcome by their covalent attachment to proteins that conferred T-cell dependent properties.[2] This principle led to the construction of vaccines against *Haemophilus influenzae* b (Hib),[3] and in countries where these vaccines are routinely used, meningitis and other diseases caused by Hib have been virtually eliminated.[4] Extension of the conjugate technology to the O-SPs of Gram-negative bacteria provided a new generation of glycoconjugate vaccines that are undergoing various phases of clinical trials.[5]

While the immunogenicity and the efficacy of the glycoconjugate vaccines are established, their structural requirements are not well defined. Further improvement of the immunologic properties of conjugate vaccines requires the knowledge of the optimal size of the saccharide, the preferred method of its attachment to the protein, and the saccharide/protein ratio necessary for optimal immunogenicity. Success in this area will depend on the availability of well-defined saccharides that are representative of the native polysaccharides.[6]

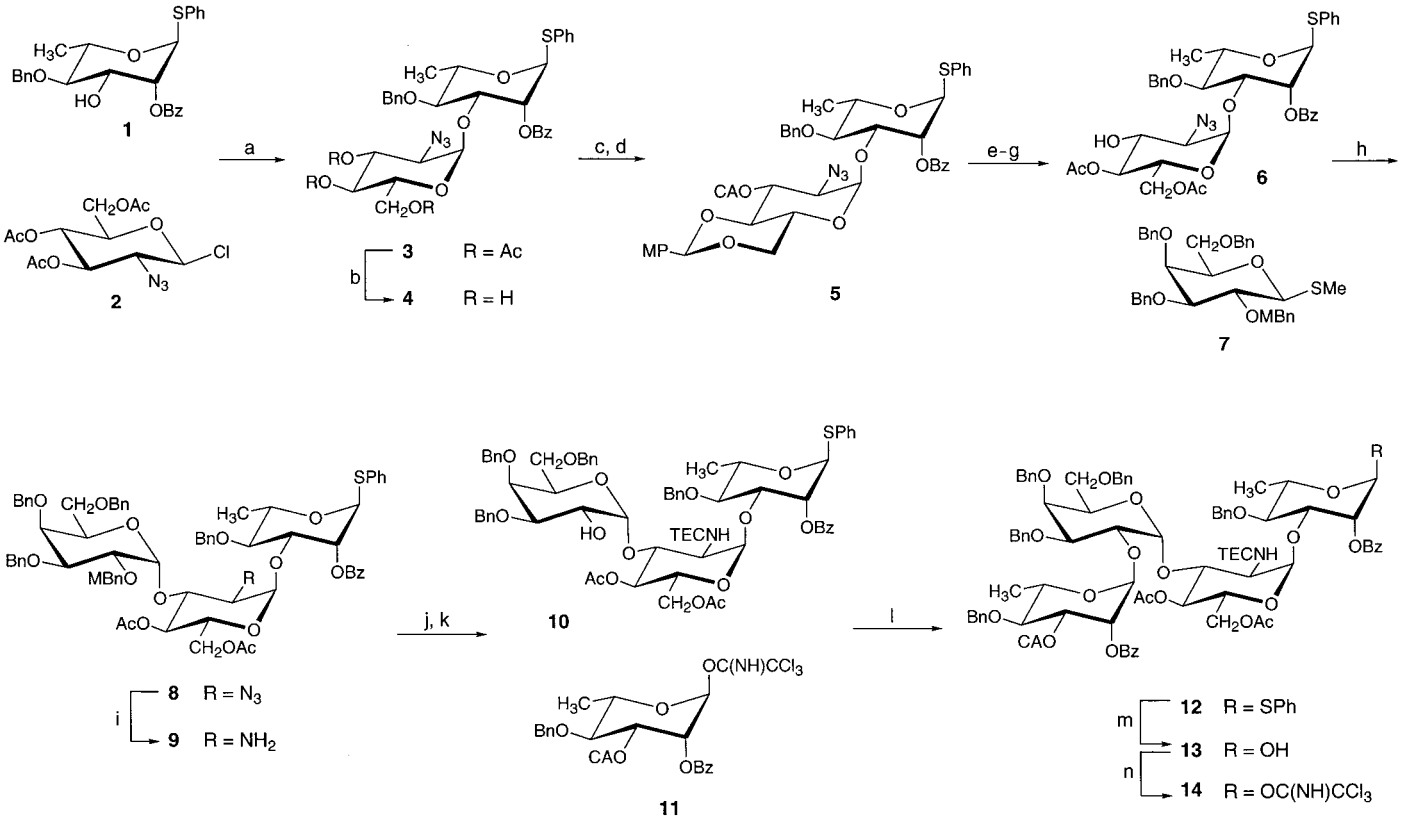
Here we describe our approach to a hexadecasaccharide fragment[7] of the O-SP (**A**) of *Shigella dysenteriae* type 1,[8] a human pathogen that is a major causative organism of endemic and epidemic dysentery worldwide.[9]

→3)-α-L-Rha*p*-(1→2)-α-D-Gal*p*-(1→3)-α-D-Glc*p*NAc-(1→3)-α-L-Rha*p*-(1→
A

The target saccharide is equipped with a spacer as the aglycon portion. A heterobifunctional linker unit was appended to this end of the saccharide assembly for covalent attachment to human serum albumin (HSA) as a model carrier protein. The single-point attachment leaves the entire saccharide chain available for interaction with B cell receptors. The average number of saccharide chains attached to HSA is defined by matrix-assisted laser desorption ionization time of flight (MALDI-TOF) mass spectrometry.

The overall strategy to the target **21** (see below) called for the assembly of a tetrasaccharide repeating unit (**12**, **14,** see Scheme 1) in a form that may be used in an iterative fashion for blockwise construction of higher oligosaccharides.[10] In this endeavor we relied on our previous experience in synthesizing related compounds.[7, 11] Of particular importance was the realization that for the iterative building of a saccharide of this size, the tetrasaccharide frame along the polysaccharide chain should correspond to that shown by formula **A**. We also found that

1) the tetrasaccharide block can be most conveniently assembled in a stepwise fashion,
2) the Gal and the Rha synthons should be installed in a prefabricated form which allows the attachment of the subsequent residue after only one deprotecting step, and that
3) the use of a prefabricated synthon for the GlcN unit has no advantage on the overall yield.



Furthermore, we concluded that intermediates with multiple azide groups should be avoided because of the difficulties that may arise in their conversion to acetamido functions.[12]

The principles established in previous studies led to the selection of four monosaccharide building blocks **1**, **2**, **7**, and **11** that were prepared as reported for related synthons.[7, 11, 13] The assembly of the tetrasaccharide **12** started with the condensation of the rhamnose derivative **1** with the chloride **2** (Scheme 1, Table 1). The nonparticipating azido group of **2**

Scheme 1. a) **1** (1.6 equiv) CF_3SO_2OAg (1.5 equiv), 2,6-di-*tert*-butyl-4-methylpyridine (0.9 equiv), CH_2Cl_2, 0 °C, 2 h, 64 %; b) $HBF_4 \cdot Et_2O$, MeOH, 23 °C, 72 h, 79 %; c) 4-methoxybenzaldehyde dimethylacetal (5.4 equiv), 10-camphorsulfonic acid (CSA) (cat), CH_2Cl_2, 23 °C, 20 min; d) $(ClCH_2CO)_2O$ (2.2 equiv), C_5H_5N, 0 °C, 10 min, 92 % for two steps; e) $HBF_4 \cdot Et_2O$, MeOH/CH_2Cl_2, 0 → 23 °C, 30 min; f) Ac_2O, C_5H_5N, 4-dimethylaminopyridine (cat), 0 → 23 °C, 1 h; g) thiourea (5.5 equiv), DMF/C_5H_5N, 23 °C, 24 h, 71 % for three steps; h) **7** (1.4 equiv), CF_3SO_2OMe (1.7 equiv), 2,6-di-*tert*-butyl-4-methylpyridine (2.9 equiv), Et_2O, 23 °C, 66 h; i) PPh_3 (2.2 equiv), CH_2Cl_2, 35 – 40 °C, 48 h, then H_2O, 35 – 40 °C, 24 h, 58 % for three steps; j) $CCl_3CH_2OC(O)Cl$ (5.8 equiv), $NaHCO_3$, acetone/H_2O, 0 °C, 3 min; k) 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (2.0 equiv), CH_2Cl_2/H_2O, 23 °C, 3 h, 82 % for two steps; l) **11** (3.5 equiv), $BF_3 \cdot Et_2O$ (0.33 equiv), CH_2Cl_2, 0 °C, 2 h, 89 %; m) $Hg(OCOCF_3)_2$ (2.0 equiv), CH_2Cl_2/H_2O, 30 min, 93 %; n) CCl_3CN (9.7 equiv), DBU (0.5 equiv), CH_2Cl_2, 23 °C, 1 h, 85 %. Bn = benzyl, Bz = benzoyl, CA = monochloroacetyl, MBn = 4-methoxybenzyl, MP = 4-methoxyphenyl.

assured sufficient stereocontrol to provide the disaccharide **3** in an acceptable yield. Treatment[11c] of **3** with HBF_4 chemoselectively removed the acetyl groups (→**4**), while the benzoate at O-2 of the rhamnose moiety survived this treatment. Next, the triol **4** was transformed to the diacetate **6**. First the 4-OH and 6-OH groups of the GlcN unit were temporarily protected to allow a monochloroacetyl group to be installed at O-3 of this residue (→**5**). Subsequent mild acid hydrolysis followed by O-acetylation and selective removal of the chloroacetyl group afforded **6** (71 % overall yield from **5**). The Gal-GlcN-Rha trisaccharide was prepared by selective activation of the methylthio galactoside[11c, d] **7** with MeOTf[14] (Tf = F_3CSO_2) in the presence of the phenylthio glycoside **6** to provide **8** in a highly stereoselective reaction. The latter was converted to the amino derivative **9** by the Staudinger reaction using PPh_3 and subsequent hydrolysis providing a 58 % overall yield for three steps. Next, the free amino group in **9** was protected with a 2,2,2-trichloroethoxycarbonyl (TEC) group[15] followed by oxidative removal[16] of the 4-methoxybenzyl group to afford the trisaccharide **10** in 82 % overall yield for two steps. The synthesis of the fully protected tetrasaccharide repeating unit was completed by reaction of **10** with the rhamnose donor **11** under $BF_3 \cdot Et_2O$ activation to afford **12** in 89 % yield.

Experience gained with a tetrasaccharide donor similar to **12** having an anomeric phenylthio group as the leaving group indicated that while such a compound can be successfully coupled with a reactive primary alcohol under I_2/TfOH activation,[17] the method is unsatisfactory for the planned iterative chain elongation. More favorable observations were arrived at with the imidate method.[18] Therefore, the phenylthio glycoside **12** was hydrolyzed with $Hg(OCOCF_3)_2$[19] to afford the hemiacetal **13** as a mixture of the α and β anomers in 93 % yield, which was converted to the imidate **14** as the α anomer, by using CCl_3CN and a catalytic amount of 1,8-diazabicyclo-[5.4.0]undec-7-ene (DBU)[18b] in 85 % yield.

As the first step in the iterative condensation sequence, the tetrasaccharide donor **14** was treated with an excess of the aglycon moiety **15** under Schmidt conditions[18] to provide the tetrasaccharide glycoside **16** in 68 % yield (Scheme 2, Table 1). The subsequent step involved the removal of the chloroacetyl group under essentially neutral conditions to afford the acceptor **17** in 96 % yield for the subsequent iterations. Three repetitive cycles involving glycosylation with the tetrasaccharide donor **14** and dechloroacetylation gave the desired target compound **19** in a protected form. Sequential deblocking that involved replacement of the TEC groups by acetyl groups (Cd/AcOH, then Ac_2O),

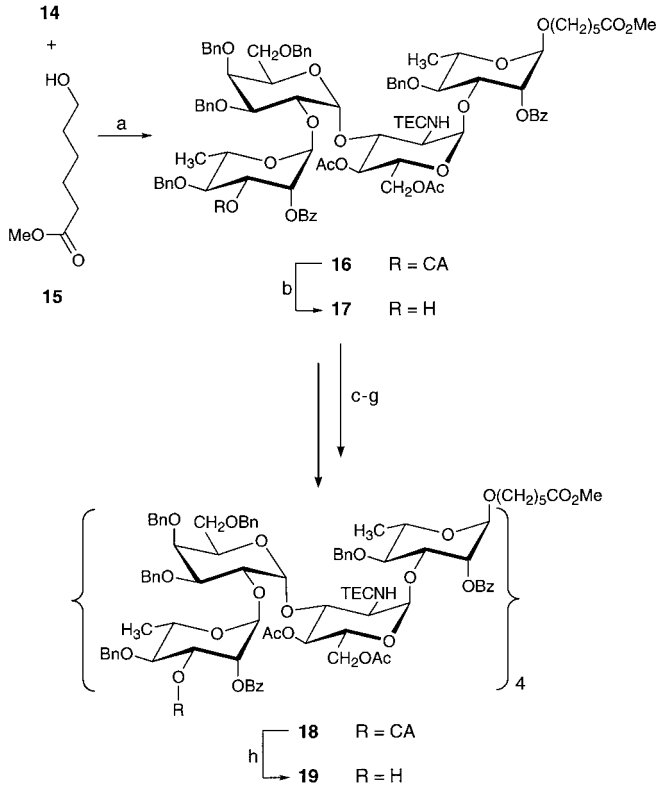
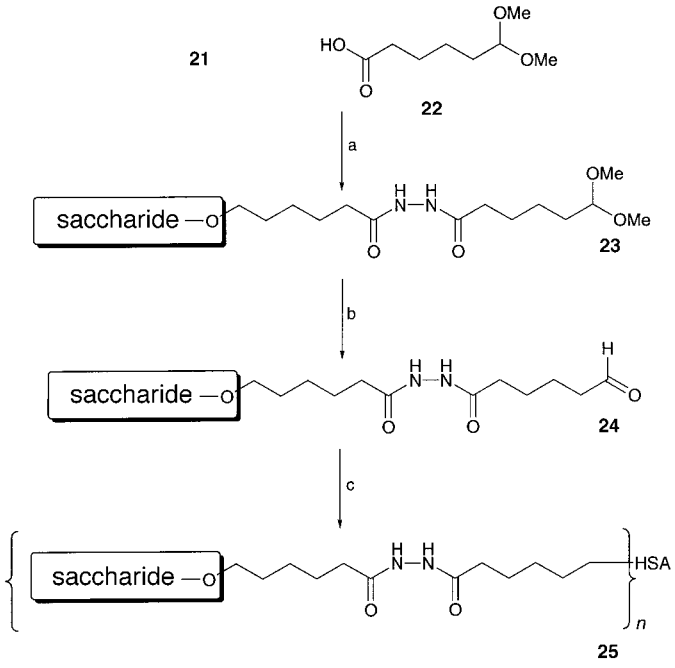
removal of the acyl protecting groups under Zemplén conditions, and hydrogenolytic cleavage of the benzyl groups afforded the target hexadecasaccharide as the methyl ester **20** from which the hydrazide **21** (Table 1) was obtained by treatment with hydrazine in a combined yield of 26% for four steps from **19**.



The acylation of the saccharide hydrazide **21** with the linker moiety[20] **22** was promoted by 1,2-dicyclohexylcarbodiimide (DCC), furnishing the intermediate acetal **23** that was deprotected with AcOH under mild conditions to afford the aldehyde **24**[21] (Scheme 3). Exposure of a solution of the linker-armed hexadecasaccharide and human serum albumin to $NaCNBH_3$ at pH 7[22] afforded the glycoconjugate **25** that was determined by MALDI-TOF mass spectrometry to have



20, R = O-$(CH_2)_5$-CO_2CH_3, $n = 2$

21, R = O-$(CH_2)_5$-$CONHNH_2$, $n = 2$

an average molecular weight of 93 kDa, and a molecular weight range of 83 – 103 kDa.[23] This corresponds to an average incorporation level of 11 saccharide chains per albumin molecule and an overall coupling efficiency of 32 %. We note that the tetra-, octa-, and the dodecasaccharide intermediates were likewise deprotected, equipped with the linker unit, and coupled to HSA, thus affording a series of compositionally related glycoconjugates for immunological studies.

In summary we have prepared the most complex, structurally defined synthetic carbohydrate – protein conjugate yet reported. The syntheses relied mostly on the Schmidt glycosylation, which proved to be highly efficient. This method as tested here offers a challenge against which new glycosylation methods should be evaluated as part of their performance test. Further improvements in the conjugation technology and preclinical evaluation of the synthetic glycoconjugates are in progress.

Reductive amination attaches the ω-aldehydoalkyl moiety to the ε-amino group of the lysine residues of proteins resulting in an ε-N-alkylated construct that preserves the original net charge of the protein (C. P. Stowell, Y. C. Lee, *Adv. Carbohydr. Chem. Biochem.* **1981**, *37*, 225 – 281).

[23] The MALDI-TOF mass spectra were recorded on a KRATOS MALDI III instrument operated at an accelerating voltage of 22 kV. The sample was dissolved in 0.1% trifluoroacetic acid and 50% acetonitrile and applied to the target sample in a sinapinic acid matrix. The molecular weight of HSA was measured as 66350 Da.

Correlation between ^{51}V NMR Chemical Shift and Reactivity of Oxovanadium(v) Catalysts for Ethylene Polymerization**

Michael Bühl*

Olefin polymerization is one of the most important industrial applications of organometallic catalysts.[1] The most widely used catalysts in both homo- and heterogeneous reactions are of the Ziegler type, that is, based on Ti and Zr species along with certain cocatalysts.[2–4] The key step (not necessarily the rate-determining one) is the insertion of the olefin into a metal – carbon bond. Several such reactions and thus many potential catalysts for olefin polymerization are known. Silica-supported vanadium catalysts have attracted some attention in this context.[5] The oxidation state of the active vanadium species is still being debated;[5] low-valent species have been typically assumed, but studies on a soluble model compound have indicated that vanadium in the oxidation state v can also be catalytically active.[6] Upon addition of alkylaluminum reagents the simpler model compound **1** also shows mild catalytic activity for ethylene polymerization.[7] From multinuclear NMR spectroscopy it has been concluded that in the active catalyst, the organoaluminum compound is coordinated to the terminal oxygen atom of **1**.[7]

$[VO(CH_2SiMe_3)_3]$ **1** $[VOMe_3]$ **2** $[V(O\cdots AlH_3)Me_3]$ **3**

Recent calculations for model systems **2** and **3**, employing gradient-corrected levels of density functional theory (DFT), have corroborated this conclusion and have outlined a plausible mechanism for ethylene polymerization by **3** [Eq. (1)].[8] The rate-determining step is ethylene insertion into a V – C bond

$$[V(O\cdots AlH_3)Me_3] + H_2C{=}CH_2 \xrightarrow{\mathbf{3(TS)}} [V(O\cdots AlH_3)(CH_2CH_2Me)Me_2] \quad (1)$$

3

via the transition structure **3(TS)**, which has approximate square – pyramidal coordination about the vanadium center.

The role of the cocatalyst is addressed here in more detail, and the dependence of the computed insertion barrier on the specific Lewis acid is examined. As the latter is also found to affect the chemical shifts of the reactant complex substantially, it is suggested that prospective cocatalysts may be identified by ^{51}V NMR spectra of their adducts with, for example, **1**.

Apart from **3**, model catalysts $[V(O\cdots X)Me_3]$ derived by addition of Lewis acids X have been investigated: none (**2**), Li^+ (**4**), SbF_5 (**5**), and H^+ (**6**). Absolute and zero-point energies[9,10] of reactant minima and transition states, as well as the resulting barriers are collected in Table 1, and the transition structures are displayed in Figure 1. As expected,

the uncatalyzed reaction (i.e. starting from **2**) has the highest computed insertion barrier, 22.2 kcal mol^{-1}. Addition of AlH_3 lowers the barrier by roughly 3 kcal mol^{-1}. Inspection of the natural charges[11] and Wiberg bond indices[12] in Figure 2 gives some information on the reason for this barrier reduction. As the coordination number at the vanadium atom is increased, in other words on going from the reactant **2** to the transition state **2(TS)**, the V – O bond order decreases and the negative charge on the oxygen atom increases. Both effects appear to be quite small, but they are somewhat more pronounced in the corresponding AlH_3 adducts. On going from **3** to **3(TS)** the negative charge on the oxygen atom increases by 13 % and the V – O bond order decreases by 7 % (Figure 2). Apparently, the Lewis acid stablilizes the negative charge on the oxygen atom more efficiently in the transition state than in the reactant complex, thereby lowering the overall barrier.

As a consequence, stronger Lewis acids should stabilize the transition structure even more effectively and should thus further reduce the barrier. For instance, with Li^+ as cocatalyst, a barrier of 17.8 kcal mol^{-1} is computed, more than 1 kcal mol^{-1} lower than that with AlH_3 (Table 1). Similar "electrostatic accelerations" have been predicted computationally for pericyclic reactions[13] and are known experimentally (for instance, the rates of Diels – Alder and ene reactions

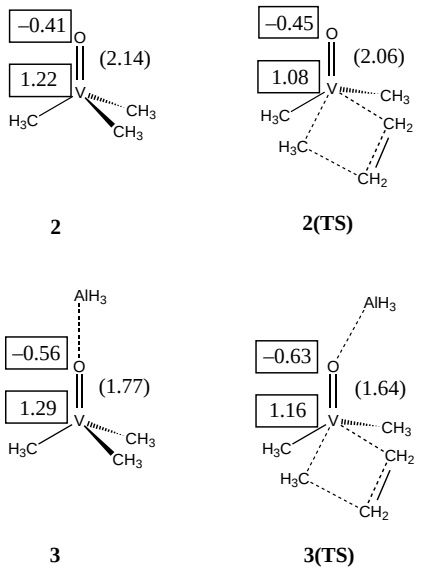

Figure 2. Natural charges (in boxes) and Wiberg bond orders (in parentheses) for **2**, **3**, and the corresponding transition structures for ethylene insertion (obtained from natural population analysis at the BP86/I level).

are enhanced by inorganic lithium salts[14]). A further reduction of the barrier to 16.9 kcal mol^{-1} is predicted when SbF_5 is the cocatalyst. Finally, with one of the strongest acids conceivable, unsolvated H^+, the computed barrier is only 11.9 kcal mol^{-1}. This result may be of little immediate relevance for chemistry in solution, but may serve as a rough estimate for the lower limit for the barrier that can be reached with this type of system. (Note that the theoretical numbers are not necessarily of quantitative accuracy; the computed trends, however, should be reliable.)

Complexation of the Lewis acid at the terminal oxygen atom affects not only the barrier, but also the chemical shifts of the oxovanadium(v) reactants. For instance, the ^{51}V signal of **1** is shifted to higher frequency by $\Delta\delta = 370$ upon coordination of $Al(CH_2SiMe_3)_3$.[7] Similar deshielding, $\Delta\delta = 345$, is obtained on going from model system **2** to its AlH_3 adduct **3** (see Table 1). Moreover, successive deshielding of the ^{51}V nucleus is computed on proceeding from **2** to compounds **4**, **5**, and **6**, with a value of up to $\Delta\delta = 851$ for the latter (Table 1). This deshielding can be understood in terms of paramagnetic contributions due to magnetically induced coupling[15] between the occupied V – C bonding MOs (one "σ_{VC}" and two "π_{VC}") and the virtual, antibonding orbital, "σ^*_{VO}". The latter is strongly stabilized upon protonation (on going from **2** to **6**), much more than the former. Hence, the energetic separation between both is reduced and the resulting paramagnetic contributions are enhanced.

As illustrated in Figure 3, the Lewis acid X affects both $\delta(^{51}V)$ of the reactants and the insertion barrier in a similar way. While there is no strictly linear relationship between these two properties, the general trend is obvious: enhanced deshielding of the ^{51}V nucleus is paralleled by a decrease of the insertion barrier.

There are several reports of empirical correlations of transition metal chemical shifts with kinetic parameters[16] and, in some cases, even with catalytic activities.[17,18] Such

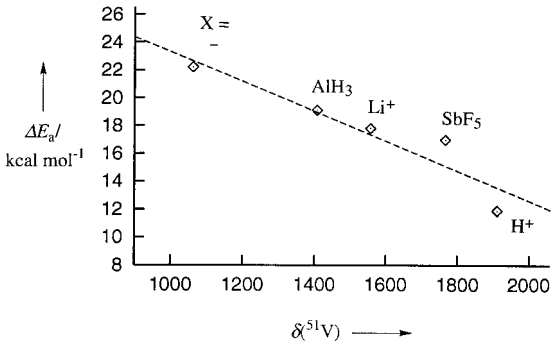

Figure 3. Correlation of DFT-derived barriers to ethylene insertion ΔE_a (BP86/I + ZPE) and chemical shifts $\delta(^{51}V)$(GIAO-B3LYP/I) for the Lewis acid adducts $[V(O\cdots X)Me_3]$.

correlations are potentially very useful because reactivities of new compounds can be estimated from the NMR spectra alone. In some cases, DFT calculations have reproduced and rationalized the experimental findings.[19] The results summarized in Figure 3 constitute the first theoretical prediction of such a NMR – reactivity correlation. When applied to the experimental system **1**, these data indicate that the polymerization activity towards ethylene may be increased by Lewis acids stronger than the alkylaluminum reagents employed so far.[7] Most significantly, it should be possible to screen suitable cocatalysts by recording ^{51}V NMR spectra of the complexes formed initially with **1**:[20] the complexes with the most deshielded $\delta(^{51}V)$ resonance should also be the most reactive ones. If the lower limit of the ethylene insertion barrier is around 12 kcal mol^{-1} as computed for **6** (with H^+ as cocatalyst), catalysts derived from **1** can most likely not match the high activity of the Kaminsky-type zirconocenes, for which propagation barriers on the order of 7 kcal mol^{-1} have been estimated.[21] Nevertheless, it would be very interesting to test experimentally whether the catalytic activity of **1** can be significantly increased by suitable cocatalysts, and whether the predicted NMR – reactivity correlation of Figure 3 can be verified (provided possible problems with the solubility and stability of potential catalysts can be overcome).

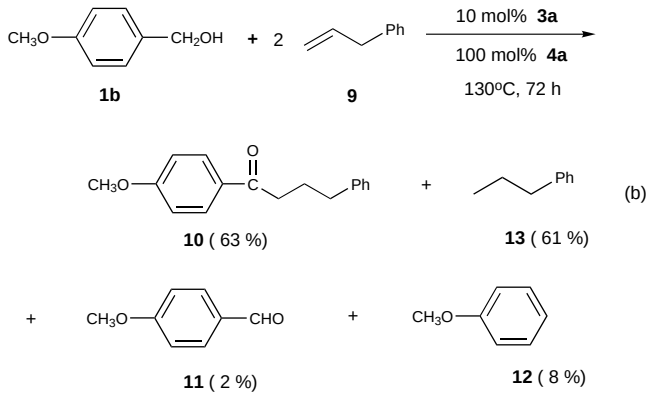
Direct Synthesis of Ketones from Primary Alcohols and 1-Alkenes**

Chul-Ho Jun,* Chan-Woo Huh, and Sang-Jin Na

Activation of the aldehydic carbon–hydrogen bond by transition metal complexes has received much attention in organic synthesis because of its potential to convert aldehydes into ketones by hydroacylation.[1] Although intramolecular hydroacylation has been studied in detail,[2] only a few methods have been reported for transition metal catalyzed intermolecular hydroacylation.[3] Recently, we developed a direct chelation-assisted intermolecular hydroacylation.[4] Primary and secondary alcohols can be oxidized to aldehydes and ketones through hydrogen transfer by a transition metal catalyst. In the course of this oxidation, hydrogen atoms are transferred to hydrogen acceptors such as ketones or alkenes to produce alcohols and alkanes, respectively.[5,6] If oxidation by transition metal mediated hydrogen transfer and hydroacylation occur consecutively with the aid of identical catalysts and olefins, it should be possible to prepare ketones directly from primary alcohols and alkenes. We describe here a one-pot synthesis of a ketone from a primary alcohol and a 1-alkene using a transition metal catalyst together with 2-aminopyridine derivatives. To the best of our knowledge, this is the first example of a direct ketone synthesis from a primary alcohol and a 1-alkene.



Benzyl alcohol (**1a**) was treated with 1-pentene (**2a**) at 130 °C for 72 h using as catalyst a mixture of [chlorotris(triphenylphosphane)rhodium(I)] (**3a**, 10 mol % based upon **1a**) and 2-amino-3-picoline [**4a**, 100 mol %; Eq. (a)]. Hexanophenone (**5a**) was isolated in 74 % yield after chromatography. The reaction proceeded quite well without a solvent. A possible mechanism for this one-pot synthesis of **5a** from **1a** and **2a** is illustrated in Scheme 1. The first step must be oxidation by hydrogen transfer, in which primary alcohol **1a** is converted into aldehyde **6** via complex **3a**. Hydrogen atoms generated from **1a** must be transferred to **2a** to afford pentane.[6] The aldehyde then reacts with **4a** to form aldimine **7** and H_2O. Formation of an aldimine from a primary alcohol and a primary amine in the presence of a transition metal catalyst is presumed to be the key step in N-alkylation of primary amines with primary alcohols.[7] Subsequent hydroiminoacylation of **2a** with **7** leads to ketimine **8**, as reported earlier.[8] Hydrolysis of **8** by H_2O, formed through the reaction of **4a** with **6**, affords ketone **5a** as the final product. Direct synthesis of **5a** from **2a** and **6** by chelation-assisted hydroacylation has already been reported.[4] Since **2a** must serve both as a hydrogen acceptor in the first step and as a hydroacylation substrate in the second step, the amount of **2a** should be at least twice that of **1a**.[9]

Scheme 1. Mechanism for the direct synthesis of ketones from primary alcohols and 1-alkenes by oxidation and hydroacylation.

To determine the intermediates, *p*-methoxybenzyl alcohol (**1b**) was allowed to react at 130 °C for 72 h with allylbenzene (**9**) under cocatalysis with **3a** (10 mol %) and **4a** (100 mol %). This resulted in a mixture of *p*-methoxy-γ-phenylbutanophenone (**10**), anisaldehyde (**11**), anisole (**12**), and propylbenzene (**13**) in 63, 2, 8, and 61 % yield, respectively, based upon **1b** [Eq. (b)].[10] Compound **13** is the hydrogenation product of **9**, while **11** is an oxidation product of **1b** and **12** the decarbonylation product of **11**. Establishment of the presence of **11** and **13** confirms that hydrogen transfer occurs from the primary alcohol to the 1-alkene.

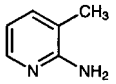
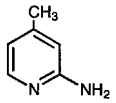
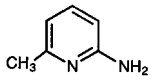
In the catalytic reaction of **1a** and **2b** with $RhCl_3 \cdot H_2O$ (**3b**) and PPh_3 under the same reaction conditions as above, heptanophenone (**5b**) was obtained in much higher yield (84%) than in the reaction with **3a**. The reason is not clear, but the active catalyst **3a** might be freshly generated in situ by the reaction of **3b** with PPh_3.[11]

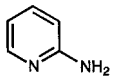
To clarify the influence of **4a**, this substance was introduced in various concentrations into the hydroacylation of **2a** with 4-biphenylmethanol (**1c**). Reaction occurred at 130 °C in the course of 72 h with the catalytic system composed of **3b** (10 mol%) and PPh_3 (Table 1). No ketone was obtained in the absence of **4a**, as expected. The yield of decarbonylation product **15** decreased with increasing concentration of **4a**. This suggests that a high concentration of **4a** retards the decarbonylation of aldehyde generated from alcohol by increasing the probability of carbon–hydrogen bond cleavage of carboxaldimine, which is present in higher concentration.

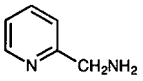
Table 1. Influence of the concentration of 2-amino-3-picoline (**4a**) on the reaction of 4-biphenylmethanol (**1c**) with 1-pentene (**2a**).[a]

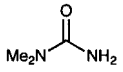






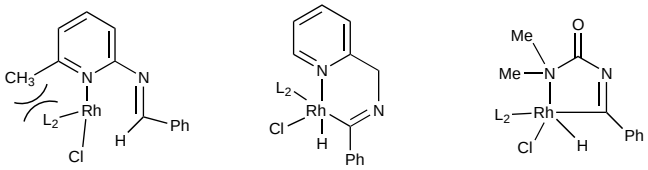






Entry	**4a** [mol%]	Yield (**5i**) [%]	**5i**[b]	**14**[b]	**15**[b]
1	20	21	55	9	36
2	50	55	86	4	10
3	100	67	92	0	8
4	200	88	100	0	0

[a] A mixture of **1c** (0.48 mmol), **2a** (4.8 mmol), **3b** (0.048 mmol), PPh_3 (0.24 mmol), and various amounts of **4a** was heated for 72 h at 130 °C. [b] Relative amounts determined by gas chromatography.



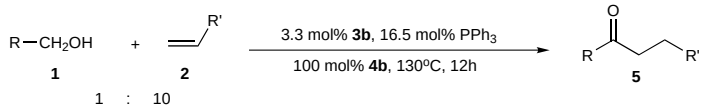
Various types of amine derivatives were examined with the catalytic system consisting of **3b** and PPh_3 (Table 2). Among 2-aminopyridine derivatives, 2-amino-4-picoline (**4b**) showed the greatest catalytic activity, and 2-amino-6-picoline (**4c**) the least. This may be because of steric hindrance by the 6-methyl group (see **16**). The nitrogen atom in the pyridinyl group would coordinate to the metallic center with difficulty in this case, so that the metal and carbon–hydrogen bonds in the aldimine would not be brought into sufficiently close proximity. 2-Aminomethylpyridine (**4e**) showed no catalytic activity, perhaps due to the formation of a less-favored six-membered ring metallacyclic complex such as **17**, or to the instability of the *N*-alkylaldimine compared with the more conjugated *N*-arylaldimine. Even *N*,*N*-dimethylurea (**4f**), which lacks the 2-aminopyridine moiety, provided a hydroacylated product in 3% yield, possibly via intermediate **18**. This clearly demonstrates that formation of the five-membered metallacyclic intermediate is a prerequisite for this reaction. No hydroacylated product was detected with triethylamine (**4g**).

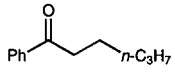
Table 2. Results of the hydroacylation of 1-pentene (**2a**) with benzyl alcohol (**1a**) to give hexanophenone (**5a**) in the presence of $RhCl_3 \cdot xH_2O$ and PPh_3 as catalyst system, as well as various amines (100 mol%).[a]

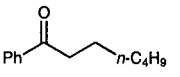
Entry	Amine		Yield [%][b]
1		**4a**	54
2		**4b**	91
3		**4c**	9
4		**4d**	63
5		**4e**	0
6		**4f**	3
7	NEt_3	**4g**	0

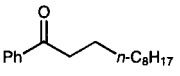
[a] A mixture of **1a** (0.48 mmol), **2a** (4.8 mmol), **3b** (0.048 mmol), PPh_3 (0.24 mmol), and an amine (0.48 mmol) was heated for 40 h at 130 °C. [b] Isolated **5a**.

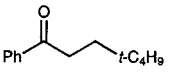
Catalytic reactions of various primary alcohols and 1-alkenes with **3b** (3.3 mol% based upon alcohol) and PPh_3 (16.5 mol%) as well as **4b** (100 mol%) at 130 °C for 12 h were also examined (Table 3). The resulting hydroacylated ketones

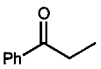


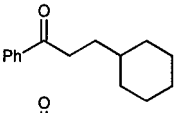


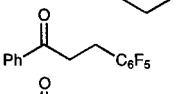


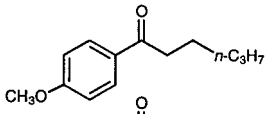


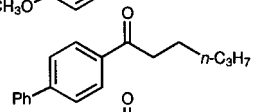


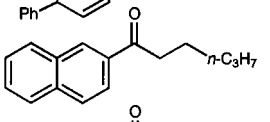


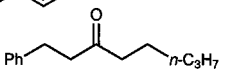












were linear, not branched systems.[12] There appear to be no limitations with respect to the 1-alkene component. Even the sterically hindered 1-alkene 3,3-dimethyl-1-butene (**2d**) provided **5d** in fairly good yield (85%). All the benzylic alcohols **1a**–**1d** provided good results, although yields with aliphatic primary alcohols like **1e** were low (22%).

We thus present a general synthesis for ketones starting from 1-alkenes and primary alcohols with the catalytic assistance of 2-aminopyridine derivatives and transition metal complexes. This newly developed synthesis achieves the generality required for a practical organic synthetic procedure.

[a] A mixture of **1** (1.435 mmol), **4b** (1.435 mmol), **3b** (0.048 mmol), PPh_3 (0.239 mmol), and **2** (14.300 mmol) was heated for 12 h at 130 °C. [b] Yield of hydroacylated product isolated by column chromatography (SiO_2, hexane/EtOAc, 5/2). [c] Benzene was used as solvent. [d] Toluene (200 mg) was added as a solvent. [e] With **3a** as catalyst. Use of the same molar quantity of **3b** and PPh_3 instead of **3a** led to the isolation of **5k** (10%).

Experimental Section

In a typical experiment, a mixture of **1a** (155 mg, 1.44 mmol), **4b** (155 mg, 1.44 mmol), and PPh_3 (62.6 mg, 0.239 mmol) was dissolved in **2a** (1000 mg, 14.3 mmol) in a 2.5-mL screw-capped vial. After the mixture had been stirred for several minutes, complex **3b** (10.0 mg, 0.048 mmol) was added, and the resulting mixture was stirred for 12 h at 130 °C. The solution was concentrated, and the residue obtained was purified by column chromatography (hexane/EtOAc, 5/2) to give 218 mg of **5a** (86% yield).

Ruthenium Carbenes Bonded to a Macrocycle: Carbon Monoxide Induced Carbene Migration Pathways from the Metal to the Ligand**

Alain Klose, Euro Solari, Carlo Floriani,* Silvano Geremia, and Lucio Randaccio

The potential of the metal–carbene functionality[1] bonded to a macrocyclic structure is still largely unexplored, except for some remarkable exceptions in metal–porphyrin chemistry, particularly in the case of the iron[2] and ruthenium[3] couple. This fact is rather surprising in the case of ruthenium, because recently the ruthenium–carbene functionality bonded to conventional ancillary ligands has had a large impact in catalysis of metathesis reactions.[4]

The present paper shows some aspects of the ruthenium–carbene unit when bonded to the easily accessible tetramethyldibenzotetraazaannulene [tmtaaH$_2$].[5] The chemistry of [Ru(tmtaa)] has so far been almost unexplored. Our starting material is not the stable [Ru(tmtaa)(PR$_3$)$_2$],[6] but the labile olefin complex **1** (Scheme 1).

Scheme 1. Synthesis of **2**–**8**. In the routes to **6** and **7** a ruthenium-to-macrocycle migration of the carbene functionality is indicated.

Reaction of **1** with diazoalkanes led to the corresponding carbene derivatives **2**–**4**,[7] which have been fully characterized. The X-ray analysis on **2**[8] is the first X-ray structure of a Ru–carbene bonded to a macrocyclic structure.

[**] This work was supported by the "Fonds National Suisse de la Recherche Scientifique" (Grant No. 20-46′590.96) and Ciba Specialty Chemicals (Basel, Switzerland).

The coordination environment of the ruthenium center is a distorted tetragonal pyramid, unlike in carbene–Fe[2a] and carbene–Os porphyrins,[9] where the metal is always hexacoordinate. The metal is displaced by 0.374(3) Å from the average N$_4$ plane towards the carbene carbon. The Ru–C23 vector is perpendicular to the N$_4$ core. The carbene C23,C24,C30 plane is almost parallel to the N1–N3 vector (torsional angles: C30,C23,Ru,N3 −6.6(6) and C24,C23,Ru,N2 −91.0(6)°). The Ru=C bond length [1.874(8) Å], which does not have any counterpart in Ru–porphyrin or macrocyclic chemistry, is rather close to those found in Ru–phosphane derivatives.[4a, e, f] The question

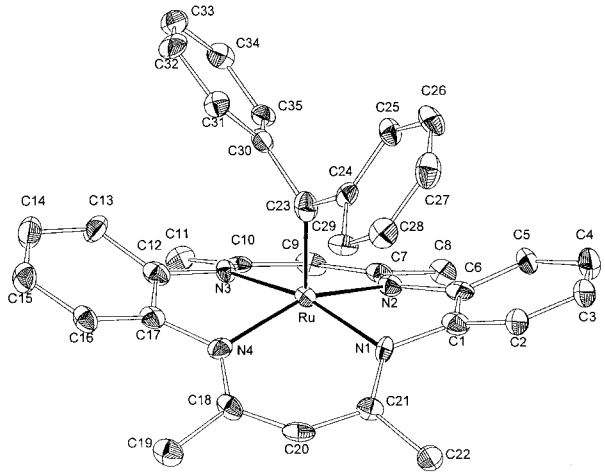

Figure 1. ORTEP drawing of **2** (thermal ellipsoids at 50% probability). Selected bond lengths [Å]: Ru–C23, 1.874(3); Ru–N1, 2.044(6); Ru–N2, 2.024(6); Ru–N3, 2.034(6); Ru–N4, 2.028(7). Bond angles [°]: Ru-C23-C24, 122.5(5); Ru-C23-C30, 122.3(5); C24-C23-C30, 116.4(6).

whether the oxidation state of Ru in **2** is II or IV can be reasonably answered by considering the Ru distance from the N$_4$ plane.[10] The value found in the present case [0.347(3) Å)] is expected for a low-spin diamagnetic d^6 center [compare with 0.216(5) Å in [Ru(tmtaa)(CO)(thf)] (**8**)].[7, 11] A much longer distance would be expected for a d^4 configuration. The tmtaa ligand has the usual saddle-shaped conformation.[5]

The carbene derivatives **2**–**4** are remarkably stable. However, when THF solutions of **2**–**4** are treated with carbon monoxide (1 atm), depending on the substituents at the carbene carbon, three different reaction pathways are observed. In the case of **2** we isolated **5**, which corresponds to the first common step of the reaction with the simple coordination of carbon monoxide *trans* to the diphenylcarbene fragment. In the case of **3** and **4**, carbon monoxide labilizes the carbene causing its migration to the *meso* carbon of the macrocycle.[5f] The reaction of the resulting free radical (intermediate A in Scheme 1) depends on the substituent R′. If R′ = H, the free radical causes the enlargement of the macrocycle to form the bent *cis*-dicarbonyl derivative **6**, whose structure has been confirmed by an X-ray analysis.[11] For R′ = COOMe (**4**), the free radical intermediate **A** delocalizes the free radical center on the COOMe substituent, which then undergoes a one-electron reduction and rearranges to form a Ru–O alkoxo bond (**7**, Figure 2).[8] The transfer of the carbene carbon to C9

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0148 $ 17.50+.50/0

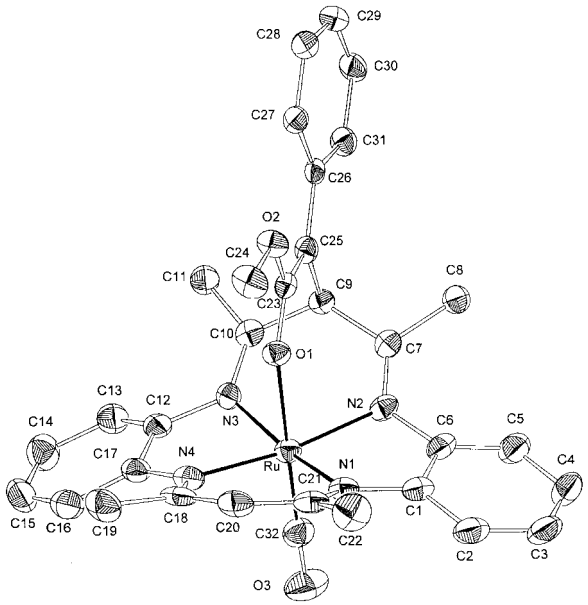

Figure 2. ORTEP drawing of **7** (thermal ellipsoids at 50% probability). Selected bond lengths [Å]: Ru–O1, 2.134(3); Ru–N1, 2.011(3); Ru–N2, 2.024(3); Ru–N3, 2.006(6); Ru–N4, 2.027(3); C7–C9, 1.518(5); C9–C10, 1.529(6); C9–C25, 1.538(5); C23–C25, 1.387(5); C23–O1, 1.260(4); C23–O2, 1.368(4).

removes the aromaticity and the planarity of the six-membered metallacycle Ru,N2,C7,C9,C10,N3; C9 is displaced 0.315(4) Å out of the N2,C7,C10,N3 plane. Consequently, C7–N2 [1.270(5) Å] and C10–N3 [1.278(5) Å] become imino groups, and the *meso*-alkylated tmtaa functions now as a monoanionic ligand. The assumption that C9 and Ru are bridged as shown in Scheme 1 is supported by a) the C23–C25 [1.390(5) Å] double bond character; b) the planarity of the bridge [torsional angle for C23-C25-C26-C27 is $-7.8(6)^\circ$]; c) some lengthening of the C23–O1 bond [1.260(4) Å], which is in agreement with a charge delocalization over the O1-C23-C25 fragment that functions as a monoanionic oxoallyl moiety.

The formation of **5**–**7**, on reaction of **2**–**4** with carbon monoxide, is extremely informative not only on the specific chemical behavior of the Ru–carbene in a macrocyclic environment, but in general on how such a functionality reacts. The Ru–carbene labilization by an incoming π acid is, in fact, the key step in the Ru–carbene assisted metathesis reaction,[4] though in the latter case the *cis*-geometrical proximity led to the reaction between the labilized carbene and the external substrate. The present investigation can serve as a model for the migration of carbene from the metal to the porphyrin in the iron systems.[2] Further applications of the present results are the use of this unconventional carbene bonded to a metal–macrocycle as a potential metathesis catalyst or as a precursor to high-valent ruthenium complexes.

Experimental Section

2: To a suspension of **1**·THF (3.77 g, 7.06 mmol) in THF (150 mL) was added a solution of diphenyldiazomethane (1.38 g, 7.10 mmol) in THF (50 mL). The mixture was stirred for 36 h, during which time it slowly became soluble with the concomitant evolution of nitrogen gas, and then concentrated to 10 mL. *n*-Hexane (30 mL) was added, and the microcrystalline material filtered off and dried in vacuo (3.55 g, 74%). Crystals suitable for X-ray analysis were grown in THF/hexane. Elemental analysis calcd for **2** ($C_{39}H_{40}N_4ORu$) (found): C 68.70 (68.78), H 5.91 (5.99), N 8.22 (8.52). ^{1}H NMR ([D$_6$]benzene, 200 MHz, 298 K): $\delta = 6.92-6.88$ (m, 4H, Ar); 6.73–6.69 (m, 4H, Ar); 6.45 (m, 10H, Ph); 4.91 (s, 2H, CH); 3.56 (m, 4H, THF); 2.13 (s, 12H, CH_3); 1.40 (m, 4H, THF). ^{13}C NMR (C_6D_6, 50.3 MHz, 298 K): $\delta = 291.8$ (C carbene). Crystals contain a THF molecule of crystallization.

7: An orange solution of **4** (0.58 g, 0.98 mmol) in THF (100 mL) was cooled (0°C) and then saturated with CO. The solution immediately became red and was kept overnight under CO. The solvent was removed in vacuo, and the product treated with hexane (30 mL), filtered, and the resulting solid dried in vacuo (0.39 g, 64%). Crystals suitable for X-ray analysis were grown in toluene/hexane (1/1). Elemental analysis calcd for **7** ($C_{32}H_{30}N_4O_3Ru$) (found): C 62.02 (61.50), H 4.88 (5.10), N 9.04 (8.92). IR (nujol, $\tilde{\nu} = 1905$ (s, CO), 1732 (m, COO) cm^{-1}. ^{1}H NMR ([D$_6$]benzene, 400 MHz, 298 K): $\delta = 7.87-6.51$ (m, 13H, Ar); 4.65 (s, 1H, HC=C); 4.48 (s, 1H, CH); 3.59 (s, 3H, OCH_3); 2.01 (s, 6H, CH_3); 1.88 (s, 6H, CH_3). ^{13}C NMR (C_6D_6, 100.6 MHz, 298 K): $\delta = 211.9$ (CO), 164.6, 161.7, 157.2, 150.9, 145.7, 142.4, 128.8, 126.9, 125.2, 122.0, 121.0, 120.6, 120.3, 109.1, 71.4, 63.7, 50.4, 23.7, 20.2.

Unprecedented C–N Coupling Following Migration of an Azido Ligand to a C=C=CRR′ Unit**

Matthias Laubender and Helmut Werner*

Dedicated to Professor Lord Lewis on the occasion of his 70th birthday

Migratory insertion of CO into metal – carbon bonds represents one of the most important reactions in organometallic chemistry and homogeneous catalysis.[1, 2] In the course of our investigations on the reactivity of metallaallenes [L_nM=C=CRR′] and metallabutatrienes [L_nM=C=C=CRR′],[3] we found that not only compounds such as *trans*-[Rh(CH=CH$_2$)(=C=C=CPh$_2$)(P*i*Pr$_3$)$_2$]—generated in situ from **1a** and CH$_2$=CHMgBr—but also those of the general composition *trans*-[Rh(OR)(=C=C=CPh$_2$)(P*i*Pr$_3$)$_2$] (R = Ph, COCH$_3$) easily undergo insertion of the C$_3$Ph$_2$ unit into the Rh–C or Rh–O bond on treatment with CO.[4] This prompted us to prepare the structurally related complexes *trans*-[Rh(X)(=C=C=CRR′)(P*i*Pr$_3$)$_2$], where X is a N-bonded ligand, to find out whether a formal insertion of the allenylidene unit into the Rh–N bond also takes place in the presence of CO. Here we report that for X = N$_3$ such a reaction occurs and, more noteworthy, that the migration of the azide is followed by an unprecedented C–N coupling to generate a substituted acrylonitrile ligand.

The chlororhodium(I) complexes **1a** – **c** react with excess NaN$_3$ in acetone/THF (1/1) at room temperature to give, after recrystallization from acetone, deeply colored **2a** – **c** as crystalline solids in practically quantitative yields (Scheme 1;

Scheme 1. L = P*i*Pr$_3$, An = *p*-C$_6$H$_4$OMe.

2a: red, **2b**: green, **2c**: violet). The most characteristic features of the spectroscopic data of **2a** – **c** (Table 1) are the three low-field signals between $\delta = 255$ and 140 for the allenylidene

Table 1. Selected spectroscopic data for **2a** – **c**, **3b**, **4a**, **c**, and **5** (without data for phosphane ligands or *tert*-butyl and aryl groups).

carbon atoms in the ^{13}C NMR spectra and the strong N=N=N stretching frequency at 2050–2060 cm^{-1} in the IR spectra. As the X-ray crystal structure analysis of **2b** (Figure 1) reveals,[5] the Rh-C1-C2-C3 chain is almost linear—as in the related chloro derivative *trans*-[RhCl{=C=C=C(*o*-Tol)Ph}-($PiPr_3$)$_2$][6]—whereas the *trans*-disposed Rh-N1-N2-N3 unit is bent. The bending of 143.7(5)° is more significant than in the analogous carbonyl compound *trans*-[Rh(N_3)(CO)(PPh_3)$_2$], in which the angle Rh-N1-N2 is 132(1)°.[7]

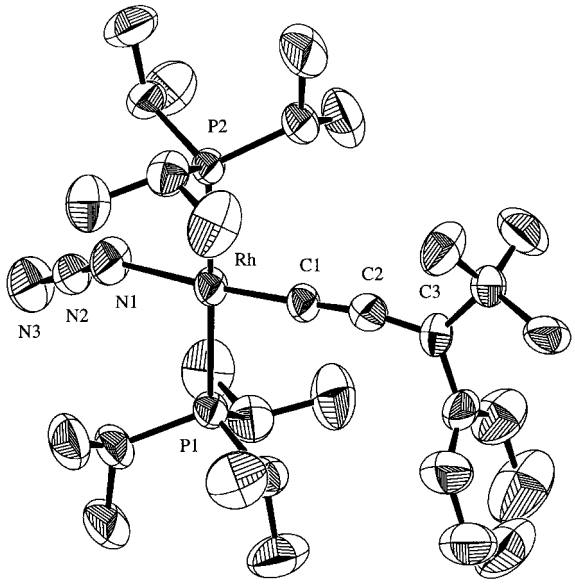

Figure 1. Molecular structure of **2b** (ORTEP plot) in the crystal. Selected bond lengths [Å] and angles [°]: Rh–P1 2.348(2), Rh–P2 2.347(1), Rh–C1 1.849(5), Rh–N1 2.057(5), N1–N2 1.177(7), N2–N3 1.161(7), C1–C2 1.269(7), C2–C3 1.348(7); P1-Rh-P2 175.59(6), C1-Rh-N1 175.7(2), P1-Rh-C1 89.4(2), P1-Rh-N1 93.5(2), P2-Rh-C1 89.9(2), P2-Rh-N1 87.4(2), Rh-C1-C2 177.6(5), Rh-N1-N2 143.7(5), N1-N2-N3 175.8(7), C1-C2-C3 169.1(6).

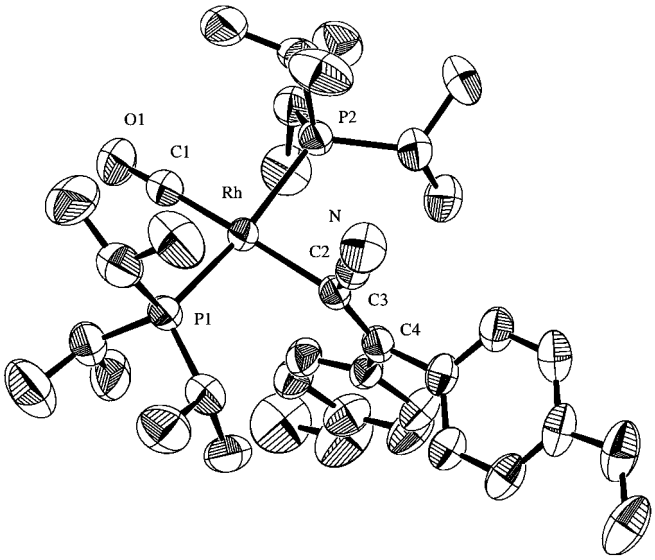
Like the phenolato- and acetatorhodium(I) derivatives *trans*-[Rh(OR)(=C=C=CPh_2)($PiPr_3$)$_2$], the azido complexes **2a–c** are highly reactive toward CO. When CO was passed through a solution of **2a–c** in toluene at −60 °C for 30 s and the temperature then slowly raised to 20 °C, yellow crystalline solids were obtained in yields of about 90 %. For R = Ph and R′ = *t*Bu the analytical composition of the isolated product corresponded to that of **3b** (see Scheme 1). In analogy to the related complexes *trans*-[Rh{C≡CC(OPh)Ph_2}-(CO)($PiPr_3$)$_2$],[4b] the ^{13}C NMR spectrum of **3b** displays two doublets of triplets at $\delta = 121.5$ and 112.8 for the carbon atoms of the C–C triple bond, and the IR spectrum two absorptions at 2100 and 2065 cm^{-1}, which are assigned to the N=N=N and C≡C stretching frequencies. Owing to these data, there is no doubt that treatment of **2b** with CO results in a migration of the N_3 ligand to the allenylidene unit and that the intact azido group in the product is linked to the γ-carbon atom of the C_3 chain.

Quite unexpectedly, the compounds obtained from **2a**, **c** and CO possess a different composition than **3b** (although they have the same color). The IR spectra display only *one* sharp absorption between 2000 and 2200 cm^{-1} (Table 1), and the ^{13}C NMR spectra *three* resonances at $\delta = 160–125$, which all show P–C coupling. These data, together with the stability of the solids toward air and moisture, indicate that the final products of the reaction of **2a** and **2c** with CO are the carbonyl(vinyl)rhodium complexes **4a** and **4c**, respectively. The assumption that they are formed via **3a** and **3c** as intermediates is consistent with the ^{31}P NMR ($\delta = 54.1$ (d, J(Rh,P) = 125.3 Hz)) and the ^{13}C NMR spectra of the species ($\delta = 127.4$ (dt, J(Rh,C) = 43.0, J(P,C) = 21.3 Hz, Rh–*C*≡C), 113.8 (br d, J(Rh,C) = 12.9 Hz, Rh–C≡*C*), 72.1 (s, C≡C–*C*)) generated by passing CO through a solution of **2a** in [D_8]THF at −55 °C. Upon warming to room temperature, this species is rapidly converted into **4a** by elimination of N_2. Theoretical work on the reactivity of unsaturated carbon chains C_n linked to a transition metal suggests that for $n = 3$ the α- and γ-carbon atoms are electron poor.[8] Therefore, it is conceivable that the supposed intermediates **3a** or **3c** rearrange to an isomer with a C(N_3)=C=CRR′ moiety. This would then eliminate N_2 to give the final product.

The X-ray crystal structure of **4c** is shown in Figure 2. The four-coordinated metal center possesses a slightly distorted square-planar configuration with Rh–C1, Rh–C3, Rh–P1, and



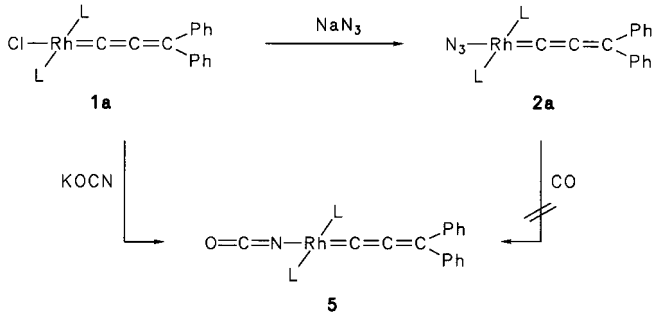


Figure 2. Molecular structure of **4c** (ORTEP plot) in the crystal. Selected bond lengths [Å] and angles [°]: Rh–P1 2.338(1), Rh–P2 2.340(1), Rh–C1 1.834(5), Rh–C3 2.106(4), C1–O1 1.146(5), C2–C3 1.428(6), C2–N 1.144(5), C3–C4 1.367(3); P1-Rh-P2 167.10(4), C1-Rh-C3 174.6(2), P1-Rh-C1 89.7(2), P1-Rh-C3 91.9(1), P2-Rh-C1 88.5(1), P2-Rh-C3 91.2(1), Rh-C1-O1 175.1(4), Rh-C3-C2 109.8(3), Rh-C3-C4 133.2(3), C3-C2-N 174.9(5), C2-C3-C4 117.0(4).

Rh–P2 distances that are quite similar to those of the butadienyl complex *trans*-[Rh{C(CH=CH_2)=CHPh}(CO)($PiPr_3$)$_2$].[9] The C1-Rh-C3 axis is nearly linear, whereas the P1-Rh-P2 axis is somewhat bent; the bending of 167.10(4)° is more pronounced than in **2b** (175.59(6)°). The plane including C2, C3, and C4 is almost perpendicular (86.8(1)°) to that formed by Rh, C1, C3, P1, and P2, which probably minimizes the repulsive interactions between the six isopropyl groups and the substituents at the C–C double bond.

In contrast to several azidometal complexes,[10] the allenylidene derivatives **2a–c** do not react with CO to give the corresponding isocyanato compounds *trans*-[Rh(NCO)-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0151 $ 17.50+.50/0

(=C=C=CRR′)(P*i*Pr$_3$)$_2$]. Therefore, one representative of this type of species was prepared by a different route (Scheme 2). Treatment of **1a** with excess KOCN in acetone/THF (1/1) at room temperature gives complex **5** as a red solid in 95%

Scheme 2. L = P*i*Pr$_3$.

yield. Under the conditions used to form **3a**, **c** (in situ) and **3b**, **5** is completely inert toward CO. As far as N-bonded ligands are concerned, the reactivity of the Rh-bonded azido group in **2a**–**c** toward CO is unique. To the best of our knowledge, there is also no precedence for the type of C–N coupling which occurs during the conversion of **2a** and **2c** into **4a** and **4c**. With regard to the lability of the intermediate observed during the formation of **4a**, it is rather surprising that the related substituted alkynyl complex **3b** is completely inert and does not react either thermally or photochemically to afford *trans*-[Rh{C(CN)=C(Ph)*t*Bu}(CO)(P*i*Pr$_3$)$_2$]. Treatment of **4a** and **4c** with trifluoracetic acid results in cleavage of the Rh–C σ bond, leading to formation of the corresponding acrylonitrile derivatives R$_2$C=CHCN (R = Ph, An) in quantitative yields.

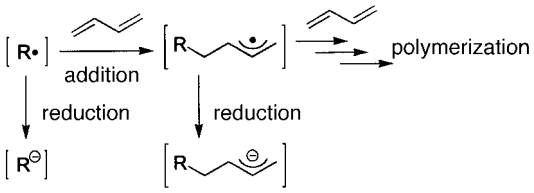
Three-Component Coupling Reactions of Alkyl Iodides, 1,3-Dienes, and Carbonyl Compounds by Sequential Generation of Radical and Anionic Species with $CrCl_2$**



Kazuhiko Takai,* Naoto Matsukawa, Akira Takahashi, and Takafumi Fujii

Although conjugated dienes are good radical-trapping agents,[1] their use in organic synthesis is quite limited because further radical addition leading to polymerization occurs. Such radical chain reactions stem from the similar reactivity of the formed allylic radicals and the starting alkyl radicals. One way to prevent the undesirable side reactions is to reduce the allylic radicals to the corresponding anions (Scheme 1). However, a strong reductant such as samarium(II) readily reduces alkyl radicals, formed from alkyl halides, to furnish alkyl anions; the lifetime of the alkyl radicals is so short that intermolecular C–C bond formation cannot occur.[2, 3] We

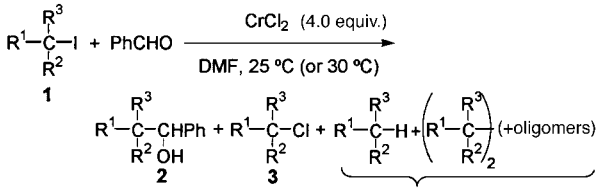
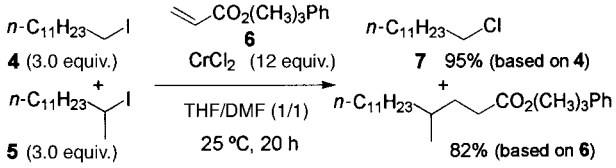


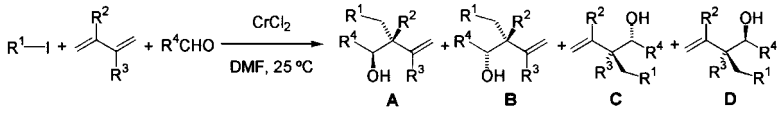
Scheme 1.

report here that chromium(II) chloride, a mild reductant, can discriminate between alkyl iodides, alkyl radicals, and allylic radicals. As a result, 1) an alkyl radical has a sufficient lifetime to undergo intermolecular addition to a 1,3-diene, and 2) radical polymerization of the 1,3-diene can be suppressed by fast one-electron reduction of the allylic radicals. The sequential process of addition and reduction[4, 5] provides an allylic chromium species[6, 7] which adds to an aldehyde to afford a three-component coupling product.



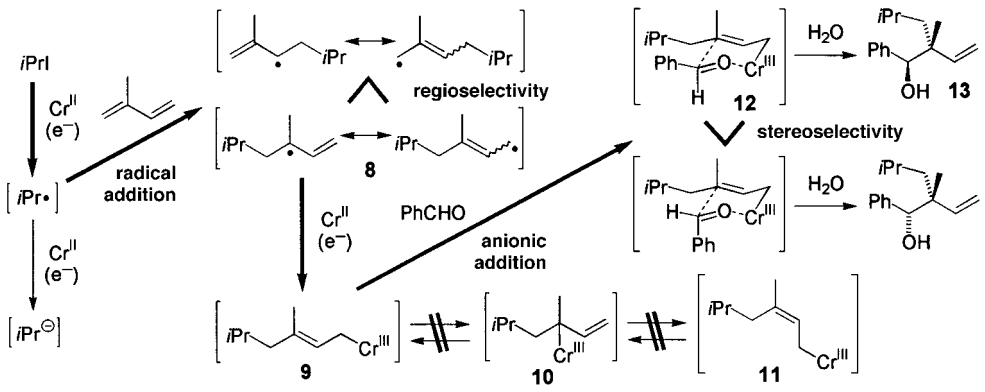
Chromium(II) salts are mild reducing agents, and reactive halides (such as allylic and benzylic halides) can be reduced to give the corresponding organochromium reagents.[8–10] However, it is more difficult to reduce simple alkyl halides in *aprotic* solvents. For example, treating a mixture of 1-iododododecane (**1a**, $R^1 = n\text{-}C_{11}H_{23}$, $R^2 = R^3 = H$) and benzaldehyde with $CrCl_2$ in DMF at 30 °C for 16 h afforded the Grignard adduct **2a** in only 7% yield, and most of the halide was recovered as 1-chlorododecane (**3a**).[4a] This result suggests that, in the case of primary alkyl iodides, the rate of substitution by the chloride ion is faster than that of one-electron reduction with a chromium(II) ion. In contrast, the reduction of secondary or tertiary alkyl iodides to form radical or anionic species proceeds smoothly under the same conditions.

Treating a mixture of the secondary alkyl iodide **1b** ($R^1 = n\text{-}C_{11}H_{23}$, $R^2 = Me$, $R^3 = H$) and benzaldehyde with $CrCl_2$ in DMF at 25 °C for 20 h gave the Grignard adduct **2b** and the alkyl chloride **3b** in 27 and 29% yield, respectively. Compounds derived from the alkyl radical (the dimer and the corresponding alkane) were also obtained in a combined yield



a) R^1 = alkyl; R^2, R^3 = H, 16 h	7%	88%	<2%	
b) R^1, R^2 = alkyl; R^3 = H, 20 h	27%	29%	44%	
c) R^1, R^2, R^3 = alkyl, 5 h	9%	<1%	84%	

of 44%. In the case of the tertiary alkyl iodide **1c** ($R^1 = n\text{-}C_{10}H_{21}$, $R^2 = R^3 = Me$), the Grignard adduct **2c** was produced in 9% yield, although most of the iodide was converted into the corresponding alkyl radicals. However, the formation of alkyl chloride **3c** was not observed. The intermediate alkyl radicals derived from the secondary iodide **5** could be trapped intermolecularly with the α,β-unsaturated ester **6** in 82% yield;[1,5,10b] the primary iodide **4** was recovered as the corresponding chloride **7** in 95% yield.



The secondary and tertiary alkyl radicals have a sufficient lifetime to undergo intermolecular addition to a 1,3-diene. Radical polymerization of the 1,3-diene did not occur, because fast one-electron reduction of the allylic radicals (leading to reactive allylic chromium species)[6, 7] took place smoothly. For example, treating a mixture of isopropyl iodide, isoprene, and benzaldehyde with $CrCl_2$ in DMF at 25 °C for 8 h produced two regioisomeric homoallylic alcohols in 53 and 13% yields, respectively (Table 1, entry 5). The major

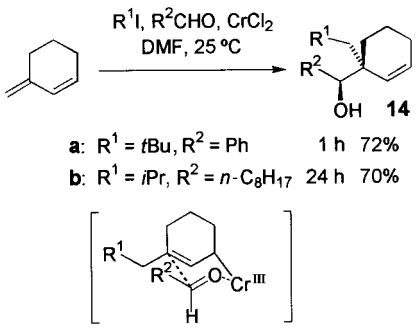
[a] The reactions were conducted on a 1.0-mmol scale. The ratios of the isomers were determined by isolation, gas chromatography, and/or NMR spectroscopy. [b] The following amounts were used per mole of nonanal: chromium(II) chloride: 0.2 mol, manganese: 2.6 mol, Me_3SiCl: 3.7 mol. The reaction was conducted in DMF/THF (1/1).



Scheme 2. Mechanism of the three-component coupling of alkyl iodides, 1,3-dienes, and aldehydes.

regioisomer contained one stereoisomer, which has isobutyl and hydroxyl groups in an *anti* geometry. The stereochemistry was determined by comparison with an authentic sample prepared by the Knochel procedure.[7] When *tert*-butyl iodide was used, the three-component addition proceeded within 10 min due to facile reduction of the iodide (entries 1–4). A catalytic system with chromium(II), manganese, and Me_3SiCl could also be employed for the three-component addition, although the regio- and stereoselectivities decreased slightly (entry 7).[11]

A mechanism which possibly explains the regio- and stereochemistry of the major isomer is shown in Scheme 2. An isopropyl radical preferentially adds to isoprene at the olefinic terminal on the side of the methyl group to form the most stable allylic radical **8**. Reduction of **8** produces the sterically favored extended allylic chromium reagent **9**. There is no fast equilibrium between the three allylic chromium compounds **9**, **10**, and **11** owing to the steric effect of γ,γ-disubstitution.[7] The chromium reagent **9** adds to benzaldehyde via the less sterically demanding six-membered transition state **12** to give homoallylic alcohol **13** selectively.[6, 7] This mechanism explains why diastereoselectivities for reactions with 2,3-dimethyl-1,3-butadiene (entries 3, 4, 9–11) are lower than for those with isoprene. Reduction of the steric difference by changing the β-substituent from H to Me decreases the selectivity of the extended allylic chromium reagents.

An example of the three-component addition to a cyclic compound is shown in Scheme 3. Because the stereochemistry of the allylic chromium reagent determines the configuration of an adduct with an aldehyde, fixation of a double bond by the cyclic system selectively produces only one of the stereoisomers **14**.

Scheme 3.

Experimental Section

Three-component coupling of isopropyl iodide, isoprene, and nonanal (Table 1, entry 6): To a mixture of $CrCl_2$ (0.74 g, 6.0 mmol)[12] in dry, oxygen-free DMF (12 mL) was added a solution of nonanal (0.14 g, 1.0 mmol), isoprene (0.20 g, 3.0 mmol), and isopropyl iodide (0.51 g, 3.0 mmol) in DMF (3 mL) at 25 °C. After the reaction mixture was stirred at 25 °C for 8 h it was poured into water (15 mL), and the mixture extracted with Et_2O (3×10 mL). The organic extracts were dried over anhydrous magnesium sulfate and concentrated. Purification by column chromatography on silica gel (hexane/Et_2O, 400/1) gave (3*R**,4*S**)-3-isobutyl-3-methyl-1-dodecen-4-ol in 70% yield (0.18 g) and 3-isobutyl-2-methyl-1-dodecen-4-ol in 21% yield (53 mg, *anti*:*syn* = 67:33).

14a: To a mixture of $CrCl_2$ (0.49 g, 4.0 mmol) in dry, oxygen-free DMF (7 mL) was added a solution of benzaldehyde (0.11 g, 1.0 mmol), 3-methylenecyclohexene (0.19 g, 2.0 mmol), and *tert*-butyl iodide (0.37 g, 2.0 mmol) in DMF (3 mL) at 25 °C. After the reaction mixture was stirred at 25 °C for 1 h it was poured into water (15 mL), and the mixture extracted with Et_2O (3×10 mL). The organic extracts were dried over anhydrous magnesium sulfate and concentrated. Purification by column chromatography on silica gel (hexane/Et_2O, 50/1) gave (1*R**,1′*R**)-(1-neopentyl-2-cyclohexenyl)(phenyl)methanol in 72% yield (0.19 g).

Dedicated to Professor Wolfgang Beck on the occasion of his 65th birthday

Reagents that function as storable sources of "naked" metal atoms or highly unsaturated organometallic groups offer exciting new possibilities in chemical syntheses owing to their facile reactions with a variety of small molecules and their strongly reducing nature.[1] Of particular significance in this regard are fused-ring arenemetal(0) complexes, which are of substantial interest as possible precursors for the general exploration of zerovalent transition metal chemistry by virtue of the remarkable lability of these arene ligands.[2] Outstanding among these are bis(naphthalene)metal(0) species,[3] for which conventional syntheses were recently reported for the first time.[4] Basolo has presented evidence to suggest that bis(anthracene)metal(0) complexes may be even more labile than their naphthalene counterparts.[5] The only previously known complex of this type, bis(anthracene)chromium(0), was obtained as an inseparable mixture of complex and excess free anthracene by the cocondensation of chromium atoms and anthracene vapor in a metal atom reactor.[6] To our knowledge, no ligand exchange reactions of this compound have been reported to date. The dearth of information on potentially interesting bis(anthracene)metal complexes prompted an investigation of their possible conventional syntheses by the interaction of main group metal anthracenes with transition metal halides. Previously, this approach yielded only mono(anthracene)metal complexes.[7] We now report on the syntheses and molecular structures of the first well-characterized metal complexes containing two coordinated anthracene ligands: $[Ti(C_{14}H_{10})_2(dmpe)]$ (**1**, dmpe = 1,2-bis(dimethylphosphino)ethane) and $[Ti(C_{14}H_{10})_2(C_5Me_5)]^-$ (**2**, counterion $[K(18\text{-crown-6})(thf)_2]^+$), THF = tetrahydrofuran). They are also of interest as the first structurally characterized Group 4 metal anthracene complexes.[8]

Reduction of $[TiCl_4(dmpe)]$ or $[TiCl_3(C_5Me_5)]$ by four equivalents of alkali metal anthracene (Na or K) in THF at −55 to −65°C gave deep red-brown or green-black solutions, from which **1** or $[K(18\text{-crown-6})(thf)_2]$-**2** were isolated in 54% or 28% yield, respectively, as satisfactorily pure, diamagnetic and deep purple or black microcrystalline substances (see Experimental Section). Reactions of pure **1** (in the presence of an additional equivalent of dmpe) or **2** in THF at −55 to −65°C with normal pressures of carbon monoxide, under the same conditions described for the corresponding alkali metal naphthalene mediated carbonylations,[9,10] provided the known $[Ti(CO)_3(dmpe)_2]$ (**3**)[11] or $[Ti(CO)_4(C_5Me_5)]^-$(**4**)[12] in 57% or 62% yields, respectively, of product isolated as the $[K(18\text{-crown-6})]^+$ salt. These syntheses, summarized in Equations 1 and 2, are very similar to previously reported

$$[TiCl_4(dmpe)] + 4\ NaC_{14}H_{10} \xrightarrow[-60\ ^\circ C]{THF} \mathbf{1} \xrightarrow[dmpe,\ -55 \rightarrow 20\ ^\circ C]{THF,\ CO} \mathbf{3} \quad (1)$$

$$[TiCl_3(C_5Me_5)] + 4\ KC_{14}H_{10} \xrightarrow[18\text{-C-}6,\ -60\ ^\circ C]{THF} \mathbf{2} \xrightarrow[-65 \rightarrow 20\ ^\circ C]{THF,\ CO} \mathbf{4} \quad (2)$$

naphthalene anion routes to these carbonyls and lend substantial credence to original suggestions that labile (naphthalene)metal complexes were involved in these and related carbonylation reactions.[13, 14] The anthracene complexes **1** and **2** appear to be substantially more stable in solution and the solid state than corresponding (naphthalene)titanium species, which could not be isolated as pure substances despite numerous attempts.[15] Nevertheless, at least in their reactions with carbon monoxide, **1** and **2** function as effective sources of

the highly unsaturated molecular fragments Ti(dmpe) and $[Ti(\eta^5\text{-}C_5Me_5)]^-$. Their reactions with similar small molecules are under investigation.

NMR solution spectra of **1** and **2** at or near room temperature established that their stoichiometries are identical to those observed in the solid state. HETCOR (i.e., ^1H,^{13}C-correlated) NMR spectra of **1** permitted identification of four equally intense quaternary ^{13}C signals at $\delta = 127.5$, 133.9, 135.3, and 148.6, which are indicative of two inequivalent ligated anthracenes. ^1H NMR spectra showed four equally intense AA′BB′ multiplets below $\delta = 5.4$, which are assigned to hydrogen atoms on two different bound anthracene rings. These spectra were temperature independent up to about 30°C, when broadening of peaks due to bound anthracenes began to occur. Unique assignments of ^1H or ^{13}C resonances to the different anthracene ligands were not possible in most cases. However, along with other supporting NMR data, the presence of a quaternary ^{13}C signal at $\delta =$ 148.6 is good evidence for the presence of one η^4-anthracene group,[16] but the hapticity of the other anthracene ligand in **1** in solution could not be definitely assigned with available data. In contrast, HETCOR NMR solution spectra of **2** at 25°C established that the anthracene ligands are equivalent: the ^1H and ^{13}C NMR spectra showed only five correlated resonances each. The absence of any anthracene ^1H resonances below $\delta = 5.4$ or quaternary ^{13}C resonances above $\delta =$ 133 effectively ruled out the possibility that **2** was an 18-electron species with two equivalent η^4-anthracene groups. Indeed, of all previously known fused-ring arene complexes of zerovalent transition metals, $[Ni(\eta^2\text{-naphthalene})(i\text{Pr}_2\text{PC}_2\text{H}_4\text{P}i\text{Pr}_2)]$ (**5**)[17] and $[Ni(\eta^2\text{-anthracene})(PEt_3)_2]$ **6**,[7f] have NMR spectral features that appear to most closely match those of **2**. These exhibit arene hydrogen resonances only above $\delta = 5.3$, and both are highly fluxional molecules, which exist predominantly as η^2-arene complexes in solution.[17] Based on the similarity of the NMR spectra of **2**, **5**, and **6**, along with the X-ray results for **2** (vide infra), it is possible that **2** may exist in solution as the 16-electron species $[Ti(\eta^4\text{-}C_{14}H_{10})(\eta^2\text{-}C_{14}H_{10})(\eta^5\text{-}C_5Me_5)]^-$, where each anthracene ligand becomes equivalent by rapid concerted η^2 to η^4 equilibria of bound terminal rings. However, available data do not rule out involvement of the 16 or 14 electron species $[Ti(\eta^6\text{-}C_{14}H_{10})(\eta^5\text{-}C_5Me_5)]^-$ (which would be closely related to $[Ti(\eta^6\text{-}C_{10}H_8)(\text{trmpsi})]$ (**7**, trmpsi = tBuSi$(CH_2PMe_2)_3$)[19]) or $[Ti(\eta^2\text{-}C_{14}H_{10})_2(\eta^5\text{-}C_5Me_5)]^-$, respectively. Clearly additional NMR studies are required to understand the solution behavior and structures of **1** and **2**.

Single crystal X-ray structural characterizations were carried out to provide detailed information on the nature of **1** and **2**.[18] Figures 1 and 2 depict their molecular structures and show that the complex $[Ti(\eta^6\text{-}C_{14}H_{10})(\eta^4\text{-}C_{14}H_{10})(\eta^2\text{-dmpe})]$ (**1**) is formally an 18 electron species, whereas $[Ti(\eta^4\text{-}C_{14}H_{10})(\eta^2\text{-}C_{14}H_{10})(\eta^5\text{-}C_5Me_5)]^-$ (**2**) is a 16-electron complex. All previous structurally characterized (arene)titanium(0) compounds, including compound **7**,[19] $[Ti(\eta^6\text{-arene})_2]$ (**8a**,**b**; arene = benzene, toluene),[20] and $[Ti(\eta^4\text{-}C_{10}H_8)_2(SnMe_3)_2]^{2-}$ (**9**),[21] are also 16-electron compounds. Compounds **1** and **2** represent rare examples of bis(arene)metal species containing identical arenes of different hapticities.[22a]

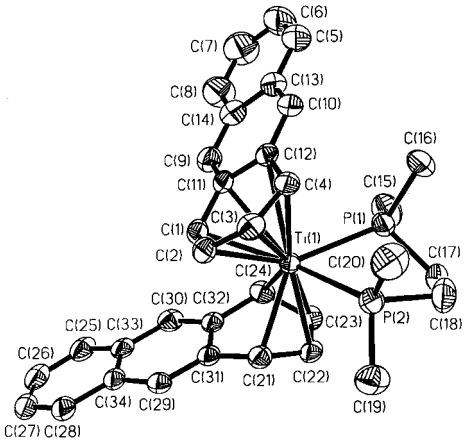

Figure 1. Molecular structure of **1** showing the labeling scheme. Thermal ellipsoids are drawn with 50 % probability boundaries, and hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Ti–C(1) 2.311(4), Ti–C(2) 2.356(4), Ti–C(3) 2.341(4), Ti–C(4) 2.322(4), Ti–C(11) 2.603(4), Ti–C(12) 2.656(4), Ti–C(21) 2.343(4), Ti–C(22) 2.320(4), Ti–C(23) 2.354(4), Ti–C(24) 2.424(4), Ti–P(1) 2.593(1), Ti–P(2) 2.626(1), C(1)–C(2) 1.399(6), C(2)–C(3) 1.398(6), C(3)–C(4) 1.419(6), C(1)–C(11) 1.447(6), C(11)–C(12) 1.459(5), C(4)–C(12) 1.431(6), C(21)–C(22) 1.433(6), C(22)–C(23) 1.375(6), C(23)–C(24) 1.427(6), C(24)–C(32), 1.463(6), C(21)–C(31) 1.464(5) C(31)–C(32) 1.443(5), C–$C_{avg.}$ for uncoordinated "exonaphthalene" carbons 1.40(3), P–$C_{avg.}$ 1.83(1); P(1)-Ti-P(2) 74.44(1).

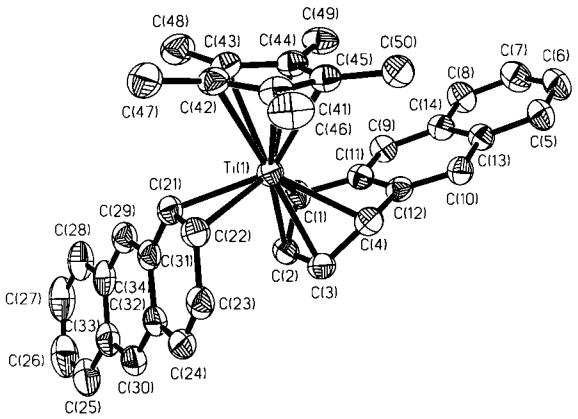

Figure 2. Molecular structure of **2** show the labeling scheme. Thermal ellipsoids are drawn with 50 % probability boundaries, and hydrogen atoms are omitted for clarity. Selected bond lengths [Å]: Ti–C(1) 2.306(3), Ti–C(2) 2.295(3), Ti–C(3) 2.305(3), Ti–C(4) 2.322(3), Ti–C(21) 2.264(3), Ti–C(22) 2.273(3), Ti–C(41) 2.444(3), Ti–C(42) 2.509(3), Ti–C(43) 2.451(3), Ti–C(44) 2.399(3), Ti–C(45) 2.407(3), C(1)–C(2) 1.452(4), C(2)–C(3) 1.386(5), C(3)–C(4) 1.430(4), C(1)–C(11) 1.469(4), C(11)–C(12) 1.444(4), C(4)–C(12) 1.473(4), C(21)–C(22) 1.476(4), C(22)–C(23) 1.441(4) C(23)–C(24) 1.352(5), C(24)–C(32) 1.448(5), C(21)–C(31) 1.453(4), C(31)–C(32) 1.450(4), C–$C_{avg.}$ of uncoordinated "exonaphthalene" carbons 1.41(3), ring C–$C_{avg.}$ of C_5Me_5 1.420(7), C–$Me_{avg.}$ of C_5Me_5 1.507(6).

Although several mono(arene)metal(0) compounds are known to contain η^2- or η^4-arene units,[7, 17, 23] **2** appears to be the first well-characterized η^2-arene complex of a low-valent early transition metal.[22b]

Distinctly nonplanar η^4-anthracene groups are present in **1** and **2**. They consist of planar coordinated diene and uncoordinated exonaphthalene components, which have normal dihedral angles of 35.5° and 31.5°, respectively, for η^4-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0156 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 1/2

anthracene complexes.[7e, 7i, 16] Coordinated diene portions of these anthracene groups have C–C distances that exhibit the usual long, short, long pattern characteristic of most early transition metal η^4-diene complexes and are indicative of the excellent acceptor ability of these ligands in **1** and **2**.[24] Little variation is seen in the Ti–C distances for the η^4-$C_{14}H_{10}$ group in **2**, and the average value of 2.31(1) Å is indistinguishable from the corresponding distance of 2.32(2) Å found in **9**, the only previously known (η^4-arene)titanium complex.[21] Analogous Ti–C distances in **1** are more variable and, except for Ti–C(22), are 0.02 to 0.13 Å longer than those in **2**. The longer Ti–C bonds in **1** relative to corresponding ones in **2** may be a result of a more crowded environment about the titanium center, since the titanium in **1** is formally seven coordinate (seven two-electron bonds), whilst that in **2** is six coordinate.

Another indication that the titanium center in **1** is relatively crowded is the fact that the Ti–C bonds to the η^6-anthracene unit are significantly longer in this complex than in **7**, which contains six-coordinate titanium.[19] Compounds **1** and **7** are otherwise closely related in that both contain fused-ring η^6-arenes, which are bent about C(1) and C(4) with dihedral angles of 15.1 and 12.4°, respectively. This folding results in three different sets of Ti–C distances, which for **1** have the following average values: Ti–C(1,4) 2.317(8), Ti–C(2,3) 2.35(1), and Ti–C(11,12) 2.63(3) Å. The Ti–C (quaternary) distances in **1** are about 0.27 Å longer than those in **7** and indicate that the formally η^6-anthracene unit is appreciably "ring-slipped" and has acquired a substantial degree of η^4-character.

The presence of the η^2-anthracene unit in **2** was unexpected. On the basis of the 18-electron formalism, both anthracenes should bind in a tetrahapto fashion, but the η^5-C_5Me_5 ligand may be sufficiently bulky to prevent this possibility. To our knowledge, the only other well-characterized (η^2-anthracene)-metal(0) compounds are the aforementioned nickel species of the formulation [Ni(η^2-$C_{14}H_{10}$)(PR_3)$_2$] (**6**, R = alkyl).[7b, f] As in the case of the nickel complexes, the η^2-anthracene group in **2** is nearly planar—the dihedral angle between the planes defined by C(21–23) and C(24–34) is only 6.2°. The C–C distances for the uncoordinated carbon atoms in the η^2-anthracene groups of **2** and the nickel complexes **6** are also similar and close to those reported for free anthracene.[25] However, the C–C distance of 1.476(4) Å of the two coordinated carbons in **2** is significantly longer than corresponding distances of 1.422(6) to 1.423(5) Å reported for **6**. This difference indicates that the 16-electron titanium(0) center more strongly participates in backbonding to the η^2-anthracene ligand than do the undoubtedly less strongly reducing 16-electron nickel(0) units. The average Ti–C distance of 2.268(5) Å for the η^2-anthracene group is longer than the Ti–C distances of 2.217–2.247(8) Å found for [Ti(η^6-C_6H_6)$_2$] (**8a**),[20a] but shorter than those for the η^4-anthracene group in **2**, vide supra. Other structural parameters for **1** and **2** are unexpectional, including those of the [K(18-crown-6)(THF)$_2$] cation, which is well separated from **2** in the crystalline lattice. Extension of this study to the synthesis of related anthracene complexes of the early transition metals is currently under examination in this laboratory.

Experimental Section

1: A solution of [$TiCl_4$(dmpe)] (1.75 g, 5.15 mmol) in THF (125 mL, −50°C) was added to a magnetically stirred slurry of $NaC_{14}H_{10}$ (21 mmol) in THF (100 mL, −60°C) and slowly warmed to 0°C over 4 h. The reaction mixture was then cooled to −60°C, filtered at −60°C, and warmed to 0°C. After removal of about 150 mL of THF in vacuo, excess pentane was added to precipitate a black microcrystalline powder. The latter was recrystallized from THF/pentane at 0°C to provide 1.54 g of **1** as sparkling black crystals. Correct C,H analysis, m.p. 194°C (with decomp.); ^{1}H NMR (300 MHz, [D_8]THF, 0°C, numbering as in Figure 1): δ = 0.92, 1.06 (m, each 6H, PCH_3), 1.62, 2.29 (m, each 2H, PCH_2), 3.18, 3.94, 4.38, 5.38 (m, each 2H, $H_{1-4,\ 21-24}$), 6.08, 6.38 (s, each 2H, $H_{9,\ 10,\ 29,\ 30}$), 6.76, 7.02 (m, each 2H, $H_{5-8,\ 25-28}$); ^{13}C{^{1}H}NMR (75.4 MHz, [D_8]THF, 0°C): δ = 13.8, 15.7 (br, PCH_3), 27.7 (t, PCH_2), 77.3, 93.8, 105.1, 105.8 (s, $C_{1-4,21-24}$), 111.1, 120.8 (s, $C_{9,\ 10,\ 29,\ 30}$), 122.6, 123.9, 125.5, 125.7 (s, $C_{5-8,\ 25-28}$), 127.5 (s, $C_{11,\ 12}$), 133.9, 135.3 (s, $C_{13,\ 14,\ 33,\ 34}$), 148.6 (s, $C_{31,\ 32}$); ^{31}P{^{1}H}NMR (121.4 MHz, [D_8]THF, 0°C): δ = 35.5 (s, dmpe). ^{1}H,^{13}C-correlated NMR spectra and trends previously established for monoanthracene or mononaphthalene metal(0) complexes,[7, 23] allowed resonances to be assigned to hydrogens and carbon on bound and unbound anthracene rings, but for quaternary carbon signals at δ = 148.6 and 127.5, the available data were insufficient to permit more detailed assignments. X-ray quality dark purple, nearly black needles of **1**·THF were grown from pentane/THF at −30°C for one week under an argon atmosphere.[18a]

2: A solution of [$TiCl_3(C_5Me_5)$] (1.43 g, 4.94 mmol) in THF (50 mL, 0°C) was added to a solution of $KC_{14}H_{10}$ (19.9 mmol) in THF (100 mL, 0°C). The reaction mixture was stirred at 0°C for 3 h. Following filtration at 0°C, 18-crown-6 (1.43 g, 5.4 mmol) was added and stirred with the filtrate for 3 h at 0°C. After removal of about 50 mL of solvent and filtration at −70°C, all but 25 mL of solvent was removed in vacuo. Addition of pentane (200 mL) caused precipitation of a black solid, which was recrystallized from THF/pentane and then THF/ether to give 1.36 g of microcrystalline black **2**. Correct C,H analysis, mp 165°C; ^{1}H NMR (300 MHz, [D_8]THF, 25°C, numbering as in Figure 2): δ = 1.65 (s, 15H, $C_5(CH_3)_5$), 3.45 (s, 24H, 18-crown-6), 5.43, 5.77 (m, each 4H, $H_{1-4,\ 21-24}$), 6.62, 6.80 (m, each 4H, $H_{5-8,\ 25-28}$), 6.91 (s, 4H, $H_{9,\ 10,\ 29,\ 30}$); ^{13}C{^{1}H}NMR (75.4 MHz, [D_8]THF, 25°C): δ = 15.9 (s, $C_5(CH_{3)5}$), 76.0 (s, 18-crown-6), 108.5, 113.4 (s, $C_{1-4,\ 21-24}$), 118.9 (s, $C_{9,\ 10,\ 29,\ 30}$), 119.1 (s, $C_5(CH_3)_5$), 121.2, 124.8 (s, $C_{5-8,\ 25-28}$), 133.3 (s, $C_{11-14,\ 31-34}$). As in the case of **1**, ^{1}H,^{13}C-correlated NMR spectra and trends previously established for similar complexes[7, 23] allowed resonances to be assigned to bound and unbound rings for the equivalent anthracene ligands in **2**. Black blocks of X-ray quality crystals of [K(10-crown-6)(THF)$_2$]·**2**·1/2 pentane were grown from pentane/THF at −30°C over a period of three weeks under an argon atmosphere.[18b]

[18] a) Crystal data for **1**·THF: $C_{38}H_{44}OP_2Ti$, $M = 626.57$, monoclinic, $P2_{1/c}$, $a = 20.5789(1)$, $b = 9.6620(1)$, $c = 16.6477(2)$ Å, $\beta = 98.797(1)^\circ$, $V = 3271.18(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.272$ g cm^{-3}, $F(000) = 1328$, $\mu(Mo_{K\alpha}) = 0.388$ mm^{-1}, $\lambda = 0.71073$ Å, $T = 173(2)$ K. The 16421 reflections measured on a Siemens SMART CCD area detector diffractometer yielded 5719 unique data ($2\theta_{max} = 50^\circ$, $R_{int} = 0.0525$, semi-empirical absorption corrections). The structure was solved by direct methods and refined by full-matrix least-squares method on F^2 with statistical weighting, anisotropic displacement parameters, constrained isotropic H atoms to give $wR2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2} = 0.1581$ on all data, conventional $R = 0.0666$ on F values of 5720 reflections having $F_o^2 > 2\sigma(F_o^2)$, GOF = 1.095 for all F^2 values and 463 refined parameters. Largest difference peak and hole (e Å^{-3}): 0.690, −0.528. All calculations were performed with SGI INDY R4400-SC or pentium computers with SHEXTL-Plus program suite. b) Crystal data for $[K(18\text{-crown-6})(thf)_2]\cdot$**2**$\cdot 1/2$ pentane: $C_{60.5}H_{81}KO_8Ti$, $M = 1023.25$, triclinic, $P\bar{1}$, $a = 13.0974(2)$, $b = 15.6482(2)$, $c = 15.7479(2)$ Å, $\alpha = 96.170(1)$, $\beta = 107.993(1)$, $\gamma = 111.119(1)^\circ$, $V = 2775.09(7)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.225$ g cm^{-3}, $F(000) = 1098$, $\mu(Mo_{K\alpha}) = 0.282$ mm^{-1}, $\lambda = 0.71073$ Å, $T = 173(2)$ K. The 14.304 reflections measured on a Siemens SMART CCD area detector diffractometer yielded 9364 unique data ($2\theta_{max} = 50^\circ$, $R_{int} = 0.0280$, semi-empirical absorption corrections). The structure was solved by direct methods and refined by the same procedure used for **1** to give $wR2 = 0.1711$ on all data, conventional $R = 0.0637$ on F values of 9368 reflections having $F_o^2 > 2\sigma(F_o^2)$, GOF = 1.075 for all F^2 values and 635 refined parameters. Largest difference peak and hole (e Å^{-3}): 1.771, −0.707. One molecule of pentane was located near an inversion center. It was ill-behaved until bond length constraints were employed for all 1,2 and 1,3 interatomic pairs after freeing C(3)S from placement on the inversion center. These atoms were refined isotropically with a common parameter for all carbon atoms. One large unidentified peak remains in the difference map near one of the THF oxygen atoms. Calculations were performed as detailed above for **1**. c) Crystallographic data (excluding structure factors) for the two structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100606. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code + (44) 1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

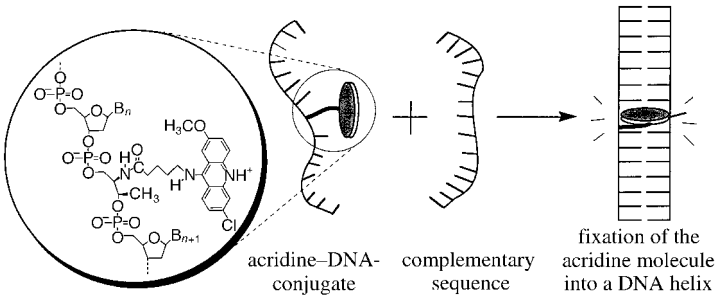
Distance Dependence of Photoinduced Electron Transfer in DNA



Keijiro Fukui and Kazuyoshi Tanaka*

The DNA helix is a useful molecular material for examining how the π stack mediates electron transfer. In recent years photoinduced electron transfers in DNA were investigated in many systems in which a donor and an acceptor randomly associate with DNA[1–6] or a donor and an acceptor are covalently linked at the terminus of DNA to avoid a multiplicity of the separation distance.[7, 8] The clearest evidence for mediation of electron transfer by the base pairs is the distance dependence; the efficiency of the reaction is represented by the β value. For a DNA–dye mixture, estimations of the β value have already been carried out.[3a,5b] Although a series of determinations of the β value is desirable, the lack of a method for introducing the dye precisely "into" the DNA helix makes it difficult to evaluate the distance dependence clearly. Here we report the distance dependence of electron transfer in a DNA helix using a novel system in which a chromophore is precisely fixed in DNA of defined sequence.

To anchor a chromophore at any desired site of a DNA and to suppress unfavorable thermal fluctuation around the chromophore, we adopted the strategy of introducing 9-amino-6-chloro-2-methoxyacridine (ACMA) at a defined internucleotide site of a DNA[9a, b] (Scheme 1). The thermal

Scheme 1. Schematic representation of the anchoring of ACMA at the desired site in a DNA helix.

stability of the helix and the fluorescence quantum yields from ACMA strongly depend on the chain length between the dye and the DNA as well as on the presence of a nucleobase at the opposite side of the acridine ring.[9c] A tetramethylene linker (Scheme 1) and adenosine at the opposite side of the ACMA unit are most suitable for fixing ACMA into a DNA helix. ACMA provides the strongest emission in the modified DNA, and the whole DNA structure shows particular thermal stability.[9c] The structure in which ACMA is intercalated between neighboring base pairs and the opposite adenosine is pushed out of the helix (extrahelical conformation) was confirmed with 2D-NMR spectroscopy.[10]

Using the corresponding acridine-phosphoramidite[9b] in a DNA synthesizer, we prepared the ACMA – DNA conjugate **I**, which consists of only adenosine and thymidine nucleotides, as well as conjugates **II** – **VIII**, which have a sequence similar to that of **I** and contain guanosine in the 5′ or 3′ directions at different distances (Table 1). To maintain the binding geometry between ACMA and the nucleobases, both sides of ACMA were fixed in purine bases (adenine or guanine). The absorption spectra of ACMA and the wavelengths of the fluorescence maxima (see below) were unchanged for a series of ACMA – DNA conjugates. Hence, the energy level of the ACMA units was identical for all ACMA – DNA conjugates.

We measured the fluorescence spectra of the ACMA units in duplexes **I** – **VIII** to investigate electron transfer through the DNA π stack under conditions in which all DNA molecules are sufficiently stable (0 °C).[9c] The fluorescence quantum yields of these duplexes are listed in Table 1, and the fluorescence spectra of **I** – **IV** are shown in Figure 1. Duplex **I**

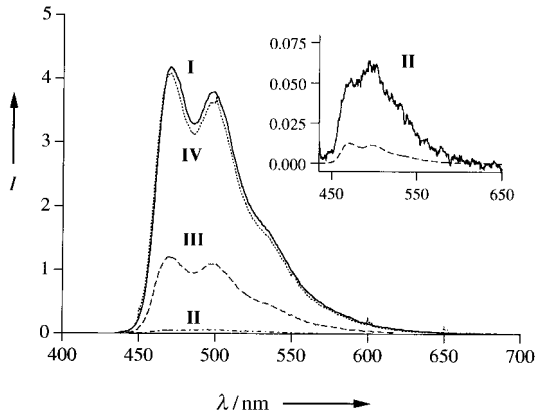

Figure 1. Fluorescence spectra of the ACMA – DNA conjugates **I** – **IV** (intensity *I* in arbitrary units). Inset: Enlarged section of the fluorescence spectrum of **II** (solid line). It can be divided into the SAS (dashed line) of the ACMA firmly fixed in a DNA helix and the nonintercalated (extrahelical) ACMA (see text and ref. [9c]).

Table 1. Fluorescence quantum yields Φ of the ACMA – DNA conjugates **I** – **VIII** and rates of electron transfer from guanine to an excited ACMA in a DNA helix.

[a] Sample concentrations: 2.5 μM in 10 mM phosphate buffer (pH 7.2) with 150 mM NaCl. The samples were slowly annealed from 60 °C and kept overnight in the dark. [Acr] stands for the artificial base-free site connecting to ACMA through a tetramethylene linker (see Scheme 1). [b] Under the assumption that the distance between the base pairs is 3.4 Å (see ref. [24]). [c] Measured at 0 °C; excitation wavelength 427 nm. [d] Determined with Equation 2 (see text). [e] Calculated using only the emission from ACMA strictly fixed in a DNA helix (see text and inset of Figure 1).

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0159 $ 17.50+.50/0

showed strong emission bands at 475 and 500 nm, which are attributed to the species-associated spectrum (SAS) of ACMA and reflect its rigid microenvironment.[9c, 11] Indeed, the decay in intensity was monoexponential with a lifetime of 22.8 ns, as measured by single-photon counting.[12] These emission bands cannot be seen for free ACMA in water or for any other ACMA – DNA conjugates;[9c] fast relaxation of the environment around the excited ACMA only gave an emission band at 500 nm.[9c, 11] These results indicate that the ACMA was precisely fixed with unique conformation in a DNA helix, and that the origin of electron transfer can be evaluated without fail.

Since the fluorescence of an ACMA unit is not quenched by a d(AT) base pair,[9c, 13, 14] **I** acts as an "inert matrix" for the photoexcited ACMA. On the other hand, guanine can quench the ACMA fluorescence,[13, 14] and this mechanism is assigned as an electron transfer [Eq. (1)]. It is impossible for an energy

$$[\mathrm{Acr}]^{+}\cdots \mathrm{dG} \xrightarrow{h\nu} [\mathrm{Acr}]^{+*}\cdots \mathrm{dG} \xrightarrow{k_{et}} [\mathrm{Acr}]\cdots \mathrm{dG}^{+} \quad (1)$$

transfer to occur because of the lack of spectral overlap; nucleobases can absorb at $\lambda < 300$ nm. It is clear from electrochemical,[15] theoretical,[16a] and chemical aspects[16b, c] that guanine is the most readily oxidizable residue.

In general, when two dyes (e. g. donor and acceptor) intercalate into a DNA helix, at least two base pairs must exist between them. Furthermore, the loading of the two chromophores in this short distance is sufficient to cause local disruption of the DNA structure of a rod-shape.[17] However, since guanine is used as an electron donor in the present study, there is no such limitation. The fluorescence intensity of duplexes **II** – **VII** clearly decreased as a function of the distance between ACMA and guanine (see Table 1 and Figure 1). For **II** and **V**, in which guanine is adjacent to ACMA, the fluorescence was strongly suppressed to about 2 % of that for **I**. The fluorescence spectra of **II** and **V**, however, showed incomplete SAS of ACMA (inset of Figure 1). These spectra contain the emission from unfixed ACMA, presumably because a very small portion of ACMA can be in an extrahelical conformation.[9c, 18] Although it is rather small, the SAS can be clearly seen.

Since ACMA and guanine are connected through many bonds (alkyl chain, amide bond, and phosphate), it is difficult to imagine that the strong quenching is due to electron transfer through these long bonds.[19, 20] Therefore, it is rational to consider that direct electron transfer occurs through the π stack between ACMA and guanine.[21] The rates of intramolecular electron transfer were evaluated with Equation (2).

$$k_{et} = \frac{1}{\tau_0}\left(\frac{\Phi_0}{\Phi} - 1\right) \quad (2)$$

Here, τ_0 is the excited-state lifetime in the absence of the quencher guanine (that is, for **I**), and Φ_0 and Φ are the fluorescence quantum yields of the ACMA – DNA conjugates in the absence (**I**)[12] or presence of guanine, respectively (**II** – **VIII**; see Table 1). The rates of electron transfer for **II** and **V** were calculated from the quantum yields of the SAS. The rates of electron transfer decrease with increasing distance between ACMA and guanine (see Figure 2). The slopes of the

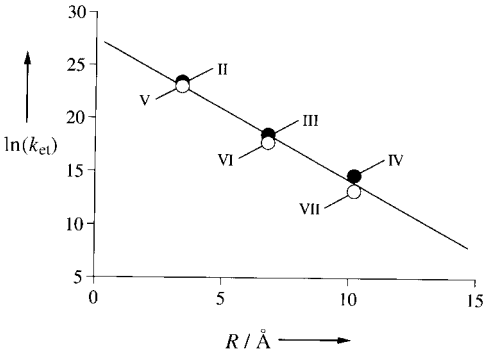

Figure 2. Correlation between the rate of electron transfer k_{et} and the separation distance R in a DNA helix for 5′ (●) and 3′ directions (○). The solid line represents the least-squares fit for the data points.

lines for the 5′ and 3′ directions are very similar, which indicates that the electronic coupling of these directions is practically identical.[26] It is noteworthy that the summation of the rates of electron transfer for **III** and **VI**, in which ACMA and guanine are separated with one d(AT) base pair, is $1.64 \times 10^8\ s^{-1}$. This value is almost identical to that of **VIII**, in which guanines exist in both sides of the ACMA with a separation of one d(AT) base pair. This result is consistent with selective intercalation of ACMA into the target position,[9c] and it can be concluded that the intercalation modes of ACMA – DNA conjugates are not perturbed by changes in base sequence near the ACMA unit.

The most common expression for the distance dependence of the rates of electron transfer can be derived from Equation (3).[19, 22] Here β stands for the effectiveness of the

$$k_{et} = A\, e^{-\beta R} \quad (3)$$

intervening base pairs between the coupling donor and acceptor, and R for the separation between them. When R is set equal to the distance along a B-DNA helix (i. e., 3.4 Å per base stacking;[17] see Figure 2), fitting the electron transfer data to Equation (3) gave a preexponential factor A of 1.20×10^{12} and a β value of 1.42 $Å^{-1}$. These values are comparable with those of protein matrices[19, 22, 23] and show that the π stack in DNA is a moderate mediator and not a special material for electron transfer. The β value is strikingly close to that recently predicted by theoretical calculations,[24] although the results of theoretical calculations are still in disagreement.[25] However, the β value for our system is larger than for electron transfer in other dye – DNA systems: 0.91 and 0.86 $Å^{-1}$ for transfer from photoexcited ethidium or acridine orange, respectively, to *N*,*N*′-dimethyl-2,7-diazapyrenium (DAP);[3a] 0.73 $Å^{-1}$ from Cu^{+} to oxidized ethidium.[5b] We account for the differences in these rates of electron transfer with the following: The donors of the systems are in an excited or high-energy state and are therefore better coupled to the corresponding high-energy bridging state in DNA.[26, 27] The electron transfer studied here occurs from the ground-state guanine with lower energy. This "hole transfer" is not well effectuated due to the high energy of the low-lying unoccupied orbital or LUMO of DNA that works as the transferring path. In fact, the reverse electron transfer for charge recombination from reduced DAP to oxidized ethidium gives

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0160 $ 17.50+.50/0

$\beta = 1.49$ Å^{-1}.[3a] This value is practically identical to that observed in the present study. However, our data is quite different from that of Murphy et al. ($\beta = 0.2$ Å^{-1}),[8a] although the same mediator was used. This large discrepancy could not be explained with the above description.

In conclusion, we measured the long-range electron transfer through a DNA helix and its distance dependence by introducing a dye precisely into a DNA helix. Since these modified DNA are readily prepared by a DNA synthesizer, it is easy to introduce the second or third dyes into the DNA structure and to change the base sequence. We are now in the position to use this system to delineate the reorganization energy, the reverse electron transfer, and the effect of base stacking[16] in a DNA π frame.

[21] We tried to measure the transient absorption spectra by using a nanosecond transient absorption spectrophotometer. However, since 1) the absorption coefficient of the oxidized guanine is very small ($\varepsilon < 2000$ M^{-1}cm^{-1} at 450 – 650 nm), 2) the absorption spectrum is entirely dominated by the fluorescence of ACMA, and 3) the rate of the reverse electron transfer would be very fast (10^9 sec^{-1}, $t < 10^{-9}$ sec), this experiment was not successful.

Overcoming a Longstanding Challenge: X-Ray Structure of a $[Co_2(CO)_6]$-Complexed Propargyl Cation**

Gagik G. Melikyan,* Stephen Bright, Todd Monroe, Kenneth I. Hardcastle, and Joana Ciurash

The ability of mono- and polynuclear transition metal clusters to dramatically enhance the stability of neighboring carbocationic centers is well documented.[1–3] NMR spectroscopy has been widely used to structurally characterize homo- and heteronuclear metal complexes;[4] on the contrary, X-ray crystallography has been used to a lesser extent because of the thermal lability and low crystallinity of organometallic cations. Chronologically, ferrocenyl-[5] and bis(tricarbonylcyclobutadienyliron)-stabilized[6] methyl cations were characterized first, followed by a variety of organometallic species[7–11] with tetrahedral (or quasi tetrahedral) metal cores (Mo_2C_2,[7] $MoCoC_2$,[7a, 8, 11] W_2C_2,[9] and $CoFeC_2$[11]). The synthesis and structure of the propargyl cation stabilized by the $[Co_2(CO)_6]$ cluster have been thoroughly investigated.[12] NMR studies[13–15] revealed two modes of fluxionality, a low-energy *antara*-facial motion of the cationic center between metal atoms, and a high-energy rotation around the bond between the cationic center and the cluster (apical C – C

double bond).[14] Although a $[Co_2(CO)_6]$-complexed propargyl cation was isolated two decades ago,[13a] the X-ray crystal structure of such a cation was hitherto unknown.[2, 12]

As a part of a continuing study of the chemistry of π-bonded organometallic radicals and carbocations,[16] we report herein the synthesis and the first X-ray characterization of a doubly stabilized $[Co_2(CO)_6]$-complexed propargyl cation. The adopted strategy consists of introducing two charge-stabilizing metallaalkyne moieties in the α position to the cationic center to enhance the thermal stability and crystallinity of target species. The starting material **1** was synthesized by a modified literature procedure[17] in 55% yield (Scheme 1). Alkyne moieties of the latter were consecutively protected with $[Co_2(CO)_6]$ groups[18] to generate mono- and diclusters **2** and **3**[19] (Figure 1), respectively. Treatment of **3** with HBF_4 resulted in the salt **4** of the corresponding complex cation, a black solid stable at ambient temperature under aerobic conditions, which rapidly decomposes in solution (CH_2Cl_2, acetone).

Scheme 1. Synthesis of **4** from the triyne **1**.

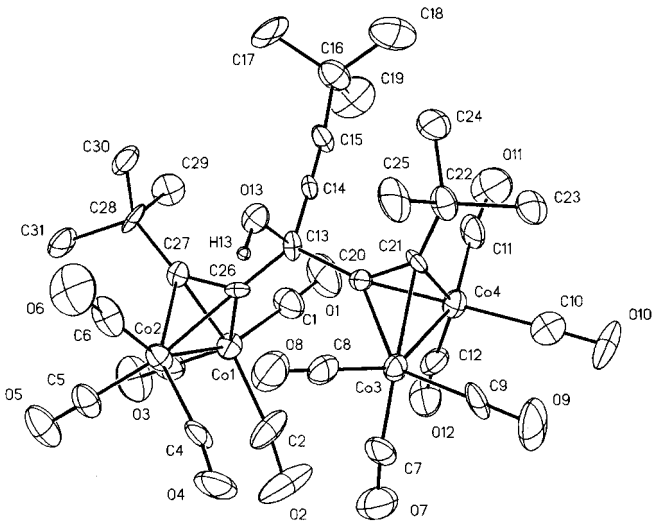

Figure 1. Molecular structure of **3** (30% probability ellipsoids). Selected interatomic distances [Å] and angles [°]: C13–C20 1.49(2), C13–C26 1.53(2), C13–C14 1.43(2), C13–Co1 3.29(1), C13–Co2 3.25(1), C13–Co3 3.26(1), C13–Co4 3.25(1); C14-C13-C20 108.9(11), C14-C13-C26 108.0(10), C20-C13-C26 119.5(12), C14-C13-O13 108.0(12), C20-C13-O13 106.0(10), C26-C13-O13 105.9(10), C27-C26-C13 133.6(12), C21-C20-C13 134.8(13), C28-C27-C26-C13 4.8(1), C22-C21-C20-C13 4.4(1); angle between the bonds C26–C27 and Co1–Co2 89.2(5), between C20–C21 and Co3–Co4 90.1(5), between Co1–Co2 and Co3–Co4 24.2(4).

The structure of **4** was characterized by low-temperature ^1H and ^{13}C NMR spectroscopy (−80 °C) and X-ray crystallography (−105 °C). In the ^1H NMR spectrum, the *tert*-butyl groups are deshielded compared to those in the neutral bis-cluster **3**. The absolute values of $\Delta\delta$ of 0.128 and 0.076 ppm for substituents at the uncomplexed and complexed triple bonds respectively, indicate a higher sensitivity of the former towards developing cationic center. Single crystals of **4** (Figure 2) were obtained by its slow precipitation from an

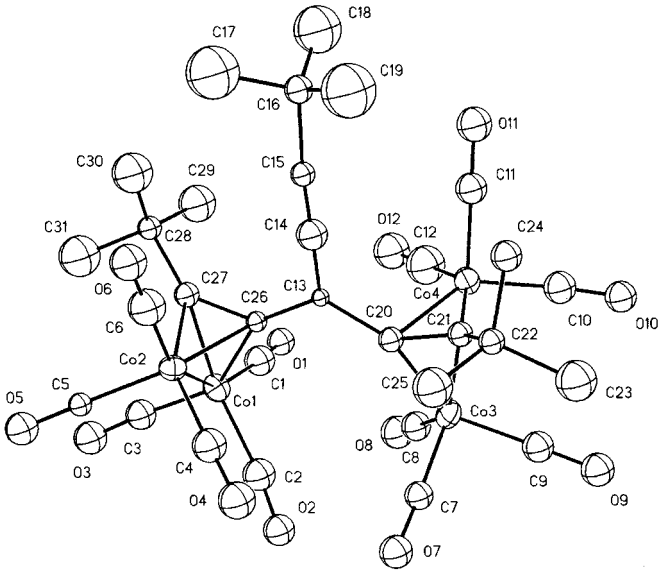

Figure 2. Molecular structure of **4** (30% probability ellipsoids; anisotropic refinement for Co atoms only).Selected interatomic distances [Å] and angles [°]: C13–C20 1.45(2), C13–C26 1.51(2), C13–C14 1.34(2), C13–Co1 3.07(1), C13-Co2 2.81(1), C13-Co3 3.27(1), C13-Co4 2.89(1), C14-C13-C20 120.5(11), C14-C13-C26 118.6(11), C20-C13-C26 120.9(10), C27-C26-C13 135.5(12), C21-C20-C13 135.9(12), C28-C27-C26-C13 55(1), C22-C21-C20-C13 43(1); angle between the bonds C26–C27 and Co1–Co2 82.3(6), between C20–C21 and Co3–Co4 89.7(6), between Co1–Co2 and Co3–Co4 88.0(5).

ethereal solution at −20 °C.[20] Generation of the cation leads to a rehybridization of the central carbon atom (C13) into sp^2, which is substantiated by its nearly flat geometry (out-of-plane $<0.5°$) and nearly ideal trigonal planar arrangement (119–121°). Covalent bonds around the cationic center are shortened slightly because of an increased s-character in hybridized orbitals; remarkably, the C13–C14 bond to the uncoordinated triple bond is more sensitive to the formation of the cation (1.43 Å in **3** vs. 1.34 Å in **4**) than the bonds to the coordinated triple bonds (C13–C20 1.49 vs. 1.45 Å; C13–C26 1.53 vs. 1.51 Å). Unexpectedly, the geometry of coordinated triple bonds (C27-C26-C13, C21-C20-C13) proved indifferent towards charge/hybridization changes of the central carbon atom (**3**: 134–135°, **4**: 136°). One of the important structural characteristics of binuclear metal complexes is the range of possible orientations of the C≡C and metal–metal bonds

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0162 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 1/2

from perpendicular to each other to nearly parallel and σ-bonded.[3] In **3**, the corresponding angles are 89.2° and 90.1°. The development of positive charge at the central carbon atom makes the metal clusters nonequivalent (the angle between C26 – C27 and Co1 – Co2 is 82.3°, that between C20 – C21 and Co3 – Co4 is 89.7°) with one of them adopting a skew geometry, that is a twist from a perpendicular orientation by 7.7°. Among the configurational changes, attendant with generation of a cation in the α-position to the cobalt cluster, is a deviated linearity of the π-bonded ligand and a shift of the cationic center towards one of the vertices. The former is quantified by the magnitude of dihedral angles C28-C27-C26-C13 and C22-C21-C20-C13. In precursor **3** both values are small (4.8° and 4.4°, respectively), indicating a nearly undistorted linear arrangement. The build-up of positive charge at C13 results in preferential coordination of the cationic center with one of the metal atoms in each cluster, and consequently, a significant departure from linearity (55° and 43°, respectively). These findings are further confirmed by analysis of nonbonding distances between the cationic center C13 and all four cobalt atoms. In **3** the central carbon is equidistant from both metal atoms (differences in bond lengths are 0.04 Å for C13 – Co1 and C13 – Co2, and 0.01 Å for C13 – Co3 and C13 – Co4); in contrast, in **4** C13 is shifted 0.26 Å closer towards Co2 and, even more, 0.38 Å towards Co4; the shortest distances are 2.81 Å and 2.89 Å for C13 – Co2 and C13 – Co4, respectively.

Experimental Section

2: a) **1**: Synthesized according to protocol given in reference [17] in a yield of 54.6 %. R_f (TLC, petroleum ether/ether 10/1) = 0.40; m.p. 101 – 102 °C (sealed capillary) (in ref. [17] m.p. 102 – 103 °C); ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): δ = 1.24 (s, 27 H; *t*Bu), 2.64 (s, 1 H; OH).

b) Monocomplexation of **1**. A solution of $[Co_2(CO)_8]$ (376 mg, 1.1 mmol) in dry ether (15 mL) was added dropwise to a vigorously stirred solution of **1** (272 mg, 1 mmol) in dry ether (20 mL) at ambient temperature under an inert atmosphere. After the addition (55 min), the reaction mixture was stirred for 2 h (monitored by TLC). Ether was evaporated in vacuum, and the residue was chromatographed on silica gel to afford **2** (483 mg, 86.5 %) as dark red crystals. R_f (TLC, petroleum ether/ether 15/1) = 0.74; m.p. 110 – 122 °C (decomp; sealed capillary); ^{1}H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): δ = 1.21 (s, 18 H; 2*t*Bu), 1.41 (s, 9 H; *t*Bu), 2.70 (s, 1 H; OH); MS-FAB: *m*/*z* (%): 557 (16) [M^+ – H], 530 (100) [M^+ – CO], 390 (15) [M^+ – 6 CO]; C,H analysis ($C_{25}H_{28}O_7Co_2$, 558.4): calcd. C 53.78, H 5.05; found C 53.89, H 5.09.

3: Analogously, treatment of **2** (407 mg, 0.73 mmol) in dry ether (20 mL) with $[Co_2(CO)_8]$ (250 mg, 0.73 mmol) in dry ether (15 mL) afforded **3** (439 mg, 71.3 %) as dark red crystals. R_f (TLC, petroleum ether) = 0.23; m.p. 84 – 101 °C (decomp; sealed capillary); ^{1}H NMR (500 MHz, CD_2Cl_2, – 80 °C, TMS): δ = 1.09 (s, 9 H; *t*Bu), 1.40 (s, 18 H; 2*t*Bu), 3.11 (s, 1 H; OH); ^{13}C NMR (125 MHz, CD_2Cl_2, – 70 °C, TMS): δ = 27.32, 29.00, 32.41, 36.26, 71.50, 84.34, 92.68, 100.41, 115.04, 200.25; MS-FAB: *m*/*z* (%): 843 (6) [M^+ – H], 788 (6) [M^+ – 2 CO], 508 (14) [M^+ – 12 CO]; C,H analysis ($C_{31}H_{28}O_{13}Co_4$, 844.3): calcd. C 44.10, H 3.34; found C 43.98, H 3.41. Single crystals suitable for X-ray structure analysis (Figure 1) were obtained by methanol vapor diffusion into a solution of **3** in pentane.

4: $HBF_4 \cdot Et_2O$ (58 mg, 0.36 mmol) was added dropwise (15 min) to a solution of **3** (101 mg, 0.12 mmol) in dry ether (30 mL) at – 20 °C under an inert atmosphere. The reaction mixture was allowed to warm to room temperature and stirred for 1 h. The ethereal layer was removed with a syringe, and the precipitate was thoroughly washed with dry ether (4 × 20 mL). The resulting complex **4** (96 mg, 88.1 %) was obtained as a black solid. ^{1}H NMR (500 MHz, CD_2Cl_2, – 80 °C, TMS): δ = 1.22 (s, *t*Bu), 1.48 (s, 2 *t*Bu); ^{13}C NMR (125 MHz, CD_2Cl_2, – 70 °C, TMS): δ = 12.25; 14.90; 32.00 (br.), 65.74; 83.58, 194 – 200 (br.). Single crystals suitable for X-ray structure analysis (Figure 2) were obtained by slow addition of HBF_4 to an ethereal solution of **3** at – 20 °C.

Synthesis and Structure of the First Transuranium Crown Ether Inclusion Complex: $[NpO_2([18]Crown\text{-}6)]ClO_4$**

David L. Clark,* D. Webster Keogh, Phillip D. Palmer, Brian L. Scott, and C. Drew Tait

Crown ether ligands[1, 2] have been studied as potential actinide extractants for many years, and they have been shown to influence the partitioning of actinides in two-phase aqueous systems.[3–5] Although many examples of crown ether ligands that extract actinides in hydrocarbon/water systems are known,[6, 7] relatively few actinide crown ether complexes in which the actinide ion is coordinated by one or more donor atoms of the crown ether have been reported.[8] There are only two inclusion compounds of *trans*-dioxoactinide cations AnO_2^{n+} in which the actinide ion is completely encapsulated by a crown ether ligand and the counterions (perchlorate[9, 10] or triflate[11]) are uncoordinated in the crystal lattice: $[UO_2([18]crown\text{-}6)]^{2+}$ (**I**) and $[UO_2(dicyclohexano[18]\text{-}crown\text{-}6)]^{2+}$. It has been claimed that synthesis of inclusion complexes from uranyl ions UO_2^{2+} and crown ether ligands requires the use of weakly coordinating anions, nonaqueous conditions, and proper choice of cavity size.[8] Indeed, the majority of actinide crown ether complexes exhibit second-sphere hydrogen bonding between the oxygen atoms of the crown ether and water molecules coordinated to the actinide center.[12–19] Well-known examples include $[UO_2(H_2O)_5([18]crown\text{-}6)_2(H_2O)(CH_3CN)_2][ClO_4]_2$ (central unit: **II**)[15] and $[UO_2(H_2O)_5([18]crown\text{-}6)][CF_3SO_3]_2$.[17]

I **II**

Crown ether inclusion complexes of a transuranic ion in any oxidation state are unknown.

On attempting to employ this well-known ability of crown ether ligands to form second-sphere hydrogen-bonded complexes of *trans*-dioxometal ions (as in **II**), we were surprised to observe the complete encapsulation of the NpO_2^+ ion by the [18]crown-6 ligand. Addition of one equivalent of [18]crown-6 to a stirred solution of NpO_2^{2+} in 1 M HX ($X = ClO_4^-$, $CF_3SO_3^-$) resulted in reduction of Np^{VI} to Np^V and formation of large turquoise crystals of $[NpO_2([18]crown\text{-}6)][X]$ (**1**[X]) over 12–24 h. The presence of an absorption band at 980 nm ($\varepsilon = 395$ M^{-1} cm^{-1}), characteristic of the NpO_2^+ ion,[20] in the NIR spectra of the crystalline solids dissolved in 1 M $HClO_4$ confirms that reduction of Np^{VI} to Np^V has occurred. Even in the presence of O_3, the Np^{VI} was reduced to **1**[X] on addition of [18]crown-6. Finally, solutions of Np^V compounds in 1 M HX, which are present as hydrated NpO_2^+ ions, react smoothly with [18]crown-6 to give **1**[X] in almost quantitative yield.

A single-crystal X-ray diffraction study of **1**[ClO_4] revealed an NpO_2^+ ion completely encapsulated by a disordered [18]crown-6 ligand.[21] The Np center of the $[NpO_2([18]crown\text{-}6)]^+$ ion is coordinated by two *trans* oxo ligands and six approximately coplanar crown ether O atoms to give an approximate hexagonal bipyramidal coordination environment (Figure 1). In the crown ether ligand, all C-O-C-C units have an *anti* (a), and the O-C-C-O units a *gauche* conformation (g), and this results in a distorted $g^-g^+g^+g^-g^+g^+$ conformation,[22] similar to that reported for **I**.[11] The Np=O bond length of 1.800(5) Å is unusually short for an NpO_2^+ ion; 1.85 Å is usual.[23, 24] The average equatorial Np–O distance of 2.594(10) Å is unusually long for a neutral oxygen-donor ligand when compared with the U–OH_2 distance of 2.43 Å in $[UO_2(OH_2)_5]^{2+}$ complexes.[15, 17] Coordination of σ-donor ligands in the equatorial plane of an *trans*-dioxo actinide ion generally results in a slight lengthening of the An=O bond, accompanied by decreased intensity of the Raman-active ν_1 O=An=O stretching band.[25] However, in **1**[ClO_4] the Np=O bond is shorter, and presumably stronger, than in the uncomplexed cation. Similar structural changes are observed in the uranyl system, for which encapsulation by [18]crown-6 results in a significant shortening of the U=O bond from 1.758(2) to 1.64(4) Å.[15, 17]

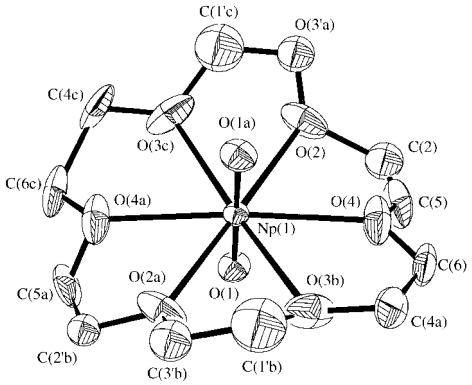

Figure 1. ORTEP plot of the molecular structure of **1** in crystals of **1**[ClO_4] (ellipsoids drawn at the 50 % probability level). Selected bond lengths [Å] and angles [°]: Np(1)–O(1) 1.800(5), Np(1)–O(2) 2.576(9), Np(1)–O(3) 2.604(10), Np(1)–O(4) 2.603(8); O(1)-Np(1)-O(2) 91.7(2), O(1)-Np(1)-O(4) 85.6(2), O(2)-Np(1)-O(4) 59.5(5), O(1)-Np(1)-O(3) 85.6(3).

For *trans*-dioxoactinide ions, the Raman-active ν_1 vibrational mode is a much better indicator of bond strength than bond length. For the $[NpO_2(H_2O)_5]^+$ ion[24] (Np=O 1.85 Å), the ν_1 vibrational mode occurs at 767 cm^{-1}.[26] Raman spectra of **1**[ClO_4] showed an intense band at 778 cm^{-1}, which is consistent with a stronger Np=O bond than in the aquo ion. To confirm this band assignment, ^{18}O was electrochemically incorporated into the Np=O unit [Eqs. (1)–(3); the asterisk

$$[NpO_2(OH_2)_n]^+ \xrightarrow[H_2^{*}O/HClO_4]{-0.2\,V\,(SCE)} [Np(^{*}OH_2)_n]^{3+}/[Np(^{*}OH_2)_n]^{4+} \quad (1)$$

$$[Np(^{*}OH_2)_n]^{3+}/[Np(^{*}OH_2)_n]^{4+} \xrightarrow[H_2^{*}O/HClO_4]{+1.22\,V\,(SCE)} [Np^{*}O_2(^{*}OH_2)_n]^{2+} \quad (2)$$

$$[Np^{*}O_2(^{*}OH_2)_n]^{2+} \xrightarrow[HClO_4]{[18]crown\text{-}6} [Np^{*}O_2([18]crown\text{-}6)][ClO_4] \quad (3)$$

indicates enrichment with ^{18}O]. Water enriched in ^{18}O (98 % ^{18}O) was added to 0.56 M NpO_2^+ (aq) in 1 M $HClO_4$ and reduced electrochemically at -0.2 V to a mixture of hydrated Np^{3+}/Np^{4+}[27] with removal of the oxo ligands. The potential was then reversed, and the mixture was oxidized to hydrated, ^{18}O-enriched $Np^{*}O_2^{2+}$ ions. The purity of the oxidized compounds was confirmed with NIR spectroscopy by monitoring the absorption band of hydrated NpO_2^{2+} at 1223 nm (ε = 45 $M^{-1}cm^{-1}$).[20] [18]Crown-6 was subsequently added, and turquoise crystals of ***1**[ClO_4] formed after cooling the mixture to 5 °C overnight. The Raman spectra of ***1**[ClO_4] crystals show ν_1 bands for all three isotopomers ^{18}O=Np=^{18}O, ^{18}O=Np=^{16}O, and ^{16}O=Np=^{16}O at 734, 751, and 780 cm^{-1}, respectively, confirming our original assignment.

The complete encapsulation of the NpO_2^+ ion by a crown ether ligand under any conditions is unprecedented, and **1**[ClO_4] represents the first structurally and spectroscopically characterized transuranium crown ether complex. The relative ease of encapsulation in aqueous solution contrasts with the related UO_2^{2+} ion, for which anhydrous conditions are necessary to ensure that the crown ether oxygen atoms bind directly to the metal center.[8] This difference attests to the ability of crown ether ligands to separate ions of almost identical chemical behavior, and the apparent preference for Np^V over Np^{VI} may be related to the differing ionic radii of these ions.[1] Although the mechanism is unknown, dicyclohexano-[18]crown-6 has been shown to separate Pu^{IV} from U^{VI} and fission products more effectively than tributyl phosphate,[3] the extractant used in the well-known Purex process.[20] The potential ability of crown ether ligands to extract actinide ions selectively from radioactive process streams or solutions of nuclear waste is particularly interesting due to its economic and environmental implications. The actinophilic nature of crown ether ligands towards other transuranic ions is under further investigation.

[21] X-ray structure analysis of **1**[ClO_4]: Siemens P4/PC diffractometer, $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), graphite monochromator, ω scan method, structure solved by Patterson und difference Fourier methods with the program SHELXS-86, space group $I4_1/a$, a = 10.686(1), b = 10.686(1), c = 16.771(1) Å, V = 1915.1(1) Å^3, ρ_{calcd} = 2.195 g cm^{-3}, Z = 4, T = 295 K. Least-squares refinement of the model based on 1383 independent reflections converged to $R1$ = 0.0261 and $wR2$ = 0.0682 with GOF = 1.111. The two crown ligands were offset by 30° to satisfy the $\bar{4}$ site symmetry, and each was refined with half occupancy. The carbon and oxygen atoms of the two disordered crown ligands were refined in a general position with site-occupancy factors of 0.5. All carbon and oxygen atomic coordinates were refined freely. Partially overlapping carbon atoms from different crown ligands were restrained to have the same U_{ij} values with a standard deviation of 0.05 Å^2 by using the SIMU command of SHELX-93. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100439. Copies of the data can be obtained free of charge on application to CCDC,

5,5′-Bicalix[4]arene: The Bridgeless Prototype of Double Calix[4]arenes of the "Head-to-Head" Type**

Placido Neri,* Alessandra Bottino, Francesca Cunsolo, Mario Piattelli, and Enrico Gavuzzo

In the past decade several double (or multiple) calixarenes[1] have been prepared as examples of higher order molecular architectures with new high-level host properties, such as allostery and cooperativity.[2] In these compounds, two (or more) calixarene units are linked at their upper or lower rims[3, 4] through one or more spacer elements. Various structural motifs have been used as spacers, including alkyl, alkenyl, and alkynyl chains, diesters, diamides, metallocenes, ethers and polyethers, sulfides, and diimines.[1, 2, 5] However, to the best of our knowledge, examples of the prototypal compounds with directly coupled (bridgeless) calixarene units have not been reported so far.[6] Here we describe the synthesis, X-ray crystal structure, and derivatization of the first double calixarene of the "head-to-head" type[7] with direct *para-para* linkage, 5,5′-bicalix[4]arene **2**.[8]

Linkage of the two calix[4]arene units was accomplished by oxidative coupling of the *p*-H-calix[4]arene **1**[9a] under conditions similar to those of Pummerer's classic binaphthol synthesis[10] (Scheme 1). A solution of **1** in hot CH_3CN was treated with solid $FeCl_3 \cdot 6H_2O$, and the suspension was heated at reflux for 4 h. Workup of the reaction mixture and column chromatography of the crude product afforded

Scheme 1. Synthesis of 5,5′-bicalix[4]arene **2** by oxidative coupling of *p*-H-calix[4]arene **1**.

bicalix[4]arene **2** (10%) and calix[4]monoquinone **3** (6%). The dimeric nature of **2** was indicated by a quasi-molecular ion at $m/z = 847$ in the positive-ion fast-atom-bombardment (FAB) mass spectrum. Correspondingly, the ^{13}C NMR spectrum contains two $ArCH_2Ar$ signals, six aromatic CH resonances, three C–OH singlets, and a diagnostic singlet at $\delta = 135.3$ attributable to quaternary carbon atoms involved in bonding of the two halves in **2**.

Both calixarene moieties are in the *cone* conformation because of the stabilizing cyclic hydrogen bond, as revealed by two broad AX systems for $ArCH_2Ar$ protons in the ^1H NMR spectrum.[1] These systems sharpen at low temperature, and a Gibbs free energy of activation $\Delta G^{\neq} = 14$ kcal mol^{-1} was estimated from the coalescence temperature for the *cone*–*cone* conformational interconversion, a value very similar to that reported for the parent monomer **1**.[9b] With respect to the biphenyl moiety, one can presume relatively free rotation around the Ar–Ar bond, with a slight deviation from coplanarity for the two aryl rings. This leads to a *syn* or *anti* orientation of the calix[4]arene units (Figure 1). Energy evaluations (MM2 and MM3) of the two geometries gave very similar values; the *anti* orientation is slightly lower in energy. Therefore, the *syn* and *anti* forms of bicalix[4]arene **2** are expected to be in equilibrium in solution (Figure 1).

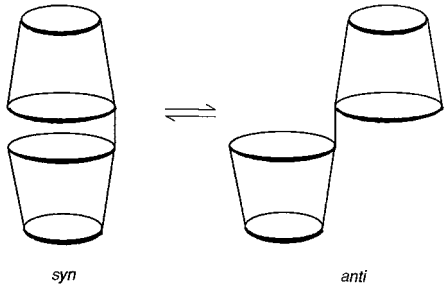

Figure 1. Schematic representation of the proposed equilibrium between the *syn* and *anti* conformations of 5,5′-bicalix[4]arene **2** in solution.

Definitive proof of the structure of **2** was obtained through single-crystal X-ray structure analysis.[11] In the crystal the molecule resembles two bowls joined together by the Ar–Ar bond (1.50(1) Å; Figure 2), with the two concavities on

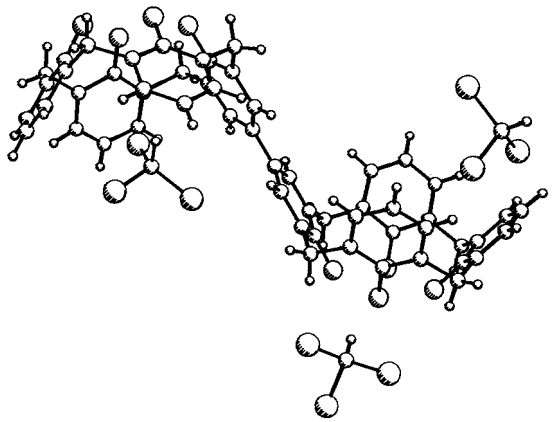

Figure 2. Crystal structure of **2** · 3 $CHCl_3$ (H, C, O, and Cl atoms are drawn as spheres of increasing size).

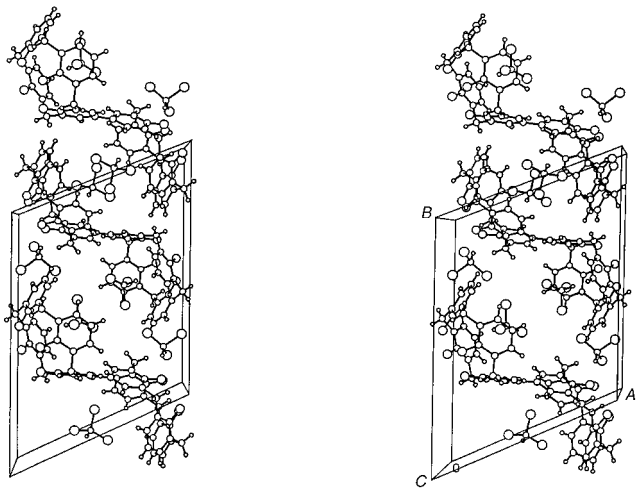
opposite sides. The bottom of each bowl is formed by four hydroxy groups. In each bowl an approximate square network of intramolecular hydrogen bonds is created by the four hydroxy groups, each acting once as donor and once as acceptor in two hydrogen bonds. The average length of the eight hydrogen bonds is 2.68 Å [minimum 2.66(1) Å, maximum 2.69(1) Å]. The angles C–O ··· O are all approximately 110°, and the hydroxy hydrogens and one of the two lone pairs from an oxygen atom presumably lie close to the plane formed by the four oxygens of each moiety. The angles O ··· O ··· O are all around 90°. The torsion angle between the Ar moieties is 35(2)°, a typical value for biphenyl systems in which there is very little conjugation between the two aromatic rings.[14] The canting angles between the mean plane of the four methylene carbons and the planes of the phenol rings vary from 51.6° to 61.4° in the two halves. The packing of the host molecules is governed mainly by van der Waals interactions, where the shortest contact is 2.96(1) Å between the O(1) atoms of two centrosymmetric molecules. The crystal contains chloroform, but only three chloroform molecules were identified because of disorder present in the solvent system. Two are included in the pseudocapsules formed by the two opposing bowls of facing centrosymmetric molecules (Figure 3), as a consequence of van der Waals interactions. The third chloroform molecule is outside the capsules, where its acidic hydrogen atom may form a possible hydrogen bond with an OH group (O ··· C = 3.30 Å, O ··· H–C = 166.3°).

Each phenol ring of bicalix[4]arene **2** can rotate freely through the 16-membered annulus, leading, in principle, to 21 extreme conformations (apart from enantiomers and *syn*/*anti* alternatives). Blocking this motion by alkylation with groups bulkier than ethyl[15] would then lead to as many atropisomers. Although this appears to be a considerable complication, it at the same time makes **2** a very appealing substrate, provided that conditions can be found for satisfactory stereochemical control of alkylation. To test this potentiality, **2** was treated



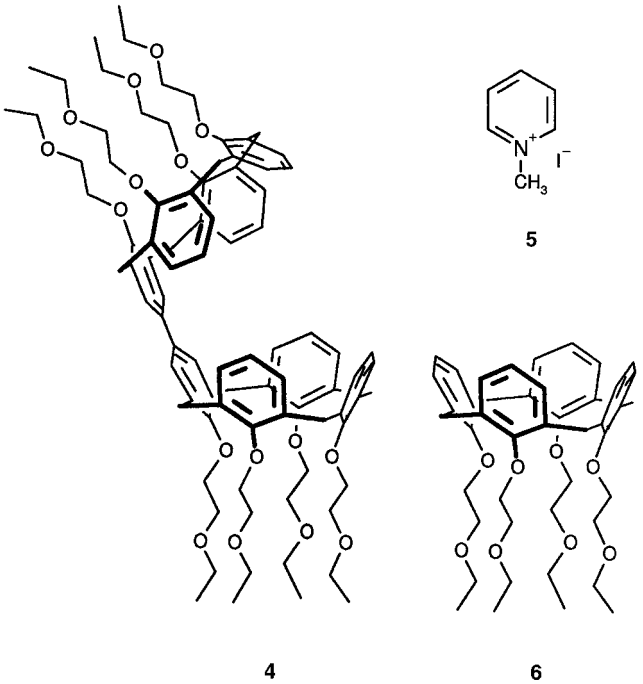


Figure 3. Crystal packing of **2** viewed along the *c* axis.

with 2-(ethoxy)ethyl bromide under conditions (NaH/DMF) known to favor alkylation products in the *cone* conformation.[16] Thus, the octakis[2-(ethoxy)ethoxy] derivative **4** fixed in a double-*cone* conformation was obtained in good yield (55 %) and high stereoselectivity. Further investigation in this direction might similarly lead to the selective preparation of other atropisomers.

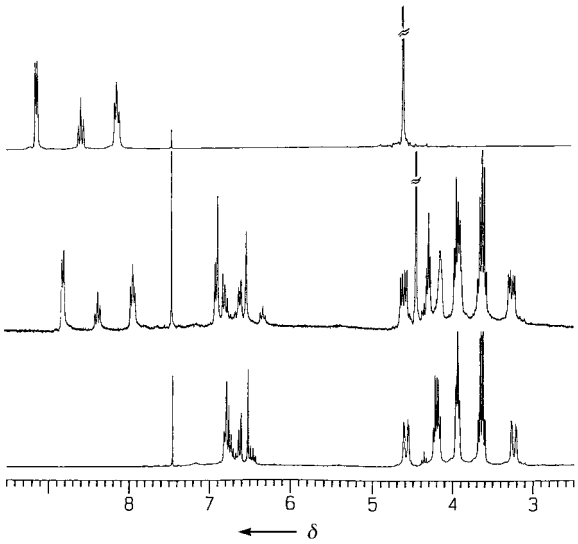
The globular architecture of the *syn* conformation of **2** suggests the potential for cooperation between the two *cone* binding sites in the *endo*-calix complexation of suitable guests. A conformationally blocked double *cone* system like **4** of

5

4 **6**

course appears preferable to this end; indeed, preliminary ^1H NMR experiments (Figure 4) revealed the ability of **4** to include the *N*-methylpyridinium cation **5** (iodide counterion). A value of 153 M^{-1} was estimated for the association constant based on NMR titration,[17a] compared with 6 M^{-1} found for

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0167 $ 17.50+.50/0



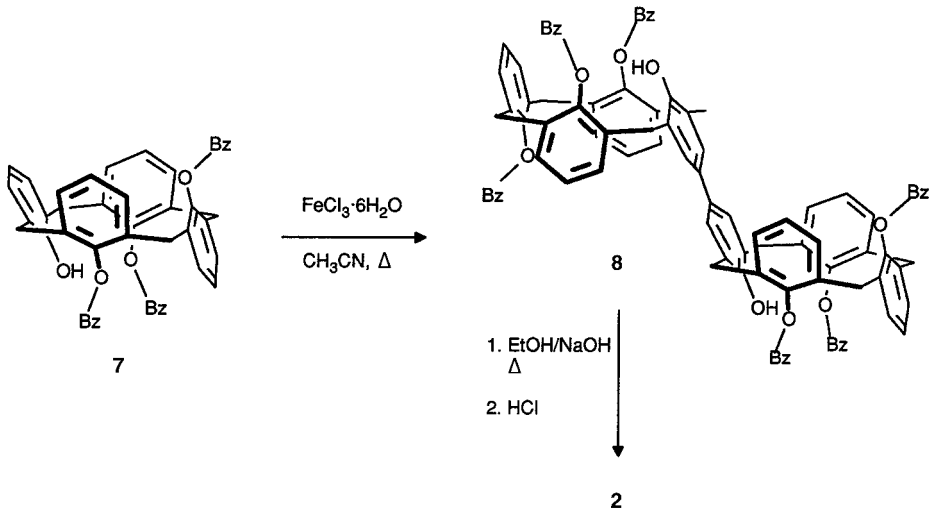


Figure 4. ^{1}H NMR spectra (250 MHz, 295 K, $CDCl_3/CD_3CN$ 5/1) of **4** (bottom), *N*-methylpyridinium iodide **5** (top), and a mixture of the two (middle).

the reference compound tetrakis[2-(ethoxy)-ethoxy]calix[4]-arene **6**.[16] This indicates the cooperative action of the two halves in cation inclusion.[17b]

The peculiar structural features of **2** and its high stereochemical potential make it an interesting new building block in host–guest and supramolecular chemistry. For this reason, the availability of larger amounts became imperative, which in turn required improvements in the synthesis. Because the main drawback to direct coupling of **1** seems to be competitive polymerization and/or polyoxidation, we were induced to try an indirect pathway for synthesizing **2** using as starting material a calix[4]arene with a single free phenolic OH group. Therefore, we subjected the readily available tribenzoate **7**, described by Gutsche et al.,[9a, 18] to oxidative coupling with $FeCl_3 \cdot 6H_2O$ (Scheme 2). This led to the dimeric hexabenzoate **8**, which upon alkaline hydrolysis gave 5,5′-bicalixarene **2** in 55–60% overall yield. With this latter procedure the way has become open for a full investigation into the potentialities of bicalixarene building blocks in supramolecular chemistry. An extension of this approach, using different coupling conditions,[20] may result in *para-para*-oligo-calixarenes with novel and interesting architectures. We are currently carrying out work in these directions.

Scheme 2. Improved synthesis of **2** through oxidative coupling of two molecules of **7**.

Experimental Section

2: A suspension of **7** (1.5 g, 2.04 mmol) and $FeCl_3 \cdot 6H_2O$ (1.10 g, 4.07 mmol) in CH_3CN (30 mL) was heated at reflux with stirring. After 1.5 h additional $FeCl_3 \cdot 6H_2O$ (1.10 g, 4.07 mmol) was added. The process was repeated several times until the starting material was completely consumed (based on TLC). The solvent was removed by evaporation in vacuo, 3 N HCl added to the residue, and the solid collected by filtration. This crude product was suspended in EtOH (85 mL), and after addition of 15% NaOH (13 mL) the mixture was heated at reflux with stirring for 7 h. Most of the EtOH was subsequently removed by evaporation in vacuo. The resulting suspension was neutralized with 1N HCl, and solid material collected by filtration. This was dissolved in CH_2Cl_2 and again filtered to remove small amounts of insoluble matter. Flash chromatography on silica gel (CH_2Cl_2/petroleum ether, 1/1) led to **2** (0.47 g, 55%). M.p. $>360\,^\circ$C; ^{1}H NMR (250.13 MHz, C_6D_6, 350 K) $\delta = 3.71, 3.76$ ($2 \times$ s, 8H each, $ArCH_2Ar$), 6.43 (t, $J = 7.8$ Hz, 2H, ArH), 6.47 (t, $J = 7.5$ Hz, 4H, ArH), 6.69–6.80 (m, 12H, ArH), 6.87 (s, 4H, Ar–ArH), 10.01 (br s, 8H, OH); ^{1}H NMR (250.13 MHz, C_6D_6, 295 K; partial spectrum): $\delta = 3.26$, 4.22 ($2 \times$ br, AX, each 8H, $ArCH_2Ar$); ^{1}H NMR (250.13 MHz, $CDCl_3$, 250 K; partial spectrum): $\delta = 3.55/4.26$ (AX, $J = 13.7$ Hz, 8H, $ArCH_2Ar$), 3.57/4.26 (AX, $J = 13.7$ Hz, 8H, $ArCH_2Ar$); ^{13}C NMR (62.9 MHz, $CDCl_3$, 295 K) $\delta = 31.7$, 31.8 (t, $ArCH_2Ar$), 122.2, 122.3, 127.8 (d, $C_{Ar}H$), 128.0, 128.1, 128.2 (s, $C_{Ar}CH_2$), 128.9($2 \times$ C), 129.1 (d, $C_{Ar}H$), 135.3 (s, C_{Ar}–C_{Ar}), 148.0, 148.7, 148.8 (s, $C_{Ar}OH$); positive-ion FAB-MS [*m*-nitrobenzylalcohol (NBA) matrix]: $m/z = 847$ [M^++H].

4: ^{1}H NMR (250.13 MHz, C_6D_6, 295 K) $\delta = 1.17$ (t, $J = 5.7$ Hz, 12H, CH_3), 1.18 (t, $J = 6.2$ Hz, 12H, CH_3), 3.18/4.71 (AX, $J = 13.3$ Hz, 8H, $ArCH_2Ar$), 3.25/4.75 (AX, $J = 13.5$ Hz, 8H, $ArCH_2Ar$), 3.37–3.49 (m, 16H, OCH_2), 3.79 (t, $J = 5.5$ Hz, 8H, CH_2CH_2), 3.88 (q, $J = 5.7$ Hz, 8H, CH_2CH_3), 4.15 (t, $J = 5.5$ Hz, 8H, $ArOCH_2$), 4.27 (t, $J = 5.6$ Hz, 4H, $ArOCH_2$), 4.28 (t, $J = 5.8$ Hz, 4H, $ArOCH_2$), 6.63–6.84 (m, 18H, ArH), 7.08 (s, 4H, Ar–ArH); ^{13}C NMR (62.9 MHz, $CDCl_3$, 295 K) $\delta = 15.3$ (q, OCH_2CH_3), 30.8, 31.0 (t, $ArCH_2Ar$), 66.4, 69.7, 73.0, 73.2 (t, OCH_2), 122.3, 126.7, 128.1 (d, $C_{Ar}H$), 134.8 (s, $C_{Ar}CH_2$), 135.1 (s, C_{Ar}–C_{Ar}), 155.5, 156.2, 156.4 (s, C_{Ar}–O); positive-ion FAB-MS (NBA): $m/z = 1425$ [M^++H].

[11] Crystal structure analysis of **2**: $C_{56}H_{46}O_8 \cdot 3\,CHCl_3$, $M_r = 1205.11$, triclinic, space group $P\bar{1}$ (no. 2), $a = 15.389(3)$, $b = 19.630(4)$, $c = 10.790(2)$ Å, $\alpha = 90.45(2)$, $\beta = 108.78(1)$, $\gamma = 67.71(1)^\circ$, $V = 2831(1)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.41$ g cm^{-3}, colorless crystals from $CHCl_3$/EtOH, crystal dimensions $0.25 \times 0.30 \times 0.45$ mm^3, θ-2θ scan ($2\theta_{max} = 124.2^\circ$), $F(000) = 1240$, room temperature. Of 9285 measured reflections, 8908 were independent ($R_{int} = 0.068$). Data were collected with a Rigaku AFC5R diffractometer with graphite-monochromated $Cu_{K\alpha}$ radiation and a 12 kW rotating anode generator. The data were corrected for Lorentzian and polarization effects, and an empirical absorption correction was applied to intensities based on azimuthal scans of several reflections; $\mu(Cu_{K\alpha}) = 45.27$ cm^{-1}, no decay correction. The structure was solved by direct methods with the program SIR 92.[12] Non-hydrogen atoms were refined anisotropically[13] except for one solvent molecule refined isotropically because of disorder. All hydrogen atoms (apart from OH) were positioned geometrically (riding model). Final refinements were carried out according to the full-matrix least-squares method based on 4189 observed reflections with $F_o > 10\,\sigma(F_o)$ and 665 variable parameters. $R = 0.117$, $R_w = 0.121$, $w = (\sin\theta/\lambda)^2$, $S = 1.38$. Maximum and minimum peaks of the final difference Fourier map: 2.20 and -1.03 e Å^{-3}; these residual electron densities could not be assigned to any chemically sensible moiety. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100536. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code + (44) 1223-336033; e-mail: deposit@chemcrys.cam.ac.uk).

Lanthanide-Assisted Self-Assembly of an Inert, Metal-Containing Nonadentate Tripodal Receptor**

Stéphane Rigault, Claude Piguet,*
Gérald Bernardinelli, and Gérard Hopfgartner

Recent fascinating applications of lanthanide, Ln^{III}, complexes as contrast agents for medical resonance imagining (MRI), luminescent stains for fluoroimmunoassays, and catalysts for the selective cleavage of RNA and DNA require close and tunable control of the coordination sphere to enhance specific structural and electronic properties.[1] The development of tailored receptors for Ln^{III} remains a challenge for synthetic chemists, since Ln^{III} ions do not display pronounced stereochemical preferences for particular bonding modes.[2] Highly preorganized macrobicyclic cryptands allow only partial control of the coordination of Ln^{III} ions,[3] and their tedious preparation has encouraged the development of Ln^{III}-assisted template syntheses of macrocyclic Shiff base complexes.[4] However, the nondirectional Ln–ligand bonds and the high sensitivity of Ln^{III} to basic conditions severely limit their use as template ions in the preparation of macrobicycles[5] and self-assembled metal-containing supramolecular compounds.[6]

A recent approach uses the segmental ligands L^1 and L^2, which are predisposed for the selective recognition of f-block metal ions. The self-assembled homotopic triple-stranded helicates $[Ln_2(L^1)_3]^{6+}$ result from the reaction of L^1 with $Ln(ClO_4)_3$,[7] while equimolar mixtures of $Ln(ClO_4)_3$ and $M(ClO_4)_2$ (M = Zn, Fe) produce head-to-head heterotopic

L^1

L^2

(HHH)-$[LnM(L^2)_3]^{5+}$

triple-stranded helicates (HHH)-$[LnM(L^2)_3]^{5+}$ (HHH = head-to-head helicate),[6] which are referred to as noncovalent lanthanide podates.[8] In the latter complexes, the facial pseudo-octahedral d-block and the pseudo-tricapped trigonal prismatic 4f-block ions display synergic structural and electronic effects that allow the design of supramolecular "devices" with predictable and tunable properties (luminescence, magnetism).[8] Here we report the selective formation of an inert, nine-coordinate metal-containing tripodal receptor by means of a related self-assembly process with Ln^{III} ions as template and subsequent modification[9] of the resulting helicate.

Cobalt is ideally suited to the preparation of inert d-block tripods since the pseudo-octahedral high spin d^7 Co^{II} ion coordinated to α,α'-diimine donors is expected to be labile. This allows the strict self-assembly of the supramolecular complex $[LnCo(L^2)_3]^{5+}$; its subsequent oxidation gives the inert low-spin d^6 Co^{III} complex with the cobalt ion in a similar pseudo-octahedral environment.[10] Electrospray (ES) MS titrations of L^2 with an equimolar mixture of $Ln(ClO_4)_3 \cdot n H_2O$ and $Co(ClO_4)_2 \cdot 6H_2O$ in acetonitrile show formation of the expected complexes $[LnCo(L^2)_3]^{5+}$ (Ln = La, Eu, Lu) together with traces of $[Co(L^2)_2]^{2+}$, as previously observed for $[LnM(L^2)_3]^{5+}$ (M = Zn, Fe).[8] Spectrophotometric titrations under the same conditions can be satisfactorily fitted to the equilibria of Equations (1) and (2) to give the stability constants $\lg(\beta_{113}^{LnCo}) = 21.7(6)$ (Ln = La), 23.2(9) (Ln = Eu), and 23.9(6) (Ln = Lu), which resemble those found for $[LnFe(L^2)_3]^{5+}$ ($\lg(\beta_{113}^{LnFe}) = 23.0(8)$, 24.6(9), and 23.6(7) for Ln = La, Eu, Lu, respectively).[8]

$$Co^{2+} + 2L^2 \rightleftharpoons [Co(L^2)_2]^{2+} \qquad \lg(\beta_{12}^{Co}) = 14.4(6) \qquad (1)$$

$$Ln^{3+} + Co^{2+} + 3L^2 \rightleftharpoons [LnCo(L^2)_3]^{5+} \qquad \lg(\beta_{113}^{LnCo}) \qquad (2)$$

At a complex concentration of 5 mM, $[LnCo(L^2)_3]^{5+}$ (Ln = La, Eu, Lu) is the only species present in acetonitrile, and the ^1H NMR spectrum displays 22 signals typical of a C_3-symmetrical head-to-head arrangement of the three strands. These are spread over a region of 100 ppm as a result of the paramagnetic Co^{II} center ($\mu_{eff} = 4.99(3)$ and 4.93(4) BM for $[LaCo(L^2)_3]^{5+}$ and $[LuCo(L^2)_3]^{5+}$, respectively, in CD_3CN at 298 K; Figure 1a).[11] Intra- and interstrand nuclear Overhauser effects (NOEs) clearly establish that (HHH)-$[LnCo(L^2)_3]^{5+}$ adopts the expected triple-helix structure[8] in which Co^{II} occupies the facial pseudo-octahedral site produced by the three wrapped bidentate binding units, and Ln^{III} the remaining nine-coordinate site. It is noteworthy that the reaction of L^2 (3 equiv) with $Co(ClO_4)_2 \cdot 6H_2O$ (1 equiv) in the absence of Ln^{III} provides mainly the 1:3 complex $[Co(L^2)_3]^{3+}$, in which the Co^{II} ion is coordinated by the three bidentate binding sites of the ligands. However, the latter complex exists in solution as a 4:1 mixture of the C_1-symmetrical *mer* and C_3-symmetrical *fac* isomers according to the integration of the ^1H NMR signals (expected statistical ratio 3:1).

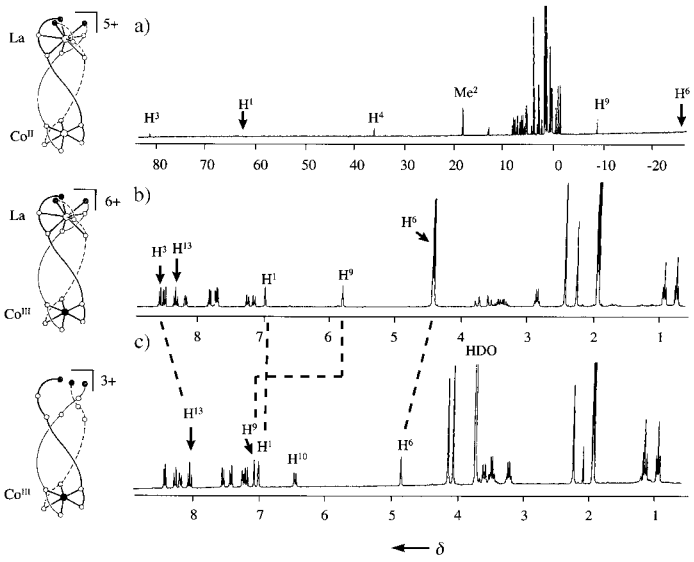

Figure 1. ^1H NMR spectra (CD_3CN) of a) (HHH)-$[LaCo(L^2)_3]^{5+}$, b) (HHH)-$[LaCo(L^2)_3]^{6+}$, and c) *fac*-$[Co(L^2)_3]^{3+}$ (12 M D_2O).

Cyclic voltammograms of (HHH)-$[LnCo(L^2)_3]^{5+}$ (Ln = La, Eu, Lu) show a quasi-reversible Co^{II}/Co^{III} oxidation wave at 0.42 V vs. SCE in acetonitrile/0.1 M NBu_4PF_6 in agreement with analogous Co^{II} complexes.[11] Oxidation with bromine in acetonitrile gives quantitatively the poorly soluble complexes (HHH)-$[LnCo(L^2)_3]^{6+}$ (Ln = La, Lu), whose ^1H NMR spectra exhibit 22 signals in the range $\delta = 0-10$, which is characteristic of diamagnetic Co^{III}. ES mass spectra confirm the exclusive formation of $[LnCo(L^2)_3]^{6+}$ (Ln = La, Eu, Lu) in solution, while specific NOEs (intrastrand: Me^2-H^3, Me^3-H^{12}, $H^{14}-H^{17,18}$; interstrand: Me^2-H^{10}, Me^3-H^5) imply that the head-to-head triple-helix structure is retained for (HHH)-$[LnCo^{III}(L^2)_3]^{6+}$. Precipitation with diethyl ether afforded the microcrystalline complex $[LaCo(L^2)_3](ClO_4)_5Br \cdot (H_2O)$. Recrystallization by slow diffusion of diisopropyl ether into a concentrated solution of the complex in acetonitrile/water (25/1) gave extremely fragile X-ray quality crystals of **1**.

$[LaCo(L^2)_3](ClO_4)_{5.5}(OH)_{0.5} \cdot 4CH_3CN \cdot 2H_2O$ **1**

The crystal structure determination of **1** confirms the presence of a head-to-head triple-helical cation (HHH)-$[LaCo(L^2)_3]^{6+}$ of approximate C_3 symmetry, together with disordered anions and solvent molecules (see Experimental Section). Figure 2 shows an ORTEP[12] stereoview of the cation perpendicular to the helical axis, and Table 1 lists the

N(bzim)-La-N(py)[b]	60.3(12)	58.8(7)	61.9(6)
N(py)-La-O(amide)[b]	62.1(12)	61.2(6)	63.7(6)

[a] Averaged for C_3 symmetry. [b] Chelate bite angles.

structural parameters obtained by averaging the distances and angles according to C_3 symmetry. The geometry around the Co^{III} center is best described as a slightly distorted octahedron flattened along the pseudo-C_3 axis as a result of chelate bite angles smaller than 90° (Table 1). The average Co – N(py) distance is slightly larger than the Co – N(bzim) distances, but both are in good agreement with the reported standard values of 2.034 and 1.946 Å, respectively.[12] Comparison with the Co – N(py) (1.96(3) Å) and Co – N(bzim) (1.92(3) Å) distances in an analogous homotopic triple-stranded helicate[13] suggests that the Co – N bonds in **1** are slightly stretched. This is also evident in the similar Fe – N(py) (2.00(3) Å) and Fe – N(bzim) (1.95(2) Å) distances in (HHH)-$[LnFe(L^2)_3]^{5+}$ [8] in spite of the about 12% larger ionic radius expected for low-spin d^6 Fe^{II}.[14] We attribute this distortion to steric constraints induced by the occupied pseudo-tricapped trigonal prismatic site. The La – Co distance is 8.865(4) Å, and detailed structural analysis of the complex indicates that (HHH)-$[LaCo(L^2)_3]^{6+}$ is structurally similar to (HHH)-$[LaFe(L^2)_3]^{5+}$, in which Fe^{II} also has the stereochemically demanding low-spin d^6 configuration.[15]

The addition of D_2O to a 5 mM solution of (HHH)-$[LnCo(L^2)_3]^{6+}$ (Ln = La, Lu) in CD_3CN (total D_2O concentration 10 M) results in decomplexation of Ln^{III}, which can be monitored by ESMS and ^1H NMR spectroscopy. The ESMS titration shows the exclusive formation of $[Co(L^2)_3]^{3+}$ (m/z 563.4), and the ^1H NMR spectrum still shows 22 signals corresponding to the quantitative formation of the C_3-symmetrical complex *fac*-$[Co(L^2)_3]^{3+}$. The ^1H NMR signals of the bidentate binding units are not significantly shifted (except for that of H^6, which is located between the Co^{III} and Ln^{III} centers in (HHH)-$[LnCo^{III}(L^2)_3]^{6+}$), whereas the signals of the tridentate units are strongly shifted—the signal for H^9 is shifted downfield by $\Delta\delta = 1.3$ owing to unfolding of the strands.[16] The signals for $H^{12} - H^{14}$ are shifted to high field by $\Delta\delta \approx 0.3$, since the associated pyridine ring is no longer coordinated to a metal ion.[8] Finally, the disappearance of the intrastrand NOEs $Me^3 - H^{12}$ and $H^{14} - H^{17,18}$ implies a *trans,trans* arrangement of the tridentate units, which is only compatible with the release of the Ln^{III} ion from the coordination site. This assumption is further supported by the use of Eu^{III} as a paramagnetic NMR probe in (HHH)-$[EuCo(L^2)_3]^{6+}$. Reaction of (HHH)-$[EuCo(L^2)_3]^{6+}$ with 12 M D_2O severely affects the signals of the protons and quantitatively produces the diamagnetic spectrum of *fac*-$[Co(L^2)_3]^{3+}$.

Treatment of (HHH)-$[LaCo^{III}(L^2)_3]^{6+}$ with a stoichiometric quantity of $(NBu)_4EDTA \cdot 6H_2O$ in acetonitrile/water (25/1) leads to formation of the insoluble salt $NBu_4[La(EDTA)]$, which can be separated by filtration. The desired inert, metal-containing tripodal receptor *fac*-$[Co(L^2)_3](ClO_4)_3(C_4H_{10}O)_{0.4} \cdot 6H_2O$ is obtained by fractional crystallization from diethyl ether as a red powder whose ^1H NMR spectrum is identical to that of the complex prepared in situ. This complex is a novel tailored helical nine-coordinate receptor which is currently being investigated in our laboratory for the selective complexation of Ln^{III}. This self-assembly with post-processing and release of the template Ln^{III} ion leads to the almost quantitative isolation of pure *fac*-$[Co(L^2)_3]^{3+}$, while direct bromine oxidation of the *mer*/*fac* mixture of $[Co(L^2)_3]^{2+}$ also gives a mixture containing only 20% of the desired *fac*-$[Co(L^2)_3]^{3+}$ and 80% of the *mer* isomer.

Experimental Section

Elemental analysis: calcd for $CoC_{100.6}H_{115}N_{21}O_18.4Cl_3$: C 56.84, H 5.45, N 13.84; found C 56.92, H 5.30, N 13.86. ^1H NMR (300 MHz, CD_3CN, TMS, 298 K): $\delta = 1.00$ (t, J = 7 Hz, 9H), 1.20 (t, J = 7 Hz, 9H), 2.35 (s, 9H), 3.28 (q, J = 7 Hz, 6H), 3.50 (q, J = 7 Hz, 6H), 3.55 (d, J = 16 Hz, 3H), 3.60 (d, J = 16 Hz, 3H), 4.13 (s, 9H), 4.15 (s, 9H), 4.98 (s, 3H), 6.59 (d, J = 8 Hz, 3H), 6.93 (s, 3H), 7.23 (d, J = 8 Hz, 3H), 7.30 (s, 3H), 7.32 (d, J = 8 Hz, 3H), 7.48 (d, J = 8 Hz, 3H), 7.52 (d, J = 8 Hz, 3H), 8.02 (t, J = 8 Hz, 3H), 8.17 (d, J = 8 Hz, 3H), 8.41 (d, J = 8 Hz, 3H), 8.44(d, J = 8 Hz, 3H). ESMS (10^{-4} M, CH_3CN): $m/z = 563.4$ $[Co(L^2)_3]^{3+}$ (95%), 894.2 $[Co(L^2)_3(ClO_4)]^{2+}$ (15%).

Crystal structure determination of **1**: A fragile red-orange crystal (0.18 × 0.30 × 0.32 mm) was mounted from the mother liquor on a quartz fiber with perfluoropolyether oil RS3000. $M_r = 2584.6$, monoclinic, $C2/c$, $a = 53.638(7)$, $b = 23.068(5)$, $c = 21.885(7)$ Å, $\beta = 92.78(1)°$, $V = 27047(11)$ Å^3 (by least-squares refinement of 20 reflections in the range $35 \le 2\theta \le 44°$), $Z = 8$, $\rho_{calcd} = 1.27$ g cm^{-3}, $F(000) = 10640$, $\mu(Cu_{K\alpha}) = 4.986$ mm^{-1}. *Data collection and processing:* Stoe STADI4 diffractometer, $T = 200$ K, $\omega - 2\theta$ scan, scan width 1.05+0.35 tanθ, scan speed 0.13° s^{-1}, $Cu_{K\alpha}$ radiation ($\lambda = 1.5418$ Å); 15658 measured reflections ($3 \le 2\theta \le 104°$, $-53 < h < 53$, $0 < k < 23$,

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0171 $ 17.50+.50/0

$0 < l < 22$), 15138 unique reflections ($R_{int} = 0.095$ for equivalent reflections) of which 8318 were observed [$|F_o| > 4\sigma(F_o)$]. Two reference reflections were measured every 45 min and showed a total decrease in intensity of 15.3%. All intensities were corrected for this drift. Data were corrected for Lorentzian, polarization, and absorption effects[17] ($A^*_{min} = 2.916$, $A^*_{max} = 5.163$). The structure was solved by direct methods with the program MULTAN 87;[18] all other calculations were performed with the XTAL[19] system and ORTEP II[12] programs. Full-matrix least-squares refinements on F with weights of $w = 1/(\sigma 2(\mathrm{Fo}) + 0.0005 F_o^2)$ gave final values $R = 0.125$ and $Rw = 0.128$ for 1460 variables and 8318 reflections. The five perchlorate ions and the four acetonitrile molecules were refined with 64 restraints on bond distances and angles. The remaining "half" perchlorate i was located in special position 4*c* and was fully disordered. Five atomic sites (of which two were in special position 4*e*) were observed for the water molecules and the half hydroxide anion. Two oxygen atoms of the perchlorate i, the carbon and nitrogen atoms of two acetonitrile molecules, and the five oxygen atoms of the water molecules were refined with isotropic displacement parameters (13 atoms), and all the other atoms (157) with anisotropic displacements parameters. The mean ratio of shift to error on the last cycle was 0.058. Hydrogen atoms were placed in calculated positions and included in F_c calculations. The final Fourier difference synthesis showed a maximum of $+1.44$ and a minimum of -2.06 e Å^{-3}. Complex **1** is isostructural with $[LaFe(L^2)_3](ClO_4)_{0.5}(CF_3SO_3)_{4.5} \cdot CH_3CN \cdot 4H_2O$ and $[EuZn(L^2)_3](ClO_4)(CF_3SO_3)_4 \cdot 4CH_3CN$.[8] Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100482. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code + (44) 1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

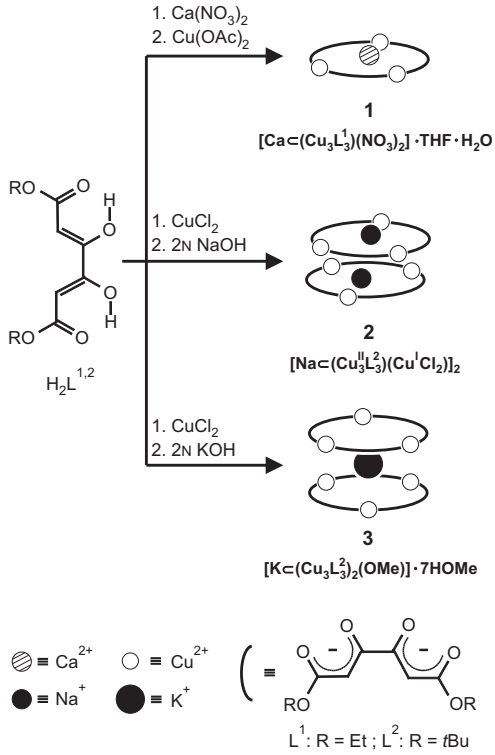
Crown Ethers, Double-Decker, and Sandwich Complexes: Cation-Mediated Formation of Metallatopomer Coronates**

Rolf W. Saalfrank,* Norbert Löw, Sabine Kareth, Verena Seitz, Frank Hampel, Dietmar Stalke, and Markus Teichert



Crown ethers, [2]cryptands, and [3]cryptands selectively complex alkali metal ions.[1] This discovery led to the construction of novel supramolecular architectures[2] capable of recognizing neutral as well as cationic or anionic substrates with formation of well-defined host–guest compounds. Recently we pointed out the structural analogy between coronates and cryptates[3] and their topologically equivalent metallacoronates and metallacryptates.[4] If one applies the knowledge of crown ethers to the chemistry of metallacrown ethers (MC),[5] the complexation of differently sized cations by metallacrown ethers should lead to metallacoronates of varying structures. Since the ionic radii of alkaline and alkaline earth metal cations differ significantly (whereas the diameter of the metallacrowns essentially does not change) the inclusion of small cations such as Na^+ or Ca^{2+} should lead to a metallacoronate with 1:1 stoichiometry, and, in contrast, encapsulation of the larger K^+ ions to a metallacrown ether sandwich complex (K^+:MC = 1:2).

Reaction of diethyl ketipinate[6] H_2L^1 with copper(II) acetate in the presence of calcium nitrate leads to green microcrystals of **1** (Scheme 1) after crystallization from tetrahydrofuran/diethyl ether. According to elemental analysis and FAB-MS data (FAB = fast atom bombardment, $m/e = 977$) **1** is a metallacoronate. Compound **1** is a neutral, trinuclear metal cluster (Figure 1), as determined by X-ray

Scheme 1.

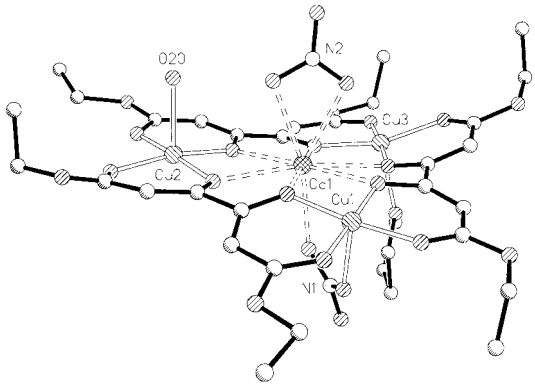

Figure 1. Molecular structure of **1**. Side view with counterion and coordinated solvent molecules; H atoms are omitted for clarity.

crystallographic analysis.[7] Formal replacement of the three copper(II) centers in the [15]metallacrown-6 system (15-MC-6) by ethylene bridges leads to the topologically equivalent crown ether [18]crown-6. The copper atoms are linked across the sides of the triangle through bis(bidentate) diethyl ketipinate dianions L^1, and each copper(II) ion is coordinated in a square-planar fashion to four oxygen atoms. Additional coordination of water, tetrahydrofuran, and nitrate leads to a square-pyramidal environment of O donors for each copper ion. The center of the resulting metallacoronand 15-MC-6 contains an encapsulated calcium ion, whose charge is compensated by two axially coordinated nitrate ions (Figure 1).

Double deprotonation of H_2L^2 by 2N sodium hydroxide and reaction of the formed dianion with copper(II) chloride dihydrate also yields the metallacoronate **2** (FAB-MS data, $m/e = 898$; see Scheme 1), whose molecular structure was determined by X-ray crystallographic analysis (Figure 2).[8]

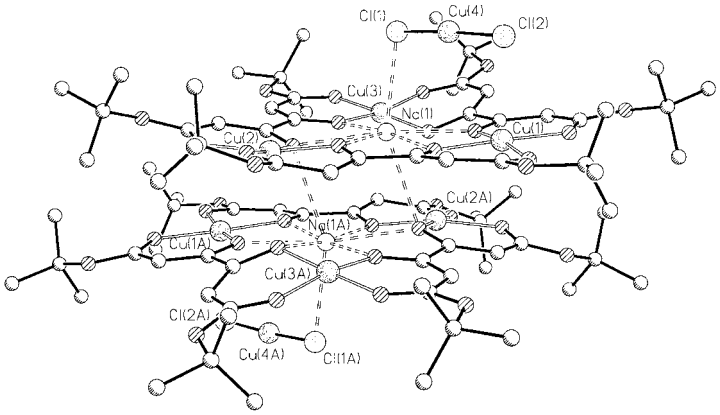

Figure 2. Molecular structure of dimer **2**. Side view; H atoms are omitted for clarity.

Metallacoronate **2** is a dimer of two $[Na \subset (Cu_3L^2_3)(CuCl_2)]$ building blocks. The monomer is composed of a $[Cu_3L^2_3]$ metallacrown with a sodium ion, which is η^6 coordinated to all oxygen atoms in the inner ring and located at the center. The counterion of the $[Na \subset (Cu_3L^2_3)]^+$ cation is a $(CuCl_2)^-$ ion[9] which coordinates to the encapsulated sodium ion through a chlorine atom. The tendency for eightfold coordination around Na^+ ions is the driving force for dimerization. The linkage of the coronates to give the dimer **2** is accomplished by coordination of one ring oxygen to the neighboring sodium center. This leads to a minor mutual deformation of the monomeric building blocks.

Whereas encapsulation of the small cations Na^+ and Ca^{2+} leads to host–guest systems of 1:1 stoichiometry, double deprotonation of di-*tert*-butyl ketipinate H_2L^2 with 2N potassium hydroxide and reaction with copper(II) chloride dihydrate affords the metallacrown ether sandwich complex **3** with 2:1 stoichiometry ($m/e = 2125$; see Scheme 1). X-ray crystallographic analysis[10] reveals that **3** is constructed of two neutral trimetallacrown-6 building blocks that are rotated relative to each other by 60° (Figure 3). The sandwichlike linkage results from a crystallographically disordered potassium ion between the two metallacrowns. The counterion of $[K \subset (Cu_3L^2_3)_2]^+$ of **3** is a methoxide ion which is bound to the encapsulated

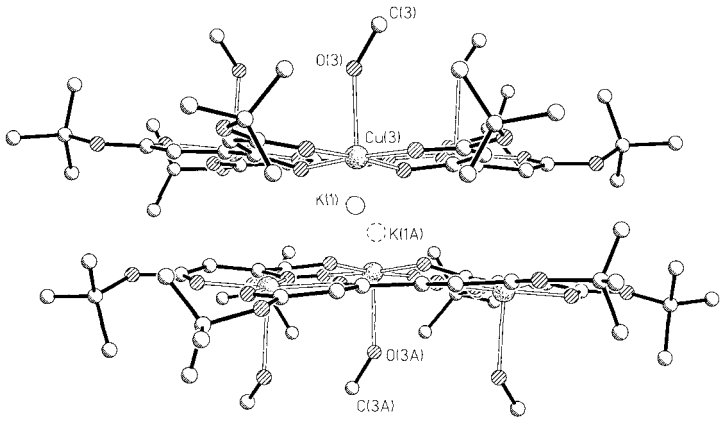

Figure 3. Molecular structure of the cation in **3**. Side view; H atoms as well as the methoxide and methanol molecules coordinated to potassium are omitted for clarity.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0173 $ 17.50+.50/0

potassium ion; methanol is coordinated to the opposite sides (not shown). The coordination spheres of the six copper centers are saturated by methanol molecules, and, thus, each Cu^{2+} ion is surrounded by O donors in a tetragonal-pyramidal fashion.

As with organocrown ethers, the size of the cation (Na^+, Ca^{2+}, or K^+) determines whether metallacoronates (**1** and **2**) or a metallacrown ether sandwich complex (**3**) are formed in the case of metallacrown ethers $[Cu_3L_3]$ ($L = L^1$, L^2).

Experimental Section

1: A solution of copper(II) acetate monohydrate (200 mg, 1 mmol) in methanol (50 mL) was added dropwise to a mixture of H_2L^1 (230 mg, 1.0 mmol) and calcium nitrate tetrahydrate (475 mg, 2 mmol) in methanol (50 mL). The dark green solution was stirred for one hour and then concentrated to 10 mL. To achieve complete precipitation of the product, water (200 mL) was added. The product was filtered, washed with water, and dried under vacuum (oil pump). Yield of dark green crystals from tetrahydrofuran/diethyl ether: 320 mg (85%); decomp above 127 °C; IR ($CHBr_3$): $\tilde{\nu} = 2960$ (CH), 1614 (C⋯O), 1524 cm^{-1} (C=C); FAB-MS (3-nitrobenzyl alcohol (*m*-NBA) matrix): *m*/*z* (%) = 977 (100, $[Ca \subset (Cu_3L^1_3)NO_3]^+$); correct elemental analysis.

2 and **3**: General procedure: Aqueous sodium or potassium hydroxide (2 mL, 2 N) was added dropwise to a solution containing copper(II) chloride dihydrate (171 mg, 1.0 mmol) and H_2L^2 (286 mg, 1.0 mmol) in methanol (100 mL). To achieve complete precipitation of the products, water (200 mL) was added. The products were filtered, washed with water, and dried under vacuum (oil pump).

2: Yield of dark green crystals from chloroform/diethyl ether: 220 mg (55%); decomp above 230 °C; IR ($CHBr_3$): $\tilde{\nu} = 2950$ (CH), 1640, 1590 (C⋯O), 1540 cm^{-1} (C=C); FAB-MS (*m*-NBA): *m*/*z* (%) = 898 (100, $[Na \subset (Cu_3L^2_3)]^+$); correct elemental analysis.

3: Yield of dark green crystals from methanol: 280 mg (73%); decomp above 180 °C; IR ($CHBr_3$): $\tilde{\nu} = 3300$ (OH), 2970 (CH), 1655, 1600 (C⋯O), 15750 cm^{-1} (C=C); FAB-MS (*m*-NBA): *m*/*z* (%) = 2125 (30, $[K \subset (Cu_3L^2_3)_2]^+$), 1082 (95, $[K \subset (Cu_3L^2_3)_2]^+$); correct elemental analysis.

Evidence for C–H···O Hydrogen Bond Assisted Recognition of a Pyrimidine Base in the Parallel DNA Triple-Helical Motif**

Judith Marfurt and Christian Leumann*

The structural and energetic influence of nonconventional C–H···O hydrogen bonds on molecular recognition has become a focus of interest. Whereas a large body of structural data evidences their importance in molecular recognition of small molecules in the crystalline state,[1] only limited experimental data is available on their contribution to biomolecular recognition in solution.[2] C–H···O hydrogen bonds have only recently begun to be used as design elements for directing intermolecular organization of small organic molecules (crystal engineering).[1, 3] Their use as a designer element for biomolecular complexation is virtually unexplored.

We recently reported on the selective recognition of G–C base pairs in DNA duplexes by parallel complementary oligodeoxynucleotides containing the unnatural nucleoside 7-(2′-deoxy-β-D-ribofuranosyl)hypoxanthine (^{7}H).[4] Although only one conventional N–H···N hydrogen bond between ^{7}H and G can be formed, the ^{7}H·G–C base triple (Figure 1) has the same stability as the canonical $\underline{C}^+$·G–C base triple ($\underline{C}$ = 5-methyl deoxycytidine) at pH 7.0, in which the base of the third strand is bound through two conventional hydrogen bonds to the purine base of the Watson–Crick duplex. Since precise structural data were lacking, we empirically attributed the extra stability to the presence of one or two C–H···O hydrogen bonds flanking the conventional hydrogen bond of the third-strand base.

To explore whether such weak electrostatic interactions can be further exploited for the recognition of DNA duplexes by oligonucleotides, we investigated the recognition of pyrimidine bases by considering such C–H···O hydrogen bonds. Specifically we investigated the interaction of a deoxyuridine unit in a DNA duplex with a ^{7}H unit in the third strand (Figure 1).

The DNA target duplexes **1** as well as the third-strand oligonucleotides **2** (Figure 2) were synthesized by standard phosphoramidite chemistry from commercially available and recently described DNA building blocks.[4] The binding efficiency of the third strands to the target duplex was

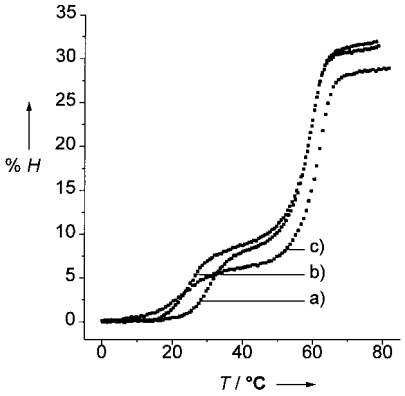
assessed by an analysis of the UV melting curve in the buffers specified.[5] The melting temperatures (T_m) for dissociation of the third strand as well as the calculated Gibbs energies for triplex formation at 25 °C (ΔG) extracted from the melting curves[6] are summarized in Figure 2. A representative collection of melting curves are depicted in Figure 3.



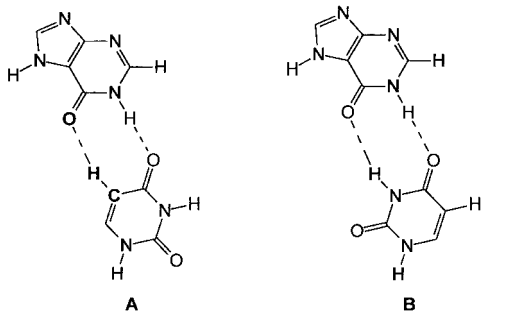


Figure 3. UV melting curves (%H = relative hyperchromicity, λ = 260 nm). a) **1·2** (**Z**·**X**–**Y** = ^{7}H·dU–A; b) **Z**·**X**–**Y** = ^{7}H·d^{F}U–A; c) **3·4**. Oligonucleotide concentration and buffer as in Figure 2 with the exception of pH 6.0 for c).

Inspection of the T_m data reveals that the oligonucleotide **2** (**Z** = ^{7}H) efficiently binds to the target duplex in which the base uracil is opposite to the ^{7}H residue (**1**; **X**, **Y** = dU, A) with formation of a ^{7}H·U–A base triple. This triplex is moderately less stable than the standard oligopurine/oligopyrimidine reference triplex displaying the conventional **Z**·**X**–**Y** = $\underline{C}^+$·G–C base triple ($\Delta T_m = -7.7$ K). If the ^{7}H residue of the third strand is placed opposite to a thymine unit (**Z**·**X**–**Y** = ^{7}H·T–A), a strong destabilization of the triplex relative to that containing the ^{7}H·U–A base triple is observed ($\Delta T_m = -11.8$ K). This corresponds to a typical mismatch situation and is due to the 5-methyl group of thymine, which completely obstructs the base-recognition process for steric reasons.

To investigate a possible energetic contribution of the C–H···O hydrogen bond to triplex stability, we replaced the 2′-deoxyuridine in the target duplex by 5-fluoro-2′-deoxyuridine (d^{F}U). The fluorine atom represents the closest non-isotopic isostere of hydrogen with an opposite electrostatic environment. As expected, this base is recognized by ^{7}H with distinctly lower affinity than uracil (ΔT_m of the corresponding triplexes = –6.0 K). This difference in T_m translates to a difference in binding enthalpy ($\Delta\Delta G$) of about –1.1 kcal mol^{-1} at 25 °C.

A similar hydrogen-bonding pattern between **X** and **Z** appears if ^{7}H in the third strand is replaced by either thymidine or 5-methyl-deoxycytidine (Figure 1, right). Indeed, replacement of ^{7}H by thymidine leads to a decrease in T_m of only 2.3 K. Thus, both nucleosides display almost equal efficiency in uracil recognition. Again, positioning the base thymine opposite to d^{F}U leads to a strong decrease in binding efficiency of the corresponding third strand ($\Delta T_m = -8.3$ K). Offering a thymidine unit in the duplex as the complexing partner for thymidine in the third strand results in a mismatch. Similar results were obtained for third strands containing 5-methyl-deoxycytidine, although on a lower affinity level. The overall lower T_m values most probably arise from the need for protonation of the base, an unfavorable process at pH 7.0.

We calculated the heat of formation (ΔH_f^0) of the base pairs **A** and **B** (Figure 4) in the gas phase with semi-empirical methods. Base pair **A** corresponds to the arrangement **Z**·**X** = ^{7}H·dU (Figure 2), whereas **B** represents an isomeric base pair

ΔH_f^0(PM3) = –5.29 kcal mol^{-1} ΔH_f^0(PM3) = –6.41 kcal mol^{-1}

Figure 4. Structures and standard heats of formation (ΔH_f^0) of base pairs **A** and **B** calculated with the semiempirical model PM3 for the gas phase as implemented in the program package Spartan V4.0 (Wavefunction Inc., USA).

between ^{7}H and uracil that is connected through two conventional hydrogen bonds. Interestingly, the heat of formation (ΔH_f^0) of base pair **A** displaying one conventional and one C–H···O hydrogen bond is only 1.12 kcal mol^{-1} less exothermic than **B**, which has two conventional hydrogen bonds. Thus, replacement of a conventional hydrogen bond by a C–H···O bridge is compromised by a loss of only about 1 kcal mol^{-1} in binding enthalpy. This is reasonably well reflected in the experimentally determined difference in stability between the triplex displaying a $\underline{C}^+$·G–C base triple and that displaying the ^{7}H·U–A base triple ($\Delta\Delta G \approx$ 2 kcal mol^{-1} at 25 °C). For comparison, typical $\Delta\Delta G$ values for the triplex containing $\underline{C}^+$·G–C and a true mismatch system are about 5 kcal mol^{-1} (e.g., T·T-A, Figure 2).

To explore the limitations of the C–H···O hydrogen bond assisted recognition of uracil with ^{7}H, we investigated the formation of the triple helix **3·4** (Figure 5), which is designed

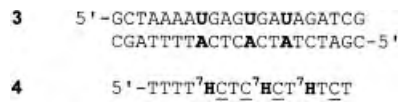

Figure 5. Sequence of the target duplex **3** and third strand **4**.

to incorporate three ^{7}H·dU interactions. This corresponds to a sequence context with a pyrimidine content of 20% in the triplex-recogniton region of the underlying duplex. As shown in Figure 3, binding at pH 6.0 is maintained even in this system with a T_m of 23.6 °C for third-strand dissociation. As expected, third-strand binding is less efficient in this case ($T_m \approx 1.5$ °C at pH 7.0) than for an all-purine target sequence under comparable conditions. We anticipate that in such systems the loss of affinity might be compensated by combining C–H···O hydrogen bond assisted recognition of pyrimidine bases with

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0176 $ 17.50+.50/0

further modifications to enhance triplex stability, for example replacing C by the 2-aminopyridine nucleoside **P** for recognition of guanine.[9, 10]

We can not definitely rule out the possibility of an energy-neutral contribution from the C–H···O arrangement in the corresponding base triples. Nevertheless, the experimental results described here are in good agreement with the general view that the energetic benefit of forming the C–H···O hydrogen bond is made up of a small, positive, direct electrostatic contribution[1] and a positive contribution due to the alleviation of a destabilizing interaction that arises if a hydrogen-bond acceptor (such as a carbonyl oxygen atom) is inactive or involved in secondary hydrogen bonding, for example, to solvent.[11] In any case, the final proof for the existence of a C–H···O hydrogen bond in the triplexes discussed here has to come from high-resolution structure analysis.

The efficient complexation of uracil by ^{7}H or T presented here is of direct relevance to the molecular recognition and folding of RNA. C–H···O hydrogen bonds in nucleic acids can compete with conventional hydrogen bonds under certain circumstances. This was shown by a recent X-ray structure analysis of an RNA duplex in which a U·U base pair built from one conventional and one C–H···O hydrogen bond was preferentially formed over an isomorphous base pair with two conventional hydrogen bonds.[12]

In applying this concept to triple-helical DNA recognition, the following restrictions have to be considered: 1. Uracil is not a DNA base, and there is no clear way to use the presented concept of C–H···O hydrogen bond assisted pyrimidine recognition for the complexation of the natural DNA base thymine. 2. Both thymidine and ^{7}H, as components of a third strand, have a primary binding preference for the purine bases adenine and guanine, respectively, which compromises the selectivity in the formation of DNA triple helices. This issue of selectivity, however, might be addressable by base design.

We have shown here that unconventional C–H···O hydrogen bonds may be advantageously used as a design element for enhancing the efficiency of weak base–base interactions in the complexation of nucleic acids. We are currently trying to expand this concept to triplex-mediated recognition of cytosine. Efficient and selective pyrimidine recognition definitely constitutes one way of extending the sequence range of triplex formation in nucleic acids, a widely sought but hitherto unsolved goal.[13]

[5] Melting curves were recorded with heating/cooling rates of 0.5 K min^{-1}. Under these conditions, melting and renaturation curves were superimposable in all cases and thus reflect equilibrium binding.
[6] The T_m data for third-strand binding in the triplexes **1·2** were independent of oligonucleotide concentration within the range 1–45 μM. The systems thus show pseudomonomolecular association, as reported previously for the parent canonical triplex.[7] Data for the Gibbs energy of formation for the triplexes (ΔG) were therefore calculated as described for a monomolecular two-state model from the experimentally determined association constant K_{ass} at 25 °C.[8]

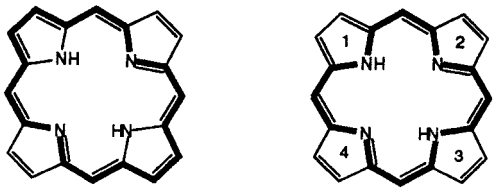
Global and Local Aromaticity in Porphyrins: An Analysis Based on Molecular Geometries and Nucleus-Independent Chemical Shifts**

Michatl K. Cyrañski, Tadeusz M. Krygowski,* Marcin Wisiorowski, Nicolaas J. R. van Eikema Hommes, and Paul von Ragué Schleyer*

Dedicated to Professor Emanuel Vogel on the occasion of his 70th birthday



How and to what extent does aromaticity contribute to the geometric and electronic structure of porphyrins? Despite its widespread use for nearly two centuries, "aromaticity" is difficult to define.[1] Usually, this is done on the basis of energetic, geometric and magnetic criteria.[2] Molecular geometries are often the most accessible, and aromaticity indices have been derived from bond lengths.[3] Recently the nucleus-independent chemical shift (NICS) was proposed as a new magnetic criterion, based on MO calculations of the magnetic shieldings at the centers or other points of aromatic systems.[4] The aim of this paper is to deduce the electronic structure of porphyrins based both on a large number of geometries retrieved from the Cambridge Structural Database [5] and on computed NICS values.

The present analysis of the molecular geometry does not use the popular depiction of the porphyrin skeleton as a bridged [18]annulene derivative.[6] Instead, we divide the porphyrin moiety into the macrocyclic "internal cross"—an 18 π-electron system of 16 atoms—and the four peripheral pyrrole rings, as shown in Scheme 1.

Scheme 1. Two models of the π-electron system of porphyrin. Left: as bridged [18]annulene derivative; right: as macrocyclic internal cross (in bold) and four pyrrole rings (1–4).

The CC and CN bond lengths in porphyrins can be perturbed by exocyclic substitution and by coordination with a metal cation. Bond lengths can be analyzed by the harmonic oscillator model of aromaticity (HOMA),[3c] which in turn may be dissected into two components, EN and GEO [Eq. (1)]. Here, n is the number of bonds taken into the

$$\mathrm{HOMA} = 1 - \alpha(R_{\mathrm{opt}} - R_{\mathrm{av}})^2 - \frac{\alpha}{n}\Sigma\,(R_{\mathrm{av}} - R_{\mathrm{i}})^2 = 1 - \mathrm{EN} - \mathrm{GEO} \qquad (1)$$

summation, and α is an empirical constant fixed to give HOMA = 0 for the hypothetical Kekule structures of aromatic systems and 1 for the system with all bonds equal to the optimal value R_{opt}.[3c, d] R_{av} stands for the average bond length, while the individual bond lengths R_{i} are obtained[7] from the Pauling definition of bond number.[8] The EN term describes changes in aromatic character due to deviation of the average bond length from the optimal value, while the GEO term reflects the consequences of bond length alternation.[7]

Of the 456 porphyrin derivatives with the highest measurement precision (i.e., with AS = 1, 2[9]) that we retrieved from the Cambridge Structural Database,[5] 32 are exocyclically substituted species, while 424 are metal complexes. In free base porphyrin, two of the four pyrrole rings (rings 1 and 3 in Scheme 1) are protonated. Since it is difficult to localize the inner hydrogen positions accurately by X-ray diffraction,[10] the harmonic oscillator stabilization energy (HOSE) model[11] was used to assign the hydrogen atoms to the pyrrole rings. Note that N-H tautomerization[12] will tend to reduce the difference between the pyrrole rings. For comparison, we calculated the optimized structures of porphyrin, its dianion, and the Mg(II)-porphyrin complex at the B3LYP/6-31G* DFT level and computed the nucleus independent chemical shift (NICS) at characteristic points at GIAO-RHF/6-31+G*. All computations were performed with the Gaussian 94 program package.[13] Figure 1 presents the calculated[12, 14] and mean experimental geometries, which are in good agreement; the HOMA, EN, GEO and NICS values are given in Table 1.

The differences between the global HOMA values for the free base porphyrins and the metal complexes are insignificant. Decrease in aromaticity due to the bond length alternation (GEO term) is about twice as large as that due to the nonoptimal average bond length (EN term). Interestingly, both terms are somewhat smaller for the complexes containing trivalent metals (M = Mn^{III}, Fe^{III}, Tl^{III}) than for the divalent metal complexes (M = Mg^{II}, Fe^{II}, Co^{II}, Ni^{II}, Cu^{II}, Zn^{II}). Hence, the HOMA values for the complexes with trivalent metals are slightly higher.

Table 1. HOMA, EN, GEO, and NICS values for porphyrins and their metal complexes.

	HOMA[a]	HOMA[b]	EN[a]	GEO[a]	NICS [ppm][b]
Porphyrin	0.652	0.666	0.107	0.240	−16.5[c]
ring (1,3)	0.666	0.702	0.132	0.202	−15.2
ring (2,4)	0.452	0.381	0.175	0.373	−4.5
internal cross	0.880	0.932	0.075	0.045	−21.7
Porphyrin metal complex	0.656	0.671	0.094	0.249	
ring (1,3)	0.566	0.556	0.158	0.276	−10.0
;ring (2,4)	0.524	0.556	0.153	0.323	−10.0
internal cross	0.872	0.906	0.071	0.057	−21.0

Porphyrin M^{III} complex	0.682		0.084	0.233	

[a] Mean experimental geometries. [b] Calculated geometries. [c] Value at ring center, see Figure 2.

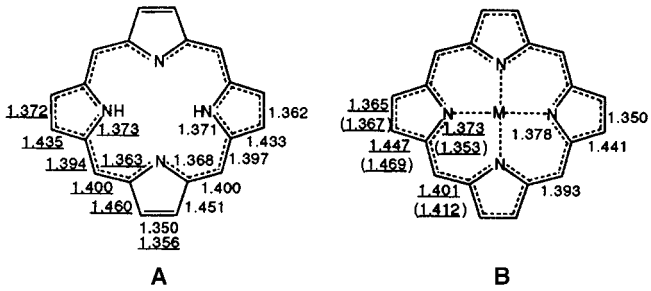

Figure 1. Mean experimental and calculated (underscored) bond lengths for porphyrin (**A**) and its metal complexes (**B**, calculated for M = Mg; values for the free anion in parentheses).

The pyrrole rings with NH groups (1 and 3) are clearly more aromatic[2d] than the other five-membered rings (2 and 4). The mean HOMA values are 0.666 and 0.452, respectively. The NICS values computed in the ring centers (Figure 2) show the difference more explicitly: the −15.2 NICS for rings 1 and 3 is identical with the pyrrole value (−15.1).[4] Thus, the NH groups are not inert bridging groups, as is suggested by the [18]annulene model, but instead are an integral part of the aromatic system. However, rings 2 and 4 have much lower NICS values (−4.5), implying that the C_2H_2 groups function as exocyclic "bridges".

Metal complexation strongly reduces the difference between the two types of pyrrole rings, but does not lead fully to D_{4h} symmetry for the porphyrin skeleton. Application of the HOSE model[11] reveals small residual differences. The HOMA values, as well as the contributing EN and GEO terms, approach the mean of the corresponding data for the free base porphyrin. This is reflected by the results of the DFT computations: The structure of the magnesium complex optimized to D_{4h} symmetry (Figure 1); the NICS at the centers of all the pyrrole rings is −10.0, the mean of the values

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0178 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 1/2

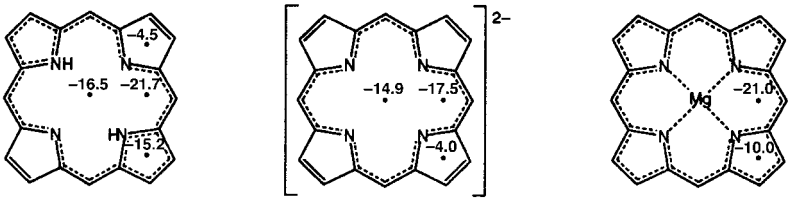

Figure 2. Computed NICS values for free porphyrin base, its dianion, and the Mg complex. The dashed lines indicate the delocalized π systems deduced from the NICS and HOMA analyses.

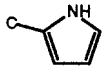

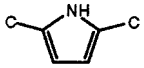

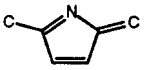

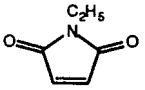

computed for uncomplexed porphyrin (Figure 2). Thus all four pyrrole rings are incorporated into the aromatic system. Interestingly, much lower NICS (only −4.0) are computed for all the pyrrole rings in the uncomplexed porphyrin dianion (Figure 2). Hence, the aromatic system of the dianion consists primarily of the *internal cross*, which must be considered to be an 18 π-electron species.

The mean HOMA values of the *internal cross* (Scheme 1) are significantly higher than those of the pyrrole rings for both the metallic and nonmetallic derivatives. The dearomatization contributions from the GEO and EN terms are comparable. The NICS values corroborate this finding. However, since computation of NICS in the center of the internal cross is impossible for the magnesium complex, we chose an additional point at the geometric mean of two adjacent C–N bonds (see Figure 2). NICS computed at this point for porphyrin is −21.7, slightly higher than the value of −21.0 computed for the Mg complex. The value for the porphyrin dianion is lower (−17.5) implying that the uncomplexed dianion is less aromatic than the Mg complex.

What is responsible for the decrease in aromaticity of the pyrrole rings, in particular rings 2 and 4, in the porphyrin macrocycle? Doubly bonded substituents are known to lead to strongly localized, quinonoid-like structures and hence to decrease the aromatic character of rings. For example, negative HOMA values and positive NICS are obtained for *para*-benzoquinone. Similar structural effects are observed for 2- and/or 5-substituted pyrroles (Table 2). The typical HOMA value for pyrroles of about 0.92 decreases substantially to 0.27, when a doubly bonded substituent is present. Similarly, the NICS value of −15.1 for pyrrole is reduced to −1.8 for 2-azafulvene. Maleimide has a negative HOMA and a positive NICS value (Table 2).

In conclusion, both the NICS values and the HOMA analyses (albeit attenuated due to the uncertainty in the hydrogen positions) agree: rings 1 and 3 in the porphyrin system can be considered to be true pyrrole rings. The π system consists of these rings and the internal cross. Rings 2 and 4 behave almost like pyrroles with doubly bonded substituents and have short, localized CC double bonds. While the dianion has four essentially localized double bonds, the corresponding metal derivatives involve all the π electrons in the aromatic system.

Table 2. HOMA, EN, GEO, and NICS values for four kinds of 2- and 5-substituted pyrrole derivatives and for *para*-benzoquinone.

Compound	HOMA	EN	GEO	NICS [ppm]

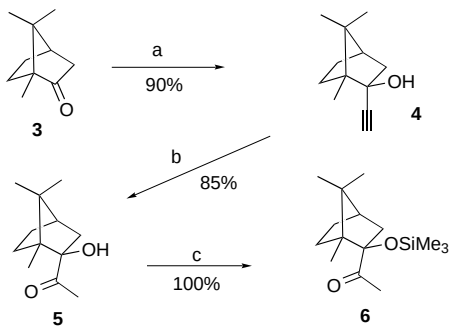
Design and Evaluation of a Practical Camphor-Based Methyl Ketone Enolate for Highly Stereoselective "Acetate" Aldol Reactions**



Claudio Palomo,* Alberto González, Jesús M. García, Cristina Landa, Mikel Oiarbide, Santiago Rodríguez, and Anthony Linden

Control of the configuration of newly forming stereogenic carbon atoms in aldol condensation processes has focused enormous efforts over the last two decades.[1] Special attention has been given to the use of chiral enolates derived from carboxylic acids[2] because of the easy final removal of the auxiliary to obtain either β-hydroxy carbonyl or 1,3-dihydroxylic compounds, which are frequently present in natural products.[3] A conceptually different, but in practice equivalent, strategy to access to these fragments lies in the use of enolates derived from chiral α-hydroxy ketones.[4] In this instance, the aldol products, upon oxidative cleavage of the α-ketol moiety, give the desired β-hydroxy carbonyl system.[5] The major drawbacks associated with this strategy are the destruction of the covalently bounded chiral adjuvant at the final stage, and the insufficient stereoselectivity generally attained with α-unsubstituted enolates.[6] Although considerable advances have been made in recent years to overcome this latter limitation by carrying out acetate aldol reactions mediated by both metal enolates bearing chiral ligands and external chiral catalysts,[7] the problem associated with enolates of chiral acetates still remains not well resolved;[8] in all but one case,[4j] the lack of stereoselection in aldol reactions with methyl ketone enolates is specially dramatic.[4b,g,h,i]

We have recently reported on the reaction of *N*-acetyl imide enolates **1** with aldehydes to give the corresponding adducts with modest levels of diastereoselectivity (Scheme 1).[9] In an attempt to take advantage of the stereodifferentiating power of the camphor skeleton more effectively, we designed the new camphor-derived enolate **2**. The conception of **2** has been guided by two major goals: a) to provoke the electrophilic aldehyde to follow a trajectory of approach closer to the camphor skeleton, and b) to force a facial discrimination between the rear side and the sterically more demanding front side of the camphor skeleton, depicted as the half-spaces defined by plane B in Scheme 1,[10] instead of the more commonly used *endo/exo* discrimination across opposite sides of plane A.[11] Accordingly, if one assumes that a chelating metal ion like lithium engages in three-point coordination, a very high diastereoselectivity should be expected through a Zimmerman–Traxler six-membered transition state.[12] From this design the methyl ketone **5**[13] (Scheme 2) is a primary candidate to evaluate the above

Scheme 1. Design of the new chiral methyl ketone enolate **2** by moving the acetyl moiety of **1** nearer to the camphor skeleton. Also shown is the transition state accounting for the aldol reaction of **2**.

Scheme 2. Synthesis of the chiral methyl ketone reagents **5** and **6**: a) HC≡CLi, THF, −78 →room temperature (RT) (*endo:exo* 97:3); b) HgO, H_2SO_4, Me_2CO, reflux; c) TMSO, TfOH cat., RT.

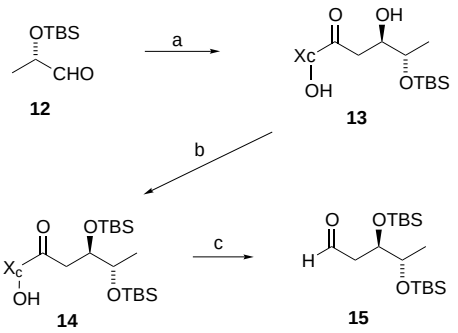
hypothesis. The crystalline **5** was prepared by addition of lithium acetylide to the commercially available (1*R*)-(+)-camphor (**3**) according to the procedure of Midland.[14] The addition proceeded in a 97:3 *endo:exo* ratio from which **4** was isolated in 90% yield after column chromatography. Standard hydration provided **5** [m.p.: 94–95°C, $[\alpha]_D^{25} = -65.6$ ($c = 1.0$ in CH_2Cl_2)] in 85% yield after crystallization from hexane.[15]



Concordant with our expectations, the corresponding aldol products obtained from the reaction of representative aldehydes with the lithium enolate of **6**, generated from **5** by silylation with *N*-trimethylsilyl-2-oxazolidinone (TMSO)[16] and subsequent treatment with lithium diisopropylamide (LDA), were indeed formed with remarkably high diastereoselectivity (Scheme 3). The diastereomeric ratio of the

Scheme 3. Diastereoselective synthesis of α-unsubstituted β-hydroxy carboxylic acids and ketones: a) LDA (1.2 equiv), THF, -78°C, 0.5 h then RCHO, 3–7 h; b) 1M HCl, MeOH or TBAF (2 equiv), THF, RT, 5 min; c) $NaIO_4$, MeOH/H_2O (2/1), RT or reflux, 12–48 h; d) $ClSiMe_2tBu$, imidazole, DMF, RT, 3 days, 86%; e) R^1MgBr, $CeCl_3$, THF or Et_2O, 0°C, 2 h; f) $Pb(OAc)_4$ (2 equiv), C_6H_6, 5°C, 2 h.

product was unchanged after desilylation to afford the adducts **7**/**8** (typically 95:5, Table 1). The stereochemical assignments for the major products **7** from the reaction with benzaldehyde, isobutyraldehyde, and pivalaldehyde were made by cleavage of the acyloin moiety[5] to afford the corresponding carboxylic acid **9** along with the recovery of the starting camphor (85–90%). The observed optical rotations of these β-hydroxy acids were then compared with published values.[17] In addition, a single-crystal X-ray analysis of the aldol **7g** corroborated the assigned configuration for the adducts. From the data in Table 1 it is evident that the reaction diastereoselectivity is independent of the nature of the aldehyde, showing generality for aromatic, α,β-unsaturated, and linear as well as branched chain aliphatic aldehydes. The excellent diastereoselectivity observed in these reactions is of particular interest in that it provides, through carbonyl addition and subsequent diol cleavage, the basis for an enantioselective synthesis of α-unsubstituted β-hydroxy ketones. For example, using organocerium reagents,[18] we could prepare the carbinols **10** [R^1 = Me, 85%; R^1 = Ph, 90%; R^1 = allyl, 80%],[19] which upon exposure to lead tetraacetate in benzene gave the α-unsubstituted β-silyoxy ketones **11** in good overall yields and essentially in optically pure form.

A further example that illustrates the efficiency of the present system is the reaction of the dianion of **5** with the α-oxy aldehyde **12** (Scheme 4), a chiral aldehyde that shows

Scheme 4. a) **5**, LDA (2.4 equiv), LiCl (6 equiv), THF, -78°C, 4 h, 75%. b) TBDMS-Cl, imidazole, DMF, RT, overnight, 90%. c) $BH_3 \cdot$THF, THF, 0°C, 7 h then $Pb(OAc)_4$ (2 equiv), C_6H_6, 5°C, 2 h, 70%.

essentially no diastereoselection with either methyl acetate or α-silyloxy methyl ketone enolates.[4b, 5b] When **12** was allowed to react with the dianion of **5** in the presence of LiCl, a mixture of diastereomeric aldols was obtained in the ratio 93:7. The major isomer **13** was isolated in 75% yield after column chromatography. A single crystal X-ray analysis of **13** confirmed the assigned configuration for the adduct.[20] Finally, diborane reduction of the keto group in the TBS-protected aldol **14** (TBS = *tert*-butyldimethylsilyl) followed by oxidative workup provided the α-unsubstituted β-silyloxy aldehyde **15** in 70% yield along with the recovery of the starting camphor.

The α-hydroxy methyl ketone enolate developed here helps to fill the existing gap with regard to the usual behavior of α-unsubstituted enolates in diastereoselective aldol reactions and, in addition, enables for the first time the recovery of the starting source of chiral information.

Table 1. Aldol condensation of the lithium enolate of **6** with representative aldehydes.[a]

Aldehyde	t [h]	**7**:**8**[b]	Yield (**7**) [%][c]

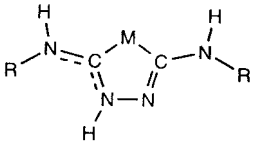
[{Pt(CN)($C_{10}H_{21}N_4$)}$_6$]: A Luminescent Hexanuclear Platinum(II) Macrocycle Containing Chelating Dicarbene and Bridging Cyanide Ligands**



Siu-Wai Lai, Kung-Kai Cheung, Michael Chi-Wang Chan, and Chi-Ming Che*

Transition metal mediated self-assembly reactions are a versatile strategy for generating supermolecules with appealing structural and spectroscopic properties.[1–6] In this context we are interested in luminescent molecular hosts[7] composed of square-planar platinum(II) complexes as building blocks, since such materials could have applications in host–guest photochemistry and as novel luminescent sensors. Fujita et al.[1] and Stang et al.[5a, b] reported the preparation of tetranuclear platinum(II) compounds with pyridine-based ligands. Here we describe the crystal structure of a novel luminescent hexanuclear platinum(II) macrocycle bearing cyclic dicarbene and bridging cyanide ligands.

1

The synthesis of a mononuclear platinum(II) complex with the chelating $C_4H_9N_4$ ligand (**1**, $R = CH_3$) by addition of methyl isocyanide and hydrazine to $K_2[PtCl_4]$ in water has long been known.[8] Subsequent investigations revealed the $[C_4H_9N_4]$ moiety to be a monoanionic planar "resonance-stabilized" dicarbene ligand.[9] In contrast, heating K_2PtCl_4, *tert*-butyl isocyanide, and hydrazine hydrate in water at reflux for one hour resulted in the formation of $[Pt(CN)(C_{10}H_{21}N_4)]_6$ (**2**), which was isolated as acetonitrile-solvated yellow crystals upon recrystallization from acetonitrile/diethyl ether.

The X-ray structure of **2** (Figure 1)[10] shows it to be a rare example of a Pt_6 macrocycle.[11] The core of **2** consists of six platinum atoms linked through crystallographically disordered[10] cyanide units and is puckered in a chairlike conformation. Alternatively, this 18-membered ring can be regarded as a open cubane-type structure in which a pair of opposite corners is missing. The other six corners are occupied by platinum atoms, and the bridging cyanide ligands form the sides. The angles within the core are in accordance with this geometry: the CN-Pt-CN angles at the corners are almost orthogonal (av 92.4°), while the Pt-C-N and Pt-N-C groups are nearly linear (av 174°).

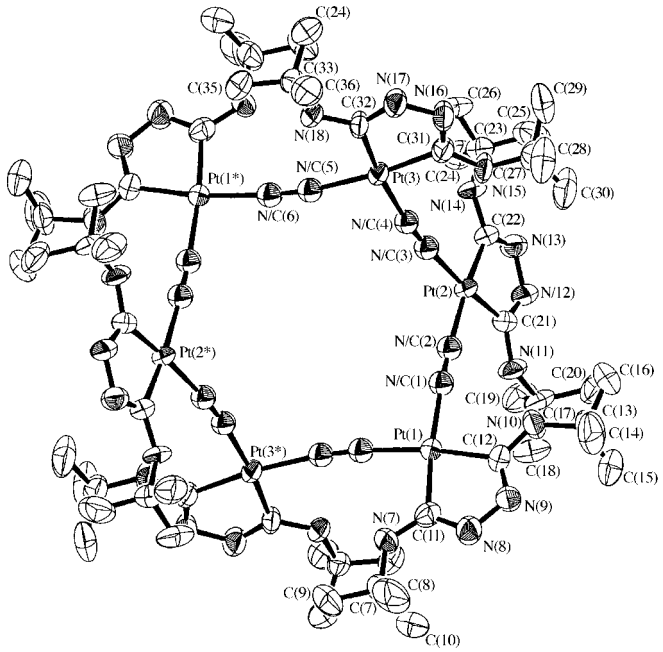

Figure 1. Crystal structure of **2** with atomic numbering scheme (40% probability ellipsoids). Hydrogen atoms and solvent molecules are omitted for clarity. Selected bond lengths [Å] and angles [°]: Pt(1)–N/C(1) 2.05(1), N/C(1)–N/C(2) 1.13(2), Pt(2)–N/C(2) 2.03(1), Pt(2)–N/C(3) 2.02(1), N/C(3)–N/C(4) 1.17(1), Pt(3)–N/C(4) 2.02(1), Pt(1)–C(11) 2.00(1), Pt(1)–C(12) 2.01(1), Pt(2)–C(21) 1.97(1), Pt(2)–C(22) 1.97(1), N(12)–C(21) 1.31(2), N(12)–N(13) 1.41(1), N(13)–C(22) 1.30(2), Pt(3)–C(31) 2.01(1), Pt(3)–C(32) 1.98(1); N/C(1)-Pt(1)-N/C(6) 92.2(5), N/C(2)-Pt(2)-N/C(3) 92.5(5), N/C(4)-Pt(3)-N/C(5) 92.4(5), Pt(1)-N/C(1)-N/C(2) 174(1), Pt(2)-N/C(2)-N/C(1) 175(1), Pt(2)-N/C(3)-N/C(4) 175(1), Pt(3)-N/C(4)-N/C(3) 174(1), C(11)-Pt(1)-C(12) 78.8(6), C(21)-Pt(2)-C(22) 78.2(6), C(31)-Pt(3)-C(32) 78.7(5), Pt(2)-C(22)-N(13) 117.5(10), Pt(2)-C(22)-N(14) 121(1), N(13)-C(22)-N(14) 120(1).

The $C_{10}H_{21}N_4$ motif (see **1**, R = *t*Bu) is analogous to the $C_4H_9N_4$ group in earlier work,[8, 9] and hence a planar PtC_2N_2 five-membered metallacycle is present. The Pt–carbene distances are in the range 1.97(1)–2.01(1) Å and are similar to those in the platinum(II) complexes *trans*-[Pt{C(NEt$_2$)(O-C(O)Ph)}(PPh$_3$)I$_2$] (1.969(7) Å),[12] [Pt(H)(CH$_2$CN)-{C(NC$_3$H$_6$)N(H)(*p*-MeOC$_6$H$_4$)}(PPh$_3$)] (2.069(4) Å),[13] and *trans*-[Pt(Me){C(NMe$_2$)Me}(PMe$_2$Ph)$_2$]PF$_6$ (2.079(13) Å).[14] Intriguingly, the Pt–C(sp^3) distance of 2.147(11) Å in the latter is only slightly longer, and this can be attributed to the *trans* influence of the carbene ligand. Nevertheless, the carbene description is vindicated by the sp^2-type hybridization of the respective carbon centers in **2**; the angles at C(21) are 122.8(10), 121(1), and 115.7(9)°. Formation of **2** can be explained as follows: two coordinated *t*BuNC ligands react with hydrazine to give the chelating dicarbene ligand, and platinum(II)-mediated dealkylation of *t*BuNC gives rise to the cyanide ligands. We note that heating a solution of $[PtCl_4]^{2-}$ and *t*BuNC in water for one hour similarly generated a partially dealkylated species, namely, $[Pt(CNtBu)_2(CN)_2]$.[15]

The absorption spectrum of **2** in methanol (Figure 2a) exhibits an intense band at 356 nm. The very high extinction coefficient of $\varepsilon_{max} = 18000\ dm^3mol^{-1}cm^{-1}$ indicates a spin-allowed charge-transfer (CT) transition, and we tentatively assign this to a Pt $\rightarrow\pi^*$(carbene) transition. Transitions within the chelating dicarbene groups are discounted, since they would occur at higher energy. The alternative assignment as a Pt $\rightarrow\pi^*(CN^-)$ transition is not favored, since mononuclear Pt^{II} cyanide derivatives bearing π-acid ligands such as phosphane or alkyl isocyanide do not absorb strongly at $\lambda > 300$ nm. For example, the lowest energy bands of [Pt(dppe)(CN)$_2$] (dppe = 1,2-bis(diphenylphosphanyl)ethane) and [Pt(CN*t*Bu)$_2$(CN)$_2$] appear at 294 and 282 nm respectively in methanol.[16] Furthermore, the Pt $\rightarrow\pi^*(CN^-)$ transition of $[Pt(CN)_4]^{2-}$ occurs at 280 nm.[17] The relatively low energy of the Pt $\rightarrow\pi^*$(carbene) transition means that the carbene ligand can readily be exploited in photochemical studies of metal-to-ligand charge transfer (MLCT) in platinum(II) derivatives.

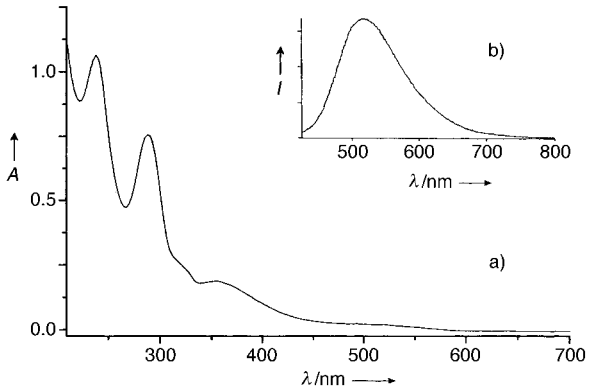

Figure 2. a) UV/Vis spectrum of **2** in methanol. b) Emission spectrum of **2** in CH_2Cl_2 (intensity *I* in arbitrary units).

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0183 $ 17.50+.50/0

Upon excitation at 350 nm at 301 K, crystalline **2** shows a structureless emission band centered at 514 nm, which at 77 K is blue-shifted to 507 nm. In a degassed solution in CH_2Cl_2 at 301 K, an emission band is observed at 519 nm with a lifetime of 0.22 μs (Figure 2b). The emission at $\lambda > 500$ nm provides further evidence for a Pt→π*(carbene) transition, since $[Pt(CN)_4]^{2-}$ displays an intense emission band at 408 nm only with a shoulder at 460 nm.[17] Despite previous studies,[18] we believe that this is the first observation of an emissive metal→π*(carbene) CT excited state in solution at room temperature. The long lifetime and high energy (ca. 2.8 eV, E_{0-0} taken as 450 nm) of the excited state imply that these platinum(II) species can undergo bimolecular photoreactions, and preliminary results confirm that the emission of **2** is quenched by *N*,*N*′-dimethyl-4,4′-bipyridinium hexafluorophosphate in dichloromethane. Future work will be directed towards probing the excited state reactivities of carbene complexes by utilizing the MLCT emission of the platinum(II) carbene moiety.

Experimental Section

2: A solution of $K_2[PtCl_4]$ (0.20 g, 0.48 mmol), *tert*-butyl isocyanide (0.20 mL, 1.93 mmol), and hydrazine hydrate (0.10 mL, 2.06 mmol) in water was heated to reflux for 1 h. The volatile components were removed in vacuo, and the residue was extracted with acetonitrile/diethyl ether. Slow evaporation of this solution at 5 °C yielded yellow crystals (yield 32 %). ^{1}H NMR (300 MHz, $CDCl_3$, 27 °C): $\delta = 1.40$ (s, *t*Bu); IR (Nujol): $\tilde{\nu} = 3453$, 3412 (N–H); 2141 (C≡N); 1562, 1535 cm^{-1} (C=N); UV/Vis (methanol): λ_{max} (ε) = 238 (95000), 288 (68000), 316 (22000), 356 nm (18000); FAB-MS: *m/z* (%) = 2510 (100) $[Pt(CN)(C_{10}H_{21}N_4)]_6^+$, 1255 (50) $[Pt(CN)(C_{10}H_{21}N_4)]_3^+$. Satisfactory elemental analysis.

[10] Crystal data for **2**: $C_{66}H_{126}N_{30}Pt_6 \cdot 10\,CH_3CN$; M = 2920.94, triclinic, space group $P\bar{1}$ (no. 2), $a = 14.713(6)$, $b = 18.186(6)$, $c = 14.042(8)$ Å, $\alpha = 101.03(3)$, $\beta = 105.84(4)$, $\gamma = 113.83(3)°$, $V = 3106(2)$ Å^3, $Z = 1$, $\rho_{calcd} = 1.561$ g cm^{-3}, $\mu = 67.55$ cm^{-1}, $F(000) = 1420$, $T = 301$ K. A yellow crystal of dimensions $0.25 \times 0.20 \times 0.35$ mm^3 was used for data collection at 301 K on a Rigaku AFC7R diffractometer (graphite-monochromatized $Mo_{K\alpha}$ radiation; $\lambda = 0.71073$ Å), ω-2θ scan mode, ω-scan angle $(0.73+0.35 \tan\theta)°$, scan speed 16.0° min^{-1} (up to six scans for reflections with $I < 15\sigma(I)$). Measurement range: $2\theta_{max} = 46°$; *h*: 0 to 16; *k*: −19 to 19; *l*: −15 to 15. Three standard reflections were measured after every 300 reflections and showed a decay of 3.74 %. The intensity data were corrected for decay, Lorentz, and polarization effects, and empirical absorption corrections based on the ψ scan of six strong reflections (min./max. transmission factors 0.671/1.000) were made. Of 9041 reflections measured, 8644 were unique with $R_{int} = 0.026$. 5738 reflections with $I > 3\sigma(I)$ were considered observed and used in the structural analysis. The structure was solved by Patterson methods, expanded by Fourier methods (PATTY), and refined by full-matrix least squares with the software package TeXsan on a Silicon Graphics Indy computer. The crystallographic asymmetric unit consists of one half of the complex molecule and five molecules of acetonitrile. The six CN groups forming the 18-membered ring system were disordered; all the atomic sites were occupied half by N atoms and half by C atoms. Atoms N(1) to N(6) and C(1) to C(6) were refined isotropically with occupation numbers of 0.5, whereby the positions and thermal parameters of the C atoms were constrained to those of the corresponding N atoms (i.e. N/C(1) to N/C(6)). The C and N atoms of the five solvent molecules had large temperature factors and were also refined isotropically. The other non-hydrogen atoms of the complex were refined anisotropically. The hydrogen atoms bonded to the N atoms of the ligand molecules were not located in difference Fourier synthesis. The other 69 H atoms (including solvent) were introduced at calculated positions with thermal parameters equal to 1.3 times that of the attached C atoms and were not refined. Convergence for 490 variable parameters by least-squares refinement on *F* with $w = 4F_o^2/\sigma^2(F_o^2)$ ($\sigma^2(F_o^2) = [\sigma^2(I) + (0.035F_o^2)^2]$) for 5738 reflections with $I > 3\sigma(I)$ was reached at $R = 0.038$ and $wR = 0.056$ and GOF = 1.67. $(\Delta/\sigma)_{max.} = 0.04$ for atoms of the complex. The final difference Fourier map was featureless with maximum positive and negative peaks of 2.40 and −0.71 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100633. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code + (44) 1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

A Convergent Route for the Total Synthesis of the Eleuthesides**

Xiao-Tao Chen, Clare E. Gutteridge, Samit K. Bhattacharya, Bishan Zhou, Thomas R. R. Pettus, Tony Hascall, and Samuel J. Danishefsky*

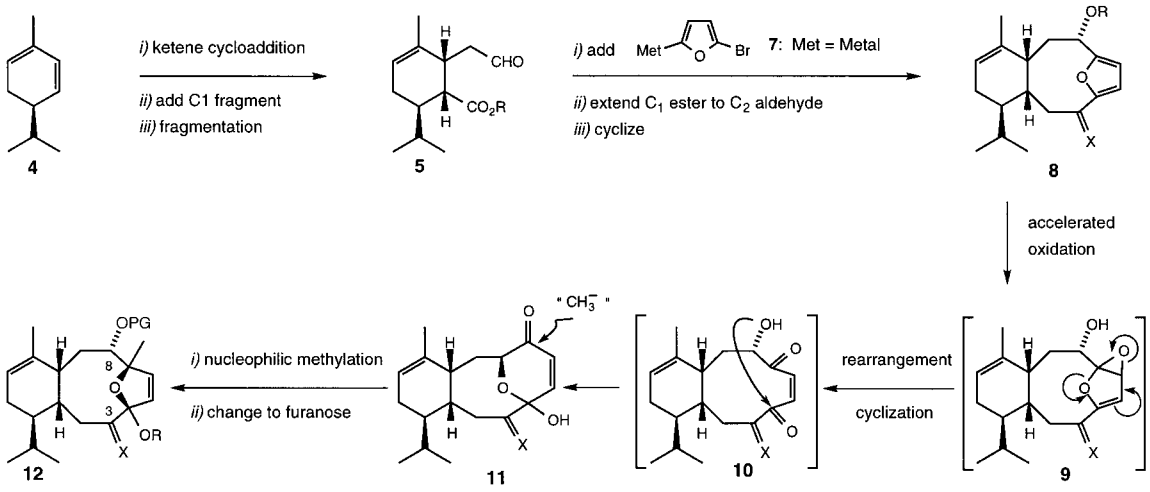
The marine environment is taking its place beside plant sources and fermentation in providing access to biologically active substances.[1] From the standpoint of organic chemistry, the aquatic biomass warrants particularly close attention, due to the richly varied structures provided therein. Moreover, the reliability of marine feedstocks as a bulk source of natural products is often less than the case with their plant and microbially derived counterparts. Hence, marine-derived natural products may well furnish excellent opportunities for the subspecialty of synthesis.

Such an opportunity is presented by a group of structurally related natural products, which we loosely group under the term "eleuthesides" (e.g. eleutherobin (**1**),[2] sarcodictyin (**2**),[3] and valdivone (**3**)[4]). These are each isolated from different marine sources. Interest in the family was considerably heightened by the recent report by Fenical et al.[2] that eleutherobin displays excellent potency in a variety of tumor cell lines and that the mechanism of its cytotoxicity involves inhibition of microtubule disassembly. Thus, at least eleutherobin (**1**), manifests a taxol—epothilone—discodermolide mode of action.[5] In light of the very interesting structures of these closely related compounds, the high potency of **1,** and the difficult availability of all of the eleuthesides from their natural habitats, this family presents a challenging opportunity for creative chemistry.

Given the discussion above, we defined the criteria for success in our synthetic venture as going beyond the completion of a ceremonial level route to the natural products. Rather, the substantive goal is that of providing significant quantities of end products for thorough biological scrutiny in the context of a detailed SAR (structure – activity relationship) investigation. An account of the attainment of a flexible and convergent synthesis of the eleuthesides is provided herein.

The underlying logic of our scheme, in qualitative terms, is implicit in Scheme 1. Reference to this scheme will identify the stages of the synthesis subsequently documented in Scheme 2 (vide infra). The chiral matrix material selected for elaboration is the readily available *R*-(−)-α-phellandrene (**4**).[6] This compound undergoes cycloaddition with a ketene derivative (dichloroketene). A C1 fragment is then appended to the modified cyclobutanone cycloadduct, and the ring is fragmented to produce a system of the type **5** with differentiated arms for subsequent elaboration.

A furanoid building block (2,5-dibromofuran (**6**)[7]) provides system **7** as a nucleophile. The remaining furyl – bromine bond constitutes a latent form of carbon nucleophilicity, to be exploited later (vide infra). In the first coupling event, system **7** is delivered to the aldehyde function of **5**. Next, the "arm" extending from the C1 ester linkage is expanded by one carbon through a cyanation reaction. An eventual acetaldehyde appendage is coupled to the "bromofuryl" carbon (C4), producing a compound of type **8**, a highly strained 2,5-furano[6]phane. In this construction, the two benzylic oxygen functions at C8 and C3 in **8,** are presented in differentiated forms. The free hydroxyl group at C8 (R = H) accelerates oxidation of the proximal furan. Following bond reorganization (**9** → **10**), ring formation between the hydroxyl and appropriate keto group leads to a pyranose of the type **11**. In this system, the C7 keto group, destined for nucleophilic methylation, has been uniquely identified. Moreover, in **11**, the setting for entry of the methyl group in the desired stereochemical sense has been established, since reaction would be directed *anti* to the more sterically demanding five-membered carbon bridge. Following suitable manipulations, the pyranose ring in **11** is rearranged to a furanose, thereby exposing the two oxygen atoms projecting from C3 and C8 of the skeleton in differentiated form (see compound **12**).



The actual steps employed for building the eleutheside are summarized in Scheme 2. To be noted here is the regiospecificity of the cycloaddition of dichloroketene to **4** (the stereoselectivity is 9:1 in favor of the shown isomer **13**).[8] The product (**14**) resulting from the dechlorination of the initial cycloadduct (**13**) is subjected to a Bredereck-type trans-

formation, leading to **15**.[9] An elegant and little appreciated acid-catalyzed fragmentation of the cyclobutanone[8, 9] exposes a formyl group and a methyl ester; the carbonyl carbon atoms of the product **16** correspond to C2 and C8 of the eleutheside. We have found that 2,5-dibromofuran (**6**) can be monolithiated; the resulting, interesting organolithium compound **7** (Met = Li) can be appended to **16** to give compound **17** and its redeemable C8 epimer, **17a**. Following suitable protection of the hydroxyl group, **18** was obtained.[10] At this point, the one-carbon ester in **18** was expanded to a two-carbon aldehyde (see compound **19**), in which the formyl carbon corresponds to the eventual C3 of the eleuthesides. The critical step leading to the metacyclophane **20** was a remarkable and stereoselective Nozaki – Kishi[11] reaction. The hydroxyl group at the future C3 was protected as its pivaloate ester (cf. **21**).

The groundwork was now secure to move on to construction of the eleutheside skeleton. After removal of the silyl

protecting group, treatment of **22** with dimethyldioxirane generates presumably an epoxide of type **9** (X = H, OPiv; see Scheme 1). Following suitable bond reorganizations, passing through presumed diketone type **10**, the pyranose derivative **23** was in hand. The predicted stereoselective nucleophilic methylation of the keto function was achieved with methyllithium, giving rise to **24**. On treatment of the latter compound with acetic anhydride, we took advantage of the fact that the masked secondary alcohol at C8 could be selectively acetylated. This paved the way for cyclization of the tertiary alcohol (corresponding to C7 of the future eleutheside) into the carbonyl group of the enone of the open form, leading to formation of compound **25**. All structural assignments asserted thus far, were corroborated by an X-ray crystallographic determination of **25** (Figure 1).[12] Compound **25** has been

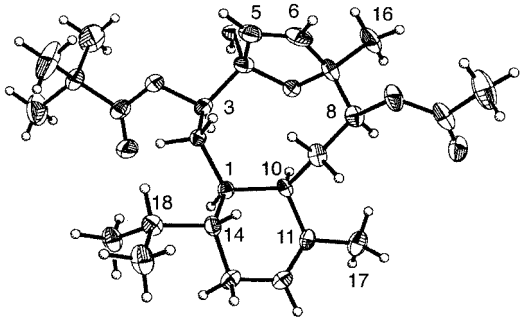

Figure 1. Crystal structure of **25**.

advanced in several directions, including the generation of the flexible platform compound, ketone **26**.

In summary, the novel chemical steps of particular interest are: 1. the elongation and fragmentation of cyclobutanone **14**, 2. the viability of 2-lithio-5-bromofuran as a readily available and functionally differentiated furano nucleophile **7**, 3. the Nozaki–Kishi reaction creating a highly strained cyclophane (**19** → **20**), and 4. the oxidative and ring–chain tautomerism manipulations leading to the differentiated eleutheside **25**. Preparations of the natural products and congeners for SAR purposes are well underway.[13,14]

Total Synthesis of Altohyrtin A (Spongistatin 1): Part 1**

Jiasheng Guo, Kevin J. Duffy, Kirk L. Stevens, Peter I. Dalko, Rebecca M. Roth, Matthew M. Hayward, and Yoshito Kishi*

In 1993 three groups independently reported the isolation and structural elucidation of a new class of macrolides (spongipyran) derived from marine sponges of the genus *Spongia*[1] and *Spirastrella*[2] (spongistatins 1 through 9), *Cinachyra*[3] (cinachyrolide A), and *Hyrtios*[4] (altohyrtins A–C). These compounds displayed extraordinarily potent cytotoxicity against a wide variety of cancer cell lines.[5, 6] Structurally, spongistatin 1 appeared to be identical to altohyrtin A and spongistatin 4 to cinachyrolide A, although no definitive proof had been previously presented. The Kitagawa group has proposed the complete structure of altohyrtin A[4c] to be that shown in structure **1**. However, this structure is in conflict with the relative configuration proposed by the Pettit[2b] and Fusetani[3] groups. In this and the following communication, we report the first total synthesis of altohyr-

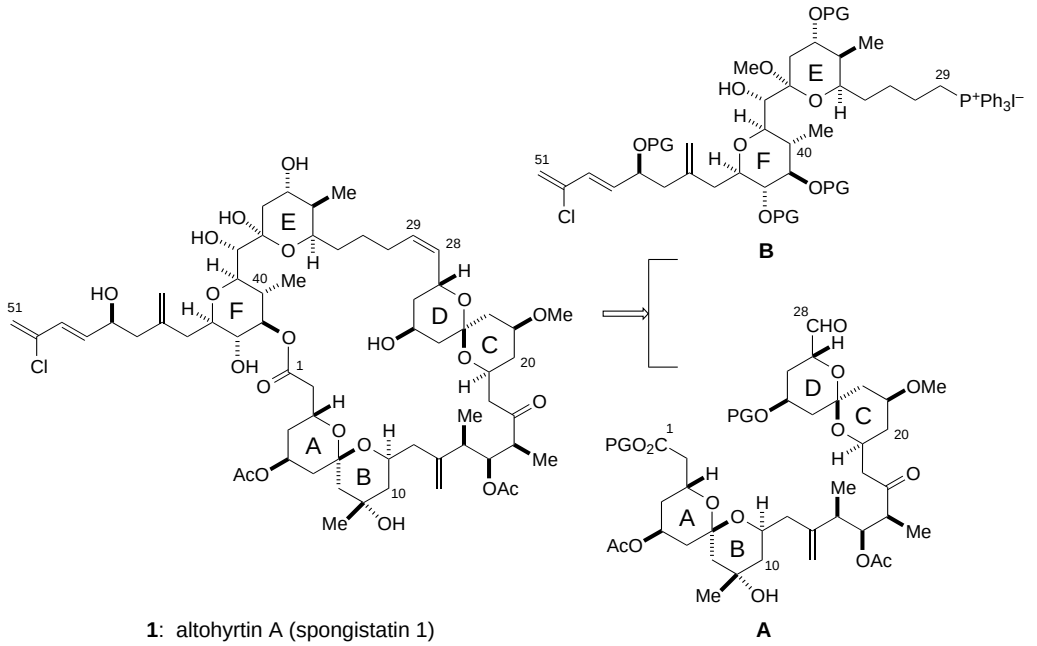

Figure 1. Retrosynthesis of altohyrtin A (spongistatin 1). PG = protecting group.

tin A (spongistatin 1), which firmly establishes the relative and absolute configuration proposed by Kitagawa.

All of the members in this class of natural products contain a 51-carbon chain, 6 pyran rings, and a 42-membered lactone ring. In addition, the most potent congeners (spongistatins 1, 4, 5, and 9)[5, 6] contain the novel chlorodiene functionality, which had neither been seen in a natural product nor synthesized before. We chose altohyrtin A (spongistatin 1) as our synthetic target, due to its historical position in this class of natural products, the availability of spectroscopic data from two independent research groups, and finally its position as the most cytotoxic congener. Several synthetic approaches to the spongipyran class of natural products have been reported,[7] and most recently a beautiful total synthesis of altohyrtin C (spongistatin 2) has been completed by Evans et al.[8]

Upon close examination of the spectroscopic data on spongipyrans disclosed by the three groups, it became evident that the correct relative and absolute configuration of altohyrtin A was most likely that proposed by Kitagawa,[4c] and thus we chose altohyrtin A (**1**) as the target for our total synthesis.[9] In the retrosynthetic analysis, **1** was dissected into the two segments **A** and **B** which could be joined by Wittig olefination of the C29 phosphonium salt with the C28 aldehyde and subsequent macrolactonization of the C1 carboxylic acid with the C41 alcohol (Figure 1). It might be expected that, to effect the proposed macrolactonization selectively, the C41 alcohol must be differentiated from the remaining alcohols, particularly the C42 alcohol. However, we recognized the possibility that such macrolactonization might take place preferentially at the C41 alcohol under controlled conditions. Therefore, we chose to leave the C41 and C42 alcohols undifferentiated for synthetic simplicity.

Based on the precedents gained in the halichondrins[10] and the polyether antibiotic (−)-A23187[11] syntheses, **A** was envisioned to arise from the intramolecular Michael addition of enone **C** (Figure 2). Enone **C** could be realized from the

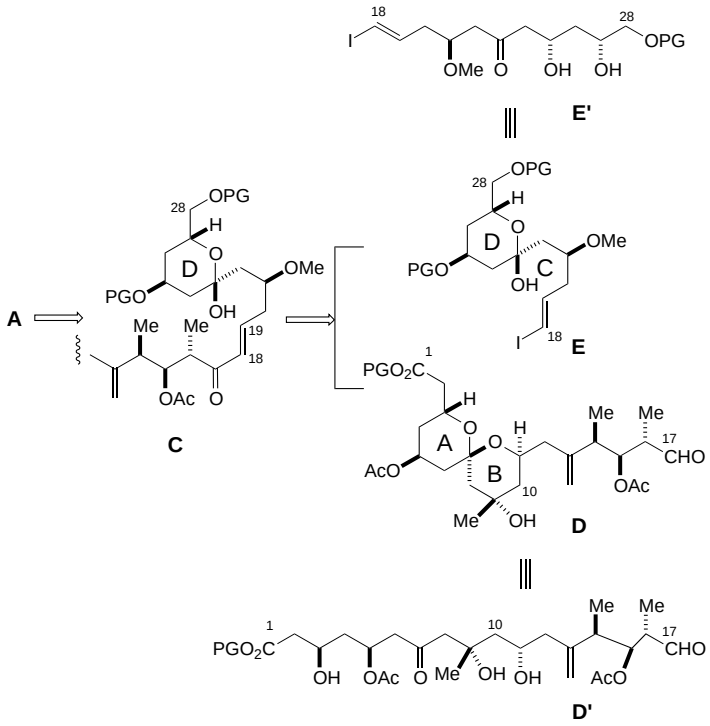

Figure 2. Retrosynthesis of the C1 – C28 fragment.

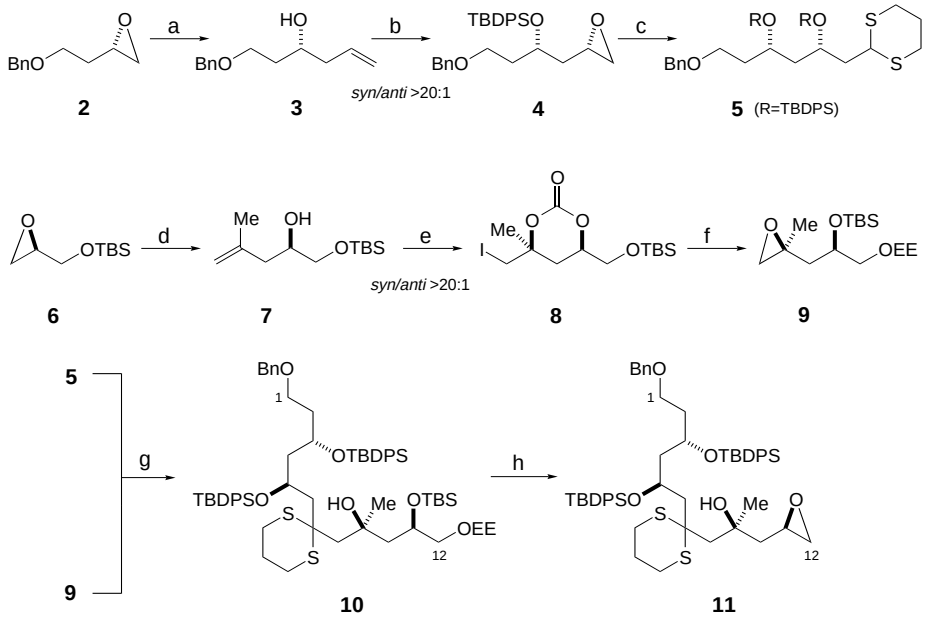
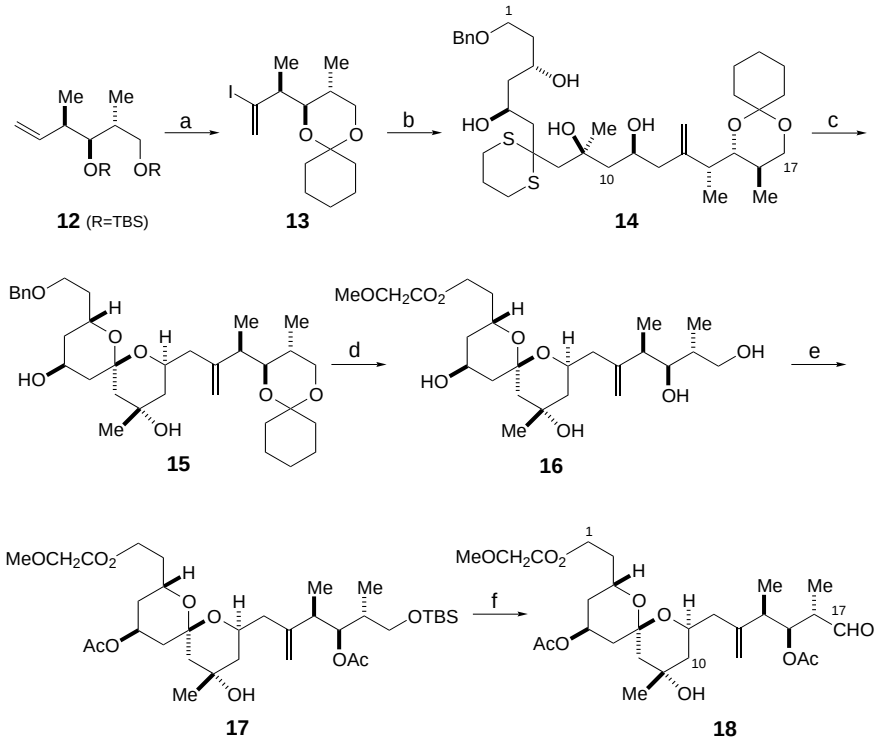


Ni^{II}/Cr^{II}-mediated coupling[12] between fragments **D** and **E**, followed by oxidation. The two building blocks **D** and **E** thus obtained should be synthetically equivalent to their open forms **D′** and **E′**. Two structural characteristics present in both **D′** and **E′** are noteworthy. A typical polypropionate structure is apparent in the C14 – C17 unit, while a 1,3-*syn*-diol structure is found repeatedly in the C3 – C5, C9 – C11, and C25 – C27 units. The synthesis of these functionalities has been studied extensively over the past few decades. We anticipated that, coupled with a well-precedented regioselective ring-opening

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3701-0188 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 1/2



of terminal epoxides with nucleophiles, the synthesis of **D**′ and **E**′ could be achieved by a combination of these methods.

Along this line of analysis, the C1 – C12 segment was synthesized as summarized in Scheme 1.[13, 14] The two key reactions in this sequence were 1) regioselective ring-opening of terminal epoxides with vinyl cuprates and dithiane anions, and 2) stereoselective iodocarbonylation under the conditions developed by Smith et al.,[15] followed by base treatment to furnish the subsequent terminal epoxide.

The C13 – C17 segment **13** was prepared from the known alkene **12**[16] (Scheme 2). The C12 – C13 bond formation was realized by ring opening of **11** with the higher order 2-thienyl

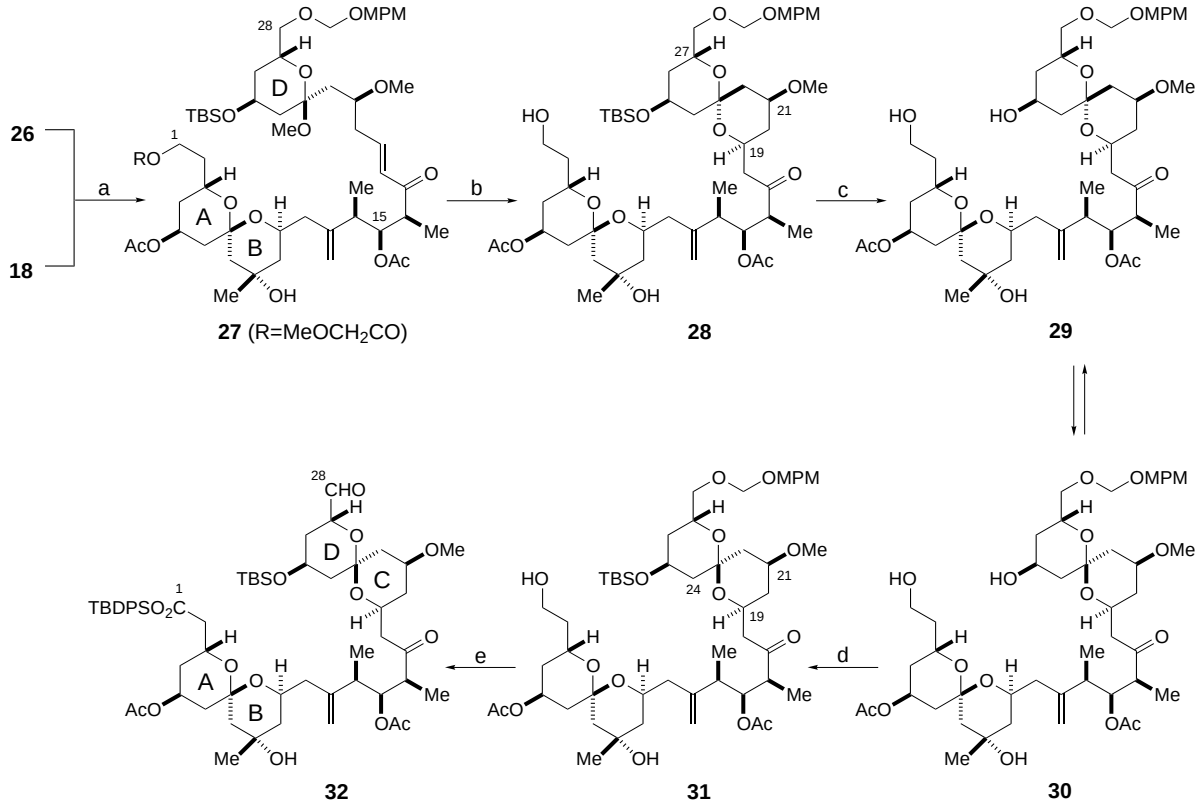
cyanocuprate[17] derived from **13**, to yield the diol. After cleavage of the silyl protecting groups, **14** was subjected to NIS-induced dithiane deprotection to form the single spiroketal **15** in good overall yield. Based on literature precedent,[18] we anticipated spiroketal formation to be stereoselective in the desired sense; indeed, NOE experiments (NOE = nuclear Overhauser enhancement) confirmed this configuration at the spirocenter. By routine synthetic operations the protecting groups of alcohols in **15** were then adjusted resulting in tetraol **16**. The protecting groups at the C1 and C17 primary alcohols were differentiated, and the C9 tertiary alcohol was left unprotected. Since the requisite C5 and C15 acetates were compatible with the remaining synthetic operations, they were installed at this juncture.[19] The C15 acetyl group was found to migrate readily to the C17 primary alcohol once the TBS protecting group was removed. Therefore, the C17 alcohol generated from **17** was immediately subjected without purification to Dess–Martin oxidation[20] to furnish aldehyde **18**.

Scheme 3 summarizes the synthesis of the *trans* vinyl iodide **26**.[21] The key reactions used in this sequence were fundamentally the same as those described for the synthesis of the C1–C17 segment. However, several comments are in order.

Scheme 3. Synthesis of the C18–C28 fragment: a) Et_3N, TBSCl, DMAP, CH_2Cl_2, 90%; 1,3-dithiane, *n*BuLi, THF, −20°C, then DMPU, then epoxide, THF, −78 → −20°C, 83%; TBAF, THF, quant.; NaH, THF, 0°C, Ts-im, 0°C, 79%; b) CuCN, vinyllithium, −78°C, then **20**, THF, −20 → 0°C, 85%; NaH, MeI, THF, 0°C, 90%; c) Et_3N, TBDPSCl, DMAP, CH_2Cl_2, 90%; CuCN, vinyllithium, −78°C, then epoxide, Et_2O, −30 → 0°C, 92%; *n*BuLi, Et_2O, BOC–ON, THF, −78 → 20°C, 96%; IBr, PhMe, −78 → 0°C, 78%; d) K_2CO_3, MeOH, 78%; imidazole, TBDPSCl, CH_2Cl_2, 91%; e) *t*BuONa, *n*BuLi, pentane, 0 → 20°C, then −78°C, **21**, THF, −78°C, then **23**, THF, −78 → −20°C, 54% and 44% recovered **23**; f) TBAF, THF, 0°C, 92%; Et_3N, TBDPSCl, DMAP, CH_2Cl_2, 72%; NIS, $CaCO_3$, MeOH, 0°C, 78%; imidazole, TBDPSCl, CH_2Cl_2, 86%; NMO, OsO_4, acetone/H_2O; $NaIO_4$, MeOH/(pH 7 phosphate buffer), 0 → 20°C; DAMP, *t*BuOK, THF, −78°C, then aldehyde, THF, −78°C, 79% over 3 steps; g) nBu_3SnH, AIBN, toluene, 105°C, 67%; $CaCO_3$, NIS, THF, quant.; TBAF, THF, 92%; iPr_2NEt, $MPMOCH_2Cl$,[36] CH_2Cl_2, 98%; TBAF, THF, quant.; imidazole, TBSCl, CH_2Cl_2, 99%.

First, while ring-opening of **20** was accomplished with the anion of TMS-acetylene allowing earlier incorporation of the alkyne moiety, clean lithiation of the resultant dithiane proved difficult. Second, deprotection of the dithiane group (step f) resulted in a single methyl ketal, whose configuration was tentatively assigned as indicated but was not established experimentally. Third, the hydrostannylation of **25**, followed by NIS treatment, yielded mainly the expected product, along with a small amount of its regio- and stereoisomers. Finally, the C25 TBDPS protecting group was required for efficient synthesis of **25** but the final deprotection to form altohyrtin A (**1**) necessitated substitution to the more labile TBS protecting group.



The completion of the synthesis of **32** is illustrated in Scheme 4. The Ni^{II}/Cr^{II}-mediated coupling[12] of **26** with **18** proceeded smoothly to yield the two expected allylic alcohols, which were oxidized to α,β-unsaturated ketone **27**. After hydrolysis to the C23 hemiketal, the crucial intramolecular Michael cyclization was effected with Triton-B to furnish spiroketal **28** with concomitant deprotection of the C1 methoxyacetate.[22] Out of four possible products, only one diastereomer was isolated. ROESY data on the C1 TBS ether of **28** clearly demonstrated the C19 stereocenter to be desired but the C23 spirostereocenter to be undesired.[23, 24] In light of recent work by Heathcock,[7b] the stereochemical outcome at this spirocenter was not surprising. This stereocenter was configurationally stable under acidic conditions with a protected C25 alcohol, but was expected to epimerize readily if the C25 alcohol was deprotected.[7b] Indeed, deprotection of **28** with HF · py in CH_3CN provided a separable 1:1 mixture of desired C23 diastereomer **30** and undesired **29**, which could be recycled efficiently under acidic conditions (HF · py/CH_3CN or CSA/CH_2Cl_2). Reprotection of the C1 and C25 alcohols with TBSOTf proceeded without compromising the integrity of C23 spiroketal stereocenter.

NMR (NOE) data on the C1 TBS-ether of **31** clearly demonstrated the desired configurations at C19 and C23.[23,24] Selective deprotection of the C1 TBS group, followed by TPAP[25] oxidation, $NaClO_2$[26] oxidation, TBDPSCl protection,[27] and finally cleavage of the C28 protecting group with DDQ[28] furnished the desired product. Interestingly, a small amount of the C23 epimeric spiroketal was isolated during the DDQ deprotection step. Finally, Dess–Martin oxidation of the C28 primary alcohol furnished **32**, the ABCD unit of the target.

Using the methods disclosed in the following communication, we completed the total synthesis of the C23 epimer of altohyrtin A from intermediate **28** with the hope that the C23 stereocenter might be equilibrated to the natural configuration. Although both altohyrtin A and its C23 epimer were relatively stable under acidic conditions (HF · py/THF, CSA/CH_2Cl_2, or HCl/$CHCl_3$), there was no evidence of inversion at the C23 stereocenter.[29] This experiment demonstrated that the macrolactone prevents epimerization at the C23 position, suggesting that the correct C23 configuration must be installed prior to macrolactonization.

[19] Careful planning of the protecting group sequence allowed incorporation of an acetate on both the C5 and C15 alcohols (spongistatin 1) or only on the C5 alcohol (spongistatin 4). Protection of the C9 tertiary alcohol was also possible with silyl groups.

[20] D. B. Dess, J. C. Martin, *J. Org. Chem.* **1983**, *48*, 4155 – 4156.

[21] The *cis* vinyl iodide corresponding to **26** might be suitable for the following key Michael cyclization, though this was not tested.

[22] The yields (50% to 80%) for the hydrolysis and subsequent Michael addition depended on the protecting group arrangement. A substrate bearing TBS groups on the C5, C9, and C15 alcohols and TBDPS on the C25 alcohol gave the best result. One of the by-products isolated in the case of **27** was the α,β-unsaturated ketone resulting from elimination of the C15 acetate.

[23] These experiments were performed by Dr. Yuan Wang at Eisai Research Institute, Andover, Massachussetts.

[24] For the C1 TBS ether of **28**, distinct NOEs between the C19 and C21 protons and between the C27 and C22(eq) protons were observed. For the C1 TBS ether of **31**, distinct NOEs between the C19 and C21 protons and between the C19 and C24(eq) protons were observed.

Total Synthesis of Altohyrtin A (Spongistatin 1): Part 2**

Matthew M. Hayward, Rebecca M. Roth, Kevin J. Duffy, Peter I. Dalko, Kirk L. Stevens, Jiasheng Guo, and Yoshito Kishi*

In the preceding communication we reported the synthesis of the ABCD unit of altohyrtin A.[1] We will now present the synthesis of the EF unit and the completion of a total synthesis of altohyrtin A.

The first step in the retrosynthetic analysis of EF fragment **B** was the C37 – C38 bond disconnection. In the synthetic direction, it was expected that this bond formation could be realized by nucleophilic addition of glycal carbanion **F** to C38 aldehyde **G**, followed by acid-catalyzed methanolysis of the resultant glycal. Fragment **G** was then disconnected into carbanion **I** and glycal epoxide **H**, which should be available from the corresponding glycal **J**.[2] We were particularly interested in this disconnection strategy because of the obvious structural similarity between **F** and **J**; **F** and **J** might be synthesized with similar chemistry or even via a common intermediate. These glycals could be prepared from the corresponding acyclic precursors **F′** and **J′**, which contain a typical polypropionate/acetate arrangement of functional groups. Among the many synthetic methods known for the preparation of polypropionates/acetates, the chemistry developed by Roush et al.[3] and by Brown et al.[4] were chosen. The proposed carbanion **I**, or its synthetic precursor, contained the novel chlorodiene functionality which, to the best of our knowledge, had never been synthesized before. It was anticipated that the chlorodiene moiety could be incorporated by the addition of an organometallic species, derived from 2,3-dichloropropene, to aldehyde **L**, followed by dehydration.

As illustrated in Scheme 1, the E-ring building block was synthesized by utilizing sequential crotyl- and allyl-boronate chemistry.[5, 6] While both the Brown and Roush methods gave the desired adducts, the Brown methodology was superior in terms of stereoselectivity. After protection of the C35 alcohol of **5** and cleavage of the C33 benzyl protecting group, **6** was transformed into glycal **7** by means of a β-ketoester to facilitate the thermally induced elimination. Finally, glycal **7** was converted into iodoglycal **8** with the method developed by Freisen;[7] the TIPS protecting groups at C29 and C35 were required for clean lithiation of the glycal. Alternatively, **6** was

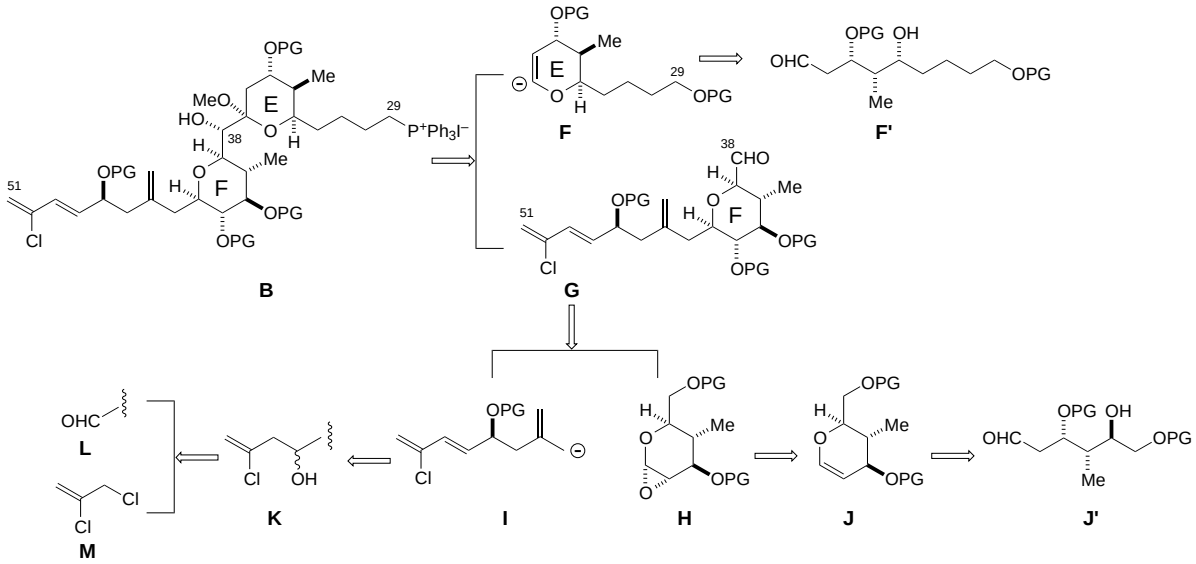

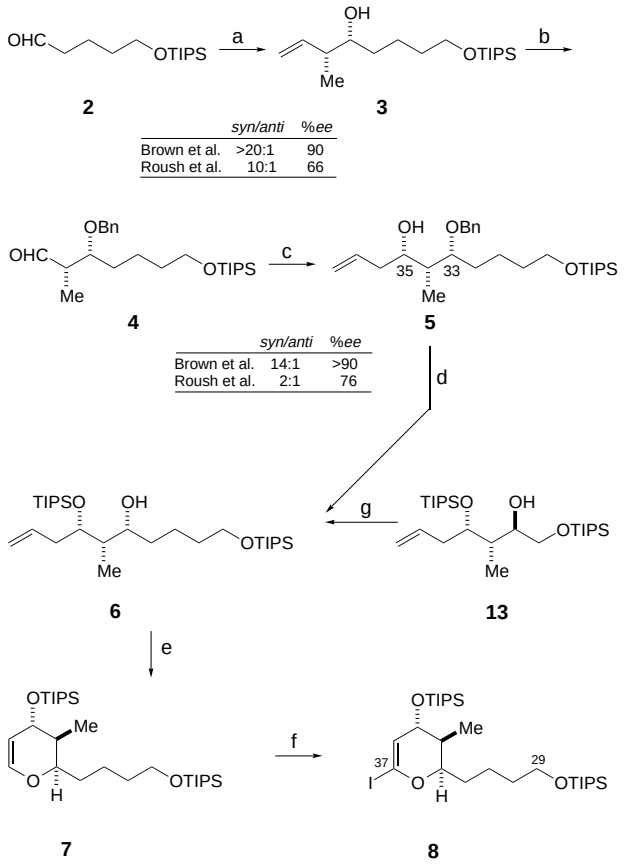

Figure. 1. Retrosynthesis of the C29 – C51 fragment (EF unit). PG = protecting group.

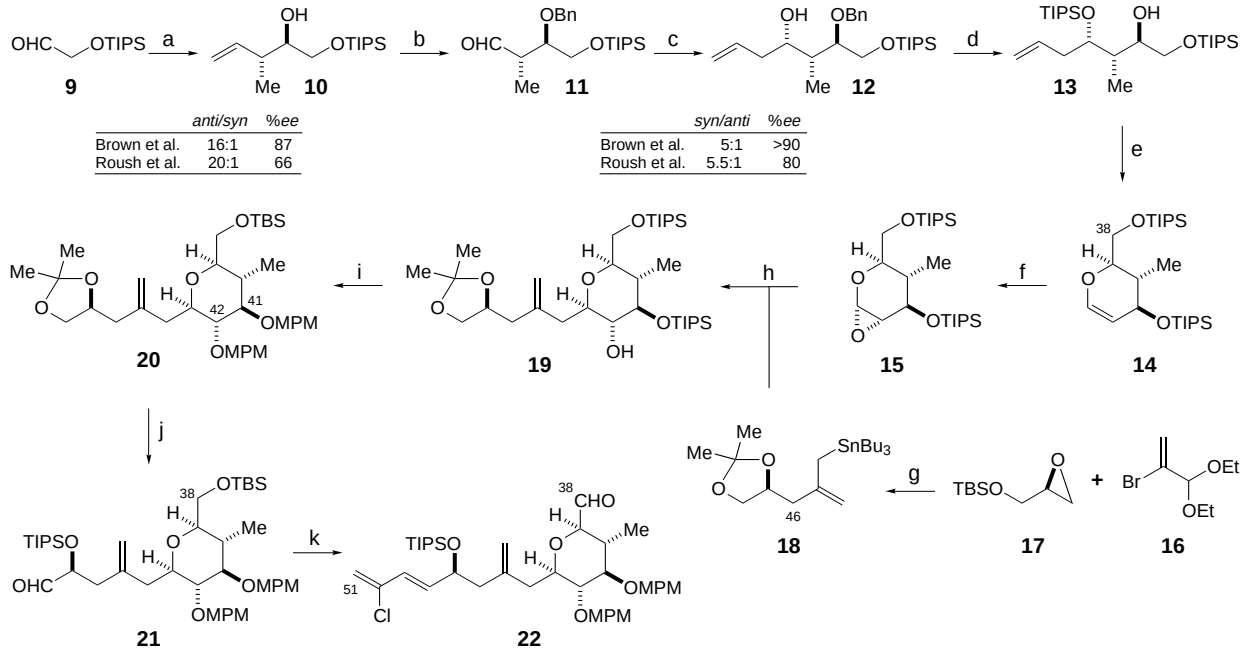
Scheme 1. Synthesis of the C29 – C37 fragment: a) (−)-Ipc$_2$-(*Z*)-crotyl boronate,[4b] THF, −78°C, 65%; b) NaH, BnBr, TBAI, THF, 0→20°C, 97%; NMO, OsO_4, THF/H_2O; $NaIO_4$, MeOH/H_2O, 0→20°C; c) (−)-Ipc$_2$-allyl boronate,[4a] PhMe, −78°C, 64% over 3 steps; d) 2,6-lutidine, TIPSOTf, CH_2Cl_2, 0→20°C; Li/NH_3, THF, −78°C, 81% over 2 steps; e) NMO, OsO_4, THF/H_2O; $NaIO_4$, MeOH/H_2O, 0→20°C; Et_3N, diketene acetone adduct, hexanes, 70°C; 125°C, 0.2 Torr, 54% over 4 steps; f) *t*BuLi, THF, −78→−30°C, then Bu_3SnCl, −78→20°C; K_2CO_3, NIS, THF, 0°C, 75% over 2 steps; g) Et_3N, MsCl, Et_2O; HF·py/py/THF, 61% over 2 steps (an additional 15% was obtained by recycling the bis-silylated starting material once); KOH, MeOH, 92%; sulfone,[30] *n*BuLi, −78→20°C, 87%; Li/NH_3, THF, −78°C, 85%.

also obtained from intermediate **13**, used in the F-ring synthesis (Scheme 2).



The same methods were used to construct the F-ring building block **14**. The TIPS protecting groups for the C38 and C41 alcohol in glycal **14** enhanced the stereoselectivity of epoxidation with DMDO;[2] only epoxide **15** was detected by ^{1}H NMR.

The synthesis of C44 – C48 segment **18** is also included in Scheme 2.[8] The C45 – C46 bond was formed by cuprate coupling between α-bromoacrolein diethyl ketal **16**[9] and (*R*)-TBS-glycidol **17** to afford the homoallylic alcohol. Acid treatment in acetone allowed concomitant deprotection of the TBS ether, formation of the acetonide, and hydrolysis of the acetal to form the α,β-unsaturated aldehyde, which was transformed into the allylstannane **18** in three steps.

Simple alkyl cuprate addition to a glycal epoxide was first reported by this group.[10] The present case required the addition of a highly functionalized allylic derivative. Although methallyl cuprates readily added to **15**, allyl cuprates bearing the C47 and C48 functionalities exhibited greatly diminished reactivity towards epoxide **15**. Among a variety of allylstannanes prepared and tested, only acetonide allylstannane **18** gave satisfactory results. While an excess of **18** was required to drive the reaction to completion, it was readily recovered from the crude reaction mixture. In this fashion, **19** was obtained in good yield with high stereoselectivity. As noted previously,[1] the C41 and C42 alcohols were masked with identical protecting groups followed by manipulation at C47 and C48 to allow for oxidation to aldehyde **21**.

Although no methodology existed to install the chlorodiene, it was known that allylindium species prepared from allylic halides react with aldehydes under mild conditions.[11] Coupling of the allylindium reagent derived from 2,3-dichloropropene[12] with aldehyde **21** cleanly afforded the two homoallylic alcohols, which were then dehydrated with Martin's sulfurane[13] to afford exclusively the *trans*-chlorodiene in high overall yield. Cleavage of the C38 TBS protecting group, followed by Swern oxidation of the primary alcohol, furnished aldehyde **22**.

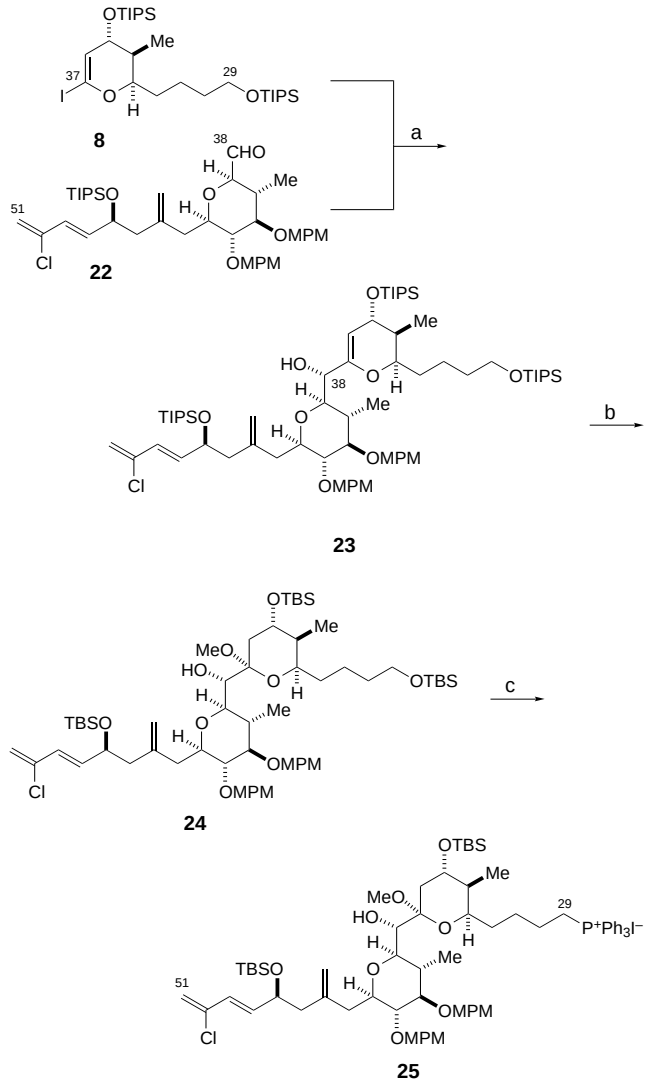
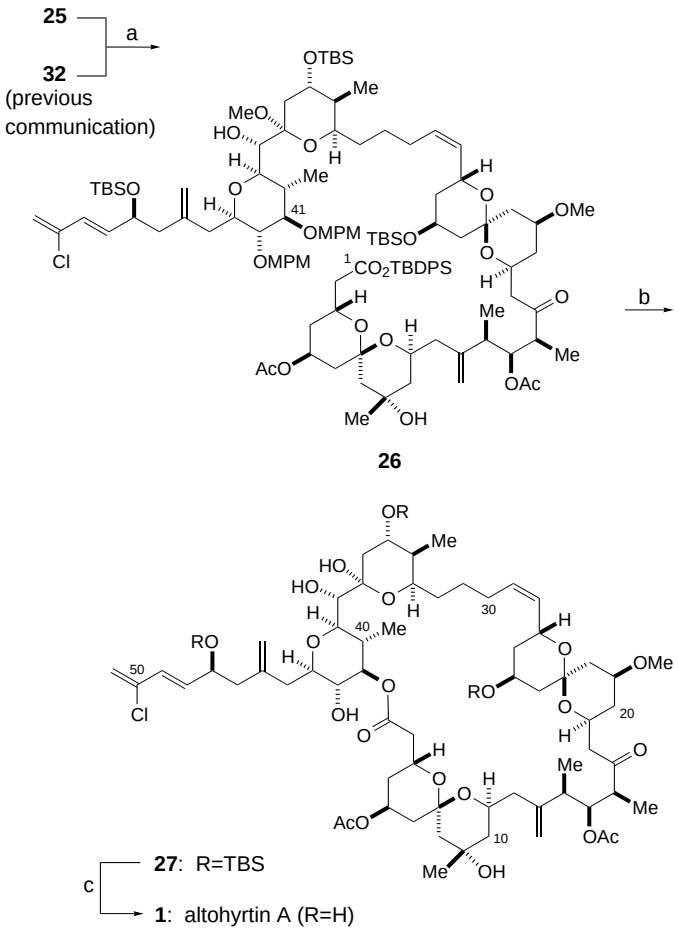


Scheme 2. Synthesis of the C38–C51 fragment: a) (*S*,*S*)-diisopropyl-(*E*)-crotyl boronate,[3b] PhMe, −78°C, 80%; b) NaH, BnBr, TBAI, THF, 0→20°C, 84%; NMO, OsO_4, THF/H_2O; $NaIO_4$, MeOH/H_2O, 0→20°C; c) (*R*,*R*)-diisopropyl-allyl boronate,[3a] PhMe, −78°C, 74% over 3 steps; d) 2,6-lutidine, TIPSOTf, CH_2Cl_2, 0→20°C; Li/NH_3, THF, −78°C, 80% over 2 steps; e) NMO, OsO_4, THF/H_2O; $NaIO_4$, MeOH/H_2O, 0→20°C; Et_3N, diketene acetone adduct, hexanes, 70°C; 125°C, 0.2 Torr, 61% over 4 steps; f) DMDO,[31] CH_2Cl_2/acetone, −10°C, quant.; g) **16**, *n*BuLi, Et_2O, −78°C, then CuI, Et_2O, −78°C, then **17**, −78→20°C, 65%; TsOH·H_2O, acetone, 64%; $CeCl_3 \cdot H_2O$, CH_2Cl_2/MeOH, then −78°C, $NaBH_4$, 83%; Ph_3P, NCS, CH_2Cl_2, 0°C, 95%; Bu_3SnLi,[32] THF, −78°C, 81%; h) $Me_2Cu(CN)Li_2$, **18**, 0°C, then **15**, −43→−15°C, 70%;[33] i) TBAF, THF, quant.; TBSCl, DMAP, CH_2Cl_2/Et_3N, 91%; KH, MPMCl, DMF/THF, 0→20°C, 81%; j) $ZnBr_2$, H_2O, CH_2Cl_2, 56% and an additonal 5% on resubmission of recovered starting material; PivCl, DMAP, CH_2Cl_2/py, 80%; 2,6-lutidine, TIPSOTf, CH_2Cl_2, 91%; LAH, THF, −78°C, 61% and an additonal 6% on resubmission of recovered starting material; oxalyl chloride, DMSO, CH_2Cl_2, −78°C, Et_3N, −78→0°C, 95%; k) In, 2,3-dichloropropene, NaI, DMF, then **21**; Martin's sulfurane, CH_2Cl_2, 85% over 2 steps; HF·py/py/THF, 76% and an additonal 10% on resubmission of recovered starting material; oxalyl chloride, DMSO, CH_2Cl_2, −78°C, 10 min, alcohol, Et_3N, −78→0°C, 89%.

The crucial coupling of the E- and F-ring building blocks (Scheme 3) was envisioned to arise from the addition of an E-ring nucleophile to the highly functionalized aldehyde **22**. Studies on model compounds suggested the importance of a chelation-controlled addition to obtain the desired configuration at C38.[14] Thus, the novel Grignard reagent was prepared by treatment of **8** with *tert*-butyllithium, followed by addition of magnesium dibromide, and was coupled with aldehyde **22** to furnish the desired alcohol **23** in excellent yield and with high stereoselectivity.[15] Attempts to form the methyl ketal directly from glycal **23** by addition of acidic methanol resulted in undesired Ferrier-type rearrangements. However, a two step procedure involving iodomethanolysis[16] and reductive dehalogenation gave a satisfactory result. Addition of bromobenzene allowed for selective reduction of the alkyl iodide in the presence of the chlorodiene. The configuration of the C38 alcohol was established by modified Mosher ester analysis on the methyl ketal of **23**.[17, 18] The TIPS protecting groups at C29, C35, C47 were switched to the more labile TBS groups at this stage.[19] After selective cleavage of the primary C29 TBS group, **24** was converted into phosphonium salt **25**. The methyl ketal present at C37 was prone to elimination to form the corresponding glycal under thermal and acidic conditions. This side reaction was significantly suppressed by addition of methanol.



As shown in Scheme 4, **25** and **32** (synthesis described in the preceding communication) were coupled by utilizing a titration protocol[20] for Wittig olefination to afford the *cis*-olefin **26** ($J_{H28,H29} = 10.0$ Hz). DDQ cleavage[21] of the C41 and C42 MPM protecting groups occurred with concomitant, but incomplete, hydrolysis of the methyl ketal. Fluoride induced removal of the silyl ester and macrolactonization under the Yamaguchi conditions[22] proceeded smoothly to furnish the desired macrolactone **27**. As anticipated,[1] macrolactonization occurred selectively at the C41 alcohol.[23] At this stage the unhydrolyzed C37 methyl ketal could be separated from the lactol.[24] Finally, cleavage of the three TBS protecting groups in **27** furnished synthetic altohyrtin A (or spongistatin 1; **1**).[25] The synthetic material was found to be identical (^{1}H NMR in [D_6]DMSO and CD_3CN, MS, $[\alpha]_D$, TLC) with the authentic sample kindly provided by Professor Motomasa Kobayashi at Osaka University. In addition, the synthetic and natural materials exhibited the same biological activity.[26,27] It is exciting and intriguing to note that the C23 epimer of alothyrtin A[1] also exhibits potent cytotoxicty.[26, 27]

In summary, this synthesis has firmly established the relative and absolute configuration proposed for altohyrtin A by the Kitagawa group. To the best of our knowledge, there has been no direct comparison of altohyrtin A and spongistatin 1. However, comparison of the ^{1}H NMR spectra for both authentic and synthetic altohyrtin A with the spectrum (CD_3CN) of spongistatin 1 deposited in the supplementary material by Pettit[28] presents a convincing case that they are indeed the same compound. Thus, this work resolves the

[8] The allylstannane was also prepared by an alternative synthetic route: addition of the 1,3-dithiane anion to TBS-glycidol, followed by cleavage of the TBS protecting group and acetonide formation, yielded the functionalized 1,3-dithiane, which was further lithiated and trapped with DMF. Reduction of the resultant aldehyde, followed by TBS-protection, dithiane deprotection, Wittig-olefination, and TBS-deprotection, gave an allyl alcohol, which was converted into **18** by adopting the last two reactions of step g in Scheme 2).

Electrochemistry of Supramolecular Systems

Pierre L. Boulas, Marielle Gómez-Kaifer, and Luis Echegoyen*

Thirty years after the inception of the field of supramolecular chemistry, the volume of work in the area continues to expand at an ever-increasing rate. Biologists, chemists, and physicists continue to take strides in this well-established discipline and are beginning to make systems with serious potential applications. As the sizes of the molecular aggregates (prepared frequently by self-assembly) continue to increase, an unusual burden is being placed on existing analytical and physical characterization tools. The classical nuclear magnetic resonance (NMR) and mass spectral (MS) techniques sometimes fall short and thus are frequently unable to provide the necessary confirmation of structure and/or function of these aggregates. Although advances in these analytical areas have been remarkable (for example, matrix-assisted laser desorption ionization (MALDI) and electrospray mass spectroscopy (ES-MS), which allow the analysis of very large molecules and aggregates), other techniques are essential for complete structural and functional characterization of supramolecular ensembles. Additionally, as the aggregates are called upon to perform specific functions, as they are in the fields of biology and materials science, measurement of their electronic properties is of fundamental importance. Electrochemical techniques can fulfill many of these specific needs in the characterization and even in the preparation of some supramolecular aggregates. Developments in the field of electrochemistry, such as the implementation of potential pulsing techniques, have increased the sensitivity of the methods and offer relatively easy detection of dilute analyte solutions. Electrochemical techniques are particularly useful and informative for species confined to the surfaces of electrode materials. In addition to serving as sophisticated analytical tools, electrochemical techniques are also useful to produce electronic changes in host and guest molecules that induce (or inhibit) supramolecular aggregation. As such, they are switching controls that offer much promise in the field of supramolecular chemistry, since they offer the possibility to turn on or off a particular intermolecular interaction and thus to read/write information at the molecular level. These switching processes can also be used to effect directed translocation of molecular or ionic species, for example, across membranes. Be they as analytical tools or as powerful effectors to change the properties and binding of supramolecular aggregates, electrochemical techniques are of fundamental and practical importance in the rapidly growing field of supramolecular science. Here we provide examples of how these techniques have been applied to analyze and to influence the properties of guest–host complexes, aggregates, and other related structures.

Keywords: aggregation · cyclic voltammetry · electrochemistry · redox chemistry · supramolecular chemistry

1. Introduction: Electrochemistry and Supramolecular Chemistry

It seems appropriate to begin this review by asking: why should the supramolecular chemist be interested in electrochemistry?

While the usual goal of an electrochemical experiment is to determine redox potentials and to correlate these with intrinsic molecular properties, the method can offer much more to the supramolecular chemist.[1] Electrochemistry, a very powerful tool for monitoring supramolecular events such as self-aggregation on solid electrode materials, can also be used to "effect" structural and electronic changes, thus offering *control* over supramolecular processes. These latter applications are less known and thus often unappreciated by many who are not familiar with the field.

Redox changes can be used to enhance (or diminish) the binding affinity of ligands for guest molecules or ions. Such ligands can thus be viewed as redox switches (Section 2). Examples include the redox-active lariat ethers,[2a–c] and flavin cyclophanes or flavinophanes.[2d] Redox-switching has also been employed in molecular shuttles as described in Section 5.[3] Similarly, electrochemistry can also lead to pronounced structural changes in supramolecular systems. Work with the helicates, a topic of recent studies by Lehn,[4]

Abruña,[5] and Constable,[6] has demonstrated that as the chelating ligands in these systems are lengthened (a septipyridine system has been studied[5d]), the nuclearity of the complexes depends upon the redox state of the chelated ions. By controlling the redox state of these ions the electrochemist can switch between di-, tri- and tetranuclear complexes.

In addition to these examples in which redox chemistry can be used to control the different binding states and the structures of some aggregates, electrochemistry can also play an important role in redox-controlled self-assembly and in the generation of new materials by electrocrystallization. We have employed the latter to prepare single crystals of reduced complexes of ruthenium with pyridine-type ligands, which have interesting physical properties.[7] Electrocrystallization has also been used in the field of metalloporphyrins to generate molecular conductors with a stacked metal-over-metal structural motif.[8]

Thus, the dual utility of electrochemistry as an "effector" to direct and control supramolecular interactions, as well as a "detector" to monitor and measure the changes makes it uniquely powerful and useful in supramolecular studies. It is certainly one of the most important techniques in the field and one of the easiest to implement.

2. Switching and External Binding Control

The topic of redox switching has been of considerable interest in supramolecular chemistry for well over two decades and is one of the most important applications of electrochemistry in this field. A thorough discussion of the topic is beyond the scope of the present work, and thus the reader is referred to a number of excellent reviews for a more detailed discussion.[2c, 9]

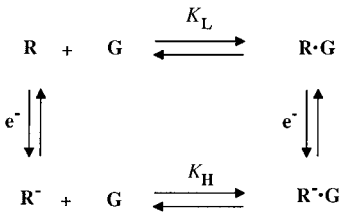
P. L. Boulas

M. Gómez-Kaifer

L. Echegoyen

Pierre L. Boulas was born in Villefranche/Saone, France, and educated in Libreville, Gabon. He received a diploma from the Ecole Nationale Superieure de Chimie et Physique de Bordeaux, France in 1992. He joined Professor Kadish's group at the University of Houston, Texas, in 1992 and received his PhD in Analytical Chemistry in 1995. His graduate research work dealt with the electrochemistry and spectroelectrochemistry of fullerenes, fullerene derivatives, and novel metalloporphyrinoids. In August 1995 he joined Professor Echegoyen's research group at the University of Miami, Florida, as a PRF/NSF postdoctoral fellow. His research focuses on the electrochemical and spectroelectrochemical characterization of fullerene derivatives and supramolecular complexes, and on the electrosynthesis of novel fullerene-derived materials.

Marielle Gómez-Kaifer was born and educated in Miami, Florida. The daughter of a physician/biochemist and an artist, she obtained a Bachelor of Fine Arts degree in 1981 and then turned toward science, gaining a double Bachelor of Science degree in Chemistry and Microbiolgy/Immunology in 1991. After earning a National Science Foundation Graduate Fellowship in 1992 she spent one year at the University of Texas at Austin and then returned to the University of Miami, where she completed her Ph.D. thesis on redox-active calixarenes, employing electrochemical, ESR, and NMR techniques. She is presently pursuing post-doctoral studies on encapsulated redox centers.



Luis Echegoyen was born in Habana, Cuba, and educated in Puerto Rico. He obtained both his B.S. and Ph.D. degrees from the University of Puerto Rico in Río Piedras in 1971 and 1974, respectively. After a one-year postdoctoral stay at the University of Wisconsin-Madison, he worked with Union Carbide Corporation for two years. He then returned to the University of Puerto Rico as assistant professor in 1977, where he was promoted to associate professor in 1980. In 1982 he took a leave of absence to work as a Program Officer in charge of Chemical Dynamics in the National Science Foundation in Washington, DC, while simultaneously holding an adjunct professorship at the University of Maryland-College Park. He then moved to the University of Miami-Coral Gables as associate professor and was promoted to professor in 1987. During calendar year 1990 he spent his sabbatical working with Prof. Jean-Marie Lehn at the Universitéˊ Louis Pasteur in Strasbourg, France. He received the Florida-American Chemical Society Award for 1996. Professor Echegoyen has published about 120 communications, papers, reviews, and monographs and his research interests have centered around supramolecular chemistry since the early eighties. His current work involves electrochemical and magnetic resonance spectroscopic studies of supramolecular systems, with a particular emphasis on their potential applications in materials science.

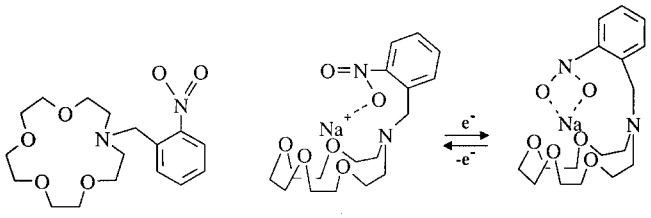
During the mid-1980s much interest centered on redox-switchable cation-binding systems as potential mimics of biological transport systems.[9c] At present redox switchable host–guest systems are frequently proposed as the chief components of potential molecular devices and sensor systems.[10] Regardless of the specific structures and their intended function, the basic principles behind electrochemical switching are the same.

2.1. The Concept of Redox Switching

The concept of an electrochemically switchable system is a simple one. The oxidized and reduced states of a switchable molecule must display differing degrees of affinity for a second species. Thus, the oxidation state determines the thermodynamic stability of the complex between the receptor and a guest species. The basis of the differential interaction in such a system is typically purely electrostatic. Either the receptor or the guest, or both, need to be redox active. The requirements of an electrochemically switchable receptor or guest are essentially the same. The redox-active component of such a system must exhibit reversible heterogeneous electron transfer kinetics and interact strongly with the binding component. When the binding interaction is strong, the complexed and the free forms will typically exhibit separate redox waves. This situation is ideal for analytical work, because the intensity of each wave is proportional to the concentration of the corresponding complexed or free molecule. In such a system there are two clearly defined binding states that are readily discerned by voltammetric techniques. These states are defined as "on–off" or more accurately, "high–low" states. Both of these forms of the switchable compound must have sufficiently high binding affinity if separate redox waves for the two states are to be observed by voltammetry.[11] This is an important consideration when trying to extract binding constant information from voltammetric data, especially if digital simulations are not performed.

An electrochemically switchable system is usually described by a simple square scheme (Scheme 1) in which the redox equilibrium is coupled with the reversible binding reaction. In this situation we assume that the receptor R is electroactive.

Scheme 1. Square scheme for a redox-switchable system.



In Scheme 1, receptor R forms more stable complexes with guest G when it is reduced (R^-) than when it is oxidized (R). Therefore K_H is much larger than K_L. The magnitude K_H/K_L is defined as the binding enhancement.

The value of K_L determines whether R or R·G is reduced at the electrode surface. When K_L is large, the already formed complex R·G is electrochemically reduced to a higher affinity state, $R^-\cdot G$. In this situation the diffusion of the guest species is not a relevant factor. In contrast, if K_L is not large, the species undergoing reduction will be R, which will subsequently bind the guest to yield $R^-\cdot G$. In this instance, after reduction of the free receptor to the "high" binding state (R^-), the complexation process is essentially diffusion controlled, that is, determined by the diffusion of available guest to the reduced receptor. Generally, two separate voltammetric waves corresponding to the redox processes of the free (R) and complexed (R·G) species will *not* be observed for systems with a low K_L value ($\leq 10^3$‰M^{-1}) unless the rate constants for complexation and decomplexation are very fast. The typical electrochemical response of a system with a low K_L value is a shift of the half-wave potential for the free host species as guest is added to the solution.[12] If efficient transport of a guest species is of interest, K_L should not be so high as to prevent the eventual release of the bound guest. For a discussion of these points, see ref. [13].

2.2. Early Examples of Redox Switches

2.2.1. Lariat Ethers and Other Macrocyclic Hosts

The foregoing principles can be readily applied to lariat ether **1** (Scheme 2),[11b, 14] which represents a typical example of a redox-active guest whose affinity for a host can be greatly

1 [Na(**1**)]$^+$ [Na(**1**)]^0

Scheme 2. The free and Na^+-bound lariat ether **1**.

enhanced upon reduction. In **1** the optimal placement of the nitro substituent (ortho to the pivot attachment) allows for strong interaction with a macrocycle-bound cation. When Na^+ is bound by the macrocyclic crown ring, it can simultaneously interact strongly with the nitroaromatic group. At substoichiometric amounts of Na^+, two reduction waves are seen, one for the free and one for the Na^+-bound species of **1** (Figure 1).[11b]

The reduction potential of [Na(**1**)]$^+$ is anodically shifted by 260 mV relative to that of **1**, because the nitroaromatic anion radical is stabilized by Na^+. The cyclic voltammetric behavior of [Na(**1**)]$^+$ can be readily simulated, and this allows the determination of the binding enhancement (K_H/K_L) from Equation (1).[11a] In this equation $E_F^{o'}$ and $E_C^{o'}$ represent the

$$K_H = K_L \exp[-F(E_F^{o'} - E_C^{o'})/RT] \quad (1)$$

formal potentials, often estimated from the half-wave potentials, of the free and complexed species, respectively. The

[11b]).

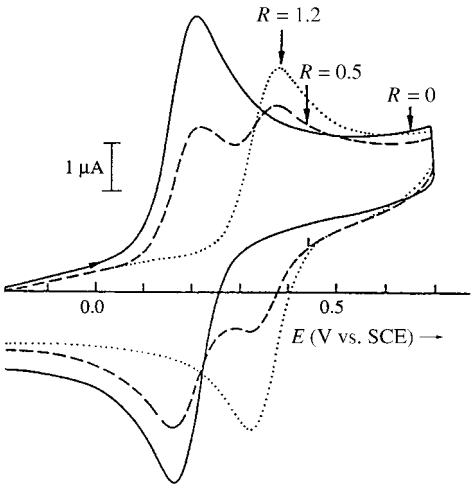
estimated binding enhancement for $[Na(\mathbf{1})]^+$ is 2.5×10^4. In many instances the potential for the wave corresponding to the reduction of the complex may shift as the cation concentration is increased. Since a change of only 10 or 20 mV results in an order of magnitude difference in the calculated binding enhancement, digital simulations of the voltammetric behavior across the full range of cation concentrations provide the best estimate of this factor. Additionally it should be noted that when $K_L \leq 10^4$ ‰M^{-1}, values of K_H may be significantly underestimated by Equation (1).[11b]

Occasionally lower peak currents are observed for the complexed species than for the free species. This effect is typically noted when a small guest, rather than the larger host (which is more common), is the redox active species. For a truly reversible process, the lower currents observed for the complexed species are really attributable to the smaller diffusion coefficient of the complex, rather than to electrochemical irreversibility or interfering chemical reactions. One such system was reported by Lehn and co-workers, who examined a polyamine macrocycle (**2**) that binds the comparatively small ferrocyanide ion.[15]

2

In this system the oxidation of ferrocyanide to ferricyanide is shifted to more positive potentials upon binding to **2**. At less than stoichiometric amounts of the polyamine ligand, two redox waves are seen. After addition of 1.2 equivalents of the macrocycle, a single wave is observed, which shows noticeably lower current intensity than the wave corresponding to the uncomplexed ferrocyanide (Figure 2).[15]



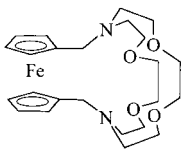


Figure 2. Cyclic voltammetry of ferrocyanide (0.9 mM in 0.1 M KCL, pH = 5.5) in the presence of increasing amounts of **2**. Platinum disk electrode, scan rate = 50 $mV s^{-1}$, potentials vs. SCE, $R = c(\mathbf{2})/c([Fe(CN)_6]^{4-})$ (reprinted with permission from ref. [15]).

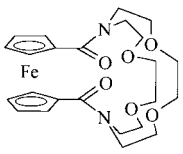


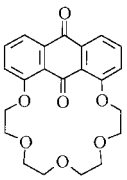
The lower current intensity is simply due to the difference in the diffusion coefficients between the free and the bound ferrocyanide species and not to a change in the overall reversibility of the system. Differences between the diffusion coefficients of the complexed and free species have been observed in the electrochemistry of other supramolecular systems such as cyclodextrin inclusion complexes.[16] For example, a decrease in the diffusion coefficient of ferrocyanide was detected upon complexation by an amino-substituted β-cyclodextrin.[16a] In these cases, simulations of the voltammetric behavior must take into account the difference in diffusion coefficients in order to accurately reproduce the observed behavior, which can include shifts in the observed redox potentials. Simulation may also be employed to extract binding constant information based on changes in the diffusion coefficient.[16a]

2.2.2. *Ferrocenyl Macrocycles and Cryptand Switches*

The development of more complex redox-switchable cation binding receptors continued at a rapid pace throughout the 1980s and early 1990s. Ferrocene-based systems were very prevalent in the literature, perhaps due to their ease of preparation and their well-behaved electrochemistry. Ferrocene undergoes a monoelectronic quasi-reversible oxidation to ferrocenium at easily attainable potentials and has the advantage of being rather insensitive to protic solvents and to the presence of molecular oxygen. Additionally, the ferrocene ligand acts as a redox antenna in that its oxidation potential is sensitive to binding with other molecules. For example, Gokel and co-workers designed structure **3** , a redox-switched system in which the ferrocene acts as the cap of a diazacryptand.[17]

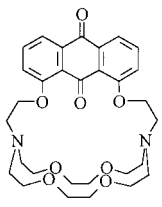
3

4



Complexation with alkali, alkaline earth, or silver ions was shown to shift the oxidation potential of the ferrocene moiety by as much as 290 mV, to more positive potentials. This is essentially a *negative* enhancement by a factor of 10^4 in favor of the neutral ferrocene ligand. (By negative enhancement we imply that oxidizing the ligand *disfavors* binding of the guest.) In this system, the binding of various cations resulted in characteristic half-wave potentials, a property with potential analytical applications.[10f] A related ferrocenyl macrocycle **4** also exhibited a "high – low" behavior with distinct oxidation waves (large K_L and $K_{H)}$ for both the free and bound forms of **4** in the presence of Be^{2+}.[18] However, differences in the cathodic and anodic current intensities suggested decomposition of the $\mathbf{4}\cdot Be^{2+}$ complex on the voltammetric time scale. In the presence of Mg^{2+}, Ca^{2+}, Sr^{2+} or Ba^{2+}, **4** exhibited voltammetric behavior typical of lower K_L systems: a single oxidation wave was observed for the free and bound ligand, at an $E_{1/2}$ shifted from that of the free ligand.[18]

Other significant results involving ferrocenyl macrocycles include the transport of cations by an electrochemically switchable ferrocenyl crown ether ligand across a bulk liquid membrane, which was achieved in 1986 by Saji and Kinoshita.[19] Transport across a CH_2Cl_2 liquid membrane was found to be enhanced upon oxidation of the ferrocene, since the Na^+ complex is destabilized in the oxidized state, favoring release of the Na^+ ion to the receiving phase.



Interestingly, Fabrizzi et al. have prepared a novel ferrocene receptor that has an *increased* affinity for cations upon oxidation.[20] Beer and co-workers have synthesized and characterized a large number of ferrocenyl receptors, as well as a series of cobaltocene- and ruthenocene-based receptor systems.[21]

2.2.3. Quinone-Based Switches

Other compounds have relied on the presence of *p*-benzoquinone and anthraquinone redox-active moieties as the switching antennae for enhanced cation binding. The quinone moiety undergoes two successive monoelectronic reductions to the anion radical and then the dianion.[22] Echegoyen et al. developed anthraquinone-based crown ethers and cryptands such as **5** and **6**.[23, 24]

5

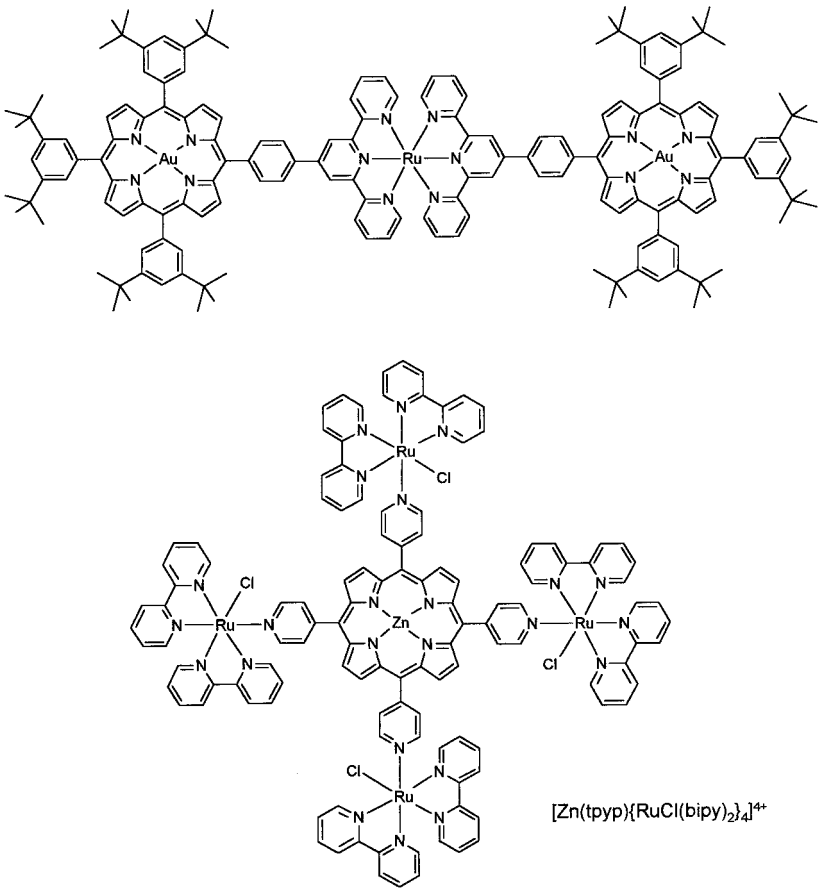
6

Compound **5** exhibits two reversible monoelectronic reduction waves in the absence of Na^+.[23] In the presence of 0.5 equivalents of Na^+ each of these waves is split into two waves, reflecting the redox processes of the free and the complexed ligand. Cryptand **6** displays even more dramatic behavior, exhibiting a 400 mV anodic shift for the reduction of the anthraquinone moiety upon binding with two Li^+ ions. Such a shift corresponds to a binding enhancement of 8×10^5.[24] Further reduction to the dianion leads to a total binding enhancement of 10^{11} relative to the neutral cryptand, a most impressive switching effect. Cryptand **6** has also shown the potential for lithium isotope discrimination.[25]

Cryptand **6** also binds Na^+ and K^+.[24] In its reduced state, **6** binds K^+ so strongly that it cannot be removed competitively by cryptand [2.2.2]. Use of anthraquinones as the redox-switchable component of cation binding compounds has continued with the work of Echegoyen and Torres, who have studied a series of anthraquinones bearing pendant diaza-crown ethers, and bis(anthraquinone) systems with diaza-crown ether spacers.[26] Na^+ binding enhancements obtained upon one-electron reduction in several of these systems have exceeded 10^5.

2.2.4. Other Switchable Systems

Various other cryptands such as azobenzene cryptands have also been studied.[27] These exhibited a greater degree of selectivity for K^+ than that of the cryptands mentioned above, which typically were selective for Na^+ or Li^+. True binding selectivity coupled with redox switching enhancement is an issue that has yet to be widely addressed and remains a challenge for future work.



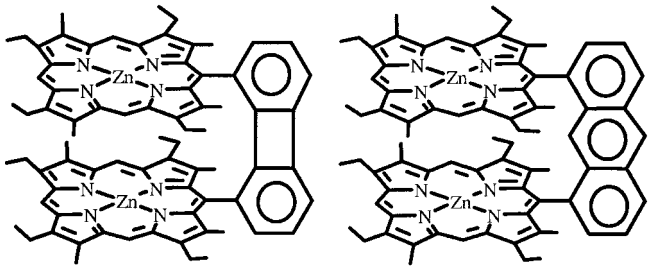
The area of anion binding enhancement by switching mechanisms has been less explored than that of cation binding. Most of the work in this area has been that of Beer and co-workers.[28] Their strategy has been to employ multiple positively charged redox moieties, which are then switched electrochemically to higher charge states. An excess of the anion guest must be added in order to see measurable changes. The effects of binding are rather modest, on the order of 50 mV or less, indicating very low binding enhancements. The reader is referred to reference [29] for further discussion of this work.

More recent work in the field of redox switching of ion binding involves the use of more complicated support frameworks. Related work will be discussed in the following sections.

3. Porphyrinoids

3.1. Porphyrins and Supramolecular Chemistry

The synthesis of porphyrinoids[28b, 30–37] is a very active field of research, and a great variety of porphyrin-like compounds with cavities of different sizes and shapes have been reported. Porphyrin-like compounds have been employed as the building blocks to form a number of supramolecular assemblies. Selected recent structural examples are shown in Scheme 3.[36]

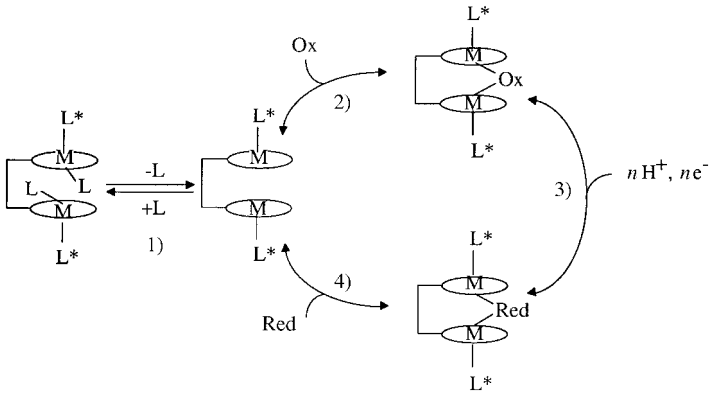


Scheme 3. Porphyrins as building blocks for supramolecular assemblies.

Considerable work has been reported in the field of the self-assembly of porphyrin oligomers and of the binding properties of these supramolecular receptors.[35] In addition to variation of the size and shape of the cavity, substitution of the porphyrinoid macrocycle is readily achieved. This allows for fine-tuning the physical and chemical properties of any given porphyrinoid ligand.[37] Some of these derivatized porphyrinoids have already revealed their potential as hosts for a variety of guest molecules.[28b, 37a–b] Thus, porphyrinoids are good precursors to supramolecular assemblies.

3.2. Cofacial Bis(metallo)porphyrinoids as Electrocatalysts

Cofacial bis(metallo)porphyrinoids (Scheme 4) were initially prepared to study the interaction between closely lying electroactive centers such as in the case of cytochromes,[38] to obtain multi-electron transfer,[39] or to find new catalysts for the reduction or oxidation of small substrate molecules such as O_2, H_2, or N_2.[40]



Catalytic activity in these systems can be easily detected with cyclic voltammetry (CV) or rotating disk electrode voltammetry (RDE).[41, 42] In the case of CV, a comparison of the current–voltage curves obtained for the substrate with a bare electrode and with an electrode modified with the cofacial bis(metallo)porphyrin will suffice to demonstrate catalytic activity. Higher current density and a decrease in the substrate overpotential when using the modified electrode are reliable indicators that the cofacial complex catalyzes the reduction or the oxidation of the substrate.[40] RDE is also very useful in that it provides more information about the kinetics of the catalytic process. In addition, rotating ring-disk electrode (RRDE) voltammetric experiments[42c] help to gain insight into the electrochemical nature of the intermediary and final products of the catalytic reaction.

[Zn_2(dpb)] [Zn_2(dpa)]

Scheme 4. Examples of cofacial bis(metallo)porphyrins.

Electrochemical studies of these porphyrins led to the conclusion that the rigidity and length of the spacer or linker between the two porphyrin units play a major role in how good a catalyst the cofacial complex is. If the spacer is too flexible, the two porphyrins do not adopt a face-to-face configuration.[43] Indeed, X-ray data revealed that the two units are laterally shifted with respect to each other to maximize $\pi-\pi$ overlap. If the two porphyrin units are too tightly linked to each other, the geometry of the cavity where the binding of the substrate occurs is not flexible enough to accommodate the structural changes that will take place during the catalytic process. If the linker is too long, communication between the two chromophores is absent. Anthracene and biphenylene linkers optimize this length/rigidity compromise.[44] A proposed overall catalytic process is schematically represented in Scheme 5.

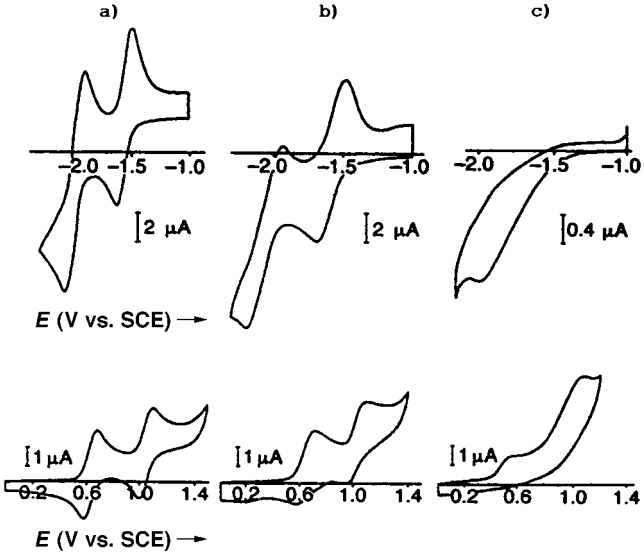
Scheme 5. Cofacial bis(metallo)porphyrins as electrocatalysts.[40] 1) Formation of the active site; 2) and 4) substrate binding or product release; 3) multielectron transfer. L* = bulky ligand blocking the outer coordination sites (solvent molecule or imidazole, for example); L = smaller ligand that can be displaced by the substrate.

The latter case exemplifies the use of electrochemistry as an effector of supramolecular events and as a detection technique. The substrate binding, which allows for the catalytic activity is controlled by the redox state of the substrate. The release of the product, on the other hand, from the cofacial bis(metallo)porphyrin is also redox-controlled.

3.3. Dendritic Porphyrins

Research on dendrimers has been expanding for the last decade.[45–50] Dendritic porphyrins are a rather important class of dendrimers that present interesting properties with potential industrial applications. They were initially synthesized with the aim of mimicking the environment that surrounds a heme center such as that of cytochrome c.[46] The first one was prepared by Inoue et al.[47] The electrochemistry of dendritic porphyrins has been studied by Diederich et al.[49, 50] In this case, electrochemistry has been used solely to measure redox potentials and correlate them with electronic properties. Some examples of dendrimers studied are shown in Scheme 6.

The redox behavior of dendritic porphyrins is markedly different from that of "simple" metalloporphyrins because of the influence of the dendrimeric branching around the porphyrin core (Figure 3).[49]



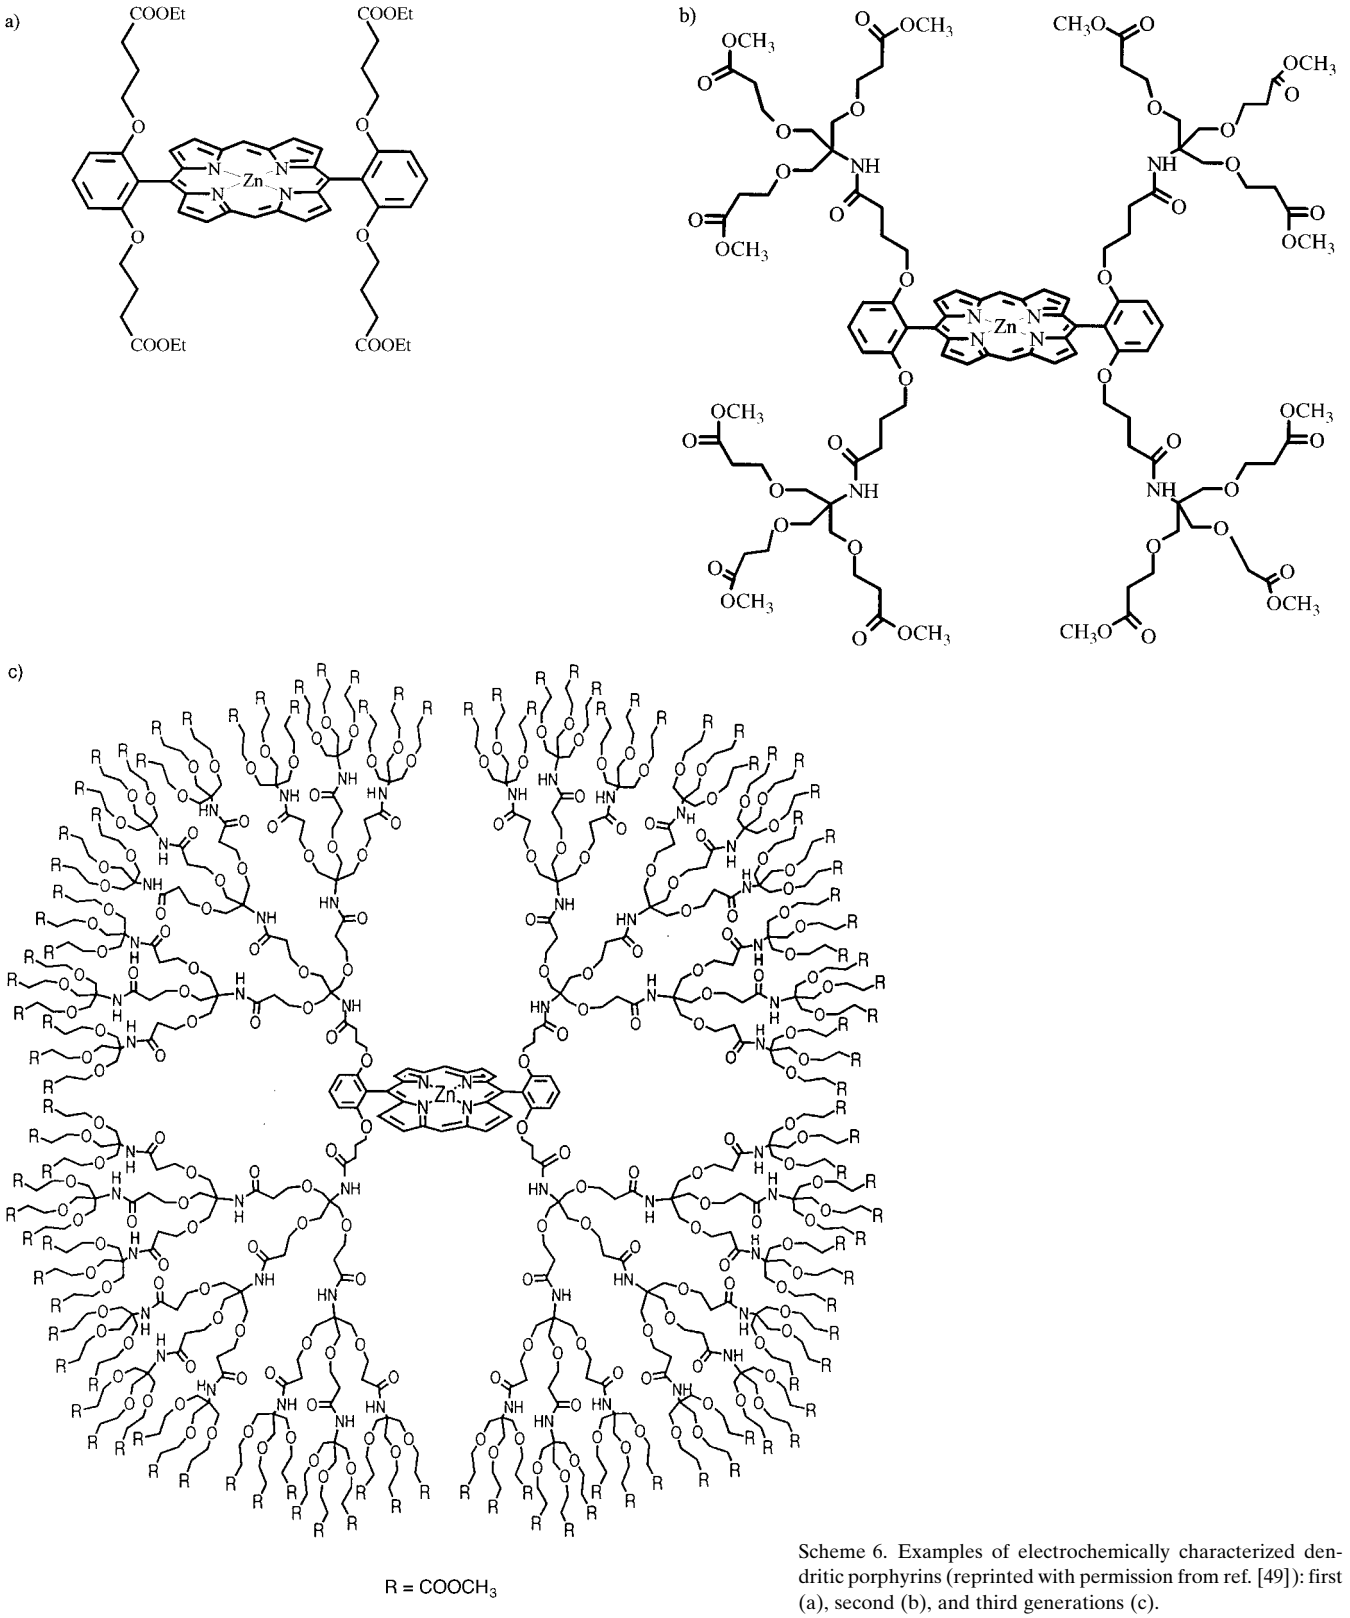


Figure 3. Cyclic voltammograms showing the reduction (top) and the oxidation (bottom) of dendritic porphyrins whose structures are represented in Scheme 6.[49] Dendrimers of a) the first, b) the second, and c) third generation. Conditions: top: THF, 0.1 M Bu_4NPF_6, Hg dropping electrode as working electrode, scan rate = 8 $V\,s^{-1}$, 25 °C; bottom: CH_2Cl_2, 0.1 M Bu_4NPF_6, platinum working electrode, scan rate = 0.1 $V\,s^{-1}$, 25 °C (reprinted with permission from ref. [49]).

As the dendrimer shell grows (Figure 3a to 3c), the porphyrin electrophore is more shielded by electron-rich dendritic branches, rendering the reductions more difficult and the oxidations easier. By the third generation, the zinc porphyrin dendrimer shows only ill-defined and mainly irreversible CV processes. The poor definition is due in part to the very small diffusion coefficient of the species, while the irreversibility results from the superimposition of redox processes involving the porphyrin core and the functional groups on the branches of the dendrimer. The dendrimeric branching not only affects the porphyrin ring-centered reactions but also the metal-centered ones. As reported by Diederich et al.[50] in the case of iron porphyrin dendrimers, the half-wave potentials for the metal-centered reductions ($Fe^{III} \rightarrow Fe^{II}$ and $Fe^{II} \rightarrow Fe^{I}$) were found to depend greatly on the size of the dendrimer surrounding the metalloporphyrin. The dendrimer was also found to shield the metal center from the external medium and particularly the solvent.[50]

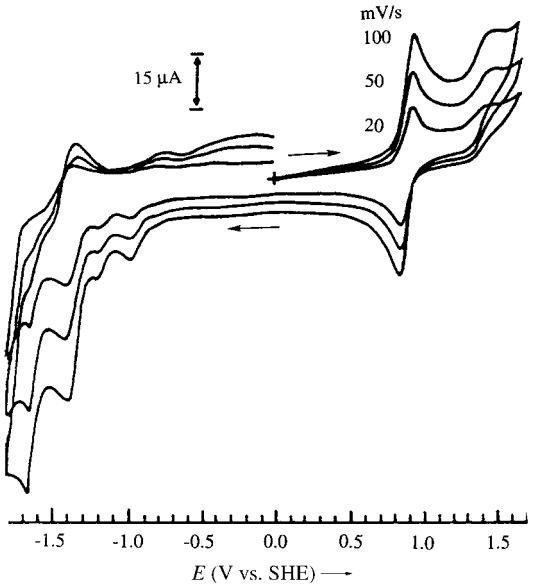
3.4. Ruthenated Metalloporphyrins

Examples of such complexes are shown in Scheme 3.[36] Although several architectures have been designed and built that make use of the ability of pyridyl-type ligands to complex ruthenium(II), only one of them, to our knowledge, has been thoroughly characterized electrochemically (Scheme 3, bot-

Scheme 6. Examples of electrochemically characterized dendritic porphyrins (reprinted with permission from ref. [49]): first (a), second (b), and third generations (c).

tom structure).[36b] The CV recorded for the tetraruthenated zinc porphyrin $[Zn(tpyp)\{Ru(bpy)_2Cl\}_4]^{4+}$ shows a multitude of redox processes (Figure 4) in agreement with the fact that four sites of electron transfer can be envisaged: the metal center, the porphyrin ring, ruthenium(II), and the pyridyl ligands.

Two reversible oxidations can be discerned in the CV. The first one at 0.92 V has the intensity of a four-electron oxidation and corresponds to a $Ru^{II} \rightarrow Ru^{III}$ reaction for each $Ru(bpy)_2$ ligand. The fact that the four Ru^{II} centers are oxidized simultaneously indicates that only very weak coupling exists between the ruthenium centers. The second



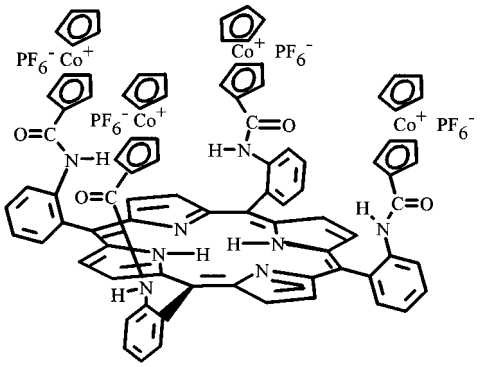


Figure 4. Cyclic voltammogram (DMF, 0.1M $TEAClO_4$, platinum disk working electrode) for the reduction and the oxidation of the $[Zn(tpyp)\{RuCl(bpy)_2\}_4]^{4+}$ (0.99mM) (reprinted with permission from ref. [36b]).

oxidation located at 1.5 V corresponds to the one-electron oxidation of the porphyrin ring. Interestingly, the first one-electron reversible reduction observed for the tetraruthenated porphyrin corresponds, as confirmed by spectroelectrochemistry, to a $Zn^{II} \rightarrow Zn^{I}$ reduction. This contrasts drastically with the electrochemistry of Zn(tpyp) for which the first reduction is ring-centered.[51] The second reduction (reversible when only the first two waves are scanned) at -1.2 V is a one-electron transfer and involves the porphyrin ring. The multi-electron process at -1.35 V is a superposition of the second porphyrin ring-centered reduction and the reduction of four bpy units, one on each $Ru(bpy)_2$ ligand. Finally, the reduction at -1.67 V is irreversible and involves the remaining four bpy ligands. The complexity of the electrochemistry of the ruthenated zinc porphyrin described above exemplifies the typical expectation when dealing with supramolecular assemblies that possess several available sites for electron transfer.

3.5. Sensing of Anions by a Porphyrin Receptor

As mentioned earlier, the porphyrin ring is amenable to chemical derivatization. A judicious choice of ligand led to the synthesis of a porphyrin (Scheme 7) with interesting anion recognition properties.[28b] This novel anion sensor presents a pronounced affinity for halides, $H_2PO_4^-$, and HSO_4^- over NO_3^-. The anion binding properties of the porphyrin sensor were monitored by NMR, UV/Vis spectroscopy, and electrochemistry. Interestingly, upon addition of anion guests to solutions containing the porphyrin host, only shifts in the oxidation potentials of the porphyrin ring and reduction potentials of the cobaltocenium ligand were detected. No influence due to anion binding was detected on the reduction potentials of the porphyrin ring.[28b]

Scheme 7. Example of a porphyrin-based anion sensor.

In two other examples a porphyrin-based system has been used for molecular recognition. The first one is the preparation of a porphyrin host for a guest analogous to ubiquinone,[52] while the second one is the synthesis of a sapphyrin–cytosine conjugate for selective through-membrane transport of guanosine 5′-monophosphate.[37a] Unfortunately none of these systems has been electrochemically characterized.

3.6. Electrochemically Induced Self-Assembling of Porphyrinoids

The porphyrin-like compounds are not only of interest because of their biological relevance but also because of their potential uses as materials, such as "molecular metals"[53] or catalysts.[40] Thus a great deal of effort has been devoted to designing and creating new conducting materials that incorporate porphyrin and its derivatives as molecular building blocks.[8, 54–56] Electrochemical[8, 55] or chemical[54, 56] oxidation of a series of metalloporphyrinoids [M(P)], where P is a phthalocyanine, a porphyrin, or a porphycene, leads to molecular conductors, which usually have the same stacked structural motif.[57] This motif is best characterized as an ABAB arrangement in which A and B are staggered by an angle that depends upon the nature of the macrocycle. Whereas the undoped materials crystallize with a stacking pattern in which the units are slipped with respect to each other, the doped materials most often crystallize in a metal-over-metal arrangement (Figure 5).[57]

The conductivity of these systems increases by several orders of magnitude from the undoped to the doped material.[54, 55] Examples of dopants include I^-, BF_4^-, PF_6^- and ReO_4^-. As mentioned earlier, these conducting materials can be prepared by chemical or electrochemical oxidation, but the latter pathway offers more alternatives than the former. Electrochemistry permits facile variation of the dopant and the ability to reach doping levels that are not accessible through chemical oxidation. Both of these factors, nature of the dopant and extent of oxidation of the metalloporphyrinoid, play a major role in the physical properties, such as conductivity, of the final product.[8, 54–57] The list of materials that have been prepared by partial oxidation of metalloporphyrinoids is vast and beyond the scope of this review. Thus we chose to describe one of the most recent examples, the

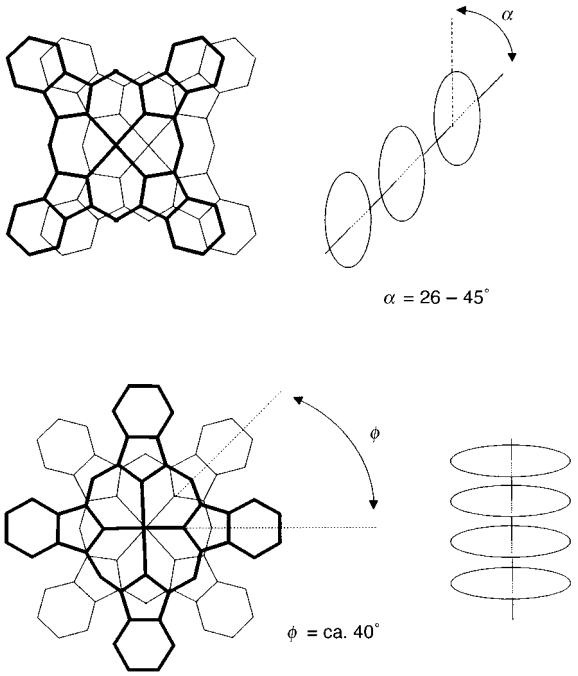

Figure 5. Schematic drawing of the strucutres of the undoped and doped crystallized metalloporphyrinoids (adapted from ref. [57]).

electrocrystallization of a new porphycene-based material, $[Ni(ompc)]_{2.5}(BF_4)_2 \cdot C_{10}H_7Cl$, where ompc stands for 2,3,6,7,12,13,16,17-octamethylporphycene.[8] Single crystals of $[Ni(ompc)]_{2.5}(BF_4)_2$ were harvested at the anode of a two-electrode system by using controlled current (5 μA) electrolysis. The unit cell consists of 10 macrocycles (Figure 6).

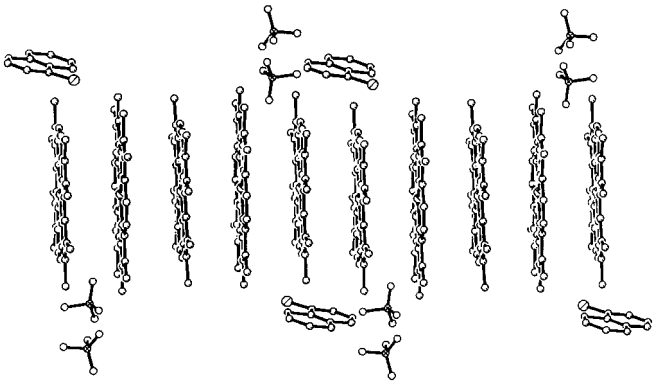

Figure 6. Stacking in the crystal of electrooxidized $[(OMPc)Ni]^+BF_4^-$ (reprinted with permission from ref. [8]).

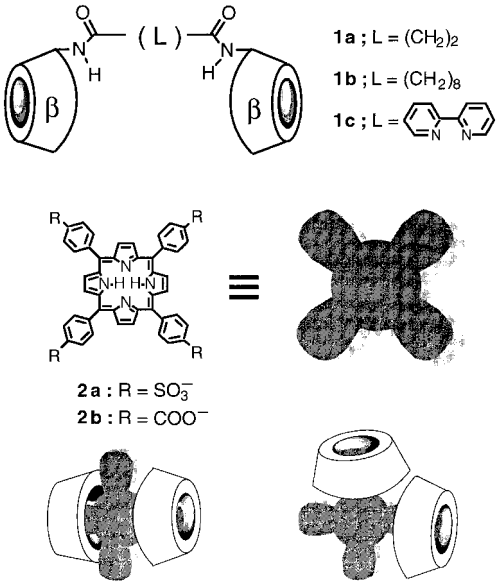
The structural motif, as expected, consists of stacked macrocycles that are staggered by 90° (Figure 5). The stacks of metallomacrocycles are surrounded by channels, which are occupied by counter anions (BF_4^-) and solvent molecules (1-chloronaphtalene). Within the crystal unit, the 10 macrocycles are arranged as pentamers. The presence of four BF_4^- anions for each pentamer suggests four oxidation sites per pentamer. Within a pentamer, the distance between the elements is 3.33 – 3.38 Å, whereas the distance between two neighboring pentamers is 3.40 Å. The 90° staggering angle between successive units is postulated to minimize the steric hindrance between the Ni porphycenes. The conductivity of this electrocrystallized porphycene at room temperature is 0.06 Ω^{-1} cm^{-1} and was found to be thermally activated.[8]



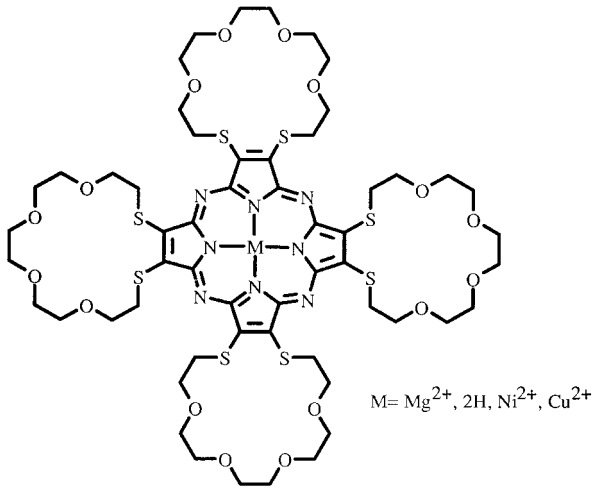
An important question for all of the conducting materials made out of metalloporphyrinoids like the one just described concerns the conduction pathway. Electrochemical studies of nickel porphycenes showed that the first reduction of these compounds is a reversible one-electron, ring-centered process.[58] Thus, it was expected that the conduction pathway in $[Ni(ompc)]_{2.5}(BF_4)_2$ was induced by intermolecular electon transfer from ring to ring. This was actually confirmed by ESR spectroscopy.[8] Modifying the central metal ion in this system, for example by replacing nickel(II) with cobalt(II), might induce another type of conductivity supported by the metal pathway of the material. Indeed, an example that displays metal-pathway conductivity, (phthalocyano)cobalt iodide, has been reported.[54d]

3.7. Outlook

Not a month goes by without a major scientific journal reporting the synthesis of a new porphyrin-based system. Thus it is an almost impossible task to follow the porphyrin literature. This last part of this section will be used to describe recently reported porphyrin-based systems that will probably play important roles in the future of supramolecular chemistry. The electrochemistry of these systems has yet to be explored and is, in our opinion, an area warranting immediate study.

First, electrochemical characterization of porphyrin oligomers is of obvious importance. Of special interest in this field are the iron and gallium porphyrin trimers recently reported by Wojaczynski et al.[59] The electrochemistry of the first binuclear $[Mn^{II}(bipy)-Fe^{III}(porphyrin)]$ could be crucial. Its potential as a biomimetic system for manganese peroxidase has already been suggested.[60] Recently porphyrin[2]catenanes, in which conformational control is exerted by simple acid – base chemistry, have been reported.[61] These systems might represent new types of supramolecular assemblies in which conformational control can be effected electrochemically or by acid–base chemistry. Finally, the self-assembly of cyclodextrins and porphyrins has already been investigated by several groups.[62, 63] Several types of porphyrin – cyclodextrin complexes have been synthesized (Scheme 8) with the aim of mimicking the hydrophobic environment around the heme center in heme proteins.[62a, b]

In addition, studies of porphyrin – cyclodextrin inclusion complexes have been justified by the search for new supramolecular catalytic systems,[62c] the inhibition of porphyrin aggregation[62d] or dimerization,[62e–g] as well as the enhancement of the spin-lattice relaxation of water protons by manganese porphyrin – cyclodextrin complexes.[62h] In spite of the interest in this area, the electrochemistry of the porphyrin – cyclodextrin inclusion compounds remains a relatively unexplored area.



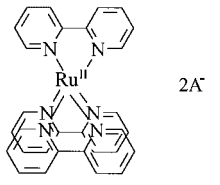
Scheme 8. Example of porphyrin–cyclodextrin inclusion complex (reproduced with permission from ref. [62].)

Since 1985 crown ethers and porphyrins have been intimately combined to generate species with multiple metal binding sites.[64] One recent example is the octathioporphyrazine crown ether,[65] the structure of which is shown in Scheme 9. Beautiful and sophisticated molecular architectures have been built from porphyrinoids and their metal complexes. As the fields of porphyrin and supramolecular chemistry merge, the tools and concepts used in both fields will surely help to create a very rich research area. Electrochemistry will, of course, play an important role in this exciting field because of the uniqueness of the information that it can provide about these systems.

4. Pyridine-Based Systems

Pyridines (py), including bipyridine (bpy), terpyridine (tpy), other extended pyridines, and biquinoline, have been among the most utilized ligands for the preparation of supramolecular structures. In this section we will consider coordination-based complexes of pyridine systems. The electrochemistry of the well-known bpy-based cyclophane systems is described in Section 5. The large number of reports in this area precludes an exhaustive review of the field. Our focus will be on the py-based cryptates, helicates, molecular wires, and the stacked and gridlike arrays that have recently dominated the supramolecular literature. We will also briefly describe the electrochemistry of dendrimer systems based on bipyridine complexes.

The majority of the complexes described here readily self-assemble, relying on the template effect provided by the transition metal ions. Since many of the metal ions are themselves electroactive, the electrochemistry of these systems is as rich and complex as that of the porphyrinoids described in Section 3. In a number of instances, changing the valence state of the transition metal ion has profound effects



Scheme 9. Framework of the octathioporphyrazine crown ether.

on the type of coordination observed in a complex. This is especially true in the case of copper complexes, some of which are described below. Changes in the oxidation state of the metal ion can also result in changes of the nuclearity of the complexes (e.g. monometallic to di- or even trimetallic structures).

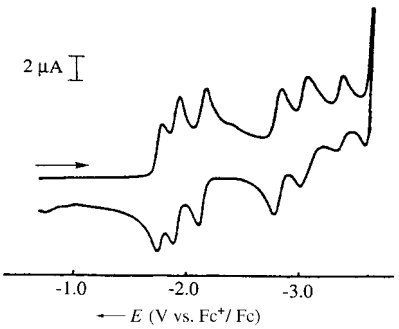
4.1. Pyridine-Based Complexes and Cryptates

Among the pyridine and polypyridine metal complexes, by far the most extensively studied ligand is bipyridine.[66] A large number of 2,2′-bipyridine (bpy) complexes with metal ions such as the tris(bipyridine) complexes are known, and most have been characterized electrochemically.[67, 68] The prototypical example of this class of complexes is $[Ru^{II}(bpy)_3]^{2+}$, which has been studied by a number of authors.[69]

Some of the most detailed work in this area was reported by DeArmond and co-workers, who studied the electrochemical and ESR behavior of $[Ru^{II}(bpy)_3]^{2+}$. This complex exhibits some characteristics that are important to describe since they are typical for this class of compound.

$[Ru^{II}(bpy)_3]A_2$ $A^- = Cl^-, PF_6^-$ etc.

In $[Ru^{II}(bpy)_3]^{2+}$ both metal- and ligand-based electron transfer processes can occur. Oxidation of $Ru^{II} \rightarrow Ru^{III}$ in the tris(bpy) complex occurs at 0.82 V vs. Fc^+/Fc in CH_3CN/TEAP (tetraethylammonium perchlorate).[70] For comparison, the Ru^{II}/Ru^{III} oxidation occurs at -0.46 V vs. Fc^+/Fc in the hexaaquo species.[71] Thus, Ru^{II} is stabilized by the chelating ligand. The free bpy ligand can accept two electrons.[72] The first electron transfers onto the bpy ligands in the $[Ru^{II}(bpy)_3]^{2+}$ complex occur (as monoelectronic reductions) at three successive potentials (Figure 7): -1.76, -1.92, and -2.14 V vs. Fc/Fc^+ in DMF/$TEAPF_6$ (tetraethylammonium hexafluorophosphate).[73a]



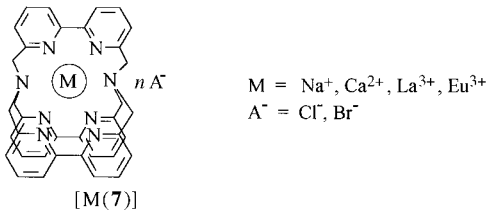


Figure 7. Cyclic voltammograms of $[Ru(bpy)_3]^{2+}$ (0.5 mM) in DMF, 0.1 M $TEAPF_6$; scan rate = 0.1 $V s^{-1}$, −54 °C (reprinted with permission from ref. [73b]).

These reductions are more facile than those of the *free* 2,2′-bpy ligand indicating that the binding to the metal ion lowers the energy of the ligand's π* orbital. The fact that these reductions occur at three different potentials, rather than at a single potential, indicates that there is electronic coupling between the bpy units in the $[Ru^{II}(bpy)_3]$ complex.[73b]

The ESR spectrum of the single-electron reduction product, $[Ru^{II}(bpy^-)(bpy)_2]^+$, shows a single broad line, the line width of which is temperature-dependent, suggesting a thermally activated delocalization (electron hopping).[74] In fact, a number of researchers have shown that the π orbitals of the bpy ligands in $[Ru^{II}(bpy)_3]^{2+}$ are isolated but that thermally activated electrons can hop from ligand to ligand.[74] Similar ESR behavior is noted for the doubly reduced (overall neutral) species.[74] After the third monoelectronic reduction step, which results in the formation of the $[Ru^{II}(bpy)_3]^-$ complex anion, some hyperfine structure emerges, indicating that the electrons are somewhat localized on the individual bpy ligands. The fourth to sixth electron reductions for this complex were observed at low temperature,[73b] and the potentials reported, −2.78, −3.00, and −3.30 V vs. Fc/Fc^+ in DMF/$TEAPF_6$, again indicate that electronic coupling exists between the ligands. The observation of six separate waves for the complex has been offered as confirmation of the so-called spatially isolated redox orbital model, in which the reduced species exhibit properties of the ligand alone.[75] Thus the presence of the metal ion simply provides a way to tune the potential at which the ligand reduction occurs. The electrochemical behavior of $[Ru^{II}(bpy)_3]^{2+}$ will be used as the standard for comparison with the other pyridine-based systems discussed below.

Tris(bipyrimidine)[70] and tris(biquinoline),[70b] tris(phenanthroline),[70b, 76] and terpyridine[77] complexes of transition metal ions have been characterized by a number of authors. A number of these complexes are of current interest in materials chemistry. We have successfully electrocrystallized several pyridine-based Ru^{2+} complexes.[7] These ligands have also been used as the framework for a series of cryptands and cryptates. Bpy cryptands can undergo electrochemical reduction, as can, in some instances, the cation bound in the corresponding cryptates (for example, a lanthanide such as Eu^{3+}). In these complexes the ligand surrounds and traps the metal in a cagelike coordination sphere (see Section 8). The electrochemistry of the cryptates $[M(\mathbf{7})]^+$ was studied by Echegoyen and co-workers.[78] For $[M(\mathbf{7})]^+$, where M = Na^+, Ca^{2+}, or La^{3+}, although six electrons may be transferred to the three bpy ligands overall, typically only the first three reductions are observed (Figure 8).

[M(**7**)]

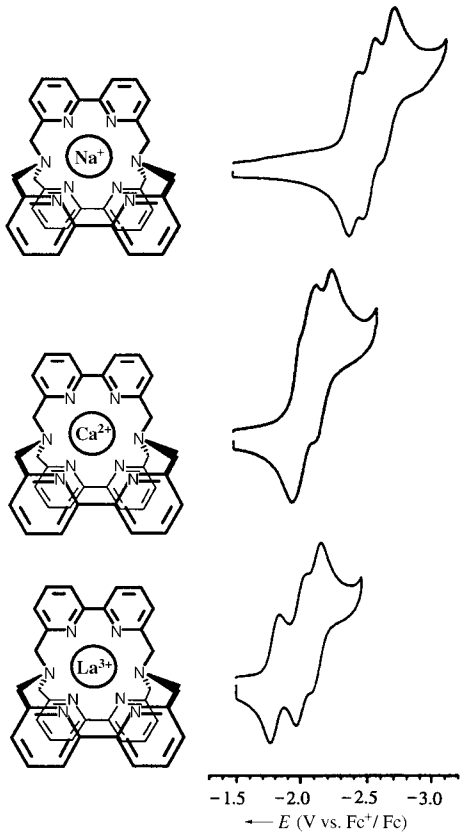

Figure 8. Cyclic voltammograms for $[Na(\mathbf{7})]^+$, $[Ca(\mathbf{7})]^{2+}$ and $[La(\mathbf{7})]^{3+}$, in DMF, 0.1 M $TBAPF_6$; Scan rate = 0.1 $V s^{-1}$ (reprinted with permission from ref. [78b]).

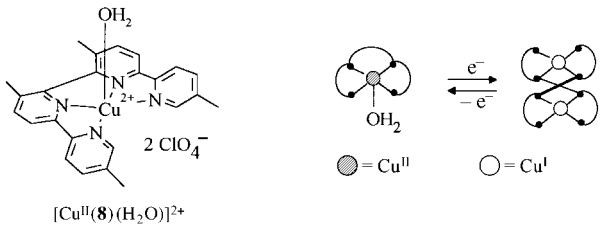


The potentials of these ligand-centered redox processes are strongly influenced by the nature of the metal ion. For example, the first reductions of $[Na(\mathbf{7})]^+$, $[Ca(\mathbf{7})]^{2+}$, and $[La(\mathbf{7})]^{3+}$ occur at −2.40, −1.98, and −1.76 V vs. Fc^+/Fc. The positive potential shift in the series Na^+, Ca^{2+}, and La^{3+} can be easily understood in terms of simple electrostatic considerations. Interestingly, $[La(\mathbf{7})]^{3+}$ showed a total of six one-electron reductions. The first three reductions correspond to the addition of one electron on each bpy unit. A noticeable gap between the third and fourth reductions reflects the electron–electron repulsion that needs to be overcome to generate the first dianionic bpy unit. Interest in the generation of new materials led to the successful electrocrystallization of $[Na(\mathbf{7})]^+$.[78a] This work is discussed in Section 8.

The electrochemistry of the $[Eu(\mathbf{7})]^{3+}$ complex has also been examined,[79] but it deviates considerably from the behavior of the systems described above. In this complex Eu^{III} undergoes reduction to Eu^{II} at -0.245 V vs. Fc/Fc^+ in DMF/$TBAPF_6$ (tetrabutylammonium hexafluorophosphate), and two pairs of poorly resolved, quasi-reversible reduction waves follow this redox couple. A number of other pyridine-based cryptates have been studied.[78b] However, for the sake of brevity they will not be described here.

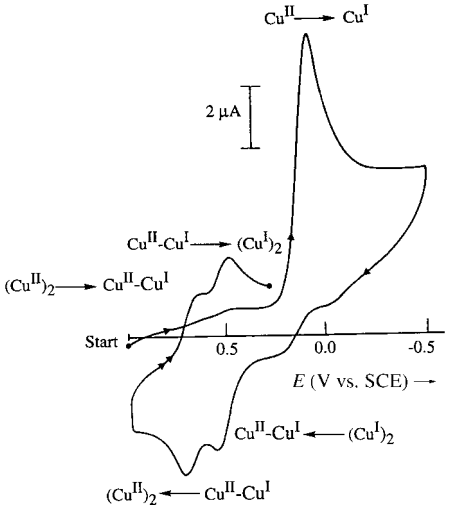
4.2. Helicates

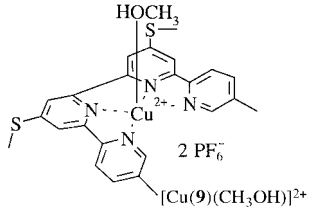
Another type of bpy-based architecture that has received considerable attention over the past decade are the helicates, which are complexes based on oligopyridine ligands that self-assemble in the presence of metal ions, to form helical structures.[80] This work was pioneered by Constable[6] and Lehn.[4] These complexes are prime examples of how redox switching can be used to control the molecular architecture.

The first reported example of a Cu^{II} system of this type was the Cu^{II}-tetramethylquaterpyridine complex $[Cu^{II}(\mathbf{8})(H_2O)]^{2+}$ [4a] (Scheme 10), prepared and characterized electrochemically

Scheme 10. Dimerization of $[Cu^{II}(\mathbf{8})(H_2O)]^{2+}$ after reduction to form a helicate.

by Lehn and co-workers. This complex can undergo monomer–dimer interconversion as a consequence of switching the oxidation state of the Cu ion. The cyclic voltammetry of $[Cu^{II}(\mathbf{8})(H_2O)]^{2+}$ shows one irreversible reduction at 0.1 V vs. SCE (Figure 9). When the potential scan is reversed after this reduction, two reversible oxidations are observed ($E_{1/2} = 0.53$ and 0.73 V vs. SCE). The reduction at 0.1 V generates $[Cu^{I}(\mathbf{8})(H_2O)]^{1+}$, which is unstable and dimerizes into $[\{Cu^{I}(\mathbf{8})\}_2]^{2+}$, a primitive helicate. The dimeric complex then undergoes two reversible oxidations (labeled $(Cu^{I})_2 \longrightarrow Cu^{II}-Cu^{I}$ and $Cu^{II}-Cu^{I} \longrightarrow (Cu^{II})_2$ in Figure 9), which lead to the mixed valence dimer $[Cu^{II}Cu^{I}(\mathbf{8})_2]^{3+}$ and the $[\{Cu^{II}(\mathbf{8})\}_2]^{4+}$ dimer, respectively. The latter eventually decomposes to regenerate the monomeric $[Cu^{II}(\mathbf{8})(H_2O)]^{2+}$ complex, albeit on a longer time scale. The monomeric Cu^{II} complex exists as a tetragonal pyramid with an apical water molecule, whereas the dimeric Cu^{I} complex exists as a dinuclear species with helical structure in which each metal center has a distorted tetrahedral environment. The difference in the half-wave potentials for the oxidation of the Cu^{I} ions in the $[\{Cu^{I}(\mathbf{8})\}_2]$ dimer indicates that the metallic centers are not electronically independent of one another. For a detailed discussion of this fascinating system the reader is referred to reference [4a].





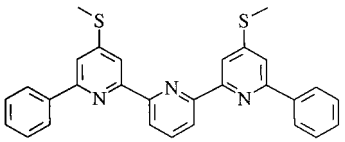


Figure 9. Cyclic voltammogram for $[Cu^{II}(\mathbf{8})(H_2O)]^{2+}$ in CH_3CN, 0.1 M NEt_4PF_6; scan rate = 0.1 $V s^{-1}$ (reprinted with permission from ref. [4a]).

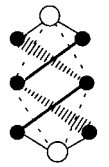
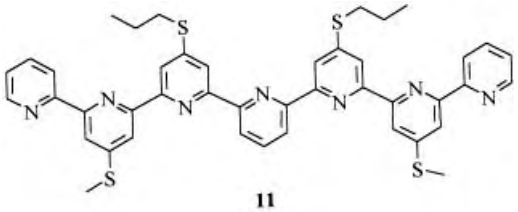
Lehn and co-workers have extended their work on the design of oligobipyridine ligands to include from two to five bipyridine ligands bridged by 2-oxapropylene linkages.[4b–d] They have also prepared Cu^{II} complexes based on oligoterpyridine structures.[4e] Constable et al. have also examined a number of oligopyridine systems,[6] complexed with a variety of transition metal ions, including a quinquepyridine ligand bearing pendant "redox spectator" ferrocene moieties.[6b] Many of these systems have been characterized electrochemically. Additionally, the electrochemical behavior of an entire series of alkylthio-substituted 2,6-oligopyridines has been reported in detail by Abruña, Potts, and co-workers.[5a–d] These authors first reported the electrochemical behavior of Cu^{II} complexes of ligand **9**, a methylthioquaterpyridine.

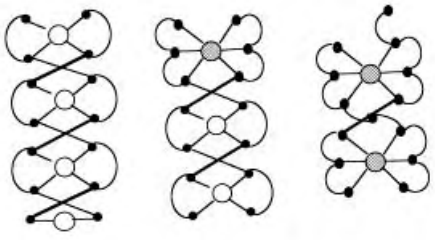


The voltammetric results obtained for $[Cu^{II}(\mathbf{9})(CH_3OH)]^{2+}$ differ somewhat from those reported for the analogous $[Cu^{II}(\mathbf{8})(H_2O)]^{2+}$. While both the Cu^{II} complexes of ligands **8** and **9** clearly dimerize upon reduction to the corresponding Cu^{I} complex, only a single wave for the oxidation to the Cu^{II} state is observed (in DMSO or DMF/TBAP) in the case of **9**; that is, no mixed valent state is apparent.[5a] Furthermore, the time scale for the regeneration of monomeric $[Cu^{II}(\mathbf{9})(CH_3OH)]^{2+}$ appears to be much shorter for the thio-substituted complex. Additionally, there is a notable difference in the $Cu^{II} \rightarrow Cu^{I}$ reduction potentials (+0.13 V vs. SSCE for $[Cu^{II}(\mathbf{8})(H_2O)]^{2+}$ and -0.07 V vs. the sodium-saturated calomel electrode (SSCE) for $[Cu^{II}(\mathbf{9})(CH_3OH)]^{2+}$) that cannot be accounted for by the negligible difference between the reference electrodes. It was proposed[5a] that such a difference might be due to the different solvents used in these studies: interaction of CH_3CN with the metal center might affect the reduction of $[Cu^{II}(\mathbf{8})(H_2O)]^{2+}$. $[\{Cu^{I}(\mathbf{9})\}_2]$ undergoes four reversible or quasi-reversible ligand-centered reductions at -1.38, -1.58, -1.83, and -2.02 V vs. SSCE. Spectroelectrochemistry of this system was also reported.[5a]

The electrochemical behavior of helical complexes based on oligopyridines from quater-, quinque-, sexi-, and septipyridine have been reported.[5a–c, 6] The structural variations observed for these helicates become more complicated as the length of the ligand increases. Cu^{II} complexes as well as Ni^{II}, Ag^{I}, Fe^{II}, Co^{II}, Zn^{II}, and Pd^{II} oligopyridine complexes have been electrochemically characterized.[5, 6] The potential difference between the redox processes that involve the metal centers of the helicates reflects the degree of interaction between the metal ions. For example, a 860 mV difference between the two successive Cu^{II}/Cu^{I} redox processes was observed for $[\{Cu^{I}(\mathbf{10})\}_2]$, where **10** is a methylthiodiphenyl-substituted terpyridine.[5c]



10



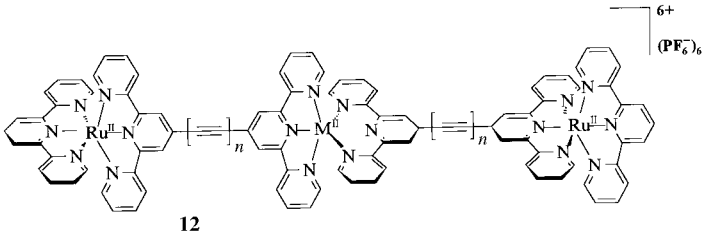
○ = Cu^{I}

The large potential difference for the reductions indicates a strong interaction between the two copper centers in the dimeric species. This agrees well with the solid-state structural data obtained on the dimeric complex which gives a $Cu^{I}-Cu^{I}$ distance of 2.6 Å.

The ultimate example of how electrochemistry can influence the structure of helicates is that of ligand **11** (Scheme 11).[5d] This ligand was used to generate bi-, tri-, and trametallic

11

○ = Cu^{I} ● = Cu^{II}



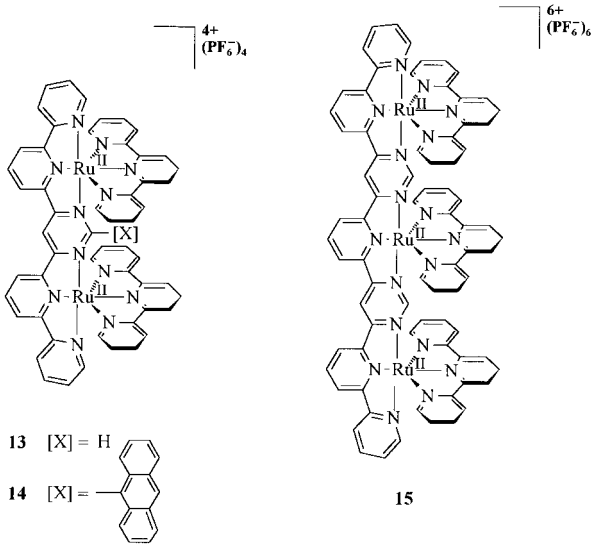
Scheme 11. Bi-, tri-, and tetranuclear complexes with ligand **11**.

species containing two Cu^{II} ions, two Cu^{I} and one Cu^{II}, or four Cu^{I} ions. In each complex, the Cu^{II} ions are expected to have an octahedral geometry and the Cu^{I} ions a tetrahedral geometry. However, whereas the dimetallic species was confirmed to have octahedral symmetry, the tetrametallic species shows evidence of a D_2-diamondlike symmetry.[5d] The Cu^{II}/Cu^{I} redox waves for $[\{Cu^{II}(\mathbf{11})\}_2]$ are quasi-reversible and located at 0.05 and 0.24 V vs. SSCE. For the trimetallic complex $[Cu^{I}(Cu^{II})_2(\mathbf{11})_2]$, the Cu-centered oxidations appear at 0.01, 0.43, and 0.82 V vs. SSCE and, as in the case of the bimetallic species, are quasi-reversible. The tetrametallic complex $[Cu^{I}_4(\mathbf{11})_2]$ undergoes four reversible one-electron oxidations involving the Cu centers at $E_{1/2} = 0.02$, 0.44, 0.84, and 1.08 V vs. SSCE. Thus, the bi-, tri-, and tetrametallic complexes all show interaction between the Cu centers. The reported ligand reductions in the tetra- and trimetallic complexes appear to differ markedly, a finding not noted in the smaller oligopyridine helicates. Reduction of the ligands were noted at -1.11, -1.27, and -1.49 V (the latter irreversible) vs. SSCE in the tetrametallic complex, while the same processes occur at -1.42, -1.62, and -1.83 V (the latter irreversible) vs. SSCE in the trimetallic complex. The transformation from the tetrametallic to the dimetallic complex was relatively slow, and spectroelectrochemical results suggested that multiple species are present and that a simple equilibrium does not exist.

One final report deserves to be mentioned in this section. Shanzer and co-workers recently prepared a triple helical system bearing bipyridine moieties.[81] This helical structure provides a coordination site for an Fe^{II} ion (bipyridine) or an Fe^{III} ion (hydroxamate). By switching the redox state of the Fe center, the ion reversibly translocates from one end of the helix to the other. Although the redox switching was accomplished chemically rather than electrochemically, this system provides a fine example of a self-assembled redox-switchable helical complex. The authors are pursuing anchoring these complexes onto conducting surfaces.

4.3. Pyridine-Based Molecular Wires

Molecular wires have been a topic of interest over the past several years.[82] We mention here a recently prepared alkyne-bridged, terpyridine-based system prepared by Harriman and Ziessel, who reported a mixed metallic wire structure **12**, containing two Ru^{II} ions and a different central ion (Zn^{II}, Fe^{II},



12

or Co^{II}).[83] The half-wave potentials for the oxidation of the Ru^{II} center in these complexes are similar to those of the parent terpy complexes, and the number of bridging alkyne units ($n = 1$ or 2) have only a small effect on the oxidation or reduction potentials of the Ru^{2+} metal centers.

4.4. Racks, Stacks, and Grids

Another very current topic is the preparation of rack molecules that self-assemble in the presence of transition

metal ions.[84] Several examples of these complexes have recently been published.[85] The electrochemistry of some of these[85b] (structures **13**–**15**) is described here.

13 [X] = H

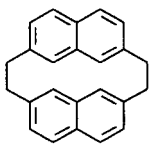
14 [X] =

15

The crystal structure of **14** displays octahedral coordination geometry about the Ru^{II} centers. The CV of **13** reveals two Ru-centered reversible oxidations at 1.41 and 1.57 V vs. SCE, while the bipyrimidine units are reversibly reduced at -0.43 and -1.03 V vs. SCE, and the terpyridine units are irreversibly reduced at $E_{pc} = -1.50$ and -1.59 V vs. SCE. A stripping peak at -1.40 V indicates absorption of the neutral species. The electrochemical behavior of **14** is similar, indicating that the anthryl spacer does not perturb the electrochemical properties of the complex. The Ru–Ru distance in **14** is 6.40 Å, which suggests a rather weak interaction between the two metal centers. The voltammetry of the trimetallic rack **15** is different, since the oxidations of the Ru^{II} ions occur in two steps, a two-electron wave at $+1.47$ V and a single-electron wave at $+1.88$ V vs. SCE. The latter process is assigned to the central Ru^{II} ion, which is likely to be more difficult to oxidize when placed between the two centers of higher charge. The ligand-based reductions in this system occur at -0.33 and -1.28 V for the bipyrimidine centers, and at -1.62 V (vs. SCE) a single irreversible adsorption wave is noted for the terpyridine units.

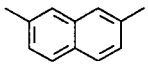
Lehn and co-workers are presently working on more complex systems involving ladders and grids that self-assemble in the presence of various transition metal ions.[86] Based on the results obtained for the helicates and rack complexes, the electrochemistry of these new molecular structures should be quite interesting.

4.5. Pyridine Dendrimers



A final topic of current interest in the field of pyridine-based systems is the preparation of pyridine-bearing dendrimers.[45] The high molecular weight of these compounds and the limited availability of material renders their electrochemical characterization challenging. Balzani et al. were among the first to report a decanuclear structure complexed to Ru^{II} and/or Os^{II}, based on a bridging bis(pyridyl)pyrazine ligand and bipyridine or biquinoline ligands.[87] These authors reported the differential pulse voltammetry of these complexes. Puddephatt and co-workers reported a bipyridine-based ligand coordinated to Pt^{II} ions,[88] while Constable et al. reported a simple terpyridine-based ligand that can be used to construct Ru^{II}(terpy) arborols.[89] A common finding for these compounds is that the redox active sites are reduced at the same potential, that is, they are not coupled. Recent work of Echegoyen and Newkome confirm these results.[90] A terpyridine dendrimer that was expanded over several generations showed waves corresponding only to the two reductions of the terpy unit. As with the porphyrin dendrimers mentioned in Section 3, the reversibility of the redox processes suffers as the dendrimer becomes more sterically hindered over successive generations.

5. Cyclophane-Based Systems



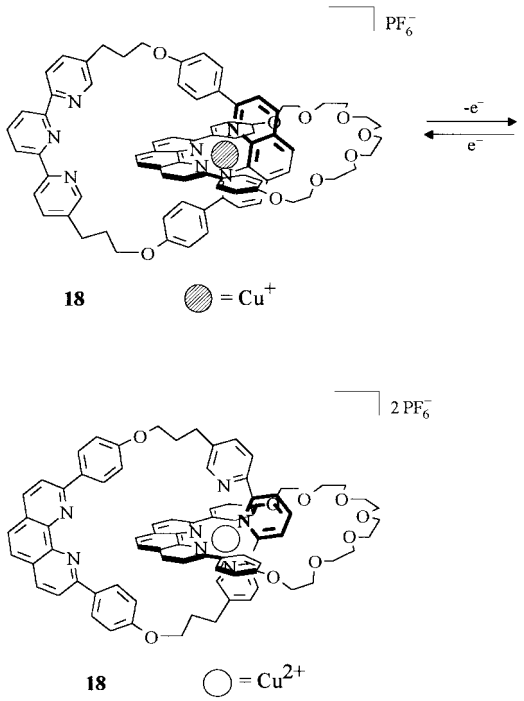
This class of compounds has been extensively studied over the last three decades, although electrochemical studies of redox-active cyclophane systems have been comparatively few. Much of the early work in this field was centered on metal complexes of simple cyclophane systems, while more recent work pursues redox-switchable binding with various guests. The electrochemical studies of cyclophane systems can be divided into three general areas: 1) electroactive cyclophanes, 2) systems involving metal coordination to cyclophanes (metallocyclophanes), and 3) cyclophanes as components of catenanes, rotaxanes, and shuttles. Calixarenes, which are a special class of cyclophane, are discussed in Section 6.

5.1. Early Studies with Cyclophanes

The early work on electroactive cyclophanes, such as the studies of Wasielewski and co-workers[91] or Sato et al.,[92, 93] aimed at investigating the electrochemistry of closely positioned redox-active centers. For example, in the naphthalene-based cyclophane **16** and its model compound 2,7-dimethylnaphthalene **17**, conformational isomerism was found to be an important determinant of the redox chemistry:[92] The oxida-

16

17



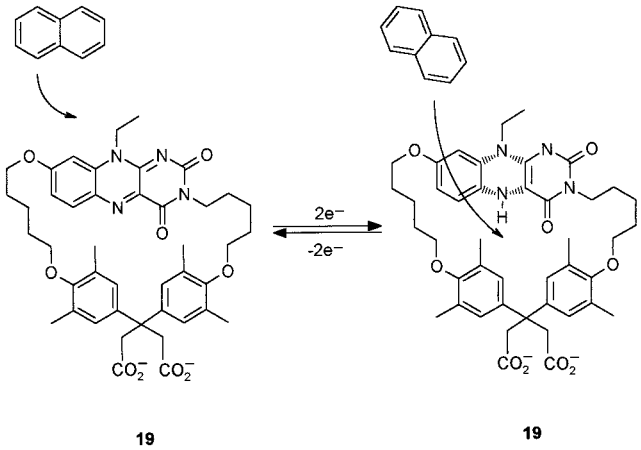
tion of the model compound **17** occurs in one step, as does that of the *cis* isomer of **16**, whereas the *trans* isomer of **16** is oxidized in two distinct steps.[92] This latter finding indicates electronic coupling between the two naphtalene units of *trans*-**16**. Some of the cyclophanes studied by these authors were

easier to oxidize than their model compounds by as much as 1 V. This is evidence for charge delocalization. A series of simple metacyclophanes with various substituents,[93] and of larger [2*n*]paracyclophane systems[94] were also characterized electrochemically in these early studies.

5.2. Metallocyclophanes

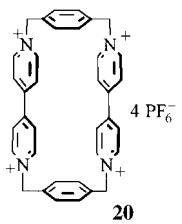
Interest in the iron and ruthenium complexes of [2*n*]cyclophanes and their electrochemistry began with the work of Boekelheide et al.,[95] but complexes with other transition metals have also been studied.[96] More recently, iron–sulfur clusters in a cyclophane cage[97] and a diamagnetic diiron–[2.2]paracyclophane complex[98] have been studied. Metal complexes of porhyrin-based cyclophanes are currently a topic of interest, studied by Staab, and co-workers[99] and Diederich et al.[100]

In the area of metal complexes of cyclophanes, an elegant example studied by electrochemistry was recently provided by Sauvage and co-workers: linkage isomerism in a catenane system **18** that contains an interlocking diphenylphenanthroline (dpp) and terpyridine (terpy) cyclophane and a dpp crown ether as metal binding ligands (Scheme 12).[101] As in



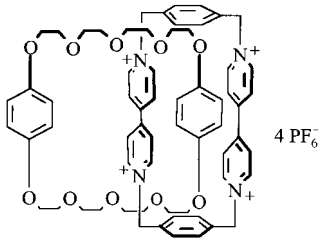
Scheme 12. The "swinging catenate" **18**: tetracoordination (top) and pentacoordination of the copper ion.

the case of the helicates, changes in the redox state of the coordinated copper ion provides redox-switchable binding to components of the catenane system. The cyclophane component of the "swinging catenate" structure **18** is capable of binding copper(I) or copper(II). Reduction of copper(II) to copper(I) results in a rearrangement from a five-coordinate (terpy/dpp, CN = 5) structure favored by copper(II) to a four-coordinate (dpp/dpp, CN = 4) copper(I) structure. The electrochemical processes are reversible in both the four-coordinate and five-coordinate species, with half-wave potentials of 0.63 V and −0.07 V vs. the saturated calomel electrode (SCE), respectively, in CH_3CN. The more negative reduction potential of the five-coordinate species reflects the greater stabilization of copper(II) in this complex. The time scale for the coordination processes was noted to be very different for the forward and reverse steps. While the oxidation $Cu^I \rightarrow Cu^{II}$ results in a slow (on the order of days) sliding of the cyclophane into the five-coordinate structure, the reverse process, reduction back to Cu^I, restores the four-coordinate geometry in a matter of seconds. The slower kinetics of the overall forward process has been attributed to other concomitant conformational changes.



5.3. Switchable Cyclophanes, Catenanes, Rotaxanes, and Shuttles

Within the past decade, attention has centered on the molecular binding capabilities of redox-switchable cyclophanes. In 1990 Diederich and co-workers were the first to report a redox-switchable cyclophane system.[2d] A flavin cyclophane, or flavinophane (**19**, Scheme 13) as termed by the



Scheme 13. Different binding modes of flavinophane **19**: the oxidized form (left) favors the binding of naphthalene at an external site, whereas the reduced form (right) forms inclusion complexes.

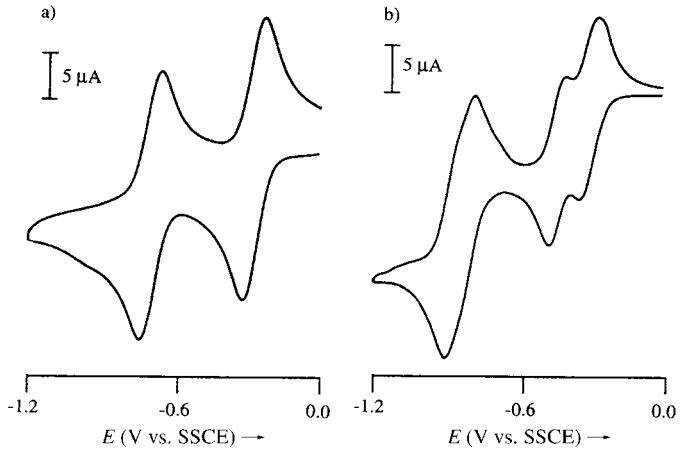
authors, displayed switchable binding ability due to a change in the geometry of the isoalloxazine unit from a planar to a "butterfly," or bent state, after a 2 e^- reduction. The reduced form of compound **19** formed inclusion complexes with naphthalene derivatives, while the oxidized form displayed external association. The association constants for these complexes are similar. The 2 e^- reduction of **19** is quasi-reversible and occurs at −0.581 V vs. Ag/AgCl in an aqueous borate buffer at pH 10.

The electrochemistry of **20** has been the subject of considerable attention.[102] This cyclophane has been elec-

21

trochemically characterized as a component of catenanes (**21**),[102c, 102e, 102f] rotaxanes (**22**),[103] and molecular shuttles (**23**).[3a] Thus, **20** can be used to exemplify effects on the redox properties of a cyclophane when it is embedded in more complicated architectures. In addition, **20** can also be used to demonstrate how electrochemistry can control the structure of a supramolecular assembly. The reversible redox processes are characteristic of the parent methylviologen unit;[102f] that is, each viologen unit can undergo two monoelectronic redox processes.

Figure 10 shows the cyclic voltammetric behavior of cyclophane **20** and that of the same cyclophane as a component of catenane **21**.[102e] The first wave in Figure 10a, a two-electron



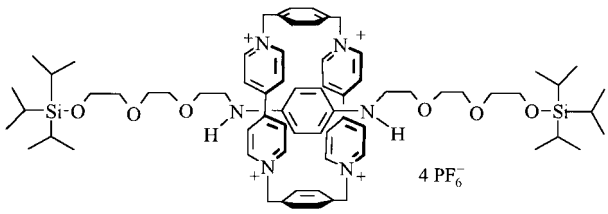


Figure 10. Cyclic voltammograms of 0.50 mM solutions of cyclophane **20** (a) and catenane **21** (b) in CH_3N, 0.1 M $TBAPF_6$; scan rate = 50 mV s^{-1}, 25°C (reprinted with permission from ref. [102e].).

process, corresponds to the reduction of the two viologen moieties (one electron each) of **20** to their corresponding cation radicals at −0.279 V vs. SSCE in $CH_3CN/TBAPF_6$, while the second wave (two electrons) corresponds to their subsequent reduction to the neutral viologens, which occurs at −0.703 V. Clearly no electronic coupling is evidenced by the voltammetry.[104] In contrast, catenane **21** exhibits three waves, the first two of which correspond to the separate monoelectronic reductions of the two viologen moieties (Figure 10b).

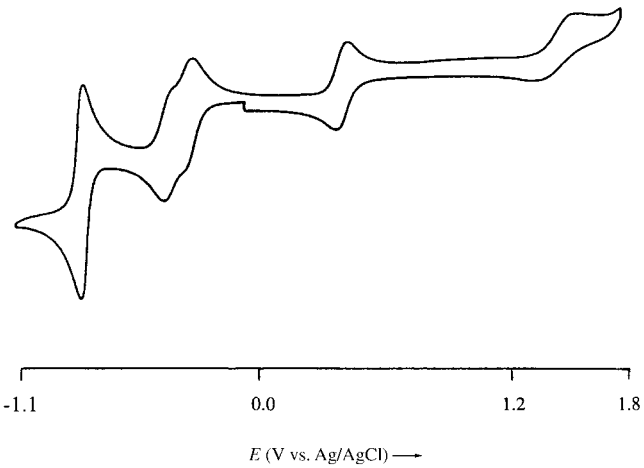
The reduction of the first viologen unit occurs at −0.307 V and the second at −0.438 V. The final two-electron reduction occurs as a single redox wave (reduction of both viologens to their neutral state) at −0.841 V. The fact that two separate reductions are observed for the first redox processes is attributed to the topological differences between the "inside" and "outside" viologen units in the catenane. The inner viologen is stabilized to a greater extent by the two-electron-rich hydroquinone units, while the "outside" viologen interacts with only one of these units. Interestingly, subsequent work on a related surface-attached catenane comprising **20** and a bis(thiol)-terminated poly(ether) hydroquinone thread does *not* show a splitting of the first reduction processes, but rather exhibits behavior similar to that of free **20** in which the first reduction of the two viologen moieties occurs as a single two-electron wave.[105]

Catenanes containing cyclic crown ethers with napthyl spacers in combination with **20** or cyclophanes with π-extended viologens have recently been examined by Stoddart and Balzani.[106] The electrochemistry of **20** in these naphthyl-bearing catenanes exhibits split waves for both the first and the second viologen reduction waves. Cyclophane **20** has also been used as a component of a series of novel [3]pseudocatenanes containing TTF-based macrocycles (TTF = tetrathiafulvalene).[107] The orientation of the cyclophane bead about the TTF moiety affected the electrochemical reversibility of the oxidation of the TTF moiety.

Cyclophane **20** has recently been used as the bead component in a rotaxane.[103] In structure **22**, both the cyclophane bead and the thread are electroactive and exhibit

22

reversible electrochemistry (Figure 11). Rotaxane **22** shows two redox waves for the first reduction of the viologen moieties at −0.272 V and −0.362 V vs. Ag/AgCl in CH_3CN/



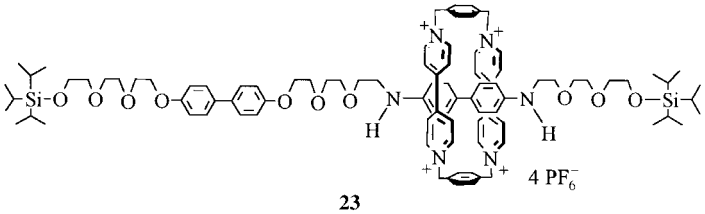


Figure 11. Cyclic voltammogram of rotaxane **22** in CH_3CN, 0.10 M $TBAPF_6$; scan rate = 200 mV s^{-1}; 25°C (reprinted with permission from ref. [103]).

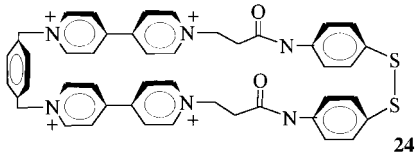
$TBAPF_6$. The second electron transfer to the viologen moieties occurs in a single step at a half-wave potential of −0.780 V vs. Ag/AgCl. While the free thread exhibits two oxidation waves at 0.203 V and 0.732 V, the thread in the



rotaxane undergoes oxidation at 0.463 V and 1.505 V (all potentials vs. Ag/AgCl). Electron transfer is thus slower, reflecting the unfavorable electrostatics.

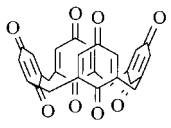
In the molecular shuttle **23**, which contains cyclophane **20** and a thread with benzidine and biphenyl stations,[3a] the electrochemistry of **20** is similar to that of the *free* cyclophane, with two-electron reductions in single waves at -0.235 V and -0.755 V vs. Ag/AgCl in CH_3CN. Relative to that of the free benzidine thread, the first oxidation of the benzidine station in **23** occurs at a more positive potential (0.570 V vs. Ag/AgCl), whereas the second oxidation occurs at a comparable potential value (0.720 V). The difficulty of the first oxidation of the benzidine station is attributable to the stabilizing presence of the cyclophane **20** bead, while the ease of the second oxidation (comparable to that of the free elongated benzidine thread) indicates that **20** has shuttled off the benzidine station to the other portions of the thread, presumably to the second (weaker) donor biphenyl station.

23

Analytical applications for **20** have also been explored: this redox-switchable receptor binds both aromatic amino acids and neurotransmitters.[108, 10d] While the solubility of **20** in organic solvents is high even in its fully reduced neutral state, its solubility in aqueous solution in the reduced state is quite poor and results in precipitation on the electrode surface. Kaifer et al. conducted binding studies with Nafion-modified electrodes.[10d] Differential pulse voltammetry of **20** was useful in the detection of binding to catechol and indole and their related neurotransmitters in the micromolar concentration range. The half-wave potential shifts exhibited by the host–guest complex were modest (10–70 mV).[10d] This work was recently extended with the self-assembly of a surface-attached cyclophane capable of molecular recognition.[109] Compound **24** self-assembles through thiol bonds with the gold electrode surface. Binding of catechol and indole at an even lower concentration range has been achieved.

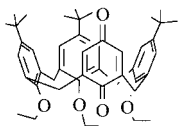
24

6. Calixarene Systems



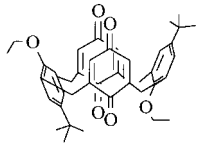
The calixarenes are a special class of cyclophanes capable of binding both neutral and charged guests. Electrochemical analyses of these systems may be divided into two broad areas: 1) electroactive calixarenes, in which the redox unit is an integral part of the σ-bonded framework, and 2) complexes of electroinactive calixarenes with electroactive guest species. The electroactive calixarenes may be further subdivided into two groups, those with the redox-active unit in the main cyclophane framework (e.g., where the phenolic groups are transformed into nitroaromatic or quinone units) and those containing electroactive pendant groups covalently attached as tethers.

6.1. Electroactive Calixarenes

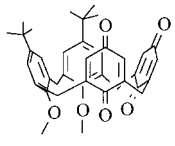


The interest in electroactive calixarenes revolves around the type, number, and location of the electroactive groups in the macrocycle. If the redox units are within the cyclophane framework, the overall size of the calixarene (as represented by the common nomenclature calix[4], calix[6], etc.) is important in understanding its redox behavior. In smaller calixarene systems, such as the calix[4]arenes, the constraints of distance and rotational flexibility are expected to influence the electrochemical behavior of the redox-active units in the basic framework dramatically. The close proximity of neighboring redox units in smaller calixarenes should have strong effects on the redox behavior. Identical neighboring redox units should reduce sequentially as opposed to simultaneously if electronic communication exists between proximal units.[104] On the other hand, the electrochemistry of pendant electroactive groups should be affected less by the size of the calixarene ring, although this may not always be the case.

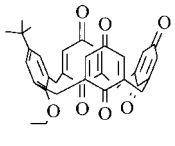
6.1.1. Calixquinones



The calixquinone series **25**–**28** provides a prototypical example of electroactive calixarenes. The first compound of the series the calix[4]quinone (**25**) was synthesized and its electrochemistry reported in 1989.[110–112] Interest in the other calixquinones quickly followed.[113–117]



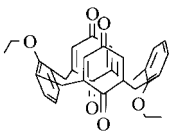
25



26

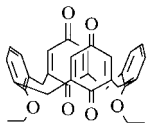
27a

27b



28

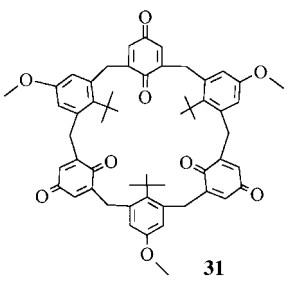
In general, compounds functionalized with quinones are capable of undergoing two-electron reductions for each quinone, the first of which is generally reversible, while the second is typically quasi-reversible.[22] The presence of protons complicates the electrochemical behavior of quinones.[22]



The redox potentials of quinones in the calix[4]quinone series **25**–**28** were found to be dependent upon the number of quinone units present as well as their respective locations[115]

and orientations.[114a] Successive quinone substitutions resulted in a greater ease of reduction, that is, a shift of the half-wave potentials to more positive values, due to electron withdrawing effects. For example, the first reduction potential of triethoxycalix[4]monoquinone (**26**) in $CH_3CN/TBAPF_6$ occurred at -0.823 V vs. Ag/AgCl, whereas for the related 1,3-diquinone **27a** the first electron reduction is -0.699 V.[115] The placement of the quinones is important for the contrasting electrochemical behavior in the isomeric diquinone compounds **27a** and **27b**,. The 1,2-substituted system **27b** is reduced more readily (by about 70 mV) than the related 1,3-substituted system **27a**. This behavior indicates that the adjacent quinone units in **27b** have a stronger electronic communication than those in the 1,3-isomer **27a**. The potential gap between successive reductions reflects the extent of this electronic communication between the neighboring redox sites. In **27a**, where the quinone moieties are opposite each other, the potential gap between the first reductions of the first quinone and second quinone units is 140 mV. In **27b** this gap increases to 300 mV. Conformations of the calix[4]quinones have been found to influence the potentials of the first and second electron reductions in the diquinones by as much as 45 mV.[114a]

The voltammetry in $CH_2Cl_2/TBAPF_6$ of chromatographically separated **29** and pure **30** revealed that the reduction of the first quinone was only slightly more positive (5 mV) in **29**



29

30

(-0.760 V vs. SCE) than reduction of the corresponding quinone unit in **30**.[114a] The effect on the *second* reduction is more pronounced, however: as the potential difference between the first and second reductions of the quinone units in **29** and **30** is 145 and 95 mV, respectively. Thus, it appears that electronic coupling between the quinone sites is stronger in the partial cone conformer **29** than in **30**.

As the calixquinone ring is enlarged on going from the calix[4] to the calix[6] and calix[8] series, the more conformational mobility leads to the electrochemical behavior typically observed for systems bearing multiple, noninteracting, identical redox units.[104] For instance, in a 1,3,5-triquinone calix[6]arene (**31**)[118] all three quinone units are reduced simultaneously at -0.587 V vs. Ag/AgCl. This contrasts with the behavior of calix[4]di- or triquinone systems, in which each quinone unit is reduced at a different potential (Figure 12).[115, 118]

31

Conceptually, the calix[6]triquinone **31** is a simple extension of the calix[4]diquinone **27**, with alternating quinone and arene units. Though the simultaneous quinone reduction

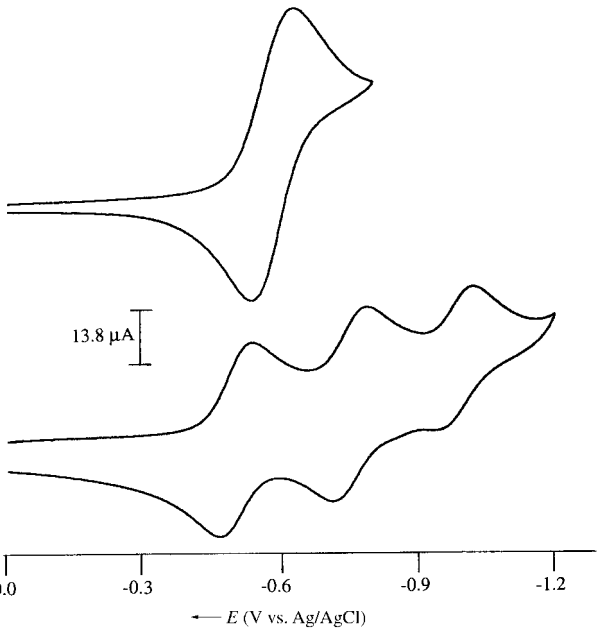


Figure 12. Cyclic voltammograms for the reduction of 1 mM solutions of calix[4]arenetriquinone (**28**)[115] (bottom) and calix[6]arenetriquinone (**31**)[118] (top) obtained on a glassy carbon electrode in CH_3CN, 0.10 M $TBAPF_6$; scan rate = 100 mV s^{-1}, 22°C.

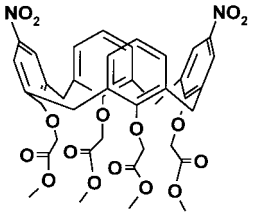
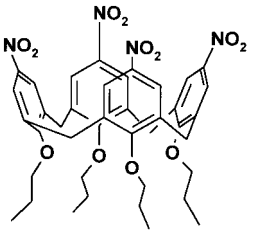
observed in **31** would appear to be a consequence of the greater conformational mobility afforded by the larger framework, results with a series of calix[6]diquinones[119] suggest that this may not always be the case, vide infra.



6.1.2. Cation Binding by Calixquinones

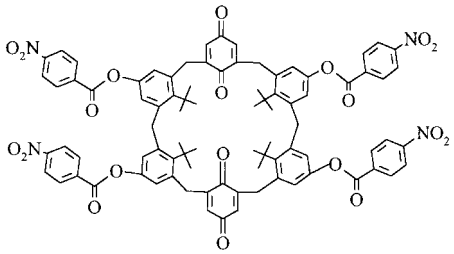
As expected, binding of calixarenes with alkali, alkaline earth, or transition metal ions, or with ammonium ions, has an effect on their electrochemistry.[115–117] The first electron reduction potentials of these compounds with binding constant on the order of those exhibited by the crown ethers shift anodically between 90–600 mV in the presence of a bound ion, corresponding to sizable binding enhancements.[115–117] Recent work has also suggested that binding to ions can affect the conformations of calixarenes.[120, 121] This point has not been directly noted as a significant factor when interpreting the electrochemistry of the free and bound calixarenes, but the finding that different conformations[114a] may well have (albeit slightly) different reduction potentials does make conformational change an important consideration when determining binding constants by electrochemical methods. Care must be exercised to assure that any potential shift used to estimate binding or binding enhancements does not include a component due to a concomitant change in the conformation of the calixarene.



6.1.3. Nitroaromatic Calixarenes

Calixarenes with nitro groups in the *para* position of the phenol rings (nitroaromatic calixarenes) have been prepared,[122] and these exhibit slightly different electrochemical behavior. In contrast to results obtained for **26**, a symmetrically 1,3-

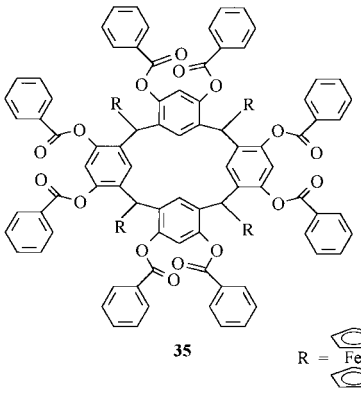
substituted calix[4]nitroarene tetramethylester **32** undergoes a quasi-reversible single-electron reduction at each nitroaromatic unit at -1.22 V vs. Ag/AgCl in CH_2Cl_2/TBAPF$_6$.[119]



32

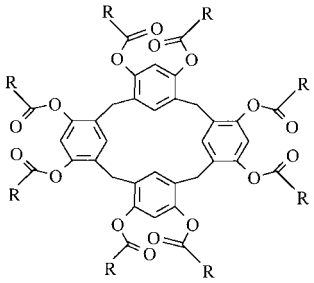
33

The cyclic voltammetry of a calixarene bearing four nitroaromatic groups (**33**) shows two two-electron reduction waves.[119] Each wave corresponds to the simultaneous reduction of diagonally opposite pairs of nitroaromatic units. A calix[6]diquinone bearing four pendant nitroaromatic esters (**34**) has also been examined.[119] In CH_2Cl_2/TBAPF$_6$ the



34

reversible first electron reduction for each of the quinones occurs at different potentials (-0.472 and -0.785 V vs. Ag/AgCl), reminiscent of the observations with **27a** and **27b**. The bulky lower rim substituents may introduce greater conformational rigidity than would normally be anticipated for the larger calix[6] system and permit greater electronic communication between the quinones than would be expected for this larger system. The second electron transfers, to the quinone radicals, occur simultaneously at -1.15 V vs. Ag/AgCl and are quasi-reversible. The four pendant nitroaromatic units are then reduced simultaneously at -1.50 V vs. Ag/AgCl in a quasi-reversible electron transfer process.



6.1.4. Calixarenes with Pendant Electroactive Groups

Attachment of pendant electroactive groups to the upper, lower, or methylene side-arm positions has been explored by several groups. Recently, Beer and co-workers utilized pendant lower rim pyrrole moieties to electropolymerize calix[4]arenes onto the surface of a glassy carbon electrode.[123] Other compounds that have been reported include calix[4]arenes and resorcinarenes with pendant metallocene units,[124] with a pendant $\{Ru(bpy)_3\}^{2+}$ group,[125] and a calix[8]arene with a pendant C_{60}.[126] The ferrocenyl resorcinarenes[124b] provide an interesting comparison between the electrochemical behavior of ferrocenyl substitution at the methylene bridge sites and that observed when the units are appended to the upper rim.

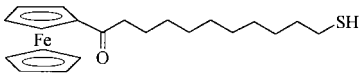
Compound **35**, a resorcinarene substituted at the methylene bridge positions, shows two separate cyclic voltammetric peaks (+0.60, +0.69 V vs. SCE) corresponding to two mono-

35

36

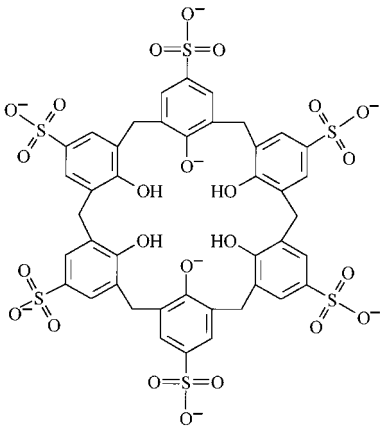
electronic processes.[124b] The two reversible waves have been ascribed to the two differing ferrocenyl environments detected in ^{1}H and ^{13}C NMR studies. In contrast, an upper rim substituted ferrocenyl resorcinarene analogue (**36**) demonstrated a single reversible oxidation wave in which the eight ferrocenyl units are independently oxidized at roughly the same potential (0.89 V vs. SCE).[124b] This result agrees with the fact that, in the latter case, the ferrocene units are farther apart from one another than they are in **35**.

6.2. Calixarene Complexes with Electroactive Guests



Another area where electrochemical studies have been useful is in the study of complexes of calixarenes with electroactive species. In complexes between sulfonic acid calix[6]arenes and surface-attached ferrocene units,[127] as well as dissolved viologen[128] and ferrocene,[129, 130] the presence of the calixarene has been shown to affect the electrochemistry of the included guest.[127–130]

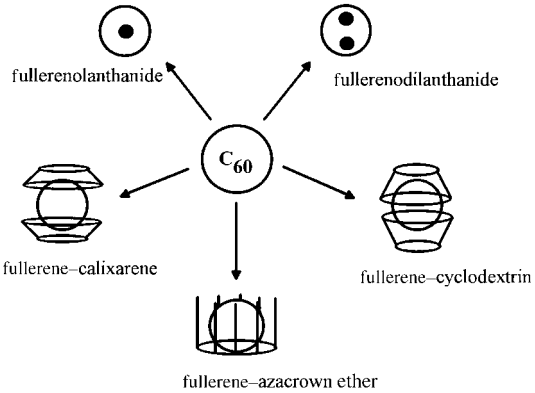
A particularly striking example is the complex between the ferrocenethiol **37** and the sulfonated host calix[6]arene **38**.[127] Compound **37** self-assembles on the surface of smooth gold electrodes and exhibits surface-confined electrochemistry. It is oxidized at a half-wave potential of 0.51 V vs. SSCE. In the presence of submicromolar amounts of **38**, the single voltammetric wave observed for pure surface-confined **37** is split into two waves, corresponding to the oxidation of the free and bound ferrocene sites. At 2 μM, a single wave is observed for **38** at the formal potential of the bound ferrocene, which occurs 90 mV more positive than that of the unbound, surface-confined ferrocene.



7. Fullerene-Based Systems

7.1. Fullerene Inclusion Complexes: Fullerenes as Hosts and as Guests

Complexes between calixarenes and fullerenes have also been of interest to a number of authors.[126, 131–135] Two types of



37

38

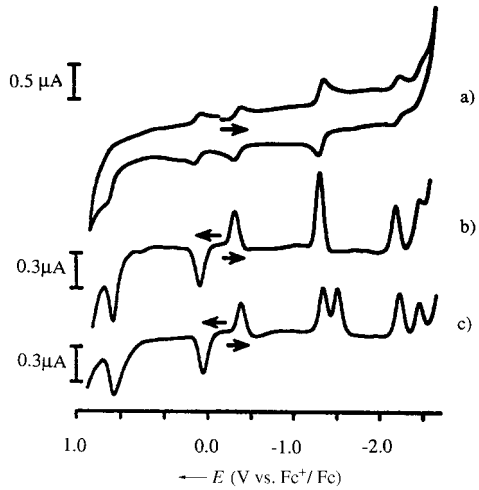
fullerene inclusion structures have been electrochemically characterized. In the first type, called endohedral fullerenes,[136] the fullerene is host to a small molecule or ion such as a lanthanide cation, while in the second type the fullerene is embedded in the cavity of a larger molecule such as a cyclodextrin,[137a–c, 137f] a calixarene,[126, 131–135, 137d] or a crown ether[137e] (Scheme 14).

Scheme 14. Supramolecular host–guest complexes with fullerenes.

7.1.1. Fullerenes as Hosts

Endohedral structures have been synthesized[136] with C_{82}, C_{84}, and C_{86} as hosts with lanthanide cations (La^{3+}, Y^{3+}, Sc^{3+}, Ce^{4+}…) as guests. These compounds are designated by the formula $M_m@C_{2n}$ where M is the lanthanide, C_{2n} the carbon cage, and $m = 1$, 2, or 3. These supramolecular structures are conceptually very intriguing, since they are formed from the ionic association between an anion (fulleride) of charge n^- and a cation (lanthanide) of charge n^+ which cannot escape from the anion. In the strictest sense of the word, these cannot be considered classical complexes, since the ion pairing interactions are not really the only ones holding together the complete structure. As a matter of fact, endohedral structures of C_{60} with noble gases are known,[138] and these are definitely not complexes, but more like "molecular rattles." In these, the noble gas molecule is incarcerated inside the fullerene but is not truly held by intermolecular electronic forces. In a way they are analogous to the catenanes, where two or more molecules are held together like the links of a chain.

The electrochemistry of fullerenolanthanides[139] is completely different from that of empty fullerenes, which usually displays equidistant one-electron reductions.[140, 141] Even though the fullerenolanthanides can be reduced by stepwise electrode processes, these reductions are not equally spaced on the potential scale, and they do not correspond always to one-electron processes. For example, $Y@C_{82}$ and $Gd@C_{82}$ undergo four reductions, but the second one is a two-electron process (Figure 13).



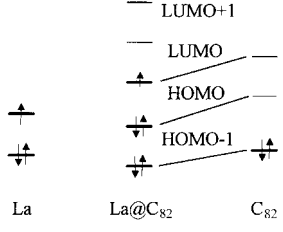


Figure 13. a) Cyclic voltammogram of $Y@C_{82}$; scan rate 20 mV s^{-1}. b) and c) Differential pulse voltammograms of $Y@C_{82}$ (b) and $La@C_{82}$ (c) in 1,2-dichlorobenzene, 0.1M $TBAPF_6$; scan rate 20 mV s^{-1} (reprinted with permission from ref. [139b]).

On the other hand, $La@C_{82}$ and $Ce@C_{82}$ undergo five distinct one-electron reductions (Figure 13). An explanation for such a peculiar electrochemical behavior for the fullerenolanthanides is still needed. Another noticeable characteristic of the electrochemistry of fullerenolanthanides is that all undergo a relatively easy reversible one-electron oxidation (see Figure 13). This might reflect the single occupancy of the HOMO for these complexes, where the metal ion is in its +3 oxidation state (Scheme 15). In other words, the ease of the first oxidation of fullerenolanthanides may be because removal of one electron in $M^{3+}@C_{82}$ leads to a closed-shell species.[139]

Scheme 15. Schematic MO diagrams of La, $La@C_{82}$, and C_{82}.

Changing the nature of the metal inside the cage affects the electrochemistry of the endohedral fullerenes only slightly. It was proposed[139b] that the 4f orbitals of the lanthanide cations do not play a significant role in the electrochemistry of fullerenolanthanides and that the first reduction and the first oxidation occur on the Singly Occupied Molecular Orbital (SOMO). The electron density of the latter is located mainly on the part of the fullerene cage closest to the lanthanide cation. Thus, the bigger the lanthanide, the closer it is to the cage and the more stabilized the negative charge on the cage. In other words, the larger the lanthanide, the easier the reduction and the more difficult the oxidation.

Very recently[139d,e] preliminary results on the physical and chemical properties of endohedral fullerene complexes containing two metal cations have appeared. Only very preliminary electrochemical data were listed, and no discussion of these data was provided in this article.

7.1.2. Fullerenes as Guests

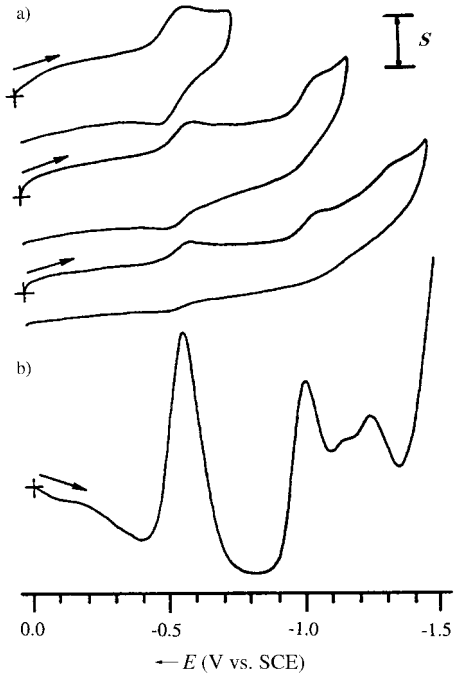
Mainly three types of inclusion complexes in which a fullerene is the guest have been synthesized: C_{60}–cyclodextrin complexes (C_{60}/CD),[137a–c,f] C_{60}–calixarene complexes,[126, 131–134, 137d] and a C_{60}–azacrown complex.[137e]

Interestingly, the inclusion of the fullerene derivative $C_{61}(C_6H_5)_2$ inside the cavity of an HIV protease was studied by computer modeling with the hope of altering the reactivity of the protease.[142a,b] The results obtained are surprisingly promising, and several laboratories are now participating in the study of the biological activity of C_{60} and its derivatives.[142c]

The electrochemistry of C_{60}/γ-CD in DMF is very similar to that of C_{60}.[137c] However, in the case of C_{60}/γ-CD, the third reduction wave is followed by a chemical reaction that produces a species yet to be identified. C_{60}/γ-CD is only slightly soluble in water, but enough dissolves to allow recording its electrochemistry (Figure 14).

Cyclic voltammetry of C_{60}/γ-CD in water containing 0.15 M $LiClO_4$ at scan rates higher than 200 mV s^{-1} reveals two reversible one-electron reductions at $E_{1/2} = -0.62$ and -1.03 V vs. SCE, and one irreversible reduction at $E_{pc} = -1.34$ V vs. SCE. At slower scan rates (<200 mV s^{-1}), only the first reduction is reversible, and, as can be shown by differential pulse voltammetry (DPV), the second reduction is followed by a chemical reaction. The authors speculated that C_{60}^{-} is still embedded in γ-CD whereas C_{60}^{2-} is released and undergoes a chemical reaction with water.

As mentioned above, a second type of supramolecular complex where a fullerene is the guest has appeared in the literature: the C_{60}/calixarene complexes.[126, 131–135, 137d] Interestingly, the only calixarene to complex C_{60} and C_{70} efficiently is **39** (Scheme 16). The forces that induce formation of such a complex are probably of the CH–π and π–π type. To our knowledge, only one report that succinctly investigated the electrochemical behavior of C_{60} in the presence of calixarenes (the diethyl esters of *para-tert*-butylcalix[8]arene, *para-tert*-butylcalix[5]arene, and *para-tert*-butylcalix[4]arene) has been published.[134] The calixarenes, whatever their size, interact or react with C_{60} anions. The products of these reactions are more difficult to reduce than C_{60} itself. During the electrochemical experiments, addition of calixarene to a solution of C_{60} also caused adsorption on the working electrode at potentials more negative than the second reduction wave of C_{60}.



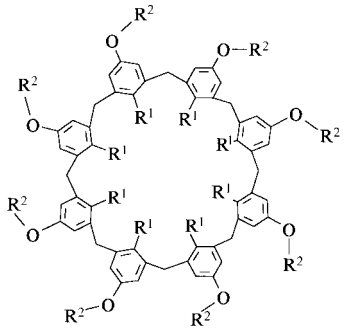


Figure 14. a) Cyclic voltammograms and b) differential pulse voltammograms of nearly saturated magenta γ-CD/C_{60} solution in water, 0.15 M $LiClO_4$; glassy carbon electrode. 7.2. Latest Work on Fullerenes Related to Supramolecular Chemistry

Recently C_{60} was derivatized with the aim of building a starting block to form supramolecular complexes. Initially Hirsch et al. reported the synthesis and electrochemistry of **42**, the Diels–Alder adduct of C_{60} with a phthalocyanine.[143] The CV of the complex reveals five reversible one-electron reductions, which involve either the fullerene or the Ni

42 $R^1 = C_7H_{15}$

metallophthalocyanine center. Reduction potentials for two complexes in which a porphyrin is covalently bonded to C_{60} have been reported.[144, 145] In both cases redox processes centered on C_{60} and on the porphyrin ligand can be observed. In all of these studies, the electrochemical results suggested that the coupling between the carbon cage and the ligand is not very effective when both molecules are in the ground state. A second example of a C_{60} derivative for further supramolecular binding is a C_{60}–$[Ru^{II}(bpy)_3]$ complex.[146]

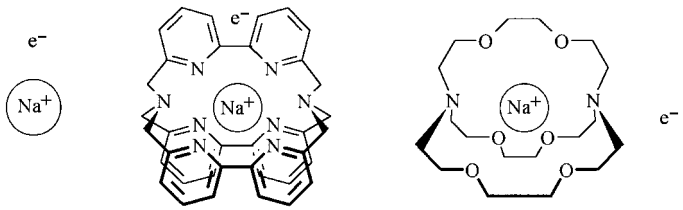
7.3. Electrocrystallization of Fulleride Salts

As already discussed, electrochemistry can be used as an effector to prepare novel materials mainly by electrocrystallization. The final electrogenerated products are crystalline supramolecular assemblies with unique properties. This is truly a field of research in which electrochemistry, supramolecular chemistry, and material science merge. The first electrochemical preparation of a fulleride salt was reported in 1991 by Wudl et al.[147] Attempts by these authors to prepare a bulk solution of C_{60}^- with tetraphenylphosphonium iodide (TPPI) as supporting electrolyte resulted in the precipitation of its salt, $C_{60}^-(TPP^+)_3(Cl^-)_2$. Because the sample precipitated as a powder, no structural information was obtained.

The first electrocrystallization of a fulleride salt was achieved by Moriyama et al. in 1993.[148] Needlelike single crystals of $C_{60}^-(PPN^+)$ ($PPN^+ = \{N[P(C_6H_5)_3]_2\}^+$) are air- and light-sensitive and showed no electrical conductivity at room temperature.[148] No detailed X-ray characterization of the crystal was provided in this article. Later the same year, Pénicaud et al. reported the X-ray characterization of electrocrystallized $[(C_6H_5)_4P]_2(C_{60})(I)_x$ ($x \ll 1$).[149] The black shiny single crystals that grew under controlled current electrocrystallization of C_{60} in a toluene/CH_2Cl_2 mixture with tetraphenylphosphonium iodide as supporting electrolyte revealed that the C_{60} monoanions were separated at least by 12.588 Å (center-to-center distance for C_{60}: $d = 10$ Å). This indicates that the C_{60} monoanions in $[(C_6H_5)_4P]_2(C_{60})(I)_x$ are isolated.[149] The tetraphenylphosphonium C_{60}^- salt was stable in air, and its conductivity at room temperature was $2-5 \times 10^{-5}\ \Omega^{-1}cm^{-1}$.[149] Interestingly, even though the C_{60} radical anions are well separated from each other, the magnetic susceptibility data did not follow a Curie–Weiss law.[149]

Controlled-potential electrocrystallization of $[(C_6H_5)_4P]$-$C_{60}\cdot[(C_6H_5)_4P]Cl$ in 1,2-dichlorobenzene was reported in 1994 by Bilow et al.[150] The black, air-stable, square-pyramidal crystals were characterized by X-ray.[150] As expected, this salt is isostructural with the one electrocrystallized by Pénicaud et al. Similarly, electrocrystallization of the tetraphenylarsonium salt of C_{60}^- was also reported.[151] It is important to note that both X-ray structures (Pénicaud's and Bilow's) showed disorder in the arrangement of the C_{60} monoanions and this precluded a clear picture of the distortions that the carbon cage undergoes upon addition of one electron. The first example of a highly ordered salt of C_{60}^- was reported in 1995.[152] $[Ni\{C_5(CH_3)_5\}_2]^+[C_{60}]^-$ was prepared by chemical reduction of C_{60} with one equivalent of decamethylnickelocene.[152] The X-ray characterization of the dark red parallelepiped crystals revealed structural evidence of a Jahn–Teller distortion of the C_{60} cage upon reduction.

In an attempt to generate new materials with interesting electrochemical and photochemical properties, Foss et al. electrocrystallized $[Ru(bpy)_3](C_{60})_2$.[153] The conductivity of powdered samples was $0.01\ \Omega^{-1}cm^{-1}$ at room temperature.[153] No photoconductivity was observed.[153] In 1994 Kobayashi et al. reported the first electrocrystallization of an alkali metal fulleride salt, $Na_{0.39}C_{60}(THF)_{2.2}$.[154] The room temperature conductivity of the sodium salt was $50\ \Omega^{-1}cm^{-1}$ and increased to $1000\ \Omega^{-1}cm^{-1}$ at 100 K.[154] This sodium salt was found to be isostructural with respect to other chemically prepared alkali metal fulleride salts, $M_xC_{60}(THF)_y$ (M = Li, Na, K).[154] The X-ray data for the electrocrystallized sodium salt indicate that there are direct interactions between the C_{60} monoanions (shortest distance of 9.93 Å), and this might explain the metallic character of the salt.[154] Only one fulleride salt made from a higher fullerene has been electrocrystallized to date.[155] Single crystals of $[(C_6H_5)_4P]_2(C_{70})[I]$ are air-stable, and their magnetic susceptibility follows a Curie-Weiss law, which suggests isolated C_{70} monoanions. This was confirmed by X-ray data, which revealed a shortest center-to-center C_{70} distance of 12.682 Å[155] ($d \approx 10$ Å for C_{70} itself, along its equatorial belt). However, as for the corresponding C_{60} salt, disorder in the crystals prevented any clear picture of how the C_{70} molecular structure is affected by the addition of one electron.



Finally, it is important to note that only salts of C_{60}^- and C_{70}^- have been electrocrystallized. No salts with higher charges have been prepared by electrocrystallization. However, chemical reduction of C_{60} to C_{60}^{2-} with either Na or cobaltocene as reducing agent has been reported.[156] Black shiny single crystals of $[PPN^+]_2C_{60}^{2-}$ are "somewhat air sensitive", and their magnetic characteristics led the authors to the conclusion that C_{60}^{2-} is paramagnetic at room temperature.[156b] The high precision of the X-ray structure obtained for the crystals of this C_{60}^{2-} salt allowed the observation that Jahn–Teller distortion in the dianion changed the icosahedral symmetry of the neutral molecule to C_i.[156a] These results reported by Boyd et al. suggests that the electrocrystallization of salts of C_{60}^{2-} and probably C_{70}^{2-} are possible and should be attempted.

8. Electrogeneration of Expanded Atomlike Structures

A conceptual link between reduced cryptates (cryptatia) and endohedral fullerene complexes exists, even though the two types of materials seem rather unrelated. A cryptatium is

obtained by reduction of a positively charged complex between cation and cryptand (cryptate)[78, 157] to its neutral form. In other words, a cryptatium can be visualized as an anionic armor surrounding a metallic heart. The analogy with endohedral fullerene structures containing metal ions[136] then becomes obvious. The endohedral fullerenes that contain metal ions inside are also made of a positively charged core surrounded by a negatively charged spherical shield. Both cryptatia and endohedral fullerene structures are neutral entities. However, if one was to approach either of these molecules on a nanometer scale, the first observation would be that of a negative electron density corresponding to the electrons located on the cryptate ligand or on the fullerene cage. Beyond this negatively charged shield, one would find the positively charged metal ion, the "nucleus" of such a "pseudo-atom." Thus both are classified as "expanded atoms."

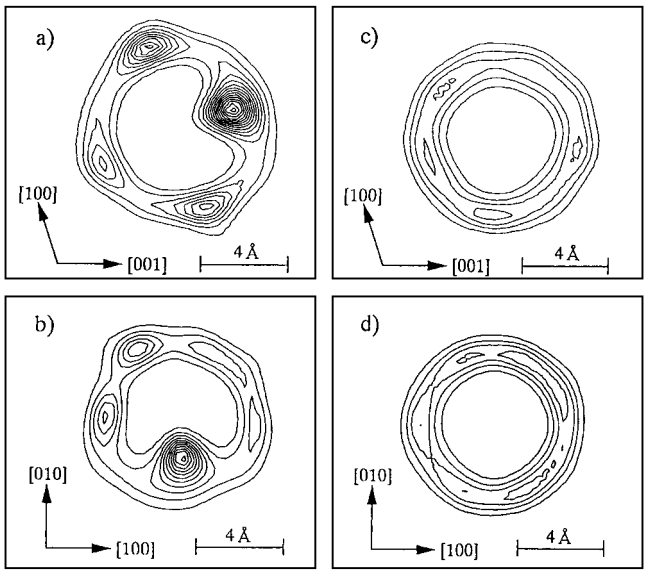
Cryptatia and endohedral fullerene complexes thus can be considered as intermediate between a metal atom and an electride[158, 159] (Scheme 17). In the metal atom, for example

Scheme 17. The relationship between an alkali metal atom (left), a cryptatium (center), and an electride (right).

sodium, the loosely bound electron is confined to the 3s orbital. Because of the very strong affinity of the cryptand [2,2,2] for metal cations such as the sodium cation, the electron of the metal in the electride is expelled from its interaction with the cationic center into the cavities present in the crystal lattice.[158] In cryptatia and endohedral fullerene structures, the electron is not confined to the corresponding s orbital of the metal cation but neither is it completely expelled from its interaction with the metal cation.

It is not a simple task to establish that in a given cryptatium, the electrons balancing the metal ion charge are located on the cryptate ligand. This was accomplished in 1991 by X-ray characterization of single crystals of the first cryptatium, $[Na \subset (bpy_3)]^0$.[78] Single crystals of this sodio-cryptatium were grown at a platinum electrode by the electrocrystallization technique, which is probably the most efficient way to grow crystals of cryptatium species. $[Na \subset (bpy_3)]^0$ (bpy_3 is a cryptand constructed from three bpy units as shown in Scheme 17) is the only cryptatium for which a crystal structure has been determined successfully to date. Its crystal structure revealed that of the three bipyridine units that are covalently linked to form the cryptand ligand, only one was planar. In addition, the $Na^+ - N$ distance for the planar bpy unit was shorter than that for the other two (2.59 vs. 2.82 – 2.83 Å). This suggests that the electron added to the cryptate ligand during its reduction is located on the flat bpy unit. Thus, the sodio-cryptatium is more accurately described as $[Na^+ \subset (bpy^-)\text{-}(bpy)_2]$.

The conceptually related endohedral fullerene systrems still have to be structurally characterized. One striking result was recently reported by Takata and co-workers, who used synchrotron X-ray diffraction spectroscopy.[160] They were able to detect the encapsulated metal ion of $Y@C_{82}$ (Figure 15).[160]



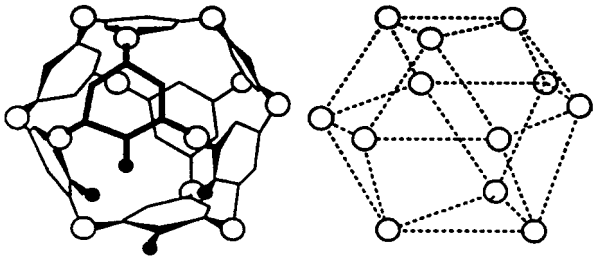


Figure 15. The maximum entropy model (MEM) electron density distribution of $Y@C_{82}$ for a) the (010) and b) the (001) sections, and of C_{82} for c) the (010) and d) the (001) sections. The contour lines are drawn from 0.0 e A^{-3} at 0.5 e A^{-3} intervals. The yttrium atom's seat inside C_{82} can be clearly seen in a) and b). (Reprinted with permission from ref. [160].)

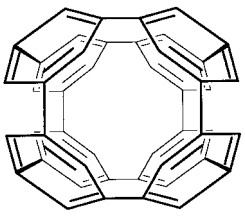
The family of compounds $[M(bpy)_3]^0$ (M = Fe, Ru, or Os) is also another example of the general class of structures defined as "expanded atoms." Even though these cationic complexes have been studied for 30 years, only recently was their potential as novel "expanded atoms" revealed.[161, 162] In these complexes the three bpy units are not covalently linked to each other; nevertheless they surround the positively charged metal center in a similar fashion to the tris(bpy) cryptand ligand. The series of compounds, $[M(bpy)_3]^0$ (M = Fe, Ru, or Os) was successfully electrocrystallized at a platinum electrode from the corresponding precursor cations, $[M(bpy)_3]^{2+}$.[7, 161] The structures of these complexes have not yet been published, but they seem to retain the original octahedral symmetry of the unreduced complex. This surprising result is currently under intense investigation. Another intriguing result with the $[M(bpy)_3]^0$ single crystals is their lack of an ESR signal. This contrasts with results reported by DeArmond et al.,[74, 163] who described a 250 G wide ESR line centered at $g = 2.23$ for the same materials but studied as powders. This might indicate interesting conducting or semiconducting properties. Only the reduced ruthenium complex has been thoroughly characterized at the present time.[162]

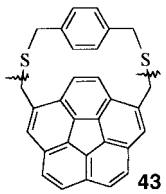
Magnetic susceptibility measurements on electrochemically prepared single crystals revealed that $[Ru(bpy)_3]^0$ is best characterized by the spatially isolated redox orbital model.[162] The reduction electrons are located on two of the three bpy units of each molecule in the ligand's π^* orbitals. A comparison

of the magnetic properties of $[Ru(bpy)_3]^0$ in solution and in the solid state suggests that removal of the solvent leads to a decrease in the energy gap between the metal dσ* and the ligand π* orbitals. The best fit of the experimental magnetic data was obtained when $[Ru(bpy)_3]^0$ was considered as a one-dimensional chain structure in which each electron on a ligand is coupled intramolecularly to the electron on the other bpy ligand and intermolecularly to the closest bpy unit of the neighboring molecule. $[Ru(bpy)_3]^0$ is a semi-conductor, and the temperature dependence of its conductivity can be rationalized with a hopping conduction mechanism.



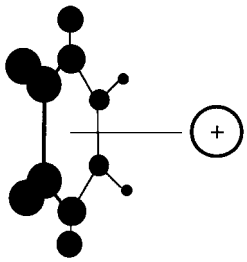
Four years ago Ross et al.[164] reported the theoretical calculations of the polarizabilities of a series of spherical molecules with encapsulated cations, the heterospherophanes (Scheme 18). These compounds, yet to be synthesized, are

Scheme 18. Schematic representation of heterospherophanes (reprinted with permission from ref. [164]). Open spheres = heteroatoms, solid spheres = selected hydrogen atoms to show steric crowding around cavity entrance.



closely related to the cryptatia and the endohedral fullerene complexes. In the particular case of the thiaspherophanes, the sulfur atoms should allow the electrons that balance the charge of the embedded cation to be delocalized over the entire molecule and, in the crystalline state, should favor intermolecular electronic coupling. The cation would be shielded by the field generated by the delocalized charge, producing a true "expanded atom."

Two recent reports are also conceptually related to "expanded atoms". In 1995 Diederich et al.[165] reported the electrochemistry of the mono- through hexakis-adducts of C_{60}. One of their conclusions was that successive rupture of the C_{60} double bonds during six successive addition processes to the cage ultimately revealed the benzenoid "cubic" cyclophane structure enclosed in the fullerene framework (Scheme 19). Synthesis (or retrosynthesis from C_{60}) of such a "cubic" cyclophane would truly represent an important step toward the synthesis of a novel "expanded atom". Finally, Siegel and co-workers[166] recently reported the synthesis of the first corannulene cyclophane (**43**), which obviously is a well-suited candidate for the synthesis of "expanded atoms" given that the "organic skin" could allow for delocalization of the excess negative charge around a centrally located and bound cation.



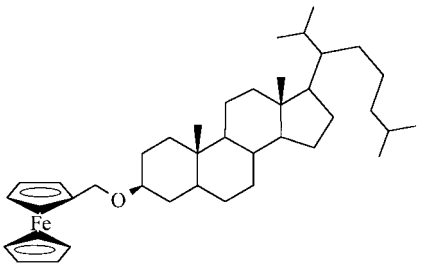
Scheme 19. Benzenoid "cubic" cyclophane structure contained in C_{60}.

In conclusion, the concept of an "expanded atom" is more than just an idea and its exploration could easily lead to the preparation of novel materials with unique properties. The most solid experimental evidence that "expanded atoms" can be made is the successful synthesis of endohedral fullerene structures. In fact, endohedral fullerenes containing more than one metal ion have been isolated and characterized.[139d, 139e] In those cases, in addition to the attractive interaction between the cations and the negatively charged fullerene sphere, one has to take into account the electrostatic repulsion between the two metal cations within the cage. In a way, the entire situation is reminiscent of charge repulsion in nuclei and their attractive interactions with the orbiting electrons in an atom.

43

In all of the previously mentioned examples of "expanded atoms", the metal cation is surrounded by a structure derived from the benzene ring. One can envisage then that cation–π interactions (Scheme 20)[167] will be omnipresent in these systems. These noncovalent bonds between cations and π-rings might be used as a driving force in the tethered synthesis of novel "expanded atoms".

Scheme 20. The cation–π interaction.

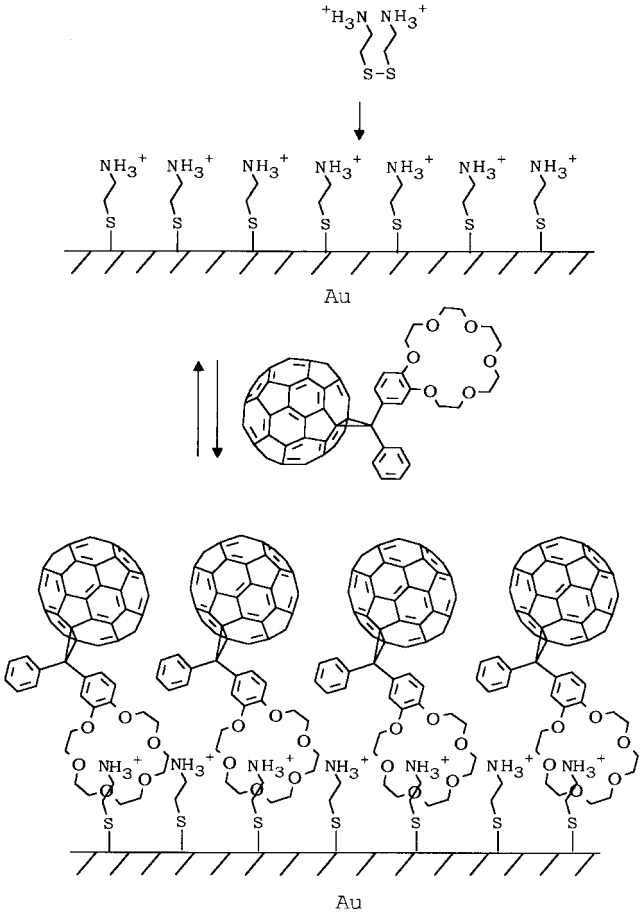


9. Potentially Functional Aggregates and Some Future Prospects

In the previous sections examples were presented of how electrochemical techniques have been used to characterize single molecules, complexes, and aggregates composed of a relatively small number of molecules. Instead of using this last section as a prophetic platform to try to preach about the future, two additional examples of work from our laboratory have been selected to illustrate how important electrochemistry is for the formation and detection of large aggregates of supramolecular assemblies. In one example, electrochemistry was used to induce the formation of liposomal aggregates,[168] while in the other it was the technique used to detect aggregate formation on a surface, which occurred spontaneously through molecular recognition.[169]

Typical natural bilayer membranes are formed from phospholipids derived from glycerol and fatty acids. The formation of these membranes primarily relies on the hydrophilic/hydrophobic balance that exists between the headgroup/tail portions of these compounds. It is this balance that confers the unusual stabilities associated with these highly organized supramolecular aggregates. Either polar or charged moieties in the headgroups interact strongly with the surrounding water medium, while the hydrophobic alkyl tails interact with each other inside the bilayer. A while back we showed that a crown ether, even uncomplexed, was suffi-

ciently hydrophilic to induce formation of nonionic liposomes (niosomes) when attached to a cholesterol group.[170]



The concept of redox switching as applied to binding control was already discussed in Section 2. In those cases, electrochemistry was used to generate charge in part of a molecule, and this charge resulted in inter- or intramolecular electrostatic interactions with species of the opposite charge, thus leading to enhanced binding. In the present context of bilayer membrane formation, electrochemical switching was used to generate charged headgroups for enhanced hydrophilicity. The switchable headgroup that was selected originally was ferrocene, and the hydrophobic tail was either cholesterol or cholestanyl (Scheme 21).[168] Electrochemical

Scheme 21. Structure of steroidal ferrocene derivatives used to form liposomes after oxidation of the ferrocene head group to ferricinium.

oxidation of the ferrocene group to ferrocinium followed by sonication in water led to the formation of stable vesicles.[168] These vesicles constitute rather complex aggregates with potential applications as redox-active drug delivery systems. Reduction of the vesicles back to their neutral states, either chemically or electrochemically, resulted in their total disruption. An extension of this work was reported very recently.[171]

A striking example of how electrochemistry is uniquely useful in characterizing the formation of architecturally complex and dimensionally large assemblies was published very recently.[169] A self-assembled monolayer (SAM) of cystamine was first allowed to form on a gold [111] electrode by following well-established procedures.[172] This monolayer, which forms spontaneously, terminates in positively charged ammonium groups, as represented in Scheme 22. If this monolayer is now exposed to a solution of a crown ether-containing compound such as the methanofullerene shown in Scheme 22, hydrogen bonding between these two functional groups should induce the formation of a secondary SAM.[173] The overall process is described in Scheme 45. Although reflectance spectroscopic techniques can be applied to characterize the formation of such monolayers at the electrode–solution interface, electrochemistry offers an easy and convenient way to establish whether such supramolecular aggregates form. Since the fullerene group is electroactive, as described in Section 7, it is very easy to detect the current for the first reduction of the fullerene moiety to its monoanionic state. The current detected for the same solution of the methanofullerene in the absence of a cystamine monolayer can be easily subtracted from that observed in the presence of the monolayer to obtain the surface concentration effect. After simulation and appropriate calibration of the electrode surface area, a surface covarage of 1.4×10^{-10} mol cm^{-2} was

Scheme 22. Formation of a cystamine monolayer on gold followed by its interaction with a benzo[18]crown-6 methanofullerene. A secondary monolayer of fullerenes is formed by self-assembly due to molecular recognition between the ammonium groups and the crown ethers.

determined. Assuming an area per molecule of 100 Å^2 for the C_{60} group, a close-packed coverage of 1.9×10^{-10} mol cm^{-2} is calculated. This means that about 75% of the surface is covered by this double self-assembly process driven.

These two examples should give the reader some concrete ideas on how electrochemistry can be used to either induce or measure the formation of rather complex supramolecular aggregates. In the field of SAMs, electrochemistry is undoubtedly one of, if not the premier, technique used to characterize the aggregates. Future uses in this field, as well as in supramolecular science, in general are certain to continue to increase in view of the power and simplicity of the techniques involved.

Addendum

Since this article was initially accepted for publication, the application of electrochemical techniques to supramolecular structures has continued apace. Here we highlight but a few of the latest articles in the field. In the area of redox switching the group of Rotello has recently reported a novel, electrochemically controlled three-component molecular switch based on hydrogen bonding.[174] Kaifer, Morán and co-workers have reported the electrochemically switchable formation of inclusion complexes of β-cyclodextrins and multisite guests,

dendrimers bearing up to 16 ferrocenyl moieties.[175] Beer and co-workers have continued to make progress in the area of anion binding and have recently reported enhanced selectivity for $H_2PO_4^-$ anions employing a calix[4]arene derivative with a pendant $[Ru^{II}(bpy)_3]^{2-}$ group.[176] With respect to cyclophane chemistry, the work of Becher and co-workers on TTF-based systems has expanded rapidly and includes pseudocatenanes, catenanes, and rotaxanes, among others.[177] In the area of pyridine-based systems, the beautiful and intricate helicates reported within the past year[178] are sure to have attracted much attention among supramolecular electrochemists, though potential solubility problems and limited amounts of material appear to have curbed reports on the electrochemical behavior of these fascinating systems.

In the area of endohedral metallofullerenes, a recent report by Suzuki and co-workers reviews the electrochemistry of $La@C_{82}$, $Ce@C_{82}$, $Gd@C_{82}$, and $Y@C_{82}$.[179] Anderson and co-workers have reported very interesting results on the electrochemistry of the trinuclear endohedral complex, $Sc_3@C_{82}$.[180] These results indicate that the MOs of the trinuclear complex are very similar in energy to those of the mononuclear complexes. However, considering that more electrons are transferred to the cage by the trimetallic system, occupancy of the energy levels is different. Therefore, its second oxidation and first reduction occur at potentials close to where the first oxidation and second reduction occur for mononuclear endohedral complexes. These considerations, along with the fact that the neutral state is EPR silent, have led the authors to suggest that $Sc_3^{4+}@C_{82}^{4-}$ represents the formal charges of the complex. Further progress in the isolation and purification of endohedral complexes has been made by Dunsch and co-workers. They have successfully isolated three stable isomers of $Tm@C_{82}$, and preliminary electrochemical studies for all three isomers have been reported.[181]

The authors wish to express their gratitude to the many people who, in one way or another, contributed to the work presented here. Particular thanks go to Professors Javier de Mendoza (Madrid), David Gutsche (Fort Worth), David Reinhoudt (Enschede), and Rocco Ungaro (Parma) for their collaboration in the field of calixarenes. A very special acknowledgement goes to Professor Jean-Marie Lehn for his inspiration and collaboration, especially in the early stages of the cryptatium work. It is also a pleasure to acknowledge the National Science Foundation, Divisions of Chemistry and Materials Research (grants CHE-9313018 and DMR-9119986), and Graduate Fellowship Program (M.G.-K.) as well as the Petroleum Research Fund, administered by the American Chemical Society (grant 27827), for their generous financial support. Special thanks go to Ms. Soomi Pyo and Eduardo Pérez-Cordero for their help with some figures and to Dr. Lourdes E. Echegoyen for her invaluable help during the last stages of the work.

ANGEWANDTE CHEMIE © WILEY-VCH

C_3 Symmetry is fascinating not only in the visual arts, as this picture by M. C. Escher demonstrates (Copyright © Cordon Art, Baarn, The Netherlands, 1997), but also in chemistry. Of particular interest are the potential advantages of chiral compounds of higher symmetry as ligands and catalysts.

C_3 Symmetry in Asymmetric Catalysis and Chiral Recognition

Christina Moberg*

Chiral recognition is a key process in all efforts aimed at obtaining enantiomerically pure chiral compounds, whether by synthetic procedures or by separation techniques. Several cooperating factors contribute to achieving high selectivity in the processes involving chiral recognition. A complete understanding of these factors is beyond the scope of today's knowledge. It is a great challenge, however, to gain a deeper understanding of the factors responsible for chiral discrimination by taking into account the important characteristics of the interacting species. These include primarily their steric and electronic properties, the various attractive intermolecular interactions, and the dynamics of the recognition process. A further factor that may be important is the symmetry properties of the interacting entities. This review highlights the role of rotational symmetry, with an emphasis on C_3 symmetry, in asymmetric catalysis and chiral recognition. The situations in which rotational symmetry is important are considered, methods for the preparation of molecules with threefold rotational symmetry are discussed, and the various types of compounds with threefold rotational symmetry and their applications in asymmetric catalysis and chiral recognition are surveyed.

Keywords: asymmetric catalysis · chirality · rotational symmetry

1. Introduction

Symmetry is a property of objects, systems, and states that is closely connected with beauty and the harmony of proportions. Symmetrical objects are often considered to be aesthetically appealing. Symmetry plays a fundamental role in such diverse disciplines as art, music, architecture, philosophy, mathematics, physics, and chemistry.[1] In problem solving the consideration of symmetry may help to simplify and systematize.[2] In chemistry molecules with symmetry exert a special attraction due to their beauty. In addition, symmetry may be advantageous in synthesis design,[3] in supramolecular self-assembly,[4] and for chemical selectivity.[5]

Chiral molecules containing symmetry elements are of special interest.[6] Among the symmetry elements, only proper rotational axes are compatible with chirality. In contrast to molecules that contain no element of symmetry and are therefore truly asymmetric (C_1-symmetric), molecules with rotational axes—and rotational axes *only*—are dissymmetric and belong to either the point groups C_n or D_n ($n>1$) or to one of the less common groups *T*, *I*, and *O*. Molecules with twofold rotational symmetry have been the subject of wide recent interest. Extensive original literature dealing with this topic and a review covering the subject have appeared.[7] The extension to threefold and higher rotational symmetries has been less noticed, although a few reviews covering the preparation of chiral molecules with high symmetry exist.[8, 9]

This survey deals with molecules having rotational symmetry and their role in asymmetric synthesis and in other processes involving chiral recognition. It mainly covers threefold symmetry, with emphasis on chiral molecules belonging to point groups C_3 and D_3. Selected compounds and their applications which have appeared in the literature or have been studied by our own group serve as examples. Some achiral ligands with threefold rotational axes that can be potentially transformed into C_3-symmetric compounds are included. Most of the results covered by previous reviews[8, 9] are not repeated here. Compounds with chiral conformations having low barriers of inversion and achiral compounds that crystallize in chiral space groups are not covered by this survey.

2. Topology

Topology, also known as "rubber band geometry", is a branch of modern mathematics that can be used for the description of molecules, conformational changes, and chemical reactions. It deals with the continuity of functions, with the connectivity of objects, and with shape, in other words, with those properties of objects that remain unchanged upon

stretching, twisting etc.[10] An object that does not have a precisely defined geometry but preserves some topological features is classified as a topological object. Molecules should thus not be considered as geometrical but as topological objects.

A tridentate ligand or a trifunctional molecule with C_3 symmetry can have four principally different topologies (Figure 1). It may be acyclic (a), "exocyclic" (b), macrocyclic

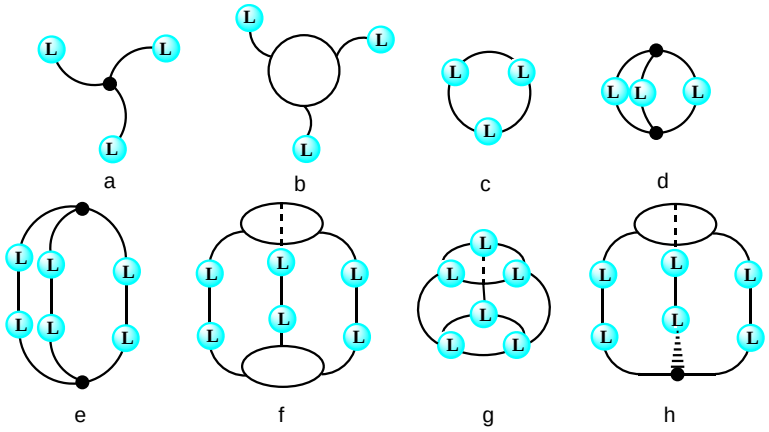

Figure 1. Topologies of structures with C_3 and D_3 symmetry.

(c), or bicyclic (d). If two twofold rotational axes perpendicular to the main axis are present, the molecule belongs to a point group of higher symmetry, D_3. Several examples of molecules are known for all of these forms. In addition, dimeric arrangements may be formed by combining any two of the structures a–d. When two equal halves are combined, the result is a species with D_3 symmetry (Figure 1e–g), whereas the combination of two unequal parts gives a molecule with C_3 symmetry (Figure 1h).

In all of these types of molecules the presence of a center of chirality (as in Figure 2a) is commonly a requirement for dissymmetry, although molecules are known in which axes of chirality cause dissymmetry. These include cyclic compounds in which the chirality originates from the direction of the array of substituents on the ring (Figure 2b).

Conformational preferences may also result in chiral species. Occasionally the barriers of inversion are sufficiently high to permit the isolation of nonsymmetric species. A

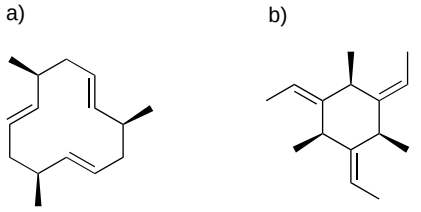

Figure 2. C_3-symmetric molecules with stereogenic centers (a) and axes (b).

further possible arrangement possessing C_3 symmetry is a triple helix.[11] Here the chirality is based on an axis of chirality. The asymmetric folding of the strands may be induced by stereogenic centers in the strands.[12]

3. Synthetic Routes: The Desymmetrization of Molecules with Higher Symmetry

Molecules belonging to point group C_3 or to a chiral group of higher order containing threefold axes can be obtained in two ways: by the proper assembly of homochiral or occasionally even achiral entities, and by the desymmetrization of molecules having improper rotational axes or mirror planes in addition to the C_3 axis. Such molecules belong to one of the following point groups: I_h, O_h, T_h, T_d, S_6, D_{6d}, D_{6h}, C_{6h}, C_{6v}, D_{3d}, D_{3h}, C_{3h}, C_{3v}.[13] The desired desymmetrization is brought about by destruction of all symmetry elements of the second kind (s, i, S_n), while symmetry elements of the first kind (C_n), at least one threefold axis, are maintained. The desymmetrization can be a change in conformation, but more important situations, in which configurationally stable species are formed, will be discussed here.

A simple illustration is given by methane (point group T_d), which, at least theoretically, can be desymmetrized in various ways. Substitution of three of the four hydrogen atoms by homochiral groups (of identical constitution) yields C_3-symmetric compounds (Figure 3a), whereas substitution of all four hydrogen atoms normally destroys the threefold rotational axes, leading to three different possible cases

Christina Moberg was born in 1947 in Gävle, Sweden and studied chemistry at the University of Stockholm (B.Sc. 1970). She then moved to the Royal Institute of Technology in Stockholm, where she earned her doctorate under the direction of Professor M. Nilsson. After a postdoctoral stay with Professor J. Normant at the Université Paris 6, she worked in the group led by Professor Åkermark at the Royal Institute of Technology before starting independent research. In 1989 she was granted a research position in organometallic chemistry by the Swedish Scientific Research Council, and she became a full professor in 1994.

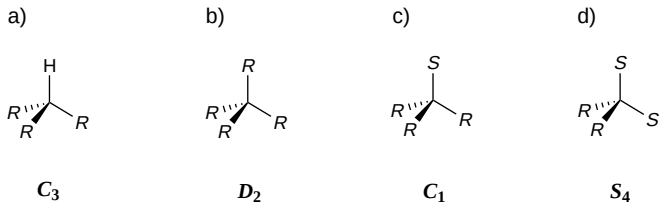

Figure 3. Symmetry of substituted methanes. *R* and *S* indicate the absolute configurations of isometric asymmetric ligands.

(Figure 3b–d). Complete substitution by homochiral groups with identical constitution yields a D_2-symmetric species; with one heterochiral substituent an asymmetric (C_1) species is obtained; and the third product is achiral since it has an S_4 symmetry axis. This topic was discussed by Mohr already at the beginning of this century,[14] and was experimentally verified half a century later by studies of esters prepared from pentaerythritol and chiral acids.[15]

The situation is different, though, when the desymmetrization is brought about by substituents with inherent C_3 symmetry. This operation is expected to yield a compound with *T* symmetry containing no less than four C_3 axes (in addition to two C_2 axes). This kind of operation has indeed been accomplished experimentally, not with methane[16] but instead with adamantane, which like methane has T_d symmetry (Figure 4).[17]

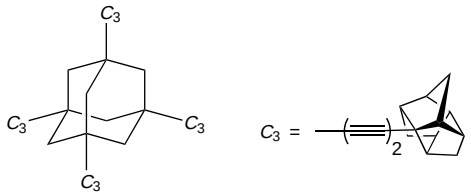

Figure 4. A *T*-symmetric adamantane derivative with four identical, C_3-symmetric substituents.

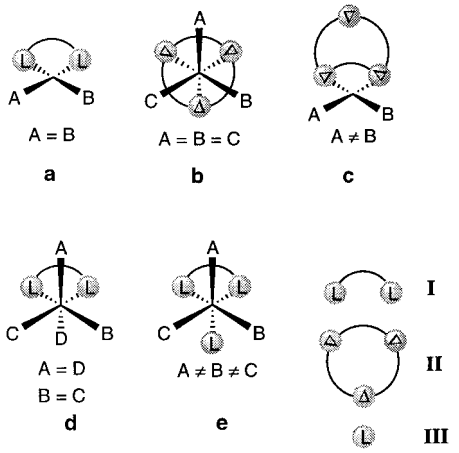
In regular polyhedra, symmetry elements of the second kind are generally destroyed while symmetry elements of the first kind are preserved by the attachment to each vertex of a chiral group having a rotational axis of the same order as and coinciding with that passing through the vertex.[9] In this manner, a chiral species having the same symmetry number as the regular polyhedron is obtained. Thus, when C_3-symmetric substituents are attached to each of the eight carbon atoms of cubane, [18] its symmetry is reduced from O_h to pure rotational *O* (with three C_4 axes and six C_2 axes in addition to the four C_3 axes). The analogous desymmetrization of an octahedral arrangement of atoms requires substituents with local C_4 symmetry, since fourfold instead of threefold axes pass through the atoms at the corners of a regular octahedron. The desymmetrization of molecules with I_h symmetry can also be achieved by a proper choice of substituents. For an icosahedral arrangement of atoms, substituents with a fivefold rotational axis at each of the twelve vertices result in *I* symmetry (with six C_5 axes and fifteen C_2 axes in addition to the ten C_3 axes). In dodecahedrane,[19] however, desymmetrization is achieved by twenty substituents with inherent threefold rotational symmetry. Since only C_1 axes pass through the vertices of a truncated icosahedron, any chiral substituent attached to each vertex would reduce its symmetry from I_h to *I*. Thus, if it were possible to add chiral groups to all of the 60 carbon atoms of buckminsterfullerene,[20] a species with *I* symmetry would be obtained.

The desymmetrization of molecules with polyhedral symmetry can also be achieved by introducing chiral groups at axes passing through the edges or faces of the polyhedra. The requirement is that the local symmetry of the group is equal to the order of the axis. C_2-Symmetric bridges would thus serve to reduce the T_d symmetry of methane to *T*.[21] Since twofold axes bisect the sides of the other regular polyhedra as well, the desymmetrization of molecules with cubic and icosahedric symmetries can be brought about analogously.

Experimentally, the simplest and probably the most common route to chiral molecules containing a threefold rotational axis is the desymmetrization of molecules containing mirror planes, inversion centers, and/or improper axes in addition to the threefold axis, but having lower symmetry than the special groups *T*, *I*, and *O*. Molecules of this type have C_{3v}, C_{3h}, D_{3h}, D_{3d} symmetry (or those having sixfold instead of threefold axes) or S_6 symmetry. A variety of simple starting materials that can serve as excellent precursors for C_3- and D_3-symmetric molecules are commercially available.



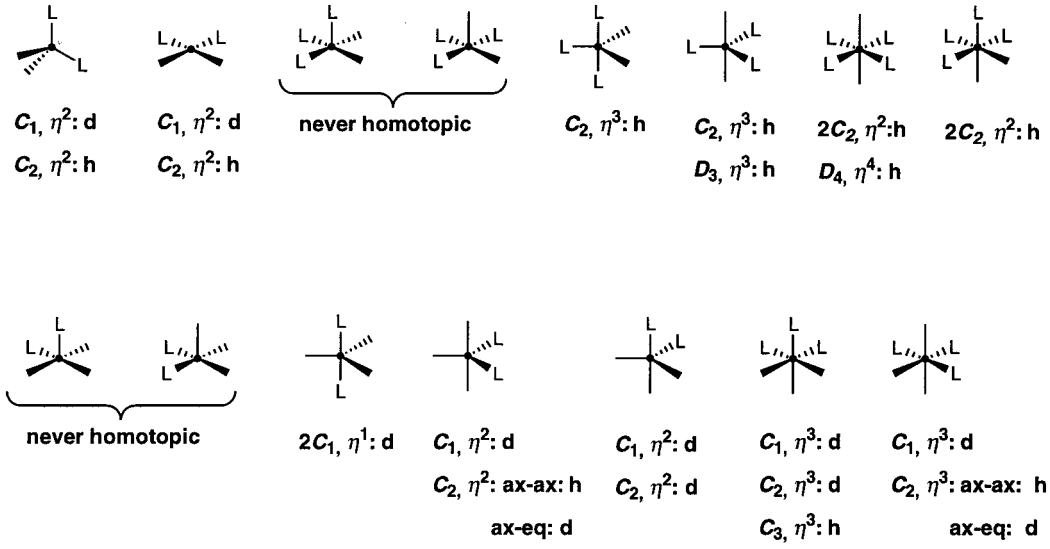
A desymmetrization procedure may also involve some asymmetric modification of a compound with higher symmetry leading to the formation of several diastereomers, which must be separated subsequently. The assembly of prochiral entities or of components in a racemic mixture is also expected to lead to a mixture of stereoisomers. This type of procedure as well as reactions performed on a prochiral, trifunctional compound with a threefold rotational axis should statistically lead to a 1:3:3:1 mixture of the *RRR*, *RRS*, *RSS*, and *SSS* isomers, although deviations may arise due to cooperative effects.

4. Metal-Binding Ligands

4.1. Metal Complexes: Molecular Equivalence Caused by Rotational Axes

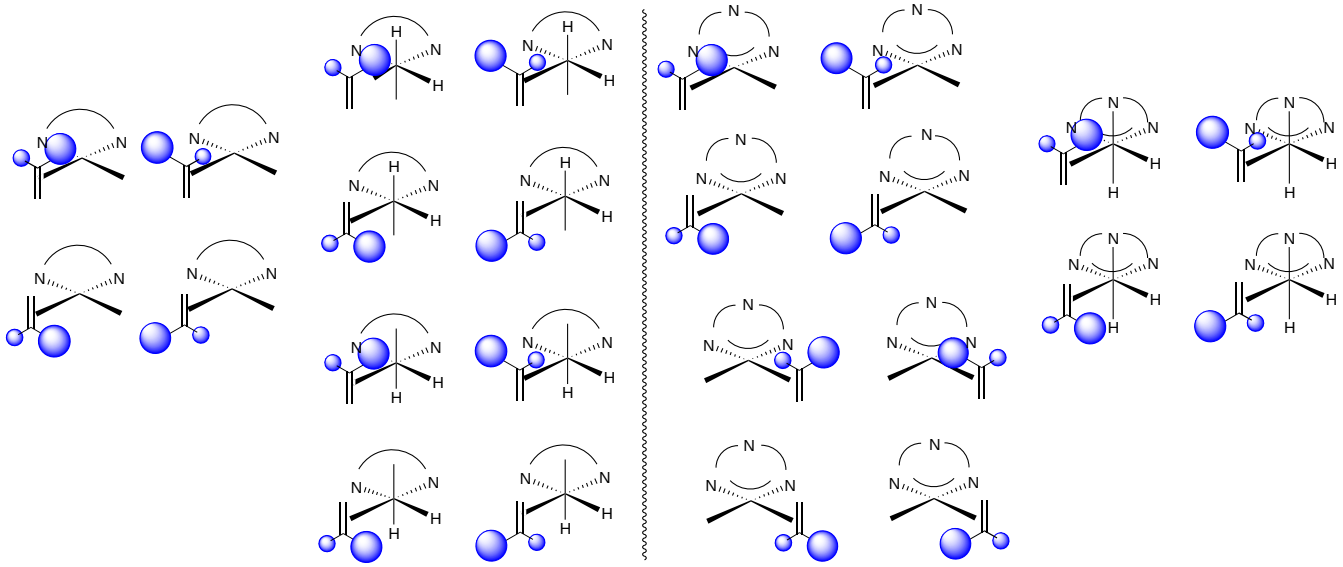
The consideration of molecular symmetry is sometimes important, since symmetry can reduce the number of possible intermediates/transition states, thus increasing the probability of success in asymmetric reactions and other chiral recognition processes. By definition, C_2 symmetry is characterized by the fact that an identical situation is obtained upon rotation of the C_2-symmetric species 180° about the rotation axis. In an event involving chiral recognition this implies that two complexes that are identical in the C_2 case would be diastereomeric in the C_1 case. With threefold symmetry each rotation of 120° yields an identical situation, thereby reducing the number of different complexes. Examples of these situations will be given and analyzed.[22]

Let us consider a square-planar metal complex containing a bidentate, C_2-symmetric ligand (Scheme 1, **a**). This is a favorable situation, since the two remaining coordination



Scheme 1. Relationships between empty coordination sites (A – D) in complexes with C_2-symmetric, bidentate (**I**) and C_3-symmetric, tridentate ligands (**II**). **III**: achiral, monodentate ligand; h = homotopic, d = diastereotopic.

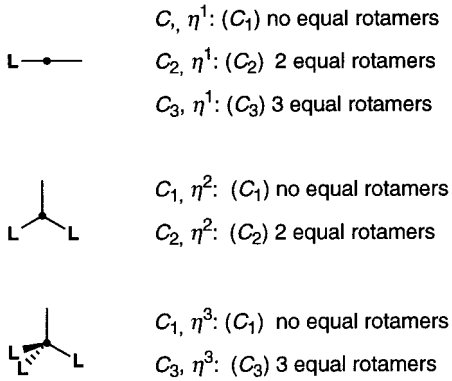
sites (A and B) are homotopic, in other words, identical. Another favorable situation is created by a tridentate, C_3-symmetric ligand in an octahedral environment (**b**), where the three remaining positions (A, B, and C) are identical (homotopic). On the other hand, this kind of ligand may yield an unfavorable situation in a square-planar arrangement where the ligand occupies two sites (**c**). Here the two remaining positions (A and B) are different (this may not be valid if the complex is dynamic and the positions are identical with time). In an octahedral environment the introduction of a bidentate, C_2-symmetric ligand results in a complex (**d**) with two sets of coordination sites, which are pairwise homotopic (A/D, B/C) but mutually diastereotopic (e.g. A/C). Addition of a monodentate ligand results in a complex with three different (diastereotopic) coordination sites (**e**). Thus, the conclusion is that C_2-symmetric ligands have favorable properties in square-planar geometries, whereas C_3-symmetric ligands are versatile in octahedral complexes.



Scheme 2 shows a more complete analysis of situations arising from the coordination of mono-, bi-, and tridentate ligands with C_1, C_2, and C_3 symmetry, respectively, in their most common coordination geometries. Homotopic coordination sites are encountered with C_2-symmetric ligands under several conditions, whereas homotopicity with C_3-symmetric ligands is restricted to a few types of complexes. The following is evident in Scheme 2: 1) Two identical coordination sites remain in tetrahedral and square-planar environments upon coordination of one bidentate ligand with C_2 symmetry and in octahedral geometry upon coordination of two such ligands. 2) Homotopic sites also result from coordination of a tridentate, C_2-symmetric ligand in trigonal-bipyramidal complexes. 3) In the presence of a C_2-symmetric ligand three sites are never homotopic in any of the coordination environments shown in Scheme 2. 4) The only situation in which homotopic coordination sites are observed with a C_3-symmetric ligand is in octahedral geometry. 5) Ligands with threefold and fourfold dihedral symmetry result in homotopic sites in trigonal-pyramidal and octahedral complexes, respectively.

Let us analyze the special case that arises when a prochiral olefin is coordinated to a complex containing either a bidentate ligand with a twofold rotational axis or a tridentate ligand with a threefold rotational axis. These situations are encountered in common catalytic processes such as hydrogenations, hydroformylations, and hydrosilylations.[23] The specific example illustrated in Scheme 3 is a catalytic hydrogenation, where the coordination of the olefin is assumed to occur before the oxidative addition of hydrogen. This is the mechanism known for catalysts prepared from noncharged rhodium(I) complexes.[23]

With two homotopic sites in the square-planar complex containing a bidentate, C_2-symmetric ligand, four possibilities exist for the coordination of the prochiral olefin (provided that the presence of only two rotamers is considered likely),

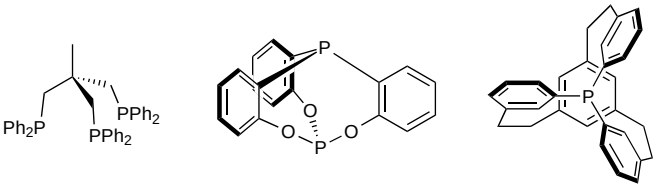


Scheme 2. Relationships between coordination sites in chiral complexes containing ligands of different denticities (η^n) and symmetries (C_n); h = homotopic, d = diastereotopic. Top: two free coordination sites; bottom: three free coordination sites; ax-ax describes the relationship between two axial coordiation sites, ax-eq that between an axial and an equatorial site.

Scheme 3. Square-planar metal–olefin complexes containing a bidentate, C_2-symmetric (left) or a tridentate, C_3-symmetric ligand (right), and isomeric complexes obtained through oxidative addition of H_2 to these complexes.

since coordination to the second site would yield a set of identical complexes due to the C_2 symmetry of the ligand. After addition of H_2 and formation of an octahedral complex, the two sites left for coordination of the olefin are no longer homotopic. Consequently, eight diastereomeric complexes are possible. In contrast, with a tridentate, C_3-symmetric ligand, only four different octahedral complexes arise due to the equivalence of the three sites. (If the olefin is equipped with an additional coordinating group, the number of isomeric complexes may be further reduced by a factor of two.) The conclusion from this analysis is that a C_2-symmetric ligand should be chosen if the selectivity is determined in a square-planar complex, whereas a C_3-symmetric ligand is the choice when the selectivity-determining step involves an octahedral complex. (If the square-planar complexes with C_3 symmetry equilibrate to render the two sites homotopic with time, a situation equivalent to that of a complex with a C_2-symmetric ligand may obviously be obtained.) As yet, this conclusion has not been unambiguously verified in practice, and it cannot be excluded that the mechanism of a particular reaction may change when a C_2-symmetric ligand is replaced by one having C_3 symmetry.

The olefin complexes in Scheme 3 are pairwise diastereomeric due to restricted rotation around the metal–olefin bond. In principle an infinite number of rotamers are possible, but only a limited number are usually observed. The symmetry properties of ligands can be exploited to reduce the number of structurally different rotamers in complexes having a single free coordination site. This is reflected by the site symmetry of that free site, as shown in Scheme 4.



Scheme 4. The influence of the symmetry (C_n) and hapticity (η^n) of a ligand L in linear, trigonal, and tetrahedral complexes on the symmetry (C_n in parentheses) of the remaining free coordination site and the number of identical rotamers.

4.1.1. *Phosphanes and Phosphites with C_3* Symmetry

The most common method for preparing chiral metal complexes is the coordination of chiral ligands to the metal ion. A large variety of such ligands are known today and their metal complexes have proven highly useful in asymmetric synthesis.[24]

Phosphane ligands have been the most commonly studied ligands for application in homogeneous catalysis. A wide range of monodentate and bidentate phosphane ligands, chiral as well as achiral, are known and some of them are applied even in industrial processes.[25]

Achiral tripodal phosphanes with threefold rotational axes have been studied extensively over the last three decades mainly by the groups of Sacconi,[26] Meek,[27] Venanzi,[28] and Bianchini.[29] The most frequently studied ligands of this type are triphos (**1**) and analogues in which the central carbon

1 **2** **3**

atom has been replaced by a heteroatom (nitrogen or phosphorus). Such compounds have proven to be versatile ligands in coordination and organometallic chemistry. They have excellent bonding properties and form complexes with metal ions in various oxidation states.

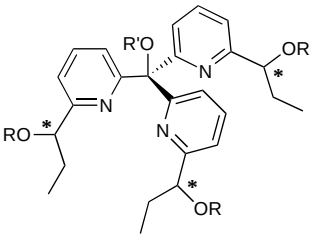
It is not surprising, therefore, that the preparation of chiral analogues was soon attempted. C_3-Symmetric monophosphanes carrying three identical chiral groups on phosphorus were used in early investigations of enantioselective, nickel-catalyzed oligomerizations.[30] In contrast, monophosphanes **2** and **3**, in which the threefold rotational axis is a chirality axis, could not be resolved due to rapid racemization.[31]

More recently, a few enantiomerically pure tripodal phosphanes with C_3 symmetry have been reported. The first examples, **4** and **5**, were prepared from cyclic lithiophosphanes and the appropriate trichloro compounds.[32] Cationic rhodium(I) complexes of **4** and **5** were both shown by X-ray structural investigations to have trigonal-bipyramidal geometry. The use of the former as a catalyst precursor for the hydrogenation of methyl acetamidocinnamate resulted in 89% enantiomeric excess, a selectivity similar to that observed when the corresponding bidentate, C_2-symmetric ligand is used (85% *ee*). In the hydrogenation of dimethyl itachonate with **4**, 94% *ee* was obtained (90% with the C_2-symmetric ligand).[33] The tridentate ligand **4** was less reactive, however, requiring higher reaction temperature and longer reaction time. This was suggested to be due to the required dissociation of one ligand arm from a stable five-coordinate intermediate. Compound **6**, another C_3-symmetric, tripodal phosphane, has centers of asymmetry on phosphorus instead of carbon (as in **4** and **5**). This tridentate ligand was prepared by Venanzi and co-workers from (*R*)-(*tert*-butyl)(methyl)(phenyl)phosphane–borane by deprotonation, reaction with trichloromethylsilane, and finally deprotection.[34] The structure of the cationic Rh^I complex of **6** was determined and shown to have a distorted square-pyramidal geometry. No reports on its ability to induce chirality in asymmetric synthesis have appeared as yet.

The tripodal, tetradentate, C_3-symmetric ligand **7** was described in 1993.[35] With Pt^0 this ligand formed a tetrahedral complex, which could be protonated and methylated to yield trigonal-bipyramidal complexes, all with C_3 symmetry. A monodentate phosphite containing three identical sugar residues, tris(1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranosido)phosphite, was also prepared recently and shown to form a tetrameric Cu^I complex with a cubane structure.[36]

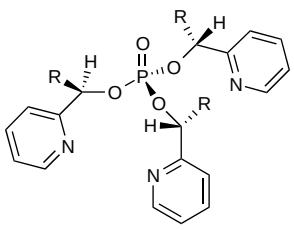
4.1.2. C_3-Symmetric Compounds Containing Pyridine Rings

In recent years nitrogen-based ligands such as pyridine derivatives[37] have replaced those containing phosphorus in many reactions mainly due to their ease of preparation and their often higher stability.[38] However, since pyridine ligands do not exert the strong *trans* effect characteristic of phosphorus ligands,[22] they sometimes have different applications.



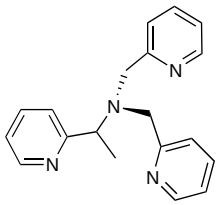
Three pyridine rings can be connected to form either acyclic, macrocyclic, or bicyclic arrangements. The first case is represented by tri(2-pyridyl)methane and derivatives such as **8**, R = H, Et, OAc.[39] This ligand was known already in the 1950s.[40] This type of compound has since been extensively studied because it can serve as a symmetric, tridentate ligand. It has thus been used to mimic the tetrahedral transition state in the reaction of carbonic anhydrase, the enzyme responsible for the fixation of carbon dioxide and its physiologically important reversible hydration to bicarbonate.[41] The active site in the enzyme is composed of a zinc ion coordinated to the imidazole side chains of three histidine residues and either a water molecule or a hydroxide ion. Mimicking this structure

with synthetic ligands is one way to gain knowledge about the mechanism of the enzymatic processes.[42]



Tripyridylmethanol **8**, R = H, can give complexes with metal ions by either N,N,N-coordination or N,N,O-coordination, whereas O-alkylated derivatives undergo symmetric N,N,N-coordination only. Transition metal complexes of this type of ligand have also proven to be important in synthetic applications, for example for use as transition metal Lewis acids.[43, 44]

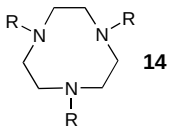
A macrocyclic arrangement of pyridine units is found in cyclophane **9**, which was prepared in four steps starting from 2,6-bis(6-bromopyridinoyl)pyridine.[45] Finally, the macrobicyclic pyridine derivative **10** was prepared by reaction of 2,6-dichloropyridine with the anion of triethanolamine.[46] Several cage compounds of this type with bipyridine incorporated in the chains have also been described.[47]



Chiral analogues, compounds lacking the vertical and/or horizontal mirror plane present in these symmetric parent compounds, can be constructed in a variety of ways. This has been realized for tripyridylmethanol **8**, R = H, by the introduction of keto substituents in the 6-positions of the pyridine nuclei and subsequent reduction of the keto groups using a chiral reagent to give compounds such as **11**.[48]

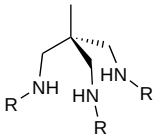
R = H, Me
R' = H, Me
11

R = Me, *t*-Bu, 2-neomenthyl
12



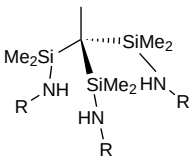
13

Although the chiral reagent was shown to afford roughly 90% *ee* upon reduction of an analogous monomer, essentially complete selectivity was observed with the trifunctional compound (instead of the expected 85.74:13.54:0.71:0.01 mixture). Another experimentally facile method is the reaction of phosphorus oxychloride with 2-(1-hydroxyalkyl)-pyridine to yield compounds of type **12**.[49] The reaction of racemic 2-(1-hydroxyethyl)pyridine with phosphorus oxychloride gave the expected 1:3 mixture of homochiral and heterochiral isomers. In contrast, reaction of the sterically more hindered 2-(1-hydroxy-2,2-dimethylpropyl)pyridine afforded a 1:1 mixture of isomers; in other words, the reaction proceeded in favor of the homochiral compound. Since enantiomerically pure 2-(1-hydroxyethyl)pyridines are available by a variety of procedures, enantiopure compounds with the structure **12** are easily accessible. Methods have also been developed that permit the grafting of the tripyridyl ligands onto various types of polystyrenes, thus allowing convenient handling.[44]

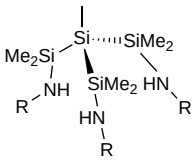


Tris[(2-pyridyl)methyl]amine adopts a helical conformation upon complexation to metal ions. The α-methyl-substituted analogue **13** was prepared in order to favor one enantiomeric conformation.[50] Although this compound has C_1 symmetry, metal complexes of the ligand probably fold in a manner similar to that expected with a trisubstituted C_3-symmetric ligand.

4.1.3. Aliphatic Amines



Several simple starting materials suitable for the preparation of amines with acyclic and cyclic topologies are commercially available. Numerous achiral 1,4,7-triazacyclononanes **14**[51] have been prepared and investigated, in particular in

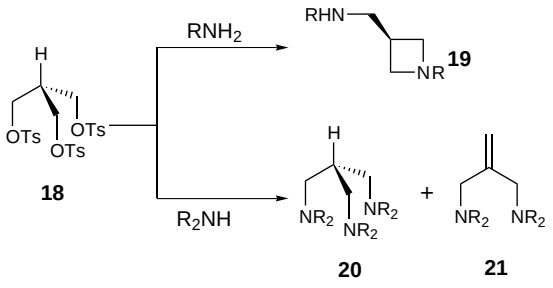


14

15

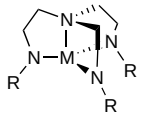
16

17



connection with studies of carbonic anhydrase mimics.[52] Compounds with three identical chiral R groups, thus with C_3 symmetry, have also been prepared.[53]

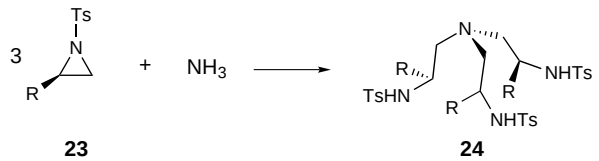
A variety of tridentate, acyclic, C_3-symmetric amines having a central carbon skeleton (**15**) or a skeleton containing silicon (**16**, **17**) have also been prepared, and some of their metal complexes have been studied.[54] The ligands with silicon atoms in their skeleton allow the complexation of larger metal ions than the ligands based on carbon only. The synthetic method used for preparing ligands **16** and **17**, the reaction of an alkylsilicon bromide with a primary amine, gives easy access to chiral analogues when a chiral primary amine is employed. A chiral analogue of **16** (R = (*S*)-CH(CH$_3$)Ph) was prepared with (*S*)-1-phenethylamine.[55]



In the triamidostannate obtained by reaction of compound **16** (R = (*S*)-CH(CH$_3$)Ph) with butyllithium followed by $SnCl_2$ the metal ion was shown to bind to the three nitrogen atoms; however, the symmetry was reduced by a lithium ion bridging two nitrogen atoms. This bridging was dynamic and resulted in time-averaged threefold symmetry.[56] The complex served as a metal-centered nucleophile and reacted with some electrophiles to yield C_3-symmetric complexes. Ti^{IV},[57] Y^{III},[57] Zr^{IV},[58] Sn^{II},[58] and Pb^{II} complexes[59] with achiral analogues of ligand **16** have also been prepared and characterized.

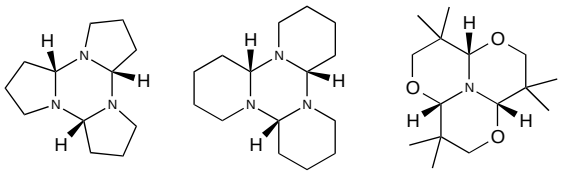
Attempts to prepare ligands analogous to **15** starting from **18**, the tritosylate of 2-hydroxymethyl-1,3-propanediol, were

less successful. Reactions with primary amines resulted in the exclusive formation of 3-(aminomethyl)azetidines **19**. Secondary amines afforded the desired triamines **20**, but the



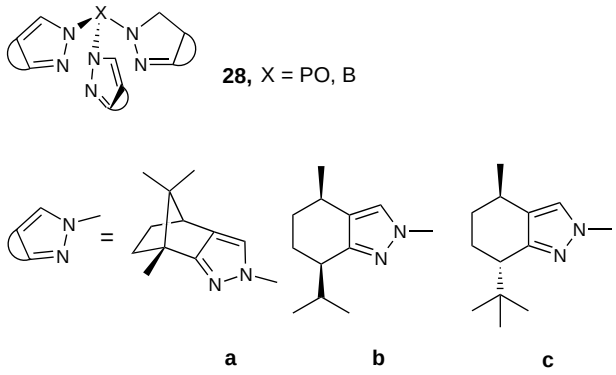
elimination of one ligand to form C_2-symmetric unsaturated amines **21** was a serious side reaction in that case (C_2:$C_3 \approx$ 1:4.4 when prolinol was used as the amine component).[60] The tritosylate of 2-hydroxymethyl-2-methyl-1,3-propanediol did not react with either primary or secondary amines.

22



Tetradentate trisaminoamine ligands like that in **22** have been the subject of extensive studies.[61] The properties of these complexes are dependent on the nature of the substituents R, and on the extent to which the bridgehead nitrogen atom takes part in the complexation.[62] Several complexes with early transition metals were recently prepared.[63] Monomeric trigonal bipyramidal complexes with vacant apical positions were obtained with Ti^{III}, V^{III}, Cr^{III}, Mn^{III}, Fe^{III} and R = *tert*-butyldimethylsilyl,[64] with M = B and R = methyl, and with M = Al and R = trimethylsilyl.[65] The boron compound was shown to adopt a chiral conformation; interconversion between the enantiomers was slow on the NMR time scale at room temperature.

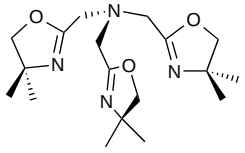
Tetradentate, tripodal, C_3-symmetric amines analogous to the ligand in **22** can probably be prepared easily by N-alkylation with chiral electrophiles. However, such ligands are expected to exert insufficient stereocontrol in catalytic reactions, since their conformation is most likely flexible. It would probably be more efficient to have the stereogenic center residing in the chelate framework. Chiral analogues such as **24** were, in fact, conveniently obtained in high yields by nucleophilic ring-opening of chiral aziridines **23** (in turn



obtained from readily available chiral aminoalcohols[66]) using ammonia as the nucleophile.[67] The aziridines have to be activated by an electron-withdrawing substituent (for example a tosyl or mesityl group) attached to the nitrogen atom in order for ring-opening to occur.

Some C_3-symmetric amines with interesting structures have been known for a long time, although no applications to catalytic reactions have been reported. 1,2-Didehydropyrrolidine[68] and Δ^1-piperideine (3,4,5,6-tetrahydropyridine)[69] trimerize spontaneously to yield **25** and **26**, respectively. C_3-Symmetric, racemic monoamines like **27** have been prepared by some different methods.[70]

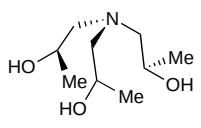
4.1.4. Dihydroborazoles and -oxazoles and Related Compounds



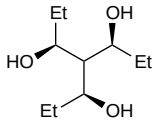
Like tripyridylmethane derivatives, tris(pyrazolyl)hydroborates have been employed in organometallic chemistry and in studies aimed at mimicking biological processes.[71] They are used as terminal ligands in the study of iron binding in proteins,[72] they are used to approximate the binding site typically found or suggested for copper(I) ions in metalloproteins, and they serve as models of carbonic anhydrase.[41] Successful results were obtained with 3-substituted tris(pyrazolyl)hydroborates, in that the desired monomeric complexes with threefold rotational axes were observed.[73] The logical extension, the preparation of C_3-symmetric chiral analogues such as **28a–c** (X = B), was readily achieved by

reaction of chiral pyrazoles with potassium tetrahydroborate.[74] Analogous ligands with a phosphorus atom joining the three heterocyclic moieties were obtained by reaction of the pyrazoles with phosphorus oxychloride. A Cu^I complex of one of these ligands was shown to catalyze the cyclopropanation of styrene with diazoesters with up to 60% *ee*.[75] The geometry around the metal ion heavily depends on the structure of the ligand: in the Tl^I complex of the tris(pyrazolyl)hydroborate prepared from **28b** the torsion angles Tl-N-N-C are close to 180°, and the Tl^I complex prepared from **28c** (X = B) has a distorted propellerlike structure.[76]

A little later three types of borate–[Rh^{I}LL] complexes (LL = 2 CO, norbornadiene, cyclooctadiene) were identified. In one type of complex the tris(pyrazolyl)borate ligand serves as an η^3 ligand, and in two other forms the ligand occupies only two coordination sites.[77] Upon irradiation the Rh^{I} carbonyl complexes of **28b** (X = B) underwent stereo- and regioselective C–H bond activation to give alkyl(hydrido)-rhodium complexes resulting from insertion of the metal in a C–H bond of a methyl substituent in the ligand isopropyl group.[78] No intermolecular C–H bond activation was observed; such processes are probably prevented by the steric bulk of the ligand.



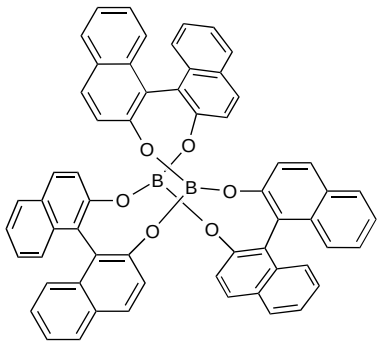
In contrast to the trispyrazolyl ligands **28**, the C_3-symmetric, tripodal trisdihydrooxazole ligand **29** forms a dimeric Cu^{I} complex, in which the metal ion is surrounded by two oxazolyl nitrogen atoms from one ligand and one from the second ligand.[79] Cu^{I} and Cu^{II} complexes of chiral analogues of **29** were shown to catalyze the oxidation of cyclopentene with *tert*-butyl perbenzoate in up to 84% *ee* (somewhat higher under conditions that gave low yields of products).[80] Tris(imidazolyl)phosphane ligands and their metal complexes have been prepared, although no chiral analogues have been reported.[81] In our group we have attempted to prepare chiral tris(dihydrooxazolyl)methanes without success.



29

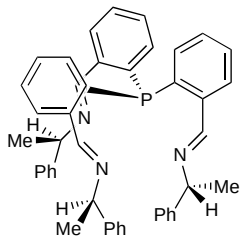
4.1.5. Alcohols

Atranes, triethanolamine derivatives in which silicon, phosphorus, tin, or other metal ions are bound to the three deprotonated hydroxy groups, have been extensively studied.[54] Examples are titanatranes, complexes with Ti^{IV}, which are monomers or dimers depending on the nature of the ligand occupying the fifth coordination site of the metal.[82] Analogous chiral metal complexes were obtained when triethanolamine was replaced by C_3-symmetric tris(2-hydroxypropyl)amine (**30**).[83] This ligand and its complexes have also been employed in asymmetric synthesis. Triol **30** has been used as a chiral auxiliary in reductions with lithium aluminum hydride,[84] and a boron compound having the same ligand has been prepared.[85] The Zr^{IV} complex of the chiral ligand has a complicated oligomeric structure but has proved to be an efficient catalyst for the ring-opening of *meso* epoxides under certain conditions; ring-opened products are obtained with high selectivity (up to 93% *ee*).[86] Mechanistic studies indicate that a dimer is the catalytically active species, and that the catalytic activity requires the cooperative action of two Zr^{IV} centers.[87] Interestingly, no stereoselectivity was observed when the *R*,*R*,*S* isomer was employed in the catalytic reaction. In contrast, the Ti^{IV} complex of **30** turned out to be a poor catalyst for this same reaction,[88] but was used for the enantioselective oxidation of sulfides to sulfoxides (up to 66% *ee*).[89] The C_3-symmetric, tridentate triol **31** has also been prepared,[90] but no reports of its use in asymmetric synthesis have appeared.



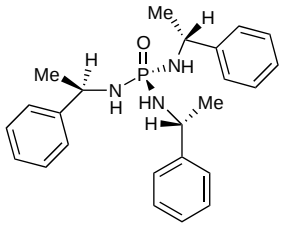
30

31



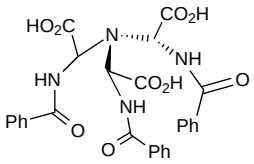
The C_3-symmetric diborate **32** was obtained from the reaction of (*S*)-(−)-1,1′-bi-2-naphthol with monobromoborane/dimethyl sulfide. This compound catalyzed the Diels–Alder reaction of cyclopentadiene and methacrolein in a highly enantioselective manner (90% *ee*, 97.4% *exo* selectivity).[91]

32



4.1.6. Other Ligands

The use of the Schiff's base **33**, obtained by condensation of tris(2-formylphenyl)phosphane with (*R*)-(+)-1-phenylethylamine, as a ligand in rhodium-catalyzed reductions was investigated.[92] A complex prepared in situ from **33** and [Rh(cod)Cl]$_2$ did not catalyze the hydrogenation of (*Z*)-α-(acetylamino)cinnamic acid at 50°C and 1 bar. Although a complex prepared in the same manner did catalyze the hydrosilylation of acetophenone, no enantioselectivity was observed. This disappointing result does not seem to be attributable to the threefold symmetry of the ligand, since an asymmetric, monodentate ligand, in which two of the chiral groups on phosphorus (in **33**) were replaced by phenyl rings, also showed poor selectivity under the same conditions.



33

The reduction of acetophenone was also performed using **34** as a chiral catalyst, but with borane/dimethyl sulfide as the reducing agent instead of a hydrosilane.[93] The results were slightly inferior to those obtained when asymmetric analogues were employed in which one or two of the chiral substituents on phosphorus (in **34**) were replaced by phenyl groups (70% yield of (*S*)-1-phenylethanol with 20% *ee*).

34

35

The synthetic pseudotripeptide **35**, which is of potential interest both as an asymmetric ligand in catalytic applications and as a model for studies of metalloenzymes (vide infra), was described in 1995.[94] In the complex obtained from **35** and [$CpTiCl_3$] the C_3 symmetry was lost because one carbonyl group is also coordinated to the metal ion. This was evident in the ^1H NMR spectrum, in which separate signals were observed for the three amide chains. The advantage of a ligand with threefold symmetry is that only one complex is formed, no matter which of the three equivalent carbonyl groups takes part in the complexation.

4.2. Lack of Rotational Symmetry May Be Advantageous

It should be noted that the benefits achieved by using reagents with rotational symmetry may also be obtained by other means, which may occasionally even be more efficient. Consider, for example, a macrocyclic metal complex that in a particular reaction coordinates a substrate in one of the two axial positions, a situation encountered, for instance, in oxidative processes.[95] The approach of a C_2-symmetric reagent from below is identical to approach from above, and the number of different reaction paths is thus reduced by a factor of two. Alternatively, only one kind of approach is also possible if one face is blocked by a pendent arm of the ligand (Figure 5).[96]

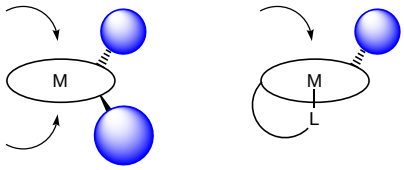


Figure 5. The approach of a substrate to macrocyclic complexes. Left: the complex is C_2-symmetric; right: the complex is C_1-symmetric and bears a blocking group. See text for details.

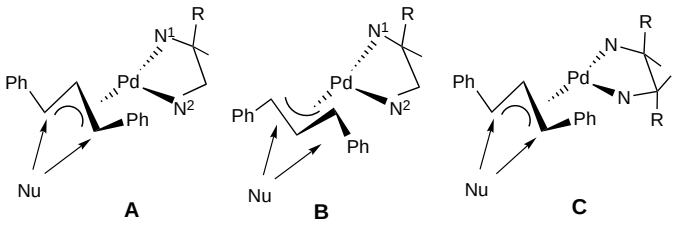
In certain situations truly asymmetric reagents offer clear advantages over reagents with rotational symmetry. In reactions where the asymmetric induction relies on the regiodifferentiating ability of the reagent, for example, the absence of rotational symmetry may likely be beneficial in given situations. Consider the attack of a nucleophile on a π-allylpalladium complex containing a prochiral (*meso*) allyl group derived, for example, from *rac*-1,3-diphenyl-2-propenyl acetate.[97] With an asymmetric ligand, two diastereomeric complexes (**A** and **B**, Figure 6) may form and both are usually



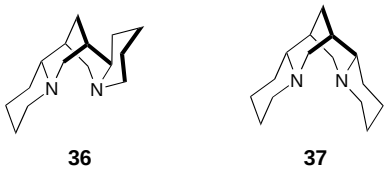


Figure 6. π-Allylpalladium complexes with C_1- (**A** and **B**) and C_2-symmetric ligands (**C**).

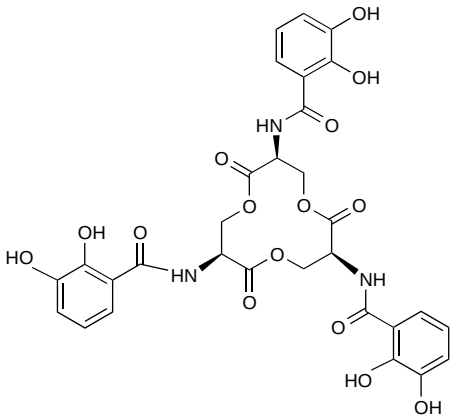
also obtained. The enantioselectivity in this case arises from regioselective attack on one of the complexes. The most abundant complex is usually the one being attacked, since the reactions are exothermic and therefore the transition states and the intermediates are close in energy.[98] With a C_2-symmetric ligand, only one complex (**C**) is obtained (rotation of the π-allyl ligand 180° yields an identical complex), and the selectivity depends on the regiodifferentiation of the reagent alone.

It is probably easier to achieve high regioselectivity when the complexing atoms in the ligand are different. Their *trans* effects are different and thus the reactivities at the two sites are different. When the coordinating atoms are different, the ligand is by definition C_1-symmetric. These arguments imply that regiodifferentiation could be an easier task in **A** and **B** (C_1-symmetric ligand) than in **C** (C_2-symmetric ligand). What is crucial in reactions employing C_1-symmetric ligands is that the diastereomeric complexes **A** and **B** have different reactivities. The advantage of using a ligand with C_2 symmetry is thus that only one complex is formed and the selectivity is determined solely by the regioselectivity. When the ligand has C_1 symmetry, however, regiodistinction may be a much simpler matter. As soon as the two complexes **A** and **B** have different properties, and one of them leads preferentially to product, the asymmetric ligand may be the more successful one.

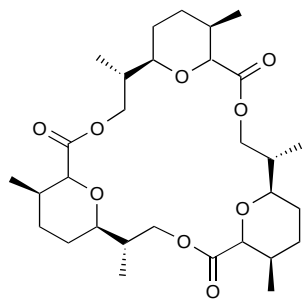
Several ligands, C_1- as well as C_2-symmetric, are known for high asymmetric induction (>99% *ee*) in the palladium-catalyzed allylation.[97, 99] It is not possible to find two ligands that differ *only* in their symmetry properties, and thus to compare the efficiencies of the different types of ligands. It is interesting, however, to compare sparteine (**36**)[100] and α-isosparteine (**37**).[101] With 1,3-diphenyl-2-propenyl acetate as



36 37

a substrate, higher selectivity was observed when the asymmetric ligand **36** was employed (92% *ee* vs 70% *ee* with **37**; both reactions in refluxing THF).[101] However, with aliphatic substrates, the C_2-symmetric ligand led to higher stereoselectivity and also turned out to be more reactive. This shows that ligands with rotational symmetry are not necessarily superior.

4.3. Natural Siderophores and Other Ionophores



In nature strong complexing agents are required to keep trivalent iron ions in solution and to enable transport.[102] This is accomplished by siderophores, a class of compounds that transport cations and promote bacterial growth. Several compounds of this type have been found in nature, for example enterobactin (**38**), which was first described in

38

1970.[103] The molecule, the cyclic triester of 2,3-dihydroxybenzoyl-L-serine, possesses C_3 symmetry. This geometry is highly advantageous, since it allows extremely efficient binding to Fe^{III} ions in an octahedral arrangement, as shown by the resistance of its iron complex towards ligand exchange with EDTA.

A variety of C_3-symmetric molecules have been prepared in attempts to mimic the properties of the natural siderophores.[104] The synthetic models typically have catecholate or hydroxamate units as ligating groups in open or bicyclic arrangements, with six oxygen atoms serving as donors.[105] Most of the models are achiral, although they contain a threefold rotational axis.[106] Ionophores aimed at complexation with metals other than iron, some of them possessing C_3 symmetry, have also been prepared. Recent examples include ionophore **39**, whose binding to alkali metal ions has been examined,[107] and similar compounds studied in the context of transmembrane ion channels.[108]

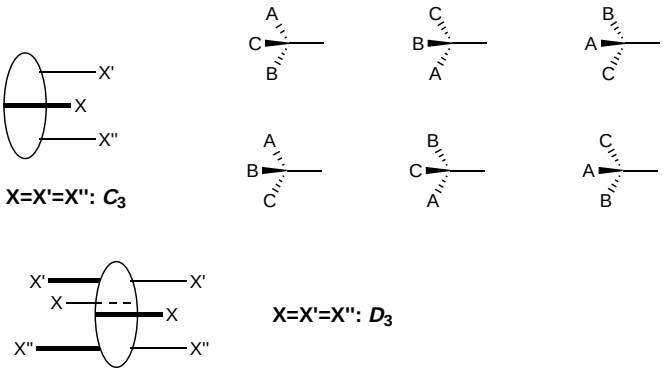
39

4.4. Octahedral Metal Complexes

Metal complexes can be chiral and belong to point group C_n or D_n even when they contain only achiral ligands.[109] The simplest example is a tetrahedral complex with four different ligands, which like the analogous carbon-based compound has C_1 symmetry. Octahedral metal complexes may be chiral as a result of the arrangement of achiral ligands around the metal ion. Frequently encountered examples are complexes in which the metal ion is coordinated to three identical bidentate ligands (Figure 7).[110] The first thoroughly

Figure 7. Enantiomeric octahedral complexes with Λ and Δ configurations.

studied examples were complexes containing a metal ion surrounded by three 1,2-diaminoethane molecules. The ligands can arrange themselves in two different ways with a mirror image relationship, and thus with different absolute configurations (Λ and Δ). Such complexes have D_3 symmetry.[111]



5. Receptors for Organic Molecules and Ions

5.1. Molecular Recognition

A common requirement for a chiral receptor is that it differentiate between the two enantiomers of a substrate. If the substrate is endowed with three sites that can interact with a receptor, the receptor should in turn contain three complementary groups for efficient complexation. Obviously, a receptor with threefold rotational symmetry should be advantageous for the complexation of a substrate with the same symmetry. This has also been unambiguously demonstrated in two sets of complexation reactions: 1) an alkylammonium ion was more strongly bound to calix[6]arenes than to calix[4]arenes (the latter lacks threefold symmetry),[112] and 2) the same ion formed a stronger complex with a hexahomotrioxacalix[3]arene having a C_3-symmetric conformation than with conformers lacking that symmetry.[113]

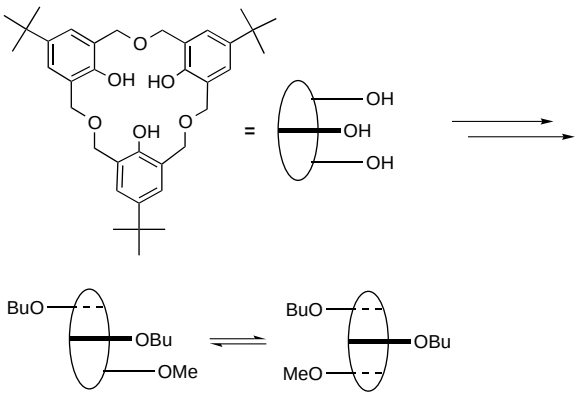
With this kind of three-point interaction, chiral discrimination is, in principle, possible. The situation is complicated by the fact that six different complexes may be formed by the interaction of the racemic substrate with the receptor (Scheme 5). With a C_3-symmetric receptor ($X = X' = X''$), each enantiomer gives rise to only one complex; in other words, there are only two possible modes of coordination, one for each enantiomer. The situation is thus simplified and the probability of chiral discrimination is increased.

If the substrate can approach the receptor from both faces, it is desirable that these faces be identical. This is the key to the favorable properties observed with many C_2-symmetric

Scheme 5. The six possible modes of binding a racemic substrate to a trifunctional receptor are reduced to only two when the receptor has C_3 symmetry. This is because for each enantiomer (top and bottom rows) the three possible binding modes lead to identical results.

compounds. If the threefold symmetry is to be kept, a receptor with D_3 symmetry, which by definition has two equal faces, is required. The general conclusion from these arguments is that when the substrate can be approached both from the front and from the back, D_3 symmetry is most efficient for decreasing the number of interactions, whereas with a bowl-shaped receptor, in which the interacting sites reside inside the cavity, C_3 symmetry is desirable.

A different solution to making the faces of a receptor homotopic was presented in 1996.[114] In this example a calixarene was trialkylated with two different electrophiles. The one used for monoalkylation was small enough to slip through the cavity, and the resulting methyl ether unit was thus able to take part in the binding at both faces (Figure 8).



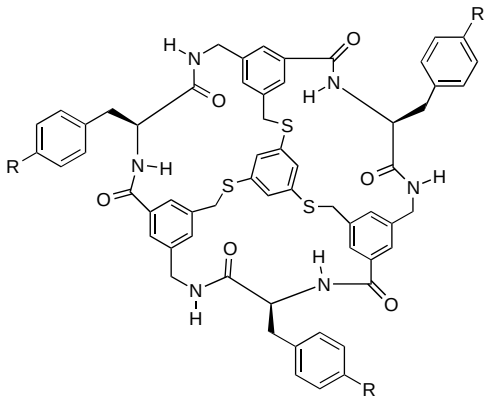


Figure 8. Alkylation transforms a C_{3v}-symmetric calixarene into a C_2-symmetric receptor, which exposes two identical faces to a reagent.

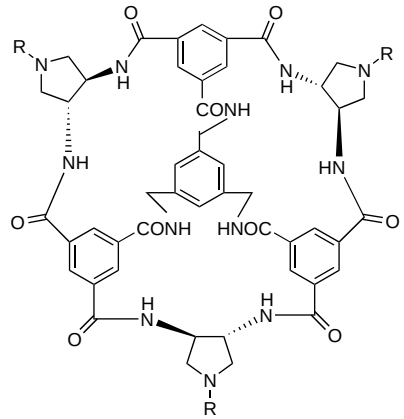
The result was that two equal faces were exposed by the receptor to an incoming substrate, and that the substrate could still be bound to three oxygen donors, two alkoxy oxygens, and one ether oxygen. A trivial case is provided by a substrate capable of being bound through a single one-point interaction. Obviously, the higher the order of the rotational axis, the higher the number of equal interactions.

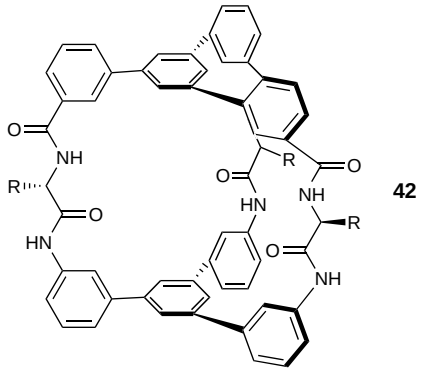


The next sections provide a survey of receptors that can bind organic molecules and ions. Several of the receptors may also form complexes with metal ions and may thus serve as ionophores as well.

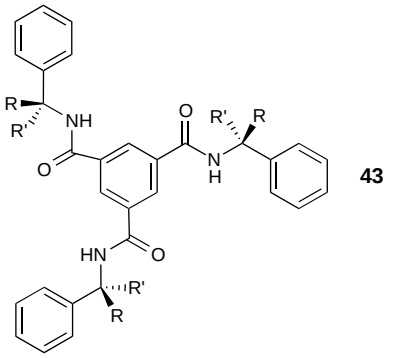
5.1.1. Peptides and Pseudopeptides

In the design of synthetic model receptors, symmetric host molecules have the advantage of more selective binding because several modes of binding are equivalent. Numerous synthetic receptors that take advantage of this feature have been described.[115] High selectivity was reported by Still for the reversible binding of peptides to some C_3-symmetric, tricyclic receptors.[116] Receptor **40** (R = H, $OCH_2CH{=}CH_2$)

40



41

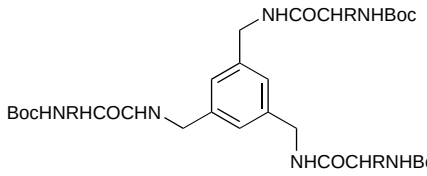


showed a high enantioselectivity in the complexation of amino acids.[117] Its potential as a resolving agent was elucidated by covalent attachment of the ligand to silica gel. Separation factors up to 21 were observed for neutral tripeptides.[118] The binding properties of an analogous receptor, **41**, in which the pyrrolidine units were linked to a dye (R = $CO(CH_2)_2CO_2$-dye), were established with a polymer-supported library of about 50 000 acylated tripeptides, where each polymer bead was coated with *one* of the tripeptides.[119]

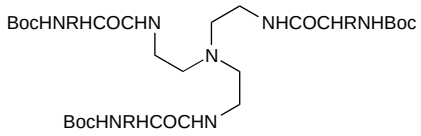
Macrocyclic C_3-symmetric amides with structures resembling that of receptor **40** were also prepared. Hexacarboxylic acids were transformed into macrolactams by reaction with (*R*,*R*)-1,2-diaminocyclohexane. No binding studies with these new receptors were reported.[120]

The cage compound **42** (R = CH_2CHMe_2, CH_2Ph), in which short peptide chains join two triarylbenzene residues, was shown to bind N-protected amino acids.[121] Chiral recognition was demonstrated upon complexation of the enantiomers of N-Z-protected glutamic acid: the complex of **42** (CH_2Ph) with the L enantiomer was 1.0 kcal mol^{-1} more stable than that with the D enantiomer. The discrimination of enantiomers having a

42

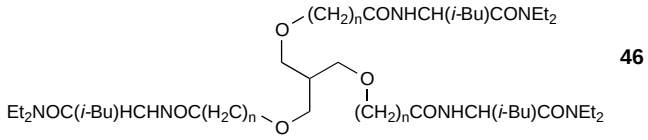


43

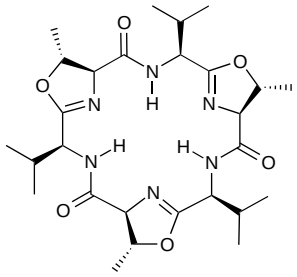


chiral center directly attached to an electron-rich aromatic ring was studied using **43**.[122]

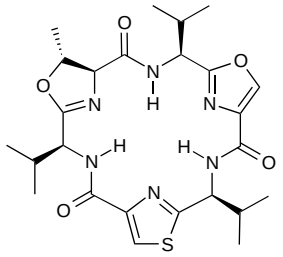
C_3-Symmetric pseudopeptides containing three parallel peptide chains were also prepared by using the triacid **35** as a reactive template.[94, 123] $CpTi^{IV}$ complexes of pseudononapeptides were shown to have C_3 symmetry based on their NMR spectra, which exhibited only one set of signals for each peptide chain. This arrangement is stabilized by hydrogen bonds. The cavity formed by the cyclic arrangement in the metal complex was believed to be too small for a hypothetical guest molecule. Some pseudopentadecapeptides were prepared with the same template. An interesting pattern of interstrand hydrogen bonding, the nature of which was shown to depend on the structure of the amino acid incorporated in the peptide and on the solvent, was found during studies of tripeptides **44** and **45**.[124] Leucine-derived **44** (R = *i*Bu) was found to have a propellerlike conformation. Studies of the ability of metal ions to serve as regulatory elements in C_3-symmetric, tripodal tripeptides showed that Li^+ generates a chiral helical conformation in **46** ($n = 1$), whereas Ca^{2+} does so in the larger analogue ($n = 2$).[125]



Some naturally occurring, C_3-symmetric or pseudo-C_3-symmetric, cyclic hexapeptides with cytotoxic activity were recently isolated. Compounds **47**[126] and **48**[127] were found in a



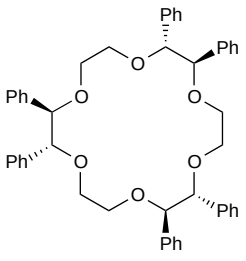
44



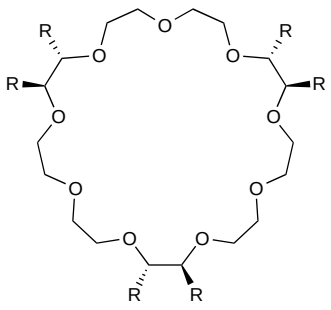
45

46

47



48

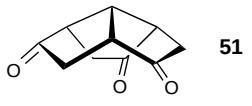


marine alga, and **47** also in a terrestrial cyanophyte.[128] The total synthesis of **47** relied on a cyclotrimerization, in which the desired trimer was formed along with a C_4-symmetric tetramer.[129]

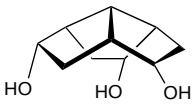
5.1.2. Crown Ethers and Podands

The D_3-symmetric [18]crown-6 ether **49** was used as a catalyst in the Michael addition of methyl phenylacetate to methyl acrylate with potassium *tert*-butoxide as base.[130] The yield was low and the enantioselectivity moderate. Similar selectivity but considerably higher yields were obtained with tetraphenyl-substituted, D_2-symmetric analogues. The best results were obtained when a C_2-symmetric, dimethyl-substituted [18]crown-6 ether was used.

49

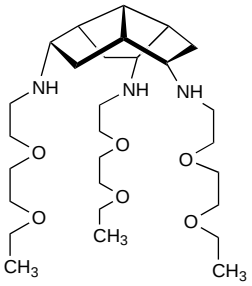


50

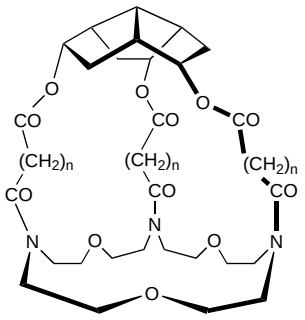


The larger [27]crown-9 ion **50** ($R = CO_2^-$) forms more stable complexes with guanidinium ion than with ammonium ion, while the reverse was found for a D_2-symmetric [18]crown-6 analogue.[131] The symmetric, uncomplexed, (*R*,*R*,*R*)*-trisbinaphthyl[18]crown-6 ether was shown to be slightly destabilized in relation to the (*R*,*R*,*S*)* diastereomer.[132] The reaction of D-diisopropylidenemannitol with diethylene glycol tosylate afforded a C_3-symmetric [27]crown-9 ether as a by-product.[133]

5.1.3. Cyclotriveratrylenes

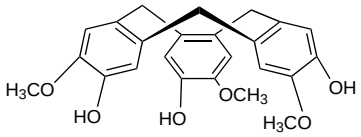


The C_3-symmetric perhydrotriquinacene ketone **51** serves as a useful precursor for the preparation of C_3-symmetric podands.[134] Catalytic hydrogenation afforded the tris(*endo* alcohol) **52**, which, however, turned out to be quite unreactive towards alkylation reagents. Instead, direct reductive amination of **51** with 1-aminooligoethers afforded aminopodands such as **53**.[135] Triketone **51** could also be used for the synthesis of cage compound **54** ($n = 2$, 3) and analogues.[136] Compound

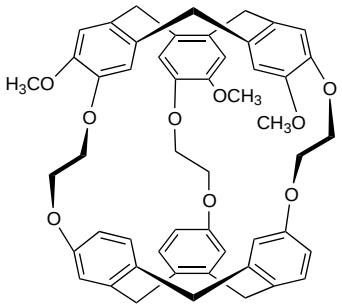


51

52

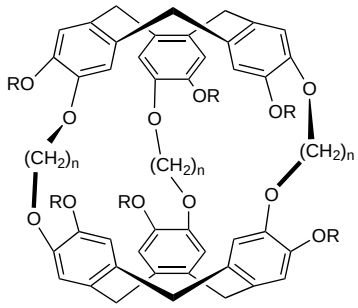


53



54

54 was shown to complex the methylammonium ion efficiently, although possibly to the external face of the polar subunit. No attempts to achieve chiral induction were reported.

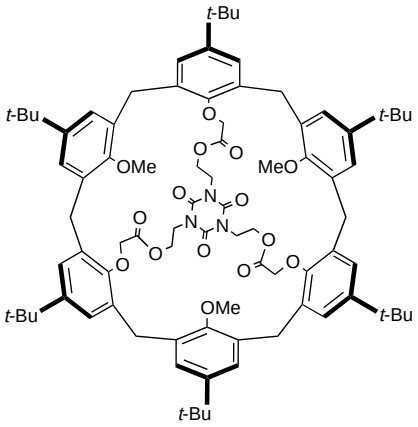


Ring inversion in cyclotriveratrylene takes place only around 200°C, and compounds of this type with two different substituents are therefore chiral under ordinary conditions. The C_3-symmetric cyclotriveratrylene **55** was described early on by Collet and Jacques.[137] The enantiomerically pure cryptophane **56** based on the same compound was shown to give an inclusion complex with racemic bromochlorofluoromethane.[138] Different ^{1}H NMR signals were observed for the guest molecules in the diastereomeric complexes formed. Interestingly, chiral recognition was achieved: one complex was favored over the other by about 1.1 kJ mol^{-1}. Analogous, D_3-symmetric compounds **57**[139] afford inclusion complexes with a variety of guest compounds such as methane ($n = 2$, R = Me),[140] isobutane ($n = 3$, R = Me),[141] tetramethylammonium ion ($n = 3$, R = Me, K = 225 000 M^{-1}), and acetylcholine ($n = 5$, $R = CH_2CO_2H$).[142] For larger members of this family of compounds ($n \geq 6$), equilibrating in–out and out–out topoisomers were observed.[143] Self-assembled, heterodimeric cyclotriveratrylenes, in which the two units are held together by hydrogen bonds, were also prepared and shown to form inclusion complexes.[144] Some new cyclotriveratrylenes bearing iodine substituents on the benzene rings are expected to serve as useful precursors for a variety of derivatives.[145]

55

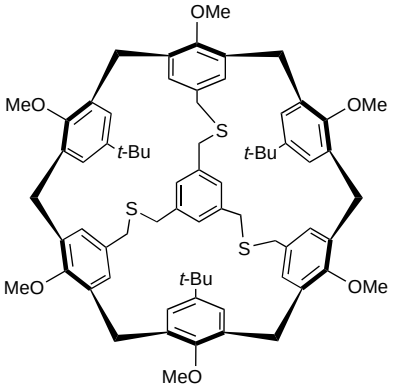
56

57



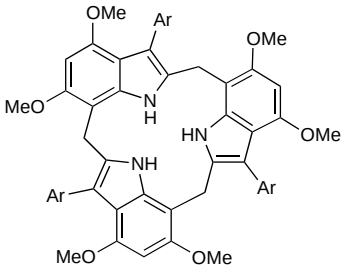
Cyclotriveratrylenes equipped with substituents suitable for complexation to metal ions have been prepared.[146] Studies of octahedral Fe^{II} complexes revealed that when complexed with a racemic host containing three bipyridine units, the absolute configuration at the metal center was determined by the absolute configuration at the cyclotriveratrylene unit: only the enantiomeric pair $M\Delta/P\Lambda$ was observed.[147]

5.1.4. Calixarenes

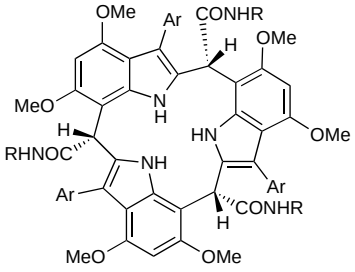


A variety of achiral calixarenes with threefold symmetry (C_{3v}-symmetric) have been prepared by proper substitution of calix[6]arenes.[148] To avoid conformational changes destroying the threefold symmetry and favorable complexing ability, the conformationally immobilized calix[6]arenes **58**[149] and **59**,[150] capped on the lower[151] and upper rim, respectively, were synthesized.

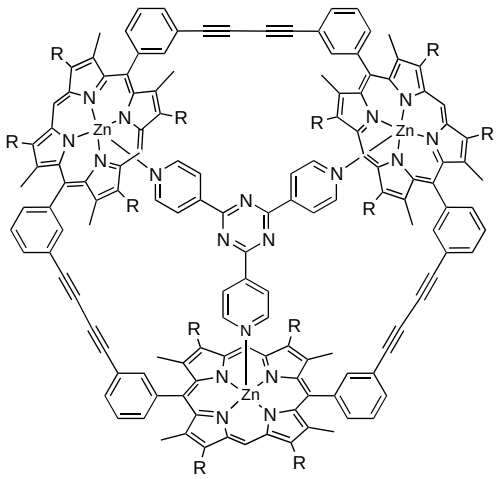
Some chiral, although not enantiomerically pure, calix[3]indols have been described.[152] Compound **60** (Ar = C_6H_5, *p*-BrC_6H_4, *p*-$MeOC_6H_4$) is achiral, however, as indicated by its ^{1}H NMR spectrum, which exhibits a singlet for the methylene protons. This is consistent with either a rapidly inverting *cone* conformer or a fluxional, flattened *partial cone* conformer. On the other hand, compound **61** (Ar = *p*-ClC_6H_4, R = Me, *t*Bu), which has substituents on the bridging methylene groups, is chiral. It was isolated as a mixture of two conformers, which could be separated for R = *tert*-butyl, Ar = *p*-ClC_6H_4.[153] The C_3-symmetric compound was obtained in 17% yield, and the stereoisomer in 45% yield.



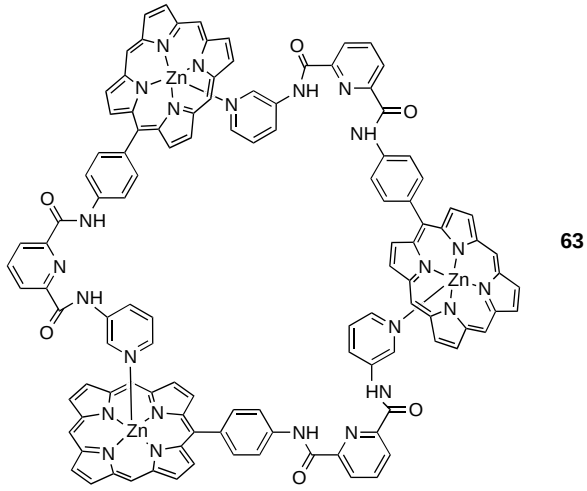
Calixarenes containing three dihydroxybiphenyl residues have been prepared.[154] Alkylation of the hydroxyl groups resulted in restricted rotation around the Ar–Ar bonds. The isomer with D_3 symmetry was, however, not observed among the atropisomers obtained.



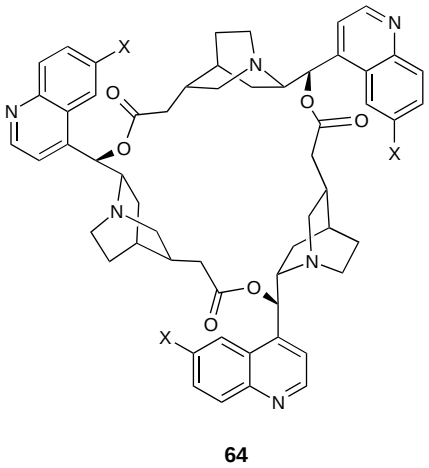
58



59



60



61

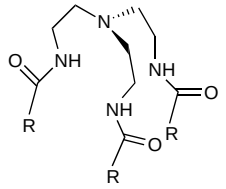
62

63

64

5.1.5. Porphyrins

The cyclic zinc porphyrin trimer **62** ($R = CH_2CH_2CO_2Me$), which has a cavity suitable for complexation of tris(4-pyridyl)-triazine, was obtained when this guest was used as a template.[155] By proper adjustment of the angle between the plane of the porphyrin ring and the pyridine ligand in the monomer, self-assembled trimers such as **63** were obtained.[156] Although the compounds described were achiral, desymmetrization to achieve C_3 symmetry can easily be imagined.

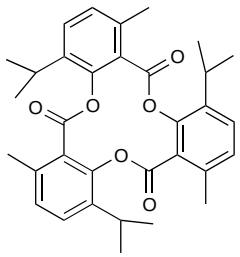


5.1.6. Other Receptors

Macrocyclic trimers of derivatives of the cinchona alkaloids quinine (**64**, X = OMe) and cinchonidine (**64**, X = H) were obtained in high yield from monomeric derivatives of the alkaloids.[157] The trimers were shown to be the thermodynamic products formed in a reversible process. A thermodynamic mixture of products consisting of dimers, trimers, and higher oligomers was also obtained by macrolactonization of cholic acid derivatives.[158]

Cyclodextrins are cyclic oligomers consisting of six, seven, or eight glycose units. The smallest member of the series, α-cyclodextrin, has been substituted symmetrically with three substituents to give C_3-symmetric receptors.[159] A trisammo-

nium derivative of α-cyclodextrin was used as a host for benzyl phosphate.[160] Recently, C_3- and C_4-symmetric cyclodextrin analogues were described which were made up of L-rhamnose and D-mannose units.[161]

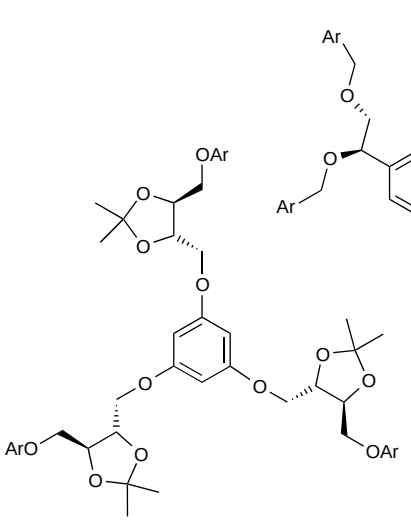


Interesting, although achiral amides **65** ($R = CH_2Cl$, $(CH_2)_4CH_3$, C_6H_5, 4-$MeOC_6H_4$), obtained from tris(2-aminoethyl)amine, were shown to serve as phosphate or sulfate receptors. The properties of the receptors depend on the structure and the substituents.[162] Examples of other achiral compounds serving as receptors for small organic molecules include macrocyclic cage compounds containing phosphane oxide units,[163] bowl-shaped or capped aryl thioethers,[164] macrocyclophanes,[165] and bridged triarylmethanes.[166] Some receptors with threefold symmetry were also included in recent reviews.[167]

65

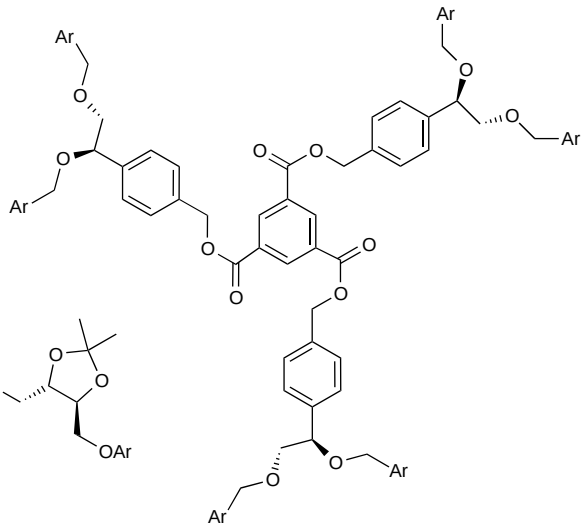
5.1.7. Clathrands

Several important clathrands (compounds acting as hosts in the solid state) possess threefold symmetry.[8,9] Although many of the hosts are achiral, propellerlike conformations have been observed for the hosts as well as for their complexes.[168] Common examples are perhydrotriphenylene (C_3 symmetry), triphenylmethane, and tri-*o*-thymotide (**66**),[169] the last two of which adopt chiral conformations.



66

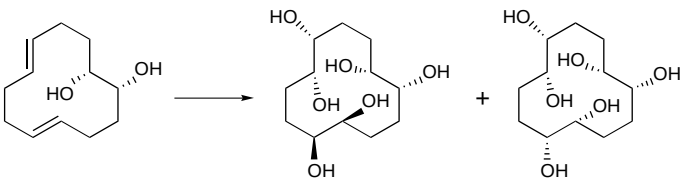
6. Other Compounds



A variety of other compounds possessing threefold symmetry, hydrocarbons as well as compounds containing functional groups, have been prepared. Surveys of such compounds are given in the reviews by Nakazaki[9] and by Farina and Morandi.[8] Only a few recent examples will be given here.

Dendrimers are three-dimensional, branched, highly ordered macromolecules.[170] Although such compounds have been known for several decades, the first syntheses of chiral dendrimers have been undertaken only recently.[171] The chirality of dendrimers may be due either to a chiral nucleus, to which achiral building blocks are attached, or to the attachment of chiral substituents to the core, or, finally, to the use of chiral building blocks, resulting in a chiral interior domain. These kinds of chiral macromolecules are expected to become useful in chemical operations including asymmetric catalysis, chiral recognition, and resolution.

A few dendrimers with overall C_3 symmetry are known. Such dendrimers have been synthesized from 1,3,5-substituted benzene derivatives and tartaric acid derivatives (**67**; only the first generation of the dendrimers is shown)[172] or 3-hydroxybutanoic acid[173] as chiral units and by asymmetric synthesis, using the Sharpless dihydroxylation reaction (**68**).[174] It is doubtful, however, whether the overall C_3 symmetry of the macromolecule is of any importance in the microenvironment of a guest molecule or of a substrate bound to a catalytically active site.



67

68

Fullerenes are carbon clusters having symmetries ranging from I_h to C_1. It is interesting to note that one of the C_{78} isomers possesses D_3 symmetry.[175]

It seems appropriate to close this survey of chiral compounds having threefold rotational symmetry with an example of a compound whose preparation relies on one of today's most potent asymmetric reactions, the Sharpless dihydroxylation.[176] Dihydroxylation of the three olefinic bonds of all-*trans*-1,5,9-cyclododecatriene is expected to yield a mixture of two compounds, **69** and **70**, which have C_2 and D_3 symmetry, respectively. Enantiomerically pure (*R*,*R*)-diol **71** afforded only small amounts of the hexol with threefold symmetry when quinuclidine or 2,5-diphenyl-4,6-bis(9-*O*-dihydroquinyl)pyrimidine, $(DHQ)_2$-PYR, was employed as the ligand in the reaction. 2,5-Diphenyl-4,6-bis(9-*O*-dihydroquinidyl)-pyrimidine, $(DHQD)_2$-PYR, gave the two compounds in a ratio of 2:1; the total yield of the D_3-symmetric compound **70** was as high as 32%.[177]

71 *(R,R)* **69** *(R,R,R,R,S,S)* **70** *(R,R,R,R,R,R)*

7. Molecules with Higher Symmetry

Some chiral compounds analogous to those described above but with higher symmetry have been reported. Examples of compounds with a single fourfold axis include some calixarenes,[178] a tetraphenylporphyrin capped with a calix[4]amide,[179] and a C_4-symmetric dendrimer.[180] C_5 through C_7 symmetries are represented by the cyclodextrins. Examples of high-symmetry compounds belonging to a dihedral group are a D_4-symmetric metallotetraphenylporphyrin,[181] a D_4-symmetric amine,[182] and a hexaamine with D_6 symmetry.[182] This last compound has symmetry number 12 and is, together with the *T*-symmetric adamantane shown in Figure 4,[17] the most symmetric chiral compound synthesized to date. Nature, however, has provided us with supramolecular assemblies of proteins[183] and viruses[184] having *O* and *I* symmetry, in other words, with symmetry numbers as high as 24 and 60, respectively.

8. Summary and Outlook

The justification for using rotational symmetry to achieve high symmetry has been discussed repeatedly, and symmetry is sometimes considered to be a more or less magic property. Symmetry is advantageous when it improves the selectivity by decreasing the number of different reaction paths and thereby the number of intermediates; what is achieved by symmetry is simply the reduction of competing alternatives. This may have a profound effect on the selectivity, as has been demonstrated repeatedly in recent years. Symmetry may also be helpful for the monofunctionalization of a compound containing several reactive sites; if the reactive groups are symmetry-related, the compound desired is obtained by functionalization at any site. Furthermore, the analysis of the observed enantioselectivity and thus the mechanistic interpretation may be simplified.

Rotational symmetry is often but not always the key to high stereoselectivity. What is always important is a thorough analysis of the symmetry and the number of possible intermediates in the reaction under study. The purpose of this survey was to present the known compounds with C_3 symmetry, which have been used or which may be useful in asymmetric synthesis or chiral recognition, and to show under which circumstances these compounds may be advantageous. Another purpose was to demonstrate that the key to high stereoselectivity is often found within the larger family of reagents with various types of rotational symmetry.

I am grateful to Professor Jean-Claude Fiaud and Professor John Osborn for encouraging me to write this review and to Dr. Hans Adolfsson, Dr. Gunhild Aulin-Erdtman, Professor Carsten Bolm, Professor Jan-Erling Bäckvall, Professor Torbjörn Norin, Dr. Tobias Rein, Professor Olof Wennerström, and Dr. Paul Wyatt for valuable criticism and comments on the manuscript. I would also like to thank one of the referees for many valuable suggestions.

Ylidic Four π Electron Four-Membered λ^5-Phosphorus Heterocycles: Electronical Isomers of Heterocyclobutadienes

Guy Bertrand*

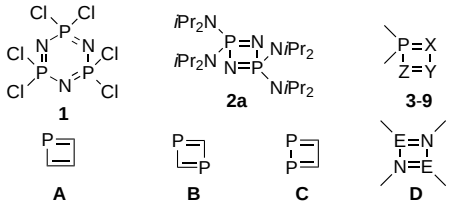
The first inorganic heterocycle, $(Cl_2PN)_3$, was discovered in the last century. Nevertheless, up to the beginning of the 1980s it was claimed that cyclodiphosphazenes $(R_2PN)_2$ could not exist because of ring strain and contraction of the N-P-N bond angles below 115°, which would cause serious interpenetration of the van der Waals boundaries of the nitrogen atoms. In 1984 we reported the synthesis and single-crystal X-ray structure analysis of the smallest member of the well-known family of cyclopolyphosphazenes, namely, tetrakis(diisopropylamino)-1λ^5,3λ^5-diphosphete. The parallel to the history of benzene and cyclobutadiene is striking, but here the comparison has to stop: Cyclobutadienes that contain λ^5-phosphorus atoms are not antiaromatic; they feature a strong ylide character with a four π electron system that follows either an island model or presents an interrupted cyclic delocalization. Despite the lack of antiaromaticity, the preparation of these heterocycles remains a challenging example of non-natural-product synthesis because of the ring strain. "Heterocyclobutadienes" of this type are very reactive, which makes them attractive precursors to a variety of novel heterocycles; the synthesis by Karsch of a spirocyclic ten-electron cation featuring an unprecedented pseudo-trigonal-bipyramidal PP_4 fragment is a good illustration. They also act as +ligands for transition metals, and preliminary results indicate that they could be used as building blocks for coordination polymers.

Keywords: antiaromaticity · phosphorus heterocycles · phosphorus ylides · strained molecules

1. Introduction

For more than a century, the synthesis and bonding description of six π electron six-membered and four π electron four-membered rings have attracted considerable attention.[1] Although benzoic acid has been known since the 16th century and benzene was discovered in 1825 by Faraday,[2] it was only in 1965 that Pettit[3] prepared an organometallic complex featuring cyclobutadiene as a ligand, and in 1968 that Gompper and Seybold[4] isolated a free cyclobutadiene derivative stabilized by push–pull effects. Outside the coordination sphere of transition metals, the parent cyclobutadiene is only stable in matrices at low temperature[5a–d] or in a molecular container, as recently shown by Cram.[5e, f]

Even by the end of the 19th century, Kekulé tried to rationalize the very peculiar stability of benzene. He stated that it was due to the structure of the ring exhibiting an alternance of single and double bonds, and introduced the oscillation theory:[6] This was the premise of aromaticity. The only mistake was to think that, as vinylogues of benzene, cyclobutadiene and cyclooctatetraene should also be aromatic and very stable, although this idea was reinforced by the synthesis of cyclooctatetraene by Willstätter in 1911.[7] In 1930 Hückel tried to rationalize the "mysterious" difference in behavior between benzene on the one hand and cyclobutadiene and cyclooctatetraene on the other using molecular-orbital theory.[8] According to the Hückel rules, annulenes of the type $(C_2H_2)_n$ have to be divided into two groups: 1) Compounds which have $(4n+2)$ π electrons, such as benzene, are stabilized by delocalization and thus aromatic. 2) Compounds which have $(4n)$ π electrons, such as cyclobutadiene, have no particular stabilization. Only one element was missing: the destabilizing effect called "antiaromaticity" in 1965 by Breslow and Dewar. Nowadays antiaromaticity accounts for 60% of the excess energy of cyclobutadiene (estimated at 35 kcal mol^{-1}); the remaining 40% is attributed to ring strain.[9] Even in the most recent book published on aromaticity (and antiaromaticity),[1a] the authors concluded: "at any rate, up to this time nobody has been able to produce a physically sound explanation to this effect"!



The aromatic and antiaromatic character is perturbed when one or more heteroatoms from the second row of the periodic system are present in the ring.[10] With an element from the third (or higher) row that possesses p orbitals for building the π system, the comparison is even more striking;[10] for

example, neither silabenzene[11] nor germabenzene[12] are stable. When the heteroatom has no p orbital available for the π system, the six-membered ring is no longer a Hückel aromatic system[13] and, consequently, the four-membered ring should not be antiaromatic.

Starting from this hypothesis, six π electron six-membered and four π electron four-membered rings featuring an element from the third row should not be particularly stable and unstable, respectively. However, it is amazing to realize that the first six-membered heterocycle of this type, the cyclotriphosphazene **1**,[14] was discovered in 1834, whereas the first vinylogue, the cyclodiphosphazene **2a** (Scheme 1), was reported by our group as recently as 1984![15]

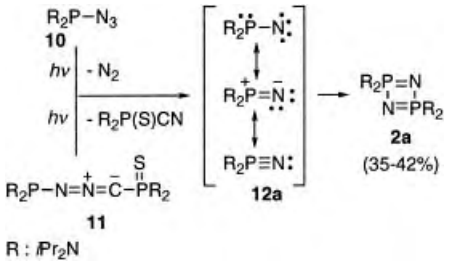
Scheme 1. Cyclotriphosphazenes **1**, cyclodiphosphazenes **2**, and four π electron four-membered heterocycles containing phosphorus (**3**–**9**, **A**–**C**) or a Group 13 element (**D**).



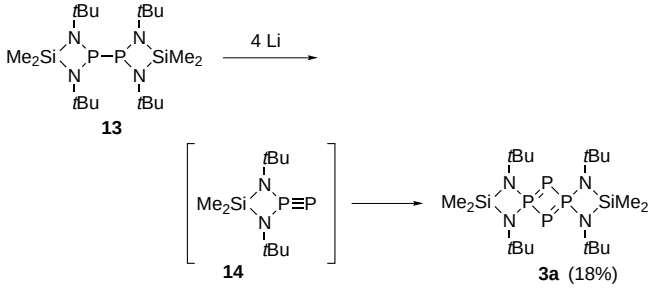
This review deals with the synthesis, bonding properties, and reactivity of four π electron four-membered rings **2**–**9**, which feature a λ^5-phosphorus atom.[16] So far, the related, but antiaromatic, λ^3-phosphete **A** and λ^3,λ^3-diphosphetes **B** and **C** (Scheme 1) are only known as transient species or as ligands for transition metal complexes; they are the subject of recent reviews.[17] On the other hand, there are very few four π electron four-membered rings featuring a main group element from the third (or higher) row. Indeed, to the best of our knowledge, there are no stable examples involving Group 14[18] or 16 elements (although some have been erroneously claimed for the latter),[19] and only a couple of compounds of type **D** involving Group 13 elements[20] (Scheme 1).

2. Synthesis

Several synthetic routes have been used to prepare the desired "λ^5-phosphacyclobutadiene" derivatives **2**–**9**. Although some routes can be used to prepare different classes of compound, none is general.

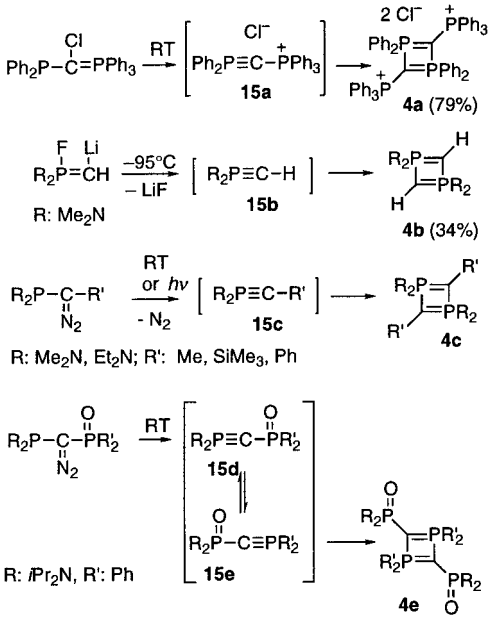
2.1. [2+2]Cycloadditions

This story begins with calculations by Trinquier,[21] which predicted that the singlet phosphanylnitrene **12** (R = H; Scheme 2) will exhibit a phosphorus–nitrogen multiple bond due to delocalization of the lone pairs n_π(P) into p_π(N) and, to some extent, n_π(N) into d_π(P). We confirmed this hypothesis



Scheme 2. Synthetic routes to the cyclodiphosphazene **2a**.

by irradiating bis(diisopropylamino)phosphanyl azide (**10**) in the presence of various trapping agents. As hoped, the products obtained resulted from simple addition across a formal phosphorus–nitrogen triple bond of the λ^5-phosphonitrile **12a**.[22] We then realized that irradiation of **10** in the absence of any trapping agent led to the head-to-tail cyclic dimer of **12a**, 2,2,4,4-tetrakis(diisopropylamino)-1,3,2λ^5,4λ^5-diazadiphosphete (**2a**, R = iPr$_2$N), in 42% yield.[15] We more recently found that photolysis of the stable nitrilimine **11** also led to the cyclodiphosphazene **2a** in 35% yield along with bis(diisopropylamino)thiophosphorylnitrile (Scheme 2).[23] Since phosphanyl azides are in general highly explosive materials,[24] the use of N-phosphorus-substituted nitrilimines seems more attractive. Unfortunately only very few nitrilimines are stable,[25] and most rearrange under irradiation into carbodiimides[26] rather than undergoing nitrogen–nitrogen bond cleavage to give a phosphonitrile.

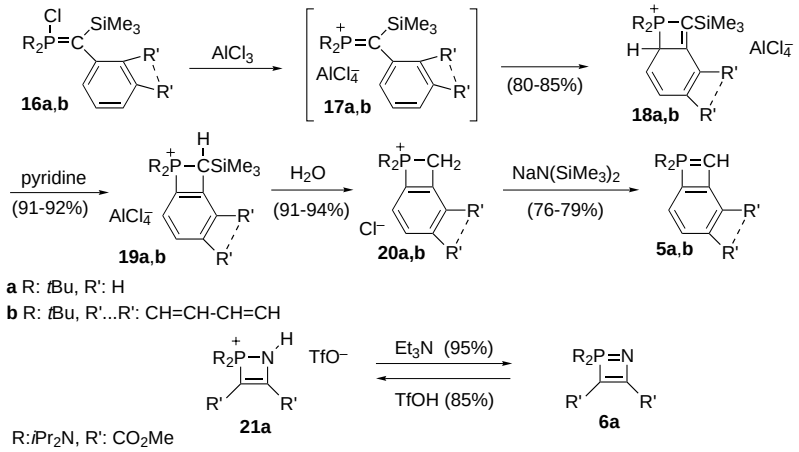


Guy Bertrand was born in Limoges (France) in 1952. He graduated from the University of Montpellier as ingénieur ENSCM and moved to Toulouse as an Attaché de Recherche CNRS in 1975. He defended his Thèse d'Etat at the University Paul Sabatier of Toulouse in 1979 and spent one year at Sanofi Recherche Company. Since 1988 he is Directeur de Recherche at the Laboratoire de Chimie de Coordination du CNRS at Toulouse. He has authored over 180 publications and patents, and his research spans a wide range of topics at the border between organic and inorganic chemistry. He received the International Council on Main Group Chemistry Award in 1993 and the Humbold Award in 1994, and was elected Membre Correspondant of the French Academy of Sciences in 1996.

The mixed-valent tetraphosphete **3**, which was recently obtained by Frank et al.,[27] formally results from dimerization of the phosphidophosphorane **14**. This transient species would be formed upon reduction of diphosphane **13** with lithium (Scheme 3).

Scheme 3. Synthesis of the mixed-valent tetraphosphete **3a**.

Head-to-tail dimerizations of transient λ^5-phosphalkynes **15** to 1λ^5,3λ^5-diphosphetes **4** were observed by Appel et al.,[28] Fluck et al.,[29] and Regitz et al[30] (Scheme 4). It is noteworthy

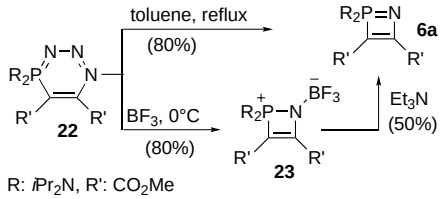


Scheme 4. Head-to-tail dimerization of transient λ^5-phosphalkynes.

that diphosphete **4e** does not originate from the dimerization of the initially generated **15d**, but from that of isomeric **15e**, which forms after a 1 →3 shift of the oxygen atom from one phosphorus atom to another.[30] This result suggests a possible equilibrium between the two isomeric *C*-phosphoryl-λ^5-phosphalkynes **15d** and **15e**; dimerization occurs with the least sterically hindered form. The very rare examples of compounds of type **15** which have been isolated do not dimerize even upon heating.[31]

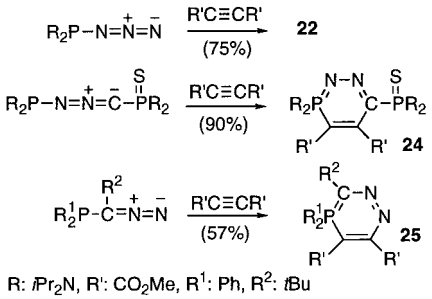
So far, all attempts to prepare λ^5-phosphetes or λ^5-aza- or diazaphosphetes by [2+2]cycloaddition of λ^5-phosphalkynes **15** or λ^5-phosphonitriles **12** with alkynes or nitriles have failed.

2.2. 1,2-Eliminations



In 1968 Gompper and Seybold prepared the first stable cyclobutadiene by deprotonation of the corresponding cyclobutadienyl salt.[4] Similarly, addition of sodium bis(trimethylsilyl)amide to 1,2-dihydrophosphet-2-ylium salts **20a** and **20b** gives rise to benzo- and naphto-λ^5-phosphetes **5a** (76% yield) and **5b** (79% yield), respectively (Scheme 5).[32] The synthesis of derivatives **20a**, **b** deserves some comment, since it explains why non-benzo-λ^5-phosphetes are not available by this route. The key step in this synthesis is the generation of transient methylene phosphonium salts[33] **17a**, **b** from P-halogenated ylides[34] **16a**, **b**. Indeed, thanks to the high electrophilicity of the phosphorus atom in **17a**, **b**, an intramolecular ring closure leading to **18a**,**b** occurs. All attempts to generate the corresponding benzo-1λ^5-phosphetes from **18a**, **b** with a strong base failed. In the presence of pyridine an irreversible and quantitative isomerization to **19a**, **b** occurs. Deprotonation of **19a**, **b** was not clean in contrast to that of **20a**, **b**, which were generated by hydrolysis of the C–Si bond in **19a**, **b**. Deprotonation of **21a** with excess triethylamine affords 1,2λ^5-azaphosphete **6a** in 95% yield[32] (Scheme 5). However, this route is of no synthetic value, since **21a** is prepared by protonation of **6a**.

Scheme 5. Synthesis of benzo-λ^5-phosphetes **5a** and **5b**.

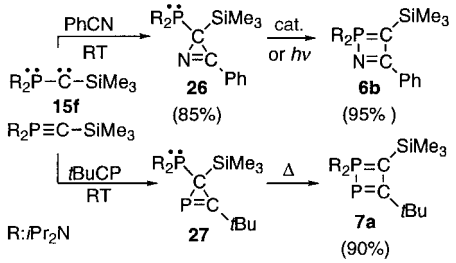


2.3. Ring Contractions

The thermal and photochemical elimination of dinitrogen from cyclic azoalkanes is an efficient method for preparing strained heterocycles,[35] including antiaromatic four-membered rings. Indeed, vapor flash pyrolysis of 1,2,3-triazines gives rise to azetes.[36] Similarly, heating 1,2,3,4λ^5-triazaphosphinine **22** in toluene under reflux for 14 h affords the 1,2λ^5-azaphosphete **6a** in 80% yield (Scheme 6).[37] Compound **6a** can also be obtained in a two-step one-pot reaction by first adding boron trifluoride to **22** at 0 °C, which initially leads to the zwitterionic heterocycle **23**, followed by decomplexation with excess triethylamine.[37b]

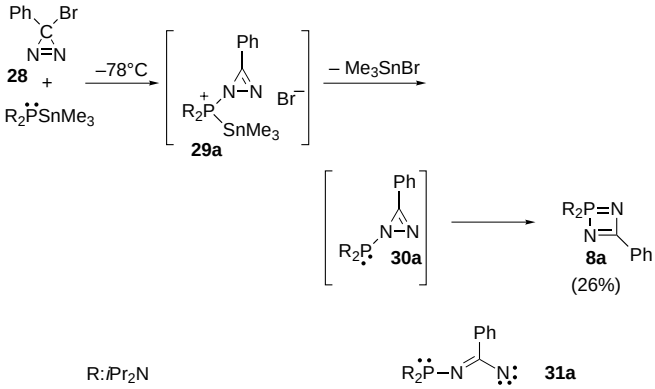
Scheme 6. Synthesis of the $1,2\lambda^5$-azaphosphete **6a** by ring contraction.

Like **22**, $1,2,3\lambda^5$- and $1,2,4\lambda^5$-diazaphosphinines **24**[38] and **25**[39] are readily available since phosphanyl-substituted 1,3-dipoles are able to react as formal 1,4-dipoles (Scheme 7).



Scheme 7. Phosphanyl-substituted 1,3-dipoles react as formal 1,4-dipoles.

However, all attempts to eliminate dinitrogen from **24** and **25** failed. The reluctance of **24** to loose N_2 is consistent with the high stability of phosphazo derivatives. Indeed, **24** features the same $R_3P{=}N{-}N{=}C<$ sequence as Staudinger–Meyer adducts (phosphane+diazo derivative), which are not precursors of phosphorus ylides.[40] In contrast, **22** features a phosphazide skeleton in a *cis* configuration, which has been postulated to be the geometry of the transition state[41] in the Staudinger reaction (phosphane+azide $\rightarrow$phosphazene+N_2). The high stability of **25** is more difficult to rationalize. Therefore, the ring-contraction route is so far restricted to the synthesis of $1,2\lambda^5$-azaphosphetes.

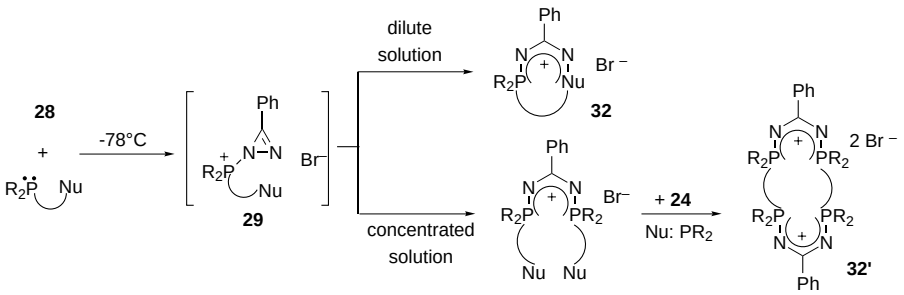


2.4. Ring Expansions

A few cyclobutadienes and azetes were prepared by ring expansions involving transient cyclopropenyl carbenes and nitrenes.[42] Similarly, 2-phosphanyl-2*H*-azirine **26** and 2-phosphanyl-2*H*-phosphirene **27** rearrange into $1,2\lambda^5$-azaphosphete **6b** (95% yield)[43] and $1\lambda^5,2\lambda^3$-diphosphete **7a** (90% yield),[44] respectively (Scheme 8). Both starting materials were prepared from our stable "carbene" **15f**.[31a–d] Although the only other example of a stable 2*H*-phosphirene was prepared using a transient carbene,[45] **26** is the first 2*H*-azirine prepared by a [1+2]cycloaddition.

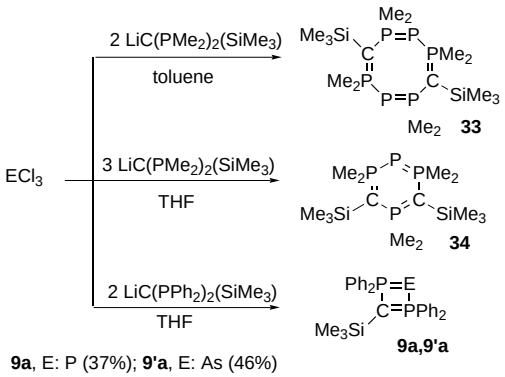
The third example of a ring expansion leading to a four π electron four-membered heterocycle involves the transient 1-phosphanyl-1*H*-diazirine **30a**. This antiaromatic four π electron three-membered ring was prepared by adding bis(diisopropylamino)trimethylstannylphosphane to 3-bromo-3-phenyldiazirine (**28**) followed by elimination of bromotrimethylstannane (Scheme 9).[46]

Scheme 8. From the stable carbene **15f** to $1,2\lambda^5$-azaphosphete **6b** and $1\lambda^5,2\lambda^3$ diphosphete **7a** by ring expansions of unsaturated three-membered heterocycles **26** and **27**, respectively.



Scheme 9. Synthesis of the transient 1-phosphanyl-1*H*-diazirine **30a** and its ring expansion to the $1,3,2\lambda^5$-diazaphosphete **8a**.

We were able to prove that the first step of the reaction proceeds by an S_N2' mechanism and leads to *N*-phosphoniodiazirine **29a**; this is in agreement with independent works by Creary[47] and Dailey[48] with other nucleophiles. We also demonstrated experimentally and with ab initio calculations that the rearrangement of **30a** to **8a** involves nucleophilic attack by the phosphorus lone pair at the second nitrogen atom of the diazirine, and not the imidoylnitrene intermediate **31a** (Scheme 9).[46b] Indeed, the parent parent compound **31** (R = H) is an unstable species on the singlet hypersurface and rearranges without requiring any activation energy to the corresponding carbodiimide. On the other hand, diazaphosphete **8a** is over 23 kcal mol^{-1} more stable than the corresponding 1-phosphino-1*H*-diazirine **30a**, and the activation energy for the rearrangement of **30a** to **8a** is around 24 kcal mol^{-1}. Interestingly, *N*-phosphoniodiazirines **29** have a reasonable lifetime, probably due to the presence of the phosphonio group, which decreases the effect of the destabilizing antiaromatic energy through "negative hyperconjugation".[49] The relative stability of **29** allows inter and intramolecular S_N2 reactions to compete. This makes the reaction of bromodiazirine with phosphanes possessing a second nucleophilic center of synthetic interest, as proven by the high-yield synthesis of mono- and dicationic heterocycles **32** and **32'**[46b] (Scheme 10).

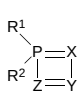


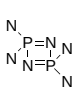
2.5. Use of Diphosphanylmethanides

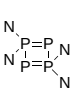
Diphosphanylmethanides are suitable starting materials for synthesizing $n\,\pi$ electron *n*-membered phosphorus hetero-

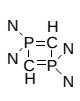
Scheme 10. Transient *N*-phosphoniodiazirines **29** as precursors for cationic and dicationic heterocycles.

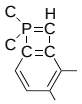
cycles.[50] It is particularly interesting that $Li[C(PMe_2)_2(SiMe_3)]$ reacts with PCl_3 in toluene to afford the eight-membered heterocycle **33**, whereas the six-membered ring **34** is formed in THF (Scheme 11).[50a] Heterocycle **34** is an

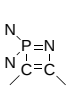


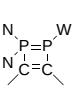


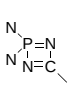


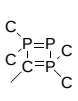


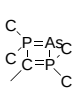






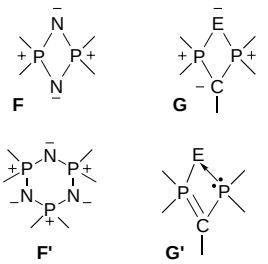






Scheme 11. Diphosphanylmethanides as precursors of $n\pi$ electron *n*-membered heterocycles.

analogue of cyclotriphosphazenes in which the three nitrogen atoms have been replaced by a phosphorus atom and two CR groups. With the more sterically crowded $Li[C(PPh_2)_2(SiMe_3)]$, the $1\lambda^5,2\lambda^3,3\lambda^5$-triphosphete **9a** was obtained in 37% yield.[50b] The same synthetic route allowed Karsch et al. to obtain the corresponding $2\lambda^3,1\lambda^5,3\lambda^5$-arsadiphosphete **9′a** in 46% yield.[50b]



3. Structural and Spectroscopic Data

Single-crystal X-ray diffraction studies were performed on several λ^5-phosphacyclobutadienes. The most important geometric parameters of derivatives **2a**,[15a] **3**,[27] **4b**,[29a] **5b**,[32] **6a**,[37a] **7′a** (a $W(CO)_5$ complex of **7a**),[44] **8a**,[51] **9a**, and **9′a**[50b] are listed in Table 1. In $1\lambda^5,3\lambda^5$-diphosphetes **2**, **3**, and **4** of type P_2X_2, the four-membered ring is organized around a crystallographically imposed symmetry center, which highlights the absolute planarity of the ring. All endocyclic P–X bond lengths are equal and lie between those of single and double bonds. Of special interest is the pinching of the ring around the nitrogen atom of **2a**, which induces a P···P distance (2.22 Å) as short as that in diphosphines.[52] Ab initio calculations[53a, b] rationalized these experimental data. Cyclodiphosphazenes **2** can be conceptualized as a sequence of amide and phosphonium units in which the negative charge of nitrogen is carried by a pure p lone pair that is perpendicular to the mean plane of the ring. Formally, this charge is equal to -1, but is in fact reduced due to σ polarization and to a certain amount of conjugation with the phosphorus atoms. The electrostatic repulsion between the nitrogen atoms explains the acute angle at nitrogen and the short P···P distance; there is no transannular P···P bonding interaction, as shown by the strongly negative overlap population. In conclusion, the four π electron system of **2** and related P_2X_2 heterocycles **3** and **4** as well as the six π electron system of cyclotriphospha-

[a] Mean deviation from the best plane of the four-membered ring.

zenes **1** basically follow the island models **F** and **F′**,[13] respectively.

In the nonsymmetrical $1\lambda^5,3\lambda^5$-diphosphetes **9a** and **9′a**[50b] the four-membered rings are not completely planar: The dicoordinated phosphorus and arsenic atoms project out of the P-C-P plane, and once again there is a pinching of the ring at the σ^2-P* (or As) atom, which induces a relatively short nonbonding λ^5-P–λ^5-P distance. The structural parameters suggest a representation of **9a** and **9′a** as cyclic bis(ylides) **G**, very comparable to **F**, or alternatively as internally donor-stabilized phosphinidenes and arsinidenes **G′**, respectively.

The four π electron system of $1\lambda^5$-phosphetes **5**–**8** cannot follow the island model, and one should therefore find an alternative way to escape from the concept of antiaromaticity. Also these four-membered rings are nearly planar, as shown by the mean deviation from the best plane (Table 1). The exocyclic P–N bonds of **6a**, **7′a**, and **8** (as in **2a** and **4b**) are rather short and are comparable to those observed in bis(diisopropylamino)phosphenium salts (1.61 Å).[54] This indicates a positive charge located on the $(R_2N)_2P$ fragment, although according to calculations[51] a delocalization of this charge towards the exocyclic amino groups seems unpronounced. All the X–Y and Y–Z bond lengths are between those of single and double bonds, indicating that the XYZ part of the rings can be regarded as an anionic propenyl system. This zwitterionic formulation of **5**–**8** is illustrated by the calculated electron density Σ (Mulliken charges) for the parent compound **8**. The value of the inner ring angle at

phosphorus is small and that of the opposite angle is large, which induces a short P···Y distance across the diagonal. Since the P–X and P–Z bond distances are long in all the derivatives, these results as a whole demonstrate that λ^5-phosphetes **5**–**8** have a rhomboidal zwitterionic structure of type **H**.

[*] Editorial comment: If the bonding number of a ring atom deviates from its standard value, according to IUPAC rules the actual bonding number is expressed by an Arabic number cited as a superscript to the Greek letter lambda, which follows the corresponding locant. In contrast to this recommendation, the Greek letter sigma is used here to indicate the structural features. The exponent gives the number of σ bonds that originate at phosphorus ring atoms.

Interestingly, the related six π electron six-membered heterocycles can be almost planar, such as various λ^5-di- and triphosphinines,[55] or have a boat conformation, such as the $1\lambda^5,3\lambda^5,5\lambda^5,2\lambda^3$-tetraphosphinine **34** reported by Karsch (interplanar angle 127°).[50a] λ^5-Diaza- and triazaphosphinines such as **24**, **25**, and **22** have a zwitterionic structure of type **H′**.[37b, 39, 51] Clearly, all these heterocycles are not aromatic.

Ab initio SCF calculations were performed on the parent benzannulated derivatives **5** and **35**–**40**.[32] Apart from the geometric parameters, the anisotropy of magnetic susceptibilies Δχ (Table 2) gives an indication of the degree of aromatic or antiaromatic character.[56] For instance, the calculated value of Δχ is strongly negative in benzene (-63.4×10^{-6} cm^{3}mol^{-1}), while much larger anisotropies are observed for π systems possessing antiaromatic character; Δχ is even positive in cyclobutadiene. Annulation of a saturated four-membered cyclic system on a benzene ring (**37** and **40**) reduces the value of Δχ by about 15%, which signifies relatively little perturbation of the electronic properties of the aromatic moiety. The small negative values of Δχ for **35**, **38**, and **39** are indicative of antiaromatic π systems. Compounds **38** and **39** are formally derived from benzocyclobutadiene **35** by replacement of one CH unit by a P or PH^+ group; both groups are able to participate in the π-electron system by (p,p)-π interactions. On the other hand, the Δχ values for the cyclic hydrocarbon anion **36** and λ^5-benzophosphete **5** are similar; this confirms that four π electron four-membered heterocycles possessing one heteroatom that has no suitable p orbital show an interrupted cyclic π delocalization.

Table 2. Calculated anisotropy of magnetic susceptibilities, Δχ [10^{-6} cm^{3}mol^{-1}].[32]

	35	**36**	**37**	**38**	**39**	**50**	**5**

[a] $\Delta\chi=\chi_{op}-\chi_{ip}$, where χ_{ip} is the average of the difference of the in-plane components of the susceptibility (op = out-of-plane; ip = in-plane).

Table 3 summarizes the most important NMR data for compounds **2**–**9**. There are some striking features. The ^{31}P NMR chemical shifts for the λ^5-phosphorus atom of all heterocycles bearing dialkylamino groups are similar; these atoms are more deshielded than those in analogous six-membered rings and linear systems. The ylid character of the P–X or P–Z bonds is indicated by the high-field chemical shifts of the corresponding nuclei, which are, however, less shielded in **5**–**7** than in **3**, **4**, and **9**; this supports the representations **F**, **G**, and **H** for **2**–**4**, **9**, and **5**–**8**, respectively. The very low field chemical shift of the signal for the carbon atom (Y) in **5**–**8** is typical of unsaturated small rings, including the antiaromatic cyclobutadienes and azetes.

The HOMO of the four-membered rings **2**–**9** is located at the X or Z atom. For example, in the parent compound **8** the

HOMO is a mixture of the nonbonding orbitals of the lone pair of the endocyclic nitrogen atoms and the nonbonding allylic π orbital of the ring (computed to be −8.7 eV).[51] Not surprisingly, the LUMO is at the carbon atom β to the λ^5-phosphorus atom. These theoretical results may serve as a good model for explaining the reactivity of **2**–**9**.

4. Reactivity

The λ^5-phosphacyclobutadienes **2**–**9** are quite reactive. It would take too long to provide a comprehensive review, and, therefore, only a few representative reactions will be presented here. They highlight the versatility of these heterocycles as well as their usefulness as starting materials in several fields.

4.1. Addition of Protic Reagents

All λ^5-phosphacyclobutadienes considered in this review are moisture-sensitive. For example, **6a** in dichloromethane reacts to give the phosphoranyl compound **41** (82% yield, Scheme 12) after contact with air for a few minutes.[37b] The

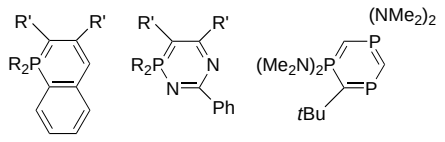
Ar: *p*-tolyl

Scheme 12. Reactivity of the 1,2λ^5-azaphosphete **6a** towards protic reagents. Tf = F_3CSO_2.

first step is certainly protonation at nitrogen. The ring opening is induced by the formation of a strong P=O bond, which converts the phosphonium center into a phosphorane. Indeed, with triflic acid, cyclic phosphonium salt **21a** was isolated in 95% yield.[32] The behavior of **6a** towards protic nucleophiles appears to depend dramatically on the nature of the nucleophiles. Although P–N bond cleavage occurs in the presence of water, P–C bond cleavage takes place upon adding *p*-cresol or *p*-thiocresol[57] to afford **42a**, **b** (85–90% yield). With primary or secondary amines a ring expansion is observed leading to five-membered heterocycles **43a**, **b** in excellent yields.[57] Derivatives of type **42** are starting materials for the synthesis of electron-poor 2-azadienes,[58] and five-membered cyclic phosphazenes **43** are not readily available by other routes.

4.2. Addition of Unsaturated Compounds

The Wittig reaction is one of the most famous and useful reactions in chemistry. Not surprisingly, classical aza-Wittig reactions were observed when azaphosphete **6a** or diazaphosphete **8a** was treated with carbon disulfide and benzaldehyde to afford thiophosphoryl and phosphoryl derivatives **44**[37b] and **45**[51] as single isomers in 35 and 85% yield, respectively (Scheme 13).

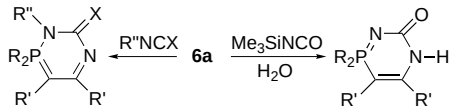


R:*i*Pr$_2$N; R': CO_2Me

Scheme 13. Two examples of classical aza-Wittig reactions.

Electron-poor alkynes are known to insert into P–C and P–N ylidic bonds.[40] Indeed, dimethylacetylene dicarboxylate cleanly inserts into the P–X bond of **5a** and **8a** at room temperature to lead to the expected benzophosphinine **46**[32] and diazaphosphinine **47**[51] in 76 and 70% yield, respectively (Scheme 14). Noteworthy is the reaction of diphosphete **4b** with *tert*-butylphosphaethyne, which provided the first triphosphabenzene **48** in 35% yield.[59]

In fact, **6a** and its congeners very often react as nonclassical Wittig reagents. For example, isocyanates and isothiocyanates



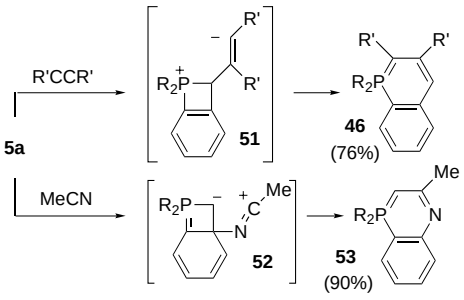
46 (76%) **47** (70%) **48** (35%)

R: *t*Bu, R': CO_2Me

Scheme 14. Some six π electron six-membered heterocycles available by addition of alkynes or phosphalkyne to four π electron four-membered phosphorus heterocycles.

have been widely employed in aza-Wittig reactions to give unsymmetrical carbodiimides and the corresponding phosphoryl and thiophosphoryl derivatives.[40] In marked contrast, phenyl isocyanate and methyl isothiocyanate react with **6a** to provide the corresponding ring insertion products **49a** (66% yield) and **49b** (90% yield), respectively;[37b] these results are reminiscent of the Dimroth rearrangement.[40b, 60] Compound **6a** also reacts with trimethylsilyl isocyanate to afford, after hydrolysis, heterocycle **50** (50% yield),[37b] which formally results from the insertion of the cumulene into the N–C bond (Scheme 15). However, insertion into the P–N bond of **6a**

49a (66%)
49b (90%)



50 (50%)

R: *i*Pr2N; R': CO_2Me
a: R": Ph, X: O; **b**: R": Me, X: S

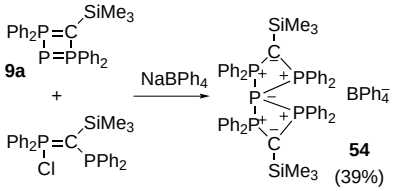
Scheme 15. Reactivity of 1,2λ^5-azaphosphete **6a** towards cumulenes.

followed by a 1,3-silyl or hydrogen shift is more likely. Intriguingly, **50** exists as a hydrogen-bonded dimer in the solid state and has a structure very similar to that of cytosine. The $C(NH_2)$ is replaced by a $P(NiPr_2)_2$ group; **50** could be considered as a "labeled" cytosine.

The only clear example for the expansion of a four-membered to a six-membered ring involving the X–Y and not the P–X or P–Z bonds is the reaction of λ^5-phosphete **5a** with acetonitrile, which leads to 1,4λ^5-azaphosphinine **53** (Scheme 16).[32] The striking difference in the behavior of **5a** towards dimethylacetylene dicarboxylate (insertion into the

R: *t*Bu, R': CO_2Me

Scheme 16. Versatile behavior of the naphto-λ^5-phosphete **5a** towards reagents with triple bonds.



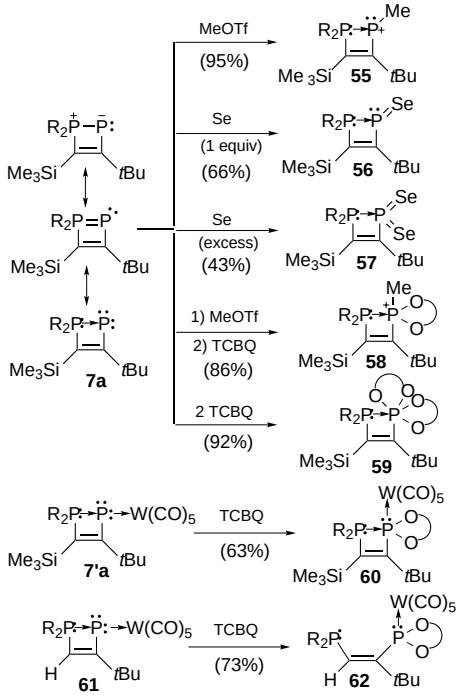
P–C bond to form **46**) and acetonitrile can be explained by considering that the HOMO of **5a** is located at the α-carbon atom, while the LUMO is at the carbon atom β to the phosphorus atom. Therefore, the electron-poor alkyne reacts with **5a** to give **51** as an intermediate, whereas the nitrogen end of the nitrile adds to the β-carbon atom to form **52** initially (Scheme 16).

In contrast to the other four-membered heterocycles discussed in this review, the 1λ^5,2λ^3-diphosphetes **3**, **7a**, and **9** seem reluctant to undergo any kind of insertion.

4.3. Reactions with Retention of the Four-Membered Ring

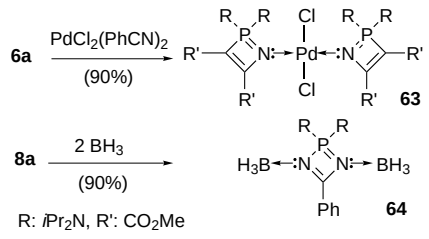
These reactions are surprisingly numerous, but the most striking results were obtained with the 1λ^5,2λ^3, 3λ^5-triphosphete **9a**[50b] and the 1λ^5,2λ^3-diphosphete **7a**.[61]

The reaction of **9a** with $[Ph_2PC(PPh_2)(SiMe_3)]^+BPh_4^-$ results in formation of the spirocyclic ten-electron cation **54** (Scheme 17), which features an unprecedented pseudo-



Scheme 17. Synthesis of a spirocyclic ten-electron cation with a pseudo-trigonal-bipyramidal PP_4 skeleton.

trigonal-bipyramidal PP_4 skeleton.[50b] Compound **54** can also be described as a tetraphosphonio-substituted phosphoranide[62] with partial charge compensation by two internal carbanion functionalities.



Methyltrifluoromethane sulfonate, a stoichiometric amount or two equivalents of elemental selenium, and two equivalents of tetrachloro-*o*-benzoquinone cleanly react with **7a** at its dicoordinate phosphorus atom to provide the corresponding heterocycles **55**, **56**, **57**, and **59** (Scheme 18), which can be regarded as phosphenium–, selenoxophosphane–, diselenoxophosphorane– and phosphorane–phosphane adducts, respectively.[61] The four-membered ring is also retained when tetrachloro-*o*-benzoquinone is added to **55**; the resulting derivative **58** is an example of a phosphonium–phosphane adduct. In other words, the σ^2-phosphorus atom of **7a** (a phosphanylidene-phosphane adduct) can extend its coordination number up to six without destroying the four-membered ring! The tendency of derivatives of **7a** and **55**–**57** to retain the ring structure can be explained by the presence of an electrophilic low-coordinate phosphorus center. It was only recently that the cyclic structure of derivatives **58** and **59**, which feature a high-coordinate phosphorus atom, was rationalized.[63] The presence of bulky substituents at the two carbon atoms of the ring induces small C-C-P angles, as proven by the formation of heterocycle **60** on the one hand and the linear adduct **62** on the other in the

reaction of diphosphetes **7′a** and **61**, respectively, with tetrachloro-*o*-benzoquinone (Scheme 18).

Scheme 18. The persistence of the P–P bond in $1\sigma^4,2\sigma^x$-diphosphetes.

In contrast to their organic analogues—in particular the azetes,[42c, 64] which give η^4-complexes—**2**–**8** usually[65] act as η^1-ligands towards transition metal complexes.[44, 66] For example, azaphosphete **6a** reacts at room temperature with half an equivalent of $[PdCl_2(PhCN)_2]$ to lead to the bis(η^1-azaphosphete)palladium(II) complex **63** in 90% yield (Scheme 19). Interestingly, two equivalents of a neutral Lewis

Scheme 19. λ^5-Aza- and -diazaphosphetes as η^1 ligands.

acid, such as BH_3, react with diazaphosphete **8a** to provide the bis-adduct **64** in 90% yield.[51] In both cases the geometric parameters and NMR data for the free and the coordinated ring are very similar, which suggests that the four π electron system is not perturbed upon complexation. From the results of both reactions presented in Scheme 19, it seems quite likely that mixed inorganic–organometallic polymers could be prepared with **8a**.

5. Summary and Outlook

These results as a whole clarify the bonding situation in four π electron four-membered heterocycles with a phosphorus atom that possesses no available p orbital for the π system. When two phosphorus atoms are present in the 1,3-positions, the four π electron system basically follows the island model. However, when there is only one phosphorus atom the negative charge is delocalized on an allylic fragment, and the positive charge is localized at the phosphorus center. In all cases there is an interrupted cyclic π delocalization, and, therefore, these compounds are not antiaromatic. Similarly, six π electron six-membered heterocycles with a λ^5-phosphorus atom are not aromatic.

Some of these four π electron four-membered heterocycles can be prepared on a multi-gram scale and are no longer laboratory curiosities. They are valuable precursors for highly functionalized neutral or cationic heterocycles and polycycles that exhibit unusual bonding situations; they are also interesting ligands for transition metals.

Most of the "λ^5-phosphacyclobutadiene derivatives" prepared so far bear bulky substituents at phosphorus atom with the exception of **9a** and **9′a**, which have phenyl substituents. Although all attempts[67] to prepare stable cyclodiphosphazenes **2** with other substituents failed, it is important to continue trying to prepare phosphacyclobutadienes bearing small substituents if one wants to use these compounds as starting materials for polymers. We have to keep in mind that phosphorus polymers (such as polyphosphazenes) have numerous peculiar and industrially important properties.

We have shown that the presence of a λ^5-phosphorus atom is sufficient to stabilize four π electron four-membered rings. Clearly other heteroatoms possessing no available p orbital should also allow the synthesis of analogous heterocycles.

At the end of this review I would like to make clear the main motivations of this work. We wanted to play tricks with the concept of antiaromaticity while seriously keeping in mind that the search for the physical reality in which this concept may be rooted is an important issue for future studies. To nonspecialists, natural-product synthesis appears to be just an intellectual game; this review deals with nonnatural-product synthesis. However, novel properties can only be discovered if new families of compounds are prepared, and history has demontrated that it is difficult to predict the impact and development of new materials or new reactions. Let us wait and see what the future of these heterocycles will be.

I would like to thank all my co-workers for their dedication, intellectual contribution, and hard work, and the CNRS for generous support of this work

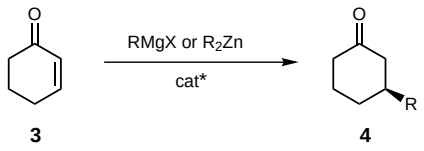
Copper-Catalyzed Enantioselective Michael Additions: Recent Progress with New Phosphorus Ligands

Norbert Krause*

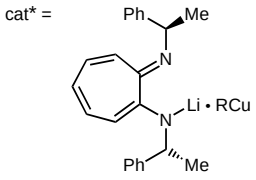
Enantioselective Michael addition of a chiral organometallic reagent to a prochiral substrate is an attractive method for creating a center of chirality in an organic molecule.[1] For this purpose chirally modified organocopper compounds of composition RCu(L*)Li can be used; the chiral nontransferable ligand L* controls the stereochemical course of the transfer of group R to the substrate **1**. By using stoichiometric amounts of these "chiral cuprates", the groups of Bertz, Corey, Dieter, Rossiter, and Tanaka obtained the 1,4-adducts **2** with good

enantioselectivities (over 90% *ee* in some cases). Naturally occuring alcohols and amines were used as chiral ligands L* (e.g., ephedrine and proline derivatives).[1] However, these investigations also revealed two fundamental problems of enantioselective Michael additions:

1) In solution organocopper compounds show dynamic behavior with equilibria between several species. If this leads to the formation of achiral, but more reactive cuprates, a loss of enantioselectivity is unavoidable. Therefore, it is crucial to develop chiral reagents which react so rapidly with the substrate that undesired competing reactions are suppressed.
2) Many chiral organocopper reagents exhibit high substrate specificity; that is, they give good stereoselectivities with only one or very few Michael acceptors.



Both problems may be solved by taking advantage of the concept of *ligand-accelerated catalysis*,[2] which involves catalytic reactions characterized by dynamic ligand-exchange processes. The presence of a suitable ligand can lead to the formation of a highly reactive and selective catalyst by self-assembly. If a chiral ligand is used, a stereoselective reaction may be favored over a nonselective one. Other advantages of catalytic transformations compared to their stoichiometric counterparts are the more efficient use of the metal and the chiral ligand, as well as the minimization of waste production.



Michael additions of organolithium, Grignard, and diorganozinc reagents to enones and other α,β-unsaturated carbonyl compounds are catalyzed inter alia by copper, nickel, and cobalt salts. The best results are obtained with copper(I) catalysts, especially those in which copper is bound to a "soft", readily polarizable center (sulfur or phosphorus).

The first reaction of this type was reported by Lippard et al. in 1988: the reaction of 2-cyclohexenone (**3**) with Grignard reagents in the presence of the chiral aminotroponeimine copper complex **5** as catalyst gave the 1,4-adducts **4** with 4–14% *ee*.[3a] The selectivity was increased to 74% *ee* by addition of hexamethylphosphoric triamide (HMPA) and silyl halides.[3b] Spescha et al.[4] used the copper complex **6**, which was obtained from a thioglucofuranose derivative, as catalyst for 1,4-additions of Grignard reagents to **3**, and observed enantioselectivities of up to 60% *ee*. The dihydrooxazolylthiophenolato copper complex **7** was employed by Pfaltz et al.[5] for the enantioselective catalysis of Michael additions to cyclic enones; the best results were obtained with tetrahydrofuran as solvent and HMPA as additive. There was a pronounced dependence of the stereoselectivity on the ring size of the substrate: 16–37% *ee* for 2-cyclopentenone, 60–72% *ee* for **3**, and 83–87% *ee* for 2-cycloheptenone. Alexakis et al.[6] used the heterocycle **8**, which is readily accessible from ephedrine, as chiral ligand for the copper(I)-catalyzed addition of diethylzinc to **3**, and obtained ketone **4** (R = Et) with 32% *ee*. Another neutral phosphorus ligand is the proline derivative **9**, with which Kanai and Tomioka[7] obtained 67–90% *ee* in the Cu(I)-catalyzed 1,4-addition of Grignard reagents to 2-cyclohexenone (**3**). Recently, Feringa et al.[8] reported the use of phosphorus amidites of type **10** in Michael additions of diethylzinc to enones. These reactions are catalyzed by copper(I) salts and by copper(II) triflate; when **3** was used as substrate, stereoselectivities of 60% *ee* (with CuOTf) and 63% *ee* (with $Cu(OTf)_2$) were obtained (a much higher value of 81% *ee* resulted with 4,4-dimethyl-2-cyclohexenone in the presence of **10**. Even when $Cu(OTf)_2$ is employed, the actual chiral catalyst is probably a copper(I) species which is formed by in situ reduction of the copper(II) complex. In all these cases, the regioselectivities (1,4- vs. 1,2-addition) and chemical yields are acceptable or good.

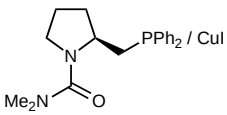
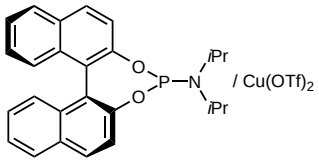
5 (4–14% *ee*[3a])
(max. 74% *ee*; + *t*Bu$_2$PhSiCl / HMPA[3b])

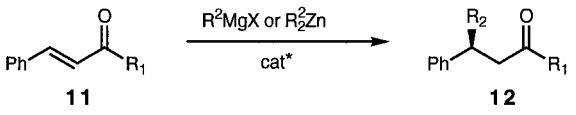


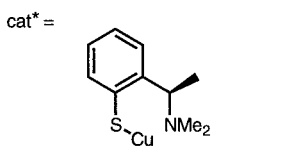
6 (max. 60% *ee*[4])



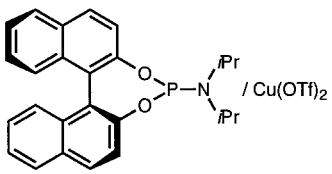
7 (60–72% *ee*; + HMPA[5])

8 (32% *ee*[6])



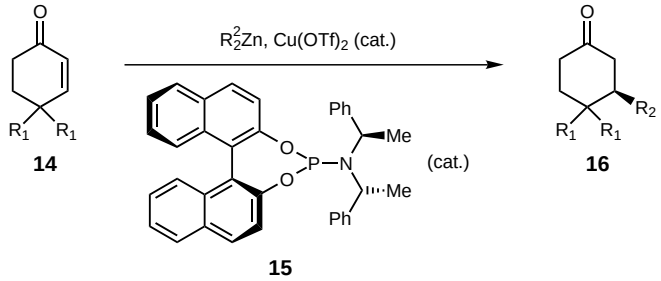


9 (67–90% *ee*[7])

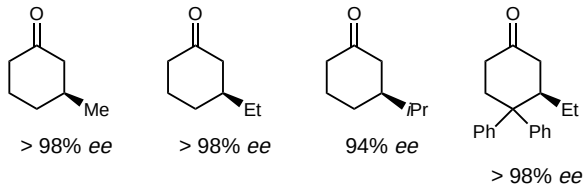


10 (63% *ee*[8])

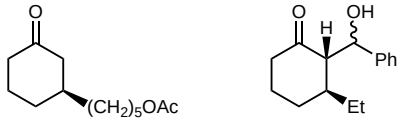
As these examples show, cyclic enones are normally used as substrates for copper-catalyzed enantioselective Michael additions. In some cases, however, good stereoselectivities were also attained with acyclic enones of type **11**. Thus van Klaveren, van Koten et al.[9] employed the copper arenethiolate **13** as catalyst for the 1,4-addition of methylmagnesium iodide to benzylideneacetone and obtained adduct **12**



13 ($R^1 = R^2 =$ Me: 76% *ee*[5])

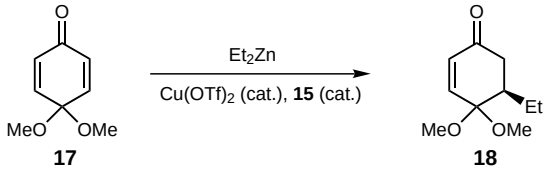


10 (R^1 = Ph, R^2 = Et: 87% *ee*[8])



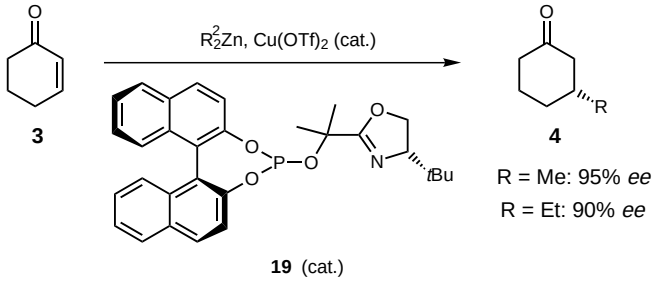
($R^1 = R^2 =$ Me) with 76% *ee*. Interestingly, this catalyst is not suitable for analogous additions to cyclic enones; similarly, the structurally related copper thiolate **7** does not catalyze enantioselective Michael additions of Grignard reagents to acyclic enones of type **11**. With **7** and **13**, complicated nonlinear relationships between the enantiomeric excesses of the catalyst and the product were observed, indicating that the product is formed via different organocopper intermediates in several reaction pathways. Progress with regard to this undesired substrate specificity was achieved with the phosphorous amidite **10**, which catalyzes not only Michael additions of organozinc reagents to cyclic enones but also to chalcone (**11**, $R^1 =$ Ph) and related acyclic substrates. In the case of the addition of diethylzinc to chalcone, a good stereoselectivity of 87% *ee* was observed.[8]

The last example shows that neutral binaphthol phosphorus ligands are particularly well suited for enantioselective Michael additions. On the basis of this structural feature, Feringa et al.[10] achieved a breakthrough. By combining C_2-symmetrical axially chiral binaphthol with C_2-symmetrical bis(1-phenylethyl)amine through a phosphorus center, they obtained the new ligand **15**, which can be used in highly enantioselective copper-catalyzed Michael additions of diorganozinc reagents to numerous cyclic enones. Here the steric properties of the substrate and the reagent are unimportant, since the transfer of methyl, ethyl, and isopropyl groups to 2-cyclohexenone takes place with high enantioselectivities ($\geq$94% *ee*) and good chemical yields (72–95%), as does the transfer of an ethyl group to 4,4-diphenyl-2-cyclohexenone. Additional functional groups can be introduced into the addition product in several ways without affecting the stereo-



> 98% *ee* > 98% *ee* 94% *ee* > 98% *ee*

95% *ee* 95% *ee*



94% *ee*

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0284 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 3

chemical course of the reaction. Thus the addition of diethylzinc to 4,4-dimethoxy-2,5-cyclohexadienone (**17**), catalyzed by **15** und $Cu(OTf)_2$, gives adduct **18** with 94% *ee*. The functionalized zinc reagent $[AcO(CH_2)_5]_2Zn$, prepared by hydroboration of the corresponding alkene and transmetalation according to Knochel's method, can be added to 2-cyclohexenone with excellent selectivity of 95% *ee*. Finally, the zinc enolates formed in these transformations can also be treated with more complex electrophiles instead of protons. For example, the three-component coupling of 2-cyclohexenone, diethylzinc, and benzaldehyde in the presence of **15** and $Cu(OTf)_2$ furnishes the expected hydroxyketone with 95% *ee*; however, the diastereoselectivities of these transformations are not yet satisfactory.[10]

With the combination of phosphorus amidite **15** and $Cu(OTf)_2$, a catalyst has been developed for the first time which can be applied with confidence to almost any combination of Michael acceptor and organozinc reagent. This system apparently exploits the pinciple of ligand-accelerated catalysis. However, an important limitation has to taken into account: Only enones with six-membered rings give high stereoselectivities (the analogous reactions of diethylzinc with 2-cyclopentenone and 2-cycloheptenone gave the adducts with 10 and 53% *ee*, respectively). Another recent report by Pfaltz et al.[11] underlines that the bridging of binaphthol and a chiral amine through a phosphorus center is a general feature of catalysts which are suitable for highly enantioselective Michael additions. In the presence of the phosphite **19** with oxazoline structure, the 1,4-additions of dimethyl- and diethylzinc to **3** also give stereoselectivities of 95 and 90% *ee*, respectively. Hopefully, this major progress will trigger further investigations leading to new chiral copper catalysts which can be applied even more generally to cyclic Michael acceptors with different ring sizes as well as to acyclic substrates.

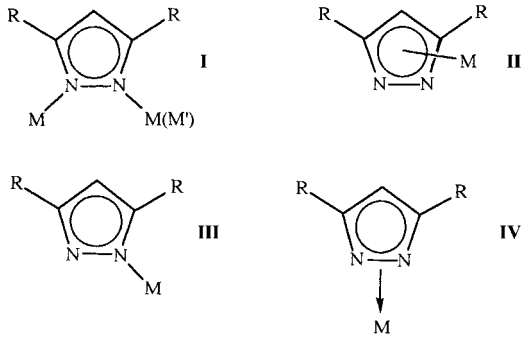
Another Surprise from Pyrazolate Ligands**

Joanna E. Cosgriff and Glen B. Deacon*

Winter et al.[1] recently synthesized two pyrazolatotitanium(IV) complexes $[Ti(\eta^2\text{-}R_2pz)_4]$ (**1**, pz = pyrazolate, R = Ph, Me) with four 3,5-disubstituted pyrazolate rings. These are the first homoleptic pyrazolato complexes, and contain exclusively η^2-pyrazolate ligands. This was followed by the synthesis of the homoleptic 3,5-disubstituted pyrazolatotantalum(V) complex $[Ta(\eta^2\text{-}Me_2pz)_3(\eta^1\text{-}Me_2pz)_2]$[2] (**2**), which has



1

2

both η^1- and η^2-pyrazolate ligands. These complexes establish η^2-pyrazolate binding as a new feature in the chemistry of d-block transition metals. There is only one previous example of η^2-binding to a d-block element: $[ZrCp_2(\eta^2\text{-pz})(thf)](BPh_4)\cdot 0.5\,thf$,[3] in which there is just one ligand of this type. The preparation of homoleptic pyrazolato complexes and in particular homoleptic (η^2-pyrazolato)titanium(IV) complexes is the most significant development in the coordination chemistry of these ligands since the unexpected discovery of *endo* bidentate (η^2) coordination in $[UCp_3(\eta^2\text{-pz})]$.[4] The bonding in $[Ti(\eta^2\text{-}R_2pz)_4]$ contrasts the expected d-block bridging bidentate coordination seen in $[\{TiCp_2(\mu\text{-pz})\}_2]$.[5] The homoleptic complexes **1** and **2** are of considerable interest as molecular precursors for chemical vapor deposition (CVD).[1, 2]

In his seminal review of pyrazole and pyrazolate coordination, Trofimenko considered two possible types of bonding for the pyrazolate ion: bridging [that is, *exo*-bidentate (**I**)] or η^5 (the pyrazolate functions as 1,2-diazacyclopentadienide).[6] However, claims of π bonding were dismissed as unsubstantiated,[6] and this mode of coordination (**II**) remains to be established. Unidentate coordination as in **III**, which is formally present in pyrazolylborates $[R_nB(pz)_{4-n}]^-$,[6, 7] was first crystallographically observed for bis[3-phenyl-5-(2′-pyridyl)pyrazolato]nickel(II).[8] In this case the coordination of

I **II** **III** **IV**

the 2′-pyridyl nitrogen atom forces the metal to comply with unidentate rather than *exo* bidentate coordination. More latterly, several complexes with η^1-pyrazolate ligands have been prepared. In these cases unidentate coordination is generally dictated by the metal: Either only certain coordination sites are available, as in *cis*-chloro(η^1-3,5-diphenylpyrazolato)bis(triphenylphosphane)platinum(II),[9] or there are electronic requirements, as in bis(η^5-cyclopentadienyl)bis(η^1-pyrazolato)molybdenum(IV)[10] or $[Me_2Ga(pz)_2]^-$.[11]

The first observation of η^2-coordinated pyrazolate ligands (complexes of type **IV**) in $[UCp_3(\eta^2\text{-pz})]$ was unexpected; the authors anticipated $[UCp_3(\mu\text{-pz})]_2$.[4] This form of binding to an f-block metal was rationalized in terms of the highly ionic, nondirectional nature of the U–N bonds and binding to the more negative side of the pyrazolate ring. Other examples of η^2-coordinated pyrazolate ligands followed for uranium[12] and then for lanthanoids. This coordination mode was initially observed together with μ-pyrazolate binding.[13, 14] In an important subsequent development the first tris(η^2-pyrazolato)lanthanoid complexes $[Ln(R_2pz)_3(L)_n]$ (L = thf, dme, Ph_3PO) were prepared by using the bulky 3,5-diphenyl- and 3,5-di-*tert*-butylpyrazolate ligands.[15] These were the first complexes with η^2-pyrazolates as the sole anionic ligands. These studies also introduced metal-based redox transmetalation/ligand exchange [Eq. (a); R = *t*Bu, Ph, R′ = C_6F_5] as a synthetic method, in contrast to the commonly used metatheses or deprotonations.[6, 7] However, the ligands were not

$$2\,Ln + 6\,R_2pzH + HgR'_2 \longrightarrow 2\,[Ln(R_2pz)_3] + 3\,Hg + 6\,R'H \qquad (a)$$

bulky enough to produce homoleptic η^2-pyrazolato complexes for the large Ln^{3+} ions, but have now proven sufficiently bulky to give such complexes for the smaller (by ca. 15%)[16] titanium(IV).[1]

The failure to observe d-block transition metal complexes of η^2-coordinated pyrazolato ligands prior to $[ZrCp_2(\eta^2\text{-pz})(thf)](BPh_4)$[3] was attributed to a correlation between common *exo* bidentate binding and the directional properties of the nitrogen donor atoms.[4, 6, 15] Even the example of $[ZrCp_2(\eta^2\text{-pz})(thf)](BPh_4)$, in contrast to the numerous

d-block transition metal complexes of μ-pyrazolate ligands,[6, 7] can be viewed as an exceptional result of the need to achieve electronic saturation (18 electrons).

The syntheses of $[Ti(\eta^2\text{-}R_2pz)_4]$[1] and $[Ta(\eta^2\text{-}R_2pz)_3(\eta^1\text{-}R_2pz)_2]$[2] by protolytic transamination [Eq. (b)] have established η^2-bound pyrazolato ligands in d-block transition metal

$$[M(NMe_2)_n]+n\,R_2pzH \longrightarrow [M(R_2pz)_n]+n\,HNMe_2 \qquad (b)$$

complexes as a general feature. Moreover, their presence in compounds such as **1** and **2** cannot be related to the need for coordinative saturation, since these complexes are 16-electron systems. In addition, the formation of **2** indicates that **1** is not sterically saturated (eight-coordinate Ti^{4+} and Ta^{5+} have similar ionic radii[16]). The formation of homoleptic, coordinative, and sterically unsaturated tetrakis(η^2-pyrazolato)titanium(IV) complexes **1** (R = Me or Ph) can be attributed to the use of a noncoordinating solvent with an elevated boiling point (toluene). This discourages coordination of an additional ligand, for example the low-boiling dimethylamine product [Eq. (b)]. There is the possibility of coordination of R_2pzH (R = Me, Ph) to give $[Ti(R_2pz)_4(R_2pzH)]$, as in the synthesis of $[La(tBu_2pz)_3(tBu_2pzH)_2]$ (Ln = La, R = *t*Bu, R′ = Ph) in Equation (a) in low-boiling petroleum ether.[17] The higher boiling point of toluene obviates this in Equation (b).

Winter et al. provided a bonding model based on ab initio calculations[1] for the $[Ti(\eta^2\text{-}R_2pz)_4]$ complexes in which electron density from the nitrogen lone pairs is placed in molecular orbitals which interact with appropriate empty d orbitals on Ti. In the calculations η^1-coordination did not constitute a minimum, and it was proposed that the presence of empty d orbitals favors η^2-bonding over η^1-bonding.[1] On this basis, the formation of $[Ta(\eta^2\text{-}Me_2pz)_3(\eta^1\text{-}Me_2pz)_2]$ is surprising. The alternative formation of $[Ta(\eta^2\text{-}Me_2pz)_5]$ is unlikely, since it is a formal 20-electron system, but $[Ta(\eta^2\text{-}Me_2pz)_4(\eta^1\text{-}Me_2pz)]$ is plausible. The steric coordination number[18] of η^2-Me_2pz is 1.54,[14] whereas that of η^1-Me_2pz should be comparable with that of one end of a bridging Me_2pz group (1.37). Therefore, the sum of the steric coordination numbers of the ligands in $[Ta(\eta^2\text{-}Me_2pz)_5]$ (7.7) is high for an ion of the size[16] of Ta^{5+}, and it reduces to 7.4 in $[Ta(\eta^2\text{-}Me_2pz)_3(\eta^1\text{-}Me_2pz)_2]$, which evidently provides the most stable steric/electronic balance (formally 16 electrons). Based on the calculations it was predicted that η^2-binding will be observed in early to middle transition metal complexes.[1] For ions of the same charge, steric factors also favor a change from η^2 to η^1 over the series. It is of interest both to test this prediction and to establish whether steric or electronic factors are dominant in determining the bonding mode.

The biggest challenge now is to achieve η^5-pyrazolate coordination (type **II**). Azacyclopentadienes can form π bonds, since η^5-bonding of the 2,5-di-*tert*-butylpyrrolyl ligand is known for main group, d-block, and f-block metals,[19] but in this case binding of nitrogen to metals is substantially blocked. It will take more ingenuity to achieve this outcome for pyrazolate ligands.

Completely Stereospecific Self-Assembly of a Circular Helicate**

Olimpia Mamula, Alex von Zelewsky,* and Gérald Bernardinelli

Self-assembly of helicates with labile metal centers has been recently a subject of great interest in the field of supramolecular chemistry.[1, 2] The inherently chiral helicates are formed as racemates if nonchiral ligands are used. Various procedures for resolution have been successfully applied in order to obtain the pure enantiomers.[3–6] The enantioselective synthesis of chiral structures in general and of supramolecular assemblies in particular is a challenge. Chiral helicating ligands can induce stereoselectivity; that is, the chiral centers of the ligands influence the chirality of the resulting helix.[7–15]

So far most studies in the coordination chemistry of helicates were carried out on structures that are noncyclic. In few cases circular helical assemblies have been reported.[5, 16–20] However, with the exception of a recently reported trinuclear species,[19] in all such cases racemates were obtained. Here we present an example of a completely stereospecific, self-assembled, circular helical structure.

We have recently shown that a family of ligands, which now comprises several molecules, is easily accessible from natural terpene type compounds.[21] These pyridine and bipyridine (bipy) ligands can be used to synthesize configurationally stable coordination compounds in which the stereochemistry at the metal center is completely predetermined by the configuration of the ligands.[22, 23] Here we describe the application of a related ligand, which was designed for stereoselective self-assembly processes.

An important feature of the molecules of the pinene-2,2′-bipyridine series is their reactivity at one center of the pinene group. Ligand **L1** (Figure 1) obtained from (−)-α-pinene is deprotonated regioselectively by lithium diisopropyl amide (LDA) at the methylene group in α-position to the pyridine ring. The carbanion obtained reacts stereoselectively (in the less hindered position opposite to the methyl groups) with almost any alkyl bromide to give various derivatives. One possibility is to connect two bipy-type moieties with α,α'-dibromo-*para*-xylene to obtain the ligand **L2**.

In contrast to other similar ligands,[23] for instance **L4** (Figure 1), **L2** cannot coordinate in a tetradentate manner to *one* coordination center because of steric constraints. We therefore tested the behavior of **L2** with labile coordination centers in view of the formation of polynuclear self-assembled structures.

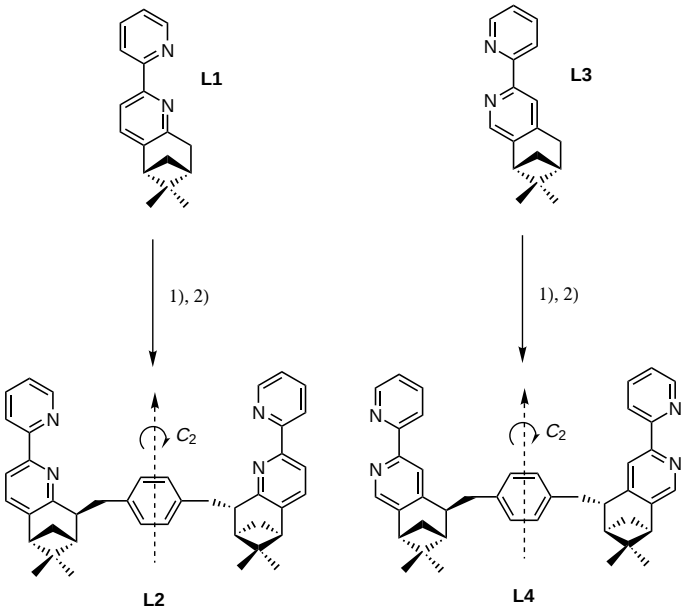

Figure 1. Synthetic pathways to chiral ligands **L2** and **L4**. 1) LDA; 2) α,α'-dibromo-*para*-xylene. The twofold axis is drawn in the structural formulas of **L2** and **L4**.

The ligand **L2** spontaneously forms a sixfold, circular single-stranded helicate with Ag^I ions (see Experimental Section), as indicated by X-ray diffraction in the solid state. NMR and circular dichroism (CD) spectroscopy in solution, as well as preliminary electrospray mass spectrometry (ES–MS) results, indicate that this species persists in the dissolved state, but detailed investigations have to be carried out to elucidate the exact behavior in solution. In addition, preliminary results with other metal ions like Cu^I show that helix formation with **L2** is a general phenomenon.

As indicated by the CD spectra of the solutions, complex formation leads to a chiral coordination unit with Ag^I. There is virtually no CD activity of **L2** in the $\pi-\pi^*$ region of the spectrum (230–320 nm). The CD activity ($\Delta\varepsilon_{314} = +16\,M^{-1}cm^{-1}$ for one metal center) of the helicate in this spectral region can be attributed to an exciton coupling.[24]

The ^1H NMR spectrum of ligand **L2** shows a half-set of protons due to its C_2-symmetry axis. The complex obtained by mixing **L2** and $AgPF_6$ at room temperature in acetonitrile in a 1:1 stoichiometric ratio shows a ^1H NMR spectrum containing the same number of lines as the free ligand (Figure 2). Two features of the ^1H NMR signals of the complex are worth special mention: a) The signals of all the aromatic protons are shifted relative to those of the free ligand. Most notably is an upfield displacement (1.45 ppm) of C20 and C24 in the xylylene bridge. This signal is broadened significantly. Spectra taken at lower temperatures (down to −40°C in CD_3CN) show a distinct sharpening of this line leading eventually to a splitting into two lines. This behavior indicates the existence of at least two rapidly exchanging species in solution. b) The lines of the methyl groups from the pinene moieties (not shown) shift to a lesser degree (about 0.5 ppm) relative to the signals of protons from the xylylene bridge, and a broadening at room temperature is observed again.

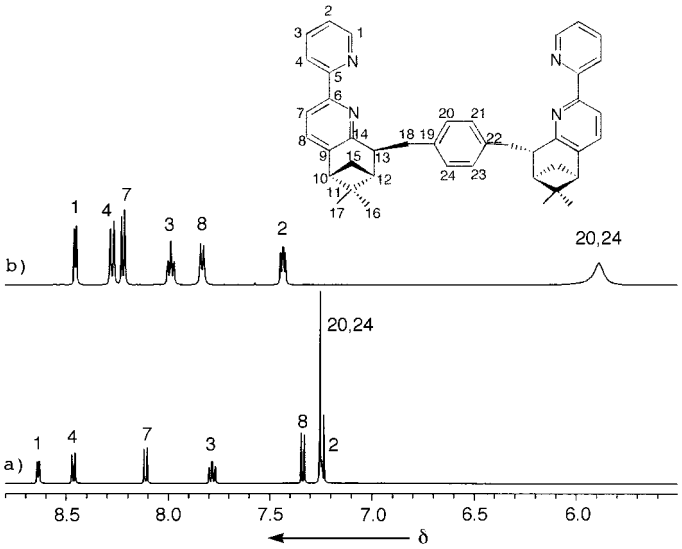

Figure 2. Partial ^{1}H NMR spectra (500 MHz, aromatic protons) of a) ligand **L2** (in $CDCl_3$ for solubility reasons; the displacements are the same in CD_3CN) and b) the Ag^{I} complex in CD_3CN. Assignment of the signals has been achieved with ^{13}C NMR, NOESY, COSY, HETCOR experimental data.

X-ray diffraction analysis of the salt of the silver complex shows the presence of a circular, hexameric, single-stranded helicate (Figure 3), which could be obtained by slow diffusion of diethyl ether into an acetonitrile solution containing **L2** and $AgPF_6$ in a 1:1 molar ratio. This structure represents a first example of a large self-assembled hexanuclear species, which is circular, helical, and predetermined in its absolute configuration. It can be considered a chiral macrocycle containing 78 atoms ($C_{60}N_{12}Ag_6$) in which one bisbidentate ligand forms a bridge between two adjacent Ag centers ($Ag\cdots Ag = 9.961(2)$ Å). The six Ag(**L2**) units making up the structure are related by a crystallographic C_6 axis (Figure 4). The silver ions are tetrahedrally coordinated by four almost equidistant (2.31 Å) nitrogen donor atoms located on two different ligands. The bite angles of the chelates are 72.0(4) and 72.7(5)°, and the dihedral angle between the two N-Ag-N chelate planes at one center is 66.8(2)°. Within each bipyridine unit of the ligand the two pyridine rings are twisted relative to each other (by 18.0(6) and 22.5(5)°). All chiral centers of the ligands, the pinene groups, are oriented towards the center of the circular structure making up two distinct layers, surrounding the chiral cavity.[25] The xylylene bridges are all nearly parallel (1.5°) to the C_6 axis and form the sides of the hexagonal skeleton (distance between two opposite xylene moieties ≈ 18.1 Å), whereas the terminal pyridines form the external shell of the circular complex. Both the absolute structure parameter (see Experimental Section) and the relation of the known chirality of the pinene group to that at the metal centers clearly indicate that the handedness of the helix is *P*. The same absolute configuration has been observed in helicates obtained with octahedral coordination centers with ligand **L4**,[26] as well as in mononuclear complexes[27] of Ru^{II}. The commercially available (+)-α-pinene yields **L1** in the other enantiomeric form, and the same sequence of reactions will afford the *M*-helical form of the circular helicate. Studies of chiral recognition when both isomers are present simultaneously in solution are in progress. The outside diameter of the hexagonal structure is about 3 nm and the cavity has a diameter of 0.84 nm. The thickness of a hexagonal disc is about 1.4 nm.

In contrast to other circular helical systems,[5, 17, 20] this structure self-assembles from the metal ion and the ligand alone. In this case there is no central element, for example an anion, which could act as a template for generating a circular structure. Thus it is demonstrated that careful design of the ligands can lead to large, highly organized systems, which is a prerequisite for the construction of molecular assemblies with well-defined functionalities. The facile ligand synthesis and the spontaneous formation of this new class of self-assembled structures makes them objects of great interest for investigations of hitherto not well understood phenomena in supramolecular chemistry. The chiral cavity of $[Ag_6(\mathbf{L2})_6]^{6+}$ looks promising for the study of stereospecific noncovalent interactions, chiral recognition, and possibly stereoselective catalytic processes.

Experimental Section

The ligand **L1** was synthesized according to published procedures.[21] Ligand **L2** was obtained from **L1** following the same procedure as for **L4**.[23]

L2 · H_2O (62.1 mg, 0.1 mmol) dissolved in 10 mL mixed solvent (acetonitrile/chloroform 5/1) was added rapidly under inert atmosphere (Ar) to a solution containing $AgPF_6$ (Fluka; 25.3 mg 0.1 mmol). The resulting colorless solution was stirred for few minutes, and after the removal of the solvents, the white powder was dried under high vacuum and analyzed. The complex can be obtained also by reaction between ligand and silver acetate in methanol followed by precipitation with NH_4PF_6.

L2: ^{1}H NMR (500 MHz, $CDCl_3$, 25°C): $\delta = 8.65$ (ddd, 2H, H(1), $^3J_{1,2} = 4.8$ Hz, $^4J_{1,3} = 1.8$ Hz, $^5J_{1,4} = 0.9$ Hz), 8.46 (ddd, 2H, H(4), $^3J_{4,3} = 8.0$ Hz, $^4J_{4,2} = 1.1$ Hz, $^5J_{4,1} = 0.9$ Hz), 8.12 (d, 2H, H(7), $^3J_{7,8} = 7.7$ Hz), 7.79 (ddd, 2H, H(3), $^3J_{3,4} = 8$ Hz, $^3J_{3,2} = 7.5$ Hz, $^4J_{3,1} = 1.8$ Hz), 7.34 (d, 2H, H(8), $^3J_{8,7} = 7.7$ Hz), 7.26 (s, 4H, H(20,24)), 7.25 (m, 2H, H(2)), 3.82 (dd, 2H, H(18b), $^2J_{18b,18a} = 13.7$ Hz, $^3J_{18b,13} = 3.8$ Hz), 3.42 (ddd, 2H, H(13), $^3J_{13,18b} = 3.8$ Hz, $^3J_{13,18a} = 11.0$ Hz, $^3J_{13,12} = 3$ Hz), 2.80 (dd, 2H, H(10), $^3J_{10,15b} = 5.5$ Hz, $^4J_{10,12} = 5.5$ Hz), 2.73 (dd, 2H, H(18a), $^2J_{18a,18b} = 13.7$ Hz, $^3J_{18a,13} = 11$ Hz), 2.58 (ddd, 2H, H(15b), $^3J_{15b,10} = 5.5$ Hz, $^3J_{15b,12} = 5.5$ Hz, $^2J_{15b,15a} = 9.8$ Hz), 2.16 (ddd, 2H, H(12), $^3J_{12,15b} = 5.5$ Hz, $^4J_{12,10} = 5.5$ Hz, $^3J_{12,13} = 3$ Hz), 1.43 (d, 2H, H(15a), $^2J_{15a,15b} = 9.8$ Hz), 1.36 (s, 6H, H(17)), 0.63 (s, 6H, H(16)). ^{13}C NMR (75.44 MHz, $CDCl_3$, 25°C): $\delta = 158.79$ (q), 156.89 (q), 153.29 (q), 149.05 (C(1)), 142.34 (q), 138.65 (q), 136.76 (C(13)), 133.73 (C(8)), 129.26 (C(20), C(21), C(23), C(24)), 123.10 (C(2)), 120.86 (C(4)), 118.00 (C(7)), 47.00 (C(10)), 46.26 (C(13)), 42.79 (C(12)), 41.25 (q, C(11)), 38.48 (C(18)), 28.40 (C(15)), 26.37 (C(17)), 20.97 (C(16)). $[\alpha]_D$ (25°C, 13.6 mg in 10 mL CH_2Cl_2) = −132. Elemental analysis calculated for $Ag_6C_{252}H_{252}N_{24}P_6F_{36}$: C 58.96, H 4.95, N 6.55%; found C 59.25, H 5.48, N 6.28%. Crystal structure determination of $[Ag(C_{42}H_{42}N_4)]_6(PF_6)_6(CH_3CN)_6(C_4H_{10}O)_3(H_2O)_{1.5}$: $M_r = 5630$; $\mu = 4.052$ mm^{-1}, $F(000) = 2901$, $\rho_{calcd} = 1.25$ g cm^{-3}, hexagonal, $P6$, $Z = 1$, $a = 26.521(3)$, $c = 12.236(2)$ Å, $V = 7453(2)$ Å^3, colorless hexagonal prism $0.26 \times 0.26 \times 0.26 \times 0.75$ mm^3; $T = 200$ K; Stoe Stadi4 diffractometer; $Cu_{K\alpha}$ radiation ($\lambda = 1.5418$ Å), 2θ range = 2–100°; $0 < h < 22$; $0 < k < 22$; $0 < l < 12$ and all antireflections; 5424 measured reflections, 5109 unique of which 4688 observables ($|F_o| > 4\sigma(F_o)$); analytical absorption corrections[28] (A* min/max = 2.295/3.215). Structure solved by direct methods,[29] all other calculations used XTAL[30] system and ORTEP[31] programs. Full-matrix least-squares refinement (on F), absolute structure parameter[32] $x = 0.00(1)$, $S = 1.73(3)$, $R = 0.046$, $\omega R = 0.063$ ($\omega = 1/[\sigma^2(F_o) + 0.002(F_o^2)]$), for 536 variables and 4688 reflections. Hydrogen atoms were placed in calculated positions. The diethyl ether and water molecules are disordered and refined with U_{iso} and population parameters of 0.5. The water molecules are located on sixfold axes with one of them at the center of the Ag_6L_6 complex. The molecular packing shows compact layers of cations with interstitial acetonitrile molecules separated by layers containing the anions, the diethyl ether molecule, and the remaining water molecules, explaining the easy cleavage of the crystals along the (110) planes. It should be noted that a large majority of crystals show important disorders or cleavages leading to a poor diffraction, very large overall displacement parameters, and enlarged or split diffraction profiles.[33]

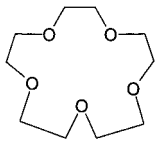
[33] Any disturbance of the equilibrium between the crystals and their mother liquor leads rapidly to the autocleavage of the crystals that become like pre-sliced salami.



Template Assembly of Polyiodide Networks at Complexed Metal Cations: Synthesis and Structures of $[Pd_2Cl_2([18]aneN_2S_4)]_{1.5}I_5(I_3)_2$ and $[K([15]aneO_5)_2]I_9$**

Alexander J. Blake, Robert O. Gould, Wan-Sheung Li, Vito Lippolis, Simon Parsons, Christian Radek, and Martin Schröder*

Although crystal engineering has become an area of increasing activity over recent years,[1–4] most interest has centered upon the use of hydrogen-bonding between suitable organic molecules to generate three-dimensional arrays and networks.[1–3] The design of inorganic networks is much less well developed[4–8] but recent examples feature cationic three-dimensional networks based on linear bridging ligands bound to tetrahedral metal ions such as Cu^I and Ag^I.[5, 6, 9] Anionic, nonzeolitic inorganic supramolecular architectures are by contrast very rare, and the only examples known involve iodine-rich compounds.[10, 11] In this context we have been interested in ascertaining whether metal cations complexed by macrocycles can be used as templates in the synthesis of extended polyiodide arrays and to achieve control over the resulting three-dimensional architectures.[12] We report herein two unique inorganic matrices composed of polyiodide arrays assembled around a hydrogen-bonded $[Pd_2Cl_2([18]aneN_2S_4)]^{2+}$ cationic polymer and around the sandwich crown ether complex $[K([15]aneO_5)_2]^+$.

$[18]aneN_2S_4$

$[15]aneO_5$

Reaction of the binuclear complex $[Pd_2Cl_2([18]aneN_2S_4)](PF_6)_2$[13] with nBu_4NI and I_2 in a 1:2:4 molar ratio in acetonitrile, followed by several days of slow evaporation of the solvent, affords black prismatic crystals in 90% yield. X-ray diffraction studies were undertaken to determine their structure.[14] The asymmetric unit consists of one I_5^- and two I_3^- ions and one and a half binuclear $[Pd_2Cl_2([18]aneN_2S_4)]^{2+}$ dications. The Pd^{II} ions are each coordinated to one N- and two S-donor atoms, and a Cl^- ligand completes the square-planar coordination. The two coordination planes lie parallel to each other but the overall binuclear dication adopts a stepped conformation in order to minimize steric interactions. Significantly, unlike the structure of the corresponding PF_6^- salt,[13] the dications are linked pairwise by hydrogen bonds between the (N)H and Cl atoms to form infinite chains in the crystal lattice [Cl···N distances 3.254(14)–3.356(12) Å; (N)H···Cl 2.57 Å] (Figure 1). The intracation Pd···Pd distances are 4.055(2) and 4.155(2) Å, while the Pd···Pd distances between adjacent cations are significantly shorter

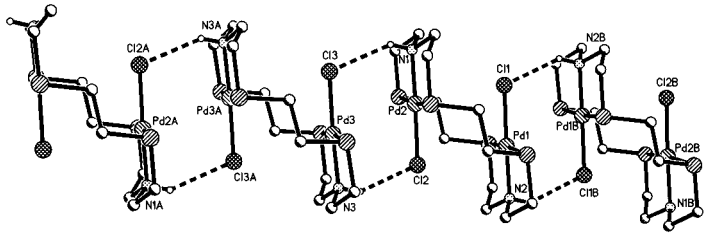


Figure 1. Structure of cation in $[Pd_2Cl_2([18]aneN_2S_4)]_{1.5}I_5(I_3)_2$.

[3.449(2), 3.463(2) Å]. The infinite chains of binuclear dications are embedded in a unique matrix of polyiodides whose fundamental units are one "L"-shaped I_5^- ion consisting of an asymmetric I_5^- ion [I(1)–I(2) 2.845(2), I(2)–I(3) 3.045(2) Å; I(1)-I(2)-I(3) = 179.69(9)°] interacting with a I_2 molecule [I(10)–I(11) 2.775(3), I(3)–I(10) 3.349(2) Å; I(2)-I(3)-I(10) = 90.00(6)°], and two slightly asymmetric I_3^- ions [I(4)–I(5) 2.904(2), I(5)–I(6) 2.959(2) Å; I(4)-I(5)-I(6) =

[**] This work was supported by the Engineering and Physical Sciences Research Council (UK). We thank the EPSRC National Mass Spectrometry Service, University of Swansea. ([18]aneN$_2$S$_4$ = 1,4,10,13-tetrathia-7,16-diazacyclooctadecane, [15]aneO$_5$ = 1,4,7,10,13-pentaoxacyclopentadecane).

176.47(6)°; I(7)–I(8) 2.948(2), I(8)–I(9) 2.929(2) Å; I(7)-I(8)-I(9) = 171.58(5)°]. The I_3^- ions, including those belonging to the I_5^- units, lie in parallel planes and form unprecedented continuous, planar two-dimensional layers. Each layer (Figure 2) may be visualized topologically as fused ribbons of 14-membered and 24-membered rings with cross-linking secondary interactions among the I_3^- ions ranging from 3.758(2) to 4.217(2) Å. Pairs of parallel and slightly interacting I_2 molecules [$I_2 \cdots I_2$ 4.257(2) Å, van der Waals diameter for

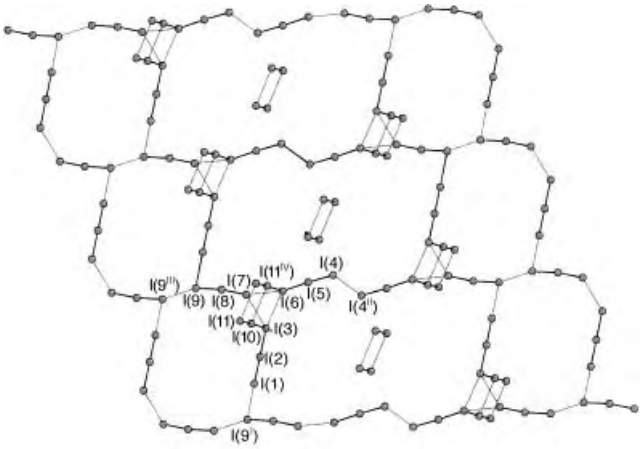

Figure 2. View of two-dimensional polyiodide layers in $[Pd_2Cl_2([18]aneN_2S_4)]_{1.5}I_5(I_3)_2$ comprising linked I_3^- ions and fused ribbons of 14-membered and 24-membered rings. Dications are omitted for clarity. Important distances [Å]: I(1)–I(2) 2.845(2), I(2)–I(3) 3.045(2), I(4)–I(5) 2.904(2), I(5)–I(6) 2.959(2), I(7)–I(8) 2.948(2), I(8)–I(9) 2.929(2), I(10)–I(11) 2.775(3), I(3)–I(10) 3.349(2), I(3)···I(6) 4.217(2), I(3)···I(7) 4.184(2), I(6)···I(7) 4.006(2), I(1)···I(9^{I}) 3.812(2), I(4)···I(4^{II}) 4.017(2), I(9)···I(9^{III}) 3.758(2), I(6)–I(11^{IV}) 3.579(2). Symmetry operation: I = $x-1, y-1, 1+z$; II = $1-x, 1-y, 1-z$; III = $2-x, 1-y, -z$, IV = $2-x, -y, 1-z$.

I = 4.3 Å[11, 12]] from two symmetry-related I_5^- ions lie orthogonal to the parallel layers and connect two of these by passing through the centers of the 24-membered rings of a third layer located between them (Figure 3). The connection of two alternating layers takes place through a reasonably short $I_5^- \cdots I_3^-$ interaction of 3.573(2) Å giving rise to an overall I_8^{2-} unit observable as an $I_2 \cdot 2I_3^-$ adduct (Figure 3), which can be

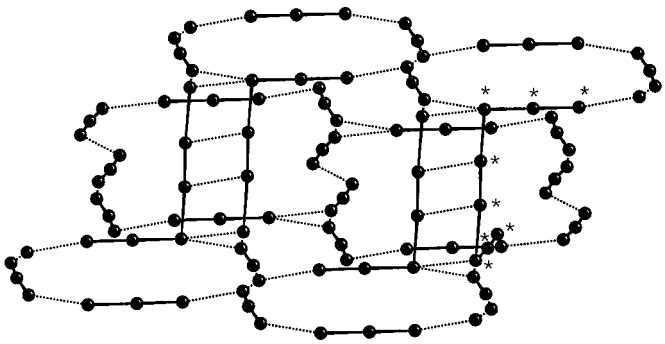

Figure 3. View of the poly-I_3^- layers linked by I_2 bridges, which connect two 14-membered rings through a 24-membered ring. Starred atoms identify one I_8^{2-} unit. Dications are omitted for clarity.

envisaged as the yarn interlocking the infinite two-dimensional poly-I_3^- sheets. The 24-membered rings of each layer measure about 25.31 × 13.31 Å: the dimensions of each half [ca. 12.65 × 13.31 Å] are similar to those of the 14-membered rings [ca. 12.18 × 14.73 Å], resulting in channels along the body diagonal of the unit cell. These channels are occupied by the chains of hydrogen-bonded binuclear complexes described above (Figure 4) and it appears that it is these chains rather than the individual dication that act as the template for the polyiodide architecture.

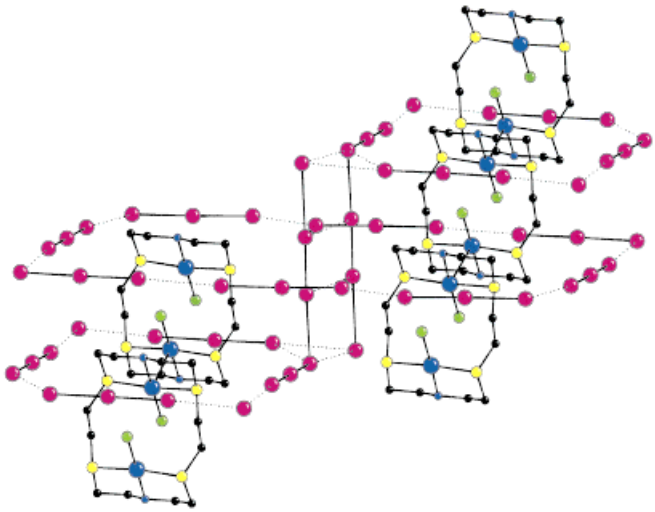

Figure 4. View of the structure of $[Pd_2Cl_2([18]aneN_2S_4)]_{1.5}I_5(I_3)_2$: chains of $[Pd_2Cl_2([18]aneN_2S_4)]^{2+}$ ions occupy channels in the three-dimensional polyiodide network.

In order to determine whether other macrocyclic complexes with different shape and charge can have the same templating effect on the self-assembly of extended polyiodide arrays, we treated $[K([15]aneO_5)_2]I$, prepared in situ by reaction of KI with two equivalents of $[15]aneO_5$, with an excess of I_2 in acetonitrile. After several days, dark red crystals were obtained by slow evaporation of the solvent. The crystal structure determination established the formulation $[K([15]aneO_5)_2]I_9$.[14] Within the cation, two crown ether ligands sandwich one K^+ ion within a ten-coordinate environment; the K–O bond lengths range between 2.62(2) and 3.21(2) Å.[20] Complex cations of this type are embedded in a three-dimensional polyiodide matrix made up of I_9^- units (Figure 5). Nonaiodides are very rare[21] and in this case each I_9^- ion can be described as an $[I_3^- \cdot (I_2)_3]$ charge-transfer complex; the three perturbed I_2 molecules have molecular distances ranging from 2.716(3) to 2.740(4) Å and interact with the slightly asymmetric I_3^- [I(7)–I(8) 2.874(3), I(8)–I(9) 2.978(3) Å; I(7)-I(8)-I(9) 178.2(2)°] through contacts of 3.396(4)–3.503(4) Å. Two of the three I_2 molecules [I(5)–I(6) and I(3)–I(4)] and the I_3^- ion [I(7)-I(8)-I(9)] lie approximately in the same plane, whereas the third I_2 molecule [I(1)–I(2)] is perpendicular to it [I(1)-I(9)-I(8) 92.4(5)°, I(1)-I(9)-I(3) 97.6(5)°]. This configuration for the I_9^- polyiodide units allows them to form a three-dimensional network of puckered cages through I···I secondary interactions of 3.732(4)–4.074(4) Å (Figure 6). Each cage measures

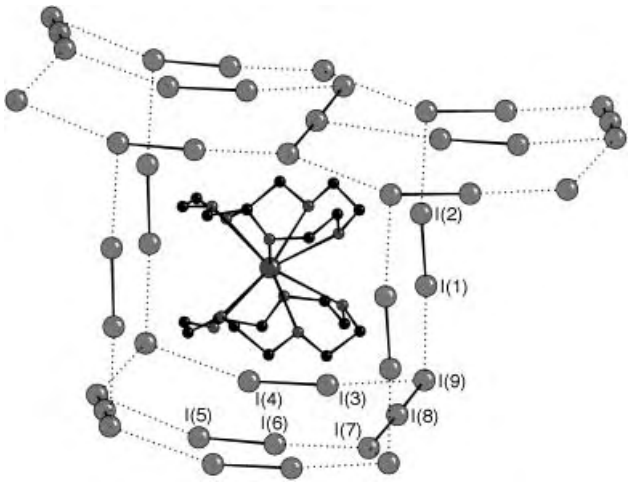

Figure 5. View of the puckered cage of I_9^- ions around the $[K([15]aneO_5)_2]^+$ cation template. Important distances [Å]: I(1)–I(2) 2.740(4), I(3)–I(4) 2.716(3), I(5)–I(6) 2.728(4), I(7)–I(8) 2.874(3), I(8)–I(9) 2.978(3), I(1)···I(9) 3.503(4), I(3)···I(9) 3.396(4), I(7)···I(6) 3.346(4).

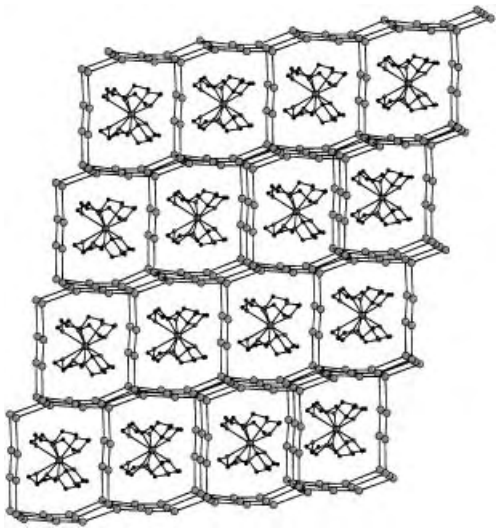

Figure 6. View of the structure of $[K([15]aneO_5)_2]I_9$ along the crystallographic *c* axis.

$9.658 \times 9.521 \times 9.959$ Å, with body diagonals of 17.371 and 17.393 Å, and the $[K([15]aneO_5)_2]^+$ ion lies nearly at the center of the cage. This polyiodide array is related to the ideal cube made up of I_7^- ions in $[Ag([18]aneS_6)]I_7$;[12] the main difference is an additional I_2 molecule in the I_9^- ion located in the middle of the lower face of each cage, which reflects the different topologies of the Ag^I and K^I complexes. There is therefore a clear link between the templating effect of I_7^-[12] and I_9^- ions. The puckered cages are arranged in a centered lattice and in projection along the crystallographic (100) axis each cage lies above the midpoint of four cages in the layer below.

Our results confirm the general principle of template condensation of three-dimensional polyiodide networks at metal cations complexed by macrocycles. The formation of polyiodide architectures may be regarded as a template reaction in the second coordination sphere of complex cations in which the unique topology of the resultant polyanionic networks depends upon the shape and charge of the template cations.

$\lambda = 0.71073$ Å]. $Z = 4$, $\rho_{calcd} = 2.531\ g\,cm^{-3}$, $F(000) = 2944$, $T = 220$ K, $\mu(Mo_{K\alpha}) = 6.692\ mm^{-1}$. Dark red block, $0.27 \times 0.27 \times 0.19\ mm^3$. Absorption correction based on ψ-scans ($T_{min} = 0.051$, $T_{max} = 0.103$). Data collection and processing: The unit cell was obtained by using the program DIRAX[19] for 19 out of 25 reflections located during a random search. The two crystallographically unique macrocycles were restrained to be geometrically similar, while the displacement parameters of the C and O atoms were subject to rigid bond and body restraints. The refinement converged to a conventional R value of 0.069 with difference map extrema of $+2.61$ and $-1.66\ e\,Å^{-3}$ and a large number of poorly agreeing data with $l = 8n$. The matrix ($-1\ 0\ -0.75/0\ -1\ 0/0\ 0\ 1$) converts the cell into an equivalent cell. Reciprocal lattice points from these two cells will coincide only when l is a multiple of 4 and the sum of the transformed indices h and k is even (because of the lattice centering). Splitting the reflections in this way and proceeding with refinement with a scale factor relating the two twin components [0.147(4)] gave a final conventional R value of 0.0624 (based on F and 3839 data with $F > 4\sigma(F)$) and w$R2 = 0.1633$ (based on F^2 and all 4690 data used during refinement) for 362 parameters. The final difference map extrema were 1.44 and $-1.46\ e\,Å^{-3}$; the Flack absolute structure parameter was 0.16(13). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-100768. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code + (44)1223336-033; E-mail: deposit@ccdc.cam.ac.uk).

Breaking the Mold of Discotic Liquid Crystals**

Joaquín Barberá, Oleg A. Rakitin, M. Blanca Ros,* and Tomás Torroba

Organic Chemistry is currently living its "supramolecular epoch". Innovative and fascinating research has been focused on the synthesis and study of "living" molecules in an interdisciplinary field.[1] Development of the chemistry of complex molecules such as crown ethers, cryptands, phthalocyanines, dendrimers, catenanes, rotaxanes, and a variety of related compounds could seem, at first sight, interesting only from an exotic or theoretical point of view. However, possibilities have turned into reality for many of these systems.[1] Researchers in Chemistry, Biology, Materials Science, and even Physics are looking at these supramolecules as unique tools for achieving the ultimate aim of miniaturization. Alternatively, chemists are also becoming increasingly interested in investigating chemistry beyond the covalent bond; a concept expressed by J. M. Lehn as "the chemistry beyond the molecule".[1b] In this case, the active supramolecular structures are obtained by simple interactions between suitable functional units.

Liquid crystals are well-known examples of supramolecular assemblies.[1, 2] Based on self-organization, they combine the properties of order and mobility, a combination which allows the broad range of applications already exploited for these systems. Calamitic liquid crystalline compounds have been known since the end of the last century. However, in 1977 a new type of liquid crystal emerged, the discotic liquid crystals (DLCs).[3] These compounds have enriched the research and the possibilities of the so-called fourth state of matter.

Discotic liquid crystals are characterized by their ability to self-organize into columns, giving rise to two-dimensional superlattices of different types.[1c, 2b, 4] Consequently, one of the main issues in relation to columnar liquid crystals is the possibility of generating one-dimensional molecular "pathways" for electron, photon, energy or ion migration.[5]

Many molecules, either of low molecular mass or polymeric, have been reported to arrange in columnar mesomorphic states.[2b, 4, 5b, 6] However, most of these systems follow common structural guidelines. In general, DLCs consist of a rigid central core (planar, conical, pyramidal, or other such geometry) surrounded by four or more flexible groups, which make up the "soft" region. In certain cases, individual molecules do not match these criteria, but they are capable of aggregating into units which do fulfill them.[6] Scarce variations to this general structure are the "carbonaceous" group of compounds,[7] which are large, disc-shaped, polycondensed aromatic molecules with high molecular mass or, in the field of the lyotropic mesophases, the chromonic liquid crystals. These latter compounds with no flexible hydrocarbon chains in their structure exhibit columnar phases in the presence of a solvent.[8] The role of the soft region is played by water or another suitable liquid.

This paper deals with a type of compound which constitutes the first exception to the above trends in the field of thermotropics. We report here the first examples of thermotropic DLCs which do not contain flexible groups, namely indenes **1**–**4** and pseudoazulene **5**.

Our interest in these organic compounds is twofold. Their synthesis has recently been reported[9] to proceed by a unified mechanism based on the initial abnormal Beckmann rearrangement of oximes to cyanides, followed by cyclization and/or exhaustive chlorination and dehydrochlorination. Furthermore, and surprisingly, when these small molecules were treated thermally and studied under polarized light, the

fluid samples exhibited birefringence. Such behavior suggested thermotropic transitions to a liquid crystalline state. Therefore we investigated the liquid crystal behavior of these compounds by polarizing optical microscopy, differential scanning calorimetry (DSC), and X-ray diffraction. The most important data obtained from these three techniques are summarized in Table 1 and Table 2.

Table 1. Optical and thermal properties of the compounds **1**–**5.**

Compound	Mesomorphic properties (T [ΔH])[a]
1	*K* (205.1 [12.2]) Col_h (230.0 [11.9]) *I*
2	*K* (183.9 [13.9]) Col_h (196.4 [12.0]) *I*
3	*K* (131.6 [9.9]) Col_h (152.3 [6.04]) *I*
4	*K* (97.3 [9.8]) *M*[b] (159.5 [1.1]) Col_h (184.8 [10.0]) *I*
5	*K* (144.0[c] [13.4]) *I I* (144.0 [0.81]) Col_h[d] (120)[e] *K*

[a] *K* = crystal, Col_h = hexagonal columnar phase, *I* = isotropic phase, *T* = temperature in °C; Δ*H* = transition enthalpy in kJ mol^{-1}. The temperatures given are for the onset of the first scan transitions. Heating and cooling scans at 10 K min^{-1}. [b] Unidentified phase. [c] Transition observed after successive cooling and heating scans. [d] Monotropic mesophase. [e] Optical data.

On examination by optical microscopy (OM) with polarized light (Figure 1) all the compounds display pseudo-focal-conic or mosaic textures on heating and form leaflike domains on cooling from the isotropic liquid (in most cases, the dendritic formations are seen more clearly without crossed polarizers). These textures strongly suggest columnar mesophases of hexagonal symmetry.[4b, 10] Likewise, on cooling some of the samples, large black areas lacking birefringence were observed. This indicates that the optical axis readily aligns normal to the glass microscope slides.

Analysis by DSC revealed melting and clearing endotherms of similar enthalpy in the range of 6–14 kJ mol^{-1}, which indicates a high degree of order within the mesophase (Figure 2). With the exception of **4**, all compounds exhibit a

single mesophase that is either enantiotropic (**1**, **2**, and **3**) or monotropic (**5**) in nature. The *Z* isomer **4** displays one intermediate peak before the clearing endotherm, which can also be detected by OM as a smoothing of the broken pseudo-focal-conic texture. On cooling, an exotherm corresponding to the liquid–mesophase transition is observed for all the compounds. However, although a clear crystallization is observed by OM and DSC for indenes **1** and **2**, no such peak is observed in the thermograms of **3**, **4**, and **5**. This fact is consistent with the subtle texture changes detected for the latter compounds on cooling to room temperature.

To confirm the observations discussed above and to obtain more information on the structures of the liquid-crystalline arrangement exhibited by these compounds, their mesophases were studied by powder X-ray diffraction with a pinhole camera equipped with a high-temperature device. Typical of crystalline structures, the patterns taken at room temperature are, in all cases, characterized by the presence of numerous diffraction rings across the whole angular region, which can only be assigned to a three-dimensional arrangement. When the samples are heated above their melting temperature, the diffraction patterns contain fewer rings, which indicates a loss of order relative to the crystalline solid. The spacings measured experimentally for compounds **1**–**5** are collected in Table 2 together with the proposed indexation and the calculated spacings.

The high temperature patterns of all the compounds considered are qualitatively very similar, although the number of diffraction rings observed depends on the particular compound. The patterns of compounds **3** and **4** taken at 145°C and 165°C, respectively, have in common the existence of a set of four sharp maxima with a reciprocal spacing ratio $1:\sqrt{3}:\sqrt{4}:\sqrt{7}$ (Figure 3). This is characteristic of a hexagonal

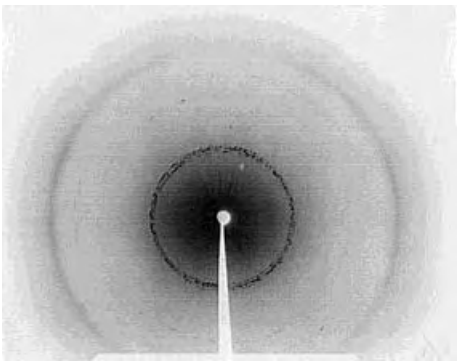

Figure 3. X-ray diffractogram of compound **4** at 165°C (Col_h mesophase).

lattice, and the four maxima can be assigned to the (100), (110), (200), and (210) reflections. The additional sharp ring observed at 3.6 Å is assigned to the (001) reflection and corresponds to the *c* parameter of the hexagonal network. The absence of reflections with Miller indices *h*, *k*, and *l* simultaneously different from zero, even on overexposed photographs, indicates that there is no three-dimensional order. All these features are characteristic of a columnar hexagonal mesophase. Moreover, when treated mechanically at the mesophase temperature range, a sample of compound **3** yielded an aligned pattern with the column axes oriented along the stretch direction. This confirms the columnar liquid-crystalline nature of the phase. The sharpness of all the diffraction rings indicates that there is long-range order not only in the plane of the hexagonal lattice, but also in the stacking direction, and thus the hexagonal columnar mesophase can be described as *ordered* (Col_{ho} mesophase). The X-ray patterns suggest that the phase exhibited by compound **4** between 97°C and 159°C (see Table 1) could be either a disordered solid or a very organized mesophase. However, we have not been able to assign its structure unequivocally.

As compounds **1** and **2** exhibit the mesomorphic state at very high temperatures, decomposition was detected after long exposure times. Furthermore, the mesophase of compound **5** is monotropic, that is, it is thermodynamically unstable and has a strong tendency to crystallize. Consequently, it was not possible to obtain long-exposure photographs for compounds **1**, **2**, and **5**, and therefore fewer maxima are observed on their X-ray photographs. Nevertheless, in spite of the absence of some reflections that were observed for compounds **3** and **4**, all the patterns are consistent with a columnar hexagonal mesophase (see Table 2).

For all the compounds except **1**, for which the extent of decomposition precludes the appearance of the corresponding reflection, the stacking distance (*c* axis of the hexagonal network) is 3.5–3.6 Å. In contrast, the hexagonal lattice constant (*a* axis) depends on the particular compound (see Table 2). On comparison of the experimental values for *a* (column diameter) with the molecular sizes estimated from Dreiding stereomodels, it can be deduced that the columns contain single molecules as stacking entities. This deduction leads to reasonable density values for the mesophases.

Discotic mesomorphism is the result of the balance between interactions of the central core and the peripheral flexible structure (soft part). The hard central core is responsible for the columnar stacking, while the flexible part acts as a lubricant and plays an active role in reducing correlation between neighboring columns. This role is usually played by conformationally disordered aliphatic chains, although in some short-chain ionic discotic materials, mesophase formation has been explained in terms of rotation of tetrafluoroborate anions which reduce correlation between the cationic columns.[11] In the compounds described in this paper, the aromatic structures constitute the hard part, while the polarizable chlorine and sulfur atoms, as well as the polar and polarizable cyano groups, behave as *unusual* soft parts through weaker molecular interactions.[12] In the solid these atoms and groups give rise to strong intermolecular attractions,[9] which become weaker as the temperature increases due to increasing thermal disorder. On melting, the weakening of the polar attractions relaxes the molecular packing, and thus the transition from the crystal to the mesophase is associated with the onset of molecular rotation.

It is worth noting the similar enthalpy changes measured for both the melting and the clearing processes for these compounds. Typical ordered hexagonal discotic liquid crystals exhibit Col_h-I enthalpies in the same range as those reported in this paper.[4, 10, 13] However, the transitions from the solid to

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0298 $ 17.50+.50/0

the Col_h state, which are attributed to the melting of the flexible chains, involve energies two to three times higher than the ones reported here.

The crystal structure of pseudoazulene **5** is hexagonal with cell constants $a = 15.57$ Å and $c = 6.815$ Å, and six molecules per unit cell.[9] The molecular packing corresponds to a pseudo-hexagonal arrangement in which the centers of close-neighboring molecules lie at $15.57/\sqrt{3} = 8.99$ Å (Figure 4a). In the solid the molecules are kept in a fixed orientation by strong intermolecular attractions. However, upon transition

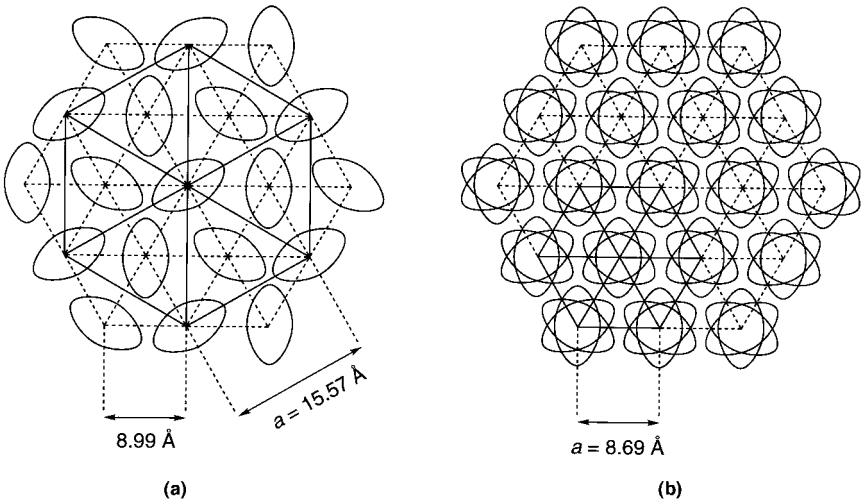

Figure 4. Schematic drawing of the structure of the crystalline phase (a), and of the Col_h mesophase (b) of compound **5** viewed along the *c* axis. The transition from the crystal to the mesophase is associated with the onset of molecular rotation: neighboring columns become less correlated.

to the mesophase these attractions become weaker, thus allowing rotation of the molecular planes around the *c* axis (Figure 4b) in such a way that the molecules project an averaged circular shape along the columnar axis (*c* axis). The transition to the liquid-crystalline state implies that neighboring columns become discorrelated, and a hexagonal columnar structure is obtained in which the interdisc interactions inside the columns are still maintained. In accordance with this, the intercolumnar parameter in the mesophase of 8.69 Å is similar to the intermolecular distance in the hexagonal crystal (8.99 Å).

In summary, we have described the first examples of thermotropic DLCs without long terminal substituents, which opens new and interesting possibilities for the study and the design of this type of material. Synthesis of other suitable compounds for the study of the relationship between structure and liquid crystal activity is currently in progress. The new scope for novel soft units within disclike systems, along with the study of the influence of their position and number on mesomorphic behavior and other physical properties (electrical, optical, etc.), provides a very promising direction for new areas of research.

Single-Molecule Magnets: Different Rates of Resonant Magnetization Tunneling in Mn_{12} Complexes**

Daniel Ruiz, Ziming Sun, Belen Albela, Kirsten Folting, Joan Ribas,* George Christou,* and David N. Hendrickson*

There is considerable and growing interest in single-molecule magnets.[1] A single-molecule magnet has a large-spin ground state with appreciable magnetic anisotropy, resulting in a barrier for reversal of the direction of magnetization. At low temperatures magnetization hysteresis loops are seen, as are out-of-phase ac susceptibility signals. The most thoroughly studied single-molecule magnet is **1**,[2–7] commonly called "Mn_{12}–acetate" or simply "Mn_{12}". In

$[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]\cdot 2HO_2CMe\cdot 4H_2O$ **1**

addition to an application as a molecular memory device, interest in these molecular magnets stems from the possibility of observing macroscopic quantum tunneling (MQT).[8] Friedman et al.[9] reported for the first time the observation of resonant magnetization tunneling for Mn_{12}–acetate molecules in a crystal. Steps were observed at regular intervals of magnetic field in the magnetization hysteresis loop for oriented crystals. This has been confirmed by others.[10, 11] Herein we present magnetization hysteresis data for several $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ complexes with different carboxylate ligands. Data are presented for oriented crystal samples. The hysteresis step heights are highly dependent on the substituent R. Thus, the rate of resonant magnetization tunneling varies appreciably from complex to complex.

Two new Mn_{12} complexes with the composition $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$, where R is either C_6H_4-2-Cl (**2**) or C_6H_4-2-Br (**3**), were prepared. As confirmed by the X-ray structure analysis,[12] complex $\mathbf{2}\cdot CH_2Cl_2\cdot 5H_2O$ possesses a $[Mn_{12}(\mu_3\text{-}O)_{12}]$ core comprising a central $[Mn^{IV}_4O_4]^{8+}$ cubane held within a nonplanar ring of eight Mn^{III} ions by eight μ_3-O^{2-} ions (Figure 1).

$[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}Cl)_{16}(H_2O)_4]$ **2**

$[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}Br)_{16}(H_2O)_4]$ **3**

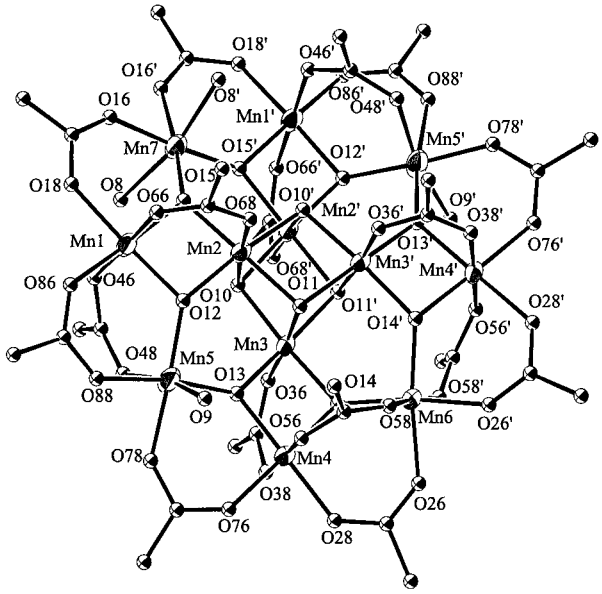

Figure 1. Structure of the core of $\mathbf{2}\cdot CH_2Cl_2\cdot 5H_2O$. The 2-chlorobenzoate rings are omitted for clarity.

Peripheral ligation of complex **2** is provided by sixteen η^2-μ-carboxylate groups and four H_2O ligands. Complex **2** is structurally similar to complex **1**. The most notable difference is the positioning of the four H_2O ligands: The acetate complex **1** has one H_2O ligand on each of four Mn^{III} ions. Complex **2** has one H_2O ligand [O9] on each of the two atoms labeled Mn5; the other two H_2O ligands [O8] are disordered together with the carboxylate oxygen atom that is shared by Mn1, Mn5, and Mn7. Complex **2** is located on a twofold axis, whereas complex **1** has a higher 2,2,2 crystal site symmetry. A variety of data, including variable-field magnetization, indicate complex **3** also has the same basic Mn_{12} core as **1** and **2**.

Magnetization hysteresis data obtained for oriented crystal samples of complexes **1**, **2,** and **3** at 2.0 K are shown in Figure 2. In each case, a few small crystals of a complex were suspended in eicosane held at 40 °C. This eicosane suspension was then introduced into a 5.5 T field, whereupon the crystals were oriented, each with their easy axis (i.e. the direction of the largest component of the crystal's magnetic susceptibility tensor) parallel to the field. The eicosane was then cooled to room temperature, which resulted in a solid wax cube with the crystals oriented with parallel easy axes. After thermal equilibration at 2.0 K, each sample was saturated in a field of +2.5 T. Then, the field was swept down to −2.5 T, and subsequently cycled back to +2.5 T. Each hysteresis loop was collected in a period of 1.5 h.

Steps are seen in the hysteresis loops for all three Mn_{12} complexes. The positions of the steps are highlighted by Figure 3, which shows the first derivative plots for the three hysteresis loops. Such steps in a hysteresis loop have been

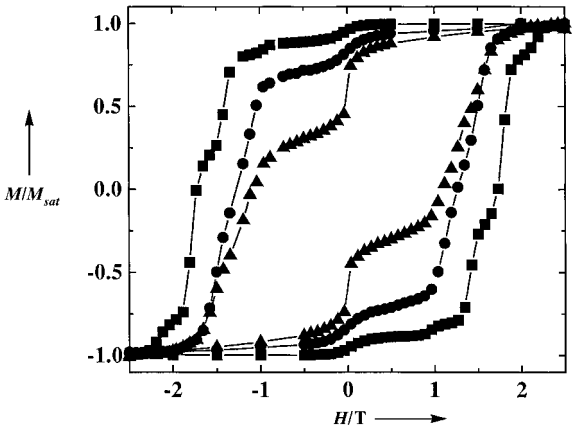

Figure 2. Magnetization hysteresis loops measured at 2.0 K for oriented crystals in eicosane matrix for three complexes: (■) acetate complex **1**; (●) 2-bromobenzoate complex **3**; (▲) 2-chlorobenzoate complex **2**. The magnetization data for each complex is plotted as a normalized value relative to the saturation magnetization M_{sat} for the complex.

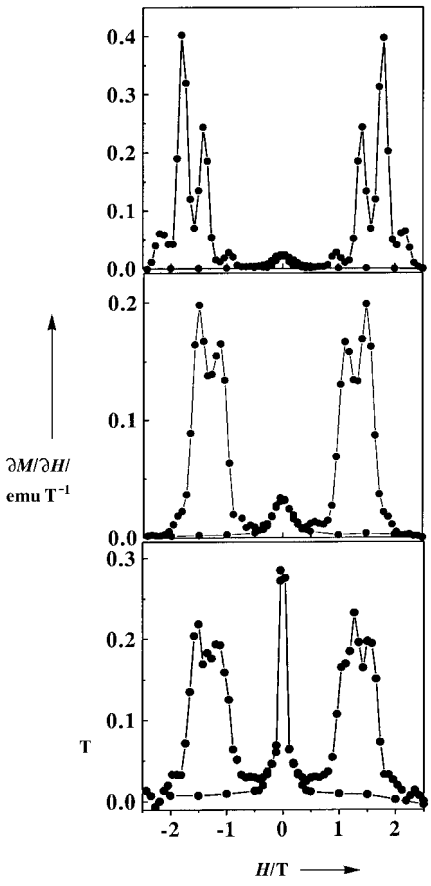

Figure 3. First derivative plots corresponding to the 2.0 K magnetization hysteresis loops shown in Figure 2. Top: acetate complex **1**; middle: Mn_{12}-2-bromobenzoate complex **3**; bottom: Mn_{12}-2-chlorobenzoate complex **2**.

shown[9–11] to be due to increases in the rate of change of the magnetization resulting from resonant magnetization tunneling. The relatively large ground-state spin of $S = 10$ together with considerable *negative* magnetic anisotropy for each molecule gives the double-well potential-energy diagram shown in Figure 4. The double well represents the change in

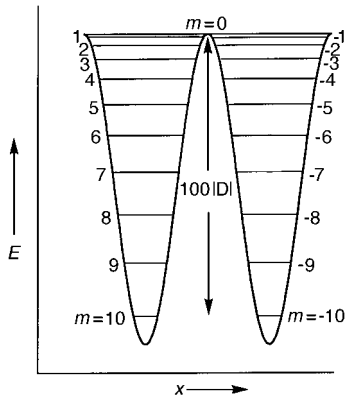

Figure 4. Plot of potential energy versus the magnetization direction for a single molecule with a $S = 10$ ground state. The axial zero-field interaction (DS_z^2) splits the $S = 10$ state into $m = \pm 10,\ \pm 9, \cdots \pm 1, 0$ levels. The barrier height U is equal to $|D|S^2 = 100\ |D|$ for the thermally activated process that involves converting the magnetic moment of the molecule from the "spin up" $m_s = 10$ level to the "spin down" $m_s = -10$ level. The diagram is drawn for zero applied field. x = Magnetization direction.

potential energy as a Mn_{12} molecule converts from the spin up to the spin down state. The application of a magnetic field stabilizes one state (e.g., $m_s = -10$) relative to the other. All of the Mn_{12} molecules populate the $m_s = -10$ when the sample is saturated in a large magnetic field. In sweeping out a hysteresis loop the first step occurs at zero field when there is an alignment of energy levels in the two parts of the double-well potential. At this point there is a resonant quantum mechanical tunneling. Additional steps are seen as the field is reversed and increased to give another alignment of levels in the two wells. Regularly spaced steps are seen[9–11] at temperatures lower than 2.0 K.

As can be seen in Figures 2 and 3, there are appreciable differences in the step heights between complexes **1**, **2,** and **3**. The scan rate and number of data points are the same for each of the three complexes. Thus, as the field is swept from +2.5 T to zero field, the first step seen for the acetate complex **1** is small. Complex **3** shows a steeper step at zero field. The steepest step is seen for complex **2**. Exactly what factors influence the rate of quantum tunneling of magnetization in these molecules is not known.[9–11] It is clear that a transverse (i.e., perpendicular to easy axis) magnetic anisotropy is needed, and this could arise from transverse quartic zero-field interactions[13] or from transverse magnetic fields caused by the nuclear spins.[14] Tunneling may not in fact occur between the lowest energy levels (e.g., $m_s = +10$ and -10 in zero field), but instead an Orbach process may be involved.[4] In this case, phonons are absorbed by a Mn_{12} molecule in a crystal exciting the molecule to a higher energy level from which it can tunnel through and/or be thermally excited over the barrier. The very appreciable differences seen in the zero-field steps for complexes **1**–**3** demonstrate a significant dependence of the observed tunneling behavior on the complex identity, and such studies should ultimately give insight about the mechanism of the tunneling; this information would be essential if the potential application of single-molecule magnets to, for example, memory devices is to be realized.

Experimental Section

Samples of complex **1** were synthesized as previously described.[15]

$[Mn_{12}(\mu_3\text{-}O)_{12}(\mu\text{-}RCOO)_{16}(H_2O)_4]$, R = C_6H_4-2-Cl, C_6H_4-2-Br: A slurry of $[Mn_{12}(\mu_3\text{-}O)_{12}(\mu\text{-}MeCOO)_{16}(H_2O)_4]$ (0.50 g, 0.25 mmol) in CH_2Cl_2 (50 mL) was treated with an excess of the corresponding carboxylic acid RCOOH (8.0 mmol). The mixture was stirred overnight in a closed flask and filtered to remove any undissolved solid. Hexanes were added to the filtrate until precipitation of a dark brown solid was observed. The resulting solid was collected by filtration and the above treatment was repeated. The resulting filtrate was layered with hexanes (100–150 mL) and stored at room temperature for several days. Since the acid was highly soluble in diethyl ether but the Mn_{12} complex was only partially soluble in this solvent, a diethyl ether/hexane(s) mixture (1:4) was used to wash the resulting solid, which was finally dried in air. Recrystallization from CH_2Cl_2/hexane(s) gave crystals of complex **2** suitable for X-ray structure analysis. Complex **2:** Elemental analysis calcd for $[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}Cl)_{16}(H_2O)_4]\cdot 4H_2O$, $C_{112}H_{80}O_{52}Cl_{16}Mn_{12}$: C 38.58, H 2.30, Cl 16.30; found: C 38.4, H 2.4, Cl 16.2%. FT-IR (KBr): $\tilde{\nu}$ = 1589, 1560, 1544, 1519, 1473, 1412, 1164, 1054, 750, 725, 702, 651, 614, 552, 522 cm^{-1}. Complex **3:** Elemental analysis calcd for $[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}Br)_{16}(H_2O)_4]\cdot 3H_2O$, $C_{112}H_{78}O_{51}Br_{46}Mn_{12}$: C 32.17, H 1.88, Br 30.64; found: C 32.1, H 1.9, Br 30.7%. FT-IR (KBr): $\tilde{\nu}$ = 1585, 1543, 1518, 1470, 1411, 1161, 1045, 1028, 747, 695, 644, 614, 552, 518 cm^{-1}.

β-Homoalanyl PNAs: Synthesis and Indication of Higher Ordered Structures**

Ulf Diederichsen* and Harald W. Schmitt

Peptide nucleic acids (PNAs) are oligomers possessing a polyamide backbone in which the nucleobases of DNA/RNA function as recognition units. The interaction of PNAs with DNA double strands or RNA have increased in importance because of their potential use in antigene or antisense therapy.[1] In contrast, helical[2] or linear PNA–PNA self-pairing complexes[3] are uncharged models that are appropriate for investigating interactions between nucleobases or between nucleobases and amino acids[4] and for examining intercalation.[5] The linearity of two complementary strands is an important structural feature of our previous investigations on α-alanyl and α-homoalanyl PNAs. It is based on the 3.6-Å distance between two consecutive amino acid side chains in the β-sheet conformation, which is similar to the stacking distance of base pairs in DNA. Here we describe the synthesis of Boc-β-homoalanyladenine (**1**) and its oligomerization to β-PNAs. UV and CD spectra suggest that the hexamer and pentamer are self-organized in higher ordered structures, which can be rationalized from model studies as being structurally inevitable.

Although there are many methods to synthesize β-amino acids[6], nucleo-β-amino acids have not been described to date. The following difficulties have to be considered in linking the nucleobase to the γ position of the side chain (Scheme 1): 1) Nucleobases are poorly soluble in most organic solvents. 2) The desired nucleophilic attack by the *N*9 nitrogen atom of

the purine competes with that by the *N*7 nitrogen atom and with intramolecular azridine formation. 3) In situ generation of the leaving group at the γ position of the amino acid appears significant. 4) Arndt–Eistert homologization of aromatic α-amino acids is expected to proceed with racemization.[6d]

The desired coupling to provide a purine attached through the *N*9 nitrogen atom to the γ position of the β-homoalanine was performed with the Mitsunobu reaction[7] (Scheme 2).

Scheme 2. Synthesis of nucleo-β-amino acid **1**: The key step is the attachment of amino acid **2** with **3** under Mitsunobu conditions (DEAD = diethyl azodicarboxylate).

At room temperature the β-homoserine derivative **2**[8] was added to 6-chloropurine (**3**) together with the Mitsunobu reagents. The direct use of adenine was not successful; the 6-chloropurine nucleo amino acid **4** could be converted into the azidopurine derivative **5**, which then was reduced and deprotected to yield **1**.[9] The presence of the *N*9 regioisomer was proven by HMQC and HMBC NMR experiments.[10] Nucleo amino acid **1** was oligomerized by solid-phase peptide synthesis (SPPS) on a 4-methylbenzhydrylamine (MBHA)–polystyrene support loaded with R-lysine(Z)-OH (Z = benzyloxycarbonyl; lysine was introduced at the C terminus for solubility reasons). The coupling was activated by *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU) and proceeded with at least 95% yield. After the oligomers were purified with HPLC (RP-C18), they were characterized with electrospray ionization mass spectrometry (ESI-MS) and ^{1}H NMR spectroscopy.

Although adenine–adenine pairing is not observed in DNA because of the helix topology, it is well established for oligomer pairing complexes[11] with a linear backbone. High stability of hexamer double strands based on A–A base pairs is known for the homo-DNA series (which contain 2′,3′-dideoxyglucopyranosyl sugar moieties, $T_m = 47\,^\circ$C)[12] as well as for α-alanyl PNA ($T_m = 31\,^\circ$C).[3] We investigated the pairing of β-homoalanyl PNAs by examining hexamer H-(β-HalA)$_6$-Lys-NH$_2$ (β-HalA = γ-(adenin-9-yl)-β-(*S*)-homoalanine, Lys-NH$_2$ = (*R*)-lysine amide). Cooperative depairing of a double strand can be recognized in UV melting curves by the sigmoidal increase in absorption upon raising the temperature. The extraordinary high stability of H-(β-HalA)$_6$-Lys-NH$_2$ was surprising; it was not possible to detect a melting point up to 95 °C (Figure 1). Furthermore, the unusual high hyperchromicity ($A_{rel.} > 40\%$) is striking. We also observed this effect with alternating G/C sequences in the alanyl PNA series for the formation of higher ordered structures.[13] The shorter oligomers H-(β-HalA)$_5$-Lys-NH$_2$ and H-(β-HalA)$_4$-Lys-NH$_2$ were synthesized to obtain UV melting curves within a measurable temperature range. Indeed, the pentamer melts at $T_m = 72\,^\circ$C ($A_{rel.} > 60\%$), and the tetramer at $T_m = 26\,^\circ$C ($A_{rel.} = 16\%$). The remarkable difference in stability and hyperchromicity of the two species (Figure 1) indicates that the structural organizations are not identical. The CD spectra of pentamer H-(β-HalA)$_5$-Lys-NH$_2$ measured at different temperatures confirm the UV melting curve. The nucleobases display a strong Cotton effect when conformationally restricted in a double strand, which begins to diminish at 40 °C when the number of flexible single strands increases. The high stabilities of adenine β-PNA oligomers is only partly the result of depairing of double strands, because the formation of higher ordered structures is indicated for the pentamer and hexamer. β-Homoalanyl PNA has a particular potential for

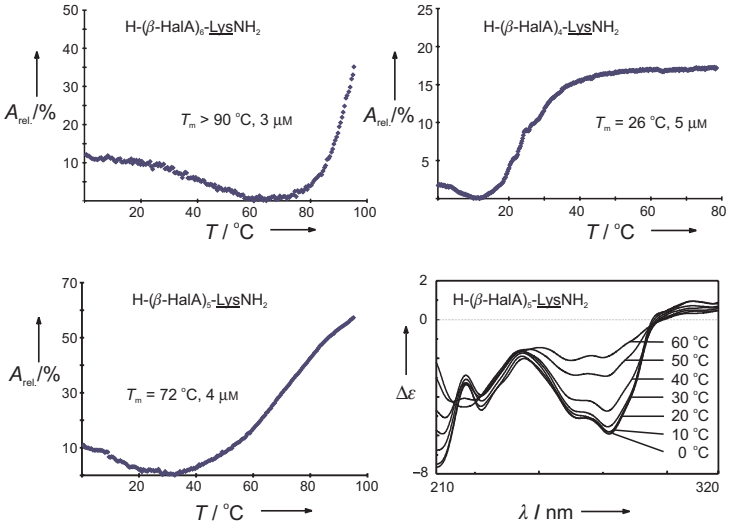

Figure 1. UV melting curves of β-PNA oligomers H-(β-HalA)$_n$-Lys-NH$_2$ ($n = 4-6$) and CD spectra of H-(β-HalA)$_5$-Lys-NH$_2$ (0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

forming higher associations, as shown by a single-strand model (Figure 2): A homochiral β-homoalanyl PNA strand with an extended conformation provides a uniform orientation of all the side chains, and all adenine bases are aligned in the same way. This leads to pairing planes based on all Watson–Crick and Hoogsteen sites, respectively.

Adenine–adenine self-pairing can be achieved in three pairing modes: the symmetrical reverse Watson–Crick and reverse Hoogsteen modes as well as the Hoogsteen mode (Scheme 3). A chain of H-(β-HalA)$_n$-Lys-NH$_2$ oligomers based on adenine self-pairing with simultaneous participation

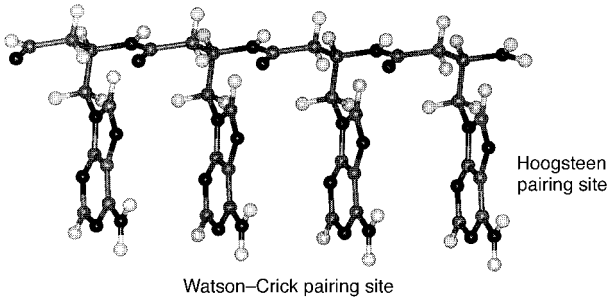

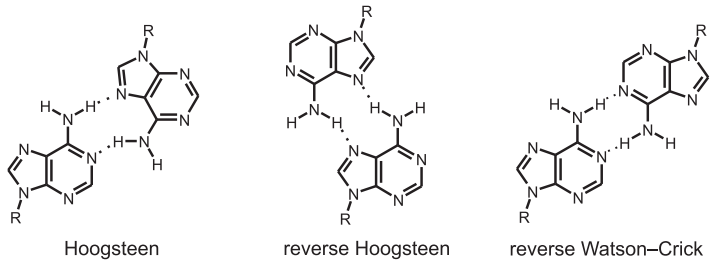

Figure 2. Model of a homochiral β-homoalanyl PNA single strand: In the extended backbone conformation, all nucleobases are uniformly aligned. This creates a pairing plane at the Watson – Crick and the Hoogsteen site.

Scheme 3. Possible adenine – adenine pairing modes.

of the Watson – Crick and Hoogsteen site is possibly responsible for the strong aggregation indicated by the melting curves.

We introduced nucleo amino acid **1** as a new building block for the synthesis of β-PNA oligomers. β-PNA is a special case of β-peptides.[14] Nevertheless, differences in structure are expected because the aggregates of β-PNA are defined by the β-peptide backbone and base-pair stabilization. The uniform alignment of all nucleobases in the extended conformation could be causal for the exceptional self-pairing of adenine oligomers in higher ordered structures. We are presently investigating the pairing possibilities and selectivities of the other canonical nucleobases as well as the influence of heterochiral base pairs.

Experimental Section

4: DEAD (1.69 g, 14.55 mmol) was added at room temperature under argon to PPh_3 (3.82 g, 14.55 mmol) in THF (18 mL) within 10 min. 6-Chloropurine (**3**, 1.45 g, 9.70 mmol) was added, and the suspension heated to 40 °C until a clear yellow solution was obtained. A solution of **2** (3.00 g, 9.70 mmol) in THF (10 mL) was added dropwise within 10 min at room temperature. After the reaction mixture was stirred for 2 d, it was heated for 4 h at 60 °C. The product was purified by consecutive flash chromatography with hexanes:ethyl acetate (1:3), hexanes:ethyl acetate (1:1), and hexanes:acetone (7:3); yield: 1.15 g (27 %). Further experiments improved the yield up to 40 %. M.p. 131 – 132 °C; $\alpha_D^{25} = 31$ ($c = 5$ in $CHCl_3$); $R_F = 0.27$ (hexanes:acetone 7:3); ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 1.21 - 1.45$ (m, 9H, *t*Bu), 2.70 (d, 2H, ^3J(H,H) = 6 Hz, α-CH_2), 4.33 – 4.43 (m, 1H, β-CH), 4.43 – 4.55 (m, 2H, γ-CH_2), 5.14 (s, 2H, CH_2–Ph), 5.30 (m, 1H, NH), 7.35 (m, 5H, Ph), 8.04 (s, 1H, H8), 8.68 (s, 1H, H2); ^{13}C NMR (62 MHz, $CDCl_3$): $\delta = 28.0$, 36.0, 46.5, 47.6, 66.8, 80.1, 128.3, 128.5, 128.6, 131.3, 135.0, 145.7, 150.9, 151.8, 152.0, 154.8, 170.4; MS: *m*/*z*: 446.3 (*M*H)$^+$; elemental analysis calcd for $C_{21}H_{24}N_5O_4Cl$: C 56.57, H 5.42, N 15.71; found: C 56.60, H 5.36, N 15.71.

5: A solution of **4** (690 mg, 1.547 mmol) and sodium azide (1.10 g, 16.92 mmol) in 2-methoxyethanol (8 mL) was heated for 5 h at 60 °C. The solvent was evaporated, and the residue suspended in ethyl acetate. After the salts were removed by filtration, the product was purified by flash chromatography with silica gel (110 g) and hexanes:ethyl acetate (3:1); yield: 512 mg (73 %); m.p. 76 – 78 °C, $[\alpha]_D^{25} = 40$ ($c = 1$ in $CHCl_3$); $R_F = 0.30$ (hexanes:ethyl acetate 1:3); ^{1}H NMR (250 MHz, [D$_6$]DMSO): $\delta = 1.15 - 1.23$ (m, 9H, *t*Bu), 2.54 – 2.86 (m, 2H α-CH_2), 4.28 – 4.42 (m, 2H, γ-CH_2), 4.44 – 4.68 (m, 1H, β-CH), 5.09 (s, 2H, CH_2–Ph), 7.00 (d, 1H, ^3J(H,H) = 8 Hz, NH), 7.33 (m, 5H, Ph), 8.48 (s, 1H, H8), 10.13 (s, 1H, H2); ^{13}C NMR (62 MHz, [D$_6$]DMSO): $\delta = 27.8$, 36.4, 47.5, 47.6, 65.7, 78.0, 119.5, 127.8, 127.9, 128.3, 135.4, 135.9, 142.7, 144.8, 145.4, 154.7, 170.1; MS: *m*/*z*: 904.8 (M_2H)$^+$, 453.2 (*M*H)$^+$; elemental analysis calcd for $C_{21}H_{24}N_8O_4$: C 55.75, H 5.35, N 24.76; found: C 55.60, H 5.52, N 24.53.

1: A solution of **5** (457 mg, 1.02 mmol) in methanol:acetic acid (9:1, 110 mL) was treated with palladium oxide hydrate (220 mg, 1.80 mmol) under argon and saturated with hydrogen. After 105 min the catalyst and the partially precipitated nucleo amino acid were separated by centrifugation, and the solid phase was extracted several times with ethyl acetate:acetic acid (9:1). Subsequent flash chromatography (ethyl acetate:methanol:water:acetic acid 40:7:3:1). Yield: 218 mg (64 %). M.p. 286 °C (decomp); $[\alpha]_D^{25} = 41$ ($c = 1$ in DMSO); $R_F = 0.36$ (ethyl acetate:methanol:water:acetic acid 10:1:1:0.5, NaCl saturated); ^{1}H NMR (500 MHz, [D$_6$]DMSO): $\delta = 0.95 - 1.03$ (m, 1.5H, *t*Bu), 1.15 – 1.30 (m, 7.5H, *t*Bu), 2.36 – 2.52 (m, 2H, α-CH_2), 4.05 – 4.20 (m, 2H, γ-CH_2), 4.21 – 4.30 (m, 1H, β-CH), 6.42 (m, 0.2H, NH), 6.90 (d, 0.8H, J = 7.1 Hz, NH), 7.13 (s, 2H, NH_2), 7.92 (s, 1H, H8), 8.12 (s, 1H, H2); ^{13}C NMR (125 MHz, [D$_6$]DMSO): $\delta = 27.6$ (*t*Bu), 37.1 (Cα), 45.8 (Cβ), 47.3 (Cγ), 77.5 (*t*Bu), 118.3 (C5), 140.6 (C8), 149.5 (C4), 152.0 (C2), 154.5 (CO of Boc), 156.0 (C6), 171.7 (COOH); the ^{13}C NMR signals were assigned with HMBC and HMQC experiments; MS: *m*/*z*: 337.1 (*M*H)$^+$; UV (H_2O): $\lambda_{max} = 263$ nm (14000).

H-(β-HalA)$_4$-Lys-NH_2: ^{1}H NMR (500 MHz, D_2O): $\delta = 1.29 - 1.35$ (m, 2H, Lys), 1.50 – 1.71 (m, 4H, Lys), 2.00 (m, 1H, Hα), 2.12 (m, 1H, Hα), 2.18 – 2.38 (m, 4H, Hα), 2.42 (m, 1H, Hα), 2.65 (m, 1H, Hα), 2.85 (m, 2H, Hε-Lys), 3.22 – 3.50 (m, 4H, Hβ, Hγ), 3.55 (m, 1H, Hβ, Hγ), 3.63 – 3.84 (m, 3H, Hβ, Hγ), 3.98 (m, 1H, Hβ, Hγ), 4.11 (m, 1H, Hα-Lys), 4.25 – 4.35 (m, 2H, Hβ, Hγ), 4.42 (m, 1H, Hβ, Hγ), 7.79 (s, 1H, H2, H8), 7.84 (s, 1H, H2, H8), 7.90 (s, 1H, H2, H8), 7.91 (s, 1H, H2, H8), 7.97 (s, 1H, H2, H8), 7.98 (s, 1H, H2, H8), 8.00 (s, 1H, H2, H8), 8.02 (s, 1H, H2, H8); MS: *m*/*z*: 1018.3 (*M*H)$^+$, 511.0 (MH$_2$)$^{2+}$.

H-(β-HalA)$_5$-Lys-NH_2: ^{1}H NMR (500 MHz, D_2O): $\delta = 1.21 - 1.40$ (m, 2H, Lys), 1.50 – 1.75 (m, 4H, Lys), 2.15 – 2.40 (m, 7H, Hα), 2.42 – 2.55 (m, 2H, Hα), 2.68 (m, 1H, Hα), 2.87 (m, 2H, Hε-Lys), 3.70 – 4.50 (m, 16H, Hβ, Hγ, Hα-Lys), 7.95 – 8.20 (m, 10H, H2, H8); MS: *m*/*z*: 1236.4 (*M*H)$^+$, 619.0 (MH$_2$)$^{2+}$.

H-(β-HalA)$_6$-Lys-NH_2: ^{1}H NMR (500 MHz, D_2O): $\delta = 1.25 - 1.38$ (m, 2H, Lys), 1.50 – 1.72 (m, 4H, Lys), 2.11 – 2.40 (m, 9H, Hα), 2.41 – 2.56 (m, 2H, Hα), 2.68 (m, 1H, Hα), 2.87 (m, 2H, Hε-Lys), 3.58 (m, 1H, Hβ, Hγ), 3.61 – 3.75 (m, 2H, Hβ, Hγ), 3.77 – 3.98 (m, 8H, Hβ, Hγ), 4.06 (m, 1H, Hα-Lys), 4.10 – 4.20 (m, 2H, Hβ, Hγ), 4.24 – 4.36 (m, 3H, Hβ, Hγ), 4.38 – 4.49 (m, 2H, Hβ, Hγ), 7.77 (s, 1H, H2, H8), 7.82 (s, 1H, H2, H8), 7.90 (m, 2H, H2, H8), 7.94 (s, 1H, H2, H8), 7.96 (s, 1H, H2, H8), 7.97 (s, 2H, H2, H8), 8.03 (s, 1H, H2, H8), 8.04 (s, 1H, H2, H8), 8.07 (s, 1H, H2, H8), 8.08 (s, 1H, H2, H8); MS: *m*/*z*: 1455.4 (*M*H)$^+$, 727.9 (MH$_2$)$^{2+}$.

The conformation of β-PNA should not be helical because of the base-pair distances of 5 Å and the maximum of two bases on top of each other, which leads to a substantial loss of stacking interactions.

Redox-Switched Exciton-Coupled Circular Dichroism: A Novel Strategy for Binary Molecular Switching**

Steffen Zahn and James W. Canary*

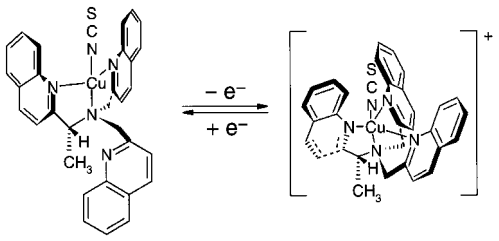
A recent and exciting prospect in the area of information technology lies in the development of molecular switches that operate with efficiency, reversibility, and resistance to fatigue.[1] The development of electrochemical switches has recently attracted much attention due to possible applications such as data storage.[2–8] Redox switches require a) components whose structures and physical properties can be turned on or off electrochemically,[3, 6–8] and b) sufficiently different optical spectra that allow the individual states to be addressed.[2, 4] Here we describe a method for generating a redox switch through redox control of the ligand conformation. This approach resulted in a novel molecular switch with reproducible redox-dependent optical properties; the switch should be easily adaptable to solid-state technology.

Our molecular redox switch is based on a) complexes in which a single metal center can exist in two different oxidation states, and b) chiral ligands having easily distinguishable optical properties. Copper(II) complexes are particularly suitable since they show fast ligand exchange, which potentiates fast signal interchange. The ligand (*S*)-*N*,*N*-bis[(2-quinolyl)methyl]-1-(2-quinolyl)ethylamine, (*S*)-α-MeTQA, was selected for this study because of the steric hindrance and strong chromophoric properties presented by the 2-quinolyl groups and the expected optimal chromophoric orientation provided by the propellerlike geometry of the complexes. Reduction of the sterically hindered Cu^{II} complex was anticipated to result in a change in the orientation of the 2-quinolyl arms with respect to the central axis (Scheme 1). Since the exciton-coupled circular dichroism (ECCD) signal generated from these complexes is critically dependent upon the distance and dihedral angle between the planar chromophores,[9] the magnitude of the ECCD spectrum was expected to vary with the oxidation state of the copper ion.

The preparation of the ligand (*S*)-α-MeTQA began with the asymmetric synthesis of (*S*)-2-(1-aminoethyl)quinoline from the 2-aminomethylquinoline imine of (+)-pinanone.[10] A single recrystallization of the L-(+)-tartrate salt of the chiral primary amine yielded the desired product with 99.7% *ee* in 19% overall yield. Alkylation of the enantiomerically pure amine with 2-bromomethylquinoline provided (*S*)-α-MeTQA in 81% yield. Copper complexes **1** and **2** were prepared by mixing homogeneous solutions of the ligand and the appropriate salt.[11, 12] The UV/Vis spectrum of **2** shows a

$[Cu^{I}\{(S)\text{-}\alpha\text{-MeTQA}\}](PF_6)$ **1**

$[Cu^{II}\{(S)\text{-}\alpha\text{-MeTQA}\}](ClO_4)(PF_6)$ **2**



d–d transition at 691 nm ($\varepsilon = 202$), which is consistent with a coordination geometry for the Cu^{II} ion that is closer to a square pyramid than the desired trigonal bipyramid.[11, 13] However, addition of one equivalent of NH_4NCS (to yield **4**) resulted in two d–d bands (719 nm, $\varepsilon = 202$; 867 nm, $\varepsilon = 296$); this indicates trigonal-bipyramidal geometry.[13] The color change of **4** from turquoise to green-yellow is due to a ligand-to-metal charge transfer (LMCT) at 420 nm ($\varepsilon = 445$).[14] Cyclic voltammograms of the copper complexes in acetonitrile or dimethylformamide were well-behaved and displayed single quasi-reversible one-electron redox waves ($i_{pa}/i_{pc} \approx 1$).[15]

The CD spectra of **1** ($A = 174$) and **2** ($A = 455$) displayed bisignate curves with remarkably large amplitudes (that is, large positive and negative Cotton effects).[16] The split CD

Scheme 1. The redox system [Cu^{I}{(*S*)-α-MeTQA}](NCS) (**3**)/[Cu^{II}{(*S*)-α-MeTQA}(NCS)]$^{+}$ (**4**). The structure of **3** was determined from ^{1}H NMR spectra at various temperatures, CD spectra, and comparison with structural data for analogous complexes.[13, 20] The geometrical arrangement of **4** is supported by CD and VIS spectroscopic data and comparison of structurally related Cu^{II} complexes.[15]

curve, the coincidence of the inflection point with the λ_{max} of the low-energy absorption band of the UV/Vis spectrum, and the large intensity of the signal are consistent with an exciton-coupling mechanism. Adding NH_4NCS to solutions of **1** and **2** resulted in a weaker signal for **3** ($A = 70$) and a stronger signal for **4** ($A = 670$, Figure 1). The intensity for **4** was such that it

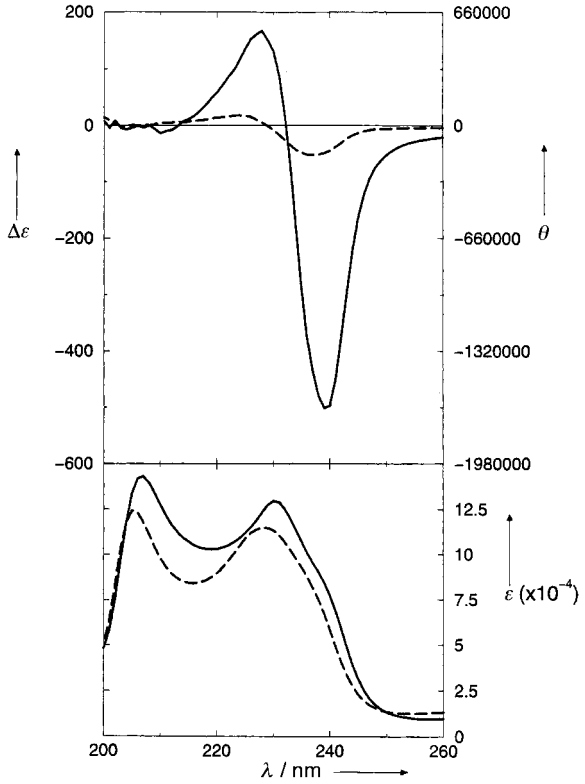

Figure 1. Circular dichroism (top) and UV/Vis spectra (bottom) of complexes **3** (dashed lines) and **4** (solid lines). UV/Vis (5 μM) and CD spectra (0.3 mM) were measured at room temperature in methanol. ε and $\Delta\varepsilon$ are given in L mol^{-1} cm^{-1}.

was possible to obtain good spectra at concentrations as low as 700 nM. Films of complex **4** prepared on quartz exhibited a CD curve that is similar in pattern and sign to that shown in Figure 1 but even more intense than that observed in methanol, as estimated by comparison with the isotropic absorption spectrum of the film. The large variation in intensity of the CD spectra of **3** and **4** was also maintained in the film.

Quantitative analysis of the CD spectra[17] of Cu^{I} complexes **1** and **3** suggest that addition of NCS^{-} displaces one quinoline arm of the ligand, which is similar to the behavior of other closely related tripodal Cu^{I} complexes.[11] Consequently, **3** provides one couplet, whereas **1** provides three couplets that together afford a much more intense spectrum. The substantially stronger intensities of **2** and **4**, compared with analogous bis(quinoline) ligands,[18] are also consistent with tetradentate coordination of the Cu^{II} ion.

To assess the ability of systems **1**/**2** and **3**/**4** to behave as reversable switches, redox cycling studies were conducted in solution and monitored by CD and UV/Vis spectroscopy. Reduction of **2** with ascorbic acid immediately gave CD and UV/Vis spectra identical to those of **1**. Reaction of **1** with ammonium persulfate was more sluggish and required 10 min at 50 °C in order to achieve the CD signal of **2**. This process was repeated three times; each cycle gave a less intense UV/Vis absorption band for **1**. However, in the presence of NCS^{-} much better results were obtained (Figure 2). Treatment of **4**

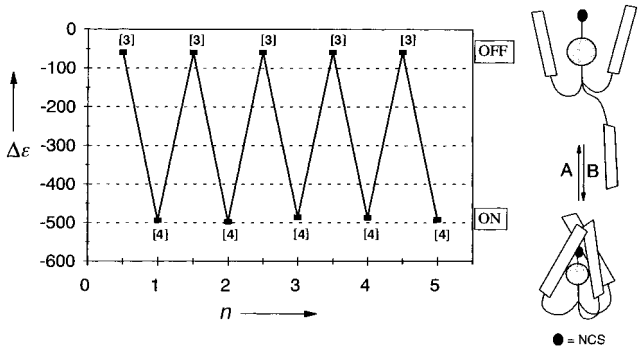

Figure 2. Left: Plot of $\Delta\varepsilon$ vs. the number of cycles n at 240 nm in methanol. The reduction of **4** to **3** proceeded with ascorbic acid, whereas **3** was oxidized back to **4** with ammonium persulfate. The average difference in signal intensity between **3** and **4** is $\Delta\Delta\varepsilon_{240} = 430$. $\Delta\Delta\varepsilon_{240}$ is the absolute difference in the $\Delta\varepsilon$ values for the binary system at 240 nm ($\Delta\Delta\varepsilon_{240} = |\Delta\varepsilon_{240(on)}| - |\Delta\varepsilon_{240(off)}|$). Right: Schematic representation of dynamic behavior of complexes **3** and **4** that leads to different arrangements of the chromophores and thus to distinct ECCD signal intensities representing the "on" and "off" states of the molecular switch. A = reduction, B = oxidation.

with ascorbic acid resulted in a CD spectrum that is identical to that of **3**, whereas oxidation of **3** with ammonium persulfate produced the CD signal of **4** immediately at room temperature.[19] Up to five cycles were carried out without a significant decrease in signal intensity; this demonstrates the superb reversibility and reproducibility of the chiroptical signal.

The magnitude of the changes in the chiroptical properties of the system **3**/**4** is quite remarkable ($\Delta\Delta\varepsilon_{240} = 430$). The low energetic barrier for the change in coordination geometry in the system **3**/**4**, its rapid response, its high signal intensities, and its stability on multiple cycling support the adaptability of

[15] For example, **1** is reduced in MeCN at $E_{1/2} = -49.9$ mV (reference: $Fc/Fc^+ = 45.6$ mV; Fc = ferrocene). The cyclic voltammogram was measured under N_2 with a standard three-electrode apparatus (glassy-carbon working electrode, Pt-wire auxiliary electrode, and 0.1M $AgNO_3$ in MeCN as reference electrode) with 0.1M $n Bu_4NPF_6$ as supporting electrolyte and a scan rate of 50 mV s^{-1}. Addition of SCN^- to the solution resulted in a shift in $E_{1/2}$ of -250 mV and afforded an improvement in the reversibility of the voltammograms. There was no indication of oxidation or reduction of SCN^- under the conditions of the experiment.
[16] Amplitude (A): difference in the $\Delta\varepsilon$ values for the two extrema of split CD curves ($A = |\Delta\varepsilon_{1C.E.}| + |\Delta\varepsilon_{2C.E.}|$).

Isocyanate-Based Dendritic Building Blocks: Combinatorial Tier Construction and Macromolecular-Property Modification**

George R. Newkome,* Claus D. Weis, Charles N. Moorefield, Gregory R. Baker, Bradley J. Childs, and Jon Epperson

In the current development of dendritic chemistry[1] the application of iterative technology is being examined from many different perspectives. These areas include the use of dendrimers and related materials as unimolecular micelles,[2] ordered network building blocks,[3] chromatography additives,[4] cancer therapeutics,[5] and electrically conducting materials.[6] Central to the construction of these macromolecular assemblies is the design and tuning of properties such as solubility, viscosity, and reactivity for specific applications. Hence it is desirable to design synthetic methods for the ready introduction of functionally diverse terminal groups.

Recently we reported the synthesis of the stable isocyanate triester **1** and its use as a building block in the rapid "dendrimerization" of protic materials and surfaces.[7] In addition, we disclosed the syntheses of the related branched

monomers[8] **2** – **5**. Each of these monomers possesses a triad of protected functional groups, an sp^3 C-branching center and a reactive isocyanate moiety. We herein report on the concept of the rapid modification of properties through combinatorial synthesis analogous to that used for the discovery of novel solid-state materials,[9] biologically active substrates,[10] and artificial receptors.[11] While dendrimers have recently been employed[12] and touted[13,14] as vehicles for the generation of standard small-molecule libraries, our combinatorial method relies on mixtures of AB_3-type monomers having varying compositions of different, yet mutually compatible building

blocks for sequential formation of "tiers" and dendrimer construction.

Reaction of the isocyanate monomers **1**–**5** with a fourth-generation poly(propylene imine) dendrimer (DSM, 32-PPI)[15] bearing 32 NH_2 groups in refluxing *tert*-butyl alcohol or dichloromethane afforded (>90%) the corresponding 96-ester **6**, 96-cyanide **7**, 96-siloxane **8**, 96-*N*-*t*-BOC compound **9**, and 96-benzyl ether **10**. Formation of these compounds is supported by their ^{13}C NMR spectra (Figures 1 and 2, Table 1). Anticipated key absorptions corresponding to the

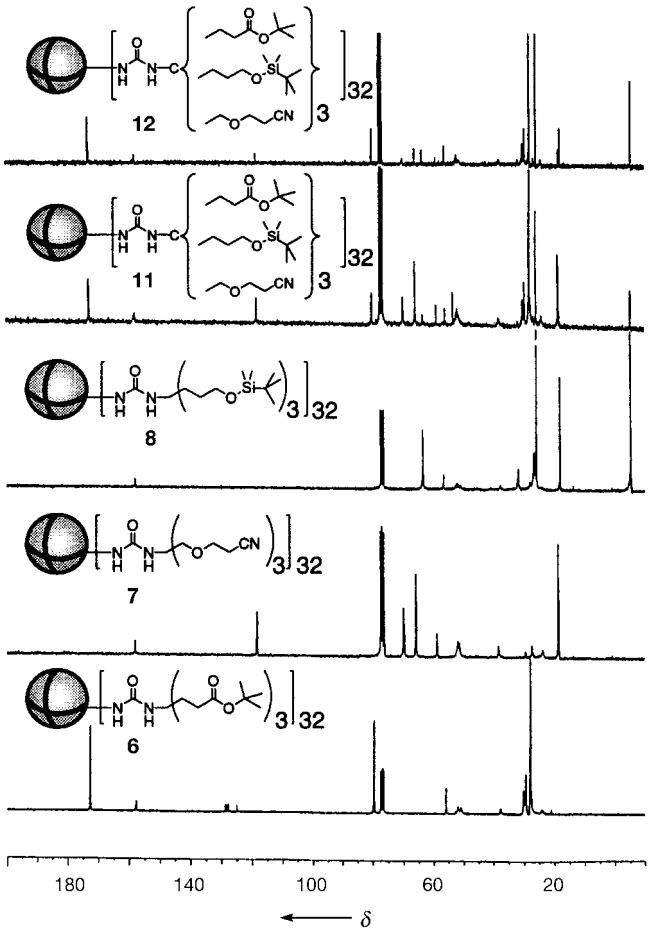

Figure 1. ^{13}C NMR spectra for the peripherally homogeneous ester, cyano, and siloxane dendrimers **6**, **7**, and **8**, respectively, and the peripherally heterogeneous dendrimers **11** (prepared from 0.5, 0.4, and 0.1 equivalents of monomers **1**, **2**, and **3**, respectively) and **12** (0.7, 0.15, and 0.15 equivalents of **1**, **2**, and **3**, respectively). Spheres represent the DSM-32-PPI dendritic core.

covalently attached 1 →3 branched monomers are observed in each spectrum (δ values): **6**: 172.7 (CO), 80.0 ($C(CH_3)$), 27.9 (CH_3); **7**: 118.4 (CN), 69.8, 65.9 (CH_2OCH_2), 18.8 (CH_2CN); **8**: 63.6 (CH_2O), 26.0 ($C(CH_3)_3$), 18.2 ($C(CH_3)_3$), −5.2 ($Si(CH_3)_2$); **9**: 156.5 (CO), 78.9 ($C(CH_3)_3$), 28.3 ($C(CH_3)_3$); **10**: 138.6, 128.4, 127.6, 127.4 (C-aryl), 72.8 ($CH_2C_6H_5$), 71.0 (CH_2CH_2O). As expected, signals attributed to the imine-based superstructure are broadened and less intense (δ values): **6**: 52.0 ($CH_2CH_2CH_2$, $CH_2CH_2CH_2CH_2$), 51.0 ($CH_2CH_2CH_2NHCONH$).

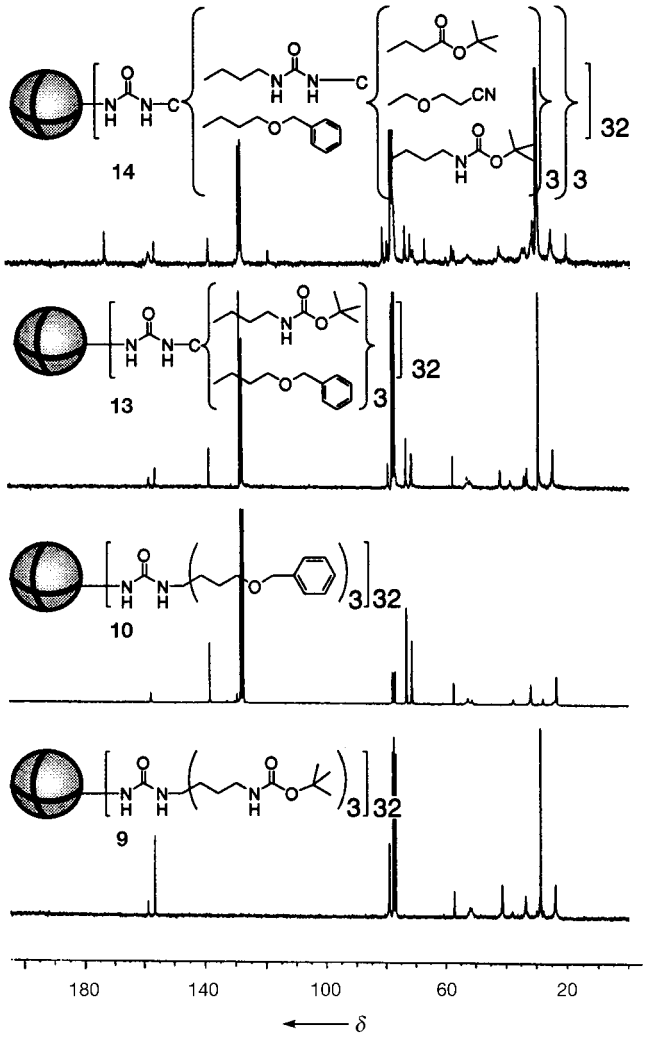

Figure 2. ^{13}C NMR spectra of dendrimers **9** and **10**, which have carbamate and benzyl ether terminal groups, respectively, and the peripherally heterogeneous dendrimers **13** (prepared from 0.5 equivalents each of monomers **4** and **5**) and **14** (prepared from **13**, see text).

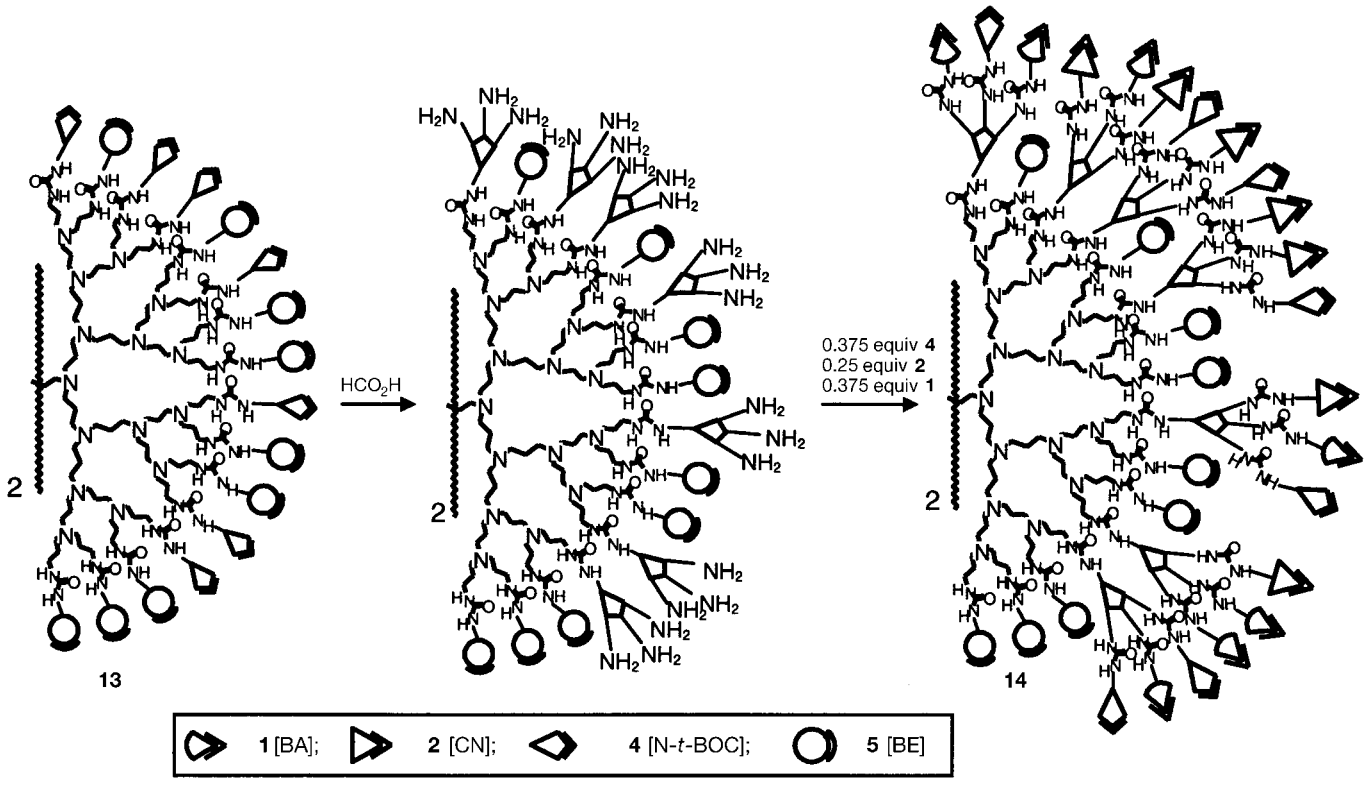

Further potential to exploit the connectivity of the isocyanate-based monomers was subsequently examined by treatment of the 32-PPI dendrimer with mixtures of monomers **1**–**3** (total of 32 equivalents). Specifically, mixtures of building blocks **1**, **2**, and **3** in various ratios [(0.5:0.1:0.4) and (0.7:0.15:0.15)] afforded the corresponding combinatorial-based dendrimers **11** and **12** (Figure 1). Evidence for the formation of these *peripherally heterogeneous* dendrimers includes the observation (after chromatographic purification) of all the pertinent ^{13}C NMR signals exhibited in the spectra of the analogous, peripherally homogeneous macromolecules **6**–**8**. More specifically, the spectrum of each peripherally heterogeneous dendrimer exhibits signals at $\delta = 172.8$, 118.3, 80.1, 63.5, 51.5, 18.7, and −5.3 (corresponding to $CO_{[BA]}$, CN, $C(CH_3)_{3[BA]}$, $CH_2O_{[Si]}$, $CH_2CH_{2[DSM]}$, CH_2CN, and $Si(CH_3)_2$, respectively). The observed low intensity and slightly broadened signals at $\delta = 157.8$ and 157.6 ($NHCONH_{[BA, Si, CN]}$) suggest that the surface is relatively rigid as a result of hydrogen bonding between the urea units and crowding of the terminal groups.

13: $\delta = 158.5$ ($NHCONH_{[N\text{-}t\text{-}BOC,\,BE]}$), 156.4 ($CO_{[N\text{-}t\text{-}BOC]}$), 138.7 ($C_1$-$Aryl_{[BE]}$), 128.6 ($C_2$-$Aryl_{[BE]}$), 127.8 ($C_{3,4}$-$Aryl_{[BE]}$), 78.9 ($C(CH_3)_{3[N\text{-}t\text{-}BOC]}$), 72.9 ($CH_2C_6H_{5[BE]}$), 71.0 ($CH_2CHO_{[BE]}$), 57.0 (*tert*-$C_{[N\text{-}t\text{-}BOC,\,BE]}$), 52.4 ($CH_2CH_2$-$CH_2CH_{2[DSM]}$, $CH_2CH_2CH_{2[DSM]}$), 51.4 ($CH_2CH_2CH_2NHCONH_{[DSM]}$), 41.2 ($CH_2CH_2NH_{[N\text{-}t\text{-}BOC]}$), 37.9 ($CH_2NHCONH_{[DSM]}$), 33.2 ($CH_2CH_2CH_{2[N\text{-}t\text{-}BOC]}$), 32.3 ($CH_2CH_2CH_2O_{[BE]}$), 28.8 ($C(CH_3)_{3[N\text{-}t\text{-}BOC]}$), 23.9 ($CH_2CH_2CH_{2[N\text{-}t\text{-}BOC,\,BE]}$, $CH_2CH_2CH_2CH_{2[DSM]}$)
14: $\delta = 173.1$ ($CO_{[BA]}$), 158.2 ($NHCONH_{[BA,\,CN,\,N\text{-}t\text{-}BOC,\,BE]}$), 156.5 ($CO_{[N\text{-}t\text{-}BOC]}$), 138.7 ($C_1$-$Aryl_{[BE]}$), 128.5 ($C_2$-$Aryl_{[BE]}$), 127.7 ($C_{3,4}$-$Aryl_{[BE]}$), 118.7 ($CN_{[CN]}$), 80.5 ($C(CH_3)_{3[BA]}$), 78.9 ($C(CH_3)_{3[N\text{-}t\text{-}BOC]}$), 72.9 ($CH_2C_6H_{5[BE]}$), 71.1 ($CH_2CH_2$-$O_{[BE]}$), 70.1, 66.0 ($CH_2OCH_{2[CN]}$), 57.1, 56.2 (*tert*-$C_{[BA,\,CN,\,N\text{-}t\text{-}BOC,\,BE]}$), 51.4 ($CH_2CH_2CH_{2[DSM]}$, $CH_2CH_2CH_2CH_{2[DSM]}$, $CH_2CH_2CH_2NHCONH_{[DSM]}$), 41.1 ($CH_2CH_2CN_{[CN]}$), 38.3 ($CH_2NHCONH_{[DSM]}$), 33.2 ($CH_2CH_2CH_{2[N\text{-}t\text{-}BOC]}$, $CH_2CH_2CH_2O_{[BE]}$), 32.2, 29.9 ($CH_2CH_2CO_{2[BA]}$), 28.7, 28.3 ($C(CH_3)_{3[BA,\,N\text{-}t\text{-}BOC]}$), 23.8 ($CH_2CH_2CH_{2[N\text{-}t\text{-}BOC,\,BE]}$, $CH_2CH_2CH_2CH_{2[DSM]}$), 18.9 ($CH_2CN_{[CN]}$)

Scheme 1 illustrates the concept of combinatorial growth as it relates to the construction of dendrimers such as **14** having surfaces with multifarious functional groups. Thus, treatment of the DSM-32-PPI dendrimer with a mixture of monomers **4** and **5** (16 equivalents each) in refluxing dichloromethane afforded the heterogeneous macromolecule **13**. Following isolation and purification, the structure of the new *hetero*-dendrimer **13** was confirmed by its ^{13}C NMR spectrum (Figure 2, Table 1), which contains the relevant signals exhibited in the spectra of both the corresponding homogeneous macromolecules **9** and **10**. Principal signals are observed at $\delta = 138.7$, 128.6, 127.8 (C-aryl$_{[BE]}$), 78.9 ($C(CH_3)_{3[N\text{-}t\text{-}BOC]}$), 72.9 ($CH_2C_6H_{5[BE]}$), 71.1 ($CH_2CHO_{[BE]}$), 41.2 ($CH_2CH_2NH_{[N\text{-}t\text{-}BOC]}$), 28.8 ($C(CH_3)_{3[N\text{-}t\text{-}BOC]}$). Removal of the BOC groups by treatment with formic acid and subsequent reaction of the free amines with a mixture of isocyanate monomers **1**, **2**, and **4** (0.375, 0.25, 0.375 equivalents, respectively) yielded the peripherally hetereogeneous dendrimer **14**. Its structure was verified by its ^{13}C NMR spectrum (Figure 2), which displays the expected peaks at $\delta = 173.1$ ($CO_{[BA]}$), 156.5

Scheme 1. Combinatorial synthesis of dendrimer **14**, which is characterized by diversity in the surface functional groups.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0309 $ 17.50+.50/0

($CO_{[N\text{-}t\text{-}BOC]}$), 138.7, 128.5, 127.7 (C-$aryl_{[BE]}$), 118.7 (CN), 80.5 ($C(CH_3)_{3[BA]}$), 78.9 ($C(CH_3)_{3[N\text{-}t\text{-}BOC]}$), 72.9 ($CH_2C_6H_{5[BE]}$), 28.7, 28.3 ($C(CH_3)_{3[N\text{-}t\text{-}BOC,\ BA]}$), 18.9 ($CH_2CN_{[CN]}$). Similar signals are observed in the spectra of the homogeneous macromolecules **6**, **7**, **9**, and **10**. Higher generation materials can easily be constructed by further selective deprotection of functional groups and subsequent treatment with any mixture of compatible isocyanate-based monomers.

A great advantage of this protocol is the potential to adjust dendritic properties by modifying the surface groups. The polyamine dendrimer afforded by liberation of the NH_2 moieties on dendrimer **13** (50:50 mixture of *N*-*t*-BOC and BE terminal groups) displays amphiphilic behavior. For example, it is highly soluble in MeOH as well as partially soluble in both H_2O and $CHCl_3$; this compound is thus reminiscent of a "universal micelle". Key ^{13}C NMR signals arising from the NH_2- and $PhCH_2O$-terminated arms collapse and broaden in the deuterated solvents $CDCl_3$ and D_2O, respectively. This can be rationalized by considering that surface groups with termini that favor solvation are extended and freely rotating, while groups with unfavorable solvent interactions are contracted and folded back into the molecular superstructure where less freedom of movement is afforded. Fréchet et al.[16] observed analogous behavior when dendritic wedges were attached to polyethylene glycol star polymers. This behavior can be modified by altering the ratio of the functional groups on the dendrimer surface. For example, a dendrimer with a 75:25 mixture of amino and benzyl ether moieties is completely miscible in H_2O and insoluble in $CHCl_3$.

Combinatorial construction of dendrimers is well suited to the rapid design and construction of nanoscale superstructures having a variety of forms and functions. The large-scale screening of vastly differing material properties should thus be possible. These dendritic materials are likely to have cavities and clefts within the framework, resulting in various degrees of local as well as overall asymmetry. As such, these materials can be viewed as being intermediate between dendrimers and classical polymers: a "polycelle". We are currently investigating their potential use as catalysts and phase-transfer agents.

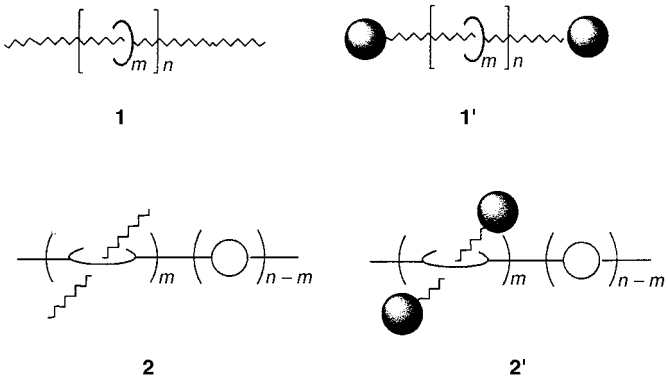
Self-Assembly of Novel Polyrotaxanes: Main-Chain Pseudopolyrotaxanes with Poly(ester crown ether) Backbones**

Caiguo Gong and Harry W. Gibson*



Physically linked molecules, rotaxanes and catenanes,[1] comprise a major research field of supramolecular chemistry[2] which has fascinated scientists in recent decades. Polyrotaxanes, in which a cyclic and a linear species (one of which is part of a macromolecule) are mechanically interlocked with each other, have also been extensively studied since their properties are different than those of conventional covalent polymers.[1, 3–10] The novel properties of these compounds often result from their unusual architectures. Therefore, designing

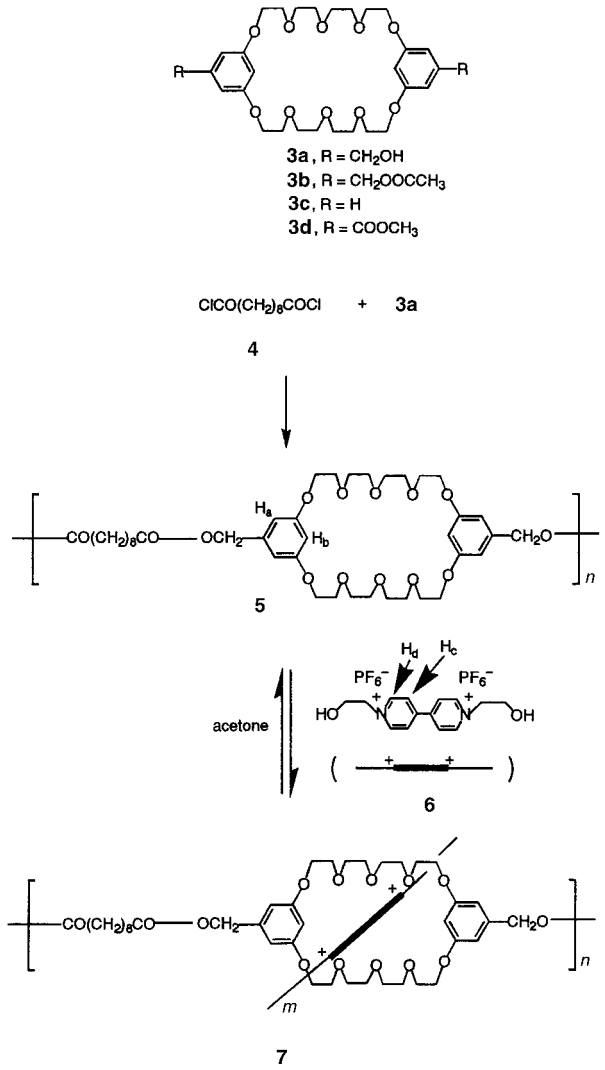
and synthesizing polyrotaxanes with new topologies is very important to polymer science. Two types of main-chain polyrotaxanes are proposed:[1a, 1d] types **1** and **1′** as well as types **2** and **2′** (Scheme 1). To our knowledge, however, only



Scheme 1. Different types of main-chain polyrotaxanes: main-chain pseudopolyrotaxanes (**1**, **2**) and main-chain polyrotaxanes (**1′**, **2′**).

main-chain polyrotaxanes of types **1** and **1′** have been constructed by threading macrocycles onto polymeric backbones.[1, 3, 5–10] Here, we report an approach to polyrotaxanes of type **2** which self-assemble by threading linear components of low molar mass through the cavities of in-chain cyclic units of a preformed poly(ester crown ether).

The difunctional macrocycles bis(5-hydroxymethyl-*m*-phenylene)-[32]crown-10 (**3a**), bis(5-acetoxymethyl-*m*-phenylene)-[32]crown-10 (**3b**), and bis(*m*-phenylene)-[32]crown-10 (BMP32C10) derivatives **3c** and **3d** were prepared by a well-established procedure.[11] Polycondensation of **3a** with sebacoyl chloride (**4**) afforded poly(sebacate crown ether) **5** (see Scheme 2), which can serve as a backbone for constructing designed main-chain polyrotaxanes.

Stoddart et al. demonstrated that bis-phenylene-based crown ethers complex with bipyridinium salts under charge transfer accompanied by hydrogen bonding and dipole–dipole interactions.[1, 12] More specifically, they found that **3c** and *N*,*N*′-dimethyl-4,4′-bipyridinium hexafluorophosphate ("paraquat") formed a pseudorotaxane.[12a] Therefore, *N*,*N*′-bis(*β*-hydroxyethyl)-4,4′-bipyridinium hexafluorophosphate (**6**)[13] is expected to penetrate the cavity of the cyclic component of **5** to form the targeted main-chain pseudopolyrotaxane **7** (Scheme 2).

Indeed, a solution of **6** in acetone immediately turned orange upon addition of **5**, indicating the formation of **7**.[1, 8, 9, 12] ^{1}H NMR spectroscopy affords direct evidence. The signals for the aromatic protons H_a and H_b of the macrocyclic moiety in **7** (Figure 1 b, c) shifted upfield upon complexation with respect to those for **5** (Figure 1 a); this is consistent with the expected complexation, that is, the existence of through-space interactions owing to π stacking between these two components.[1, 8, 9, 12] All these signals are time-averaged; no peaks corresponding to threaded and unthreaded structures exist in the room-temperature spectra. Therefore, although the cyclic component was incorporated into the backbone, the complexation is still rapid on the ^{1}H NMR time scale.

Scheme 2. Preparation of poly(sebacate crown ether) **5** and polyrotaxane **7**.

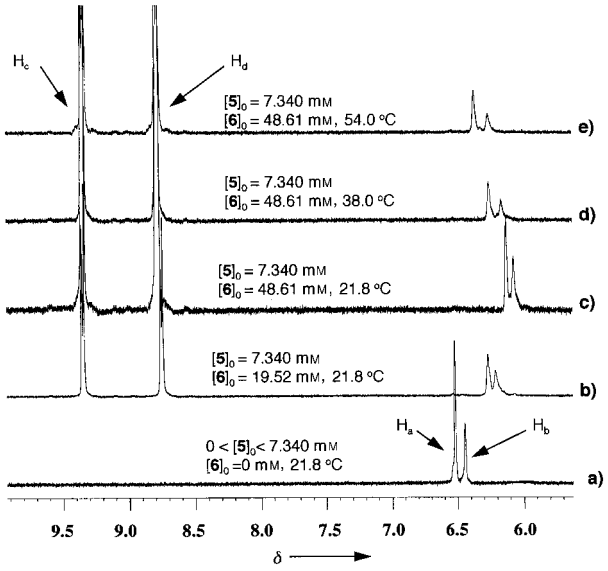


Figure 1. The expanded aromatic regions of the 400-MHz ^{1}H NMR spectra of a) **5** and b–e) solutions of **5**, **6**, and **7** of different compositions and at different temperatures in [D_6]acetone.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0311 $ 17.50+.50/0

Since the complexation is rapid, the chemical shifts for the totally complexed form (e.g. H_a or H_b of the cyclic moiety in **7**) are necessary to calculate the equilibrium constant K.[2a] The continuous titration of a solution of **5** with **6** according to Benesi–Hildebrand method[14] gave the corresponding Δ values for proton H_b (Table 1). The plot of $1/\Delta$ versus $1/[\mathbf{6}]_0$ (Figure 2) afforded K and Δ_0, which are 39.6 M^{-1} and

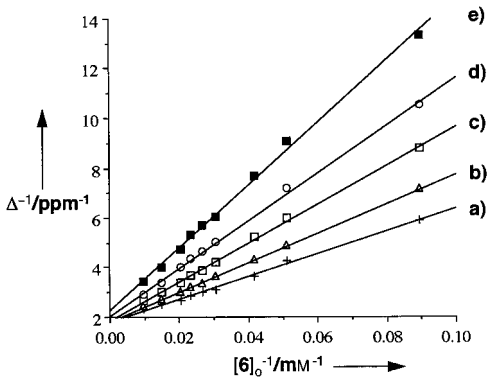

Figure 2. Benesi–Hildebrand plots for the formation of polyrotaxane **7** at a) 21.8, b) 30.0, c) 38.0, d) 46.0, and e) 54.0 °C in acetone.

0.556 ppm, respectively, for the formation of **7** in acetone at 21.8 °C (Table 2). For any other given stoichiometry the percentage of threaded macrocycle, that is, the threading efficiency [m/n value; fraction of cyclic repeat units threaded = [**7**]/([**5**] + [**7**])] can be derived (Table 1).

Table 1. The feed concentrations of **5** and **6**, the changes in chemical shift, and the threading effiencies of **7** in [D_6]acetone at 21.8 °C.

$[\mathbf{5}]_0$[a] [mM]	$[\mathbf{6}]_0$ [mM]	δ_0/Δ[b]	m/n for **7**[c]
0–7.340[d]	0	6.441/0.000	0

[a] Based on the cyclic units. [b] Based on the chemical shift of H_b (measured with ^{1}H NMR spectroscopy[14]). [c] Calculated according to ref. [14]. [d] Polymer **5** by itself is only partially soluble in acetone.

Because the complexation is exothermic, increasing the temperature disfavors rotaxane formation. This is indicated by the fact that the signals for H_a and H_b are shifted downfield at higher temperatures (Figure 1c–e). To quantitively understand the effect of temperature on the complexation, K values were measured at different temperatures according to the above-mentioned method (Figure 2b–e and Table 2); K indeed decreases with increasing temperature. From the van't Hoff plot (Figure 3a) ΔH was determined to be -1.93×10^4 J mol^{-1}, and ΔS -35.0 J K^{-1} mol^{-1}. Therefore, as shown

Table 2. Equilibrium constants and changes in free energy for the complexation of **5** and **6** at different temperatures in [D_6]acetone.

T [K][a]	Slope[b] [mM ppm^{-1}]	Intercept[b] [ppm^{-1}]	R^2[b]	Δ_0[b] [ppm]	K[b] [M^{-1}]	ΔG [kJ mol^{-1}]
295.0	45.6	1.80	0.996	0.556	39.6	–9.02
303.2	59.3	1.83	1.000	0.547	30.9	–8.65
311.2	78.0	1.87	0.998	0.535	23.9	–8.21
319.2	95.8	2.07	0.998	0.484	21.6	–8.15
327.2	126	2.28	0.996	0.439	18.0	–7.88

[a] ±0.1 K. [b] Based on the Benesi–Hildebrand plot (Figure 2).

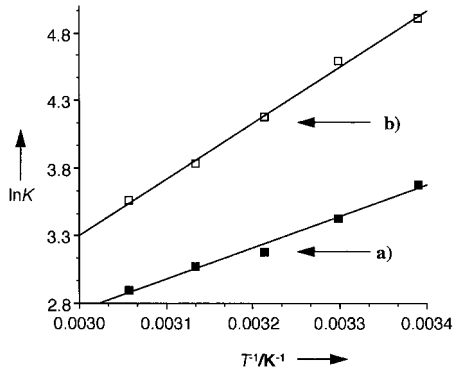

Figure 3. van't Hoff plots for a) the polymer system **5** + **6** and b) the model system **3b** + **6**. Curve a): intercept: -4.21; slope: 2.32×10^3 (K); $R^2 = 0.985$. Curve b): intercept: -9.17; slope: 4.16×10^3 (K); $R^2 = 0.997$.

in Figure 4, the threading efficiency m/n of polyrotaxane **7** can be controlled by simply varying the temperature and the concentration; that is, the m/n values for **7** increase for higher ratios of **6** to **5** at a given temperature as well as for a given concentration at lower temperatures.

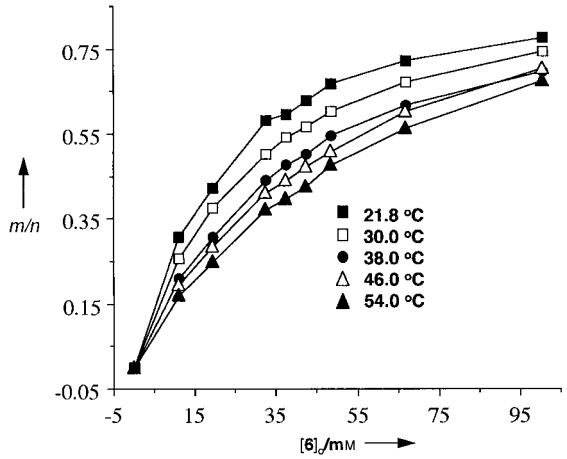

Figure 4. The relationship between the threading efficiency (m/n) of **7** and the feed concentration of **6** with $[\mathbf{5}]_0 = 7.340$ mM in [D_6]acetone at different temperatures.

The K value at room temperature for the polymeric system is much lower than that reported for the complexation of monomeric **3c** with **6** (760 M^{-1}, room temperature).[12a] To take into account the possible effect of the ester linkage in **5**, a

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0312 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 3

model study was carried out with the diester derivative **3b** and **6**. The K value obtained ($135\,\text{M}^{-1}$ at 21.8 °C)[16] is also higher than that for the polymeric system ($39.6\,\text{M}^{-1}$ at 21.8 °C, Table 1). We believe that is the difference is due to the reduced flexibility of the cyclic units in **5**. For π stacking to occur, the phenylene rings of the macrocycle have to rotate towards each other relative to their parallel but nonoverlapping comformation in the uncomplexed state.[12a, 17] As soon as they are incorporated into the polymer backbone, rotation of these phenyl rings becomes much more difficult because it involves local or probably more extensive chain movement; this leads to enthalpic penalties and consequently a lower K value. Indeed, ΔH is more negative for the model system ($-3.46\times10^4\,\text{J mol}^{-1}$, Figure 3b). On the other hand, the ethyleneoxy units of the cyclic moiety in polymer **5** are restricted and expected to be less flexible than in the free macrocycle **3b**, whereas both will be rigidified upon complexation with **6**; this results in a more negative ΔS for the model system ($-76.2\,\text{J K}^{-1}\text{mol}^{-1}$)[16] than for polymeric **7**.

Because of its new topology polyrotaxane **7** had different physical properties than the starting polymer **5**. Polymer **5** is only partially soluble in acetone (Table 1), and paraquat **6** is insoluble in THF. Pseudopolyrotaxanes **7**, however, are soluble in both acetone and THF. Furthermore, the reduced viscosity of **7** prepared with reagent concentrations of $[\mathbf{5}]_0 = 7.427\,\text{mM}$ and $[\mathbf{6}]_0 = 22.28\,\text{mM}$ ($m/n = 0.430$[18]) is $0.215\,\text{dL g}^{-1}$, which is much higher than the value of $0.122\,\text{dL g}^{-1}$ for **7** prepared with $[\mathbf{5}]_0 = 7.427\,\text{mM}$ and $[\mathbf{6}]_0 = 1.857\,\text{mM}$ ($m/n = 0.0544$[18]) in acetone at 21.8 °C. The higher viscosity indicates a larger hydrodynamic volume for the pseudopolyrotaxane **7** with higher m/n.

Polymer **5** is a colorless elastomer with a glass-transition temperature T_g of −6.3 °C. Interestingly, **7** ($m/n = 0.69$)[19] obtained by freeze-drying a solution of **5** and **6** (molar ratio 1:0.75) is a glassy orange material with a T_g of 85.6 °C; the higher for **7** is attributed to its increased rigidity after complexation. The orange color proved that the rotaxane structure **7** in solution remained in the solid state after freeze-drying. This is very important, because use of these pseudopolyrotaxanes in the solid state becomes possible.

We have demonstrated an approach to novel main-chain polyrotaxanes of type **2** (Scheme 1) for the construction of pseudopolyrotaxane **7** by threading linear species **6** through the cavities of the cyclic repeat units of polymacrocycle **5**. Polyrotaxane **7** has a higher viscosity and higher T_g than its starting backbone **5**, and shows different solubility characteristics. The m/n value for the solution of the polyrotaxane increases with increasing amounts of bipyridinium salt **6** as well as with decreasing temperature. The values of K, ΔH, and ΔS provide the basis for predicting the threading efficiency for the preparation of analogous polyrotaxanes. Since bipyridinium guest **6** bears two hydroxy groups, **7** can further react, for example, with diisocyanates to form interesting networks. We are currently studying such systems.

Experimental Section

6: Macrocycle **3a** (150.0 mg, 0.6272 mmol) and **4** (374.3 mg, 0.6272 mmol) were dissolved in a mixture of diglyme and dimethyl sulfoxide (DMSO; 4 mL, 1/1 v/v) at 60 °C. Polymerization proceeded for 2 d at this temperature under N_2. The product was purified by precipitation into methanol (100 mL) to afford **6** (421.1 mg, 88 %), $M_n = 14.9\,\text{kg mol}^{-1}$, PDI = 1.97 (gel permeation chromatography with polystyrene standards).

[14] The association constant K is calculated according to the Benesi – Hildebrand method[15] as follows: For a given temperature and a given feed concentration of one component (e.g. $[\mathbf{5}]_0$), the feed concentration of another component (e.g. $[\mathbf{6}]_0$) is changed: $1/\Delta = 1/(\Delta_0 K[\mathbf{6}]_0) + 1/\Delta_0$, where $\Delta = \delta_f - \delta$, $\Delta_0 = \delta_f - \delta_c$, and δ, δ_c, and δ_f are the time-averaged chemical shifts of the partially complexed, totally complexed, and unthreaded forms, respectively (e.g. H_a and H_b of **5**). Therefore, K, Δ_0, and m/n (threading effiency $= \Delta/\Delta_0$) were calculated (Table 2) from the plot of $1/\Delta$ vs. $1/[\mathbf{6}]_0$ (Figure 2).

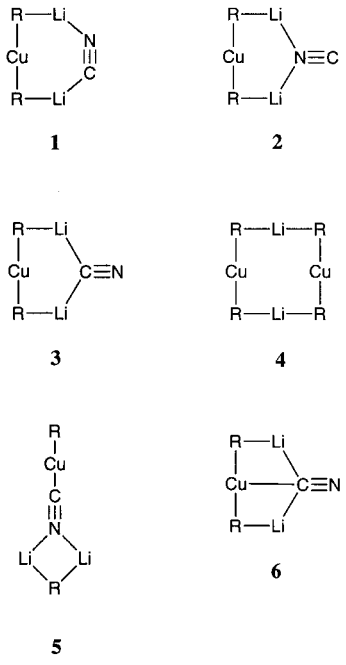
Chemistry, *Vol. 6* (Eds.: J. L. Atwood, J. E. D. Davies, D. D. MacNicol, F. Vögtle), Pergamon, Oxford, **1996**, pp. 425–482.

[16] The values for K, ΔH, and ΔS were also determined by the Benesi–Hildebrand method.[14, 15] K values in [D$_6$]acetone: 135 M^{-1} at 21.8 °C, 98.1 M^{-1} at 30.0 °C, 65.6 M^{-1} at 38.0 °C, 46.1 M^{-1} at 46.0 °C, 34.9 M^{-1} at 54.0 °C; $\Delta H = -34.6 \times 10^4$ J mol^{-1}; $\Delta S = -76.2$ J K^{-1} mol^{-1} (Figure 3b).

[17] The crystal structure of **3c** indicates an open cavity (4.9 × 7.8 Å) which undergoes a small conformational change when it complexes with paraquat.[12a] However, **3d** in the solid state has a collapsed cavity (0.75 × 7.8 Å), perhaps due to crystal packing forces and not intrinsic conformational preferences: Y. Delaviz, J. S. Merola, M. A. G. Berg, H. W. Gibson, *J. Org. Chem.* **1995**, *60*, 516–522.

[18] The values for m/n were calculated by the method specified in ref. [14].

[19] The solution of **5** and **6** in acetone was slowly cooled to −90 °C and then frozen with an acetone/dry ice bath. The solvent was removed under high vacuum to afford an orange solid, pseudopolyrotaxane **7**. The m/n value was calculated from K (4748 M^{-1}), which was estimated from the measured ΔH and ΔS values.



The Use of ^{15}N NMR Spectroscopy To Resolve the "Higher Order Cyanocuprate" Controversy: ^{15}N, ^{6}Li, and ^{13}C NMR Spectroscopic Investigations of CuCN-Derived Butyl Cuprates**

Steven H. Bertz,* Karolina Nilsson, Öjvind Davidsson, and James P. Snyder*

In the modern era of organocopper chemistry,[1] the first cyanocuprate experiments involved the addition of one equivalent of RLi to CuCN to prepare cyanocuprates RCu(CN)Li.[2] Two-bond ^{13}C-^{13}C coupling constants ^2J across copper proved that the R group and the CN group are both bonded to the same Cu in these 1:1 reagents.[3] In 1981 Lipshutz et al. added two equivalents of RLi to CuCN and claimed not only a new class of highly reactive reagents but a new *kind* of organocopper(I) species, the "higher order cyanocuprates."[4] Spectroscopic evidence was not presented, but NMR and IR data were reported later.[5]

Subsequently, Bertz showed that the ^{13}C NMR chemical shifts of the cuprates prepared from two equivalents of RLi and CuCN or CuI were the same and that the shift of the CN carbon atom was independent of the electronic nature of R.[6] In contrast, the chemical shifts of the CN carbon atoms in the "lower order" cyanocuprates RCu(CN)Li vary with R.[3, 6] These observations and the absence of ^2J in the 2:1 compounds cast grave doubt on the higher order formulation $R_2Cu(CN)Li_2$.[4, 7] Extended X-ray absorption fine structure (EXAFS)[8, 9] investigations by Penner-Hahn, Knochel, Frenking et al. and IR[10] studies by Penner-Hahn, Snyder et al. supported the conclusions of these NMR studies. Theoretical investigations by Snyder et al.[11] and Penner-Hahn, Knochel, Frenking et al.[9] indicated that higher order structures are 20–30 kcal mol^{-1} higher in energy than lower order alternatives.

Various lower order structures have been proposed for the 2:1 reagents, for example, **1**–**3**. They are related to the Gilman dimer **4** by the substitution of CN^- for R_2Cu^- in three archetypal ways: 1) one Li atom is attached to N and one to C, 2) both Li atoms are bonded to N, and 3) both Li atoms are bonded to C. While initial theoretical studies favored variants of **1**–**3**,[11] all of these cyano-Gilman reagents are close

enough in energy to be viable candidates. We have now prepared the 1:1 and 2:1 reagents, BuCu(C^{15}N)^{6}Li and Bu$_2$Cu^{6}Li · ^{6}LiC^{15}N, respectively, as well as intermediate stoichiometries from Bu^{6}Li and CuC^{15}N.[12] The results of this ^{15}N NMR study, coupled with theoretical calculations reported herein, strongly support structure **1** over the others.

Figure 1 shows the ^{15}N NMR spectra of solutions in [D$_8$]THF at −80 °C when a) 1.0, b) 1.3, or c) 2.0 equivalents of Bu^{6}Li is added to CuC^{15}N.[12] The 1:1 reagent BuCu(C^{15}N)-^{6}Li is characterized by a singlet at $\delta = -129.3$ (6 Hz width at

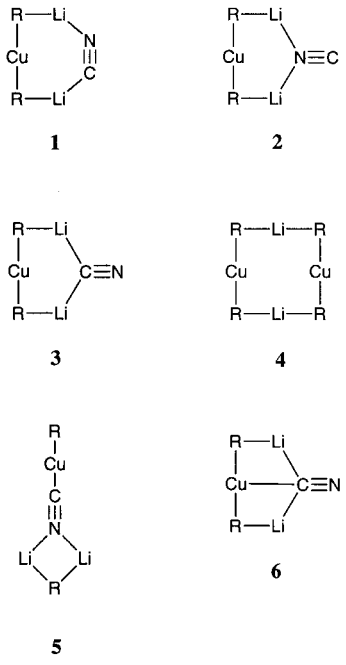
Chemistry, *Vol. 6* (Eds.: J. L. Atwood, J. E. D. Davies, D. D. MacNicol, F. Vögtle), Pergamon, Oxford, **1996**, pp. 425–482.

[16] The values for K, ΔH, and ΔS were also determined by the Benesi–Hildebrand method.[14, 15] K values in [D$_6$]acetone: 135 M^{-1} at 21.8 °C, 98.1 M^{-1} at 30.0 °C, 65.6 M^{-1} at 38.0 °C, 46.1 M^{-1} at 46.0 °C, 34.9 M^{-1} at 54.0 °C; $\Delta H = -34.6 \times 10^4$ J mol^{-1}; $\Delta S = -76.2$ J K^{-1} mol^{-1} (Figure 3b).

[17] The crystal structure of **3c** indicates an open cavity (4.9 × 7.8 Å) which undergoes a small conformational change when it complexes with paraquat.[12a] However, **3d** in the solid state has a collapsed cavity (0.75 × 7.8 Å), perhaps due to crystal packing forces and not intrinsic conformational preferences: Y. Delaviz, J. S. Merola, M. A. G. Berg, H. W. Gibson, *J. Org. Chem.* **1995**, *60*, 516–522.

[18] The values for m/n were calculated by the method specified in ref. [14].

[19] The solution of **5** and **6** in acetone was slowly cooled to −90 °C and then frozen with an acetone/dry ice bath. The solvent was removed under high vacuum to afford an orange solid, pseudopolyrotaxane **7**. The m/n value was calculated from K (4748 M^{-1}), which was estimated from the measured ΔH and ΔS values.



The Use of ^{15}N NMR Spectroscopy To Resolve the "Higher Order Cyanocuprate" Controversy: ^{15}N, ^{6}Li, and ^{13}C NMR Spectroscopic Investigations of CuCN-Derived Butyl Cuprates**

Steven H. Bertz,* Karolina Nilsson, Öjvind Davidsson, and James P. Snyder*

In the modern era of organocopper chemistry,[1] the first cyanocuprate experiments involved the addition of one equivalent of RLi to CuCN to prepare cyanocuprates RCu(CN)Li.[2] Two-bond ^{13}C-^{13}C coupling constants ^2J across copper proved that the R group and the CN group are both bonded to the same Cu in these 1:1 reagents.[3] In 1981 Lipshutz et al. added two equivalents of RLi to CuCN and claimed not only a new class of highly reactive reagents but a new *kind* of organocopper(I) species, the "higher order cyanocuprates."[4] Spectroscopic evidence was not presented, but NMR and IR data were reported later.[5]

Subsequently, Bertz showed that the ^{13}C NMR chemical shifts of the cuprates prepared from two equivalents of RLi and CuCN or CuI were the same and that the shift of the CN carbon atom was independent of the electronic nature of R.[6] In contrast, the chemical shifts of the CN carbon atoms in the "lower order" cyanocuprates RCu(CN)Li vary with R.[3, 6] These observations and the absence of ^2J in the 2:1 compounds cast grave doubt on the higher order formulation $R_2Cu(CN)Li_2$.[4, 7] Extended X-ray absorption fine structure (EXAFS)[8, 9] investigations by Penner-Hahn, Knochel, Frenking et al. and IR[10] studies by Penner-Hahn, Snyder et al. supported the conclusions of these NMR studies. Theoretical investigations by Snyder et al.[11] and Penner-Hahn, Knochel, Frenking et al.[9] indicated that higher order structures are 20–30 kcal mol^{-1} higher in energy than lower order alternatives.

Various lower order structures have been proposed for the 2:1 reagents, for example, **1**–**3**. They are related to the Gilman dimer **4** by the substitution of CN$^-$ for R$_2$Cu$^-$ in three archetypal ways: 1) one Li atom is attached to N and one to C, 2) both Li atoms are bonded to N, and 3) both Li atoms are bonded to C. While initial theoretical studies favored variants of **1**–**3**,[11] all of these cyano-Gilman reagents are close

enough in energy to be viable candidates. We have now prepared the 1:1 and 2:1 reagents, BuCu(C^{15}N)^{6}Li and Bu$_2$Cu^{6}Li · ^{6}LiC^{15}N, respectively, as well as intermediate stoichiometries from Bu^{6}Li and CuC^{15}N.[12] The results of this ^{15}N NMR study, coupled with theoretical calculations reported herein, strongly support structure **1** over the others.

Figure 1 shows the ^{15}N NMR spectra of solutions in [D$_8$]THF at −80 °C when a) 1.0, b) 1.3, or c) 2.0 equivalents of Bu^{6}Li is added to CuC^{15}N.[12] The 1:1 reagent BuCu(C^{15}N)-^{6}Li is characterized by a singlet at $\delta = -129.3$ (6 Hz width at

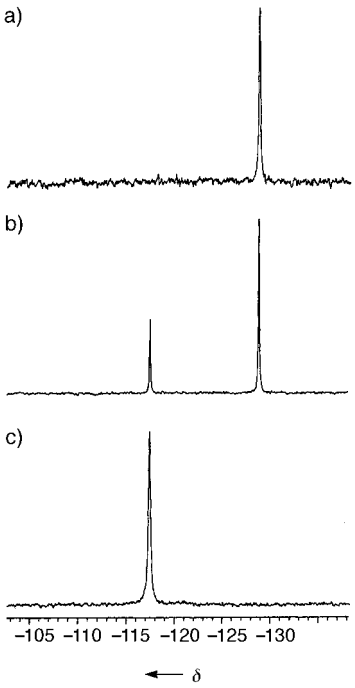

Figure 1. ^{15}N NMR spectra (50.65 MHz) in [D_8]THF at $-80\,^{\circ}$C of the cuprates prepared from various ratios of Bu^{6}Li:CuC^{15}N: a) 1:1, b) 1.3:1, and c) 2:1.

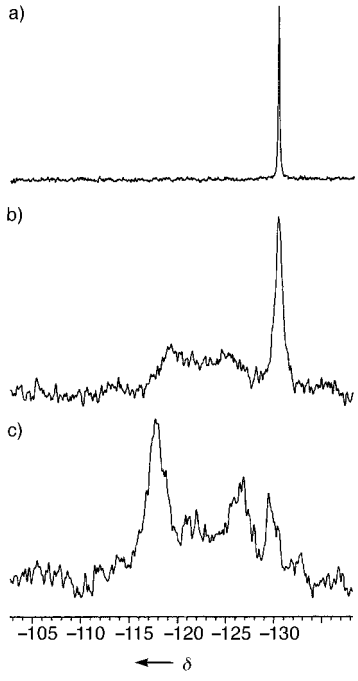

Figure 2. ^{15}N NMR spectra (50.65 MHz) in [D_{10}]diethyl ether at $-80\,^{\circ}$C of the cuprates prepared from various ratios of Bu^{6}Li:CuC^{15}N: a) 1:1, b) 1.4:1, and c) 2:1.

half-height, $\Delta\nu_{1/2}$), measured on a scale that assigns a value of $\delta = 0$ to neat nitromethane and $\delta = -77.7$ to trimethylsilylcyanide (TMSCN).[13] The spectrum of the 2:1 reagent $Bu_2Cu^6Li \cdot {}^6LiC^{15}N$ is a singlet at $\delta = -117.5$ ($\Delta\nu_{1/2} = 10$ Hz) under these conditions. The spectrum of a mixture with intermediate stoichiometry (Figure 1b) has both peaks at their characteristic chemical shifts in the expected ratio. No "free" ^{6}LiC^{15}N is observed in any of these spectra.

Figure 2a shows that the ^{15}N NMR spectrum of the 1:1 reagent in [D_{10}]ether at $-80\,^{\circ}$C is also a singlet ($\delta = -130.5$, $\Delta\nu_{1/2} = 6$ Hz). It is critical that the BuLi be added slowly with sonication if the BuCu(CN)Li is to be obtained as pure as in Figure 2a. In contrast, the spectrum of the 2:1 reagent (Figure 2c) is dramatically different in [D_{10}]diethyl ether: there is a relatively broad peak at $\delta = -118.0$ ($\Delta\nu_{1/2} = 120$ Hz), but there is also a plethora of peaks at chemical shifts between the values for the 2:1 and 1:1 species. The intermediate peaks are due to aggregates (see below). Upon warming the sample to $-50\,^{\circ}$C, all the ^{15}N peaks in this spectrum coalesce into a single broad peak ($\delta = -121.5$, $\Delta\nu_{1/2} = 55$ Hz).

With 1.4:1 stoichiometry in [D_{10}]diethyl ether (Figure 2b), there was little of the 2:1 reagent ($\delta = -118$, 5%) relative to the 1:1 reagent ($\delta = -130.5$, $\Delta\nu_{1/2} = 50$ Hz, 35%) or "intermediate" species. When the reactant ratio was reduced to 1.3:1, the $\delta = -118$ peak increased to 15% of the total area as the intermediate peaks decreased to 25%, and when this solution was cooled from $-80\,^{\circ}$C to $-100\,^{\circ}$C, it further increased to 25% as the intermediate area diminished to 10%. The addition of THF to the [D_{10}]diethyl ether solution also converts the intermediate peaks cleanly to the $\delta = -118$ and -130 peaks. The effects of solvent, concentration, and temperature are similar to those observed for RLi,[14] and it can be concluded that the intermediate peaks in this case correspond to aggregates derived from both cuprates.[15]

The ^{6}Li NMR spectra contain vital new information.[12b] In [D_8]THF at $-80\,^{\circ}$C, the 1:1 and 2:1 reagents give rise to peaks at $\delta = -1.40$ ($\Delta\nu_{1/2} = 1$ Hz) and -1.18 ($\Delta\nu_{1/2} = 5$ Hz), respectively.[16] In the sample with 1.3:1 stoichiometry in [D_8]THF, there is a single peak at an intermediate chemical shift ($\delta = -1.25$, $\Delta\nu_{1/2} = 1$ Hz) instead of two peaks, as in the corresponding ^{15}N spectrum (Figure 1b). Apparently, an exchange process renders the Li ions equivalent, but not the N atoms. The ^{6}Li spectrum of BuCu(C^{15}N)^{6}Li in [D_{10}]diethyl ether is a single peak at $\delta = -0.87$ ($\Delta\nu_{1/2} = 2$ Hz). The major ^{6}Li peak in the spectrum of the 2:1 reagent in [D_{10}]diethyl ether is $\delta = -0.66$ ($\Delta\nu_{1/2} = 20$ Hz). The usual samples of the 2:1 reagent in this solvent had minor peaks at $\delta = 1.03$ and 1.90 (10.8% and 10.6% of the total area). These peaks have not been definitively assigned;[17] nevertheless, it is clear from the ^{15}N and ^{6}Li spectra that the situation in diethyl ether is much more complex than had previously been appreciated.

No ^{6}Li-^{15}N couplings could be observed for either the 1:1 or 2:1 reagent in [D_{10}]diethyl ether at temperatures down to $-110\,^{\circ}$C.[18] This is not unexpected: ^{6}Li-^{13}C couplings have not been observed for organocuprates $R_2CuLi \cdot LiI$, $R_2CuLi \cdot LiCN$ or RCu(CN)Li (R = Me, Et, Bu, Ph),[3, 6] in spite of the fact that the corresponding organolithium compounds RLi do exhibit such couplings.[14] In light of the ^{6}Li NMR results presented above, rapid exchange of Li is responsible for the lack of coupling with this nucleus.

The only discernible ^{13}C-^{15}N coupling is the cyano-doublet ($J = 11.7$ Hz) at $\delta = 149.35$ ($\Delta\nu_{1/2} = 7$ and 9 Hz) in the ^{13}C spectrum of BuCu(C^{15}N)^{6}Li in [D_8]THF. Broadening precluded measurement of coupling in the CN peak ($\delta = 158.82$,

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0315 $ 17.50+.50/0

$\Delta\nu_{1/2} = 35$ Hz) for $Bu_2Cu^6Li \cdot {}^6LiC^{15}N$ in this solvent. In [D_{10}]diethyl ether $BuCu(C^{15}N)^6Li$ has a broad peak at $\delta =$ 150.96 ($\Delta\nu_{1/2} = 80$ Hz), and the best spectrum of $Bu_2Cu^6Li \cdot {}^6LiC^{15}N$ has one at $\delta = 159.55$ ($\Delta\nu_{1/2} = 80$ Hz). Previously, ^{13}C NMR peaks at $\delta = 152$ and 163 were assigned without theoretical justification to "higher order" species.[5b]

The ^{15}N NMR chemical shifts measured for the 2:1 organocuprate in this study can be interpreted with the aid of calculations. Relative ^{15}N shifts were calculated by using Chesnut's locally dense basis set concept.[19] The calculations (Becke3LYP/6-311G*/GIAO)[20] were performed on the methyl analogues of **1**–**6** (R = Me) which also have one coordinated H_2O per Li to approximate ethereal solvation. We denote these hydrated methyl derivatives, which are the usual model compounds,[9, 11] as **1a**–**6a**. They were also performed on CN^- and TMSCN. We have scaled all the calculated ^{15}N NMR shifts so that TMSCN is set at the literature value $\delta = -77.7$.[13, 21] The ^{15}N NMR shift for "naked" CN^- is then $\delta = -125.8$, which is in reasonable agreement with the observed values for aqueous KCN ($\delta = -104$ to -106),[21] especially when the effect of solvation is considered. The calculated shifts for **1a**–**3a** are $\delta = -113.9$, -161.9, and -81.1, respectively, and for **5a** the calculated value is $\delta = -185.5$. Higher order structure **6a** has a calculated shift of $\delta = -81.2$. Only structure **1a** gives good agreement with the measured values (ca. $\delta = -118$) for the 2:1 species in this study.

There is no evidence that any of the minor species observed in solutions of the 2:1 reagent are higher order cuprates, which in any event would be unfavorable energetically.[11] Moreover, our results do not indicate how tightly the R_2Cu^- core in **1** is bonded to the $LiCNLi^+$ moiety, nor do they rule out minor equilibrium amounts of other species such as **2** or **3** (see below).

The IR stretching frequencies calculated for cyanide in methyl analogues **1a** and **3a** (2101 and 2099 cm^{-1}, respectively) are consistent with the observed value for $Me_2CuLi \cdot LiCN$ in THF (2115 cm^{-1}).[10] A recent ^{13}C NMR study by Berger et al. concluded that the "dimethylcuprate core" in $Me_2CuLi \cdot LiCN$ is the same as in "halide-free" Me_2CuLi,[22a] which is consistent with **1**–**3**, but not **5**. Cryoscopy indicates that $Me_2CuLi \cdot LiCN$ is essentially monomeric in THF,[22b] which is consistent with **1**–**3** or **5**, although some dissociation was postulated. ^{15}N NMR spectroscopy is the first technique that allows all the structures that have been proposed for the major component of the 2:1 reagent to be ruled out except **1**, which is in good agreement with both ^{15}N NMR and IR measurements.

We believe that the location of the CN is now "triangulated" by two independent experimental techniques and by calculations. These results establish that the very useful[23, 24] organocopper compounds prepared from two equivalents of RLi and one equivalent of CuCN are cyanide-modified Gilman reagents and not "higher order cyanocuprates." Consequently, they should be called *cyano-Gilman reagents* and written $R_2CuLi \cdot LiCN$ in analogy with other Gilman reagents based on linearly bonded copper(I) structural units ($R_2CuLi \cdot LiI$, $R_2CuLi \cdot LiBr \cdot DMS$ (DMS = dimethyl sulfide), $R_2CuLi \cdot LiOTf$, etc.[23]). NMR spectroscopic measurements were responsible for the first doubt about the higher order formulation of the cyanocuprates,[3, 6, 25] and they have now come full circle to definitively settle the ensuing controversy.[24]

Experimental Section

All NMR spectra were obtained on a Varian Unity 500 spectrometer at the canonical frequencies (^{15}N: 50.65; ^{13}C: 125.7; ^6Li: 73.6 MHz). All NMR shifts were calculated by using the "low frequency positive" convention.[13b] ^6Li NMR spectra were referenced with external 0.3 M ^6LiCl in [D_4]methanol set at $\delta = 0$. ^{13}C NMR spectra were referenced to the solvent signals: $\delta =$ 14.60 (ether) or $\delta = 25.37$ (THF). ^{15}N NMR spectra were referenced with 4 M TMSCN in [D_8]THF set at $\delta = -81.7$.[13c]

$CuC^{15}N$ (12.7 mg, 0.14 mmol, MSD Isotopes) was sealed under Ar in an NMR tube (∅ 5 mm) with a rubber septum and Teflon tape. A 0.5 mL aliquot of freshly-distilled [D_{10}]diethyl ether was added by syringe and the contents were sonicated before being cooled to $-78\,^\circ C$ (dry ice/acetone). A 30 μL aliquot of 2 M Bu^6Li (0.06 mmol, precise titer determined by Gilman double-titration)[12a] in pentane was added, and the mixture was sonicated at $0\,^\circ C$ for 1.0 min. It was then cooled to $-78\,^\circ C$ for 3 min, and the cycle was repeated two more times. The tube was inserted in a ceramic spinner, wiped with an ethanol-soaked tissue, and lowered into the NMR probe, precooled to $-80\,^\circ C$. The ^{13}C NMR spectrum was obtained to confirm the identity of the product,[3, 6] and then the ^{15}N and ^6Li spectra were measured.

Another 30 μL of 2 M Bu^6Li was added to the tube, and the above procedure was repeated to get high-quality spectra of 0.2 M $BuCu(C^{15}N)^6Li$. A small amount of $CuC^{15}N$ remained at the bottom of the tube to make sure none of the 2:1 reagent was present. (None was detected by ^{13}C, ^{15}N, or ^6Li NMR.) When the Bu^6Li was added all at once to $CuC^{15}N$ in [D_{10}]diethyl ether, the spectrum resembled the one in Figure 2b.

Addition of a third 30 μL aliquot gave a mixture of 1:1 and 2:1 reagents, which was analyzed by ^{13}C NMR spectroscopy to determine the ratio of cyano-carbon atoms and from this the effective titer of the Bu^6Li. The ratio of these reagents was also determined by integration of the ^{15}N NMR spectra. For the final sample of 2:1 reagent, a total of 1.90 equiv of Bu^6Li was used, as calculated from the effective titer.

Vellekoop, R. A. J. Smith, J. P. Snyder, *ibid.* **1995**, *14*, 1213 – 1220, except that 5 mm tubes were used instead of 10 mm. See also Experimental Section.
[13] a) B. Wrackmeyer, *Z. Naturforsch. B* **1988**, *43*, 923 – 926; b) D. E. J. Arnold, S. Cradock, E. A. V. Ebsworth, J. D. Murdoch, D. W. H. Rankin, D. C. J. Skea, R. K. Harris, B. J. Kimber *J. Chem. Soc. Dalton Trans.* **1981**, 1349 – 1351; c) reference [13a] reports $\delta = -77.7$ vs. nitromethane for TMSCN and reference [13b] observes $\delta = 254.7$ vs. tetramethylammonium iodide (both with ca. 10% [D_6]benzene for lock). The latter is $\delta = -82.6$ vs. nitromethane. We measure $\delta = -79.7$ vs. nitromethane, which is close to the average ($\delta = -80.1$) of the previous measurements. Since nitromethane freezes at $-29\,^\circ$C, we believe more work needs to be done on a primary standard, and we provisionally take the TMSCN shift to be $\delta = -77.7$, as listed in a critical review.[21] For 4 M TMSCN in [D_8]THF, we measure $\delta = -81.7$ on this scale. Since the calculated shifts are referenced to the same value as the experimental ones, our conclusions are independent of the standard.

[15] Similar observations have been reported for PhCu and Ph_2CuLi: S. H. Bertz, G. Dabbagh, X. He, P. P. Power, *J. Am. Chem. Soc.* **1993**, *115*, 11 640 – 11 641.
[16] a) There are also small peaks at $\delta = 0.56$ and 1.26 (each about 5% of the total area) in the ^{6}Li spectrum of the 2:1 reagent which may be attributable to CN-free cuprates, presumably similar to "halide-free" cuprates: E. C. Ashby, J. J. Watkins, *J. Am. Chem. Soc.* **1977**, *99*, 5312 – 5317; b) see also reference [25a].
[17] These minor peaks may be assigned to ^{6}LiC^{15}N and Bu^{6}Li, respectively, possibly in the form of a 1:1 complex. The "LiCN" was not detectable in the ^{15}N spectra of these samples, due to its low concentration and the broadness of its peak. One preparation contained about 20% of the presumed ^{6}LiC^{15}N · Bu^{6}Li (^{6}Li peaks at $\delta = 0.95$ and 1.83) and had a ^{15}N peak at $\delta = -67.5$ ($\Delta\nu_{1/2} = 95$ Hz). The peak at $\delta = 1.83$ was assigned to Bu^{6}Li by a standard addition experiment.
[18] The samples froze out at $-120\,^\circ$C. This was also true with the mixed solvent system THF/[D_{10}]diethyl ether/pentane.

Analysis of the Symmetry of Crystal Packing Forces by Methyl Proton Tunneling: A Strategy for the Unambiguous Assignment of the Magnetic Jahn – Teller Effect in Molecules**

Upali A. Jayasooriya,* Roderick D. Cannon, Christopher E. Anson, Elisha Karu, Ahmed K. Saad, John P. Bourke, Gordon J. Kearley, and Ross P. White

Recent work on polynuclear complexes of magnetic metal ions is tending to confirm a hypothesis that was put forward some time ago in which it was stated that in such complexes there is an inherent tendency towards structural distortion with lowering of symmetry, due to spin-frustration or the magnetic Jahn – Teller effect.[1] For example, according to X-ray diffraction studies the complex $[Cu_4OCl_6(OPPh_3)_4]$ crystallizes in a cubic lattice in which the molecules are located on sites of tetrahedral symmetry; however, recent FTIR measurements have revealed a lower symmetry, as shown by splittings of the vibrational frequency of the central oxygen atom.[2] Other systems have triangular clusters, and inelastic neutron scattering (INS) measurements have shown that these deviate from equilateral symmetry at low temperatures.[3] But before attempting to assign structural anomalies to intrinsic forces within the metal atom cluster as such, it is important to consider to what extent they may be driven by extrinsic forces, such as crystal packing or steric hindrance between peripheral groups in the ligands, unrelated to electronic forces at the center.

One classic approach to such problems is to compare structures of two materials that are chemically as similar as possible, apart from the asymmetry of the electron configuration. This has worked well in studies of Jahn – Teller effects in mononuclear systems, for example by comparing structures of copper(II) and zinc(II) complexes with identical ligands and counterions.[4] A similar approach to the phenomenon of spin-frustration or magnetic Jahn – Teller effect would need isostructural pairs of magnetic and nonmagnetic polynuclear

complexes, but no suitable materials are known at present. Another approach to this problem is to embed the magnetic cluster at the center of a large "soft" ligand environment, and place this in turn at a crystal lattice point that is close to the idealized high symmetry. In such a strategy, what is needed is a technique that can sense structural anomalies at the periphery of the complex. If such anomalies are *not* found, but the central cluster is still found to be distorted, the case for saying that the distortion is intrinsic will be strong.

Herein we present the phenomenon of rotational tunneling of protons in units such as methyl groups as a sensitive tool for detecting extrinsic structural distortions. Using a test substance whose structure and spectra have been well studied, we show that six peripheral methyl groups can be distinguished into at least three structural types reflecting small differences in local environment.

A preliminary investigation of the proton tunneling in salts of the chromium complex ion $[Cr_3O(OOCCH_3)_6(OH_2)_3]^+$ by using INS showed at least two features for the chloride salt, a single broad overlapping peak for the perchlorate, and none for the nitrate.[5] We have now measured new tunneling spectra of the chloride salt at higher resolution, and we have compared the normal salt with a sample containing a statistical mixture of CH_3 and CD_3 groups. The purpose of the latter experiment is to detect any coupling between adjacent methyl rotors. Relatively large differences in the tunneling frequencies between the CH_3 and CD_3 groups will result in a decoupling of these rotors. The results show that at least three methyl group environments can be distinguished. A detailed introduction to the application of INS including rotational tunneling is given in a special issue of the journal *Spectrochimica Acta*.[6]

$[Cr_3O(OOCCH_3)_6(H_2O)_3]Cl \cdot 6H_2O$ was synthesized as previously,[7] and a sample containing a statistical mixture of CH_3 and CD_3 groups was prepared by starting with an equimolar mixture of acetic acid and perdeuterioacetic acid. INS spectra were recorded on finely powdered samples sealed in aluminum cans; the thickness was calculated to provide about 10% total scattering. The detectors were calibrated based on a spectrum of vanadium metal. Data reduction was carried out with the standard programs PRIME and CROSSX available at the Institut Laue-Langevin.

The INS spectra of the labeled and unlabeled samples are shown in Figure 1. X-ray powder diffraction patterns of the two samples were identical confirming that they have the same crystal and molecular structure. The differences between the two INS spectra are striking: two peaks, A and D, in the all-^1H sample, reappear almost unchanged in frequency as A and D in the $^1H/^2H$ sample, but at least two other peaks, B and C, in the all-^1H sample, collapse into one broad peak E in the $^1H/^2H$ sample. An empirical Gaussian fitting to the $^1H/^2H$ sample spectrum is consistent with the intensity ratios A:E:D = 1:4:1.

At room temperature $[Cr_3O(OOCCH_3)_6(H_2O)_3]Cl \cdot 6H_2O$ crystallizes in the space group $P2_12_12$; four molecules per unit cell occupy crystallographically general sites.[8] Below a phase transition at about 211 K it changes to $P2_12_12_1$, with the unit cell doubled in size to contain two inequivalent sets of four trinuclear complex cations;[9] that is, there are twelve structurally distinct methyl groups. The C–C distances between the methyl groups are such that intramolecular coupling can be discounted; the shortest intermolecular C–C distances in X-ray crystal structure at room temperature[10] are consistent with intermolecular coupling. Four of the methyl-C atoms per molecule have nearest neighbor methyl-C atoms within a distance of 3.37–3.66 Å and the other two have their nearest neighbors at distances of 3.7 and 3.8 Å. These values may be compared with distances of about 3.5 Å in other acetate materials in which coupling between rotors has been observed.[11]

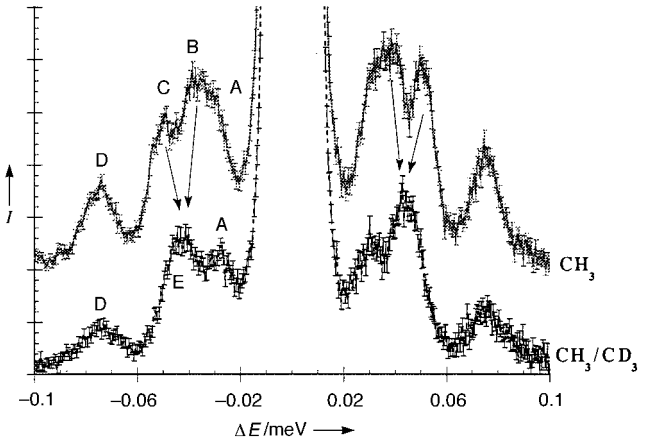

Figure 1. Methyl tunneling spectra of $[Cr_3O(OOCMe)_6(H_2O)_3]Cl \cdot 6H_2O$ recorded at $T = 2$ K (in the neutron down scattering mode) on the instrument IN5 at the Institut Laue-Langevin, Grenoble, France. Upper curve: Me = CH_3; lower curve: Me = 1:1 statistical distribution of CH_3 and CD_3 groups.

In the earlier work on the chloride salt, two possible reasons for the observed spectral profile were proposed, that is inequivalent environments of methyl groups, and coupling between pairs of very similar methyl groups, the two not being mutually exclusive. The observed intensity ratios suggest that both possibilities do in fact occur. That is, all twelve methyl groups are involved in tunneling, four of them rotating independently but grouped into two pairs with similar potentials to give the unshifted bands A and D, while the other eight are coupled intermolecularly in pairs, with similar interaction potentials, giving a set of overlapping peaks observed as bands B and C. On going over to the "scrambled" sample, which is a mixed crystal containing all possible molecules $[Cr_3O(OOCCH_3)_n(OOCCD_3)_{6-n}(H_2O)_3]^+$, the independent methyl groups remain unaffected, apart from a 50% reduction in numbers, but the coupled pairs become decoupled, and collapse to band E.[*]

From the widths and shapes of the observed spectral peaks in Figure 1, it is clear that these consist of many nearly coincident overlapping peaks. It may be possible to resolve them further by working at still lower temperatures, but with the present data we can still attempt an estimate of the methyl

[*] Another factor that should be taken into consideration in isotopic substitution experiments is lattice compression, which can produce blue shifts, but the lack of significant shifts of bands A and D, and also the observation of a red shift of band C, both suggest that lattice compression is not a significant complication here.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0318 $ 17.50+.50/0

group rotation potentials and the inter-rotor coupling potentials. Such two-rotor systems have been described in detail,[11] though these were usually for simpler crystal structures in which the rotating pairs are coaxial. According to Clough et. al.,[12] the Hamiltonian operator for a pair of coaxially coupled methyl rotors is given by Equation (1), where B is a

$$\mathscr{H} = B\left(\frac{\partial^2}{\partial\theta^2}+\frac{\partial^2}{\partial\phi^2}\right)+V(\theta)+V'(\phi)+W(\theta,\phi) \quad (1)$$

constant, θ and ϕ are rotational coordinates of the two rotors, $V(\theta)$ and $V'(\phi)$ are the potentials for rotation of the methyl groups in their respective sites, and $W(\theta,\phi)$ is the coupling term which, considering only a threefold contribution, can be written according to Equation (2). For $V(\theta)$ and $V'(\phi)$ a Fourier series is used [Eq. (3)], where W and V_{3n} are constants and $N \leq 2$. $V'(\phi)$ is assumed to be equal to $V(\theta)$ in the simplified model used.

$$W(\theta,\phi) = \frac{W}{2}\{1-\cos 3(\theta-\phi)\} \quad (2)$$

$$V(\theta) = \sum_{n=0}^{N} V_{3n}\cos 3n\theta \quad (3)$$

The resulting energy level diagram is shown in Figure 2, which also shows the allowed transitions and their theoretical

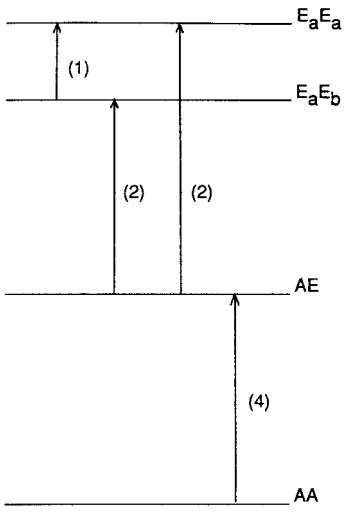

Figure 2. Energy level diagram showing the allowed transitions for two methyl groups coupled under a threefold potential. Energy levels are labeled with the symmetry species, according to reference [11]. Figures in parentheses are the relative intensities predicted for the INS spectrum.

relative intensities. A fit of this model to the spectrum of the all-H sample results in the band energies and assignments given in Table 1. The fit of calculated and observed spectra for the all H-sample is shown in Figure 3. The $(E_aE_a \leftarrow E_aE_b)$ transition is calculated to be at about 3 μeV, and is thus hidden within the elastic peak. Although the model used here is oversimplified, it provides a quantitative measure of the potentials felt by these peripheral methyl groups, which are due mainly to packing forces in the solid state.

Table 1. Summary of fitted tunneling energies ΔE [μeV] for $[Cr_3O(OOCMe)_6(H_2O)_3]Cl\cdot 6H_2O$ and its partially deuterated analogue.[a]

Me = CH_3 observed value[a]		calculated value[c]		Me = CH_3/CD_3 observed value[a]

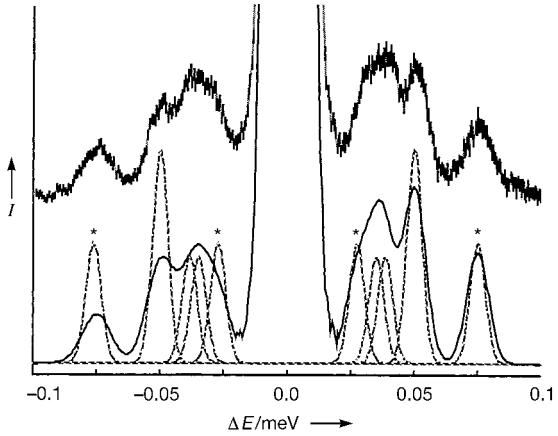

Figure 3. Methyl tunneling spectra of $[Cr_3O(OOCCH_3)_6(H_2O)_3]Cl\cdot 6H_2O$ recorded at $T = 2$ K (in neutron down scattering mode), showing the fit of the model described in the text. Upper curve: observed; lower curve: calculated. The bands labeled with an asterisk are tunneling transitions of the uncoupled methyl groups.

The vibrational spectrum of $[Cr_3O(OOCCH_3)_6(H_2O)_3]Cl\cdot 6H_2O$ in the region 100–150 cm^{-1} supports this interpretation. As measured by INS[5] it shows a strong peak at about 150 cm^{-1} and three others closely spaced at 100–130 cm^{-1}. A subsequent single-crystal Raman study has identified the 150 cm^{-1} band as the symmetric breathing mode of the oxo-centered metal triangle.[13] The other three peaks can therefore now be assigned to methyl torsions; the central peak is broader and stronger than the two side peaks, in agreement with the above conclusions on the methyl group environments.

The studies presented here clearly illustrate the sensitivity of the rotational tunneling of protons in methyl groups to the local environment. Polymetallic molecular systems with ligands such as carboxylic acids, provide useful systems for the investigation of the distortions that result from effects like the magnetic Jahn–Teller effect. As shown elsewhere,[3] the Cr_3 triangles in the present complex are "scalene" in the sense that all three Cr–Cr antiferromagnetic coupling constants are different. Inelastic magnetic neutron scattering and IR spectroscopy provide accurate information on the symmetry of the central metal core, while rotational tunneling of protons probes the symmetry of the external packing forces. Further

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0319 $ 17.50+.50/0

work including a low-temperature structure determination will be needed to establish whether or not there is a correlation between central and external geometries for this molecule. Other systems containing probable proton tunneling groups such as NH_3 will also be suitable candidates for this purpose.

[14] The detailed fitting procedure was as follows. On the basis of the observed spectra the coupling scheme referred to in the text was adopted. This gave the energy level scheme shown in Figure 2, and four bands with transition probabilities in the ratio 1:2:2:4. These were assigned as one low-energy transition (not observed), two overlapping transitions (band B), and a fourth transition (band C). Diagonalization of the Hamiltonian matrix within a refinement cycle allowed V and W to be adjusted to give a best fit to the observed transitions; the relative intensities are constrained to the calculated ratios. This gave $V = 62$ meV and $W = 21$ meV, and the energies listed in Table 1.

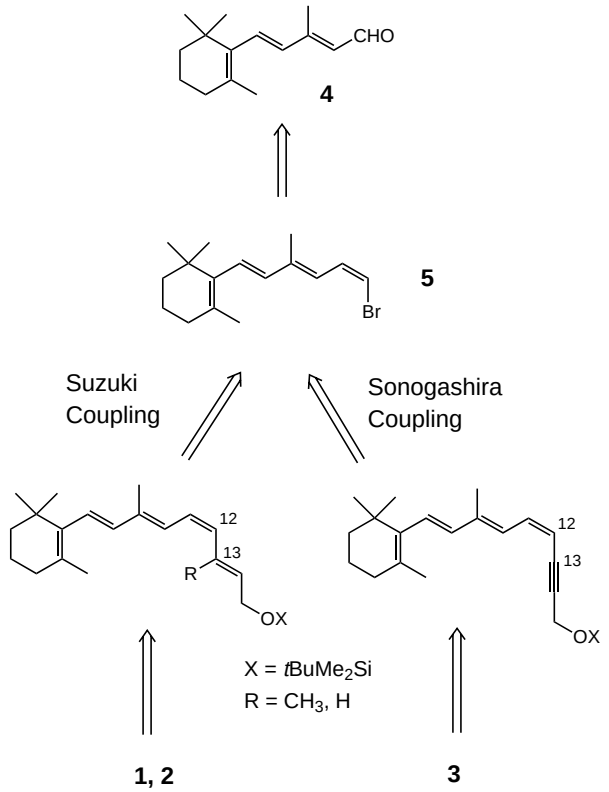
Stereocontrolled Synthesis of (11*Z*)-Retinal and Its Analogues**

Jun'ichi Uenishi,* Reiko Kawahama, Osamu Yonemitsu, Akimori Wada, and Masayoshi Ito

(11*Z*)-Retinal is a key chromophore in the visual system of the retina, which assembles with an apo-protein (opsin) to form rhodopsin.[1] When rhodopsin is exposed to photons, it is promoted to an excited state which induces a bleaching process by an enzymatic cascade. Thus, the signal is delivered to the brain through synaps, and vision is possible.[2] Although part of this mechanism was previously revealed, many unexplained interactions still remain for the visual pigments, and, in particular, the mode of action for sensing color has yet to be clarified. To study such a mechanism, pure (11*Z*)-retinal and its analogues are highly desired.[3] However, the stereoselective synthesis of pure (11*Z*)-retinals has been difficult, since they are unstable towards light, heat, acids, and bases; isomerization, condensation, or polymerization are promoted. Although a number of syntheses of (11*Z*)-retinal and its analogues have appeared, all required a separation of the stereoisomers at a certain stage.[3] The synthetic problem is largely due to the lack of a reliable method for controlling the (*Z*)-alkenyl unit at the C11 position in the conjugated pentaene system.

Since we succeeded in synthesizing conjugated polyenes bearing a (*Z*)-alkenyl component,[4] (11*Z*)-retinal was a natural target for our polyene syntheses. Furthermore, this synthetic method is able to supply a number of (11*Z*)-retinal derivatives in a stereochemically pure form. Here we describe the first strictly stereocontrolled synthesis of (11*Z*)-retinal (**1**) and its analogues **2** and **3**.

1 R = CH_3 **3**
2 R = H



Scheme 1 summarizes the retrosynthesis of the (11*Z*)-retinals. Cleavage of the C12 – C13 bond gives rise to the important and flexible intermediate **5**, which couples with an appropriate alkenylboronic acid or alkyne by Pd-catalyzed cross-coupling reactions to afford **1**, **2**, and **3** with retention of

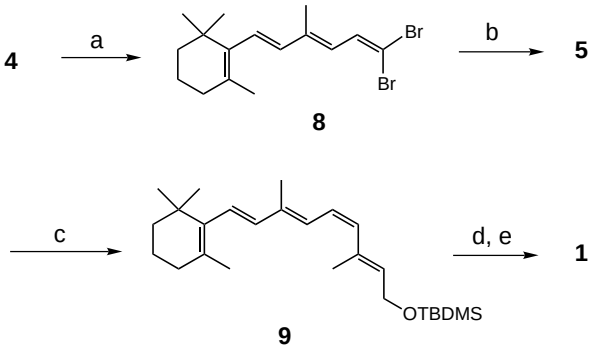
the geometries. It is important that this coupling is conducted very mildly without isomerization of the (11*Z*)-double bond in the conjugated pentaene. The key intermediate **5** can be obtained in geometrically pure form from the known aldehyde **4**[5] by the method we developed.[4]

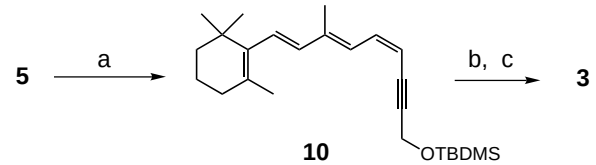


Scheme 1. Retrosynthesis of **1**–**3**; X = protecting group.

The synthesis of **1** requires the coupling partner **7**, which corresponds to the C13–C15 carbon chain; the synthesis of **7** is described in Scheme 2. A regio- and stereoselective addition of the tributylstannyl cuprate[6] to 2-butyn-1-ol gave (*E*)-3-tributylstannyl-2-buten-1-ol (**6**) in 83% yield.[7] Protection of the primary alcohol group of **6** with *t*BuMe$_2$SiCl (TBDMSCl) afforded the corresponding silyl ether in 93% yield. The tributylstannyl group was substituted with boronic acid in the three steps by the standard method:[8] 1) treatment of the alkenylstannane by alkenyllithium with BuLi, 2) quenching of the resulting alkenyllithium with triisopropyl boronate, and 3) hydrolysis of the boronate to boronic acid. The sequence gave **7** in 57% yield based on 2-butyn-1-ol.

Scheme 2. Synthesis of alkenylboronic acid **7**. a) $(Bu_3Sn)_2CuCNLi_2$, MeOH, THF, −10 °C; b) TBDMSCl, KH, THF, RT; c) 1. BuLi, THF, −78 °C; 2. B(O*i*Pr)$_3$; 3. aq HCl.

The construction of **1** from **4** is shown in Scheme 3. Aldehyde **4** was dibromomethylenylated at 0 °C with carbon tetrabromide and triphenylphosphane in dichloromethane[9] to afford **8** in 88% yield.[10] Stereoselective hydrogenolysis of **8** with tributyltin hydride in the presence of a catalytic amount



Scheme 3. Synthesis of **1**. a) CBr_4, PPh_3, CH_2Cl_2, 0 °C; b) cat. $[Pd(PPh_3)_4]$, Bu_3SnH, C_6H_6, RT; c) **7**, cat. $[Pd(PPh_3)_4]$, KOH, Ag_2CO_3, THF, RT; d) Bu_4NF, THF, RT; e) $BaMnO_4$, CH_2Cl_2, RT.

of $[Pd(PPh_3)_4]$ proceeded very cleanly to give **5** in 86% yield exclusively. This is an unstable molecule which decomposed easily upon exposure to light or acid. However, if kept in frozen benzene in the presence of a small amount of triphenylphosphane at −20 °C, **5** can be stored for one month. The Suzuki coupling of **5** with **7** was carried out in THF at room temperature in the presence of a catalytic amount of $[Pd(PPh_3)_4]$, Ag_2CO_3, and an aqueous solution of KOH to give **9** in 77% yield with retention of configuration. Removal of the silyl ether protecting group of **9** with tetrabutylammonium fluoride and successive oxidation with $BaMnO_4$ furnished isomerically pure **1** (85% yield over two steps). The spectroscopic data was in accordance with those reported for (11*Z*)-retinal.[11]

In the same manner as described for **1**, 13-demethyl-(11*Z*)-retinal (**2**) was obtained in 58% yield from **5**. Coupling of **5** with (*E*)-3-(*tert*-butyldimethylsilyl)oxy-1-propenyl-1-boronic acid[12] (90%, based on the recovery of **5**) followed by removal of the silyl ether protecting group (85%) and oxidation of the alcohol (76%) afforded **2** without the formation of any other stereoisomers.[13]

Palladium-catalyzed cross-coupling of **5** with O-protected propargyl alcohol introduced a C13 alkynyl component to form **3** instead of the *E*-ethenyl functionality in **1**. Scheme 4 depicts the synthesis of **3**. Intermediate **5** was coupled with

Scheme 4. Synthesis of **3**. a) *tert*-Butyldimethylsilyl propargyl ether, cat. $[Pd(PPh_3)_4]$, cat. CuI, *i*Pr$_2$NH, C_6H_6, RT; b) Bu_4NF, THF, RT; c) $BaMnO_4$, CH_2Cl_2, RT.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0321 $ 17.50+.50/0

tert-butyldimethylsilyl propargyl ether in the presence of $[Pd(PPh_3)_4]$ (5 mol%), CuI, and diisopropylamine in benzene under the standard Sonogashira conditions[14] to give **10** in 88% yield. The reaction proceeded without isomerization of the (11*Z*)-double bond. After the TBDMS group was quantitatively removed with Bu_4NF, the primary alcohol obtained was oxidized with $BaMnO_4$ to give **3** (68% yield over two steps).[15]

We have demonstrated an efficient and concise synthesis of geometrically pure (11*Z*)-retinals, in which a construction of the conjugated pentaene system involving the (*Z*)-alkenyl unit is achieved. (11*Z*)-Retinals prepared by this method exhibit perfect purity in their geometry. An advantage of this method is that it can be used to prepare a wide range of (11*Z*)-retinals and thus offers a further development in the research of vision.

Experimental Section

8: PPh_3 (1.92 g, 7.32 mmol) was added all at once to an ice-cooled, stirred solution of **4** (400 mg, 1.83 mmol) and CBr_4 (912 mg, 2.75 mmol) in CH_2Cl_2 (30 mL). The mixture was stirred for 5 min at the same temperature and then purified by column chromatography (silica gel, hexane) to give a mixture of **8** and retroionylidene bromide (638 mg, 8.8:1 ratio) in a combined yield of 98%. Oil; $R_f = 0.62$ (hexane); ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.03$ (6H, s), 1.44–1.50 (2H, m), 1.57–1.66 (2H, m), 1.71 (3H, d, $J = 0.9$ Hz), 1.91 (3H, d, $J = 1.2$ Hz), 2.01 (2H, br t, $J = 6.2$ Hz), 6.01 (1H, d, $J = 10.9$ Hz), 6.13 (1H, d, $J = 16.1$ Hz), 6.33 (1H, dd, $J = 16.1$, 0.8 Hz), 7.27 (1H, d, $J = 10.9$ Hz); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 13.5$, 19.2, 21.7, 28.9 (2C), 33.1, 34.2, 39.6, 90.7, 125.7, 129.6, 130.0, 133.6, 136.8, 137.6, 139.5; MS (70 eV): *m*/*z* (%): 376 (M^+, 52), 374 (M^+, 100), 372 (M^+, 50), 361 (19), 359 (34), 357 (20), 295 (11), 293 (11), 214 (29), 199 (38); HR-MS calcd for $C_{16}H_{22}Br_2$ (M^+): 376.0047, 374.0068, 372.0088; found: 376.0043, 374.0089, 372.0089.

5: A solution of Bu_3SnH (0.84 mmol, 2.27 mL, 0.37 M in benzene) was added to a mixture of **8** (298 mg, 0.8 mmol) and $[Pd(PPh_3)_4]$ (37 mg, 0.032 mmol) in benzene (5.7 mL) at room temperature. The mixture was stirred for 20 min, diluted with hexane (30 mL), washed with water (2 mL) and brine (2 mL), and dried over $MgSO_4$. The extract was concentrated under reduced pressure below 10 °C and purified by column chromatography (alumina, hexane) to give **5** (203 mg) in 86% yield. After addition of PPh_3 (30 mg), the mixture was frozen in benzene at −20 °C for storage. Oil; $R_f = 0.59$ (hexane); UV (hexane): $\lambda_{max} = 301$, 239 nm; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.03$ (6H, s), 1.44–1.49 (2H, m), 1.57–1.67 (2H, m), 1.72 (3H, d, $J = 0.8$ Hz), 1.94 (3H, d, $J = 1.0$ Hz), 2.02 (2H, br t, $J = 6.2$ Hz), 6.18 (1H, d, $J = 16.2$ Hz), 6.20 (1H, d, $J = 7.1$ Hz), 6.30 (1H, d, $J = 16.2$ Hz), 6.33 (1H, d, $J = 11.0$ Hz), 6.98 (1H, dd, $J = 11.0$, 7.1 Hz); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 13.3$, 19.2, 21.7, 28.9 (2C), 33.0, 34.2, 39.6, 108.2, 124.8, 128.9 (2C), 129.8, 137.2, 137.6, 139.7; MS (70 eV): *m*/*z* (%): 296 (M^+, 85), 294 (M^+, 99), 281 (21), 279 (18), 215 (100), 199 (35); HR-MS calcd for $C_{16}H_{23}Br$ (M^+): 296.0963, 294.0983; found: 296.0958, 294.0979.

9: $[Pd(PPh_3)_4]$ (42 mg, 0.036 mmol), an aqueous solution of KOH (7.2 mL, 2 N), and Ag_2CO_3 (398 mg, 1.44 mmol) were successively added at room temperature to a mixture of **5** (104 mg, 0.36 mmol) and **7** (268 mg, 0.88 mmol) in degassed THF (2.6 mL). The reaction mixture was stirred for 3 h at the same temperature, diluted with 10% ether in hexane (40 mL), washed with water (3 × 5 mL) and brine (5 mL), and dried over $MgSO_4$. The organic extract was condensed under reduced pressure below 10 °C, and the oily residue purified by column chromatography (silica gel, diethyl ether/hexane, 2/98) to give **9** (111 mg) in 77% yield. The material is very light-sensitive, and should be handled in the dark. Oil; $R_f = 0.18$ (hexane); UV (hexane): $\lambda_{max} = 322$, 236 nm; ^{1}H NMR (300 MHz, C_6D_6): $\delta = 0.08$ (6H, s), 0.99 (9H, s), 1.11 (6H, s), 1.44–1.51 (2H, m), 1.54–1.63 (2H, m), 1.73 (3H, s), 1.76 (3H, d, $J = 0.8$ Hz), 1.85 (3H, d, $J = 1.1$ Hz), 1.95 (2H, br t, $J = 6.2$ Hz), 4.26 (2H, d, $J = 6.6$ Hz), 5.88 (1H, t, $J = 6.6$ Hz), 5.90 (1H, d, $J = 11.8$ Hz), 6.28 (1H, d, $J = 16.0$ Hz), 6.38 (1H, d, $J = 16.0$ Hz), 6.38 (1H, dd, $J = 12.0$, 11.8 Hz), 6.88 (1H, d, $J = 12.0$ Hz); ^{13}C NMR (75 MHz, C_6D_6): $\delta = -5.0$, 12.3, 17.2, 18.4, 19.7, 21.9, 26.1 (2C), 29.1, 33.2, 34.5, 39.9, 60.4, 125.2, 127.0, 127.4, 129.1, 132.4, 133.4, 134.3, 136.8, 138.3, 138.9; MS (70 eV): *m*/*z* (%): 400 (M^+, 100), 385 (9), 343 (8), 269 (8), 254 (12), 199 (9); HR-MS calcd for $C_{26}H_{44}OSi$ (M^+): 400.3162; found: 400.3167.

10: A mixture of **5** (100 mg, 0.34 mmol), *tert*-butyldimethylsilyl propargyl ether (115 mg, 0.68 mmol), diisopropylamine (95 μL, 0.68 mmol), $[Pd(PPh_3)_4]$ (20 mg, 0.017 mmol), and CuI (6.5 mg, 0.034 mmol) in degassed benzene (3.4 mL) was stirred at room temperature for 30 min. The reaction mixture was diluted with hexane and washed with water (2 mL × 2) and brine (2 mL). The organic layer was dried over $MgSO_4$ and evaporated under reduced pressure below 10 °C. The crude mixture was purified by column chromatography (silica gel, diethyl ether/hexane, 2/98) to give **10** (115 mg) in 88% yield. The material is very light-sensitive, and should be handled in the dark. Oil; $R_f = 0.17$ (hexane); UV (hexane): $\lambda_{max} = 324$, 252 nm; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.15$ (6H, s), 0.93 (9H, s), 1.03 (6H, s), 1.44–1.49 (2H, m), 1.57–1.66 (2H, m), 1.72 (3H, d, $J = 0.9$ Hz), 1.95 (3H, d, $J = 0.9$ Hz), 2.02 (2H, br t, $J = 6.0$ Hz), 4.53 (2H, d, $J = 2.5$ Hz), 5.46 (1H, d, $J = 10.6$ Hz), 6.17 (1H, d, $J = 16.0$ Hz), 6.27 (1H, d, $J = 16.0$ Hz), 6.56 (1H, d, $J = 12.1$ Hz), 6.76 (1H, dd, $J = 12.1$, 10.6 Hz); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = -5.0$, 12.7, 18.3, 19.2, 21.7, 25.9 (2C), 28.9, 33.1, 34.2, 39.6, 52.5, 82.6, 95.2, 107.6, 126.9, 128.7, 129.8, 136.2, 137.4, 137.7, 139.1; MS (70 eV): *m*/*z* (%): 384 (M^+, 31), 369 (3), 327 (2), 149 (100); HR-MS calcd for $C_{25}H_{40}OSi$ (M^+): 384.2849; found: 384.2838.

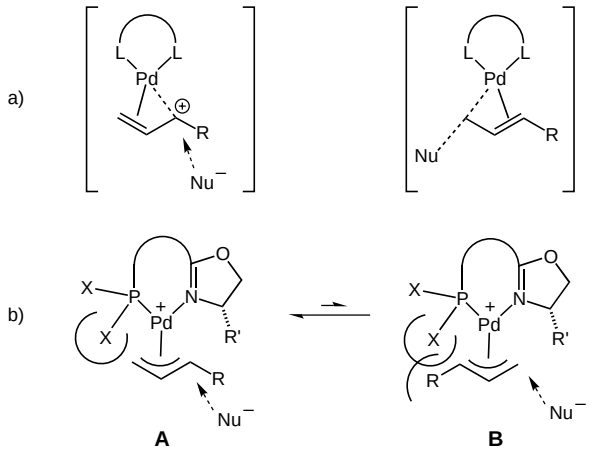
New Ligands for Regio- and Enantiocontrol in Pd-Catalyzed Allylic Alkylations

Roger Prétôt and Andreas Pfaltz*



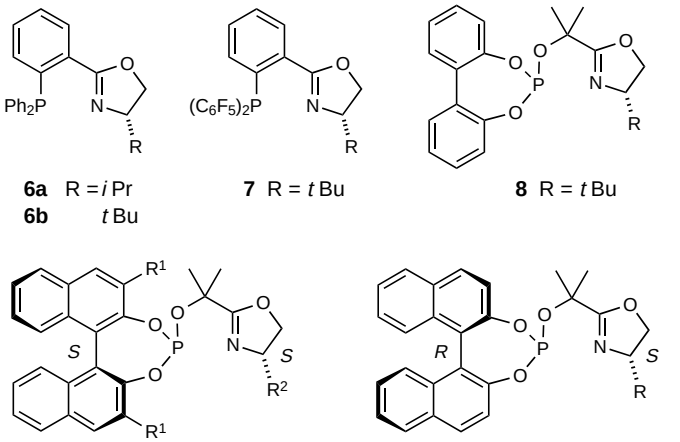
During the last few years dramatic progress has been made in the enantiocontrol of palladium-catalyzed allylic alkylations. New chiral ligands have been developed which can induce impressive levels of enantioselectivity in reactions with stabilized carbanions and various N-, O-, and S-nucleophiles.[1] However, the lack of regiocontrol is often a problem. For example, monosubstituted allylic substrates such as **1** and **2** (R = aryl) generally react predominantly at the unsubstituted allyl terminus (Scheme 1).[2] Consequently, the achiral, linear product **5** is formed rather than the chiral, branched isomer **4** or its enantiomer *ent*-**4**, which are the preferred products for applications in asymmetric synthesis. Although predominant formation of the branched isomers has been observed with achiral catalysts derived from other metals[3] (most notably W and Ir), the development of enantioselective catalysts for this class of substrate remains a challenge.

Scheme 1. Pd-catalyzed allylic alkylations generally produce the same products, regardless of whether substrate **1** or **2** is employed.

In 1995 we reported on the conversion of (*E*)-3-aryl-2-propenylphosphates **1** (R = aryl, X = OP(O)(OEt)$_2$) into chiral malonic acid derivatives **4** (Nu = CH(CO$_2$Me)$_2$).[4] High enantiomeric excesses and moderate to good regioselectivities were achieved with a tungsten catalyst prepared from the chiral (phosphanyloaryl)dihydrooxazole ligand **6a**[5] (see Scheme 3). The corresponding (*Z*) isomers and racemic substrates **2**, on the other hand, afford low enantioselectivities, in contrast with analogous Pd-catalyzed reactions, which generally proceed via rapidly equilibrating allyl intermediates and, therefore, in most cases give identical results with these three types of substrates.

Here we describe a new class of palladium catalysts that afford good enantio- and regioselectivities with both achiral and racemic aryl-substituted substrates **1** and **2**. The design of these catalysts was based on the following considerations: 1) Nucleophilic attack by an S_N2-type process should take place preferentially at the less substituted allyl terminus, whereas the opposite regioselectivity would be expected in an S_N1-like reaction via a cationic transition state (Scheme 2a).

Scheme 2. Nucleophilic attack in the Pd-catalyzed allylic alkylation. a) Transition states in S_N1- (left) and S_N2-like (right) processes. b) Steric encumbrance introduced by bulky substituents X on the P atom of the ligand favors attack of the substituted allyl terminus.



In order to enhance the S_N1 character, we decided to introduce electronegative substituents at the coordinating P atom that render the Pd center more electrophilic. 2) Steric factors affecting the equilibrium between allyl intermediates **A** and **B** also can play an important role (Scheme 2b). Bulky groups at the P atom are expected to destabilize isomer **B** as well as the transition states of the reaction pathways leading from **B** to the corresponding substitution products. Therefore, a pathway via **A** should be preferred and, assuming that nucleophilic attack at the allyl terminus *trans* to the Pd – P

bond is electronically favored,[6] reaction at the substituted allyl end should be facilitated. Although there are certainly other factors affecting the regioselectivity, these straightforward concepts put us on the right track.

Replacement of the phenyl groups at the P atom of **6b** by electron-withdrawing pentafluorophenyl groups (→**7**, Scheme 3)[7] shifted the regioselectivity in the desired direction from 4:96 to 48:57 (Table 1). A similar effect was observed when ligand **8** was used, which has a biphenylphosphite group in place of the diphenylphosphane substituent.

Scheme 3. Chiral ligands L* tested in the Pd-catalyzed allylic alkylation.

1a **4a** **5a**

Table 1. Results of enantioselective allylic alkylation [Eq. (1)] using different ligands L*.[a]

L*	Yield [%][b]	*ee* of **4a** [%][c]	**4a**:**5a**[d]
6b	90	78	4:96
7	87	84	47:53
8	75	81	63:37
9a	84	86	69:31
9a	86	90	76:24[e]
10	80	79	46:54
9b	92	77	68:32
9c	84	91	39:61
9d	88	92	55:45

[a] 1 mol% $[Pd(C_3H_5)Cl]_2$, 2.4 mol% L*, 50°C, CH_2Cl_2, 2 h; 2 equiv of $CH_2(CO_2Me)_2$ and *N*,*O*-bis(trimethylsilyl)acetamide (BSA), 4 mol% KOAc, 23°C, 18 h.[12] [b] Total yield of purified (*S*)-**4a** and (*E*)-**5a** after chromatography. [c] Determined by HPLC (Chiralcel OJ).[4] All reactions gave the (*S*)-(−) enantiomer. [d] Determined by GC analysis of the crude reaction mixture and ^{1}H NMR analysis after chromatography. [e] Reaction in benzene.

The regio- and enantioselectivities could be further improved by introduction of a second stereogenic unit derived from binaphthol. The best results were obtained with ligand (*S*,*S*)-**9a**; the (*R*,*S*) diastereomer **10**, derived from (*R*)-binaphthol, gave lower regio- and enantioselectivities. Apparently, the enantioselectivity is determined largely by the chiral dihydrooxazole ring. The chiral binaphthol unit has a minor, but still significant effect. The analogous isopropyldihydrooxazole ligand **9b** gave a somewhat lower *ee* value; the phenyldihydrooxazole ligand **9c**, on the other hand, was inferior in terms of regioselectivity. Introduction of two *ortho*-methyl groups in the binaphthol system (→**9d**) improved the enantioselectivity, but the regioselectivity decreased. The best results were achieved with ligand **9a** in benzene at 23°C (90% *ee*, **4a**:**5a** 76:24; Table 1) and in dichloromethane at −35°C (88% *ee*, 79:21).

Even better regio- and enantioselectivities were obtained with 1-naphthyl-substituted allylic acetates **1b** and **2b** (Table 2). The achiral substrates **1a**–**1c** afforded essentially the same regio- and enantioselectivities as the corresponding racemic isomers **2**. Apparently, the intermediate allyl complexes undergo rapid isomerization before they react with the nucleophile in the slower selectivity-determining step. The limitations of these catalysts become apparent with substrates **1d** and **2e**, which react with distinctly lower selectivities.

Table 2. Allylic alkylation of various substrates **1** and *rac*-**2** using ligand **9a** (Scheme 1; X = OAc, Nu = $CH(CO_2Me)_2$).[a]

	R	Yield [%][b]	*ee* of **4** [%][c]	**4**:**5**[d]

[a] For experimental conditions see Table 1. [b] Total yield of **4** and **5** after chromatography. [c] Determined by HPLC analysis (Chiralcel OJ and OD-H). Configurations of **4a** and **4b** were assigned by comparison to ref. [4]. [d] Determined by GC analysis of the crude reaction mixture and ^{1}H NMR analysis after chromatography. [e] Determined by GC analysis (Chiraldex G-TA). [f] Reaction in benzene.

A comparison of 3-phenyl-2-propenyl acetate **1a** with the corresponding *p*-methoxyphenyl- and *p*-cyanophenyl-2-propenyl acetates confirms that the regioselectivity is strongly affected by electronic factors. While the electron-donating *p*-methoxy substituent enhances the regioselectivity from 69:31 to 76:24 in favor of the chiral isomer (76% *ee*), the cyano group has the opposite effect, resulting in a reversed product ratio of 13:87 with the linear isomer **5** as the main product.

The synthesis of ligands **9** is straightforward (Scheme 4). Starting from various amino alcohols, hydroxy acids, and diols, a wide range of analogues can be readily prepared in this way. Libraries of ligands that are accessible by this route could be used to further optimize the selectivities obtained so far.

Our results demonstrate how the regioselectivity of allylic alkylations can be changed by systematic modification of the electronic and steric properties of the ligand attached to the

palladium catalyst. By using a new type of chiral P,N ligand, practically useful enantio- and regioselectivities have been obtained in the reaction with 1- and 3-aryl-2-propenyl acetates.[8] Although at present the range of substrates that afford good selectivities is limited to aryl-substituted derivatives, the concepts used for the design of ligands **9** may serve as guidelines for the development of new catalysts for different classes of substrates. In addition, these ligands have other possible applications in asymmetric catalysis.[9]

Experimental Section

9a: All reactions were performed under argon in degassed solvents. A solution of **10**[10] (1.1 g, 3.2 mmol) in toluene (10 mL) was added dropwise to Et_3N (2.6 g, 25.7 mmol) in toluene (20 mL) at $-78^\circ C$. This solution was stirred for 5 min at $-78^\circ C$ before a solution of **11**[11] (0.6 g, 3.2 mmol) in toluene (5 mL) was added quickly. The solution was allowed to gradually warm up to room temperature and stirred for 12 h. The white precipitate was removed by filtration. Evaporation of the solvent afforded a yellow oil, which was purified by column chromatography (silica gel, 3.0×20 cm; *n*-hexane/EtOAc 4/1, $R_f = 0.4$) to afford (*S*,*S*)-**9a** (890 mg, 56%) as an amorphous solid. $[\alpha]_{589} = +269$ ($CHCl_3$, $c = 3.1$, 23°C); ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 0.96$ (s, 9H; *t*Bu), 1.65 (s, 3H; Me), 1.75 (s, 3H; Me), 3.95–4.00 (m, 1H; HCN), 4.20–4.35 (m, 2H; CH_2O), 7.22–7.52 (m, 8H; arom. CH), 7.89–7.96 (m, 4H; arom. CH); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 25.8$ (*t*Bu), 28.1 (d, $J = 7.9$ Hz; Me), 28.2 (d, $J = 5.7$ Hz; Me), 33.9 (*t*Bu), 69.7 (CH_2O), 75.7 (CHN), 77.2 (C), 121.9/122.4 (arom. CH), 123.2 (arom. C), 124.5 (d, $J =$ 3.1 Hz; arom. C), 124.6/124.8/125.8/126.0/126.9/127.0/128.1/128.2/129.3/130.0 (arom. CH), 131.1/131.4/132.7/132.8 (arom. C), 147.9 (d, $J = 2.3$ Hz; arom. C), 148.0 (d, $J = 3.7$ Hz; arom. C), 168.3 (C=N); ^{31}P NMR (100 MHz, $CDCl_3$): $\delta = 151.5$.

Catalytic reactions (Tables 1 and 2) were carried out according to the literature procedure.[12] Purification and analytical data of the products are described elsewhere.[3b, 4].

Synthesis of a New Class of Solvent-Sensitive Fluorescent Labels

James J. La Clair*

Charge transfer (CT) labels such as 5-(dimethylamino)-naphthalene-1-sulfonyl (dansyl) chloride have been used extensively for the detection, characterization, and localization of carbohydrates, phospholipids, proteins, oligonucleotides, and numerous other synthetic and natural substances.[1] These materials typically experience shifts in their UV/Vis absorption and/or fluorescence bands depending on the nature of their solvent shells.[2] This effect together with modifications of fluorescence lifetimes, extent of intersystem crossing, and fluorescence quantum yield have encouraged

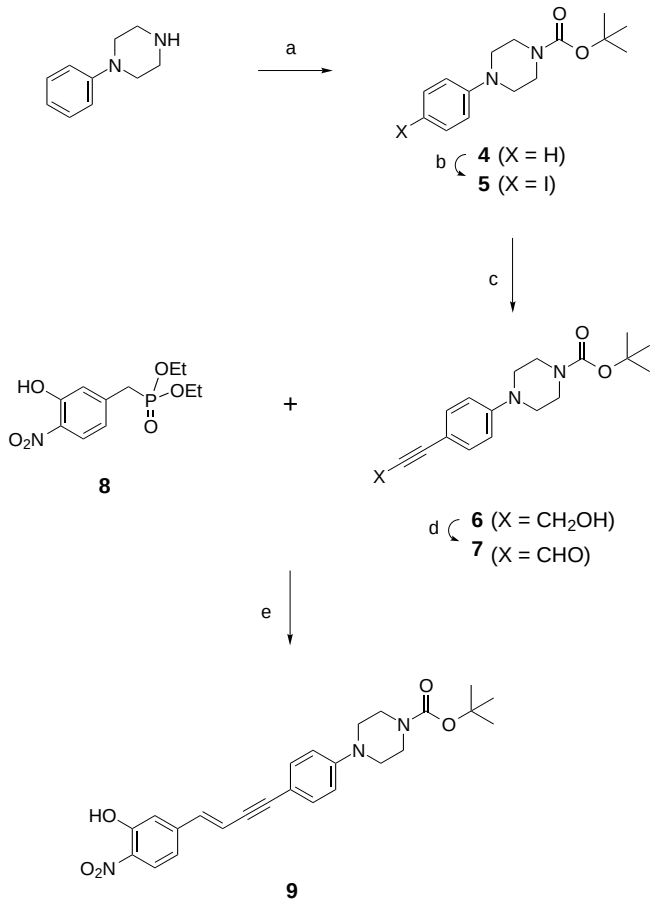
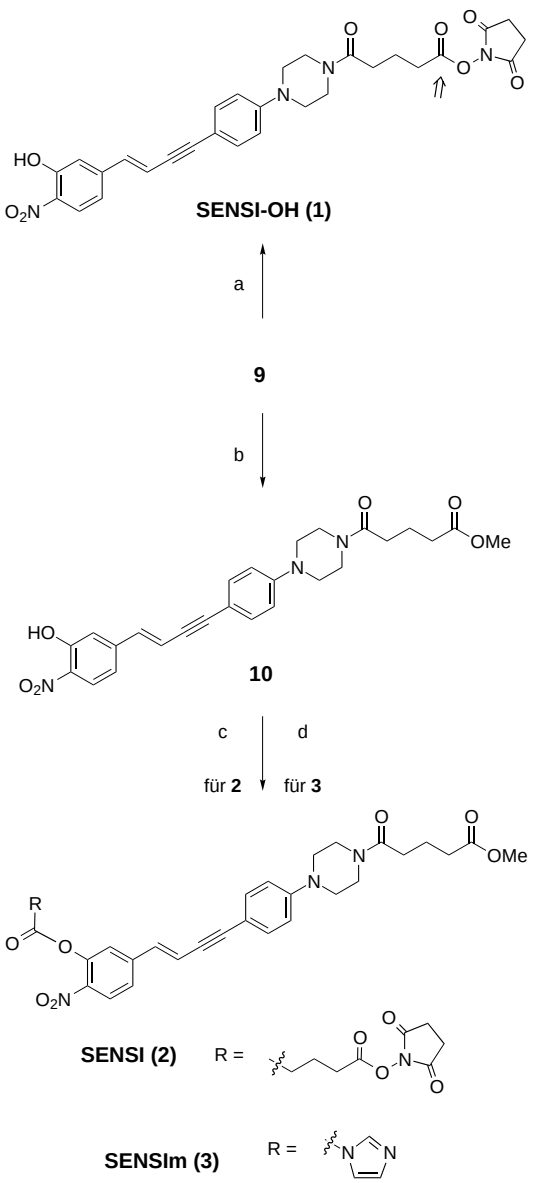
the use of such compounds as practical sensors for monitoring interactions between biologically relevant macromolecules.[3] Because of the extent of its aromaticity, the dansyl group absorbs light between $\lambda = 190$ and 400 nm, limiting its excitation primarily to the ultraviolet region.[4] We describe here the synthesis of a new class of intramolecular charge-transfer labels that absorbs both visible and ultraviolet light, displays dramatic solvent sensitivity, and can be detected at the single-molecule level.



Recent studies have shown that fluorescence from 1-[4-(*N,N*-dimethylamino)phenyl]-4-(3-hydroxy-4-nitrophenyl)-3-(*E*)-buten-1-yne (DHNB) is dramatically affected by the nature of its solvent shell, whereas its UV/Vis absorption is altered only minimally.[5] For example, DHNB dissolved in methanol absorbs light with a maximum at 421 nm ($\varepsilon = 50\,800\ cm^{-1}M^{-1}$) and fluoresces at 528 nm with a quantum efficiency of 0.000017. However, in a nonpolar aprotic solvent such as *n*-hepane the absorption maximum undergoes a bathochromic shift to 435 nm ($\varepsilon = 47\,400\ cm^{-1}M^{-1}$), and the fluorescence quantum yield is enhanced by approximately 1000-fold to 0.0188 and 0.0205 at 593 and 570 nm, respectively. In an effort to devise new systems for monitoring the interactions of single molecules, we employed DHNB to selectively detect single aggregates of a complex consisting of a carbohydrate and a protein.[5] This communication describes the synthesis of a family of DHNB derivatives that can be used to label a wide variety of biologically significant molecules.

Scheme 1 depicts the current design, which mimics the functionality in the DHNB group. A hydroxy group adjacent

Scheme 1. Design of a new fluorescence label.



to the nitro group enhances the fluorescence quantum yield and serves as a site for the attachment of an additional functionality.[6] The dimethylamino group of DHNB was then replaced with a piperazine unit, which not only enhances the water solubility of the dye but also provides a handle for further linkage. *N*-Phenylpiperazine was chosen as the starting material for this synthesis because it is commercially available and inexpensive (ca. 1 DM per gram). Synthesis of the model compound begins with the halogenation of protected piperazine **4**[7] with iodine in a biphasic mixture of aqueous sodium bicarbonate and dichloromethane (Scheme 2). After one recrystallization, iodide **5** was coupled with the aid of transition metal catalysis to the C terminus of propargyl alcohol. The resulting alcohol **6** was then oxidized to aldehyde **7** with manganese dioxide, and subsequently

Scheme 2. a) Di-*tert*-butyl dicarbonate, Et_3N, DMAP, CH_2Cl_2, 0 °C → RT, 94 %; b) 1. iodine, $NaHCO_3$, CH_2Cl_2, H_2O, 12–15 °C, 10 min; 2. RT, 30 min, 90 %; c) propargyl alcohol, $[PdCl_2(PPh_3)_2]$, CuI, Et_3N, THF, RT, 18 h, 85 %; d) MnO_2, CH_2Cl_2, RT, 6 h, 98 %; e) 1. addition of NaHMDS in THF to **8** in DMF, 0 °C → RT, 1 h; 2. addition of **7** in THF, −20 °C → RT, 8 h, 62 %.

condensed with the dianion of phosphate **8**[6] to produce **9** (Table 1). The overall yield of this process ranged from 41 to 45 % on a one-gram scale. Deprotection of piperazine **9** with sulfuric acid in wet tetrahydrofuran provided a junction for attachment of a wide variety of reactive linkages. For example, the amine-reactive label SENSI-OH (**1**) was prepared by allowing the deprotected piperazine to react with glutaric anhydride and then converting the terminal carboxylic acid group into an *N*-hydroxysuccinimide ester functionality with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC; Scheme 3). The phenol function can also be used as a site for linkage, as shown in SENSI (**2**). Attachment to this site offers the advantage that the bond can be broken hydrolytically. Synthesis of **2** was achieved by converting the *t*boc-protected derivative **9** into **10**[8] (Table 1, *t*boc = *tert*-butoxycarbonyl), which in turn reacted with *N*-hydroxysuccinimidyl glutaryl chloride to provide **2**. Other systems, such as the one-carbon-linked SENSIm (**3**), were prepared by the same route. These three derivatives readily reacted with bovine serum albumin (BSA) under standard conditions. Addition of four equivalents of **1** per equivalent of BSA provided conjugates containing approximately 2.1 molecules of dye per molecule of BSA. The efficiency of the two phenol-

linked derivatives **2** and **3** was much lower (1.2 and 0.8 fluorescent units per molecule of BSA, respectively). This is probably a result of hydrolysis of the phenolic ester linkage during coupling. The conjugates of BSA with **2** and **3** were stable between pH 5.9 and 8.1, where only minimal dye release was visible during dialysis.[9] However, considerable hydrolysis occurred outside this region, often leaving only small amounts of label intact.

The spectroscopic properties of the new materials resemble those of DHNB. For instance, the UV/Vis absorption maximum of **10** was red-shifted by 33 nm upon changing the solvent from *n*-heptane to methanol (Table 2). The extinction coefficient was largest in aromatic solvents such as benzene and toluene, and decreased with increasing polarity. The intensity of the B band was between 14 and 63% greater than that of the K band in most solvents other than DMF.[10] The fluorescence band of **10** shifted by 111 nm and was 120 times more intense when methanol was replaced by *n*-heptane. Enhancement of fluorescence intensity was only one-eighth that observed with the parent DHNB. This may be due to the fact that the piperazine ring has a greater tendency to conjugate with the aryl π system than the dimethylamino group, which restricts its freedom to rotate and form additional fluorescence states.[11] As indicated in Table 3, single

[a] The reported data have been averaged over several iterations with deviations of less than 5%. Unavoidable traces of moisture undoubtedly decreased the intensity of these values. Precautions were taken to minimize contact with moisture, and all solvents were either purchased dry or distilled. [b] E_T is a measure of solvent polarity. See ref. [2a]. [c] The K band is defined as the lower and the B band as the higher wavelength band. [d] The range is defined as the region within which the signal intensity exceeded 5% of the maximum absorption or fluorescence. [e] Quantum yields were standardized against the value 0.70 for rhodamine B in ethanol.

Table 3. Single-molecule detection of **10**.[a]

Solvent	Detection limit [nM][b]	Extent of decomposition after 5 min [%]
n-heptane	0.015	1

$CHCl_3$	0.95	3
acetone	14	4
DMF	17	3
acetonitrile	89	2
ethanol	128	2
methanol	205	5
water	625	4

[a] Excitation with an argon ion laser at 457 nm (0.5 mW). The fluorescence was observed through a filter with a cutoff at 545 nm. [b] The detection limit is the concentration at which transients from single molecules were no longer resolved from the baseline.

molecules derived from these dyes were detectable at submicromolar concentrations in polar solvents (e.g., THF, chloroform, acetone, acetonitrile, DMF, ethanol, methanol, and water) with the aid of a confocal fluorescence correlation spectrometer.[12] Single molecules were detected at far lower concentrations in nonpolar solvents such as *n*-heptane, providing a gain in response of approximately 40000 for selective detection of single molecules. Investigations into the use of these markers as a probe for interactions between molecules and lipophilic surfaces are currently in progress.

Experimental Section

5: Di-*tert*-butyl dicarbonate (4.5 g, 20.6 mmol) was added in small portions over 15 min to a mixture of *N*-phenylpiperazine (3.0 mL, 19.6 mmol), triethylamine (8.2 mL, 58.9 mmol), and 4-dimethylaminopyridine (DMAP; 86 mg) in anhydrous CH_2Cl_2 (100 mL) at 0 °C. Ten minutes after addition was complete the mixture was warmed to room temperature (RT). After 1.5 h it was diluted with CH_2Cl_2 (200 mL) and water (100 mL), and extracted. The aqueous phase was further extracted with CH_2Cl_2 (2 × 100 mL). The combined organic extracts were washed with saturated aqueous NaCl, dried over Na_2SO_4, and concentrated to yield 4.87 g (94%) of **4**. Iodine (5.0 g, 19.7 mmol) was added over 45 min to a mixture of **4** (5.46 g, 20.8 mmol) and $NaHCO_3$ (2.62 g, 31.2 mmol) in CH_2Cl_2 (80 mL) and water (60 mL), which was kept between 12 and 15 °C. After addition was complete the mixture was warmed to room temperature, and this temperature was maintained for 30 min. The mixture was then diluted with CH_2Cl_2 (500 mL) and water (100 mL), and the organic phase was collected and washed consecutively with water (50 mL), a solution ofL sodium thiosulfate (100 m), water (2 × 100 mL), and a saturated solution of aqueous NaCl (100 mL). The crude product was dried over Na_2SO_4, concentrated, and recrystallized from *n*-hexane/THF (10/1) to yield 6.95 g (90%) of **5**.

9: A mixture of **5** (1.17 g, 3.02 mmol), $[PdCl_2(PPh_3)_2]$ (21.2 mg, 0.032 mmol), and CuI (5.7 mg, 0.032 mmol) in THF (2 mL) and triethylamine (5 mL) was degassed by rapid bubbling of dry argon through it for 15 min. 2-Propyn-1-ol (0.193 mL, 3.32 mmol) was then added to the vigorously stirred mixture. Three hours later a second batch of $[PdCl_2(PPh_3)_2]$ and CuI was added. The reaction was complete within 18 h. Strict maintenance of an argon atmosphere was crucial to the yield of this step. The crude solution was filtered through silica gel (30 g) with methanol/ethyl acetate (5/95), and the eluate was concentrated. Flash chromatography (SiO_2, ethyl acetate/hexane 1/3) led to pure **6** (815.2 mg,

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0328 $ 17.50+.50/0 *Angew. Chem. Int. Ed.* **1998**, *37*, No. 3

85%). Activated MnO_2 (0.507 g, 5.83 mmol) was added to **6** (615.0 mg, 1.94 mol) in CH_2Cl_2 (18 mL) at RT. After 6 h the reaction mixture was purified directly by flash chromatography (SiO_2, ethyl acetate/hexane 1/3), yielding 602.1 mg (98%) of **7**. Sodium bis(trimethylsilyl)amide (4.79 mL, 1.0 M in THF, 4.79 mmol) was added to a solution of phosphonate **8** (621 mg, 2.15 mmol) in DMF (6.0 mL) at 0 °C. The solution was warmed to RT after 30 min at 0 °C and kept at RT for 20 min, after which it was again cooled to −20 °C. A solution of aldehyde **7** (376.5 mg, 1.19 mmol) in THF (10 mL) was added by syringe. After 8 h at room temperature water (5 mL) was added, the pH adjusted to 7 with 5% aqueous HCl, and the mixture further diluted with a saturated solution of aqueous NaCl (10 mL). The crude product was obtained by extraction with THF/CH_2Cl_2 (1/9, 3 × 40 mL), drying over Na_2SO_4, and concentration. Flash chromatography (SiO_2, $CHCl_3$/hexane 1/2) and recrystallization from *n*-heptane/THF (10/1) yielded 331.4 mg (62%) of **9**.

1: Concentrated sulfuric acid (130 μL) was added to **9** (82.1 mg, 0.178 mmol) in THF/H_2O (1/9, 9 mL) at 0 °C. After 20 min a saturated solution of aqueous sodium bicarbonate was added until a pH of 6.5 was reached, followed by a saturated solution of aqueous NaCl (15 mL). The crude product was obtained by extraction with THF/CH_2Cl_2 (1/9, 3 × 60 mL), drying over Na_2SO_4, and concentration. The residue was treated with glutaric anhydride (26.4 mg, 0.231 mmol) and DMAP (≈3 mg) in anhydrous THF (8 mL). After 2 h at room temperature *N*-hydroxysuccinimide (40.9 mg, 0.356 mmol) was added followed by EDC (119.4 g, 0.623 mmol). Twelve hours later water (10 mL) was added, and the pH adjusted to 6.5 with dilute Hcl. The mixture was extracted with THF/CH_2Cl_2 (1/9, 3 × 80 mL), dried over Na_2SO_4, and evaporated. Recrystallization from *n*-heptane/THF (2.5/1) provided 80.7 mg (81%) of pure **1**.

2: Concentrated sulfuric acid (80 μL) was added to **9** (49.5 g, 0.107 mmol) in THF/H_2O (1/9, 5 mL) at 0 °C. After 20 min a saturated solution of aqueous sodium bicarbonate was introduced until the pH reached 7.0, followed by a saturated solution of aqueous NaCl (10 mL). The crude product was obtained by extraction with THF/CH_2Cl_2 (1/9; 3 × 40 mL), drying over Na_2SO_4, and concentration. The residue was immediately dissolved in anhydrous THF (5 mL) and treated with glutaric anhydride (14.6 mg, 0.128 mmol) and DMAP (≈2 mg). After 2 h at room temperature anhydrous methanol (0.2 mL) was added followed by EDC (61.7 mg, 0.321 mmol). Esterification was complete after 4 h (TLC). Water (10 mL) was then added, and the product isolated by adjustment of the pH to 6.5 with dilute HCl followed by extraction with THF/CH_2Cl_2 (1/9, 3 × 40 mL), drying with Na_2SO_4, and rotary evaporation. Recrystallization from *n*-hexane/THF (3/1) provided 39.2 mg (77%) of pure **10**. *N*-Hydroxysuccinimidyl glutaryl chloride (81.1 mg, 0.327 mmol) was added to **10** (41.9 mg, 0.0953 mmol) and DMAP (ca. 1 mg) in anhydrous THF (5 mL). After 12 h at room temperature water was added (10 mL), and the product isolated by adjustment of the pH to 6.5 with dilute HCl followed by extraction with THF/CH_2Cl_2 (1/9, 3 × 30 mL). The extract was dried over Na_2SO_4 and concentrated by rotary evaporation. Recrystallization from a mixture of *n*-heptane/THF (3/1) led to 40.9 mg (64%) of **2**.

Coupling with BSA: Bovine serum albumin (BSA) used in these studies was purchased from Sigma, product A7030. A solution of **1** (1.2 mg, 2.14 μmol) in DMF (50 μL) was added in five portions to a solution of BSA (35.9 mg, 0.54 μmol) in a phosphate-buffered solution of NaCl (PBS, 5 mL; 0.15 mM NaCl, 8.1 mM Na_2HPO_4, 1.5 mM NaH_2PO_4). The mixture was allowed to react to completion for 8 h at room temperature, diluted with water (5 mL), dialyzed extensively against water (Spectra/por MWCO 12000–14000), and lyophilized to dryness. An absorption spectrum was recorded from 2–3 mg of this material, which was dissolved in 500 μL of PBS. The approximate number of fluorophores per protein molecule was then calculated based on the known absorption of **1** in PBS and the concentration of labeled BSA.

Crystal Structures of Chiral Diastereoisomers of a Carbon-Based High-Spin Molecule**

Josep Sedó, Nora Ventosa, Daniel Ruiz-Molina, Montserrat Mas, Elies Molins, Concepció Rovira, and Jaume Veciana*

The study of organic magnetic materials constitutes a whole field of basic research which has grown because of the capacity of covalent bonds to enhance magnetic interactions.[1] Owing to the versatility of organic synthesis, organic materials can be prepared that display two or more unusual physicochemical properties simultaneously, for instance, magnetism and electron transfer or electron transport.[2a–c] Nevertheless, there are still no examples of purely organic materials that have magnetic properties and are chiral;[3] novel properties are expected for such compounds.[4] Here we report for the first time the crystal structures of the stereoisomers and the resolution of optically active enantiomers of a purely organic high-spin molecule having carbon radical centers.

Open-shell compound **1** was synthesized by an established two-step procedure from its chlorinated hydrocarbon precursor.[5a–c] Both its electrochemical and spectroscopic properties

1 R = H
2 R = Cl

(Table 1) are similar to those of the previously described perchlorinated analogue **2**,[5c] but the absence of chlorine atoms in all *meta* positions leads to an improved solubility in apolar solvents and, apparently, a greater tendency to form high-quality single crystals. For triphenylmethyl-based molecules with three radical centers such as **1** theoretical studies[5,6] led us to assume that only two pairs of enantiomers were expected,[5c] one having C_2 symmetry and one showing D_3 symmetry. Crystallization efforts in *n*-alkanes yielded systematically the same kind of crystalline material. One of these samples afforded a single crystal of **1**/*n*-heptane 1:1 clathrate suitable for X-ray diffraction which, once solved, showed the

Table 1. Electrochemical and spectroscopic properties of **1** and **2**.

	1	**2**[a]
$E^{1/2}$[b]	− 0.07	− 0.41
	− 0.35	− 0.71
	− 0.62	− 1.00
$\lambda(\varepsilon)$[c]	377 (7.2×10^4)	388 (9.1×10^4)
	495 (3.1×10^3)	508 (4.6×10^3)
	539 (3.0×10^3)	558 (4.4×10^3)

[a] Data of **2** are from ref. [5c] and are given for comparison. [b] Standard reduction potentials ($E^{1/2}$) measured in V vs. $Ag^+/AgCl$ in 0.1 M (tBu$_4$N)PF$_6$ solution of CH_2Cl_2 using Pt wires as working and counter electrodes; [c] Wavelengths (λ) in nm and molar extinction coefficients (ε) in $M^{-1}cm^{-1}$.

structure of the C_2 diastereomer (Figure 1, top).[7a] Only once were we lucky enough to get a single crystal of **1**/*n*-pentane 2:1 clathrate[7b] containing the D_3 diastereomer (Figure 1, bottom). Both crystal structures are centrosymmetric and contain racemic mixtures of enantiomers. Molecules such as **1** and **2** may be thought of as constituted of three triphenylmethyl moieties sharing the innermost ring. From the conformational point of view, the overall molecular symmetry is determined by the combined helicities—plus (*P*) or minus (*M*)—of all the propellerlike moieties. In a D_3 conformation all three moieties have the same helicity (in other words, the combined helicity is either *PPP* or *MMM* depending on the enantiomer in question). In contrast, in a C_2 conformation the helicity of one of the moieties is opposite to that of the other two (in other words, the combined helicity of its enantiomers is either *MMP* or *PPM*). In terms of geometry, the helicity in each moiety may be expressed by the sign of the torsion angle defined by the following four atoms: the bridge-C(ar) atom of the innermost ring, the radical-C atom, the bridge-C(ar) atom of an external aromatic ring, and the *ortho*-C(ar) atom of the ring that is *syn* with respect to the first bridge-C(ar) atom. The noncoplanarity is thus accounted for by the absolute value of this torsion angle (Figure 1, insets). As a matter of fact, molecules of **1**/*n*-heptane clathrate show average torsion angles of $48 \pm 5°$, $48 \pm 2°$, and $-45 \pm 3°$, while those of **1**/*n*-pentane clathrate have average angles of $50 \pm 2°$, $49 \pm 2°$, and $49 \pm 1°$. Notwithstanding minor distortions due to crystal packing forces, these values indicate that the structures formally correspond to C_2 and D_3 conformations of **1**, respectively. The degree of noncoplanarity in each moiety is very similar to that found in simple triphenylmethyl monoradicals,[5a] indicating that the strongest steric interactions by far are those in the immediate surroundings of the radical center inside each moiety. Moreover, in both conformers all the distances between the geometrical centers of aromatic rings belonging to different moieties are greater than 5 Å, and no van der Waals contacts between atoms of different moieties are evident. Overall, triphenylmethyl moieties of **1** can be considered to be fairly independent of each other, regardless of the specific conformation. The three open-shell centers of both diastereomers show no or small deviations from planarity of at most 0.10 Å, which is in agreement with the values measured for analogous monoradicals.[5a] Bond lengths such as C(radical) – C(ar) average out at 1.46 ± 0.01 Å for the C_2 isomer and 1.49 ± 0.04 Å for the D_3, implying partial delocalization of the unpaired electron towards the aromatic

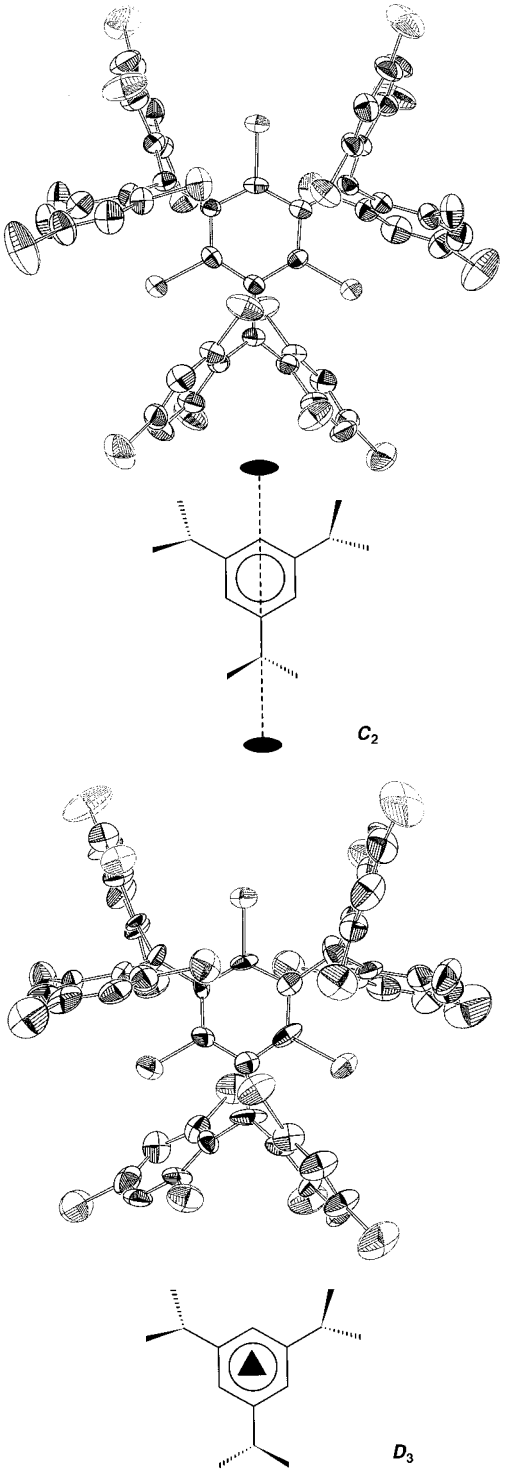

Figure 1. ORTEP views of the crystallized diastereomers of **1** having C_2 (top) and D_3 symmetry (bottom). Insets show schematically the orientation of the principal symmetry axis for each diastereomer.

rings. Other relevant bond lengths such as C(ar)–C(ar) (1.39 ± 0.03 Å for the C_2 isomer, 1.38 ± 0.03 Å for the D_3) and C(ar)–Cl (1.73 ± 0.01 Å and 1.74 ± 0.03 Å, for the C_2 and D_3 isomers, respectively) largely coincide with those observed in highly chlorinated triphenylmethyl radicals.[5a] Intermolecular distances in both crystals are very similar to those observed in analogous monoradical compounds[5a] so that regions with the largest spin densities of neighboring molecules are far away from each other.

Standard reversed-phase HPLC confirmed that **1** crystallizes in a single diastereomeric form (C_2) almost systematically, in the same way as its perchlorinated analogue **2**.[5c] This diastereomer is the most abundant one in solution, even though in such media it converts very slowly into the other diastereomer at room temperature, indicating a high energy barrier for this process. Such a dynamic process can be quenched by lowering the temperature and it can be therefore properly characterized. Thus, we determined an equilibrium constant at 298 K for the interconversion process in acetonitrile/THF (2:1) of $K_{eq} = C_2/D_3 = 0.34 \pm 0.01$. This value remains largely unchanged in other solvent mixtures such as toulene/CH_2Cl_2 (3:1). Kinetic studies of the C_2/D_3 equilibrium yielded an activation free energy of $\Delta G^{\neq}_{298} = 93 \pm 1$ kJ mol^{-1}. We carried out analytical chiral chromatography on the pure C_2 diastereomer of **1** in hexane/2-propanol (90:10) using an on-line dual detection technique (UV and polarimetry) in order to resolve the C_2 diastereomer into its optically active enantiomers. As expected, the UV signal recorded throughout shows two peaks (Figure 2) which, in spite of a slight overlap, can be mathematically deconvoluted. The area of

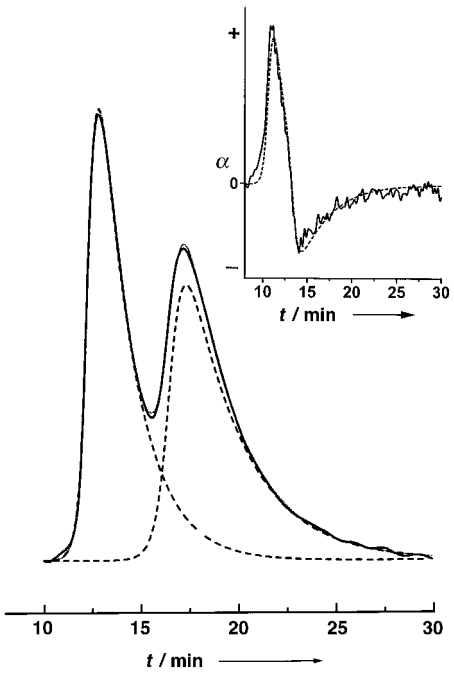

Figure 2. HPLC resolution of the C_2 racemic mixture of **1**. UV signal (240 nm); heavy line: experimental; thin line: simulated; dashed line: deconvoluted peaks. The ratio of peak areas is 1.04 ± 0.02. Inset: polarimetric signal (589 nm); solid line: experimental; dashed line: simulated. The separation was carried out using a Daicel CHIRALPAK OT(+) column (0.46 × 25 cm) with a flow rate of 1.0 mL min^{-1}, *n*-hexane/2-propanol (9:1) at 261 K.

both peaks is the same, as required for the resolution of any racemic mixture. This data was used further to simulate the polarimetric signal (Figure 2, inset). Despite a poor signal-to-noise ratio due to the concentration of the chiral species, an

excellent agreement between simulation and experiment was found, fully confirming the resolution of the two truly enantiomeric species.

The ESR spectrum of the C_2 diastereomer of **1** in frozen media shows a pattern characteristic of a single molecule in a quartet spin state. The derived zero-field splitting parameters (Table 2) are in accordance with the assignment of nonaxial

Insets show the half-field signal at 115 K (left), and the one-third-field signal at 5 K (right).

the spectrum requires the presence of about 25 % of another diastereomer with axial symmetry. This finding is in full agreement with the expected D_3 symmetry of **1** as well as with the C_2/D_3 equilibrium ratio estimated by HPLC analysis. At higher concentrations of the radical, and in accordance with the expected $S = 3/2$ spin state for the molecule, both the $\Delta M_s = \pm 2$ ($g \sim 4$) and $\Delta M_s = \pm 3$ ($g \sim 6$) signals at half and one-third of the original field, respectively, are clearly observed in the ESR spectra (Figure 3, insets). Since signals in the $g \approx 6$ spectral range only for states higher than or equal to a quartet, the evidence of the latter signal provides straightforward proof of the spin state of **1**. The dependence of the integrated intensity of this signal with temperature followed the Curie law in the temperature range 4–70 K, confirming that **1** has a $S = 3/2$ high-spin ground state in diluted, frozen solutions. Furthermore, both magnetic susceptibility and magnetization measurements on a polycrystalline sample of **1** showed Curie–Weiss behavior typical of a robust quartet state ($S = 3/2$) with thermally inaccessible (up to 300 K) low-spin excited states, ($C = 1.83$ emu K mol^{-1} and $\theta = -0.3$ K) although the structure is nonplanar.[8] The very low value of the Weiss constant indicates that the intermolecular interactions are very weak and, if anything, antiferromagnetic. Therefore, the overall magnetic behavior is close to that of an ideal paramagnet, in complete agreement with the long intermolecular distances observed in the reported crystal structures.

We have described the synthesis and most relevant properties of the first purely organic high-spin molecule which was resolved into its enantiomers by chiral HPLC. The isomerism was characterized by a combination of indirect techniques and, for the first time, by single-crystal X-ray diffraction. In this respect, the two solid-state structures, each corresponding to a different diastereomer of the molecule, constitute the first two examples of crystal structures of a carbon-based high-spin radical.

A Chemically and Electrochemically Switchable [2]Catenane Incorporating a Tetrathiafulvalene Unit**

Masumi Asakawa, Peter R. Ashton, Vincenzo Balzani,* Alberto Credi, Christoph Hamers, Gunter Mattersteig, Marco Montalti, Andrew N. Shipway, Neil Spencer, J. Fraser Stoddart,* Malcolm S. Tolley, Margherita Venturi,* Andrew J. P. White, and David J. Williams*

Highly efficient constructions of mechanically interlocked molecules,[1] such as catenanes and rotaxanes, have followed rapidly in the wake of the development of self-assembly[2] in synthetic supramolecular chemistry.[3] The opportunity now exists to control the relative dispositions of one component with respect to the other(s) in such molecules by either chemical[4] or electrochemical[4a, 5] means. In this context, the tetrathiafulvalene[6] (TTF) unit represents a particularly attractive building block, since it can be oxidized sequentially and reversibly to the monocation ($E_{1/2}=+0.32$ V) and the dication ($E_{1/2}=+0.72$ V). Its redox properties, together with its ability to form[7, 8] a strong green 1:1 complex in both the solution and solid states with cyclobis(paraquat-*p*-phenylene) tetrakis(hexafluorophosphate),[9] have been largely responsible for its incorporation into the thread-like components of pseudorotaxanes,[10] as well as into catenanes[11] and rotaxanes.[8, 12] Here, we describe 1) the self-assembly of a [2]catenane comprising a macrocyclic polyether ring with two π-electron-rich "stations"—namely a 1,5-dioxynaphthalene moiety and a TTF unit—and the π-electron-deficient cyclobis(paraquat-*p*-phenylene),[9] 2) its solid-state structure and superstructure, 3) its spectroscopic characterization in solution, and 4) its ability to be switched both chemically and electrochemically, at the molecular level, between two different "states".

The [2]catenane $\mathbf{5}\cdot 4PF_6$ was self-assembled in 23% yield, as a pure compound, by employing a "*cis*–*trans*" isomeric mixture of the crown ether incorporating TTF (**3**) as a template for the formation of catenated cyclobis(paraquat-*p*-phenylene) from $\mathbf{4}\cdot 2PF_6$ and paraxylylene dibromide (Scheme 1). A 55% yield of **3** was obtained by treatment of

Scheme 1. The self-assembly of the [2]catenane $\mathbf{5}\cdot 4PF_6$ in which the TTF crown ether **3** obtained from diol **1** and dibromide **2** in the presence of a base serves as template for the formation of the cyclobis(paraquat-*p*-phenylene) tetracation.

the TTF-diol **1**[13] with NaH in THF containing the dibromide **2**.[14] Slow diffusion of iPr_2O into a MeCN solution of $\mathbf{5}\cdot 4PF_6$ produced deep bluish-green crystals suitable for X-ray structural analysis.[15] In the solid state the TTF portion of the crown ether is positioned on the "inside" of the tetracationic cyclophane and the 1,5-dioxynaphthalene ring system "alongside" it[16] (Figure 1). The TTF is steeply inclined to the plane of the cyclophane, its central C–C bond subtending an angle of 74° to this plane—a value that is noticeably larger than the 66° observed in the 1:1 complex formed[7,8] between TTF and the cyclobis(paraquat-*p*-phenylene) tetracation.[9] It is important to note that, of the two

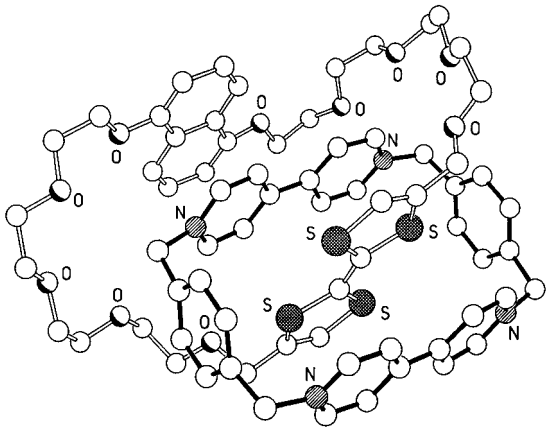

Figure 1. A ball-and-stick representation of the solid-state structure of the [2]catenane $\mathbf{5}^{4+}$.

possible constitutional isomers of the disubstituted TTF, *only* the "*trans*" isomer is observed in the solid state; the [2]catenane structure thus displays a chiral plane.[17] The complex is stabilized by the normal combination of $\pi-\pi$ stacking interactions[18] and [C–H···O] hydrogen bonds[19] from α-bipyridinium hydrogen atoms (the latter, in one instance, to the second oxygen atom from the TTF in one polyether chain and, in the other, to the first oxygen atom from the TTF in the other polyether chain).[20] The catenane molecules pack to form "conventional" polar stacks with a 3.29 Å separation between the 1,5-dioxynaphthalene and bipyridinium ring systems of *C*-face centrally translated molecules.

The UV/Vis spectrum of the [2]catenane $\mathbf{5}\cdot 4PF_6$ (Figure 2, curve a) reveals a charge transfer (CT) absorption band centered on 835 nm ($\varepsilon = 3500\,M^{-1}cm^{-1}$) characteristic of structures containing a TTF unit "inside" the tetracationic

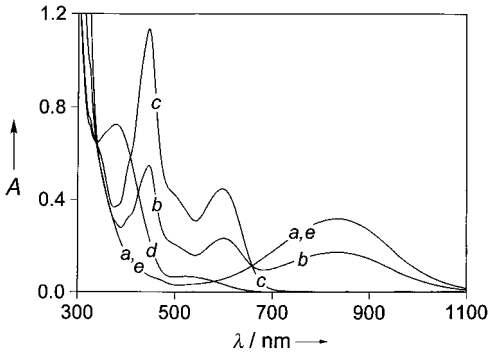

Figure 2. Absorption spectra (MeCN, 298 K) of a 9×10^{-5} M solution of [2]catenane $\mathbf{5}^{4+}$ (curve a) and of the same solution after addition of 0.4, 1.0, and 2.0 equiv of $Fe(ClO_4)_3$ (curves b–d). Addition of 2 equiv of ascorbic acid gives back the original spectrum (curve e).

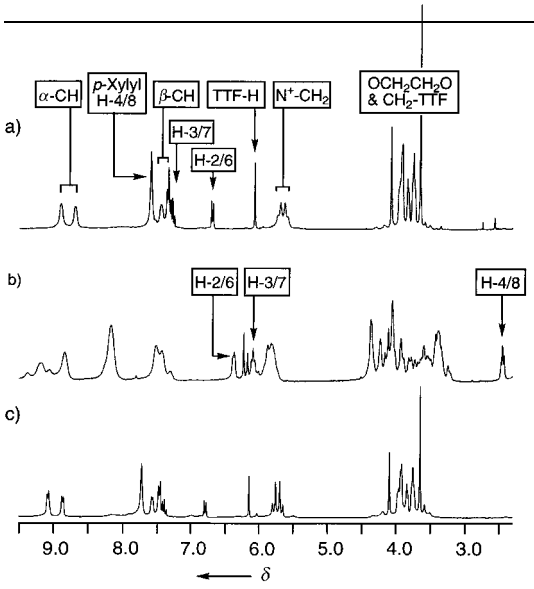
cyclophane.[10] Furthermore, no absorption band is observed in the 500–560 nm region for the CT interaction that would result from the 1,5-dioxynaphthalene moiety's being located "inside" the cyclophane.[5e] Not only does the ^1H NMR spectrum (Figure 3a) recorded in CD_3CN support this conclusion, it also indicates[21] that only *one* of the two constitutional isomers possible for the arrangement with the TTF unit "inside" the tetracationic cyclophane—almost certainly the "*trans*" isomer, which is the only isomer observed in the solid state (Figure 1)—is present.

We hypothesized that it should be possible to trigger total and completely reversible redox switching between the two translational "isomers" of the [2]catenane $\mathbf{5}^{4+}$ by either chemical or electrochemical means (Scheme 2). We now demonstrate the truth of this hypothesis in a series of experiments where the redox switching of the [2]catenane between two different "isomeric" states [$\mathbf{5}^{4+}$ and $\mathbf{5}^{5+}$ and/or $\mathbf{5}^{6+}$] is monitored by ^1H NMR and UV/Vis spectroscopy (when the switching is driven chemically) and by cyclic voltammetry (when the switching is driven electrochemically).

The chemical switching of $\mathbf{5}^{4+}$ was performed by redox reactions. In the ^1H NMR experiments, oxidation of the TTF unit of $\mathbf{5}^{4+}$ (concentration: 3.6×10^{-3} M) was carried out in

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0334 $ 17.50+.50/0



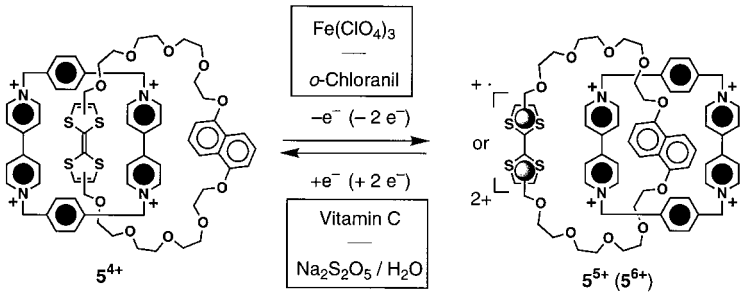


Figure 3. Partial ^{1}H NMR spectra (300 MHz) recorded in CD_3CN of a 3.6×10^{-3} M solution of the [2]catenane $\mathbf{5}^{4+}$ (a), after addition if 2 equiv of *o*-chloranil (b), and after reduction of $\mathbf{5}^{4+}$ with 2.2 equiv of $Na_2S_2O_5$ and isolation of the [2]catenane $\mathbf{5}^{4+}$ as its PF_6^- salt (c).

Scheme 2. The chemically and electrochemically triggered redox switching of [2]catenane.

CD_3CN with two equivalents of *o*-chloranil. After oxidation, the resonance (Figure 3b) for the protons attached to the 4- and 8-positions of the 1,5-dioxynaphthalene moiety is shifted significantly to higher fields and is centered on $\delta = 2.45$: the proton resonances for H-2/6 and H-3/7 appear at $\delta = 6.27$ and $\delta = 5.99$, respectively. The difference between the δ values for H-4/8, H-2/6, and H-3/7 upon oxidation of the TTF unit of the [2]catenane with *o*-chloranil and those of the free, unoxidized macrocycle are -5.33, -0.64, and -1.37, respectively. They are of a similar magnitude to those previously reported[5e, 14, 21] and so support the conclusion that the 1,5-dioxynaphthalene moiety of the macrocycle is encircled by the tetracationic cyclophane after oxidation of the TTF group. Moreover, the integrals for these particular resonances indicate that this mechanical state is the one that is populated exclusively. The ^{1}H NMR spectrum exhibits very little paramagnetic peak broadening, indicating[22] the preferential formation of the oxidized species $\mathbf{5}^{6+}$. Reduction of $\mathbf{5}^{6+}$ with 2.2 equivalents of $Na_2S_2O_5$ in CD_3CN in the presence of a few drops of H_2O and subsequent counterion exchange with NH_4PF_6, followed by evaporation of the solvent, washing of the dark green residue with H_2O, drying, and redissolving it in CD_3CN, yielded an ^{1}H NMR spectrum (Figure 3c) that was virtually identical with the original one (Figure 3a), confirming that the TTF unit is once again residing inside the cavity of the tetracationic cyclophane as shown in $\mathbf{5}^{4+}$ in Scheme 2.

In the UV/Vis experiments ($\mathbf{5}^{4+}$ concentration: 9×10^{-5} M), $Fe(ClO_4)_3$ was used as an oxidant in MeCN solution. As shown in Figure 2, addition of the oxidant (up to 1 equiv) caused a continuous decrease in the intensity of the CT band at 835 nm, characteristic of the encircling of the TTF unit by the tetracationic cyclophane. Accompanying this decrease, an increase in the intensity of the absorption bands with $\lambda_{max} =$ 450 and 600 nm, characteristic of the mono-oxidized form of the TTF unit,[23] was observed (Figure 2, curve c). As a consequence of these spectral variations, the color of the solution changes from dark green to maroon. The CT band ($\lambda_{max} = 515$ nm) due to the encirclement of the naphthalene moiety by the tetracationic cyclophane,[5b,e] expected on the basis of the ^{1}H NMR results, cannot be seen because it is hidden by the more intense bands of the oxidized TTF unit. Further addition of the oxidant (up to 2 equiv) caused the disappearance of the absorption bands of mono-oxidized TTF and formation of a new band ($\lambda_{max} = 375$ nm), which may be attributed to the bis-oxidized TTF unit.[24] An important observation is that the band due to the encirclement of the naphthalene moiety by the tetracationic cyclophane can now be seen (Figure 2, curve d). On addition of 1 equiv of ascorbic acid (as reductant), the bands of the TTF radical cation were completely restored. Further addition of 1 equiv of ascorbic acid yielded the original absorption spectrum with the characteristic CT band due to the encirclement of the TTF unit by the tetracationic cyclophane (Figure 2, curve e). Identical spectral changes have been obtained with Ag powder as reductant in place of ascorbic acid.

In conclusion, the ^{1}H NMR and UV/Vis experiments show clearly that the oxidation/reduction cycle of the TTF unit causes switching between the two translational "isomers" of $\mathbf{5}^{4+}$ (Scheme 2).

Switching can also be induced electrochemically. On electrochemical oxidation,[25] the two processes involving the TTF unit ($+0.28$ and $+0.70$ V vs SCE in crown ether **3**) and, at more positive potentials, the oxidation of the 1,5-dioxynaphthalene moiety ($+1.17$ V vs SCE in **3**) are expected.[26] Furthermore, since the ^{1}H NMR spectroscopic data show that the only observed "isomer" of $\mathbf{5}^{4+}$ has the TTF unit residing in the "inside" position, in the catenane the first oxidation of the TTF unit should be displaced toward more positive potentials relative to those of the free crown ether **3**. This prediction is confirmed by the experimental results. However, contrary to what happens in the crown ether, the first oxidation process of the TTF unit is characterized by a very large separation between the anodic and cathodic peaks. On increasing the scan rate, the former moves toward more positive potentials, the latter toward less positive potentials. At a scan rate of 50 mV s^{-1}, there is only one anodic peak at $+0.80$ V vs SCE, whose current intensity indicates the occurrence of a bielectronic process. Therefore, at this potential, the second oxidation of TTF also takes place; this process is reversible (halfwave potential $+0.76$ V vs SCE) as indicated by the cathodic part of the scan. The oxidation of the 1,5-dioxy-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0335 $ 17.50+.50/0

naphthalene moiety is strongly displaced toward positive potentials (+1.60 V vs SCE) relative to those of the free crown ether.

The scan-rate dependence of the separation between the anodic and cathodic peaks of the first oxidation process of the TTF unit of $\mathbf{5}^{4+}$ indicates that oxidation is followed by a reaction taking place on the time scale of the electrochemical experiment.[27] The nature of such a reaction is elucidated by the following observations: 1) the second oxidation of the TTF unit is reversible, which shows that the system does not undergo any further reaction after one-electron oxidation; 2) the strongly positive potential value for oxidation of the 1,5-dioxynaphthalene moiety indicates that it is trapped within the tetracationic cyclophane.[28] These features strongly suggest that the action taking place as a consequence of the first oxidation of the TTF unit is the circumrotation of the macrocyclic polyether with respect to the tetracationic cyclophane to yield the translational "isomer" with the 1,5-dioxynaphthalene moiety positioned "inside" the cyclophane (Scheme 2). This observation is consistent with the dethreading observed[10b] upon one-electron oxidation of a pseudorotaxane in which a TTF-containing thread is located "inside" the tetracationic cyclophane. We have also found by fluorescence measurements that a 1,5-dioxynaphthalene-containing thread like **2** replaces the TTF unit "inside" the tetracationic cyclophane when the TTF moiety is mono-oxidized.

We have shown that total and completely reversible switching between the two translational "isomers" of catenane $\mathbf{5}^{4+}$ can be performed by either chemical or electrochemical oxidation/reduction cycles.[29] The process, which is accompanied by a clearly detectable color change, can be followed by ^{1}H NMR spectroscopy, UV/Vis spectroscopy, and cyclic voltammetry. This result represents a further step toward the design of chemical systems whose structures and properties can be controlled by use of external stimuli.

Experimental Section

3: NaH (288 mg, 12.0 mmol) was suspended in dry, degassed THF (280 mL) and a mixture of the diol **1**[13] (925 mg, 3.50 mmol), and the dibromide **2**[14] (2.24 g, 3.50 mmol) in dry, degassed THF (250 mL containing 50 mg of both LiBr and CsOTs) was added with stirring during 20 h while refluxing under Ar. After refluxing and stirring had been continued for a further 72 h, the reaction mixture was cooled down to 10°C, and wet THF (20 mL) was added with care. The solvents were removed under vacuum, and the residue extracted into CH_2Cl_2 (2 × 250 mL). The combined organic layers were washed with saturated aqueous NaCl solution (50 mL) and H_2O (4 × 30 mL), before being dried ($MgSO_4$) and concentrated under reduced pressure to afford a residue which was subjected to column chromatography (SiO_2:CH_2Cl_2/MeOH 30:1). The macrocycle **3** was isolated as a yellow wax (1.61 g, 55%). MS (LSI): $m/z = 740$ [M^+]; ^{1}H NMR (CD_3CN, 300 MHz, 25°C): $\delta = 3.40-3.72$ (m, 26H), 3.84–3.94 (m, 6H), 4.18–4.28 (m, 6H), 6.85–6.95 (m, 2H), 7.31–7.41 (m, 2H), 7.47–7.84 (m, 2H); ^{13}C NMR (CD_3CN, 75.1 MHz, 25°C): $\delta = 51.9$, 62.0, 69.1, 70.2, 70.4, 71.2, 71.6, 72.1, 73.4, 106.9, 115.1, 118.6, 126.5, 127.6, 155.3. Elemental analyses calcd for $C_{34}H_{44}O_{10}S_4$: C 55.11, H 5.99, S 17.31; found C 54.99, H 5.98, S 17.4.

$\mathbf{5}\cdot 4PF_6$: A solution of **3** (1.39 g, 1.88 mmol), $\mathbf{4}\cdot 2PF_6$ (1.33 g, 1.88 mmol) and *p*-xylylene dibromide (496 mg, 1.88 mmol) in dry, degassed DMF (125 mL) was stirred under Ar for 5 days, and then the solvent was removed under vacuum. After the residue had been extracted with CH_2Cl_2, MeCN was added. Undissolved polymeric material was filtered off, and the MeCN solution concentrated to a residue, which was subjected to column chromatography (SiO_2, MeOH:2N NH_4Cl:$MeNO_2$ 4:1.5:1.5). The darkish green fraction was collected, the solvent evaporated off, the residue dissolved in H_2O (100 mL), and a saturated aqueous solution of NH_4PF_6 was added until no further precipitation occurred. The precipitate was filtered off, washed with H_2O (2 × 10 mL), and dried under vacuum. The pure [2]catenane $\mathbf{5}\cdot 4PF_6$ was obtained as a bluish-green solid (808 mg, 23%). M.p. 300°C; MS (LSI): $m/z = 1840$ [M^+], 1695 [$M-PF_6$]$^+$, 1551 [$M+H-2PF_6$]$^+$, 1406 [$M+H-3PF_6$]$^+$; ^{1}H NMR (CD_3CN, 300 MHz, 25°C): $\delta = 3.50-4.00$ (m, 32H), 4.08 (br s, 4H), 5.55–5.78 (m, 8H), 6.08 (br s, 2H), 6.68–6.73 (m, 2H), 7.24-7.31 (m, 2H), 7.32–7.37 (m, 4H), 7.40–7.60 (m, 4H), 7.60–7.70 (m, 10H), 8.65–8.75 (m, 4H), 8.85–9.00 (m, 4H); ^{13}C NMR (CD_3CN, 75.1 MHz, 25°C): $\delta = 65.2$, 68.5, 68.6, 70.4, 70.5, 70.7, 71.1, 71.3, 71.6, 72.0, 106.6, 114.6, 119.8, 125.0, 125.3, 126.9, 133.5, 136.7, 143.9, 144.3, 145.5, 146.4, 154.6. Elemental analysis calcd for $C_{70}H_{76}F_{24}N_4O_{10}S_4P_4$: C 45.66, H 4.16, N 3.04, S 6.96; found C 45.55, H 4.28, N 3.18, S 7.1.

[15] Crystal data for $\mathbf{5}\cdot 4\,PF_6\cdot 6\,MeCN$: monoclinic, space group *Cc* (no. 9), $a = 21.780(1)$, $b = 16.294(1)$, $c = 27.436(2)$ Å, $\beta = 93.94(1)^\circ$, $V = 9713.9(8)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.428$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 24.5$ cm^{-1}, $T = 203$ K, 6549 independent reflections measured, 5555 observed with $|F_o| > 4\sigma(|F_o|)$, $2\theta \leq 114^\circ$, refined on F^2 to $R_1 = 0.072$, $wR_2 = 0.183$ for 1023 parameters. The polarity of the structure was determined from the Flack parameter. The data were collected on a Siemens P4/RA diffractometer with ω scans and graphite monochromated $Cu_{K\alpha}$ radiation. The structure was solved by direct methods. The non-hydrogen atoms of the crown, the PF_6^- anions, and the included MeCN molecules were refined anisotropically; due to a shortage of observed data, the non-hydrogen atoms of the tetracation were refined isotropically. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-100460. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ (fax: int. code + (44) 1223 336-033; e-mail: deposit@ccdc.cam.ac.uk).

[16] The $OC_6H_{10}O$ vector of the "alongside" 1,5-dioxynaphthalene moiety is inclined by 18° to the mean plane of the tetracation.

[17] The [2]catenane molecules crystallize in a noncentrosymmetric space group, which contains a glide plane. Hence there are equal numbers of enantiomeric molecules present in the crystal.

[18] C. A. Hunter, J. K. M. Sanders, *J. Am. Chem. Soc*. **1990**, *112*, 5525 – 5534; C. A. Hunter, *Chem. Soc. Rev.* **1994**, *23*, 101 – 109.

[19] a) G. R. Desiraju, *Angew. Chem*. **1995**, *107*, 2541 – 2558; *Angew. Chem. Int. Ed. Engl*. **1995**, *34*, 2311 – 2327; b) T. Steiner, *Chem. Commun*. **1997**, 727 – 734.

[20] The mean interplanar separations between the "inside" disubstituted TTF ring system and the "inside" and "alongside" bipyridinium units are 3.43 and 3.37 Å, respectively; the separation between the "alongside" 1,5-dioxynaphthalene moiety and the "inside" bipyridinium unit is 3.31 Å. Hydrogen bonds between α-bipyridinium hydrogen atoms on the "inside" bipyridinium unit and the two polyether oxygen atoms have the following geometries: [C ··· O] 3.39 and 3.12 Å, [H ··· O] 2.43 and 2.40 Å; C–H ··· O angles 174° and 132°. The diametrically opposite sulfur atoms adjacent to the "*trans*"-substituted carbon atoms lie about 3.6 Å from the centroids of their proximal para-xylylene rings.

[21] When a 1,5-dioxynaphthalene moiety is located "inside" the tetracationic cyclophane, the H-4,8 protons resonate (M. Asakawa, P. R. Ashton, S. E. Boyd, C. L. Brown, R. E. Gillard, O. Kocian, F. M. Raymo, J. F. Stoddart, M. S. Tolley, A. J. P. White, D. J. Williams, *J. Org. Chem*. **1997**, *62*, 26 – 37) at very high field ($\delta = 2.1 – 2.6$). The fact that these naphthalene ring protons in the [2]catenane give rise to a masked signal (identified by a COSY experiment) in the region $\delta = 7.60 – 7.70$ confirms unequivocally that the 1,5-dioxynaphthalene moiety of the macrocycle is not located inside the tetracationic cyclophane. Intimate encirclement of the TTF unit by the tetracationic cyclophane was confirmed by 2D ROESY experiments (400 MHz, CD_3CN, 31°C, 200 ms mixing time), which display cross-peaks between the OCH_2 protons attached to the TTF core, and both the α-bipyridinium and the *p*-xylyl protons of the tetracationic cyclophane. No cross-peaks could be observed indicating that none of the 1,5-dioxynaphthalene moiety is located inside!

[22] The reduction potential of *o*-chloranil (+0.83 V: L. Horner, E. Geyer, *Chem. Ber.* **1965**, *98*, 2016 – 2045) substantiates the formation of the dicationic TTF species $\mathbf{5}^{6+}$. The UV/Vis spectrum (concentration: 9×10^{-5} M) recorded in MeCN shows no absorbance at $\lambda_{max} = 600$ nm, which is characteristic of $\mathbf{5}^{5+}$. The other typical band for the mono-oxidized TTF species at $\lambda_{max} = 450$ nm is hidden by the more intense band of *o*-chloranil ($\lambda_{max} = 435$ nm). Clear evidence for the presence of the bisoxidized TTF unit is provided by mass spectrometry. When examined with electrospray ionization (VG ProSpec mass spectrometer) in MeCN as solvent, the predominant ions observed for a 3:1 mixture of $\mathbf{5}^{4+}$ and *o*-chloranil are $m/z = 775$ and 468. They correspond to the loss of two and three PF_6^- counterions. On observation of the isotopic abundances for these species, the ion corresponding to loss of two counterions at $m/z = 775$ is doubly charged, as evidenced by the 0.5 u separation between the isotopes. The ion at $m/z = 468$ is shown to be triply charged with an isotopic separation of 0.3 u. A freshly prepared sample obtained after mixing *o*-chloranil and $\mathbf{5}^{4+}$ in a 2:1 ratio shows a peak at $m/z = 898$ as the most abundant in the spectrum. This peak corresponds to the incorporation of one counterion derived from *o*-chloranil into the [2]catenane. Once again, this species was found to be doubly charged by examination of isotopic abundances. Additionally, the spectrum shows peaks at $m/z = 775$ and 468. These peaks are the major ones for a sample recorded after standing for one week. The isotopic separations of these ions confirm that they are doubly ($m/z = 775$) and triply ($m/z = 468$) charged species. None of the spectra obtained show evidence for the presence of a monocationic species. As expected with reference to the second oxidation potential of the crown ether **3**, oxidation with *o*-chloranil yields preferentially $\mathbf{5}^{6+}$. We would like to thank one of the referees for asking us to comment on the nature of the oxidation state of the TTF unit.

[24] G. Schukat, E. Fanghänel, *J. Prakt. Chem*. **1985**, *327*, 767 – 774.

[25] The electrochemical experiments were carried out in argon-purged MeCN solutions with a Princeton Applied Research 273 multipurpose instrument interfaced to a personal computer, with cyclic voltammetry and differential pulse voltammetry techniques. The exact configuration and procedures for these measurements have been reported in Ref. [5e].

[26] A detailed study of the interesting electrochemical behavior of crown ether **3** will be reported elsewhere.

[27] The alternative explanation, based on lack of reversibility of the electrode process due to restricted access to the inside TTF unit, can be ruled out on consideration of the behavior observed for all the catenanes and rotaxanes previously investigated. See, for example: a) Ref. [5b]; b) P. R. Ashton, R. Ballardini, V. Balzani, M. Belohradsky, M. T. Gandolfi, D. Philp, L. Prodi, F. M. Raymo, M. V. Reddington, N. Spencer, J. F. Stoddart, M. Venturi, D. J. Williams, *J. Am. Chem. Soc*. **1996**, *118*, 4931 – 4951.

[28] We have found that oxidation of a 1,5-dioxynaphthalene moiety in "alongside" and "inside" positions occurs at +1.30 and +1.55 V vs SCE, respectively, in a catenane made of the cyclobis(paraquat-*p*-phenylene) tetracation and a crown ether (1/5DN38C10) containing two 1,5-dioxynaphthalene moieties.

[29] Since, strictly speaking, $\mathbf{5}^{4+}$ and $\mathbf{5}^{5+}$($\mathbf{5}^{6+}$), with their different oxidation states, are *not* isomers, we have introduced quotation marks round the term *isomer(s)* in our discussion of these two catenated species.

Triphenylphosphonioacetylide: A Species Isoelectronic with Isocyanides

Hans Jürgen Bestmann,* Wilhelm Frank, Claus Moll, Andreas Pohlschmidt, Timothy Clark, and Andreas Göller

In memory of Gerrit L'abbé

We have for some time been interested in "naked" carbon chains such as **1**–**4**, which are stabilized by donor and acceptor groups.[1, 2] Carbon chains stabilized by donors and acceptors have an even number of carbon atoms with betaine-like character (**1**, **2**), whereas the corresponding compounds

stabilized with two donors have an odd number of carbons and belong to the heterocumulene ylides (**3**, **4**).[3] In the course of this work, questions arose regarding the structure, stability, and reactivity of **5**, in which the C_2 unit is only stabilized by a single donor without an acceptor. This compound can be described by structures **5a** and **5b**/**5b′**. The former can be viewed as a triphenylphosphonioacetylide, whereas **5b**/**5b′** would be regarded as (methylenecarbenylidene)triphenylphosphoranes. Compound **5** is thus isoelectronic with isocyanides.

We utilized several computational techniques to determine the bond lengths, angles, and charge distribution in **5**: the semiempirical MO packages VAMP 6.1[4] and SPARTAN 4.1.1[5] with the PM3 Hamiltonian operator,[6] as well as ab initio [7, 8] and density functional theory (DFT)[9] techniques within Gaussian94.[10] Ab initio and DFT calculations relied on the following methods and basis sets:[8] HF/6-31G(d),[11] MP2/6-31G(d),[12, 13] MP2/6-311+G(d,p), and Becke3LYP/6-311+G(d).[9] Stationary points were characterized as minima or transition states at the appropriate level of calculation. NMR chemical shifts and coupling constants were calculated by the IGLO method[14] with DeMon 1.0.[15] In this case, PW91/IGLO-II//Becke3LYP/6-31G(d) was used for **5**, and PW91/IGLO-III//Becke3LYP/6-311+G(d) for the unsubstituted model compound **6**.

According to semiempirical calculations (Table 1), **5** is linear (P-C_α-C_β 179.98°). The most important bond lengths are

Table 1. Calculated geometries and energies for **5**.

Quantity	PM3	Becke3LYP/6-31G(d)
C–C [pm]	124.1	126.1
C–P [pm]	154.8	167.6
P–C(Ph) [pm]	180.4	183.8
C-P-C(Ph) [°]	112.3	110.2
E_{total}	180.471[a]	−1112.37540[b]
NIMAG[c]	0	1
ZPE[d]	175.424[a]	0.28353[b]

[a] In kcal mol^{-1}. [b] In Hartree. [c] NIMAG: Number of imaginary frequencies. [d] ZPE: Zero-point energy.

154.8 pm (P–C_α) and 124.1 pm (C_α–C_β); the latter is slightly longer than a C–C triple bond.[16] The PPh_3 group bears a net positive charge of +1.14 centered on the phosphorus atom (+2.14 on the P atom, −1.00 on all the phenyl rings combined). The most negative site is at C_α with a charge of −1.18, whereas C_β is practically neutral with a charge of +0.04 (Table 2).

Dipole moments for the individual atoms were derived with the help of the natural atomic orbital point charge (NAO-PC) method.[17] These experimentally nonobservable variables are a measure of the anisotropy of the atomic polarizability. The β-carbon atom in **5** has a dipole moment of 2.00 D, one of the largest yet ascertained with this technique. The molecule has essentially C_{3v} symmetry (the planes of the three phenyl rings intersect at angles of 120° at the P-C-C axis).

DFT Becke3LYP/6-31G(d) optimization (with the symmetry constrained to C_{3v}) gives slightly different values (Table 1). The C_α–C_β and P–C_α distances are 126.1 and 167.6 pm, respectively, and these bonds are expected to become somewhat longer upon inclusion of electron correlation. Atomic charges derived from an natural bond orbital (NBO) population analysis (C_α: −1.01, C_β: +0.02, P: +1.70, PPh_3: +0.99) agree well with those obtained by the NAO-PC method, which can be seen as a confirmation of the effectiveness of semiempirical techniques. Calculation of the normal vibrations for **5** at the Becke3LYP/6-31G(d) level results in one imaginary vibration with a frequency of −53 cm^{-1}. This vibration, which may be a result of numerical errors in the DFT integration, corresponds to a slight bending of the P-C-C unit.

To obtain more information about whether **5** is linear or not, we performed calculations at higher levels on the model compound **6**. H_3P–C_2 was therefore first optimized with C_{3v} symmetry (Table 3). At the RHF/6-31G(d), MP2/6-31G(d), and Becke3LYP/6-311+G(d) levels, this structure proved to be a minimum on the energy hypersurface. Only the structure optimized at the MP2/6-311+G(d,p) level proved to be a second-order saddle point with two imaginary vibrations. Structure **6** was therefore optimized without symmetry constraints (C_1, Table 3). The resulting geometry deviates

slightly from C_s symmetry, and **6** is nonlinear with a P-C-C angle of 172°. We assume that the corresponding angle is similar in **5**.

Calculations at all levels agree that the P-C-C unit can be bent very easily (frequencies 0–100 cm^{-1}). The difference in energy between **6** with C_{3v} symmetry and **6** with C_1 symmetry is only 0.00002 Hartree (0.01 kcal mol^{-1}) at the MP2/6-311+G(d,p) level; the nonlinearity should have no experimentally observable consequences. The calculated geometries show short C−C distances (124.3–127.3 pm) that suggest a C−C triple bond, as for the triphenyl compound. The P−C bond lengths (164.4–165.6 pm) are also short and lie in the range of formal P−C double bonds (cf. CH_2=PH 167.5 pm at the MP2/6-31G(d) level). The C-P-C(Ph) angle in the phenyl-substituted compound **5** is, as expected, somewhat smaller than the analogous C-P-H angle in **6**.

Coulson and Mulliken charges are very similar for semiempirical (PM3) and ab initio Hartree–Fock calculations. The phosphorus atom carries less charge in **6** because charge delocalization to the phenyl rings is not possible. Atom C_β is essentially neutral, C_α negatively charged, and P positive (+0.6 e). Methods that take electron correlation into account (MP2 and DFT) give results with the opposite trends, dependent on the basis set. The changes are most extreme for Becke3LYP/6-311+G(d) calculations: C_β now has a partial negative charge (−0.42e), whereas the other atoms are all slightly positive.

The three highest occupied molecular orbitals of **6** (Figure 1) are two almost degenerate orthogonal π orbitals (HOMO and HOMO − 1) with C−C bonding character and

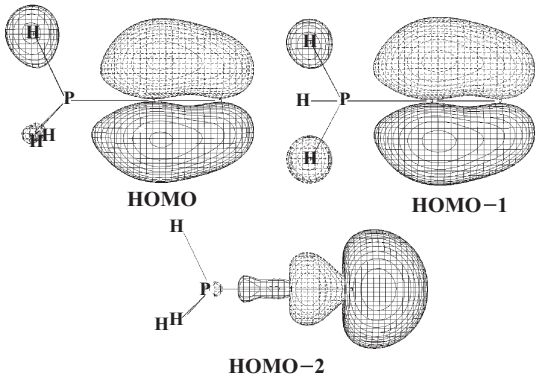

Figure 1. The orbitals HOMO, HOMO − 1, and HOMO − 2 for **6** (HF/6-31G(d)//Becke3LYP/6-311+G(d), PSI88[18]).

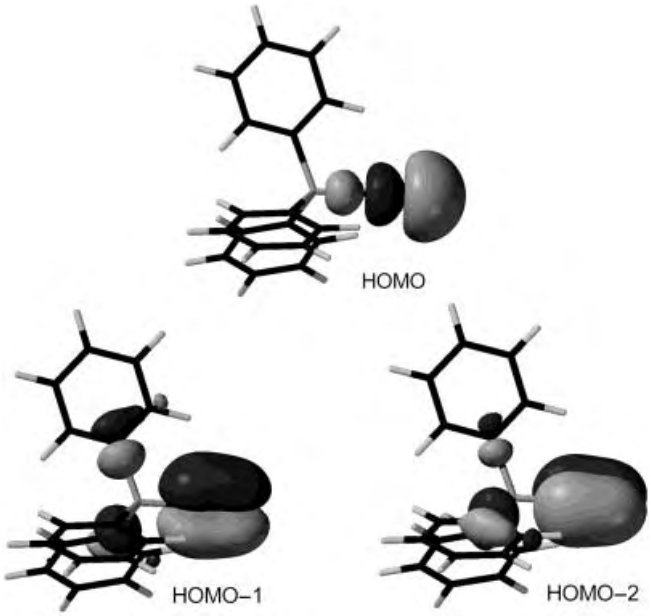
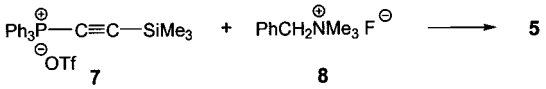
a σ orbital (HOMO − 2) with a large orbital lobe beyond C_β (lone pair) and significant C−C bonding character. Strong polarization of all three MOs leads to an accumulation of electron density at the lone pair and on C_α this is not fully reflected in the calculated net atomic charges. In **5**, only the ordering of these three MOs is changed (Figure 2). In this case, the lone pair is the HOMO (σ orbital). All these calculations point to the fact that it is not possible to formulate a single Lewis structure for **5** that correctly reproduces the geometry and charge distribution.

To synthesize **5** a solution of the known (silylethinyl)phosphonium salt **7**[19] in dichloromethane was added dropwise to benzyltrimethylammonium fluoride (**8**) in the same solvent at





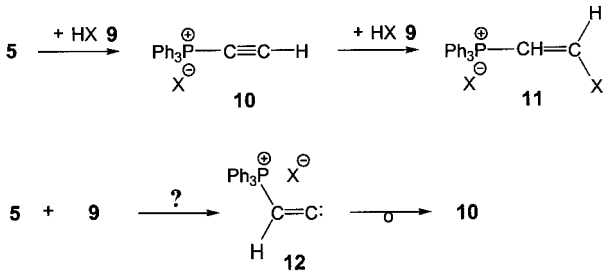


Figure 2. The orbitals HOMO, HOMO – 1, and HOMO – 2 for **5** (PM3/Spartan 4.1.1).

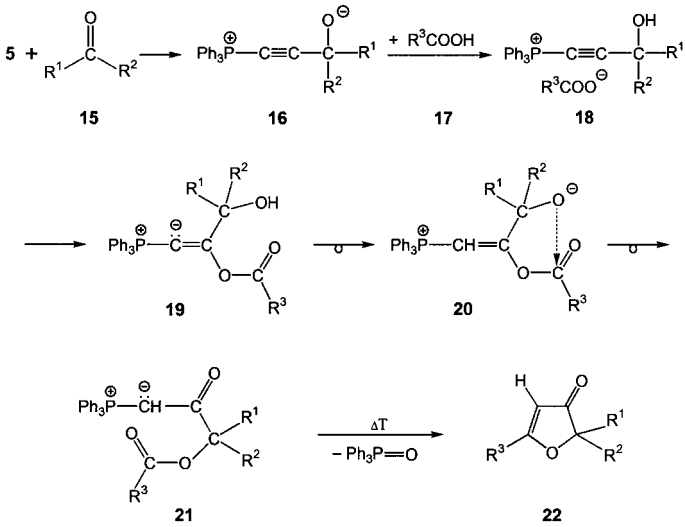
– 90 °C. The low-temperature (– 78 °C) ^{31}P NMR spectrum of the product showed (apart from small amounts of by-products) only one signal at $\delta = -13.85$. The signals of starting material **7** at ($\delta(^{31}P) = 5.22$, $\delta(^{29}Si) = -9.78$) had disappeared. Since **5** is stable only at low temperature and

decomposes upon warming to room temperature, all spectra were recorded at – 78 °C. Because the ^{13}C NMR data were not completely clear, we prepared ^{13}C-enriched **7**.[20] The corresponding ^{13}C NMR spectrum showed doublets for C_α and C_β (C_α: $\delta = 83.87$, $^1J(P,C) = 161.7$ Hz; C_β: $\delta = 133.03$, $^2J(P,C) = 18.4$ Hz). After desilylation of **7** to **5** the signals for C_α and C_β appeared at $\delta = 83.15$ (d, $^1J(P,C) = 132.4$ Hz) and 228.90 (d, $^2J(P,C) = 12.8$ Hz). These data support the results of the calculations extremely well (Table 4). The large downfield shift in the signal for C_β in **5** with respect to that for **7** (over 95 ppm) shows that this atom is electron deficient. The observed P–C_α coupling constant lies between the usual values for alkenyl- (ca. 90 Hz)[21] and alkinylphosphonium salts (ca. 180 Hz),[22] indicating some nonlinearity of the molecule in solution.[23] The ^{31}P NMR spectrum of ^{13}C-labeled **5** shows (apart from a singlet at – 13.687 ppm for the ^{12}C isotopomer) two doublets at $\delta = -13.693$ and – 13.710, which result from coupling of C_α or C_β of the two ^{13}C isotopomers with the phosphorus atom. The ^{31}P NMR signal of **5** is shifted upfield, as are those for **4** ($R^2 = C_6H_5$)[2] and other phosphaallene ylides.[24] The IR spectrum of **5** shows a sharp peak at 1957 cm^{-1} (**7**: 2135 cm^{-1}); cumulated ylides also absorb in this range.[23]

Compound **5** reacts with acids HX (**9**) initially to form ethinylphosphonium salts **10**, which could be characterized by ^{31}P NMR spectroscopy as intermediates between – 78 and – 30 °C (Scheme 1). A possible insertion into the H–X bond,

Scheme 1. Reaction of **5** with **9** (X = OMe, Cl, OCOMe) and possible reaction pathways that proceed directly via **10** or via carbene intermediate **12**.

which might be expected on the basis of the carbene structure **5b**/**5b**′, is not observed. At about 0 °C a further reaction with **9** takes place to give the vinylphosphonium salts **11**, which are formed as mixtures with widely differing *Z*:*E* isomeric ratios.[25] We assume that electrophilic attack at the β-carbon atom of **5** occurs to lead to a dynamic back-polarization of electron density from C_α to C_β. In principle, nucleophilic attack on the negatively charged α-carbon atom might be possible to form the vinylidenecarbenephosphonium salt **12**, which would be expected to undergo rapid rearrangement to the ethinylphosphonium salt **10** (Scheme 1).[26] However, in a series of experiments (e.g., reaction with electrophiles in the presence of alkenes) we found no evidence for the formation of carbene **12** or similar intermediates substituted at the α-carbon atom. Reaction of **5** with trifluoromethanesulfonic acid methyl ester (**13**) gives the propinylphosphonium salt **14**.



We further investigated whether **5**, which is isoelectronic with isocyanides, undergoes reactions analogous to the Passerini reaction.[27] We therefore treated solutions of **5** at – 78 °C with a ketone (**15**) and then at – 40 °C with carboxylic acid **17** (Scheme 2), and isolated the corresponding (3-acyloxy-2-oxo-alkylidene)triphenylphosphorane **21** about five hours later (Table 5). We assume that betaine **16** is initially formed and then is protonated by **17** to give alkynylphospho-

nium salt **18**. The carboxylate anion then adds at the position β to phosphorus in a slow reaction at room temperature. The resulting phosphaallene ylide **19** in turn undergoes a proton shift to provide **20**. The reaction sequence is terminated by an acyl shift to give **21**. The similarity between this sequence and the Passerini reaction is clear. Upon heating in benzene or toluene at reflux, acyl ylides **21** undergo an intramolecular Wittig reaction[28] to yield 2,2,5-trisubstituted 3(2*H*)-furanones **22** (cf. Table 5).

If **7** is desilylated in the presence of triphenylborane (**23**) at $-78\,^{\circ}C$, (triphenylphosphonioethinyl)triphenylborate (**24**),[29] which belongs to the phosphonioboratoacetylenes **1**, is formed in 84% yield. A comparison of the X-ray crystal structure of **24**[29] with that of **1**,[1] in which one phenyl is replaced by a

methyl group, shows no significant differences. The C_α–C_β distance in **24** (124.3 pm) is slightly greater than that in the analogue (121.6 pm), [1] and both molecules are slightly bent (**24**: P-C_α-C_β 177°, B-C_β-C_α 171.3°).

Experimental Section

All operations were carried out under a nitrogen atmosphere and in absolute solvents.

5 (in solution): **8** (169 mg, 1.0 mmol) was dissolved/suspended in CH_2Cl_2 (2 mL) and cooled to $-90\,^{\circ}C$. A solution of **7** (509 mg, 1.0 mmol) in CH_2Cl_2 (3.5 mL) was added dropwise over a period of 10 min. A deep red solution was obtained, which appeared yellow when viewed as a thin layer. To complete the reaction, the mixture was stirred for about 10 min and allowed to warm to $-78\,^{\circ}C$. Smaller batches (0.6 mmol) in absolute CD_2Cl_2 were prepared to obtain low-temperature spectra.

21: To a solution of **5** at $-78\,^{\circ}C$ was added an aromatic or aliphatic ketone (**16**, 5.0 mmol). The mixture was first allowed to react for 10 min at $-78\,^{\circ}C$, and then maintained for 30 min at $-40\,^{\circ}C$ before an aromatic or aliphatic carboxylic acid (**17**, 0.8 mmol) was added. The mixture was allowed to warm to room temperature and then stirred for 5 h. From this point on, a nitrogen atmosphere was no longer necessary. The solution was evaporated to 2 mL and washed with Et_2O (10 mL), and the residue was twice precipitated from CH_2Cl_2/Et_2O (little CH_2Cl_2). The oily red residue was discarded. The combined ether phases were evaporated, and the crude acyl ylides **21** chromatographed over silica gel with ethyl acetate as eluent.

A Three-Dimensional Framework with Accessible Nanopores: $RbCuSb_2Se_4 \cdot H_2O$**

Jason A. Hanko and Mercouri G. Kanatzidis*

The synthesis of nonoxidic chalcogen-based open frameworks is motivated by the prospect of obtaining interesting semiconducting analogues of zeolites.[1] Planned syntheses of open-framework structures based on germanium and tin sulfides were reported in 1989.[2] This discovery led to a rapid expansion in this area, and compounds such as $[Et_4N]_2Cu_2Ge_4S_{10}$,[3] $[Me_4N]_2MGe_4S_{10}$ (M = Mn,[4, 5] Fe,[5, 6] Co,[5] Zn[5]), and $[Me_4N]_6(Cu_{0.44}Ge_{0.56}S_{0.73})Ge_4S_{10}$[7] were prepared. Hydrothermal synthesis is a common route to these materials. Solid-state lattices can be generated by the self-assembly of the appropriate molecular building blocks in the presence of organic template ions. Using this approach, we have demonstrated that $[EQ_3]^{3-}$ (E = As, Sb; Q = S, Se) units are versatile building blocks from which interesting compounds such as KBi_3S_5,[8] $[Ph_4P]InSe_{12}$,[9] $[Me_4N]HgAs_3S_6$,[10] $[Me_4N]RbBiAs_6S_{12}$,[11] and $[Co(en)_3]CoSb_4S_8$[12] can be made. A transition metal is not necessary for the formation of extended structures. Several of these germanium,[13] tin,[14–22] and antimony sulfide[23, 24] frameworks are also accessible by condensation of molecular building blocks.

Here we report on the new three-dimensional material $RbCuSb_2Se_4 \cdot H_2O$ (**1**), which was prepared by heating CuCl with Rb_3SbSe_3[25] and Ph_4PBr in H_2O at 130 °C. The black needlelike crystals are insoluble in common organic solvents. Compound **1** has a three-dimensional framework in which tetrahedral Cu centers are connected to both pyramidal $SbSe_3$ and square-pyramidal $SbSe_5$ units.[26] The novel feature of this framework is the presence of large channels running along the [010] direction (Figure 1). The channels have an irregular

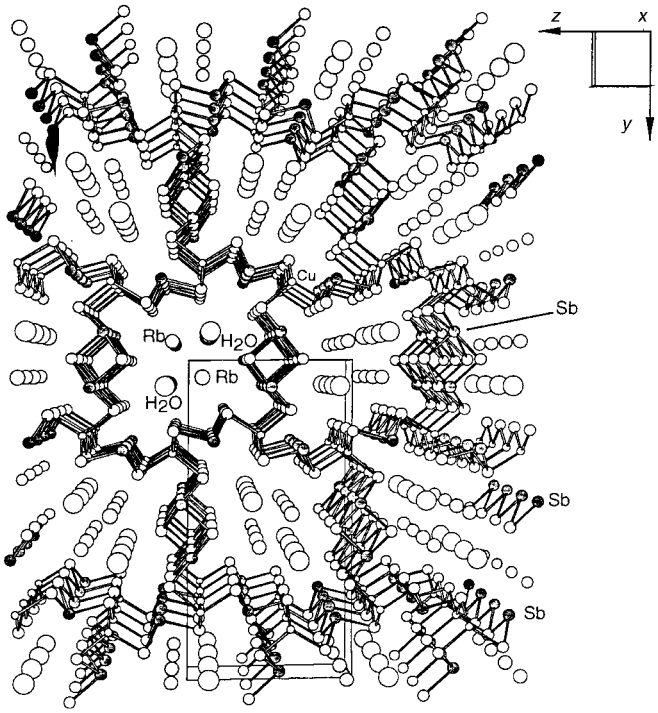

Figure 1. View of the structure of **1** along the *b* axis showing the channels occupied by the rubidium centers and water molecules.

cross section with dimensions of 11.29 × 10.52 × 8.16 Å (Figure 2). Another unique feature is the presence of two kinds of $[SbSe_2]_n^{n-}$ chains which run parallel to the channels. One is a single $[SbSe_2]_n^{n-}$ chain of corner-sharing pyramids in which all of the terminal Se centers on the same side; the Sb–Se bond lengths range from 2.556(4) to 2.726(3) Å (av 2.66(5) Å), and the Se-Sb-Se angles from 95.5(1) to 99.1(1)°. The other contains associated double $\{[SbSe_2]_2\}_n^{2n-}$ chains with Sb–Se bond lengths in the range 2.585(4)–2.972(3) Å (av 2.83(8) Å) and Se-Sb-Se angles between 84.8(1) and 173.9(1)°. Such double chains are also found in Sb_2Se_3.[27] Figure 2 highlights the two different $[SbSe_2]_n^{n-}$ chains. The $[SbSe_2]_n^{n-}$ single chains are connected to the Cu atoms to give corrugated $CuSbSe_2$ sheets composed of alternating rows of tetrahedrally coordinated Cu and pyramidally coordinated Sb units. These sheets are held together by the $\{[SbSe_2]_2\}_n^{2n-}$ double chains, which complete the tetrahedral coordination sphere of the Cu atoms

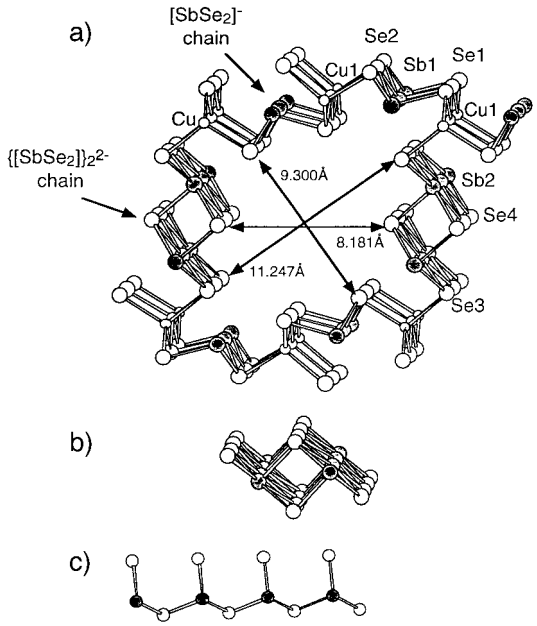

Figure 2. a) Section of the framework of **1** (Rb cation and water molecule omitted for clarity) with selected bond lengths [Å] and angles [°]: Cu(1)–Se(1) 2.489(3), Cu(1)–Se(1′) 2.489(3), Cu(1)–Se(2) 2.499(6), Cu(1)–Se(4) 2.480(5), Sb(1)–Se(1) 2.556(4), Sb(1)–Se(2) 2.726(3), Sb(1)–Se(2′) 2.726(3), Sb(2)–Se(3) 2.585(4), Sb(2)–Se(3′) 2.972(3), Sb(2)–Se(3″) 2.972(3), Sb(2)–Se(4) 2.823(3), Sb(2)–Se(4′) 2.823(3); Se(2)-Sb(1)-Se(1) 99.1(1), Se(2′)-Sb(1)-Se(1) 99.1(1), Se(2)-Sb(1)-Se(2′) 95.5(1), Se(3)-Sb(2)-Se(4) 89.7(1), Se(3)-Sb(2)-Se(3′) 84.8(1), Se(4)-Sb(2)-Se(4′) 91.2(1), Se(4)-Sb(2)-Se(4) 88.5(1), Se(3)-Sb(2)-Se(4) 91.3(1), Se(3)-Sb(2)-Se(4) 173.9(1), Se(4)-Cu(1)-Se(1) 110.6(1), Se(1)-Cu(1)-Se(1′) 108.4(1), Se(2)-Cu(1)-Se(4) 108.4(1), Se(2)-Cu(1)-Se(1) 109.4(1). b) View of the $[SbSe_2]_2^{2-}$ double chain. c) View of the $[SbSe_2]_n^{n-}$ single chain.

and form the three-dimensional framework. The Cu centers have a slightly distorted tetrahedral coordination environment. The Cu–Se bonds range from 2.480(5) to 2.499(6) Å, and the Se-Cu-Se angles from 108.4(1) to 110.6(1)°.

Thermogravimetric analysis (TGA, Figure 3) showed two significant weight loss steps. A one-step mass loss of 2.65 % at 200 °C corresponds to the loss of the water molecule (calcd 2.47 %). This was followed by a one-step mass loss, with a shoulder, of 22.48 % at 380 °C, corresponding to the loss of two Se atoms (calcd 22.33 %). The X-ray diffraction pattern of the remaining powder, which had been heated to 600 °C, indicated the presence of a crystalline solid; however, it did not match that of Sb_2Se_3 or any known Cu/Se or Cu/Sb/Se phase. The thermal stability of the material after loss of the water molecule was investigated by interrupting the TGA at 300 °C and cooling to room temperature. The powder X-ray diffraction pattern of the residue did not match that of **1**, showing that the loss of the water molecule results in the collapse of the framework. Compound **1** exhibits topotactic ion-exchange properties, a key criterion for assessing the performance of the framework as a host. The facile removal of Rb^+ ions indicates substantial mobility of the alkali metal ions and water molecules in the tunnels. By using a mild solid-state exchange method developed by us,[28] the Rb^+ cations can readily be exchanged with other, smaller cations such as Li^+, Na^+, and NH_4^+, which were used in the form of their iodides. The degree of exchange was determined by energy dispersive spectrosopy (EDS). The compositions of the exchanged materials were $Rb_{0.2}Li_{0.8}CuSb_2Se_4$, $Rb_{0.2}Na_{0.8}CuSb_2Se_4$, and $Rb_{0.4}(NH_4)_{0.6}CuSb_2Se_4$, for the Li^+, Na^+, and NH_4^+ ions, respectively.

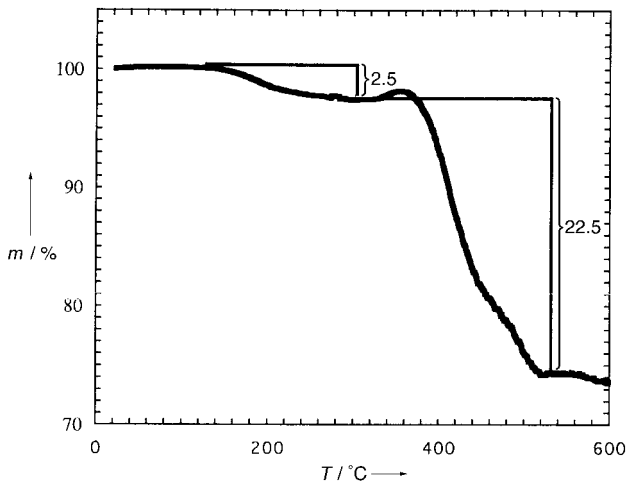

Figure 3. Therogravimetric analysis of **1** in the temperature range 25–600 °C.

The optical spectrum of **1** reveals the presence of a sharp optical gap of 1.32 eV, which suggests that the material is a semiconductor. The far-IR spectrum of **1** shows a broad absorption around 211 cm^{-1}, which can be tentatively assigned to Cu–Se stretching modes. The Raman spectrum of **1** displays a single strong band at about 233 cm^{-1}, which is assigned to Sb–Se stretching modes, and two shoulders at about 209 and 186 cm^{-1}, which are assigned to Cu–Se stretching vibrations.

Compound **1** has a unique structure and is the first example of a quaternary selenoantimonate with an open three-dimensional framework and proven ion-exchange properties.

Experimental Section

1 was synthesized by heating a mixture of CuCl (0.01 g, 0.10 mmol), Rb_3SbSe_3 (0.186 g, 0.30 mmol), Ph_4PBr (0.168 g; 0.40 mmol), and H_2O (0.2–0.5 mL) at 130 °C for 3 d in a sealed Pyrex tube. The product was isolated by washing with copious degassed methanol and dried with ether. The resulting product was a 50/50 mixture of black needles of $RbCuSb_2Se_4 \cdot H_2O$ and red platelets. The SEM/EDS analysis of the red platelets gave an average composition of $PCu_{2.0}Sb_{3.3}Se_{3.2}$, which suggests that they contains Ph_4P^+ ions.

Generation and Trapping Reactions of a Formal 1:1 Complex between Singlet Carbon and 2,2′-Bipyridine**

Robert Weiss,* Silvia Reichel, Matthias Handke, and Frank Hampel

Dedicated to Professor George A. Olah on the occasion of his 70th birthday

2,2′-Bipyridine is a classical chelating ligand for metals as well as nonmetals in different oxidation states and bonding types.[1,2] However, to our knowledge analogous complexes are unknown for all oxidation states of carbon. Here we report a first compound of this kind. In 1994 we described the first S_N reactions at the α-carbon atom of aryliodonio diazo compounds.[3] Using $AsPh_3$ as nucleophile, we obtained the diazo compound **1**, which served as starting material for the new class of compounds.

The reaction of **1** with trifluoromethanesulfonic acid (HOTf, Scheme 1) afforded the arsonium salt **2** in high yield

Scheme 1. Synthesis of **3**-2 OTf and its deprotonation to **4**-OTf.

as the result of an acid-induced fragmentation of the *tert*-butyl ester functionality, followed by a proto-dediazonation.[4] Compound **2** is a potent 1,1-bis(electrophile) which reacted with a host of neutral nucleophiles to form symmetrical and unsymmetrical geminal bis(onio)-substituted salts.[5] Accordingly, the reaction of **2** with 2,2′-bipyridine provided the cyclic bis(onio)-substituted salt **3**-2 OTf, a bis(azonia) analogue of fluorene. Under the reaction conditions, this C–H-acidic

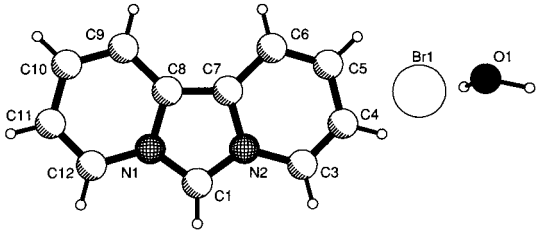
compound was converted into **4**-OTf with excess 2,2′-bipyridine (Scheme 1) and isolated as **4**-Br after anion exchange (yield: 75% relative to **2**); this salt crystallizes more readily.[6] Figure 1 shows the result of the X-ray structure analysis of **4**-Br · H_2O.[7]



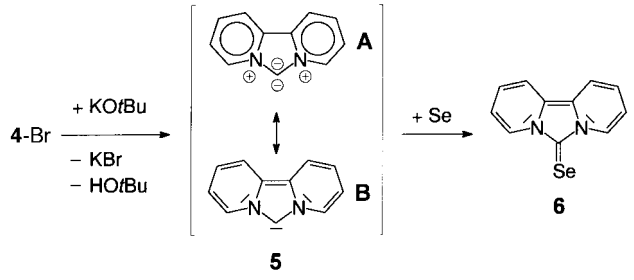


Figure 1. Structure of **4**-Br · H_2O in the crystal. Important bond lengths [Å] and angle [°]: C1–N1 1.338, N1–C8 1.394, C7–C8 1.387, C8–C9 1,41, C9–C10 1.34, C10–C11 1.41, C11–C12 1.33, C12–N1 1.39; N1-C1-N2 107.6.

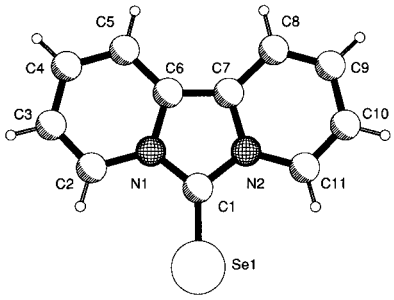
A noticeable feature in the ^1H NMR spectra of **4**-Br and **4**-OTf is the large $^1H-^{13}C$ coupling constant (232.59 Hz) for the C–H bond in the five-membered ring. This coupling constant almost corresponds to sp hybridization of the C atom in this bond (the exact value is $sp^{1.15}$).[8] A PM3 calculation, combined with an NBO analysis,[9] provided a hybridization of $sp^{1.23}$. This unprecedented result can also be reached qualitatively by applying Bent's rules:[10] The carbon atom bridging the six-membered rings in **4** ("bridging C atom") has two strongly electronegative substituents (the N centers), which should induce a higher p character in the C hybrid orbitals associated with them. This automatically leads to a higher s proportion in the remaining σ orbital of the bridging C atom with a trigonal-planar environment.

With an excess of HOTf in THF, **4**-Br was quantitatively converted into the dicationic salt **3**-2 OTf, the first σ complex of an S_E reaction at an imidazolium system to be isolated. The $^1H-^{13}C$ coupling constant of 170.65 Hz for the geminal C–H bonds corresponds to $sp^{1.93}$ hybridization in these bonds, which is highly unusual for a saturated C atom.[8]

Salt **4**-Br was deprotonated to the neutral species **5** in a fast and quantitative reaction with KO*t*Bu in THF at $-30\,^\circ C$ (Scheme 2). Under these reaction conditions, **5** was stable for several hours. The ^{13}C NMR spectrum of the reaction mixture shows five signals in the range of $\delta = 114-129$ and a sixth signal at $\delta = 196.41$ for the bridging C atom. This value is shifted upfield only slightly with respect to the corresponding signals for Arduengo carbenes[11] and, according to research by Chen et al. on dimerized Arduengo carbenes,[12] cannot be ascribed to a dimer of **5**. Compound **5** can be trapped in high yields by a number of electrophiles.[13] For example, the reaction with selenium led to the chalcogenone **6**, which was characterized by X-ray structure analysis (Figure 2).[14]

Scheme 2. Subsequent reactions of **4**-Br.



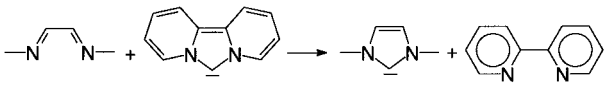


Figure 2. Structure of **6** in the crystal. Important bond lengths [Å] and angle [°]: Se1–C1 1.826, C1–N1 1.364, C1–N2 1.378, N1–C6 1.39, C6–C7 1.377, N1–C2 1.39, C2–C3 1.34, C3–C4 1.41, C4–C5 1.34, C5–C6 1.41; N1-C1-N2 103.8.

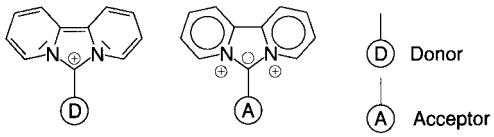
Compound **6** is characterized by a large degree of localization of the double bonds of the hydrocarbon moiety and partial delocalization in the selenourea structural element. The C(Se)–N bonds are longer and the C–Se bond is shorter in **6** than in an open-chain selenourea (each by about 0.04 Å).[16] This indicates that the hybridization of the bridging C atom corresponds to that in **4**-Br.



The two-step deprotonation of dication **3** leads to a far-reaching electronic reorganization. Whereas **3** contains two aromatic rings, **4** (in **4**-Br · H_2O, see Figure 1) is characterized by resonance structure **4B** (see Scheme 1) with a reduced bipyridine subsystem. Further deprotonation of **4** should then lead to an even more strongly localized π system, which according to ab initio calculations (3-21G*)[17] is better represented by the resonance structure **5B** (typical of arduengo carbenes) than by the bis(ylide) form **5A** (see Scheme 2). The latter is probably relevant for the description of excited states and gives an indication of the structural relationship of this class of compounds with "true" bis(ylides) such as carbodiphosphoranes. These were recognized early on as formal complexes of an excited singlet C atom with two molecules of triorganophosphane as stabilizing donor ligands.[18] By analogy, **5** can be seen as a chelate complex of such a C atom and 2,2′-bipyridine. Model calculations (3-21G*) for C1-transfer reactions with suitable reaction partners show that this view, beyond formal considerations, is supported by thermodynamics. Therefore, **5** should react according to the isodesmic Equation (1) with *N,N*′-dimethyl-

1,4-diazabutadienein a highly exothermic reaction ($\Delta H_f = -51.06$ kcal mol^{-1}) to the corresponding stable imidazol-2-ylidene and 2,2′-bipyridine. This should render **5** much more suitable for C1 transfer than Arduengo carbenes. Kinetic factors should be decisive for the experimental realization.

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0345 $ 17.50+.50/0

When an electrophile is coordinated to the nucleophile **5**, two electronic limiting cases can be distinguished for the resulting adducts: If the substituent at the bridging C atom shows donor character, resonance structure **7** dominates (e.g. selone **6**). If, on the other hand, the substituent is an acceptor, the adduct is characterized by resonance structure **8** with complementary polarization. We have already experimentally verified this structural classification.[19] Introducing carbene **5** into organic and inorganic substrates thus creates a type of

7 **8**

ligand which optimally adapts to the electronic needs of the substrate. The two-step bipyridinium redox system of **5**, which is immanent in the system, can flexibly fulfill the electronic demands on the bridging C atom with its reduced (situation in **7**) and oxidized forms (situation in **8**) as a built-in umpolung reagent. Corresponding adducts of Arduengo carbenes do not show a comparable electronic flexibility.

Experimental Section

All reactions were carried out under a nitrogen atmosphere with anhydrous, N_2-saturated solvents in Schlenk vessels. Correct elemental analyses (C,H,N) are available.

2: Diazo compound **1** (4.560 g, 7.65 mmol) was dissolved in CH_2Cl_2 (20 mL), and HOTf (0.71 mL, 8.0 mmol) added. After gas formation had ceased the mixture was stirred for 36 h at room temperature; the color became brown-red in the process. The solution was then concentrated under vacuum to about 5 mL. The white product was precipitated with Et_2O (150 mL), isolated by filtration, washed with Et_2O (25 mL), and dried under vacuum for 2 h; yield: 4.303 g (91 %). ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 6.52$ (s, 2H; CH_2), 7.73 (m, 12H; C_6H_5), 7.82 (m, 3H; C_6H_5); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 68.51$ (CH_2), 118.13 (C1), 118.16 (q, ^1J(C,F) = 320 Hz; $F_3CSO_3CH_2$), 120.47 (q, ^1J(C,F) = 320 Hz; $F_3CSO_3^-$), 131.24 (C3/C5), 133.05 (C2/C6), 135.10 (C4); ^{19}F NMR (470 MHz, $CDCl_3$, C_6F_6): $\delta = -73.07$ ($F_3CSO_3CH_2$), -78.62 ($F_3CSO_3^-$).

4-Br: A solution of **2** (1.208 g, 1.95 mmol) in CH_3CN (60 mL) was treated with 2,2′-bipyridine (0.671 g, 4.30 mmol) and heated at reflux for 5 d. After removal of the solvent under vacuum the residue was stirred for 2 h in Et_2O (50 mL), filtered, washed with Et_2O (15 mL), and dried for 2 h under vacuum. The solid was dissolved in CH_2Cl_2 (50 mL), and a solution of Bu_4NBr (1.290 g, 4.00 mmol) in CH_2Cl_2 (10 mL) added. After 2 h the mixture was filtered to remove insoluble components. A yellow-brown solid was then precipitated with Et_2O (100 mL), isolated by filteration, washed with Et_2O (20 mL), and dried under vacuum for 2 h. Crystallization from EtOH afforded dark yellow **4**-Br; yield: 0.365 g (75 %). Crystals suitable for X-ray structure analysis formed in a supersaturated solution in EtOH at ambient temperature. ^{1}H NMR (400 MHz, [D$_6$]DMSO): $\delta = 7.56$ (m, 4H), 8.69 (m, 2H), 9.07 (m, 2H), 10.40 (s, 1H); ^{13}C NMR (100 MHz, [D$_6$]DMSO): $\delta = 116.01$ (bridging C atom), 118.76, 120.38, 121.71, 122.65, 123.34.

3-2 OTf: Salt **4**-Br (0.295 g, 1.18 mmol) was suspended in (THF) 20 mL, and HOTf (0.23 mL, 2.61 mmol) added at $-20\,^\circ$C. After 18 h the mixture was filtered. The white solid isolated was washed with THF (10 mL) and Et_2O (10 mL), and was dried under vacuum for 2 h; yield: 0.497 g (90 %). ^{1}H NMR (400 MHz, CD_3CN): $\delta = 7.41$ (s, 2H; CH_2), 8.41 (m, 2H), 8.97 (m, 4H), 9.35 (m, 2H); ^{13}C NMR (100 MHz, CD_3CN): $\delta = 77.65$ (CH_2), 120.72 (q, ^1J(C,F) = 320 Hz; CF_3), 125.28, 131.35, 142.95, 144.21, 150.34.

5: KO*t*Bu (0.065 g, 0.58 mmol) was added to a suspension of **4**-Br (0.097 g, 0.39 mmol) in THF (3 mL) at $-30\,^\circ$C. After 30 min the inorganic components (KBr, excess KO*t*Bu) were removed by filteration over Celite at $-60\,^\circ$C. The orange filtrate was examined with NMR spectroscopy. ^{13}C NMR (100 MHz, THF, $-30\,^\circ$C, [D$_6$]acetone): $\delta = 114.12$, 117.44, 117.64, 121.83, 128.72, 196.41.

Chemical Synthesis of a Circular Protein Domain: Evidence for Folding-Assisted Cyclization**

Julio A. Camarero, Joanna Pavel, and Tom W. Muir*

The chemical-ligation approach to the condensation of peptide fragments offers a unique route for generating proteins possessing both natural[1] and unnatural topology.[2] Of the various architectures possible, one of the most fascinating from the perspective of both protein engineering and protein folding is the circular topology.[3] Although head-to-tail cyclization is commonly used to constrain the structure of small peptides,[4] relatively little is known about the affect of this modification on the structure and function of a protein. Indeed, the bulk of our current knowledge is based on the pioneering work of Creighton and co-workers on a cyclized version of bovine pancreatic trypsin inhibitor (BPTI) prepared by random chemical cross-linking.[3] Here we demonstrate that a backbone-cyclized protein domain, prepared by an intramolecular version[5] of Kent's native chemical ligation,[6] is able to spontaneously fold into a functional, native-like conformation. In addition, we provide evidence that the rate of cyclization is related to the folded state of the protein.

Our initial studies on protein cyclization focussed on the WW domain from the human Yes kinase-associated protein (YAP).[7] This protein domain possesses a globular structure composed of a three-stranded antiparallel β sheet which positions the flexible N and C termini in close proximity.[8] Given that native chemical ligation is tolerant to the presence of chemical denaturants,[6] it was anticipated that insights into the effect of this juxtaposition on the chemical reaction rate would be forthcoming.

The strategy used to synthesize the circular WW domain is shown in Scheme 1. Key to our approach was the generation

Scheme 1. Synthesis of the circular WW protein domain **2**.

of the linear polypeptide precursor **1**, which contains both groups necessary for native chemical ligation: an N-terminal cysteine residue and a C-terminal thioester group.[9] Cyclization of fully unprotected **1** to give the circular WW domain **2** was remarkably clean and extremely rapid (Figure 1). The ligation product was characterized as **2** by a combination of

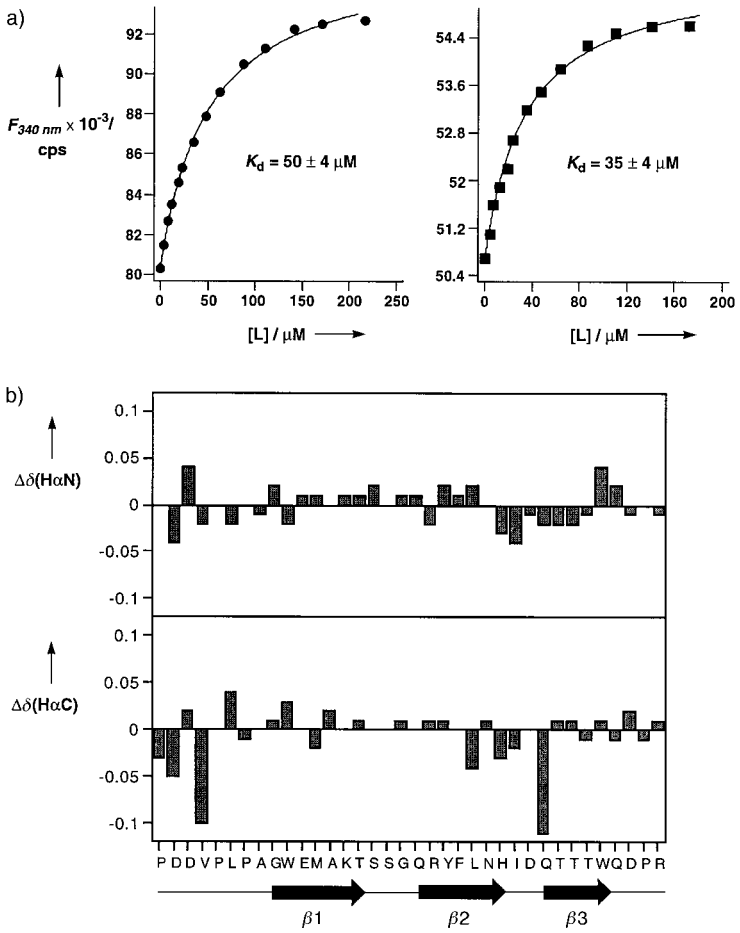

Figure 2. a) Binding of the linear (●) and circular (■) forms of the WW domain to the proline-rich ligand Ac–GTPPPPYTVG–NH_2 (L); cps = counts per scan. b) Summary of the ^{1}H NMR assignments for the main-chain protons: $\Delta\delta$(HαN) and $\Delta\delta$(HαC) are the deviations in the chemical shifts of the backbone protons in the circular WW domain from those in the the linear WW domain. The location of the secondary structure elements are shown at the bottom.[8]

electrospray mass spectrometry (ES-MS), tryptic digestion, and Edman sequencing.[10]

The YAP WW domain binds to proline-rich peptides containing the consensus sequence PPxY.[11] A fluoresence-based ligand-binding assay was used to study the functional consequences of backbone cyclization of the YAP WW domain (Figure 2a). As predicted based on the native structure of the protein, cyclization of the WW domain has no deleterious effect on ligand-binding activity. Indeed, the circular protein has a slightly higher affinity for ligands than its linear counterpart (dissociation constants $K_{d(cyclic)} = 35$ and $K_{d(linear)} = 50\,\mu$M).[12] Interestingly, the ligand affinity was the same regardless of whether the cyclic protein had been prepared in the presence or absence of 6 M guanidinium chloride (GdmCl), suggesting that the folding process is not inhibited by the cyclic topology.

The solution structures of the circular and linear YAP WW domains complexed to ligands were studied by two-dimensional homonuclear NMR spectroscopy. Deviations in the chemical shifts for the main-chain protons in the core β-sheet structure of the linear[13] and circular domains were uniformly less than 0.05 ppm, indicating that the same global fold is common to both versions of the molecule (Figure 2b). The NMR samples were prepared by simply dissolving the proteins, which had been purified by HPLC, in phosphate buffer containing the ligand. Given that HPLC purification is denaturing, this again indicates that the circular protein, like its linear counterpart, can spontaneously fold in the presence of the ligand.

The influence of the fold in the WW domain on the cyclization rate was investigated by performing the reaction in the presence and absence of chemical denaturant. Addition of 6 M GdmCl to the ligation buffer had a marked effect on the rate of cyclization: The reaction was approximately one order of magnitude faster under folding conditions than under unfolding conditions (Figure 3). Interestingly, linear polypeptide **1** was cleanly converted into cyclic **2**, regardless of whether 6 M GdmCl was present or absent in the ligation buffer. This rate enhancement on going from unfolding to folding conditions is significant and can be understood in terms of the proximity of the N and C termini within the native conformation of the protein. Under folding conditions the local concentration of the cysteinyl and thioester reactive functionalities would be expected to be higher than under unfolding conditions; this leads to a more rapid reaction for the former.[14] Therefore, the cyclization reaction is assisted by the native conformation of the protein.

We have generated a functional circular version of a WW protein domain by intramolecular chemical ligation. It is expected that several emerging areas in protein engineering will benefit from the ability to efficiently prepare backbone-cyclized polypeptides from unprotected linear precursors. For example, backbone cyclization provides a general way of constraining minimized protein sequences and complements the use of disulfide bonds.[15] Equally, new opportunities are created in sequence permutation by combining chemoselective cyclization with subsequent main-chain cleavages. Finally, our observation that the kinetics of protein cyclization are sensitive to changes in protein structure

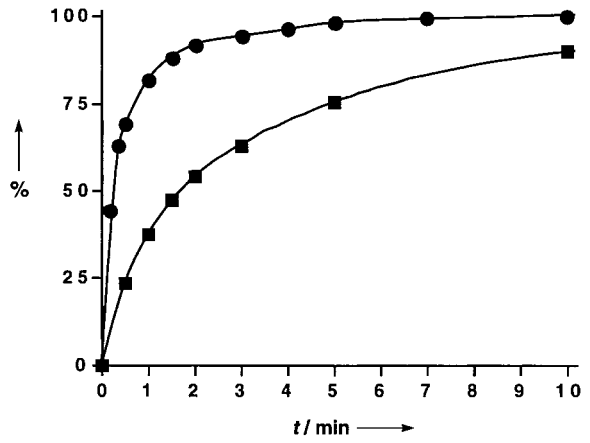

Figure 3. Progress of the cyclization under folding (0 M GdmCl, ●) and unfolding conditions (6 M GdmCl, ■).

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0348 $ 17.50+.50/0

suggests a potential application of this approach in the study of protein-structure dynamics.

Experimental Section

All peptide synthesis were carried out according to the in situ neutralization/HBTU activation protocol for Boc solid-phase peptide synthesis (HBTU = benzotriazol-1-yl-*N*-tetramethyluronium hexafluorophosphate).[16] Peptide thioester **1** was prepared by selective thioesterification of the corresponding peptide thioacid (prepared on a glycine–thioester support)[17] with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB, Ellman's reagent) as previously described[5a] and purified by preparative HPLC. ES-MS: observed mass: 5546.3(1.4) Da; calcd for $C_{244}H_{361}N_{65}O_{76}S_4$: 5545.5 (monoisotopic), 5549.0 (average isotope composition).

Cyclization: Purified **1** (0.4 μmol, 2.2 mg) was dissolved to a final concentration of about 50 μM in a freshly degassed buffer containing 0.1 M sodium phosphate and 1 mM ethylenediamine tetraacetate (EDTA) at pH 7.5 and 0.05 volume % each of PhSH and BnSH. In cyclization reactions carried out under unfolding conditions, 6 M GdmCl was included in the above buffer. To monitor the course of the reaction, small aliquots (50 μL) of the reaction mixture were periodically removed, quickly quenched by addition of 5% trifluoroacetic acid in water (20 μL), and investigated by analytical HPLC. The degree of conversion of **1** into **2** was calculated based on the absorption at 280 nm. The overall yield for the cyclization reaction following HPLC purification was 1.8 mg (0.32 μmol, 81%). Circular protein **2** was characterized by ES-MS and tryptic digestion. ES-MS: observed mass: 5348.5(1.0) Da; calcd for $C_{237}H_{356}N_{64}O_{72}S_3$: 5346.5 (monoisotopic), 5350.0 (average isotope composition).

Tryptic digestion of **2**: Cyclic **2** (100 μg) was dissolved in 0.1 M tris(hydroxymethyl)aminomethane (Tris)/HCl buffer (pH 8.4, 200 μL). Lyophilized trypsin (10 μg, sequencing grade, Sigma) was then added, and the reaction maintained at 37 °C for 3 h; a solution of 1,4-dithiothreitol (DTT, 50 mM, 20 μL) was subsequently added. The three expected fragments T1 (H–AMLSQGCFEIPDDVPLPAGWEMAK–OH), T2 (H–TSSGQR–OH), and T3 (H–YFLNHIDQTTTWQDPR–OH) were isolated by HPLC and characterized by ES-MS and Edman sequencing.

The isotherms for ligand binding were obtained by monitoring the intrinsic Trp fluoresence at 340 nm as a function of the concentration of the ligand at 22 °C. In all cases, the protein concentration was kept at 2 μM in a buffer containing 40 mM sodium phosphate, 50 mM NaCl, and 1 mM DTT at pH 7.2. Equilibrium dissociation constants were extracted from the curves by assuming a 1:1 receptor–ligand complex.[18]

Two-dimensional ^{1}H NMR spectra were measured on a Bruker DPX-400 spectrometer (400.132 MHz). The NMR samples were dissolved in a buffer containing 10 mM sodium phosphate, 100 mM NaCl, 1 mM [D_{10}]DTT, 0.02% NaN_3, and 10% D_2O at pH 6.2. A series of TOCSY and NOESY experiments[19] were recorded at 278 K on samples containing both linear and circular WW domains with WW ligand (protein concentrations 0.6–1.2 mM; ratio of peptide to protein 3:1). Typical mixing times were 30 ms for TOCSY experiments and 50–250 ms for NOESY experiments.

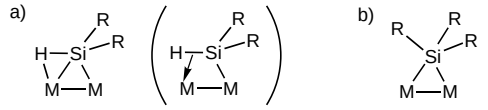
A Symmetrically Bridging Triarylsilyl Ligand in a Dinuclear Rhodium Complex: Synthesis and Structure of [LRh(H)(μ-Cl)(μ-SiAr$_2$)(μ-SiAr$_3$)Rh(H)L] (Ar = Ph, *p*-FC$_6$H$_4$; L = P*i*Pr$_3$)**



Kohtaro Osakada,* Take-aki Koizumi, and Takakazu Yamamoto*

Bridging coordination of a secondary silyl group ($SiHR_2$) in dinuclear complexes has become common for late transition metals.[1] The complexes reported so far contain both a σ bond between Si and one metal and a three-center, two-electron bond (3c–2e; π bond) between the Si–H group and the second metal center (Scheme 1a).

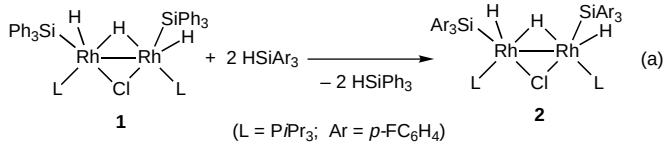
Scheme 1. Common (a) and seldom (b) coordination modes of secondary and tertiary silyl groups in dinuclear metal complexes.



The μ-η^1,η^2-coordination of the ligand results in two M–Si bond lengths that are significantly different from each other. Complexes with a tertiary silyl ligand in a bridging coordination (Scheme 1b) seem to be less stable than with a primary or secondary silyl ligand, since it has no Si–H group to stabilize M-Si-M coordination by Si-H-M 3c–2e bonding. Multinuclear Cu complexes whose metal centers are bridged by extremely bulky $Si(SiMe_3)_3$ ligands were isolated.[2] Dinuclear complexes with a bridging tertiary silyl ligand are of interest as models for the transition state of the migration of the tertiary silyl ligand from one metal to the other in a dinuclear framework (Scheme 2).[3, 4] Bridging coordination of PR_3 ligands that are isolobal to SiR_3^- ligands has already been

Scheme 2. Migration of a tertiary silyl group to the second metal center in dinuclear metal complexes.

established.[5] Here we report the synthesis and structure of novel dinuclear Rh complexes with a bridging triarylsilyl ligand that coordinates symmetrically to the two Rh centers.

Figure 1 shows the molecular structure of **4**, which has two Rh centers bridged by chloride, bis(4-fluorophenyl)silylene, and tri(4-fluorophenyl)silyl ligands.[8] The distances from the Rh centers to the Si atom of the triarylsilyl ligand are similar (2.444(4), 2.487(3) Å) and significantly longer than the bond lengths between the Si center of the silylene ligand and the Rh

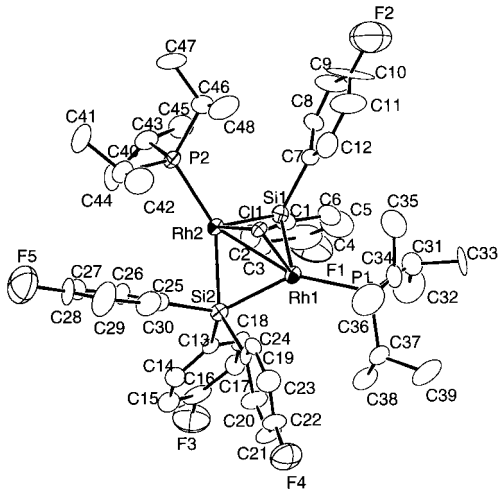

Figure 1. A perspective ORTEP drawing of the crystal structure of **4**. centers (2.290(3), 2.250(3) Å). They are longer than the Rh–Si bond lengths already reported (2.203–2.379 Å)[9] and comparable even to that in a Rh-H-Si 3c–2e bond (2.487 Å).[1d] This is in contrast to the structure of Cu complexes containing $Si(SiMe_3)_3$ ligands, in which the Cu–Si bonds to the bridging and nonbridging ligands do not show significant differences in length.[3] The NMR spectra of **3** and **4** are consistent with the above structure. The ^{1}H NMR spectra show peaks due to two equivalent nonbridging hydrido ligands at $\delta = -17.40$ and -17.60, respectively;[10] the positions of the hydrogen atoms were not determined in the crystal structure analysis of **4**.

The ^{1}H and ^{31}P{^{1}H} NMR spectroscopic measurements of the thermal transformation of **1** to **3** in C_6D_6 revealed there are no Rh complexes other than **1** and **3** throughout the reaction. Conversion of **1** into **3** obeys first-order kinetics ($k = 4.41 \times 10^{-5}\ s^{-1}$ at 333 K). This indicates that the reaction proceeds in an intramolecular fashion, most probably by oxidative addition of a Si–C bond of an arylsilyl ligand onto the metal center followed by coupling of the phenyl group of this ligand with a hydride ligand and release of benzene. Activation of Si–C bonds under mild conditions has been found for reactions of various organotransition metal complexes.[1g, 11]

We succeeded in isolating rhodium complexes with a symmetrically bridging triarylsilyl ligand. The complexes show unexpectedly thermal stability, although the Rh–Si bond is significantly longer than common Rh–Si single bonds. Smooth conversion of a nonbridging triarylsilyl ligand into a bridging one corroborates the proposed mechanism for migration of the silyl ligand between the metal centers in dinuclear complexes (Scheme 2).

Experimental Section

3: A solution of **1** (264 mg, 0.24 mmol) in toluene (5 mL) was stirred for 2 h at 70 °C. During the reaction the color of the solution changed from yellow to orange. Gas-chromatographic analysis of the solution showed quantitative formation of benzene. The $^{31}P\{^1H\}$ NMR spectrum of the mixture after the reaction showed only the signal for **3**. Addition of pentane caused separation of **3** as yellow-orange crystals, which were collected by filtration and recrystallized from toluene/pentane (71 mg, 29% yield). The similar reaction of **2** gave **4** in 51% yield.

The kinetic measurements of the conversion were carried out in a thermostatted (70 °C) NMR probe by following the changes in the intensities of the ^1H NMR signal for the hydrido ligands of **1**. Dioxane was used as an internal standard.

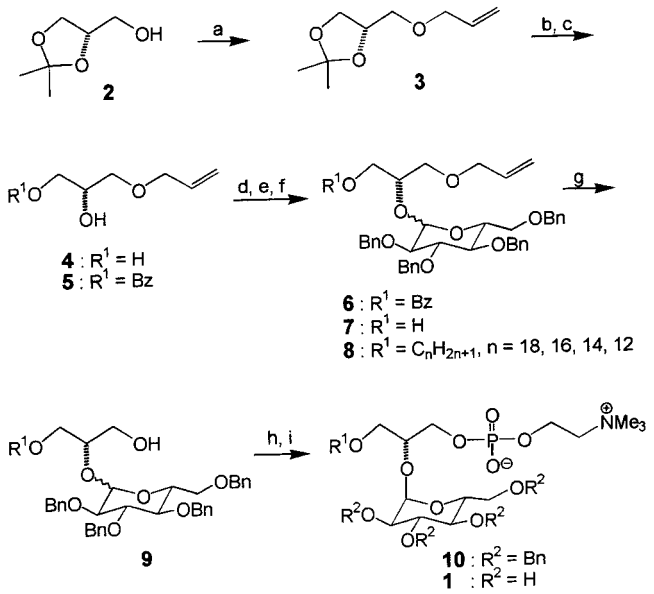
A Glucose-Containing Ether Lipid (Glc-PAF) as an Antiproliferative Analogue of the Platelet-Activating Factor**



Michael Mickeleit, Thomas Wieder, Michael Arnold, Christoph C. Geilen, Johann Mulzer, and Werner Reutter*

It has long been known that the platelet-activating factor (PAF) is a biologically highly active phosphoglyceride,[1] and various PAF analogues have been reported as inhibitors of proliferation.[2] However, since synthetic phospholipids are strongly cytotoxic, their therapeutic use has hitherto been restricted to topical applications.[3] We reported earlier the synthesis of a new type of glyceroglucolecithin (Glc-PC)[4] which displayed antiproliferative activity without cytotoxicity at concentrations below 10 μmol L^{-1}. We now present the glycoside of the ether analogue [1-*O*-octadecyl-2-*O*-α-D-glucopyranosyl-*sn*-glycero(3)]phosphorylcholine (Glc-PAF, **1**), which is formally derived from the PAF by exchanging the 2-acyl group for a glucose molecule.

The glycerol skeleton is provided by the starting material (*S*)-isopropylidene glycerol (**2**),[5] whose hydroxyl group is protected as the allyl ether functionality in **3** for introduction of the end groups (Scheme 1). The primary hydroxyl group of the diol **4** released upon acid hydrolysis cannot react directly to form an ether, and it is therefore first converted into a terminal benzoate ester group.[6] Compound **5** undergoes

Scheme 1. Synthesis of **1**. a) NaH, allyl bromide, THF, 0 °C (98 %); b) AcOH/H_2O (60/40) (73 %); c) BzCl, DMAP, py, 0 °C (76 %); d) 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl fluoride, $AgClO_4$, $SnCl_2$, 4-Å molecular sieves, Et_2O, −15 °C (81 %); e) KOH/MeOH (30 %), MeOH, (91 %); f) NaH, RBr, THF, 80 °C (83–98 %); g) Pd/C (10 %), *p*-toluenesulfonic acid, MeOH/*i*PrOH/H_2O (4/4/1), 80 °C (70–94 %); h) 1. $POCl_3$, Et_3N, $CHCl_3$, 0 °C; 2. choline tosylate, py, 0 °C (47–74 %); i) H_2 (2 atm), Pd/C (5 %), MeOH (71–97 %); Bn = benzyl, Bz = benzoyl, DMAP = 4-(dimethylamino)pyridine, py = pyridine, R = C_nH_{2n+1}, n = 18, 16, 14, 12.

reaction with 2,3,4,6-tetra-*O*-benzyl-β-D-glucopyranosyl fluoride[8] at the secondary alcohol functionality to provide glycoside **6**[9] according to Mukaiyama et al.[7] After saponification of the benzoate, the resulting compound **7** is converted into the ether with the appropriate alkyl bromide. Since the activity of choline-containing phospholipid analogues strongly depends on the length of the alkyl chain,[10] the chain length of the ether introduced at this stage (C_{18}, C_{16}, C_{14}, and C_{12}) corresponds to that of a biologically relevant derivative. Formation of the ether is highly temperature-dependent, and complete conversion into **8** does not occur until 80 °C.

Before introducing the final glycerol substituent (i.e. the phosphate), the original allyl ether must be cleaved by hydrogenolysis.[11] Alcohol **9** is then esterified with phosphoryl chloride, and the resulting dichloroester is immediately converted into the desired phosphocholine derivative **10** with choline tosylate.[12,13] Cleavage of the benzyl protecting groups presented considerable problems in the synthesis of the ester analogue Glc-PC. The ethers are, however, much more reactive, and the products are obtained in good yields after only short periods of hydrogenation. Starting from **2**, gram quantities of **1** were synthesized in nine steps with a total yield of 25 %.[14]

The biological activity of **1** was determined in a serum-free cell-culture system of human keratinocytes (HaCaT cells) by measuring three typical cell parameters. First, it was shown that **1** (n = 18) is nontoxic at concentrations below 4 μmol L^{-1} (Figure 1 a). Higher concentrations cause marked cell damage; the median lethal dose (LD_{50}) was 9 μmol L^{-1}. The growth-inhibitory properties of **1** were then investigated. As

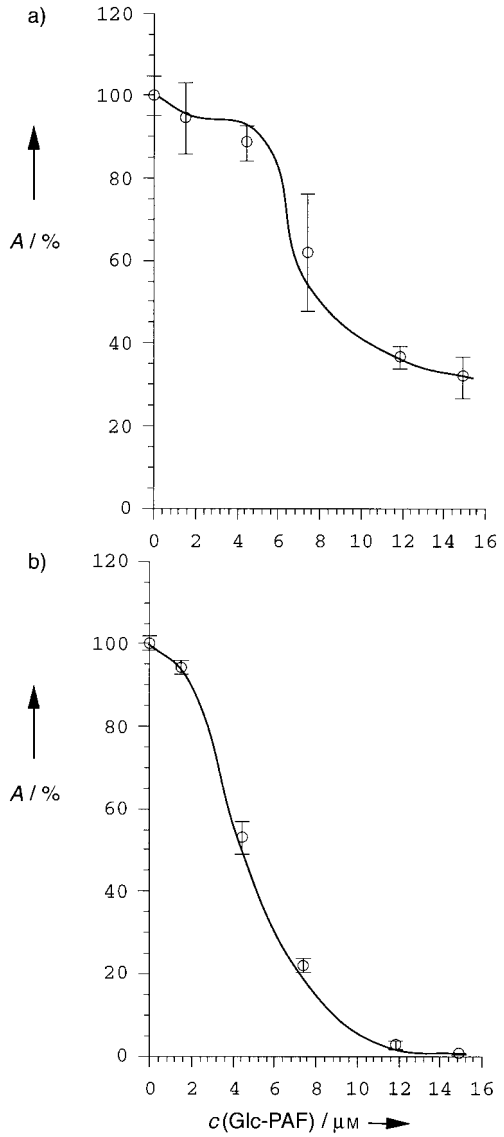

Figure 1. Influence of **1** (n = 18) on the viability (a) and proliferation (b) of HaCaT cells. Both are expressed as a percentage A of the value measured for the control experiment; c = concentration. Four experiments were carried out per data point. See the Experimental Section for details.

shown in Figure 1 b, nontoxic concentrations of **1** (n = 18) as low as 4 μmol L^{-1} inhibit proliferation. The inhibition curve shows a half-maximal inhibitor concentration (IC_{50}) of 4.8 μmol L^{-1}, which is well below the LD_{50} value. In view of the detergentlike structure of **1**, cytotoxicity may be attributed to cell lysis and/or the initiation of programmed cell death (apoptosis),[15] which is characterized biochemically by the appearance of ordered arrangements of internucleosomal DNA fragments.[16] To further characterize the cell death caused by **1**, we determined the proportion of apoptotic HaCaT cells by measuring the number of cytosolic nucleosomes after treatment of the cells for 20 h with the synthetic ether lipid. At low but antiproliferative concentrations of **1** (n = 18; 1.5, 4.5 and 7.4 μmol L^{-1}), the number of apoptotic cells showed a concentration-dependent increase; the greatest (tenfold) increase was observed for 7.4 μmol L^{-1} (Figure 2). At concentrations of 14.9 and 29.8 μmol L^{-1} there was a marked decrease in the number of apoptotic cells, as

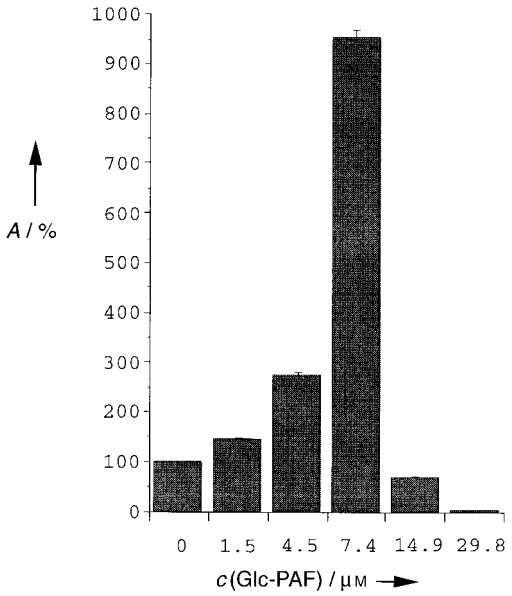

Figure 2. Influence of **1** ($n = 18$) on the apoptosis of HaCaT cells, which is expressed as the percentual enrichment A of apoptotic cells in comparison to the control experiment; c = concentration. Four experiments were carried out per data point. See the Experimental Section for details.

determined by the presence of cytosolic nucleosomes. This indicates that the cells were damaged by lysis at these higher concentrations. According to these data, **1** is a proliferation inhibitor which initiates programmed cell death in keratinocytes at concentrations below 7.5 μmol L^{-1}. Compared with the above-mentioned Glc-PC ($LD_{50} = 17$ μmol L^{-1} and $IC_{50} = 9$ μmol L^{-1} under the experimental conditions described above), **1** ($n = 18$) is not only biologically more active, but also more toxic. The synthesis of other derivatives with 2-glycosidic substituents and different alkyl side chains will be necessary to determine the structure – activity relationships of this new type of compound.

Experimental Section

Cell culture: The spontaneously immortalized human keratinocyte cell line HaCaT[17] was incubated in serum-free keratinocyte growth medium.[18] Compound **1** was dissolved directly in the keratinocyte growth medium.

Cytotoxicity test: Confluent HaCaT cells were incubated for 6 h with different concentrations of **1**. The cytotoxicity of **1** for HaCaT cells was determined in comparison with the control experiments (which did not contain **1**) by measuring the activity of alkaline phosphatase as described.[19]

Measurement of proliferation: HaCaT cells were sown at a cell density of about 20000 cells per cm^2. After adhesion the cells were incubated for 48 h with different concentrations of **1**. The cell count was determined as described[20] after staining with 0.1 % crystal violet in PBS, and compared with the control.

Measurement of apoptosis: Confluent HaCaT cells adapted to keratinocyte growth medium were treated for 20 h with different concentrations of **1**. The medium was removed, and the adherent cells released from the dish with a solution containing 0.1 % trypsin and 0.02 % ethylenediaminetetraacetic acid (EDTA). The cells were then washed off with serum-containing medium (10 % fetal-calf serum in Rosewell Park Memorial Institute (RPMI) medium) and combined with the previously removed medium. The cells were pelleted by centrifugation for 5 min at 300 g, washed once with serum-containing RPMI medium, and pelleted again. The cell pellet was incubated for 30 min in 1 mL of lysis buffer, and the resulting lysate centrifuged for 10 min at 13000 g to remove nonbound antibodies. Nucleosomes were then determined in the lysate and in the control with a commercially available enzyme-linked immunosorbent assay (ELISA) from Boehringer Mannheim according to the instructions provided by the manufacturer. An aliquot of each sample (20 μL) was pipetted into a well of a streptavidin-coated microtiter plate followed by immune reagent (80 μL; made up of 1 part peroxidase-conjugated anti-DNA antibody, 1 part biotinylated anti-histone antibody, and 18 parts incubation buffer) and incubated for 2 h at room temperature. After threefold washing incubation buffer, and the quantity of bound peroxidase-conjugated anti-DNA antibody was quantified by a peroxidase-catalyzed color reaction with measurement at 405 nm in the ELISA reader. The increase in the number of apoptotic cells was calculated by comparing the extinction of the treated sample with that of the corresponding control. The specificity of the method was tested by applying it to cells treated with suitable apoptosis-inducing substances (cell membrane-penetrating ceramides). In addition, electron microscopy of the treated cells revealed typical apoptotic changes, such as membrane evaginations and chromatin condensations, which were correlated with the results of the ELISA test.

Artificial Photosynthesis: Mimicking Redox Asymmetry**

Andrew C. Benniston,* Philip R. Mackie, and Anthony Harriman*

One intriguing aspect of the bacterial photosynthetic reaction center (RC) is the redox asymmetry of the cofactors: Electron transfer proceeds only along the L branch of an almost symmetrically twinned set of reagents.[1, 2] The M branch is apparently excluded, since the effective dielectric constant of the surrounding medium differs.[3, 4] A slightly higher polarity around the L branch favors electron transfer along this direction,[5] although the reaction can be made to proceed along the M branch in mutagenically modified RC complexes.[6] We now describe a model system that is similar to the RC complex: The two chemically identical electron acceptors bound to the primary donor have different reduction potentials because of their environment. This effect is achieved by wrapping an electron-donating crown ether around one of the acceptor moieties, thereby excluding access to polar solvent molecules and further attenuating its electron affinity with charge-transfer interactions.

Cyclophane **1** [functionalized with ruthenium(II) bis(2,2′-bipyridine)], the corresponding metalated [2]catenane **2**, and the free catenated ligand **3** were synthsized by standard

1 **2** **3**

procedures[7] and characterized by ^{1}H NMR spectroscopy and mass spectrometry. For **2** and **3**, as with analogous nonmetalated [2]catenanes, an electron-poor tetracationic 4,4′-bipyridinium-based cyclophane is interlocked with a complementary electron-donating macrocycle.[8]

The structural feature that is most important to the present study is the asymmetry of the two 4,4′-bipyridinium dications bound to the metal complex in **2**. The absence of a suitable internal ^{1}H NMR probe prevented direct measurement of the rate at which the macrocycle migrates between these two cationic units. Such studies were possible for **3** in [D$_6$]acetone; in particular, signals for the degenerate 6,6′ protons of the 2,2′-bipyridine unit are readily observable from $+25$ to $-60\,^\circ$C. At the coalescence temperature ($T_c = -33\,^\circ$C) the rate constant for this process was estimated as 88 s^{-1}, and the Gibbs energy of activation as 12.5 kcal mol^{-1}. The rate of interchange at the coalescence temperature, which corresponds to a lifetime of about 11 ms, indicates that the two interlocked rings in **2** are frozen on the time scale of the electron transfer.

Electrochemical studies of **2** in deoxygenated acetonitrile showed that the metal center undergoes a quasi-reversible one-electron oxidation with a half-wave potential E^0 of 1.29 ± 0.02 V versus the standard calomel electrode (SCE). At higher potentials, oxidation peaks can be resolved for the external ($E^0 = 1.44 \pm 0.02$ V vs. SCE) and internal ($E^0 = 1.73 \pm 0.04$ V vs. SCE) hydroquinol units of the crown ether. Upon reversing the scan, reduction peaks for the external ($E^0 = -0.32 \pm 0.01$ V vs. SCE) and internal ($E^0 = -0.45 \pm 0.01$ V vs. SCE) viologens were observed before the appearance of a two-electron peak ($E^0 = -0.85 \pm 0.03$ V vs. SCE) corresponding to formation of the neutral viologens. Similar electrochemical behavior was found for the nonmetalated **3** and for related [2]catenanes.[8, 9] The redox potentials for internal and external viologens differ because of a) the relative accessibility to polar solvent molecules and b) the interaction with electron-donating hydroquinol units. These factors combine to introduce significant (130 meV) redox asymmetry into **2**. The metal center in cyclophane **1** is oxidized at $E^0 = 1.29 \pm 0.02$ V vs. SCE, whereas the 4,4′-bipyridinium-based cyclophane undergoes one-electron reduction at $E^0 = -0.28 \pm 0.01$ V vs. SCE.

Because of the inherent redox asymmetry in **2**, we might expect light-induced electron transfer to occur selectively from the metal center to the external viologen in view of the more favorable thermodynamic driving force. To ensure that the rate of the forward electron transfer does indeed depend on the driving force, we first studied the noncatenated system **1**. Although **1** is not luminescent at room temperature, weak luminescence characteristic of the metal complex was observed at 77 K upon excitation at 565 nm. Transient absorption spectral studies at 20 °C indicate that the triplet excited state of the Ru^{II} complex, which is formed within the laser pulse, has a lifetime of (12 ± 2) ps; the parent compound tris(2,2′-bipyridine)ruthenium(II) has a lifetime of about 1 μs. After decay of the triplet state the spectra show the presence of a mixture of the Ru^{III} complex and the singly reduced form of the 4,4′-bipyridinium-based cyclophane. Decay of these redox intermediates occurred by first-order kinetics with a lifetime of (35 ± 3) ps. The overall reaction is fast because of the close proximity of the reactants; a similar conclusion was reached by Mallouk et al. for a related system that, however, was not part of a cyclophane.[10]

The triplet energy of the metal complex was determined to be about 1.90 eV from the low-temperature emission spectrum. The thermodynamic driving force[11] for light-induced reduction of the viologen subunits in acetonitrile was estimated as $\Delta G^0 \approx -0.36$ eV, which indicates that the reaction is likely to fall within the "normal Marcus region".[12]

Charge recombination is much more favorable ($\Delta G^0 \approx -1.60$ eV) and is likely to occur within the "inverted Marcus region". These expectations were confirmed by measuring the rates of forward and reverse electron transfer between -30 and $+65\,^{\circ}C$. The activation energies E_A of (0.070 ± 0.002) and (0.010 ± 0.001) eV, respectively, were derived from the linear Arrhenius plots for forward and reverse electron transfer. The total reorganization energy λ for forward electron transfer was calculated to be about 0.85 eV based on Marcus theory [Eq. (1)].[12]

$$E_A = \left(\frac{(\lambda + \Delta G^0)^2}{4\lambda}\right) \quad (1)$$

The rate constant for the forward electron transfer (k_{CS}), but not that of the charge recombination (k_{CR}), depends on the polarity of the surrounding solvent, as expressed in terms of the static dielectric constant ε_S. In highly polar solvents such as propylene carbonate ($\varepsilon_S = 62$), k_{CS} has an optimal value of about $10^{11}\,s^{-1}$ but decreases progressively as the polarity is reduced (Figure 1), subject to solubility restrictions.

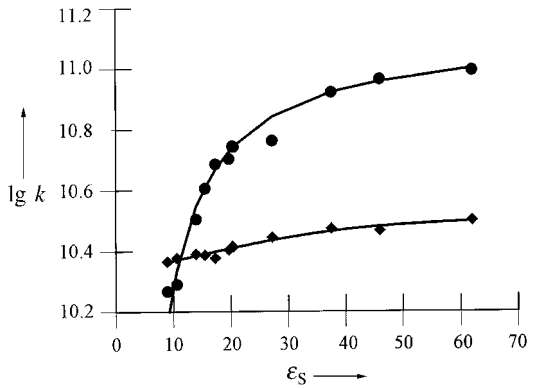

Figure 1. Effect of the dielectric constant on the rate constants for the forward electron transfer (●) and subsequent charge recombination (◆) measured for **1** after laser excitation at 565 nm. Solvents used (ε_S): propylene carbonate (62), dimethyl sulfoxide (46), acetonitrile (37.5), propionitrile (27.2), isobutyronitrile (20.4), butyronitrile (20.3), valeronitrile (19.7), hexanenitrile (17.3), 4-methylvaleronitrile (15.5), octanenitrile (13.9), 1,2-dichloroethane (10.6), dichloromethane (8.9).

Because the electron transfer is under activation control (i.e., $-\Delta G^0 \approx 0.4\lambda$), we attribute the decreased rate to a smaller thermodynamic driving force in less polar solvents due to weaker solvation of reactants and products. The important conclusion of these studies is that k_{CS} increases with increasing solvent polarity and with increasing temperature.

Similar transient spectroscopic studies were made with the catenane **2**, whose two electron-poor arms show disparate reduction potentials in acetonitrile. Laser excitation resulted in immediate formation of the triplet excited state of the ruthenium(II) complex, which decayed by first-order kinetics with a lifetime of (17 ± 2) ps. The triplet state decayed by way of electron transfer to the adjacent cyclophane ($k_{CS} \approx 5.9 \times 10^{10}\,s^{-1}$), as demonstrated by transient absorption spectroscopy (Figure 2), followed by subsequent charge recombination ($k_{CR} \approx 2.4 \times 10^{10}\,s^{-1}$) to restore the ground state. The redox intermediates survive for about (42 ± 4) ps. By measuring the rate of the forward electron transfer in acetonitrile as a function of temperature, the activation energy for this process was found to be (0.062 ± 0.002) eV. In contrast, charge recombination, which must occur in the inverted Marcus region ($\Delta G^0 \approx -1.6$ eV), is almost activationless. Upon application of Equation (1), λ is estimated to be about 0.75 eV; the forward electron transfer lies in the normal Marcus region ($-\Delta G^0 \approx 0.4\lambda$), in which the rate increases with increasing driving force.

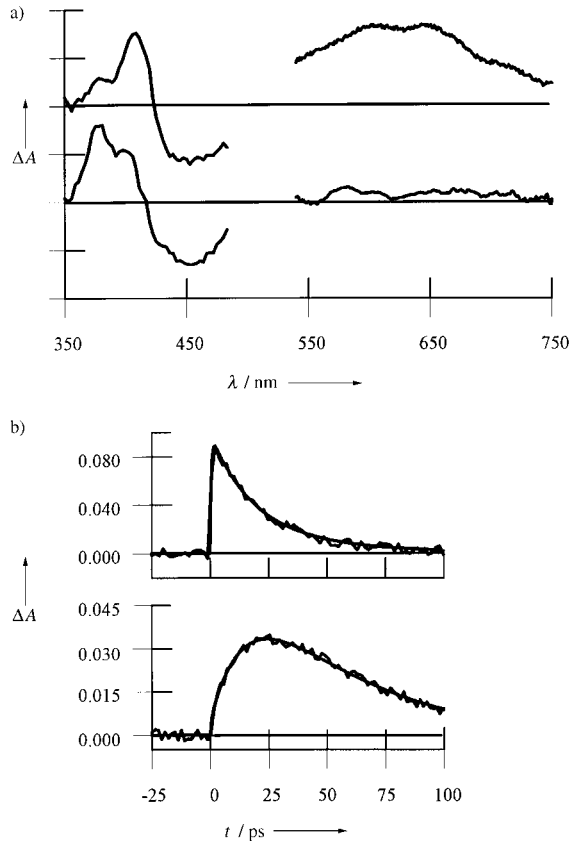

Figure 2. a) Transient differential absorption spectra recorded 1 ps (lower curve) and 25 ps (upper curve) after laser excitation of **2** in acetonitrile at 20 °C. b) Decay profiles showing formation and decay of the triplet state of the ruthenium(II) complex at 370 nm (top) and of the radical ion pair at 620 nm (bottom).

Consequently, the rate of electron transfer to the external viologen ($\Delta G^0 = -0.32$ eV) is expected to exceed that to the internal viologen ($\Delta G^0 = -0.19$ eV). Indeed, providing that λ and the electronic-coupling matrix element are identical for both viologens, a redox asymmetry of 130 meV would create a fivefold difference in rate. Therefore, electron transfer to the external viologen should account for about 85 % of the overall

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0355 $ 17.50+.50/0

deactivation of the excited state. This remains a theoretical hypothesis, however, since the two viologens cannot be distinguished by spectroscopic means. Even so, it seems reasonable to anticipate that highly directional electron transfer can be induced by environmental effects of the type proposed here.

Experimental Section

The syntheses of **1**, **2**, and **3** starting from readily prepared 4,4′-bis-(methylene-4,4′-bipyridinium)-2,2′-bipyridyl bis(hexafluorophosphate) have been reported.[7] Solvents were purified by standard methods, and dielectric constants were taken from the literature.[13] For all laser spectroscopic studies, excitation was carried out at 565 nm with a 0.3-ps laser pulse delivered from a Nd-YAG pumped pyromethene dye laser similar to that described in ref. [14].

Solid-Phase Immobilization of a New Epoxidation Catalyst**

Simon Krijnen, Hendrikus C. L. Abbenhuis,* Rob W. J. M. Hanssen, Jan H. C. van Hooff, and Rutger A. van Santen

The heterogenization of homogeneous catalysts is an important topic in liquid-phase oxidation catalysis.[1] Recently we reported on the use of the titanium(IV) silsesquioxane $[\{(c\text{-}C_6H_{11})_7Si_7O_{12}\}Ti(\eta^5\text{-}C_5H_5)]$ **1**[2] as an active and robust homogeneous catalyst for alkene epoxidation.[3] Under the catalytic conditions employed, **1** is stable and does not leach

titanium, which makes it an attractive candidate for heterogenization. Here we report on the immobilization of **1** in an MCM-41 molecular sieve,[4] for which we especially exploited its strong adsorption in the MCM-41 channel. The resulting self-assembled materials are active, truly heterogeneous, and recyclable catalysts for alkene epoxidation in the liquid phase.

The adsorption of the silsesquioxane **1** from hexane into an MCM-41 molecular sieve occurs quickly and can be followed easily by UV/Vis spectroscopy in solution by monitoring its intense 216 nm band. We investigated MCM-41 molecular sieves with Si/Al ratios of 42, 125, and ∞. The adsorption kinetics of **1** are typical for "single-file diffusion",[5] indicating that its actual adsorption takes place inside the MCM-41 channels. Because of this fast and complete adsorption, the loading of **1** can be adjusted easily by varying its total amount in solution. The maximum loading for the MCM-41 host with a Si/Al ratio of 42 was found to be 97 milligrams of **1** per gram

of MCM-41 (i.e. 4.3 mg Ti/g MCM-41). FT-IR analysis of MCM-41 materials (KBr pellet) with a maximum loading of **1** showed, superimposed on the vibration bands characteristic for MCM-41, bands typical for **1**: cyclohexyl and cyclopentadienyl C–H vibrations (2854, 2928 cm^{-1}) together with a very characteristic cyclopentadienyl C–C vibration (1449 cm^{-1}).

The titanium silsesquioxane containing materials efficiently catalyze the epoxidation of cyclooctene at 50°C with *tert*-butyl hydroperoxide (Table 1, Figure 1). The scope of the reaction

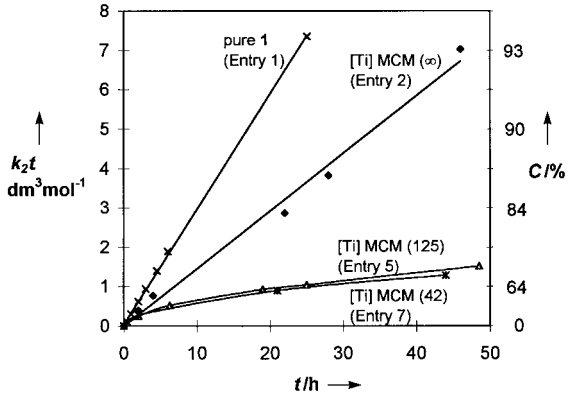

Figure 1. Second-order rate parameter k_2t for the catalytic epoxidation with [Ti] catalysts (Table 1, entries 1, 2, 5, 7). Left axis: $k_2t = 1/[A]_t - 1/[A]_0$ ($[A]_t$ = concentration of cyclooctene at time t and $[A]_0$ = concentration of cyclooctene at $t = 0$). Right axis: conversion C versus time t. All reactions were performed with equimolar amounts of alkene and dried *tert*-butyl hydroperoxide (7.2 mmol each) in hexane (4.0 mL).

includes also the epoxidation of norbornene and 1-octene.[3] With the aluminum-free MCM-41 molecular sieves, in particular, high catalytic activity and heterogeneity was obtained. The data show that the presence of aluminum in MCM-41 reduces the activity of the catalyst (Table 1, entries 2–7).[6] Moreover, under epoxidizing conditions these catalysts quantitatively leached **1** from its aluminum-containing mesoporous host, thus rendering the catalysis homogeneous.

Fortunately, the undesired leaching of the aluminum-containing catalysts can be completely stopped when the MCM-41 molecular sieves are treated with the silylating agent $SiCl_2Ph_2$ prior to catalysis (Table 1, entries 3, 5, 7).[7] The unresolved phenyl signals of the $(\text{-O-})_2SiPh_2$ functions are found in the ^{13}C MAS NMR spectrum (100 MHz) at $\delta = 127.3$ and $\delta = 134.3$. BET analysis on an impregnated MCM-41 sample clearly showed a decrease in both pore diameter and mesopore volume upon adsorption of the silsesquioxane **1** as well as an increase in surface area due to the additional surface of **1** (Table 2). The effect of the silylation is also expressed in both a reduced pore diameter and a reduced mesopore volume.

Table 1. Activity of **1** immobilized in mesoporous MCM-41 or silica for the epoxidation of cyclooctene.[a]

Entry	[Ti] Catalyst (Si/Al ratio)	Silylated samples[c]	Heterogeneous?[d]	Conv. [%][e] [mol mol^{-1} h^{-1}]	TOF[f]
1	**1**	–	–	95	287

[a] All reactions were performed with equimolar amounts of alkene and dried *tert*-butyl hydroperoxide (1.8 mmol each) in hexane (1.0 mL) and with 60 mg catalyst. [b] Catalysts with the prefix [Ti] contain complex **1** (1.2 mg Ti/g MCM-41); otherwise reference is being made to blank experiments without **1**. [c] $SiCl_2Ph_2$ was used as the silylating agent. [d] Catalysts are defined as heterogeneous when at 30% conversion and after direct filtration, no subsequent conversion takes place in the filtrate. [e] Conversion of cyclooctene determined by ^1H NMR spectroscopy after 22 h. Selectivities towards the epoxide >95%. [f] Initial turnover frequency (TOF) determined after 2 h. [g] Since the reaction was homogeneous the conversion is not relevant.

Table 2. BET results for the series of aluminum-free MCM-41 materials employed in catalysis.[a]

Entry[b]	Cat.	Surface area [$m^2 g^{-1}$]	Modus pore diameter [nm]	Micropore volume [$cm^3 g^{-1}$]	Mesopore volume [$cm^3 g^{-1}$]
10	MCM (∞)	552	2.9	0.20	0.15
2	[Ti]-MCM (∞)	610	2.7	0.20	0.10
3	[Ti]-MCM (∞) silylated	540	2.3	0.16	0.05

[a] All data have a maximum error of 5%; the error in the mesopore volume is roughly 20%. The [Ti]-MCM-41 samples were loaded with 25 milligrams of **1** per gram of MCM-41. [b] Entries as in Table 1.

The activity of the aluminum-containing heterogeneous catalysts obtained by the silylation procedure decreased in the course of alkene epoxidation (see Figure 1). Interestingly, the aluminum-free catalyst showed no deactivation at all, in either silylated or nonsilylated form. The kinetic data obtained for heterogeneous catalysis employing [Ti]-MCM-41 (∞) and for homogeneous catalysis by the complex **1** can be described by overall second-order rate equations (see Figure 1). All heterogeneous catalysts can be easily recovered by filtration; the aluminum-free catalyst can even be reused at least three times without an apparent loss of activity.

Even when a smaller silylation agent like $SiCl_2(CH_3)_2$ is used, an active, heterogeneous, nonleaching catalyst is obtained. This result indicates that the apolarity of the framework determines whether the catalyst will leach its active complex **1**, and not that **1** is physically trapped by the silylating agent.

The influence of the polarity of the framework on the adsorption of substrates was investigated by monitoring the competitive adsorption of 1,2-epoxyoctane and 1-octene. When an aluminum-containing MCM-41 molecular sieve was used, the 1,2-epoxyoctane/1-octene ratio decreased from 1 to 0 in several minutes, while in the case of an aluminum-free MCM-41 this ratio levels off at about 0.2. This demonstrates that the affinity of the hydrophilic aluminum-contain-

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3703-0357 $ 17.50+.50/0

ing MCM-41 for the more polar epoxide is higher than that of the relatively hydrophobic aluminum-free MCM-41 framework. This observation is supported by thermogravimetric analysis, which indicated that both the water content and the dehydration temperature for the aluminum-free MCM-41 (1%, 49°C) are much lower than that of the the aluminum-containing MCM-41 (5%, 60°C). The higher polarity of the aluminum-containing MCM-41 materials is likely to induce leaching.[8] In contrast, the degree of apolarity of an aluminum-free MCM-41 molecular sieve is ideal for both strong adsorption of the catalyst, leading to a heterogeneous system, and diffusion of the organics through the MCM-41 channel. In contrast to physically enclosed systems, this will lead to a *self-assembled heterogeneous catalyst* that is prone to neither leaching nor deactivation.[9]

Conventional silica gel (Silica Grace SG360, total pore volume ca. $0.9-1.0\ cm^3\,g^{-1}$, surface area roughly $600\ m^2\,g^{-1}$) also adsorbs complex **1**. During catalyst testing, however, this material undergoes a significant degree of leaching (see Table 1). From this finding we conclude that a silica with channel-type pores such as an aluminum-free MCM-41 molecular sieve is essential for an irreversible adsorption of the silsesquioxane complex.

Experimental Section

The different MCM-41 samples were prepared following the procedure used by Beck et al.[10] and adapted by Busio et al.[4] In a typical adsorption experiment 50 mL of a 10^{-3} M solution of **1**[2b] in hexane (p.a., Acros) was added slowly to a suspension of 2 g of dried MCM-41 in hexane (50 mL), and the suspension was stirred for 24 h. The impregnated MCM-41 was subsequently filtered off, washed with hexane (3×20 mL), and dried in air at 80°C for 24 h.

In a typical silylation experiment 0.5 g of a dried and degassed impregnated MCM-41 sample was refluxed in a solution of 70 mL of hexane with 2.5 g of dichlorodiphenylsilane (96%, Acros) under an inert atmosphere for 72 h. The obtained material was filtered off, washed with hexane (3×20 mL) and acetone (p.a., Acros, 3×20 mL), and dried in air at 80°C for 24 h.

A Biomimetic Synthesis of a Porphobilinogen Precursor Using a Mukaiyama Aldol Reaction**

André R. Chaperon, Thomas M. Engeloch, and Reinhard Neier*

Dedicated to Professor Dieter Seebach on the occasion of his 60th birthday

The tetrapyrrolic "pigments of life" fulfill many different functions and therefore have a special position among natural pigments.[1] The structures of the intermediates (δ-aminolevulinic acid (ALA, **1**) and porphobilinogen (PBG, **2**)) leading to uroporphyrinogen (Uro) III (**3**), the precursor of all tetrapyrroles, were determined in the early 1950s (Scheme 1).[2] Even early on, the second and third steps of this elegant and convergent biosynthesis could be mimicked chemically.[3]

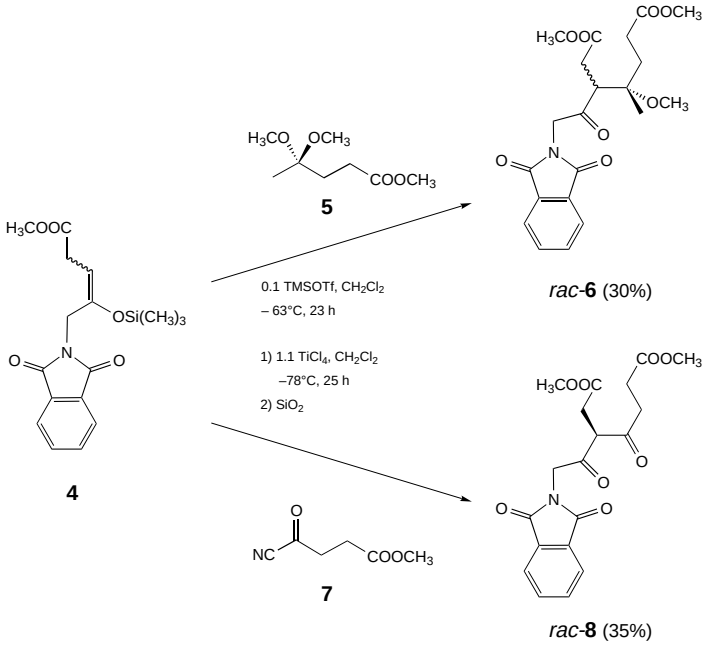
In this context the question arose whether the biosynthesis of porphobilinogen (**2**), which formally corresponds to a Knorr synthesis, could be imitated in the test tube.[4] Despite efforts in different laboratories the process could not be imitated satisfactorily so far. We are examining whether one can imitate the mechanism for the biosynthesis of **2** proposed by Shemin and Nandi[5] and use it for the synthesis of pyrroles.[6] We report here on the synthesis of an N-protected derivative of PBG, which relies on the Mukaiyama aldol reaction.[7] Since the structure determination of **2** 40 years ago, six different synthetic strategies have been developed.[2a, 8] Despite the simplicity of the structure, the synthesis of this natural product in large quantities has remained difficult. In recent years several groups have developed novel approaches to porphobilinogen (**2**).[9]



The starting point for our synthesis was the preparation of alkyl-substituted pyrroles using the two-step procedure consisting of a Mukaiyama aldol reaction followed by the reduction of the azido function to give the amino group.[6] The silyl enol ether **4**, obtained from 5-phthalimidomethyllevulinate in 93% yield, was required as starting material for our synthesis.[10] Because **4** is not very nucleophilic, we were unable to couple it under standard conditions with the acetal of 5-azidomethyllevulinate.[6] At temperatures below -40°C $TiCl_4$ was not active enough to catalyze the aldol reaction. At temperatures above -40°C we only could observe decomposition of the starting materials. When we used Lewis acids like TMSOTf[11] or the "super-Lewis acid" $(TMS)B(OTf)_4$ described by Davis[12] we could induce the aldol reaction with the dimethyl acetal of methyllevulinate (**5**). We applied the conditions described by Noyori et al.[11a] with 0.11 equiv TMSOTf as catalyst and were able to isolate 30% of the pure diastereoisomer *rac*-**6** (Scheme 2).

Even with these Lewis acids the crucial C–C bond formation could not be achieved when protected precursors of 5-aminolevulinate were employed. Increasing the reactivity of the carbonyl component seemed the most promising way to solve the problem. When **4** was allowed to react with acylcyanide **7**, the cyanohydrin could be detected in the crude reaction product. However, after aqueous extraction and purification by column chromatography the hydrolysis product *rac*-**8** was obtained in 35% yield (Scheme 2).

Under optimized conditions at -20°C and with $TiCl_4$, which had been freed from HCl by distillation over polyvinylpyridine, the aldol product *rac*-**9** was obtained in 60 to 87% yield (Scheme 3). One diastereoisomer of the aldol

Scheme 3. Synthesis of the protected porphobilinogen **11**.

Scheme 2. Aldol reaction with silyl enol ether **4**.

product *rac*-**9** could be obtained in 47% yield in analytically pure form after crystallization. Attempts to reduce the cyanohydrin *rac*-**9** directly met with limited success. For the synthesis we protected crude *rac*-**9** by reaction with 2-propenol acetate; the acetylated aldol product *rac*-**10** was obtained in 56% yield. Even the reduction of *rac*-**10** proved to be difficult, but finally we were able to reduce *rac*-**10** smoothly at 65°C under 120 atm H_2 in the presence of Raney nickel. After column chromatography we obtained the protected porphobilinogen **11**[13] in 54% yield and in analytically pure form. Removal of the protecting groups in two steps has been described previously.[14]

We were able to obtain the protected porphobilinogen **11** in a convergent way starting from two easily obtainable starting materials. The central step of the synthesis is the Mukaiyama aldol reaction between the regioselectively formed silyl enol ether **4** as the nucleophile and acylcyanide **7** as the electrophile. Reducing the acetylated cyanohydrin *rac*-**10** yields directly the protected porphobilinogen **11**. This synthesis

follows the proposal for the biosynthesis made by Nandi and Shemin almost 30 years ago. In contrast to the published syntheses of **11**, the correctly functionalized side chains are introduced with the two starting materials used for the synthesis of the pyrrole ring; subsequent functionalization is therefore not necessary. The bonds formed in this synthetic scheme are the same as those formed in the biosynthesis catalyzed by porphobilinogen synthase. The overall yield starting from 5-phthalimidomethyllevulinate is 25%. The synthesis can be used to obtain selectively labeled porphobilinogen.

First Isolation and Structural Characterization of a Nickel(III) Complex Containing Aliphatic Thiolate Donors**

Jan Hanss and Hans-Jörg Krüger*

Dedicated to Professor Richard H. Holm on occasion of his 65th birthday

The discovery of a nickel site with a thiolate-rich ligand environment in hydrogenases some 15 years ago stimulated considerable interest in nickel(II) thiolate complexes and their redox behavior.[1] Because of the recent crystal structure determination of the enzyme from the sulfate-reducing bacterium *Desulfovibrio gigas*, the initial description of the nickel site as a mononuclear metal center was revoked, and the heterobimetallic nature firmly established.[2] Efforts towards modeling the structure and reactivity of the active site in nickel-containing hydrogenases are now shifting from the synthesis of mononuclear nickel thiolate complexes towards the synthesis of thiolato-bridged iron–nickel complexes. However, one of the original tasks for inorganic chemists has, to our knowledge, never been accomplished: namely, the preparation *and* isolation of a stable mononuclear nickel(III) complex with aliphatic thiolate donors[3] in the coordination environment. Here we report on the first successful isolation and structural characterization of such a complex.

Previous endeavors to synthesize mononuclear nickel(III) complexes with aliphatic thiolates utilized the nickel(II) complexes depicted in Scheme 1.[4] Although solutions of

Scheme 1. Nickel(II) complexes with aliphatic thiolate ligands which have been used to electrochemically generate nickel(III) complexes in solution.[4]

the relatively stable nickel(III) complexes $[Ni(nbdt)_2]^-$ and $[Ni(emi)]^-$[4] could be electrochemically generated, no solid compounds were isolated. Recently, we showed that stable copper(II) and even copper(III) complexes can be prepared with the quadruply deprotonated ligand *N*,*N*′-1,2-phenylenebis(2-sulfanyl-2-methylpropionamide) (H_4phmi).[5] With respect to its donor-atom set, H_4phmi is related to some of the

ligands depicted in Scheme 1. In general, nickel(III) complexes are more difficult to synthesize than copper(III) complexes, because Ni^{III}/Ni^{II} redox potentials are more positive than those of isostructural Cu^{III}/Cu^{II} redox pairs.[6] In addition, presumably due to the presence of an unpaired electron, nickel(III) complexes display a more pronounced tendency to decompose than the corresponding copper(III) complexes. One of the major obstacles to the synthesis of nickel(III) thiolate complexes is autoreduction of the metal ion by the coordinated thiolates with concomitant formation of disulfides.[7] This seems to be less of a problem when the thiolate-donor functionality is somewhat sterically protected, as in $[Ni(nbdt)_2]^-$ and $[Ni(emi)]^-$. For nickel(III) amidate complexes, a well-known decomposition pathway involves the presence of a hydrogen atom in an α position with respect to the amidato functionality.[8] Because no hydrogen atom is present in an α position to any donor functionalities in H_4phmi, in contrast to the amidethiol ligands used in previous studies, this ligand was deemed suitable for synthesizing nickel(III) complexes that are stable enough to be isolated.

The red nickel(II) complex $(NEt_4)_2[Ni(phmi)]$ (**1**) was prepared according to Equation (a). Based on the diamagnetism and electronic absorption spectrum of the complex, a

(a)

$(NEt_4)_2[Ni(phmi)]$ **1**

square-planar coordination geometry is attributed to the nickel ion. Owing to severe disorders in the crystal lattice of **1**, a structure determination was carried out on a single crystal of $K(PPh_4)[Ni(phmi)]$ (**2**).[9] As expected, the nickel ion is coordinated to two deprotonated amide and two thiolate groups. In agreement with the results for **1**, the NiN_2S_2 coordination environment in **2** is essentially square planar, and the nickel ion deviates from the least-squares N_2S_2 plane by only 0.022 Å. The potassium ion bridges the two thiolate sulfur atoms (3.173 – 3.208 Å) and is further bound in a tetrahedral geometry to two amide oxygen atoms of adjacent $[Ni(phmi)]^{2-}$ moieties (2.559 – 2.672 Å). Despite the coordinated potassium ion, the average Ni–N and Ni–S bond lengths of 1.879 ± 0.005 and 2.171 ± 0.005 Å, respectively, (see legend of Figure 1) are very similar to those found in $[Ni(ema)]^{2-}$.[4b] Electrochemical data suggest that in solution the potassium ion is no longer bound to the complex anion $[Ni(phmi)]^{2-}$.

The cyclic voltammograms of complexes **1** and **2** in acetonitrile reveal an electrochemically reversible oxidation at -0.71 V (versus the ferrocene/ferrocenium redox potential; all following potentials are given with respect to this redox pair). Quantitative electrolysis at -0.51 V provides a blue solution after the passage of 0.98 electrons per complex anion; upon re-reduction of the solutions at -0.91 V, more than 95% of the original nickel(II) complex is recovered. Spectrophotometric examination of the stability of the dissolved oxidized complex over time reveals that even after 50 days under an atmosphere of nitrogen 90% of the complex $[Ni(phmi)]^-$ is still present. This observation warrants the claim that isolation of the oxidized species is feasible. Indeed, quantitative bulk electrolysis of **2** in acetonitrile results in analytically pure crystals of blue $(PPh_4)[Ni(phmi)]$ (**3**) after recrystallization from acetone/diethyl ether.

The structure determination of **3** (Figure 1)[9] demonstrates that the coordination environment and the square-planar coordination geometry around the nickel ion are preserved upon oxidation (the nickel ion deviates from the least-squares

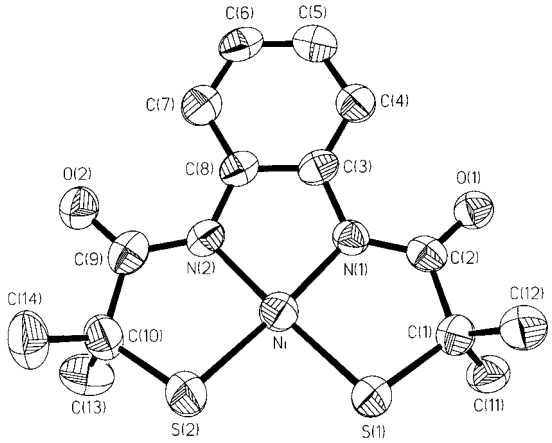

Figure 1. Perspective view of the structure of the $[Ni(phmi)]^-$ ion in **3** (thermal ellipsoids at the 50% probability level) and the atom-numbering scheme. Selected bond lengths [Å] and angles [°] in the $[Ni(phmi)]^-$ ion [in the two crystallographically independent $[Ni(phmi)]^{2-}$ ions in the crystal lattice of **2**]: Ni–S(1) 2.119(3) [2.168(1), 2.174(1)], Ni–S(2) 2.109(3) [2.166(1), 2.174(1)], Ni–N(1) 1.849(6) [1.878(2), 1.874(2)], Ni–N(2) 1.863(7) [1.882(2), 1.880(2)]; S(1)-Ni-S(2) 93.11(11) [96.09(3), 96.10(3)], S(1)-Ni-N(1) 90.40(22) [89.35(6), 89.20(6)], S(1)-Ni-N(2) 176.19(24) [175.18(6), 174.89(6)], S(2)-Ni-N(1) 175.59(23) [174.07(6), 174.66(6)], S(2)-Ni-N(2) 90.27(23) [88.73(6), 88.96(6)], N(1)-Ni-N(2) 86.31(30) [85.85(8), 85.74(8)].

N_2S_2 plane by 0.007 Å). Within a distance of 6 Å there are no axial donor atoms at the nickel ion. With respect to **2**, the average Ni–N and Ni–S bond lengths in **3** are reduced to 1.856 ± 0.007 Å and 2.114 ± 0.005 Å, respectively. A comparison of the C–C and C–N bond lengths of the phenylenediamide moieties of **2** and **3** indicates essentially no change within the 3σ criterion. In addition, these bond lengths are very different from those reported for an oxidized cobalt complex,[10] in which oxidation does take place at the phenylenediamide portion of the ligand (Table 1). Although the interatomic S–S distance substantially decreases from 3.224 Å in **2** to 3.069 Å in **3**, there is no bonding interaction between the two sulfur atoms. These structural results serve as the first piece of evidence that the oxidation is mainly metal-centered. A substantial shortening of the Ni–N and Ni–S bonds is not expected to occur, since the electron is not removed from a strongly σ-antibonding orbital during the oxidation of the nickel(II) complex. The rather modest decrease of 0.023 Å for the Ni–N bonds is related to the stronger electrostatic interactions between the more electro-

[a] Averaged bond lengths from the two crystallographically distinct complex anions. [b] From ref. [10], with the numbering schemes adapted to those of complexes **2** and **3**.

positive central ion and the negatively charged ligand donor atoms. The slightly greater decrease in the Ni–S bond length by 0.057 Å may be explained by the lack of a potassium ion bridging the two sulfur atoms in **3**.

The magnetic moment of **3** is 1.78 μ_B, which corresponds to a low-spin complex. As with $[Ni(emi)]^{-}$,[4b] no ESR spectrum is observed for **3** at room temperature or at 100 K. However, at 10 K a spectrum of solid **3** doped into the isomorphous crystal lattice of the diamagnetic complex $(PPh_4)[Cu(phmi)]$ reveals a very broad rhombic signal with apparent g values at 2.55, 2.14, and 2.00. This indicates a short electron spin relaxation time due to a relatively small energy separation between the electronic ground and excited states. This conclusion is also supported by the observation that the NIR region of the electronic absorption spectrum of **3** contains a d–d transition at rather low energy (5120 cm^{-1}). In the presence of excess pyridine (py) in the solution of **3**, the powder spectrum of the frozen solution at 100 K (Figure 2)

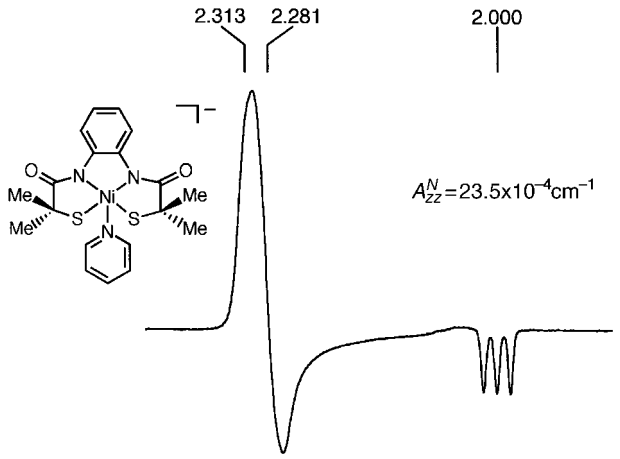

Figure 2. X-band ESR spectrum of a frozen solution of $[Ni(phmi)(py)]^{-}$ ions in dimethylformamide containing excess pyridine at 100 K (the g values are indicated).

shows a nearly axial signal with g values at 2.313, 2.281, and 2.000. The splitting of the g_z component into three lines of equal intensities due to superhyperfine coupling ($A_z^N = 25$ G) with the nuclear spin ($I_N = 1$) of a single nitrogen donor atom is consistent with the formation of the monoadduct $[Ni(phmi)(py)]^{-}$. The formation of a similar monoadduct upon addition of pyridine to a solution containing the complex $[Ni(emi)]^{-}$ was reported.[4b] The large anisotropy and the average g values of 2.23 and 2.20 for $[Ni(phmi)]^{-}$ and $[Ni(phmi)(py)]^{-}$, respectively, indicate that the unpaired electron mainly resides in a metal-based orbital. The fact that g_x and g_y are larger than g_z and that g_z is 2.00, together with the observation of a superhyperfine splitting of the g_z component, clearly establish a $\ldots(d_{z^2})^1$ electron configuration for the ground state of $[Ni(phmi)(py)]^{-}$. The observation of an ESR spectrum at 100 K only after addition of pyridine is interpreted to mean that axial coordination of a pyridine molecule raises the energy of the d_{z^2} orbital enough to cause less mixing between the ground and the excited states and, therefore, an increase of the electron spin relaxation time.

The results presented here reveal that the oxidized species contains an authentic nickel(III) ion coordinated to aliphatic thiolate groups. In dimethylformamide, the Ni^{III}/Ni^{II} redox potential of **1** (–0.78 V) is about 120 mV more positive than that of $[Ni(emi)]^{2-}$, although the stability of the oxidized complex $[Ni(emi)]^{-}$ is inferior to that of **3**. Therefore, our investigation demonstrates that the stability of nickel(III) thiolate complexes is determined only to a certain extent by the lowest possible redox potential; abolishing or at least retarding possible decomposition pathways (e.g. by introducing steric hindrance around the thiolate donors or by avoiding the presence of any hydrogen atoms in an α position to the donor functionalities in the ligand) plays a larger role, at least for the currently discussed amidato–thiolato nickel complexes.

The original challenge for inorganic chemists to prepare *and* isolate stable nickel(III) complexes with aliphatic thiolates in the coordination sphere has finally been met. However, as with the recently reported copper complexes, the stabilization of the high oxidation state of the nickel ion is only achieved because the highly polarizable, negatively charged nitrogen donor atoms of the deprotonated amide functionalities can supply the electropositive metal ion with sufficient electron density to avoid autoreduction of the nickel(III) ion by the coordinated aliphatic thiolates.

Experimental Section

1: Under strictly anaerobic conditions, a solution of *N*,*N*′-1,2-phenylene-bis(*S*-acetyl-2-sulfanyl-2-methylpropionamide) (200 mg, 0.5 mmol), KOH (140 mg, 2.5 mmol), and NEt_4Cl (166 mg, 1.0 mmol) in absolute EtOH (40 mL) was stirred for 0.5 h before a suspension of $Ni(OAc)_2\cdot 4H_2O$ (124 mg, 0.5 mmol) in absolute EtOH (30 mL) was added. After the reaction mixture was heated at reflux for a short time, the solvent was completely removed in vacuo. The residue was treated with CH_3CN (40 mL), and the resulting red solution filtered. Slow diffusion of Et_2O into the solution in CH_3CN afforded a red crystalline material, which was collected, washed with Et_2O, and dried in vacuo to yield analytically pure **1** (235 mg, 75 % yield). Elemental analysis calcd for $C_{30}H_{56}N_4NiO_2S_2$: C 57.41, H 8.99, N 8.93; found: C 57.18, H 8.85, N 8.90; absorption spectrum (CH_3CN): λ_{max} (ε_M) = 550 (85.6), 439 (280), 359 (7020), 248 (36 900), 232 nm (37 600); ^1H NMR (360 MHz, CD_3CN, anion): $\delta = 8.64$ (dd, 2H), 6.46 (dd, 2H), 1.23 (s, 12H).

Complex **2** was synthesized analogously with PPh_4Cl. However, based on the elemental analysis and the NMR spectrum, **2** is contaminated with $(PPh_4)_2[Ni(phmi)]$.

3: In a glove box, a mixture of $K(PPh_4)[Ni(phmi)]$ and $(PPh_4)_2[Ni(phmi)]$ (0.336 mmol based on the passed charge) in CH_3CN (10 mL) containing

0.05 M PPh_4Cl as supporting electrolyte was exhaustively oxidized at −0.51 V. The electrolysis was carried out at a platinum-net electrode with a PAR Model 273A Potentiostat/Galvanostat controlled by the PAR Model 270 Research Electrochemistry Software. After the oxidation was completed, the electrolyte PPh_4Cl was precipitated by diffusion of Et_2O into the resulting blue solution. Removal of the solvent from the filtered solution yielded a dark blue solid, which was redissolved in acetone (10 mL) under nitrogen. Diffusion of Et_2O into this solution afforded analytically pure **3** as dark blue, leafletlike crystals (128 mg, 54 % yield). Elemental analysis calcd for $C_{38}H_{36}N_2NiO_2PS_2$: C 64.60, H 5.14, N 3.97; found: C 64.63, H 5.12, N 4.12; absorption spectrum (CH_3CN): λ_{max} (ε_M) = 1953 (54.5), 940 (sh, 3410), 843 (3970), 573 (1330), 388 (3070), 337 (sh, 3710), 274 (sh, 21 400), 266 (sh, 25 700), 253 (sh, 28 700), 230 nm (60 600).

[3] The synthesis of nickel(III) complexes with aliphatic thiolate ligands is considerably more difficult than that of complexes with thiolates in which the sulfur donor atom is bound to a sp^2-hybridized carbon atom owing to the lower redox potential of the thiolate functionality and, therefore, the greater propensity towards disulfide formation. In addition, the authenticity of the trivalent oxidation state of the nickel ion has to be verified for all complexes in which the thiolate sulfur atom is directly bound to a sp^2-hybridized carbon atom whose p orbital is part of an extended π molecular orbital system. The Catalytic Enantioselective Construction of Molecules with Quaternary Carbon Stereocenters

Elias J. Corey* and Angel Guzman-Perez

The catalytic asymmetric synthesis of structurally complex naturally occurring organic molecules and other highly useful chiral substances represents a new frontier for synthetic chemistry and an ideal testing ground for the remarkable new synthetic chiral catalysts, whose impact on all of chemistry promises to be profound. Catalytic enantioselective methodology provides a powerful new option for synthesis planning and execution, which complements the use of chiral starting materials, chiral controller groups (auxiliaries), or enzymic catalysis. The synthesis of complex molecules with quaternary (fully substituted) stereocenters, one of the most demanding tasks in multistep synthesis, presents simultaneously a challenge to catalytic enantioselective processes and an opportunity to demonstrate their power and potential. In addition, the problems that inevitably arise in the execution of a synthesis of a complex molecule provide a stimulus and a sense of direction for new discovery. In this article several of the most promising new catalytic enantioselective methods are reviewed from the point of view of their application to the construction of complex chiral molecules with quaternary stereocenters. It is safe to predict that this field of chemistry will grow enormously in the coming decades and will have great intellectual and practical impact.

Keywords: asymmetric catalysis · chirality · enantioselective addition · quaternary stereocenters · total synthesis

1. Introduction

Organic chemistry has undergone a revolution in the last two decades. The development of new and highly enantioselective processes has become a major focus of chemical synthesis, and the use of chiral catalysts is displacing chiral auxiliaries and reagents as the method of choice for asymmetric synthesis. An efficient chiral catalyst allows for large quantities of optically active product to be obtained on use of relatively small amounts of enantiopure material, without the need for the removal and recovery of a chiral auxiliary. Furthermore, the most practical catalytic methods utilize an inexpensive and readily available chiral ligand, and provide high and predictable enantioselectivity across a wide range of substrates.[1] The application of such catalytic asymmetric reactions to the synthesis of challenging natural products has assumed increasing importance not only to demonstrate their value, but also to understand these methods better and improve them, thereby increasing their generality. The asymmetric construction of molecules with quaternary carbon stereocenters, that is, carbon centers with four different nonhydrogen substituents, represents a very challenging and dynamic area in organic synthesis. The preparation of compounds containing these centers with *catalytic* enantioselective reactions is particularly demanding. This review presents a concise survey of some modern and highly selective methods for the catalytic construction of these compounds, using representative recent examples. The many excellent noncatalytic, diastereoselective, or biochemical methods will not be discussed here.[2]

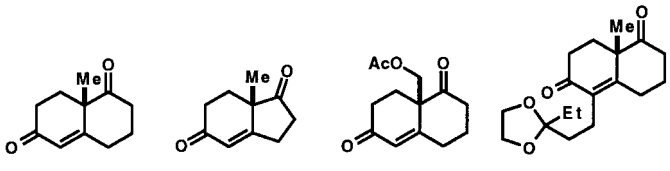
2. Catalytic Methods Applicable to the Direct Synthesis of All-Carbon-Substituted Quaternary Carbon Stereocenters

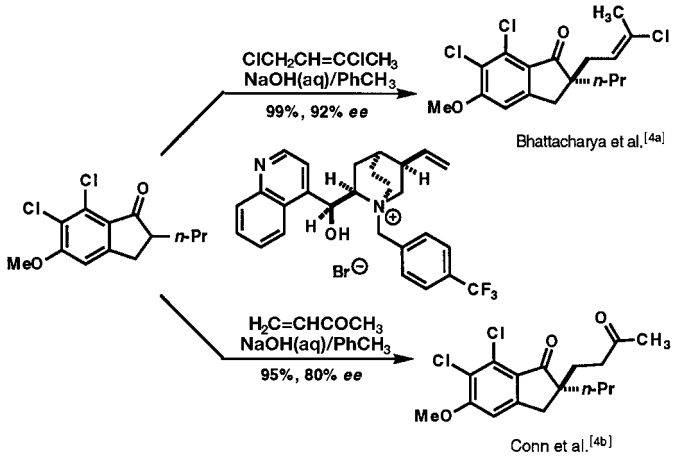
2.1. Robinson Annulation and Intramolecular Aldol Reaction Catalyzed by Amino Acids



The enantioselective version of the classical Robinson annulation has been applied to the synthesis of optically active diketones, which are useful in the preparation of a variety of terpenes and other natural products. The transformation involves the discrimination between two enantiotopic carbonyl groups in an intramolecular aldol reaction, which involves

 © WILEY-VCH Verlag GmbH, D-69451 Weinheim, 1998 1433-7851/98/3704-0389 $ 17.50+.50/0

an enamine of the triketone and the chiral α-amino acid catalyst (Scheme 1). For example, the fused bicyclic compounds shown in Scheme 2, which include the Wieland–Miescher ketone, were prepared in this manner. The products could be recrystallized until optically pure.[3]



Scheme 1. Enantioselective aldol cyclization. CSA = (+)-camphorsulfonic acid.

Scheme 2. Chiral products from amino acid catalyzed cyclization of achiral precursors, including the Wieland–Miescher ketone (extreme left).

2.2. Alkylation and Michael Addition Reactions

Alkylations and Michael additions are useful and versatile reactions; however, few instances of highly enantioselective catalytic versions of these transformations for the synthesis of quaternary stereocenters have been demonstrated to date. A noteworthy example is the use of the phase-transfer catalyst *N*-(4-trifluoromethylbenzyl)cinchoninium bromide by Merck scientists for the synthesis of alkylated indanones as promising drug candidates (Scheme 3).[4]

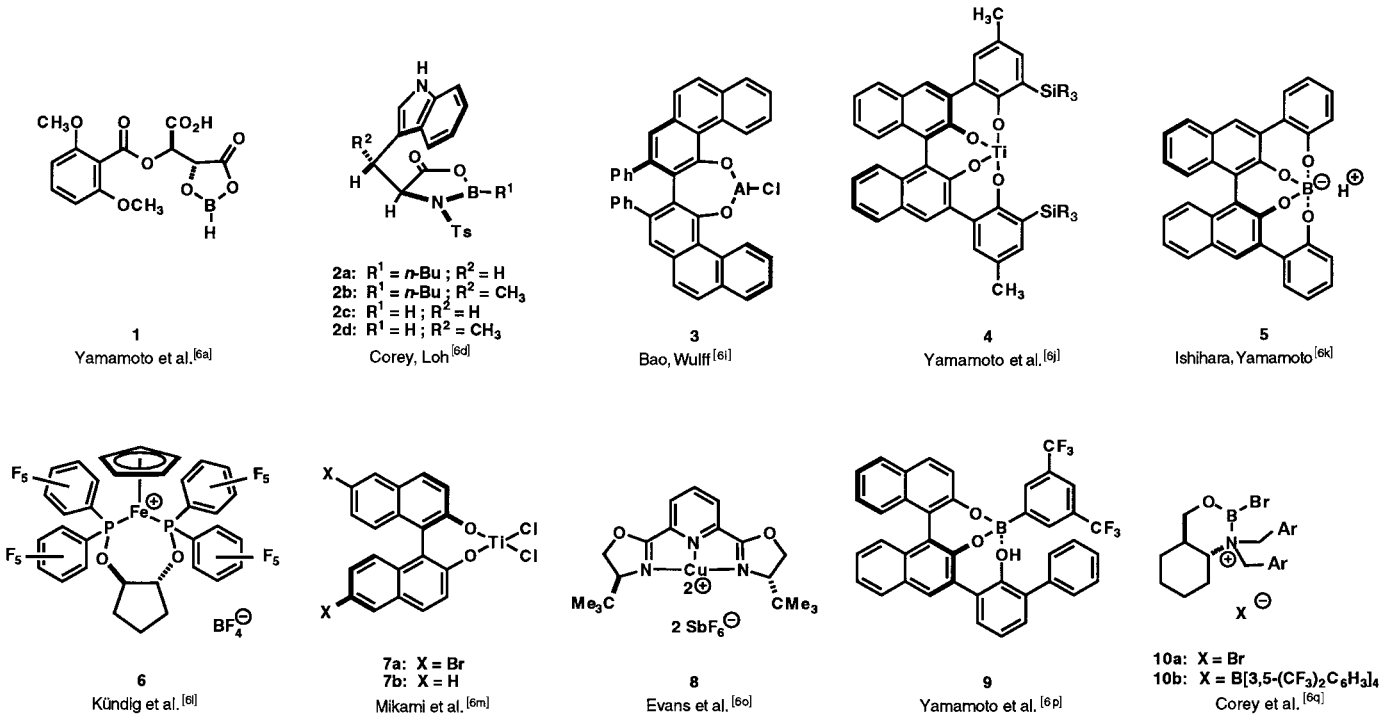
Scheme 3. Enantioselective alkylation by phase-transfer catalysis.

2.3. Diels–Alder Reactions

The Diels–Alder cycloaddition is arguably one of the most useful and powerful transformations available to the synthetic chemist. Great effort has been devoted to the development of catalytic enantioselective versions of this reaction.[5] The enantioselective Diels–Alder reaction of 2-substituted acroleins is particularly interesting, because it provides products with a quaternary stereocenter. Scheme 4 presents a collection of Lewis acid catalysts (**1**–**10**) that have been applied successfully to the asymmetric Diels–Alder reaction of 2-substituted acroleins.[6]

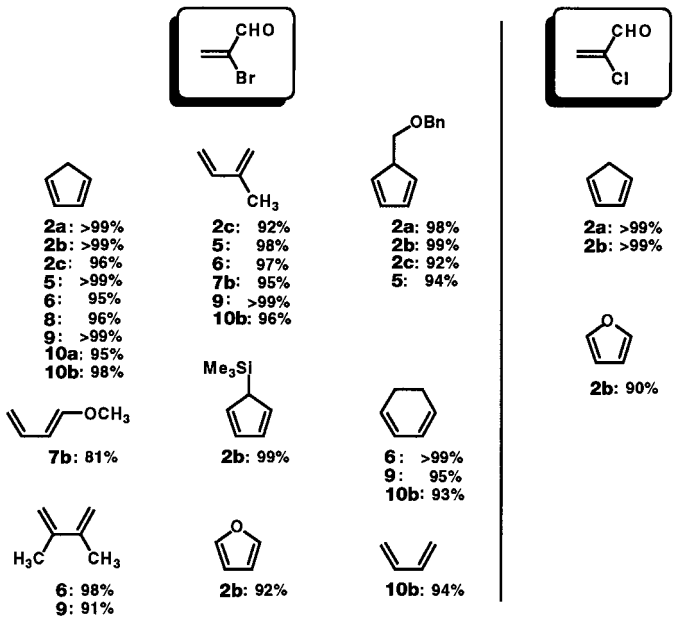
The asymmetric Diels–Alder reactions of 2-haloacroleins have attracted considerable attention not only because of the high reactivity and selectivity obtained with these dienophiles, but also because of the exceptional synthetic versatility of the resulting adducts.[6d] The excellent enantioselectivities resulting from the reactions of 2-bromoacrolein and 2-chloroacrolein with a variety of dienes are summarized in Scheme 5. In

Elias J. Corey, born 1928 in Methuen about 50 km north of Boston, studied Chemisty from 1945 to 1950 at the Massachusetts Institute of Technology, where he gained his doctorate for work on synthetic penicillins under John C. Sheehan. In January 1951 he joined the University of Illinois at Urbana-Champaign as an Instructor in Chemistry and was promoted to full Professor in 1956 at the early age of 27. Since 1959 he has been at Harvard University. His many scientific successes were crowned with the Nobel Prize for Chemistry in 1990. For as long as he can remember he has enjoyed study, adventure, and discovery.

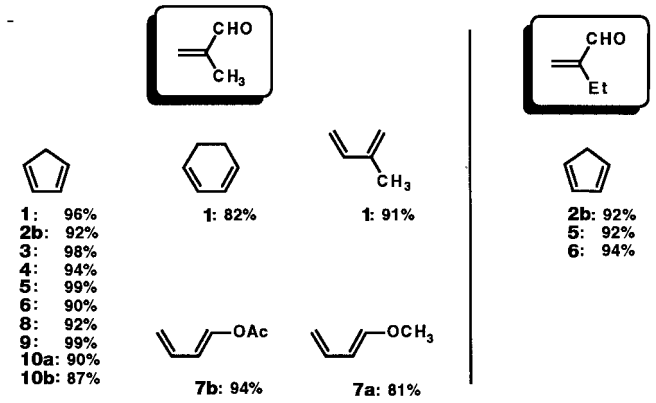


E. J. Corey

A. Guzman-Perez

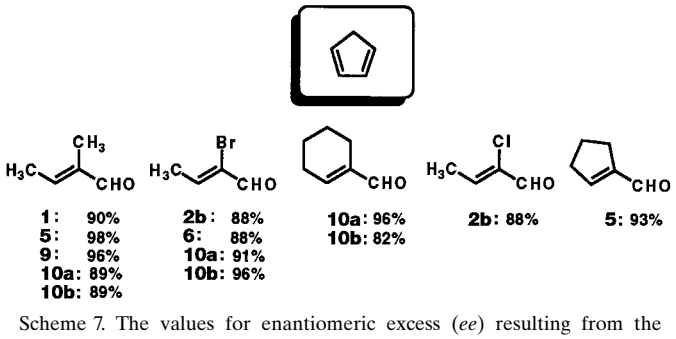


Angel Guzman-Perez was born in 1967 in Mexico City (Mexico) and obtained his Bachelor's degree in Chemistry at the National Autonomous University of Mexico. He worked for a year (1990–1991) at Syntex Research (Palo Alto, California, USA) in the medicinal chemistry department and then joined the Ph.D. program at Harvard University under the direction of Professor E. J. Corey to study new methods for the asymmetric synthesis of natural products. He received the Ph.D. degree in Chemistry in 1997 and now works in drug discovery at Pfizer Central Research (Groton, Connecticut, USA).



Scheme 4. Effective catalysts for the synthesis of Diels–Alder adducts with quaternary stereocenters. R = *o*-tolyl, Ar = 3,5-$Me_2C_6H_3$.

addition, 2-alkylacroleins such as 2-methylacrolein and 2-ethylacrolein produce favorable results with several dienes, but are less versatile than their 2-halo counterparts as shown in Scheme 6. Furthermore, certain 2,3-disubstituted acroleins afford promising selectivities in the reaction with cyclopentadiene (Scheme 7).



The application of these reactions to the total synthesis of natural products (especially with catalysts **2**) has recently commenced. For example, Marshall and Xie synthesized a

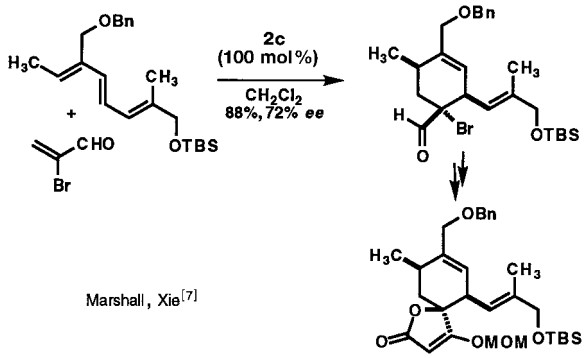
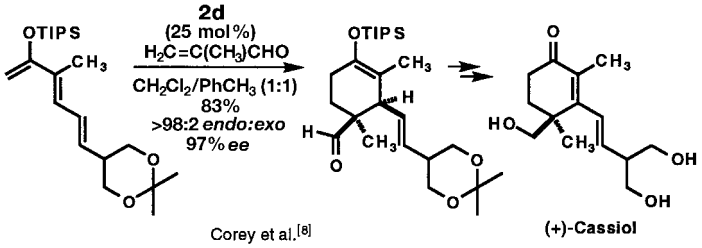
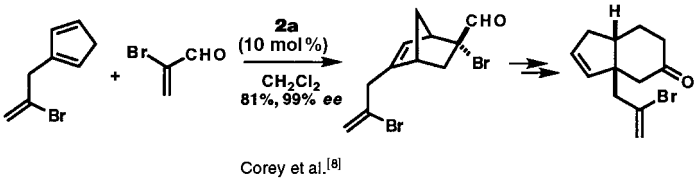


Scheme 6. The values for enantiomeric excess (*ee*) resulting from the asymmetric Diels–Alder reaction of 2-methylacrolein and 2-ethylacrolein with several dienes on catalysis with the indicated compounds.



Scheme 7. The values for enantiomeric excess (*ee*) resulting from the asymmetric Diels–Alder reaction of several 2,3-disubstituted acroleins with cyclopentadiene on catalysis with the indicated compounds.

Diels–Alder cycloadduct bearing a quaternary stereocenter using stoichiometric amounts of catalyst **2c**, and converted it into the spirotetronate subunit of kijanolide (Scheme 8).[7]

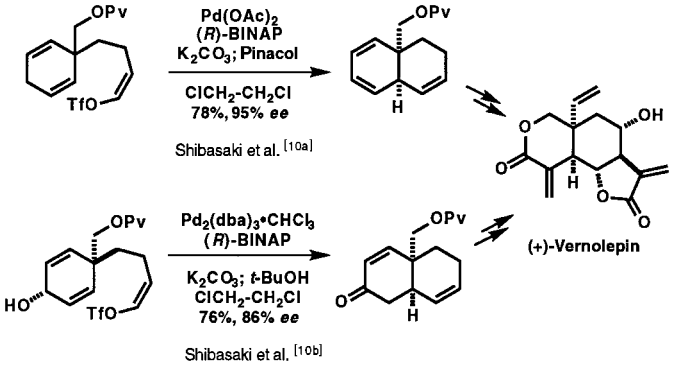


Scheme 8. Enantioselective Diels–Alder route to the spirotetronate unit of kijanolide. MOM = methoxymethyl, TBS = *tert*-butyldimethylsilyl.

Furthermore, the enantioselective Diels–Alder reaction between a trisubstituted electron-rich open-chain diene and 2-methylacrolein catalyzed by oxazaborolidine **2d** was used to accomplish an efficient synthesis of the potent antiulcer agent cassiol in 97% *ee* (Scheme 9). The high enantioselectivity of the key cycloaddition is the collective result of critical modifications to the substrate, catalyst, and reaction solvent.[8]

Scheme 9. Enantioselective total synthesis of (+)-cassiol. TIPS = triisopropylsilyl.

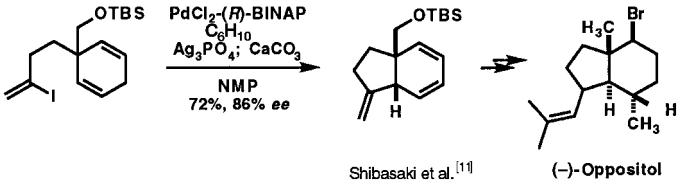
Finally, a Diels–Alder reaction involving catalyst **2a** was used as a key step in an especially simple enantioselective synthesis of gibberellic acid via the bicyclic ketone shown in Scheme 10.[8]



Scheme 10. Catalytic enantioselective Diels–Alder reaction for the synthesis of gibberellic acid.

2.4. Heck Reactions

The enantioselective version of the intramolecular Heck reaction is an extremely effective C–C bond construction. Its utility has already been demonstrated in the synthesis of several natural products containing quaternary stereocenters. Two general strategies have been applied in this field: the differentiation of enantiotopic olefinic bonds in molecules with prochiral quaternary centers and the differentiation of the enantiotopic faces of C–C double bonds.[9]

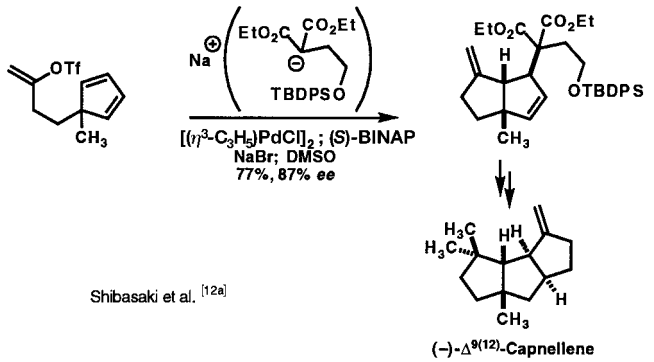


2.4.1. Heck Reactions That Differentiate between Enantiotopic Groups

The asymmetric synthesis of vernolepin has been accomplished in two ways by Shibasaki and co-workers (Scheme 11). The key step in both cases is the differentiation of enantiotopic C–C double bonds by an intramolecular Heck reaction.[10]

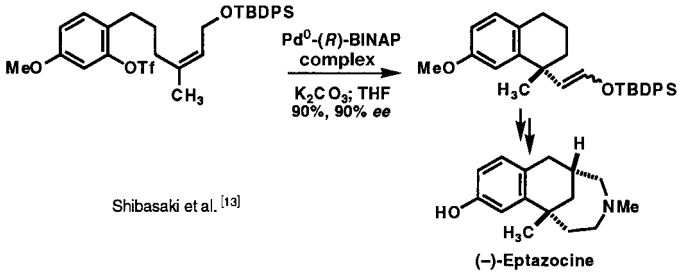
Scheme 11. Asymmetric intramolecular Heck reaction for the synthesis of vernolepin. BINAP = 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl, dba = dibenzylidenacetone, PV = pivaloyl.

Furthermore, the synthesis of a *cis*-hydrindan was accomplished employing a similar strategy as outlined in Scheme 12. The product of this Heck reaction allowed for the formal asymmetric synthesis of oppositol and prepinnaterpene. Interestingly, the use of an *endo*-vinyl iodide instead of the *exo*-vinyl iodide shown afforded product in only 3% *ee*.[11]



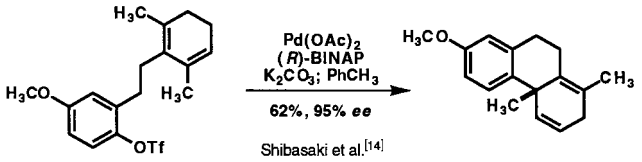
Scheme 12. Synthesis of (−)-oppositol. NMP = *N*-methyl-2-pyrrolidone.

The asymmetric Heck reaction has also been applied to the synthesis of compounds containing two fused five-membered rings by the use of prochiral cyclopentadienyl systems. The transformation initially generates a π-allylpalladium species, which is then trapped with a suitable nucleophile to complete the catalytic cycle. Nucleophiles that have been used for this purpose include acetate, an amine, and dicarbonyl-stabilized enolates. For example, in the synthesis of $\Delta^{9(12)}$-capnellene the π-allyl intermediate was captured with a malonate anion to provide the desired product of 87% *ee* with complete diastereo- and regioselectivity (Scheme 13).[12]



2.4.2. Heck Reactions That Differentiate between Enantiotopic Faces

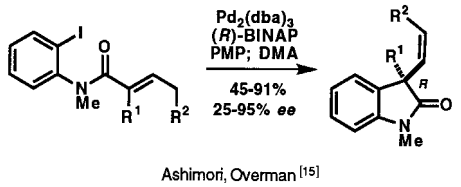
The use of an intramolecular Heck reaction that differentiates between enantiotopic faces was demonstrated by Shibasaki and co-workers for the synthesis of eptazocine. The



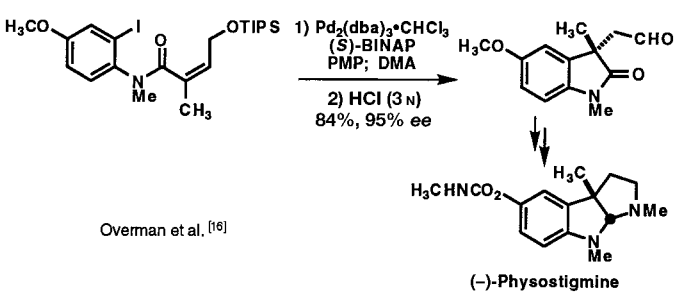
Scheme 13. Heck alkylation/cyclization route to (−)-capnellene. TBDPS = *tert*-butyldiphenylsilyl.

Z-olefinic substrate provided better results than the corresponding *E* isomer (Scheme 14).[13]

Scheme 14. Enantioselective synthesis of (−)-eptazocine.



A synthetic intermediate in the synthesis of a number of diterpenes, including kaurene, abietic acid, and a bruceantin analogue, was prepared by a regio- and face-selective Heck reaction (Scheme 15).[14]

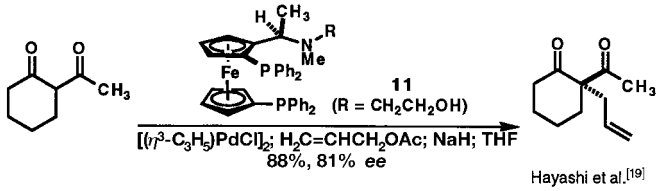


Scheme 15. Enantioselective route to hydrophenanthrenes.

Overman and Ashimori reported the construction of several 2-oxindoles from the corresponding aryl iodides through intramolecular Heck reactions. Either enantiomeric product, depending upon whether the HI scavenger used is Ag_3PO_4 or 1,2,2,6,6-pentamethylpiperidine (PMP), can often be obtained with good enantioselectivity by using a single enantiomer of BINAP (Scheme 16). The reason for this behavior is not known.[15]

The enantioselective synthesis of physostigmine was accomplished with the methodology outlined above. As observed by Shibasaki and co-workers in their eptazocine synthesis, the *Z* olefin provided better results than the corresponding *E* isomer (Scheme 17).[16, 17]

Scheme 16. Enantioselective route to 2-oxoindolines. DMA = *N*,*N*-dimethylacetamide, PMP = 1,2,2,6,6-pentamethylpiperidine. If PMP is used instead of $AgNO_3$, the *S* enantiomer is formed (74–99%, 63–81% *ee*).

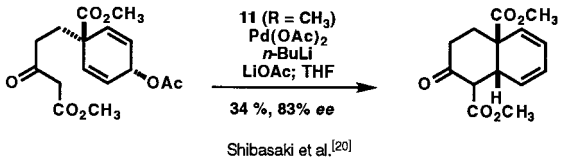


Scheme 17. Enantioselective route to (−)-physostigmine.

2.5. Palladium-Catalyzed Allylation Reactions[18]

2.5.1. Allylation Reactions That Differentiate between Enantiotopic Faces

The palladium-catalyzed allylation of active methine compounds employing a chiral ferrocene diphosphane ligand (**11**, R = CH_2CH_2OH) was reported by Hayashi and co-workers. For example, the sodium enolate of 2-acetylcyclohexanone undergoes a face-selective reaction with a chiral η^3-allylpalladium species generated in situ from allyl acetate and a catalytic Pd^0 complex with this ligand (Scheme 18). The high



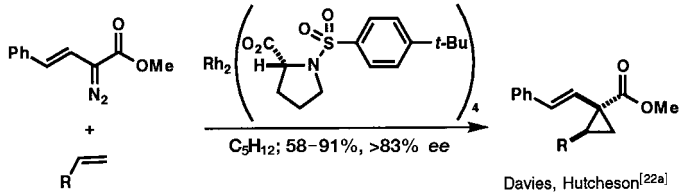
Scheme 18. Enantioselective alkylation of a 1,3-diketone.

enantioselectivity obtained with this ligand is ascribed to secondary attractive interactions between the terminal hydroxyl group of the ligand and the approaching prochiral enolate of the diketone.[20]

2.5.2. Allylation Reactions That Differentiate between Enantiotopic Groups

An intramolecular palladium-catalyzed allylation reaction was used by Shibasaki and co-workers to accomplish the differentiation of enantiotopic olefinic bonds in a molecule with a prochiral quaternary center. This strategy is reminiscent of the one discussed in the context of the Heck reaction (Section 2.4) and results in the enantioselective establishment of a quaternary stereocenter. The best results are obtained

with the indicated *trans* diastereomer of the substrate instead of the *cis* diastereomer, and with **11** (R = CH_3) as the ligand (Scheme 19).[20]

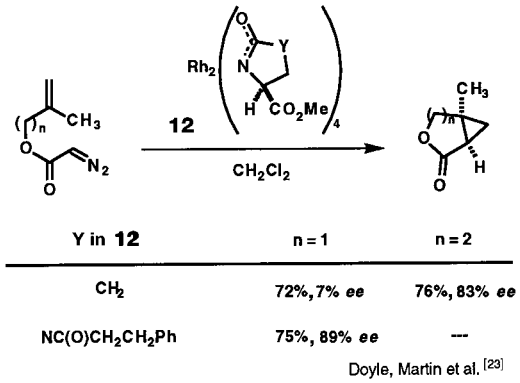


Scheme 19. Enantioselective intramolecular alkylation.

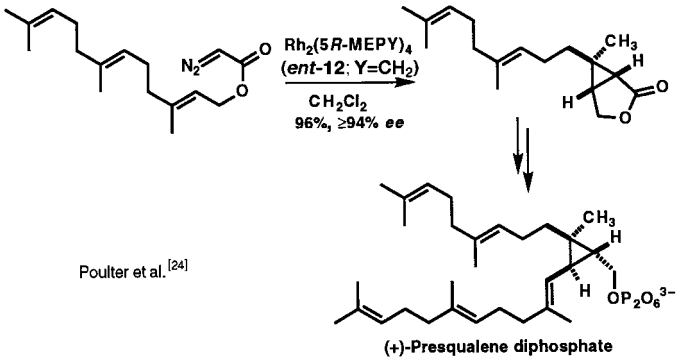
2.6. Rhodium-Catalyzed Cyclopropanation Reactions

The reaction of olefins with α-diazocarbonyl compounds in the presence of chiral rhodium or copper catalysts offers significant potential as a general method for the asymmetric synthesis of cyclopropanes. Rhodium(II) catalysts have been especially useful for the synthesis of optically active cyclopropanes containing quaternary stereocenters.[21]

2.6.1. Intermolecular Cyclopropanation Reactions



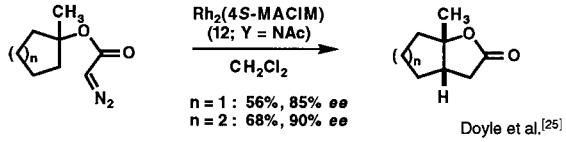
The intermolecular rhodium-catalyzed asymmetric cyclopropanations often result in products of good enantioselectivity but low *diastereoselectivity*. A noteworthy example of a rhodium-catalyzed intermolecular cyclopropanation that proceeds with both high diastereo- and enantiocontrol utilizes methyl (*E*)-2-diazo-4-phenylbut-3-enoate as shown in Scheme 20. The presence of a vinyl substituent on the diazo compound is essential for obtaining good selectivities in this reaction.[22]



Scheme 20. Catalytic enantioselective intermolecular [2+1] cycloaddition.

2.6.2. Intramolecular Cyclopropanation Reactions

Unlike intermolecular cyclopropanations, the intramolecular reactions can only produce one diastereomer due to geometric constraints of the fused bicyclic product, and accordingly have seen substantially more use in synthesis. The enantioselective intramolecular reaction of a variety of alkenyl diazoacetates catalyzed by chiral rhodium carboxamides [Rh_2(5*S*-MEPY)$_4$] (**12**, Y = CH_2) and [Rh_2(4*S*-MPPIM)$_4$] (**12**, Y = NC(O)CH_2CH_2Ph) was studied by Doyle, Martin, and co-workers. Optically active bicyclic lactones containing quaternary stereocenters are obtained when 1,1-disubstituted and trisubstituted olefins are used in the reaction (Scheme 21).[23] This methodology was applied by Poulter and co-workers to the efficient asymmetric synthesis of presqualene diphosphate (Scheme 22).[24]

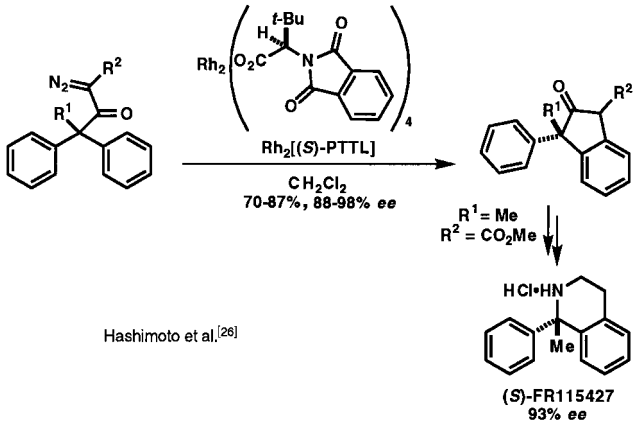


Scheme 21. Catalytic enantioselective intramolecular [2+1] cycloaddition.

Scheme 22. Enantioselective synthesis of (+)-presqualene diphosphate.

2.7. Rhodium-Catalyzed C–H Insertion Reactions

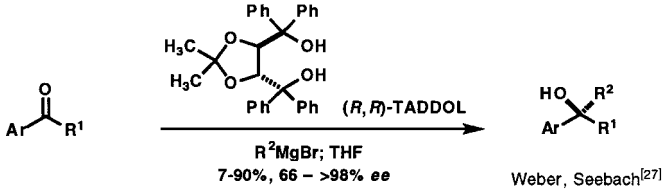
In addition to cyclopropanation reactions, rhodium(II) catalyzes the selective intramolecular insertion of diazoacetates into C–H bonds. The enantioselective version of this reaction[21a] allows for the differentiation of enantiotopic aliphatic C–H bonds of molecules with prochiral quaternary stereocenters. The resulting bicyclic lactones are obtained in high optical purity (Scheme 23).[25]



Scheme 23. Enantioselective cyclization by intramolecular C–H insertion.

In addition, an asymmetric rhodium-catalyzed aromatic C–H bond insertion has also been demonstrated and applied to the total synthesis of FR115427 (Scheme 24).[26]

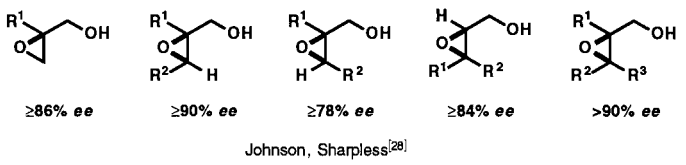
3. Catalytic Methods Applicable to the Synthesis of Heteroatom-Substituted Quaternary Carbon Stereocenters



3.1. Addition of Carbon Nucleophiles to Ketones

A conceptually straightforward approach to the preparation of enantiopure tertiary alcohols is the addition of

Scheme 24. Enantioselective synthesis of (*S*)-FR115427.

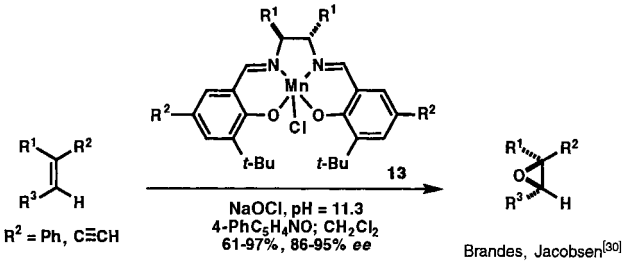


organometallic reagents to prochiral ketones in the presence of a chiral catalyst. This approach, which simultaneously forms a stereocenter and a C–C bond, has been realized for the synthesis of secondary alcohols from aldehydes. Recently, Seebach and Weber developed an effective asymmetric addition of alkyl Grignard reagents to ketones with stoichiometric amounts of (*R*,*R*)-TADDOL as shown in Scheme 25. The best results are obtained with alkyl aryl ketones. The chiral ligand was also used in substoichiometric amounts but this resulted in somewhat lower enantioselectivity.[27]

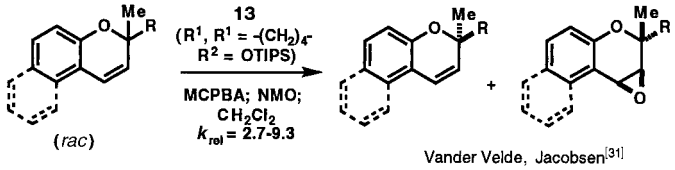
Scheme 25. Enantioselective carbonyl alklylation.

3.2. Katsuki–Sharpless Asymmetric Epoxidation Reactions (KSAE)

The KSAE of allylic alcohols is, to date, one of the most predictable and widely used catalytic asymmetric reactions. The reaction (employing diethyl or diisopropyl tartrate, *tert*-butylhydroperoxide, titanium(IV) isopropoxide, and molecular sieves in CH_2Cl_2 or toluene) provides 2,3-epoxy alcohols containing quaternary centers as shown in Scheme 26 in



Scheme 26. Chiral 2,3-epoxy alcohols from Katsuki–Sharpless oxidation.

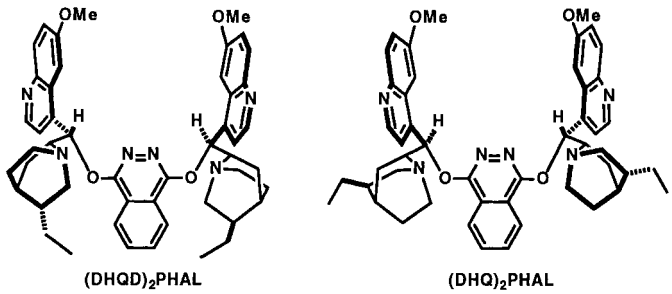


excellent enantioselectivity when 2-substituted, disubstituted, and trisubstituted allylic alcohols are used. The KSAE has been applied in numerous occasions to the synthesis of molecules containing quaternary stereocenters, and the topic has been extensively reviewed; consequently, it will not be discussed here.[28]

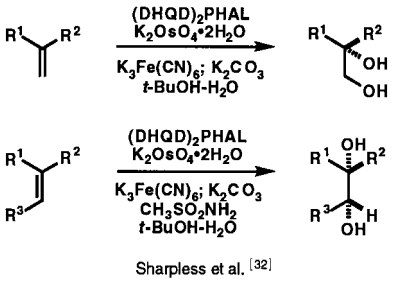
3.3. Jacobsen Epoxidation Reactions

The Jacobsen epoxidation of conjugated *cis*-disubstituted and trisubstituted olefins catalyzed by manganese–salen complexes (**13**) is highly enantioselective (Scheme 27).[29] Epoxides with quaternary stereocenters are obtained from the latter olefin class.[30] Furthermore, the kinetic resolution of racemic chromenes with the Jacobsen epoxidation exhibits promising relative rate (k_{rel}) values (Scheme 28).[31]

Scheme 27. Jacobsen enantioselective epoxidation.

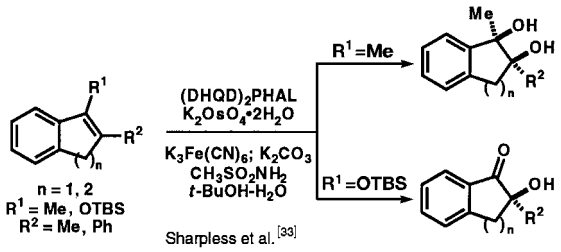


Scheme 28. Kinetic resolution by Jacobsen epoxidation. MCPBA = *m*-chloroperbenzoic acid, NMO = *N*-methylmorpholin-*N*-oxide.



3.4. Sharpless Asymmetric Dihydroxylation Reactions

The cinchona alkaloid catalyzed asymmetric dihydroxylation (AD) has emerged as one of the most general methods for the enantioselective functionalization of olefins. The most common catalysts for the reaction are bis(cinchona) alkaloids such as the quinidine derivative $(DHQD)_2PHAL$ and its pseudo-enantiomer, the quinine derivative $(DHQ)_2PHAL$ (Scheme 29). Products containing quaternary stereocenters are typically obtained in high enantioselectivity by AD of 1,1-disubstituted and trisubstituted olefins (Scheme 30). A variety of groups can be tolerated on or near the olefinic carbons, such as ketone, ester, amide, halogen, sulfide, ether, carbamate, and silane functionalities. Furthermore, enynes and polyenes have been oxidized regio- and enantioselectively.[32] Although the AD of tetrasubstituted olefins is challenging, promising results have been reported (Scheme 31).[33]



Applications to the synthesis of complex molecules have begun to emerge. A regioselective asymmetric dihydroxyla-

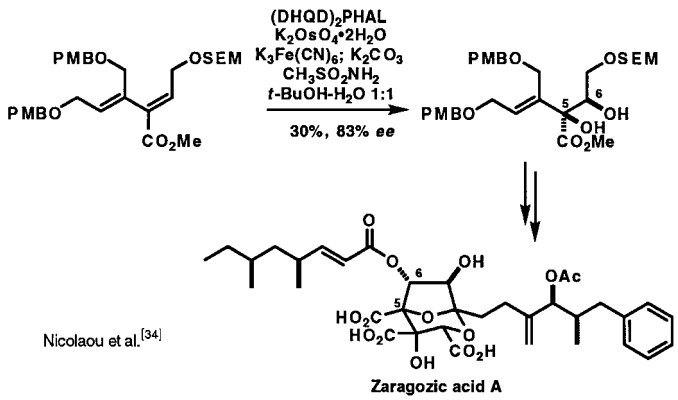
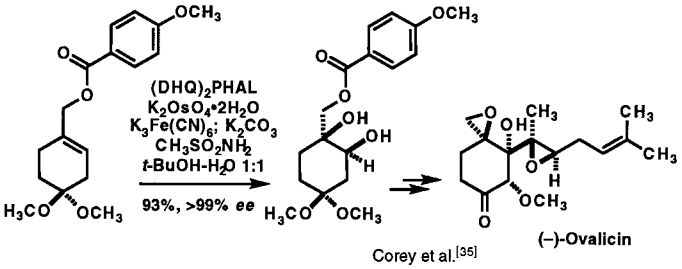


Scheme 30. Sharpless asymmetric dihydroxylation.

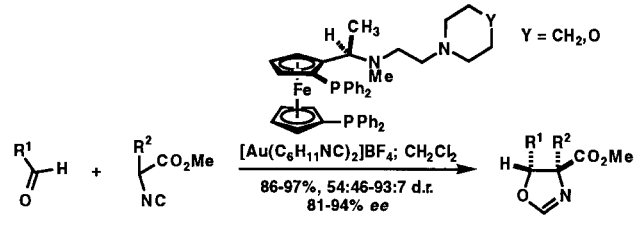
Scheme 31. Asymmetric dihydroxylation of tetrasubstituted olefins.



tion introduced the absolute stereochemistry in Nicolaou's synthesis of zaragozic acid A (Scheme 32).[34]

The key step in the synthesis of ovalicin is a novel application of the Sharpless asymmetric dihydroxylation in which a 4-methoxybenzoyl group is attached to the allylic alcohol substrate to produce a dramatic enhancement in enantioselectivity from 18% *ee* to greater than 99% *ee*

Scheme 32. Asymmetric dihydroxylation route to zaragozic acid A. In the asymmetric dihydroxylation, 44% of the starting material is recovered. PMB = *p*-methoxybenzyl, SEM = 2-(trimethylsilyl)ethoxymethyl.



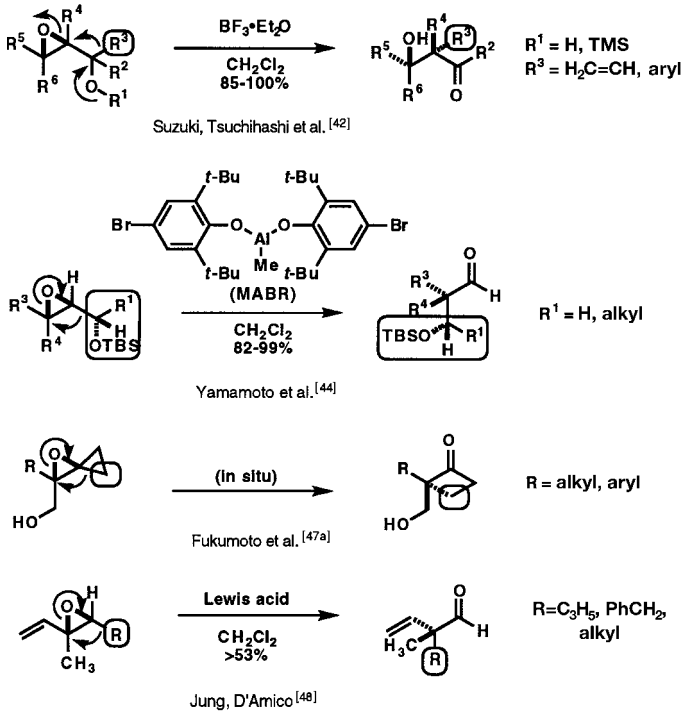
(Scheme 33).[35] The development of this novel application was guided by a mechanistic model recently proposed for AD, which predicted the specific binding of the 4-methoxybenzoyl unit of the substrate to the U-shaped binding pocket of the cinchona alkaloid/OsO_4 catalyst.[36] The reaction was extended to the highly selective dihydroxylation of a variety of allylic 4-methoxybenzoates, homoallylic 4-methoxyphenyl ethers, and other related compounds.[37, 38]

Scheme 33. Enantioselective synthesis of (−)-ovalicin.

3.5. Gold-Catalyzed Aldol Reactions

Aldol-type reactions form one of the most important classes of C–C bond forming transformations due to their ability to generate highly functionalized compounds. A noteworthy example of the catalytic enantioselective aldol processes that are currently becoming available to the synthetic chemist is the gold(I)-catalyzed reaction between α-isocyanocarboxylates and aldehydes.[39] In particular, methyl 2-alkylisocyanoacetates undergo this reaction in the presence of a gold(I) complex with chiral bis(phosphino)ferrocene ligands to afford the corresponding optically active 4-methoxycarbonyldihydrooxazoles (Scheme 34). These useful heterocycles can be hydrolyzed to enantiomerically enriched α-alkylserines and α-alkylthreonines.[40]

Scheme 34. Ito–Hayashi enantioselective route to dihydrooxazoles.



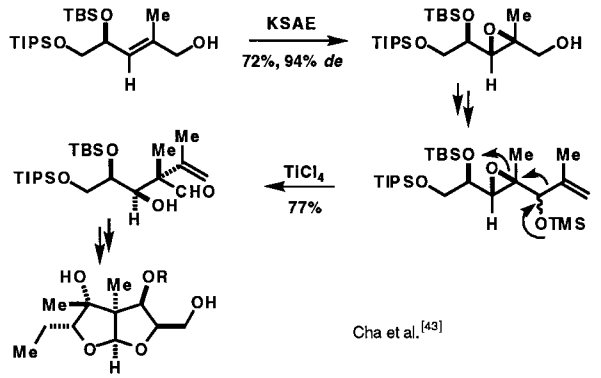
4. Methods Applicable to the Indirect Synthesis of Quaternary Carbon Stereocenters by a Catalytic Asymmetric Reaction Followed by Chirality Transfer

Intramolecular chirality-transfer reactions (also called self-immolative reactions), in which a chiral center is sacrificed as another is enantiospecifically created, are important for the construction of molecules containing quaternary stereocenters. Often in these approaches, a *catalytic enantioselective*

reaction is used to establish an initial chiral center. Subsequently, an *enantiospecific* intramolecular reaction, typically a rearrangement, destroys the original center and transfers the chirality to a newly created quaternary carbon atom. Commonly, a heteroatom-substituted stereocenter is destroyed at the expense of a less readily established all-carbon-substituted quaternary center.

4.1. Asymmetric Epoxidation—1,2-Rearrangement Strategies[41]

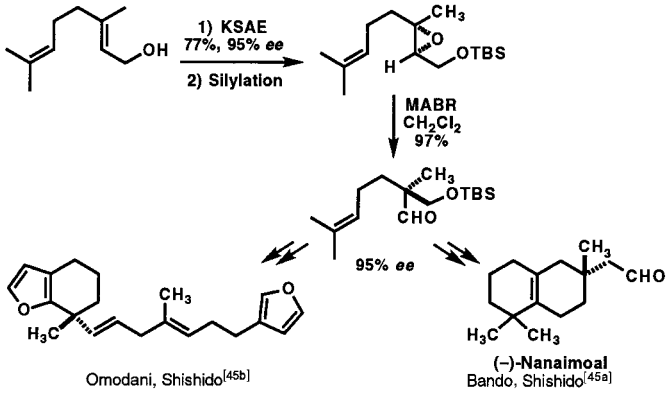
As discussed in Section 3.2, the KSAE of allylic alcohols is a general and predictable reaction that makes optically active 2,3-epoxy alcohols readily available. Consequently, the enantiospecific 1,2-rearrangement of these epoxides and their derivatives has been thoroughly studied and can be subdivided into four groups: the Suzuki–Tsuchihashi, Yamamoto, Fukumoto, and Jung variants (Scheme 35). The last three rearrangements are all mechanistically very similar but differ in the epoxide substituents, migrating group, and Lewis acid used.



Scheme 35. Cationic rearrangements of chiral oxiranes.

4.1.1. Suzuki–Tsuchihashi Epoxide Rearrangements

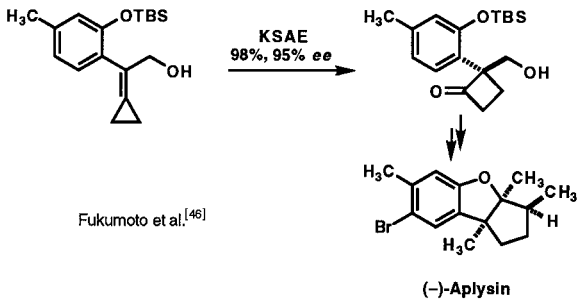
The Suzuki–Tsuchihashi rearrangement is mechanistically similar to the pinacol rearrangement and results in the 1,2-migration of a vinyl or aryl group.[42] It was applied together with a KSAE to the synthesis of the bis(tetrahydrofuran) core of asteltoxin (Scheme 36).[43]



4.1.2. Yamamoto Epoxide Rearrangements

The Yamamoto rearrangement involves the 1,2-migration of a 1-(*tert*-butyldimethylsilyloxy)alkyl group, typically a 1-

Scheme 36. Enantioselective synthesis of a (+)-asteltoxin subunit.

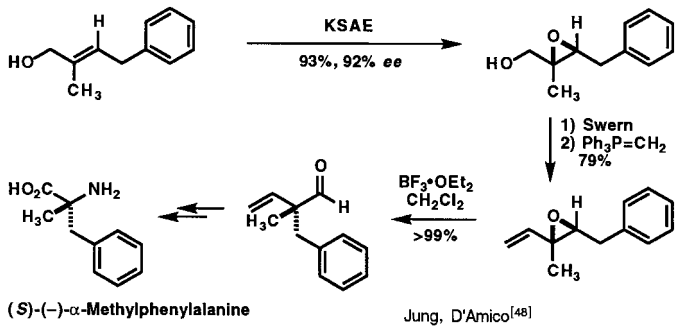


(*tert*-butyldimethylsilyloxy)methyl group.[44] A KSAE, followed by silylation and Yamamoto rearrangement, was utilized for the synthesis of nanaimoal and of the enantiomer of a naturally occurring marine furanoterpene (Scheme 37).[45]

Scheme 37. Synthesis of (−)-nanaimoal and the enantiomer of a natural marine furanterpene.

4.1.3. Fukumoto Epoxide Rearrangement

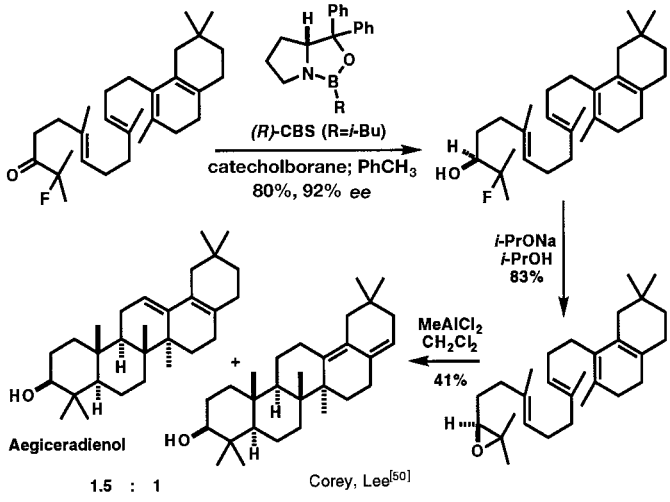
The Fukumoto variant is notable in that a stereospecific rearrangement occurs spontaneously during the KSAE of a 2-substituted 2-cyclopropylidenethanol. The natural product aplysin was synthesized in this manner (Scheme 38).[46, 47]



Scheme 38. Synthesis of (−)-aplysin.

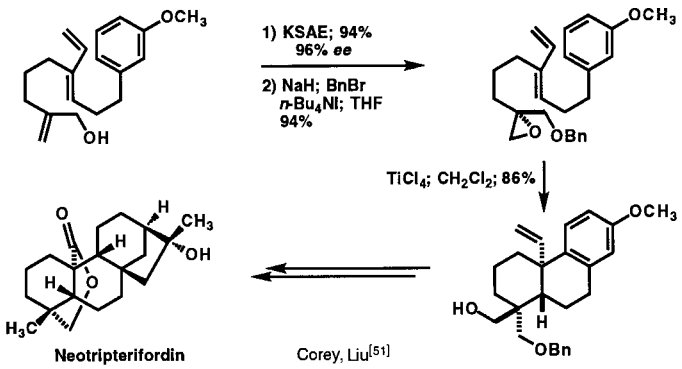
4.1.4. Jung Epoxide Rearrangement

The Jung rearrangement of optically active vinyl epoxides is relatively flexible with respect to the migrating group. It was



applied to the synthesis of (*S*)-(−)-α-methylphenylalanine as shown in Scheme 39.[48]

Scheme 39. Synthesis of (*S*)-(−)-α-methylphenylalanine by Jung rearrangement.

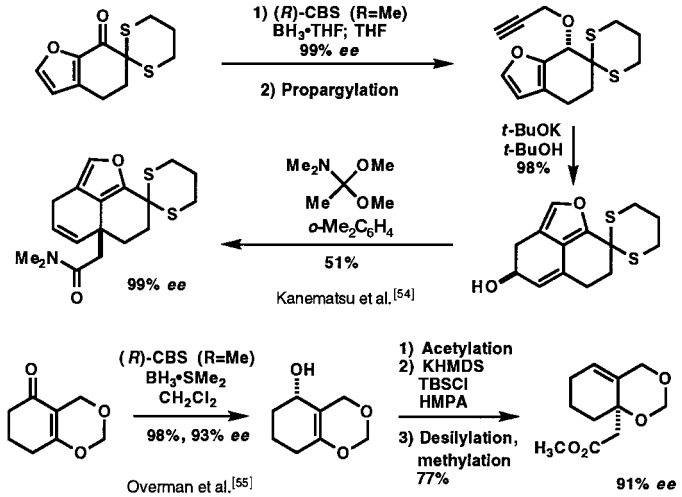


4.2. Chirality Transfer by Cationic Cyclization Reactions

The Lewis acid promoted olefin-cation cyclization[41] of optically active epoxides has been applied to the enantiospecific synthesis of molecules with quaternary stereocenters. For instance, the synthesis of β-amyrin, erythrodiol, and oleanolic acid was accomplished through the common intermediate aegiceradienol, itself a natural product, as shown in Scheme 40. Aegiceradienol was prepared stereospecifically by oxazaborolidine-catalyzed (CBS) reduction[49] of the indicated α-fluoroketone to provide the corresponding fluorohydrin in high enantiomeric purity, followed by ring-closure to the epoxide and enantiospecific olefin-cation cyclization. The latter reaction results in the formation of three new quaternary stereocenters, two new tertiary stereocenters, and three new rings in a single synthetic operation.[50]

Scheme 40. Enantioselective route to pentacyclic triterpenes.

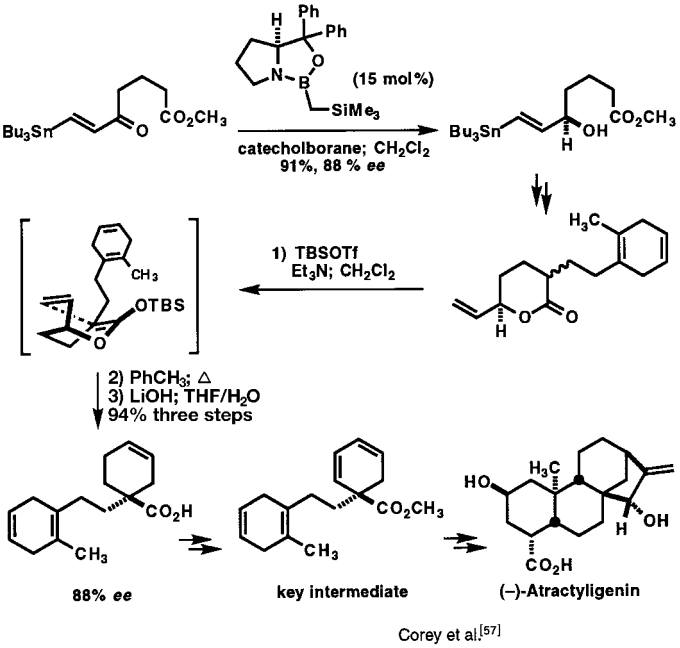
Recently, the synthesis of neotripterifordin was accomplished by a Katsuki–Sharpless asymmetric epoxidation followed by a stereospecific olefin-cation double cyclization, which provided exclusively the indicated intermediate with three stereocenters in high yield (Scheme 41).[51, 52]



Scheme 41. Enantioselective synthesis of neotripterifordin.

4.3. Strategies Based on the Claisen Rearrangement[53]

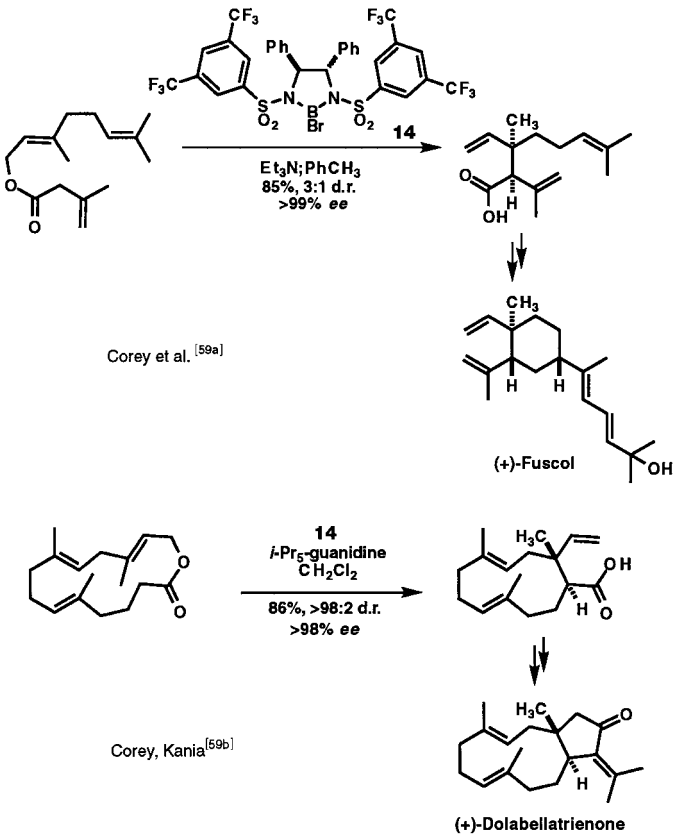
4.3.1. Chirality Transfer by Claisen Rearrangements



The Claisen rearrangement has been a mainstay of organic synthesis due to its wide applicability and high stereospecificity. Additionally, it is an excellent method for the transfer of chirality from an optically active secondary alcohol to a quaternary carbon center. This approach is especially useful, because several types of allylic alcohols are available by catalytic enantioselective reactions. For example, the preparation of a useful key intermediate for the synthesis of naturally occurring fused furans was accomplished by a sequence involving a highly enantioselective CBS reduction, a furan ring transfer reaction, and an enantiospecific Claisen rearrangement (Scheme 42).[54]

Scheme 42. Introduction of angular substituents by enantioselective CBS reduction followed by Claisen rearrangement. KHMDS = potassium bis(trimethylsilyl)amide.

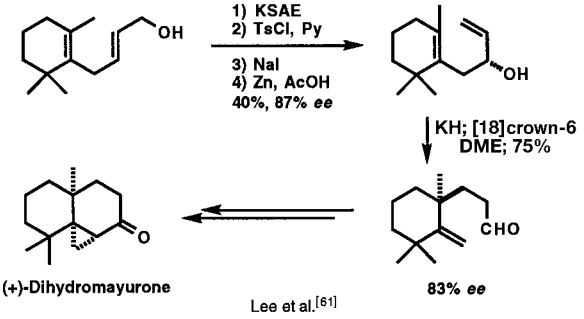
Likewise, the basic skeleton of the cardenolides was stereospecifically synthesized by Overman and co-workers through the CBS reduction of a tetrasubstituted enone, followed by an Ireland–Claisen rearrangement of the resulting allylic alcohol (Scheme 42). The rearrangement proceeds with high stereochemical fidelity as evidenced by the high enantiomeric excess of the product.[55]



Furthermore, the challenging quaternary carbon center of a key intermediate for the synthesis of atractyligenin was established by the CBS reduction of a β-tri-*n*-butylstannyl enone followed by chirality transfer from the resulting secondary alcohol to the desired quaternary site by an Ireland–Claisen rearrangement (Scheme 43). The high enantioselectivity obtained in the CBS reduction is a result of remote steric interactions[56] between the β-tri-*n*-butylstannyl substituent of the enone and the trimethylsilylmethyl group on the boron atom of the catalyst, which strongly disfavor the minor diastereomeric reduction pathway.[57]

Scheme 43. Enantioselective synthetic route to (−)-atractyligenin.

4.3.2. *Claisen Rearrangements with Chiral Reagents*



The Ireland–Claisen rearrangement of several allylic esters with chiral diazaborolidine reagent **14** results in substituted 4-alkenoic acids of high enantiomeric and diastereomeric purity.[58] This process has been utilized successfully to install the quaternary stereocenters in fuscol and dolabellatrienone (Scheme 44). Although these transformations require stoichiometric amounts of the chiral boron compound, the reagent is readily available and recyclable, and it provides outstanding results.[59]

Scheme 44. Asymmetric synthesis of cyclic diterpenoids by enantioselective Claisen rearrangement.

4.4. Strategies Based on Anionic Oxy-Cope Rearrangements

The anionic oxy-Cope rearrangement[60] is an alternative method for the transfer of chirality from a secondary alcohol to a quaternary stereocenter. For example, in a synthesis of dihydromayurone the stereochemistry of a secondary allylic alcohol is installed by KSAE. Subsequently, this alcohol undergoes anionic oxy-Cope rearrangement to generate a quaternary stereocenter through a putative chairlike transition state with approximately 95% stereochemical fidelity (Scheme 45).[61]

Scheme 45. Enantioselective synthesis of (+)-dihydromayurone by oxy-Cope rearrangement.

5. Summary and Outlook

The progress in the catalytic asymmetric synthesis of molecules containing quaternary carbon stereocenters, both by direct and indirect methods, has been astounding. Despite these impressive recent advances, many unsolved problems remain. These include limitations with regard to scope and frequent practical problems associated with catalyst preparation and use, especially on large scale. Nonetheless, continued exploratory research on catalytic enantioselective method-

ology and the underlying basis for enantioselectivity can be expected to provide new and powerful methods for the construction of a wide range of complex molecules.

We are grateful to the Schering-Plough Corporation, the National Institutes of Health, and the National Science Foundation for generous financial support.

Electroluminescent Conjugated Polymers—Seeing Polymers in a New Light

Arno Kraft, Andrew C. Grimsdale, and Andrew B. Holmes*

A major recent development in the field of molecular electronics has been the discovery of electroluminescent conjugated polymers—that is, fluorescent polymers that emit light when excited by the flow of an electric current. These materials may now challenge the domination by inorganic materials of the commercial market in light-emitting diodes. Conjugated polymers are particularly versatile because their physical properties (color, emission efficiency) can be fine-tuned by manipulation of their chemical structures. The development of polymer-based light-emitting devices has been accompanied by an increased understanding of the processes involved in device function and breakdown, and the systematic modification of the properties of the emissive polymers by synthetic design has become a vital component in the optimization of light-emitting devices. In this account we present an overview of the synthesis and properties of electroluminescent polymers and demonstrate through examples the development of the field. There are many aspects of fundamental science to be studied in order to realize commercial applications of this serendipitous discovery. Opportunities for synthesis abound.

Keywords: conjugation · electrochemistry · luminescence · materials science · polymers

1. Introduction

The role of polymers in the electronics industry has been traditionally associated with insulating properties, whether these be for isolating metallic conductors or for use in photoresist technology. From that starting point it was the pioneering work of MacDiarmid, Heeger, and Shirakawa et al. that inspired chemists and physicists to consider the opportunity of using polymers as conductors. While the scientific community had started to accept the concept of conjugated polymers as semiconductors, no-one was prepared for the discovery of the plastic sandwich that would emit light when simply connected to a battery. The discovery in Cambridge of electroluminescence (EL), that is the emission of light when excited by flow of an electric current, in conjugated polymers[1] has provided a new impetus to the development of light-emitting devices (LEDs) for display and other purposes.[2] Organic electroluminescent displays represent an alternative to the well-established display technologies based on cathode-ray tubes and liquid-crystal displays (LCDs), particularly with respect to large-area displays for which the existing methods are not well suited.

Inorganic electroluminescent materials have been known for many years, and LEDs based on these materials have been commercially available since the early 1960s. They have been widely used in a variety of applications. EL from molecular organic materials was discovered about the same time, but it was only in the mid-1980s that devices using fluorescent organic dyes showing brightnesses and operating voltages suitable for commercial applications were developed by Tang and Van Slyke,[3] and by Saito and Tsutsui et al.[4] Monochromatic displays based on such devices are reportedly due to be released on the commercial market in 1997 or 1998.[5, 6] Inorganic semiconducting and organic dye materials have to be deposited as thin films by the relatively expensive techniques of sublimation or vapor deposition, which are not well suited to fabrication of large-area devices. For these reasons, the possibility of using fluorescent conjugated polymers, which can be readily deposited from solution as thin films over large areas by spin-coating or doctor blade techniques, is most attractive. Considerable research efforts have gone into the development of electroluminescent polymers for use in LEDs, and in this review we aim to give an overview of the progress made in this area. Polymer LEDs are expected to have commercial applications as backlights

2. Poly(phenylene vinylene)s—A Case History

Electroluminescence in conjugated polymers was first discovered during investigations into the electrical properties of poly(1,4-phenylene vinylene) (PPV; **6**),[1] the simplest and cheapest poly(arylene vinylene).

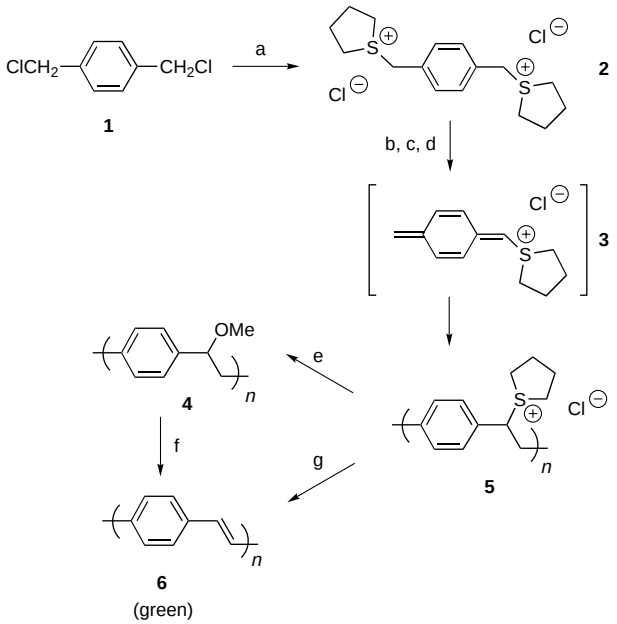
2.1. The Synthesis of Poly(*p*-phenylene vinylene)—Precursor Polymer Routes

PPV (**6**) is a bright yellow, fluorescent polymer. Its emission maxima at 551 nm (2.25 eV) and 520 nm (2.4 eV) are in the yellow-green region of the visible spectrum. The polymer is insoluble, intractable, and infusible. Any synthesis of PPV directly from a monomer produces an insoluble material, which cannot be easily processed; solution processing by spin-coating is, however, particularly desirable as it yields high-quality transparent thin films for the production of polymer

A. Holmes

A. Kraft

A. Grimsdale



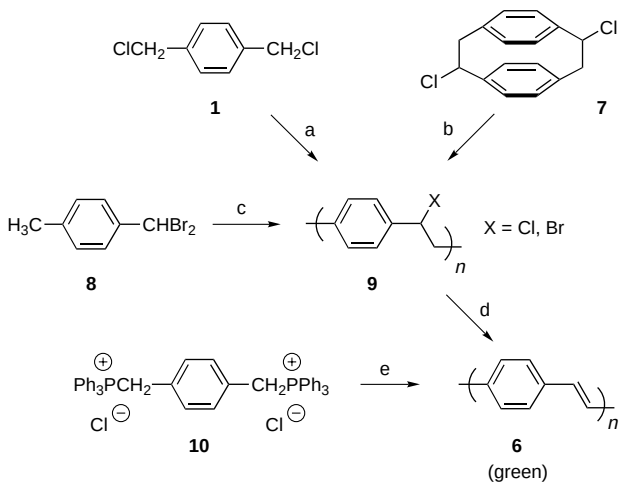
Andrew Holmes was born in Melbourne, Australia, in 1943 and received his early education at the University of Melbourne. He obtained his Ph.D. in 1971 in the field of annulene chemistry with Prof. Franz Sondheimer at University College London, and then carried out postdoctoral research at the Eidgenössische Technische Hochschule, Zürich with Prof. A. Eschenmoser on the total synthesis of vitamin B_{12}. In 1972 he was appointed University Demonstrator (Assistant Lecturer) and in 1977 Lecturer in the University Chemical Laboratory at the University of Cambridge. In 1989 he commenced a collaboration with Prof. R. H. Friend in molecular electronics, which led to the discovery of electroluminescence of poly(para-phenylene vinylene). *Dr. Holmes has been the Director of the Melville Laboratory for Polymer Synthesis since 1994. Current research interests embrace the synthesis of functional macromolecules and biologically active natural products.*

Arno Kraft, born 1961 in Darmstadt, Germany, studied chemistry at the Universität Würzburg. He then worked in the group of Prof. M. Christl on the synthesis of and NMR spectroscopic investigations of benzvalene derivatives, and obtained his Ph.D. in 1989. After a brief stay with Prof. G. Erker, he joined Andrew Holmes as a postdoctoral research fellow. During the following three years he worked on the development of electroluminescent polymers and charge-transporting materials. He left Cambridge in 1993 to start independent research for his habilitation at the Universität Düsseldorf. His current interests include highly soluble and, at the same time, highly self-associating and self-assembling dendrimers and branched macromolecules.

Andrew Grimsdale, born 1963 in Waiouru, New Zealand, is a graduate of the University of Auckland. He worked on the synthesis of analogues of biologically active drimane sesquiterpenes with Prof. R. C. Cambie and obtained his Ph. D. in 1990. He then joined Prof. A. Pelter at the University of Wales in Swansea, where he investigated photochromic and electroactive organic materials. In 1994 he moved to Cambridge where he began research with Andrew Holmes into novel electroluminescent polymers. In 1997 he returned to Auckland.

EL devices. This dilemma is conveniently resolved by the use of a solution-processible precursor polymer. The sulfonium precursor route to PPV was introduced by Wessling and Zimmerman,[25, 26] and was subsequently modified and optimized by other groups.[27–29] The principle has been applied, not only to PPV and its derivatives, but also to a whole range of PPV-related copolymers.

Scheme 1 outlines the standard preparation of PPV (**6**).[28] Treatment of 1,4-bis(dichloromethyl)benzene (**1**) with tetrahydrothiophene results in the formation of the bis-sulfonium

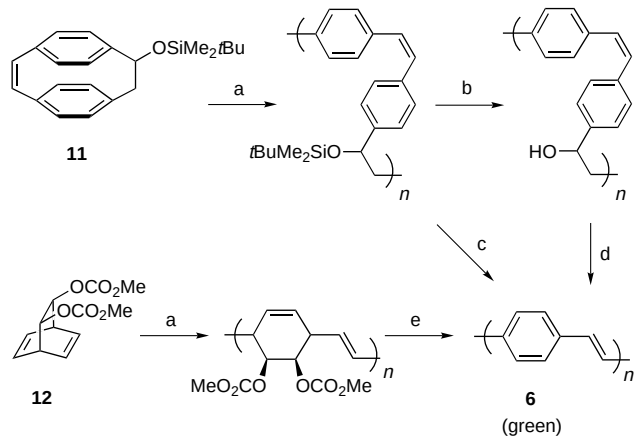


Scheme 1. Synthesis of PPV (**6**): a) tetrahydrothiophene, MeOH, 65 °C; b) NaOH, MeOH/H_2O or Bu_4NOH, MeOH, 0 °C; c) neutralization (HCl); d) dialysis (water); e) MeOH, 50 °C; f) 220 °C, HCl(g)/Ar, 22 h; g) 180–300 °C, vacuum, 12 h.

salt **2**. Other sulfides such as dimethyl sulfide can be employed, but unwanted side reactions occur at sulfonio groups during subsequent steps.[27] Polymerization of a methanolic solution of monomer **2** is induced by the addition of slightly less than 1 mol equivalent of aqueous sodium hydroxide at 0–5 °C. If more base is used, the resulting polymer solutions become brightly colored owing to partial base-induced elimination of the sulfonio groups. The mechanism of this polymerization deserves further investigation. Studies[26, 30] have shown that the presence of radical trapping agents such as oxygen can severely lower the molecular weight of the polymer, which would suggest that the *p*-quinodimethane intermediate **3** undergoes radical polymerization, although anionic propagation cannot be completely excluded. The reaction is in practice best performed under an inert atmosphere and is terminated by neutralization with dilute hydrochloric acid. The almost colorless solutions of precursor polymer **5** are then dialyzed against distilled water to remove impurities having low molecular weight. The molar mass of the precursor polymer **5** cannot be determined easily by gel-permeation chromatography owing to the polyelectrolyte nature of the polymer. Treatment with refluxing methanol gives a neutral polymer **4** which on gel-permeation chromatography characterization shows a number-average molar mass M_n of $\geq 100000\ g\,mol^{-1}$.[31]

The precursor polymer **5** is converted into PPV (**6**) by heating thin films (spin-coated with thickness of typically 100 nm) in the temperature range of 180–300 °C for 12 h under vacuum (10^{-6} mbar).[1, 28] Under these conditions the by-products of the elimination (tetrahydrothiophene and hydrogen chloride) escape easily. It has been reported that traces of oxygen during the conversion step reduce the luminescence quantum efficiency in the final PPV film. This has been attributed to the formation of carbonyl groups that are believed to quench luminescence.[32–34] The formation of such groups was reported to be suppressed by performing the conversion in a reducing atmosphere of nitrogen and hydrogen.[32, 33] PPV prepared under these conditions has higher fluorescence and EL quantum efficiencies.[35] Our own experience is that a nitrogen atmosphere suffices. When conducting the elimination step under argon, Schwoerer et al.[36, 37] found that conversion already occurred at 160 °C. Vanderzande et al.[38] and Müllen et al.[29] then showed that the conversion temperature could be further reduced by using the bromide instead of the chloride salt of precursor polymer **5**, which allows the conversion to occur at temperatures as low as 100 °C. This enables LEDs to be fabricated on flexible polymer foil substrates, for example on indium-tin oxide (ITO)-coated poly(ethylene terephthalate) (PET). Films of PPV can also be deposited by Langmuir–Blodgett techniques[39] and by simple dip-coating. The resulting PPV shows remarkably good luminance properties given that these techniques contaminate PPV with surfactant residues.[40–43] Highly aligned free-standing thin films and fibers of PPV can be formed by pre-ordering the precursor polymer **5** in a lyotropic liquid-crystalline phase before thermal conversion.[44] This type of nanocomposite might show promise for polarized emission.

Other methods have also been exploited to prepare PPV suitable for LEDs. The materials produced by these routes, however, may differ from PPV prepared by the Wessling route in molar mass, molar mass distribution, film quality, nature and amount of defects and impurities, output of waste materials etc., and of course the resulting device efficiency and lifetimes may also vary considerably. A modified Wessling (quinodimethane) synthesis, based on the elimination of sulfinyl or sulfonyl groups instead of sulfonio groups, has been reported by Vanderzande et al.[45–47] Galvin et al.[48] favored a xanthate precursor polymer soluble in organic solvents and claimed that it gave better quality PPV films and higher device efficiencies than the standard route.



PPV films are also accessible by chemical vapor deposition (CVD) of compounds of type **1**[49] and **8** or of chlorinated cyclophane **7**.[50] In all cases the intermediate α-halo-precursor polymer **9** film is further converted to PPV **6** at 200 °C under vacuum (Scheme 2), but LEDs made with these films showed quite low (0.002 %) efficiencies (see Section 2.2).[49, 51] Electropolymerization of **10** gave PVV films, but absorption and emission spectra were blue-shifted with respect to material produced by other methods, indicating that the electropolymerized material had a shorter conjuga-

Scheme 2. Alternative synthetic routes to PPV (**6**): a) 500 – 700 °C, 0.01 mbar; b) 580 °C, 10 Pa; c) 800 – 900 °C, 0.01 mbar, then 60 °C, 0.1 mbar; d) 200 °C, vacuum; e) CH_3CN, 5.5 V.

tion length owing to incomplete elimination of the phosphonio groups.[52]

Ring-opening metathesis polymerization (ROMP) in principle offers the opportunity for precise control of polydispersity and microstructure. Applications to conjugated polymers such as polyacetylene are well-documented,[21] and promising routes to PPV are also emerging. The siloxy-substituted cyclophane **11**[53] or bicyclic monomer **12**[54] are typical substrates for ROMP and afford well-defined precursor polymers, which are converted to PPV **6** by thermal elimination (Scheme 3).

Scheme 3. ROMP routes to PPV (**6**): a) [Mo(=NAr)(=CHCMe$_2$Ph)-{OCMe(CF$_3$)$_2$}$_2$]; b) Bu$_4$NF; c) HCl(g), 190 °C; d) 105 °C; e) 280 °C.

2.2. Simple Electroluminescent Devices Based on PPV—A Basic Polymer LED

As a material, PPV has several advantages over classical inorganic light-emitting semiconductors. First the ease of processing permits PPV to be spread onto large areas and curved surfaces. Second PPV shows the tensile properties expected for a chain-extended polymer: its elastic moduli and tensile strength are almost as high as those of polyaramide fibers. This, of course, helps the polymer "to survive" under the harsh conditions prevailing during device operation.

In a light-emitting diode (LED) or electroluminescent device (Figure 1), the thin film of light-emitting material is sandwiched between two electrodes, one of which has to be

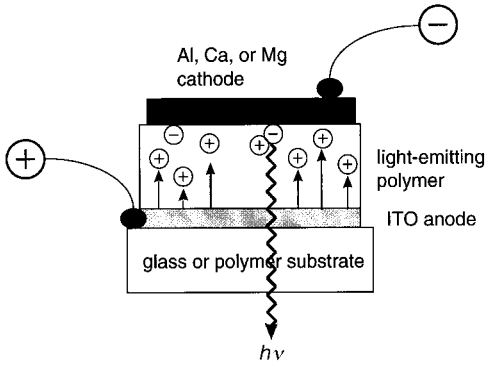


Figure 1. Schematic drawing of a single-layer electroluminescent device. An applied electric field leads to injection of holes (positive charges; the majority charge carriers in polymers such as PPV) and electrons (usually the minority charge carriers) into the light-emitting polymer film from the two electrode contacts. Formation of an electron-hole pair within the polymer may then result in the emission of a photon. Since holes migrate much more easily through PPV than electrons, electron-hole recombination takes place in the vicinity of the cathode.

semitransparent. Under an applied bias (voltage), oppositely charged carriers (electrons and holes) are injected into the emissive layer(s) from the opposing contacts, and are swept through the device by the high ($>10^5$ V cm^{-1}) electric field. Some of the electrons and holes combine within the emissive material to form triplet and singlet excited states. The singlets are indistinguishable from the excited states of photoluminescence (PL), the fluorescence process resulting from photoexcitation of the ground state (Figure 2).

A common measure of the efficiency of electroluminescent devices is the number of photons emitted per electron injected. This is the internal efficiency, which is based on the assumption that all the light generated is received by the viewer. External efficiencies are a factor of $2n^2$ smaller than internal efficiencies, where n is the refractive index of the polymer.[55] For a polymer having a typical refractive index of 1.4 this factor would be four, and external quantum efficiencies for the current family of polymers fall within the range 0.1 – 5 %.

It should also be noted that EL efficiencies are dependent on the distance of the emitting dipoles from the metal electrode.[56] Power conversion efficiences (W W^{-1}) are quoted by device engineers. These values are reached by multiplying the external quantum efficiency by the ratio of the photon energy and the drive voltage. The power efficiency should be as high as possible in order to maximize device longevity, and, at the same time, devices have to be bright at low current and low electric field. The luminous efficiency (lm W^{-1}) is the power conversion efficiency multiplied by the luminous efficacy (in lumens per watt).[19] The luminous efficacy is a conversion factor that takes account of the fact

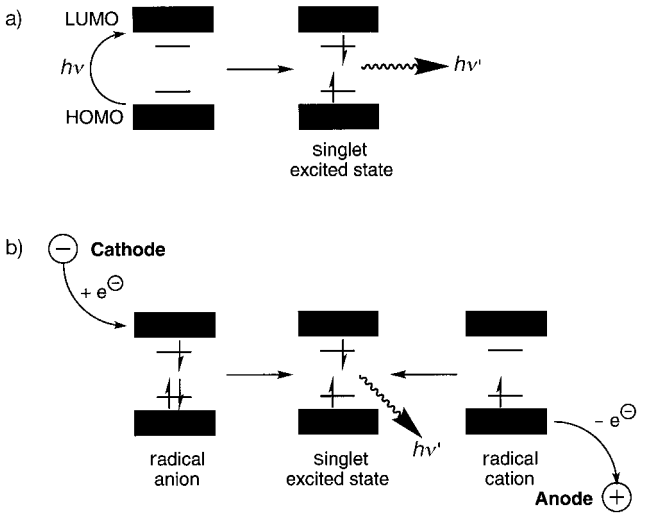

Figure 2. a) Irradiation of a fluorescent polymer excites an electron from HOMO to LUMO. In a typical conjugated polymer, two new energy states are generated upon relaxation within the original HOMO – LUMO energy gap and are each filled with one electron of opposite sign (singlet excited state). The excited polymer may then relax to the ground state with emission of light at a longer wavelength than that absorbed (photoluminescence). b) In a polymer LED, electrons are injected into the LUMO (to form radical anions) and holes into the HOMO (to form radical cations) of the electroluminescent polymer. The resulting charges migrate from polymer chain to polymer chain under the influence of the applied electric field. When a radical anion and a radical cation combine on a single conjugated segment, singlet and triplet exited states are formed, of which the singlets can emit light.

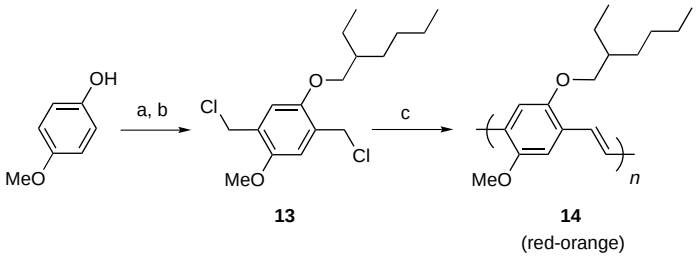
that the eye is more sensitive to green than to red and blue light. Current values reported for luminous efficiencies range between 1 – 2 lm W^{-1}, and values as high as 10 lm W^{-1} for the best devices have been reported. Luminance (cd m^{-2}) and luminance per unit of current density are also measures of device efficiency. Typical luminances for laptop displays are about 100 cd m^{-2}, but much higher luminances would be required for a matrix addressing scheme that avoids the need for thin film transistors behind each pixel.

The choice of the correct electrode combination is crucial to the operation of a polymer light-emitting diode (Figure 1). There has been considerable progress in understanding the dopant behavior of negatively charged metal contacts at the metal– polymer interface.[18] Single-layer devices are typically fabricated by solution-coating a thin film of polymer on indium-tin oxide (ITO)-glass and by vacuum evaporation of a cathode. These device structures will be denoted as ITO/polymer/metal in the remainder of this review. An early device configuration ITO/PPV/Ca had an average internal efficiency of 0.1 %.[57, 58] Glass or PET substrates with a thin (ca. 15 nm) transparent ITO layer are commercially available. The mixed-metal oxide has a high work-function, which matches the HOMO energy level of PPV and makes it convenient for hole injection (i.e. removal of an electron from the HOMO) into the polymer.

Other metals and oxides such as gold,[1] Al/Al_2O_3,[1] and SnO_2[59] have also been tested for electroluminescent polymers but in only a few cases gave better performance. Calcium as a result of its reactivity (especially its moisture sensitivity) may not be the preferred electrode for use in commercial devices unless excellent encapsulation can be realized, and a less reactive low-work-function metal would generally be favored. Aluminum has been a compromise, but the internal efficiency of a PPV light-emitting device using ITO and Al electrodes is only 0.01 % owing to poor electron injection.[58] Introduction of a thin layer of aluminum oxide between the PPV and Al layer (i.e., Al/Al_2O_3 as cathode) can result in a marked improvement in device efficiency as a result of carrier confinement.[60]

Heterostructure LEDs made from self-assembled multilayers of PPV and polyanions such as sulfonated polyaniline have also been constructed and found to emit bright yellow-green light with low turn-on voltages.[61–66] The self-assembled multilayer technique so far seems to enable exceptional control of the device thickness, and has recently been extended to include ruthenium-based complexes.[67] The improvement of power efficiency and stability of EL devices by addition of an extra charge-transporting layer between the PPV and the cathode[58, 68–77] is discussed in Section 3.2.

2.3. Solution-Processible Poly(phenylene vinylene)s—Direct Deposition of Electroluminescent Polymers



Following the discovery of electroluminescence in PPV, LEDs from PPV derivatives that are soluble in the conjugated form were reported independently by Ohnishi et al. at Sumitomo,[78] and by Braun and Heeger at Santa Barbara.[79, 80] Such soluble polymers no longer require thermal treatment during device fabrication, which is the drawback of the PPV precursor route, although they tend to have lower glass transition temperatures. It should be pointed out that, while the precursor polymer **5** is usually processed from methanolic solutions (and, like PPV, does not dissolve or swell in chloroform), almost all soluble PPV derivatives used in EL devices are processible from solvents that do not cause swelling of PPV or its precursor polymer **5**. This difference in solubility can be applied advantageously to the design of multilayer devices that consist of sandwich structures with layers of different polymers, for example, PPV and substituted PPVs (Section 3.3.).[81, 82]

Poly[(2,5-dialkoxy-1,4-phenylene)vinylene]s with at least one long, solubilizing alkoxy side chain (e.g., 2-ethylhexyloxy, 3,7-dimethyloctyloxy, 2-methylpentyloxy, or dodecyloxy)[78, 79, 83–87] dissolve in various organic solvents such as chloroform or tetrahydrofuran. In addition, their emission maximum is red-shifted [to ca. 590 nm (2.1 eV)] compared with that of PPV. The long side chains, which keep the conjugated polymer backbones apart from each other, apparently have a beneficial effect on the polymers' fluorescence and electroluminescence quantum yields.

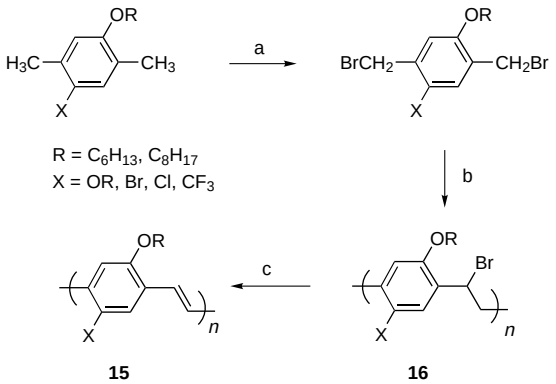
Dialkoxy-substituted PPVs can be prepared by a sulfonium precursor route as described for the synthesis of PPV.[28, 86, 88–90] Although the Wessling route may be used to make soluble PPV derivatives, a dehydrohalogenation – condensation polymerization, first developed by Gilch et al.,[91] is generally preferred. It proceeds through base-promoted 1,6-elimination of 1,4-bis(halomethyl)benzene derivatives.[78, 84, 85, 92]

This shortens the preparation of the conjugated polymer by two steps, and can result in substantially increased yields. As with the Wessling procedure, the polymerization mechanism could involve a quinodimethane, an anionic intermediate, or a carbenoid species. Molar masses of soluble poly[(2,5-dialkoxyphenylene)vinylene]s, obtained by the polymerization of bis(chloromethyl) compounds with potassium *tert*-butoxide, are comparable with those obtained by the sulfonium precursor route.

Scheme 4 shows the synthesis of the most studied dialkoxy-PPV: MEH-PPV (**14**).[84, 86] The branched side chain in MEH-PPV has a favorable effect on the solubility of the polymer—

13 **14** (red-orange)

Scheme 4. Preparation of MEH-PPV (**14**): a) 3-(bromomethyl)heptane, KOH, EtOH, reflux, 16 h; b) HCHO, concd. HCl, dioxane, 20 °C, 18 h, reflux, 4 h; c) KO*t*Bu, THF, 20 °C, 24 h.



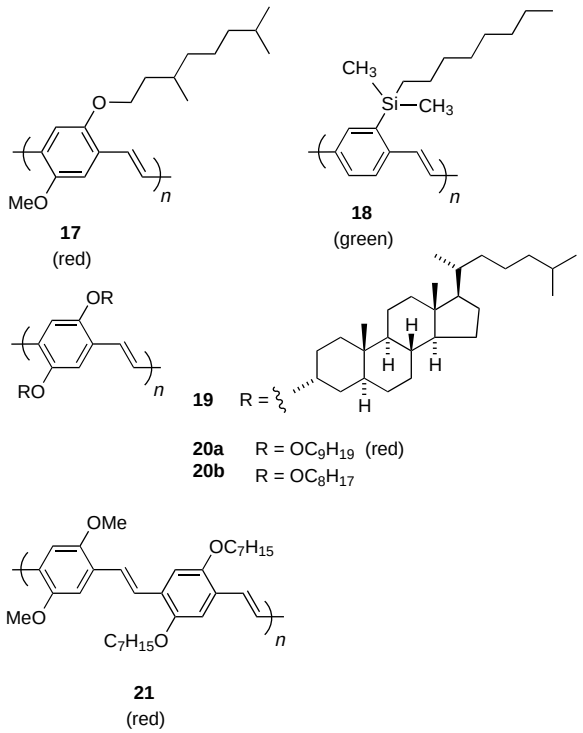
indeed, the polymer dissolves easily in solvents such as tetrahydrofuran, chloroform, or xylene. A related polymer **17** (OC_1C_{10}-PPV) with a 3,7-dimethyloctyloxy side chain has been been the subject of investigation by workers at Philips and Hoechst.[17]

The bis(chloromethyl) compound **13** is synthesized by alkylation of 4-methoxyphenol followed by chloromethylation.[79, 83, 84, 86] Polymerization of the monomer **13** is induced with a tenfold excess of potassium *tert*-butoxide in tetrahydrofuran and gives the bright red-orange MEH-PPV (**14**). Careful control of concentration is needed to avoid gelation. Purification involves several reprecipitations in methanol. A simple electroluminescent device (ITO/MEH-PPV/Ca) already achieves a quite respectable efficiency of 1.0 %.[79, 93] Insertion of a thin hole-blocking layer of poly(methyl methacrylate) film by Langmuir–Blodgett deposition is reported to give up to a fourfold increase in quantum efficiency with aluminum cathodes.[94] Devices have also been constructed with doped silicon as anode, thus opening the possibility of integrating polymer LEDs with silicon-chip technology.[95, 96]

Most of the reports of polymer LEDs described ITO on glass as the hole-injecting contact. Polyaniline (PANi), a long-known conducting polymer, presents an interesting alternative to ITO in devices using MEH-PPV, as, although it is deeply colored, it has an optical window coinciding with the maximum of emission for MEH-PPV. Using a layer of acid-doped PANi on ITO reduces the drive voltage of the device and causes an increase in device efficiency by a factor of 30 %. Such devices can produce peak luminances of over 10000 cd m^{-2} at drive voltages of 5 V, with external quantum efficiencies of 2–2.5 %, and luminous efficiencies of 3–4.5 lm W^{-1}.[97] Furthermore, replacement of the ITO-coated glass substrate by a polyaniline-coated PET sheet enables the manufacture of a flexible electroluminescent device.[83, 98] As the PET/PANi/MEH-PPV/Ca device consists of flexible polymers (with the exception of the calcium cathode), it can be safely deformed even during operation (inside a glove box). While this is an interesting application of PANi, it should be noted that ITO-coated PET is commercially available as an alternative flexible anode of reasonable mechanical stability.[36] A cylindrical polymer LED with layers of a transparent polyaniline electrode and MEH-PPV wrapped around a cylindrical metal cathode has been constructed; in this example the reactive electrode is protected by a sandwich of polymers.[99]

A significant recent development has been the introduction of a sulfonic acid-doped polyethylenedioxythiophene conducting polymer either in combination with ITO glass or alone as an anode. Quite spectacular improvements in device efficiency and reduction in drive voltage are observed in two-layer devices fabricated with this material.[100, 101] Gel-processing of a blend of MEH-PPV in polyethylene gives access to oriented films that show anisotropies of 60:1 in their fluorescence emission spectra; the preferred direction of emission is parallel to the draw axis.[102, 103] Rubbing alignment of a poly(dialkoxyphenylene vinylene) is the most effective way of orienting material to achieve polarized EL.[104, 326] Such oriented emission might find use for back-lighting in a liquid-crystal display. Orientation is also possible using Langmuir–Blodgett techniques for film deposition.[105]

Electroluminescent poly(2,5-dialkoxy-1,4-phenylene vinylene)s other than MEH-PPV have been similarly prepared.[85, 86, 106, 107] If less than one equivalent of base is used, a soluble α-halo precursor polymer **16** is obtained that can be converted into the conjugated polymer **15** (Scheme 5)[85, 108]—



15 **16**

Scheme 5. The halo-precursor route to substituted PPVs: a) NBS, CCl_4, *hν*; b) KO*t*Bu, THF; c) 160–220 °C, vacuum, 4 h.

this is known as the halo-precursor route and has some advantages if the precursor polymer is more soluble, if vapor deposition methods are used, or if incomplete conversion to a partially conjugated polymer is envisaged (Section 3.1.).

Branched side chains, as in MEH-PPV, generally enhance solubility more than linear ones of identical length and number of carbon atoms or heteroatoms. With increasing size

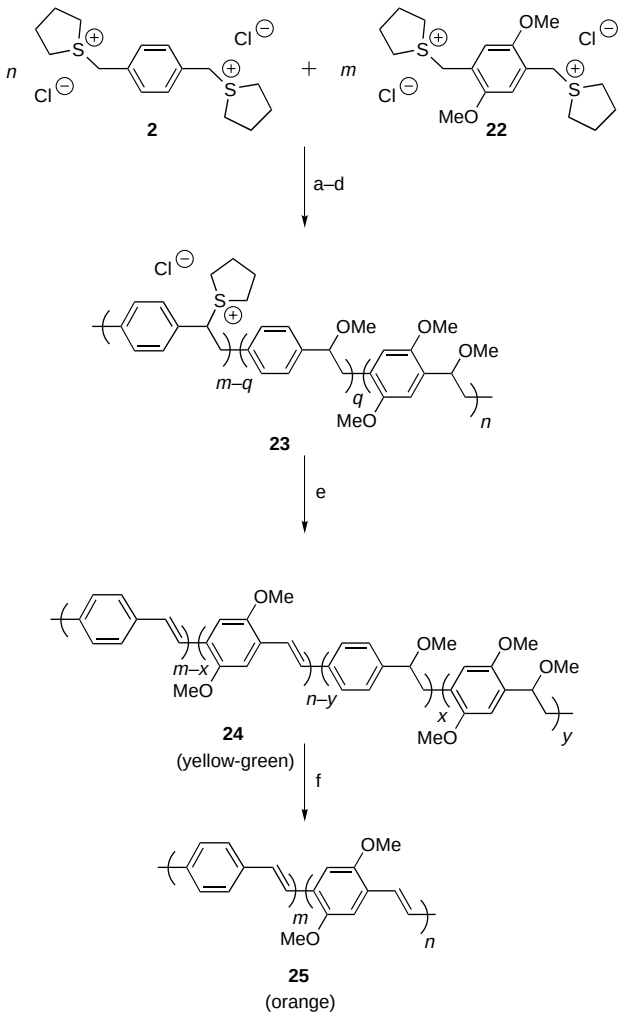
of the alkoxy group, EL efficiency passes though a maximum and decreases again with even larger side chains;[78] very large substituents, for example cholestanoxy as in **19**,[106, 109] seem to overpower and "dilute" the semiconducting properties of the conjugated polymer (Scheme 6). The highest external EL

Scheme 6. Examples of soluble, dialkoxy-substituted PPV derivatives.

efficiency reported to date for a single layer device using dialkoxy-substituted PPV derivatives is 2.1% for a device made by Philips with **17**.[17] This polymer EL device has a luminance of 100 cd m^{-2} with a luminous efficiency of 3 lm W^{-1} at a drive voltage of 2.8 V. A group at Hoechst has achieved the same quantum efficiency and luminance with a flexible device using an ITO anode on PET, with a slightly lower luminous efficiency of 2 lm W^{-1} at a driving voltage of 3.4 V and a current density of 4.5 mA cm^{-2}.[17] The introduction of a silyl group as in DMOS-PPV (**18**) widens the band gap so as to give emission of green light.[110–114] Yoshino et al.[115] have employed poly(2,5-dinonyloxy-1,4-phenylene vinylene) (**20a**), which forms a nematic liquid-crystalline state upon melting. When cooled to room temperature, the polymer remains oriented and has a lower energy gap (2.08 eV) than in an unoriented film (2.21 eV) formed by casting from chloroform solution. Rubbing of a film of this material also induces molecular orientation, and gives rise to oriented electroluminescence.[116] This technique has also been applied to a smectic liquid-crystalline copolymer of distyrylbenzene linked by long chain polyester flexible spacer groups.[117]

Other polycondensations have been used to prepare soluble PPV derivatives. Wittig condensation of terephthaldicarboxaldehydes with arylene–bisphosphylidenes furnishes alternating PPV copolymers.[118] An alkoxy-substituted PPV copolymer (**21**) prepared in this manner was found to show orange (585 nm) emission.[118] Similar PPV copolymers have been prepared by Heck coupling of dihalobenzenes with divinylbenzenes.[119]

3. Improvement of Device Efficiency—Making EL Polymers Competitive



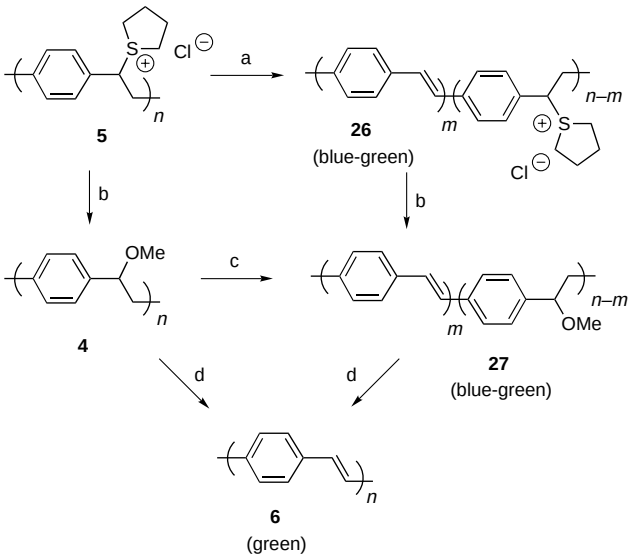
High efficiencies and reliability are the principle requirements of molecular and polymeric light-emitting materials for commercial applications.[19] The optimum goal is to obtain maximum power efficiency and brightness at minimum drive voltage and current density. This combination should afford devices having long lifetimes. The improvement of EL devices therefore requires optimization of the electroluminescent polymer and/or the device structure. Whereas it took about thirty years for an inorganic semiconductor to reach luminous efficiencies of several lm W^{-1}, organic light-emitting polymers have reached this level of performance in less than ten years. It is evident that the efficiencies of molecular and polymer organic LEDs have been dramatically improved in a short time, and are beginning to compete with those obtained for conventional inorganic LEDs.

3.1. The Use of Copolymers—Finessing the Properties

For the majority of conjugated polymers investigated so far, electron injection has proved to be more difficult than hole injection, that is, the polymers are more easily oxidized than reduced. This has been largely remedied by the use of metals with a low work-function (especially Ca) as the cathode material. However, calcium is highly susceptible to atmospheric degradation. Although this can be retarded by encapsulation, it would be beneficial to use less moisture- and oxygen-sensitive metals. If the barrier for electron injection from such metals is to be lowered, the polymer must be modified so that the energy of its LUMO matches the work function of the cathode. Copolymers of one kind or another present an attractive solution to this problem.

Copolymers containing a combination of different arylene units can be much more versatile than homopolymers and may even be chemically tuned to provide a range of materials with considerably improved EL properties. This was for the first time exemplified by statistical copolymers of PPV and poly[(2,5-dimethoxy-1,4-phenylene)vinylene], although other copolymers having interrupted conjugation have also been investigated.[57, 120–123]

By a modification of the sulfonium precursor route the two monomers **2** and **22** are copolymerized in the presence of sodium hydroxide in a water–methanol mixture (Scheme 7). The ratio of the units in the resulting (presumably statistical) copolymer **23** depends on the feed ratios of the two sulfonium salt monomers. The use of a solvent mixture leads to selective substitution of the sulfonio groups by methoxy groups. This occurs at a faster rate at those benzylic carbon atoms that are attached to the more activated dimethoxyphenylene rings. As a result, copolymer **23** has two leaving groups at the benzylic carbon atoms; the methoxy groups are adjacent to all the dimethoxyphenylene and a few phenylene units, and sulfonio



Scheme 7. Synthesis of PPV/dialkoxy-PPV copolymers: a) NaOH, MeOH/H_2O, 0 °C, 1 h; b) HCl; c) dialysis (water); d) MeOH; e) 220–300 °C, vacuum, 12 h; f) 220 °C, HCl(g)/Ar, 22 h.

groups are next to most of the phenylene units. Thermal conversion of thin (typical thickness 100 nm) films of **23** results in complete elimination of the sulfonio and only partial elimination of the methoxy leaving groups, which gives polymer **24** with interrupted conjugation. Complete elimination of all leaving groups to furnish the fully conjugated polymer **25** requires thermolysis under acidic conditions.

The electroluminescent device efficiency of polymer **24** varies with the composition of the copolymer and has its peak with a copolymer prepared from a 9:1 feed ratio of salts **2** and **22**. The maximum internal efficiency in this case is 0.3%, demonstrating a 30-fold improvement compared with that of PPV (0.01%) in the same device configuration (Al-Al_2O_3/polymer/Al).[120, 124] The shortening of the conjugated segments actually improves fluorescence yields and electroluminescence efficiency, probably originating from a reduction in nonradiative processes such as diffusion of the excited states to quenching sites. On the other hand, a large fraction of interruptions in the conjugated chain will lower the mobility of charged carriers. Somewhere in between lies an optimum for electroluminescence efficiency. The principle has been applied to other copolymers.[123] Alkoxy- and alkyl-substituted poly(phenylene vinylene)s prepared by the dehydrohalogenation route also yield interrupted copolymers having relatively high EL efficiencies.[123] In addition, statistical copolymer **23** has found use in forming lithographically patterned copolymers and waveguides.[120, 121]

A simple modification of the PPV synthesis gives access to PPV-derived blue-shifted light-emitting polymers with a high concentration of interruptions in the conjugated chain. Partial conversion of precursor homopolymers **4** or **5** produces statistical copolymers **26** and **27** with regions of saturated and unsaturated units (Scheme 8).[125, 126] The conversion of

Scheme 8. Synthesis of partially conjugated PPV copolymers: a) Bu_4NOH, MeOH; b) MeOH, 50 °C; c) 300 °C, vacuum, 12 h; d) 220 °C, HCl(g)/Ar, 22 h.

sulfonium precursor polymer **5** to **26** may be accomplished by either thermal or base treatment. Although **26** is prone to further elimination, Heeger et al. have found that conversion at 160 °C for 2 h gave a copolymer of the type **26** with fairly good long-term stability and emission efficiency.[127]

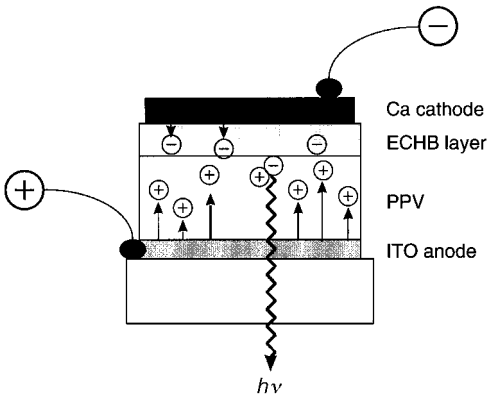
Another approach to raising the efficiency of PPV is the introduction of disorder into the chain, thus interfering with polymer chain packing. Son et al.[128] have synthesized amorphous PPV by using a modified Wessling procedure with a xanthate leaving group. The resulting PPV has a mixture of *cis*- and *trans*-alkene units, which affects conjugation and interferes with packing. Internal efficiencies of up to 0.22% for single-layer devices with aluminum cathodes and 2% for double-layer devices using an electron-transporting layer (see Section 3.2) are reported. It is not clear whether the improvements in efficiency arise from interruptions to conjugation or from reduced intermolecular order owing to the presence of *Z* double bonds. The authors favor the latter explanation.

Hörhold et al have reported poly(arylene vinylene)/poly(phenylene vinylene) alternating copolymers in which the arylene substituent carries in-chain phenylamino groups. These have the effect of dramatically reducing the oxidation potential compared with that of PPV-based polymers (and are therefore photoconductors), and offer interesting possibilities as electroluminescent materials as well.[129]

3.2. Multilayer Devices—Raising Device Efficiency with Additional Charge-Transporting Layers

The electroluminescent conjugated polymer devices discussed so far were mostly single layer devices, that is, they have the conjugated polymer sandwiched directly between anode (high work-function electrode) and cathode (low work-function electrode). Unless the barriers between these contacts and the HOMO (or LUMO) of the polymer are identical or zero, one type of charge carrier (either holes or electrons) will be preferentially injected. For a discussion of factors affecting charge injection the reader is referred to the article by Blom et al.[130] and the excellent reviews by Greenham and Friend,[14] and Sheats et al.[19].

For PPV, the injection of holes predominates. To increase the efficiency of devices, electron injection has to be significantly boosted. The use of certain additional layer(s) of materials can promote the passage of electrons through the layer and, at the same time, provides a barrier to the passage of holes. Such a layer is called an electron-conducting/hole-blocking (ECHB) layer. A suitable ECHB material should have an electron affinity equal to or greater than the electron affinity of PPV. As illustrated by Figure 3, holes are increasingly confined in the PPV layer, and the site of recombination of holes and electrons (where the emission takes place) is then moved away from the metal–polymer interface, which is known to act as a quenching site. In contrast, hole injection is not a problem with devices made from PPV. When a device with a hole-transporting layer (between the anode and the PPV layer) was tested, the efficiency of the device actually decreased, indicating that the main limiting factor in PPV-based LEDs is indeed electron injection and transport.[131]



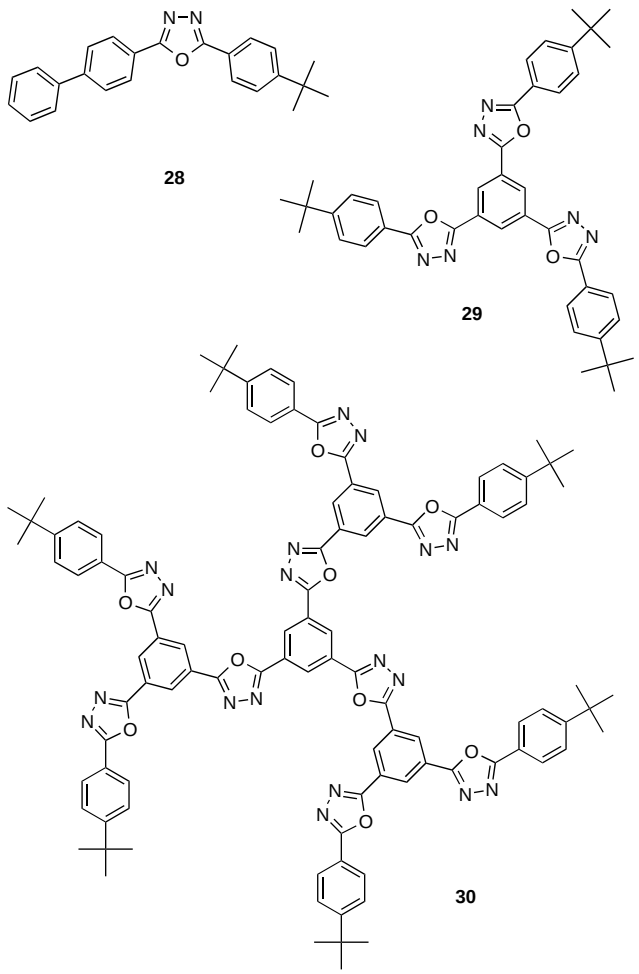


Figure 3. In this improved bilayer device structure for a polymer LED an extra ECHB layer has been inserted between the PPV and the cathode metal. The ECHB material enhances the flow of electrons but resists oxidation. Electrons and holes then accumulate near the PPV/ECHB layer interface. Charge recombination and photon generation occur in the PPV layer and away from the cathode.

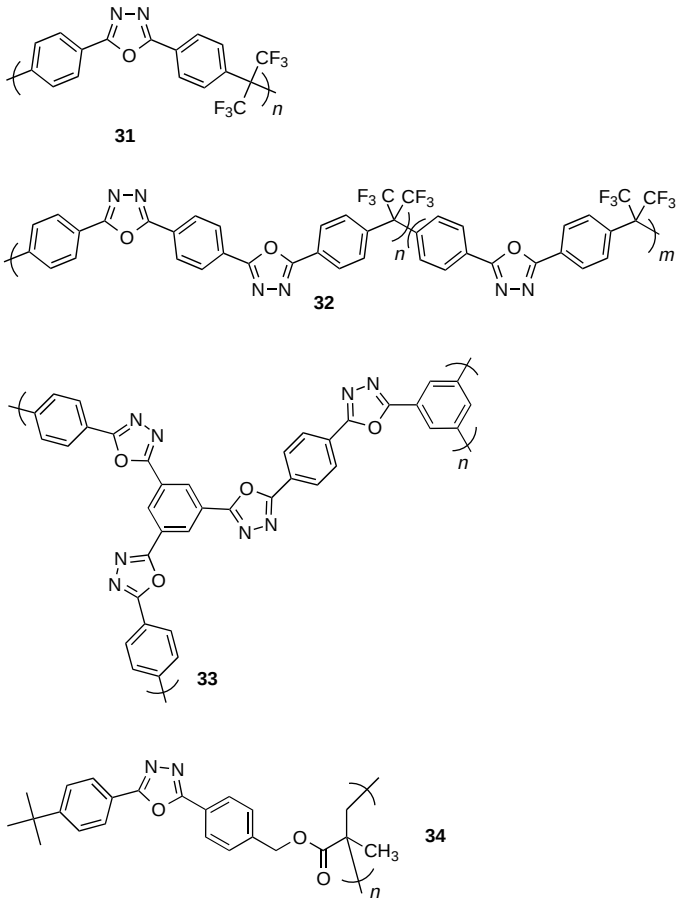
The principle behind the design of ECHB materials is well exemplified by oxadiazoles, the first and most extensively investigated class of ECHB materials. Following the successful use of 2-(4-biphenylyl)-5-(4-*tert*-butylphenyl)-1,3,4-oxadiazole (PBD) (**28**) in sublimed film EL devices,[3, 4] PBD has long been a favored compound (Scheme 9). Oxadiazoles



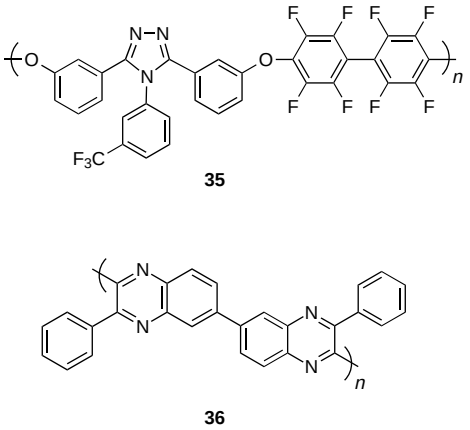
Scheme 9. Examples of oxadiazole-containing electron-transporting materials.

are electron-deficient, making PBD an extremely poor hole acceptor. It has a number of advantages: it is available in high purity, sublimes, can be spin-coated as a dispersion in a range of standard polymers such as poly(methyl methacrylate) (PMMA),[68] and can be blended with electroluminescent polymers.[112, 132–134] However, some incompatibilities with polymers exist that may lead to phase separation or crystallization especially at higher temperatures. Crystallization may be retarded by using a solid dispersion of PBD in an insulating polymer (PMMA).[68] As the ITO/PPV/PBD-PMMA/Ca device then becomes thicker owing to the extra layer, the voltage required to drive the device needs to be increased. This drawback is outweighed by a rise in internal EL efficiency from 0.1% (for an ITO/PPV/Ca device) to 0.8% (for ITO/PPV/PBD-PMMA/Ca). However, higher current densities cause a drop in device efficiency as a result of quenching by the high amount of accumulated holes at the PPV/PBD-PMMA interface.

The incorporation of identical redox sites within the same molecule has been used successfully in the design of charge-transporting compounds for electrophotography (photocopiers and laser printers). Since electron hopping is the main charge-transport mechanism in ECHB materials, increasing the number of (in this case) oxadiazole units would therefore

seem a promising way to improve the charge-transporting properties.[135] The idea was extended to the design of branched and highly symmetrical compounds such as the radialene **29**,[136] starburst structures,[137, 138] and small dendrimers like **30**.[138, 139] These materials have high glass-transition temperatures and form stable glasses, which minimize the problems of crystallization. Although the large numbers of branches in these materials should have made electron-transfer more efficient because of enhanced charge migration opportunities, they have not shown any improvement over PBD.

While low molar mass compounds are much easier to purify, incorporation of the active electron-transporting moieties into amorphous polymers should at least mitigate the problem of crystallization. Several polymeric analogs of PBD have been prepared with the oxadiazole unit either in the main or the side chain. A number of examples of poly(aromatic oxadiazole)s with satisfactory performance have been reported.[70, 72, 77, 136, 140] Solubility is mainly influenced by the frequency of solubilizing flexible spacer groups as in **31**, or the use of copolymer structures as in **32** (Scheme 10). A hyperbranched oxadiazole polymer **33**, which



Scheme 10. Examples of oxadiazole-containing electron-transporting polymers.

is soluble in trifluoroacetic acid, was prepared by a one-step procedure, but its electron-transporting properties were mediocre, perhaps caused by defects within the polymer.[136]

Poly(methacrylate)s with ECHB-active oxadiazole side chains (e. g., **34**) have been prepared by radical polymerization and show good film-forming properties.[77, 141–143] However, their device performance has not fulfilled expectations, as higher drive voltages are required to achieve the improvement in efficiency.

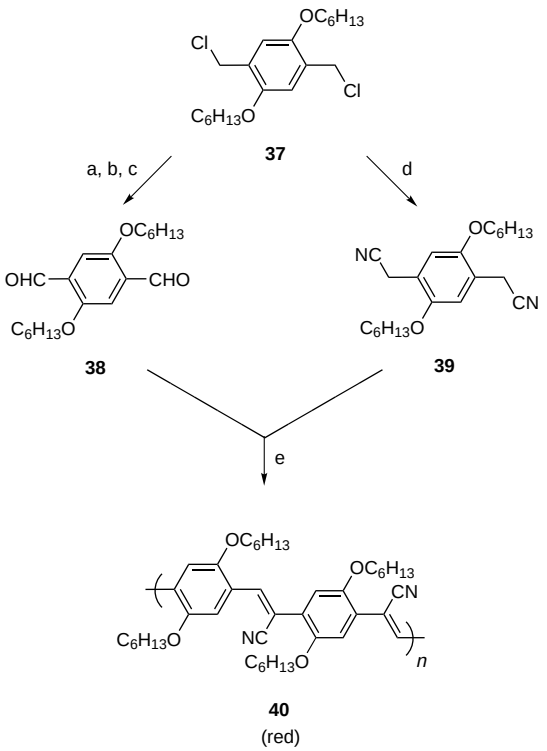
Since oxadiazoles have not proved entirely successful as ECHB materials, attention has turned to other classes of materials. Nitrogen heterocycles such as 1,2,4-triazoles, 1,3,5-triazines,[325] or quinoxalines are of particular recent interest. The turn-on voltage in devices with an ECHB layer consisting of the polymer **35**, which contains a 1,2,4-triazole unit, is surprisingly unaltered from LEDs without an electron-transporting layer (Scheme 11).[69, 76] The electron-deficient nitro-

Scheme 11. Examples of a triazole- and a quinoxaline-containing electron-transporting polymer.

gen atoms in poly(phenyl quinoxaline) (**36**) also enhance the electron affinity of the polymer. This material has been shown to greatly enhance the efficiency of devices that use soluble PPV derivatives.[144] The materials discussed above have undoubtedly made a significant contribution towards improvement in device efficiency. A more successful approach may be to increase the electron affinity of the emissive polymer as will be discussed in Section 4.

3.3. Multilayer Devices with More Than One Electroluminescent Polymer—Towards White Light Emission

Other multilayer devices than those discussed in Section 3.2 can be constructed from at least two electroluminescent polymers. If carefully chosen, they show light emission from more than one layer provided that the polymers have small and controlled variations in energy gap from one layer to the next. This is necessary to avoid any build-up of space-charge at the interfaces between polymer layers. The first example of this type of LED consisted of an ITO/MEH-PPV/PPV/copolymer **24**/Ca device.[81] When one polymer is coated on top of another polymer layer, it is important that the process does not cause swelling or dissolution of the already deposited layer, and that good quality interfaces are obtained. Since



PPV and the sulfonium copolymer precursors are insoluble in chloroform, and MEH-PPV is insoluble in methanol, such a multilayer structure could be produced by spin-coating successive layers onto ITO without intermixing between MEH-PPV and the precursor layers. The precursor polymers **5** and **23** were then converted into the conjugated polymers and, after deposition of calcium, the device emitted orange light with the emission spectrum stretching from 800 nm (1.55 eV) through to 490 nm (2.5 eV). It was therefore concluded that electroluminescence occurred from both the red-light-emitting MEH-PPV, which was furthest away from the cathode, and from PPV, which showed yellow-green EL. The broadening of the emission spectrum further suggested how, in principle, to fabricate a white light source from a sandwich of several EL layers. A more recent multilayer device design developed by Yoshino et al.[145–147] uses layers of the blue-emitting polymer **75a** and of red-emitting materials such as the poly(3-alkylthiophene) **49a** separated by a charge-transport layer. Depending on the bias either red or blue light is emitted, while under alternating current bias emission from both materials is observed.

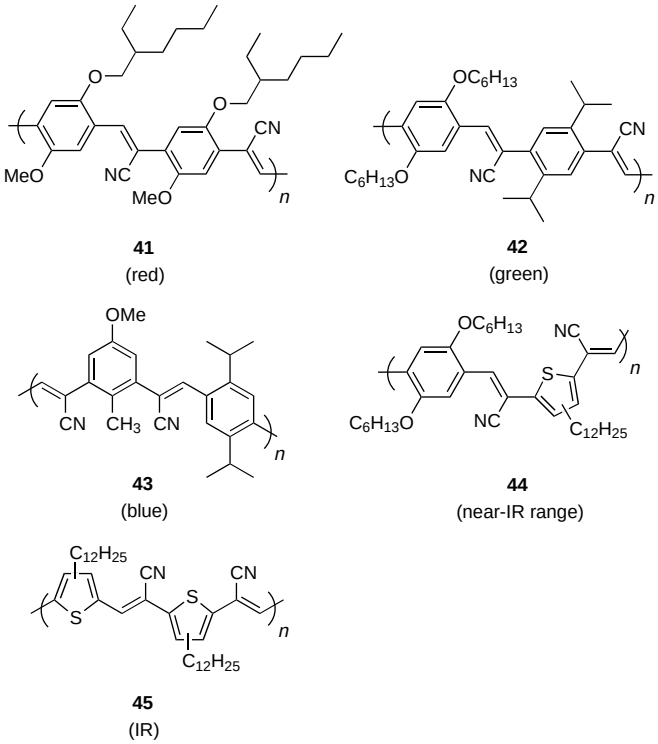
4. Polymers with Higher Electron Affinity—Luminescent Transport Layers

The ideal light-emitting polymer should be both fluorescent and avoid the need for an extra electron-transporting material. It should also function with cathode metals other than calcium. Calculations[148] have shown that a cyano substituent (and presumably other electron-withdrawing groups) on the ring or vinylene moiety of PPV lowers the HOMO and LUMO energies and increases the electron affinity of the polymer, thus improving the efficiency of electron injection and the potential efficiency of a polymer LED. Unfortunately, the Wessling (quinodimethane) route to poly(arylene vinylene)s is unsatisfactory when electron-withdrawing substituents are involved, and alternative polymerization or polycondensation methods need to be employed.

4.1. CN-PPV—Highly Luminescent Electron-Deficient Polymers

CN-PPV (**40**), a dialkoxy-substituted PPV derivative with cyano-groups on the vinylene units should be regarded as an alternating copolymer in this context. It is readily available by a Knoevenagel condensation[149] between equimolar amounts of the terephthaldehyde **38** and the benzene-1,4-diacetonitrile derivative **39**, both obtained from the same starting material **37**. The condensation reaction takes place upon addition of excess tetrabutylammonium hydroxide (or potassium *tert*-butoxide) in a tetrahydrofuran/*tert*-butanol mixture at 50 °C (Scheme 12).[150] Polymer **40** precipitates and can be easily isolated. Careful control of reaction conditions is required to avoid Michael additions (and consequently crosslinking), which may lead to polymers with inferior EL properties, and purification by reprecipitation is essential to obtain high quality polymer. CN-PPV is a brilliant

Scheme 12. Synthesis of CN-PPV (**40**): a) NaOAc; b) KOH, EtOH; c) pyridinium chlorochromate; d) NaCN; e) KO*t*Bu or Bu_4NOH, *t*BuOH, THF, 50 °C.



red, fluorescent material with a molar mass typical for polycondensates.

The HOMO–LUMO gap of CN-PPV (590 nm; 2.1 eV) is mainly determined by the effect of the alkoxy substituents, which also serve to promote solubility in chloroform, and thus ensure processibility of the conjugated polymer; the cyano substituents contribute only to an increase in the electron affinity of the polymer compared with PPV. Cyclic voltammetry studies show that the cyano groups shift the onset of reduction by about 0.6 V.[136] The low HOMO–LUMO gap of CN-PPV also indicates that the nitrile groups do not introduce any significant steric torsion in the conjugated poly(2,5-dialkoxyphenylene vinylene) chain.

Internal efficiencies of red-emitting ITO/CN-PPV/cathode devices can reach 0.2 % with calcium as well as aluminum cathodes. This is particularly noteworthy because other conjugated polymers such as PPV suffer from at least a tenfold reduction in efficiency when the electron-injecting contact is changed from Ca to Al. Since CN-PPV shows much higher electron affinity than PPV owing to the introduction of cyano groups, the device efficiency is now determined by hole injection at the ITO electrode. As a result of this, the introduction of a hole-transporting layer improves EL efficiencies considerably. PPV is a suitable hole-transporting polymer, and CN-PPV can be easily spin-coated on top of an insoluble PPV layer. Two-layer electroluminescent ITO/PPV/CN-PPV/cathode metal devices operate with very high internal (4 %) efficiencies.[151, 152] Significant lifetimes were only observed with high-quality polymer, demonstrating once more the importance of purification. The emission (λ_{max} =

710 nm) occurs exclusively from the lower energy CN-PPV, with no evidence of electroluminescence from the PPV layer. Although this appears to be in contrast to the multilayer devices discussed in Section 3.3, CN-PPV apparently acts more like a sink for charge carriers and excited states rather than to permit any emission from another EL polymer (namely PPV) to occur.

The synthetic route is extremely flexible and lends itself to considerable variation, enabling the synthesis of many other α-cyano PPV derivatives (Scheme 13).[123, 153] Some of these

Scheme 13. Color range available for CN-PPV derivatives.

show similarly high emission efficiencies in double-layer devices with PPV.[12, 154] In particular, MEH-CN-PPV (**41**) is processible in solvents such as toluene and exhibits very high EL device efficiencies. The improvement in processibility clearly contributes significantly to the improved device efficiency. A double layer device ITO/PPV/**41**/Al produces red-orange (600 nm) light with a power efficiency of 5 cd A^{-1} corresponding to a luminous intensity of over 1000 cd m^{-2} at a drive voltage of 6 V.[12, 154] This corresponds to a luminous efficiency of 2.5 lm W^{-1}.

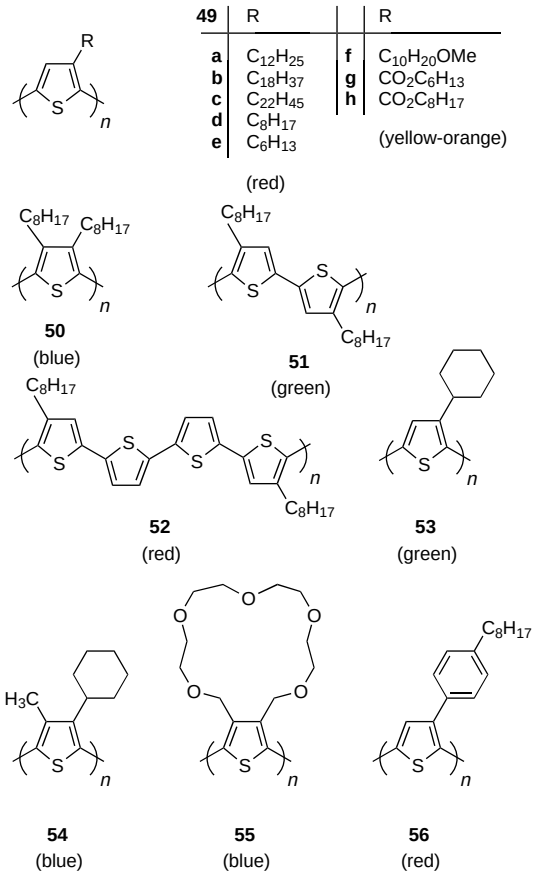
Color variations over a wide range of wavelengths have been demonstrated. The bulky isopropyl substituents of **42** cause a blue-shift and green light emission (510 nm), while incorporation of *meta*-linkages, as exemplified by those in **43**, results in blue fluorescence. The thiophene group in **44** reduces the HOMO – LUMO energy gap to 1.75 eV (740 nm), and the polymer shows substantial emission in the near infrared region. An ITO/PPV/**44**/Al device was the first polymer-based IR-emitting LED.[155] Replacement of both arylene rings with thiophene groups in **45** reduces the energy gap even further to 1.56 eV (800 nm).[153, 156]

4.2. Other High-Electron-Affinity PPV Derivatives—Electron-Deficient Building Blocks

Apart from CN-PPV, other PPV derivatives with electron-withdrawing substituents, this time on the arylene ring, have been investigated for EL applications (Scheme 14). Poly-

46 (X=Cl) **47** (X=Br) (red) **48** (yellow-orange)

Scheme 14. High-electron-affinity PPV derivatives with electron-withdrawing groups on the aromatic ring.



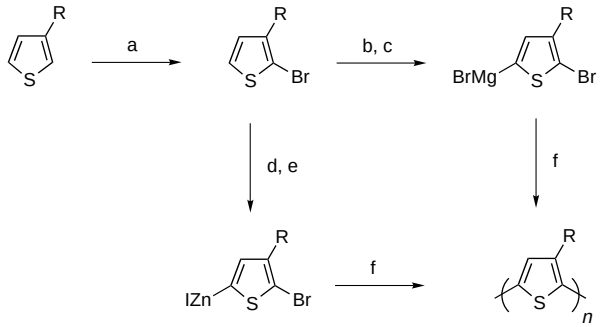
(phenylene vinylene)s **46** and **47** bearing halide and alkoxy groups on the ring are accessible through the Wessling method.[157] High molar masses required rigorous purification of the monomers and optimization of the polymerization conditions. We have found that PPV derivatives with bromo (**47**)[158] or trifluoromethyl (**48**) substituents[159, 160] can be readily obtained by a bromo-precursor route (see Scheme 5) or by Horner – Wittig polycondensation.[159] Polymer **48** in particular shows higher electron affinities than PPV. The halogen-substituted PPVs **46** and **47** were found to emit red ($\lambda_{max} = 620 - 630$ nm) light,[157] while the trifluoromethyl derivative **48** emits yellow to yellow-orange ($\lambda_{max} = 540 - 570$ nm) light. The PL quantum yields for **48** are much lower than for PPV and single-layer devices gave only weak emission, and EL internal efficiencies reached 0.01 % in double-layer devices with PPV as hole-injecting layer and Al as cathode.[160, 161] In view of their poor PL quantum yields these materials are more likely to prove useful as ECHB than as emissive materials.

5. Color Tuning—Varying the HOMO – LUMO Gap

A major advantage of polymers as EL materials is the ease with which their structures can be altered, thus enabling the chemist to tune the properties by modifying their structures. In this section we wish to illustrate both the wide range of polymer structures, which can be used for EL purposes, and also to show how the properties, especially the emission color, can be adjusted by varying the aromatic ring, the substituents, and the regioregularity of the conjugated polymer.

5.1. Poly(3-alkylthiophene)s—A Good Red

Poly(3-alkylthiophene)s provide a good example of how the color of emission can be varied in polymer LEDs by modifying both the polymer structure and the design of the devices (Scheme 15). Soluble poly(3-alkylthiophene)s **49** are readily prepared by the polymerization of the corresponding



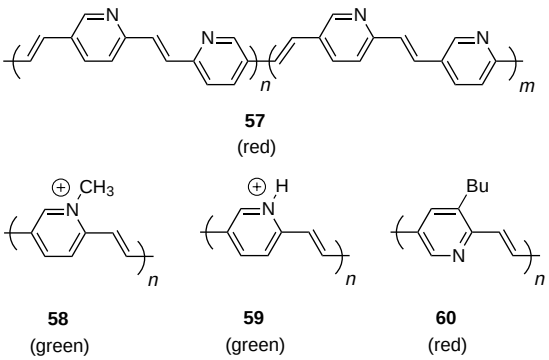
Scheme 15. Poly(alkylthiophene) derivatives and their emission color range.

3-alkylthiophene monomers in the presence of excess ferric chloride,[162] or by nickel-catalyzed coupling of dihalothiophenes with thiophene-bis(magnesium halide)s.[163, 164] Red electroluminescence (emission maxima at about 640 nm) from **49a–e**, which have alkyl chain lengths varying from 6 to 22 carbon atoms, has been reported by various groups.[165–169] The emission intensity became larger with increasing chain length, possibly owing to the improved confinement of excitons. Homopolymers based on 3-alkylthiophenes exhibit good red color purity, but they tend to have rather low fluorescence quantum yields. The use of charge carrier confinement layers[166] or doping with fluorescent dye materials[170] markedly increases device efficiency. Substitution of the hydrocarbon side chains as in **49f–h**[171, 172] produced a slight blue shift in the emission maximum and gave yellow-orange emission.

The emission frequency depends considerably on the nature and regularity of the side chains on the polymers. Hadziioannou et al.[173] studied alkylated polythiophenes **50**–**52** and reported that there was a correlation between their emission maximum and the inverse number of thiophenes between two consecutive head-to-head (2,2′-coupled) dyads. Thus the polymer **50** showed an emission maximum at 460 nm (2.7 eV), while **51** and **52** had emission maxima at 530 (2.35 eV) and 550 nm (2.25 eV), respectively. Similarly, the emission maximum for Holdcroft and Xu's[174, 175] poly(3-hexylthiophene) (**49e**) was blue-shifted with increasing amounts of head-to-head dyads. Similar blue shifts can be obtained by introducing bulky substituents; the cyclohexyl substituted polythiophene **53** has its emission maximum in the green (555 nm).[176–178] Blue emission can be obtained by substitution at both the 3- and 4-positions as in **54** (460 nm)[177–179] or **55** (470 nm).[180] Bilayer devices containing the 4-octylphenyl-substituted poly[α,α'-bithienyl] analogue of **56** and a thick layer of PBD **28** emit white light due to the simultaneous emission of three colors.[181] The red and green emission can be suppressed in favor of near ultraviolet emission (397 nm) for a device using a blend of the polythiophene **56** and **28** with a further layer of **28** as emissive material.[134] The blue shifts can be attributed to the twisting of the conjugated backbone out of coplanarity due to the bulky substituents.

Greater control of emission colors requires the ability to control polymer regioregularity. When thiophenes are polymerized with ferric chloride or by Grignard coupling reactions, the resulting polymers are regiorandom, with a preponderance of head-to-tail (2,5′-) coupling, varying from 52 to 80 % according to the method used.[164] Some control can be obtained in specific cases. For example, coupling of oligomeric alkylthiophenes results in regioregular copolymers,[173, 182] while polymerization of a 3-arylthiophene with ferric chloride under carefully controlled conditions can give high-molecular-weight, regioregular (94 % head-to-tail) polymers such as **56**[183] because the aryl group preferentially stabilizes the cationic charge in the intermediates at the 2-position. More general routes for the synthesis of regioregular (head-to-tail) poly(3-alkylthiophene)s have been developed by McCullough et al.[184–187] and Rieke et al.,[188, 189] who utilized nickel-catalyzed coupling of 2-halo-5-metallothiophenes (Scheme 16). These routes require extremely pure monomers for high molecular weights to be produced.

Scheme 16. Routes to regioregular poly(3-alkylthiophene)s: a) Br_2, HOAc, 15 °C; b) LiN*i*Pr$_2$, −40 °C; c) $MgBr_2$, diethyl ether, −40 °C; d) I_2, HNO_3, CH_2Cl_2; e) Rieke zinc; f) $[Ni(Ph_2PCH_2CH_2PPh_2)]Cl_2$ or $[Ni\{Ph_2PCH_2CH(CH_3)PPh_2\}]Cl_2$.



High regioregularity and a minimum amount of head-to-head dyads greatly influence the color of emission, and it is no surprise that the UV/Vis absorption spectrum of regioregular poly(3-hexylthiophene) (**49e**) indicates a longer conjugation length than observed for the corresponding regiorandom material.[190] McCullough et al. found that regioregular **49e** also showed a higher EL quantum efficiency than its regiorandom counterpart.[191] Comparison of regioregular

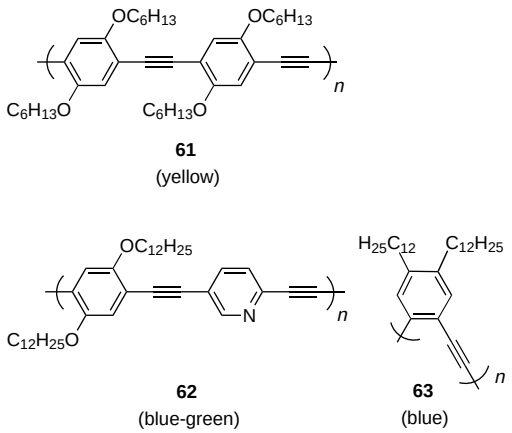
and regiorandom **49a** and **49e** prepared by us, however, showed no significant differences in their emission spectra or efficiencies.[192, 193]

The emissive properties of regioregular statistical copolymers can be tuned by varying the length of the alkyl side chain and the relative ratios of the organometallic monomers.[186, 194] We have also prepared poly(3-alkylthiophene) copolymers with side chains containing terminal azide groups which have enabled us to cross-link the deposited films so as to produce insoluble materials for use in multilayer devices.[195] Polarized emission from stretch-oriented polythiophenes has been observed.[196] An oriented film of poly[3-(10-methoxydecyl)thiophene] (**49f**) has been deposited by Langmuir–Blodgett techniques and shown to emit polarized electroluminescence.[197]

5.2. Electron-Deficient Aromatic Rings

Color control by alteration of substituents and regioregularity is also illustrated by the pyridine-based analogue **57** of PPV and its derivatives (Scheme 17). Stille coupling of 2,5-

Scheme 17. Pyridine-based analogues of PPV.



dibromopyridine and 1,2-bis(tributylstannyl)ethylene [198] gives **57** as an orange powder that is soluble in *m*-cresol. Alkylation and protonation furnish the N-alkylated **58** and N-protonated **59** derivatives, respectively. Both are soluble in chloroform although **58** tends to decompose in the presence of nucleophiles. Coupling of 3-butyl-2,5-dibromopyridine gives the substituted polymer **60**,[199, 200] which is soluble in conventional organic solvents.

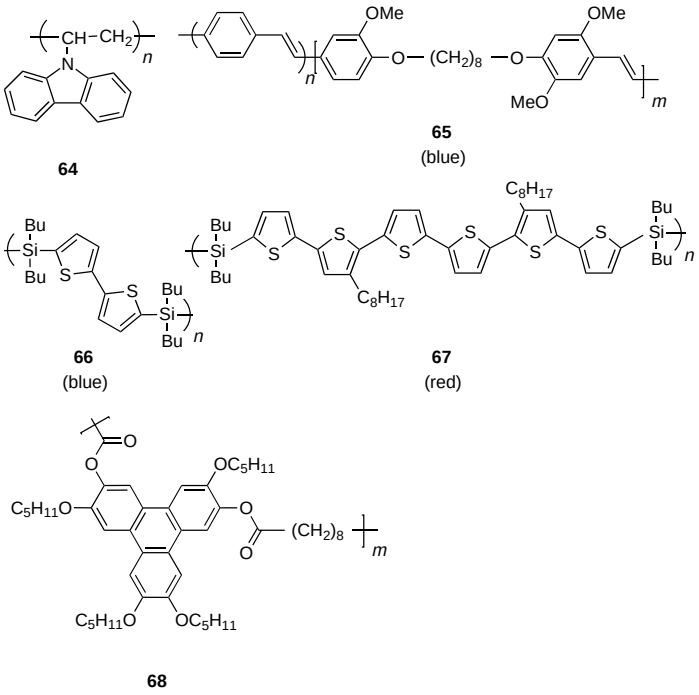
The parent polymer **57** has a PL maximum in the red region (590 nm). The C-alkylated polymers **60** exhibit a red-shift to 630 nm, whereas a blue-shift to 540 nm is seen for the N-alkylated polymer **58**. Protonated polymer **59** has a more complex spectrum with emission maxima at 535 and 570 nm.

Owing to the lower symmetry of the pyridine ring, polymer **57** can exist in three regioisomeric forms: head-to-tail, head-to-head, and random. Swager et al.[201] have prepared the regioregular head-to-tail and head-to-head polymers and found that the three isomers show different UV/Vis absorption, PL, and EL emission spectra, with EL emission maxima of 575 nm (random), 584 nm (head-to-tail) and 605 nm (head-to-head).[202]

5.3. Poly(phenylene ethynylene)s—Stiffening the Polymer Chain

LEDs based on poly(phenylene ethynylene)s such as **61** (the dehydro-analogues of PPVs) are typically prepared by Sonogashira coupling of diethynylbenzenes and dihalobenzenes (Scheme 18).[203, 204] The synthesis and properties of poly-

Scheme 18. Examples of poly(phenylene ethynylene)s.



(arylene ethynylene)s have recently been reviewed by Giesa.[205] Poly(phenylene ethynylene) **61** shows yellow emission with maxima around 600 nm,[203, 206, 207] whereas the corresponding dialkoxy-PPVs give rise to red or red-orange emission. Incorporation of a 2,5-pyridinediyl unit (**62**) gives a blue-shift and blue-green emission ($\lambda_{max} = 480$ nm).[208] Blue (410 nm) emission is obtained from poly(3,4-dialkyl-1,6-phenylene ethynylene)s **63**,[209] prepared by palladium cross-coupling reaction of a 3,4-dialkyl-1,6-diiodobenzene and a 3,4-dialkyl-1,6-diethynylbenzene. Steric interactions may cause twisting of the polymer chain which reduces the effective conjugation length, but other factors also probably contribute to the overall emission characteristics. The poly(phenylene ethynylene)s have received some attention in the patent literature, but have been generally rather disappointing in EL applications.

5.4. Polymers with Isolated Chromophores—The Best of Both Worlds?

An alternative approach to designing a polymeric EL material is to blend a fluorescent dye in an inert polymer matrix such as polystyrene. Unfortunately, such blends often do not electroluminesce because the volume fraction of the electroactive species is too low. However, if an electroactive polymer such as poly(vinyl carbazole) (PVK) **64** is included, blends with tiny amounts of luminescent material can yield quite bright electroluminescent devices. An extension of this concept is to link the luminescent chromophore covalently to a polymer.

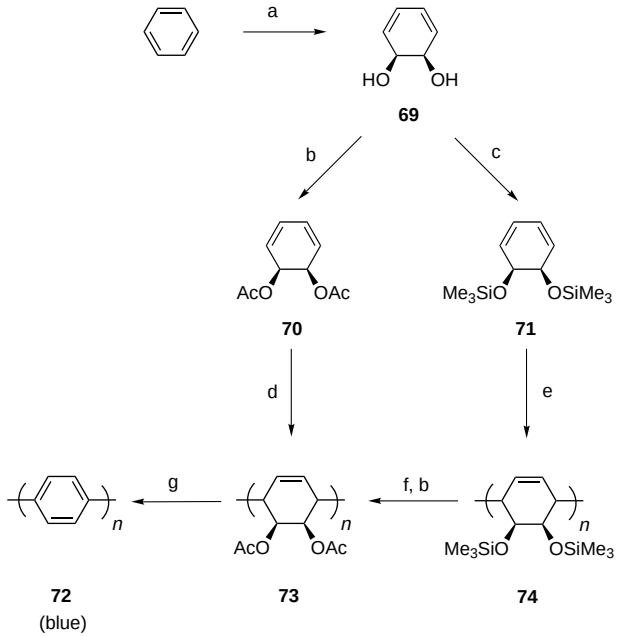
In polymers with isolated chromophores, the color is determined by altering the conjugation length of the chromophore. For example, Klavetter et al.[210] has prepared copolymers of type **65** by Wittig condensation using varying amounts of a flexible-chain dialdehyde and a bis-ylide

(Scheme 19). The emission peak of **65** ranges from 2.75 eV (460 nm) (blue) to 2.25 eV (550 nm) (yellow-green) depending on the amount of flexible linker content. Thus, the emission color can be easily altered by simply changing the comonomer feed ratio.

Scheme 19. Examples of polymers with isolated chromophores.

Hadziioannou et al. have prepared oligothiophene-dibutylsilane copolymers such as **66** or **67**[211–214] whose emission maxima range from blue (415 nm) for **66** to red (612 nm) for **67** according to the number of thiophene and silane units. The red-shift produced by increasing the number of silane units is slight and the emission color is mainly determined by the number of thiophene units. At present the advantages of the embedded chromophore polymers over the more traditional fully conjugated materials remain to be demonstrated.

Polymers that have special features of processibility in addition to high luminescent properties are particularly attractive. Much can be expected from improving supramolecular order. The recent work of Ringsdorf, Haarer et al. on discotic columnar phases involving triphenylene stacks shows much promise.[215] For example, the liquid-crystalline polymer **68** incorporating these structural features had a particular tendency to orient parallel to the film surface. Perhaps not surprisingly, this material showed steep current–voltage curves, low threshold fields, and high charge carrier mobilities.[216, 217]



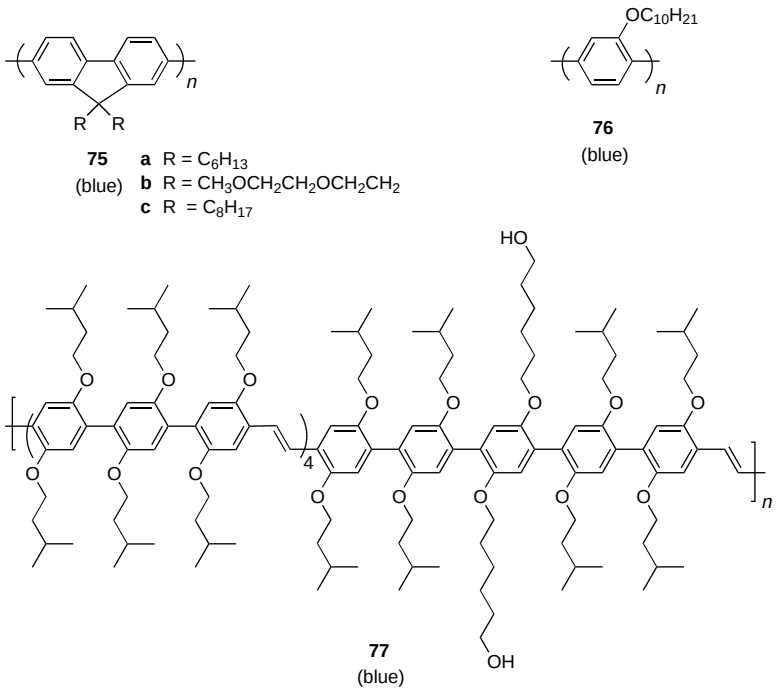
6. Blue Light-Emitting Polymers—The "Holy Grail"

The preceding sections outlined how a wide variety of conjugated electroluminescent polymers gives access to a whole range of emission colors. Multicolor display applications require at least three basic colors: red, green, and blue. Blue EL—already difficult to achieve with inorganic semiconductors—has been sought in conjugated polymers having a high HOMO–LUMO energy gap, and in copolymers containing high HOMO–LUMO, short conjugated segments. The search for a stable, highly efficient, bright blue light-emitting polymer continues. The following milestones have been passed.

6.1. Poly(*para*-phenylene)s—The Blue Paradigm

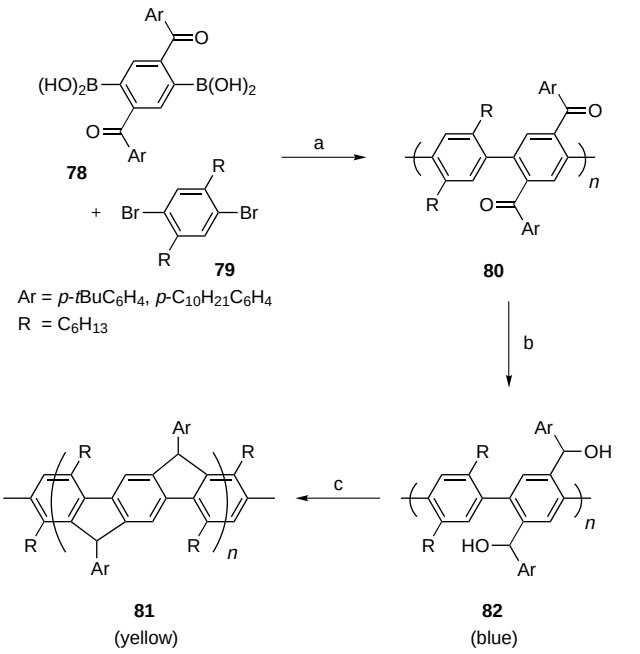
The design of blue-emitting electroluminescent polymers based on PPV-type materials with interrupted conjugation (Section 3.1) suffers from the drawback that emission occurs usually from the more conjugated segments, and the emission spectrum is therefore broadened and red-shifted. The alternative use of short, defined PPV oligomers will be discussed in succeeding sections (6.2 and 6.3). High HOMO–LUMO gap polymers are required for blue light emission. The first blue-emitting ($\lambda_{max} = 470$ nm) polymer LED was made by Yoshino et al.[218] using poly(9,9-dihexylfluorene) (**75a**) by oxidative coupling of the fluorene monomer with ferric chloride.[219, 220] This material has a poly(*para*-phenylene) (PPP) backbone, and derivatives of PPP **72** have been the focus of much research into the development of blue-emitting polymers. Higher polyarylenes have been little studied, possibly owing to the difficulties associated with their synthesis.

Leising et al.[221, 222] were the first to describe the use of PPP **72** as a blue light emitter [$\lambda_{max} = 459$ nm (2.7 eV)]. Like PPV, unsubstituted PPP is insoluble and not processible. Although films of oligomeric (9–10mer) poly(phenylene)s can be obtained by vacuum deposition,[223] the preparation of the polymer again requires suitable precursor routes (a topic recently reviewed by Gin and Conticello[224]). The original synthesis of unsubstituted PPP employs the ICI route based on *cis*-1,2-cyclohexadienediol (**69**) as starting material (Scheme 20).



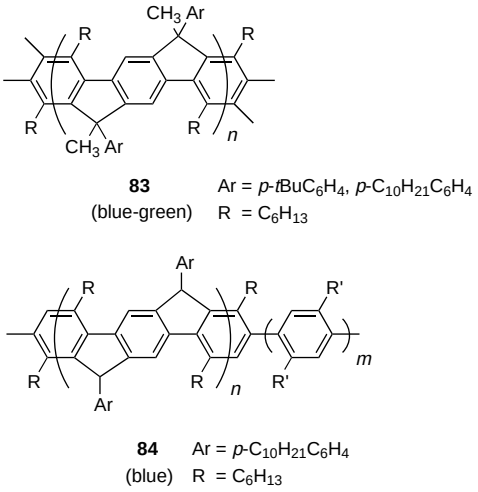
Scheme 20. Precursor routes to PPP (**72**): a) *Pseudomonas putida*; b) Ac_2O, pyridine; c) Me_3SiCl, DMAP, pyridine; d) azoisobutyronitrile AIBN, 70 °C; e) bis[(η^3-allyl)(trifluoroacetato)nickel(II)]; f) Bu_4NF, MeOH; g) 310–340 °C, Ar.

Radical-initiated polymerization of diacetate **70** furnishes the PPP precursor polymer **73**, which suffers from lack of stereoregularity and contains about 15% of 1,2-linkages.[225, 226] Thermal elimination of acetic acid finally gives the conjugated polymer **72** accompanied by some oligomer formation through chain scission. A number of other diesters have been polymerized by the same method (again with 10–15% of 1,2-linkages in the polymer) and thermally converted to PPP, of which the dimethyl carbonate and dipivaloyl esters yield the polymers with the highest molar masses.[227] Regioregular PPP is accessible through a nickel-catalyzed stereoregular polymerization of **71**. Despite the regioregularity and low polydispersity of the resulting polymer **74**, there are only limited reports on the electroluminescence of PPP derived from it.



Much interest concentrates also on solution-processible poly(*para*-phenylene)s made soluble by suitable alkyl, aryl, alkoxy, or perfluoroalkyl[228] solubilizing groups. PPP derivatives with solubilizing alkyl side chains are the most important, and these are available through transition-metal-catalyzed polycondensations (reviewed by Schlüter and Wegner[229]), especially the Suzuki coupling of arylboronic acids and bromoarenes (optimized by Wegner et al.[230–232]), and the nickel-catalyzed coupling of substituted dihalobenzenes (reviewed by Yamamoto[233]), hydroquinone bistriflates,[234] or bis(mesylates).[235, 236] Although the degree of polymerization is usually rather limited, the molar masses of the polycondensates are sufficiently high (above 10000 g mol^{-1}) to form robust films for EL applications by spin-coating from solution. Various groups have used the resulting polymeric materials to make blue-emitting LEDs.[105, 237–242] The best devices so far reported have used the decyloxy derivative **76** (Scheme 21). External efficiencies of up to 3% have been achieved for double layer devices ITO/PVK/**76**/Ca, and of 0.8% with other, more air-stable, metal cathodes.[240] Polarized emission has been obtained from a device using an oriented Langmuir–Blodgett film of a dialkoxy PPP derivative.[105] Internal efficiencies of 4% have been measured for blue-emitting (460 nm) devices using the copolymer **77**, containing alternating terphenylene vinylene and quinquephenylene vinylene units, with calcium electrodes.[243]

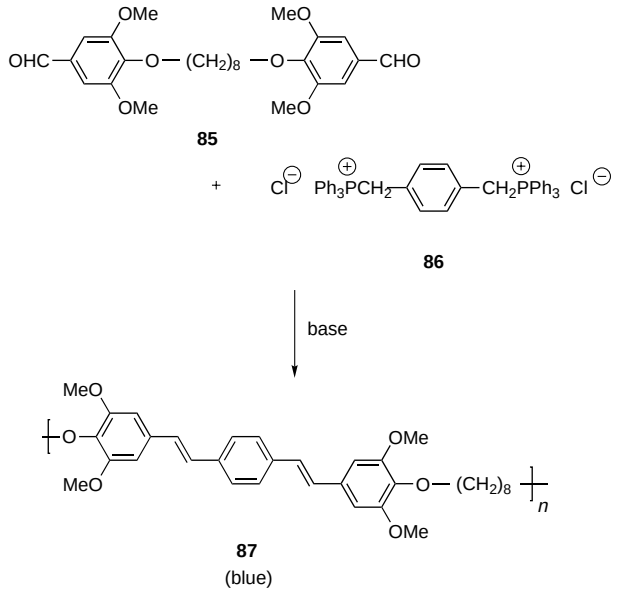
The inclusion of solubilizing side groups on the PPP backbone has the drawback that the additional substituents twist the substituted phenylene rings considerably out of plane. This drastically decreases the interaction of the aromatic π-electron system, and an unwanted additional blue-shift in the emission spectrum compared with that for PPP is usually accompanied by a drop in fluorescence quantum yield. The twist cannot occur if the PPP backbone is planarized by incorporation into a ladder polymer. Scherf and Müllen were the first to show that structurally regular ladder-type polymers can be derived from a two-step route in which a soluble poly(*para*-phenylene) is prepared by a Suzuki aryl–aryl coupling of monomers **78** and **79**. After reduction of **80**, the resulting precursor polymer **82** is then subjected to another polymer-analogous intramolecular Friedel–Crafts ring-closing reaction to give **81**. The ladder formation occurs with surprisingly high regularity, and no indications of defects such as cross-linking or incomplete cyclization were found (Scheme 22).[244, 245] Molar masses of the structurally well-defined, soluble, ladder-type poly(para-phenylene)s (LPPPs) **81** are typically up to 20000 g mol^{-1}. The phenylene rings in the ladder polymers are almost planar and the homopolymer shows a broad emission between 650 and 450 nm in the solid state, in contrast to the polymer's sharp fluorescence emission around 450 nm in solution. The large Stokes shift (leading to yellow instead of blue light emission) is especially enhanced after annealing, and has been attributed to the formation of excimers owing to interchain interactions and π-stacking between the planarized conjugated segments.[246–249]



In some cases, blue emission has been observed from LPPP films but it remained unstable over time, again a result of the formation of yellow-emitting aggregates.[248] Slight structural variations have been suggested to inhibit the aggregation of planarized ladder-PPPs. After introduction of a methyl group at the methine bridge, the resulting ladder polymer **83**[250] shows stable blue-green emission with external efficiencies of up to 4% (Scheme 23).[251–253] Even more productive are random interruptions in the conjugated chain. In statistical copolymers **84**, called "step-ladder" copolymers, the conjugated chain is disrupted because the LPPP segments are connected by twisted oligophenylene spacers. These copolymers give stable films which remain blue-emitting even after annealing.[248] Pure blue emission with 0.1% internal efficiency can also be accomplished by diluting the ladder homopolymer (1–10 weight%) in a poly(vinylcarbazole) **64** hole-transporting poly-

Scheme 21. Examples of soluble PPP derivatives.

Scheme 22. Synthesis of ladder-PPP (**81**): a) $[Pd(PPh_3)_4]$; b) $LiAlH_4$; c) BF_3.

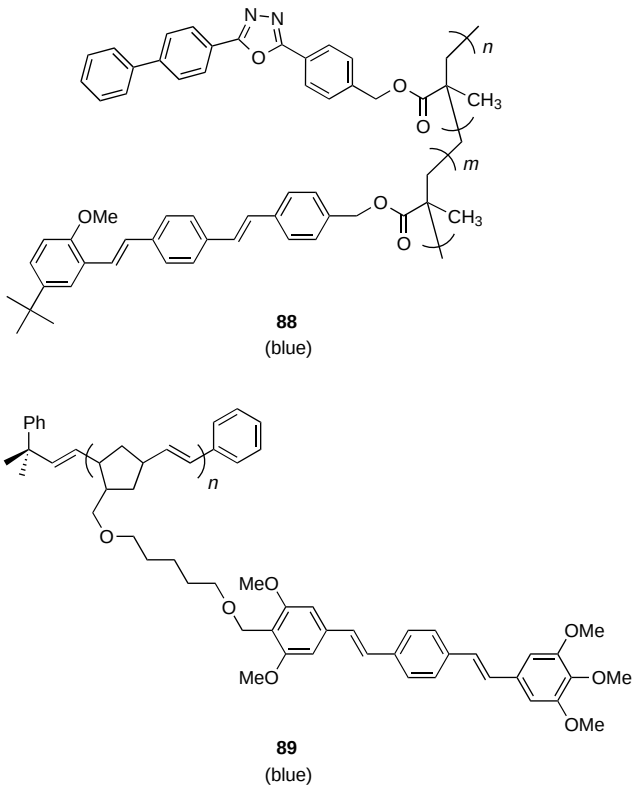


Scheme 23. Examples of blue-emitting, ladder-type PPP derivatives.

mer matrix.[254] This presumably inhibits aggregation. The above-mentioned poly(9,9-dihexylfluorene) (**75a**)[168, 218, 255] has a structure halfway between PPP and LPPP. A similar derivative BDOH-PF (**75b**) has been prepared by Pei and Yang.[256] Very little lifetime data is available for these materials as their development is in its infancy. However, the polyfluorene derivative **75c** has shown considerable promise in a number of applications.[257]

6.2. Polymers with Isolated Main-Chain Chromophores—Polycondensates by Wittig Reaction

Since the wavelength of the emitted light is dependent on the conjugation length of the chromophore, lowering this length will result in a blue-shift in the emission. One way to achieve a blue-emitting polymer, therefore, is to interrupt the conjugation of the polymer at short intervals with nonconjugated segments in between. As was discussed in Section 3.1 above, simple modification of the PPV synthesis gives access to PPV-derived blue light-emitting polymers with a high concentration of a fluorescent chromophore and, at the same time, with a statistical range of short conjugation lengths (see Scheme 8). This method, however, only allows limited control of the conjugation length. Another way to polymers with well-defined fluorescent π-electron systems makes use of a Wittig condensation of an arylene bisphosphonium salt **86** with a bisbenzaldehyde **85** already containing a spacer unit (Scheme 24). This has been used, for example, to make

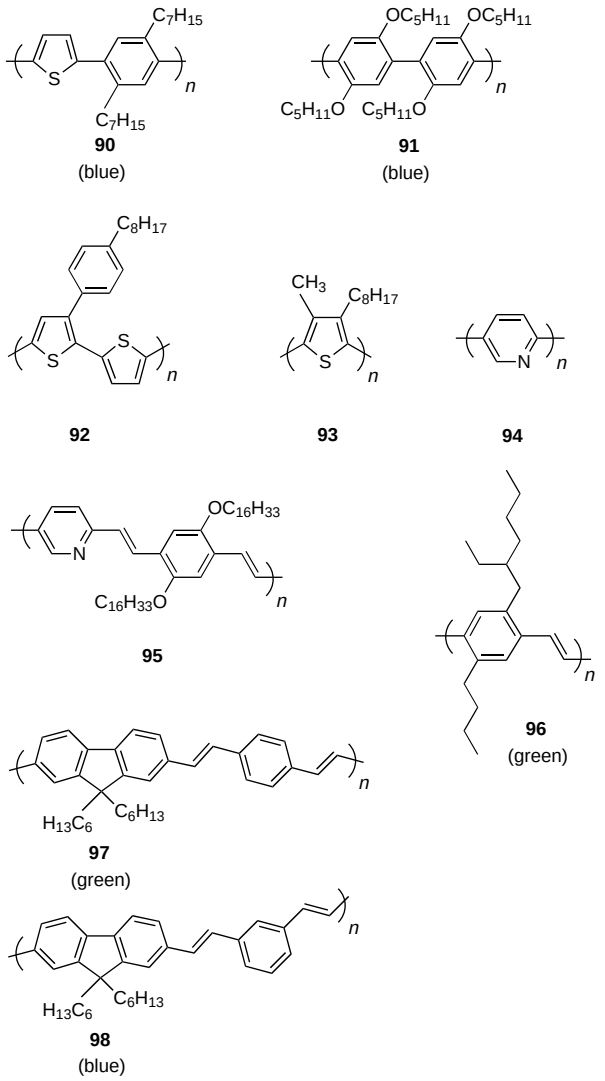


Scheme 24. Synthesis of a blue-emitting copolymers with isolated chromophore by Wittig reaction.

polycondensate **87** in which the oligomeric PPV segments are separated by flexible polymethylene spacers.[258–262] Such polyethers give blue or blue-green emission ($\lambda_{max} = 470-495$ nm).

6.3. Polymers with Conjugated Side-Chain Chromophores—"Comb" Lumophores

Another approach towards polymers with well-defined chromophores is based on polymers with luminescent conjugated side chains. As the backbone can now be any nonconjugated "standard" polymer, this enables, in principle, utilization of the considerable body of expertise developed in classical polymer synthesis to adjust the physical properties of the polymer. Our own efforts have concentrated on polymethacrylates such as the copolymers **88** bearing diaryloxadiazole charge-transporting and distyrylbenzene emissive units as side chains (Scheme 25).[74, 136, 141] Bilayer devices with **88** as emissive layer and PPV as hole-transport layer showed blue emission ($\lambda_{max} = 457$ nm) (with a tail in the yellow-green region, owing to emission from PPV, and an efficiency of 0.037 %). The polymers **88** unfortunately were not very stable,



Scheme 25. Examples of electroluminescent polymers with side-chain chromophores.

degrading on storage, photoexcitation, and particularly during device operation. Significant improvements can be obtained by cross-linking.[143]

Schrock et al.[263] have used ROMP on a norbornene monomer with a side chain distyrylbenzene chromophore attached to produce polymer **89**, which shows blue ($\lambda_{max} =$ 475 nm) electroluminescence with 0.3% internal efficiency and a turn-on voltage of 12 V when calcium was the cathode. The efficiency increased to 0.55% for a blend of **89** and an oxadiazole electron-transporting material although the turn-on voltage was also raised considerably.

7. Blends and Combinations of Polymers with Other Materials—A Potpourri of Electroluminescent Materials

Improvements in electroluminescence efficiencies have been made by blending conjugated polymers. For example, Nishino et al.[264] found that blending the red-emitting polymers MEH-PPV (**14**) and poly(3-hexylthiophene) (**49e**) gave an initial increase in LED external efficiency up to a maximum of 1.7% (with a calcium cathode and 1 weight% of **49e**), which is twice the efficiency of a device made from pure MEH-PPV and three orders of magnitude higher than for pure **49e**. The emission spectra showed that the emitted light came from both polymers. Similarly, Salaneck et al.[265] have found that blue (2.6 eV, 490 nm) emission from the alternating copolymer **90**[266] was enhanced by blending it with the soluble PPP copolymer **91** (Scheme 26). A ratio of 1:9 for

Scheme 26. Examples of polymers used as blends, in SCALE and in other devices.

90:**91** produced the highest external quantum efficiency (1.9%) with a peak emission at 474 nm at a bias field of 6×10^7 V m^{-1}. Polymer **91** (460, 400 nm) as a single-layer ITO/**91**/Ca device emits two peaks at a bias field of 6×10^7 V m^{-1} and current density of 0.2 mA mm^{-2}.

Even greater enhancements in emission efficiency arise from blending conjugated polymers with partially conjugated polymers. Shim et al.[267, 268] found that blends of MEH-PPV (**14**) and a blue-emitting copolymer [similar to] **87** showed emission largely from **14**. The emission maximum was blue-shifted by 20–40 nm from that of MEH-PPV. The best efficiency (Al cathode, **87**:**14** = 15:1) was nearly 500 times greater than that for a device made from pure MEH-PPV. As blending of MEH-PPV with insulating polymers, for example polystyrene, enhances emission efficiency by a factor of less than 10, dilution effects clearly play only a minor part in the enhancement observed. The higher efficiency of the blend is therefore attributed to the charge-transporting properties of copolymer **87** leading to confinement of charge on MEH-PPV. Promising results with blends of the closely related polymers **97** and **98** offer opportunities for stable blue devices.[269]

Inganäs et al. have shown that blends of polymers with different emission colors are suitable for devices with variable-color, even white light emission. A blend of the polymers **53**, **54**, **56**, and **92** was used to construct a device in which emission can be tuned from red to green by controlling the applied voltage.[177, 178, 270] A similar blend of polymers **53**, **56**, and **93** in PMMA emits white light.[271] The PMMA acts as an insulating matrix and reduces the degree of exciton transfer between the polymers. Another approach employs a blend of a tristyrylamine in various host polymers such as the polyester Durel, polynorbornene, and poly(vinyl pyridine). The emission of the chromophore depends in this case strongly on the matrix.[216]

Devices can be constructed by using combinations of conjugated polymers and nonpolymeric materials. Yoshino et al.[272, 273] have shown that a device containing a mixture of red-orange-emitting **20b** and the green-emitting fluorescent dye tris(8-hydroxyquinolatino)aluminum produces a voltage-dependent variable emission of orange to green light. Blending of polythiophene **49e** with fluorescent dyes has been found to enhance the EL intensity at constant voltage by a factor of up to 70 with an increase in efficiency at constant luminance of up to 20-fold.[132, 274] With an oxadiazole dye as dopant, the emission color changed from red-orange to white when the voltage was increased.

8. Recent Advances

8.1. Degradation—Oxygen and Water
