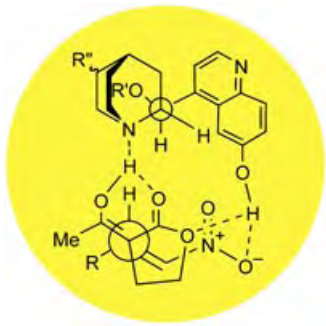
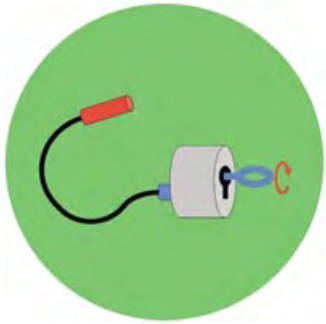
Cover Picture



Lei Wang and Peter G. Schultz*



Unnatural amino acids can be incorporated as new building blocks into the genetic codes of both prokaryotic and eukaryotic organisms to facilitate studies of protein structure and function. Over 30 unnatural amino acids with modified side chains have been genetically encoded in response to unique triplet and quadruplet codons. L. Wang and P. G. Schultz describe in their Review on page 34 ff. chemical and biochemical approaches that have been developed to manipulate protein structure and add new amino acids to the genetic code.

Metallocenes
R. E. Mulvey and co-workers report the selective deprotonation of one benzene ring of bis(benzene)chromium by amide bases with Na^{+}/Mg^{2+} or K^{+}/Mg^{2+} as counter ions in their Communication on page 68 ff. No reaction takes place with the monometallic amides.

Asymmetric Catalysis
In their Communication on page 105 ff., L. Deng and co-workers describe the use of chiral organocatalysts for the diastereoselective and enantioselective formation of adjacent tertiary and quaternary stereocenters in Michael additions to nitroalkenes.

Molecular Functional Units
A molecular machine that is based on the redox-coupled exchange of guest molecules in cucurbit[8]uril complexes and functions in a similar way to a chain lock is presented by K. Kim and co-workers in their Communication on page 87 ff.

Open Access and *Angewandte Chemie*

The German Chemical Society (Gesellschaft Deutscher Chemiker, GDCh), the owner of *Angewandte Chemie*, has recently discussed open access and issued an official statement,[1] a summary of which is featured in the box on the right. But what is open access? "Open access to scientific information means the free, unrestricted, and immediate access to data and results of publicly supported scientific work." This definition was given by Robert Schlögl in issue 11/2004 of the German Chemical Society's membership magazine in his plea for open access ("Partnership instead of Monopoly").[2] A counterargument was presented in the same issue by Peter Gregory under the title "All Things to All Men".[3] Elsewhere, the motivation behind the open access movement was recently summarized as follows: "The aim of the open access initiative is to build up a comprehensive, open, and sustainable network of scientific information that supports the self-organization of scientists and the reflection of scientific knowledge in scientific discourse and that allows fair and equal conditions for competition between value-added-service providers."[4] So, free access, is it? Who would oppose such a suggestion, at least as a reflex reaction? However, one suddenly feels that one is perhaps being misled: Partnerships, free access, networking, self-organization, discourse, value-added services, and, of course, sustainability—these words from the vocabulary of the well-meaning conceal much and reveal little. Isn't free access to food, medication, and public transport an even more justifiable goal?

What are the motives behind the open access movement in which a wide spectrum of opinions are represented? The positions portrayed above[2,4] are, however, representative, and I have taken them as a starting point for my discussion as they were presented prominently in the widely read magazines of the German Chemical Society[2] and the German Physical Society.[4] It is often claimed by open access protagonists that renowned big publishers make "fat profits" from their "monopolies".[2,4] Justifiably, many scientists and librarians feel frustrated with the high prices of some, but by no means all, journals, which sometimes are even of a poor quality. However, these journals are—for understandable reasons—provided with articles by scientists (even though there may be more affordable and higher-quality options); they have respectable scientists as editors and advisors, and there are obviously enough customers/libraries who are prepared to pay the price and so contribute to the "fat profits of the big publishers". Is such indignation not hypocritical when one lives in a profit-driven society? What happens when profits are not made can be read about daily in the newspapers! And finally: The cost of all scientific publications has increased in the last two decades (only) in direct proportion to the number of published articles,[5] that is, the increase in the price of journals is only disproportionate when compared with the general cost of living, but that is comparing apples with pears.

The cost of all scientific publications has increased in the last two decades in direct proportion to the number of published articles

"Journals based on the open access model should lead to a higher quality of science and promote scientific discourse"[4] is another argument in favor of open access. One is tempted to ask: Aren't there enough forums for scientific discourse or do the current journals

Summary of a Statement by the GDCh on Open Access

Open access is an interesting and important topic in the discussions on the future of scientific publishing. However, at this point in time there are still risks, open questions, and challenges associated with this model. Further experience must be gained in open access, or indeed any other new models, before a balanced opinion can be made regarding the advantages of these approaches over the traditional processes.

The Gesellschaft Deutscher Chemiker (German Chemical Society, GDCh) will monitor future developments closely and will be open to results from discussions on this issue. The GDCh will participate actively and constructively in such discussions to ensure that any transitions in scientific publishing are carried out fairly so that the needs of all those involved are met and that business models are adopted to reflect the new electronic publishing tools.

Regardless of the open access debate, the GDCh appeals to all its members to avoid submission of their scientific papers to overpriced journals. In particular, members are encouraged to submit their manuscripts to journals that are owned or partly owned by the GDCh and whose price structures have been endorsed by the GDCh.

Of utmost importance to the GDCh and its members is that there be no loss in quality regardless of the publication concept adopted. The scientist must be confident about where he/she can find relevant information. In accordance with its statutes, the GDCh will always strive to maintain these principles.

DOI: 10.1002/anie.200462726

somehow prevent this discourse? Is there insufficient information, or are we actually drowning in it? When the secondary literature or a reference leads one to an article that one wants to read, is it really that difficult to obtain, even when the local library does not have it? Please have your own answers to these questions. Regarding the quality of science, the work is usually complete by the time it is published. Nevertheless, the publication process does, indeed, have a lot to do with the quality, and open access is a threat to the high quality journals (see below).

Open access is a threat to the high quality journals

Regarding the costs involved in open access, R. Schlögl and T. Velden have recently emphasized in the magazine of the Max Planck Society: "However, contrary to popular belief, comprehensive free access to research results is not cheaper than the current system of paper journals".[6] Paper journals sounds defamatorily old-fashioned but the current system has for a number of years now clearly not been one of paper journals—all important journals are electronically available, linked to each other, and provide the opportunity to present additional Supporting Information (raw data, movies, etc.); all this is a result of heavy investments from the slandered publishers of paper journals.

It is too bad that in an open access model with the same costs, users of scientific literature who themselves produce little or no publications, for example, scientists in industry, will not contribute to the expenses. In the open access model the authors should pay for each published article, and amounts between €500 and €10000 per article were mentioned. The authors should obtain the money from sponsoring agencies and institutions, whose coffers would, however, not be getting any fuller through open access. Alternatively, scientists should draw from the library budget, which, after all, would no longer require as much money—but just try asking your librarian! It is clear that the open access model would result in more "information management", "cash-flow control", and blatantly "more bureaucracy".

Open access will lead to more bureaucracy

It is said that the quality of scientific publications should be promoted by open access, through discourse, networking, etc. These are fine "soft words" but, if one wants to produce high-quality scientific journals, money is required more than ever in times of electronic publishing: for hard- and software, as well as for supersoftware, humans, and the words of the Nobel Prize winner in chemistry, Lord Todd, also hold in this case: "Hard work is the minimum requirement—creativity, intelligence, and motivation are also needed". If journal editors are to be paid directly by the authors for each accepted manuscript, then the "economization of the individual article" will be the order of the day. And it is naïve to believe that the fact that editors are paid a determined amount of money by the author for each accepted article will not have an influence on the decision. It is well known that the very good journals invest a much greater amount of editorial effort than the less-good and even bad journals (and they do exist[7]). As authors only have to pay for accepted articles—it is, indeed, difficult to imagine that anyone could be made to pay for a rejection—access to top journals would only be possible for those who are extremely well-funded. Alternatively there will be a leveling of journals: all journals, all articles, all scientists would be equally good. So much regarding the quality of scientific journals in the age of open access.

To maintain and further improve the quality of *Angewandte Chemie*, a dozen and a half chemists and half a dozen colleagues from different backgrounds work together. They are supported by an Editorial Board and an International Advisory Board, both of the highest caliber, as well as by numerous scientists from around the world. Even though access to *Angewandte Chemie* is not free, the number of monthly full-text downloads is phenomenal—far ahead of

the "second-best" of the over 400 journals in Wiley InterScience. The most important prerequisite to produce a top journal is the receipt of many good manuscripts. *Angewandte Chemie* received more than ever in 2004 (see Table 1 as well as Figures 1 and 2): Approximately 20% more Communications were submitted, 16% more were published (1072 versus 923), and the rejection rate increased from 64% to 65% (during the first six months). Increasingly more chemists outside organic and inorganic chemistry, the fields the journal traditionally focused on, are publishing in *Angewandte Chemie*. The journal is therefore continuously fulfilling the mission to serve chemistry in its entire breadth. Of course, (Mini)Reviews, Highlights, and Essays also contribute to the quality of the journal, and it is especially gratifying that the Essays, a section started in the millennium year 2000, often draw spontaneous praise from our readers. They do not, however, draw a lot of citations. Nevertheless the Impact Factor rose from 7.671 to 8.427 (see Figure 3). Furthermore, it is most pleasing to see how rapidly publications in *Angewandte Chemie* are noticed and bear fruit in the work of others. This is reflected in the extremely high Immediacy Index of 1.655 (see Figure 4). This value implies that each manuscript published in *Angewandte Chemie* in 2003 was on average cited in the same year 1.66 times (papers in the last two or three months of a year have literally no chance of being cited in the same year). Obviously, speed matters: From now on, *all* articles will be published electronically as soon as possible in the Early View mode on Wiley InterScience prior to their appearance in print, usually several weeks later. In 2005, the Editorial team will continue their efforts to fill each issue with the highest quality articles from all fields of chemistry in a most reader-friendly package. The best never rest.

Peter Gölitz

P.S.: Two strong trends of the last few years continue: 1) The productivity of Chinese scientists is rapidly increasing as is the quality of their papers. It is therefore to be expected that more manuscripts from Chinese authors can be seen in the pages of *Angewandte Chemie*. And it is equally important that the *Chinese Journal of Chemistry* will be copublished from 2005 onwards by the Shanghai Institute of Organic Chemistry

Chemistry—A European Journal

To mark the 10th Anniversary of *Chemistry—A European Journal*, a one-day symposium will be held on Friday April 15, 2005, entitled "Chemistry—A European Conference: Stimulating Concepts in Chemistry".

Keynote Speakers:
José Barluenga (Oviedo, Spain), Steve Ley (Cambridge, UK), Frans De Schryver (Leuven, Belgium), Günter Schmid (Essen, Germany), Fraser Stoddart (UCLA, USA), George Whitesides (Harvard, USA)

Location:
Institut de Science et d'Ingénierie Supramoléculaires (ISIS), Université Louis Pasteur, 8, allée Gaspard Monge, 67083 Strasbourg Cedex, www-isis.u-strasbg.fr.

Free Registration:
Registration for the conference is free of charge and can be done preferably directly online through the German Chemical Society (GDCh) at http://10th-anniversary.chemeurj.org.

Organization:
The Symposium has been co-organized by the 14 European Chemical Societies (EU ChemSoc) that jointly own *Chemistry—A European Journal*, and Wiley-VCH. Further details regarding the Program, Registration, and Accommodation are available on the *Chemistry* homepage: http://10th-anniversary.chemeurj.org.

Gold Redox Catalysis for Selective Oxidation of Methane to Methanol

As good as gold: The activation and selective oxygenation of inert C–H bonds, as in methane, is a demanding problem. It is now shown that the combination of gold as a catalyst and H_2SeO_4 as the oxidant results in a 94% selectivity for CH_3OSO_3H at 28% CH_4 conversion (see scheme). These results mean that gold now claims its place alongside the other noble metals as a methane oxidation catalyst.

Reviews

Breaking the code: A large number of novel amino acids have been incorporated into the genetic codes of both prokaryotic and eukaryotic organisms (see schematic representation). These remove the limitations imposed by the existing 20 amino acid codes and should make it possible to generate proteins and perhaps entire organisms with new or enhanced properties.

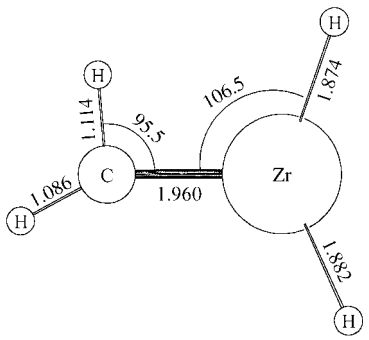
Metal-Free, Organocatalytic Asymmetric Transfer Hydrogenation of α,β-Unsaturated Aldehydes



The effect of pore size on the radiolytic production of hydroxyl radicals has been investigated in silica controlled pore glasses (CPGs) by means of the HO•-induced conversion of coumarin into 7-hydroxycoumarin (7-OHC). Production of 7-OHC decreases with decreasing pore size (see plot). This effect is not attributed to the capture of HO• at the water/silica interface but to the modified diffusion regime in such confined environments.

A question of size: Two N-protected macrocyclic enediynes have been synthesized by intramolecular N-alkylation. The smaller 12-membered enediyne, upon deprotection, yields a stable amine. In contrast, the amine generated from the 13-membered enediyne forms the aminol, which in turn undergoes a spontaneous Bergman cyclization (see scheme).

Diffusion or activation control: Free CN^- ions are generally alkylated at carbon (see picture). N-attack is only observable in diffusion controlled reactions with carbocations. Since isonitrile formation in reactions with $[Ag(CN)_2]^-$ is due to the change of the nucleophile, the explanation of these regioselectivities by the hard and soft acids and bases principle has to be abandoned.

F. Arnold Receives ACS Medal

The Francis P. Garvan–John M. Olin Medal administered by the American Chemical Society has been awarded since 1937 to women in the USA for distinguished service to chemistry. The recipient for 2005 is Frances H. Arnold of the California Institute of Technology (Caltech) in Pasadena. After studying mechanical and aerospace engineering at Princeton University, she first worked at the Solar Energy Research Institute in Golden, CO (USA). In 1980, she decided to continue her studies with a focus on biotechnology and completed her PhD in 1985 in the research group of Henry Blanch at the University of California, Berkeley. She then undertook postdoctoral research with Ignacio Tinoco (Berkeley) and Jack Richards (Caltech), before becoming assistant professor in 1987 at Caltech, where she is now Professor of Chemical Engineering and Biochemistry. She is a member of the US National Academy of Engineering.

F. Arnold

Arnold's research focuses on engineering enzymes, biosynthetic pathways, and genetic regulatory circuits by directed evolution. Her research group also develops software for modeling circuits and networks. Arnold is a member of the Editorial Advisory Board of *ChemBioChem*, where she recently reported on the "Thermostabilization of a Cytochrome P450 Peroxygenase".[1a] In *Angewandte Chemie* she recently described "A Self-Sufficient Peroxide-Driven Hydroxylation Biocatalyst".[1b]

B. Meunier Becomes President of the CNRS

Bernard Meunier has been appointed president of the Centre National de la Recherche Scientifique (CNRS) by the French government. He suceeds the atmospheric researcher Gérard Mégie, who died recently. The CNRS was founded in 1939 on the initiative of several scientists, including the Nobel Prize winner in physics, Jean Perrin, and conducts publicly funded fundamental research in all disciplines. Of its 26000 employees, about 12000 are scientific researchers. Since 1966, the CNRS institutes have been closely linked to university laboratories.

B. Meunier

Meunier studied organometallic chemistry with Robert Corriu and Hugh Felkin. He has worked for the CNRS since 1973: first at the Institute for the Chemistry of Natural Products in Gif-sur-Yvette near Paris, then since 1979 at the Laboratory of Coordination Chemistry in Toulouse, where he has been associate director since 2003. He has also taught at the Ecole Polytechnique in Paris since 1993 and has been a member of the French Academy of Sciences since 1999. His research interests encompass biomimetic catalysis, oxidation reactions, bioinorganic chemistry, and medicinal chemistry. In issue 1/2005 of *ChemBioChem* he reports on "Porphyrin Derivatives for Telomere Bindung and Telomerase Inhibition",[2a] and in a Review in *Advanced Synthesis & Catalysis* he recently described biomimetic catalysts for the oxidative activation of drugs.[2b] Meunier is a member of the Editorial Board of the *European Journal of Inorganic Chemistry* and the Editorial Advisory Board of *ChemBioChem*.

D. Kurth Accepts Position in Tsukuba

From April 2005 the sun will rise earlier for Dirk G. Kurth than it does now: The group leader at the Max-Planck-Institut für Kolloid- und Grenzflächenforschung (MPIKG) in Golm near Potsdam (Germany) will become the first foreign director of a research group at the National Institute for Materials Science (NIMS) in Tsukuba (Ibaraki, Japan). Kurth studied chemistry in Köln, Aachen (Germany), and Albuquerque (NM, USA) and completed his PhD in 1993 at Purdue University in West Lafayette (IN, USA) under the guidance of T. Bein (now at the Universität München (Germany)) on thin organic films on metallic substrates. He then spent two years as a postdoctoral fellow with J.-M. Lehn in Strasbourg (France). In 1996, he moved to join the research group of H. Möhwald at the MPIKG, and at the beginning of 2004 started lecturing at the Universität Potsdam.

D. Kurth

Kurth's research is concentrated on the development of functional modules in hierarchically structured materials for molecular functional units and supramolecular machines. His research group recently reported in *Angewandte Chemie* on directed self-assembly of nanoparticles at oil/water interfaces and in *ChemPhysChem* described the nanoscopic structure of a supramolecular polyelectrolyte–amphiphile complex.[3]

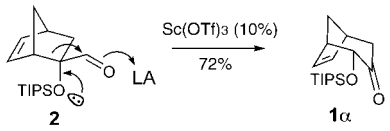
Cycloadditions

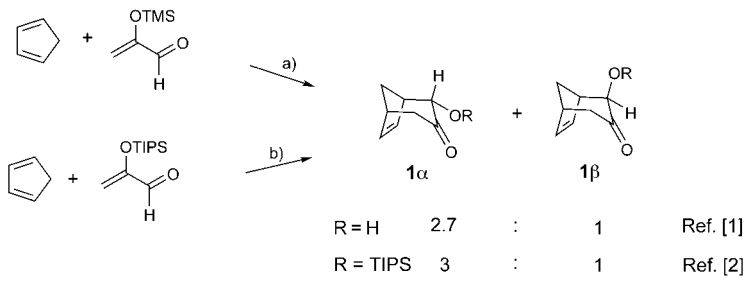


[4+3] Cycloadducts from Lewis Acid Mediated Reactions of Acroleins with Cyclopentadiene

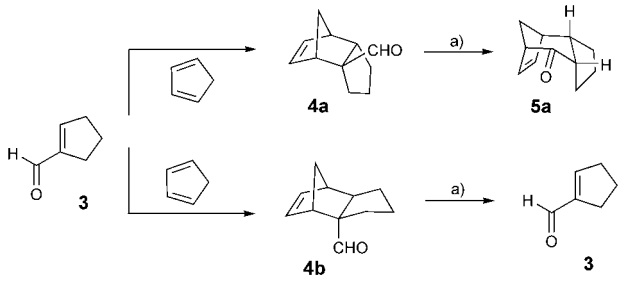
*Barbara Niess and H. Martin R. Hoffmann**

Keywords:
cage expansion · cycloaddition · Diels–Alder reaction · domino reactions · Lewis acids

More than 20 years ago Sasaki et al.[1] reported the Lewis acid promoted cycloaddition of 2-silyloxyacrolein to cyclopentadiene, which led to the isolation of the diastereomeric [4+3] cycloadducts **1α** and **1β** (Scheme 1). A variation of the silyl substituent and of the Lewis acid made little difference (Scheme 1), although starting materials and products were, of course, easier to handle.[2]



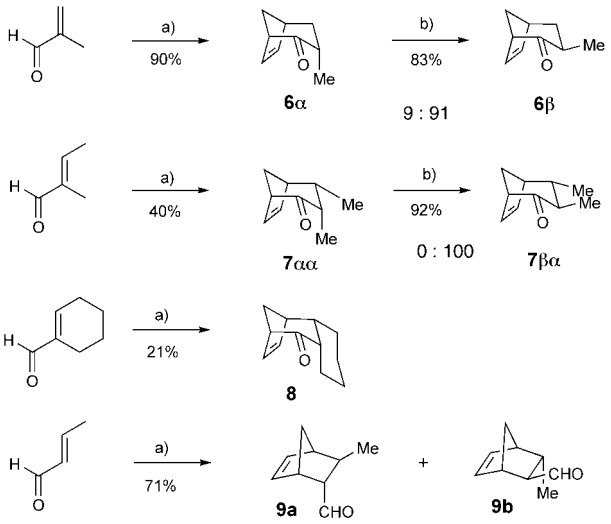
Davies and Dai[3] have now looked more closely at a series of Lewis acid promoted cycloadditions of cyclopentadiene to acroleins and obtained a variety of [4+3] cycloadducts. They also showed that a 5-norbornene-2-carbaldehyde is frequently implicated as an intermediate en route to the final [4+3] cycloadduct. For example, by using a microwave-assisted procedure, they first prepared Diels–Alder adduct **2**, which was then subjected to the original reaction conditions (10% $Sc(OTf)_3$, CH_2Cl_2, 0 °C)[2] to obtain the **1α** adduct (Scheme 2).



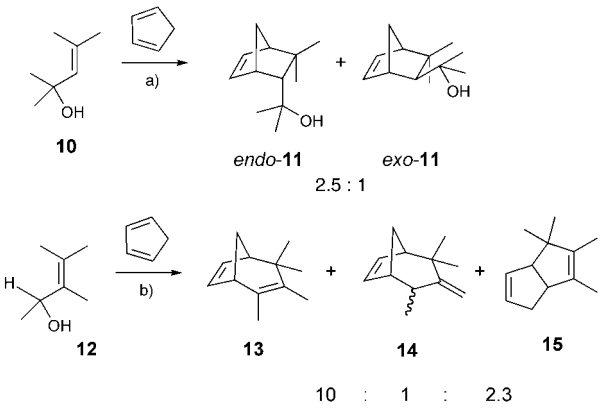
Scheme 2. Scandium triflate mediated rearrangement. LA = Lewis acid.

Tricyclic Diels–Alder adducts **4a** and **4b** were prepared from cyclopentene-1-carbaldehyde (**3**). Adduct **4a** has a sterically accessible formyl group on the *exo* face of the molecule: upon treatment with $AlCl_3$ ring expansion to **5a** occurred. In contrast, the diastereomeric adduct **4b** with a more shielded *endo* formyl group regenerated the substituted acrolein **3** in what appears to be the reverse of the forward reaction, that is, a retro-Diels–Alder reaction (Scheme 3).

Despite the intensive work on Diels–Alder additions of acroleins to cyclopentadiene, Davies and Dai showed that a number of very simple alkylated acroleins, including the parent 2-methacrolein, afford formal [4+3] rather than kinetic [4+2] cycloadducts under appropriate Lewis acid catalysis. For example, the cage-expanded adducts **6α** and **7αα** were formed from 2-methacrolein and 2-methyl-2-butenal, respectively (Scheme 4). Upon subsequent treatment of the respective products with HCl, the more-stable equatorial **6β** was formed predominantly and the diequatorial **7βα** epimer was formed exclusively. The *cis*-decalin system **8** is formed in lower yield (21%) than the five-membered-ring annulated **5a** (92%) (Scheme 3). 2-Butenal, which lacks the α-alkyl group, furnished conventional



Scheme 1. Reagents and conditions: a) $SnCl_4$, CH_2Cl_2, −78 °C, 72%; b) $Sc(OTf)_3$ (10 mol%), CH_2Cl_2, 0 °C, 72%. TMS = trimethylsilyl; TIPS = triisopropylsilyl.



Scheme 3. Reagents and conditions: a) $AlCl_3$ (1.1 equiv), CH_2Cl_2, −78→0 °C, 2 h, 92% **5a**; 84% **3**.

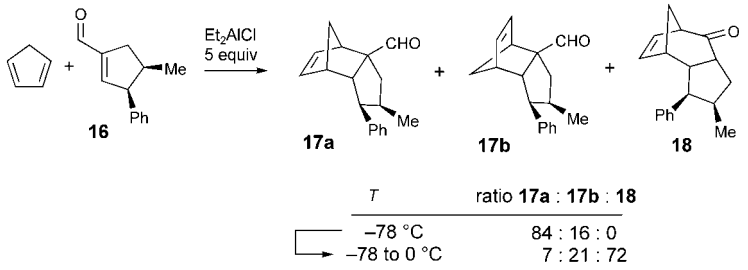
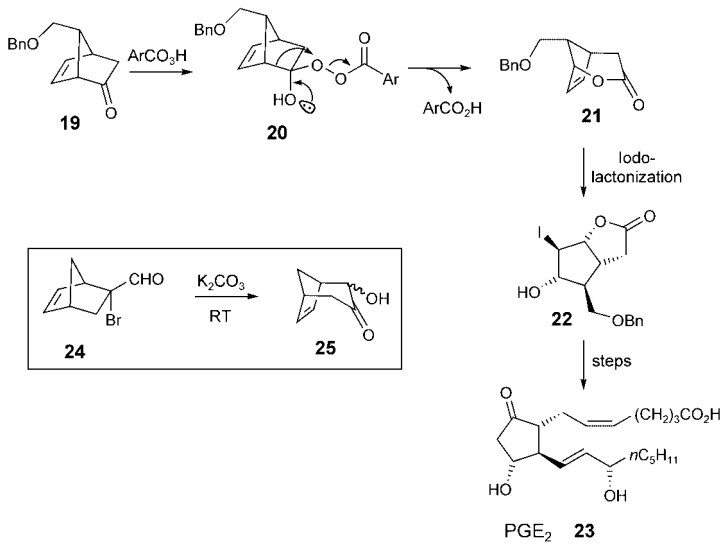
Scheme 4. Reagents and conditions: a) $AlCl_3$ (1.1 equiv), cyclopentadiene (2.5 equiv), CH_2Cl_2, −78→0°C; b) HCl (1.0 equiv), room temperature, 30 min.



Scheme 5. Reagents and conditions: a) H_2O, TsOH, pentane; b) H_2O, TsOH, pentane, 0°C→RT, 24 h, 69–73%. Ts = *p*-toluenesulfonyl.

Diels–Alder adducts **9a** and **9b** (Scheme 4).

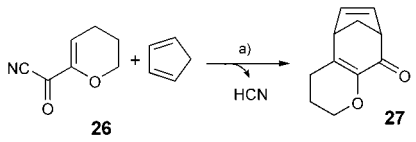


In retracing the possible origins of this unusual behaviour, we note that borderline dienophile/allyl cation reactivity is also encountered for acid-catalyzed cycloadditions of methylated allyl alcohols (Scheme 5). Whereas tetramethylated allyl alcohol **10** gives mainly Diels–Alder adducts *endo*-**11** and *exo*-**11**,[4] placement of one methyl group at the central position of the allyl moiety as in **12** affords unconventional [4+3] adducts **13** and **14**, accompanied by [3+2] adduct **15**, in a dehydrative cycloaddition.[5]

In the presence of Et_2AlCl at −78°C, the more complex cyclopentene aldehyde **16** and cyclopentadiene combined to form diastereomeric annulated norbornenes **17a** and **17b**. Of the four possible primary Diels–Alder adducts, only these two correspond to an attack of the dienophile from the more accessible π face with *exo*-orientated Me and Ph groups. When the reaction mixture was quenched at 0°C, the rearranged adduct **18** with six stereocenters in total was isolated as the major tricyclic product (Scheme 6). Again, product **17a** with the formyl group *syn* to the neighboring methylene bridge rearranged rather than the diastereomeric **17b** (see also Scheme 3).

The observed [3.2.1] cage expansion is driven by the release of ring strain and appears to mimic the isoelectronic Baeyer–Villiger oxidation of norbornenone, which has been known for over three decades: The α-hydroxy peroxy appendage can rotate freely in the *exo* position to adopt a stereoelectronically favorable alignment and conformation for the 1,2-shift to [3.2.1] bicyclic lactone **21** to occur (Scheme 7). Iodinated lactone **22** contains five stereocenters and is a key intermediate in Corey's route to prostaglandins.[6] The α-ketol rearrangement

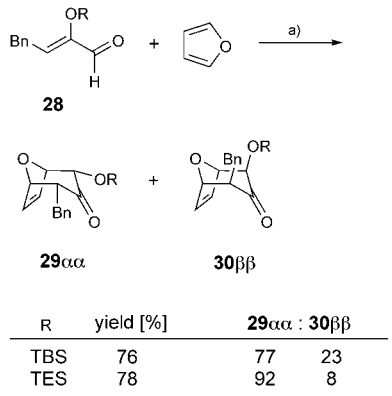
Scheme 6. Addition of cyclopentene aldehyde **16** to cyclopentadiene.



Scheme 7. Baeyer–Villiger and α-ketol rearrangement.

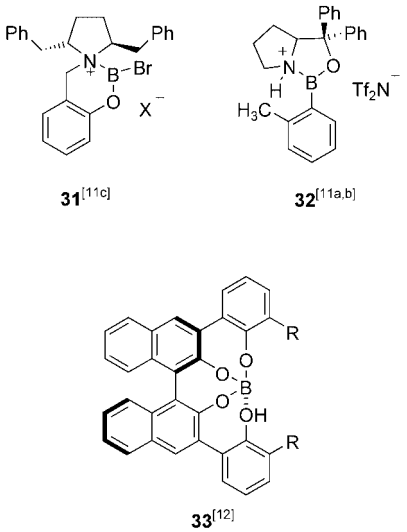
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of an α-bromoaldehyde such as **24** has also been observed to proceed under mild conditions (Scheme 7).[6,7]



In assessing the scope of the Lewis acid mediated route to bridged seven-membered rings we should bear in mind that not only α,β-unsaturated enals, but also activated α,β-unsaturated enones and push–pull olefins such as **26** give [3.2.1] bicyclic products. In this case, an α,β-unsaturated enone **27** is formed instead of an α-ketol with loss of HCN (Scheme 8).[8] The product is sufficiently stable for isolation under these conditions.

Scheme 8. Reagents and conditions: a) $AlCl_3$, toluene, −78→0°C, 12 h, 70%.

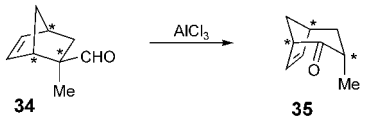


Cyclohexadiene adducts of acroleins are less strained than cyclopentadiene adducts and ring expansion does not occur.[3] Similarly, Diels–Alder adducts with furan are less likely to undergo ring expansion. The reported formation of **29αα** and *syn*-diaxial **30ββ** from furan and enal **28**[9] is characteristic of a W-configured allyl cation equivalent and a compact/extended transition state in a direct [4+3] cycloaddition rather than the [2.2.1] oxabicyclic intermediate (Scheme 9).[10]

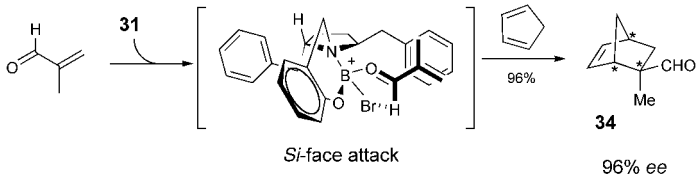
It is of special interest that 5-norbornene-2-carbaldehyde derivatives that contain a quaternary center can be obtained in a stereocontrolled fashion.[11–13] In fact, the asymmetric synthesis of these aldehydes has become a benchmark for testing and inventing a host of new chiral Lewis acids. These have been constantly improved and refined over a period of at least one decade. For example, boron-centered **31**–**33** have been shown to be highly efficient in the synthesis of **34** (Scheme 10).[11,12]

R	yield [%]	29αα : 30ββ	
TBS	76	77	23
TES	78	92	8

Scheme 9. Reagents and conditions: Me_2AlCl (1.0 equiv), CH_2Cl_2, −78°C, 12 h. TBS = *tert*-butyldimethylsilyl; TES = triethylsilyl.



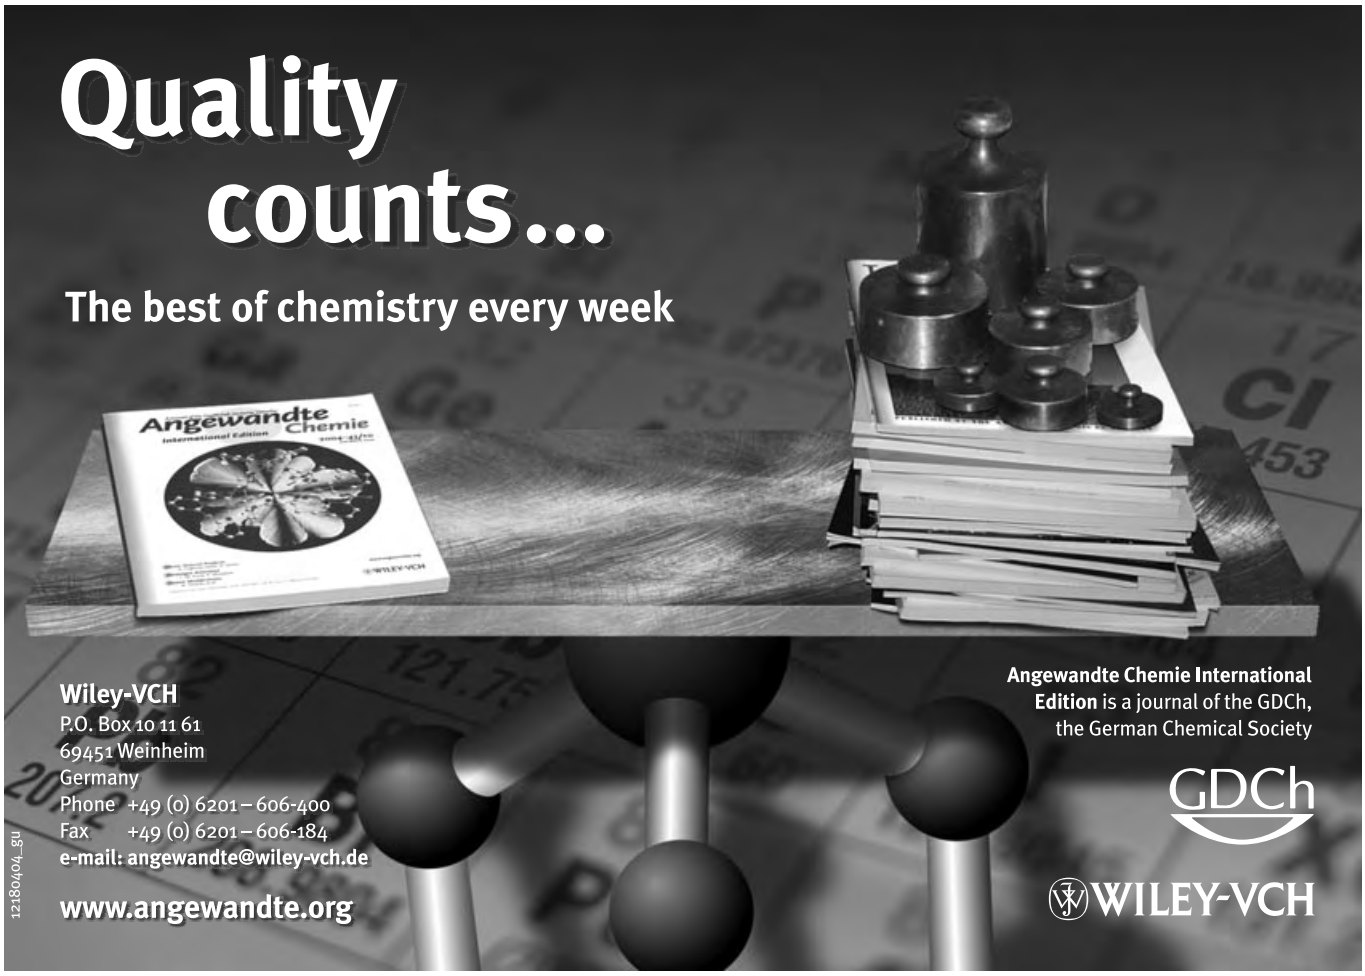
Scheme 10. Chiral Lewis acids for the asymmetric Diels–Alder reaction.



The chiral catalyst **31**, which is based on local C_2 symmetry grafted on bidentate amino phenol, is probably a two-point Lewis acid that involves a bond between the boron atom and the formyl oxygen atom as well as unusual hydrogen bonding of the formyl hydrogen atom. In combination with a suitable "benzenoid wall", the transition state is set up for *exo* addition of cyclopentadiene to the *Si* face (Scheme 11).[11c]

Apart from cationic oxaborolidinium salts such as **32**, various cationic ruthenium species with the transition metal as the stereocenter afford **34** and its enantiomer with high enantiomeric excesses in high chemical yield.[13] Interestingly, these asymmetric catalysts have been so carefully tuned to their task that the potential consecutive [3.2.1] rearrangement appears not to take place. Presumably, the initial Diels–Alder addition has a lower activation energy than the subsequent cage expansion, which requires cleavage of at least one σ bond. However, neighboring oxygen participation (e.g. **2**→**1α**, Scheme 2, and α-ketol rearrangement) lowers the barrier to ring expansion. Whereas α-alkyl substitution is less effective than α-silyloxy substitution, the construction and study of further push–pull olefins, including those with α-sulfur substituents and other heteroatoms, are clearly called for.

Davies and Dai report that the rearrangement of **34** to **35** is feasible with $AlCl_3$ (>1 equiv) and also $Sc(OTf)_3$, which are more electrophilic and sterically more accessible Lewis acids than those in Scheme 10. The [3.2.1] adduct is formed with three stereocenters and complete conservation of chirality (Scheme 12). [4+3] Adducts such as **35** are of continued interest, most recently for constructing chiral cage molecules as drug leads.[14]



Scheme 12. Lewis acid induced rearrangement of chiral precursor **34**.

Scheme 11. Catalytic asymmetric Diels–Alder reaction of 2-methacrolein with cyclopentadiene.[11c]

Homogeneous Catalysis

Gold Redox Catalysis for Selective Oxidation of Methane to Methanol

Dirk E. De Vos and Bert F. Sels*

Keywords:
gold · homogeneous catalysis · methane · oxidation · selenium

The challenge posed by the activation and selective oxygenation of inert C–H bonds, as in methane, has haunted chemists for many years. Gas-phase reactions, such as the oxidative coupling of methane to ethane and ethylene, and the direct conversion of methane into oxygenates, have met with limited success.[1] The need for high selectivity has incited scientists to investigate liquid-phase reactions at more moderate temperatures.

The origins of transition-metal catalyzed CH_4 oxidation chemistry can be traced back to the early work of Snyder and Grosse.[2] They oxidized methane with fuming sulfuric acid at 263 °C employing an $HgSO_4$ catalyst, and obtained oxygenated and sulfonated methane derivatives in a summed yield of 44 %. In an evolved version of this process, it was demonstrated that the reaction is mediated by the Hg^{II}/Hg^{I} redox couple (Table 1).[3] At the same time, Shilov discovered that Pt^{II}/Pt^{IV} is capable of oxidizing alkanes to alcohols;[4] with Pt^{II} chelated by a bipyrimidine ligand and SO_3 as the oxidant, methane was oxidized to a 72 % yield of methanol and its esters.[5] In a recent paper, Periana and co-workers now report that the combination of gold as a catalyst and H_2SeO_4 as the oxidant results in a 94 % selectivity for CH_3O-SO_3H at 28 % CH_4 conversion.[6] As a common feature of all these reactions, the first step is the formation of a M–CH_3 intermediate, possibly by electrophilic substitution on a Hg^{II} or Pt^{II} species.[4b,c,7,8] With this knowledge, the step towards gold then seems straightforward, since Au^{I} is isoelectronic with Hg^{II}, and Au^{III} shares its electronic configuration with Pt^{II}.

This new example of homogeneous gold catalysis joins a series of discoveries made largely in the last decade.[9] Ionic gold, either as Au^{I} or Au^{III}, has been found to catalyze asymmetric aldol reactions and carbonylations.[10] The Lewis acid properties of Au^{n+} have been exploited to promote the addition of oxygen nucleophiles, such as water, to alkynes, or to catalyze C–C bond formations using alkynes.[11] Ionic gold also catalyzes the hydroarylation of alkynes with electron-rich aromatics or furans.[12] This reaction is strongly reminiscent of analogous Pd^{II}-catalyzed couplings, which have been proposed to start with the activation of the aromatic C–H bond by an electrophilic Pd^{II} compound.[13] While it is tempting to propose that with gold, auration of the aromatic compound is the first step, it seems more likely that gold-catalyzed hydroarylation is a classical Friedel–Crafts reaction.

While the previous list is by no means exhaustive, it is clear that none of these reactions involves changes of the gold redox state, even if two redox states of gold, that is, Au^{I} or Au^{III}, are readily accessible. In the case of the coupling of arenes, one might project that, as with Pd^{II}/Pd^{0}, an oxidative coupling of aromatics and olefins to alkenylaromatics might proceed, but attempts to devise such a redox process with gold have not yet been successful.[12a]

Only a small number of homogeneous gold-mediated redox reactions have been reported. Ionic gold catalyzes the oxidation of alkanes with H_2O_2 to alkyl hydroperoxides, for example, but this is probably a free radical process.[14a] $[AuCl_2(NO_3)]$ promotes the oxidation of thioethers to sulfoxides at room temperature and 1 atm of O_2. In this case, the thioether, in a slow step, reduces Au^{III} to Au^{I}, which is quickly reoxidized by O_2 to Au^{III}, without any Au^{0} formation (Scheme 1). This process demonstrates the feasibility of Au^{III}/Au^{I} redox cycling in organic reactions.[14b] In addition, ionic gold catalyzes the oxidative carbonylation of aniline to phenylcarbamates with O_2 as the oxidant.[15] The same reaction is known to be catalyzed by the Pd^{II}/Pd^{0} redox couple;[15c] however, in the gold case, it is not fully clear whether ionic gold or colloidal zerovalent gold is the actual catalyst.

The new successful application of gold in the catalytic methane oxidation critically depends on the use of selenic acid as an oxidant. Periana et al. previously showed that Au^{III} stoichiometrically oxidizes methane to methanol.[3] Only with H_2SeO_4 as the oxidant, the system actually turns over. As selenic acid is one of the few known reagents to dissolve Au^{0}, it may even re-dissolve colloidal Au^{0} particles if these were to form in the drastic reaction conditions. On the other hand, the spontaneous reaction between H_2SeO_4 and methane should not be neglected. Comparison with blank experiments shows that about 20 % of the CH_3OH formation may be due to the background reaction.

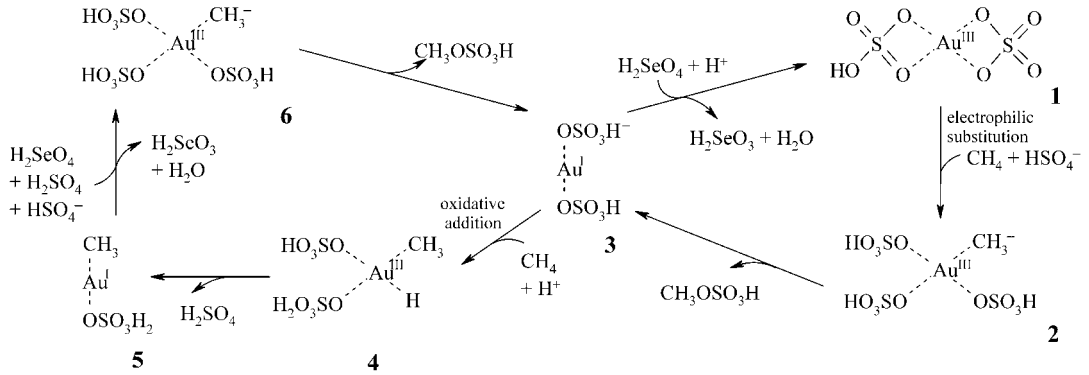
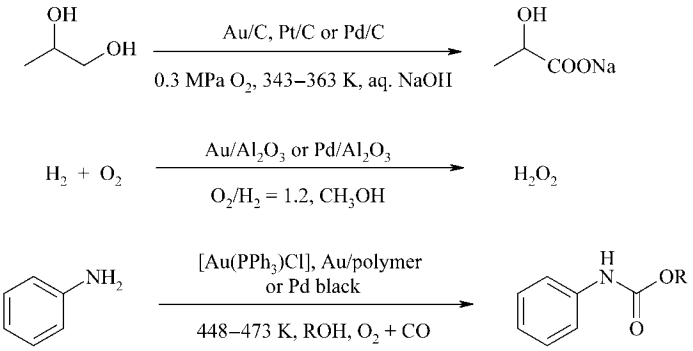
Au^0	3 M SeO_3 in 96% D_2SO_4	453	8	77% CH_3OSO_3D	0.18 M	580	32	3.6	[6]
	3 M SeO_3 in 96% D_2SO_4 + 2% SO_3		28	94% CH_3OSO_3D	0.63 M	29	8	2.7	[6]

[a] Eventual concentration of methanol and derivatives. [b] Molar ratio CH_4:catalyst. [c] TON = turnover number = moles of product per mole of catalytic metal. [d] TOF = turnover frequency = moles of product per mole of metal per time. [e] Maximal values, obtained in separate experiments. [f] bpym = 2,2′-bipyrimidine.



Scheme 1. Au^{III}/Au^{I} redox cycling in organic reactions.

Such a spontaneous reaction does not necessarily decrease the selectivity: protection of methanol as methyl bisulfate greatly reduces the reactivity of the CH_3 group, not only for electrophilic activation, but also for radical processes initiated by hydrogen-atom abstraction.[16]



As can be expected based on both experiment and calculation, the catalytic cycle comprises formation of an Au–CH_3 compound, oxidation of the metal, and product elimination, though not necessarily in this order. In the analogous platinum reactions, the oxidation of the metal precedes the product elimination;[4b,5,8] in the case of mercury catalysis, the product is eliminated before reoxidation of Hg^{I}.[3] What will be the order of the steps in case of gold catalysis? This sequence depends on whether methane is activated on Au^{I} (by oxidative addition, **3**→**4** in Scheme 2) or on Au^{III} (by electrophilic substitution, **1**→**2** in Scheme 2). While the majority of gold is present as Au^{III}, a pathway starting with oxidative addition of CH_4 on Au^{I} is energetically favored and therefore should be considered as well.

In evaluating the future applications of this discovery, environmental issues should be considered. While selenium is needed in small quantities in food as a micronutrient, it is quite toxic at high concentrations. This means that the selenium has to be confined to the reactor; selenium leaks, for example, as selenite in waste water or as SeO_2 in offgases must be avoided. Secondly, the reaction is performed in H_2SO_4; methanol recovery implies dilution with water, and next, the sulfuric acid must be concentrated again. It is therefore worthwhile to consider other inert solvents, such as water. Sen and co-workers and Sames and co-workers have demonstrated that catalytic C–H activation on electrophilic Pt^{II} is possible in water,[17] but the very low solubility of methane still needs to be dealt with

Scheme 3. Examples of gold-, platinum-, and palladium-catalyzed reactions.

($0.25\ g\,L^{-1}$ at 100 °C and 2 MPa). Finally, it is possible to recycle the selenic acid, by oxidation of the H_2SeO_3 with Cl_2 or H_2O_2. To obtain a commercially viable process, TOFs larger than $3000\ h^{-1}$, and a 5 M concentration of oxygenates would probably be needed (compare values in Table 1). Particularly regarding CH_4 conversion and TON, platinum catalysis seems still more promising than gold catalysis. In any case, major advances are still required before the metal-catalyzed methane oxidations can result in an industrial process.

Strikingly, both in heterogeneous and homogeneous oxidation catalysis, gold is no longer considered inert, but presents itself as an intriguing alternative to platinum and palladium, with often superior characteristics (Scheme 3). Just like metallic supported Pt^0 and Pd^0, Au^0/C oxidizes alcohols to acids, but the gold catalysts are less affected by metal leaching or by poisoning by strong adsorption of acids.[18] In the direct production of H_2O_2 out of H_2 and O_2, supported gold can be used instead of palladium; the formed hydroperoxide can be employed in situ for propene epoxidation.[19] The similar role of palladium and gold in oxidative carbonylation of amines has been discussed before.[15] With the discovery by Periana and co-workers for the Au-catalyzed methane oxidation,[6] gold claims its place in this domain as well, alongside other noble metals.

DOI: 10.1002/anie.200460627

Although chemists can synthesize virtually any small organic molecule, our ability to rationally manipulate the structures of proteins is quite limited, despite their involvement in virtually every life process. For most proteins, modifications are largely restricted to substitutions among the common 20 amino acids. Herein we describe recent advances that make it possible to add new building blocks to the genetic codes of both prokaryotic and eukaryotic organisms. Over 30 novel amino acids have been genetically encoded in response to unique triplet and quadruplet codons including fluorescent, photoreactive, and redox-active amino acids, glycosylated amino acids, and amino acids with keto, azido, acetylenic, and heavy-atom-containing side chains. By removing the limitations imposed by the existing 20 amino acid code, it should be possible to generate proteins and perhaps entire organisms with new or enhanced properties.

1. Introduction

The genetic codes of all known organisms specify the same 20 amino acid building blocks. These building blocks contain a limited number of functional groups including carboxylic acids and amides, a thiol and thiol ether, alcohols, basic amines, and alkyl and aryl groups. Although various arguments have been put forth to explain the nature and number of amino acids in the code,[1–3] it is clear that proteins require additional chemical groups to carry out their natural functions. These groups are provided through posttranslational modifications including phosphorylation, methylation, acetylation, and hydroxylation; cofactors; and in rare cases, organisms have evolved novel translational machinery to incorporate either selenocysteine or pyrrolysine.[4,5] The need for additional factors in so many protein-mediated processes suggests that while a code consisting of 20 amino acids is sufficient for life, it may not be ideal. Consequently, the development of a method that makes possible the systematic expansion of the genetic codes of living organisms might enable the evolution of proteins, or even entire organisms, with new or enhanced properties. Moreover, such methodology would dramatically increase our ability to manipulate protein structure and function both in vitro and in vivo. This in turn would allow a more classical chemical approach to the study of proteins, in which carefully defined changes in the steric or electronic properties of an amino acid are correlated with changes in the properties of proteins.[6–8] Herein we provide an overview of both chemical and biochemical approaches that have been developed in the past to manipulate protein structure, and review in depth recent advances that have made it possible to add new amino acids to the genetic codes of both prokaryotic and eukaryotic organisms.

2. Chemical Approaches

2.1. Chemical Modification of Proteins

Reagents that allow the selective chemical modification of amino acid side chains have proven quite useful in assigning functional roles to amino acid residues in proteins. Selectivity depends on the number and reactivity (dependent on both steric and electronic factors) of a particular amino acid side chain. Typical modifications include the oxidation or alkylation of cysteine residues, acylation of either the N-terminal α-amino group or the ε-amino group of lysine, and the condensation of amines with the carboxylate groups of aspartate or glutamate. In some cases it is possible to exploit the unique reactivity of active-site residues for selective chemical modification. For example, treatment of the protease subtilisin with phenylmethanesulfonyl fluoride, followed by reaction with thioacetate and hydrolysis, selectively converts the serine residue at the active site into a cysteine residue (Figure 1 a).[9,10] This mutant thiosubtilisin has diminished proteolytic activity, but still functions as an esterase. Similar approaches have been used to generate a redox-active selenosubtilisin[11,12] and selenotrypsin[13] (Figure 1 b).

Chemical modification has also been used to introduce reactive molecules, biophysical probes, tags, and other non-peptidic groups selectively into proteins. Cysteine is the most commonly used residue for this purpose because of its relatively low abundance in proteins and the increased nucleophilicity of the thio group relative to the side chains of other amino acids. Moreover, site-directed mutagenesis makes it possible to selectively introduce a cysteine residue at any desired site in a protein, in many cases without loss of function. This residue can then be modified, typically by either disulfide bond exchange or alkylation reactions.

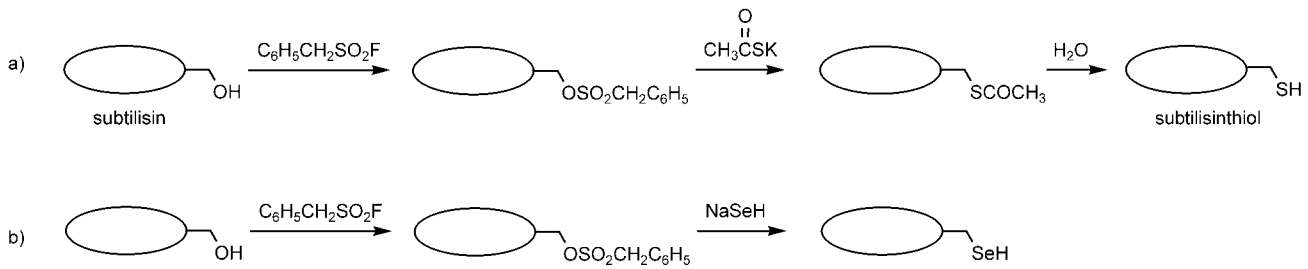

Figure 1. Selective conversion of the hydroxy group of serine to a thio (a) or seleno group (b).

Cysteine modification has been used to alter the catalytic properties of proteins. For example, Kaiser and co-workers conjugated different flavin analogues to the cysteine residue in the active site of papain to generate oxidoreductases that oxidize hydrophobic dihydronicotinamide derivatives (Figure 2a).[14–16] Conversely, an oligonucleotide binding site was introduced into a Lys116→Cys mutant of the nonspecific deoxyribonuclease staphylococcal nuclease to generate a semisynthetic enzyme that selectively cleaves DNA adjacent to the target sequence (Figure 2b).[17]

Cysteine has also been used to introduce a variety of biophysical probes into proteins. For example, a photoactivatable cross-linking agent (Figure 2c) was tethered to an Asp161→Cys mutant of catabolite gene activator protein to probe the interaction of this protein with the α subunit of RNA polymerase during transcriptional activation.[18] Meares and co-workers attached ferric EDTA to proteins through the Cys residue to generate oxidative cleavage reagents that can be used to map protein–protein and protein–nucleic acid complexes (Figure 2d).[19–23] Likewise, Harbury and co-workers have created a powerful chemical footprinting technique termed misincorporation proton–alkyl exchange,[24] which is based upon selective cleavage of the protein backbone at cysteine residues by 2-nitro-5-thiocyanobenzoic acid (Figure 2e).[25] In the related "substituted cysteine accessibility method" (SCAM) the surface accessibility of residues is inferred by the ability of the corresponding cysteine mutant to react with charged or polymeric reagents.[26,27] Nitroxide spin

Peter Schultz received his B.S. and Ph.D. (1984) from Caltech. He joined the Berkeley faculty in 1985 and moved to the Scripps Research Institute in 1999 where he is currently the Scripps Professor of Chemistry and the Director of the Genomics Institute of the Novartis Research Foundation. His interests focus on catalytic antibodies; the development and application of combinatorial methods in biological chemistry, drug discovery, and materials science; and new building blocks for the genetic code. He is a founder of numerous companies, and his awards include the Alan T. Waterman Award (NSF), the Wolf Prize in Chemistry, the Paul Ehrlich Prize, and membership in the National Academy of Sciences and Institute of Medicine.

Lei Wang received both his BS in organic chemistry (1994) and M.S. in physical chemistry (1997) from Peking University, where he conducted research on nanoparticle properties using scanning probe microscopy. From 1997 to 2002, he pursued graduate studies at the University of California, Berkeley under the guidance of Prof. Peter G. Schultz, where he developed a general method for genetically introducing unnatural amino acids into proteins in live cells. He is currently a postdoctoral fellow in Prof. Roger Y. Tsien's group at the University of California, San Diego.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

labels (Figure 2 f) and environmentally sensitive fluorophores have also been conjugated to various proteins through the Cys residue to probe side-chain dynamics and backbone fluctuations.[28–30] Recently, it was shown that biarsenical ligands (FlAsH and ReAsH) can selectively bind to a tetracysteine motif Cys-Cys-Pro-Gly-Cys-Cys in proteins with high affinity and specificity (Figure 2 g).[31,32] The fluorescence of the biarsenical dyes is greatly enhanced after binding to the target site, thus making possible the selective introduction of a fluorophore into proteins in cells.

Another chemical method that has been used to selectively modify proteins involves the oxidation of N-terminal Ser or Thr residues with periodate to form an aldehyde, which can subsequently react with hydrazide or aminooxy groups to form stable conjugates. In one application the reaction of aminoxypentane with the N-terminal aldehyde group of the β-chemokine RANTES yielded a potent inhibitor of HIV-1 infection.[33] Similar chemistry has been used to selectively couple biotin and fluorescent reporters to the N-termini of peptides and proteins,[34] and for the chemoselective ligation of peptides (see Section 2.3).

Chemical modification is clearly a useful method for altering protein properties, including the synthesis of therapeutic proteins conjugated to polyethylene glycol (PEG; for example, Neulasta, PEG-Intron). Nonetheless, this approach relies on the unique reactivity of an amino acid side chain. Thus, the intrinsic selectivity and overall efficiency of the approach is limited.

2.2. Chemical Synthesis

Stepwise solid-phase peptide synthesis (SPPS),[35] pioneered by Merrifield in 1963, has greatly facilitated the synthesis of peptides and small proteins (< 100 amino acids) containing unnatural amino acids.[36] Examples include the substitution of a pyridoxamine phosphate derivative for Phe 8 of the C-peptide to afford a ribonuclease S with transaminase activity,[37] and the incorporation of iminodiacetic acid into the S-peptide which allows the activity of RNase S to be switched on/off by addition of Fe^{III} ions.[38] In other examples, D-amino acids and arginine analogues have been incorporated into luteinizing hormone-releasing hormone to improve affinity,[39–41] and Leu and Val were replaced with their fluorinated analogues (5,5,5-trifluoroleucine and 4,4,4-trifluorovaline, respectively) in the coiled-coil region of the yeast transcription factor GCN4 to increase protein stability.[42] In addition, unnatural amino acids bearing olefinic side chains have been inserted into the C-peptide of RNase A to form cyclic peptides by subsequent metathesis reactions, which resulted in increased resistance to proteases,[43] and 5,5-dimethylproline was substituted for Pro 93 in RNase A to lock the peptide bond into a *cis* conformation as a probe of protein folding.[44]

To overcome the size limitations of SPPS, efficient strategies have been developed to ligate synthetic peptides together to make larger proteins,[45] including a chemoenzymatic strategy[46] (see Section 2.3) and chemical ligation.[47] The latter process takes advantage of chemoselective coupling reactions (for example, thioester,[47] oxime,[48] thiazolidine/oxazolidine,[49,50] thioether,[51] and disulfide[52] bond formation) of unique functional groups incorporated into peptides (Figure 3). Template molecules have also been used to bring together the respective C- and N-termini of the two peptide fragments, thus enabling formation of an amide bond by intramolecular acyl transfer reactions (Figure 3 c).[53] An ingenious strategy termed "native chemical ligation" obviates the need for such a template and allows the direct coupling of peptide fragments to form a native peptide linkage (Figure 3 d).[54,55] In this method, a peptide with an α-thioester at its C-terminus is first ligated to a second peptide with an N-terminal Cys residue through a transthioesterification reaction. The thioester-linked intermediate then undergoes an irreversible S→N acyl rearrangement to form a native peptide bond at the ligation site. This method typically requires an N-terminal Cys residue at the ligation site, but recently it has been shown that an auxiliary sulfhydryl group can be used which is removed after ligation, thus making ligation possible at a non-Cys residue.[56] Native chemical ligation can be routinely used for the preparation of polypeptides comprising over 100 amino acid residues in length.

The emergence of chemical ligation methods has made it possible to incorporate unnatural amino acids into larger proteins. For example, an HIV-1 protease analogue was synthesized in which the amide CONH linkage between Gly 49 and Ile 50 was replaced with a COS linkage by thioester ligation to probe the contribution of this backbone hydrogen bond to catalytic activity.[57] In other studies native chemical ligation has been used to replace Tyr 10 of rubredoxin with tyrosine analogues to modulate the redox properties of this protein,[58] to modify erythropoietin with carbohydrate analogues,[59] and to incorporate fluorophores into chymotrypsin inhibitor 2 for single-molecule studies of protein folding.[60] Intramolecular native chemical ligation has also been used to create cyclic peptides and proteins.[61–63]

Chemical synthesis allows a large variety of unnatural amino acids to be incorporated into peptides and proteins. It is particularly useful for the incorporation of amino acid analogues that are toxic to cells or incompatible with the translational machinery (for example, the synthesis of an all D-amino acid protein[64,65]). Chemical synthesis also allows isotopic labels (for example, ^{2}H-, ^{13}C-, or ^{15}N-labeled amino acids) to be inserted into proteins at specific locations for spectroscopic studies. On the other hand, chemical synthesis can be problematic with peptides or proteins that have poor solubility, and becomes tedious, low yielding, and expensive when applied to larger proteins.

2.3. Semisynthesis

An alternative approach to the generation of larger proteins containing unnatural amino acids involves semisynthesis in which synthetic peptides are ligated to a truncated native protein generated by chemical cleavage, proteolysis, or recombinant methods.[66,67] In comparison to SPPS, much larger peptide fragments can be recombinantly expressed or

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

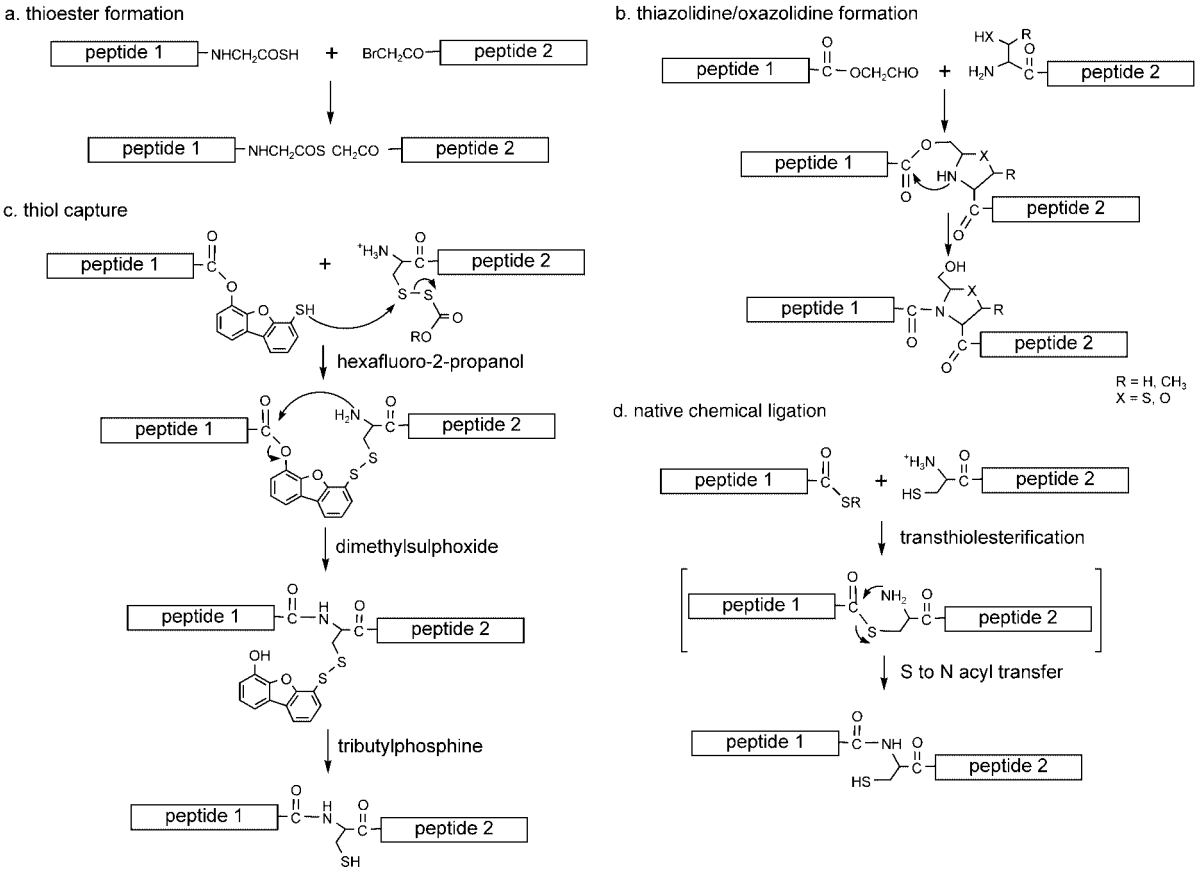

Figure 3. Examples of chemoselective reactions for peptide ligation.

derived from natural proteins, thus allowing access to larger proteins. One such semisynthetic method is based on the autocatalytic re-ligation of peptide fragments generated by cyanogen bromide (CNBr) cleavage of proteins, a phenomenon first noted by Dyckes et al. in 1974.[68] CNBr cleavage results in a C-terminal homoserine lactone, which reacts with a free N-terminus to reform the full-length protein. This approach has been used to insert a number of unnatural amino acids into cytochrome *c*.[69–71]

Enzyme-assisted peptide ligation has also been used for protein semisynthesis.[72] Peptide hydrolysis catalyzed by proteases can be reversed by altering the reaction conditions to favor aminolysis over hydrolysis,[73–76] for example, by adding organic cosolvents to suppress ionization of the α-carboxylic acid group. Alternatively, a peptide with a C-terminal ester can be condensed with the N-terminal amino group of a second peptide to form a ligated protein. Such methods have been used, for example, to incorporate D-Ala into human growth hormone releasing factor to increase protease resistance.[77,78] A significant improvement to this method involves the use of a mutant protease which has decreased hydrolytic activity but can still catalyze amide-bond formation with a C-terminal ester.[79] Kaiser and co-workers were the first to use a subtilisin mutant with a Ser→Cys mutation in the active site[9,10] for peptide ligation.[79] This mutant was further improved by Wells and co-workers to generate a subtiligase, a subtilisin double mutant (Ser221→Cys and Pro225→Ala) that has tenfold higher peptide ligase activity than thiosubtilisin.[80] Subtiligase has been used to assemble a mutant RNase A in which the active-site residues His12 and His119 were independently replaced with 4-fluorohistidine.[46] Similar approaches have also been used to incorporate biotin, heavy atoms, and polyethylene glycol into proteins.[81]

Chemoselective ligation can also be used in semisynthesis as long as an orthogonal functional group can be conveniently included at the terminus of the recombinant peptide. For example, Rose and co-workers enzymatically coupled a hydrazide to the C-terminus of a peptide fragment from human granulocyte colony-stimulating factor (G-CSF), and chemically generated an N-terminal aldehyde on the complementary peptide fragment through oxidation with periodate.[82] These two peptides spontaneously re-ligate to form a G-CSF mutant with a hydrazone linkage.

A technique termed expressed protein ligation (EPL) has greatly facilitated the use of native chemical ligation in protein semisynthesis by generating a recombinant protein with a C-terminal α-thioester for subsequent chemical ligation with a second peptide (Figure 4).[83–86] The C-terminal thioester intermediate is generated from an intein-mediated protein-splicing reaction in which a mutation in the intein blocks the final splicing step. In EPL, a recombinant protein is expressed in-frame with the mutant intein, and exogenous thiol is added to cleave the recombinant protein from the

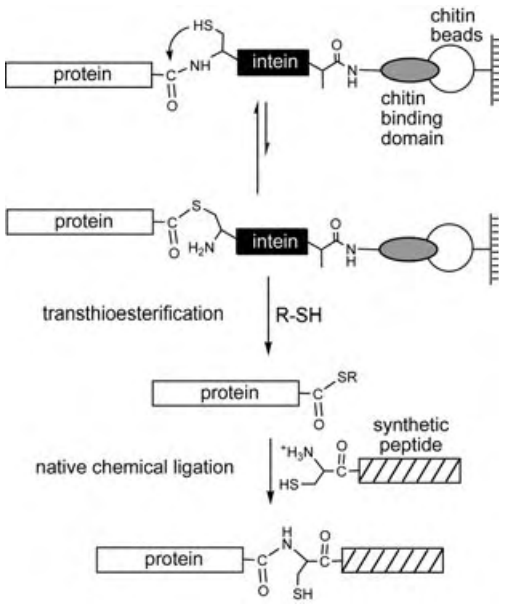

Figure 4. Expressed protein ligation.

partially rearranged splicing intermediate. The resulting α-thioester derivative can subsequently react with an N-terminal Cys peptide (prepared synthetically or enzymatically) to afford the semisynthetic product.[87–89] In addition to an N-terminal cysteine residue, N-terminal homocysteine[90,91] and selenocysteine[92–94] can also be used in native chemical ligation and EPL, thus resulting in the selective incorporation of these amino acids into the semisynthetic protein at the ligation site.

EPL can be used to incorporate fluorophores into the C-terminus,[83,95,96] middle,[97,98] or N-terminus[88] of proteins. In an elegant experiment Muir and co-workers introduced both tetramethylrhodamine and fluorescein into c-Crk-II (a substrate of the Abelson nonreceptor protein tyrosine kinase, c-Abl) to monitor the phosphorylation of c-Crk-II by c-Abl through fluorescence resonance energy transfer (FRET).[99,100] FRET pairs have also been introduced by EPL and/or Cys labeling into different components of the RNA polymerase holoenzyme and RNA polymerase-promoter open complex of *E. coli*.[101,102] In another application, a synthetic fragment of eglin which contained either kynurenine or norvaline at position 25 was ligated to a complementary peptide displayed on phage in which two residues making van der Waals contacts with residue 25 were randomized.[103] After ligation, phage-bearing mutant folded eglins were isolated that accommodate the unnatural side chains in the hydrophobic core. EPL has also been used to introduce posttranslational modifications (for example, glycosylated[104,105] and lipidated amino acids,[106] as well as analogues of phosphorylated amino acids[107–109]) selectively into proteins to study their effects on protein structure and function. Mutations to the protein backbone have also been generated with EPL. For example, Raines and co-workers replaced the Asn 113–Pro 114 residues of RNase A with a reverse-turn mimic composed of the two β-amino acid residues (*R*)-nipecotic acid–(*S*)-nipecotic acid[110] to generate a mutant RNase with the same ribonucleolytic activity as the wild-type enzyme and enhanced thermal stability.

Semisynthesis methods are quite powerful and allow access to larger proteins than does chemical synthesis. The method does, however, require appropriate sites for cleavage and ligation, and becomes cumbersome for internal sites in large proteins or when large amounts of proteins are required. In addition, all of the chemical methods described above are not easily applied to in vivo studies of protein structure and function.

3. In Vitro Biosynthetic Approaches to Protein Mutagenesis

3.1. Methodology

A variety of in vitro (cell-free) methods have been developed to incorporate unnatural amino acids into proteins by using the existing protein biosynthetic machinery of the cell. These methods take advantage of the fact that anticodon–codon recognition between messenger RNA (mRNA) and transfer RNA (tRNA) is largely independent of the structure of the amino acid linked to the 3′-terminus of the acceptor stem of the tRNA. This "adaptor hypothesis"[111,112] was elegantly demonstrated by showing that a cysteinyl-$tRNA^{Cys}$, when converted into an alanyl-$tRNA^{Cys}$ by treatment with H_2/Raney nickel, efficiently incorporates alanine into a polypeptide chain in vitro in response to the cysteine codon UGU.[112] These experiments were extended to derivatives of other common amino acids by the chemical modification of enzymatically aminoacylated tRNAs with synthetic reagents and probes. For example, treatment of Lys-$tRNA^{Lys}$ with *N*-acetoxysuccinimide affords (N^{ε}-acetyl-Lys)-$tRNA^{Lys}$, which can be used to insert N^{ε}-acetyl-Lys into proteins in a cell-free rabbit reticulocyte system.[113] Unfortunately, these methods lead to incorporation of the modified amino acid at all sites in a protein specified by the codon for the modified tRNA. The derivatized amino acid is also inserted in competition with the underivatized amino acid thus leading to heterogeneous protein product. In addition, substitutions are limited to derivatives of the common amino acids which can be generated under reactive conditions that do not hydrolyze the labile aminoacyl ester linkage between the terminal 3′-adenosine group and the amino acid, and do not chemically inactivate the tRNA.

Extension of this approach to a larger variety of amino acids required more general methods for the selective aminoacylation of tRNAs. Misaminoacylation of the tRNA with unnatural amino acids using aminoacyl-tRNA synthetases is problematic because of the high specificity of these enzymes.[114,115] Direct chemical acylation of the tRNA is not practical because of the large number of reactive sites in the tRNA. Consequently, semisynthetic methods were developed in which truncated tRNAs (with the 3′-terminal mono- or dinucleotide removed) are enzymatically ligated to chemically aminoacylated mono- and dinucleotides. For example, Hecht and co-workers developed an approach in which the dinucleotide pCpA is chemically acylated with an N^{α}-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

protected amino acid and then enzymatically ligated to a truncated tRNA ($tRNA^{-CA}$, which is missing the terminal dinucleotide pCpA at the 3′-acceptor stem) with RNA ligase.[116] A number of unnatural amino acids were incorporated into the first position of dipeptides by this method.[117–119] However, this approach suffered a number of limitations: yields of the aminoacylation reaction were quite poor and the N-terminal protecting group of the amino acid could not be efficiently removed without hydrolysis of the aminoacyl ester, thereby limiting substitution to P-site donors and, consequently, the peptide N-terminus (Figure 5). Later,

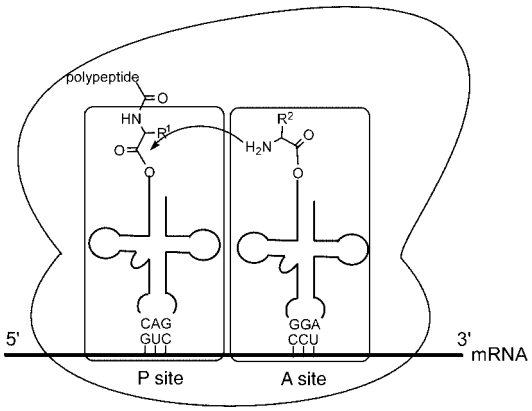

Figure 5. Schematic representation of ribosome and its P site and A site.

Brunner and co-workers developed a method to prepare a fully deprotected aminoacyl-pCpA and ligate it to the truncated tRNA to afford an aminoacyl tRNA which could be used as an A-site donor.[120] Nonetheless, the yields for the synthesis of the acylated dinucleotide were again poor. This method also does not overcome the above limitations associated with use of an endogenous *E. coli* tRNA for delivery of an amino acid including competition with host amino acids and multisite incorporation. Nonetheless, experiments with chemically aminoacylated tRNAs suggested that the natural translational machinery can accept a wide range of unnatural amino acid side chains.

A general in vitro method which allows the site-specific incorporation of a large number of unnatural amino acids into proteins with excellent translational fidelity was reported by us in 1989 (Figure 6).[121] This approach takes advantage of the degeneracy of the three stop codons UAA, UAG, and UGA (termed nonsense codons). These codons do not encode amino acids, but rather signal termination of polypeptide synthesis by binding release factors.[122,123] Since only one stop codon is required for the termination of protein synthesis, two "blank" codons exist in the genetic code which can be used to uniquely specify an unnatural amino acid. Indeed, nonsense suppressor tRNAs (tRNAs that insert one of the common amino acids in response to a stop codon) have been shown to incorporate a number of common amino acids efficiently into proteins both in vivo and in vitro.[124,125] In particular, experiments using [^{3}H]Phe, and later experiments with α-hydroxy

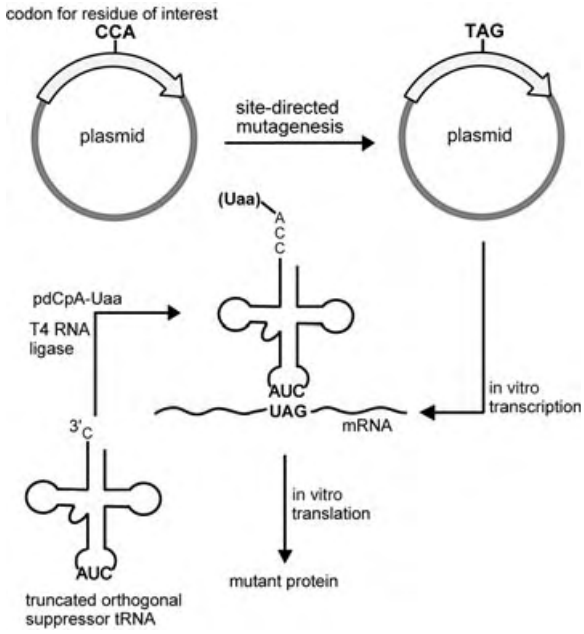

Figure 6. An in vitro biosynthetic method for the site-specific incorporation of unnatural amino acids into proteins. Uaa = unnatural amino acid.

acids, demonstrated that the desired amino acid could be selectively incorporated at the position specified by UAG in an in vitro translation system.[121,126]

Another requirement for the selective incorporation of unnatural amino acids into proteins is a tRNA that uniquely recognizes this blank codon and efficiently incorporates its cognate amino acid into the growing polypeptide chain. Importantly, this tRNA must be orthogonal to the endogenous aminoacyl-tRNA synthetases of the host organism from which the in vitro translation system is derived, that is, it must not be a substrate for any of the aminoacyl-tRNA synthetases present in the in vitro protein-synthesis extract. If the suppressor tRNA were recognized by an endogenous aminoacyl-tRNA synthetase, the tRNA could be subject to proofreading (deacylation of the noncognate amino acid) and/or re-aminoacylation with the cognate amino acid. This would result in either low suppression efficiency or the incorporation of a common amino acid in competition with the desired unnatural amino acid in response to the nonsense codon.

An orthogonal amber suppressor tRNA derived from yeast phenylalanine-tRNA ($tRNA^{Phe}_{CUA}$) was constructed for use in an *E. coli* in vitro protein transcription–translation system.[125,127–130] In this tRNA nucleotides 34–37 in the anticodon loop were replaced by 5′-CUAA-3′ to create an efficient suppressor tRNA. Runoff transcription provided a functional suppressor tRNA in relatively large quantities.[131,132] A modification of the two-step method originally developed by Hecht and co-workers[116] was developed to efficiently aminoacylate the orthogonal tRNA. It was found that the cyanomethyl ester of an N^{α}-protected amino acid selectively monoacylates the 2′,3′-hydroxy groups of the dinucleotide to give the desired aminoacylated product in

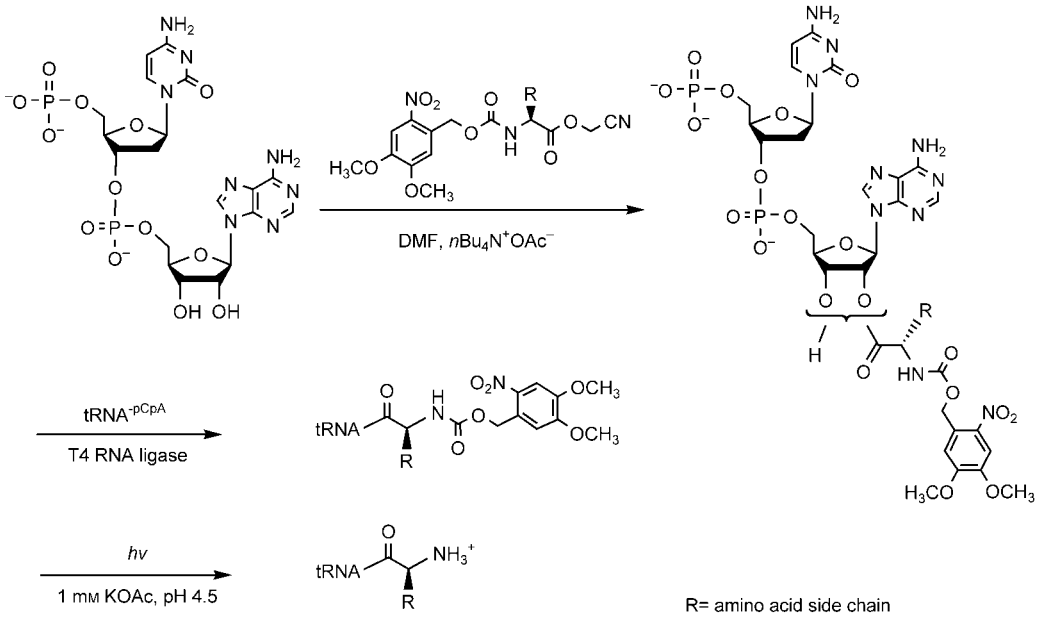

Figure 7. Strategy for the chemical aminoacylation of $tRNA^{Phe}_{CUA}$ using an amino acid cyanomethyl ester protected with a photochemically removable group.

high yield, thereby obviating the need to protect and deprotect the dinucleotide (Figure 7).[133] Replacement of cytidine with deoxycytidine in pCpA simplified the synthesis and eliminated another reactive 2′-OH group without affecting biological activity. The α-amino group of the amino acid and any reactive side-chain groups are protected as their nitroveratryloxy carbamate, ester, or ether derivatives prior to acylation of the dinucleotide.[134,135] These protecting groups can be removed photochemically from the intact aminoacyl-tRNA (after ligation) in high yield under mildly acidic conditions which prevent deacylation of the aminoacyl-tRNA.[133] This aminoacylation protocol is relatively straightforward, proceeds in high yield (both the aminoacylation and ligation reactions), and has been used to incorporate a wide variety of unnatural amino acids into proteins.[136]

The first demonstration of this general approach for the site-specific incorporation of unnatural amino acids into a protein in vitro involved the generation of mutant β-lactamases containing *p*-nitrophenylalanine, *p*-fluorophenylalanine, or homophenylalanine substitutions at Phe66.[121] Mutagenesis with the chemically acylated suppressor tRNA was carried out with an *E. coli* in vitro transcription–translation system consisting of an *E. coli* S-30 extract that contains all of the factors required for transcription and translation, and plasmid DNA containing the gene of interest with a TAG amber codon encoding the unnatural amino acid. Although relatively small quantities of purified protein were obtained (typical yields are 5–30 μg protein per mL), the specificity and fidelity of incorporation were shown to be very high by peptide mapping experiments. Shortly thereafter, a similar approach was reported by Chamberlin and co-workers, in which a suppressor tRNA derived from *E. coli* $tRNA^{Gly}$ was used to incorporate [^{125}I]Tyr site-selectively into a 16-mer peptide.[137]

Over 50 different amino acids and analogues have been incorporated site-specifically into proteins with high fidelity by the above methodology.[136] These include conformationally restricted amino acids (for example, methanoproline, cyclopropylglycine, and α-methyl-L-leucine), amino acids with spin labels and photoaffinity labels as side chains, amino acids with altered acidities and hydrogen-bonding properties, photocaged amino acids, α-hydroxy acids, and amino acids with unusual steric properties (for example, *tert*-butylglycine).

3.2. Applications

In vitro methods for unnatural amino acid mutagenesis have been applied to a large number of problems in protein chemistry, including protein folding, enzyme mechanism, and signal transduction. In addition, this methodology has been used to introduce a variety of biophysical probes into proteins.[138] For example, to determine the degree to which side-chain hydrogen bonding stabilizes the folded state of proteins, Tyr27 in staphylococcal nuclease (SNase) was substituted with several fluorinated tyrosine analogues (Figure 8a).[139] Denaturation studies of the corresponding mutants revealed a free-energy correlation between stability constant K_{app} and the pK_a value of the Tyr27 hydroxy group (Figure 8b), thus providing strong evidence that intramolecular hydrogen bonds between side chains can preferentially stabilize the folded state of a protein relative to the unfolded state in water. To determine the contribution of the main-chain hydrogen bonds to protein stability, several backbone amide linkages in α-helix 39–50 of T4 lysozyme were replaced with ester linkages by incorporating α-hydroxy acids at the N-terminus, the middle, and C-terminus of the helix, respec-

tively (Figure 9a).[140] The ester group is a conservative replacement for an amide group since both esters and amides are isosteric and exist mainly in the *trans* conformation.[141] These mutations effectively substitute a good hydrogen-bond acceptor (the amide carbonyl group) with a considerably weaker hydrogen-bond acceptor (the ester carbonyl group).[142] It was found that at the N- and C-terminal positions, where only one hydrogen-bonding interaction is perturbed, the ester substitution destabilizes the protein by 0.9 and 0.7 kcal mol^{-1}, respectively. Introduction of ester linkage in the middle of the helix, where two hydrogen-bonding interactions were altered, destabilizes the protein by 1.7 kcal mol^{-1}. Similarly, amide to ester substitutions introduced in antiparallel β sheets were found to decrease the stability by 1.5–2.5 kcal mol^{-1} (Figure 9b).[143] These results provide evidence that backbone hydrogen-bonding interactions involving the amide groups, like side-chain hydrogen bonds, contribute significantly to protein stability.

3.3. Extensions and Improvements of Methodology

A number of improvements have been made to increase the levels of in vitro protein expression. For example, an *E. coli* tRNA^{Asn}-derived suppressor led to a significant improvement in suppression efficiency relative to the yeast $tRNA^{Phe}_{CUA}$ for incorporation of polar unnatural amino acids in the *E. coli* in vitro system.[144] Mild heating of an S-30 extract derived from an *E. coli* release factor 1 (RF1) temperature-sensitive strain increased UAG suppression by decreasing the competition between RF1 and the suppressor tRNA for the amber stop codon.[145] Optimization of the preparation and composition of the *E. coli* S-30 extract, as well as removal of inhibitory by-products generated during the translation reaction, also greatly improved yields of the protein.[146]

Efforts have also focused on encoding unnatural amino acids with codons other than nonsense codons. For example, the rare arginine codon AGG has been used to direct the incorporation of several phenylalanine analogues into a polypeptide using a chemically aminoacylated $tRNA^{Ile}_{CCU}$.[147] In this case, the naturally occurring cognate tRNA, although present in minor amounts, competes with the synthetic tRNA to incorporate Arg and generate heterogeneous full-length protein (in contrast to truncated protein in the case of the nonsense codon). In the case of the rare AGG codon, lowering the arginine concentration in the in vitro protein synthesis reaction mixture decreased such competition.[148] Some organisms do not use all of the triplet codons; these noncoding codons can be used to specify additional amino acids. For example, the unassigned codon AGA in *Micrococcus luteus* has been used to insert Phe in an in vitro transcription/translation extract from *M. luteus*.[149] Recently, a purified in vitro translation system consisting of only ribosomes, initiation factors, and elongation factors was used to simultaneously incorporate several unnatural amino acids into peptides in response to sense codons.[150] If the efficiency can be improved, this system may ultimately allow the synthesis of peptides and proteins containing multiple unnatural amino acids.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Frameshift suppression of four-base codons can also be used to introduce unnatural amino acids into proteins in vitro. The proper reading frame is maintained only when the extended codon is translated by the suppressor tRNA to afford a full-length protein containing the unnatural amino acid; translation of the triplet codon by an endogenous tRNA results in frameshifting and premature termination. To reduce this competition, the first three nucleotides in most extended codons correspond to either stop or rare codons. In one example, Sisido and co-workers replaced the anticodon of the yeast $tRNA^{Phe}$ with different four-base anticodons, and incorporated a variety of phenylalanine analogues into streptavidin with an in vitro *E. coli* translation system.[151–156] By using two chemically aminoacylated frameshift suppressor tRNAs that recognize either CGGG or AGGU, they were able to simultaneously incorporate 2-naphthylalanine and a 7-amino-4-nitrobenz-2-oxa-1,3-diazole (NBD) derivative of lysine into streptavidin, although the efficiency was quite low (9%).[157] Incorporation efficiency was improved to 64% when efficient four-base codons (CGGG and GGGU) were used.[158] A five-base CGGUA-UACCG codon-anticodon pair was also shown to direct incorporation of unnatural amino acids into streptavidin.[159]

A codon–anticodon pair containing unnatural bases (iso-C)AG-CU(iso-dG) has been used to incorporate iodotyrosine into a short peptide with the rabbit reticulocyte lysate.[160] This study convincingly showed that the ribosome tolerates nucleotides with unnatural bases, and that iso-C and iso-dG can direct translation with reasonable efficiency. However, the mRNA and tRNA containing iso-C and iso-dG must be chemically synthesized, thus making this method impractical for most applications.

Unnatural amino acid mutagenesis has been extended to *Xenopus* oocytes by microinjection of the mutant mRNA and a chemically aminoacylated yeast $tRNA^{Phe}$-derived amber suppressor (Figure 10).[161] The translational machinery of the oocyte inserts the unnatural amino acid at the position specified by UAG. Later, an amber suppressor derived from *Tetrahymena thermophila* $tRNA^{Gln}$ was found to improve the efficiency and fidelity of unnatural amino acid incorporation.[162] This method has been used for structure–function studies of integral membrane proteins, which are generally not amenable to in vitro expression systems.[163,164] For example, fluorinated tryptophan derivatives were incorporated at Trp149 in the binding domain of the nicotinic acetylcholine receptor. A correlation between the receptor activation by acetylcholine (Ach) and the degree of fluorination on tryptophan suggested that the quaternary ammonium center of Ach forms a cation–π interaction with the indole side chain of αTrp149.[165,166] A significant limitation of this method is that the suppressor tRNA has to be chemically aminoacylated with the unnatural amino acid in vitro, and the acylated tRNA is consumed as a stoichiometric reagent during translation and cannot be regenerated. Therefore, yields of proteins are low and highly sensitive techniques, such as patch clamp, are required to characterize the mutant proteins.

The in vitro mutagenesis methodology described above has been used to site-specifically incorporate a large number of unnatural amino acids into various proteins. Mutagenesis studies using unnatural amino acids have provided important insights into protein structure and function. However, the method is technically demanding, the yields of mutant proteins are quite low, and the study of proteins in cells is limited by the need for microinjection and inability to regenerate the aminoacyl tRNA. Moreover, the nature of the amino acid side chain is limited by the aminoacylation chemistry and the stability of the aminoacyl tRNA linkage.

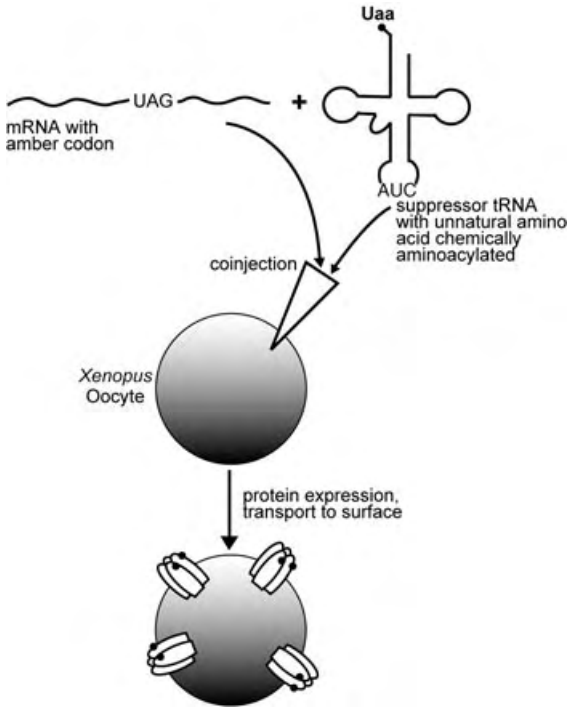

Figure 10. Microinjection of chemically aminoacylated tRNA and mutant mRNA into *Xenopus* oocytes.

4. In Vivo Protein Mutagenesis

The ability to incorporate unnatural amino acids directly into proteins in vivo has several advantages over in vitro methods including high yields of mutant proteins, technical ease, and the potential to study proteins in cells or multicellular organisms. The latter can be accomplished either by substitution of one of the common 20 amino acids with an unnatural amino acid, or by augmenting the genetic code of the host organims with a "21st" unnatural amino acid. In the former case, the unnatural amino acid typically replaces the common amino acid throughout a protein (and the proteome), often in competition with a common amino acid, and results in heterogeneous proteins. In the second approach, unnatural amino acids are *added* to the genetic repertoire without deletion of a common amino acid, thus resulting in an expanded genetic code and the ability to produce proteins consisting of more than 20 building blocks.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

4.1. Site-Directed Mutagenesis

The development of site-directed mutagenesis by Smith and co-workers provided a powerful in vivo method to substitute amino acids in proteins with any of the other common 20 amino acids.[167] Amino acid substitutions are generated by mutating the codon for the amino acid of interest to a codon encoding the desired mutant. This method has dramatically expanded our ability to manipulate protein structure and probe protein structure–function relationships. Notable early examples included studies of β-lactamase,[168,169] tyrosyl-tRNA synthetase (TyrRS),[170] dihydrofolate reductase,[171] trypsin,[172] and subtilisin.[173] Mutagenesis studies of *Bacillus stearothermophilus* TyrRS by the Fersht research group were used to quantify the contributions of various amino acid side chains to the binding of substrates, intermediates, and transition states along the reaction pathway of this enzyme.[174] In other examples, replacement of the complementarity-determining regions of a human antibody with those of a mouse antibody afforded a humanized antibody with the specificity of the latter;[175] site-directed mutagenesis has also been used to modify the specificity of Zn^{2+} finger proteins.[176–183]

Many variants of site-directed mutagenesis have been developed. For example, cassette mutagenesis allows for the rapid generation of all possible mutations at a single site.[184] Homologue- and alanine-scanning mutagenesis provide valuable information about protein function in the absence of structural data.[185,186] Random mutagenesis by error-prone polymerase chain reaction (PCR) or mutator strains allows for a less biased examination of structure–function relationships over a larger sequence space.[7,187–189] Genetic recombination methods, such as DNA shuffling,[190] a recombinative PCR process akin to molecular breeding, can be used to generate libraries of variants from a pool of parent genes. Desired protein properties can be rapidly evolved from these variants with appropriate selections or screens. All of these methods have greatly accelerated our ability to probe protein structure and function and evolve novel protein properties. Unfortunately, all are also limited to substitutions among the common 20 amino acids.

4.2. The Use of Auxotrophic Bacterial Strains To Incorporate Unnatural Amino Acids

More than 50 years ago it was found that many analogues of the common 20 amino acids inhibit the growth of bacteria.[191–193] This observation led to speculation that these analogues are incorporated into proteins by the protein biosynthetic machinery. To test this possibility, Tarver and co-workers fed rats[194] and *Tetrahymena*[195] with the ^{14}C-labeled methionine analogue ethionine. The detection of radioactivity in the isolated protein and peptides from these organisms strongly suggested that unnatural amino acids could in fact be misincorporated into proteins. To efficiently incorporate analogues of the common 20 amino acids into bacterial proteins, Cohen and co-workers used an auxotrophic bacterial strain that cannot biosynthesize the corresponding common amino acid. Induction of protein expression in media in which this common amino acid is replaced with its analogue results in the accumulation of a mutant protein containing the unnatural amino acid (Figure 11).[196]

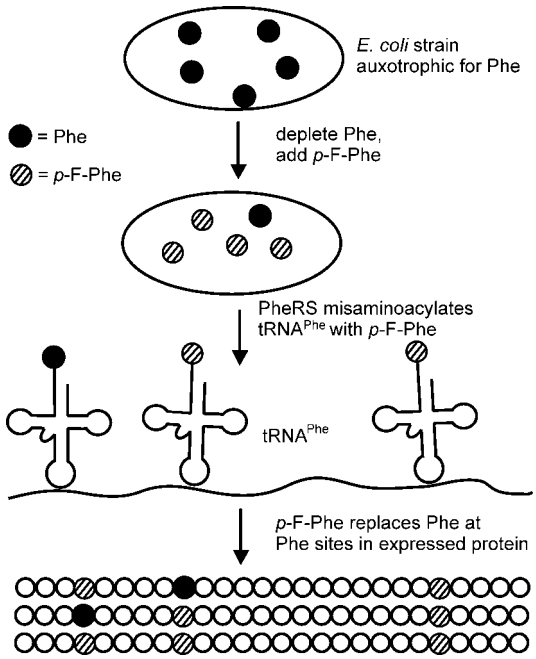

Figure 11. Multiple substitution of phenylalanine by *p*-fluorophenylalanine (*p*-F-Phe) using a phenylalanine auxotrophic strain.

This approach was used to incorporate *p*-fluorophenylalanine into β-galactosidase in an *E. coli* strain auxotrophic for phenylalanine.[196] Fluorophenylalanine was found to partially replace phenylalanine and tyrosine throughout the protein. Selenomethionine was similarly incorporated into β-galactosidase using a methionine auxotroph.[197,198] Over 60 analogues of the common 20 amino acids have subsequently been incorporated into proteins by this method.[193,199] Typical substitutions include replacement of hydrogen with fluorine, methylene with oxygen or sulfur, and ring substitutions. For example, tryptophan has been replaced with tryptazan,[200] arginine with canavanine,[201] methionine with norleucine,[202] leucine with trifluoroleucine,[203] and the phenyl ring of phenylalanine with thioenyl or furyl rings. Most of the early work focused on studies of the effects of amino acid analogues on bacterial growth and protein synthesis and processing.[199] More recently these methods have proven valuable for incorporating NMR and X-ray probes into proteins.

4.2.1. Relaxing the Substrate Specificity of Aminoacyl-tRNA Synthetases

Incorporation of amino acid analogues by the above approach relies on the promiscuity of aminoacyl-tRNA synthetases. However, these enzymes have very high substrate specificity to insure high fidelity in protein translation, which limits substitutions to close structural analogues of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

common 20 amino acids. For example, although thiaproline can be incorporated quantitatively into proteins, oxaproline and selenaproline cannot.[204] To overcome this limitation, a number of research groups have attempted to relax the substrate specificity of the aminoacyl-tRNA synthetases. Hennecke and co-workers first reported that replacement of Ala294 with Gly in *E. coli* phenylalanyl-tRNA synthetase (PheRS) increases the size of the substrate binding pocket and results in the acylation of $tRNA^{Phe}$ with *p*-chlorophenylalanine (*p*-Cl-Phe).[205] An *E. coli* strain harboring this mutant PheRS allows the substitution of phenylalanine with *p*-Cl-Phe.[206] Tirrell and co-workers later used this mutant synthetase to incorporate *p*-bromo-, *p*-iodo-, *p*-cyano-, *p*-ethynyl-, and *p*-azidophenylalanine as well as pyridylalanine.[207,208] Similarly, a point mutation (Phe130→Ser) near the amino acid binding site of *E. coli* tyrosyl-tRNA synthetase allows azatyrosine to be incorporated more efficiently than tyrosine.[209] In these cases, the isolated protein typically contains a mixture of both the common and unnatural amino acid at the site of substitution.

4.2.2. Attenuating the Proofreading Activity of Aminoacyl-tRNA Synthetases

The fidelity of tRNA aminoacylation is maintained both by substrate discrimination and by proofreading of noncognate intermediates and products. Therefore, synthetases with impaired proofreading activity can also be used to incorporate unnatural amino acids into proteins by allowing close structural analogues of the cognate amino acid to escape the editing function. This approach was first demonstrated with a valyl-tRNA synthetase (ValRS) from *E. coli* (Figure 12).[210] ValRS can misaminoacylate $tRNA^{Val}$ with Cys, Thr, or aminobutyrate (Abu), but these noncognate amino acids are subsequently hydrolyzed by the editing domain. After random mutagenesis of the *E. coli* chromosome, a mutant ValRS was selected that has a mutation in the editing domain, which causes charging of $tRNA^{Val}$ with Cys. Since Abu sterically resembles Cys (the thiol group of Cys is replaced with a methyl group in Abu), the mutant ValRS also incorporates Abu into proteins when this mutant *E. coli* strain is grown in the presence of Abu. Mass spectrometric analysis shows that about 24% of valine is replaced by Abu at each valine position in the native protein. Tirrell and co-workers subsequently used a Thr252→Tyr252 mutant for the partial incorporation of six leucine analogues into proteins.[211]

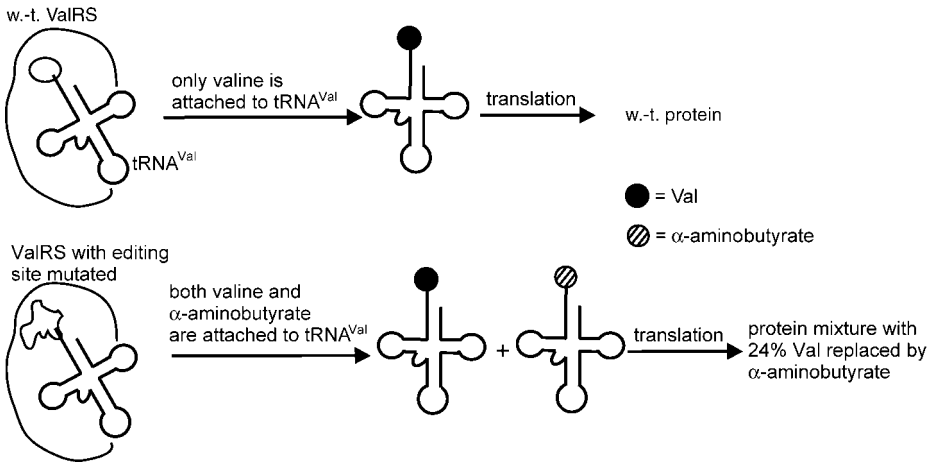

Figure 12. Incorporation of α-aminobutyrate by a ValRS mutant with reduced proofreading activity. w.-t. = wild-type.

4.2.3. Applications

One of the most important applications of the auxotrophic strain method of mutagenesis is the incorporation of amino acid analogues containing heavy atoms for phase determination in X-ray crystallography. Substitution of methionine with selenomethionine is a convenient way to introduce a heavy atom for multiwavelength anomalous diffraction.[212,213] Similarly, telluromethionine[214–216] and β-selenolo[3,2-β]pyrrolylalanine[217] have been incorporated into proteins using methionine and tryptophan auxotrophic *E. coli* strains, respectively.

Isosteric analogues of amino acids have also been incorporated into proteins in *E. coli* to study protein folding, stability, and activity. In one example, norleucine, selenomethionine, and telluromethionine (in which the sulfur atom of methionine is replaced with methylene, Se, and Te, respectively) were incorporated into human annexin V to probe the effects of side-chain packing interactions on protein stability.[218] Similar studies have been carried out with fluorinated amino acids;[219–221] for example, incorporation of trifluoroleucine and hexafluoroleucine in place of leucine resulted in increased thermal and chemical stability of a leucine-zipper protein.[222,223]

Amino acid analogues can also be used as spectroscopic probes. For example, the fluorescence emission maximum and intensity of a barstar mutant containing a tryptophan to aminotryptophan mutation are sensitive to the pH value of the local environment,[224] and replacement of Tyr66 of enhanced cyan fluorescent protein with 4-aminotryptophan significantly red-shifts the emission peak to produce a "gold" fluorescent protein ($\lambda_{max} = 574$ nm).[225] Fluorine-substituted amino acids can be used as NMR probes. For example, fluoromethionine has been substituted for methionine in bacteriophage λ-lysozyme to study ligand binding by ^{19}F NMR spectroscopy,[226–228] and fluorinated tryptophan has been incorporated for ^{19}F NMR studies in cyan fluorescent protein[229] and the chaperone PapD.[230]

Nonproteinogenic functional groups that provide selective handles for further protein modification have also been introduced into proteins by these methods. Examples include the replacement of phenylalanine with electroactive 3-thienylalanine,[231] and the substitution of methionine with alkenes and alkynes.[232–235]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Azidohomoalanine has been incorporated using a methionine auxotrophic strain, and can be selectively modified with triarylphosphine reagents by Staudinger ligation,[236] or with alkyne reagents by a copper(I)-catalyzed cycloaddition reaction.[237] Finally, a computationally designed *E. coli* PheRS mutant was used to partially incorporate *p*-acetylphenylalanine into proteins; the ketone group was subsequently labeled with biotin hydrazide under mild conditions.[238]

Though very useful, the use of auxotrophic strains for mutagenesis has a number of limitations. This method is not site-specific—all sites corresponding to a particular amino acid throughout a protein (and the entire proteome) are replaced with the amino acid analogue. The extent of incorporation of the unnatural amino acid may also vary—only in rare cases can quantitative substitution be achieved since it is difficult to completely deplete the endogenous amino acids inside the cell. Finally, this method is applicable in general only to close structural analogues of the common amino acids, since substitutions must be tolerated both by the synthetase and at all nonpermissive sites in the proteome in which a particular amino acid is incorporated.

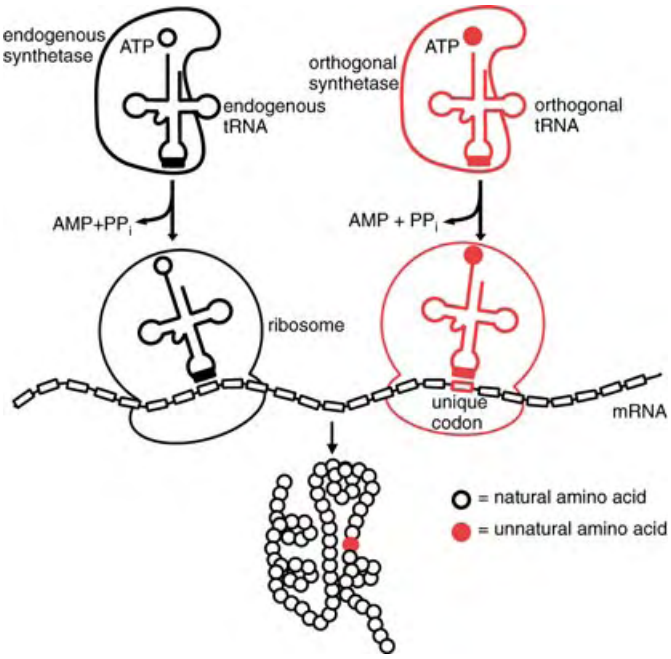

Figure 13. A general approach for the site-specific incorporation of unnatural amino acids into proteins in vivo. PP$_i$ = pyrophosphate.

5. An Expanded Code

Site-directed mutagenesis allows the selective substitution of amino acids in a protein with the other common 20 amino acids. The use of auxotrophic strains allows the substitution of an amino acid with a close structural analogue throughout the proteome, typically in competition with the corresponding common amino acid. Ideally, one would like to be able to carry out the equivalent of site-directed mutagenesis, but with unnatural mino acids. This scenario requires that the unnatural amino acid be genetically encoded by a unique codon in a manner similar to that of the common 20 amino acids.

5.1. Methodology

The "21st" amino acid selenocysteine (Sec) is naturally encoded by an in-frame UGA non-sense codon that is translated by a unique Sec-tRNA^{Sec} (generated by enzymatic modification of seryl-tRNA^{Sec}) in the presence of a special elongation factor and a *cis*-acting element in the mRNA.[4] However, in theory the only requirements to genetically encode unnatural amino acids in vivo are a unique tRNA–codon pair, a corresponding aminoacyl-tRNA synthetase (hereafter referred to as a synthetase), and the unnatural amino acid (Figure 13). The tRNA must be constructed such that it is not recognized by the endogenous aminoacyl-tRNA synthetases of the host, but functions efficiently in translation (an orthogonal tRNA). This tRNA must deliver the novel amino acid in response to a unique codon that does not encode any of the common 20 amino acids. A new aminoacyl-tRNA synthetase (an orthogonal synthetase) is also required that aminoacylates the orthogonal tRNA, but none of the endogenous tRNAs. This synthetase must aminoacylate the tRNA with only the desired unnatural amino acid and no endogenous amino acid. Likewise, the unnatural amino acid cannot be a substrate for the endogenous synthetases. Finally, the amino acid must be efficiently transported into the cytoplasm when added to the growth medium, or biosynthesized by the host.[239]

This potentially general approach to mutagenesis with unnatural amino acids was initially developed using *E. coli*, since it is easily genetically manipulated, has a high transformation efficiency, and many established selections and screens already exist. Initially the amber nonsense codon (UAG) was used to encode the unnatural amino acid since it is the least used of the three stop codons in *E. coli* and *S. cerevisiae*. Moreover, some *E. coli* strains contain natural amber suppressor tRNAs that efficiently incorporate common amino acids without significantly affecting growth rates (most genes essential for normal *E. coli* growth do not end in TAG).[240,241] Amber suppressors can also be engineered, and both natural and engineered amber suppressors have been routinely used for conventional protein mutagenesis in *E. coli*[124,125,242] as well as the in vitro introduction of unnatural amino acids into proteins. In addition, nonsense suppressors have been either identified or generated for use in mammalian cells,[243,244] yeast,[245,246] and *C. elegans*.[247,248] Therefore, it should be possible to use UAG or UGA for the incorporation of unnatural amino acids into proteins in a variety of organisms without adverse effects on the growth of the host organism.

Our initial attempts to generate an orthogonal amber suppressor tRNA/synthetase pair involved modifying the specificity of an existing *E. coli* tRNA/synthetase pair. Key nucleotides at the tRNA/synthetase interface were mutated to reduce the affinity of the tRNA for its cognate synthetase, while maintaining orthogonality to the other endogenous synthetases. A mutant synthetase was then evolved from the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cognate wild-type synthetase that uniquely recognizes the mutant orthogonal tRNA, but at the same time retains its orthogonality with the endogenous tRNAs in *E. coli*. Based on the X-ray crystal structure of the complex of *E. coli* glutaminyl-tRNA synthetase (GlnRS) and $tRNA_2^{Gln}$,[249] three sites in $tRNA_2^{Gln}$ which make specific contacts with GlnRS were mutated.[250,251] These mutant tRNAs were tested individually in in vitro aminoacylation reactions and in vivo amber codon suppression assays, and an efficient orthogonal amber suppressor tRNA was identified. A library of mutant GlnRSs was then generated and mutants were selected based on their ability to aminoacylate the orthogonal tRNA. Although mutant *E. coli* GlnRSs were evolved that charge the orthogonal tRNA, the best mutant aminoacylates the orthogonal tRNA at approximately 10% the rate of wild-type $tRNA^{Gln}$. An ideal orthogonal synthetase should not acylate any endogenous *E. coli* tRNAs, since even modest misacylation of a wild-type tRNA with an unnatural amino acid will result in misincorporation of the unnatural amino acid at other sites in the protein. The inability to generate an orthogonal glutaminyl tRNA/synthetase pair, together with the finding that mutations within the tRNA interact in complicated, non-additive ways,[250] prompted us to examine alternative strategies.

A second approach to the generation of an orthogonal tRNA/synthetase pair involves the use of a heterologous tRNA/synthetase pair from another organism in *E. coli*. This approach is based on the observation that some prokaryotic tRNA/synthetase pairs do not cross-react to any significant degree with their eukaryotic counterparts, as a result of differences in the tRNA identity elements.[127,252] For example, it has been shown that *E. coli* GlnRS lacks the N-terminal RNA-binding domain present in *S. cerevisiae* GlnRS and does not aminoacylate yeast $tRNA^{Gln}$.[253] We therefore tested and found that the yeast amber suppressor $tRNA^{Gln}$ (*Sc* $tRNA^{Gln}_{CUA}$) is also not a substrate for *E. coli* GlnRS, yet functions efficiently in translation in bacteria. Moreover, whereas the yeast GlnRS does not aminoacylate any *E. coli* tRNAs, it does aminoacylate the amber suppressor *Sc* $tRNA^{Gln}_{CUA}$ in vitro.[254] Therefore, the *S. cerevisiae* $tRNA^{Gln}_{CUA}$/GlnRS is an orthogonal pair in *E. coli*. Unfortunately, no mutant yeast GlnRS could be evolved that aminoacylates the orthogonal tRNA with an unnatural amino acid in *E. coli*, possibly because of the low intrinsic activity of the synthetase in bacteria. Yeast tRNA/synthetase pairs specific for various hydrophobic amino acids were also examined,[255] and attention was focused on the $tRNA^{Tyr}$/TyrRS pair, since TyrRS does not have a proofreading function and the prokaryotic and eukaryotic $tRNA^{Tyr}$s have significant differences (Figure 14). Indeed, in vitro studies have shown that $tRNA^{Tyr}$ of *S. cerevisiae* and *H. sapiens* cannot be aminoacylated by bacterial synthetases, nor do their TyrRS aminoacylate bacterial tRNA.[256,257] Unfortunately, in vivo amber codon suppression assays showed that the amber suppressor $tRNA^{Tyr}_{CUA}$ derived from either *S. cerevisiae* or *H. sapiens* is not orthogonal in *E. coli*.[258]

We then focused our attention on archaea as a source of orthogonal tRNA/synthetase pairs for use in *E. coli*. Archaeal aminoacyl-tRNA synthetases are more similar to their eukaryotic than prokaryotic counterparts in terms of homology and tRNA recognition elements.[115] However, unlike synthetases from eukaryotic cells, which are often expressed poorly or have low activities in *E. coli*, synthetases from archaea can be expressed efficiently in *E. coli* in active form. In addition, the availability of more than 16 archaeal genome sequences, together with the absence of introns in their genomes, facilitates the cloning of archaeal synthetase genes. Finally, it has been shown that almost all the tRNAs of *Halobacterium cutirebrum*, an archaeal halophile, cannot be charged by *E. coli* synthetases.[127]

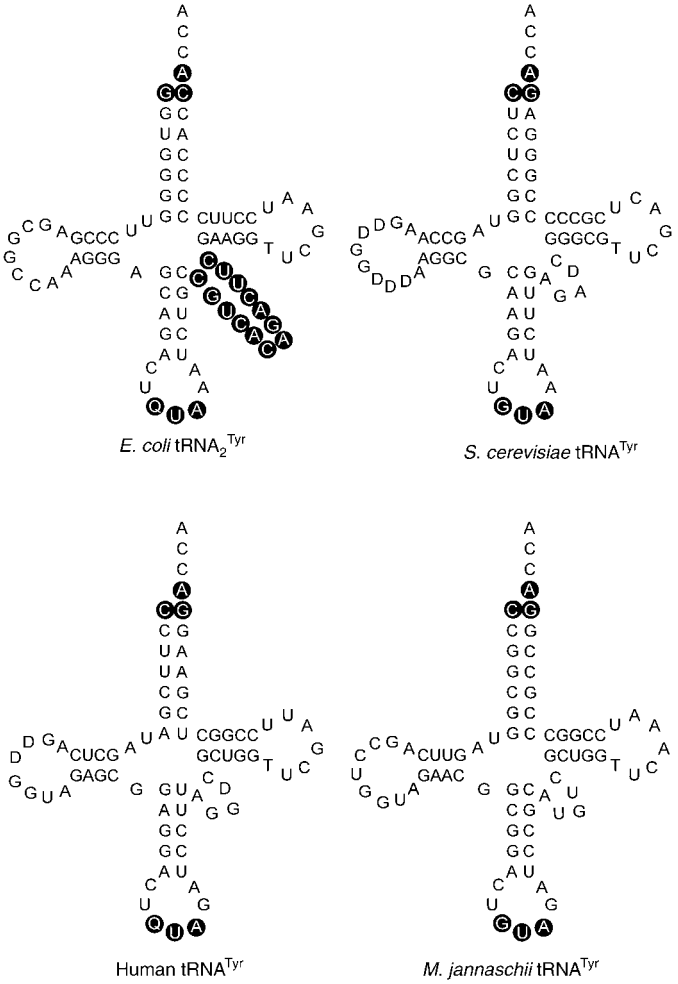

Figure 14. Comparison of $tRNA^{Tyr}$s from different species. Major identity elements are shaded in black. Prokaryotic $tRNA^{Tyr}$ has a long variable arm and a G1:C72 pair, in contrast to the short arm and C1:G72 pair in eukaryotic and archaeal $tRNA^{Tyr}$.

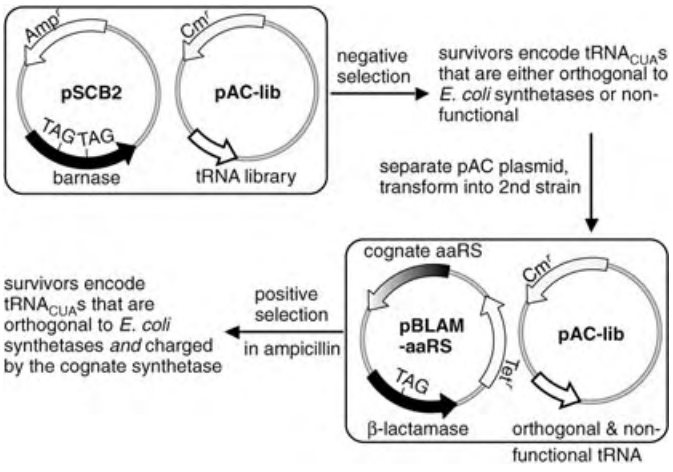
The amber suppressor tyrosyl-tRNA/synthetase pair derived from *Methanococcus jannaschii* was the first orthogonal *E. coli* pair generated from archaea.[258] *M. jannaschii* TyrRS (*Mj*TyrRS) discriminates tRNAs with C1:G72 (an eukaryotic recognition element) from those with G1:C72 (a prokaryotic recognition element), and does not aminoacylate crude tRNA from *E. coli*.[259] In addition, *Mj*TyrRS is missing most of the C-terminal binding domain for the anticodon loop of its $tRNA^{Tyr}$, which suggests that identity elements outside

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the anticodon region are mainly responsible for recognition by TyrRS and the orthogonality of this pair. Mutation of the anticodon loop of this tRNA should therefore have minimal effect on its recognition by other synthetases and its affinity for *Mj*TyrRS. Indeed, when cells expressing a β-lactamase gene with an amber codon at a permissive site are cotransformed with both a suppressor *M. jannaschii* $tRNA^{Tyr}_{CUA}$ ($Mj tRNA^{Tyr}_{CUA}$) and *Mj*TyrRS, they survive in the presence of high concentrations of ampicillin (suppression of the amber mutation results in the production of full-length β-lactamase allowing cells to survive in ampicillin).[258] Unfortunately, while this result shows that the $Mj tRNA^{Tyr}_{CUA}$ is an excellent substrate for *Mj*TyrRS in *E. coli*, we did observe a low but significant level of aminoacylation of this tRNA by endogenous synthetases.

A general strategy for the selection of orthogonal tRNAs in *E. coli* was then developed to further reduce recognition of the $Mj tRNA^{Tyr}_{CUA}$ by endogenous *E. coli* synthetases, while preserving activity with both the cognate synthetase and translational machinery (for example, the ribosomal A site, elongation factor Tu, etc.).[260] This method consists of a combination of negative and positive selections with a mutant suppressor tRNA library in the absence and presence of the cognate synthetase, respectively (Figure 15). In the negative selection, amber nonsense codons are introduced into the barnase gene at sites permissive to substitution by other amino acids. When a member of the suppressor tRNA library is aminoacylated by an endogenous *E. coli* synthetase (that is, it is not orthogonal to the *E. coli* synthetases), the amber codons are suppressed and the ribonuclease barnase is produced, resulting in cell death. Only cells harboring orthogonal or nonfunctional tRNAs can survive. All surviving clones are then subjected to a positive selection in which an amber codon is placed in the β-lactamase gene at a permissive site. tRNAs that are good substrates for the cognate synthetase are selected based on their ability to suppress the amber codon and produce active β-lactamase. Cells harboring nonfunctional tRNAs, or tRNAs that cannot be recognized by their cognate synthetase, will be sensitive to ampicillin. Therefore, only tRNAs that: 1) are not substrates for endogenous *E. coli* synthetases; 2) can be aminoacylated by the synthetase of interest; and 3) function in translation will survive both selections.



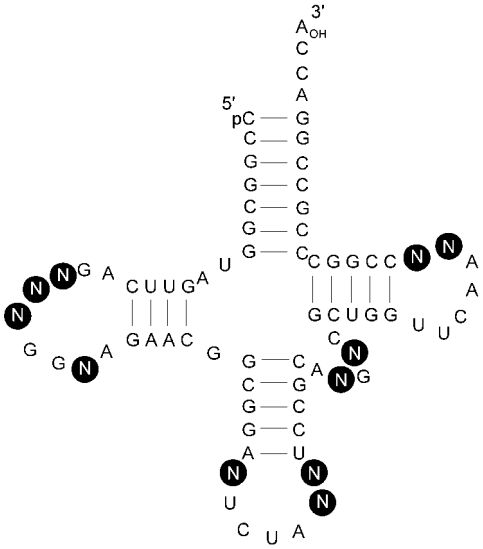


Figure 15. Negative and positive selections used to evolve orthogonal tRNAs.

Eleven nucleotides of the $Mj tRNA^{Tyr}_{CUA}$ that do not interact directly with the *Mj*TyrRS were randomly mutated to generate a suppressor tRNA library (Figure 16). This tRNA

library was passed through rounds of negative and positive selection to afford a mutant tRNA ($mutRNA^{Tyr}_{CUA}$) that suppresses the β-lactamase amber mutant at a level comparable to the background level in *E. coli*, thus indicating that this mutant tRNA is a poorer substrate for *E. coli* synthetases than the wild-type $Mj tRNA^{Tyr}_{CUA}$. When the $mutRNA^{Tyr}_{CUA}$ is coexpressed with *Mj*TyrRS, cells survive at high concentration of ampicillin, which indicates that the tRNA is still aminoacylated by its cognate TyrRS and functions efficiently in translation.[260] The low background and high activity of this $mutRNA^{Tyr}_{CUA}$/*Mj*TyrRS pair make it an excellent orthogonal pair in *E. coli*.

Next the substrate specificity of the orthogonal synthetase was altered so that the cognate orthogonal tRNA is charged with only the desired unnatural amino acid and none of the common 20 amino acids. Amino acid promiscuity in the orthogonal synthetase will result in proteins with a mixture of common and unnatural amino acids at the site of mutation. For example, in an attempt to site-specifically incorporate *p*-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fluorophenylalanine (*p*-F-Phe) into proteins, a yeast amber suppressor $tRNA^{Phe}_{CUA}$/PheRS pair was introduced into an *E. coli* strain auxotrophic for Phe and unable to utilize *p*-F-Phe.[261] Since yeast PheRS aminoacylates its cognate tRNA with both Phe and *p*-F-Phe, 64–75% *p*-F-Phe is incorporated at the site of mutation; the remainder is Phe and Lys (even in the presence of an excess of *p*-F-Phe added to the growth media). Moreover, 7% *p*-F-Phe is found at sites encoded by the Phe codon, which indicates that the endogenous *E. coli* PheRS incorporates *p*-F-Phe in addition to Phe.

We have developed a systematic and general approach to evolve mutant synthetases that selectively aminoacylate their cognate orthogonal tRNA with unnatural amino acids.[262] Based on the crystal structure of the homologous TyrRS from *Bacillus stearothermophilus*, five residues (Tyr32, Asn123, Asp158, Ile159, and Leu162) in the active site of *M. jannaschii* TyrRS that are within 6.5 Å of the *para* position of the aryl ring of bound tyrosine were randomized to all possible common amino acids (Figure 17). These residues

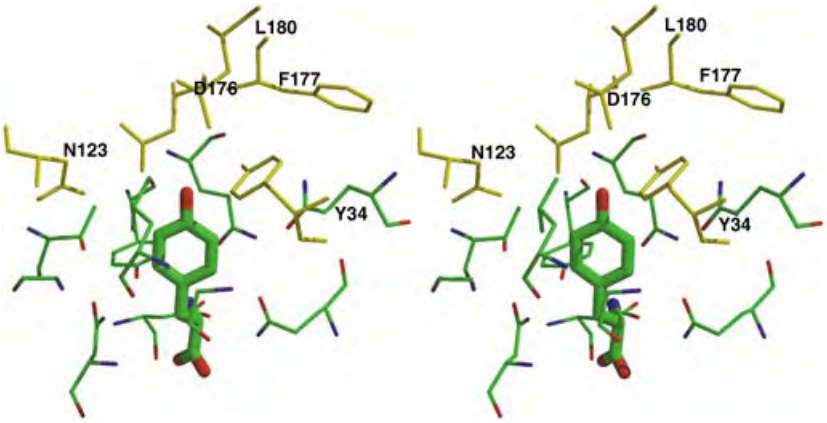

Figure 17. Stereoview of the active site of TyrRS. Residues from *B. stearothermophilus* TyrRS are shown. Corresponding residues from *M. jannaschii* TyrRS are Tyr32 (Tyr34), Glu107 (Asn123), Asp158 (Asp176), Ile159 (Phe177), and Leu162 (Leu180) with residues from *B. stearothermophilus* TyrRS in parentheses; mutated residues are in yellow.[262]

were all initially mutated to alanine to avoid a high background of wild-type TyrRS. The resulting inactive Ala_5 TyrRS was used as a template for PCR mutagenesis to generate the TyrRS library by mutation of the five sites to NNK (N = A, T, G, or C and K = G or T). The size of this library was 1.6×10^9 to ensure complete coverage of all possible mutants. A positive selection was then applied which is based on suppression of an amber stop codon in the chloramphenicol acetyltransferase (CAT) gene in the presence of the unnatural amino acid and chloramphenicol (in contrast to β-lactamase which is secreted into the periplasm, CAT localizes in the cytoplasm). Surviving cells were then grown in the presence of chloramphenicol and in the absence of the unnatural amino acid. Those cells that did not survive were isolated from a replica plate supplemented with the unnatural amino acid. The mutant synthetase genes were isolated from these cells, recombined in vitro by DNA shuffling, and transformed back into *E. coli* for further rounds of selection with increasing concentrations of chloramphenicol (Figure 18).

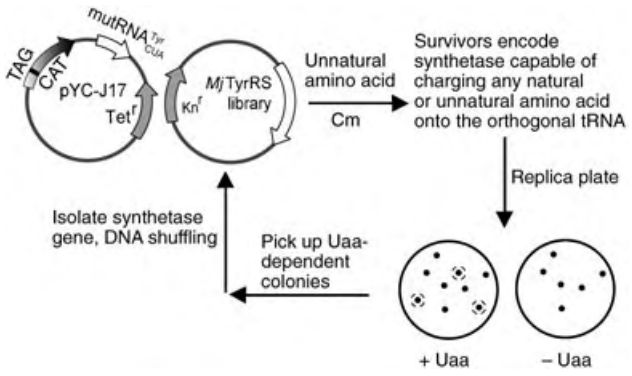

Figure 18. A general positive selection and negative screen scheme for evolving synthetases specific for unnatural amino acids. Cm = chloramphenicol, Uaa = unnatural amino acid.

This selection scheme was first used to generate an *Mj*TyrRS mutant synthetase capable of selectively inserting *O*-methyl-L-tyrosine (OMeTyr) into proteins in response to the amber codon.[262] OMeTyr is structurally similar to tyrosine and phenylalanine and provided an excellent opportunity to test the degree of translational fidelity that can be achieved by this approach. After two rounds of selection and DNA shuffling, a clone was evolved whose survival in chloramphenicol was highly dependent on the addition of 1 mM OMeTyr to the growth media. Cells survived in the presence of chloramphenicol when OMeTyr was added to the growth media, but died in the absence of the amino acid. An OMeTyr mutant of *E. coli* dihydrofolate reductase (DHFR) was generated and characterized to demonstrate that the observed phenotype arises from the site-specific incorporation of OMeTyr by the $mutRNA^{Tyr}_{CUA}$/mutant TyrRS pair in response to an amber stop codon. The third codon of the *E. coli* DHFR gene was mutated to TAG, and a His_6 tag was added to the C-terminus to facilitate protein purification and separation from endogenous DHFR. Full-length DHFR was produced only when the mutant TyrRS, the $mutRNA^{Tyr}_{CUA}$, and OMeTyr were all present (Figure 19). Insertion of OMeTyr in response to the TAG codon was confirmed by mass analysis of both the intact protein and tryptic fragments. No incorporation of tyrosine or other amino acids at the TAG position was observed, and OMeTyr was incorporated only in response to TAG and not any other sites. The growth rate of *E. coli* was not significantly affected and the protein yield was 2 mg L^{-1} in minimal media, which corresponds to 77% of the yield of wild-type DHFR. These results demonstrated for the first time that one could rationally engineer bacteria that genetically encode an unnatural amino acid with high efficiency and translational fidelity.[262]

We then attempted to genetically encode L-3-(naphthyl)-alanine, which represents a significant structural perturbation

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

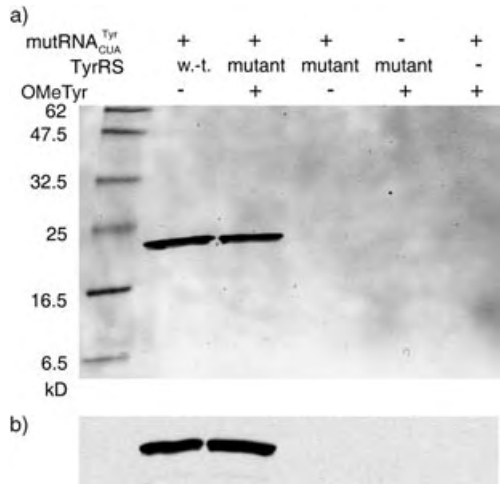

Figure 19. Accumulation of *E. coli* DHFR protein under different conditions. a) Silver-stained sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) of purified DHFR. The left lane is a molecular weight marker. b) Western blot of the protein gel. A penta-His antibody was used to detect the six-histidine tag at the COOH terminus of DHFR.

relative to tyrosine.[263] A slightly different mutant TyrRS library (in which Tyr 32, Asp 158, Ile 159, Leu 162, and Ala167 were randomized) was constructed from which four mutant synthetases were identified that have high activity for this unnatural amino acid. One round of DNA shuffling of these four synthetase genes resulted in a mutant synthetase (SS12) with enhanced activity for L-3-(naphthyl)alanine and greatly reduced activity for endogenous amino acids. An amber codon was introduced in the middle of the gene of mouse DHFR to verify incorporation of the unnatural amino acid. Protein expression and mass-spectrometric analysis confirmed that the mutRNA$_{CUA}^{Tyr}$/SS12 mutant synthetase selectively incorporates L-3-(naphthyl)alanine into proteins with an efficiency and fidelity rivaling that of the common 20 amino acids.[263] This result suggested that the above methodology may be applicable to a large variety of unnatural amino acids.

Alternative selection schemes for evolving the amino acid specificity of the orthogonal *Mj*TyrRS have been developed subsequently. One approach involves passing the mutant synthetase library through a positive selection based on the ability of the mutant synthetase to suppress amber mutations introduced at permissive sites in the CAT gene in the presence of an unnatural amino acid as described above. A negative selection is then applied in which those synthetases that recognize endogenous amino acids are eliminated in the absence of the unnatural amino acid. The negative selection is based on suppression of amber nonsense mutations introduced in the barnase gene.[254] Pilot selections of inactive *Mj*TyrRS and OMeTyr specific mutant synthetases from a large pool of wild-type *Mj*TyrRS were used to optimize the selection conditions for the *M. jannaschii* mutRNA$_{CUA}^{Tyr}$/TyrRS pair.[264] A barnase mutant with three amber codons (encoded in pLWJ17B3) was found to provide optimal selection stringency and enrichment efficiency.[265] Survivors of both the positive and negative selections encode synthetases that charge the orthogonal tRNA with only the unnatural amino acid. More mutations can be introduced by mutagenesis or DNA shuffling into these synthetase genes to generate second-generation synthetase libraries, which can be used for further rounds of selection until a mutant synthetase with a desired activity is evolved. This new scheme (Figure 20) has been used to evolve *M. jannaschii* mutRNA$_{CUA}^{Tyr}$/TyrRS orthogonal pairs for a wide variety of unnatural amino acids (see Section 5.2). By varying the stringency, order, and number of the positive and negative selection steps one can likely affect both the activity and fidelity of the evolved synthetase.[265]

A second method for evolving aminoacyl-tRNA synthetase specificity relies on an amplifiable fluorescent reporter of amber suppression.[266] A T7/GFPuv reporter (pREP) was created in which suppression of amber codons introduced at

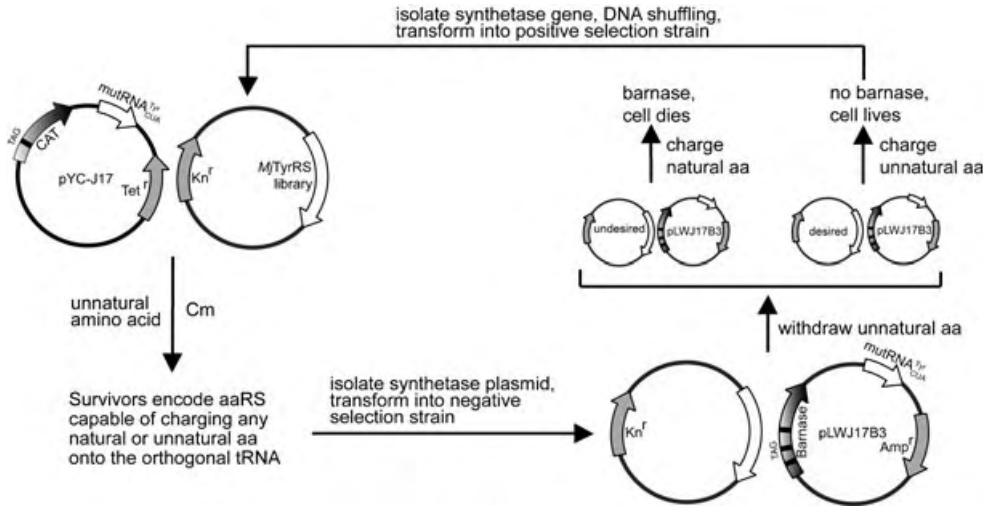

Figure 20. A general positive and negative selection scheme for evolving synthetases specific for unnatural amino acids.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

permissive sites in the gene for T7 RNA polymerase produces full-length protein, which in turn drives the expression of green fluorescent protein (GFPuv). This construct was combined with the above CAT reporter (pYC-J17) to yield pREP(2)/YC-JYCUA which contains the orthogonal mutRNA$^{Tyr}_{CUA}$, the amber mutant of CAT, and the T7/GFPuv reporter genes (Figure 21 a).[266] When *E. coli* containing this reporter are transformed with a mutant *Mj*TyrRS library and grown in the presence of an unnatural amino acid, active synthetases can be identified based on fluorescence and/or chloramphenicol resistance. Cells are subsequently grown in the absence of unnatural amino acid and chloramphenicol, and nonfluorescent cells containing the desired mutant synthetase are collected by fluorescence-activated cell sorting (FACS). The advantages of this method are that a single strain of *E. coli* can be used to perform both positive and negative selections, and cells containing the reporter can be replicated in the presence and absence of amino acid and visually inspected for amino acid dependent fluorescence (Figure 21 b).[266] Alternatively, this chloramphenicol and FACS double-positive selection can also be followed by the barnase negative selection.[265]

A direct positive selection has also been developed in which an antibody specific for an unnatural amino acid (or peptide containing the amino acid) is used to enrich phage into which the unnatural amino acid is incorporated (Figure 22).[267] A C3 peptide with an amber mutation is fused to the N-terminus of the VSCM13 phage coat protein pIII, such that C3TAG phage production requires suppression of the amber stop codon. Cells harboring a phagemid that expresses an orthogonal suppressor tRNA and a synthetase library are infected with the C3TAG phage. An active synthetase results in suppression of C3TAG and display of its cognate amino acid on the phage surface. The phage pool is then incubated with immobilized monoclonal antibodies directed against the unnatural amino acid to isolate only those phage carrying the synthetase specific for the unnatural amino acid. Phage displaying Asp were enriched over 300-fold from a pool of phage displaying Asn in a simulated selection using antibodies raised against the Asp-containing epitope.

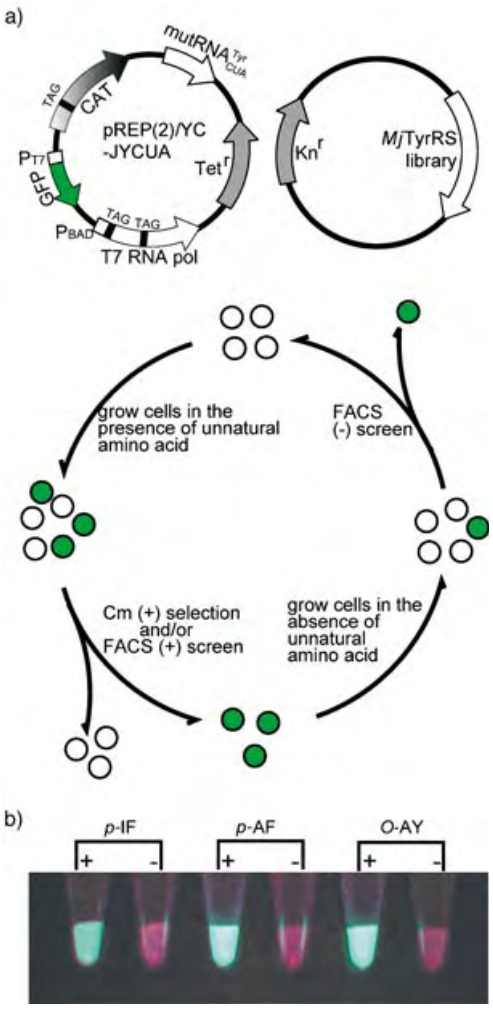

Figure 21. a) A system for evolving synthetase specificity that combines a fluorescent reporter with a chloramphenicol-based selection. b) Green fluorescence can be used to verify unnatural amino acid dependent GFP expression.

Phage containing an active synthetase display the unnatural amino acid on the phage surface and are selected with immobilized monoclonal antibodies.

5.2. A Survey of Genetically Encoded Unnatural Amino Acids

The above selections have been used to add over 30 novel amino acids to the genetic code of *E. coli* (Figure 23).[262,263,266,268–275] These include: 1) various substituted tyrosine and phenylalanine analogues such as *O*-methyl-L-tyrosine (**1**),[262] *p*-amino-L-phenylalanine (**5**),[266] 3-nitro-L-tyrosine (**15**),[276] *p*-nitro-L-phenylalanine (**29**),[276] *m*-methoxy-L-phenylalanine,[276] and *p*-isopropyl-L-phenylalanine (**4**);[266] 2) amino acids with aryl azide (**10**) and benzophenone (**11**) groups that can be photo-cross-linked;[269,270] 3) amino acids that have unique chemical reactivity including *p*-acetyl-L-phenylalanine (**6**) and *m*-acetyl-L-phenylalanine (**9**),[271,273] *O*-allyl-L-tyrosine (**3**),[268] *O*-(2-propynyl)-L-tyrosine

cosamine-*O*-serine (**14**) and α-*N*-acetylgalactosamine-*O*-threonine (**25**);[275] 7) fluorescent amino acids with naphthyl (**2**), dansyl (**24**), and 7-aminocoumarin (**23**) side chains;[263,276] 8) photocleavable and photoisomerizable amino acids with azobenzene (**16**) and nitrobenzyl Cys, Ser, and Tyr side chains (**18**–**20**);[276] 9) the phosphotyrosine mimetic *p*-carboxymethyl-L-phenylalanine (**17**); 10) the glutamine homologue homoglutamine (**28**);[276] and 11) 2-aminooctanoic acid (**31**). This list suggests that synthetases can be evolved for a large number of structurally diverse amino acid side chains, which range from sugars to extended aromatic groups. Moreover, it appears that the ribosome and elongation factors also tolerate considerable structural diversity, which is consistent with previous in vitro mutagenesis studies.

In general these unnatural amino acids are incorporated with excellent fidelity and efficiency by their cognate tRNA/synthetase pairs. Each pair was characterized by their ability to confer chloramphenicol resistance to cells transformed with the CAT amber mutant gene in the presence and absence of a particular unnatural amino acid.[262] Secondly, each orthogonal tRNA/synthetase pair was used to incorporate the corresponding unnatural amino acid into proteins at permissive sites in the genes for *E. coli* or mouse DHFR,[262,263] the Z domain of protein A,[268,271] or myoglobin.[266] Each protein was tagged with hexahistidine and purified. Milligram quantities of the mutant protein could be purified per liter of minimal media by using the unnatural amino acid and the orthogonal tRNA/synthetase pair. Yields were typically 25–50%, and in some cases greater than 75% that obtained with the wild-type protein.[262,263] High-resolution mass spectrometry was also used to analyze the intact protein and tryptic digests[271] to confirm that only the unnatural amino acid is incorporated in response to the TAG codon and at no other site in the protein.

Many of these unnatural amino acids have novel properties that are useful for a variety of biochemical and cellular studies. For example, two amino acids (*p*-azidophenylalanine (**10**) and *p*-benzoylphenylalanine (**11**)) have side chains that can be photo-cross-linked both in vitro and in vivo.[269,270,277] Benzophenone is a particularly useful photo-cross-linker since it absorbs at relatively long wavelengths (ca. 360 nm), and the excited state inserts efficiently into carbon–hydrogen bonds.[278] Indeed, a mutant homodimeric glutathione S-transferase with *p*-benzoylphenylalanine substituted at the dimer interface could be crosslinked in greater than 50% yield in the cytoplasm of *E. coli* (Figure 24). These amino acids should be useful for studies of protein–protein and protein–nucleic acid interactions in vitro and in vivo, for studies of protein structure and dynamics, and for the identification of receptors for orphan ligands. They should also allow the selective immobilization of proteins and cells on surfaces in defined orientations.

The keto-containing amino acids *p*-acetylphenylalanine (**6**; *p*-Ac-Phe) and *m*-acetylphenylalanine (**9**) can be used for the selective chemical modification of proteins, especially those proteins with multiple cysteine residues.[271,273] The ketone group undergoes a variety of reactions including addition, aldol, transamination, and isomerization reactions. It reacts with hydrazides, alkoxyamines, and semicarbazides

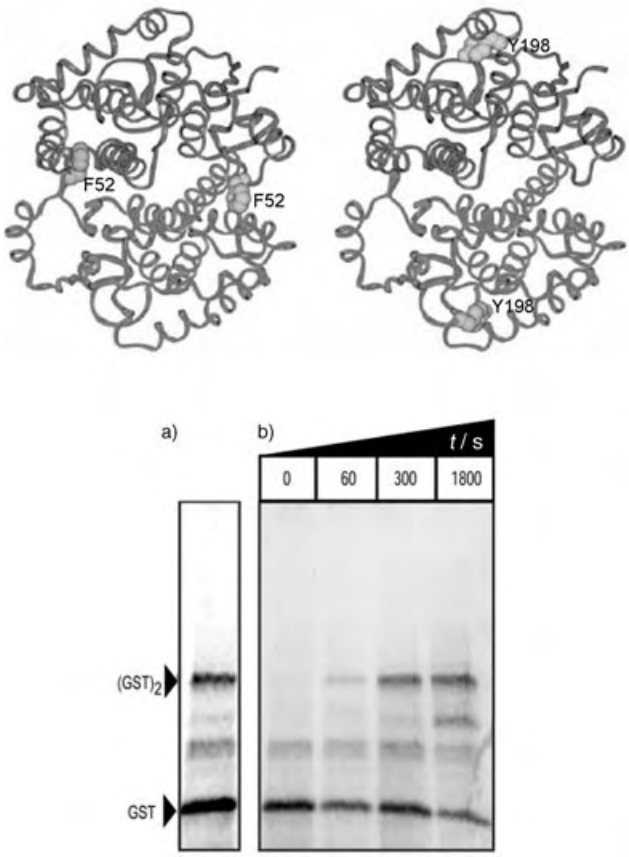

Figure 24. Residues Phe52 (top left) and Tyr198 (top right) of GST were mutated to *p*-benzoylphenylalanine (pBpa). a) Purified GST (Phe52pBpa) was cross-linked in vitro and detected by Western blot with an anti-GST antibody. b) The covalent dimerization of GST (Phe52-pBpa) in *E. coli* as a function of cellular irradiation at 365 nm, detected as in (a). Tyr198-pBpa GST could not be cross-linked.

under aqueous, mild conditions to produce hydrazone, oxime, and semicarbazone linkages that are stable under physiological conditions. For example, the in vitro reaction of a *p*-Ac-Phe mutant of the Z domain protein with 1 mM fluorescein hydrazide at pH 6.5 led to labeling of the protein with fluorescein in a 1:1 molar ratio in greater than 90% yield (Figure 25a).[271] Homogenous glycoprotein mimetics were also generated by labeling *p*-Ac-Phe-containing proteins with aminooxy sugars in $>90\%$ yield (Figure 25b). Oligosaccharides with defined structures were covalently attached to proteins either by adding additional saccharides to the pendant sugar with glycosyltransferases, or by directly coupling an aminooxy-derivatized glycan in one step.[279] Similarly, keto-containing mutants were efficiently labeled with hydrazide derivatives of biotin (Figure 25c) and polyethylene glycol. The latter should allow the generation of homogeneous proteins site-specifically derivatized with PEG with very high chemical purity. In addition, *m*-acetylphenylalanine has been used to efficiently label in vivo a keto-containing mutant of the *E. coli* membrane protein LamB with any of three water soluble fluorophores (Cascade blue, Alexa 568, or Alexa 647).[273] In a related experiment, copper-

A His_6 tag was added to the C-terminus of both wild-type and mutant protein and was detected with His_6-specific antibody in Western blot analysis. Only the *p*-acetylphenylalanine-containing protein was labeled with biotin and thus detected by the biotin-specific anitibody. d) Protein derivatization with PEG through a copper-mediated cycloaddition reaction and SDS PAGE analysis.

mediated [2+3] cycloaddition reactions between mutant proteins containing either alkyne or azido unnatural amino acids **10** or **13** and a corresponding azide- or alkyne-derivatized chemical label have been used to selectively modify proteins with fluorophores and polyethylene glycol in high yield (> 75 %, Figure 25 d).[280] In addition, we have recently shown that thioester-containing amino acids can also be used to selectively modify proteins with nonpeptidic groups.[281]

Protein glycosylation is an essential posttranslational modification in eukaryotic cells, which can modulate protein folding and secretion, biological activity, serum half-life, and localization.[282] Although a variety of methods have been developed to obtain pure glycoforms of a protein,[283–286] most impose severe restrictions on the size, quantity, and/or quality of the glycoprotein produced. In an effort to provide a general solution to this problem, we attempted to alter the specificity of the *Mj*TyrRS to accept β-*N*-acetylglucosamine-*O*-serine (β-GlcNAc-Ser, **14**). The esterified amino acid was used to facilitate transport into the cell, where it is subsequently deacetylated by cytosolic esterases. Mutant synthetases were isolated that site-specifically incorporate the glycosylated

amino acid into myoglobin in response to the amber codon with high translational fidelity and in a yield roughly 20–30% that of wild-type myoglobin. An enzyme-linked immunosorbent assay demonstrated significant binding of the GlcNAc-specific lectin *Bandeiraea simplicifolia* II (BSII) to the β-GlcNAc-Ser mutant myoglobin, whereas no binding was observed for the wild-type myoglobin.[275] Moreover, the *O*-GlcNAc-serine mutant myoglobin could act as a substrate for galactosyltransferases. Incubation of the myoglobin mutant containing the GlcNAc side chain with radioactive UDP[6-H^3]Gal in the presence of β-1,4-galactosyltransferase resulted in radiolabelled product (Figure 26).[275] This approach has also been used to selectively introduce α-GalNAc-Thr into proteins, and is currently being extended to a number of other O- and N-linked sugars.[275] We are also attempting to genetically encode other posttranslationally modified amino acids including methylated and acetylated lysine, as well as phosphorylated tyrosine, serine, and threonine. Recently, an *Mj*TyrRS mutant was evolved that selectively incorporates *p*-carboxylmethyl-L-phenylalanine (**17**), which is a stable mimetic of phosphotyrosine that can be used for studies of signal transduction. In addition, the incorporation of 2-aminooctanoic acid **31** suggests that it may be possible incorporate lipid-modified amino acids directly into proteins.

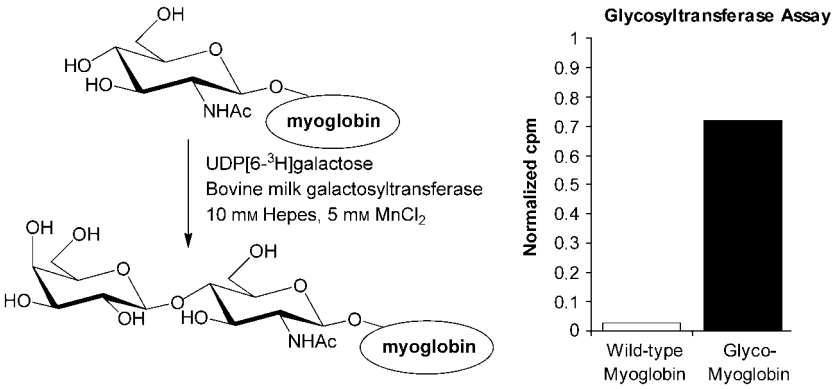

Figure 26. Direct incorporation of β-GlcNAc-Ser into myoglobin in *E. coli* and extension by addition of galactosyltransferase and UDP[6-^{3}H]galactose.

The ability to genetically encode heavy-atom-containing amino acids should facilitate phase determination in X-ray crystallography. To this end, an orthogonal tRNA/synthetase pair has been evolved that selectively incorporates *p*-iodophenylalanine (**7**, *p*-iodo-Phe) in response to the amber codon.[265] The yield of a mutant *p*-iodo-Phe-containing Z domain protein was around 60% of the wild-type protein (5.5 mg L^{-1} versus 9.2 mg L^{-1} in minimal medium). Bacteriophage T4 lysozyme with either residue Ser44 or Phe153 mutated to *p*-iodo-Phe was expressed, purified, and crystallized to determine the utility of *p*-iodophenylalanine for single-wavelength anomalous dispersion (SAD) phasing (the anomalous signal ($\Delta f''$) of iodine at 8 keV is 6.91, six times that of selenium (1.15)). The crystal structure was solved at 1.54-Å resolution by SAD phasing with the incorporated iodine atom using a laboratory $Cu_{K\alpha}$ X-ray source.[287]

Green fluorescent protein (GFP) is a powerful biological tool, which allows protein expression, localization, dynamics, and interactions to be directly visualized in intact cells.[288] However, in many cases the size of GFP and the fact that GFP can only be incorporated as an N- or C-terminal fusion are significant limitations. GFP also requires time for fluorophore maturation. The ability to co-translationally incorporate unnatural amino acids containing relatively small fluorescent side chains would minimize structural perturbations to the host protein, provide a broader range of spectral properties, and allow more control over the location of the fluorescent reporter (namely, at any permissive surface residue, rather than just the N- or C- terminus). To this end, we have evolved *M. jannaschii* TyrRSs that selectively incorporate 7-aminocoumarin (**23**) and 7-hydroxycoumarin into proteins in *E. coli*,[289] as well as an orthogonal *E. coli* leucyl synthetase that incorporates the dansyl-containing amino acid **24** (Figure 23) into proteins in yeast.[290] The environmentally sensitive coumarin-containing amino acid **23** has been used to monitor the unfolding of apo myoglobin and interaction of GroEL with its substrates.

Another novel amino acid that has been incorporated into proteins is dihydroxyphenylalanine (DHP, **12**).[274] DHP can undergo two-electron oxidation to the corresponding quinone (Figure 27), and should be useful to both probe and manipulate electron-transfer processes in proteins. The redox-active amino acid 5-hydroxytryptophan has also been selectively incorporated into proteins in mammalian cells in response to an opal codon (see below). This amino acid undergoes electrochemical oxidation to form an efficient cross-linking agent in vitro. Unnatural amino acids may also be used to perturb the electronic properties of a protein. For example, introduction of several unnatural amino acids in place of Tyr65 in GFP led to blue shifts in the emission spectra and altered quantum yields.[272] In addition, deuterated and ^{15}N-labeled derivatives of OMeTyr have also been site-selectively incorporated into proteins as NMR probes.[327]

Finally, the azobenzene-containing amino acid **16**[291] and the photocaged amino acids nitrobenzyl-Cys, -Ser, and -Tyr **18**–**20**[292] have recently been incorporated into proteins in *E. coli* and/or yeast. These amino acids make possible the in vivo regulation of protein activity by light. For example, mutation of the active site cysteine residue in the proapoptotic protease caspase 3 to nitrobenzylcysteine led to a catalytically inactive enzyme, whose activity could be restored

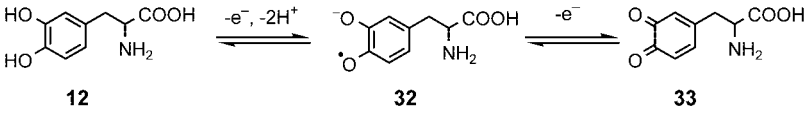

Figure 27. Oxidation of DHP **12** to DHP-semiquinone radical **32**, which is readily oxidized to DHP-quinone **33.**

by photocleavage of the nitrobenzyl protecting group (Figure 28). The azobenzene-containing amino acid can be photochemically converted from the *trans* into the *cis* isomer and therefore provides an opportunity to photoregulate a variety of biological processes in vivo. For example, this amino acid has been used to photoregulate the binding of cAMP to the catabolite activator protein of *E. coli*.[291]

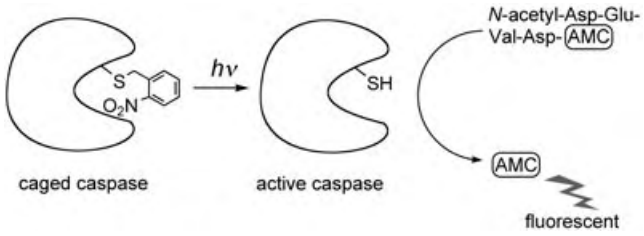

Figure 28. A photocaged caspase with an active-site nitrobenzylcysteine. AMC = 7-amino-4-methylcoumarin.

We have been surprisingly successful in identifying *M. jannaschii* TyrRS mutants with altered specificities, the majority of which are from a library with five active site residues randomized.[239,262] Crystallographic studies of the wild-type and mutant synthetases provide an opportunity to examine the origins of amino acid specificity in this important class of enzymes. A comparison of the active-site structures of bound and unbound wild-type *Mj*TyrRS indicates that there are significant structural changes that occur upon binding of tyrosine (Figure 29).[293,294] Asp 158 moves closer to the active site to bind the tyrosine hydroxy group, while Tyr 32 moves away to accommodate the hydroxy group of the tyrosine residue of the substrate. In addition, the Tyr 151 side chain rotates 60° to form a 2.9-Å hydrogen bond with the α-amino group of tyrosine. Recent determination of the X-ray crystal structure of a *p*-bromophenylalanine-specific synthetase suggests that the structural plasticity evident in the wild-type synthetase plays a major role in the generation of the specificity of this mutant enzyme.[276] This mutant synthetase differs from the wild-type synthetase by five mutations (Y32L, E107S, D158P, I159L, and L162E). Surprisingly, helix α8 of the mutant is disrupted and residues 158, 159, and 162, which line the active site in the wild-type synthetase, are flipped out of the active site in the mutant. Residues H160 and Y161, which are exposed to solvent in the wild-type structure, flip in to form a new binding pocket with extensive van der Waals contacts to *p*-bromophenylalanine. We are constructing new libraries to randomize this entire region (residues 158–162) to take advantage of the observed flexibility in this region to further evolve the activity of this synthetase.

Given the above successes and the availability of additional orthogonal tRNA/synthetase pairs, it is likely that many other unnatural amino acids can be genetically encoded. We are currently attempting to evolve orthogonal tRNA synthetase pairs that selectively incorporate amino acids containing spin labels, *p*-cyanophenylalanine (an IR probe), metal-binding amino acids, and backbone-modified amino acids (for example, *N*-methyl amino acids, β-amino acids, and α-hydroxy acids). In addition, a number of approaches are being explored to further increase the yields of the mutant proteins. These include optimizing the expression levels (and induction protocols) of the orthogonal tRNA and synthetase as well as carrying out selections for synthetases in rich versus minimal media. Indeed, it has been shown by Cho and co-workers that such changes can afford up to 750 mg L^{-1} quantities of mutant proteins.[328] Synthetase and tRNA mutants with increased activities can also be generated by additional rounds of mutagenesis and selection, or by rational design using X-ray crystal structures of mutant synthetase–amino acid complexes. Indeed, it has recently been shown that the affinities of aminoacylated tRNAs for elongation factor Tu (EF-Tu) and the ribosomal A site vary, depending on the attached amino acid and tRNA.[295] We are also beginning to examine the role of endogenous factors in determining the efficiency and fidelity of unnatural amino acid incorporation by using transposon and chemical mutagenesis, and complementation with genomic DNA libraries. For example, transposon mutations in the *fis* gene have been identified that improve the efficiency of amber suppression in some cases. Similar approaches may also increase the transport of some unnatural amino acids and lead to further improvements in suppression efficiency by random mutations in the ribosome, release factors, tRNA genes, etc.

The availability of bacteria with additional genetically encoded amino acids allows one to experimentally test

whether additional amino acids can lead to proteins with enhanced chemical or biological properties, or provide an evolutionary advantage for an organism.[265] A library of unnatural amino acids can be introduced at all sites in a target protein by using an amber codon walking strategy. Alternatively, mutagenesis can be used to introduce amber codons at random sites in the genome, and the resulting strains grown on media containing each of the above unnatural amino acids. These libraries can then be subjected to a variety of selective pressures, and mutations that provide a growth advantage can be mapped and the resulting protein characterized.

In a related experiment we have shown that unnatural amino acids can be efficiently incorporated into polypeptides fused to the pIII protein of a filamentous phage to generate an infectious phage.[296] This process allows large libraries of phage-displayed peptides and proteins to be created with both natural and unnatural amino acid building blocks, which can subsequently be screened for novel binding and/or catalytic properties.

5.3. Amino Acid Biosynthesis.

In all the above studies the amino acid must be added to the growth media and taken up by the cell in order to be incorporated into a protein in response to the amber codon. There are a large number of amino acid and amine transporters that are relatively nonspecific, and as a consequence, most amino acids we have assayed are transported into *E. coli* cytoplasm from the growth media and accumulate in significant concentrations. In some cases it is necessary to use enzymatically labile derivatives of highly polar amino acids or to mutate/delete enzymes that degrade the amino acid.

An alternative to adding exogenous amino acids to the growth media involves engineering a pathway for the biosynthesis of the unnatural amino acid directly in the host organism. To this end a completely autonomous 21 amino acid bacterium has been generated that contains genes for the biosynthesis of *p*-amino-L-phenylalanine (*p*-AF, **5**) from simple carbon sources,[297] an aminoacyl-tRNA synthetase[266] that uses *p*-AF (and no other endogenous amino acids), and a tRNA[262] that delivers *p*-AF into proteins in response to the amber codon. *p*-AF was biosynthesized from chorismic acid (an intermediate in aromatic amino acid biosynthesis) using the *papA*, *papB*, and *papC* genes from *S. venezuelae* in combination with a nonspecific *E. coli* transaminase (Figure 30). *E. coli* containing *papA–C* produced *p*-AF at levels comparable to those of the other aromatic amino acids and had normal growth rates. In the presence of a *p*-AF-specific, orthogonal mutRNA$^{Tyr}_{CUA}$/synthetase pair, *E. coli* transformed with *papA-C* produced mutant proteins containing *p*-AF at sites encoded by the amber codon with excellent yields and fidelity.[297] In addition to *p*-AF, it should be possible to biosynthesize and genetically encode other amino acids in vivo as well, including methylated, acetylated, and glycosylated amino acids.

5.4. Quadruplet Codons

The ultimate number of unnatural amino acids that can be encoded in any organism is limited by the number of noncoding codons. In addition to nonsense codons, it should be possible to use rare codons to encode unnatural amino acids, although it is likely that some competition with the cognate amino acid will occur. Alternatively, it may be possible to generate a synthetic *E. coli* variant in which rare codons are deleted from the wild-type genome (by replacing them with degenerate codons specifying the same amino acid) and instead used to encode unnatural amino acids.

It should also be possible to use quadruplet codons and cognate suppressor tRNAs with expanded anticodon loops to encode additional amino acids. There are many examples of naturally occurring +1 frameshift suppressors including UAGN (N = A, G, C, or T) suppressors derived from Su7 which encodes glutamine,[298] *sufJ*-derived suppressors of ACCN codons encoding threonine,[299] and CAAA suppressors derived from tRNA^{Lys} and tRNA^{Gln}.[300] Moreover, genetic selections have been used to identify efficient four- and five-base codon suppressor tRNAs from large libraries of mutant tRNAs.[301,302] In these studies, a tRNA library in which the anticodon loop of tRNA$^{Ser}_2$ (positions 31–38) was replaced with all possible eight base-pairing sequences was crossed with a library containing all possible four-base codon sequences encoding Ser70 of β-lactamase. Efficient pairs of suppressor and four-base codon were identified by an in vivo selection strategy,[301] including a mutant tRNA with an anticodon loop sequence of CUUCCUAG that efficiently

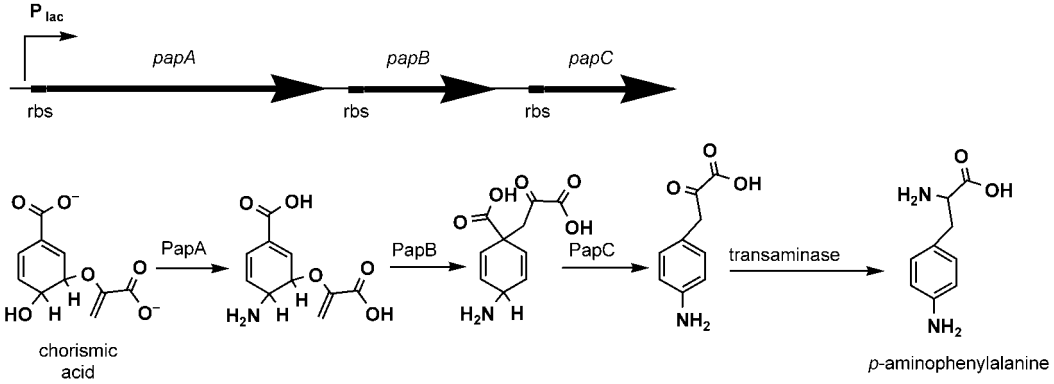

Figure 30. Biosynthesis of *p*-aminophenylalanine in *E. coli* by introducing *papA*, *B*, and *C* genes from *S. venezuelae*.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

suppresses an AGGA codon.[302] In this case, suppression of AGGA is competing with the rare codon AGG, which may account for the efficiency and lack of toxicity of this suppressor tRNA. Frameshift suppressor tRNAs can efficiently incorporate a number of the common 20 amino acids into proteins in vivo,[303] and as described above, chemically aminoacylated frameshift suppressors have also been used to incorporate unnatural amino acids into proteins in in vitro translation systems with four- and five-base codons.

Recently, an orthogonal four-base suppressor tRNA/synthetase pair was generated from archaeal $tRNA^{Lys}$ sequences (see Section 5.5) that efficiently and selectively incorporates the unnatural amino acid homoglutamine into proteins in *E. coli* in response to the quadruplet codon AGGA.[304] Frameshift suppression with homoglutamine does not significantly affect protein yields or cell growth rates, and is mutually orthogonal with amber suppression. This approach allows the simultaneous incorporation of two unnatural amino acids at distinct sites within proteins. For example, orthogonal AGGA-specific and TAG-specific tRNAs were expressed in the presence of a myoglobin with Gly24→AGGA and Ala75→TAG mutations (Figure 31). The corresponding orthogonal *O*-methyl-L-tyrosine-specific and homoglutamine-specific synthetases were combined in a second plasmid. When cells cotransformed with both plasmids were grown in the presence of the two amino acids, 1.7 mg L^{-1} of mutant myoglobin was produced. The overall suppression efficiency was approximately 25%. No protein was produced when either of the two unnatural amino acids was excluded. Electrospray mass spectrometric analysis of the full-length protein confirmed that myoglobin contained both unnatural amino acids.[304] This work suggests that neither the number of available triplet codons nor the translational machinery itself represents a significant barrier to further expansion of the code.

5.5. Other Orthogonal tRNA/Synthetase Pairs in E. coli

A "consensus suppressor strategy" has recently been developed for the rational design of additional orthogonal tRNA/synthetase pairs for use in *E. coli*.[305] In the first application of this strategy an orthogonal synthetase was generated from the *Methanobacterium thermoautotrophicum* leucyl synthetase. The corresponding suppressor tRNA was based on the consensus sequence of multiple archaeal leucyl tRNAs. The anticodon loop of this consensus tRNA was replaced with the sequence CUXXXAA, where XXX is the reverse complement sequence of distinct nonsense codons. To improve suppression efficiency and further reduce recognition of this tRNA by endogenous *E. coli* synthetases, mutations were introduced into the stems of the consensus tRNA sequence and the resulting mutant tRNA library was subjected to the general negative and positive selections described above.[260] The two most significant features identified from these studies for an efficient amber orthogonal suppressor tRNA are a CU(X)XXXAA anticodon loop and the lack of noncanonical or mismatched base pairs in the stem regions.[260,305] An orthogonal tRNA/synthetase pair derived from the archaeal $tRNA^{Glu}$ sequences and the glutamyl tRNA synthetase from *Pyrococcus horikoshii* has also been generated by this strategy (Figure 32).[306] Both orthogonal pairs have comparable suppression efficiencies to the tyrosyl pair derived from *M. jannaschii*. Other orthogonal pairs have also been reported in the literature for use in *E. coli*. An orthogonal $tRNA^{Asp}_{CUA}$/AspRS pair was derived from yeast $tRNA^{Asp}$/AspRS,[307] in which a yeast AspRS E188K mutant was used to improve recognition for the amber suppressor $tRNA^{Asp}_{CUA}$.[307,308] An *E. coli* initiator $tRNA^{fMet}$ amber mutant together with a mutant yeast TyrRS also form an orthogonal pair in *E. coli*.[309] These synthetases have different active sites and may be useful for evolving specificities for other types of amino acids.

5.6. Genetically Encoding Unnatural Amino Acids in Yeast

The same general strategy developed to genetically encode unnatural amino acids in bacteria should also be applicable to higher organisms. This approach requires the generation of orthogonal tRNA/synthetase pairs for each

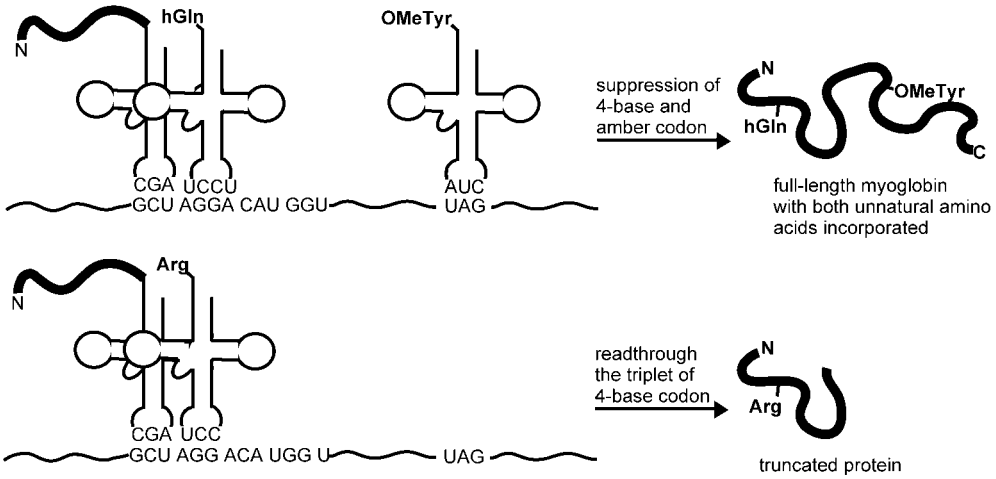

Figure 31. Simultaneous incorporation of the two unnatural amino acids homoglutamine (hGln) and *O*-methyl-L-tyrosine (OMeTyr) into myoglobin by suppression of a four-base codon and an amber nonsense codon.

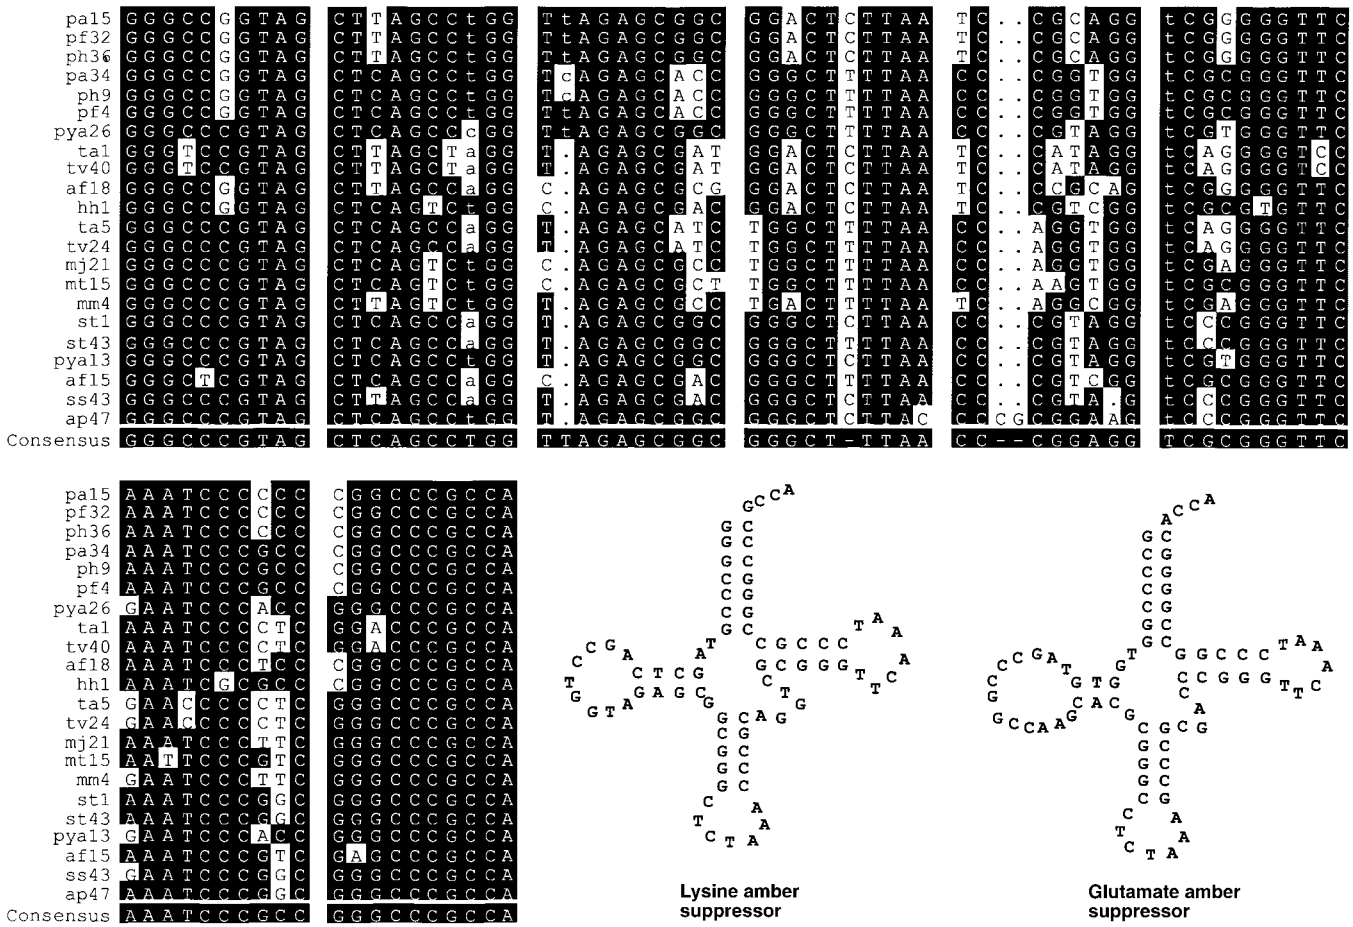

Figure 32. Archaeal lysyl and consensus tRNAs and the derived lysyl and glutamyl amber suppressors.

organism of interest. Most orthogonal tRNA/synthetase pairs that have been reported for eukaryotes are derived from bacterial pairs, reflecting the fact that the divergence of both sequence identity and identity elements of tRNAs from prokaryotes to eukaryotes is greater than that from eukaryotes to archaea and between one eukaryote and another. The transcription of a tRNA gene in eukaryotic cells depends on RNA polymerase III and its associated factors, which recognize A and B box sequences that are internal to the tRNA structural gene.[310] Some bacterial tRNAs that diverge from the eukaryotic A and B box sequence are not efficiently biosynthesized or processed in eukaryotic cells and their sequences need to be modified accordingly.[244,311] While all *E. coli* tRNA genes encode full sequences of tRNAs, many bacterial and archaeal and nearly all eukaryotic tRNAs have the 3′-CCA sequence added enzymatically by tRNA nucleotidyltransferase. Thus, it may also be necessary to delete the 3′-CCA in the tRNA gene imported from *E. coli*.[312] In addition, the generation of a functional tRNA in some cases requires specific 5′ and 3′ flanking sequences, the removal of introns, posttranscriptional nucleotide modifications, as well as export to the cytoplasm through an exportin-tRNA-dependent process.[313–315]

A number of orthogonal tRNA/synthetase pairs have been generated for use in eukaryotic organisms. For example, it has been shown that *E. coli* tyrosyl amber suppressor $tRNA^{Tyr}_{CUA}$ is not aminoacylated by eukaryotic synthetases and acts as an amber suppressor in *S. cerevisiae* in the presence of *E. coli* TyrRS.[316,317] In addition, *E. coli* TyrRS does not aminoacylate yeast tRNAs.[318] Thus, *E. coli* $tRNA^{Tyr}_{CUA}$/TyrRS functions as an orthogonal pair in yeast. A human initiator-tRNA-derived amber suppressor together with *E. coli* GlnRS form another orthogonal pair for use in yeast.[309] In addition, the *E. coli* $tRNA^{Gln}_{CUA}$/GlnRS pair has also been used in mammalian cells for efficient suppression of the amber codon.[244]

To selectively introduce an unnatural amino acid into proteins in eukaryotes, Yokoyama and co-workers screened a small collection of designed active-site variants of *E. coli* TyrRS in a wheat-germ translation system and discovered a mutant synthetase that utilizes 3-iodotyrosine more effectively than tyrosine.[319] This mutant synthetase was used with the *B. stearothermophilus* $tRNA^{Tyr}_{CUA}$ to incorporate 3-iodotyrosine into proteins in mammalian cells.[311]

To develop a general selection scheme in yeast analogous to that used in *E. coli* for evolving synthetases specific for unnatural amino acids, we created a selection strain of *S. cerevisiae* (MaV203:pGADGAL4 (2 TAG)) that contains the transcriptional activator protein GAL4 in which the codons at two permissive sites were mutated to amber

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

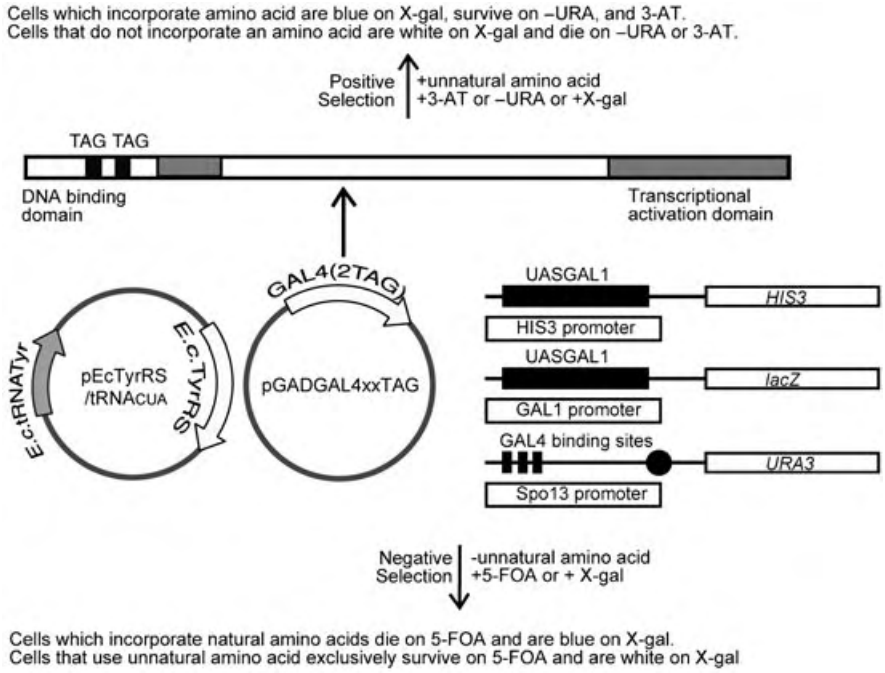

Figure 33. A scheme for selecting mutant synthetases specific for unnatural amino acids in yeast.

nonsense codons (Figure 33). Suppression of these amber codons leads to the production of full-length GAL4, which in turn drives transcription of genomic GAL4 responsive *HIS3*, *URA3*, and *LACZ* reporter genes. Expression of *HIS3* and *URA3* complements the histidine and uracil auxotrophy in this strain and provides a positive selection for clones expressing active tRNA/synthetase pairs. On the other hand, addition of 5-fluoroorotic acid (5-FOA), which is converted into a toxic product by URA3, results in the death of cells expressing active tRNA/synthetase pairs. In the absence of the unnatural amino acid, this serves as a negative selection to remove synthetases specific for endogenous amino acids. Like GFP, the *lacZ* reporter can serve as an additional marker to colormetrically identify active synthetase from inactive ones.

Initially we used the orthogonal *E. coli* $tRNA^{Tyr}_{CUA}$/TyrRS pair[316,317] to incorporate unnatural amino acids into proteins in yeast. A mutant *E. coli* TyrRS library (10^8 in size) was constructed by randomizing five residues in the active site based on the crystal structure of the homologous TyrRS from *Bacillus stearothermophilus* (Figure 17[262]). By using the selection method described above, aminoacyl-tRNA synthetases were identified that incorporate several unnatural amino acids including *p*-acetyl-L-phenylalanine, *p*-azido-L-phenylalanine, *p*-benzoyl-L-phenylalanine, *O*-methyl-L-tyrosine, *p*-iodo-L-tyrosine, and *O*-(2-propynyl)-L-tyrosine.[280,320] To characterize the fidelity and efficiency of unnatural amino acid incorporation an amber mutant of human superoxide dismutase was overexpressed in the presence of each tRNA/synthetase pair with or without the cognate unnatural amino acid. In the presence of the unnatural amino acid, superoxide dismutase could be purified (yields are ca. 0.05 mg L^{-1} corresponding to 20–40 % of wild-type protein); no superoxide dismutase was produced in the absence of added amino acid.[320] The purified superoxide dismutase was shown by mass spectrometry to contain the desired unnatural amino acid and no other amino acid at the specified site. A similar approach has been used to evolve orthogonal *E. coli* leucyl tRNA/synthetase pairs that incorporate long-chain, photocaged, and fluorescent amino acids into proteins in yeast in response to the amber nonsense codon.[276]

5.7. Genetically Encoding Unnatural Amino Acids in Mammalian Cells

While unnatural amino acids have been incorporated into proteins in mammalian cells in the past,[321,322] these efforts have relied primarily on transfection of amber suppressor tRNAs that are acylated in vitro. This approach severely limits the amount of overall protein that can be produced since the suppressor tRNA must be introduced exogenously and cannot be recycled in vivo by an appropriate aminoacyl-tRNA synthetase. Ideally one would like to identify tRNA/synthetase pairs that are orthogonal in mammalian cells, and evolve the substrate specificity of the synthetase such that it can selectively charge a desired unnatural amino acid in vivo.

Since the *E. coli* $tRNA^{Tyr}_{CUA}$/TyrRS pair is orthogonal in mammalian cells (in addition to yeast), and the translational machinery of yeast is similar to that of higher eukaryotes, it should be possible to evolve the specificity of this synthetase in yeast (which is well-suited for genetic selections with large libraries) and transfer the optimized tRNA/synthetase pairs directly to mammalian cells. Unfortunately, *E. coli* $tRNA^{Tyr}_{CUA}$ does not express well in mammalian cells, presumably because of the lack of intact A and B boxes.[311] However, Yokoyama and co-workers showed that the *B. stearothermophilus* $tRNA^{Tyr}_{CUA}$ can function with *E. coli* TyrRS to suppress the TAG codon with tyrosine in vivo. Moreover, this tRNA is not aminoacylated by any endogenous synthetase in mammalian cells.[311] Indeed, coexpression of an *E. coli* mutant TyrRS led to the incorporation of 3-iodo-L-tyrosine into proteins in response to the TAG codon in both Chinese hamster ovarian cells and human embryonic kidney 293 cells with approximately 95 % fidelity.[311] We have shown that several of the *E. coli* TyrRS mutants evolved in yeast can be used in conjunction with a *B. stearothermophilus* $tRNA^{Tyr}_{CUA}$ to incorporate unnatural amino acids into proteins in mammalian cells.[323] However, the suppression efficiencies are low, suggesting that improved synthetases or suppressors, or increased expression levels will be required to generate useful amounts of protein.

An orthogonal *B. subtilis* $tRNA^{Trp}_{UCA}$ ($Bs tRNA^{Trp}_{UCA}$)/tryptophanyl-tRNA synthetase (TrpRS) has also been developed for use in mammalian cells. Wang and co-workers had previously shown that *B. subtilis* $tRNA^{Trp}$ ($Bs tRNA^{Trp}$) is not

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

a substrate for TrpRS from yeast and mammalian cells.[324] To test whether the *Bs*tRNA$^{Trp}_{UCA}$ is also orthogonal and can function as an opal suppressor, the codon for Trp68 in a modified bacteriophage T4 fibritin *foldon* gene under control of a CMV promoter[325] was mutated to TGA. Suppression experiments in human 293T cells together with in vitro aminoacylation assays showed that *B. subtilis* TrpRS (*Bs*TrpRS) aminoacylates only *Bs*tRNA$^{Trp}_{UCA}$ and no other endogenous mammalian tRNAs, and that the expressed *Bs*tRNA$^{Trp}_{UCA}$ is charged only by its cognate *Bs*TrpRS and not by other endogenous mammalian synthetases.[326]

The crystal structure of the homologous *Bacillus stearothermophilus* TrpRS was then used to rationally design a synthetase mutant (V144P*Bs*TrpRS) that selectively charges 5-substituted Trp analogues. Val144 points directly towards C5 of tryptophan, thus leading to unfavorable steric interactions with any tryptophan analogue containing a substituent at the C5-position. Mutation of Val144 to a smaller amino acid might be expected to accommodate 5-substituted tryptophan analogues. This mutant was generated and assayed for its ability to suppress the opal nonsense codon in the *foldon* gene in the presence of 5-hydroxytryptophan (5-HTPP). Indeed, expression of full-length protein was seen only in the presence of 5-HTPP (Figure 34).[326] No full-length protein was expressed in the absence of 5-HTPP under otherwise identical conditions, which indicates that this mutant synthetase does not use an endogenous amino acid as a substrate. Electrospray mass spectrometry of the mutant foldon protein verified site-specific incorporation of 5-HTPP at position 68 with a fidelity of $>97\,\%$. The yield of the 5-HTPP mutant protein was approximately 100 $\mu g\,L^{-1}$ of culture, compared to that of about 1 $mg\,L^{-1}$ for wild-type protein. To evolve the *Bs*TrpRS to charge more complex tryptophan analogues, the *Bs*tRNA$^{Trp}_{UCA}$/*Bs*TrpRS can be moved back into the yeast system and the selection scheme described above can be used to isolate desired synthetase mutants from a large library of active-site mutants.

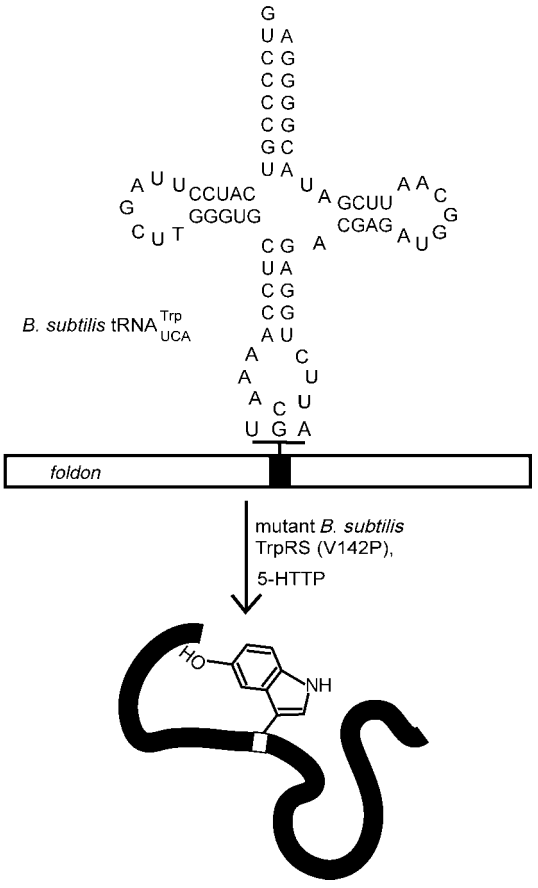

Figure 34. Incorporation of 5-HTTP into the foldon in mammalian cells by suppression of the opal nonsense codon.

6. Outlook

The approach described above has proved remarkably effective in allowing us to add a large number of novel amino acids to the genetic codes of both prokaryotic and eukaryotic organisms. Coincidently, it has recently been shown that nature has evolved a similar strategy (an orthogonal amber suppressor tRNA/synthetase pair) to genetically encode the unnatural amino acid pyrrolysine in *Methanosarcina barkeri*.[5] Future work in this field will likely focus on expanding the nature and number of amino acids that can be genetically encoded in both prokaryotic and eukaryotic organisms, including multicellular organisms. Additional orthogonal pairs that suppress three- and four-base codons are also being developed. It may even be possible to delete rare redundant codons from the *E. coli* genome and use them instead to encode unnatural amino acids. The ability to genetically encode unnatural amino acids should provide powerful probes, both in vitro and in vivo, of protein structure and function. It may also allow the rational design or evolution of proteins with novel properties. Examples might include homogeneous glycosylated or PEG-derivatized therapeutic proteins with improved pharmacological properties, fluorescent proteins that act as sensors of small molecules and protein–protein interactions in the cell, or proteins whose activity can be photoregulated in vivo. It should also be possible to incorporate non-amino acid building blocks into proteins or perhaps even create biopolymers with entirely unnatural backbones. Finally, the ability to add novel amino acids to the genetic codes of organisms will allow us to experimentally test whether there is an evolutionary advantage for organisms with more than 20 amino acid building blocks.

Communications

The spotlight is on the classical organometallic molecule bis(benzene)chromium, which this year celebrates its 50th anniversary. Easy to dimetalate, its monometalation on a preparative scale has thus far proved elusive. The synergic action of Na/Mg or K/Mg bases allows its selective deprotonation. For more information, see the Communication by R. E. Mulvey and co-workers on the following pages.

Metalation Reactions

Synergic Monodeprotonation of Bis(benzene)chromium by Using Mixed Alkali Metal–Magnesium Amide Bases and Structural Characterization of the Heterotrimetallic Products**

Eva Hevia, Gordon W. Honeyman, Alan R. Kennedy, Robert E. Mulvey, and David C. Sherrington*

Developed by Elschenbroich in the late 1960s,[1] the reaction of bis(benzene)chromium with TMEDA-activated *n*BuLi still represents today the standard method for metalating the sandwich complex (TMEDA is *N*,*N*,*N*′,*N*′-tetramethylethylenediamine). Metalation plays a pivotal part in the development of bis(benzene)chromium chemistry,[2] which celebrates its 50th anniversary in 2005,[3] as in transforming the parent neutral compound to a more reactive carbanionic form, it opens up a gateway to a plethora of selectively functionalized derivatives.[4] The original lithiation method, which employs a 5:1 molar excess of base, produces mainly the heteroannular dilithio derivative "$[Cr(C_6H_5Li)_2]$" in yields of about 50% at best, as determined indirectly by mass spectrometric studies of D_2O-quenched reaction mixtures. Lithiation of one benzene ring strongly activates the molecule towards a second lithiation (on the other ring), hence the yield of the monolitho derivative "$[Cr(C_6H_5Li)(C_6H_6)]$" is always much poorer (typically 5–20%). A lack of crystallographic evidence means that neither lithio reagent has been structurally authenticated, though an analogy with the TMEDA adduct of heteroannular dilithioferrocene $[\{Fe(C_5H_4)_2\}_3Li_6\cdot(TMEDA)_2]$[5] suggests both could be molecularly complex. Following our recent report[6] that ferrocene can be regioselectively tetrametalated by the synergic action of mixed sodium/magnesium tris(diisopropylamide), manifested in the sixteen-membered inverse crown complex $[\{Fe(C_5H_3)_2\}Na_4Mg_4(i\mathrm{Pr}_2\mathrm{N})_8]$, we posed the question "how would such synergic base mixtures behave towards bis(benzene)chromium?". The surprising and contrasting answers to this question when the π-arene complex is subjected to synergic amide mixtures based on either 1,1,1,3,3,3-hexamethyldisilazide (HMDS) or 2,2,6,6-tetramethylpiperidide (TMP) provides the basis for this Communication. Moreover, all of the metal products synthesized in this study have been successfully characterized crystallographically, thus belatedly revealing the first crystal structures of polar metal complexes of bis(benzene)chromium.[7]

In the first synergic trial, treatment of bis(benzene)chromium with an equimolar mixture of potassium HMDS and magnesium bis(HMDS) afforded $[\{\{K\cdot[Cr(C_6H_6)_2]_2\}^+[Mg(HMDS)_3]^-\}_\infty]$ (**1**; Scheme 1). No metalation has taken place during the synthesis, thus reflecting the relatively weak basic character of HMDS, instead the bis(benzene)chromium acts as a π ligand to the K^+ cation, which forms an ion-pair "-ate" complex with the $[Mg(HMDS)_3]^-$ ion. However, this is still a synergic reaction in the sense that neither homometallic component KHMDS or $Mg(HMDS)_2$ reacts unilaterally with bis(benzene)chromium under similar conditions to those employed in the preparation of **1**. In the molecular structure of **1** (Figure 1)[8] two distinct bis(benzene)chromium molecules π bond to the K^+ ion, which, in turn, engages with the $[Mg(HMDS)_3]^-$ ion through $K\cdots CH_3Si(Me_2)$ agostic interactions. One of the bis(benzene)chromium molecules (labeled Cr2) bridges to

Scheme 1. Comparative reactions of bis(benzene)chromium with homometallic and heterometallic base mixtures.

the K^+ ion of a neighboring molecule, thus extending the structure through a metal-rich $\{K(C_6H_6)Cr(C_6H_6)K'\}$ sandwich and making the K^+ ion four-coordinate overall (counting both the anion and neutral ligands as single coordination points). Disorder in one of the bis(benzene)chromium molecules renders the dimensions in which it is involved meaningless, but other key dimensions are listed in the legend to Figure 1. To the best of our knowledge, the cationic moiety of **1** is unprecedented and as such represents with the other

new complexes reported herein, the first characterized bis(benzene)chromium complexes of any alkali metal. An indirect comparison can be made with the recently reported ferrocene complex $[\{K\cdot[Fe(C_5H_5)_2]_2\cdot(toluene)_2\}^+\{Mg(HMDS)_3\}^-]$.[9]

A distinct change of the reaction solution from brown to deep red gave cause for optimism that metalation had occurred during the synergic trials of the stronger base TMP, as a similar color change accompanies lithiation of bis(benzene)chromium. Composed of butylsodium or benzylpotassium, dibutylmagnesium, TMPH, and TMEDA in a 1:1:3:1 stoichiometry, the synergic base mixture was employed in a 4:1 molar excess with respect to bis(benzene)-chromium (Scheme 1). Each reaction afforded a red crystalline product, namely $[NaMg\{Cr(C_6H_5)(C_6H_6)\}(TMP)_2\cdot(TMEDA)]$ (**2**) or $[KMg\{Cr(C_6H_5)(C_6H_6)\}(TMP)_2\cdot(TMEDA)]$ (**3**). Thus, surprisingly, in contrast to the lithiation precedent, these sodium and potassium congeners show metalation (formally magnesiation) selectively on only one ring, leaving the second benzene ring untouched. Even when the molar excess of base is increased to 10:1, **2** and **3** are still the only isolable products, thus indicating that synergic monometalation deactivates the second benzene ring (and the remaining H sites of the phenyl ring) towards metalation. Moreover, the yields of **2** and **3** of the isolated solids (first batch 64 and 67%, respectively), are unquestionably high for metallo compounds of bis(benzene)chromium, which are usually used in situ without isolation or characterization. Homometallic control reactions that employ the same TMPH/TMEDA mixtures but with only a single metallic reagent (butylsodium, benzylpotassium, or dibutylmagnesium) failed to similarly promote metalation of added bis(benzene)chromium, thus confirming that the selective metalation behind the syntheses of **2** and **3** is also synergic in origin.

The molecular structures of **2** (Figure 2)[10] and **3** (Figure 3)[11] share many common features. These include a central near-planar, four-element MNMgC ring [counting

bis(benzene)chromium as formally a ligand that coordinates through a single C atom]; a Mg-attached, terminal TMP ligand; and, bidentate TMEDA chelation of the alkali metal (Na or K). Another salient feature, which has become a distinguishing trademark of inverse crown chemistry[12] is the σ/π distinction of the s-block metal–arene bonding, which reflects the relative size, polarizability, and hardness or softness of the particular type of metal atoms involved. Refilling the position vacated by the H atom, the lower polarity Mg atom forms a stronger, more covalent bond with the anionic C center, the predominately σ character of which can be discerned from its near coplanarity with the plane of the phenyl ring [deviation of Mg from plane: 0.005(3) Å in **2**; 0.290(3) Å in **3**]. In contrast, the higher polarity (and softer) alkali-metal atoms occupy skewed positions above the Ph ring to engage electrostatically with its π face. The closest contact is to the anionic C1 center [2.705(2) Å in **2**; 2.917(2) Å in **3**], where charge is most concentrated, and there are other short contacts to proximate atoms, one for Na [2.910(2) Å to C(2)] and, reflecting the larger cation size and softer character, two for K [3.018(2) Å to C(2); 3.228(2) Å to C(6)]. All other M···C(Ph) distances exceed 3.38 Å and 3.44 Å in **2** and **3** respectively. Dimensions involving Mg atoms vary little between **2** and **3** [e.g., Mg–C1, 2.197(2) Å and 2.172(2) Å, respectively; C1-Mg-N2, 104.39(8)° and 103.54(7)°, respectively], which is consistent with Mg being the anchoring metal center that templates the anionic ligand set into a distorted trigonal planar, pseudoate arrangement about it. The TMEDA-chelated M atoms affix loosely to this template to form a contacted ion pair. Interestingly, the shortest interatomic distance for Na is with the μ-N(TMP) atom [2.455(2) Å; the distance to C1 is 0.250 Å longer], whereas for K the corresponding distances are equally short [to C1, 2.917(2) Å; to μ-N(TMP), 2.920(2) Å]. Furthermore, the K–μ-N(TMP) contact is significantly longer than the K–N(TMEDA) distances (mean, 2.841 Å), which is the reverse of that found for Na [mean Na–N(TMEDA) distance, 2.519 Å, compared with 2.455(2) Å for Na-C1]. Hence it can be deduced that the K center has a greater affinity for binding to the softer areneide than to the harder N anion. The close proximity between the terminal TMP ligand and the non-metalated benzene ring, coupled with the overhanging of the TMEDA molecule above the Ph ring, suggest that the simultaneous attachment of a second TMP-Mg-TMP-M-TMEDA coordination arc (concomitant with a second deprotonation) could possibly be ruled out on steric grounds (though electronic factors may also contribute to the inertness of **2** and **3** towards further deprotonation). It must also be stressed that the synergic Na–Mg/K–Mg bases will themselves be extremely sterically demanding, much more so than *n*BuLi. Thus, in the usual lithium reagent methodology there is no such steric control, hence the selectivity of monometalation is lost and dimetalation readily proceeds.

Further studies will address how different synergic bases will behave towards bis(benzene)chromium and, in view of their ready availability in pure crystalline form, whether **2** and **3** (in the mould of the lithio precedents) can be employed as access reagents to monofunctionalized bis(benzene)chromium derivatives.

Experimental Section

All reactions were carried out under a protective argon atmosphere.

Synthesis of **1**: K(HMDS) (2 mL of a 0.5 M solution in toluene, 2 mmol) was added to a solution of $Mg(HMDS)_2$ in heptane, which was prepared in situ by treating *n*/*s*Bu_2Mg (1 mL of a solution in heptane, 1 mmol) with HMDS(H), (0.422 mL, 2 mmol) at reflux for two hours. The solution was heated at reflux for one hour then left to reach room temperature. Bis(benzene)chromium (0.208 g, 1 mmol) was added and the resulting solution was heated at reflux for another hour. Toluene was added (10 mL) to completely dissolve the dark green precipitate that had formed and the reaction mixture was then heated to reflux for a further hour. The resulting solution was left to cool overnight to facilitate crystallization. A large crop of green/black needle-shaped crystals was obtained. Yield: 34.4% (0.33 g). M.p.: 228 °C. ^{1}H NMR (400.13 MHz, [D_8]toluene, 300 K): $\delta = 0.45$ (s, CH_3, $Mg[N\{Si(CH_3)_3\}_2]_3$), 4.28 ppm (broad s, $Cr(\eta^6\text{-}C_6H_6)_2$). ^{13}C{^{1}H} NMR (100.63 MHz, [D_8]toluene, 300 K): $\delta = 7.35$ (CH_3, $Mg[N\{Si(CH_3)_3\}_2]_2$), 74.74 ppm ($Cr(\eta^6\text{-}C_6H_6)_2$).

Synthesis of **2**: *n*BuNa (0.4 g, 5 mmol) was suspended in hexane (20 mL). *n*/*s*Bu_2Mg (5 mL of a 1 M solution in heptane, 5 mmol) and TMPH (2.5 mL, 15 mmol) were added. The resulting pale yellow solution was stirred for 30 minutes and TMEDA (0.75 mL, 5 mmol) was introduced. The slightly cloudy pale yellow solution was filtered through Celite and $[Cr(C_6H_6)_2]$ (0.26 g, 1.25 mmol) was added. The reaction mixture was heated at reflux for 45 minutes and a change from brown to red was observed. Allowing the solution to cool slowly to room temperature produced a crop of red crystals. Yield: 64% (0.52 g). ^{1}H NMR (400.13 MHz, [D_8]thf, 300 K): $\delta = 4.61$ (d, 2H, H_{ortho}, C_6H_5), 4.16 (t, 2H, H_{meta}, C_6H_5), 4.10 (m, 1H, H_{para}, C_6H_5), 4.03 (s, 6H, C_6H_6), 2.30 (s, 4H, CH_2, TMEDA), 2.15 (s, 12H, CH_3, TMEDA), 1.62 (m, 4H, TMP), 1.30 (s, 24H, CH_3, TMP), 1.18 ppm (m, 8H, TMP). ^{13}C{^{1}H} (100.63 MHz, [D_8]thf, 300 K): $\delta = 105.4$ (C_{para}, C_6H_5), 88.7 (C_{ortho}, C_6H_5), 79.4 (C_{meta}, C_6H_5), 75.9 (C_{ipso}, C_6H_5), 72.2 (C_6H_6), 59.1 (CH_2, TMEDA), 53.2 (N-*C*, TMP), 46.6 (CH_3, TMEDA), 42.8 (TMP), 36.4 (CH_3, TMP), 21.6 ppm (TMP). An as-yet unidentified minor product with signals at 4.71 (d) 4.22 (m), 4.07 (s) was also present in the ^{1}H NMR spectrum.

Synthesis of **3**: BzK (0.65 g, 5 mmol) was suspended in hexane (20 mL). *n*/sBu_2Mg (5 mL of a 1 M solution in heptane, 5 mmol), TMPH (2.5 mL, 15 mmol) and TMEDA (0.75 mL, 5 mmol) were added and the resulting mixture was stirred for 1 h affording a slightly cloudy red solution which was filtered through Celite. $[Cr(C_6H_6)_2]$ (0.26 g, 1.25 mmol) was subsequently added and the reaction mixture was heated under reflux for 45 minutes. Allowing the red solution to cool slowly to room temperature produced a crop of red crystals. Yield: 67% (0.55 g). (400.13 MHz, [D_8]thf, 300 K): $\delta = 4.71$ (d, 2H, H_{ortho}, C_6H_5), 4.16 (t, 2H, H_{meta}, C_6H_5), 4.08 (m, 1H, H_{para}, C_6H_5), 3.98 (s, 6H, C_6H_6), 2.30 (s, 4H, CH_2, TMEDA), 2.15 (s, 12H, CH_3, TMEDA), 1.68 (m, 4H, TMP), 1.28 (s, 24H, CH_3, TMP), 1.23 ppm (m, 8H, TMP). ^{13}C{^{1}H} (100.63 MHz, [D_8]thf, 300 K): $\delta = 107.6$ (C_{para}, C_6H_5), 89.3 (C_{ortho}, C_6H_5), 79.6 (C_{meta}, C_6H_5), 76.2 (C_{ipso}, C_6H_5), 71.7 (C_6H_6), 59.3 (CH_2, TMEDA), 53.2 (N-*C*, TMP), 46.5 (CH_3, TMEDA), 42.8 (TMP), 36.5 (CH_3, TMP), 21.8 ppm (TMP).

Functional Materials

Highly Interpenetrated Metal–Organic Frameworks for Hydrogen Storage**

*Banu Kesanli, Yong Cui, Milton R. Smith, Edward W. Bittner, Bradley C. Bockrath, and Wenbin Lin**

Metal–organic frameworks (MOFs) provide an interesting avenue to novel materials through fine-tuning their structures by a modular construction approach.[1] A variety of MOFs have recently been explored for potential applications, such as nonlinear optics, size-, shape-, and functional-group-selective sorptions, and catalysis.[2] Many of the perceived applications for MOFs require accessible large pores, which presents a significant challenge owing to a strong tendency of interpenetration in such very open frameworks. In contrast to a vast number of porous non-interpenetrated MOFs, only a few examples of porous interpenetrated MOFs have been reported.[3]

Kitagawa et al. have pioneered the studies on the adsorption of small molecules (such as methane and oxygen) by microporous MOFs.[4] More recent results by Rosi et al. further suggested that microporous MOFs are able to store hydrogen at a capacity unmatched by other materials.[5] It was believed that favorable interactions exist between aromatic rings of MOFs and hydrogen molecules.[6] We hypothesize that microporous interpenetrated MOFs would be ideal candidates for the sorption of small gaseous molecules. Interpenetration can be utilized to strengthen the interaction between the gaseous molecule and the framework by an entrapment mechanism in which a hydrogen molecule is in close proximity with several aromatic rings from interpenetrating networks.[7] Herein we report the design of highly interpenetrated aromatic-rich MOFs and preliminary data on their hydrogen and methane sorption capacities.

New aromatic-rich, dicarboxylic acids 6,6′-dichloro-2,2′-diethoxy-1,1′-binaphthyl-4,4′-dibenzoic acid (L_1-H_2) and 6,6′-dichloro-2,2′-dibenzyloxy-1,1′-binaphthyl-4,4′-dibenzoic acid (L_2-H_2) were prepared by Suzuki coupling reactions between

Scheme 1.

4-methoxycarbonylphenylboronic acid and previously reported 6,6′-dichloro-4,4′-dibromo-1,1′-binaphthyl starting materials followed by hydrolysis (Scheme 1).[8] Single crystals of $[Zn_4(\mu_4\text{-}O)(L_1)_3(dmf)_2]\cdot 4\,DMF\cdot 3\,CH_3OH\cdot 2\,H_2O$ (**1**) and $[Zn_4(\mu_4\text{-}O)(L_2)_3]\cdot 5\,DMF\cdot 5\,C_2H_5OH\cdot H_2O$ (**2**) were obtained by treating $Zn(ClO_4)_2$ with L_1-H_2 in DMF and MeOH or ZnI_2 with L_2-H_2 in DMF and EtOH in the presence of dimethylaniline at 50 °C for two days. The formulations of **1** and **2** were supported by IR, microanalysis, and thermogravimetric analysis (TGA) results.

Compound **1** adopts a 3D interpenetrating network structure that is built from two distinct $[Zn_4(\mu_4\text{-}O)(L_1)_3(dmf)_2]$ clusters (Figure 1a).[9] While one of the L_1 ligands adopts an *exo*-tridentate coordination mode, the other L_1 ligands adopt *exo*-tetradentate coordination mode. One of the two $[Zn_4(\mu_4\text{-}O)(L_1)_3(dmf)_2]$ clusters contains three Zn^{II} centers in tetrahedral and one in a trigonal bipyramidal coordination geometry that are bridged by a μ_4-O atom and five carboxylate groups of L_1 ligands, while the other contains three Zn^{II} centers in tetrahedral and one in an octahedral coordination geometry that are bridged by a μ_4-O atom and six carboxylate groups of L_1 ligands. Each of the two $[Zn_4(\mu_4\text{-}O)(L_1)_6(dmf)_2]$ clusters is completed by the coordination of two DMF molecules. Each type of $[Zn_4(\mu_4\text{-}O)(L_1)_6(dmf)_2]$ cluster in **1** is interlinked by the carboxylate groups of L_1 ligands to generate an extended neutral 3D network of a cubic topology that is built upon six-connected nodes. The 3D network of **1** thus possesses very large cubic cavities of approximately $19\times19\times19$ Å (Figure 1b). However, **1** avoids extremely large void space by forming a fourfold interpenetrated structure (Figure 1c). Even after fourfold interpenetration, **1** still possesses significant void space that is occupied by disordered DMF, MeOH, and H_2O guest molecules.[10] These void spaces can be accessed from open channels (Figure 1d) of approximately 4.1×5.0 Å along the *a* axis, of 3.2×4.0 Å and 2×2.5 Å along the *b* axis, and of 4.7×5.4 Å and 1.8×3.4 Å along the *c* axis. The effective free volume of **1** was calculated by PLATON analysis as 46.1% of the crystal volume (15168 $Å^3$ out of the 32912 $Å^3$ unit cell volume).

Compound **2** adopts a similar fourfold 3D interpenetrating network structure that is built from C_3-symmetric $[Zn_4(\mu_4\text{-}O)(L_2)_3]$ clusters.[9] All the Zn centers in the $[Zn_4(\mu_4\text{-}O)(L_2)_3]$ cluster have tetrahedral geometry through coordination to a

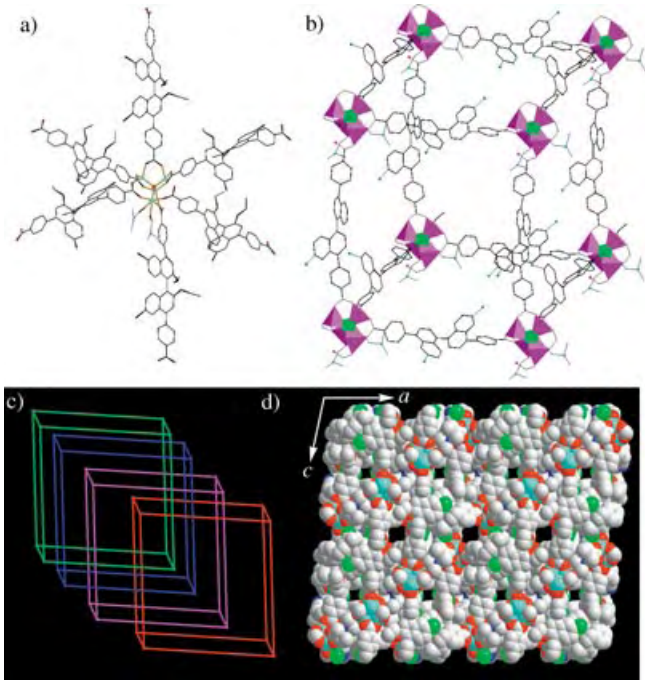

Figure 1. a) A view of the one of the $[Zn_4(\mu_4\text{-}O)(L_1)_6(dmf)_2]$ clusters of **1** b) A view of the cubic cavity formed by the 3D network (ethoxy groups have been omitted for clarity; the purple and green polyhedra represent the cluster building unit. c) A schematic presentation of the fourfold interpenetration in **1**. d) A space-filling model of **1** as viewed down the *b* axis (solvent molecules have been omitted); gray C, red O, blue N, green Cl, turquoise Zn.

μ_4-oxygen atom and three oxygen atoms of the bridging carboxylate groups of the L_2 ligands. There are no coordinating solvent molecules in the structure of **2**. Just like **1**, the $[Zn_4(\mu_4\text{-}O)(L_2)_3]$ clusters in **2** are linked by L_2 ligands to form an extended 3D network structure of a cubic topology. The 3D network structure of **2** contains cubic cavities of approximately $19\times19\times19$ Å. The porosity of **2** is drastically reduced by adopting fourfold interpenetration, and the void space in **2** is filled with five DMF, one H_2O, and five ethanol guest molecules as established by TGA and elemental analysis. PLATON analysis indicated that the effective free volume of **2** was 41.4% of the crystal volume (5257 $Å^3$ out of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

12699 Å^3 unit cell volume). A smaller percent effective free volume of **2** compared to **1** is consistent with the presence of larger benzyloxy groups in **2**. The void space of **2** is only accessible along the *c* axis by open channels of approximately 1.3×4.5 Å.

Single-crystal X-ray diffraction studies, TGA, and elemental analyses demonstrated the inclusion of disordered guest molecules in **1** and **2**. Powder X-ray diffraction studies further indicated that the long-range order of the framework structures of **1** and **2** was retained upon complete removal of the guest molecules (see Supporting Information). Permanent microporosity of **1** and **2** was unambiguously established with CO_2 adsorption measurements at 0 °C. Samples of **1** and **2** were soaked in CH_2Cl_2 overnight and then evacuated at 85 °C for 12 h before CO_2 adsorption measurements. Type 1 behavior was observed for the CO_2 adsorption isotherms of both **1** and **2**, which is characteristic of solids with micropores. Compounds **1** and **2** possess a BET surface area of 502 and 396 $m^2 g^{-1}$, respectively. The micropore volume for **1** is 0.20 $mL g^{-1}$ and for **2** is 0.13 $mL g^{-1}$.[11] Smaller surface area observed for **2** is consistent with its percent effective free volume calculated with PLATON.

We have examined gas storage behaviors of **1** and **2** at room temperature. Hydrogen adsorption isotherms were taken using a pulse mass analyzer[12] in the 0.9–48 bar pressure range on samples of **1** and **2** that had been heated at 150 °C for 1 h to remove the included solvent molecules. The H_2 uptakes are calculated to be 1.12 wt % for **1** and 0.98 wt % for **2** at 48 bar (Figure 2, Table 1), which corresponds to H_2 storage capacity of 124.7 $mL g^{-1}$ for **1** and 109.6 $mL g^{-1}$ for **2**.[12] The H_2 uptake of **1** and **2** is reversible for at least six times. For comparison, MOF-5 reported by Rosi et al.[5] exhibits a H_2 uptake of 1.65 wt % ($\approx$1.5 times that of **1**) using our procedures under the same conditions. These hydrogen uptake results for **1** and **2** are comparable to H_2 storage capacities of purified single-walled carbon nanotubes and only slightly inferior to the best MOFs (which have surface areas of 5–10 times those of **1** and **2**).[5,12,13] Methane-adsorption measurements indicated a room-temperature methane uptake of 11.0 wt % (154 $mL g^{-1}$) for **1** and 9.5 wt % (133 $mL g^{-1}$) for **2**. These methane storage capacities are lower than those of the best MOFs, which is consistent with the smaller microporous surface areas of **1** and **2**.

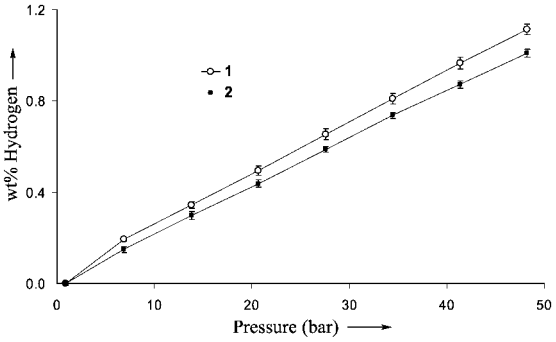

Figure 2. Hydrogen adsorption isotherms of **1** and **2** at 25 °C. The data points represent averages of six consecutive runs and the error bars indicate run-to-run variations.

Table 1: Porosity and gas storage capacity of **1** and **2**.

Sample	Surface area $m^2 g^{-1}$[a]	Pore volume $mL g^{-1}$[b]	Void volume %[c]	wt% H_2	wt% CH_4
1	502	0.20	46.1	1.12	11.0
2	396	0.13	41.4	0.98	9.5

[a] Determined from fits of adsorption data to the BET equation. [b] Calculated using the DR equation. [c] Estimated from PLATON calculations

Our results agree with an earlier observation that large surface area and pore volume are not the only recipe for the attainment of H_2 storage materials.[13a] That significant H_2 uptake is detected in the highly interpenetrated networks of **1** and **2** points to new directions for the design of efficient H_2 storage materials by utilizing interpenetration to strengthen the interaction between H_2 molecules and the framework by multiple contacts with several aromatic rings from the interpenetrating networks. Similar to triple-junction sites in carbon nanotube bundles,[6] such storage sites would have higher H_2 binding energy which is another key to the development of practical H_2 storage materials.

In summary, we have synthesized and characterized two novel fourfold interpenetrated MOFs of cubic topology that exhibit significant H_2 uptake at 25 °C. The ready tunability of these MOFs should allow the optimization of both H_2 storage capacity and H_2 binding energy in future generations of MOFs.

Experimental Section

1: A mixture of $Zn(ClO_4)_2 \cdot 6H_2O$ (3.7 mg, 0.01 mmol) and L_1-H_2 (0.01 mmol) was placed in a small vial containing DMF (0.5 mL), MeOH (0.2 mL), and *N*,*N*′-dimethylaniline (5 μL). The vial was sealed, heated at 50 °C for 48 h, and allowed to cool to room temperature. The crystals suitable for X-ray diffraction were collected by filtration, washed with diethyl ether, and dried in air. Yield: 81 %. Elemental analysis calcd (%) for $C_{135}H_{136}Cl_6Zn_4N_6O_{30}$, C 57.97, H 4.86, N 3.00; found: C 57.96, H 4.85, N 3.79, IR: $\tilde{\nu}$ = 3487 (m), 2978 (w), 2924 (w), 1660 (m), 1603 (s), 1552 (m), 1508 (m), 1411 (s), 1373 (m), 1343 (s), 1324 (m), 1213 (w), 1189 (w), 1155 (w), 1088 (m), 1059 (w), 1019 (m), 948 (w), 866 (w), 816 (w), 788 (w), 723 (w), 699 (w), 625 cm^{-1} (w).

Carbon dioxide adsorption studies were carried out at 0 °C on a Quantachrome-1C surface-area analyzer. Details of hydrogen adsorption studies were described in ref. [12].

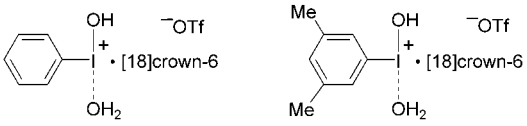
Coordination Chemistry

Synthesis, Characterization, and Reaction of Crown Ether Complexes of Aqua(hydroxy)(aryl)iodonium Ions

Masahito Ochiai, Kazunori Miyamoto, Yukie Yokota, Takashi Suefuji, and Motoo Shiro*

The Koser reagent, [hydroxy(tosyloxy)iodo]benzene (**1**; Ts = *p*-toluenesulfonyl), is a useful oxidizing agent for a range of organic substrates.[1] It has been reported that upon dissolution in water the λ^3-iodane undergoes complete ionization to give the hydroxy(phenyl)iodonium cation (PhI^+OH).[2] The hydroxy(phenyl)iodonium ion does not form an ion pair with a tosylate ion and is presumed to be ligated with at least one water molecule at an apical site of the iodine(III) center. This aqua(hydroxy)(phenyl)iodonium ion **2** ($L = H_2O$) is highly soluble in water with a pK_a value of 4.30 at 20 °C.

1 **2** **3**



Iodosylbenzene is a polymer bridged by secondary I···O hypervalent interactions,[3] and hence is essentially insoluble in both nonreactive organic solvents and water at near neutral pH conditions;[4] however, at pH < 2.3 iodosylbenzene is highly soluble in water, in which **2** ($L = H_2O$) was also assumed to be a primary monomeric species.[2]

Aqua complexes of λ^3-iodanes with a water molecule coordinated to an iodine(III) center are unique, and there are no well-established precedents. Therefore, direct evidence supporting the proposed structure of **2** ($L = H_2O$) is highly desirable. Recently, Wirth and co-workers synthesized an interesting chiral hydroxyiodonium ion **3**, in which the oxygen atom of the *ortho* methoxymethyl group replaces the tosylate ligand of the Koser reagent with a near-linear O–I···O triad.[5] We have reported the isolation and characterization of the crown ether complex **2**·BF_4^- (L = [18]crown-6) of hydroxy(phenyl)iodonium ion. In this complex, an oxygen atom of the crown ether is tightly bound to the iodine(III) center at the apical site and forms a T-shaped structure with linear O–I···O hypervalent bonding.[6] Herein, we report the first synthesis

and characterization of the aqua complexes **4** (Tf = trifluoromethanesulfonyl) of (hydroxy)(aryl)iodonium ions, which are stabilized by the coordination of [18]crown-6 through secondary I···O bonding. The crystalline crown ether complex **4a** is stable at ambient temperature and oxidizes a variety of functional groups under mild conditions, especially in water.

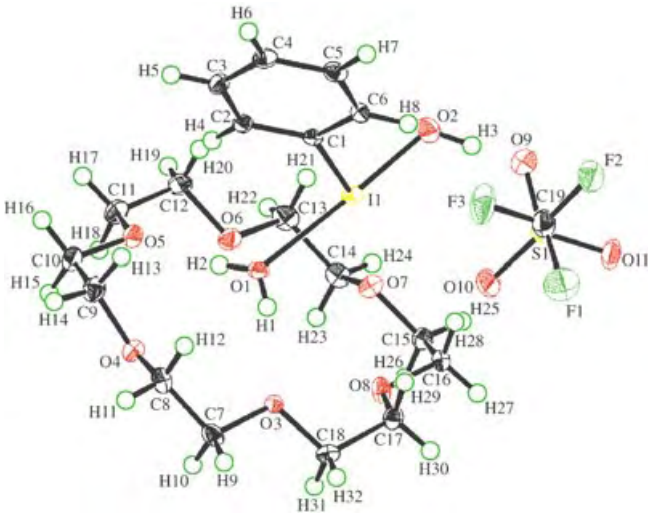
4a **4b**

The exposure of (diacetoxyiodo)benzene to trimethylsilyl trifluoromethanesulfonate (1.1 equiv) in the presence of [18]crown-6 (1 equiv) in dichloromethane at −50 to 0 °C under nitrogen resulted in ligand exchange at the iodine(III) center. The aqua crown ether complex **4a** was obtained in 91 % yield as a white powder after repeated decantation with hexane and diethyl ether at −40 °C. Complex **4b** was prepared in a similar way from 3,5-dimethyl(diacetoxyiodo)benzene[7] in 92 % yield. The aqua complex **4a** is soluble in dichloromethane, chloroform, acetonitrile, acetone, and methanol, but not in the less polar solvents diethyl ether and hexane. Interestingly, complex **4a** is stable in the solid state as well as in solution: No decomposition was detected when it was left standing in air at room temperature for 10 days. As a solution in $CDCl_3$, the half-life ($t_{1/2}$) of **4a** at room temperature was found to be approximately 2 weeks, whereas that of the crown ether complex **2**·BF_4^- (L = [18]crown-6) is only 6 hours as a solution in dichloromethane.[6]

In the ^{1}H NMR spectrum of **4a** in CD_3CN, the signals for the aromatic hydrogen atoms are comparable to those reported for hydroxy(phenyl)(triflato)-λ^3-iodane.[8] The observed downfield shift (0.05 ppm) of a methylene singlet for **4a** relative to that for [18]crown-6 suggests the formation of a crown ether complex in solution. The ^{13}C NMR signal for [18]crown-6 (δ = 71.2 ppm in CD_3CN) is shifted to higher field (δ = 70.8 ppm) in the complex.

Recrystallization from acetone/diethyl ether/hexane at −30 °C afforded single crystals of **4a** suitable for X-ray crystallographic analysis.[9] Figure 1 illustrates a T-shaped structure, ligated with one water molecule at the apical site of the iodine(III) center of hydroxy(phenyl)iodonium ion with a near-linear O1-I1-O2 triad (173.96°). Including the close contact between one of the crown ether oxygen atoms, O7, and the iodine center, the complex adopts a distorted square-planar geometry around the iodine atom. A rms deviation of 0.082 Å was observed for I1, O1, O2, O7, and C1 from their least-squares plane, and the sum of the iodine-centered bond angles is Σ°I = 360.1°.

The linear O1-I1-O2 hypervalent bonding[10] is highly unsymmetrical, as observed in polymeric iodosylbenzene



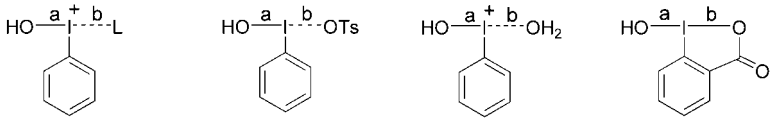


Figure 1. ORTEP drawing of **4a**. Selected bond lengths [Å] and angles [°]: I1–C1 2.117(2), I1–O2 1.967(2), I1–O1 2.392(2), I1···O7 2.942(2), O3···H1 2.04(4), O5···H2 1.91(4), O9···H3 1.9582, C1-I1-O2 92.32(3), C1-I1-O1 81.80(8), O2-I1-O1 173.96(7).

(2.04 and 2.38 Å).[3] The hydroxy ligand in **4a** is tightly bound to the iodine(III) center with an O2–I1 distance of 1.967 Å, which is slightly shorter than that predicted for covalent radii (1.99 Å), whereas the water ligand is loosely bound (O1–I1, 2.392 Å). Scheme 1 depicts the varying degrees of the unsymmetrical nature of the hypervalent bonding in the known hydroxy-λ^3-iodanes, in which HO–I bond distances (a) increase in the order shown from left to right. Interestingly, the other I–O distances (b) decrease in this order. It is noteworthy that the hypervalent bonding of a neutral water molecule to the iodine(III) center in **4a** is much stronger than that of the tosylate anion in the Koser reagent (**1**).

Scheme 1. Distances of hypervalent O–I–O bonding interactions in hydroxy-λ^3-iodanes.

The ligated water molecule is in firm contact with [18]crown-6 through two hydrogen-bonding interactions, O3···H1 and O5···H2. Furthermore, the highly acidic nature of the hydroxy ligand (pK_a 4.3)[2] results in another hydrogen-bonding interaction with the triflate anion (O9···H3, 1.9582 Å). All of these close contacts are responsible for the enhanced thermal stability of complex **4a**. Based on the structure of **4a**, a monomeric iodosylbenzene species in an aqueous acidic medium is proposed to be a tetracoordinate square-planar iodonium ion **6**, in which two water molecules

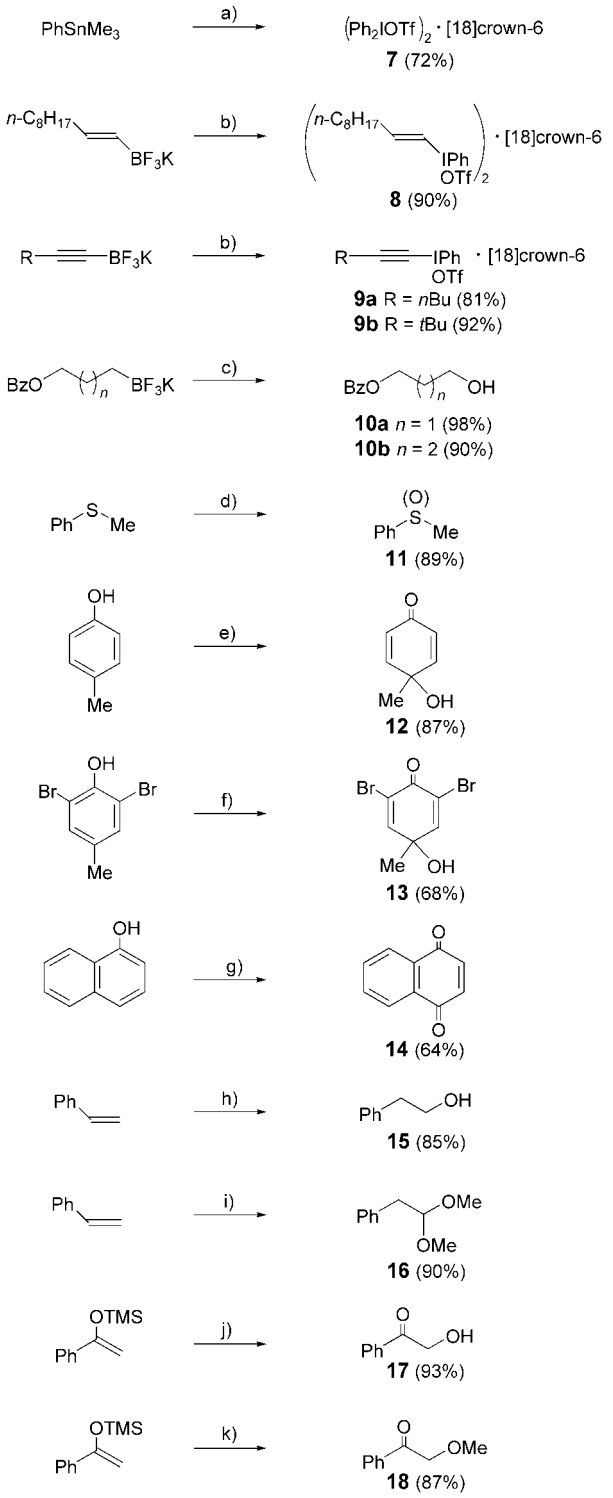
6

coordinate to the iodine center through hypervalent interactions.

The aqua complexes **4** serve as versatile oxidizing agents, especially in water, which is, of course, a safe, cheap, and environmentally benign solvent. The reactions shown in Scheme 2 illustrate the broad range of their applications. The exposure of phenyltrimethylstannane to **4a** in water at room temperature resulted in facile ligand exchange at the iodine center and afforded the diphenyl-λ^3-iodane·[18]crown-6 complex **7**.[11] Similarly, borate–λ^3-iodane exchange of 1-alkenyl and 1-alkynyl trifluoroborates produced the corresponding 1-alkenyl λ^3-iodane and 1-alkynyl λ^3-iodane complexes with [18]crown-6 (e.g. **8** and **9**) in high yields.[12,13] On the other hand, the reaction with alkyl trifluoroborates resulted in the introduction of a hydroxy group to yield primary alcohols **10**. All of these reactions proceed smoothly without further activation of **4a** by adding an external acid catalyst.



The oxidation of sulfides and *p*-substituted phenols in water produced sulfoxides and *p*-quinols, respectively. The yield of 2,6-dibromo-*p*-quinol **13** increased to 68% when the aqua complex **4b** was used instead of **4a** (55%). 1-Naphthol gave naphthoquinone (**14**) in good yield. The oxidation of styrene in water produced phenylacetaldehyde, and after reduction with $NaBH_4$ 2-phenylethanol was obtained in 85% yield. The use of methanol as a solvent afforded the dimethyl acetal **16**.[14] The α-hydroxy ketone **17** was obtained by the oxidation of a silyl enol ether in the presence of water, whereas in methanol a methoxy group was introduced at the α position to give **18**.

We have presented the synthesis and characterization of a crown ether complex of aqua(hydroxy)(phenyl)iodonium ion, which is assumed to be a primary monomeric iodosylbenzene species in an acidic aqueous medium. The complex is stable in the solid state as well as in solution and serves as a versatile oxidant in water.

Experimental Section

4a: Trimethylsilyl trifluoromethanesulfonate (152 mg, 0.69 mmol) was added dropwise at −50 °C under nitrogen to a solution of (diacetoxyiodo)benzene (200 mg, 0.62 mmol) and [18]crown-6 (164 mg, 0.62 mmol) in CH_2Cl_2 (6.7 mL). The mixture was gradually warmed to 0 °C over 4 h. The solvent was evaporated under an aspirator vacuum at 0 °C to give a yellow oil, which was washed several times with hexane and diethyl ether by decantation at −40 °C to give **4a** (368 mg, 0.56 mmol, 91%) as a white powder. Recrystallization of **4a** (100 mg) from acetone/diethyl ether/hexane at −30 °C gave colorless prisms (35 mg): m.p. 61–63 °C; ^{1}H NMR (400 MHz, CD_3CN): $\delta = 8.24$ (d, $J = 8.0$ Hz, 2H), 7.78 (t, $J = 7.3$ Hz, 1H), 7.64 (dd, $J = 8.0$, 7.3 Hz, 2H), 3.56 ppm (s, 24H); ^{13}C NMR (75 MHz, CD_3CN): $\delta = 136.3$, 134.4, 132.4, 123.3, 70.8 ppm; IR (nujol): $\tilde{\nu} = 3564$, 3485, 1354, 1285, 1109, 1038, 965, 842, 638 cm^{-1}; elemental analysis calcd (%) for $C_{19}H_{32}F_3IO_{11}S$ (652.42): C 34.98, H 4.94; found: C 35.22, H 4.88.

4b: Colorless prisms (recrystallized from acetone/diethyl ether/hexane at −30 °C): m.p. 59–61 °C; ^{1}H NMR (400 MHz, $CDCl_3$): $\delta =$ 7.75 (br s, 2H), 7.21 (br s, 1H), 3.69 (s, 24H), 2.36 ppm (s, 6H); ^{13}C NMR (75 MHz, CD_3CN): $\delta = 142.6$, 135.9, 133.6, 123.3, 70.8, 21.2 ppm; IR (nujol): $\tilde{\nu} = 3515$, 1354, 1258, 1107, 1032, 961, 838,

Scheme 2. Reaction of the aqua complexes **4** with nucleophiles under nitrogen. a) **4a** (1.5 equiv), H_2O, room temperature, 6 h; b) **4a** (1.5 equiv), H_2O, RT, 3 h; c) **4a** (1.2 equiv), H_2O, room temperature, 3 h; d) **4a** (1 equiv), H_2O, 0 °C, 3 h; e) **4a** (1.2 equiv), H_2O, 0 °C→RT, 3 h; f) **4b** (1.5 equiv), H_2O, room temperature, 6 h; g) **4a** (2.1 equiv), H_2O, 0 °C→RT, 3 h; h) 1. **4a** (1.1 equiv), H_2O, room temperature, 3 h; 2. $NaBH_4$ (2.2 equiv), MeOH, room temperature, 0.5 h; i) **4a** (1.1 equiv), MeOH, room temperature, 26 h; j) **4a** (1.1 equiv), H_2O/MeCN 2:5, 0 °C, 1 h; k) **4a** (1.1 equiv), MeOH, −78 °C→RT, 7 h. 639 cm^{-1}; elemental analysis calcd (%) for $C_{21}H_{37}F_3IO_{11.5}S$ (689.50): C 36.58, H 5.41; found: C 36.29, H 5.14.

8: Potassium *trans*-1-decenyl trifluoroborate (9.9 mg, 0.04 mmol) was added at room temperature under nitrogen to a solution of **4a** (39 mg, 0.059 mmol) in H_2O (2.5 mL), and the mixture was stirred for 3 h. The mixture was extracted with CH_2Cl_2 four times. The combined organic phases were filtrated and evaporated under an aspirator vacuum to give an oil, which was washed several times with hexane and then with hexane/diethyl ether by decantation at 0 °C to give a 1:1.3 mixture of *trans*-1-decenyl(phenyl)(trifluoromethanesulfonato)-λ^3-iodane and [18]crown-6 (30.6 mg, 0.036 mmol, 90 %) as a white powder. Recrystallization from dichloromethane/ethyl acetate/hexane at −30 °C gave **8** as colorless needles: m.p. 71.5–72 °C; ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 7.95$ (d, $J = 8.2$ Hz, 4H), 7.70 (t, $J = 7.3$ Hz, 2H), 7.54 (dd, $J = 8.2$, 7.3 Hz, 4H), 6.85–6.72 (m, 4H), 3.69 (s, 24H), 2.34 (q, $J = 7.3$ Hz, 4H), 1.44 (quint, $J = 7.3$ Hz, 4H), 1.32–1.19 (m, 20H) 0.88 ppm (t, $J = 6.8$ Hz, 6H); IR (nujol): $\tilde{\nu} = 3042$, 1563, 1265, 1223, 1152, 1101, 1031, 956, 838, 754, 638 cm^{-1}; elemental analysis calcd (%) for $C_{46}H_{72}F_6I_2O_{12}S_2$ (1249.03): C 44.23, H 5.81; found: C 44.55, H 5.93.

Nanotechnology

Efficient Generation of Photocurrents by Using CdS/Carbon Nanotube Assemblies on Electrodes**

*Laila Sheeney-Haj-Ichia, Bernhard Basnar, and Itamar Willner**

The organization of functional semiconductor nanoparticles (NPs) on surfaces, and specifically electrodes, attracts substantial research efforts.[1] Semiconductor NP architectures on surfaces have been used to assemble photoelectrochemical cells,[2,3] to tailor light-emitting diodes,[4] to fabricate electrochromic devices,[5] and to organize sensor systems.[6,7] The photochemical excitation of semiconductor NPs to form an electron–hole pair is the primary event for the photocurrent generation. However, the transfer of conduction-band electrons to the electrode (or the supply of electrons from the electrode to the valence-band holes)—the processes that lead to the photocurrents—are hampered by the competing electron–hole recombination process, which degrades the

photogenerated species and prohibits the generation of the photocurrent. To enhance the photocurrent, the retardation of the recombination of the electron–hole species is essential. Different approaches to maximize charge separation in semiconductor NP architectures have been suggested. These include the use of molecular electron-relay semiconductor NP structures, in which the electron–hole is spatially separated by trapping the electrons in the relay units.[8,9] Conductive polymer films, which contact CdS nanoparticles with electrodes, act as efficient electron-transport matrices that retard the recombination reactions.[10] Hybrid composite semiconductor nanoclusters[11] or hybrid metal/semiconductor NP systems[12] were used for the enhanced generation of photocurrent. There the coupling of the two semiconductors CdS and SnO_2 resulted in improved photoelectrochemical properties of the hybrid material which were attributed to improved charge separation. The transfer of the CdS conduction-band electrons to the SnO_2 conduction band resulted in the separation of the electron–hole pair onto two different semiconductor particles. Similarly, the enhanced photocurrents[12] and photocatalytic properties[13] of metal/semiconductor composite nanostructures were attributed to the spatial separation of the electron–hole pair in the two nanoparticles.

Carbon nanotubes are an attractive material for application in electronic or sensor devices.[14] Carbon nanotubes (CNTs) are formed by the folding of graphite sheets, and the formation of conductive or semiconductive CNTs depends on the folding angle of the graphite sheets.[15] Conductive CNTs usually reveal high values of conductivity.[16] Different electronic applications of CNTs have been reported in recent years which include the organization of memory devices[17] or transistors.[18] Also, CNTs have been used as active sensing elements[19] and as building blocks of biosensors.[20] Numerous methods to functionalize the edges or ends of CNTs with chemical groups that enable the binding of the CNTs to other units or surfaces have been developed.[21,22] The organization of assemblies of CNT and semiconductor NP on electrodes might provide a new structure for improved photoelectrochemistry. To our knowledge, only one study has been reported on the assembly of a CNT/ZnO NP hybrid system,[23] but no function or photoelectrochemical properties of the system were addressed. Here we report the assembly of CdS NP/CNT hybrid systems on electrode surfaces. The system reveals efficient photoelectrochemical functions.

Fullerenes were previously employed as a carbon-based nanomaterial for photoelectrochemical applications.[24] The C_{60} nanostructure exhibits electron-acceptor properties. Its reversible redox activity was studied in detail,[25] and different photoelectrochemical studies have used C_{60} as an electron acceptor for mediated electron transport and the generation of photocurrents. For example, photoexcited polyphenylenevinylene polymers were used as electron donors for C_{60}, and the resulting composites resulted in the effective formation of photocurrents.[26] In stark contrast to C_{60}, CNTs do not display reversible electrochemistry and do not exhibit electron-acceptor features. The documented high conductivity of CNTs (1.0×10^{6}–$3.0\times10^{6}\,S\,m^{-1}$)[16] renders them conductive nanowires rather than charge traps. Thus, the enhanced photocurrents in the present system originate from improved electron transport through the conductive wires in contrast to the mediated electron transfer in the C_{60} systems.

Scheme 1 depicts the method to assemble the CdS/CNT monolayer on a Au electrode. The CNTs were purified and

Scheme 1. The assembly of the CdS NP/CNT system on a Au electrode, and the photoinduced charge transport in the system. TEOA = triethanolamine, h^+ = hole.

"cut" by using a mixture of concentrated sulfuric and nitric acids (3:1, 98 % and 70 %, respectively) to yield CNTs with an average length of $\approx$10–100 nm as determined by TEM experiments. This procedure introduces carboxylic acid functionalities at the ends of the CNTs as well as some carboxylic acid units at the CNT sidewalls. The Au electrode was functionalized with a primary monolayer of cysteamine to which the CNTs were then coupled. The CdS NPs (5 nm, protected a capping monolayer of cysteamine and 2-thioethanesulfonic acid) were then coupled to the ends of the CNTs.

Microgravimetric quartz crystal microbalance (QCM) analyses allowed the surface coverage of the components to be characterized. The modification of the surface with the CNTs is controlled by the duration of the coupling process. Figure 1 shows the frequency changes (Δf) that occurred upon modification of the cysteamine monolayer-functionalized Au surface with the CNTs that were cut for a period of 4 h in acid solution. After $\approx$4 h of coupling, the frequency change reaches a constant value that translates to a weight coverage of $\approx3.14\times10^{-6}\,g\,cm^{-2}$ ($\Delta f=-575$ Hz). The CNT-functionalized surface was then modified with the CdS NPs. The absorbance spectrum of the CdS NPs revealed a shoulder at $\approx$400 nm which is consistent with the size of the NPs. The CdS NPs were then coupled to the CNTs associated with the electrode in the presence of 1-ethyl-3-(3-dimethyaminopropyl)carbodiimide (EDC). The microgravimetric analysis of the coupling of the CdS NPs to the CNTs assembled on a Au/quartz crystal (2 h of coupling) indicated a frequency change of -270 Hz that corresponds to a surface coverage of $\approx4.7\times$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

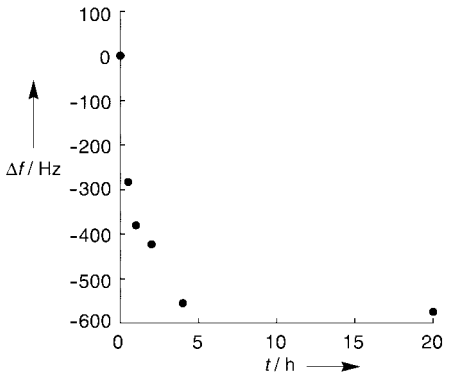

Figure 1. Time-dependent frequency changes (Δf) of a cysteamine-functionalized Au/quartz crystal upon the coupling of CNTs that had undergone oxidative digestion for 4 h. The coupling was performed with dicyclohexylcarbodiimide (0.01 M) in DMF in the presence of the CNT (5 mg mL^{-1}). Frequencies were recorded in air.

10^{12} particles cm^{-2}. Further evidence for the coupling of the CdS NPs to the surface was obtained from X-ray photoelectron spectroscopic (XPS) measurements. After the modification of the CNT interface with the CdS NPs for 2 h, the electrons characteristic of Cd(3d), C(1s), and Au(4f) at 404, 283.8, and 82.65 eV, respectively, were observed in a ratio of 4.1:48.9:21.0%. After 4 h of modification, the coverage of the CdS NPs increased as seen by the ratio of the intensities 4.3:50.1:15.9% for the Cd(3d), C(1s), and Au(4f) electrons, respectively.

The assembly of the CdS NPs and CNTs on the surface was also characterized by AFM. Figure 2a shows the image of the CNTs that were covalently linked to a Au surface during a modification time of 10 minutes (CNTs generated by acidic digestion for 4 h were used in this experiment). Vertically aligned (standing) CNTs are observed with a maximum height of $\approx$20 nm. By allowing longer durations for the modification step, high-density coverage of the surface by the CNTs was observed. Figure 2b shows the AFM image of the surface after the covalent attachment of the CdS NPs. Higher objects ($\approx$25 nm) are observed which suggests that the semiconductor NPs are linked to the ends of the CNTs (it is impossible to exclude the binding of the CdS NPs to the sidewalls of the CNTs). Figure 2c shows the AFM image of a surface modified with CdS NPs which was obtained after coupling to the CNT-modified Au surface during 4 h. From the surface area of the electrode and the size of the CdS NPs, a random and densely packed monolayer of NPs was observed with a surface coverage of $\approx 4.5 \times 10^{12}$ particles cm^{-2}. The microgravimetric analyses of the surface revealed a surface coverage of $\approx 4.7 \times 10^{12}$ particles cm^{-2}. This value, taken together with the AFM image, suggests that a densely packed monolayer of the semiconductor NPs is associated with the electrode. The AFM images of the CNTs that were linked to the surface during short modification periods (Figure 2a and b) show heights of 10 to 30 nm, whereas the TEM image reveals a substantially higher dispersity of 10 to 100 nm. This may originate from the relatively low concentration of longer CNTs in the mixture and the lower reactivity of the longer CNTs in the coupling process. In fact, similar

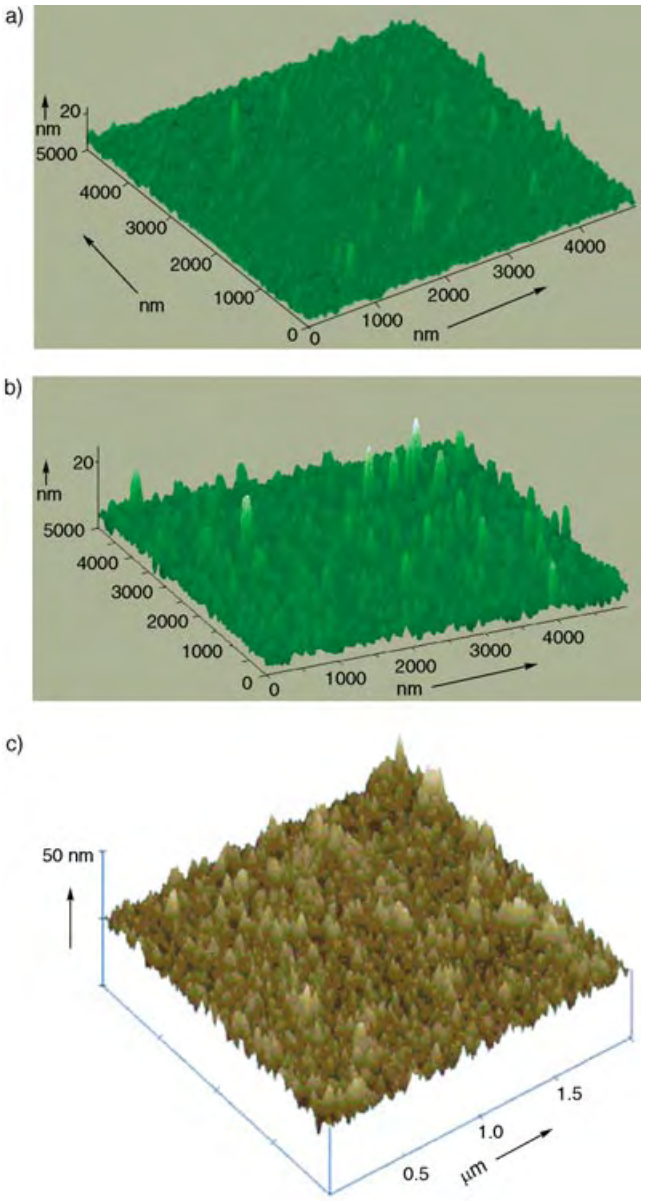

Figure 2. AFM images of the cysteamine-functionalized Au surface upon a) the coupling of CNTs (reaction time: 10 min; oxidative digestion: 4 h), b) after the subsequent coupling of the modified CdS NPs (reaction time:2 h), and c) after the coupling of the CNTs (oxidative digestion: 4 h) to the surface (reaction time: 4 h) and the subsequent binding of the CdS NPs (reaction time: 2 h).

AFM results were previously reported for CNT-modified surfaces that employed CNT prepared by an analogous procedure to the present study.[21]

The photoelectrochemical properties of the CdS NP/CNT-functionalized electrodes, which were generated from CNTs that were digested in the acidic solution for 4 h, were examined. The photocurrent generated by the functionalized electrode in the presence of triethanolamine as a sacrificial electron donor was examined in an electrolytic aqueous phosphate buffer solution (0.1 M, pH 10). The resulting photocurrent action spectrum is depicted in Figure 3, curve (a). The photocurrent spectrum follows the profile of the absorption

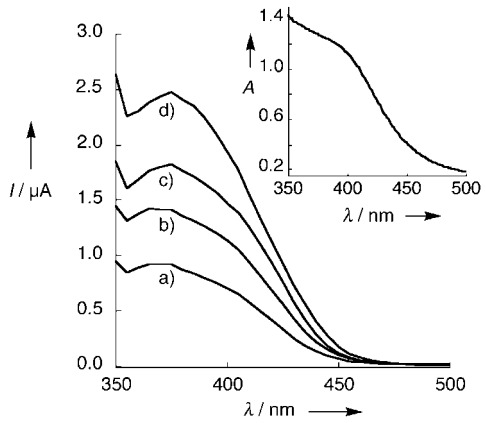

Figure 3. Photocurrent action spectra observed with Au electrodes modified with CdS NP/CNT systems, in which the CNTs were allowed to undergo oxidative digestion during a) 4 h, b) 6 h, c) 8 h, or d) 10 h. In all of the experiments, the resulting CNT interfaces were treated with the CdS NPs during 2 h. Photocurrent spectra were recorded in phosphate buffer solution (0.1 M, pH 10) that contained triethanolamine (0.02 M). Inset: Absorbance spectrum of the CdS nanoparticles (5 nm) capped with cysteamine/2-thioethanesulfonic acid (1:10).

spectrum of the CdS NPs which indicates that it originates from the excitation of the semiconductor NPs. No photocurrent is generated in the absence of triethanolamine. In a control experiment, no photocurrent was observed upon irradiation of a CNT-functionalized electrode that lacked the CdS NPs in the presence of triethanolamine. This result indicates that the photocurrent originates from the CdS NPs and that the CNTs are not photoactive in the process. The generated photocurrent is, however, impressively high, $I(\lambda_{390}) = 0.83\ \mu A$, for the CNT/CdS NP monolayer. From the intensity of the light absorbed by the sample, we estimate that the quantum efficiency for the photon-to-electron conversion is 25%.

In a further control experiment, a monolayer of CdS NPs was assembled on a Au electrode by the covalent coupling of the NPs to an electrode functionalized with a monolayer of cysteic acid. The microgravimetric characterization of the assembly of the monolayer on a Au/quartz crystal indicated a surface coverage of 5.1×10^{12} particles cm^{-2}. Although the surface coverage of the NPs in the monolayer assembly is very similar to that observed in the CdS NPs/CNT system, the photocurrent generated by the system that lacks the CNT connectors is substantially lower, $I(\lambda_{390}) = 0.05\ \mu A$, and the photon-to-electron quantum efficiency is $\approx 1.5\%$. Thus, we conclude that the CNTs which bridge the CdS NPs to the electrode play a major role in the enhanced generation of photocurrents.

We further examined the effect of the lengths of the CNTs on the resulting photocurrent. It is established that the longer time intervals of acidic digestion of the CNTs yields shorter tubes. Accordingly, we digested the CNTs for different lengths of time and used the resulting CNTs to assemble the bridged CdS NP-functionalized electrodes. Unfortunately, we were unable to determine the lengths of the CNTs obtained upon the acidic digestion process owing to a broad dispersity. Thus, we assume that prolongation of the digestion time leads to a decrease in the length of the CNTs (without actual quantification of the length of the bridging units). Figure 3 shows the photocurrents generated by the CdS NP/CNT-functionalized electrodes, which consist of CNTs that were acid-digested for different lengths of time, as bridging units. The photocurrent action spectra follow the profile of the absorbance spectrum of the CdS NPs (see Figure 3, Inset) which implies that the photocurrent originates from the excitation of the semiconductor NPs. The photocurrents obtained reveal that the photocurrent is enhanced as the digestion time of the CNTs is increased (shorter linking CNTs). Table 1 summarizes the surface coverage, the photocurrent intensities at $\lambda = 390$ nm, and the photon-to-electron quantum efficiencies of the CdS NPs in the systems with the different CNTs. The quantum efficiencies increase as the digestion time increases (shorter CNTs), and for CNTs digested for 4, 6, 8, and 10 h, the quantum yields correspond to 25, 39, 51, and 70%. From the data in Table 1 we see that the surface coverages of the CdS NPs in the different systems are comparable.

Table 1: Microgravimetric quartz-crystal-microbalance analyses of the CdS/CNT systems assembled on Au/quartz crystals and the respective surface coverage values.

System[a]	Δf [Hz] SWCNT	Δm [$g\,cm^{-2}$]	Δf [Hz] CdS NP	Particles [cm^2]
a	−575	3.14×10^{-6}	−270	4.66×10^{12}
b	−520	2.83×10^{-6}	−310	5.34×10^{12}
c	−450	2.45×10^{-6}	−238	4.12×10^{12}
d	−320	1.74×10^{-6}	−287	4.96×10^{12}
CdS monolayer[b]			−294	5.07×10^{12}

[a] The different systems comprise CNTs that were subjected to oxidative digestions during a) 4 h, b) 6 h, c) 8 h, or d) 10 h. [b] The surface loading of a CdS NP system directly coupled to the electrode is provided for comparison.

The results clearly demonstrate the very efficient generation of photocurrents in the CNT-bridged CdS NP assemblies. Although we have no firm explanation for the enhanced photocurrents, we speculate and suggest a possible origin for these observations on the basis of the known properties of CNTs. The photocurrent originates from the photoexcitation of the semiconductor NPs which yields an electron–hole pair. The injection of the conduction-band electrons into the electrode yields the photocurrent, whereas the electron donor (in solution) provides the electrons to the valence-band holes to thus complete the photocurrent generation cycle (see Scheme 1). The electron–hole recombination is a competing process to the electron-injection mechanism, and thus the photocurrent efficiency is low. The CNT connectors which bridge the CdS NPs to the electrode may then facilitate the photocurrent generation by trapping the conduction-band electrons, a process that results in charge separation and retardation of the recombination process. That is, the conductive CNT wires provide efficient paths for the transport of the conduction-band electrons to the electrode. This

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

explanation, based on the conductance of the CNT connector is, however, contradicted by the observation of a dependence on the length of the CNT. Whereas charge-transport rates in ideal CNTs should be almost length-independent, the CNTs employed in the present study are far-from-ideal wrapped graphite sheets. The oxidative acidic digestion of the CNTs not only shortens the CNTs, but it introduces defects into the sidewalls, which consist of phenolic, ketone, or carboxylic acid functionalities. These units disrupt the conjugation within the graphite sheets and act as local defect sites for charge transport.

The effect of defects in CNTs on the charge-transport properties has been considered theoretically by using a "back-scattering" model.[27] According to this model, as the electron reaches a defect site, it is back-scattered to find an alternative conjugated path to be transported along the CNT. As the number of defects in the CNT increases with its length, charge transport along the CNT will be dominated by its length. That is, the charge injection of the conduction-band electrons to the CNTs, leads to charge separation by entrapment of the electrons in the CNT wire. The chemically generated local defects in the CNTs affect, however, the efficiency of the charge separation. As the CNTs are longer, more defects exist in the connecting wires and thus the back-scattering process retards the conductance of the trapped electrons to the electrode. The trapped electrons in the CNTs can then recombine with the valence-band holes to result in lower quantum yields for the photon-to-electron conversion process as the CNTs become longer.

An alternative mechanism for the observed enhanced photocurrent in the system is based on the semiconductive properties of the CNTs. The band-gap structure of CNTs has been studied,[28] and interparticle–CNT electron transfer could lead to charge separation and enhanced photocurrents. The low population of semiconductive CNTs in the carbon nanotube mixture, and particularly the enhanced photocurrents observed with shorter CNTs, probably exclude any function of the semiconductive CNTs in the enhanced generation of photocurrents. For shorter CNTs, larger band gaps are formed which would perturb the interparticle–CNT electron-transfer process. Thus, if semiconductive CNTs participate in the generation of photocurrents, one would anticipate to observe lower yields of photocurrents for shorter CNTs, in contrast to the experimental observations.

In conclusion, the present study has demonstrated unprecedented high quantum yields for the generation of photocurrents by using semiconductor nanoparticles/carbon nanotubes as a hybrid system. The results suggest that the length of the CNTs plays a major role in the formation of photocurrents and probably the defects in the CNT affect the extent of charge separation that follows the photoexcitation of the CdS NPs. More experiments which employ CNTs of low length dispersity are underway to further characterize the system.

Experimental Section

Single-walled CNTs (SWCNTs; Carbolex, Sigma) were purified by heating the as-received nanotubes in nitric acid (3 M) at reflux for 48 h. The resulting CNTs were isolated by centrifugation and rinsed with NaOH solution (1 mM) until pH 7.0. The purified long SWCNTs were then chemically shortened by oxidation in a mixture (3:1) of concentrated sulfuric acid (98%) and nitric acid (70%): the samples were sonicated in an ice/water bath during 4, 6, 8, or 10 h. The solutions containing the SWCNTs were centrifuged, then the samples were washed with NaOH solution (1 mM) until pH 7.0, and the CNTs were then dissolved in DMF (*N*,*N*-dimethylformamide). This procedure yielded shortened SWCNTs with terminal carboxylate groups.

Cysteamine-protected CdS nanoparticles were prepared according to a reported procedure.[12b] The surface of a Au electrode was modified with a monolayer of a mixture of 2-thioethanol and cystamine (3:1 ratio), and the shortened SWCNTs were covalently linked to the amino groups of the cysteamine monolayer-functionalized Au surface in the presence of dicyclohexylcarbodiimide (DCC; 1×10^{-2} M) in DMF (2-thioethanol was incorporated in the mixed monolayer to prevent nonspecific adsorption of the SWCNTs onto the electrode surface and also to prevent the coupling of the SWCNTs through their sidewalls to the surface). The modified electrodes were treated with a solution of cysteamine-stabilized CdS nanoparticles (1 mg mL^{-1}, 2 mL) in HEPES buffer, which included 1-ethyl-3-(3-dimethyaminopropyl)carbodiimide (EDC), for 2 h. The assembly of the CdS monolayer on the Au surface was prepared according to the published procedure.[12b]

Microgravimetric QCM measurements were performed with a QCM analyzer (Fluke) by using Au/quartz crystals (AT-cut, 10 MHz). Photoelectrochemical experiments were performed with a home-built photoelectrochemical system that includes a 300W Xe lamp (Oriel, model 5258), a monochromator (Oriel, model 74000, 2-nm resolution), and a chopper (Oriel, model 76994). XPS analyses were performed with a Kratos AXIS-HS spectrometer equipped with a monochromatic $Al_{K\alpha}$ source. Usually scans were run at 45 or 75 W. All data acquisitions were performed in a hybrid mode by using electrostatic and magnetic lenses and detection pass energies of 40–80 eV. AFM images were recorded in the tapping mode in air with a Smena B instrument (NT-MDT, Russia), with a 30-μm scanner, NCS-16 cantilevers (resonance frequency 180 KHz), a scan rate of 1.5–2.5 Hz, and a cantilever oscillation amplitude of the order of 20–40 nm.

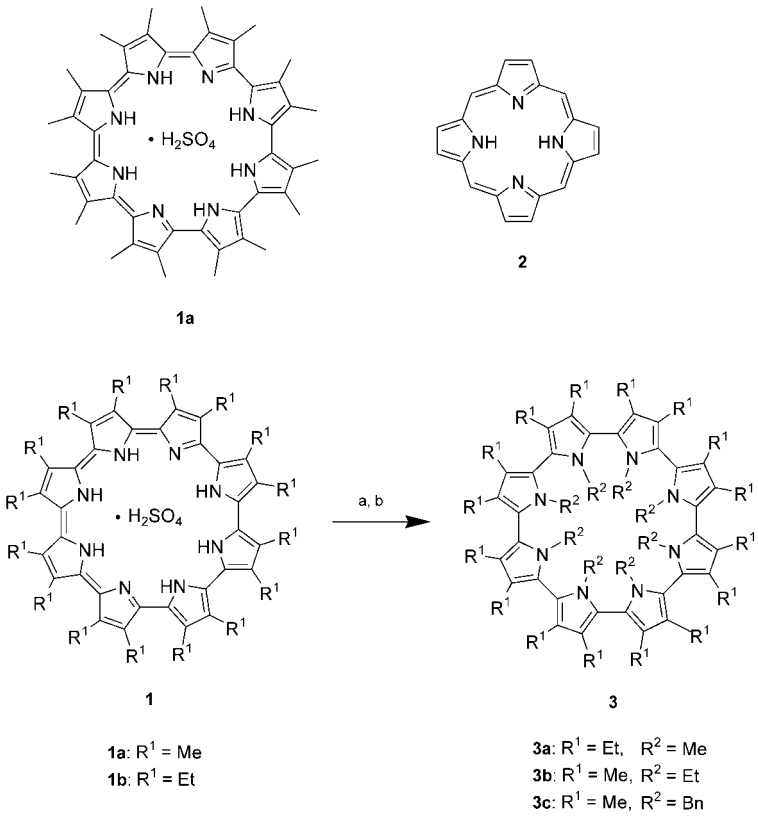
Porphyrin Analogues

Reductive N Alkylation of Cyclo[8]pyrroles**

Thomas Köhler, Zhongping Ou, Jeong Tae Lee, Daniel Seidel, Vincent Lynch, Karl M. Kadish, and Jonathan L. Sessler**



Cyclo[8]pyrrole (**1**), although lacking bridging meso carbon atoms, may be considered as a larger analogue of porphyrin (**2**) in that it is flat and aromatic (see Scheme 1).[1] For this reason, we have been interested in exploring the chemical behavior of cyclo[8]pyrrole and contrasting it to that of the porphyrins. In previous work, we have found that cyclo[8]-pyrrole in its diprotonated form may be reduced electrochemically to produce a formally antiaromatic 32-π-electron species under conditions that are much less forcing than those needed to reduce typical porphyrins.[2] Here we report that cyclo[8]pyrrole, upon treatment with NaH and an alkyl halide, undergoes chemical reduction to produce an octa-N-

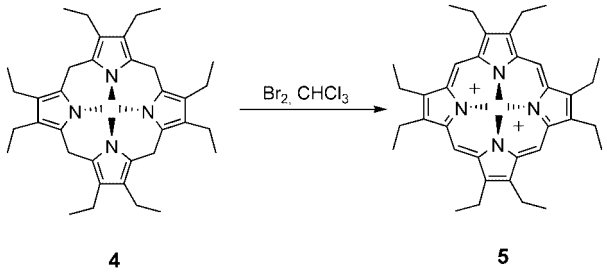
Scheme 1. Reaction sequence used to effect the reduction and N alkylation of cyclo[8]pyrroles **1**. a) NaH, THF, Ar, room temperature; b) R^2X, Ar, reflux, 12 h. R^2 = Me, Et, or Bn, Bn = benzyl.



alkylated product, **3**. This reaction sequence is to the best of our knowledge without precedent in the literature regarding porphyrins. Furthermore, in the case of larger substituents, the synthesized products, namely **3b** and **3c**, are without direct analogy in the case of simple porphyrins/porphyrinogens.[3]

N,*N*′,*N*″,*N*‴-(tetramethyl)octaethylporphyrinogen (**4**), the porphyrin analogue of **3a**, was reported in a doctoral dissertation from the group of Professor Franck in 1986.[4] However, in contrast to **3a** (see below), **4** was not produced through reductive alkylation, but rather it was generated by the cyclization of N-substituted diethylpyrrole. Compound **4** is not only a direct analogue of **3a**, but it is also a historically important intermediate in porphyrin chemistry. In particular, Vogel et al. used it to produce the long-sought-after *N*,*N*′,*N*″,*N*‴-(tetramethyl)octaethylporphyrin dication (**5**) in 1989 (Scheme 2).[5]

Nonetheless, our own efforts to produce this nonaromatic, tetrapyrrolic macrocycle by using the reductive alkylation procedure to generate **3** failed to give isolable quantities of product.[6] This difference in reaction behavior thus highlights an important difference between porphyrin (**2**) and cyclo[8]-pyrrole (**1**). It also underscores the fact that compounds **3** represent a new, potentially interesting class of functionalized oligopyrroles. Scheme 1 summarizes the chemistry involved in the conversion of **1** into **3**. Briefly, treatment of **1** with NaH under an inert atmosphere, followed by addition of an alkylating agent (methyl iodide, ethyl iodide, and benzyl bromide in the case of **3a**, **3b**, and **3c**, respectively), and heating the mixture at reflux for 12 h produces the corresponding N-alkylated derivatives **3** in 64–70% yield. In contrast to the diprotonated form of **1**, which dissolves in organic solvents to produce solutions that are yellow–brown in color, the products obtained in this way were essentially colorless. Such a lack of color is consistent with the absence of an extended conjugation pathway. Evidence for the proposed lack of aromaticity came from the ^{1}H NMR spectroscopic data. In contrast to the observations reported by Vogel for **5** ($\delta = -4.59$ ppm for the protons of the CH_3 group—a result of the diamagnetic ring current),[5] the signals of the N-alkylated fragments were not shifted upfield (e.g. for **3a**, the signals for the protons from CH_3 appear at $\delta = 2.65$ ppm).

Further support for the nonaromatic and unconjugated nature of **3** comes from solid-state X-ray diffraction structural analyses (Figure 1, A–C).[7–9] The structures of **3a**, **3b**, and **3c** reveal that the eight nitrogen substituents adopt an alternating up–down orientation. As a result, the macrocycle as a whole is highly distorted from planarity and appears to be almost bowl-like in nature. Whereas **3a** shows N_1-$C_{\alpha1}$-$C_{\alpha2}$-N_2 torsional angles of 67° (average), **3b** and **3c** are both characterized by smaller torsional angles (61° and 58°, respectively). Nonetheless, the alkyl fragments in **3b** and **3c** are located almost perpendicular to the mean plane of the heterocyclic ring. The compounds reveal bond lengths of approximately 1.37 Å for the C_α–C_β bonds in all three cases, whereas the C_β–$C_{\beta'}$ bond lengths are in the range of 1.40–1.42 Å. This nonequivalence in bond lengths is consistent with localized pyrrole aromaticity and stands in contrast to what is seen in the aromatic precursor **1** in which the pyrrolic C–C bond lengths are much more similar.[1] Furthermore, the C–C distances between adjacent pyrrole units in **3** are of the order of 1.46 Å, as expected for an electron-localized system that lacks extensive conjugation.

The hallmark of porphyrinogen systems is their ability to undergo oxidation to the corresponding aromatic systems: for example, the conversion of porphyrinogen **4** to the dication **5**. To test whether this might be possible with the reduced

Scheme 2. Oxidation of the N-tetramethylated porphyrinogen **4** to the aromatic dication **5**. For details, see reference [5].

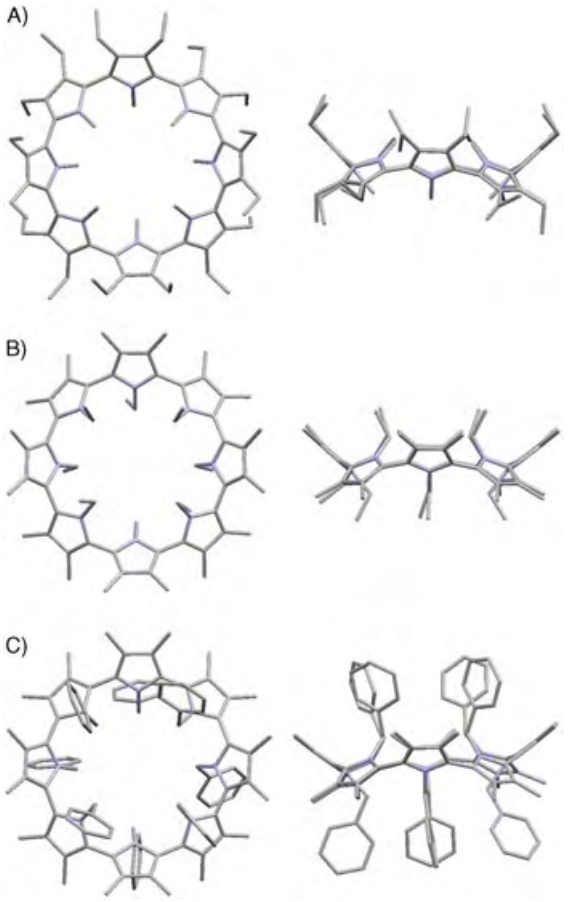

Figure 1. Single crystal X-ray diffraction analyses. Top and side views of mercury-rendered wire-frame structures of A) **3a**,[7] B) **3b**,[8] and C) **3c**.[9] Hydrogen atoms are removed for clarity; half a molecule of methylene chloride (**3a**) and one molecule of methylene chloride and half a molecule of benzene (**3c**) have also been omitted. Blue N.

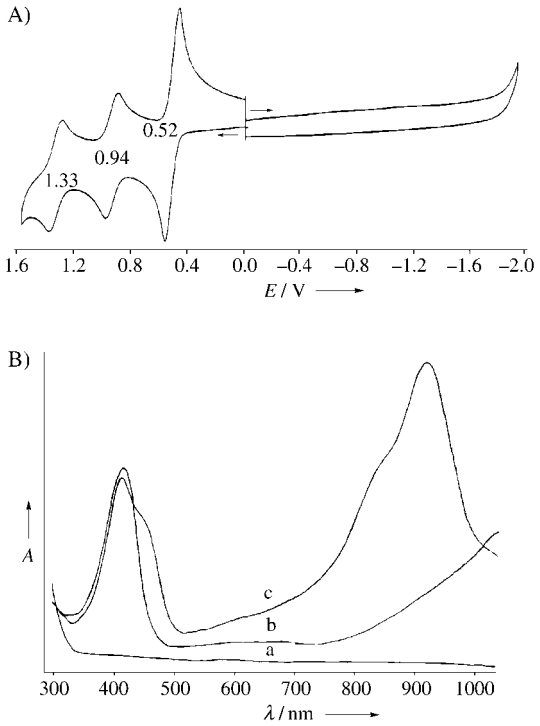

Figure 2. A) Cyclic voltammograms (vs SCE) of **3a** (in CH_2Cl_2 with TBAP (0.1 M)) and B) UV/Vis spectra of **3a** a) before and b) after the first two-electron oxidation at 0.70 V and c) after the second one-electron oxidation at 1.10 V (in CH_2Cl_2 with TBAP (0.2 M)).

cyclo[8]pyrrole derivative **3a**, a series of electrochemical and spectroelectrochemical studies were carried out in CH_2Cl_2 containing tetra-*n*-butylammonium perchlorate (TBAP, 0.1 or 0.2 M). Three reversible oxidations are observed at $E_{1/2} = 0.52$, 0.94, and 1.33 V, the first of which is a two-electron-transfer process. No reductions are seen under these experimental conditions up to a potential of −2.0 V vs SCE (saturated calomel electrode; see Figure 2A).

The N-alkylated macrocycle **3a** displays no significant absorption bands in the region $\lambda = 325$–1100 nm. However, upon two-electron oxidation of this species at 0.70 V in a thin-layer spectroelectrochemical cell, an initial product was observed and is assigned as the dication $\mathbf{3a}^{2+}$, which is characterized by a spectrum with two bands at $\lambda = 415$ and 1036 nm, respectively (see curve b in Figure 2B). The λ_{max} of these bands correspond to the Soret and Q-type bands seen for the diprotonated form of the 30-π-electron cyclo[8]pyrrole (**1a**). Upon further oxidation of $\mathbf{3a}^{2+}$ in a thin-layer cell at 1.10 V, a high intensity Q type band at $\lambda = 917$ nm is observed (see curve c in Figure 2B). This spectrum is assigned to the π-cation radical, $\mathbf{3a}^{3+}$, which has one unpaired electron as inferred from ESR measurements. Similar spectra were obtained upon bulk controlled-potential electrolysis. A summary of the spectral data is given in Table 1.[11]

Table 1: UV/Vis spectral data of 30-π-electron systems, determined from thin-layer spectroelectrochemistry in CH_2Cl_2.

compound	λ_{max} [nm]	
	Soret band	Q band
cyclo[8]pyrrole **1a**	431[a]	1112[a]
N-methylated cyclo[8]pyrrole dication $\mathbf{3a}^{2+}$	415	>1040[b]
radical π cation $\mathbf{3a}^{3+}$	415[c]	917[c]
N-benzylated cyclo[8]pyrrole dication $\mathbf{3c}^{2+}$	450	>1040[b]

[a] Taken from reference [1]. [b] Lower limit: the exact determination was limited by the spectral response of the instrument. [c] Shoulders are also observed at 447 nm and 845 nm.

Upon bulk controlled-potential electrolysis of **3a** at 0.70 V in CH_2Cl_2 containing TBAP (0.2 M) for 15 min, a strong signal in the ESR spectrum at $g = 2.004$ was observed (see Supporting Information). However, when the controlled-potential electrolysis was carried out for a longer time (45 min), the intensity of the signal of the ESR spectrum decreased and became negligible. This leads us to suggest that a comproportionation reaction occurs between the neutral compound, **3a**, and the oxidized species, presumably $\mathbf{3a}^{2+}$,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which is produced as the result of a two-electron oxidation. This comproportionation reaction gives rise to $\mathbf{3a}^{+}$, which exhibits an ESR signal. The final product, $\mathbf{3a}^{2+}$, is expected to be ESR-inactive provided that the two holes (unpaired spins), which are produced upon oxidation, are paired. Further oxidation at 1.10 V leads to the formation of a species with a strong ESR signal at $g = 2.007$ and $\Delta H = 7.8$ G (see Supporting Information). Such values are consistent with a π-cation radical and leads us to propose that the product of this oxidative process is the triply oxidized species, $\mathbf{3a}^{3+}$.

Currently, we are working to affirm the results of spectroelectrochemistry by chemical oxidation. We have found, for instance, that treatment of colorless solutions of **3a** in methylene chloride with perchloric acid, acidic aqueous solutions of chromate and bromate under heterogeneous conditions, or with bromine (but not with iodine) under homogeneous conditions gives rise to a compound (or a mixture of compounds) whose spectrum also resembles that of the acid salt **1a**. Unfortunately, the spectral features ascribed to the presumed compound produced in this way, namely $\mathbf{3a}^{2+}$, begin to fade over the course of 0.5 h which leads us to infer that the product is not stable under these conditions at ambient temperature. Nonetheless, these findings, when considered in conjunction with the results of the bulk electrolysis experiments described above, suggest that it might be possible to isolate dicationic products of general structure $\mathbf{3}^{2+}$ or even their more-oxidized radical-cation analogues $\mathbf{3}^{3+}$ under appropriate conditions. Efforts are currently directed to this end. We are also working to test the generality of the reductive alkylation procedure of Scheme 1 by applying it, for example, to other expanded porphyrin systems.[12] Besides this, we are exploring the use of **3**, with its unique "four up, four down" orientation, as a possible scaffold for further synthetic elaboration, such as in the construction of self-assembled arrays and polytopic receptor systems.

Experimental Section

Unless otherwise noted, solvents and reagents were reagent-grade and were used without further purification. Tetrahydrofuran (THF) was dried by passage through two columns of activated alumina. The bipyrrolic precursors were prepared as described previously.[13] ^{1}H and ^{13}C NMR spectra were measured at 25 °C on a Varian Unity Innova at 300 and 400 MHz, respectively. UV/Vis spectra were recorded on a Beckman DU 640B spectrophotometer. High-resolution CI and FAB mass spectra were measured with a VG ZAB2-E mass spectrometer.

3c: Under an argon atmosphere, sodium hydride (60% suspension in mineral oil; 95 mg, 2.38 mmol) was added to a solution of cyclo[8]pyrrole **1a** (49.2 mg, 58.5 μmol) in dry THF (20 mL), and the mixture was stirred at room temperature for 30 min. Then, benzyl bromide (335 μL, 2.8 mmol) was added, and the solution was heated under reflux for 12 h. The solution was allowed to cool to room temperature, then aqueous NaOH solution (1M, 10 mL) was added along with CH_2Cl_2 (20 mL). After stirring this mixture for 20 min, the phases were separated, and the aqueous phase was extracted further with CH_2Cl_2 (10 mL). The combined organic phases were dried over anhydrous sodium sulfate, and the solvent was removed in vacuo. The residue was passed through a short plug of silica gel using CH_2Cl_2 as the eluent. Compound **3c** was isolated as a white–amber-colored crystalline product (66 mg, 70%). ^{1}H NMR (300 MHz, $CDCl_3$): $\delta =$ 1.68 (s, 48H, CH_3), 5.09 (s, 16H, benzyl-CH_2), 6.34–6.37 (m, 16H, phenyl-*H*), 6.83–6.88 (m, 16H, phenyl-*H*), 6.94–6.99 ppm (m, 8H, phenyl-*H*); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 9.82$, 48.91, 121.08, 123.96, 126.50, 126.67, 127.76, 138.17 ppm. HRMS (FAB); *m*/*z*: calcd for $C_{104}H_{104}N_8$: 1464.8384; found: 1464.8410 ([M^+]).

[3] During the course of this work, the preparation and full structural characterization of a tetra-N-benzylated *meso*-tetrakis(3,5-di-*tert*-butyl-4-oxocyclohexa-2,5-dienylidene)porphyrinogen, obtained from the four-fold N alkylation of the parent *meso*-tetra(oxocyclohexadienylidene)porphyrinogen (generated by oxidation of the corresponding *meso*-substituted (4-hydroxyphenyl)porphyrin), was reported. However, this procedure apparently cannot be successfully applied to produce the corresponding unoxidized (that is, "normal") porphyrinogen starting from, for example, *meso*-unsubstituted porphyrins. See J. P. Hill, I. J. Hewitt, C. E. Anson, A. K. Powell, A. L. McCarty, P. A. Karr, M. E. Zandler, F. D'Souza, *J. Org. Chem.* **2004**, 69, 5861–5869. [6] That porphyrins may be reduced to produce porphyrinogens (and other reduced species) is historically well appreciated. See, for instance: H. Fischer, H. Orth, *Die Chemie des Pyrrols*, Band *II, II.* Haelfte, Akad. Verlagsgesellschaft, Leipzig, **1940**. However, conversion of these species to **4** and its analogues is apparently problematic. For instance, our attempts to N alkylate calix[4]pyrrole (*meso*-octamethylporphyrinogen) by treatment with excess *n*-butyllithium followed by ethyl bromoacetate did not result in an N-alkylated product analogous to **4**. Rather, very effective β-pyrrolic C alkylation was observed. See P. A. Gale, J. L. Sessler, W. E. Allen, N. A. Tvermoes, V. Lynch, *Chem. Commun.* **1997**, 665–666.
[7] Structural data for compound **3a**: Single crystals suitable for X-ray diffraction studies of compound $\mathbf{3a}\cdot 0.5\,CH_2Cl_2$ were obtained by slow evaporation of its solution in methylene chloride and methanol. Data were collected on a Nonius Kappa CCD diffractometer by using a graphite monochromator with $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). $C_{72.50}H_{105}ClN_8$, $M_r = 1124.09$, monoclinic, space group $P21/n$, $a = 16.7530(5)$ Å, $b = 24.4090(6)$ Å, $c = 18.3380(9)$ Å, $\alpha = 90.000(2)°$, $\beta = 112.488(2)°$, $\gamma = 90.000(11)°$, $V = 6928.6(4)$ Å^3, $Z = 4$. Full matrix least-squares on F^2 was used as the refinement method. Final $R1$ ($I > 2\sigma(I)$) = 0.1093; $wR2$(all data) = 0.1932.[10]
[8] Structural data for compound **3b**: Single crystals suitable for X-ray diffraction studies of compound **3b** were obtained by vapor diffusion of methylene chloride into a solution of the macrocycle in methanol. Data were collected on a Nonius Kappa CCD

diffractometer by using a graphite monochromator with $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). $C_{64}H_{88}N_8$, $M_r = 969.42$, orthorhombic, space group *Pbcn*, $a = 12.6903(1)$ Å, $b = 28.1058(3)$ Å, $c = 17.2872(2)$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, $V = 6165.84(11)$ Å^3, $Z = 4$. Full matrix least-squares on F^2 was used as the refinement method. Final $R1$ ($I > 2\sigma(I)$) = 0.1445; $wR2$(all data) = 0.1534.[10]

[9] Structural data for compound **3c**: Single crystals suitable for X-ray diffraction studies of compound **3c**·CH_2Cl_2·0.5 C_6H_{14} were obtained by vapor diffusion of *n*-hexane into a solution of the macrocycle in methylene chloride. The data were collected on a Nonius Kappa CCD diffractometer by using a graphite monochromator with $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). $C_{108}H_{113}Cl_2N_8$, $M_r = 1593.96$, orthorhombic, space group *Pbca*, $a = 26.5693(3)$ Å, $b = 24.2573(3)$ Å, $c = 28.3957(2)$ Å, $\alpha = 90°$, $\beta = 90°$, $\gamma = 90°$, $V = 18301.0(4)$ Å^3, $Z = 8$. Full-matrix-block least-squares on F^2 was used as the refinement method. Final $R1$ ($I > 2\sigma(I)$) = 0.0560; $wR2$ (all data) = 0.1462.[10]

[10] For further details on the crystal-structure data and structure refinements for **3a**, **3b**, and **3c**, see the Supporting Information. CCDC-248431 (**3a**), CCDC-248429 (**3b**), and CCDC-248430 (**3c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB21EZ, UK; fax: (+44) 1223-336-033; or deposit@ccdc.cam.ac.uk).

[11] Spectral features similar to those seen in the case of the thin-cell spectroelectrochemical studies are observed after carrying out both the first two-electron and second one-electron oxidations by bulk electrolysis. However, the shoulder at 447 nm seen in Figure 2B was not seen in the case of the latter experiments. We are currently exploring the significance of this finding.

[12] In preliminary work, we have found that the reaction sequence used to produce **3a** from **1a** could be successfully applied to cyclo[6]pyrrole[2] to produce the corresponding reduced hexa-N-methylated macrocycle—the smaller homologue of **3a**.

Host–Guest Chemistry

Molecular Loop Lock: A Redox-Driven Molecular Machine Based on a Host-Stabilized Charge-Transfer Complex**

*Woo Sung Jeon, Eunju Kim, Young Ho Ko, Ilha Hwang, Jae Wook Lee, Soo-Young Kim, Hee-Joon Kim, and Kimoon Kim**

Dedicated to Professor Dong H. Kim

Artificial molecular machines have received much attention in recent years because of their potential application in the creation of nanometer-scale molecular devices.[1,2] A wide variety of molecular machines such as shuttles,[3a] rotors,[3b] muscles,[3c] ratchets,[3d] pistons and cylinders,[3e] scissors,[3f] and elevators[3g] have been reported. Nevertheless, the design and synthesis of new molecular machines that are reminiscent of macroscopic machines would further widen the scope of this area of chemistry.

Cucurbit[8]uril (CB[8]),[4] a member of the host family cucurbit[*n*]uril, which has a cavity that is similar to that of γ-cyclodextrin, exhibits remarkable host–guest properties including the encapsulation of a hetero-guest-pair inside the cavity.[5] For example, it encapsulates methyl viologen (MV^{2+}) and 2,6-dihydroxynaphthalene ($Np(OH)_2$) inside the cavity to form the stable 1:1:1 complex $\mathbf{1}^{2+}$. Formation of the complex is driven by the markedly enhanced charge-transfer (CT) interaction between the electron-deficient and electron-rich guest molecules inside the hydrophobic cavity of CB[8].[5a] This discovery led us to build several novel supramolecular assemblies such as supramolecular amphiphiles that led to

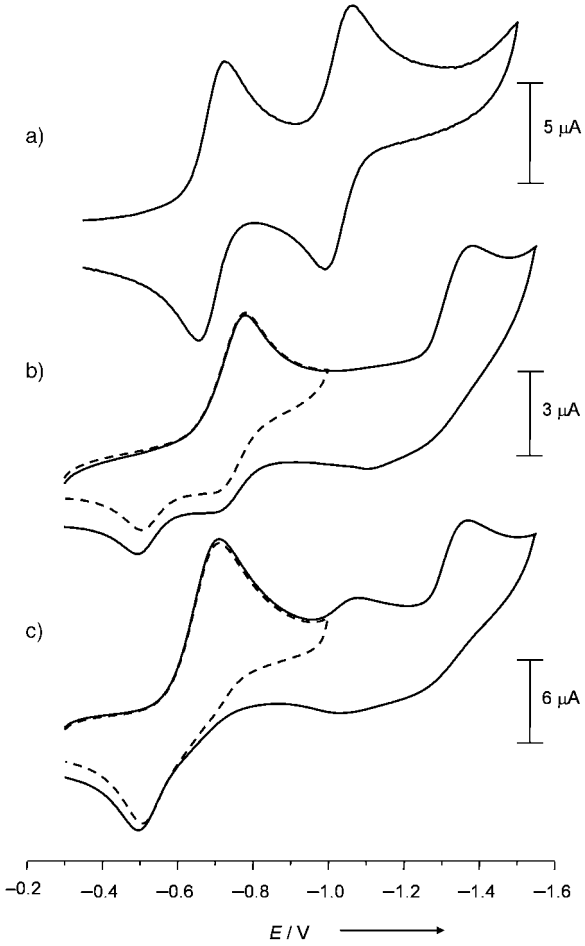
vesicles,[5b] molecular loops,[5c] supramolecular polymers on surfaces,[5d] and molecular necklaces[5e] by exploiting the host-stabilized CT interactions. Despite the progress in the construction of self-assembly systems, the redox properties of the host-stabilized CT complexes, in particular, the interplay between the redox process and the exchange of the guest within the host-stabilized CT complexes have not been reported. These properties may provide a novel operating principle of molecular machines or stimuli-responsive materials. Herein we report the redox-coupled guest-exchange properties of CB[8]-stabilized CT complexes which demonstrate the interconversion of hetero- and homo-guest-pair inclusion in a molecular host triggered by an external stimulus (Scheme 1). We also report a molecular loop lock, a novel redox-driven molecular machine based on this phenomenon.

Treatment of a mixture of methyl viologen (MV^{2+}) and the ternary complex $\mathbf{1}^{2+}$ (1:1) with a reducing agent such as sodium dithionite ($Na_2S_2O_4$) results in a drastic change in the UV/Vis spectrum. The appearance of new absorption bands at $\lambda = 365$, 540, and 884 nm (see Supporting Information) supports the near-quantitative formation of the 2:1 inclusion complex $(MV^{+\bullet})_2\subset CB[8]$ $(\mathbf{2}^{2+})$[6] and free $Np(OH)_2$ (Scheme 1). Introduction of O_2 into the solution regenerates $\mathbf{1}^{2+}$ and MV^{2+}. This behavior is confirmed by UV/Vis and NMR spectroscopy, and this result demonstrates the reversible conversion of hetero- and homo-guest-pair inclusion inside CB[8] triggered by a redox stimulus.

The redox-coupled guest-exchange process was further investigated by cyclic voltammetry (Figure 1). Methyl viologen (MV^{2+}) shows two reversible waves that correspond to the redox couples $MV^{2+}/MV^{+\bullet}$ and $MV^{+\bullet}/MV^0$ (Figure 1a). Compared to MV^{2+}, $\mathbf{1}^{2+}$ exhibits a moderate negative shift of the first reduction peak and a large negative shift of the second reduction peak (Figure 1b). Furthermore, the oxidation process that corresponds to the first reduction process of $\mathbf{1}^{2+}$ shows two peaks at −0.71 V and −0.50 V (vs SCE—saturated calomel electrode), the latter of which is almost the same as that for the oxidation of $\mathbf{2}^{2+}$.[6] With increasing scan rates the oxidation peak at −0.71 V increases, whereas the peak at −0.50 V decreases (see Supporting Information), as often seen in processes that involve electron transfer followed by a chemical reaction. The addition of MV^{2+} (1 equiv) results in a small positive shift of the first reduction wave, disappearance of the oxidation peak at −0.71 V, and concomitant increase of the peak at −0.50 V (Figure 1c).[7] A spectroelectrochemical study shows that the absorption spectrum of the species generated by the electrolysis of $\mathbf{1}^{2+}$ (applied potential, −0.85 V vs SCE, in the presence or absence of MV^{2+} (1 equiv)) is essentially identical to that of $\mathbf{2}^{2+}$ (see Supporting Information). Taken together, these results suggest that the reduction of $\mathbf{1}^{2+}$ initially generates the one-electron-reduced species $\mathbf{1}^{+\bullet}$, which contains $MV^{+\bullet}$ and $Np(OH)_2$ encapsulated in CB[8], and then reacts with free $MV^{+\bullet}$ to undergo the rapid guest exchange that leads to $\mathbf{2}^{2+}$ and free $Np(OH)_2$ (see Supporting Information). Note that the regeneration of $\mathbf{1}^{2+}$ and MV^{2+} by the oxidation of $\mathbf{2}^{2+}$ and $Np(OH)_2$ probably does not follow the reverse pathway because the 1:1 mixture of $\mathbf{2}^{2+}$ and $Np(OH)_2$ is thermodynamically far more stable than the 1:1 mixture of $\mathbf{1}^{+\bullet}$ and $MV^{+\bullet}$. Instead, it is more likely to occur through another pathway that involves the initial generation of the 1:1 complex $MV^{2+}\subset CB[8]$ by the oxidation of $\mathbf{2}^{2+}$, as we



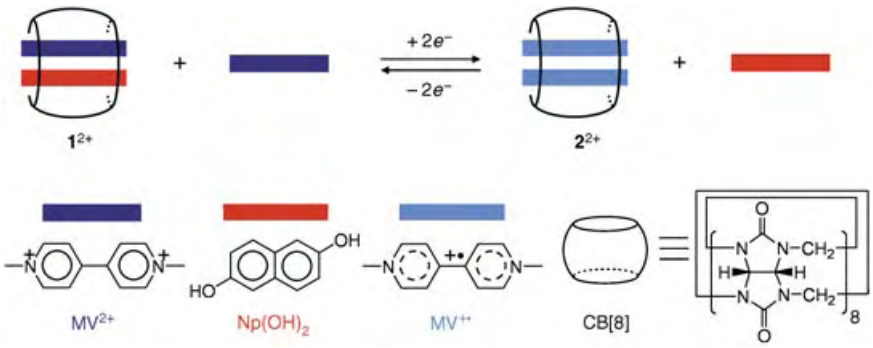


Figure 1. Cyclic voltammograms of a) MV^{2+} (0.5 mM) and b) $\mathbf{1}^{2+}$ (0.5 mM) in the absence of free MV^{2+}, and c) $\mathbf{1}^{2+}$ (0.5 mM) in the presence of free MV^{2+} (1 equiv) in phosphate buffer solution (0.1 M, pH 7.0). Scan rate = 100 mV s^{-1}; – – – different scan rate.

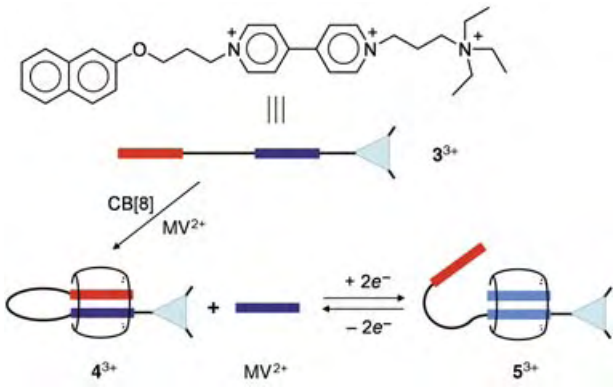

Scheme 1. Interconversion of hetero- and homo-guest-pair inclusion in CB[8] triggered by a redox stimulus. MV = methyl viologen, $Np(OH)_2$ = 2,6-dihydroxynaphthalene, CB[8] = cucurbit[8]uril.

demonstrated previously,[6] which then reacts with free $Np(OH)_2$ to produce $\mathbf{1}^{2+}$ (see Supporting Information).

The discovery of the redox-coupled guest-exchange process prompted us to design and synthesize a redox-driven molecular machine that behaves as a molecular loop lock, which can be switched on and off (locked and unlocked) by means of a key and a redox stimulus (Schemes 2 and 3). The guest molecule $\mathbf{3}^{3+}$, which contains a naphthalen-2-yloxy (Np) unit and a viologen unit linked to each other by a flexible

Scheme 2. Formation of the molecular loop lock $\mathbf{4}^{3+}$ (folded "locked" state) through the formation of an intramolecular CT complex inside CB[8], and the redox-induced formation of ternary complex $\mathbf{5}^{3+}$ (open "unlocked" state).

tether as well as a bulky cationic unit at the terminal,[8] was synthesized in four steps (see Supporting Information). Treatment of $\mathbf{3}^{3+}$ with CB[8] (1 equiv) in water resulted in the exclusive formation of the stable 1:1 complex $\mathbf{4}^{3+}$ through the formation of the intramolecular CT complex between the Np and viologen units inside CB[8], as confirmed by ESI-MS and UV/Vis and NMR spectroscopy analyses (see Supporting Information). In particular, the upfield-shifted signals for the protons of the Np and viologen units and the downfield-shifted signals for the protons of the linker and cationic terminal in the ^{1}H NMR spectrum of $\mathbf{4}^{3+}$ (see Supporting Information) are consistent with the formation of a molecular loop[5c] with a "closed" or "locked" conformation as illustrated in Scheme 2.

The ^{1}H NMR spectrum of $\mathbf{4}^{3+}$ is not affected by the addition of MV^{2+} (1 equiv) which indicates that the 1:1 host–guest complex formed by the intramolecular CT interaction is much more stable than the ternary complex formed by the intermolecular CT interaction between the Np unit of $\mathbf{4}^{3+}$ and MV^{2+} inside CB[8]. However, treatment of a solution containing $\mathbf{4}^{3+}$ and MV^{2+} (1 equiv) with $Na_2S_2O_4$ results in the formation of the ternary complex $\mathbf{5}^{3+}$ (Scheme 2) in which the one-electron-reduced viologen unit of $\mathbf{3}^{2+\bullet}$ interacts with $MV^{+\bullet}$ inside CB[8]. The formation of this complex was confirmed by the appearance of new absorption bands at $\lambda =$ 368, 550, and 890 nm, which are characteristic of a CB[8]-stabilized viologen radical-cation dimer (Figure 2).[9,10] Owing to the paramagnetic nature of $\mathbf{5}^{3+}$, the signals for the Np unit are broad, but are clearly observed by NMR spectroscopy (Figure 3).[10] Furthermore, the chemical shift values ($\delta \approx 7$–

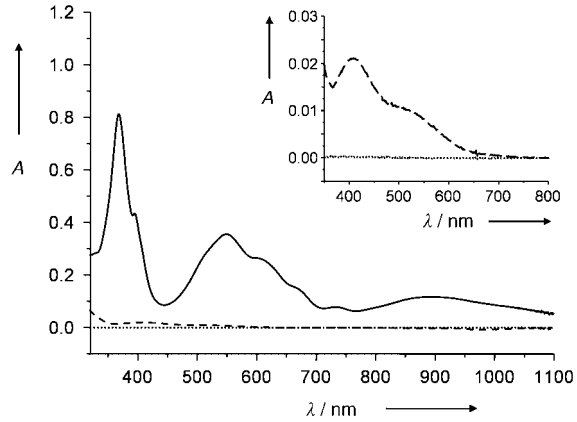

Figure 2. Absorption spectra of $\mathbf{4}^{3+}$ (0.25 mM) before (----- and inset) and after (——) reduction with $Na_2S_2O_4$ in the presence of MV^{2+} (1 equiv) in carbonate buffer (pH 10.0). Optical path = 1 mm; ••••• zero absorption.

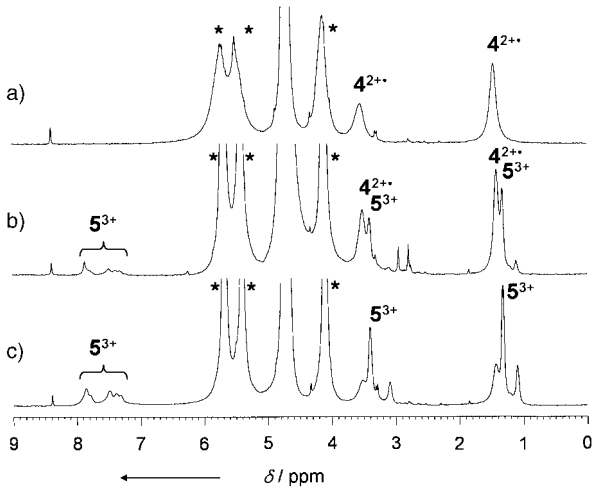

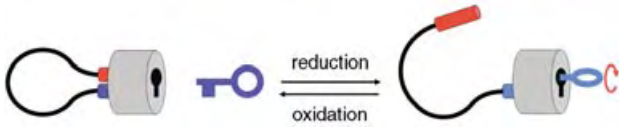

Figure 3. ^{1}H NMR spectra obtained after reduction of $\mathbf{4}^{3+}$ with $Na_2S_2O_4$ in carbonate buffer (pH 10.0) a) in the absence of MV^{2+}, b) in the presence of MV^{2+} (0.5 equiv), and c) in the presence of MV^{2+} (1.0 equiv). The signals labeled with * correspond to the CB[8] host.

8 ppm) for the protons of $\mathbf{5}^{3+}$ are close to those for free $\mathbf{3}^{3+}$ which indicates that the Np unit is now located outside CB[8] and that $\mathbf{5}^{3+}$ has an open or "unlocked" conformation as schematically shown in Scheme 2. Introduction of O_2 into the solution of $\mathbf{5}^{3+}$ regenerates $\mathbf{4}^{3+}$ and MV^{2+} as confirmed by UV/Vis and NMR spectroscopy. Thus, $\mathbf{4}^{3+}$ with a "closed" conformation is converted into $\mathbf{5}^{3+}$ with an "open" conformation upon reduction in the presence of MV^{2+}, and the process can be reversed by oxidation.[11] This system thus behaves as a molecular loop lock that can be locked and unlocked with a key and a redox stimulus (Scheme 3): The two species $\mathbf{4}^{3+}$ and $\mathbf{5}^{3+}$ represent the locked and unlocked states, respectively, and MV^{2+}, which is activated by reduction, plays the role of the key. It may be regarded as a "safeguarded" lock that requires not only a key but also an activation process to open.[10,12,13]

In summary, we have demonstrated the redox-coupled guest-exchange of CB[8]-stabilized CT complexes which illustrates unprecendented interconversion, triggered by an

Scheme 3. Illustration of the working mode of a molecular loop lock with a key.

external stimulus, of hetero- and homo-guest-pair inclusion in a molecular host. Furthermore, we have synthesized a redox-driven molecular machine based on this phenomenon that behaves as a molecular loop lock, which requires both a key and an activation process to open. Further studies on the novel molecular machine and its applications are in progress.

Experimental Section

3·3Br**:** The tribromide salt of *N*-(3-(naphthalen-2-yloxy)propyl)-*N*′-(3-(trimethylamino)propyl-4,4′-bipyridinium) ($\mathbf{3}^{4+}\cdot 3\,Br^-$) was prepared according to a reported procedure[5c] with a minor modification. Detailed procedures are described in Supporting Information.

4·3Br**:** CB[8]·H_2SO_4·16H_2O (20.0 mg, 11.6 μmol) was added to a solution of **3**·3Br (7.0 mg, 9.7 μmol) in D_2O (4 mL), and the resulting mixture was sonicated for 1 min. Undissolved solid was filtered off, and the filtrate was slowly evaporated under reduced pressure to yield the title product (18.2 mg, 92%). ^{1}H NMR (500 MHz, D_2O, 25 °C, TMS): $\delta = 8.84$ (d, J(H,H) = 6.3 Hz, 1H; Py), 8.79 (d, J(H,H) = 6.6 Hz, 2H; Py), 8.76 (d, J(H,H) = 6.3 Hz, 1H; Py), 6.85–6.78 (m, 2H; Py, Np), 6.74 (d, J(H,H) = 6.5 Hz, 3H; Py, Np), 6.65 (d, J(H,H) = 8.9 Hz, 1H; Np), 6.62 (d, J(H,H) = 4.8 Hz; Np), 6.56 (d, J(H,H) = 8.1 Hz, 1H; Np), 6.51 (d, J(H,H) = 3.4 Hz, 2H; Np), 6.06 (d, J(H,H) = 1.9 Hz, 1H; Np), 5.72 (dd, J(H,H) = 9.2, 15.3 Hz, 16H; CB[8]), 5.47 (s, 16H; CB[8]), 5.08–5.02 (m, 2H; Py-CH_2), 4.91–4.88 (m, 2H; Py-CH_2), 4.62–4.57 (m, 2H; OCH_2), 4.21–4.16 (dd, J(H,H) = 9.2, 15.3 Hz, 16H; CB[8]), 3.66 (t, J(H,H) = 9.1 Hz, 2H; NCH_2), 3.57–3.56 (m, 6H; NCH_2), 2.99–2.66 (m, 4H; CH_2), 1.46 ppm (t, J(H,H) = 7.11 Hz, 9H; CH_3); HRMS (ESI-MS): m/z: calcd for $C_{80}H_{90}N_{35}O_{17}$ [M-3Br]$^{3+}$: 604.2418; found: 604.2411.

C. Fettinger, K. Kim, *J. Am. Chem. Soc.* **2004**, *126*, 1932.

[6] We previously demonstrated that the 1:1 inclusion complex MV^{2+}⊂CB[8] undergoes disproportionation to form an equal mixture of the 2:1 complex $\mathbf{2}^{2+}$ (($MV^{+\cdot}$)$_2$⊂CB[8]) and free CB[8] upon chemical or electrochemical reduction and that the reaction is reversible: W. S. Jeon, H.-J. Kim, C. Lee, K. Kim, *Chem. Commun.* **2002**, 1828.

[7] The small, reversible wave at −1.1 V in Figure 1c, which increases with increasing scan rates, corresponds to the $MV^{+\cdot}$/MV^0 redox couple of free $MV^{+\cdot}$. The subsequent spectroelectrochemical study revealed no absorption bands that correspond to free monomeric $MV^{+\cdot}$ after electrolysis of $\mathbf{1}^{2+}$ in the presence of MV^{2+} (1 equiv, see Supporting Information) which implies that the reaction between $\mathbf{1}^{+\cdot}$ and $MV^{+\cdot}$ that leads to $\mathbf{2}^{2+}$ is relatively slow on the timescale of cyclic voltammetry experiments. The second reduction wave of $\mathbf{1}^{2+}$ in the absence (Figure 1b) or presence (Figure 1c) of MV^{2+} is apparently related to the reduction of the 2:1 complex $\mathbf{2}^{2+}$ generated in the first reduction step, but we do not clearly understand this process at the moment.

[8] The bulky cationic unit was introduced at the terminal to prevent the formation of intermolecular CT complexes and intermolecular viologen radical-cation dimers inside CB[8] upon reduction. Another role of the cationic terminal unit is to improve the solubility of the complex after reduction.

[9] The bands at $\lambda = 368$, 550, and 890 nm can also be attributed to $\mathbf{2}^{2+}$ (($MV^{+\cdot}$)$_2$⊂CB[8]), which may be generated during the reduction process. However, the intensity of the band at $\lambda =$ 368 nm increases linearly with increasing concentrations of MV^{2+} (0–1.0 equiv) and is almost twice as high as that of $\mathbf{2}^{2+}$ generated by the reduction of a 1:1 mixture of MV^{2+} and CB[8] at the same concentration (see Supporting Information). These results thus indicate that the amount of $\mathbf{2}^{2+}$ generated during this reduction process is insignificant. Besides the bands that are assigned to $\mathbf{5}^{3+}$, shoulders at $\lambda = 395$ and 610 nm are observed (Figure 2) which can be attributed to the one-electron-reduced species $\mathbf{4}^{2+\cdot}$ and $MV^{+\cdot}$ that are in equilibrium with $\mathbf{5}^{3+}$. It also suggests that the reduction of a 1:1 mixture of $\mathbf{4}^{3+}$ and MV^{2+} first generates $\mathbf{4}^{2+\cdot}$ and $MV^{+\cdot}$, which further react to produce $\mathbf{5}^{3+}$ (see Supporting Information).

[10] Treatment of $\mathbf{4}^{3+}$ with $Na_2S_2O_4$ in the absence of MV^{2+} produces the one-electron-reduced species $\mathbf{4}^{2+\cdot}$, whose UV/Vis spectrum is similar to that of $MV^{+\cdot}$ which indicates that the viologen unit of the guest molecule exists in its radical-cation form. Owing to the paramagnetic nature of the species, the signals for the protons from the stopper unit ($\delta \approx 1.4$ and ≈ 3.5 ppm) are broad. However, the signals are clearly observed in the ^{1}H NMR spectrum of $\mathbf{4}^{2+\cdot}$ whereas those for the Np unit are not, which indicates that the Np unit is still in close proximity to the viologen radical-cation unit. This result in turn suggests that $\mathbf{4}^{2+\cdot}$ maintains the same "locked" conformation with the one-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

electron-reduced viologen and Np units located inside CB[8]. Thus, the molecular loop lock does not open in the absence of the key (MV^{2+}) and the activation process (reduction).
[11] Preliminary electrochemical studies confirmed that this reversible process can also be triggered by electrochemical stimuli. Details of the electrochemical behavior of $\mathbf{4}^{3+}$ and related compounds will be published elsewhere in due course.
[12] A "safeguarded" switch has been reported: J. W. Lee, K. Kim, K. Kim, *Chem. Commun.* **2001**, 1042.

Analytical Methods

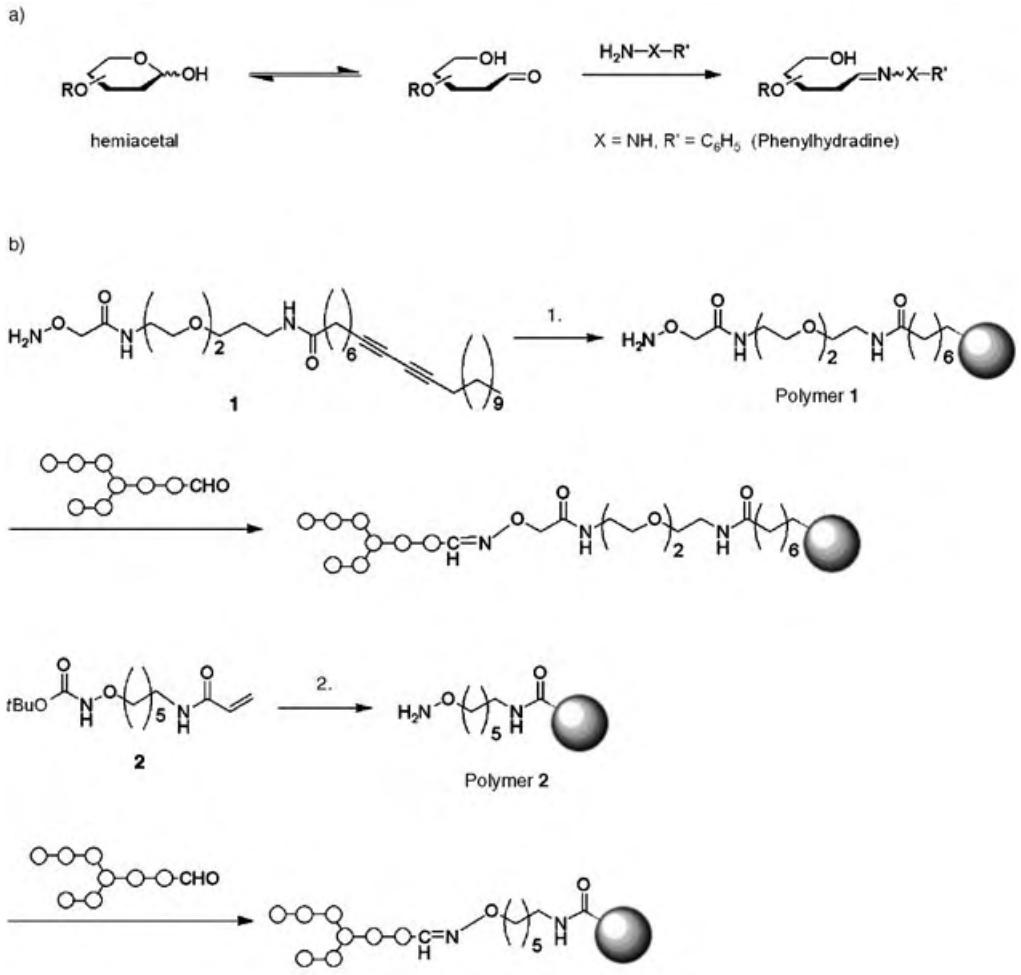
High-Throughput Protein Glycomics: Combined Use of Chemoselective Glycoblotting and MALDI-TOF/TOF Mass Spectrometry**

Shin-Ichiro Nishimura, Kenichi Niikura, Masaki Kurogochi, Takahiko Matsushita, Masataka Fumoto, Hiroshi Hinou, Ryousuke Kamitani, Hiroaki Nakagawa, Kisaburo Deguchi, Nobuaki Miura, Kenji Monde, and Hirosato Kondo*

Glycosylation is one of the posttranslational modifications of proteins in eukaryotes. This step is thought to modulate a wide range of protein functions both on the cellular surfaces and within the cells.[1] This highly dynamic process in which rapid changes in the carbohydrate structures occur in response to cellular signals or cellular stages result in the key informational markers of some serious human diseases. For example, it is known that carbohydrates of IgG can be drastically altered to form unusual structures in patients with rheumatoid arthritis[2] and specific carbohydrates are used as tumor-associated markers in pancreatic and colon cancers.[3] Recently, it has also been reported that the oligosaccharides of the therapeutic human IgG play a critical role of enhancing antibody-dependent cellular cytotoxicity.[4] Glycosylation of nuclear and cytoplasmic proteins with a GlcNAc residue is ubiquitous in nearly all eukaryotes and is a crucial event in posttranslational modifications for regulating protein functions within the cells.[1b] Dynamic perturbations in *O*-GlcNAc regulation have been implicated in the etiology of type II diabetes, cancer, and neurodegenerative diseases.[5]

Although there have been substantial advances in our understanding of the effects of glycosylation on some biological systems, we still do not fully understand the specific functional roles of carbohydrates and the relationship between their structures and functions. The major difficulty in carbohydrate sequencing is a consequence of the fact that the purification of trace amounts of oligosaccharides requires extremely tedious multistep processes. This is because crude sample mixtures prepared by enzymatic digestion from cells, organs, serum, etc. usually contain large amounts of impurities such as peptides, lipids, and salts. These technical problems in the sequencing of carbohydrates make it impossible to achieve high-throughput protein glycomics. We report herein that the combined use of two novel techniques, chemoselective glycoblotting and MALDI-TOF/TOF mass spectrometry,[6] allows for both facile purification and precise analysis of common oligosaccharides and glycopeptides from native glycoproteins.

The concept of the "sugar family tree," constructed by Fischer,[7] motivated us to use the chemoselective "glycoblotting" technique, which has become a key feature in the efficient isolation of carbohydrates in this study. Fischer found that the reaction of glucose, mannose, and major oligosaccharides with phenylhydrazine proceeds smoothly to give the corresponding stable phenylhydrazone derivatives under mild basic and aqueous conditions. Once oligosaccharides are released from glycoconjugates, they can be regarded as a general class of the compound library which have an aldehyde or ketone group at each reducing terminal. As indicated in Scheme 1a, aldehydes preferentially react with reagents bearing hydrazine-like functional groups. Fischer-type reagents do not need any catalyst or reducing agent to accelerate the reaction with sugars and the reactions usually proceed under mild conditions. However, the reactions of aldehydes with primary amino groups require some activating reagent for the formation of stable products. As a result, carbohydrates preferentially react with Fischer-type reagents even in the presence of large amounts of peptides or amino acids with primary amino groups.



The unique chemical characteristics of the sugar family encouraged us to design novel polymers for capturing only carbohydrates from crude samples on the basis of the

Scheme 1. Fischer's concept and glycoblotting by Fischer-type polymer reagents. a) Reactions of carbohydrates with Fischer's reagents. b) Syntheses and reactions of Fischer-type polymer reagents: 1) liposomes prepared with phosphatidylcholine-related monomer, then UV (254 nm) irradiation, 2) radical copolymerization (ammonium persulfate) with acrylamide, followed by deprotection with 4 N HCl.

chemoselective ligation strategy. From considerations of the chemical stability, the handling of reagents, and the feasibility to the general synthesis of versatile polymer materials, we have developed several Fischer-type polymer reagents with reactive and stable oxylamino functional groups by polymerization of a diacetylene-containing lipid derivative **1** or an acrylamide-type derivative **2** (Scheme 1b). Liposomes composed of diacetylene-containing reagent **1** and phospholipid derivatives can be readily polymerized by UV irradiation to produce polymer-based nanoparticles having a mean diameter of 200–300 nm. Compound **2** gives a water-soluble polymer on radical copolymerization with acrylamide. We evaluated the feasibility of the polymers displaying oxylamino functional groups as a useful platform for the "trap and release" of the target oligosaccharides and glycopeptides.

The general protocol for the isolation and analysis of carbohydrates proposed here is simple and easy: a) Trapping carbohydrates by mixing polymers with unpurified proteolytic digest; b) collecting polymers by spin filtration from a crude mixture of peptides, salts, and other impurities; and c) releasing and subsequent MALDI-TOF MS analysis of the target carbohydrates (Figure 1). In this study we selected the *N*-glycans of human IgG to test the efficiency of protein glycomics in the strategy, since the importance of substantial structural alteration of IgG *N*-glycans has been extensively investigated,[3,8] The structural characterization of human IgG *N*-glycans was carried out using crude IgG samples obtained from human serum (100 μL, Figure 1). The merits of glycoblotting are evident since MALDI-TOF MS analysis of oligosaccharides trapped on the polymer has proven to be remarkably improved by using trapping and spin filtration (Figure 2b). When the crude digest was directly subjected to MALDI-TOF MS analysis we obtained an extremely complex spectrum (Figure 2a). The precursor ion peaks, which correspond to the *N*-glycans, cannot be distinguished from numerous other signals in the spectrum because of an excess amount of peptide impurities. As anticipated, highly sensitive and singly charged precursor ion peaks were generated in the presence of α-cyano-4-hydroxycinnamic acid (CHCA) and these greatly facilitated the subsequent sequencing and quantitative analysis of the oligosaccharides. In addition, it was found that the fragmentation of the precursor ions by the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

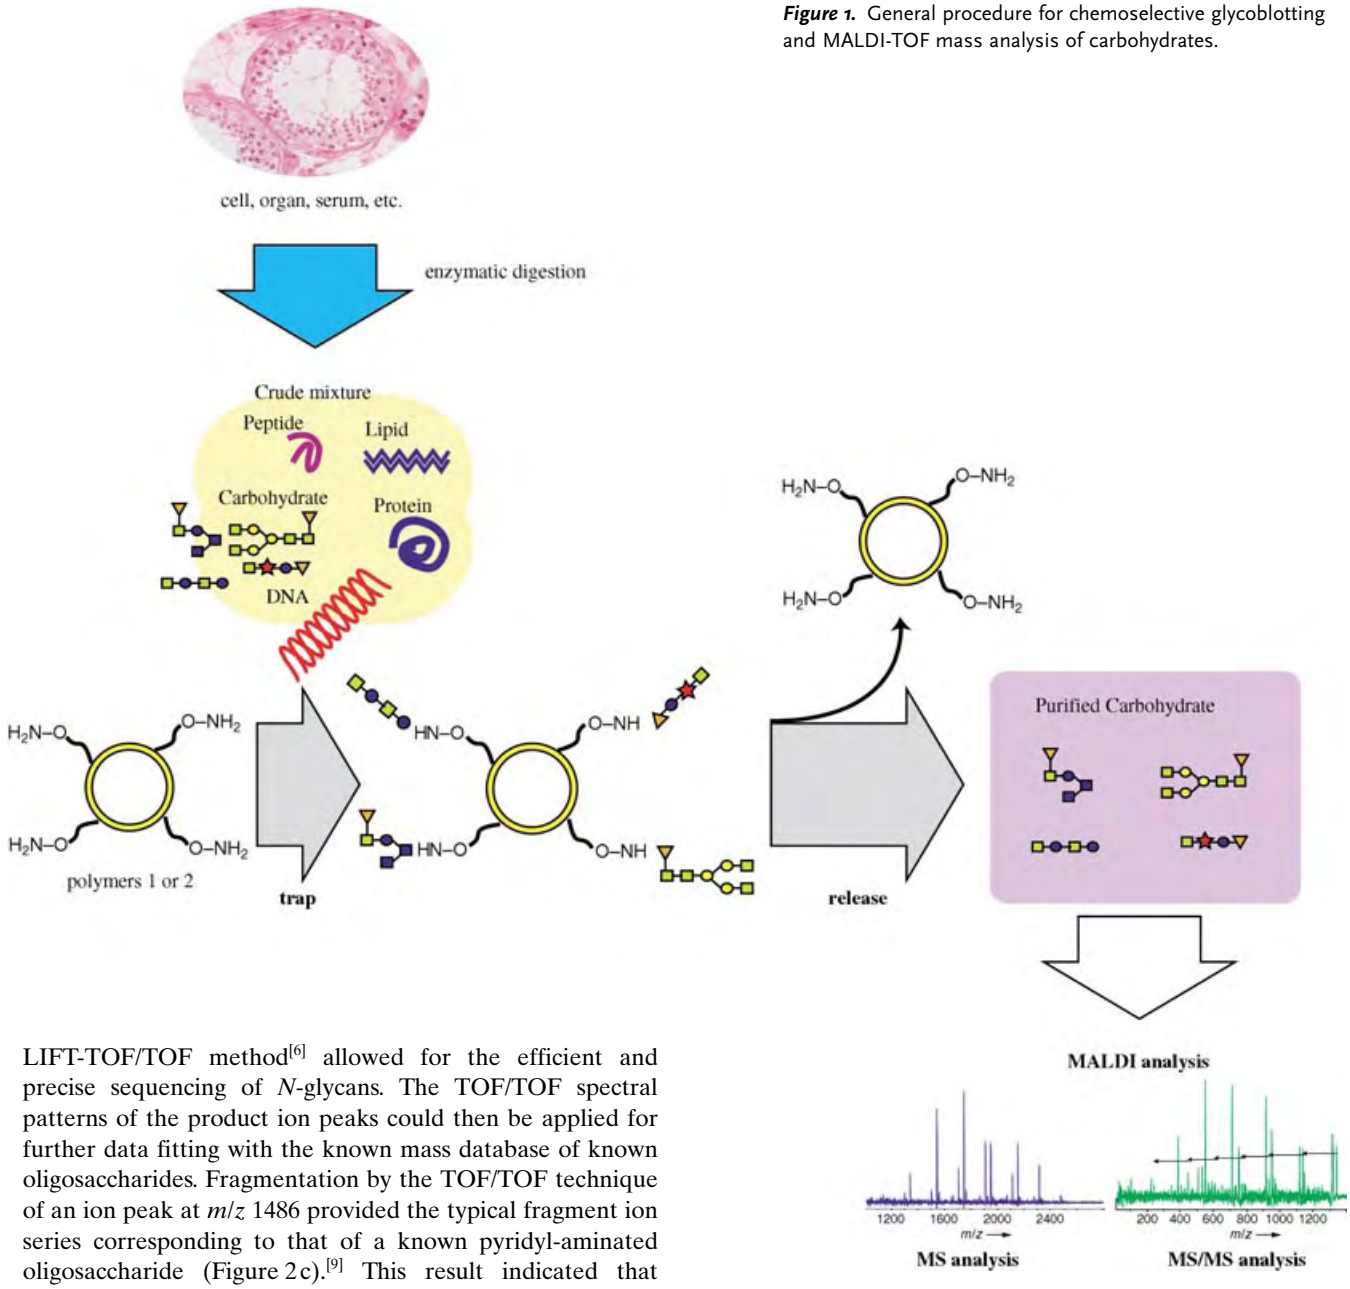

Figure 1. General procedure for chemoselective glycoblotting and MALDI-TOF mass analysis of carbohydrates.

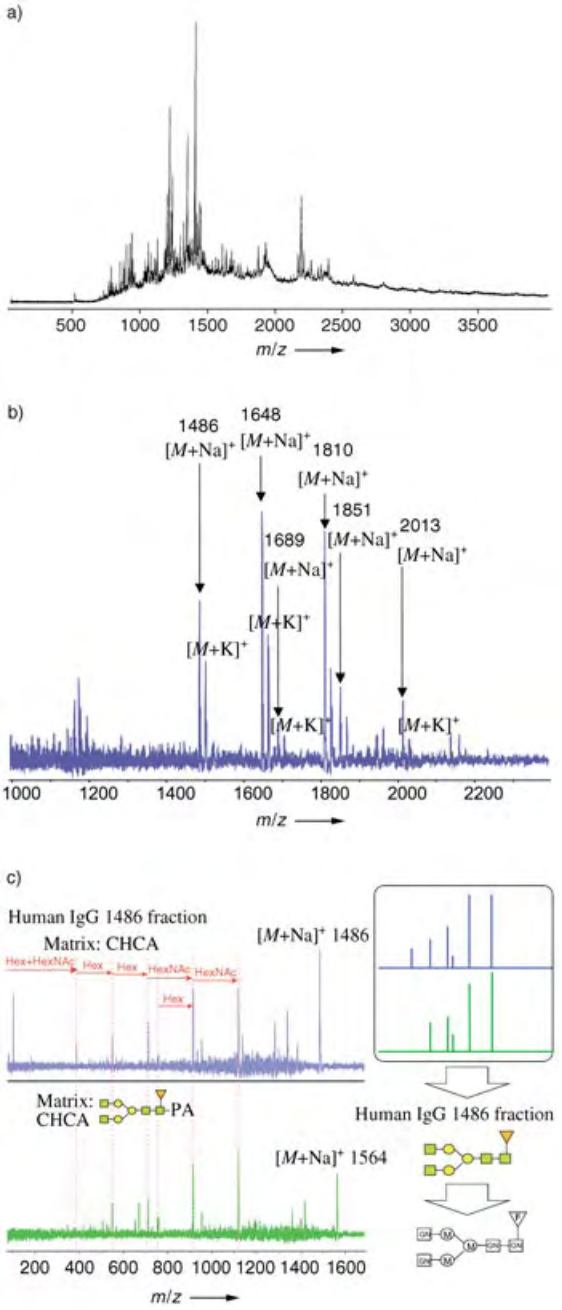
LIFT-TOF/TOF method[6] allowed for the efficient and precise sequencing of *N*-glycans. The TOF/TOF spectral patterns of the product ion peaks could then be applied for further data fitting with the known mass database of known oligosaccharides. Fragmentation by the TOF/TOF technique of an ion peak at *m*/*z* 1486 provided the typical fragment ion series corresponding to that of a known pyridyl-aminated oligosaccharide (Figure 2c).[9] This result indicated that carbohydrate mass fingerprinting (CMF) analysis by the MALDI-TOF/TOF method allows for the precise structural identification of oligosaccharides captured from glycoproteins by glycoblotting.

It was clearly suggested that the structure of each oligosaccharide measured by the MALDI-TOF instrument was in good agreement with the data obtained by a conventional HPLC-based analysis of the corresponding pyridyl-aminated derivatives prepared from human IgG.[10] The relative intensity of each carbohydrate response given by the two methods exhibited quite similar results (see the Supporting Information), which suggests that the polymer captures carbohydrates with a reaction efficiency in proportion to the amount of each oligosaccharide existing in the sample mixtures. This result means that glycoblotting is a general and versatile method for trapping a variety of carbohydrates bound to proteins.

The CMF analysis based on TOF/TOF can also be used to determine the ratio of oligosaccharide isomers, as shown in the analysis of the ion peak at *m*/*z* 1648 (see Figure 3). The observed fragmentation of this precursor ion peak was found to be a mixture of two structural isomers and the analysis using the correlation coefficient calculated by using the known compounds enabled the ratio of the two isomers to be estimated as 62:38.

Our attention was next directed toward the application of the glycoblotting strategy for the identification of the *O*-GlcNAc site present in abundance in nucleocytoplasmic glycoproteins.[1b] Recently, we succeeded in the high-throughput identification of *O*-glycosylation (*O*-GalNAc) sites by high-speed analysis in the LIFT-TOF/TOF mode of the ion peaks of the glycosylated products in the presence of 2,5-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



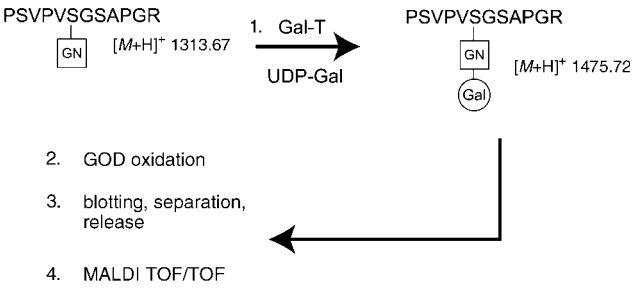


Figure 2. MALDI-TOF analysis of human IgG *N*-glycans. a) MALDI-TOF mass spectrum of crude *N*-glycans before glycoblotting. b) Major precursor ion peaks of *N*-glycans obtained by glycoblotting. c) Fragmentation by MALDI-LIFT-TOF/TOF tandem mass spectroscopy. Fragmentation of the precursor ion at *m*/*z* 1486 was performed according to the conditions reported previously in the presence of CHCA as a matrix.[11] Precise structural identification was carried out by comparing the fragmentation pattern of the known pyridyl-aminated oligosaccharide. All measurements were performed using an Ultraflex TOF/TOF mass spectrometer equipped with a reflector, and controlled by the Flexcontrol 1.2 software package (Bruker Daltonics GmbsH, Bremen, Germany). Ions generated by a pulsed UV laser beam (nitrogen laser, $\lambda = 337$ nm) were accelerated to a kinetic energy of 23.5 kV. Metastable ions generated by laser-induced decomposition of the selected precursor ions were analyzed without any additional collision gas. Precursor ions were accelerated to 8 kV and selected in a timed ion gate. The fragments were further accelerated by 19 kV in the LIFT cell, and their masses were analyzed after the ion reflector passage. Masses were automatically annotated by using XMASS 5.1.2 NT.

dihydroxybenzoic acid (DHB).[6a] To test the feasibility of glycoblotting and the subsequent TOF/TOF analysis of glycopeptides, we preliminarily investigated the enzymatic modification of a synthetic glycopeptide (PSVPVS(*O*-GlcNAc)GSAPGR) which was identified as the *O*-GlcNAc-modified peptide derived from basic phosphoprotein.[11] This glycopeptide was subjected to: a) Galactosylation with galactosyl transferase (GalT)[12] and b) oxidation with galactose oxidase (GOT) to generate a terminal aldehyde group at the C-6 position of the modified galactose residue (Scheme 2). A

Scheme 2. Strategy for the analysis of *O*-GlcNAc modified peptides.

crude glycopeptide mixture was directly used for further blotting with polymer reagent **2** and the subsequent analysis by MALDI-TOF mass spectrometry. Since peptide fragments bearing oligosaccharides prepared by tryptic digestion often exhibited poor solubility in water, water-soluble Fischer-type reagents may be a useful alternative to nanoparticles in terms of the efficiency. The TOF/TOF MS spectrum of the precursor ion at *m*/*z* 1473.71 measured with DHB gave highly sensitive and ideal fragmentation patterns because of the glycopeptide containing a (CHO)Galβ→4GlcNAcβ→Ser residue (Figure 4b). As anticipated, fragmentation in the presence of the DHB matrix occurred preferentially at peptide bonds without serious de-*O*-glycosylation (elimination) or fragmentation (cleavage) in the carbohydrate moiety. This characteristic greatly facilitated the identification of the O-glycosylation site in the target molecule (Figure 4c). This result suggests that the aldehyde attachment by enzymatic derivatization of the *O*-GlcNAc-modified peptide enables a high-throughput identification of O-glycosylation sites based on the glycoblotting method.[13] The merit of the present strategy is evident because the identification of new *O*-GlcNAc-modified proteins and the sites of modification would facilitate more global studies of the regulatory role of this posttranslational modification.

In conclusion, this study demonstrated that glycoblotting based on oxylamino-containing polymers (Fischer-type polymer reagents) could generally be used for capturing both common oligosaccharides and aldehyde-attached glycopeptides derived by enzymatic modifications. It should be noted that the efficiency and versatility in the capturing of carbohydrates from the crude proteolytic digests is crucial for ideal and practical protein glycomics. Therefore, the combined use of glycoblotting and high-performance MALDI-TOF/TOF analysis provides us with a new promising

[13] An aldehyde group generated at the C-8 position of the terminal sialic acid of a glycoprotein can also be trapped by this method. The feasibility of this strategy was preliminarily demonstrated by trapping the tryptic digest of fetuin in which the diols at the C-8 and C-9 positions of sialic acids were selectively converted into aldehyde groups by treating with 1 mM $NaIO_4$ solution at 0 °C for 30 min (data not shown). The present method can not be used for the analysis of glycopeptides displaying high mannose-type oligosaccharides, since it seems that specific conversion of a terminal mannose residue into an appropriate aldehyde derivative is difficult.

C–C Coupling

(Z)-Bis(alkylzinc)imido-1,2-di(2-pyridyl)ethene: Intramolecular Stabilization of a Bis(alkylzinc)imide**

Matthias Westerhausen, Alexander N. Kneifel, and Alexander Kalisch*

Dedicated to Professor Nils Wiberg on the occasion of his 70th birthday

The oxidative metal-mediated C–C coupling reaction of (2-pyridylmethyl)(trialkylsilyl)amines succeeds smoothly with dialkylzinc [Eq. (1)] or tin(II) bis[bis(trimethylsilyl)amide].[1] The influence of the standard potential as well as the role of the steric demand of the nitrogen-bonded trialkylsilyl and zinc-bonded alkyl groups have been investigated.[2] The N-bonded trialkylsilyl substituent is obligatory to prevent side reactions. The reaction of dialkylzinc with 2-py-CH_2NH_2 (py = pyridyl) yields several products which can be explained by a combination of oxidative C–C coupling and transamination reactions. After protolysis of this reaction mixture a small amount of *cis*-1,2-di(2-pyridyl)aminoethene (**1**; Scheme 1) can be isolated in a reproducible procedure.[3] However, we were not able to detect the zincated 1,2-di(2-pyridyl)aminoethene during the reaction. Amine **1** crystallized as the eneamine tautomer, an equilibrium with the imine tautomer was not detectable with spectroscopic methods.

(1)

Even 30 years ago, doubly zincated primary amines of the type $[RN(ZnR')_2]$ were of interest as catalysts for polymerization reactions,[4] however, these compounds were poorly characterized and more recent attempts to prepare bis(alkylzinc)alkyl- and -arylimides by zincation of primary alkylamines failed.[5,6] The polymerization reactions are also

explainable under the assumption that monozincated amines and dialkylzinc coexist during the polymerization reaction, unequivocal data for the biszincated amines were not reported.[4] With stronger metalating reagents imides were synthesized successfully. Thus magnesium phenylimides and related compounds were prepared by Power and co-workers.[7] Similar observations were reported for geminal carbdianions; whereas geminal doubly magnesiated[8] and lithiated[9] carbdianions were characterized by X-ray crystallography, the corresponding zinc derivatives tend to avoid the formation of two Zn–C bonds to one carbon atom.[10] Therefore, to date, only one zinc derivative, which was prepared by a rather complex reaction, has been reported.[11]

The reaction of an excess of diethylzinc with bis(2-pyridylmethyl)amine in toluene yields **2** (Scheme 1). The first

Scheme 1. Proposed mechanism for the formation of **2**

reaction step is the zincation of $(2\text{-pyCH}_2)_2$NH, the resulting compound **A** was identified by NMR spectroscopy.[12] Heating of this reaction solution under reflux for more than twenty hours led to the C–C coupling product **B** under elimination of zinc metal. The excess of dialkylzinc metalated the intermediate **B** at the endocyclic CH moieties giving compound **C** and ethane. Finally, a subsequent deamination (rearrangement) reaction gives **2**. A complex similar to **B** which has $AlMe_2$ fragments instead of the ZnEt moieties has been observed by Trepanier and Wang[13] as a minor dark-brown product in the reaction of $AlMe_3$ and $(2\text{-pyCH}_2)_2$NH. However, a concise mechanism for its formation was not proposed.

The protolysis of **2** with acetamide led to a nearly quantitative formation of *cis*-1,2-dipyridylaminoethene (**1**). The NMR spectroscopic parameters of **1**[3] and **2** (Table 1) differ remarkably little. This observation can be understood by taking into account that in both compounds the eneamine tautomer is formed and stabilized by N···Zn (**2**) and N···H (**1**) contacts to the pyridyl moieties, respectively.

Table 1: NMR spectroscopic data for **2** (solvent: $[D_8]$THF).[a]

Assignment	^{1}H NMR δ[ppm]	^{13}C{^{1}H} NMR δ[ppm]

$\delta(ZnCH_2CH_3)$	1.25	12.9

[a] The assignment of the pyridyl (pyr) resonances signals to a specific pyridyl group was not possible.

The asymmetric unit of **2** is represented in Figure 1. The zinc atoms are both bonded to the imide nitrogen atom N2 and fixed by additional bonds to the pyridyl bases which leads

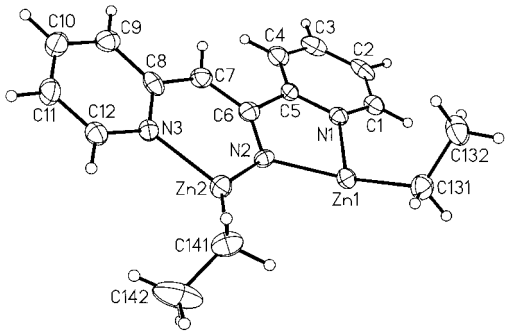

Figure 1. Molecular structure of **2**. Thermal ellipsoids set at 30% probability, the H atoms are drawn with arbitrary radii. Selected bond lengths [pm]: Zn1-N1 209.0(5), Zn1-N2 200.0(4) (Zn1-N2′ 225.4(4)), Zn1-C131 198.1(6), Zn2-N2 192.5(5), Zn2-N3 204.9(4), Zn2-C141 197.4(8), N2-C6 134.2(7), N1-C1 132.4(7), N1-C5 133.3(7), C1-C2 138(1), C2-C3 140(1), C3-C4 136.3(9), C4-C5 134.9(8), C5-C6 156.6(8), C6-C7 138.1(8), C7-C8 141.7(8), C8-C9 141.5(8), C9-C10 136.4(9), C10-C11 136(1), C11-C12 133.7(8), N3-C8 136.9(7), N3-C12 135.9(7).

to a nearly planar molecule. In the solid state **2** is a dimer (Figure 2) with a crystallographically imposed C_2 axis ($-x$, $-y$, z).

In **1** an isolated eneamine fragment with characteristic C–C single bonds to the attached pyridyl fragments was found[3] whereas in **2** the ligand's anionic charge is partly delocalized within the neighboring pyridyl moiety (Scheme 2). The consequence of the delocalization is a shortening of the C6–N2 bond of the imide moiety (**1**: 137.8(6) pm;[3] **2**: 134.2(7) pm) and a lengthening of the adjoining C6–C7 double bond (**1**: 129.5(6) pm;[3] **2**: 138.1(8) pm). The C7-C8 bond length of **2** is 141.7(8) pm which supports a multiple-

bond character and a delocalization of the anionic charge into the pyridyl moiety. This situation weakens the aromaticity of this pyridyl ligand which gives rise to bond lengthening within this heterocycle (N3, C8–C12).

Owing to the dimer formation in which Zn1 and N2 are the bridging atoms the zinc atom Zn1 is four-coordinate whereas Zn2 is in a distorted trigonal planar environment. Owing to the additional electrostatic attraction the Zn1–N2 and Zn2–N2 bond lengths to the imide function are smaller than the Zn1–N1 and Zn2–N3 values of the pyridyl substituents. The intermolecular Zn1–N2′ separation of 225.4(4) pm is large and can be interpreted as an interaction between the occupied nitrogen-centered p orbital with the empty p orbital at the zinc atom. The trans-annular nonbonding Zn1···Zn1′ separation is 290.4(1) pm whereas the Zn1···Zn2′ separation is larger (305.24(9) pm).

Scheme 3. Schematic representation of **D**.

The reaction conditions, such as temperature, substituents at N, and stoichiometry play a key role during the formation of **2**. At low temperatures the C–C coupling reaction is extremely slow and **D** (Scheme 3) forms from **A** in an unstirred toluene solution.[14] At elevated temperatures the C–C coupling reaction is favored and **2** becomes the major product.

Experimental Section

All manipulations were carried out in an anhydrous argon atmosphere. The solvents were thoroughly dried and distilled under argon.

Synthesis of **2**: Diethylzinc in n-hexane (20 mL of a 1.0 M solution, 20 mmol) was added slowly to a solution of bis(2-pyridylmethyl)-amine (1.8 mL; 10.0 mmol) in toluene (20 mL). The solution turned red-brown. After stirring at room temperature for 1 day the solution was heated under reflux for 22 h. During this time zinc metal precipitated. The hot solution was filtered and the filtrate collected and cooled to room temperature. Then the volume was reduced to a few milliliters. At room temperature 1.24 g of red prisms of **2** (3.2 mmol, 32 %) precipitated. M.p. 264 °C. Elemental analysis calcd (%) for $C_{16}H_{19}N_3Zn_2$, 384.12 g mol^{-1}: C 50.03, H 4.99, N 10.94; found C 50.16, H 4.99, N 10.74. MS (EI, *m*/*z*): 383 (M^+–H, 2), 355 (383-Et, 14). NMR data see Table 1.

Crystal data for **2**:[15] red cubes, $C_{16}H_{19}N_3Zn_2$, $M_r = 384.08$, orthorhombic, space group *Fdd*2 (no. 43), $a = 1339.73(7)$, $b = 4211.6(2)$, $c = 1150.00(5)$ pm, $V = 6.4888(5)$ nm^3, $\rho_{calcd} = 1.573$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 2.953$ mm^{-1}, $Z = 16$ (8 dimers), 5736 reflections were collected on a Siemens P4 diffractometer with a CCD area detector at 193(2) K using graphite monochromated $Mo_{K\alpha}$ radiation, 1797 independent reflections ($R_{int} = 0.0490$), 196 refined parameters, $wR_2 = 0.0743$ (on F^2), $R1 = 0.0293$ (on 1748 reflections with $I > 2\sigma(I)$), $s = 1.079$, residual electron density 426/–332 e nm^{-3}.

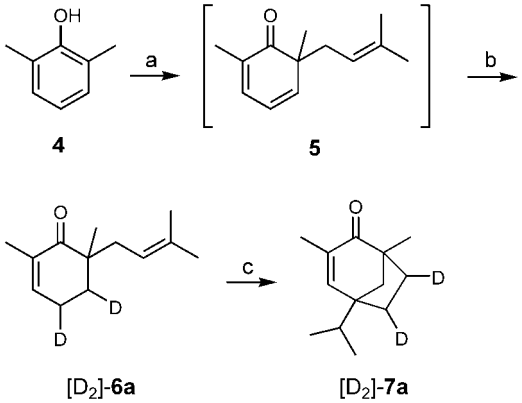
Lewis Acids in Organic Synthesis

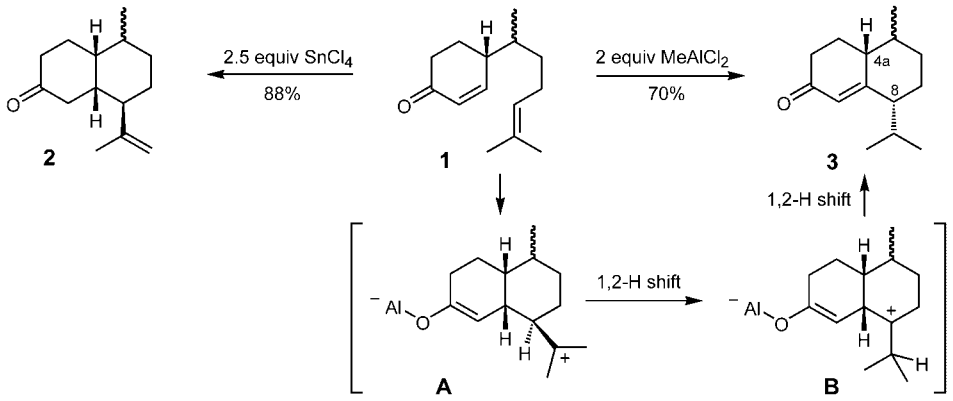
Alkyl Aluminum Halide Promoted Intramolecular Cyclization of ω-Allyl-cycloalk-2-enones: Access to Bridged Bi- and Tricyclic Compounds



Andreas Goeke, Daniel Mertl, and Gerhard Brunner*

Dedicated to Professor Günter Helmchen

The cationic cyclization of olefins has been developed as an important methodology in organic synthesis.[1] Since Stork and Burgstahler and Eschenmoser et al. rationalized the proton-catalyzed biological cyclization of polyprenoids,[2] a variety of different initiators of this and related reactions have been developed.[3] Intramolecular Lewis acid promoted conjugate additions of olefins to α,β-unsaturated ketones or aldehydes belong to this category,[4] although, depending on the Lewis acid, the course of such cyclizations can be different. Snider et al. demonstrated that cyclohexenone **1** reacted in the presence of $SnCl_4$ to compound **2** which is the product of a concerted Lewis acid induced ene reaction,[5] while treatment of **1** with two equivalents of $MeAlCl_2$ (or $EtAlCl_2$) resulted in naphthalenone **3** (Scheme 1).[6] It was deduced that this compound was generated by two consecutive 1,2-H shifts of zwitterionic intermediates **A** and **B** rather than by one 1,3-H shift as the relative configuration of the stereogenic centers C4a and C8 was determined to be *anti*.



This unique behavior of alkyl aluminum halides as Lewis acids was partially explained by their Brønsted base-like character: Any adventitious water will be scavenged by forming an alkane and a new Lewis acid.[7]

While investigating novel syntheses of functionalized odorants,[8] we observed a novel and unexpected $EtAlCl_2$ promoted cyclization of cyclohexenone **6a** to bicyclo[3.2.1]octenone **7a** (see Table 1, entry 1) which displays a pleasant woody vetiver-like odor.[9] To better understand this reaction, labeled substrate [D_2]-**6a** was prepared by a selective deuteration of unstable trienone **5**[10] which was accessible by C-alkylation of phenol **4** (Scheme 2).[11] After cyclization,

Scheme 2. Synthesis of [D_2]-**7a** by deuteration of trienone **5**. Conditions: a) NaH, toluene, prenyl chloride; b) MeOH, Pd/C, D_2; c) 1.5 equiv $EtAlCl_2$, toluene.

the overall deuterium incorporation of [D_2]-**6a** was retained in [D_2]-**7a**, which indicates a) the methylene-bridge in **7a** stems from the prenyl group and b) the deuterated positions of the cyclohexenone unit of **6a** are not the locations of intermediate zwitterions.

Scheme 1. Ene reaction versus cationic cyclization of **1**.[6]

Further investigation (Table 1) revealed that the cyclization tolerates cycloalkenones of different substitution at R^1–R^6 and also of different ring sizes, although yields decrease with increasing steric strain (entries 3,4) and increasing ring size (entries 8,9). Additional unsaturation in substituents R^2,R^4, and R^6 (entries 5,6,7) neither disturbed the cationic cyclization, nor was a competitive or subsequent cyclization observed in these cases.[12] The yields dramatically decreased

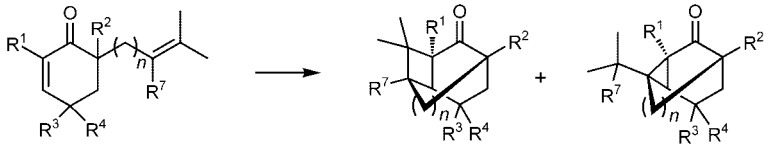
with R^5 or $R^6 = H$, which reflects the necessity of cation stabilization at the 3′ position of the allylic substituent in ketone **6** (Table 1, entry 10). Entry 11 shows that an additional ester group in substrate **6k** consumes at least one equivalent of the Lewis acid by a competitive complexation, although esters were shown to be less basic than ketones.[13]



The outcome of the cyclization does change completely with different substitution patterns of ketones **8**[10] (Table 2). In these cases, mixtures of tricyclic compounds **9** and **10** were usually obtained, in ratios not very much influenced by varying steric demand of the substituents R^3 and R^4. However, cyclization of compound **8a** (R^3, $R^4 = H$) led to a mixture of **9a** and **11a** (see Scheme 3) while the transformation of homoallylic derivative **8f** provided compound **10f** exclusively.

These observations are in accordance with the proposed mechanism in Scheme 3. It can be explained by a sequence of 1,2-H and alkyl shifts that were proposed by Snider et al.[6,7]

The conversion of compounds **6** (and **8a**) follows path A. The initially formed zwitterion results from cyclization of the enone–$EtAlCl_2$ complex with the allyl side chain being in an *s-trans* conformation. Subsequent 1,2-H (or methyl) shift followed by intramolecular alkyl migration generates compounds **7** (**11a**). In path B, the allyl side chain of compounds **8** may be sterically (R^3,R^4 = alkyl, $R^7 = Me$) pushed into a *s-cis* conformation which gives, after the initial cyclization, the cation close to the enolate. This effect may also be caused by angular strain that occurs during the cyclization of homoallylic derivative **8f**. The quenching of charges in the zwitterionic intermediate at this stage results in compounds **9**. However, the 1,2-R^7 shift is rapid enough to allow path B to be partially terminated by the formation of compounds **10**.

In summary, the novel $EtAlCl_2$-induced cyclization of 6-allyl cyclohexenones is a flexible tool for the synthesis of bi- and tricyclic compounds. The scope and limitations were investigated with respect to substitution patterns.

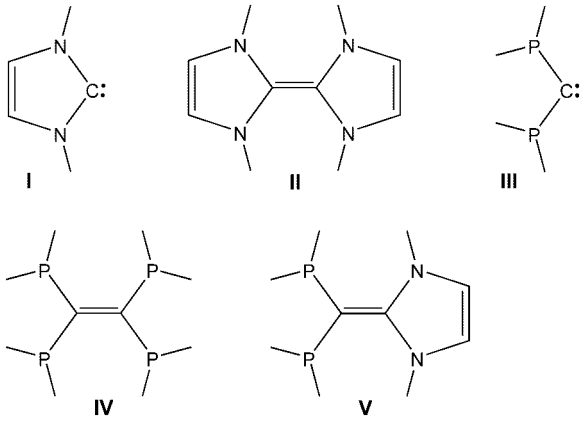
Hybrid Carbenes

Imidazoline-Functionalized Diphosphines: Models for N-Heterocyclic Carbene–Diphosphinocarbene Coupling**

Javier Ruiz, Marta E. G. Mosquera, Gabriel García, Fernando Marquínez, and Víctor Riera*

N-Heterocyclic carbenes **I** derived from imidazol-2-ylidene, also referred to as Arduengo carbenes, are important compounds whose isolation as stable, free molecules has greatly contributed to the development of carbene chemistry in recent years.[1] They show no tendency to dimerize to afford tetraazafulvalenes **II**, except under special circumstances,[2] unlike the corresponding saturated N-heterocyclic carbenes. In contrast, related diphosphinocarbenes **III** are not isolable, and have been reported in the literature only as transient species,[3,4] whereas their corresponding dimers **IV** are known to be stable.[5] As far as we are aware, no example of coupling of both types of carbenes (**V** in Figure 1) has been described.



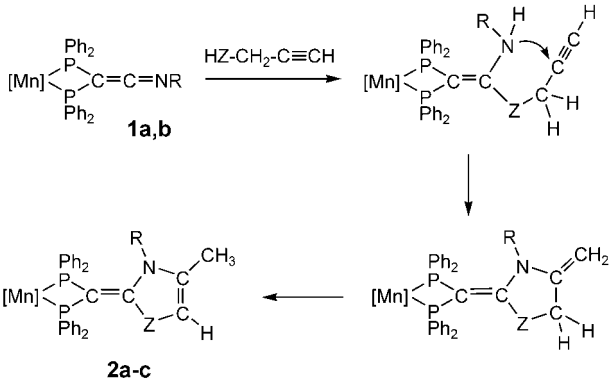


Figure 1. Schematic representation of imidazol-2-ylidenes and diphosphinylcarbenes, and their coupling products.

We report here the metal-assisted synthesis of new diphosphine ligands bearing an imidazoline residue that can serve as models of N-heterocyclic carbene–diphosphinocarbene coupling. The synthesis of analogous oxazoline-functionalized diphosphines is also described.

The diphosphinoketenimine ligand coordinated in the cationic complex $[Mn(CO)_4\{(PPh_2)_2C{=}C{=}NPh\}]^+$ (**1a**)[6] reacts with propargylamine in refluxing toluene to afford **2a** (Scheme 1), which is a diphosphine complex containing an

Scheme 1. Proposed mechanism for the formation of complexes **2a–c**. [Mn] = $[Mn(CO)_4]^+$. **1a**: R = Ph; **1b**: R = *p*-tolyl. **2a**: R = Ph, Z = NH; **2b**: R = Ph, Z = O; **2c**: R = *p*-tolyl, Z = NMe.

imidazoline functionality. This complex is formed in a cycloaddition process involving the ketenimine fragment of the ligand. This result is in sharp contrast to the reaction of free diphosphinoketenimines with propargylamines, which affords phosphinine derivatives due to the additional involvement of a phosphorus atom in the cycloaddition process.[7] As proposed in Scheme 1, a likely mechanism for the formation of **2a** implies, in a first step, nucleophilic attack of the amine to the ketenimine to afford an enediamine derivative. Then, a 5-*exo*-dig addition of the phenylamino moiety to the alkyne leads to the formation of an imidazolidine cycle, which is converted into the corresponding imidazoline residue by a 1,3 proton shift from the endocyclic methylene group to the exocyclic one. This results in a change of the C=C bond position and the formation of a conjugated six-π-electron system. The reaction of **1a** with propargyl alcohol proceeds similarly to give the corresponding diphosphine complex **2b** bearing an oxazoline functionality (Scheme 1).

It is well known that the reaction of ketenimines with amines and alcohols usually gives the corresponding amidine and imidate derivatives, respectively.[8] However, as far as we are aware, no reaction of organic ketenimines with propargylic amines or alcohols has been reported thus far. The reaction described here therefore represents a completely new method for the formation of imidazoline and oxazoline functionalities by a new cyclization process.

The spectroscopic data of **2a**,**b** (see the Experimental Section) are in agreement with the proposed formulation. Moreover, their solid-state structures were confirmed by X-ray analysis (Figure 2 and Figure 3).[9] The most important feature in the structures of **2a** and **2b** is the presence of the imidazoline and oxazoline cycle, respectively, which is coplanar with the PCP skeleton of the diphosphane. The C1–C2 bond lengths in **2a** (1.429(4) Å) and **2b** (1.385(6) Å) are, to varying degrees, intermediate between single and double bonds, as are the P1–C1 and P2–C1 distances and the

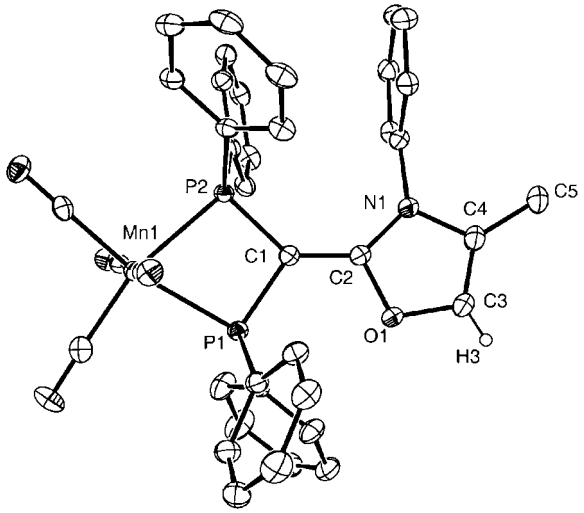

Figure 3. A view of the structure of the cation of **2b**. Selected bond lengths [Å] and angles [°]: P1-C1 1.781(4), P2-C1 1.770(4), C1-C2 1.385(6), N1-C2 1.338(6), N1-C4 1.422(5), O1-C2 1.364(5), O1-C3 1.398(6), C3-C4 1.335(7); P1-Mn-P2 71.09(4), P1-C1-P2 99.7(2), N1-C2-O1 107.9(3), N1-C2-C1 135.4(4), O1-C2-C1 116.7(4).

different interatomic distances in the imidazoline and oxazoline cycles (see the legends for Figure 2 and Figure 3). These data are consistent with a bond description in the diphosphine ligand resulting from the contribution of two resonance structures, as illustrated in Figure 4 for the imidazoline case (olefinic form **a** and imidazolium ylide form **b**). Obviously, in the ylidic form the negative charge of the diphosphinomethanide fragment is stabilized by charge delocalization through the metallacycle, whereas the positive one is stabilized by π-donation from the nitrogen lone-pairs. If we consider complexes **2a** and **2b** as models for carbene–carbene coupling, the structural data described here are in agreement with the well-

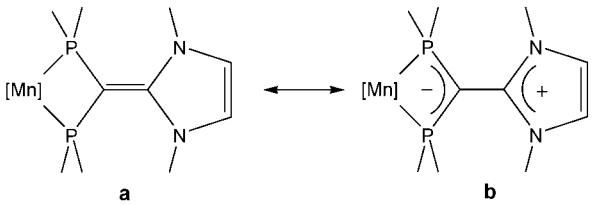

Figure 4. Resonance structures of imidazoline-functionalized diphosphane complexes. [Mn] = $[Mn(CO)_4]^+$.

known nucleophilic character of N-heterocyclic carbenes[10] and the electrophilic character of transient metalladiphosphinocarbenes,[11] whose coupling should lead to a net charge-transfer from the former to the latter, thus justifying the contribution of structure **b** in Figure 4. The IR spectra of **2a** and **2b** in the ν_{CO} region (see the Experimental Section), which show absorptions at values intermediate between those of diphosphine complexes and diphosphinomethanide derivatives,[12] support the above interpretation and indicate that the new diphosphines are strongly basic. Note that these absorptions occur at lower frequency in **2a** than in **2b**. This reflects the fact that the imidazoline fragment is a better electron donor than the oxazoline fragment, which also explains why the C1–C2 bond in **2b** is shorter than that in **2a**.

The $^{31}P\{^1H\}$ NMR spectra of **2a**,**b** at room temperature in CD_2Cl_2 show a single resonance, which suggests free rotation around the C1–C2 bond. For **2a**, this single signal is maintained when the spectrum is recorded at −80 °C, whereas it splits into two resonances, corresponding to the two inequivalent phosphorus atoms, in the case of **2b**. This observation agrees with the proposal outlined above that C1–C2 bond in **2b** has higher multiple-bond character than in **2a**.

Substituted propargylamine also reacts with coordinated diphosphinoketenimines in a similar manner. Thus, reaction of $[Mn(CO)_4\{(PPh_2)_2C{=}C{=}N\text{-}p\text{-tolyl}\}]^+$ (**1b**) with methylpropargylamine affords **2c** (Scheme 1), whose spectroscopic data are similar to those of **2a**. However, the structural data derived from the X-ray analysis (Figure 5) show appreciable changes that deserve comment. Thus, the plane of the imidazoline ring in **2c** is orthogonal to the PCP plane, with the methyl substituent of the nitrogen atom apparently locked between two phenyl groups of different phosphorus atoms. Consequently, the C1–C2 bond in **2c** (1.461(9) Å) is clearly longer than in **2a** (1.429(4) Å) and **2b** (1.385(6) Å), which suggests that the imidazolium ylide resonance form is dominant for **2c**.

The structural and spectroscopic data of complexes **2a–c** discussed above allow us to conclude that the degree of charge transfer from the five-membered heterocycle to the metallacycle through the C1–C2 bond, and therefore the basicity of the new diphosphines, can be modulated by changing either the heteroatoms in the cycle (imidazoline or oxazoline), the substituents at these heteroatoms, or the extent of molecular motion around the C1–C2 bond.

To summarize, we have described a new cycloaddition reaction for the formation of imidazoline and oxazoline functionalities, which consists of the treatment of coordinated

diphosphinoketenimines with propargylamines or propargyl alcohol. The resulting functionalized diphosphine ligands can be considered as models for the coupling of either N-heterocyclic carbenes or N,O-heterocyclic carbenes with diphosphinocarbenes. These models raise the experimental challenge of coupling imidazol-2-ylidenes (Arduengo-type carbenes) with phosphinocarbenes (Bertrand-type carbenes) to yield new types of electron-rich olefins, which should behave as strongly basic phosphines.

Experimental Section

All reactions and manipulations were performed under an atmosphere of dry nitrogen by using standard Schlenk techniques. Solvents were distilled from appropriate drying agents under dry nitrogen prior to use. Chemical shifts of the NMR spectra are referenced to internal $SiMe_4$ (^1H and ^{13}C) or external H_3PO_4 (^{31}P).

2a·ClO_4: $[Mn(CO)_4\{(PPh_2)_2C{=}C{=}NPh\}]ClO_4$ (**1a**·ClO_4; 0.05 g, 0.066 mmol) was dissolved in 20 mL of toluene, and $NH_2CH_2C{\equiv}CH$ (10 μL, 0.13 mmol) was added to this solution. The mixture was then refluxed for 30 min. Cooling the solution to room temperature led to the formation of yellow crystals that were suitable for X-ray analysis. Yield: 0.04 g, 76%. Elemental analysis (%) calcd for $C_{39}H_{30}ClMnN_2O_8P_2$: C 58.04, H 3.75, N 3.47; found: C 57.87, H 4.03, N 3.53; IR (CH_2Cl_2): $\tilde{\nu}$ = 2081(s), 2009 (sh), 1999 (vs), 1979 (s) cm^{-1}. ^1H NMR (300 MHz, CD_2Cl_2): δ = 8.28 (s, 1H, NH), 7.8–6.6 (m, 26H, Ph + =CH), 1.60 (s, 3H, CH_3) ppm; $^{31}P\{^1H\}$ NMR (121.5 MHz, CD_2Cl_2): δ = 3.7 (br) ppm.

2b·ClO_4: $HOCH_2C{\equiv}CH$ (20 μL, 0.33 mmol) was added to a solution of **1a**·ClO_4 (0.05 g, 0.066 mmol) in 10 mL of toluene. The mixture was then refluxed for 15 min. A solid precipitated out of the solution upon cooling, which was isolated and dried under vacuum. Crystals suitable for X-ray analysis were obtained from a mixture of $CHCl_3$ and hexane (1:1.5). Yield: 0.03 g, 57%. Elemental analysis (%) calcd for $C_{39}H_{29}ClMnNO_9P_2$: C 57.97, H 3.62, N 1.73; found: C 57.75, H 3.62, N, 1.58; IR (CH_2Cl_2): $\tilde{\nu}$ = 2083 (s), 2014 (s), 2001 (vs), 1985 (s) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$): δ = 6.6–8.0 (m, 26H, Ph + =CH), 1.26 (s, 3H, CH_3) ppm; $^{13}C\{^1H\}$ NMR (75.5 MHz, CH_2Cl_2/D_2O): δ = 8.1 (s, CH_3), 50.4 (t, $^1J_{C,P}$ = 47 Hz, P_2C), 156.8 (s, OCN), 212.3 (br, 4 × CO) ppm; $^{31}P\{^1H\}$ NMR (121.5 MHz, CD_2Cl_2): δ = 8.7 (br) ppm.

2c·ClO_4: $NH(CH_3)CH_2C{\equiv}CH$ (13 μL, 0.16 mmol) was added to a solution of $[Mn(CO)_4\{(PPh_2)_2C{=}C{=}N\text{-}p\text{-}tolyl\}]ClO_4$ (**1b**·ClO_4; 0.10 g, 0.13 mmol) in 40 mL of toluene. The mixture was then refluxed for 50 min. A solid precipitated out of the solution on cooling, which was isolated and dried under vacuum. Crystals suitable for an X-ray diffraction study were obtained from crystallization from a $CHCl_3$/hexane mixture (1:1.5). Yield: 0.09 g, 83%. Elemental analysis (%) calcd for $C_{41}H_{34}ClMnN_2O_8P_2$: C 58.97, H 4.10, N 3.35; found: C 59.09, H 4.08, N 3.58; IR (CH_2Cl_2): $\tilde{\nu}$ = 2079 (s), 2010 (m), 1990 (vs) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$): δ = 7.6–6.9 (m, 24H, Ph), 2.63 (s, 3H, NCH_3), 2.22 (s, 3H, $PhCH_3$), 1.91 (s, 3H, CH_3) ppm; $^{13}C\{^1H\}$ NMR (75.5 MHz, CH_2Cl_2/D_2O): δ = 11.7 (s, CH_3), 22.3 (s, $PhCH_3$), 27.7 (t, $^1J_{C,P}$ = 45 Hz, P_2C), 35.6 (s, NCH_3), 213 (s, 4 × CO) ppm; $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$): δ = 16.1 (br) ppm.

Asymmetric Catalysis

Stereocontrolled Creation of Adjacent Quaternary and Tertiary Stereocenters by a Catalytic Conjugate Addition**

*Hongming Li, Yi Wang, Liang Tang, Fanghui Wu, Xiaofeng Liu, Chengyun Guo, Bruce M. Foxman, and Li Deng**

Adjacent quaternary and tertiary stereocenters as in structure **1** are common structural motifs in complex natural products. In principle, the stereocontrolled conjugate addition of a prochiral trisubstituted carbon nucleophile to a prochiral β-substituted Michael acceptor with a chiral catalyst could provide a one-step construction of such highly congested motifs from simple precursors [Eq. (1)]. However, this

(1)

requires the catalyst to impart both high enantioselectivity and diastereoselectivity in a sterically demanding, intermolecular C–C bond formation that simultaneously creates both the quaternary and tertiary stereocenters. This task has proven to be a formidable challenge. Among numerous literature examples,[1–3] to our knowledge there are only two catalytic asymmetric conjugate additions that afford the 1,4-adducts containing adjacent carbon-substituted quaternary and tertiary stereocenters in excellent enantioselectivity and with a diastereomeric ratio (d.r.) of greater than 10:1 for a substantial number of trisubstituted carbon Michael donors.[2] Herein, we report an asymmetric conjugate addition mediated by a chiral bifunctional organocatalyst that affords high enantioselectivity and diastereoselectivity for several structurally distinct classes of trisubstituted carbon nucleophiles. This reaction allows the direct and stereocontrolled construction of a wide variety of adjacent carbon- or heteroatom-substituted quaternary and tertiary stereocenters.

Readily accessible cinchona alkaloids **2** have been identified recently as effective catalysts for the enantioselective conjugate addition of dimethyl malonate and ethyl acetoacetate to nitroalkenes.[4,5] These results prompted us to examine

conjugate additions involving trisubstituted carbon nucleophiles, especially those that could be conveniently generated in situ from readily available racemic carbonyl compounds. Screening of catalysts **2** for the addition of cyclic ketoester **3A** to nitroalkene **4a** in THF at room temperature revealed that Q-**2b** affords excellent enantioselectivities (94 and 95% *ee*) for both diastereomers of the 1,4-adducts, which were, however, generated in only a 4.5:1 ratio (Scheme 1). Interestingly, the reaction temperature was found to have a dramatic impact on the diastereoselectivity. Conjugate addition at −60°C afforded a d.r. of 18:1 with 99% *ee* for the major diastereomer.

Following this encouraging result, we examined a wide variety of trisubstituted carbon Michael donors in conjugate additions to nitroalkenes **4** mediated by Q-**2** (Table 1, Figure 1). Outstanding diastereoselectivity and enantioselectivity were obtained with various cyclic and acyclic β-ketoesters (**3A–D**). Similarly high enantioselectivity was also observed for the 2-substituted 1,3-diketone **3E**; the diastereoselectivity decreased noticeably but is yet of synthetic utility. Importantly, high diastereoselectivity and enantioselectivity can also be attained with trisubstituted carbon Michael donors that are not 1,3-dicarbonyl compounds (**3F–H**), including even those bearing a heteroatom substituent (**3F–G**). It is noteworthy that catalysts Q-**2** accept this unprecedented scope of trisubstituted carbon Michael donors and still tolerate a wide range of nitroalkenes (**4a–f**) bearing aryl, heteroaryl, and alkyl groups with varying electronic and steric properties.

[d] Determined by HPLC analysis. [e] Here 15 mol% catalyst was used. [f] Here 20 mol% catalyst was used. [g] Yield of the pure major diastereomer.

Mechanistic studies were carried out to gain insight into the transition-state assembly of this reaction. The absolute configuration of **5Dd** generated using Q-**2b** and the relative configuration of **5De** has been determined by X-ray crystallography.[6] We established that the asymmetric Michael addition follows a first-order dependence on the catalyst, the donor, and the acceptor.[6] We also found that the reaction proceeds at significantly higher stereoselectivities in aprotic solvents (THF, ether, and toluene) rather than protic solvents (MeOH, EtOH), which could form hydrogen bonds with either the catalyst or the substrates. To delineate the active conformer for the flexible catalysts **2** in the transition state, we compared their stereoselectivities with those of **6** (Figure 2),[7] a conformationally rigid catalyst, in Michael additions utilizing a variety of combinations of donors and acceptors. The remarkably similar d.r. and *ee* profiles thus exhibited by QD-**2** and **6** provide powerful evidence to support a *gauche*-open active conformer for catalysts **2** in the transition state (Table 2).[8–9] These results are also noteworthy for establishing QD-**2** and **6** as efficient catalysts for the asymmetric Michael addition.

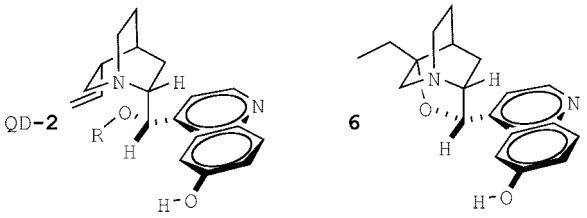

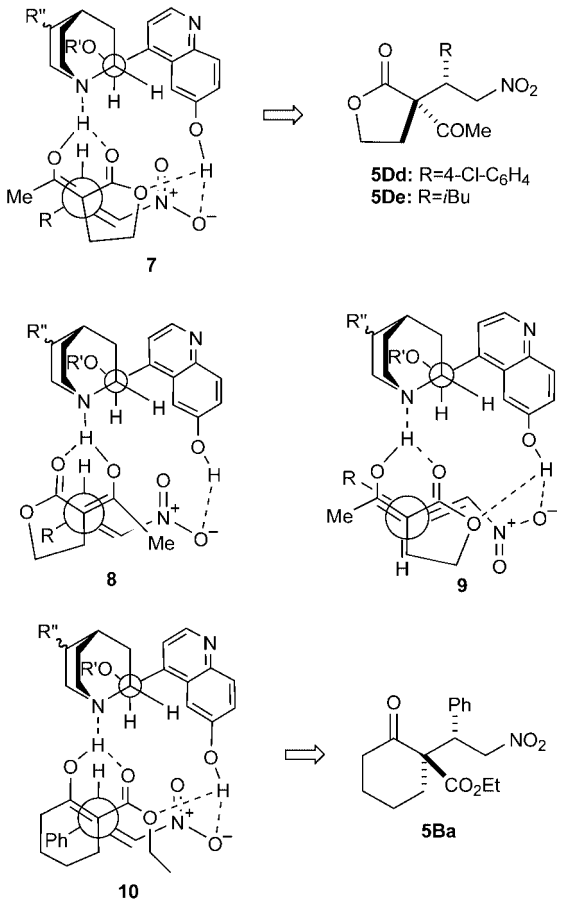

Figure 2. Catalyst QD-**2** shown as its *gauche*-open conformer and catalyst **6**.

With this key insight into the active conformer of the catalysts **2**, the kinetic results consistent with an acid–base bifunctional catalysis mode, and the observed solvent effect indicating an important role played by hydrogen-bond interactions between the catalyst and the substrates, we propose the transition-state model **7** to rationalize the stereochemical outcome of the asymmetric Michael addition (Scheme 2). In this model cinchona alkaloids **2** and **6** adopt a *gauche*-open conformer to simultaneously activate and orient the Michael donor and the acceptor by means of a network of hydrogen-bonding interactions. The substituents of the two bond-forming carbons are in a staggered rather than eclipsed arrangement. Alternative transition states generating the other stereoisomers are relatively disfavored due to either the loss of hydrogen-bond interaction between the chiral catalyst and the substrates (as in **8**) or the engagement of unfavorable eclipsed interactions between the substitutents of the bond-forming carbons (as in **9**). Application of this model (as in **10**) predicts that the adduct **5Ba** should have the relative configuration shown in Scheme 2. Gratifyingly, this was confirmed by X-ray structure analysis.[6]

Scheme 2. Stereochemical model for Michael additions catalyzed by QD-**2** or **6**.

[a] Reactions were run under the same conditions as described in Table 1 (see the Supporting Information).

In summary, we have developed a highly enantioselective and diastereoselective catalytic conjugate addition for a direct, stereocontrolled construction of adjacent carbon- or heteroatom-substituted quaternary and tertiary stereocenters from readily available starting materials. With exceptionally wide scopes for both the trisubstituted carbon Michael donors and the Michael acceptors, this experimentally simple new method should be useful for the synthesis of many multifunctional chiral building blocks containing adjacent quaternary and tertiary stereocenters that were previously not easily accessible. The stereochemical outcome of the reaction can be rationalized by a transition-state model, which is derived from mechanistic studies that clarify the active conformer of the bifunctional cinchona alkaloid catalyst in the transition state.

Organocatalysis

Metal-Free, Organocatalytic Asymmetric Transfer Hydrogenation of α,β-Unsaturated Aldehydes**

*Jung Woon Yang, Maria T. Hechavarria Fonseca, Nicola Vignola, and Benjamin List**

Asymmetric catalytic hydrogenations are used in the large-scale industrial production of pharmaceuticals and fine chemicals and also by all living organisms. While chemical hydrogenations require metal catalysts or the use of stoichiometric amounts of metal hydrides,[1] living organisms typically rely on organic cofactors such as nicotinamide adenine dinucleotide (NADH) in combination with metalloenzymes.[2] Until now, metal-free catalytic asymmetric hydrogenations have been unknown in chemical synthesis and seem to be rare in nature.[3] Here we show that a small organic molecule effectively catalyzes a highly enantioselective biomimetic transfer hydrogenation of α,β-unsaturated aldehydes using a synthetic dihydropyridine cofactor.

Industrially, metal-catalyzed hydrogenations are the most often used catalytic asymmetric processes. The complete removal of metal impurities from the reaction product, though difficult, is generally required in the production of pharmaceutical intermediates because of toxicity concerns.[4] Organocatalysis is a rapidly growing area of research, and one of its advantages is the general lack of metals.[5] We have recently developed an amine-catalyzed nonasymmetric transfer hydrogenation of α,β-unsaturated aldehydes **1** with Hantzsch ester **2** [Eq. (1)].[6]

(1)

This reaction is the first example of a completely metal-free transfer hydrogenation of olefins.[7] We could also show that enantioselective iminium catalysis of the reaction is in principle possible. Iminium catalysis has recently been introduced as a powerful organocatalytic method for carbonyl transformations such as conjugate additions and cycloadditions.[8] We have now completed an extensive screening of several synthetic and commercially available Hantzsch dihydropyridines and chiral ammonium salt catalysts and report here on an efficient enantioselective variant of our transfer hydrogenation.

We found that upon treating aromatic, trisubstituted α,β-unsaturated aldehydes **5** with a slight excess of dihydropyridine **6** and a catalytic amount of MacMillan imidazolidinone salt **7** at 13 °C in dioxane, the corresponding saturated aldehydes **8** were obtained in high yields and excellent enantioselectivities [Eq. (2), Table 1].

Like our nonasymmetric variant, the enantioselective reactions are generally clean and highly chemoselective, and carbonyl reduction or aldolization products were not detected. We also investigated the influence of the stereochemistry at the double bond. Remarkably, when we subjected both the isolated pure *E* or *Z* isomers of 4-nitro-substituted derivative **5c** to our reaction conditions, the same *R* enantiomer of product **8c** was obtained and with the same enantiomeric ratio of 97:3. Similarly, (*E*)/(*Z*)-**5c** mixtures always gave the same result and, independent of their exact ratio, all furnished (*R*)-**8c** in 97:3 e.r. Thus, our process is *enantioconvergent*, a highly desirable yet rare feature of a catalytic asymmetric reaction, where a mixture of stereoisomers furnishes only one product enantiomer. As a practical

consequence of this feature, the unsaturated aldehyde starting material of our reaction may be used as a mixture of *E* and *Z* isomers as obtained from common synthetic procedures such as the Wittig reaction.

Mechanistically, we assume the reaction to proceed by formation of iminium ion **9**, which presumably isomerizes quickly via dienamine **10** (Scheme 1). The following rate-determining hydride transfer from dihydropyridine **6** to enal (*E*)-**9** via transition state **A** proceeds faster than to (*Z*)-**9** [$k(E) > k(Z)$] and, as a result, saturated aldehyde (*R*)-**8** is formed predominantly.

In summary we have described the first completely metal-free catalytic asymmetric transfer hydrogenation. In our

Scheme 1. Proposed mechanism of the organocatalytic asymmetric transfer hydrogenation.

iminium catalytic reaction α,β-unsaturated aldehydes are highly efficiently reduced by means of transfer hydrogenation from a dihydropyridine. Attractive features of the process are 1) its high yields, chemo-, and enantioselectivities, 2) its enantioconvergence, and 3) its simplicity and practicability. Applications in the synthesis of natural products, pharmaceuticals, and fine chemicals may be envisioned.

Experimental Section

General procedure for the asymmetric transfer hydrogenation reaction: To a stirred solution of α,β-unsaturated aldehyde **5** (0.5 mmol) in dioxane (7 mL) at 13 °C was added catalyst **7** (20.4 mg, 0.05 mmol, 10 mol %) and, after five minutes, crystalline dihydropyridine **6** (129.2 mg, 0.51 mmol). After a reaction time of 48 h the mixture was poured into distilled water (20 mL) and extracted with dichloromethane (2 × 15 mL). The combined organic layers were dried ($MgSO_4$), filtered, and concentrated. The product was isolated by flash chromatography (SiO_2, ethyl acetate/hexane) to give the saturated aldehyde product **8**. Aldehydes **5a–f** were synthesized according to previously reported methods and their analytical data as well of those of aldehydes **8** match literature values.[9] The absolute configuration of (*R*)-**8f** was determined by measurement of its optical rotation and comparision to the literature value.[10] Enantiomeric ratios were determined by chiral stationary phase GC-analysis.

Chemistry in Porous Materials

Radiolysis of Confined Water: Production and Reactivity of Hydroxyl Radicals**

Sarah Foley, Patricia Rotureau, Serge Pin, Gérard Baldacchino, Jean-Philippe Renault, and Jean-Claude Mialocq*

As technology progresses to the nanoscale, the question of how chemical reactions are perturbed by the size of the environment needs further consideration. Such supramolecular steric effects provide new strategies to orientate reactivity towards desired functionality.[1,2] Confinement and interfacial phenomena are expected to have dramatic effects on reaction rates and mechanisms.[3] However, studies on these effects are still very limited, as most kinetic methods are difficult in a nanometer-confined environment.[2,4] Radiolysis of liquids is an efficient tool which can be used to investigate chemical reactivity in complex environments. As ionizing radiation induces reactions throughout the entire sample, whatever its complexity, information on the chemical reactivity at the microscopic scale can be obtained from macroscopic analytical strategies. Such studies of radiation-induced chemical processes in nanostructured materials have mostly been concerned with the effects on the solid material itself[5] or the reactivity of molecules adsorbed at the solid surface.[6] The present study aims to establish how radiation affects the reactivity of radiolytically produced radicals within nanometric water-filled pores in comparison to that in homogeneous solutions.

Radiation chemists have thus typically sought a target that can trap radicals in order to generate a change in some easily measurable property, as in chemical dosimeters.[7] Such traps are useful since they can probe cavities of any size and shape. High sensitivity can be achieved by choosing a system in which radiolysis results in the formation of a fluorescent compound and thus can be detected by spectrofluorimetry.[8,9] One of these profluorescent compounds is coumarin, which has the advantage of only measuring the formation of the $HO^{\bullet}$ radical whilst disregarding other primary radiolysis species. In aqueous solution, nonfluorescent coumarin is converted on irradiation into fluorescent 7-hydroxycoumarin (7-OHC).[10–14] The fluorescence intensity is proportional to the number of 7-OHC molecules formed, and this in turn is proportional to the locally available $HO^{\bullet}$ concentration down to 10^{-8} mol dm^{-3}. Such a selectivity and sensitivity with respect to $HO^{\bullet}$ can not be achieved by measuring the bleaching of a dye under irradiation.

We have determined the concentration of 7-OHC produced in a variety of controlled pore glasses (CPGs) with pore sizes ranging from 8 to 300 nm[15,16] to ascertain the influence of pore size on radiolytic radical production and reaction in a confined space. Figure 1 shows the fluorescence of 7-OHC

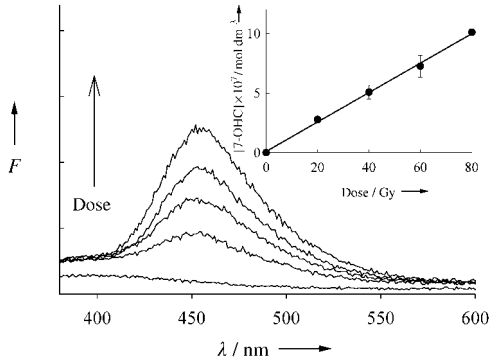

Figure 1. Fluorescence spectra of 7-OHC extracted from irradiated CPG of 200 nm pore size (excitation wavelength 332 nm, excitation and emission slits 0.5 mm, gamma irradiation with ^{137}Cs, 2 Gy min^{-1}). The inset shows the concentration of 7-OHC produced as a function of dose.

produced when 1 mM coumarin was irradiated in a CPG with a pore size of 200 nm. To ensure that all the 7-OHC produced in the CPG was extracted, control experiments were performed in which aqueous solutions of coumarin containing varying concentrations of 7-OHC were mixed with the CPGs. The amount of 7-OHC that could be extracted from these glasses was measured by using a fluorescence calibration curve down to 2×10^{-8} mol dm^{-3}; $95\pm5\%$ of the 7-OHC introduced could be recovered, irrespective of the CPG used. The concentration of 7-OHC produced in the pore was determined from the extraction coefficient of 95% and the fluorescence calibration curve. The results for a CPG with a pore size of 200 nm are shown in the inset of Figure 1. The concentration of 7-OHC produced remains proportional to the dose, as in aerated homogeneous solutions. Similar results were obtained for all the CPGs. The concentration of 7-OHC produced was also measured for CPGs with pore sizes of 8, 50, and 300 nm filled with solutions flushed by N_2O. Under these conditions, the reducing hydrated electrons e^-_{aq} are converted into HO$^\bullet$ radicals. Thus, in homogeneous solution, N_2O induces a 40% increase in the production of 7-OHC.[11] After exposure of the porous material to N_2O, the concentration of 7-OHC is increased by a factor of 1.5 relative to that obtained under Ar, a value which is in good agreement with that obtained by Makrigiorgos et al.,[11] and which shows that HO$^\bullet$ radicals are responsible for the formation of 7-OHC. The similarities between the behavior of coumarin in homogeneous solutions and in porous glasses and the possibility to efficiently quantify the 7-OHC produced allowed us to apply the capture of HO$^\bullet$ radicals by coumarin to the case of confined water.

Figure 2 shows how the concentration of 7-OHC in CPGs varies as a function of the pore size of the glass. The amount of solution added was equal to the available pore volume. The concentration of 7-OHC produced per Gy absorbed by water (the radiolytic yield) increases with increasing pore size of the CPGs. When the pore diameter decreases from 100 to 8 nm, the radiolytic yield of 7-OHC is divided by three, and thus we can assume that the radiolytic yield of HO$^\bullet$ radicals decreases by the same amount. Above a pore diameter of 150 nm, the behavior of confined coumarin solutions is similar to that of homogenous solutions.[10,17]

Such results can be attributed either to a cagelike effect which favors radical recombination in the pores[2] or to an enhanced surface reaction of HO$^\bullet$ at the water/silica interface.[18] To identify a possible role of this interface, CPGs with pore sizes of 8, 50, and 300 nm were filled with various amounts of 1 mM coumarin solution and irradiated as described above. In hydrophilic porous materials such as CPGs and Vycor glasses, when the amount of solution decreases, first the center of the pore empties leaving a layer of water on the silica surface, after which the thickness of this layer gradually diminishes.[19] The concentration of 7-OHC produced per Gy absorbed by water was determined as described above. The radiolytic yield of 7-OHC was found to increase when the amount of solution in the pores was decreased but the coumarin concentration was kept constant, that is, the thickness of the water layer on the silica decreased and the relative amount of silica surface available for a possible capture reaction of the HO$^\bullet$ radical on the surface increased (Figure 3a). The increase in the 7-OHC radiolytic yield shows that the capture of HO$^\bullet$ radicals at the surface is not efficient. At constant coumarin concentration, the only explanation for this increase is thus enhancement of radiolytic production of HO$^\bullet$ radicals.

Figure 3b shows the 7-OHC production per gram of glass and per Gray when the degree of pore saturation is increased. This value increases linearly with respect to the amount of water confined in the pores, but has a positive intercept. The linear increase with respect to the filling of the pore is due to

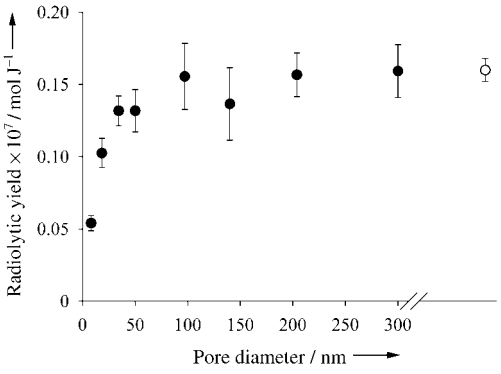

Figure 2. Effect of pore size on the yield of 7-OHC in CPGs. The empty circle refers to the yield in solution taken from Louit et al.[10]

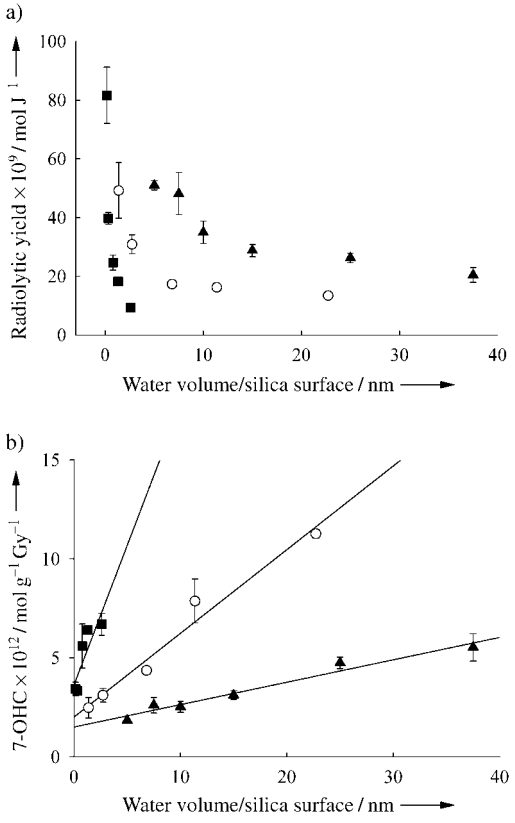

Figure 3. a) Yield of 7-OHC as a function of the ratio of introduced coumarin solution volume with respect to the wetted silica surface area for CPGs with pore sizes of 8 (■), 50 (○), and 300 nm (▲). b) Total amount of 7-OHC produced per gram of CPG and per Gray directly received by the glasses as a function of this ratio.

the direct radiation–water interaction, that is, to the direct production of hydroxyl radicals in water. On the other hand, the intercept is linked to an overproduction of oxidative species at the water/silica interface. Such an overproduction can be associated with energy transfer from the oxide to the adsorbed water.[20] As expected, this energy transfer is more efficient for materials with a large specific surface area, that is, for smaller pores. Therefore, the contribution of water to the production of HO• radicals can be separated from the surface contribution. A more accurate determination of the effects of confinement on 7-OHC production inside the pores can be obtained by subtracting the surface contribution. When this is done for the data in Figures 2 and 3b, the amount of HO• available for reaction with coumarin is decreases by a factor of almost 6 for 8 nm pores and by a factor of 1.5 for 50 nm pores with respect to the amount for 300 nm pores.

To explain this effect, we must take into account that the quantity of 7-OHC produced is the result of competition between recombination of radiolytic radicals and their capture by coumarin. In the 8 nm pores the hydroxyl radicals cannot migrate as far apart as in bulk water, and thus they recombine faster with radicals produced in the same radiolytic track than they can react with a solute such as coumarin.[21] This recombination is reminiscent of the recombinations of both the primary and secondary geminate radical pairs resulting from photolysis of ketones in the "void space" of MFI zeolites, although the diameters of the cylindrical channels and their spherical intersections are smaller (5.5 and 9 Å, respectively).[2] This acceleration of the reaction induced by confinement has been theoretically described by Tachiya in micelles.[22] From this model, such cage effects are not expected to be effective for pore sizes as large as 50 nm. A complementary explanation for the observed results can be provided by the model of Barzykin and Tachiya which was developed for gels.[23] In porous media, reactions on long timescales are expected to be slowed down by local depletion and impaired diffusion, especially for low concentrations of reactants. We assume that this slowing down of the capture of HO• radicals by coumarin can explain part of the decrease in radiolytic yield of 7-OHC in porous glasses.

These results show that the effects of confinement, clearly identified at the nanopore scale, are important even at the mesopore scale, and this suggests the need to completely reevaluate our knowledge of reactivity in this type of environment. Experiments are underway to better understand the effects of confinement on the rates of radical reactions.

[21] A simple way to understand the confinement effect of 8 nm pores is to evaluate whether HO• reacts with coumarin before reaching the pore wall. Taking $D = 2.3 \times 10^{-9}\ m^2 s^{-1}$ for the diffusion constant of HO• (G. V. Buxton, C. L. Greenstock, W. P. Helman, A. B. Ross, *J. Phys. Chem. Ref. Data* **1988**, *17*, 513) one can estimate the average time needed for a hydroxyl radical to reach the pore wall as 5 ns. If the reaction constant between hydroxyl radical and coumarin is taken as $k = 8.2 \times 10^9\ mol^{-1} dm^3 s^{-1}$ (K. Gopakumar, U. R. Kini, S. C. Ashawa, N. S. Bhandari, G. U. Krishnan, D. Krishnan, *Radiat. Eff.* **1977**, *32*, 199) the half-life of HO• in 10^{-3} mol dm^3 coumarin solution is about 85 ns. According to this analysis, confinement in 8 nm pores can effectively prevent diffusion of HO• out of their production site and increase their recombination with their parent radicals prior to reaction with coumarin.

C–H Activation

$[H_2C{=}ZrH_2]$: The Simplest Carbene Hydride Complex, Agostic Bonding, and C–H Activation of CH_4 to Form $[(CH_3)_2ZrH_2]$**

Lester Andrews, Han-Gook Cho, and Xuefeng Wang*

High oxidation state transition-metal complexes with a carbon–metal double bond have proven important for understanding the nature of metal coordination and for catalysts in alkene-metathesis and alkane-activation reactions.[1–3] Several early transition-metal alkylidenes are agostic,[1] and these compounds provide the opportunity to characterize the agostic interaction of hydrogen to a transition-metal center in a simple carbene complex (most agostic interactions involve much more complicated systems) and to help understand the important alkane C–H bond-activation process (a key step in many transition-metal catalyzed reactions).[4–8]

The simplest compound of this type is the methylidene complex, $[H_2C{=}MH_2]$, which is an ideal model system to examine substituent effects and the agostic interaction. Such Group 4 compounds have been investigated by electronic-structure calculations using small basis sets and shown to have symmetrical structures without agostic interactions.[9–11] Recently we have treated laser-ablated Ti, Zr, and Hf atoms with CH_3F and prepared the fluorine substituted $[H_2C{=}MHF]$ derivatives.[12–14] These methylidene species result from α-hydrogen migration in the initial $[CH_3MF]$ intermediate. Our electronic-structure calculations using basis sets with polarization functions reveal a tilted CH_2 group and provide evidence for agostic interaction in the $[H_2C{=}MHF]$ molecules.

The simple $[H_2C{=}MH_2]$ analogues contain two intense infrared chromophores, namely the CH_2 and MH_2 groups, which are sensitive to the distortion associated with intramolecular agostic bonding. Hence the IR spectrum of $[H_2C{=}ZrH_2]$ can provide evidence for agostic interaction through symmetry lowering in the molecule, as can computations using large basis sets. In particular, a simple count of [CHD=ZrHD] isotopomers provides a ready method to confirm agostic interactions in this simplest possible carbene complex, as only two isotopomers (*cis* and *trans*) will be formed if there is no agostic interaction (C_{2v} or C_s symmetry), but four isotopomers (*cis* and *trans* for H and for D in the agostic position) if there is agostic interaction (C_1 symmetry). We report herein the first experimental characterization of $[H_2C{=}ZrH_2]$ and demonstrate the agostic C–H···Zr interaction from the IR spectrum in solid neon and from density functional structure and frequency calculations.

The laser-ablation matrix-IR experiment has been described elsewhere.[15,16] Briefly, laser-ablated zirconium atoms (Johnson–Matthey) reacted with CH_4 (Matheson), $^{13}CH_4$, CD_4, CH_2D_2 (Cambridge Isotopic Laboratories) in excess neon (Spectra Gases) during condensation on a CsI window at 5 K. IR spectra were recorded at 0.5 cm^{-1} resolution on a Nicolet 750 spectrometer with HgCdTe detector. Samples were irradiated by a mercury arc lamp (175 W, globe removed), were annealed, and more spectra were recorded.

Complementary density functional theory (DFT) calculations were performed using the Gaussian 98 package,[17] B3LYP density functional, 6-311++G(2d,p) basis sets for C and H atoms, and SDD pseudopotential and basis set for the Zr atom to provide a consistent set of vibrational frequencies for the reaction products. Geometries were fully relaxed during optimization, and the optimized geometry was confirmed via vibrational analysis. All the vibrational frequencies were calculated analytically.

IR spectra are illustrated in Figure 1 in the Zr–H stretching region for laser-ablated Zr and CH_4 (0.4% in neon). Four new product absorptions are observed at 1546.2 and 1581.0 cm^{-1} (labeled **1**) and at 1587.5 and 1617.2 cm^{-1} (labeled **di**). The bands increased on $\lambda > 530$ nm and 240–380 nm irradiations. Annealing to 10 K sharpened and slightly increased these absorptions, and produced a new 1551.0 cm^{-1} satellite feature (labeled **1′**). Further annealing to 11 K increased the 1587.5, 1617.2 cm^{-1} set, decreased the 1546.2, 1581.0 cm^{-1} pair (**1**), and increased the satellite (**1′**). Continued annealing to 12 K increased the high-wavenumber set (**di**) another 10%, almost destroyed the low-wavenumber pair (**1**), markedly increased the 1551.0 cm^{-1} satellite and an associ-

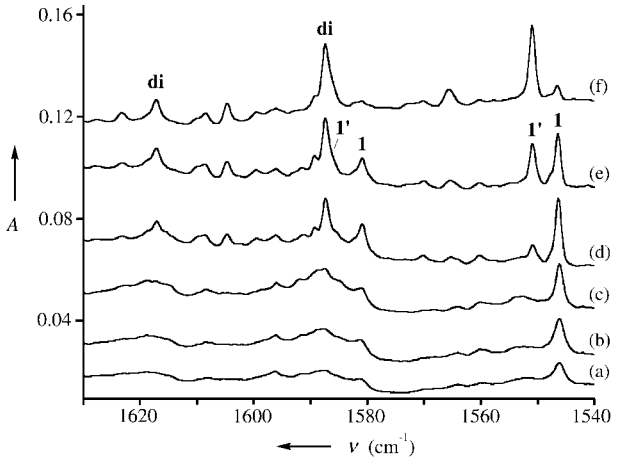

Figure 1. IR spectra in the 1630–1540 cm^{-1} region for laser-ablated zirconium co-deposited with CH_4 in excess neon at 5 K. a) 0.4% CH_4 in neon deposited for 45 min, b) after $\lambda > 530$ nm irradiation for 20 min, c) after 240–380 nm irradiation for 20 min, d) after annealing to 10 K, e) after annealing to 11 K, and f) after annealing to 12 K. For a discussion of the bands **1** (assigned to $[H_2C{=}ZrH_2]$), **1′**, and **di** (assigned to $[(CH_3)_2ZrH_2]$) see the text.

ated 1586 cm^{-1} shoulder absorption (also labeled **1′**). Subsequent visible and UV irradiation (not shown) decreased the 1586, 1551.0 cm^{-1} (**1′**) features in favor of the original 1581.0 and 1546.2 cm^{-1} bands (**1**) and slightly decreased the 1617.2 and 1587.5 cm^{-1} absorptions (**di**).

Table 1 lists these frequencies, their unshifted $^{13}CH_4$ counterparts, and analogous displaced CD_4 reaction product bands. These absorptions have H/D frequency ratios of 1.389–1.396, which characterize Zr–H stretching vibrations. Figure 2 shows spectra in the Zr–H and Zr–D stretching regions for reactions with CH_4, CH_2D_2, and CD_4 after UV irradiation. The important new information is that two new mixed H, D absorptions (marked **4**,**6** and **3**,**5**) appear between the low-wavenumber pair (**1**) in each region and one new mixed H, D band (marked **di**) appears between the high-wavenumber pair (**di**) in each region. Finally, all the **di** bands increase markedly on annealing.

Table 1: IR bands [cm^{-1}] observed for laser-ablated zirconium atom reactions with methane in excess neon.

CH_4	$^{13}CH_4$	CD_4	CH_2D_2	CH_2D_2	Identity
1617.2	1617.2	1158.1	1616.2	–	$[(CH_3)_2ZrH_2]$
			1602.2	1150.5	$[(CH_3)_2ZrHD]$
1587.5	1587.5	1142.6	1587.5	1142.5	$[(CH_3)_2ZrH_2]$
1586 sh	1586 sh	1136.9			$[H_2C{=}ZrH_2]$[a]
1581.0	1581.0	1133.1	1580.7	1132.7	$[H_2C{=}ZrH_2]$
1551.0	1551.0	1115.2	1550.1	1115.5	$[H_2C{=}ZrH_2]$[a]
1546.2	1546.2	1112.3	1545.5[b]	1112.5[c]	$[H_2C{=}ZrH_2]$

634.5	629.8	499.4			$[H_2C{=}ZrH_2]$
593.4	592.2	–			$[(CH_3)_2ZrH_2]$
564.2	559.2	469.7			$[(CH_3)_2ZrH_2]$

[a] Bands owing to different neon packing configuration. [b] Additional bands at 1554.4 and 1571.0 cm^{-1} with annealing counterparts at 1558.7 and 1573.3 cm^{-1} for [CHD=ZrHD] isotopomers. [c] Additional bands at 1116.2 and 1129.2 cm^{-1} with annealing counterparts at 1118.9 and 1133.0 cm^{-1} for [CHD=ZrHD] isotopomers.

The lower frequency region contains four associated weaker absorptions at 757.0, 634.5, 593.4, and 564.4 cm^{-1} (not shown). On photolysis and annealing the 757.0, 634.5 cm^{-1} bands track with the low-wavenumber pair in the Zr–H stretching region (1581.0 and 1546.2 cm^{-1} (**1**)), and the 593.4 and 564.4 cm^{-1} absorptions follow the 1617.2, 1587.5 cm^{-1} pair (**di**). A weak 1375.1 cm^{-1} band and the 1125.0 cm^{-1} absorption (Figure 2c, **di**) also track with the **di** bands. The $^{13}CH_4$ and CD_4 isotopic counterparts are given in Table 1.

Calculations were performed for $[H_2C{=}ZrH_2]$ using the B3LYP density functional, and the global minimum energy C_1 structure with no symmetry is illustrated in Figure 3. The CH_2 group is tilted owing to the agostic C–H···Zr interaction. Additional calculations using the BPW91 functional and the MP2 method[17] gave similar skewed structures. When C_{2v} symmetry was imposed, the resulting planar structure which gives two imaginary frequencies is 0.8 kcal mol^{-1} higher in energy. Clearly, the planar form is unstable and relaxes along the imaginary CH_2 rocking and ZrH_2 wagging motions to the stable C_1 structure.

The C–H···Zr separation computed for the C_1 structure, 2.345 Å, is slightly longer

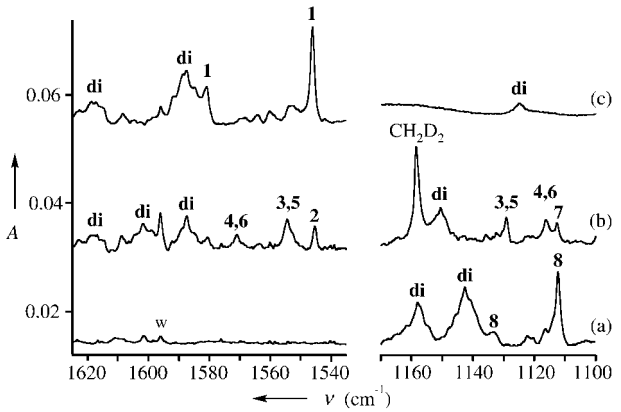

Figure 2. IR spectra in the 1620–1540 cm^{-1} Zr–H stretching and 1170–1100 cm^{-1} Zr–D stretching regions for laser-ablated Zr co-deposited with CH_4, CH_2D_2, and CD_4 in excess neon at 5 K for 45 min and subjected to $\lambda > 530$ and 240–380 nm irradiations. a) 0.4% CD_4 in neon, b) 0.6% CH_2D_2 in neon, and c) 0.4% CH_4 in neon. For discussion of the spectra see text; **1**–**8** indicate bands from the correspondingly numbered isotopmers in Scheme 1 **di** = isotopomers of $[(CH_3)_2ZrH_2]$, w = water.

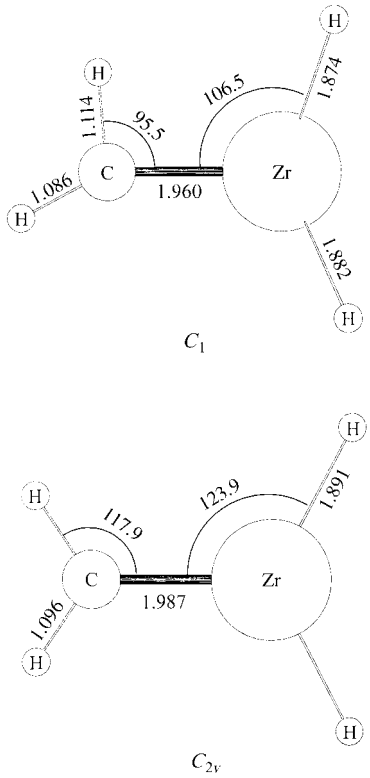

Figure 3. Minimum energy C_1 and C_{2v} symmetry structures computed for $[H_2C{=}ZrH_2]$ at the B3LYP/6-311++G(2d,p)/SDD level of theory.

than agostic bonds measured for Cr and W complexes in crystals (2.24 and 2.27 Å),[6] but shorter than the agostic bond length computed (2.379 Å) for a model Ir complex using basis sets with polarization functions.[7] Since agostic bond energies in the 10–15 kcal mol^{-1} range have been determined for the Group 6 complexes,[6] our slightly longer agostic bond in [H_2C=ZrH_2] is probably almost as strong.

Computed frequencies listed in Table 2 provide the basis to identify agostic [H_2C=ZrH_2] from four observed frequencies and [CHD=ZrHD] isotopic modifications. The 1581.0 and 1546.2 cm^{-1} absorptions are due to symmetric and antisymmetric stretching modes of a ZrH_2 group: [ZrH_2] itself has been observed at 1519 cm^{-1} in solid argon and at 1530 cm^{-1} in solid neon.[18,19] The related satellite features at 1586 and 1551.0 cm^{-1} are due to a different neon packing configuration around the Zr center that is formed on annealing and destroyed on photolysis. The observed ZrH_2 modes are just below computed ZrH_2 modes for both structures, and these discrepancies are in line with that expected for the B3LYP density functional,[20] but structural assignment cannot be made on this basis. However, a definitive choice can be made from the [CHD=ZrHD] isotopomers since the symmetrical form has two and the agostic form has four such variants. Our calculations for *cis* and *trans* planar [CHD=ZrHD] predict the same ZrHD stretching modes ($\pm$0.1 cm^{-1}) for each isomer so only one DZr–H and one HZr–D mode would be observed in each region. However four such bands are found (Figure 2b **3**,**4**,**5**,**6**). Our calculations describe four distinct [CHD=ZrHD] isotopmers (**3**, **4**, **5**, and **6** in Scheme 1), and two of these isotopmers have Zr–H and Zr–D stretching modes that are different from those of the other two isotopmers. Our calculations predict **3** and **5** to have a Zr–H stretching mode 9.2 cm^{-1} above the strong antisymmetric stretching mode of **1** and a Zr–D stretching mode 13.3 cm^{-1} above the strong antisymmetric stretching mode of **8** (compare Figure 2 a–c). These bands are observed 8.3 and 17.0 cm^{-1} higher, respectively. In like manner our calculations find **4** and **6** to have strong Zr–H and Zr–D stretching modes 21.6 cm^{-1} above **1** and 4.2 cm^{-1} above **8**, and these bands are observed 24.8 and 4.0 cm^{-1} higher, respectively. The bands labeled **2** and **7** in Figure 2 arising from [D_2C=ZrH_2] and [H_2C=ZrD_2] are predicted to be shifted 0.1 cm^{-1} from **1** and **8**, and 0.7 and 0.2 cm^{-1} differences are found.

Table 2: Harmonic vibrational frequencies [cm^{-1}] computed for the C_1 and C_{2v} structures of [H_2C=ZrH_2] shown in Figure 3.

Mode Description	C_1		C_{2v}

Scheme 1. Isotopmers of [H_2C=ZrH_2].

The excellent agreement between experiment and theory for Zr–H and Zr–D stretching modes in four different CHD=ZrHD isotopomers (**3**, **4**, **5**, and **6**) with H or D in the agostic bonding position confirms the identification and the C_1 symmetry agostic structure for [H_2C=ZrH_2]. Although [H_2C=ZrH_2] is isoelectronic in the valence shell with the fundamentally and industrially important symmetrical, planar ethylene molecule, H_2C=CH_2, the d orbitals on zirconium support agostic bonding to one methylene hydrogen and reduce the symmetry in the [H_2C=ZrH_2] molecule.

Additional spectroscopic evidence for the C_1 structure is found in the lower frequency C–Zr stretching and CH_2 wagging modes, whose vibrational character and thus isotopic shifts depend heavily on molecular symmetry. The C_{2v} structure has a strong mixed C–Zr stretching, CH_2 bending mode computed at 742 cm^{-1} with an 8.9 cm^{-1} ^{13}C shift, whereas the C_1 structure has a strong mostly C–Zr stretching mode computed at 762 cm^{-1} with a 17.4 cm^{-1} ^{13}C shift. A pure ^{12}C–Zr diatomic oscillator would shift 26 cm^{-1} for ^{13}C–Zr in this region. Hence the observed 757.0 cm^{-1} absorption with 19.6 cm^{-1} ^{13}C shift fits the C_1 frequency prediction very well and the C_{2v} prediction very poorly. Our calculation for the C_1 structure slightly under estimates the ^{13}C shift and over estimates the D shift for this mode. The C_{2v} structure has a strong CH_2 wagging mode computed at 720 cm^{-1} whereas for the C_1 structure this mode is computed at 661 cm^{-1}. The associated absorption observed at 634.5 cm^{-1} is clearly in line with the C_1 and not the C_{2v} results, and the isotopic shifts are appropriate for this assignment.

The 1617.2 and 1587.5 cm^{-1} absorptions (labeled **di** in Figure 1) are assigned to dimethyl zirconium dihydride, [$(CH_3)_2ZrH_2$]. These frequencies may be compared to the antisymmetric stretching mode for [ZrH_4] observed at 1623 cm^{-1} in solid argon and at 1648 cm^{-1} in solid neon.[18,19] Our calculations predict a very stable molecule with effectively C_{2v} symmetry and strong Zr–H_2 stretching modes at 1673 and 1642 cm^{-1}, which are only 3.4% higher than the observed values, which is slightly better agreement than found above for [CH_2=ZrH_2]. The [$(CD_3)_2ZrD_2$] counterparts at 1158.1 and 1142.6 cm^{-1} and single intermediate -ZrHD species bands at 1602.2 and 1150.5 cm^{-1} confirm this assign-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ment (Figure 2b). The next strongest lower frequency ZrH_2 bending and deformation modes predicted at 612 and 569 cm^{-1} are observed at 593.4 and 564.2 cm^{-1}, and weaker CH_3 bending and deformation modes computed at 1419 and 1166 cm^{-1} are found at 1375.1 and 1125.0 cm^{-1}. This is the first report of a Group 4 dimethyl dihydride. The $[(CH_3)_2TiF_2]$ analogue has been observed in similar Ti reactions with CH_3F.[12]

The zirconium atom reaction with methane apparently proceeds with excited zirconium atoms produced in the laser ablation process[16] or by irradiation,[21] this is because the C–H activation to form the $[CH_3ZrH]$ intermediate requires activation energy.[22] Then α-hydrogen transfer[23] gives $[H_2C{=}ZrH_2]$, Equation (1).

$$Zr^* + CH_4 \rightarrow [CH_3ZrH]^* \rightarrow [H_2C{=}ZrH_2] \quad (1)$$

Our calculations show that $[CH_3ZrH]$ ($^3A''$) and $[H_2C{=}ZrH_2]$ (^1A) have comparable energies.[24] However, the reaction with a second CH_4 molecule to form $[(CH_3)_2ZrH_2]$ appears to be spontaneous on annealing in solid neon. The $[(CH_3)_2ZrH_2]$ molecule is computed to be 65 kcal mol^{-1} more stable than $Zr(^3F)$ and two methane molecules, and the reaction in Equation (2) is exothermic by 44 kcal mol^{-1}. Alkylidene complexes are also known for their roles in C–H activation processes,[2] and the reaction in Equation (2) provides a simple example of the C–H activation process for methane.

$$[H_2C{=}ZrH_2] + CH_4 \rightarrow [(CH_3)_2ZrH_2] \quad (2)$$

Herein we have demonstrated how matrix IR spectroscopy and electronic structure calculations can work together to identify novel molecules with unique bonding interactions.

contrast, target-guided synthesis (TGS) approaches employ the target proteins themselves for assembling potent inhibitors from reactive building blocks within the confines of their binding sites. In principle, hit discovery by TGS becomes independent of the actual function of the target because it relies solely on its ability to bind reagents and hold them in close proximity until they become connected through the "arranged" chemical reaction. Since the initial report of TGS by Rideout et al. 20 years ago,[1,2] several approaches have been developed: dynamic combinatorial chemistry,[3–12] stepwise target-guided synthesis,[13,14] and kinetically controlled target-guided synthesis.[15–23] The latter approach employs irreversible reactions to assemble highly reactive reagents (strong electrophiles or nucleophiles, metathesis catalysts etc.), which can cause side reactions or even destroy the enzymic target. In contrast, the in situ click chemistry approach to TGS[15,24] employs the completely bioorthogonal [1,3]-dipolar cycloaddition reaction between azides and acetylenes which was pioneered by Rolf Huisgen.[25] This process is self-contained, hence there are no external reagents, catalysts, or byproducts that might interfere, and the reactants themselves are "invisible" in biological milieu. Most importantly, the cycloaddition reaction, which is slow at room temperature, is accelerated tremendously when azide and acetylene groups are held together in close proximity to lead to irreversible formation of triazoles.[26–28] Previously, we have employed this approach to assemble acetylcholinesterase (AChE) inhibitors with subpicomolar binding affinities from reagents that carried known active- and peripheral-site binders.[15,24]

We now report the identification of novel carbonic anhydrase (CA) inhibitors using in situ click chemistry. Carbonic anhydrases are zinc-containing enzymes that catalyze the interconversion of HCO_3^- and CO_2. They are involved in key biological processes connected with respiration and the transport of CO_2/HCO_3^-, acid secretion and pH control, bone resorption, calcification, tumorigenicity, and many others.[29,30] Systemically and topically administered carbonic anhydrase inhibitors have long been used to control the elevated intraocular pressure associated with glaucoma.[31,32] Most inhibitors are aromatic or heteroaromatic sulfonamides[30,33,34] whose anion coordinates to the Zn^{2+} ion in the active site.[35]

Inspired by the work of Whitesides and co-workers on 4-carboxybenzenesulfonamide-derived carbonic anhydrase inhibitors,[33,36–39] we selected the acetylenic benzenesulfonamide **1** as a reactive scaffold for capturing complementary azide reagents to form "divalent" CA inhibitors in situ (see Scheme 1).[40] Scaffold **1** binds to bovine carbonic anhydrase II (bCA II) with nanomolar affinity ($K_d = 37$ nM ± 6), as determined by a competition assay with 5-(dimethylamino)-1-napthalenesulfonamide (dansyl amide, DNSA).[33,41] A total of 24 azide reagents, which cover 6 different structural themes, were employed as complementary reagents for in situ click chemistry screening. α-Azido carboxamide derivatives were best represented as we intended to probe for analogues of the peptidic carboxybenzenesulfonamide-derived inhibitors reported by Whitesides.[33,36–39]

The in situ click chemistry experiments were conducted in parallel by using 96-well microtiter plates. Each well con-

Scheme 1. In situ screening protocol and reagents. Control experiments to test for false-positive results were performed under identical conditions either in the absence of enzyme or in the presence of bCA II and ethoxazolamide (200 μM; see Figure 1).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tained a mixture of bCA II (30 μM), the acetylene (60 μM), and a given azide reagent (400 μM) in phosphate buffer solution (pH 7.4).[41] The formation of the product was monitored by HPLC analysis and mass spectrometric detection through electrospray ionization and selected ion mode monitoring (LC/MS-SIM).[24] Under these conditions, over 99% of the active sites are occupied by ethynyl benzenesulfonamide (**1**), whereas the formation of triazole product from the enzyme-free background reaction remains below the LC/MS-SIM detection limit after 40 h at 37°C. In fact, the acetylene concentration can be raised to as high as 400 μM without producing detectable amounts of triazoles which demonstrates that the uncatalyzed reaction is extremely slow. Two sets of control experiments were conducted in parallel to test for false positives: Each acetylene/azide combination was incubated with mixtures of enzyme and the known active-site inhibitor ethoxazolamide (200 μM) (see Figure 1 and Table 2) and with bovine serum albumin (BSA) in place of bCA II.

Analysis of each reaction mixture by LC/MS-SIM revealed that 12 out of 24 reagent combinations had led to the formation of triazole products in the presence of the enzyme. Of these, 11 combinations did not form triazoles in the corresponding control experiments in the presence of BSA or enzyme/inhibitor, thereby validating these compounds as in situ hits and demonstrating that their formation required the enzyme active site to be accessible. Figure 1 illustrates the results for the acetylene/azide pair **1**/**4**. Most of the in situ hits are derived from α-substituted azido acid amides. The two exceptions are reagents **2** and **3**, which are azide derivatives of a coumarin and a piperidine, respectively. Conversely, 9 out of 12 azides that do not react in situ are not based on α-substituted azido acid platforms.

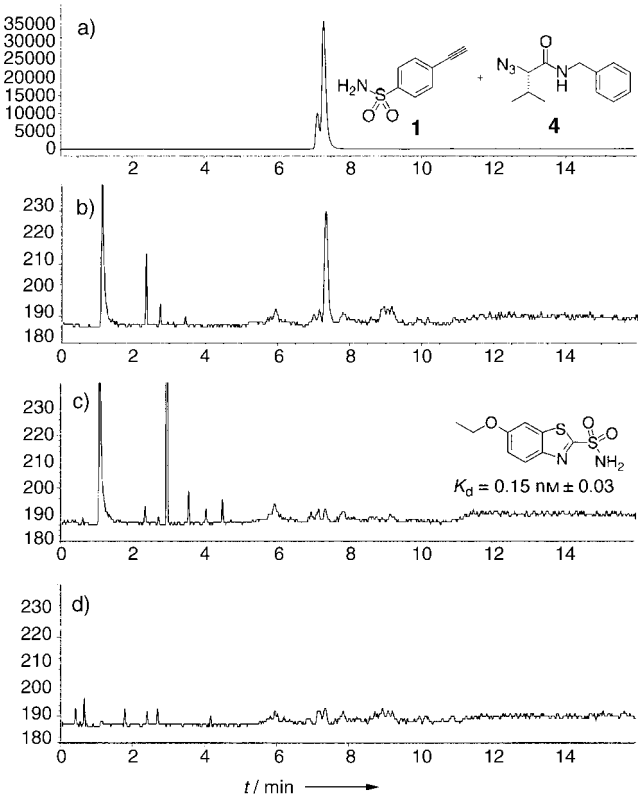

Figure 1. Results of in situ click chemistry between acetylene **1** and azide **4**, monitored by HPLC. a) Thermal reaction (85°C, 6 d): triazole products between 7.1 and 7.3 min; b) Reaction with bCA II (1 mg mL^{-1}; 37°C, 40 h): product at 7.3 min; c) bCA II (1 mg mL^{-1}), ethoxazolamide (200 μM; 37°C, 40 h); d) Bovine serum albumin (1 mg mL^{-1}) instead of bCA II (37°C, 40 h).

A comparison of the in situ reaction products with pure 1,4-disubstituted ("*anti*") triazoles, which were prepared by the Cu^{I}-catalyzed reaction of the precursor azides and acetylenes,[42,43] and *syn*/*anti*-triazoles, which were prepared by thermal cycloaddition, by LC/MS-SIM reveals the enzyme reaction to be highly *anti*-selective, in contrast to the thermal cycloaddition (see Supporting Information). The great *anti* selectivity further supports the notion that the formation of the product is enzyme controlled.

For the determination of inhibition constants at 25°C, all 24 *anti*-triazoles were synthesized from their respective acetylene/azide precursors under the copper-catalyzed reaction conditions recently developed in the laboratories of Sharpless/Fokin and Meldal.[42,43] The dissociation constants for these compounds were measured with a fluorescence-based assay,[39,44] which uses DNSA as a reporting ligand that is displaced by the test compound.[41]

Without exception, the in situ hit compounds display significantly higher binding affinities for bCA II (K_d = 0.2–7.1 nM) than the acetylene scaffold **1** (K_d = 37 nM ± 6) or the azide reagents (high micromolar affinities and above) from which they are derived (Table 1 and Table 2). These results demonstrate that the azide/acetylene in situ click chemistry can be used to produce enzyme inhibitors in which only one of the components binds well to the target. The dissociation constants of the triazoles prepared in situ compare favorably with those of the drugs acetazolamide (K_d = 6.4 nM) and ethoxazolamide (K_d = 0.15 nM; see Table 2). Of the six azide chemotypes in this initial screen (see Scheme 1), α-azido acid derived triazolyl benzenesulfonamides gave the most potent inhibitors with subnanomolar dissociation constants (Table 1). The amide residue can vary over a wide range without leaving the subnanomolar regime which suggests that the azido acid residues, and not the amide substituents, are responsible for high activity. From the reagents that were not derived from azido acids (Table 2), only the hydrophobic stilbene derivative **7** gave a product with low nanomolar activity. The other structural types were much less active: the runners-up were the coumarin and piperidine derivatives **8** and **9**, which displayed a 5 to 7.5 times higher affinity than the starting acetylene **1**.

Interestingly, six out of ten compounds that were not formed by the enzyme were also highly active with dissociation constants of less than 7.5 nM. These results demonstrate that compounds that are formed in situ are very likely to be potent inhibitors—in this case without exception—whereas the reverse is not true which leads to "false negatives" from the perspective of in situ screening. We do not regard this as a drawback because the in situ hits invariably display high binding affinities, that is, there are no "false positives". The best in situ hits (Table 1) have a 185-times higher binding

Table 1: Summary of in situ click chemistry experiments and dissociation constants of azido acid derived triazolyl benzenesulfonamides with K_d values of less than 7.5 nM.

	R	In situ hit	K_d [nM]	
				high affinity
	*i*Pr	Yes	0.2–0.5	
	Bn	Yes	0.2–0.4	
	*i*Pr	Yes	0.4–0.5	
 **5**	Bn	Yes	0.5–0.9	
	Bn	No	0.5 ± 0.1	
	Bn	No	0.5 ± 0.1	
	*i*Pr	Yes	0.8 ± 0.2	
	Bn	Yes	0.9 ± 0.1	
	H	No	1.1–1.4	
 **6**	*i*Pr	Yes	1.9–2.3	
	*i*Pr	Yes	2.4 ± 0.4	
	*i*Pr	No	2.6 ± 0.2	
	H	No	7.0 ± 0.5	
				low affinity

Table 2: Summary of in situ click chemistry experiments and dissociation constants.

Reagent	In situ hit	K_d [nM]
 **7**	No	1.0–1.5
 **8**	Yes	4.9 ± 0.7
 **9**	Yes	7.1 ± 0.4
 **1**	N/A	37 ± 6
 **10**	N/A	38 ± 10
 ethoxazolamide	N/A	0.15 ± 0.03
 acetazolamide	N/A	6.4 ± 0.9

affinity to bCA II than the scaffold **1**, and the worst in situ hits are still more than five times as potent.

Even though the inhibitors were formed by bovine CA II, they also strongly inhibit the human enzyme (hCA II). Compounds **5** and **6** have dissociation constants of 1.2 nM (± 0.3) and 0.9 nM (± 0.2), respectively; that is, their potency is comparable to acetazolamide ($K_d = 0.9$ nM ± 0.05).[45]

Interested to what extent the binding affinities of the in situ products are influenced by the newly-formed triazole moiety, for example, by changing the pK_a value of the sulfonamide, we prepared *N*-methyltriazole **10** (Table 2). Its dissociation constant ($K_d = 38$ nM ± 10) is almost identical to that of the parent acetylene **1** which demonstrates that the triazole does not affect the binding affinity significantly and suggests that the increased affinity of the hit compounds formed in situ is largely provided by favorable binding interactions with substituents that are more remote on the azide component. Furthermore, a lack of direct triazole–protein interactions would indicate that the [3+2] cycloaddition reaction in this system is more dependent on entropic stabilization of the transition state, in contrast to the AChE system, in which the presence of strong protein–triazole attractive interactions suggests that the rate enhancement is partially due to enthalpic stabilization effects.[16] All in all, the triazole-containing linker appears to be suboptimal in the bCA II system as the observed dissociation constants are much larger than the theoretical optimum of approximately 50 pM, which is calculated based on the known affinities of scaffold **1** ($K_d = 37$ nM) and the azide reagents (high micromolar to low millimolar) and assumes the complete absence of positive or negative linker effects.[46] We are currently optimizing the linker with the aid of in situ click chemistry and investigating the ligand/protein interactions on a molecular level by X-ray crystallography.

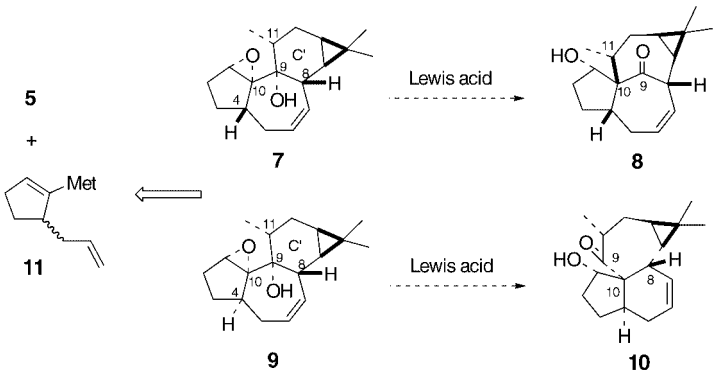
Synthetic Methods

Rapid Access to the "in,out"-Tetracyclic Core of Ingenol**

*Oleg L. Epstein and Jin Kun Cha**

Ingenol (**1**), a prototypical diterpene of ingenanes, was first isolated from *Euphorbia ingens* by Hecker and co-workers.[1] Along with esters of the structurally related phorbol (**2**), the naturally occurring C3-monoesters of **1** are known to be among the most potent tumor promoters. The mode of action of these esters at the molecular level is believed to be associated with binding to protein kinase C, a key enzyme involved in cell signal transduction, and with mimicking the function of 1,2-diacylglycerol, the endogenous activator of the enzyme.[2] Surprisingly, certain ester derivatives of **1** were reported to possess anti-leukemic and anti-HIV activity.[3] Biological activity of this class of natural products is thus significantly altered by subtle, yet little-understood, structural modifications. For more than two decades these structurally complex molecules have attracted many studies directed toward total syntheses.[4,5] The highly strained "inside–outside" intrabridgehead stereochemistry of the BC ring system of **1** presents a particularly taxing synthetic challenge.[6] Several attractive solutions were developed by several groups,[7,8] culminating in an elegant total synthesis of (±)-**1** by Winkler et al.[9] followed by another by Kuwajima and co-workers.[10] Nonetheless, an efficient, convergent approach to **1** remains highly desirable. To this end, we report herein a rapid assembly of the carbocyclic core of **1** by a pinacol rearrangement.



Our key strategy for addressing the requisite inside–outside *trans* stereochemistry of **1** with concomitant, diastereoselective construction of the quaternary C10 center was based on a 1,2-alkyl shift (**3**→**1**) at a late stage by adaptation of the Tsuchihashi–Suzuki rearrangement of 2,3-epoxy alcohols or silyl ethers (Scheme 1).[11–13] We speculated that a related 1,2-alkyl shift may well be involved in the biosynthesis of **1** for the conversion of its ABC′D ring system into the ABCD ring system.[14,15] Among several possible variations within this approach (A + C′D→ABC′D), a most expedient route to **3** seemed available by ring-closing olefin metathesis of **4** for the formation of the rigid, yet relatively strain-free, seven-membered ring B.[16] In turn, **4** could be prepared by straightforward coupling of two fragments of comparable complexity, **5** and **6**. Particularly attractive was the innate

Scheme 1. Retrosynthetic analysis of **1**. X = alkyl or alkenyl group, Met = metal.

convergence of the overall approach which could provide a most expeditious route to **1** and its analogues.

For our preliminary study, we chose to employ a simplified derivative of **6**, namely **11**, which is devoid of oxygen and remaining functionalities, to establish the feasibility of a convergent synthesis of the complete tetracyclic core of **1** (Scheme 2). According to molecular models, the stereochemistry about C4 was considered to be of principal importance to the key Lewis acid catalyzed rearrangement of **3** with respect to the antiperiplanar stereoelectronic requirements to ensure the desired migration of the C9–C11 (ingenol numbering) bond. With the natural configuration at C4 (e.g. **7**), the epoxide C10–O bond is antiperiplanar to the C9–C11 bond as required for the conversion of **7**→**8**, whereas the C8–C9 bond is nearly orthogonal. However, in the case of the opposite configuration at C4 (e.g. **9**), migration of only the undesired C8–C9 bond that occupies the antiperiplanar alignment could occur. These considerations prompted us to utilize racemic **11**

Scheme 2. Met = metal.

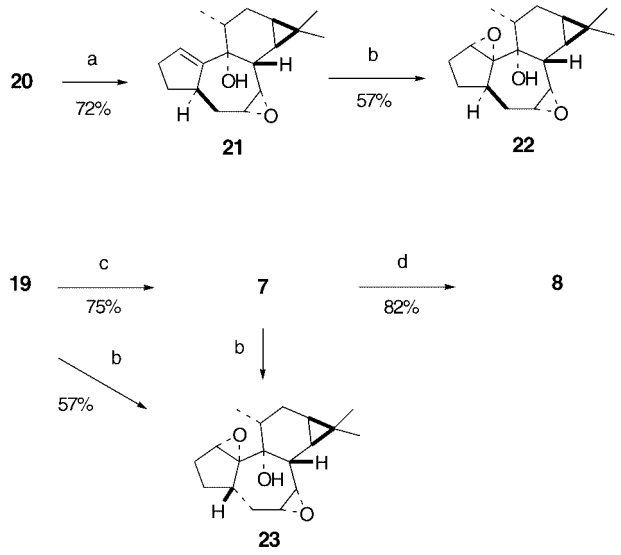
so that the stereochemical outcomes of both C4 epimers could be assessed simultaneously.



Our study began with the ketone **12**, which was readily prepared in large quantities from (+)-3-carene according to the method of Paquette et al. (Scheme 3).[17] Formation of the

Scheme 3. Reagents and conditions: a) LiHMDS, MeI, −78 to 0 °C; b) LiHMDS, TMSCl; c) Et_2Zn, CH_2I_2; d) K_2CO_3, MeOH; e) $[Pt_2Cl_4(C_2H_4)_2]$; f) *t*BuLi (2 equiv); g) TBAF; h) SO_3Py, DMSO, *i*Pr_2NEt; i) Ph_3PCH_3Br, NaHMDS; j) RCM. HMDS = hexamethyldisilazide, TBS = *tert*-butyldimethylsilyl, Tris = 2,4,6-triisopropylbenzenesulfonyl, TMSCl = trimethylsilyl chloride, TBAF = tetra-*n*-butylammonium fluoride, Py = pyridine, DMSO = dimethylsulfoxide, RCM = ring-closing metathesis.

kinetic enolate of **12** with LiHMDS (lithium hexamethyldisilazide) followed by alkylation with methyl iodide yielded **13** as a single diastereomer in 81% yield. Alternatively, **13** was obtained through subsequent ring opening of **14** with $[Pt_2Cl_4(C_2H_4)_2]$. This served to corroborate the α stereochemistry of the C11 methyl group in **13** from NOE measurements (interaction between the hydrogen atom at C13 and the hydrogen atoms of the methyl group at C18 in **13**). Addition of the 5-allylcyclopentenyl subunit to **13** was best achieved by means of the lithium reagent of **15**, which was prepared in situ by the Shapiro reaction,[18] to yield **16** in 75–88% yield. To set the stage for the construction of the seven-membered ring B, **16** was then converted into **18** by standard methods to give an inseparable 1:1 mixture of the two C4 epimers in 62% overall yield. Ring-closing olefin metathesis of **18** (5 mM in CH_2Cl_2) with Grubbs' second-generation catalyst (10 mol%) and heating at reflux proceeded smoothly to give **19** and **20** in excellent yield.

Following chromatographic separation of **19** and **20**, treatment of the less-polar isomer **20** with MCPBA (*m*-chloroperbenzoic acid) or *t*BuOOH–$VO(acac)_2$ resulted in regioselective epoxidation at the C6–C7 double bond to furnish **21** (Scheme 4). Upon prolonged exposure to MCPBA, the latter was converted into bisepoxide **22**. In sharp contrast, epoxidation of the more-polar isomer **19** with *t*BuOOH–$VO(acac)_2$ afforded the desired C1–C10 epoxide **7** in 75% yield. The bisepoxide **23** was obtained by treating **7** with MCPBA. On the basis of these conspicuous differences in the epoxidation of **19** and **20**, their C4 configuration was assigned as shown in Scheme 3. Inspection of molecular models clearly reveals that the hydroxy group at C9 in **20** is located in closer proximity to the C6–C7 double bond. Finally, upon exposure of epoxide **7** to $AlMe_3$ (3 equiv), the key Lewis acid mediated semipinacol rearragement proceeded cleanly to afford the desired ingenane **8** as the sole isomer (82% yield) which contains the complete skeleton of ingenol (**1**). The "inside–outside" stereochemistry of **8** was in accord with mechanistic considerations and difference-NOE measurements. Irradiation of the hydrogen atom at C8 ($\delta = 3.85$ ppm) showed diagnostic nuclear Overhauser enhancements at C(4)–H, C(11)–H, C(12)–H_β, and C(16)–Me.[7b] The indicated stereochemistry was subsequently confirmed by single crystal X-ray analysis of **8**.[19] Note that under identical conditions, bisepoxide **22** produced a complex mixture of polar products presumably owing to ring opening of epoxide(s), whereas bisepoxide **23** was found to be relatively inert to rearrangement conditions.

Scheme 4. Reagents and conditions: a) MCPBA or *t*BuOOH/$VO(acac)_2$; b) MCPBA; c) *t*BuOOH/$VO(acac)_2$; d) $AlMe_3$, CH_2Cl_2, −78 to 0 °C.

In conclusion, the demanding "inside–outside" stereochemistry of ingenol (**1**) and the stereoselective construction of the quaternary center at C10 have been successfully addressed by the pinacol-type rearrangement of an epoxy alcohol to develop a convergent synthesis of the fully assembled tetracyclic core of **1**. Thus, **8** was prepared in 8 steps from the known, readily available ketone **12**. We believe our approach holds promise in completing a concise, convergent synthesis of ingenol itself and its analogues by preinstallation of all the necessary functionalities in fragment

treatment,[3] and biological labeling, tracking, imaging, detection, and separations.[4] For these applications, major efforts have recently been devoted to the synthesis of magnetic iron oxide nanoparticles.[5] Generally, magnetic iron oxide nanoparticles can be prepared by co-precipitating ferrous and ferric ions in aqueous solution. However, variations in the molar ratio of Fe^{3+} and Fe^{2+} often lead to rather complicated changes in the crystalline structures of the iron oxides obtained.[6] Both pH and the ionic strength, which play critical roles in the preparations, also affect the surface chemical composition of the magnetite nanoparticles.[5] Furthermore, the relatively poor size uniformity and low crystallinity of magnetic iron oxide nanoparticles obtained to some extent limit their use in many applications. Although sol–gel and hydrothermal methods were proven to be effective in increasing the crystallinity, the magnetic nanoparticles obtained exhibit poor solubility or dispersibility.[7] Recently, Alivisatos et al. reported a thermal decomposition approach to synthesize nearly monodisperse maghemite nanocrystals.[8] Sun et al. succeeded in preparing monodisperse magnetite nanocrystals by decomposition of [Fe(acac)$_3$](acac = acetylacetonate) in the presence of 1,2-hexadecanediol, oleic acid, and oleylamine.[9] Hyeon et al. obtained high-quality maghemite nanocrystals by thermal decomposition of [Fe(CO)$_5$] followed by oxidation with $(CH_3)_3NO$.[10] However, the direct products of the thermal decomposition method are generally soluble in organic solvents. Sophisticated post-preparative approaches are required to make those magnetic nanocrystals water-soluble,[11] and this limits their applications in biomedical fields. Furthermore, the mechanisms for the formation of magnetic nanocrystals by thermal decomposition are far from clear.[8–10]

Recently, we demonstrated the possibility of producing water-soluble magnetite nanocrystals by the thermal decomposition method using strong polar 2-pyrrolidone as a coordinating solvent.[12] Here we report the preparation of magnetite nanocrystals by using hydrated ferric salts as iron precursors instead of costly [Fe(acac)$_3$]. In addition, the mechanism leading to Fe_3O_4 in 2-pyrrolidone is discussed.

$FeCl_3{\cdot}6H_2O$ was used as a single iron source in the preparation of magnetic nanocrystals. Figure 1 shows TEM images of three typical samples of iron oxide nanoparticles obtained after refluxing a certain amount of $FeCl_3{\cdot}6H_2O$ in 2-pyrrolidone for 1, 10, and 24 h. Their average particle sizes are 4, 12, and 60 nm, respectively. In addition to the difference in size, the nanoparticles also change their shape with increasing reflux time. During the early stages, spherical nanoparticles appear and then grow larger and larger, and finally they lose the original shape and form cubic particles after 24 h. The crystalline structure of the samples shown in Figure 1 was determined by powder XRD. The diffraction patterns and relative intensities of all diffraction peaks match well with those of JCPDS card 19-0629 for magnetite. The electron diffraction pattern inserted in Figure 1c also supports the magnetite crystal structure. In addition, FT-IR spectra of the particles exhibit characteristic peaks of magnetite at around $\tilde{\nu} = 589\ cm^{-1}$.[13]

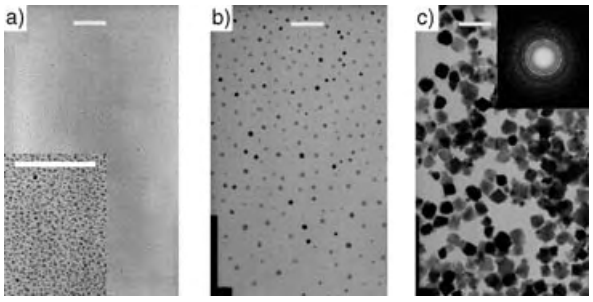

Figure 1. TEM images of nanoparticles obtained after $FeCl_3{\cdot}6H_2O$ was refluxed in 2-pyrrolidone for 1, 10, and 24 h, respectively. The inset in a) is an enlarged part. The scale bar corresponds to 100 nm.

The magnetic properties of the as-prepared magnetite nanoparticles were investigated with a vibrating sample magnetometer (VSM). Figure 2 presents the magnetic hysteresis curves of the nanocrystals shown in Figure 1. The saturation magnetization increases from 3 to 59 to 84 emu g^{-1} with increasing reflux time, which can be attributed to the growth of particle size and enhancement in crystallinity. Samples a and b in Figure 1 are superparamagnetic at room temperature, while the cubic particles exhibit a magnetic coercivity of 85 Oe. This is because their size already exceeds the critical size of single magnetic domains.[14]

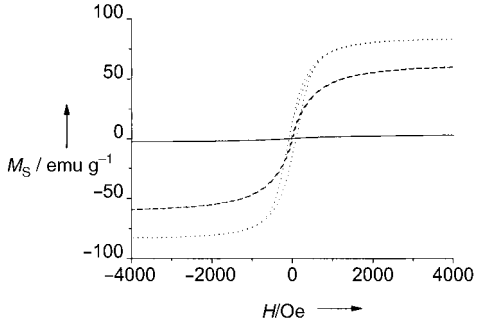

Figure 2. Room-temperature magnetization curves of the magnetic nanocrystals shown in Figure 1: 4 nm (solid line), 12 nm (dashed line), and 60 nm (dotted line) magnetite nanocrystals.

Similar to our previous report, the as-synthesized magnetite nanocrystals reported here can also be dissolved in water under both acidic and alkaline conditions, especially when the particles are smaller than 10 nm. This makes our investigation significant since $FeCl_3{\cdot}6H_2O$ is a very inexpensive iron source. To the best of our knowledge, the current synthetic approach is the first example using $FeCl_3{\cdot}6H_2O$ as a single iron source to prepare water-soluble Fe_3O_4 nanocrystals by the high-temperature wet-chemical approach. Therefore, nearly nothing is known about the mechanism leading to Fe_3O_4 nanocrystals in this reaction system. To investigate the formation of Fe_3O_4 nanocrystals in 2-pyrrolidone, photoelectron spectroscopy (PES) was used to analyze the small molecules released during the reaction. A stream of nitrogen carried these small molecules through a glass U-tube whose bottom was immersed in liquid nitrogen in a Dewar flask. Then the U-tube was connected to a double-chamber UPS machine-II for PES measurements.

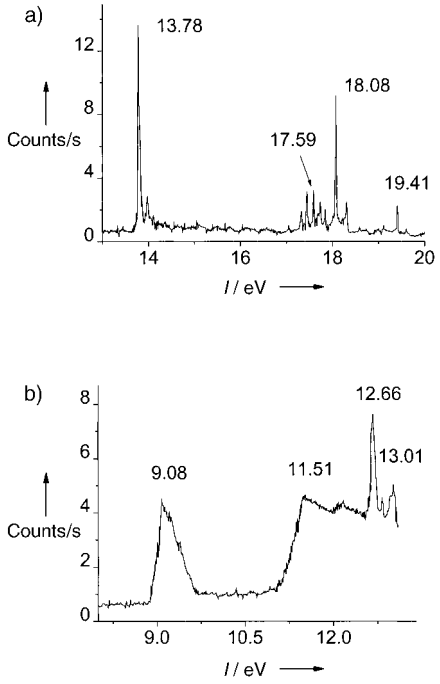
He I photoelectron spectroscopy is a powerful tool for characterizing unstable, metastable, and transient species.[15] The gaseous species entrapped in the glass U-tube were released on slow addition of alcohol to the Dewar flask. Gases with different boiling points were released successively. The photoelectron spectrum of the early released gas is shown in Figure 3a. The peaks centered at 13.78, 17.59, 18.08, and



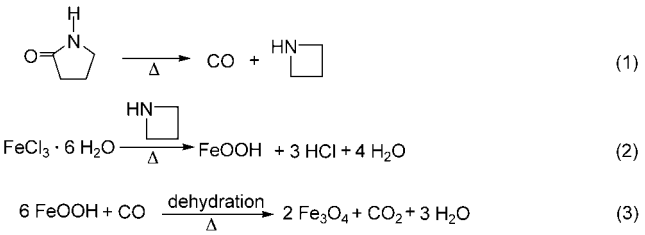


Figure 3. Photoelectron spectra of gaseous species released during the preparation of magnetite nanocrystals. Spectra a) and b) were recorded in sequence with increasing temperature.

19.41 eV are characteristic for carbon dioxide.[16] The generation of carbon dioxide during reflux indicates that 2-pyrrolidone is not stable at its boiling point even in an oxygen-free environment. The photoelectron spectrum of the gaseous species released at higher temperature is shown in Figure 3b. The PES peaks at 12.66 and 13.01 eV can be attributed to water,[16] and those at 9.08 and 11.51 eV can be assigned to the first and second bands of azetidine according to a previous report.[17] In addition, hydrogen chloride was also detected when the initial concentration of $FeCl_3{\cdot}6H_2O$ was relatively high.

In accordance with these results, a possible mechanism leading to magnetite nanocrystals is proposed in Scheme 1. In fact, the thermal decomposition of 2-pyrrolidone is rather complex. We observed that prolonged reflux of 2-pyrrolidone also generated fluorescent species in solution. Therefore, Scheme 1 does not depict all decomposition reactions that take place. Only those related to the formation of magnetite nanocrystals are shown. Since carbon dioxide and azetidine were released during reflux, it can be deduced that thermal decomposition of 2-pyrrolidone produces carbon monoxide and azetidine by cleavage of the acylamide bond. Azetidine catalyzes the hydrolysis of $FeCl_3{\cdot}6H_2O$ to form ferric oxide hydroxide (FeOOH) which is then partially reduced by CO.

Scheme 1. Chemical reactions involved in the formation of magnetite nanoparticles. Equation (2) is a process involving dissolution of $FeCl_3{\cdot}6H_2O$ in 2-pyrrolidone and azetidine-catalyzed hydrolysis of $FeCl_3$.

Upon dehydration it forms magnetite and carbon dioxide is released as a by-product. The thermal decomposition of 2-pyrrolidone and the formation of intermediate CO also explains why only magnetite was produced even when $[Fe(cup)_3]$ (cup = *N*-nitrosophenylhydroxylamine) or $[Fe(acac)_3]$ was used instead of $FeCl_3{\cdot}6H_2O$ in the preparation.

To provide direct proof for the generation of carbon monoxide, a typical identification reaction was used to determine CO. At room temperature CO can reduce Pd^{2+} to give black precipitates of Pd metal. We purged the reaction system with nitrogen during reflux and allowed the N_2 flow to pass successively through a glass tube filled with KOH powder and a flask with H_2SO_4 solution. At the end of this gas line, a fine glass tube was used to introduce the N_2 flow into an aqueous solution of $PdCl_2$. Black precipitates were observed after long enough time and shown to be Pd metal by TEM measurements. The *d* spacings of 0.2244, 0.1945, 0.1391, 0.1190, and 0.0894 nm calculated from selected-area electron diffraction on the black precipitates match well with the *d* values for (111), (200), (220), (311), and (331) lattice planes of Pd metal, respectively.

In summary, we have presented a simple route to synthesize water-soluble magnetite nanocrystals by refluxing inexpensive $FeCl_3{\cdot}6H_2O$ in 2-pyrrolidone. Differently sized and shaped magnetite nanocrystals can be obtained simply by varying the reaction time. Carbon monoxide generated during the reaction plays a critical role in the formation of magnetite nanocrystals, since it partly reduces Fe^{3+} to Fe^{2+}. We believe this novel synthetic approach will not only pave a new way for the preparation of water-soluble magnetite nanocrystals but also provide a new route for mass production of high-quality magnetic nanocrystals, since much more concentrated colloidal solutions can be directly obtained by the current method.

Experimental Section

In a typical synthesis of magnetite nanocrystals, a solution of 10 mmol $FeCl_3{\cdot}6H_2O$ in 100 mL 2-pyrrolidone was first purged with nitrogen to remove oxygen and then heated to the boiling point of 2-pyrrolidone. Samples were taken after the mixture was refluxed for 1, 10, and 24 h, and then cooled to room temperature. A threefold volume of methanol/diethyl ether (1:3) was added to precipitate the nanoparticles. The resultant black precipitate was washed with acetone several times and then dried for characterization.

The magnetite nanocrystals were characterized by TEM, XRD, FTIR, and VSM. TEM images were obtained on a JEM-2010

microscope. XRD patterns were obtained with a Rigaku D/Max-2500 diffractometer equipped with a rotating anode and a $Cu_{K\alpha 1}$ radiation source ($\lambda = 1.54056$ Å). FT-IR spectra were recorded on a Bruker EQUINOX55 FT-IR spectrometer. VSM spectra were collected on a homemade magnetometer.

PES measurements were performed on a double-chamber UPS machine-II. Argon and methyl iodide were used as internal standards for measurements.

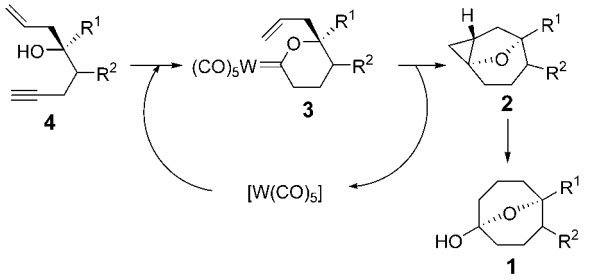
Medium-Ring Compounds

Tandem $[W(CO)_5]$-Catalyzed Cycloisomerization–Cyclopropanation Reactions Directed toward the Synthesis of Eight-Membered Carbocycles**

José Barluenga, Alejandro Diéguez, Félix Rodríguez, and Francisco J. Fañanás*

Dedicated to Professor José Elguero on the occasion of his 70th birthday

The development of new metal-catalyzed reactions for the formation of carbon–carbon bonds is a major research area in organic chemistry.[1] Of particular significance are those tandem processes which allow the formation of several new bonds in a single step from readily available starting materials, thus increasing efficiency and minimizing the amount of waste generated.[2] The potential of Group 6 Fischer carbene complexes to undergo unusual reactions has been widely demonstrated since their discovery almost 40 years ago.[3] However, one of the most important drawbacks of these complexes is that a stoichiometric amount has to be used. Only very few examples of catalytic processes in which a Group 6 Fischer carbene complex is implied have been reported.[4,5] Moreover, for several years we have pursued a program related to the development of new methodologies for the synthesis of medium-sized rings promoted by Fischer carbene complexes.[6] Thus, recently we reported a new one-pot process for the synthesis of eight-membered carbocycles by the use of ketone enolates and alkenyl carbene complexes.[7] To avoid the use of stoichiometric amounts of metallic species and to extend the scope of this method, we initiated an investigation directed toward the design of a catalytic version of this process. These studies culminated with the discovery of a tandem $[W(CO)_5]$-catalyzed cycloisomerization–cyclopropanation reaction, which has been used as the key step for the synthesis of eight-membered carbocycles.



In our previous studies in this field we demonstrated that eight-membered rings **1** were readily available from tricyclic compounds **2** generated from cyclic Fischer carbene complexes **3** (Scheme 1).[7] We envisaged that these complexes **3** could be obtained through a cycloisomerization reaction of 4-alkyn-1-ol derivatives **4** promoted by pentacarbonyltungsten

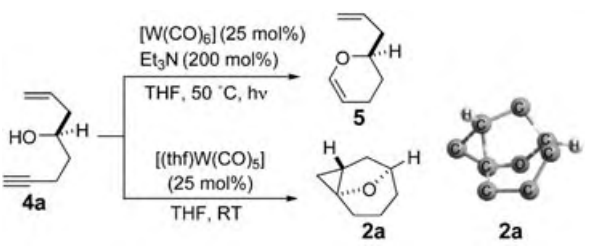

Scheme 1. Proposed catalytic cycle for the synthesis of tricyclic compounds **2**, and further transformation into eight-membered carbocycles **1**.

complexes.[8] The subsequent cyclopropanation reaction of complexes **3** should generate the tricyclic compounds **2**, with regeneration of the pentacarbonyltungsten species. Thus, a catalytic process as shown in Scheme 1 could be feasible.

Our initial attempts to promote the tandem sequence described above employed the method developed by McDonald et al. for the synthesis of cyclic enol ethers from 4-alkyn-1-ol derivatives.[4c] The established conditions for this cycloisomerization are treatment with triethylamine or 1,4-diazabicyclo[2.2.2]octane (dabco, 200 mol%) in the presence of $[W(CO)_6]$ (5–25 mol%) under constant irradiation, with THF as the solvent.

Unfortunately, when we employed this method with the starting alkynol derivative **4a**, the reaction did not lead to the expected tricyclic compound **2a**; instead the cyclic enol ether **5** was obtained exclusively (Scheme 2). This result indicates

Scheme 2. Different reaction conditions for the cycloisomerization reaction of the alkynol derivative **4a**.

that the carbene complex **3a** ($R^1 = R^2 = H$) formed does not undergo cyclopropanation of the double bond of the allylic moiety, but instead reacts with the triethylamine present in the reaction medium to give the enol ether **5**. It was clear at this point that an alternative method to generate the catalytic $[W(CO)_5]$ species in the absence of an amine was required. We next turned our attention to the use of preformed $[(thf)W(CO)_5]$. To our delight, when we treated the alkynol derivative **4a** with $[(thf)W(CO)_5]$ (25 mol%) in THF at room temperature for 24 h, the tricyclic compound **2a** was obtained in 90% yield (Scheme 2; for clarity, a 3D representation of compound **2a** has been included).[9]

To check the scope of the reaction, a number of allyl-substituted 4-alkynol derivatives **4** were tested. As summarized in Table 1 (method A), the reaction gave the expected tricyclic compounds **2** in very high yield starting from both

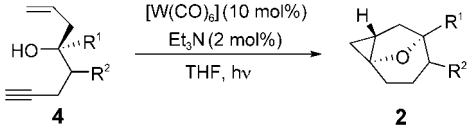

Table 1: Tricyclic compounds **2** from the catalytic cycloisomerization reaction of alkynol derivatives **4**.

4	R^1	R^2	2	Method A[a] Yield [%][c]	Method B[b] Yield [%][c]

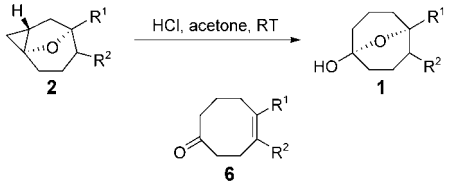
4j[g]	H	OBn	**2j**[h]	91	–

[a] The alkynol **4** was stirred as a solution in THF with preformed $[(thf)W(CO)_5]$ (25 mol%) at room temperature for 24 h. [b] A solution of the alkynol **4** in THF was irradiated with $[W(CO)_6]$ (10 mol%) and Et_3N (2 mol%) for 12 h. [c] Yield of the isolated product based on the starting alkynol **4**. [d] Racemic mixture. [e] In this case the amount of $[W(CO)_6]$ can be decreased to 5 mol% without any observed decrease in the yield of the reaction. [f] The racemic 1*S**,2*S** diastereoisomer was used. [g] The 4*S*,5*S* enantiomer was used. [h] The 1*R*,3*S*,5*S*,6*S* enantiomer was obtained; $[\alpha]_D^{20} = -26.7$ ($c = 0.45$, CH_2Cl_2).

secondary and tertiary alcohol derivatives **4**. The reaction is completely diastereoselective, and a single diastereoisomer of the product was observed in all cases.[9] It should be noted that the alternative diastereoisomer would be significantly more strained. The enantiopure tricyclic compound **2j** was isolated when the reaction was performed with the alkynol derivative **4j**.

A minor drawback of this method for the catalytic synthesis of tricyclic compounds **2** is the fact that the catalyst has to be generated in a separate vessel by irradiation of a solution of $[W(CO)_6]$ in THF and then added to the solution of the corresponding alkynol derivative. However, the conditions described by McDonald et al.[4c] for the in situ generation of $[W(CO)_5]$ species were shown not to be applicable to our substrates as a result of the amine-promoted formation of enol ethers analogous to **5** (see Scheme 1). We reasoned that we could find appropriate catalytic conditions if we were able to lower the amount of amine used to such an extent that the amine could only act to stabilize the $[W(CO)_5]$ species. With this idea in mind, we carried out a set of experiments with different $[W(CO)_6]$/triethylamine ratios under a variety of reaction conditions. We were delighted to find that constant irradiation at 350 nm of a solution of the corresponding alkynol **4** in THF in the presence of 10 mol% of $[W(CO)_6]$ and only 2 mol% of triethylamine gave similar results to those obtained when preformed $[(thf)W(CO)_5]$ was used (Scheme 3 and Table 1, method B). As before, the



Scheme 3. Cycloisomerization reactions of alkynols **4** with catalytic amounts of $[W(CO)_6]$ and Et_3N to give compounds **2**.

reaction led to a single diastereoisomer of the products in all cases studied.[9]

To illustrate the synthetic utility of the tungsten-catalyzed process described, we further transformed the tricyclic compounds **2** into eight-membered carbocycles **1** following the protocol developed previously by our research group.[7] Thus, the treatment of compounds **2** with hydrochloric acid in acetone at room temperature yielded the corresponding eight-membered carbocycles **1** (Table 2).[9] Under the same

Table 2: Eight-membered carbocycles **1** or **6** from tricyclic compounds **2**.

[a] Yield of the isolated product based on the starting cyclic ether **2**. [b] The 1*R*,4*S*,5*S* enantiomer was obtained; $[\alpha]_D^{20} = -13.0$ ($c = 1.15$, CH_2Cl_2).

reaction conditions, dehydrated compounds **6** were obtained when the R^1 group of the starting compound **2** was an electron-rich aryl group (i.e. **2g**) or an alkenyl group (i.e. **2h**). Interestingly, compounds with structures analogous to that of **1h** ($R^1 = H$, $R^2 = OBn$, 1*R*,4*S*,5*S* enantiomer) have shown remarkable activity as herbicides. The methodology described herein provides straightforward access to such compounds.[10]

In summary, we have developed an effective and general method for the synthesis of eight-membered carbocycles based on a new tandem tungsten-catalyzed cycloisomerization–cyclopropanation reaction. This process is one of very few examples of a catalytic reaction in which a heteroatom-stabilized Fischer carbene complex is implied. The method described herein opens the door to the development of new catalytic methods which avoid the use of large quantities of metallic species, thus overcoming one of the main limitations of Fischer carbene complexes. Moreover, as the procedure has been shown to be applicable to the synthesis of functionalized and biologically active compounds from very simple starting materials, it is expected to find wide application in organic synthesis.

Coupling Reactions

Catalytic Reductive Coupling of Epoxides and Aldehydes: Epoxide-Ring Opening Precedes Carbonyl Reduction**

*Carmela Molinaro and Timothy F. Jamison**

Transition-metal-catalyzed reductive coupling reactions have attracted considerable interest for several decades since the development of reductive polymerization of carbon monoxide by Fischer and Tropsch.[1] Hydroformylation[2] and the Nozaki–Hiyama–Kishi reaction[3] are other important examples, and in the past decade dozens of nickel- and rhodium-catalyzed reductive coupling reactions have also been described.[4] Represented among these transformations are diverse coupling partners, catalysts, and mechanisms, yet what they have in common is the formation of a carbon–carbon bond. In contrast, with the exception of reductive etherification of carbonyl groups and acetals,[5] catalytic reductive C–O bond formation has remained largely unexplored,[6,7] despite the recent emergence of transition-metal-catalyzed carbon–oxygen bond-forming methods[8] and the importance of oligosaccharides, ribonucleic acids, epoxy resins, natural products, and pharmaceuticals. We now report the first example of such a transformation that employs epoxides (Table 1). Several lines of evidence suggest, perhaps counterintuitively, that carbonyl reduction occurs after epoxide-ring opening.

Recently we reported that a species derived from $[Ni(cod)_2]$ and Bu_3P catalyzes the inter- and intramolecular reductive coupling of alkynes and terminal epoxides to give homoallylic alcohols.[4a,9] To account for several observations, we proposed that epoxide-ring opening occurred prior to carbon–carbon bond formation, possibly by way of a metallaoxetane.[9a,10–11] We reasoned that this species would likely have very different reactivity patterns to those of the epoxide itself, and accordingly we have begun to investigate catalytic reductive coupling reactions of epoxides with other functional groups, including aldehydes.

We initially examined a number of nickel(II) and nickel(0) complexes and found that, at room temperature and without added solvent, both $[Ni(cod)_2]/PBu_3$ and $[NiCl_2(PBu_3)_2]$ catalyzed a reductive ring-opening reaction between 1,2-epoxybutane and benzaldehyde in the presence of Et_3B, giving the 1-benzyl ether of 1,2-butanediol with high selectivity (Table 1, entries 1–2). Superior results (Table 1, entries 3–11) were obtained with $[(Ph_3P)_3RhCl]$ (also without added solvent), representing the first use of Et_3B as reductant in a reaction promoted by the Wilkinson catalyst. Sterically

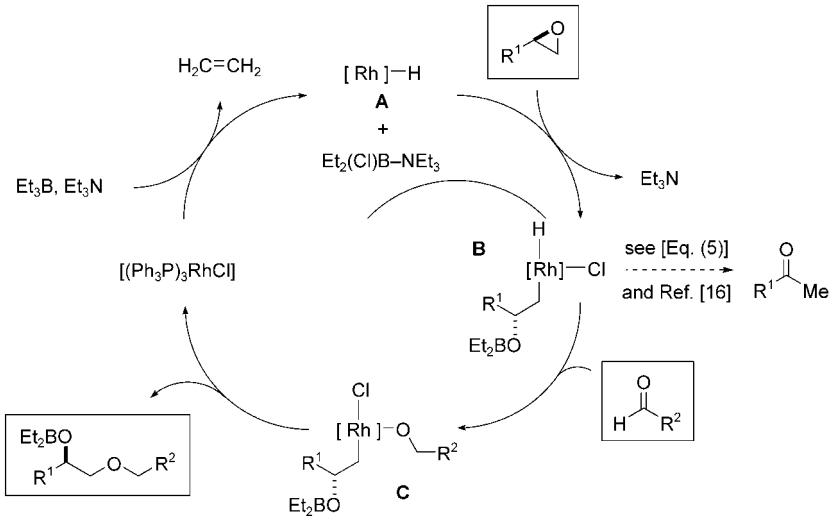
[a] Standard procedure: To the catalyst specified and, where indicated, Et_3N (20 mol%) at room temperature were added the epoxide, aldehyde, Et_3B (200 mol%, dropwise). The mixture was stirred for 16 h and purified by silica-gel chromatography. See Supporting Information for details. cod = cycloocta-1,5-diene.

encumbered epoxides such as *tert*-butyloxirane and isopropyloxirane underwent near-quantitative reductive coupling when a substoichiometric amount of Et_3N was included (Table 1, entries 5–8). Other aromatic and heteroaromatic aldehydes were also effective (Table 1, entries 9–11). The reaction between isobutyraldehyde and 1,2-epoxyoctane proceeded in 15% yield (Table 1, entry 12).[12] Several ketones (benzophenone, acetophenone, cyclohexanone, and 2-octanone) underwent catalytic reductive coupling in 10–25% yield. Despite the large variation in steric and electronic properties of the epoxides in the above examples, the regioselectivity of the ring-opening reaction was universally $>95:5$, a significant observation as aryl and alkyl oxiranes often undergo ring opening with the opposite sense of regioselectivity.[13–14]

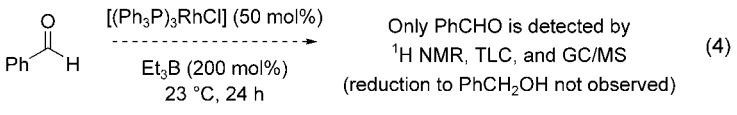
Three examples are worthy of further comment. The one-step Rh-catalyzed reductive coupling shown in Equation (1) demonstrates the tolerance of acid-labile functional groups that would be problematic in a more traditional two-step approach, for example, reduction with $NaBH_4$ and acid-promoted epoxide opening. Complementarity to Jacobsen's methods of enantioselective epoxide opening by oxygen-centered nucleophiles[15] is demonstrated in Equation (2)

 DOI: 10.1002/anie.200461705 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

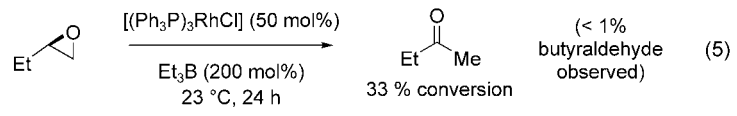
(Boc = *tert*-butoxycarbonyl). Phenolic hydroxy groups are typically more reactive than aliphatic hydroxy groups in [(salen)Co]-catalyzed ring openings,[15e–f] yet in the Rh/Et_3B system the former are unreactive which allows the aldehyde to function as a masked hydroxymethyl group. Finally, as shown in Equation (3), the stereochemical integrity of the epoxide is preserved in these transformations.



It might be expected that reduction of the aldehyde would initiate these reactions, giving a nucleophilic metal alkoxide that would then open the epoxide. However, we have found no evidence whatsoever to support this mechanistic framework. Reduction of the aldehyde does not occur in the absence of epoxide, even with 50 mol% catalyst [Eq. (4)], and isomerization of the epoxide to a methyl ketone[16] occurs in the absence of aldehyde [Eq. (5)]. It is unlikely that this process is a Lewis acid promoted 1,2-H shift as a terminal epoxide would generally rearrange to an aldehyde.[13b,17]



The reactivity of epoxides toward Rh complexes[16,18] [Eq. (5)] and the fact that the aldehyde is not reduced in the absence of epoxide [Eq. (4)] can both be explained by a catalytic cycle in which reduction of the carbonyl follows epoxide opening (Scheme 1).[19] A combination of $[(Ph_3P)_3RhCl]$, Et_3B, and Et_3N affords ethylene, $Et_2(Cl)B\text{-}NEt_3$ and species **A**, which opens the epoxide,[16] possibly assisted by Et_2BCl, leading to **B** and the regeneration of Et_3N. In other words, Et_3N may serve to temper the Lewis acidity of Et_2BCl.[20] Coordination of the aldehyde to **B**[21] and formal reduction of the carbonyl could occur at this stage to provide **C**, and C–O bond formation through reductive elimination of the product as a borinate ester would complete the catalytic cycle. A similar mechanism involving nickel (Table 1, entries 1–2) can also be envisioned.[9a,10]



Several other experiments and observations also support this proposal. Ethylene is present in the atmosphere above the reaction mixture (^{1}H NMR spectroscopic analysis of head gas samples). In support of **B** (or a related species), ^{11}B NMR spectra of a mixture of all reaction components except for the aldehyde show the appearance of a new signal at $\delta = 53$ ppm (see Supporting Information), representative of $Et_2B\text{-}OR$.[22]

One could also imagine a mechanism in which a Rh species undergoes addition to the aldehyde,[23] the resulting alkoxide opens the epoxide, and then the Rh–C bond is reduced thereafter. To account for the results in Equation (4), therefore, the carbonyl addition would have to be reversible, and the results of Equation (5) and several ^{11}B NMR spectroscopy experiments (see above) would necessarily have to originate from a process not directly involved in the catalytic cycle. Nevertheless, as in the mechanism shown in Scheme 1, epoxide-ring opening still precedes carbonyl reduction in this alternate framework.

Scheme 1. Proposed mechanism for the catalytic reductive coupling of epoxides and aldehydes.

In summary, only off-the-shelf reagents and catalysts are required to effect both a reduction and a carbon–oxygen bond formation in the reductive coupling of two of the most readily available functional groups to provide differentially modified, synthetically useful 1,2-diols in a single catalytic operation. The regioselectivity of this process is very high; none of the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

minor regioisomer can be detected by ^{1}H NMR spectroscopic analysis of the unpurified product mixtures. This method circumvents one of the key problems of catalytic C–O bond formation, β-elimination of a carbinol hydrogen atom to give an aldehyde (or ketone) and an M–H species that is often catalytically inactive.[8d] Moreover, as all evidence suggests that epoxide-ring opening occurs prior to reduction of the aldehyde, other functional groups might also undergo reductive coupling with epoxides by way of proposed intermediate **B**. Thus, these first examples of metal-catalyzed reductive C–O bond formation of epoxides not only are of inherent utility, but also provide a starting point for the development of other useful catalytic reductive C–X coupling methods.

[19] Rhodium is required for catalysis. Neither reductive coupling (i.e. product formation) nor reduction of the aldehyde occurs when $[(Ph_3P)_3RhCl]$ is omitted from the reaction. Similarly, when $[(Ph_3P)_3RhCl]$ is omitted but Ph_3P is included in the reaction, neither product formation nor aldehyde reduction is observed.

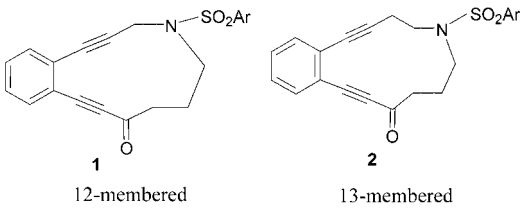
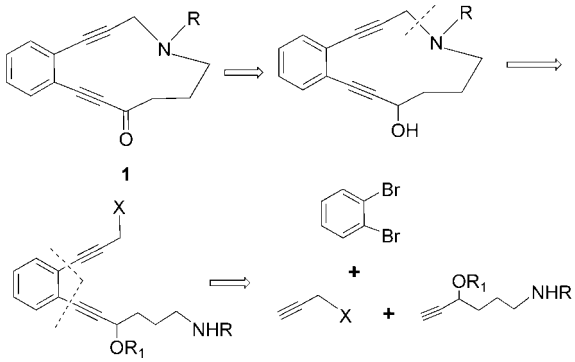
Enediynes

Activation of Macrocyclic Enediynes by Transannular Cyclization**



Amit Basak, Sandip Kumar Roy, and Subrata Mandal*

Species containing single electrons were long known to possess cytotoxic activity through DNA damage; however, this property could not be utilized in the development of antitumor agents because methods to generate radicals under mild conditions were not known until Mother Nature revealed how it could be done through the chemistry of naturally occurring enediynes.[1] Although these enediynes possess potent antitumor activity, their extreme toxicity acted as a deterrent for their direct medical use. This prompted chemists to synthesize analogous molecules with the hope of reducing the toxicity without sacrificing the antitumor activity to a great extent. Designed enediynes can be broadly classified into two groups: one comprising intrinsically reactive enediynes stabilized by the use of a locking device. Fusion of small strained rings,[2] incorporation of sp^2-carbon atoms,[3] tuning of redox characteristics,[4] and the ability to undergo allylic rearrangement[5] are some examples of locking devices. The other group comprises ambiently unreactive enediynes, usually acyclic, that are made active in situ by a suitable triggering reaction such as isomerization to eneyne allenes,[6] and ligation to metal ions.[7] Examples are also known in which a reactive enediyne core has been generated from a prodrug. As macrocyclic enediynes[8] with 11-membered rings or higher are stable at physiological temperature, it would be possible to broaden the scope of the second approach if an intramolecular transannular reaction were carried out to reduce the ring size of a large macrocyclic enediyne, which in turn should enhance the rate of the Bergman cyclization (Scheme 1).[9] Herein, we report the synthesis of two novel macrocyclic N-substituted enediynyl



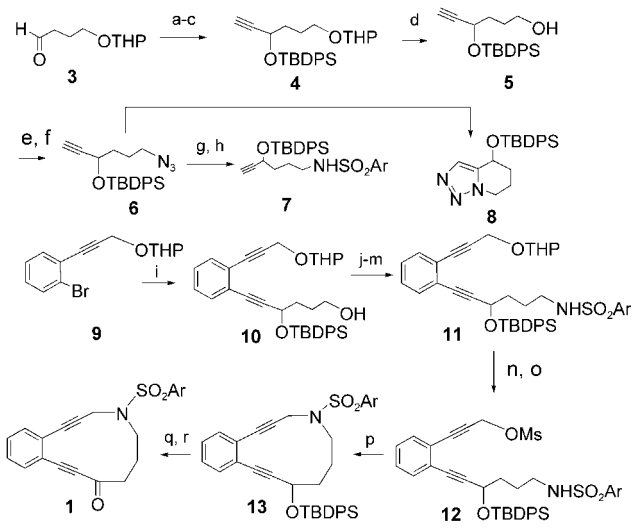
Scheme 1. Design of macrocyclic enediynes.

ketones **1** and **2**. Ways to control their chemical and biological activity are also reported. To our knowledge, this is the first

example of the use of a transannular reaction for enediyne activation,[10] although transannular reactions have been used to activate promitosene, a precursor to mitosene, under photoirradiation conditions.[11]

The retrosynthesis of the enediyne **1** (Scheme 2) involves three critical bond-forming reactions, namely the construction

Scheme 2. Retrosynthesis of enediyne **1**.



of the enediyne framework by two successive Sonogashira couplings,[12] followed by macrocyclization by intramolecular N-alkylation.[13] The actual synthesis was, however, executed with a slight modification. Azide **6**, the precursor for the protected amine **7** proved to be unstable as it undergoes facile intramolecular cycloaddition with the alkyne functionality.[14] This forced us to do the second palladium(0)-mediated coupling with protected hydroxy alkyne **5** instead of **7** (Scheme 3). The resulting enediyne **10** was converted into the 4-nitrosulfonamide **11** by the following sequence of

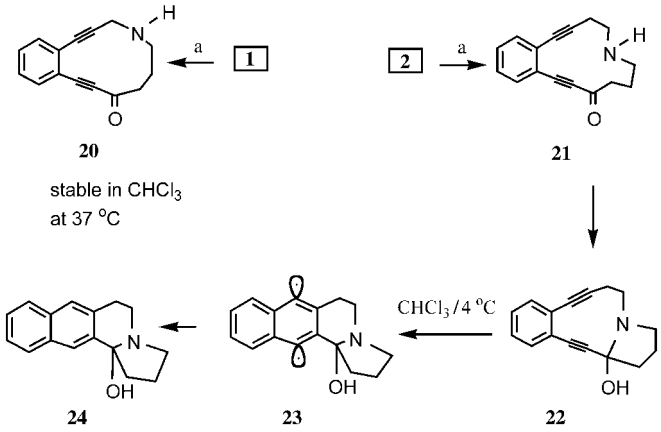
reactions: mesylation, displacement with NaN_3,[15] reduction into the amine,[16] and protection with 4-nitrobenzene sulfonyl chloride. Removal of THP followed by treatment with mesyl chloride and Et_3N furnished the mesylate **12**. Intramolecular N-alkylation in K_2CO_3/DMF under high dilution worked quite well to give the 12-membered enediyne **13** as the only isolable product in about 60% yield.[17] This was then converted into the ketone **1**.



The synthesis of the 13-membered enediyne **2** could not be achieved in a similar way as intramolecular N-alkylation at a homopropargylic center is known to produce only the elimination product.[18] The synthesis was completed by intramolecular N-alkylation in the reverse direction (Scheme 4). As expected, this step was free from any elimination. The structures of the cyclic enediynes were confirmed by NMR and mass spectral studies. The appearance of peaks at m/z 431 [$M-Na^+$] for **1** and at m/z 423 [$M-H^+$] and 445 [$M-Na^+$] for **2** in the mass spectrum (ES+ mode) confirmed that only intramolecular N-alkylation has occurred and ruled out the formation of any dimeric or oligomeric products during cyclization.

The sulfonamido ketone **1** was then deprotected by using thiophenol and K_2CO_3 in DMF[19] to generate the 12-membered free amino ketone **20**.[20] Compound **20** proved to be stable at room temperature and no significant decomposition was observed when a solution of **20** in $CHCl_3$ was kept at 37°C for seven days. Moreover, **20** could be converted back to the starting sulfonamide **1** upon treatment with 4-nitrobenzenesulfonyl chloride and triethylamine, thus demonstrating the inherent stability of **20**. Attempts to induce transannular cyclization to the aminol with catalytic amounts of *p*-toluenesulfonic acid (PTSA) also failed. On the contrary,

Scheme 4. deprotection of the sulfonamido group in ketone **2** gave the product amine **21**, which remained mostly in the unstable aminol form **22** (as indicated by its inability to be reconverted to the starting sulfonamide **2**). The aminol, being a 10-membered enediyne, decomposes in $CHCl_3$ even at 4°C ($t_{1/2}$ ~ 40 h) to give the new product **24**.[21] The occurrence of a Bergman cyclization was indicated by the disappearance of all four acetylenic carbon atoms, which are now replaced by signals for aromatic carbon atoms. The probable mechanism of formation of **24** is shown in Scheme 5. That the mechanism

Scheme 5. Fate of aminoenediynes. a) PhSH, K_2CO_3, DMF, RT.

involves the generation of the diradical **23** is also supported by the interaction of the enediyne with supercoiled DNA. Thus **22** showed single-strand cuts to generate form II when incubated with double-stranded plasmid DNA (pBR 322) in the supercoiled form (Figure 1). The corresponding sulfonamido ketone **2**, under similar conditions, did not show any DNA damage, thus ruling out a possible cleavage mechanism by the Michael addition of nucleophilic bases of DNA to the

unsaturated carbonyl system. The stability of the 12-membered amino ketone **20** is ascribed to its inability to undergo the transannular reaction, as it involves the formation of a nine-membered enediyne, which is a kinetically disfavored reaction.[22]

In conclusion, we have synthesized two novel N-based macrocyclic enediynes and have been able to activate one of these by a transannular reaction. The use of a 4-nitrophenylsulfonyl group as a deactivating device that renders the nitrogen non-nucleophilic has been demonstrated. Thiol-mediated deprotection can act as a triggering mechanism that activates the enediyne through an intramolecular cyclization reaction. When the protected amino ketone **2** was incubated with supercoiled DNA in the presence of glutathione, a biological thiol, at a pH of 8.0, it was able to cleave supercoiled DNA (Figure 2). This observation has proven

our design; namely, the activation by way of a biological thiol-mediated triggering of enediyne towards Bergman cyclization. Considering the repertoire of amine-protecting groups and different methods for their deprotection, our design offers a wide array of triggering mechanisms for the development of antitumor agents that work through generation of diradicals.

[20] Experimental procedure for the deprotection of the 4-nitrosulfonamido group: Thiophenol (1.1 equiv) and K_2CO_3 (2.2 equiv) were added to a solution of **1** or **2** (0.12 mmol) in DMF (5 mL), and stirred under argon for 1 h. The mixture was then partitioned between EtOAc and water (2 × 25 mL each). The combined organic layers were washed with water (3 × 25 mL), dried (Na_2SO_4), and evaporated under vacuum at room temperature. The free amine **20** or the aminol **22** was isolated by column chromatography using CH_2Cl_2–MeOH (10:1) as eluent (yield ~75%). Selected ^{1}H NMR data: For **20** (200 MHz, $CDCl_3$): $\delta = 7.22$–7.18 (bm, 1H; aryl-H), 7.04–6.90 (m, 3H; aryl-H), 6.87 (bs, 1H; NH), 3.74 (s, 2H; NCH_2CC), 2.95 (t, ^3J(H,H) = 6.3 Hz, 2H; NCH_2CH_2), 2.65 (t, ^3J(H,H) = 6.1 Hz, 2H; $COCH_2$), 2.05 ppm (m, 2H; NCH_2CH_2). For **22** (200 MHz, $CDCl_3$): $\delta = 7.46$ (m, 1H; aryl-H), 7.25–6.84 (m, 3H; aryl-H), 6.59 (bs, 1H; OH), 3.04–2.85 (m, 4H; $CH_2NCH_2CH_2CC$), 2.75 (m, 2H; NCH_2CH_2CC), 2.60 (m, 2H; $C(OH)CH_2$), 2.04 ppm (m, 2H; $NCH_2CH_2CH_2$).

[21] Cyclization of aminol **22**: The solution of aminol (40 mg) in $CHCl_3$ was kept at 4°C for seven days and periodically monitored by TLC. After evaporation of the solvent, the cyclized product **24** was isolated by column chromatography over silica gel using hexane–EtOAc (5:1) as eluent (17 mg, ~45%). ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 7.70$ (dd, ^3J(H,H) = 8.5, 1.1 Hz, 1H; aryl-H), 7.69 (dd, ^3J(H,H) = 8.5, 1.1 Hz, 1H; aryl-H), 7.15 (m, 4H; aryl-H), 6.45 (s, 1H; OH), 3.03 (m, 3H; $CHNCH_2$), 2.82 (m, 2H; ArCH, NCH), 2.23 (m, 1H; ArCH), 1.95 (m, 1H; C(OH)CH), 1.68 ppm (m, 3H; C(OH)CH, $C(OH)CH_2CH_2$); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 135.9$ (quaternary C), 133.7 (quaternary C), 133.4 (quaternary C), 133.1 (quaternary C), 129.5 (CH), 129.3 (CH), 128.3 (CH), 127.4 (CH), 126.6 (CH), 125.4 (CH), 68.9 (quaternary C), 50.6 (CH_2), 45.4 (CH_2), 36.9 (CH_2), 29.7 (CH_2), 22.8 ppm (CH_2); Mass (ES+): m/z: 239 [M^+], 221 [M^+-H_2O]. Keeping a solution of the amine **22** in $CDCl_3$ gave a mixture of deuteriated as well as monochloro products.

[22] Attempted intramolecular N-alkylation to produce a nine-membered enediyne failed. The reaction produced only the dimer [Eq. (2)] as shown below. (A. Basak, J. C. Shain, U. K. Khamrai, K. Rudra, A. Basak, *J. Chem. Soc. Perkin Trans. 1* **2000**, 1955).

Natural Products Synthesis

Total Synthesis of Halipeptin A: A Potent Antiinflammatory Cyclic Depsipeptide**

*Shouyun Yu, Xianhua Pan, Xianfeng Lin, and Dawei Ma**

The halipeptins A (**1**) and B (**2**) are two cyclic depsipeptides that were isolated from the sponge *Haliclona* species by Gomez-Paloma and co-workers.[1,2] Initially, their structures were misassigned as the 17-membered cyclic depsipeptides containing an unusual oxazetidine.[1] One year later the same group reported the revised structures of these two compounds

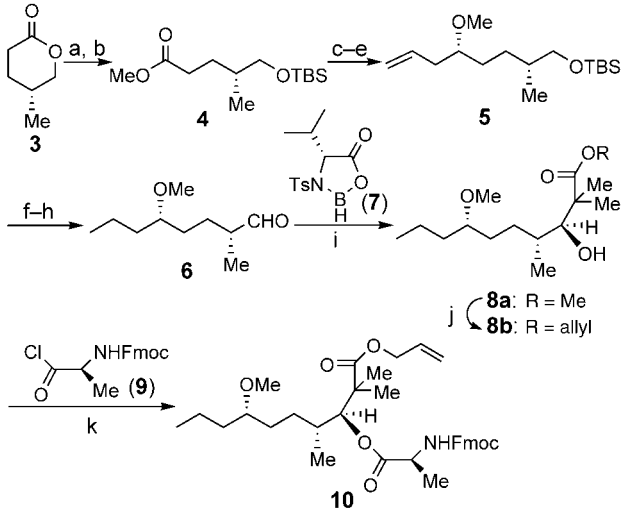
as those shown in Scheme 1 which bear two L-alanine residues, an α-methylcysteine unit connected to one of the L-alanine residues through a methylthiazoline ring, and two new residues that had not been discovered from natural

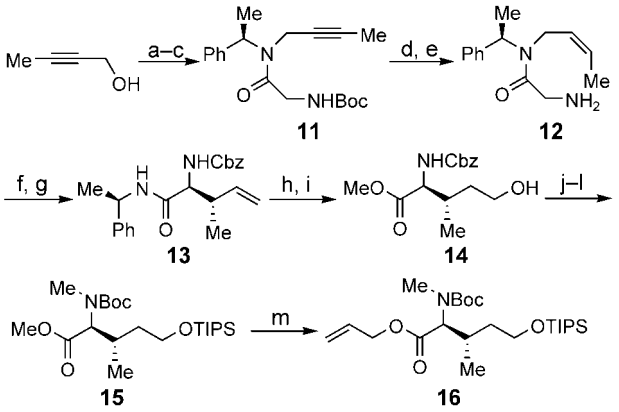


Scheme 1. Structures and retrosynthetic analysis of halipeptins A (**1**) and B (**2**). PG = protecting group.

sources:[2] 3-hydroxy-2,2,4-trimethyl-7-methoxy (or hydroxy) decanoic acid (HTMMD or HTMHD) and *N*-methyl-δ-hydroxyisoleucine (NMeOHIle). Preliminary pharmacological tests revealed that halipeptin A has potent antiinflammatory activity (60% reduction of carrageenan-induced edema at an intraperitoneal dose of 0.3 mg kg^{-1} in mice).[1] The unique structures and important biological characteristics of halipeptins A and B have attracted considerable synthetic attention.[3] As part of the continuing efforts to synthesize of cyclic peptides,[4] we report herein the first total synthesis of halipeptin A and the confirmation of its stereochemistry.

Our retrosynthetic analysis of halipeptin A is outlined in Scheme 1. As this molecule is highly methylated, the most critical problem in its assembly is the connection of the sterically hindered units with other amino acid residues. We envisaged that two less hindered positions could be reserved for late-stage connections, namely the Ala1–NMeOHIle and HTMMD–Ala2 sites. Our plan therefore required the assembly of an ester part **A** and an amide unit **B**, and hence the stereoselective synthesis of the HTMMD, NMeOHIle, and methylthiazoline residues. Because the configurations of C7 of the HTMHD and Cα of the two alanine residues were all established as *S*, the ring system of halipeptin A might have a 1*R*,4*S*,7*S*,10*S*,14*S* configuration, and hence the residues with the corresponding stereochemistry were considered as primary targets. Furthermore, ready racemization at C14 directed by the methylthiazoline group would be another critical problem,[5,6] and therefore the protecting groups for the above two units should be removable under mild conditions.

As depicted in Scheme 2, our assembly of the HTMMD unit started from (*R*)-4-methyl-5-valerolactone (**3**), an oxidative degradation product of diosgenin.[7] Ring opening of **3** with methanolic sodium methoxide followed by protection of the hydroxy group as a silyl ether provided **4**. After the ester **4** was reduced to an aldehyde with DIBAL-H, the chain was extended through an asymmetric allylboration based on the procedure of Brown and Racherla[8] to deliver a homoallylic alcohol, which was treated with NaH/MeI to produce ether **5**. Cleavage of silyl ether **5** with TBAF, hydrogenation of the terminal C-C double bond, and Swern oxidation afforded aldehyde **6**. At this stage we planned to build the β-hydroxy-α,α-dimethyl ester part in the HTMMD by an enantioselective chiral borane-mediated aldol reaction.[9] Accordingly, treatment of a mixture of the aldehyde **6** and 1-(trimethylsiloxy)-1-methoxy-2-methyl-1-propene with the borane **7** at −78 °C produced methyl ester **8a** in 95% yield as a single isomer, which was transformed into allyl ester **8b** through hydrolysis and subsequent alkylation. Esterification of the alcohol **8b** with an *N*-protected L-alanine group proved to be challenging. The method of Yamaguchi and co-workers[10] and other activated ester procedures were unsuccessful. However, we found that coupling of **8b** with acyl chloride **9**[11] at −15 °C in the presence of DMAP (0.5 equiv) gave our desired product **10** in good yield. Notably, both the amount of DMAP used and the reaction temperature are critical, as extensive racemization occurred at Cα of the L-alanine residue when this reaction was conducted at 0 °C in the presence of 0.5 equivalents of DMAP or at −15 °C in the presence of 1 equivalent of DMAP, and low conversion was attained when



Scheme 2. a) NaOMe, MeOH, 0 °C→RT, 82%; b) TBSCl, imidazole, DMF, 98%; c) DIBAL-H, diethyl ether, −100→−90 °C; d) D-B-allyldiisopinocampheylborane; then H_2O_2, NaOH, 90% over three steps; e) NaH, MeI, DMF, room temperature, 91%; f) TBAF, THF, room temperature, 90%; g) Pt/C, H_2, EtOAc, room temperature, 99%; h) Swern oxidation, 85%; i) **7**, 1-(trimethylsiloxy)-1-methoxy-2-methyl-1-propene, −78 °C, 95%; j) aqueous LiOH, THF, MeOH; then allyl bromide, K_2CO_3, DMSO, 92%; k) **9**, DMAP (0.5 equiv), iPr_2NEt, CH_2Cl_2, −15 °C, 95% yield based on 90% conversion of **8b**. TBS = *tert*-butyldimethylsilyl, DMF = *N*,*N*-dimethylformamide, DIBAL-H = diisobutylaluminum hydride, DMSO = dimethyl sulfoxide, TBAF = tetrabutylammonium fluoride, DMAP = 4-dimethylaminopyridine.

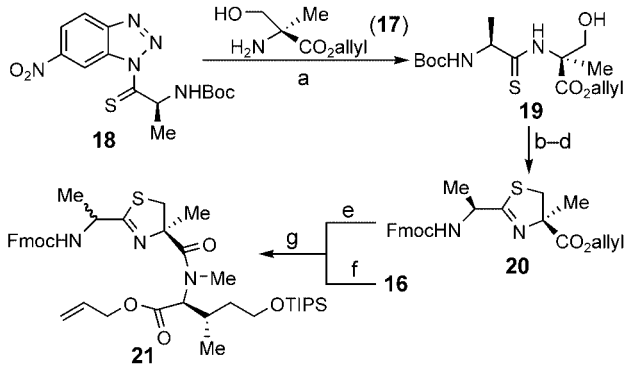
the coupling was carried out at 0 °C in the presence of 0.2 equivalents of DMAP.

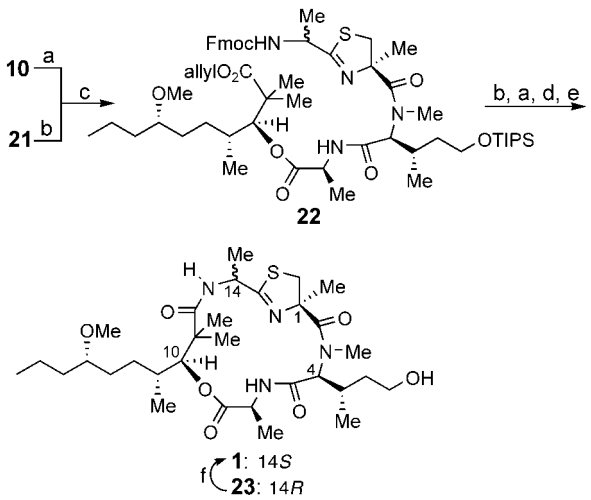


The construction of the NMeOHIle unit relied on an asymmetric aza-Claisen rearrangement developed by Tsunoda et al.[12] Although in their report only diastereoselective rearrangement of *N*-substituted *N*-(*E*)-2-butenylpropanamides to *syn* products was mentioned, based on related studies[13] we reasoned that if olefin (*Z*)-**12** was used, the desired *anti* compound would be the major product. To this end, mesylation of 2-butyn-1-ol followed by introduction of the chiral auxiliary (*R*)-α-methylbenzylamine and subsequent condensation with *N*-Boc-Gly yielded amide **11** (Scheme 3).

Scheme 3. a) MsCl, Et_3N, 82%; b) (*R*)-α-methylbenzylamine, 80%; c) $BocNHCH_2CO_2H$, EDCI, HOBT, *i*Pr_2NEt, 96%; d) Lindlar catalyst, H_2, diethyl ether, 91%; e) CF_3CO_2H, CH_2Cl_2, 96%; f) LiHMDS, THF; g) benzyl chloroformate, Et_3N, 52% over two steps; h) HCl (5 M), MeOH, reflux; then CH_2N_2, diethyl ether, 76%; i) BH_3·THF complex; then H_2O_2, pH 7 buffer, 72%; j) TIPSCl, imidazole, DMAP, 89%; k) Pd/C, H_2, $(Boc)_2O$, MeOH; l) Ag_2O, MeI, DMF, 50 °C, 94% over two steps; m) aqueous LiOH, THF, MeOH; then allyl bromide, K_2CO_3, DMSO, 92%. Ms = methanesulfonyl, Boc = *tert*-butoxycarbonyl, EDCI = ethyl dimethylaminopropyl carbodiimide chloride; HOBT = 1-hydroxy-1*H*-benzotriazole, HMDS = hexamethyldisilazide, TIPS = triisopropylsilyl.

Hydrogenation of **11** with Lindlar catalyst and subsequent deprotection with trifluoroacetic acid delivered the **12**. Exposure of **12** to LiHMDS afforded the aza-Claisen rearrangement products,[12] which were masked with Cbz to give a mixture of diastereomers. ^{1}H NMR spectroscopic analysis revealed that the ratio of the major isomer **13** to other isomers was about 3:1, and pure **13** was isolated in 52% overall yield by recrystallization. Next, removal of the chiral auxiliary from **13** followed by treatment with CH_2N_2 provided a methyl ester, which was then elaborated into the alcohol **14** through a hydroboration–oxidation reaction. After the hydroxy group of **14** was masked as a silyl ether and the *N*-protecting group was changed, methylation was carried out to give **15**. Finally, the methyl ester of **15** was saponified and the resulting acid was treated with allyl bromide to furnish **16**. Notably, Izzo and co-workers recently reported a method to elaborate the NMeOHIle unit through a similar strategy.[3c]

In a parallel procedure, treatment of (*S*)-α-methylserine allyl ester (**17**) with the thioacylating agent **18**[14] produced the thioamide **19**. The Boc protecting group was exchanged for a Fmoc group, and subsequent exposure to DAST[15] afforded the methylthiazoline **20** (Scheme 4). Removal of the allyl protecting group from **20** by a Pd^0-catalyzed reaction[16] gave



Scheme 4. a) Et_3N, CH_2Cl_2, 50%; b) CF_3CO_2H, CH_2Cl_2; c) FmocOSu, Na_2CO_3, dioxane, H_2O, 75% for two steps; d) DAST, CH_2Cl_2, −78 °C, 89%; e) $[Pd(PPh_3)_4]$, *N*-methylaniline, CH_2Cl, room temperature; f) $AlCl_3$, CH_2Cl_2; g) BEP, *i*Pr_2NEt, CH_2Cl_2, 71% from **16**. Fmoc = 9-fluorenylmethyloxycarbonyl, Su = succinimide; DAST = (diethylamino)sulfur trifluoride; BEP = 2-bromo-1-ethyl pyridinium tetrafluoroborate.

the corresponding acid, which was coupled with the amine liberated from **16**[17] in the presence of BEP[18] as an activating agent to deliver the dipeptide part **21**. Partial racemization at Cα of the L-alanine residue still occurred, even under the very mild conditions, and two isomers (3:1) were determined by ^{1}H NMR spectroscopy. Clearly, installation of the methylthiazoline ring at the ultimate stage of this total synthesis might avoid the racemization problem.[5] Toward this goal, we attempted to link the NMeOHIle residue to various *N*-substituted (*S*)-α-methylserines, but failed to obtain any coupling products as a result of steric hindrance.

The final steps of the synthesis of halipeptin A are described in Scheme 5. Deprotection of **10** with diethylamine and of **21** through palladium-mediated reactions liberated the amine and acid, respectively, which were coupled to afford **22**. Sequential deprotection of **22** provided an amino acid, which was subjected to macrocyclization. To our delight, this transformation worked well in the presence of HATU[19] as the coupling agent and delivered **1** (27% yield from **22**) and its 14-epimer **23** (5% yield from **22**) after cleavage of the silyl ether with TBAF. The 5:1 ratio for **1** to **23** indicated that isomerization at C14 occurred after cyclization because the ratio for two isomers in **21** was only 3:1. Indeed, partial conversion of **23** into **1** (≈2.4:1) was seen by exposure **23** to TBAF in THF. A similar phenomenon was observed by the groups of Wipf[5b] and Pattenden.[5c] The analytical data of **1** were identical with those reported and thus confirmed the stereochemistry of halipeptin A proposed by Gomez-Paloma and co-workers.

Today, the vast majority of antiinflammatory drugs are cyclooxygenase (COX) enzyme inhibitors and lead to several side effects. The unique structures of the halipeptins imply that their mechanism of action is different to that of current drugs, thus making them ideal leads for the discovery of novel

Surface Analysis

Tip-Enhanced Raman Spectroscopy of Benzenethiol Adsorbed on Au and Pt Single-Crystal Surfaces**

Bin Ren, Gennaro Picardi, Bruno Pettinger,* Rolf Schuster, and Gerhard Ertl*

Raman spectroscopy (RS) provides rich spectral and structural information on gaseous, liquid, and solid samples. However, the Raman process usually exhibits a very low cross section of the order of $(d\sigma/d\Omega)_{RS} \sim 10^{-31}$–$10^{-28}\,cm^2\,sr^{-1}$. This hampers its wide application, particularly when only a small number of scatterers can be probed, as is the case for adsorbate systems on (smooth) interfaces. This situation changed in the mid-1970s with the discovery of surface-enhanced Raman spectroscopy (SERS) on rough silver surfaces. The tremendous enhancement arises from cooperative "electromagnetic" and "chemical" enhancement mechanisms.[1,2] In the course of the 30 years of research on SERS, the height of the surface enhancement and the efficiency of the Raman instrumentation have improved substantially, permitting the study of monolayers and submonolayers of adsorbates. Recently, Raman spectroscopy of even single molecules has been achieved on Ag and Au nanoparticles.[3,4]

Initially, only noble metals were known to exhibit SERS. In the meantime SERS has also been observed for adsorbates on rough transition-metal surfaces.[5] Further applications have been found by using UV light to excite the SERS, and in some cases even surface-enhanced resonance Raman scattering of adsorbates, for example, for SCN^- and CO adsorbed on roughened rhodium surfaces, has been observed.[6] Most applications of SERS are, however, limited to rough surfaces, in which typically a variety of different adsorption sites are exposed, often hampering the assignment of spectral features to specific vibrational modes. It is therefore highly desirable to record Raman spectra of flat single-crystal surfaces, which would allow the identification of the adsorbed species and the determination of their bonding sites and molecular orientation. This knowledge could then be transferred to more complex systems, such as roughened surfaces and supported catalysts. However, Raman studies on single-crystal surfaces have been extremely difficult so far because of insufficient intensity due to the absence of or only minor level of SERS enhancement for smooth interfaces. Thus, only very few investigations have been reported in this field, and they were performed in vacuum,[7] in an electrochemical environment,[8] or in a special attenuated total reflection (ATR) cell, which makes use of the resonant excitation of surface plasmons leading to a rather moderate enhancement of electromagnetic fields at the interface.[9]

Recently, a new approach has been developed to enhance the Raman scattering intensity, by combining Raman microscopy with scanning probe microscopy such as atomic force microscopy (AFM), scanning near-field optical microscopy (SNOM), or scanning tunneling microscopy (STM). Its central element consists of an illuminated AFM, SNOM, or STM tip (either covered with Ag or Au film or made from a silver or gold wire) placed in close vicinity to a sample surface; in other words, the tip is operated either in contact or tunneling mode.[10–16] Upon illumination, localized surface plasmons are excited in the tip–metal gap, producing a large, local increase of the electromagnetic field relative to that of the incident light. This results in a tremendous increase of the Raman intensity (which is proportional to the 4th power of the field enhancement).[10–18] Moreover, the enhanced signal stems from a subwavelength region having the size of the tip apex or an even smaller diameter; in other words, its extension is only of a few tens of nanometers. Since the enhancement is restricted to the tip–substrate gap, there is no surface roughness needed, and (if the proper tip is chosen) the enhancement can be created also on flat transition-metal surfaces. In this way, Raman spectroscopy and scanning probe microscopy (SPM) can be combined to take advantage of the high spatial resolution of SPM and the rich chemical information of Raman spectroscopy. This approach is known as tip-enhanced Raman spectroscopy (TERS) and is sometimes referred to as apertureless SNOM.

In a previous paper, we presented mainly TERS results for malachite green isothiocyanate on gold single-crystal surfaces. Its absorption band is well centered at the excitation wavelength; therefore, for the adsorbed dye a resonance Raman scattering (RRS) process occurs, yielding a weak, but measurable RRS signal in the absence of the gold tip. The approach of the tip to the Au(111) surface causes a tremendous increase of the Raman scattering by many orders of magnitude.[16] In addition, we presented the spectra of malachite green isothiocyanate on a Pt(110) substrate as well as of CN^- on Au(111. Here we further demonstrate the general power of TERS.

The test system we employed was a self-assembled monolayer of benzenethiol on Pt(110). The TERS spectra are shown in Figure 1. As spectrum a shows, no Raman signal can be detected if the STM tip is retracted by about 1 μm or if it is completely absent. When, however, the Au tip is moved into the tunneling position above the Pt(110) substrate (at a distance of about 1 nm above the surface), high-quality spectra can be obtained (spectra b–f in Figure 1). The Raman signal of the most intense peak is about 20 counts

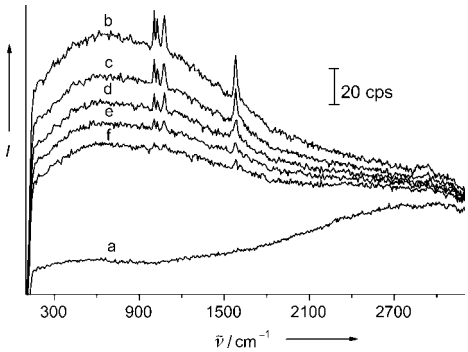

Figure 1. TERS for benzenethiol at Pt(110). Spectrum a was measured with a retracted tip. Spectra b–f were recorded in the tunneling mode and were recorded sequentially. Laser power: 5 mW.

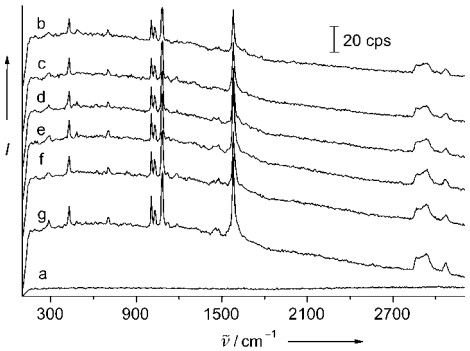

Figure 2. TERS for benzenethiol at Au(110) at reduced laser power. Spectrum a was recorded with a retracted tip. Spectra b–f were recorded in the tunneling mode and were recorded sequentially. Laser power: 0.5 mW.

per second (cps) and decreases slightly with time, showing a decay process reminiscent of the bleaching of dye molecules upon illumination. However, adsorbed benzenethiol is not expected to have an appropriate absorption band in the wavelength region of the excitation laser we used. Thus, the intensity decay must be attributed to the very high electromagnetic field generated in the close vicinity of the tip apex, possibly leading to the photodesorption or photodecomposition of benzenethiol. This conclusion was confirmed by decreasing the laser power by a factor of ten and probing a new patch on the surface. Under these conditions the signal became fairly stable; the three most prominent bands are clearly visible with a signal-to-noise ratio of 3:1, and the intensity of the strongest band was then about 3.4 cps (not shown). If one considers the signal intensity of 24 cps found with full laser power, this indicates that even for the first spectrum, a part of the surface benzenethiol had already been decomposed, leading to a decreased signal intensity.

To exclude SERS created by surface defect sites and to produce an ideally flat substrate, the Pt(110) surface was flame-annealed. In the absence of the tip, no Raman signals from benzenethiol adsorbed on a smooth Pt(110) surface were observable. In the presence of the tip, the TERS signal obtained from this Pt surface was reasonably intense. Although it takes 60 s to acquire a spectrum with a sufficiently high signal-to-noise ratio, the recording of a Raman spectrum of optically nonresonant species adsorbed at a smooth Pt(110) surface represents a breakthrough in the field of surface Raman spectroscopy.

For comparison, a Au(110) substrate was used, which was also flame-annealed to produce a smooth, well-defined surface and to exclude any contribution of roughness-induced SERS. When the tip was in the retracted position, only a low-intensity, flat background signal was observed without spectral features from adsorbed benzenethiol (Figure 2). When the tip was brought into the tunneling mode, very strong peaks of benzenethiol could be observed over a broad, curved baseline, similar to the case of Pt. The maximum peak intensity is about 64 cps with the reduced laser power, which is about twenty times higher in intensity than that measured for the Pt(110) surface. In both experiments (Figure 1 and Figure 2) the same gold tip was used and the relative positions of the gold tip to the laser beam and substrate were essentially unchanged. Therefore, both experiments can be compared quantitatively. Obviously, the use of a gold substrate leads to an excellent optical coupling between tip and substrate, thus better meeting the conditions for surface plasmon excitation and generation of a strong enhancement in the tip–substrate gap. The 20-fold difference in the Raman intensities on Au and Pt, though surprisingly low, is due to the optically different nature of the two samples, causing a different reflectivity, absorption, and tip–substrate coupling.[17]

In general, different substrates will exhibit different interactions with the adsorbate, which can lead to (slightly) different vibrational frequencies and relative intensities. This accounts for the power of vibrational spectroscopies as analytical tools. A careful examination of Figure 1 and Figure 2 shows that there is a 7-cm^{-1} blue shift for the benzenethiol band at around 1070 cm^{-1} having an a_1-type symmetry.[19] The Raman frequency is about 1068 cm^{-1} on Pt and shifts to 1075 cm^{-1} on Au. For clarity, we expanded the spectra in this frequency region and displayed them as Figure 3. In addition to the frequency shifts we observe a distinct change of the relative intensities in the frequency region from 950 to 1150 cm^{-1}. Since there are only small frequency shifts and changes of the relative intensities upon adsorption, the typical spectroscopic pattern of benzenethiol is preserved. Thus, the assignment of the benzenethiol bands,

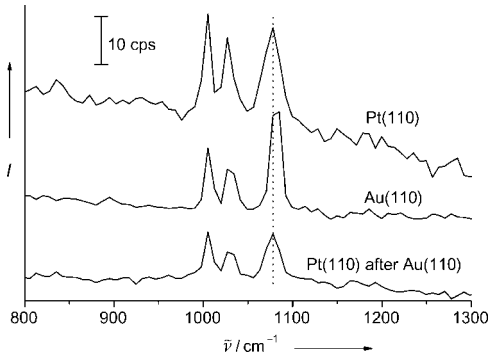

Figure 3. Expanded TERS spectra for sequential experiments, performed at first on Pt(110), then on Au(110), and finally on a Pt(110) surface again. All other experimental conditions were the same as those in Figure 2.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as given in ref. [19], can be transferred to the TERS spectra. Note the large baseline in all spectra. Presumably, it arises mainly from the surface plasmon continuum of the tip–substrate gap and to a minor extent from the contamination of tip or substrate. To prove that the frequency shift is not an artifact, spectra on Pt(110) were recorded before and after the Au(110) spectrum, using the same tip. Both Pt spectra exhibit the same spectral features, which are clearly different from those of Au(110).

TERS provides, therefore, a diagnostic tool for determining to which surface the observed benzenethiol is bound. Furthermore, the experimental results in Figure 3 prove that the vibrational frequency at 1068 cm^{-1} arises from benzenethiol bound to a Pt surface, and not to the Au tip. Hence, the observed TERS signals seen in the spectra a–c stem from benzenethiol bound to the substrates. Additional evidence is provided by the change of the relative intensities. In the spectrum of liquid benzenethiol the 998-cm^{-1} band is the strongest, and the 1075-cm^{-1} band is relatively weak. [19] However, in both cases of Pt and Au substrates the 1075 cm^{1} peak becomes stronger than the 998 cm^{1} band. This situation is more pronounced in the Au system, where the intensity of the 1075-cm^{-1} band is much higher than that of the 998-cm^{-1} band. Since both bands are assigned to the vibrations having the same a_1 symmetry, the differences in the peak intensity ratios cannot be explained by different orientations of benzenethiol on the surface. In a recent report on pyridine adsorption on transition-metal surfaces, it was pointed out that the change in relative intensity may be due to the different interactions of pyridine with the metal surfaces;[20] similar reasons may apply in the case of benzenethiol on Pt and Au, as discussed here. It should be noted at this point that the substrate sensitivity of the spectra proves that the signal stems from (sub)monolayers.

To demonstrate the general applicability of TERS, spectra were also recorded for other adsorbates, for instance, 4-pyridine-4-thiol (4-PT, Figure 4). The four Raman bands appearing at 1011, 1099, 1207, and 1617 cm^{-1} present the essential spectral features of 4-PT on metal surfaces. The peak intensities are even stronger than in the case of benzenethiol. However, during our study of 4-PT we noticed that the Au tip can be contaminated easily by the 4-PT. The signal of 4-PT on the Au tip is weaker than on Au(110) and, hence, does not alter spectroscopically the TERS signal of 4-PT on Au(110). However, on Pt(110) the signal from the tip becomes comparable with the TERS of 4-PT from the substrate and, hence, the two spectra will mix. A possible reason for the easy contamination may be that the S and N atom of 4-PT can form strong bonds to the substrate. When the tip approaches the tunneling position, it may pick up some 4-PT molecules from the substrate, because the Au atoms of the tip form strong bonds with the N atoms of the 4-PT molecules. At the same time S–Au bonds with the substrate are weakened. Apparently, molecules with multiple bonding sites have an inherent tendency to contaminate the tip.

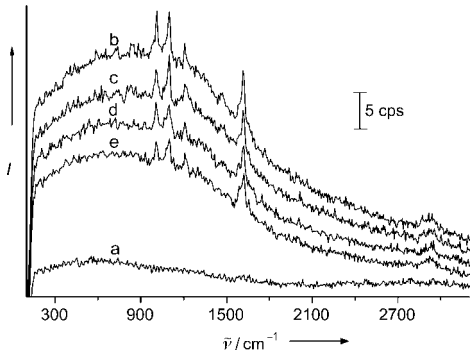

Figure 4. TERS for pyridine-4-thiol on Au(110) at reduced laser power. Spectrum a was recorded with a retracted tip. Spectra b–f were recorded in the tunnelling mode and were recorded sequentially. Laser power: 0.5 mW.

From earlier estimates on the lateral extension of the enhanced field[16] we conclude that the spatial resolution of TERS corresponds roughly to the size of the tip used, which in the present case had a radius of about 30 nm. On the other hand, theoretical predictions point to an even stronger confinement of the electromagnetic field, down to a tiny spot 9 nm in diameter for 30-nm tip radius and a tunneling distance of 1 nm.[21] These two values may be seen as upper and lower limits of the actual extension of the enhanced field, highlighting the enormous power and resolution of this technique for (sub)wavelength microscopy.

Our present study illustrates that the detection of species adsorbed in (sub)monolayer quantities on smooth single-crystal metal surfaces is no longer a difficult task, even if the adsorbates exhibit moderate or weak Raman cross sections. For adsorbates on single-crystal surfaces, additional information (such as on molecular orientation) can be achieved by choosing appropriate light polarization in TERS and analyzing the response with respect to surface selection rules. With the high spatial resolution of TERS applied to the study of probe molecules having a high sensitivity to the binding site, it might become possible to reveal the role of terraces, steps, and different facets during the adsorption process or in the course of chemical reactions in catalytic and electrochemical processes. The surface structure might be varied continuously from atomically flat to mildly and highly roughened surfaces, in order to smoothly bridge the gap between model single-crystal surfaces and real catalyst surfaces. Even TERS studies on single catalyst particles are within reach. Additionally, TERS may provide clues to the nature of SERS-active sites, a still unresolved issue. In contrast to SERS, where the chemical enhancement provides an important contribution to the overall enhancement, TERS does not require this type of chemical interaction between the adsorbed molecule and the substrate. TERS will be developed as a valuable analytical tool, providing simultaneous spectroscopic and microscopic information in the nanometer region, which ultimately may include single-molecule detection and investigation, an aspect that has been addressed previously.[14,16]

Experimental Section

The STM tip was fabricated by electrochemically etching a gold wire 0.25 mm in diameter at 2.4 V DC in a mixture of fuming hydrochloric acid and ethanol (1:1).[22] The tip was cleaned with Milli-Q water immediately after etching. Tip radii obtained with this method were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

around 30 nm. Before every experiment, the Pt and Au single crystals were flame-annealed in order to produce atomically flat surfaces. Monolayer adsorption of benzenethiol was accomplished by dipping freshly flame-annealed single-crystal electrodes into a 0.01 M solution of benzenethiol in ethanol for 3 to 4 min and then rinsing with copious amounts of ethanol to remove adsorbed multilayers. A similar procedure was used to prepare pyridine-4-thiol monolayers except that a shorter time, ca. 2–3 min, sufficed.

The TERS experiment was conducted using an Olympus microscope attached to a Raman spectrograph (LabRam 1000 from DILOR) together with a homemade adapter to redirect the incident laser beam and to collect the Raman signal at an angle of roughly 60° to the surface normal of the single-crystal surface.[16] The microscope objective was an Olympus ×50 long-working-distance objective with an numerical aperture of 0.5. The laser power (He–Ne, 632.8 nm) on the sample was about 5 mW, which can be reduced through a set of neutral density filters. The STM was an in-house built instrument, which was solidly connected to the sample stage of the microscope through an extended arm.[14] Sample and tip were placed in the laser focus with an *x*–*y* translation stage, while the beam was focused using the vertical translation stage of the microscope. The focusing as well as the coarse approach of the tip toward the sample were monitored by means of the microscope and an auxiliary CCD camera. The acquisition time for each spectrum in the sequential acquisition mode was 60 s, and the time interval between each spectrum was about 1 s. Tunneling current and voltage (referenced to sample) were 1 nA and −150 mV, respectively, resulting in a tunneling gap in the order of 1 nm, which is slightly larger than that in vacuum due to the presence of a thin layer of water between the tip and the surface.

Reaction Mechanisms

Ambident Reactivity of the Cyanide Ion: A Failure of the HSAB Principle**

*Alexander A. Tishkov and Herbert Mayr**

Dedicated to Professor Christoph Rüchardt on the occasion of his 75th birthday

The ambident reactivity of the cyanide ion is one of the classical examples used to illustrate the application of the Klopman–Salem equation and the hard and soft acids and bases (HSAB) principle. According to Fleming, *"alkyl halides in simple S_N2 reactions are soft electrophiles; thus it is appropriate for cyanide to react from the soft end of the ion. When a silver ion is present (other Lewis acids like zinc and mercuric ion behave similarly), the halide ion is assisted in leaving the carbon atom, and in the transition state there is now a greater development of charge on the carbon atom undergoing substitution. Carbonium ions are hard electrophiles, and therefore it is again appropriate that on this occasion cyanide ion should react from the harder end of the ion."*[1]

Comparable statements are found in many textbooks, including the latest edition of March's Organic Chemistry.[2] Although Pearson had already indicated problems of the HSAB principle in explaining the ambident reactivity of the

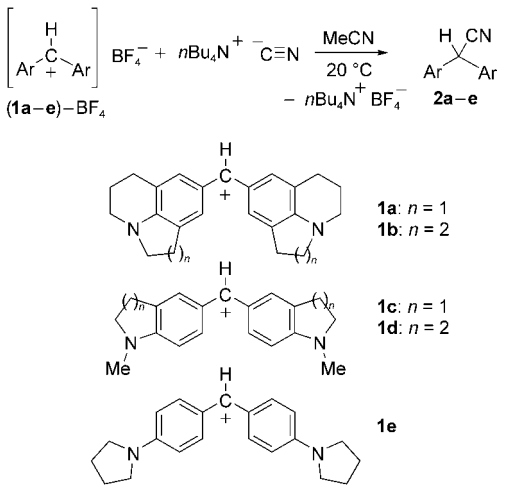
cyanide ion,[3] experimental evidence that cast doubt on this interpretation has largely been ignored. For example, the report by Songstad and co-workers[4a] that trityl chloride and perchlorate react with unassociated cyanide ions to form predominantly triphenylacetonitrile and only 10% of isocyanotriphenylmethane received little attention (Scheme 1).

Scheme 1. Reaction of trityl chloride and perchlorate with cyanide ions (Songstad and co-workers).[4a]

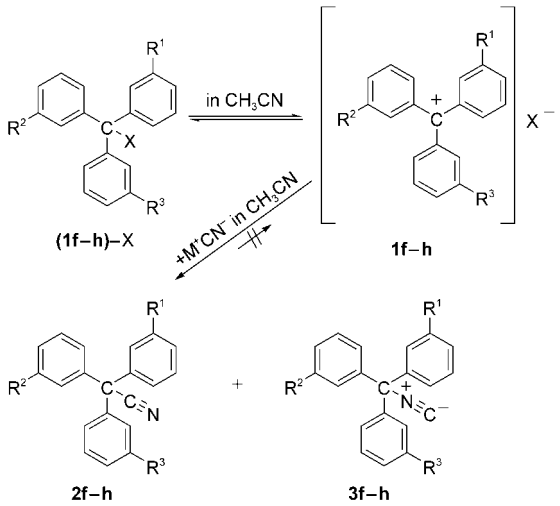
In 1985, Carretero and Ruano reported the retention of configuration in the reaction of *erythro*- and *threo*-2-bromo-3-methylthiobutanes (Scheme 2) and found that "*the observed*



Scheme 2. Reaction of 2-bromo-3-methylthiobutane with cyanide ions (Carretero and Ruano).[4b]

regioselectivity with both metal cyanides cannot be explained as variations in the hardness of the electrophilic carbon induced by the interactions between the metal cation and the halogen."[4b] Their clear conclusion, "*that the reactions between alkyl halides and metal cyanides … are not a good example for illustrating the Klopman–Salem equation*" also found little resonance.

We recently reported that the HSAB principle cannot explain the ambident reactivity of the thiocyanate ion in alkylation reactions, since hard carbocations as well as soft haloalkanes preferentially attack the soft sulfur terminus.[5] Only when diffusion control is reached, can the attack of carbocations at the nitrogen atom compete with attack at the sulphur atom. We now report that the knowledge of the diffusion control limit is also key to understanding the ambident reactivity of the cyanide ion.



Scheme 3 shows that the highly stabilized benzhydrylium ions (**1a**–**e**)–BF_4 react with nBu$_4$N$^+$CN$^-$ in acetonitrile to give the corresponding diaryl acetonitriles **2a**–**e**.[6] As any produced isocyanomethanes would reionize and successively yield the thermodynamically more stable nitriles **2a**–**e**, the outcome of the reaction presented in Scheme 3 does not give information about the site of the kinetically controlled attack.[7]

Treatment of 3-chlorophenyldiphenylmethyl chloride (**1g**–Cl) with nBu$_4$N$^+$CN$^-$ under the same conditions as shown in Scheme 3 yields a mixture of nitrile **2g** and isonitrile **3g**, as revealed by the presence of absorptions at $\tilde{\nu} = 2240$

tion conditions, indicating that the product ratios listed in Scheme 4 are the result of kinetic control.

The reactions of (**1f–h**)–X with $[Ag(CN)_2]^-$ lead to the selective formation of the isonitriles **3f–h** (Scheme 5).[8] Since

Scheme 5. Selective isonitrile formation in the reaction of (**1f–h**)–X with $[Ag(CN)_2]^-$; X = Cl or Br.

the nucleophilic substitutions of trityl halides described in Scheme 4 and 5 generally follow the S_N1 mechanism, it is clear that the observed reversal of regioselectivity is not due to a change in mechanism from S_N2 to S_N1, but to modification of the cyanide ion by coordination with silver.

How can the C/N ratios, reported in Scheme 4, be explained? We recently showed that the correlation Equation (1) also describes the rates of reactions of stabilized carbocations with anions (*k* is the second-order rate constant at 20 °C, *E* is a nucleophile-independent electrophilicity parameter, and *N* and *s* are electrophile-independent nucleophilicity parameters).[9,10]

$$\log k_{20^\circ C} = s(E + N) \quad (1)$$

When the reactions of (**1a–e**)–BF_4 with $nBu_4N^+CN^-$ were monitored photometrically in acetonitrile by using previously described methodology,[10] second-order kinetics were observed with the rate constants listed in Table 1.

Table 1: Rate constants for the reactions of the benzhydrylium ions **1a–e** with tetra-*n*-butylammonium cyanide (CH_3CN, 20 °C).

	Electrophilicity *E*[a]	k_C [$M^{-1}s^{-1}$]
1a	−10.04	2.42×10^4
1b	−9.45	5.50×10^4
1c	−8.76	1.31×10^5
1d	−8.22	3.58×10^5
1e	−7.69	1.12×10^6

[a] From reference [9].

From the linear part of the $\log k_C$ versus *E* correlation (Figure 2) one can derive $N = 16.3$ and $s = 0.70$ for the C nucleophilicity of CN^- in acetonitrile. Extrapolation indicates that k_C reaches diffusion control for carbocations with

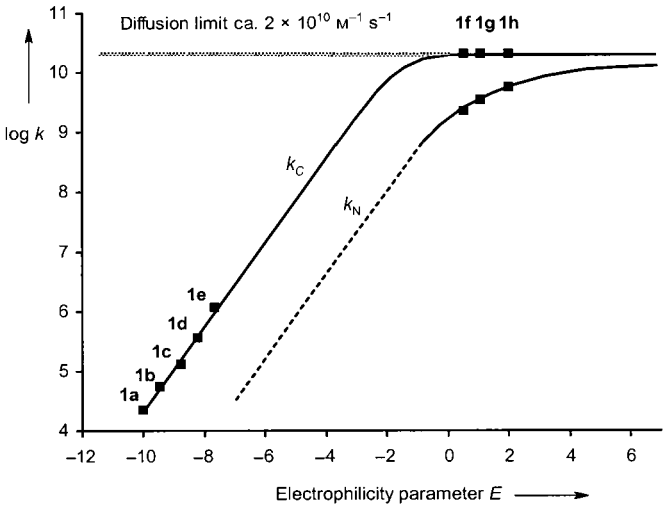

Figure 2. Plot of $\log k$ for the reactions of the benzhydrylium ions **1a–e** and the tritylium ions **1f–h** with the cyanide ion versus the electrophilicity parameters *E* of these carbocations.[9,10a]

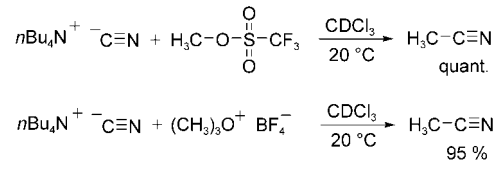

$E > 0$.[11] As all carbocations with $E > 0$ can thus be assumed to react with CN^- with the same rate constant of $2\times10^{10}M^{-1}s^{-1}$ (C attack), the product ratios reported in Scheme 4 can be used to estimate k_N, that is, the rate constants for attack at the cyanide nitrogen atom. Figure 2 illustrates that the decrease in the **2**/**3** ratio ($= k_C/k_N$) as the electrophilicities of the carbocations **1f–h**[10a] grow from 0.5 to 2.0 can be explained by the fact that C attack has already reached diffusion control while N attack approaches the diffusion limit. Even when the exact location of these borders is problematic, it is clear from Figure 2 that carbocations that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are less stabilized than Ph_3C^+ undergo barrierless combination reactions with free CN^- in acetonitrile. Attempts to explain C/N ratios by traditional transition-state models must, therefore, be obsolete.

S_N1 reactions with participation of the cyanide anion are problematic in protic solvents. As the nucleophilicity of CN^- decreases significantly in protic solvents (e.g., in water $N = 9.19$ and $s = 0.60$),[10a] carbocations generated under such conditions usually react faster with the solvent than with CN^-.[12] Thus, the reaction of 1-chloro-1-(4-methoxyphenyl)-ethane with KCN in ethanolic solution yields the corresponding ethyl ether in almost quantitative yield.[13] Reactions of *tert*-haloalkanes with alkali-metal cyanides in alcohols give particularly low yields of substitution products owing to the high basicity of CN^-. Depending on the reaction conditions, small amounts of *tert*-cyanoalkanes are formed along with tertiary ethers and elimination products.[14]

In summary, C attack is generally preferred whenever carbocations react with free CN^-. Let us now turn to S_N2 reactions of the cyanide ion: It has long been known that haloalkanes react with alkali-metal and onium cyanides with preferential formation of nitriles.[15] Even in the reaction of KCN with the relatively hard methylating agent dimethyl sulfate, the preferential formation of acetonitrile was observed.[16,17] We have now studied the reactions of tetra-*n*-butylammonium cyanide with the even harder S_N2 alkylating agents methyl triflate and trimethyloxonium tetrafluoroborate in $CDCl_3$ and observed the exclusive formation of acetonitrile in both cases (^1H and ^{13}C NMR spectroscopy, Scheme 6).

Scheme 6. Exclusive formation of acetonitrile in the reactions of tetra-*n*-butylammonium cyanide with the hard S_N2 alkylating agents methyl triflate and trimethyloxonium tetrafluoroborate.

In conclusion, electrophilic alkylations at free CN^- occur preferentially at carbon, regardless of whether the S_N1 or S_N2 mechanism is involved and whether hard or soft electrophiles are employed. Preferred N attack, as postulated for hard electrophiles by the HSAB principle, could not be observed with any alkylating agent. Isocyano compounds are only formed with highly reactive electrophiles that react without an activation barrier because the diffusion limit is approached (Figure 2). We therefore claim that the knowledge of absolute rate constants and not of the hardness of the reaction partners is needed to predict the outcome of alkylations of the cyanide ion.

Cubane Rearrangements

The Protonation of Cubane Revisited**

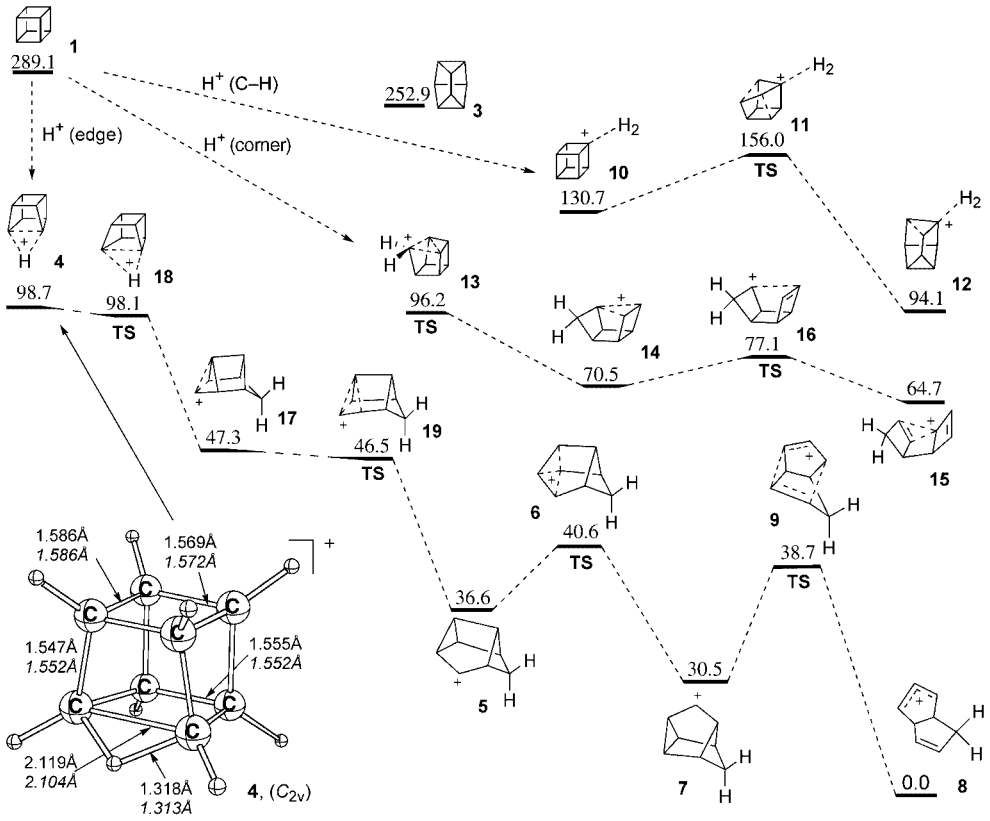
Andrey A. Fokin, Boryslav A. Tkachenko, Pavel A. Gunchenko, and Peter R. Schreiner**

Dedicated to Professor A. G. Yurchenko on the occasion of his 70th birthday

Protonation of saturated hydrocarbons is the simplest and practically most important electrophilic reaction.[1] Small alkanes like methane, ethane, and isobutane[2] form well-defined protonated species, and their experimental proton affinities (PAs) are excellently reproduced computationally.[3–5] However, the current data on the protonations of strained hydrocarbons are rather controversial, and facile rearrangements are thought to account for the difficulties encountered in measuring the PAs.[6] Cyclopropane (strain energy(E_{str}) = 27.2 kcal mol^{-1}) is an exception because the number of energetic downhill paths is very limited and the barrier for the ring opening of corner-protonated $C_3H_7^+$ to the 2-propyl cation is high. The experimental PA of cyclopropane (179.4 kcal mol^{-1} [7]) is well reproduced computationally (179.3 kcal mol^{-1} at CCSD(T)/cc-pVTZ//CCSD(T)/cc-pVDZ for corner-protonated $C_3H_7^+$).[8] In contrast to cyclopropane which displays secondary C–H bonds only, a surprisingly small range of PAs is characteristic for a number of hydrocarbons with tertiary C–H bonds. These hydrocarbons differ considerably in their strain energies, for example, dodecahedrane (PA = 201.7 kcal mol^{-1},[9] E_{str} = 65.4 kcal mol^{-1} [10]), adamantane (PA = 175.7 kcal mol^{-1},[11] E_{str} = 6.3 kcal mol^{-1} [12]), and cubane[13] (PA = ca 200 kcal mol^{-1},[7,9] E_{str} = 161 kcal mol^{-1} [14]). For these systems the question remains: How much does the strain energy affect the proton affinity of a saturated hydrocarbon and to what extent should isomerizations be considered? The experimental PA of cubane (**1**) measured by ion-cyclotron resonance spectroscopy[9] is surprisingly low and was recently questioned by Koppel et al.[15] on the basis that **1** rearranges rapidly to cuneane so that the PA is attributed to the energy change of the entire protonation/rearrangement/deprotonation process. However, cuneane is also highly strained, so where one does stop? Are there any other rearrangement paths for protonated cubane? Herein we address both computationally and experimentally the question to what extent the cubane cage is able to survive electrophilic attack[16] and what the most favorable paths for the reaction of **1** with a proton are.

Despite enormous strain, cubane[15,17,18] is kinetically quite stable because breaking just one C–C bond causes only minor structural changes and hence only little relief of strain. However, cleavage of a second C–C bond is highly exothermic and followed by rapid rearrangements. For instance, thermolysis[16,19] and single-electron oxidation[20] of **1** leads to cyclooctatetraene. In contrast, mild radical reagents[21] lead to substitution products with conservation of the cubane cage.[22] Electrophilic cubane conversions are limited to reactions of soft electrophiles like metal ions,[18] and a number of fascinating rearrangements (e.g., to *syn*-tricyclooctadiene (**2**) with Pd^{2+} and to cuneane (**3**) with Ag^+ and Li^+) are preparatively useful.[18,23]

The attack of a proton on cubane is highly exergonic and all of our and previous[9,15,16,24] attempts to locate $C_8H_9^+$ protonated minima retaining the cubane cage at various levels of density functional theory (DFT) failed. When DFT methods are used, edge-protonated cubane (**4**, Scheme 1) is not a minimum and converges to the tetracyclo[4.2.0^{2,4}.0^{3,8}]oct-5-yl cation (**5**)[25] upon optimization without symmetry constrains. This structure is energetically much too low to account for the "experimental" gas-phase basicity of **1** (ca. 200 kcal mol^{-1}).[7,9] The explanation for this discrepancy was proposed[15] to lie in the rapid conversion of **1** to **3** via **5** followed by deprotonation. However, our computations[26] at this level indicate that there is a low-energy path from **5** via transition structure (TS) **6** to the lower-lying cation **7**, which can subsequently rearrange to the more stable bicyclo[3.3.0]octadienyl **8** via TS **9**. The discrepancies between experiment and theory are simply unacceptable and require careful scrutiny of both the high-energy part of the $C_8H_9^+$ potencial enery surface (PES) and the theoretical treatment.



First of all, the gas-phase protonation of hydrocarbons with tertiary C–H bonds results in weakly bound complexes ($R^+\cdots H_2$) as shown both experimentally[2] and computationally[5] for isobutane as well as computationally for adamantane;[11] the situation for cubane is expected to be similar. Small, strained hydrocarbons like cyclopropane[8] and cyclobutane[4] form structures protonated at a C–C bond. To test the DFT findings we used Møller-Plesset perturbation theory (MP2) utilizing a correlation-consistent Dunning basis set (cc-pVDZ) and considered (Scheme 1) the attack of a proton on **1** at a C–H bond (top), corner (middle), and edge (bottom); MP2 is known to be very suitable for the description of highly delocalized carbocations, even when DFT approaches fail.[27] As the formation of the cubyl cation in the condensed phase is well documented,[28] we also searched for the products of the

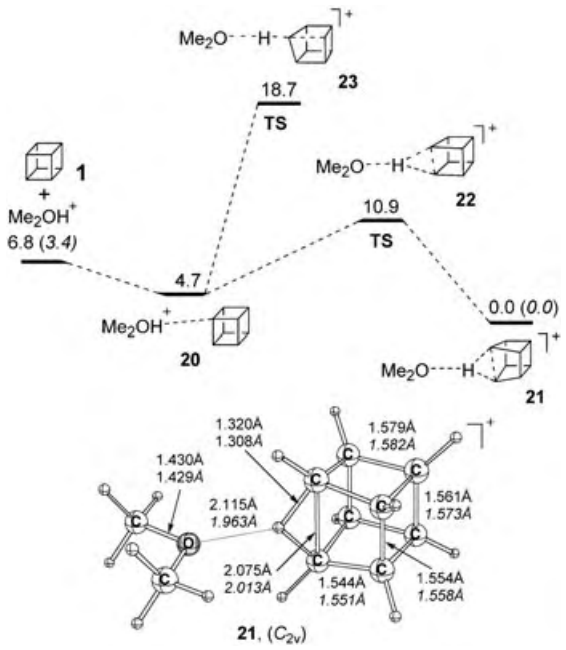
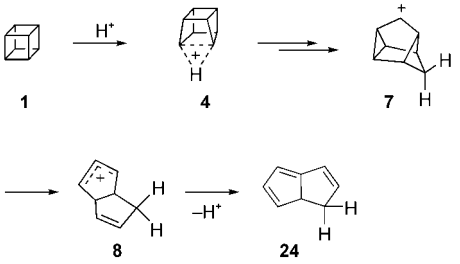
Scheme 1. The computed paths for the protonation of cubane (**1**) (ΔH_0 in kcal mol^{-1} at CCSD(T)/cc-pVDZ//MP2/cc-pVDZ + ΔZPVE) and the structure of edge-protonated cubane **4** at MP2/cc-pVDZ and CCD/cc-pVDZ (in italics).



formal "hydride" abstraction with H^+. Similar to isobutane and adamantane, **1** forms a weakly bound complex with H_2 (**10**) upon protonation.[29] The absolute value of the reaction enthalpy[30] ($\Delta H_0 = -158.0$ kcal mol^{-1}) is approximately 40 kcal mol^{-1} higher than the "experimental" gas-phase basicity and proton affinity of **1**; in other words, **10** cannot be the high-energy $C_8H_9^+$ species resulting from protonation. Complex **10** is connected via TS **11** with the complex of the 2-cuneyl cation with H_2 (**12**), which is 195.0 kcal mol^{-1} lower in energy than **1**. Although this value is only slightly lower than the "experimental" PA[7,9] of cubane, the barrier for the rearrangement of **10** to **12** is too high (25.3 kcal mol^{-1}) for it to occur in a weakly bound complex such as **10**.

Corner-protonated cubane **13** in not a minimum and converges upon optimization without symmetry constrains to **14**, which is connected with protonated *syn*-tricyclooctadiene **15** via TS **16**. Cation **14** is also too stable ($\Delta\Delta H_0 = 219$ kcal mol^{-1}) to stand for the "experimental" PA of cubane. In contrast, edge-protonated cubane **4** *is* a true minimum that is 190.4 kcal mol^{-1} below **1** + H^+ (Scheme 1) at MP2/cc-pVDZ. Reoptimization at the coupled cluster CCD/cc-pVDZ as well as at the decisive CCSD(T)/cc-pVDZ levels of theory also identifies **4** as a minimum. The cubane cage opening to the "boat" structure **17** through TS **18** is barrierless. As the ZPVE correction is larger than the difference in electronic energies, the TSs appear to have a lower energy than the starting minima. This simply means that the reaction is barrierless and highly exothermic; **17** is connected with cation **5** via another low-lying TS **19**.



The PA of **1** previously was determined with a bracketing experiment in which the equilibrium reaction between cubane and protonated 2-propyl ether was examined using the FT/ICR technique.[9] Computations show that edge-protonated cubane **4** is not able to survive under these experimental conditions (155 °C, time from 0.1 to 25 s),[9] as its rearrangement is barrierless. To define the most favorable path for the proton transfer, we modeled the reaction of cubane with protonated dimethyl ether. Because of the size of the system we employed both DFT (B3LYP/6-311 + G**) and MP2/cc-pVDZ (for selected highly symmetrical structures), which both gave very similar results for this part of the PES (Scheme 2). Encounter complex **20** forms mildly exergonically (−2.1 kcal mol^{-1}, B3LYP/6-311 + G**) and proceeds to a complex of edge-protonated cubane with methyl ether **21** via TS **22**.[31] The barrier for the alternative corner attack (TS **23**) is 7.8 kcal mol^{-1} larger. The geometry of the hydrocarbon moiety of **21** is virtually identical to that of **4**.

Thus, in the FT-ICR experiment the protonation of cubane should give cation **8** (Scheme 1 and Scheme 3).[32] This is followed by deprotonation to give 1,8-dihydropentalene (**24**) after back proton transfer to the base,[33] and this hydrocarbon probably forms in the ICR chamber. The proton affinity of **24** computed at different levels is about 200 kcal mol^{-1}, which is in perfect agreement with the experimental

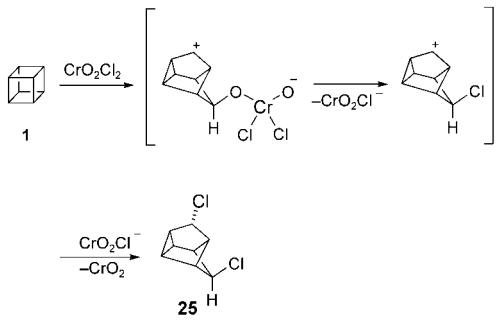
Scheme 2. The proton transfer from protonated dimethyl ether to cubane (ΔG_{298} in kcal mol^{-1}, B3LYP/6-311+G**, MP2/cc-pVDZ, in italics) and the structure of edge-protonated cubane in the complex with dimethyl ether (**21**) at B3LYP/6-311+G** and MP2/cc-pVDZ (in italics).



Scheme 3. The rearrangement of cubane in the protonation/deprotonation process.

value obtained previously for the reaction of cubane with protonated bases.[7,9]

The key conclusion derived from Scheme 1 is that the most favorable follow-up transformation of **4** is the rearrangement to **5** and further to the low-lying cation **7**. Thus, the reaction of cubane with electrophiles should first give a derivative of the tetracyclic cation **7**, which is stable towards deprotonation (to the anti-Bredt olefin) and may be stabilized in solution due to more effective solvation relative to that of cation **8**. These conclusions are fully supported by our experimental observation that the reaction of cubane with the electrophile CrO_2Cl_2 (Scheme 4) gives a single diastereomer of dichloride **25**.[34] This product forms through trapping of the *exo*-4-substituted tetracyclo[3.3.0.0^{2,8}.0^{3,6}]oct-7-yl cationic structure with the reagent.

In summary, we find that both H^+ and $(CH_3)_2OH^+$ favor an edge attack on **1** leading to C–C bond protonated minima (**4** and **21**, respectively) where the positive charge is delocalized over the entire σ cage. However, under the experimental gas-phase conditions protonated cubane **4** can only survive the early protonation stages very briefly because the barriers for rearrangements are simply too low. Careful scrutiny of the $C_8H_9^+$ PES starting from cubane gives 1,8-dihydropentalene (**24**) as the final product along the most favorable protonation/isomerization/deprotonation downhill path. We suggest that hydrocarbon **24** is responsible for the "experimental" proton affinity of cubane measured previously by the ICR technique.

Scheme 4. The experimentally found rearrangement of cubane in its reaction with CrO_2Cl_2.

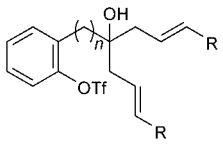
Asymmetric Heck Reaction

Catalytic Desymmetrizing Intramolecular Heck Reaction: Evidence for an Unusual Hydroxy-Directed Migratory Insertion**



Martin Oestreich, Fernando Sempere-Culler, and Axel B. Machotta*

As reflected by a remarkable number of beautiful applications to the synthesis of structurally intriguing natural products,[1] the asymmetric intramolecular Heck reaction[2] has evolved as a prominent carbon–carbon bond-forming process.[3] The invention of asymmetric variants of Heck cyclizations has been approached by two distinct strategies: by indirect[4] and by direct[5] formation of stereogenic carbon centers.

Indirect construction of stereogenic carbons was realized by asymmetric Heck cyclization of prochiral precursors **A** (PG = protecting group), which emerged as privileged substrates for these so-called group-selective cyclizations. How-

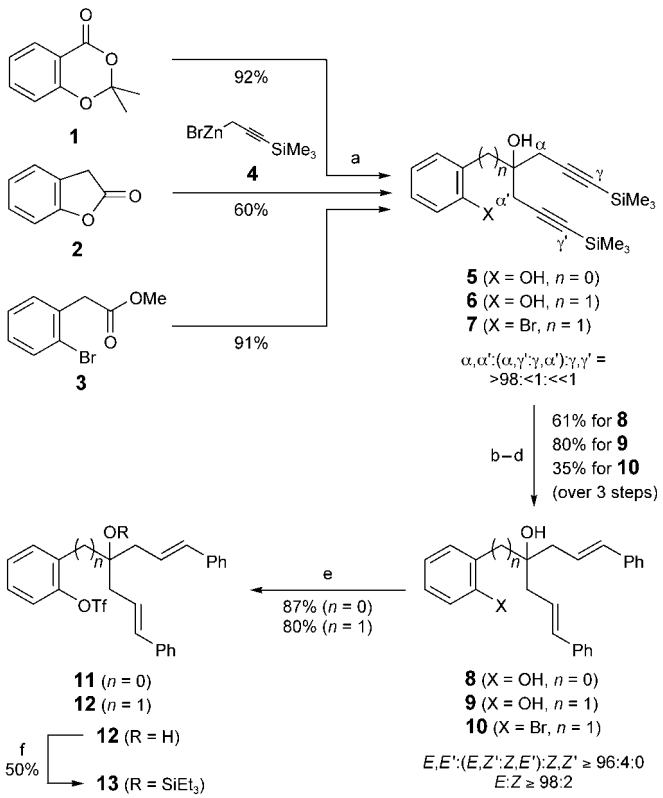
ever, despite elegant investigations by Shibasaki et al.,[6] this methodology appears to be restricted to systems **A** in which the enantiotopic groups are incorporated into a cyclic framework.[7,8] Interestingly, desymmetrizing Heck cyclizations of less rigid systems **B** have not been reported so far.[9]



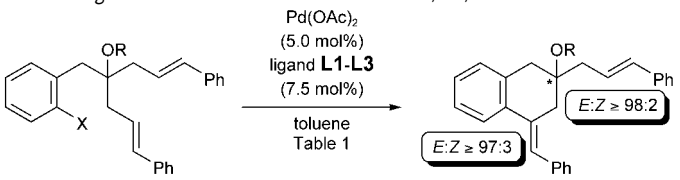
We envisioned compounds **B** as attractive substrates for an exploratory analysis of such desymmetrization reactions. In this paper, we wish to communicate the first catalytic desymmetrizing intramolecular Heck reaction of open-chain precursors **B** as well as experimental evidence for an unusual catalyst-directing hydroxy group[10] in these ring closures.

In the initial phase of the project, we extensively surveyed reaction conditions for the desymmetrization of prototype **B** (R = H, $n = 1$), but the enantiomeric excesses obtained were only moderate ($\leq 40\%$ *ee*).[11] These findings led us to consider the introduction of aryl groups at the terminal positions of the allyl moieties in **B** (R = Ph, $n = 1$). We anticipated that such a modification would have two beneficial effects: 1) prevention of post-Heck double-bond migration on account of the styrene unit and 2) improvement of enantioselectivity due to increased steric hindrance and aryl–aryl interactions.

The requisite cyclization precursors **11** and **12** were prepared starting from acetonide **1** and lactone **2**, respectively (Scheme 1). The direct synthesis of bishomoallylic alcohols from esters by twofold allylation employing γ-substituted allyl metal reagents is rather delicate since there is no general methodology available for controlling regio- and diastereoselectivity. We developed a reliable reaction sequence consisting of regioselective bispropargylation using zinc reagent **4** and diastereoselective reduction with aluminum hydrides.[12] Application of this procedure to **1** and enolizable **2** provided **5** ($n = 0$) and **6** ($n = 1$), respectively, in excellent regio- (**1**→**5** and **2**→**6**) and diastereoselectivities (**5**→**8** and **6**→**9**). Chemoselective triflation of final diol **8** was rather capricious due to the proximity of the hydroxy groups, whereas triflation of **9** proceeded smoothly (**8**→**11** and **9**→**12**, Scheme 1). The preparation of the corresponding aryl bromide **10** was accomplished by the identical protocol (**3**→**7**→**10**, Scheme 1).

When we subjected diene **12** to standard Heck reaction conditions (5.0 mol% $Pd(OAc)_2$, 7.5 mol% (*R*)-binap (**L1**), K_2CO_3, 80 °C) in various solvents,[13a] we were pleased to find exclusive formation of a single isomer **14**[14] with substantially improved enantioselectivity (Table 1, entry 1).[13b] Replacing **L1** by its cognate derivative **L2** resulted in slightly diminished selectivity (Table 1, entry 2); conversely, the novel binap surrogate (*S*)-Cl-MeO-biphep (**L3**),[15] for which applications in asymmetric Heck chemistry are unprecedented,[16] gave the best enantioselectivity (Table 1, entry 3).[17]

Complete conversion accompanied by enhanced enantioselectivity was achieved even at 60 °C and 50 °C (Table 1, entries 4–6). Though, intramolecular migration of the triflyl group (transtriflation) became a competing reaction pathway at temperatures below 50 °C and the prolonged reaction times required. In an attempt to prevent this undesired side reaction, we prepared the silyl ether of **12** (**12**→**13**, Scheme 1). Unexpectedly, cyclization of **13** under reaction conditions identical to those for **12** provided **15** in almost racemic form (Table 1, entry 7). Similarly, the deoxygenated substrate **17** furnished **18** with poor enantioselectivity (Scheme 2).[18]



Scheme 1. Preparation of cyclization precursors **10**–**13**. Reaction conditions: a) **4**, THF, RT; b) TBAF·3 H_2O, THF, RT; c) PhI, $[Pd(PPh_3)_2Cl_2]$, CuI, Et_3N; d) Red-Al ($n = 0$) or $LiAlH_4$ ($n = 1$), THF, RT; e) Tf_2O, 2,6-lutidine, DMAP, CH_2Cl_2, −30 °C→RT ($n = 0$) and $PhNTf_2$, Cs_2CO_3, DMF, RT ($n = 1$); f) Et_3SiOTf, 2,6-lutidine, CH_2Cl_2, 0 °C. DMAP = 4-*N*,*N*-dimethylaminopyridine, DMF = *N*,*N*-dimethylformamide, Red-Al = sodium bis(2-methoxyethoxy)aluminum dihydride, TBAF = tetra-*n*-butylammonium fluoride, Tf = trifluoromethanesulfonyl.

This pronounced effect (88 vs. 0–18% *ee*) indicated that the unprotected hydroxy group plays the pivotal role in the stereochemistry-determining step of the ring closure of **12**. A plausible assumption is that the free hydroxy group acts as a catalyst-directing group. We verified this further by conducting Heck cyclizations of **12** in the presence of equimolar amounts of an alcohol additive (MeOH or *t*BuOH).[19] Consistently, cyclization of **12** furnished **14** in merely moderate enantiomeric excess (Table 1, entries 8 and 9). Obviously, the external hydroxy group interferes with intramolecular coordination of the catalyst by the tertiary hydroxy group of **12**.

Moreover, ring closures of **17** and **12** occur at markedly different rates. Whereas the cyclization of **12** is complete after 20 h at 50 °C, conversion of **17** is low. This accelerating effect also supports the hypothesis that these Heck cyclizations involve intramolecular coordination of the catalyst.[20] Changing the position of the unprotected hydroxy group relative to the aryl triflate moiety had a similar effect. Bishomoallylic alcohol **11**, which produces a five-membered carbocycle, cyclized in low yield and poor enantioselectivity (**11**→**19**, Scheme 3).

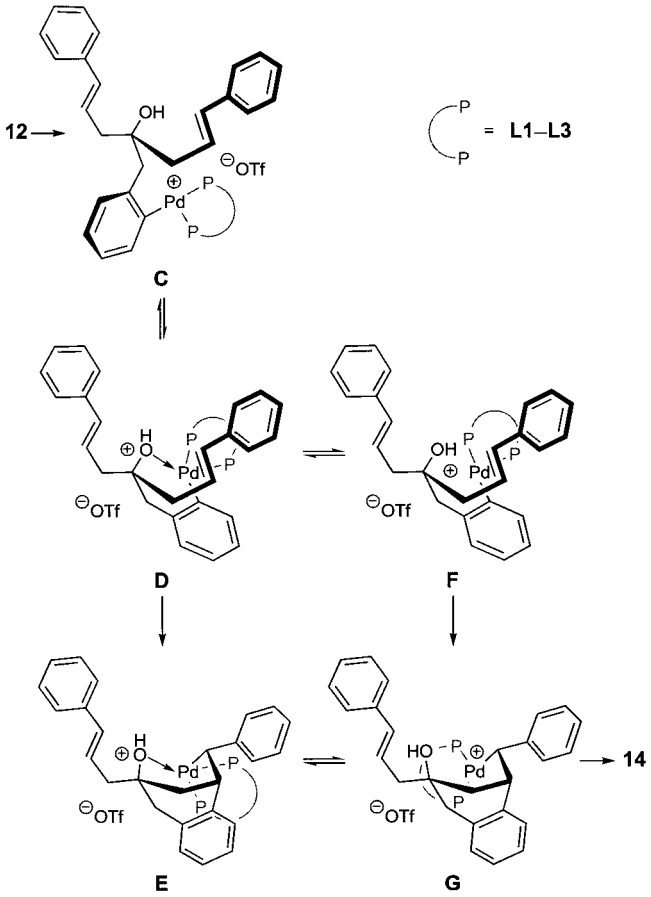
Scheme 3. Desymmetrizing intramolecular Heck reaction of **11**.



To clarify whether the free hydroxy or the corresponding alkoxy group functions as the directing group we screened several bases (Table 1, entries 10–13). Except for strong inorganic bases, all other bases tested had only minor influence on the enantiomeric purity of **14**. In particular, the enantioselectivity is unaffected when NaOAc is added, which implies that the free hydroxy group is possibly operating as a weak ligand for the palladium catalyst.

Coordination of the hydroxy group requires a free coordination site at the palladium center which, in principle, is available under so-called cationic reaction conditions.[2,3] In a control experiment, we performed the Heck cyclization under neutral conditions[21] employing the appropriate aryl bromide **10**. As expected, the level of enantioselectivity was low (Table 1, entry 14). Based on these observations, we propose a mechanism in which the cationic arylpalladium species **C** is reversibly coordinated by the tertiary hydroxy group to form a six-membered ring (**C** and **D**, Scheme 4). The fate of key intermediate **D** is unclear since migratory alkene insertion involving pentacoordinate palladium complexes is not completely understood (**D**→**E**).[21,22]

In our case, a modified scenario appears to be likely: coordination of the hydroxy group in **D** generates a highly ordered transition state which allows for efficient differentiation of the formerly enantiotopic branches. Either a dissociative (**D**→**F**→**G**) or an associative (**D**→**E**→**G**) migratory insertion is a plausible reaction pathway providing **14**. The high enantioselectivity observed for **12** could stem from the ideal proximity of the hydroxy group and the palladium center.[23]

In summary, we have elaborated a catalytic desymmetrizing intramolecular Heck reaction of a structurally novel substrate class. These investigations have revealed a conceptually interesting role of a hydroxy group as a catalyst-directing group in an asymmetric Heck reaction.[10] In addition to further studies directed towards a more refined mechanistic understanding, we are currently exploring the use of chiral alcohols as additional ligands in asymmetric Heck reactions. Application of this methodology to the formal total synthesis of anthracyclines will be reported in due course.[24]

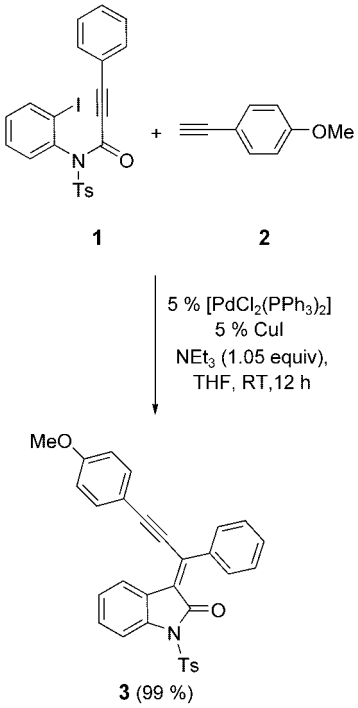
Domino Reactions

A Domino Sequence Consisting of Insertion, Coupling, Isomerization, and Diels–Alder Steps Yields Highly Fluorescent Spirocycles**

*Daniel M. D'Souza, Frank Rominger, and Thomas J. J. Müller**

The coupling–isomerization reaction[1] (CIR, [Eq. (1)], EWG = electron-withdrawing group) of electron-deficient (hetero)aryl halides and (hetero)arylpropargyl alcohols



(1)

under the conditions of the Sonogashira coupling[2] is a mild and efficient route to enones, in particular, to 1,3-di(hetero)arylpropenones, known as chalcones. In the past years this new chalcone synthesis has been applied to novel consecutive one-pot multicomponent syntheses of pharmaceutically relevant heterocycles.[1,3] Mechanistically, the CIR can be rationalized as a rapid palladium/copper-catalyzed alkynylation reaction followed by the slow base-catalyzed isomerization of a propargyl alcohol into an enone. Although the proposed allenol intermediate is elusive and highly reactive, the major potential of the CIR clearly lies in selectively addressing allenol derivative intermediates by thermodynamically and kinetically favored intramolecular trapping reactions. Conceptually, the installation of the electron-withdrawing functionality required for the isomerization step by means of an organometallic elementary step such as the insertion of an alkyne into a carbon–palladium bond[4] followed by a CIR would be more than a methodological extension of the CIR; it could also provide access to heterodomino reactions.[5,6] Here, we describe a new domino reaction based upon a sequence of CIR and the Diels–Alder reaction.

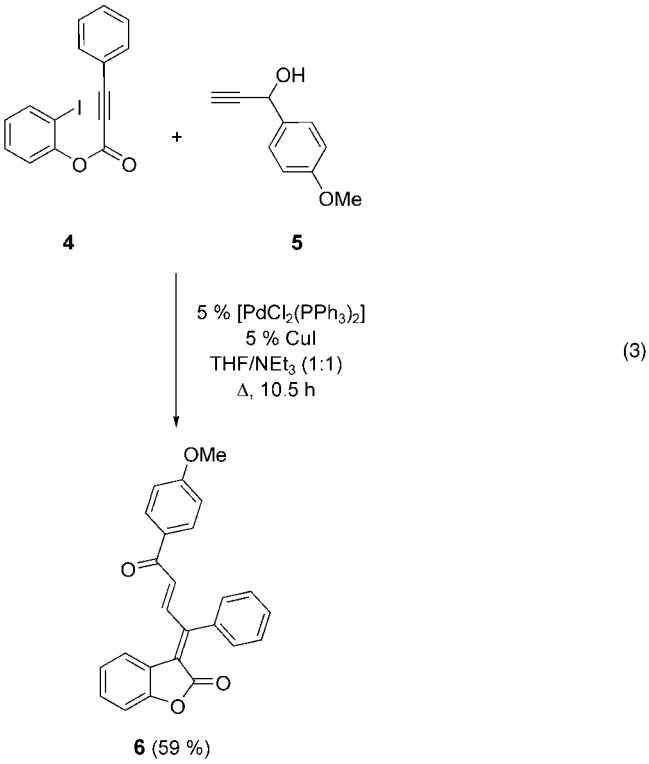
Financial support by the Fonds der Chemischen Industrie and the Dr.-Otto-Röhm Gedächtnisstiftung is gratefully acknowledged. The authors also thank Benjamin Willy for experimental assistance and the BASF AG for the generous donation of chemicals.

Intramolecular Heck reactions[7] have been developed into a widely applied method and have culminated in impressive domino sequences like the Negishi "zipper" reactions;[4] however, the termination of insertion cascades by Sonogashira alkynylation[2] has remained unexplored to date.[8] Therefore, we first tested a Sonogashira sequence with an intermediate alkyne insertion. Upon reaction of *N*-(iodophenyl)alkynamide **1**[9] and *p*-methoxyphenylacetylene (**2**) in THF at room temperature and in the presence of one equivalent of triethylamine and catalytic amounts of $[PdCl_2(PPh_3)_2]$ and CuI the bright yellow dihydroindolone **3**[10] was obtained in quantitative yield [Eq. (2), Ts = tosyl].

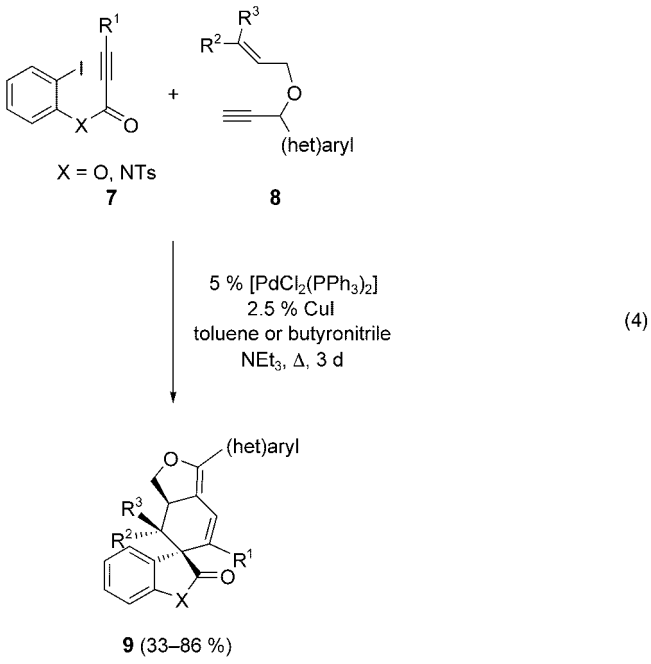


(2)

The *E* configuration of the double bond of the newly formed enyne functionality is unambiguously supported by the characteristic crosspeaks in the NOESY spectrum for interactions between the anisyl protons and the benzo protons in the 4- and 5-positions of the indolone moiety. Mechanistically, this stereospecific formation of the enyne can be rationalized by a sequence of oxidative addition of a palladium(0) species into the carbon–iodine bond of **1** followed by coordination and intramolecular *syn* insertion of the arylpalladium species to furnish a configurationally stable *E*-vinylpalladium derivative. Finally, the terminating intermolecular cross-coupling by transmetalation of the in situ formed copper acetylide and reductive elimination produces the enyne product **3**.

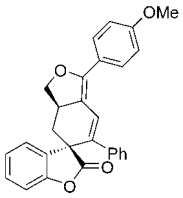
Analogously, the CIR of the *ortho*-iodophenyl alkynoate **4**[9] and the *p*-anisylpropargylalcohol (**5**) in a 1:1 mixture of THF and triethylamine heated at reflux and in the presence of catalytic amounts of $[PdCl_2(PPh_3)_2]$ and CuI furnishes benzofuranone **6**[10] in 59% yield [Eq. (3)]. Thorough NMR spectroscopic analysis (^1H, ^{13}C, DEPT, COSY, NOESY, HETCOR, and HMBC experiments) unequivocally supports

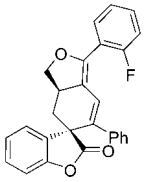
 DOI: 10.1002/anie.200461489 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

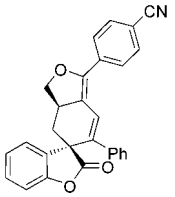


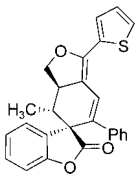
the *E* configurations of the disubstituted enone ($\delta = 6.76$, 9.20, doublets, $^3J = 15.5$ Hz) and the tetrasubstituted double bond generated by the insertion, coupling, and isomerization steps.

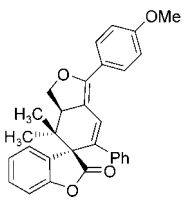
(3)











As a consequence of the insertion–CIR an electron-deficient diene can be readily constructed. For a highly reactive allenol intermediate in the CIR (see above), the transient should be an enallene, a class of particularly reactive dienes in Diels–Alder reactions. Hence, we set out to conduct the insertion–CIR with a propargyl allyl ether, not only to shut off the irreversible allenol–enone tautomerism but also to employ a tethered dienophile functionality as a trap for an intramolecular [4+2] cycloaddition with inverse electron demand. The reaction of alkynoyl *ortho*-iodo ester or amide **7**[9] and propargyl allyl ether **8**[9] in the presence of catalytic amounts of $[PdCl_2(PPh_3)_2]$ and CuI in a mixture of toluene or butyronitrile and triethylamine heated at reflux produces the hitherto unknown class of spiro[benzofuranon-tetrahydroisobenzofurans] and spiro[dihydroindolone-tetrahydroisobenzofurans] **9**[10] in moderate to excellent yields [Eq. (4), Table 1]. In this process the formation of four new carbon–carbon bonds leads to a complex tetracyclic framework with high efficiency.

The structures of the spirocycles **9** were unambiguously supported by spectroscopic (^{1}H, ^{13}C and DEPT, COSY, NOESY, HETCOR and HMBC NMR experiments, IR, UV/Vis, mass spectrometry) and combustion analyses. Additionally, the molecular structure was corroborated by X-ray structure analyses of the benzofuranone **9d** and the dihydroindolone **9h** (Figure 1).[11] Most interestingly, in the crystal structure the thienyl (**9d**) and the phenyl substituents (**9h**) in the 3-position of the isobenzofuran moiety are almost

[a] Reaction conditions: A mixture of 1.0 equiv of **7**, 1.1 equiv of **8** (0.1 M in toluene/triethylamine 1:1 for **9a–e**, in butyronitrile/triethylamine 1:1 for **9f–k**), 0.05 equiv of $[PdCl_2(PPh_3)_2]$, and 0.025 equiv of CuI was heated at reflux for 48–36 h. [b] Yields refer to yields of compounds **9** isolated after flash chromatography on silica gel and crystallization and estimated to 95% pure by NMR spectroscopy and elemental analysis.

addition of the aryl halide **7** to the Pd^0 species generated in situ, the arylpalladium halide **10** intramolecularly coordinates and inserts the tethered triple bond by means of *syn*-carbopalladation to furnish stereospecifically the cyclized vinylpalladium species **11** with a β-acceptor substitution. Transmetalation of the copper acetylide **12** generated in situ gives rise to the palladium complex **13**, which readily undergoes reductive elimination and liberates the electron-poor vinylpropargyl allyl ether **14**. The triethylamine-catalyzed propargyl–allene isomerization furnishes the electron-poor enallene **15**, which reacts in an intramolecular [4+2] cycloaddition to conclude the sequence with the formation of the spirocycle **9** via an *anti-exo* transition state in the Diels–Alder step (as deduced from the X-ray structure analysis of **9d**, entry 4).

Most distinctively, upon irradiation with UV light all members of this new class of spirocycles display a pronounced and intense blue to yellow-green fluorescence with large Stokes shifts in solution and in the solid state (see Figures 2, 3, and 4, Table 2). Therefore, they are promising candidates for a new class of fluorophores with a rigid spirocyclic framework. In the emission spectra of **9** around the same energies a maximum is always accompanied by a shoulder either blue-shifted (**9a**, **9c**, **9f**, and **9g**) or red-shifted (**9h** and **9i**). For the lower energy emission maxima (**9a**, **9c**, and **9f**) the apparent fluorescence color is yellow-green to green, whereas the higher energy bands (**9g**, **9h**, and **9i**) cause a bright blue fluorescence. In a first approximation as derived from the absorption and emission behavior, the excited state structure of **9** shows only a minor dependence of the substitution pattern. In contrast, the absorption properties, as reflected by the longest wavelength maxima, strongly depend on the electronic nature of and the substituents on the conformationally fixed (1*Z*,3*Z*)-1-phenyl-4-(hetero)arylbutadiene chromophor (comparable to *trans-cis*-1,4-diphenylbutadiene). Hence, the Stokes shifts range from 5900 to 7500 cm^{-1}. Most interestingly, upon photoexcitation the model *trans-cis*-1,4-diphenylbutadiene does not fluoresce at

Table 2: Absorption and emission maxima of selected spirocycles **9** (recorded in CH_2Cl_2, $T = 298$ K).

all but undergoes conformational twisting and an efficient internal conversion to return to the ground state.[12] This peculiar behavior of the spirocyclic 1-phenyl-4-(hetero)aryl-butadienes **9** can be attributed unequivocally to a structurally fixed ground-state conformation.

In conclusion, we have developed a new domino reaction consisting of insertion, CI, and Diels–Alder reactions that furnishes spirocyclic benzofuranones and dihydroindolones **9** in moderate to excellent yields. Furthermore, this hitherto known class of spirocycles displays an intense blue to green

fluorescence. Studies addressing the synthetic scope of the domino reaction and the photophysical and pharmacological properties of these new poly(hetero)cyclic entities are currently underway.

Experimental Section

9h: To a deaerated mixture of 6 mL of butyronitrile and 6 mL of triethylamine in an oven-dried screw-cap vessel were added successively **7b** (752 mg, 1.50 mmol), **8g** (330 mg, 1.65 mmol), $[PdCl_2(PPh_3)_2]$ (53 mg, 0.08 mmol), and CuI (14 mg, 0.07 mmol). This mixture was stirred at room temperature for 2.5 h and then heated at reflux temperature for 48 h. The reaction mixture was allowed to cool to room temperature, the solvents were removed in vacuo, and the residue was chromatographed on silica gel (hexane/ethyl acetate, 2:1) and crystallized from pentane/diethylether to give 740 mg (86%) of **9h** as colorless crystals with blue fluorescence, m.p. 219 °C. ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 0.73$ (s, 3H; CH_3), 1.21 (s, 3H; CH_3), 2.44 (s, 3H; CH_3), 3.91 (dd, $J = 10.0$, 12.4 Hz, 1H; CH), 4.23 (dd, $J = 8.7$, 12.4 Hz, 1H; CH), 4.53 (dd, $J = 8.7$, 9.7 Hz, 1H; CH), 6.44 (dd, $J = 1.2$, 8.3 Hz, 2H; CH), 6.68 (dd, $J = 7.5$, 8.2 Hz, 2H; CH), 6.90 (tt, $J = 1.1$, 7.4 Hz, 2H; $CH_{arom.}$), 7.01 (s, 1H; $CH_{olef.}$), 7.19 (m, 2H; $CH_{arom.}$), 7.23 (dd, $J = 1.0$, 7.6 Hz, 1H; $CH_{arom.}$), 7.29 (dd, $J = 1.3$, 7.6 Hz, 1H; $CH_{arom.}$), 7.34–7.45 (m, 4H; $CH_{arom.}$), 7.67 (m, 2H; $CH_{arom.}$), 7.85 (d, $J = 8.4$ Hz, 2H; $CH_{arom.}$), 8.04 ppm (d, $J = 8.2$ Hz, 1H; $CH_{arom.}$); ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 16.8$ (CH_3), 21.6 (CH_3), 21.9 (CH_3), 39.9 ($C_{quat.}$), 47.7 (CH), 62.3 ($C_{quat.}$), 70.2 (CH_2), 109.5 ($C_{quat.}$), 112.8 (CH), 122.8 (CH), 124.4 (CH), 126.1 (CH), 126.2 (CH), 127.2 (CH), 127.9 (CH), 128.0 (CH), 128.5 (CH), 129.0 (CH), 129.1 (CH), 129.5 (CH), 129.6 (CH), 130.7 ($C_{quat.}$), 131.6 ($C_{quat.}$), 134.1 ($C_{quat.}$), 134.9 ($C_{quat.}$), 139.0 ($C_{quat.}$), 141.1 ($C_{quat.}$), 145.1 ($C_{quat.}$), 152.8 ($C_{quat.}$), 174.9 ppm ($C_{quat.}$); EI MS (70 eV): *m*/*z* (%): 573 (M^+, 100), 418 ($M^+ - SO_2C_6H_4CH_3$, 32), 267 (10), 201 (10); HRMS calcd for $C_{36}H_{31}NO_4S$: 573.1974, found: 573.1957; Elemental analysis calcd for $C_{36}H_{31}NO_4S$ (573.7): C 75.37, H 5.45, N 2.44, S 5.59; found: C 75.04, H 5.33, N 2.65, S 5.63.

Bioorganic Chemistry

Unprecedented Lipoxygenase/Hydroperoxide Lyase Pathways in the Moss *Physcomitrella patens***

*Thomas Wichard, Cornelia Göbel, Ivo Feussner, and Georg Pohnert**

Lipoxygenase (LOX) pathways are involved in the production of important signal and defensive metabolites in mammals, higher plants, and algae.[1–4] In these pathways molecular oxygen is introduced into a polyunsaturated fatty acid to form an intermediate hydroperoxide, which may then be cleaved to give shorter chain-length oxygenated products. Interestingly, different principles of transformations have been identified. While plants use almost exclusively C_{18} fatty acids for the production of oxylipins,[1] algae and animals rely predominantly on the transformation of C_{20} fatty acids.[3,5] In animals cleavage of the intermediate hydroperoxy fatty acids is achieved by a dual function of LOXes, while plants and algae rely often on hydroperoxide lyases (HPLs) to produce shorter chain oxylipins.[1–3] Due to their central importance, LOX/HPL pathways have been well investigated in these organisms, but nearly nothing is known about related transformations in mosses. Since mosses are located phylogenetically between higher plants and algae, the biosynthetic pathways are of special interest.

Certain mosses are known to release unbranched unsaturated C_8 and C_9 alcohols and aldehydes, but until now the pathways to and function of these metabolites have not been addressed.[6,7] We report here that the moss *Physcomitrella patens* releases volatile oxylipins upon tissue damage. These include (*E*)-non-2-enal (**4**) known from higher plants, which has a cucumberlike odor, (*R*)-1-octen-3-ol (**1**) (94% *ee*),[8] a major aroma compound from mushrooms, (*E*)-oct-2-en-1-ol (**2**), and (*E*)-oct-2-enal (**3**; Figure 1). In mushrooms (*R*)-**1** is derived from linoleic acid, which is transformed by a 10-LOX and a lyase activity to give (*E*)-10-oxodec-8-enoic acid as a second fragment.[9–11] In higher plants linoleic acid is also a precursor for the generation of (*E*)-non-2-enal (**4**) and (*Z*)-non-3-enal (**8**). There, a 9-LOX and a 9-HPL produce the C_9 aldehyde **8** and 9-oxononanoic acid.[2,12]

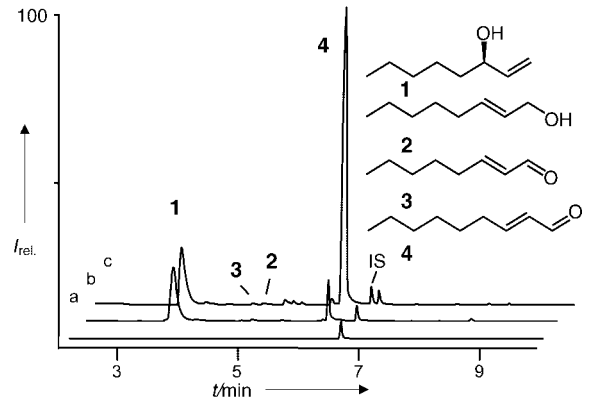

Figure 1. a) GC/MS of the SPM-extract of volatiles from *P. patens*; b) same as a) from the wounded moss; c) same as b) in the presence of 200 μg arachidonic acid (**5**)/~100 mg *P. patens*. IS = internal standard 2-decanone.

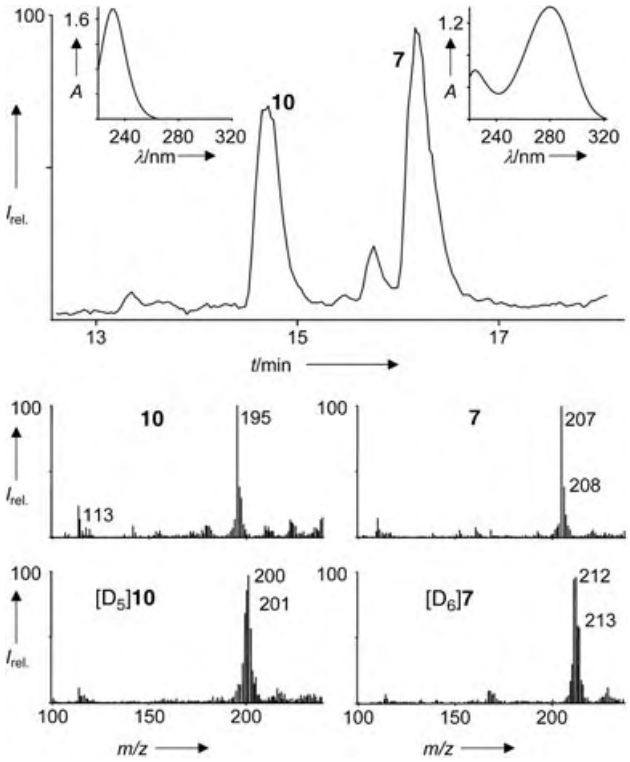
In our investigations on the biosynthesis of the volatile oxylipins from *P. patens* we found that external application of linoleic or α-linolenic acid did not result in significantly increased production of **1**–**4** or related higher unsaturated metabolites. Moreover, neither 10-oxodec-8-enoic acid nor 9-oxononanoic acid, metabolites formed from analogous pathways in plants and mushrooms, were detected. These results imply that mosses rely on other precursors for the generation of **1**–**4**. In contrast to higher plants, *P. patens* is also rich in arachidonic acid (**5**),[13] which could, judging from the position of the double bonds, also be a possible precursor for these volatile oxylipins. Indeed, externally applied arachidonic acid (**5**) was transformed with high efficiency into **1**–**4**. This could be shown impressively by administration of [D_8]arachidonic acid to *P. patens* cell preparations, which resulted in deuterated **1** (>400% labeled), **2**, **3**, and **4** (>1100% labeled) (Figure 1). This surprising fact—arachidonic acid (**5**) has not been identified as a precursor for **1**–**4** in any other organisms—prompted us to investigate the pathways in more detail. Trapping experiments with dimethyl sulfide revealed that an arachidonate 12-LOX is involved in the transformations. Using this reagent, intermediate hydroperoxy fatty acids are transformed into the corresponding alcohols, which are not further metabolized by HPL.[3] In intact moss we found no endogenous hydroxylated fatty acids after reduction; however, after only a few seconds after tissue damage, (*S*)-12-hydroxyarachidonic acid ((*S*)-12-HETE, 83% *ee*), (*S*)-15-HETE (56% *ee*), and minor amounts of nearly racemic 11-HETE were detected. The related 11-hydroperoxide, 11-HPETE, could also be a precursor for the C_9 volatiles, but since it is found only in minor amounts as a racemate, it is most likely an autoxidation product of arachidonic acid and not involved in enzymatic pathways. In the presence of **5** the amount of 12-hydroperoxyeicosatetraenoic acid (12-HPETE, **6**) increased drastically within 30 seconds after wounding and decreased over the next 16 minutes—the time required for the formation of **1**–**4** and oxo-acids (see the Supporting Information). Accordingly, (*S*)-12-HPETE, which arises from the LOX-mediated oxidation of arachidonic acid (**5**), is an intermediate in the biosynthesis of **1**–**4**.

To further investigate the mechanism of fatty acid transformation in *P. patens* we identified the fragments generated from **6** in addition to **1**–**4**. The HPLC-MS chromatograms obtained from *P. patens* preparations before and after tissue damage were used to identify two dominant metabolites derived from fatty acids. The UV spectrum ($\lambda_{max} = 279$ nm) of the less polar metabolite is characteristic for an α,β,γ,δ-unsaturated carbonyl compound, and the mass spectrum suggested an oxidized C_{12} carboxylic acid (Figure 2). These



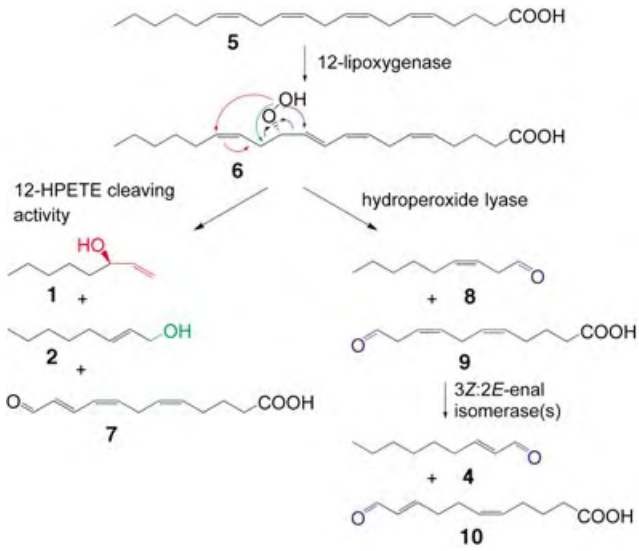


Figure 2. Top: LC/MS of wounded *P. patens* in the presence of 200 μg arachidonic acid (**5**)/~100 mg *P. patens*. The inserts show the UV-spectra of the metabolites **7** and **10**, respectively. Bottom: Negative ionization mass spectra for the unlabeled (above) and labeled (below) oxo-acids after transformation of **5** or [D_8]-**5**.

data matched those of (5*Z*,8*Z*,10*E*)-12-oxododeca-5,8,10-trienoic acid (12-ODTE, **7**) and co-injection with synthetic **7**[14] finally proved the structure. The other metabolites could be identified as 11-oxoundeca-5,9-dienoic acid (11-OUDE, **10**).[15]

These assigned structures are in accordance with biosynthetic considerations on the generation of the oxylipins shown in Scheme 1. The identified structures suggest that **5** is transformed without prior degradation by, for example, β-oxidation, into the hydroperoxide **6**, which then undergoes cleavage to give the oxo-acids and volatiles. This biosynthetic path was further supported by incubations of damaged moss with [D_8]arachidonic acid. Mass spectra of **6**, **7** and **10** showed mass shifts of +8, +6 and +5, respectively, when the labeled acid was present (see Figure 2 and the Supporting

Scheme 1. Proposed arachidonate 12-LOX/HPL pathways in *P. patens*. After administration of [D_8]-arachidonic acid (**5**) [D_8]-HPETE (**6**) can be trapped as intermediate. [D_2]-C8-fragments and [D_6]-**7** as well as [D_3]-**4** and [D_5]-**10** are formed in the subsequent reactions. All 8 deuterium labels of **5** are thus found in the respective intermediates and break down products.

Information). The corresponding high degree of labeling of **6** and the shorter chain oxylipins indicates that **5** is the precursor of all the oxylipins shown in Scheme 1.

These results show that *P. patens* employs hitherto unknown pathways for the production of known LOX/HPL products. The biosynthesis of **1**, **2**, and **4** is initiated by a 12-LOX, which provides **6** as a substrate for HPL or other fatty acid cleaving enzymes. Further transformation of **6** results in the C_8 metabolites **1** and **2** together with **7** as the second fragment (Scheme 1). Interestingly, **7** has been detected previously in arachidonic acid stimulated human platelets.[16] It acts as an agonist towards human neutrophils, presumably interacting with the leukotriene B4 binding site.[17] Compound **7** is also known as deleterious metabolite from diatoms,[18,19] but there (1*E*,3*E*)-octa-1,3-diene results as the second fragment from a 12HPETE.[14] In *P. patens* **6** can also be transformed into (*Z*)-non-3-enal (**8**) and (5*Z*,8*Z*)-11-oxoundeca-5,8-dienoic acid (**9**), presumably by an HPL. In analogy to well-known transformations in higher plants, these intermediates may be transformed quickly by a 3*Z*:2*E*-enal isomerase to give **4** and **10** (Scheme 1).[12,20]

Our findings show that hitherto unknown LOX pathways are involved in the biosynthesis of a multitude of oxylipins in *P. patens*. The moss produces metabolites typical for animals, plants, algae, and mushrooms by new transformations of arachidonic acid, combining in a unique way metabolic themes from all these organisms. Mosses are known to be highly resistant to herbivores and pathogens, and in higher plants this type of resistance is often mediated by lipoxygenases.[21] We are particularly interested in determining if and how the newly identified biosynthetic pathways contribute to the production of putative signal or defensive metabolites involved in this remarkable resistance.

Experimental Section

General: Cultures of *P. patens* were obtained from Prof. Dr. Ralf Reski, Freiburg, and were cultivated as described.[22] Preparation of samples for MS analysis: A 5-mL aliquot of a dense culture was left to settle, and the medium was removed by pipetting. The resulting pellet with a wet weight of 100–200 mg was resuspended in 1 mL of fresh medium and used directly or treated with 20 μL of 10 mg mL^{-1} solutions of fatty acids in EtOH. The suspension was sonicated and cooled in an ice bath for 2 min. For SPME analysis the vial was sealed with a Teflon septum, and a polydimethyldiloxane-coated fiber (Supelco, Taufkirchen, Germany) was inserted for 15 min in the gas phase. Analysis by GC/MS was performed as described.[14] Commercially available reference compounds were used for the identification of **1**–**4**. For LC/MS analysis, the moss preparation was treated 30 s or 16 min after sonication with the same volume of MeOH. The sample was centrifuged for 5 min (12000 rpm), and the supernatant was used directly for analysis on an Agilent HP1100/Finnigan LCQ.

The intermediate hydroperoxy fatty acids were trapped by addition of a 10% solution of dimethyl sulfide in methanol to preparations previously treated with arachidonic acid (**5**). The *ee* value was determined by a known method.[23] For calculation, means of measurements after 30 s, 2 min, 8 min, 15 min, and 30 min were used.

Multimetallic Catalysts in Organic Synthesis

This first book to comprehensively cover this hot topic presents the information hitherto scattered throughout smaller reviews or single book chapters to provide an introduction to this rapidly expanding field.
In ten chapters, the international team of expert authors treats asymmetric syntheses, new transformations, and organometallic reactions using homo- and hetero-bimetallic catalysts. Written for advanced researchers, this very timely publication is of significant benefit to organic and organometallic chemists in both academia and industry.

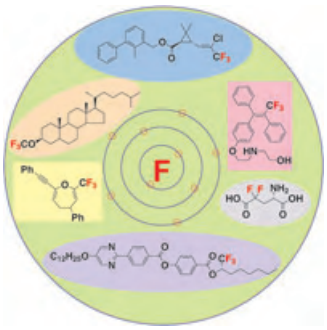
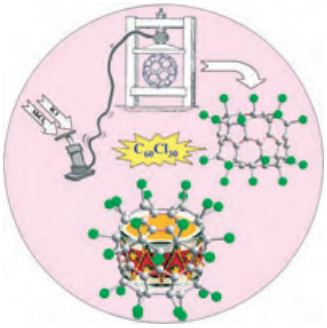
Cover Picture



Lutz F. Tietze,* Konrad M. Sommer, Julia Zinngrebe, and Florian Stecker



A domino reaction consists of several consecutive transformations in which the functions required for one reaction are generated in the preceding bond-formation or fragmentation step. L. F. Tietze et al. applied this concept to the synthesis of vitamin E described on page 257 ff. They developed an enantioselective palladium-catalyzed process for the construction of the chiral chroman framework with 96% *ee* and concomitant introduction of part of the side chain.

Fluorination
The demand for an electrophilic fluorinating agent that is easy to handle, stable, and highly reactive ultimately led to the development of selectfluor. C.-H. Wong and co-workers discuss the applications and reaction mechanisms of this reagent in their Review on page 192 ff.

Organofluorine Compounds
Fluorine substitution can have a dramatic effect on the properties of organic compounds, including pharmaceuticals and materials. Methods for the synthesis of organofluorine compounds are reviewed by T. Hiyama and M. Shimizu on page 214 ff.

Fullerenes
In their Communication on page 234 ff. P. A. Troshin, S. I. Troyanov et al. describe a highly chlorinated stable fullerene consisting of a cylinder-shaped carbon cage.

Selectfluor: Mechanistic Insight and Applications

A versatile reagent: The search for more efficient and readily available sources of electrophilic fluorine culminated in the development of selectfluor (see scheme), which is both highly reactive and safe to handle. This Review presents the myriad of applications of selectfluor and discusses possible reaction mechanisms. The perspectives for fluorinated compounds in medicine and biology are also investigated.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The incorporation of fluorine into organic molecules is a powerful strategy for the discovery of potent biologically active agents and versatile materials that exhibit unique functions (see scheme). The availability of such fluorinated compounds is critically dependent on synthetic fluorine chemistry. Novel synthetic methods for the preparation of a variety of organofluorine target molecules are described.

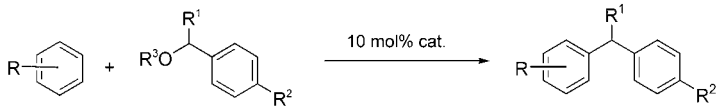
Modern Synthetic Methods for Fluorine-Substituted Target Molecules

Communications



Chlorination of C_{60} with $SbCl_5$, ICl, or ICl_3 at 220–250 °C gives the highly chlorinated fullerene $C_{60}Cl_{30}$. The carbon cage of the $C_{60}Cl_{30}$ molecule has a unique cylindrical shape (see picture), composed of two aromatic six-membered rings located opposite each other and one equatorial aromatic 18π trannulene belt. DFT calculations suggest that $C_{60}Cl_{30}$ is the final product of [60]fullerene chlorination.

The high-nuclearity bismuth oxo cluster $[Bi_{22}O_{26}(OSiMe_2tBu)_{14}]$ (see structure) was obtained by partial hydrolysis of $Bi(OSiMe_2tBu)_3$. A hydrophobic layer of silanolate groups covers the bismuth oxo core, the structure of which is closely related to that of β-Bi_2O_3. Both the bismuth oxo cluster and the bismuth silanolate precursor decompose to give the sillenite-type compound $Bi_{12}SiO_{20}$.

Cluster Compounds

D. Mansfeld, M. Mehring,* M. Schürmann ——— 245 – 249

From a Monomeric Bismuth Silanolate to a Molecular Bismuth Oxo Cluster: $[Bi_{22}O_{26}(OSiMe_2tBu)_{14}]$

Conformation-dependent tuning of color: Starting from aryloxy-substituted perylene bisimides two isomeric diagonally (A) and laterally (B) bridged macrocycles were synthesized (see picture) for three different bridge lengths. These isomers comprise different conformational features and can, therefore, be used as molecular probes to deduce the conformational influence on the optical properties of this important class of fluorophores in solution.

Fluorination Reagents

Selectfluor: Mechanistic Insight and Applications

*Paul T. Nyffeler, Sergio Gonzalez Durón, Michael D. Burkart, Stéphane P. Vincent, and Chi-Huey Wong**

Keywords:
electrophilic addition · electrophilic substitution · fluorination · fluorine · reaction mechanisms

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
DOI: 10.1002/anie.200400648

The replacement of hydrogen atoms with fluorine substituents in organic substrates is of great interest in synthetic chemistry because of the strong electronegativity of fluorine and relatively small steric footprint of fluorine atoms. Many sources of nucleophilic fluorine are available for the derivatization of organic molecules under acidic, basic, and neutral conditions. However, electrophilic fluorination has historically required molecular fluorine, whose notorious toxicity and explosive tendencies limit its application in research. The necessity for an electrophilic fluorination reagent that is safe, stable, highly reactive, and amenable to industrial production as an alternative to very hazardous molecular fluorine was the inspiration for the discovery of selectfluor. This reagent is not only one of the most reactive electrophilic fluorinating reagents available, but it is also safe, nontoxic, and easy to handle. In this Review we document the many applications of selectfluor and discuss possible mechanistic pathways for its reaction.

1. Introduction

The introduction of fluorine substituents into organic molecules has a long history of development. In particular, the development of (diethylamino)sulfur trifluoride (DAST)[1] set the standard by which all nucleophilic fluorinating reagents are compared. Though many sources of nucleophilic fluorine existed, fewer sources of electrophilic fluorine were available. Initially, molecular fluorine was the sole source for electrophilic fluorinations, but because of the ease of $F^{\cdot}$ formation and the extremely dangerous properties of F_2 (highly toxic, strong oxidant with little or no specificity, potential runaway free-radical reactions), the development of alternate sources of electrophilic fluorine was essential. The first electrophilic fluorine reagent, fluoroxytrifluoromethane (CF_3OF), was reported by Barton et al.[2] The introduction of other reagents followed, including perchloryl fluoride ($FClO_3$),[3,4] xenon difluoride (XeF_2),[5] nitrogen oxide fluorides,[6] and several other hypofluorides[7,8] (Scheme 1). Although these reagents served as a safer alternative to fluorine gas and found widespread application in research and industry, the need for a stable and nontoxic form of electrophilic fluorine still remained.

Recently, a new class of electrophilic fluorinating reagents with the general structure $R_2N{-}F$ or $R_3N^+{-}F$ began to gain popularity. In comparison to the previous reagents, these compounds were milder, safer, more stable, and less expensive to produce. Furthermore, some of these compounds proved to be as reactive as established reagents in some cases, while also capable of a degree of selectivity that was previously unattainable. Efforts by Umemoto et al. led to the first isolatable *N*-fluoropyridinium salts, which had good activity and were amenable to commercial production.[9] The important role of the counteranion, which influences the reactivity, selectivity, and stability of the reagent, was also demonstrated.[10] DesMarteau and co-workers later reported the discovery of *N*-fluorobis[(trifluoromethyl)sulfonyl]imide (**2**), accessed by the reaction of bis[(trifluoromethyl)sulfonyl]-imide with fluorine gas (Scheme 2).[11,12] The synthesis of this compound, which is still one of the most powerful sources of

Scheme 1. Electrophilic fluorinating reagents.

electrophilic fluorine, was a step forward in the identification of a stable source of electrophilic fluorine with desirable physical properties. One major drawback of **2** is that it is not commercially available, so that the use of fluorine gas for its preparation in the laboratory is ultimately required. More recently, the development of the reagent selectfluor (**1**, Figure 1) presented a major advance for electrophilic fluorination, as it is a reliable, mild, stable, and effective source of electrophilic fluorine that lends itself to large-scale synthesis and is commercially available. A number of reagents, each with its advantages and disadvantages, currently exist for the electrophilic incorporation of fluorine and have been the subject of several reviews.[13–16] This Review focuses on the versatility of the selectfluor reagent and its applications, and includes some mechanistic insight into plausible reaction pathways.

1

Figure 1. Selectfluor, 1-chloromethyl-4-fluorodiazoniabicyclo[2.2.2]octane bis(tetrafluoroborate).

2. Selectfluor: Properties and Preparation

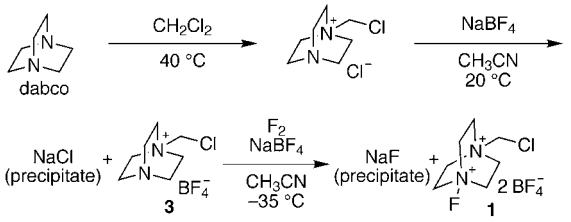
Selectfluor,[15,17] an exceptionally stable, virtually nonhydroscopic crystalline solid, represents a significant improvement on traditional electrophilic fluorinating agents, which require special handling and tend to be synonymous with danger. In an extreme experiment to demonstrate its stability (and to satisfy the United States Department of Transportation regarding the risks associated with transporting a potentially dangerous compound), a self-accelerating decomposition temperature (SADT) test was performed, in which a 55-gallon drum filled with selectfluor was heated to 56 °C for 7 days; during this time the temperature remained constant within ±5 °C.[18] Selectfluor has been found to be stable at temperatures up to 195 °C, although the inventors warn that bulk samples should only be heated above 80 °C with caution.[15] Therefore, a significant advantage of the selectfluor reagent remains its remarkable stability, as a result of which it has become a commercially available, hazard-free source of fluorine.

Compared to F_2, which is extremely toxic, selectfluor is relatively harmless. Toxicology studies revealed an oral LD_{50} (dose needed to kill 50% of the subjects) of 640 mg kg^{-1} for male adult rats; skin exposure up to 2.0 g kg^{-1} led to no lethality in rats.[15,18] Only mild eye and skin irritation was observed in studies with rabbits and guinea pigs. Selectfluor also failed to demonstrate any signs of mutagenic or carcinogenic activity. Studies showed that the ecological and environmental effects of selectfluor were also minor: Its impact on algal growth, sewage-sludge respiration, and the toxicity of several species were found to be within acceptable levels.

Paul T. Nyffeler was born in Stromsburg, Nebraska in 1976. He received his BA in 1999 from Carleton College, where he studied the stereochemistry of enolate reactions under the tutelage of Prof. Jerry Mohrig. He then moved to The Scripps Research Institute, where his ongoing research in the laboratory of Chi-Huey Wong includes the diazotransfer reaction, regioselective azide reductions, fluorinated glycolipids, and the study of dihydrogen trioxide.

Sergio G. Durón received his BS in chemistry from the University of Texas at Austin in 1995. After a year at Hoechst-Celanese, he moved to the University of Illinois at Urbana-Champaign, where he carried out research on the total synthesis of batzelladine A with David Y. Gin. After completing his PhD he pursued postdoctoral studies at The Scripps Research Institute with Chi-Huey Wong on new methods for the one-pot synthesis of complex oligosaccharides and the synthesis of fluorinated carbohydrates. He is currently at Kalypsys, Inc. in San Diego.

Mike Burkart was born in Arlington, Texas in 1972 and received his BA in chemistry from Rice University. During his graduate studies with Chi-Huey Wong at The Scripps Research Institute, he explored the synthetic chemistry of fluorinated carbohydrates and their application as enzyme inhibitors. Following postdoctoral studies with Chris Walsh at Harvard Medical School, he initiated his own research group in 2002 at the University of California, San Diego. His current research interests include natural product biosynthesis and antibiotic design.



Stéphane Vincent received his PhD in bioorganic chemistry from the Université Louis Pasteur (Strasbourg, France) with Charles Mioskowski. After postdoctoral studies first at The Scripps Research Institute in the research group of Chi-Huey Wong and then in Strasbourg with Jean-Marie Lehn, he took up a permanent position as a CNRS researcher in 2001 in the laboratory of Pierre Sinaÿ (Ecole Normale Supérieure, Paris). His research interests include the glycosciences, biocatalysis, and mechanistic enzymology.

Chi-Huey Wong received his BS and MS from the National Taiwan University, and his PhD in chemistry from the Massachusetts Institute of Technology. After a year as a postdoctoral fellow at Harvard University, he moved to Texas A&M University in 1983. He became Professor of Chemistry in 1989 at The Scripps Research Institute (Ernest W. Hahn Chair). His research interests encompass organic and chemoenzymatic methods in synthesis with a specific focus on the study of carbohydrate-mediated biological recognition.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The preparation of selectfluor, which is produced in multiton quantities per year, was designed to be simple, flexible, and efficient.[18,19] The most practical procedure for the production of selectfluor involves the preparation of the precursor **3** by initial alkylation of 1,4-diazabicyclo[2.2.2]octane (dabco, also known as triethylenediamine (TEDA)) with the dichloromethane solvent (Scheme 3). After counterion exchange with sodium tetrafluoroborate and subsequent precipitation of sodium chloride from the acetonitrile solution, fluorination with F_2 provides **1**. Variations on this scheme allow not only the synthesis of commercial selectfluor on industrial scales, but also the preparation of a variety of derivatives with different characteristics and reactivities.

Scheme 3. Method for preparing **1**.[18,19]

The choice of the peripheral alkyl group on the dabco moiety has the greatest impact upon the reactivity and cost of production of the general class of F-TEDA-X reagents, which includes **1**.[15] Derivatives that have been made range from the simple methyl derivative **4a** to the highly reactive 2,2,2-trifluoroethyl derivative **4j** (Figure 2). The most powerful variant of the F-TEDA-X reagents is **4j**, which even fluorinates benzene. In general, the more electron withdrawing the alkyl substituent is, the more electrophilic the fluorine group will be. From an economic standpoint, the chloromethyl derivative **1** is an ideal reagent, as it has the second-highest reactivity and can be synthesized conveniently. The least reactive compounds are those with methyl, ethyl, or octyl substituents. However, all F-TEDA-X derivatives are reactive enough to fluorinate both pyridine and quinuclidine, demonstrating their superior reactivity over *N*-fluoropyridinium and *N*-fluoroquinuclidinium reagents.

Figure 2. F-TEDA-X derivatives. Tf = trifluoromethanesulfonyl.

The counterion employed with selectfluor can have an impact on both the reactivity and the cost of the final compound. In earlier studies, no obvious effect of the counterion on the reactivity had been observed, leading to the commercialization of the tetrafluoroborate salt.[15] However, recent studies demonstrated that the use of the trifluoromethanesulfonate (triflate) salt **4g** for the fluorination of glycals led to decreased side-product formation and higher yields of the desired product than with **1**.[20] This outcome was rationalized by the greater solubility of the triflate salt of selectfluor in the desired solvent (nitromethane) and the fact that no bisfluorinated by-products are formed, a side reaction that occurs with **1**.

The desired counteranion can be introduced by exploiting the low solubility of metal halides in various solvents (Scheme 4).[15,17,18] The procedure involves initial alkylation with dichloromethane, which also serves as the solvent, followed by the addition of lithium tetrafluoroborate, yielding **5a** upon filtration. A different counterion can be incorporated during fluorination by using one of three methods. The first method (Scheme 4, method A), primarily used for small-scale reactions, involves fluorination of **5a** at −35 °C in acetonitrile, then addition of the desired counteranion in the form of the lithium or sodium adduct, filtration, and evaporation. In the second method (Scheme 4, method B), used for industrial-scale production, fluorine is added to a solution of **5a** and the appropriate lithium salt in acetonitrile. This process does not require the separate addition of the salt after fluorination, but does introduce the complication of precipitate formation during the reaction. The third method involves the formation of a Lewis acid (LA) adduct with **5a** prior to fluorination (Scheme 4, method C). On small scales this method is ideal, since no precipitate is formed, and therefore no filtration is needed to provide the pure product. As F_2 gas is used in all methods, either at reduced pressures or diluted with an inert gas such as N_2, any attempts to produce these types of reagents should be undertaken by trained people who are fully aware of the dangers associated with molecular fluorine. Fortunately, because of the efficiency and economic feasibility of this process, selectfluor is commercially available, precluding the need for its preparation.

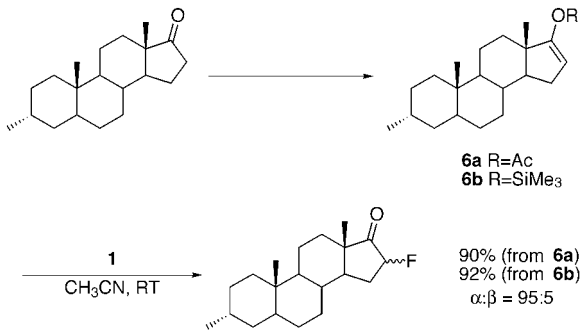
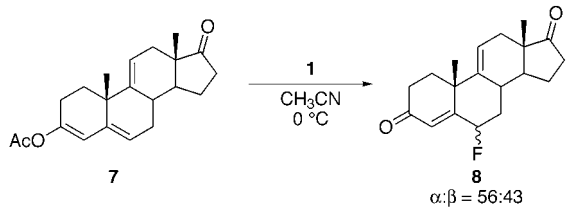
3. Electrophilic Fluorination with Selectfluor



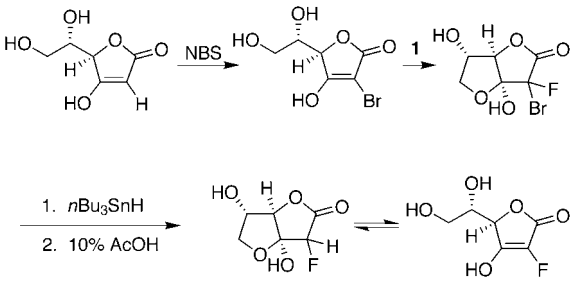
Since the publication of the original patent[19] that described the discovery of selectfluor, the scope of its application has become vast, thus demonstrating the necessity for reagents with the electrophilic fluorination potential of selectfluor. In fact, in a rather remarkable case, Chambers et al. showed that selectfluor is capable of fluorinating unfunctionalized hydrocarbons.[21] Taken together with the examples to follow, there seems to be virtually no end to the number of substrates amenable to transformation by selectfluor.

3.1. Solvent Requirements and Restrictions



As a dication, selectfluor is soluble in only a few polar solvents, namely, acetonitrile, *N*,*N*-dimethylformamide (DMF), and water.[15] Nitromethane may also be used, since it is inert and sufficiently polar to dissolve the reagent.[20,22] Such a solvent is particularly effective when solvent participation, such as that by acetonitrile in glycosylations, is not desired. The use of nitromethane may also be advantageous when acidic conditions have to be avoided, as it precludes the need for a base or proton sponge. Recently, the use of ionic liquids, such as triflate, tetrafluoroborate, and phosphorous hexafluoride salts of 1-ethyl-3-methylimidazolium or 1-butyl-3-ethylimidazolium, for reactions with **1** has received attention.[23,24] As reaction efficiencies are higher for many substrates in these reusable and environmentally friendly media, these studies have opened an interesting avenue for further investigation.

3.2. α Fluorination of Carbonyl Functionalities



The incorporation of a fluorine substituent adjacent to a carbonyl group is a common reaction motif. This transformation can be carried out by initial conversion of the carbonyl functionality into an enol ester (e.g. **6a**) or a silyl enol ether (e.g. **6b**) prior to reaction with selectfluor (Scheme 5).[25] Fluorinated glucocorticoid derivatives are of great interest in the field of medicinal chemistry, and Herrinton and co-workers reported that selectfluor was the best reagent for converting **7** into **8** (Scheme 6).[26] In a further investigation into the effects of fluorine substituents on the behavior of bioactive compounds, Ge and Kirk reported the synthesis of fluorinated derivatives of L-ascorbic acid (Scheme 7) and tetronic acid (Scheme 8).[27,28] The tetronic acid group is found in many important biologically active compounds. By protecting the carbonyl group as a silyl enol ether, Hoffman and Tao were able to synthesize fluorinated peptide analogues with high diastereo- and enantioselectivity.[29] The incorporation of fluorine into β-diketones is readily accomplished by the reaction of selectfluor with the corresponding enolate salts.[25,30] This transformation is not limited to enolates: The sodium salts of some phosphonates have also been fluorinated in moderate yield. Alternatively, α,α-difluoroketones can be formed regioselectively by the reaction of selectfluor with alkynes.[31]

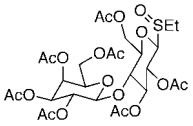
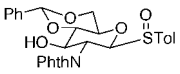
3.3. α Fluorination and Oxidation of Thioethers

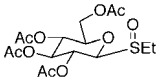
Reactions of thioether-containing compounds with selectfluor lead to interesting synthetic products. For example,

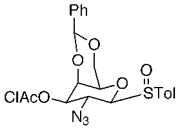
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

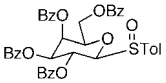
thioethers with α protons can be converted into α-fluorosulfides in reasonable yields (Scheme 9).[25] This process occurs by initial reaction of the sulfide with selectfluor in acetonitrile

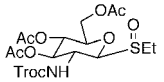


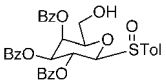


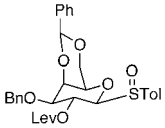


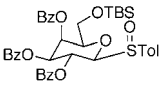


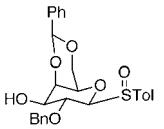












Scheme 9. α Fluorination of thioethers.[25]

at room temperature to form a fluorosulfonium salt (e.g. **9**). It was proposed that this intermediate undergoes a Pummerer-like rearrangement upon treatment with a base, such as triethylamine or 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), providing the α-fluorosulfide product **10**.

Selectfluor is also an excellent reagent for the conversion of thioglycosides into the corresponding glycosyl sulfoxides (Table 1).[20] These reactions are typically complete within 20 min at 0 °C in acetonitrile/water mixtures. Essentially quantitative yields were observed for all substrates examined.

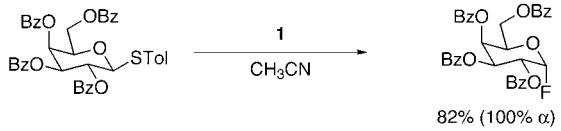


Table 1: Oxidation of thioglycosides to sulfoxides.[20]

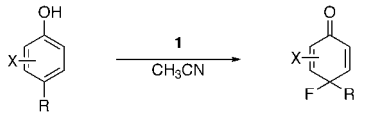
3.4. Synthesis of Glycosyl Fluorides

The inherent thiophilic properties of electrophilic fluorine provide a useful avenue for accessing fluorinated compounds. One possible route is the conversion of thioglycosides into the corresponding glycosyl fluorides with selectfluor (Scheme 10).[32] This method is an improvement on previous methods with DAST, which was successfully used by Nicolaou et al. to synthesize glycosyl fluoride donors.[33]

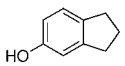
Scheme 10. Direct conversion of thioglycosides into α-fluoro sugars.[32]

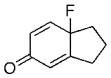
Glycosyl fluorides can be accessed directly from anomeric hemiacetals in one step by using the reagent combination of selectfluor and dimethylsulfide (Scheme 11). This reaction

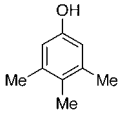
Scheme 11. Proposed mechanism for the substitution of an anomeric hydroxy group for a fluorine substituent in the presence of methyl sulfide and **1**.[20,32]

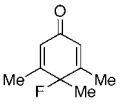


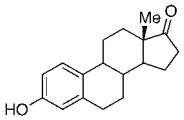
demonstrates the potential of this combination as a safe alternative to potentially explosive DAST for the conversion of alcohols into fluorides.[20,32] Selectfluor was also shown to promote glycosylation with thioglycoside donors in high yields.[20,32] Its application in the glycosylation of 2-deoxy-thioglycosides is exceptional, as other methods of activation fail as a result of the high reactivity of the glycosyl donors.[34]

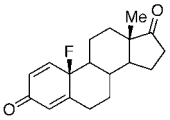












3.5. Fluorination of Aromatic Compounds

Selectfluor has proven to be a competent reagent for the fluorination of substituted aromatic systems. Banks et al. reported that of all the F-TEDA series (Figure 2) only the 2,2,2-trifluoroethyl derivative **4j** fluorinates benzene, albeit in very low yields when aqueous acetonitrile is used (3.5 % after 48 h at 80 °C).[15] Higher yields, up to 20 % conversion, were observed when trifluoroacetic acid (10 % *v*/*v*) was added. Many substituted aromatic compounds could readily be fluorinated with selectfluor.[15] Electron-donating substituents are known to increase the rate of formation and yield of the fluorinated compounds. For example, when methoxybenzene was exposed to **1**, a 1:1 mixture of 2- and 4-fluoro(methoxy)-benzene was obtained in high yield (72 % conversion). Stavber et al. found that substituted phenols are fluorinated by **1**, in an efficient synthesis of 4-fluorocyclohexadienone derivatives (Table 2).[35] Flanagan et al. employed **1** in the synthesis of aromatic fluorescent dyes, which were used in DNA-sequencing.[36]

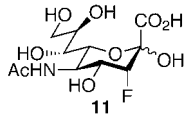
3.6. Fluorination of Alkenes

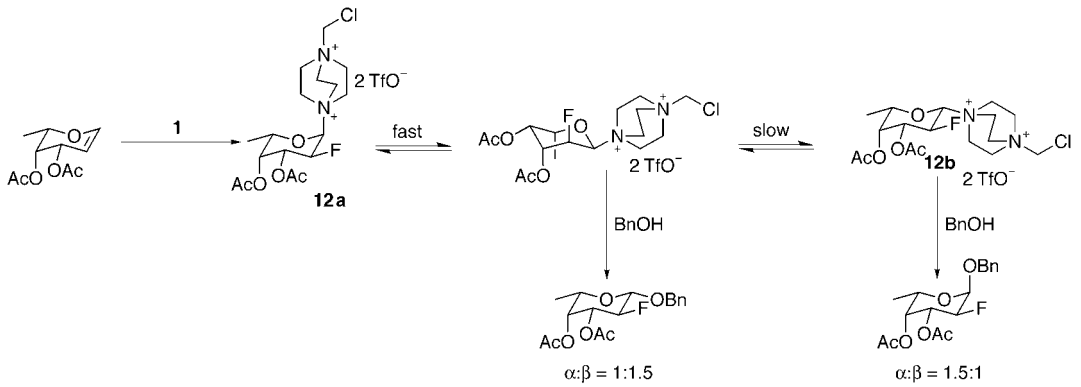
The susceptibility of alkenes to functionalization with electrophilic species provides a convenient handle for fluorination with selectfluor. Lal,[25] as well as Stavber et al.,[37] demonstrated that 1,2-fluoroethers can be prepared from alkenes by treatment with **1** in the presence of alcohols. Stavber et al. studied the kinetics of this reaction[38] and reported that the transformation was not limited to alcohols, but that 1,2-fluoroamides could also be made efficiently with various amines.[39] Castro et al. selectively introduced fluorine into 3-[3-(piperidin-1-yl)propyl]indoles with **1** in excellent yields. One fluorinated analogue had a higher oral absorption than the corresponding nonfluorinated derivative.[40]

Alkenes contained within the enol ether moiety of glycals are also susceptible to fluorination by **1**. Selectfluor is capable of converting glycals into the corresponding 2-deoxy-2-fluoroglycosides in excellent yield (Scheme 12).[20,22,32,41] Many alcohols, including other protected sugars, can be used as acceptors in this reaction. The fluorination and subsequent glycosylation occur as a two-step one-pot reaction. By employing this methodology, 2-fluoroglycosyl derivatives of the cardiotonic oleandrigenin and the antibiotic daunorubicin were accessed in good yields (Scheme 13). The synthesis of fluorinated analogues of current pharmaceuticals



Scheme 12. Proposed mechanism for the fluorination and glycosylation of glycals.[20,22,32,41]

Scheme 13. 2-Fluoroglycosyl derivatives of oleandrigenin and daunomycinone.[20] Piv = pivaloyl.

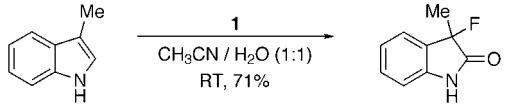


represents a potential avenue for the design of more potent inhibitors.[20] This transformation is not limited to the use of alcohols as acceptors; glycosyl azides, bromides, fluorides, and acetamides can also be formed in high yields starting from glycal precursors. Although pyranosyl glycals are generally employed, furanosyl glycals can also be used successfully. A potential application of this strategy may be the derivatization of 3-fluorosialic acid (**11**) starting from glycal precursors. The resulting products have been shown to be potent selective inhibitors of the influenza virus. They bind to hemagglutinin and neuraminidase, thus limiting the infectious ability of the virus.[42,43]

11

Detailed ^{19}F NMR spectroscopic studies were undertaken to gain insight into the stereoselectivity of anomer formation and fluorination in glycals.[20] These studies demonstrated that **1** adds to the alkene functionality of the glycal in a *syn* fashion, yielding an intermediate of the type **12a**, which then slowly anomerizes to the more thermodynamically stable intermediate **12b** (Scheme 14). Thus, α selectivity is observed if the *syn* adduct has sufficient time to epimerize to the thermodynamically more stable intermediate. Furthermore, it was demonstrated that the steric demands of both the nucleophile and the glycal also play an important role in the anomeric selectivity, with increasing steric bulk favoring α selectivity. Several factors were also shown to influence the efficiency of the reaction. The use of nitromethane as the solvent in lieu of acetonitrile and the replacement of tetrafluoroborate as the counteranion with triflate led to

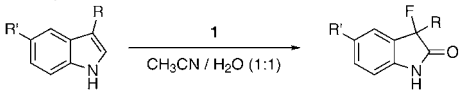
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 14. The conformation and configuration at the anomeric center of the intermediates determine the anomeric selectivity in reactions of glycals.[20]

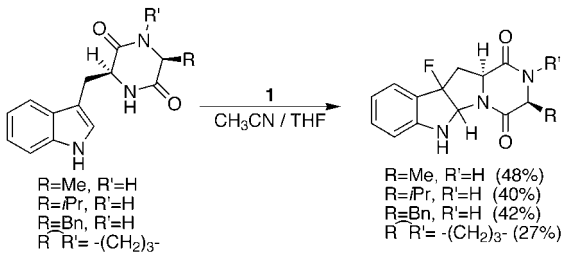
increased yields, decreased reaction times, and a dramatic decrease in the formation of side products. The choice of protecting groups on the glycal and the steric hindrance of the alcohol acceptor had a significant influence on the selectivity of the reaction.

3.7. Electrophilic Fluorination of Indoles



Indoles are convenient precursors in the synthesis of many biologically active molecules, and their derivatives are also useful probes for the study of enzymatic mechanisms and metabolic pathways. Fluorinated analogues containing indole moieties can be useful tools for the elucidation of various biological processes. Indole derivatives can be fluorinated efficiently by using selectfluor to provide various fluorooxindole derivatives (Scheme 15).[44] This method takes advantage of the nucleophilic character of the enamine functionality contained within the indole moiety. The choice of solvent was crucial, as the products decomposed when only acetonitrile was used. Although mixtures of acetonitrile with either methanol or trifluoroethanol were tolerated, the best results were obtained with a 1:1 mixture of acetonitrile and water. The generality of this method was further demonstrated by the successful electrophilic fluorination of other indoles (Table 3, entries 1 and 2), including biologically relevant indoles, such as tryptophan (entry 3), tryptamine (entry 4), and serotonin (entry 5) derivatives. In all cases, their conversion into the fluorooxindoles was efficient.

Scheme 15. Fluorination of an indole.[44]



The functionalization of indoles with selectfluor was further extended to the synthesis of some hexahydropyrazino[1′,2′-1,5]pyrrolo[2,3-*b*]indole-1,4-dione derivatives. This indole moiety is present in a wide variety of natural products, including gypsetin[45,46] and brevianamide E.[47] The synthesis of the fluorinated core of these biologically relevant molecules by using **1** is illustrated in Schemes 16 and 17).[48]

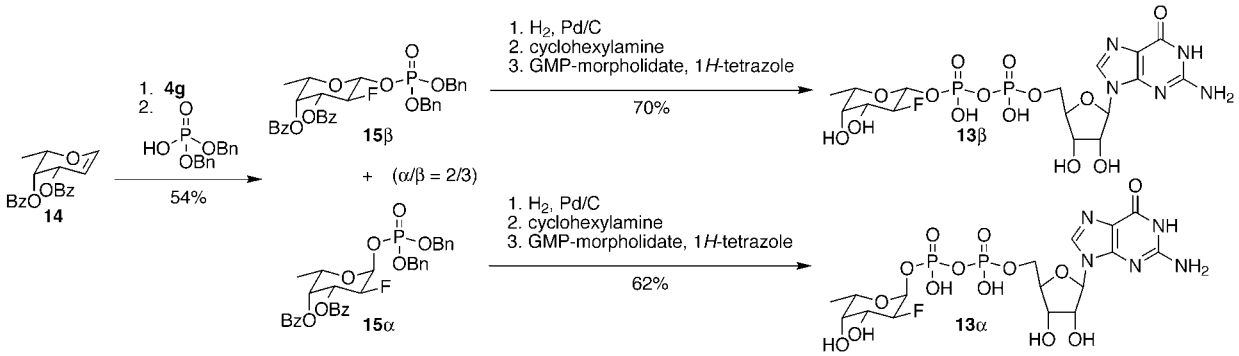
3.8. Synthesis of Vinyl and Alkyl Fluorides

Selectfluor is a versatile reagent for the synthesis of alkenyl and alkyl fluorides. McCarthy and co-workers reported the electrophilic fluorination of vinyl stannanes with selectfluor.[49] Widdowson and co-workers applied this strategy to steroid derivatives containing vinyl stannane groups to prepare fluorinated steroid products (Scheme 18),[50] thus providing a potentially useful method for the synthesis of ^{18}F-labeled steroids for applications in

Scheme 18. Conversion of a vinyl stannane into a fluoride.[50]

positron emission tomography (PET). Greedy and Gouverneur showed that this transformation is not limited to tin-containing species, but that vinyl silanes are also suitable substrates (Scheme 19).[51] The use of 1 equivalent of **1** leads to fluoroalkene products. Interestingly, in the presence of an excess of **1** in acetonitrile, solvent participation in the formation of α,α-difluoro-substituted products was observed. Furthermore, the addition of methanol or water to the reaction mixture led to the incorporation of alcohol and ether groups in the α,α-difluoro-substituted products.

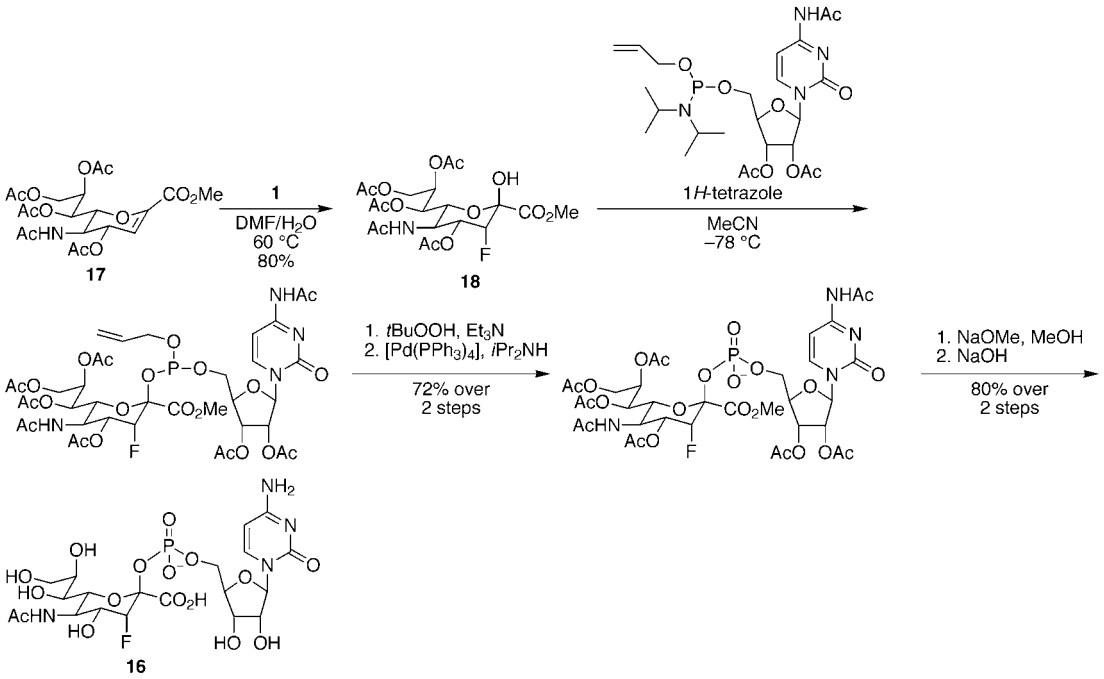
Scheme 19. Conversion of vinyl silanes into fluoroalkanes or α,α-difluoroethers.[51]



3.9. Oxidative Phosphorylation: Synthesis of 2-Fluoro Sugar Nucleotides

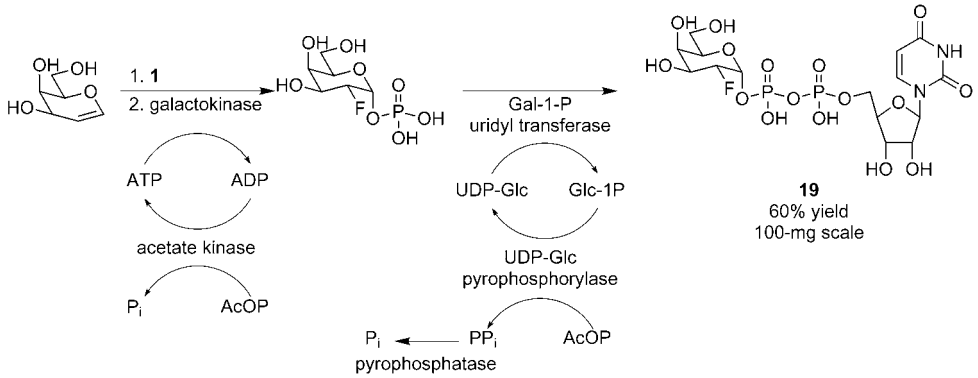
The substitution of the 2-hydroxy group of monosaccharides with fluorine provides useful analogues with which to probe enzyme mechanisms. However, to be introduced into a biological system, the corresponding nucleotide diphosphate must be synthesized, which usually requires many tedious steps involving selective protecting-group manipulations. Recently, new methods for the synthesis of 2-fluoro sugar diphosphates and nucleotide diphosphates with selectfluor have simplified the preparation of these valuable substrates.

The direct oxidative fluorophosphorylation of glycals with selectfluor provides protected 2-fluoroglycosyl phosphates in a one-pot procedure.[20] The synthesis of α- and β-2-fluorofucosylguanine diphosphate (GDP-2F-Fuc; **13**α and **13**β, respectively) is a demonstrative example of this general strategy (Scheme 20). The electrophilic fluorination of 3,4-di-*O*-benzoylfucal (**14**) with **4g**, followed by the addition of dibenzyl phosphate, provided the protected 2-fluorofucosyl phosphate **15** in 54% yield and an α/β ratio of 2:3. After chromatographic resolution, deprotection, and subsequent coupling to GMP-morpholidate, both anomers of **13** were obtained in moderate yield.[52]



N-Acetylneuraminic acid (NeuAc), also known as sialic acid, is a structurally unique carbohydrate involved in many recognition processes of cell surfaces, including viral infection, inflammation, and cell signaling.[42] Synthetic analogues of this monosaccharide have been utilized to probe cell-surface recognition,[53] and could be useful in other areas of research. As the synthesis of CMP-3F-NeuAc (**16**; CMP = cytidine monophosphate) was hindered by the ester group adjacent to the anomeric center, a three-step fluorophosphorylation was employed (Scheme 21).[42] The glycal derivative **17** of sialic acid was treated with **1** in the presence of water to form the hemiacetal **18**, which was phophitylated by using standard phosphoramidite chemistry. Oxidation and palladium-catalyzed deallylation, deacetylation, and saponification then provided the desired product in good yield.

The use of selectfluor to prepare fluorinated monosaccharides is also amenable to the one-pot chemoenzymatic synthesis of sugar nucleotide diphosphates (Scheme 22).[52] The electrophilic fluorination of galactal with **1** was conducted in water to provide 2-fluorogalactose, which, after pH



Scheme 20. Synthesis of α-GDP-2F-Fuc (**13**α) and β-GDP-2F-Fuc (**13**β).[20,52]

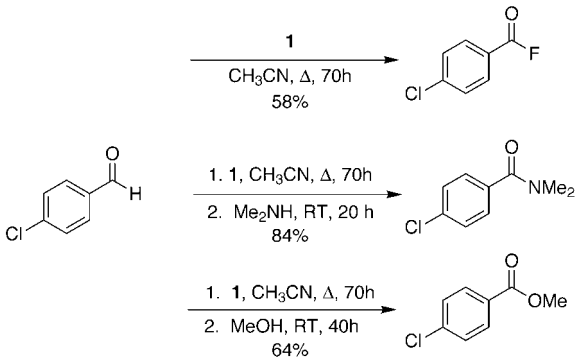
Scheme 21. Synthesis of CMP-3F-sialic acid.[42]

Scheme 22. Chemoenzymatic synthesis of UDP-2F-Gal.[52]

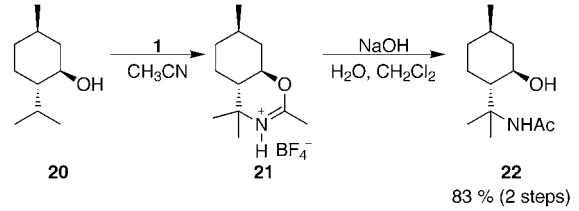
adjustment, was phosphorylated by galactokinase. Adenosine triphosphate (ATP), the phosphate source for this transformation, was generated economically in situ with an ATP synthase and a stoichiometric amount of acetyl phosphate. Upon completion of the reaction, the pH was again adjusted, and galactose-1-phosphate uridyltransferase was added. The desired product **19** is formed in good yield, and the procedure can be carried out on a preparative scale.

4. Other Transformations with Selectfluor



4.1. Oxidation of Benzylic Alcohols

Alongside numerous examples of the use of selectfluor for the electrophilic fluorination of organic molecules, reactions with selectfluor that lead to nonfluorinated products have also been discovered. Banks et al. capitalized on the oxidative properties of selectfluor for the synthesis of benzaldehyde derivatives from benzylic alcohols in moderate yields.[54] The authors postulated that the reaction most likely proceeds through radical fluorination at the benzylic position initiated by a single-electron transfer (SET), followed by the rapid loss of HF to yield the aldehyde product. They also found that **1** could oxidize benzaldehyde derivatives to the corresponding benzoic acids in good to excellent yields via a benzoyl fluoride intermediate (Scheme 23). Furthermore, they demonstrated that aldehydes can be converted into amides and esters in good yields.

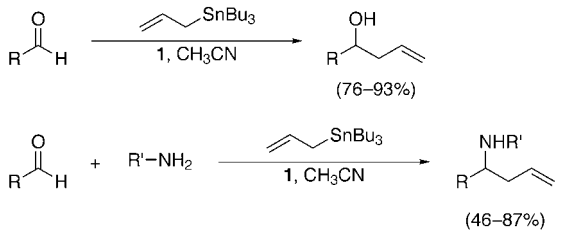


4.2. Oxidation of Tertiary Carbon Centers

In an interesting transformation of (−)-menthol (**20**), remote functionalization of alcohols in the presence of excess selectfluor was demonstrated (Scheme 24).[55] The reaction

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 23. Oxidative functionalization of *p*-chlorobenzaldehyde.[54]

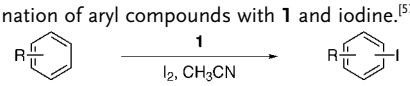


Scheme 24. Remote functionalization of (−)-menthol.[55]

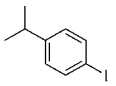
proceeds through initial formation of a tertiary carbocation, which subsequently reacts with the solvent (in this case acetonitrile), and the resulting intermediate is trapped intramolecularly by the alcohol group through a Ritter-like mechanism. The oxazinium salt **21** formed is then hydrolyzed under basic conditions to provide the functionalized menthol derivative **22**. The presence of a tertiary carbon center β to the alcohol group is a prerequisite for this reaction. This method was found to be general, as a similar reaction occurs in propionitrile and butyronitrile, albeit in lower yields. The authors also proposed an SET mechanism to account for the observed transformation.

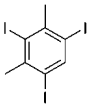
4.3. Selectfluor-Mediated Allylstannation of Aldehydes and Imines

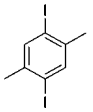
A unique application of selectfluor as a promoter for the allylstannation of aldehydes and imines was reported recently.[56] Generally, strong Lewis acids, such as aluminum trichloride and titanium tetrachloride, which require the exclusion of moisture and strict maintenance of an inert atmosphere, are employed in this reaction. With selectfluor the desired homoallylic alcohols and amines are produced in good yields with excellent tolerance of moisture and air (Scheme 25). The reactions of aromatic and aliphatic aldehydes usually proceed to completion within hours when a stoichiometric amount of **1** is used. With a catalytic amount of **1** (0.05 equiv) longer reaction times (24 h) are required and yields are lower (≈60% conversion). In the absence of selectfluor no product formation was observed. Although the mechanism for this transformation is not well understood, it can be speculated that **1** may act as a Lewis acid to activate the

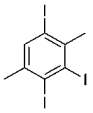


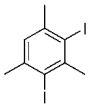
Scheme 25. Allylstannation of aldehydes and imines.[56]









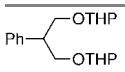


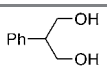
aldehyde for nucleophilic addition. However, one can also imagine that the effective Lewis acid may be the tri-*n*-butyltin cation, formed in conjunction with allyl fluoride from the reaction between allyl(tri-*n*-butyl)tin and **1**.

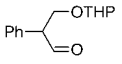
4.4. Selectfluor-Mediated Functionalization of Aromatic Systems

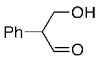
Although selectfluor is most often used as an electrophilic reagent for the introduction of fluorine substituents, it can also mediate the electrophilic addition of other common anions. The inherent electrophilic activity of **1** has been exploited recently for the conversion of nucleophilic compounds into electrophilic reagents. It has been known for some time that selectfluor decomposes in the presence of iodide ions,[15] but when mixed with molecular iodine it forms a potent iodonium source. Stavber et al. reported that alkylated aromatic rings can be iodinated in excellent yield in acetonitrile by using iodine and **1** (Table 4).[57] The reaction

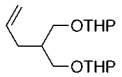
Table 4: Iodination of aryl compounds with **1** and iodine.[57]

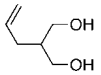


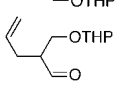


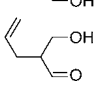












Substrate	Aryl/**1**/I_2	Product	Yield [%]
	1:0.75:0.75		95
	1:0.6:0.6		93
	1:5:5		72
	1:1.5:1.5		89
	1:5:5		73
	1:0.6:0.6		96
	1:1.1:1.1		87

is usually carried out with substoichiometric quantities of the reagents, but when excess I_2 and **1** were used, bis- and trisiodinated products were formed. This transformation is not limited to activated benzene derivatives, as aryl alkyl ketones could be converted into aryl α-iodoketones in excellent yields.[58] A solvent effect was noted in this reaction: With methanol the α-iodoketones were formed, whereas the use of acetonitrile led to aryl iodide species. A three-component mixture of the alkyl aryl ketone, iodine, and **1** was required for any reaction to occur. Selectfluor also proved useful for the conversion of common anions into electrophilic reagents. The reaction of **1** with the sodium or potassium salts of Cl^-, Br^-, SCN^-, and NO_2^- converts the anions into the corresponding electrophilic cations, which are capable of the electrophilic functionalization of a variety of activated benzene derivatives.[59] In general, the potassium salts are more reactive than the sodium salts, and the reactivity decreases in the order $Cl^+ > Br^+ > SCN^+ > NO_2^+$. The reaction is substrate dependent and proceeds faster for some nucleophiles in DMF and for others in acetonitrile. Acetate and trifluoroacetate could be converted into the corresponding electrophilic species for a limited number of substrates, but with other anions (CN^-, OCN^-, CH_3O^-, CH_3S^-) no reaction occurred under any conditions investigated.

4.5. Protecting-Group Removal

Selectfluor is a useful reagent for the removal of some common protecting groups. The protection of alcohols as their tetrahydropyranyl (THP) ethers was reported as early as 1934.[60,61] This protecting group still sees widespread application as a result of its low cost, ease of introduction, and stability. The addition of stoichiometric amounts of selectfluor leads to the selective, mild cleavage of THP ethers in high yields (Table 5).[62] Under these mild conditions, aldehydes and olefins are tolerated. The protecting group *p*-methoxybenzylidene, commonly employed for the protection of 1,3-diols, can also be removed easily in high yields with an excess amount of **1** (Table 6).

Table 5: Deprotection of THP ethers with **1**.[62]

Substrate	Product	Yield [%]
		94
		92
		95
		89

The most useful deprotection by **1** is arguably the cleavage of dithianes (Table 7). Dithianes have found wide application in synthesis as a result of their stability and accessibility. They

		85
		95
		85
		80

are commonly used as umpoled synthons and for the protection of aldehydes and ketones.[63] However, one major drawback to the use of dithiane groups is that mercury salts, which are highly toxic and an environmental hazard, are required for their removal. Selectfluor is capable of cleaving 1,3-dithianes in excellent yields in less than 5 min, with the formation of innocuous by-products.[62] It has been proposed that **1** acts as a Lewis acid in this process, but various other reaction pathways are imaginable, including oxidation.

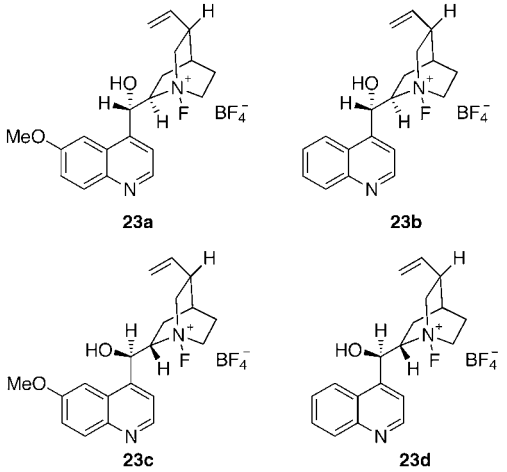
5. Enantioselective Transformations

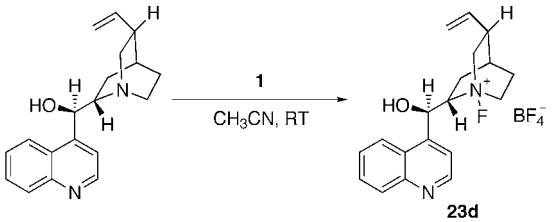
Selectfluor has been utilized, either directly or indirectly, in many types of enantioselective reactions. Enders et al. described the regio- and enantioselective electrophilic fluorination of enantiopure α-silylketones, but selectfluor found limited success in this reaction.[64] Although indirect and substrate-directed enantioselective reactions with selectfluor can be useful, the enantioselective fluorination of nucleophilic substrates has been studied the most intensively.

The first report of an asymmetric α fluorination was by Differding and Lang, who described the enantioselective fluorination of an enolate with camphor-based *N*-fluoro sultams.[65] These chiral electrophilic sources of fluorine provided the anticipated α-fluorocarbonyl compounds upon treatment with various metal enolates. Depending on the substrate, enantioselectivities of up to 70% *ee* were observed.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Improved enantioselective fluorinations were observed with a new class of charged $[N-F]^+$ reagents. Selectfluor was used to prepare the *N*-fluoroammonium derivatives **23a–d** of cinchona alkaloids by transfer fluorination (Figure 3, Scheme 26).[66–68] The fluorinated reagents **23a–d** were





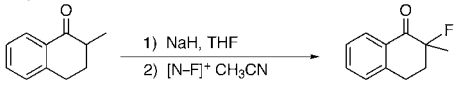


Figure 3. *N*-Fluoroammonium derivatives of cinchona alkaloids for enantioselective electrophilic fluorination.[66–68]

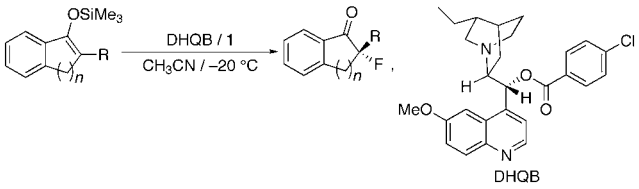
Scheme 26. Synthesis of the fluorinated cinchona alkaloid F-CD-BF_4.[66–68]



tested in the enantioselective fluorination of the sodium enolate of 2-methyl-1-tetralone, providing the product in up to 98% yield and with up to 50% *ee* (Table 8). Higher enantioselectivities (up to 94% *ee*) were later observed with modified *N*-fluoro cinchona alkaloids.[69] In a similar manner, enantioselective fluorinations with a reagent combination of a cinchona alkaloid derivative and **1** were demonstrated (Table 9).[70] This method bypasses the isolation of the *N*-fluoroammonium salt and therefore constitutes a one-pot

Table 8: Enantioselective fluorination with $[N-F]^+$ cinchona alkaloids (see Figure 3).[66–68]

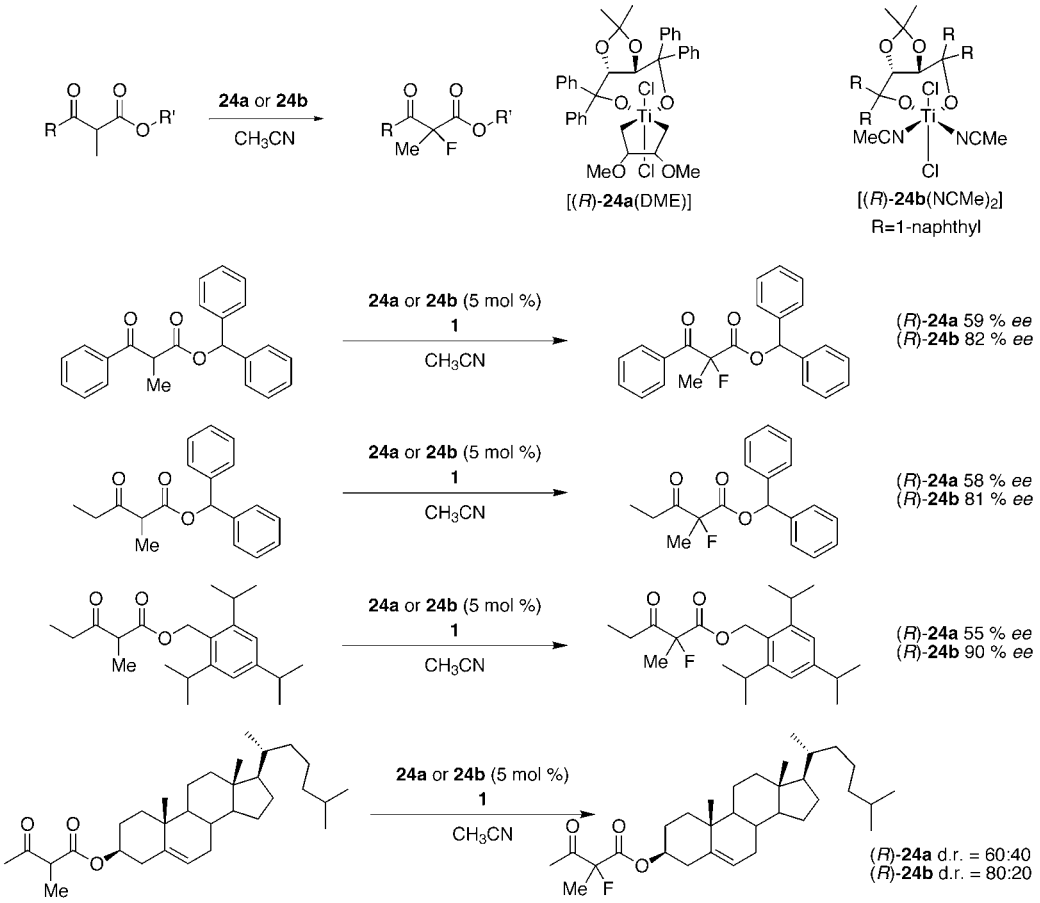
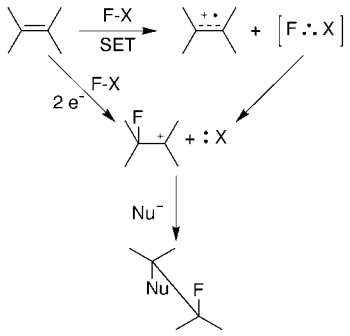
Et	2	67	*R*	71
Bn	2	71	*S*	95



procedure, in which a mixture of the cinchona alkaloid and **1** can be added to a variety of substrate types, including silyl enol ethers. Both cyclic and acyclic carbonyl compounds were fluorinated in good to excellent yields with selectivities sometimes greater than 90% *ee* by this method, which is also useful for β-keto esters (up to 80% *ee*) and acyclic β-cyano esters (up to 87% *ee*). Significant progress has been made in the development of an enantioselective electrophilic fluorination method. In most cases cinchona alkaloids and selectfluor have been used in a transfer fluorination to access the corresponding chiral electrophilic fluorination reagents. This strategy has proved to be very practical, especially because of the commercial availability of the cinchona alkaloid derivatives.

A major breakthrough would be the development of catalytically active enantioselective fluorination reagents. The systematic investigation of the catalytic activity of various transition-metal complexes in the electrophilic fluorination of ketones led to the discovery that the taddol-modified (taddol = α,α,α′,α′-tetraaryl-2,2-dimethyl-1,3-dioxolan-4,5-dimethanol) titanium complexes **24a** and **24b** are highly efficient catalysts for the enantioselective fluorination of β-keto esters (Scheme 27).[71] It was hypothesized that the interaction of the ketoester with the Lewis acidic catalyst induces enolization, and that the resulting enol is then fluorinated enantioselectively with **1**. This mechanistic rationalization is supported by previous reports of a rate enhancement in the fluorination of ketones with *N*-fluoropyridinium salts in the presence of zinc(II) chloride.[10] Further mechanistic details[72] were reported.



6. Mechanism of Fluorination with Selectfluor: Electron Transfer or S_N2 Reaction?

The mechanism of fluorination with N–F reagents has been a subject of debate since their introduction. There are two possible mechanistic pathways: single-electron transfer (SET) or nucleophilic S_N2 substitution. As shown in Scheme 28, both SET and S_N2 pathways lead to the same product, in this case a fluorinated carbocation. Banks and coworkers initially voiced support for a SET mechanism to

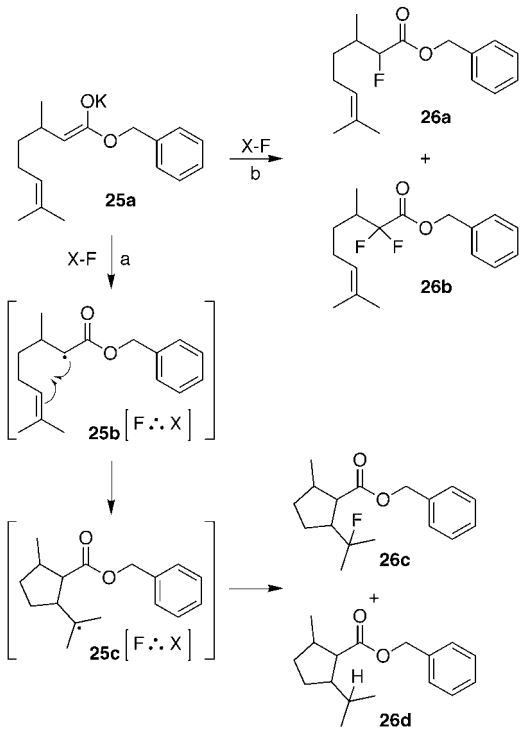
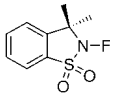
Scheme 27. Catalytic enantioselective electrophilic fluorination with chiral titanium complexes.[71] DME = 1,2-dimethoxyethane.

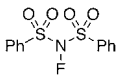


Scheme 28. Single- and two-electron processes in the presence of **1** can result in identical products.

explain reactions with selectfluor,[54] but later spoke of "… a substrate-dependent mechanistic continuum [S_N2(F)↔fully developed SET process] …"[15] As discussed below, the difference between the two mechanisms is probably smaller than it appears, and the limits of current methods to study extremely fast reactions inhibit the definitive elucidation of the operative mechanism.

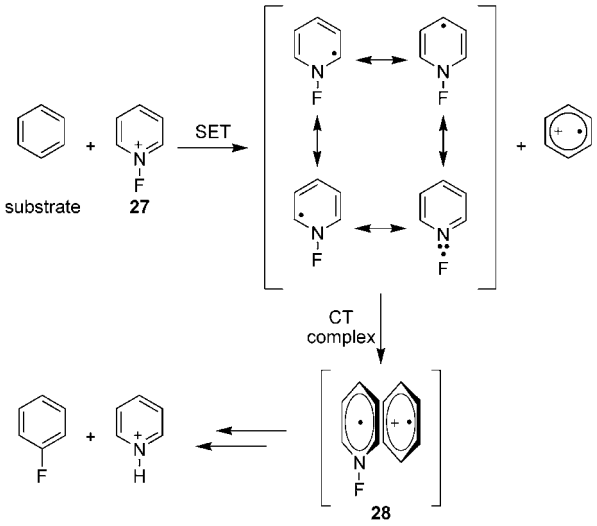
Supporters of the nucleophilic-substitution theory have undertaken creative and elegant experiments to refute the intermediacy of discrete radical species. Differding and co-workers were the first to use radical clocks to monitor the reaction for the presence of intermediate radicals.[73,74] Their experiment was based on the following logic: If the potassium enolate **25a** were to react in an SET process, the resulting radical **25b** would undergo cyclization to the radical **25c** (Scheme 29). The recombination of **25c** and atomic fluorine would produce some amount of **26c** and **26d**, thus proving the existence of radicals in the reaction. Their results clearly demonstrated that no products of cyclization were formed in the reaction, providing support for the notion that electrophilic fluorination does not involve SET (Table 10).





However, other issues have to be taken into account. The cyclization of a 5-hexenyl radical has been shown definitively to occur at a rate of approximately $1 \times 10^5\ s^{-1}$;[75] however, according to Differding and Rüegg, **25b** is not a pure alkyl radical, but is subject to the electronic effects of the adjacent ester group. Furthermore, it was determined by laser flash photolysis that the absolute rate constant for the reaction of atomic fluorine (F•) with a solvent is between 10^9 and $10^{11}\ s^{-1}$,[76] some four to six orders of magnitude faster than the fastest possible closing of a 5-hexenyl radical. Since the reactivity of F• was studied by the abstraction of a hydrogen atom from the solvent and found to be diffusion controlled,[76] the recombination of F• with any alkyl radical should proceed at an equal or greater rate.

The arguments for an SET pathway for fluorination by N–F reagents are quite compelling, but they must be interpreted



Scheme 29. Experimental attempt to differentiate between SET (a) and two-electron-transfer (b) reactions with **25a**.[73,74]

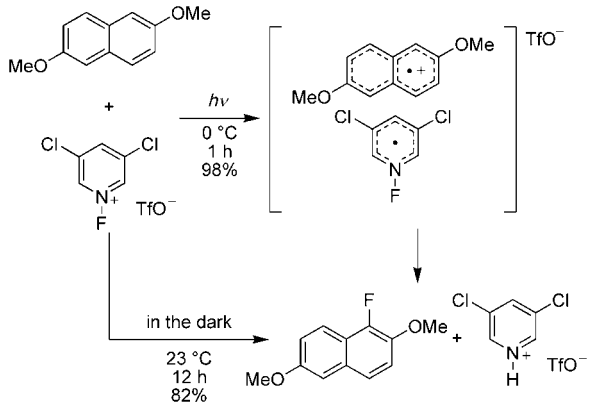
transition state for the SET reaction with organolithium compounds occurs in such an early phase of the reaction that F· reacts with the solvent preferentially, with no formation of the desired product. Kochi and co-workers later suggested that the stability of the organic radicals has a strong influence upon whether fluorinated product is generated, or HF from the reaction of F· with the solvent and numerous other organic side products.[79] In the end, Umemoto may have been correct in his interpretation of the data,[10] but until this question is addressed further, caution should be employed when invoking this argument to support an SET mechanism with N–F reagents.

Much stronger evidence for the SET mechanism was found first by Umemoto et al.[10] and later by Kochi and co-workers.[79,80] Umemoto et al. commented on a color change that occurred when **27** reacted with 2-napthol and a disappearance of the color as the reaction proceeded further. They surmised that the color change was caused by the formation of a π complex between the reagent and the substrate (Scheme 30).[10] Later, Kochi and co-workers attrib-



Scheme 30. Electrophilic fluorination via a charge-transfer (CT) complex as an intermediate.[10]

with caution. Umemoto et al. observed that the reaction of *N*-fluoropyridinium salts with Grignard reagents provided alkyl fluorides, whereas their reaction with the related organolithium reagents did not.[10] They used this finding to justify the notion that N–F reagents react through SET, since Grignard reagents were shown to react in such a manner. However, work by Holm and Crossland showed that Grignard reagents can react by an S_N2 mechanism.[77] Thus, the degree of SET versus S_N2 character of reactions of Grignard reagents depends on several factors. Furthermore, Yamataka et al. reported that organolithium reagents react almost exclusively by SET. They suggested that the rate-determining step is the electron transfer, unlike for Grignard reagents, in which case the recombination of the radicals is the rate-determining step.[78] If both studies are taken together, one possible interpretation of the finding of Umemoto et al. is that the uted this color change to a charge-transfer complex, thus relating the mechanism of electrophilic aromatic fluorination with that of electrophilic aromatic nitration.[79,80] The latter was elegantly shown by Perrin to proceed by SET.[81] Single-electron transfer from the substrate to **27** results in a complex between F· and pyridine, which could be stabilized by the donation of a π electron from pyridine to yield the charge-transfer complex **28**. Kochi and co-workers also found evidence for the participation of the charge-transfer complex as a reaction intermediate by demonstrating that photoexcitation at the CT band led to a dramatic increase in the rate of fluorination and the yield relative to the corresponding thermochemical reaction (Scheme 31).[79]

Selectfluor and the other compounds of this general class are the only electrophilic fluorination reagents for which no clear evidence has been found for the intermediacy of radical

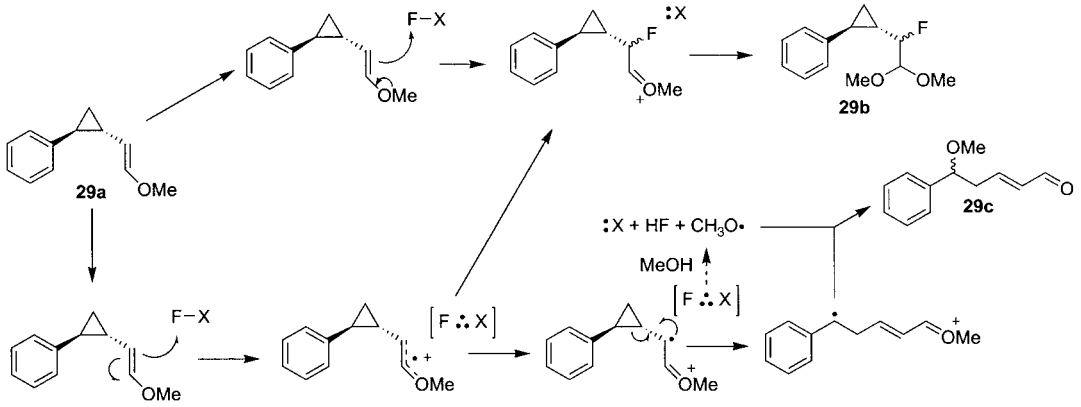
Scheme 31. Comparison of photochemical and thermochemical reaction products.[79]



intermediates. The DesMarteau reagent (**2**, Scheme 2) is inhibited by *p*-dinitrobenzene,[12] an efficient electron-transfer quencher, and *N*-fluoropyridinium reagents display CT bands indicative of SET, as described previously.[10] No evidence for radical intermediates was identified in reactions of **1** with **29a** (Scheme 32),[20] a derivative of a phenylcyclopropyl radical trap that was shown to undergo ring opening at rates as high as $2\times10^{11}\ s^{-1}$.[82] Comparison of the fluorinating reagents **4g** and **30**, which is known to react by the SET mechanism, led to inconclusive results, as **29b** was formed from **29a** in virtually identical yield in the two reactions (Table 11). Furthermore, the findings of Horner et al. indicate that numerous other factors, such as solvent polarity and the choice of nucleophile, may complicate the use of enol ether

Table 11: Yields of isolated products from reactions of electrophilic fluorinating reagents with **29a**.[20]

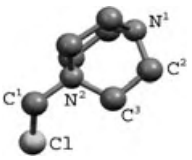
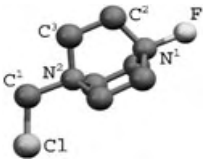
radical traps to detect radical intermediates.[83] However, the fact that 2,2,6,6-tetramethylpiperidine *N*-oxide (TEMPO), which is oxidized by a suitable oxidant (Cl_2, Br_2, XeF_2, etc.) by liberation of a single electron,[84] reacts rapidly with selectfluor[20] strongly suggests that selectfluor can participate in SET reactions. Based on this evidence and on additional data supporting SET with other N–F reagents, it is probable that SET also occurs with selectfluor, but that the radical intermediates are strongly destabilized and therefore unlikely to be detected. As **1**, unlike **2** and **27**, lacks a polarizable p-electron-donor center to stabilize F•, the unstabilized fluorine radical would react immediately with the radical cation formed from the substrate by SET. Thus, the use of radical traps, such as the phenylcyclopropyl radical system,[82] would be inappropriate, since they only measure rates below the diffusion limit. This hypothesis was supported by molecular dynamics calculations performed by Togni and co-workers on a simplified system. Their results indicated that the lifetime of the intermediate radicals is approximately 3×10^{-15} s:[72] roughly 1000 times shorter than the time required for phenylcyclopropylmethyl radical to rearrange. If an SET mechanism were operative in the case of selectfluor, then only the first of two distinct reactions could be monitored: the SET from the substrate to **1**, and not the subsequent recombination of the proximal radicals. As the reaction of F• with the solvent occurs at the rate of diffusion (see above),[76] the reaction of F• with an existing radical must also be at least as fast as diffusion. Hence, the recombination of the carbon-centered radical and F• would most likely occur faster than the rearrangement of the solvent, making solvent interaction, and therefore rates of diffusion, irrelevant. These arguments suggest why selectfluor only displays net S_N2 reactivity.

An explanation for the greater electrophilic reactivity of selectfluor over other R_3N^+–F reagents can most readily be derived from the unique orbital configuration of dabco and from an X-ray crystallographic analysis. Recently, electron momentum spectroscopy[85] confirmed a long-standing theoretical prediction by Hoffmann et al.[86] that the lone pairs of electrons on the two nitrogen atoms of dabco do not occupy the expected orbitals according to classic valence bond theory,[87–89] but instead are delocalized throughout the entire molecule. The discovery that the radical cation of dabco was exceptionally stable[90] was directly attributed by





Scheme 32. Proposed mechanisms for the electrophilic fluorination of **29a**.[20]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Hoffmann et al. to a through-bond interaction in the molecule.[86] Theoretical calculations suggest that "F^+" is ten times more unstable than atomic fluorine.[91] The structural changes that occur upon the fluorination of **31** to give selectfluor (see X-ray crystal structures)[92] suggest that the fluorine center has more radical than "fluoronium" character, as the electron density in the rest of the molecule decreases (Table 12).

Table 12: Structural comparison of the nonfluorinated cation **31** and **1**.[92]

	31	**1**
Structure		
Bond lengths/ interatomic distances [Å]		
N^1–N^2	2.559	2.477
N^2–C^1	1.491	1.525
C^1–Cl	1.760	1.715
Bond angles [°]		
N^1-C^2-C^3	108.61	107.79
N^2-C^3-C^2	108.65	110.59

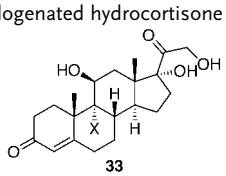
Compensation occurs through a shortening of the C–C bonds, in agreement with the through-bond (not through-space) interactions postulated by Hoffmann et al.,[86] and a simultaneous lengthening of the N–CH_2Cl bond and contraction of the CH_2–Cl bond. The contraction of the CH_2–Cl bond is suggestive of partial double-bond character between the methylene and chlorine centers. Therefore, the resonance structure **31c**, with fluorine as a radical, a double bond between the methylene and chlorine groups, and dabco as a radical cation, is perhaps a more realistic interpretation of the molecular structure of selectfluor (Scheme 33). These results

Scheme 33. Possible resonance structures for **1**.

are consistent with the high reactivity of **1** and its ability to react in an SET process, since the addition of a single electron to this system would allow the formation of F· and restore the electronic state of **31** to that prior to fluorination. Rearrangement of the bonds of **31** would follow, returning it to the more stable configuration determined by crystallography and leaving unstabilized F· to react immediately with the newly formed carbon radical.

Despite extensive research into the possible reaction mechanisms of N–F reagents, a definitive answer has not been found and may remain undiscovered as a result of the difficulty of assessing reactions in this timeframe. Even if a reaction were known to proceed exclusively by SET followed by radical recombination, the two reactions might occur in such rapid succession that the intermediate is not detected. William Jencks once wrote, "An intermediate is, therefore, defined as a species with a significant lifetime, longer than that of a molecular vibration of $\sim 10^{-13}$ s, that has barriers for its breakdown to both reactants and products."[93] When reactions proceed at rates greater than 10^{11} s^{-1}, arguments for or against an SET mechanism become pointless. In our view selectfluor is capable of reacting through an SET mechanism, as evident by its reaction with TEMPO, but in the case of electrophilic fluorination the radicals, if formed at all, react too quickly to be detected. Thus, based on our previous work,[20] the only definitive answer is that if SET is occurring, the radicals involved react faster than rates of diffusion, and anything beyond that will probably remain unproven.

7. Selected Applications of Fluorinated Compounds



The fluorination of molecules has many applications in organic chemistry. For example, the high electronegativity of fluorine can be used to modulate the electronic properties of a molecule, and ultrasensitive ^{19}F NMR spectroscopy is a useful analytical technique for monitoring reactions and obtaining molecular information (e.g. by Mosher ester analysis for the determination of enantiomeric excess).[94,95] However, the applications of fluorinated molecules in biology are even more intriguing. Perhaps the oldest examples of fluorinated biologically relevant molecules are salts of fluoroacetate, the active component of the poison derived from the South African gifblaar plant (*Dichapetalum cymosum*).[96] Biochemically, fluoroacetate is converted into fluoroacetyl CoA, which enters the tricarboxylic acid (TCA) cycle. Fluoroacetyl CoA condenses with oxaloacetate to form fluorocitrate (an effective inhibitor of aconitase), which shuts down the TCA cycle, resulting in convulsions, ventricular fibrillation, and death.

7.1. Fluorinated Glucocorticoids

The first reported use of fluorination to enhance the activity of a medicinally useful compound was by Fried and Sabo in 1954.[97] A year earlier, they had described the synthesis of derivatives of the glucocorticoid hydrocortisone (**33a**), a steroid hormone with anti-inflammatory and thymolytic activity. Substitution of the 9-αH atom of hydrocortisone acetate for an iodine, bromine, or chlorine atom resulted in an increase in activity relative to that of the natural compound only in the case of the chlorine derivative **33c**.[98] The general trend in this series suggested that the activity was inversely proportional to the size of the halogen substituent, thus prompting the synthesis of the fluorinated derivative.[97] As can be seen in Table 13, **33b** is more than ten times as active as naturally occurring hydrocortisone; more importantly, these studies established fluorination as a promising method for improving the activity of pharmacologically relevant compounds. Several examples of fluorinated glucocorticoids and their corresponding activities can be found in Figure 4.[99] As

stated previously, Herrinton and co-workers determined that **1** is a highly efficient fluorinating reagent for the synthesis of **8**.[26]

7.2. Fluorinated Glycosyltransferase Inhibitors

Carbohydrates with a fluorine atom adjacent to the anomeric center demonstrate inhibitory activity towards some glycosyltransferases and allow insight into enzyme mechanisms.[100] Given the important role of oligosaccharides in biological processes, the selective inhibition of certain mammalian glycosyltransferases could be a potential strategy against cancer proliferation, xenotransplant rejection, and tissue inflammation. Fucose, sialic acid, and galactose moieties in particular are essential components of oligosaccharides and determinant structural motifs for specific biological phenomena.

The inhibition of several glycotransferases by fluorinated sugars has been investigated by our research group.[52,101] Four different fucosyltransferases were chosen for this inhibition study (FucT-III, V, VI, and VII), as well as α-2,6-sialyltransferase and two galactosyltransferases (the configuration-inverting bovine β-1,4-GalT and the configuration-retaining α-1,3-GalT). For FucT, the fluorinated fucose analogues **13α**, **13β**, and **34** displayed K_i values that were similar to or less than the K_M value for GDP-Fuc (Table 14). Similar results were obtained for the inhibition of sialyltransferase with **16** (Table 15). The K_i value for the inhibition of β-1,4-GalT by α-

Table 14: Inhibition of four human fucosyltransferases.[52,101]

	GDP-Fuc	 **13β**	 **34**	 **13α**
	K_M [μM]	K_i [μM]	K_i [μM]	K_i [μM]
FucT-III	33.6	38 ± 4	22 ± 10	–
FucT-V	18.8	4 ± 0.6	3.4 ± 1	36 ± 4
FucT-VI	9	10 ± 2.4	1 ± 0.5	2 ± 1
FucT-VII	8	21 ± 2	11 ± 2	–

Table 15: Inhibition of a sialyl- and two galactosyltransferases.[52]

Glycosyltransferase	Inhibitor	K_i [μM]
α-2,6-SialylT (K_M = 15 mM)	 **16**	5.7 ± 2
β-1,4-GalT (K_M = 3 ± 6 mM)	 **19**	2.0 ± 0.3
α-1,3-GalT (K_M = 17 ± 3 mM)		245

UDP-2F-Gal (**19**) is approximately equal to the K_M value for the enzyme with the natural substrate, but for the inhibition of α-1,3-GalT, the only configuration-retaining enzyme in the study, a K_i value was observed that was 14-fold lower than the K_M value with the natural substrate.

Earlier mechanistic studies with FucT-V demonstrated a secondary isotope effect with deuteriated GDP-[1-^{2}H]-fucose and competitive inhibition by **12β**.[101] Similar inhibition patterns were found for FucT-III, VI, and VII.[52] Given the 90% homology between these enzymes, it was proposed that they may share a considerable number mechanistic features, including the formation of an oxycarbenium-like transition state. These considerations also took into account the inhibition of fucosyl transferases by **34**. Evidence suggests that the replacement of the hydroxy groups at the 6- or 2-position, equidistant from the endocyclic oxygen atom, leads to similar electronic effects—a potentially valuable result for future inhibitor design. The good inhibition observed with the anomerically nonnatural **13α** indicates that the binding

domain of fucosyltransferases allows stereochemical flexibility.

Recent syntheses of potent inhibitors of α-2,6-sialyltransferase have elucidated important conformational parameters of the transition-state structure, including sp^2 character at the anomeric position.[102–106] However, a cationic transition state, predicted based on the quaternary structure at the anomeric carbon atom, has not yet been demonstrated. CMP-3F-sialic acid (**16**) has been found to be a competitive inhibitor (K_i = 5.7 μM), thus supporting the involvement of an oxycarbenium intermediate in the transition state.[42]

Interesting results were obtained with galactosyltransferases.[52] The configuration-inverting β-1,4-GalT was as susceptible to competitive inhibition by **19** as other inverting glycosyltransferases (Figure 5), whereas the configuration-

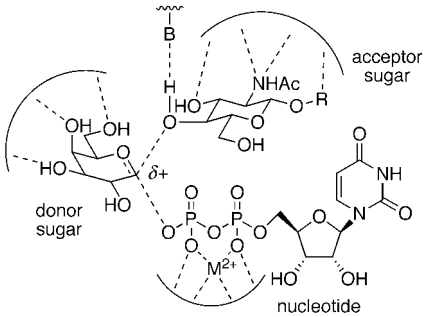

Figure 5. Putative transition state for configuration-inverting β-galactosyltransferase.[52]

retaining α-1,3-GalT was only weakly inhibited (K_i = 245 μM, K_M = 17 μM). These results suggest that the mechanisms by which these two galactosyltransferases catalyze the glycosylation may be strikingly different. This would be consistent with the differences observed for the glycosidases as a function of their inverting or retaining nature.[107] Since a double displacement mechanism could rationally be invoked for the retaining α-1,3-GalT, experiments were conducted to determine whether **19** was a slow inactivator of this enzyme. On the time scale of the experiments performed, no inactivation was observed, demonstrating that the enzyme does not form a covalent adduct with the fluorinated substrate **19**. In the case of various retaining glycosidases, 2-fluoroglycosides had been shown to form covalent adducts, which is evidence of the nucleophilic role of carboxylate groups present in the vicinity of the anomeric center. Indeed, some 5-fluoroglycosides proved to be better, albeit very unstable, inactivators than the corresponding derivatives fluorinated at the 2-position.[108]

7.3. Electrophilic Fluorination for ^{18}F Positron Emission Tomography

The use of radioactive isotopes for chemotherapy and the elucidation of reaction pathways is well established. Another useful application for certain nuclei that decay through positron (β^+) emission is positron emission tomography (PET).[109] For some nuclei of small atomic mass, radioactive decay occurs by the emission of a positron, which is a positively charged particle with the mass of an electron. Collision of a positron with an electron results in annihilation and the release of a gamma-ray photon. The radiation can be analyzed by a photomultiplier in similar way to the detection of X-rays. A substance containing a β^+ emitter can be introduced into a living organism and then localized noninvasively by detecting the emitted gamma rays in a 3D image of the organism.

Common positron-emitting nuclei include ^{11}C, ^{15}O, ^{13}N, and ^{18}F (Table 16). ^{18}F has a relatively long half-life of almost

Table 16: Physical properties of β^+-emitting radionuclides.[109]

Radionuclide	$t_{1/2}$ [min]	β^+ decay [%]	Maximum specific activity[a]	Maximum energy [MeV]	Maximum linear range in H_2O [mm]
^{11}C	20.40	99	3.4×10^{11}	0.96	4.12
^{13}N	9.96	99	6.9×10^{11}	1.19	5.39
^{15}O	2.07	99.9	3.4×10^{12}	1.72	8.2
^{18}F	109.70	97	6.3×10^{10}	0.635	2.39

[a] Defined as the number of decay events per second per mole.

2 h, which makes it possible to carry out synthetic manipulations on substrates without significant loss of activity. The other nuclei must be used immediately upon formation (usually occurs in a cyclotron) because of their shorter half-lives. ^{18}F-labeled reagents can be delivered to nearby sites, such as hospitals and universities, making research more practical. Finally, the positrons emitted from ^{18}F have much lower kinetic energy than those from the other nuclei, which translates to shorter distances between emission and annihilation, and thus to higher resolution.

Fluorination with ^{18}F is limited by the small number of labeled reagents that can be made. The bombardment of ^{18}O-labeled water with high-energy protons results in the absorption of a proton by each ^{18}O nucleus, followed by the emission of a neutron, to provide nucleophilic ^{18}F ions, which can be separated by ion exchange. Alternatively, the absorption of a high-energy deuteron by a ^{20}Ne nucleus in a gas mixture of Ne with 0.1 % F_2, followed by the emission of an α particle, gives $^{18}F_2$ gas for electrophilic fluorination. Labeled molecular fluorine has been used directly for electrophilic fluorinations, but it has also been converted into other electrophilic fluorinating reagents, such as acetyl [^{18}F]fluoride ($AcO^{18}F$),[110,111] [^{18}F]fluoropyridones,[112,113] [^{18}F]fluoro-*N*-sulfonamides,[114] and labeled xenon difluoride ($Xe^{18}F_2$).[115,116]

The use of ^{18}F and other positron-emitting nuclei necessitates fast and simple chemistry, as well as safeguards against the dangers of handling radioactive material. All manipulations for the synthesis of ^{18}F-labeled compounds (including purification) must be completed in approximately 1–2 h to ensure sufficient active material for clinical use. The use of automated synthesizers and robotics has shortened the length of time needed to synthesize compounds and eliminates the dangers associated with the handling of radioactive material.

Many different applications of ^{18}F-labeled compounds in PET have been described. The first ^{18}F-labeled compound to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

be used in PET was [2-^{18}F]fluoroglucose for monitoring glucose metabolism in organs.[117–119] This method is still the most popular use of PET, with applications in oncology, cardiology, and neurology. Dopamine metabolism can be monitored by ^{18}F-labeled L-DOPA, a technique that is useful in neurological diseases, such as schizophrenia and Parkinson's disease (DOPA = 3-(3,4-dihydroxyphenyl)alanine).[120] Steroids labeled with ^{18}F have been used to image breast and prostate tumors.[121]

The development of ^{18}F-labeled selectfluor would revolutionalize electrophilic fluorination in much the same way as the development of the unlabeled reagent, and would enable the synthesis of labeled compounds with more complex structures by existing methodologies. For example, the synthesis of the fluorinated daunorubicin analogue in Scheme 13 can be carried out quickly enough that ^{18}F could be introduced.[122] As the use of PET as a noninvasive imaging technique becomes more widespread, there will be increased demand for new methodology for the incorporation of ^{18}F into molecules of interest in a safe, efficient, and selective manner. Because of its general applicability, high reactivity, and safety, selectfluor is a reagent with great potential for the development of new fluorination methods.

8. Conclusion

Electrophilic fluorination is an extremely useful and viable method for the incorporation of fluorine into organic molecules and a natural complement to nucleophilic fluorination. Although initially molecular fluorine was the only available reagent, the demand for a safe alternative has led to a plethora of reagents that deliver fluorine effectively under electrophilic conditions. Over the years the development of safer and milder reagents ultimately led to the discovery of selectfluor, which now represents the hallmark for stability, reactivity, and mildness within the realm of electrophilic fluorinations. Furthermore, the unique reactivity of selectfluor enables deeper insight into complex reactions and demands new experiments and methods to probe the underlying mechanisms.

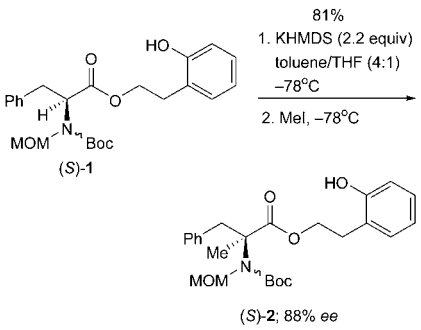
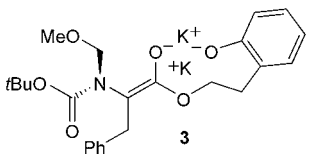
Asymmetric Synthesis

Recent Developments in the Transfer of Chirality within Enolate Alkylation Reactions



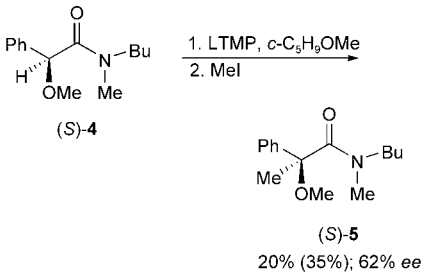
Jason Eames and Michael J. Suggate*

Keywords:
alkylation · asymmetric synthesis · conformational chirality · enantioselectivity · enolates



The transfer of chirality within asymmetric synthesis is very well documented.[1] Over the last 25 years, a significant number of these reports have focused on the transfer of chirality from covalently bound chiral auxiliaries to prochiral enol(ate)s.[2] Since 1990,[3] the use of chiral enolate complexes (obtained through complexation of chiral Lewis acids to achiral enol(ate)s) has become more commonplace.[4] However, recent studies have revealed that the use of such an additional chiral component bound to the enolate may not be required for an enolate to be intrinsically chiral.[5]

Kawabata, Fuji, and co-workers elegantly showed[6] that an enantiomerically pure α-amino ester (*S*)-**1** can be alkylated enantioselectively by simple treatment with KHMDS at −78 °C, followed by addition of a suitable S_N2-active electrophile, such as methyl iodide, to give the required substituted ester (*S*)-**2** with 88 % *ee* (Scheme 1). This process is believed to occur via a chelated enolate **3**, which contains axial chirality along the C2–N axis of the enolate owing to the differential substitution pattern of the amino substituent (Scheme 2). This chirality is evidently dynamic, as the enolate is known to racemize at −40 °C over a period of 80 min. The use of a tethered phenol in (*S*)-**1** was found to be particularly important as this group additionally stabilized the enantiomerically pure chiral conformer **3** by at least one order of magnitude relative to that of the ethyl ester,[6] and consequently gave better levels of enantioselectivity. For this chiral enolate conformer, there appear to be two elements of stereogenicity: 1) the oxygen atom of the ester (C–O–CH_2-) motif and 2) the nitrogen atom of the amino group. Both these dynamic components have the potential to enhance the conformational stability of the enolate and to improve the levels of enantioselectivity.



This approach has been extended towards the synthesis of enantiomerically enriched amides such as (*S*)-**5** (Scheme 3).[5] This strategy is similar to that used for the ester in that it relies on an unsymmetrically substituted amino group present within the amide (*S*)-**4** to induce conformational chirality within the corresponding enolate **6** (Scheme 4). The origin of chirality in this enolate is slightly different to that of the enolate **3**,[6] as there only appears to be axial chirality along the C2–N bond. (This

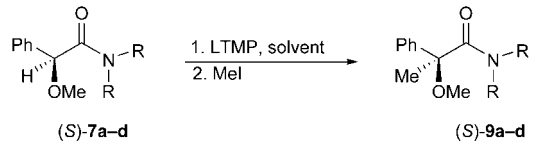
refers to enolate **6**.) Deprotonation of the amide (*S*)-**4** with LTMP in cyclopentyl methyl ether and subsequent C-alkylation of the intermediate lithium enolate **6**[7] with MeI gave the required substituted amide (*S*)-**5** with moderate levels of enantioselectivity (Scheme 3).

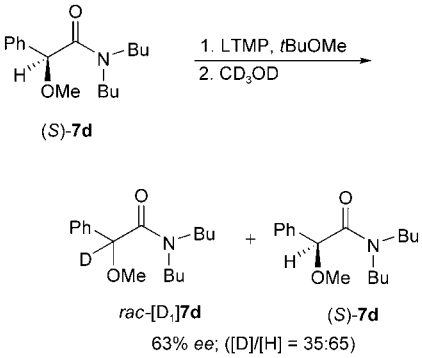


At a glance, this study undoubtedly suggests that the formation of an enolate **8** derived from a chiral symmetrically N,N-disubstituted amide (*S*)-**7**, which has no axial chirality (owing to the substitution pattern of the amino group), and subsequent alkylation would almost certainly lead to the racemic product *rac*-**9** (Scheme 5). However, Kawabata, Fuji, and co-workers recently disproved this idea.[5] They discovered that alkylation of a lithium

Scheme 5. Proposed alkylation of enolate **8**.

enolate derived from a symmetrically N,N-disubstituted amide (*S*)-**7** can lead to an enantiomerically enriched amide (*S*)-**9** with moderate, but significant, enantioselectivity (up to 64% *ee*) (Scheme 6). These results suggest that there is a less clear element of asymmetry present within the lithium enolate aggregate (surrounding the lithium enolate **8**) to account for this enantioselectivity. It is particularly noteworthy that the levels of enantioselectivity are evidently dependent on the levels of diastereoselective C-alkylation of the intermediate chiral lithium enolate **8**, and consequently the relative amount of enantiomerically pure enolate may be significantly underestimated.

The levels of stereocontrol were found to be dependent on the structural nature of the alkyl substituents in (*S*)-**7** and independent on whether the amide was unsymmetrically or symmetrically

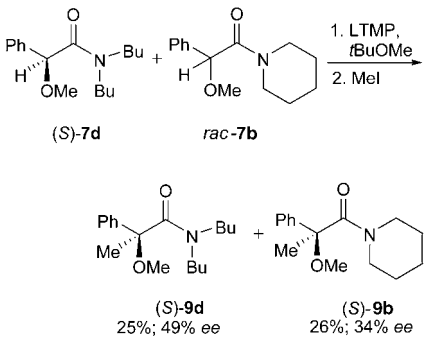


Entry	Starting Material	R	R	Solvent	Product	Yield [%][a]	*ee* [%]
1	**7a**	-$(CH_2)_4$-		*t*BuOMe	(*S*)-**9a**	34 (82)	44
2	**7b**	-$(CH_2)_5$-		*t*BuOMe	(*S*)-**9b**	27 (68)	41
3	**7c**	Me	Me	*t*BuOMe	(*S*)-**9c**	27 (68)	44
4	**7d**	*n*Bu	*n*Bu	*t*BuOMe	(*S*)-**9d**	25[b] (71)	56
5	**7d**	*n*Bu	*n*Bu	THF	(*S*)-**9d**	72 (95)	0
6	**7d**	*n*Bu	*n*Bu	*c*-C_5H_9OMe	(*S*)-**9d**	30[c] (90)	64

Scheme 6. Enantioselective alkylation of amides (*S*)-**7a–d** with methyl iodide. [a] In brackets yields based on recovered starting material. [b] Recovered amide (*S*)-**7d** was isolated with 86% *ee*. [c] Recovered amide (*S*)-**7d** was isolated with 89% *ee*.

N,N-disubstituted; both types of amides, (*S*)-**4** and (*S*)-**7a–d**, gave similar enantioselectivities (62 and 44–56% *ee*, respectively) under identical conditions (Scheme 3 and Scheme 6, entries 1–4). The structural nature of the solvent was found to be very important for the level of enantioselectivity; a symmetric ether such as THF gave no enantioselectivity, whereas unsymmetric ethers such as *tert*-butyl methyl ether and cyclopentyl methyl ether gave moderate stereocontrol (Scheme 6, entries 4–6).

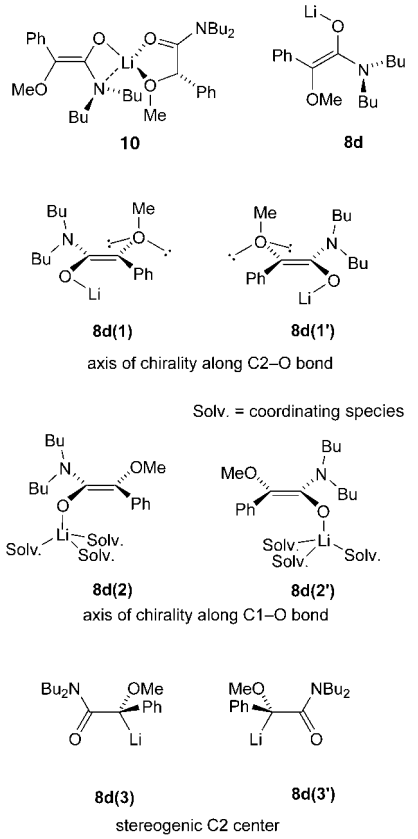
A weakness of this approach appears to be the low conversion of the amides (*S*)-**7** into the required enantiomerically enriched methylated amides (*S*)-**9**. The yields were consistently low (25–34%; Scheme 6, entries 1–4). The starting amides were easily recovered in good yield, and in some cases there was some loss of enantiomeric purity (Scheme 6, entries 4 and 6). To determine the amount of enolate formation, Kawabata, Fuji, and co-workers[5] chose to deprotonate the amide (*S*)-**7d** with LTMP and quench the resulting lithium enolate with CD_3OD; the D-labeled amide (*S*)-[D_1]**7d** was obtained in quantitative yield with moderate D incorporation ([D]/[H] = 35:65; Scheme 7). The enantiomeric excess of this mixture ((*S*)-**7d** and [D_1]**7d**) was found to be 63% *ee*. This presumably shows that deprotonation of amide (*S*)-**7d** and subsequent formation of enolate **8d** occurs in approximately 35% yield. As this virtually mirrors the loss in enantiomeric excess (37%), it appears that stereorandom



Scheme 7. Deprotonation and *C*-deuteriation of amide (*S*)-**7d**.

deuteration of the enantiomerically pure/enriched enolate **8d** may have occurred.

In an attempt to gain further insight into and comprehension of the origin of this stereocontrol, amides (*S*)-**7d** and *rac*-**7b** (equimolar mixture) were deprotonated with LTMP (1.1 equiv) in *tert*-butyl methyl ether at −78°C, and the resulting enolates were methylated with methyl iodide to give the required amide (*S*)-**9d** in 25% yield with 49% *ee* and the enantiomerically enriched amide (*S*)-**9b** in 26% yield with 34% *ee* (Scheme 8). This intermolecular transfer of chirality from the amide (*S*)-**7d** to *rac*-**7b** is particularly intriguing and suggests the possibility of mixed aggregates.[5]



Kawabata, Fuji, and co-workers argued[5] that the chirality transfer may occur from the remaining enantiomerically pure parent amide (*S*)-**7d** within

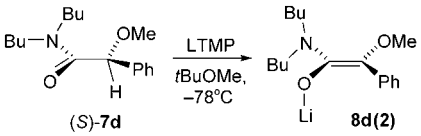
Scheme 8. Intermolecular transfer of chirality from amide (*S*)-**7d** to amide (*S*)-**9b**. 59% of (*S*)-**7d** and 67% of *rac*-**7b** were recovered.

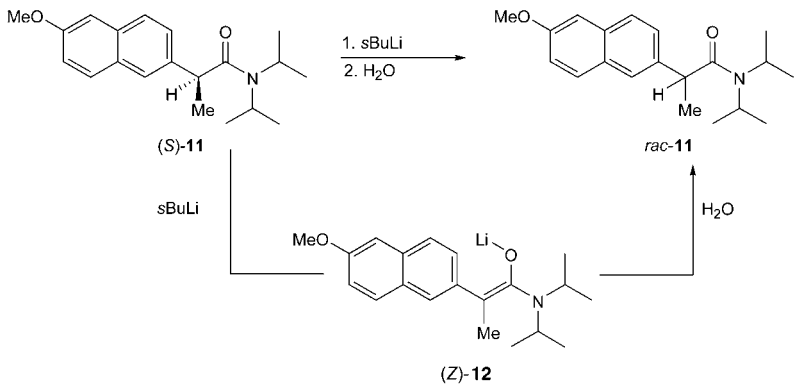


10, the lithium aggregate of the enolate (Scheme 9). Diastereoselective alkylation of the intermediate enolate present in **10** with methyl iodide could potentially lead to the required methylated amide **9d**.[8] They also noted that the original enolate **8d** could potentially have a plane of chirality as a result of restricted rotation around the C2–OMe bond in **8d(1)**, but argued that this rotational barrier would be too small

Scheme 9. Proposed intermediates in the enantioselective alkylation of amide **7d**.

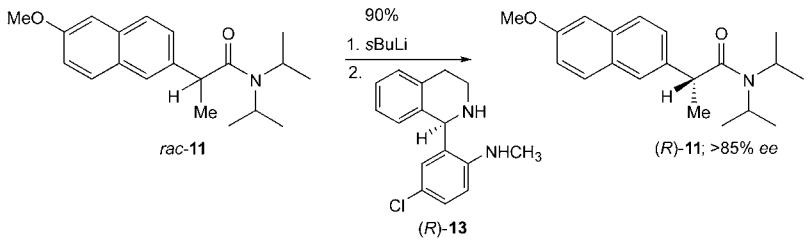
to prevent racemization of this enolate at −78 °C (Scheme 9). However, the rotational barrier of the C1–OLi bond in enolate **8d(2)** may be larger owing to the presence of additional aggregation (to the residual tetramethylpiperidine, solvent, and parent amide). Other possibilities include the formation of chiral C-lithiated intermediates (e.g., **8d(3)**); however, this could be discounted, as related enolates are known to be O-lithiated.[9]

In principle, initial formation of the lithium enolate **8d(2)** may be preferred as a result of the stereospecific deprotonation of the amide (*S*)-**7d** with the lithium amide LTMP (Scheme 10). This



Scheme 10. Proposed deprotonation of amide (*S*)-**7d** to give conformationally chiral enolate **8d**.

deprotonation process was previously shown to occur via a chelated six-membered transition state,[9,10] and intrinsically the resulting enolate would appear to be enantiomerically pure irrespective of its configuration. It was noted that incorporation of additives such as tetramethylethylenediamine, which are known to promote deaggregation by favoring the formation of more-defined mono- or dimeric enolates, only served to lower the overall enantioselectivity from 64 to 33% *ee*; in both cases, the (*S*)-amide **9b** was favored.



The structures of related prochiral lithium enolates have been determined by single-crystal X-ray diffraction.[9] These lithium enolates were shown to exist as tetra- or dimeric aggregates that contain a plane or point of symmetry. It appears that simple fragmentation of these aggregates to form a combination of monomeric enolates, however, has the potential to lead to (conformationally) chiral intermediates.[11]

The consequence of dynamic enolate chirality has wider implications for other stereoselective processes, for example in the enantioselective C-protonation of enolates to give enantiomerically enriched carbonyl derivatives.[12] Within this area, the intermediate enolate ideally needs to be achiral. However, if the resulting enolate is conformationally chiral, both enantiomeric enolates need to interconvert faster than the rate of stereoselective proton transfer in order to give the required carbonyl derivatives with moderate enantiomeric purity under kinetic control. Vedejs and co-workers[13] reported efficient racemization of a related amide (*S*)-**11** by deprotonation with *s*BuLi followed by C-protonation with H_2O to give the corresponding racemic amide **11** (Scheme 11). In light of findings by Kawabata, Fuji, and co-workers,[5] this suggests that the resulting enolate **12**, if chiral, either racemizes rapidly or is not facially selective C-protonated; in both cases the racemic amide **11** would be formed. However, the racemization would have to be rapid to allow access to both enantiomeric enolates, as protonation with an enantiomerically pure acid, for example, amine (*R*)-**13**, leads to the complementary enantiomerically

Scheme 12. Enantioselective synthesis of amide (*R*)-**11**.

enriched amide (*R*)-**11** in high yield (90%) with greater than 85% *ee* (Scheme 12).

In conclusion, Kawabata, Fuji, and co-workers reported[5] an unprecedented transfer of chirality during the alkylation of amides derived from mandelic acid and achiral amines. These reactions proceed by the formation of an intermediate chiral enolate **8** by deprotonation of amides (*S*)-**7** with a lithium amide. Subsequent alkylation of these enolates with MeI leads to the required enantiomerically enriched methylated amides (*S*)-**9**. The origin of this remarkable stereoselective process is thought to be the formation of mixed lithium aggregates such as **10**. However, there could potentially be other forms of hidden chirality present within the enolate substructure and associated aggregates that could assist in this type of enantioselective C-alkylation.

Fluorine has come to be recognized as a key element in materials science: in heat-transfer agents, liquid crystals, dyes, surfactants, plastics, elastomers, membranes, and other materials. Furthermore, many fluorine-containing biologically active agents are finding applications as pharmaceuticals and agrochemicals. Progress in synthetic fluorine chemistry has been critical to the development of these fields and has led to the invention of many novel fluorinated molecules as future drugs and materials. As a result of the electronic effects of fluorine substituents, fluorinated substrates and reagents often exhibit unusual and unique chemical properties, which often make them incompatible with established synthetic methods. Thus, the problem of how to control the unusual properties of compounds with fluorine substituents deserves much attention, so as to promote the design of facile, efficient, and environmentally benign methods for the synthesis of valuable organofluorine targets.

1. Introduction

As the most electronegative element, fluorine has played a key role in recent pharmaceutical, agrochemical, and materials science. As the incorporation of fluorine and/or fluorine-containing groups into an organic molecule often drastically perturbs the chemical, physical, and biological properties of the parent compound (Figure 1), it is thought that the synthesis of desired fluorinated compounds should lead to the invention of novel agents and materials endowed with prerequisite functions.[1] Since a basic discussion of such fluorine effects is found in many books and reviews,[1,2] we do not cover them in detail herein. Instead we draw your attention to the very recent special issue of *ChemBioChem* on "Fluorine in the Life Sciences", which provides a very comprehensive and up-to-date picture of fluoroorganic compounds and fluorine effects.[3]

Because naturally occurring organofluorine compounds are rare, target organofluorine compounds are accessible solely by organic synthesis. With respect to chemical reactivity and stability, fluorinated compounds behave in a unique manner owing to so-called inductive and resonance effects caused by fluorine.[4] For example, fluorine-substituted carbocations are stabilized by the donation of nonbonding electron pairs on the fluorine atom, whereas electrostatic p–n repulsion between an anionic center and the lone pairs of electrons on the fluorine atom destabilizes a fluorine-substituted anionic center (Figure 2). Similarly, n–π repulsion between the lone pairs and a π-electron system pushes the π electrons far apart. Furthermore, a resonance effect operates in which the lone pairs participate in conjugation with the π system.

Like various other fluorine-containing groups, trifluoromethyl groups at C(sp^2) and C(sp^3) centers always withdraw electrons to destabilize cations and to stabilize anions (Figure 3). This anion stabilization can also be understood to be a result of negative hyperconjugation, an overlap of an anionic p orbital with the σ* orbital of a C–F bond.[5]

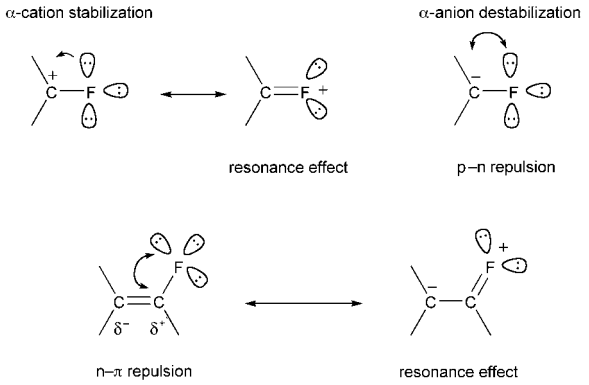

Figure 2. α-Fluorine effects.

Figure 3. α-CF_3 effects on carbocations and carbanions.

Trifluoromethyl groups also strongly affect chemical reactivity. For example, nucleophilic substitution at a trifluoromethyl-substituted carbon atom is not an easy process. The difficulty is attributed to destabilization of the transition state by fluorine and also to electrostatic repulsion between a nucleophile and the lone pairs of electrons on the fluorine atoms. There are many phenomena that can be understood in terms of C–H···F or C–M···F interactions, although such interactions are still a topic of controversy.[6]

In view of the unique characteristics of fluorine, it is easy to recognize that conventional synthetic methods are not always applicable to the synthesis of organofluorine compounds. Thus, a deep understanding of the nature of reaction mechanisms, reagents, and synthetic strategies based on the unique chemical and physical properties of fluorine is essential.[7] Herein we describe some novel synthetic methods, particularly those we have developed over the last two decades for the preparation of fluorine-substituted target molecules, focusing on oxidative desulfurization–fluorination, synthetic reactions based on fluorine-containing polyhaloalkyl metal reagents and CF_3-substituted oxiranyl lithium reagents, and the asymmetric synthesis of 1,1,1-trifluoro-2-alkanols.

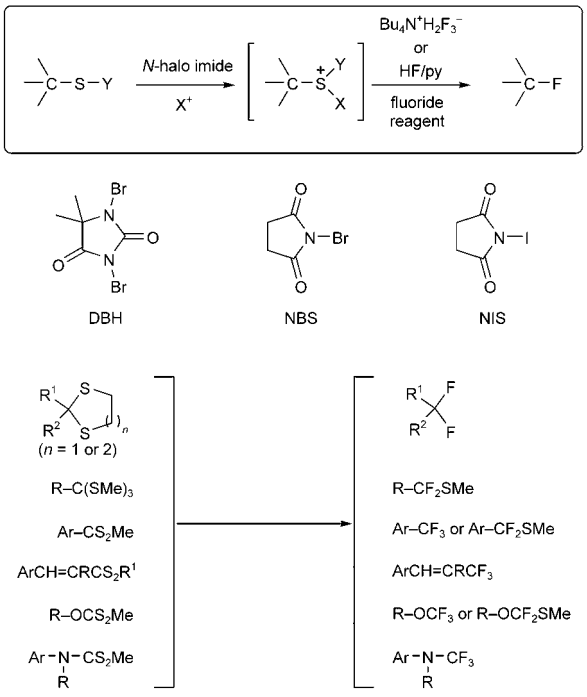
2. Classification of Synthetic Methods

Synthetic methods for the synthesis of organofluorine compounds are roughly classified into two basic strategies: the fluorination method and the building-block method. Fluorination includes C–F bond formation through the transformation of a C–H bond or a functional group by treatment with a fluorinating reagent, such as elemental fluorine (F_2), hydrogen fluoride (HF), or derivatives thereof.[8] This is a straightforward method for the introduction of fluorine atoms into target molecules, especially when the fluorination can be carried out with high regio- and chemoselectivities. However, the handling of such fluorinating reagents requires special apparatus, techniques, and care, as the reagents are usually extraordinarily reactive and toxic, often as a result of corrosive HF that is released. Hence, methods that employ reagents with moderate reactivity under mild conditions are needed for the facile synthesis of fluorine-containing target molecules.

The building-block method involves appropriate chemical transformations starting from fluorinated small molecules (building blocks).[9] Since standard experimental procedures are applicable, this approach is more familiar to synthetic chemists. The ready availability and easy handling of fluorine-containing building blocks are essential for the success of this approach. However, fluorine substitution very often causes abnormal behavior with regard to the reactivity and/or selectivity of these building blocks relative to that of their nonfluorinated counterparts, thus providing a challenge to synthetic chemists to overcome these fluorine effects.

3. Oxidative Desulfurization–Fluorination

Many reagents for nucleophilic fluorination are now available. Representative examples are hydrogen fluoride (HF, b.p. 19.54 °C), its aqueous solution (hydrofluoric acid), sulfur tetrafluoride (SF_4), and diethylaminosulfur trifluoride (DAST); these reagents are, however, very reactive, corro-



Born in Osaka in 1946, Tamejiro Hiyama completed his PhD in engineering at Kyoto University in 1975 (mentor: Hitoshi Nozaki). He undertook postdoctoral research at Harvard University with Yoshito Kishi, received the Young Chemist Award of the Chemical Society of Japan in 1980, and in 1981 started his own research team at Sagami Chemical Research Center. He moved in 1992 to Tokyo Institute of Technology as Professor, and since 1997 has been Professor of Organic Materials at Kyoto University. His research interests include organofluorine and organosilicon chemistry, as well as the synthesis of biologically active substances and materials with novel functionality.

Masaki Shimizu was born in 1965 in Tokyo. He completed his PhD at Tokyo Institute of Technology in 1994 (Takeshi Nakai and Koichi Mikami). He was a research associate at Mitsubishi Chemical Co., then from 1995 at Tokyo Institute of Technology. In 1998, he moved to Kyoto University as Assistant Professor. He spent one year at Massachusetts Institute of Technology as a postdoctoral fellow (S. L. Buchwald) and was promoted to Associate Professor at Kyoto University in 2003. His research interests focus on synthetic methods with organofluorine compounds and organometallic reagents, and functional organosilicon materials.

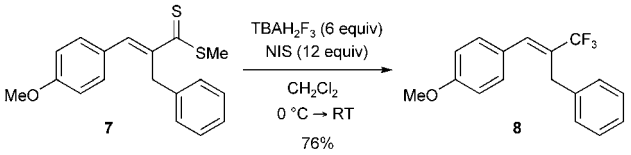
sive, and toxic. When they are modified for more convenient handling, their nucleophilicity often decreases. To facilitate nucleophilic attack of a substrate by the modified reagent, electrophilic substrate activation by an oxidant is quite effective, as exemplified in the halofluorination of alkenes and alkynes,[10] the thio- and selenofluorination of alkenes,[11] and nitrofluorination.[12] We have applied this concept to organosulfur compounds, a readily accessible class of organic compounds (Scheme 1).[13] The basic idea involves activation

Scheme 1. Oxidative desulfurization–fluorination. py = pyridine.

of a C–S bond by a positive halogen generated from *N*-iodosuccinimide (NIS), *N*-bromosuccinimide (NBS), or 1,3-dibromo-5,5-dimethylhydantoin (DBH), followed by nucleophilic substitution with a fluoride ion from HF/pyridine (Olah reagent) or tetrabutylammonium dihydrogen trifluoride ($TBAH_2F_3$). This methodology is called oxidative desulfurization–fluorination and is applicable to the preparation of various types of organofluorine compounds. The scope is summarized in Scheme 1. The following paragraphs present some representative examples that demonstrate the versatility of this method.

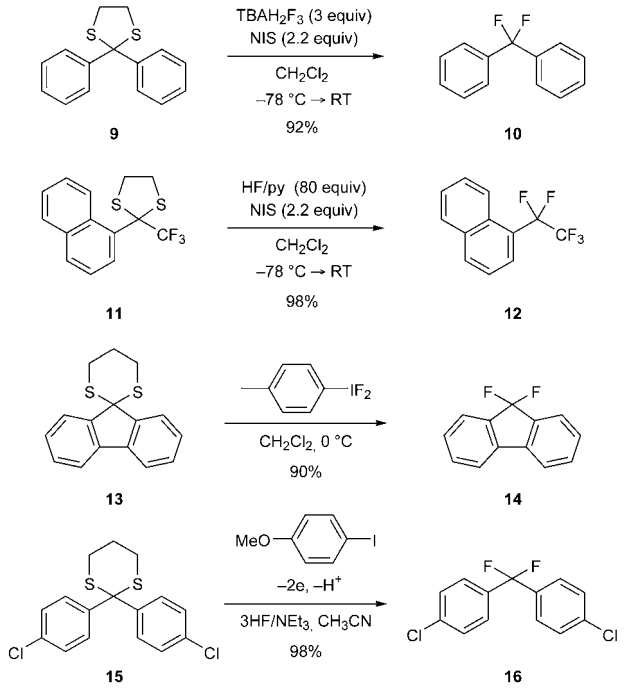


Trifluoromethyl-substituted aromatic compounds can be prepared from the corresponding arenedithiocarboxylates with $TBAH_2F_3$ and DBH.[14] For example, the *ortho* lithiation of *p*-cresol methoxymethyl (MOM) ether (**1**), followed by trapping of the resulting anion **2** with carbon disulfide and then with iodomethane, produces the dithiocarboxylate **3**, which is smoothly converted into the trifluoromethyl-substituted *p*-cresol derivative **4** in good overall yield (Scheme 2). The trifluorination of dithiocarboxylates is applicable to heteroaromatic compounds, such as the quinoline derivative **5**: A combination of DBH and 70% HF/pyridine as the

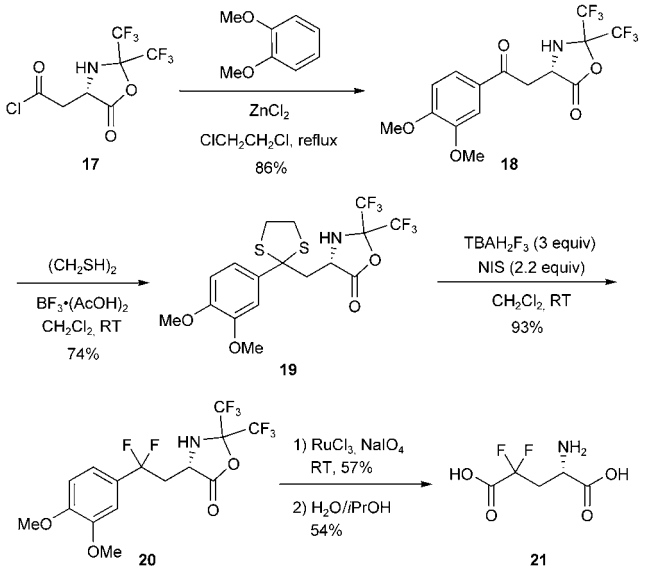
Scheme 2. Synthesis of trifluoromethyl-substituted aromatic compounds. TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine.

fluoride source was the best system for the transformation of electron-deficient heteroaromatic compounds.

The α,β-unsaturated dithiocarboxylate **7** undergoes trifluoromethylation with a combination of $TBAH_2F_3$ and NIS, giving rise to the 1-aryl 3,3,3-trifluoropropene **8** (Scheme 3).[14] Other combinations (HF/pyridine in place of $TBAH_2F_3$; DBH or NBS in lieu of NIS) were ineffective for this transformation.



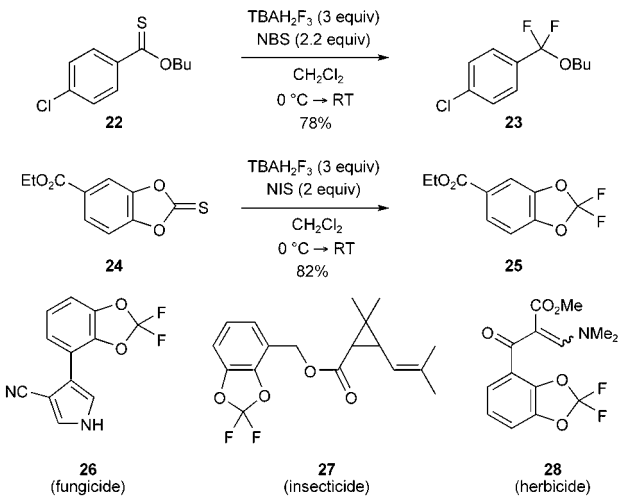
Scheme 3. Synthesis of the 1-aryl 3,3,3-trifluoropropene **8**.



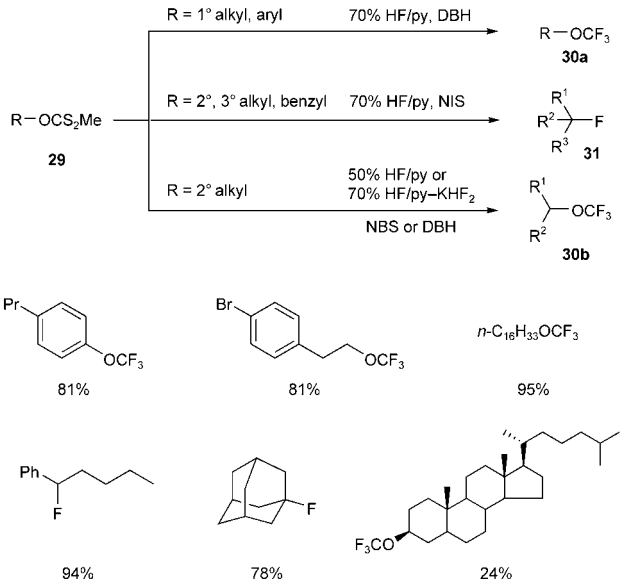
Since the introduction of a *gem*-difluoromethylene moiety into biologically active but unstable agents considerably improves their biostability, there is a need for facile and versatile methods for the construction of difluoromethylene groups.[15] Upon treatment with NIS and $TBAH_2F_3$ or HF/pyridine, the dithioacetals of benzophenone **9** and 1-naphthyl trifluoromethyl ketone **11** afford **10** and **12**, respectively, in high yields (Scheme 4).[16] When DBH is employed as the oxidant, the difluorination is sometimes accompanied by halogenation of the aromatic ring. The same type of transformation can be performed with *p*-$CH_3C_6H_4IF_2$ and electrochemically generated *p*-$(MeO)C_6H_4IF_2$ (Scheme 4).[17] The synthetic utility of this strategy is demonstrated by the synthesis of the difluoroglutamic acid **21** (Scheme 5).[18]

Difluoroalkyl ethers and difluoromethylenedioxy compounds can be prepared from thione esters and thione carbonates, which are in turn readily accessible from esters and carbonates by treatment with the Lawesson reagent ((*p*-$(MeO)C_6H_4P(=S)S)_2$).[19] For example, in the presence of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 4. Oxidative desulfurization–fluorination of dithioacetals derived from aryl ketones.

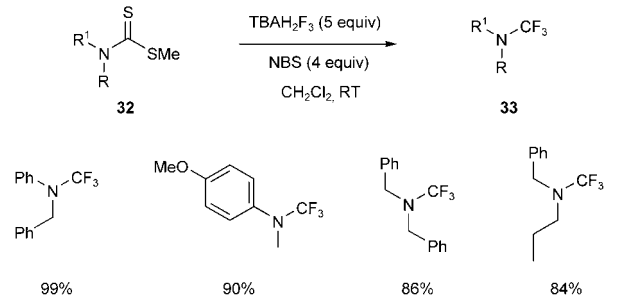


Scheme 5. Synthesis of the difluoroglutamic acid **21**.

$TBAH_2F_3$ and NBS (or NIS) the thione ester **22** and carbonate **24** are converted into **23** and **25**, respectively, in good yields (Scheme 6). This approach is useful for the preparation of biologically active substances containing a difluoromethylenedioxy moiety, such as **26**, **27**, and **28**.

Trifluoromethyl ethers **30a** of primary alcohols and phenols can be prepared from the corresponding xanthates **29** with 70% HF/pyridine and DBH (Scheme 7).[20] In contrast, the treatment of xanthates derived from secondary or tertiary alcohols with 70% HF/pyridine and NIS results in

Scheme 6. Preparation of difluoroalkyl ethers and difluoromethylenedioxy compounds.



Scheme 7. Synthesis of trifluoromethyl ethers and alkyl fluorides from dithiocarbonates.

fluorination, giving rise to secondary or tertiary fluorides **31**, respectively. However, the use of milder fluorinating reagents, such as 50% HF/pyridine or 70% HF/pyridine with KHF_2, for the reaction of secondary xanthates **29** allows the isolation of secondary alkyl trifluoromethyl ethers **30b**. This reaction is in sharp contrast with that carried out in the presence of $TolIF_2$ in which only fluorination products are formed.[21] 3β-Trifluoromethoxycholestane prepared by this method was found to act as a chiral dopant for twisted-nematic liquid-crystal displays.[22] Cyclohexyl trifluoromethyl ethers prepared in a similar way are potential future materials for TFT (thin-film transistor for active matrix) displays.[23]

Dithiocarbamates **32**, readily available from secondary amines, carbon disulfide, and methyl iodide, are converted

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

into trifluoromethyl amines **33** by treatment with $TBAH_2F_3$ and NBS (Scheme 8).[23] This protocol is applicable to both aromatic and aliphatic amines. Aryl trifluoromethylamines are stable to moisture, whereas dialkyl trifluoromethylamines are easily hydrolyzed. The presence of a trifluoromethyl group on the nitrogen atom retards oxidation of the amino group.

Scheme 8. Synthesis of trifluoromethylamines.

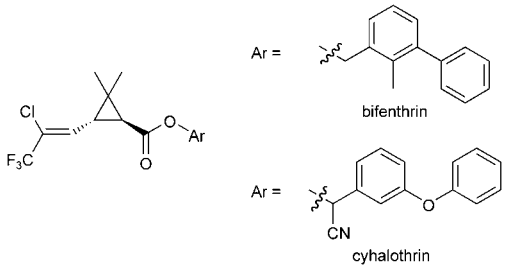
The trifluoromethylation of heteroarenedithiocarbamates **34** with DBH at 0 °C or room temperature gives trifluoromethylamines **35**, whereas the same reaction in CH_2Cl_2 at reflux causes selective bromination of the aromatic ring at the *para* position as well as trifluorination to produce **36** (Scheme 9).[23]

Scheme 9. Oxidative desulfurization–fluorination of heteroaryl dithiocarbamates.

4. Fluorine-Containing Polyhaloalkyl Metal Reagents

Since halogen–metal exchange is a relatively facile process, the reduction of commercially available fluorine-containing polyhaloalkanes, so-called halons, with a metal or an organometallic reagent would be a versatile method for the generation of fluorine-containing carbenoids, if the stability and reactivity of the reagents could be controlled.[24]

The artificial pyrethroids bifenthrin and cyhalothrin, both of which contain $CH{=}C(Cl)CF_3$ in lieu of $CH{=}CMe_2$ or $CH{=}CCl_2$, are highly potent, exhibiting remarkably enhanced activity relative to nonfluorinated congeners (Figure 4).[25] We have established a practical and stereocontrolled approach to



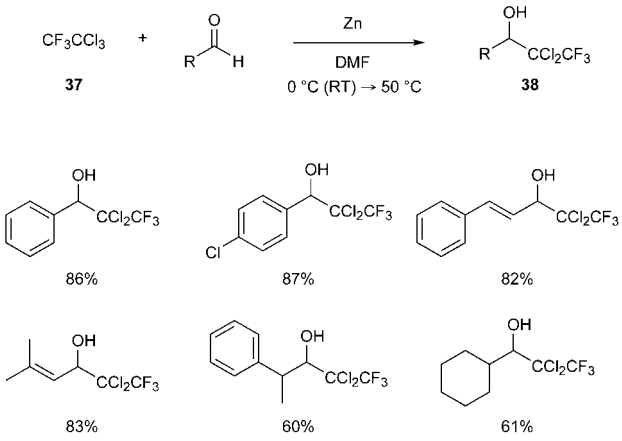


Figure 4. Examples of artificial pyrethroids.

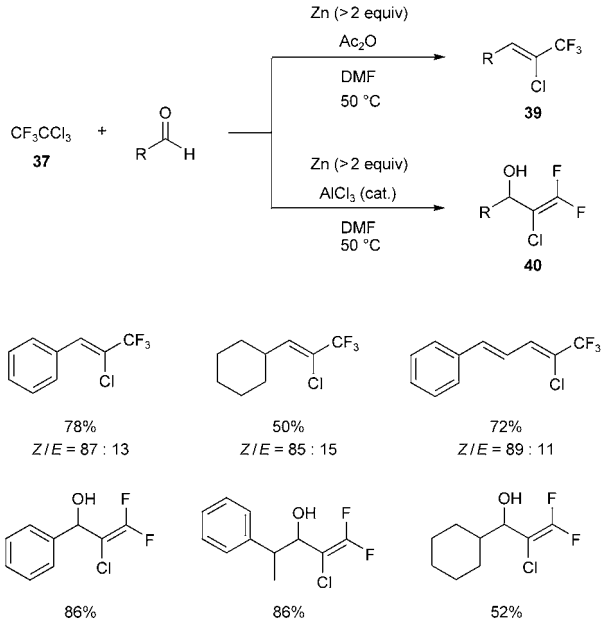
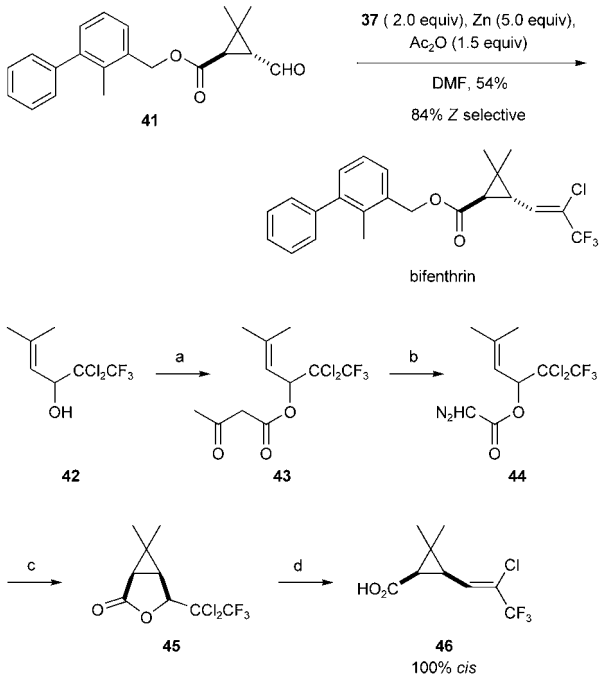


di- and trifluorinated synthetic pyrethroids based on the addition of CF_3CCl_2ZnCl to aldehydes and reductive olefination of the adducts.[26] The two-step transformation can also be carried out in one pot. The reduction of CF_3CCl_3 (**37**) with zinc metal in DMF at 50 °C generates the thermally stable zinc carbenoid CF_3CCl_2ZnCl, which reacts with various aldehydes, including aromatic, aliphatic, and α,β-unsaturated aldehydes, to give alcohols **38** in good yields (Scheme 10). A similar transformation was disclosed independently by Lang and coworkers, who were successful in isolating the carbenoid and showed it to be monomeric in the solid state by single-crystal X-ray diffraction.[27,28]

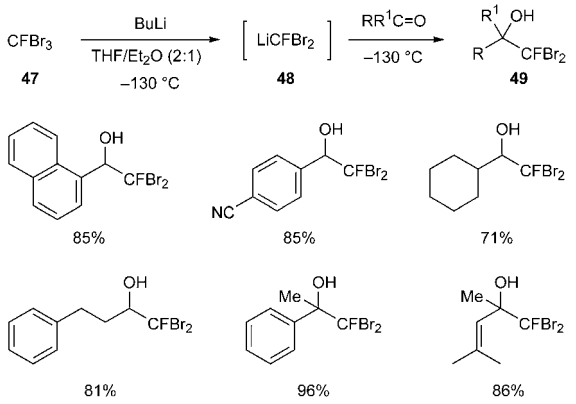
Scheme 10. Generation of CF_3CCl_2ZnCl and addition to aldehydes. DMF = *N*,*N*-dimethylformamide.



The use of zinc in excess (> 2 equiv) in the presence of acetic anhydride in DMF at 50 °C induces reductive β elimination of chloride and acetate ions to afford 2-chloro-1,1,1-trifluoro-2-alkenes **39** in one pot with *Z* selectivity. 2-Chloro-1,1-difluoro-1-alken-3-ols **40** are obtained conveniently by the 1,2-elimination of chloride and fluoride when a catalytic amount of aluminum chloride is employed instead of acetic anhydride (Scheme 11).[29]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 11. One-pot synthesis of polyfluorinated alkenes **39** and **40** from CF_3CCl_3.

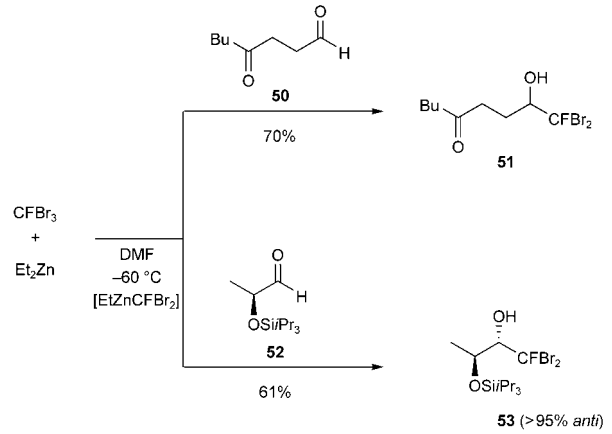


The synthetic versatility of this method is demonstrated by a one-step synthesis of bifenthrin, in which the non-methyl substituents on the cyclopropane ring are in a *trans* relationship (Scheme 12).[30] In a complementary sequence, the *cis* cyclopropanecarboxylic acid **46** can be formed stereoselectively from the adduct **42** through diazoacetylation,

Scheme 12. Synthesis of bifenthrin and the *cis* cyclopropane **46**: a) diketene, K_2CO_3 (88%); b) TsN_3, NEt_3, then NaOH (82%); c) [Cu(acac)$_2$], dioxane (75%); d) Zn, DMF (84%). acac = acetylacetonate, Ts = *p*-toluenesulfonyl.

intramolecular cyclopropanation, and reduction with zinc. The present method constitutes a practical approach to the preparation of 3,3,3-trifluoroprop-1-enyl-substituted cyclopropanecarboxylic acids, a key fragment of highly potent artificial pyrethroids.

In contrast to that of perfluoroalkyl metal reagents, the chemistry of monofluoroalkyl metal reagents still remains to be explored. We succeeded in generating dibromofluoromethyllithium (**48**), which underwent addition to carbonyl derivatives as shown in Scheme 13.[31] The carbenoid reagent



Scheme 13. Generation of $LiCFBr_2$ (**48**) and addition to carbonyl compounds.

48 is prepared by the treatment of tribromofluoromethane (**47**) with butyllithium at −130 °C in a solvent mixture of THF/Et_2O (2:1) in the presence of the aldehyde or ketone substrate. A variety of dibromofluoromethylated alcohols **49** were prepared in high yields in this way. Since **48** reportedly undergoes decomposition through α elimination leading to :CFBr even at −116 °C,[32] its generation at −130 °C in the presence of an electrophile is essential for the success of the transformation.

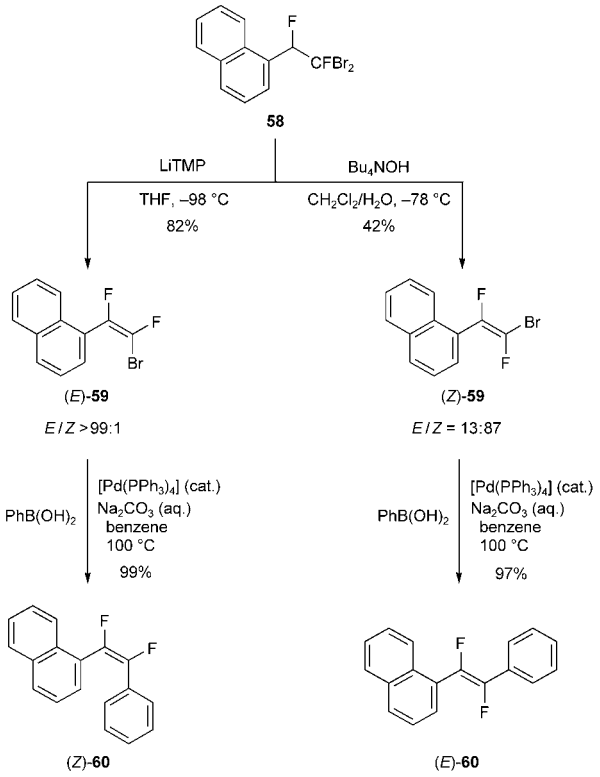
An alternative reagent to **48** is a zinc carbenoid prepared by bromine–zinc exchange of tribromofluoromethane with diethylzinc in DMF at −60 °C. The zinc carbenoid makes it possible to perform the whole transformation at higher temperatures with high chemoselectivity: Aldehydes are favored significantly over ketones.[33] For example, the ketoaldehyde **50** reacts with the carbenoid to give only the aldehyde adduct **51** (Scheme 14). Diastereoselective addition to the lactaldehyde silyl ether **52** is also possible with the zinc reagent.

Fluoroolefins play essential roles in liquid-crystalline materials as well as peptide isosteres and enzyme inhibitors.[34] Since the physical properties and biological activity of fluoroolefins greatly depend on configuration, their stereocontrolled synthesis is indispensable. For the stereoselective synthesis of various types of fluoroolefins, stereodefined bromofluoroolefins serve as valuable precursors, as the cross-coupling of bromofluoroolefins with various organometallic reagents in general proceeds to give the target molecules with retention of configuration.[35] Therefore, any new method for

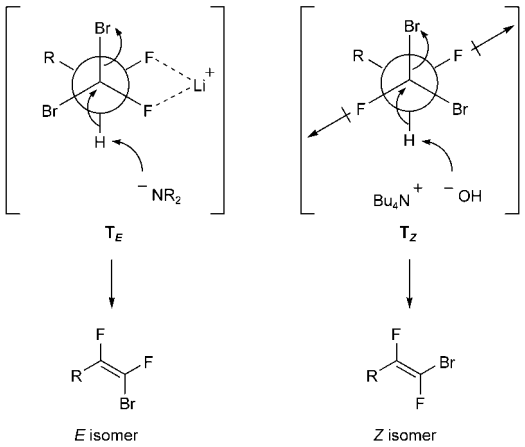
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 14. Chemoselective and stereoselective addition of $EtZnCFBr_2$ to aldehydes.

the facile and stereoselective synthesis of bromofluoroolefins[36] leads to a versatile entry to fluoroolefins.



To this end, dibromofluoromethylated alcohols **49** serve as the precursors of bromofluoro- and bromodifluoroolefins. Acetates **54** derived from **49** ($R^1 = H$) are converted into (*E*)-1-bromo-1-fluoro-1-alkenes **55** stereoselectively upon treatment with EtMgBr (15 equiv) and iPr_2NH (5 equiv), as shown in Scheme 15. On the other hand, bromine–magnesium exchange of the tosylate **56** ($R = Ph(CH_2)_2$) with Et_2Mg (1.5 equiv) provides **57** with high *Z* selectivity.

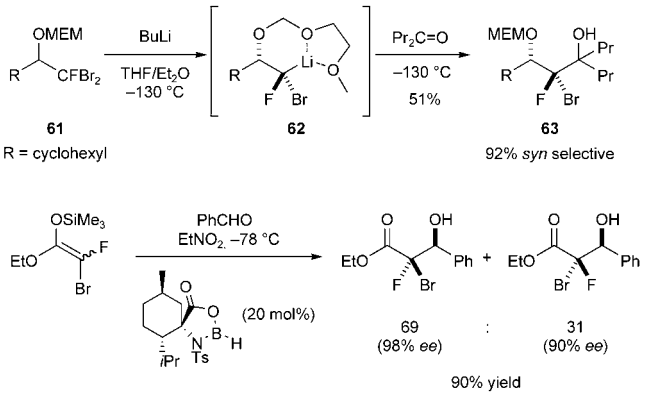


Scheme 15. Stereoselective synthesis of bromofluoroolefins.

The synthesis of 1-bromo-1,2-difluoro-1-alkenes was carried out by dehydrobromination of 1,1-dibromo-1,2-difluoroalkanes, which can be readily prepared from **49** by fluorination with DAST at −78 °C. The treatment of **58** with lithium 2,2,6,6-tetramethylpiperidide (LiTMP) produces (*E*)-**59** as a single diastereomer, whereas (*Z*)-**59** forms preferentially when the metal-free base tetrabutylammonium hydroxide is employed (Scheme 16). These bromides couple with various aryl metal reagents (metal = B, Si, Sn, or Zn): The reaction with $PhB(OH)_2$ is illustrated in Scheme 16.

The stereoselectivity observed in the base-dependent elimination of **58** can be rationalized by a transition-state model that involves chelation of a metal center for *E*-selective elimination and dipole–dipole repulsion of C–F bonds for *Z*-selective elimination with a metal-free base (Scheme 17). In other words, dehydrobromination with LiTMP should proceed via $\mathbf{T}_E$, in which two fluorine atoms are in a synclinal arrangement as a result of Li–F chelation, to produce the

Scheme 16. Stereodivergent synthesis of difluoroolefins.



Scheme 17. Transition-state models for stereoselective dehydrobromination.

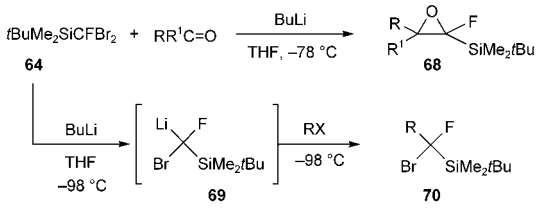
E isomer. On the other hand, the elimination of HBr takes place with Bu_4NOH via $\mathbf{T}_Z$, wherein two C–F bonds prefer to adopt an antiperiplanar arrangement owing to dipole–dipole repulsion, thus giving the *Z* isomer.

Treatment of the MEM (methoxyethoxymethyl) ether **61** with BuLi in THF/Et_2O (2:1) at −130 °C generates the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

corresponding lithium carbenoid **62**, which can be trapped selectively with 4-heptanone to give the 2-bromo-2-fluoro-1,3-alkanediol derivative **63**.[37] The stereochemical outcome can be explained by the stereoselective generation of the carbenoid **62** through chelation of the lithium ion by the oxygen atoms of the MEM group. The enantioselective synthesis of 2-bromo-2-fluoro-1-hydroxy derivatives is possible by aldol reactions of bromofluoroketene ethyl silyl acetals with aldehydes catalyzed by a chiral Lewis acid (Scheme 18).[38]

Scheme 18. Diastereoselective and enantioselective construction of 2-bromo-2-fluoro-1-alcohols.

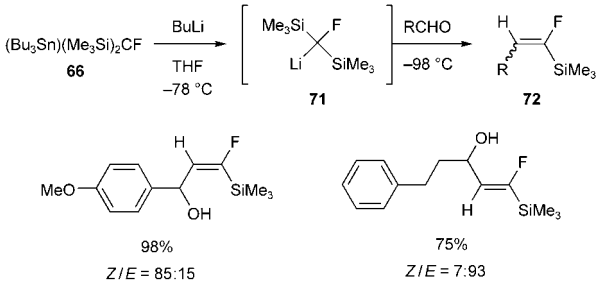


One possibility to improve the thermal stability of fluorine-substituted carbenoids derived from tribromofluoromethane is the introduction of a silyl group at the carbenoid carbon atom, as silyl groups can stabilize an anionic center. Furthermore, the silyl group in the product offers opportunities for functional-group transformations.[39] The fluoromethanes **64**, **65**, and **67** substituted with one, two, or three silyl groups, respectively, are readily prepared by the treatment of $CFBr_3$ (**47**) at −130 °C with appropriate stoichiometric amounts of butyllithium in the presence of a chlorosilane (Scheme 19).[40] The fluorobis(silyl)stannylmethane **66** is accessible from **65** through lithiation followed by stannylation. The mixed fluorometallomethane **66** can alternatively

Scheme 19. Preparation of poly(triorganosilyl)methanes from **47**.

be prepared directly from **47** by stepwise silylation and stannylation of the corresponding carbenoids.

The generation of the *tert*-butyldimethylsilyl-substituted carbenoid **69** and its addition to carbonyl compounds is possible at −78 °C, thus clearly demonstrating, as expected, that **69** is more stable than **48**, which should be handled at −130 °C (Scheme 20). When the reaction mixture is warmed to room temperature, 1-fluoro-1-silyloxiranes **68** are produced in good to excellent yields. No product resulting from

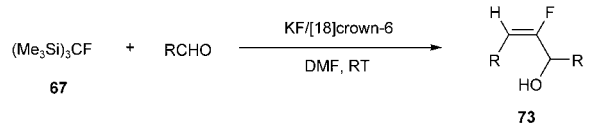


Scheme 20. Addition to carbonyl compounds and alkylation of the silicon-substituted carbenoid **69**.

the Peterson elimination or the Brook rearrangement is formed. The Darzens-type substitution proceeds at the fluorine-substituted carbon atom, a reaction that is thought to be difficult to achieve in an intermolecular sense.[41] Thus, it is evident that the accelerating effect of silicon surpasses the retarding effect of fluorine for the nucleophilic substitution at the α carbon atom.[42] Furthermore, the anion stabilization by silicon allows the addition of an electrophile after the generation of **69** at −98 °C, so that alkylation of **69** with alkyl halides is possible.

Whereas bromine–lithium exchange of **65** to generate fluorobis(trimethylsilyl)methyllithium (**71**) in the presence of aldehydes is unsuccessful, tin–lithium exchange of **66** with butyllithium can be performed successfully at −78 °C to give **71**, which then reacts with aldehydes to produce 1-fluoro-1-trimethylsilyl-1-alkenes **72** through addition to the carbonyl group followed by a Peterson elimination (Scheme 21).[43] The stereochemical outcome depends on R in the aldehyde RCHO.

The activation of a carbon–silicon bond by a fluoride ion is a highly useful strategy in organic synthesis with organosilicon reagents.[44] This strategy is also highly effective in synthetic fluorine chemistry. For example, trimethyl(trifluoromethyl)-silane reacts with a wide variety of electrophiles upon treatment with Bu_4NF (TBAF). Similarly, the treatment of



Scheme 21. Synthesis of 1-fluoro-1-silyl-1-alkenes **72**.

(polyfluoroethenyl)silanes with a catalytic amount of tris-(diethylamino)sulfonium difluoro(trimethyl)silicate generates the corresponding naked polyfluoroethenyl anions, which react with aldehydes to produce polyfluorinated allylic alcohols conveniently.[45]

We have found that fluoro(tris(trimethylsilyl))methane (**67**) reacts with 2 molar equivalents of an aromatic aldehyde in the presence of an equimolar amount of KF/[18]crown-6 in DMF at room temperature to give 2-fluoro-1,3-diaryl-2-propen-1-ols **73** in *E*/*Z* ratios of roughly 2:1 (Table 1). The

Table 1: Fluoride-mediated addition of **67** to aldehydes.

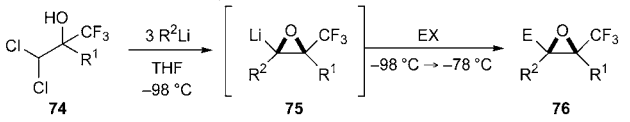
5	*p*-PhC_6H_4	68	67:33

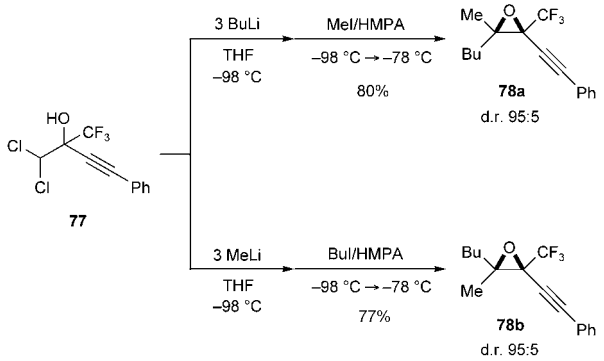
one-pot transformation involves the generation and addition to an aldehyde of the fluorine-substituted naked anion, a Peterson elimination leading to an α-fluoroalkenyl silane, generation of an α-fluoroalkenyl anion, and final aldehyde addition, and thus allows the conversion of three carbon–silicon bonds into a C–C single bond and a C=C double bond in a single operation.



5. Trifluoromethyl-Substituted Oxiranyl Lithium Reagents

Oxiranyl lithium reagents have recently emerged as a highly versatile class of reagents for the stereoselective synthesis of functionalized oxiranes and alkenes.[46] However, fluorine-containing oxiranyl lithium compounds remained unexplored until 2001, when we reported our results on trifluoromethyl-substituted oxiranyl lithium reagents.[47a]

The synthetic elaboration of CF_3-substituted β-oxido carbenoids derived from 3,3-dichloro-1,1,1-trifluoroalkan-2-ols **74** has led to the discovery that oxiranyl lithium intermediates **75** are efficiently produced at −98 °C with 3 equivalents of R^2Li and react with such electrophiles as chlorotrimethylsilane, isopropoxy(pinacolato)borane, and carbonyl compounds, to afford tri- and tetrasubstituted oxiranes **76** in good yields (Table 2).[47] Worthy of emphasis are: 1) the simultaneous nature of oxirane formation and the introduction of the substituent R^2, 2) the high diastereoselectivities observed (d.r. > 95:5) in the formation of **76**, 3) the *cis* arrangement of CF_3 and Li in **75**, and 4) the diastereotopic discrimination between the two chlorine substituents in the acyclic substrate **74**.



With an alkyl halide as the electrophile E–X, the stereodivergent synthesis of tetrasubstituted oxiranes is achieved

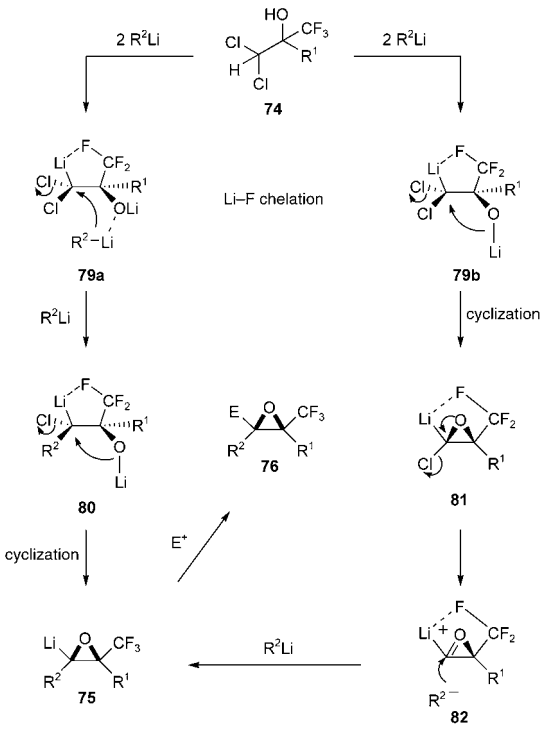
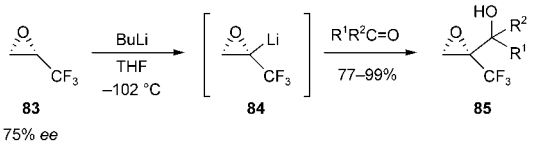
through the proper choice of R^2Li and E–X. For example, the treatment of **77** with BuLi and then with a solution of iodomethane in HMPA afforded **78a**, whereas the other diastereomer **78b** was obtained by the methyllithium-mediated generation of **75** followed by trapping with 1-iodobutane in HMPA (Scheme 22).



Scheme 22. Stereodivergent synthesis of tetrasubstituted oxiranes. HMPA = hexamethyl phosphoramide.

A proposed mechanism for the stereoselective generation of **75** is shown in Scheme 23. At first, it is thought that **74** reacts with 2 equivalents of R^2Li to produce the β-oxido carbenoid **79a** (or **79b**).[48] The assumption of a favored Li–F-chelated conformation as shown in **79a** (or **79b**) leads to two possible pathways: One pathway is the substitution of chlorine in **79a** by R^2Li through coordination with OLi to produce **80**, which should undergo intramolecular cyclization to generate **75**. Intermediate **75** should be stable enough at −98 °C to react with an electrophile and produce **76**. Alternatively, the cyclization of **79b** first gives the chlorolithiooxirane **81**, which might liberate a chloride ion to form the oxyrenium ion **82** by participation of the lone pair of electrons on the oxygen atom. The intermediate **82** is apparently unstable and is trapped immediately by another molecule of R^2Li from the face opposite to Li–F chelation to afford **75**.



Very recently, the trifluoromethyl-substituted oxiranyl anion **84** was generated successfully from optically active 2,3-

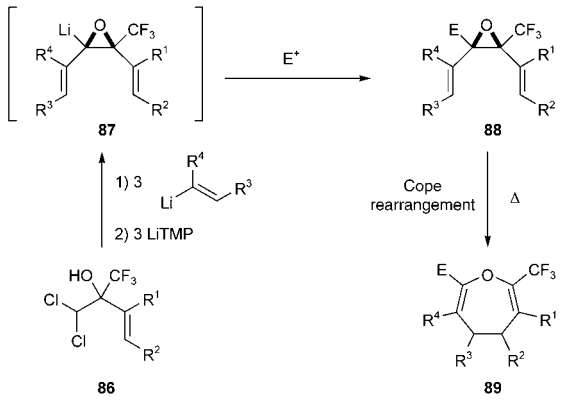
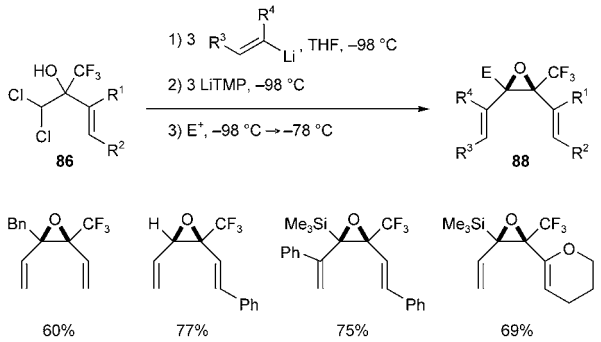
epoxy-1,1,1-trifluoropropane (**83**, 75% *ee*) and BuLi in THF at −102 °C (Scheme 24).[49] The configuration of **84** was reported to be stable below −78 °C. Its reaction with aldehydes and ketones gives alcohols **85**.



Scheme 24. Generation and reactions of α-CF_3-substituted oxiranyl lithium.

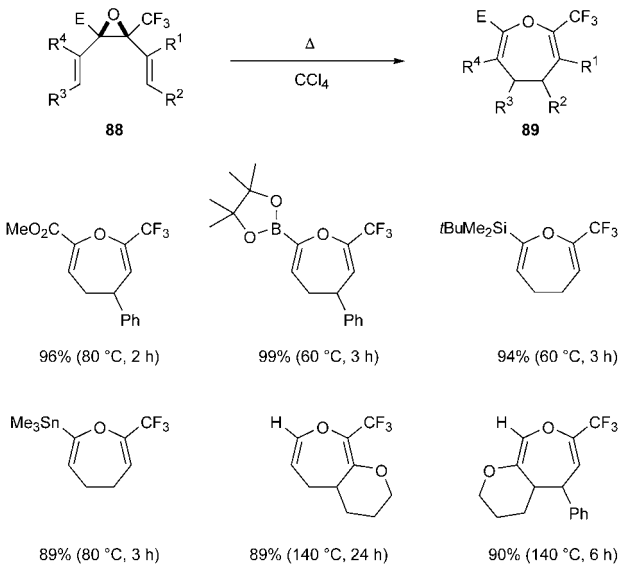
6. A Facile Route to Seven-Membered Oxacycles



Much attention is focused on seven-membered oxacycles, such as oxepanes and oxepins, owing to their occurrence in biologically active natural products and to valence-bond isomerization between oxepin and benzene oxide.[50] As the incorporation of a CF_3 group into biologically active compounds can alter their properties, facile methods for the synthesis of CF_3-substituted seven-membered oxacycles, a novel class of CF_3-containing compounds, is of particular interest in the quest for potent biologically active substances.

The Cope rearrangement of 2,3-bis(alkenyl)oxiranes would appear to be an attractive approach to the construction of such oxacycles. However, this strategy has remained unrealized, mainly because 1) bis(alkenyl)oxiranes with the essential *cis* arrangement are hard to construct, 2) the rearrangement requires relatively high reaction temperatures, and 3) available disubstituted oxiranes are limited to precursors of 2,7-unsubstituted oxepins. Thus, tri- and tetrasubstituted oxiranes have remained unexplored because of the lack of efficient and stereoselective access routes.[51] We envisaged that it would be possible to prepare 2-CF_3-substituted 2,3-*cis*-bis(alkenyl)oxiranes **88** readily if the protocol for the stereoselective generation of CF_3-substituted oxiranyl lithium compounds was applicable to alkenyl-substituted dichlorohydrins **86** and alkenyl lithium intermediates (Scheme 25).

Scheme 25. Synthetic plan for the preparation of 2-trifluoromethyl-4,5-dihydrooxepins.



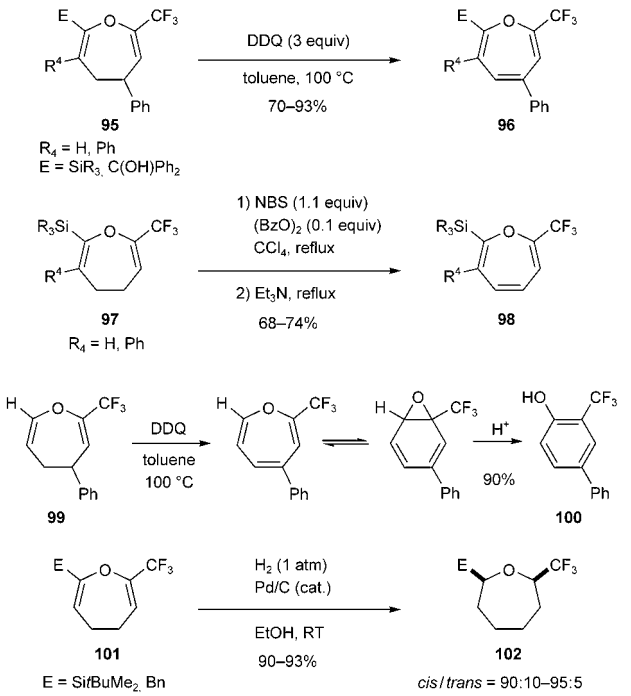
Regretfully, however, no trace of the desired reaction took place under the original conditions, probably as a result of the low basicity of the alkenyl lithium intermediates and/or the low acidity of a methine proton of **86**. After many trials, we found that the addition of LiTMP (3 equiv) to a solution of **86** and an alkenyl lithium compound is a highly effective way to generate oxiranyl lithium intermediates **87**, which can be trapped with a variety of electrophiles (E^+) to give **88** with excellent *cis* selectivity (Scheme 26).[52]

Scheme 26. Synthesis of *cis* bis(alkenyl)oxiranes **88**.

The Cope rearrangement of **88** proceeded smoothly upon heating at 60–140 °C to afford **89** in good to excellent yields (Scheme 27).[52] The rate of the reaction depends on the substituent E. If E is bulky, it appears to force the two

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 27. Cope rearrangement of **88**.



terminal C(sp^2) atoms close together, thus accelerating the rearrangement. If the starting substrate contains a cyclic olefin, oxepins with a fused framework, which are otherwise difficult to prepare, are obtained.

An additional feature of the present approach is the versatility of products containing metalloid elements introduced during the preparation of oxiranes **88**. Thus, a tin or boron substituent is readily converted into an aryl, alkenyl, or alkynyl group by a Pd-catalyzed cross-coupling reaction with an aryl, alkenyl, or alkynyl halide, respectively (Scheme 28).

Scheme 28. Coupling reaction of metal-substituted oxepins.

Dihydrooxepins **95** and **97** are readily converted into oxepins **96** (by oxidation with DDQ) and **98** (by allylic bromination–dehydrobromination with NBS and NEt_3), respectively, as illustrated in Scheme 29.[52] Oxidation of the 7-unsubstituted 4,5-dihydrooxepin **99** with DDQ produces **100** through equilibration of the oxepin to a benzene oxide,

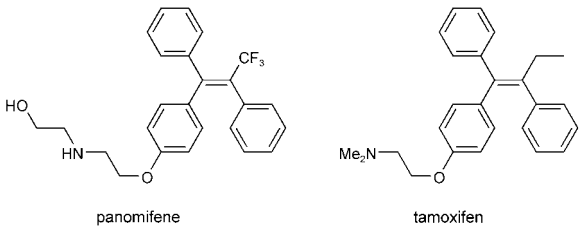
Scheme 29. Oxidation and reduction of 2-CF_3-4,5-dihydrooxepins. Bn = benzyl, Bz = benzoyl, DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

followed by acid-induced isomerization. Finally, 2-CF_3-substituted oxepanes **102** are readily available through the catalytic hydrogenation (1 atm) of **101** in the presence of 5% Pd/C.

7. Stereoselective Synthesis of CF_3-Containing Tetrasubstituted Alkenes

The regio- and stereoselective synthesis of tetrasubstituted alkenes is always a challenging issue in organic synthesis.[53] In particular, fluorine-containing tetrasubstituted alkenes are crucial in the search for potential fluorinated drugs. For example, panomifene is reported to exhibit antiestrogenic activity superior to that of tamoxifen, a widely used drug for the treatment of breast cancer (Figure 5).[54]

As oxiranyl lithium compounds are known to react with organometallic reagents, such as RLi, R_3Al, R_2Zn, and R_4CeLi, to give alkylated alkenes,[55] we first attempted unsuccessfully to apply this methodology to **103**. Fortunately,



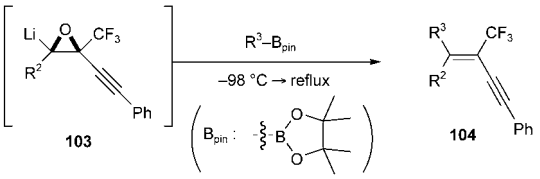


Figure 5. Examples of nonsteroidal antiestrogens.

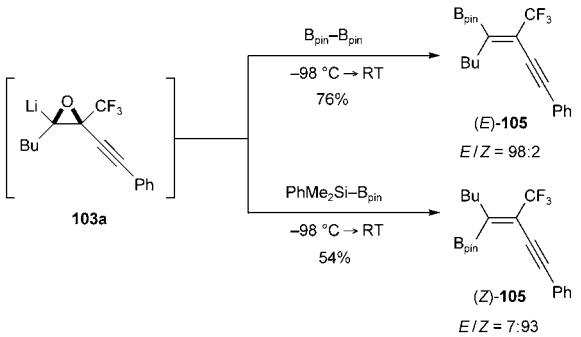
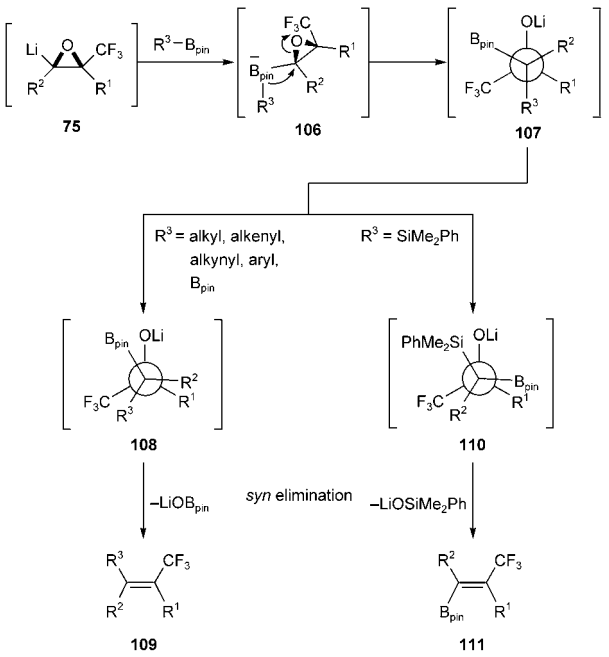
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



we have since found that the treatment of **103** with organo(-pinacolato)borane reagents R^3–B_{pin} (pin = pinacolato) affords tetrasubstituted alkenes stereoselectively in good yields, with CF_3 and R^3 in a *cis* relationship (Table 3). An

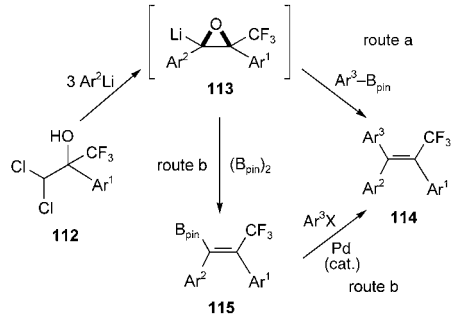
Table 3: Stereoselective synthesis of CF_3-containing tetrasubstituted alkenes.



Entry	R^2	R^3	Yield [%]	d.r.
1	Bu	PhC≡C	74	>95:5
2	Bu	(*E*)-BuCH=CH	56	>95:5
3	Bu	Ph	66	97:3
4	Ph	Bu	84	96:4

appropriate combination of R^2 and R^3 allows the preparation of either stereoisomer at will (entries 3 and 4 of Table 3). The stereodivergent synthesis of β-CF_3-substituted alkenyl boronates **105** is also possible when bis(pinacolato)diboron or dimethylphenylsilyl(pinacolato)boron is employed with **103**. The stereochemical outcome with the diboron reagent is opposite to that observed with the silylborane and the same as that with R^3–B_{pin} (Scheme 30).

Scheme 30. Stereoselective synthesis of CF_3-containing tetrasubstituted alkenes.

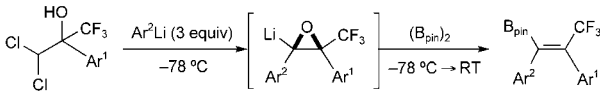


The stereoselective and stereodivergent formation of (*E*)- or (*Z*)-**105** can be explained by assuming that a *syn* elimination of $LiOB_{pin}$ or $LiOSiPhMe_2$ takes place in the last step, as illustrated in Scheme 31. First, **75** reacts with the borane reagent R^3–B_{pin} to give the borate **106**, which undergoes 1,2-migration of the substituent R^3 and opening of the oxirane to generate the lithium alkoxide **107**.[56] If R^3 is an alkyl, alkenyl, alkynyl, aryl, or boryl group, minimal rotation is required to attain the conformation **108**, in which the carbon–boron and carbon–oxygen bonds are eclipsed. The alkene **109** is then produced by the *syn* elimination of $LiOB_{pin}$.[57] When the silylborane is employed (i.e. R^3 in **106** is the silyl group), a rotation of 180° would be required for $LiOSiMe_2Ph$ to be eliminated in a *syn* fashion to give **111**. The elimination of

Scheme 31. Mechanism for stereoselective alkene formation.

$LiOSiMe_2Ph$ rather than $LiOB_{pin}$ might be expected, as a $PhMe_2Si$ group is more oxophilic than a B_{pin} group.

Based on these results, it seemed that various CF_3-substituted triaryl ethenes **114**, including panomifene, would be accessible if diaryl-substituted oxiranyl lithium intermediates **113** are generated successfully from Ar^1-substituted dichlorohydrins in the presence of Ar^2Li and react with Ar^3–B_{pin} smoothly (route a in Scheme 32).[58] However, this



Scheme 32. Synthetic plan for the preparation of CF_3-substituted triaryl ethenes.

expectation was not fulfilled, although it was shown that intermediate **113** was generated quite efficiently even at −78 °C. Hence, we took another approach (route b), which involves the preparation and cross-coupling of β-CF_3-substituted alkenyl boron reagents **115**.[59] Thus, the lithiooxirane **113** is first generated from **112** with Ar^2Li at −78 °C and then allowed to react with the diboron reagent to produce **115** in good yields with high *E* selectivities (Table 4).

The Pd-catalyzed cross-coupling reaction of **115** (route b in Scheme 32) with a variety of aryl iodides was carried out

successfully in the presence of a 5 M aqueous solution of Cs_2CO_3 to give **114** as a single stereoisomer in high to excellent yields (Table 5).[59] The coupling reaction under anhydrous conditions causes deborylation of **115** to some extent. Neither electron-donating nor electron-withdrawing groups on Ar^1 or Ar^2 affect the reaction. The demethylation of **114d** with NaOEt followed by the introduction of a 2-(2-hydroxyethyl)aminoethyl moiety completed a facile synthesis of panomifene.[59]

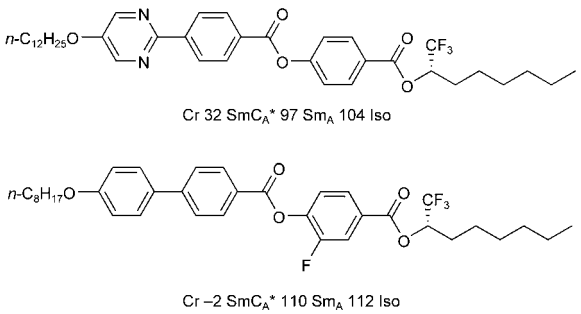
8. Asymmetric Synthesis of 1,1,1-Trifluoro-2-alkanols

In recent years, many optically active organofluorine compounds have been employed in the pharmaceutical, agrochemical, and materials sciences. For example, many antiferroelectric liquid crystals contain optically active 1,1,1-trifluoro-2-alkanols as key fragments that contribute to the stabilization of the SmC_A phase (Figure 6). Accordingly, the enantioselective synthesis of such fluorinated alcohols has been a target in organic synthesis.[60] We have designed novel methods for the efficient synthesis of 1,1,1-trifluoro-2-alkanols, including the asymmetric synthesis of trifluoromethyl-substituted hemiacetals and their stereospecific nucleophilic substitution.[61]

In our studies on asymmetric hemiacetal synthesis we found that bubbling gaseous trifluoroacetaldehyde, generated from 1-ethoxy-2,2,2-trifluoroethanol (**118**) and polyphosphoric acid (PPA), into a solution of an alcohol in toluene in the presence of a preprepared (*R*)-binol–Ti(O*i*Pr)$_2$ catalyst yielded the optically active hemiacetal **119**, which then underwent acylation with an acid chloride or sulfonyl chloride at low temperatures to give the optically active mixed acetal (*S*)-**120** (Table 6).[62] Alternatively, optically pure 1-alkoxy-2,2,2-ethyl tosylates are accessible by the optical resolution of racemic tosylates by chiral preparative HPLC (Daicel chiralpak AD or chiralcel OD).[63] The presence of the CF_3 group makes it possible to isolate otherwise unstable α-alkoxyalkyl tosylates.



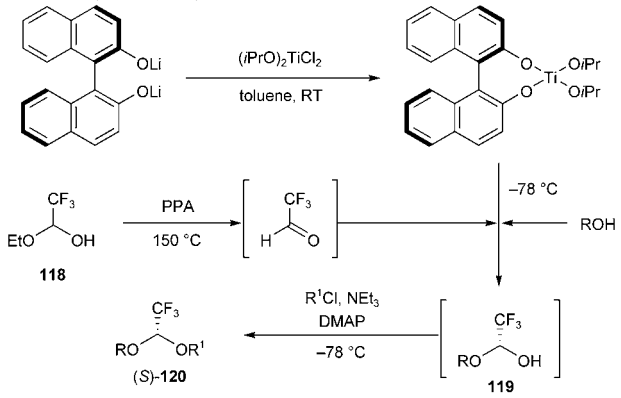


Figure 6. Examples of antiferroelectric liquid crystals.

DMAP = 4-dimethylaminopyridine.

Hemiacetal tosylates (*S*)-**121** react with organoaluminum, organoboron, and organozinc reagents to give substitution products with inversion of configuration.[64] The best overall results with respect to the yields and *ee* values of the isolated products were obtained with aluminate reagents (Table 7). This study demonstrated for the first time that intermolecular nucleophilic substitution is possible at a CF_3-substituted carbon atom to form a carbon–carbon bond. We should emphasize at this point that the alkoxy substituent in **121** assists in this process by increasing the reactivity of the

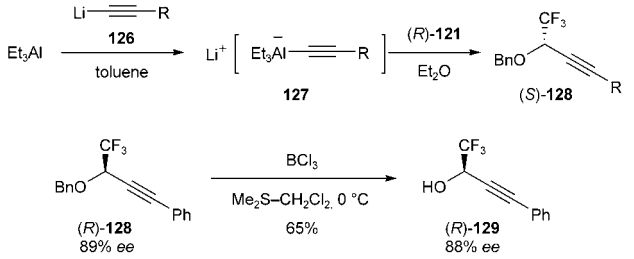
5	$LiBEt_4$	RT	32	95
6	$LiZnEt_3$	RT	30	96

otherwise unreactive CF_3-substituted alkyl tosylates. Thus, the presence of the substituent OCH_2Ph α to a CF_3 group in **121** is essential for the success of the nucleophilic substitution. The intramolecular nucleophilic substitution of 1,1,1-trifluoro-2-alkanol derivatives with an amino group or a cyano-stabilized carbanion is reported to take place with inversion of configuration, giving rise to trifluoromethyl-substituted aziridines and cyclopropanes, respectively.[65]



The versatility of the present approach is demonstrated by the preparation of 1,1,1-trifluoro-2-alkanols (Scheme 33).

Scheme 33. Efficient route to optically active 1,1,1-trifluoro-2-alkanols.

Thus, the titanocene-catalyzed hydroalumination of 1-alkenes with $LiAlH_4$ produces regioselectively lithium tetraalkyl aluminates **123**, which undergo stereospecific substitution with (*R*)-**121** to give (*S*)-**124**. The hydrogenolysis of (*S*)-**124** under a hydrogen atmosphere in the presence of 5% Pd/C gives optically active alcohols (*S*)-**125**. Any alkanol of the type **125** can be prepared from the corresponding readily available 1-alkene and the tosylate **121** by this sequence.[66]

As only one alkyl group in aluminates takes part in the substitution, the use of mixed aluminates that transfer a required moiety to the exclusion of the less reactive groups is more practical. Indeed, 1-alkynyl trialkyl aluminum compounds are appropriate for this purpose.[67] Thus, mixed aluminates **127**, prepared from commercially available triethylaluminum and the requisite alkynyl lithium reagent **126**, undergo reaction with (*R*)-**121** selectively and stereospecifically to afford alkynylated products (*S*)-**128** with inversion of configuration (Scheme 34). The catalytic hydrogenation of (*R*)-**128** at 1 atm with PtO_2 furnishes the benzyl ether (*R*)-**124**

Scheme 34. Alkynylation of the optically active tosylate (*R*)-**121** with the mixed aluminate **127**.

(R = Ph), whereas debenzylation of (*R*)-**128** with BCl_3 and Me_2S gives the alcohol (*R*)-**129**, leaving both the CF_3 and C≡C functional groups untouched.

9. Summary

Herein we have reviewed our progress during the last two decades in synthetic fluorine chemistry. A fluorination method (oxidative desulfurization–fluorination) has been developed, as well as building-block methods in which readily available CF_3CCl_3, $CFBr_3$, $CF_3COCHCl_2$, $CF_3CH(OH)OEt$, and their derivatives are used in combination with organometallic reagents. These novel synthetic methods have allowed the convenient preparation of a variety of fluorine-containing target molecules. The presence of fluorinated or perfluorinated substituents often induces unusual phenomena, which may be ascribed ultimately to the strong electron-withdrawing effect of these substituents. From this point of view, insight into synthetic fluorine chemistry opens possibilities for the design of new reactions/reagents not only in organofluorine chemistry but also in general organic synthesis and organometallic chemistry. We hope this Review may foster research in related fields.

Communications

The highly chlorinated, thermally stable [60]fullerene $C_{60}Cl_{30}$ contains a cylinder-shaped carbon cage consisting of two aromatic six-membered rings and one equatorial 18π-trannulene belt separated by two 15-membered belts of sp^3 carbon atoms bearing Cl substituents. Find out more about the synthesis and properties of $C_{60}Cl_{30}$ in the Communication by P. A. Troshin, S. I. Troyanov et al. on the following pages.

Fullerenes

Synthesis and Structure of the Highly Chlorinated [60]Fullerene $C_{60}Cl_{30}$ with a Drum-Shaped Carbon Cage**

Pavel A. Troshin, Rimma N. Lyubovskaya, Ilya N. Ioffe, Natalia B. Shustova, Erhard Kemnitz, and Sergey I. Troyanov**

Halogenated fullerenes are versatile precursors for the synthesis of various complex derivatives, some of which exhibit promising properties for material science applications.[1] To date, considerable success has been achieved in preparation and structural characterization of fullerene bromides[2] and fluorides.[3] Despite numerous reports on chlorination of C_{60} by different reagents,[4] only two individual compounds have been isolated so far. The structure of $C_{60}Cl_6$ formed in the reaction of ICl with C_{60} in benzene was deduced from the ^{13}C NMR and IR spectra.[4b] $C_{60}Cl_{24}$ was synthesized using VCl_4 and $SbCl_5$; a tetrahedral structure similar to that of $C_{60}Br_{24}$[2a,d] was assigned to this chloride on the basis of a comparison between the experimental and theoretically calculated IR spectra.[5]

Here we report the synthesis and structural characterization of the novel, highly chlorinated fullerene $C_{60}Cl_{30}$. This chlorofullerene can be prepared using chlorinating agents such as ICl, ICl_3, and $SbCl_5$. Typically, 50–100 mg of C_{60} and a large excess (~2 g) of chlorinating agents were sealed in glass ampules and heated at 220–250 °C for one to three days. Then, the ampules were opened, and the excess of the chlorinating agents and their decomposition products were removed in vacuo at 150 °C. Pure $C_{60}Cl_{30}$ (**1**) was formed in the reaction of C_{60} with $SbCl_5$, whereas chlorination by ICl yielded the $C_{60}Cl_{30}\cdot 2\,ICl$ solvate (**2**), both as dark-orange crystals stable in air. The IR spectrum of $C_{60}Cl_{30}$ is presented in Figure 1. The most prominent bands are observed at $\tilde{\nu} = 439$, 450, 471, 479, 730, 775, 822, 854, 895, 903, 918, 958, 993, and 1447 cm^{-1}.[6]

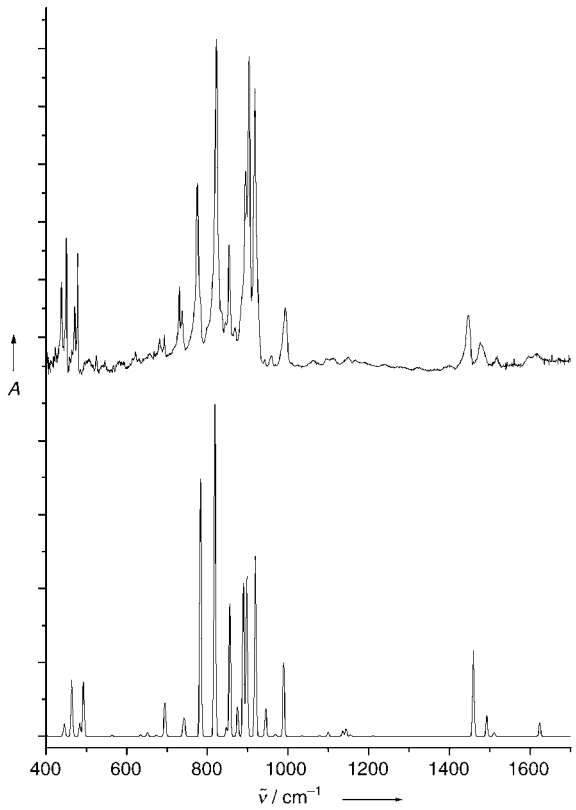

Figure 1. The experimental (top) and calculated (bottom) IR spectra of $C_{60}Cl_{30}$.

$C_{60}Cl_{30}$ is insoluble in most common organic solvents such as diethyl ether, 1,4-dioxane, CH_2Cl_2, $CHCl_3$, and CCl_4; it is poorly soluble in CS_2, toluene, and chlorobenzene; and its solubility in 1,2-dichlobenzene was estimated at roughly 0.2 mg mL^{-1}. The thermal stability of $C_{60}Cl_{30}$ appears to be remarkably high: its decomposes into C_{60} and Cl_2 at 450–500 °C (Figure 2), which is about 120 °C higher than the temperature ranges previously reported for $C_{60}Cl_{24}$.[4b,5] The mass loss for $C_{60}Cl_{30}$, 60.1 %, corresponds well to the calculated value of 59.75 %.

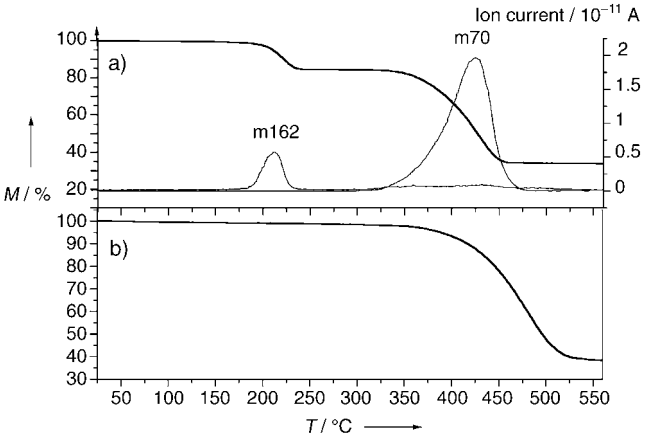

Figure 2. Thermoanalytical data for $C_{60}Cl_{30}\cdot 2\,ICl$ (a) and $C_{60}Cl_{30}$ (b).

X-ray single-crystal structures of both $C_{60}Cl_{30}$ (**1**) and $C_{60}Cl_{30}\cdot 2\,ICl$ (**2**) were determined with good accuracy.[7] While the isolated molecule of $C_{60}Cl_{30}$ should possess D_{3d} symmetry, crystallographically imposed symmetry in **1** and **2** becomes reduced to C_i and C_{2h}, respectively. There are two planar aromatic six-membered rings on the opposite sides of the cage and an equatorial 18π all-*trans* annulene (*trannulene*) belt in the chlorofullerene molecule (Figure 3). $C_{60}Cl_{30}$ is the first molecule in which the trannulene belt is separated from the benzenoid rings by two 15-membered rings of sp^3 carbons bearing chlorine atoms. Such a structural arrangement results in the unique cylindrical, drumlike shape of the carbon cage.

The fluorofullerene molecule $C_{60}F_{18}$ contains one six-membered planar aromatic fragment which is surrounded by the fluorinated belt of 15 sp^3 carbons.[8] The S_N2' substitution of three additional outlying fluorine atoms by various malonate groups yields compounds having the composition $C_{60}F_{15}[CX(COOR)_2]_3$, which also contain [18]annulene belts. These subunits satisfy the magnetic and geometric criteria of aromaticity, even though they are not completely isolated from the rest of the π system.[1,9]

The IR spectroscopic and mass spectrometric study of the products collected before the completion of the reaction revealed that tetrahedral $C_{60}Cl_{24}$ is an intermediate in the synthesis of $C_{60}Cl_{30}$. Noteworthy, the formation of D_{3d} $C_{60}Cl_{30}$ from T_h $C_{60}Cl_{24}$ requires rearrangement of at least 18 Cl atoms over the fullerene cage. The analogous migration of fluorine atoms yielding the most thermodynamically stable structures is called the "fluorine dance" and is known for the fluorination of $C_{60}F_{36}$ to give $C_{60}F_{48}$[10a] and for the transformation of C_1 $C_{60}F_{36}$ into C_3 $C_{60}F_{36}$ by fluorine rearrangement.[10b] The formation of $C_{60}Cl_{30}$ from $C_{60}Cl_{24}$ is the first observation of the "chlorine dance". The thermally induced "chlorine dance" appears to be slow enough for other possible intermediates to be isolated by termination of the reaction at a certain stage.

Quantum chemical calculations at the DFT level of theory were performed to examine the relative stability of various higher chlorides of C_{60}.[11] Two main factors were found to influence the stability of chlorofullerenes beyond $C_{60}Cl_{24}$: destabilizing van der Waals repulsions between the adjacent chlorine atoms and the stabilizing effect of the aromatic fragments such as benzenoid rings. Particularly high steric strain was observed for the structures containing chlorine atoms surrounded by three others ("triple contacts"). Ruling out the "triple contacts" results in a maximum of two isolated benzenoid rings in the closed-shell chlorofullerene molecules. One of two possible structures containing two aromatic six-membered rings and no "triple contacts" corresponds exactly to the presently found isomer of $C_{60}Cl_{30}$. It is approximately 110 kJ mol^{-1} more stable than the second possible $C_{60}Cl_{30}$ isomer, which is characterized by nonparallel arrangement of two aromatic six-membered rings. The remarkable thermal stability of $C_{60}Cl_{30}$ might have a kinetic origin since detachment of any chlorine atom would perturb the stable aromatic fragments. $C_{60}Cl_{30}$ probably represents the terminal stage of C_{60} chlorination since further chlorine attachment would involve a strongly unfavorable destruction of the aromatic rings.

The averaged experimental and calculated molecular structures of $C_{60}Cl_{30}$ are in very good agreement (Table 1). The aromatic six-membered rings are almost perfectly planar; the sum of the valence angles involving aromatic carbons exceeds 359.9°; and the 6/6 (*a'*) and 5/6 (*a''*) C–C bonds in these rings are virtually equal. Similar equalization of the 6/6 (*h*) and 5/6 (*i*) bonds is seen in the equatorial trannulene ring, which serves as additional evidence of its aromatic character. The sp^3–sp^3 C–C bonds appear to be strongly elongated, reaching a value of 1.70 Å (*e*). For comparison, similar bonds in $C_{60}F_{18}$ and $C_{60}F_{36}$ are "only" 1.67 Å long.[9,12] The calculated IR spectrum of $C_{60}Cl_{30}$ is in a good agreement with the experimental one (Figure 1).

It is known that oxygen can attack the elongated C–C bonds in $C_{60}F_{18}$, which results in their cleavage and formation of intramolecular ethers.[13] Impurities of $C_{60}F_{18}O$ in some $C_{60}F_{18}$ samples have been observed by means of X-ray single-crystal diffraction.[9b] In these cases, the presence of oxygen was manifested in the characteristic maxima near the elongated C–C bonds on electron density maps. Similar peaks were found for **1a** (synthesized with nonpurified $SbCl_5$),[7] where one of the *e* bonds was elongated up to

Table 1: C–C and C–Cl bonds [Å] in $C_{60}Cl_{30}$ according to the averaged data[a] for structures **1** and **2** and DFT calculations.

Bond type[b]	**1**	**2**	Calcd
C–C			
a′, sp^2–sp^2, 6/6	1.367	1.372	1.372
a″, sp^2–sp^2, 5/6	1.377	1.374	1.380
b, sp^2–sp^3, 5/6	1.476	1.476	1.479
c, sp^3–sp^3, 6/6	1.576	1.582	1.582
d, sp^3–sp^3, 5/6	1.622	1.620	1.628
e, sp^3–sp^3, 5/6	1.693	1.699	1.699
f, sp^2–sp^3, 5/6	1.509	1.509	1.509
g, sp^2–sp^3, 6/6	1.494	1.494	1.496
h, sp^2–sp^2, 6/6	1.381	1.386	1.381
i, sp^2–sp^3, 5/6	1.391	1.392	1.391
C–Cl			
1	1.776	1.772	1.800
2	1.788	1.786	1.815
3	1.787	1.779	1.811

[a] Estimated standard deviations of individual bond lengths in **1** and **2** are 0.002 Å and 0.003–0.004 Å, respectively. [b] Bond labels are defined in the Schlegel diagram in Figure 3.

1.722 Å, as compared to 1.690 Å for the rest two *e* bonds. Taking into account a statistical averaging with the parent $C_{60}Cl_{30}$, this additional elongation indicates the presence of the $C_{60}Cl_{30}O_2$ ether (about 7 %) with two cleaved C–C bonds.

The chemical properties of $C_{60}Cl_{30}$ may be rather versatile. Firstly, the weak elongated C–C bonds can be regarded as a convenient site for further derivatization of this molecule. The benzenoid moieties can allow organometallic η^6-coordination, as it was previously observed for $C_{60}F_{18}$.[14] Our preliminary experiments showed that $C_{60}Cl_{30}$ can undergo nucleophilic substitution reactions though significantly slower than $C_{60}Cl_{24}$. Detailed investigation of $C_{60}Cl_{30}$ reactivity is a subject for further studies.

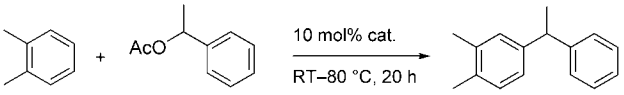
Homogeneous Catalysis

Transition-Metal-Catalyzed Benzylation of Arenes and Heteroarenes**

*Kristin Mertins, Irina Iovel, Jette Kischel, Alexander Zapf, and Matthias Beller**

Dedicated to Professor Rüdiger Selke on the occasion of his 70th birthday

The majority of known fine chemicals, pharmaceuticals, agrochemicals, dyes, etc. contain aromatic and/or heteroaromatic substructures. To vary and improve the properties of these compounds functionalization reactions of the aromatic core are of fundamental importance to organic chemistry. In the past and still today most aromatic products are prepared on the industrial level by well-known classic transformations such as Friedel–Crafts alkylations, Friedel–Crafts acylations, nitrations, and halogenations.[1] Although these methods work reliably with a variety of substrates, they often have major drawbacks such as drastic reaction conditions (high temperature, strong acidic conditions), low regioselectivity, and large amounts of (salt) by-products. In addition it is common that the construction of specific C–C bonds on the aromatic core requires several steps including introduction of activating groups and protection and deprotection steps. Therefore, the development of new direct C–C coupling reactions of arenes has become an important topic in organometallic chemistry and catalysis. Recent elegant examples of such catalytic functionalization reactions include the addition of olefins to acetophenones (Murai reaction)[2] and aromatic imines,[3] novel additions of olefins to electron-rich arenes[4] and heterocycles,[5] the addition of arenes to alkynes,[6] the carbonylation of heterocycles,[7] the intramolecular cyclization of arylalkynes,[8] and the C-arylation of heteroarenes.[9]



In the past we have mainly focused on transformations of aryl chlorides using the C–Cl bond as an activating and directing functionality.[10] Because of the obvious advantages of direct C–H transformations over palladium-catalyzed reactions of aryl halides, we initiated a program to search for new catalysts for C–C coupling reactions of arenes. Herein, we report our first results and show that various transition-metal catalysts are capable of benzylating activated and nonactivated arenes and heteroarenes with high yield and selectivity under mild conditions.

[**] This work was supported by the State of Mecklenburg-Western Pomerania and the Bundesministerium für Bildung und Forschung ("Nachhaltige Aromatenchemie"). We thank Prof. Dr. M. Michalik, Dr. W. Baumann, Dr. C. Fischer, H. Baudisch, and S. Buchholz (all IfOK) for excellent assistence with the analyses.

Initially we were attracted by the reaction of benzyl alcohol and its derivatives with arenes leading to diarylmethane-type compounds. The diarylmethane motif is found in a number of biologically active compounds such as piritrexim,[11a] trimethoprim,[11a] avrainvilleol,[11b] papaverine,[11c] beclobrate,[11d] and anastrozole[11e] and in a precursor in the synthesis of letrozole.[11e] Diarylmethane derivatives are used to prepare electroactive and photoactive oligomers and polymers based on fluorenes.[12] Friedel–Crafts reactions of benzylic alcohols and halides have been studied with traditional Brønsted and Lewis acids,[13] more recently with lanthanide and actinide triflates,[14] and also with heterogeneous catalysts.[15] Surprisingly few transition-metal catalysts based on palladium and ruthenium have been described to date for this type of reaction.[16] While palladium complexes have been used only on a stoichiometric basis for this reaction,[17] ruthenium complexes required high temperatures (200 °C) and gave the corresponding diarylmethanes generally in low to moderate yield (22–77 %).[18]

In our search for new and improved catalysts we studied the benzylation of *o*-xylene with 1-phenylethyl acetate as a model reaction (Scheme 1). A variety of Brønsted acids, transition-metal salts, and organometallic complexes were tested under mild conditions (80 °C). Selected results are given in Table 1. In the presence of catalytic amounts

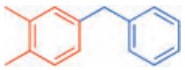
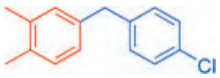
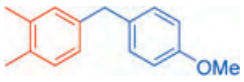
(10 mol%) of various Brønsted acids (HCl, H_2SO_4, HOAc, *p*-toluenesulfonic acid) the benzylated product 1-(3,4-dimethylphenyl)-1-phenylethane (**1**) was obtained at best in low yields (≤2%; Table 1, entries 1–4); however, to our surprise a variety of Rh, Ir, Pd, and Pt salts proved to be suitable catalysts for the test reaction. In addition, also [(mesitylene)-$W(CO)_3$] gave a significant yield (61%) of the desired product (Table 1, entry 6). At 80°C excellent results (99% yield of **1**) were obtained in the presence of hydrated $IrCl_3$, $H_2[PdCl_4]$, and $H_2[PtCl_6]$ (Table 1, entries 12, 17, and 21, respectively).[19] Good to quantitative yields of **1** (up to 99%) were observed even at room temperature using $IrCl_3$ and $H_2[PtCl_6]$ (Table 1, entries 14 and 23, respectively). Although for convenience most of the screening were conducted for 20 h, it is noteworthy that the reaction with $H_2[PtCl_6]$ at 80°C is complete within 1 h. In some cases a significant difference between the conversion and yield of **1** is observed (e.g., Table 1, entries 2, 6, 10). Here, side reactions of 1-phenylethyl acetate such as elimination, oligomerization, and polymerization of the resulting styrene take place.

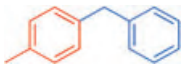
With reliable catalysts for the benzylation of *o*-xylene in hand, we were interested in the benzylation of other arenes and heteroarenes (Table 2) and in the use of different benzylating agents (Table 3). Although a number of the active transition-metal salts listed in Table 1 also catalyze these reactions, only the results with the most active and selective catalysts ($IrCl_3$ and $H_2[PtCl_6]$) are listed in Tables 2 and 3. As expected, a variety of electron-rich arenes such as toluene (87%), anisole (>99%), 1,4-dimethoxybenzene (92%), and 2-naphthol (96%) gave the corresponding benzylated products in good to excellent yield. In addition, heteroarenes, for example, 2,5-dimethylfuran (85%), benzofuran (91%), and 2-methylthiophene (96%) react very well. Interestingly, even nonactivated substrates such as benzene (62%) and more challenging starting materials such as 4-chloroanisole (99%)[20] and 2-methoxybenzaldehyde (67%) gave the corresponding products selectively. It is important to note that the last example constitutes one of the very rare cases of a selective Friedel–Crafts reaction in the presence of an aldehyde group!

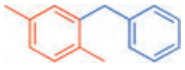
Finally, we set out to study the scope and limitation of the benzylating agent in more detail (Scheme 2). As shown in

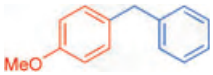


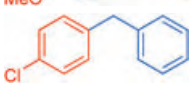












Scheme 2. Benzylation of arenes with different benzylation reagents. cat. = $H_2[PdCl_6]\cdot 6H_2O$, $IrCl_3\cdot n H_2O$.

Table 3 apart from 1-phenylethyl acetate also benzyl acetate and 4-chlorobenzyl acetate react with *o*-xylene in the presence of $H_2[PtCl_6]$ at 80°C (Table 3, entries 1, 4). In addition, benzyl methyl carbonate (66%) and benzyl alcohol (48%) also gave the desired product in moderate yields (Table 3, entries 2, 3). More interestingly, the reaction of benzyl acetate and chlorobenzene proceeded in good yield (57%). It is important to note that this latter reaction is one of the few successful Friedel–Crafts benzylations that work well also with deactivated arenes.

With regard to the mechanism, the presented reactions clearly operate by means of electrophilic aromatic substitu-

Table 3: Reactions with different benzylation reagents.[a]

tion. Thus, different regioisomers can be formed; however, in a number of cases (Table 2, entries 1, 7–10, 14, 16, 17) the benzylation proceeds regioselectively to produce only one product. By comparing the results in the presence of simple Brønsted acids and our transition-metal catalysts we propose that the active benzylation reagent is not a protonated benzyl acetate. In addition, we exclude the existence of a "free" benzylic carbocation because labeled $Ph^{13}CH_2OH$ does not lead to a scrambling of the ^{13}C atom by tropylium ion formation. However, reaction of enantiomerically pure 1-phenylethyl acetate with *o*-xylene results in a racemic mixture of **1**. Basically, the transition-metal center should stabilize the carbocation intermediate and prevent unproductive formation of styrene and subsequent polymerization. Based on the reactivity of the applied catalysts we rule out both a transition-metal-based C–H activation pathway as well as a simple oxidative addition to the benzyl acetate.

In summary, we have developed a new general benzylation reaction of aromatics. Arenes and heteroarenes can be easily benzylated in the presence of several transition-metal compounds, of which $IrCl_3$ and $H_2[PtCl_6]$ are the most active catalysts. Often the reactions proceed under mild conditions (RT–80 °C; no strong acid or base) with high selectivity. Interestingly, even nonactivated arenes and substituted benzyl alcohol derivatives can be applied successfully in this reaction.

Experimental Section

All reactions were carried out in air without any special precautions. ^1H and ^{13}C NMR spectra were recorded on a Bruker ARX 400 spectrometer. Chemical shifts (δ) are given in ppm and the residual solvent served as the internal standard. Gas chromatography was performed on a Hewlett Packard HP 6890 chromatograph with a HP5 column. Mass spectra were recorded on an AMD 402/3 mass spectrometer. Chemicals and solvents were purchased from Fluka and Aldrich and used as received.

General procedure for benzylation of *o*-xylene: In a pressure tube, 1-phenylethyl acetate (0.50 mmol) and catalyst (10 mol%, 0.050 mmol) were dissolved in *o*-xylene (10 mL). Hexadecane (50 μL) was added as internal GC standard. The reaction mixture was stirred 20 h before aliquots were removed and analyzed by GC to determine the yield and conversion. For isolation of the products the reaction was quenched with water. The aqueous phase was extracted with dichloromethane. The combined organic layers were dried over $MgSO_4$, and the solvents were removed under reduced pressure. The product was purified by column chromatography on silica gel (70–230 mesh, *n*-heptane/ethyl acetate (50:1)). ^1H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta = 1.5$ (d, $J(H,H) = 7.2$ Hz, 3H; CH_3), 2.1 (s, 6H; $2\,ArCH_3$), 4.0 (q, $J(H,H) = 7.2$ Hz, 1H; CH), 6.9–7.2 ppm (m, 8H; CH arom.); ^{13}C NMR (101 MHz, $CDCl_3$, 25 °C): $\delta = 18.3$, 18.8, 20.9, 43.2, 123.8, 124.8, 126.5, 127.3, 127.9, 128.6, 133.1, 135.4, 142.8, 145.6 ppm; MS (70 eV): *m/z* [%]: 210 (40) [M^+], 195 (100) [$C_{15}H_{15}^+$], 91 (10) [$C_7H_7^+$].

Stereogenic Metal Centers

Helical Chirality in Pentacoordinate Zinc Complexes—Selective Access to Both Pseudoenantiomers with One Ligand Configuration**

*Michael Seitz, Sabine Stempfhuber, Manfred Zabel, Martin Schütz, and Oliver Reiser**

The controlled construction of complexes with stereogenic metal centers ("chiral-at-metal complexes") is an important task because of the potential impact on various areas of chemical research, for example, supramolecular chemistry, asymmetric catalysis, or biological recognition. Since the first separation of the enantiomers of an inorganic coordination compound in 1911 by Werner,[1] the area of inorganic stereochemistry has emerged as a rapidly growing field, especially over the last years. In particular, the transfer of chirality from chiral, nonracemic organic ligands to metal centers with a variety of coordination geometries has attracted great interest.[2,3]

Predetermined chirality around a trigonal-bipyramidal-coordinated metal center is rather rare and normally favored with tripodal ligands.[4] Except for the complexes described herein, only three other examples with topologically linear ligands exist.[4a–c] To date, only the employment of enantiomeric (trivial) or diastereomeric[4b] ligands is suitable to enforce the formation of opposite chiral configurations.

In our case, only two achiral donor atoms are exchanged in an otherwise isosteric ligand to complete this task. To the best of our knowledge, this is the first time that this phenomenon is observed. The closest analogy can be seen in the cobalt complexes of ligand **1**:[5] Whereas **1a** forms an octahedral complex with Δ_2 configuration upon complexation

with Co^{III}, ligand **1b** gives rise to a mixture of two complexes, one of which was identified as the Λ_2-configured species.

We recently reported the novel pentadentate bis(oxazoline) ligand **6b** (Scheme 1), which forms octahedral Co^{II} or

Scheme 1. Synthesis of **6a** and **6b**. Figure 1. Crystal structures of the cations of the complexes Λ_2-**7a** and Δ_2-**7b**.[16] Hydrogen atoms have been omitted for clarity, except for the ones at the stereocenters of the oxazolines. a) Front view. b) Top view (phenyl rings have been omitted for clarity). C gray, H white, N blue, O red, S yellow, Zn pink.

Ru^{II} complexes with exclusive Δ_2 configuration.[6] Herein we describe trigonal-bipyramidal Zn^{II} complexes of **6a** and **6b**,[7] which differ only in the heteroatom at the benzylic position of the pyridine (O versus S).

Ligands **6** were readily assembled from the known oxazoline **2**[8] in a modular fashion. After deprotonation of **2** with NaH, the resulting anion was trapped with the pyridine dielectrophile **4**[9] to give **6a** in 88% yield. Analogously, tosylation of **2** resulted in **3**,[6] which was treated with the pyridine dinucleophile **5**[6,10] to yield **6b** in 72% yield.

The zinc complexes[11] were prepared by mixing equimolar amounts of zinc(II) perchlorate hexahydrate and the corresponding ligand **6** in THF at ambient temperature (Scheme 2). The precipitated complexes **7** were recrystallized from acetonitrile/diethyl ether to give colorless crystals that were suitable for X-ray crystallographic analysis.

The crystal structures of **7a** and **7b** show two pentacoordinate zinc complexes with distorted trigonal-bipyramidal geometry (Figure 1, Table 1). The complexes each have a single but opposite configuration at the metal center: Λ_2 for **7a** and Δ_2 for **7b**. This remarkable reversal in helical folding around the metal center is not easy to understand. The N_{py}–Zn and N_{oxaz}–Zn distances are approximately equal in both complexes, and the Zn–O (2.22 and 2.27 Å) and the Zn–S (2.53 Å) distances are within normal limits. The most pronounced difference is the stronger distortion of the oxygen (O-Zn-O = 153°) atoms towards the pyridine moiety relative to that of the sulfur atoms (S-Zn-S = 169°), which is dictated by the fact that the benzylic C–O bond (1.44 Å) is shorter than the corresponding C–S (1.81 Å) bond.

To assess the energy difference between the particular helical folding of ligands **6a** and **6b** in the zinc complexes, ab initio calculations at the second-order Møller–Plesset perturbation theory (MP2) level were performed. Geometry optimizations were carried out for the two complex cations Λ_2-**7a** and Δ_2-**7b** and the corresponding pseudoenantiomers Δ_2-**7a** and Λ_2-**7b**.[12] The geometry optimizations reflect well the geometries found in the X-ray crystal structure of Λ_2-**7a**

[a] py = pyridine, oxaz = oxazoline.

and Δ_2-**7b**; the bond lengths and angles found for the pseudoenantiomers Δ_2-**7a** and Λ_2-**7b** are all in the normal range and are similar to their counterparts.[11]

Two different steric interactions can be identified which work in opposite directions for the Λ_2 and Δ_2 configuration of each complex. In the Λ_2 configuration, the phenyl substituents of the oxazoline rings point toward the pyridine backbone, as manifested in the especially close distance between the *ortho* carbon atom of the phenyl ring and the heteroatom X (Figure 2a). This interaction is especially severe for Λ_2-**7b**

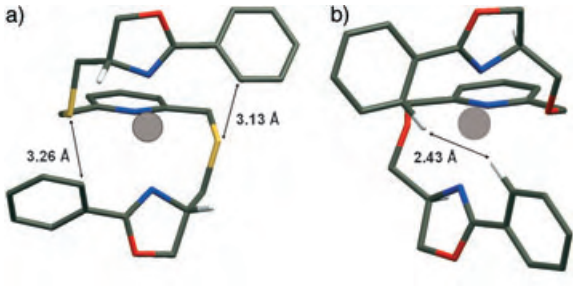

Figure 2. Calculated structures of Δ_2-**7a** and Λ_2-**7b**. C gray, H white, N blue, O red, S yellow, Zn gray ball.

(C–S distance 3.13 and 3.26 Å, sum of van der Waals radii for C and S = 3.50 Å), clearly favoring Δ_2-**7b** (C–S distance 3.43 Å). The same trend is seen for **7a** (Λ_2-**7a**: C–O distance 3.01 and 3.19 Å; Δ_2-**7a**: C–O distance 3.77 Å), but still acceptable in Λ_2-**7a** owing to the smaller van der Waals radius of oxygen (C+O = 3.22 Å).

The second steric interaction that must be considered is the distance between the two phenyl rings (Figure 2b). In the Λ_2 configuration, these phenyl rings are especially close to each other as manifested in the distance between two of the *ortho*-hydrogen atoms (Δ_2-**7a**: 2.43 Å; Δ_2-**7b**: 2.46 Å), whereas in the corresponding Λ_2 configuration the phenyl rings are far away from each other. This interaction seems to be particularly unfavorable in Δ_2-**7a** (sum of van der Waals radii of two hydrogen atoms is 2.40 Å), resulting in the exclusive formation of Λ_2-**7a**. In agreement with this analysis, the calculations predict a decrease in energy on going from the pseudoenantiomers Δ_2-**7a** and Λ_2-**7b** to the experimentally confirmed structures Λ_2-**7a** and Δ_2-**7b** of 2–4 kcal mol^{-1} (X = O) and 6–8 kcal mol^{-1} (X = S), respectively.

Remarkably, the Δ_2 configurations exhibit perfect C_2 point-group symmetry, whereas this symmetry is distorted to C_1 for the Λ_2 conformers. The ab initio calculations and the measured X-ray structures both agree with this distortion. As a consequence, the Λ_2 conformers exist in two isometric versions on their higher symmetric potential-energy surfaces, which in the present case correspond to the molecular symmetry group C_2(M).[13] The Λ_2 configurations of C_2 point-group symmetry are likely to be saddle points (transition structures) on the interconversion pathways connecting the two related C_1 versions. Hence, the vibrational ground state splits for the Λ_2 conformers.

The solution behavior of **7a** and **7b** was investigated by means of NMR and CD spectroscopic analysis of the bulk material obtained in the complexation experiments. The ^{1}H and the ^{13}C NMR spectra[11] in CD_3CN show a single species for each complex. As expected, the signals for the complexed ligands are shifted downfield with respect to the free ligands. In particular, the ^{13}C NMR spectra clearly show the C_2 symmetry of the complexes in both cases, as well as the pentacoordination of the ligand, indicated by the strong downfield shift of the signals for the quaternary carbon atom of the oxazolines (**6a**→**7a**: 164.9 to 175.4 ppm; **6b**→**7b**: 164.6 to 172.7 ppm). Therefore, both species must be either Δ_2 or Λ_2.

CD spectroscopic analysis of the complexes in CH_3CN solution showed a quasi-mirror image of the n→π* transition (Figure 3), which indicates a quasi-enantiomeric relationship between the two zinc complexes. Application of the sector rules for C_2-symmetric pyridines put forward by Palmer and co-workers[14] predicts the configuration around the zinc atom

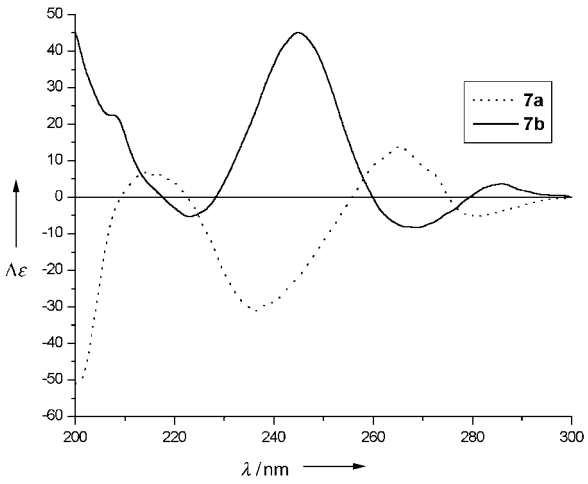

Figure 3. CD spectra of the complexes Λ_2-**7a** and Δ_2-**7b** in CH_3CN.

as Λ_2 for **7a** and Δ_2 for **7b**, in complete agreement with the crystal structures.

In summary, a new ligand system is introduced that allows the completely stereoselective transfer of chirality from the pentadentate bis(oxazolines) to a trigonal-bipyramidal coordinated central metal atom in the solid state as well as in solution. For the first time, two opposite, pseudoenantiomeric configurations were observed with a single ligand design, that is, **6a** and **6b** differ only by two single atoms and are otherwise stereochemically identical.

[12] The ab initio energy-minimization calculations were performed with the new analytic local MP2 gradient based on density fitting (DF-LMP2).[15a] The SVP AO basis set by Schäfer et al.[15b] together with the SVP/MP2FIT and TZVP/MP2FIT fitting basis sets[15c] (the former for the LMP2, the latter for the Hartree–Fock specific parts of the gradient[15a]) was used. For zinc, a quasi-relativistic energy-adjusted pseudopotential based on the Ne-like Zn^{20+} core together with the related 6s5p3d AO basis set[15d] was employed. At the minimum-energy geometries of Λ_2-**7a** and Δ_2-**7a**, single-point energy calculations were also performed with the TZVP basis set by Schäfer et al.[15e] in conjunction with the TZVP-MP2FIT and TZVPPMP2FIT fitting basis sets,[15c] and an additional set of f functions with exponent 3.22 on the Zn center.

Cluster Compounds

From a Monomeric Bismuth Silanolate to a Molecular Bismuth Oxo Cluster: $[Bi_{22}O_{26}(OSiMe_2tBu)_{14}]$**

Dirk Mansfeld, Michael Mehring, and Markus Schürmann*

Recent interest in bismuth oxide based materials including heterometallic phases, such as Bi/Mo/O,[1,2] Bi/Ti/O,[3] Bi/Nb/O,[4] Bi/Sr/Ta/O,[5] and Bi/V/O[6] stems from their use as catalysts, ferroelectric devices, oxide ion conductors, and non-toxic pigments. In addition, bismuth oxide (doped with 4 atom% of a transition metal) was suggested to serve as a

 DOI: 10.1002/anie.200461476 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

selective sensing material for the detection of NO.[7] Traditionally, the synthesis of bulk bismuth oxide materials is carried out at high temperature starting from compounds such as bismuth nitrate or bismuth subcarbonate. However, homo- and heterometallic bismuth alkoxides have been shown to be potential precursors for the synthesis of bismuth oxide materials by the sol–gel process and chemical vapor deposition (CVD).[8,9] Thus, in recent years several homo- and heterometallic bismuth alkoxides including a few bismuth oxo alkoxide clusters with up to nine bismuth atoms have been fully characterized,[2,9–13] however there is little information on their siloxide counterparts. Single examples of bismuth silanolates have been reported,[11,14,15] but to date $Bi(OSiPh_3)_3(thf)_3$[11] and $Bi(OSiPh_2tBu)_3$[15] are the only ones characterized by single-crystal X-ray diffraction. We have sought to use compounds of the type $Bi(OSiR_3)_3$ for the preparation of bismuth oxide based materials, because the thermally induced decomposition of bismuth silanolates was expected to give Bi_2O_3 and $R_3SiOSiR_3$. Our assumption was supported by the observations, that heterometallic bismuth and antimony alkoxides are able to either partially eliminate ethers (ROR), with formation of low-nuclearity metal oxo clusters, or to eliminate an alkene, to give MOH and subsequent condensation to give oxo clusters.[13,16] For example, partial elimination of hexamethyldisiloxane occurs when $Sb(OSiMe_3)_3$ is treated with $NaOSiMe_3$ to give the cluster $[Na_4Sb_2(O)(OSiMe_3)_8]$.[17] Bismuth silanolates are expected to react in this way as the heat of formation of a siloxane is significantly higher than that of the corresponding ether and elimination of a silaethene from a silanyloxide is not very likely. Another advantage of bismuth silanolates compared with simple bismuth alkoxides is their higher solubility, which is crucial for solution-based approaches to novel materials. Herein we report the synthesis, characterization, and thermally induced decomposition of $Bi(OSiMe_2tBu)_3$ (**1**), and the partial hydrolysis of **1** to give the novel high-nuclearity metal oxo cluster $[Bi_{22}O_{26}(OSiMe_2tBu)_{14}]$ (**2**).

The bismuth silanolate $Bi(OSiMe_2tBu)_3$ (**1**) was prepared in high yield by the reaction of $Bi(OtBu)_3$ with $tBuMe_2SiOH$ [Eq. (1)]. The low-melting-point solid is easily purified by Kugelrohr-distillation under reduced pressure.

$$Bi(OtBu)_3 + 3\,Me_2tBuSiOH \rightarrow Bi(OSiMe_2tBu)_3\,(\mathbf{1}) + 3\,tBuOH \quad (1)$$

Single crystals of compound **1** were obtained after the neat compound was warmed to give an oil then cooled to −20 °C. The molecular structure of **1** is given in Figure 1. The coordination geometry of **1** is best described as a trigonal pyramid with three oxygen atoms and the bismuth atom occupying the apical positions. The Bi–O bonds are in the range 2.003(14)–2.054(16) Å which is comparable with the values reported for $Bi(OSiPh_3)_3(thf)_3$ (2.04(1) Å)[11] and $Bi(OSiPh_2tBu)_3$ (2.041(4)–2.062(4) Å).[15] The O-Bi-O angles are between 94.0(5)° and 99.6(6)° and thus, indicate a strong s-character of the lone-pair. In contrast to bismuth alkoxides that associate through intermolecular Bi···O bonds, the bulky organic groups in monomeric **1** prevent such secondary interactions. Note, that in $Bi(OSiPh_3)_3(thf)_3$ three solvent molecules complete the coordination sphere at the bismuth atom and $Bi(OSiPh_2tBu)_3$ forms a dimer as a result of intermolecular bismuth–π interactions. Compound **1** can be evaporated at 150 °C in vacuum (10^{-2} Torr) without decomposition and it is highly soluble in common organic solvents, such as THF, $CHCl_3$, diethyl ether, benzene, and hexane.

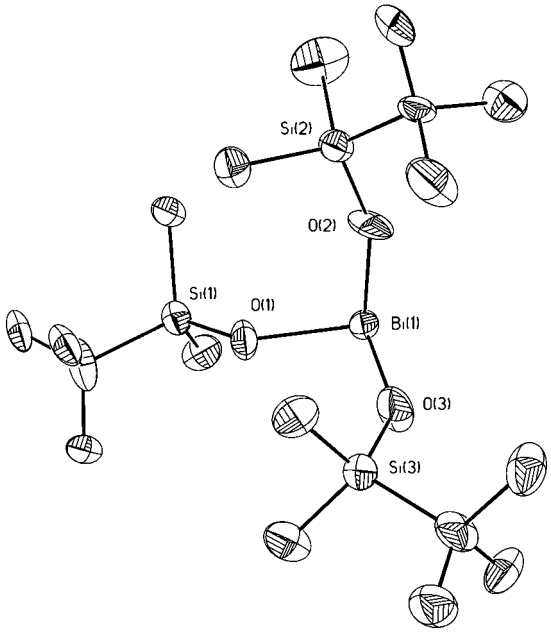

Figure 1. Molecular structure of **1** (thermal ellipsoids set at 30% probability); two crystallographically independent but structurally similar molecules are found in the crystal lattice. Selected bond lengths [Å] and angles [°]: Bi(1)-O(1) 2.054(10), Bi(1)-O(2) 2.006(15), Bi(1)-O(3) 2.018(12), Si(1)-O(1) 1.615(12), Si(2)-O(2) 1.596(16), Si(3)-O(3) 1.595(13); O(1)-Bi(1)-O(2) 97.0(5), O(1)-Bi(1)-O(3) 96.9(5), O(2)-Bi(1)-O(3) 97.9(7), Si(1)-O(1)-Bi(1) 134.0(7), Si(2)-O(2)-Bi(1) 156.6(8), Si(3)-O(3)-Bi(1) 144.3(8).

Hydrolysis of **1** in benzene occurs slowly upon contact with air moisture to give the bismuth oxo cluster $[Bi_{22}O_{26}(OSiMe_2tBu)_{14}]$ (**2**) [Eq. (2)]. If the benzene is evaporated slowly the yield is almost quantitative and only crystals are formed. When the rate of hydrolysis is increased by the addition of water or by fast evaporation of the solvent a, to date uncharacterized, amorphous material is obtained. Note that, single crystals of **2** together with amorphous material were also isolated upon hydrolysis of **1** in *i*PrOH.

$$22\,Bi(OSiMe_2tBu)_3\,(\mathbf{1}) \xrightarrow[\text{benzene}]{\text{air moisture}} [Bi_{22}O_{26}(OSiMe_2tBu)_{14}]\,(\mathbf{2}) + 52\,HOSiMe_2tBu \quad (2)$$

The ^1H NMR spectrum of a solution of compound **1** in $[D_6]$benzene which had been exposed to air moisture to give a significant amount of single crystals of **2** showed exclusively signals assigned to $tBuMe_2SiOH$ and the starting material **1**. Apparently, a rapid and clean conversion of the bismuth silanolate **1** into the bismuth oxo cluster **2** takes place. The high-nuclearity cluster **2** ($M_r = 6851\ g\,mol^{-1}$) is almost insoluble in all common solvents but can be dispersed in organic media without decomposition.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The molecular structure of **2** is best described as being composed of a $[Bi_{22}O_{26}]^{14+}$ core which is covered by a hydrophobic layer of 14 tBuMe$_2$SiO$^-$ ligands (Figure 2). Eight of the silanolate oxygen atoms are μ_2-bridging to

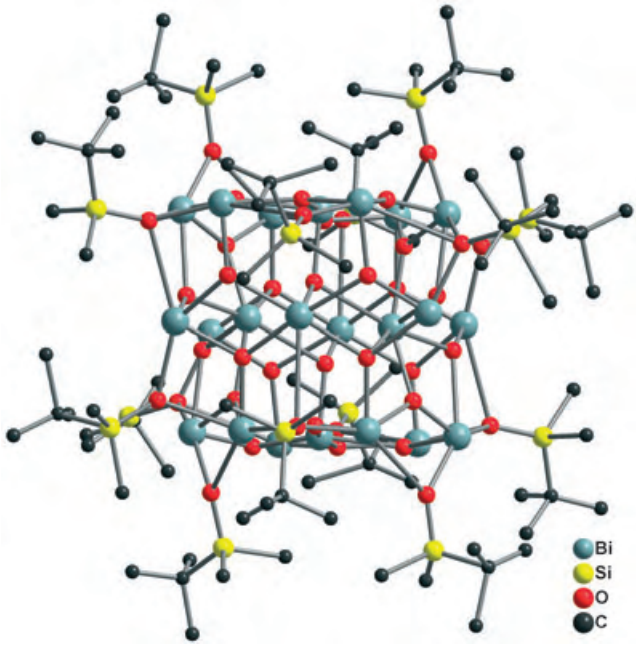

Figure 2. Molecular structure of **2**; hydrogen atoms are omitted for clarity.

bismuth and six silanolate oxygen atoms have a μ_3-coordination mode. The corresponding Bi–O bonds lie between 2.126(9) and 3.347(11) Å. These bonds are significantly shorter than the sum of the van der Waals radii of bismuth (r_{vdW}(Bi) = 2.40 Å)[18] and oxygen (r_{vdW}(O) = 1.50 Å).[19] The $[Bi_{22}O_{26}]^{14+}$ core is composed of the layers A, A′, and B (Figure 3). The symmetry-related layers A and A′ are

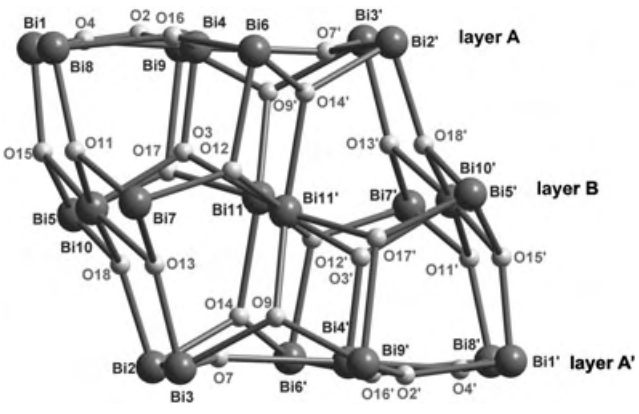

Figure 3. View of the $[Bi_{22}O_{26}]^{14+}$ core structure of **2**; the structure is composed of three layers containing 7 (layer A and A′) and 8 bismuth atoms (layer B); symmetry transformation used to generate equivalent atoms: $a = -x+{}^1/_2, -y+{}^1/_2, -z$; typical bond lengths and angles are found in the ranges: Bi-O 2.037(8)–2.655(8) Å; Bi-O-Bi 93.6(3)–138.2(4)°; O-Bi-O: 67.5(3)-171.8(3)° (details are given in the Supporting Information).

composed of seven bismuth atoms and six μ_3-bridging oxygen atoms. Two of these oxygen atoms (O9 and O14) are coordinated to two bismuth atoms of layer A and to one bismuth atom of layer B. The other oxygen atoms of layer A are exclusively coordinated to bismuth atoms of layer A. The bismuth–μ_3-oxygen atom bonds are in the range 2.037(8)–2.655(8) Å and the sums of the bond angles amount to 355.8–358.4° assuming a μ_3-coordination. Notably, several additional bismuth–oxygen separations that are slightly smaller than the sum of the van der Waals radii are present, but these do not significantly disturb the μ_3-coordination. Layer B is built from eight bismuth atoms and fourteen oxygen atoms. All the oxygen atoms of this layer are coordinated to two bismuth atoms of layer B and to one bismuth atom of layers A or A′. Assuming μ_3-coordination the deviation of the sum of the bond angles (Bi-O-Bi 342.9–356.2°) from the ideal value of 360° is significantly larger than the corresponding sum of bond angles associated with layers A and A′. The oxygen atoms O3 and O3′ show the largest deviation (Bi-O-Bi 342.9°), which is also reflected by the bond lengths. For these atoms, two short Bi–O bonds of 2.112(9) and 2.157(7) Å, a significantly longer Bi–O bond of 2.835(8) Å, and an additional bismuth–oxygen separation of 3.036(9) Å all of which are smaller than the sum of the van der Waals radii of bismuth and oxygen are found. Thus, the coordination geometry of these oxygen atoms might alternatively be described to be between a μ_3- and μ_4-coordination. The Bi–O bonds involving the other μ_3-oxygen atoms of layer B are in the range 2.039(9)–2.481(9) Å. Notably, the oxygen atoms O13 and O18 also have additional Bi–O separations that are below the sum of the van der Waals radii (O18–Bi11 3.121(3) Å and O13–Bi11′ 2.768(3) Å) but the sum of their bond angles is close to 360° (Bi-O13-Bi 354.0°, Bi-O18-Bi 356.2°).

The bismuth–oxygen core structure of the cluster built from the bismuth atoms Bi7, Bi10, Bi11 and their symmetry related counterparts in layer B resembles the structure of β-Bi_2O_3[20] although the bond lengths and angles show large deviations. The core structure of **2** is best described as a $[Bi_2O_2]_n$ ladder-type arrangement which is also found in β-Bi_2O_3 and α-Bi_2O_3 (Figure 4). However, the structural fragment in **2** might alternatively be described as being composed of two dimerized heterocubane-like subunits in which one vertex is not occupied. This Bi_3O_4 building unit is observed in β-Bi_2O_3 but not in α-Bi_2O_3. The mean Bi–O bond lengths in the $[Bi_2O_2]_n$ units of **2** (2.42 Å) and β-Bi_2O_3 (2.40 Å) are comparable, but individual bond lengths deviate by 0.11–0.96 Å between the two structures. Similarly, large deviations are observed for corresponding Bi-O-Bi bond angles.

We have initiated preliminary studies on the thermally induced decomposition of both **1** and **2**. Thermolysis in the temperature range 25–700 °C gave $Bi_{12}SiO_{20}$ (JCPDS 80–0627) as the final material.[21] In both cases, the content of residual carbon was negligible. However, decomposition in the temperature range 25–350 °C gave β-Bi_2O_3 (JCPDS 78-1793) as the only crystalline product apart from small quantities of amorphous SiO_2. At temperatures slightly above 400 °C the metastable β-Bi_2O_3 reacts with SiO_2 to give the sillenite phase $Bi_{12}SiO_{20}$.[22] In the differential thermal analysis (DTA) diagram this process is indicated by an

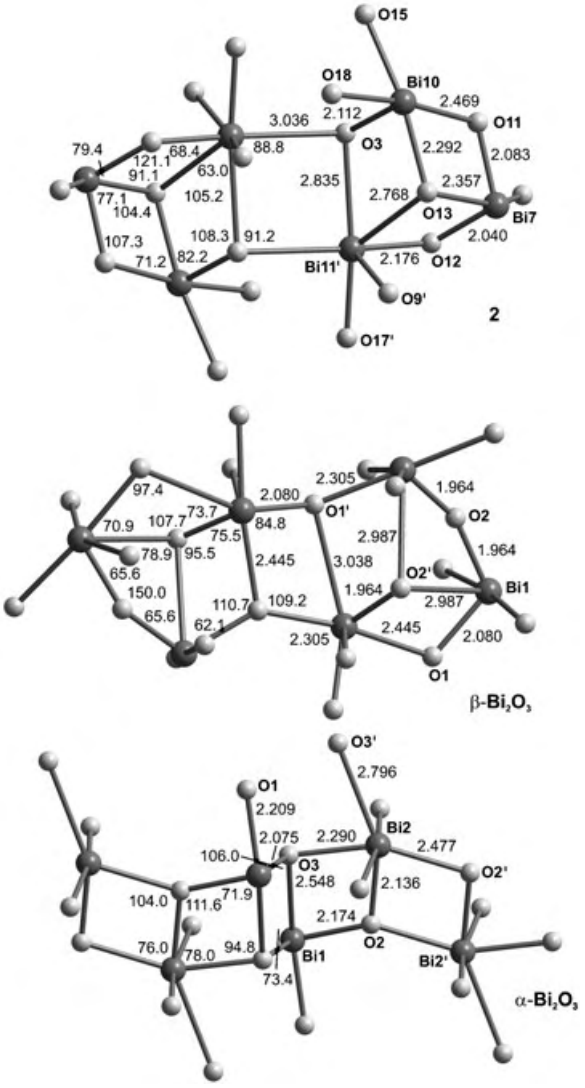

Figure 4. Comparison of bond lengths [Å] and angles [°] within the typical $[Bi_2O_2]_n$ ladder-type arrangements in **2**, β-Bi_2O_3, and α-Bi_2O_3.

exothermic peak which is not accompanied by a weight loss. The thermolysis of the layered compounds $(BiO)_2(CO_3)$ and BiO(OMe) is also reported to give metastable β-Bi_2O_3 whereas hydrolysis of $Bi(OEt)_3$ in benzene gives α-Bi_2O_3.[20,23,24]

In conclusion, we have reported the synthesis and characterization of $Bi(OSiMe_2tBu)_3$ (**1**) which is volatile and highly soluble in polar as well as in non-polar solvents. With these properties, compound **1** is a potential precursor for bismuth oxide based materials prepared by the sol–gel process and the CVD technique. The high-nuclearity cluster $[Bi_{22}O_{26}(OSiMe_2tBu)_{14}]$ (**2**) results from partial hydrolysis of **1**. This cluster has a diameter close to 2 nm and can be regarded as a silanolate capped "molecular bismuth oxide". It has potential as a model compound with which to study the formation and surface chemistry of metal oxide nanoparticles. Thermolysis of compounds **1** and **2** below 350 °C gave metastable β-Bi_2O_3. An explanation on the molecular level for the formation of β-Bi_2O_3 is offered by the molecular structure of **2** which contains the basic structural motif of β-Bi_2O_3 within its $[Bi_{22}O_{26}]^{14+}$ core. Decomposition of both **1** and **2** at higher temperatures gave the sillenite-type compound $Bi_{12}SiO_{20}$ which is of interest because of its electro-optical properties and potential use as holographic storage material.[25]

Experimental Section

1: A solution of $tBuMe_2SiOH$[26] (15.47 g, 117.20 mmol) in toluene (50 mL) was added dropwise to a solution of $Bi(OtBu)_3$[12] (16.68 g, 38.88 mmol) in toluene (100 mL) at room temperature. The solution was stirred at room temperature overnight. After removal of the solvent and *t*BuOH in vacuo at 40 °C the residue was dissolved in *n*-pentane. The solid material was removed by filtration, the filtrate was collected and the solvent was removed in vacuo (10 mbar) at 40 °C. Kugelrohr distillation of the crude product (150 °C, 1.4×10^{-2} mbar) gave colorless **1** (21.30 g, 91 %) m.p. 63 °C. ^{1}H NMR (200.13 MHz, C_6D_6): $\delta = 0.24$ (s, 6H, $SiCH_3$), 1.06 ppm (s, 9H, CCH_3); ^{13}C NMR (50.33 MHz, C_6D_6): $\delta = 0.85$ ($SiCH_3$), 19.84 (CCH_3), 26.37 ppm (CCH_3); ^{29}Si NMR (59.63 MHz, C_6D_6): $\delta = 13.7$ ppm; Elemental analysis calcd (%) for $C_{18}H_{45}Bi_1O_3Si_3$ (602.8): C 35.9, H 7.5; found: C 35.6, H 8.0; IR (KBr): $\tilde{\nu} = 2952$ (s), 2928 (s), 2893 (s), 2884 (s), 2855 (s), 2821 (w), 2799 (w), 2767 (w), 2735 (w), 2708 (w), 2645 (w), 1471 (s), 1463 (s), 1443 (w), 1434 (w), 1407 (m), 1387 (m), 1360 (m), 1254 (s), 1213 (w), 1091 (w sh.), 1040 (w sh.), 1006 (m sh.), 939 (s sh.), 880 (vs b.), 830 (s sh.), 769 (s), 671 (s), 666 (s), 576 (m sh.), 554 (s), 499 (s), 470 (m) cm^{-1}.

2: Slow evaporation of the solvent under air moisture from a solution of $Bi(OSiMe_2tBu)_3$ (**1**, 10.20 g, 16.92 mmol) in benzene almost quantitatively gave $\mathbf{2}\cdot2C_6H_6$ with m.p. 108 °C (decomp). Elemental analysis calcd (%) for $C_{96}H_{222}Bi_{22}O_{40}Si_{14}$ (7007.56): C 16.5, H 3.2; found: C 16.4, H 3.1. IR (KBr): $\tilde{\nu} = 3090$ (w), 3071 (w), 3034 (w), 2946 (s), 2922 (s), 2879 (s), 2851 (s), 2805 (w sh.), 2796 (w sh.), 2765 (w sh.), 2731 (w sh.), 2704 (w sh.), 2645 (w sh.), 1470 (s), 1462 (s), 1443 (m), 1429 (m), 1403 (m), 1386 (m), 1357 (m), 1327 (m), 1250 (s), 1209 (m), 1036 (w sh.), 1005 (m sh.), 909 (s b.), 826 (s), 813 (s), 784 (m sh.), 764 (s), 681 (m), 660 (s), 540 (vs b.), 475 (s b.) cm^{-1}.

Single crystal X-ray diffraction analyses were carried out at 173 K with a Nonius Kappa CCD for a colorless plate of dimensions $0.02\times0.08\times0.04$ mm^3 (**1**) and a colorless block of dimensions $0.12\times0.10\times0.06$ mm^3 ($\mathbf{2}\cdot2C_6H_6$). Crystal data for **1**: $C_{18}H_{45}BiO_3Si_3$, $M_r = 602.79$, monoclinic, $P2_1/n$, $a = 13.452(3)$, $b = 10.0431(18)$, $c = 39.891(6)$ Å, $\beta = 90.891(6)°$, $V = 5335.2(17)$ Å^3, $Z = 8$, $\mu(Mo_{K\alpha}) = 6.757$ mm^{-1}, 9758 unique data ($\theta_{min} = 2.95°$, $\theta_{max} = 25.50°$), 5141 data with $I \geq 2\sigma(I)$, R (obs) = 0.0817, wR (all data) = 0.2344. The residual peaks in the final difference Fourier map range between 4.692 and -1.964 e Å^{-3}. The high residual peak is located at a distance of 0.918 Å from Bi1. After merging the equivalent reflections and after corrections for Lorentz, polarization, and absorbtion effects using SCALEPACK[27] ($T_{min} = 0.774$, $T_{max} = 0.341$), an internal R value of 0.128 was obtained. Crystal data for $\mathbf{2}\cdot2C_6H_6$: $C_{96}H_{222}Bi_{22}O_{40}Si_{14}$, $M_r = 7007.56$, monoclinic, $C2/c$, $a = 30.8244(10)$, $b = 22.4631(15)$, $c = 24.9469(5)$ Å, $\beta = 91.739(7)°$, $V = 17265.1(17)$ Å^3, $Z = 4$, $\mu(Mo_{K\alpha}) = 22.484$ mm^{-1}, 15700 unique data ($\theta_{min} = 2.92°$, $\theta_{max} = 25.45°$), 7399 data with $I \geq 2\sigma(I)$, R (obs) = 0.0465, wR (all data) = 0.0829. The residual peaks in the final difference Fourier map range between 2.308 and -1.899 e Å^{-3}. After merging the equivalent reflections and after corrections for Lorentz, polarization, and absorbtion effects using SCALEPACK[27] ($T_{min} = 0.346$, $T_{max} = 0.164$), an internal R value of 0.069 was obtained. Two $SiMe_2tBu$ (C21–C36) and two *t*Bu (C65, C66, C73–C76) groups were refined isotropically. CCDC-243439 and CCDC-243440 contain the supplementary crystallographic data for this paper. Macrocyclic Perylene Bisimides

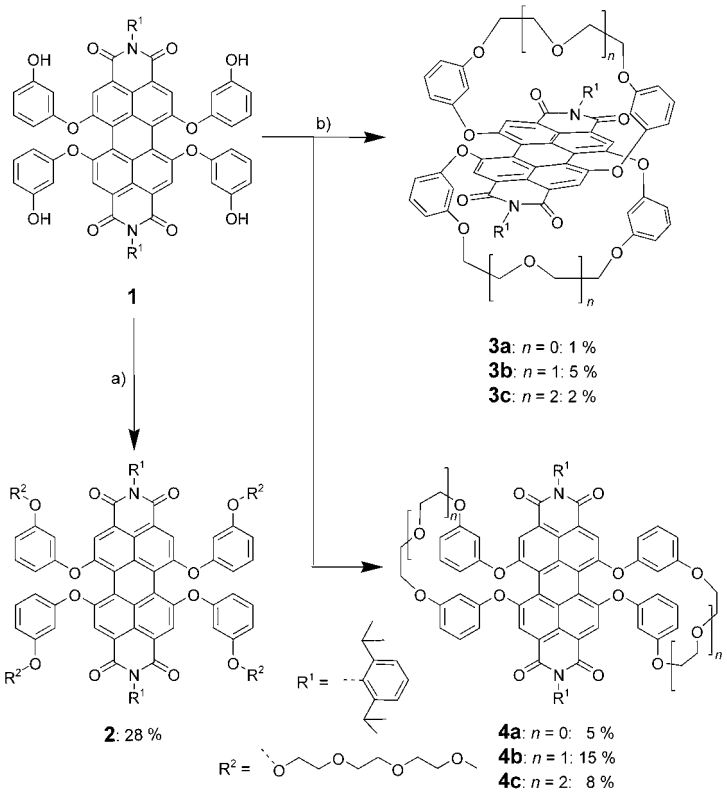
Perylene Bisimide Based Macrocycles: Effective Probes for the Assessment of Conformational Effects on Optical Properties**

*Peter Osswald, Dirk Leusser, Dietmar Stalke, and Frank Würthner**



Dedicated to Professor Johann Weis on the occasion of his 60th birthday

Scheme 1. Schematic presentation of diagonally bridged (A) and laterally bridged (B) macrocyclic perylene bisimides.

During the last few years, perylene bisimides bearing phenoxy substituents in the bay positions have been developed to become one of the most useful classes of fluorophores. They can be diversely functionalized at the imide and the bay phenoxy units to achieve desired optical and electrochemical properties.[1] Indeed, in multichromophoric dendritic perylene bisimides[2] as well as in self-organized metallosupramolecular squares[3] or mesoscopic assemblies[4] highly efficient energy- and electron-transfer processes have been demonstrated—such supramolecular arrays based on phenoxy-substituted perylene bisimides (PPBIs) may serve as artificial light-harvesting systems.[5] Furthermore, PPBIs show potential for application in solar cells,[4b,6] polymeric light-emitting diodes,[7] and as molecular probes in biological systems.[8] Despite this remarkable versatility of PPBIs, the effect of different conformations on the optical properties of this class of fluorophores has been barely explored. Single-molecule spectroscopic studies revealed that different conformations—that is, the twist of the perylene bisimide chromophore and the orientation of the phenoxy groups—have an effect on the photophysical properties of *immobilized* PPBIs.[9] Nevertheless, conformational effects on the optical properties of perylene bisimides in solution have not been reported yet.[1b]

To identify the conformational effect on the optical properties of PPBI chromophores, conformationally restricted macrocyclic perylene bisimides, which are diagonally bridged through 1,7- and 6,12-linkages (Scheme 1, A) seem to be properly suited since the conformational freedom of the perylene core should be restricted in these systems and a particular conformation of the phenoxy substituents can be achieved through variation of the length of the bridging unit. Oligo(ethylene glycol) units were chosen as the bridging unit because, on the one hand, this functionality can be introduced in perylene bisimide by etherification of the resorcin groups in the bay positions and, on the other hand, the chain length can be varied through the appropriate choice of ditosylates. Herein we present the synthesis (Scheme 2) of diagonally bridged macrocyclic perylene bisimides **3a–c** as well as the corresponding laterally bridged isomers **4a–c**, and report on their optical properties in comparison to those of the open-chain reference compound **2**, which confirm a pronounced conformational effect on the optical properties of perylene bisimides.

Scheme 2. a) H_3C-$(OCH_2CH_2)_3$-O-*p*-Tos, Cs_2CO_3, DMSO, argon, 80°C, 5 h; b) *p*-Tos-O-CH_2CH_2O-$(CH_2CH_2O)_n$-*p*-Tos (n = 0–2), Cs_2CO_3, DMSO, argon, 100°C, 5 h. Tos = tosyl, DMSO = dimethyl sulfoxide.

As shown in Scheme 2, compound **2** was synthesized by etherification of **1** with 2-[2-(2-methoxyethoxy)ethoxy]ethyl tosylate and cesium carbonate in DMSO at 80 °C in 28 % yield. The macrocyclic perylene bisimides **3a–c** were synthesized by employing batch cyclization as a convenient one-pot macrocyclization method with a perylene bisimide concentration of 6×10^{-3} M.[10] For this purpose **1** was treated with the corresponding oligo(ethylene glycol) ditosylates and cesium carbonate in DMSO at 100 °C. After purification by column chromatography the diagonally bridged macrocyclic perylene bisimides **3** were isolated in 1–5 % yield and the laterally bridged isomers **4** were obtained in 5–15 % yield for mono-, di-, and tri(ethylene glycol) chains.[11]

The presence of four resorcin units in the precursor bisimide **1** causes formation of isomeric bis(macrocycles) by etherification. Only based on spectroscopic data, in particular ^{1}H NMR data, reliable assignment of the isolated macrocycles to a particular isomer is not possible. Therefore, crystallization of the macrocycles has been carried out and single crystals suitable for X-ray diffraction were obtained in the case of **3b** and **4a** by dissolving the compounds in dichloromethane, subsequent addition of equal amounts of methanol, and slow evaporation of dichloromethane at room temperature.

Figure 1 shows the molecular structures of **3b** and **4a** in the crystal.[12] Compound **3b** possesses the envisioned macrocyclic structure with the bridging units lying above and below the perylene core. A further characteristic feature of this diagonally bridged isomer is an almost perpendicular orientation of the phenoxy substituents relative to the perylene core which resembles a conformation suggested based on molecular modeling studies of related noncyclic compounds.[9] For the macrocyclic systems **3** an interconversion between the conformational enantiomers (*M*⇄*P*) as observed for nonrigid twisted perylene bisimides[13] is not possible because in the case of **3** a bond cleavage is required. Thus, these systems possess favorable structural features to assess the conformational effect of the bay phenoxy substituents on the optical properties of this class of chromophores. The twist angle between the two naphthalene units of the perylene core of **3b** was determined to 33° and is thus higher than that known for a phenoxy-substituted diazadibenzoperylene derivative,[14] which underlines the rigid character of these isomers.

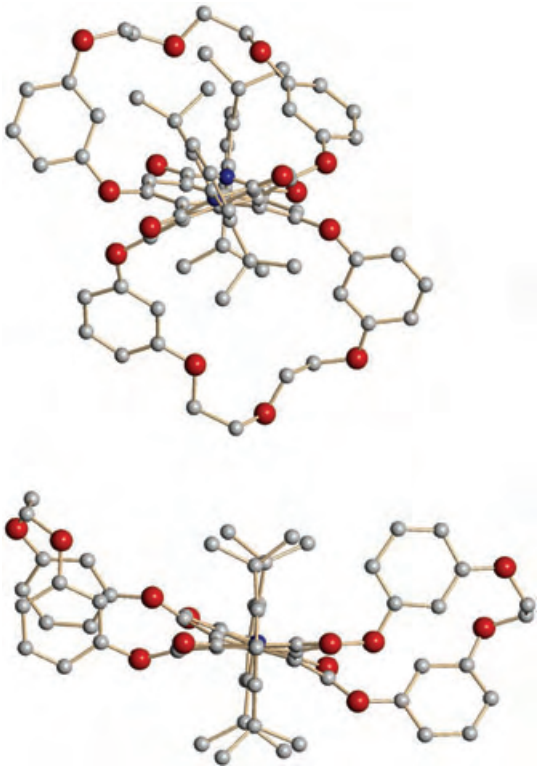

Figure 1. Molecular structures of **3b** (top, *P* enantiomer) and **4a** (bottom, *P* enantiomer). View along the N–N axis of the perylene bisimide showing the twisted nature and the cyclic structure of both isomers. Note that both centrosymmetric crystal structures contain *P* and *M* enantiomers (for crystal packing see the Supporting Information).

The molecular structure of **4a** shows that the phenoxy groups are connected laterally through the ethylene glycol groups and that the twist angle between the two naphthalene units is 25°. Whereas the phenoxy groups in **3b** are orthogonally orientated, in **4a**, they are horizontally orientated to the perylene core.

Although single crystals could not be obtained for all compounds, the structures of **3a**,**c** and **4b**,**c** could be unequivocally assigned by comparison of their ^{1}H NMR data with those of **3b** and **4a**. For this purpose, the resonance of the proton situated between the two oxygen atoms of the resorcin substituents is particularly informative, because this proton is differently shielded by the aromatic ring current in lateral and diagonal isomers (see the Supporting Information).

The optical properties of the macrocyclic perylene bisimides were investigated by UV/Vis, steady-state, and time-resolved fluorescence spectroscopy. The absorption spectra of laterally bridged macrocycles **4** (Figure 2) show typical patterns for PPBIs with a maximum around 580 nm assigned to the $S_0 \rightarrow S_1$ transition, a shoulder of the second vibronic transition, and a broad maximum at 450 nm belonging to the $S_0 \rightarrow S_2$ transition. For the derivatives **4b** and **4c**, the absorption maxima as well as the molar absorption coefficients are in good agreement with that of the reference compound **2**; thus, **2** may possess a similar conformation to that of the lateral isomers. Only the smallest macrocycle **4a**

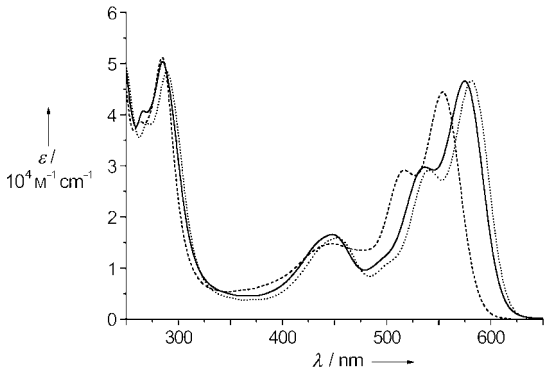

Figure 2. Absorption spectra of **4a** (dashed line), **4c** (dotted line), and the reference compound **2** (solid line) in dichloromethane.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

adopts an exceptional position because the maximum of the $S_0 \rightarrow S_1$ transition is hypsochromically shifted by 20 nm compared to that of **4b** and a decrease of the molar absorption coefficient is observed. This shift is presumably due to the conformational restriction imposed by the short spacer units.

For the diagonally bridged macrocycles **3** significant spectral differences were observed compared to those of the reference compound **2**. The absorption maxima of the $S_0 \rightarrow S_1$ transition are shifted up to 41 nm towards shorter wavelength from 575 nm (**2**) to 545 nm (**3a**,**c**) and 534 nm (**3b**) (Figure 3).

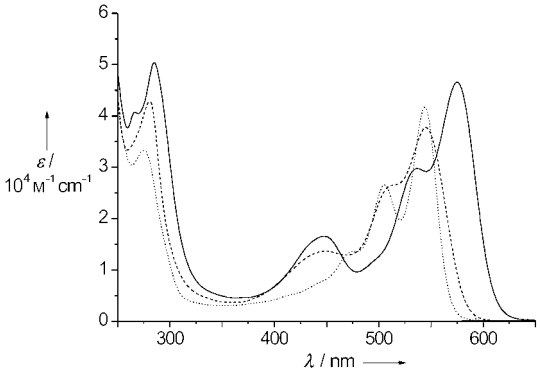

Figure 3. Absorption spectra of **3a** (dotted line), **3c** (dashed line), and the reference compound **2** (solid line) in dichloromethane.

This hypsochromic shift and the observed pronounced hypochromicity may be attributed to the formation of a conformer with less conjugation between the phenoxy groups (+M effect) and the electron-deficient perylene bisimide.[15]

The fluorescence properties of the reference compound **2**, diagonal isomers **3**, and lateral isomers **4** are given in Table 1 (emission spectra are shown in the Supporting Information). As the data reveal, fluorescence quantum yields and lifetimes of the lateral isomers **4a–c** are indistinguishable with that of the reference compound **2**, which again indicates that the behavior of these isomers is similar to that of the open-chain PPBI derivatives. In contrast to the situation with the lateral isomers **4**, the fluorescence quantum yields of the diagonally bridged macrocycles **3** are much lower than that of the reference compound **2**. This effect is clearly related to an increase of the nonradiative rate constants k_{nr} (**2** < **3c** < **3b** < **3a**), whereas the radiative rate constants k_r are almost identical for all compounds presented here.

Table 1: Emission properties of macrocyclic perylene bisimides in dichloromethane.

	λ_{max} [nm]	ϕ_{fl}[a]	τ_{fl} [ns][b]	k_r [s^{-1}][c]	k_{nr} [s^{-1}][d]
2	609	0.89	5.6	1.6×10^8	2.0×10^7
3a	562	< 0.02	< 0.5	$> 4.0\times10^7$	$> 2.0\times10^9$
3b	573	0.09	0.8	1.1×10^8	1.1×10^9
3c	582	0.43	2.7	1.6×10^8	2.1×10^8
4a	588	0.78	5.4	1.4×10^8	4.1×10^7
4b	605	0.82	5.3	1.6×10^8	3.4×10^7
4c	606	0.84	5.6	1.5×10^8	2.9×10^7

[a] $\phi_{fl} \pm 0.03$. [b] $\tau \pm 0.5$. [c] $k_r = \phi_{fl}\tau^{-1}$. [d] $k_{nr} = (1-\phi_{fl})\tau^{-1}$.

Based on the fact that the spectroscopic data of the diagonally bridged isomers **3** differ significantly from those of the reference compound **2**, it can be concluded that non-macrocyclic PPBIs do not exhibit a perpendicular orientation of the phenoxy residues in solution. Instead, based on the observed optical properties of the macrocyclic perylene bisimides **4**, which are similar to the non-macrocyclic reference **2**, a conformation with horizontal orientation of the phenoxy groups is most likely for non-macrocyclic PPBI dyes such as **2** in solution. These results establish for the first time the conformational effect on the optical properties of these chromphores in solution. The question to what extent the charge-density distribution and, hence, the optical properties of the perylene core correlate to the various conformations will further be investigated. The results of the current study will be of major impact to the development of improved molecular probes for biological systems,[8] applications of these dyes in single-molecule spectroscopy,[9] and the development of PPBI based fluorescence sensors.[16] In this context the isolation of enantiopure macrocyclic dyes **3a–c** is one of our particular goals.

Atmospheric Chemistry

The SF_5O_x Radicals, $x = 0$–3**

Marc Kronberg, Stefan von Ahsen, Helge Willner, and Joseph S. Francisco**

Sulfur hexafluoride, SF_6, has found widespread use beyond its original application as an insulator gas in electrical high-voltage equipment and switchgear boxes.[1] It is a major plasma etching gas now commonly used in the semiconductor industry.[2] Because SF_6 is an excellent source of fluorine atoms upon strong excitation and contains no carbon, it leaves no carbonaceous deposits in the plasma etching process.[3–5] An attractive feature of SF_6 is its nonflammability and chemical inertness. Surprisingly, the environmental concerns of the long-term usage of SF_6 have become an issue only recently as a result of its increasing abundance in the atmosphere.[6,7] Because SF_6 is a greenhouse gas with a global-warming potential that is 23900 times higher than that of CO_2, this also has contributed to the growing concern about its atmospheric impact.[8] Recent studies of the environmental consequences of the decomposition of SF_6 have attempted to characterize the breakdown products that result from electrical discharges.[9–12] The main products observed under various spark arc and corona discharge conditions are SF_2O, SF_2O_2, and SF_4O. Detailed mechanisms to describe their formation remain unclear.[13,14] The observation of the even stronger greenhouse gas SF_5CF_3, chemically related to SF_6, in stratospheric air samples has further raised questions of the atmospheric consequence of these species.[15] At present the molar ratio of SF_5CF_3 relative to SF_6 amounts to about 4%. Here we report on the spectroscopic characterization of the key radical species SF_5, a product of the photodissociation of SF_6 and SF_5CF_3, and the radicals SF_5O, SF_5OO, and SF_5OOO, which form in the oxidation reactions of the SF_5 radical.

The SF_5 radical: Smardzewski et al.[16] found two new IR bands at 812 and 552 cm^{-1} from the photodissociation of SF_5X compounds (X = F, Cl, Br, SF_5). The same bands were observed in reactions of F atoms with SF_4, which confirmed the presence of the SF_5 radical. Andrews et al.[17] also isolated the SF_5 radical in an Ar matrix and observed an additional IR band at 885 cm^{-1}. Since these studies, other bands of SF_5 have not been reported nor has the UV spectrum of SF_5 been published.

The SF_5 radical belongs to the symmetry point group C_{4v}. Hence, the nine normal modes are represented by three A_1, two B_1, one B_2, and three E modes, of which only the A_1- and E-type vibrations are IR active. In order to measure all six IR-active modes, a much more efficient synthesis for matrix-isolated SF_5 radicals was needed. For this purpose the thermally labile precursors S_2F_{10},[18] SF_5NO_2,[19] and $N(SF_5)_3$[20,21] highly diluted in Ne or Ar were flash thermolyzed at low pressures and subsequently quenched as matrices. All three precursors resulted in the same set of IR matrix bands with three additional weak bands at 633.0, 524.7, and 387.2 cm^{-1} (Ne matrix). In Table 1 the bands are assigned by comparison with the calculated band positions and intensities. The UV spectrum of SF_5 was obtained from the matrix-isolated thermolysis products of SF_5NO_2 diluted in Ne. Because a 1:1 mixture of SF_5 and NO_2 is present in the matrix, the cross sections of SF_5 were determined by calibration[22] using the UV spectrum of the by-product NO_2, and a reference spectrum of NO_2 could be used in turn for subtraction. The UV spectrum of SF_5 shows a structureless weak absorption beginning at about 235 nm ($\sigma < 10^{-20}$ cm^2) and ending at 200 nm with an absorption cross section of 1.1×10^{-18} cm^2 (see the Supporting Information). Hence, SF_5 should be photostable in the stratosphere, as the

[a] A relative intensity of 100 corresponds to 918 km mol^{-1} for SF_5 and 397 km mol^{-1} for SF_5OO. [b] Low-frequency modes in cm^{-1}, (rel. int.), assignment: 530 (2.4), $\nu_8 A'$; 488 (0.03), $\nu_9 A'$; 426 (0.25), $\nu_{15} A''$; 408 (0.35), $\nu_{10} A'$; 329 (0.13), $\nu_{11} A'$; 315 (0.00), $\nu_{16} A''$; 282 (0.05), $\nu_{17} A''$; 218 (0.09), $\nu_{12} A'$; 82 (0.01), $\nu_{18} A''$.

reaction with oxygen is expected to be its dominant fate. This is similar to the known atmospheric fate of the radical CF_3, which is converted rapidly into CF_3OO in the presence of O_2.[23]

The SF_5O radical: Merill and Cady postulated that the SF_5O radical results from irradiation of bis(pentafluorosulfur) peroxide, F_5SOOSF_5.[24] Czarnowski and Schumacher[25,26] also suggested the formation of SF_5O from the thermal decomposition of the peroxide. Neither of these studies identified the radical, although a study by Feliz and Schumacher,[27] in which CO was added to F_5SOOSF_5 during photolysis, showed that carbon monoxide was oxidized to CO_2 providing indirect evidence for the existence of SF_5O.

Quantum chemical calculations predict the SF_5O radical to have C_{2v} symmetry (and not C_{4v}) as an SO bond with participation of an oxygen sp or p orbital results in a p-type singly occupied molecule orbital (SOMO) mainly located at the O atom. This orbital geometry is inconsistent with a fourfold axis. Our observed IR spectrum of SF_5O isolated in Ne matrix obtained by flash thermolysis of SF_5OOSF_5 and SF_5OOOSF_5 is consistent with this finding. The observed IR band positions are presented in Table 2 and Figure 1 and are in accordance with the computational data. From the 15 fundamentals (six A_1, one A_2, four B_1, four B_2 modes) only the A_2 mode is IR inactive. Six fundamentals were observed while for the missing modes the calculations predict either a low frequency (not yet measured) and/or a very low intensity. Photolysis of SF_5O in a Ne matrix with full radiation of a xenon or mercury high-pressure lamp resulted in a slow decrease of its IR bands, yielding mainly SF_4O and fluorine atoms, and as a minor channel $SF_4 + OF$ (see Figure 1). Hence, SF_5O is a weak UV absorber (for its Ne matrix UV spectrum, see the Supporting Information).

The SF_5OO radical: The existence of the SF_5OO radical was first postulated by Czarnowski and Schumacher[25,26] in the mechanism for formation of the trioxide $F_5SOOOSF_5$. The trioxide is accessible by photolysis of SF_5Cl in the presence of a large excess of oxygen at low temperatures. Feliz and Schumacher[27] suggested that the SF_5 radicals, the primary photolysis products together with chlorine atoms, rapidly add molecular oxygen. Schumacher and co-workers could not identify the SF_5OO radicals directly in their experiment. They argued that SF_5OO is unstable and the bimolecular self reaction yielding SF_5O and O_2 is very fast.

Indeed, in our experiments conducted in an oxygen matrix, SF_5 adds O_2. However, flash thermolysis of the trioxide SF_5OOOSF_5 in excess of noble gas yields $SF_5O + SF_5 + O_2$, although a mixture of SF_5O and SF_5OO is expected.

Table 2: Calculated [B3LYP/6-311++G(3df,3pd)] and observed IR band positions and relative intensities of the matrix-isolated radicals SF_5O and SF_5OOO.

[a] A relative intensity of 100 corresponds to 407 km mol^{-1} for SF_5O and 499 km mol^{-1} for SF_5OOO. [b] Low-frequency modes of SF_5O in cm^{-1}, (rel. int.), assignment: 475 (inactive), $\nu_7 A_2$; 416 (0.74), $\nu_{10} B_1$; 350 (0.00), $\nu_{15} B_2$; 324 (0.00), $\nu_6 A_1$; 289 (0.09), $\nu_{11} B_1$. [c] Low-frequency modes of SF_5OOO in cm^{-1} (rel. int.): 518 (0.04), 477 (0.00), 458 (0.81), 346 (0.00), 328 (0.42), 320 (1.0), 193 (1.3), 67 (1.6), 63 (0.30), 44 (0.02), 22 (0.01). [d] Intensity affected by overlap with SF_4O bands.

The $F_5S–O_2$ bond in SF_5OO must be weaker than the O–O bonds in the trioxide. For the trioxide a bonding energy of 106 kJ mol^{-1} and for $SF_5–OO$ a dissociation energy of about 55 kJ mol^{-1} were estimated.[25,26] Our observations are in agreement with these data. DFT calculations [B3LYP/6-311++G(3df,3pd)] predict a dissociation energy of 19.1 kJ mol^{-1}, which represents a lower limit as the bond strengths of weak bonds are generally underestimated.

SF_5OO is expected to show C_s symmetry, like many other peroxy radicals. Hence, all 18 fundamentals (twelve A′ and six A″) should be observable in the IR spectrum. The typical feature in the IR spectrum of matrix-isolated SF_5OO is the

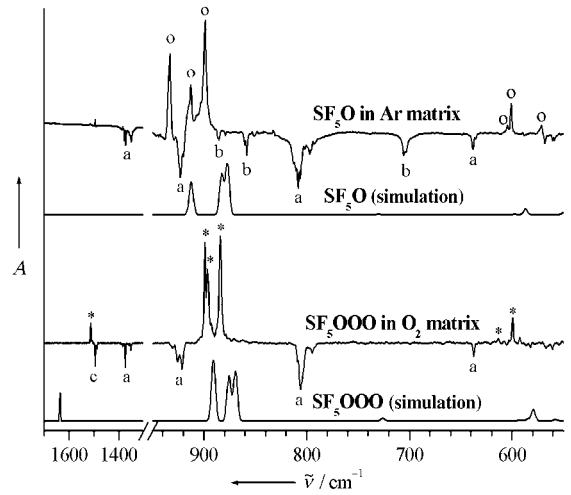

Figure 1. Upper half: IR spectrum of SF_5O radicals isolated in an Ar matrix; bands of the SF_5O radical are labeled with (o). The simulated spectrum of SF_5O is shown underneath. Lower half: IR spectrum of SF_5O radicals isolated in an O_2 matrix; bands of the product SF_5OOO are labeled with (*). The simulated spectrum of SF_5OOO is shown underneath. Both experimental IR spectra are difference spectra from spectra measured before and after photolysis. The photolysis products show negative bands while the absorptions of the photolyzed radicals are positive. The assigned absorptions of the photolysis products belong to SF_4O (a), SF_4 (b), and FOO (c).

presence of an absorption at 1135 cm^{-1}, which is assigned to the O–O stretching mode. The seven most intensive fundamentals were observed while the eleven missing modes have low intensities and/or are outside the experimental spectral range. Band positions and intensities are in good agreement with the calculated data (see Table 1).

The SF_5OOO radical: Trioxy radicals are formed when a highly electronegative oxy radical interacts with molecular oxygen. In analogy to CF_3OOO[28] the radical SF_5OOO is observed in an oxygen matrix. The IR-matrix spectrum of SF_5OOO has several dominant features that distinguish the trioxy radical from SF_5O (see Table 2 and Figure 1): 1) a strong band at 1513 cm^{-1}, assigned as ν(OO) of the terminal OO bond; 2) a strong red shift of the stretching modes of the SF_5O moiety; 3) significant differences in the intensities of the SF_5O fundamentals when recorded with O_2 or Ar as matrix materials; 4) the rapid UV photolysis of O_2-matrix-isolated SF_5OOO while SF_5O photolyzes one order of magnitude slower when isolated in Ne matrix. In oxygen matrix photolysis produces SF_4O and FOO.

The computations predict a structure with C_1 symmetry, close to C_s, and a SF_5O–OO bond length of 2.36 Å. Table 3 presents the (calculated) structural data and some properties of the SF_5O_x radicals, $x = 0$–3. The calculated structures are shown in the Supporting Information.

With the characterization of the SF_5O_x ($x = 0$–3) radicals, their existence is now proven. Nevertheless, their significance in atmospheric chemistry has to be considered. A summary of the important oxidation reactions in the atmosphere is shown in Figure 2. SF_6 photolysis is possible only in the upper stratosphere as the solar flux in the high-energy UV region is significant only above the ozone layer. The formed SF_5 radicals react with O_2 rather than degrade photochemically due to the high concentration of molecular oxygen in the atmosphere. The peroxy radical is probably in equilibrium with the SF_5 radical as the calculations and experiments predict only a weak F_5S–O bond. However, the peroxy radical can be reduced by reaction with NO, CO, or O_3 forming the oxy radical SF_5O. The oxy radical is expected to be photostable but, in equilibrium with the SF_5OOO radical, it will be photolyzed much faster. SF_5O is expected to oxidize atmospheric trace compounds like NO. Independent of the degradation process—thermal or photochemical—SF_5O is

converted to SF_4O, which is thermally and photochemically stable. The latter compound undergoes hydrolysis to form SO_2F_2, which is even more stable. Because hydrolysis requires significant water concentration, a downward diffusion of SF_4O and/or SO_2F_2 from the stratosphere into more humid air should be observable. Finally, SO_2F_2 hydrolyzes very slowly (yields sulfuric acid and HF) which makes it suitable as a tracer for SF_6 or SF_5CF_3 degradation in the atmosphere.

Experimental Section

Precursors for the thermal radical generation: The compounds S_2F_{10}, $N(SF_5)_3$, and SF_5NO_2 were used as sources for SF_5 radicals. S_2F_{10}[29] and $N(SF_5)_3$[20] were prepared as described in the literature. SF_5NO_2 was provided by N. Lu (group J. S. Thrasher).[19] For SF_5O generation the compounds SF_5OOSF_5[25] and SF_5OOOSF_5[26] were used and prepared according to literature procedures.

Generation of the radicals in matrix: SF_5 or SF_5O radicals were generated by low-pressure flash thermolysis of the respective precursors diluted 1:1000 with Ne or Ar and subsequent quenching of the reaction products in a noble-gas matrix. The stable precursors S_2F_{10} and SF_5NO_2 were mixed with the excess noble gas in a 1-L stainless-steel storage container. The labile precursors $N(SF_5)_3$, SF_5OOSF_5, and SF_5OOOSF_5 were placed in a U-trap mounted directly in front of the matrix support and cooled to temperatures of −65 °C, −125 °C, −120 °C, respectively (maintaining the respective vapor pressures are in the 10^{-3}-mbar range). A flow of nobel gas passed the cooled samples achieving a mixing ratio of noble gas to host close to 1:1000. Finally, the gas mixture passed the thermolysis device that was mounted directly in front of the matrix support and heated to 400 °C for S_2F_{10}, 340 °C for SF_5NO_2, 400 °C for $N(SF_5)_3$, 420 °C for SF_5OOSF_5, and 200 °C for SF_5OOOSF_5. The matrix support (Cu block) was held under high vacuum, and the matrices were formed at 16 K (Ar) or 6 K (Ne). About 1 mmol of noble gas was used in a typical experiment and deposited within 10–20 min.

SF_5OO and SF_5OOO were generated by isolating SF_5 or SF_5O in O_2 matrix at 16 K. Photolysis experiments on the matrix-isolated species were carried out with UV light from a 150-W Xe (AMKO) or Hg high-pressure lamp (TQ 150, Heraeus) or from a Hg low-pressure lamp (TK 15, Heraeus)—in some cases in combination with a 235-nm cutoff filter (Schott). Details of the matrix apparatus are given elsewhere.[30]

IR spectra of the matrix-isolated species were recorded with a FT-IR spectrometer (IFS 66 v/S, Bruker) with a resolution of 1 cm^{-1} (Ar, O_2 matrix) or 0.25 cm^{-1} (Ne matrix) in reflection mode. A KBr (or a 6-μm Mylar/Ge for SF_5 far-IR) beamsplitter was used together with a DTGS detector, and 64 scans were co-added. UV spectra of Ne-matrix-isolated compounds were measured in reflection mode using a quartz fiber optic (Hellma) with a Lambda 900 spectrometer (Perkin Elmer). An integration time of 1 s per data point, a data point spacing of 1 nm, and a slit width of 0.5 nm were applied.

All calculations were performed using the Gaussian98 software package.[31] For accurate structures, energies, and vibrational frequencies the density functional[32] method B3LYP[33,34] and a 6-311++G(3df,3dp) basis set was used. Within the IR simulation procedure for each normal mode a Gaussian function was derived which is characterized by three parameters: calculated band position, calculated total (integrated) intensity as given in the G98 output file, and a half height width set to 4 cm^{-1}. Integrated intensity and absorption differ only by a constant factor for a Gaussian band profile.

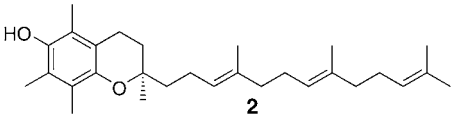
Domino Reactions

Palladium-Catalyzed Enantioselective Domino Reaction for the Efficient Synthesis of Vitamin E**

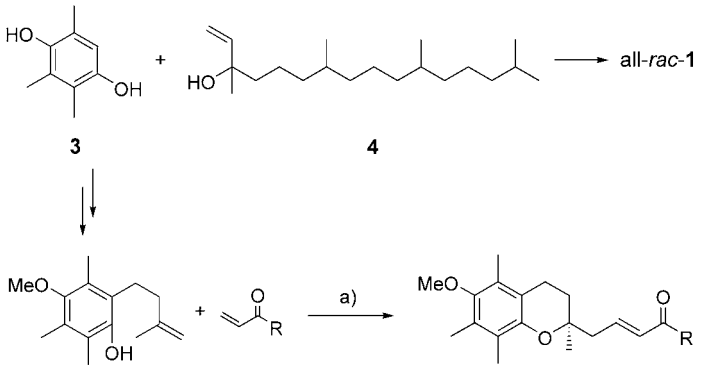


Lutz F. Tietze, Konrad M. Sommer, Julia Zinngrebe, and Florian Stecker*

Dedicated to Professor Hiriyakkanavar Ila on the occasion of her 60th birthday

Vitamin E is one of the fat-soluble vitamins and a collective term for all tocopherols and tocotrienols. The vitamin E family consists of eight natural compounds which, depending upon the degree of methylation of their aromatic ring, are specified as α, β, γ and δ. All possess a chroman framework with a stereogenic center at C2 with *R* configuration (examples: α-tocopherol: **1**, α-tocotrienol: **2**).[1] Natural α-tocopherol (**1**) with the *R* configuration at all stereogenic centers has the most pronounced biological activity. Vitamin E acts as an antioxidant and is considered an essential protective factor against lipid peroxidation; in particular, it protects polyunsaturated fatty acids essential for animal and human metabolism by capturing highly reactive free radicals formed in the body as by-products of normal oxidative metabolism and which cause irreversible destruction of cell membranes.[2]

1



2

Industrially α-tocopherol (**1**) is produced on a large scale by the acid-catalyzed reaction of trimethylhydroquinone (**3**) with all-*rac*-isophytol (**4**; see Scheme 1), whereby a mixture of eight stereoisomers is formed. However, in this reaction compounds with an *S* configuration in the chroman framework and thus of far lower antioxidant action are also formed.[3] Thus, from the point of view of industry there is considerable interest in the development of a process for the efficient enantioselective construction of α-tocopherol (**1**); this applies especially to the stereoselective formation of the stereogenic center on the chroman ring, if possible with the concomitant introduction of the side chain.

There are already a number of enantioselective synthetic methods for **1**, which are not suitable, however, for industrial use.[4] Here we describe a new enantioselective palladium-catalyzed method[5] which allows not only the formation of the chiral chroman framework[6] with an enantioselectivity of 96% *ee* but also the simultaneous introduction of part of the side chain of vitamin E within the context of a domino reaction.[7]. This sequence comprises an enantioselective Wacker oxidation[8] and a subsequent Heck reaction (Scheme 1).[9]

The substrate for the domino reaction, alkene **5**, was obtained in an overall yield of 60% from trimethylhydroquinone (**3**) in a few steps by acid-catalyzed condensation with methyl vinyl ketone and reaction with the Lombardo reagent.[10] The reaction of **5** with methyl acrylate in dichloro-

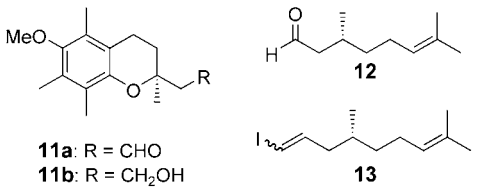
methane in the presence of catalytic amounts of $Pd(TFA)_2$ (TFA = trifluoroacetate), the chiral ligand (*S*,*S*)-*i*Pr-BOXAX **6a**,[11] and *p*-benzoquinone afforded the desired chroman **7a** with 96% *ee* in 84% yield;[12] comparably good selectivities were obtained with (*S*,*S*)-Bn-BOXAX (**6b**). The selectivity was significantly lower with the use of **6c** as ligand which was obtained from (*L*)-*t*leucine; similar effects have already been observed in other catalytic processes.[13] The domino reaction was also carried out with methyl vinyl ketone to provide **7b**; however, in this case the yield and the selectivity (84% *ee*) were lower. The reaction with simple alkenes such as 3-methyl-1-pentene failed to yield the desired product.



We assume that in the first step of the domino reaction **5** coordinates enantiofacially through its double bond to the chiral catalyst generated from $Pd(TFA)_2$ and the enantiomerically pure **6**. The resulting intermediate **8** reacts further by oxypalladation to give **9** with formation of the chroman framework and construction of the stereogenic center (Scheme 2). The palladium species can then form the intermediate **10** in a subsequent Heck reaction with acrylate or methyl vinyl ketone, which leads to the final product **7** and Pd^0 in a β-hydride elimination. It is necessary for the catalytic

Scheme 2. Mechanism of the palladium-catalyzed domino reaction of **5**.

cycle that Pd^0 is reoxidized to Pd^{2+}; this is achieved by the addition of *p*-benzoquinone, which does not interfere with the course of the reaction.

Numerous possibilities are plausible for the further conversion of **7a** or **7b** to α-tocopherol (**1**). Thus the unsaturated ester **7a** was converted into the respective diol by dihydroxylation[14] with AD-mix-β. Subsequent oxidative cleavage with sodium periodate afforded aldehyde **11a**, which can be converted into α-tocopherol (**1**) in a few steps by known methods.[15] Direct cleavage of **7a** by ozonolysis to give

11a was not successful. We reduced aldehyde **11a** to alcohol **11b** so that the absolute configuration of the stereogenic center in **7a** could be determined by comparison of the data with known values.[16] Alternatively we prepared vitamin E from ketone **7b** by reaction with the vinyl iodide **13** readily obtained from (*R*)-citronellal (**12**) followed by subsequent dehydration and hydrogenation.

The enantioselective domino reaction described here facilitates the efficient and stereoselective construction of the chroman framework of vitamin E with concomitant introduction of part of the side chain in high yield with very good *ee* values.

[12] A mixture of palladium trifluoroacetate (7.1 mg, 0.0214 mmol, 0.1 equiv) and (*S*,*S*)-*i*Pr-BOXAX **6a** (40.7 mg, 0.0856 mmol, 0.4 equiv) in CH_2Cl_2 (0.1 mL, degassed) was stirred for 30 min at room temperature, then treated with *p*-benzoquinone (93.1 mg, 0.855 mmol, 4.0 equiv), and stirred for a further 10 min. A solution of **5** (50 mg, 0.214 mmol, 1.0 equiv) and methyl acrylate (91.9 mg, 1.07 mmol, 5.0 equiv) in CH_2Cl_2 (0.20 mL, degassed) was added to the suspension, and the mixture was stirred at room temperature for 3.5 d (TLC control). At the end of the reaction the mixture was treated with 1N HCl (5 mL) and the aqueous phase extracted with Et_2O (3 × 5 mL). The combined organic phases were washed with 1N NaOH solution (3 × 5 mL) and dried over $MgSO_4$, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography (*n*-pentane/diethyl ether). Chroman **7a** (57 mg, 0.181 mmol, 84 %) was obtained as a clear oil. The enantiomeric excess was determined by HPLC on a chiral phase (OD-Chiracel, hexane/isopropanol) and gave a value of 96 % *ee*. The absolute configuration was determined by conversion into the alcohol **11b** and comparison of the optical rotation with known literature values.[16] ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.23$ (s, 3H, 2′-CH_3), 1.77 (dd, 1H, $J = 7.1$, 14.2 Hz, 3′-H_a), 1.85 (dd, 1H, $J = 7.1$, 14.1 Hz, 3′-H_b), 2.09, 2.14, 2.19 (3 × s, 9H, 5′-CH_3, 7′-CH_3, 8′-CH_3), 2.45 (ddd, 1H, $J = 1.2$, 8.2, 14.1 Hz, 4-H_a), 2.53 (ddd, 1H, $J = 1.2$, 8.2, 14.1 Hz, 4-H_b), 2.60 (t, 2H, $J = 7.1$ Hz, 4′-H_2), 3.63 (s, 3H, 6′-OCH_3), 3.74 (s, 3H, 1-OCH_3), 5.88 (dt, 1H, $J = 1.2$, 15.9 Hz, 2-H), 7.05 ppm (dt, 1H, $J = 7.8$, 15.9 Hz, 3-H); ^{13}C-NMR (50.3 MHz, $CDCl_3$): $\delta = 11.66$, 11.76, 12.52 (5′-CH_3, 7′-CH_3, 8′-CH_3), 20.43 (C4′), 24.38 (2′-CH_3), 31.20 (C4), 42.31 (C3′), 51.44 (1′-OCH_3), 60.36 (6′-OCH_3), 74.22 (C2′), 117.1 (C4a′), 123.1 (C8′), 123.8 (C2), 125.8 (C7′), 128.1 (C5′), 144.7 (C3), 147.1 (C8a′), 149.7 (C6′), 166.7 ppm (C1); $[\alpha]_D^{20} = +15.4$ ($c = 0.52$, $CHCl_3$); IR (KBr): $\tilde{\nu} = 2977$ cm^{-1} (CH), 2936, 1725 (C=O); UV (CH_3CN): λ_{max} (lgε): 202.5 nm (5.609), 287.0 (1.558); MS (70 eV, EI): *m*/*z* (%) = 179 (30), 219 (60), 318 (100) $[M]^+$. $C_{19}H_{26}O_4$ (318.41): calcd: 318.1831; found: 318.1831 (HRMS).

Cluster Synthesis

Formation of Ir–Rh and Ir–Mo Bonds by Using an Ancillary *ortho*-Carborane-1,2-diselenolato Ligand**

Guo-Xin Jin, Jian-Qiang Wang, Chen Zhang, Lin-Hong Weng, and Max Herberhold*

Since the discovery of 1,2-dicarba-*closo*-dodecaborane(12), the chemistry of this exceptionally stable carborane and its 1,7- and 1,12-isomers has aroused considerable interest.[1] 1,2-Dicarba-*closo*-dodecaborane-1,2-dichalcogenolates (*ortho*-carborane dichalcogenolates) can be used as the voluminous and chemically robust chelate ligands to form half-sandwich complexes of the type $[Cp^*M\{E_2C_2(B_{10}H_{10})\}]$ ($Cp^* = \eta^5$-C_5Me_5, M = Co, Rh, Ir; E = S, Se).[2] These sterically congested, mononuclear coordination compounds can be stored conveniently and used for further transformations in a controlled way under various conditions. In particular, addition reactions at the metal atom have been accomplished,[3] and formation of a metal-to-boron bond and/or substitution of the carborane cage in the positions B(3)/B(6) have been achieved.[4] Another attractive possibility, the formation of heteronuclear metal–metal bonds through bridge support by an ancillary *o*-carboranyl dichalcogenolato ligand has not been explored so far, to our knowledge.

We have previously described the 16-electron "pseudo-aromatic" iridium complex $[Cp^*Ir\{Se_2C_2(B_{10}H_{10})\}]$ (**1**),[5] and suggested that this species may undergo further transformations owing to its electron deficiency at the iridium center. In exploring the reactivity of the 16-electron iridacycle **1** towards various transition-metal complexes, we discovered the formation of heterometallic clusters in which carborane 1-2-diselenolates act as bridging chelate ligands. We report here the first trinuclear cluster complexes, which have been obtained from the half-sandwich iridium complex **1** by reactions with $[\{RhCl(cod)_2\}]$ and $[Mo(CO)_3(py)_3]$. The products, *cis*-$[\{Cp^*Ir[Se_2C_2(B_{10}H_{10})]\}_2Rh]$ (**2**), *trans*-$[\{Cp^*Ir[Se_2C_2(B_{10}H_9)]\}Rh\{[Se_2C_2(B_{10}H_{10})]IrCp^*\}]$ (**3**), and $[\{Cp^*Ir[Se_2C_2(B_{10}H_{10})]\}_2Mo(CO)_2]$ (**4**), were characterized by X-ray crystallography.

The 16-electron complex **1**, which was synthesized from $[\{Cp^*IrCl_2\}_2]$ and dilithium carborane 1,2-diselenolate,[5] reacts with $[\{Rh(cod)Cl\}_2]$ (cod = cycloocta-1,5-diene) in THF to give the dark red trinuclear complex **2** together with a violet trinuclear derivative **3** (Scheme 1). Complex **3** can be obtained in higher yield when longer reaction times are applied. In refluxing toluene solution, the *cisoid* complex **2** is converted in more than 90% yield to the *transoid* complex **3** which contains a boron–iridium bond. Both **2** and **3** are diamagnetic. In **2**, the iridium atoms have been reduced from Ir^{III} to Ir^{II}, apparently by $[\{Rh^{I}(cod)Cl\}_2]$. In **3**, one of the two *ortho*-carborane groups is drawn sufficiently close to the iridium center to initiate B–H activation, affording the corresponding cyclometalated ligand species. This kind of metal-induced B–H activation has also been observed in other cases.[4,6] The first indication of cyclometalation in **3** is the appearance of a singlet in the ^{11}B NMR spectrum at $\delta = -19$ ppm, which is characteristic of metal-bonded boron atoms.[7] The Ir–B bond formation causes the molecule to become unsymmetrical, as confirmed by two singlets at $\delta = 2.17$, 2.21 ppm in the ^{1}H NMR spectrum of **3**. The NMR data are consistent with the results of an X-ray structure analysis of **3**, which proves beyond doubt the existence of the Ir–B and of the two nonequivalent Ir–Rh bonds.

The molecular structures of **2** and **3** are shown in Figure 1.[8] In the molecule **2** the four selenium atoms of the two *ortho*-carborane diselenolato ligands surround the central rhodium atom in a distorted tetrahedral arrangement; the two Se-Rh-Se planes are twisted by 63.1° with respect to one other. The two Cp* rings and the two carborane 1,2-diselenolato ligands are in *cisoid* arrangements. The diselenairidacycles in **2** are nonplanar as a result of the coordination of the Se atoms to rhodium. The Ir–Rh distances in **2** (2.7097(11), 2.6630(11) Å) may therefore be compared with the corresponding distances in the *trans*-trinuclear complex **3** (2.663(3) Å), in $[RhIr(CO)_3(dppm)_2]$ (2.7722(7) Å),[9] $[RhIr(CH_3)(CO)_3(dppm)_2](CF_3SO_3)$ (2.743(1) Å),[10] and in $[(Cp^*IrS)_2Rh(cod)][RhCl_2(cod)]$ (2.906(1) and 2.913(9) Å).[11] The Ir–Se distances (2.4280(12)–2.4637(13 Å) in **2** are in the normal range of Ir–Se single bonds, but significantly longer than those in the "pseudo-aromatic" $IrSe_2C_2$ ring in **1** (2.3753(9) and 2.3656(9) Å).[5]

In complex **3** the iridium atoms of the Ir_2Rh backbone have retained their Cp* rings in a *transoid* arrangement (Figure 1b). The Rh center is six-coordinate with a distorted

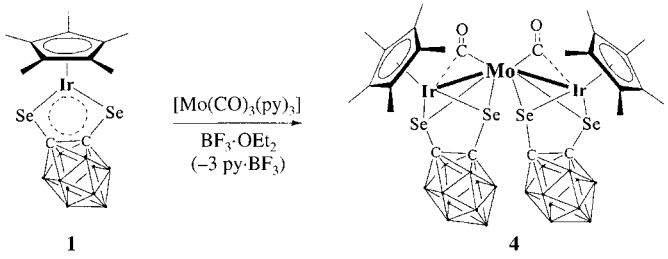
trigonal-prismatic geometry. The central Rh atom and the four Se atoms form a plane (deviations 0.015 Å). The Ir(1) atom adopts a three-legged piano-stool configuration with two Se and one B atom, and owing to the cyclometalation of the diselenolato ligand at Ir(1) it participates in two four-membered metallacyclic rings, the dihedral angle between the planes (Ir(1)-B(3)-C(2)-Se(2) and Ir(1)-B(3)-C(1)-Se(1)) of which is 100°. Owing to the formation of the Ir(1)–B(3) bond



1 2 3

Scheme 1. Synthesis of **2** and **3**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(2.02(4) Å), the dihedral angle at the Se(1)···Se(2) vector in the Ir(1)Se_2C_2 ring is 78.4°, in contrast to the angle of 123.8° at the Se(3)···Se(4) vector in the Ir(2)Se_2C_2 ring. The Ir(1)–Rh(1) bond (3.074(3) Å) is longer than the Ir(2)–Rh(1) bond(2.663(3) Å), which can be rationalized by the fact that the formal oxidation ("valence") state is +3 for Ir(1) and +2 for Ir(2).

Complex **1** reacts with $[Mo(CO)_3(py)_3]$ (py = pyridine) in the presence of more than three equivalents of BF_3 in diethyl ether to give the red, mixed-metal complex **4**. The combination of $[Mo(CO)_3(py)_3]$ and BF_3 can be used as an effective way to generate a reactive $[Mo(CO)_3]$ fragment.[12] Complex **4** comprises two diselenairidacycles bridged by a molybdenum dicarbonyl unit; consistent with this, two strong bridging carbonyl absorptions are observed in the IR spectrum of **4** at 1859 and 1794 cm^{-1}.

1 **4**

The iridium atoms of the Ir_2Mo backbone in **4** have retained their Cp* rings (Figure 2). The Mo center is eight-coordinate with a dodecahedral geometry; the two Se-Mo-Se planes are twisted by 36.8° with respect to one another. The two Ir–Mo single bonds (2.7820(19), 2.8189(17 Å) are each supported by a symmetrically bridging *ortho*-carborane-1,2-diselenolato ligand. The Ir–Se bond lengths (2.4827(16), 2.4458(18)) are close to those in the complexes **2** and **3**, with an Ir(1)-Mo(1)-Ir(2) angle of 144.46(4)°. The planar pseudo-aromatic system of the iridadiselenolene heterocycle **1** is no longer present in **4**; the dihedral angles at the Se···Se vector in the $IrSe_2C_2$ rings are 134.8° and 135.9°, respectively.

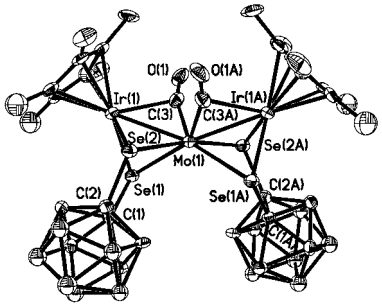


Figure 2. Molecular structure of **4**. Selected bond lengths [Å] and angles [°]: Ir(1)-Mo(1) 2.7820(19), Ir(2)-Mo(1) 2.8189(17), Ir(1)-Se(1) 2.4827(16), Ir(1)-Se(2) 2.4458(18), Ir(1)-C(3) 2.557(12), Mo(1)-Se(1) 2.687(2), Mo(1)-Se(2), 2.5972(18), Mo(1)-Se(3) 2.6520(19), Mo(1)-Se(4) 2.6519(18), Mo(1)-C(3) 1.978(11), C(1)-C(2) 1.611(15); Ir(1)-Mo(1)-Ir(2) 144.46(4), Se(1)-Ir(1)-Se(2) 82.63(5), Se(1)-Ir(1)-Mo(1) 61.06(5), Se(2)-Ir(1)-Mo(1) 59.16(4), Se(1)-Mo(1)-Se(2) 76.00(5), Se(1)-Mo(1)-Se(3) 105.39(5), Se(1)-Mo(1)-C(3) 79.2(3), Ir(1)-Se(1)-Mo(1) 64.98(5), Ir(1)-Se(2)-Mo(1) 66.88(6), Mo(1)-C(3)-Ir(1) 74.5(4).

The formation of heteronuclear metal–metal bonds in complexes **2**–**4** by reactions of the 16-electron complex **1** involves redox processes, during which Ir is partially reduced by low-valent transition-metal complexes, such as the fragments [RhCl(cod)] and $[Mo(CO)_3]$. The synthesis of the Ir_2M (M = Rh, Mo) clusters **2**–**4** demonstrates that complex **1** can serve as a useful building block for heteronuclear complexes.

Experimental Section

All manipulations were carried out under an argon atmosphere by using standard Schlenk techniques; all solvents were dried and deoxygenated before use.

Preparation of **2** and **3**: $[\{Rh(cod)Cl\}_2]$ (49 mg, 0.1 mmol) was added to the green solution of **1** (251 mg, 0.4 mmol) in THF (30 mL). The mixture was stirred for three days; the color changed first to black and then gradually to deep red. After removal of the solvent, the residue was chromatographed on silica gel. Elution with toluene/hexane (2:1) gave **3** as a violet zone, yield 32% (86 mg). Recrystallization from toluene/hexane afforded air-stable dark red crystals. Elemental analysis calcd (%) for $C_{24}H_{49}B_{20}Se_4Ir_2Rh$: C 21.24, H 3.64; found: C 21.11, H 3.62; ^1H NMR (500 MHz, $CDCl_3$, 25 °C, TMS): δ = 2.17(s, 15H; C_5Me_5), 2.21 ppm (s, 15H; C_5Me_5); ^{11}B NMR (160 MHz; $CDCl_3$, 25 °C): δ = −2.23, −5.05, −6.27, −8.32, −10.43, −11,72, −13.50, −14.68, −19.15 ppm (Ir–B); IR (KBr disk): $\tilde{\nu}$ = 2583 cm^{-1}(ν_{B-H}). The second red zone was eluted with CH_2Cl_2/hexane (1:4), yield 38% (103 mg). Recrystallization from benzene/hexane afforded air-stable red crystals of **2**. Elemental analysis calcd (%) for $C_{24}H_{50}B_{20}Se_4Ir_2Rh$: C 21.23, H 3.71; found: C 21.08, H, 3.68; ^1H NMR (500 MHz, $CDCl_3$, 25 °C, TMS): δ = 2.06 (s, 30H; C_5Me_5); ^{11}B NMR (160 MHz; $CDCl_3$, 25 °C): δ = −4.42, −6.51, −8.32, −10.95 ppm; IR (KBr disk): $\tilde{\nu}$ = 2569 cm^{-1}(ν_{B-H}).

Preparation of **4**: $BF_3{\cdot}OEt_2$ (0.26 mL, 47%, 1.0 mmol) was added dropwise at room temperature to a mixture of **1** (125 mg, 0.20 mmol) and $[Mo(CO)_3(py)_3]$ (42 mg, 0.10 mmol) in diethyl ether (50 mL). The deep blue suspension was stirred for 8 h, then the solvent was removed and the residue chromatographed on silica gel. The component in the first band was eluted with toluene/hexane (1:4) and recrystallized from toluene/hexane at −18 °C to give red crystals of **4**, yield 56% (78 mg). Elemental analysis calcd (%) for $C_{26}H_{50}B_{20}Se_4O_2Ir_2Mo$: C 22.19, H 3.58; found: C 21.80, H 3.52; ^1H NMR (500 MHz, $CDCl_3$): δ = 1.91(s, 30H; C_5Me_5); ^{11}B NMR (160 MHz, CD_3Cl): δ = −4.28, −7.13, −8.90, −10.91; IR (KBr disk): $\tilde{\nu}$ = 2580 cm^{-1}(ν_{B-H}), 1859, 1794 cm^{-1}(ν_{CO}).

Nanotubes

VS_2 Nanotubes Containing Organic-Amine Templates from the NT-VO_x Precursors and Reversible Copper Intercalation in NT-VS_2**

*Helen Annal Therese, Frank Rocker, Andreas Reiber, Jixue Li, Michael Stepputat, Gunnar Glasser, Ute Kolb, and Wolfgang Tremel**

Dedicated to Professor Philipp Gütlich on the occasion of his 70th birthday

Soon after the discovery of carbon nanotubes[1] the layered chalcogenides WS_2 and MoS_2 were reported as the first inorganic analogues of these hollow-cage structures.[2] Subsequently, more fullerene-type structures of inorganic compounds have been made, among them BN,[3] V_2O_5,[4] Tl_2O[5] as well as layered metal chalcogenides, such as TiS_2,[6] $NbSe_2$,[7] or ReS_2.[8] A common feature of most cage-forming compounds are their layered 2D-structures, which are able to bend or curl and to avoid vacant bonding sites through the formation of intralayer linkages. Meanwhile a number of methods for the synthesis of chalcogenide nanotubes have been devised. The most successful among them are the reductive sulfidization of oxide nanoparticles using H_2S,[9] the reduction of trichalcogenides with H_2,[7] chemical transport with iodine,[10] and the sulfidization of reactive metal halide precursors on a carbon nanotube template.[11] A conversion of preformed oxide nanotubes into their respective sulfide counterparts with preservation of the tubelike structures, however, has not been observed to date. Herein we report the first synthesis of chalcogenide VS_2 nanotubes with intercalated organic molecules by the sulfidization of a tubelike VO_x precursor. The VS_2 nanotubes are remarkable, as bulk VS_2[12] (and the VSe_2 analogue[13]) can only be obtained as A_xVS_2 (A = alkali metal, Cu) or self-intercalated non-stoichiometric (metal-excess $V_{1+x}S_2$) compounds.[14]

The starting material for the synthesis of the VS_2 nanotubes (NT-VS_2) were vanadium oxide nanotubes (NT-VO_x, $x \approx 2.3$), their synthesis is given in the Experimental Section. A representative low-resolution transmission electron micro-

scopic (TEM) image of NT-VO_x is given in Figure 1a. It shows that the NT-VO_x is the main product; the tubes are 0.5–5 μm long and have an outer diameter between 50 and 150 nm. Upon sulfidization of NT-VO_x with H_2S at 225 °C, VS_2 nanotubes (NT-VS_2) are formed. A scanning electron micrograph (SEM) of a typical NT-VS_2 obtained after sulfidization (Figure 1b), shows that the structure and the morphology of the VO_x tubes are preserved during the oxide into sulfide conversion. The SEM micrograph also indicates the high yield of NT-VS_2 obtained by this method. Full conversion into NT-VS_2 was observed for NT-VO_x intercalated with dodecyl amine (C_{12}-amine) but not with hexadecyl amine (C_{16}-amine). Reaction temperatures higher than 250 °C lead to a total collapse of the VS_2 tube structure.

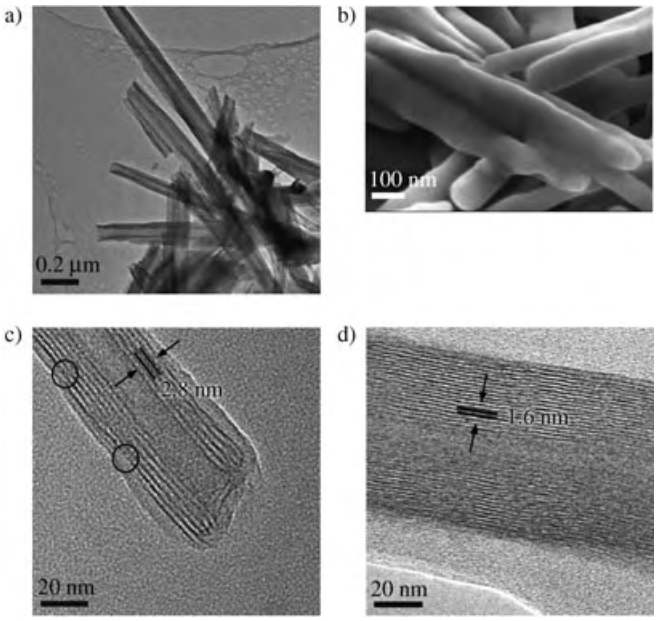

Figure 1. a) Low-resolution overview TEM image of VO_x nanotubes used as a starting material for the synthesis of NT-VS_2. b) Overview SEM image of NT-VS_2 obtained after sulfidization of NT-VO_x. c) HRTEM image of a single VS_2 nanotube with a layer separation of 2.8 nm, a flat cap, and a partially crystalline or amorphous coating. Imperfections are marked by a circle. d) HRTEM image of a NT-VS_2 obtained from NT-VO_x intercalated with C_{12}-amine. The layer separation is 1.6 nm.

That NT-VO_x has been sulfidized to produce NT-VS_2 is evidenced by the high-resolution TEM images (HRTEM) in Figure 1c. All the NT-VS_2 tubes are hollow, most of them are open, around 20% have flat caps, which make a 90° connection with the outer wall of the cylinder. The flat caps give an additional indication that structure of the NT-VO_x precursor is preserved during the sulfidization. Although the inner VS_2 layers of the tubes are smooth and almost free of defects, the outermost VS_2 layer is partially incomplete (Figure 1c), and each VS_2 tube is surrounded by a coating of amorphous VS_2. In addition, the outermost VS_2 layer exhibits a number of defects, this could be due to an incomplete reconstruction of the outer shell of the oxide precursor during the sulfidization step.

Figure 1c and d show HRTEM images of a partially and a fully sulfidated VS_2 nanotube with lattice fringes corresponding to a layer separation of approximately 2.8 nm (partially sulfidated) and 1.6 nm (fully sulfidated), values which are significantly larger than the layer separation in bulk VS_2 (0.57 nm). The observed layer spacing corresponds to the separation of the VO_x layers in the starting material, which in turn was determined by the chain length of the template molecules used in the synthesis of NT-VO_x. This result indicates that the template layer is partially intact in the VS_2 product, a hypothesis which is supported by the IR spectra of NT-VO_x before and after sulfidization (Figure 2). The IR spectra of alkylamine-templated NT-VO_x, given in Figure 2a (C_{16}-amine) and Figure 2b (C_{12}-amine), show strong vibrational bands characteristic of alkyl C–C stretching mode at 2920 cm^{-1} and 2850 cm^{-1}. The vibrational bands characteristic of V–O bond appear at 991, 791, 721, 575, and 480 cm^{-1}. The bands corresponding to V=O stretching and V-O-V deformation modes are shifted to lower frequencies compared to the crystalline V_2O_5.[15,16] A new band at 721 cm^{-1}, which can be attributed to V–NH_2 vibration, indicates that the amine groups of the templates are bound to the vanadium atoms in NT-VO_x. Chemical analysis of the NT-VS_2 samples show that the C_{16}-amine intercalated NT-VO_x does not convert fully, as also indicated by the characteristic broad V–O band at 990 cm^{-1} in the IR spectrum of the corresponding NT-VS_2. The products also tend to retain part of the intercalated templates, which can be deduced from the vibrational absorption bands at 2920 cm^{-1} and 2850 cm^{-1} (Figure 2c). On the other hand, complete sulfidization was achieved when C_{12}-amine templated NT-VO_x was reduced, as indicated by the absence of all V–O bands from the IR spectrum, while retaining part of the templates (see Figure 2d). Furthermore, the results of elemental analyses indicate a partial thermolysis (NH_3 loss) of the template during the sulfidization step.

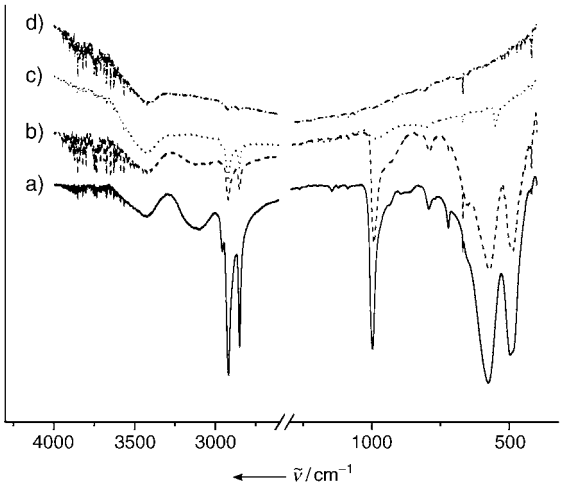

Figure 2. The FT-IR spectra of NT-VO_x samples before and after sulfidization. a) NT-VO_x with C_{16}-amines and b) NT-VO_x with C_{12}-amines, before conversion, c) NT-VS_2 with C_{16}-amines and d) NT-VS_2 with C_{12}-amines, after conversion.

To ascertain whether the $VO_x \rightarrow VS_2$ conversion was complete, we performed additional energy dispersive X-ray (EDX) analyses of the products. Figure 3a shows the EDX spectrum of a partially sulfidized product (C_{16}-amine template). The EDX analyses show high sulfur content for the outermost regions of the tube, whereas significant oxygen content is found in the interior. This result demonstrates that the VO_x nanotubes are converted layer by layer to NT-VS_2. Figure 3b shows the EDX spectrum of a fully sulfidized VS_2 nanotube (C_{12}-amine). The V:S ratio of 1:2 (accuracy $\pm 1\%$) is almost constant over the wall cross section, independent of the beam position. The results indicated that for C_{12}-amine-intercalated NT-VO_x the conversion is almost complete whereas for C_{16}-amine-intercalated NT-VO_x the sulfidization is incomplete.

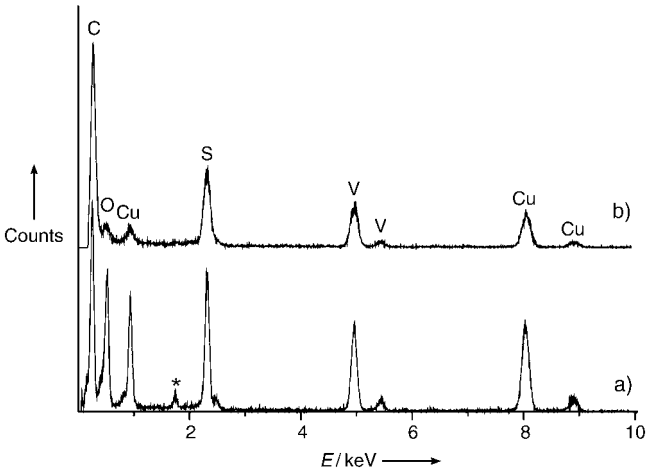

Figure 3. EDX spectra of isolated hollow VS_2 tubes. The spectra show signals arising from V, O, and S atoms. Incomplete reaction of C_{16}-amine-templated nanotube is indicated by the much greater intensity of the peak arising from oxygen in (a) than that in the spectrum of the VS_2 nanotube shown in (b) in which the C_{12}-amine template was used. The peak marked by * is due to the detector.

Studies on electrochemical intercalation of copper into a partially sulfidized NT-VS_2 have revealed that the intercalation of copper up to a composition $Cu_{0.77}VS_2$ can be achieved. NT-VO_x intercalates alkali, alkaline-earth, and a number of transition metals.[17] Studies on copper intercalation of NT-VO_x by chemically methods, through exchanging the intercalated templates with copper ions in a liquid medium, show that a small fraction (0.08 mole) of copper could be intercalated, and that the exchange resulted in considerable changes in the structure and the morphology of the starting material.[18] In contrast, no electrochemical copper intercalation was possible in NT-VO_x. The discharge/charge voltage profile of copper intercalation into 4.4 mg of NT-VS_2 is shown in Figure 4. The voltage of the working electrode dropped gradually with the insertion of copper until a limiting composition, $Cu_{0.77}VS_2$, is reached. This result corresponds to a total capacity of 360 mA h g^{-1}. The copper is reversibly deintercalated in the subsequent oxidation to regain a composition of VS_2. The cycle can be repeated, although there is a small degree of irreversibility. The capacity of the reversible copper intercalation corresponds to a specific capacity of 314 mA h g^{-1}, in comparison, graphite has a theoretical capacity of 372 mA h g^{-1}.[19]

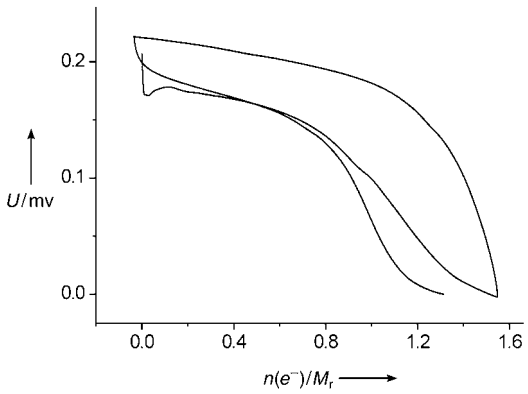

Figure 4. Plot of discharge/charge potential (U) versus the amount of electrons in mol ($n(e^-)$)intercalated per formula weight of VS_2 (M_r) during copper-intercalation studies.

The reason for the easy copper intercalation and high capacity value of NT-VS_2 in comparison with the other non-carbon nanotubes could be due to the defects that form during the conversion of NT-VO_x into NT-VS_2. This situation is in line with reports of chemically etched single-walled nanotubes (SWNTs)[20] and ball-milled MoS_2 nanotubes[21] showing better storage capacity than their untreated (unactivated) starting counterparts. The etching and ball-milling processes greatly increase the number of defects in the nanotube structures. In contrast, chemical intercalation of silver and gold was not possible with NT-VS_2, whereas VO_x nanotubes could easily be filled with gold colloids and were always heterogeneous, irrespective of their diameter and length. The gold colloids could chemically be connected to linear chains with the aid of dithiols and mechanically recovered from the VO_x tubes.

In summary, we have demonstrated that oxide nanotubes containing template molecules intercalated between the layers can be converted into sulfide nanotubes under retention of the tubelike structure. The amine-intercalated NT-VS_2 is the first layered chalcogenide nanotube in which organic molecules are inserted between the layers. In addition, we have demonstrated the reversible copper intercalation in these chalcogenide nanotubes.

Experimental Section

Vanadium oxide nanotubes (NT-VO_x) were prepared from vanadium(v) alkoxides and primary monoamines ($C_nH_{2n+1}NH_2$; with $n =$ 12 or 16) by a sol–gel reaction[4] and subsequent hydrothermal treatment. After washing and drying, the NT-VO_x was subjected to H_2S treatment in a tubular furnace at 225 °C for 22 h.

The resulting products were characterized by X-ray powder diffraction in reflection geometry, (Siemens D8 powder diffractometer, $Cu_{K\alpha}$ radiation), scanning electron microscopy (LEO 1530 field-emission SEM, 6 kV extraction voltage), and by high-resolution transmission electron microscopy (Philips TECNAIF F30 electron microscope; field-emission gun, 300 kV extraction voltage) equipped

with a high-angle annular dark-field detector (HAADF), a Gatan imaging filter (GIF), and an energy dispersive X-ray analysis (EDX) system. IR studies of the samples were carried out using a Mattson Instruments 2030 Galaxy FT-IR spectrometer. Elemental analysis was performed with an Elemental Analyser Vario EL (Elementar Analysensyteme). The X-ray powder patterns are almost featureless, which indicates a low degree of long-range order. The elemental analysis of NT-VS_2 revealed that only a fraction (~25%) of the template is preserved.

VS_2 nanotubes were electrochemically intercalated with copper. For intercalation studies 4–7 mgs of the NT-VS_2 sample was ground well with Teflon powder, pressed between a platinum mesh and used as a working electrode. A copper ring and a copper wire were used as counter and reference electrodes. The cell was discharged and charged in galvanostatic mode, in an aqueous electrolyte under air (1 mol L^{-1} $CuSO_4$) and at a current density $j_c = 50\ \mu A\,cm^{-2}$.

Cluster Compounds

Mass Spectrometric Investigations of the Dissociation of $[C@W_6Cl_{17}]^-$ Ions in the Gas Phase**

Ralf Burgert, Katharina Koch, Hansgeorg Schnöckel, Martina Weisser, Hans-Jürgen Meyer,* and Hans Georg von Schnering*

Dedicated to Professor Martin Jansen on the occasion of his 60th birthday

The first steps into the field of metal-cluster compounds with endohedral hetero atoms were the planned synthesis and structural characterization of $[HNb_6I_{11}]$ by Simon[1] as well as the identification of $[Ru_6C(CO)_{17}]$.[2–4] Since then, the $[M_6X_{12}]$ clusters of the transition elements and their substituted variants have been discussed in particular detail.[5–7] In recently published experiments on the synthesis of octahedral tungsten halogenide clusters, the carbon-centered compounds $[C@W_6Cl_{16}]$ (**1**) and $[C@W_6Cl_{18}]$ (**2**), formed as by-products, have been detected for the first time; their formation can be put down to the fact that the commercially available educt WCl_4, besides containing WCl_5 und $WOCl_4$, was also soiled with 1,2,4,5 tetrachlorobenzene which provided a source of carbon atoms.[8] Based on this knowledge, the synthesis of **1**

und **2** was optimized and the bonding properties were described in detail based on the crystal-structure examination.[8,9] Now we have developed an improved synthesis, in which the lithium as well as the calcium salts of the ion $[C@W_6Cl_{18}]^{2-}$ ($\mathbf{2}^{2-}$) are generated.[10,11] Independent from our findings, the generation of the $\mathbf{2}^{2-}$ during the synthesis of **1** from WCl_6 and CCl_4 with elemental bismuth as the reducing agent was described recently.[12] Cyclovoltametric experiments in addition to structural data helped to examine the stability of the various ions $[C@W_6Cl_{18}]^{n-}$ ($\mathbf{2}^{n-}$ $n = 1, 2, 3$) and formed the basis for the discussion of the bonding properties of these clusters.[12]

Herein we describe for the first time investigations on a structurally characterized endohedral cluster species by FT-ICR-MS (ion cyclotron resonance mass spectrometry). In these experiments $\mathbf{2}^{2-}$ and the cluster ion $[C@W_6Cl_{17}]^-$ ($\mathbf{3}^-$; which is formed after loss of Cl^-) are transferred into the gas phase entirely, without any initial decomposition. Thus, the decomposition of $\mathbf{3}^-$ can be observed step by step in different isolation and collisionally activated dissociation (CAD) experiments.[13]

First, a polycrystalline $[Li_2(\mathbf{2}^{2-})]$ sample was analyzed by laser desorption ionization (LDI). A multitude of tungsten chloride clusters (many of them C-bearing) could be identified, however none of them had the composition of $\mathbf{2}^{2-}$ or $\mathbf{3}^-$.[14]

Electrospray ionization (ESI) proved to be more efficient.[15–17] In accordance with earlier experiments[12] even sensitive compounds, such as heavy cluster ions,[18] can be transferred into the gas phase without disintegration and subsequently investigated. Figure 1 a shows the anion spectrum of a freshly prepared green solution of $[Li_2(\mathbf{2}^{2-})]$ in methanol. Along with small traces of $[C@W_6Cl_{18}]^-$ ($\mathbf{2}^-$) only the isotope pattern of $\mathbf{3}^-$ can be detected. The ESI mass spectrum of the same solution about 30 min later, shows new signals (Figure 1 b) which can be assigned to the ion $\mathbf{2}^{2-}$ as well as to the dissociation products $\mathbf{4}^-$ and $\mathbf{5}^-$ described below.[19]

To examine the stepwise fragmentation of this cluster in the gas phase, several isolation and dissociation experiments were performed. First, the most intensive signal (m/z 1718) out of the great number of isotopomers of $\mathbf{3}^-$ could be isolated (Figure 2). The fragmentation of $\mathbf{3}^-$ takes place after collisionally activated dissociation by radio frequency (RF) irradiation and admission of argon (SORI-CAD).[20] Three new signal groups are observed which can be assigned to the compounds $[C@W_5Cl_{13}]^-$ ($\mathbf{4}^-$), $[C@W_4Cl_9]^-$ ($\mathbf{5}^-$), and $[C@W_3Cl_6]^-$ ($\mathbf{6}^-$). To confirm experimentally that the dissociation of $\mathbf{3}^-$ proceeds by a consecutive mechanism in which two WCl_4 and one WCl_3 fragment are sequentially split from the parent cluster, each of the species $\mathbf{4}^-$, $\mathbf{5}^-$, and $\mathbf{6}^-$ was isolated once more and dissociated by collisional activation. The resulting fragments proved to be both $\mathbf{5}^-$ and $\mathbf{6}^-$ (from $\mathbf{4}^-$) and $\mathbf{6}^-$ (from $\mathbf{5}^-$; Figure 2). During the fragmentation of $\mathbf{6}^-$ only the appearance of Cl^- is observed. Based on these experimental findings the reaction channel shown in Equation (1) is deduced.

$$[C@W_6Cl_{17}]^-\ (\mathbf{3}^-) \xrightarrow[\Delta E_1]{-WCl_4} [C@W_5Cl_{13}]^-\ (\mathbf{4}^-) \xrightarrow[\Delta E_2]{-WCl_4} [C@W_4Cl_9]^-\ (\mathbf{5}^-) \xrightarrow[\Delta E_3]{-WCl_3} [C@W_3Cl_6]^-\ (\mathbf{6}^-) \quad (1)$$

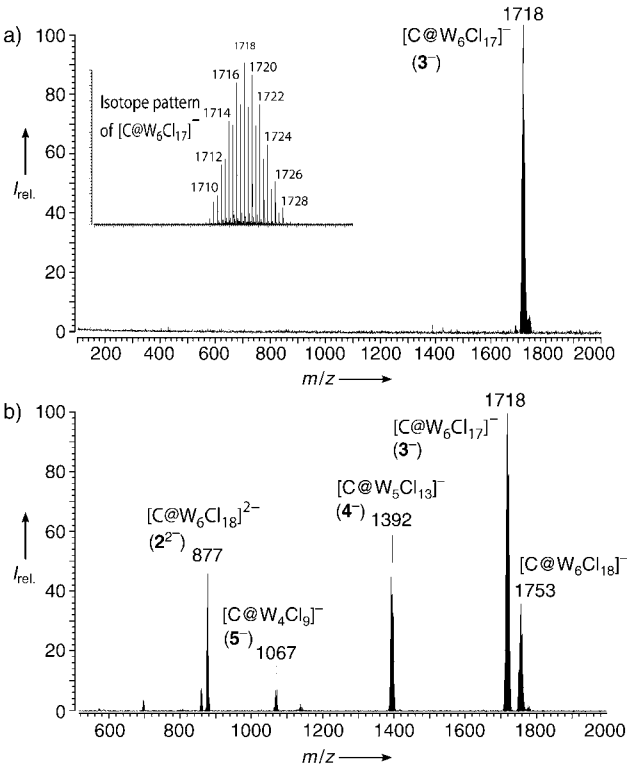

Figure 1. a) Mass spectrum (by electrospray ionization, ESI) of a freshly prepared solution of $[Li_2(\mathbf{2}^{2-})]$ in methanol. b) Mass spectrum (by electrospray ionization, ESI) of an aged solution of $[Li_2(\mathbf{2}^{2-})]$ in methanol (the experiment was performed under identical conditions to those used to obtain Figure 1 a, in particular the skimmer voltages (−20 V) were similar).

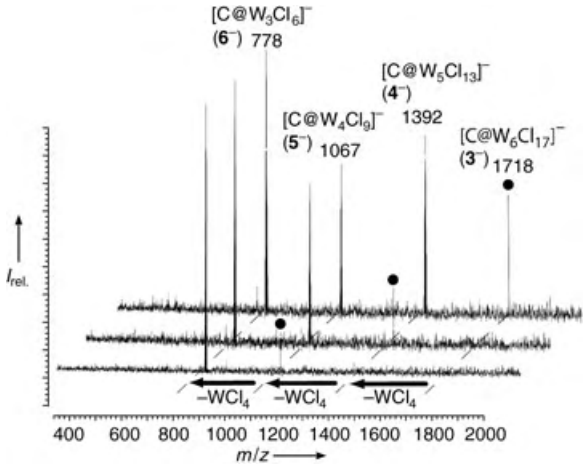

Figure 2. SORI-CAD experiments: The products after the collisionally activated dissociation of $\mathbf{3}^-$, $\mathbf{4}^-$, and $\mathbf{5}^-$. The marked signals (●) were previously isolated isotope selectively.

These fragmentation processes are of note as both WCl_4 and WCl_3 are used as starting compounds for the synthesis of $\mathbf{2}^{n-}$.[21]

However, determination of the dissociation pathway of $\mathbf{6}^-$ by mass spectrometric methods is not possible, because no further fragmentation of $\mathbf{6}^-$ into smaller ionic $[C@W_xCl_y]^-$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

units is detected. Moreover, no conclusions can be made regarding the stabilizing function of carbon or about the structures of the fragments involved in the dissociation process. In experiments with our apparatus configuration the energy amounts ΔE_1, ΔE_2, ΔE_3, which are necessary for the dissociation, can not be determined by CAD.

To find answers to these questions concerning the structure of the intermediates as well as the energy balance during the dissociation processes, we performed density functional theory (DFT) calculations.[22,23] To check the reliability of the energetic aspect of these calculations we examined the isodesmic disproportionation reaction given in Equation (2).

$$2\,WCl_{4(g)} \rightarrow WCl_{6(g)} + WCl_{2(g)} \quad (2)$$

Using highly correlated CCSD(T)/TZVPP methods[24] a ΔE value of 337 kJ mol^{-1} is obtained which is close to the values calculated by the DFT methods mentioned above (334 kJ mol^{-1}).[25,26] Therefore, the dissociation energies determined by DFT methods in equation (1) should be an adequate basis for the discussion of the experimentally found results: $\Delta E_1 = 196$ kJ mol^{-1}, $\Delta E_2 = 63$ kJ mol^{-1}, and $\Delta E_3 = 256$ kJ mol^{-1}.

In Figure 3 a–d the calculated structures of $\mathbf{3}^-$, $\mathbf{4}^-$, $\mathbf{5}^-$, and $\mathbf{6}^-$ are displayed. Detailed information and interatomic distances of all the ions calculated by this method can be found in the Supporting Information.

The mass spectrometric methods used here cannot answer the question of the fragmentation of $[C@W_3Cl_6]^-$ ($\mathbf{6}^-$), since no further fragmentation to smaller $[C@W_xCl_y]^-$ units is observed. A plausible reaction channel could be a simple electron loss from $\mathbf{6}^-$, since for $[C@W_3Cl_6]$ an electron affinity of 332 kJ mol^{-1} was calculated. However, the exclusive detection of Cl^- ions from the dissociation $\mathbf{6}^-$ suggests a different reaction channel. Under preparative conditions, as in the synthesis of $\mathbf{2}^{2-}$ (see above) a reduction could be possible where, apart from Cl^- ions, only the neutral starting compounds emerge [Eq. (3)]. For this hypothetical mode of dissociation we calculated an energy amount of +306 kJ mol^{-1}.[27]

$$[C@W_3Cl_6]^- \rightarrow Cl^- + {}^1/_4\,WCl_4 + CCl_4 + {}^{11}/_4\,W_{(s)} \quad (3)$$

The hypothesis of this reaction path is supported by approximate calculations, for alternative dissociation pathways giving products such as $[C@W_2]$, $[C@W_2Cl_2]$, and $[ClW_3]$, they predict a significantly higher energy requirement. Thus, the reaction in Equation (3) seems to be a plausible suggestion, especially after consideration of retrosynthesis. The results obtained experimentally and by quantum chemical methods for the dissociation of $\mathbf{3}^-$ via $\mathbf{6}^-$ demonstrate that the smallest carbon-containing tungsten cluster $[C@W_3Cl_6]^-$ detected in experiments is possibly one of the first clusters generated in syntheses that start from solid tungsten, WCl_4, and CCl_4 [Eq. (3)].

The results reported herein raise the principle questions, to what extent the insertion of a carbon atom in these clusters is reflected in the energy balance and how strongly a carbon

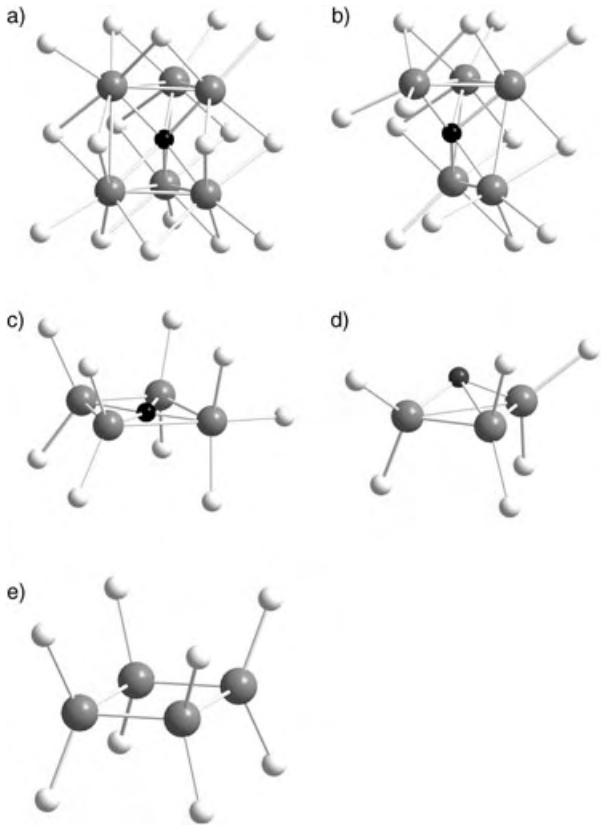

Figure 3. Calculated DFT structures of the fragment ions $\mathbf{3}^-$ (a), $\mathbf{4}^-$ (b), $\mathbf{5}^-$ (c), $\mathbf{6}^-$ (d), and of the hypothetical $[W_4Cl_8]$ molecule **8** (e).

atom is bound? Since with the neutral cluster $[C@W_4Cl_8]$ (**7**), which is derived from $[C@W_4Cl_9]^-$ ($\mathbf{5}^-$), our experiments provide a good model compound with which to try and answer these questions, we investigated the following DFT-supported idea: the removal of a carbon atom from **7** to generate the hypothetical $[W_4Cl_8]$ molecule (**8**; Figure 3 e) requires 699 kJ mol^{-1}.[28] This calculated energy gain for the insertion of a carbon atom into a molecular tungsten-atom framework corresponds to the experimentally determined energy gain which results from the formation of solid tungsten carbide WC from tungsten metal and carbon (752 kJ mol^{-1}).[29] Thus, carbon-centered metal clusters such as **1** are suitable molecular models for the topological and energetic situation in the appropriate solid-state compounds.[30]

In addition to the results for the bonding energy of carbon in the endohedral tungsten clusters reported herein, the dissociation experiments in the gas phase of $\mathbf{3}^-$, $\mathbf{4}^-$, and $\mathbf{5}^-$ as well as the accompanying quantum-chemical calculations make it seem plausible that the recently presented synthesis of **2** and $\mathbf{2}^{2-}$ also proceeds over the observed intermediates, in particular because the educts WCl_4/WCl_3 of the synthesis were released. This conclusion is also based on the fact that the intermediate products $\mathbf{4}^-$ and $\mathbf{5}^-$ can be detected in a methanol solution of $[Li_2(\mathbf{2}^{2-})]$ after ageing.

Since, to date, only **2** and $\mathbf{2}^{n-}$ ($n = 1,2,3$) can be obtained in the crystalline state, it is a challenge for future preparative investigations to isolate and characterize the cluster frag-

ments presented herein. Furthermore, through the comparison of the experimental data with quantum-chemical calculations (see Supporting Information) the accuracy of the simple bonding descriptions[31,32] of the mostly open-shelled structures presented could be verified.

Experimental Section

The experiments presented here were performed on an Ionspec ULTIMA FT-ICR mass spectrometer with a 7.0 T magnet, equipped with both a MALDI and an electrospray (Analytica) ion source.

For the electrospray ionization a solution of $[Li_2(\mathbf{2}^{2-})]$ in methanol (approximately 10 mg mL^{-1}) was sprayed slowly (2 μL min^{-1}) through a stainless steel capillary (with an internal diameter of 100 μm) into an inert gas atmosphere (nitrogen). The ions lose their solvent and arrive over several intermediate stages in an ultrahigh vacuum area, which is generated with a differential pump system (consisting of a rotary vane pump, a turbo molecular pump, and two cryo pumps). The ions are transferred into a hexapole through a glass capillary (with voltages of 3900 V, and −140 V on their nickel coated ends) and a skimmer (−20 V), wherein they are stored for 1500 ms. Within the hexapole the pressure is approximately 10^{-6} mtorr. The ions finally arrive at the ICR cell (at 10^{-10} mtorr) through a quadrupole.

For the SORI-CAD experiments ions were selected by SWIFT-isolation (SWIFT = stored wave inverse Fourier transformation) and accelerated by a RF-pulse in the presence of a collision gas (argon) at 10^{-8} mtorr.[33] The excitation frequency is about 200 Hz higher than the cyclotron frequency, with a amplitude of 5–15 V and a duration of 1000 ms.

[9] In particular the structures of the cluster units with and without endohedral C-atoms, as well as the dramatic changes in the symmetry (from quasi-octahedral to trigonal prismatic) were described in detail and discussed therein (see ref [8]). In agreement with the observation, our own DFT calculations show that $[W_6Cl_{18}]$ with octahedral W_6-framework is favored over the trigonal-prismatic arrangement by around 70 kJ mol^{-1}. In addition we found that for the C-centered cluster $[C@W_6Cl_{18}]$ the trigonal-prismatic arrangement is more favored than the octahedral by around 260 kJ mol^{-1}.

[19] In all the experiments the skimmer potential was kept at a constant −20 V. The comparison of Figure 1a and Figure 1b shows that fragmenting reactions caused by the difference of potential between capillary exit and skimmer can be excluded. These findings can be interpreted that $\mathbf{3}^-$ (and Cl^-) arises during the dissolving of $\mathbf{2}^{2-}$, see Figure 1a. We explain the presence of $\mathbf{2}^{2-}$ in an aged solution by the following equilibrium reaction: at the beginning the equilibrium is exclusively on the side of $\mathbf{3}^-$ and the Cl^- ions. By a substantial increase of the Cl^- concentration (also experimentally observed) the equilibrium is shifted in favor of $\mathbf{2}^{2-}$. These additionally needed Cl^- ions are released during the aging processes, which also yields the fragments $\mathbf{4}^-$ and $\mathbf{5}^-$. This conclusion could be confirmed by the fact that after addition of Cl^- (as tetrabutylammonium chloride), $\mathbf{3}^-$ was no longer detected while $\mathbf{2}^{2-}$ could still be observed.
[20] SORI-CAD (sustained off-resonance irradiation collision activated dissociation). A small shift in the excitation frequency compared to the cyclotron frequency ensures that excitation only occurs with the flank of the RF pulse. The kinetic energy of the system is raised moderately over 1000 ms to give an energy distribution of the particles according to Boltzmann statistics. By collision-induced conversion into internal energy the weakest bonds in the cluster molecule finally break. J. W. Gauthier, T. R. Trautman, D. B. Jacobson, *Anal. Chim. Acta* **1991**, *246*, 211.
[21] The appearance of $\mathbf{4}^-$ and $\mathbf{5}^-$ (however not $\mathbf{6}^-$) in an aged methanol of $[Li_2(\mathbf{2}^{2-})]$ solution shows clearly that they represent intermediate stages in the decomposition of $\mathbf{3}^-$, and probably also in the assembly. The absence of $\mathbf{6}^-$ in this context demonstrates that the spectrum in Figure 1b actually shows the composition of the aged solution, and the decomposition products $\mathbf{4}^-$ and $\mathbf{5}^-$ are not the results of fragmenting reactions caused by differences of potential between glass capillary and skimmer within the medium pressure range.

[23] Although compounds of heavy transition metals can be described only to a limited extent correctly in this way, Schimmelpfennig et al. recently reported on DFT calculations for different tungsten chlorides, which are in agreement with the experimental data.[26] We therefore oriented ours approach towards these methods (B3LYP-functional, with quasirelativistic core potential (ecp) in combination with the TZVPP basic set), and thus confirmed bond lengths from the crystallographic data of $[C@W_6Cl_{18}]$.

[25] Unfortunately, there exists only imprecise data for the chemical energy of our experimental reaction: In ref. [29], ΔH_R is quoted with a value of 166 kJ mol^{-1} at a tolerance of $\pm$190 kJ mol^{-1} (!) and therefore can not be used to judge the quality of the calculation methods. All energy values calculated herein relate to the respective molecular structures at 0 K. We abstained from a correction with respect to the zero-point vibrational energy, this contribution for the educts and products is almost identical so that according to our approximate calculations the energy difference is only about (5 ± 5) kJ mol^{-1}.

[26] B. Schimmelpfennig, U. Wahlgren, O. Gropen, A. Haaland, *J. Chem. Soc. Dalton Trans.* **2001**, 1616.

[27] For $W_{(s)}$ in Equation (3) we have used the evaporation heat (850 kJ mol^{-1}) from ref. [29], and thus corrected the calculated reaction energy for Equation (3) with $W_{(g)}$.

[28] In cooperation with H.-J. Himmel a study of the cluster molecules $[W_2Cl_4]$, $[W_4Cl_8]$, and $[W_6Cl_{12}]$ is in preparation where the possibility of multiple bonding is discussed in comparison to organic compounds with aromatic bonding relations.

Mesoporous Materials

Three-Dimensional Mesoporous Chromium Oxide: A Highly Efficient Material for the Elimination of Volatile Organic Compounds**

Anil K. Sinha and Kenichirou Suzuki*

Increasingly strict legislation for controlling the atmospheric emission of industrial volatile organic compounds (VOCs), which contribute to photochemical smog, ground-level ozone, and toxic air emissions,[1–4] has made the catalytic combustion of hydrocarbons a vital topic of research for the development of new processes for limiting air pollution by VOCs.[5] Oxides of transition metals such as Mn, Cr, Cu, and Co are the most commonly used, cost-effective catalysts for complete oxidation of VOCs,[6–9] and crystalline chromium oxide, which favors the formation of CO_2, is the most promising candidate for the total oxidation of organics.[10]

Ordered mesostructures of transition-metal oxides[11,12] are of immense interest in areas such as catalysis, sorption, chemical and biological separation, photonic and electronic devices, and drug delivery,[13] and well-ordered mesoporous oxides of Mn,[14] Ti,[15,16] V,[17] Zr,[18] W,[15] Nb,[15,17] and Ta[15,18] have been reported. However, the preparation of three-dimensionally (3D) ordered mesoporous oxides of Cu, Co, Cr, Ni, and Fe is more difficult, although it has been possible to prepare unstable lamellar phases of these materials. Recently, hexagonally ordered mesoporous nickel oxide[19] and wormhole-like mesoporous iron oxide[20] have been reported. However, nanoporous 3D structure of oxides are more suitable for application as catalysts or adsorbents as they do not suffer from mass-transfer limitations and therefore allow the easier diffusion of reactants.[21] Transitional-metal oxides are more susceptible to hydrolysis, redox reactions, or phase transitions and possess a number of different coordination numbers and oxidation states, which makes it rather difficult to prepare mesoporous structures from them, unlike silica and aluminosilicates, which can easily form stable mesoporous structures. A neutral templating route has been successfully used for the synthesis of metal-oxide mesostructures[11,15] that are less readily accessible by electrostatic-templating pathways.[12,16]

Herein we demonstrate for the first time that a 3D mesoporous chromium oxide material, prepared by a neutral templating route, shows an exceptionally high removal/oxidation ability for VOCs (toluene, acetaldehyde) after calcination. For transition-metal oxides, control of the rates of precursor hydrolysis, condensation of metal species, and precipitation of mesostructured oxides, for example by slow crystallization, is an important prerequisite for the enhanced framework cross-linking[22,23] that leads to a stable mesoporous structure. We therefore used a metal nitrate salt precursor, a mixed nonaqueous, ethylene glycol/propanol medium, and poly(alkylene oxide) block copolymers as template to prepare a very stable 3D mesoporous structure. The mixed nonaqueous medium allows a very slow crystallization (gelation) process, which favors the formation of a stable mesostructure by enhanced framework cross-linking. Our intention was to exploit such a material with 3D mesoporosity, large surface area, high oxidizing power, and probable ready evolution of active lattice oxygen, to prepare a commercially viable, cost-effective catalyst/sorbent system for the efficient removal of VOCs at low temperatures.

The as-synthesized mesoporous chromium oxide samples were transparent, and formed a fluffy, foamlike material after heating in air at 150 °C. Thermogravimetric experiments indicated that the template molecules could be completely removed by calcinating the samples at 400 °C; this was confirmed by C,H analysis.

Typical X-ray diffraction (XRD) patterns for the mesostructured chromium oxide before and after organic-template removal are shown in Figure 1a. The as-made chromium

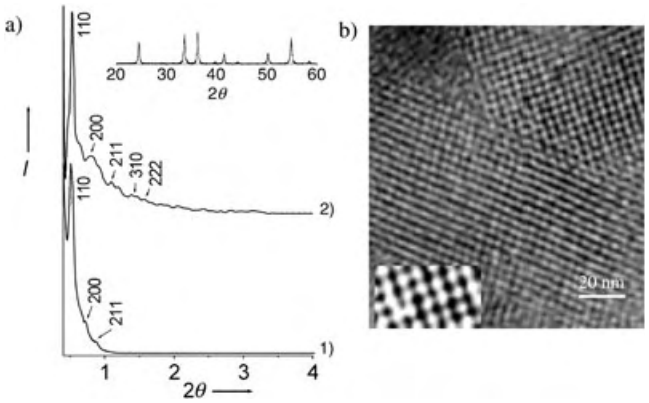

Figure 1. a) XRD pattern of mesoporous chromium oxide: 1) as-made and 2) template-free (heated to 150 °C and extracted with ethanol); b) TEM image of the template-free mesoporous chromium oxide. Inset: the reconstructed image of a selected region.

inorganic/polymer mesostructure shows diffraction peaks with lattice spacings, d, of 173, 122, and 100 Å. The d-value ratios for these peaks are $\sqrt{2}:\sqrt{4}:\sqrt{6}$, and they are indexable as (110), (200), and (211) reflections, respectively, in the cubic $Im3m$ space group. Five major XRD peaks, with d spacings of 150, 106, 87, 67, and 61 Å and d-value ratios $\sqrt{2}:\sqrt{4}:\sqrt{6}:\sqrt{10}:\sqrt{12}$, are observed after removal of the organic block-copolymer template. They are similarly indexable as the (110), (200), (211), (310), and (222) reflections of the cubic $Im3m$ space group. The basal spacing is observed to decrease by 23 Å upon removal of the template due to lattice contraction. The wide-angle X-ray diffraction pattern of the

 DOI: 10.1002/anie.200461284 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

template-free calcined sample (Figure 1a, inset) clearly shows peaks that can be indexed according to the rhombohedral phase of crystalline Cr_2O_3, thus indicating the presence of trivalent Cr in the sample. However, the presence of other mixed-valent Cr species cannot be ruled out because X-ray photoelectron spectroscopy (XPS; vide infra) revealed the presence of Cr species with different oxidation states.

The XRD peak assignment was further confirmed by transmission electron microscopy (TEM). The TEM image of the mesopore arrangement is shown in Figure 1b, where a regular arrangement of bright spots and ordered channels is observed that is attributed to the three-dimensional cubic ordered arrangement of mesopores.

The N_2 adsorption–desorption isotherm and Barret–Joyner–Halenda (BJH) pore-size distribution for the 3D mesoporous chromium oxide are presented in Figure 2. The

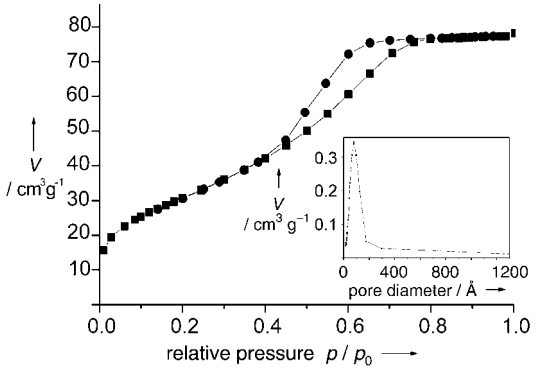

Figure 2. N_2 sorption isotherm and pore-size analysis (inset) of the mesoporous chromium oxide calcined at 400 °C.

sample exhibits a type-IV isotherm that is typical of mesoporous materials, with a well-defined step in the adsorption curve between partial pressures, p/p_o, of 0.4 to 0.8, and a large hysteresis loop due to capillary condensation in the mesoporous channels and/or cages. BJH analysis of the adsorption data, assuming cylindrical pores, shows that the calcined mesoporous chromium oxide has a mean pore-size of 7.9 nm and a wall thickness of 13.3 nm, as estimated from the XRD unit-cell parameter (a_o) value of 21.2 nm. The absence of textural mesoporosity is indicated by a plateau at a relative pressure of about 0.8 to 1.0. The template-free sample (after ethanol extraction) has a surface area of 212 $m^2 g^{-1}$, which decreases to 96 $m^2 g^{-1}$ after calcination at 400 °C and to 78 $m^2 g^{-1}$ after calcination at 500 °C.

A sample (0.4 g) of the 3D mesoporous chromium oxide calcined at 500 °C showed the highest toluene removal ability among all these materials, with 52% toluene removal and 11 ppm CO_2 formation (2% conversion) after 25 h at room temperature (sample 3 in Figure 3). The toluene-removal ability increased to 65%, with 66 ppm CO_2 formation (12% conversion), when the temperature was increased to 85 °C (sample 4). An increase in toluene-removal ability with increasing temperature is an indication of catalytic oxidation of toluene at low temperatures. This is the first report of partial catalytic decomposition of VOCs by mesoporous transition-metal oxides at low temperature. In comparison,

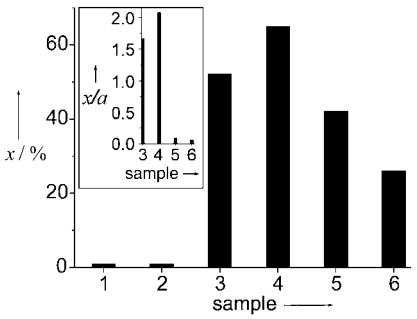

Figure 3. Toluene removal (x) over various chromium oxide samples: 1) commercial Cr_2O_3, 2) commercial CrO_3, 3) mesoporous CrO_x (at room temperature), 4) mesoporous CrO_x (at 85 °C), 5) mesoporous SiO_2 (room temperature), 6) mesoporous SiO_2 (at 85 °C). The inset shows the toluene removal per unit area of the samples (x/*a*).

mesoporous silica with a surface area of 1120 $m^2 g^{-1}$ showed 42% toluene removal at room temperature (sample 5), which decreased to 26% when the reaction temperature was increased to 85 °C (sample 6). Even though the 3D mesoporous chromium oxide has a surface area about 10 times lower than that of mesoporous silica, it still shows a much higher toluene-removal ability. The toluene-removal ability per unit area is about 18 times higher at room temperature, and about 35 times higher at 85 °C, for mesoporous chromium oxide than for mesoporous silica (Figure 3, inset). It was possible to achieve 94% toluene removal with 1.0 g of 3D mesoporous chromium oxide (see Supporting Information). Commercial hexavalent and trivalent chromium oxide (Wako Chemicals) samples (samples 1 and 2) gave less than 1% toluene removal. A high-surface-area amorphous chromia aerogel (278 $m^2 g^{-1}$),[24] which contains mostly trivalent chromium species (from XPS analysis), also showed a low toluene-removal performance (< 10%).

The X-ray photoelectron spectrum of the mesoporous chromium oxide sample shows a broad band, which indicates the presence of Cr in multiple oxidation states from +2 to +6 (see Supporting Information) with about 75% of the Cr present in the +3, or lower, oxidation state. This implies that the mixed oxidation state of the 3D mesoporous chromium oxide sample, as well as its high surface area and 3D mesoporosity, is probably responsible for the exceptionally high toluene-removal ability. Strong π–d[25] and d–σ interactions,[26] the possibility of ready evolution of active lattice oxygen species, as well as the high oxidizing power of higher valent Cr species favored by lattice strain, is probably responsible for the excellent toluene-removal ability of this mesoporous chromium oxide. In fact, when the toluene combustion reaction was evaluated in a flow reactor the toluene decomposition was found to start well below 100 °C, and it was possible to achieve 100% toluene combustion at temperatures of 280–300 °C (see Supporting Information).

These 3D mesoporous oxides could therefore be excellent materials for the sorption of VOCs at room temperature. The adsorbed VOCs can then be directly decomposed by the same catalyst at higher temperatures, thereby eliminating the need for the elimination of VOCs from the sorbent as is required for conventional VOC-removal materials such as activated

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

carbon or porous silica. We were able to completely decompose the toluene adsorbed on the surface of the catalyst by thermal treatment at around 350 °C, and the regenerated catalyst could be reused without any loss in activity. XPS analysis did not show any change in the oxidation state of Cr after regenerating the 3D mesoporous oxide. There was also little change in the surface area of the regenerated catalysts. Further work on the long-term use of these catalysts is still underway to determine the total catalyst lifetime and coking behavior.

The 3D mesoporous chromium oxide catalyst (0.4 g) also removed 94% of the acetaldehyde from a 27 ppm acetaldehyde feed in air after reaction at room temperature for 25 h.

In summary, we have reported a commercially viable 3D mesoporous chromium oxide sorbent/catalyst with an exceptionally high VOC elimination ability. We expect to be able to develop a novel, dual-function sorbent/catalyst material—under ambient conditions the material acts as a selective sorbent for the VOCs, then, when it is heated to higher temperature, it acts as an effective and selective deep-oxidation catalyst for the VOCs so that the recovery and/or incineration step required in the case of currently available commercial VOC adsorbents can be eliminated. These mesoporous oxides also have potential applications as catalysts for various organic transformations, as supports, adsorbents, and separation materials, and in sensors, porous electrodes or electrolytes, and electromagnetic and electronic devices.

Experimental Section

Triblock copolymer F-127 ($HO(CH_2CH_2O)_{106}(CH_2CH(CH_3)O)_{70}(CH_2CH_2O)_{106}H$) and chromium nitrate were used as the template and inorganic source, respectively. The typical molar gel composition was 134 Cr:1115 propanol:1080 EG:1 F-127 (or P-123). In a typical synthesis, F-127 block copolymer (1 g) was dissolved in a mixture of propanol (5 g) and ethylene glycol (EG; 5 g). $Cr(NO_3)_2{\cdot}3H_2O$ (2.42 g) was added to this solution with vigorous stirring over 30–40 min. The resulting sol solution was then aged at 40–50 °C for 7–14 days and then heated gradually (1 °C min^{-1}.) to 150 °C. Finally, the organic template molecules were removed by extracting with ethanol. The samples were further calcined by heating gradually (1 °C min^{-1}) to 300–500 °C.

A gas mixture containing 103.3 ppm toluene, 20% oxygen, and the balance as nitrogen was used as the evaluation gas. A 0.4-g sample of each of the aforementioned catalysts and the evaluation gas were put in a 5-L gas container. The gas was analyzed after different time intervals by GC (Shimadzu, column Sp-1000) and a CO_2 analyzer (LI-6262, LI-COR, Inc.). The toluene conversion was determined from the equation: toluene removal (%) = [{(toluene concentration in gas container without catalyst) − (toluene concentration in gas container with catalyst)}/toluene concentration in gas container without catalyst] × 100.

A packed-bed reactor was used to evaluate the catalysts' activity in the complete oxidation of toluene (space velocity 30000 h^{-1}; toluene: 100 ppm; oxygen: 18%; and the balance of nitrogen). At the onset of the reaction the catalyst was pretreated with reactant mixture at 180 °C for 1.5 h to prevent over-estimation of toluene conversion caused by adsorption of toluene during the initial stages of the test.

Nanostructures

Germanium-Catalyzed Growth of Zinc Oxide Nanowires: A Semiconductor Catalyst for Nanowire Synthesis**

*Zheng Wei Pan, Sheng Dai, Christopher M. Rouleau, and Douglas H. Lowndes**

The vapor–liquid–solid (VLS) crystal growth mechanism, first proposed by Wagner and Ellis in 1964 for Si-whisker growth,[1] has been widely used to guide the growth of a wide range of nanowires, such as Group IV (such as Si and Ge),[2–7] III–V (such as GaAs and InP),[5,6] and II–VI (such as ZnS and ZnSe)[5,7] semiconductors, and oxides (such as ZnO and SiO_2).[8–10] In this mechanism, a catalyst nanoparticle serves as a preferential site for the absorption and dissolution of reactants from the vapor phase, directs the nanowire's growth direction, and defines the diameter of the nanowire. A common morphological feature of VLS-grown nanowires is that each nanowire is terminated at one end by a catalyst nanoparticle with a diameter similar to that of the nanowire. The catalysts used so far are usually metals, with the most popular ones being gold[3–9] and iron.[2]

ZnO is recognized as a promising photonic material in the blue-ultraviolet (UV) region due to its wide bandgap (3.37 eV) and large exciton binding energy (60 meV). Stimulated by recent reports of room-temperature UV lasing from ZnO nanowires,[9] ZnO, in the form of nanowires, nanorods, and nanobelts, is attracting a great deal of attention from the research community. Various methods have been developed for synthesizing these one-dimensional ZnO nanostructures, such as metal-catalyzed VLS growth,[8,9,11] physical vapor deposition,[12–14] chemical vapor deposition (CVD),[15] metal-organic vapor-phase epitaxy,[16] metalorganic CVD,[17] template-assisted growth,[18] and various solution methods.[19,20] Among these techniques, metal-catalyzed VLS growth has the advantage of allowing the controlled and patterned growth of ZnO nanowires,[8,9,11] and yields nanowires from well-defined and/or patterned sites on surfaces that could facilitate the integration of ZnO nanowires for characterization and their use in devices.

We report here that Ge, a Group IV semiconductor, can be used as an efficient catalyst for high-yield growth of very long (up to several hundred micrometers), extremely straight, and quasi-aligned arrays of single-crystalline ZnO nanowires in a VLS process. The Zn source was generated by carbothermal reduction of ZnO powder. The Ge catalyst was provided either by the vapor, generated by carbothermal reduction of GeO_2 powder, or by patterning Ge dots on a SiO_2-coated Si wafer by photolithography. Several kinds of substrates were used for nanowire growth, such as alumina plates, sapphire wafers, silicon wafers, and copper grids.

Figure 1a shows a low-magnification scanning electron microscopy (SEM) image of the ZnO nanowires grown on an alumina substrate. A white layer of high-density ZnO nanowires with a uniform thickness of about 150 μm has formed on the substrate surface. The nanowires tend to grow normal to the substrate surface to form a quasi-aligned nanowire array (Figure 1b). They are well-faceted with hexagonal cross-sections (Figure 1c, d), which indicates that the Wurtzite-type

ZnO nanowires grow along the ⟨0001⟩ direction. One unique feature of our nanowires is that they are terminated at their growing ends by very large spherical particles with diameters of up to several micrometers. The presence of particles at the ends of the nanowires is suggestive of a VLS growth process.[1–3] Indeed, as shown in Figure 1c, the fact that wire A slices the tip of wire B, and that the tips of wire A and wire C are stuck together, strongly suggests that the large particles were in the liquid or semi-solid state during the growth. Energy-dispersive X-ray spectroscopy (EDS) analyses conducted with a transmission electron microscope (TEM) show that the particles are Ge with traces of Zn, whereas the nanowires contain Zn and O with traces of Ge (< 1 atom %) (Figure 1e). This indicates that the particles atop the nanowires are Ge and that the nanowires are Ge-doped ZnO. We therefore conclude that our ZnO nanowires grow by a Ge-catalyzed VLS process. To the best of our knowledge, this is the first example of a nonmetal catalyzing nanowire growth. (Note that Ge has been used before as a growth medium in the synthesis of millimeter-scale GaAs whiskers, but it was subsequently found to be present in the core and throughout the entire length of the whisker.[21])

The Ge-catalyzed ZnO nanowires are very straight and very little curvature was observed over the full length of some of the hundreds-of-micrometers-long nanowires. Detailed SEM investigations across the entire nanowire growth region showed that, within the nanowire formation regime (500–650 °C), the sizes of both the nanowires and the Ge particles increase with temperature. After 30 min of growth, the diameters and lengths of the nanowires are in the ranges 50–400 nm and 50–200 μm, respectively. The diameters of the Ge particles, however, vary from 0.5 to 4 μm, about 5–15 times those of the associated nanowires. These Ge-particle diameters are much larger than for metal-catalyzed nanowire growth, for which the diameters of the catalyst particles are similar to those of the nanowires.[2–6] The present nanowires grow very rapidly, with rates of up to 400 μm h^{-1} at a growth temperature of about 600 °C; this is about one order of magnitude faster than Au-catalyzed ZnO nanowire growth.[8,9] Unlike metal-catalyzed nanowire growth, in which the diameter of the nanowires is mainly determined by the size of the catalyst particles,[2–6] it seems that the diameter of the Ge-catalyzed ZnO nanowires is less influenced by the Ge particle size. For example, as shown in Figure 1f, the nanowires that result from a 3.5-μm-diameter Ge particle (the largest one) and a 1-μm-diameter Ge particle (the smallest one) have essentially the same diameter (~100 nm). This may explain the fact that even though the Ge particle grows up with time by continuously absorbing Ge species from the vapor, the diameter of each nanowire is almost constant over most of its length. (Note that a tapered morphology can be observed over the first few micrometers of the nanowires, probably due to the significant increase of the size of the Ge particle at the initial growth stage.)

The Ge-catalyzed ZnO nanowire growth is substrate independent. Besides alumina substrates, ZnO nanowires were also grown on sapphire and silicon wafers, and even on copper TEM grids. Figure 1g is an SEM image of ZnO nanowires grown on a sapphire wafer. It shows long (up to 100 μm), very straight, and quasi-aligned ZnO nanowires that terminate in large Ge particles. Figure 2a is a low-magnification SEM image of ZnO nanowires grown on the bars of a copper TEM grid consisting of hexagonal windows. In each

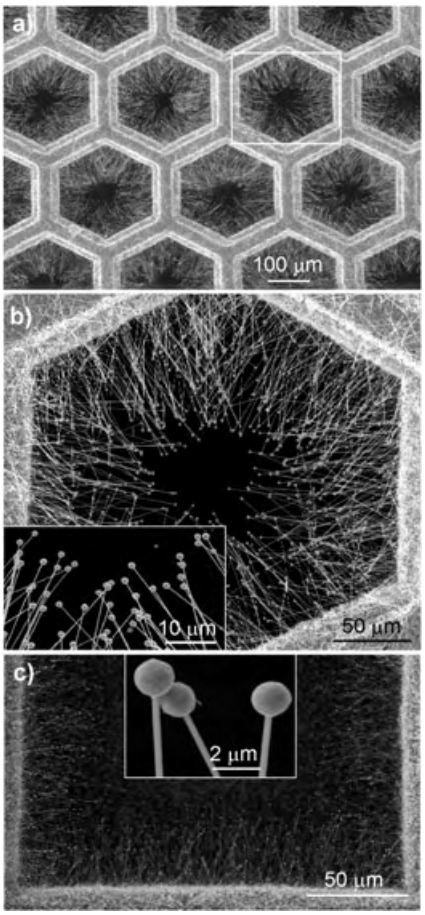

Figure 2. SEM images of Ge-catalyzed ZnO nanowires grown on copper TEM grids. a) Low-magnification SEM image of ZnO nanowires grown on a copper grid with hexagonal windows. b) An enlargement of the boxed region in Figure 2a. The inset shows a high-magnification image of the nanowires. c) An SEM image of ZnO nanowires grown on a copper grid with square windows. The inset shows a high-magnification image of the nanowires.

hexagonal window straight ZnO nanowires tend to grow along the surface normal of each edge of the hexagon; they converge upon the window center (Figure 2b). Such a growth phenomenon was also observed on a TEM grid consisting of square windows (Figure 2c).

TEM studies of the ZnO nanowires provide further insight into the morphology of these materials. Figure 3a and b show the TEM images of the ZnO nanowires grown directly on TEM grids. It is clear that the nanowires are very straight, have a uniform diameter along their axes, and terminate in large spherical Ge particles. High-resolution TEM investigations show that the ZnO nanowires are structurally uniform and single crystalline. Figure 3c is a high-resolution TEM image of a thin, single-crystalline ZnO nanowire, and Figure 3d is an atomic-resolution image of the surface of a nanowire. These images clearly show the (0001) atomic planes

The inset is an electron-diffraction pattern of the crystalline nanowire recorded along the $[2\bar{1}\bar{1}0]$ zone axis. d) An atomic-resolution image showing a clean and structurally perfect nanowire surface.

(separation: 0.52 nm) perpendicular to the nanowire axis, thus indicating that $\langle 0001 \rangle$ is the preferred growth direction of these Wurtzite-type ZnO nanowires. The single-crystal nature of the nanowires and their $\langle 0001 \rangle$ growth direction were confirmed by the electron-diffraction pattern recorded perpendicular to the nanowire's long axis, as shown in the inset of Figure 3c, which could be indexed as the $[2\bar{1}\bar{1}0]$ zone axis of crystalline ZnO. The surfaces of the nanowires are clean, atomically sharp, and without any amorphous sheathed phase (Figure 3d).

In metal-catalyzed semiconductor nanowire growth, binary or pseudobinary phase diagrams are usually used to predict catalysts and growth conditions.[2,5] Although no Ge–ZnO phase diagram is available, this principle can be rationally applied to the present Ge-catalyzed ZnO nanowire growth by considering both the conventional Ge–Zn binary phase diagram[22] and the in-situ oxidation of Zn into ZnO during growth.[8] The Ge–Zn phase diagram is characterized by a eutectic reaction at 394 °C and 94.2 atom % Zn. This implies that a Ge-catalyzed VLS-type process can take place if the concentration of Zn is higher than 94.2 atom %. Such high-Zn-content Ge–Zn droplets can be readily formed since in the source materials the amount of ZnO present is about 10 times that of GeO_2 (molar ratio). When the droplets become supersaturated, ZnO nanowires are formed, possibly by the in situ reaction between Zn and a small amount of CO/O_2 present in the reaction chamber, as happens in Au-catalyzed ZnO nanowire growth.[8] The CO gas is formed by the carbothermal reduction of ZnO and GeO_2, whereas the oxygen mainly originates from leaks in our reaction system.[10]

For the Ge-catalyzed ZnO nanowire growth reported above, Ge was fed from the vapor, and the Ge catalyst particles formed on the substrate surface at the initial growth stage were randomly distributed. However, recent studies on metal-catalyzed VLS nanowire growth have shown that the controlled growth of nanowires at certain locations can be achieved from well-defined metal-catalyst particles on substrate surfaces.[4,8,9] To achieve such controlled growth from Ge, and to verify the catalytic effect of Ge on ZnO growth, we patterned uniformly sized Ge dots (~0.5 μm in diameter and 75 nm thick), with a spacing of about 5 μm, on a SiO_2-coated Si wafer by photolithography (Figure 4, upper inset), and

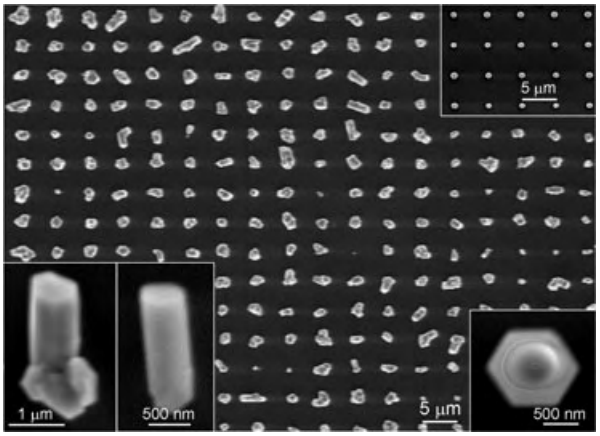

Figure 4. SEM images of a ZnO nanorod pattern grown on a Ge-dot pattern. The top-right inset shows the Ge-dot pattern. The bottom-left insets show two typical morphologies of the nanorods. The bottom-right inset is the top view of a hexagonal nanorod, showing a hemispherical hollow at the upper end of the nanorod.

carried out ZnO growth. Subsequent SEM studies (Figure 4) revealed the formation of a ZnO nanorod array that conforms to the Ge-dot pattern with high fidelity; the region without Ge dots remains completely clean. These observations clearly demonstrate the feasibility of highly deterministic control of ZnO nanowire growth at predetermined Ge-dot locations, as well as the catalytic capability of Ge for ZnO nanorod array synthesis. However, the nanorods in Figure 4 are much shorter (< 2 μm) than the nanowires described above, and no Ge particles were observed at the nanorod tips after the growth experiment at 900 °C for 1 h. This may be explained by considering the different sources of Ge and evolution of Ge particle sizes in these two kinds of syntheses. For the growth shown in Figure 1–3, the Ge particles can grow (up to 4 μm) by continuously absorbing Ge species from the vapor, so that they have sufficient volume to absorb Zn and O species to sustain fast growth of long ZnO nanowires. In contrast, for the Ge-dot pattern the Ge dots' initial volume is only about 3 % of that of even a 1-μm-diameter Ge particle, and therefore the Ge dots decrease in size, and finally disappear, due to the continuous evaporation of Ge without replenishment. This process results in a much lower growth rate and short ZnO nanorods. Indeed, hemispherical hollows with diameters

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

similar to those of the original Ge dots were usually observed at the top ends of the nanorods (Figure 4, bottom right inset). These are possibly left by the evaporated Ge dots, thus confirming this model. Further work is underway to deterministically grow ZnO nanowires with controllable lengths and locations using a variety of well-defined Ge dots.

The photoluminescence (PL) spectra of the Ge-catalyzed ZnO nanowires were measured by using a Xe lamp (325 nm) as the excitation source. Figure 5 shows a room-temperature

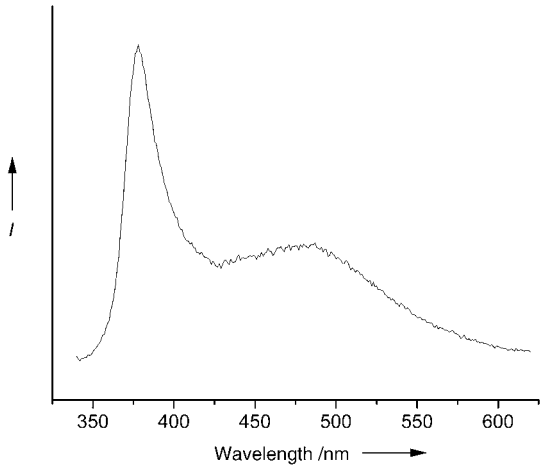

Figure 5. Photoluminescence spectrum of ZnO nanowires showing an intense UV emission at 378 nm and a weak green emission peaking at about 490 nm.

PL spectrum recorded from the ZnO nanowires grown on an alumina substrate. An intense UV emission at 378 nm and a weak, broader green emission peaking at about 490 nm were detected. While the UV-band emission corresponds to the near-band-edge free excitonic emission, the green-band emission is commonly referred to as deep-level or trap-state emission.[8] The observation of an intense free-exciton peak at room temperature strongly suggests that the Ge-catalyzed ZnO nanowires are of high optical quality. The origin of the deep-level emission in ZnO is not yet clearly understood, but is generally attributed to singly ionized oxygen vacancies[23] and extrinsic impurities.[24,25] Since our ZnO nanowires are structurally uniform and single crystalline, the weak green emission presumably arises mainly from the trace amount of Ge present in the nanowires, which could provide the green luminescence by either donor–acceptor pair or donor–hole recombination.[24,25]

Taken together, the above results show that semiconductor Ge can act as an efficient catalyst for high-yield growth of very long, extremely straight, and quasi-aligned arrays of single-crystalline ZnO nanowires by a VLS process. The use of Ge as the catalyst enriches and broadens the current understanding of the conventional VLS nanowire growth mechanism in which metals have generally been used as the catalysts. Our results suggest that it should be possible to prepare nanowires of other oxides or of compound semiconductors by using Ge or other nonmetallic elements as the catalysts. Moreover, the ZnO nanowires and synthesis methods reported here could offer opportunities for further fundamental research as well as technological applications. For example, it should be readily possible to apply electrodes to these straight and long nanowires for transport measurements, and the deterministic growth may have important practical implications, for example, for near-UV light emitting arrays.

Experimental Section

Nanowire synthesis: The ZnO nanowires were synthesized in a tube furnace system[10] by carbothermal reduction of ZnO powder in the presence of semiconductor Ge as the catalyst. The Ge catalyst was provided either from the vapor generated by carbothermal reduction of GeO_2 powder or by patterning Ge dots on a SiO_2-coated silicon wafer by photolithography. For the syntheses in which Ge was provided from the vapor, ZnO powder, carbon black, and GeO_2 powder (1:1:0.1 molar ratio) were ground together and transferred into an alumina boat. The boat was then positioned at the center of an alumina tube that was inserted into a horizontal tube-furnace. Several alumina (or silicon wafer or sapphire wafer) strips ($30 \times 10\ mm^2$) were placed downstream one-by-one to act as nanowire-growth substrates. The starting materials were then heated to 900 °C under an argon atmosphere at a flow rate of 50 sccm and a pressure of about 250 Torr for 30 min. The reactant vapors (Zn, Ge, CO, and O species) generated by carbothermal reduction of ZnO and GeO_2 were carried and transported by the argon flow to the substrates, where ZnO nanowires grew. After the furnace had cooled down to room temperature, ZnO nanowires were found on all exposed surfaces (including the top surface and four side surfaces) of the substrates located in the region at temperatures of about 500–650 °C.

For the patterned growth of ZnO nanowires, the Ge-dot patterns were prepared by photolithography using a GCA Autostep 200 *i*-line stepper system.[26] A 4-inch Si wafer coated with a 1-μm-thick SiO_2 layer was used as the substrate. The wafer was spin-coated with approximately 500 nm of photoresist (Shipley Megaposit 955-CM 0.9) at 6000 rpm for 30 s. After baking at 90 °C for 90 s, the wafer was exposed using a step size of 15 mm and a 25×25 mm aperture. At $5\times$ reduction, we obtained a 5×5 array of 5×5 mm die on a 15 mm pitch. After exposure, the wafer was baked at 120 °C for 90 s, developed for 60 s (Shipley Microposit MF-CD-26), and then reactive-ion-etched for 30 s ($308\ mW\,cm^{-2}$ with 0.1 Torr O_2 at 50 sccm) to eliminate the photoresist residue. At this stage, the wafer had many small windows (~0.5 μm in diameter on a 5 μm pitch) within the photoresist and was ready for metallization. A 75-nm-thick layer of Ge was then deposited onto the patterned substrate at room temperature by electron-beam evaporation. Finally, liftoff was performed by soaking the wafer in acetone to remove all the unnecessary Ge, leaving a 5×5 array of 5×5 mm squares on a 15 mm pitch. Within each square there was an array of Ge dots with a diameter of 0.5 μm, a thickness of 75 nm, and a spacing of 5 μm, as shown in the upper inset of Figure 4.

The Ge-dot-patterned substrates were then loaded onto a 20-cm-long graphite crucible filled with equal amounts of ZnO powder and carbon black, with the catalyst side facing down and a vertical distance between the Zn source and substrates of about 3–5 mm. The growth was conducted at 900 °C for 1 h in an argon flow. During these experiments, we noted that rodlike ZnO nanostructures were grown only on the Ge-dot patterns located in the region at a temperature of about 650–800 °C, about 150 °C higher than the nonpatterned growth described above. Below about 650 °C, no ZnO nanorods were grown, and the Ge-dot patterns seemed unchanged. Above about 800 °C, however, the Ge dots evaporated completely and thus no nanorods were formed.

Characterization: The morphology of the as-synthesized nanowires was examined with a Philips XL-30 SEM operating at 10 kV.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The microstructure was characterized with a Philips CM200 high-resolution TEM operating at 200 kV. The composition of the nanowires was analyzed by an energy-dispersive X-ray spectrometer attached to the TEM. The photoluminescence study was carried out at room temperature on a SPEX Fluorolog-3 spectrofluorometer using a Xe lamp as the excitation source. The excitation wavelength was 325 nm.

Rotaxane Synthesis

Selective Synthesis of Two Constitutionally Isomeric Oriented Calix[6]arene-Based Rotaxanes**

Arturo Arduini, Flavio Ciesa, Marcello Fragassi, Andrea Pochini, and Andrea Secchi*

Rotaxanes are key compounds for the construction of synthetic molecular machines.[1,2] In spite of the remarkable achievements in their synthesis, as well as in the control of the movement of the wheel along the dumbbell component,[3] the synthesis of rotaxanes endowed with an unequivocal and predetermined relative orientation of the wheel/dumbbell systems still represents a relatively unexplored field.[4] In fact, the structure of the cyclic component employed is often related to that of a two-dimensional macrocycle, such as a crown ether, or three-dimensional symmetrical hosts, such as cucurbitols,[5] and thus have degenerate properties on the two sides of the wheel that face the two identical[6] or different[7] stoppers of the dumbbell. In the cases where the three-dimensional and nonsymmetrical cyclodextrins are used as the wheel, an axle can thread the cyclodextrin from both rims, thus leading to a mixture of orientational pseudorotaxane isomers[8] in which the orientation of the cyclodextrin along the axle is virtually unpredictable.[9] It could, however, be foreseen that a predetermined orientation of the components within these interlocked systems could endow devices with new properties.

A relatively new type of wheel that can be used in this context is the calix[6]arene platform. We have shown that triphenylureidocalix[6]arene derivatives can act as heteroditopic receptors and form remarkably stabile pseudorotaxanes with dioctylviologen salts ($K_s = 1.3 \times 10^6\,\text{M}^{-1}$)[10] as well as a calixarene-based rotaxane based on this axle/wheel dyad.[11] The binding properties of triphenylureidocalix[6]arene (**1**) were used to address the threading of an asymmetrical dipyridinium axle that threads the wheel exclusively from the upper rim in the apolar solvent C_6D_6 to yield an oriented pseudorotaxane.[12]

Herein it is demonstrated that the binding features of **1** can be exploited to control the orientation of the pseudorotaxane stoppers by using two different stoppers to yield an asymmetric [2]rotaxane having an unequivocal orientation of the wheel with respect to the different stoppers, and that an

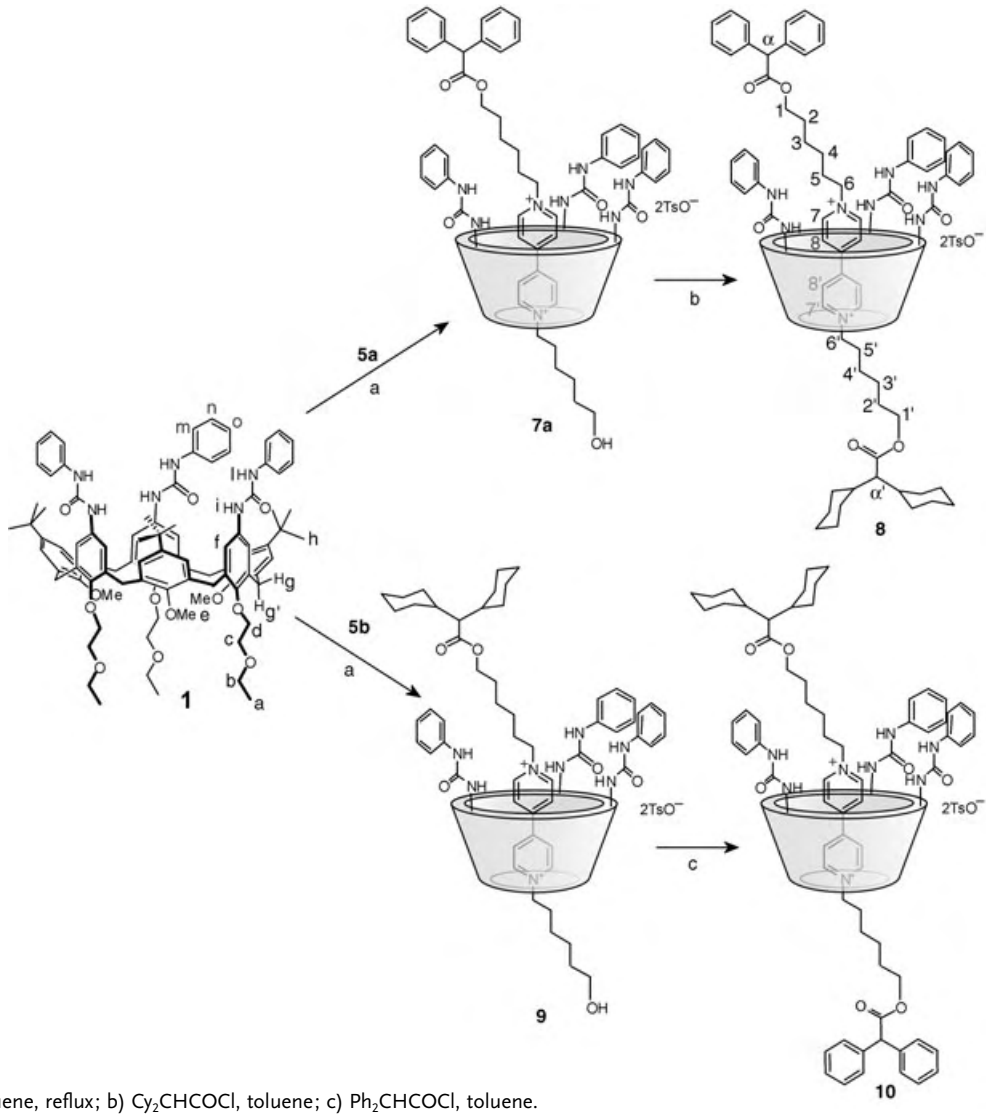
axle based on the 4,4′-bipyridyl group can also thread through the wheel from its lower rim.



The design of the axial component was based on the observations that the position of the two identical diphenylacetyl stoppers of a calix[6]arene-based rotaxane with respect to the calixarene rims can be established by NMR techniques.[12]

Axle **5a**, in which the 4,4′-bipyridyl unit is functionalized with two C_6 alkyl chains, one of which bears a diphenylacetyl stopper at one side and the other an alcoholic OH group to be used for further stoppering, was synthesized from 6-hydroxyhexyl tosylate **2** in 12% overall yield according to Scheme 1. Wheel **1** was added to a solution of **5a** in toluene to effect the threading reaction. An excess of dicyclohexylacetyl chloride was added to the homogeneous deep red solution thus obtained to stopper the alcoholic OH group of the pseudorotaxane **7a** (Scheme 2). Rotaxane **8** was isolated in 25% yield after chromatographic separation.

Dumbbell **6** was also synthesized for comparison and enable the structure of **8** to be established (Scheme 1). The ^{1}H NMR spectrum of **8** in C_6D_6 shows that the calixarene

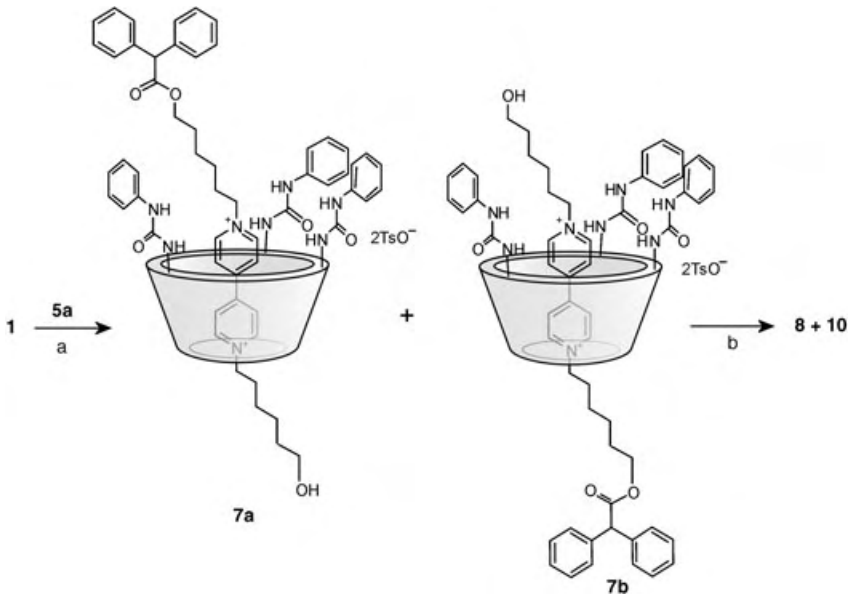
wheel rearranges and assumes a more-stiffened cone structure. The downfield shift of almost $\Delta\delta = 2$ ppm of the resonances of the six NH protons indicates their involvement in hydrogen bonding with the two tosylate anions of **5a**, as also shown by X-ray structural data.[13] The position of the calixarene along the axle was established by looking at the variation in the chemical shifts of the protons of the dumbbell portion between C1 and C1′ relative to those of **6** (see Scheme 2 for numbering). In particular, the protons from C2 to C6′ in **8** undergo a substantial upfield shift, while those from C5′ to α′ are downfield shifted to a much smaller extent. The relative orientation of the dumbbell C_6 spacers with respect to the calixarene rims were established through ROESY experiments, which showed cross peaks between protons 4 and 5 of the axle and protons m, n, and o of the wheel (see Supporting Information).



The lack of ROE cross peaks between the two different stoppers and the corresponding hexyl chains, or with protons of the wheel, precluded the existence of equivalent matching spacer—stopper groups. Nevertheless, the presence of only one signal for proton α at $\delta = 5.24$ ppm in the NMR spectrum of **8**[12] enables it to be assumed that the diphenylacetyl stopper is positioned at the upper rim of the wheel, while the dicyclohexyl one points toward the lower rim of the calixarene.

To confirm the structure of **8**, and also to exclude the presence of other rotaxanes in the reaction mixture, the rotaxane isomer **10** (see Scheme 2) was also synthesized (in 18% yield) by employing the new axle **5b**, which is characterized by the presence of a dicyclohexylacetic stopper (see Scheme 1). As expected, the ^{1}H NMR spectrum of **10** shows that the conformation of the calix[6]arene is almost exactly the same as that observed in **8**. However, the protons of the dumbbell portion between C3′ to C6 in **10** are substantially shifted upfield, while those from C5 to C1 are shifted downfield. The presence of only one singlet at $\delta =$ 5.23 ppm strongly suggests that the diphenylacetyl stopper is in proximity to the lower rim in **10**, while the dicyclohexyl stopper is oriented toward the upper rim of the calixarene (see the Supporting Information).

These data can be tentatively explained if it is considered that axles **5a** and **5b** are present as tight ion pairs during the initial formation of the pseudorotaxane in toluene and as such can not fit into the calixarene cavity. These conditions maximize the hydrogen-bonding ability of the ureido NH groups toward the axle counteranion(s) that thus pivot the cationic portion of the axles to thread through the wheel exclusively from the upper rim. The high kinetic stability of the oriented pseudorotaxane that forms favors the stoppering of the OH group that protrudes from the lower rim of the wheel, without any detectable axle–wheel isomerization.

At this point a question came apparent: are these results sufficient to exclude the threading of some of the axles **5a** or **5b** from the lower rim, or is this direction of threading prevented because of the insufficient size of the calix[6]arene annulus for these guests? Acetonitrile should decrease the extent of ion pairing of the axle and hence limit the magnitude of the pivoting role exerted by the ureido groups of the wheel during threading.

Pseudorotaxane formation in CD_3CN was thus studied by ^{1}H NMR spectroscopy by equilibrating **1** and **5a** in a 1:1 molar ratio. In the spectrum of the solution thus obtained, most of the signals appeared as broad peaks and this prevents accurate assignment. However, the presence of three singlets at $\delta = 5.11$, 5.13, and 5.14 ppm (relative ratio 9:59:32) in the region where the proton α of the diphenylacetyl moiety resonates suggested that this proton existed in three different environments. In particular, the signal at $\delta = 5.11$ ppm was easily assigned to the free axle while the other two were tentatively assigned to the two isomeric pseudorotaxanes **7b** and **7a**. A similar distribution of products was also observed by dissolving the oriented pseudorotaxane **7a** that had formed in C_6D_6 in CD_3CN. This observation shows that the oriented pseudorotaxane **7a** can dissociate into its components in acetonitrile and that the threading/dethreading processes can occur from both calix[6]arene rims, thus yielding both pseudorotaxanes isomers (see the Supporting Information). This result clearly indicates that the calix[6]-arene annulus is also large enough to thread on to the axle from the lower rim, and that indeed, in acetonitrile, the control elements governing the exclusive threading from the upper rim operate—if at all—only to a limited extent. Both rotaxanes **8** and **10** were obtained in 24% yield as unique chromatographic fractions by treating **1**, axle **5a**, and dicyclohexylacetyl chloride in acetonitrile (Scheme 3). Their ^{1}H NMR spectra in C_6D_6 correspond exactly to the sum of rotaxanes **8** and **10**, and thus indirectly demonstrate that only

Scheme 3. a) CH_3CN, reflux; b) $Cy_2CHCOCl$.

one of the two constitutionally isomeric rotaxanes had formed in the apolar toluene (see the Supporting Information).

The study of the unidirectional movement of the wheel along the axle of the new oriented calix[6]arene-based rotaxanes under the action of electrochemical stimuli is under investigation.

Cluster Compounds

The Formal Conversion of SiOH Protons into Hydrides by Germanium(II) Species Leads to the Formation of the Germanium(IV) Hydride Cluster $[(RSiO_3GeH)_4]$**

Umesh N. Nehete, Vadapalli Chandrasekhar, Herbert W. Roesky, and Jörg Magull*

Dedicated to Professor Manfred Meisel on the occasion of his 65th birthday

We have been interested for some time in the synthesis and characterization of metallosiloxanes containing the Si-O-M motif[1] (M = main-group or transition-metal atom). Utilizing the multifunctional N-bonded silanetriol $RSi(OH)_3$ (R = (2,6-iPr$_2$C$_6$H$_3$)N(SiMe$_3$)) we have successfully assembled a number of polyhedral metallosiloxanes with a high metal/silicon ratio.[1] Many such compounds have been shown to be structural models for complex, naturally occurring metallosilicates or synthetic metal-containing zeolites.[2] Some compounds, such as $[(RSiO_3TiOR^1)_4]$ (R = (2,6-iPr$_2$C$_6$H$_3$)N(SiMe$_3$), R^1 = Et, iPr)[3] have been shown to be catalysts for the epoxidation of olefins.[4] Recently we have been intrigued by the varied products obtained in the reaction of $RSi(OH)_3$ with tin substrates. Thus, while tin(IV) reagents, such as $PhSnCl_3$, react with $RSi(OH)_3$ to afford the cubic compound $[(RSiO_3SnPh)_4]$ or the bicyclic compound $[(RSiO_3)_2(PhSn)_3]$[5] analogous reaction with $[Sn\{N(SiMe_3)_2\}_2]$ proceeds in an entirely different manner. The product of this reaction is a hexatin(II) assembly $[(SnO)_6(R_2Si_2O_3)_2]$ which is formed as a result of an in situ generated disiloxanetetrol $[(RSi(OH)_2)_2O]$.[6] In view of this unusual reactivity, it was of interest to probe analogous germanium compounds. It is also noted that only a handful of structurally characterized compounds containing the Ge-O-Si linkage are known $[(Ph_2Ge)_2(Ph_2Si)_2O_4]$,[7a] $[(Me_2Ge)_2(Ph_2Si)_2O_4]$,[7a] $[(Cl_2Ge)_2(t$BuSi$)_2O_4]$,[7b] $[(Et_2Ge)_2(Ph_2Si)_2O_4]$,[7c] $[(Ph_2Ge)_2(Ph_2Si)_2O_3]$,[7d] $[(t$Bu$_2$Ge)(Ph$_2$Si)$\{[(CH_2)_3NMe_2]_2Sn\}O_3]$.[7e] Herein, we report the first polyhedral germanium siloxane $[(RSiO_3GeH)_4]$ (R = (2,6-iPr$_2$C$_6$H$_3$)N(SiMe$_3$)). This species also is the first example of a Ge-O-Si containing compound with terminal functional Ge–H units. Although other Group 14 species, such as

$[(HSiO_3)_4]$, are known,[8] the corresponding germanium or germanium siloxane analogues have not been reported. The synthesis of $[(RSiO_3GeH)_4]$ also involves an unprecedented oxidative addition of an SiO–H bond to a germanium(II) center, which leads to the formal conversion of the OH proton into a hydride. The oxidative addition of an alcohol to an alkylgermanium(II) compound is known.[9]

The reaction of the germanium(II) amide[10] $[Ge\{N(SiMe_3)_2\}_2]$ with $RSi(OH)_3$[11] in a 1:1 molar ratio afforded $[(RSiO_3GeH)_4]$ (**1**) in about 64% yield (Scheme 1). The

Scheme 1. Synthesis of compound **1**.

colorless crystals of **1** were obtained at room temperature from its saturated solution in hexane. Compound **1** is soluble in a large number of common organic solvents including hydrocarbons such as hexane and pentane. Compound **1** has been characterized by analytical, spectroscopic, and X-ray crystallographic techniques (see Figures 1 and 2).[12] Compound **1** is thermally quite stable and is also stable under the conditions of the EI mass spectrometry. The EI-mass spectrum of **1** shows the molecular ion peak at 1592.5 (100%) $[M^+]$.

The presence of the Ge–H motif is also detected in the ^{1}H NMR spectrum as a singlet at $\delta = 5.83$ ppm.[13] The ^{29}Si NMR spectrum shows a single resonance ($\delta = -87.4$ ppm) for the core of **1** indicating the equivalence of the silicon atoms, while the IR spectrum exhibits the characteristic Ge–H stretching frequency ($\tilde{\nu} = 2211$, 2184 cm^{-1}).[13] The formation of **1** involves the oxidation of germanium(II) to germanium(IV). We assume that the first step of the reaction involves the intermediate $[\{RSi(OH)O_2Ge\}_2]$ (**1a**; Scheme 1) which can result from a condensation of the germanium amide with the silanetriol. The next step is the fusion of two molecules of **1a** through an intermolecular oxidative addition reaction of SiO–H with germanium(II) centers. Such a process leads to a concomitant Ge-O-Si bond formation. Alternatively it may be possible that first an oxidative addition of $RSi(OH)_3$ to $[Ge\{N(SiMe_3)_2\}_2]$ occurs with an elimination of $H[N(SiMe_3)_2]$ resulting in the formation of **1**. Although oxidative addition reactions are common in organometallic chemistry, we have found no precedence for an oxidative addition reaction involving the SiOH group. Moreover, during the course of this reaction the proton of the SiOH group is formally converted into a hydride.

Compound **1** crystallizes in the monoclinic space group *C*2/*c* (Figure 1and Figure 2).

The structure of **1** can be described as a polyhedral cubic cage where the alternate corners of the cube are occupied by germanium and silicon atoms. The edges of the cube contain

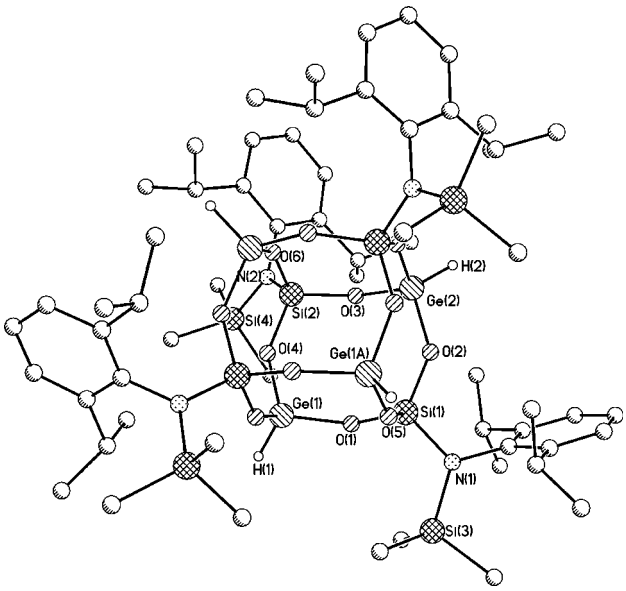

Figure 1. Molecular structure of **1**.

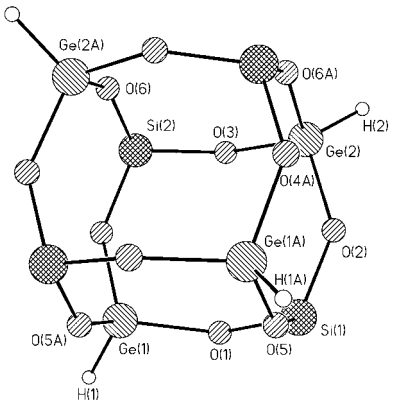

Figure 2. Core structure of **1**. The substituents on the silicon atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ge(1)-O(5A) 1.737(1), Ge(2)-O(6A) 1.738(1), Ge(1)-O(1) 1.740(1), Ge(2)-O(2) 1.745(1), Ge(1)-O(4) 1.741(1), Ge(2)-O(3) 1.742(1), Ge(1)-H(1) 1.40(2), Ge(2)-H(2) 1.38(2), Si(2)-O(6) 1.623(1), Si(2)-O(4) 1.623(2), Si(2)-O(3) 1.628(1), Si(1)-O(2) 1.620(2), Si(1)-O(5) 1.628(2), Si(1)-O(1) 1.628(1); Si(2)-O(4)-Ge(1) 142.78(9), Si(1)-O(5)-Ge(1A) 142.55(10), Si(1)-O(1)-Ge(1) 140.74(9), Si(1)-O(2)-Ge(2) 142.52(9), Si(2)-O(3)-Ge(2) 140.05(9), Si(2)-O(6)-Ge(2A) 142.55(9).

oxygen atoms which act as bridging atoms between germanium and silicon. Each of the six-faces of the cube is made up of a puckered eight-membered $Ge_2O_4Si_2$ ring. The average bond lengths in **1** are Ge–O 1.7405 Å, Si–O 1.625 Å, and Ge–H (1.39 Å). The Ge-O-Si bond angle (av. 141.86°) indicates the bent nature of this bond. In the eight-membered rings $[(Me_2Ge)_2(Ph_2Si)_2O_4]$,[7a] $[(Cl_2Ge)_2(t\mathrm{BuSi})_2O_4]$,[7b] and $[(Et_2Ge)_2(Ph_2Si)_2O_4]$,[7c] the Ge–O and Si–O bonds are 1.77(6) and 1.60(7), 1.69(4) and 1.63(4), 1.75(5) and 1.61(6) Å, respectively. The Ge-O-Si bond angles observed for these compounds are 136.9(3), 158.8(2), and 142.0(3)°. These parameters compare well with those observed for **1**. The Ge–H bond length in **1** (1.39(2) Å) is similar to that in *p*-anisylgermane (1.40 Å).[13a]

In conclusion, we have prepared the first cubic polyhedral cage compound that contains Ge-O-Si linkages. The formation of this compound occurs by an unprecedented oxidative addition reaction involving the SiOH unit to a germanium(II) center.

Experimental Section

1: $[Ge\{N(SiMe_3)_2\}_2]$ (1.2 g, 3.06 mmol) was slowly added to a stirred suspension of the silanetriol (1.0 g, 3.06 mmol) in hexane (20 mL) and THF (3 mL). During the addition the milky suspension of silanetriol changes to a colorless clear solution. This clear solution was stirred for 12 h at room temperature. The volatile components were removed in vacuo to obtain a white product. To this hexane (9 mL) was added. Colorless crystals of **1** were obtained from the concentrated solution after two days at room temperature. Yield: 0.78 g (64 %), m.p. 251 °C (decomp), ^{1}H NMR (300 MHz, C_6D_6, TMS): $\delta = 0.19$ (s, 36 H, $Si(CH_3)_3$), 1.22, 1.24 (d, $J = 6.85$ Hz, 48 H, $CH(CH_3)_2$), 3.55 (sept, $J = 6.85$ Hz, 8 H, $CH(CH_3)_2$), 5.83 (s, 4 H, Ge*H*), 7.04 ppm (s, 12 H, aromatic); ^{29}Si NMR (99 MHz, C_6D_6, TMS): $\delta = 6.55$ ($SiMe_3$), −87.4 ppm (SiO_3); IR (Nujol, KBr): $\tilde{\nu} = 2211$ (m), 2184 (m, GeH), 1439 (m), 1318 (m), 1248 (s), 1183 (m), 1079 (s), 1045 (s), 1022 (s), 976 (s), 904 (s), 878 (m), 840 (s), 799 (s), 752 (s), 738 (s), 685 (w), 611 (m), 545 (m) cm^{-1}; EIMS (70 eV): *m*/*z* (%) 1592.5 (100) [M^+]; Elemental analysis (%) calcd for $C_{60}H_{108}Ge_4N_4O_{12}Si_8$ (1592.58) C 45.25, H 6.84, N 3.52; found: C 44.80, H 6.94, N 4.05.

Living Polymerization

Tri- and Tetracarbanionic Initiators by a Lithium/Halide Exchange Reaction: Application to Star-Polymer Synthesis**

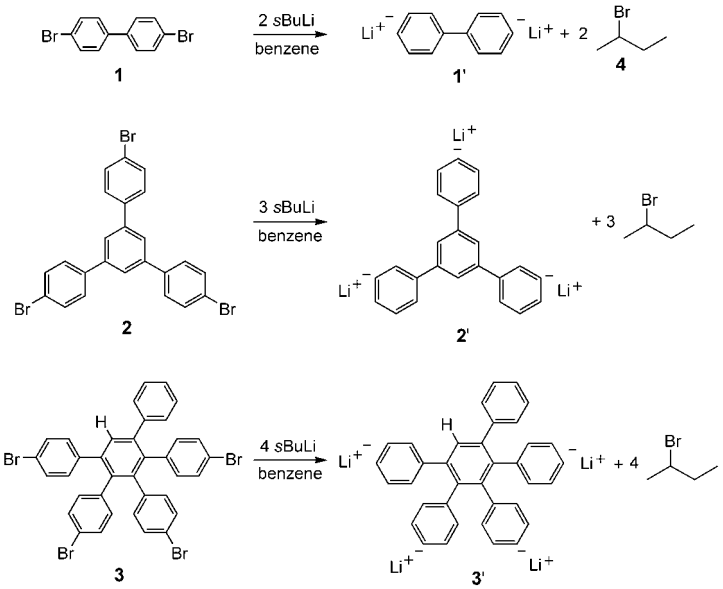
*Rachid Matmour, Arnaud Lebreton, Constantinos Tsitsilianis, Ioannis Kallitsis, Valérie Héroguez, and Yves Gnanou**

Although well described by a mechanism involving the formation of ate complex intermediates, especially in the case of aryl halides, and routinely used for the preparation of simple organolithium reagents, lithium/halogen exchange reactions could never be successfully applied to the synthesis of precisely defined polylithium organic compounds.[1] Indeed polylithiations of multihalide organic molecules by reagents such as *tert*-butyllithium or *sec*-butyllithium are reported to result at best in moderate yields and to afford products with different degrees of substitution.[2–6] The reasons that are generally held responsible for the impracticality of polylithiation, especially when the halogen atoms to be substituted are attached to the same carbon atom or to adjacent carbon atoms, are twofold. α-Lithium halide eliminations and intermolecular couplings between the lithiated reagent and the halide-substituted species are two important competing reactions that have long prevented polylithiation reactions being considered practical. Another reason for the lack of attention paid to multiple metal/halide exchange is the fact that polylithiated compounds have limited solubility in most organic solvents, since they form rather insoluble aggregates.[7]

For instance, in polymer chemistry polylithiation has never been contemplated for the reasons mentioned above; had it been mastered and the experimental conditions worked out, polylithiation would be a viable and straightforward route to prepare multicarbanionic initiators for the synthesis of star-shaped polymers. So far the only possibility of generating such multicarbanionic initiators was lithiation by addition to multivinyl compounds, but the very small number of reports on this synthetic strategy indicates that it is not a convenient route. Indeed it requires the prior synthesis of multivinyl compounds that would not homopolymerize on addition of organolithium reagents.[8] These constraints explain why the only initiator of precise functionality ever synthesized by this method is the tricarbanionic compound of Quirk et al., which was obtained by addition of *sec*-butyllithium to a molecule containing three 1,1-diphenylethylene-type unsaturated moieties.[9]

We report here a novel approach to the preparation of polylithium organic compounds by lithium/halogen exchange and their use as initiators for the synthesis of miscellaneous star polymers by anionic means. This method relies on the metalation of poly(aryl halide)s whose halogen atoms are carried by separate aryl rings and not by adjacent carbon atoms as in previous cases. Unlike regular halogen/metal exchanges, metalation in our case could be conducted at room temperature and in apolar medium, since the polylithiated species formed were unexpectedly found to be soluble in the presence of σ/μ-coordinating ligands; this remarkable feature could be further exploited for star polymer synthesis.

To successfully demonstrate the viability of our method, we utilized commercially available bis(aryl halide) **1** and also designed two poly(aryl halide)s carrying respectively three (**2**) and four (**3**) halo groups, which were synthesized by using reported procedures.[10,11] Compound **2** was obtained from 4-bromoacetophenone diethyl ketal and acetyl chloride with samarium trichloride as catalyst, and **3** was prepared in excellent yields (>90%) by Diels–Alder reaction of 2,3,4,5-tetrakis(*p*-bromophenyl)cyclopentadienone and phenylacetylene with extrusion of carbon monoxide (see Supporting Information for the ^{1}H NMR spectra of **2** and **3**). Next, **1**, **2**, and **3** were treated with stoichiometric amounts of *sec*-butyllithium in benzene to generate **1′**, **2′**, and **3′**, the corresponding di-, tri-, and tetracarbanionic initiators (Scheme 1).



The formation of 2-bromobutane (**4**) was monitored by GC (see Supporting Information). In all three cases the yields were quantitative, and only 2-bromobutane and the corresponding protonated polyaryl compounds were formed as products. No coupling between 2-bromobutane and the polycarbanionic species **1′**, **2′**, or **3′** was ever detected, that is, in apolar medium no such side reactions occurred. However, the resulting polylithiated species were insoluble in benzene and therefore could not be used as such for

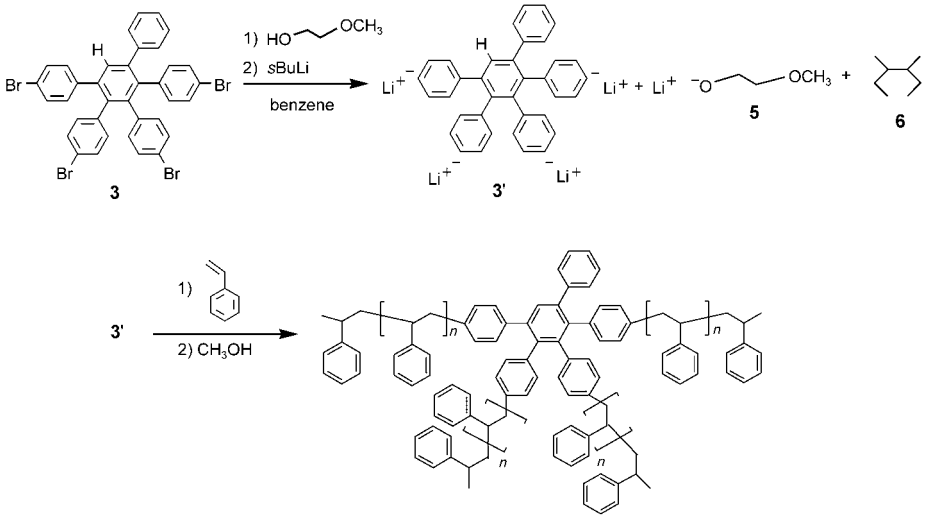
Scheme 1. Synthesis of dilithiated (**1′**), trilithiated (**2′**), and tetralithiated (**3′**) initiators.

initiation purposes; the investigated monomers (styrene, butadiene, 1,1-diphenylethylene) failed to react with these aggregates. Various additives were therefore employed to solubilize the polycarbanionic species. The ligand that proved most efficient at solubilizing these carbanionic aggregates regardless of their functionality was lithium 2-methoxyethoxide (**5**). This σ/μ ligand was previously employed by Teyssié et al. to prevent lithium enolates from aggregating in apolar medium and thus bring about a living anionic polymerization of methacrylic monomers.[12] A ratio of [lithium 2-methoxyethoxide] to [C_6H_4Li groups] of four was necessary to obtain fully soluble initiators in benzene (see Supporting Information). In these attempts at solubilizing **1′**, **2′**, and **3′**, **5** was prepared separately by reaction of *sec*-butyllithium with 2-methoxyethanol, but in the subsequent polymerization experiments **5** was simply generated in situ by addition of *sec*-butyllithium prior to lithium/halide exchange by **1**, **2**, or **3**.



Before triggering polymerization by monomer addition, we managed to neutralize **4** that resulted from the lithium/halide exchange reaction; even though **4** is inert enough not to react with poly(aryl lithium)s **1′**, **2′**, and **3′**, it is sufficiently electrophilic to deactivate the growing carbanionic chains of polystyrene or polybutadiene. Indeed, in a separate experiment conducted under stoichiometric conditions in benzene, we observed such deactivation of polystyryllithium anions by **4** in the presence of *N*,*N*,*N′*,*N′*-tetramethyethylenediamine, when **4** completely disappeared within less than 30 min. To neutralize **4** prior to monomer addition one equivalent of *sec*-butyllithium was added and the formation of 3,4-dimethylhexane (**6**) was monitored by GC (see Supporting Information). After checking that the neutralization of **4** was complete, the polymerization of styrene or butadiene could be triggered by addition of the corresponding monomer (Scheme 2). On deactivation of the living carbanionic chains by ethylene oxide after complete monomer consumption, ω-hydroxy three- and four-armed polystyrene and polybutadiene stars could be isolated from **2′**, **3′** as initiators. α,ω-Dihydroxy telechelic polymers were obtained from **1′**.

Analysis by GC and size exclusion chromatography (SEC) indicated the complete consumption of initiators. No peak attributable to residual **1**, **2**, or **3** could be detected in the low molar mass region, and the only trace seen was a narrow and monomodal peak corresponding to the expected star or linear polymer in the high molar mass region (Figure 1).

Such narrow molar mass distribution ($\bar{M}_w/\bar{M}_n < 1.1$) reflects a rate of initiation by **1′**, **2′**, or **3′** comparable to that of propagation (Table 1). The structure of the polymer formed and specially the star character could be established first by ^{1}H NMR analysis on polybutadiene samples with low degrees of polymerization (see Supporting Information). From the ratio of the integrals of the signal for the aromatic core ($\delta = 6.8$–7.3 ppm) to that for the methylene protons of the $-CH_2OH$ chain ends ($\delta = 3.7$ ppm) the actual functionality of the various samples prepared could be determined: functionalities close to three and four for the three- and four-arm polybutadiene stars, respectively, and close to two for the telechelics were obtained.

Characterization of both linear and star polystyrene and polybutadiene samples by SEC with a light-scattering detector (SEC-LS) also showed an excellent agreement between experimental and expected values of molar masses.

Further evidence for the three- and four-arm star structures was obtained by comparing the intrinsic viscosity [η] of our samples with that of linear polymers. Indeed, a classical

Scheme 2. Synthesis of four-armed polystyrene stars.

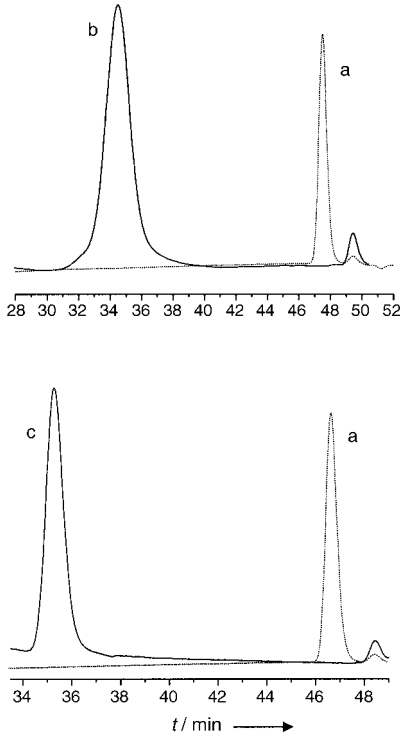

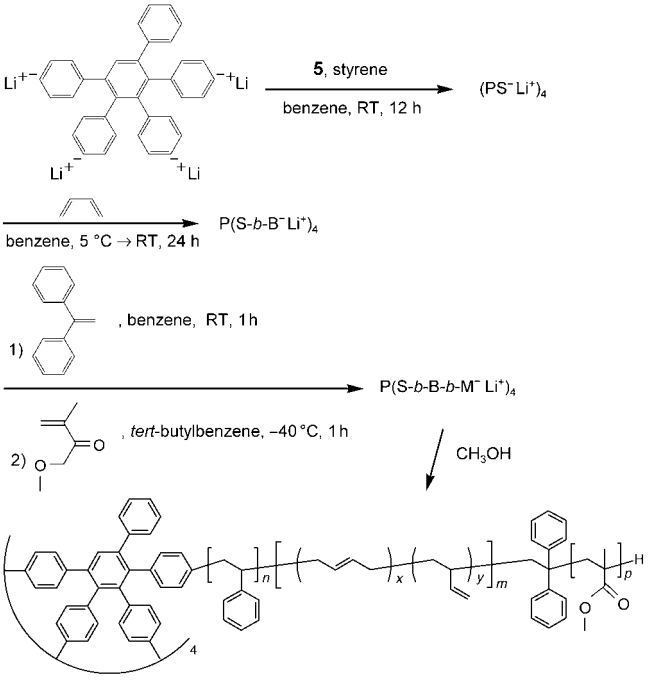

Figure 1. SEC eluograms of $(PS)_4$ polystyrene and $(PB)_4$ polybutadiene stars. a) Protonated version of **3′**. b) Polystyrene star. c) Polybutadiene star.

means to probe starlike architectures and their actual functionality is to determine $g' = [\eta]_{star}/[\eta]_{linear}$. As can be seen in Table 1, the calculated g' values are close to those predicted by theoretical models.[13] These results thus confirm that the target structures were actually obtained and validate the pertinence of our novel approach to star synthesis by anionic means.

After demonstrating the efficiency of these di-, tri-, and tetracarbanionic initiators for the synthesis of polystyrene and polybutadiene telechelics and stars, $(ABC)_n$ ($n = 2$–4) linear and star block terpolymers were derived by sequential anionic polymerization of styrene (S), butadiene (B), and methyl methacrylate (M) with **1′**, **2′**, or **3′** as initiator. These novel architectures—P(S-*b*-B-*b*-M)$_2$ pentablock terpolymers from **1′**, P(S-*b*-B-*b*-M)$_3$ and P(S-*b*-B-*b*-M)$_4$ star block terpolymers from **2′** and **3′**, respectively—were prepared by the same sequence of monomer addition as for the synthesis of P(S-*b*-B-*b*-M) linear block terpolymers (Scheme 3).[14]

Scheme 3. Reaction scheme for the synthesis of SBM star block terpolymers.

Since lithium 2-methoxyethoxide (**5**) was present as an additive to solubilize **1′**, **2′**,or **3′**, methyl methacrylate could be polymerized under living conditions, as disclosed by Teyssié et al.,[12] from polybutadienyllithium anions. Prior to the addition of M, polybutadienyllithium anions were end-capped with 1,1-diphenylethylene (DPE) to reduce the probability of side reactions at the ester group of M while initiating its polymerization. The reaction medium was also diluted with *tert*-butylbenzene and the temperature decreased to −40 °C to further prevent the above-mentioned side reactions. Upon addition of M, the color of the medium changed from the characteristic red of diphenylethyllithium carbanions to colorless. By taking an aliquot before introduction of each type of monomer, the formation of these SBM-based architectures could be easily followed by SEC (see Supporting Information).

The absolute molar mass of the first PS block could be determined by SEC-LS; as for PB and PM blocks their respective molar masses were deduced by ^{1}H NMR spectroscopy, given the known molar masses of their precursors (Table 2,

[a] Determined by SEC in THF by using a multiangle laser light scattering detector. The d*n*/d*c* value of PS was 0.183 cm^3 g^{-1} in THF. [b] Derived from refractometric detector. [c] Determined by ^{1}H NMR spectroscopy from the molar mass of the polystyrene block, assuming 100% efficiency in the initiation of the second and third blocks. [d] Calculated from ^{1}H NMR spectra.

Figure 2). In all cases narrow molar mass distributions were observed for the three types of structures, that is, the growth of the three blocks occurred under living conditions. In some instances, P(S-*b*-B-*b*-M)$_{3,4}$ star block terpolymers were contaminated with P(S-*b*-B)$_{3,4}$ precursors (less than 10%) but the latter could be easily removed by fractionation through a silica column.

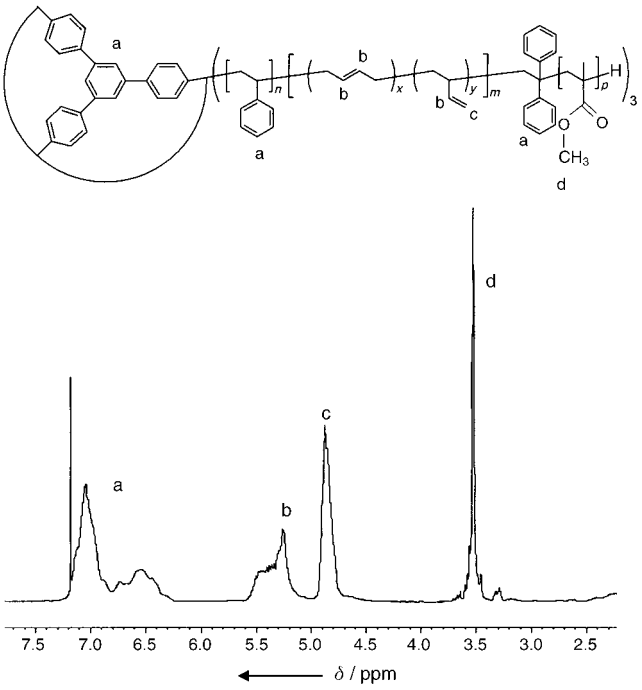

Figure 2. ^{1}H NMR spectrum ($CDCl_3$, 400 MHz) of P(S-*b*-B-*b*-M)$_3$ star block terpolymer.

In summary, halogen/lithium exchange reactions have been successfully applied to generate di-, tri-, and tetracarbanionic species from bis-, tris- and tetrakis-bromoaryl compounds. The use of a σ/μ ligand was instrumental in obtaining polycarbanionic initiators soluble in apolar medium, and the subsequent preparation of various well-defined star-shaped (co)polymers. These are the first examples of three and four-armed polystyrene and polybutadiene stars synthesized by the "core-first" method using anionic polymerization. Analysis of the macromolecular architectures obtained by SEC-LS, ^{1}H NMR spectroscopy, and viscometry all endorse the star character and functionalities of three and four for the samples derived from **2′** and **3′**, respectively. The efficiency of the latter was even exploited to synthesize P(S-*b*-B-*b*-M)$_3$ and P(S-*b*-B-*b*-M)$_4$ star block terpolymers. The phase separation and morphologies that develop in such materials are currently under investigation and will be compared with those reported for linear SBM copolymers.[15] The synthesis of a compound carrying ten bromoaryl moieties by Diels–Alder reaction between a diarylacetylene and a tetraphenylcyclopentadienone is contemplated. Such halogen/metal exchange chemistry is ripe to be applied for the derivatization and/or the selective "construction" of C–C bonds in polycyclic aromatic hydrocarbons.[16]

Mesoporous Silica Nanoparticles

Generalized Fluorocarbon-Surfactant-Mediated Synthesis of Nanoparticles with Various Mesoporous Structures**

*Yu Han and Jackie Y. Ying**

Research on the synthesis of mesoporous materials has mainly focused on mesostructural diversity,[1–4] compositional flexibility,[5–8] and morphological control.[9–12] The ability to obtain mesoporous particles with a controlled particle size would be important for many practical applications. For example, ultrafine mesoporous particles would be very useful in catalysis and gas adsorption, since they would provide greater pore accessibility and facilitate molecular diffusion. They could also act as the host matrix for the synthesis of quantum dots and magnetic nanoparticles in functional materials and bio-imaging applications.[13] Ultrafine mesoporous particles could also act as carriers for drugs, genes, and proteins for novel biomedical applications.[14,15] Some examples of ultrafine mesoporous particles have been sporadically reported,[16–23] but the type of mesostructure, the degree of structural ordering, and the range of pore sizes are limited. Herein we describe a simple wet-chemical method that enables the synthesis of nanometer-sized particles (50–300 nm) with tunable pore sizes in the range 5–30 nm. This fluorocarbon-surfactant-mediated synthesis can be generalized to achieve various pore structures, including 3D cubic $Im\bar{3}m$, 3D cubic $Fm\bar{3}m$, 2D hexagonal $p6m$, foamlike, and disordered pores, as well as different material compositions.

Our syntheses were carried out in a weakly acidic medium (pH 1.6–1.8), in which a homogeneous solution was formed by mixing a soluble silica precursor, a nonionic triblock copolymer surfactant $EO_xPO_yEO_x$ (EO = ethylene oxide, PO = propylene oxide), and the cationic fluorocarbon surfactant FC-4 ($C_3F_7O(CFCF_3CF_2O)_2CFCF_3CONH(CH_2)_3N^+(C_2H_5)_2-CH_3I^-$). In some cases, the organic swelling agent 1,3,5-trimethylbenzene (TMB) was also added to adjust the pore size or vary the mesostructure. Fluorocarbon surfactants have much higher surface activity than common surfactants. Moreover, unlike the hydrocarbon chains of common surfactants, which are hydrophobic but lipophilic, fluorocarbon chains are hydrophobic and lipophobic. Therefore, hydrocarbon and fluorocarbon surfactants are either immiscible or only partially miscible under most conditions.[24]

In our synthetic strategy, the triblock copolymer surfactant would act as the supramolecular template for the periodic mesostructure, whereas the fluorocarbon surfactant would be used to control the growth of mesoporous particles. The process could be described as follows: The weakly acidic conditions would promote a slow hydrolysis of silica precursors, and the hydrolyzed silica species would co-assemble with triblock copolymer surfactants to form well-defined mesophases, whose structures and pore sizes would depend on the type of copolymer and the amount of organic additives. Simultaneously, fluorocarbon surfactants would surround the silica particles through $S^+X^-I^+$ interactions, thereby limiting the growth of silica particles. By this approach, five different mesoporous structures were successfully obtained with nanometer particle sizes (denoted IBN-1 to IBN-5 in Table 1).

Table 1: Mesoporous nanoparticles obtained with the fluorocarbon-surfactant-mediated synthesis.[a]

Sample	Mesostructure	Template	BET surface area [$m^2 g^{-1}$]	Pore volume [$cm^3 g^{-1}$]	Pore size [nm][b]
IBN-1	3D cubic ($Im\bar{3}m$)	F127	779	0.73	5.8
IBN-2	3D cubic ($Fm\bar{3}m$)	F127 + TMB	804	0.65	9.5
IBN-3	mesocellular foam	P65 + TMB	821	0.72	19.5
IBN-4	2D hexagonal ($p6m$)	P123	709	0.88	6.4
IBN-5	disordered	F108	575	0.54	5.2

[a] Fluorocarbon surfactant FC-4 was used in all syntheses to limit the particle size. [b] Calculated from the adsorption branch of the N_2 sorption isotherm by using the BJH method.

Figure 1a shows an SEM image of calcined IBN-1 that was prepared with Pluronic F127 triblock copolymer ($EO_{106}PO_{70}EO_{106}$) and fluorocarbon surfactant FC-4 by using the synthetic approach described above (see Experimental Section for details). IBN-1 was composed of relatively uniform particles of 100–300 nm. A TEM image (Figure 1a, inset) revealed that these particles are well dispersed with little aggregation. The XRD pattern of calcined IBN-1 (Figure 1e) showed two well-resolved peaks with d spacings of 116 and 82 Å, which could respectively be indexed as the 110 and 200 diffractions of cubic symmetry with a lattice constant of $a = 164$ Å. The high-resolution TEM (HRTEM) images of this material taken at [100], [110], and [111] incidences and the corresponding Fourier transforms (FT) are shown in Figure 1b–d, respectively. IBN-1 particles displayed morphologies that were in good accordance with their cubic symmetry (for example, square and hexagonal particle morphologies were observed in [100] and [111] directions, respectively). The highly ordered arrangement of mesopores that could be observed over the entire particle in all cases indicated the high quality of the sample. The reflections in the FT patterns could be indexed as 110, 200,

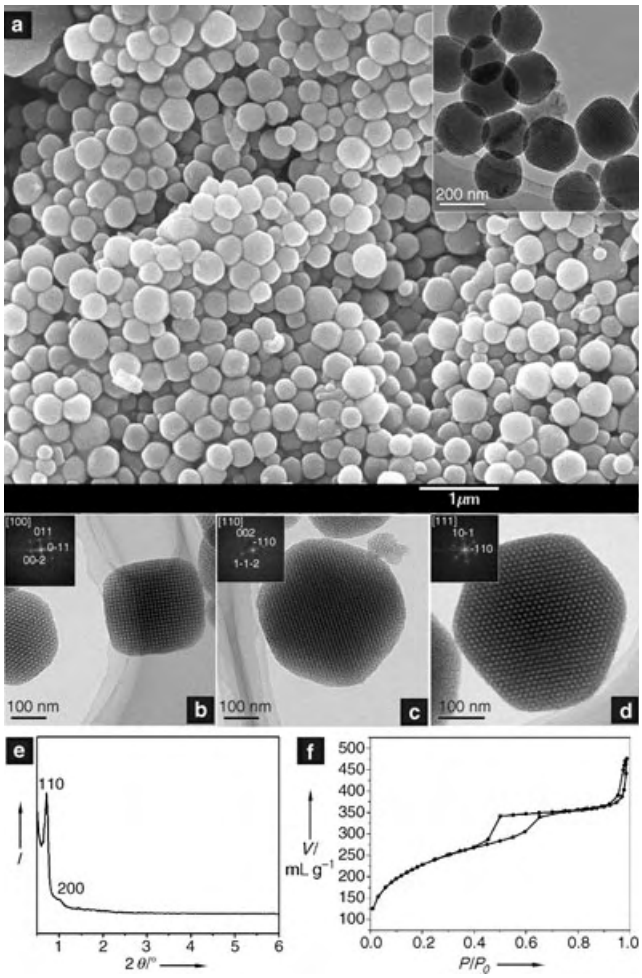

Figure 1. Calcined IBN-1. a) SEM image (inset: TEM image). b)–d) HRTEM images taken at [100], [110], and [111] incidences (insets: the corresponding FT patterns). e) XRD pattern. f) N_2 adsorption/desorption isotherm.

211, and 220 of a cubic phase ($Im\bar{3}m$ space group) with a large lattice constant of $a = 165$ Å, consistent with the XRD findings. IBN-1 has a type IV N_2 adsorption/desorption isotherm with a type-H_2 hysteresis loop (Figure 1 f), which suggests that the mesopores are cagelike. The average pore diameter was calculated to be 5.8 nm from the adsorption branch of the isotherm by using the Barrett–Joyner–Halenda (BJH) method. Besides the well-defined mesopores, this material showed interparticle (textural) porosity (as evidenced by the adsorption step at high relative pressures of > 0.9), which constituted a quarter of the total pore volume of 0.73 $cm^3 g^{-1}$. IBN-1 has a high BET surface area of 779 $m^2 g^{-1}$.

IBN-2 was synthesized under conditions similar to those for IBN-1, except that a large amount of TMB was added (see Table 1). It is composed of well-dispersed particles of 50–300 nm (Figure 2 a). The N_2 sorption isotherm (Figure 2 a, inset) showed that IBN-2 has cage-type pores averaging 9.5 nm in size, which are much larger than those of IBN-1 due to the addition of TMB as swelling agent. High-resolution TEM images taken at various incidences (Figure 2 b–d) showed well-ordered large pores in IBN-2. The spots in the

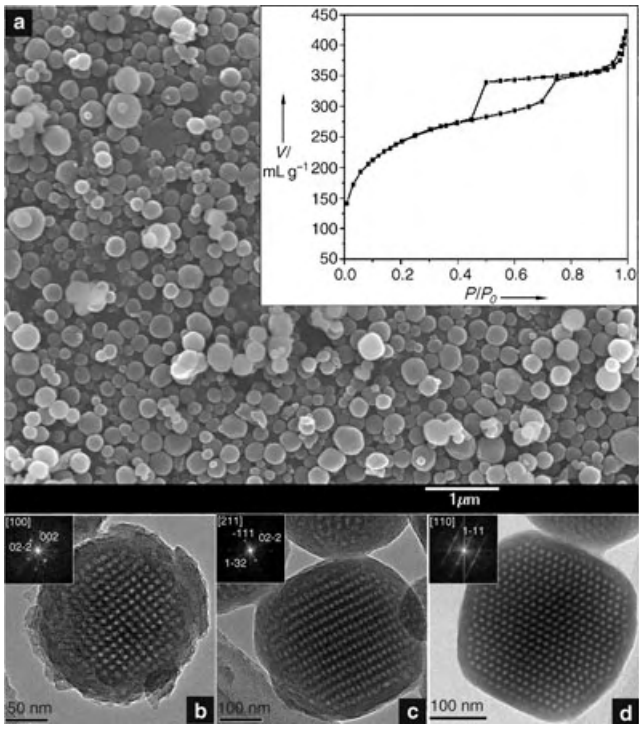

Figure 2. Calcined IBN-2. a) SEM image (inset: N_2 adsorption/desorption isotherm). b)–d) HRTEM images taken at [100], [211], and [110] incidences (inset: corresponding FT patterns).

FT patterns (Figure 2 b–d, insets) were indexed as 111, 200, 220, 311, and 222 reflections of a cubic system with a large lattice constant of $a = 220$ Å. According to extinction rules and previous studies,[25,26] IBN-2 could be assigned to a face-centered cubic structure ($Fm\bar{3}m$). Notably, the FT pattern for [110] incidence showed strong diffuse streaks along the $[1\bar{1}1]$ direction, which suggest the presence of mixed phases. This was confirmed by the corresponding TEM image (Figure 2 d), which illustrated narrow cubic close-packed (ccp, ABCABC…) bands with periodicity in twin relation. In addition, some 3D hexagonal domains with the cages arranged in hexagonal close-packed (hcp, ABAB…) mode were also observed between the cubic twins as a transitional phase (see Supporting Information). This is the first report of an intergrowth of cubic and 3D hexagonal phases in such a small particle; similar intergrowth has been observed in bulk mesoporous silicas such as FDU-1[25] and SBA-12.[26]

Mesocellular foam (MCF) is a novel mesostructured silica material templated by oil-in-water microemulsions.[27,28] The ultralarge mesopores (25–40 nm) have made MCF particularly useful as catalyst support and separation medium for processes involving large substrates. Conventional MCF has a cauliflower-type morphology with a particle size of tens of micrometers.[27] Using our fluorocarbon-surfactant-mediated synthesis, we obtained spherical MCF nanoparticles (50–300 nm), denoted IBN-3 (Figure 3 a). In this synthesis, Pluronic P65 ($EO_{20}PO_{30}EO_{20}$) and TMB were used as the surfactant and oil, respectively, for the formation of a microemulsion template. The ultralarge foamlike pores in the particles obtained could be easily seen by TEM, even at

relatively low magnification (Figure 3a, inset). The HRTEM image showed that the pores are about 20 nm in diameter (Figure 3b), consistent with the average adsorption BJH pore size (19.5 nm; Table 1). The pore diameter of IBN-3 could be tailored in the range 15–30 nm, without changing the particle size and morphology, by varying the amount of TMB added in the synthesis.

IBN-1, IBN-2, and IBN-3 all have cage-type mesopores, as evidenced by the type-H_2 hysteresis loops in their sorption isotherms. The fluorocarbon-surfactant-mediated synthesis could also be used to obtain nanoparticles with channel-like mesopores. For example, IBN-4, which was templated by Pluronic P123 ($EO_{20}PO_{70}EO_{20}$), exhibited a mesostructure typical of a 2D hexagonal phase (*p6m*) with a lattice constant of $a = 105$ Å (Figure 4b and c). IBN-4 showed channel-type mesopores with a uniform diameter of 6.4 nm, as calculated from the N_2 sorption isotherm, which has a type-H_1 hysteresis loop (Figure 4d). Most of the IBN-4 particles have a rodlike morphology (200–400 nm long and 50–150 nm wide; Figure 4a), in good accordance with their 2D hexagonal mesostructure.

Periodic mesoporous organosilicas (PMOs) were reported independently in 1999 by three groups.[29–31] We employed 1,2-bis(trimethoxysilyl)ethane and F108 ($EO_{132}PO_{50}EO_{132}$) as precursor and surfactant template, respectively, in our fluorocarbon-surfactant-mediated synthesis to prepare nanoparticles of PMO (IBN-5). The ^{29}Si MAS and ^{13}C CP/MAS NMR spectra (Figure 5d and e) showed that all of the Si atoms in the material are bonded covalently to C atoms and the framework consists of $SiO_{1.5}CH_2CH_2SiO_{1.5}$ structural units. Both SEM and TEM images (Figure 5a and inset) showed that IBN-5 consisted of fairly uniform particles of about 100 nm in size. However, unlike the pure silica materials discussed above, IBN-5 nanoparticles are not well-dispersed. The mesopores in IBN-5 could be observed by TEM, but the contrast was relatively weak (Figure 5a, inset) due to the disordered pore arrangement. Only one peak appeared in the XRD pattern (Figure 5b), a further indication of the lack of long-range order in IBN-5. Nevertheless, the pore size distribution in IBN-5 (centered at ca. 5.2 nm) was still narrow, as illustrated by the sharp step (at $P/P_0 \sim 0.6$) in the adsorption isotherm (Figure 5c). The presence of substantial textural porosity, as judged from the isotherm, revealed that the interparticle voids were still accessible despite the particle agglomeration.

Fluorocarbon surfactant FC-4 was used in all syntheses described above, without which large, irregular mesoporous particles were obtained instead of well-defined nanoparticles. On the other hand, no precipitates were formed if only FC-4 was used without copolymer surfactant. These results illustrate that the use of fluorocarbon surfactant is essential for forming ultrafine particles, while the mesostructures are templated by copolymer surfactant. The function of fluorocarbon surfactant in controlling the particle size is believed to be associated with its special surface activity and immiscibility with copolymer surfactant, which allows them to be enriched at the particle periphery during the particle formation which consequently limits the particle growth. This mechanism is supported by a recent publication which reported the use of a

mixture of copolymer F127 and cationic fluorocarbon surfactant IC-11 to obtain a new core–shell structure in silica particles.[22] In that study, IC-11 and F127 gave rise to the mesoporosity in the shell and the mesoporosity in the core, respectively, due to the phase separation of fluorocarbon surfactant from copolymer surfactant, with ordered packing of fluorocarbon surfactant around the silica particles. In our case, however, the FC-4 micelles were most likely packed around the silica particles in a disordered manner, since no ordered pattern was observed at the edge of the particles.

The optimal ratio of FC-4 to copolymer surfactant for nanoparticle synthesis depends on the nature of the copolymer. For example, when the concentration of FC-4 was kept within 2.0–2.5 wt%, as used in our syntheses, the triblock copolymers with relatively long hydrophilic EO segments [for example, F127 ($EO_{106}PO_{70}EO_{106}$) and F108 ($EO_{132}PO_{50}EO_{132}$)] could be used over a wide range of concentrations (0.5–3 wt%) to produce IBN-1 and IBN-5, respectively. In contrast, the triblock copolymer with low EO/PO ratio [for example, Pluronic P123 ($EO_{20}PO_{70}EO_{20}$)] had to be used at low concentrations (0.5–1 wt%) in the synthesis of IBN-4, or large particles with an irregular morphology were obtained. This was possibly because different copolymers have different miscibilities with FC-4.[32–34] In general, the longer its hydrophobic PO segment, the more solubilizing power the triblock copolymer has, and therefore the more likely it would form mixed micelles with fluorocarbon surfactant.[32] Thus, a copolymer surfactant with a large hydrophobic volume (for example, P123), would involve most of the FC-4 molecules in forming mixed micelles at relatively high concentrations, but when its concentration was kept low, excess FC-4 molecules would still contribute to controlling particle growth.[34] For cases that involve TMB addition (for example, IBN-2 and IBN-3), low concentrations of copolymer should be used, since TMB will increase the hydrophobic volume of the copolymer micelles, and consequently increase the tendency to form mixed micelles with FC-4.

Moreover, mildly acidic conditions (pH 1.6–1.8) and a moderate reaction temperature (25–30 °C) were necessary for the syntheses. Stronger acidity or higher temperature would promote a rapid, uncontrolled hydrolysis/condensation of silica species which would not lead to the formation of ultrafine particles with a regular morphology. Weaker acidity with a pH value above 2.0 would not promote the co-assembly of surfactant and silica species, and lower reaction temperature would result in materials with poorly ordered mesostructures.

Experimental Section

IBN-1: 0.65 g of Pluronic F127 and 0.8 g of FC-4 were dissolved in 40 mL of aqueous HCl solution (0.02 M), and 2.2 g of tetraethyl orthosilicate (TEOS) was added. The solution was stirred at 30 °C for 20 h, and then transferred to an autoclave for further condensation at 100 °C for 1 d. The product was collected by centrifugation, dried in air, and calcined at 550 °C for 5 h for surfactant removal. Details on the syntheses of other mesoporous nanoparticles are described in the Supporting Information.

XRD patterns were obtained with a Siemens D5005 diffractometer by using $Cu_{K\alpha}$ radiation. SEM images were obtained on a JEOL JSM-6700F electron microscope. TEM experiments were performed on a JEOL JEM-3010 electron microscope with an acceleration voltage of 300 kV. The nitrogen sorption isotherms were obtained with a Micromeritics ASAP 2020M system; the samples were degassed for 10 h at 150 °C before the measurements. ^{29}Si and ^{13}C CP/MAS NMR spectra were recorded with a Bruker AV500WB system with a 4 mm DVT CP/MAS probe; chemical shifts for both spectra were referenced to tetramethylsilane (TMS) at 0 ppm.

Conducting Materials

The First Proton-Conducting Metallic Ion-Radical Salts**

Akane Akutsu-Sato, Hiroki Akutsu, Scott S. Turner, Peter Day, Michael R. Probert, Judith A. K. Howard, Tomoyuki Akutagawa, Sadamu Takeda, Takayoshi Nakamura, and Takehiko Mori*

Metallic materials that also conduct protons are being sought because of their potential as components in solid-state electrochemical devices, such as batteries and fuel cells.[1] To date, the search has concentrated mainly on purely inorganic materials, and in particular continuous lattice oxides. In fact, there is a clear lack of candidates among electronically conducting organic molecular crystals, despite the existence of proton-conducting polymers, such as perfluorinated Nafion. Recently a 2,2′-[2,5-cyclohexadiene-1,4-diylidene]-bis(propanedinitrile) (TCNQ) charge transfer complex of benzimidazolyl–benzimidazole was shown to exhibit coupled protonic and electronic conductivity, and a TCNQ complex of 1,4-diazabicylo[2.2.2]octane also exhibited proton transfer.[2] Herein we report what we believe to be the first molecular ion-radical salts that are metallic conductors at room temperature, and also show a high proton conductivity. We provide evidence that the mobility of both protons and electrons is

high in these lattices because of a unique crystal structure consisting of layers of organic donor molecules interleaved with arrays of stacked crown ether molecules. The crown ether molecules form "pipes" filled with water molecules. The crystal structure, resolved from X-ray data recorded at 30 K,[3] gives strong indication of a hydrogen-bonding network, which gives rise to the protonic conductivity.

The series of cation-radical salts (BEDT-TTF)$_4$[(Cat)M-(C_2O_4)$_3$]G, where BEDT-TTF = bis(ethylenedithio)tetrathiafulvalene, has proven to be an exceptionally fruitful source of different collective electronic ground states, promoted by the ease with which the monocation Cat, 3d metal M^{3+}, and neutral guest molecule G can be varied. Thus we found the first examples of paramagnetic superconductors (Cat = H_3O; M = Cr, Fe; G = PhCN, $PhNO_2$)[4] and the first case of polymorphism, in the whole realm of solid-state chemistry, that arose from different spatial distributions of chiral enantiomers $[M(C_2O_4)_3]^{3-}$ in a racemic lattice.[5] By inserting asymmetrically substituted aromatic G molecules in cavities within the anion sublattice, it has also been possible to synthesize unique conducting salts containing a superlattice of two different packing types (α and β'') of the BEDT-TTF cations.[6] The present salts also contain superlattices of cation layers but, instead of being made up from two different arrangements of the BEDT-TTF molecules, they consist of BEDT-TTF and crown ether molecules that incorporate both H_2O and H_3O^+ or NH_4^+ ions.

β''-(BEDT-TTF)$_4$[(Cat)M^{III}(C_2O_4)$_3$]$_2$[(Cat)$_2$([18]crown-6 ether)]·5H_2O, where M^{III} is Cr or Ga (**1** and **2**, respectively) and Cat is H_3O^+ or NH_4^+, were synthesized by electrochemical crystallization. Both **1** and **2** crystallized in the triclinic space group ($P\bar{1}$). From single-crystal X-ray diffraction data recorded at 150 K,[7] the structure of the Cr salt has been resolved, with all Cat molecules assigned to H_3O^+. X-ray data recorded at 30 K on the Ga salt established the molecular structure, but in addition enabled many of the protons to be resolved.[8] The crystal structure consists of successive layers of BEDT-TTF with a β'' packing motif (layer A), Δ-[(Cat)M(C_2O_4)$_3$] (layer B), (Cat/H_2O)·[18]crown-6 (layer C), and Λ-[(Cat)M(C_2O_4)$_3$] (layer D) arranged in the sequence …ABCDA… (Figure 1). Within experimental error the C–C and C–S bond lengths of the crystallographically inequivalent BEDT-TTF are equal and from the correlation between bond length and charge in BEDT-TTF salts,[9] these identify a mean charge on each cation of +0.5, as seen in the β'' phase paramagnetic superconductors.

Considering the stoichiometry of **1** and **2** and the known charges of the molecular species, overall charge neutrality requires four monocations (Cat), which could be H_3O^+ or NH_4^+. The 30 K structure refinement of **2** confirms the Cat molecules, embedded in the anionic oxalate layers, are all well ordered NH_4^+ ions. In this case there is a marginal improvement in the residual factors for occupancy by nitrogen as compared to oxygen. The remaining cations are predicted to be located in the channels formed by the stack of crown ether molecules. The water molecules found in the channels, refined with a fixed 50% occupancy, form zigzag hydrogen-bonded chains that align with the axis of the crown ether stacks. Additional electron density is located, off the stack axis between adjacent crown ether molecules. Refinements were carried out to try to distinguish between the preferred occupancy of these sites as oxygen or as nitrogen atoms, but these refinements were inconclusive. Despite the very low-temperature diffraction data, there is not sufficient information therein to identify individual atomic sites for occupancy by nitrogen or oxygen in these channel regions. Figure 2 shows the zigzag hydrogen-bonded network within the crown ether stacks, with these atoms assigned as oxygen.

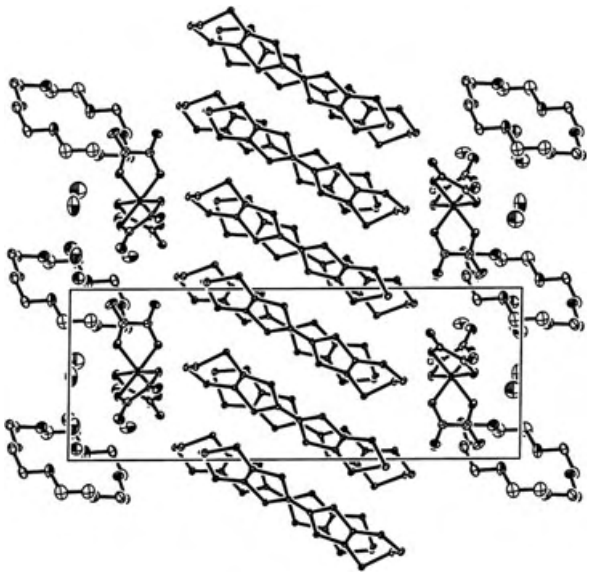

Figure 1. The crystal structure of **2** at 30 K, showing the sequence of BEDT-TTF, [(Cat)Ga(C_2O_4)$_3$], and crown ether layers. Protons have been removed for clarity.

Four-probe DC electrical conductivity measurements on single crystals of **1** and **2** with current flow parallel to the layers reveals high electronic conductivities at room temperature (300 $S\,cm^{-1}$ for **1** and 200 $S\,cm^{-1}$ and **2**) with temperature dependence characteristic of a metal. However, in each case the resistance shows an upturn at lower temperature, which occurs at 190 K for **1** and 240 K and **2** (Figure 3). These metal–semiconductor transitions contrast with the behavior of other BEDT-TTF salts of tris(oxalato)metallates, which have metal–superconducting transitions.[4]

Measurements of proton conductivity of **1** and **2** from 260–297 K made on pellet samples, show specific conductivities varying from 10^{-6} to 10^{-3} $S\,cm^{-1}$ over this temperature range (Figure 4a). For each compound the conductivity is activated, as anticipated, but does not follow a simple Arrhenius Law. Instead the measured activation energies change slightly for **1** from 1.06–1.59 eV and for **2** from 1.01–1.92 eV with the lower activation energy at higher temperatures and a gradual change across approximately 280 K. For a similar measurement on Nafion 117 (Figure 4a) there is a constant activation energy of 0.27 eV. A slight discontinuity in protonic conductivity at about 280 K can be seen clearly in Figure 4a for **1** and to a lesser extent for **2**. Typical complex impedance plots are shown for **1** in Figure 4b. The relatively high values of the room-temperature specific conductivity are comparable to those found in polymeric electrolytes of the polyethylene oxide type.[10] The mechanism of the proton

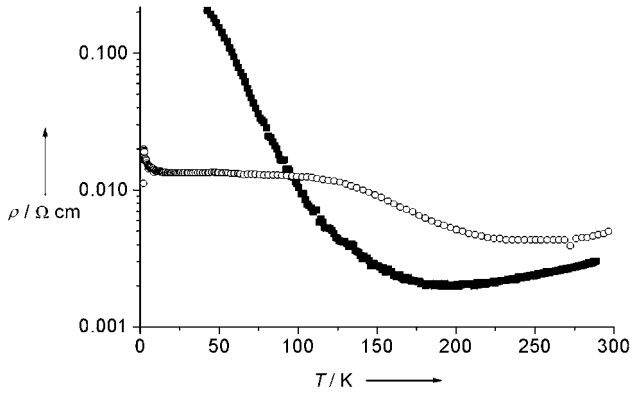

Figure 3. Four-probe single-crystal electronic conductivity of **1** (■) and **2** (○).

conductivity is not known. However, it has been established that significant proton conductivity can be mediated by a diffusion mechanism involving NH_4^+/H_2O or NH_4^+/H_3O^+ species. The former has been found in $(NH_4)_4[Fe(CN)_6]\cdot 1.5\,H_2O$ and the latter in the polytungstate $(NH_4)_{10}[W_{12}O_{41}]\cdot 5\,H_2O$,[13] albeit with smaller absolute conductivities than the compounds presented herein.

Solid-state NMR spectra were studied as a function of the temperature in the diamagnetic salt **2**, under magic-angle spinning (MAS) and static conditions. At room temperature, the high-resolution ^1H spectrum of a fully protonated sample

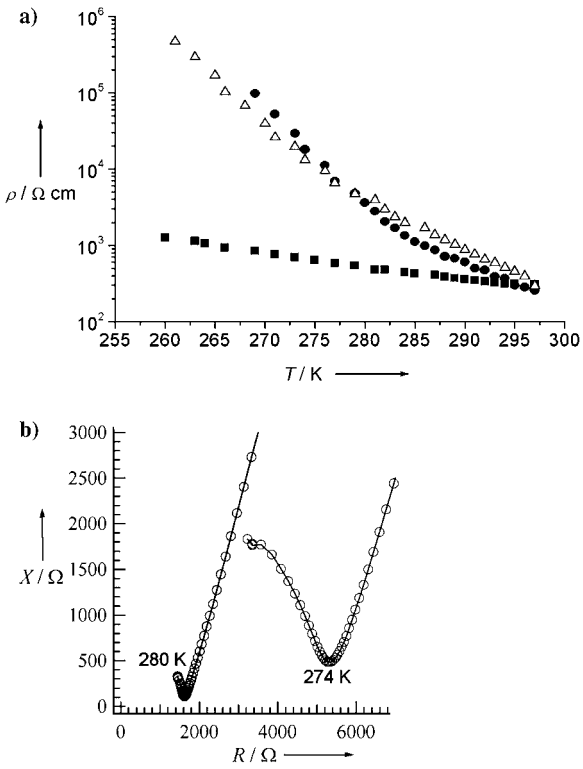

Figure 4. a) Proton conductivity of **1** (△), **2** (●), and Nafion 117 (■) from 260–297 K with logarithmic y axis; b) typical complex impedance plots for **1** at 274 and 280 K.

consisted of three resonance signals A ($\delta = 7.7$ ppm), B ($\delta = 4.3$ ppm), and C ($\delta = 4.8$ ppm) with intensity ratio 1:0.3:>2 and widths of 1.6, 0.6, and 7.4 ppm, respectively. Signal A can be assigned to H_2O, H_3O^+ (and/or NH_4^+) since it corresponds to a signal, found in the ^2H NMR spectrum, which appears when a sample is prepared with D_2O. A separate experiment indicates that the chemical shift of ND_4 is $\delta = 7.4$ ppm, similar to the shift of signal A. It is difficult to distinguish between deuterated water and this species since the details of hydrogen bonding, not known from crystallography, could affect the chemical shifts. Signal C is assigned to the $-CH_2-$ group of BEDT-TTF and the [18]crown-6 ether. The assignment of signal C is supported by its behavior at low temperature; in the wide-line ^1H NMR spectrum at 130 K it splits into a doublet with a separation of approximately 30 kHz, which is typical for the nuclear dipole interaction between the two protons in a $-CH_2-$ group. Furthermore, the signal is absent in the ^2H NMR spectrum of the sample when exchanged with D_2O. Signal B, which is much weaker and narrower than the other two, is tentatively assigned to water molecules adsorbed on the surface of the crystallites. The increasing line width of signal C in the wide-line ^1H NMR spectrum of the fully protonated sample (Figure 5) clearly indicates freezing of the thermal fluctuations of the $-CH_2-$ on lowering the temperature. In contrast, the width of signal A, remains relatively constant and small (11 kHz) between 130 and 250 K before decreasing further between 250 and 300 K. The ^2H NMR spectrum of the D_2O sample further confirms an almost isotropic and rapid rotation of those molecules producing signal A, at least down to 195 K.

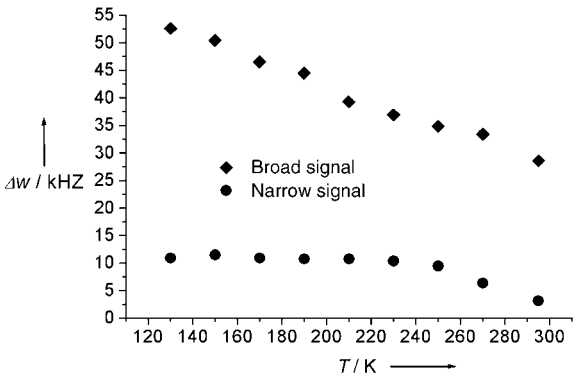

Figure 5. Temperature dependence of the spectral width (Δw) of the wide-line ^{1}H NMR spectra of a fully ^{1}H substituted sample of **2**. The spectral width of BEDT-TTF and [18]crown-6 $-CH_2-$ groups (◆) and of H_2O (●) including the weak signal (signal B, see text) are shown.

In summary, we have identified the first molecular ion-radical salts that are both protonic and metallic conductors. The high values of both the ionic and electronic conductivities at room temperature are especially noteworthy and are attributed to the presence of discrete conducting layers in the crystal consisting of either organosulfur molecules or of crown ether stacks containing disordered H_2O, H_3O, and/or NH_4. This discovery expands the search for other mixed ionic-electronic conductors among the large and versatile family of TTF and BEDT-TTF ion-radical salts.

Experimental Section

The BEDT-TTF salts were prepared by in situ oxidation of BEDT-TTF (12 mg) in an H-shaped electrochemical cell in the presence of a racemic solution of $(NH_4)_3[M(C_2O_4)_3]$ (M = Cr, Ga; 120 mg), [18]crown-6-ether (250 mg) and four drops of distilled H_2O in a mixture of freshly distilled CH_3CN (10 mL) and CH_2Cl_2 (10 mL). A constant current of 1 μA was applied across the cell and thin dark brown elongated plates of the product grew on the Pt anode in 2–3 days. Elemental analysis calcd (%) for (BEDT-TTF)$_4$[$(NH_4)M(C_2O_4)_3$]$_2$[$(NH_4)_2$([18]crown-6)]·5H_2O): **1** C 29.58, H 3.18, N 2.16; found: C 29.48, H 2.91, N 1.70; **2** C 29.30, H 2.77, N 2.14; found: C 29.47, H 2.82, N 2.17

Single-crystal DC conductivity were made using four contacts (15 μm diameter Au wires attached to the crystals with Au paste) and an Oxford Instruments Maglab 2000 cryostat with EP probe.

Temperature-dependent protonic conductivity was measured by the AC impedance method in the frequency range $100–5\times10^6$ Hz using an HP4194A impedance analyzer. The sample, prepared as a compressed pellet with a diameter of 3 mm, was enclosed by a Teflon ring to avoid short circuit, this pellet was then sandwiched by proton-conducting Nafion 117 (Aldrich). The sample was clamped by metal electrodes, and was inserted into a Daikin PS24SS cryogenic refrigerating system. The conductivity was measured in vacuo ($<10^{-3}$ torr).

Solid-state high-resolution ^{1}H and ^{2}H NMR spectra were measured by a magic-angle spinning technique with spinning speed of 25 (^{1}H NMR) and 7 kHz (^{2}H NMR) using a Bruker DSX 300 spectrometer. Echo pulse sequence synchronized with spinning speed was used for ensuring the phase of all spinning side-band signals. The thermometers of the NMR probes were calibrated by standard samples. Wide-line ^{1}H NMR spectrum under static conditions was measured by the solid echo pulse sequence $\pi/2_x$-τ-$\pi/2_y$; the $\pi/2$ pulse width and τ were 1.5 μs and 15 μs, respectively.

Molecular Recognition

1D Saturation Transfer Difference NMR Experiments on Living Cells: The DC-SIGN/ Oligomannose Interaction**

Silvia Mari, Diego Serrano-Gómez, F. Javier Cañada, Angel L. Corbí, and Jesús Jiménez-Barbero**

Dedicated to Professor Luis Castedo on the occasion of his 65th birthday

Molecular recognition by specific targets is at the heart of the drug discovery process. Recently, it has been demonstrated that NMR screening is ideal for finding ligands that bind to a receptor.[1] Although modern NMR experiments and technologies permits the exploration of the interaction process using nanomole quantities of the receptor, in some cases the availability of the target protein might pose a problem in the detection of the molecular recognition event, especially in the case of membrane-bound proteins. On this basis, we hypothesized that receptor-rich living cells could be used as a first step to screen the binding of different molecules to some types of receptors. The study of the role of the carbohydrate-binding C-type lectin and lectin-like receptors in the immune system is a topic of current interest. In particular, the dendritic-cell-specific ICAM-3-grabbing non-integrin (DC-SIGN) receptor[2] mediates the binding and internalization of a large array of pathogens including HIV,[3] Ebola virus,[4] SARS-CoV,[5] *Leishmania* amastigotes,[6] *Mycobacterium tuberculosis*,[7] *Schistosoma mansoni*, *Helicobacter pylori*,[8] and *Candida*[9] in a Man- or Fuc-dependent manner.[10] Moreover, DC-SIGN plays an important role in the establishment of the initial contact between the dendritic cell and naive T lymphocytes through recognition of ICAM-3,[2] and also mediates dendritic cell trafficking through interactions with endothelial ICAM-2.[11] In this context, *Saccharomyces cerevisiae* mannan has been shown to compete with most of these DC-SIGN-dependent pathogen recognitions.[12] Herein, we demonstrate that the direct interaction between the DC-SIGN receptor and *S. cerevisiae* mannan may be easily detected by simple 1D saturation transfer difference (STD) NMR experiments[13] that employ living cells directly, without the necessity for isolating the protein receptor. This evidence may open new avenues in the drug discovery process, since NMR spectroscopy may also provide key structural information.

The cell line K562 transfected with the prototype DC-SIGN, namely K562-CD209 (DC-SIGN+),[12] and mock-transfected K562 (DC-SIGN−) were employed. These two cell types differ only in the expression of the receptor DC-SIGN on the cell surface. Thus, the untransfected cells were used as a control. The K562-CD209 DC-SIGN expression level was determined by flow cytometric analysis (see the Supporting Information). The *S. cerevisiae* mannan was obtained from Sigma and its average molecular weight was estimated to be 100 kDa by DOSY NMR experiments[14] (see the Supporting Information).

To perform the STD NMR experiments, about 5×10^6 cells were counted, washed, and dissolved in deuterated phosphate-buffered saline (PBS), and mannan (5 mg) was dissolved in the same deuterated PBS. Typical NMR tube volumes were 600 μL. Additional experiments with a commercial beta-glucan preparation, which does not bind to DC-SIGN, were also performed as blank experiments. All the experiments were repeated three times, and carried out using different batches. The estimated concentration of DC-SIGN in the NMR tube was approximately 0.1 μM.[15,16]

NMR control experiments were recorded in all cases. As illustrated in Figure 1, the STD control spectrum (Figure 1 d) of mannan confirmed that the on-resonance irradiation ($\delta =$ 6.8 ppm, aromatic region) did not affect the mannan signals.

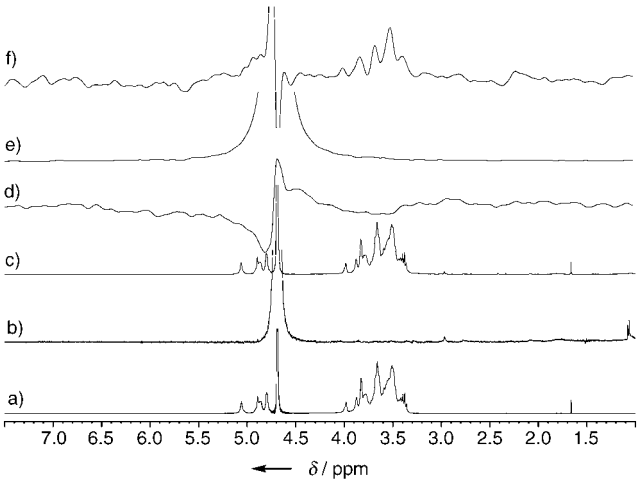

Figure 1. a) ^{1}H NMR spectrum of mannan in PBS; b) ^{1}H NMR spectrum of K562-CD209 cells in PBS, enhanced 20×; c) ^{1}H NMR spectrum of mannan with K562-CD209 cells in PBS; d) STD reference spectrum of mannan: number of scans (NS) = 256, on-resonance frequency = 6.8 ppm, off-resonance frequency = 100 ppm, total saturation time = 2 s, enhanced 100×; e) STD reference spectrum of K562-CD209 cells under the same experimental conditions as (d), enhanced 600×, signals enhanced 16×; f) STD spectrum of mannan with K562-CD209 cells: NS = 64, on-resonance frequency = 6.8 ppm, off-resonance frequency = 100 ppm, signals enhanced 800×. All the samples (cells and mannan) were dissolved in deuterated PBS at pH 7.3 containing $CaCl_2$ (1 mM). Total sample volumes were 600 μL.

Identical results were obtained with saturation at $\delta = 1.3$ ppm (aliphatic side-chain region). Control NMR data of the living cells were acquired in an analogous manner (Figure 1 b and e). The cells used to obtain these spectra were then centrifuged and the pellet was dissolved in the mannan solution used to generate the spectra in Figure 1 a and d.[17] The resulting reference spectrum is shown in Figure 1 c, while its corresponding STD NMR spectrum is displayed in Figure 1 f. The mannan signals are observed unambiguously. Thus, irradiation at the aromatic or aliphatic regions protons of the DC-SIGN receptor protein expressed in living cells results in transfer of magnetization to the polysaccharide protons. The control spectra support the notion that the observed process is specific for the interaction of living cells of K562-CD209 (DC-SIGN+) with mannan. Indeed, when the same set of experiments was repeated with mock-transfected K562 cells (DC-SIGN−) instead of K562-CD209 (DC-SIGN+) cells, no mannan signals were detected in the STD NMR experiment (Figure 2 f). Additional reference experiments were performed using beta-glucan as the ligand. In this case, and as expected for a molecule that does not bind to DC-SIGN, no STD signals were observed with either cell line (data not shown), which supports the NMR-based detection of the specific interaction between the K562-CD209 cells and mannan.

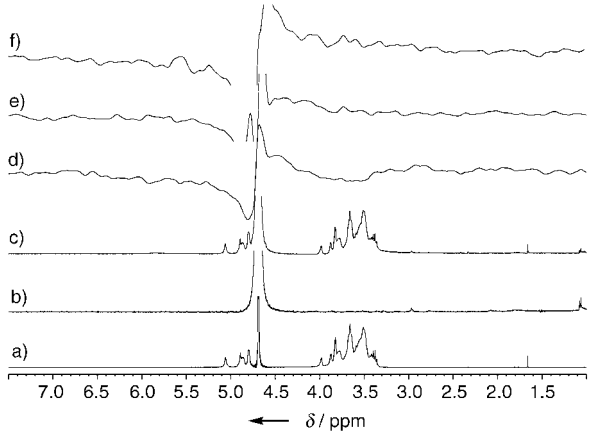

Figure 2. a) ^{1}H NMR spectrum of mannan in PBS; b) ^{1}H NMR spectrum of K562 (DC-SIGN−) cells in PBS enhanced 4×; c) ^{1}H NMR spectrum of mannan with K562 (DC-SIGN−) cells in PBS enhanced 10×; d) STD reference spectrum of mannan: NS = 256, on-resonance frequency = 6.8 ppm, off-resonance frequency = 100 ppm, total saturation time = 2 s, enhanced 600×; e) STD reference spectrum of K562 (DC-SIGN−) cells under the same experimental conditions as (d), signals enhanced 400×; f) STD spectrum of mannan with K562 (DC-SIGN−) cells: NS = 64, on-resonance frequency = 6.8 ppm, off-resonance frequency = 100 ppm, signals enhanced 800×.

Direct detection of interactions between a ligand and a membrane protein by employing living cells could open new possibilities in the screening of compound libraries in a fast and efficient way. By using our current experimental setup for this K562-CD209/mannan system robust data have been obtained with 32 scans, which correspond to a total experimental time of 3 minutes, and includes a recycling of the mannan solution from a previous experiment. The cells were checked by optical microscopy before and after the NMR experiments to determine their biological stability, and cell viability was also evaluated by the Trypan Blue exclusion method. Both assays demonstrated that cell viability was not significantly affected during the NMR experiments (see the Supporting Information).

In conclusion, receptor–ligand interactions with integral membrane proteins may be investigated by 1D STD NMR spectroscopy as the initial step in screening processes, which use living cells directly in a manner similar to that previously reported for detecting virus–ligand and platelet–ligand interactions.[16] This protocol represents a significant advance in molecular recognition studies, since it eliminates time-consuming purification processes, especially in the case of receptors that are difficult to isolate.[18]

Experimental Section

Cells: K562 cells were cultured in RPMI media supplemented with 10% fetal calf serum (FCS), 2-[4-(2-hydroxyethyl)-1-piperazinyl]-ethanesulfonic acid (HEPES, 25 mM), and glutamine (2 mM; complete medium). DC-SIGN-expressing K562 transfectants (K562-CD209) have been previously described,[12] and were cultured in complete medium supplemented with G418 (300 μg mL^{-1}, Gibco).

NMR experiments: All the experiments were recorded on a Bruker 500-MHz instrument at 283 K. A basic STD sequence was used, with the on-resonance frequency variable between $\delta = 6.8$ and 1.3 ppm.[13] The off-resonance frequency was maintained at 100 ppm. A train of 40 Gaussian-shaped pulses of 50 ms each was employed, with a total saturation time of the protein envelope of 2 s. All the samples (cells and mannan) were dissolved in deuterated PBS at pH 7.3 containing $CaCl_2$ (1 mM) previously exchanged with D_2O. Total sample volumes were 600 μL.

Flow cytometry and antibodies: Cellular phenotypic analysis was carried out by indirect immunofluorescence. Monoclonal antibodies used for cell-surface staining included 9E10 (anti-c-Myc) and MR-1 (anti-DC-SIGN, CD209).[12] All incubations were performed in the presence of human immunoglobulin G (50 μg mL^{-1}) to prevent binding through the Fc portion of the antibodies. Flow cytometric analysis was performed with an EPICS-CS instrument (Coulter Científica, Madrid, Spain) using log amplifiers.

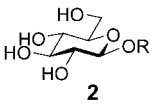
Molecular Recognition

Carbohydrate Recognition in Water by a Tricyclic Polyamide Receptor**



*Emmanuel Klein, Matthew P. Crump, and Anthony P. Davis**

Carbohydrate recognition in aqueous solution remains an important challenge in supramolecular chemistry.[1] Saccharides are complex, irregular, and multifunctional, while their hydroxylated exteriors blend well with water. Even nature has difficulty; binding constants of proteins with monosaccharides peak at approximately $10^7\,M^{-1}$, a remarkably low value for biological molecular recognition.[1a,2] Synthetic receptors that exploit covalent B–O bonds have been relatively successful,[1b,3] but there are still few reports of binding in water through noncovalent interactions.[1a,4] Such systems are of special interest as they shed light on natural carbohydrate recognition, a process of fundamental biological significance.[5]

A few years ago, we reported the octa-amide **1a** as a receptor for octyl glycosides in organic media.[6] The tricyclic

1a: X = OC_5H_{11}
1b: X = O^-
1c: X = NH(OBn)(OBn)(OBn)
1d: X = NH(CH$_2$CO$_2^-$)$_3$

2

core **1** was specifically targeted at β-glucosyl derivatives **2**. It was supposed that the axial hydrogens in **2** would make C–H–π contacts with the biphenyl surfaces, while the equatorial substituents would form hydrogen bonds to the isophthalamide spacers. Accordingly, **1a** showed high affinities for **2**

(R = octyl) and was less effective for the α anomer or octyl β-D-galactoside. Our prime objective, however, was recognition in water. In this more-challenging medium, hydrogen bonding would provide less (if any) impetus for binding, but, in compensation, the C–H–π interactions should be reinforced by the hydrophobic effect. Tetracarboxylate **1b** could not be employed owing to aggregation in water. Attempts to use a tris(hydroxymethyl)methyl solubilizing group also foundered, although precursor **1c** proved useful for phase-transfer experiments.[7] We now describe the synthesis of dodecacarboxylate **1d** and report that this polyanion provides, at last, an opportunity to study carbohydrate recognition by **1** in homogeneous aqueous solution.

Scheme 1. Synthesis of **6**: a) *tert*-butyl acrylate, NaOH, DMSO, H_2O; b) 1,3,5-benzenetricarbonyl trichloride (excess), *i*Pr_2NEt, THF; c) aq. NaOH (2 M); d) aq. HCl (3.5 M); e) C_6F_5OH, DCC, THF. DMSO = dimethylsulfoxide, DCC = *N*,*N*′-dicyclohexylcarbodiimide.

Receptor **1d** was prepared as shown in Schemes 1 and 2. The active ester **6** was synthesized from tris(hydroxymethyl)aminomethane **3** through the aminotriester **4**[8] and diacid **5** (Scheme 1). The biphenyl unit **7** was prepared as previously reported.[7] Acid deprotection of **7** followed by cyclization with **6** under high dilution gave macrocycle **8** (Scheme 2). Hydrogenolysis of **8** followed by a second [2+2] macrolactamisation gave the protected macrocycle **9**. The sodium salt of dodecacarboxylate **1d** was obtained through deprotection of **9** with trifluoroacetic acid followed by treatment with sodium hydroxide. ^{1}H NMR spectra of solutions in D_2O/H_2O consisted of sharp signals (Figure 1) and did not vary with concentration in the range 1–4 mM. Receptor **1d** was therefore assumed to be monomeric in aqueous solution at approximately 1 mM.

Preliminary NMR titration studies on the dodeca-*tert*-butyl ester **9** confirmed that, as expected, this macrocycle binds carbohydrates in the organic solvent system $CDCl_3$/CD_3OD (92:8). The K_a value for octyl β-D-glucopyranoside was 600 M^{-1}, which is similar to those obtained previously for **1a**[6] and **1c**.[7] Variations in the chemical shifts were also similar to those for the earlier systems. More significantly, the addition of glucose **10** to **1d** in D_2O/H_2O yielded qualitatively similar NMR effects. In particular, the signal for the inward-directed spacer protons, B (for labeling, see Figure 1), moved downfield, whereas that for the annular amide protons, NH^a, moved upfield and split into two (Figure 2). The signal for the protons C of the biphenyl group also split and moved

Scheme 2. Synthesis of **1d**: a) TFA, CH_2Cl_2; b) **6**, *i*Pr_2NEt, THF, high dilution; c) H_2, 10% Pd/C, THF/methanolic ammonia (1:1); d) **6**, *i*Pr_2NEt, THF, high dilution; e) TFA, CH_2Cl_2; f) aq. NaOH (1 M). Boc = *tert*-butoxycarbonyl, Cbz = benzyloxycarbonyl, TFA = trifluoroacetic acid.

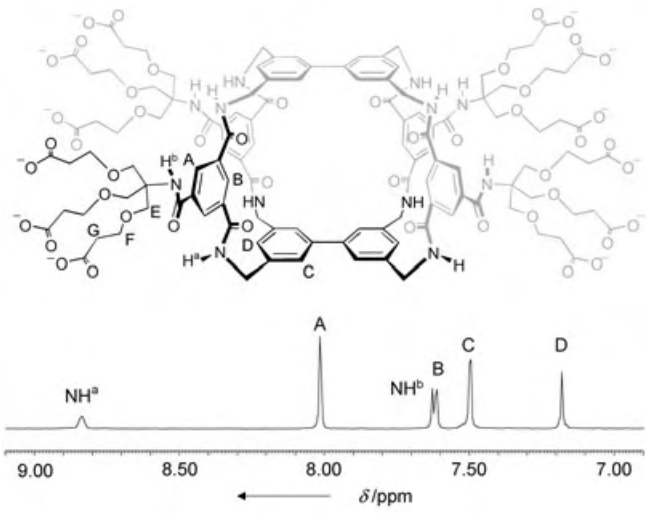

Figure 1. Partial ^{1}H NMR spectrum (600 MHz, 93:7 H_2O/D_2O) of receptor **1d**.

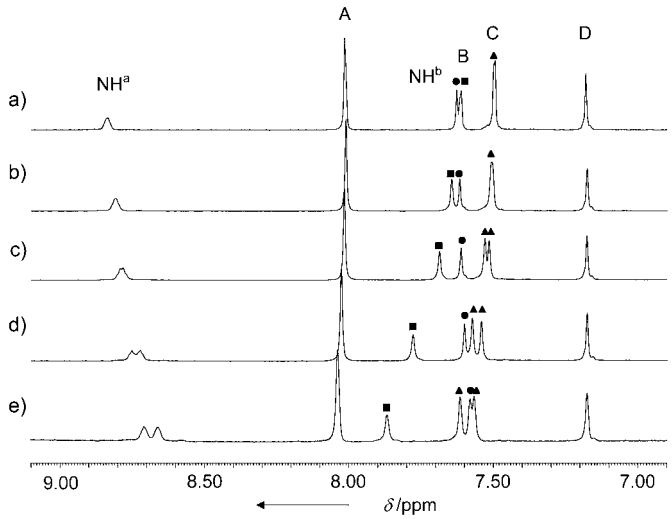

Figure 2. ^{1}H NMR spectra (600 MHz, 93:7 H_2O/D_2O) of receptor **1d** after addition of increasing amounts of D-glucose **10**: a) 0, b) 20, c) 50, d) 200, and e) 1000 equivalents. ● = NH^b, ■ = protons B, ▲ = protons C.

downfield. The splitting of the eight equivalent NH^a and C protons into groups of 4 is expected for a D_{2h} receptor that interacts with an asymmetrical substrate.[6] As illustrated in Figure 3a the motions could be fitted, to high accuracy, to a 1:1 binding model. The resulting binding constants varied according to the history of the glucose solution. For freshly dissolved glucose with an anomeric ratio α/β of 72:28 a K_a value of 4.6 M^{-1} was obtained in D_2O. For glucose that had been equilibrated overnight (α/β = 40:60), the binding constant was 9.2 M^{-1}. The figures imply substantial selectivity for the β anomer; indeed, they are consistent with $K_a \approx 14\,M^{-1}$ for β-glucopyranose and $< 1\,M^{-1}$ for the α anomer.[9]

Binding to other carbohydrates (**11**–**24**) was followed by NMR spectroscopy to yield the association constants shown in Table 1, page 301. Errors may be high for the smaller K_a

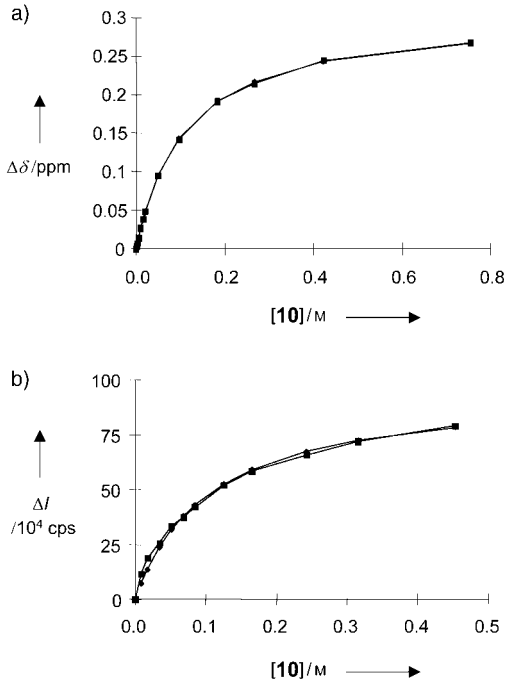

Figure 3. Theoretical (◆) and experimental (■) binding curves for a) NMR titration of **1d** + **10** (proton B) and b) fluorescence emission titration of **1d** + **10** (cps = counts per second; λ_{ex} = 266 nm, λ_{em} = 475 nm).

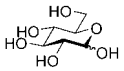
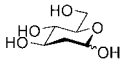
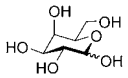
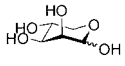
values (especially when $K_a \approx 2\,M^{-1}$), but selectivities are clearly significant. The receptor shows a notable preference for β-glucosyl units in accordance with the original design and with previous work on **1a** and **1c**. Thus the highest K_a values are to methyl β-D-glucoside **15** and cellobiose **22**. The selectivity for **22** relative to lactose **23** and maltose **24** is especially striking and mirrors the results in organic media for an "extended", terphenyl-based analogue of **1a**.[10] Other units with all-equatorial substitution (2-deoxy-D-glucose **17** and D-xylose **18**) are also bound well by the receptor. Remarkably, the removal of hydroxyl groups does not enhance binding—**17** is no more strongly bound than glucose, while rhamnose **20** and fucose **21** are poor substrates.

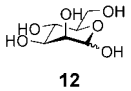
The formation of the complexes was also detected by means of fluorescence spectroscopy. On addition of substrates to **1d**, the fluorescence emission was enhanced and shifted slightly in wavelength (see Supporting Information). Analysis by curve fitting (see Figure 3b) yielded the binding constants shown in Table 2 which are in good agreement with the values obtained through ^{1}H NMR titrations.

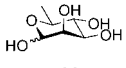


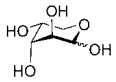


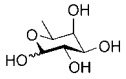


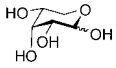


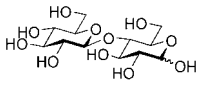


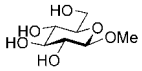


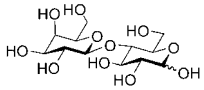


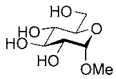












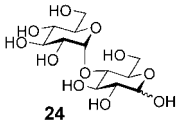


Table 2: Association constants (K_a) between receptor **1d** and carbohydrates as measured in H_2O by fluorescence titration.[a]

Carbohydrate	K_a [M^{-1}]	Carbohydrate	K_a [M^{-1}]
D-glucose (**10**; α/β 40:60)	9.5	methyl α-D-glucoside (**16**)	5.7
methyl β-D-glucoside (**15**)	32	D-xylose (**18**)	3.8

[a] $T = 296$ K. Data were analyzed by using a nonlinear least-squares curve-fitting program implemented within MS Excel 2000. Quoted figures were derived from the peak for proton B (see Figure 1); peaks for protons C and (sometimes) A could also be followed and gave closely consistent results. For binding curves and further details, see Supporting Information. [b] Freshly dissolved in D_2O. Anomeric ratio was monitored by ^1H NMR spectroscopy and was found to remain roughly constant throughout the titration. [c] Solution in D_2O allowed to equilibrate before use. For further information on anomeric ratios, see Supporting Information. [d] Very small. Minor signal movements, almost linear with substrate concentration.

Information on the geometry of the **1d**·glucose complex was provided by NOESY experiments. A portion of the spectrum is shown in Figure 4. Cross-peaks are observed between glucose protons (β anomer only) and receptor protons B, C, and NH^a, whereas connections from substrate to externally directed protons A, NH^b, and D are weak or

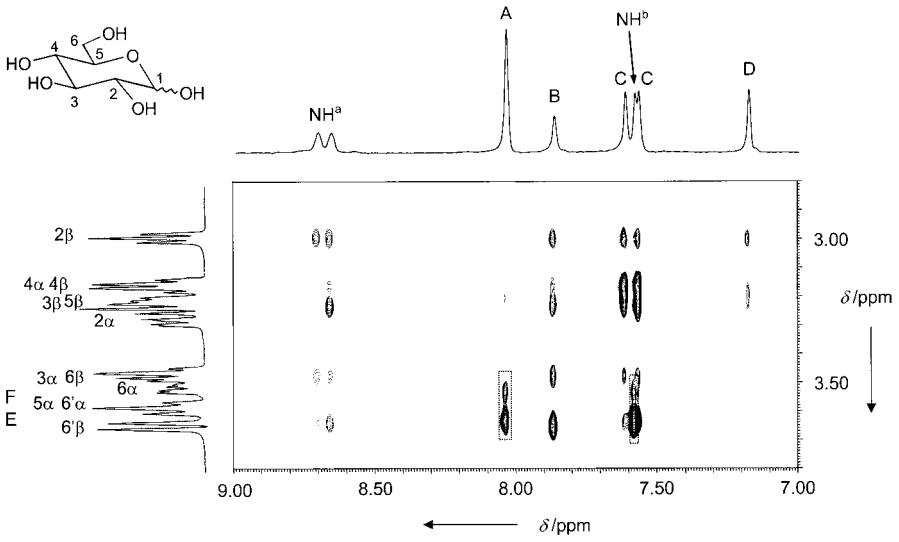

Figure 4. Partial NOESY spectrum of receptor **1d** and 1000 equivalents of D-glucose (**10**) in H_2O/D_2O 93:7 (600 MHz). The horizontal axis covers the region 7.0–9.0 ppm, which includes aromatic and NH protons of the receptor (for atom labeling, refer to Figure 1). The vertical axis covers 2.8–3.8 ppm, which includes protons 2–6 of glucose. The region plotted vertically also includes protons F and E of the receptor which are invisible in the 1D spectrum owing to the disparity in concentrations. Intramolecular cross-peaks that involve these signals are framed by dotted lines (•••••). All other cross-peaks represent intermolecular contacts. For further details see Supporting Information.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nonexistent. These data provide strong evidence that the carbohydrate is bound in the interior of the macrotricyclic structure. Both protons B and C appear to show cross-peaks with all of the carbohydrate protons, but the cross-peaks between protons B and proton H^6 of glucose, and those between proton C and the axial protons H^3, H^4, and H^5, are especially strong. Our proposed binding geometry, with "axial→biphenyl" and "equatorial→isophthaloyl" orientations, thus receives some support.

In conclusion we have shown that, in the form of **1d**, the tricyclic cage **1** can bind carbohydrates in water. Affinities are low, but selectivities are significant. The designed preference for β-glucosyl which was previously demonstrated in organic solvents is retained in the saccharides' natural environment. The formation of complexes has been characterized by ^{1}H NMR spectroscopy and confirmed by a second, independent technique, namely fluorescence spectroscopy. Tricycle **1** is thus established as a carbohydrate receptor with consistent behavior across a wide range of media. This property should allow its use in studies which complement those on natural receptors and further elucidate the principles underlying biological carbohydrate recognition.

Green Heterogeneous Catalysis

Renewable Olefins from Biodiesel by Autothermal Reforming**

*Ramanathan Subramanian and Lanny D. Schmidt**

Olefins are the largest volume chemical intermediates produced in the chemical industry, with global annual production over 300 billion lbs per year (1 lb = 0.454 kg).[1] Olefins are produced almost exclusively from ethane or other light alkanes (naphtha) in a process called steam cracking. This process involves homogeneous pyrolysis at approximately 800 °C in a tube furnace with a residence time of about 1 s. It has been estimated that 30 % of all pollution from chemical plants comes from steam cracking owing to NO_x emissions and unburned hydrocarbons in the flame required to heat the tube furnace.

Approximately 10 % of petroleum is consumed in the production of olefins and related chemicals. To reduce our reliance on fossil fuels, it would be desirable to produce olefins from renewable fuels that produce no net CO_2 emissions to contribute to global warming. To reduce pollution in olefins production, it would also be desirable to use partial oxidation rather than steam cracking. This possibility is discussed herein.

Biodiesel is the methyl ester formed by the reaction of triglyceride vegetable oils with methanol. From soy oil, there are five major ester compounds with the typical composition: methyl palmitate (12 %), methyl stearate (5 %), methyl oleate (25 %), methyl linoleate (52 %), and methyl linolenate (5 %).

Double bonds (all in the *cis* configuration) occur exclusively after carbon atoms 9, 12, and 15 for fatty acids containing one, two, and three double bonds, respectively.

We[2] and others[3] have shown that the partial oxidation of ethane or other light alkanes (naphtha) can be used to produce olefins in autothermal reactors with as high as 85% selectivity for ethylene. We recently showed that higher alkanes, such as *n*-decane and *n*-hexadecane, can also be converted into olefins in high selectivity.[4] However, olefinic esters, such as those contained in biodiesel, are not expected to be reformed under autothermal oxidation because of the carbon formation that is expected from the presence of double bonds. Moreover, the oxidation of aliphatic esters could result in substantial decarboxylation giving low-value products.

The apparatus and procedures reported herein have been described elsewhere for experiments with *n*-decane, *n*-hexadecane, and diesel fuel.[4–6] Liquid fuels were injected into the reactor (Figure 1, inset) by using an automotive fuel injector that sprayed droplets onto the wall of a quartz tube heated to approximately 300 °C. The catalyst was a mixture of 2.5% Rh and 2.5% Ce deposited on α-Al_2O_3 ceramic foam from nitrate salt solutions, which was then dried and heated in an oven to 600 °C. Experiments were conducted at several flow rates, but only results at 4 standard litres min^{-1} are shown herein. Products were analyzed by dual column gas chromatography (GC) and by GC-mass spectrometry.

Figure 1 shows conversions of biodiesel and O_2 along with the back-face temperature of the catalyst plotted versus the carbon to oxygen (C/O) ratio, calculated assuming 18.8 carbon atoms per molecule. C/O = 1 represents one oxygen atom from O_2 per carbon atom in the biodiesel. It is seen that the conversions of biodiesel and of O_2 are $>90\%$ for most conditions.

Figure 2 shows the selectivities for the major products formed in the partial oxidation of biodiesel. The selectivities are based on H atoms for H_2 and C atoms for all other species. All H and C containing products add to 100%. At C/O = 0.9, the selectivity for H_2 is 85% and for CO is 80%, as the C/O ratio increases, the selectivity towards these species decrease rapidly as the "total hydrocarbons" (that is, all products C_2 through C_{15}) increase. The total-combustion products CO_2 (not shown) remain $<13\%$ for all C/O ratios. Species C_2 through C_5 are almost exclusively olefins, and larger species comprise both olefins and olefinic esters.

Figure 3 shows the selectivity for the production of ethylene, propylene, 1-butene, and 1-pentene versus C/O ratio for biodiesel. Ethylene dominates the small olefins with a maximum of approximately 25%, followed by propylene and smaller amounts of higher olefins.

Since biodiesel contains exclusively linear C_{16} and C_{18} fatty acids, its molecular weight and isomers should correspond closely to *n*-hexadecane which has been studied with rhodium catalysts.[4] Since the catalyst used herein was Rh–Ce, we repeated all of the experiments reported above on this catalyst using *n*-hexadecane. These results are shown as open symbols and dashed curves in Figure 1, Figure 2, and Figure 3. It is seen that conversions and selectivities correspond closely between biodiesel and *n*-hexadecane. The maximum H_2

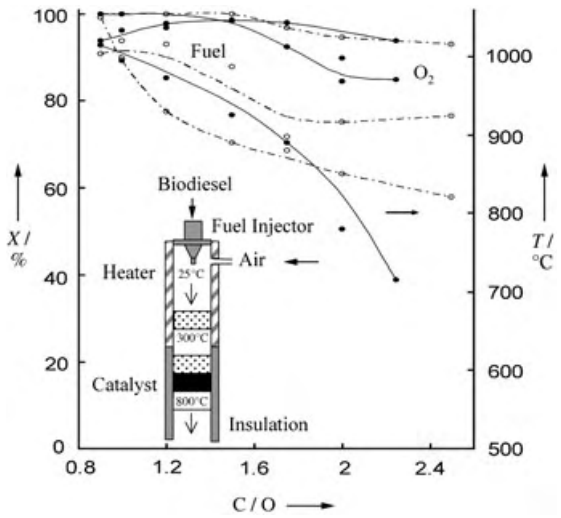

Figure 1. Fuel and oxygen conversions (*X*) and reactor temperature (*T*) versus C/O ratio for the partial oxidation of biodiesel (closed symbols and solid curves) and *n*-hexadecane (open symbols and broken lines). From the bottom, the first two curves indicate the temperatures (right-hand scale) for the partial oxidation of biodiesel (solid line) and *n*-hexadecane (broken line), the next two curves indicate fuel conversion (left-hand scale) for biodiesel (solid line) and *n*-hexadecane (broken line), and the top two curves indicate oxygen conversion (left-hand scale) for the partial oxidation of biodiesel (solid line) and *n*-hexadecane (broken line). The catalyst was a mixture of 2.5% Rh and 2.5% Ce deposited on an α-Al_2O_3 ceramic foam and the total flow rate was 4 standard litres min^{-1}, which corresponds to a catalyst contact time of approximately 5 ms. Liquid fuels were injected into the reactor using an automotive fuel injector. Cold air, admitted near the injector, rapidly mixed with the vaporized fuel with temperature and concentration gradients that minimized the potential for autothermal ignition before the reactor. Inset: schematic representaion of the reactor.[4–6]

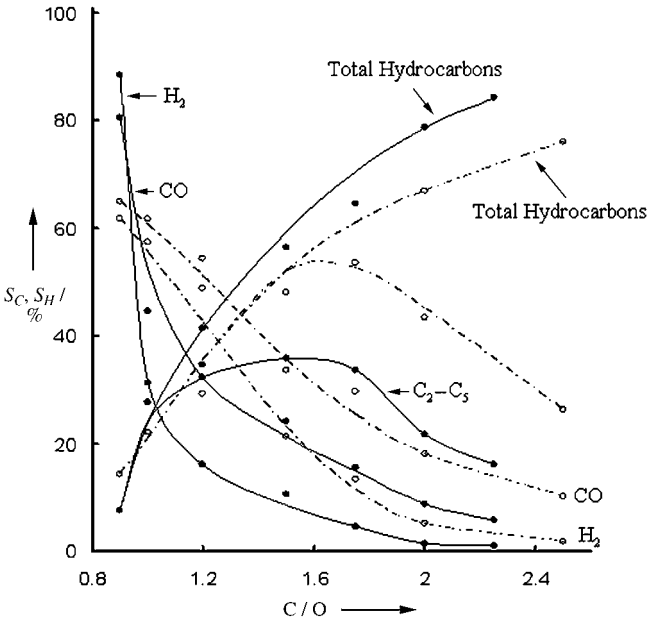

Figure 2. Selectivities *S* for the major products (H_2, CO, C_2–C_5 hydrocarbons, and total hydrocarbons) obtained from the autothermal oxidation of biodiesel with an Rh–Ce catalyst (closed symbols and solid curves) and from *n*-hexadecane over the same catalyst (open symbols and broken lines); see text for details.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

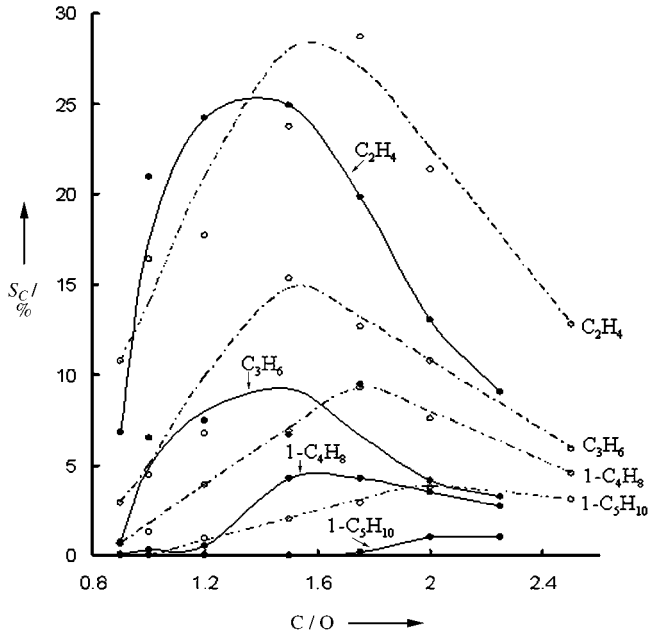

Figure 3. Selectivity *S* for the formation of ethylene, propylene, 1-butene, and 1-pentene versus C/O ratio from the partial oxidation of biodiesel (closed symbols and solid curves) and *n*-hexadecane (open symbols and broken lines). Methane is the only significant saturated alkane for which the selectivity is less than 8% (not shown).

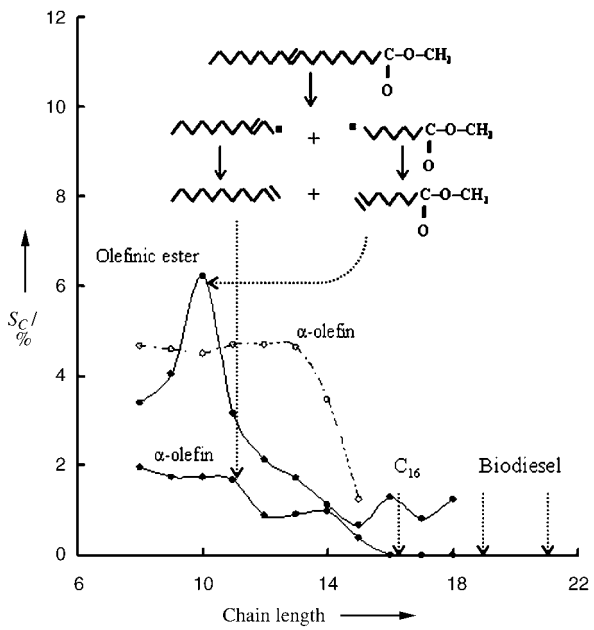

Figure 4. Plots of selectivities *S* for different species versus the chain length of the products observed at C/O = 2.25. 90% of the molecules present in biodiesel have a double bond between the ninth and tenth carbon atoms. Dissociation occurs mostly near this double bond because the allylic radical thus formed is resonance stabilized, this leads to a large amount of olefinic ester with a chain length of C_{10}. In contrast, *n*-hexadecane undergoes random C–C scission, which leads to nearly equal amounts of all α-olefins up to C_{14} (open symbols and broken line).

selectivity appears to be higher for biodiesel, but this is sensitive to the exact C/O ratio and reactor temperatures. The GC chromatograms of the products from biodiesel and *n*-hexadecane indicate that α-olefins and olefinic esters are formed from biodiesel, but only α-olefins are formed from *n*-hexadecane. Figure 4 shows plots of selectivities for different species versus the chain length of the products.

All of these processes are initiated by surface oxidation reactions on the rhodium surface that produces primarily H_2, H_2O, CO, and CO_2. These reactions occur near the entrance of the catalyst (probably within the first millimeter) where the surface is nearly free of carbon.[4] Most or all of the other products including olefins and olefinic esters arise from homogeneous reactions that occur after most O_2 has been consumed,[4] and rapid quenching within 20 ms prevents secondary reactions that would make many products. Further, most of the ester linkages survive the 800 °C of the reactor.

We never observed deactivation or extinction of the reaction under any conditions up to C/O = 3 for at least 50 h and this strongly indicates that carbon in the catalyst is not forming in sufficient quantities to block the rhodium surface sites that are required for oxidation reactions. Once all the O_2 has been consumed, we believe that the rhodium sites are carbon covered (up to 5% carbon by weight of the monolith), but this does not cause time-dependent results, so a steady state is rapidly obtained.

For *n*-hexadecane the process is fitted quite well assuming a very simple mechanism, dissociation of the parent molecule into two radicals [Eq. (1)] followed by the elimination of the H atom on the carbon atom in the position β to the radical [Eq. (2)] to produce the corresponding α-olefins.

$$n\text{-}C_{16}H_{34} \rightarrow C_mH_{2m+1}^{\bullet} + C_{16-m}H_{33-2m}^{\bullet} \quad (1)$$

$$C_mH_{2m+1}^{\bullet} \rightarrow C_mH_{2m} + H^{\bullet} \quad (2)$$

The alternative to β-H elimination is β-scission of C–C bond [Eq. (3)] which produces ethylene and a smaller alkyl radical.

$$C_mH_{2m+1}^{\bullet} \rightarrow C_{m-2}H_{2m-3}^{\bullet} + C_2H_4 \quad (3)$$

This reaction can continue producing ethylene until the final radical is ethyl or propyl which dehydrogenates to form ethylene or propylene. Since β-H elimination has a lower activation energy than the elimination of the alkyl to form ethylene, it is predicted that high temperature (lower C/O ratio) favors small olefins and low temperature (high C/O ratio) favors longer-chain olefins (Figure 2 and Figure 3).

Biodiesel is of course more complex than *n*-hexadecane because of the ester group and because there is at least one double bond in 90% of the molecules (shown in Figure 4 for methyl oleate). Dissociation should occur mostly at C–C bonds because the C=C and C–O bonds are stronger. The most likely C–C bond dissociation occurs where the activation is lowest and, this is where the allylic radical stabilizes one of the radicals as a resonance structure, R = C–C• and R-C=C•.

Since in soy oil the first double bond always occurs between the ninth and tenth carbon atom in the fatty acid, the most likely dissociation location in 90% of biodiesel mole-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cules occurs between the eighth and ninth carbon atoms (Figure 4).

From these radicals, the ester radical will undergo β-H elimination to produce an olefinic ester with a chain length of ten carbon atoms. The allylic radical will eliminate H to form an α-olefin with 11 carbon atoms.

This simple argument predicts that the dominant olefinic ester will have a chain length of C_{10}. Note from Figure 4 that this is exactly the maximum selectivity observed in the olefinic ester. Since the olefin side of the dissociated radicals can continue to dissociate, it is predicted that α-olefins with 11 carbon atoms or less but seldom more are produced, as shown in Figure 4.

Vegetable oils are widely produced throughout the world, and their production is increasing rapidly.[7] These supplies are probably adequate to replace production of most small olefins with renewable sources instead of petroleum. The short-chain-olefin selectivities we obtain from biodiesel are only around 40%, but all the other products (H_2, CO, α-olefins, and olefinic esters) all have considerable value. Only the CO_2 produced is irretrievably lost as a valuable chemical, so 90% of the carbon in vegetable oils can in principle be converted into chemicals and fuels by autothermal reforming. Olefins typically are priced at about \$0.25 per lb, so vegetable oil below \$3 per gallon should be a competitive source of olefins (\$0.20 per lb). An industrial olefins plant is capable of producing up to 1 billion lb per year by steam cracking. Our process produces about 1 lb per day from a 3 cm^2 reactor, 1 cm in depth, so a reactor would have to be approximately 4.5 meters diameter to match the output of the industrial olefin plant. We have not optimized flow rates, catalyst, preheat, or other variables, so it is likely that improvements in efficiency and yield will be possible. The H_2 selectivity was approximately 85% at the lowest C/O ratio (0.9). Higher H_2 selectivities can be obtained by using H_2O dilution to lower the temperature and increase the CO_2/CO ratio by promoting the water gas shift reaction in staged reactors.[8,9]

Ultimately, it will be necessary to replace fossil fuels by renewable fuels because of issues of supply, global warming, and pollution. The constraints on using renewable fuels as an energy source are considerable because of their limited supply and the need to produce energy at low cost. However, chemicals have a much higher value and require smaller amounts of material than fuels, so the production of chemicals from renewable fuels appears to be less difficult.

The simplicity of the products and product distribution obtained from biodiesel indicates that the mechanism could be as simple as that outlined in Figure 4. The process produces both short-chain and longer-chain olefins and olefinic esters. Since both short-chain olefins and short-chain olefinic esters have considerable value in polymer and copolymer production, this process could be quite attractive as an alternative to making polymers from fossil fuels.

Diruthenium Complex

A Spin-Admixed Ruthenium Complex**

M. Carmen Barral, Santiago Herrero, Reyes Jiménez-Aparicio, M. Rosario Torres, and Francisco A. Urbanos*

Ruthenium complexes attract great attention because of their potential use in electronic and magnetic devices.[1] Multiply bonded diruthenium compounds, in particular, have been investigated as models or building blocks to construct magnets, wires, switches, and other molecular devices.[2] Among this type of compounds the diruthenium(II,III) complexes are the most widely studied owing to their unusual stability.[3,4] In general, they have three unpaired electrons in accordance with a ground state electronic configuration of $\sigma^2\pi^4\delta^2(\pi^*\delta^*)^3$ owing to close spacing of the π^* and δ^* orbitals, as predicted by the theoretical studies of Norman et al.[5] This electronic configuration has been observed in all complexes containing the $[Ru_2(\mu\text{-}L)_4]^+$ unit with L = carboxylate, amidate, hydroxypyridinate, or aminopyridinate.[3,4] When L is a triazenide or formamidinate ligand, the energy difference between the π^* and δ^* levels is larger, and the electronic structure $\sigma^2\pi^4\delta^2\pi^{*3}$ is favored.[6] However, only a few examples of low-spin diruthenium(II,III) complexes with this

electronic configuration are known.[6,7] Moreover, $[Ru_2Cl(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3]$ (DPhF = *N*,*N*′-diphenylformamidinate)[8] has three unpaired electrons, whereas the derivative $[Ru_2(NCS)(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3]$ is a low-spin complex with only one unpaired electron.[7] Chen and Ren also reported high- and low-spin diruthenium(III) complexes with the same core but different axial ligands.[9]

The high sensitivity of the magnetic moment to the nature of the axial ligand in this class of compounds challenged us to find the limit at which the difference in energy between the π* and δ* levels becomes similar to the electron-pairing energy. The aim was to design compounds whose magnetic properties are very sensitive to small changes in the environment.

To facilitate the search for a suitable axial ligand we prepared in good yield an air-stable compound with a labile water molecule at the axial position, namely, $[Ru_2(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3(H_2O)]BF_4{\cdot}0.5\,CH_2Cl_2$ (**1**). Crystals of **1** were used for all measurements, including an X-ray diffraction study.[10]

The crystal structure of **1** (Figure 1) shows an eclipsed paddle-wheel disposition of the equatorial acetate and diphenylformamidinate ligands with a torsion angle of less

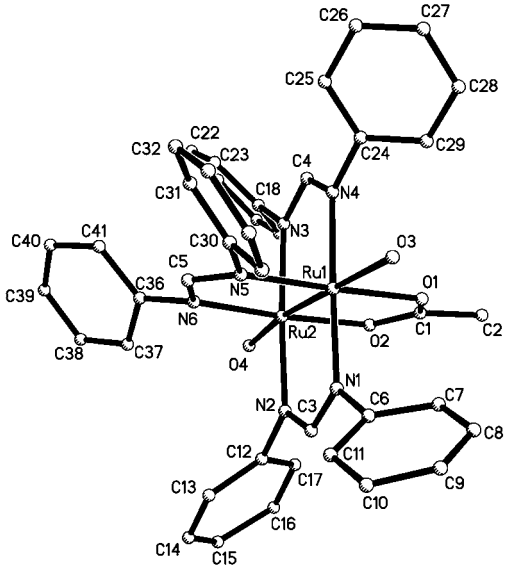

Figure 1. PLUTO view of the cationic unit $[Ru_2(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3(H_2O)]^+$ in **1**. Hydrogen atoms are omitted for clarity.

than 0.5°. The water molecule is coordinated to the axial positions of the diruthenium units with 50% occupancy. The metal–metal bond (2.3503(9) Å) is longer than in the parent compounds $[Ru_2Cl(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3]$ (2.3203(5) Å)[8] and $[Ru_2(NCS)(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3]$ (2.3182(11) Å).[7]

Complex **1** shows exceptional magnetic behavior (Figure 2), intermediate between those observed for the chloro and the isothiocyanato derivatives. The μ_{eff} value at room temperature corresponds to the presence of two unpaired electrons (3.09 μ_B). Similar values for the magnetic moment (between $S = 1/2$ and $S = 3/2$) were also found at room temperature for diosmium(II,III) complexes such as

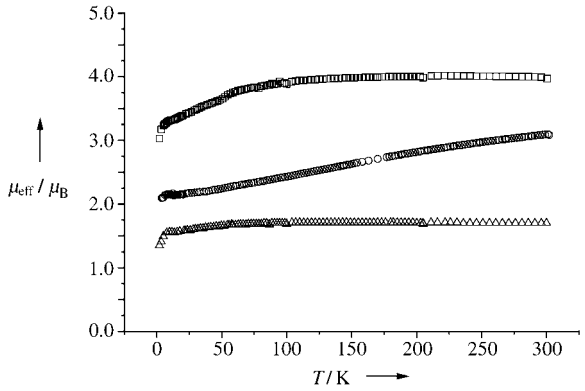

Figure 2. Magnetic moment curves versus temperature for $[Ru_2Cl(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3]$ (□), $[Ru_2(NCS)(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3]$ (△), and $[Ru_2(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3(H_2O)]BF_4{\cdot}0.5\,CH_2Cl_2$ (**1**; ○).

$[Cp_2Co][Os_2Cl_2(\mu\text{-}O_2CPr)_4]$[11] and $[Os_2Cl(\mu\text{-}chp)_4]$ (chp = 6-chloro-2-hydroxypyridinate)[12]: 2.73 and 2.90 μ_B, respectively. However, $[Os_2Cl(\mu\text{-}fhp)_4]$ (fhp = 6-fluoro-2-hydroxypyridinate) has a magnetic moment of 3.70 μ_B.[13] at room temperature. These intermediate values were ascribed to some important contributions of the $S = 1/2$ and $S = 3/2$ spin states.[11–14] Unfortunately, the absence of magnetic data for a wide temperature range prevented the authors from providing a more satisfactory explanation.

Our attempts to simulate the experimental curve of μ_{eff} versus T for **1** as a thermal spin equilibrium (spin crossover) between the $S = 1/2$ and $S = 3/2$ spin states or as a physical spin mixture were unsuccessful. However, this magnetic behavior can be explained by considering a quantum mechanical spin admixture which generates a new discrete spin state by mixing of the $S = 1/2$ and $S = 3/2$ spin states. This mixing of states takes place through spin–orbit coupling[15] when both spin configurations are close in energy (with a difference comparable to or less than the spin–orbit coupling constant).

Such spin admixtures have been observed in several first-row transition-metal complexes, mainly for low-symmetry iron compounds in which high, low, and intermediate spin states are possible.[15] To our knowledge, there is no example of complexes of metals of the second and third transition series that show this type of magnetic behavior. This is not surprising given the usually large energy gap between the different spin states for these type of compounds. However, in complexes with a $[Ru_2(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3]^+$ core, the $S = 1/2$ and $S = 3/2$ spin states are sufficiently close in energy that either can be obtained by variation of the axial ligand. Furthermore, ruthenium is a second-row transition metal, for which significant spin–orbit interactions can be expected. Indeed, in compounds of this kind with three unpaired electrons, the drop in magnetic moment at low temperatures indicates the presence of zero-field splitting, the magnitude of which is related to the strength of the spin–orbit coupling. Therefore, these diruthenium compounds could form spin-admixed ground states with an appropriate axial ligand, as observed in complex **1**. This finding and the potential of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

compound **1** to be used as a building block open the door to designing supramolecular materials with special magnetic properties.

Experimental Section

1 was prepared by adding $AgBF_4$ (0.118 g, 0.606 mmol) to a suspension of $[Ru_2Cl(\mu\text{-}O_2CMe)(\mu\text{-}DPhF)_3]$[8] (0.526 g, 0.596 mmol) in 10 mL of THF. The mixture was protected from light and stirred for 1 day. The bluish solution was filtered though Celite, and the solvent was removed by evaporation. The residue was dissolved in 10 mL of dichloromethane (hydrous), and the resulting solution was layered with 80 mL of hexane. When the diffusion was complete, the crystals were collected. Yield: 81 %. Elemental analysis (%) calcd for **1**: C 50.14, H 3.95, N 8.45; found: C 50.16, H 4.03, N 8.44; IR (KBr): $\tilde{\nu}$ = 3058, 3036, 2959, 1626, 1592, 1531, 1488, 1439, 1316, 1216, 1083, 1057, 1027, 1001, 940, 842, 777, 739, 696, 659, 619, 519 cm^{-1}; UV/Vis (MeOH): λ_{max} (ε) = 495 (5900), 564 nm (6000 $M^{-1}cm^{-1}$); Λ = 118.6 $\Omega^{-1}cm^2mol^{-1}$; ESI-MS ($CHCl_3$): *m/z*: 848 [M^+-H_2O].

Magnetic susceptibility was measured on a Quantum Design MPMSXL SQUID susceptometer and corrected for diamagnetic contributions. The differences in the magnetic behavior for samples prepared directly from crystals to those prepared by crushing the crystals to form disks under pressure are insignificant.

Allylations

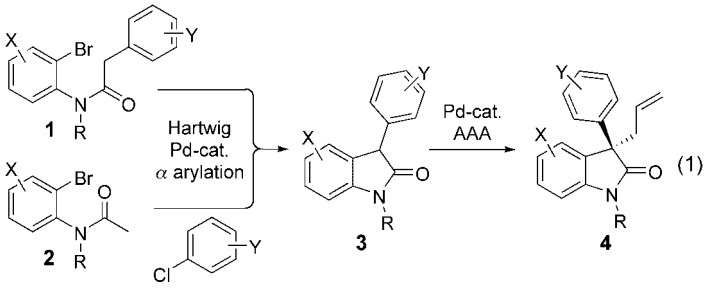
Palladium-Catalyzed Asymmetric Allylation of Prochiral Nucleophiles: Synthesis of 3-Allyl-3-Aryl Oxindoles**

Barry M. Trost and Mathias U. Frederiksen*

The generation of quaternary centers with control of absolute stereochemistry represents a fundamental challenge in synthetic organic chemistry.[1] In this area, we have examined the ability of asymmetric allylic alkylation (AAA) to control stereochemistry at prochiral nucleophiles, a particularly daunting challenge given its direct attack at the face of the allyl fragment opposite to that bound to the metal. Our success with a few classes of nucleophiles exemplified by β-ketoesters,[2] ketones,[3] among others,[4–6] encouraged us to examine new classes of nucleophiles of particular significance such as lactam enolates.

The 3-alkyl-3-aryl oxindole structural motif is a prominent feature in a number of biologically active natural products, for example, diazonamide A[7] and leptosin D,[8] as well as several pharmaceutically active compounds.[9] In spite of the importance of this structural motif, few general methods exist for its construction. Aside from the elegant asymmetric intramolecular Heck reaction developed by Overman and co-workers,[10] only scattered examples based on Pd-catalyzed α arylation[11] and asymmetric acyl transfer have been reported.[12] Pd-catalyzed AAA represents a conceptually novel and flexible approach to this important structural class, especially when combined with the powerful Pd-catalyzed α-arylation protocols for the synthesis of 3-aryl oxindoles developed by Hartwig and co-workers.[11,13] When used in concert, these processes would readily give access to structurally complex oxindoles endowed with a quaternary stereocenter from simple and readily available starting materials [Eq (1)]. Herein we report the successful development of this strategy.

Our studies commenced with a comprehensive matrix screen of bases in the presence of our standard set of ligands **5**–**7** in the Pd-catalyzed AAA reaction of oxindole **8** to form **9** (Table 1).[14] These experiments revealed large variations in yield and enantioselectivity, for example, the use of potassium carbonate in conjunction with ligands **5**–**7** showed a dramatic increase in both yield and *ee* values (Table 1, entries 1–3) relative to other counterions (results not shown). Weaker bases showed better compatibility with this reaction (Table 1, entries 4 and 5). Interestingly, 10 mol% KF gave essentially identical results to the stoichiometric reaction (Table 1, entries 5 and 6). This trend was also observed when nonmetal bases such as Et_3N (Table 1, entries 7 and 8) were used. When BSA was utilized, a spectacular increase in the *ee* value by 36% (from 40 to 76% *ee*) was observed when the base loading was lowered from 1 to 0.1 equivalent (Table 1, entries 9 and 10).



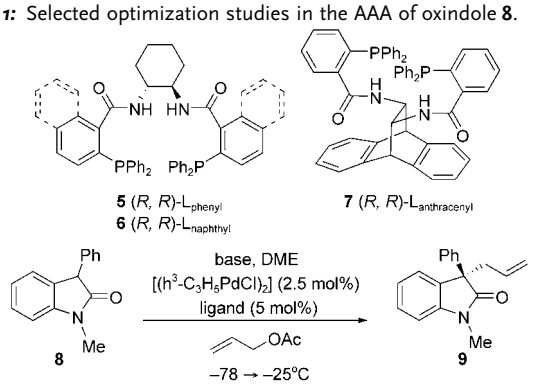


Table 1: Selected optimization studies in the AAA of oxindole **8**.

Entry	Ligand	Base (equiv)	Yield [%][a]	*ee* [%][b]
1	**5**	K_2CO_3 (1.1)	68	19
2	**6**	K_2CO_3 (1.1)	81	28
3	**7**	K_2CO_3 (1.1)	83	56
4	**7**	AcOK (1.1)	92	47
5	**7**	KF (1.1)	86	64
6	**7**	KF (0.1)	84	65
7	**7**	Et_3N (1.1)	66	73
8	**7**	Et_3N (0.1)	66	78
9	**7**	BSA[c] (1.1)	91	40
10	**7**	BSA[c] (0.1)	59	76

[a] Yield of isolated product after chromatography. In all cases, the yields based on recovered starting material are nearly quantitative (>98%). [b] Determined by chiral HPLC. [c] BSA = *N*,*O*-bis(trimethylsilyl)acetamide.

These observations combined with the proficiency of AcOK in this reaction suggested that the addition of only a catalytic amount of base was necessary to initiate the enolization, as ionization of allyl acetate maintained the catalytic concentration of base. However, either the enolate or enol may function as the nucleophile. As oxindoles tautomerize to hydroxyindoles, it seemed reasonable to probe whether it was in fact the latter that acted as the

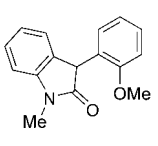
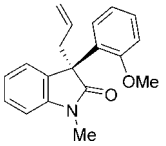
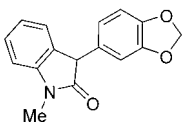
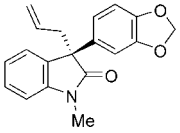
nucleophile. In this case, the reaction should proceed without any external base. It was expected that the rate of tautomerization, and thus the rate of reaction, would be influenced by the polarity of the solvent (Table 2).

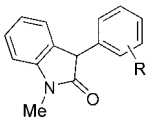
Table 2: Selected additive effects in the AAA of oxindole **8**.

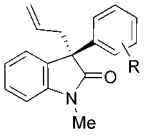


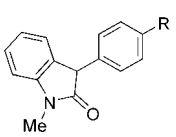


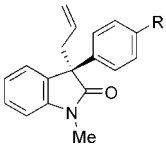


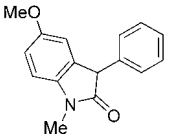


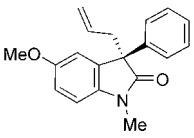


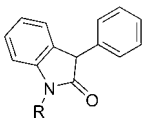


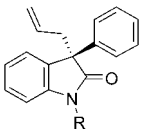












Entry	Solvent	*t* [h]	Yield [%][a]	*ee* [%][b]
1	DME	2	95	61
2	THF	2	75	72
3	CH_2Cl_2	12	31	61
4	PhMe	12	72	78
5[c]	PhMe	12	93	81

[a] Yield of isolated product after chromatography. In all cases, the yields based on recovered staring material are quantitative. [b] Determined by chiral HPLC. [c] *t*BuOH (4 equiv) was used as an additive in this reaction.

In accord with our predictions, the reaction proceeded when carried out in DME (1,2-dimethoxyethane) in the absence of any additives. The reaction was completed in 2 h at 4 °C and afforded **9** in excellent yield with 61 % *ee* (Table 2, entry 1). The reactions in THF occurred with higher enantioselectivity than the reactions in DME (Table 2, entry 2). Further optimization with respect to solvent showed that toluene allowed the highest enantioselectivity, albeit in lower yield (Table 2, entry 4). Reasoning that the oxindole–hydroxindole tautomerization would be significantly faster in hydroxylic media, we next examined the effect of various polar additives in their ability to promote the key tautomerization. After much experimentation, we found that the addition of 4 equivalents of *t*BuOH was optimal and provided the desired product **9** in 93 % yield with 81 % *ee* (Table 2, entry 5).[15] Notably, the yields based on returned starting material are always nearly quantitative, which serves as a testament to the extraordinary selectivity of this reaction. In summary, the use of *t*BuOH (4 equiv), $[(\eta^3\text{-}C_3H_5PdCl)_2]$ (2.5 mol %), and **7** (5 mol %) in toluene at 4 °C under neutral conditions became our standard reaction conditions for the synthesis of 3-aryl oxindoles.

With the optimized procedure established, we sought to examine the scope of the reaction. Thus a number of different aryl oxindoles were prepared and subjected to the standard conditions (Table 3).[16] Significant structural variation in the oxindole system can be accommodated in this reaction.[17] For example, an *ortho*-methoxy group is tolerated (Table 3, entry 1) and the sterically demanding product is obtained in good yield (72 %) with excellent enantioselectivity (97 % *ee*). Otherwise, the method is compatible with electron-rich (Table 3, entries 2–5 and 7) and electron-poor (Table 3, entry 6) aryl groups as well as aryl chloride substituents (Table 3, entry 8). The oxindole core may also be modified. Thus, both the benzo moiety (Table 3, entry 9) and the N-protecting group may be changed as well (Table 3, entries 10–14), for example, the trimethylsilylmethyl group (TMSM) can

Table 3: Scope of Pd-catalyzed AAA of 3-aryl oxindoles.

be used (Table 3, entry 11). This group is interesting owing to the known propensity of such substrates to undergo dipolar cycloadditions,[18] and as such should give access to structurally diverse scaffolds. Other protecting groups may be incorporated, although at a slight detriment to the enantioselectivity. The lower *ee* values attained are intriguing: In the case of aromatic protecting groups (Table 3, entry 12), the lower enantioselectivity may be due to favorable interactions with the phenylphosphino moiety of the ligands which alter the approach of the nucleophile. MOM and SEM aminals (Table 3, entries 13–14) are likely to form stable hydrogen-bonded chelates that confer higher steric demands on the hydroxyindole nucleophile. Simple substituents (e.g. TMSM) may place their sterically demanding groups "outside" the chiral pocket, thereby allowing an ideal approach of the nucleophile to the Pd–allyl complex.

In summary, we have developed an enantioselective palladium-catalyzed AAA reaction for the synthesis of 3-alkyl-3-aryl oxindoles. The salient features of this approach

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are: 1) extraordinarily mild reaction conditions, 2) good to excellent enantioselectivity in the generation of sterically congested quaternary stereocenters, 3) broad substrate scope, and 4) enantioselective access to important structural motifs from readily available and cheap starting material through two Pd-catalyzed processes.

[14] The depicted configuration is based on the absolute stereochemistry of products derived from the Pd-catalyzed AAA of the closely related 3-alkyl oxindoles, which were converted into known compounds: B. M. Trost, M. U. Frederiksen, unpublished results.
[15] The rate of tautomerization does not seem to be influenced by the addition of *t*BuOH alone, as preliminary ^{1}H NMR spectroscopic analyses of a solution of **8** in [D_8]toluene in the presence or absence of *t*BuOD do not differ appreciably. The addition of tetrabutylammonium acetate (5 mol%) shows significant exchange, whereas catalytic amounts of tetrabutylammonium chloride does not. We attribute this to a general acid–general base catalyzed enolization effected by *t*BuOH in combination with the acetate anion generated in situ.
[16] 3-Aryl oxindoles were prepared by α arylation; see Supporting Information for details.
[17] Despite the efficiency of this process, we have so far been unable to expand the scope with respect to other electrophiles.

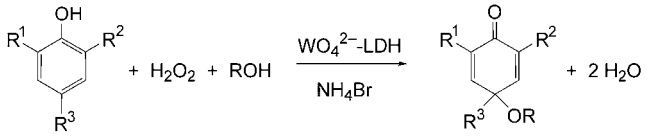
Synthetic Methods

Bromide-Assisted Oxidation of Substituted Phenols with Hydrogen Peroxide to the Corresponding *p*-Quinol and *p*-Quinol Ethers over WO_4^{2-}-Exchanged Layered Double Hydroxides**

*B. F. Sels, D. E. De Vos, and P. A. Jacobs**



The selective oxidation of substituted phenols to yield 4-hydroxycyclohexa-2,5-dienones (*p*-quinols) and their ethers has been intensely investigated in view of their applications as antioxidants, antibiotics, and antitumor agents.[1,2] Besides electrolytic[3] and photosensitized[4] approaches, procedures for quinol preparation require stoichiometric amounts of oxidants, such as Bi^{III} or Tl^{III} salts,[5,6] oxygen at high pressure,[7] hydrogen peroxide,[8] or particularly electrophilic halogens,[9] such as I^{III} reagents, chlorine, or bromine. In view of the risks associated with handling such reactive species, much attention has recently been devoted to the in situ generation of halonium species from harmless halides by using oxygen or hydrogen peroxide.[10] As with haloperoxidase enzymes, this halide oxidation requires a catalyst. Most haloperoxidase mimics reported until now are only effective at extremely low pH values. However, we developed a heterogeneous haloperoxidase-like catalyst based on WO_4^{2-}-exchanged layered double hydroxides (WO_4^{2-}-LDH), which strongly accelerates the halide oxidation with hydrogen

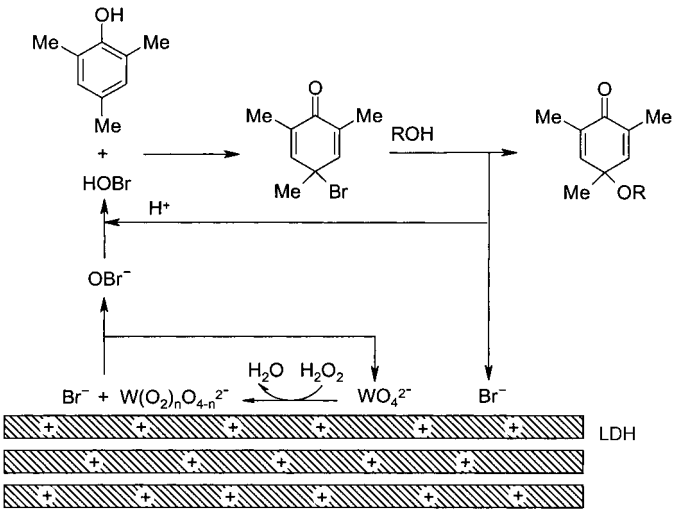
peroxide even at mild pH values.[11] Based on this method, we anticipated the overall transformation of substituted phenols to quinol ethers with hydrogen peroxide in the presence of a bromide salt, the WO_4^{2-}-LDH catalyst, and the appropriate alcohol. If successful, this one-pot synthesis could provide a new route towards the highly valuable *p*-quinol ethers:



Initial investigations focused on the oxidative methoxylation of mesitol (**1**) with hydrogen peroxide in methanol in the presence of a bromide source and 1 mol% WO_4^{2-} exchanged on LDH (Table 1). Hydrogen peroxide was added slowly to the reaction mixture. We employed LDHs as supports with varying compositions $M^{II}_{1-x}M^{III}_x(OH)_2[(WO_4^{2-})_{xy/2}(A^-)_{x(1-y)}]\cdot m H_2O$ ($M^{II} = Zn^{II}$, Ni^{II}, Mg^{II}; $M^{III} = Al^{III}$, Ga^{III}; $A^- = Cl^-$, NO_3^-).[12] In our experience, the oxidative bromination proceeds fastest with LDHs with a large degree of isomorphous substitution ($x = 0.37$) and with tungstate contents of 20–25% of the total anion exchange capacity ($y = 0.25$–0.30). Ni^{II}- and NO_3^--containing LDHs have especially high productivities: quinol ether **1a** was produced in 87% yield within 30 min (Table 1, entry 1). With Mg^{II} in the hydroxide layers or with Cl^- as the counterion, the yield of **1a** is only slightly lower (Table 1, entries 2–3). In contrast, with the homogeneous catalyst Na_2WO_4, only 21% of **1a** is formed after 6 h (Table 1, entry 4). This result highlights the importance of the LDH support in facilitating the bromide oxidation (Scheme 1). Indeed, the cationic surface, decorated with peroxotungstate anions, attracts bromide anions and thus compensates for the repulsion between the negatively charged reaction partners Br^- and peroxotungstate. As a result, the bromide-oxidation rate is increased tremendously. In the absence of either WO_4^{2-}-LDH or Br^-, no product was observed after 12 h (Table 1, entries 5–6). As a solvent, a methanol/ethyl acetate mixture proved suitable, though satisfactory yields were also obtained in pure methanol or other methanol-containing mixtures (73–85%, data not shown). However, when acetone is used or when the water content is too high, the yields of **1a** drastically drop to lower values (32 and 72%; Table 1, entries 7–8).

Table 1: Br^--assisted oxidation of mesitol (**1**) to 4-methyoxy-4-methylcyclohexa-2,5-dienone (**1a**).[a]

Entry	Catalyst, conditions	Yield[b] (Conversion) [%]	*t* [h]	*p*/*o*[c]

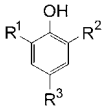
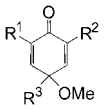
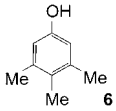
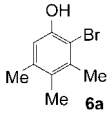
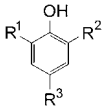
[a] Conditions, unless mentioned otherwise: WO_4^{2-}-LDH ($Ni_{0.64}Al_{0.36}(OH)_2[(WO_4^{2-})_{0.045}(NO_3^-)_{0.27}]\cdot 0.6\,H_2O$) (17 mg), MeOH/EtOAc/$H_2O$ (10 mL; 30:68.5:1.5 vol%), NH_4Br (0.15 M), **1** (0.06 M), aqueous H_2O_2 (35 wt%; added at 2.8 mmol h^{-1}), 60°C. Product yields and identities were determined by GC and GC–MS, and, after product extraction with diethyl ether, by ^1H and ^{13}C NMR spectroscopic analysis. [b] Yield of *p*- and *o*-quinol ethers. [c] Molar ratio of *p*- and *o*-quinol ethers.

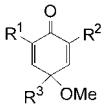


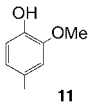


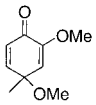


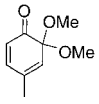












Scheme 1. Bromide-assisted oxidation of mesitol with H_2O_2 to the corresponding *p*-quinol (ether) over WO_4^{2-}-exchanged layered double hydroxide.

The synthetic utility of this heterogeneous tungstate-catalyzed oxidation was evaluated with a wide range of variously substituted phenols (Table 2). Alkylated phenols undergo the Br^--assisted oxidative methoxylation in moderate to excellent yields, especially when the *ortho* and *para* positions are substituted (Table 2, **1–4**; 81–91%). However, when the *ortho* or *para* positions are unsubstituted, stable brominated phenols are the main products (**5–6**). This limitation does not hold for the *p*-alkoxylated phenols (**7–10**), and high yields of the *p*-benzoquinone monoketals are obtained, irrespective of the substitution pattern. A considerable benefit of the catalytic procedure is that the products are not transketalized. Thus, the WO_4^{2-}-LDH can be used for the synthesis of mixed ketal 4-ethoxy-4-methoxycyclohexa-2,5-dienone (**8a**). When Tl salts are used as the oxidant, **8a** is not accessible because of Tl^{III}-induced transketalization.[6,13] Reactions with *o*-alkoxylated phenols, **11**, are less selective and give rise to a mixture of products, including the *o*-quinone monoketal **11b**. The latter is unstable and dimerizes through a Diels–Alder mechanism.[9f]

Finally, the use of various alcohol nucleophiles was evaluated in Table 3. If the bromide salt is sufficiently soluble in the solvent mixture and the alcohol is not too bulky (as for example, *tert*-butyl alcohol), many alcohol reagents lead to the quinol ether products in good yields (75–91%). The oxidative alkoxylation is highly *para*-selective, with *p*/*o* ratios >20:1, in contrast to most existing procedures.[9,14]

10	*t*BuOH		3.2	n.d.	3 (85)

[a] Conditions as in Table 1, except that methanol is replaced by other alcohols.

As is known from previous mechanistic work,[11b] hydrogen peroxide is activated by the tungstate to give peroxotungstates, which in turn oxidize Br^- into hypobromite. As shown in Scheme 1 and in agreement with literature reports,[15,16] subsequent electrophilic bromination of mesitol (**1**) by HOBr generates the 4-bromocyclohexa-2,5-dienone intermediate, which in some reactions was detected as a transient product in small amounts by GC–MS. Under neutral conditions, this compound rapidly reacts with the alcohol to form the quinol ether,[15,17] and the eliminated HBr can participate in a new catalytic cycle. Under acidic conditions, the same 4-Br compound rearranges into the stable 3-bromomesitol.[9e] Clearly, for the success of the overall transformation, it is essential to avoid acidity, which underlines again the need for a haloperoxidase mimic capable of halide oxidation under neutral conditions.

Regarding the efficiency of hydrogen peroxide, it is important to avoid the unproductive reduction of OBr^- by excess hydrogen peroxide, which yields singlet oxygen. Whether this occurs depends on the hydrogen peroxide concentration, the pH value of the reaction conditions, and the reactivity of the phenol. In the case of **1** in 0.15 M NH_4Br, dropwise addition of hydrogen peroxide at a maximum rate of 500 mol (mol W)$^{-1}$ h^{-1} resulted in reasonable yields based on the concentration of hydrogen peroxide.

Careful analysis of the products from **1** showed that the *p*-quinol 4-hydroxy-2,4,6-trimethylcyclohexa-2,5-dienone (**1c**) was always formed in small amounts. Since **1b** is a drug and vitamin E precursor,[2] we briefly investigated its formation. In reaction conditions similar to those given in Table 3, and in a water/THF solvent mixture (9:1), **1c** is produced in 91% yield, with only 2,6-dimethylquinone as a minor byproduct.

In conclusion, we have designed a one-pot metal-catalyzed procedure for the synthesis of 4-alkoxy- or 4-hydroxy-substituted cyclic 2,5-dienones in good yields from a broad range of phenol substrates. Although this particular class of phenol oxidations has often been performed with stoichiometric oxidants, we propose a metal-catalyzed route based on the clean oxidant hydrogen peroxide. A unique feature of the WO_4^{2-}-LDH/NH_4Br/H_2O_2 catalytic system is that high bromide-oxidation rates are decoupled from strong acidity which allows a high chemoselectivity for the desired quinol products to be reached.

Solid Electrolytes

Rapid I^-/I_3^- Diffusion in a Molecular-Plastic-Crystal Electrolyte for Potential Application in Solid-State Photoelectrochemical Cells**

Qing Dai, Douglas R. MacFarlane, Patrick C. Howlett, and Maria Forsyth*

A molecular plastic crystal based electrolyte is described which has almost liquidlike diffusion properties for I^-/I_3^-, a redox couple of interest in photoelectrochemical cells. These cells, which are typically composed of TiO_2 photoanodes covered with dye molecules or a conducting polymer and a liquid-based electrolyte, are currently under intense investigation because of their relatively low-cost materials and extremely simple fabrication techniques.[1] Although dye-sensitized nanocrystalline solar cells (DSSCs) offer high efficiency, comparable to that of amorphous silicon solar cells, a major disadvantage of such devices is the necessity of using a liquid-based electrolyte which includes the dissolved I^-/I_3^- redox couple.[2] A number of difficulties in encapsulation of this liquid electrolyte considerably hinder the long-term stability of these devices. Thus hole-transporting organic materials,[3,4] *p*-type semiconductors,[5] and polymers incorporating the redox couple have been investigated to replace the organic solvent-based liquid electrolytes for solid-state DSSCs.[6–8] Wang et al. have succeeded in employing quasi-solid-state electrolytes based on room-temperature ionic liquids, which yielded up to 7% efficiency in AM 1.5 sunlight.[9,10] However, so far, true solid-state DSSCs have still shown much lower efficiency because of the mass transport limitation of current electrolytes.

In the past we have investigated a family of ionic plastic crystals[11–13] and molecular plastic crystals[14,15] for potential application in Li batteries and fuel cells. In the present study,

succinonitrile, a molecular plastic crystal, was chosen for investigation as a solvent with potential application in solid-state photoelectrochemical cells. This material was chosen because of its similarity to acetonitrile and glutaronitrile, which are commonly used as solvents for DSSCs. Succinonitrile displays the typical behavior of a molecular plastic crystal and has potentially good solvent properties.[16–19] The plastic phase is stable between 233 and 331 K in a body-centered cubic (bcc) structure.[15–20] In this phase the molecules exist in three isomeric conformations: two (identical) *gauche* and one *trans* isomer,[15–19] which are interrelated by a 120° rotation around the central C–C bond.[15–20,22] The bcc unit cell contains two molecules with the C–C bonds oriented along the diagonals of the cube.[16,19,21,23] Below 233 K the molecules exist exclusively in the *gauche* conformation.[16,20] At 233 K the material undergoes a phase change to a plastic phase. The disorder in this phase is related to *trans–gauche* isomerization (involving rotation about the central C–C bond) of the molecules and molecular jumps from one diagonal position of the cubic structure to another.[19,23] Hawthorne and Sherwood suggested that the availability of three possible conformers in succinonitrile has a major effect on the diffusion capability of the molecules, whereby the *trans* isomers act as "impurities" that create monovacancies in the lattice[16,23] and hence lead to high molecular diffusivity. These properties triggered our interest in the concept of fast I^-/I_3^- diffusion in a molecular plastic crystal. Here we communicate our preliminary results which support this concept. The materials described are the first examples of electrolytes based on molecular plastic crystals and exhibit mass transport rates high enough to be of relevance to applications such as DSSC.

The plastic crystal based electrolyte is composed of 0.375 M tetrabutylammonium iodide and 0.225 M iodine in succinonitrile. The redox couple showed good miscibility with succinonitrile, and the electrolyte was a waxy solid at ambient temperature. Typical thermal traces are presented in Figure 1 (left axis). Apparently, the solid–solid transition temperature does not change significantly on addition of the redox couple, as would be expected if the transition is an equilibrium thermodynamic phase change related to structural changes of the matrix phase. The melting behavior is complex, but it is apparent that the material is in a completely solid state below 45 °C. This is still low enough to allow fabrication of a DSSC with the electrolyte in the liquid state, which ensures good penetration into the pores of the nanocrystalline TiO_2. Comparing the enthalpy of the solid–solid transition of succinonitrile in the mixture (65.3 $J\,g^{-1}$) with the expected value (66.5 $J\,g^{-1}$) indicates that the physical properties of succinonitrile itself are not changed after addition of the solutes. Figure 1 (right axis) shows the ionic conductivity. There is a significant step in the conductivity at the melting point, as compared with the pure material, which is consistent with the presence of a significantly greater number of mobile ionic species. The NMR diffusivities and the apparent transport numbers of the cation and the anions are also listed in Table 1. The NMR data suggest that mobile succinonitrile molecules diffusing in the matrix do so at a faster rate (1.3×10^{-6} cm^2s^{-1}) than the cation. The calculated transport numbers further indicate that the mobilities of both I^- and I_3^- are much higher than that of the cation in the succinonitrile electrolyte system.

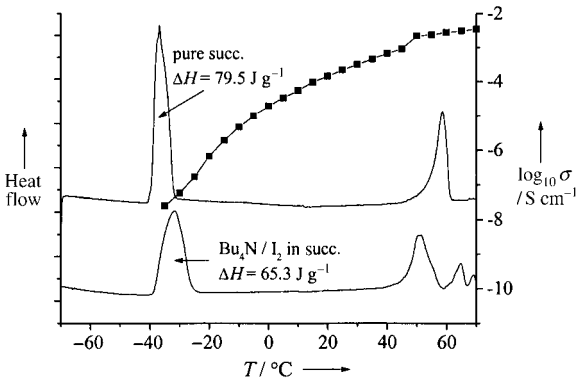

Figure 1. Conductivity (■, right axis) versus temperature for succinonitrile doped by 0.375 M Bu_4NI/0.225 M I_2 and its DSC thermogram (left axis). The thermogram of pure succinonitrile is shown for comparison.

Table 1: Diffusion properties of a molecular plastic crystal based electrolyte at 25 °C (error: ±5%).

	D_{app} [10^{-6} cm^2s^{-1}]		D_{PFG} [10^{-6} cm^2s^{-1}]		Transport number[a]		
	I_3^-	I^-	succ.	Bu_4N^+	I_3^-	I^-	Bu_4N
Bu_4NI/I_2	1.6	6.5	1.3	0.53	0.23	0.64	0.13

[a] The transport number t was calculated from the formula: $t(I_3^-) = [I_3^-]D_{app}(I_3^-)/\{[I_3^-]D_{app}(I_3^-)+[I^-]D_{app}(I^-)+[Bu_4N]D_{PFG}(Bu_4N)\}$.

Figure 2 shows the linear sweep of the molecular plastic crystal based electrolyte. The apparent diffusion coefficients

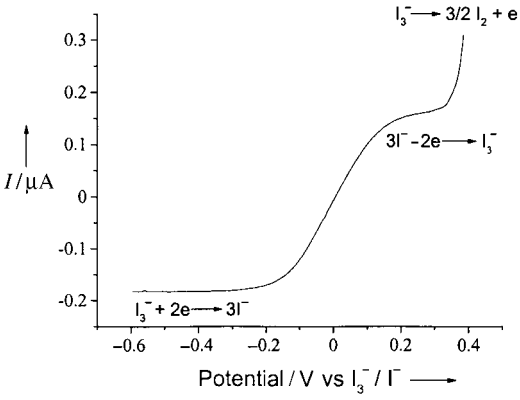

Figure 2. Linear sweep of molecular plastic crystal based electrolyte with Pt ultramicroelectrode at 25 °C. Scan rate: 50 $mV\,s^{-1}$.

D_{app} of iodide and triiodide (Table 1) were calculated from the anodic and cathodic limiting current I_{lim} by using Equation (1)[24] where n is the number of electrons per molecule, F

$$I_{lim} = 4nFDCr \qquad (1)$$

the Faraday constant, C the concentration, and r the radius of the electrode. Comparable data for a commonly used liquid

solvent (acetonitrile) were reported by Matsumoto et al.[25] and recently for a gelled ionic liquid by Wang et al.[10] The results indicate that the diffusivity of I_3^- in the plastic solid is higher than in the gelled ionic liquid. Diffusivities that are higher in the solid state than in the corresponding liquid state have been observed previously[26] and are related to defect motion in the ordered crystalline lattice. Moreover, $D_{app}(I^-)$ in the plastic crystal based electrolyte is 4.7 times larger than in the gel electrolytes.[9,10] The high diffusivity of the iodide ion may reflect the formation of polyiodide species, so that iodide transport is facilitated in a Grotthus-type mechanism. A spectroscopic investigation of these species is underway.

Figure 3 presents short-circuit current densities J_{sc} as a function of light intensity for the plastic crystal electrolyte. For comparison, J_{sc} of the conventional organic liquid electrolyte system under 1 Sun illumination is also shown.

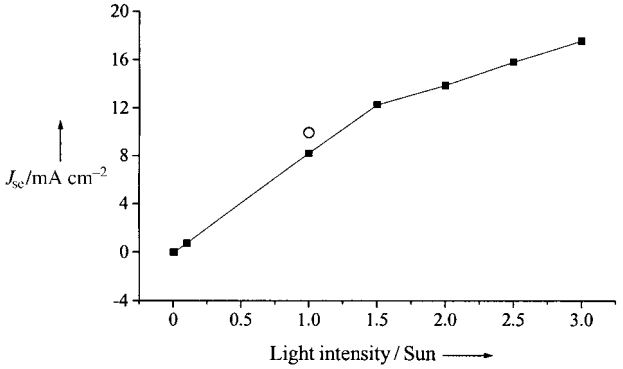

Figure 3. Short-circuit current J_{sc} as a function of light intensity for plastic crystal (■) and organic liquid (○) electrolytes. Photoelectrode size: 5×5 mm.

As described in the Experimental Section, these cells did not contain optimized photoanodes, and the standard thin electrolyte layer (25-μm thick Surlyn) was unavailable; therefore, J_{sc} for the conventional organic liquid electrolyte system is not as high as some published data at 1 Sun illumination. Nevertheless, the data in the figure also show that the electrolyte is capable of carrying currents as high as 18 mA cm^{-2} in the solid state, which corresponds to some of the highest published 1 Sun currents. Furthermore, under 1 Sun conditions, J_{sc} of the plastic crystal electrolyte system reaches 82.8% of that of the conventional liquid electrolyte system. All these values are of sufficient magnitude to be of interest for photoelectrochemical cells. Further increases in short-circuit current for both electrolyte systems are possible by optimizing the electrolyte systems, the TiO_2 working electrode, and the thickness of the electrolyte layer.

This is the first example of a DSSC based on a plastic crystalline electrolyte with high current-carrying capacity. Although the melting point of about 45 °C of the succinonitrile electrolyte system is somewhat low for practical devices for outdoor applications, it is high enough for devices for indoor application. More important, the new concept established here will be very helpful in developing other types of plastic crystal systems with rapid I^-/I_3^- mobility and higher melting points for potential application in photoelectrochemical cells. Further work to optimize the electrolyte composition and cell construction, to characterize the device performance of the succinonitrile electrolyte in photoelectrochemical cells, and to explore better plastic crystal electrolyte systems for application in photoelectrochemical devices are underway.

Experimental Section

Analytical grades of succinonitrile, tetrabutylammonium iodide, and iodine were used. Tetrabutylammonium iodide was recrystallized and iodine was sublimed prior to use. The sample was prepared in an N_2-filled glove box and dried under vacuum at 65 °C for at least 48 h before the measurements. The thermal properties were measured on a Perkin Elmer DSC7 at a scanning rate of 20 °C min^{-1}. Solid–solid phase transition temperatures T_{s-s} and melting/liquid points T_m were determined as a function of composition. Conductivity measurements were carried out in a locally designed conductance cell. During the measurements, the temperature was raised at a steady rate of 0.3 °C min^{-1}. An electrochemical cell equipped with a Pt ultramicroelectrode of 6.4 μm radius as the working electrode, a Pt wire as the counterelectrode, and a Pt wire pseudoreference electrode were used to study mass transport in the electrolyte at 25 °C. ^{1}H NMR pulsed field gradient (PFG) diffusion experiments were used to determine the diffusion coefficients of the doped species in the sample on a Bruker Advance 300 spectrometer at 25 °C.

DSSCs were constructed from TiO_2-coated transparent conducting oxide (TCO) plates (purchased from STA Ltd, Australia), $[Ru(dcbpy)_2(SCN)_2]$ (dcbpy = 2,2′-bipyridyl-4,4′-dicarboxylate), and a Pt-catalyzed TCO counterelectrode. Prior to dye adsorption, electrodes were heated at 450 °C for 15 min to remove any adsorbed water. The electrodes underwent chemical adsorption in the dye solution at 80 °C for 12 h. A 200-μm thick Surlyn gasket was then cut to fit around the TiO_2 film on the electrodes and seal the cells during heating. The plastic electrolyte was sandwiched between the electrodes by filling the cell with the molten electrolyte under vacuum. For comparison, the conventional volatile electrolyte (0.5 M LiI and 0.04 M I_2 in acetonitrile) was then administered by capillary force into the open sandwich cell. The TiO_2 electrodes were soaked in a solution of 0.1 M 4-*tert*-butylpyridine (Aldrich) in acetonitrile (BDH) just before constructing the cells. The current–voltage curves were determined under illumination with an 80-W halogen lamp (Phillips). Labview 6.1 (National Instruments) drove a Keithley 2400 source meter to record the current across a linear voltage sweep from −0.2 to 0.8 V. Light intensity corresponding to 1 Sun was determined by a luxmeter (RS Components, 180–7133). The cells were tested by using an externally calibrated photodiode. Cells were mounted on a heat sink and measurements were limited to less than 1 min to minimize temperature rises.

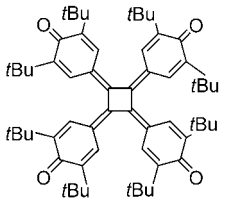
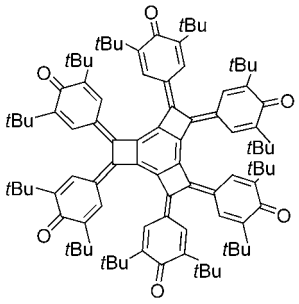
Conjugated Systems



A Hexapentaene-Extended Quinocumulene Cyclotrimerized to a Tricyclobutabenzene Derivative**

Takeshi Kawase, Yuichiro Minami, Naoki Nishigaki, Satoshi Okano, Hiroyuki Kurata, and Masaji Oda**



Quinocumulenes are extended biphenoquinones in which two quinoid rings are linked through a cumulenic π system. In 1967 West and Zecher reported the synthesis of the butatriene-extended quinocumulene **1**.[1] Later, this quinocumulene was shown to undergo thermal or metal-catalyzed dimerization to form [4]radialene derivative **2**.[2] However, a further extension of conjugation had not been explored to

date. We have synthesized a new hexapentaene-extended quinocumulene **3** from the corresponding extended 4,4′-biphenol, and found that **3** underwent cyclotrimerization to form the novel tricyclobutabenzene derivative **4**. Tricyclobutabenzene derivatives have been extensively studied from synthetic[3] and theoretical[4] points of view. Although hexamethylenetricyclobutabenzene (**5**) has been regarded as a key model compound concerning the bond alternation of the central benzene ring,[4,5] no derivative has been prepared so far. We describe herein the mechanism of formation, the molecular structure, and physical properties of **4** as a first derivative of **5**.

A biphenol **6** as a promising precursor of **3** was synthesized from 1-acetoxy-2,6-di-*tert*-butyl-4-ethynylbenzene[6] by Eglinton coupling and deprotection of the acetyl groups under weak alkaline conditions in 77% total yield. The new quinocumulene **3** was readily prepared by treatment of **6** with silver oxide (AgO) in benzene at room temperature for 15 min in 72% yield. The presence of *tert*-butyl groups at C2 and C6 is critical to the formation of **3**, because oxidative treatment of the biphenols **7**–**9**[7] with AgO gave polymeric materials, probably owing to the high reactivity of the corresponding quinocumulenes. Actually, even **3** is thermally labile; when heated at 100 °C in the absence of solvent, **3** was converted into an insoluble material.

Scheme 1. Proposed mechanism for the formation of **4**.

A reaction mixture of **6** and AgO was allowed to stand at room temperature for 3.5 h which led to the disappearance of the generated **3** and the appearance of new products in the mixture. The highly symmetrical cyclotrimer **4** was isolated as a sole product in 54% yield. On the other hand, treatment of **3** with freshly prepared AgO even for 3 days afforded unchanged **3**. Notably, even in the absence of AgO, **4** was obtained almost quantitatively by mixing a solution of **3** and **6** (3:1) in chloroform. The reaction process can be monitored by ^{1}H NMR spectroscopy (see Supporting Information). NMR spectroscopic experiments revealed the stepwise formation of dimer **10**, an acyclic trimer **11**, and **4** (Scheme 1). The reaction of **6** with **3** afforded **10**, and the reaction of **10** and **11** with **3** led to **11** and **4**, respectively. The quinone **3** acts as an oxidizing agent toward these biphenols. In fact, the reaction stopped when **3** is no longer present in the solution. The high lability of **10** and **11** to silica gel chromatography has so far prevented their isolation and further characterization; however, the structures can be deduced from the ^{1}H NMR spectra. Treatment of monoacetate **12** (prepared by partial deprotection of the diacetate of **6**) with AgO afforded the corresponding dimer **13** in 60% yield (Scheme 2). Moreover, when exposed to air or heated at 60 °C, **11** was readily converted into **4**. These results support the assignments. It was already known that oxidation of 2,6-di-*tert*-butyl-4-phenylethynylphenol (**14**) with appropriate oxidizing agents led to the formation of the bismethylenecyclobutene **15** in good yield (Scheme 2).[8] A radical species **16** (Scheme 1) is postulated as a reactive intermediate of the reaction. The intermediate **16** could dimerize through the allenic resonance structure to yield a conjugated bisallene.

Scheme 2. Oxidative dimerization of **12** and **14**.

This, in turn, could cyclize to **15**.[9] In analogy with the mechanism, the cyclotrimerization of **3** would start with the oligomerization of the corresponding monoradical **17** generated by redox reaction of **3** with **6** or AgO used as shown in Scheme 1.

Good single crystals of **4** (with solvent molecules in a 2:1 ratio) were collected from a solution in dioxane.[10] Figure 1 reveals that the molecule has a considerably distorted propeller structure largely deviated from the ideal C_3 symmetry; the torsion angles between the exo methylene double bonds on the same cyclobutane ring are 11.7°, 60.4°, and 62.2°. In particular, the two quinomethide rings involving C27 and C69 carbons are largely curved and slightly twisted from the central benzene plane, probably as a result of steric repulsion of the bulky *tert*-butyl groups. Table 1 shows the

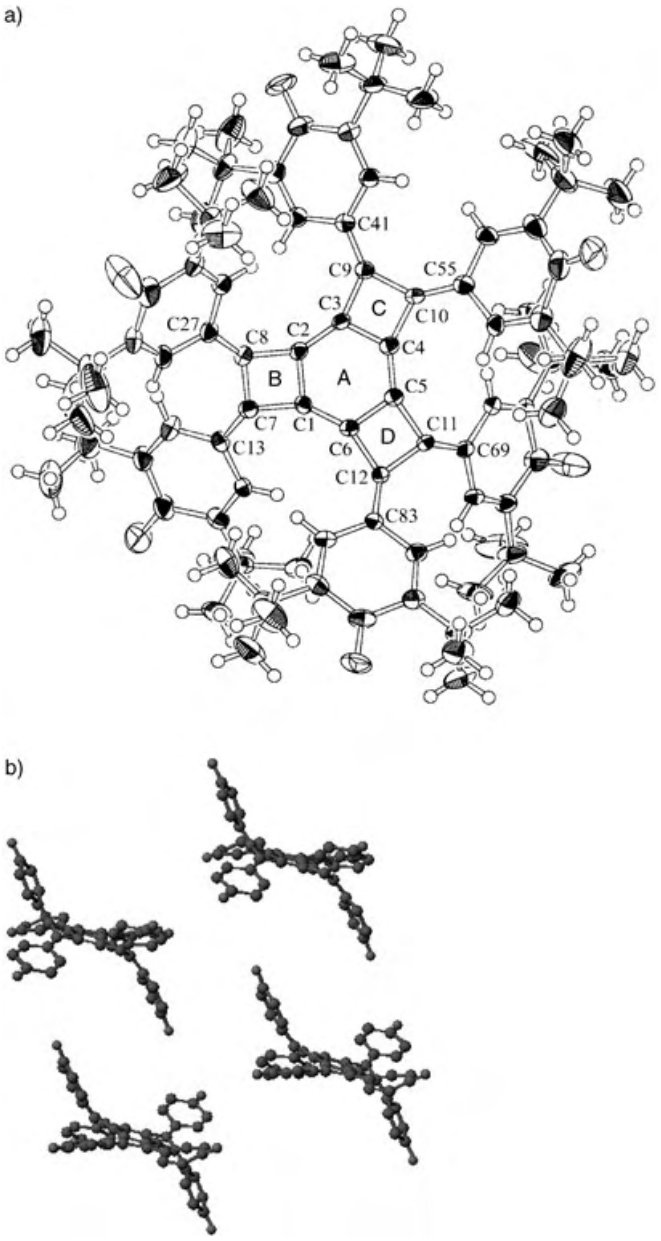

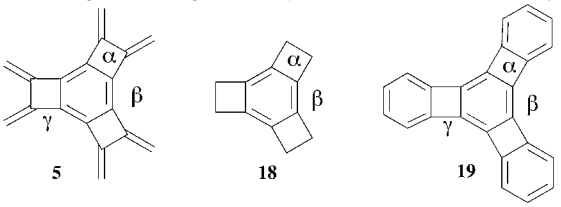

Figure 1. Single crystal structure of **4**: a) ORTEP drawing with 50% probability; b) molecular packing; *tert*-butyl groups and hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: C1–C2 1.441(5), C2–C3 1.373(5), C3–C4 1.426(5), C4–C5 1.381(5), C5–C6 1.435(4), C6–C1 1.371(5), C1–C7 1.483(5), C2–C8 1.477(5), C3–C9 1.489(5), C4–C10 1.478(4), C5–C11 1.487(5), C6–C12 1.487(5), C7–C8 1.507(5), C9–C10 1.515(5), C11–C12 1.499(5), C7–C13 1.362(5), C8–C27 1.370(5), C9–C41 1.360(5), C10–C55 1.372(5), C11–C69 1.357(5), C12–C83 1.357(6); C41-C9-C10-C55 11.7(10), C69-C11-C12-C83 60.4(7), C13-C7-C8-C27 62.2(8); torsion angles between least squares planes: AB 9.4(2), AC 4.3(2), AD 11.1(2), BC 12.1(2), BD 15.4(2), CD 14.7(2).

observed bond lengths of the central benzene rings of **4**, tricyclobutabenzene **18**,[3d] and triangular [4]phenylene **19**[3b] together with the calculated values of **5**.[4b] Despite its nonplanarity, the values of **4** are similar to those of **5**. The degree of bond alternation of these compounds is in the order **19** ≫ **4** > **18**. In conclusion, the present results have experimentally proven that the aromatic character of the outer benzene rings of **19** plays an important role in the high degree of bond alternation of the central benzene ring.

Table 1: Average bond lengths of tricyclobutabenzene derivatives (Å).

	4	5	18	19
α	1.434	1.430	1.413	1.494
β	1.375	1.385	1.390	1.336
γ	1.484	1.484	–	1.500

Selected spectral data for **3** and **4** are shown in Table 2. The longest absorption maximum of **3** is considerably longer than those of **1** (486 nm in C_6H_6) and biphenoquinone **20** (426 nm in CH_2Cl_2). The trimer **4** shows intense absorptions in the visible region of about 400–600 nm which is responsible for its deep coloration. The absorption curve is similar to that of **2**; the longest absorption band of **4** is 20–30 nm shorter and the second-longest absorption band is ≈50 nm longer than

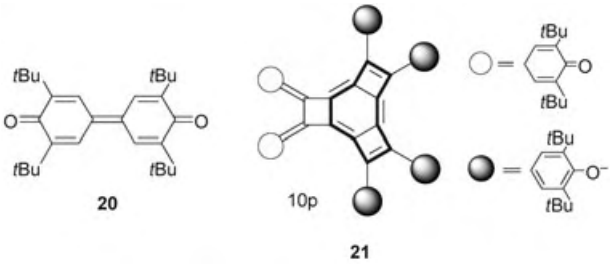

Table 2: Selected spectral data for new extended quinones **3**, **4**, **10**, **11**.

those of **2**.[2] The carbonyl stretching of **3** (1586 cm^{-1}) is almost similar to that of **1** (1590 cm^{-1}), despite the extension of conjugation. On the other hand, the relatively high values of **2** (1630 cm^{-1}), **4** (1617 cm^{-1}), **13** (1608 cm^{-1}), and **15** (1609 cm^{-1})[11] are consistent with the order of distortion of the biphenoquinone structures. Because the average twist angle between the quinomethide rings of **2**[2] (36°) is the largest in these compounds.

The electrochemical properties of **3** and **4** as new electron acceptors were examined by cyclic voltammetry. The reduction potentials of **1**–**4** and **20** are summarized in Table 3.

Table 3: Reduction potentials of extended quinones **1**–**4**, **20**.

	$^1E_{1/2}$	$^2E_{1/2}$	$^3E_{1/2}$	$^4E_{1/2}$
1	−0.65	−0.85		
2	−0.52	−0.85		
3	−0.42	−0.76		
4	−0.61	−0.89	−1.03	−1.35
20	−0.96	−1.29		

V vs. Ag/Ag^+ ($Fc/Fc^+ = +0.26$ V) in 0.1 M nBu_4NClO_4/CH_2Cl_2, sweep rate 100 $mV s^{-1}$.

Quinocumulene **3** shows two sets of highly reversible one-electron reduction waves together with one irreversible oxidation wave (1.40 V). The longest conjugation of **3** in these compounds would account for the highest electron affinity. Moreover, **4** exhibits four sets of highly reversible one-electron reduction waves within the measurable range (1.5 to −2.4 V). The results suggest the facile formation of the tetraanion **21**, which has a 10π electronic periphery.

These results suggest that 2,6-di-*tert*-butyl-4-ethynylphenol derivatives would act as versatile building blocks for the construction of extended diphenoquinone derivatives with novel structure and redox properties.

Tandem Reactions

Enantiospecific Strategy Towards Oxygen-Bridged Terpenoids: Tandem Transannular-Cyclization and Ring-Contraction Processes**

*Antonio Rosales, Rosa E. Estévez, Juan M. Cuerva, and J. Enrique Oltra**

The transannular cyclization of medium-sized rings contributes to the enhancement of molecular rigidity and structural complexity, two properties often associated with biological activity in small molecules.[1] In fact, there are several naturally occurring terpenoids with a transannular oxygen

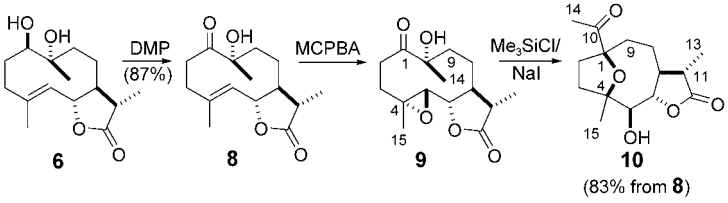
bridge in their 1,4-epoxycyclodecane system, such as dihydroparthenolide diol (**1**),[2] eremantholide A (**2**),[3] and eleutherobin (**3**),[4] all of which show interesting pharmacological properties. The 1,4-epoxycyclononane system, however, is considerably less widespread among natural products, although some examples have been reported.[5] Bioactive terpenoids with the 1,4-epoxycyclodecane motif have attracted the attention of chemists, and different total syntheses of **2**[6] and **3**[7] have been described. Moreover, some procedures for the synthesis of 1,4-epoxycyclononanes have been developed,[8] and other tetrahydrofuran derivatives have recently been prepared by radical tandem reactions.[9] These total syntheses, however, are generally restricted to the preparation of only one or a few specific compounds, require numerous steps and generally give low overall yields.

Hemisynthesis can be a valuable alternative to total synthesis, especially when nature provides sufficient quantities of homochiral raw materials that can easily be isolated from renewable sources. This is true of germacrolides (+)-costunolide (**4**) and (+)-11β,13-dihydrocostunolide (**5**, see Scheme 1), which can be obtained in (multi)-gram quantities from the commercially available extract Costus Resinoid.[10] Additional amounts of these compounds can also be obtained by chemical synthesis.[11] We therefore deemed that accessible germacrolides might well be a suitable starting material for the enantiospecific synthesis of both 1,4-epoxycyclodecanes and 1,4-epoxycyclononanes as they require relatively simple but selective chemical transformations based on the different reactivity shown by the double bonds located at $\Delta^{1(10)}$ and Δ^{4} of the cyclodecadiene ring (Scheme 1).[12]

Scheme 1. Hypothetical strategy for the synthesis of oxygen-bridged terpenoids from accessible germacrolides.

Scheme 2. Enantiospecific synthesis of **1** from **5**. NMO = *N*-methylmorpholine *N*-oxide, MCPBA = *m*-chloroperbenzoic acid, Py = pyridine, Ts = *p*-toluenesulfonyl.



To prove our hypothesis, we selected (+)-dihydroparthenolide diol (**1**) as the first synthetic target. To determine the absolute stereochemistry of natural **1**, we started the synthesis with homochiral (+)-11β,13-dihydrocostunolide (**5**), which was obtained from commercial Costus Resinoid.[10b] Selective dihydroxylation of **5** by using the Upjohn procedure[13] allowed us to obtain diol **6**[14] with a yield of 64%. Treatment of **6** with MCPBA (*m*-chloroperbenzoic acid) in the presence of pyridine furnished epoxide **7**, which was submitted to the next step without further purification. Thus the acid-induced transannular cyclization of crude **7** provided (+)-dihydroparthenolide diol (**1**) in 79% yield (from **6**). The spectroscopic data for synthetic **1** as well as optical rotation measurements[15] agreed with those reported for natural (+)-dihydroparthenolide diol, thus confirming the chemical structure of this metabolite. As the absolute stereochemistry of (+)-11β,13-dihydrocostunolide (**5**) is known,[16] the chemical synthesis of **1** from **5** suggests that the absolute configuration of natural **1** is that as depicted in Scheme 2.

We subsequently approached the second part of our hypothesis, that is, a tandem reaction combining transannular-cyclization and ring-contraction processes that we hoped would lead to 1,4-epoxycyclononanes. Owing to both entropy and enthalpy factors, the synthesis of nine-membered carbocycles by ring-closing procedures is rendered quite difficult.[8a,17] Nine- and ten-membered rings, however, have similar total strain levels,[18] and therefore ring-contraction processes from cyclodecanes to cyclononanes should not be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

seriously hindered by thermodynamic phenomena. Surprisingly, synthetic chemists have not yet exploited this procedure probably owing to the lack of a suitable technique.[19] Within this context we considered that with the anchimeric assistance provided by an OH group located at C-10, an epoxyketone such as **9** might undergo acid-induced transannular cyclization followed by a ring-contraction process that leads to 1,4-epoxycyclononanes (see Scheme 1), and thus open a novel synthetic way towards nine-membered carbocycles.

To this end we prepared crude **9** (Scheme 3) and treated it without further purification with a substoichiometric quantity of Me_3SiCl/NaI. In this manner, we obtained oxygen-bridged cyclononane **10** with a yield of 83% (from **8**).[20] Analysis of HRMS and ^{13}C NMR spectra of **10** supported the tricyclic nature of this product, and the IR spectrum showed bands assignable to alcohol, ketone, and γ-lactone groups. Moreover, in the ^{1}H NMR spectrum, signals at $\delta = 3.75$ (d, $J = 8.9$ Hz, H-5) and 4.30 (t, $J = 9.0$ Hz, H-6) indicated that the

Scheme 3. Enantiospecific synthesis of **10** from **6**. DMP = Dess–Martin periodinane.

OH group was equatorially juxtaposed to the *trans*-fused γ-lactone. The signal for the hydrogen atoms of a methyl ketone unit also appeared in this spectrum at $\delta = 2.19$ (s, 3H, H-14) together with those of two other methyl groups at $\delta = 1.36$ (s, 3H, H-15) and 1.20 (d, $J = 6.9$ Hz, 3H, H-13). The chemical shifts and multiplicities of the protons of these two methyl groups indicate that the former ($\delta = 1.36$) is attached to an oxygenated quaternary carbon center and that the latter ($\delta = 1.20$) is coupled to H-11 ($\delta = 2.32$, dq, $J = 6.9$, 12.0 Hz). The ^{13}C NMR spectrum showed signals for quaternary oxygenated carbon centers at $\delta = 86.0$ (C-4) and 89.0 (C-1), which correspond to the heads of the oxygenated bridge. Furthermore, the HMBC (heteronuclear multiple-bond correlation) spectrum showed correlations between H-5 and C-4, between H-15 and C-4, and between H-14 and C-1, and firmly support structure **10**. Finally, the NOE observed between H-15 and H-6 may be explained by assuming a 1*S*,4*S*,6*S* stereochemistry in which H-6 and the oxygen bridge are situated on the same side of the cyclononane ring (see Figure 1).[21]

The chemical transformation of **9** into **10** represents an unprecedented tandem reaction that provides a straightforward synthetic means of obtaining the otherwise elusive nine-membered carbocycles. This method works well at room temperature under mild conditions, needs only catalytic proportions of Me_3SiCl/NaI, and conforms to the principles of selectivity and atom- and step-economy required in contemporary chemistry.[22] The reaction also produces a substantial increase in molecular rigidity and structural

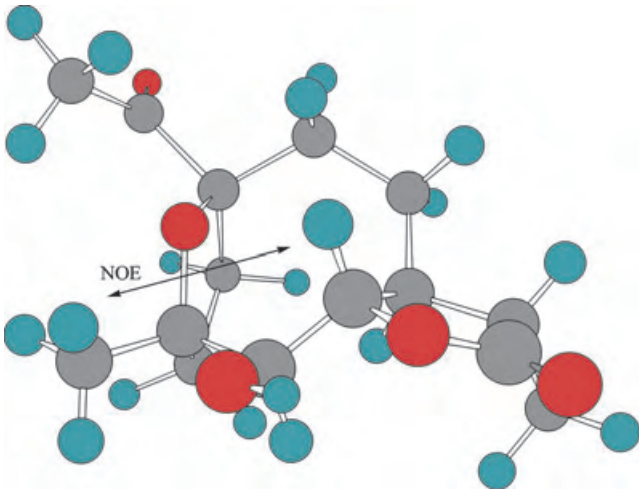


Figure 1. Minimized energy conformation of **10.** NOE between H-6 and H-15. O = red, C = gray, H = blue.

complexity in only one step, thus proving itself to be a potentially useful tool for diversity-oriented synthesis.[1]

Finally, we embarked upon the preparation of (−)-1β,10α-epoxy-11β,13-dihydrocostunolide (**11**) by the selective epoxidation of **5**.[10b] The results obtained in the synthesis of **1** (Scheme 2) suggest that the allylic oxidation at C-3 of **11** followed by the acid-induced transannular cyclization of the corresponding epoxy-alcohol (see Scheme 1) will give the 1,4-epoxycyclodecane model shown by eremantholide A (**2**) and eleutherobin (**3**), a task we are currently engaged on.

In summary, we present an enantiospecific strategy for the synthesis of oxygen-bridged terpenoids from accessible germacrolides. This method has proved to be useful for obtaining antimycobacterial (+)-dihydroparthenolide diol (**1**) and 1,4-epoxycyclononane **10**. The synthesis of **10** employs a novel tandem reaction that combines a transannular cyclization with a ring-contraction process and opens up a new approach to nine-membered carbocycles.

Geochemistry

Hydrogen Processing by Fe^{III}-Exchanged Montmorillonite: A Unique Geochemical Protocol**

Boyapati M. Choudary, Mannepalli L. Kantam, Kalluri V. S. Ranganath, and Kottapalli K. Rao*

Hydrogen processing, such as the production of hydrogen by the reduction of protons and consumption of hydrogen by oxidation, is of renewed interest since hydrogen is regarded as a fuel for the future. Hydrogen has long been known as a biofuel—it can be produced by many microbes under anaerobic conditions and then consumed later on as a fuel[1]—and [Fe]-hydrogenase is known to produce hydrogen, whereas [NiFe]-hydrogenase consumes it.[1–4] During hydrogen production by [Fe]-hydrogenase, the electrons are relayed by hydride clusters. Hydrogenase model compounds, developed from complex and tedious synthetic protocols, are known to facilitate heterolytic H_2 activation and H/D exchange reactions or produce hydrogen catalytically in cyclic voltammetry.[5] Initial results from divergent approaches to the production of hydrogen by photoreduction of protons[6] or by water cleavage[7–9] are quite encouraging.

The Earth's crust has abundant reserves of hydrogen buried in it. Besides dehydrogenation of minerals, such as $Mg(OH)_2$ and silanols of silicates, the interaction of water with the reduced form of Fe^{II}, which is available in the subsurface of the Earth, is thought to contribute to the production and existence of such huge reserves of hydrogen.[10,11] However, the presence of only low quantities of this reduced form of Fe^{II}, which produces hydrogen stoichiometrically, brings into question the extent to which this process contributes to hydrogen production in the Earth's crust.[11] Another geochemically important reaction is the formation of dihydrogen and pyrite from FeS and H_2S under anaerobic conditions.[12]

Despite several attempts, the classical, stoichiometric production of hydrogen in situ by the reduction of protons with Fe^0 powder and acids, which is currently used in industry for the reduction of nitroarenes to anilines and acetanilides,[13] has not yet been transformed into a catalytic reaction. We therefore conceived a nonbiological and nonphotochemical catalytic system for the production of hydrogen by a simple electron-transfer protocol with I^- as the electron source and metal-ion-exchanged montmorillonite clay as the catalyst. This clay is known to promote electron transfer and is abundant in the Earth's crust.[14] The standard Gibbs energy change of reaction for the formation of H_2 and I_2 from H^+ and I^- at room temperature, $\Delta G°$, is $+25.79\ kJ\,mol^{-1}$. Even though the free-energy change ($\Delta G°$) is positive, the above "uphill" reaction has been realized previously by choosing a suitable catalyst and reaction conditions.[15,16] We report herein a unique geochemical protocol for the effective, catalytic electron-transfer from I^- to H^+ to generate I_2 and H_2, two products of commercial importance. The reaction occurs at room temperature, employs carboxylic acids as proton source, iodide ions as electron source, and is catalyzed by recyclable Fe^{III}-exchanged montmorillonite (Fe^{III}-mont) [Eq. (1)].

$$2\,H^+ + 2\,I^- \xrightarrow{Fe^{III}\text{-mont}} H_2 + I_2 \qquad (1)$$

The superiority of Fe^{III}-mont over the other catalysts in terms of turnover number in hydrogen production is clearly evidenced by the results summarized in Table 1 (see also Supporting Information). The activity is correlated to the higher number of acidic sites, which increase with the increased valence state of the cation.[17] Furthermore, the production of hydrogen increases as the percentage of iron in the montmorillonite increases (Figure 1). This result unambiguously demonstrates that iron is the active ingredient in the clay support.

Table 1: Production of hydrogen gas catalyzed by Fe^{III}-mont at different temperatures using water/carboxylic acids as the proton source.

Entry	Proton Source	T [°C]	H_2 evolution (μmol)	Turnover number[a]
1	acetic acid	25	1562.5	8.0, 8.0[b]
2	acetic acid	60	2700.0	13.8
3	acetic acid	150	3370.0	17.3, 17.2[b]
4	propionic acid	150	5400.0	27.7
5	hexanoic acid	150	9370.0	48.0
6	water	25	446.0	2.3
7	water	60	713.8	3.7, 3.7[c]

[a] The calculation is given in the Supporting Information. [b] HI was used in place of NaI. [c] Fourth recycle of the catalyst.

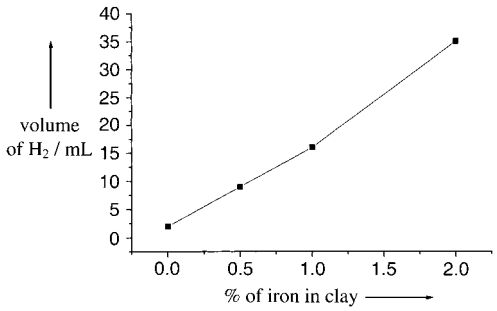

Figure 1. A plot of volume of hydrogen liberated (mL) versus the amount of iron (%) in the clay.

Hydrogen production is enhanced when higher homologues of organic acids or higher temperatures are used (Table 1). The maximum production of hydrogen was found to be 9.37 mmol per g of catalyst using hexanoic acid (Table 1, entry 5). When the production of hydrogen was attempted under identical conditions, but with water as the proton source, no reaction was observed. However, the reaction proceeded well after the addition of a small amount of I_2 as initiator. This result indicates that I_2 reacts initially with I^- to form I_3^- in situ, as determined spectrometrically;[18] it is known that I_3^- is a better electron source to induce proton reduction.[19] The formation of both H_2 and I_3^- at identical rates in an aqueous medium, plotted in Figure 2 as a function of time, further reinforces the proposal that I_3^- is indeed the electron source here. These results are impressive when compared with other examples of electron transfer from I^- to H^+, which require temperatures of 300–400 °C and employ either expensive, noble-metal catalysts or an iodine–sulfur thermochemical process.[15,16] There was no oxygen evolution from the reaction, which further confirms that the electron transfer occurs from the iodide only. Moreover, deactivation of the catalyst was not noticed even after the fifth cycle in the production of hydrogen; the XRD pattern of the catalyst recovered after the fourth recycle remains unchanged (Table 1, entries 1, 5, 7).

In an effort to extend the scope of this reaction and to demonstrate the production and consumption of hydrogen in the reaction catalyzed by Fe^{III}-exchanged montmorillonite, the reductive N-acylation of azo-, cyano-, and nitroarenes was accomplished, in a one-pot reaction, under reflux conditions (Table 2). The selective reduction of azo-, cyano-, and nitroarenes in the presence of other susceptible functional groups, such as carbonyl and chloro groups, is a significant achievement. The catalyst, used for four cycles, shows a slight decrease in activity after each run (Table 2, entry 7). These catalytic reactions effected by the cheap and readily available Fe^{III}-mont are superior to the nonregenerable, stoichiometric hydride reagents or the expensive catalysts needed to reduce azo-[20,21] or cyanoarenes[22–24] under hydrogen pressure. Sim-

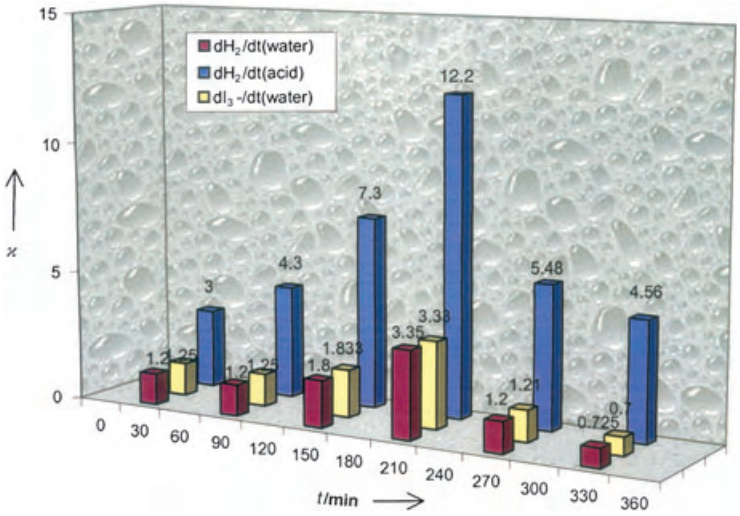

Figure 2. The activity profile diagram for the formation of both H_2 and I_3^- at identical rates in aqueous medium at 60 °C as a function of time. A mixture of catalyst (1.0 g), sodium iodide (40 mmol), and carboxylic acid/water (50 mL) (when water is used as proton source 0.0250 g of iodine was added initially) was heated to 60 °C. x = formation rate of d/dt H_2 or I_3^- [μmol min^{-1} g cat^{-1}].

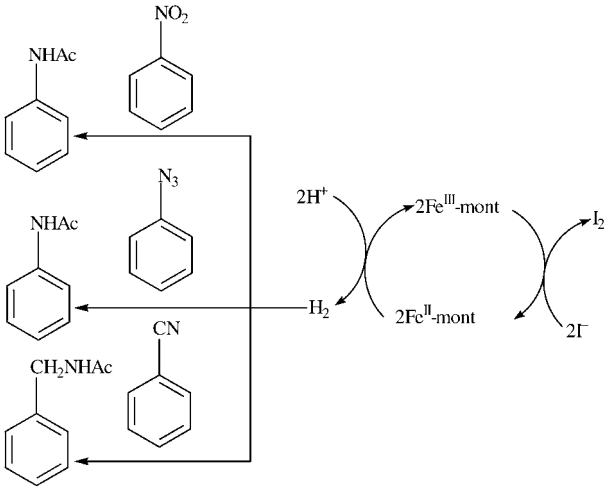

Table 2: Reductive N-acylation of azo-, cyano-, and nitroarenes catalyzed by Fe^{III}-mont.[a]

Entry	Substrate	t [h]	Yield [%]
1	2-azidoanisole	0.50	98, 92[b]
2	4-azidonitrobenzene	0.50	98
3	4-azidochlorobenzene	0.50	100
4	2-azidobenzoic acid	0.50	92
5	benzonitrile	20.0	60
6	benzyl cyanide	20.0	80
7	nitrobenzene	12.0	82, 70,[c] 5[d]
8	*p*-nitroanisole	12.0	74
9	*p*-chloronitrobenzene	16.0	63
10	1-nitronaphthalene	12.0	70

[a] For azoarenes: NaI/acetic acid under reflux; for cyano- and nitroarenes: NaI/propionic acid under reflux. [b] HI/acetic acid under reflux. [c] Fourth recycle of the catalyst. [d] $FeCl_3/FeSO_4$.

ilarly, the reduction of nitroarenes[25–28] is usually performed by nonregenerable, stoichiometric carbonyl complexes or by expensive catalysts under hydrogen or CO pressure.

Fe^{III}-mont was obtained by following a reported procedure.[29] The X-ray photoelectron spectrum ($Fe\,^{2p}_{3/2}$ band) of a catalyst sample generated by the treatment of freshly prepared Fe^{III}-mont with NaI highlights the predominance of Fe^{II} species. However, the heterogeneous catalyst obtained after reductive acylation of nitrobenzene shows larger amounts of Fe^{III} in the montmorillonite (Figure 1 in the Supporting Information). These results provide strong evidence that, upon treatment with NaI, the Fe^{III} centers in Fe^{III}-mont are predominantly reduced to Fe^{II}, which is, in turn, reoxidized to Fe^{III} during the reductive acylation of nitrobenzene. The redox cycle Fe^{III}/Fe^{II}, involving the relay of two electrons from I_3^- to H^+ to form hydrogen, is thus established in the present system (Scheme 1). Conversely, the reductive acylation of nitroarenes conducted in the presence of an

Scheme 1. Fe^{II}/Fe^{III} redox cycle in the production and consumption of hydrogen.

equimolar ratio of $FeCl_3$ or $FeSO_4$ instead of Fe^{III}-mont, under otherwise identical conditions, afforded the desired products in less than 5% yield. These results reinforce our observation that the montmorillonite is an excellent support that facilitates the redox reaction.

In conclusion, the geochemical approach presented here, which provides unambiguous evidence for the production of hydrogen by reduction of protons with the iodide anion as an electron source, even at room temperature, opens up enormous opportunities in hydrogen chemistry. Production of hydrogen by geochemicals, as described here, provides evidence that the vast quantities of hydrogen found in the Earth's crust may be formed by a similar process. The cogeneration of H_2 and I_2 by simple electron transfer has great potential for the economical production of iodine and hydrogen. This methodology has also been used for the catalytic and selective reductive N-acylation of a variety of functional groups.

Experimental Section

General procedure for the production and consumption of hydrogen in the reductive N-acylation of azo-, cyano-, and nitroarenes: A mixture of carboxylic acid (acetic acid for azoarenes and propionic acid for cyano- and nitroarenes; 40 mmol), sodium iodide (40 mmol), substrate (10 mmol), and Fe^{III}-montmorillonite (1.0 g) was placed in a 100-mL, two-necked, round-bottomed flask, which was sealed with a rubber septum and fitted with a reflux condenser. The reaction mixture was then heated to reflux. After completion of the reaction (as monitored by GC), the reaction mixture was filtered. The filtrate was taken up in ethyl acetate (50 mL) and quenched with a 1% $Na_2S_2O_3$ solution (20 mL) to remove the iodine. It was then washed with a 5% sodium bicarbonate solution to remove the unreacted carboxylic acid. The resulting mixture was concentrated under vacuum and the crude product was purified by column chromatography using ethyl acetate/hexane (1:5) as eluent to yield the pure product.

Protein Self-Assembly

Polar Assembly in a Designed Protein Fiber**

*Andrew M. Smith, Steve F. A. Acquah, Neil Bone, Harold W. Kroto, Maxim G. Ryadnov, Marryat S. P. Stevens, David R. M. Walton, and Derek N. Woolfson**

Self-assembling systems are found extensively in biology.[1] An improved understanding of these systems would fuel efforts to engineer novel, bioinspired assemblies through de novo design. Interest in the area is intense because an ability to engineer or design water-soluble self-assembling systems offers routes to novel biomaterials with potential applications in nanobiotechnology.[2–6]

Self-assembling systems based on peptides, proteins, DNA, and RNA are all being explored.[2–6] Furthermore, "living templates", namely fungal hyphae, are being used to direct the hierarchical assembly of nanoparticles.[7] Our focus has been on peptide-based assemblies.[8–10] Specifically, we are interested in making self-assembling fibers and networks from straightforward, synthetically accessible peptide building blocks.

Considerable work has been done to mimic fibrous protein assemblies by using predominantly β-structured peptides that form amyloid-like fibrils.[2,11,12] Relatively less has been done with α-helix-based assemblies.[3,8,13] We have focused on fibrous assemblies based on the α-helical coiled coil, which is a widespread and well-understood protein–protein interaction motif.[14–16]

Specifically, we have combined rules for coiled-coil assembly to design a self-assembling-fiber (SAF) system comprising two complementary peptides, SAF-p1 and SAF-p2.[8] Unlike natural and previously designed coiled coils, which form blunt-ended structures,[14,17] the SAF peptides were engineered to make offset dimers with complementary sticky ends to promote longitudinal assembly into fibers (Figure 1). Helical assembly was confirmed by using circular dichroism spectroscopy and X-ray fiber diffraction,[8] and

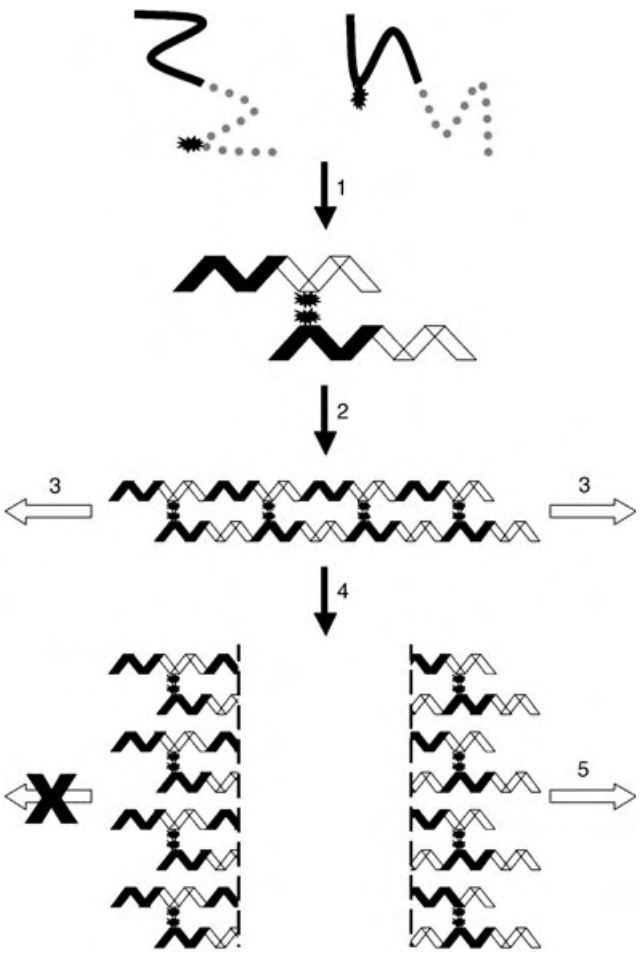

Figure 1. A model for SAF fibrillogenesis. Each SAF peptide is represented by a polar strand with a basic (solid lines) N-terminal half, an acidic (broken/hollow lines) C-terminal half, and a single asparagine residue (starred). These features direct the assembly of a sticky-ended heterodimer (step 1). These heterodimers then assemble longitudinally to give double-stranded coiled-coil protofibrils (step 2). We assume that, at this stage, extension occurs by the addition of peptide building blocks to either end of the protofibril (step 3). At some point the protofibrils have enough affinity for one another to assemble laterally and thicken (step 4). These thickened fibers are polar; that is, when one type of the SAF peptide is added to matured fibers it is selectively recruited to just one end of the fibers (step 5).

more recently by FTIR spectroscopy (unpublished data). Fiber formation was confirmed by electron microscopy (EM), which revealed that the fibers were linear, extended many microns, and were $\approx$45 nm thick:[8] approximately 20 times thicker than expected for coiled-coil dimers.[18] One explanation for thickening is that two-chain assemblies form nascent structures (protofibrils) that assemble further laterally to form the matured, thick fibers (Figure 1). Herein we describe experiments initially conceived to follow lateral assembly directly in water. We also show that this relatively straightforward system displays the unexpected and potentially exploitable feature of polar assembly.

To follow the process of lateral assembly directly in solution we performed the following experiment: A cysteine residue was introduced into SAF-p2a—a variant of SAF-p2—to make SAF-p2aCys (Table 1). This peptide was used to make two fluorescently labeled peptides: one containing fluorescein and the other rhodamine. Each labeled peptide was incorporated separately and at low levels (0.05% total peptide) into otherwise standard SAF-p1:SAF-p2a fiber preparations. When visualized by confocal fluorescence microscopy, the resulting fibers appeared green and red, respectively, and otherwise normal. By mixing these fibers and recording images over time we observed the formation of matured fibers through the emergence of thickened yellow structures (Figure 2a–c). The yellowing did not result from subunit exchange between the solution and fibers, however,

because some of the fibers showed distinct red and green halves and yellow central regions, thus indicating that red and green fibers must have merged in a manner consistent with our model for fibrillogenesis (Figure 1).

We conducted the following additional experiment to probe how individual (or at least small numbers of) peptides were recruited to matured fibers: Fibers containing the fluorescein-labeled peptide were assembled as described above and matured for 16 h, after which time fiber formation had essentially ceased, and the concentration of free monomers had fallen to the critical concentration for fibrillogenesis ($\approx$30 μM).[19] At this point, rhodamine-labeled SAF-p2a was added. Intriguingly, as shown in Figure 2d, the rhodamine-labeled monomers appeared to be selectively recruited to just one end of the matured fibers.

To examine this finding further, and to test the possibility of making nano-to-micron-scale barcodes,[20] but from self-assembling biomolecules, we conducted a further experiment: First, unlabeled fibers were grown for 24 h. Rhodamine-labeled SAF-p2a was then added, and the sample was left to mature for 24 h, followed by the addition of fluorescein-labeled SAF-p2a and further maturation for 24 h. The result was fibers with one end labeled red followed by green (Figure 3). Although there was some background staining of the unlabeled fibers, it was clear that only one end of each fiber was labeled and, moreover, that labeling was in the correct (red–green) order as prescribed in the experiment.

What gives rise to polar assembly in our system? The SAF peptides themselves are polar: They each have a positively charged N-terminal half and a negatively charged C-terminal half (Figure 1).[8] As a result, the designed heterodimeric building block for the fibers, in which the C-terminal half of SAF-p1 binds to the N-terminal half of SAF-p2a and vice versa, will be polar. Thus, the longitudinally extended coiled-coil protofibrils will be polar. On this basis, there may be preferred protofibril–protofibril arrangements that could lead to polar matured fibers. In turn, the different ends of these matured fibers could be distinguished by new incoming peptides (Figure 1), as observed. Indeed, a theory for this type of polar assembly has been advanced,[21] although examples of this type of assembly for soft materials appear to be restricted to natural protein fibers, such as microtubules, intermediate filaments, and collagens,[1,22,23] and, most recently, the fibril form of the yeast prion protein Ure2p.[24] This unexpected mimicry in our relatively simple, designed binary peptide system is intriguing and may shed light on both natural and synthetic self-assembly processes in general. Furthermore, and in view of current attention being given to the generation of bioinspired materials for applications in nanobiotechnology,[2,3,11,25–28] our findings offer promise for nano-to-micron-scale engineering of self-assembling systems from the bottom up in water; for example, the directed incorporation of functionalized peptides—that is, either regularly spaced along the fibers, or specifically located at one end of the fibers—can be envisaged based on the observations presented herein.

Experimental Section

Peptide synthesis: Peptides were made chemically on a pioneer peptide synthesis system (PE Applied Biosystems, CA, USA) by using standard Fmoc-based solid-phase protocols (Fmoc = 9-fluorenylmethoxycarbonyl). Two approaches were taken to introduce the fluorescent labels: For our initial experiments (Figure 2), labeled peptides were prepared by conjugating SAF-p2a-Cys (Table 1) with either fluorescein-5-maleimide or tetramethylrhodamine-5-maleimide (Molecular Probes) by the protocols of the supplier. The labeled peptides were purified on PD 10 columns (Amersham Biosciences, Buckinghamshire, UK) by using the protocol of the supplier. For the later experiments (Figure 3), succinimidyl esters of 5- (and 6-)carboxyfluorescein and 5- (and 6-)carboxytetramethylrhodamine were used to label the lysine residue introduced into SAF-p2a-Lys (Table 1), which was specifically deprotected and subjected to reaction during peptide synthesis by analogous procedures to those published elsewhere.[10] Peptides were purified by semipreparative reversed-phase HPLC and, when necessary for dye–peptide conjugates, beforehand by using PD-10 columns. The final constructs were identified by MALDI-TOF mass spectrometry (Micromass Ltd, Manchester, UK): *m/z*: calcd for SAF-p1: 3174, found: 3175 $[M+H]^+$; calcd for SAF-p2: 3128, found: 3129 $[M+H]^+$; calcd for SAF-p2a: 3325, found: 3326 $[M+H]^+$; calcd for SAF-p2a-Cys: 3300, found: 3301 $[M+H]^+$. Mass increases of 359, 413, 427, and 481 Da were detected for carboxyfluorescein-, carboxytetramethylrhodamine-, fluorescein-5-maleimide-, and tetramethylrhodamine-5-maleimide-labeled SAFs, respectively.

Fluorescence microscopy: For the "kinetic-mixing" experiments (Figure 2a--c), the unlabeled peptides SAF-p1 (100 μM) and SAF-p2a (100 μM) were mixed with the labeled peptide (0.1 μM) in MOPS (3-

(*N*-morpholino)propanesulfonic acid; 10 mM, pH 7). The sample was allowed to mature for 16 h at 20 °C prior to each experiment. The matured solutions were then mixed and either visualized immediately or incubated for a further 24 or 48 h before examination. In the first "polar-assembly" experiment (Figure 2d), fluorescein-labeled fibers were prepared as described above. After the 16-hour incubation the rhodamine-labeled peptide (0.1 μM) was added, and the solution was left for 24 h before examination. For these experiments, samples were visualized by using an x60 oil-immersion lens on a BioRad MRC 600 confocal microscope with a krypton/argon mixed-gas laser, dual-excitation filter, and K1 (520 nm, fluorescein) and K2 (585 nm, rhodamine) filter-block set. Data were collected by using COMOS (BioRad). Images were contrast stretched and false colored red or green before overlaying the two halves.

For the experiments presented in Figure 3, unlabeled fibers were formed first by using our standard protocol (100-μL samples, 100 μM in each of SAF-p1 and SAF-p2a, MOPS (10 mM, pH 7), incubation at 20 °C for 24 h); the sample was then made up to 1 μM in rhodamine-labeled SAF-p2a and incubated for a further 24 h; finally, the sample was made up to 1 μM in fluorescein-labeled SAF-p2a and incubated for a further 24 h. The experiment was repeated with the introduction of the labels in the opposite order (data not shown). Fluorescence and differential interference contrast (DIC) images were recorded on a Carl Zeiss Vision widefield microscope fitted with x10 and x40 LD lenses, a krypton/argon mixed-gas laser, a dichromic mirror, and two light filters (520 nm (filter set 10) for fluorescein and 585 nm (set 15) for rhodamine). Data were collected by using an ORCA ER camera. Images were false colored red or green before they were overlayed by using the Carl Zeiss Vision imaging software.

Supramolecular Chemistry

Liquid-Crystalline Assembly from Rigid Wedge–Flexible Coil Diblock Molecules**

*Jung-Keun Kim, Min-Ki Hong, Jong-Hyun Ahn, and Myongsoo Lee**

There is a growing interest in the rational design of new self-assembling molecules that possess various chemical or biological functionalities and self-assemble into tunable and predictable supramolecular structures.[1] Among self-assembling molecular systems, a dendritic molecular architecture has proved to be a promising scaffold for nanometer-sized aggregation structures including spheres and cylinders.[2–6] Rod–coil block molecules represent another class of self-assembling systems that are increasingly used for the construction of supramolecular architectures with well-defined shape.[7] The supramolecular structures can be precisely controlled by systematic variation of the type and relative length of the respective blocks.[8,9]

Incorporation of a rigid wedge-shaped building block into a diblock molecular architecture gives rise to a novel class of self-assembling systems consisting of a rigid wedge and a flexible coil because the molecule shares certain general characteristics of both dendrons and block copolymers.

Wedge-shaped molecules based on a short flexible coil should self-assemble into discrete supramolecular structures with a highly curved surface, similar to self-assembling dendron molecules. As the length of the flexible coil increases, however, supramolecular structures with a flatter interface might be formed as a result of the increased effective area of the flexible coil and consequent space-filling requirement. Therefore, a combination of the organizing principles of dendritic wedges and block copolymers may open up new possibilities for the design of unique supramolecular arrangements from wedge-shaped dendritic building blocks.

This work focuses on a novel combination of the above perspectives, in which wedge–coil diblock molecules consisting of a rigid wedge and a flexible poly(ethylene oxide) (PEO) coil were investigated. The self-assembling behavior of

these diblock molecules in the melt state was studied by optical polarized microscopy, differential scanning calorimetry (DSC), and X-ray scattering measurements. The molecules self-assembled successively, as the length of the PEO chain increased, into 3D micellar cubic (with *Im3m* and *Pm3n* lattices), 2D hexagonal columnar, 3D perforated lamellar, and smectic-like lamellar structures in the melt state.

The synthesis of rigid wedge–flexible coil diblock molecules, which consisted of the wedge-shaped rigid aromatic segment containing peripheral tetradecyloxy groups and a flexible PEO chain, started with the preparation of an aromatic scaffold with a tetradecyloxy periphery according to the procedures described previously.[10] The final wedge–coil diblock molecules were synthesized by an etherification reaction of a phenolic precursor with the appropriate tosyl-terminated PEO chains. The resulting block molecules were purified by column chromatography on silica gel with ethyl acetate as the eluent and then further purified by preparative gel-permeation chromatography (prep. GPC, see the Experimental Section). The resulting molecules were characterized by NMR spectroscopy, elemental analysis, GPC, and MALDI-TOF mass spectroscopy, and the data were shown to be in full agreement with the structures presented.

As shown in Table 1, all of the molecules had a thermotropic liquid-crystalline structure after melting. The wide-angle X-ray diffraction patterns of all the molecules in the melt state are characterized by a diffuse scattering, which confirms their liquid-crystalline nature. However, a significant structural variation in the melt state was observed as the length of the PEO segment was varied, as evidenced by optical microscopic textures and small-angle X-ray diffraction scattering (SAXS, Figure 1). Compounds **1a** and **1b**, which are based on a short PEO chain, exhibited a lack of birefringence between crossed polarizers, thus indicating the presence of a 3D cubic liquid-crystalline phase. The SAXS study of **1a** revealed a number of well-resolved reflections corresponding to a body-centered cubic structure with *Im3m* symmetry and a lattice parameter of 11.6 nm. However, the SAXS pattern of **1b** appeared to correspond to a 3D cubic structure with a *Pm3n* space group symmetry with a lattice constant of 20.3 nm. These results indicate that the symmetry change in the 3D cubic phase, from an *Im3m* to a *Pm3n* symmetry, occurs with increasing chain length. This symmetry change was also observed for the 3D micellar cubic phase of other dendritic molecules on changing the temperature.[11] The number of molecules per sphere in spherical supramolecular structures is estimated to be 200 and 237 for **1a** and **1b**, respectively.

In contrast, compound **1c** displayed a birefringent mesophase upon melting of the crystalline phase. SAXS studies confirmed the formation of a 2D hexagonal columnar structure with a lattice constant $a = 10.3$ nm, which is in accordance with the phase assignment made by optical microscopy (Figure 2a). Remarkably, further cooling from the hexagonal structure gave rise to a metastable perforated lamellar structure. On cooling from the hexagonal columnar mesophase, arc-shaped striations appeared on the pseudo-focal conic domains at 45 °C (see Supporting Information), which was indicative of transformation into a 3D hexagonal structure. This finding was confirmed by SAXS experiments that showed a number of reflections with low intensity in addition to a strong reflection at a lower angle, which can be

indexed as a 3D hexagonal close-packed structure with lattice constants of $a = 12.3$ nm and $c = 9.2$ nm (Figure 1 d). The peak intensity associated with the (001) reflection appeared to be the most intense, which suggests that the fundamental structure is lamellar, similar to that of the perforated lamellar structure reported previously.[9,12] Thus, this 3D hexagonal structure can be considered as a system of perforated aromatic layers with in-plane hexagonal packing of coil perforations. The consequent layers are stacked in a bilayer AB–AB arrangement to generate 3D order. The tendency of a hexagonal columnar phase to transform into a perforated lamellar phase on cooling is consistent with the results from rod–coil systems described previously.[9c,13]

Compound **1d** displayed a stable perforated lamellar mesophase. Small-angle X-ray scattering revealed a similar diffraction pattern to that of the lower-temperature mesophase of **1c**, which indicates the presence of a bilayer lamellar structure with in-plane hexagonally ordered coil perforations ($a = 14.5$ nm and $c = 11.0$ nm). This phase identification is further supported by transmission electron microscopy (TEM) and optical microscopic observations. The TEM images stained with RuO_4 showed a layered structure with in-plane light-colored coil domains in a matrix of dark rod segments (Figure 3 a). An arc-shaped pseudofocal conic

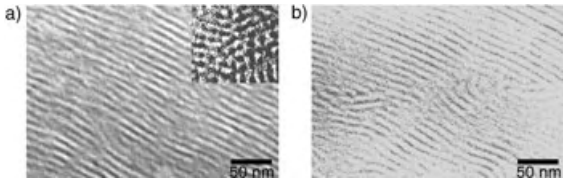

Figure 3. Representative TEM images of a) an ultramicrotomed film of **1d** stained with RuO_4 revealing an ordered array of alternating light-colored PEO layers and dark aromatic layers. texture was observed on an optical polarized microscope (Figure 2 b) on cooling from the isotropic liquid, which supports the formation of a 3D hexagonal structure.[9b] In contrast, compound **1e** exhibited a smectic A phase, as confirmed by optical microscopic texture and X-ray diffraction studies. The layer thickness obtained from the X-ray diffraction pattern appeared to be 11.5 nm, that is, much smaller than the estimated molecular length (17.1 nm by CPK models), and suggests that the molecules are packed with a monolayer lamellar structure in which the rigid wedge segments are interdigitated. This result is further supported by TEM experiments that showed much thinner dark aromatic layers compared to those of **1d** (Figure 3 b). These findings indicate that increasing coil length leads to transformation of a bilayer to an interdigitated monolayer structure.

The results described above demonstrate the capability of manipulating the supramolecular structure by grafting flexible PEO chains of different lengths to the apex of the same wedge-shaped rigid building block (Figure 4). The variation in the supramolecular structure can be rationalized by considering the microphase separation between the dissimilar parts of the molecule and the space-filling requirement of the flexible PEO chains. The molecules based on a short PEO chain can be packed with a radial arrangement to fill the space efficiently, which results in a spherical supramolecular

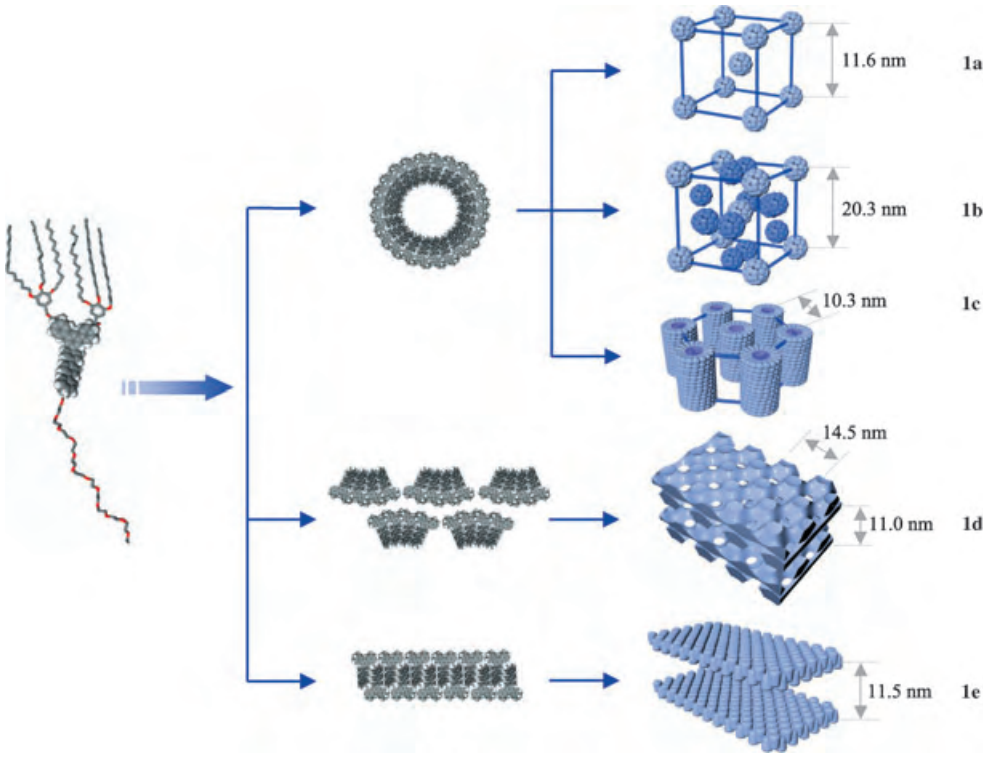

Figure 4. Schematic representation of supramolecular structures formed by wedge-shaped molecules.

structure. Increasing the length of the PEO chain results in more space for the chains being required while maintaining the radial arrangement of the rigid segments. Consequently, the discrete PEO domains will be extended to an infinitely long cylindrical domain in which the coils are less confined, which results in the formation of a 2D hexagonal columnar structure. Further increasing the length results in the rigid wedge-shaped segments assembling into a perforated lamellar structure with a radial arrangement of rigid segments, which allows a greater volume for the PEO chains to explore compared to that of the columnar structure. The radial arrangement of the wedge-shaped rigid segments eventually transforms into a parallel arrangement with interdigitation, to produce a flat interface while maintaining a constant density of the rigid hydrophobic domain. This transformation results in a monolayer lamellar structure as in the case of **1e**.

The self-organization phenomena of the series of rigid wedge–flexible coil diblock molecules demonstrate that systematic variation in the coil length can regulate the supramolecular structure, from 3D micellar cubic with different lattices, 2D hexagonal columnar, and perforated lamellar to smectic-like liquid crystalline assemblies. The primary force responsible for this structural change is believed to be the combination of shape complementarity and microphase separation between rigid and flexible segments. Compared to other self-assembling systems based on dendritic molecules,[2–6,11,14] the remarkable feature of the wedge-shaped building blocks investigated here is their ability to self-assemble not only into spherical cubic and columnar structures, but also into an unusual bilayer lamellar structure with in-plane hexagonally ordered coil perforations. These results demonstrate that this approach of controlling supramolecular structures using wedge-shaped building blocks and only a small variation in the length of grafted coils allows unexpectedly complex superstructures to be produced.

Mesoporous Materials

Single-Crystal Mesoporous Silica Ribbons**

*Jianfang Wang, Chia-Kuang Tsung, Ryan C. Hayward, Yiying Wu, and Galen D. Stucky**

Mesoporous materials have many present and potential future applications for catalysis, chemical and biological separations, chromatography, photonic and electronic devices, drug delivery, and energy storage.[1] They are typically synthesized with amphiphilic organic molecules as templates through the cooperative assembly between these molecules and inorganic species. Since their discovery, control of ordered mesoporous structures and pore sizes has been widely investigated by changing synthetic conditions and by using different types of amphiphiles, including small charged surfactant molecules and large block copolymers. Meanwhile, progress has also been made in the assembly of surfactant molecules and inorganic species into mesoporous materials with a wealth of morphological shapes and internal pore architectures, such as spheres,[2] gyroids,[3] fibers,[4–6] tubules,[7] and thin films,[8] for a variety of applications. Furthermore, cooperative assembly between inorganic and organic components has recently become an exciting approach for the development of novel multifunctional materials.[9]

Ribbon-shaped one-dimensional nanostructures made of transition metals,[10] transition metal oxides,[11] and II–VI semiconductor compounds[12] have been extensively investigated owing to their distinctive geometries, novel physical and chemical properties, and potential applications in magnetic, electronic, and photonic devices. These inorganic ribbons are prepared by using either a vapor–solid or a solution–solid process. They exhibit the same crystallographic structures as the corresponding bulk materials and are usually enclosed by low-index facets with rectangular cross sections. Here, we report the synthesis of single-crystal mesoporous silica ribbons by using small cationic surfactant molecules. These ribbons have tracklike pore channels that are oriented perpendicular to the length of the ribbon and are hexagonally

packed together. The internal pore architecture of these ribbons is significantly different from the two-dimensional hexagonal mesostructure. Previously, helically twisted silica ribbons were prepared with a chiral phospholipid, but they have a lamellar mesostructure that collapses upon calcination.[13] Furthermore, silica ribbons with hexagonal mesoporous structures have been prepared with electrospinning, but the organization of their pore channels is polycrystal-like with the pore channels in different domains oriented randomly.[14] To the best of our knowledge, there have been no reports on the formation of single-crystal-like mesostructured silica ribbons with highly organized pore channels remaining after calcination.

In the past, a two-phase route has been used to synthesize one-dimensional mesostructured silica materials with silica precursor molecules dissolved in an oil phase and surfactant molecules dissolved in a separate water phase.[4,15] The morphologies and internal pore architectures of the resulting mesostructured products depend strongly on the supply of silica precursor molecules that diffuse from the oil phase through the interface to the water phase.

In contrast, we believe that a one-phase synthesis procedure carried out in dilute aqueous solutions of surfactant molecules and hydrolyzed silica species might be used to reduce the nucleation and growth rates of mesostructured products. By this procedure, their morphological shapes and internal pore architectures would be largely determined by the cooperative assembly between silica species and surfactant molecules in a single aqueous growth solution. With this in mind, we have developed a one-phase route to synthesize one-dimensional mesostructured silica materials with cationic hexadecyltrimethylammonium or hexadecylpyridinium surfactants as templates and tetraethyl orthosilicate (TEOS) as a silica precursor under acidic conditions. This approach has been used to selectively synthesize either mesostructured silica nanofibers that have hexagonal fiber cross sections with pore channels aligned parallel to the fiber axis or mesostructured silica fibers that have circular fiber cross sections with pore channels wound circularly around the fiber axis with an acid concentration of approximately 4.0 M.[6] The one-phase route can readily expand the kinetic control range of synthetic parameters, including the concentration of the acid, temperature, concentrations of the surfactant and the silica precursor, and the type of surfactant, and it has the potential to allow the synthesis of more complicated mesostructured configurations. Indeed, we found that the one-phase synthesis with an acid concentration in the range of 1.0–2.0 M led to the formation of one-dimensional mesostructured silica materials that were all in the form of ribbons.

After the one-phase synthesis, fiberlike flocculates were seen suspended in the growth solutions. Scanning electron microscopy (SEM) images taken of the flocculates, which were isolated, washed with distilled water, and dried, indicate that they consist of a large quantity of fiberlike structures with typical lengths of the order of several hundreds of micrometers (Figure 1a). SEM imaging at higher magnifications reveals that the geometrical shape of the silica fiberlike structures is a ribbon (Figure 1a, inset), which is clearly distinct from the shape of the previously reported mesostructured fibers.[4–6] Each silica ribbon has a relatively uniform width along its entire length, and the typical widths of the ribbons are in the range of 0.4–1.5 μm. Some ribbons were seen twisted along both their length and width axes, which suggests that as-synthesized mesostructured silica ribbons have a low bending stiffness. Low-angle X-ray diffraction (XRD) measurements show that the as-synthesized ribbon sample exhibits two diffraction peaks, which remain after calcination (Figure 1b), indicating that these ribbons are ordered mesostructures. The diffraction patterns can be indexed according to a two-dimensional hexagonal lattice. The determined lattice constant for the as-synthesized ribbons is $a = 4.7$ nm, which reduces to $a = 4.3$ nm after calcination.

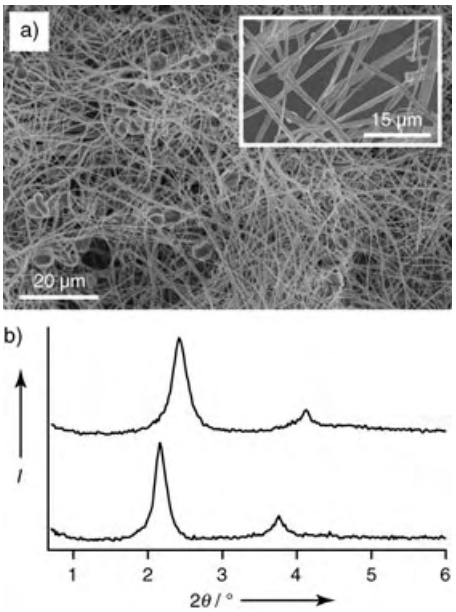

Figure 1. Mesoporous silica ribbons. a) SEM image of the mesostructured ribbons synthesized with hexadecylpyridinium bromide (C_{16}PB) surfactant. Inset: a magnified SEM image showing clearly the ribbon shape of the synthesized products. b) Low-angle XRD patterns recorded on the as-synthesized (lower; $d(100) = 4.09$ nm, $d(110) = 2.35$ nm, $a = 4.7$ nm) and calcined (upper; $d(100) = 3.65$ nm, $d(110) = 2.15$ nm, $a = 4.3$ nm) ribbons.

Low-magnification transmission electron microscopy (TEM) images confirm that the geometrical shape of the fiberlike structures is a ribbon (Figure 2a) and that each ribbon has a uniform width along its length (Figure 2b). From the TEM images taken at high magnifications of the individual ribbons that are flat and straight, hexagonally packed pore channels are observed at the edge of each ribbon, whereas parallel fringes oriented perpendicular to the length of the ribbon are observed in the central region of the ribbon (Figure 2c). In fact, the hexagonally packed pore channels are visible at both the left and right edges of each ribbon. Moreover, the hexagonally packed pore channels at the edges and the parallel fringes in the central region can be seen over the entire length of the individual ribbons that are straight and untwisted, which demonstrates that these ribbons are structurally uniform.

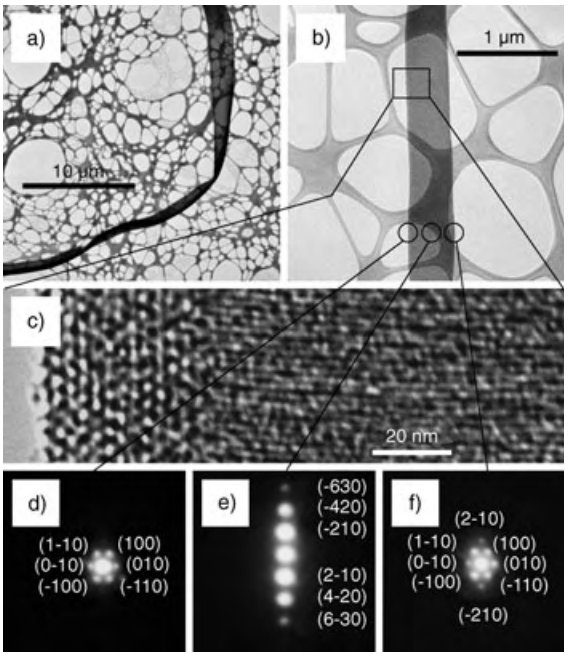

Figure 2. TEM images of mesoporous silica ribbons showing their geometrical shape and internal pore architecture. The ribbons were synthesized with C_{16}PB surfactant and calcined. a) TEM image of a twisted ribbon that shows the characteristic ribbon shape. b) TEM image of a straight ribbon that shows a uniform width along its length. c) Zoomed-in TEM image of the boxed area in Figure 2b that shows hexagonally packed pore channels at the edge and parallel fringes oriented perpendicular to the length of the ribbon in the central region of the ribbon. d)–f) Selected-area electron diffraction patterns taken at the left edge, in the central region, and at the right edge, respectively, of the ribbon shown in Figure 2b. The diffraction patterns are indexed according to a two-dimensional hexagonal lattice. The zone axes for Figure 2, d–f, are [001], [120], and [001], respectively.

The organization of the pore channels in the mesoporous silica ribbons is also revealed by the selected-area electron diffraction patterns recorded at the edges and in the central region of the individual ribbons. Hexagonal diffraction patterns are observed at the edges (Figure 2, d and f) and a string of diffraction spots are obtained in the central region (Figure 2e) which indicates that each mesoporous ribbon is single-crystalline. The diffraction patterns recorded at the edges and in the central region can be indexed separately according to a two-dimensional hexagonal lattice, with zone axes [001] and [120], respectively.

To further verify the morphological characteristics and ascertain the internal pore architecture of the mesoporous silica ribbons, we performed microtoming to cut thin cross-sectional slices of the ribbons. Figure 3, a and c show the TEM images of the cross sections that are perpendicular to the length of the ribbon. These cross sections are semicircular at the edges and rectangular in the central region. The cross-sectional TEM images at higher magnifications reveal that the pore channels in the central region are aligned parallel to the width of the ribbon (Figure 3b) and those at the edges curve around semicircularly (Figure 3d). These pore channels appear to be tracklike, and the curvatures of the pore channels from outside to inside at the edges become increasingly larger. The pore channels that are close to the central region curve back to make sharp turns of 180° and the innermost channel becomes a single straight pore channel. Furthermore, we also observed cross sections that are parallel to the length of the ribbon (Figure 3, e and f) as judged on the basis of the cross-sectional size and the organization of the pore channels. With this viewing configuration, hexagonally packed pore channels aligned parallel to the width of the ribbon are observed.

Taking together all of the structural observations of the mesoporous ribbons, including selected-area electron diffraction patterns and high-magnification TEM images recorded from different viewing directions, we have constructed a three-dimensional model of the internal pore architecture of the mesoporous silica ribbons (Figure 4). Each ribbon is composed of a large number of tracklike pore channels that are oriented perpendicular to the length of the ribbon and are hexagonally packed together. For a ribbon with a thickness of 120 nm, a width of 800 nm, and a length of 100 μm, which are the typical dimensions of these mesoporous ribbons, it is estimated that there are about 4×10^5 tracklike pore channels with perimeters in the range of 1 to 2 μm. It is remarkable that such a large number of the pore channels with a uniform pore size and varying perimeters can assemble together with such high order to form a mesoporous ribbon.

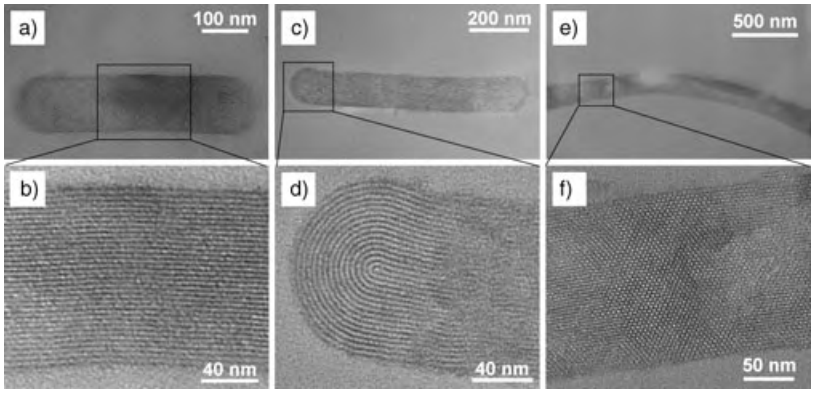

Figure 3. Cross-sectional TEM images of mesoporous silica ribbons showing their geometrical shape and internal pore architecture. The ribbons were synthesized with C_{16}PB surfactant and calcined. a) TEM image of a cross section that is perpendicular to the length of the ribbon. The ribbon has a width-to-thickness ratio of approximately 4.3. b) Zoomed-in TEM image of the boxed area in Figure 3a that shows parallel pore channels in the central region of the ribbon. c) TEM image of a cross section that is perpendicular to the length of the ribbon. The ribbon has a width-to-thickness ratio of about 7.0. d) Zoomed-in TEM image of the boxed area in Figure 3c that shows pore channels curving back at the edge of the ribbon. e) TEM image of a cross section that is parallel to the length of the ribbon. Only a short segment is shown here: the actual length of the ribbon is more than 10 μm. f) Zoomed-in TEM image of the boxed area in Figure 3e that shows hexagonally packed pore channels. The occurrence of blurred lattice structures in some regions of the ribbons is probably due to the nonuniform distribution of strain induced by microtoming.

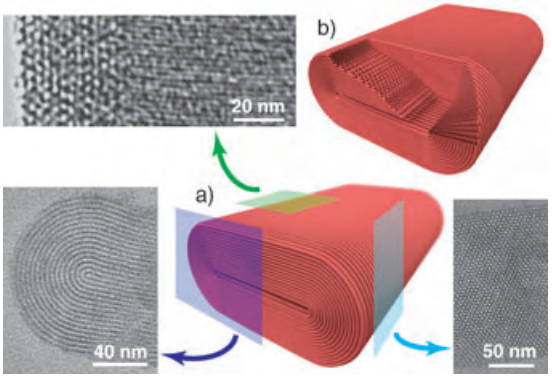

Figure 4. Three-dimensional model of the pore structure of individual mesoporous silica ribbons. a) Overview with overlapping planes showing the relationship between recorded TEM images and different viewing directions relative to the ribbon. b) A portion is cut away to show the internal pore architecture.

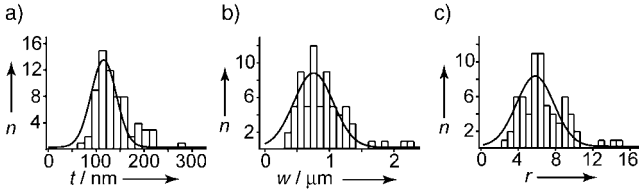

Figure 5. Size distributions of the calcined mesoporous silica ribbons synthesized with C_{16}PB surfactant: a) thickness (t), b) width (w), and c) width-to-thickness ratio (r). The number of counted ribbons is 68.

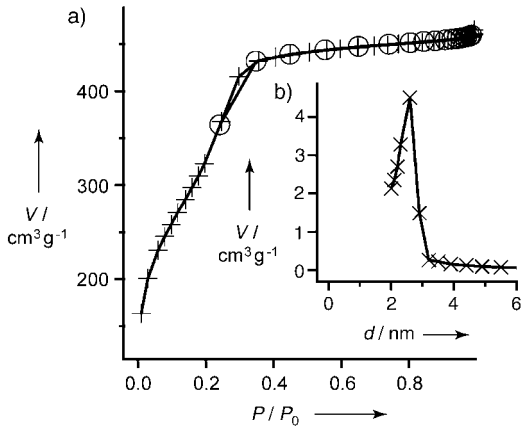

Figure 6. Nitrogen adsorption–desorption measurements of mesoporous silica ribbons obtained with C_{16}PB surfactant. a) Sorption isotherms (+ = adsorption, ○ = desorption). b) BJH pore size distribution obtained from the adsorption branch (d = diameter).

According to the three-dimensional model, hexagonally packed pore channels at the edges and parallel fringes in the central region are visible under TEM imaging when a mesoporous ribbon that stays flat and straight is viewed normal to its flat portion. The top and bottom surfaces of the flat portion of the ribbon are enclosed by ±(010) facets. On the basis of the organization of the pore channels as shown in Figure 4, the spacing between the neighboring parallel fringes in the central region should be half of the hexagonal lattice constant at the edges, which is in excellent agreement with the measurements made by using the TEM images as shown in Figure 2c. Furthermore, it can be seen from the model that tracklike pore channels are visible on the cross sections that are perpendicular to the length of the ribbon, and hexagonally packed pore channels are visible on the cross sections that are parallel to the length of the ribbon, which is also in agreement with our observations from TEM.

The internal pore architecture of the mesoporous silica ribbons is not a simple truncation of the two-dimensional hexagonal mesostructure. As described above, the pore channels in the mesoporous ribbons are curved at the edges with a tracklike conformation. Unlike the transition metal oxide ribbons, which are enclosed by low-index facets and have rectangular cross sections,[11] the mesoporous silica ribbons have smooth external surfaces without sharp edges. There have been no reported materials that exhibit such structures. The closest structural analogy are ribbons obtained from the spontaneous hierarchical self-assembly of highly charged cytoskeletal filamentous actin and cationic lipid membranes.[16] These ribbons also exhibit tracklike cross sections, but are composed of folded two-dimensional lipid bilayers sandwiched between two layers of actin.

The size distributions of the mesoporous silica ribbons were measured from the cross-sectional TEM images taken on microtomed samples (Figure 5). The ribbons have an average thickness of (120 ± 30) nm, an average width of (0.8 ± 0.3) μm, and an average width-to-thickness ratio of (6 ± 2).

The nitrogen adsorption–desorption isotherms measured at −196 °C for the calcined mesoporous silica ribbons are shown in Figure 6a. The isotherms can be classified as type IV isotherms without hysteresis. The ribbons exhibit a nitrogen Brunauer–Emmett–Teller (BET) surface area of 1200 $m^2 g^{-1}$, and the single-point total desorption pore volume at a relative pressure of 0.98 is 0.71 $cm^3 g^{-1}$. The Barrett–Joyner–Halenda (BJH) pore size distribution plot (Figure 6b) determined from the adsorption branch shows a sharp peak at 2.6 nm with a full width at half maximum (FWHM) of 0.8 nm.

In summary, single-crystal mesoporous silica ribbons that are 50–250 nm thick, 0.4–1.5 μm wide, and hundreds of micrometers long have been synthesized by using a one-phase route in dilute aqueous solutions of surfactants and silica species under acidic conditions. The mesoporous ribbons have excellent long-range order with tracklike pore channels oriented perpendicular to the length of the ribbon and hexagonally organized. Our one-phase route to the selective synthesis of one-dimensional mesostructured silica ribbons, together with our previously reported mesostructured silica nanofibers with controlled cross-sectional shapes and internal pore architectures,[6] provides a relatively simple reaction system for further developing theoretical models for the cooperative assembly between inorganic and organic components. Understanding the thermodynamics and growth kinetics involved in the formation of the mesostructured materials of particular morphological shapes and internal pore architectures can further help in creating novel inorganic–organic hybrid functional materials with desired hierarchical structures through the cooperative assembly between inorganic and organic building components.[9]

Experimental Section

Mesostructured silica ribbons were prepared with cationic hexadecyltrimethylammonium or hexadecylpyridinium surfactants and TEOS (tetraethyl orthosilicate) silica precursor. In a typical synthesis batch with C_{16}PB (hexadecylpyridinium bromide) surfactant, a 37 wt% solution of HCl (6.51 g) was mixed with distilled water (43.49 g), and C_{16}PB (0.21 g) was dissolved into this mixture. The resulting solution was stirred until the surfactant molecules were dissolved completely. TEOS (177 μL) was then added. After the solution was stirred at room temperature for 10 min, it was transferred to a 60 mL glass vessel. The vessel was closed and kept in an isothermal oven at approximately 65 °C for 2 days. Within this period of time, fiberlike flocculates suspended in the solution were observed. The flocculates were removed after growth, washed with distilled water, and dried at 100 °C in air. The yield of mesostructured ribbons from each synthesis was estimated to be about 25 wt%. To remove cationic surfactants, dried ribbon samples were calcined in a box furnace in air at 500 °C for 5 h, with a ramp rate of 1 °C min^{-1}. We found that mesostructured silica ribbons can only be synthesized within a certain range of concentration of HCl. The reaction composition with which ribbons can be obtained for C_{16}PB is 100 H_2O:2.0–3.5 HCl:0.02 C_{16}PB:0.03 TEOS (in molar ratio). Furthermore, mesostructured ribbons can also be obtained from the syntheses with hexadecyltrimethylammonium chloride (C_{16}TMAC), hexadecyltrimethylammonium bromide (C_{16}TMAB), and hexadecylpyridinium chloride (C_{16}PC) surfactants. The reaction compositions using C_{16}TMAC, C_{16}TMAB, and C_{16}PC for producing mesostructured ribbons are 100 H_2O:1.5–2.5 HCl:0.02 C_{16}TMAC:0.03 TEOS, 100 H_2O:1.5–2.5 HCl:0.02 C_{16}TMAB:0.03 TEOS, and 100 H_2O:2.0–3.5 HCl:0.02 C_{16}PC:0.03 TEOS, respectively. In contrast, ribbons were not obtained from syntheses that involved trimethylammonium surfactants with dodecyl, tetradecyl, or octadecyl hydrophobic tails. Low-angle XRD patterns with a step of 0.02° and time-per-step of 2 s were obtained on a Scintag PADX diffractometer by using Cu K_α radiation. SEM studies were performed on a JEOL 6340F microscope operating at 2–5 keV. TEM studies were carried out on a JEOL 2010 microscope operating at 200 keV. Silica ribbon samples were dispersed into ethanol and then deposited onto either silicon wafers or copper grids coated with carbon-stabilized lacey formvar for SEM or TEM imaging, respectively. To obtain cross-sectional TEM images, ribbon samples were embedded into a thermocurable resin (Eponate 12 kit, Ted Pella) and kept at 60 °C overnight. The embedded ribbon samples were then microtomed into thin slices of around 70 nm thickness, which were transferred onto bare copper grids for TEM observations. Nitrogen adsorption and desorption isotherms were measured using a Micromeritics TriStar 3000 system at liquid nitrogen temperature (−196 °C) after the samples were degassed with flowing nitrogen at 200 °C overnight.

Metal–radical interactions are at the heart of many biocatalysts that contain transition metals. The cover picture shows the structure of a dicopper(II) complex in which a phenoxyl radical bridges the metal centers. The three spins are ferromagnetically coupled, as the black arrows indicate. In their Communication on page 438 ff., F. Thomas and co-workers describe the synthesis, structure, and properties of this type of complex. The stability and reactivity are dictated by the nuclearity of the complex and the nature of the coordinating solvent.

Palladium Catalysts
In the Minireview on page 366 ff., R. Vilar and U. Christmann summarize the latest advances in the development of Pd complexes, in particular with carbenes and phosphines as supporting ligands, as catalytic systems for cross-coupling reactions.

Synthesis Strategies
A "toolbox of methods" based on halogen–metal exchange of aromatic substrates leads to the regiochemically exhaustive functionalization of valuable building blocks. This concept is introduced by M. Schlosser in his Review on page 376 ff.

Peptide Structures
A. I. Jiménez et al. report in their Communication on page 396 ff. their observation of two consecutive γ turns in a crystalline linear dipeptide through analysis of the solid-state conformations.

Chemoenzymatic Synthesis of Building Blocks for Statin Side Chains

Biocatalysis: Enzymatic transformations have become competitive methods for the synthesis of complex organic compounds. The wide range of possibilities offered by biocatalysis for the synthesis of target molecules are highlighted based on the example of the statins. This class of compounds, which includes rosuvastatin (see picture), are good inhibitors of cholesterol synthesis and dominate the market for cholesterol-lowering drugs.

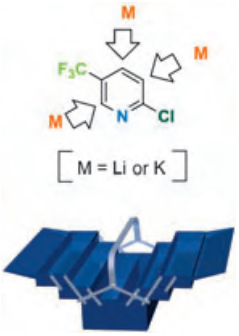
Monoligated Palladium Species as Catalysts in Cross-Coupling Reactions



A matter of size: Lately, new catalysts based on complexes of palladium with electron-rich and bulky ligands have been developed for the activation of less-reactive aryl chlorides in cross-coupling reactions to generate C–E bonds (E = C, N, O, S). The enhanced reactivity of the catalysts is attributed to the formation of unsaturated [Pd^0L] species (see scheme; L = phosphines or carbenes).

Reviews

Like a wildcard in a card game, the introduction of a metal into aromatic or heterocyclic building blocks ensures a maximum of target flexibility in the synthesis (see scheme). It can be replaced with a wide range of electrophiles and thus offers a convenient access to virtually any functionalized derivative. The ultimate objective of this "toolbox" approach is not to miss any structural opportunity inherent in a new substituent pattern.

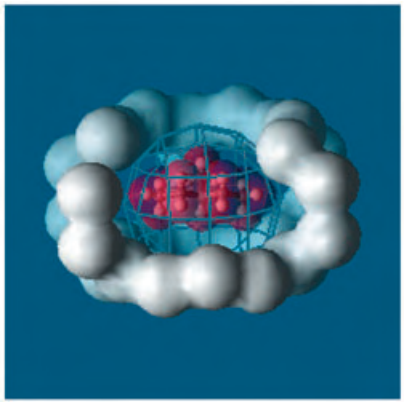
Communications



Which way to turn? For the very first time, a linear dipeptide has been shown to accommodate two consecutive γ turns in the solid state. An aminocyclopropane carboxylic acid has overridden the tendency of proline to induce a β-turn conformation in Pro-Xaa dipeptides (see X-ray crystal structure; blue: N, red: O, dashed lines show H bonds).

First Observation of Two Consecutive γ Turns in a Crystalline Linear Dipeptide

Yanking chains and rattling cages: Depending on their radius of gyration, molecules either retain or lose their ability to rotate inside zeolite cages (see picture). Such differences in rotational adsorption entropy result in a preferential uptake of branched alkanes over their linear structural isomers in zeolites such as MCM-22 which allows the separation of the two types of molecules.

A single tandem operation allows rapid access to a variety of substituted N-functionalized indoles. The nitrogen atom of the indole nucleus is incorporated through Pd-catalyzed aryl and alkenyl C–N bond-forming reactions (see scheme; dba = dibenzylideneacetone). Amine, aniline, amide, carbamate, and sulfonamide functional groups can be introduced efficiently.

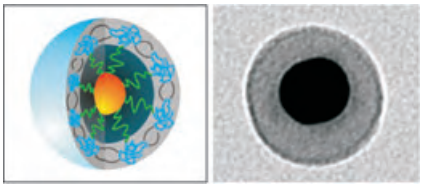
Palladium-Catalyzed Tandem Alkenyl and Aryl C–N Bond Formation: A Cascade N-Annulation Route to 1-Functionalized Indoles



Symmetrical 1,3-diynes result from the oxidative homocoupling reaction of alkynylstannanes with an aryldifluoro-λ^3-bromane in the presence of $BF_3 \cdot Et_2O$ (see scheme, Ar = *p*-$CF_3C_6H_4$). The reaction involves a Michael addition of alkynylstannanes to the initially formed alkynyl-λ^3-bromanes. Cross-coupling of alkynyl-λ^3-bromanes with alkynylstannanes affords unsymmetrical 1,3-diynes (see scheme).

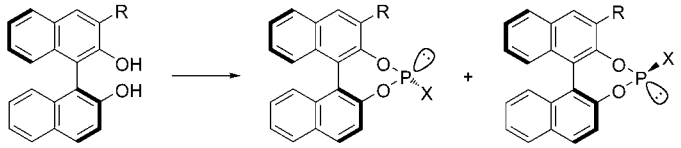
Plated gold: Self-assembly of core/shell nanostructures occurs spontaneously when gold nanoparticles are combined with amphiphilic block copolymers. Polymer cross-linking then topologically fixes the composite nanostructure (see picture). The thickness of the polymer shell, as well as the optical and chemical properties of the composite nanostructure, are precisely determined by the



molecular characteristics of the assembled block copolymer.

Nanoparticles

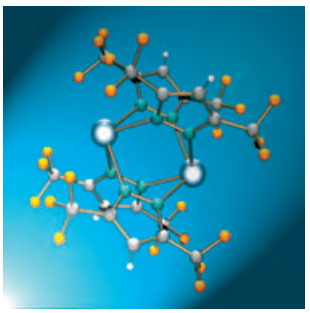
Bioorganic Chemistry

L. Kröck, A. Heckel* ——— **471 – 473**

Photoinduced Transcription by Using Temporarily Mismatched Caged Oligonucleotides

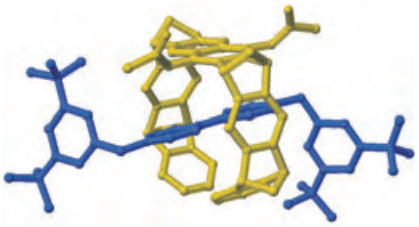


Spatial and temporal control of the function of DNA with light: In oligonucleotides, protected ("caged") thymidine can act as a temporary mismatch in base pairing and, for example, prevent transcription. The photolabile caging group can be removed by light (see picture), fully restoring an intact DNA strand.

Tin Complexes

F. Breher,* H. Rüegger ——— **473 – 477**

Distannenes Turned Inside Out: Bis(stannylenes) with an Unusual Structural Motif

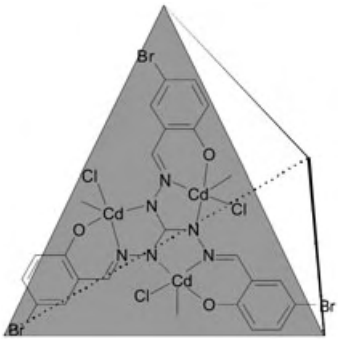


Alkene analogues: Simple acid–base reactions of $[Sn\{N(SiMe_3)_2\}_2]$ with 3,5-substituted pyrazoles, H(3,5-R_2pz) ($R = CF_3$ and CMe_3), give the homoleptic tin(II) pyrazolyl compounds, $[\{Sn(3,5\text{-}R_2pz)_2\}_2]$. Owing to additional N-donor functionalities in the tin-bound ligand the two stannylene entities dimerize in a head-to-tail fashion (see structure) and not through a covalent Sn–Sn bond. Thus, the title compounds can be described as analogues of quadruply R-bridged alkenes.

Dendritic Effects

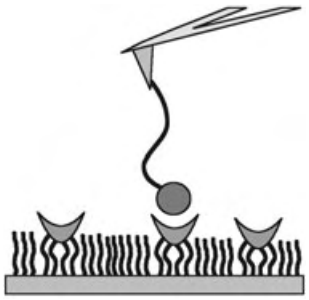
C. A. Schalley,* C. Verhaelen, F.-G. Klärner, U. Hahn, F. Vögtle ——— **477 – 480**

Gas-Phase Host–Guest Chemistry of Dendritic Viologens and Molecular Tweezers: A Remarkably Strong Effect on Dication Stability



Size does matter: Viologen dications (blue) substituted with dendrons form strong host–guest complexes with molecular tweezers (yellow) in solution and in the gas phase (see picture). Complexation even stabilizes dications which are intrinsically unstable as "naked" species in the high vacuum of a mass spectrometer. A remarkably pronounced effect of dendrimer size on the stability of these dications switches their fragmentation between two mechanisms.

Cage Compounds



I. M. Müller,* D. Möller, C. A. Schalley ——— **480 – 484**

Rational Design of Tightly Closed Coordination Tetrahedra that are Stable in the Solid State, in Solution, and in the Gas Phase

No way out: Small guest cations, such as $[Et_4N]^+$ template the formation of stable and tightly closed octaanionic metallosupramolecular tetrahedra (see picture). Since $[Et_3NH]^+$ is co-encapsulated with exactly one water molecule, the filling of space seems to be a more pivotal factor for the templation than the symmetry of the cation. X-ray crystallography excellently agrees with NMR spectroscopy and ESI-FT-ICR mass spectrometry data.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Pulling power: The specific interaction of individual (alkyl) ammonium residues with a resorc[4]arene cavitand that is attached to a gold surface are investigated. Measurements are made by attaching the residue to the cantilever of an atomic force microscope (AFM; see picture). The results confirm that the affinity of the guest for the host depends of their mutual steric compatibility.

S. John and G. Ozin Receive Brockhouse Canada Prize

Sajeev John and Geoffrey Ozin of the University of Toronto (Canada) have received the first Brockhouse Canada Prize of the Natural Sciences and Engineering Research Council of Canada (NSERC). The prize, accompanied by a research grant of CAN$ 250000, is to be awarded annually for outstanding results in an interdisciplinary NSERC-funded project. It is named after the Canadian physicist Bertram N. Brockhouse, who was awarded the 1994 Nobel Prize for the development of neutron spectroscopy.

S. John

G. Ozin

Theoretical physicist Sajeev John and materials chemist Geoffrey Ozin have together developed photonic crystals in which light can be trapped. These crystals, which are based on inverse silicon opals, should form the basis of optical microchips that operate at the speed of light. After John's concept had been rejected by many scientists around the world, he came across Ozin at his own university in 1998. Ozin had 30 years of experience in zeolite chemistry, also on a nanometer scale. The collaboration of theory and experiment of these two researchers is as fruitful as their backgrounds are different.[1a] Ozin's article on nanocrystallinity in anatase thin films is highlighted on the cover of issue 2/2005 of *Small*.[1b]

Ozin completed his PhD at the University of Oxford (UK) and since 1969 has been at the University of Toronto, where he currently holds the Canada Research Chair in Materials Chemistry. John completed his PhD in physics at Harvard University (USA). From 1986 to 1989 he was assistant professor at Princeton University, where he co-invented the concept of photonic band gap materials. He now holds the Canada Research Chair in Physics at the University of Toronto.

Polymer Award to C. J. Hawker

Craig J. Hawker is to receive the 2005 ACS Award in Applied Polymer Science. Hawker studied chemistry in Queensland (Australia) and completed his PhD in 1988 at the University of Cambridge (UK) with A. R. Battersby on the biosynthesis of vitamin B12. Following postdoctoral research with J. M. J. Fréchet at Cornell University (USA), he returned in 1990 to the University of Queensland. Since 1993 he has worked at the Almaden Research Center of IBM in San José, California and since 2001 has also been adjunct professor at the University of Queensland.

C. J. Hawker

Hawker's research encompasses synthetic polymer chemistry and materials for nanotechnology (microelectronics and biotechnology). For example, he is interested in the structuring of surfaces on the nanometer scale. To overcome the disadvantages of top-down and bottom-up approaches, he works on methods based on imprinting and subsequent polymerization. In both 2003 and 2004 he was the co-author of cover-picture articles in *Angewandte Chemie*: on the synthesis of triazole dendrimers, and on the structured cross-linking of silsesquioxanes.[2]

Noyori Prize to D. Seebach

The Ryoji Noyori Prize is awarded by the Society of Synthetic Organic Chemistry, Japan and sponsored by the company Takasago. The prize of US$ 10000 is awarded in recognition of outstanding contributions to asymmetric synthetic chemistry. The recipient for 2004, selected by a committee composed of four people from Japan and three from abroad, is Dieter Seebach of the ETH Zürich (Switzerland).

Seebach, a former member of the Editorial Board of *Angewandte Chemie*, completed his PhD at the Universität Karlsruhe (Germany) with R. Criegee, then undertook postdoctoral research with E. J. Corey at Harvard University. In 1971 he became professor in Giessen (Germany), and then in 1977 at the ETH Zürich. His research is broadly concerned with the development of methodology in organic chemistry. One of his current projects focuses on β-peptides; he recently reported on their secondary structure in *Angewandte Chemie*.[3a] A comprehensive review on this topic appeared in 2004 in *Chemistry & Biodiversity*.[3b] Over a period of almost 30 years *Angewandte Chemie* has published 11 Reviews by Seebach on a wide range of topics, including umpolung, Ti and Zr nucleophiles, and asymmetric synthesis. His Review on the future of organic synthesis is legendary.[3c]

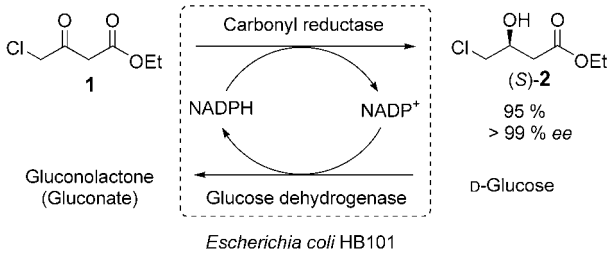
Enzyme Catalysis

Chemoenzymatic Synthesis of Building Blocks for Statin Side Chains

*Michael Müller**

Keywords:
enzyme catalysis · inhibitors · natural products · statins · steroids

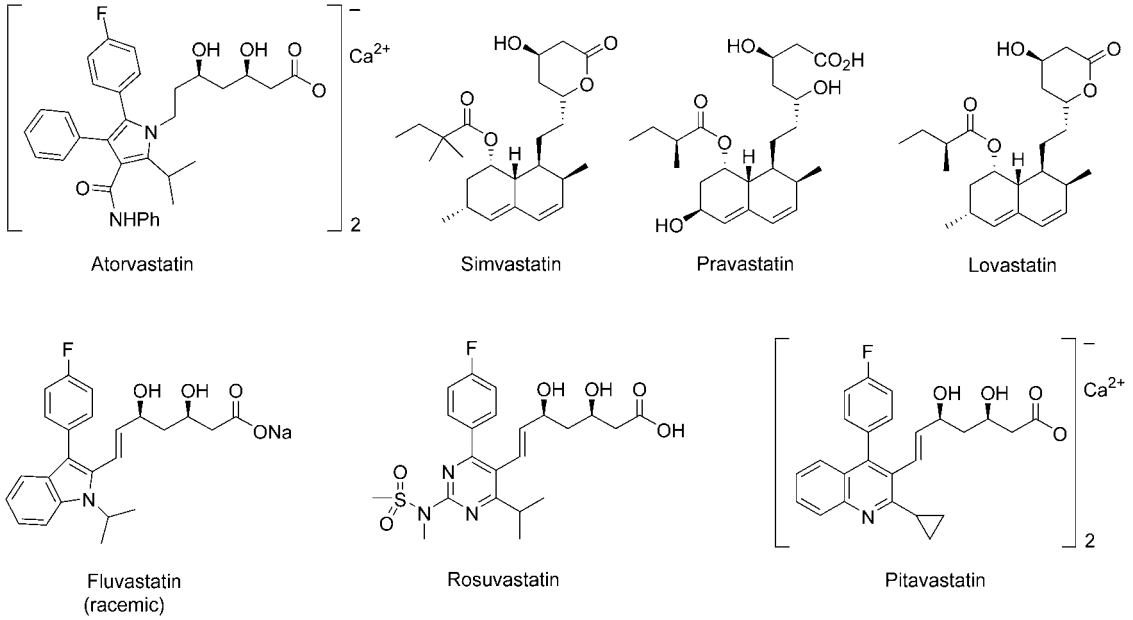
Dedicated to Heinz G. Floss on the occasion of his 70th birthday



Statins[1] inhibit the enzyme HMG-CoA reductase (HMG = 3-hydroxy-3-methylglutaryl), which catalyzes the reductive conversion of HMG-CoA into mevalonate, an early and rate-limiting step in cholesterol biosynthesis. This inhibition leads to decreased levels of LDL cholesterol (LDL = low-density lipoprotein). Large-scale clinical trials with the statin class of cholesterol-lowering drugs have shown the relationship between diminished levels of LDL cholesterol and decreased morbidity and mortality from coronary heart disease.[2] Moreover, statins also decrease levels of triglycerides and increase levels of HDL cholesterol (HDL = high-density lipoprotein).

The market for cholesterol-lowering drugs, valued at more than US$20 billion and thus the largest in the pharmaceutical sector, is dominated by the statins. In 2003, revenues of US$9.2 billion (2002: US$8.0 billion) and US$6.1 billion (2002: US$6.2 billion) were recorded for atorvastatin and simvastatin, respectively, which means that these pharmaceuticals are the two top-selling drugs in the world. Relative to simvastatin, pravastatin (2003: US$2.8 billion), and lovastatin (the first statin marketed in 1987), which are all derived from microorganisms through partial synthesis, the synthetic HMG-CoA reductase inhibitors atorvastatin,[3] fluvastatin, and rosuvastatin (approved by the US Food and Drug Administration in August 2003)[4] are increasing in value.[5] With pitavastatin (NK 104) the next candidate is in phase III clinical trials.[2b] All statins have in common a homochiral side chain pharmacophore in the form of a 3,5-dihydroxy acid[6] and a (hetero)aromatic or cyclic residue (Scheme 1).

As a result of their extremely high market value and the requirement for high chemical and stereochemical purity (> 99.5 % *ee*, > 99 % *de*), immense effort has been invested in the production of synthetic statins by competing research groups. Pharmaceutical, chemical, and biotechnological companies have recently developed various chemoenzymatic strategies in which different biocatalysts are used for the stereoselective synthesis of the 3,5-dihydroxy acid side chain (Scheme 2). Several remarkable achievements have been made in the optimization of the biocatalytic step for application on an industrial scale. These examples nicely demonstrate that for the synthesis of a specific target molecule many different enzymatic transformations are applicable.



The established strategy of enantioselective reduction of alkyl 4-chloroacetoacetates (Scheme 2 A), such as **1**, has been optimized by Shimizu and coworkers in collaboration with scientists at Kaneka. Permeabilized cells of a recombinant *E. coli* strain that overproduces both an alcohol dehydrogenase (ADH, in the form of carbonyl reductase from *Candida magnoliae*) and glucose dehydrogenase from *Bacillus megaterium* were used in a biphasic organic solvent/aqueous buffer system for the production of ethyl (*S*)-4-chloro-3-hydroxybutanoate ((*S*)-**2**) in enantiopure form. Product concentrations of 63 g L^{-1} were observed in the organic phase, and the product was isolated in 95 % yield,[7] but much higher product concentrations might also be attainable.[7c] The main disadvantages of this system are the high concentration of the coproduct gluconate and the utilization of nonliving cells. The use of living organisms that express both the catalyst and the cofactor-regenerating enzyme might enable continuous production with high total turnover numbers for the catalyst and the cofactor NAD(P)H.[8]

Chemists at Avecia Pharmaceuticals (formerly Zeneca, formerly ICI) have developed a biocatalytic alternative to the problematic diastereoselective reduction of 3-hydroxyketones **3**, which is

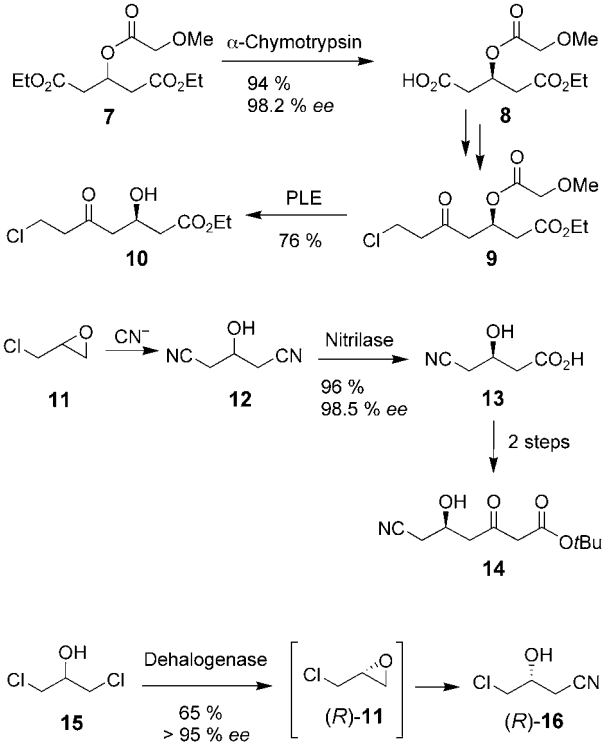
a price-limiting factor on an industrial scale because of ecological and economic concerns. The bioreduction of (*S*)-**3** with cells of *Pichia angusta* resulted in the formation of the desired diastereomerically pure triol in 80% yield (substrate concentration 25 g L^{-1}). Immobilized lipase from *Candida antarctica* (Chirazyme L2) provided access in very high yield to regioselectively acetylated **4**, which was used in the synthesis of the important building block **5**.[9] Depending on the strain and on the substituent at C6, either the *syn* or the *anti* 1,3-diol (e.g. **6**) is obtained.[10b] A similar approach has been developed by scientists at Kaneka, for example with *Candida magnoliae*.[10]

The research group of Patel (Bristol-Myers Squibb) used cell suspensions of *Acinetobacter calcoaceticus* for the stereoselective direduction of ethyl 6-benzyloxy-3,5-dioxohexanoate. The corresponding diol was isolated in 85% yield with 97% *ee* (Scheme 2B).[11]



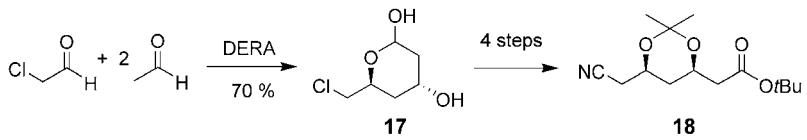
The known desymmetrization of prochiral 3-substituted glutarates by enzymatic hydrolysis (Scheme 2C)[12] has been optimized by chemists at Ciba Speciality Chemicals for the synthesis of **8** on a kilogram scale.[13] α-Chymotrypsin, an extremely cheap and robust biocatalyst, is used in the selective hydrolysis of the triester **7**. The process is characterized by a high substrate concentration (285 g L^{-1})[14] and a 94% yield of the isolated product with 98.2% *ee*. After chain elongation, the methoxyacetyl ester is removed selectively by hydrolysis in the presence of pig-liver esterase (PLE) (**9**→**10**); the ethyl ester is left untouched.[14] Because of the potential for flexible functionalization of the monoprotected glutarate **8**,[13] this strategy, like the following, in principle allows access to both enantiomers of 3-hydroxy-5-oxohexanoates and 5-hydroxy-3-oxohexanoates.

Burk and co-workers (Diversa) identified more than 200 new nitrilases by using large genomic libraries created by extracting DNA directly from environmental samples. Four of the enzymes

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

identified were employed successfully in the desymmetrization of 3-hydroxyglutaronitrile (**12**), which is readily available from epichlorohydrin (**11**; Scheme 2D). Subsequently, a highly enantioselective nitrilase was created through site-saturation mutagenesis. The optimized efficient enzymatic transformation, which was performed on a gram scale with a substrate concentration of 3 M, is characterized by a high volumetric productivity. After a reaction time of 15 h, the product (98.5% *ee*) was isolated in 96% yield, which corresponds to a space–time yield of 619 $g L^{-1} d^{-1}$.[15]

The dehalogenase-catalyzed racemic resolution of *rac*-**2** was described by Kasai and co-workers (Daiso).[16] Prochiral 1,3-dichloro-2-propanol was used in the synthesis of (*R*)-4-chloro-3-hydroxybutyrontrile ((*R*)-**16**) via (*R*)-epichlorohydrin ((*R*)-**11**). The dehalogenase enzyme catalyzes both the reversible removal of HCl from 1,3-dichloro-2-propanol and the introduction of the cyano group.[17] The enantiomer (*S*)-**16** can be obtained in two steps starting either from racemic epichlorohydrin or from prochiral 1,3-dichloro-2-propanol.[18]



Recently, scientists at Codexis together with Roger Sheldon described the combination of a ketoreductase- and a dehalogenase-catalyzed one-pot transformation (Scheme 2E).[19] Although this is an interesting approach, the published data are not yet adequate for the application of this two-step transformation on a larger scale.

Another highly attractive approach has been developed by scientists at DSM[20] based on a transformation introduced by Wong and co-workers.[21] The 2-deoxyribose-5-phosphate aldolase (DERA) catalyzed formation of the pyran **17** proceeds through asymmetric C–C bond formation starting from the cheap bulk chemicals acetaldehyde and chloroacetaldehyde. Although the reaction characteristics published in the initial article were not very promising (low substrate concentration, high catalyst loading, 7-day reaction time), this biotransformation is now in operation on an industrial scale.[20c] The optimized enzymatic transformation, which is performed at low temperature (2–4 °C), is characterized by a high final product concentration (> 100 $g L^{-1}$).[20a]

Recently, scientists at Diversa applied the strategy of screening genomic libraries prepared from environmental DNA, as mentioned in the case of nitrilases, for the identification of improved DERA enzymes.[22] More than 15 DERA enzymes were discovered, one of which was used to optimize the process on a 100-g scale. By using a fed-batch strategy, which is necessary because of substrate inhibition, Burk and co-workers obtained **17** (> 99.5% *ee*, 96.6% *de*) in a final concentration of 93 $g L^{-1}$ and were able to decrease the amount of enzyme used to 2 wt%. In addition, Wong and co-workers recently reported the DERA S238D mutant catalyzed transformation of 3-azidopropionaldehyde with two molecules of acetaldehyde.[21d] Thus, the building block **18** for the atorvastatin side chain is accessible through a straightforward chemoenzymatic five-step synthesis starting from cheap bulk chemicals.

These examples demonstrate that state-of-the-art enzymatic transformations have reached an extraordinary level, making them valuable and competitive methods for use in the chemical and pharmaceutical industry. Clearly,

biocatalysis is "growing up" in terms of its acceptance by chemists. Biocatalytic strategies offer innovative solutions to problems such as crossed-aldol reactions, the regio- and stereoselective reduction of 1,3-diketones, the stereoselective formation of 1,3-diols, and the desymmetrization of prochiral compounds. These approaches will also have an impact on the development and elucidation of non-enzymatic transformations, as well as on the training of chemistry, pharmacy, and biology students.

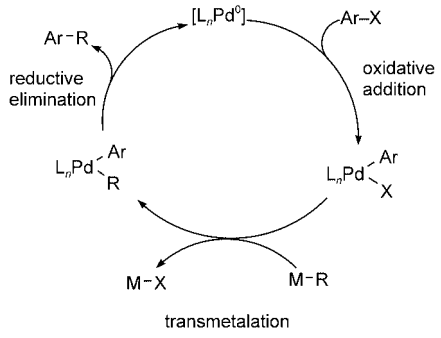
Palladium Catalysts

Monoligated Palladium Species as Catalysts in Cross-Coupling Reactions

*Ute Christmann and Ramón Vilar**



Keywords:
amination · carbenes · cross-coupling · palladium · phosphines

Palladium-mediated cross-coupling reactions are attractive organometallic transformations for the generation of C–C, C–N, C–O, and C–S bonds. Despite being widely employed in small-scale syntheses, cross-coupling reactions have not found important industrial applications because until recently, only reactive aryl bromides and iodides could be used as substrates. These substrates are generally more expensive and less widely available than their chloride counterparts. Over the past few years, new catalytic systems with the ability to activate unreactive and sterically hindered aryl chlorides have been developed. The new catalysts are based on palladium complexes that contain electron-rich and bulky phosphine or carbene ligands. The enhanced reactivity observed with these new systems has been attributed to the formation of unsaturated and reactive [PdL] species which can readily undergo oxidative addition reactions with ArX to yield [Pd(Ar)X(L)].

1. Introduction

Palladium-mediated cross-coupling reactions to form C–C, C–N, C–O, and C–S bonds are among the most powerful organometallic transformations employed in organic synthesis. These reactions are generally thought to proceed through a mechanism that involves three distinctive steps (see Scheme 1). First, an aryl halide reacts with the palladium(0) center through an oxidative addition reaction. This is followed by a transmetalation reaction to yield a palladium(II) complex that contains the two moieties to be coupled. The final step is the reductive elimination of the product with the concomitant regeneration of the active palladium(0) catalyst. In this mechanism, the nature of the aryl halide substrate is very important in the determination of the rate-limiting step. For example, for aryl chlorides and unactivated aryl bromides, it is often found that the oxidative addition is the rate-limiting step.

Initially, cross-coupling reactions had an important limitation: only reactive aryl bromides and iodides could be used as substrates. However, as aryl chlorides are more widely available and generally less expensive than their bromide and iodide counterparts, there has been a growing interest to find catalytic systems that can successfully catalyze cross-coupling reactions with these substrates. The past few years have seen important advances in this direction, with part of this success owed to the development of new palladium complexes which contain electron-rich and bulky ligands (namely phosphines and carbenes) that improve their catalytic activity in coupling

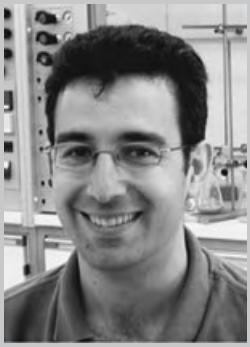
reactions. The enhanced reactivity observed with these new systems has been attributed to the formation of unsaturated [PdL] species, which can readily undergo oxidative addition reactions to yield [Pd(Ar)X(L)].

Herein we present the most important advances that have been made over the past few years in the development of catalytic systems that use bulky and electron-rich ligands for cross-coupling reactions. As several excellent reviews[1–16] and books[17,18] on palladium-catalyzed coupling reactions have already been published, we limit our discussion to examples in which monoligated palladium species have been implicated in the catalytic process.



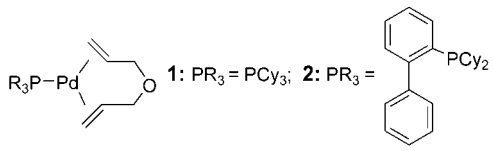
2. Palladium Catalysts Supported by Bulky and Electron-Rich Ligands

2.1. Phosphines

Several groups have established that the combination of bulky and electron-rich phosphines with different sources of palladium generate species that show high catalytic activity in cross-coupling reactions. In 1998, Nishiyama and co-workers showed that mixtures of $P t Bu_3$ and either $Pd(OAc)_2$ or $[Pd_2(dba)_3]$ (dba = dibenzylideneacetone) had unusually high activities in amination reactions.[19] The same year, Littke and Fu reported that a mixture which contained $[Pd_2(dba)_3]$ and $P t Bu_3$ was highly active as a catalyst for the Suzuki coupling reaction of a broad spectrum of aryl halides.[20] A more detailed study by Fu and co-workers, in which the catalytic properties of palladium complexes with different phosphines as ligands were compared by using different aryl halides as substrates, gave further insight into the catalytic mechanism.[21] In these studies, it was shown that a mixture of $[Pd_2(dba)_3]$ and $P t Bu_3$ catalyzed the Suzuki cross-coupling of vinyl and aryl halides (including chloride) with arylboronic acids, whereas $Pd(OAc)_2$ in the presence of PCy_3 (Cy = cyclohexyl) generated a good catalyst for the cross-coupling reaction of vinyl and aryl triflates with arylboronic acids. The system with $P t Bu_3$ showed high selectivity with the order of reactivity $I > Br > Cl \gg OTf$. Interestingly, it was shown that the optimal palladium/phosphine ratio for high catalytic activity was between 1 and 1.5, which suggested that a monophosphine–palladium complex may be the catalytically active species. It was observed that $[Pd(P t Bu_3)_2]$ was a very poor catalyst for the Suzuki coupling of 3-chloropyridine and *o*-tolylboronic acid (7% conversion). However, addition of the phosphine-free species $[Pd_2(dba)_3]$ to $[Pd(P t Bu_3)_2]$ to generate the $[Pd(P t Bu_3)]$ species produced an important increase in activity (91% conversion).

These studies were followed by various reports which showed that other types of cross-coupling reactions occur readily in the presence of a range of palladium sources and bulky phosphine ligands. Littke and Fu also demonstrated that a mixture of $[Pd_2(dba)_3]$ and $P t Bu_3$ yields a general catalyst system for Stille cross-coupling[22] and Heck reactions.[23] Hartwig and co-workers, on the other hand, reported that this palladium/phosphine combination produces an excellent catalyst for the arylation of ketones and malonates.[24,25] They also studied in detail the formation of C–N bonds catalyzed by palladium in the presence of bulky and electron-rich phosphines such as $P t Bu_3$, PCy_3, $PAd(t Bu_2)$ (Ad = 1-adamantyl), and $(Ph_5Fc)P t Bu_2$ (Q-phos; Fc = ferrocenyl).[26–28] In most cases, standard palladium sources such as $[Pd_2(dba)_3]$ and $Pd(OAc)_2$ were employed to generate the catalytic species in the presence of the corresponding phosphine. Further studies by Hartwig and co-workers showed that the previously reported palladium(I) dimer $[Pd_2(\mu\text{-}Br)_2(P t Bu_3)_2]$[29,30] could be used as a novel single-source precatalyst for cross-coupling reactions.[31] Unparalleled rates for amination and Suzuki–Miyaura cross-coupling reactions of aryl chlorides and bromides were observed with this complex. The high reactivity of this compound was attributed to the formation of the monoligated species $[Pd(P t Bu_3)]$ by either a disproportionation reaction or by the direct reduction of the dipalladium complex in the presence of the substrate and a base.

Beller and co-workers reported an efficient catalytic system for cross-coupling reactions based on the sterically demanding phosphine, $PAd_2(n Bu)$.[32] A mixture of $Pd(OAc)_2$ and this phosphine generates catalysts for the amination of aryl chlorides, the Suzuki coupling of aryl halides and boronic acids, and the α-arylation of ketones. In these reports, a detailed comparison of the activity of several catalytic systems was carried out that highlighted the influence of the supporting phosphine, the palladium/phosphine ratio, and the quantity (mol%) of the catalyst in the corresponding cross-coupling reactions. Furthermore, Beller and co-workers isolated the monophosphine–palladium(0) complexes **1** and **2** (see Scheme 2) which were used as efficient catalysts for Suzuki cross-coupling reactions.[33] The effectiveness of these complexes as catalysts is directly related to their ability to



Ramón Vilar, born in Mexico City in 1969, completed his PhD (1996) on the synthesis and catalytic properties of palladium cluster compounds in the group of Prof. D. M. P. Mingos at Imperial College London. He remained at Imperial College as a lecturer and was appointed Senior Lecturer in 2003. Since April 2004, he is an ICREA Research Professor at the Institute of Chemical Research of Catalonia (ICIQ). His current research interests include the organometallic chemistry of palladium and supramolecular chemistry of metal complexes.

Ute Christmann, born in Peine (Germany), studied chemistry at the University of Hamburg. After completing her diploma with Prof. D. Rehder, she started her PhD (2002) in the group of Dr. R. Vilar at Imperial College, London (currently at ICIQ, Tarragona). Her research interests include the activation of small molecules by palladium(I) dimers and organometallic catalysis.

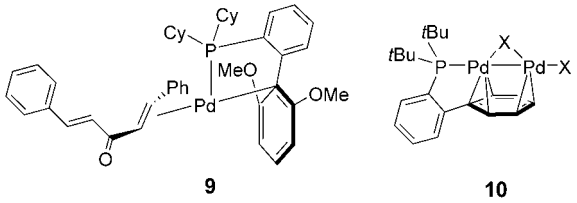
liberate the coordinated diene to generate the corresponding 12-electron species [PdL].

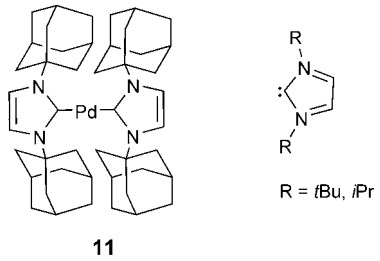


In the late 1990's, Buchwald and co-workers reported an important set of phosphines which proved to be excellent supporting ligands for the palladium-catalyzed formation of C–C, C–N, and C–O bonds with substrates such as aryl chlorides and bromides (see Scheme 3).[34–36] The effective-

Scheme 3. Buchwald's biaryl phosphine ligands and a cyclometallated palladium complex, **7**, of one such ligand (see References [6, 37]).

ness of these systems was attributed to a combination of electronic and steric properties of the ligands that favor both the oxidative addition and reductive elimination steps in the catalytic cycle. The formation of monoligated palladium species with biaryl phosphines was also invoked to be responsible for the rapid oxidative addition of the aryl halide substrates to the palladium(0) center. More recently, Buchwald's group reported a second generation of phosphines (see **5** and **8** in Scheme 3) with improved activities that demonstrate the generality of the catalyst system for a wide range of cross-coupling reactions.[37] As part of these studies, it was shown that the source of palladium and the phosphine/palladium ratio had an important impact on the catalytic performance of the system.

Besides the use of common palladium sources such as $Pd(OAc)_2$ and $[Pd_2(dba)_3]$, a single-component precatalyst based on a cyclometallated biaryl phosphine **7** was reported as a convenient air- and moisture-stable complex for aryl amination reactions.[38] It has been suggested that the biaryl group in Buchwald's phosphines may contribute to the stabilization of monophosphine–palladium complexes by establishing π interactions with the palladium(0) center. This is supported by the recent isolation of the complexes [Pd(dba)(L)] (where L = **4a**, **6**, or **8**) in which there is indeed a π interaction between the metal center and the aromatic system of the biaryl group (see **9**, Scheme 4).[39–41] The ability of this type of phosphine to stabilize unusual coordinations around metal centers can also be seen in the palladium dinuclear complex **10** in which $PtBu_2(bph)$ (bph = biphenyl)

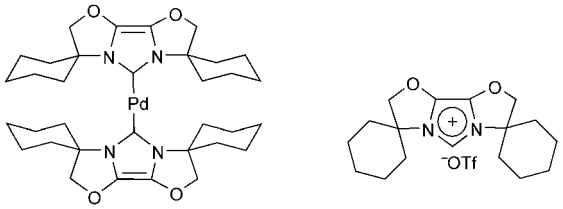


Scheme 4. Representation of a monometallic palladium(0) complex and a dinuclear palladium(I) compound with the π interactions between the metal center and the corresponding biaryl phosphine shown. X = Br, Cl.

bridges the two palladium centers through a μ_2-η^3:η^3-coordinated phenyl group (see Scheme 4).[41] This species catalyzed the amination reaction of aryl chlorides and bromides. The system is phosphine-deficient, thus it is likely that $[Pd\{PtBu_2(bph)\}]$ species are generated and these act as the true catalysts.

2.2. N-Heterocyclic Carbenes

Palladium complexes of N-heterocyclic carbenes (NHCs) can also be used as catalysts to activate aryl chlorides for cross-coupling reactions. For this type of reaction to occur at low temperatures and with reasonable yields, sterically demanding NHCs need to be employed (see Scheme 5). Some of these bulky ligands were successfully prepared and used in catalytic coupling reactions by the groups of Herrmann,[42] Beller,[43] Nolan,[44–46] Glorius,[47] and Cloke.[48]



Scheme 5. General N-heterocyclic carbenes (NHC) that are commonly used as ligands in cross-coupling reactions and a palladium(0) homoleptic NHC complex **11**.

The ratios of ligand/palladium, the steric bulk of the ligand, and the source of palladium were shown to be very important in defining the catalytic activity of the system. Furthermore, mechanistic studies suggested that monoligated palladium(0) complexes are implicated in the catalysis. Herrmann and co-workers reported that homoleptic palladium complexes $[Pd(NHC)_2]$ are good catalysts for the Suzuki

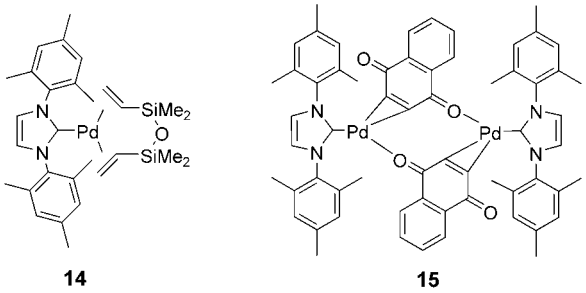
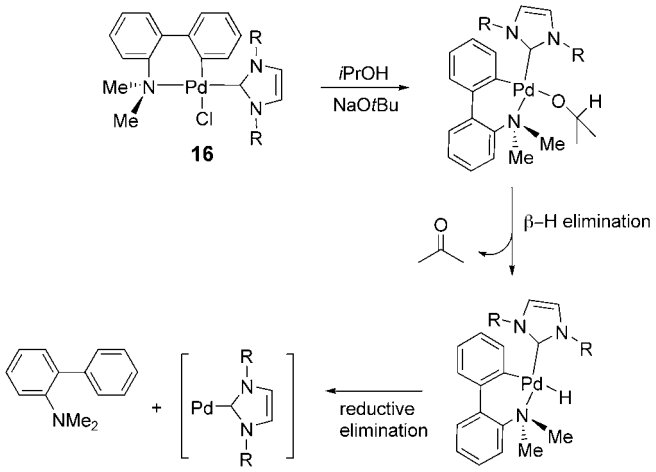
coupling of aryl chlorides.[49] The activity of this type of complex is highly dependent on the steric bulk of the carbene ligand. In particular, the complex $[Pd(NHC)_2]$ **11**, in which the NHC is the very sterically demanding 1,3-bisadamantylimidazolin-2-ylidene (see Scheme 5), proved to be an excellent catalyst for the Suzuki coupling of aryl chlorides at ambient temperature.



More recently, Glorius and co-workers reported the new homoleptic palladium complex **12**, which comprised the sterically demanding but flexible NHC ligand derived from **13** (see Scheme 6).[47] In contrast to the complexes described by Herrmann,[49] complex **12** proved to be catalytically inactive in the Suzuki coupling reaction at room temperature. However, a catalyst prepared from $Pd(OAc)_2$ and only one equivalent of the imidazolium salt **13** showed excellent catalytic activity for Suzuki cross-coupling reactions of aryl chlorides and even of sterically demanding substrates at room temperature. The authors attributed the high activity of this catalyst system to the formation of monoligated palladium–carbene complexes.

12 13

Scheme 6. Palladium(0) complex **12** with a geometrically flexible N-heterocyclic carbene ligand derived from the imidazolium salt **13**. OTf = trifluoromethylsulfonyl.



The potential role played by monoligated palladium–carbene complexes in cross-coupling reactions has also been studied by Beller and co-workers, who reported that the monocarbene–palladium(0) complexes **14** and **15** (see Scheme 7) act as good catalysts for Heck reactions of aryl chlorides (above 140 °C).[43] It was suggested that these complexes can generate the active 12-electron [PdL] species under the catalytic conditions. Interestingly, compound **14** has shown remarkable productivities and selectivities for the telomerization of 1,3-dienes with alcohols.[50,51] The good catalytic properties of this complex were attributed to the presence of unsaturated [PdL] species.

14 15

Scheme 7. Monocarbene–palladium(0) complexes.

Nolan and co-workers reported that the monocarbene–palladium(II) complex **16** (see Scheme 8) generated good catalytic species for Suzuki–Miyaura coupling reactions and Heck reactions of sterically hindered aryl chlorides at room temperature.[44,52] The isolation and identification of the organic fragments liberated in the initial steps of these reactions led the authors to propose a mechanism in which [Pd(NHC)] species, which act as the true catalysts, were generated (see Scheme 8).

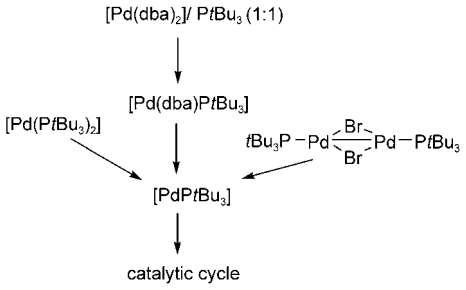
3. Mechanistic Studies



The experimental evidence described in the previous sections indicates that palladium in the presence of bulky and electron-rich ligands (either phosphines or carbenes) yields active catalytic systems for a wide range of cross-coupling reactions. The experimental observations also indicate that the source of palladium and the ratio of palladium/ligand employed have a great impact on the catalytic activity of the corresponding system. Some detailed mechanistic studies have now appeared which support the important catalytic role that monoligated palladium complexes play in cross-coupling reactions. To understand the mechanism of action of the catalytic species (and to optimize consequently conditions to enhance their catalytic properties), it is important to consider the different steps involved in the process. First, the generation of the catalytically active species from the corresponding palladium precursor needs to be considered; this step has demonstrated to be rate-limiting in several cases. After the "true" catalyst is generated, the oxidative addition of the aryl halide to the palladium(0) center takes place (which is favored by electron-rich ligands). Following a transmetalation reaction, the final step is the reductive elimination of the product,

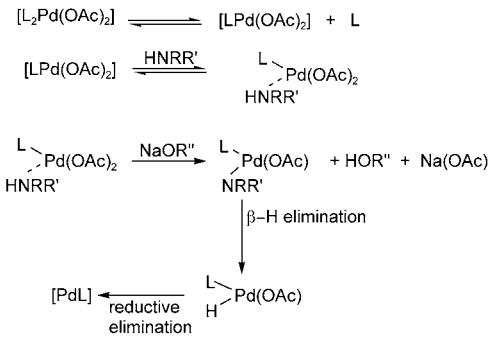
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the rate of which is usually increased by the coordination of bulky ligands to the palladium center. Furthermore, the mechanism of the catalysis can also be significantly influenced by the nature of the base added to the system.

3.1. Formation of Catalytically Active Species from Palladium Precursors

It is first necessary to address the step in which the catalytically active species are generated from the corresponding palladium precursors. Several authors have shown that even when the same phosphine or carbene ligand is used in a particular reaction, the source of palladium employed has an important influence on the catalytic rates. For example, Hartwig and co-workers recently published a study on the palladium-catalyzed amination of five-membered heterocyclic halides in which various combinations of palladium precursors and P*t*Bu$_3$ were tested as catalysts for the reaction of 3-bromothiophene with *N*-methylaniline (see Scheme 9).[28] The fastest reactions were observed with the

Scheme 9. Scheme showing the different potential routes employed by Hartwig and co-workers to generate the catalytically active [Pd(P*t*Bu$_3$)] species.[28]



palladium(I) dimer [Pd$_2$(μ-Br)$_2$(P*t*Bu$_3$)$_2$], whereas those conducted with [Pd(P*t*Bu$_3$)$_2$] were very slow. If [Pd(dba)$_2$] was added to the latter, the reaction was faster than with the homoleptic diphosphine compound. Interestingly, the rate of reactions catalyzed by 1:1 mixtures of [Pd(dba)$_2$] and P*t*Bu$_3$ depended on the mixing time: Catalytic reactions conducted after allowing [Pd(dba)$_2$] and P*t*Bu$_3$ to mix for five minutes proceeded approximately three times faster than those conducted after mixing the two components for one hour. Note: the formation of [Pd(P*t*Bu$_3$)$_2$] from [Pd(dba)$_2$] and P*t*Bu$_3$ takes approximately one hour. These investigations strongly suggest that the efficiency of the formation of the monophosphine complex [Pd(P*t*Bu$_3$)] controls the rates of the amination reaction.

Analogous observations were reported by Littke and Fu, who used P*t*Bu$_3$ in palladium-catalyzed C–C bond formation,[4] by Glorius and co-workers, who used bulky carbenes as supporting ligands,[47] and by Buchwald and co-workers, who used (biphenyl)phosphines in C–N and C–C bond-forming reactions.[6,40,53,54] In these reports, the ability of the system to generate monoligated [PdL] species was proposed to be very important in the rate of catalysis.

Strieter, Blackmond, and Buchwald recently reported that the bulkiness of the phosphine group controls not only the catalytic activity of palladium complexes in amination reactions, but also the rate of the activation of the catalyst.[53] They used reaction calorimetry to study the amination of *p*-chlorotoluene with morpholine in the presence of catalytic systems, which comprised mixtures of Pd(OAc)$_2$ and different biaryl phosphines. With the trisubstituted isopropyl biaryl phosphine **5** (see Scheme 3), higher initial rates were observed relative to those observed with the less sterically demanding P*t*Bu$_2$(bph) phosphine (**4a**). In an additional experiment, the reactivities of the catalyst systems with the *ortho*-substituted biaryl phosphines **3c**–**3e** were compared with the reactivity of the trisubstituted biaryl phosphine **5**. Across the series **5**, **3c, 3d**, and **3e**, a 10-fold difference in the reaction rate was observed, and the highest activity was shown for the bulkier phosphine **5**.

In these studies, it was also demonstrated that the amine has an important effect on the activation of the catalyst. When the catalyst system derived from **3c**–**3e** was preincubated with the amine, although the initial rate was increased in comparison to the corresponding system without preincubation, the subsequent reactions displayed a decrease in the rate. In contrast, the preincubation of the phosphine **5** with the amine did not seem to influence the initial rates of consecutive reactions. This implicates the amine in the activation of the catalyst and indicates that the less bulky ligands **3c**–**3e** require longer exposure to the amine to reach a steady-state concentration of the active catalyst.

The sensitivity of the activation of the catalyst to the size of the phosphine suggests that dissociation of the phosphine from a diphosphine–palladium(II) species takes place. On the basis of the results described above, Strieter, Blackmond, and Buchwald proposed a mechanism in which monophosphine–palladium species are formed by the dissociation of [PdX$_2$(PR$_3$)$_2$] (see Scheme 10).[53] Slow dissociation (observed

Scheme 10. Mechanism for the generation of [PdL] catalytically active species (L = biaryl phosphine) proposed by Strieter, Blackmond, and Buchwald on the basis of calorimetric studies (see Reference [53]).

for the less bulky phosphines) of the palladium(II) complexes resulted in slower activation of the catalyst. This clearly indicates the important relationship between the steady-state concentration of the palladium catalysts and the size of the supporting phosphine.

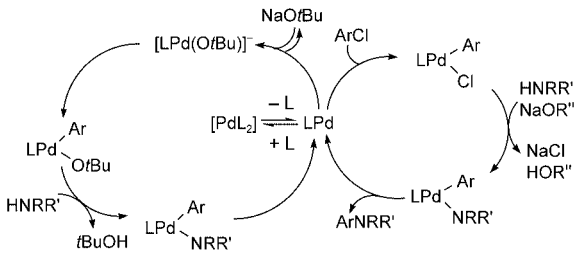
3.2. The Oxidative Addition Step



Several studies have been carried out to establish the effect of different ligands on the oxidative addition step of the catalytic cycle. Sterically demanding ligands have the ability to stabilize low-coordination palladium complexes (in particular monoligated species) which, owing to their low electron count, are more reactive. On the other hand, electron-donating ligands generate an electron-rich metal complex which undergoes faster oxidative addition reactions.

In a series of papers published in the mid 1990's, Hartwig and co-workers proposed monoligated palladium species as important intermediates in the catalytic amination of aryl halides using P(*o*-tolyl)$_3$ as a supporting ligand.[55] The oxidative addition of various aryl halides to [Pd{P(*o*-tolyl)$_3$}$_2$] generated the palladium(II) dimer [Pd$_2$Ar$_2$(μ-X)$_2${P(*o*-tolyl)$_3$}$_2$] where only one phosphine per palladium was present. Kinetic data demonstrated that this dimetallic compound was formed by oxidative addition to the monoligated species [Pd{P(*o*-tolyl)$_3$}] through a dissociative mechanism.[56–58]

More recently, Brown and co-workers[59] showed the mechanism of oxidative addition to [Pd(PR$_3$)$_2$] complexes to be highly sensitive to the bulkiness of PR$_3$ (where PR$_3$ = PCy$_n$*t*Bu$_{3-n}$, n = 0, 1, 2, 3). Complexes with PR$_3$ = P*t*Bu$_3$ or PCy*t*Bu$_2$ undergo oxidative addition with aryl halides by a dissociative mechanism, whereas [Pd(PR$_3$)$_2$] complexes with the less bulky phosphines PCy$_2$*t*Bu and PCy$_3$ follow an associative mechanism. The dissociative mechanism for the bulkier phosphines has been substantiated by the recent isolation by Hartwig and co-workers of a series of tricoordinated palladium(II) compounds with general formula [Pd(Ph)X(PR$_3$)] (PR$_3$ = PAd*t*Bu$_2$, P*t*Bu$_3$, or (Ph$_5$Fc)P*t*Bu$_2$; X = Br, I, or OTf).[60,61] These complexes were obtained in good yields by treating the phenyl halides with either [Pd(PR$_3$)$_2$] or with mixtures of [Pd(dba)$_2$] and one equivalent of the corresponding phosphine. This suggests that the tricoordinated products are formed through oxidative addition of the phenyl halide to monophosphine–palladium(0) complexes. The rates of oxidative addition reactions to generate the [Pd(Ph)X(PR$_3$)] complexes correlate well with the catalytic rates observed for the corresponding systems in cross-coupling reactions.

The X-ray crystal structures of [Pd(Ph)X(PR$_3$)] revealed that these species have a T-shaped monomeric geometry with the phenyl ring located in a position *trans* to the open coordination site of the metal. The structural characterization also showed weak agostic interactions between the palladium center and a C–H bond from a ligand—this was suggested to be the interaction that stabilizes the unusual geometry of these complexes. More recently, the palladium(II) complexes [Pd(*p*-anisyl)(NAr$_2$)(PR$_3$)] (PR$_3$ = (Ph$_5$Fc)P*t*Bu$_2$, FcP*t*Bu$_2$; Ar = 3,5-(CF$_3$)$_2$C$_6$H$_3$) were reported and their crystal structures revealed the absence of agostic interactions although they also have T-shaped geometries around the palladium center.[62] In the context of palladium-catalyzed coupling reactions, these tricoordinated species are very important because they demonstrate the possibility to obtain monophosphine complexes in which both of the substrates to be coupled are attached to the metal center.[63]

In 2001, Hartwig and co-workers proposed that the catalytic reaction of aryl chlorides with amines in the presence of alkoxide bases occurs by two concurrent mechanisms (see Scheme 11).[64] In one of these mechanisms, the alkoxide base

Scheme 11. Proposed concurrent catalytic cycles for the amination of aryl halides; the left-hand cycle depicts the anionic path.[64]

participates directly in the oxidative addition step to generate a monophosphine anionic active species.[65] This proposed mechanism could explain the observation that several cross-coupling reactions with the same aryl halide substrate and catalyst system required different conditions and reaction times. This is also consistent with the experimental observation that the amination of aryl halides with weak or strong bases require very different temperatures and catalyst loadings.

Despite the increasing interest in the use of palladium–NHC complexes as catalysts in cross-coupling reactions (see Section 2.2), their mechanism of action remains unclear. To gain a better understanding of this process, Caddick, Cloke, and co-workers carried out mechanistic investigations into the catalytic amination of aryl chlorides using [Pd(NHC)$_2$] (where NHC = *cyclo*-C{N(*t*Bu)CH}$_2$).[48] Their studies indicated that the oxidative addition of the aryl chloride is the rate-limiting step, and that the reaction takes place through a dissociative mechanism—as also observed with palladium complexes that contain bulky phosphines. Variable-temperature NMR spectroscopy experiments showed the dissociation of [Pd(Ar)Cl(NHC)$_2$] into the monoligated [Pd(Ar)Cl(NHC)] complex upon heating. Under conditions typical of catalytic amination, it was proposed that this dissociation of the complex into monocarbene–palladium species is the rate-determining step.

3.3. Reductive Elimination of the Final Product

The final step in the catalytic cycle corresponds to the reductive elimination of the coupled product from the metal center (see Scheme 1). It is generally accepted that this step is faster when palladium is coordinated to electron-withdrawing and sterically demanding ligands. It has also been shown that for very bulky ligands, the steric properties dominate over the electronic properties and even electron-donating ligands (such as the phosphines and carbenes discussed so far) accelerate the reductive elimination reaction. Although there are several studies which discuss the reductive elimination step of "classical" cross-coupling catalysts, only a few reports

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

have appeared in which this process is analyzed for catalyst systems with bulky and electron-rich ligands that favor monoligated palladium species. This is probably because the reductive elimination step is rarely rate-limiting when these bulky ligands are used.

The reductive elimination of different organic partners to generate C–C, C–N, C–O, and C–S bonds can proceed through different mechanistic pathways.[66–68] The supporting ligands, the ability of the metal complex to dissociate, and the nature of the substrates to be coupled have an important influence on which of the paths is followed. Three-coordinated palladium(II) complexes have often been postulated as the intermediate species that form the coupled product by reductive elimination. Until recently, the implication of such species was postulated mainly from kinetic and computational data. Early kinetic studies by Stille and Loare on C–C bond-forming reactions already suggested that the dissociation of a phosphine group from the palladium(II) complex was required prior to the reductive elimination step.[67] More recently, it was suggested that three-coordinated palladium(II) complexes (with bulky biaryl phosphines) are involved in the formation of diaryl ethers.[34,69] Although the exact mechanism of the reductive elimination step in these reactions is still unknown, Buchwald and co-workers proposed some hypotheses and found that for electron-deficient aryl halides, the most likely mechanism for the reductive elimination involves the transfer of a phenolate group from palladium to the *ipso*-carbon atom of the aryl halide. This intermediate is then converted into the diaryl ether to regenerate the palladium(0) species. In contrast, for electron-rich and electronically neutral aryl halides, the most likely mechanism involves a three-centered transition state.

The importance of three-coordinated palladium(II) intermediates in the reductive elimination step has been recently confirmed by Hartwig and co-workers, who reported the first fully characterized three-coordinated aryl–palladium amido complexes (see Section 3.2).[62] The reaction of 2-thienyl bromide with $[Pd(P\mathit{t}Bu_3)_2]$ in the presence of $KNAr_2$ yielded $[Pd(thienyl)(NAr_2)(P\mathit{t}Bu_3)]$, which was isolated and structurally characterized (analogous complexes with $(Ph_5Fc)P\mathit{t}Bu_2$ and $FcP\mathit{t}Bu_2$ were prepared by treating $[Pd(Ar)Br(PR_3)]$ with $KNAr_2$). Upon heating these complexes in toluene, reductive elimination reactions took place and the corresponding amine was formed. The rate of reductive elimination from the three-coordinated palladium complex $[Pd(p\text{-anisyl})(NAr_2)(P\mathit{t}Bu_3)]$ was compared with the rate of the analogous reaction from the four-coordinated complex $[Pd(p\text{-anisyl})(NAr_2)(dppf)]$ (dppf = 1,1′-bis(diphenylphosphino)ferrocene). The three-coordinated complex underwent reductive elimination at −10 °C to form the triarylamine product in 91% yield and with a half-life of 10 minutes. In contrast, the four-coordinated complex eliminated the triarylamine with a half-time of 55 minutes at 75 °C. These results strongly point toward three-coordinated palladium complex intermediates in the reductive elimination step of the catalytic cycle.

Hartwig and co-workers also recently presented a detailed mechanistic study of the reductive elimination of aryl halides from the dimeric arylpalladium(II) halide complexes $[Pd_2Ar_2(\mu\text{-}X)_2\{P(o\text{-tolyl})_3\}_2]$ (X = Cl, Br, I) upon addition of the hindered alkylphosphines $P\mathit{t}Bu_3$.[72] As stated earlier, it is generally accepted that reductive elimination is faster for complexes with weakly electron-withdrawing ligands because these ligands can remove some electron density from the metal center to generate favorable conditions for the reduction. Consequently, it would be expected that electron-rich phosphines such as $P\mathit{t}Bu_3$ would not favor the reductive elimination step. However, this recent study showed that coordination of $P\mathit{t}Bu_3$ to the palladium center induces reductive elimination of the aryl halide and indicates that the steric properties of this phosphine override its electronic effects.This is an important observation in the context of cross-coupling reactions as it suggests that $P\mathit{t}Bu_3$ indeed has a unique combination of steric and electronic properties to favor both the oxidative addition of the aryl halide (owing to its highly electron-donating properties) and the reductive elimination of the coupled product (owing to its steric bulk).

4. Conclusions and Outlook

The past few years have seen important advances in the development of highly-active catalysts to carry out cross-coupling reactions with unreactive and sterically hindered aryl halide substrates (with particular emphasis on aryl chlorides). To develop these new catalytic systems, a series of sterically demanding and electron-rich phosphine and N-heterocyclic carbene ligands have been employed. As shown throughout this review, there is increasing evidence to suggest that the ability of these ligands to stabilize monoligated palladium species is responsible for their enhanced reactivity. The generation of the catalytically active [PdL] species and the oxidative addition of the aryl halide onto the palladium(0) center are generally considered the rate-limiting steps. The steric bulk of the ligands discussed here has proved to be very important in the stabilization of the unsaturated [PdL] species, which is needed to initiate the catalytic cycle. Also, the electron-rich properties of the ligands favor the oxidative addition of the aryl halide onto the palladium(0) center even when the substrate is sterically hindered and unreactive. Besides their implication in cross-coupling reactions, unsaturated [PdL] complexes have also been invoked as the catalytically active species in some highly selective and efficient telomerization reactions.

The success of the systems described here provides a good basis for a more rational approach to the design and development of new catalytic systems for cross-coupling reactions. Important structure–activity relationships have been already established which open possibilities for the design of more-active and general catalytic systems. An important challenge remains the search for catalytic systems that not only activate unreactive aryl halides but also C–H bonds. Furthermore, the knowledge that has already been generated should stimulate the investigation of other organometallic transformations that could benefit from these ligand/metal systems.

such species would be too unstable to be detected or isolated under cross-coupling reaction conditions. In several of the T-shaped structures recently reported by Hartwig and co-workers, there is a stabilizing agostic interaction; however, in the more recent examples, such an interaction is not observed which indicates that that 14-electron T-shaped palladium(II) complexes can indeed be isolated.

E. Heilbronner / F. A. Miller

A Philatelic Ramble through Chemistry

278 pages with 1025 color reproductions.
Softcover. € 79.00/ sFr 116.00.
ISBN 3-906390-31-4

A Philatelic Ramble through Chemistry is a light-hearted, historically based survey of chemistry and some related topics in physics. It is illustrated with more than 1000 beautiful color reproductions of postage stamps and covers. Many stories and anecdotes have been included. The book provides delightful personal reading and may be useful for courses on the history of chemistry. It is a source of numerous anecdotes which instructors can use to enliven their lectures.

Softcover edition!

Praise for the Hardcover Edition

'This is a gem of a book. [...] I recommend it to all those to whom chemistry means more than an academic discipline, but a multi-faceted part of human culture, as Heilbronner and Miller so beautifully demonstrated.'
Interdisciplinary Science Reviews

'The creation of an exceptional book must be driven not only by knowledge but also by passion. This book by two chemists, Heilbronner and Miller, is clearly the product of a love for the world of postage stamps as well for chemistry in its widest sense.'

Synthesis Strategies

The 2 × 3 Toolbox of Organometallic Methods for Regiochemically Exhaustive Functionalization

*Manfred Schlosser**

Keywords:
halogen–metal permutation · metalation · protecting groups · regioflexibility · synthesis planning

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
DOI: 10.1002/anie.200300645

This Review describes a concept aimed at rational and maximal structure proliferation. To this end, simple aromatic or heterocyclic starting materials, often bulk chemicals, are converted into all regionisomerically possible polar organometallic intermediates (mostly lithiated species), which then may be combined with any of the countless electrophiles to provide attractive new building blocks, particularly functionalized derivatives. The practical implementation relies on a set ("toolbox") of sophisticated recipes developed by mechanistically guided modification of the two most prominent exchange methods used for the generation of polar organometallic compounds: hydrogen–metal and halogen–metal interconversion. These mutant methods ("old methods in a new outfit") amplify the existing options for organic synthesis by ensuring maximum regioflexibility. At the same time they offer new insight into factors that govern organometallic reactivity and provide hints on how to alter or finetune this reactivity judiciously.

4. Synopsis, Perspectives, and Outlook 390

1. Introduction

"There remains no fundamentally new synthetic method to be discovered, at least not in main group chemistry."[1] This sentence gives the general sense of a statement written more than a decade ago which was widely regarded as provocative, although its truth is evident. The knowledge of organic reactions has attained a level of completeness and sophistication that makes it inconceivable that a major mode of reactivity has remained unidentified. This should by no means discourage us from exploring novel modifications and applications of known methods or to test new combinations of methods. The situation resembles cartography at the beginning of the 20th century. After the expeditions of Livingstone, Stanley, Hedin and many other heroic explorers, there was no empty space left on the globe. Nevertheless, one had to wait for the survey by satellites before all the missing details could be filled in. Furthermore, even nowadays one must keep track of the continuous changes in the terrestrial profile caused by climatic effects or by human activities such as diking polders or building dams.

Any synthetic method is characterized by its scope and limitations. Thus, an extension of its application will inevitably alter its track record and, as a corollary, its perceived potential. Moreover, when exposed to a new scenario, methods are rarely reproduced exactly but are generally adapted to the task by appropriate modifications. In this respect, synthetic methods can be compared to living organisms subject to evolutionary pressure, which manifests itself in mutations and metamorphosis if not reincarnation.

The choice of a method, no matter whether in its original or in an adapted version, must clearly be subordinated to the purpose. The endeavors summarized in the present Review were aimed at the elaboration of procedures that enable the substitution and, in particular, the functionalization of simple and inexpensive starting materials, so-called bulk chemicals, at any vacant position. On this basis, we suggest *regiochemically exhaustive functionalization* as a new benchmark for structural proliferation. The practical realization of the concept relies on a set ("toolbox") of tailormade organometallic methods ("mutant methods") which have been developed by adjusting the *two* most widespread modes for the generation of polar organometallic intermediates, the hydrogen–metal and halogen–metal interconversion reactions, each in *three* directions ("2×3").[2] The accomplishments underscore once again the virtues of the organometallic approach, in particular its simplicity and versatility.

2. Regioflexibility in Hydrogen–Metal Exchange

The permutational hydrogen–metal interconversion belongs to the family of acid–base reactions and one might thus expect the least-basic organometallic product to form preferentially or exclusively. Fortunately, however, the real outcome depends on several factors such as inductive electron withdrawal, metal coordination, and steric hindrance, the interplay of which can be modulated by the reaction conditions. This offers the opportunity to discriminate between competing pathways and, under favorable conditions, to control the outcome of a reaction by orienting it at will in any one of two or three possible directions.

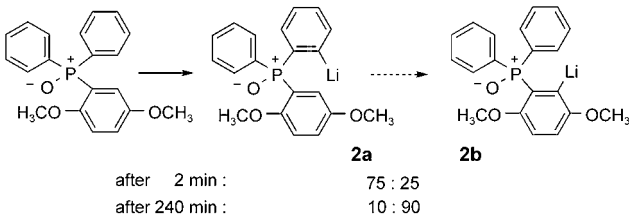
2.1. The Second-Chance Bonus: Thermodynamics versus Kinetics

Transition states and ground states do not necessarily reflect the influence of structural parameters to the same or to a proportional degree. For example, steric hindrance or coordinative assistance may, but need not, affect rates differently than equilibrium positions.

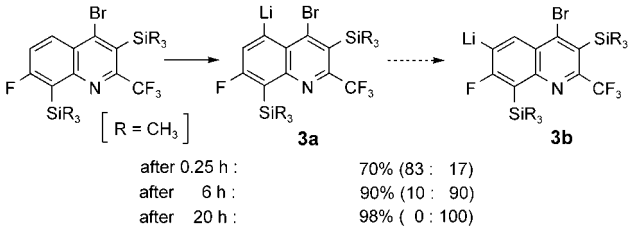
2.1.1. Steric Hindrance versus Electronic Stabilization

The first documented example of a conflict between steric accessibility and coordinative binding featured 2-(3,4-dimethoxyphenyl)ethyl-*N*,*N*-dimethylamine ("tetramethyldopamine") as the substrate.[3] When this reagent was treated with butyllithium at −75 °C in a 97:3 mixture of diethyl ether and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (TMEDA), metalation occurred at the unhindered 5-position. However, at +25 °C the initially produced intermediate **1a** slowly (in the course of 15 h; incomplete experimental details) displaced the metal by transmetalation to the 2-position (isomer **1b**) where coordination with the nitrogen-bearing side chain provides extra stability (Scheme 1).



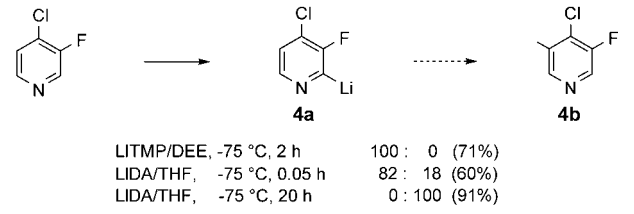
Scheme 1. Basicity-lowering isomerization of intermediate **1a** by transmetalation [Tool 2.1].

As the regioisomeric composition of the crude mixtures has never been rigorously established, a mutual contamination of the isomeric species **1a** and **1b**, one dominant at −75 °C and the other at +25 °C, cannot be ruled out. A careful investigation[4] of the reaction between (2,5-dimethoxyphenyl)diphenylphosphine oxide and *tert*-butyllithium did, indeed, reveal imperfect regioselectivity after short and long metalation times. The more-basic and the less-basic intermediate **2a** and **2b** were present in 75:25 and 10:90 ratios when quenched after 2 and 240 min, respectively (Scheme 2).[4]



Manfred Schlosser was born in Ludwigshafen (Germany). He studied chemistry (and, to a lesser extent, medicine) at the University of Heidelberg (PhD 1960, Prof. Georg Wittig). After his habilitation in Heidelberg (1966), he became Senior Physician at the German Cancer Center in Heidelberg. In 1971 he succeeded Prof. Jiři Sicher at the University of Lausanne, from where his laboratory was later transferred to the Federal Institute of Technology. A significant part of his research is aimed at a deeper understanding of chemical reactivity in general and the behavior of organometallic species in particular.

Scheme 2. Basicity-lowering incomplete isomerization of intermediate **2a** by transmetalation [Tool 2.1].



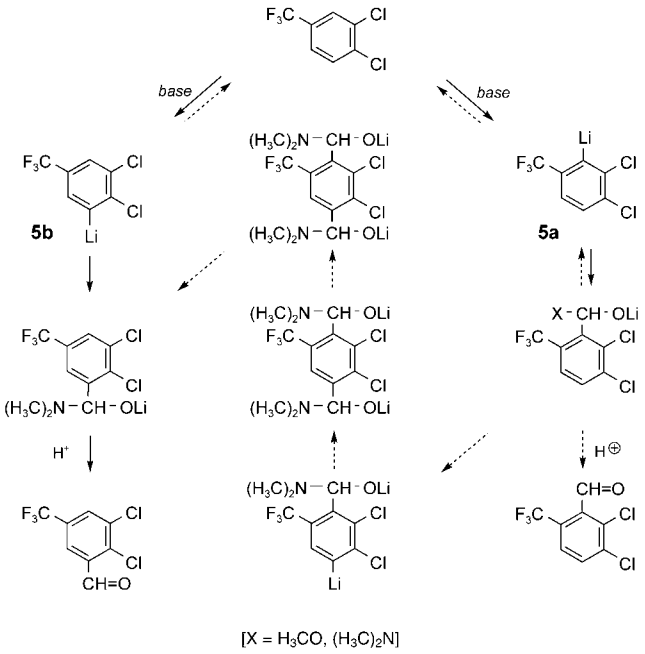
When 4-bromo-7-fluoro-2-trifluoromethyl-3,8-bis(trimethylsilyl)quinoline was treated with lithium diisopropylamide (LIDA) in tetrahydrofuran at −75 °C, deprotonation occurred concomitantly at the 5- and 6-positions in a 5:1 ratio.[5] The major intermediate **3a** then isomerized slowly, but ultimately completely to the less-basic component **3b**[5] (Scheme 3). The

Scheme 3. Basicity-lowering isomerization of intermediate **3a** by transmetalation [Tool 2.1].

initial preference for the 5-lithio species can be tentatively attributed to inductive neighboring-group assistance provided by the bromine atom and to a buttressing effect[6–9] exerted by the 8-trimethylsilyl substituent discriminating against attack at the 6-position.

Perfect optional site selectivity was achieved when 4-chloro-3-fluoropyridine served as the substrate.[10] With LIDA in tetrahydrofuran at −75 °C virtually the same scenario as described in the preceding paragraph was encountered. After 3 min, two metalated species **4a** and **4b** were present (82:18 ratio) and it took again 20 h until regioisomeric homogeneity in favor of the more-stable isomer **4b** was reached (Scheme 4). The more-basic isomer **4a** can be generated

Scheme 4. Basicity-lowering isomerization of intermediate **4a** by transmetalation [Tool 2.1].



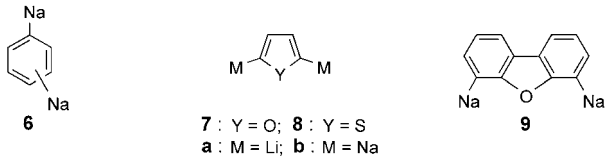
with lithium 2,2,6,6-tetramethylpiperidide (LITMP) in diethyl ether at −75 °C exclusively, under conditions in which transmetalation and consequently equilibration are negligible. The kinetic preference for the 2-position is dictated by the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tendency of the metal-bearing base to dock at the nitrogen atom of the heterocyclic ring, an interaction that is particularly effective in solvents of low polarity.

2.1.2. Coupled Equilibria

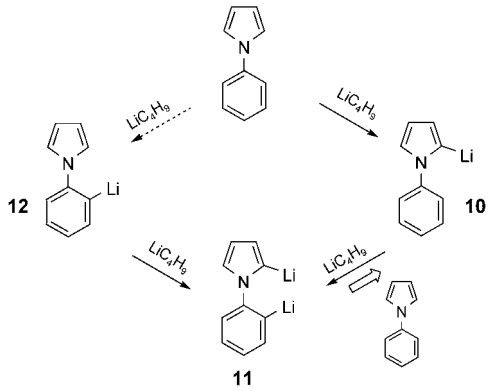
A spontaneous "uphill equilibration" of an organometallic species into a more-basic isomer would, of course, violate the laws of thermodynamics. It can nevertheless be realized if the equilibration is coupled to trapping steps, one of which is reversible and the other not. As disclosed in patents of the Nippon Soda Company,[11,12] butyllithium in tetrahydrofuran at −75 °C promotes the metalation of 3,4-dichlorobenzotrifluoride at the 2-position. The subsequent addition of methyl formate afforded a transient *O*-lithiated hemiacetal which spontaneously eliminated lithium methoxide to release the 2,3-dichloro-6-(trifluoromethyl)benzaldehyde.[11] In contrast, when the intermediate **5a** was intercepted with *N*,*N*-dimethylformamide instead and the reaction mixture kept at +25 °C for several hours before being neutralized, the former aldehyde and the isomeric 2,3-dichloro-5-(trifluoromethyl)-benzaldehyde were obtained in a 1:7 ratio (Scheme 5).[12] Recently, the temperature-controlled regiodivergence of aryllithium formylations has been successfully extended to 1,2,4-trichlorobenzene.[13]



Scheme 5. Acid–base equilibria promoting the spontaneous, though slow conversion of an initially formed *O*-lithiated hemiaminal into a sterically less-congested isomer, each of them being the precursor to a different aldehyde [Tool 2.1].

The mechanistic implications are not yet elucidated. The direct interconversion of two *O*-lithio hemiaminals formed by addition of the species **5a** and **5b** to *N*,*N*-dimethylformamide through reversible decomposition to the precursor components appears feasible. Based on experimental and computational gas-phase acidities in this series,[14,15] the free energies of the competing organolithium reagents **5a** and **5b** can be estimated to differ by not much more than 1 kcal mol^{-1}. Alternatively, the more congested *O*-lithio hemiaminal (derived from **5a**) could isomerize to the less-hindered one (derived from **5b**) via an *O*,*O*′-dilithiated bishemiaminal. In either case, accidentally formed dimethylamine and lithium dimethylamide would have to mediate the protonation and deprotonation steps.

2.1.3. Mono- versus Dimetalation



Dimetalated compounds such as phenylenedisodium (**6**; as a mixture of *meta* and *para* isomers),[16,17] furan-2,5-diyldisodium (**7a**),[18] furan-2,5-diyldilithium (**7b**),[19] thiophene-2,5-disodium (**8a**),[20] thiophene-2,5-diyldilithium (**8b**),[19] and dibenzofuran-4,6-diyldisodium (**9**)[21,22] have been known for a long while (Scheme 6). Their synthetic value is quite limited as they can only lead to symmetrically

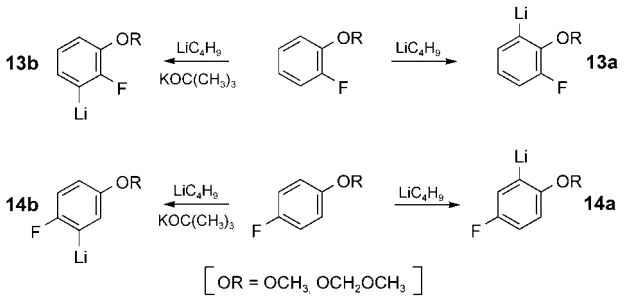
Scheme 6. A few typical (het)arenediyldimetal reagents.

substituted derivatives. One can generally preclude the generation of dimetalated species by avoiding any excess of the metalating reagent and by working in a solvent of sufficient polarity such as tetrahydrofuran.

Despite such precautions, organodimetallic reagents may nevertheless emerge along with the monometalated species. This happens to be the case with *N*-phenylpyrrole (Scheme 7).[23] Upon treatment with butyllithium in neat diethyl ether and in the presence of TMEDA mainly the α,*o*-dilithio species **11** is produced via the α-lithio intermediate **10** (not the *o*-lithio intermediate **12**).[23] Evidently, neighboring-group assistance[24] provided by the C$^{\alpha}$–Li bond that is formed first confers a kinetic advantage on the second metalation step. However, the *N*-*o*-phenylene-α-pyrryldilithium is ther-

Scheme 7. Removing the undesired dimetalated species **11** by its "incubation" with the metal-free precursor *N*-phenylpyrrole [Tool 2.1].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

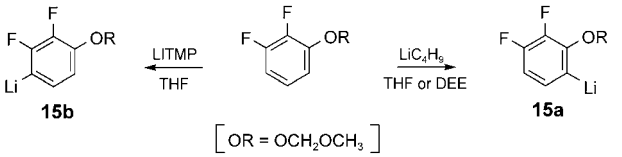


modynamically less stable and therefore slowly reverts to the monometal species **10** by reaction with the unconsumed *N*-phenylpyrrole[23] (Scheme 7).

2.2. Reagent-Modulated Optional Site Selectivity

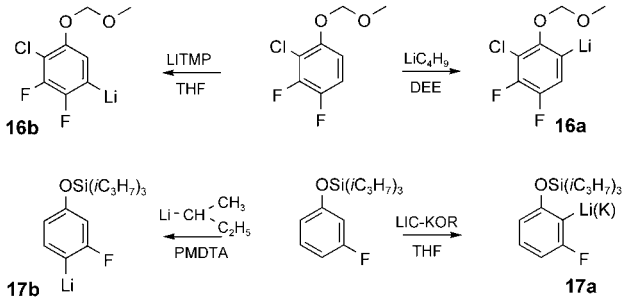
The mechanism-based matching of neighboring groups and reagents is the easiest way to implement regioflexibility. The concept and its application have already been extensively reviewed.[2b,25,26] Hence only a few highlights will be revisited below and a few recent results added.

2.2.1. Arenes as Substrates



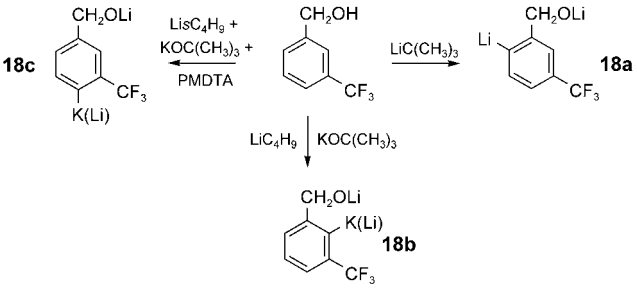
The first authentic case of an optionally site-selective metalation is still a prototypical example. In the presence of butyllithium, both 2- and 4-fluoroanisole were found to undergo clean deprotonation at the position adjacent to the oxygen atom,[27] thus generating the intermediates **13a** and **14a**. Clearly, when entering the transition state as a monomer or dimer rather than as a tetrameric aggregate, the required extra coordination can be easily supplied by the nearby methoxy group. In contrast, when the butyllithium was first complexed with potassium *tert*-butoxide or *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDTA) the metalation occurred at the position adjacent to the fluorine atom to give intermediates **13b** and **14b**, again exclusively.[27] As the reagent is optimally coordinated from the beginning in this case, the relative basicities of the organometallic intermediates now become the crucial factor. The superior inductive effect of fluorine relative to oxygen secures a more-efficient stabilization and hence a bigger driving force. As demonstrated recently,[28] the *O*-methoxymethyl-protected 2- and 4-fluorophenols exhibit the same regioselectivity divergence towards free and complexed organolithium bases (Scheme 8).

Scheme 8. Perfectly site-selective metalation of 2- and 4-fluoroanisole at a position either adjacent to the halogen or the oxygen atom [Tool 2.2].



Similar principles apparently govern the case of the *O*-methoxymethyl protected 2,3-difluorophenol. It was found to react with butyllithium at C6 and with LITMP at C4 to afford intermediates **15a** and **15b**, respectively (Scheme 9).[29]

Phenols in general are ideal reagents for tracking optional site selectivities. Butyllithium in diethyl ether at −75 °C

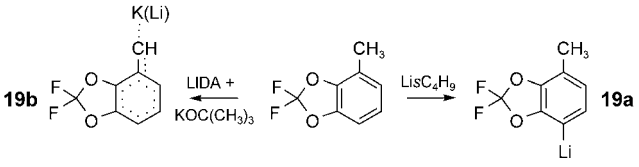


Scheme 9. Optional site selectivity in the metalation of *O*-methoxymethyl-protected 2,3-difluorophenol [Tool 2.2].

abstracts a proton from 3-chloro-1,2-difluoro-4-(methoxymethoxy)benzene at the position adjacent to the oxygen atom, whereas LITMP in tetrahydrofuran (again at −75 °C) metalates the 6-position next to the fluorine atom (intermediates **16a** and **16b**, respectively.[30] The superbasic mixture (LIC-KOR) of butyllithium and potassium *tert*-butoxide attacks 1-fluoro-3-(triisopropylsilyloxy)benzene exclusively at C2 whereas *sec*-butyllithium in the presence of PMDTA reacts preferentially (with a regioselectivity of >90 %) at C4, adjacent to the fluorine atom, giving rise to intermediates **17a** and **17b**, respectively (Scheme 10).[30]

Scheme 10. Optional site selectivity in the metalation of *O*-methoxymethyl-protected 2-chloro-3,4-difluorophenol and *O*-triisopropylsilyl-protected 3-fluorophenol [Tool 2.2].

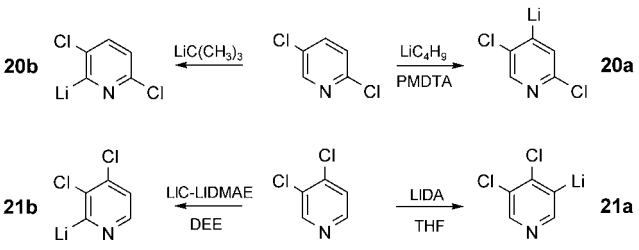
3-(Trifluoromethyl)benzyl alcohol offers a triple choice of regioselectivity depending on the nature of the metalating reagent employed.[31] Treatment in tetrahydrofuran with *tert*-butyllithium generated the intermediate **18a**, with LIC-KOR the intermediate **18b**, and with *sec*-butyllithium in the presence of PMDTA and potassium *tert*-butoxide the intermediate **18c** (Scheme 11), thus providing 5-trifluoromethyl-2-



Scheme 11. Optional site-selective generation of three isomeric organometallic reagents starting from the same precursor, 3-(trifluoromethyl)-phenol [Tool 2.2].

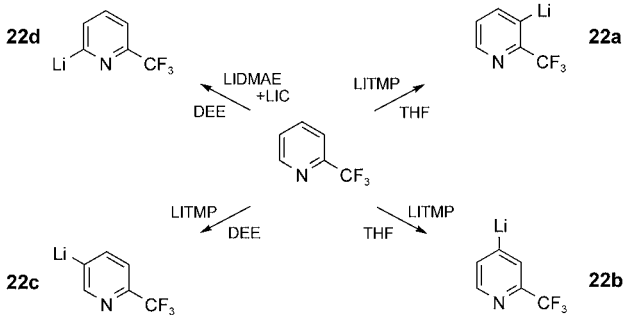
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

benzofuran-1(3*H*)-one or 7-trifluoromethyl-2-benzofuran-1(3*H*)-one or 4-hydroxymethyl-2-(trifluoromethyl)benzoic acid after trapping with carbon dioxide and subsequent acidification.[31] Although the yields are admittedly poor (12%, 47%, and 25%, respectively), they refer to regioisomerically uncontaminated, isolated products.[31]



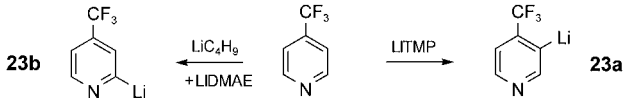
One new example can be added to the impressive list of optional site selectivities discriminating between aromatic and benzylic positions.[26] 2,2-Difluoro-4-methyl-1,3-benzodioxole was deprotonated by *sec*-butyllithium exclusively at C7, thus giving intermediate **19a**, whereas only derivatives of the benzyl metal species **19b** were isolated after treatment with LIDA in the presence of potassium *tert*-butoxide (Scheme 12).[32]

Scheme 12. Optional site-selective deprotonation of 2,2-difluoro-4-methyl-1,3-benzodioxole at either the benzylic or the aromatic 7-position [Tool 2.2].



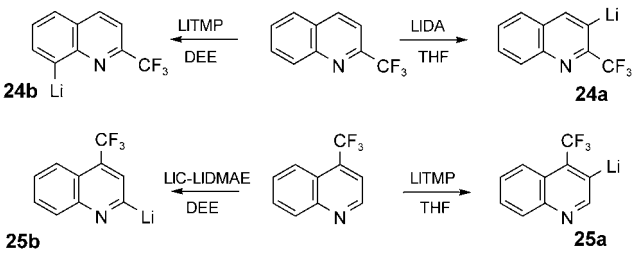
2.2.2. *Heterocycles as Substrates*

2,5-Dichloropyridine reacted with PMDTA-activated butyllithium at the 4-position and with *tert*-butyllithium at the 6-position, thus setting free the intermediates **20a** and **20b**, respectively.[33] The 3,4-isomer underwent deprotonation at the 5-position (intermediate **21a**) when LIDA was used and at the 2-position (intermediate **21b**) when LITMP was used (Scheme 13).[33] The regioselectivity of the latter transformation did not exceed 90%[33] but became quantitative when LITMP was replaced by the Caubère base[34] (i.e., butyllithium in the presence of lithium 2-dimethylaminoethoxide, LIC-LIDMAE).[35]



Scheme 13. Optional site selectivity in the metalation of 2,5- and 3,4-dichloropyridine [Tool 2.2].

2-(Trifluoromethyl)pyridine exhibits reagent-dependent selectivity at any of the four vacant positions.[36] When treated with LITMP in tetrahydrofuran at −75 °C for 6 h, selective metalation at C3 gave intermediate **22a**. However, when the reaction was quenched after only 15 min, 3- and 4-substituted derivatives resulting from intermediates **22a** and **22b**, respectively (2:3 ratio).[36] Again, the use of LITMP, but in diethyl ether as the solvent at −75 °C, allowed the preferential metalation of 2-(trifluoromethyl)pyridine at C5 (intermediate **22c**). Finally, deprotonation took place solely at the 6-position (producing intermediate **22d**) when the Caubère base was employed in diethyl ether at −75 °C (Scheme 14).[36]



Scheme 14. Optional site selectivity in the metalation of 2-(trifluoromethyl)pyridine [Tool 2.2].

4-(Trifluoromethyl)pyridine has only two different positions. LITMP in tetrahydrofuran abstracted a proton selectively from the 3-position (intermediate **23a**), whereas the Caubère base promoted deprotonation neatly at the 2-position (intermediate **23b**) (Scheme 15).[36]

Scheme 15. Optional site selectivity in the metalation of 4-(trifluoromethyl)pyridine [Tool 2.2].

2-(Trifluoromethyl)quinoline[36] underwent clean metalation in the presence of LIDA at the 3-position to produce intermediate **24a**, whereas LITMP, again in tetrahydrofuran at −75 °C, abstracted protons concomitantly from the 3- and 4-positions (3:2 ratio). However, the latter reagent in diethyl ether (at −75 °C) attacked the 8-position exclusively (intermediate **24b**). 4-(Trifluoromethyl)quinoline[36] reacted with LITMP in tetrahydrofuran at the 3-position and with the Caubère base at the 2-position, thus giving rise to intermediates **25a** and **25b**, respectively (Scheme 16).

Scheme 16. Optional site selectivity in the metalation of 2- and 4-(trifluoromethyl)quinoline [Tool 2.2].

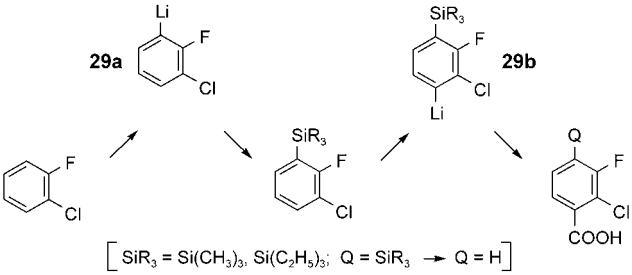
2.3. Deploying Protecting Groups

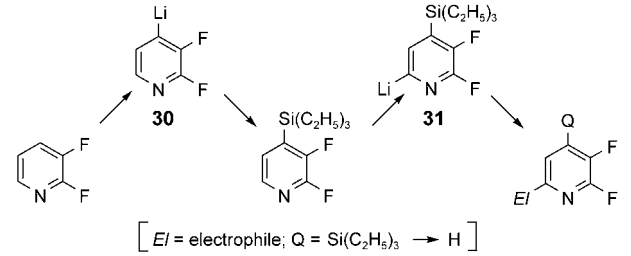


One has to differentiate between a protecting group located directly at a (hetero)aromatic ring or at its periphery. In the latter case, the group is attached to a heteroatom such as oxygen, sulfur, nitrogen, or phosphorus.

2.3.1. Switching Functional Groups On and Off

Although *O*-lithiated carboxy groups do activate neighboring positions towards metalation,[37–39] their effect remains fairly weak unless amplified by an additional electronegative substituent at C3. This enables regioflexibility as most other heterosubstituents outperform a competing lithiooxycarbonyl group by their superior *ortho*-directing power. The lithium salt of 4-fluorobenzoic acid is concomitantly attacked by *sec*- or *tert*-butyllithium at the 2- and 3-positions, whereas excess LITMP exclusively deprotonates the 3-position (up to 86% of trapping product derived from a lithium benzoate **26b**).[38,40] In contrast, the carbonyl group displays a very strong activating effect on its proximal positions when integrated into an *N*-alkyl-, *N*-aryl- or *N*,*N*-dialkylcarbamoyl unit. Thus, 4-fluorobenzanilide is cleanly deprotonated at the C2 (intermediate **26a**).[41] An amino group can be deactivated by replacing the N-bound hydrogen atoms with trialkylsilyl or, alternatively, activated by combining it with an acyl group, for example, *tert*-butoxycarbonyl (Boc).[42] In this way, either the 2- or the 4-position of 3-fluoroaniline can be metalated, generating the species **27a** or **27b**. Finally, oxidation or complexation at the phosphorus center with borane renders triarylphosphines more reactive or less reactive towards organometallic bases, respectively. For example, 3-anisyldiphenylphosphine oxide was smoothly deprotonated by LIDA at the 2-position (intermediate **28a**),[43] whereas the corresponding phosphine–borane adduct reacted solely at the 4-position, remote from the P atom (intermediate **28b**)[43] and this quite sluggishly even when the superbasic LIC-KOR mixture was used. Although the (phosphonio)boronate has a zwitterionic structure like the phosphine oxide, it lacks lone-pair electrons and is hence unable to coordinate organometallic reagents (Scheme 17).

Scheme 17. Selective introduction of a metal at the 2- or 3-position of *p*-fluorobenzoic acid, at the 2- or 4-position of *m*-fluoroaniline, and at the 2- or 4-position of *m*-anisyldiphenylphosphine, depending on the choice of the functionality-protecting group [Tool 2.3].

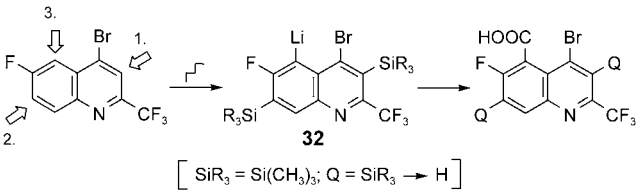


Scheme 18. Deactivation of the more-reactive position adjacent to the fluorine atom in 1-chloro-2-fluorobenzene by the introduction of a trialkylsilyl protecting group [Tool 2.3].

2.3.2. Steric Screening

1-Chloro-2-fluorobenzene undergoes metalation selectively at the position next to the lighter halogen atom (intermediate **29a**).[44] To favor the opposite regioselectivity, in other words, to realize an *o*→*o′ deflection*, one has to block the site adjacent to the fluorine atom by introducing a trialkylsilyl substituent, lithiating again (generating intermediate **29b**), delivering the electrophile, and removing the protecting group (Scheme 18).[9] The latter step can be brought about as a protodesilylation (with acids, bases, or fluoride ions in the presence of proton sources), as a halodesilylation (with molecular bromine or iodine), or even as a nitrodesilylation.

The introduction of a trialkylsilyl group at the 4-position of a pyridine ring shields the neighboring 3- and 5-positions. The reagent can only attack the intrinsically least acidic sites surrounding the nitrogen atom. In this way, 6-substituted derivatives of 2,3-difluoropyridine were prepared via intermediates **30** and **31** (Scheme 19).



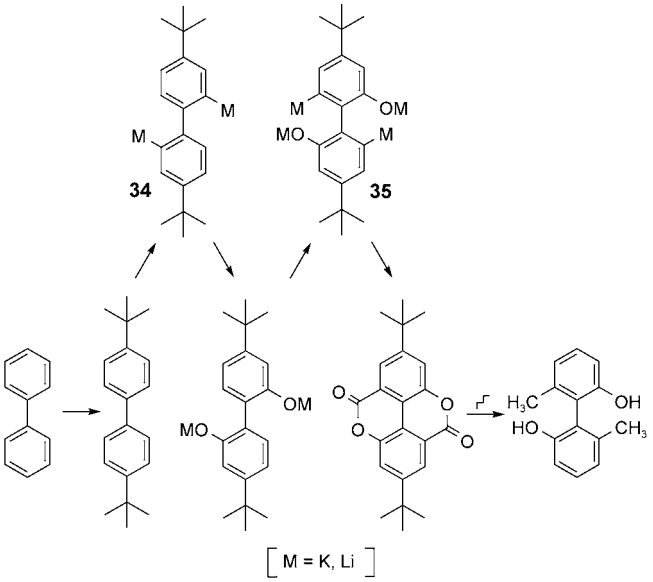
Scheme 19. Blocking the deprotonation of 2,3-difluoropyridine at both the 4- and 5-positions with a bulky 4-triethylsilyl group [Tool 2.3].

Multiple silylation allows one to inactivate progressively the most-reactive sites in a complex substrate and even to open a second battlefield by moving from one ring of an annulated system to the next. Thus, after a first and second

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

LIDA-promoted metalation, two trimethylsilyl groups could be successively introduced at the 3- and 7-positions of 4-bromo-6-fluoro-2-(trifluoromethyl)quinoline before the third lithiation at the 5-position (Scheme 20). Carboxylation of the intermediate **32** and subsequent deprotection afforded the 4-bromo-6-fluoro-2-(trifluoromethyl)quinoline-5-carboxylic acid (Q = H) as the final product.[5]

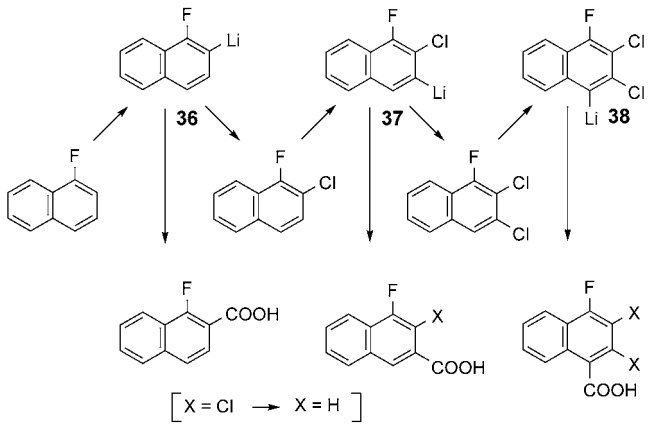
Scheme 20. Blocking the deprotonation of 4-bromo-6-fluoro-2-(trifluoromethyl)quinoline at the 3-, 7-, and 8-positions with two 3,7-trimethylsilyl groups [Tool 2.3].



Possible complications may originate from the bulkiness of the trialkylsilyl groups and may distort the regular substrate behavior. Alkyl lithium reagents and lithium dialkyl amides abstract a proton exclusively from the halogen-neighboring 4-position of 1,3-difluoro-2-(trialkylsilyl)benzene derivatives to generate intermediates **33a**, whereas the corresponding 1,3-dichloro-2-(trialkylsilyl)benzene compounds react with alkyl lithium reagents or lithium dialkyl amides and the 1,3-dibromo congeners react with LIDA or LITMP preferentially or exclusively at the 5-position (remote to the halogen atom), thus giving rise to the intermediates **33b** (Scheme 21).[45,46] Details of how this untypical *buttressing effect* operates are not yet clear.[48–50]

Scheme 21. Deprotonation of (2,6-dihalophenyl)trialkylsilanes deflected from the 4- to the 5-position when the halogen is chlorine or bromine.

Trimethylsilyl groups have been sporadically used in earlier work to deactivate otherwise more-acidic sites. However, as they may undergo deprotonation themselves,[51,52] it is often deemed advisable to replace them with triethylsilyl[46,47,53] or, occasionally, even with triisopropylsilyl[17] groups.

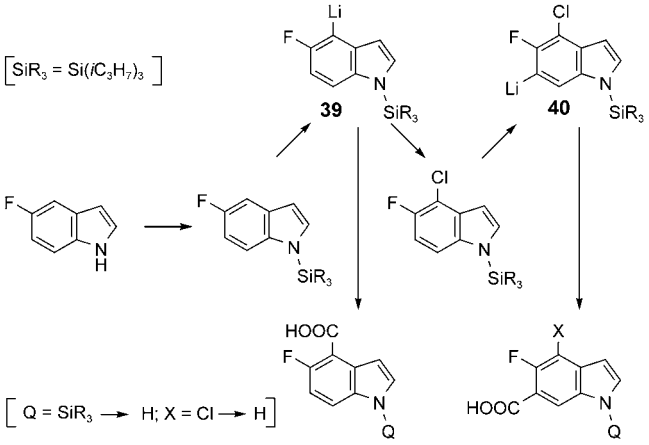


Any bulky substituent, in particular tertiary alkyl groups, can fulfill the same task. 1,3-Di(*tert*-butyl)benzene was metalated by the LIC-KOR superbase exclusively at the 5-position.[54] Two *tert*-butyl groups were readily introduced at the 4,4′-positions of biphenyl.[55] Subsequent treatment with 2 equivalents of LIC-KOR followed by fluorodimethoxyborane and hydrogen peroxide gave, via intermediate **34**, the 4,4′-di(*tert*-butyl)biphenyldiyl-2,2′-diol (OM = OH).[56] A second double metalation generates intermediate **35**, and trapping with carbon dioxide converts it into a bislactone, the carbonyl units of which could be reduced to methyl groups. The final *tert*-butyl deprotection was accomplished with aluminum trichloride as the catalyst and provided the final product 6,6′-dimethylbiphenyl-2,2′-diol (Scheme 22).[56]

Scheme 22. Blocking the base attack at the 3,3′,5,5′-positions of biphenyl by two 4,4′-*tert*-butyl groups [Tool 2.3].

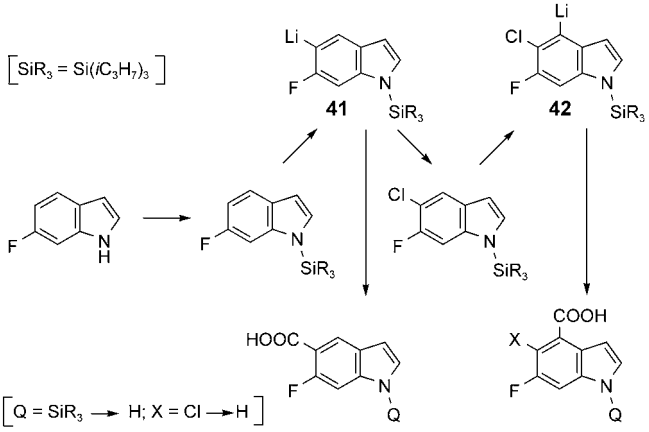
2.3.3. *Blocking the Most Reactive Site and Simultaneous Activation of the Neighboring Position*

When, after metalation, trialkylsilyl groups are introduced into aromatic or heterocyclic substrates, they wipe out the reactivity potential of the formerly most-acidic site and at the time they sterically screen the immediate vicinity against any further attack. As a consequence, *ortho*-protected substrates such as 1-fluoro-2-(triethylsilyl)naphthalene[57] (Scheme 23) prove to be completely inert towards organometallic reagents,



Scheme 23. Deflection of the base attack from the 2- to the 3- and 4-positions of 1-fluoronaphthalene by site-protecting chlorine atoms [Tool 2.3].

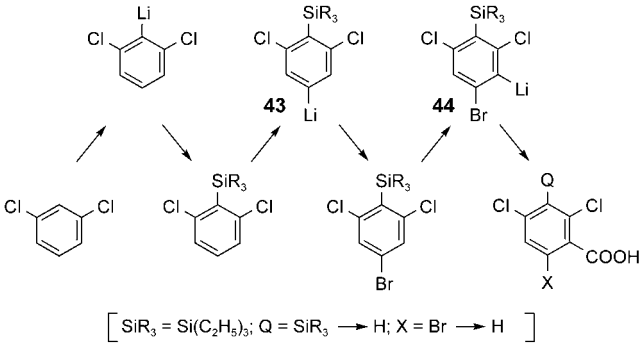
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



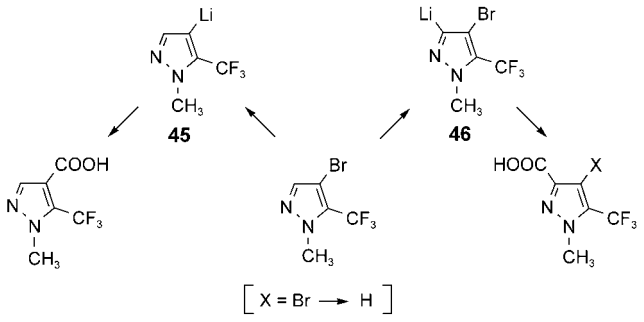
including superbases. In contrast, 2-chloro-1-fluoronaphthalene (prepared via intermediate **36**) readily underwent metalation at the 3-position now activated by the neighboring halogen (intermediate **37**; Scheme 23).

When another chlorine atom was introduced at this site, the resulting 2,3-dichloro-1-fluoronaphthalene (98%) was functionalized after a further deprotonation (intermediate **38**), at the 4-position this time. The heavier chlorine atom could be selectively removed by catalytic hydrogenation or reduction with zinc[58] to afford the 4-fluoronaphthalene-1-carboxylic acid (87%).[57].

The potential of chlorine to act simultaneously as a protecting and activating substituent in organometallic synthesis is immense. For reasons of space, the present survey will confine itself to two further examples. Triisopropylsilyl-protected 5-fluoroindole could be readily metalated at the 4- or, after chlorination, 6-positions (intermediates **39** and **40**, respectively) before being trapped with carbon dioxide and deprotected (Scheme 24).[59] In the same way, 6-fluoroindole could be functionalized via the intermediates **41** and **42** to afford the 6-fluoroindole-5-carboxylic acid and 6-fluoroindole-4-carboxylic acid, respectively (Scheme 25).[59]



Scheme 24. Deflection of the base attack from the 4- to the 6- position of 5-fluoroindole by a 4-chloro substituent [Tool 2.3].



Scheme 25. Deflection of the base attack from the 5- to the 4- position of 6-fluoroindole by a 5-chloro substituent [Tool 2.3].

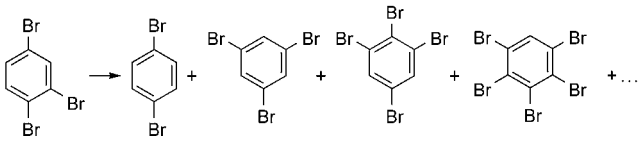
Bromine has a more restricted area of application as a protecting group than chlorine. It can, nevertheless, be most valuable when chlorine cannot be considered, for example, when the chlorine substituent must be present during the synthesis as it is part of the target molecule. Such a situation is encountered with the conversion of 1,3-dichlorobenzene into 2,4-dichlorobenzoic acid.[46] After silyl protection of the most acidic 2-position, the next metalation occurred preferentially at the remote 5-position. Interception of the resulting intermediate **43** with 1,2-dibromoethane provided a new substrate which could only undergo deprotonation of the 4-position when treated with LIDA, thus generating intermediate **44**. Carboxylation and removal of the bromo and triethylsilyl makeup afforded the desired product (Scheme 26).

Scheme 26. Protection of the 4-position of (2,6-dichlorophenyl)triethylsilane and activation of its 3-position by the introduction of a 4-bromo substituent [Tool 2.3].

Bromine offers the additional advantage that it can be introduced to electron-rich aromatic and heterocyclic rings under mild conditions. Thus, iron salt catalyzed bromination of 1-methyl-5-(trifluoromethyl)pyrazole gave the 4-bromo derivative in satisfactory yield (67%). The organolithium species **45**, which results from the halogen–metal permutation accomplished with *tert*-butyllithium, could be trapped as the carboxylic acid (88%).[60] LIDA-promoted deprotonation of the same 4-bromo derivative followed by carboxylation of the resulting species **46** and eventual reduction made the 1-methyl-5-(trifluoromethyl)pyrazole-3-carboxylic acid accessible in 65% overall yield (Scheme 27).[60] When the starting material 1-methyl-5-(trifluoromethyl)pyrazole was treated

Scheme 27. Protection of the 4-position of 1-methyl-5-(trichloromethyl)-pyrazole and activation of its 3-position by the introduction of a 4-bromo substituent [Tool 2.3].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



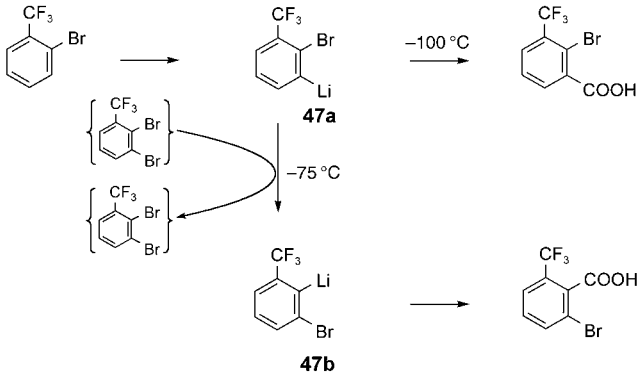
directly with LIDA and carbon dioxide, a mixture of the 4- and -3-carboxylic acids was formed in poor yield (25–33% and 2–6%, respectively).[60]

3. Regioflexibility in Halogen–Metal Exchange

The bromine–lithium and iodine–lithium permutation, discovered almost simultaneously by Wittig,[61] Gilman,[62] and their respective collaborators, was for a long while considered a mature method lacking both appeal and surprise. However, the last years marked a revival. Owing to new insight and techniques, the halogen–metal permutation has recaptured its former role as one of the most important and versatile methods in organic synthesis. From a methodological point of view, new exchange reagents such as the commercial isopropylmagnesium chloride and lithium tributylmagnesate[63,64] opened new avenues. At the same time the strategic options have been enlarged by devising new routes to difficultly accessible haloarene precursors. Moreover, methods have been developed to address a single halogen atom selectively, even when the substrate contained one or two other halogen substituents.

3.1 Deprotonation-Triggered Heavy-Halogen Migration

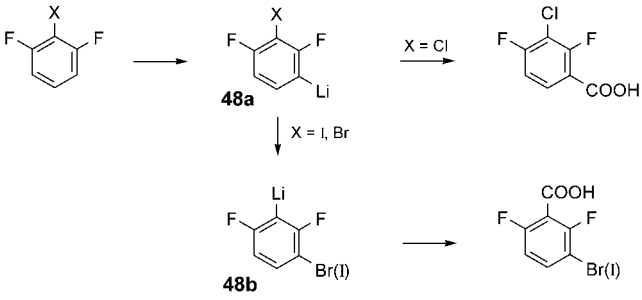
When polybromoarenes, for example, 1,2,4-tribromobenzene, are exposed to the action of strong bases such as sodium amide in liquid ammonia, a manifold of isomerization and dismutation products are obtained (Scheme 28).[65,66] Bunnett[67] coined the euphemistic term "halogen dance" for this randomization process although "halogen muddle" may be a more appropriate label.



Scheme 28. Halogen scrambling upon treatment of 1,2,4-tribromobenzene with sodium amide.

The seemingly messy outcome of such experiments nevertheless conveys the message that the isomerization of readily available halogenated compounds into less-accessible ones is feasible and that one only has to find ways to make such reactions selective. Several conditions must be met if one wishes to achieve a unidirectional transformation. The base must be employed in stoichiometric amounts and it must be powerful enough to deprotonate the substrate irreversibly. Finally, a basicity gradient must exist that makes the conversion of the initially produced intermediate into an isomer energetically attractive. On the other hand, one does not need to worry about how the isomerization might be brought about. Accidentally produced polyhaloarenes are always present in trace amounts and can act as catalytic turntables, promoting a permanently ongoing halogen–metal permutation.

3.1.1. Halogen Migration in the Arene Series

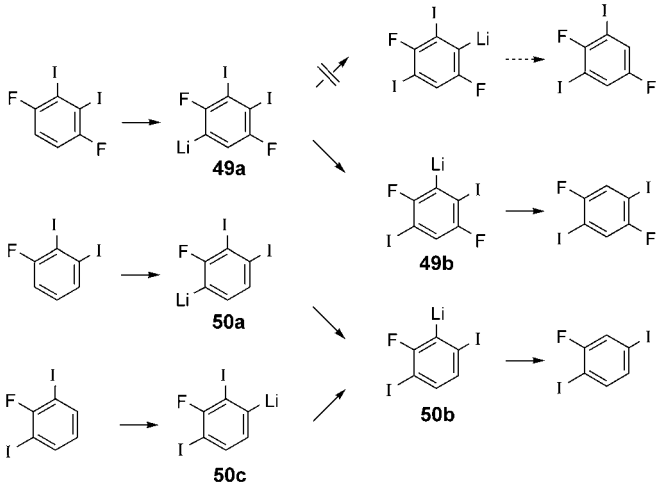


The first synthetically useful example of this kind still gains the beauty contest. When 2-bromobenzotrifluoride is treated with LITMP in tetrahydrofuran at −100 °C, a proton was abstracted from the position adjacent to the bromine atom. The resulting 2-bromo-3-(trifluoromethyl)phenyllithium (**47a**) could be trapped with an electrophile.[68] However, at −75 °C it isomerized quantitatively to 2-bromo-6-(trifluoromethyl)phenyllithium (**47b**), for which 2,3-dibromobenzotrifluoride acts as the exchange catalyst (Scheme 29).[68]

Scheme 29. Basicity-lowering heavy-halogen migration converting 2-bromo-3-(trifluoromethyl)phenyllithium into its 2,6-isomer [Tool 3.1].

This stop-and-go isomerization ("stop" at −100 °C, "go" at −75 °C) is only possible when the first lithiation is fast and the halogen–metal exchange only slightly exothermal, in other words, the driving force for swapping places between bromine and lithium atoms is moderate. If these conditions are not fulfilled, the first intermediate cannot be intercepted at all or only along with the isomerization product.

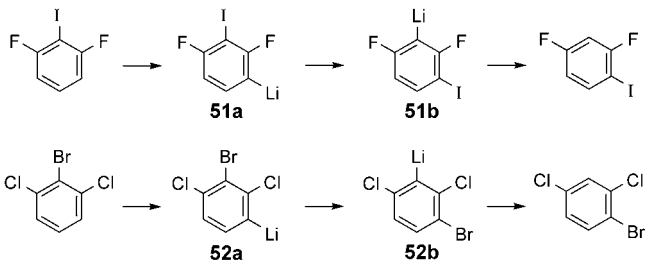
Initiated by the deprotonation of a position adjacent to a halogen atom, the basicity-gradient-driven halogen migration implies that a halogen–metal permutation is the final key step. Therefore it is restricted to bromo- or iodoarenes; chlorine atoms are unable to change places under such conditions. Whereas 1,3-difluoro-2-iodobenzene and 2-bromo-1,3-difluorobenzene (Scheme 30) experience both deprotonation (intermediate **48a**) and isomerization (intermediate **48b**)



Scheme 30. Basicity-lowering isomerization of 3-bromo-2,4-difluorophenyllithium and 2,4-difluoro-3-iodophenyllithium by heavy-halogen migration [Tool 3.1].

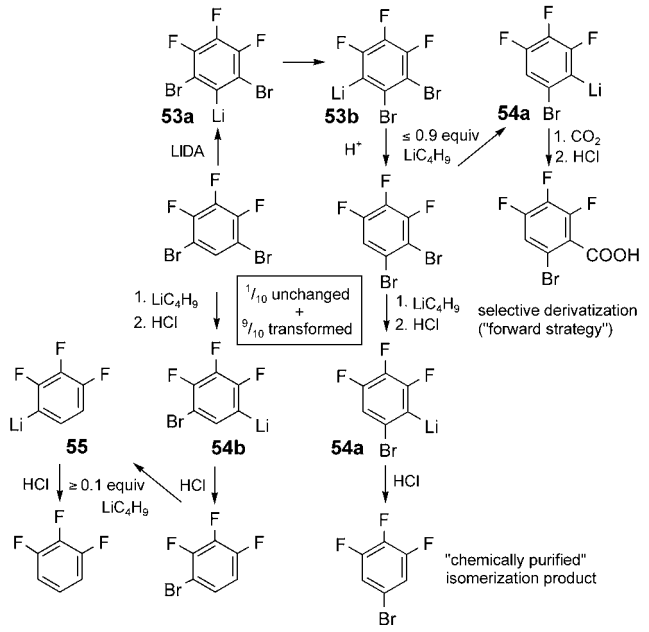
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

already at temperatures as low as −125 °C, the *ortho*-lithiated 2-chloro-1,3-difluorobenzene remains intact up to −50 °C (when β elimination of lithium fluoride sets in).[9]



Iodine migrates with particular ease. Typical examples are the regioselective conversion of 1,4-difluoro-2,3-diiodobenzene into 1,4-difluoro-2,5-diiodobenzene (via intermediates **49a** and **49b**) and the product-convergent isomerizations of 1-fluoro-2,3-diiodobenzene and 2-fluoro-1,3-diiodobenzene (via intermediates **50a**, **50b**, and **50c**; Scheme 31). The latter substrate requires the use of LITMP, whereas all reactions triggered by deprotonation at a position adjacent to a fluorine atom can be accomplished with LIDA.[69]

Scheme 31. More examples of basicity-gradient-driven isomerizations of haloaryllithium reagents (intermediates **49a**, **50a**, and **50c**) by iodine migration [Tool 3.1].



The isomerization does often not go to completion unless the reaction time is prolonged or an excess of the base is added. Thus, one frequently obtains the migration product as the major component contaminated with 10–20 % of starting material. Sometimes the two compounds can be readily separated by column chromatography. In general, however, it is more convenient to destroy the remaining starting material by addition of the stoichiometrically required quantity of butyllithium. In this way, pure 2,4-difluoro-1-iodo-benzene and 1-bromo-2,4-dichlorobenzene were isolated after isomerization starting from 1,3-difluoro-2-iodobenzene[69] and 2-bromo-1,3-dichlorobenzene[9] via intermediates **51a** and **51b** and **52a** and **52b**, respectively, and followed by a "kinetic cleanup" (Scheme 32).

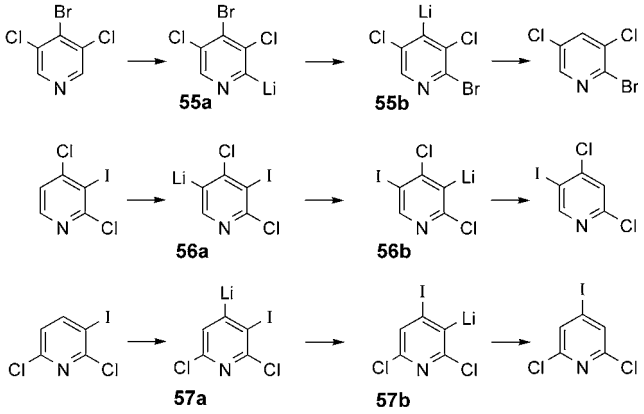
The chemical purification step can be executed at two different levels if the substrate subjected to isomerization by halogen migration contains two heavy halogen atoms, one of which has to be sacrificed. To illustrate the existing options, let us assume the LIDA-promoted conversion of 1,5-dibromo-2,3,4-trifluorobenzene via intermediates **53a** and **53b** into 1,2-dibromo-3,4,5-trifluorobenzene loses momentum when a 1:9 product distribution is attained. After neutralization one bromine atom in the main component is flanked by two halogen neighbors. It represents the most activated center and is hence displaced first. If a properly dosed amount of

Scheme 32. Still more examples of basicity-gradient-driven heavy-halogen migrations, this time requiring "kinetic cleanup" [Tool 3.1].

butyllithium (0.8–0.9 equiv) is employed, it can be selectively transformed (via intermediate **54a**) and, after functionalization, the product readily separated[70] (Scheme 33). Alternatively, one may entirely reduce the isomeric products *via* the

Scheme 33. Two complementary options for the kinetic purification of incompletely isomerized haloarenes as exemplified with a 1:9 mixture of 1,5-dibromo-2,3,4-trifluorobenzene and 1,2-dibromo-3,4,5-trifluorobenzene [Tool 3.1].

lithiated species **54a** and **54b** to a 1:9 mixture of monobromo compounds, destroy the contaminating 1-bromo-2,3,4-trifluorobenzene (the heavy halogen of which is activated by the neighboring fluorine atom) selectively by adding the required quantity of butyllithium (0.1–0.2 equiv) and to remove, after neutralization, the trifluorobenzene by evaporation (Scheme 33).[70]



The principles outlined above are generally applicable. This has been demonstrated by numerous examples of deprotonation-triggered halogen migrations including those starting from 1,5-dibromo-2,4-difluoro-3-(triethylsilyl)benzene,[45] 1,5-dibromo-2,3,4-trichlorobenzene,[9] 1,5-dibromo-2,4-dichloro-3-fluorobenzene,[7] 1-bromo-2,3,4-trifluoro-5-iodobenzene,[70] and 1-bromo-2,4-difluoro-5-iodo-3-(triethylsilyl)benzene.[45]

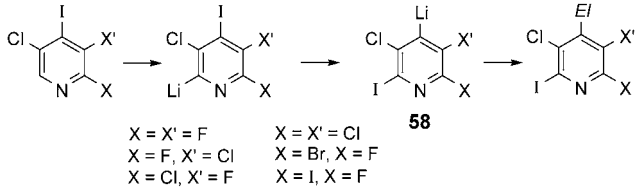
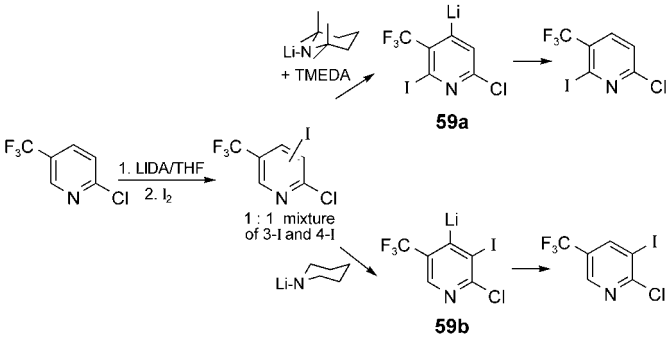
3.1.2. Halogen Migration in the Heterocyclic Series

Five- and six-membered heterocycles are more acidic than benzene; therefore even moderately strong bases such as lithium amide in liquid ammonia suffice to effect rapid deprotonation. If a suitably located bromine or iodine atom is present, heavy-halogen migrations can be observed. Such processes have been investigated more or less extensively by the groups of Gronowitz (thiophenes),[71,72] van der Plas (isothiazoles,[73] pyrazoles,[74] thiophenes[75]), Reinecke (thiophenes),[76,77] Shibuya (thiophenes),[78] Taylor (thiophenes),[79] Fröhlich (furans,[80,81] thiophenes[82,83]), and Quéguiner (pyridines,[84,85] quinolines[86]).



An indepth investigation of polyhalopyridines revealed an unexpectedly large synthetic potential for the method. Thus, 4-bromo-3,5-dichloropyridine, 2,4-dichloro-3-iodopyridine, and 2,6-dichloro-3-iodopyridine could be isomerized by LIDA-promoted heavy-halogen migration via intermediates **55a**,**b**, **56a**,**b**, and **57a**,**b** to afford 2-bromo-3,5-dichloropyridine, 2,4-dichloro-5-iodopyridine, and 2,6-dichloro-4-iodopyridine, respectively. The final products were purified by chromatography or crystallization (Scheme 34).[33]

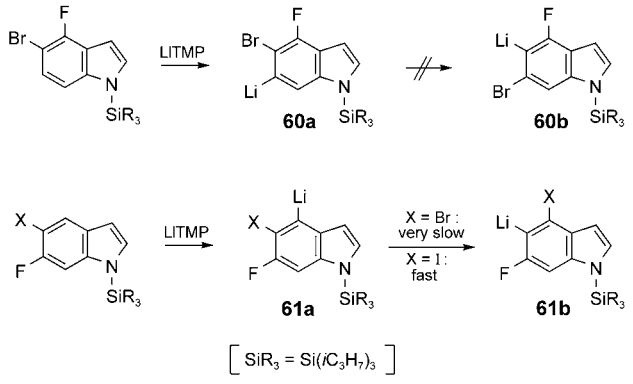
Scheme 34. Basicity-lowering isomerization of lithiated halopyridines by bromine or iodine migration [Tool 3.1].



Analogously, but with LITMP as the base, an iodine migration was accomplished by using 5-chloro-2,3-dihalo-4-iodopyridines as the substrates. The isomerized organolithium species **58** were either quenched with water (*El* = H) or dry ice (*El* = COOH) (Scheme 35).[87,88]

An intriguing optional site selectivity was discovered when a 1:1 mixture of 2-chloro-3-iodo- and 2-chloro-4-iodo-5-(trifluoromethyl)pyridine, easily accessible by consecutive

Scheme 35. Further examples of halopyridine isomerizations by deprotonation-triggered iodine migration [Tool 3.1].

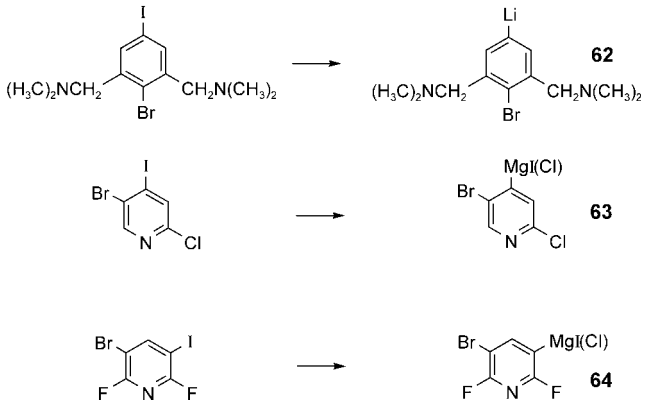


treatment of the commercially available 2-chloro-5-(trifluoromethyl)pyridine with LIDA in tetrahydrofuran for 2 h at −75 °C and elemental iodine, was treated with a variety of amide-type bases. After exposure to the bulky LITMP–TMEDA adduct in tetrahydrofuran for 2 h at −75 °C, 6-chloro-2-iodo-3-(trifluoromethyl)pyridine was obtained in 62 % yield (via intermediate **59a**) and was separated from the dismutation products 2-chloro-5-(trifluoromethyl)pyridine (10 %) and 6-chloro-2,4-diiodo-3-(trifluoromethyl)pyridine (8 %) by simple distillation (Scheme 36). Conversely,

Scheme 36. Regiodivergent isomerization of 2-chloro-4-iodo-5-(trifluoromethyl)pyridine by iodine migration to the 3- or 6-position, depending on the choice of base [Tool 3.1].

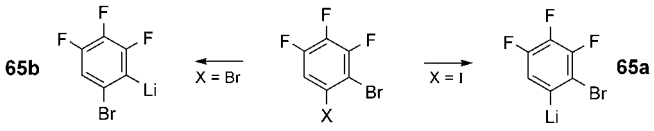
virtually pure 2-chloro-3-iodo-5-(trifluoromethyl)pyridine was isolated, though in moderate yield (33 %), when lithium piperidide was allowed to interact with the mixture of 3- and 4-iodo regioisomers for 24 h in tetrahydrofuran at −75 °C, thus generating intermediate **59b** (Scheme 36).[89]

Another surprise was encountered in the indole series. When 5-bromo-4-fluoro-1-(triisopropylsilyl)indole was treated with LIDA or LITMP, clean deprotonation occurred at the 6-position, but the lithiated intermediate **60a** (characterized by carboxylation) did not isomerize at all to the more stable species **60b** (Scheme 37).[59] Likewise, halogen migration did not occur with the 4-lithiated 5-bromo-6-fluoro-1-(triisopropylsilyl)indole (**61a**, X = Br).[59] On the other hand, the analogous 5-iodo compound reacted rapidly with PMDTA-activated LITMP to give directly and quantitatively (via **61a**, X = I) the isomerized species **61b** (Scheme 37).[59]



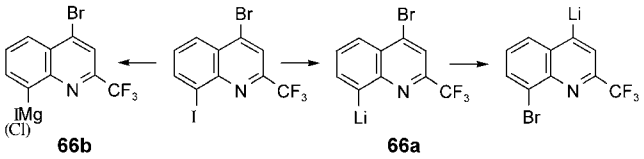
Scheme 37. Rapid isomerization of *N*-protected and 6-lithiated 6-fluoro-5-iodoindole, but no analogous bromine migration [Tool 3.1].

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



3.2. Discriminating between Different Halogen Substituents

Regardless of whether one has the reductive insertion of metals into halo compounds in mind or permutational halogen–metal interconversion, the well-known order of reactivity is the same. Iodine is displaced faster than bromine (by several powers of ten)[90] and chlorine is exchange-resistant, except in unusual situations. Thus, bromoiodobenzenes can be converted selectively into the corresponding bromophenyllithium reagents.[91–94] 2-Bromo-1,3-bis(dimethylamino)-5-iodobenzene reacts with *tert*-butyllithium to produce the 5-lithio species **62**.[95] Similarly, 5-bromo-2-chloro-4-iodopyridine[89] and 3-bromo-2,6-difluoro-5-iodopyridine[96] smoothly react with isopropylmagnesium chloride to afford the intermediates **63** and **64**, respectively (Scheme 38).

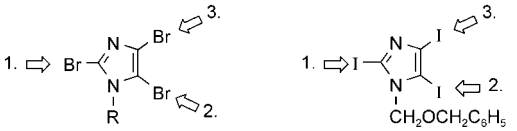


Scheme 38. Iodine participates in halogen–metal permutations much more readily than does bromine; chlorine does not compete at all [Tool 3.2].

Treatment of 2-bromo-3,4,5-trifluoro-1-iodobenzene with butyllithium in tetrahydrofuran at −100 °C afforded cleanly the intermediate **65a**.[70] In contrast, the 1,2-dibromo-3,4,5-trifluorobenzene gave rise to intermediate **65b** under the same conditions,[70] as the displacement of the bromine atom at the 2-position (which is now flanked by two other halogens) is now the energetically favored route (Scheme 39).

Scheme 39. Generating two different organometallic species (**65a** or **65b**), depending on whether 2-bromo-3,4,5-trifluoro-1-iodobenzene or 1,2-dibromo-3,4,5-trifluorobenzene serves as the substrate of a halogen–metal permutation [Tool 3.2].

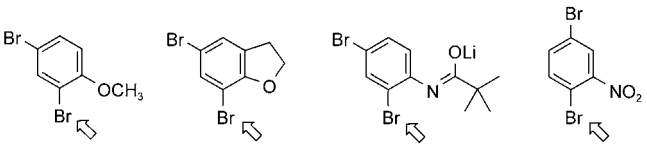
At this stage a word of warning may be appropriate. A subsequent positional scrambling may compromise an initially perfect discrimination between iodine and bromine. Although 4-bromo-8-iodo-2-(trifluoromethyl)quinoline reacted with both isopropylmagnesium chloride and butyllithium under selective iodine–metal displacement, only the organomagnesium intermediate **66b** persisted as such, whereas the lithium species **66a** isomerized by positional permutation of the bromine and lithium atoms (Scheme 40).[97]



Scheme 40. Alternative conversion of 4-bromo-8-iodo-2-(trifluoromethyl)quinoline into a 4- and an 8-metal-bearing species [Tool 3.2].

3.3. Discriminating between Seemingly Equal Halogen Atoms

Modern synthesis has to cope more and more with structural complexity. For reasons of logistic simplicity, it would be advantageous to allow the presence of just one kind of halogen substituent, preferably bromine, and then to replace them successively by metal atoms and ultimately by various functional groups or other substituents. This raises the question of how to discriminate chemically between formally identical halogen atoms.



A spectacular case of sequentially controlled regioselectivity was reported which featured 1-alkyl-protected 2,4,5-tribromoimidazole[98–100] and 2,4,5-triiodoimidazole.[101,102] When butyllithium was employed as the exchange reagent, first the halogen at the 2-position, then that at the 5-position, and eventually that at the 4-position was replaced by the metal (Scheme 41).

Scheme 41. Controlled replacement of three heavy-halogen atoms from 2,4,5-trihaloimidazoles by sequential halogen–metal permutations.

3.3.1. Activation by Neighboring Heteroatoms

If there is only one heteroatom besides the halogen, the outcome of the permutation experiment is, in general, safely predictable. It is always the halogen atom adjacent to the electronegative substituent that has the highest exchange priority (Scheme 42). When 2,4-dibromoanisole is exposed to isopropylmagnesium chloride, first the bromine atom next to the methoxy group is exchanged;[103] 5,7-dibromo-2,3-dihydro-1-benzofuran[104] reacts exclusively at the position adja-

Scheme 42. Discrimination between two formally equal halogen atoms through neighboring-group assistance [Tool 3.3].

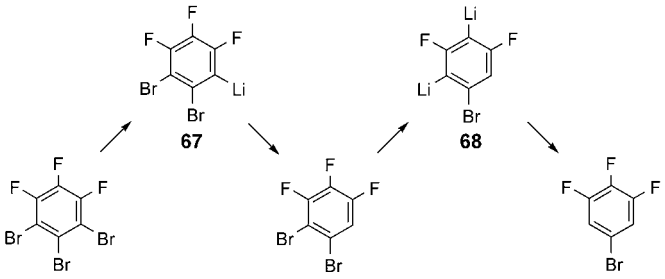
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cent to the oxygen atom. In the same way, 2,4-dibromo-*N*-pivaloylaniline[105] (after deprotonation of the NH center) and 1,4-dibromo-2-nitrobenzene[106] exhibit an absolute selectivity in favor of the bromine atom adjacent to the nitrogen atom (Scheme 42).

The "kinetic cleanup" described in the Section 3.1.1 also depends on the activation provided by neighboring heteroatoms. It was shown that fluorine or chlorine atoms are most effective in this context.

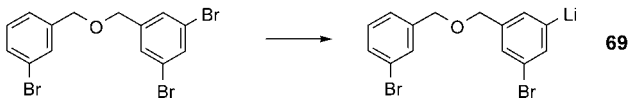
The activation provided by the neighboring heteroatom can be exploited in a different way too. The approach may be termed the Echternach procedure, as it boils down to a two-steps-forward-one-step-back strategy. Although historically unproven,[107] it has become a stereotyped description of the Echternach dancing procession as a forward and backward hopping of pilgrims, a choreography of locomotion that is nowadays regarded as an allegory of human behavior in general and political practice in particular.

As mentioned in Section 2.1, 1-phenylpyrrole can be easily subjected to a double metalation at an α- and an *o*-position (intermediate **11**). Trapping with 1,2-dibromoethane gives α,*o*-dibromo-*N*-phenylpyrrole in high yield. When this compound was treated with 1 equivalent of butyllithium, only the halogen atom attached to the heterocyclic ring was removed.[23] The 1-(2-bromophenyl)pyrrole isolated after neutralization is an isomer of α-bromo-*N*-phenylpyrrole, which can be readily prepared from 1-phenylpyrrole by consecutive monometalation (intermediate **10**) and bromination (Scheme 43).



Scheme 43. The Echternach route to 1-(2-bromophenyl)pyrrole [Tool 3.3].

It may sometimes even be worthwhile to opt for a three-steps-forward-two-steps-back bargain. 1,2,3-Trifluorobenzene was readily converted into 1,2,3-tribromo-4,5,6-trifluorobenzene by repetitive alternating treatments with LIDA and bromine. Subsequent reactions with butyllithium at −100 °C and methanol (via intermediates **67** and **68**) eliminate the bromine atoms located next to a fluorine site one after the other, thus leading to 5-bromo-1,2,3-trifluorobenzene, which is difficult to make directly (Scheme 44).[70]



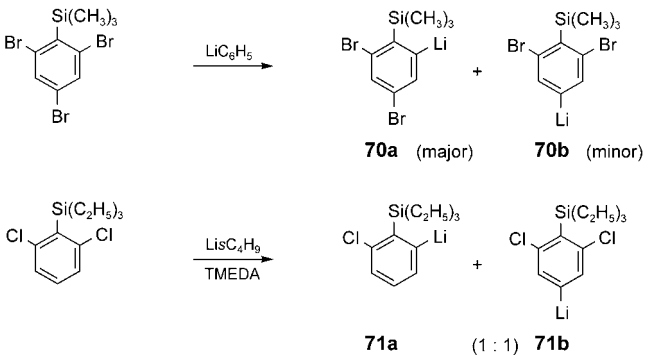
3.3.2. *Activation by Remote Heterosubstituents*

Systematic investigations by Leroux[90] have revealed striking differences in the rates of butyllithium-promoted

Scheme 44. Three steps forward two steps back: conversion of 1,2,3-trifluorobenzene into its 5-bromo derivative [Tool 3.3].

halogen–metal permutation processes with bromobenzene and heterosubstituted congeners. Thus, 1,3-dibromobenzene and 1-bromo-3,5-difluorobenzene were found to react faster (by several powers of ten) than the parent compound. The activating effect of the additional halogen substituent was also demonstrated in another way by an intramolecular competition experiment. In the presence of butyllithium, 1,3-dibromo-5-{[(3-bromobenzyl)oxy]methyl}benzene exclusively underwent halogen–metal permutation at the multiply substituted ring, affording the intermediate **69** and, after quenching with dry ice, a carboxylic acid with two halogen-bearing rings (Scheme 45).[108]

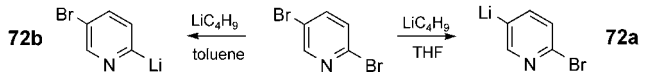
Scheme 45. Site-selective halogen–metal exchange owing to remote activation: 3,3′,5-tribromodibenzyl ether as the substrate [Tool 3.3].



3.3.3. *Steric Acceleration*

As trialkylsilyl groups shield *ortho* hydrogen atoms against the deprotonating attack of organometallic reagents, one might expect them to exert a similar retarding or suppressing effect on halogen–metal permutations. The contrary proves to be true. Apparently, steric pressure overrides steric hindrance. The departure of a voluminous heavy-halogen atom from the immediate vicinity of a bulky silyl substituent means relief of strain. This must be the reason why (2,4,6-tribromophenyl)trimethylsilane produced mainly the 2-lithio species **70a** (rather than its 4-isomer **70b**) when treated with ethereal phenyllithium[9] and why (2,6-dichlorophenyl)triethylsilane underwent a totally unexpected chlorine–lithium displacement in the presence of *sec*-butyllithium along with metalation at the 5-position, as reflected by the 1:1 ratio of the intermediates **71a** and **71b** (Scheme 46).[9]

3.3.4. *Solvent-Modulated Optional Site Selectivity*



In 1977 Parham et al.[109] reported the halogen–metal permutation between 2,5-dibromopyridine and butyllithium in tetrahydrofuran to take place at the 5-position (remote

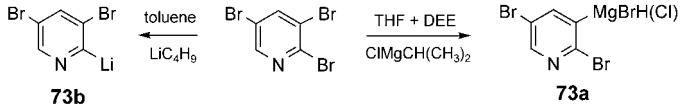


Scheme 46. Facilitated halogen–metal permutation at sites adjacent to silyl groups owing to relief of steric strain [Tool 3.3].

from the nitrogen atom) to afford intermediate **72a**. However, the same reaction performed again at −75 °C, but in toluene this time, replaces the halogen atom at the 2-position (intermediate **72b**; Scheme 47).[110] Evidently, the coordinating capacity of the nitrogen atom dictates the course of the reaction in apolar solvents such as toluene, whereas in ethereal media simply the least-basic species (in other words, metal compounds of the 4- rather than of the 3- not to speak of the 2-pyridyl anion[111]) is generated (Scheme 47).

Scheme 47. Solvent-dependent, optional site-selective halogen–metal permutation of 2,5-dibromopyridine as substrate [Tool 3.3].

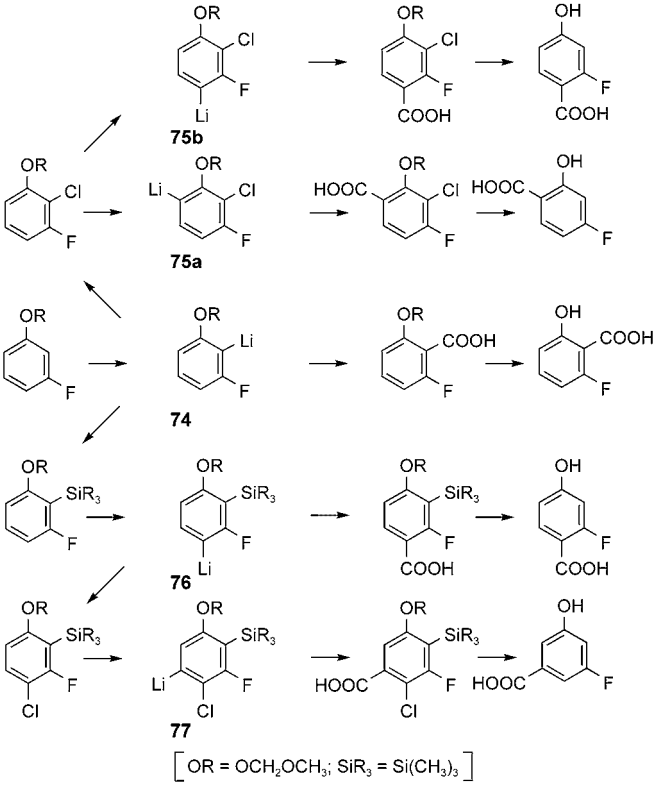
This solvent dependence of the reaction is a most fascinating, if rare, phenomenon. Up to now only one further example has been discovered. When treated with isopropylmagnesium chloride in tetrahydrofuran at 0 °C or butyllithium in toluene at −75 °C, 2,3,5-tribromopyridine accommodates the metal at the 3- or 2-position, producing intermediates **73a** or **73b** and, after iodination, 2,5-dibromo-3-iodopyridine (77 %) and 3,5-dibromo-2-iodopyridine (75 %), respectively (Scheme 48).[89]

Scheme 48. Solvent-controlled halogen–metal permutation at the 2- or 3-position of 2,3,5-tribromopyridine [Tool 3.3].

4. Synopsis, Perspectives, and Outlook

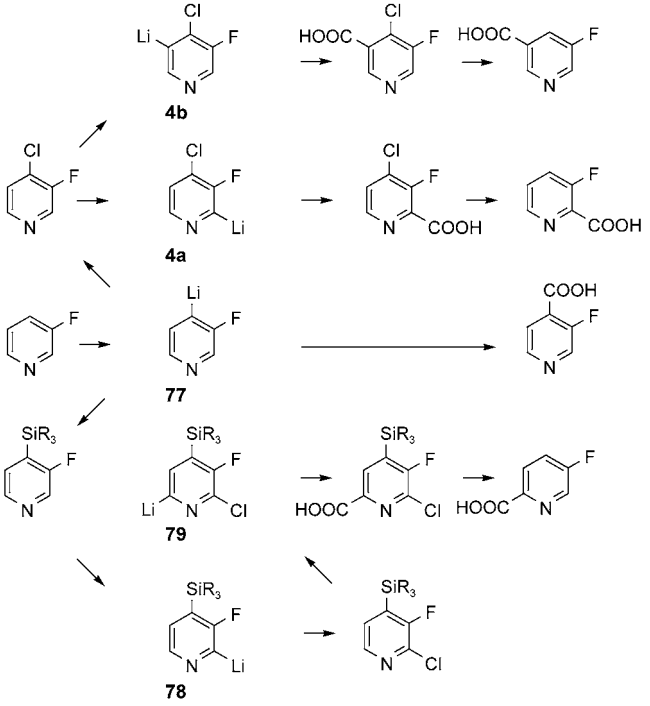
In the preceding two Sections of this Review various possibilities were considered as to how regioselectivity can be secured in the derivatization of aromatic and heterocyclic substrates. Having thus examined the individual parts of a kit of methods separately, we now have to find how they fit together, what they have in common, and where they are complementary.

Although it may be clear, attention should be paid to a unique virtue of the organometallic approach to structure proliferation. A metal can be compared to a joker in a card game: it can be replaced by any known electrophile. This means that the same intermediate can potentially be converted into hundreds of new compounds, even if only a handful of trapping reagents are used to play a role in systematic investigations as those described above. Moreover, the choice of the electrophile and, as a corollary, of the target structure can be deferred until the last step of the reaction sequence. Such features hold the promise of unmatched synthetic flexibility and of access to an immense molecular diversity whenever organometallic species act as the turntables.



4.1. The Holy Grail: Regiochemically Exhaustive Functionalization

The goal defined in the Introduction was to make any vacant position of a given aromatic or heterocyclic substrate amenable to selective substitution. It cannot be tested mathematically but only empirically whether or not this challenge can be met by a suitable combination of the organometallic methods described above. Exhaustive regiochemical substitution has been successfully demonstrated in numerous model studies; three more-elaborate, though still typical, examples are presented below.



O-Methoxymethyl-protected 3-fluorophenol was rapidly metalated by butyllithium or *sec*-butyllithium at C2, and the intermediate **74** was trapped with dry ice to afford 2-fluoro-6-hydroxybenzoic acid. The use of chlorotrimethylsilane or 1,1,2-trichloro-1,2,2-trifluoroethane as the electrophile led to [(2-fluoro-6-methoxymethoxy)phenyl]trimethylsilane and 2-chloro-1-fluoro-3-(methoxymethoxy)benzene, respectively. The latter compound reacted with butyllithium exclusively at the 4-position, adjacent to the oxygen atom (thus generating intermediate **75a**), to give 4-fluoro-2-hydroxybenzoic acid upon consecutive carboxylation, acid hydrolysis, and reduction. However, when LITMP was employed, the deprotonation occurred at the 6-position, adjacent to the fluorine atom (intermediate **75b**), and ultimately led to the isomeric 2-fluoro-4-hydroxybenzoic acid. [(2-Fluoro-6-methoxymethoxy)phenyl]trimethylsilane, the other interception product, underwent metalation also solely at the position adjacent to the fluorine atom (producing intermediate **76**). The [(3-chloro-2-fluoro-6-methoxymethoxy)phenyl]trimethylsilane obtained upon chlorination was converted into 3-fluoro-5-hydroxybenzoic acid by consecutive metalation (intermediate **77**), carboxylation, fluoride-mediated protodesilylation, acid hydrolysis, and reduction (Scheme 49).[22]

3-Fluoropyridine, another fairly inexpensive starting material, is deprotonated by LIDA at C4. In this way, 3-fluoropyridine-4-carboxylic acid became immediately accessible. 4-Chloro-3-fluoropyridine, prepared by chlorination of the organometallic intermediate **78**, provided 3-fluoropyridine-2-carboxylic acid in a short sequence consisting of

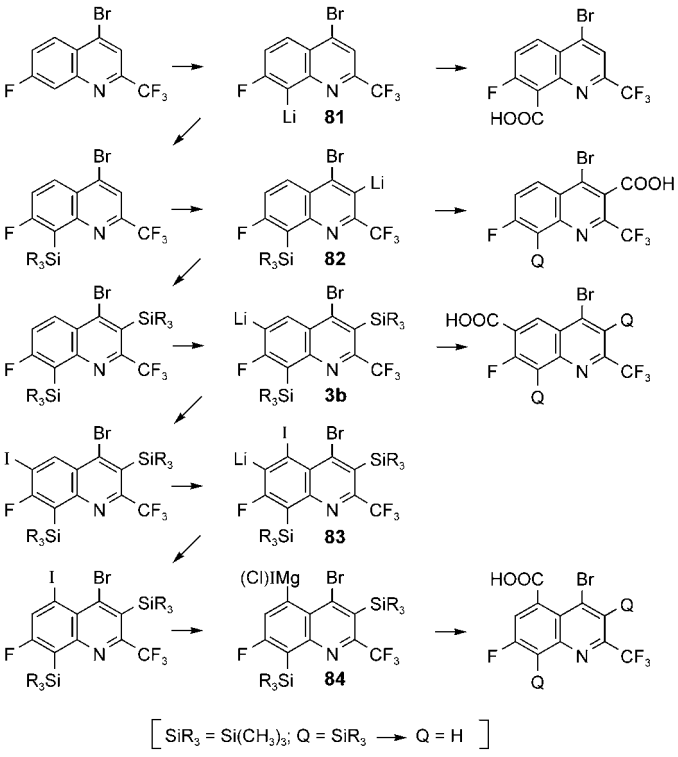

Scheme 49. The regiochemically exhaustive conversion of 3-fluorophenol into all four possible fluorohydroxybenzoic acids.

Scheme 50. The regiochemically exhaustive conversion of 3-fluoropyridine into all four possible fluoropyridinecarboxylic acids.

metalation (intermediate **4a**) with LITMP in diethyl ether, carboxylation, and reduction. However, it sufficed to replace the metalating reagent LITMP in diethyl ether with LIDA in tetrahydrofuran to revert the site selectivity completely. This time a proton was abstracted from the 5-position (neighboring the chlorine atom; intermediate **4b**) and ultimately 5-fluoropyridine-3-carboxylic acid was isolated. Finally, 5-fluoropyridine-2-carboxylic acid was made in seven steps involving intermediates **78**, **79**, and **80** by successive metalation and silylation, metalation and chlorination, metalation and carboxylation terminated eventually by deprotection (Scheme 50).[10]

The LIDA-promoted deprotonation of 4-bromo-7-fluoro-2-(trifluoromethyl)quinoline occurred first at the 8-position (intermediate **81**; Scheme 51). This opened the entry, by carboxylation, to 4-bromo-7-fluoro-2-(trifluoromethyl)quinoline-8-carboxylic acid or, by trimethylsilylation, to a silane that underwent the next deprotonation at the 3-position (generating intermediate **82**). Carboxylation and protodesilylation afforded 4-bromo-7-fluoro-2-(trifluoromethyl)quinoline-3-carboxylic acid or, after another trimethylsilylation, a 3,8-bissilane that, when treated with LIDA, generated a mixture of 5- and 6-lithiated species, which fortunately equilibrated completely in favor of the latter component (**3b**; see Section 2.1.).[5] Carboxylation and subsequent deprotection gave 4-bromo-7-fluoro-2-(trifluoromethyl)quinoline-6-carboxylic acid (Scheme 51). Iodination followed by deprotonation-triggered halogen migration and neutralization of intermediate **83** afforded a 5-iodo derivative that, when

Scheme 51. The regiochemical exhaustive conversion of 4-bromo-7-fluoro-2-(trifluoromethyl)quinoline into the four possible 4-bromo-7-fluoro-2-(trifluoromethyl)quinolinecarboxylic acids.

subjected to a halogen–metal permutation with isopropylmagnesium chloride followed by carboxylation of the resulting Grignard compound **84** and protodesilylation, provided 4-bromo-7-fluoro-2-(trifluoromethyl)quinoline-5-carboxylic acid (Scheme 51).[5]

Further examples of regiochemically exhaustive functionalizations of bulk chemicals will be published periodically. The toolbox methods were, for instance, recently applied to prepare numerous chloro(trifluoromethyl)pyridine carboxylic acids, which are attractive building blocks for medicinal and agrochemical research.[89]

4.2. The Mechanistic Basis

According to widespread prejudice, organometallic reactions are unpredictable. This belief reflects a regrettable scarcity of valid information. Mechanistic and, in particular, kinetic studies of reactions involving metal derivatives in apolar media are complicated and hence have been largely neglected. On the other hand, it would be simpleminded to believe that one could have designed and elaborated the *toolbox methods* randomly or in a trial-and-error approach. To accumulate the required knowledge and insight, we have invested much time and effort in the assessment of gas-phase acidities, exchange equilibria of organolithium species, organometallic reaction rates, and related phenomena. Even a short survey of this work would go beyond the scope of the present article. Therefore, the reader is referred to a forthcoming review.[112]

The author is indebted to a marvelous team of competent collaborators. Major contributions to the present subject are credited to Carla Bobbio, Fabrice Cottet (now at AMCIS, Bubendorf), Assunta Ginanneschi, Joanna Gorecka, Christophe Heiss, Olivier Lefebvre, Frédéric Leroux (now at the University of Strasbourg), Giuseppe Mangano, Marc Marull, Elena Marzi, Florence Mongin (now at the University of Rennes, Thierry Rausis, and Jean-Noël Volle. Financial support was provided by the University of Lausanne, the Federal Institute of Technology at Lausanne, the Swiss National Science Foundation, Bern (grant 20-100′336-02), and the Federal Office for Education and Science, Bern (grant 97.0083 linked to the TMR project FMRXCT-970129 and grant C02.0060 linked to the COST-D24 project WG0006-02).

Communications

The dipeptide Ac-L-Pro-D-c_3Dip-NHMe, which incorporates a cyclopropane amino acid, adopts two consecutive γ turns that are stabilized by intramolecular hydrogen bonds. For more details on this conformation, which has not been seen before in crystalline short linear peptides, see the Communication by A. I. Jiménez et al. on the following pages.

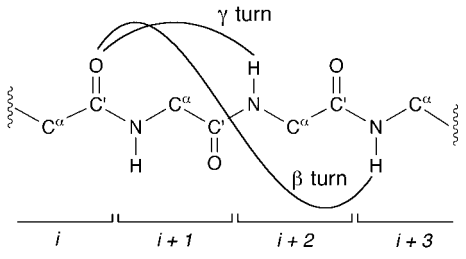
Peptide Structures



First Observation of Two Consecutive γ Turns in a Crystalline Linear Dipeptide**

Ana I. Jiménez, Gema Ballano, and Carlos Cativiela*

Dedicated to Dr. Michel Marraud

Reverse turns (or bends) are elements of primary importance both in the structure and function of peptides and proteins.[1] They give rise to a sharp reversal in the polypeptide chain, thus conferring on proteins their globular character. Turns have been suggested to play a role in the initial stages of protein folding and to be propitious sites for molecular recognition and receptor binding. Many naturally occurring oligopeptides have been proposed to adopt turns in their bioactive conformation.[1,2]

Different types of bends have been recognized according to the number and spatial arrangement of the residues involved. The most common is the β turn,[1,3] which involves four consecutive amino acids (*i* to *i*+3, Figure 1) and is generally stabilized by an intramolecular hydrogen bond between the CO group at position *i* and the NH group at *i*+3. Several subclasses of β turns are further distinguished on the basis of the backbone dihedral angles (φ,ψ) associated with the central *i*+1 and *i*+2 positions. Types I and II (Figure 1) are the most widely distributed and differ essentially in the orientation of the middle peptide group. The other main category of chain reversal is the so-called γ turn,[1,4] which is tighter and less common than the β bend. The γ turn is centered at a single residue (*i*+1, Figure 1), usually with a hydrogen bond between the CO and NH groups at positions *i* and *i*+2, respectively.

	ϕ	ψ	ϕ	ψ
βI turn	–60	–30	–90	0
βII turn	–60	120	80	0
γ turn	–75	60		

Figure 1. Schematic representation of the intramolecular hydrogen bond that stabilizes the β turn (*i*+3→*i*) and the γ turn (*i*+2→*i*) in a peptide chain. The ideal torsion angles of the central residues for the γ turn and the most common types of β turn are indicated.

We are involved in a research project aimed at evaluating the relative stability of the βI and βII turns in model peptides RCO-L-Pro-Xaa-NHR′ that incorporate different constrained α-amino acids at the *i*+2 position (Xaa).[5] Such terminally protected dipeptides constitute the smallest systems able to accommodate the β-turn conformation. As part of these investigations we undertook the study of the L-Pro-c_3Dip sequence, where c_3Dip denotes each enantiomer of α,β-methanodiphenylalanine,[6] a cyclopropane analogue of phenylalanine. The results of the solid-state conformational analysis, of high structural relevance, are reported herein.

Racemic *N*′-methyl-2,2-diphenyl-1-aminocyclopropanecarboxamide[7] (H-c_3Dip-NHMe) was coupled to *N*-*tert*-butoxycarbonyl-L-proline by the mixed-anhydride method (Scheme 1). Column chromatography allowed the separation of the resulting diastereomeric dipeptides (**1a**, **2a**), which were isolated in optically pure form. The difficulties encountered in growing single crystals from these compounds prompted us to replace the N-terminal urethane protecting group with different amide groups. Single crystals suitable for X-ray diffraction analysis were finally obtained from the pivaloyl derivative **2b** and the acetyl derivative **1c**.

Scheme 1. Synthesis of L-Pro-c_3Dip dipeptides. Reagents and conditions: a) *i*BuOCOCl, NMM, THF, −15 °C; b) column chromatography (CH_2Cl_2/*i*PrOH 93/7); c) 3 N HCl/EtOAc, RT; d) *t*BuCOCl, NMM, $CHCl_3$, 0 °C; e) Ac_2O, NMM, $CHCl_3$, RT. NMM = *N*-methylmorpholine.

The crystalline structure of dipeptide **2b** (Figure 2) revealed an L (or *S*) configuration for the c_3Dip residue. The molecule adopts a β-turn conformation with the terminal pivaloyl CO and methylamide NH groups intramolecularly hydrogen bonded (N···O: 2.97 Å; N–H···O: 156°). The (φ,ψ) torsion angles of the L-Pro (−63,133) and L-c_3Dip (69,−2) residues correspond to a β bend of type II (Figure 1). It should be noted that the βI turn is energetically more favorable for L-Pro-L-Xaa dipeptides in low-polarity solvents[5a,8] but, in general, this conformation is not retained in

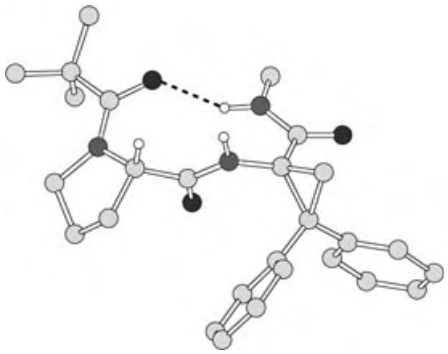

Figure 2. X-ray diffraction structure of Piv-L-Pro-L-c_3Dip-NHMe (**2b**) accommodating a βII turn. The intramolecular $i+3\rightarrow i$ hydrogen bond is indicated by a dashed line. Only the proline C^α and the amide hydrogen atoms are shown.

the solid state, where the βII turn becomes preferred because it allows the Xaa NH group to participate in intermolecular contacts.[5a,d,8] The L-c_3Dip NH site in **2b** is actually hydrogen bonded to a carbonyl group of a neighboring molecule. In comparison, RCO-L-Pro-D-Xaa-NHR′ dipeptides are more prone to βII folding under all environmental conditions and have been found to invariably crystallize in the βII form.[5,8]

On the basis of the above discussion, Ac-L-Pro-D-c_3Dip-NHMe (**1c**) was expected to accommodate a βII turn in the solid state. Surprisingly, a conformation consisting of two consecutive γ turns was found (Figure 3). The (φ,ψ) torsion

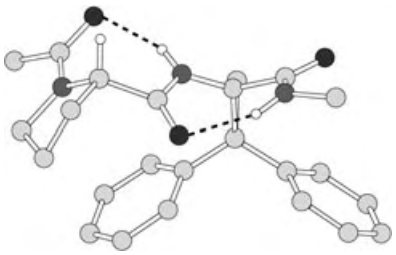

Figure 3. X-ray diffraction structure of Ac-L-Pro-D-c_3Dip-NHMe (**1c**) exhibiting two consecutive γ turns, each stabilized by an intramolecular $i+2\rightarrow i$ hydrogen bond (dashed lines). Only the proline C^α and the amide hydrogen atoms are shown.

angles for both L-Pro (−82,61) and D-c_3Dip (−72,47) lie close to the typical values (−75,60),[1] with the larger deviation being observed for the ψ angle of the D-c_3Dip residue. However, the excellent agreement between the observed ψ value and that predicted from theoretical calculations[9] for the γ-turn minimum energy conformation of cyclopropane residues bearing a phenyl substituent *cis* to the CO terminus ($\psi=47°$) is remarkable, and appears to reflect a balance between steric and hyperconjugative effects. Whatever the origin of this deviation, it does not seem to impede the appropriate alignment of the L-Pro CO and methylamide NH sites, which form a strong intramolecular hydrogen bond (N···O: 2.81 Å, N–H···O: 147°), as do the acetyl CO and D-c_3Dip NH groups (N···O: 2.78 Å, N–H···O: 152°).

The solid-state conformation exhibited by compound **1c** is of extraordinary structural significance. Although much less frequent than β bends, γ turns are found to be abundant in crystallized proteins,[10] where they are stabilized or induced by long-range interactions. Such a source of stabilization is not possible in small peptides and γ turns are observed almost exclusively in poor-solvating media,[1] that is, in the absence of competing intermolecular hydrogen-bonding interactions either with the solvent or with other peptide molecules in the crystal. A few examples of X-ray diffraction structures exhibiting a γ turn have been reported for cyclic oligopeptides—mostly pentapeptides with proline at the turn center—while this conformation is extremely uncommon in acyclic sequences.[1,8b,11] The double γ turn encountered in **1c** is, therefore, unique among crystalline short linear peptides. Moreover, a survey of the Cambridge Structural Database[12] indicates[13] that this is the first report in which proline accommodates a γ-turn conformation in the solid state in the absence of the constraints imposed by backbone cyclization. Proline is, in fact, the proteinogenic amino acid with the highest folding propensity[10b,14] and has been shown to adopt the γ-turn conformation in low-polarity solvents,[1b,c,15] a capacity that is not maintained in the solid state, where proline is overwhelmingly found in the (−60,−30) or (−60,140) region of the (φ,ψ) map.[1b,5,8,10b,14,16]

Accordingly, the γ-turn disposition accommodated by proline in **1c** can be ascribed to the presence of the contiguous D-c_3Dip residue, whose conformational tendencies appear to prevail over those of proline. The latter consideration is of special relevance given that proline is the proteinogenic amino acid with the strongest conformational preferences.[10b,14] Cyclopropane α-amino acids have been suggested as promising candidates for γ-turn stabilization on the basis of theoretical and experimental studies.[5c,d,9,17] However, the fact that theoretical calculations on small peptides generally overestimate the stability of γ-folded conformers,[18] together with the limited experimental evidence available to date, made it premature to proclaim the capacity of such residues to promote γ-turn conformations.

The result reported here constitutes the first unequivocal evidence of the ability of a cyclopropane α-amino acid to adopt a γ-turn disposition in a nonpropitious environment and to influence the overall folding of the peptide chain. Clearly, much work remains to be done to determine the precise conditions under which c_3Dip is able to nucleate γ turns and, thereafter, to establish its scope as a γ-turn inductor. The finding of an α-amino acid with a clear preference for the γ-turn conformation would be of enormous help in the stabilization of this structural motif in bioactive peptides, as well as in the construction of appropriate models to study the factors that govern γ folding.

The X-ray crystal structures of **2b** and **1c** were solved by direct methods using SHELXS-97.[19a] Refinement was performed using SHELXL-97[19b] by the full-matrix least-squares technique. Hydrogen atoms were located by calculation, with the exception of the cyclopropane and NH protons, which were found on the E map. CCDC-243527 (**2b**) and -243526 (**1c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or deposit@ccdc.cam.ac.uk).

X-ray data for **2b** ($C_{27}H_{33}N_3O_3 \cdot 3/2\,H_2O$): $M_r = 474.59$, orthorhombic, space group $P2_12_12$, $a = 11.0690(10)$, $b = 23.498(2)$, $c = 10.1750(10)$ Å, $V = 2646.5(4)$ Å^3, $Z = 4$; $\rho_{calcd} = 1.191$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.081$ mm^{-1}, $T = 293(2)$ K, $F(000) = 1020$, $2\theta_{max} = 50.1°$; 3449 reflections collected, of which 3241 unique ($R_{int} = 0.0308$). Final R indices (2380 observed reflections, $I > 2\sigma I$): $R_1 = 0.0529$, $wR_2 = 0.1257$; final R indices (all data): $R_1 = 0.0784$, $wR_2 = 0.1409$. Highest residual electron density 0.19 e Å^{-3}.

X-ray data for **1c** ($C_{24}H_{27}N_3O_3$): $M_r = 405.49$, orthorhombic, space group $P2_12_12_1$, $a = 10.4010(2)$, $b = 12.6760(2)$, $c = 15.8660(3)$ Å, $V = 2091.82(7)$ Å^3, $Z = 4$; $\rho_{calcd} = 1.288$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.086$ mm^{-1}, $T = 173(2)$ K, $F(000) = 864$, $2\theta_{max} = 53°$; 13835 reflections collected, of which 4276 unique ($R_{int} = 0.0559$). Final R indices (3738 observed reflections, $I > 2\sigma I$): $R_1 = 0.0409$, $wR_2 = 0.0855$; final R indices (all data): $R_1 = 0.0501$, $wR_2 = 0.0892$. Highest residual electron density 0.15 e Å^{-3}.

Molecular Separations

Rotational Entropy Driven Separation of Alkane/Isoalkane Mixtures in Zeolite Cages**

Joeri F. M. Denayer, Refik A. Ocakoglu, Ilbige C. Arik, Christine E. A. Kirschhock, Johan A. Martens, and Gino V. Baron*

Molecular separation and purification processes are key operations in chemical industry.[1] High separation power is obtained in separation processes that are based on adsorption in zeolite micropores.[2] Molecular separation on zeolites can originate from several types of interactions. Electrostatic interactions are responsible for the selective adsorption of nitrogen from air, in the drying of gases, and the removal of polar impurities such as carbon monoxide, mercaptans, or organic chlorides from gases and liquids.[3,4] Shape-selectivity separation arises from the subtle matching of the size and shape of guest molecules and zeolite micropores.[5] Generally, adsorption and diffusion of more-bulky molecules is restricted by the small pore size. To boost octane ratings in gasoline, linear alkanes are sieved from the more-bulky branched alkanes by using narrow-pore molecular sieves.[5,6] Herein we take advantage of cage structures offered by special zeolite adsorbents such as MCM-22. The retention of alkane molecules in MCM-22 is governed by rotational freedom in its cages. The preferential adsorption of isopentane over *n*-pentane in MCM-22 zeolite is a first example of such rotational entropy driven separation.

The adsorptive separation power of a solid is determined by the equilibrium constants of adsorption of the molecules of interest. These equilibrium constants in turn relate to the adsorption enthalpy (the energetic interaction between the molecule and the host environment of the zeolite pore) and the adsorption entropy (the loss of freedom that a molecule experiences in the transition from the gaseous state to the adsorbed state). Depending on the strength of interaction and the pore type, molecules that are confined in zeolite pores lose rotational and translational freedom.[7] In large tubular pores, at least one degree of translational freedom is retained along the axis of the pore. However, in zeolite cages, translational freedom is severely reduced, hence the contribution of molecular rotation to the entropy becomes an essential factor in the relative adsorption equilibria of molecules of different sizes and shapes.[8]

The ability of a molecule to rotate in a cage can be estimated by comparing the radius of gyration of its van der Waals volume R_g, which assumes rotation around the centre of mass, to the radius R_c of the largest sphere that fits into the van der Waals contour of the cage or pore. Minimal loss of rotational entropy is combined with maximal energetic interactions when the sphere that circumscribes the rotational motion of the molecule matches the internal surface of the cage; that is, when the radius ratio R_g/R_c equals unity. The equilibrium adsorption properties of linear and branched alkanes on zeolites that comprise cages or tubular pores were determined to investigate this effect. Isoalkanes, with their shorter carbon backbone, have a smaller radius of gyration and a more spherical shape than their linear counterparts, thus they might rotate more easily in zeolite cages which could lead to their preferential adsorption.

Mordenite and ZSM-22 have one-dimensional pores with dimensions of $0.70 \times 0.65\ nm^2$ and $0.45 \times 0.55\ nm^2$, respectively (Figure 1). NaY contains spherical supercages with a diameter of 1.23 nm that are connected by windows of 0.73 nm (Figure 1). MCM-22 contains large nonspherical supercages of 1.82-nm height that are accessible through 10-ring apertures of $0.40 \times 0.54\ nm^2$ (Figure 1).[9] The top and bottom part of the MCM-22 supercages are pockets of 0.7–

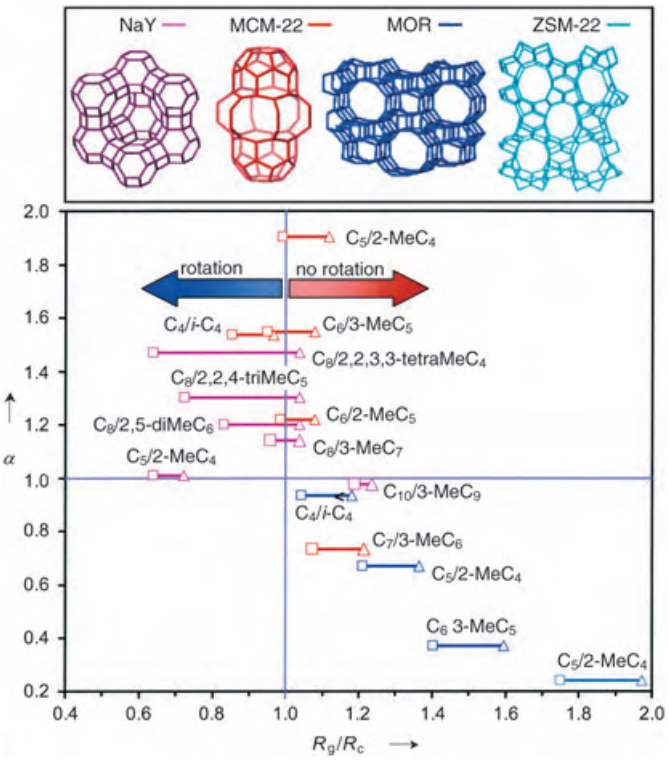

Figure 1. Ratio (α) of low coverage adsorption constants of branched and linear alkanes on MCM-22, NaY, Mordenite (MOR), and ZSM-22 plotted against the radius ratio R_g/R_c. $R_{g(i)}$ and $R_{g(n)}$ represent the radii of gyration of the iso- and *n*-alkanes, respectively, and R_c represents the radius of the largest sphere that fits in the zeolite cage. △ corresponds to $R_{g(n)}/R_c$ and □ corresponds to $R_{g(i)}/R_c$.

0.8 nm in diameter, whereas the broadened central part of this supercage, which resembles a squeezed ellipsoidal cage, is capable of hosting larger molecules. MCM-22 and related materials show interesting adsorption, diffusion, and catalytic properties.[10–15]

Separation factors (α), which are computed as the ratios of the Henry adsorption constants for branched over linear alkanes, are plotted against radius ratios R_g/R_c in Figure 1. For Mordenite and ZSM-22, separation factors of less than 1 are observed which indicates that the linear alkanes are adsorbed preferentially. *n*-Alkanes and isoalkanes have a radius of gyration which is larger than the largest sphere that fits in the tubular pores of Mordenite and ZSM-22, so rotational freedom is severely restricted for both types of molecules. For *n*-butane/isobutane on Mordenite, the preference for the linear alkane is the least pronounced. The radius of gyration of isobutane is only slightly larger than R_c for this zeolite.

With MCM-22 and NaY, a reversal of the normal order of selectivity is observed for several *n*-alkane/isoalkane couples. A selective adsorption of the isoalkane is observed for isobutane, 2-methylbutane, and 2- and 3-methylpentane on MCM-22. The largest separation factor (1.9) is obtained for the *n*-pentane/2-methylbutane couple. The sphere circumscribing the rotation of 2-methylbutane neatly fits into the pocket of the upper and lower parts of the MCM-22 supercage (Figure 2a), whereas *n*-pentane is unable to rotate in that volume. 2-Methylpentane and 3-methylpentane are too large to enable rotation in the pockets of MCM-22, but their gyration spheres fit into the central part of the MCM-22 supercage (Figure 2b).

A pronounced selectivity in favor of the isoalkane is also observed with 2,2,3,3-tetramethylbutane, 2,2,4-trimethylpentane, 2,5-dimethylhexane, and 3-methylheptane on NaY (Figure 1). *n*-Octane is a little too large to rotate freely in the NaY supercages, whereas its isomers retain rotational freedom. The selectivity becomes more pronounced when the difference in R_g between the branched and linear alkanes increases (Figure 1).

With smaller alkanes (e.g. *n*-pentane/2-methylbutane on NaY), the rotation of the *n*-alkane is barely hampered and the differences in rotational freedom between linear and branched alkanes are minor (Figure 1). Consequently, only a low selectivity for the branched alkane is observed. Similarly, when the isoalkane becomes too large to rotate in the zeolite cage, it loses its advantage in rotational freedom and selectivity in favor of the linear chain is observed (e.g. *n*-decane/3-methylnonane on NaY and *n*-heptane/3-methylhexane on MCM-22).

Differences in rotational freedom between molecules are reflected in the adsorption entropy. In Figure 3, the adsorption entropy is plotted as a function of adsorption enthalpy for

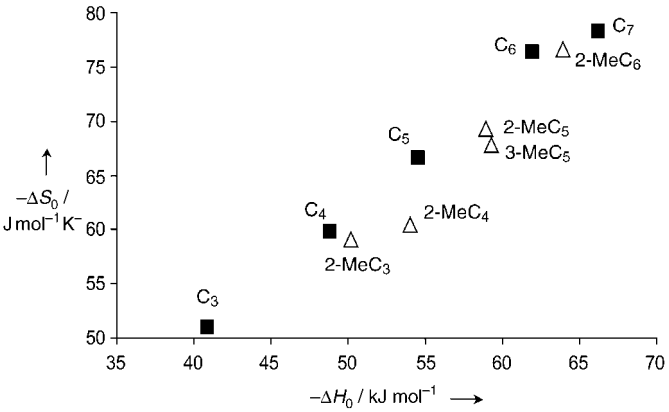

Figure 3. Compensation plot between the adsorption entropy and enthalpy for C_3–C_7 *n*-alkanes (■) and their methyl-branched isomers (△) on zeolite MCM-22.

MCM-22. For a branched molecule to have a higher Henry adsorption constant than its linear isomer, it needs to have a combination of adsorption enthalpy and entropy that results in a lower Gibbs free energy of adsorption. 2-Methylbutane, 2-methylpentane, and 3-methylpentane obviously lose much less entropy in the adsorbed state relative to their linear isomers. For example, the entropy loss of 3-methylpentane is lower than that of *n*-hexane by 9.0 J mol^{-1} K^{-1}. Consequently, these isoalkanes are adsorbed preferentially over their linear isomers despite their less favorable adsorption enthalpy. For the *n*-heptane/2-methylhexane couple, the difference in adsorption entropy is only 1.7 J mol^{-1} K^{-1} as a result of the restricted rotation of 2-methylhexane. Compared to *n*-butane, isobutane has a slightly higher adsorption enthalpy (*n*-butane: 48.8 kJ mol^{-1}; isobutane: 50.1 kJ mol^{-1}) which is explained by a better agreement between the shape of isobutane and the pockets of MCM-22. Moreover, isobutane has a less-negative adsorption entropy, which indicates that this molecule loses less freedom in the adsorbed state than its linear isomer although it is more strongly interacting.

By exploiting rotational entropy effects, separation patterns that are different from those found typically

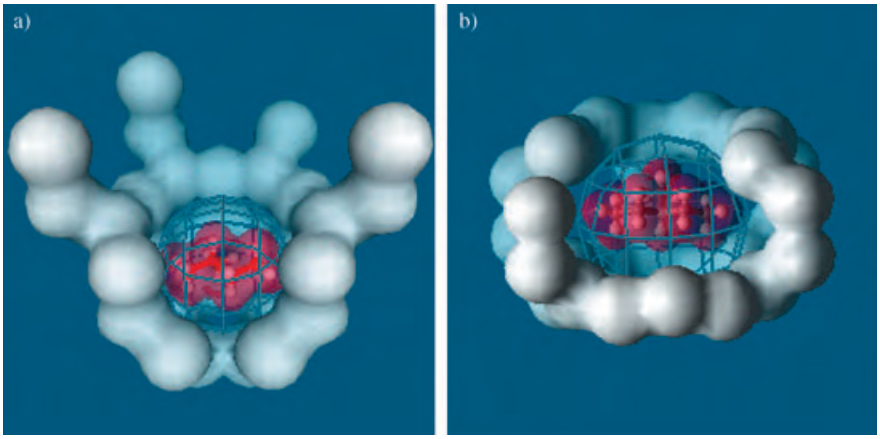

Figure 2. a) A molecule of 2-methylbutane with its radius of gyration in the lobe of the MCM-22 supercage and b) 3-methylpentane in the central part of the MCM-22 supercage.

can be obtained. Figure 4, a–c, show the chromatograms obtained after injection of mixtures of linear and branched alkanes on zeolite columns. With Mordenite, 2-methylbutane elutes first from the column followed by *n*-pentane (Figure 4a). This order of affinity is common to zeolite types studied previously.[16–18] On an MCM-22 column, the retention order is reversed as a result of the higher adsorption equilibrium constant of the branched alkane (Figure 4b). Even more remarkable is the separation of a ternary mixture of differently branched alkanes on MCM-22 (Figure 4c). *n*-Hexane elutes between 2-methylpentane and 2,2-dimethylbutane; the bulkiest dibranched isomer is too large to enter the MCM-22 supercages and therefore elutes first.[10–12] Figure 4, d and e, show breakthrough profiles for *n*-pentane/2-methylbutane and *n*-butane/isobutane mixtures separated on an MCM-22 column. The branched alkanes are selectively trapped inside the MCM-22 pores and displace the adsorbed linear alkanes along the column profile until the composition inside the pores reaches thermodynamical equilibrium. Also under these conditions whereby the MCM-22 pores are saturated with molecules, a good separation with selectivity for the branched alkanes is found.

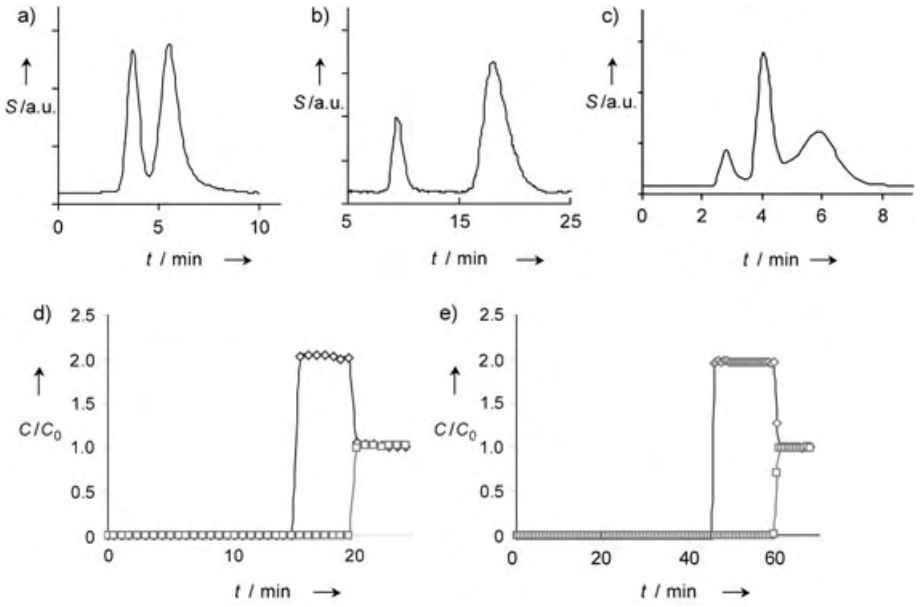

Figure 4. a–c) Chromatograms of *n*-alkane/isoalkane mixtures obtained on zeolite columns at 200 °C (*S* = detector signal): a) separation of *n*-pentane and 2-methylbutane on Mordenite, b) separation of *n*-pentane and 2-methylbutane on MCM-22, and c) separation of *n*-hexane, 3-methylpentane, and 2,2-dimethylbutane on MCM-22. d) and e) Breakthrough profiles obtained on an MCM-22 column at 130 °C with a total hydrocarbon pressure of 0.2 bar (*C* = concentration): d) equimolar *n*-pentane (◇)/2-methylbutane (□) mixture, e) equimolar *n*-butane (◇)/isobutane (□) mixture.

Recent molecular modeling studies demonstrated that a selective uptake of isoalkanes from *n*-/isoalkane mixtures might occur at high pressures and high zeolite loadings in zeolites with tubular pores of 0.6–0.75 nm because more of these shorter isoalkanes can be packed into a single file relative to the linear chains.[19,20] The effect observed in the present work already occurs at low pressure with isolated molecules adsorbed in zeolite cages rather than in tubular pores and does not invoke molecular packing phenomena. To investigate whether the preference of MCM-22 for monobranched alkanes extends beyond the low-coverage domain, where adsorbed molecules are isolated from each other, the adsorption selectivity for a *n*-pentane/2-methylbutane mixture was determined in the liquid phase at complete saturation of the pores of MCM-22. Also under these conditions, 2-methylbutane was selectively adsorbed with a separation factor between 2-methylbutane and *n*-pentane of 1.4.

In summary, a new principle for molecular separation based on differences in molecular rotation in zeolite cages has been introduced. Rotational entropy driven separation could be useful in the separation of structural isomers, such as *n*- and isoalkanes, aromatic compounds, or possibly other mixtures of differently shaped molecules. The recent development of new porous materials with much larger cavities than the ones investigated here opens perspectives for new, entropic-based separations with larger molecules.[21]

Experimental Section

MCM-22 (Si:Al 30) was synthesized according to the method described in US Patent 5146029.[22] ZSM-22 (Si:Al 30) was prepared according to the procedure reported by Ernst et al.[23] NaY (CBV100, Si:Al 2.5) and Mordenite (CP-500C-11, Si:Al 5.5) were purchased from Zeolyst. Chromatographic and breakthrough experiments were performed to study the adsorption properties of these adsorbents.[2] Adsorption equilibrium Henry constants were calculated from the first moment of the chromatographic response curves. Linearity of the experiments and absence of diffusion limitations was confirmed with different amounts of injection and by using different carrier flow rates. A detailed explanation of the experimental setup and procedure can be found elsewhere.[24] From the temperature dependence of the Henry coefficients (K'), the adsorption enthalpy (ΔH_0) is calculated according to Equation (1). The adsorption entropy (ΔS_0) is calculated by using Equation (2)[20] and Equation (3), wherein ρ_c is the crystal density of the zeolite, T corresponds to the temperature (K), and R is the universal gas constant.

$$K' = K'_0 e^{\frac{-\Delta H_0}{RT}} \quad (1)$$

$$\Delta G_0 = -R\,T \ln(K' \rho_c\, R\,T) \quad (2)$$

$$\Delta S_0 = \frac{\Delta H_0 - \Delta G_0}{T} \quad (3)$$

The adsorption selectivity in the liquid phase was determined by using a static method at room temperature.[25]

Nitrogen Heterocycles

Palladium-Catalyzed Tandem Alkenyl and Aryl C–N Bond Formation: A Cascade N-Annulation Route to 1-Functionalized Indoles**

Michael C. Willis, Gareth N. Brace, and Ian P. Holmes*

Indoles are preeminent amongst the heterocyclic motifs found in both designed medicinal agents and in natural products, and accordingly there exists a large and varied selection of methods for their preparation.[1] The majority of syntheses incorporate the key nitrogen atom of the indole nucleus early in the synthetic route. This can be problematic if systematic variation of the *N*-substituent is required without recourse to functionalization of the relatively non-nucleophilic indole N–H group. Herein we describe a tandem palladium-catalyzed process that allows installation of a diverse range of functionalized N units in a cascade indole-forming event that combines the introduction of the nitrogen atom with cyclization.

Palladium catalysis has had a major impact on indole synthesis;[2] arguably, the most important of the many reported methods are those based on Pd-catalyzed coupling of *o*-haloanilines with unsaturated carbon units.[3] Syntheses based on intra- and intermolecular Pd-catalyzed aryl–C–N bond formation,[4] the preparation of intermediates used in Fischer indole syntheses,[5] together with the use of Pd catalysis to functionalize intact indole rings[6] have all been the subjects of recent interest. To effect the desired cascade process, we focused on the introduction of functionalized nitrogen derivatives to an acyclic carbon framework **1** under the action of Pd catalysis; tandem alkenyl C–N and aryl C–N formation would then provide the indole structure (Scheme 1). Palladium-catalyzed aryl C–N bond formation

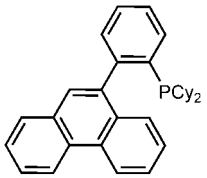
is now a well-established synthetic tool[7] and alkenyl C–N systems are also beginning to appear.[8] However, to the best of our knowledge, no examples of such a tandem process have been reported.[9]



The biological relevance of *N*-arylated indoles,[10] together with the steric and electronic challenges associated with aniline nucleophiles, prompted us to select the union of triflate **1a**[11] with aniline as a platform to evaluate our proposed synthesis. Literature precedents suggested that for Pd-catalyzed C–N bond-forming processes, ligand choice is highly dependent on the electronic and steric properties of both the nucleophilic and electrophilic reaction components,[7] suggesting that identification of a catalyst capable of mediating both aryl and alkenyl C–N bond formation would present a challenge; in the event, phenanthrene ligand **3**[12] and dpephos (**4**)[13] were the most successful.[14] Dpephos has the advantage that it is commercially available

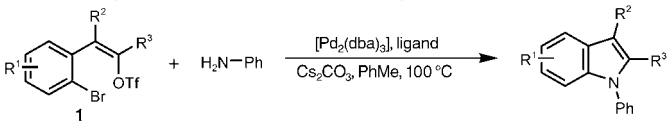
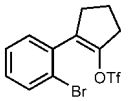
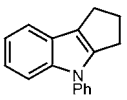
and was selected for further application. Under optimized conditions ($[Pd_2(dba)_3]$, dpephos, Cs_2CO_3, PhMe, 100 °C, 20 h) the coupling of triflate **1a** with aniline delivered the required indole in 83% yield (Table 1, entry 1).

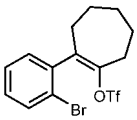
The scope of the process with respect to the N fragment was found to be broad and allowed good yields of indoles for a varied range of coupling partners (Table 1). Substituted aryl, alkyl, and benzyl amines all performed well, although the steric hindrance associated with the cyclohexyl group resulted in a lower reactivity (Table 1, entries 1–7). The use of 4- and 2-chloroanilines is notable as it allows the potential for product functionalization by subsequent palladium catalysis.[15] Hydrazine functionality could be readily incorporated, with the resultant protected 1-aminoindole being produced in high yield (Table 1, entry 8). For electron-poor nucleophiles, the use of xantphos (**5**)[13] as ligand was optimal. Under these modified conditions carbamate, sulfonamide, and amide functionalities were all incorporated in good yields (Table 1, entries 9–14). The use of propionamide has the benefit of also allowing efficient access to the free indole NH function; addition of ethanolic KOH prior to workup delivers the deprotected indole in 80% yield (Table 1, entry 13).

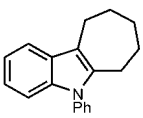
The required bis-activated carbon frameworks **1** could be conveniently prepared by triflate formation on the corresponding arylated ketones,[14] which in turn were readily available by Pd-catalyzed arylation of the parent ketone with a 1,2-dihaloarene.[16,17] For example, triflate **1a** was prepared from the arylation of cyclohexanone with 2-bromo-iodobenzene in the presence of a $[Pd_2(dba)_3]$/xantphos catalyst system followed by triflate formation with $PhNTf_2$ (Scheme 2).

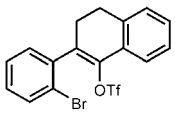


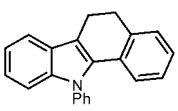


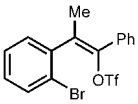


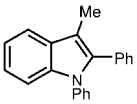


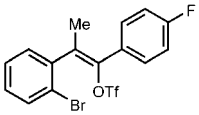


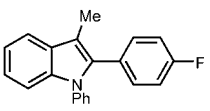


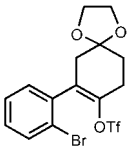


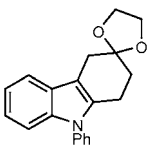


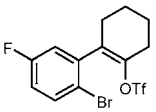


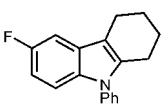


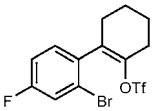


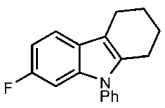


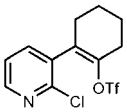


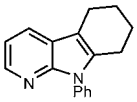












Scheme 2. Preparation of triflate **1a**.

Variations in the ketone and aryl halide components were explored with aniline as the nitrogen unit (Table 2). Indole formation was effective for a variety of architectures; five-, six-, and seven-membered cyclic ketones, simple acyclic, and aryl- and ketal-functionalized[18] ketones were all incorpo-

rated efficiently. Medicinally attractive fluorine-substituted arenes together with simple heterocycles could also be readily introduced.

In summary, we have developed a new palladium-catalyzed route to *N*-functionalized indoles in which the N fragments are introduced in a single-step cascade sequence onto an acyclic carbon framework. A wide range of electronically and structurally varied N fragments can be introduced through a tandem C–N bond-forming process that employs commercially available catalyst components. This new synthesis allows the nitrogen atom of the indole core to be introduced as the final synthetic operation. The cyclization precursors are assembled from the union of a ketone and a 1,2-dihaloarene; variations in both components is well tolerated and allows the efficient synthesis of structurally varied indole systems. Studies to apply similar tandem processes to alternative heterocyclic motifs are underway.

Experimental Section

General procedure (Table 1, entry 1): Cesium carbonate (420 mg, 1.30 mmol) was added to an oven-dried flask charged with $[Pd_2(dba)_3]$ (12 mg, 0.01298 mmol) and dpephos (17 mg, 0.0312 mmol) under nitrogen. The flask was evacuated and back-filled with nitrogen three times. The reagents were suspended in anhydrous toluene (1.10 mL) and 2-(2-bromophenyl)cyclohexen-1-yl triflate (200 mg, 0.519 mmol) and aniline (58 mg, 0.057 mL, 0.623 mmol) were added under nitrogen. The reaction was heated at 100°C for 20 h. After cooling, the reaction mixture was diluted with diethyl ether (≈5 mL) and water (25 mL). The product was extracted with diethyl ether (3×25 mL). The combined organic extracts were washed with HCl (1M; 2× 25 mL) and brine (20 mL) and then dried over $MgSO_4$, filtered, and concentrated in vacuo. The product was purified by flash chromatography (1% diethyl ether/petroleum ether) to yield the title compound (106 mg, 83%) as an off-white solid.

Synthetic Methods

1-Alkynyl(aryl)(tetrafluoroborato)-λ³-bromanes as Highly Efficient Michael Acceptors: Uncatalyzed Conjugate Addition of 1-Alkynyl(trialkyl)stannanes To Yield Symmetrical and Unsymmetrical 1,3-Butadiynes**

Masahito Ochiai, Yoshio Nishi, Satoru Goto, and Hermann J. Frohn*

In contrast to alkynylboron, -aluminium, and -nickel reagents, alkynylcopper species do not efficiently transfer the alkynyl group to electron-deficient olefins and alkynes in a conjugate fashion owing to the strength of the alkynyl–copper(I) bond.[1,2] Michael addition of alkynylstannanes appears to be a very difficult process, probably owing to the low polarity of a C–Sn bond, and there are no well-established precedents for the direct reaction. Specially designed alkynylstannanes with enhanced reactivity such as ynaminostannanes ($R_2NCCSnMe_3$) undergo conjugated addition toward acetylenedicarboxylates in MeCN under heating at reflux.[3] Palladium(0)-catalyzed Michael-type addition of alkynylstannanes to conjugated ynones and alkynoates by using an iminophosphine ligand was recently reported.[4] Herein we report bromine(III)-mediated homocoupling of alkynylstannanes to yield symmetrical 1,3-butadiynes that involves uncatalyzed Michael addition reactions of alkynylstannanes to highly electron-deficient alkynyl-λ³-bromanes.

Despite extensive studies on the chemistry of 1-alkynyl(phenyl)-λ³-iodanes,[5] little is known about the closely related group 17 1-alkynyl(aryl)-λ³-bromanes **3**, mostly because of the considerable difficulty of their synthesis. Recently, we reported the synthesis and characterization of 1-alkynyl(aryl)(tetrafluoroborato)-λ³-bromanes **3** through ligand exchange of a difluoro-λ³-bromane with alkynylstannanes.[6] Thus, exposure of 1-(trimethylstannyl)-1-alkyne **1** to an excess of *para*-trifluoromethylphenyl(difluoro)-λ³-bromane (**2**; 1.5 equiv; prepared from *para*-trifluoromethylphenyl(trimethyl)silane by ligand exchange with bromine trifluoride at −78 to −25 °C in dichloromethane) in the presence of $BF_3{\cdot}Et_2O$ at −78 °C in dichloromethane afforded 1-alkynyl(aryl)-λ³-bromane **3** in high yields (Scheme 1). Use of excess amounts of the 1-alkynylstannanes **1** (>2 equiv) relative to difluoro(aryl)-λ³-bromane **2** dramatically changed the reaction course and afforded the homocoupling products 1,3-butadiynes **4** in good yields.

Scheme 1. TBDMS = *tert*-butyldimethylsilyl, TMS = trimethylsilyl.

Rigid and sterically undemanding diacetylene moieties are frequently embodied in many natural products and find increasing application as key structural elements in synthetic receptors for molecular recognition.[7] Reaction of difluoro-λ³-bromane **2** with 2.2 equivalents of 1-decynylstannane **1a** in the presence of $BF_3{\cdot}Et_2O$ (1.2 equiv) from −78 °C to room

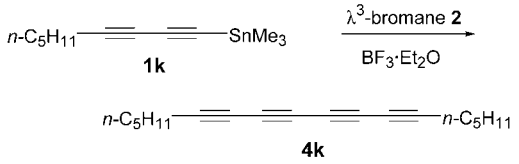
temperature in dichloromethane under argon resulted in oxidative homocoupling with the formation of icosa-9,11-diyne (**4a**) in 69% yield (Table 1, Entry 3). The use of 2 equivalents of $BF_3{\cdot}Et_2O$ led to a slight improvement in the yield (72%), whereas in the absence of $BF_3{\cdot}Et_2O$ no formation of the diyne **4a** was observed. 1-Decynyl(tributyl)-stannane also afforded the diyne **4a** in 78% yield. However, the attempted dimerization of 1-decynyl(trimethyl)silane and -germane gave poor results and large amounts of the reactants were recovered (Table 1, Entries 6 and 7).

Table 1: Reaction of substituted 1-alkynes with difluoro-λ^3-bromane **2**.[a]

Entry	1-Alkynes	$BF_3{\cdot}Et_2O$ [equiv]	4	Yield [%][b]
1	**1a**	0	**4a**	0
2	**1a**	1[c]	**4a**	49
3	**1a**	1.2	**4a**	69
4	**1a**	2	**4a**	72
5	n-C_8H_{17}—≡—$SnBu_3$	1.2	**4a**	78
6	n-C_8H_{17}—≡—$GeMe_3$	1.2	**4a**	17
7	n-C_8H_{17}—≡—$SiMe_3$	1.2	**4a**	0



[a] Unless otherwise noted, reactions were carried out by using 2.2 equivalents of an alkyne in dichloromethane in the presence of $BF_3{\cdot}Et_2O$ from −78°C to room temperature during 5 h under argon. [b] Isolated yields. [c] Reaction conditions: −78°C, 2.5 h.

Our initial examination of the substrate generality for oxidative homocoupling of 1-alkynylstannanes **1** is shown in Table 2. Dimerization of simple primary, secondary, and tertiary alkylethynyl(trimethyl)stannanes afforded the 1,3-butadiynes **4b–e** in good yields (74–83%). 1,10-Dichlorodecadiyne **4g** was obtained in 69% yield from 5-chloropentynylstannane **1g**. However, phenylethynyl(trimethyl)stannane (**1f**) gave 1,4-diphenyl-1,3-butadiyne (**4f**) in only 33% yield. Ethynyl- and siloxy-substituted alkynyl(trimethyl)stannanes **1h** and **1i** gave 1,3-diynes in moderate yields. Selective coupling of trimethyl(trimethylsilylethynyl)stannane (**1j**) resulted in the formation of bis(trimethylsilyl)-1,3-diyne **4j**, although in a low yield (27%). The use of trimethylstannyl-1,3-diyne **1k** provided directly the conjugated octatetrayne **4k** (40%; Scheme 2). Both tetrabutylstannane and phenyltrimethylstannane do not undergo oxidative homocoupling.

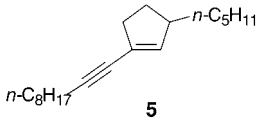
Table 2: Oxidative homocoupling of alkynylstannanes **1** by reaction with difluoro-λ^3-bromane **2**.[a]

Entry	1	4	Yield [%][b]
1	**1b**	**4b**	74
2	**1c**	**4c**	83
3	**1d**	**4d**	76 (87)
4	**1e**	**4e**	80
5	**1f**	**4f**	33
6	**1g**	**4g**	69 (84)
7	**1h**	**4h**	45
8	**1i**	**4i**	47
9	**1j**	**4j**	27

[a] Reactions were carried out by using 2.2 equivalents of an alkyne **1** in dichloromethane in the presence of $BF_3{\cdot}Et_2O$ (1.2 equiv) from −78°C to room temperature during 5 h under argon. [b] Isolated yields. Yields obtained after GC are quoted in parentheses.

Scheme 2.

On the basis of our previous report[6] as well as the observation that the oxidative homocoupling of 1-alkynylstannane **1a** to yield the diyne **4a** does not take place in the absence of $BF_3{\cdot}Et_2O$ (Table 1, Entry 1),[8] it seems reasonable to assume that the bromine(III)-mediated homocoupling of 1-alkynylstannane **1** probably involves the initial formation of 1-alkynyl(aryl)(tetrafluoroborato)-λ^3-bromane **3** through ligand exchange and its further reaction with excess 1-alkynylstannane **1**. In fact, treatment of 1-decynyl-λ^3-bromane **3a** with 1-alkynylstannane **1a** at room temperature under argon afforded the 1,3-diyne **4a** in 59% yield. The reaction does not require activation with Lewis acids. Interestingly, in this reaction a 4% yield of the cyclopentene **5** was also produced.[9] The reaction with 1-decynyl(trimethyl)germane provided a comparable result with formation of a small amount of **5** (Table 3, Entry 2).



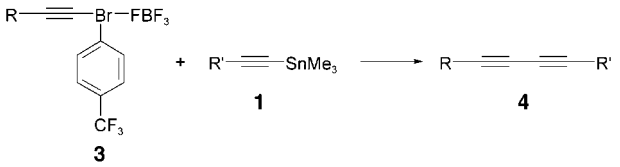


Table 3: Uncatalyzed cross-coupling of alkynyl-λ^3-bromanes **3** with alkynylstannanes **1** and -germanes.[a]

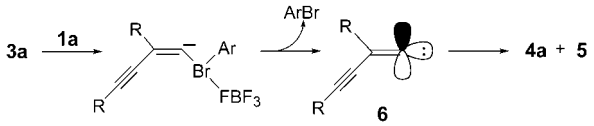
Entry	3	Alkyne	4	Yield [%][b]
1	**3a**	**1a**	**4a**	59
2	**3a**	n-C_8H_{17}—≡—$GeMe_3$	**4a**	64
3	**3a**	**1c**	**4l**	76
4	**3a**	**1e**	**4m**	71
5	**3a**	**1f**	**4n**	66
6	**3c**	**1a**	**4l**	76
7	**3c**	**1e**	**4o**	74
8	**3e**	**1a**	**4m**	71

[a] Reactions were carried out by using 2.2 equivalents of an alkyne in dichloromethane at room temperature for 5 h under argon. [b] Isolated yields.



The cross-coupling reaction makes it possible to synthesize unsymmetrically substituted 1,3-butadiynes **4l–o** (Scheme 3, Table 3). For instance, reaction of **3a** with alkynylstannanes **1c** and **1e** afforded the unsymmetrical butadiynes **4l** (76%) and **4m** (71%; Table 3, Entries 3 and 4), which were also produced by the reaction of the inverse combinations (reaction of **1a** with **3c** and **3e**, respectively).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 3.

Isolation of the byproduct cyclopentene **5** clearly indicates that the reaction of **3a** with **1a** involves the intermediacy of alkylidene carbene **6**, which is produced by Michael addition of 1-alkynylstannane **1a** and the subsequent reductive elimination of the aryl-λ^3-bromanyl group (Scheme 4). A

Scheme 4. R = *n*-C_8H_{17}, Ar = *p*-$CF_3C_6H_4$.

1,2-shift of the alkynyl group in **6** produces **4a**, while competing intramolecular 1,5 carbon–hydrogen insertion affords **5**.[5,10] High migratory aptitude of alkynyl groups in alkylidene carbenes and carbenoids are well established.[11]

The most important step in this mechanism should be an uncatalyzed Michael addition of 1-alkynyl(trimethyl)stannane **1** with rather low nucleophilicity to 1-alkynyl-λ^3-bromane **3**. Entry 2 in Table 3 shows that the less nucleophilic 1-decynyl(trimethyl)germane also serves as an efficient Michael donor toward **3**. The question arises why simple alkynylstannanes and -germanes undergo uncatalyzed conjugate addition toward **3**. We believe that the highly electron-deficient nature of 1-alkynyl-λ^3-bromanes **3**, evoked by a large electron-withdrawing inductive effect of an aryl(tetrafluoroborato)-λ^3-bromanyl group with a substituent constant σ_I of 1.63 (for PhBr(BF_4)),[12] will be responsible for this unusual addition reaction. Actually, 1-alkynyl(aryl)-λ^3-iodanes associated with a reduced inductive effect ($\sigma_I = 1.35$ for PhI(BF_4)) do not function as Michael acceptors, and no formation of 1,3-butadiyne **4a** was observed in the attempted reaction of 1-decynyl(*para*-trifluoromethylphenyl)(tetrafluoroborato)-λ^3-iodane with 1-alkynylstannane **1a** under the conditions described.

To better understand these differences in reactivity in λ^3-bromanes and λ^3-iodanes, density functional theory (DFT) calculations on the simplified 1-propynyl derivatives **7** were carried out (Figure 1). The acetylenic π^* orbital (LUMO+4) of 1-propynyl(phenyl)(fluoro)-λ^3-bromane **7a** is lower in energy than that for the λ^3-iodane **7b** (LUMO+4; 0.04672 eV for **7a**, 0.04778 eV for **7b**). Mulliken atomic charges show that the Cβ carbon atom in **7a** is apparently more positive than that in **7b**.

In summary, we have presented the first example of uncatalyzed Michael addition reactions of simple 1-alkynyl-(trimethyl)stannanes, a reaction which is involved in difluoro-λ^3-bromane-mediated coupling of 1-alkynylstannanes to yield

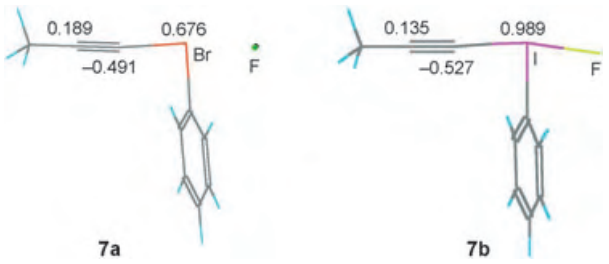


Figure 1. Mulliken atomic charges at Cα, Cβ, Br, and I calculated with the B3LYP/LanL2DZ method (Gaussian 03W).

symmetrical 1,3-butadiynes. Tandem Michael addition–carbene rearrangements of 1-alkynyl(aryl)-λ^3-bromanes with 1-alkynylstannanes provides a new route for the synthesis of unsymmetrical 1,3-butadiynes.[7]

Experimental Section

4a (Table 1, Entry 3): A solution of difluoro[4-(trifluoromethyl)-phenyl]-λ^3-bromane (**2**; 34 mg, 0.13 mmol) in dichloromethane (0.2 mL) followed by $BF_3{\cdot}Et_2O$ (22 mg, 0.16 mmol) were added dropwise to a stirred solution of 1-decynyl(trimethyl)stannane (**1a;** 86 mg, 0.29 mmol) in dichloromethane (0.8 mL) at −78 °C under argon. The mixture was gradually warmed to room temperature over 5 h. The reaction mixture was quenched with water and extracted with dichloromethane. The organic layer was dried over anhydrous sodium sulfate and concentrated under aspirator vacuum to give an oil, which was purified by preparative TLC (SiO_2, hexane/dichloromethane 4:1) to give a mixture (25.9 mg) of **4a** and **5** (95:5; 69% and 4%, respectively). **4a**: ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 2.25$ (t, $J =$ 7.4 Hz, 4H), 1.52 (quint, $J = 7.4$ Hz 4H), 1.41–1.33 (m, 4H), 1.33–1.21 (m, 16H), 0.88 ppm (t, $J = 6.3$ Hz, 6H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 77.5$, 65.3, 31.9, 29.2, 29.1, 28.9, 28.4, 22.7, 19.2, 14.1 ppm; IR (neat): $\tilde{\nu} = 2925$, 2855, 2233, 1465, 1377, 722 cm^{-1}; MS (70 eV): *m*/*z* (%): 274 (2) [M^+], 245 (3), 231 (3), 217 (9), 203 (8), 189 (4), 175 (10), 161 (19), 147 (22), 133 (31), 119 (43), 105 (56), 91 (100), 79 (65); HRMS: calcd for $C_{20}H_{34}$ [M^+]: 274.2661; found: 274.2663. A pure sample of **5** was obtained by preparative GC (20% silicon GE SF-96, 3 m). **5**: ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 5.89$ (br s, 1H), 2.69 (m, 1H), 2.46–2.34 (m, 2H), 2.31 (t, $J = 7.4$ Hz 2H), 2.12–2.02 (m, 1H), 1.53 (quint, $J = 7.4$ Hz 2H), 1.45–1.21 (m, 19H), 0.95–0.84 ppm (6H); IR ($CHCl_3$): $\tilde{\nu} = 2928$, 2856, 1465, 1265 cm^{-1}; MS (70 eV): *m*/*z* (%): 274 (22) [M^+], 203 (100) [M^+-C_5H_{11}]; HRMS: calcd for $C_{20}H_{34}$ [M^+]: 274.2661; found: 274.2651. **4l** (Table 3, Entry 7)**: 1a** (59 mg, 0.2 mmol) was added to a stirred solution of 3,3-dimethyl-1-butynyl-λ^3-bromane **3c** (35 mg, 0.09 mmol) in dichloromethane (2 mL) at room temperature under argon. The reaction mixture was stirred for 5 h, quenched with water, and extracted with dichloromethane. The organic layer was dried over anhydrous sodium sulfate and concentrated under aspirator vacuum to give an oil, which was purified by preparative TLC (SiO_2, hexane) to give **4l** as a colorless oil (15 mg, 76%). ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 2.25$ (t, $J = 7.2$ Hz, 2H), 1.51 (quint, $J = 7.2$ Hz, 2H), 1.42–1.33 (m, 2H), 1.32–1.25 (m, 8H), 1.24 (s, 9H), 0.88 ppm (t, $J = 6.7$ Hz, 3H); ^{13}C NMR (75 MHz, $CDCl_3$) $\delta = 85.0$, 78.8, 65.0, 63.9, 31.9, 30.6, 29.2, 29.1, 28.9, 28.4, 27.9, 22.7, 19.3, 14.1 ppm; IR ($CHCl_3$): $\tilde{\nu} = 2929$, 2858, 2147, 1457 cm^{-1}; MS (70 eV): *m*/*z* (%): 218 (9) [M^+], 203 (24), 189 (50), 175 (22), 161 (61), 147 (58), 133 (61), 119 (96), 105 (100), 91 (60); HRMS: calcd for $C_{16}H_{26}$ [M^+]: 218.2035; found: 218.2041.

[8] Ligand exchange of difluoro-λ^3-bromane **2** with alkynylstannanes **1** to yield 1-alkynyl-λ^3-bromanes **3** requires activation with $BF_3{\cdot}Et_2O$ with which hypervalent F-Br-F bonding in **2** is efficiently polarized by the coordination of BF_3 and the positive charge on the bromine(III) is increased.

[9] Cyclopentene **5** was also obtained as a byproduct (3–5%) in the bromine(III)-mediated homocoupling of **1a** (Table 1, Entries 2–4).

[10] An alternative ligand-coupling pathway on bromine(III) of (n-$C_8H_{17}CC)_2Br(p$-$CF_3C_6H_4$), produced by ligand exchange through the nucleophilic attack of alkynylstannane **1a** at the polarized bromine of **3a**, could account for the formation of 1,3-butadiyne **4a**. The observation that the diphenyls Ph-Ph and p-$CF_3C_6H_4Ph$ are not formed on the attempted dimerization of phenyl(trimethyl)stannane by the reaction with difluoro-λ^3-bromane **2** strongly suggests a tandem Michael addition–carbene rearrangement pathway. However, involvement of the ligand-coupling reaction as a competing minor process can not be rigorously ruled out. For ligand coupling in hypervalent compounds, see: a) S. Oae, Y. Uchida, *Acc. Chem. Nanoparticles

Core/Shell Gold Nanoparticles by Self-Assembly and Crosslinking of Micellar, Block-Copolymer Shells**

*Youngjong Kang and T. Andrew Taton**

Core/shell nanoparticle architectures, in which a layer of inorganic or organic material surrounds an inorganic nanoparticle core, have been investigated both as a means to improve the stability and surface chemistry of the core nanoparticle and as a way of accessing unique physical properties that are not possible from one nanomaterial alone. As examples, silica shells isolate metal and semiconductor particle surfaces from interfacial chemistry;[1,2] gold shells allow covalent attachment of thiol ligands to particles[3] and generate unique optical signatures;[4] semiconductor shells increase the quantum yield of semiconductor nanoparticle cores;[5] and polymeric shells aid the compatibility of nanoparticles in polymer hosts.[6] Whereas inorganic shells are typically grown from the surface of the particle core, a number of methods have been described for generating organic polymer shells, including polymerization from particle-bound initiators,[7] direct attachment of functionalized polymers to surfaces,[8] layer-by-layer deposition,[9] and synthesis of the particle in the presence of polymeric ligand.[10,11] In all of these cases, the specific chemical interaction of the particle surface and the surface-bound polymer must be explicitly tailored in order to form the shell.

Diblock copolymer amphiphiles spontaneously form polymer monolayers on surfaces, and the thickness and composition of the assembled layer are determined by the lengths and properties of the component blocks.[12] Because this assembly can be driven by desolvation of one of the two polymer blocks and does not depend on any specific polymer–surface interaction, we hypothesized that block copolymers could be used to form shells around nanoparticle cores without chemical anchoring. Herein, we report the assembly of metal-core, block-copolymer-shell nanoparticles in which the structure and composition of the combined material are programmed in advance by the choice of particle and copolymer starting materials. Furthermore, we demonstrate that cross-linking the assembled shell leads to a permanent core/shell structure and physically isolates the core from its environment.

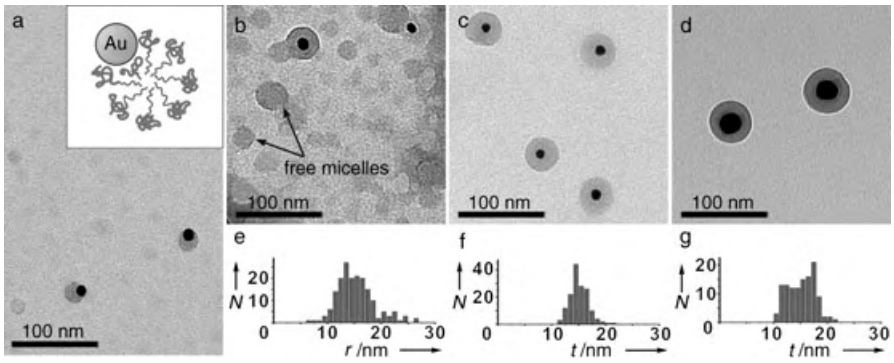
Our approach to the synthesis of copolymer-encapsulated nanoparticles (Scheme 1) employs block copolymers and cross-linking chemistry that were developed by Wooley and co-workers for shell-crosslinked micelles.[13] Briefly, poly(styrene-block-acrylic acid) (PS-b-PAA) and poly(methylmethacrylate-block-acrylic acid) (PMMA-b-PAA) copolymer surfactants with narrow molecular-weight polydispersities (PDI < 1.3) were synthesized through atom-transfer radical polymerization.[14,15] Amphiphilic copolymer was initially dissolved in DMF (*N*,*N*-dimethylformamide), which is a good solvent for both the hydrophobic (PS or PMMA) and the hydrophilic (PAA) polymer blocks. Citrate-capped Au nanoparticles[15,16] in aqueous solution were centrifuged and resuspended in DMF. The samples of polymer and nanoparticles in DMF were combined in the presence of a small amount of 1-dodecanethiol, which hydrophobically functionalizes the surfaces of the particles and directs them to the hydrophobic interior of a micellar shell.[17] Water was gradually added to this mixture to simultaneously desolvate both the particles and the hydrophobic polymer block from solution. In the absence of copolymer surfactant, the dodecanethiol-modified nanoparticles precipitated quickly from DMF as water was added. In the absence of dodecanethiol, the nanoparticles remained outside the assembled block-copolymer micelles. Transmission electron microscopy (TEM) images of these assemblies indicated that the external polyacrylate block of the micelles associated with the surfaces of the nanoparticles (Figure 1 a)[18] presumably by displacing bound citrate. However, for dodecanethiol-functionalized Au, the added water acted as a selective nonsolvent (that is, a solvent that does not solubilize a specific material) for both the hydrophobic polymer block and the hydrophobically modified nanoparticles and induced the formation of micelles around the nanoparticles (Figure 1 b). Micelle encapsulation was conducted with a substantial excess of polymer to limit the number of micelles that contained multiple particles. This process was successful for polymers with short PAA blocks (PS_{250}-b-PAA_{13}, PS_{160}-b-PAA_{13}, PS_{100}-b-PAA_{13}, and $PMMA_{240}$-b-PAA_{13}).[15]



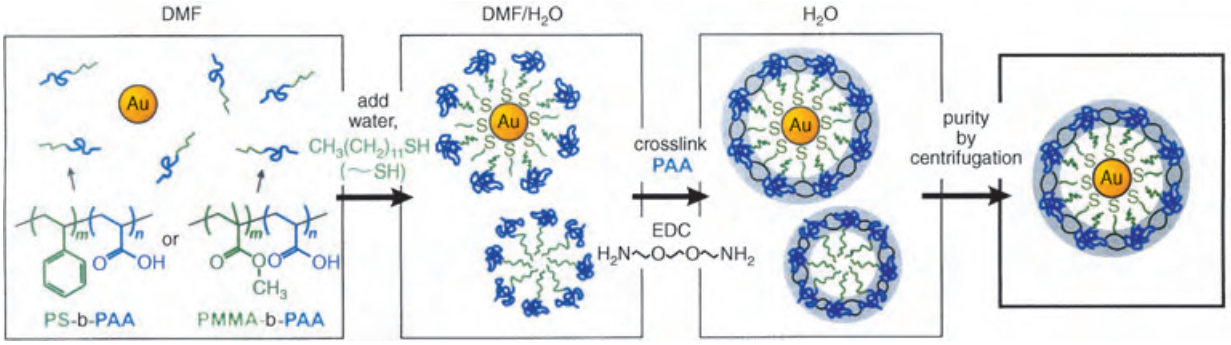


Figure 1. a–d) TEM images of Au nanoparticles encapsulated within PS_{250}-b-PAA_{13} micelles. a) Poorly encapsulated 12-nm Au nanoparticles exposed to PS_{250}-b-PAA_{13} in the absence of dodecanethiol. Empty copolymer micelles distort to maximize interactions between the polyacrylate corona and the surface of the Au nanoparticle. b) Encapsulated Au nanoparticles treated with dodecanethiol and PS_{250}-b-PAA_{13}, before purification. Nanoparticles are localized at the center of the micelles. c) Purified encapsulated 12-nm Au nanoparticles. d) Purified encapsulated 31-nm Au nanoparticles. e–g) Histograms of e) the radius (r) of empty micelles isolated from encapsulated 12-nm Au nanoparticle supernatant, f) the shell thickness (*t*) of encapsulated 12-nm Au nanoparticles, and g) the shell thickness of encapsulated 31-nm Au nanoparticles. *N* = number. See Supporting Information for the TEM images used to obtain the histograms.

The assembled copolymer was permanently fixed by cross-linking the polyacrylate block of the micelles with 2,2′-(ethylenedioxy)bis(ethylamine) and 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide methiodide in water (see Scheme 1). After cross-linking, excess reagents were removed by dialysis of the suspension against H_2O. Fixed core/shell nanoparticles were separated from empty micelles by five or more consecutive cycles whereby the suspension was centrifuged, the supernatant was discarded, and the solid was resuspended in H_2O. After this treatment, the suspension consisted solely of micelles filled with Au nanoparticles (Figure 1, c and d). For Au nanoparticles larger than 10 nm in diameter, every micelle contained exactly one nanoparticle. Despite our presumption that a statistical distribution of particles might lead to a few micelles that contain two or more particles, no such structures were observed. For smaller (4-nm diameter) nanoparticles, however, multiple particles were sometimes encapsulated in each micelle.[15] Averaged over

more than 100 particles, the shell thicknesses for 12- and 31-nm Au nanoparticles encapsulated in PS_{250}-b-PAA_{13} ("Au@PS_{250}-b-PAA_{13}") were 15.1 ± 1.7 nm and 15.2 ± 2.5 nm, respectively, whereas the average radius of empty PS_{250}-b-PAA_{13} micelles isolated from the encapsulated 12-nm Au nanoparticle solution was 15.2 ± 3.5 nm. So, whereas the copolymer shell thickness could be predicted on the basis of the radius of empty copolymer micelles, the shells were consistently more uniform in size than the micelles. The fact that only single nanoparticles were found in each micelle as well as the uniformity of the micellar shells suggest that the encapsulated particles offer a spherical surface template for micelle assembly. Flat surfaces have been shown to template the formation of uniform surface layers of block copolymers.[12] Here we demonstrate that this phenomenon is observed even when the curvature of the surface is smaller in scale than the thickness of the polymer layer. This is surprising given that the micelles are much larger than the nanoparticles and could presumably accommodate multiple particle guests.

The optical properties of the Au nanoparticles can be controlled by variation of the composition of the copolymer shell which is consistent with the theoretical prediction that surface plasmon resonance energies decrease as the refractive index of the surrounding medium increases.[19] In water ($n = 1.33$), citrate-capped 31-nm-diameter Au particles show a characteristic absorbance maximum $\lambda_{max} = 529$ nm (Figure 2a). However, the higher refractive indices of PMMA

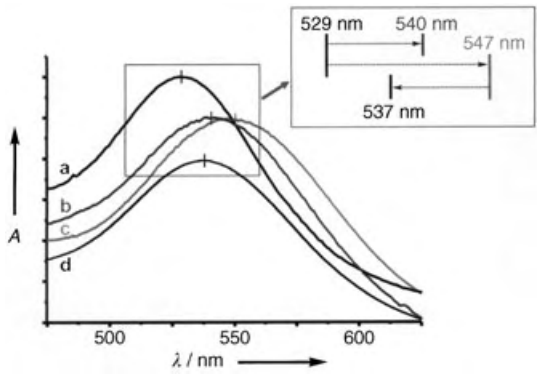

Figure 2. Shift of the surface plasmon resonance spectra upon encapsulation of Au nanoparticles (absorbance intensities are normalized). a) The absorbance spectrum of aqueous 31-nm-diameter gold nanoparticles. The spectrum is red-shifted by encapsulation within $PMMA_{240}$-b-PAA_{13} (b) or within PS_{250}-b-PAA_{13} (c). The spectrum is blue-shifted when the PS_{250}-b-PAA_{13} polymer shell is swollen with THF (d).

($n = 1.49$) and PS ($n = 1.59$) lead to red-shifted absorbance spectra for Au@$PMMA_{240}$-b-PAA_{13} ($\lambda_{max} = 540$ nm) and Au@PS_{250}-b-PAA_{13} ($\lambda_{max} = 547$ nm; see Figure 2, b and c). Similar plasmon shifts have been reported for Au nanoparticles within silica shells[1,20] in which the higher refractive index of SiO_2 ($n = 1.47$) results in higher values of λ_{max}.

In water, the glassy polystyrene block of the cross-linked copolymer shells provides a physical barrier that isolates and protects encapsulated nanoparticles from their chemical environment. When exposed to aqueous cyanide etching solution, citrate-capped gold nanoparticles are typically oxidized to $[Au(CN)_2]^-$ ions within seconds. Copolymer-encapsulated Au nanoparticles were stable indefinitely to much higher concentrations of etchant (Figure 3). By con-

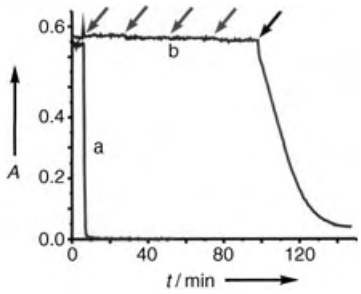

Figure 3. a) Cyanide-induced decomposition of citrate-stabilized, 12-nm Au nanoparticles in water. Similar, immediate decomposition was observed for dodecanethiol-stabilized nanoparticles.[15] b) Exposure of encapsulated 12-nm Au nanoparticles (within a PS_{250}-b-PAA_{13} shell) in water to a 25-fold molar excess of KCN (5-mM aqueous solution) every 20 min (gray arrows; total 100-fold molar excess), followed by the addition of 20 vol% THF after 100 min (black arrow). The absorbance was measured at the values of λ_{max} (519 nm and 529 nm for curves a and b, respectively). The initial 8% drop of absorbance upon addition of THF is attributed to a change in the refractive index of the solvent.[15]

trast, surface-bound molecular[21] and homopolymer[11] monolayers and silica shells[22] have been shown to be permeable with respect to cyanide corrosion. The permeability of the micellar shell could be modulated by addition of an organic cosolvent to the aqueous suspension of the particles to solvate the hydrophobic polymer block. For example, addition of 20 vol% THF to the suspension of encapsulated Au nanoparticles in a solution containing cyanide resulted in immediate etching (Figure 3). Variation of the degree of shell cross-linking had no effect on the extent or rate of etching which demonstrates that solvation of the shell, rather than the physical porosity of the polymer network, regulates exposure to etching. Further evidence of THF infiltration and swelling of the inner micelle block with THF was observed by a blue shift of the optical absorbance spectrum of the nanoparticles (in the absence of cyanide, Figure 2d). This shift reflects the contribution of the lower refractive index of THF ($n = 1.41$) to the PS environment around each nanoparticle.

Even though organic solvents solubilize the hydrophobic micelle block, chemical cross-links prevent the surfactant from dissolving away. As a result, micelle-encapsulated nanoparticles were found to be soluble in essentially any solvent that was compatible with either the hydrophobic or hydrophilic component polymers.[15] For example, nanoparticles encapsulated in PS-b-PAA were soluble in solvents in which PS can be dissolved, but notably not in acetone or 1:1 *i*PrOH/MEK (methyl ethyl ketone), which are both nonsolvents for PS. Also, nanoparticles encapsulated in PMMA-b-PAA were soluble in solvents in which PMMA can be dissolved, but not in cyclohexane, which is a nonsolvent for PMMA.

Because the shells were fixed, the solvated polymer cores could be desolvated again to regenerate the original glassy core/shell nanostructures. Au@PS_{250}-b-PAA_{13} particles dis-

solved in an organic solvent such as THF could be returned to aqueous solution by exhaustive dialysis against H_2O. TEM images of these particles were indistinguishable from images of the originally synthesized, aqueous particles. On the basis of these results, we anticipate that copolymer micelle encapsulation could be used as a general aid to disperse nanoparticles in otherwise incompatible matrices. Along these lines, Au@PS_{250}-b-PAA_{13} was readily dispersed from solvent into bulk PS, and Au@$PMMA_{240}$-b-PAA_{13} into bulk PMMA, to form homogeneously pink-colored composite plastics.

In conclusion, we have demonstrated surface-templated self-assembly of copolymers around nanoparticles as a route to defined core/shell nanostructures. This approach yielded core/shell architectures in which the dimensions and properties of the nanostructures were determined by the characteristics of the component polymer blocks. We are currently applying this approach to other lyophilic nanoparticles such as TOPO-coated quantum dots[23] and oleic acid coated magnetic nanoparticles.[24] We anticipate that micelle encapsulation will allow shell functionalization, biomolecular conjugation, and polymer processing to be performed on nanomaterials that might otherwise show poor or no ligand chemistry.[25]

[17] A prerequisite of our encapsulation method is that the starting nanoparticles must be transiently stable in the encapsulation medium. Large (diameter > 5 nm), citrate-capped nanoparticles slowly precipitate from suspension in the presence of alkanethiol ligands, so the nanoparticles were functionalized with alkanethiol in situ. However, smaller alkanethiol-functionalized particles were prepared separately before encapsulation.

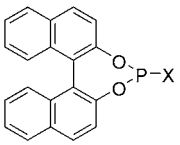
Asymmetric Catalysis

Binol-Derived Monodentate Phosphites and Phosphoramidites with Phosphorus Stereogenic Centers: Novel Ligands for Transition-Metal Catalysis**



Manfred T. Reetz, Jun-An Ma, and Richard Goddard*

Recently three groups independently reported that binol-derived monodentate phosphites **1a**,[1] phosphonites **1b**,[2] and phosphoramidites **1c**[3] are efficient ligands in rhodium-catalyzed asymmetric olefin hydrogenation (*ee* values = 90–99%; binol = 2,2′-dihydroxy-1,1′-binaphthyl). A preliminary

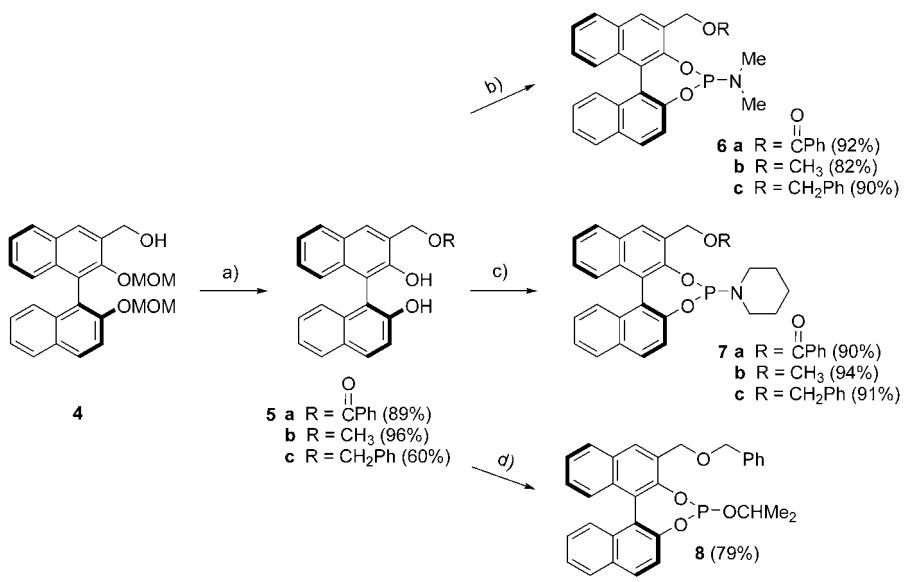
c X = NR_2

mechanistic study by our group shows that two monodentate phosphorus compounds are bonded to rhodium in the hydrogenation transition state. In an extension of this work we demonstrated that mixtures of two different monodentate phosphorus ligands can be used in a combinatorial approach.[4] Since binol is one of the cheapest chiral auxiliaries currently available, chemical modification resulting in the formation of new modular ligands appears attractive.

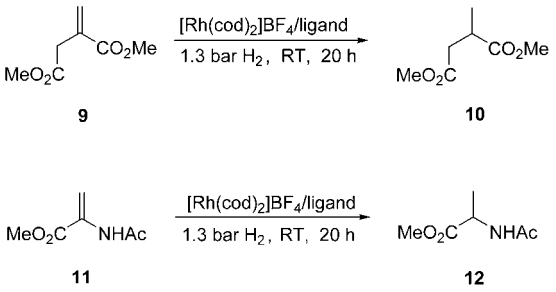
We wondered whether binol derivatives bearing a single *ortho*-substituent as in (*S*)-**2** (Scheme 1) can serve as starting materials for structurally unusual monodentate phosphorus ligands. This modification would not only reduce C_2 to C_1 symmetry, it would also lead to the creation of a stereogenic center at phosphorus (R_P and S_P in diastereomers **3**; Scheme 1).[5] Herein we report the synthesis of this novel class of phosphorus ligands and their use in rhodium-catalyzed olefin hydrogenation.



2 **3** *diast*-**3**

Scheme 1. Formation of diastereomeric ligands with stereogenic phosphorus centers.

Starting from the known methoxymethyl (MOM) protected (*S*)-binol-derivative **4**,[6] compounds **5a–c** were readily prepared which were then treated with $P(NMe_2)_3$ in boiling toluene. This reaction resulted in excellent yields of the phosphoramidites as diastereomeric mixtures or as pure compounds: **6a** (S,S_P:S,R_P = 2:1), **6b** (S,S_P pure), and **6c** (S,S_P:S,R_P = 10:1; Scheme 2). Reaction of **5a–c** with PCl_3/NEt_3 at −78 °C followed by treatment with piperidine provided phosphoramidites **7** (Scheme 2), the S,R_P compounds being the major diastereomers in these cases. The formation of the major diastereomers appears to be kinetically controlled under these conditions, because heating compound **7a** at 110 °C for 48 h changed the diastereomeric ratio S,R_P:S,S_P from 3:1 to 2.3:1. Treatment of compounds **5** with PCl_3/NEt_3 followed by reaction with an alcohol in the presence of NEt_3 provides the analogous phosphites, for example phosphite **8** (S,R_P:S,S_P = 3.8:1; Scheme 2).



Some of the diastereomers were separated by crystallization, others by HPLC. The configuration assignments were

4

b R = CH_3 (96%)
c R = CH_2Ph (60%)
6 a R = CPh (92%)
b R = CH_3 (82%)
c R = CH_2Ph (90%)
7 a R = CPh (90%)
b R = CH_3 (94%)
c R = CH_2Ph (91%)
8 (79%)

Scheme 2. Synthesis of phosphoramidites **6** and **7** and phosphite **8**. a) 1. RX/base, 2. CH_3OH/HCl; b) $P(NMe_2)_3$/toluene, 110 °C, 1–2 h; c) 1. PCl_3/Et_3N, Et_2O, −78→0 °C, 2. piperidine/Et_3N, Et_2O, RT, 24 h; d) 1. PCl_3/Et_3N, Et_2O, −78→0 °C, 2. *i*PrOH/Et_3N, Et_2O, RT, 24 h.

then made on the basis of an X-ray structural analysis of the major diastereomer of **6a**, which has the S,S_P configuration,[7] and in other cases by comparison of ^{31}P NMR spectroscopy data. In the ^{31}P NMR spectrum the signal of the S,S_P ligands appears at higher δ values than that of the S,R_P diastereomers, a conclusion that was corroborated by the X-ray data of another derivative (see below). Subsequently, the first rhodium-catalyzed hydrogenations were performed with olefins **9** and **11** (Scheme 3).

9 **10**
11 **12**

Scheme 3. Rhodium-catalyzed hydrogenation of olefins **9** and **11**; cod = cyclooctadiene.

Table 1 reveals that excellent enantioselectivities were achieved in some but not all cases and that the absolute configuration of the binol ligand dictates the direction of enantioselectivity. In the case of the hydrogenation of itaconic acid dimethyl ester (**9**) using ligand **6a** the configuration at the phosphorus center also plays a significant role. The pure S,S_P ligand leads to an *ee* value of 96.3 % (*S*; Table 1, entry 1), whereas the pure S,R_P diastereomer is less efficient (*ee* = 72.5 % *S*, entry 4). Thus, the S,S_P diastereomer represents the matched case. The mixtures of diastereomeric ligands give rise to intermediate *ee* values (entries 2 and 3). These

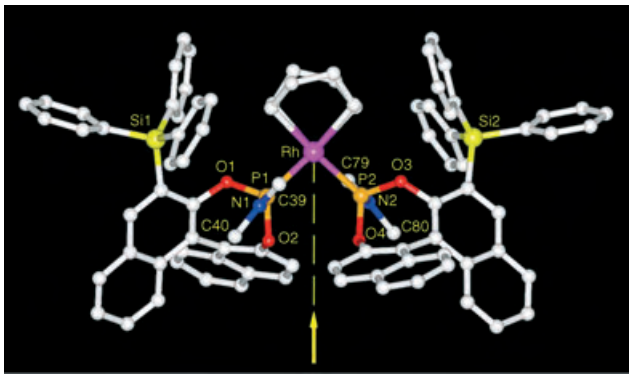
[a] All reactions in CH_2Cl_2; Rh:L = 1:2; Rh:olefin = 1:200; 1.3 bar; 20 h; 100% conversion in all cases.

mixtures constitute a more complex case because, as the rhodium center is coordinated by two binol ligands, three catalysts are actually involved, namely Rh(S,S_P/S,S_P), Rh(S,R_P/S,R_P), and Rh(S,S_P/S,R_P), each is present in a different amount and reacts with a different rate. Table 1 shows that with **9**, in five cases the *ee* values exceed 96%, which is distinctly better than the 87% *ee* resulting from the use of the parent C_2-symmetric phosphoramidite **1c** (R = CH_3).[3a] The mixture of diastereomeric phosphites **8** leads to a respectable 91.3% *ee* (entry 10), but at present we do not know how the pure diastereomers perform. In the hydrogenation of olefin **11**, ligand **6a** (S,S_P pure) also constitutes the matched case, but the cooperative effect is not as pronounced (entry 11 versus 14).

We phosphorylated the known (*S*)-binol derivatives **13**[8] which resulted in formation of phosphoramidites **14a–e**, and in two cases proceeded with complete diastereoselectivity (Scheme 4).

The X-ray structural analysis of the triphenylsilyl-derivative **14e** shows the free ligand to have the S,S_P configuration.[7] The precatalyst [Rh(**14e**)$_2$(cod)]BF_4 was also characterized by X-ray crystallography (Figure 1).[9] The metal cation has an almost ideal twofold axis of symmetry despite a highly unsymmetrical crystal environment caused by the



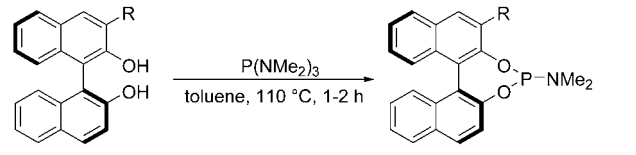


Figure 1. Structure of the cation of [Rh{(S,S_P)-**14e**}$_2$(cod)]BF_4 showing the almost exact twofold axis of symmetry passing through the Rh atom (arrow). Selected interatomic distances [Å], angles, and torsion angles [°]: Rh-P1 2.277(1), Rh-P2 2.275(1), P1-N1 1.640(2), P2-N2 1.633(3), C39···Rh 3.381(3), C79···Rh 3.377(3), P1-Rh-P2 94.89(2), C39-N1-P1-Rh 5(1), C79-N2-P2-Rh 3(1).[9]

$[BF_4]^-$ ion and CH_2Cl_2 solute of crystallization. This situation suggests that crystal-packing effects are not the cause of the high symmetry. An electron-donating effect of nitrogen onto phosphorus which is passed onto the positively charged rhodium center seems to be operating. Another feature is a weak C–H···Rh$^+$ interaction between one of the H atoms of a methyl group in the planar $N(CH_3)_2$ moiety and the metal.[10] Although the rhodium complexes of the other ligands which have less-bulky *ortho*-substituents could not be crystallized to date, they may have similar structures.

Upon employing the ligands **14** in the rhodium-catalyzed hydrogenation of olefins **9** and **11**, some remarkable observations were made (Table 2). The methyl derivative **14a** behaves much like the ligands **6**, **7**, and **8**, affecting *S* selectivity (91% *ee*, entry 1). In contrast, upon using the phenyl derivative **14b**, we were surprised to observe *R* selectivity (entries 2–5). This effect is opposite to what occurs when using the C_2-symmetric parent compounds (*S*)-**1** which also originates from (*S*)-binol; all of the parent ligands are known to be *S*-selective in the hydrogenation of **9** (**1a** (R = *i*Pr): 89.2% *ee*;[1] **1b** (X = CH_3): 90% *ee*;[2] **1c** (R = CH_3): 87% *ee*).[3a] Reversal of enantioselectivity on using ligand **14b** occurs both in the matched case S,R_P with 70% *ee* (entry 5) and in the non-cooperative combination S,S_P (20.6% *ee*, entry 2). This result means that breaking the symmetry of the ligands from C_2 to C_1 by introduction of an *ortho*-phenyl group induces a reversal of enantioselectivity which is independent of the configuration at the stereogenic phosphorus center. We also note that mixtures of diastereomers **14b** result in distinctly higher enantioselectivities than the use of the respective pure ligands themselves, *ee* values up to 90.3% being achieved (entries 3 and 4). The use of two diastereomers constitutes a novel extension of our concept of employing mixtures of two different monodentate ligands[4]

and raises fundamental theoretical questions. The fact that the triphenylsilyl-derivative **14e** is a poor ligand for catalysis can be rationalized on the basis of the crystal structure of [Rh{(S,S_P)-**14e**}$_2$(cod)]BF_4 (Figure 1). The silyl groups are so bulky that hydrogenation may actually be inhibited; the rhodium complex with only one phosphoramide ligand may function as the actual (pre)catalyst.

In summary, we have prepared and characterized a new class of binol-derived monodentate phosphorus ligands bearing phosphorus stereogenic centers. They are excellent ligands in rhodium-catalyzed olefin hydrogenation, a result which raises important mechanistic questions. On the practical side, this new class of modular phosphorus compounds enlarges the structural diversity of binol-derived monodentate phosphorus ligands, which means that they are also candidates for our combinatorial approach using mixtures[4] of chiral monodentate phosphorus ligands in hydrogenation and in other transition-metal-catalyzed reactions.

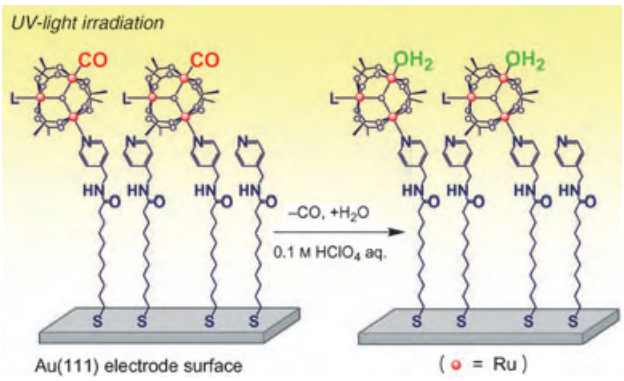
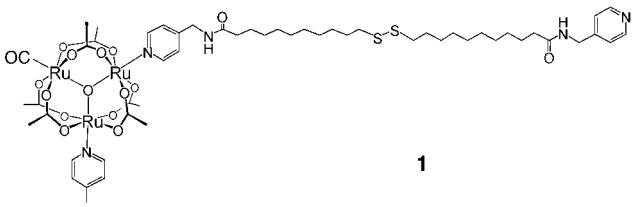
SAM Photochemistry



Photoconversion of a Redox-Active Self-Assembled Monolayer: In Situ Probing of Photoinduced CO Dissociation from a Triruthenium Cluster Center on Gold**

Masaaki Abe, Takuya Masuda, Toshihiro Kondo, Kohei Uosaki,* and Yoichi Sasaki**



Investigations on the photoreactivity of molecular compounds assembled on solid surfaces or at solid/solution interfaces are a prerequisite for the photochemical design of functional molecular thin films.[1] Extensive studies have been made on the fabrication of photoresponsive molecular layers on electrode surfaces by using organic, inorganic, and biological building blocks, in which, for example, isomerization,[2] chemical bond formation and cleavage,[3] and directional electron transfer are observed.[4]

Photoinduced ligand substitution is an additional potential candidate for controlling surface properties of thin films that are constructed from transition-metal coordination compounds. Although significant progress has been made in solution-phase photoinduced substitution reactions,[5] their application to precise tuning of thin-film properties at solid surfaces have rarely been exploited to date.[6] Here we describe the in situ observation and analysis of photoinduced CO dissociation from a self-assembled monolayer (SAM) of a triruthenium cluster on Au(111), which is, to our knowledge, the first well-defined example of clean photoconversion of a redox-active SAM that leads to a significant shift of the redox potential. We also report on photocurrent generation by the present SAM, which is an unprecedented finding for this class of cluster molecules. This study thus provides a new route to photochemical design of redox-active molecular films on electrode surfaces, which should be of considerable use in molecular electronics and devices.

Scheme 1 illustrates the proposed photochemical reaction in the SAM. We employed disulfide-functionalized, CO-ligated triruthenium cluster **1** as photoresponsive molecule.[7] This compound was chosen because of its well-defined photoinduced CO dissociation in solution[8] and the availability of a methodology for preparing densely packed SAMs on the surface of a gold electrode.[7] Trinuclear clusters of this type[9] have been used to construct ligand-bridged extended molecular architectures by chemical synthesis[10–14] and layer-by-layer deposition on gold surfaces,[15] as well as to fabricate a ligand switching device.[16] Complex **1** is a mixed-valent $Ru_3^{II,III,III}$ complex in which the +II oxidation state is localized at the ruthenium site bound to CO[17,18] (here we designate the triruthenium redox moiety as $\{Ru^{II}\text{-}CO\}Ru^{III}Ru^{III}$). The CO ligand of **1** remains coordinated to the ruthenium center in the SAM as long as the $\{Ru^{II}\text{-}CO\}Ru^{III}Ru^{III}$ oxidation state is maintained, but it dissociates when the one-electron-oxidized $\{Ru^{III}\text{-}CO\}Ru^{III}Ru^{III}$ state is prepared electrochemically by holding the applied potential at +0.8 V (vs Ag/AgCl in 0.1 M $HClO_4$) to form an H_2O-terminated SAM as the result of interfacial ligand substitution.[7]

Scheme 1. Proposed photoinduced CO dissociation from a monolayer of **1** self-assembled on Au(111). L = 4-methylpyridine.

1

Cyclic voltammetry was used to probe photoinduced CO dissociation from the redox-active SAM on Au(111). A SAM-modified Au(111) disk ($A = 0.44\ cm^2$), together with a platinum-coil counterelectrode and an Ag/AgCl reference electrode, was placed in a photoelectrochemical cell filled with an Ar-purged aqueous solution of 0.1 M $HClO_4$. An Hg lamp (250 W; Ushio, USH-250D) was employed for irradiation through the 2 mm-thick quartz-plate window of the cell. To probe the photolytic reaction of the SAM, cyclic voltam-

mograms (CVs) were recorded at constant time intervals of irradiation. During irradiation, the electrode potential was held at +0.3 V, a value that is more negative than $E_{1/2}$ of the SAM, to avoid electrochemical dissociation of CO from the cluster center.[7]

Figure 1 shows changes in CV on photolysis of an SAM of **1** on Au(111) in contact with 0.1 M $HClO_4$ aqueous solution at RT. Prior to irradiation (Figure 1a), the CV shows a redox

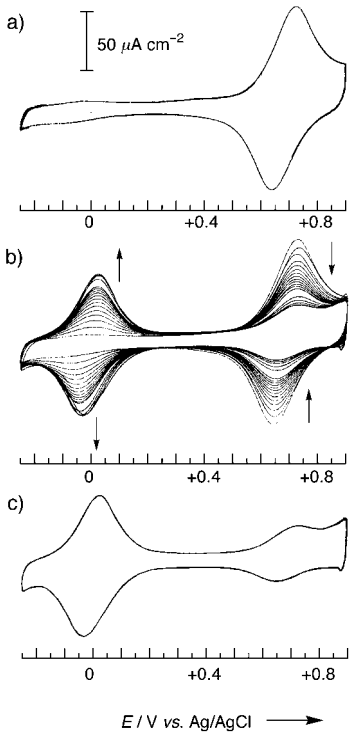

Figure 1. CVs of the SAM-modified Au(111) electrode. a) Prior to irradiation. b) Sequential variation in CV during UV irradiation ($0 < t < 520$ s). Upward and downward arrows represent the increase and decrease, respectively, in current of the redox waves. c) After 520 s irradiation. Electrolyte: 0.1 M aqueous $HClO_4$. Applied potential during irradiation: +0.3 V versus Ag/AgCl. Scan rate for CV: 500 $mV s^{-1}$.

wave which corresponds to the $\{Ru^{II}\text{-}CO\}Ru^{III}Ru^{III}/\{Ru^{III}\text{-}CO\}Ru^{III}Ru^{III}$ process[7] at +0.68 V versus Ag/AgCl with a surface coverage of $\Gamma = 2.5 \times 10^{-10}$ mol cm^{-2}. When the SAM-modified Au(111) electrode was exposed to UV light from the Hg lamp (Figure 1b), the redox wave at $E_{1/2} = +0.68$ V decreased in intensity, while a new redox wave appeared and increased in intensity at $E_{1/2} = 0.00$ V, a value that is very close to that of the H_2O-terminated SAM generated electrochemically.[7] This value is also close to that of CO-free solvento complex $[Ru_3(\mu_3\text{-}O)(\mu\text{-}CH_3COO)_6(4\text{-methylpyridine})_2(H_2O)]^+$ dissolved in acetonitrile containing 0.1 M nBu_4NPF_6 ($E_{1/2} = +0.04$ V vs Ag/AgCl).[19] After 520 s of UV exposure (Figure 1c), nearly complete transformation of the monolayer is observed. More direct evidence for photolytic dissociation of CO was obtained by IR spectroscopy.[20] The SAM of **1** assembled on Au(111) displays an intense absorption peak due to ν(CO) at $\tilde{\nu} = 1944$ cm^{-1}, which exhibits, as expected, a significant decrease in intensity after photolysis.

The photoinduced transformation was quantitatively analyzed by integrating charge density under the two redox waves presented in Figure 1. Figure 2a shows charge density profiles of surface-assembled **1**, H_2O-terminated photoproduct, and the sum of the two against irradiation time. As is visible from Figure 2b, the photoinduced dissociation of CO

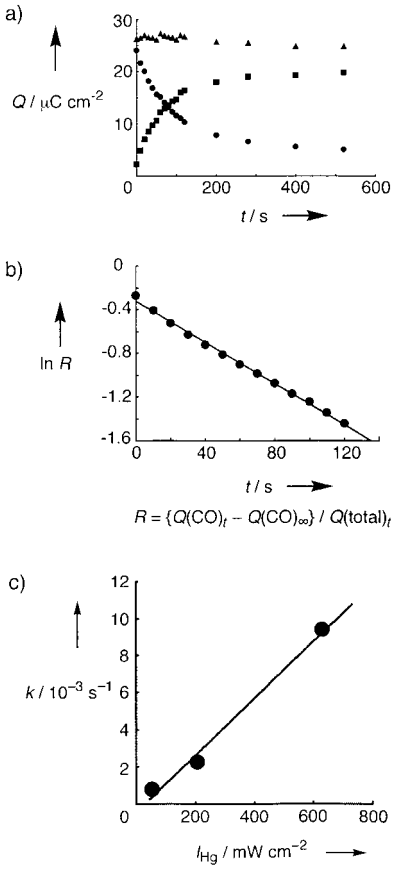

Figure 2. Analysis of photoinduced CO dissociation. a) Variation of charge Q of surface species obtained from CVs presented in Figure 1. ●: CO-terminated SAM; ■: H_2O-terminated SAM; ▲: sum of the two components. b) First-order plot of the decay of CO-terminated SAM as a function of irradiation time t. c) Linear dependence of the rate constant k for CO dissociation on light intensity I_{Hg}.

is well described by first-order kinetics with a rate constant of $(2.3 \pm 0.1) \times 10^{-3}$ s^{-1} at a light intensity of 210 mW cm^{-2}. The rate constant increases linearly with increasing light intensity (Figure 2c). Changing the electrolyte solution from 0.1 M $HClO_4$ to 0.05 M H_2SO_4 does not affect the rate constant of photodissociation; this suggests that the electrolyte anions do not participate in the photoexcited state of the cluster.

We emphasize that the photochemical transformation of the monolayer is clean: the two redox-active moieties remain undesorbed from the surface during irradiation (Figure 2a). The preservation of the monolayer on the electrode surface was also supported by a reductive desorption experiment (0.5 M aqueous KOH solution), which showed a well-defined Au–S desorption peak at −0.92 V for the photolytically

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

generated H_2O-terminated SAM.[21] We speculate that the closely packed character of the photoactive cluster moieties, as well as the deaerated conditions employed for the measurement, minimize possible photodegradation of the SAM.[22]

We recently established photoinduced dissociation of CO from $[Ru_3(\mu_3\text{-}O)(\mu\text{-}CH_3COO)_6(pyridine)_2(CO)]$ in CH_3CN.[8] Photoexcitation at the cluster-to-CO ligand charge-transfer band at about 300 nm results in dissociation of CO to afford the corresponding CH_3CN complex $[Ru_3(\mu_3\text{-}O)(\mu\text{-}CH_3COO)_6(pyridine)_2(CH_3CN)]$ with a quantum yield of 0.012 at 298 K, while an intense absorption band at $\lambda_{max} = 585$ nm is not totally responsible for CO dissociation. In the present study, the importance of photoexcitation wavelength for triggering ligand substitution at the monolayer/solution interface was demonstrated by two experiments. First, when irradiation was performed with an Hg lamp through long-pass cutoff filters, the rate constant for CO dissociation ($k = 5.3 \times 10^{-4}\ s^{-1}$ for $\lambda > 340$ nm and $1.4 \times 10^{-4}\ s^{-1}$ for $\lambda > 380$ nm) became approximately one order of magnitude smaller than that obtained on unfiltered irradiation, that is, the photoactive band(s) lies in the UV region. Irradiation at 400 nm or longer wavelength does not cause any CO dissociation. Second, irradiation with visible light from an Xe lamp (630 mW cm^{-2}) also retarded the photoinduced substitution ($k = (8.1 \pm 0.1) \times 10^{-4}\ s^{-1}$).[23]

An additional interesting feature of the present SAM is the observation of photocurrent generation. Figure 3 shows the photocurrent action spectrum of the monolayer assembled on Au(111) and the UV/Vis absorption spectrum of **1** in acetonitrile. The anodic photocurrent response of the monolayer is shown in the inset. The photocurrent action spectrum shows a remarkable dependence on the irradiation wavelength. The maximum photocurrent was observed for excitation at 320 nm, while the photocurrent intensity was markedly decreased at shorter and longer wavelengths. Irradiation at 350 nm or longer wavelength did not lead to photocurrent generation, which clearly shows the inactivity of the absorption band in the visible region ($\lambda_{max} = 584$ nm) in the photocurrent response. The maximum peak of the action spectrum definitely corresponds to the location of the absorption shoulder in **1**, which has been tentatively assigned to cluster-to-ligand or cluster-to-CO charge-transfer transitions.[8] Since the intensity of the monochromated light employed here is fairly low (280 μW cm^{-2}), the action spectrum obtained indeed reflects the photocurrent response of the CO-terminated SAM. We note that the monolayer shows reproducible photocurrent data as long as the {Ru^{II}-CO} bond in **1** remains intact. Work to accurately determine the nature of the photocurrent and to fully address its mechanism is currently in progress. Our preliminary observation indicates that the aqua-terminated monolayer formed on intense irradiation of its CO-terminated counterpart also exhibits an anodic photocurrent but with much lower intensity. These observations indicate that photochemical ligand replacement can be used to tune not only the redox potential but also the photocurrent characteristics of our SAM on Au.

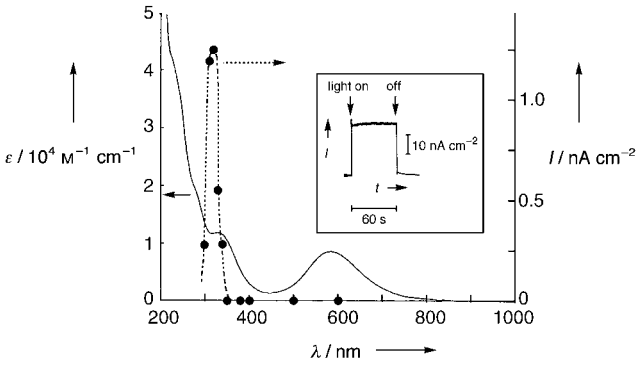

Figure 3. Absorption spectrum of **1** in acetonitrile (solid line) and photocurrent action spectrum (filled circles) of the monolayer of **1** on Au(111) in contact with 0.1 M $HClO_4$. Monochromated light intensity: 280 μW cm^{-2}. Applied potential: +0.3 V versus Ag/AgCl. Inset: anodic photocurrent response with irradiation from an Hg lamp (210 mW cm^{-2}).

In conclusion, we have described photochemical ligand substitution reaction of a redox-active SAM for the first time. We expect that suitable selection of photoresponsive coordination compounds, a CO-ligated triruthenium complex in our case, may offer a route to significant development in the fabrication of redoxactive and photoactive layers that can show device characteristics at an electrochemical interface.

Experimental Section

The Au(111) disk for SAM preparation was electrochemically etched and annealed as described in ref. [24]. The surface area was estimated from a cyclic voltammogram recorded in 0.1 M aqueous H_2SO_4, based on the charge under the cathodic wave due to gold oxide reduction.[25] The roughness factor of the Au(111) surface was 1.15. Prior to SAM formation, the Au(111) disk surface was flame-annealed with a hydrogen burner and slowly cooled in air. For SAM formation, the disk was immersed in an ethanol solution of **1** (50 μM) for 2 d at RT. The SAM-modified Au(111) was rinsed with ethanol and Milli-Q water, dried by blowing nitrogen gas over the surface, and it was subjected to photoelectrochemical measurements. The electrode potential was controlled by a Hokuto Denko HA-151 potentiostat, while the external potential was provided by a Hokuto Denko HB-111 function generator. The light intensity was determined by an optical power meter. For recording of the photocurrent action spectrum, monochromated light from the Hg lamp was used. The light intensity was adjusted to 280 μW cm^{-2} for each measurement.

the diseased tissue.[1] To obtain high quantum yields and effective energy absorption, PSs generally need to have large π-conjugation domains such as a porphyrin structure. Therefore, most conventional PSs easily form aggregates, which produce a self-quenching effect of the excited state, in aqueous medium as a result of their π–π interactions and hydrophobic characteristics. These issues can be overcome, as we reported previously, by segregating PSs into the focal core of dendrimers (dendrimer porphyrins (DPs), Figure 1b).[2] DPs are attractive for biomedical purposes because of their predictable structures, that is, their monodisperse molecular weight and tunable three-dimensional structures, and their flexibility for a high density of tailored functional groups on the periphery.[3] Indeed, third-generation DPs with 32 cationic or anionic peripheral groups exhibit a high solubility in aqueous medium and have a high quantum yield for the generation of singlet oxygen, which leads to an appreciable photocytotoxicity.[2] These advantageous features of DPs are facilitated to an even greater extent by their inclusion into stealth nanocarriers, thus improving their longevity in blood circulation and results in their gradual accumulation in solid tumors through the enhanced permeation and retention (EPR) effect.[4] Furthermore, as demonstrated here, the inclusion of DPs into a novel type of nanocarrier, that is, polymeric micelles, has led to an unprecedented increase in the photocytotoxicity without compromising either the photophysical properties of DPs in regard to their efficient photochemical reactions or the physicochemical properties of the carriers necessary for tumor-selective delivery.

A novel polymeric micelle system[5] for PDT is based on an electrostatic assembly of an anionic DP,[6] which consists of zinc porphyrin at the focal core with a third generation of poly(benzyl ether) dendritic frameworks having 32 negative charges on the periphery, and poly(ethylene glycol)–poly(L-lysine) block copolymer (PEG-*b*-PLL) in aqueous media (polyion complex (PIC) micelles; Figure 1b).[7] The DP-incorporated micelles (DP/m), prepared with a stoichiometric ratio of negatively charged DP and positively charged PEG-*b*-PLL, were approximately 64 nm in diameter with an extremely narrow size distribution in physiological saline solution (Figure 2a). Our previous study using static light scattering (SLS) measurements demonstrated that an individual DP/m contains an average of 38 DP molecules and the micelles have a remarkable stability against salt concentrations,[7] which indicates the clear stabilization effect by the 32 negative charges of DP in the micellar structure. The dependency of the formation of DP/m on the pH value was investigated by dynamic and static light scattering (DLS and SLS) measurements. Figure 2b shows the pH-dependent changes in the translational diffusion coefficient (D_T) and normalized $(Kc/\Delta R(0))^{-1}$ (normalized to the micelle at pH 7.4) of DP/m, where D_T is related to the hydrodynamic size based on the Stokes–Einstein equation, and the normalized $(Kc/\Delta R(0))^{-1}$ value is related to the changes in the average apparent molecular weight of the micelles. Both the hydrodynamic size and normalized $(Kc/\Delta R(0))^{-1}$ value basically remained unchanged in the pH range from 6.4 to 8.5 (Figure 2b). However, the diameter of the micelles gradually

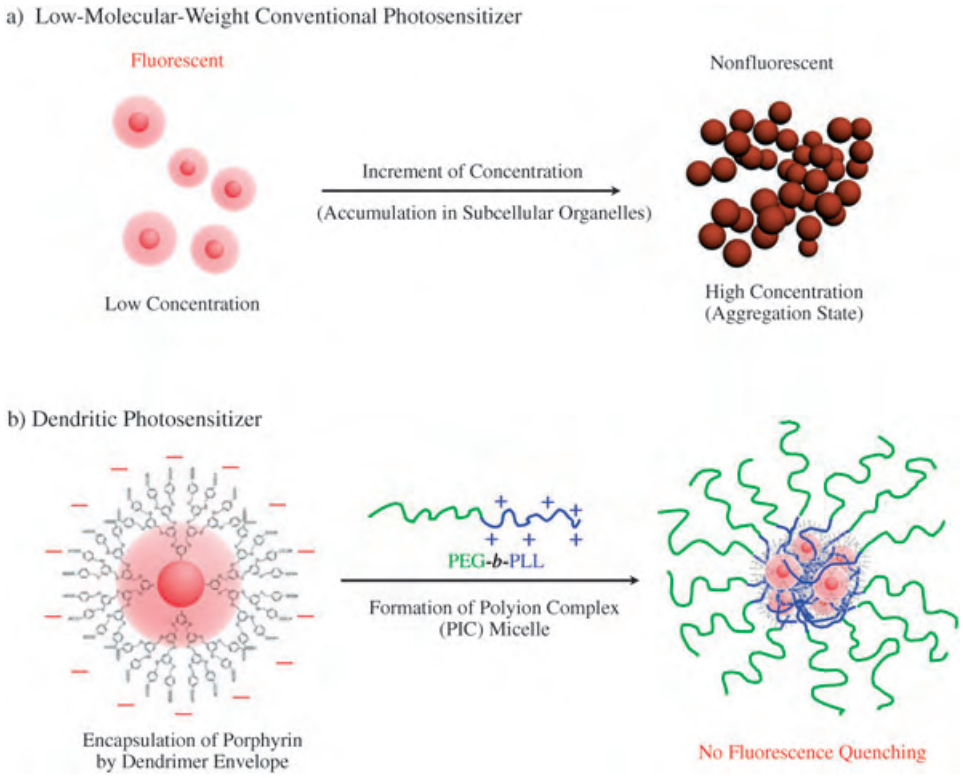

Figure 1. a) Conventional PS aggregate at a high concentration which results in quenching of PSs. b) Formation of polyion complex (PIC) micelles through electrostatic assembly of anionic dendrimer porphyrins (DPs) and PEG-*b*-PLL copolymers. The dendrimer envelope of DP can sterically prevent aggregation of the center porphyrin, thus there is no fluorescence quenching of the center porphyrin.

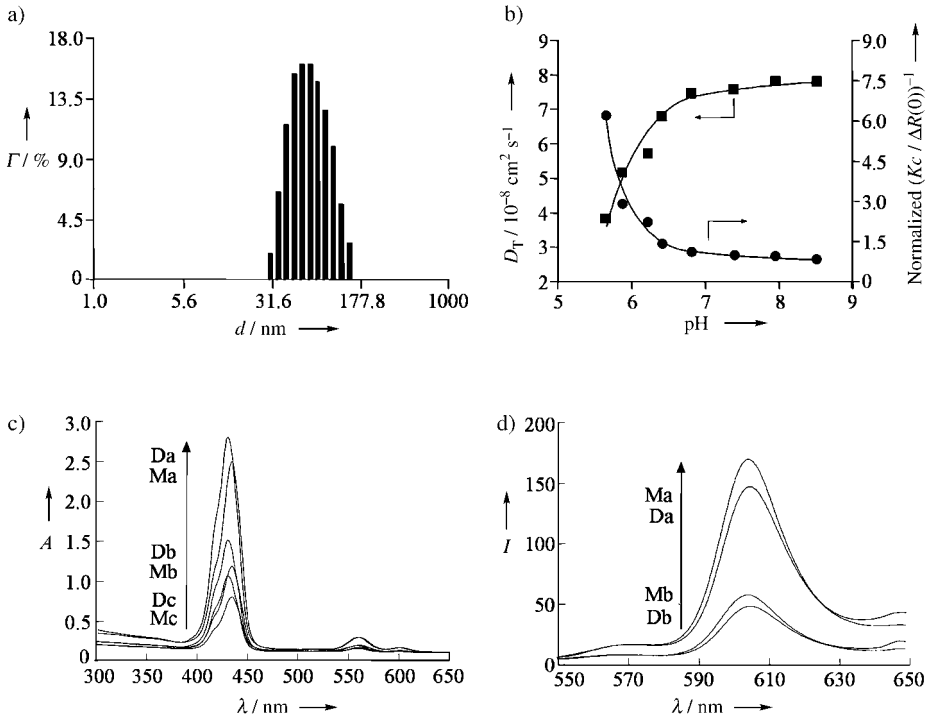

Figure 2. Physical properties of DP and DP/m. a) DLS histogram of DP/m in 150 mM NaCl at 25 °C; d = diameter. b) Dependency of the translational diffusion coefficients D_T (■) and normalized $(Kc/\Delta R(0))^{-1}$ (●) on the pH value for DP/m (1 mg mL^{-1}), measured by DLS and SLS, respectively, at 25 °C. c) Electronic absorption spectra of DP alone and DP/m in PBS (pH 7.4; a = 12 μM, b = 4 μM, c = 2 μM, D: DP, M: DP/m). d) Fluorescence emission spectra of DP alone and DP/m in PBS (pH 7.4; a = 12 μM, b = 4 μM, D: DP, M: DP/m).

increased with an increased apparent molecular weight below pH 6.4 (Figure 2b), and finally precipitated at pH 5.6, which indicates the acid-responsive feature of the micelles. Protonation of DP occurred under acidic pH conditions and resulted in the diminution of the electrostatic interaction between DP and PEG-*b*-PLL. Thus, the well-defined core–shell structure may become more diffuse and a merging of the micelles may take place. This pH-responsive behavior of the micelles allows their effective accumulation in solid tumors in response to the low pH value of the tumor tissue[8] or in an endosomal compartment in the tumor cells while achieving stable circulation in the bloodstream.

The electronic absorption and emission spectra of DP and DP/m are shown in Figure 2c and d, respectively. Unlike low-molecular-weight PSs,[9] DP clearly maintained its absorption and emission intensity in spite of the formation of micelles. The incorporation of DP into the micelles resulted in a 5-nm red-shift for the Soret band of the porphyrin core and a hypochromicity of about 5% (Figure 2c). Both of these effects are likely to be caused by the formation of an electrostatic assembly of charged porphyrins and oppositely charged compounds.[10] The shrinkage of the hydrophobic dendrimer frameworks, which arises from the relaxation of the charge repulsion of the negatively charged DP surface by the formation of an electrostatic assembly, may contribute to the hypochromicity.[11] Interestingly, although the local concentration of DP within each micelle is assumed to be extremely high, DP/m emitted a more intense fluorescence at 610 nm (Figure 2d). Unlike conventional PSs, the dendritic envelope of DP is able to prevent the porphyrin core from undergoing collisional quenching, even at an appreciably high concentration that induces self-quenching of the conventional PSs (Figure 1a).[12] Thus, encapsulation of the porphyrins by the dendritic envelope in the micellar structure is most likely to prevent fluorescence quenching (Figures 1b and 2d). Also, the high microviscosity in the micellar core could restrain the internal molecular motion of DP, which might lead to the inhibition of the nonradiative decay and is related to the increased fluorescence intensity of DP/m (Figure 2d).[13] In connection with this observation, the photoinduced oxygen consumption of DP and DP/m was measured in phosphate-buffered saline (PBS) containing 10% fetal bovine serum (FBS) as a singlet oxygen acceptor (Figure 3). Very interestingly, the result revealed that the oxygen consumption level of

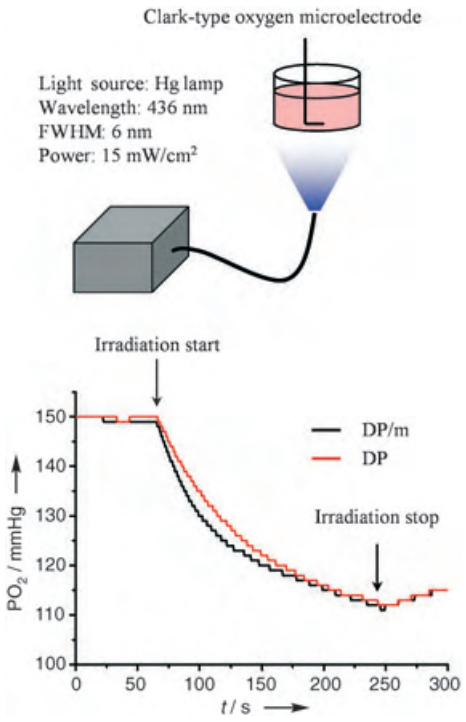

Figure 3. Experimental setup for the measurement of oxygen consumption and the results obtained. FWHM = full width of half maximum height.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

DP/m was almost identical to that of the free DP in PBS, which indicates that the singlet oxygen molecules can successfully escape the micellar structure. From the standpoint of the application to PDT, the DP ensures an effective photochemical reaction of the porphyrin core regardless of the local concentrations. It is possible that the DP/m attain an elevated concentration of local singlet oxygen, which cannot be achieved by other formulations containing conventional PSs.

However, the cellular uptake of free DP and DP/m increased with the incubation time, and DP/m showed six- to eightfold higher uptake levels than free DP (Figure 4a). In

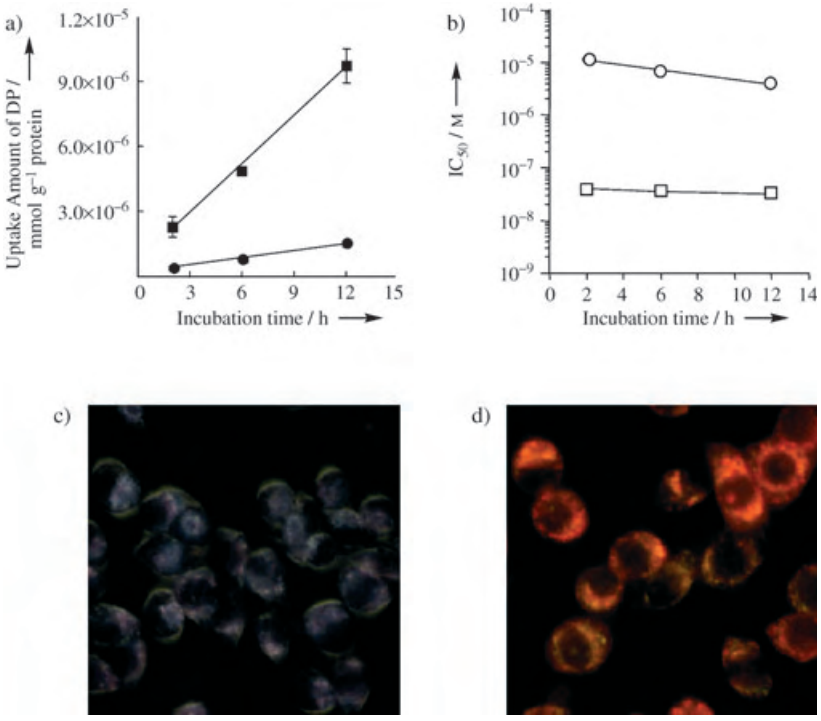

Figure 4. Results of in vitro evaluations of DP and DP/m. a) Cellular uptake level of DP (●) and DP/m (■) as a function of incubation time ($n=3$). LLC cells were incubated with dendrimers and the micelles at 12 μM of DP-equivalent concentration. b) Incubation time dependency of 50% growth inhibitory concentration (IC_{50}) of DP (○) and DP/m (□) after photoirradiation. c, d) Microscopy images of LLC cells incubated with 10 μM of DP (c) and DP/m (d) for 8 h. A Zeiss filter set (excitation: BP 395–440 nm; beam splitter: FT 460 nm; emission: LP 470 nm) was used.

view of the negatively charged surface of mammalian cells,[8] charge neutralization of DP by PEG-*b*-PLL could improve the cellular uptake of DP/m. The improved uptake of DP/m was also confirmed by microscopic observations (Figure 4c and d). No fluorescence quenching was observed for the cells incubated with DP/m, although the sensitizers are assumed to be extremely concentrated in the subcellular organelles such as the endosomes and lysosomes. This observation contrasts with the fact that the conventional mesochlorin e_6 conjugated *N*-(2-hydroxypropyl) methacrylamide (HPMA) copolymers exhibit fluorescence quenching when the cells are incubated with HPMA at an extremely high concentration.[14] The dendritic envelope of DP could prevent aggregation of the porphyrin in the subcellular loci, thus ensuring effective production of singlet oxygen for the photocytotoxicity.

Notably, the photocytotoxicity of DP/m was remarkably improved compared to that of free DP (Figure 4b). Incorporation of DP into the micelles resulted in an approximately 130–280-fold increased photocytotoxicity (Figure 4b). Such a distinctly enhanced photocytotoxicity of DP/m may not be fully explained by the six- to eightfold increase in their cellular uptake shown in Figure 4a; therefore, DP/m may have specific mechanisms to increase their photocytotoxicity. Recently, PEGylated chlorin e_6 and PEG-based polymeric micelles were reported to show an enhanced localization in several cytoplasmic organelles including the mitochondria.[15] Presumably the outer PEG layer of the DP/m and the microenvironment around DP, as mentioned above, may have a role in altering the intracellular mechanism of DP to increase the photocytotoxicity. Recently, several interesting observations concerning the intracellular mechanism have been reported. For example, Berg et al. proposed a photochemical internalization (PCI) in which the photodamage to endosomal membranes can burst the endocytic vesicles, which allows endosomal escape of macromolecules into the cytosol.[16] From this point of view, DP/m may localize in the cytoplasmic organelles susceptible to photodamage following endosomal escape of the micelles during photoirradiation. The DP/m are assumed to produce a significantly high concentration of singlet oxygen as a result of effective separation of the center porphyrin by the dendritic envelope. The mechanism for the efficient generation of singlet oxygen within the micellar structure remains to be explained. However, a dendritic structure that prevents aggregation of the center porphyrin should be essential for the enhanced photocytotoxicity of DP/m. Further investigation to address the detailed mechanisms of the enhanced photocytotoxicity of DP/m, together with dendrimer size and morphological effect, is now in progress.

In summary, the photodynamic efficacy of the DP was dramatically improved by inclusion into micelles. This process resulted in a more than two orders of magnitude increase in the photocytotoxicity compared with that of the free DP, as a result of the accumulated singlet oxygen in the intracellular compartment as well as the modulated intracellular localization related to the micellar structure. Furthermore, the DP/m system has a relevant size range (ca. 100 nm) and high stability for intravenous administration, with resultant EPR effect, and may have a high utility for in vivo PDT of cancer and macular degeneration, the study of which is now in progress.

Experimental Section

PEG-*b*-PLL was synthesized by the polymerization of the *N*-carboxy anhydride of N^{ε}-Z-L-lysine initiated by CH_3O-PEG-NH_2 (12000 g mol^{-1}) in DMF, followed by deprotection of the Z group according to a previously reported method.[17] The M_w/M_n ratio and degree of polymerization of PLL were determined to be 1.11:1 and 41 by gel-permeation chromatography and ^{1}H NMR spectroscopy,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

respectively. DP was synthesized as previously described,[6] and its purity was confirmed by a single peak in the MALDI-TOF mass spectrum (8030 g mol^{-1}). The DLS and SLS measurements of DP/m were performed using a Photal dynamic laser-scattering DLS-7000 spectrometer (Otsuka Electronics Co., Ltd., Osaka, Japan). The UV/Vis and fluorescence spectra were measured on a V-550 spectrophotometer and on an FP-777 spectrofluorometer (JASCO, Tokyo, Japan), respectively.

Lewis lung carcinoma (LLC) cells were used in the cell culture studies. In the quantitative analysis of the cellular uptake of DP, the cells incubated with free DP and DP/m were lyzed in 5% SDS solution, followed by measurement of the fluorescence intensity at 609 nm (excitation at 432 nm). In the cytotoxicity assay, the cells were photoirradiated for 10 minutes with broadband visible light using a xenon lamp (150 W) equipped with a filter passing light of 400–700 nm (fluence energy: 180 kJ cm^{-2}). The viability of the cells was evaluated by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay.

Oxygen consumption was measured by using a Clark-type oxygen microelectrode with a tip diameter of 200 μm (PO_2-100DW, Eikou Kagaku Co., Ltd., Tokyo, Japan). The microelectrode was inserted into the PBS, which contained 3.13 μM of DP or DP/m and 10% FBS as a singlet oxygen acceptor, so that the tip was 100 mm above the bottom of the solution. An Hg lamp (436 nm, FWHM: 6 nm, 15 mW cm^{-2}) was used for light irradiation. The solution was static and exposed to the atmosphere. Before each measurement, the system was calibrated in saline solution bubbled with air, in which the oxygen partial pressure was assumed to be 150 mm Hg.

NMR Spectroscopic Methods (1)

Stretched Poly(vinyl acetate) Gels as NMR Alignment Media for the Measurement of Residual Dipolar Couplings in Polar Organic Solvents**

*J. Christoph Freudenberger, Sebastian Knör, Kyryl Kobzar, Dominik Heckmann, Thomas Paululat, Horst Kessler, and Burkhard Luy**

Residual dipolar couplings (RDCs) have revolutionized the NMR-based structure determination of large biomolecules[1–4] and lately demonstrated their potential in the field of small molecules.[5–12] The measurement of RDCs relies on the partial orientation of the molecule of interest, for which a so-called alignment medium is necessary. In aqueous solution a variety of alignment media are known, for example,

bicelles,[13] filamentous phage,[14] liquid-crystalline phases,[15] or stretched polyacrylamide-based gels.[16,17] For relatively apolar organic solvents, liquid crystals such as poly-γ-benzyl-L-glutamate (PBLG)[5–7,18] or deuterated 4-*n*-pentyl-4′-cyanobiphenyl (PCBP)[19] as well as stretched polystyrene (PS)[11] and polydimethylsiloxane (PDMS)[12] gels are used to obtain structural information from RDCs. For polar organic solvents such as methanol or DMSO, however, no alignment medium is available yet. Herein we propose the use of stretched poly(vinyl acetate) (PVAC) gels for partial orientation of molecules dissolved in polar organic solvents.

Crosslinked PVAC-polymer sticks were produced in a similar way to that described previously for PS.[11] Glass tubes with inner diameters of 2.4 mm, 3.4 mm, and 4.0 mm were sealed by melting one end and dried carefully. They were then treated with a 1:1 mixture of chlorotrimethylsilane and dichloromethylsilane for 18 h to ensure hydrophobic glass surfaces. After being washed with dichloromethane, the tubes were dried at 50 °C. Vinyl acetate (Fluka) and adipic acid divinyl ester (ABCR) were filtered with basic aluminum oxide (pH 10) and distilled under reduced pressure. The monomers then were degassed for 15 min under vacuum in an ultrasonic bath and ventilated with argon. Immediately afterwards, vinyl acetate, adipic acid divinyl ester, and azoisobutyronitrile were mixed in the desired concentrations and transferred to the glass tubes. The open end was sealed by melting, and polymerization was carried out for 5 days at 45 °C and for another 2 days at 60 °C.

As a first test, we put crosslinked PVAC sticks in various organic solvents and watched the swelling behavior. The sticks exhibited swelling in essentially all tested solvents, such as chloroform, THF, dioxane, benzene, ethyl acetate, acetone, acetonitrile, methanol, and dimethyl sulfoxide (DMSO). We repeated the swelling inside NMR tubes and added $CDCl_3$ (5% *v*/*v*) to the non-deuterated solvents to allow the monitoring of any induced anisotropy by the deuterium quadrupolar splitting ν_Q. In all cases, significant splittings with relatively sharp lines could be observed (Table 1) after allowing the gels to equilibrate for 13 days. Furthermore, we recorded the dependence of the quadrupolar splitting on the amount of crosslinker used for polymerization for four solvents (DMSO, MeOH, THF, and dioxane; Figure 1). The resulting curves are similar to that observed for PS gels,[11] corroborating the general trend that higher crosslinking concentrations lead to stronger induced anisotropies.[12]

In a next step we tested the alignment properties of norcamphor in PVAC gels swollen in the four deuterated solvents available in our laboratory. Norcamphor (Table 2) was chosen

Table 1: Quadrupolar deuterium splittings [Hz] of $CDCl_3$ (5% *v*/*v*) added to PVAC sticks (0.1% *v*/*v*) cross linker, 3.4 mm and 4.0 mm inner diameter) swollen in various non-deuterated solvents.

as a sample for two reasons: it is highly soluble in almost every organic solvent and its protons all point in different directions. In [D_6]DMSO, CD_3OD, CD_3CN, and $CDCl_3$ we were able to measure at least six D_{CH} RDCs and derive the alignment tensors by using the program PALES with the *bestFit* option[20] (Table 2). Interestingly, the four alignment tensors differ significantly: D_a/D_r ratios differ for the four solvents and the axial component for methanol even has the opposite sign compared to the others. We can only speculate about this different behavior, but most probably specific interactions of the solvents with the polymer and/or the solute lead to this phenomenon. However, the most important result for the use of stretched PVAC gels as alignment media is that RDCs in the desired range of ± 20 Hz can be measured in all cases.

RDCs should be especially important for the structure determination of natural products. We therefore applied the method also to the well-characterized antibiotic sphaeropsidin A as a more realistic test sample.[21–23] After diffusion of ≈ 6 mg of sphaeropsidin A into an already swollen PVAC/DMSO gel with a quadrupolar $CDCl_3$ splitting of 10.1 Hz, two coupled HSQC spectra, optimized for aliphatic and olefinic nuclei, were acquired on a Bruker DMX900 spectrometer (Figure 2). Compared to sphaeropsidin A cross peaks, relatively strong PVAC and DMSO signals are present in both spectra, but D_{CH} RDCs can still be measured in most cases since sphaeropsidin A and PVAC signals do not overlap. Only the methylene protons attached to C_{11} show significant overlap and second-order effects so that a reliable RDC measurement was not possible. All couplings were carefully measured by extracting slices out of the 2D spectra and applying the phase correction approach described in detail elsewhere.[9] As a starting point we looked at the eight C–H vectors containing the atoms C1, C2, C3, C5, and C14. The diastereotopic protons of the methylene groups of C2 and C3 were easily derived by using the simple method to distinguish between axial and equatorial C–H vectors.[9] The initial alignment tensor calculated from six unambiguous D_{CH} couplings (also including C–H vectors from C5 and C14) then allowed the prochiral assignment of the methylene groups containing C1 and C12 (for methodology used, see references [6,7]). This is remarkable, because in both cases the difference in distance of axial/equatorial or *syn*/*anti* protons, respectively, to unambiguously identified neighboring protons such as 5-H or the methyl group containing C17 is only ≈ 0.1 Å, too small to be identified reliably by NOE studies. By deriving D_{CC} RDCs from the measured D_{CH} couplings with the formula given in reference [7], finally also the methyl groups at C4 could be assigned. RDCs of spin pairs containing C15, C16, and C17 could not be fitted to any reasonable structural model. This most probably is indicative for intrinsic dynamics that lead to averaged RDCs at this part of the molecule. Taking into account the significant changes in chemical shifts of C14–C16, and 14-H–16-H, it might even be concluded that the gel introduces a difference in population of the exchanging conformations in this region. However, this effect is not yet understood. The 12 remaining assigned RDCs were used to refine the alignment tensor that is shown together with the correspondence of experimentally determined and back-calculated RDCs in Figure 3b–d. The correlation factor R^2 of 0.966 in this case is a clear indication that the structural model is consistent with the experimental data, which also can be seen easily in Figure 3e.

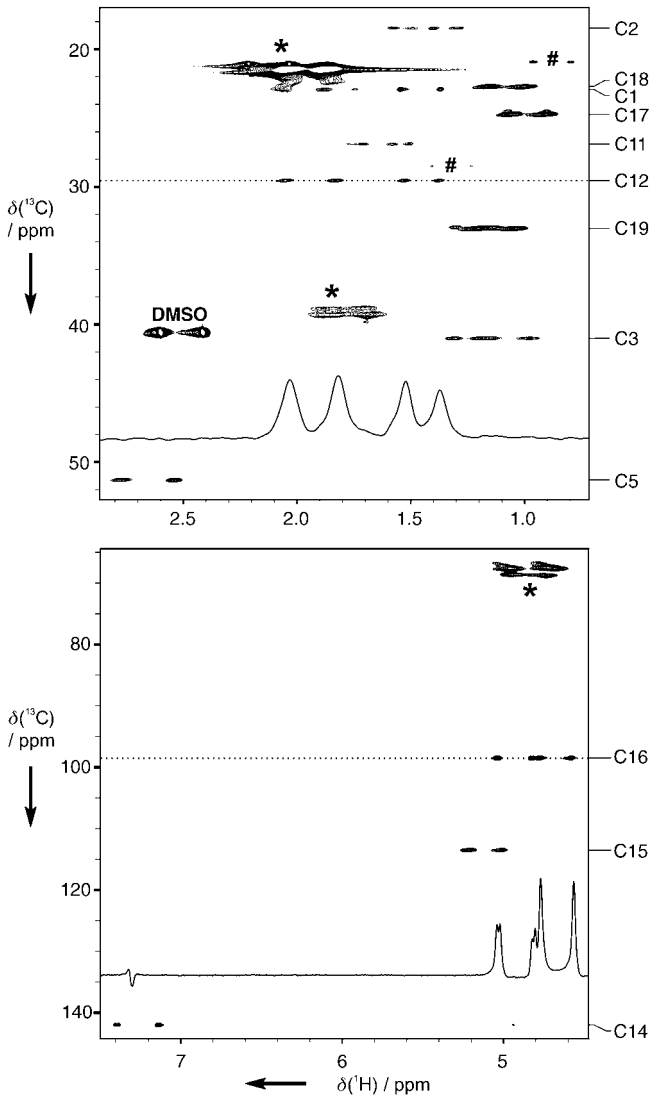

Figure 2. Aliphatic (top) and olefinic (bottom) coupled $^{13}C,^{1}H$-HSQC spectra acquired on ≈ 6 mg of sphaeropsidin A dissolved in a PVAC/DMSO gel. DMSO signals (DMSO), PVAC signals (*), and signals originating from unpolymerized monomers (#) are indicated in the spectra. Slices at the dotted lines are shown to give an impression on the overall quality of the cross peaks.

In summary, stretched PVAC gels can be used as scalable alignment media for polar organic solvents. With this possibility the gap between relatively apolar solvents such as dichloromethane or chloroform and aqueous solutions is closed and RDCs can now be measured in practically all common NMR solvents. The applicability of the new alignment method was demonstrated on norcamphor and the antibiotic sphaeropsidin A. Although PVAC signals did not pose a serious problem in heteronuclear correlation experiments, more sophisticated NMR spectroscopy methods such

NMR Spectroscopic Methods (2)

A DMSO-Compatible Orienting Medium: Towards the Investigation of the Stereochemistry of Natural Products**

*Peter Haberz, Jonathan Farjon, and Christian Griesinger**

The elucidation of the relative stereochemistry of asymmetric centers of organic molecules is an important challenge in chemistry since it requires the simultaneous determination of conformation and configuration. Whereas conventional NMR spectroscopy parameters such as NOE and ^3J coupling constants, which provide internuclear distances and dihedral angles, yield the configuration of stereocenters in rigid compounds, this approach is difficult or impossible in cases in which the molecule is flexible or the stereocenters are remote in the bonding network. Residual dipolar couplings (RDCs) provide additional structural restraints, as has been abundantly shown in structural biology,[1] and might enhance the power of NMR spectroscopy in the determination of the conformation and configuration of small organic molecules at the same time. They rely on the weak alignment of molecules in solution and provide angular as well as distance information that are not contained in the NOE or J coupling values. RDCs have proven to be very efficient in the stereochemical assignment of moieties and hold promise as parameters for the determination of the stereochemistry, even in nonrigid molecules.[2]

Although a large variety of alignment media exist for aqueous solutions, such as filamentous phages,[3] phospholipid bicelles,[4] Otting phase,[5] and gels,[6] only few are currently available for organic molecules that cannot be dissolved in water. So far, only chiral liquid-crystalline media such as poly-γ-benzyl-L-glutamate (PBLG) or poly-γ-ethyl-L-glutamate (PELG),[2] which are compatible with $CHCl_3$, CH_2Cl_2, *N*,*N*-dimethylformamide (DMF), THF, and 1,4-dioxane and cross-linked polystyrene (PS),[7] which is compatible with $CHCl_3$ and THF, have been used. These media are limited to the mentioned solvents. Furthermore, PBLG aligns more-complex organic molecules so strongly that the resolution and sensitivity of ^{1}H spectra are dramatically lowered by line broadening. The PS orients weakly enough; however, it is incompatible with polar organic solvents. Therefore, additional alignment media are required.

Herein we introduce a copolymeric crosslinked polyacrylamide (PH gel), the first alignment medium compatible with dimethyl sulfoxide (DMSO), which has excellent solvent properties and is widely used in organic chemistry. The amount of alignment is much lower than that of PBLG, as can already be appreciated from the narrow ^{1}H-resonance lines observed for (+)-menthol in DMSO in PH-gel (Figure 1). Moreover, our results show that PH-gel is also compatible with DMF and D_2O.

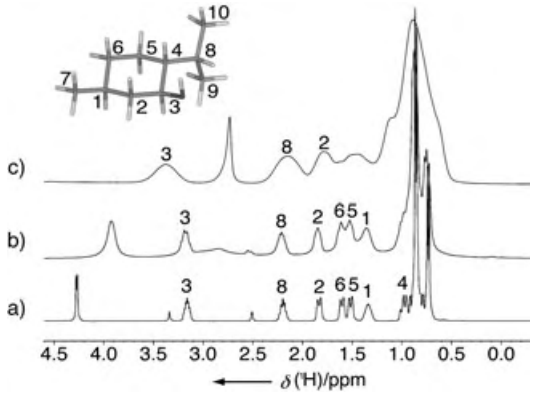

Figure 1. ^{1}H NMR spectra (400 MHz, 298 K) of (+)-menthol in a) DMSO, b) PH gel/DMSO, and c) PBLG/$CDCl_3$.

The PH gel can easily be obtained by the copolymerization of 2-(acrylamido)-2-methylpropanesulfonic acid (AMPS; ionizable monomer) with *N*,*N*-dimethylacrylamide (DMAA; comonomer) in the presence of *N*,*N*′-methylenebisacrylamide (BIS) as linker and ammonium persulphate (APS) as radical initiator.[8] The washed PH gel is dried on a glass capillary. It is then introduced into a 5-mm NMR tube, and the desired solvent is added (Figure 2). Within 1–2 days, the gel reswells and is compressed owing to the constraints of the glass wall.[7] The capillary allows the gel to be centered between the bottom of the tube and the surface of the solvent level within the NMR tube, which facilitates the reswelling of the gel. In contrast to the observations of Grzesiek et al.[6b] no significant stretching on the capillary could be determined. After 5 days, the deuterium spectra of the solvent show a quadrupolar splitting up to 4 Hz, indicating the alignment in the sample. The gel concentration of the NMR samples mentioned below needs to be adopted to obtain the described alignment.

The versatility of the PH gel is demonstrated on four different molecule/solvent-systems: (+)-menthol in DMSO and in DMF, the cyclic depsiheptapeptide hormaomycin[9] in DMSO, and a decasaccharide[10] in water (chemical formulas are shown in the Supporting Information). To measure the RDCs, t_2-coupled ^{1}H,^{13}C-HSQC[11] spectra were recorded in the presence (anisotropic solution) and in the absence (isotropic solution) of the orienting PH gel. The scalar $^1J_{CH}$

and total couplings $^1J_{CH}+{}^1D_{CH}$ can then be measured individually after extraction of the HSQC traces in the F2 dimension for all ^{13}C-bound protons of the studied molecule. The difference between the two coupling constants then results in the RDCs $^1D_{CH}$.[12] However, this method proved unreliable in cases in which the size of the RDC is small. To improve the precision of the RDCs, the corresponding traces from the isotropic and anisotropic HSQC spectra were superimposed and then fitted, based on the peak shapes (Figure 3). For the more difficult cases in which the spectral pattern of the isotropic and anisotropic traces were different, an exponential apodization function was applied to the spectra obtained from isotropic solution before the superimposition. This method determines the dipolar couplings directly and results in a significantly improved accuracy. The direct comparison of the upfield components of the anisotropic and isotropic spectra and similarly for the downfield components of the anisotropic and isotropic spectra as opposed to the extraction of the J value from the isotropic and the $J+D$ value from the anisotropic spectra is a small change in the extraction procedure, but is essential and beneficial owing to the strong coupling effects.

As a first test molecule, (+)-menthol was dissolved in [D$_6$]DMSO and the solution was introduced with a polyacrylamide gel stick (PH gel concentration 8 % *w*/*v*) into an NMR tube. The resulting quadrupolar splitting on the deuterium spectrum of the solvent was 4 Hz. The sign of the $^1J_{CH}$ couplings is always positive.[13] In weakly orienting media, $^1D_{CH}$ couplings are generally smaller than $^1J_{CH}$ couplings, and therefore the total coupling $^1J_{CH}+{}^1D_{CH}$ has a positive sign. All dipolar couplings are in the range 1.8–4.8 Hz. The single-value-decomposition module (SVD)[14] of the program PALES[15] was used to fit ten experimental dipolar couplings (excluding the $^1D_{CH}$ couplings of the isopropyl group because of its flexibility) to a reference structure. As there is no available crystal structure for (+)-menthol, we used the modified crystal structure of (−)-menthol, for which the chirality was inverted and the proton positions were optimized by conjugate-gradient energy minimization. The correlation factor R is 0.97. A similar fit ($R=0.96$) was obtained

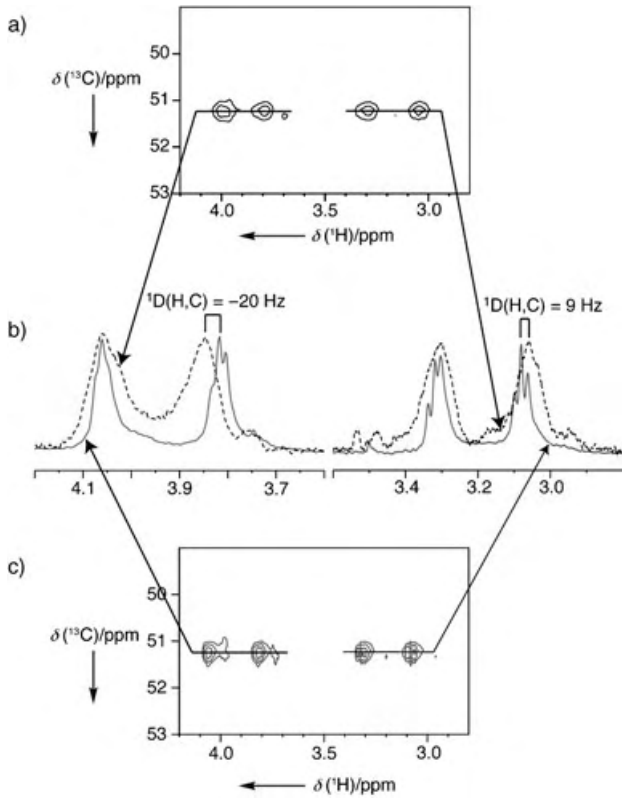

Figure 3. ^{1}H,^{13}C-HSQC spectra (t_2-coupled) of a sample of hormaomycin in DMSO (50 mM) recorded on a 600-MHz spectrometer equipped with a TXI cryoprobe at 298 K. a) Section of the anisotropic HSQC spectrum, b) superimposed traces through the anisotropic HSQC section (dotted line) and the isotropic HSQC section (solid line), c) section of the isotropic HSQC spectrum.

with a (+)-menthol/PH gel sample (PH gel concentration 12 % *w*/*v*) in DMF (see Supporting Information). The range of the dipolar couplings for this sample is 0.6–2.6 Hz. Menthol is a rather spherical molecule and it therefore orients more weakly than nonspherical molecules of similar size.

Finally, the following two experiments demonstrate the versatility of the PH gel. First, the cyclic depsiheptapeptide hormaomycin, which has a molecular weight of 1130 g mol^{-1}, was oriented in a PH gel/DMSO alignment medium resulting in a quadrupolar deuterium splitting for [D$_6$]DMSO of 2 Hz. Sections of the isotropic and anisotropic HSQC spectra show RDCs that range from −20 to 29 Hz, a range in which they can be evaluated easily and accurately. Experimental traces for two geminal methylene protons of the 4-[(*Z*)-propenyl]-proline residue are depicted in Figure 3. In the second application, we investigated a decasaccharide with a molecular weight of 1804 g mol^{-1}. It was dissolved in D$_2$O and aligned with the PH gel, causing a quadrupolar deuterium splitting for D$_2$O of 3 Hz. The measured $^1D_{CH}$ ranged from −22 to 28 Hz. The amount of alignment is scalable (see Experimental Section).

In summary, we have shown that a reliable alignment can be obtained by using PH gel with DMSO and other solvents for complex organic molecules of various sizes. The magnitude of the dipolar couplings is in a range in which they can be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

evaluated accurately since they are large enough to be measured with an acceptable spectral resolution since $^1H,^1H$ dipolar couplings do not cause extensive line broadening. Further research is underway in which this gel is being used to solve stereochemical problems in organic molecules that can neither be crystallized nor dissolved in water or chloroform.[16]

Experimental Section

PH-gel: AMPS, DMAA, and BIS (1:1:0.026) were dissolved in purified water to a total monomer concentration of 0.75 mol L^{-1}. The pre-gel solution was inserted into a gel cylinder with an inner diameter of 5.4 mm and polymerized for 2 h at 70 °C initiated by ammonium persulphate ($\approx$0.0015 g mL^{-1}). The gels were washed once with NaOH solution (0.02 M) and at least four times with water, each time for several hours. The swollen gels were dried on a glass capillary (diameter ~0.3–0.4 mm) under vacuum at 25–30 °C. The alignment is scalable by varying the diameter of the gel cylinder.

Polymers

Aqueous Dispersions of Extraordinarily Small Polyethylene Nanoparticles**

*Ludmila Kolb, Vincent Monteil, Ralf Thomann, and Stefan Mecking**

Dedicated to Professor Wilhelm Keim on the occasion of his 70th birthday

Emulsion polymerization is among the most important polymerization processes.[1] As a product, polymer latices that are stable colloidal aqueous dispersions of polymer particles of about 50 nm to 1 μm in size are obtained. About ten million tons annually of polymer latices are used for a variety of applications, such as environmentally friendly coatings and paints.

To date, polymer latices are produced industrially by free-radical polymerization exclusively. Styrene–butadiene copolymers, acrylate homo- and copolymers, and vinyl acetate polymers are the major industrial products.[1,2] The range of polymer microstructures accessible by free-radical polymerization and corresponding materials properties is limited. For example, the synthesis of dispersions of saturated inert polymers, which do not bear hydrolyzable groups is a challenge.[1] It is desirable to synthesize dispersions from simple olefins obtained directly from cracking of hydrocarbon feedstocks. This process would avoid the need to convert the cracked products to monomers such as acrylates or vinyl esters, which consumes energy and raw materials.[3] We and the group of Claverie have recently reported the synthesis and properties of polyethylene dispersions by catalytic polymerization in emulsion.[4–6]

For traditional free-radical polymerization, the synthesis of very small particles is the subject of increasingly intense effort.[7,8] Microemulsion polymerization is a particularly suitable, albeit special, technique. Latices of, for example, polystyrene particles as small as 10 nm diameter have been prepared by microemulsion polymerization.[8] A strong limitation is that microemulsions only form under specific

conditions that require large quantities of alcohols, or other organic solvents, and surfactants.

Concerning the aforementioned catalytic polymerization of ethylene in emulsion, a fine initial dispersion of the catalyst at the beginning of the reaction is a general prerequisite to obtain a large number of sub-micrometer polymer particles, that is, a polymer latex. This is usually achieved by using a miniemulsion technique. A solution of a liphophilic catalyst precursor (a nickel(II) complex) in a small amount of hydrocarbon solvent is dispersed in the continuous aqueous medium in the form of miniemulsion droplets.[9] Exposure to ethylene results in the formation of latices with the average sizes of polymer particle ranging from about 100 nm to 1 μm.[4,5] Although this technique enables the synthesis of polymer latices with lipophilic catalysts without the need for modifications to achieve water-solubility, a synthesis of much smaller particles would be desirable.[10] An aqueous solution of a hydrophilic catalyst clearly represents the highest possible initial degree of dispersion of the catalyst precursor, and therefore appears to be of interest for the synthesis of small particles.[11]

An active and easily accessible hydrophilic catalyst was obtained by the reaction of stoichiometic amounts of chloranil, potassium 4-(diphenylphosphino)benzene-sulfonate (TPPMS), and bis(1,5-cyclooctadiene)nickel ([Ni(cod)$_2$]).

possible structure of catalyst precursor
Ar = Ph, 4-$C_6H_4SO_3K$
L = solvent, monomer

As for a similar recently reported lipophilic catalyst,[4d] it can be speculated that a Ni^{II}-κ^2*P,O* phosphanylphenolate complex is the active species [Eq. (1)]. Catalyst preparation was performed in a small volume of 2-propanol (see the Supporting Information for experimental details). A careful choice of this solvent was found to be crucial to enable the reaction of the apolar chloranil with the polar TPPMS.

Figure 1. Optical appearance of a dispersion (2 wt% polyethylene).

Exposure of the catalyst in an aqueous solution that contained sodium dodecyl sulfate (SDS) as a surfactant to ethylene afforded clear or only slightly turbid products, despite an observed consumption of ethylene (Figure 1).

Apparently, latices consisting of extremely small particles with sizes far below the wavelength of visible light are formed. Dynamic light scattering (DLS) reveals volume average particle sizes < 20 nm (Table 1). Transmission electron microscopy (TEM) and atomic force microscopy (AFM) confirm these findings. TEM images of microtome cuts of latex particles embedded in a solid matrix[12] show very small particles (Figure 2) in accordance with AFM images of samples obtained by drying

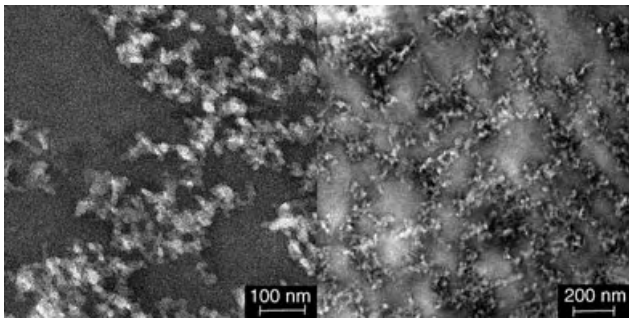

Figure 2. TEM micrographs of microtome cuts of latices.

the dispersions at room temperature (Supporting Information).

The course of the polymerization reaction was followed by using a mass flowmeter at a constant ethylene pressure of 40 bar at different polymerization temperatures (Table 1, entries 1–5; Figure 3). Although the reaction is sluggish at room temperature, satisfactory activities are observed at elevated temperatures of 50 to 70 °C, and the catalyst retains activity over the duration of the experiments (2 h).[13] Average catalyst activities over two hours range up to 2370 mol(ethylene) mol(Ni)$^{-1}$ h^{-1}. Further studies revealed that the polymerization continues for more than seven hours at 60 °C (see the Supporting Information). At 80 °C substantial catalyst deactivation within one hour is observed. Catalyst activities increase strongly with ethylene pressure in the range investigated (Table 1, entries 3, 6, and 7).

Incidentally, the results clearly demonstrate that efficient catalytic latex synthesis can be carried out without any water-immiscible liquid hydrocarbon phase. This offers some clear advantages for applications and for fundamental studies in comparison to the aforementioned miniemulsion technique. The simplification of the system, that is, the absence of

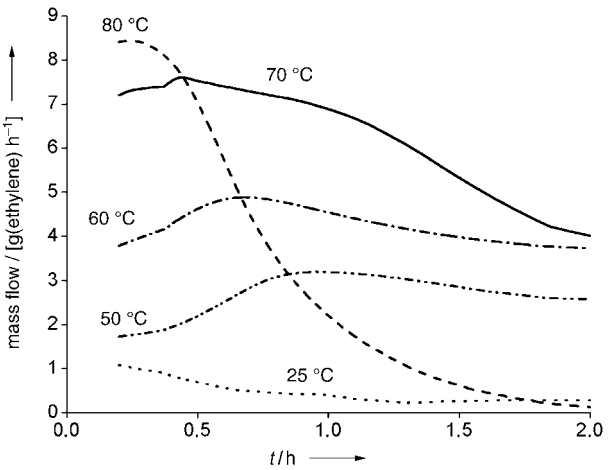

Figure 3. Temperature dependence of catalyst activity and stability over time (40 bars constant ethylene pressure, for the conditions see Table 1).

additional organic droplets, enables future studies of, for example, particle-formation processes.

Dispersions with a solids content of up to 15 wt% polymer were obtained without optimization. Up to about 6 wt%, the latices were transparent. The latices obtained were colloidally stable for more than six months. As for the amount of alcohol used in catalyst preparation, reduction from the usual 10 mL to 2 mL, which corresponds to only 2 vol% relative to the aqueous phase, had no significant effect on polymerization rate or otherwise. Increasing the scale of reaction from 0.1 L to 0.6 L did not result in a decrease in catalyst activity or dispersion stability (conditions of entry 3 in Table 1; 600 μmol Ni; dispersion obtained: 10.5% solids content).

A very simple picture of particle formation would involve initial chain growth on active sites dissolved in the aqueous phase and subsequent nucleation of one polymer particle per active catalyst molecule as continued chain growth results in increased hydrophobicity; the (surfactant-stabilized) particles thus formed continue to grow. However, further possibilities to be considered are, for example, the coalescence of already-existing particles (well-known from free-radical polymerization in general), the entry of a growing chain into an already-existing particle before nucleating a new particle, or the catalyst leaving an existing particle to nucleate a new one. In addition to the obvious possible complexity of particle-formation processes, it is not trivial to verify the number of active sites, particularly for the in situ catalyst system investigated. Nonetheless, it is interesting to know as a rough guideline the number of latex particles versus the number of metal centers to within an order of magnitude. From the number-average sizes of the latex particle, a ratio of Ni center:particle of only around 20 to 30 has been calculated. This high number of particles translates to a very efficient particle formation and stabilization in the polymerization investigated (particularly when keeping in mind that not all nickel added is necessarily present as an active site).

Concerning the microstructure of the dispersed polymer, ^{1}H and ^{13}C NMR spectroscopy demonstrate the formation of linear polyethylene as expected (see the Supporting Information). Number-average molecular weights ($\bar{M}_n$) of polyethylenes determined by high-temperature gel-permeation chromatography (GPC) are in the range of $\bar{M}_n = 1.4 \times 10^3$–$6 \times 10^3\ g\,mol^{-1}$. This is in accordance with $\bar{M}_n$ calculated from ^{1}H NMR spectra as well as T_m values.[14] As expected, molecular weights decrease with increasing reaction temperature due to an increase in β-hydride transfer. Interestingly, preliminary investigations by differential scanning calorimetry (DSC) on the polymer dispersions demonstrate stability of the colloids up to 140 °C and reveal high supercoolings of 55 °C due to an independent crystallization of individual droplets during the cooling cycle (cooling rate $10\ K\,min^{-1}$),[4e,15] which differs greatly from classical heterogeneous nucleation in bulk samples ($T_m - T_c = 18$ °C).

In summary, stable aqueous polyethylene dispersions consisting of extraordinarily small particles are reported. To our knowledge, such small stable polyethylene particles are not accessible by any other means. An easily prepared, robust catalyst is utilized for their synthesis.

Experimental data given in the Supporting Information: Catalyst preparation and polymerization procedure; ^{1}H and ^{13}C NMR spectra of polyethylene; DSC of latex and of bulk polymer; AFM images.

[9] Please note that the catalytic polymerization reactions of ethylene discussed differ from typical free-radical miniemulsion polymerization of a preformed miniemulsion of a liquid monomer. Gaseous ethylene monomer is fed continuously to the reaction mixture subsequently to miniemulsification of the catalyst solution.
[10] The water-immiscible hydrocarbon solvent introduced with the miniemulsion can be disadvantageous. Claverie and co-workers even suggested that swelling of the polymer by the added liquid hydrocarbon is mandatory to enable polyethylene formation at all; the amount of polymer attainable is limited to about 60% of the overall organics content, which would prohibit any commercial application.[5c] While we can not support this suggestion quantitatively from our experience,[4,11] the necessity of a certain amount of liquid hydrocarbon for any efficient ethylene polymerization remains questionable.
[11] Ethylene polymerization by water-soluble complexes has been demonstrated:see reference [4a] and F. M. Bauers, PhD thesis, University of Freiburg (Germany), **2003**. However, low polymer yields in combination with the synthetic effort for the catalyst precursors hampered any further studies.
[12] Microtome cuts were investigated, as in regular TEM aggregation of the sample during preparation hampered its analysis.
[13] Such elevated temperatures are beneficial to any technical-scale polymerization process to enable removal of the heat of reaction without the need of energy-consuming refrigeration of the coolant.

Fullerenes

Preparation and Structural Characterization of Two Kinetically Stable Chlorofullerenes, $C_{60}Cl_{28}$ and $C_{60}Cl_{30}$**

Sergey I. Troyanov, Natalia B. Shustova, Alexey A. Popov, Lev N. Sidorov, and Erhard Kemnitz*

Dedicated to Professor Arndt Simon on the occasion of his 65th birthday

Compared with bromo- and fluorofullerenes, fullerene chlorides have been studied to a lesser extent. However, they can find versatile application as synthons for valuable derivatives.[1] According to various sources, the reactions of [60]fullerene with different chlorinating agents yield $C_{60}Cl_n$ products with a bulk composition that varies from $C_{60}Cl_6$ to $C_{60}Cl_{40}$.[2] The most reliable data have been obtained for $C_{60}Cl_6$, which was prepared by treatment of C_{60} with ICl in solution in benzene. Its molecular structure was first suggested on the basis of ^{13}C NMR spectroscopy and was later confirmed in the structural study of related phenyl and methyl derivatives.[2b,3]

In our previous publication, higher chlorides of the variable-valency elements were suggested as effective chlorinating agents for fullerenes.[4] The use of $SbCl_5$ or VCl_4 resulted in the selective synthesis of T_h-$C_{60}Cl_{24}$ with high yields and isomeric purity. The structure was deduced by comparison of the experimental and theoretically calculated IR spectra. Very recently, a novel chlorofullerene, D_{3d}-$C_{60}Cl_{30}$, was synthesized and structurally characterized.[5] Here we report the preparation of two new chlorofullerenes, C_1-$C_{60}Cl_{28}$ and C_2-$C_{60}Cl_{30}$, which have been characterized by means of X-ray single-crystal diffraction studies, IR spectroscopy, and quantum chemical calculations.

Pure T_h-$C_{60}Cl_{24}$ can be prepared by reacting C_{60} (30 mg) with VCl_4 (2 g) in sealed ampoules at 160 °C for 14 days.[4] An increase in the reaction time was accompanied by the appearance of new bands in the IR spectra and the disappearance of the bands characteristic of T_h-$C_{60}Cl_{24}$. After 2 months heating, a new compound was formed with a ratio of Cl:C of 29 ± 1 according to elemental analysis data.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/anie.200462139

The IR spectrum of the new compound is presented in Figure 1a.[6] Crystallization from bromine yielded a solvate whose composition $C_{60}Cl_{30}\cdot 1.5\,Br_2$ (**1**) was established by single-crystal X-ray crystallography.[7]

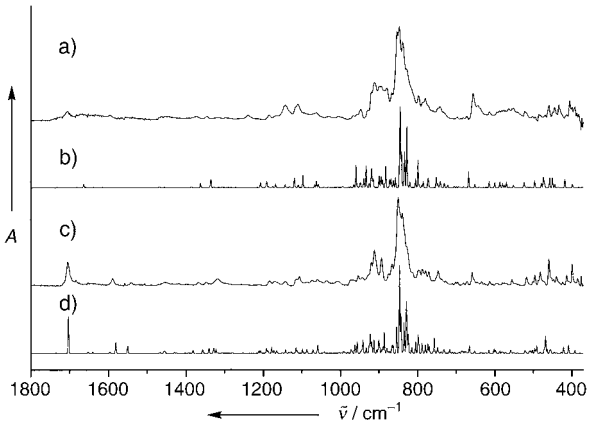

Figure 1. Experimental and calculated IR spectra of C_2-$C_{60}Cl_{30}$ (a and b) and C_1-$C_{60}Cl_{28}$ (c and d).

Chlorination of C_{60} with iodine monochloride at 120 °C for 30 days resulted in the formation of dark-brown crystals whose composition $C_{60}Cl_{28}\cdot ICl$ (**2**) was also determined by X-ray crystallography.[7] The IR spectrum of **2** is shown in Figure 1c. Some other experiments carried out at the same temperature for a shorter time revealed the presence of T_h-$C_{60}Cl_{24}$ in the reaction mixture according to IR spectra. Notably, the reaction of T_h-$C_{60}Cl_{24}$ with $SbCl_5$ at 300 °C for two days afforded pure D_{3d}-$C_{60}Cl_{30}$.

The formation of the chlorofullerenes $C_{60}Cl_{28}$ (**2**) and $C_{60}Cl_{30}$ (**1**) is quite remarkable. Their molecular structures are characterized by the presence of two planar aromatic rings (which are inclined to one another) and two long chains of sp^3-hybridized carbon atoms that bear chlorine atoms (Figure 2 and Figure 3). The $C_{60}Cl_{28}$ molecule has no symmetry elements (C_1), although the counterparts of most atoms (except C35 and C42) are located following 180° rotation around the pseudo-C_2 axis (parallel to the view directions on Figure 2 (left) and Figure 3 (left)). The addition of two Cl atoms to the $C_{60}Cl_{28}$ molecule at positions C35 and C42 produces the $C_{60}Cl_{30}$ molecule, which then possesses a (non-crystallographic) twofold axis (Figure 2b).

Quantum chemical DFT (density functional theory) calculations of the molecular structures of the chlorofullerenes[8a] revealed a comparatively good agreement between experimental and calculated C–C bond lengths. C–C bonds can be separated into five major groups according to their nature: isolated double bonds that connect nonaromatic sp^2-hybridized carbon atoms (average length, calcd for $C_{60}Cl_{28}$: 1.355; observed: 1.344 Å), aromatic bonds (calcd: 1.392; observed: 1.385 Å), $C(sp^2)$–$C(sp^2)$ bonds between two double

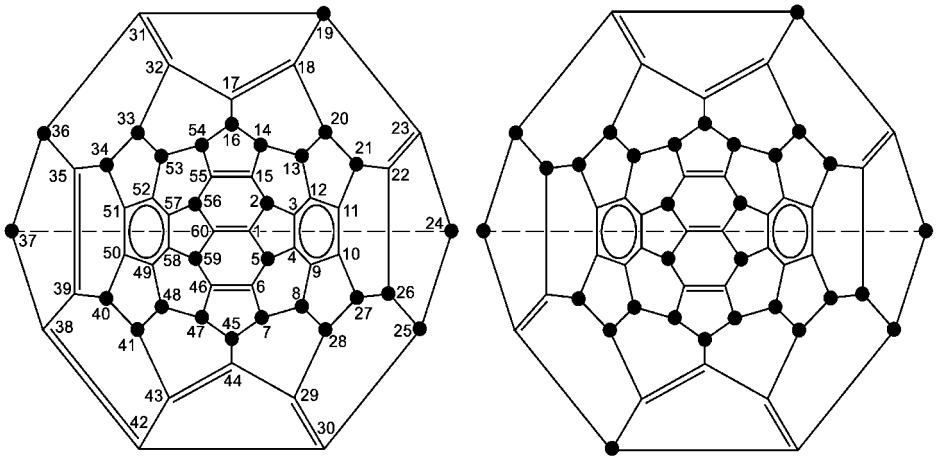

Figure 2. Schlegel diagrams of C_1-$C_{60}Cl_{28}$ and C_2-$C_{60}Cl_{30}$ with a numbering scheme for carbons that is identical for both molecules. For convenience, a nonstandard numbering scheme was used that fixed the sum of the numbers for equivalent positions in C_2-$C_{60}Cl_{30}$ to 61.

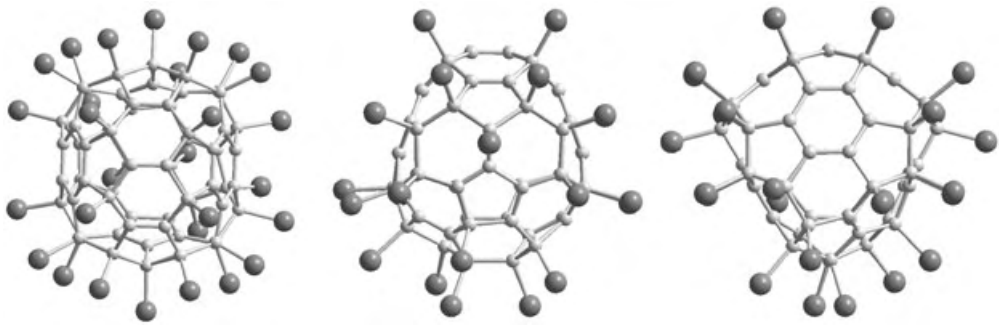

Figure 3. Top and side views of the C_1-$C_{60}Cl_{28}$ molecule.

bonds (calcd: 1.439; observed: 1.443 Å), C(sp^2)–C(sp^3)bonds (calcd: 1.500; observed: 1.500 Å), and, finally, considerably elongated C(sp^3)–C(sp^3) bonds (calcd: 1.621; observed: 1.615 Å). Especially long C–C bond lengths (up to 1.65–1.66 Å) are observed for the 6/6 bonds of this latter type. A similar correspondence has been found for the $C_{60}Cl_{30}$ molecule. However, the addition of two Cl atoms to the $C_{60}Cl_{28}$ molecule results in local repositioning of the double bonds. Thus, bond lengths (Å) of 1.37–1.44–1.36 in the C35–C39–C38–C42 fragment in **2** become 1.53–1.33–1.44 in **1**.

IR spectra for C_1-$C_{60}Cl_{28}$ and C_2-$C_{60}Cl_{30}$ revealed their close similarity, especially in the range of the strongest absorptions between 700 and 1000 cm^{-1}. The most prominent differences in the spectra of **1** and **2** can be found for two bands at 1705 and 1589 cm^{-1} that are characteristic of $C_{60}Cl_{28}$ (Figure 1 d). According to DFT vibrational simulations, which give a very good match with the experimental spectrum (Figure 1 c) of $C_{60}Cl_{28}$ (**2**), these characteristic modes correspond, respectively, to the stretching vibration of the double bond between two pentagons (C38–C42) and the symmetric vibration of two double bonds in the "bare" pentagon (C29–C30 and C43–C44). In other words, these vibrations are located on the fragment which is subjected to further chlorination to yield C_2-$C_{60}Cl_{30}$ (**1**) and therefore these bands are absent in the calculated IR spectrum of the latter (Figure 1 b). At the same time, the experimental IR spectrum of **1** (Figure 1 a) showed weak absorptions near 1705 and 1589 cm^{-1} which indicates the presence of a small amount of $C_{60}Cl_{28}$ in the sample.

Chlorination of C_{60} with $SbCl_5$ or ICl carried out at higher temperature (above 250 °C) finally resulted in another chlorofullerene, namely, D_{3d}-$C_{60}Cl_{30}$.[5] DFT B3LYP computations of the relative energies[8b] show that C_2-$C_{60}Cl_{30}$ synthesized in this work is 78 kJ mol^{-1} less stable than the D_{3d} isomer. Moreover, the C_1-$C_{60}Cl_{28}$ isomer is 6 kJ mol^{-1} less stable than the hypothetical C_2-$C_{60}Cl_{28}$, which could be obtained by the removal of two chlorine atoms from D_{3d}-$C_{60}Cl_{30}$.[9] Hence, DFT computations favor the alternative addition patterns, especially for $C_{60}Cl_{30}$. Indeed, a sample of **1** heated with $SbCl_5$ at 300 °C for 2 days has been completely transformed into D_{3d}-$C_{60}Cl_{30}$ according to the IR spectra.

Experimental observations as well as theoretical calculations, therefore, unambiguously demonstrate that C_1-$C_{60}Cl_{28}$ and C_2-$C_{60}Cl_{30}$, which have been synthesized and investigated in this work, are kinetically stable chlorofullerenes. Owing to similarity in the addition patterns, C_2-$C_{60}Cl_{30}$ can be easily obtained from C_1-$C_{60}Cl_{28}$ by the addition of two chlorine atoms. Substantial differences in the addition patterns for T_h-$C_{60}Cl_{24}$ (no aromatic rings, only isolated double bonds), C_1-$C_{60}Cl_{28}$ or C_2-$C_{60}Cl_{30}$ (two nonparallel aromatic rings), and D_{3d}-$C_{60}Cl_{30}$ (two parallel aromatic rings along with equatorial 18-π trannulene belt) prevent transformation of less-chlorinated fullerenes into more-chlorinated ones by the simple addition of chlorine atoms (with an exception pointed out above). Therefore, such transformations should include the rearrangement of many chlorine atoms on the fullerene cage and can be regarded as a "chlorine dance".[10] Similar phenomena, "fluorine dance", were found to proceed in the course of fluorination of C_{60}.[11] If the chlorination of C_{60} occurs at temperatures lower than 200 °C, some intermediates of "chlorine dance" can be isolated in their pure form as shown in this work. At higher chlorination temperatures, only the thermodynamically stable D_{3d}-$C_{60}Cl_{30}$ should be obtainable.

In summary, the family of chlorofullerenes is growing. Besides $C_{60}Cl_6$, T_h-$C_{60}Cl_{24}$, and D_{3d}-$C_{60}Cl_{30}$, two new compounds have been isolated, C_1-$C_{60}Cl_{28}$ and C_2-$C_{60}Cl_{30}$, with the latter being the less stable isomer of $C_{60}Cl_{30}$. Their molecular structures contain two inclined aromatic rings and chains of "chlorinated" carbon atoms. C_1-$C_{60}Cl_{28}$ can be easily transformed into C_2-$C_{60}Cl_{30}$ by the addition of two chlorine atoms, a situation that is unique for known halogenated C_{60} structures. Finally, these molecules are kinetically stable intermediates in the process of "chlorine dance" on the way from $C_{60}Cl_{24}$ to the thermodynamically stable D_{3d}-$C_{60}Cl_{30}$.

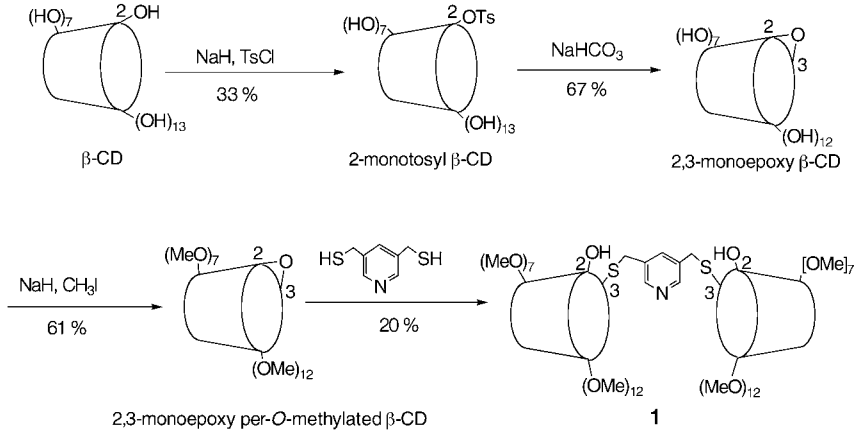
Dioxygen Binding to a Simple Myoglobin Model in Aqueous Solution**

Koji Kano, Hiroaki Kitagishi, Masahito Kodera, and Shun Hirota*

Herein we report reversible dioxygen binding to a simple model system of myoglobin composed of a per-*O*-methylated β-cyclodextrin (CD) dimer having a pyridine linker (**1**) and [tetrakis(4-sulfonatophenyl)porphinato]iron(II) ([Fe^{II}(tpps)]) in aqueous solution. Myoglobin (Mb) and hemoglobin (Hb) form stable O_2 adducts in aqueous solution at a neutral pH value. Globin plays an essential role in stabilizing the O_2 adduct in biological systems. Without this protein, oxyheme is immediately oxidized to a Met form by the action of a proton or hydroxide ion.[1] Heme is protected from acid- or base-induced autoxidation by the globin that surrounds the iron porphyrin (FePor). Many model systems of Mb and Hb were examined after the development of the picket-fence porphyrin by Collman et al.[2,3] In most model systems O_2 binding was achieved in organic solvents, where a trace amount of water had to be removed from the system. The concept proposed by Collman's research group has been expanded into the binding of O_2 to hydrophobic picket-fence Fe^{II} porphyrins, which are included in vesicles[4] or albumin[5] in aqueous media. Although dendrimers with Fe^{II}Por cores were expected to mimic the function of Mb or Hb, no stable O_2 adducts were formed in these systems in aqueous solution.[6,7] Since the O_2 adduct of the dendrimers is efficiently formed in absolute toluene,[6] it is evident that construction of a hydrophobic pocket for placing the iron(II) center of an FePor is the essential factor for realizing O_2 binding in aqueous solution. In the present model system, we used the striking ability of per-*O*-methylated β-CD to include water-soluble tetraarylporphyrins and yield extremely stable 1:2 (Por:CD) inclusion complexes in aqueous solution.[8] Two per-*O*-methylated β-CD moieties were linked by a bridge involving a pyridine ligand. Such a CD dimer (**1**) worked well as a simple Mb model in aqueous solution.

1



The synthesis of **1** (Scheme 1) was carried out by using the method reported by Lawrence et al.[9] The changes in the absorption spectrum of [Fe^{III}(tpps)] in phosphate buffer of pH 5.0 were measured as a function of the concentration of **1** (Figure 1) to examine whether **1** forms a suitable complex in which two CD moieties include the sulfonatophenyl groups at the 5 and 15 positions of [M(tpps)] (M = metal ion) and the pyridine ligand coordinates to the M^{II} or M^{III} site of the porphyrin. No μ-oxo dimer was formed at pH 5.0 and the predominant species involving [Fe^{III}(tpps)] was the diaqua complex [$Fe^{III}(H_2O)_2$(tpps)].[10] The Soret band of [$Fe^{III}(H_2O)_2$(tpps)] at 388 nm shifted to 421 nm upon addition of **1**. The spectral changes were sharply saturated after the addition of one equivalent of **1**, which indicated the formation of a very stable 1:1 complex between [$Fe^{III}(H_2O)_2$(tpps)] and **1**. Analysis of the titration curve provided a binding constant

Scheme 1. Synthetic route of **1**. Ts = toluene-4-sulfonyl.

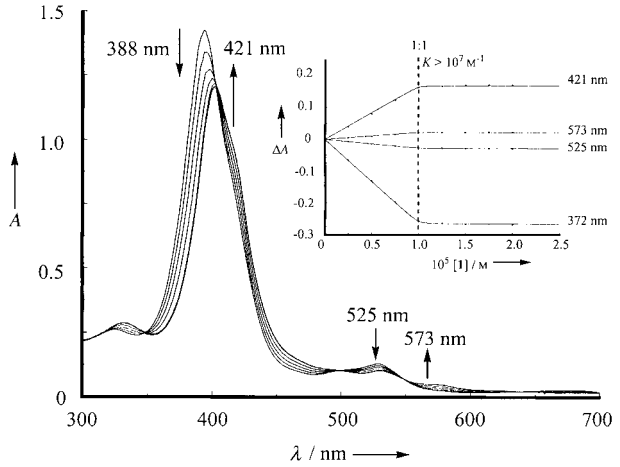

Figure 1. UV/Vis spectral changes of $[Fe^{III}(tpps)]$ (1×10^{-5} M) as a function of [**1**] in 0.05 M phosphate buffer at pH 5.0 and 25 °C. The titration curves were analyzed by the nonlinear least-squares method to estimate *K*.

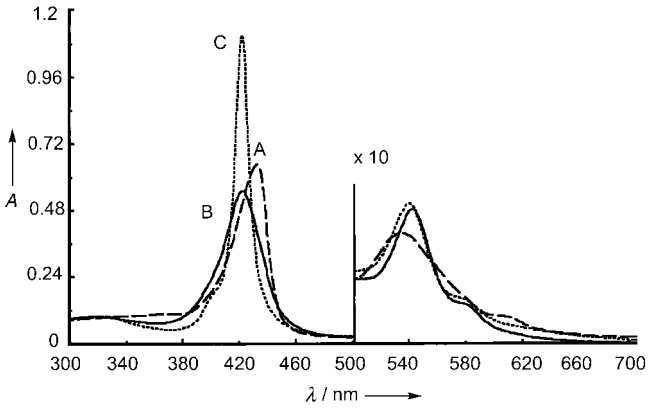

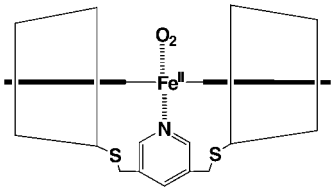

Figure 2. UV/Vis absorption spectra of $[Fe^{II}(tpps)(\mathbf{1})]$ (5×10^{-6} M) in the deoxy form (A) as well as the O_2-coordinated (B) and CO-coordinated forms (C) in 0.05 M phosphate buffer at pH 7.0 and 25 °C. The method of sample preparation is given in the text.

(K) for complexation of $[Fe^{III}(H_2O)_2(tpps)]$ with **1** of $> 10^7\,M^{-1}$, although the exact K value could not be determined. The ^1H NMR spectrum of the $[Fe^{III}(tpps)]$/**1** system in D_2O at pD 4.4 showed signals arising from the pyrrole β-protons at $\delta = 51$, 53, and 55 ppm (see the Supporting Information), which suggests the formation of a complex in a five-coordinate admixed intermediate spin state.[11] Such a complex should be pyridine-coordinated $[Fe^{III}(tpps)(\mathbf{1})]$ which has the desired structure. The pH-dependent UV/Vis absorption spectral changes suggest that the pyridine nitrogen–Fe^{III} coordination bond of the $[Fe^{III}(tpps)(\mathbf{1})]$ complex dissociates to give $[Fe^{III}(H_2O)_2(tpps)(\mathbf{1})]$ below pH 3 and $[Fe^{III}(OH)(tpps)(\mathbf{1})]$ above pH 7. The ^1H NMR signals resulting from the pyrrole β-protons at pD 0.5 appeared at $\delta = 71$ and 66 ppm as two singlets, which supports the formation of $[Fe^{III}(H_2O)_2(tpps)(\mathbf{1})]$ in a six-coordinate admixed intermediate spin state. Meanwhile, the pyrrole β-protons were observed at $\delta = 84$ ppm as a broad singlet at pD 8.7, which is ascribed to $[Fe^{III}(OH)(tpps)(\mathbf{1})]$ in a five-coordinate high-spin state. In addition, $[Zn^{II}(tpps)]$ was used as a divalent metalloporphyrin in place of $[Fe^{II}(tpps)]$. The structure of the complex of $[Zn^{II}(tpps)]$ and **1** was estimated by UV/Vis spectroscopy. As in the case of $[Fe^{III}(tpps)]$, an extremely stable 1:1 complex was formed and the pyridine moiety of **1** coordinated to the zinc ion above pH 3 (see the Supporting Information). From these findings, it can be expected that **1** forms a 1:1 complex with $[Fe^{II}(tpps)]$, in which the pyridine moiety of **1** can act as a proximal ligand.

Two equivalents of $Na_2S_2O_4$ were added to an aqueous solution of a mixture of $[Fe^{III}(tpps)]$ and **1** in an argon atmosphere to prepare a stock solution of $[Fe^{II}(tpps)]$ complexed with **1**, which was diluted by N_2-saturated phosphate buffer at pH 7.0 for measurement of the absorption spectrum (Figure 2). The Soret band of $[Fe^{II}(tpps)]$ included by **1** appeared at 433 nm ($\varepsilon_{max} = 129\,600$), which corresponds to the band from a five-coordinate high-spin Fe^{II}Por species.[12] Careful introduction of O_2 into a solution of $[Fe^{II}(tpps)(\mathbf{1})]$ caused a change in the absorption spectrum and a new Soret band appeared at 423 nm ($\varepsilon_{max} = 110\,400$). Replacing O_2 by CO resulted in a sharp Soret band appearing at 422 nm ($\varepsilon_{max} = 222\,600$) as a consequence of coordination of CO to $[Fe^{II}(tpps)]$. These spectral changes strongly suggest that the Soret band at 423 nm which appeared when the complex was formed in the O_2 atmosphere should be ascribed to $[Fe^{II}(O_2)(tpps)(\mathbf{1})]$.

The formation of the $[Fe^{II}(O_2)(tpps)(\mathbf{1})]$ complex was confirmed by ^1H NMR and resonance Raman spectroscopy. The ^1H NMR signals of the $[Fe^{II}(tpps)(\mathbf{1})]$ complex in anaerobic D_2O were broad because of the paramagnetic nature of the sample. These broad signals appeared at $\delta = 40$–

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

60 ppm (with TSP as an external standard) and can be ascribed to a five-coordinate high-spin [Fe^{II}(tpps)] ($S=2$) complex.[13] This solution was charged with O_2, and all NMR signals between $\delta=0$ and 10 ppm were sharpened, which indicated the formation of a six-coordinate low-spin state ($S=0$). In other words, the ^{1}H NMR spectrum supports the formation of the [$Fe^{II}(O_2)$(tpps)(**1**)] complex. The sample obtained by replacing the O_2 atmosphere with CO was also diamagnetic.

The formation of the Fe^{II}–O bond was verified by resonance Raman spectroscopy (Figure 3). The sample was prepared by introducing $^{18}O_2$ into a phosphate buffer solution

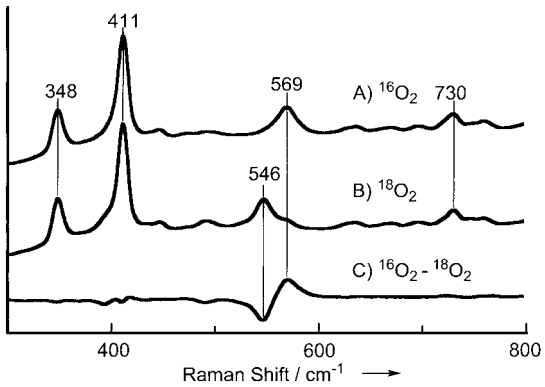

Figure 3. Resonance Raman spectra of the $^{16}O_2$ (A) and $^{18}O_2$ (B) adducts of the [Fe^{II}(tpps)(**1**)] complex (5×10^{-5} M) and the difference spectrum (C) between spectra A and B. Experimental conditions: 0.05 M phosphate buffer at pH 7.0; room temperature; 413.1 nm excitation; 12 mW power.

of the [Fe^{II}(tpps)(**1**)] complex at pH 7.0 and room temperature. A Raman signal was observed at 546 cm^{-1}, which was characterized as the stretching band of the Fe^{II}–^{18}O bond.[14] When the measurement was repeated after the sample had stood in air for a while, the band shifted to 569 cm^{-1}, which is ascribed to the Fe^{II}–^{16}O bond. On the basis of these data, it is concluded that a Fe^{II}–O bond is formed. In the case of horse heart Mb, the stretching bands of the Fe^{II}–^{18}O and Fe^{II}–^{16}O bonds appear at 545 and 571 cm^{-1}, respectively,[14] which is in good agreement with the bands measured in the present system.

The rates of autoxidation of the [$Fe^{II}(O_2)$(tpps)(**1**)] complex were determined by following the absorbance at the Soret band, and the results are summarized in Table 1. The [$Fe^{II}(O_2)$(tpps)(**1**)] ($\lambda_{max}=423$ nm) was gradually decomposed to [Fe^{III}(OH)(tpps)(**1**)] ($\lambda_{max}=418$ nm) and the half-life

Table 1: First-order rate constants (k) and half-lives ($t_{1/2}$) for the autoxidation of [$Fe^{II}(O_2)$(tpps)(**1**)] at 25 °C.

pH	k [h^{-1}]	$t_{1/2}$ [h]
4.0[a]	0.053	13.1
5.0[a]	0.055	12.6
6.0[a]	0.041	16.9
6.0[b]	0.020	34.7
7.0[b]	0.023	30.1
8.0[b]	0.024	28.9

[a] In 5 mM succinate buffer. [b] In 5 mM phosphate buffer.

($t_{1/2}$) of the [$Fe^{II}(O_2)$(tpps)(**1**)] complex was 30.1 h in phosphate buffer at pH 7.0. Interestingly, [$Fe^{II}(O_2)$(tpps)(**1**)] was still stable in aqueous acidic solution at pH 4.0 ($t_{1/2}=13.1$ h). The O_2 adduct of beef heart Mb is much more unstable in the lower pH region ($t_{1/2}=11$ h at pH 7 and 0.5 h at pH 5).[15] Such novel stabilization of the [$Fe^{II}(O_2)$(tpps)(**1**)] complex might be achieved by blocking the Fe^{II} center with two per-*O*-methylated β-CD moieties. Most water molecules seem to be excluded from the cleft of the [$Fe^{II}(O_2)$(tpps)(**1**)] complex, which was more stable in phosphate buffer at pH 6.0 than in succinate buffer at the same pH value. This observation might be ascribed to a slow anion-catalyzed autoxidation[1] caused by weak coordination of the CO_2^- group of the succinate anion to the iron center, since it is known that inorganic anions accelerate the autoxidation of oxyMb.[1]

The affinity of the present system for dioxygen was determined from the changes in the absorption spectrum of the [Fe^{II}(tpps)(**1**)] complex as a function of the partial pressure of O_2.[6b] The O_2 affinity ($P_{1/2}$) in 0.05 M phosphate buffer at pH 7.0 and 25 °C was 17.5 ± 1.7 Torr, which is larger than that of sperm whale Mb (0.29 Torr) and is somewhat smaller than the $P_{1/2}$ value of human Hb in the T state (26 Torr).[3]

The bound O_2 could be released from [$Fe^{II}(O_2)$(tpps)(**1**)] by introducing N_2 into the system. The present system showed good reversibility in the O_2 binding–releasing cycles, although gradual autoxidation occurred (see the Supporting Information).

In the present study, we found that **1** is an excellent model of Mb that binds O_2 reversibly in aqueous solution. Recently, a CD/Fe^{II}Por ensemble having a complex structure was prepared as a hemoprotein model which binds dioxygen, although no details of O_2 binding were investigated.[16] The present study introduced a new system to the family of metalloprotein models composed of CDs and metal complexes.[17]

Experimental Section

2,3-Monoepoxy-β-cyclodextrin,[18] 3,5-dimercaptomethylpyridine,[9a] and [Fe^{III}(tpps)][19] were synthesized according to the procedures reported in the literature.

2,3-Monoepoxy per-*O*-methylated β-cyclodextrin: 2,3-Monoepoxy-β-CD (2.00 g, 1.45 mmol) was added to a mixture of dry DMF (80 mL) and THF (30 mL) under an Ar atmosphere. After the mixture became translucent, the solution was cooled to 0 °C. NaH (1.39 g, 58.0 mmol) was added to the solution, and the mixture was stirred for 1 h at 0 °C. CH_3I (3.6 mL, 58.0 mmol) was added dropwise over a period of 20 min, and then the mixture was warmed to room temperature. After stirring the reaction mixture overnight, methanol (4 mL) was added to quench the reaction. The solvent was removed under reduced pressure, and the residue was extracted with $CHCl_3$ (100 mL) and H_2O (100 mL). The combined organic layer was separated and washed with aqueous $Na_2S_2O_3$ (100 mL) and then with H_2O (100 mL). The $CHCl_3$ layer was dried over Na_2SO_4 and concentrated. The residue was purified by column chromatography on silica gel with gradient elution from $CHCl_3$ to $CHCl_3$/acetone (5:2 (v/v)) to give 2,3-monoepoxy per-*O*-methylated β-CD as a colorless solid (1.50 g, 61 %). ^{1}H NMR (400 MHz, $CDCl_3$): $\delta=5.19$–5.00 (m, 7H), 3.92–3.19 ppm (m, 99H); MS (MALDI-TOF, α-cyano-4-hydroxycinnamic acid (α-CHCA)) m/z 1406.6 (calcd for $[M+Na]^+$: 1406.46). Elemental analysis (%) calcd for $C_{61}H_{106}O_{34}\cdot0.5\,CHCl_3$: C 51.18, H 7.44, O 37.69; found: C 51.15, H 7.42, O 38.26.

1: A solution of 2,5-dimercaptomethylpyridine (50 mg, 0.29 mmol) in methanol (2 mL) was added to a solution of 2,3-monoepoxy per-*O*-methylated β-CD (1.0 g, 0.72 mmol) in aqueous 0.1M $NaHCO_3$ (25 mL). The mixture was refluxed under Ar for 24 h. After cooling the reaction mixture to room temperature, it was extracted with $CHCl_3$ (50 mL × 5) and the organic layer was dried over Na_2SO_4. The solvent was removed under reduced pressure, and the residue was purified by column chromatography on silica gel with gradient elution from $CHCl_3$/acetone (5:2 (v/v)) to $CHCl_3$, and then to $CHCl_3$/MeOH 10:1 (v/v) to give **1** as a colorless solid (0.21 g, 20%). ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 8.50$ (s, 2H, pyH^2), 7.81 (s, 1H, pyH^4), 5.28–5.00 (m, 12H, H^{1B-G}), 4.62 (d, 2H, $J = 7.6$ Hz, H^{1A}), 4.35 (m, 2H, H^{5A}), 4.10–3.14 (m, 200H, $-OCH_3$ and other H$^{2-6}$ protons), 3.03 ppm (dd, 2H, $J = 10.8$, 2.8 Hz, H^{3A}). The assignments of the ^{1}H NMR spectrum were performed by measuring the H–H COSY spectrum and by comparison with literature values.[9a,18b] MS (FAB, *m*-nitrobenzyl alcohol): *m*/*z* 2938 (calcd for M^+: 2938.23). Elemental analysis (%) calcd for $C_{129}H_{221}NO_{68}S_2$: C 52.73, H 7.58, N 0.48, O 37.03; found: C 51.96, H 7.31, N 0.62, O 36.89. The ^{1}H NMR and H–H COSY spectra of **1** are shown in the Supporting Information.

UV/Vis absorption spectra were measured on a Shimadzu UV-2100 spectrophotometer with a thermostatic cell holder. ^{1}H NMR spectra were recorded on a JEOL JNM-A400 spectrometer (400 MHz) in D_2O (CEA, 99.9%) using sodium 3-trimethylsilyl[2,2,3,3-$^2H_4$]propionate (TSP, Aldrich) as an external standard or in $CDCl_3$ (CEA, 99.8%) and tetramethylsilane as an internal standard. Mixed O_2–N_2 gases with various partial pressures of oxygen were prepared with a KOFLOC GM-4B gas-mixing apparatus (Kyoto, Japan). $P_{1/2}$ values were determined according to the procedure described in the literature.[6b,20] The average value of five repeated measurements was employed.

Metal–Radical Complexes

An Unprecedented Bridging Phenoxyl Radical in Dicopper(II) Complexes: Evidence for an $S=\frac{3}{2}$ Spin State**

Fabien Michel, Stéphane Torelli, Fabrice Thomas, Carole Duboc, Christian Philouze, Catherine Belle, Sylvain Hamman, Eric Saint-Aman, and Jean-Louis Pierre*

The cooperativity between a radical and a transition-metal ion in a single molecular entity is demonstrated in highly sophisticated biocatalysts.[1] Galactose oxidase, which has an

active site composed of a tyrosyl radical magnetically coupled to a cupric ion, nicely exemplifies this synergy. In this example the two redox centers work together to promote the two-electron oxidation of primary alcohols to give aldehydes.[2] For a better understanding of the metal–radical interaction (and its biological relevance), transition-metal complexes involving one or two coordinating radicals have been characterized recently.[3] So far no complexes with a bridging radical have been reported. We describe herein an unprecedented metal–radical system, a dicopper(II) μ-phenoxyl complex. This was achieved using the dicopper(II) complexes of the dinucleating ligand HL. Its oxidative chemistry is compared to that of the copper(II) complex of the mononucleating analogue HL′.

When two equivalents of $Cu(ClO_4)_2{\cdot}6H_2O$ and HL were mixed in acetonitrile in the presence of one equivalent of NEt_3, complex $[L(CH_3CN)_2Cu_2]^{3+}$ (**1**) was obtained as its ClO_4^- salt.[4] Its crystal structure (Figure 1) shows that the ligand binds two copper(II) atoms having square-pyramidal geometry through coordination to three nitrogen atoms from the ligand (two pyridyl N atoms and one tertiary amino group) and one from an exogenous acetonitrile molecule. The coordination sphere is completed by an oxygen atom of a μ-phenolato group, which bridges the two metal centers having a separation of 4.06 Å. The use of HL and two equivalents of both $Cu(ClO_4)_2{\cdot}6H_2O$ and NEt_3 affords complex $[L(\mu OH)Cu_2]^{2+}$ (**2**) as its ClO_4^- salt.[5,6] Its crystal structure (Figure 1) has been previously reported:[5] the coordination sphere of the copper atoms contains three nitrogen atoms from the ligand (two pyridyl and one tertiary amino group) completed by two oxygen atoms (from one phenolato and one hydroxo groups) which bridge the metal centers. The two copper ions have trigonal-bipyramidal coordination geometry, with a Cu–Cu distance of 2.98 Å. Addition of one equivalent of $Cu(CF_3SO_3)_2$ or $Cu(ClO_4)_2{\cdot}6H_2O$ to HL′ in acetonitrile in the presence of one equivalent of NEt_3 affords the dimer $[L'Cu]_2^{2+}$ (**3**) as its $CF_3SO_3^-$ or ClO_4^- salt (Figure 1).[4] In **3** each copper atom is coordinated by two pyridyl nitrogens, one amino nitrogen, and two μ-phenolato oxygens (one from each ligand), and the intermetallic distance is 3.12 Å. This dimer is relatively stable, as reflected by its K_{py} value of 0.297 M^{-1}.[7] All the ligands thus afford copper(II) complexes involving at least one coordinating μ-phenolato unit.

The UV/Vis spectra of **1** (Figure 2), **2**, and **3** exhibit a μ-phenolato-to-copper charge-transfer (CT) transition in the region between 450 and 550 nm, and a broad absorption at

Selected bond lengths [Å] and angles [°]: $[L(CH_3CN)_2Cu_2]^{3+}$ (**1**): Cu1-O1 2.170(2), Cu2-O1 2.150(2), Cu1-Cu2 4.059(5), Cu1-O1-Cu2 140.0(1); $[L(\mu OH)Cu_2]^{2+}$ (**2**):[5] Cu1-O1 1.997(3), Cu2-O1 2.039(3), Cu1-Cu2 2.980(9), Cu1-O-Cu2 95.2(2); $[L'Cu]_2^{2+}$ (**3**): Cu1-O1 2.077(2), Cu1-O2 1.923(2), Cu2-O1 1.917(2), Cu2-O2 2.303(2), Cu1-Cu2 3.123(5), O1-Cu1-O2 82.72(7), O1-Cu2-O2 77.05(7).

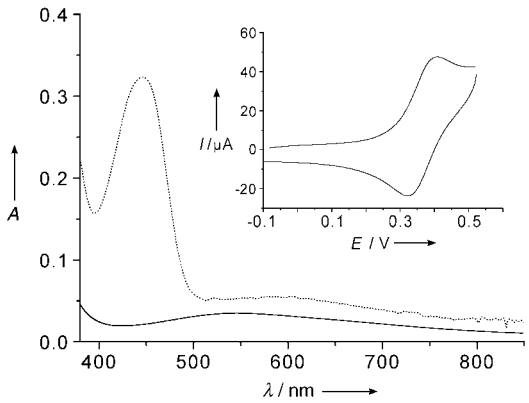

Figure 2. Electronic spectra of 0.1 mM solutions of **1** (solid lines) and electrochemically generated $\mathbf{1}^{\bullet+}$ (dotted lines) recorded in CH_3CN (0.01 M TBAP) at 233 K ($l = 1$ cm). Inset: Cyclic voltamogram (under Ar atmosphere) of **1** (1 mM in CH_3CN, 0.1 M TBAP) at 298 K; scan rate: 0.1 Vs^{-1}.

higher wavelengths attributed to d–d transitions.[8] The X-band EPR spectrum of **1** in CH_3CN exhibits a $\Delta M_S = \pm 2$ transition at $g = 4.3$, associated with spin triplet resonances at $g = 2.24$ and 1.99, indicating that the two copper(II) atoms are weakly ferromagnetically exchange-coupled. The zero-field splitting (zfs) parameters ($D = 0.036\ cm^{-1}$, $E = 0\ cm^{-1}$) and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$g_{\parallel} = 2.30$, $g_{\perp} = 2.07$ were obtained from simulation. Using the point dipole approximation,[9] we calculated a 4.5-Å separation between the two copper(II) atoms, a value in reasonable agreement with the X-ray structure analysis. Complex **2** is EPR-silent, indicating that the two copper(II) atoms are strongly antiferromagnetically exchange-coupled, due to optimal magnetic orbital overlap.[5] Complex **3** exhibits a ferromagnetic coupling between the two copper atoms similar to that in **1** but with larger zfs parameters ($D = 0.080\ cm^{-1}$, $E = 0.027\ cm^{-1}$, $g_1 = 2.04$, $g_2 = 2.06$, $g_3 = 2.12$), as is expected for a complex with a shorter intermetallic separation. (The complex $[L'(py)Cu]^+$ exhibits a $S_{Cu} = \frac{1}{2}$ signal typical for a mononuclear copper(II) complex).

The cyclic voltammograms of **1** (Figure 2 inset) and **2** in CH_3CN (0.1 M tetrabutylammonium perchlorate (TBAP)) display a reversible one-electron wave in the positive region of potentials ($E_{1/2} = 0.36$ V vs Fc^+/Fc, $\Delta E_p = 0.09$ V and $E_{1/2} = 0.45$ V, $\Delta E_p = 0.09$ V for **1** and **2**, respectively), attributed to the oxidation of the μ-phenolato moiety into a μ-phenoxyl radical.[10] This signal is irreversible both for **3** (at $E_p^a = 0.45$ V) and $[L'(py)Cu]^+$ (at $E_p^a = 0.14$ V), showing that the radical evolves on the experiment timescale. Complexes **1**–**3** are thus oxidized in the same potential range, highlighting that the structure of the complex affects weakly the oxidation potential of the μ-phenolato ligand. However, $[L'(py)Cu]^+$ is oxidized at a potential 0.3 V lower, which can be explained by the lower electron density at the oxygen atom of a μ-phenolato ligand compared to that of a phenolate group. In addition, we have previously shown that species such as **3** do not retain their dimeric structure upon oxidation: if they are stable enough to be generated, the phenoxyl radical species evolve towards the corresponding monomers.[11] Thus, only **1** and **2** could be oxidized to give complexes with bridging phenoxyl radicals.
