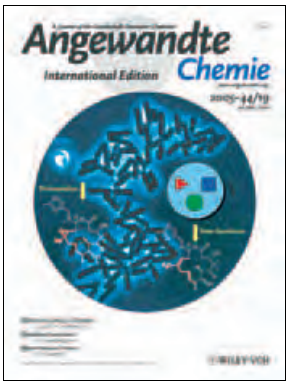
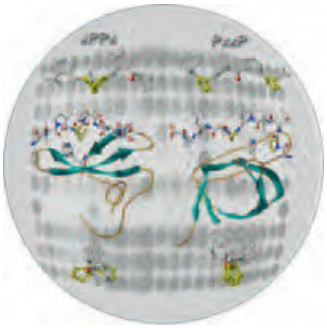
Cover Picture



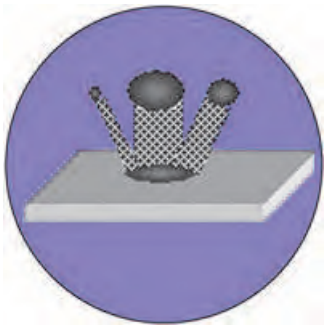
Alexey Rivkin, Ting-Chao Chou, and Samuel J. Danishefsky*

Synthetic and biological studies of epothilone B (isolated from a myxobacterium) led to the discovery of a 26-trifluoro analogue that is remarkably active in treating xenograft tumors in nude mice. These findings underscore the potential of using natural products as leads, in conjunction with directed total synthesis, in the quest for new drugs. S. J. Danishefsky and co-workers present their synthetic strategy along with biological data in their Minireview on page 2838 ff.



Protein Recognition
Many cellular processes involve proline-mediated protein–protein interactions. In their Review on page 2852 ff. L. J. Ball, H. Oschkinat, et al. describe the structural characteristics of the binding domains concerned and the complexes formed.

Magnetic Nanoparticles
T. Hyeon et al. obtain 6 to 13 nm monodispered magnetic iron oxide nanoparticles by a technique that they report in their Communication on page 2872 ff. The method is a variation of a seed-mediated growth approach.



Nanowires
Quasi-parallel nanowires that originate from well-controlled single particle sites are formed in the low-temperature chemical vapor deposition process described by H. Dai and co-workers in their Communication on page 2925 ff.

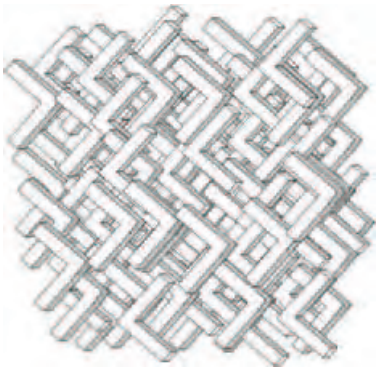
Highlights

V for victory? Theory has suggested that V-shaped molecules may provide a route to biaxial nematic liquid crystals (see picture). The identification of a biaxial nematic phase is, however, a challenging task. Even if it is yet to be agreed that the hunt is over, it appears that this path is well worth pursuing.



Liquid Crystals

Minireviews

A retrospective account of the discovery through chemical synthesis of the second-generation epothilone drug candidates the 9,10-dehydroepothilones (e.g. fludelone (**1**)) is presented. The importance of natural products as leads in drug development is highlighted, as well as the use of molecular editing through chemical synthesis to fine-tune the biological and pharmacodynamic properties of the natural product to develop a viable drug.

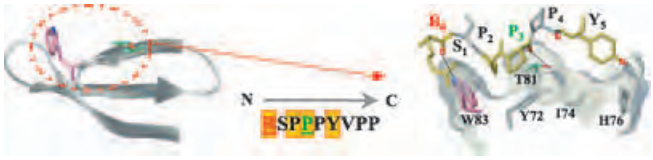
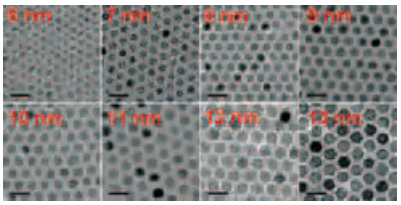
Reviews

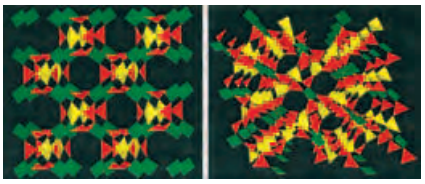


Solving the mystery of mutual attraction: Proline-mediated protein–protein interactions are involved in the regulation of numerous essential cellular processes. Analysis of the structures of complexes formed between proline-rich peptides and their respective binding domains (see figure) reveals fundamental features of this mechanism of recognition, which is highly specific, yet only requires low binding affinities.

Communications

Accurate to size: Monodisperse magnetic iron oxide nanoparticles with a continuous size spectrum of 6–13 nm have been synthesized by a procedure similar to seed-mediated growth and characterized by transmission electron microscopy (see picture) and magnetic measurements. This method yields monodisperse nanoparticles directly without a size-selection process.



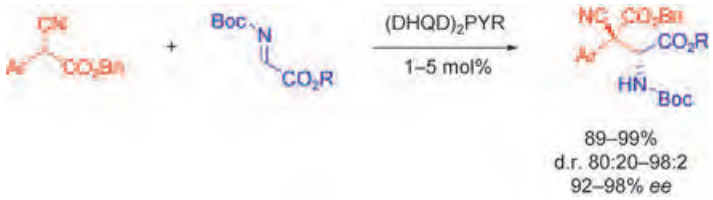


Three not of a kind: Two metal–organic nets sustained by three different molecular building blocks, triangles, squares, and tetrahedra, are prepared and characterized. The shapes (see picture red triangles, green squares, yellow tetrahedra) reveal how appropriate combinations of vertex-linked polygons or polyhedra afford novel topologies that could be prototypal of an even wider range of organic and metal–organic compounds.

For the USA and Canada:

Air freight and mailing in the USA by Publications Expediting Inc. 200 Meacham Ave., Elmont, NY 11003. Periodicals postage paid at Jamaica NY 11431. US POSTMASTER: send address changes to *Angewandte Chemie*, Wiley-VCH, 111 River Street, Hoboken, NJ 07030. Annual subscription price for institutions: US$ 4948.00/4498.00 (valid for print and electronic / print or electronic delivery); for individuals who are personal members of a national chemical society, or whose institution already subscribes, or who are retired or self-employed consultants, print only: US$ 394.00. Postage and handling charges included. All Wiley-VCH prices are exclusive VAT.

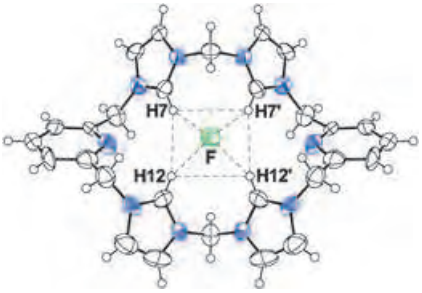
Contents



Metal-free catalysis: Highly functionalized molecules with two contiguous stereocenters are easily accessed in high yield with high enantio- and diastereoselectivity by using a commercially available organocatalyst ($(DHQD)_2PYR$, see scheme). The easily removed Boc protecting group in the product is an added value to this method as an important tool in asymmetric synthesis.

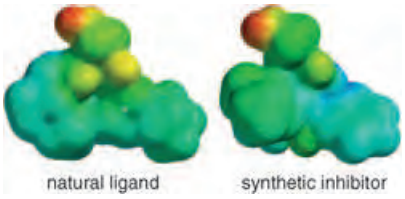
Asymmetric Synthesis

An effective macrocyclic ionophore for F^- ions that contains an array of positively charged imidazolium units has been prepared. The calix[4]imidazolium[2]pyridine cation formed a complex with F^- ions in a 1:1 stoichiometry, as shown by binding studies using ^1H NMR spectroscopic analysis, X-ray crystallographic determination (see structure), and density functional calculations.

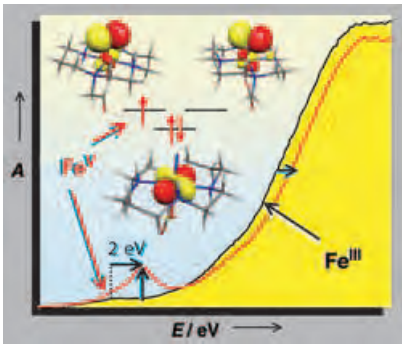


Supramolecular Chemistry

Inhibitors of the interaction between protein VLA-4 and its natural ligand VCAM-1 have been designed, even though the structure of the protein remains unresolved. The rational design relied on the simulation of the steric and electronic properties of the active loop of VCAM-1, whose structure is known (see picture), and the inhibitors were readily prepared by stereoselective stepwise [3+2] cycloadditions.



Synthetic Inhibitors

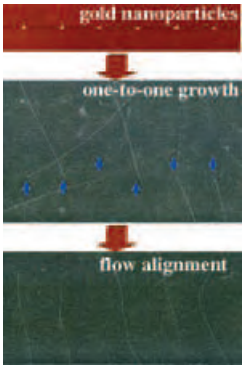


Low-spin, high-valent iron centers: A high-valent iron–nitrido species containing a Fe^V center is accessible by the photolysis of $[(cyclam\text{-}ac)Fe^{III}N_3]^+$. The identity of the resulting $[(cyclam\text{-}ac)Fe^{V}(N)]^+$ species was verified by spectroscopic methods, magnetic susceptibility data, and DFT calculations (see picture). Unexpectedly, the analysis provides strong evidence for a low-spin d^3 ($S = 1/2$) ground-state electron configuration at the Fe^V center.

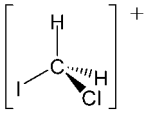
Bioinorganic Chemistry

Contents

Several breakthroughs in nanowire synthesis are reported for germanium nanowires grown from gold nanoparticle seeds by a low-temperature chemical vapor deposition process. Conditions were optimized to observe the formation of nanowires in near-quantitative yields, and post-growth flow-alignment was used to obtain quasi-parallel nanowires that originate from well-controlled singleparticle sites (see images).

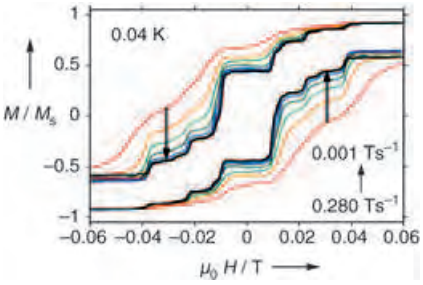


Nanostructures



The vibrational spectrum of $[CH_2{}^{35}ClI]^+$ (see formula) was recorded by mass-analyzed threshold ionization (MATI) spectrometry. Spin–orbit effects were used in density functional calculations to determine the structure of the ground state of the cation. The results suggest that spin–orbit terms should be treated the same as other relativistic effects in some cases.

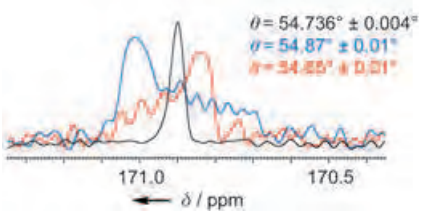
Dihalomethane Structures



Staircase-like structures in the hysteresis loops at 0.04 K (see picture) are shown by doped single crystals of $TBA[(Pc)_2Tb^{III}_{0.02}Y^{III}_{0.98}]^-$ (Pc = phthalocyaninato, TBA = tetrabutylammonium), the first lanthanide single-molecule magnet. They are assigned to resonant quantum tunneling of magnetization between entangled states of the electron and nuclear spin systems. The Dy complex was also studied.

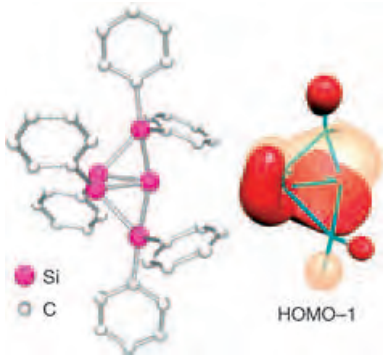
Single-Molecule Magnets

Right angles: In solid-state magic-angle spinning (MAS) NMR spectra, the line widths of carbonyl carbon atoms in polycrystalline cholesteryl acetate are found to be as narrow as 0.039 ppm if the magic angle is adjusted very accurately, that is, within $\pm 0.004°$ (see picture). The line broadening observed for slightly miss-set angles is mostly due to residual chemical shift anisotropy (CSA) interactions. Long spin-echo life times up to $T_2' = 3.6$ s open the way to sophisticated NMR methods.



NMR spectroscopy

Contents

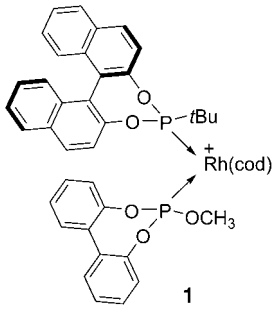


Reaction of a disilenide with $SiCl_4$ produces a silicon cluster with π-bonding topology reminiscent of a Möbius array, as determined by structural data and DFT calculations (see picture). Partially hydrogenated silicon clusters are important for the optical properties of many silicon materials. The availability of a derivative that is stable in the absence of surrounding Si^0 yields insight into the structure of such compounds.

Cluster Compounds

It can come as a surprise to plant lovers to find the fruit bodies of *Leucocoprinus birnbaumii* (see picture) in their flower pots. This fragile fungus, which is harmless to plants, owes its yellow color to the unusual alkaloids birnbaumin A and B, in which a 1-hydroxyindole-3-glyoxylic acid amide is attached through a tetramethylene unit to *N*-hydroxyoxamidine. *N*-Hydroxyoxamidines have not been described previously.

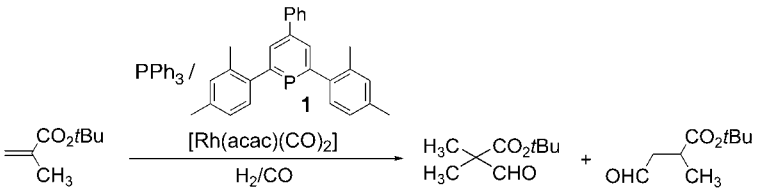
Structure Elucidation



1

Mixed (pre)catalysts such as **1** arise when $[Rh(cod)_2]BF_4$ is combined with a 1:1 mixture of a BINOL-derived monodentate phosphonite or phosphite ligand and a configurationally fluxional atropisomeric phosphite with a biphenol backbone. These systems provide excellent results for the Rh-catalyzed asymmetric hydrogenation of β-acylamino acrylates. BINOL = 2,2′-dihydroxy-1,1′-binaphthyl; cod = cycloocta-1,5-diene.

Combinatorial Catalysis



1 + 1 ≠ 2: The mixture of triphenylphosphine and phosphinine **1** with $[Rh(acac)(CO)_2]$ forms a hydroformylation catalyst that effects the preferential formation of the branched product, even though each ligand alone mediates the opposite regioselectivity. Similar effects were observed for a series of other ligand combinations.

Dendrimers: Platforms for Chemical Functionality**

Jean-François Nierengarten*

Since the pioneering work of F. Vögtle in the late 1970s, the synthetic concept based on repetitive growth with branching units has been extensively investigated leading to a wide range of core–shell macromolecular structures now recognized as dendrimers.[1] In recent years, the rapid advances in dendrimer synthesis have moved toward the creation of functional dendrimers with increased attention to potential applications. Because of their intrinsic branched structure, dendrimers are original scaffolds for the preparation of high molecular weight compounds. One of the most appealing features is the possibility of tuning their properties by changing the number, chemical nature, and relative position of functional units within the branched structure. In this way, dendritic architectures are capable of generating specific properties. The exploitation of this new type of macromolecule in a variety of applications ranging from materials science to biology were the focus of the recent Leopoldina Meeting in Heidelberg, Germany organized by L. H. Gade and H. Werner with the support of the Deutsche Akademie der Naturforscher "Leopoldina" and the Sonderforschungsbereich 623.

The first session immediately revealed the large diversity of structures in the field of dendrimers. The opening lecture of K. Müllen (Mainz, Germany) focused on polyphenylene-based dendrimers[2] which have a rigid framework in contrast to most types of dendrimers. As a result, these compounds are shape-persistent and can therefore define the positioning of active functions in the core, the dendritic scaffold, or on the surface. The latter structural peculiarity, for example, was used to produce multichromophoric systems in which the intramolecular energy transfer events between multiple dyes can be controlled through their relative distance and orientation within the dendritic framework. These studies are not only important for the fundamental understanding of photoinduced processes, but appears to be of great interest for the design of single-photon emitters. A. D. Schlüter (Zürich, Switzerland) presented the preparation and characterization of dendritic monomers as well as their polymerization to give functionalized dendronized polymers. The thickness of these polymers is in the range of several nanometers and they can be visualized by AFM as elongated wormlike structures;[3] they are amongst the largest molecules ever synthesized.

Dendritic-based materials are widely used as soluble supports in homogeneous catalysis,[4] enabling easy recycling of the catalyst through nanofiltration. This concept was the main focus of the communications of J. N. H. Reek (Amsterdam, The Netherlands), R. J. M. Klein Gebbink (Utrecht, The Netherlands) and D. Astruc (Bordeaux, France). The dendritic framework can be functionalized with the catalyst either at the core or at the periphery, which determines catalytic performance to a great extent. Of particular interest is the use of noncovalent interactions to attach the catalytic entities to a dendritic scaffold. The research group from Utrecht, for example, has developed a new type of cationic core–shell dendrimer architecture derived from oligoamine core molecules, in which permanent cationic charges are located at the cores of the resulting dendrimers. With ionic exchange reactions, a predefined number of anionic guest molecules with catalytic properties can be affiliated with these dendrimers. The reversible nature of this type of anchoring allows controlled de- and re-functionalization of the support, which enables facile reuse of the support. An example is depicted in Figure 1.

R. M. Crooks (College Station, Texas, USA) is also focused on applications in the field of catalysis,[5] but his approach is completely different. The materials he described were synthesized by a template method in which metal

  DOI: 10.1002/anie.200501226

ions are sorbed into the dendrimer interior and subsequently subject to chemical reduction to yield nearly monodisperse metal particles of oxidation state 0 and diameters of less than 4 nm. The dendrimer component of these composites serves not only as a template for nanoparticle preparation, but also to stabilize the nanoparticle, making it possible to tune solubility and to enhance catalytic selectivity. These materials have been used for a broad range of catalytic reactions, including hydrogenations, Heck coupling, and Suzuki reactions.

In the field of materials science, the nanometer scale of dendrimers is believed to allow the elaboration of complex nanoarchitectures and devices. J.-P. Majoral (Toulouse, France) highlighted the role played by phosphorus dendrimers developed in Toulouse for the development of organic–inorganic hybrid materials and for the controlled modification of inorganic surfaces.[6] Particularly appealing is the work involving the application in DNA chips. A 5'-amino-modified 35mer oligonucleotide (probe) was spotted onto slides modified with dendrimers bearing peripheral aldehyde units (Figure 2). The resulting imine bonds as well as the remaining aldehydes were reduced. Hybridization was then carried out with a fluorescent 15mer Cy5-labeled complementary strand (target). These "dendri-chips" are very stable and reusable. Indeed, repeated hybridization/stripping cycles were possible without any loss of signal. In addition, the detection limit of such chips was found to be better than most of the commercially available activated slides. This high sensitivity is particularly interesting and probably results from the three-dimensional form of the dendrimers which keeps the oligonucleotides away from the solid surface of the chip.

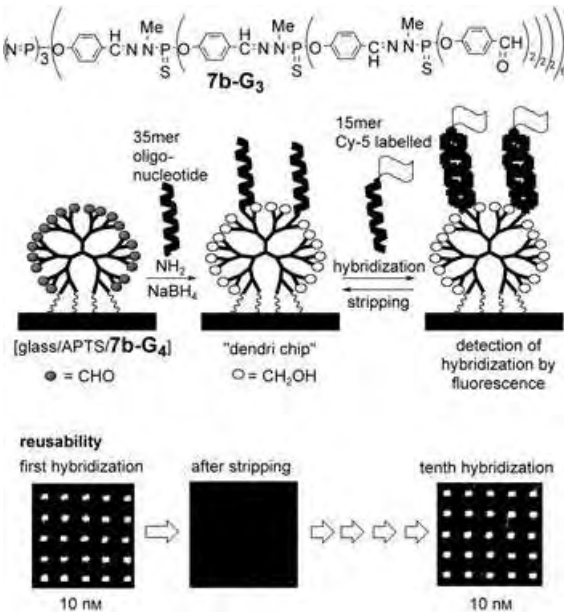

Figure 2. Top: elaboration of a "dendri-chip" with dendrimers as spacers. Bottom: fluorescence detection of hybridization of the 15mer Cy-5 labeled oligonucleotide on the "dendri-chip". Results after 10 hybridization/stripping sequences with a target concentration of 10 nM. (kindly provided by J.-P. Majoral and A.-M. Caminade, Toulouse, France).

Core–shell-structured nanotransporters have gained great attention over the last year for the transport of active substances.[7] R. Haag (Berlin, Germany) presented the latest advances of his research group in the use of dendritic architectures for the delivery of DNA and drugs. He introduced a new molecular nanotransport system suitable for the encapsulation of both polar and nonpolar molecules. The architecture of this universal type of nanocarrier consists of two shells with different polarity arranged around a dendritic core. Linkers between the shells or between the shell and core can be either chemically stable or chemically labile. In this manner the liberation of encapsulated molecules can be induced by external signals, such as a change in pH.

The final lecture given by F. Vögtle (Bonn, Germany) was an overview of the field. He clearly demonstrated that dendrimers have already shown a wide range of unique physical and chemical properties that make them attractive for medicinal chemistry and the preparation of new advanced materials. Dendrimer applications encompass a wide range of technologies. One of the most important conclusions is that many developments rely on new materials and our ability to obtain an intimate understanding of their properties. Modern organic synthesis is the starting point of this research, as compounds must first be made and studied, and then modified to improve their properties towards projected applications. In the long run, there will be a move toward the design and creation of an increasing number of new materials for direct industrial application.

Liquid Crystals

V-Shaped Molecules: New Contenders for the Biaxial Nematic Phase

*Geoffrey R. Luckhurst**

Keywords:
bent-core molecules · biaxial nematic · liquid crystals · mesophases · phase transitions

Since their discovery in the 1880s, the number of different thermotropic liquid-crystal phases has grown, with an increasingly complex molecular organization observed within the phases. The discovery of new phases has often been accidental, although in recent years theoretical predictions have stimulated such discoveries; the twist grain boundary phase formed on introducing molecular chirality into smectic phases is an excellent example.[1] Another example of the prediction of a liquid-crystal phase is the biaxial nematic phase. The simplest and commercially most important liquid crystal is the uniaxial nematic phase, N_U, which is taken to have $D_{\infty h}$ symmetry. The term uniaxial is borrowed from the field of optics and indicates that plane-polarized light can travel along just one axis without a change in its state of polarization. This axis is the optic axis, and on a molecular level it corresponds to the axis also known as the director and denoted by the apolar unit vector, ***n***, along which the constituent rodlike molecules tend to be orientationally ordered.

Although the molecules that form the majority of thermotropic liquid crystals are certainly elongated,[2] they do not have the infinite rotation axis often assumed for them. From the molecular structure of a typical calamitic mesogen, such as 4,4′-dimethoxyazoxybenzene shown in Figure 1a, it is clear that its shape is boardlike and that its symmetry is closer to D_{2h} than $D_{\infty h}$. In 1970 Freiser[3] suggested that this reduction in molecular symmetry should result in the formation not only of the uniaxial nematic but also of a new nematic phase. He termed the new phase as biaxial, N_B, to indicate that there are now two axes along which plane-polarized light can travel without a change in the state of polarization, consistent with the D_{2h} symmetry of the phase. The molecular organization within the new phase is sketched in Figure 1b; the three directors, ***l***, ***m***, and ***n***, are associated with the preferred orientation of the three symmetry axes of the orthorhombic molecular blocks. It was also predicted that as the molecular biaxiality increased, so the stability of the biaxial with respect to the uniaxial nematic phase increased until at a unique value of the biaxiality the isotropic phase underwent a second-order transition directly to the biaxial nematic phase.[3,4] This unique value is known as a Landau point. This behavior is in clear contrast to the first-order uniaxial-nematic–isotropic transition, although the biaxial-nematic–uniaxial-nematic transition is second order. These predictions concerning the transitions have proved to be of value in attempting to characterize the nature of the phases for real nematogens.

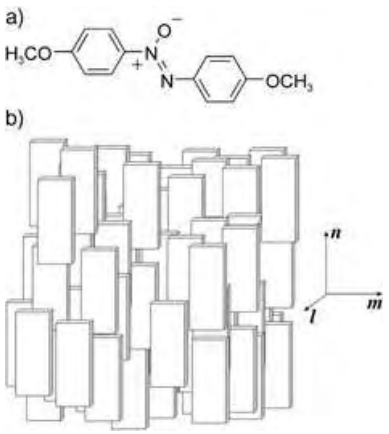

Figure 1. a) The biaxial structure of a typical mesogenic molecule, and b) the organization of the molecular blocks in a biaxial nematic phase.

The design and synthesis of biaxial molecules with sufficient anisotropy to form liquid-crystal phases is relatively straightforward in principle, but it was not until 16 years after Freiser's seminal prediction that the first claim to have found the biaxial nematic phase appeared.[5] There then followed a number of such claims for materials in which the molecular biaxiality resulted from a mixture of rodlike and disklike structural elements in the molecule.[6] In view of the manifest molecular biaxiality, it was perhaps to be expected that they would exhibit the biaxial nematic phase. A variety of techniques were employed to identify the phase,[7] and one such method was based on the observation of the optical texture under the polarizing microscope, which is so powerful in assigning other liquid-crystal phases. More significantly, the biaxiality in tensorial properties such as the refractive index or dielectric permittivity should provide the most convincing demonstration of the phase symmetry. However, the determination of this biaxiality is not trivial as it is usually necessary to apply constraints to the system to align two of the directors uniformly throughout the sample, while the third will follow the other two. In the case of the refractive

  DOI: 10.1002/anie.200500709

index, conoscopy provides an extremely sensitive method with which to determine the biaxiality.[7] However, this is also its weakness because the surfaces used to align the thin film may induce a phase biaxiality that could be responsible for any small optical biaxiality that is observed.[7]

In principle, ^{2}H NMR spectroscopy provides a more powerful approach as the bulk phase is studied and the directors are not required to be uniformly aligned.[8,9] This method has been applied to at least three compounds that were claimed to form a biaxial nematic phase, and it was found that the nematic phase is, in fact, uniaxial.[10–12] It would seem that although the molecules are certainly biaxial, the uniaxial nematic phase crystallizes or is interrupted by a smectic phase before the anticipated biaxial nematic phase can be formed.

This failure to find a compound capable of exhibiting the biaxial nematic phase suggests that the molecular design needs to be guided more quantitatively by theory and that possibly other strategies should be explored. One new approach that has been suggested is to use a bent molecule, which we refer to as V-shaped, although the terms bent-core, banana-like, or boomerang-like are also employed. In V-shaped molecules, two rodlike mesogenic groups are linked together through a central unit, as shown in Figure 2a. Such a molecule is clearly biaxial and displays near-C_{2v} symmetry. What is needed, however, is the value of the inter-arm angle (θ_V) that will maximize the stability of the biaxial nematic. This parameter has been studied theoretically with a model based purely on repulsive molecular interactions[13] and subsequently with another model using, implicitly, both attractive and repulsive anisotropic interactions.[12]

For a symmetric V-shaped molecule, the dependence of the transition temperatures on the inter-arm angle predicted by the latter model[12] is shown in Figure 2b. For the linear conformation, the system can only form a uniaxial nematic, but as the molecule is bent a biaxial nematic is introduced and the uniaxial-nematic–isotropic transition temperature falls. The Landau point is found when the angle adopts the tetrahedral value of 109.47°, which is identical to that predicted by the model based on repulsive interactions.[13] The phase diagram in Figure 2b also shows a conservative estimate of the lowest temperature at which the system is expected to crystallize, and it is immediately apparent that the range of angles for which the biaxial nematic phase should be observed is extremely small, at approximately $\pm 2°$. Such a narrow range is consistent with the limited concentration and temperature range over which lyotropic biaxial nematics are found to exist.[14] Of course, the fundamental units in thermotropic and lyotropic liquid crystals are quite different, however, the macroscopic order parameters that characterize the two nematic phases are the same.

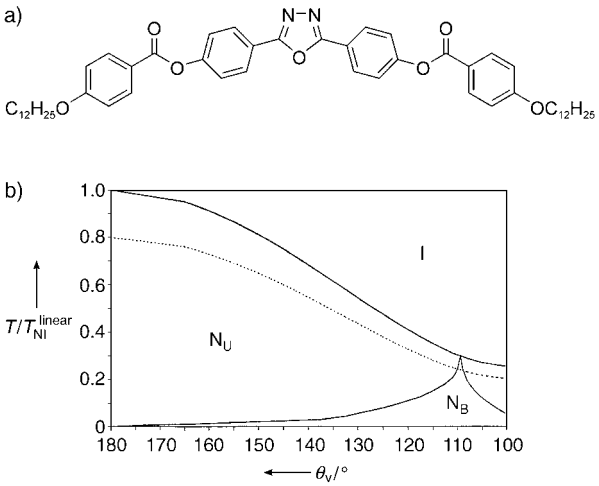

Figure 2. a) The structure of a V-shaped mesogenic molecule, and b) the predicted dependence of the transition temperatures on the inter-arm angle (θ_V). T_{NI}^{linear} is the nematic–isotropic transition temperature for the linear conformation.

One of the first V-shaped molecules for which a biaxial nematic phase was claimed is that shown in Figure 2a. The compound displays the phase sequence isotropic and nematic followed by two unidentified smectic phases.[15] The angle between the two mesogenic arms is about 140° and this is far outside the range for which a biaxial nematic has been predicted. However, the large transverse electrical dipole may stabilize the biaxial phase, although such interactions might be expected to result in a polar biaxial nematic.[16] It is important that the evidence supporting the phase assignment is strong. This evidence involves the optical texture, which is consistent with a biaxial nematic but is not unequivocal. Conoscopy shows that the refractive index is biaxial, but this biaxiality is small and its temperature variation is weak. This observation contrasts with theoretical predictions and the behavior found for a lyotropic biaxial nematic.[14]

The bulk system has been studied by ^{2}H NMR spectroscopy, which is a challenging experiment given the very high temperatures (173–222 °C) over which the biaxial nematic exists. Detailed simulations of the spectra suggest that the phase is biaxial, although the phase biaxiality is relatively small and not as sensitive to changes in temperature as theory predicts. The other significant piece of evidence in support of the phase biaxiality is provided by X-ray scattering studies.[17] Alignment of the ***n*** director by a magnetic field results in an unusual small-angle scattering pattern which seems to indicate that the ***m*** director is also aligned, although the origin of the torque responsible for this is not clear. The directors for a biaxial nematic formed from V-shaped molecules are shown in Figure 3a.

In a second experiment, surfaces were used to align the ***n*** director in the plane of the surface and surprisingly the small-angle scattering pattern again suggests that the ***m*** director is also aligned in the plane but orthogonal to ***n***. Application of an electric field orthogonal to the surface causes the ***m*** director to align parallel to the electric field and so orthogonal to the surface to result in a significant change in the scattering pattern. This does suggest that the nematic phase is indeed biaxial as the wide-angle scattering shows that the orientation of the ***n*** director is unchanged. However, there is always the possibility that the electric field ($E = 6\,\mathrm{MV\,m^{-1}}$) polarizes the phase and so induces the phase biaxiality, although the field may be somewhat small to achieve this.

The evidence presented concerning the phase symmetry of compounds formed from V-shaped molecules certainly suggests that the synthesis of

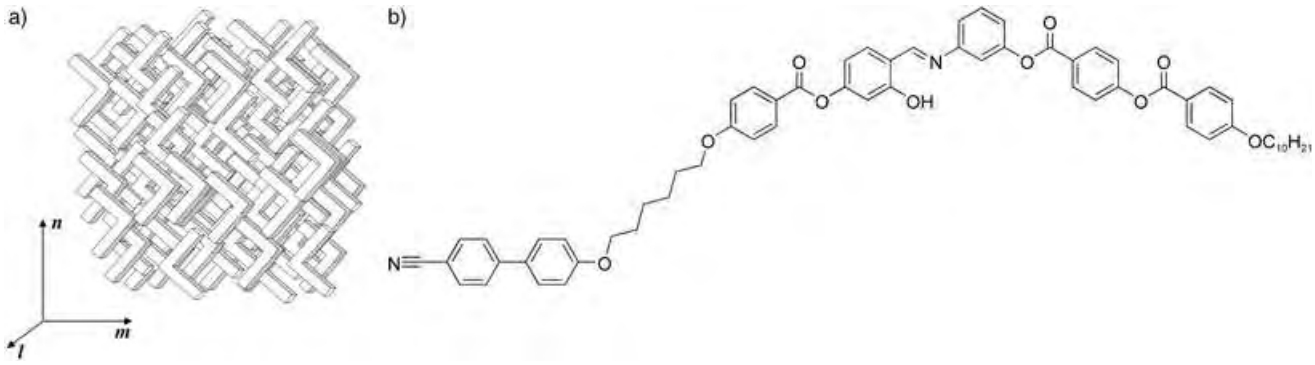

Figure 3. a) The molecular organization in a biaxial nematic phase formed from V-shaped molecules, and b) the structure of an elaborated nonsymmetric V-shaped mesogenic molecule.

analogous structures preferably with lower transition temperatures would be of merit. Such compounds would facilitate the experiments to determine the phase symmetry and would remove any concerns over the thermal stability of the compounds. Another design strategy, in addition to changing the interarm angle, would be to make the anisotropy of the two arms different, as theory shows that this effect should also change the stability of the phase. Indeed a more elaborate, nonsymmetric V-shaped molecule, shown in Figure 3b, has been reported in which a rodlike unit is attached by means of a flexible spacer to the V-shaped unit.[18] In its all-*trans* conformation this extra group would remove the equivalence of the two mesogenic arms. However, the flexibility of the spacer, the terminal decyloxy chain, and the links to the central unit means that the molecule will adopt a range of conformations, often not V-shaped, and have a lower biaxiality. In consequence, the overall molecular biaxiality is difficult to judge. Nonetheless, evidence from the studies of optical texture and conoscopy suggest that the nematic phase is biaxial. However, experience has shown that this evidence is not sufficient and that definitive confirmation of the biaxial symmetry of the nematic phase requires NMR spectroscopy and possibly X-ray scattering experiments.

Epothilone Derivatives

On the Remarkable Antitumor Properties of Fludelone: How We Got There**

*Alexey Rivkin, Ting-Chao Chou, and Samuel J. Danishefsky**

Keywords:
anticancer drugs · drug development · epothilones · natural products · total synthesis

Dedicated to Professor George Olah

Small-molecule natural products are presumably often biosynthesized with a view to optimizing their ability to bind to strategic proteins or other biomolecular targets. Although the ultimate setting in which a drug must function may be very different, the use of such natural products as lead compounds can serve as a significant head start in the hunt for new agents of clinical value. Herein we reveal the synergistic relationship between chemical synthesis and drug optimization in the context of our research program around the epothilones: how synthesis led to the discovery of more-potent epothilone derivatives, and discovery inspired the development of new synthetic routes, thus demonstrating the value of target-directed total synthesis in the quest for new substances of material clinical benefit.

1. Introduction

Nature, during the course of evolution, has provided prospectors with a diverse and formidable collection of structurally complex, small-molecule natural products. Indeed, it is likely that the many structures that have been discovered to date represent only a miniscule fraction of what nature, in principle, has to offer.[1]

Although the field of natural products is certainly cluttered with uninspiring "me too" entries, from time to time those busily engaged in the isolation, biological screening, purification, and structure determination of collections of natural products are rewarded. They may well discover architecturally truly novel compounds, whose properties prompt the launching of new directions in biological and even clinical research.[2]

To bring forth a new drug capable of providing real patient benefit while meeting the appropriately discerning standards of regulatory agencies is a daunting task characterized by high failure rates. Those committed to drug discovery can't help but be sensitive to the staggering set of risk factors that bestride the complex path from concept to approved, valuable drug. The discovery and study of small-molecule natural products has been a productive setting in the discovery of drugs.[3] Clearly we are far from understanding the evolutionary forces and developmental advantages in the biosynthesis of small molecules in plants, corals, bacteria, fungi, and higher organisms. At least for the present, it can be said that leads from small molecule natural product structures (for example, steroids, prostaglandins, β-lactams, polyketides, aminoglycosides, and statins) allow one to enter the intimidating arena of drug discovery at a later stage in the development progression than other modalities, including the mass screening of pharmaceutical sample collections and commercially available combinatorial libraries.

Why do such small-molecule natural product structures present such an advantage? Presumably they are often biosynthesized with a view to optimizing their ability to bind to strategic proteins or, in some instances, other biomolecular targets. Binding to strategic proteins is a key feature of virtually all drugs. Aside from their often exquisitely novel structural motifs, honed and fine-tuned by evolution for their interactivity with pertinent biomolecules, small-molecule natural products come with the built-in advantage that, by definition, they have been maintained in some biologically

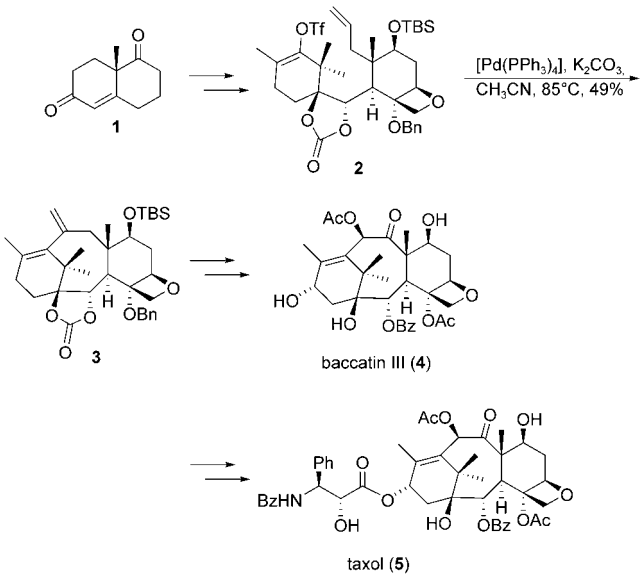
viable entity. This genealogy, however different in context from the ultimate setting in which a drug must function, and however imperfect a marker it is for predicting pharmacodynamics and safety profiles, can already be seen as a significant head start in the hunt for new agents of clinical value.

2. Natural Product Anticancer Agents: From Taxol to the Epothilones

2.1. Total Synthesis

Natural products have made a huge impact on drug discovery, particularly in the quest for new antitumor agents.[4] A well-known example of a clinically important agent, initially discovered through the screening of plant natural products, is taxol (**5**).[5] The value of taxol (subsequently renamed paclitaxel) in the treatment of several types of early-stage cancers and even some metastatic tumors is well established.[6] Also of established usefulness is a semisynthetic variant of taxol termed taxotere.[7] Both compounds inhibit microtubule depolymerization, which is an essential phase in mitosis. Other semisynthetic taxoids are at various stages of development.

The involvement of our research group in the study of taxol was initially inspired largely by chemical interests.[8] It has been our custom to make use of the rich structural diversity of small, biologically generated natural products to organize and focus our thoughts about the strategy and methodology of chemical synthesis. In the case of taxol, we sought to take advantage of smooth access to either enantiomer of the Wieland–Miescher ketone (**1**; Scheme 1). Moreover, we hoped to integrate the various stereochemical biases within the Wieland–Miescher ketone with a suitable degradative strategy to facilitate access to baccatin III (**4**), a precursor to taxol. In the event, a key transformation (**2**→**3**), masterminded by Dr. John Masters, did occur. However, the confidence and optimism occasioned by the stunning utilization of an intramolecular Heck reaction by Masters soon gave way to near desperation, as the route from **3** to **4** proved exceptionally troublesome as a result of difficulties associated with selectively excising the external methylene group. It was only the imaginative persistence of Dr. Wendy Young and Dr. J. T. Link, along with that of Masters, that allowed us to chart and realize a path to reach the natural



Scheme 1. Synthesis of taxol. Bn = benzyl, Bz = benzoyl, Tf = trifluoromethanesulfonyl, TBS = *tert*-butyldimethylsilyl.

product. We note, parenthetically, that for all of the frustrations and disappointments of the total synthesis, we were able to deliver the appropriate enantiomer of taxol (**5**) without the need for resolution and without recourse to relay synthesis (in which a fragment of the natural product is used as a starting material). These particular conditions had not been met in the two total syntheses of taxol completed previous to our own.[9,10]

Accomplishments on a chemistry level notwithstanding, our taxol effort did not deliver on one of its central purposes. Initially, we had hoped to synthesize late-stage intermediates containing the requisite side chain and housing the pharmacophores critical for the bioactivity of taxol. The complications of the final steps of the total synthesis left us with precious little material (and energy!) for structure–activity investigations.

This failing at the discovery level was particularly unfortunate since taxol is far from an ideal drug.[11] Although cytotoxic side effects are not unexpected in a tubulin-targeting agent, taxol carries two additional liabilities. The first arises from difficulties associated with its formulation. These problems are overcome by recourse to various delivery

Alexey Rivkin received his BS in chemistry and biochemistry from the University of California, San Diego in 1996. He completed his PhD in 2001 at the University of Pittsburgh, where he focused on synthetic studies of the structurally intriguing natural product penitrem D under the guidance of Dennis P. Curran. He then worked as an NIH postdoctoral fellow with Samuel Danishefsky at the Memorial Sloan-Kettering Cancer Center, where his synthetic studies of epothilones led to the discovery and development of the (E)-9,10-dehydroepothilones. He is currently a medicinal chemist at Merck.

Ting-Chao Chou completed his PhD at Yale University and is currently director of the Preclinical Pharmacology Core Laboratory at the Memorial Sloan-Kettering Cancer Center in New York. He was Professor of Pharmacology at Cornell University from 1988 to 2000, and has been honorary professor at the Chinese Academy of Medical Sciences since 1993. The median-effect equation he created and the combination-index equation he created with P. Talalay, along with the computer software Biosoft, UK, have received over 2000 citations in over 250 biomedical journals.

vehicles, which create their own safety and tolerance issues in real treatment settings. Perhaps even more serious is the vulnerability of paclitaxel to disablement at the clinical level by innate or acquired multidrug resistance (MDR). All too often it proves impossible to overcome MDR by increasing the dosage of the toxic drug. These complications in the aggregate often lead to "taxol failure" in the clinic with reemergence of the disease in metastatic form.

It was in this setting of seeking "life after taxol" that we heard a report about a new anticancer agent, which functioned by the taxol mechanism. The epothilone family of natural products had been discovered at the Gesellschaft für Biotechnologische Forschung mbH (GBF) by Höfle and associates, following an extremely well-executed pharmacognosy program. The Höfle group had postulated possible applications of epothilones in various agricultural contexts.[12] Broad multidisciplinary interest in the epothilones was aroused following a milestone publication by a natural products discovery group led by Bollag at Merck.[13] The features of the Merck disclosure that were most provocative were that the new family of natural products, known as epothilones (Scheme 2), seemed to owe their cytotoxic

properties against various cancer cell lines to the same tubulin-interference mechanism exhibited by taxol. However, importantly, unlike taxol, epothilones A (**6**) and B (**7**) seemed to be remarkably effective against apparent MDR cell lines.[14] As discussed above, taxol failure is often attributable to the onset of MDR. Although the absolute configuration of the epothilones was not known at that time, their overall structures suggested that they would constitute a more manageable challenge from the point of view of chemical synthesis than taxol derivatives. Accordingly, we hoped that total synthesis as a means of drug discovery would be more productive with the epothilones than had been the case with the taxol program.

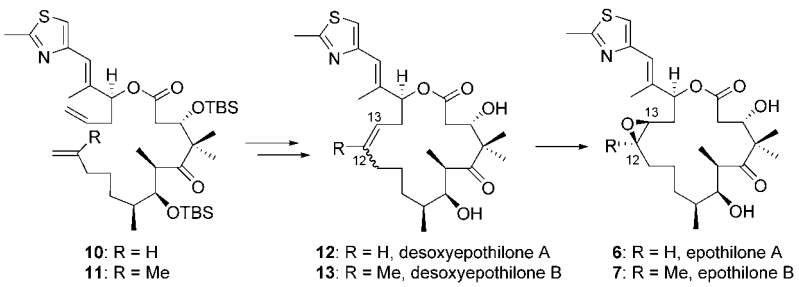
A focused effort directed towards the synthesis of the epothilones by chemical means could not be launched until their configurations were defined. The Merck group was apparently not pursuing the full definition of configuration.[13] As noted above,[12] the actual discovery of the epothilones went back to pioneering studies by Höfle et al. However, it was not until a key publication, again from the research group of Höfle, that the configurations of epothilones A and B were revealed.[15] This information led to a disciplined effort towards total synthesis with an ultimate view to biological investigation. Indeed, since we had no access to epothilones in any quantity for independent investigations, total synthesis would be our only recourse. We identified epothilones A (**6**) and B (**7**) as our targets for total synthesis. We started by targeting epothilone A, which lacks the methyl group at C12, in the hope that lessons learned in that foray would serve us well in the synthesis of epothilone B, which was reported to be the more potent compound.[16]

Herein we relate, in a retrospective way, the interactive relationship between chemical synthesis and drug optimization in our research program around the epothilones. It was this synergism that led to the discovery of the remarkable (*E*)-9,10-dehydro-12,13-desoxyepothilones **8** and **9**, particularly the congener **9** bearing a trifluoromethyl group rather than a methyl group at C12.[17] We describe how this discovery flowed from a unique synergy between chemistry and preclinical experimental pharmacology. We have reason to believe that this type of interdisciplinary interaction offers excellent prospects in a variety of projects.

It is important to emphasize a matter of policy that influenced the design of our syntheses to a considerable extent. From the outset, our orienting goal was to produce adequate quantities of preclinical lead compounds to carry out in vivo evaluations in xenograft mouse models. We assigned to this goal a far higher degree of urgency than to the mass screening of individual compounds in vitro. Since our resources were clearly finite, the decision to place emphasis on evaluations of in vivo efficacy implicitly meant that we would make fewer compounds, albeit in larger quantities than are generally prepared in total syntheses in an academic environment. This decision in turn placed a very high premium on the attainment of high levels of stereoselectivity in the individual steps.

Accordingly, we could ill afford to deal with complex mixtures of stereoisomers. It seemed probable to us from the outset that ring-closing metathesis (RCM), by then a very popular method for forming cyclic olefins,[18] would, in the case of the epothilones, lead to an *E*/*Z* mixture of stereoisomers at the C12–C13 double bond if a precursor such as **10** or **11** was used (Scheme 3).[19] This expectation proved accurate. We thus came to favor cross-coupling strategies in which the eventual C12–C13 double-bond geometry was already defined in the olefinic precursors. Incidentally, we were aware that in placing emphasis on quality syntheses to

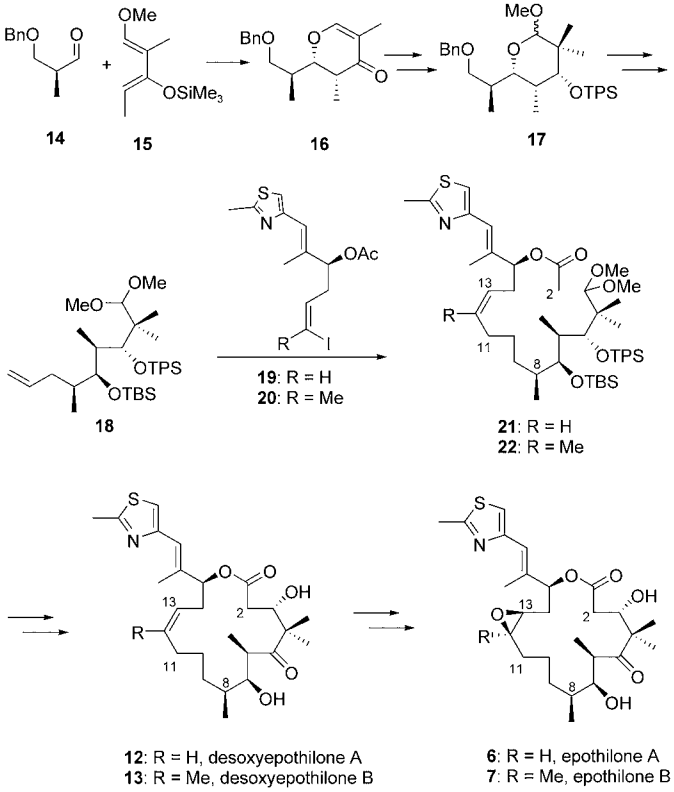
Samuel Danishefsky completed his BS at Yeshiva University in 1956 and his PhD at Harvard University with Peter Yates. After postdoctoral studies at Columbia University with Gilbert Stork he began his independent academic career in 1963 at the University of Pittsburgh, where he became professor in 1971. In 1980, he moved to Yale University, but returned to New York in 1993 as Professor of Chemistry at Columbia University and Kettering Professor at the Memorial Sloan-Kettering Cancer Center. His research interests include synthetic strategy, reagent development, cytotoxic natural products, and fully synthetic carbohydrate-based tumor antigens.



Scheme 3. Synthesis of epothilones by ring-closing metathesis.

produce carefully thought-out structures, we were deviating from the prevailing trends—based on stochastic approaches—of those times. We return to this issue toward the end of this Minireview.

We were attracted to the palladium-mediated B–alkyl Suzuki cross-coupling, a reaction that was underappreciated at the time, to establish the C12(sp^2)–C11(sp^3) bond.[20] The synthesis of EpoA commenced with compound **16**, prepared by taking advantage of chemistry developed to a large extent by our research group.[20] Thus, the Lewis acid catalyzed diene–aldehyde cyclocondensation reaction[21] of **14** and **15** afforded dihydropyrone **16** in high yield and with high relative and absolute stereoselectivity (Scheme 4). This compound was converted into intermediate **18**, which underwent the key B–alkyl Suzuki reaction with **19** to afford **21**. A virtually unprecedented ester enolate–aldehyde macrocyclization[22] followed by appropriate functional-group manipulations led us to desoxyepothilone A (dEpoA, **12**). Epoxidation of the 12,13-alkene with dimethyldioxirane proceeded with very high regio- and stereoselectivity (15–20:1 in favor of the β epoxide[23]) to complete the first total synthesis of epothilone A (EpoA, **6**).[24] Happily, the logic of the synthetic route was readily adapted to the first synthesis of EpoB (**7**).[16b] The key features of the pioneering effort are adumbrated in Scheme 4. Experimental protocols have been described in detail in the literature.



Scheme 4. First reported total synthesis of EpoA and EpoB.

2.2. Biological Activity

With synthetically derived material in hand, we soon confirmed the various claims in the literature concerning inhibition of microtubule disassociation and the cytotoxicity of epothilones A and B.[25] Remarkably, in vitro experiments revealed that the 12,13-desoxy precursor of EpoB (i.e. dEpoB) also exhibited tubulin-stabilization properties within the range of those of EpoB, though the cytotoxicity was diminished.[12] By permuting the total synthesis described above in various ways, we built a family of epothilone congeners, which served to define the first in vitro SAR (structure–activity relationship) map of the epothilones.[20] We were able to determine which structural elements of the epothilones could be modified without loss of cytotoxicity or tubulin-binding characteristics.

Although our initial syntheses of EpoA and EpoB were quite long, our newly launched drug-discovery program benefited greatly from their high stereoselectivity. With considerable diligence, we were able to accumulate adequate quantities of totally synthetic probe structures for meaningful in vivo determinations. The experiments involved implanting human tumor cells into immunodeficient mice and assessing the effects of the drugs on the growth profiles of the tumors. We also conducted parallel investigations on tumors that had become insensitive to various known anticancer drugs as a consequence of MDR. Hence, these fully synthetic drug samples could be used to determine whether the claims of Bollag and co-workers about MDR insensitivity (for example, in the case of epothilone B)[12] were also true in an in vivo setting. We conducted the first in vivo investigations with epothilone B. Our findings were highly worrisome. Although the potency of EpoB was certainly indicated, its toxicity profile was quite serious: deaths and troubling weight losses resulted even at doses as low as 0.6 mg kg^{-1} (Table 1).

With appropriate changes in dosing, it might well have been possible to learn to administer EpoB in such a way as to achieve useful therapeutic indices that would justify its

Table 1: Toxicity of EpoB and dEpoB in normal nude mice.

Group	Dose [mg kg^{-1}][a]	Deaths
control	–	0/4

dEpoB (**13**)	25	0/6

[a] QDx4 (administered every day, 4 doses in total), intraperitoneal (i.p.). [b] Mice died of toxicity on day 5,6,6,7,7,7,7,7.

potential development as a drug. In fact, Novartis did enter this drug into phase I clinical trials.[26] However, we were concerned that toxicity issues would, in the end, prevent EpoB from maturing into the sort of breakthrough drug we sought to discover.

We hypothesized that perhaps the serious toxicity of EpoB was partly the consequence of nonspecific toxicity superimposed on tubulin-directed antimitotic properties. It seemed that the 12,13-epoxide of EpoB could well be a source of nonselective toxicity.[16] Thus, we wondered whether "molecular editing" of the epoxide in favor of a *cis*-12,13-alkene would give rise to agents with reduced toxicity and therefore broader and more exploitable therapeutic indices.

3. Second-Generation Epothilones

3.1. Desoxyepothilone B: Synthesis and Activity

As dEpoB had demonstrated cytotoxicity and tubulin-binding characteristics comparable to those of taxol in vitro, but with activity in MDR cell lines reminiscent of that of EpoB, we decided to evaluate this compound in vivo. Multigram quantities of synthetic dEpoB (**13**) were required for this task and delivered by later-generation syntheses (see below).

Comprehensive in vivo studies showed dEpoB to be much more promising than EpoB itself with respect to the usefulness of its therapeutic index (Table 1).[25e] Subsequently, we expanded our efforts by examining the effects of various formulations, routes, and schedules of intravenous (i.v.) administration. We discovered that dEpoB performed similarly to paclitaxel in tumor xenografts such as MX-1, in which each demonstrated a complete tumor remission. Similar results were seen in the treatment of HT-29 colon tumor and SK-OV-3 ovarian tumor with dEpoB and taxol. However, strikingly superior effects of dEpoB relative to taxol were observed against multiple-drug-resistant (MDR) tumors in our own models. For example, dEpoB (30 mg kg^{-1}, 6-h i.v. infusion, Q2Dx5 = administered every other day, 5 doses in total) demonstrated a full curative effect when administered to nude mice bearing the resistant human lymphoblastic T-cell leukemia CCRF-CEM/paclitaxel, which was 57-fold resistant to paclitaxel (Figure 1 a).

Additionally, the superior effects of dEpoB relative to other commonly used anticancer agents were clearly shown in the treatment of adriamycin-resistant MCF-7/Adr tumor xenografts with frontline chemotherapeutic agents, such as paclitaxel (24 mg kg^{-1}), adriamycin (3 mg kg^{-1}), vinblastine (0.8 mg kg^{-1}), and etoposide (VP-16, 30 mg kg^{-1}), each at the maximal tolerated doses. In these evaluations, adriamycin demonstrated a lack of therapeutic effect even at the nearly lethal dose, and vinblastine, etoposide, and paclitaxel showed little therapeutic effect. Upon treatment with dEpoB, a significant decrease in tumor size was observed (Figure 1 b).

As a consequence of these promising preclinical successes with dEpoB, it became important for us to develop a more concise route for its synthesis. Some of the drawbacks of the first-generation synthesis[20] included the awkwardness of the introduction of the C4 *gem*-dimethyl group, the multistep chain extension of the C9 benzyl ether, and the nonstraightforward opening of the pyran system to expose the C3 aldehyde. We sought to overcome these issues while still making use of the stereoselective B–alkyl Suzuki route.

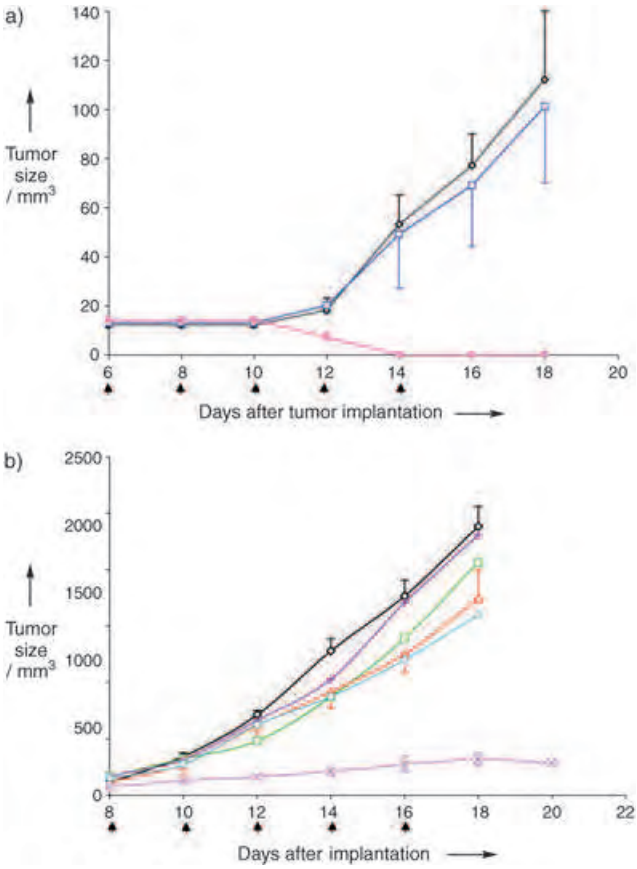

Figure 1. Activity of dEpoB against a) paclitaxel-resistant tumors and b) an adriamycin-resistant mammary adenocarcinoma: a) ◇ control; □ paclitaxel, 20 mg kg^{-1}; × dEpoB, 30 mg kg^{-1}; b) ◇ control; □ vinblastine, 0.8 mg kg^{-1}; △ paclitaxel, 24 mg kg^{-1}; × dEpoB, 30 mg kg^{-1}; + adriamycin, 3 mg kg^{-1}; ○ etoposide (VP-16), 30 mg kg^{-1}.

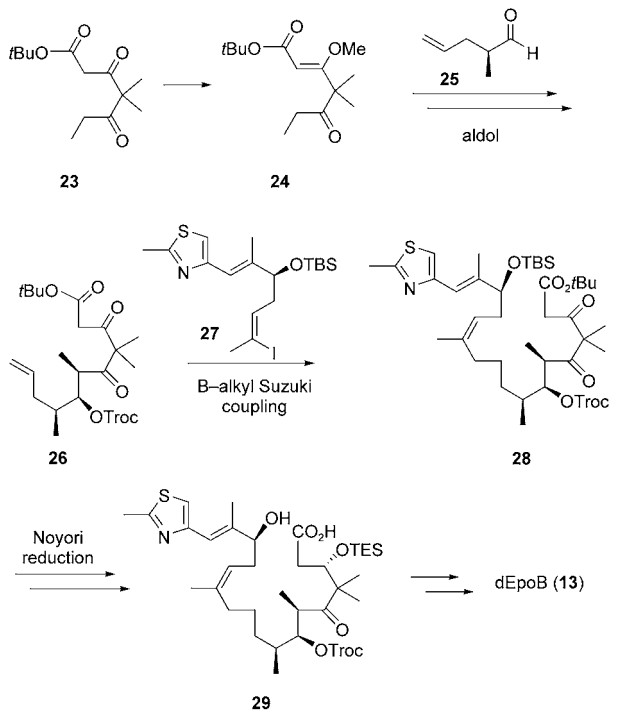
We were able to achieve these objectives in our second-generation synthesis of dEpoB (Scheme 5).[27] This route commenced with the readily available β-ketoester **23**. Following the conversion of **23** into enol ether **24**, an aldol reaction with aldehyde **25** and subsequent manipulations eventually gave β-ketoester **26**. The opposite enantiomer of aldehyde **25** had already been prepared by Overman and co-workers[28] through recourse to Evans oxazolidinone methodology,[29] which makes use of a suitable auxiliary to direct the diastereofacial sense of C2–C3 bond formation. Suzuki coupling of **26** and **27** afforded **28**. The stereocenter at C3 was installed by a Ru–binap-catalyzed reduction developed by Noyori et al.[30] Ultimately, macrolactonization of **29**, followed by deprotection, led to dEpoB (**13**). A total of about 60 g of fully synthetic dEpoB was prepared by this route.

We were now able to evaluate dEpoB relative to taxol, epothilone B, and a semisynthetic 15-desoxy-15-aza congener, which had also been entered into clinical trials.[31] We also



Scheme 5. A more streamlined synthesis of dEpoB. Troc = trichloroethoxycarbonyl.

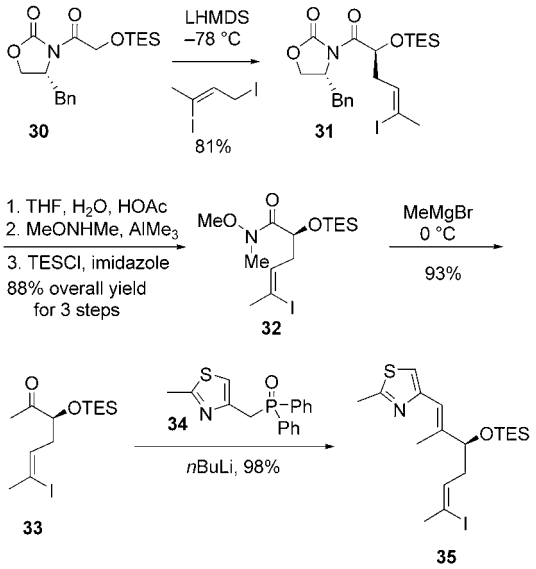
looked into questions such as the stability of dEpoB to lactone-ring opening in various in vivo models and the performance of dEpoB in vivo against sensitive or resistant tumors. In our judgment, based on xenograft models, dEpoB demonstrated major advantages over potential competitors in the range of its likely therapeutic index and in its robustness with respect to MDR disablement. These results have been documented extensively.[25c–e]

Another important event in the progression of desoxyepothilone B to clinical evaluation was the entry of the Kosan Biosciences Company as a licensee of Sloan-Kettering for further development of the compound. Brilliantly, and with great diligence, our commercial collaborators solved the problem of obtaining desoxyepothilone B by fermentation methods.[32] Their success in doing so was much facilitated by their highly advanced technology, which promoted the expression of **13** through the modification of particular polyketide metabolites by controlling the biosynthesis of such polyketides.[32] Our collaborators were able to prepare the compound for phase I clinical trials. The human clinical evaluations, which commenced at the end of 2001, have advanced to a phase II stage in a much expanded effort, which now includes the participation of the company Hoffmann-La Roche.[33]

3.2. (E)-9,10-Dehydroepothilone Derivatives

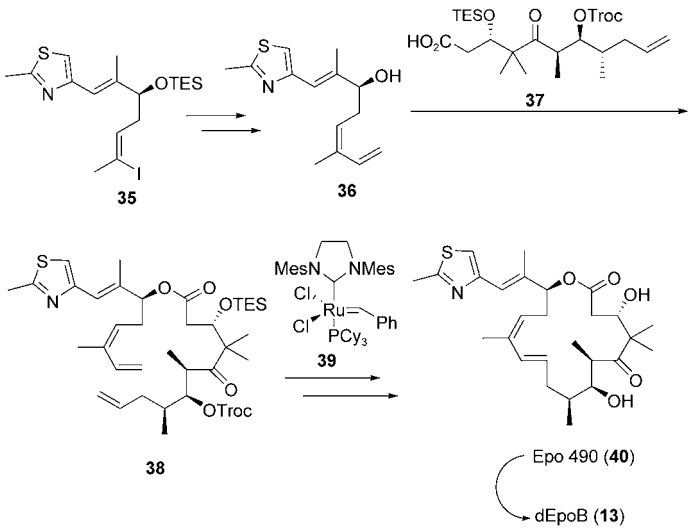
The very effective and timely involvement of Kosan in the project also provided another important step in our progression to the (*E*)-9,10-dehydro compounds, including fludelone. In the course of their pivotal fermentation work, Kosan scientists detected and isolated, albeit in small amounts, a desoxy and dehydro derivative of epothilone B, which they named epothilone 490 (Epo 490).[34] The Kosan investigators recognized Epo 490 as the derivative of EpoB without the 12,13-epoxide and with an additional *E* double bond at C10–C11. We looked upon Epo 490 as a dehydro version of dEpoB (**13**). However, the chemical transformation of dEpoB into this new Kosan metabolite was far from a straightforward matter. We were anxious to take advantage of our previous extensive efforts in total synthesis to gain access to meaningful amounts of Epo 490. In other words, we would try to adapt the total synthesis we had developed for dEpoB to target Epo 490 directly.

To understand the steps taken in the development of the new synthesis, it is important to be familiar with the then state-of-the-art synthesis of the vinyl iodide component (compound **35**) for the Suzuki coupling process. Since we have described previously the many methods that were explored during the course of our investigations, we can quickly turn to the optimal method for preparing this alcohol. The route is summarized in Scheme 6.[35]



Scheme 6. Synthesis of the left-hand fragment **35**. TES = triethylsilyl, LHMDS = lithium hexamethyldisilazide.

A postdoctoral colleague, Dr. Jon Njardarson, offered an interesting proposal for the synthesis of epothilone 490. His idea brought us back to a more careful consideration of the RCM method, which had been left on the sidelines for the reasons discussed above. The coupling of the iodoalkene **35** with a suitable vinyl derivative should give substrate **36**. Following esterification with **37**, ring-closing metathesis could well lead to the desired (*E*)-10,11-(*Z*)-12,13-diene, which, upon appropriate functional-group transformations, should allow access to epothilone 490 (**40**). Indeed, this synthesis was soon completed (Scheme 7).[36] The exact method for introducing the vinyl group involved a Stille cross-coupling reaction of **35** with tri-*n*-butylvinylstannane. Since Epo 490 could be smoothly converted into **13** by a selective imide



Scheme 7. Total synthesis of epothilone 490 by ring-closing metathesis. Mes = 2,4,6-trimethylphenyl.

reduction, the chemistry described in Scheme 7 constitutes an independent total synthesis of dEpoB.

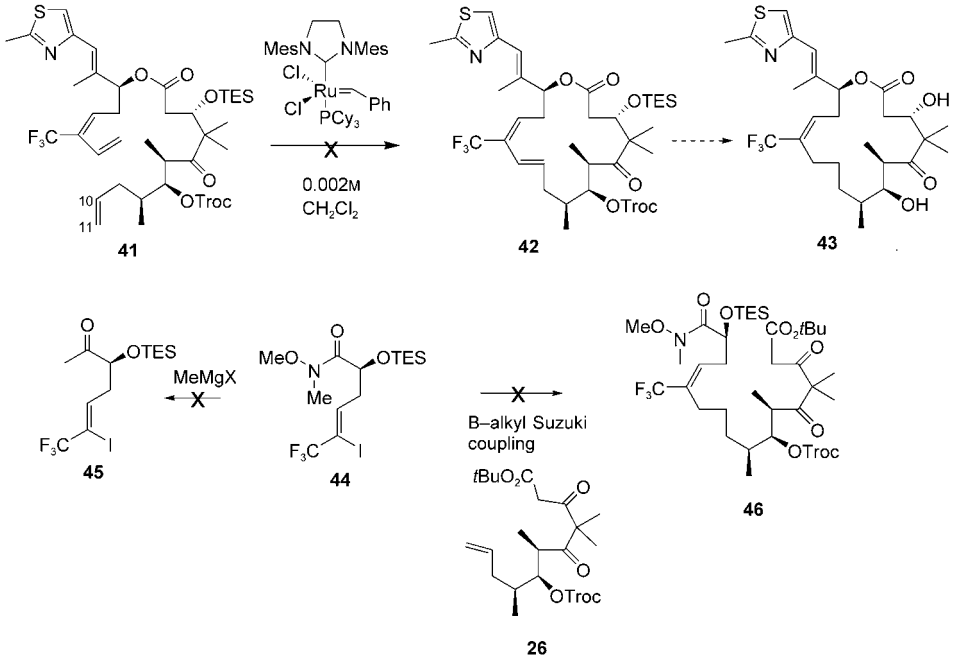
Unfortunately, the excellent in vitro results observed with epothilone 490 did not translate to in vivo experiments conducted with mouse xenografts on our fully synthetic material. Although clear evidence for the suppression of tumor growth could be found, tumor shrinkage, let alone disappearance, was not observed.[21] On the basis of biostability studies, we believed that this lack of translation to an in vivo setting might be specific to the mouse tumor host.

Thus, pharmacostability studies suggested that Epo 490 is particularly unstable with respect to esterase action in mouse sera. Remarkably, the compound was actually quite stable in human sera of cell homogenates. However, in the real world of advancing oncostatic agents for development, progress depends rather critically on the promising performance of the agent in the mouse models. Although the Epo 490 project continues to provide a forum for testing interesting chemistry, efforts to utilize Epo 490 as a drug have been discontinued in our laboratory.

Concurrently with the Epo 490 project, we undertook the synthesis and evaluation of a 26-trifluoro epothilone derivative. In this connection, we were not unmindful of many instances in which the strategic incorporation of fluorine atoms can lead to major effects on drug activity, including altered lipophilicity, incremental stabilization to metabolism, and modified binding affinities.[37] Even in the absence of a clear-cut rationale for doing so, we set out to synthesize dEpoB derivatives with a trifluoromethyl group at C12.

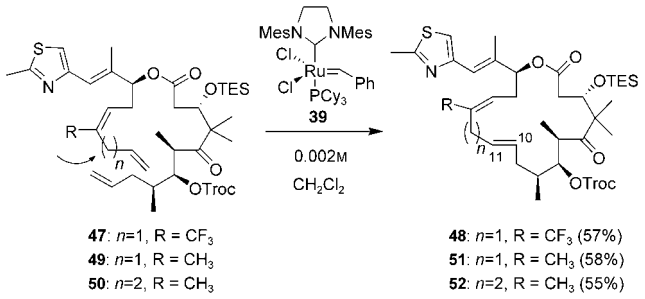
Naively, we assumed that the hard-won lessons from the synthesis of dEpoB could be readily transferred to the problem at hand. Thus, at the outset we set as our targets 26-trifluoro compounds in both the Epo 490 family (see compound **42**) and the dEpoB series (see **43**).[38] Surprisingly, the strategies that had worked well in the syntheses of the nonfluorinated congeners failed in the presence of the trifluoromethyl group. Thus, with the trifluoromethyl group installed, ring-closing metathesis (**41**→**42**), nucleophilic methylation of the Weinreb amide (**44**→**45**), and B–alkyl Suzuki coupling (**44**+**26**→**46**) were all unsuccessful (Scheme 8).[39]

Clearly, we had significantly underestimated the consequences of the inclusion of the trifluoromethyl group for our synthesis. Since a Stille cross-coupling reaction had allowed us to construct the precursor **41**, we investigated the possibility of introducing an allyl group at the future C12 vinylic carbon atom en route to a 26-trifluoro epothilone derivative. We hoped that the inclusion of even a single methylene spacer would attenuate the effects of the trifluoromethyl group, thus enabling the realization of a RCM reaction. Happily, with the



Scheme 8. Failed strategies for the synthesis of 26-trifluoro-dEpoB.

one carbon spacer in place, RCM of **47** did produce compound **48** in a respectable yield (Scheme 9). Now, of course, the epothilone functions were displayed in the context of a 17- rather than a 16-membered ring. Not surprisingly, the

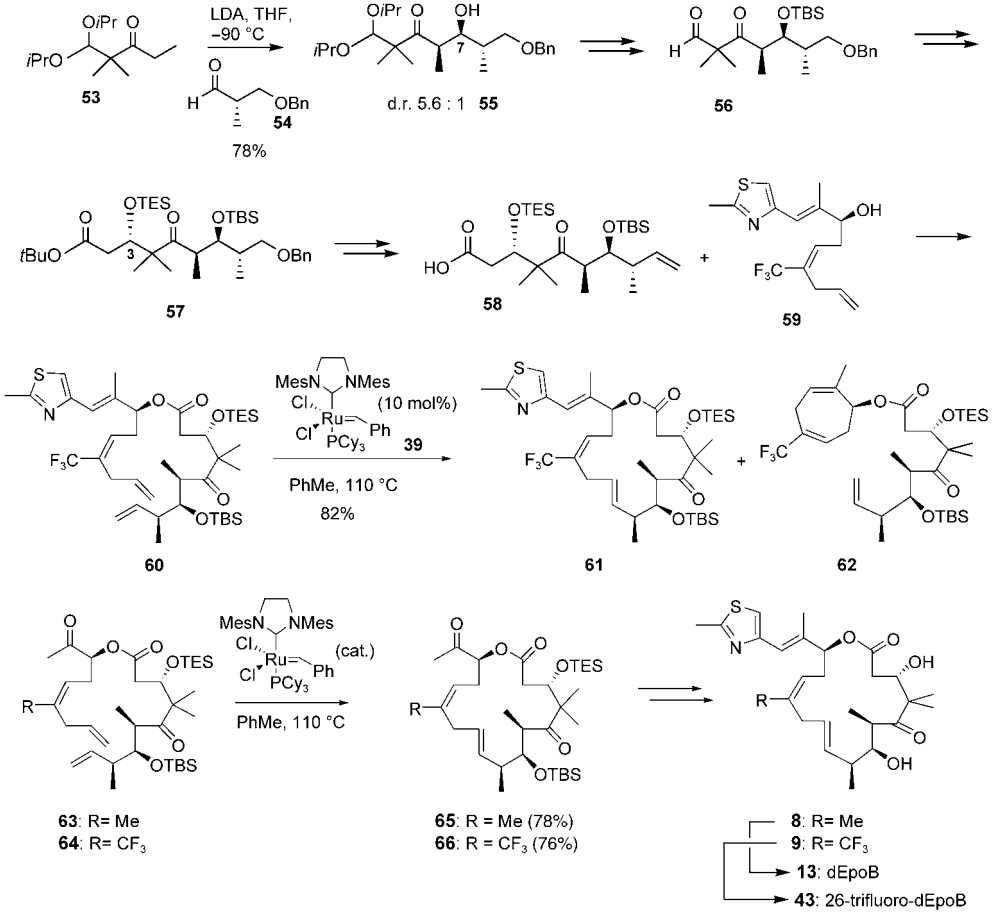


Scheme 9. Successful ring-closing metathesis.

same sequence could be carried out to give the analogue **51** containing a dehydrohomodesoxyepothilone B scaffold and a methyl group at C12.[40] To broaden our SAR base, we also introduced a butenyl function on the C12 vinylic carbon atom. RCM of this compound led to the epothilone macrolide **52**. Remarkably, in all cases the double bonds formed in the RCM reactions were exclusively of the *E* configuration.

In a fateful set of experiments, we examined the in vitro activity of these ring-expanded epothilones. As it turned out, the 18-membered-ring congener **52** was totally inactive. By contrast, the 17-membered-ring compound **51** exhibited substantial in vitro activity. This result at first seemed puzzling, as Nicolaou and co-workers had reported that the monodihydro congener of **51**, in which the C10–C11 bond was saturated, was devoid of useful epothilone activity.[41] This observation led us to speculate that perhaps this second double bond of our synthetic construct could also impart exploitable incremental biological function to epothilones with the usual 16-membered macrocycle.

The limitations imposed on our operative synthetic schemes by the trifluoromethyl group really left us with only one option if we were to stay within the broad parameters of our route. We would take advantage of the fact that the trifluoromethyl group does not interfere with Stille-like allylation. Furthermore, with the single methylene spacer in place, olefin metathesis in the ring-closing mode was indeed a viable reaction. To get back to the 16-membered ring, we would now have to delete one carbon atom from the component containing the carboxylic acid functionality in the esterification reaction. A key reaction in the assembly of this component would now be a chelation-controlled aldol reaction of **53** and **54** (Scheme 10). The aldehyde **54** was obtained smoothly from readily available 2-hydroxybutyric acid—a charter member of the chiral pool. Hence, a fringe benefit of targeting the dehydro-dEpoB system was that we could now dispense with the need for recourse to a chiral



Scheme 10. Synthesis of 9,10-dehydroepothilones through ring-closing metathesis.

auxiliary to reach the previously used aldehyde **25**.[28] Ring-closing metathesis of **60** in the presence of the recently developed catalyst **39** provided exclusively the *E* isomer **61** along with the corresponding 7-membered-ring side product **62** in a 1:3 ratio and 82% combined yield.

At last, we had succeeded in preparing a 12,13-desoxy compound with a 16-membered ring and the desired trifluoromethyl group. However, the major RCM product was the unwanted cycloheptadienyloxy compound **62** arising from extrusion of the thiazole side chain. Clearly, this result did not meet our goal of a viable total synthesis for drug discovery and, hopefully, development.

We postulated that this problem might be resolved by resequencing the steps of the synthesis and conducting the RCM with the ketone precursor to the thiazole side chain still in place. We tested this proposal on the 12-methyl substrate **63** and were pleased to discover that the desired RCM adduct was obtained in 78% yield. Olefination of the ketone with emplacement of the thiazole unit occurred in high yield to give, after deprotection, the desired compound **8**.[42]

When we carried out this synthesis, **8** was believed to have been previously synthesized. Indeed, the compound claimed to be **8** was reported to be only marginally cytotoxic.[43] We were therefore surprised to find that the spectroscopic properties of our synthesized **8** were not consistent with those reported for the compound previously thought to be **8**. The actual structure of the compound originally assigned as **8** has been reevaluated and shown to be an isomer in which the C12–C13 double bond is in the *E* configuration.[44] The real compound **8** had, in fact, never before been prepared and, accordingly, never been evaluated as a potential antitumor agent.

Having established the feasibility of the modified RCM–olefination strategy with the methyl substrate **63**, we refocused our attention on the ultimate goal of synthesizing 26-trifluoro-9,10-dehydro-dEpoB (**9**). Happily, we were able to utilize the same set of transformations to obtain the desired compound **9**, which we named fludelone, from ketone **64** in high yield (Scheme 10).[17b,42]

In the title of this retrospective, we posed the question as to "How We Got There". We had fashioned a special and highly selective sequence of reactions for the total synthesis of the epothilones. As matters transpired, the chemistry needed for the incorporation of the 12-CF_3 group required us to access the 9,10-dehydro series, in which we found a new family of epothilone drugs with extremely promising biological activity. We conclude with a summary of the rather remarkable and promising findings from evaluations of these 9,10-dehydro compounds.

4. Biological Activity of Fludelone

Having synthesized the 12-proteo analogue **8** as a chemical model, we set out to examine its biological activity, in part to set a baseline for comparison with fludelone (**9**). Indeed, compound **8** seems to be a promising second-generation drug candidate. As described elsewhere,[17] it is significantly more potent than dEpoB (**13**) and is much more stable in a variety of biological contexts than **13**. The treatment of various xenograft tumor models with compound **8** led to dramatic tumor shrinkage in these model in vivo contexts (Figure 2). However, although the drug completely suppressed tumor growth, there were obstacles to full tumor eradication with **8**. The problem was that the greater toxicity of **8** (maximum tolerated dose in xenografts is about 4 mg kg^{-1}) made it difficult to dose with sufficient amounts of the drug to remove the last traces of tumor. The exploitable therapeutic index of **8**, particularly in clinical settings, awaits fuller exploration.

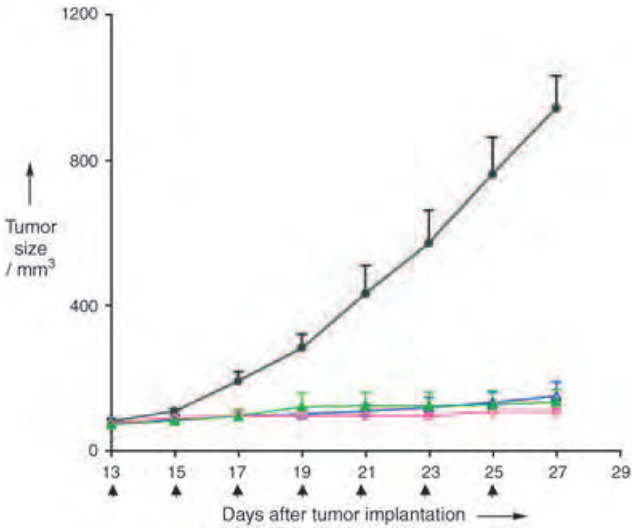


Figure 2. Therapeutic effect of 9,10-dehydro-dEpoB (**8**) in nude mice bearing the HCT-116 xenograft (6-h i.v. infusion (except 5-mg kg^{-1} dosage: i.v. injection), Q2Dx7 = administered every other day, 7 doses in total, $n = 3$; arrows indicate drug administrations): ● control; △ 3 mg kg^{-1}; ◇ 4 mg kg^{-1}, ($n = 4$); ▲ 5 mg kg^{-1}.

By contrast, the 26-trifluoro derivative fludelone (**9**) exhibits a remarkably broad therapeutic index in vivo in xenografts. Dramatic results are observed for a range of tumors. Indeed, fludelone has emerged as our star compound in the epothilone series. The data given below form the basis of our preclinical case.

All chemotherapeutic experiments in vivo were carried out with human-tumor xenografts in immunodeficient nude mice. For all its imperfections, this model is the one most widely used in evaluating antitumor lead compounds prior to clinical trials. Remarkably, the treatment of MX-1 xenografts with 25-mg kg^{-1} dosages of fludelone resulted in complete tumor disappearance and the absence of any relapse for over two months after the suspension of treatment (see Figure 3). Most importantly, these therapeutic successes can be achieved either by 6-h i.v. infusion (Figure 3) or by oral administration (Figure 4). In contrast, the treatment of the MX-1 xenografts by oral administration of taxol did not appreciably affect the tumor, which highlights another significant advantage of fludelone (see Figure 4). The treatment of taxol-resistant tumor xenografts with fludelone administered by 6-h i.v. infusion can lead to complete tumor remission (Figure 5),

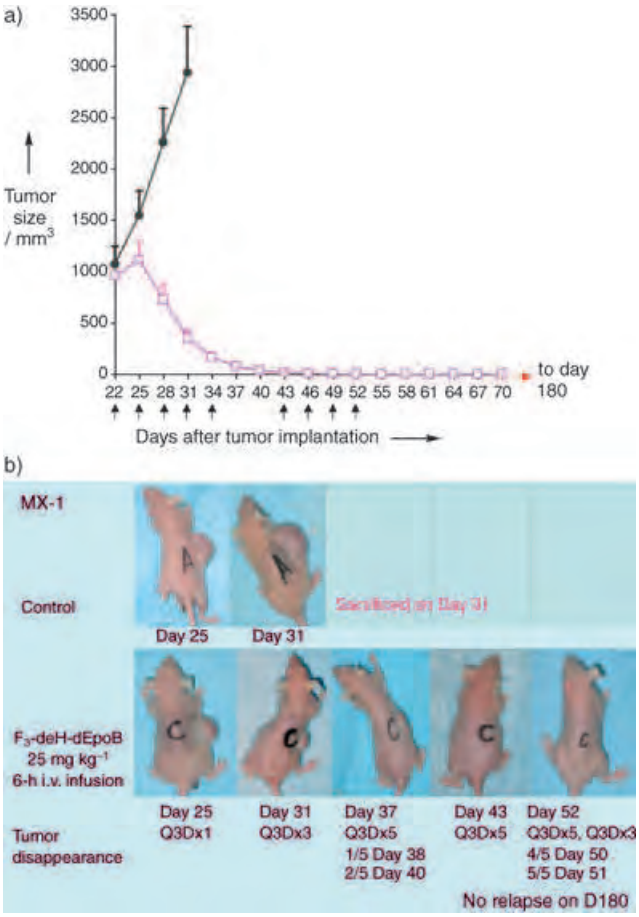

Figure 3. Therapy of an extra-large MX-1 tumor xenograft: a) MX-1 tumor tissue (50 mg) was implanted subcutaneously (s.c.) on day 0. Tumor-size changes in the vehicle-treated control (●) and fludelone-treated group (25 mg kg^{-1}, □; $n=5$ in each group) were observed. On day 22 (D22), when the size of the tumor had reached 960 ± 132 mg (about 3.4% of body weight), fludelone treatment was commenced. Fludelone (25 mg kg^{-1}, 6-h i.v. infusion, Q3Dx5) was given on D22, D25, D28, D31, and D34, as indicated by the arrows. The second cycle of treatment, following a 9-day rest, was given on D43, D46, D49, and D52. For the fludelone-treated group, 5/5 tumors disappeared (on D38, D40, D50, D50, D51). Observation was continued Q3D for up to 180 days, and no relapse was observed 128 days after cessation of treatment on D52. b) Photographs of the nude mice (one mouse each selected from the control group and the treated group) taken on D25, D31, D37, D43, and D52.

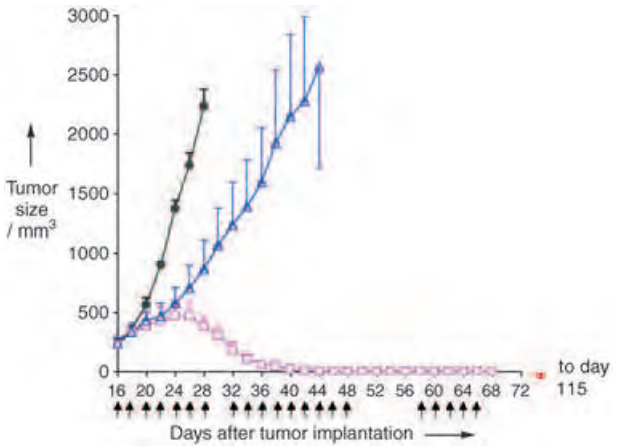

Figure 4. Therapeutic effects against the human mammary carcinoma MX-1 xenograft by orally administered fludelone or paclitaxel (taxol). Female nude mice were used. Fludelone (30 mg kg^{-1}, □, $n=3$) was given orally Q2Dx7 beginning D16 after tumor implantation and then Q2Dx9 on D32 to D48, as indicated by arrows. The tumors of all three mice disappeared (on D40, D45, and D48). As consolidation therapy, a third cycle of treatment was given Q2Dx5 from D58 to D66 when all mice were tumor free on D48. There was no relapse observed on D115 (49 days after stopping treatment). Control (●, $n=2$) received the vehicle only. A comparative experiment was carried out in parallel with taxol (30 mg kg^{-1}, △, $n=3$) with oral dosing beginning D16, Q2Dx3; the dose was then increased to 40 mg kg^{-1}, Q2Dx3 (D22–D26) and then 60 mg kg^{-1}, Q2Dx3 (D28–D40).

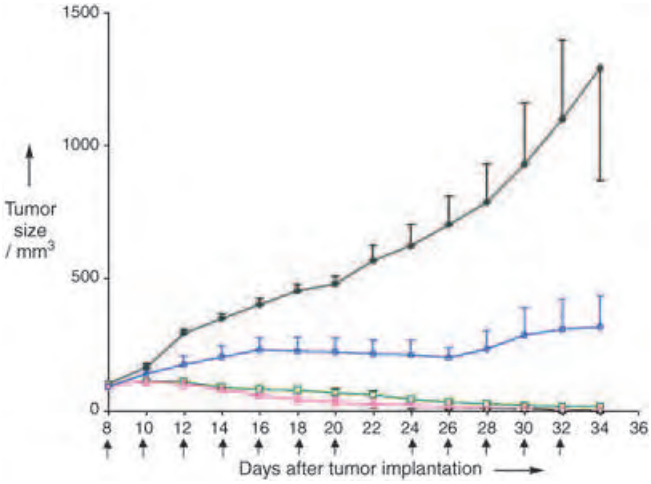

Figure 5. Therapeutic effects against the taxol-resistant human T-cell lymphoblastic leukemia CCRF-CEM/taxol xenograft by fludelone and taxol. Tumor tissue of CCRF-CEM/taxol (44-fold resistant in vitro), 50 mg/mouse was implanted s.c. into nude mice on day 0. Treatment (6-h i.v. infusion) started on D8 with fludelone (15 mg kg^{-1}, □, $n=3$ and 30 mg kg^{-1}, △, $n=4$) or taxol (20 mg kg^{-1}, ○, $n=4$), Q2Dx7 (D8 to D20), D22 dose was skipped, and then treatment was resumed Q2Dx5 on D24, D26, D28, D30, and D32, as indicated by arrows. The control group (●, $n=4$) received the vehicle only. With fludelone at a dose of 15 mg kg^{-1}, the tumor of 1/3 mice disappeared on D37, and at a dose of 30 mg kg^{-1} the tumors of 3/4 mice disappeared on D22, D22, and D32.

whereas the treatment of human colon carcinoma (HCT-116, Figure 6) with fludelone by 6-h i.v. infusion can lead to a complete "cure". The experiments with human-mammary-carcinoma (MX-1) and human-colon-carcinoma (HCT-116) xenografts in nude mice lasted 6.0 and 6.6 months, respectively. There was no tumor relapse in either experiment during 4.3 and 5.3 months, respectively, following the cessation of treatment. For the HCT-116 experiment, taxol and fludelone were used at 20 mg kg^{-1} and both caused tumor disappearance. However, the taxol-treated group relapsed 1.1 months after treatment was discontinued, whereas the animals treated with fludelone were tumor free for over 5.3 months.

These results are based on a particularly long and thorough therapeutic study with xenografts and demonstrate the longest periods of complete remission that have been

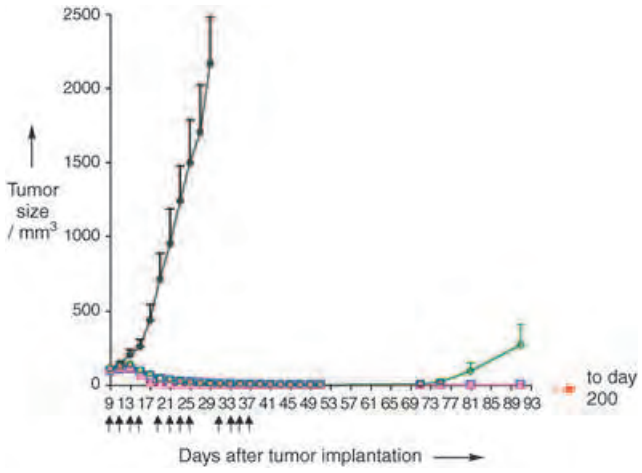

Figure 6. Therapeutic effects against the human colon carcinoma HCT-116 xenograft by fludelone and taxol. HCT-116 tumor tissue (50 mg/mouse) was implanted s.c. into nude mice on day 0. Treatment (Q2Dx4, 6-h i.v. infusion) was carried out for three cycles on D9, D11, D13, D15; D19, D21, D23, D25; and D31, D34, D35, D37 with fludelone (20 mg kg^{-1}, □ and 30 mg kg^{-1}, △), and taxol (20 mg kg^{-1}, ○); control: ●; $n = 4$ in each group. Complete tumor disappearance in all mice occurred (on D33, D35, D41, D45 for fludelone (20 mg kg^{-1}), on D21, D23, D33, D41 for fludelone (30 mg kg^{-1}), and on D33, D33, D41, D45 for taxol (20 mg kg^{-1})). There was no tumor relapse observed in either fludelone-treated group on D200. However, the group treated with taxol (○) suffered relapses on D71, D75, D81, and D81, which correspond to the 34th, 38th, 41st, and 41st day after stopping treatment.

reported either with parenteral or oral administration of a single antitumor agent. It is relatively common to find compounds that suppress tumor growth. It is rarer to find a drug candidate that causes tumor shrinkage, and particularly rare for a compound to shrink the tumor to the point of nondetectability. The dramatic finding regarding fludelone is that tumors did not relapse during observation for 4.3 months or longer (i.e. $>20\%$ of a typical mouse lifespan). This type of result has very few counterparts in the literature.[45] The achievement of complete tumor disappearance and long-term remission by oral treatment could well be of particular significance, as it could lead to outpatient home usage. Furthermore, the use for drug delivery of cremophor vehicles, which can themselves lead to severe allergic reactions, could be avoided.

It is important to keep in mind that the ultimate purpose of chemotherapeutic research is to provide clinically valuable treatment for cancer patients. Although the results of the xenograft studies discussed herein are certainly very encouraging, it remains to be seen whether these dramatic findings will translate to human patients. Thus, only progression to clinical trials will fully establish the value of these novel, later-generation epothilones as effective anticancer agents. However, we are prepared to predict that the dramatic preclinical performance of the 9,10-dehydro-dEpoB epothilones will spur much research in synthesis, compound optimization, and biotarget identification.

5. Concluding Remarks

We conclude our documentary of retrospection with some thoughts of a more general nature. With continuing advances in the technology of isolation, purification, and characterization, the number of natural products available in the future for screening could increase dramatically. This expansion in the reservoir could certainly lead to a substantial increase in lead structures for drug discovery. The ongoing study of the epothilones serves to underscore the value of target-directed total synthesis in the quest for new substances of material clinical benefit.

This point is well worth making in the current research environment, which favors recourse to massive numbers of compounds for screening in preference to smaller numbers of hypothesis-driven candidate structures based on natural product leads. Although we readily concur that it is not inconceivable that purely chance-driven diversity collections may give rise to successful drug candidates, we would assert that the wisdom inherent in natural products, now augmented by the growing field of chemical synthesis, represents a valuable resource that has been little appreciated of late.[46] In essence, we are suggesting that in the drug discovery process there are two directions that can be taken. One possibility is to hurl a mind-boggling number of compounds at a problem. There is certainly merit in this approach. For reasons of personal taste, we prefer to make fewer compounds by tapping the generous hints provided by nature and exploiting the resources of human creativity and improvisation. This lesson may in itself prove to be a valuable fringe benefit of the journey which led us to fludelone.

Protein Recognition

Recognition of Proline-Rich Motifs by Protein–Protein-Interaction Domains

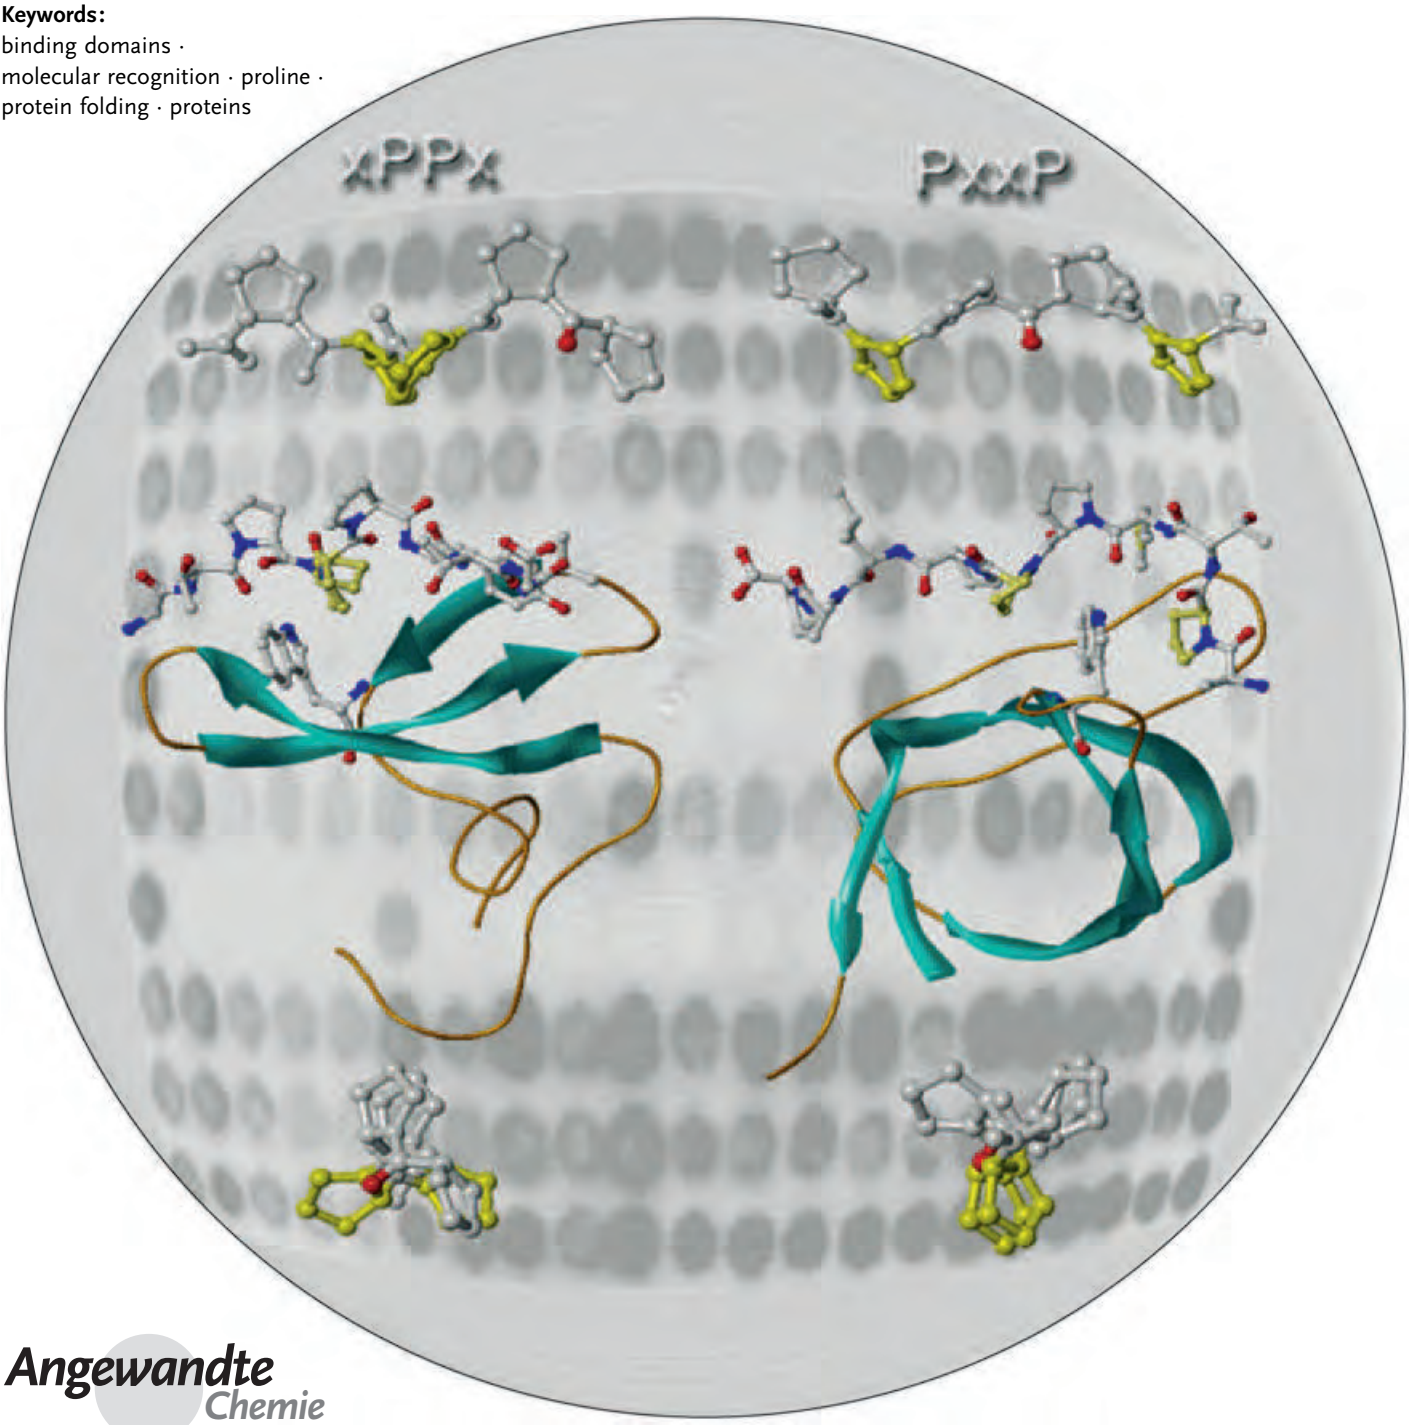
binding domains · molecular recognition · proline · protein folding · proteins



DOI: 10.1002/anie.200400618

Protein–protein interactions are essential in every aspect of cellular activity. Multiprotein complexes form and dissociate constantly in a specifically tuned manner, often by conserved mechanisms. Protein domains that bind proline-rich motifs (PRMs) are frequently involved in signaling events. The unique properties of proline provide a mechanism for highly discriminatory recognition without requiring high affinities. We present herein a detailed, quantitative assessment of the structural features that define the interfaces between PRM-binding domains and their target PRMs, and investigate the specificity of PRM recognition. Together with the analysis of peptide-library screens, this approach has allowed the identification of several highly conserved key interactions found in all complexes of PRM-binding domains. The inhibition of protein–protein interactions by using small-molecule agents is very challenging. Therefore, it is important to first pinpoint the critical interactions that must be considered in the design of inhibitors of PRM-binding domains.

From the Contents

1. Introduction

Modular proteins involved in signal transduction utilize highly conserved noncatalytic adaptor domains to mediate protein–protein interactions during the formation of multiprotein signaling complexes. These interactions must fulfill certain requirements: First, accurate recognition of the binding partner is required to guarantee a highly specific interaction. Second, the interaction must be readily reversible to allow complexes to dissociate again as soon as a stimulus is removed, thus requiring affinities in the micromolar to nanomolar range.

A number of different families of protein–protein-interaction domains have been described to date (for reviews, see references [1–6]). In many cases, the domains recognize target core motifs containing phosphorylated residues. Well-known examples are the Src-homology 2 (SH2) domains and the phosphotyrosine-binding (PTB) domains, which bind core sequence motifs containing phosphorylated tyrosine residues.[7–9] The Forkhead-associated (FHA) domains found in a variety of signaling proteins bind phosphoserine- and phosphothreonine-containing peptides. It was suggested that FHA domains may act as SH2 equivalents in phosphoserine- and phosphothreonine-dependent signaling pathways.[10] Members of the 14-3-3 family of proteins and class IV WW domains also bind phosphoserine and phosphothreonine, thus revealing interesting and unexpected similarities between these families.[10–12] Another well-known family of protein-interaction domains is the postsynaptic density/disc large/ZO1 (PDZ) family, which recognize and bind the extreme C-terminal sequences of their binding partners.[7] Furthermore, several domain families are known that recognize peptides containing proline-rich motifs (PRMs). These PRM-binding domains, which form the focus of this Review, are highly abundant and particularly interesting in the context of multicomponent signaling events.

1.1. Recognition of Proline-Rich Motifs by PRM-Binding Modules

Six distinct families of PRM-binding modules are currently known: the Src-homology 3 (SH3) domains,[13,14] the WW domains,[15,16] the EVH1 domains,[17–19] the GYF domains (also known as CD2-binding domains),[20,21] the UEV domains,[22,23] and the single-domain profilin proteins.[24,25] All interact with their target PRMs with K_d values typically in the range of 1 to 500 μM and rely on interactions with core-flanking epitopes to achieve the necessary specificities. The high-resolution structures of representative members from each family of PRM-binding domains known to date are shown in Figure 1. The N and C termini of the domains are generally located relatively close together, thus allowing the domains to slot into their respective host proteins with minimal disruption of the overall protein structure, while the domains themselves are exposed and accessible to recruit target proteins. Highly conserved clusters of exposed aromatic residues, sometimes referred to as "aromatic cradles",[26] are a characteristic of all PRM-binding domains and are necessary for the recognition of specific PRMs (see Figure 1). The relative orientation of the aromatic side chains of these clusters and the distances between the side chains determine the specificity of PRM recognition.

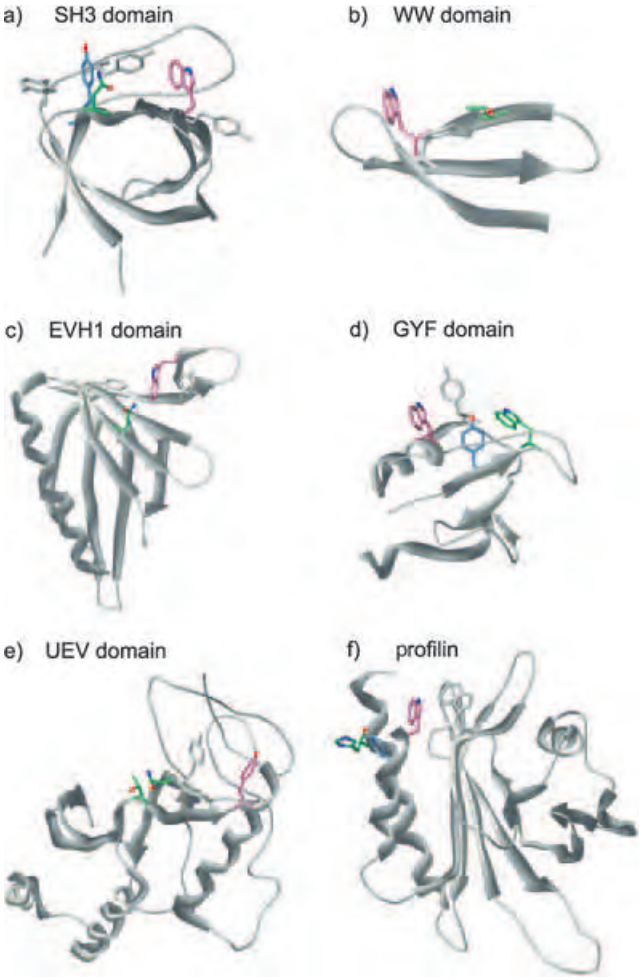

Figure 1. Three-dimensional structures of representative examples of each of the known families of PRM-binding domains in complexes with PRM-containing peptides: a) SH3 domain of human Fyn tyrosine kinase (1fyn); b) WW domain of human dystrophin (1eg4); c) EVH1 domain of mouse Evl (1qc6); d) GYF domain of human CD2BP2 (1l2z); (e) UEV domain of human Tsg101 (1m4p); f) profilin from human platelets (1cjf). The figure shows the overall folds of the domains and the location of the peptide-binding site comprising the exposed, aromatic clusters. The peptide ligand docks onto this site by packing proline rings into the hydrophobic cavities surrounding the Trp (pink) and Tyr (blue) side chains. Residues of the binding site indicated in green form additional hydrogen bonds to the peptide.

PRM-binding domains recognize specific 3–6-residue proline-containing sequences comprising so-called "core motifs" within accessible target peptides of 5–10 amino acids in length in the binding partner. These core motifs are often recognized by several members of a family of domains. Within a domain family, the affinity and specificity of a particular domain for a given target peptide is further modulated by additional, highly localized interactions between the core-flanking epitopes of the peptide and exposed side chains on the domain surface (known as epsilon determinants[27]). The core-flanking epitopes can consist of single amino acid residues, small groups of residues, post-translationally modified residues, or combinations of those residue types, and can be located either N or C terminally to the core motif (Fn and Fc, respectively[27]). Depending on the binding energies contributed by these additional interactions, domains of a given family will show different preferences for a certain core motif. Conversely, a single domain can recognize a number of different peptides with binding affinities within a certain range. This ligand degeneracy enables many signaling proteins to perform multiple or overlapping functions.

This Review examines in detail the specific structural requirements for PRM recognition by each of the six different families of PRM-binding domains. The preferences of these families for distinct core motifs are discussed in the light of the high-resolution NMR spectroscopic and X-ray crystal structures now available for a large number of these domains and their complexes with peptide ligands. The derivation of consensus binding motifs within target peptides by peptide-library screening, in particular by using the SPOTs synthesis technique,[28–32] is also discussed. By combining the available structural and binding data, we have identified a number of general features common to all known PRM-binding domains and their complexes. The presence of these structural features in other proteins could be a useful indicator of PRM-binding activity and may aid the search for possible binding partners. Furthermore, this information could provide new clues about the function of these proteins.

1.2. Proline Conservation in PRMs and the PPII Helix

The proline-rich target peptides recognized in signaling events generally contain several consecutive proline residues,

Linda J. Ball studied chemistry at the University of Oxford (UK) and graduated with a PhD in biochemistry and structural biology from the University of Cambridge (UK) in 1997. She then carried out postdoctoral research as an EMBO Fellow on protein-structure determination in the research group of Prof. Oschkinat in the Department of NMR-Supported Structural Biology at the FMP Berlin (Germany). She now pursues independent research at this institute on the use of NMR spectroscopy to probe the structures and interactions of signaling domains and cytoskeletal regulatory proteins.

Ronald Kuehne studied biochemistry at the Martin-Luther-Universität Halle-Wittenberg (Germany), where he completed his PhD in biochemistry in 1980. Following a period in the research group for molecular modeling at the Institute of Drug Research, he is now head of the research group for molecular modeling/ligand design at the FMP. His research is focused on modeling protein–ligand interactions by using molecular-dynamics simulations and automated docking procedures.

some of which are absolutely necessary for binding, while others appear to be less important. The patterns of proline conservation observed can be largely explained in terms of the secondary structure adopted by poly-L-proline in aqueous solution. The conformational restriction of the torsion angles of the peptide backbone, $\Phi = -78°$ and $\Psi = +146°$, results in an extended structure known as the left-handed polyproline II (PPII) helix.[33–36] This structure, shown in Figure 2a, has pseudo C_3 rotational symmetry about the helical axis with exactly three residues per turn. It is therefore not surprising that the majority of proline-rich target sequences found in nature repeat with a periodicity of three (e.g. PxxPxxP or PPxPPxPP). The PPII structure thus forms a unique recognition motif with the proline side chains and carbonyl groups of the peptide backbone exposed to the solvent at regular intervals. The absence of intramolecular hydrogen bonding in the PPII helix (as a result of the absence of a backbone amide functionality in proline) leaves the backbone carbonyl groups freely available to undergo intermolecular hydrogen-bond formation with the PRM domains. Furthermore, the carbonyl group of proline is more electron-rich than those of all other natural amino acids,[33,37,38] thus making proline a very good hydrogen-bond acceptor. The PPII structure also possesses a second, C_2 rotational pseudosymmetry axis perpendicular to the long axis of the helix. A rotation of 180° about this axis leaves the peptide backbone and the side chains in approximately the same position (see Figure 2b). This property leads to the possibility of binding in two orientations (often termed forward and reverse), in which the same recognition elements of the peptide are used, as well as the same hydrogen-bond donors of the side chains and hydrophobic clefts of the domain. For SH3 domains, WW domains, and profilins, both forward and reverse ligand binding have been reported. Nevertheless, different classes of domains within a given PRM-binding family generally show distinct preferences for either N–C- or C–N-oriented peptides.

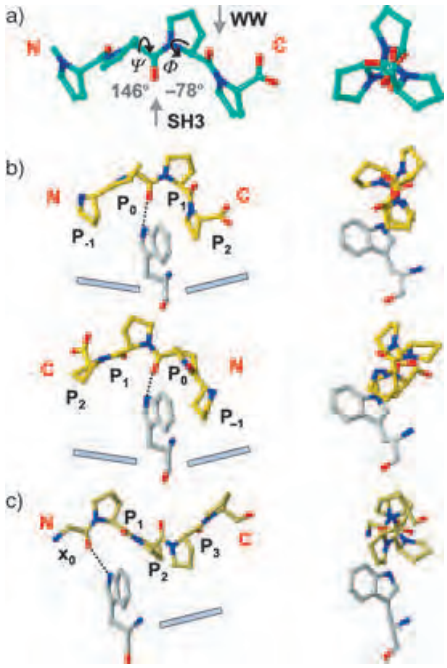

Figure 2. a) Left-handed polyproline II (PPII) helix, side on and in cross section to show the perpendicular C_2 and C_3 rotational pseudosymmetries. b) Binding mode 1 (SH3 and EVH1 domains, and profilin). The peptide forms an umbrella-like structure around the exposed hydrogen-bond-donating aromatic side chain (Trp or Tyr) of the domain. The same hydrogen-bond donors are utilized regardless of peptide orientation. c) Binding mode 2 (WW, GYF, and UEV domains). The domain binds to the opposite side of the PPII peptide. Gray bars give an idea of the rough shape of the binding pocket formed by aromatic side chains surrounding the PRM-recognition cluster of the domain.

The PRM-binding domains may approach the peptides from opposite sides, as indicated by the arrows in Figure 2a. In the case of profilin, the first and fourth proline residues in the peptide sequence (P_{-1} and P_2 in Figure 2b) are oriented toward the domain as a result of the C_3 pseudosymmetry of the PPII structure. The Cβ, Cγ, and Cδ atoms are in close contact with the domain, thus leading to the general conservation pattern PxxP in the profilin ligands. In the second binding mode, observed, for example, with the WW domains, two adjacent proline residues pack into a hydrophobic groove (Figure 2c). In this case, the Cβ atom of P_1 and the Cδ atom of P_2 are the most critical recognition elements within the peptide and make the closest contact with the domain. Some variation is possible in the first position of the dipeptide unit (as all amino acids except glycine have a Cβ atom), but the second position must be occupied exclusively by a proline residue, as only proline has Cδ substitution at the amide nitrogen atom. Thus, the conservation pattern xP

Jens Schneider-Mergener studied chemistry in Bielefeld and München (Germany) and completed his PhD in biochemistry at the Ludwig-Maximilians-Universität München in 1986. After postdoctoral research from 1987 to 1990 at the California Institute of Technology (USA), he became a group leader at the medical faculty Charité of the Humboldt-Universität zu Berlin in 1991, and was appointed associate professor there in 1999. His research focuses on the role of peptides in biomedical research. He also founded the company Jerini AG, which pioneers peptide-based drug discovery and development.

Hartmut Oschkinat studied chemistry at the University of Frankfurt (Germany), where he completed his PhD in 1986. After postdoctoral research with Prof. Bodenhausen at the University of Lausanne (Switzerland), he was an NMR spectroscopist at the Max-Planck-Institut für Biochemie in Martinsried (Germany). In 1992, he completed his habilitation in biophysical chemistry at the Technische Universität München and moved to the EMBL in Heidelberg. Since 1998 he has been Head of the Department of NMR-Supported Structural Biology at the FMP and Professor of Structural Chemistry at the Freie Universität Berlin.

results for the dipeptide unit, and this conserved motif packs into the so-called "xP"-binding groove of the domain.[39]

The favored mode of binding clearly determines the pattern of proline conservation in the ligand motif: either PxxP (mode 1) or xPPx (mode 2). Amino acids other than proline then complete the core motif to provide specificity for a given family and class of domain. With longer interfaces, that is, when the proline-rich sequences of the ligand are long enough (e.g. in the case of SH3 and profilin complexes), combinations of both binding modes described above are observed (see Figure 3).

A further advantage of interactions with peptides that have proline-rich segments is the low entropic cost of binding. As two well-defined, preformed surfaces come into contact when a PRM docks onto its binding site, the decrease in entropy upon binding is minimized. One of the main reasons for this effect is the low number of degrees of rotational freedom in proline residues along the peptide backbone relative to other amino acids. It has been estimated that each degree of rotational freedom in a dipeptide is equivalent to 3.5 kJ mol^{-1} at 300 K,[40] and since the dipeptide xP has only two, rather than the usual four degrees of rotational freedom about the backbone bonds, each occurrence of the motif xP leads to an increase in the ΔG value for complex formation by 7 kJ mol^{-1}.[40] The smaller drop in entropy on binding therefore affords complexes with PRM peptides a greater overall binding energy than complexes with more flexible peptides. The affinities of PRM interactions may also be increased by the occurrence of several PRMs in close multiple tandem repeats, for example in the proteins zyxin and ActA, which bind Ena/VASP EVH1 domains,[41,42] and for the cytoplasmic tail region of CD2, which is bound by GYF domains.[20]

Although proline usually dominates the composition of PPII helices, a number of other amino acids are often found flanking or interleaved with the proline residues. The presence of the amino acid Glu in and around PPII helices is very common, as the hydrogen-bonding pattern in polyglutamic acid promotes the formation of the PPII structure. Other amino acids often found in proline-rich peptides of four residues or more in length are Gln, Arg, Ala, Leu, Ser, Asp, and His.[43]

2. SH3 Domains

The Src-homology 3 (SH3) domains are small protein-interaction modules of about 60 residues (Figure 1a) found in a large number of eukaryotic cytoskeletal and signaling proteins.[44–46] The various functions of proteins that contain SH3 domains include the control of cell compartmentalization, the localization of proteins to cytoskeletal microfilaments and membrane ruffles, and the regulation of enzymatic activities.[1]

2.1. Classification of SH3 Domains and Target-Sequence Preference

SH3 domains generally bind proline-rich sequences containing the characteristic PxxP motif (a more accurate description of the consensus sequence is PpϕP, in which p is usually a proline residue and ϕ is a hydrophobic residue (usually Leu, Pro, or Val)[27]). To date, SH3-domain classification has been based solely on whether a peptide ligand binds in a forward (N-to-C-terminal) or reverse (C-to-N-terminal) orientation. (The former is also referred to in the following as orientation 1, the latter as orientation 2.) SH3 domains of class 1 recognize sequences with a positive charge at their N terminus (consensus (R/K)xxPxxP), whereas SH3 domains of class II bind in the reverse orientation peptides containing a positively charged residue at their C terminus (consensus PxxPx(R/K); Table 1).[14,35,47] This broad classification scheme seems insufficient for such a large family of domains, and a more detailed classification is needed. To this end, comprehensive studies of peptide recognition by different SH3 domains, chosen from specificity classes identified by phage-display experiments, are currently underway to determine more-detailed ligand specificities of these domains.[112] The results of such studies will not only enable a more thorough classification of SH3 domains, but will also help to identify binding partners in the cell.

Table 1: Different binding domains for PRM-containing peptides.[a]

	Domain family and class	Example host protein	Consensus PRM
1.	SH3 domains		
	class I	Src, Yes, Abl, Grb2-A, Lyn, PI3K, Fyn,	(R/K)pϕPxϕP
	class II	Src, cortactin, p53BP2, PLCγ, Crk-A, Nck SH3-B, CAP SH3-C, amphiphysin	ψPpϕPϕ(R/K)
2.	WW domains		
	class I	BAG3, YAP65, Nedd-4, dystrophin	(L/P)Pp(Y/*po*Y)
	class II	FBP-11	PPLP p
	class III(a)	FE65	(p/ϕ)P(p/g)PPpR
	class III(b)	FBP21	(p/ϕ)PP(R/K)gPp
	class IV	Ess1, PIN1, Nedd-4	(*po*S/*po*T)P
	class V	PRP40-2	(p/ϕ)PPPPP
3.	EVH1 domains		
	class I	Ena, Mena, VASP, Evl	(D/E)FPxϕP
	class II	Homer-1a, Vesl-2	PPxx(F/Y)
4.	GYF domains	cytoplasmic tail of CD2	(R)xxPPgxR
5.	UEV domains	viral Gag protein	P(T/S)AP
6.	profilin	profilin (single-domain protein)	poly-L-proline

[a] ψ, ϕ, and x represent aliphatic, hydrophobic, and any amino acid residue, respectively; *po*S = phosphoserine, *po*T = phosphothreonine. Lower-case letters represent favored but not highly conserved residues. When more than two copies of a domain occur in a host protein, the one closest to the N terminus is labeled A.

2.2. The SH3/PRM Interface and Rationalization of Consensus SH3 Target Sequences

The high-resolution NMR spectroscopic and X-ray crystal structures now available for many different SH3 domains in complexes with proline-rich peptides[13,48–58] enable us to identify important, recurring features and to rationalize the consensus peptide sequences. Figure 3a,b shows detailed SH3/PRM interfaces for representative examples of ligand binding in the forward and reverse orientations. Two exposed aromatic side chains (Trp and Tyr) of the domain form hydrogen bonds to the carbonyl oxygen atoms of the peptide. The PPII conformation of the peptide ensures that the first and fourth proline residues of a PxxP target sequence pack efficiently into the hydrophobic pockets around the exposed Tyr residue of the domain. The most closely packed peptide residues are highlighted in yellow in Figure 3.

The PPII helix extends only over the peptide fragment from positions (0) to (6) in orientation 1 ($_0$MPPPLPP$_6$ in Figure 3a) and contains both of the two binding sites shown in Figure 2b,c. The exposed Trp residue is surrounded by a PxxxP motif that does not adopt a PPII helix structure. In this binding mode the ligand adopts a conformation that resembles a double umbrella, with the PPII-helix umbrella (PxxP) located around the central hydrogen-bonded Tyr residue (see Figure 2b). An alternatively shaped (PxxxP) umbrella surrounds the exposed, hydrogen-bonded Trp side chain. In orientation 2, the Trp

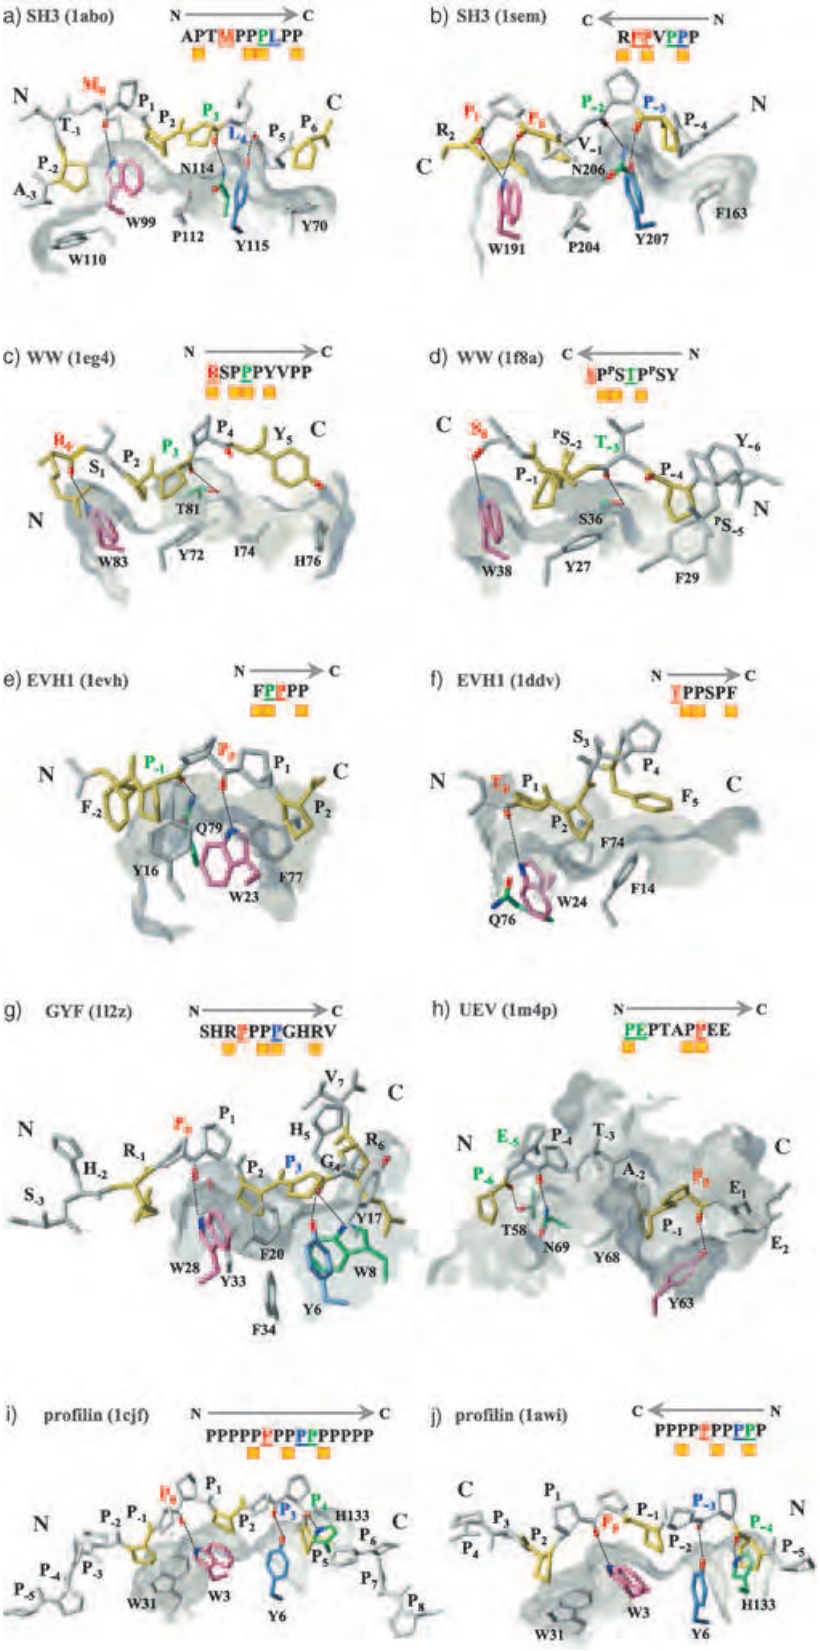

Figure 3. Detailed intermolecular interactions of representative members of each of the known PRM-binding families with their peptide ligands. Examples of both orientations of peptide binding: a), b) SH3 domain; c), d) WW domain; i) j) profilin. No reverse peptide orientation has yet been reported for the EVH1 domains, but two significantly different binding modes are known in which the peptide binds in the same orientation (e,f). g) ,h) Single binding modes known to date for the GYF and UEV domains. Pink: aromatic residue (hydrogen-bond donor) which forms the base of the primary stem of the "umbrella structure" (usually Trp, but Tyr in the UEV domain); blue: aromatic residue (hydrogen-bond donor) which forms the base of the second stem in the "double umbrella" (Tyr); green: more variable hydrogen-bond donor (Asn, Thr, Ser, Gln, or His); yellow: ligand side chains which make close hydrophobic contacts with the domain. The ligand sequence is shown above each complex with hydrogen-bond-acceptor residues underlined (red: hydrogen bond to Trp/Tyr, primary stem; blue: hydrogen bond to Tyr, second stem; green: hydrogen bond to more variable residue). Color coding of ligands corresponds to that in Tables 2–7. Yellow boxes: positions in close contact with the domain. The primary hydrogen-bond-acceptor residue in the ligand is assigned the number zero. Only those peptide residues that were detected in the three-dimensional X-ray crystal or NMR spectroscopic structures are shown. The full-length peptides in all of the complexes analyzed are given in the PDB codes (in brackets).

residue is instead surrounded by an RxP motif (Figure 3b). In both orientations, the Tyr and Trp hydrogen bonds are supported by a further hydrogen bond from an Asn side chain. The preference for a hydrophobic amino acid, not necessarily proline, at the less conserved, central position indicated by ϕ in the PpϕP motif, is explained by the side-on contacts this residue makes with the domain surface (see Figures 2 and 3). Substitution of one of the two most highly conserved proline residues by any other natural amino acid generally results in loss of binding. However, the replacement of one of these "essential" residues by an *N*-substituted amino acid can actually lead to increased binding affinities.[59] This observation could have important implications for the design of selective SH3 inhibitors.

2.3. Influence of "Core-Flanking" Ligand Residues

The two orientations of peptide binding are made possible by the symmetry of the PRMs, which allow the formation of very similar hydrogen-bonding networks in both orientations (Figure 2b). The hydrogen-bond acceptors are the carbonyl oxygen atoms of the peptide residues labeled in red, blue, or green in the sequence fragments in Figure 3. The corresponding hydrogen-bond-donating residues of the domain are colored similarly. Ligand orientation is determined by core-flanking interactions which do not involve proline residues and which can be either N terminal or C terminal to the core PRM. A positively charged residue next to the PRM usually forms a salt bridge with an appropriately positioned, oppositely charged residue on the domain surface. In cases of near-palindromic forward and reverse peptide sequences, binding is often observed in both orientations. The SH3 domain of Src, for example, binds both the peptide RPLPPLP and the "reverse" peptide PPVPPR (conserved proline residues are underlined).

2.4. Alternative Modes of Ligand Binding in SH3 Domains

In addition to the two orientations described above, several alternative SH3/PRM binding modes have also been described. For example, the peptide-binding groove of the SH3 domain recognizes a discontinuous epitope comprising nonsequential amino acid residues brought together by the tertiary structure of the binding partner. The SH3 domain of the p53-binding protein, p53BP2, interacts in this way with two segments of the L3 loop of p53.[60] The positions of the residues in the discontinuous binding epitope are determined by the overall structure of p53 and do not form a linear PRM core motif of the type discussed above.

A further discontinuous binding surface was identified for the SH3 domain of Csk. This domain binds a 25-residue peptide from the Pro/Glu/Ser/Thr-rich region (PEST region) of the PEP protein. To bind this peptide, the SH3 domain of Csk requires two separate interactions with the ligand: both the conventional PPII-helix recognition and additional interactions with two sequential hydrophobic residues (Ile and Val) located closer to the C terminus of the peptide.[58] NMR spectroscopic studies of the two interaction sites on the Csk SH3 domain showed them to have independent dynamics.[58]

In another unusual class of SH3–ligand binding interaction, the specificity for a particular target sequence can be modified by the dimerization of SH3 domains. The SH3 domain of Eps8, the receptor substrate of epidermal growth factor, forms intertwined dimers.[61] The dimer interface partially overlaps with the PxxP-binding site, so that in the dimeric form a new face is presented with altered ligand specificity. The intertwined SH3 dimer does not recognize the usual PxxP motif, but instead binds the new motif PxxDY.[62] SH3 domains may thus use multimerization as a mechanism to alter their binding specificity for particular partners in response to cellular requirements.

A number of intramolecular SH3-domain interactions have also been observed. The Src, Hck, and Abl proteins all contain multiple SH3 domains as well as SH2 and catalytic kinase domains. The SH3 domains interact with a linker region between the SH2 and catalytic kinase domains to hold them in a catalytically inactive conformation.[63–68] In another example, an SH3 domain of Itk, the cellular oncogene product, binds to an intramolecular KPLPPTP sequence.[69] Such interactions with intramolecular PRMs clearly play important roles in the regulation of eukaryotic signal transduction and cytoskeletal events.

Several SH3 interactions with sequences that are not proline-rich have also been reported. The C-terminal SH3 domain of the Gads T-cell adaptor protein binds a peptide from SLP-76 that contains an RxxK consensus sequence.[70] In this complex, the peptide adopts a right-handed helical conformation very different to the left-handed PPII helices observed for proline-rich peptides. Further examples include the recognition of a RKxxYxxY consensus by a number of class I SH3 domains.[47] Unlike for the majority of class I interactions, for which either an Arg or a Lys residue is required, in this case both positively charged residues are required for SH3 binding.

3. WW Domains

The WW domain is a protein module composed of 34–40 amino acids found in a number of signaling and regulatory proteins (Figure 1b).[71–73] Two highly conserved tryptophan residues give the domain its name. One of these residues is essential for folding, and the other is exposed on the protein surface. The latter forms part of an exposed hydrophobic cluster in which the side chains of a Trp/Tyr combination form an angle of approximately 90° which defines the shape of the proline-binding cavity.[16,26] In the WW domain of YAP65, the human Yes-kinase-associated protein, the whole cluster comprises Trp39, Tyr28, and Leu30.

3.1. Classification of WW Domains and Target-Sequence Preference

The results of many peptide-binding studies and substitution screens have allowed the identification of consensus

binding sequences for a large number of WW domains. The five known classes of WW domains are categorized according to ligand preference[74–76] and summarized in Table 1. Class I WW domains, such as that of YAP65, recognize an (L/P)Pp(Y/*po*Y) motif[77,78] (in which *po* represents a phosphorylated residue[27]). It has been proposed that tyrosine phosphorylation regulates the activity of these domains, although many domains have been observed to bind phosphorylated sequences with only slightly reduced affinities.[79] The second class of WW domains binds specifically to a PPLPp motif. An example of this class is the WW domain of the formin-binding protein FBP-11. The third class binds Pro-Arg-rich motifs. These domains can be further separated into two independent subclasses that recognize sequences of the type (p/ϕ)P(p/g)PPpR and (P/ϕ)PP(R/K)gpPp,[76,80] which are bound, for example, by the WW domains of FE65 and FBP21, respectively. Members of the fourth class of WW domains, such as the PIN1 WW domain, bind motifs (*po*S/*po*T)P in which proline residues are preceded by phosphorylated serine or threonine residues.[11,12,76] Finally, a fifth class, which includes the two tandemly repeated N-terminal WW domains of the yeast PRP40 protein, binds uninterrupted polyproline sequences of the type (p/ϕ)PPPPP, in which the first residue of the sequence must be hydrophobic.[76] Interestingly, both PRP40 WW domains also recognize class 1 and class 2 binding motifs.[81] It has been suggested that these tandemly repeated domains could participate in bridging interactions by binding simultaneously to PRMs in separate binding partners, thereby holding together complex interaction networks.[81]

Although different classes of WW domains show preferences for specific ligand PRMs, a considerable degree of ligand degeneracy is observed, as is illustrated by the results of peptide-library screening by the SPOTs technique and peptide-binding studies. Figure 4a shows the preferred amino acid sequences of the class I human YAP65 WW domain when screened for binding against six doubly substituted variants of the known PPPY binding motif.[113] In this experiment, residues at each of the variable positions within the PPPY motif were substituted simultaneously for all other 19 amino acids in two-dimensional grids. It was found that the YAP65 WW domain binds strongly only to motifs containing Tyr in the last position and either Pro or Leu in the first position of the sequence, thus confirming the consensus motif (L/P)PxY. Significantly weaker interactions were detected with motif sequences containing Arg or Tyr in the first position (e.g. YRPY, RRPY, RPRY, YPRY). If the first (Pro) and last (Tyr) positions are retained, Lys or Ala can also occur in position (3), thus confirming the PPxY consensus (see also Figure 3c). Figure 4b shows the effect of the substitution of a single amino acid within a longer, PPPY-containing YAP65 ligand of the sequence GTPPPPYTVG by all natural amino acids.[16,82] The minimal binding motif PPPY was obtained by shortening the peptide systematically from the N and C termini (Figure 4c).[82] Interestingly, very little tolerance toward the exchange of individual amino acids in the peptide

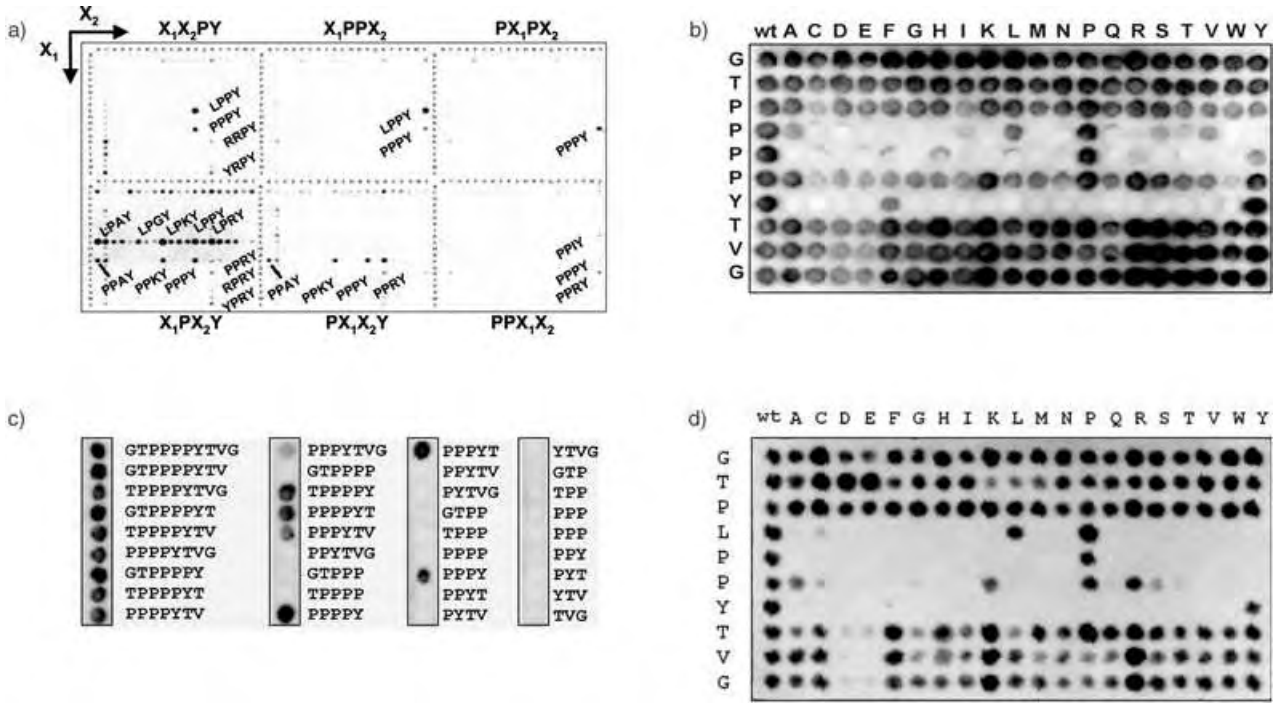

Figure 4. a) Double amino acid substitution analysis of the PPPY binding motif of class 1 WW domains (shown for the WW domain of human YAP65). All possible combinations of doubly substituted variants of this motif were synthesized on six two-dimensional grids. The different pairs of simultaneously substituted amino acids X_1 and X_2 are shown on the vertical and horizontal axes of each grid. b) Single amino acid substitution analysis of GTPPPPYTVG showing the most-conserved residues; wt = wild type. c) Minimization of the binding epitope; the minimal binding motif is PPPY. d) Single-substitution analysis of GTPLPPYTVG; similar overall conservation as in (b), with generally weaker overall binding to the WW domain.

core sequence was observed for GTPLPPYTVG (Figure 4d), probably as a result of the weaker interaction of the peptide with the domain when L replaces P in the (L/P)PxY motif. The absolute requirement for the second proline residue in the (L/P)PxY motif is clear from Figure 4. This residue appears to be a prerequisite for the correct docking of the PPII helix onto the hydrophobic peptide-binding groove of the class I WW domain.

In a "reverse substitution" experiment,[83] each of the 47 residues of the entire human YAP65 WW domain were substituted in turn (Figure 5). This experiment allowed the identification of the critical residues of the WW domain that are needed for both fold stabilization and ligand-binding activity (in this case to the 13-mer EYPPYPPPPYPSG[84]). High levels of conservation in residues of the protein core most likely indicate the involvement of those residues in folding, but high conservation in known surface-exposed residues suggests strongly that these residues are important for ligand interactions and hence protein function. In a more recent study, which combined the SPOTs synthesis technique with native-peptide ligation, many thousands of variants of the human YAP65 WW domain were created on cellulose membranes for the systematic study of three simultaneous substitutions (at positions L30, H32, and Q35).[31] Although GTPPPPYTVG and EYPPYPPPPYPSG peptides are known to bind the human YAP65 WW domain in vitro, the biological relevance of these complexes within the cell is still unclear.

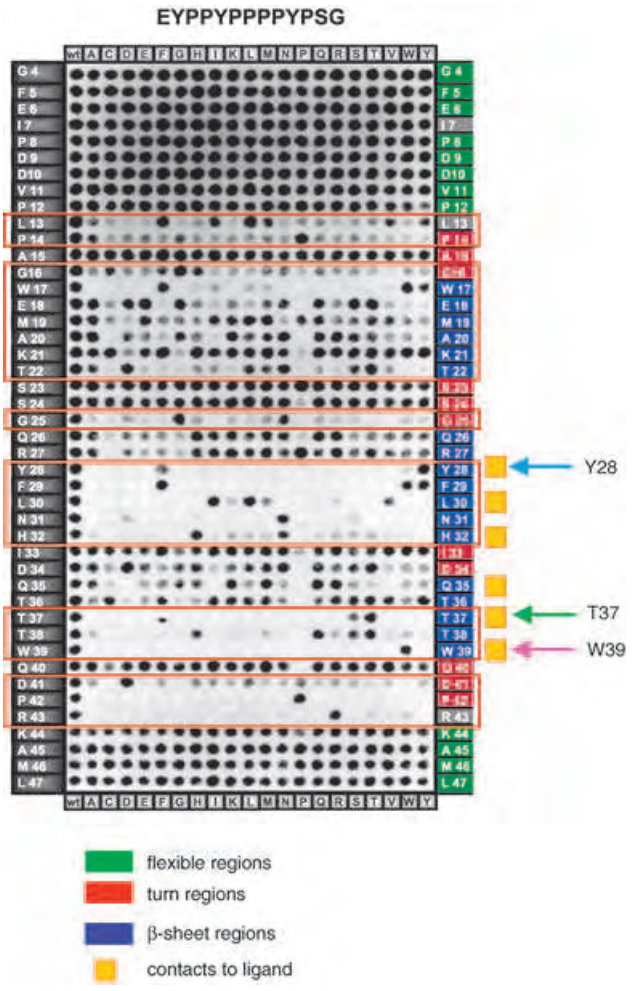

Figure 5. "Reverse" SPOTs scan in which all 42 amino acids of the WW domain of YAP65 were substituted while keeping the peptide sequence of the ligand constant (EYPPYPPPPYPSG; reprinted with the permission of Toepert et al.[83]). Red boxes: important regions of the WW domain for peptide binding. These include regions of secondary structure necessary for maintaining the WW fold and surface-exposed residues required specifically for ligand binding. The amino acid residues of the aromatic cluster are very highly conserved. In contrast, the flexible regions (green) are unimportant for peptide binding.

3.2. The WW/PRM Interface and Structural Rationalization of Consensus Target Sequences of the WW Domain

Inspection of the high-resolution structures of complexes of WW domains with proline-rich peptides[12,26,82,85] allows rationalization of the preferred core motifs of the ligand. The peptide is approached by the WW domain from the opposite side—compared to SH3–peptide complexes—of the PPII helix (see Figure 2), thus resulting in the close packing of two consecutive proline rings (highlighted in yellow) into the hydrophobic groove of the WW domain (Figure 3c,d). For example, the class I WW domain of dystrophin[26] binds a PPPY motif (Figure 3c), whereby the two underlined proline residues pack into the hydrophobic groove between Tyr72 and Trp83. Furthermore, the close packing of the peptide Tyr residue (PPPY) into another hydrophobic groove, on the other side of the Tyr72 side chain, explains the conservation of this peptide core residue. The substitution of this Tyr residue for Phe (PPPF) attenuated binding to the YAP65 WW domain by a factor of three.[16] This result implies the loss of a hydrogen bond and/or less-efficient packing of the aryl residue in the second hydrophobic groove.

The ligand in the WW complex shows only one half of the umbrella-like structure observed in SH3/PRM interactions (see Figure 2c). Again, the exposed Trp side chain forms a central hydrogen bond to a carbonyl oxygen atom of the ligand (position (0)) at the stem of this structure. A further hydrogen bond from the side chain of either a Thr or a Ser residue of the domain to the carbonyl oxygen atom at position (3) of the ligand depends on the orientation of the ligand (Thr in orientation 1, Ser in orientation 2; see Figure 3c,d and Tables 2–7). The same hydrogen-bond-donating side chains of the domain are used for each of the two possible peptide orientations. The hydrogen-bond-acceptor residues of the ligand (shown in red, green, and blue in Figure 3c,d) are also arranged similarly in both orientations.

3.3. The Significance of Non-proline Residues in the PRM

The orientation of ligand binding by WW domains is determined by non-proline residues within the core PRM, such as the Tyr residue at the C-terminal end of PRMs that bind specifically to WW domains of class I. In contrast to the ligands of SH3 and EVH1 domains, the PRM core residues of WW ligands are alone important for binding affinity and specificity determination; thus, these ligands contain a very

Table 2: SH3 domains with peptides in orientations 1 and 2.[a],[b]

[a] Quantitative comparison of important conserved hydrogen bonds and important conserved angles between planar residues on the domain and in the ligand found in interactions with PRMs. Yellow boxes: Ligand side chains which pack closely into the domain surface. Potential hydrogen-bond donors are underlined and colored red for Trp, blue for Tyr, and green for other hydrogen-bond donors. Ligand-residue numbering begins with (0) for the first hydrogen-bond to Trp/Tyr (see Figure 3). Residues N terminal to (0): gray background, negative number; residues C terminal to (0): white background, positive number. Only the peptide residues detected in the experimental structures are numbered. In cases in which forward and reverse peptide orientation is known, the complexes are divided into two groups. The corresponding peptide sequences are then written from left to right either from N to C terminus or C to N terminus, respectively, to highlight patterns of conserved prolines. ψ, ϕ, and x represent aliphatic, hydrophobic, and any residue, respectively. Lower-case letters: favored residues which are not 100% conserved. [b] SH3 complexes with both forward and reverse ligand orientations; consensus binding sequences: (N)-$\underline{\psi}$p$\phi\underline{\text{Pp}}\phi$P-(C) (forward) and (C)-(R/K)$\underline{\text{pP}}\phi\underline{\text{pP}}$p-(N) reversed. ($\kappa$ and λ are nonpeptide elements described in the PDB files: 1nlo, 1nlp).

small recognition epitope. Even short peptides of the type Ac-PPPPY-NH_2 bind to WW domains with full affinity.[82] The singular importance of the PRM core residues is also clear from the high degree of tolerance toward the substitution of amino acids at all positions outside the core PRM (Figure 4). Structurally, these observations can be rationalized by the small size of the WW domain and the small surface available for ligand interactions. All affinity, specificity, and orientation determinants must therefore be encoded in a very short core amino acid sequence.

Table 4: EVH1 binding modes 1 and 2 with the same peptide orientation.[a],[b]

4. EVH1 Domains

The Ena/VASP homology 1 (EVH1) domains[86–89] are protein-interaction modules of about 115 residues in length (Figure 1c) found in a large number of multidomain signaling proteins. This group includes the Ena/VASP family of proteins, which modulate actin cytoskeleton dynamics, the Wiscott–Aldrich syndrome proteins (WASP), which regulates actin assembly downstream of Cdc42 and phosphatidylinositol-4,5-bisphosphate (PIP_2) signaling pathways, and the synaptic terminal protein families Homer and Vesl, which are thought to play a role in long-term potentiation in excitatory synapses.[90] The structures of the EVH1 domains of the VASP, Mena, Evl, Homer, and N-WASP proteins[42,91–94] show a high similarity to the structures of the pleckstrin homology (PH) and phosphotyrosine-binding (PTB) domains[95] despite a low degree of sequence similarity with these families.

4.1. Classification of EVH1 Domains on the Basis of PRM Consensus Sequences

Three classes of EVH1 domains have been identified so far on the basis of ligand preference[86] (Table 1). The first class comprises the Ena/VASP proteins, which recognize specifically the FPPPP sequences found in focal adhesion proteins, such as zyxin and vinculin. Closely spaced FPPPP repeats also occur in the ActA protein of the intracellular pathogen *Listeria monocytogenes*.[87,96] The EVH1 domains of

the Homer/Vesl family of postsynaptic-receptor-associated proteins form the second class. These proteins recognize the consensus target sequence PPxxF found in the metabotropic glutamate receptors (mGluRs), inisitol-1,4,5-triphosphate receptors (IP3Rs), ryanodine receptors (RyRs), and Shank proteins.[97,98] The third class comprises the WASP/N-WASP EVH1 domains. The N-WASP EVH1 domain is not known to bind any independent, short peptides, but does bind intramolecularly to a 25-residue peptide from the WASP-interacting protein (WIP) when this peptide is expressed together with the domain, fused to its N terminus by a linker five amino acids in length.[94]

Single-residue peptide-substitution experiments (SPOTs analyses) have identified the consensus PRM recognized by class I EVH1 domains as FPxϕP (in which ϕ is a hydrophobic residue[27]). Figure 6 shows the data for the substitution

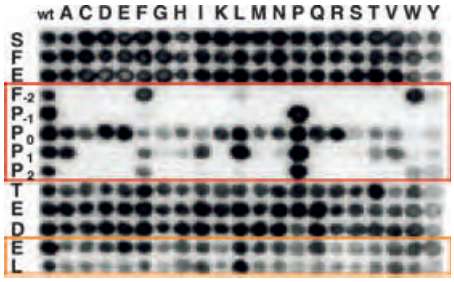

Figure 6. Single amino acid substitution analysis of the EVH1-domain-binding peptide SFEFPPPPTEDEL from the ActA protein of *Listeria monocytogenes*. The figure shows the class 1 EVH1 domain from the human VASP protein.[42] Red box: conserved target PRM; orange box: additional ActA-affinity-increasing epitope.

analysis with a ligand of the EVH1 domain of the human VASP protein.[42] The peptide residue which participates in hydrogen-bond formation with the conserved Trp residue on the domain surface (corresponding to Trp 23 in VASP and Mena proteins) is defined as position (0). Proline residues in positions (-1) and (2) (FPPPP) are essential for binding to EVH1, whereas the proline residues in positions (0) and (1) (FPPPP) need not be conserved. Position (0) is largely nonspecific and can accommodate almost any other amino acid without loss of EVH1-binding ability, whereas position (1) must be occupied by a hydrophobic residue (Pro, Leu, Ala, Ile, or Val) for EVH1 binding to be maintained.[86] Proline residues are nonetheless often found at these central positions, probably because of the excellent hydrogen-bond-acceptor properties of this amino acid and because proline is ideally suited to induce a PPII helical structure in the ligand.

4.2. The EVH1/PRM Interface and Structural Rationalization of Consensus PRM Sequences for EVH1 Binding

The structures of the class I EVH1/PRM complexes[42,92,93] show that PRMs are recognized by clusters of three highly conserved aromatic residues on the surface of the domain (Figure 1c). In the Mena protein (see Figure 3e), this recognition triad comprises the residues Tyr 16, Trp 23, and Phe 77. In class I EVH1/PRM complexes the P_{-1} and P_2 residues of the FPPPP ligand pack into the hydrophobic binding pockets created by the side chains of Tyr 16 and Trp 23, and Trp 23 and Phe 77 (Mena numbering) of the EVH1 domain to form an umbrella-like structure (see Figure 2b), which is stabilized by a hydrogen bond from Trp 23 to P_0 (see Figure 3e).[42,92,93] The close hydrophobic contacts of P_{-1} and P_2 with the domain, and especially the coplanar contacts of the proline rings with the side chain of Trp 23, explain the conservation of these proline residues in the PRM consensus sequence. In contrast, P_0 makes no contact with the domain surface and P_1 makes only side-on contacts, thus resulting in the tolerance of many amino acid types in position (0) and the requirement for a hydrophobic residue at position (1) (Figure 6).

In the class II Homer proteins, Tyr 16 is replaced by Ile 16, thus altering the shape of the hydrophobic pocket which binds P_{-1} in the Mena complex. Additionally, Met 14 (Mena) is replaced by the aromatic residue Phe 14 (Homer). This substitution provides a new binding pocket for the side chains of P_1 and P_2 in the Homer peptide TPPxxF between the side chains of Phe 14, Trp 24, and Phe 74. The F_5 residue of the ligand forms a further close contact with the domain (Figure 3f). Thus, the ligand preferences of these different classes of EVH1 domains are determined by just a small number of amino acid substitutions in the PRM-recognition triad.[86]

A second hydrogen bond between Gln 79 (Mena numbering) of the domain and the carbonyl oxygen atom of P_{-1} is also present in class I EVH1 interactions. On the basis of the structural information gathered so far on EVH1–ligand complexes, it is tempting to predict that this second hydrogen bond should also be present in class II interactions. However, the peptide studied in the Homer 1a complex terminated at position (0) (Figure 3f) and therefore lacked a correctly positioned hydrogen-bond acceptor. This peptide would therefore need to be extended by at least one additional N-terminal amino acid to test this hypothesis.[86]

4.3. Peptide Orientation, Specificity, and the Role of PRM-Flanking Residues

To date, the binding of independent peptides to EVH1 domains has only been detected in one orientation. In class I (Ena/VASP) EVH1/PRM complexes, the PRM consists of a Phe residue followed by a short PPII helix (i.e. FPPPP). The Phe side chain packs into a specific groove in the domain,[42,93] thus determining the orientation of the ligand. The location of the Phe residue in the TPPSPF ligand of the class II (Homer 1a) EVH1 domain at the opposite (C-terminal) end of the PRM would seem to suggest a reverse binding mode for this peptide. However, the crystal structure of the complex showed that TPPSPF binds the Homer 1a EVH1 domain in the same orientation as FPPPP binds the Ena/VASP EVH1 domains.[91] The Phe residues are therefore in contact with different sites in the respective domains. In each case, this Phe residue determines the positioning or "register" of PRM binding to the EVH1 domain. Interestingly, the intramolec-

ular interaction of the N-WASP EVH1 domain with its N terminally fused WIP peptide occurs in the opposite orientation.[94] However, as this is not an intermolecular EVH1/PRM interaction, it is not discussed in detail herein.

The binding affinities of isolated core motifs for EVH1 domains range from very weak to undetectable.[42] Therefore, further interactions are needed to increase these affinities to biologically useful levels. Epitopes more distant from the PRM form additional hydrophobic, hydrogen-bonding, or electrostatic interactions. The affinity-increasing epitope of the ActA surface protein of *Listeria monocytogene*s comprises just two amino acids, EL, which are located C terminally to the FPPPP motif. This epitope interacts with a hydrophobic patch located in close proximity to the main peptide-binding groove on the surface of the EVH1 domain.

5. GYF Domains

The GYF domains, named after the conserved GYF motif in their primary sequences (also known as CD2-binding domains), are 86-residue protein modules (Figure 1d) which bind proline-rich sequences of the type PPPPGHR (Table 1). The GYF domain of the CD2-binding protein 2 (CD2BP2) binds the PPPPGHR-SQAPSHR-PPPPGHR tandem repeat[20] found in the cytoplasmic tail of the CD2 cell-surface receptor protein responsible for T-cell activation.[99] The three-dimensional solution structure of the unbound GYF domain from CD2BP2 revealed a novel fold for this family of domains, and residues important for binding to the CD2-tail peptide were identified by the analysis of the ^{1}H,^{15}N chemical shifts at increasing peptide concentration.[21] As seen in all other families of PRM-binding domains, a conserved, exposed aromatic cluster was found to be crucial for peptide binding.

5.1. The GYF/PRM Interface

The solution structure of the GYF domain in a complex with the peptide SHRPPPPGHRV shows this binding mode in more detail (Figure 3g).[100] The exposed cluster of aromatic residues that comprise the peptide binding site in the GYF domain extends over a larger area than the aromatic clusters of other PRM-binding domains. The three aromatic residues Phe20, Trp28, and Tyr33 form one half of the cluster (a subcluster) with a hydrogen bond between the ε-NH group of Trp28 and P_0 of the ligand as observed in WW domain interactions (Figure 2c). The side chains of R_{-1} and P_2 of the peptide pack into the hydrophobic grooves on either side of the Trp28 ring. Tyr6, Trp8, and Tyr17 form a second subcluster, in which Trp8 and Tyr6 both form hydrogen bonds to the carbonyl oxygen atom of the closely packed ligand residue P_3. Residues G_4 and R_6 make further close contacts with the surface of the domain. On the basis of the structure of the complex, we predict that the residues that make the closest contacts with the domain (highlighted in yellow in Figure 3g) should be the most highly conserved in the PRM and the most crucial for GYF recognition,[100] whereas the substitution of residues whose side chains are exposed to the solution with other amino acids should have a smaller effect on binding affinity. This reasoning leads to a predicted consensus PRM of (R)xxPPgxR for GYF domains.

6. UEV Domains

The UEV (ubiquitin E2 variant) domain is a 145-residue module (Figure 1e) found in the human Tsg101 protein (tumor susceptibility gene 101). The domain is recruited by the major structural proteins of the HIV and Ebola viruses to facilitate viral budding. In nonlytic viruses this interaction is essential for replication. The UEV domain binds specifically to P(T/S)AP peptide motifs in these binding partners with typical K_d values for PRM interactions[22,23] (Table 1).

6.1 The UEV/PRM Interface

The solution structure of the Tsg101 UEV domain in a complex with the peptide PEPTAPEE from the HIV-1_{NL4-3} $p6^{Gag}$ protein ($K_d = 3\ \mu M$)[22] is shown in Figure 3h. The exposed aromatic cluster of the UEV domain is generally quite similar to those of the other PRM-binding domains, but with the main difference that it lacks the Trp side chain present in all the other families. In the UEV domain, Tyr63 (colored pink in Figure 3h) forms the primary hydrogen bond to the peptide. The interface is most similar to that seen in WW interactions (see Figure 2c), and one would expect the two consecutive ligand residues P_{-1} and P_0, which are buried in a hydrophobic pocket on one side of Tyr63 of the domain, to be the most conserved residues of the UEV ligands. However, to date there are no data available for peptide substitution of UEV-binding peptides. The UEV–peptide interface is also characterized by further hydrogen bonds between the exposed Asn69 and Thr58 side chains (shown in green) and the carbonyl oxygen atoms of the peptide residues E_{-5} and P_{-6}, respectively. A potential bifurcated hydrogen bond involving the carbonyl oxygen atom of the peptide residue T_{-3} and side chains Ser143 and Arg144 of the UEV domain has also been proposed (not shown in Figure 3h).[22] No hydrogen bond is formed between Tyr68 (blue) and the ligand because of the orientation of the Tyr ring.

7. Profilins

Profilins are a family of small (12–15 kDa), ubiquitous proteins involved in the regulation of actin-filament assembly and actin polymerization. They differ from the other modules discussed herein in that they are independent, single-domain proteins rather than modules that are part of larger host proteins. Profilins are known to bind simultaneously to monomeric G-actin[101] and poly-L-proline (pLP)[25,102] (Table 1). They also bind phosphatidylinositol-4,5-bisphosphate (PIP_2), a component of the phosphatidylinositol cycle involved in cell signaling events. This interaction causes dissociation of the profilin/actin complex. The crystal structures of isoforms I and II of the profilin of *Acantha-*

moeba,[92,103,104] the plant profilin of *Arabidopsis thaliana* (a major human allergen),[105] and bovine profilin, both isolated[106] and in a complex with bovine actin,[25] have all been solved and were found to be highly similar.[105]

7.1 The Profilin/pLP Interface

The pLP-recognition site of profilin involves residues Trp3, Tyr6, Ile21, Gly23, Trp31, Ala33, Tyr133, (His133 in bovine profilin), and Leu134, as shown by X-ray and NMR spectroscopy,[107,108] mutagenesis,[109] and fluorescence-quenching experiments.[107,110]

Like SH3 and WW domains, profilins are known to bind their proline-rich ligands in either of two possible orientations (Figure 3i,j). In all crystal structures of profilin obtained to date, four aromatic side chains (Trp3, Tyr6, His133, and Trp31) are exposed in a cluster on the protein surface. In a similar manner to the cluster residues in SH3 domains, the side chains of the profilin cluster are ideally arranged to accommodate two turns of a PPII helix. The pLP ligand docks onto the profilin surface with every third proline residue packed closely into the pockets between the side chains of Trp3 and Tyr6, and Tyr6 and His133, to form a double-umbrella-like structure (Figure 3i,j). Conserved hydrogen bonds in profilin complexes are formed between the hydrogen-bond donors in Trp3 and Tyr6 and the carbonyl oxygen atoms of P_0 and P_3. These two hydrogen bonds form the stems of the "umbrellas". A further hydrogen bond exists between His133 and the carbonyl oxygen atom of P_4.

7.2. Peptide Orientation, Specificity, and Affinity in the Absence of PRM-Flanking Residues

As the ligands of profilins consist of long chains of consecutive proline residues (usually six or more in succession), the possibility of aromatic or hydrophobic side chains being used as anchors for defining the register of ligand binding is excluded. Hence, multiple profilin/pLP complexes may form, with "frame-shifted" binding of the pLP ligand in the peptide-binding groove, as observed in the X-ray crystal structure of the complex formed between human-platelet profilin (HPP) and a pLP decamer. In this case two distinct structures, HPP-A and HPP-B, were reported.[24] Additionally, since all side chains in pLP ligands are pyrrolidine rings, there can be no polar or electrostatic stabilizing interactions with the protein. Therefore, the complexes can only be stabilized and their binding affinity controlled by hydrogen bonds, hydrophobic interactions, and steric restrictions. The lack of non-proline, core-flanking residues, which in other PRMs modify specificity and binding affinity, explains the observation that all cellular profilins bind pLP with similar affinities,[24] and that profilins can bind the same ligand in both orientations.[111]

8. General Features of Protein Interactions with PRMs

Comparison of the different classes of PRM-binding interfaces reveals a number of general features that recur in PRM recognition:

1) All domains bind the PRMs of their respective ligands through a cluster of surface-exposed aromatic side chains, sometimes referred to as an "aromatic cradle". The distances and angles between the aromatic side chains define the shape of the proline-binding cavity.[16,26]
2) Binding of the ligand involves a conserved network of hydrogen bonds, and coplanar arrangements of proline residues and aromatic rings.
3) The register and orientation of the ligand are determined by non-proline residues located at one end of the core motif. These residues usually have a large side chain that acts as an "anchor". Typical examples are the Arg, Tyr, and Phe residues of certain classes of ligands of the SH3, WW, and EVH1 domains, respectively.
4) Additional epitopes which flank the core PRM serve to fine-tune the ligand-binding affinities.

8.1. Key Structural Characteristics of PRM-Recognition Sites

Recognition of PRMs is determined by the precise three-dimensional arrangement of the exposed aromatic side chains. The most important feature of the binding sites is the presence of hydrogen-bond-donor aromatic residues (Trp, Tyr) whose side chains are oriented perpendicular to the protein surface to allow for efficient hydrogen-bond formation with the oxygen atom of a carbonyl group in the peptide backbone of the ligand. These amino acid residues are directly flanked by other aromatic residues, whereby an angle of approximately 90° to the hydrogen-bond donor is formed (see Figure 1). The flanking aromatic side chains may be oriented either parallel or perpendicular to the protein surface, but in each case they form a hydrophobic, approximately right-angled cavity into which the proline side chains of the ligand pack efficiently.

8.2. Conserved Hydrogen-Bonding Networks and Recognition of Proline Rings

The PRM-containing peptides are recognized by their respective domains as PPII helices, and the domains may approach the peptides from either of two sides (see arrows in Figure 2a). In the binding mode observed for SH3, EVH1, and profilin (Figure 2b), the key hydrogen bond is formed between the aromatic side chain of Trp and a carbonyl oxygen atom of the ligand. This hydrogen bond forms the stem of an umbrella-like structure, and the proline residues pack against the aromatic ring of the hydrogen-bond donor (see Tables 2, 4, and 7). In the ideal case of a ligand with a true PPII helical structure (e.g. FPPPP), the hydrogen-bonded carbonyl group (in the underlined residue) is at the center of the four-proline-

residue motif. The two central proline residues do not interact with the protein surface and may be substituted for other residues, whereas the two outer proline residues are packed into the domain and are highly conserved. The proline rings are approximately coplanar with the aromatic ring of the key hydrogen-bond donor (see columns 4 and 5 in Tables 2, 4, and 7) and form head- or side-on hydrophobic contacts with the flanking aromatic side chains in the binding site (see Figure 3). The hydrogen bond is thus in a hydrophobic environment in which hydrophobic interactions and hydrogen bonding occur cooperatively. These interactions occur in both binding orientations, as highlighted in Figure 2b. In each case, P_{-1} and P_2 are approximately coplanar to the aromatic ring of the hydrogen-bond donor and make contacts with the other aromatic rings of the ligand-binding site through their Cβ, Cγ, and Cδ atoms. This binding mode recognizes sequences of the type PxxP, which form the umbrella around the aromatic residue of the domain; this aromatic residue forms the hydrogen bond to the carbonyl oxygen atom of x_0.

The second binding mode, observed in WW, GYF, and UEV domains, involves the binding of the PPII helix from the opposite side (Figure 2a,c) but relies essentially on the same structural features. An aromatic hydrogen-bond donor (usually Trp) is oriented perpendicular to the surface and forms a hydrogen bond to a carbonyl group in the peptide backbone. One proline residue of the ligand lies roughly coplanar to the aromatic ring (for angles and hydrogen bonds, see Tables 3, 5, and 6). This situation corresponds to one of the two halves (right or left) of the complexes shown in Figure 2b. However, in this binding mode, the peptide continues with another proline residue, which forms coplanar contacts with a second aromatic residue of the domain (Figure 3c). This aromatic side chain, which is approximately parallel to the protein surface and perpendicular to the critical Trp residue, does not form a hydrogen bond to the ligand. In this binding mode, contact is made between peptides with two sequential proline residues and a single hydrophobic binding pocket on one side of the hydrogen bond (the "xP" pocket) through the Cβ and Cδ atoms, respectively, of the peptide.[39] Examples are the PPxY and PPLP motifs of WW domains.

These general principles are illustrated for selected complexes of PRM-binding domains in Figure 3. In SH3 and profilin complexes, double-umbrella structures are generally observed in which two hydrogen bonds (from the Trp and Tyr side chains of the domain) form the stems of two individual umbrella-like structures. The exception is SH3 complexes in orientation 2, in which the Trp involved in hydrogen bonding is surrounded by a much shorter RxP sequence. The interfaces contain a further hydrogen bond from either an Asn or a His side chain of the domain. The essential difference between these complexes is that in complexes with SH3 domains (orientation 1) the ligand umbrellas are separate and only one is of the typical PPII helix geometry, whereas in profilin complexes, the pLP ligand forms two turns of an idealized PPII helix, with the proline residue being shared between the two umbrella stems. EVH1 domains bind PRMs in a similar way but use just a single hydrogen bond as the stem of the umbrella structure (Figure 3c). The PRM-binding mode of WW, GYF, and UEV domains (Figure 3c,d,g,h) differs from those described above in that the main hydrogen-bond-donating side chain (pink) is not surrounded by two coplanar proline rings, but instead one proline from the ligand packs in a coplanar manner on one side of the aromatic ring. Both PRM-binding modes recognize ligands in both forward and reverse orientations.

The importance of the coplanar interactions of the proline rings with the aromatic side chains that they surround can be substantiated in several ways. First, in peptide-substitution analyses (Figures 4 and 5), the coplanar proline residues (yellow in Figure 3) are shown consistently to be those that are essential for binding and confer specificity to the ligand. Second, these proline residues are highly conserved in the PRMs recognized by the respective domains. Tables 2–7 summarize the angles made between the most closely packed proline side chains of the ligands and the Trp and Tyr residues of the aromatic clusters in the different PRM-binding domains. Within any given family of PRM-binding domains, these angles are generally similar.

A key characteristic of PRM complexes is the conserved network of hydrogen bonds involving the exposed aromatic residues (see Figure 3). In most cases, further hydrogen bonds are formed from additional surface-exposed Asn, Thr, Ser, His, or Gln side chains (Tables 2–7; green residues in Figure 3) to the oxygen atoms of carbonyl groups in the peptide backbone. These additional interactions vary according to the class of PRM-binding domain and provide scope for ligand specificity within domain families (see Figure 3). The lengths of the hydrogen bonds from these residues are given in Tables 2–7 for all structures of PRM complexes deposited in the Protein Data Bank (PDB).

8.3. Position and Orientation of the Ligand: The Role of the Proline and "Anchoring" Residues in the Core Motif

As a result of its highly symmetrical structure, the PPII helix is able to bind a protein domain in either of two opposite orientations through contacts with the same hydrogen-bond donors and orthogonal aromatic rings, regardless of the peptide orientation. Furthermore, the repetitive nature of this structure allows the possibility of docking at a number of positions along a peptide-binding groove. The phenomenon of multiple binding orientations and multiple "frame-shifted" ligand positioning have been described for SH3 domains, WW domains, and profilins.[24,57] The correct positioning and orientation of a particular peptide must therefore be determined by interactions with non-proline residues of the core PRM: These may be any combination of electrostatic, polar, hydrophobic, or hydrogen-bonding interactions.

A number of charged or hydrophobic residues generally form part of the core PRMs and act as "anchors" to specify ligand orientation. Good examples are the Phe residue in the FPPPP motif targeted by the Ena/VASP family of EVH1 domains; the Phe residue of the PPxxF motif recognized by Homer EVH1 domains; the tyrosine residue of the PPxY motif targeted by the human YAP65 WW domain;[16] and the Arg, Lys, and His residues of the PPxPx(R/K/H) peptides

targeted by class II SH3 domains.[14,35,57] As the substitution of these anchoring residues often results in loss of binding, they are considered an integral part of the core binding motif.

8.4. Control of Specificity and Binding Affinity by More-Distant Residues

Core-flanking epitopes and anchoring residues outside of the PRM can greatly enhance binding affinities and thus play a crucial role in determining specificity. They can increase the degree of specificity of the ligand to allow discrimination between PRM-binding domains within the same family. For example, a lysine residue in the peptide PPPALPPKKR from the C3G protein makes the ligand highly specific for the c-Crk SH3 domain, whereas the same peptide does not bind the SH3 domains of Nck, Src, Abl, phospholipase Cγ, and spectrin.[56] Similarly, a Glu–Leu epitope found in the peptide sequence SFEFPPPPTEDEL of the ActA surface protein of *Listeria monocytogenes* provides ActA with a high specificity for class I EVH1 domains.[42,96] The presence of this epitope increases the EVH1-binding affinity of ActA strongly enough that it successfully outcompetes natural, cellular EVH1-domain-binding proteins, such as zyxin and vinculin, which lack this affinity-increasing epitope. Such affinity-determining epitopes are highly specific to the proteins that contain them, making them interesting templates for the rational design of novel specific inhibitory drugs.

9. Conclusions and Outlook

The binding of low-molecular-weight ligands to proteins requires the synergy of a number of well-balanced interactions. Prior to the synthesis of nonpeptidic competitors of natural PRM ligands, it is necessary to understand how these interactions contribute to the formation and stability of the interfaces between proline-rich peptide motifs and their respective binding domains. In the ideal case, the oxygen atom of a carbonyl group in the peptide backbone interacts with a hydrogen-bond-donating aromatic residue (Trp or Tyr) oriented perpendicular to the domain surface to form a hydrogen bond. The two peptide side chains immediately flanking the peptide carbonyl group involved in the hydrogen bond are exposed to the solvent. The subsequent two side chains on either side (usually proline rings) are positioned in a near-coplanar arrangement with the hydrogen-bonded aromatic side chain they surround, so that they pack into hydrophobic cavities in the protein surface. In the majority of high-resolution structures analyzed, the angles between the planes of the aromatic ring of the domain and the surrounding proline rings were less than 30° (see Tables 2–7). To optimize the hydrophobic contacts with the proline rings of the peptide, the domain surface contains rigid, hydrophobic "boxes" formed by additional aromatic residues arranged at roughly 90° to the hydrogen-bond-donating side chain (i.e. parallel to the domain surface). These aromatic residues make head-on contacts with the γ and δ carbon atoms of the proline rings of the ligand. As a result of the conformational restriction of the PPII helix structure of the peptides, binding occurs between two well-defined, preformed surfaces, thus minimizing the entropic costs of binding and conformational strain in the complex.

How can the survey presented herein help us in planning synthetic efforts to mimic PRM-containing peptides? First, the considerable data now available on WW, EVH1, and SH3 interactions should facilitate the design of inhibitors of these domains. Very short peptides comprising as few as five residues can bind with considerable affinity. We therefore assume that compounds in the range of 500 to 700 Da could be designed that may be able to bind with high affinity and selectivity to a PRM-binding domain. Second, suitable ligands must be able to participate in hydrogen-bonding interactions with the exposed aromatic side chain of the domain, as well as hydrophobic interactions with the specific hydrophobic cavities next to this exposed aromatic residue. A "hydrophobic chelator" around this exposed aromatic residue would allow an optimal interaction.

The detailed analysis presented herein incorporates and expands upon previous studies of PRM complexes, which have highlighted the importance of hydrophobic ridges between aromatic side chains as cavities for *N*-substituted amino acids.[26,39] In nature, of course, these cavities accept proline residues, but they can also be occupied by other hydrophobic residues, such as leucine and methionine, as shown by substitution analyses with peptide libraries. This interaction alone is likely to be very weak, but in combination with the conserved hydrogen bond in this hydrophobic environment considerable affinities can be reached. The models for binding presented herein also explain the strict conservation of tryptophan and tyrosine residues as exposed hydrogen-bond donors present in all PRM-binding domains. Phenylalanine is thus not observed in these positions, but is often found as part of the supporting "aromatic cradles"[26] or "boxes", which optimize the hydrophobic interaction. The aromatic rings of most of the PRM-binding sites are arranged nearly perpendicular to the domain surface, as can be appreciated from Figure 1. The observations presented herein should form a basis for the establishment of fundamental rules for the identification of further PRM-binding domains, and should also be useful for the rational design of PRM mimics.

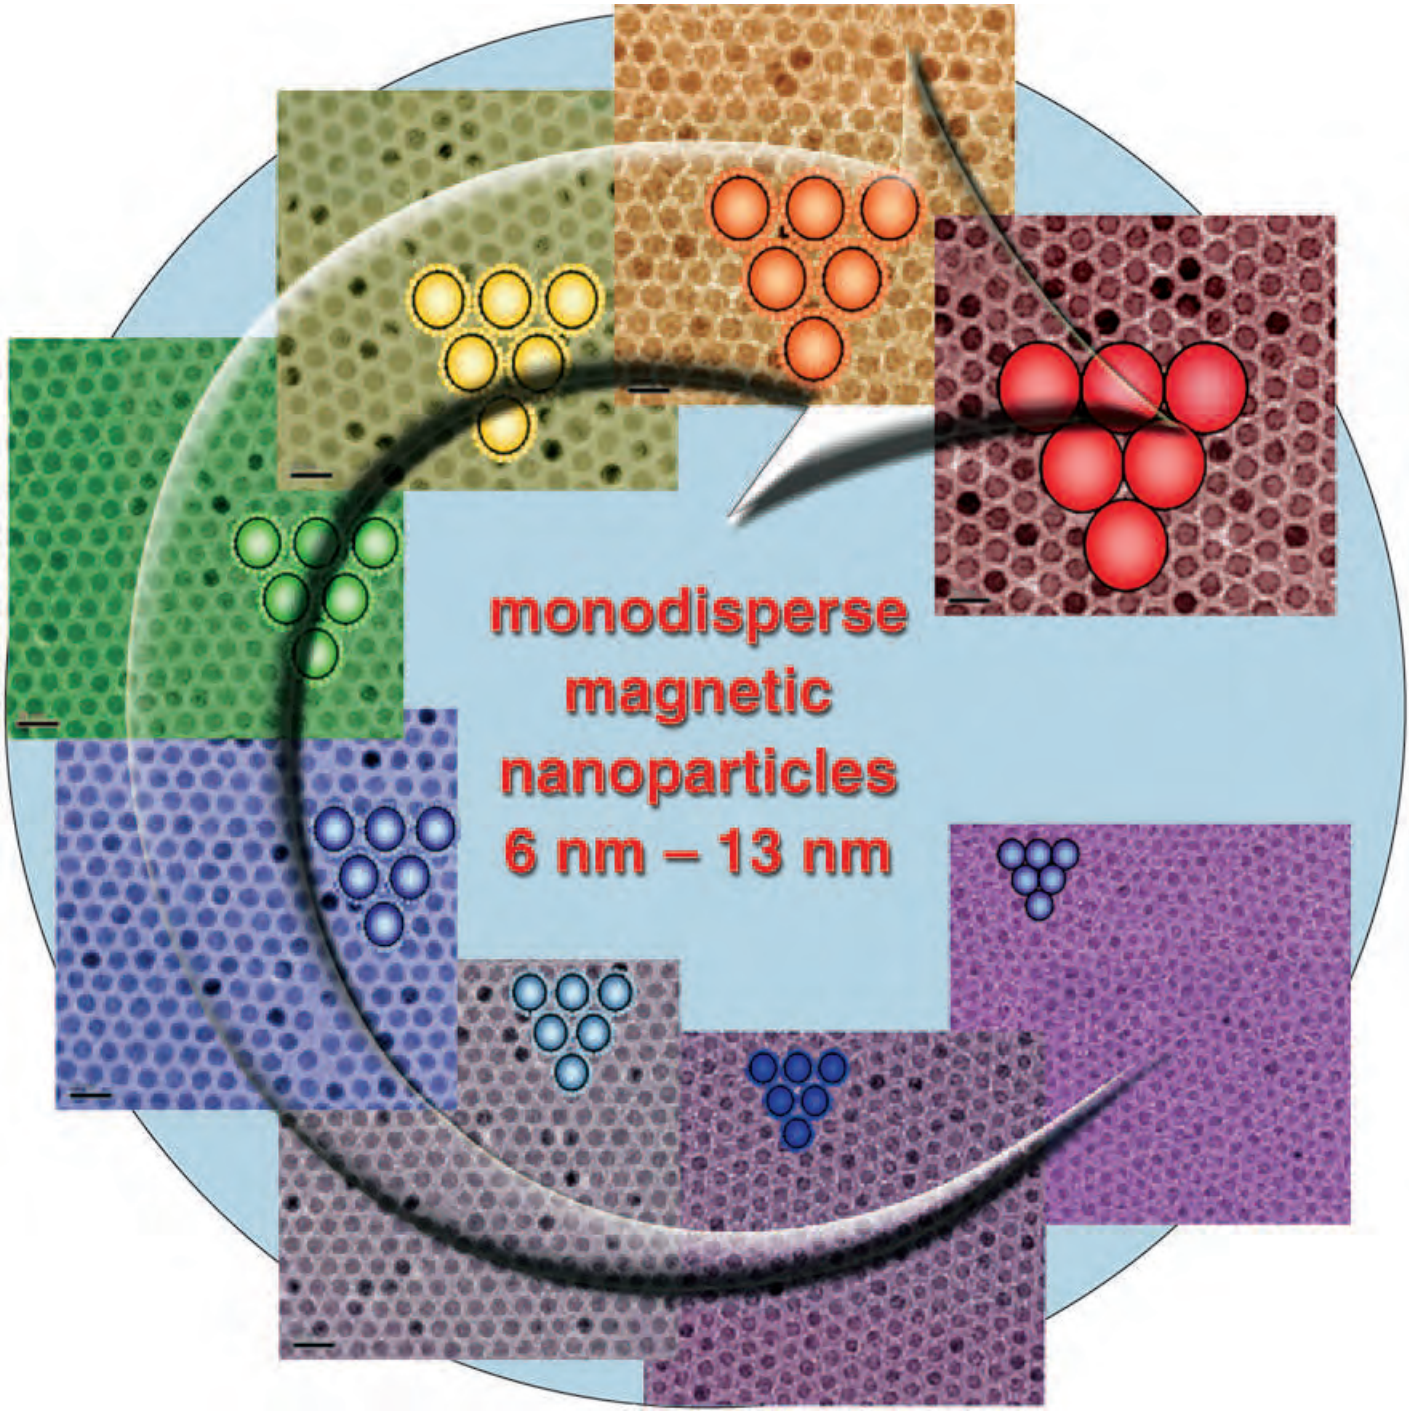
Communications



Monodisperse magnetic iron oxide nanoparticles with a continuous size spectrum of 6–13 nm were produced by controlled growth on previously synthetisized monodisperse nanoparticle seeds. The detailed synthetic procedure and characterization is described in the communication by T. Hyeon et al. on the following pages.

  DOI: 10.1002/anie.200461665

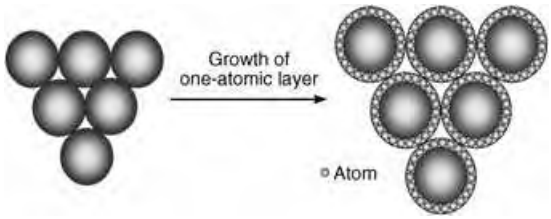
Nanoparticle Synthesis

One-Nanometer-Scale Size-Controlled Synthesis of Monodisperse Magnetic Iron Oxide Nanoparticles**

*Jongnam Park, Eunwoong Lee, Nong-Moon Hwang, Misun Kang, Sung Chul Kim, Yosun Hwang, Je-Geun Park, Han-Jin Noh, Jae-Young Kim, Jae-Hoon Park, and Taeghwan Hyeon**

The synthesis of nanoparticles has been intensively pursued not only for their fundamental scientific interest but also for many technological applications,[1] monodisperse nanoparticles (standard deviations $\sigma \leq 5\%$) with controlled particle sizes are of key importance because the electrical, optical, and magnetic properties of these nanoparticles depend strongly on their size.[2,3]

Recently, several colloidal chemical synthetic procedures have been developed to produce monodisperse nanoparticles of various materials. In the classical LaMer mechanism, a short burst of nucleation from a supersaturated solution is followed by the slow growth of particles without any significant additional nucleation, thereby achieving a complete separation of nucleation and growth.[4] Various similar procedures have been employed to synthesize almost monodisperse nanoparticles of CdSe,[5] related II–VI semiconductors,[5] and magnetic materials.[6] Watzky and Finke introduced a novel synthetic procedure that combines slow, continuous nucleation and fast, autocatalytic surface growth.[7] More recently, seed-mediated growth has been employed for the synthesis of larger metallic nanoparticles on smaller seeds. For example, Buhro and co-workers reported the synthesis of monodisperse nanoparticles of Bi, Sn, and In using Au nanoclusters as seeds.[8] In addition, monodisperse nanoparticles of Au,[9] Fe,[10] and Fe_3O_4[11] have been synthesized following similar procedures. Many monodisperse gold nanoparticles have been synthesized by a digestive ripening process or by surfactant exchange reactions.[12] The ultimate goal in the synthesis of nanoparticles is atomic-level size-controlled synthesis, similar to atomic layer deposition in thin-film processing,[13] of monodisperse nanoparticles without a size-selection process (Scheme 1), which has yet to be achieved.



Scheme 1. Direct and atomic-scale controlled synthesis of monodisperse nanoparticles.

Our research group has developed new procedures for the synthesis of monodisperse nanocrystals of metals,[1e,4] metal oxides,[15] and metal sulfides[16] without going through a laborious size-sorting process. In these syntheses, metal–surfactant complexes generated in situ are thermally decomposed to form monodisperse nanoparticles. We report herein the synthesis of monodisperse iron oxide nanoparticles with a continuous size spectrum of 6–13 nm.

The process conditions required for the synthesis of monodisperse particles of micrometer size are relatively well established,[17] and a similar principle is expected to apply to the synthesis of monodisperse nanoparticles. It would be ideal if a certain species contributes exclusively to growth, instead of participating in both nucleation and growth processes, which means that the growth process is separated from additional nucleation. Such a separation between nucleation and growth is necessary for the direct synthesis of monodisperse nanoparticles, and this condition must have been satisfied in our previous direct synthesis of monodisperse iron nanoparticles.[1e,15a] On analyzing these procedures,[1e,15a] we tried to distinguish the species that contributes to nucleation from that which contributes to growth and reached a conclusion that pentacarbonyliron mainly contributes to nucleation, whereas the iron oleate complex generated in situ contributes exclusively to growth. We also found that the nucleation resulting from the thermal decomposition of pentacarbonyliron takes place at relatively low temperature, whereas the growth derived from the decomposition of the iron oleate complex occurs at a higher temperature. In other

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

words, nucleation and growth seem to be ideally separated in our procedure. Consequently, we reasoned that if we prepare the iron oleate complex separately and use the complex as a growth source, we might synthesize monodisperse iron nanoparticles with controlled size by the additional incremental growth of the previously synthesized monodisperse iron nanoparticles. The overall process is similar to seed-mediated growth.[8–11]

As we described previously, we were able to synthesize monodisperse iron nanoparticles with sizes of 4, 8, and 11 nm from reaction mixtures containing 1:1, 1:2, and 1:3 molar ratios of pentacarbonyliron and oleic acid, respectively. Solutions containing 1.5, 3.0, and 4.5 mmol of the iron oleate complex were prepared by heating appropriate amounts of pentacarbonyliron and oleic acid in dioctyl ether at 403 K for 12 h. After refluxing the mixtures generated from the various combinations of the iron nanoparticles and the iron oleate solutions, we were able to synthesize monodisperse iron nanoparticles with particle sizes of 6, 7, 9, 10, 12, 13, and 15 nm (Table 1).

Table 1: Size of final iron nanoparticles produced from combinations of initial monodisperse iron nanoparticles and iron oleate solutions.

Final iron nanoparticles [nm]	Initial iron nanoparticles [nm]	Iron oleate solution [mmol]
6	4	1.5
7	4	3.0
9	8	1.5
10	8	3.0
12	11	1.5
13	11	3.0
15	11	4.5

These iron nanoparticles were readily oxidized to iron oxide on exposure to air.[18] The transmission electron microscopy (TEM) images of the air-oxidized iron oxide nanoparticles are shown in Figure 1. All of the nanoparticles, except the 6-nm-sized particles ($\sigma = 8.5\,\%$), exhibit particle-size distributions with standard deviations (σ) of less than 5%. These monodisperse nanoparticles were obtained directly without a size-selection process, and the synthetic procedure is highly reproducible. We expect that this concept of continuous growth without additional nucleation should be applicable to the incremental 1-nm size-controlled synthesis of monodisperse nanoparticles of many other materials. Subsequent further oxidation of these nanoparticles with trimethylamine *N*-oxide produced monodisperse and highly crystalline iron oxide nanocrystals. The TEM images of the resulting chemically oxidized nanocrystals are very similar to those obtained before the chemical oxidation in terms of particle sizes and their distributions, and the high-resolution transmission electron microscopy (HRTEM) images reveal their highly crystalline nature (see the Supporting Information).

The iron oxide nanocrystals were characterized by X-ray powder diffraction (XRD), X-ray absorption spectroscopy (XAS), and X-ray magnetic circular dichroism (XMCD). The XAS and XMCD measurements were performed at Pohang Light Source 2A1 beamline. The XRD patterns of the nanocrystals (Figure 2a) were assigned to the (111), (220), (311), (400), (422), (511), and (440) reflections of the inverse spinel structure of maghemite (γ-Fe_2O_3; JCPDS no. 39–1346). It should be noted that the standard XRD patterns of magnetite (Fe_3O_4) and maghemite are nearly identical. As the particle sizes get larger, the XRD peaks become narrower (Figure 2b), and the particle sizes calculated from the Scherrer formula match well with those obtained from the TEM data (see the Supporting Information).

X-ray absorption spectroscopy (XAS) and X-ray magnetic circular dichroism (XMCD) measurements at the Fe $L_{2,3}$ edges were carried out for the quantitative identification of the compositions of the iron oxide nanocrystals. Figure 3a, b show the XAS spectra and XMCD results, respectively, of the iron oxide nanocrystals with diameters of 4, 6, 8, 9, 11, and 13 nm, in comparison with those of two reference materials, bulk γ-Fe_2O_3 (maghemite) and bulk Fe_3O_4 (magnetite), which have nearly the same spinel crystal structure with only about 1% difference in the cubic lattice constant. Both the XAS and MCD spectra of the 4-nm-sized nanocrystals are very similar to those of γ-Fe_2O_3, which contains only a Fe^{3+} ion. As the particle size increases, the line shapes gradually change and both spectra for the iron oxide nanocrystals with a large particle size became similar to those of Fe_3O_4, which contains Fe^{3+} and Fe^{2+} ions. From the XAS and XMCD results, we were able to make a quantitative estimation of the compositions of the iron oxide nanocrystals in the form of $(\gamma\text{-}Fe_2O_3)_{1-x}(Fe_3O_4)_x$. The estimations are $x = 0.20 \pm 0.05$, 0.35 ± 0.05, 0.44 ± 0.05, 0.52 ± 0.05, 0.62 ± 0.05, 0.64 ± 0.05, and 0.65 ± 0.05 for the 4-, 6-, 8-, 9-, 11-, 12-, and 13-nm-sized nanocrystals, respectively. Therefore, γ-Fe_2O_3 is the dominant phase of the small 4-nm-sized iron oxide nanocrystals, whereas the fraction of the Fe_3O_4 component gradually increases with increasing particle size.

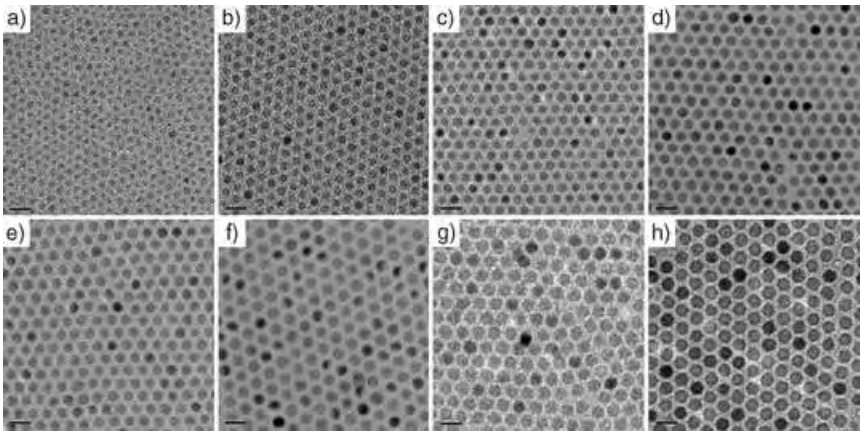

Figure 1. TEM images of a) 6-, b) 7-, c) 8-, d) 9-, e) 10-, f) 11-, g) 12-, and h) 13-nm-sized air-oxidized iron oxide nanoparticles showing the one nanometer level increments in diameter. (The enlarged TEM images and particle-size distribution histograms are supplied in the Supporting Information.)

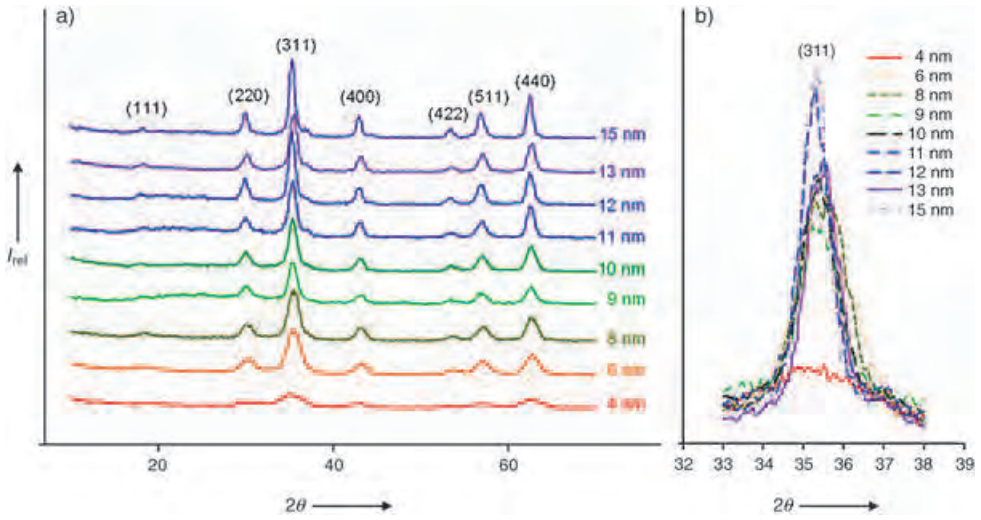

Figure 2. a) XRD patterns of iron oxide nanocrystals of 4, 6, 8, 9, 10, 11, 12, 13, and 15 nm, and b) the change of the (311) peak intensity of each nanocrystal.

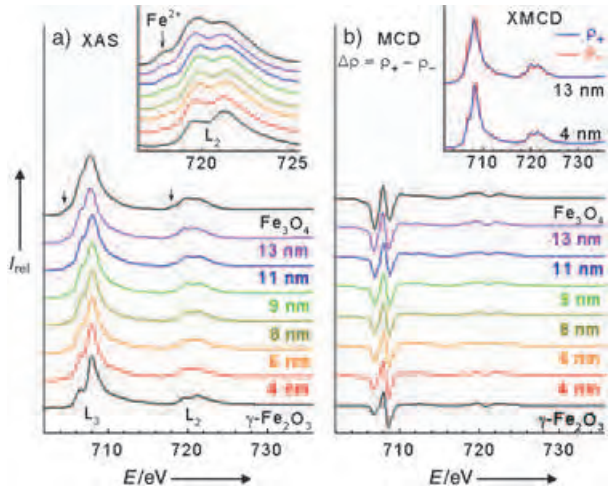

Figure 3. Fe $L_{2,3}$ edge a) XAS and b) XMCD spectra of 4, 6, 8, 9, 11, and 13 nm iron oxide nanocrystals compared with those of bulk reference materials (γ-Fe_2O_3 and Fe_3O_4). The magnified L_2 region XAS spectra of the nanocrystals and XMCD spectra of the 4 and 13 nm nanocrystals are shown in the insets of (a) and (b), respectively.

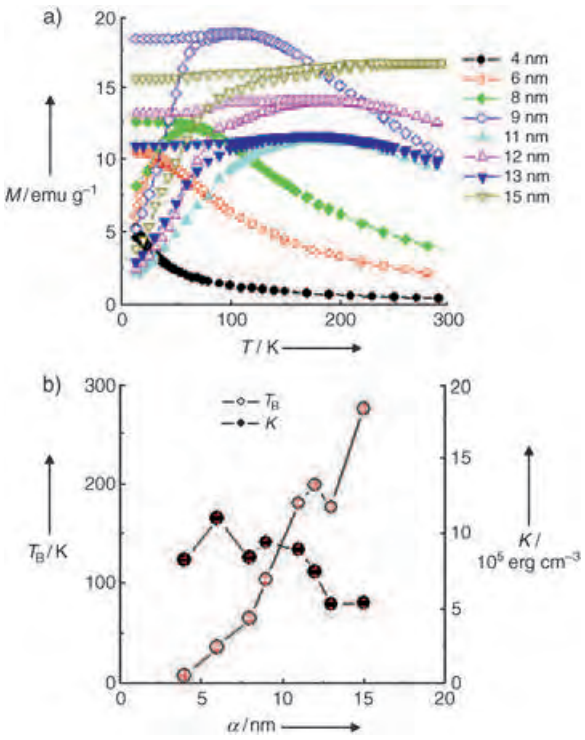

Figure 4. a) Temperature dependence of magnetization measured after zero-field cooling (ZFC) and field cooling (FC) at 100 Oe for 4, 6, 8, 9, 11, 12, 13, and 15 nm particles. b) Size dependence of the blocking temperature, T_B, obtained from M(T) in Figure 4a. The magnetic anisotropy constant, K, was obtained as described in the text.

The magnetic properties of these iron oxide nanocrystals were studied using a vibrating sample magnetometer (Lake Shore, 9300). Figure 4a shows the temperature dependence of magnetization measured at 100 Oe from 300 to 14 K. All our samples show superparamagnetic behavior at high temperatures. However, on cooling, the zero-field-cooled magnetization begins to drop and deviate from the field-cooled magnetization at the blocking temperature T_B. For the 4 nm sample, the blocking temperature seems to be close to the lowest temperature measured (14 K). For further measurements of the magnetization down to 2 K, we used a SQUID magnetometer and found that the blocking temperature is 8 K. With increasing particle size, the blocking temperature increases continuously (Figure 4b); for example, the blocking temperature increases to 275 K for the 15-nm-sized nanocrystals. We then used the measured blocking temperature to calculate the magnetic anisotropy constant K by using the formula: $K = 25 k_B T_B V^{-1}$,[19] where k_B is the Boltzman constant, T_B is the measured blocking temperature, and V is the total volume of a particle whose diameter was determined from TEM measurements. Considering that all our samples are spherical and, consequently, there is no shape anisotropy involved for the nanocrystals, the dominant anisotropy should be because of magnetocrystalline anisotropy. It is noticeable

that, unlike other nanocrystals, the magnetic anisotropy constant does not increase significantly with a reduction in particle size. For comparison, the magnetic anisotropy constant[20] of bulk Fe_3O_4 is 4×10^5 erg cm^{-3}, which is slightly higher than that of our 15-nm-sized sample. This unusual result seems to be because of the strong dipolar interactions between the nanoparticles, which might mask the size dependence of the magnetic anisotropy. In fact, the peaks in the magnetic susceptibility appear to be much broader than would be expected for monodisperse nanoparticles, thus demonstrating the strong dipolar interaction in our samples.

In conclusion, we have synthesized monodisperse iron oxide nanoparticles with a continuous size spectrum of 6–13 nm. The synthesis of iron nanoparticles with particle sizes of 6, 7, 9, 10, 12, 13, and 15 nm was achieved by the controlled additional growth of the previously synthesized monodisperse iron nanoparticles; the overall synthetic procedure is similar to seed-mediated growth. These monodisperse nanoparticles were obtained directly without a size-selection process, and the synthetic procedure is highly reproducible. Subsequent chemical oxidation produced monodisperse and highly crystalline iron oxide nanocrystals. This concept of continuous growth without additional nucleation could be applicable to other materials for the incremental, 1-nm size-controlled synthesis of monodisperse nanoparticles.

Experimental Section

Monodisperse 4-, 8-, and 11-nm-sized iron oxide nanoparticles were prepared as described previously.[15a] For example, to prepare 11-nm-sized monodisperse iron nanoparticles, $[Fe(CO)_5]$ (0.2 mL, 1.52 mmol; Aldrich, 99.999%) was added to a mixture containing dioctyl ether (10 mL; Aldrich, 90%), and oleic acid (1.28 g, 4.56 mmol; Aldrich, 99%) at 373 K. The resulting mixture was heated to reflux and kept at that temperature for 1 h. During this process, the initial orange solution gradually became black. It was then cooled to room temperature and anhydrous trimethylamine *N*-oxide (0.34 g, 4.56 mmol, prepared from $(CH_3)_3NO{\cdot}2H_2O$: Aldrich, 98%) was added. The mixture was then heated to 403 K in an argon atmosphere and maintained at this temperature for 2 h, whereupon the solution became brown. The reaction temperature was slowly increased to reflux and the reflux continued for 1 h; the color of the solution gradually turned from brown to black. The solution was then cooled to room temperature, and ethanol was added to yield a black precipitate, which was then separated by centrifugation. Starting mixtures containing $[Fe(CO)_5]$ and oleic acid in 1:1 and 1:2 molar ratios yielded iron oxide nanoparticles of 4 and 8 nm, respectively.

Iron oleate complex solutions with three different concentrations were prepared by mixing $[Fe(CO)_5]$ (0.2 mL, 1.52 mmol), dioctyl ether (10 mL), and oleic acid (0.43 g, 1.52 mmol; 0.85 g, 3.04 mmol; or 1.28 g, 4.56 mmol; respectively) which were heated at 403 K for 12 h to form the iron oleate complex solutions designated as 1.5, 3.0, and 4.5 mmol, respectively. For the synthesis of iron nanoparticles of the desired sizes, various combinations of the iron oleate solutions and the iron nanoparticle suspensions (before the chemical oxidation with trimethylamine *N*-oxide) were mixed (Table 1). The resulting solution was heated to reflux for 1 h to produce iron nanoparticles that were further oxidized with anhydrous trimethylamine *N*-oxide to produce highly crystalline iron oxide nanocrystals.

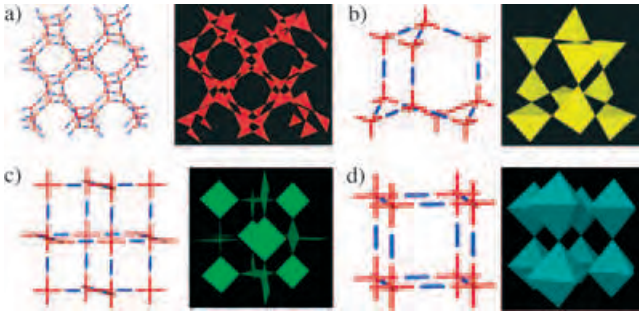
Coordination Polymers

Ternary Nets formed by Self-Assembly of Triangles, Squares, and Tetrahedra**

*Zhenqiang Wang, Victor Ch. Kravtsov, and Michael J. Zaworotko**

It has now been almost thirty years since Wells catalogued network structures in crystals[1] in a manner that has facilitated the crystal engineering[2] of a wide range of infinite 2D and 3D nets. That crystal engineered nets invoke geometric design principles means that a chemically diverse range of molecular building blocks (MBBs) are available for study as exemplified by coordination polymers (i.e. metal–organic networks),[3] polymers sustained by organometallic linkages[4] and hydrogen-bonded organic networks.[5] Coordination polymers are particularly attractive targets for study: metal coordination and cluster geometries are diverse but they are controllable in a manner that facilitates the design of nets with predictable topology and dimensions; metal moieties can be pre-selected so as to impart functional properties, such as magnetism,[6] luminescence[7] or, in the case of open-framework nets, permanent porosity;[3c,e,8] multifunctional organic ligands can also be selected for their geometric attributes. Coordination polymers can be rationalized and designed using the "node-and-spacer" approach,[3a,b] which simplifies molecular building blocks into topological points and lines. Aesthetically pleasing and potentially functional coordination polymers that have been isolated in recent years are exemplified by (10,3)-a,[9] NbO,[10] diamondoid,[11] and primitive cubic nets.[12] An alternative strategy for the interpretation and design of nets takes into account the shape of the MBBs and represents nets as being sustained by vertex-linked polygons or polyhedra (VLPP).[6a,13] As revealed by Scheme 1, the aforementioned four net types



Scheme 1. Four unitary nets represented in both node-and-spacer and VLPP format: a) (10,3)-a net, b) diamondoid net, c) NbO net, d) primitive cubic net.

can be visualized as being either "node-and-spacer" or VLPP networks. From the VLPP perspective, the four nets shown in Scheme 1 are all examples of unitary nets in that they are built entirely from one type of polygon or polyhedron. The VLPP approach comes into its own for binary nets, that is, nets sustained by pairs of polygonal or polyhedral MBBs. The structural diversity possible from even the simplest of MBBs is exemplified by (3,4)-connected nets. If squares are connected exclusively to triangles and vice versa, two distinct (3,4)-connected binary nets have been isolated: the Pt_3O_4[14] and twisted boracite nets.[13a,15] Likewise, if tetrahedra are linked exclusively to triangles and vice versa, two additional (3,4)-connected binary nets are accessible, the boracite[16] and cubic C_3N_4 nets[17] (Scheme 2). Herein we address how the VLPP approach can be extended to ternary nets, that is, those sustained by a combination of three polygons or polyhedra.

We report the synthesis and crystal structures of two compounds that represent prototypal examples of ternary VLPP nets sustained by three distinct MBBs: $[\{[Zn_6(btc)_4(isoquinoline)_6(MeOH)]H_2O(benzene)_2\}_n]$ (USF-3; btc = 1,3,5-benzenetricarboxylate), and $[\{[Zn_6(btc)_4(isoquinoline)_4(MeOH)_2](MeOH)_8(chlorobenzene)\}_n]$ (USF-4). USF-3 and USF-4 are sustained by vertex linkage of triangular, square, and tetrahedral MBBs and represent to our knowledge the first reported examples of ternary nets. The

triangular MBB utilized in this study is the 1,3,5-benzenetricarboxylate anion (**A**). The square MBB is the previously reported $Zn_2(RCO_2)_4$ (**B**) and the tetrahedral MBBs are $Zn_2(RCO_2)_2(RCO_2)_2$ (**C**) or $Zn_2(RCO_2)_3(RCO_2)$ (**C′**), for USF-3 and USF-4, respectively, Scheme 3. Zinc(II)-based MBBs were selected because such a wide variety of zinc(II) carboxylate chromophores have been documented.[3d] The formation of the two new ternary nets and the relative ratio of **B** and **C** (2:1) in USF-3 or **B** and **C′** (1:2) in USF-4 appear to be controlled by template molecules and reaction conditions. It is of note that the Zn^{II} and btc can generate other supramolecular isomers[3a] in the presence of other solvents or templates.[9b,13a] Zinc nitrate, 1,3,5-benzenetricarboxylic acid, and isoquinoline in methanol templated by benzene affords USF-3 whereas similar reaction conditions give rise to USF-4 if chlorobenzene is employed as a template. This difference in products obtained is presumably a reflection of the relative size of the template molecules.

The structures of USF-3 and USF-4 were determined by X-ray single-crystal diffraction[18] and they are depicted in Figure 1 and Figure 2, respectively. There are two different Zn^{II} chromophores present in USF-3: square "paddle-wheel"

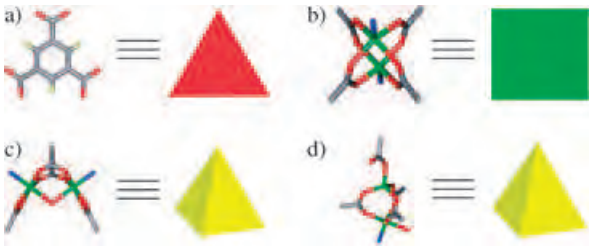

Scheme 3. Molecular building blocks (MBBs) employed in the ternary nets USF-3 and USF-4: a) **A**, b) **B**, c) **C**, d) **C′**.

MBBs, **B**, and pseudo-tetrahedral **C**, in a ratio of 2:1. **B** is perhaps the most frequently used MBB and is present in over 1200 crystal structures that have been deposited in the Cambridge Structural Database (CSD).[19] MBB **C** is far less common than **B** and comprises a binuclear Zn^{II} unit, two bridging carboxylate groups, one bridging oxygen atom, and two chelating carboxylate groups. Methanol and/or isoquinoline serve as axial ligands. As revealed by Figure 1, USF-3 is generated from vertex linking of **A**, **B**, and **C** in the ratio 4:2:1, thereby retaining the 4:3 ratio necessary for sustaining a (3,4)-

connected net in which 3-connected nodes are exclusively linked to 4-connected nodes and vice versa. Ideally, these three types of MBBs would generate a net structure with large open channels; however, no such channels are observed in USF-3 because isoquinoline, a bulky molecule, is protruding and blocking the possible channels. As a result, there are two different types of cavities within which disordered benzene molecules are trapped (see Supporting Information). One water molecule per asymmetric unit is also present, which engages in hydrogen bonding with the bridging methanol molecules. Thermal gravimetric analysis (TGA) and X-ray powder diffraction data suggest that USF-3 is stable up to at least 130 °C whereas further heating above 180 °C leads to collapse of the framework (see Supporting Information). USF-4 also has two Zn^{II} MBBs: a mixture of **B** and a different pseudo-tetrahedral MBB **C**′. The overall ratio of **A**: **B**: **C**′ is 4:1:2. MBB **C**′ features a binuclear Zn^{II} unit, three bridging carboxylate groups, and one monodentate carboxylate. USF-4 also has cavities but open channels are precluded by the presence of coordinated isoquinoline molecules. However, USF-4 possesses a higher free volume[20] than USF-3, 32.2% versus 19.3%, in which methanol and disordered chlorobenzene molecules are located. Thus, USF-3 and USF-4 are the first reported examples of (3,4)-connected ternary nets: triangular, square, and tetrahedral MBBs in the ratios 4:2:1 and 4:1:2, respectively.

That USF-3 and USF-4 might have general implications in the context of designing coordination polymers can be justified by the following considerations. First, although it is established that knowledge of molecular symmetry facilitates the design and synthesis of nets in a systematic manner, until now this has been limited to unitary or binary nets. USF-3 and USF-4 suggest that the use of three or perhaps even more MBBs could represent a facile approach to the construction of VLPP nets with unprecedented topologies. Second, the recently discovered porous metal–organic structures that are capable of guest-induced shape-responsive fitting represent a class of materials that resemble the degree of induced-fit behavior of bioenzymes, such as metalloproteins.[21] That the formation of USF-3 and USF-4 is so dependent upon the presence of guest/template illuminates a possible mechanism for translating structural information from an external medium into the formation of a novel framework. Third, although considerable effort in the field of coordination polymers has been devoted to the pursuit of new structures with unprecedented topologies,[3] discovery and recognition of novel three-periodic nets remains a nontrivial experience. USF-3 and USF-4 are based upon unique connectivity and they represent two examples of hitherto undocumented (3,4)-connected nets.[1] The Schläfli symbols for USF-3 and USF-4 are $(6{\cdot}6{\cdot}6)_4(6_2{\cdot}6_2{\cdot}8_2{\cdot}8_2{\cdot}12_2{\cdot}12_2)_2(6_2{\cdot}6_2{\cdot}8{\cdot}8{\cdot}8{\cdot}8)$ and $(4{\cdot}6{\cdot}8)_2(6{\cdot}6{\cdot}8_2)_2(6{\cdot}6{\cdot}8{\cdot}8{\cdot}10_4{\cdot}*)$ $(4{\cdot}6{\cdot}6{\cdot}8{\cdot}8{\cdot}10_4)_2$, respectively.[22] Therefore, USF-3 can be regarded as an "intermediate" structure between boracite and twisted boracite, as implied by their vertex symbols. USF-4 represents a more complicated and less symmetric (3,4)-connected net.[1,22] Nevertheless, the new structures are inherently modular and they are sustained by MBBs with shapes that are found throughout molecular chemistry. Therefore, there is every reason to assert that nets with the same topologies as USF-3 and USF-4 will be accessible from a much wider range of MBBs. However, it must be noted that the existence of USF-3 and USF-4 is at least partly a reflection of the tendency for Zn^{II} to exhibit multiple coordination geometries and the one-pot synthetic process employed herein is unlikely to be successful for other metals. In our opinion, as the number of MBBs increases, synthetic strategies will likely have to focus upon preformed MBBs rather than those generated in situ.

In summary, we have demonstrated that molecular triangles, squares, and tetrahedra are capable of self-assembling at their vertices to generate VLPP ternary nets. Such a ternary approach to generation of VLPPs is inherently modular in nature and consequently we anticipate it to be a strategy that will prove to be feasible for other combinations of molecular polygons and polyhedra.

Experimental Section

USF-3: A solution of 1,3,5-benzenetricarboxylic acid (140 mg, 0.667 mmol) and isoquinoline (0.350 mL, 3.00 mmol) in methanol (20 mL) was heated gently for about 10 min and then carefully layered onto a solution of $Zn(NO_3)_2{\cdot}6H_2O$ (297 mg, 1.00 mmol) in methanol/benzene (3:1, 20 mL). Colorless single crystals formed within 12 h under ambient conditions (217 mg, 59.6% yield).

USF-4: A solution of 1,3,5-benzenetricarboxylic acid (70 mg, 0.33 mmol) and isoquinoline (0.177 mL, 1.50 mmol) in methanol (20 mL) was carefully layered onto a solution of $Zn(NO_3)_2{\cdot}6H_2O$ (149 mg, 0.500 mmol) in methanol/chlorobenzene (2:1, 20 mL). Colorless single crystals formed within 12 h under ambient conditions (56 mg, 30.9% yield).

Crystal data for USF-4: $M_r = 2170.27$, monoclinic, $P2_1/n$, $a = 14.5949(14)$, $b = 12.5583(12)$, $c = 25.741(3)$ Å, $\beta = 100.093(2)°$, $V = 4644.9(8)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.552\ g\,cm^{-3}$, $2\theta_{max} = 54.00°$ ($-18 \le h \le 13$, $-14 \le k \le 16$, $-29 \le l \le 32$), $T = 100$ K, 21791 measured reflections, $R1 = 0.0644$ and $wR2 = 0.1296$ for 6924 reflections ($I > 2\sigma(I)$), and $R1 = 0.1007$, $wR2 = 0.1418$ for 10044 independent reflections (all data) and 649 parameters, GOF = 1.003. Data were collected on a Bruker SMART-APEX CCD diffractometer using $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), operating in the Ω and ϕ scan mode. All crystal data were corrected for Lorentz and polarization effects, and the SADABS program was used for absorption correction. The structures were solved by direct methods and the structure solutions and refinements were based on $|F^2|$. All non-hydrogen atoms were refined with anisotropic displacement parameters, whereas hydrogen atoms were placed in calculated positions and given isotropic U values 20% higher than the atom to which they are bonded. All crystallographic calculations were conducted with the SHELXTL software suite. CCDC-260729 (USF-3) and CCDC-260730 (USF-4) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Microarray Immobilization

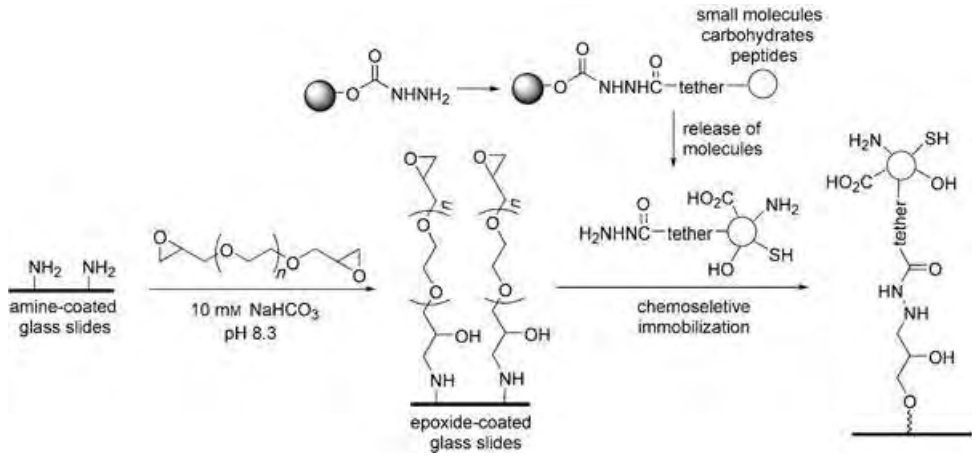
Fabrication of Chemical Microarrays by Efficient Immobilization of Hydrazide-Linked Substances on Epoxide-Coated Glass Surfaces**

*Myung-ryul Lee and Injae Shin**

Small molecules that regulate biological processes serve as valuable tools in studies of the functions of biomolecules, especially proteins, as well as in the development of drugs.[1] An important component of efforts that target the discovery of bioactive molecules is high-throughput screening. Technologies that rely on the use of DNA, protein, and carbohydrate microarrays have been widely employed to accelerate the selection of lead compounds and as high-throughput analytical tools in genomic, transcriptomic, proteomic, and glycomic research.[2–4] Microarray platforms enable the simultaneous assessment of a large number of samples that are available in limited quantities.

Similarly, small-molecule microarrays have been used as high-throughput methods to identify substances that selectively bind to proteins.[5] Most of the small molecules of interest in these efforts possess a number of different functional groups, such as hydroxy (OH), amino (NH_2), carboxy (CO_2H), and sulfanyl groups (SH). The major requirement of techniques used to fabricate small-molecule microarrays is that immobilization of the diversely functionalized compounds to the modified surfaces must be highly selective. Strategies that employ efficient and chemoselective ligation processes would be generally applicable to the fabrication of microarrays that possess covalently linked, biologically interesting molecules. Herein we describe a novel chemoselective immobilization process in which hydrazide-containing compounds react with epoxides coated on glass slides. This new technique has been applied to the efficient construction of chemical microarrays, which have been used to evaluate protein binding to peptides and small molecules.

Several criteria must be met in designing a general method to prepare diverse chemical microarrays. Firstly, the diverse substances containing the specific functional groups used for selective reactions with the modified solid surfaces must be easily prepared by solid-phase synthesis. Also, functional groups that will selectively react with the small molecules must be readily incorporated onto the solid surfaces. Lastly, following their release from a solid support, the diversely structured and functionalized small molecules must undergo site-specific covalent attachment to the modified surfaces. Strategies employing highly chemoselective ligation reactions fit these criteria. We have investigated a novel technique for immobilization, which relies on the use of reactions between hydrazide-containing small molecules and epoxide-coated glass slides (Scheme 1). The hydrazide groups are incorporated into the small molecules while they are attached to a solid support and are used as a handle in their solid-phase synthesis.[6] The epoxide-derivatized glass slides are easily created by immersing amine-coated glass slides into a solution of poly(ethylene glycol) diglycidyl ether (3% solution in 10 mM $NaHCO_3$, pH 8.3).[7]



Scheme 1. Strategy for the fabrication of a chemical microarray based on the immobilization of hydrazide-containing compounds on epoxide-derivatized glass slides.

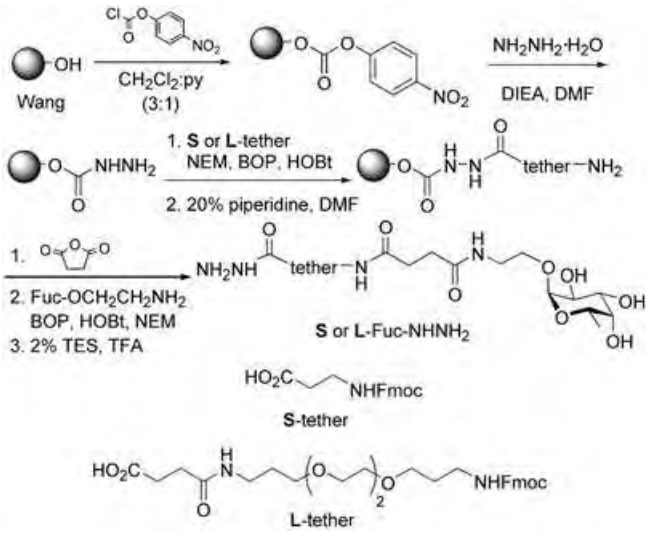
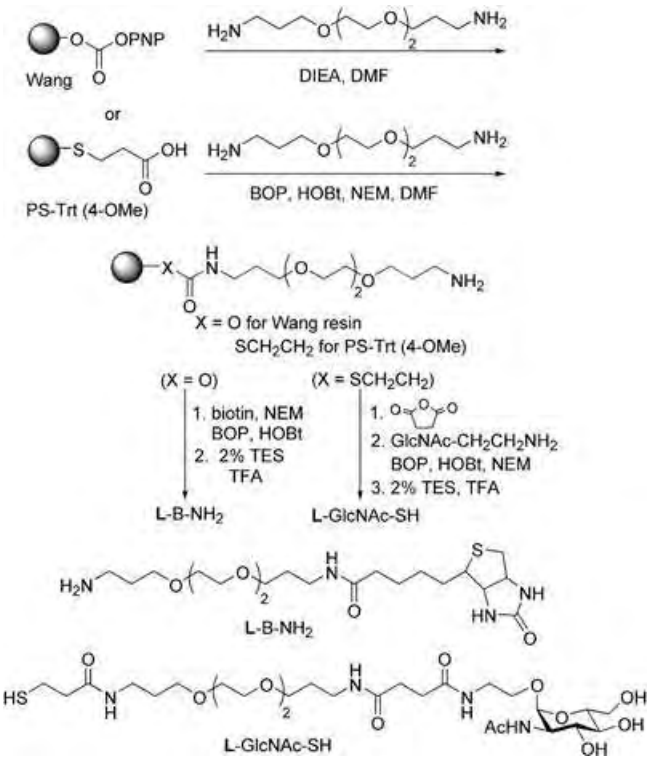
A hydrazide-linked fucose probe (**S**- or **L**-Fuc-$NHNH_2$, **S**: short, **L**: long; Scheme 2) was used to probe optimal conditions (pH, time, and concentration) for the immobilization process. Preparation of **S**- or **L**-Fuc-$NHNH_2$ was initiated by transforming alcohol groups on a Wang resin into *p*-nitrophenyl carbonates.[8] The resulting resin was then treated with hydrazine to yield the hydrazide-containing resin, which was coupled with the Fmoc-protected **L** or **S** tether in the presence of NEM, BOP, and HOBt. The amino groups

 DOI: 10.1002/anie.200462720



Scheme 2. Synthesis of the hydrazide-linked fucose probes **S**- and **L**-Fuc-$NHNH_2$. Py: pyridine, DIEA: ethyldiisopropylamine, DMF = *N*,*N*-dimethylformamide, NEM = *N*-ethylmorpholine, BOP = 1-benzotriazolyloxytris(dimethylamino)phosphonium hexafluorophosphate, HOBt = 1-hydroxybenzotriazole, TES = triethylsilane, TFA = trifluoroacetic acid, Fmoc = 9-fluorenylmethoxycarbonyl.



Scheme 3. Synthesis of amine-linked biotin (**L**-B-NH_2) and thiol-linked GlcNAc (**L**-GlcNAc-SH) probes. PNP = *p*-nitrophenyl.

produced by treatment of the resin with piperidine were treated with succinic anhydride to generate carboxylic acids, which underwent an amide-bond-forming reaction with aminoethyl α-fucopyranoside. Finally, the desired compounds were released from the resin by treatment with 2% TES in TFA.

In order to find the proper immobilization conditions, a solution of **L**-Fuc-$NHNH_2$ was printed onto the epoxide-derivatized glass slides and then the resulting slides were probed with Cy5-labeled *Aleuria aurantia* lectin (Cy5-AA) for 1 h (Cy5: indodicarbocyanine).[9] It was found that substrate concentrations of 0.5–1 mM and times of 3–4 h at pH 3–5 were appropriate for efficient immobilization reactions.[8]

An important feature of the method we have developed for constructing small-molecule microarrays is chemoselectivity. This was demonstrated in studies of selective attachment of hydrazides onto the epoxide-coated surfaces in the presence of other potent nucleophilic groups, such as amines and thiols. For these studies, amine-linked biotin (**L**-B-NH_2) and thiol-linked *N*-acetylglucosamine (**L**-GlcNAc-SH) probes were synthesized on solid supports by using *p*-nitrophenol-activated Wang and 2-carboxyethanethiol 4-methoxytrityl polystyrene (PS-Trt-(4-OMe)) resins, respectively (Scheme 3).[8]

A 1:1 mixture of **L**-Fuc-$NHNH_2$ and **L**-GlcNAc-SH (1 mM in 30% glycerol in 100 mM sodium phosphate, pH 3–10) was applied to the epoxide-functionalized slides, which were then treated with Cy5-AA and Cy3-labeled *Triticum vulgaris* lectin (wheat germ agglutinin; Cy3-TV; Cy3: indocarbocyanine).[9] Fluorescence analysis showed that the hydrazide substrate (**L**-Fuc-$NHNH_2$) was selectively immobilized in reactions conducted at low pH values, while the thiol substrate (**L**-GlcNAc-SH) underwent a more efficient reaction with the epoxide residues at a higher pH value, when the thiol moiety is deprotonated (Figure 1a).

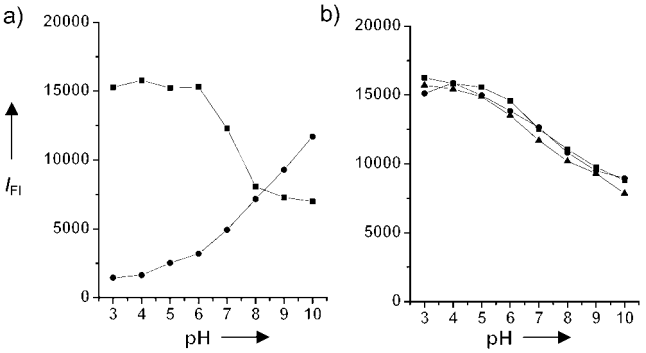


Figure 1. a) Immobilization of **L**-Fuc-$NHNH_2$ in the presence of one equivalent of **L**-GlcNAc-SH (■ probed with Cy5-AA, ● probed with Cy3-TV). b) Immobilization of **L**-Fuc-$NHNH_2$ in the presence of **L**-B-NH_2 (■ **L**-Fuc-$NHNH_2$ only, ● **L**-Fuc-$NHNH_2$:**L**-B-NH_2 (1:1), ▲ **L**-Fuc-$NHNH_2$:**L**-B-NH_2 (1:4); all probed with Cy5-AA).

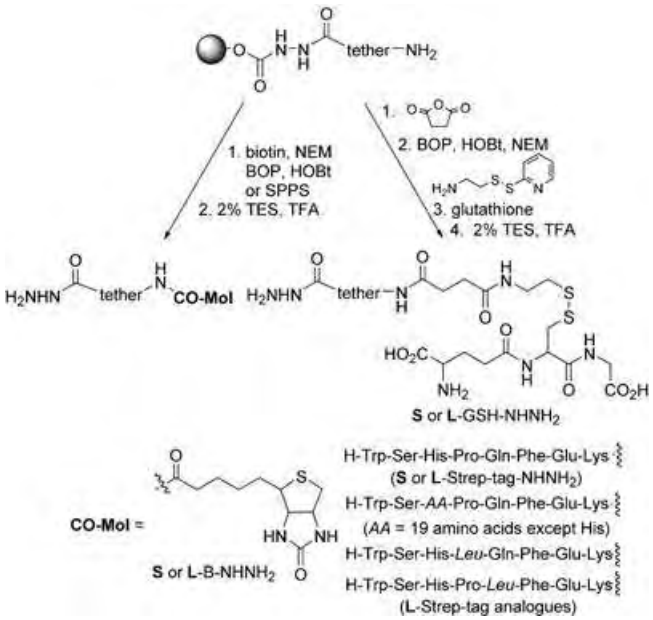
Next, selective attachment of hydrazides to the epoxide-coated slides in the presence of amines was examined. Mixtures of **L**-Fuc-$NHNH_2$ and **L**-B-NH_2 (1:1 and 1:4 in 30% glycerol in 100 mM sodium phosphate, pH 3–10) were applied to the epoxide-derivatized slides and then probed with Cy5-AA. Since in some biologically interesting substrates (especially peptides) several amino groups are present, these immobilization reactions were run with mixtures

containing an excess of **L**-B-NH_2 of up to four molar equivalents. As shown in Figure 1 b, the fluorescence intensity of spots containing **L**-Fuc-$NHNH_2$ was barely changed when **L**-B-NH_2 was present, a result indicating that hydrazide-linked fucose (**L**-Fuc-$NHNH_2$) was selectively attached to the surface over the range of pH 3–10 even when a large excess of amine-containing biotin was used. The results of these competition experiments demonstrate that hydrazides are immobilized on the epoxide-coated surface more rapidly than substrates with both amine and thiol functional groups.

As part of a practical application of this technique to the fabrication of chemical microarrays, we synthesized hydrazide-linked substrates containing biotin (**S**- or **L**-B-$NHNH_2$), peptides (**S**- or **L**-GSH-$NHNH_2$, **S**- or **L**-strep-tag-$NHNH_2$ and its analogues), and phenanthridinium derivatives (Schemes 4 and 5).[8] The strep-tag peptide sequence and its



Scheme 4. Synthesis of hydrazide-linked probes containing biotin, glutathione (GSH), or the streptavidin tag (strep tag) and its analogues.

analogues were directly assembled on solid supports by using the conventional Fmoc strategy. Strep-tag analogues were prepared by replacing the histidine residue with 1 of the other 19 amino acids or by replacing the proline and glutamine residues with leucine. GSH was coupled to the resin by using a disulfide exchange reaction. Four phenanthridinium derivatives for acetylcholinesterase (AChE) inhibitors were prepared by solution-phase synthesis and subsequently coupled to the carboxylic acid derivatized resin.

Eight **S**/**L**-tethered fucose-, glutathione-, biotin-, and strep-tag-containing hydrazides (1 mM in 30% glycerol in 100 mM sodium phosphate, pH 5) were microspotted onto the epoxide-derivatized glass slides and then incubated with Cy5-AA, Cy3-streptavidin, Cy3-avidin, or glutathione S transferase (GST). GST incubation was followed by treatment with fluorescein isothiocyanate (FITC) labeled anti-GST antibody. As shown in Figure 2 a–d, fucose, glutathione, and the strep

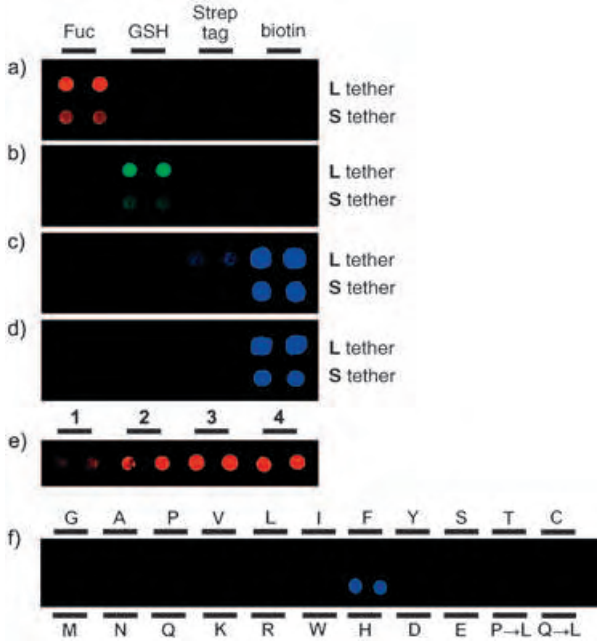

Figure 2. Fluorescence images of chemical microarrays containing fucose, GSH, the strep tag, and biotin, when probed with a) Cy5-AA, b) GST followed by FITC-labeled anti-GST antibody, c) Cy3-streptavidin, and d) Cy3-avidin. Fluorescence images of chemical microarrays containing e) phenanthridinium derivatives probed with Cy5-AChE (**1** COR = H, **2** COR = cyclohexylcarbonyl, **3** COR = allyloxycarbonyl, **4** COR = phenylacetyl) and f) strep tag and its analogues probed with Cy3-strepavidin (single letter amino acid codes given for the residue that replaced histidine in the strep tag, P→L: replacement of proline with leucine in the strep tag, Q→L: replacement of glutamine with leucine in the strep tag). Spot size: ≈100 μm, distance between centers of spots: ≈250 μm.

tag were selectively recognized by AA, GST, and streptavidin, respectively. The strep tag is known to bind to streptavidin rather than avidin and, as expected, microspots containing

this substance were recognized only by streptavidin.[10] Microspots containing biotin display much stronger fluorescence than strep-tag microspots because the binding affinity of streptavidin to biotin is much greater than that of streptavidin to the strep tag.[11] Interestingly, microspots produced by reaction of **L**-tethered substrates bound to the corresponding proteins more tightly than those with **S**-tethered substrates. The fluorescence intensities of microspots containing **L**-tethered compounds are more than twice as strong as those of microspots containing **S**-tethered ones.

Small-molecule microarrays with four phenanthridinium derivatives were also fabricated by following the method described above. Fluorescence analysis of slides treated with Cy5-AChE showed that substituted phenanthridinium derivatives bound to the proteins more strongly than their unsubstituted derivatives (Figure 2e).[12] Finally, we constructed peptide microarrays with the **L**-tethered strep tag and 21 of its analogues. The peptide microarrays, after probing with Cy3-streptavidin, showed that streptavidin only bound to the strep tag (Figure 2f). This is consistent with previous results showing that the amino acid sequence His-Pro-Gln is critical for streptavidin binding.[13]

In conclusion, a new, efficient, and simple method for fabricating chemical microarrays has been developed. The technique employs selective immobilization reactions of hydrazide-linked small molecules with epoxides on the solid surfaces. The length of the tether between the hydrazide groups and the active ligands governs protein binding; slides containing longer tethers exhibit stronger binding of proteins than those with shorter tethers. The immobilization technique is suitable for covalently attaching diverse compounds, including small molecules, carbohydrates, and peptides, to glass surfaces. The utility of this method is shown by its application to the fabrication of peptide and small-molecule microarrays, which have been used to screen for selective protein binding. We believe that the chemoselective ligation reaction developed in this effort will find many applications in the preparation of bioconjugates, such as neoglycopeptides, peptide–nucleic acid conjugates, and tagged peptides.

Anticancer Agents

Structure and Unique Interactions with DNA of a Cationic *Trans*-Platinum Complex with the Nonplanar Bicyclic Piperidinopiperidine Ligand**

*Yousef Najajreh, Dmitri Prilutski, Yael Ardeli-Tzaraf, Jose Manuel Perez, Elena Khazanov, Yechezkel Barenholz, Jana Kasparkova, Viktor Brabec, and Dan Gibson**

The ability of square-planar platinum(II) complexes to covalently bind to cellular DNA and distort its structure has had an overwhelming impact on the lives of many cancer patients worldwide. The anticancer drug cisplatin (Figure 1a), exerts its cytotoxic effect by binding covalently to two adjacent guanine residues on the same DNA strand (1,2-GpG cross-link), and the ensuing distortion of the DNA, triggers cellular processes that lead to the death of the cancer cell.[1,2] The two crucial properties of cisplatin that make it an efficient anticancer agent are its inertness that enables it to survive the onslaught of the plethora of platinophiles in the extra- and intracellular fluids on the way to the DNA, and its ability to distort the DNA.[3,4] Cisplatin is an extremely effective anticancer agent, whose clinical success is marred by the ability of tumors to acquire resistance to the drug. One approach to try and overcome the acquired resistance to cisplatin was to prepare platinum(II) complexes having *trans* geometry that are incapable of binding two adjacent guanines on the same strand, so they end up forming other lesions with the DNA and distort it differently than cisplatin. Transplatin itself (Figure 1b) is not cytotoxic, yet, several classes of *trans*-platinum complexes with planar heterocyclic amine ligands, bulky aliphatic amine ligands or iminoether ligands, or nonplanar heterocyclic amine ligands have displayed a variety of DNA binding properties as well as impressive cytotoxic properties.[5–11]

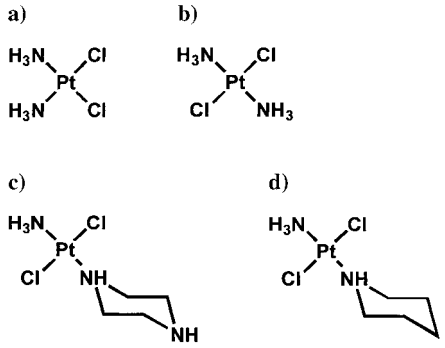

Figure 1. The structures of platinum complexes. a) cisplatin; b) transplatin; c) *trans*-$[PtCl_2(NH_3)(pz)]^+$; d) *trans*-$[PtCl_2(NH_3)(pip)]$.

We have recently reported on the preparation, cytotoxicity and the DNA-binding properties of *trans*-platinum complexes with piperazine (pz) and piperidine (pip) ligands (Figure 1c and d), which circumvent cisplatin resistance in human ovarian cancer cell lines.[12,13]

Piperazine was selected as a ligand because we wanted a soluble, cationic, *trans*-platinum complex that will not only covalently modify the DNA, but in addition, the ligand itself will interact with the DNA at a second site which is removed from the Pt^{II} modification site.

As a natural extension of this rationale, we have recently prepared the complex *trans*-$[PtCl_2(NH_3)(pip\text{-}pip)]\cdot HCl$ (**1**),[14] and now we report its X-ray crystal structure and some of its DNA-binding and pharmacological properties. X-ray quality crystals were obtained by slow evaporation from aqueous solution (Figure 2a).[15] The conformation of the two piperidine rings together with the molecular dimensions are depicted in Figure 2b. Structurally, we can divide the molecule into three parts: 1) the platinum(II) coordination sphere, 2) the first piperidine ring, and 3) the second piperidine ring. The platinum forms the usual square-planar coordination geometry with the Pt–Cl bond lengths around 2.30 Å and the Pt–N bonds around 2.06 Å.

In the solid state structure both piperidine rings adopt the chair conformation (Figure 2b). While the platinum can in

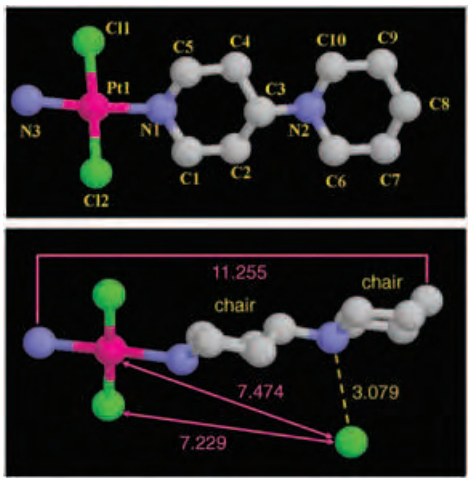

Figure 2. a) The X-ray crystal structure of **1**. b) A side view of the same structure showing that both piperidine rings are in the chair conformation and that N2 is hydrogen bonded to the chloride counterion (yellow dotted line). Depicted in pink are the distances between both ends of the complex (top) and between the platinum region and the hydrogen-bond acceptor (bottom).

principle, bind to either the equatorial or axial lone pair of N1, in this case the platinum is bound to the equatorial position, probably to minimize steric repulsions. N2 is protonated, conferring one positive charge to the complex, making it water soluble, and causing it to crystallize as a salt, with a Cl^- counterion (Figure 2b) that is hydrogen bonded to N2 (N···Cl distance of 3.079 Å). The positive charge is 6.44 Å from the metal center allowing the ligand to interact with hydrogen-bond acceptors at a distance of approximately 7 Å.

We performed an NMR spectroscopic analysis of this complex, and assigned the ^1H and ^{13}C resonance signals (see Supporting Information). The most interesting feature was the NOESY that appears in Figure 3. In phase sensitive NOESY, cross peaks that have the same phase as the diagonal peaks are not NOE[14] peaks but exchange peaks. In the spectrum of **1**, the phases of all the cross peaks of the first piperidine ring (protons 1–3) are opposite to those of the

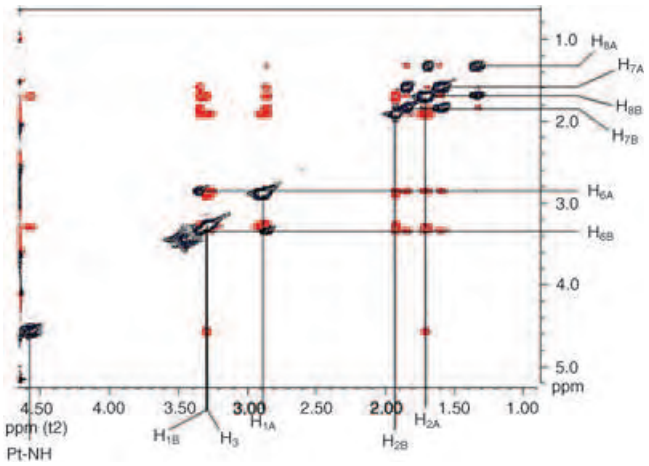

Figure 3. The NOESY spectrum of **1** showing negative contours in black and positive contours in red. For details see text.

diagonal peaks, while all the cross peaks originating from the second piperidine ring (protons 6–8) have the same phase as the diagonal peaks. This result indicates that the cross peaks generated by the protons of the second piperidine ring are exchange peaks and that the second ring is fluxional and its conformation is rapidly changing on the NMR time scale.

The $t_{1/2}$ of the covalent binding of cisplatin and transplatin to DNA is 120 min, and the rate-determining step is the aquation of the first chloride ligand to form the cationic $[PtCl(H_2O)(NH_3)_2]^+$.[16] The classic kinetic studies with square-planar Pt^{II} complexes teach that substitution reactions proceed by an associative mechanism involving a trigonal-bipyramidal intermediate, and that a dramatic decrease of substitution rate occurs for complexes with sterically hindered ligands.[17] Thus, it seems reasonable to expect that the steric hindrance of the bulky bicyclic pip-pip ligand will cause compound **1** to bind to DNA significantly slower than cisplatin or transplatin. The $t_{1/2}$ of the covalent binding of **1** to calf thymus DNA (CT-DNA) is 11 min,[18] indicating extremely rapid binding to DNA.

We studied the rate of conversion of *trans*-$[PtCl_2(NH_3)$-(pip-pip)$]^+$ into *trans*-$[PtCl(H_2O)(NH_3)$(pip-pip)$]^{2+}$ by UV spectroscopy and by ^{195}Pt NMR spectroscopy. The UV spectra of 0.1 mM of **1** (Figure 4) and of *trans*-$[PtCl(H_2O)(NH_3)$(pip-pip)$]^{2+}$ (Figure 4) were recorded and the value of A_{275}/A_{250} was determined (2.3 for **1** and 1.0 for *trans*-$[PtCl(H_2O)$-(NH_3)(pip-pip)$]^{2+}$). Over two hours at 37 °C, no change in the

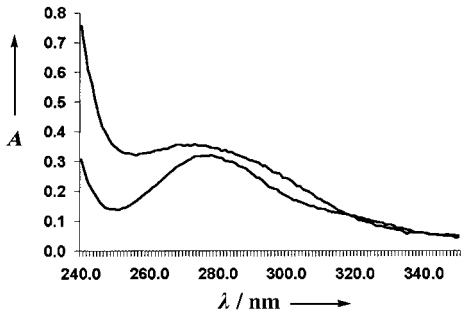

Figure 4. The UV spectra of **1** (lower trace) and *trans*-$[PtCl(H_2O)(NH_3)$-(pip-pip)$]^{2+}$ (upper trace).

UV spectrum of **1** could be detected indicating that no significant aquation occurred during this time. As an additional check, 5 mM aqueous solution of **1** was warmed to 37 °C in a 10-mm NMR tube and a spectrum was acquired every 5 min for 2 h. Over the two hour period the spectrum remained unchanged having a single resonance signal at $\delta = -2177$ ppm and no traces of *trans*-$[PtCl(H_2O)(NH_3)$(pip-pip)$]^{2+}$ at $\delta = -1895$ ppm. Thus, we think that the binding of **1** to the DNA occurs by an initial, rapid, electrostatically driven, "pre-association" of the complex with the double-stranded DNA (dsDNA) that positions the platinum center in the correct orientation for direct substitution of the Cl by the N7 of the purines. The $t_{1/2}$ values for the neutral *trans*-$[PtCl_2(NH_3)$(pip)$]$ (**2**) (113 min), and the cationic *trans*-$[PtCl_2(NH_3)$(pz)$]^+$ (**3**) (20 min), and *trans*-$[PtCl_2$(pz)(pip)$]^+$ (**4**) (22 min), coupled with the fact that no hydrolysis was observed in a 2 hour period for compounds **3** and **4**, support

the claim that electrostatics are the most important factor in determining the platination rate.

The *trans*-$[PtCl_2(pip)(pz)]^+$ ion can be considered the symmetric analogue of the *trans*-$[PtCl_2(NH_3)(pip\text{-}pip)]^+$ ion in the sense that they both have two nonplanar six membered rings and both have a cationic charge that is removed from the metal center. The nonsymmetric **1** binds DNA twice as fast as its symmetric analogue, *trans*-$[PtCl_2(pz)(pip)]^+$, and twice as fast as the less bulky cationic complex *trans*-$[PtCl_2(NH_3)(pz)]^+$. This situation may be due to either the location of the charge relative to the platinum center or to the flexibility of the second pip ring of **1**. Also, the binding of **1** stabilizes CT-DNA more than the symmetric analogue (raising the Tm by 14 °C for **1** and 7.9 °C for *trans*-$[PtCl_2(pz)(pip)]^+$ for $r_b = 0.05$; Tm is the melting temperature at which 50 % of the DNA double helix is denatured, r_b is the number of molecules of the platinum compound bound per nucleotide). Another feature of the unique interaction of **1** with the DNA is the 30° unwinding angle of dsDNA compared with 13° for cisplatin and 17° for the symmetric compound. The additional unwinding may be associated with the interaction of the pip-pip ligand with the duplex upon covalent binding of platinum.

The cytotoxicity of **1** was measured against three pairs of cisplatin sensitive and resistant cancer cell lines (A2780/A2780cisR, 41M/41McisR, and CH1/CH1cisR) that encompass all known resistance mechanisms to cisplatin.[19–22] Compound **1** is twice as potent as cisplatin in all three cisplatin-resistant cell lines (IC_{50} (compound concentration which induces 50 % cell death) values against A2780cisR, CH1cisR, and 41McisR are 24, 15, and 48 μM, respectively, for **1**, versus 38, 23, 107 μM for cisplatin) demonstrating the ability of this complex to circumvent all of the three known resistance mechanism to cisplatin. It is of note that the nonsymmetric 1 is 2–5 times more potent against the resistant cell lines than the symmetric analogue.

In summary, we described a new type of platinum complex that has a *trans* configuration, is asymmetric, has a singly charged nonplanar semifluxional bicyclic ligand, that binds extremely rapidly to DNA by direct substitution (not requiring initial aquation as does cisplatin), distorts DNA in a unique manner and circumvents all of the known cisplatin-resistance mechanism in human ovarian cancer cell lines.

Experimental Section

The compound **1** was prepared in a similar way to that described in ref. [11].

All NMR spectroscopy experiments were performed on an INOVA 500 MHz spectrometer using standard pulse sequences. The data were processed with VNMR or MestRe-C using cosine-squared apodization in both dimensions for the phase-sensitive experiment and unshifted sinbell for in both dimensions for the AV experiments.

The DNA binding studies have been performed as described.[12,13]

The cytotoxicities studies have been performed as previously described.[11]

Nanoporous Materials

Nanoporous Polyelectrolyte Spheres Prepared by Sequentially Coating Sacrificial Mesoporous Silica Spheres**

*Yajun Wang, Aimin Yu, and Frank Caruso**

Mesoporous silicas (MS), porous materials with extremely high surface areas and pore sizes in the range of 2 to 50 nm, have attracted significant interest since being reported in the early 1990s.[1,2] Owing to their unique pore structures, these materials have been utilized as hosts for the template synthesis of various materials, including metal,[3] metal oxide,[4] carbon,[5] and polymer[6] replicas. In a typical synthesis strategy, the constituent materials (e.g., metal precursors, sucrose, organic monomers) are infiltrated into the mesopores. Reduction, carbonization, or cross-linking reactions are then performed to obtain an interconnected network, and the silica template is removed by dissolution. Despite these studies, there has been no report on the sequential infiltration and coating of MS materials with preformed polymers for the fabrication of controlled porous polymer structures. Porous polymer materials, especially in particulate form, are of interest in a diverse range of applications, including drug delivery, molecular separation technology, and as hosts for chemical synthesis.[7]

A facile approach for coating MS is to exploit electrostatic interactions between the MS support and charged polymers (polyelectrolytes, PEs) through solution self-assembly. Sequentially depositing PEs of opposite charge by the layer-by-layer (LbL) technique would potentially permit the formation of PE multilayers inside the MS pores. Since its introduction in 1991,[8,9] the LbL method has been widely used to deposit multilayers of various materials (such as, polymers, enzymes, nanoparticles, dyes) on both planar[10] and colloidal[11] supports. More recent studies have focused on the use of porous substrates, such as macroporous titania,[12] polycarbonate membranes,[13] alumina membranes,[14] and porous calcium carbonate microparticles.[15] However, there has been no report of the LbL assembly of PEs in MS structures and, more specifically, of the LbL MS-templated formation of porous materials with interconnected polymer networks.

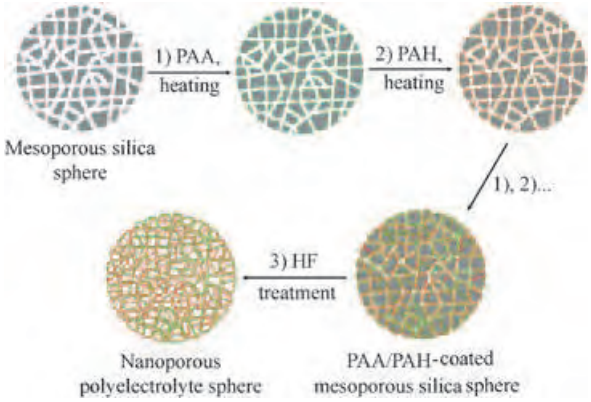
[**] This work was supported by the Australian Research Council (Discovery Project and Federation Fellowship Schemes) and the Victorian State Government, Department of Innovation, Industry and Regional Development, Science, Technology and Innovation initiative. The Particulate Fluids Processing Centre is acknowledged for support. J. Quinn, Q. Li and B. Radt are thanked for assistance with SEM, FTIR, and CLSM experiments, respectively.

Herein, we report the LbL coating of MS spheres with PEs and the subsequent removal of the silica templates to obtain micrometer-sized nanoporous PE spheres (NPS). The procedure for the preparation of the NPS involves two main steps, as depicted in Scheme 1. The first entails the LbL deposition of oppositely charged PEs (poly(acrylic acid) (PAA) and poly(allylamine hydrochloride) (PAH)) within the MS spheres, with subsequent cross-linking of each PE layer by heating. In the second step, the MS template is removed by exposure to hydrofluoric acid (HF). A main advantage of this approach is that it offers a general and versatile route to the preparation of nanoporous PE materials of diverse and tailored composition, as it is based on sequential self-assembly. Hence, it is applicable to a broad range of PEs. Further, the LbL method is largely independent of substrate morphology, making it amenable to MS of different shapes and sizes to generate porous PE networks. Herein we focus on the use of spherical MS particles in the micrometer size range, as these systems represent an interesting class of materials as supports for immobilization and encapsulation of various species (e.g., biomacromolecules). In this study, we also demonstrate the high capacity of the prepared NPS for enzyme entrapment.



Scheme 1. Schematic illustration showing the preparation of nanoporous polyelectrolyte spheres (NPS). 3-aminopropyltriethoxysilane (APTS)-modified bimodal MS (BMS) spheres were layer-by-layer coated with PEs of opposite charge (PAA and PAH; multiple repetition of steps 1 and 2), with the samples heated (160 °C for 2 h) after deposition of each PE to partially cross-link the layers. The BMS template was then dissolved by exposure to HF (step 3), yielding intact NPS.

The MS spheres, prepared according to an established method,[16] possess a bimodal pore structure; that is, smaller pores in the 2–3 nm range and larger pores between 10–40 nm.[16] The particles, herein denoted as BMS (bimodal MS) spheres, have a diameter of 2–4 μm, a surface area of 630 $m^2 g^{-1}$ and a pore volume of 1.72 $mL g^{-1}$. We chose to employ BMS spheres for several reasons: 1) BMS possesses a high pore volume (1.2 $mL g^{-1}$) for the 10–40 nm pores, making it suitable for infiltration and adsorption of PEs; 2) the three-dimensional disordered pore structure and thin pore walls (ca. 3 nm) facilitates the formation of interconnected nanoporous PE networks after removal of the BMS templates; and 3) the spherical morphology aids in monitoring shape and size

  DOI: 10.1002/anie.200462135

variations as a result of LbL PE coating. The BMS surface was first functionalized by grafting a layer of 3-aminopropyltriethoxysilane (APTS) onto the BMS skeleton.[17] This process introduces amine (NH_2-) surface functional groups to the BMS, which promotes specific adsorption of the subsequently deposited PAA through interaction of the $-NH_2$ and $-COOH$ groups. The APTS-grafted BMS (APTS–BMS) spheres have a surface area of 465 $m^2 g^{-1}$ and a pore volume of 1.32 $mL g^{-1}$. The large mesopores (10–40 nm) have a volume of approximately 1.0 $mL g^{-1}$.

Polyelectrolyte solutions were prepared by dissolving PAA or PAH in deionized water containing sodium chloride (NaCl), without adjusting the pH value. PAA ($M_w = 2000$) was deposited onto the APTS–BMS spheres from an aqueous 5 $mg mL^{-1}$ PAA solution of pH 2.9 containing 0.7 M NaCl. Adsorption was conducted at 20 °C for 15 min with sonication (to aid the transport of the PEs into the mesopores[13]), and subsequent shaking for 6 h. Excess PAA was removed by four cycles of centrifugation (500 *g* for 3 min) and washing with 0.1 M NaCl. PAH ($M_w = 15000$) was deposited from an aqueous 5 $mg mL^{-1}$ PAH solution of pH 4.3 with 0.7 M NaCl. To facilitate infiltration into the pores of the APTS–BMS spheres, low molecular weight PEs were used,[13] and NaCl was added to the adsorption solution to promote coiling of the PE molecules.[18] Cross-linking of each PE layer was performed by heating the dried sample at 160 °C for 2 h.[19,20] Under this treatment, amide bonds are formed by the $-COOH$ groups (in PAA) and the $-NH_2$ moieties (in PAH or on the APTS–BMS template), enhancing the structural stability of the layers.[19,20] It was found that without the cross-linking process, the PE layers partially desorbed from the mesopores during subsequent PE adsorption steps, forming aggregates on the particle surface and in solution.[21]

Evidence for the successive deposition of PAA and PAH within the pores of the APTS–BMS spheres was obtained by Fourier transform infrared (FTIR) experiments. FTIR spectra of the APTS–BMS particles as a function of PAA and PAH deposition steps are shown in Figure 1 a. For the APTS–BMS spheres, the absorption band at 1635 cm^{-1} (A) is assigned to the Si–OH vibrations[22] and the N–H bending (scissoring) vibrations of APTS. The peaks at 1720 (B), 1570 (C), and 1400 (D) cm^{-1} are attributed to the $-COOH$ carbonyl and $-COO^-$ asymmetric and symmetric stretches, respectively, of PAA.[19,23] The large fraction of non-ionized acid groups in the PAA chains is caused by the low assembly pH value in our experiments.[24] The intensities of the peaks at 1635 cm^{-1} (assigned to the N–H bending (scissoring) vibration of PAH for layer number = 2) and at 1720 cm^{-1} increase with PAH and PAA layer number, respectively, confirming the sequential deposition of PAA/PAH multilayers. The following observations can be made from the spectra: a) The presence of $-COOH$ (from PAA) after heating at 160 °C indicates that only partial cross-linking of the layers occurs, which is in agreement with earlier work.[19] Only about 10–15 % reduction in intensity of this peak was observed after heating the films. b) The amide bonds formed as a result of cross-linking (peak at $\nu \approx 1670$ cm^{-1}) are not discernible, largely because of the relatively low degree of cross-linking and masking from the peak at 1635 cm^{-1} (arising from the APTS-BMS substrate and PAH).[19,22] c) The total amount of PAA deposited per APTS–BMS particle increases with PAA layer number, although the amount adsorbed per layer decreases with increasing PAA layer number (Figure 1 b).[25] This trend is attributed to increased blockage of the larger mesopores in the APTS–BMS templates with increasing PE layer number.

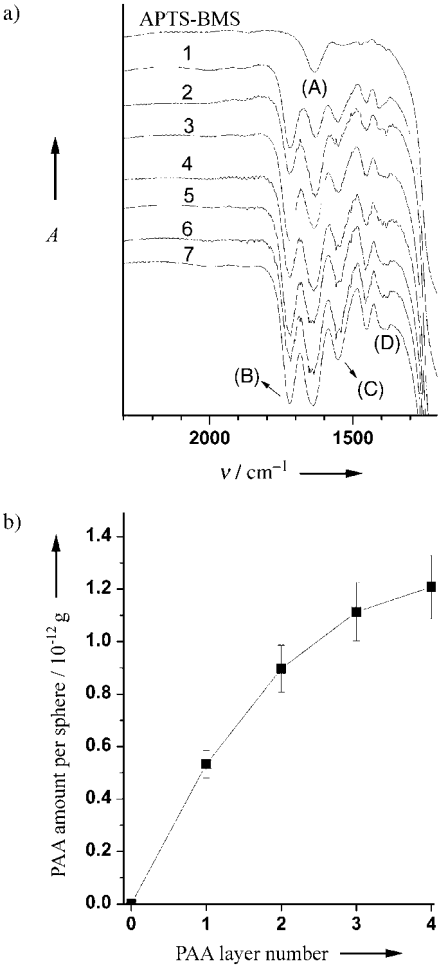


Figure 1. a) FTIR spectra of the APTS–BMS spheres before and after the alternate deposition of PAA and PAH layers. The deposited layers were partially cross-linked by heating at 160 °C for 2 h prior to recording each spectrum. The numbers correspond to the number of PE layers deposited, commencing with PAA. APTS–BMS spheres were used as the internal reference for measuring each spectrum. The spectra are shifted vertically for clarity. b) The amount of PAA deposited on the APTS–BMS particle as a function of layer number was determined from the ratio of the peak at 1720 cm^{-1} (PAA) with the peak at 800 cm^{-1} (APTS–BMS).[25] The relative strength of the PAA signal compared to the APTS–BMS signal was determined to be 2.4 by measuring the IR spectrum of a 1:1 (weight) mixture of PAA and APTS–BMS powders. The APTS–BMS has an average weight of 4.3×10^{-12} g, assuming the particle has a size of 2.5 μm and a density of 0.53 $g mL^{-1}$.

To examine the influence of sphere porosity, we used MS spheres with only 2–3 nm pores and nonporous silica spheres for comparison. No distinguishable peaks arising from PAA and PAH in the FTIR spectra of either of the PAA/PAH-coated silica spheres were observed, even after deposition of seven layers (i.e., 3.5 PAA/PAH bilayers). This result indicates that PE deposition predominantly occurs in the

larger mesopores of the APTS–BMS particles, and that the contribution to the FTIR intensities from PE adsorption on the outer surface of the particles is negligible.

Nitrogen adsorption measurements were also conducted to follow the changes in the surface area of the APTS–BMS spheres after PE deposition. The first layer of adsorbed PAA dramatically decreased the surface area from 465 $m^2 g^{-1}$ (APTS–BMS template) to 284 $m^2 g^{-1}$. This decrease is caused by the high PAA loading and blocking of some of the mesopores. Deposition of subsequent PAH and PAA layers resulted in a surface area decrease of approximately 20 $m^2 g^{-1}$per PE adsorption step. After deposition of seven layers, the surface area of the coated spheres was approximately 160 $m^2 g^{-1}$. These data further confirm the stepwise deposition of PEs within the APTS–BMS spheres.

NPS were prepared by exposing the PAA/PAH-coated APTS–BMS spheres to an aqueous 10 wt% HF solution for 12 h. Silica particles readily decompose in HF to form $[SiF_6]^{2-}$ ions, which can readily diffuse through PE multilayers.[26] Effective removal of the BMS template was demonstrated by energy-dispersive X-ray (EDX) analysis and FTIR experiments. EDX data showed that only a small amount of silicon (0.8%) was detected after removal of the BMS template (not shown). The small residual amount of silicon probably arises from silicon-alkyl groups ($\equiv$Si-$(CH_2)_3$-NH_2), which are stable in the presence of HF.[27] These groups are introduced into the sample through the APTS modification of the BMS particles.

Spherical NPS were obtained for samples that comprise two or more PAA and PAH layers. Figure 2 shows TEM and

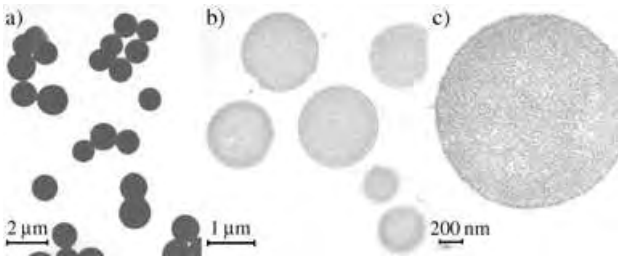

Figure 2. TEM images of the NPS that comprises a) $(PAA/PAH)_2/PAA$ (5-NPS) and ultramicrotomed thin sections of the same spheres at b) low and c) higher magnification. The 5-NPS were partially cross-linked by heating at 160°C for 2 h after deposition of each PE layer. Images (b) and (c) show the porosity of the PE spheres. The large difference in the diameters seen is a result of the ultramicrotoming process.

Figure 3 SEM images of 5-layer $[(PAA/PAH)_2/PAA]$ NPS (5-NPS). These NPS retain the original shape of the BMS templates, and do not show signs of collapse, as is typically observed for PE capsules.[9] The diameters of the resulting NPS were found to depend on the number of PE layers deposited on the template APTS–BMS particles. APTS–BMS spheres coated with more PE layers underwent less shrinkage. For example, the PAA/PAH NPS (2-NPS) had diameters ranging from 0.8–1.3 μm, representing shrinkage of around 55–60%, compared with the original APTS–BMS templates, in which over 90% of APTS–BMS particles are within 2–3 μm. The 7-NPS were between 1.4–2.1 μm, 25–30% smaller than the template particles. No aggregation of the NPS was observed from TEM (Figure 2a). The inner structure of the NPS was examined by TEM of ultramicrotomed (approximately 90 nm thin slices) spheres. Figure 2b confirms that the PEs infiltrated into the BMS spheres, as PE can be seen in the interior of the NPS. At higher magnification (Figure 2c), a homogeneous porous structure with a pore size distribution of around 5–50 nm is clearly seen, confirming the nanoporosity of the spheres. SEM images of broken spheres (not shown) confirmed the interconnected PE network of the spherical particles. SEM also revealed the NPS to be individual particles, with no obvious aggregation of the particles observed (Figure 3a). At higher magnification, the roughness

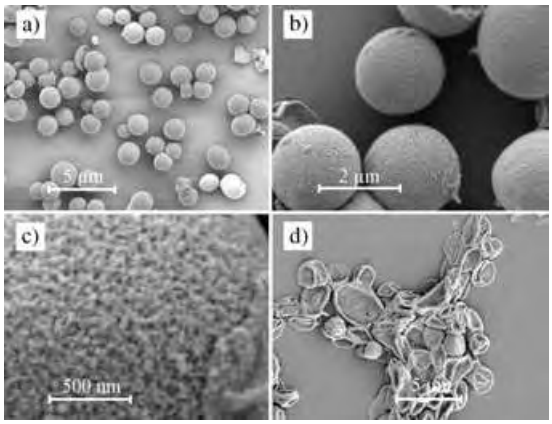

Figure 3. SEM images of 5-NPS $[(PAA/PAH)_2/PAA]$ at different magnifications (a, b, c), and $(PAA/PAH)_2/PAA$ capsules prepared when PAA and PAH are deposited in the absence of added salt in the adsorption solution (d). The 5-NPS and capsules were partially cross-linked by heating at 160°C for 2 h after deposition of each PE layer.

and porosity of the spheres is apparent (Figure 3b), with homogeneous pores in the range of approximately 10–50 nm seen (Figure 3c). Figure 3d shows the collapsed capsule structure of the product prepared by the same procedure when the PE layers were deposited in the absence of salt. This indicates that, as mentioned above, the salt facilitates PE coiling and penetration into the mesopores of the BMS templates. In the absence of salt, the PEs assume a more linear conformation[18] and therefore will be mainly restricted to the surface. We note that the highly efficient role of the APTS–BMS spheres as templates for the preparation of interconnected porous particles is attributed to the abundant and disordered pore structure of the larger mesopores and high surface area (465 $m^2 g^{-1}$) of the APTS–BMS particles. For example, a recent study employing porous (radial channel-like) $CaCO_3$ microparticle templates (surface area ca. 8.8 $m^2 g^{-1}$) resulted in PE microcapsules that collapse when dried,[15] which is in stark contrast to the free-standing NPS reported herein.

The capacity of the NPS as hosts for the immobilization of biomacromolecules was investigated through lysozyme adsorption studies. Approximately 10 mg of the NPS were dispersed in 15 mL of a 1 mg mL^{-1} lysozyme ($M_w = 14.6$ kDa) solution containing 50 mM phosphate buffer (pH 7.0). The

immobilization and distribution of enzyme in the NPS were examined by confocal laser scanning microscopy (CLSM). Figure 4 shows the CLSM images of the 5-NPS after incubation in fluorescein isothiocyanate-labeled lysozyme

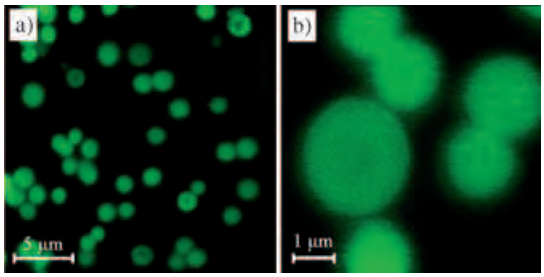

Figure 4. CLSM images of FITC-labeled lysozyme immobilized in the 5-NPS at a) low and b) higher magnification. The 5-NPS were partially cross-linked by heating at 160 °C for 2 h after deposition of each PE layer.

(FITC-lysozyme) for 1 h, and subsequent washing with water. The images show that FITC-lysozyme is distributed homogeneously throughout the NPS. The amount of enzyme immobilized by the NPS was determined spectrophotometrically by measuring the difference in lysozyme absorbance at 280 nm before and after adsorption. For the 5-NPS, the weight of the NPS increased by approximately 90 % after lysozyme immobilization, corresponding to 6.7×10^{-17} mol of lysozyme per sphere. This value corresponds to a concentration of about 470 mg mL^{-1} of lysozyme in 5-NPS, which is approximately a factor of two times larger than that obtained for the direct immobilization of lysozyme onto BMS spheres under the same conditions (220 mg mL^{-1}), and for that reported for bovine serum albumin in poly(styrene sulfonate)/PAH capsules with a "matrix-type interior" (250 mg mL^{-1}).[15] The high enzyme immobilization capacity of the NPS is attributed to the nanoporous PE framework in the NPS.

In conclusion, intact NPS with an interconnected PE network have been prepared by the LbL assembly of PEs onto APTS–BMS spheres and subsequent removal of the template. Electron microscopy data show that the NPS have pores ranging from 5–50 nm. The NPS show excellent capacity for immobilization of enzymes (lysozyme). Since the LbL method is amenable to the deposition of diverse PEs, the preparation of NPS of controlled composition and functionality can be achieved by the reported approach. This feature will facilitate designing NPS for the uptake of various species, such as macromolecules, low-molecular-weight drugs, pesticides and fragrances, and nanoparticles through, for example, electrostatic association or hydrogen bonding with the NPS host. The broad range of MS materials available with tunable size, morphology and porosity will enable the preparation of tailored porous PE materials that are envisaged to find application in biocatalysis, separation technology, and controlled drug delivery systems.

[21] Under the conditions used (low M_w PEs and relatively high NaCl concentrations), partial desorption of the adsorbed PE layer by the incoming PE from solution occurs. Such effects ("PE stripping") have been been observed before (Z. Sui, D. Salloum, J. B. Schlenoff, *Langmuir* **2003**, *19*, 2491). Sonication may also cause some removal of adsorbed PE.

[25] Since the peak around 1635 cm^{-1} is a combination of the Si–OH vibration of the APTS–BMS spheres and the N–H bending (scissoring) vibrations of the APTS and PAH, and overlaps with the amide band owing to film cross-linking, calculation of the adsorbed amount of PAH is complicated. Therefore, we chose to analyze the peak at 1720 cm^{-1} originating from PAA.

Virus-Decorated Biocomposites

Engineering Virus Functionalities on Colloidal Polyelectrolyte Lipid Composites**

*Martin Fischlechner, Olaf Zschörnig, Jörg Hofmann, and Edwin Donath**

The fabrication of functional supramolecular assemblies of nanometer dimensions consisting of both biological and artificial constituents is an exciting and rapidly developing new field at the intersection of biology, chemistry, and physics.

[**] This research was supported by a grant from Volkswagenstiftung within the framework of the program "Complex Materials". We thank D. Enderlein and C. Götte for support in RLP preparation and analysis, I. Estrela-Lopis for an introduction to the fabrication of polyelectrolyte–lipid composites, and B. Benke for the design of Figure 1.

From the standpoint of pure research it is challenging to study the structure and function of these "bionanocomposites". In addition, smart biocomposite systems for drug delivery and artificial vectors for gene therapy should have exciting applications in medicine.

In the course of evolution nature designed viruses, small particles that defy categorization as actual living entities or just small assemblies of biomolecules. Viruses actually are nanocomposites consisting of only a few polymeric species and often equipped with a lipid membrane. They carry genetic information for their replication but need a host cell to accomplish reproduction. The virus envelope, composed of less than a handful of macromolecular species, nevertheless, bears all the functions needed to recognize and enter a host cell. This is exploited in various biotechnological applications such as protein production, vaccine design, development of genetic libraries, and gene therapy.

If it would be possible to engineer colloidal particles with surfaces bearing the functionality of viruses, this would be a novel means for the delivery of a variety of materials into cells and tissues. A possible strategy would be to fabricate composite particles or capsules equipped on their surface with all the necessary virus functions for cell-membrane passage. This approach could be used, for example, to deliver a cocktail of material packed into a small colloidal entity into cells; this is not easy to do with the existing delivery devices. In this communication we describe how such virus-modified particles have been fabricated by the Layer-by-Layer (LbL) approach originally introduced for macroscopic surfaces,[1] and how their functionality has been proved.

Through the consecutive adsorption of oppositely charged polyions on colloidal particles, multilayers can be fabricated.[2] Their thickness and composition can be tuned on the nanometer scale. When this synthetic method is applied to colloids with soluble cores, capsules can be fabricated.[3] Various functions can be added by either employing functional species for adsorption or by subsequent modification.[4] Capsules can be loaded with different materials,[5] and lipid bilayers can be added.[6]

At the same time molecular biology, in particular, virology, provides a variety of tools for genetic engineering. Techniques for the manipulation of viruses are well established. Various proteins and peptides can be expressed at the virus surface.[7] These modified viruses thus provide great flexibility in the choice of biologically engineered surfaces. Combining the assembly of virus-like LbL colloids and capsules with genetic engineering thus would open novel pathways for fabricating functional bionanocomposites of complex but fully controlled interfacial composition. They may be useful as combinatorial entities in a variety of biomedical and biotechnological applications such as diagnostics, vaccination, and delivery.

In this work, Rubella-Like Particles (RLPs)[8] were employed as the virus-like material. These particles are identical copies of the lipid-enveloped rubella virus (RV) except without the virus RNA. The RLPs can be harvested from CHO cells transfected with an expression plasmid containing a cDNA of the RV subgenomic RNA. RV binds to its host cell surface, and induces endocytosis and fusion with

  DOI: 10.1002/anie.200460763

the late endosomal membrane. Binding and fusion are mediated by the rubella virus membrane protein E1 present in a complex with E2, the only other membrane protein of the rubella virus. The E1 protein function is triggered by pH, a feature displayed by many lipid-enveloped viruses. Cell-membrane binding occurs at physiological pH, while fusion with the late endosomal membrane takes place under the acidic conditions inside the endosome. The fusion competence of the E1 protein[9] is activated at low pH.

The protocol for the fabrication of RLP-decorated LbL colloids is illustrated in Figure 1. Initially a polyelectrolyte multilayer consisting of poly(allylamine hydrochloride) (PAH) and poly(sodium 4-styrenesulfonate) (PSS) was assembled onto a colloidal core. A variety of cores may be used, which can be removed afterwards, resulting in hollow polymeric capsules. The next step consisted in adding a phosphatidylserine (PS) bilayer onto this polyelectrolyte multilayer cushion. Small unilamellar PS vesicles[10] were incubated with the LbL-coated colloids having as the top layer the positively charged PAH. A bilayer was formed spontaneously by vesicle adsorption and spreading. The existence and stability of this PS bilayer was proved by means of confocal laser scanning microscopy (CLSM).[11]

On incubation of PS-coated LbL colloids with RLPs at low pH (pH 4), the particles attached to the lipid layer by electrostatic forces and subsequently fused with the membrane, presenting RV envelope proteins E1 and E2 on the surface. Tryptophane fluorescence spectroscopy was used to detect the presence of the RLPs. When the RLP-coated colloids were transferred into a buffer with pH 7.4, those RLPs which did not fuse at pH 4 desorbed, as revealed by the tryptophane fluorescence in the supernatant (see Figure 2). The amino termini of the RV E1 and E2 proteins as well as the amino groups of the virus lipids, mostly sphingomyelin, were labeled with tetramethylrhodamine. Their localization was then studied by means of CLSM (see Figure 3). The presence of the virus components was demonstrated by the homogeneous fluorescent coat on the colloids. Furthermore, SDS polyacrylamide gel electrophoresis revealed the presence of the complete set of structural RV proteins on the colloids (data not shown).

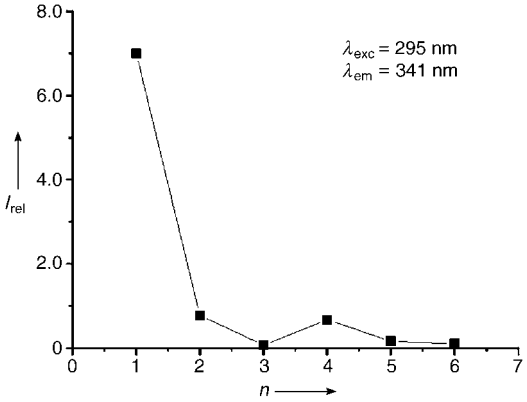

Figure 2. Tryptophane fluorescence intensity (I_{rel} in arbitrary units) in supernatants of washing cycles (n) following incubation of lipid polyelectrolyte composite particles with RLPs. Washings 1–3 were performed in 0.2 M phosphate/0.1 M citrate buffer at pH 4, washings 4–6 in 0.2 M phosphate/0.1 M citrate buffer at pH 7.4. RLPs that did not fuse with the lipid layer were desorbed and were detected by the small jump of fluorescence in the supernatant from washing cycle 4.

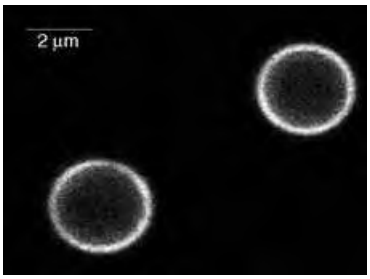

Figure 3. Fluorescence of rhodamine-labeled RLPs engineered on PS polyelectrolyte-coated silica particles.

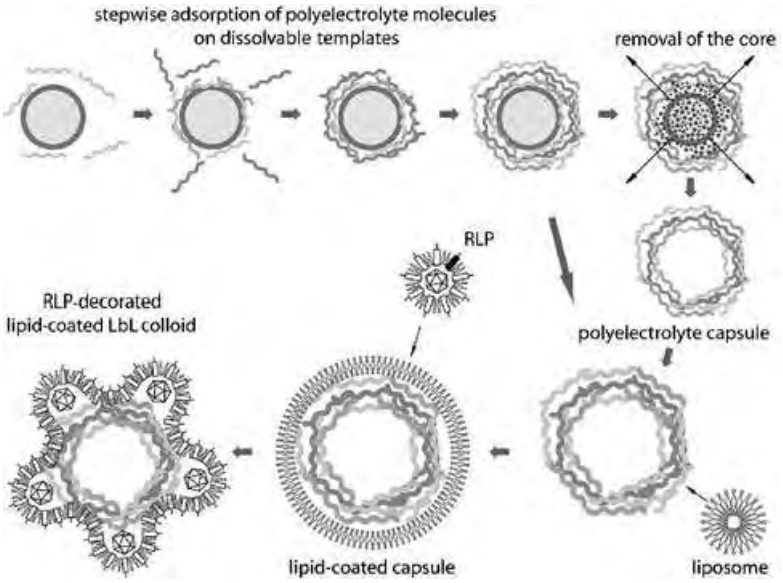

Figure 1. Protocol for engineering virus functionality on polyelectrolyte lipid composite colloids and capsules. Removal of the core is optional.

The octadecylrhodamine (R18) dequenching assay[12] was used to demonstrate the mixing of the virus membrane with the PS layer present on the colloids. The probe was added to RLPs in such a concentration that its fluorescence was partly quenched. Upon fusion it should mix with the bilayer of the target, resulting in dilution of the probe and partial dequenching of fluorescence. At pH 4 it was found that at least one-fourth of the applied RLPs had fused with the PS layer, whereas at neutral pH the observed small dequenching indicated fusion of not more than a few percent. In addition, Foerster energy transfer was demonstrated between the top polyelectrolyte layer containing FITC-labeled PAH and the R18 probe, which proves that the distance between the two labels is on the order of only a few nanometers. Because of the size of the capsid structure of the RLPs, significant energy transfer is possible only if the R18 probe

present in the RLP envelope is able to dilute laterally in the phosphatidylserine bilayer of the capsules.

Figure 4 reveals that E1 epitopes are indeed presented on the surface of the fabricated composite colloids. Here a monoclonal antibody raised against the major immunodominant epitope of E1 was applied. To reduce unspecific binding of the primary as well as secondary antibody to the particle surface, several blocking reagents were tested. Satisfying results were obtained with protamine sulphate, while the use of bovine serum albumine lead to considerable background signals.[13]

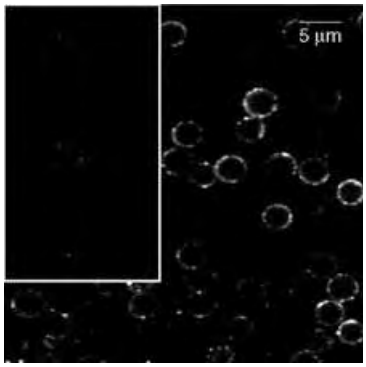

Figure 4. Confocal image of immunofluorescence against rubella virus E1 epitope on engineered silica particles. The presence of E1 is revealed by the fluorescence of the secondary antibody bound to the primary antibody against E1. The inset shows the control under identical fluorescence conditions.

The key function of the virus surface is the binding to a host cell surface, induction of endocytosis, and subsequent fusion with the late endosome membrane. In order to demonstrate the retained biological activity and functionality of E1, these engineered constructs were presented to living cells. As shown in Figure 5, LbL-coated colloids and capsules were taken up by endocytosis into Vero cells.[14] The endocytosed particles form clusters of fluorescence near the nucleus. The degree of uptake depends strongly on the nature of the top layer. While coated particles with PS as the top layer were rarely found inside the cells, those colloids which had been fused with the RLPs were effectively incorporated. The difference in uptake between the RLP-decorated PS and only PS as the top layer of the colloids can be clearly attributed to the presence of viral envelope proteins.

It is worth mentioning that particles with the polycation PAH on their surface were also found in large amounts inside the Vero cells. In this case, cell damage was observed. The uptake of particles with PAH as the top layer is probably initiated by their strong binding. This nonspecific binding was avoided when various negatively charged biopolyelectrolytes were utilized as the top layer. It is not known yet if they got stuck in the endosome or had gained access to the cytosol. This remains an exciting unresolved question for further experiments involving selective targeting and delivery of incorporated substances such as DNA[15] and proteins. Defoliation of the multilayer and improved biodegradability of the composite constituents are other issues for future research.

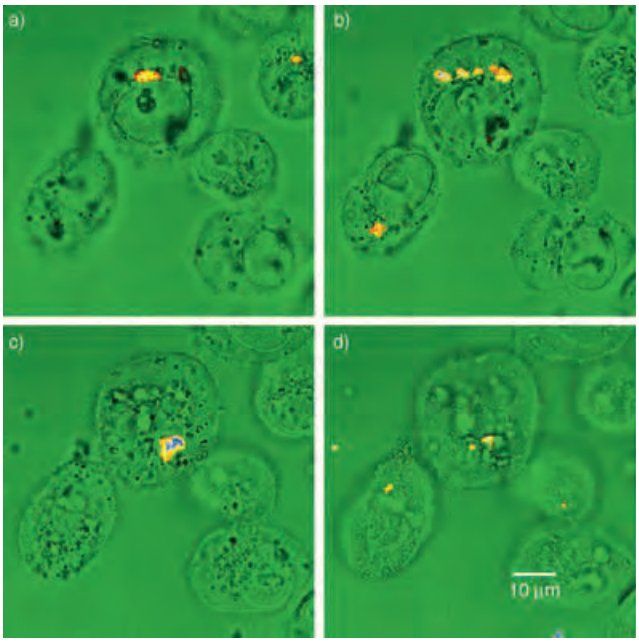

Figure 5. Uptake of 1-µm RLP-coated fluorescent LbL colloids (the fifth layer contained FITC-labeled PAH) into Vero cells. The images in a)–d) represent four consecutive confocal scans from top to bottom through the cultured Vero cells. Fluorescent colloids forming clusters near the nucleus can be identified by their red to bright yellow color. The blue color in the fluorescent spots indicates the overflow of intensity.

We conclude that the surface of lipid and polyelectrolyte multilayer coated colloids and capsules can be modified with rubella-like particles. It is very likely that this can be also achieved with other viruses or virus-like particles that infect cells by endosomal uptake.[16] This could be utilized potentially for the development of particle or capsule systems with targeting properties utilizing the specific binding properties of certain viral proteins. Moreover, with the well-developed techniques in genetic engineering, it should be possible to add membrane proteins of nonviral origin to the surface of viruses or virus-like particles. Hence, it may be possible to fabricate particles with virus functions at their surfaces along with other desired biological properties in designed arrangements on the nanometer scale. Considering all these features together, this technique could be a general approach for the transfer of biological functionalities of various kinds onto colloids, capsules, and flat surfaces.

Experimental Section

Materials: Silica particles with diameters of 3 µm and 1 µm were purchased from microparticles GmbH (Berlin, Germany). Poly(allylamine hydrochloride) ($M_w \approx 70000$) and poly(sodium 4-styrenesulfonate) ($M_w \approx 70000$) were purchased from Aldrich. L-α-Phosphatidylserine (brain, porcine; sodium salt; 20 mg mL^{-1} in chloroform) (PS) was purchased from Avanti Polar Lipids, Inc.

RLP preparation: RLPs were isolated according to the method of Hobman et al.[8] Briefly, permanent transformed CHO cells were grown on triple flasks (Nunc) at 37 °C in 5% CO_2 atmosphere. The RLPs were secreted into the supernatant of transfected cells. The

culture medium was concentrated initially using an Amicon hollow fiber equipment (H1-100) and subsequently with an Amicon stirring cell. The concentrated solution was processed on a Sepharose 4B-Cl chromatography column. Protein content was determined using the bichinonic acid assay from Sigma.

Addition of the lipid layer: The lipid bilayer was formed by adsorption of unilamellar vesicles to multilayer-coated colloids or capsules with PAH as the top layer. Vesicles and the substrates were stirred for 30 min at 37 °C on an Eppendorf Thermomixer Comfort in 0.1 M NaCl. After incubation, tween 80 (Serva, Heidelberg/New York) was added to a final concentration of 0.05 % (v/v), and the vesicles were incubated for another 5 min and subsequently washed four times with 0.1 M NaCl or PBS.

Fusion procedure: Fusion of rubella-like particles onto the lipid-coated colloids was conducted in 0.2 M phosphate/0.1 M citrate buffer at pH 4 by incubation with RLPs for 30 min at 37 °C followed by four washings with a 0.2 M phosphate/0.1 M citrate buffer, pH 7.4. For a total particle surface of 0.01 m^2, 200 μL RLPs in 0.2 M phosphate/0.1 M citrate buffer pH 4 (1 mg mL^{-1} protein) were used.

Octadecylrhodamine dequenching assay: The phospholipid content of the RLPs was estimated according to the method of Bardeletti et al.[17] The protocol for labelling RLPs with R18 (octadecyl rhodamine B, chloride salt; Molecular Probes, Inc.) was as follows: A 2-mM solution of R18 in methanol was added to RLPs in PBS corresponding to a final concentration of 4 % (mol/mol) R18 per lipid. The labeling reaction was performed at room temperature for 1 h in the dark. Subsequently, the RLPs were purified over a Sephadex G75 column. Fractions were analyzed by fluorescence spectroscopy for simultaneous occurrence of label and protein. Triton-X-100 (Merck, Darmstadt/Germany) was used at a final concentration of 0.1 % (v/v).

Immunofluorescence: Coating the particles with protamine sulfate (from herring, Sigma) prior to fixation with paraformaldehyde prevented unspecific binding of the primary antibody. Lipid polyelectrolyte particles as the negative control and particles coated with RLPs were incubated with 1 mL protamine sulfate (1 mg mL^{-1} in 0.1 M NaCl) for 10 min at room temperature. Three washings in PBS followed. The samples were spotted on a glass slide and incubated for 30 min with paraformaldehyde (2 % w/v). Subsequently, the primary antibody (Mab < Rubella > M-1B9-IgG, kindly provided by Roche Diagnostics, Germany) diluted 1:200 in PBS/1 % BSA, centrifuged for 10 min/14 krpm) was added, and the particles were incubated for another 2 h. The samples were washed five times in PBS for 10 min. Then the secondary antibody (Anti-mouse-IgG Cy3, Sigma #C 2181) diluted 1:75 in 1 % BSA in PBS, centrifuged at 10 min/14 krpm) was added. An incubation for 1 h and three washings in PBS each for 5 min followed.

Uptake in Vero cells: Vero cells were grown in Dulbecco's modified eagle medium alpha with Glutamax (Gibco BRL) on LAB-Tek slides (Nunc) to confluency. Coated particles 1 μm in diameter were pipetted to the cells in a ratio of 3:1, and the cells were incubated overnight at 37 °C in 5 % CO_2 atmosphere. Prior to examination the samples were washed three times with PBS.

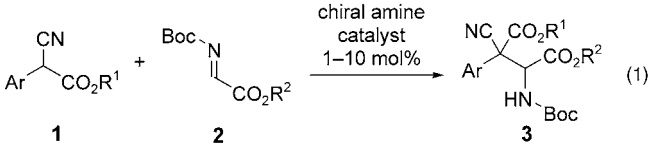
Asymmetric Synthesis

Direct Organocatalytic and Highly Enantio- and Diastereoselective Mannich Reactions of α-Substituted α-Cyanoacetates**

*Thomas B. Poulsen, Carlos Alemparte, Steen Saaby, Marco Bella, and Karl Anker Jørgensen**



The Mannich reaction is a fundamental C–C bond-forming reaction in synthetic organic chemistry.[1] The development of an asymmetric version of this reaction is of great importance, and would allow chemists to control the configuration of the new stereocenters formed. Several catalytic enantioselective versions of the Mannich reaction have emerged that are based on chiral metal complexes.[2] Recently, metal-free (organocatalytic) systems have complemented and occasionally challenged established metal-based systems.[3] In particular, the use of chiral secondary amines as organocatalysts has been successful for a range of transformations, including the asymmetric Mannich reaction.[4] The latter takes place via a chiral enamine intermediate which undergoes nucleophilic addition to the imine in an enantioselective manner.

Alternatively, chiral tertiary amines have also been successfully applied in various organocatalytic transformations,[3,5] acting as nucleophilic,[6] phase-transfer,[7] and chiral-base catalysts.[8] However, this concept has not yet been applied to the Mannich reaction, despite the potential for the straightforward formation of highly functionalized products that contain attractive structural features.[9]

Recently, we described a highly enantioselective procedure for the direct amination of α-aryl-substituted cyanoacetates and β-dicarbonyl compounds with the chiral tertiary amine catalyst β-isocupreidine, derived in one step from inexpensive and commercially available quinidine.[8d] As the use of α-substituted cyanoacetates as nucleophiles in catalytic asymmetric reactions has been limited so far,[10] we were interested in expanding the methodology to encompass C–C bond-forming reactions. Herein we report the development of a new organocatalytic approach to the direct Mannich reaction, which affords highly functionalized products with two consecutive stereogenic carbon atoms, one of which is quaternary by all-carbon substitution [Eq. (1)].[11] Furthermore, this approach employs an α-imino ester with the readily removable *tert*-butoxycarbonyl (Boc) protecting group on the nitrogen atom.

Owing to the structural similarity of *N*-Boc-protected α-imino esters and dialkyl azodicarboxylates, we first attempted the conditions previously developed for the amination reaction.[8d] The Mannich reaction of a *tert*-butyl cyanoester with β-isocupreidine as the catalyst in toluene gave a high product yield, but with an unexpectedly poor enantioselectivity (< 20 % *ee*) and a negligible diastereoselectivity as well.

Therefore, an extensive screen of reaction conditions was undertaken, and some of the results are listed in Table 1. Variation of the catalyst (entries 1–6) showed the commercially available $(DHQD)_2PYR$ to be the most effective in both enantio- and diastereoselectivity. The nature of the cyanoacetate ester group is critical for the stereochemical outcome of the reaction. A decrease in size from *n*-propyl to methyl caused a slight decrease in the enantioselectivity of the major diastereomer (entries 6 and 7). The bulkier isopropyl group had a beneficial effect (entry 8) but a larger group was less effective (entry 9). Finally, the benzyl group gave optimal results, and the Mannich product was obtained with considerable preference for one of the two possible diastereomers, and with excellent enantioselectivity (96 % *ee*, entry 10). The influence of the structure of the α-imino ester **2** was also evaluated, but was found to be less significant when benzyl cyanoacetates were applied.[12] An increase in temperature caused a decrease in reaction selectivity (entries 11 and 12).

A further optimization of the reaction conditions (entries 13 and 14) showed that CH_2Cl_2 is a better solvent than Et_2O and surprisingly, better than toluene as well. The latter observation differs from what is intuitively expected in asymmetric reactions involving ion pair intermediates—namely that the highest selectivities are obtained in nonpolar, noncoordinating media.[13]

A decrease in catalyst loading is clearly desirable for a catalytic reaction. Although organocatalysis has proven successful in many respects, most of these processes require 10 mol % or more of the catalyst for sufficient product formation and maintenance of stereoselectivity. The reaction reported herein can be performed without notable loss of selectivity even with a catalyst loading of 1 mol % (entries 15 and 16). Finally, a controlled slow addition of the imine electrophile was found to be beneficial (entry 17).

An important advantage of this catalytic stereoselective Mannich reaction is the use of *N*-Boc-protected imines, generated in situ by dehydrobromination of Boc-protected α-bromoglycine esters.[14] A drawback for many reactions of α-imino esters with an electron-withdrawing group (commonly tosyl) on the nitrogen atom has been the subsequent deprotection step.[15] This synthetic problem has been overcome with the present methodology, however, as the Boc protecting group is easily removed.

[a] Catalyst structures available in Supporting Information. [b] Determined by ^1H NMR spectroscopy of the crude product mixture. [c] Determined by CSP-HPLC analysis; values for both diastereomers given (CSP = chiral stationary phase). [d] The opposite enantiomers were obtained in this case. [e] Slow addition of the imine over a period of 30 min.

The optimized conditions were used to evaluate the scope of the Mannich reaction.[16] A series of benzyl α-aryl-α-cyanoacetates **1e–l** were combined with *N*-Boc-protected imines **2a–c** in reactions catalyzed by $(DHQD)_2PYR$ (5 mol%) (Table 2). Substituents present in the *meta* and *para* positions were well-tolerated (entries 2–5), providing the *N*-Boc-protected products in high yields with excellent enantioselectivities of the major diastereomer. Likewise, the polyaromatic 2-naphtyl derivative **1i** is a useful substrate (entry 6), which gave Mannich product **3i** in essentially quantitative yield with 96% *ee* in the major *u*-diastereomer, which was favored by a factor of 88:12 over the minor *l*-diastereomer.[17]

Heteroaromatic and disubstituted aromatic substrates **1j** and **1k** also afforded the Mannich products with satisfactory selectivities (entries 7, 8). Interestingly, the *ortho*-substituted bromocyanoester **1l** displayed anomalous behavior relative to the other substrates. The reaction was still very clean, but favored formation of the *l*-diastereomer instead, and the *u*-diastereomer was obtained with a disappointing 11% *ee* (entry 9). Further developments revealed that a mere change of the reaction solvent from CH_2Cl_2 to toluene drastically changed the stereochemical outcome of the reaction. With toluene as the solvent, the *u*-diastereomer was favored once more, although with low selectivity. Importantly, however, the enantiomeric excess increased to 90%. The different behavior of substrate **1l** was substantiated by the fact that the structure of the α-imino ester electrophile **2** had a significant influence on the diastereoselectivity of the reaction. A change in the ester substituent from an ethyl group in **2a** to an isopropyl group in **2b** improved the reaction selectivity to a value similar to those observed with the other substrates (entry 10). A further increase in the bulk of the ester substituent (to *t*Bu) provided the Mannich product **3n** in quantitative yield and with almost perfect stereoselectivity (entry 11). Importantly, the opposite enantiomer of the Mannich products can also be

efficiently accessed with commercially available pseudoenantiomeric $(DHQ)_2PYR$ as the catalyst (entries 1 and 11). Alkyl-substituted cyanoacetates also underwent the Mannich reaction to afford high yields of the corresponding products. However, lower enantio- and diastereoselectivities were observed.[18]

The absolute and relative configurations of the Mannich reaction products were assigned by X-ray crystallographic analysis.[19] Compound **3o** was prepared under the standard reaction conditions discussed above. Recrystallization from a mixture of TBME and hexane precipitated the minor diastereomer (TBME = *tert*-butyl methyl ether). The mother liquor was evaporated, and the compound was slowly crystallized from a mixture of EtOAc/hexane to give **3o** as a single stereoisomer (fine colorless needles, mp = 110–111 °C) with the configuration as shown in Figure 1. Through comparison of HPLC traces and NMR spectra, the same configuration for the Mannich products **3e–n** could be inferred.

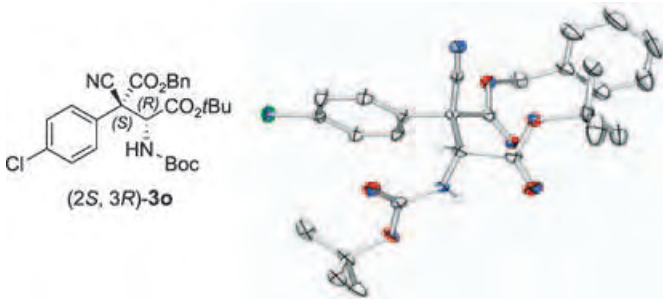

Figure 1. X-ray crystallographic structure of (2*S*,3*R*)-**3o**.

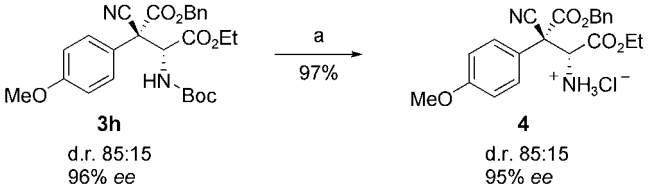
The use of *N*-Boc-protected imines **2** as electrophilic partners in the Mannich reaction allows straightforward deprotection of the products. Under standard conditions, compound **3h** was deprotected to afford the hydrochloride salt **4** in 97% yield, without affecting the diastereomeric or enantiomeric excess values (Scheme 1).



Scheme 1. Removal of the Boc protecting group: a) HCl (4 M) in 1,4-dioxane, room temperature, 5 h.

The substrate tolerance of the catalytic system was further demonstrated by the use of the β-ketoester **5** derived from 1-indanone as the nucleophilic partner in the Mannich reaction (Scheme 2). The reaction smoothly afforded the *N*-Boc-protected Mannich product **6** in high yield and essentially as a single diastereomer. We were pleased to find that the major diastereomer was obtained in 96% *ee*.

In summary, we have reported the first highly enantioselective and diastereoselective Mannich reaction of α-substituted cyanoacetates and a β-ketoester with commercially available $(DHQD)_2PYR$ as the metal-free organic chiral catalyst. An interesting solvent effect was demonstrated in reactions of an *ortho*-bromo-substituted substrate which gave dramatic changes in stereoselectivity. Work is currently underway toward a mechanistic understanding of this system and its use as a synthetic tool in asymmetric synthesis.

Supramolecular Chemistry

A Calix[4]imidazolium[2]pyridine as an Anion Receptor**

Kavitha Chellappan, N. Jiten Singh, In-Chul Hwang, Jung Woo Lee, and Kwang S. Kim**

The design and synthesis of efficient receptors capable of binding biologically and environmentally important anionic species is an emerging field in supramolecular chemistry.[1] Anion receptors with amide, pyrrole, urea, ammonium, and guanidinium groups as binding sites form N–H···A^- hydrogen bonds.[2] In contrast, we have studied several benzene- and anthracene-based receptors with two or three imidazolium units which bind effectively with anionic species through (C–H)$^+$···A^- hydrogen-bonding interactions.[3] The discovery of calix[4]pyrroles as anion receptors has led to detailed studies and further synthetic modifications being carried out for use in a range of applications, including anion sensing and transport.[4] Synthesis of these receptors to selectively sense

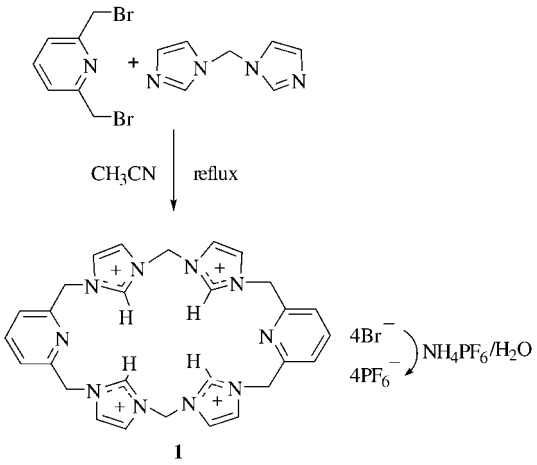
 DOI: 10.1002/anie.200500119

fluoride ions is of special importance because of the unique properties and hygienic importance of the fluoride ion.[5] The ionic hydrogen-bonding interactions formed by the imidazolium moieties, which are stronger than the hydrogen-bonding interactions formed by the pyrrole and urea moieties (see the Supporting Information), could be used to improve the binding affinity of the receptor for the anion. In particular, a receptor designed so that it possessed an array of positively charged imidazolium moieties in a calix form should have an enhanced binding affinity towards anions. The selectivity order of the anions could also be varied by adjusting the cavity size of the receptor. Herein, we report the first example based on this design, calix compound calix[4]imidazolium[2]-pyridine (**1**), and discuss its synthesis, characterization, and recognition abilities.

The reaction of equal quantities of 1-(1*H*-imidazol-1-ylmethyl)-1*H*-imidazole and 2,5-bis(bromomethyl)pyridine in acetonitrile followed by anion exchange with NH_4PF_6 afforded **1**-$(PF_6)_4$ as colorless microcrystals after recrystallization from acetone (Scheme 1). Single crystals of **1**-Br_4 and



Scheme 1. Synthesis of **1**.

1-$(PF_6)_4$ were obtained from water/ethanol and acetonitrile/acetone solutions, respectively. Macrocycle **1** was characterized on the basis of the spectroscopic data of these salts (see the Supporting Information) and X-ray diffraction analysis.

Single-crystal structures of **1**-$Br_4{\cdot}6H_2O$ and **1**-$(PF_6)_4{\cdot}2$MeCN are shown in Figure 1. Macrocycle **1** adopts a chairlike conformation with all four imidazolium $(C{-}H)^+$ groups pointing towards the center of the macrocyclic core. Two of the four counteranions are "sandwiched" between two adjacent macrocycles and the other two are located outside the cage with no apparent interaction with the macrocycle. Compound **1** has many potential hydrogen-bond donor sites and a relatively large cavity; consequently, it is expected to be an interesting complexing agent for various anions.

Binding studies of **1**-$(PF_6)_4$ with various anions (F^-, Cl^-, Br^-, I^-, CH_3COO^-, and HSO_4^-) were carried out in dry CD_3CN and [D_6]DMSO by monitoring the changes in the chemical shift of the $(C{-}H)^+$ hydrogen atom in the imidazo-

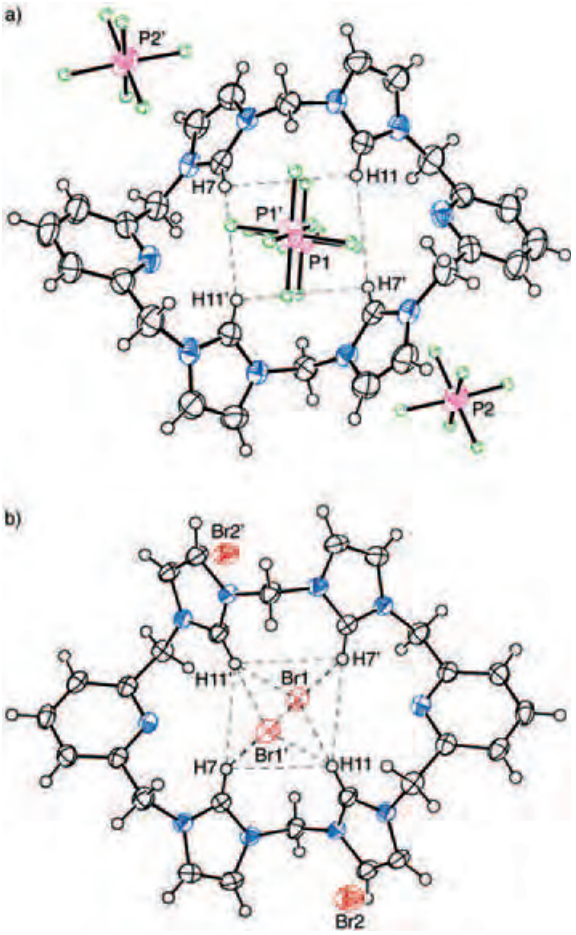


Figure 1. Crystal structures of a) **1**-$(PF_6)_4{\cdot}2CH_3CN$ and b) **1**-$Br_4{\cdot}6H_2O$. The displacement ellipsoids are given with 50% probability, except for the F atoms in the PF_6^- ion. The CH_3CN and H_2O molecules are omitted for clarity. All the anions (PF_6^- and Br^-) are located outside the cage with no direct interactions with the imidazolium moieties.

lium moiety during ^{1}H NMR spectroscopic titrations. The addition of an equimolar amount of fluoride anions as the tetrabutylammonium salt (tetrabutylammonium fluoride (TBAF)) to **1**-$(PF_6)_4$ induced a large downfield chemical shift $\Delta\delta$ of the positively charged imidazolium $(C{-}H)^+$ hydrogen atom to $\Delta\delta = 3.14$ ppm in CD_3CN, whereas the shift was $\Delta\delta = 1.77$ ppm in [D_6]DMSO; further addition caused no other significant changes in the chemical shift. Job-plot analysis showed a maximum change in chemical shift at a mole fraction of 0.5, thus indicating a 1:1 binding stoichiometry (see the Supporting Information). The bridging CH_2 group between the two imidazolium groups also showed $\Delta\delta = 0.87$ and 0.30 ppm in CD_3CN and [D_6]DMSO, respectively. The addition of one equivalent of tetrabutylammonium chloride (TBACl) moves the resonance of the $(C{-}H)^+$ hydrogen atom of **1** from $\delta = 9.42$ to 10.02 ppm and up to $\delta = 10.49$ ppm after addition of two molar equivalents in [D_6]DMSO, thus inferring a more complicated binding pattern. The association constant K_a, calculated with the HOSTEST program,[6] revealed evidence of strong binding with the fluoride anions in a 1:1 stoichiometry. The titration

curves for all the other anions tested were best fit to 1:2 receptor/anion stoichiometries. The association constant for **1**-$(PF_6)_4$ with F^-, Cl^-, Br^-, and I^- ions exceeded $K_a \approx 10^5$ by ^{1}H NMR spectroscopic titrations in CD_3CN, so the highly polar solvent [D_6]DMSO was employed for the quantitative analysis of anion binding with **1**-$(PF_6)_4$. The binding constants (M^{-1}) were found to be $K_1 = 28\,900$ for F^- ions, $K_1 = 2030$ and $K_2 = 2790$ for Cl^- ions, and $K_2 \gg K_1$ for Br^-, I^-, and HSO_4^- ions. It should be noted that the binding constant for the F^- ions was obtained in the presence of a trace amount of water which arose from the use of the trihydrate salt. The binding constants for $H_2PO_4^-$ ions were not determined because of the disappearance of the imidazolium $(C-H)^+$ hydrogen atom signal after the addition of one equivalent of the anions during ^{1}H NMR spectroscopic titration.

Crystals of the **1**-F$(PF_6)_3$ complex of sufficient quality for X-ray diffraction studies[7] were obtained by the addition of TBAF·3H_2O to a solution of **1**-$(PF_6)_4$ in acetonitrile (Figure 2). This structure determination further supported the idea that host **1** binds a single fluoride anion. Orientation of all the four $(C-H)^+$ groups of **1** towards the cavity anchors the fluoride anion in the center of the macrocyclic core through strong H–F interactions (with distances of 1.991 and 2.082 Å for H7···F and H12···F, respectively; CH_2···F = 2.576 Å).

Interestingly, crystallization of the host complex **1**-$(PF_6)_4$ with TBACl (molar ratio = 1:1) from acetonitrile solution afforded crystals of **1**-$Cl_2(PF_6)_2$ of sufficient quality for X-ray diffraction studies, which showed that the receptor/anion ratio was 1:2 (Figure 3a).[7] It is of note that the addition of one equivalent of tetrabutylammonium bromide (TBABr) to **1**-$(PF_6)_4$ results in a crystal in which the unit cell contains two layers: one composed of **1**-$Br_2(PF_6)_2$ and the other composed of the free receptor **1**-$(PF_6)_4$ (Figure 3c). The structure of the **1**-$Br_2(PF_6)_2$ layer is analogous to the structure of **1**-$Cl_2(PF_6)_2$ (Figure 3b). The chloride and bromide anions, as they are larger and favor nonspherical or surface conformations[8] in order to keep the extra electron in a large empty space, do not fit in the center of the cavity of **1**, unlike the fluoride anion, and the two chloride anions reside 2.194 Å above and below the plane, slightly offset from the center of the macrocyclic core. One chloride anion forms strong interactions with the

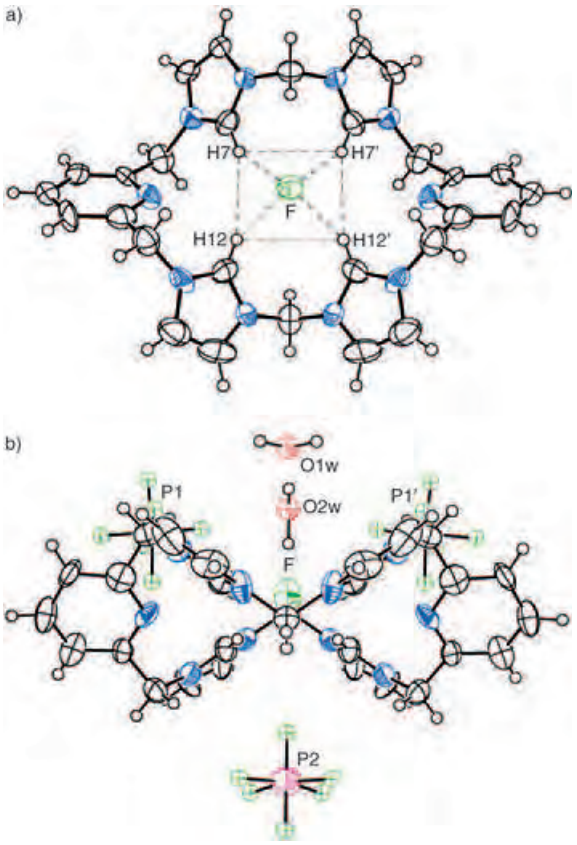

Figure 2. View of the molecular structure of **1**-F$(PF_6)_3$·2H_2O. a) Top view of the **1**-F unit and b) side view of **1**-F$(PF_6)_3$·2H_2O, with displacement ellipsoids at 50% probability.

H(11) and H(7) protons of the imidazolium rings at distances of 2.610 and 2.759 Å, respectively, whereas the other chloride anion is closer to the H(7′) and H(11′) protons and forms interactions with them at distances of 3.075 and 3.498 Å, respectively.

We further investigated the conformations of the free receptor and the receptor/anion complexes using B3LYP/6-31G(+)* density functional calculations (see the Supporting Information). The binding energy of **1** with F^- ions in the gas

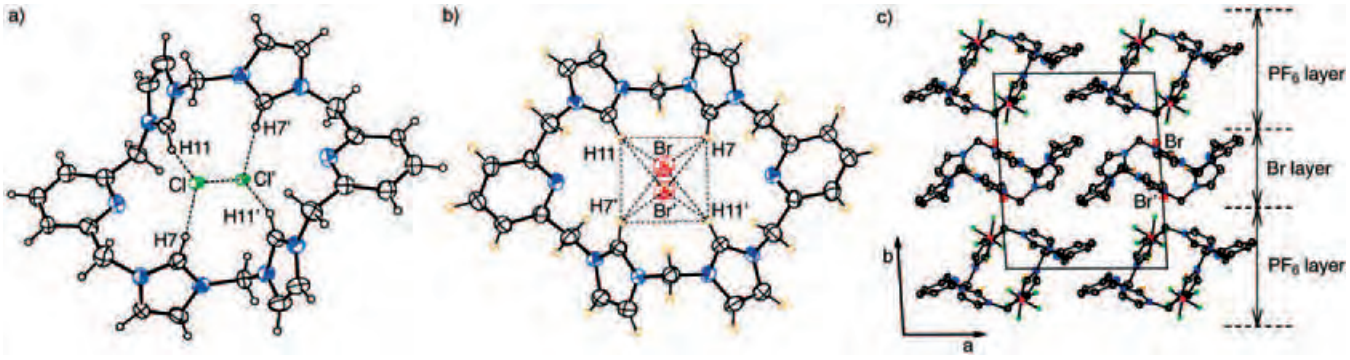

Figure 3. a) Crystal structure of the {**1**-Cl_2} unit from **1**-$Cl_2(PF_6)_2$·2CH_3CN, with displacement ellipsoids at 50% probability. The PF_6^- ions and CH_3CN molecules are omitted for clarity. b) Single-crystal structure of the {**1**-Br_2} unit from $\mathbf{1}_2$-$Br_2(PF_6)_6$, with displacement ellipsoids at 50% probability. c) Unit cell structure of [**1**-Br_2][**1**-$(PF_6)_2$][PF_6]$_4$·2CH_3CN, with displacement ellipsoids at 30% probability except for the F atoms in the PF_6^- ion.

phase is 315.9 kcal mol^{-1}, which is larger than those of the Cl^- and Br^- ions (279.2 and 273.3 kcal mol^{-1}, respectively) but is less stable than the **1**:2 F complex (537.2 kcal mol^{-1}; Table 1). However, the gain in free energy in DMSO favors the formation of the **1**:F complex over the **1**:2 F complex by 1.3 kcal mol^{-1} and the 1:1 complexes of **1** with Cl^- and Br^- ions by approximately 2 and 3 kcal mol^{-1}, respectively.

Table 1: Experimental free energies and calculated interaction energies for **1**/anion complexes (kcal mol^{-1}).[a]

Anion	K_a [M^{-1}] ([D$_6$]DMSO)		$-\Delta G_{NMR}$	$-\Delta E^{gas}_{calcd}$	$-\Delta E^{sol}_{calcd}$	$-\Delta G_{scaled}$
	K_1	K_2				
F^-	28900	–	6.08	315.9 (537.2) [304.9]	20.29 (16.14) [19.96]	6.09 (4.84) [5.99]
Cl^-	2030	2790	4.51/4.70	279.2(477.9)	13.80(19.52)	4.14(5.86)
Br^-	100	10700	2.73/5.49	273.3(469.7)	10.13(14.97)	3.04(4.49)
I^-	130	3330	2.88/4.80	–	–	–
CH_3COO^-	5040	1940	5.05/4.48	–	–	–
HSO_4^-	40	1120	2.18/4.16	–	–	–

[a] The association constants K_a (M^{-1}) were measured using ^{1}H NMR spectroscopic titrations (25 °C). Errors estimated to be $<10\%$. The anions were used as their tetrabutylammonium salts. ΔE^{gas}_{calcd} is the interaction energy in the gas phase at the B3LYP/6-31(+)G* level of theory. $\Delta E^{sol}_{calcd} = \Delta E^{sol}_{1/anion} - \Delta E^{sol}_{sol/anion} - \Delta E^{sol}_{TBA\ anion}$, where $\Delta E^{sol}_{1/anion}$ is the interaction energy of the **1**/anion complex in DMSO based on the isodensity surface polarized continuum model (IPCM), $\Delta EE^{sol}_{sol/anion}$ is the interaction energy of the anion with the solvent molecules in the first solvation shell of an anion. $\Delta EE^{sol}_{TBA\ anion}$ (sol = DMSO) is the interaction energy of the tetrabutylammonium ion with the anion in solution. The countercation correction was applied only to the F^- ions as this effect is not significant for the other anions.[9] The free energy change (ΔG_{scaled}) was obtained approximately by scaling the internal energy change, on the basis of the results of the internal versus the free solvation energy of the halide anions in the first solvation shell.[8] Values in parentheses are for 1:2 complexes, values in square brackets are for a 1:1 complex in which the F^- ions interact with one extra water molecule.

This result is in agreement with the experimental K_a values and the formation of the 1:1 complex from the host **1** and the F^- ions as observed in the crystal structure. The presence of one water molecule associated with the F^- ions lowers the free energy by 0.1 kcal mol^{-1} in DMSO, thus suggesting that the presence of a trace amount of water in DMSO slightly weakens the interactions between the receptor and the fluoride anion, which is in agreement with the experimental results.[2h] However, the 1:2 complexes of **1** with the Cl^- and Br^- ions in DMSO are more stable than the corresponding 1:1 complexes, respectively. The method used for these calculations described herein, although not accurate, helps us to predict the selectivity order of the receptor for the anions and determine whether a 1:1 or 1:2 complex will be formed.

In summary, we have synthesized novel macrocyclic anion receptor **1** that has an array of positively charged imidazolium units and has proved to be an effective receptor for F^- ions. Modification of this system would allow the development of a new class of calix containing many positively charged moieties that would be suitable for anion recognition by ionic hydrogen-bonding interactions and as precursors for N-heterocyclic carbenes for application in metal-coordination chemistry.[10]

Synthetic Inhibitors

Application of Stereocontrolled Stepwise [3+2] Cycloadditions to the Preparation of Inhibitors of $\alpha_4\beta_1$-Integrin-Mediated Hepatic Melanoma Metastasis**

*Aizpea Zubia, Lorea Mendoza, Silvia Vivanco, Eneko Aldaba, Teresa Carrascal, Begoña Lecea, Ana Arrieta, Tahl Zimmerman, Fernando Vidal-Vanaclocha, and Fernando P. Cossío**

Dedicated to Professor Cecilia Sarasola

Intravascular circulation of cancer cells represents a frequent event along neoplasic progression that seriously increases the probability of occurrence of metastasis. However, the adhesion of blood-borne cancer cells to the microvascular wall is a prerequisite for metastatic cell implantation at target organs. Similar to capillary homing of leukocytes, this process is proinflammatory cytokine-inducible and the mechanism involves specific binding between cancer and endothelial cell adhesion molecules.[1] Previously, we and others reported that integrin "very late antigen 4" (VLA-4, $\alpha_4\beta_1$) accounts for melanoma cell adhesion to endothelium in metastasized organs.[2] As vascular adhesion cell molecule 1 (VCAM-1) is the natural ligand of VLA-4, the VLA-4–VCAM-1 interac-

tion may, therefore, constitute an interesting molecular target for innovative therapy against melanoma dissemination. However, no results on the antimetastatic effects of synthetic VLA-4/VCAM-1 inhibitors have been reported to date, although interesting studies on synthetic inhibitors of the VLA-4/VCAM-1 interaction have been recently reported.[3] Herein, we demonstrate that small synthetic molecules which are designed to mimic the minimal requirements for binding between the natural macromolecules completely abrogate 1) melanoma cell adhesion to cytokine-activated endothelial cells and 2) melanoma cell responses to soluble and immobilized VCAM-1, and 3) efficiently inhibit metastatic development in vivo, without significantly affecting their cell viability, proliferation rate, or major metabolic activities.

Structural and electronic features of VCAM-1 were first examined in order to reproduce these features in the synthetic inhibitors.[4] The crystal structure of domains 1 and 2 of VCAM-1 has been resolved by X-ray diffraction analysis.[5] Additionally, directed mutagenesis studies have determined that the CD loop in domain 1 of VCAM-1 is crucial for binding to VLA-4[5] (Figure 1 a). In the solvated molecule, the carboxymethyl group of Asp_{40} has considerable conformational freedom and is surrounded by a relatively hydrophobic environment (Figure 1 b). We reasoned that the compounds shown in Table 1 could mimic the structural and electronic features of the Ile39-Asp40-Ser41-Pro42 sequence of domain 1 of VCAM-1 (Figure 1 c). Thus, the carboxymethylamido chain of these novel compounds reproduces the binding ability of Asp40, whereas the remaining groups provide the environment required for simulating the structural and electrostatic features of the remaining residues. Furthermore, the pyrrolidine ring confers the necessary restriction of conformational freedom to the molecule to mimic the energetically available conformations of the CD loop in the β barrel of domain 1 of VCAM-1 (Figure 1 b and c). Therefore, these unnatural highly substituted pyrrolidine rings should bind to VLA-4 to disrupt VLA-4/VCAM-1-interaction-dependent mechanisms.

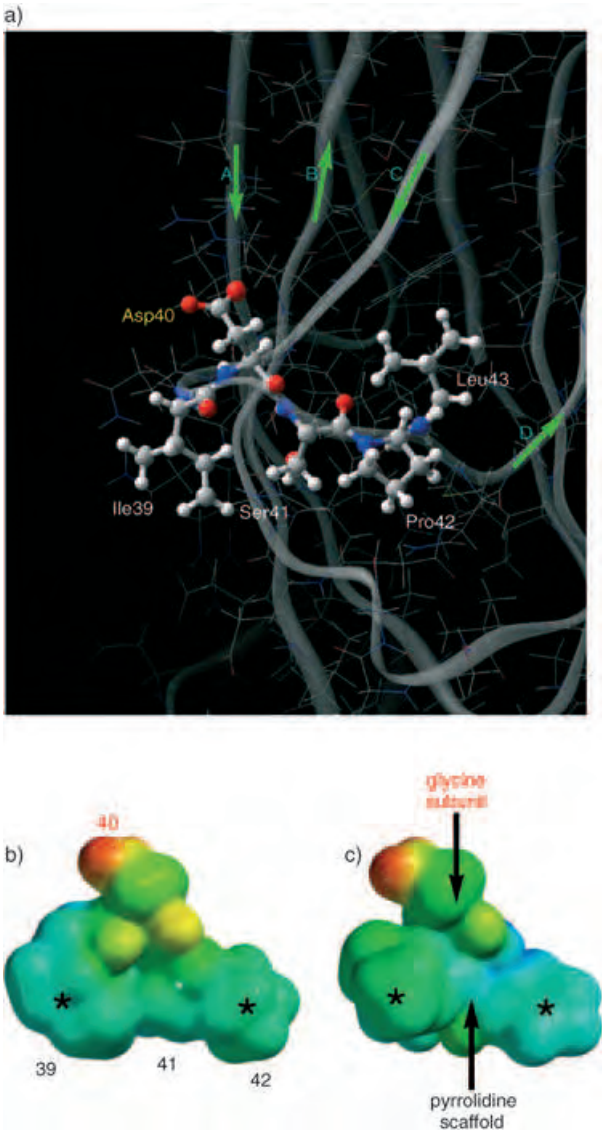

Figure 1. a) X-ray crystal structure (taken from ref. [5]) of the active loop of VCAM-1 which is involved in binding with integrin VLA-4. b), c) Electrostatic potential projected onto the electron density of the Ile39-Asp40-Ser41-Pro42 tetramer (b) and inhibitor **11d** (c); energies range from −138.2 (red) to +100.2 kcal mol^{-1} (blue); asterisks (*) indicate the hydrophobic regions in both structures.

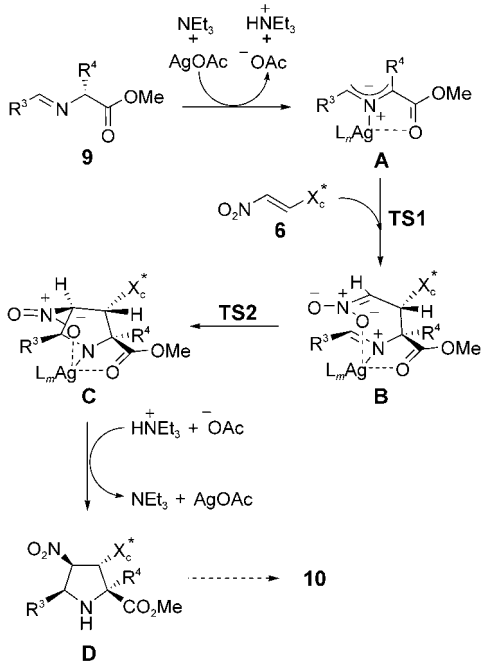
[a] *c*Hex = cyclohexyl, *c*Pr = cyclopropyl, Bn = benzyl.

The new compounds **11** were synthesized in 12 preparative steps according to the design depicted in Table 1 and Scheme 1 (for more details, see Supporting Information). The starting materials were readily accessible and inexpensive chemicals such as L-α-amino acids (glycine, alanine, valine, and leucine), halides **3**, and aldehydes **7**. The key step in the synthetic route shown in Scheme 1 is the formal [3+2] cycloaddition between *E*-nitroalkenes **6** and imines **9** to yield pyrrolidines **10**. This reaction takes place with complete

DMP = 2,2-dimethoxypropane, Ts = *p*-toluenesulfonyl, DMF = *N*,*N*-dimethylformamide, DMSO = dimethylsulfoxide, DMP = 2,2-dimethoxypropane, TEA = triethylamine, DIPEA = diisopropylethylamine, DME = 1,2-dimethoxyethane, MeGly = glycine methyl ester, DECP = diethylcyanophosphonate.

stereocontrol when R^3 is a phenyl group, and R^1 = Me or Et (compounds **10a,c–e,g,i,j**). When R^3 is an alkyl group, the stereocontrol is variable and ranges from greater than 99:1 when R^3 = *t*Bu (**10b**) to 91:9 when R^3 = *c*Hex (**10f**) or *c*Pr (**10h**). In the case of pyrrolidine **10k**, which has a chiral group at R^3, three stereoisomers were obtained in a ratio of 77:15:8.

Previous studies[6] have shown that the reaction between π-deficient alkenes and metalated azomethine ylides takes place through a stepwise mechanism, not a concerted mechanism, to give the [3+2] cycloadduct. The first step comprises a Michael-type nucleophilic attack of the α carbon atom of the azomethine ylide **A**, which forms in situ, on the β carbon atom of the nitroalkene (Scheme 2). The cyclization step takes place by means of an intramolecular Henry-type reaction between the intermediate nitronate moiety and the iminic fragment of the zwitterionic intermediate denoted as **B** in Scheme 2.



Scheme 2. Mechanism of formation of cycloadducts **10** from the reaction between imines **9** and nitroalkenes **6**. X_c^* = chiral group.

To understand the origins of the stereocontrol of the reaction, we computed the two possible diastereomeric transition-state structures **TS1** and **TS1′** for the model system depicted in Figure 2.[7] As shown in Figure 2 and Scheme 2, part of the stereocontrol of the reaction stems from the retention of configuration of the *E*-nitroalkene and the

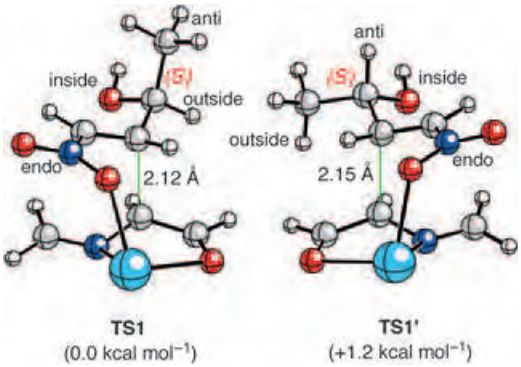


Figure 2. Ball-and-stick representations of the fully optimized structures of transition-state structures **TS1** and **TS1′** (C gray, O red, N dark blue, Ag light blue); green lines represent the new sigma bonds that form; see ref. [7] for further details.

chelated nature of the metalated azomethine ylide. The diastereoselectivity can be explained in terms of a two-electron interaction between the localized σ* orbital of the C–C bond that forms and the localized σ orbital of the antiperiplanar C–CH_3 bond, with the alkoxy group occupying the inside position with respect to the pyrrolidine ring that forms, as seen in Figure 2. The alternative diastereomeric transition-state structure **TS1′**, in which the C–H bond is *anti* with respect to the new C–C bond that forms, is more than 1 kcal mol^{-1} higher in energy than **TS1** and corresponds to high stereocontrol in favor of the (2*S*,3*R*,4*S*,5*S*) cycloadduct, provided that groups which are bulkier than methyl are used. The absolute configuration of the new stereogenic centers was verified by X-ray diffraction analysis on compound **11d** and confirmed the validity of our computational results.[8]

Next, the potential VLA-4 antagonism of compounds **11** was tested through a previously established model[2b] on VLA-4/VCAM-1-interaction-dependent B16M cell adhesion to primary cultured hepatic sinusoidal endothelial (HSE) cells in vitro. As shown in Figure 3, both B16M cell adhesion to TNF-α (tumor necrosis factor alpha)-treated HSE—which increases VCAM-1 expression on endothelial cells—and H_2O_2-treated B16M cell adhesion to unstimulated HSE cells—which increases VLA-4 activation in cancer cells—significantly increased relative to their respective untreated control cells ($P < 0.01$, where P is the statistical probability value).[2b] Preincubation of B16M cells with compounds **11** and measurement of adhesion to HSE resulted in variable responses as shown in Figure 3. Interestingly, compounds **11b** and **11h** with *t*Bu and *c*Pr groups at R^3, respectively, did not show any significant antiadhesive activity. Similarly, compound **11e**, with a 2,6-difluorophenyl group at R^2 and a methyl group at R^1 was also almost inactive. In contrast, the presence of a quaternary atom at the α-position of the pyrrolidine ring (R^4 = Me), such as in **11j**, did not result in a significant loss of activity.

To assess if interactions other than VLA-4/VCAM-1 were involved in the inhibitory activity of compounds **11**, we used the chemical shift perturbation method[9] on the I domain of the α_2-subunit of $\alpha_2\beta_1$-VLA-2 integrin which is also relevant in melanoma metastasis and binds different ligands such as collagen or laminin.[10] ^{15}N–^{1}H heteronuclear single-quantum coherence (HSQC) NMR spectra[9] of uniformly ^{15}N-labeled I domain were recorded in the presence and the absence of inhibitors **11a–j**. In these spectra each amino acid of the I domain appeared as a cross-peak that corresponds to the NH group of its amide backbone. Analysis of the spectra at different pH values (pH 6.5 and 7.4) and at different temperatures (T = 283 and 298 K, see Supporting Information) did not lead to any significant shift of the cross-signals upon addition of the inhibitors, which indicates the lack of binding and, therefore, the high selectivity of these compounds with respect to integrin VLA-2.

Although the best activity in vitro was shown by compound **11f**, which has a cyclohexyl group at R^3, preliminary assays in vivo were carried out with **11d** (R^3 = Ph) because of its higher solubility in water. Additionally, **11d** displayed comparable antiadhesive activity to monoclonal antibodies against murine VLA-4 (Figure 3b). Furthermore,

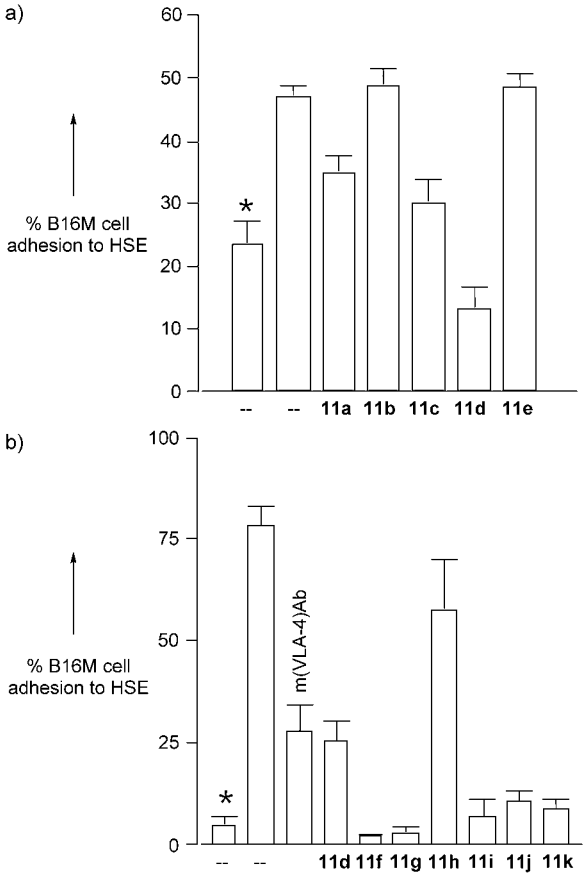

Figure 3. Inhibition of adhesion between HSE and B16M cells by compounds **11**. The degree of inhibition was measured on a) TNF-α-activated cultured HSE cells and b) H_2O_2-pretreated melanoma B16M cells. Asterisks (*) indicate the inhibition measured on unstimulated HSE. The concentration of compounds **11** was 50 μg per 1×10^6 B16M cells. The lyophilized compounds were dissolved in DMSO and diluted to a final working stock solution of 5 mg mL^{-1} in serum-free medium. 1×10^6 B16M cells resuspended in 300 μL of serum-free medium were preincubated with **11** (10 μL of stock solution, 50 μg) for 15 min at 37 °C before the adhesion assay. m(VLA-4)Ab denotes rat anti-mouse CD49d monoclonal antibody (Serotec Ltd, Oxford, UK) against VLA-4. In this case, B16M cells were incubated with 10 μg mL^{-1} of m(VLA-4)Ab before the adhesion assay. The results are the mean standard deviation of three independent experiments, each performed in sextuplicate (n = 18).

addition of **11d** compound to IL-1β (interleukin-1β)-treated melanoma cells completely abrogated their adhesion to immobilized VCAM-1 and prevented vascular endothelial growth factor (VEGF) production induced by soluble-VCAM-1-stimulated cells (see Supporting Information), which confirms the potent VLA-4 antagonism of compound **11d**. Finally, metastasis density and volume significantly decreased ($P < 0.01$) by 60% and 95%, respectively, in mice that were intrasplenically injected with **11d**-pretreated B16M cells relative to those that received untreated cells (Figure 4). Parallel measurements on cell viability and cytotoxicity, intracellular oxidative metabolism, and cell-proliferation rates of **11d**-treated melanoma cells excluded that antimetastatic effects of **11d** compound may have been caused by

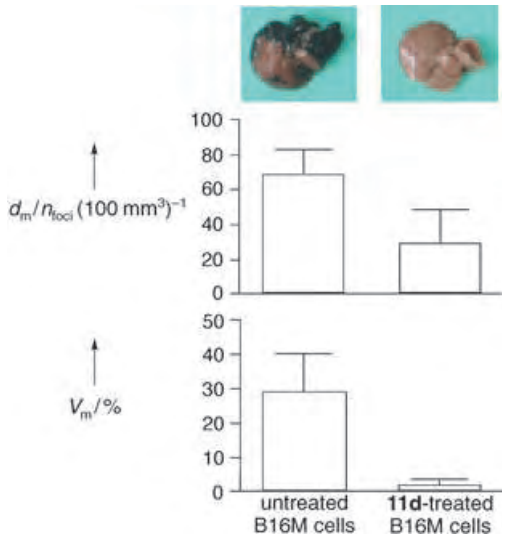

Figure 4. Antimetastatic activity of compound **11d** on male C57BL/6J mice (6 to 8 weeks old). At least 30 mice were used per experiment, and each experiment was carried out 3 times. The bars on the left correspond to the control group. The test group was treated with **11d**-preincubated B16M viable cells (50 μg per 1×10^6 B16M cells). Livers were removed on day 12 after intrasplenical injection of B16M cells and photographed. Photographs on the left and on the right correspond to livers obtained from the control and test groups, respectively. Metastases can be identified as black melanotic nodules. Metastasis density (d_m) was measured as the number of foci per 100 mm^3 of liver, and metastasis volume (V_m) was measured as the percentage fraction of liver volume occupied by metastases.

indirect effects on cell functions other than those specifically operated through a VLA-4-dependent mechanism.[11]

In summary, we have described a new family of inhibitors of the VLA-4/VCAM-1 interaction that 1) block the in vitro adhesion of melanoma cells to microvascular endothelium induced by proinflammatory cytokines and oxidative stress, 2) prevent melanoma cell production of VEGF induced by VCAM-1 in vitro, and 3) exhibit a potent antimetastatic activity in vivo. These small synthetic molecules fulfill the bioavailability requirements proposed by Lipinski et al.[12] Finally, the synthetic route developed for these inhibitors was convergent, completely regio- and stereoselective, versatile, and did not require sophisticated experimental devices or purifications. Therefore, it is well-suited to extensive studies of structural variation to refine the biological properties of the most promising lead compounds.

Bioinorganic Chemistry

The Geometric and Electronic Structure of [(cyclam-acetato)Fe(N)]$^+$: A Genuine Iron(V) Species with a Ground-State Spin $S = 1/2$**

Núria Aliaga-Alcalde, Serena DeBeer George, Bernd Mienert, Eckhard Bill, Karl Wieghardt, and Frank Neese**

High-valent transition-metal complexes play a crucial role as intermediates in the reaction cycles of metalloenzymes[1,2] and, consequently, the synthesis of low-molecular-weight compounds that model the active sites is a major challenge in synthetic inorganic chemistry. Many of these observed heme- and non-heme enzyme intermediates contain terminal oxo ligands.[2] While in recent years a number of heme- and non-heme Fe^{IV}=O complexes have been prepared and spectroscopically characterized,[3] much less is known about the corresponding high-valent iron–nitrido species despite their possible involvement in enzymes from the biogeochemical nitrogen cycle. However, over the course of the last few years a number of high-valent non-heme metal–nitrido species containing V^V, Cr^V, Mn^V, and Fe^V ions have been prepared by atom and/or group-transfer reactions or by photolysis.[4,5] We note that Wagner and Nakamoto[5c,d] have previously reported the photochemical generation of $[Fe^V(N)(TPP)$ (TPP^{2-} = tetraphenylporphinate(2−)) and measured its resonance Raman spectrum. Most recently, Betley and Peters synthesized and characterized the distorted tetrahedrally coordinated terminal Fe^{IV}–nitrido species $[PhBP^iPr_3]Fe^{IV}N$ ($[PhBP^iPr_3] = [PhB(CH_2P^iPr_2)_3]^-$).[6] This compound was shown to be diamagnetic at room temperature and exhibit ^{15}N NMR resonances near $\delta = 952$ ppm and a ν(FeN) stretching frequency of 1034 cm^{-1}. Furthermore, density functional theory (DFT) calculations at the B3LYP level of theory predicted a very short Fe≡N bond of 1.49 Å.

Efforts in our group to characterize high-valent iron–nitrido species started with the synthesis of two non-heme azidoiron(III) precursors, *cis*- (**1**) and *trans*-$[(cyclam)Fe^{III}(N_3)_2](ClO_4)$ (**2**), by using the spectroscopically innocent ligand cyclam (1,4,8,11-tetrazacyclotetradecane).[5a] Photolysis of **2** in a frozen matrix yielded products that were assigned to Fe^{II} (ca. 29%) and Fe^V (ca. 54%) species on the basis of zero-field Mössbauer spectroscopy.[5a] It was concluded that homolytic Fe–N_3 cleavage (to give Fe^{II} and $N_3^{\bullet}$; photoreduction) and heterolytic N–N cleavage (to give Fe^VN and N_2; photooxidation) both occur.[5a] Subsequently, the synthesis and photolysis of $[(cyclam\text{-}ac)Fe(N_3)]^+$ (cyclam-ac^- = 1,4,8,11-tetraazacyclotetradecane-1-acetate) (**3**) was reported.[5b] It was shown that photolysis at $\lambda > 420$ nm, that is, irradiation into the $N_3^- \rightarrow Fe$ ligand-to-metal charge transfer band at 80 K, resulted in >80% conversion to the desired $[(cyclam\text{-}ac)Fe(N)]^+$ species (**3ox**) and dinitrogen. A spin state of $S = 3/2$ was initially proposed for complex **3ox** by comparing the field-dependent Mössbauer spectra (>1 T) with previous data for complex **2**.[5b]

We have now undertaken an in depth spectroscopic and computational study of **3** and **3ox** to elucidate the electronic structure of this fascinating high-valent system. Herein, we present our initial results of X-ray absorption spectroscopy (XAS)/extended X-ray absorption fine structure (EXAFS) spectroscopy together with Mössbauer spectroscopy, magnetic susceptibility data, and electronic structure calculations at the density functional theory (DFT) level. The results reveal that, unexpectedly, the ground-state total spin of the $(FeN)^{2+}$ core is $S = 1/2$ and not $S = 3/2$ as has been previously assumed based on the results of EPR and Mössbauer spectroscopy.[5]

The fitting of the zero-field Mössbauer spectra[5b] of a solid sample of **3**, which was irradiated at 80 K, shows the superposition of two subspectra (not shown): a minor quadrupole doublet (ca. 16% relative intensity) with parameters corresponding to the starting material (**3**), with a chemical shift $\delta = 0.27(2)$ mm s^{-1} and a quadrupole splitting of $|\Delta E_q| = 2.30(2)$ mm s^{-1}, and second, an intense symmetric quadrupole doublet at $\delta = -0.02(2)$ mm s^{-1} with a quadrupole splitting of $|\Delta E_q| = 1.60(2)$ mm s^{-1} (**3ox**, ca. 84% relative intensity). Other side products were not observed in the solid sample of **3ox**. The values of the isomer shift and quadrupole splitting of the main solid beige species were very similar to those found in the past for $[(cyclam\text{-}ac)Fe(N)]^+$ in acetonitrile solution ($\delta = -0.04(2)$ mm s^{-1} and $|\Delta E_q| = 1.67(2)$ mm s^{-1}).[5b] It is therefore concluded that photolysis in the solid state is an efficient method to obtain high yields of solid **3ox** without the presence of the photoreduced Fe^{II} species. Moreover, the photooxidized species produced by photolysis in frozen solution and in the solid state are spectroscopically indistinguishable.

The Mössbauer results, in particular, the low isomer shift of **3ox**, are consistent with a high-valent species and have previously led to the formulation of **3ox** as an Fe^V species.[5] Independent experimental data to corroborate this conclusion and to obtain further information about the electronic and geometric structure of **3ox** are highly desirable. An ideal local probe of the geometric and electronic structure of the central iron is XAS. The XAS edge is sensitive to the electronic structure and may be used as an indicator of the oxidation state.[7,8] The pre-edge region is particularly diag-

  DOI: 10.1002/anie.200462368

nostic and an increase of about 1 eV per oxidation state is typical for first-row transition metals. In addition, the pre-edge region provides a measure of 3d–4p mixing and thus increased intensity may be induced by exceptionally short metal–ligand bonds. EXAFS data give complimentary metrical information, providing very accurate metal–ligand bond lengths.

A comparison of the Fe K-edge spectra of **3** and **3ox**, which, for technical reasons, were recorded in frozen butyronitrile solution, is shown in Figure 1. It is observed that the

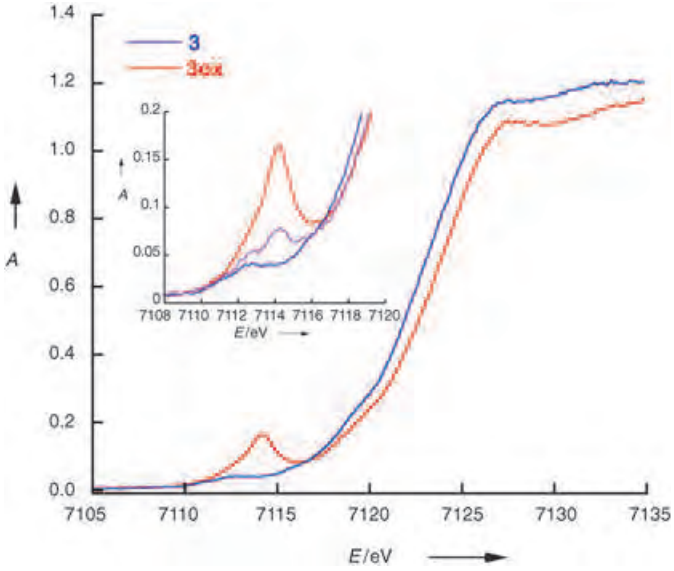

Figure 1. Iron K-edge X-ray absorption spectra of **3** (blue) and **3ox** (red). The inset is an expansion of the pre-edge region. The spectrum shown in purple was taken at an intermediate stage of illumination. *A* = normalized absorption.

pre-edge of **3ox** (at 7114.2 eV) is shifted to higher energy than **3** by about 2 eV (Fe^{III}; 7112.4 eV), consistent with a two-electron oxidation. To our knowledge, the pre-edge position of **3ox** is at the highest yet observed energy for any iron complex ($Fe^{IV}O$ edges are typically observed at about 7113.2 eV,[9] when using a reference calibration point of 7111.2 eV for the first inflection point of an Fe foil). The position of the rising edge (7123.0 eV for **3** versus 7124.1 eV for **3ox**) is also consistent with an increase in oxidation state; however, an exact assignment may be complicated by the presence of shake-up or shake-down transitions superimposed on the rising edge. Furthermore, a very intense pre-edge feature develops in **3ox** (with an area of 27 ± 2 units) at about 7114.2 eV, which is consistent with grossly increased 4p mixing into the 3d manifold and consequently with a short metal–ligand bond being formed in **3ox**. Similar features have previously been observed in high-valent $Fe^{IV}O$ species[9] and appear to be characteristic of high-valent sites with a short metal–ligand bond.

Figure 2 shows a comparison of the non-phase shift corrected Fourier transforms and EXAFS data, together with the best fits (Table 1), for complexes **3** and **3ox**. The best fit of complex **3** was obtained by including two Fe–N/O

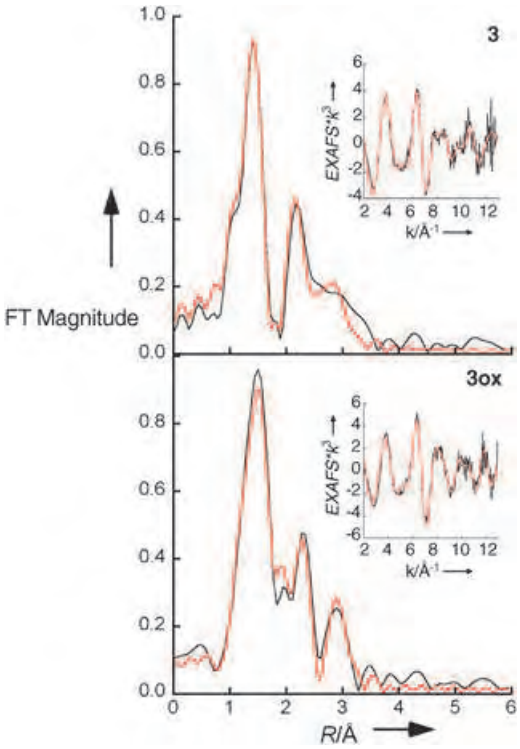

Figure 2. Comparison of non-phase shift corrected Fourier transforms for **3** and **3ox**. Experimental data are shown in black and fits in red. The insets show the respective EXAFS data.

Table 1: EXAFS fit results for **3** and **3ox**.

	R [Å]	σ^2 [Å^2]	ΔE_0	Error[a]
		3		
2 Fe–N/O	1.94	0.0018	−9.25	0.353
4 Fe–N/O	2.07	0.0064		
6 Fe–C	2.83	0.0063

5 Fe–N/O	2.02	0.0079		
6 Fe–C	2.85	0.0047		
4 Fe–C	3.02	0.0033		
2 Fe–C	3.36	0.0026		

[a] Error is given by $\Sigma[(\chi_{obsd}-\chi_{calcd})^2 k^6]/\Sigma[(\chi_{obsd}{}^2 k^6]$.

contributions at a distance of 1.94 Å and four Fe–N/O at 2.07 Å, with outer-shell Fe–C contributions from the cyclam ligand (Figure 2, top). It should be noted that separation of these two contributions is just beyond the resolution limit of the data (ca. 0.14 Å). Fits were also attempted with a single Fe–N/O shell at 1.98 Å, giving excellent agreement with the crystallographic values,[5b] but a significantly larger residual. In either case an average Fe–N/O coordination sphere of 1.98–2.03 Å is obtained, in reasonable agreement with the crystallography.

The best fit to **3ox** (Figure 2, bottom) was obtained by including five Fe–N/O contributions at 2.02 Å and one short Fe–N distance at 1.61 Å, with additional outershell Fe–C contributions from the cyclam ligand. However, the Debye–

Waller value (σ^2) for the short Fe–N component is quite large. This value becomes much more reasonable[10] (0.006 Å^2) by decreasing the coordination number associated with the short Fe=N interaction to 0.5. The necessity of this decrease is consistent with incomplete conversion of **3ox**, as discussed above. Fits which did not include the short 1.61 Å Fe–N interaction had a significantly higher error (normalized error = 0.403) and a long frequency beat pattern, consistent with a short Fe–N vector, in the fit residual (see Supporting Information) which is clearly not observed for in the residual of **3** (see Supporting Information).[11] In addition, fits were also attempted starting with the short Fe–N distance at 1.73 Å, however, allowing this value to float resulted in a value of 1.60 Å for the shortest Fe–N distance. Finally, any attempt to modify the background subtraction always led back to the conclusion that the longest feasible Fe=N distance is $\leq$1.65 Å. We conclude from this data that there indeed is a short Fe=N bond of about 1.60 Å in **3ox**.

In our DFT calculations, we have considered two possible reaction products that differ in their spin multiplicities: a doublet (^{2}**3ox**) and a quartet (^{4}**3ox**) ground state were taken into consideration. Previously, the reaction was assumed to lead to a quartet species ^{4}**3ox** despite this being a spin-forbidden process. At the time this appeared to be reasonable because Fe^V species (d^3) are isoelectronic with the analogous Cr^{III} and Mn^{IV} species which invariably have $S = 3/2$ ground states. Quite surprisingly, the B3LYP DFT calculations on **3ox** even after inclusion of zero-point energies and solvent effects predict a doublet ground state ^{2}**3ox** (Figure 3).

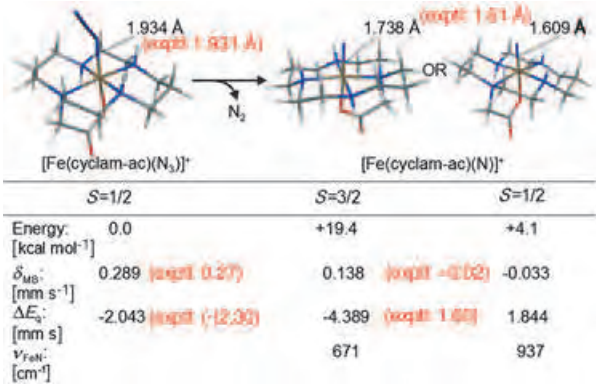

Figure 3. Computed structures, energies, and properties of **3ox**, ^{4}**3ox**, and ^{2}**3ox** (experimental values in red).

However, it is known that DFT methods are biased in favor of low-spin states.[12] Thus, despite the considerable energy difference of about 15 kcal mol^{-1} (ca. 14 kcal mol^{-1} in MeCN) between ^{2}**3ox** and ^{4}**3ox**, which is outside the accepted error bars of the B3LYP method, one is well advised in seeking more evidence in favor of such an unusual spin-state assignment. As will be elaborated in detail elsewhere, the magnetic properties of **3ox** are not straightforwardly interpreted, owing to the presence of other doublet and quartet terms lying close to the ground state. Thus, EPR, MCD, and magnetic Mössbauer analyses require a more elaborate spin Hamiltonian model than is usual for $S = 1/2$. However, the presence of a doublet ^{2}**3ox** species could be experimentally corroborated from a magnetic susceptibility measurement (Figure 4). Since the macroscopic susceptibility data are much less sensitive to details of the electronic structure, we could

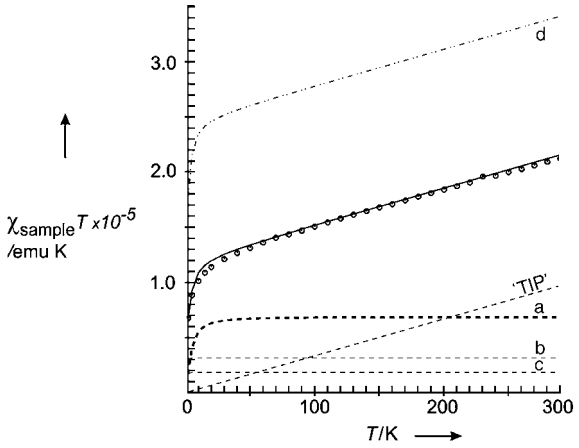

Figure 4. Temperature dependence of the magnetic susceptibility times temperature of a powder sample of photolyzed **3** (open circles) and deconvolution into three major paramagnetic components (traces a–c) and a TIP-like contribution ('TIP', temperature-independent paramagnetism). The 'TIP' arises most probably from minor contamination of small magnetic (oxide) particles (2%). The weights of the different paramagnetic contributions are given in molar percentages that were calculated with molecular weights of $M_r = 472.1$ g mol^{-1} (**3ox**, $S = 1/2$, 57%, trace a), $M_r = 500.1$ g mol^{-1} (**3**, 26%, $S = 1/2$, trace b), $M_r = 458.1$ g mol^{-1} ([(cyclam-ac)Fe^{II})], $S = 2$, 15%, trace c). Diamagnetic contributions were not taken into account since their signal is hidden under the 'TIP' contribution. The dashed lines for the contributions from ^{2}**3ox**, **3**, and the Fe^{II} component are simulations with the usual spin-Hamiltonian.[5a] The upper line in the graph (d) corresponds to the fitting of the data when the spin ground state of **3ox** is taken to be $S = 3/2$.

apply the usual spin Hamiltonian approach for a simulation of the temperature-dependence of χT for a powder sample. The data are perfectly deconvoluted into three paramagnetic contributions, namely from the remaining starting complex **3** (26%, $S = 1/2$) and an Fe^{II} contamination from some photoreduction (15%, $S = 2$), and from the target material ^{2}**3ox** which is the major component (57%, $S = 1/2$). Since the relative amounts of the different constituents correspond within a narrow error margin of $\pm$1.4% of an 80 K Mössbauer spectrum of an aliquot of the SQUID sample (see Supporting Information), we trust that **3ox** in fact has indeed the postulated doublet ground state. By contrast, the trace (d) in Figure 4 demonstrates that there it is not possible to fit the data under the assumption of a $S = 3/2$ ground state for **3ox**.

Rather interestingly, the optimized structures of ^{2}**3ox** and ^{4}**3ox** show a large difference in the computed Fe=N bond lengths, which are 1.609 Å for ^{2}**3ox** and 1.738 Å for ^{4}**3ox**. We note that the Fe^{III}–N_3 distance in low-spin **3** is accurately predicted by the calculations (1.934 Å calculated versus 1.931 Å (X-ray) and 1.94 Å (EXAFS)). Since DFT is typically accurate within 0.01–0.03 Å for short and strong metal–ligand bonds such as the ones formed with oxo ligands in complexes

analogous to **3** and **3ox**,[5b,10] this provides strong evidence that the short Fe=N bond observed by EXAFS spectroscopy indeed corresponds to ^{2}**3ox** and not to ^{4}**3ox**.

Further strong evidence for the doublet ground state of **3ox** is obtained from the calculated Mössbauer parameters of ^{2}**3ox** and ^{4}**3ox**: the calculated isomer shifts are $-0.033\ mm\,s^{-1}$ and $0.138\ mm\,s^{-1}$, respectively. Thus, the experimental value of $-0.02\ mm\,s^{-1}$ agrees only with the computed isomer shift of ^{2}**3ox**. Based on previous isomer shift calculations, the error in the predicted value is expected to be less than $0.1\ mm\,s^{-1}$.[10,13,14] Consequently, the calculations provide strong evidence for ^{2}**3ox** and not ^{4}**3ox** being the observed species. The calculation of the quadrupole splitting is in line with this result, giving values of $-4.39\ mm\,s^{-1}$ for ^{4}**3ox** and $+1.84\ mm\,s^{-1}$ for ^{2}**3ox** compared with the experimental value of $|\Delta E_q| = 1.60\ mm\,s^{-1}$. The large value calculated for ^{4}**3ox** is far from that derived from the experiment and outside the error bar of the calculations which usually give results within about $0.3\ mm\,s^{-1}$ of those from the experiment even in complicated bonding situations.[14,10] As an independent check we note that the Mössbauer parameters calculated for **3** are in excellent agreement with the experimental values ($\delta_{calcd} = 0.289\ mm\,s^{-1}$, $\delta_{exptl} = 0.27\ mm\,s^{-1}$; $|\Delta E_q^{calcd}| = 2.04\ mm\,s^{-1}$, $|\Delta E_q^{exptl}| = 2.30\ mm\,s^{-1}$).

Having fairly rigorously established that ^{2}**3ox** is the species produced in the photolysis experiments, we want to briefly comment on the nature of the iron–nitrido bond in this unprecedented bonding situation (Figure 5). It is well known

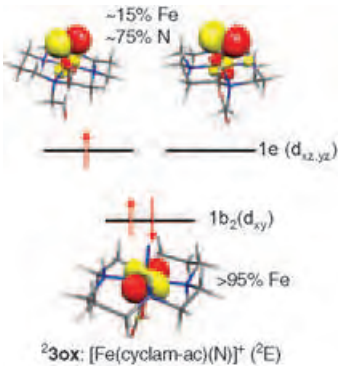

Figure 5. Ground-state electronic configuration of ^{2}**3ox**. The quartet state configuration is obtained by occupying all three MOs with one spin-up electron.

that in distorted octahedral environments the metal d orbitals split into an (almost) degenerate π-(anti)bonding t_{2g} and an (almost) degenerate σ-(anti)bonding set. However, if there is a dominant short metal–ligand bond, as in the present case of high-valent species, the splittings in both sets may become very large and often exceed 1 eV.[4h] In this case, the general rules about relative spin-state energetics as contained in the Tanabe–Sugano diagrams for octahedral symmetry may fail to hold, and in addition, there will be a very large anisotropic covalency induced by the strongly covalent metal–ligand bonds to the terminal oxo or nitride ligand. For the d^3 system examined here, the splitting between the almost pure metal d_{xy} orbital and the metal-derived $d_{xz,yz}$ orbitals apparently becomes so large that it is energetically more favorable to assume the (orbitally degenerate) configuration $^2E((d_{xy})^2\text{-}(d_{xz,yz})^1)$ (in approximate C_{4v} symmetry) as compared to the "canonical" configuration $^4A_2((d_{xy})^1(d_{xz})^1(d_{yz})^1)$. This will be further elaborated by high-level multireference ab initio calculations together with the results from MCD spectroscopy in a forthcoming paper. We indeed observe in the DFT calculations a very large anisotropic covalency of the iron–nitrido bond with the two metal-derived $d_{xz,yz}$ orbitals having only about 15% metal and as much as 75% N character according to a Löwdin population analysis. Moreover, the 4p character in the unoccupied metal-d derived MOs increases from 0.2% in **3** to 5.8% in ^{4}**3ox** and 7.3% in ^{2}**3ox.** The dramatic increase in 4p character explains the very intense XAS pre-edge feature of **3ox** (despite the decrease in 3d character). The very low metal character in the formally metal $d_{xz,yz}$ orbitals is, to a certain extent, underestimated by DFT calculations. Highly correlated ab initio methods provide somewhat larger values. However, a very large amount of charge transfer from N^{3-} to Fe^V is already expected on electrostatic grounds. Thus, a possible formulation of the electronic structure as a resonance between $Fe^V(S_{Fe}=3/2)N^{3-}(S_N=0) \leftrightarrow Fe^{III}(S_{Fe}=1/2)N^-(S_N=1)$ seems plausible for ^{4}**3ox**, whereas ^{2}**3ox** may best be represented by the resonance structures of the type $Fe^V(S_{Fe}=1/2)N^{3-} \leftrightarrow Fe^{II}(S_{Fe}=0)N^{\cdot}(S_N=1/2)$. The system will nevertheless behave to a certain extent like a d^3 system and we prefer to formulate the species as an Fe^V species. It is noted that the amount of charge transfer from N^{3-} to Fe^V is much larger than from O^{2-} to Fe^{IV} in $(FeO)^{2+}$ where the metal-derived $d_{xz,yz}$ orbitals are more equally shared between Fe and O.[3b,15]

The large calculated increase in Fe–N distance of about 0.13 Å in ^{4}**3ox** compared to ^{2}**3ox** is nicely explained by the strongly antibonding character of the $1e(d_{xz,yz})$ set, which is doubly occupied in ^{4}**3ox** but only singly occupied in ^{2}**3ox**. Likewise, we have calculated an increase in the harmonic vibrational Fe=N stretching frequency from $671\ cm^{-1}$ in ^{4}**3ox** to $937\ cm^{-1}$ in ^{2}**3ox** corresponding to an increase in force constant from about $0.19\ mdyn\,Å^{-1}$ to about $0.42\ mdyn\,Å^{-1}$. These numbers tend to be reliable from DFT but an independent experimental confirmation is, unfortunately, missing. In terms of formal bond order, one has to view the $(FeN)^{2+}$ core as a highly covalent unit with a double bond in ^{4}**3ox** and a bond of order 2.5 in ^{2}**3ox**. It is most intriguing that the ground state of ^{2}**3ox** is (almost) orbitally degenerate and will thus feature two low-lying Kramers doublets. As will be elaborated in detail elsewhere, this situation is experimentally difficult to distinguish from a zero-field split spin quartet state and leads to fascinatingly complicated magnetic behavior.

In summary, we have shown in this work through a combination of theory and experiment that photolysis of the non-heme Fe^{III}–N_3^- complex **3** in the solid state nearly quantitatively affords the desired genuine Fe^V–nitrido complex **3ox**. This complex features a highly unusual, almost orbitally degenerate, spin doublet ground state with a short (1.60 Å) Fe=N distance corresponding to a Fe=N bond of order 2.5. While in terms of the formal oxidation state, there is no doubt that **3ox** is to be formulated as an iron(v) species, the spectroscopic oxidation state[16] in this system is much harder

to determine unambiguously. In particular, the XAS and Mössbauer parameters are in full agreement with a highly oxidized iron center, whereas the DFT calculations, which lead to agreement with the spectroscopic experiments, show an excessive transfer of negative charge from the nitride ligand to the central iron.

Experimental Section

The irradiation process of **3** was performed on a suspension of powder samples in liquid N_2 over 4 h with a Rayonet Photochemical Reactor (RPR-100) equipped with 419 nm tubes. The photolysis process was followed optically by changes in the color of the species, from red-brown to pale beige, and monitored by IR spectroscopy. Mössbauer and magnetic susceptibility data were collected and analyzed as reported previously.[5] For SQUID measurements (radiation for about 10 h), the sample powder was not in direct contact with liquid N_2, but sealed in a flask to avoid condensation of water and subsequent deterioration during sample transfer to the SQUID magnetometer at ambient temperature.

XAS data for complexes **3** and **3ox** were recorded at the Stanford Synchrotron Radiation Laboratory (SSRL) on focused beam line 9–3, as previously described.[17] Internal energy calibration was performed by assigning the first inflection point of the Fe foil spectrum to 7111.2 eV. XAS samples of **3** (ca. 2 mM) were dissolved in degassed PrCN, loaded into 2 mm Lucite XAS cells with polypropylene windows and then frozen immediately in liquid nitrogen prior to XAS measurements. The photooxidation of **3** to **3ox** was performed in liquid N_2 by exposure for about 1.5 h to a 1000 W Xenon arc lamp equipped with a monochromator and a long pass filter for energy selection at 420 nm. During XAS measurements, samples were maintained at a constant temperature of 10 K by an Oxford Instruments CF1208 continuous-flow liquid-helium cryostat. Data were processed and analyzed as described in reference [17]. Samples were monitored for photoreduction throughout the course of data collection. Only those scans, which showed no evidence of photoreduction were included in the final averages.

Electronic structure calculations were performed with the program package ORCA developed in our laboratory. Structures were optimized at the BP86 level of DFT with polarized triple-ζ basis sets.[18] Calculation of the harmonic force fields of all species at the same level proved all structures to be local minima on the potential energy surface and provided vibrational frequencies used to calculate zero-point energies and thermal corrections. Total electronic energies were calculated with the TZVPP basis set and the B3LYP functional. The same functional was used together with special basis sets for the prediction of Mössbauer parameters.[14] Environmental effects were modeled with the conductor like screening model (COSMO) as implemented in ORCA and using acetonitrile ($\varepsilon = 36.6$) as solvent.

Nanoparticles

Molecular Recognition by Calix[4]arene-Modified Gold Nanoparticles in Aqueous Solution**

T. Robert Tshikhudo, Domenico Demuru, Zhenxin Wang, Mathias Brust, Andrea Secchi, Arturo Arduini, and Andrea Pochini**

The concept of exploiting metal clusters for nanotechnology applications dates back to the development of the original Au_{55} cluster by Schmid et al. in 1981.[1] Over the past decade, so-called monolayer protected clusters (MPCs) of gold and, to a lesser extent, silver have been studied extensively owing to their extreme stability and the plethora of tunable properties that are controlled by the particle size and by the ligand chemistry.[2–8] The stability is usually achieved by the use of thiolate ligands, which form a protective shell around the particles to which they are attached by the strong Au–S interaction. Typical sizes of MPCs range from 1 to approximately 40 nm depending on the preparation method used. Since most preparations lead to materials that are insoluble in water a comparatively small number of studies have been carried out in aqueous systems.[9–18] In particular, in view of future bioanalytical applications it is, however, desirable to develop new MPC systems that are not only stable and soluble in water, but also capable of molecular recognition in aqueous systems. Very stable, yet chemically versatile water-soluble MPCs are obtained when a sulfanylalkyl oligo(ethylene glycol) is used as a stabilizing ligand.[16] Herein we report the preparation and chemical properties of 14-nm gold MPCs, which are stabilized in this way and, in addition, carry in their ligand shell calix[4]arene moieties, which confer their specific molecular recognition properties to the particles. Calixarenes are host molecules which can bind cationic guests strongly and with high specificity depending on the size of the calixarene cavity.[19,20] Some of us have recently shown that, in non-aqueous systems, the incorporation of calixarenes in 1.5–4-nm MPCs can enhance their affinity to guest molecules.[20] By themselves, calixarenes are completely insoluble in water, which significantly limits their potential applications as molecular recognition units. The sulfanylalkyl oligo(ethylene glycol) ligands in the system described herein act therefore not only as stabilizers for the MPCs but also as solubilizers for the attached calix[4]arene units. It is thus now possible to demonstrate molecular recognition by an unmodified calixarene cavity in water. The particles prepared have been characterized by transmission electron microscopy (TEM) and by UV/Vis, and NMR spectroscopy. Specific recognition of immobilized cationic pyridinium moieties by the calixarene-modified MPCs in aqueous solution has been demonstrated by a simple color test and by atomic force microscopy (AFM).

The preparation of the calixarene-modified nanoparticles is schematically illustrated in Figure 1. Citrate-stabilized gold

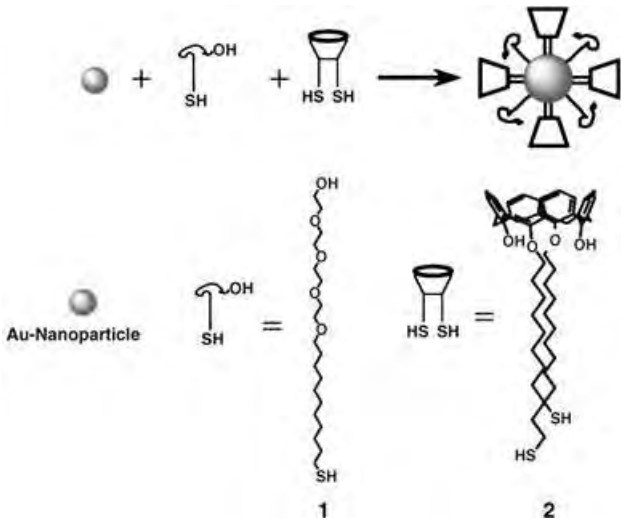

Figure 1. Reaction scheme illustrating the one-step stabilization and functionalization of gold nanoparticles with **1** and **2** carried out in a THF/water mixture.

hydrosols were treated with a 2:1 mixture of the stabilizing ligand (1-sulfanylundec-11-yl) tetraethylene glycol (**1**) and 25,27-bis(11-thio-1-oxyundecan)-26,28-dihydroxycalix[4]arene (**2**) in a water/THF solvent system to directly give the modified particles **3**, which were isolated from excess ligand material by centrifugation. Given the conformation of the relatively rigid **2** it is reasonable to assume that both thiol functionalities of **2** bind to the surface of the same gold particle. Otherwise, cross-linking of particles by bisthiol bridges and precipitation of aggregates could be expected,[21] but this has not been observed in this case. On the contrary, the particles are extremely stable and can be centrifuged, dried, and re-suspended in aqueous solution several times without loss of material. The ruby red suspensions are very robust against non-specific aggregation. For example, unlike most other hydrosols, the particles do not aggregate even in a 2 M sodium chloride solution. They exhibit a characteristic plasmon absorption band in the UV/Vis spectrum at 526 nm and their size is that of the original citrate-stabilized particles (14 ± 1 nm) as confirmed by TEM (Figure 2).

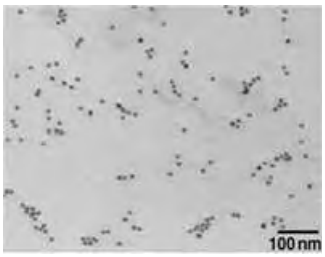

Figure 2. TEM image of the 14-nm gold nanoparticles **3**, that are stabilized and functionalized with **1** and **2**.

The molecular composition of the ligand shell has been studied by ^{1}H NMR spectroscopy (Figure 3). As expected, the spectrum of the particles shows significant peak broadening, in particular of the methylene protons adjacent or close to the sulfur atom that binds to the surface of the particle. This effect is chiefly due to the lack of mobility of the closely packed molecules in the ligand shell, which on the nanometer scale resembles a solid-state material. Several other factors contributing to line broadening in NMR spectra of MPCs have also been suggested, and the phenomenon is still subject to some debate.[5,6,14] Although the broadening of the features impedes a more detailed interpretation, it is apparent that all the main characteristic features of the two different ligands are present in the spectrum of the particles. Importantly, slightly broadened signals between $\delta = 6.6$ and 7.2 ppm, which are characteristic of the aromatic protons in the calixarene cavity are clearly present in the spectrum of the particles. This result indicates the inclusion of **2** in the ligand shell. It can be inferred from previous studies of peptide-stabilized MPCs of the same size that the number of thiol ligands is typically between 800 and 1000 molecules per gold particle.[18] Under the assumption of similar adsorption kinetics for both **1** and **2** it can thus be estimated that each gold particle carries on the order of 300 molecules of **2**. A quantitative analysis of the binding properties of the material will be required to confirm this estimate. Such experiments are underway. The binding properties of a solution-free, water-soluble model calix[4]arene derivative towards *N*-alkyl pyridinium salts in D_2O are given quantitatively in the Supporting Information. The molecular recognition properties of the particle-bound calixarene in water are qualitatively demonstrated by specific binding studies using two different chemically modified substrates (Figure 4). In the simplest case the substrate

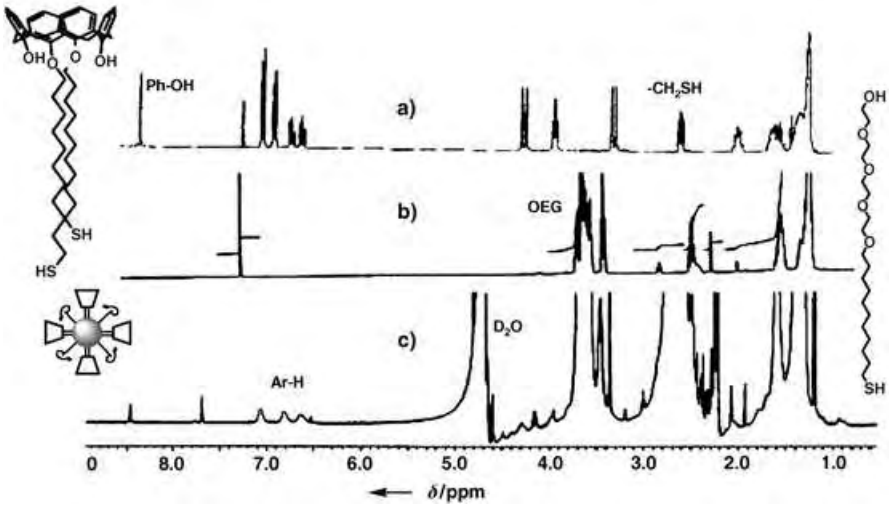

Figure 3. ^{1}H NMR spectra of **2** (a) and **1** (b) in $CDCl_3$, and of **3** (c) in D_2O showing that **1** and **2** have been attached to the gold nanoparticles (the signals of the methylene protons adjacent to the thiol and oligoethylene glycol (OEG) protons are marked). In particular, the signals of the aromatic protons (Ar-H) in spectrum (c) indicate the presence of the calixarene cavity in the ligand shell of the particles.

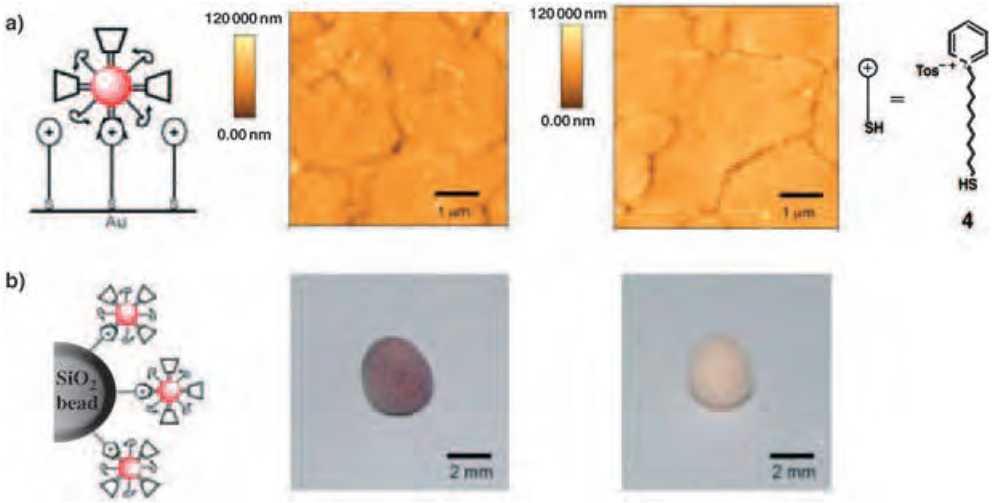

Figure 4. Specific binding of the calixarene-modified gold nanoparticles **3**, from aqueous solution to a self-assembled monolayer (SAM) of the pyridinium ions of **4** (Tos = (4-methylphenyl)sulfonyl) on a gold surface shown by AFM (a) and to a molecular sieve bead primed with **4** (b). The control experiments (right) show the nonspecific attachment of only very few particles to the SAMs (a) and no visible attachment of particles to the molecular sieve beads (b).

was prepared by the nonspecific adsorption of **4** (Figure 4) to white molecular sieve beads. For non-aqueous media it is known that the cationic pyridinium moiety is specifically recognized by calix[4]arenes.[20] The nanoparticles **3** bind specifically from aqueous solution to the molecular sieve beads primed with **4** indicating that the calixarene cavity of **2** exhibits its characteristic cation binding properties also in aqueous media and when immobilized in the ligand shell of the MPCs. This binding interaction is easily observed with the naked eye owing to the intense red color of the gold nanoparticles. A number of control experiments clearly confirmed that both the pyridinium and the calixarene moieties have to be present to achieve any attachment of MPCs to the molecular sieve beads. Further binding studies were carried out by AFM using a self-assembled monolayer (SAM) of **4** on a flat gold surface as the substrate. As demonstrated in the AFM images in Figure 4 a the calixarene-modified nanoparticles **3** were found to bind selectively to this SAM from aqueous solution, while binding to clean gold surfaces occurred only as a non-specific minority event. MPCs without calixarene in their ligand shell did not show any significant binding to the SAMs or to clean gold surfaces.

In conclusion, we have introduced a very simple route for the preparation of water-soluble calixarene-functionalized MPCs of gold. Importantly, it has been demonstrated that in an aqueous environment the calixarene retains its molecular recognition properties, which have been utilized herein to bind the MPCs selectively to chemically modified substrates. The MPCs also act as readily detectable markers of the specific recognition events demonstrating a high potential for simple, color-based diagnostic tests, for example, those required for many routine bioanalytical applications. The preparative method is very general and can readily be adapted to other artificial molecular recognition systems. Particularly attractive is the opportunity demonstrated, to make totally water insoluble recognition systems amenable to aqueous solutions, which again is of interest in the context of bioanalytical applications of MPCs.

Experimental Section

Citrate-stabilized gold nanoparticles of 14 nm diameter were prepared following the classical Turkevich Frens procedure.[22,23] Briefly, an aqueous solution of sodium citrate (10 mL, 17 mM) was added to a boiling aqueous solution of $HAuCl_4$ (180 mL, 0.3 mM), and the reaction mixture was heated under reflux for 30 min. It was then allowed to cool to room temperature, stirred overnight, and filtered before use (0.45 μm millipore filter). **1** was synthesized as described in [24]. **2** was synthesized as described in [20].

3: THF (12.5 mL) was added to an aqueous solution of citrate-stabilized gold nanoparticles (12.5 mL, 2.9 nM). To this mixture, solutions of **1** (10 mg, 0.025 mmol, 0.5 mL) and **2** (10 mg, 0.012 mmol, 0.5 mL) in THF were added simultaneously under stirring. It was stirred for 3 h and filtered (0.45 μm millipore filter). The particles were purified by repeated centrifugation (3 times) at 11000 rpm (Sigma 1-13 model) and re-dispersion in water. A molar absorption coefficient of $4.2 \times 10^8\,M^{-1}cm^{-1}$ (at 526 nm) based on gold nanoparticles of 15 ± 1.2 nm diameter was used to calculate a final concentration of 1.5 nM (12.5 mL).[25] For ^1H NMR spectroscopy pellets of centrifuged particles were dried under vacuum overnight and re-dissolved in D_2O.

4: Thioacetic acid S-[11-(toluene-4-sulfonyloxy)-undecyl] ester (**a**) was prepared by refluxing a mixture of toluene-4-sulfonic acid undec-10-enyl ester (5 g, 15.4 mmol) and thioacetic acid (2.3 g, 31 mmol) in toluene (200 mL) for 3 h under exclusion of oxygen and in the presence of a catalytic amount of 2,2′-azobis[(2-methyl)-propanenitrile] (AIBN) and subsequent removal of the solvent by rotary evaporation. The solid crude product was dissolved in CH_2Cl_2, washed with water and sodium hydrogen carbonate, and purified by column chromatography (silica gel, hexane 90%/ ethyl acetate 10%) to give a yellowish viscous solid (90% yield). Pyridine (0.5 g, 5 mmol) was added to a solution of **a** in acetonitrile (2 g, 5 mmol, 100 mL) and heated under reflux for 24 h. The solvent was removed by rotary evaporation and the pure white solid product was obtained by precipitation in ethyl acetate/acetone in good yield (80%). This white solid (2 g, 4 mmol) and *para*-toluene sulfonic acid (1 g, 7 mmol) were dissolved in methanol (20 mL) and heated under reflux overnight then the solvent was removed by rotary evaporation. Precipitation of the resulting mixture in CH_2Cl_2 yielded a pure white sticky solid product **4** (75% yield). SAMs of **4** on gold (gold films of approximately 250-nm thickness on quartz glass, Arrandee) were prepared by overnight immersion of the cleaned and flame-annealed substrates in a solution of **4** in $CHCl_3$ (5 mL, 1.2×10^{-4} M) and subsequent thorough rinsing with $CHCl_3$ and drying in a stream of nitrogen. Single molecular-sieve beads (4 Å type, Aldrich) were modified by overnight immersion in solutions of **4** (2.5 mL, 1.2×10^{-4} M) in chloroform. After removal from the solution, the beads were washed thoroughly with chloroform and allowed to dry at room temperature. Specific recognition experiments were carried out by overnight immersion of the substrates (SAMs and beads) in a solution of **3** (0.034 nM, 2.5 mL for SAMs and 1.2 nM, 1.5 mL for beads). Adequate control experiments were performed to exclude the possibility of nonspecific binding.

For spectroscopic data and elemental analyses see the Supporting Information.

Metallaboranes

Synthesis and Characterization of [*exo*-$BH_2(Cp^*M)_2B_9H_{14}$] (M = Ru, Re), and the Conversion of the Ruthenaborane into [$(Cp^*Ru)_2B_{10}H_{16}$] with an Open Cluster Framework Based on a Capped Truncated Tetrahedron**

*Sundargopal Ghosh, Bruce C. Noll, and Thomas P. Fehlner**

The evolution of main-group and transition-metal cluster structural chemistry since the development of the electron-counting rules in the 1970s is an important achievement of modern inorganic chemistry.[1,2] The useful connection between cluster geometry and electronic structure defined by the electron counting rules provides a solid foundation for the rational approach to larger clusters and nanoparticle systems that lie between small clusters and bulk crystalline materials with extended structures.[3]

Given the firm connection between the cluster-electron count and the cluster geometry for subicosahedral main-group clusters, it could be assumed that the structures of clusters based on supraicosahedral frameworks will provide similar unambiguous information. Not so. For example, 14 skeletal electron pair (sep), 12-fragment heteroatomic clusters with carbon or carbon plus a transition metal exhibit at least five different open cluster shapes depending on heteroatom content.[4–6] Even the structure of the 13-vertex closed carborane cluster, 1,2-μ-$C_6H_4(CH_2)_2$-3-Ph-1,2-$C_2B_{11}H_{10}$, is a variant of the docosahedral structure found by calculations most stable for the 13-vertex homonuclear borane (Scheme 1).[7] In this case, the additional stabilization achieved by generating vertices of connectivity four for the carbon centers more than compensates for that lost in converting a diamond into a rhombus arrangement. Thus for supraicosahedral clusters, the energy differences between possible geometries are much smaller than for subicosahedral clusters and the stabilization achieved by accommodating the properties of hetero atoms determines the observed cluster shape.

Herein novel boron-rich metallaboranes with geometries based on supraicosahedral frameworks provide a carbon-free comparison and demonstrate further structural types. These observations do not define the basic supraicosahedral framework structures for homonuclear boranes even though more of the structures accessible can be mapped out empirically. In addition, provided barriers for interconversion are large relative to room-temperature, intermediates in the cluster-building process are also likely to be isolated. As shown below, this characteristic of supraicosahedral cluster frameworks has allowed us to isolate and characterize a metallaborane with an unusual structure and to demonstrate that it is an intermediate in the boron cluster framework expansion reaction.

In terms of systematic cluster expansion, the most versatile metal is rhenium where known Re_2B_n frameworks run from $n = 4$ to 10.[8] Ruthenium offers fewer compounds[9,10] but revisiting both systems utilizing large BH_3 excess and forcing conditions permits the isolation of three different compounds with the molecular formula [$Cp^*_2M_2B_{10}H_{16}$], M = Ru or Re, $Cp^* = C_5Me_5$. With formal electron counts of 14 and 13 sep they offer an interesting case study for electron counting/supraicosahedral cluster relationships.

The structure of [$Cp^*_2Ru_2B_{10}H_{16}$] (**1**) is shown in Figure 1.[11] The presence of an exopolyhedral boron atom (B11) is clear from the structure solution and the assigned positions of the associated hydrogen atoms (not all found) are completed by two dimensional ^1H–^{11}B NMR spectroscopy experiments. The principal cluster framework of **1** contains one vertex of connectivity six occupied by a ruthenium atom; hence, it can be derived from a 13-vertex docosahedron that is missing two vertices of connectivity five and six. This is the geometry adopted by many 14 sep, 12 fragment metallacarboranes (one vertex of connectivity six unoccupied); however, the formal electron count of **1** is only 13 sep (the

bridging BH_2 unit adds one electron). Some ways by which transition metals can stabilize framework geometries with vertices of high connectivity have been discussed and the susceptibility of these large clusters to secondary factors, such as heteroatom effects, has been pointed out above.[8]

The external BH_2 fragment of **1** bridges a B–Ru edge and is bonded to the boron atom B12 by a B-H-B bridge, that is, the boron atom B12 has no terminal hydrogen atom. On heating, **1** slowly converts exclusively into $[Cp^*_2Ru_2B_{10}H_{16}]$ (**2**). The ^{11}B NMR spectrum of **2** exhibits three rather than 10 resonance signals (found for **1**) and none of these signals corresponds to an exopolyhedral borane. Reinsertion of the borane and formation of a cluster framework with higher symmetry is implied and the solid-state structure in Figure 2

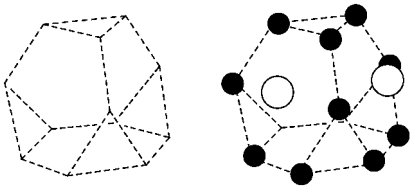
shows a 12-atom open framework for **2** of C_{2v} symmetry with 6 B-H-B bridges on the open face.[11] The framework can be derived from a capped truncated tetrahedron of a type observed for naked tin clusters in the solid state.[12] As shown in Scheme 1, the two metal atoms occupy two of the four hexagonal faces; the other two hexagonal faces plus the two adjacent three-connect vertices are unoccupied. Like the



Scheme 1. Left: a truncated tetrahedron. Right: representation of a 12-vertex $[Cp^*_2Ru_2B_{10}H_{16}]$ framework where two ruthenium atoms cap two of the four hexagonal faces of a truncated tetrahedron and two adjacent 3-connect vertices are missing; ● B, ○ Ru.

tetrahedron, this cluster shape requires $n+4$ sep; hence, **2** requires 18 sep whereas formally only 14 sep are available.

$[Cp^*_2Re_2B_{10}H_{16}]$ (**3**) was isolated from a reaction mixture that also contains the closed series of compounds $[Cp^*_2Re_2B_nH_n]$, the structure of **3** is shown in Figure 3. The

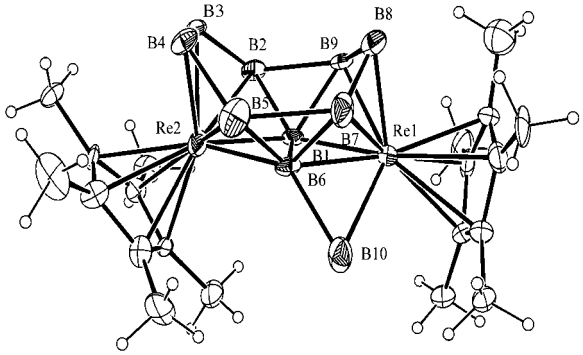


Figure 3. Molecular structure of **3**. Selected bond lengths [Å] and angles [°]: Re1-B1 2.15(3), Re1-B7 2.20(4), Re2-B5 2.11(4), B1-B6 1.71(4), B5-B7 2.13(6), B6-B10 1.91(5), B2-B9 1.96(5); B1-Re1-B8 79.9(13), B8-Re1-B6 81.0(15), B8-Re1-B9 48.5(17), B9-B1-Re2 129.7(19), B9-B1-Re1 69.9(14), B6-B5-B4 118(3).

heavy-atom framework corresponds to $[exo\text{-}BH_2\text{-}(Cp^*Re)_2B_9H_{14}]$, and is the same as **1** despite the fact that two rhenium atoms provide two fewer valence electrons than two ruthenium atoms![11] The X-ray structure did not provide the positions of any hydrogen atoms but the NMR spectroscopy results suggest, in contrast to **1**, that the boron atom (B6) of the borane bridged B–Re edge forms a B-H-Re bridge to the other rhenium center rather than a B-H-B bridge to the B atom of the exo-BH_2 fragment. Heating **3** under the same conditions as **1** results in the degradation of **3** but no evidence for either rearrangement to a single cage or hydrogen loss to produce $[Cp^*_2Re_2B_{10}H_{10}]$ was forthcoming.

First observed in metallacarborane chemistry,[13] the exopolyhedral BH_2 group now found in both **1** and **3** is likely to be of mechanistic importance in boron fragment growth of metallaboranes. A smaller ruthenacarborane cluster containing a exopolyhedral BH_2 group was shown earlier to be a versatile intermediate. Depending on substituents and conditions, it can undergo reinsertion of the BH_2 bridge, loss of the bridge, or participation of the bridge in external cluster hydroboration to give unusual organoborane cage substituents.[14,15] In principle, then, the same possibilities

exist for **1** and **3**. Reversible metal-cluster fragment extrusion is known in metallacarborane chemistry[16] and this mechanistic feature is now shown to apply to main-group-cluster fragments as well. Evidence for its role in other cluster systems can now be sought.

Experimental Section

1: Colorless **1** was isolated by silica gel thin layer chromatography (TLC) with hexane in 12% yield (20 mg) from the products of the reaction of $[(Cp^*Ru)_2B_4H_8]$ (0.15 g, 0.28 mmol) in toluene (30 mL) with BH_3·THF (10 equiv) at 105 °C for 28 h. MS (FAB) P^+(max) 597 (isotopic pattern for 2 Ru and 10 B atoms), $^{12}C_{20}{}^{1}H_{46}{}^{11}B_{10}{}^{101}Ru_2$ calcd: 600.2617; obsd: 600.2642. ^{11}B NMR (C_6D_6, 128 MHz, 22 °C): $\delta = 24.9$ (s, br, $J_{B\text{-}H} = 50$ Hz, 1 B-H-B), 18.1 (d, $J_{B\text{-}H} = 126$ Hz, 1 B), 14.7 (br, 1 B), 14.9 (br, 1 B), 11.5 (d, $J_{B\text{-}H} = 140$ Hz, 1 B), 6.5 (d, $J_{B\text{-}H} = 144$ Hz, 1 B), 4.6 (d, $J_{B\text{-}H} = 142$ Hz, 1 B), −0.8 (d, $J_{B\text{-}H} = 128$ Hz, 1 B), −4.9 (br, 1 BH_2), −6.1 ppm (d, $J_{B\text{-}H} = 152$ Hz, 1 B), ^{1}H NMR (C_6D_6, 400 MHz, 22 °C): $\delta = 4.18$ (partially collapsed quartet (pcq), 1 BH_t (H_t = terminal)), 3.24 (pcq, 1 BH_t), 3.18 (pcq, 2 BH_t), 2.79 (pcq, 1 BH_t), 2.73 (pcq, 1 BH_t), 2.59 (pcq, 1 H of BH_2), 2.44 (pcq, 2 BH_t and 1 H of BH_2), 1.76 (s, 15 H, 1 Cp*), 1.52 (s, 15 H, 1 Cp*), −0.81 (br, 1 B-H-B); −2.34 (br, 1 B-H-B); −2.97 (br, 1 B-H-B); −3.28 (br, 1 B-H-B); −5.10 (br, 1 B-H-B); −5.24 ppm (br, 1 B-H-B); IR (hexane): $\tilde{\nu} = 2498$w, 2464w cm^{-1} (B-H_t). Elemental analysis (%) calcd for $^{12}C_{20}{}^{1}H_{46}{}^{11}B_{10}{}^{101}Ru_2$: C 40.25, H 7.77; found: C40.50, H 7.69.

2: Compound **1** (0.05 g, 0.08 mmol) in [D_6]benzene (0.7 mL) heated for 12 days at 80 °C gave colorless **2** (20 mg, 40%) after TLC hexane. MS (FAB) P^+(max) 597 (isotopic pattern for 2 Ru and 10 B atoms), $^{12}C_{20}{}^{1}H_{46}{}^{11}B_{10}{}^{101}Ru_2$ calcd: 600.2617; obsd: 600.2616. ^{11}B NMR (C_6D_6, 128 MHz, 22 °C): $\delta = 24.8$ (d, $J_{B\text{-}H} = 120$ Hz, 2 B), 14.2 (d, $J_{B\text{-}H} = 122$ Hz, 4 B), 11.2 ppm (d, $J_{B\text{-}H} = 115$ Hz, 4 B); ^{1}H NMR (C_6D_6, 400 MHz, 22 °C): $\delta = 3.96$ (pcq, 2 BH_t), 3.49 (pcq, 4 BH_t), 2.88 (pcq, 4 BH_t), 1.62 (s, 30 H, 2 Cp*), −2.77 (br, 4 B-H-B); −3.53 ppm (br, 2 B-H-B); IR (hexane): $\tilde{\nu} = 2504$w, 2476w cm^{-1} (B-H_t).

3: Brown **3** (0.004 g, 4%) was isolated by TLC with hexane from the products of the reaction of $[(Cp^*Re)_2B_4H_8]$ (0.1 g, 0.14 mmol) in toluene (30 mL) with BH_3·THF (10 equiv) at 95 °C for 18 h. MS (FAB) P^+(max) 765.45 (isotopic pattern for 2 Re and 10 B atoms), $^{12}C_{20}{}^{1}H_{46}{}^{11}B_{10}{}^{186}Re_2$ calcd: 765.3544; obsd: 765.3568 (Exact mass calculated for $[M^+-2]$; ^{11}B NMR (C_6D_6, 128 MHz, 22 °C): $\delta = 68.6$ (br, $J_{B\text{-}H} = 50$ Hz, 1 ReHB), 13.2 (d, $J_{B\text{-}H} = 122$ Hz, 1 B), 4.1 (br, 2 B); 2.9 (br, 1 B), 0.25 (br, $J_{B\text{-}H} = 60$ Hz, 1 B), −5.7 (d, $J_{B\text{-}H} = 140$ Hz, 1 B), −8.9 (d, $J_{B\text{-}H} = 142$ Hz, 1 B), −15.3 (d, $J_{B\text{-}H} = 136$ Hz, 1 B), −19.8 ppm (br, 1 BH_2); ^{1}H NMR (C_6D_6, 400 MHz, 22 °C): $\delta = 4.88$ (pcq, 1 BH_t), 3.84 (pcq, 1 BH_t), 3.66 (pcq, 1 BH_t), 3.41 (pcq, 1 BH_t), 3.11 (pcq, 1 H of BH_2), 3.00 (pcq, 1 H of BH_2), 2.89 (pcq, 1 BH_t), 2.73 (pcq, 1 BH_t), 1.30 (pcq, 1 BH_t), −0.07 (pcq, 1 BH_t), 1.79 (s, 15 H, 1 Cp*), 1.68 (s, 15 H, 1 Cp*), −1.41 (br, 1 B-H-B), −2.22 (br, 1 B-H-B), −3.67 (br, 1 B-H-B), −5.43 (br, 1 B-H-B), −7.06 (br, 1 B-H-B), −15.09 ppm (br, 1 Re-H-B). binding site/signaling subunit approach, in which molecular coordination sites are covalently attached to chromogenic/fluorogenic reporters which transduce guest coordination into optical signals. Recently, two additional methodologies have been developed. One is the chemodosimeter approach, which is related to the use of guest-induced irreversible reactions,[2] and the other is the displacement protocol, which also involves the use of a binding site and a signaling reporter, although here the two subunits are not covalently attached but form a molecular ensemble.[3–5] In the latter systems addition of a certain guest to solutions of the sensing ensemble results in a displacement reaction: the binding site coordinates to the guest, and the signaling subunit is released. This method, inspired by displacement reactions in immunoassay protocols,[6] has been recently reported for the sensing of small anions with very good results.[7,8] This approach has several advantages. For instance, the noncovalent anchoring of binding sites and indicator groups allows a large number of combinations to be tested with minimum effort in order to obtain tuned sensing systems. Furthermore, these sensing ensembles usually operate in pure water or water/organic solvent mixtures. However, the displacement approach also has several limitations. One restriction is that the spectroscopic characteristics of the indicator in the molecular ensemble must be different to those in its noncoordinated form.[3] Another disadvantage is that sometimes it requires extensive and time-consuming synthetic efforts to finally obtain somewhat complex receptors.

All of these systems are based on the use of molecular anion hosts[2] having in common the presence of binding sites placed in suitable cavities that fit in size and charge with the guest to be coordinated and sensed. These binding pockets have typically been obtained by the use of 1,3,5-trisubstituted 2,4,6-triethylbenzene scaffolds[7i,8a,8e–8h] or cages incorporating metal complexes.[7b–h,8c,8d,8i] Following a different approach, we and others recently reported that adequately functionalized nanosized cavities in mesoporous solids can somehow mimic active-site cavities found in biological systems.[9–13] Our aim was to demonstrate that functionalized pores in mesoporous solids could act as binding pockets and be used as anion hosts in chromogenic displacement assays. The protocol is schematically shown in Figure 1. Suitable nanosized pores are functionalized with appropriate binding sites. The functionalized solid is then loaded with a dye capable of coordinative interaction with the anchored coordination sites. In the presence of a target anion displacement of the dye into the solution is achieved and results in colorimetric detection of the guest.

To check this idea, host solids **S2** and **S3** containing nanoscale cavities with anion-binding sites were prepared and loaded with suitable dyes. The mesoporous starting material UVM-7[14] was first treated with an excess of 3-aminopropyltriethoxysilane to yield solid **S1** (Scheme 1). Solid **S2** was obtained by reaction of **S1** with an excess of 2-methylthio-2-imidazoline hydroiodide in refluxing methanol for 16 h.[15] Solid **S3** was synthesized by reaction of **S1** with mannose in the presence of sodium cyanoborohydride.[16] Both solids were exhaustively washed and dried (40% yield). Solid **S2** was then converted to solid **S2**-**1** by loading with the dye

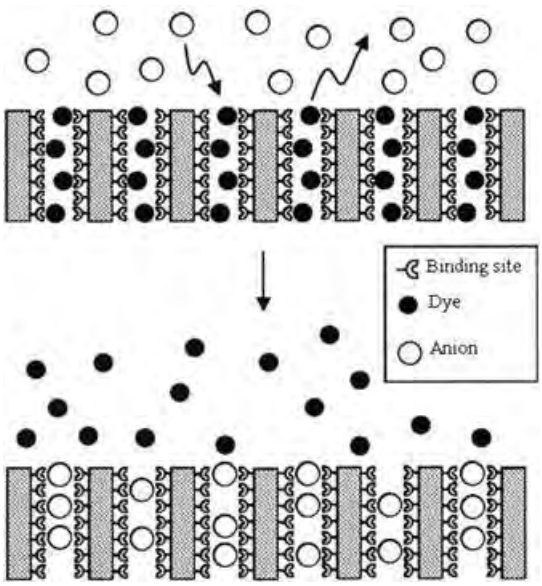

Figure 1. Idealized representation of the use of functionalized mesoporous materials in colorimetric displacement assays.

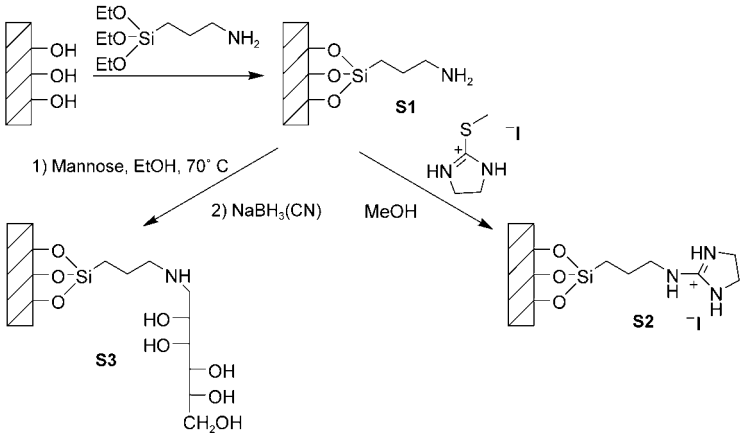
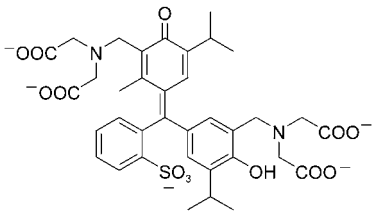
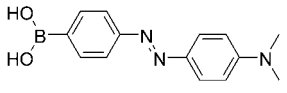


Scheme 1. Synthesis of solids **S1**, **S2**, and **S3**.

Methylthymol blue (**1**), which contains four carboxy groups and is expected to form strong complexes with guanidinium groups.[17] In a similar manner, solid **S3** was loaded with azoic dye **2** to give solid **S3**-**2**.[18] This dye was selected because of



1



2

the well-known affinity of boronic fragments towards carbohydrate residues. Solids were washed until no elimination of dye was observed. Table 1 lists the chemical composition of the active solids, calculated from thermogravimetric and

Table 1: Functionalization of **S2** and **S3**.

Solid	Binding molecules[a]/SiO_2	Solid	Dye/SiO_2[a]
S2	6.4×10^{-2}	**S2-1**	1.5×10^{-2}
S3	8.4×10^{-2}	**S3-2**	3.7×10^{-2}

elemental analysis. The guanidine content of **S2** was determined by analysis of the iodide counterion after dissolution in 34 wt% aqueous HF. The dye content of **S2-1** was calculated by colorimetric analysis after dissolution as for **S2**.

Figure 2b (inset) shows the ^{29}Si MAS-NMR spectrum of **S1**, in which the presence of two peak groups, assigned to the Q ($\delta = -105, -97, -87$ ppm) and T silicon centers ($\delta = -61, -53$ ppm), clearly indicates anchoring of the silane derivative

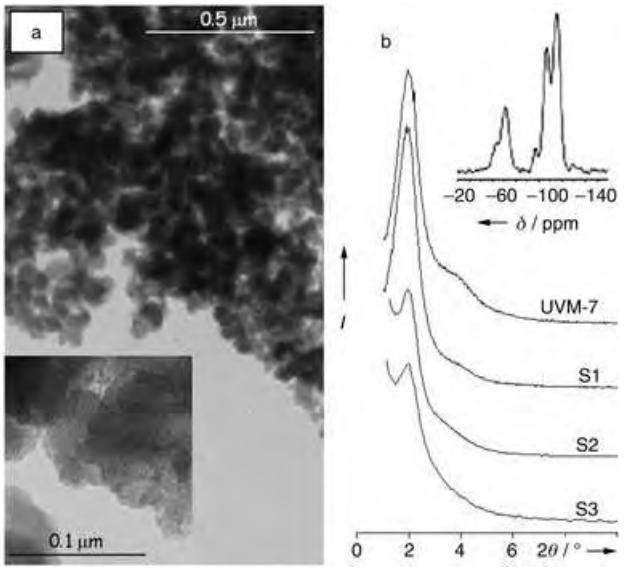

Figure 2. a) TEM micrograph of the guanidinium-functionalized solid after loading with methylthymol blue (**S2-1**). b) Powder XRD pattern of **S2** and **S3** compared with those of their precursors UVM-7 and **S1**. Inset: ^{29}Si MAS-NMR spectrum of functionalized **S1**.

to the silanol groups of the silica surface. Peak deconvolution gave a ratio of Q and T centers of 3:1, in good accordance with the chemical analysis. The successive functionalization process is displayed in Figure 3 which shows the IR spectra of the solids. In **S1**, bands due to OH vibrations have disappeared, and others related to the presence of NH_2 and CH_2 groups can be seen. In **S2**, bands assigned to the guanidinium groups are clearly observed (e.g., 1670 and 1600 cm^{-1}, assignable to the NH δ vibration). In the spectrum of **S2-1** bands due to dye vibrations (e.g., 1625 and 1404 cm^{-1}, assignable to the carboxylate groups) are observed. For solids **S3** and **S3-2**

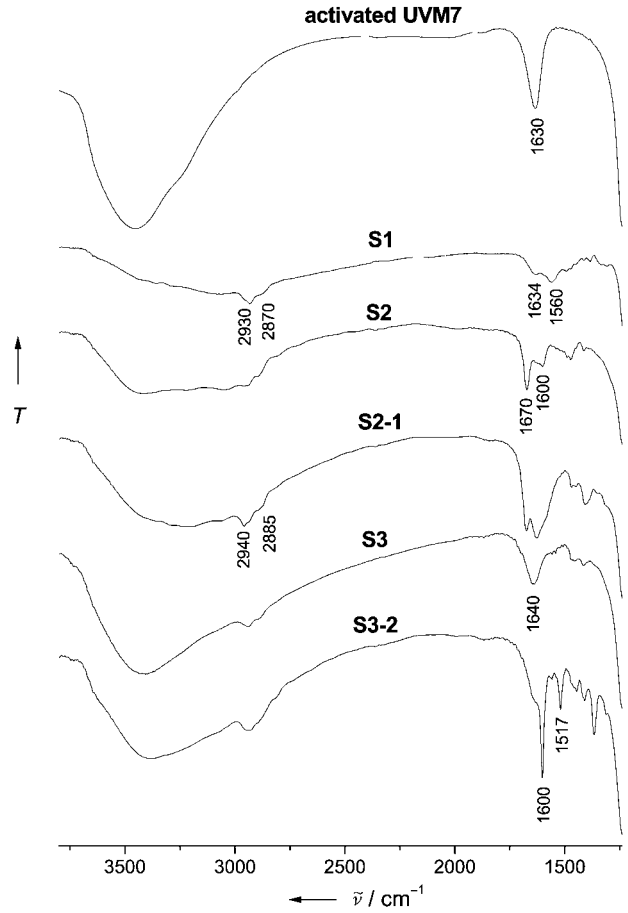

Figure 3. IR spectra of UVM-7, **S1**, **S2**, **S2-1**, **S3**, and **S3-2**. *T* = transmittance.

the bands due to the mannose residue and the azoic dye were also observed in the corresponding spectra.

Structural characterization of the solids was carried out by TEM, powder XRD, and isothermal adsorption/desorption of N_2. Figure 2a shows a representative TEM micrograph of solid **S2-1** with the characteristic texture of UVM-7-type materials. Additionally, the inset clearly shows that the wormholelike MCM-41-type mesoporosity of the inorganic matrix is still present. Similar TEM images were obtained for the other materials. Figure 2b shows the variation of the powder XRD pattern of the UVM-7 matrix as it is functionalized to obtain **S2** and **S3**. The gradual intensity decrease is related to the loss of contrast as the amount of organic material anchored to the matrix increases. This increase in the organic fraction also influences the porosity of the obtained material. Table 2 summarizes the values obtained from the N_2 adsorption/desorption isotherms. A gradual decrease in specific surface area is associated with a concomitant decrease in pore size and volume. The changes are more pronounced for the small mesopores than for the large textural pores.

Guanidinium groups are known to undergo hydrogen-bonding interactions with carboxy groups, and therefore the **S2-1** ensemble was tested in displacement assays in water in the presence of the carboxylates citrate, succinate, lactate, malate, acetate, oxalate, propionate, formate, oxalacetate,

Table 2: Specific surface area and porosimetric data of **S1** and **S2**.

Solid	Specific surface area [$m^2 g^{-1}$]	Pore size[a] [nm]	Pore size[b] [nm]	Pore volume[a] [$cm^3 g^{-1}$]	Pore volume[b] [$cm^3 g^{-1}$]
S1	870	2.67	41.1	0.72	0.68
S2	377	2.1	35.4	0.24	0.58
S2-1	156	<1.7	18.2	0.08	0.21

[a] MCM-41-type pores. [b] Textural pores.

tartrate, maleate, malonate, glutarate, adipate, pimelate, and phthalate. The ensemble was suspended in water at pH 7.5 (HEPES 0.01 M) in the presence of a certain carboxylate, and after 10 min the mixture was filtered and the absorbance at 604 nm (visible band of dye **1**) measured. The results are summarized in Figure 4. A citrate-selective response was found that indicates that the binding pockets in **S2** are capable of recognizing this anion due to favorable coordination with respect to other carboxylates. Figure 4 also shows the calibration curve with citrate. No changes were observed in the presence of inorganic anions such as phosphate, sulfate, nitrate, carbonate, chloride, iodide, or bromide.

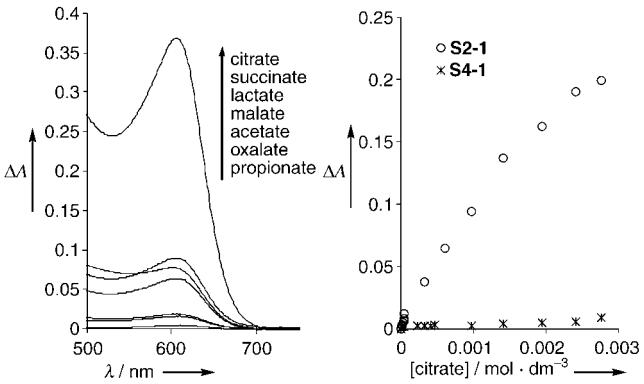

Figure 4. Left: Vis spectra (after filtering) of **S2-1** ensembles in the presence of different carboxylates. As examples, the responses to citrate, succinate, lactate, malate, acetate, oxalate, and propionate are shown. No significant response was found for other carboxylates. Right: citrate calibration curves for **S2-1** and **S4-1**. A detection limit for citrate of about 2×10^{-5} mol dm^{-3} was found for **S2-1**.

To test the effect of the nanoscale pores, we prepared **S4**, a similar material to **S2** but obtained from fumed silica (200 $m^2 g^{-1}$), which lacks the homogeneous porosity characteristic of mesoporous solids (**S4**: 1.5×10^{-2} guanidinium molecules per SiO_2, **S4-1**: 3.6×10^{-3} dye molecules per SiO_2; both values as molar ratios). Studies with citrate and **S4-1** (see Figure 4) showed a very poor response compared to that of **S2-1**. Despite the similar functionalization of **S2** and **S4**, their responses are remarkably different. This suggests that the presence of cylindrical-shaped pores in **S2** could favor spatial proximity between guanidinium subunits and thus enhance the coordinating ability of the binding groups in the nanoscale pockets towards citrate. This enhanced response was not observed for the nonporous surface of **S4**.

To further study the utility of the concept shown in Scheme 1, colorimetric sensing of borate in water/acetonitrile (80/20 v/v) was developed by using the **S3-2** ensemble. The ensemble was suspended at neutral pH in the presence of borate, and after 5 min the mixture was filtered and the band at 455 nm (due to release of **2** into the solution) measured. Dye displacement was observed in the presence of borate due to selective borate coordination with the diol groups in the surface of **S3**. Dye displacement is selective for borate (see Figure 5) and it is, as far as we know, the first chromogenic system based on supramolecular concepts for sensing the environmentally relevant borate anion.

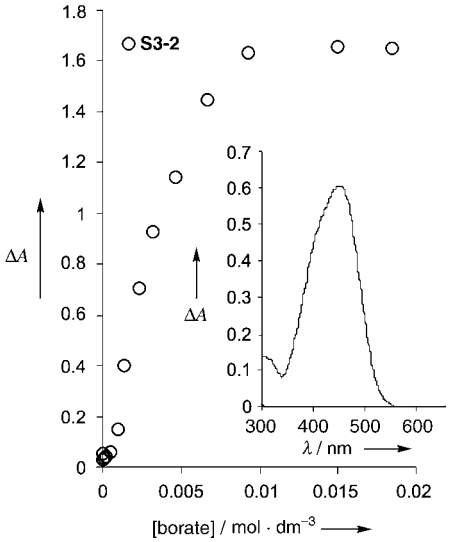

Figure 5. Borate calibration curve for **S3-2** (detection limit ca. 6×10^{-5} mol dm^{-3}). Inset: Vis spectrum (after filtering) of **S3-2** in the presence of borate and a mixture of different anions typically present in water (chloride, phosphate, sulfate, carbonate, etc.).

In summary, we have shown that functionalized mesoporous solids can act as binding pockets in anion-recognition processes. In particular, we have developed solids for displacement colorimetric assays in water for the selective detection of citrate and borate. We believe these findings can open new perspectives in the use of solids as hosts in solid-state/supramolecular chemistry concepts. The possibility of using a large number of mesoporous materials functionalized with different binding sites makes the approach suitable for the design of new chromo/fluorogenic probes for target guests.

Fluorescent Probes

2,4-Dinitrobenzenesulfonyl Fluoresceins as Fluorescent Alternatives to Ellman's Reagent in Thiol-Quantification Enzyme Assays**

Hatsuo Maeda, Hiromi Matsuno, Mai Ushida, Kohei Katayama, Kanako Saeki, and Norio Itoh*

Since its first description in 1959,[1] 5,5′-dithio-bis(2-nitrobenzoic acid) (DTNB or Ellman's reagent) has been used widely for the quantification of thiols, especially for assays of various enzymes including acetyl- and butyrylcholinesterase (AChE and BChE, respectively)[2] in which substrates release thiols through enzymatic reactions.[3] 4,4′-Bipyridyl disulfide[4] and 5-(2-aminoethyl)dithio-2-nitrobenzoic acid[3] were also shown to be useful for colorimetric analyses of thiols. However, fluorescent or chemiluminescent thiol probes would be more practical than these chromogenic probes for enzyme assays, especially for high-throughput programs to screen enzyme inhibitors as new drugs. Recently, the use of a dioxetane-disulfide derivative as a chemiluminescent probe in place of DTNB led to an improved sensitivity of the AChE assay with acetylthiocholine (ASCh) by a factor of ten.[5] However, the assay required a rather tedious procedure in

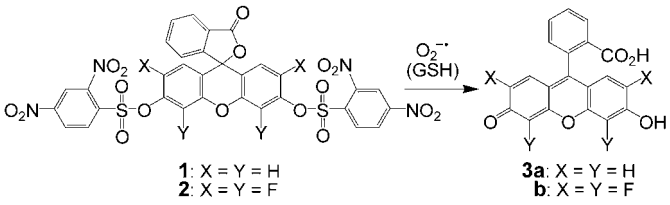
  DOI: 10.1002/anie.200500114

which the enzyme reaction and detection steps were performed independently owing to the limited solubility of the chemiluminescent probe in aqueous media.

At present, a wide variety of fluorescent probes for thiols are available.[6] Among them, maleimide-type probes CPM[6] and ThioGlo_3,[7] and a haloalkyl-type probe monobromobimane[6] may be utilized for thiol-determination enzyme assays. However, these probes have disadvantages that attenuate their utility in enzyme assays. CPM and ThioGlo_3 suffer from limited solubility in aqueous media, similar to the dioxetane-disulfide chemiluminescent derivative mentioned earlier, as well as inevitable side reactions of their maleimide groups to form fluorescent byproducts. Also, under mild conditions, reactions of monobromobimane with thiols are relatively slow.[8] Thus, these fluorescent probes have found applications in the labeling of biopolymers and derivatization of thiols for separation analysis rather than in enzyme assays.

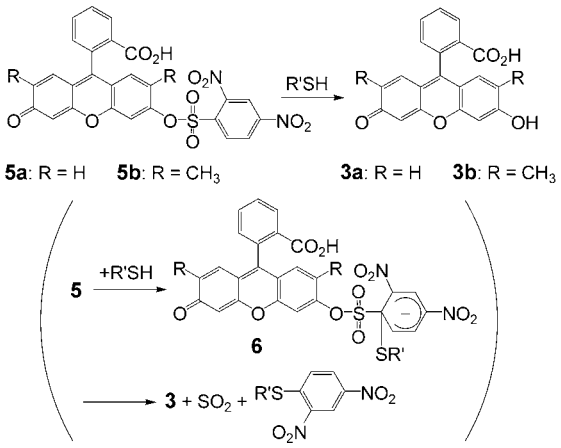
Recently it was found that **2** (Scheme 1) works as a highly specific probe for superoxide ($O_2^{-\bullet}$) based on deprotection of 2,4-dinitrobenzenesulfonyl (DBS) groups by $O_2^{-\bullet}$, whereas **1**



Scheme 1. A previously reported fluorescent probe for superoxide.

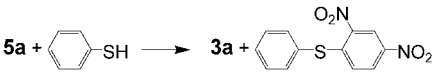
is transformed to **3a** much more effectively upon reaction with glutathione (GSH) through nucleophilic aromatic substitution[9,10] than with $O_2^{-\bullet}$.[11] The latter observation provided us with a clue for the design of novel fluorescent probes for thiols. So far, nucleophilic aromatic substitution has been capitalized only as a derivatizing reaction for the separation analysis of thiols with halogenated benzofurazans.[12] This fact also encouraged us to develop thiol probes based on nucleophilic aromatic substitution. Compound **1** is unlikely to work as a thiol probe as the observed fluorescence response of **1** toward GSH was relatively small. However, changing the protection mode with DBS groups from bis to mono was expected to enhance not only the reactivity toward thiols but also its solubility in aqueous media. Furthermore, it is well known that nucleophilic aromatic substitution proceeds more effectively as the acidity of leaving groups decreases.[10] These considerations led us to design **5b** as well as **5a** (Scheme 2) as fluorescent alternatives to DTNB for thiol-quantification enzyme assays. Herein we describe the characteristics of **5** as thiol probes and their utility in screening assays for ChE inhibitors.

As expected, monoprotection with a DBS group imparted to **5** a high degree of solubility in aqueous media. Working solutions of these probes were prepared by 200-fold dilution of ethanolic solutions of **5** with aqueous HEPES buffer (pH 7.4, HEPES = *N*-(2-hydroxyethyl)piperazine-*N*′-2-ethanesulfonic acid). Relative quantum efficiencies (Φ_{fl}) of **5a** and **5b** in HEPES buffer (pH 7.4) were 0.0007 and 0.0003,



Scheme 2. Probes **5** for thiols, and the reactions that give rise to their fluorescent products **3**, as used in this study.

respectively, relative to **3a** in 0.1 M NaOH ($\Phi_{fl} = 0.85$) as standard.[13] Similar estimates of Φ_{fl} for **3a** and **3b**[14,15] in the same buffer were 0.75 and 0.58, respectively. Compound **5a** was treated at room temperature with PhSH (1.1 equiv) in HEPES buffer (pH 7.4) containing 5% EtOH. After 10 minutes, **5a** was almost completely consumed and (2,4-dinitrophenyl)phenylsulfide was isolated in 96% yield [Eq. (1)]. No byproducts other than PhSSPh (4%) were



(1)

observed. Additionally, only 0.7 and 1.1% of **5a** and **5b**, respectively, decomposed to the corresponding compound **3** after 1 hour of incubation in buffer solution at 37 °C. These results demonstrate that conversion of **5** into **3** is a useful reaction for the determination of thiols in aqueous media, through the switching "on" of fluorescence. Also, its hydrolysis at a negligible level is the only expected side reaction in aqueous solution.

Excitation and emission spectra were recorded at several intervals during the reaction of **5** with GSH at 37 °C in HEPES buffer (pH 7.4, see Figure 1). As soon as GSH was added, excitation and emission peaks for **3** appeared in the spectra as a result of its generation from **5**, with rapidly increasing intensity that stabilized 10 minutes after the initial incubation. The rate constants k_{obsd}[16] for reaction of **5a** or **5b** with GSH at pH 7.4 and 37 °C were 1.7×10^2 and $1.4 \times 10^2\ M^{-1}\ s^{-1}$, respectively. Compounds **5** reacted with cysteine (Cys) and $H_2NCH_2CH_2SH$ (AET) with rate constants that were similar to those for GSH, while deprotection of **5** by $HSCH_2CH_2CO_2H$ (MPA) was about ten times slower than that by GSH (Table 1). The rate constant k for the reaction of DTNB with GSH at 25 °C is $3.5 \times 10^4\ M^{-1} s^{-1}$.[17] For comparison the k values of the present probes are included in Table 1 and indicate that compounds **5** react with GSH approximately ten times slower than DTNB. However, this fact was not a disadvantage for determining thiols with **5**. When an assay

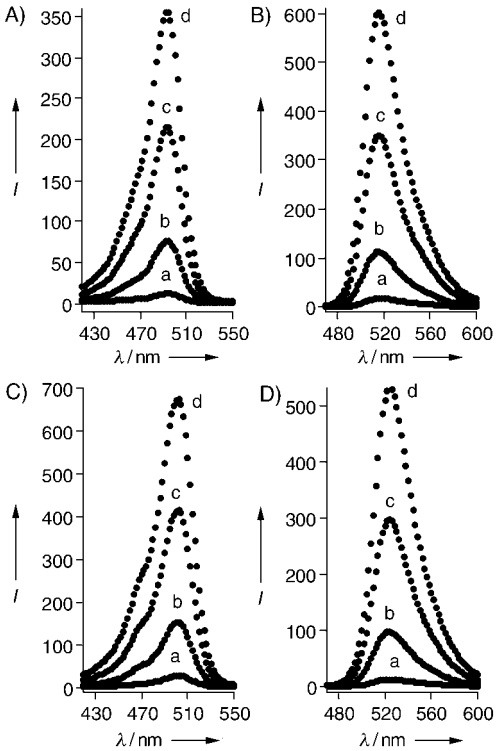


Figure 1. Excitation and emission spectra of **5a** (A, B) and **5b** (C, D) measured at 37 °C at a) $t = 0$, b) $t = 1$, c) $t = 4$, and d) $t = 10$ minutes after addition of GSH (final concentration: 50 μM; $\lambda_{em} = 560$ nm, $\lambda_{ex} = 460$ nm). Final concentrations of solutions of **5** were 25 μM in HEPES buffer (10 mM, pH 7.4, 3 mL) containing 0.5% EtOH.

with **5** was performed for the thiols described in Table 1 in a 96-well microtitre plate, detection limits of less than 2.0 pmol/well were noted for GSH, Cys, and AET, and a linear calibration curve was obtained for each of these thiols up to 1000 pmol/well. Sensitivity, as expressed by the slope of the calibration curves, suggested that **5b** was slightly more sensitive than **5a**.

Dependency of the present fluorometric assay on pH was also examined for the reaction of **5b** with GSH, and **5b** was found to act as a probe down to pH 7.0, although the slope of the calibration curve obtained at pH 7.0 was about one-quarter of that determined at pH 7.4. The fluorescence intensities of **3b** at pH 7.0 and 6.6 (HEPES buffer) were 88 and 74%, respectively, of that measured at pH 7.4. Thus, the lower increase in fluorescence on reaction of **5b** with GSH at pH values lower than 7.4 is ascribed to a decrease in the reactivity of GSH at lower pH values. The observed pH dependency would not militate against application of the present fluorometric assay to thiol-quantification enzyme assays, as assays of various enzymes with DTNB are generally carried out at pH 7.5–8.0.

The results of fluorometric assays using **5** of human erythrocyte AChE and serum BChE with ASCh and butyrylthiocholine (BSCh) as substrates, respectively, are shown in Figure 2. Each of the enzyme reactions was performed in HEPES buffer (pH 7.4) at 37 °C for 10 minutes. Fluorometry with **5b** enabled the determination of AChE and BChE, even at 0.05 and 0.001 mU/well (1 mU of AChE (or BChE) is defined to hydrolyze 1 nmol of ASCh (or BSCh) per minute at pH 7.4 and 37 °C), respectively. The detection limits for these analytes with **5a** were 0.05 and 0.01 mU/well, respectively. Compound **5b** also performed better than **5a** for the ChE assay. Thus, the fluorometric assay with **5b** was applied to determine inhibitory constants (IC_{50}) of some ChE inhibitors. After a mixture of **5b**, ChE, its substrate, and a ChE inhibitor was incubated at 37 °C for 10 minutes, an increase in fluorescence intensity was observed. Inhibition curves were analyzed by a four-parameter logistic regression to afford IC_{50} values. The results are summarized in Table 2, which also includes the constants determined with DTNB. A good correlation was obtained

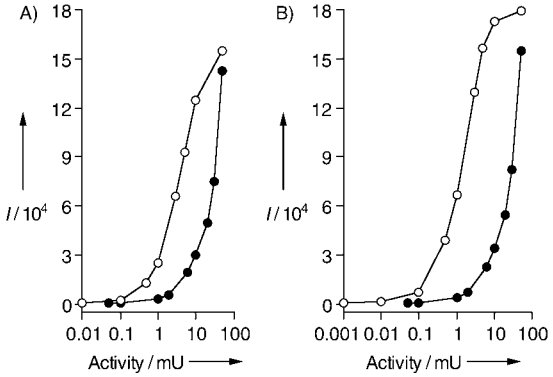

Figure 2. Assays of human erythrocyte AChE (●) and serum BChE (○) in the presence of **5**. Assays were performed after incubating a mixture of the analyte ChE (10 μL), its substrate (ASCh for AChE and BSCh for BChE, respectively; 1.0 mM, 10 μL in H_2O), and either A) **5a** or B) **5b** (25 μM, 170 μL in HEPES (10 mM, pH 7.4) containing 0.5% EtOH) in a 96-well microtitre plate at 37 °C for 10 minutes. The final volume of the reaction mixture was adjusted to 200 μL by addition of H_2O (10 μL). See main text for definition of mU (activity).

Table 1: Characteristics of **5a** and **5b** as fluorescent probes for GSH, Cys, MPA, and AET.[a]

	Thiol	k_{obsd} [$M^{-1}s^{-1}$] for reaction with thiols[b]	Assay	
			Detection limit [pmol]	Sensitivity [au $pmol^{-1}$][c]
5a	GSH	1.7×10^2 (3.9×10^3)	2.0	22.0
	Cys	2.7×10^2 (4.0×10^3)	2.0	27.5
	MPA	1.8×10 (5.0×10^4)	10	2.6
	AET	6.4×10^2 (5.0×10^3)	2.0	27.3
5b	GSH	1.4×10^2 (3.3×10^3)	0.7	31.9
	Cys	2.5×10^2 (3.6×10^3)	2.0	36.3
	MPA	1.5×10 (4.0×10^4)	5.0	3.5
	AET	5.3×10^2 (4.1×10^3)	1.0	31.6

[a] All data were obtained with **5** (final concentration: 25 μM) in HEPES buffer (10 mM, pH 7.4) containing 0.5% EtOH at 37 °C. GSH = glutathione, Cys = cysteine, MPA = 3-mercaptopropanoic acid, AET = 2-aminoethanethiol. [b] The numbers in parentheses are the rate constants k for the reaction of **5** with the corresponding thiolate anion estimated with $k = k_{obsd}(1+10^{pK_a-pH})$, with 8.75, 8.54, 10.84, and 8.23 used as the microscopic pK_a values of sulfhydryl groups in GSH, Cys, MPA, and AET, respectively.[18] [c] au = arbitrary units.

Table 2: Comparison of IC_{50} of ChE inhibitors on human erythrocyte AChE and serum BChE obtained with **5b** and DTNB

Inhibitor	Probe	IC_{50} [nM]		Selectivity for AChE[a]
		AChE	BChE	
donepazil	**5b**	11.8 ± 1.5	5260 ± 290	446
	DTNB[b]	19 ± 7	4100 ± 1800	216
BW284C51	**5b**	58.0 ± 5.4	19800 ± 750	341
	DTNB[c]	18.8	48000	2550
physostigmine	**5b**	142.0 ± 3.9	2090 ± 42	14.7
	DTNB[d]	27.9 ± 2.4	16.0 ± 2.9	0.57
tacrine	**5b**	111.0 ± 5.3	11.5 ± 1.2	0.10
	DTNB[b]	108 ± 7	29 ± 2	0.27

[a] Expressed as IC_{50} for BChE divided by IC_{50} for AChE. [b] See Ref. [2b]. [c] See Ref. [2c]. [d] See Ref. [2d].

between the IC_{50} values afforded by the present method and the DTNB method, except for physostigmine. This is likely a result of not preincubating ChE and each inhibitor before commencing the enzymatic reaction in the present method (all values cited using Ellman's method were estimated after a preincubation step). In fact, physostigmine is known to exhibit strong inhibitory activity against ChE only after preincubation for rather long periods of time.[19]

In conclusion, almost-nonfluorescent compounds **5** are transformed effectively to highly fluorescent **3** through reaction with thiols in aqueous buffer, with significantly shorter reaction times under mild conditions and without any side reactions, except for a low level of their hydrolysis. Thus, compounds **5** may be used as fluorescent probes for thiols and allow a simple and reliable fluorometric system for measuring ChE inhibitory activities to be developed. It is believed that fluorometry with **5** facilitates thiol-quantification assays of various types of enzymes as a high-throughput technique for screening enzyme inhibitors as new drugs. Further studies along these lines are currently underway in our laboratory.

Nanostructures

Deterministic One-to-One Synthesis of Germanium Nanowires and Individual Gold Nanoseed Patterning for Aligned Nanowire Arrays**

*Dunwei Wang, Ryan Tu, Li Zhang, and Hongjie Dai**

Germanium nanowires (GeNWs) have attracted much attention in recent years[1–9] owing to the advanced electrical properties of germanium, such as high carrier mobilities,[10] and the facile chemical synthesis of single-crystal GeNWs at relatively low temperatures (well below 400 °C).[5] Various synthetic methods for crystalline GeNWs that use gold nanoparticles as seeds have been reported and include chemical vapor deposition (CVD),[5,8,9,11] physical vapor deposition (PVD),[2,3] and solvothermal reactions.[1,4] Never-

theless, one-to-one growth (1-1 growth) in which each gold particle seed produces one nanowire[12] and the chemistry needed for such growth is not well-established for GeNWs. To achieve this goal is important for the deterministic synthesis of nanowires with controlled yield, size, growth locations, and orientations.

Here, we demonstrate excellent control over the synthesis of GeNWs by low-temperature CVD. GeNWs have been obtained in 100% yield relative to the gold nanoparticle seeds, and by understanding and optimizing the growth chemistry, we report 1-1 correspondence of GeNWs with gold seeds and that the optimum growth temperature for GeNWs is dependent on the size of the gold nanoparticle. We have also developed a method of patterning individual gold nanoparticles and growing GeNWs in 100% yield from the well-defined nanoparticle arrays. Furthermore, we show that the orientation of the GeNWs grown from the patterned sites can be manipulated by a post-growth flow-aligning treatment to afford quasi-parallel arrays of GeNWs with well-defined spacing.

The synthesis of GeNWs reported herein is based on a previous CVD method[5] with the slight modification that a low-pressure CVD (LPCVD) system (Figure 1a) is used instead of the atmosphere-pressure CVD (APCVD) system used previously. GeNWs were grown at various temperatures in the range of 270–400 °C on substrates decorated with preformed gold nanoparticles (diameter, $d = 5$–50 nm) by using GeH_4 as the precursor for germanium. As shown previously, the growth mechanism is well-described by the vapor–liquid–solid (VLS) model.[5,13,14] A main advantage of synthesis by LPCVD over APCVD is that the concentration of GeH_4 in the CVD system is better controlled by varying the pressure in the system than by diluting GeH_4 with carrier gases. The partial pressure of GeH_4 for optimum growth of GeNWs is between 4–8 Torr, below which the yield of nanowires is low as a result of insufficient feedstock and above which undesirable pyrolysis of GeH_4 is observed. Another important advantage of the LPCVD approach is the rapid removal by vacuum pumping of O_2 and H_2O trapped in the system which efficiently reduces the contaminants in the system and leads to highly reproducible growth results between experiments.

The main outcome of the current work is that the optimum growth condition of GeNWs is size-dependent; that is, the temperature at which optimum 1-1 growth of GeNWs is observed varies with the size of the gold seeds. Under a fixed partial pressure of GeH_4 (p_{GeH4}) of 5 Torr, the optimum growth temperature for gold seeds of diameter $d = 20 \pm 2$ nm is around 295 °C, under which temperature every gold seed can produce a GeNW (Figure 1b and c). The total number of nanowires grown matches the number of starting gold nanoparticle seeds, and the nanowires originate from the positions of the starting particles (Figure 1b). The quantitative yield and 1-1 growth at 295 °C for the 20-nm particles are robust and have been reproduced with ten batches of samples. For larger gold seeds ($d = 50 \pm 3$ nm), the optimum growth temperature for the GeNWs is approximately 310 °C and 1-1 growth was observed (Figure 2b). At a lower temperature of

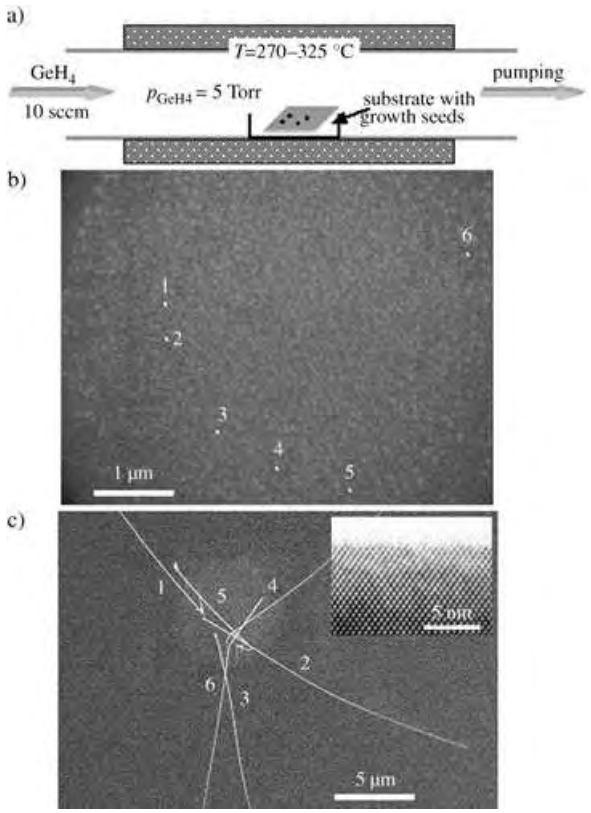

Figure 1. One-to-one growth of 20-nm GeNWs. a) Schematic of the LPCVD setup (sccm = standard cubic centimeters per minute), b) SEM image of six gold nanoparticles ($d \approx 20$ nm) as growth seeds, and c) SEM image of the six GeNWs grown from the gold seeds labeled in (b). (The inset shows a high-resolution transmission electron microscopy image of a single-crystalline GeNW grown under the same conditions as those shown in the main panel).

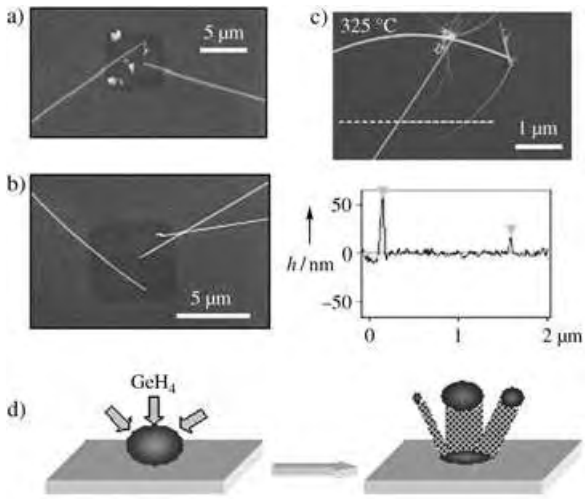

Figure 2. Growth results from 50-nm gold seeds at a) 295, b) 310, and c) 325 °C. Several blotches in (a) correspond to gold particles that have failed to produce nanowires. 1-1 growth is observed in (b) which suggests that the optimum growth of nanowires occurs at 310 °C for 50-nm seeds. The lower panel in (c) is a height (h) profile measured by atomic force microscopy (AFM) of GeNWs grown at 325 °C which shows that smaller ($d \approx 20$ nm) nanowires grow alongside 50-nm GeNWs. d) A schematic of multiple nanowires grown from one large parent particle.

295 °C, not all of the 50-nm gold seeds were capable of producing GeNWs (Figure 2a). On the other hand, if the growth temperature was high (e.g. at 325 °C), the 50-nm gold seeds produced more GeNWs than the number of starting seed particles and, interestingly, nanowires with diameters that are much smaller than the starting particles ($d \approx 50$ nm) were observed (Figure 2c). This observation suggests that splitting of the gold seeds with $d \approx 50$ nm into smaller particles occurred to produce smaller nanowires at the higher growth temperature (Figure 2d).

The optimum growth temperatures of GeNWs by CVD for gold seed particles with diameters in the range of 5 to 50 nm are summarized in Figure 3. A general trend is that

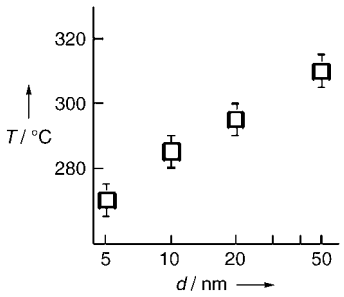

Figure 3. Size-dependent conditions for the growth of nanowires. A plot of the optimum temperature (T) for growth of the GeNW as a function of the size of the gold particle seeds, and hence the size of the nanowire, by CVD under a fixed partial pressure of 5 Torr of germane. For each particle size, the optimum growth temperature is denoted by a hollow square and the error bars span less than 10 °C.

smaller gold seeds can nucleate and grow nanowires at lower temperatures. For large particles ($d \approx 50$ nm) a low growth temperature produces GeNWs in low yields, and too high a temperature tends to overproduce wires as a result of splitting of gold seeds. These results can be explained by considering several key factors involved in the VLS growth process. The first factor is that the eutectic melting temperature of Ge–Au is size-dependent and higher for larger particles. Such size-dependence of the melting temperature has been documented for single- and binary-element particles.[15,16] It is therefore reasonable that larger particles require a higher temperature for efficient supersaturation and growth to occur. Second, diffusion of germanium in the gold particle is an important kinetic factor of the VLS growth process. The size of the gold seeds determines the length over which germanium must diffuse to saturate the Ge/Au solution for nucleation and growth of one nanowire from the seed particle. Higher temperatures will facilitate diffusion of germanium and thus the growth of nanowires from larger particles. The third factor is the feedstock supply of germanium. Higher temperatures will lead to more-efficient decomposition of the GeH_4 precursor and provide an efficient supply of germanium needed for larger gold particles.

The VLS growth of nanowires from large gold seed particles appears to be diffusion-limited. At high temperatures, the feeding of germanium precursor could be rapid while the diffusion of the feedstock atoms in gold may not be sufficiently high to supersaturate a large particle. Rather, smaller regions of the gold cluster are supersaturated rapidly, which leads to nucleation and growth of smaller nanowires from the parent gold particle (Figure 2d). In a control experiment, we attempted to grow germanium and silicon nanowires from GeH_4 and SiH_4, respectively, by using ultra-large gold particles with $d \approx 250$ nm. At all of the temperatures tested, we were unable to observe 1-1 growth from these large particles and always observed the growth of only small wires as a result of splitting of the gold particles. We believe that the diffusion limitation for the growth of large nanowires and the size-dependent growth of nanowires is general to the synthesis of various nanowire materials by the VLS mechanism.

With the 1-1 growth understood, we next pursued patterning of individual gold nanoparticles to achieve 1-1 growth of GeNWs at controlled locations and with monodispersed sizes by first using electron-beam lithography to pattern arrays of small gold islands on a substrate (Figure 4a).

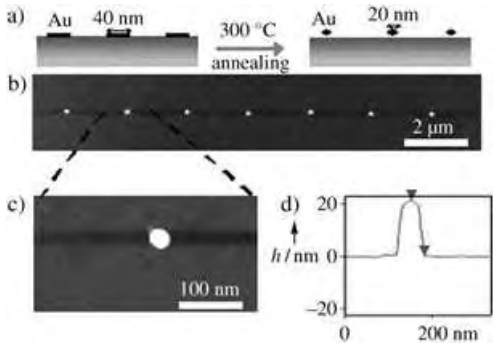

Figure 4. Patterning of individual gold nanoparticles. a) Schematic of the patterning process, b) AFM image of an array of Au dots regularly spaced at 2 μm, c) magnified AFM image of one gold nanoparticle, and d) height profile that shows the size of the gold nanoparticle ($h \approx 20$ nm) in (c).

The islands were 40-nm wide with various thicknesses (1–10 nm) and were formed by an evaporation and lift-off technique. Upon annealing at 300 °C, Au atoms in each island aggregated to form well-defined gold dots with controllable diameters in the range of 5–50 nm (the size of the dot is dependent on the thickness of the metal in the 40-nm-wide islands). Figure 4b shows an array of regularly spaced gold particles with $d \approx 20 \pm 3$ nm formed by this method. CVD growth using the optimum conditions identified in Figure 3 for 20-nm gold seeds led to successful 1-1 growth of GeNWs from the nanoparticle arrays (Figure 5). This result demonstrates that the synthesis of nanowires can be well-controlled at the single-particle level by making use of the understanding of the growth of nanowires as well as the state-of-the-art lithographic patterning technique.

We also explored the possibility to control the orientations of the GeNWs in an approach that utilized fluid flow[17,18] to manipulate and reorient the GeNWs grown from the patterned gold particle arrays, as shown schematically in Figure 5a. In the VLS tip-growth process, one of the ends of an as-grown GeNW is anchored onto the substrate at the point from which it grows, as highlighted by arrows in

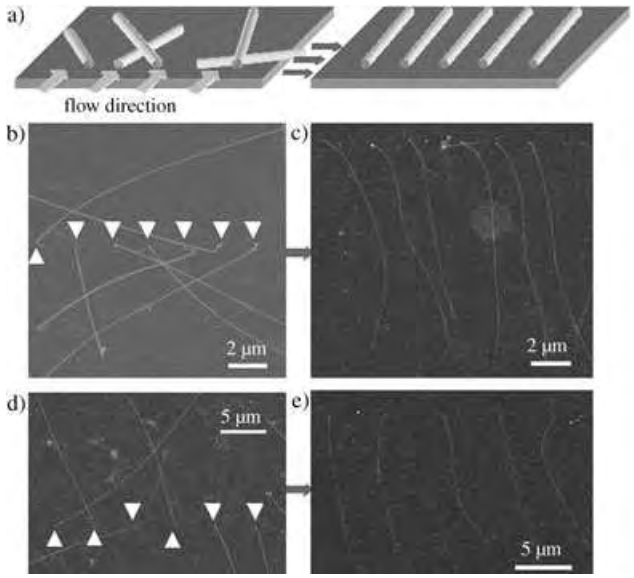

Figure 5. Post-growth reorientation of nanowires. a) Schematic of the process to flow-align GeNWs grown from an array of patterned gold seeds, b) SEM image of GeNWs grown from an array of 20-nm Au dots similar to those in Figure 4b (the arrows indicate the original positions of the Au dots and the fixed ends of the as-grown GeNWs), c) SEM image of quasi-aligned GeNWs (2-μm pitch) after flow treatment of the sample in (b), and d) and e) SEM images of GeNWs grown in a one-to-one manner from patterned Au dots (5-μm pitch) before (d) and after (e) flow-alignment.

Figure 5b and d, and acts as a pivotal point for the wire. After a stream of deionized water is flowed across the substrate surface, the nanowires are reoriented towards the flow direction and become quasi-aligned while maintaining the same spacing between their pivoted ends (Figure 5c and e).

In summary, we have demonstrated controlled one-to-one synthesis of GeNWs in near-quantitative yields from gold seed particles. Size-dependent optimum growth conditions for the GeNW have been identified. For gold seeds with diameters of less than 50 nm, underproduction, 1-1 growth, and overproduction can occur depending on the conditions. Growth of large GeNWs appears to be diffusion-limited. These results have generic implications in the synthesis of other types of nanowires through the VLS mechanism. Patterning and positioning of individual gold nanoparticles was observed by lithographic patterning and used for successful one-to-one nanowire growth. Finally, post-growth flow-alignment was used to obtain quasi-parallel nanowires that originate from well-controlled locations. These results are important to the fundamental synthesis of nanomaterials and may find important applications in various fields including high-performance nanoelectronics.

Experimental Section

Deposition of preformed gold nanoparticles: A silicon substrate was soaked in an aqueous solution of 3-aminopropyltriethylsilane (APTES; 12 μL APTES in 20 mL H_2O) for 2 minutes. After thorough rinsing with deionized H_2O and blow-drying with N_2, the substrate was then soaked in a solution of Au colloids (5–50 nm) for 5 minutes. The resulting density of Au particles on the substrate was determined by the concentration of the colloidal solution. For instance, a prepared solution of 20-nm Au colloids (Ted Pella, Inc., CA, USA) contains 10^{11} nanoparticles mL^{-1}. Dilution by 1000 was performed to obtain a concentration of 10^8 cm^{-3}. When deposited on a silicon substrate, a density of approximately 1 particle/3 μm^2 could be reliably obtained with such a concentration. After deposition of Au nanoparticles, calcination in air at 300 °C for 15 minutes was carried out to remove organic residues. The as-prepared substrate was imaged by scanning electron microscopy (SEM, FEI XL30 Sirion) to record the locations of individual nanoparticles in certain regions. Then, the substrate was subjected to CVD growth followed by SEM imaging of the same regions to correlate the synthesized nanowires with their parent nanoparticle seeds.

CVD synthesis of GeNWs: In a typical experiment, the CVD quartz tube chamber (2.54 cm) was first evacuated to its base pressure of 150 mTorr and then heated up to a growth temperature in the range of 270–325 °C. The chamber was then filled with precursor species of GeH_4 (germane, 10% in He, Voltaix Inc. NJ, USA) to the desired growth pressure (total pressure $\approx$ 50 Torr, $p_{GeH4} \approx 5$ Torr) and maintained at that pressure throughout the growth. During this process, GeH_4 was flowed at a rate of 10 sccm (standard cubic centimeters per minute). At the end of the reaction, the feeding of GeH_4 was stopped and the chamber was pumped to its base pressure again and cooled down to room temperature. (One of the criteria of optimum growth is that the quartz growth chamber after CVD should be free of pyrolytic deposits of GeH_4).

Patterning of individual gold nanoparticles: A 100-nm-thick film of polymethylmethacrylate (PMMA) was formed by spin-coating onto a Si substrate. Electron beam lithography (Raith 150) was used to create wells in the PMMA film with dimensions of 40×40 nm^2. A Au film of 1–10 nm thickness was then deposited onto the PMMA-patterned substrate in an electron-beam evaporator, followed by lift-off of the PMMA to afford 40-nm-wide Au islands. The substrate was then annealed in Ar at 300 °C for 15 minutes during which time the small Au islands aggregated to form single Au nanoparticles.

Manipulating the orientations of nanowires after one-to-one growth: After CVD growth of GeNWs on a substrate with patterned Au dots, a droplet of H_2O was placed onto the substrate to cover the as-grown GeNWs. N_2 was then flowed to blow-dry the surface along a desired direction. After this simple process, the nanowires were quasi-aligned with the flow direction.

Dihalomethane Structures

A Dramatic Spin–Orbit Effect Observed in the Vibrational Frequencies of the Chloroiodomethane Cation**

*Mina Lee, Hyoseok Kim, Yoon Sup Lee, and Myung Soo Kim**

Several theoretical studies have suggested that a spin–orbit-induced isomer may be found for a molecule of the as-yet-unknow superheavy element 118, that is, $(118)F_4$,[1] but there have been no reports of an experimentally observed molecule for which the inclusion of spin–orbit effects is essential for the correct identification of the ground state structure. We report here a molecular ion, $[CH_2ClI]^+$, for which spin–orbit interactions are crucial for the identification of the structure and vibrational frequencies of the correct ground state. Theoretically, the spin–orbit interaction is part of the relativistic effect. The importance of relativity for the description of heavy atoms is well recognized.[2] Scalar relativistic effects are routinely included in electronic-structure calculations of molecules containing heavy elements through the use of relativistic effective core potentials (RECP), but spin–orbit interactions are usually omitted when deriving optimized structures partly because of the assumption that their influence on the molecular structures is negligible and partly due to computational difficulties. Even when spin–orbit terms are available in RECPs, the usual treatment involves perturbational inclusion of these terms after the variational determination of orbitals and structures. Quantum chemical calculations employing RECPs and spin–orbit operators from the start have been available for some time.[3] The spin–orbit density functional theory (DFT) method available in NWChem is particularly useful for the present purpose of demonstrating spin–orbit effects on geometries since the geometry can be optimized with both electron correlations and spin–orbit interactions included.[4]

We have been investigating the reactivity of mixed dihalomethane cations for some time. Hence, we have recorded the vibrational spectra of the cations by mass-analyzed threshold ionization (MATI) spectrometry.[5] Figure 1 shows the MATI spectrum of CH_2ClI recorded by monitoring $[CH_2{}^{35}ClI]^+$ in the electronic ground state. The most intense peak at around 78644 cm^{-1} corresponds to the 0–0 band. The distance of each peak from the 0–0 band in this spectrum corresponds to the vibrational frequency of the cation. CH_2ClI has nine nondegenerate normal modes: modes 1–6, with a' symmetry, and modes 7–9, with a'' symmetry. All the fundamentals and overtones of the totally symmetric modes, a', are dipole-allowed, while only the even-numbered overtones of the a'' modes are allowed. Utilizing the selection rule and the frequencies in the neutral species,[6] plausible assignments can be made for the prominent peaks; these are listed in Table 1. Modes 2 and 3 are due to CH_2 motion, modes 4 and 5 are C–Cl and C–I stretchings, respectively, and mode 6 is I–C–Cl bending. Other peaks in the spectrum are due to overtones and combinations.

Our normal routine is to perform quantum chemical calculations for the vibrational frequencies, isotope shifts, and Franck–Condon factors to confirm, improve, or revise the phenomenological assignments. In particular, results from the DFT/B3LYP calculations have been found to be adequate in most cases.[5] When we performed DFT/B3LYP calculations for $[CH_2ClI]^+$ with Gaussian 98, using a well-known RECP for iodine such as LanL2DZ,[7] we always obtained two distinct stationary states, $^2A'$ and $^2A''$, formed by removal of an electron from in-plane and out-of-plane iodine nonbonding orbitals, respectively. Even though their energies are nearly the same, their geometries are noticeably different because of the partial antibonding characteristics contained in essentially iodine nonbonding orbitals. The vibrational frequencies in the two states are also noticeably different, suggesting that the observed spectrum would be a superposition of two spectra.

The fact that a rather straightforward phenomenological assignment of the MATI spectrum was possible is not compatible with the calculated results. Moreover, the experimental frequencies could not be correlated with the calculated results with the accuracy expected for the DFT/B3LYP results (± 15 cm^{-1}). We thought that neglecting the spin–orbit effect could be one possible cause of this discrepancy, and we therefore performed the spin–orbit DFT calculations implemented in NWChem for neutral and cationic CH_2ClI in the electronic ground states using RECPs with the effective spin–

[a] Calculated at the B3LYP level using the RECP of ref. [8] for halogen atoms and aug-cc-pVTZ for other atoms. The spin–orbit term in the same reference was used when needed. [b] Mulliken notation. [c] Raman spectroscopic data taken from ref. [6].

orbit potentials reported in ref. [8] for the halogen atoms. The size of the basis set was increased until the basis-set dependence of the vibrational frequencies became less than 15 cm^{-1}. To determine the importance of the spin–orbit terms, all the calculations were done with and without the spin–orbit potential but with the same RECP. The calculated equilibrium geometries of the neutral species and the cation have C_s symmetry. The optimized geometry of the neutral species is hardly affected by the spin–orbit terms (Table 2). For the cation, however, only one equilibrium geometry was obtained with the spin–orbit terms, instead of the two found in their absence. For the double group symmetry of the fine structure state in the presence of spin–orbit terms, both the ground and lowest excited states of the cation have the same symmetry. Unlike the DFT calculations without the spin–orbit terms, the spin–orbit DFT calculations did not locate the second state as the lowest fine-structure state. The second state is well separated, by about 4000 cm^{-1}, from the ground state.[9]

The most striking influence of the spin–orbit terms on the cation geometry (Table 2) is observed for the I–C–Cl bond angle. With the aug-cc-pVTZ basis set, these are 96.1° and 116.1° for $^2A'$ and $^2A''$, respectively, in the absence of the spin–orbit terms, and 106.0° in their presence. The trend observed in the vibrational frequencies (Table 1) is similar. The influence of the spin–orbit terms on the vibrational frequencies of the neutral is not significant, and the results are compatible with the experimental data. In the case of the cation, however, the two sets of frequencies calculated without the spin–orbit terms could not be correlated with the experimental data. The single set of vibrational frequencies obtained with the spin-obit terms, however, agrees well with the experimental data. For example, the I–C–Cl bending, mode 6, has the frequencies 163 and 180 cm^{-1} in $^2A'$ and $^2A''$, respectively, in the absence of the spin–orbit terms and 112 cm^{-1} in their presence; the experimental frequency is 114 cm^{-1}.

To the best of our knowledge, this is the first time that a dramatic spin–orbit effect has been observed for the vibrational frequencies and the shape of the ground state of a polyatomic molecule. The presence of an iodine atom is certainly a factor responsible for the above observation. Also important is the fact that two nearly degenerate electronic states with different geometries are present for the radical

Table 2: Bond length [Å] and angles [°] of CH_2ClI and $[CH_2ClI]^+$ in the electronic ground state without (w/o) and with (w) the spin–orbit effect.[a]

C_s	CH_2ClI			$[CH_2ClI]^+$		
		w/o S.O.	w S.O.	w/o S.O.[c]		w S.O.[d]

[a] Calculated under the same conditions as in Table 1. [b] Microwave spectroscopic data taken from ref. [10]. [c] Two distinct stationary geometries with nearly the same energy appear in the absence of the spin–orbit term. [d] Only one stationary geometry is obtained in the presence of the spin–orbit term.

cation in the absence of the spin–orbit effect. The spin–orbit interactions lift this accidental orbital degeneracy by mixing two states strongly in the region connecting two minima.

The lack of experimental data displaying noticeable spin–orbit effects has been one of the justifications for ignoring its computational treatment even for molecules with quite heavy elements. The present results suggest that spin–orbit terms should be treated the same as other relativistic effects in some cases, and demonstrate unequivocally that accounting for the relativistic effect can be critical for the studies of radicals with heavy atoms. Also to be noted is that the calculated frequencies do not match the experimental results as well as in other systems reported previously,[3b] even when the spin–orbit terms are included, which implies that further refinement and improvement are desirable for the treatment of relativistic effects in open-shell systems. The present data provide a useful benchmark in the computational treatment of the relativistic effect. Preliminary studies indicate that the spin–orbit effect is important for other cations with an iodine atom.

Experimental Section

The vacuum ultraviolet (VUV) radiation generated by four-wave mixing in Kr was overlapped with the CH_2ClI molecular beam to excite the neutral species to their Rydberg states. These were ionized by an electric field pulse applied after a time delay. Measuring the molecular ion current as a function of the VUV wavelength gives the MATI spectrum, which is essentially a vibrational spectrum of the molecular cation.

Single-Molecule Magnets

Quantum Tunneling of Magnetization in Lanthanide Single-Molecule Magnets: Bis(phthalocyaninato)terbium and Bis(phthalocyaninato)dysprosium Anions**

Naoto Ishikawa, Miki Sugita, and Wolfgang Wernsdorfer**

Single-molecule magnets (SMMs) are the class of high-spin molecules that exhibit magnetization hysteresis at low temperature, that is, the property of macroscopic magnets.[1–5] Most SMMs are composed of several transition-metal ions, whose spins are coupled by strong exchange interactions to give a large effective spin with a predominant uniaxial anisotropy. The quantum nature of SMMs is manifested by staircase hysteresis loops,[5,6] temperature-independent relaxation,[7–12] and quantum phase interference.[13] The discovery of these phenomena led to potential applications in quantum computing.[14]

The finding of slow magnetization relaxation in lanthanide complexes has opened the possibility of constructing

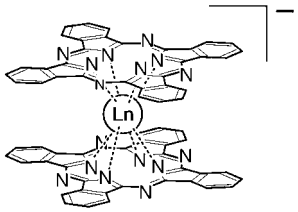
SMMs containing only a single metal ion as a magnetic center.[15] Alternating current (ac) magnetic susceptibility measurements have been reported for the bis(phthalocyaninato)terbium anion $[Pc_2Tb]^-$ (Pc = dianion of phthalocyanine) and an isostructural dysprosium complex $[Pc_2Dy]^-$ above 2 K.[15,16] One of the important results was that slow



magnetization relaxation was observed in temperature ranges that were significantly higher than those of previously known transition-metal SMMs. For example, the peak positions in the χ'' versus T plot (χ_M'' refers to the out-of-phase component of ac susceptibility) of the Tb and Dy complexes are at 40 and 10 K, respectively, for a 1-kHz ac frequency.[15,16] The Arrhenius analysis showed that the dominant relaxation path in the high-temperature range, above 25 K for $[Pc_2Tb]^-$ and 3 K for $[Pc_2Dy]^-$, is a thermally activated Orbach process that involves excited substates in the ground multiplet.[16] Hysteresis loops were measured at 1.7 K; however, no clear evidence of quantum tunneling was observed because of instrumental limitations.[16]

Herein, we report magnetic hysteresis measurements for these lanthanide single-ion SMMs in the subkelvin temperature range. Clear evidence of quantum tunneling of magnetization (QTM) is presented for the first time. We found that the quantum process in these single-ion SMMs is a result of the resonant quantum tunneling between entangled states of electron and nuclear spin systems, which was first reported for the scheelite-structured compound $LiYF_4$ doped with trivalent Ho ions.[17]

The compounds were prepared as reported in the literature[18,19] with certain modifications.[20] The doped single-crystalline samples were prepared by recrystallization from a mixed solution of TBA[Pc_2Ln] (TBA = tetrabutylammonium) and TBA[Pc_2Y] with a [Ln]/[Y] ratio of 1:49 in acetone. All measurements were performed using the micro-SQUID technique (SQUID is a superconducting quantum interference device).[21] The field was aligned parallel to the easy axis of magnetization by the transverse field method.[22]

Figure 1 shows magnetization versus field measurements for the diluted sample of the $[Pc_2Tb]^-$ ions at 0.04 K and several field scan rates. These hysteresis loops present a clear staircase-like structure, which indicates the occurrence of QTM. Such measurements were also performed on less-diluted and undiluted TBA[Pc_2Tb] samples, and revealed similar features that were, however, significantly broadened because of magnetic dipolar interactions among adjacent molecules. Notably, the figure shows no clear step at $\mu_0 H = 0$ T.

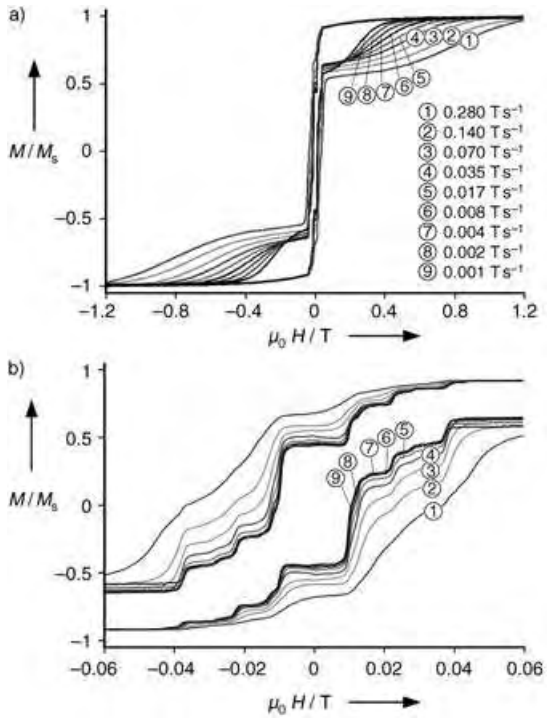


Figure 1. a) Hysteresis loops at 0.04 K for a single crystal of TBA[$(Pc)_2Tb_{0.02}Y_{0.98}$] measured at several field scan rates. The applied magnetic field was aligned along the easy axis of magnetization. b) Enlargement of the hysteresis loops in (a).

In known transition-metal-cluster SMMs, where energy separations between substates with different $|S_z|$ values are of the order of 1–10 cm^{-1}, QTM occurs when energy levels of two substates coincide under an appropriate magnetic field and the states are brought to resonance. In the lanthanide single-ion SMM $[Pc_2Tb]^-$, such level crossings occur only at very high fields because the substates are separated by a few hundred cm^{-1}.[20,23,24] This situation is illustrated in Figure 2a, which shows a Zeeman diagram for the $J = 6$ ground multiplet

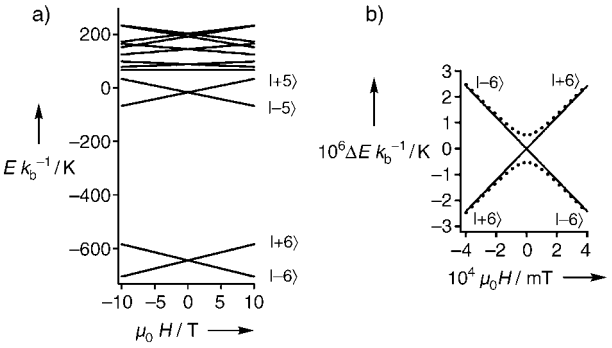

Figure 2. a) Zeeman energy diagrams as a function of longitudinal magnetic field for the $J = 6$ ground multiplet with the ligand-field parameters determined for TBA[Pc_2Tb] in a previous work:[20] $A_2^0\langle r^2\rangle = 414\ cm^{-1}$, $A_4^0\langle r^4\rangle = -228\ cm^{-1}$, and $A_6^0\langle r^6\rangle = 33\ cm^{-1}$. b) Enlargement of the region around the intersection between the lowest substates. The dotted lines are obtained with an additional $A_4^4\langle r^4\rangle O_4^4$ ligand-field term with $A_4^4\langle r^4\rangle = 10\ cm^{-1}$. The plot shows a tunnel splitting of 1.05×10^{-6} K.

of TBA[Pc_2Tb] obtained by using the ligand-field (LF) parameters previously determined.[20]

Figure 2b shows the enlargement of the area around zero field for the lowest $J_z = \pm 6$ substates. Under the assumption that all off-diagonal matrix elements of the LF Hamiltonian are negligible,[20] no mixing occurs among the two sublevels at $\mu_0 H = 0$ T (solid lines). In the case of C_4 symmetry, the LF terms $A_4^4\langle r^4\rangle O_4^4$ and $A_6^4\langle r^6\rangle O_6^4$, which comprise the off-diagonal elements that couple $|J_z\rangle$ and $|J_z-4\rangle$ states, can take nonzero values.[25] The plots with dotted lines in the Zeeman diagram are calculated with a small nonzero $A_4^4\langle r^4\rangle$ value. This result illustrates that the $J_z = \pm 6$ substates are brought to resonance at $\mu_0 H = 0$ T, thus giving rise to an "avoided level crossing" which allows QTM to occur.

This picture itself, however, provides only an insufficient explanation for the step structures observed at nonzero magnetic fields. Terbium has a nucleus with $I = 3/2$ spin in a natural abundance of 100%. It is therefore necessary to take into account the interaction between the $(4f)^8$ system and the nucleus. Exact numerical diagonalization of a $[(2J+1)(2I+1) \times (2J+1)(2I+1)]$ matrix, which includes the above ligand-field parameters, the hyperfine interaction $A_{hf}\boldsymbol{JI}$, and the nuclear quadrupole interaction term $P\{I_z^2 - 1/3\, I(I+1)\}$, was performed. Figure 3 shows the Zeeman diagram for the eight $|J_z\rangle\,|I_z\rangle$ states created from the combinations of the $J_z = \pm 6$ doublets and $I = 3/2$ quartets. The level intersections are seen at 13 magnetic-field positions. All step positions observed in Figure 1 are reproduced by using $A_{hf} = 0.0173\ cm^{-1}$ and $P = 0.010\ cm^{-1}$. The four largest avoided level crossings are indicated. An important conclusion drawn from this numerical study is that the inclusion of the nuclear quadrupole term is mandatory to explain the seemingly irregularly arranged staircase structures in the hysteresis loops of $[Pc_2Tb]^-$. The hyperfine interaction term alone cannot account for all the steps observed. This finding is in sharp contrast to the situation for Ho ions in a $LiYF_4$ matrix where equidistantly positioned steps were observed which have been fully explained by the hyperfine interaction alone.[17]

Figure 4 shows hysteresis loops for the $[Pc_2Dy]^-$ complex at 0.04 K with varied field scan rates. A steep drop in magnetization is observed near zero field, unlike the in the Tb case. Apart from this zero-field step, only slight indications of steps can be seen at about $\mu_0 H = 7$ and 14 mT. Small remanent magnetization is present at low sweep rates.

The situation for the Dy complex is more complicated than that for the Tb complex. There are seven naturally occurring isotopes of Dy, namely, ^{156}Dy, ^{158}Dy, ^{160}Dy, ^{161}Dy, ^{162}Dy, ^{163}Dy, and ^{164}Dy, with a natural abundance of 0.06, 0.01, 2.34, 18.91, 25.51, 24.90, and 28.18%, respectively. ^{161}Dy and ^{163}Dy have a nuclear spin of $I = 5/2$ while other nuclear species have $I = 0$.

In the cases of $I = 0$, there is only one level crossing at $\mu_0 H = 0$ T. However, no tunneling should occur because of the Kramers theorem of spin parity. This theorem asserts that no matter how unsymmetric the crystal field, an ion possessing an odd number of electrons (that is, a half-integer spin system) must have a ground state that is at least doubly degenerate (that is, no tunnel splitting), even in the presence

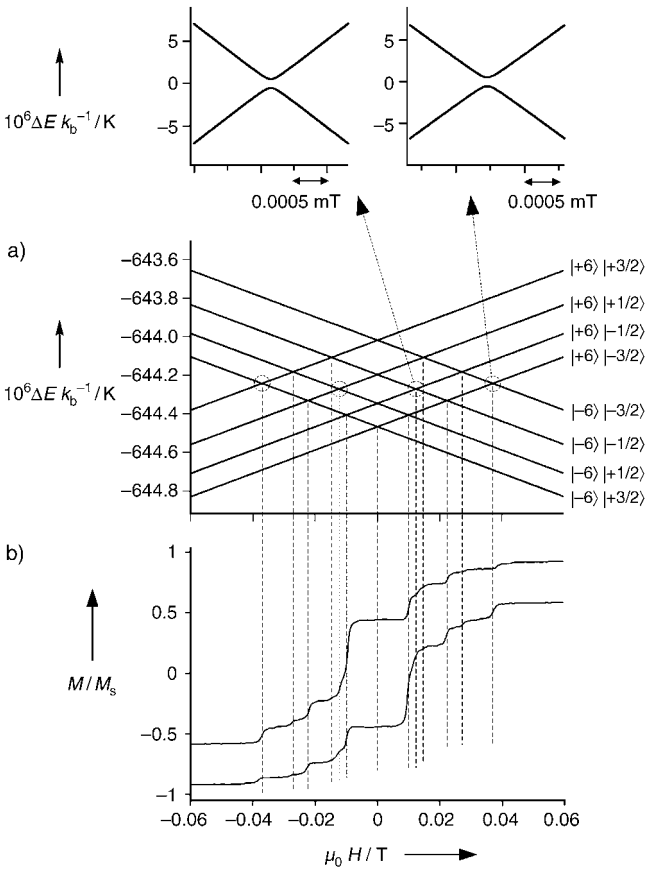

Figure 3. a) Zeeman diagrams for the lowest $J_z = \pm 6$ substates combined with the $I = 3/2$ nucleus state calculated with the LF parameters used in Figure 2b, $A_{hf} = 0.0173\ cm^{-1}$ for the hyperfine interaction term, and $P = 0.010\ cm^{-1}$ for the nuclear quadrupole interaction term. The circles indicate the positions where avoided level crossing occurs. b) Hysteresis loop at 0.04 K for a single crystal of TBA[$(Pc)_2Tb_{0.02}Y_{0.98}$] measured at 0.001 Ts^{-1}.

of crystal fields and spin–orbit interactions.[26] Hence, the Dy complexes with $I = 0$ should not contribute to the step structure. However, the Dy complexes with a nuclear spin $I = 5/2$ have avoided level crossings because two coupled half-integer spins ($J = 13/2$ and $I = 5/2$) lead to an integer total spin. Figure 5 shows the Zeeman diagram for the lowest sublevels calculated for the $I = 5/2$ case, with the same value for $A_4^4\langle r^4\rangle$ as in the above Tb case and the LF parameters determined previously.[20] Five avoided level crossings are seen. The hyperfine constant A_{hf} was assumed to be $0.0042\ cm^{-1}$, so that the avoided level crossings coincide with the positions indicated by the broken lines in Figure 4. A major difference from the Tb case concerns the tunnel splitting: the gaps are smaller by two orders of magnitude. This may be the reason why in the Dy case no clear step structures are observed at $\mu_0 H \neq 0$ T. Generally, a greatly reduced gap leads to significantly smaller tunneling probability according to the Landau–Zener model.[27]

In conclusion, we have shown the occurrence of QTM in the first lanthanide SMMs, $[Pc_2Tb]^-$ and $[Pc_2Dy]^-$ ions, by hysteresis loop measurements of doped single crystals in the subkelvin temperature range. There is a fundamental differ-

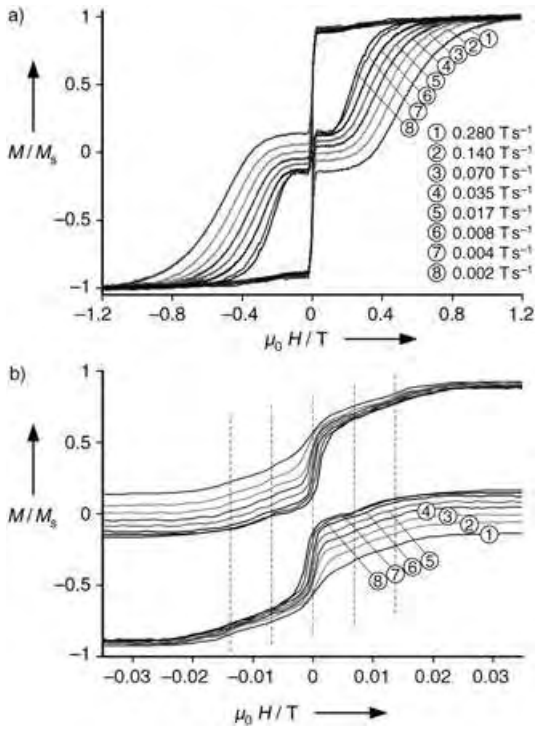

Figure 4. a) Hysteresis loops at 0.04 K for a single-crystalline sample of TBA[$(Pc)_2Dy_{0.02}Y_{0.98}$] measured at several field scan rates. The applied magnetic field was aligned along the easy axis of magnetization. b) Enlargement of the hysteresis loops in (a). The broken lines indicate the expected quantum resonances.

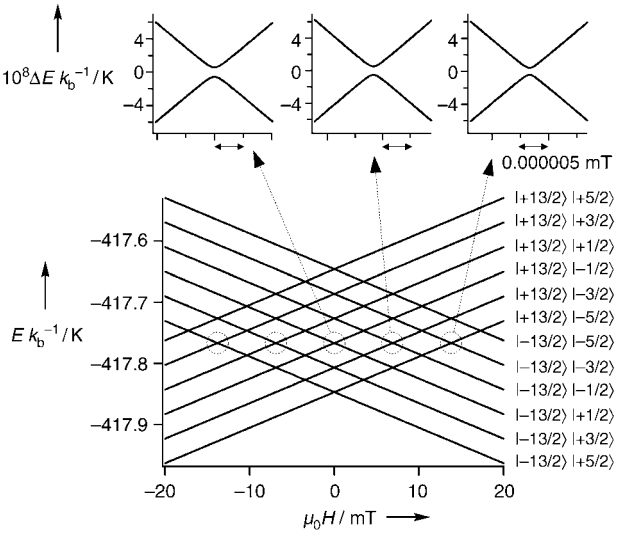

Figure 5. Energy as a function of the longitudinal magnetic field for the lowest $J_z = \pm 13/2$ substates combined with the $I = 5/2$ nucleus state calculated with the LF parameters previously determined[20] and $A_4^4\langle r^4\rangle = 10\ cm^{-1}$. The hyperfine constant is assumed to be $A_{hf} = 0.0042\ cm^{-1}$. The circles indicate the positions where avoided level crossing occurs.

ence in the mechanism of QTM between the lanthanide SMMs and the previously known transition-metal-cluster SMMs. The latter mechanism exhibits QTM between different substates $|S_z|$, whereas the former manifests QTM between the entangled states $|J_z\rangle|I_z\rangle$ of the electron and nuclear spin system.[17] The Tb complex with $J_z = \pm 6$ ground doublet and $I = 3/2$ nuclear spin gives avoided level crossings at the intersection of $|6\rangle|I_z'\rangle$ and $|-6\rangle|I_z\rangle$. In the Dy case, only ^{161}Dy and ^{163}Dy complexes, with a nonzero nuclear spin of $I = 5/2$, can exhibit avoided level crossings at the intersection of $|13/2\rangle|I_z\rangle$ and $|-13/2\rangle|I_z'\rangle$.

NMR spectroscopy

High-Resolution NMR Spectroscopy in Solids by Truly Magic-Angle Spinning**

*Sasa Antonijevic and Geoffrey Bodenhausen**

There is an ever increasing interest in obtaining high-resolution NMR spectra of $S = 1/2$ nuclei, such as ^{13}C, in solids. Solid-state NMR spectroscopy is important for material science, for (bio)organic chemistry, for protein structure determination,[1–3] and for the characterization of pharmaceutical products (e.g., crystalline polymorphism).[4] The combination of magic-angle spinning (MAS) with heteronuclear dipolar decoupling leads to line narrowing, and hence to an improvement of both resolution and sensitivity (peak-height-to-noise ratio). Herein, we show that the line width of ^{13}C resonances can be narrowed to 0.039 ppm (3.9 Hz for ^{13}C at 100.6 MHz or 9.4 T). Such a narrow resonance is observed for carbonyl carbon atoms of polycrystalline cholesteryl acetate if the magic angle ($\theta_m = \arccos 3^{-1/2} \approx 54.736°$) is adjusted very accurately, that is, within $|\Delta\theta| = |\theta - \theta_m| = 0.004°$, as commonly done for satellite-transition magic-angle spinning (STMAS) NMR spectroscopy of quadrupolar nuclei.[5,6] The lower limit of the line width (which is inversely proportional to the effective spin-echo decay time constant T_2') can be as little as 0.09 Hz for carbonyl carbon atoms in choresteryl acetate. We also demonstrate by ^{207}Pb NMR spectroscopy that temperature gradients across the sample (which lead to a distribution of isotropic chemical shifts) can provide an important contribution to the line width, in addition to imperfect decoupling,[7] structural disorder,[8] and magnetic susceptibility effects.[8–10]

A common way to adjust the magic angle is to optimize the envelope of ^{79}Br rotational echoes in KBr. Herein we suggest a procedure that is more sensitive, and involves two steps: First, the angle can be adjusted to an accuracy of $|\Delta\theta| < 0.01°$ ($\Delta\theta$ = deviation from the magic angle) by minimizing the residual ^2H quadrupolar splitting in a rotor-synchronized MAS spectrum of a deuterated sample, such as $[D_6]\alpha$-oxalic acid dihydrate. The residual splitting (Figure 1) allows the angle θ to be determined if it is miss-set by more than $|\Delta\theta| = 0.01°$. A fine adjustment to an accuracy $|\Delta\theta| < 0.004°$ can be achieved by maximizing the height of the $ST_1 \rightarrow CT$ shifted-echo signal in a one-dimensional ^{87}Rb STMAS spectrum of $RbNO_3$.[6]

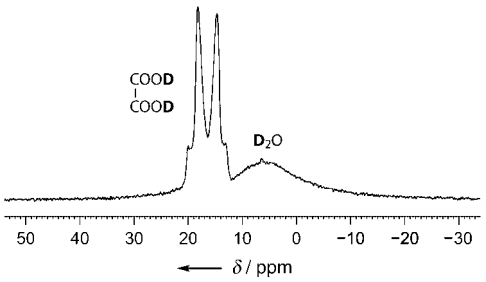

Figure 1. Rotor-synchronized ^2H MAS spectrum (spinning speed $\nu_R = 20$ kHz) of $[D_6]\alpha$-oxalic acid dihydrate. The broad hump to the right stems from motionally averaged water deuterons.[11] The residual quadrupolar powder pattern to the left, which stems from the carboxyl deuterons, allows the deviation from the magic angle to be estimate as $\Delta\theta = -0.036$.

Samples packed in 2.5 mm outer diameter ZrO_2 rotors were spun at 30 kHz (unless otherwise stated) in a standard Bruker triple resonance CPMAS probe in a 9.4 T widebore magnet of an Avance 400 spectrometer. The static field homogeneity was shimmed for ^{13}C line widths in adamantane $\Delta\nu = 3$ Hz (full width at half-height). Cross-polarization (CP) was used with a proton radio-frequency (RF) amplitude of 85 kHz. Two-pulse phase modulation (TPPM) proton decoupling was used during signal acquisition with 100 kHz RF amplitude, pulse-widths of 3.9 μs, and a phase difference between two successive pulses of 35°. Amino acids (Cambridge Isotope Laboratories), and cholesteryl acetate (Fluka) were used without further purification or recrystallization.

Figure 2a shows the ^{13}C CPMAS spectrum of cholesteryl acetate recorded at the magic angle. The line widths $\Delta\nu = 1/(\pi T_2^*)$ (full width at half-height) of the ^{13}C resonances range from 3.9 Hz for the carbonyl carbon to 12.6 Hz for some protonated carbons atoms (Table 1), and are even narrower than previously reported.[12] The width $\Delta\nu = 3.9$ Hz (only 0.9 Hz more than the line width of the plastic crystalline adamantane) is, to our knowledge, the narrowest ^{13}C resonance reported for polycrystalline solids. Intentional deviations from the magic angle $\Delta\theta = 0.134°$ and 0.234° (Figure 2b, c) lead to an increase in the line widths. Not all resonances are broadened to the same extent. The carbonyl signals enlarged in Figure 3 feature residual chemical shift anisotropy (CSA) powder line shapes that are scaled by $(3\cos^2\theta - 1)/2 = -0.00333$, $+0.00211$, and 0 for Figure 3a, b, and c, respec-

Table 1: Twelve ^{13}C resonances in cholesteryl acetate.[a]

δ_{iso} [ppm]	170.90	141.47	121.78	73.49	52.71	41.57	37.48	34.27	32.84	28.48	21.32	13.89
$1/(\pi T_2^*)$ [Hz]	3.9	5.2	7.3	6.0	9.4	9.1	4.1	12.6	6.6	6.9	4.8	10.1
T_2' [ms]	3600	2300	130	160	150	60	420	70	150	90	370	280
$1/(\pi T_2')$ [Hz]	0.09	0.14	2.4	2.0	2.1	5.3	0.75	4.5	2.1	3.5	0.86	1.1

[a] Apparent line widths $\Delta\nu = 1/(\pi T_2^*)$, time constants T_2' of echo decays, and corresponding homogeneous (best possible) line widths $1/(\pi T_2')$. Partial assignments can be found in the work of De Paëpe et al.[12]

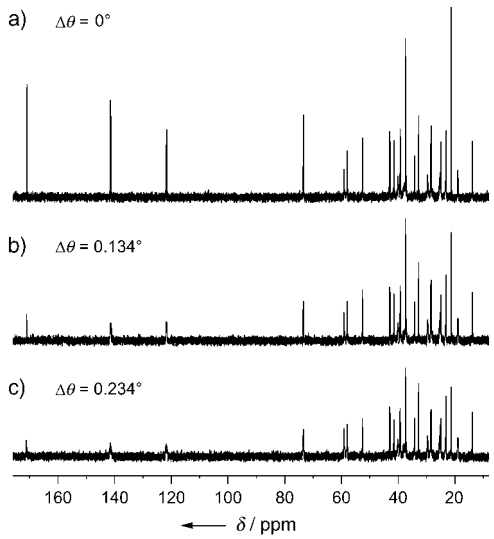

Figure 2. ^{13}C CPMAS spectra of cholesteryl acetate recorded at 9.4 T (100.6 MHz) as a function of the angle θ a) at the magic angle, that is, $\Delta\theta = 0$, b) and c) at deviations from the magic angle. The CP contact time was 1 ms, the recycle interval 4 s, the acquisition time 0.273 s for each of 1280 transients. No line broadening was applied.

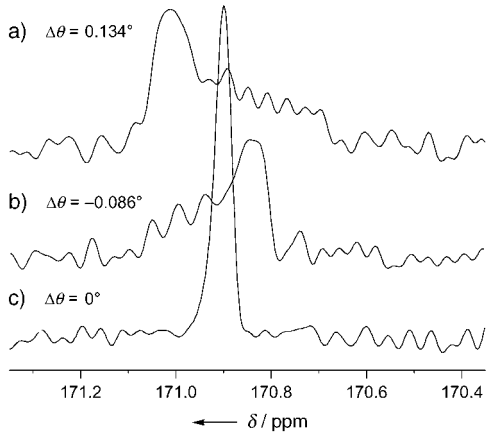

Figure 3. ^{13}C CPMAS resonances of the carbonyl carbon in cholesteryl acetate recorded as a function of the angle θ (spectrum c) at the magic angle, that is, $\Delta\theta = 0$. b) and a) at deviations from the magic angle, featuring scaled powder patterns characteristic of a symmetrical CSA tensor. With scaling factors $(3\cos^2\theta - 1)/2 = -0.00333$ (a) and $+0.00211$ (b) predicted from residual observed quadrupolar splittings in ^2H MAS spectra, powder patterns can be simulated that closely match the two spectra observed with $\Delta\theta \neq 0$ if the CSA principal components are assumed to be $\delta_{xx} = \delta_{yy} = 138.9$ ppm and $\delta_{zz} = 234.9$ ppm. The widths of the scaled powder patterns are directly proportional to the static magnetic field ($B_0 = 9.4$ T in this case).

tively, corresponding to $\Delta\theta = 0.134°$, $-0.086°$, and $0°$. It is remarkable that the residual scaled CSA effects are not masked by broadening owing to imperfect decoupling, structural disorder, temperature gradients, and magnetic susceptibility effects.

In comparison to cholesteryl acetate, amino acids often exhibit greater line widths, usually ascribed to magnetic susceptibility and structural disorder. The accurate adjustment of the magic angle also plays a significant role as demonstrated in ^{13}C CPMAS spectra of L-alanine (Figure 4).

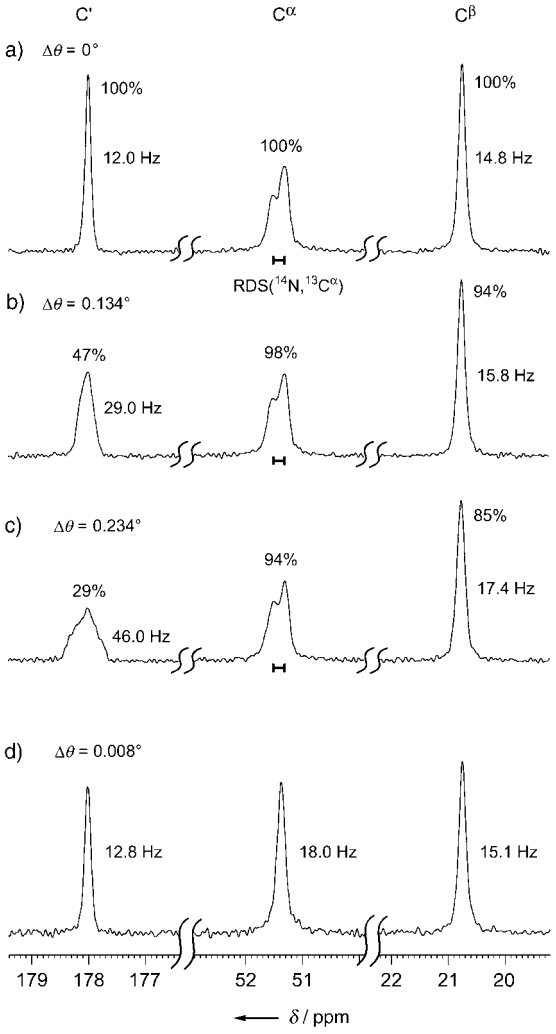

Figure 4. ^{13}C CPMAS spectra of a)–c) [^{14}N]L-alanine at different $\Delta\theta$ values and d) [^{15}N]L-alanine. The spectra result from averaging 640 transients with a recycle interval of 2 s. The CP contact time was 500 μs. The acquisition time was 0.136 s. No line broadening was applied.

For $\Delta\theta \neq 0$, the main contributions to the line widths again originate from residual CSA effects. The CSA tensors in L-alanine, determined independently by Ye et al.,[13] give $\delta_{CSA} = -70, -20, -12$ ppm and $\eta_{SA} = 0.79, 0.35$ and 1 for C′, C^{α} and C^{β}, respectively, using the definitions $\delta_{CSA} = \delta_{zz} - \delta_{iso}$, $\eta_{SA} = (\delta_{yy} - \delta_{xx})/\delta_{CSA}$, and re-ordering the principal components so that $|\delta_{zz} - \delta_{iso}| \geq |\delta_{xx} - \delta_{iso}| \geq |\delta_{yy} - \delta_{iso}|$. The line widths of the C′ and C^{β} resonances of L-alanine in Figure 4a are only 12 and 15 Hz, significantly narrower than previously reported under slightly different experimental conditions.[7] The C^{α} line widths are so narrow that a 1:2 doublet of approximately 20 Hz can be clearly observed. The doublet arises from the residual dipolar splitting (RDS) (^{14}N,^{13}C), also known as second-order quadrupole-dipole cross term.[14–18] This dipolar splitting is not completely eliminated by MAS because the large quadrupular interaction of the ^{14}N nucleus tilts the axis of quantization of the ^{14}N spin away from the direction of the static magnetic field, so that the angular dependence of the interaction cannot be averaged out by spinning at the magic angle.[14–16] In ^{15}N enriched L-alanine by contrast (Figure 4d), the dipolar ^{15}N-^{13}C coupling is averaged to zero, and the C^{α} line collapses to a singlet.

The C^{α} resonance of natural-abundance glycine in Figure 5a has a slightly asymmetric peak (full width at half-height 48.6 Hz) tailing towards high frequency which can be ascribed to an ill-resolved RDS(^{14}N,^{13}C). The C′ carbon shows a symmetric resonance with a line width of 30.5 Hz. Selective enrichment of the C^{α} atom (Figure 5b) results in a splitting of the C′ resonance into a doublet of 53 Hz arising from the scalar coupling $^{1}J(C',C^{\alpha})$. The ability to resolve this doublet strongly depends on the accurate setting of the magic angle, since $\Delta\theta \neq 0$ leads to a residual CSA interaction (it was determined by Ye et al. that $\delta_{CSA} = -71$ ppm[13]). The line widths of the C′ and C^{α} resonances in glycine are not significantly affected by ^{13}C enrichment of the C^{α} site.

The observed line widths $\Delta\nu = 1/(\pi T_2^*)$ can be compared with the limiting homogeneous line widths $\Delta\nu' = 1/(\pi T_2')$.[7,19,20] The limiting homogeneous line widths provide a good criterion to evaluate the performance of proton decoupling.[7] The T_2' values reported in Table 1 were determined from the mono-exponential decays of spin echoes. The defocusing and refocusing intervals τ were chosen to be multiples of the rotor period, while the longest delay was $2\tau = 150$ ms. For cholesteryl acetate, the T_2' time constants and corresponding line widths $\Delta\nu' = 1/(\pi T_2')$ are listed in Table 1. The longest $T_2' = 3.6$ s was found for the carbonyl carbon, corresponding to $\Delta\nu' = 0.09$ Hz. Such long T_2' time constants make it possible to design very complex pulse sequences, well beyond those currently used in liquid-state NMR spectroscopy. The width of 3 Hz observed under similar conditions for adamantane ($\nu_r = 10$ kHz) is believed to be mostly due to B_0 inhomogeneity. The experimental width for the carbonyl carbon signal being 3.9 Hz, the difference of 3.9–0.09–3 = 0.81 Hz must therefore be due to magnetic susceptibility effects, to a chemical shift dispersion arising from structural disorder, and to temperature gradients.[19] For the protonated carbon atoms in cholesteryl acetate, T_2' is much shorter, which indicates that the observed width is due in part to incomplete proton decoupling. In $^{13}C^{\alpha}$-enriched glycine, $T_2'(C^{\alpha}) = 52$ ms, while in natural abundance L-alanine $T_2' = 403$ for C′, 73 for C^{α}, and 69 ms for C^{β}. To evaluate the performance of decoupling with a slight miss-set of the angle, spin-echo decay curves were recorded for $\Delta\theta = 0.134°$. The resulting T_2' values in L-alanine were found to be 466 for C′, 75 for C^{α}, and 69 ms for C^{β}, that is, there is a slight increase for the C′ resonance, and little effect for C^{α} and C^{β}.

Friction results in sample heating and temperature gradients across the sample, which leads to line broadening.[21–24] Nuclei such as ^{207}Pb have isotropic shifts with a pronounced temperature dependence.[24] The ^{207}Pb MAS spectra of $Pb(NO_3)_2$ (Figure 6) show that different spinning

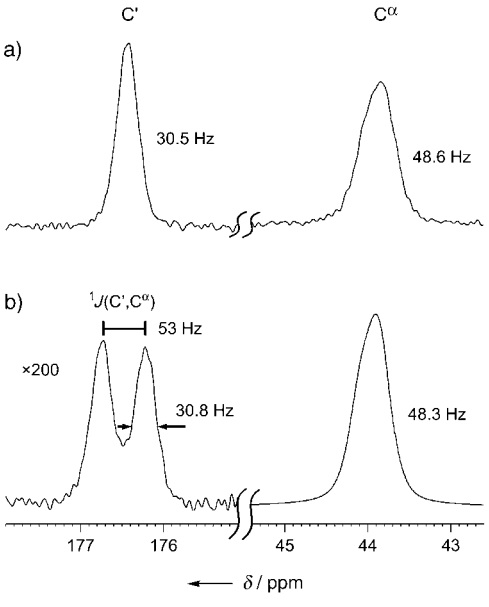

Figure 5. ^{13}C CPMAS spectra of a) natural-abundance glycine and b) glycine enriched in ^{13}C at the C^{α} position, recorded at the magic angle. The $^{1}J(C',C^{\alpha})$ coupling in (b) can be read directly from the spectrum. The spectra result from averaging 640 transients with a recycle interval of 2 s and a CP contact time of 1 ms. The acquisition time was 0.136 s. No line broadening was applied.

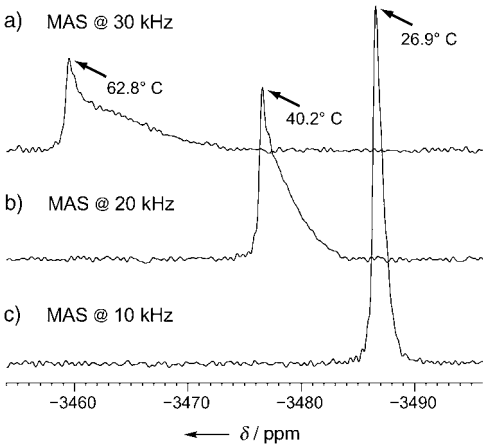

Figure 6. ^{207}Pb MAS spectra of $Pb(NO_3)_2$ recorded at different spinning rates, which lead to different temperature gradients across the sample. The spectra result from averaging of 320 transients with a recycle interval of 5 s.

Table 2: Differences ($\Delta\delta_{iso}$) between isotropic chemical shifts of ^{13}C of cholesteryl acetate observed at temperatures of 39 °C ($\delta_{iso}(39°)$) and 17 °C ($\delta_{iso}(17°)$).[a]

δ_{iso} [ppm][b]	170.90	141.47	121.78	73.49	52.71	41.57	37.48	34.27	32.84	28.48	21.32	13.89

$\Delta\delta_{iso}/\Delta T$ [ppm/°][d]	0.010	0.014	0.010	0.015	0.013	0.015	0.013	0.009	0.014	0.012	0.013	0.014

[a] Nominal temperatures measured by a thermocouple in the air flow near the rotor. [b] The isotropic shifts in the first row correspond to 39 °C. [c] $\Delta\delta_{iso} = \delta_{iso}(39°) - \delta_{iso}(17°)$. [d] Derivatives $\Delta\delta_{iso}/\Delta T$ in ppm/degree. Partial assignments can be found in the work of De Paëpe et al.[12]

rates affect the temperature gradients. The absolute temperature is calibrated from the chemical shift difference of the two proton resonances in liquid methanol, which can be spun up to 30 kHz.[25] The temperature distribution across the sample is asymmetric, and its range increases from about 3° at 10 kHz to as much as 17° at 30 kHz. To estimate contributions from temperature gradients to line widths of ^{13}C spectra obtained under similar conditions, we recorded spectra of cholesteryl acetate and L-alanine in natural abundance at two different nominal temperatures. All line widths remain the same, but various downfield shifts are observed. The differences in chemical shifts $\Delta\delta = \delta_{iso}[39°] - \delta_{iso}[17°]$ for cholesteryl acetate are given in Table 2. For L-alanine $\Delta\delta = 20$ for C′, 30 for C^{α}, and 25 Hz for C^{β}. Clearly, the temperature gradient in the samples of cholesteryl acetate and L-alanine are much smaller than in $Pb(NO_3)_2$, otherwise the lines would be much broader and feature an asymmetry like that in Figure 6. Materials have different densities, heat capacities, electric and thermal conductivities, and dielectric properties, all of which can affect heating under sample rotation and RF irradiation. It is conceivable that the combined effects of mechanical friction and RF heating lead to a (fortuitous) reduction of the temperature gradients across our samples. The deliberate reduction of temperature gradients should lead to further improvements in resolution.

To summarize, we have shown that the accuracy of the adjustment of the magic angle is critical to obtain high-resolution MAS NMR spectra. The main contribution to the line widths in ^{13}C spectra recorded with a slight miss-set of the angle is due to residual CSA interactions. For quaternary carbon atoms, the increase in line widths is therefore greater than for proton-carrying carbon atoms. For the latter, the performance of heteronuclear proton decoupling is more critical, although it is not significantly affected by a small miss-set of the angle. Nevertheless, the observed line widths are still larger than the homogeneous limit given by the time-constant T_2' of spin echo decays. The remaining line widths are believed to be mainly due to magnetic susceptibility effects and to chemical shift dispersion arising from structural disorder or temperature gradients. Such effects can limit resolution at higher fields.

Two Faces of a Biomimetic Non-Heme HO–Fe^{V}=O Oxidant: Olefin Epoxidation versus *cis*-Dihydroxylation**

Arianna Bassan, Margareta R. A. Blomberg, Per E. M. Siegbahn, and Lawrence Que, Jr.**

The family of non-heme iron complexes—exemplified by $[Fe^{II}(tpa)(CH_3CN)_2]^{2+}$, where tpa is the tetradentate tripodal tris(2-pyridylmethyl)amine ligand—efficiently utilizes H_2O_2 to carry out stereospecific olefin epoxidation and *cis*-dihydroxylation.[1–4] The latter reaction was not previously known to be catalyzed by a synthetic iron complex and is precedented only in the chemistry of Rieske dioxygenases,[5] non-heme iron enzymes responsible for *cis*-dihydroxylation in the biodegradation of arenes by soil bacteria. Isotope-labeling experiments on the biomimetic reaction show the involvement of a highly selective metal-based oxidant capable of introducing water into the product.[1,2] This oxidant is proposed to result from the low-spin complex $[Fe^{III}(tpa)(H_2●)(OOH)]^{2+}$ (**1**) and be a formally H●–Fe^{V}=O species (**2**; ● indicates an oxygen atom with isotope labeling), both shown in Figure 1.

Previous DFT calculations have demonstrated the feasibility of an O–O bond heterolysis mechanism that leads to an $S = 3/2$ *cis*-HO–Fe^{V}=O species with a short Fe–O bond (1.66 Å) and a longer Fe–OH bond (1.77 Å).[6] The three unpaired electrons are mainly distributed on the iron atom (1.58), the oxo oxygen atom (1.0), and the hydroxo oxygen atom (0.44): a spin distribution not unlike that found for compounds I of heme peroxidases and cytochrome P450 and related model complexes.[7,8] The corresponding sextet and doublet states of HO–Fe^{V}=O lie more than 10 kcal mol^{-1} higher in energy than the quartet ground state.[9]

Further DFT calculations presented herein provide new insight into how this unique oxidant can carry out both olefin epoxidation and *cis*-dihydroxylation. Hence, the present study focuses on the subsequent reaction of **2** with olefins (see the Supporting Information) to reveal that olefin epoxidation and *cis*-dihydroxylation in fact represent different faces of the same oxidant.

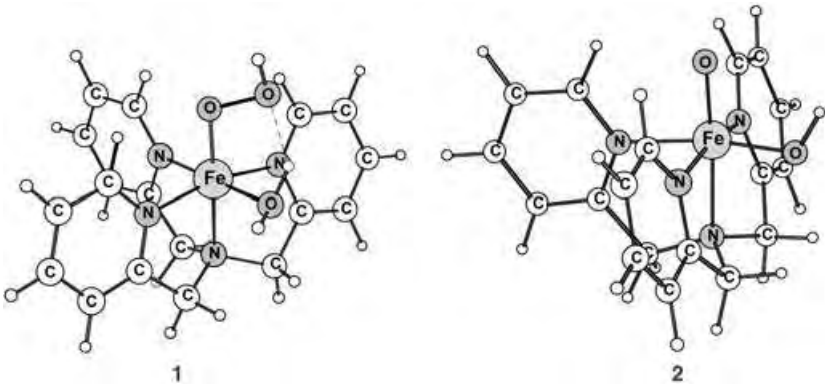

Figure 1. Structures of the $[Fe^{III}(tpa)(H_2O)(OOH)]^{2+}$ precursor (**1**) and the proposed metal-based *cis*-HO–Fe^{V}=O oxidant (**2**).

The key results of our DFT study are illustrated by the energy profiles in Figure 2, showing that **2** can react with olefins (namely, 2-butene) through two different channels. As shown on the left, the oxo group attacks the olefin to form the C1–O1 bond and intermediate **A**-Fe^{IV} (path A). On the right, the hydroxo ligand attacks the olefin to form the C2–O2 bond and intermediate **B**-Fe^{IV} (path B). Both intermediates have an iron(IV) center and a radical on the partially oxidized substrate.

Intermediate **A**-Fe^{IV} is an iron(IV) complex with a hydroxide ($r_{Fe-O2} = 1.79$ Å) and the partially oxidized olefin as ligands. The formation of the new C1–O1 bond is exergonic by 2.5 kcal mol^{-1} and involves an activation energy of 7.8 kcal mol^{-1}; solvent effects (+3.1 kcal mol^{-1}), entropy effects (+0.6 kcal mol^{-1}), and big-basis effects (+2.1 kcal mol^{-1}) contribute to increase the barrier by 5.6 kcal mol^{-1}. Unpaired spin density can be found on the metal center (1.53), the partially oxidized olefin (0.97), and the remaining ligands (0.50). Antiferromagnetic coupling of the unpaired electron on the partially oxidized olefin with those of the metal center affords an $S = 1/2$ state that is more stable by about 1–2 kcal mol^{-1} than the corresponding $S = 3/2$ state. Thus, a spin crossing between the quartet and the doublet surfaces may occur in the vicinity of this intermediate during the course of epoxidation. Intermediate **A**-Fe^{IV} in the $S = 1/2$ state decays spontaneously and without any significant barrier to the epoxide in the first coordination sphere of iron. No low-energy pathway producing the *cis*-diol from **A**-Fe^{IV} can be found. Almost identical barriers were obtained when epoxidation of propene was investigated.

In contrast, *cis*-dihydroxylation of the olefin occurs when the hydroxo ligand of **2** attacks the substrate, thus leading to

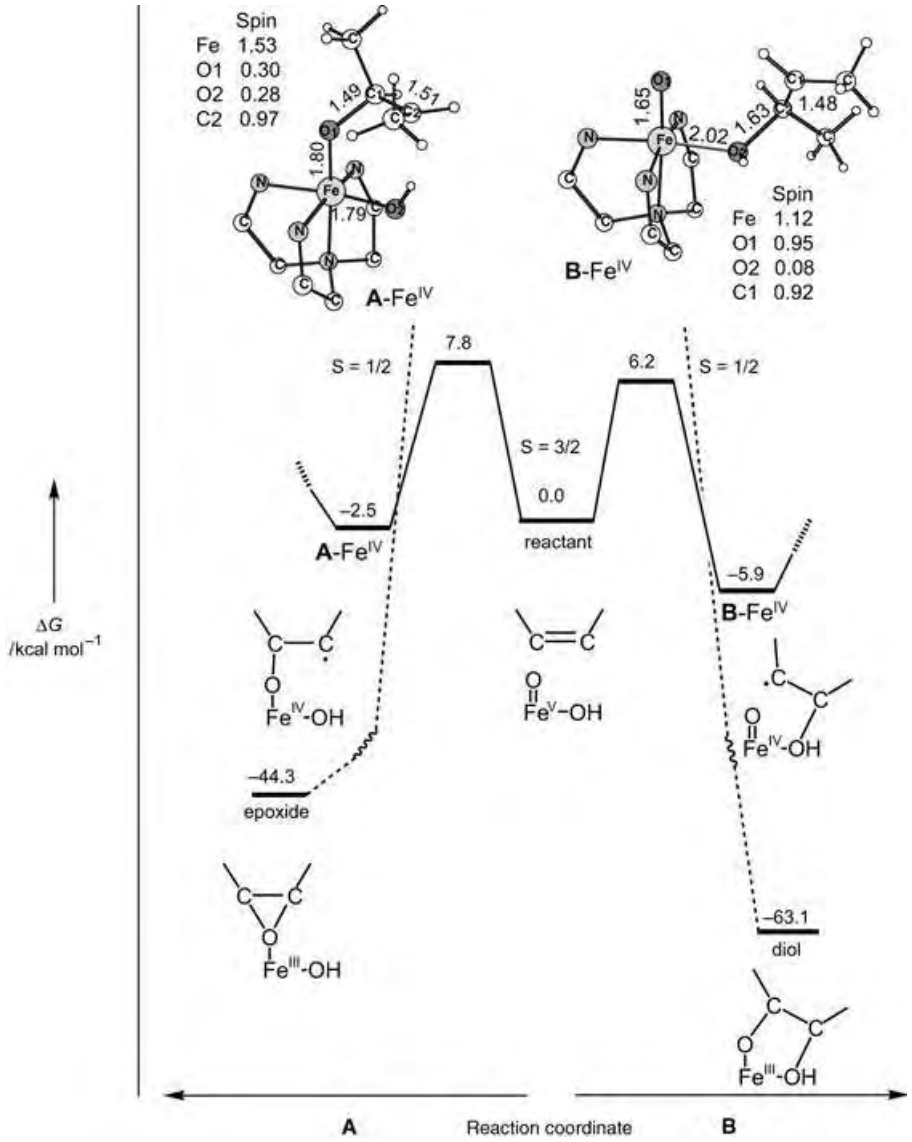

Figure 2. Energy profiles for olefin epoxidation (path A) and olefin *cis*-dihydroxylation (path B).

the formation of intermediate **B**-Fe^{IV}. The Fe=O double bond is maintained ($r_{Fe\text{-}O1} = 1.65$ Å) in this species and a weak C2–O2 bond ($r_{C2\text{-}O2} = 1.63$ Å) is formed. For the $S = 3/2$ state of **B**-Fe^{IV}, unpaired spin density can be found on the metal center (1.12), the oxo oxygen atom (0.95), and the partially oxidized olefin (0.97). The transition state for C2–O2 bond formation in propene was found to have an energy barrier of 6.2 kcal mol^{-1}, a value which includes solvent effects (2.2 kcal mol^{-1}), big-basis effects (1.5 kcal mol^{-1}), and thermal and zero-point corrections (0.6 kcal mol^{-1}). In the case of butene, the corresponding transition-state structure could not be optimized but is approximated to have a relative energy similar to that of the propene complex. As with the epoxidation pathway, a spin crossing from the quartet to the doublet state of **B**-Fe^{IV} results in the formation of the product, because the $S = 1/2$ state readily leads to the diol without any significant energy barrier. In line with the chemistry of other transition metal oxides, for example, osmium tetroxide,[10] the concerted [3+2] addition of HO–Fe=O across the olefin C=C bond was also probed, but all attempts to optimize the corresponding structure led to a transition state where only one C–O bond was initially formed.

We also considered the possibility that *cis*-diol is produced from the initially formed epoxide. Figure 3 shows the calculated energy profile for this conversion for the $S = 5/2$ state, which is the ground state for both products (see the Supporting Information). Figure 3 also reports the energy required for epoxide dissociation from the metal center. Interestingly the epoxide-to-diol conversion is disfavored relative to epoxide release from the metal center by approximately 7 kcal mol^{-1}. Thus, diol formation most likely occurs by the direct reaction of olefin with the HO–Fe^{V}=O species, rather than via the epoxide.

The Fe(tpa) family of complexes are unique oxidation catalysts that are capable of both olefin epoxidation and *cis*-dihydroxylation.[4] As previously suggested,[1,2,6] it is likely that a high-valent iron–oxo species is formed along the reaction pathway, and our DFT calculations have provided insight into the mechanism of olefin oxidation by the exceptional HO–Fe^{V}=O oxidant. It is possible that epoxidation may also occur by direct attack of the precursor Fe–OOH on the olefin, and a preliminary study in this direction has suggested that such a pathway is slightly disfavored over the competing O–O bond cleavage to generate the HO–Fe^{V}=O oxidant.

If the Fe(tpa) catalysts carry out olefin oxidation via the high-valent iro–oxo species, then epoxidation occurs by attack of the oxo oxygen atom on the olefin, and *cis*-dihydroxylation is initiated by attack of the hydroxo oxygen atom, followed by rebound of the incipient carbon radical with the oxo oxygen atom. This scheme provides a rationale for the observed incorporation of one oxygen atom from H_2O_2 and one oxygen atom from solvent into the diol product.[2] Such a mechanism may also explain why the oxygen atom of the epoxide derives principally, but not exclusively, from H_2O_2. Previous DFT calculations have determined that oxo–hydroxo tautomerization of the H●–Fe^{V}=O species leading to label scrambling has an energy barrier of about 10 kcal mol^{-1},[9] a value that is somewhat higher than that computed here for olefin epoxidation, so oxo attack on the olefin would be expected to occur before significant label scrambling occurs, in agreement with experimental observations.

Lastly, the calculations reveal that olefin epoxidation and *cis*-dihydroxylation have comparable activation barriers, with the latter being favored by about 1 kcal mol^{-1} (Figure 2). On the basis of transition-state theory, this difference predicts a diol-to-epoxide ratio of about 5:1. Experimentally, the *cis*-diol

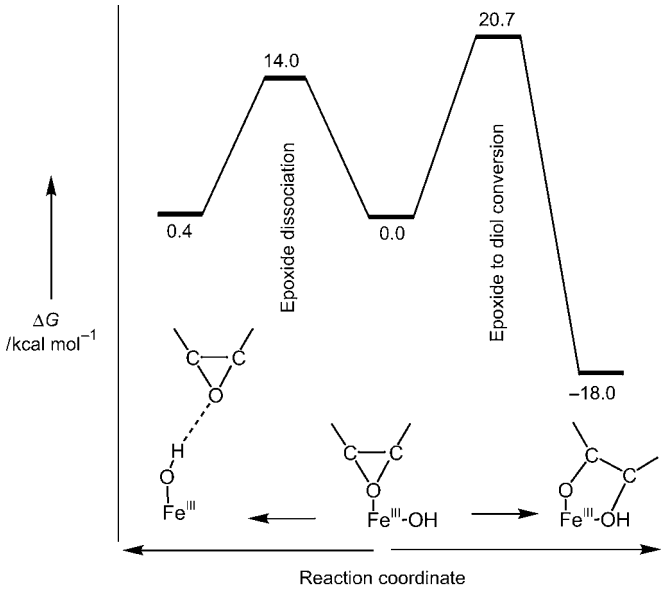

Figure 3. Energy profiles for epoxide dissociation and epoxide-to-diol conversion for the $S = 5/2$ state.

product is indeed favored over the epoxide, but only by factors of 1.2–3, depending on the olefin, results well within the accuracy of the present computational approach.

These new insights, only obtainable from DFT calculations thus far, provide a solid foundation for understanding the reaction mechanisms of a new family of bio-inspired non-heme iron catalysts for olefin oxidation. The stage has thus been set for future work aimed at rationalizing the strong preference for epoxide products by related Fe(bpmen) and α-Fe(bpmcn) catalysts[11] as well as the exclusive production of *cis*-diol product in the oxidation of electron-deficient olefins like acrylate and fumarate by the Fe(tpa) catalyst.[12]

Methods

The energy profiles and the structures included in the present study were obtained employing the B3LYP functional and using the quantum chemical programs Jaguar 4.2[13] and Gaussian 98.[14] Fully optimized transition states were obtained through the evaluation of the second derivatives with respect to the nuclear coordinates of approximate structures. Hessians for reactants, intermediates, and transition states were used to derive the zero-point effects and the thermal corrections necessary for determining Gibbs free energies. Free energies are reported including zero point and thermal effects, evaluated for 298.15 K. Relative free energies for epoxidation and *cis*-dihydroxylation were calculated with a supermolecular approach including both the metal complex and the olefin (see, for example, Figure S1 in the Supporting Information). This is likely to underestimate the energy barriers but does not affect the conclusions of this study.

An effective core potential was used to describe the iron atom. In the geometry optimizations and in the Hessian evaluations all the other atoms were described by a standard double zeta basis set, labeled lacvp in Jaguar. The final B3LYP energies for the fully optimized structures were computed using a basis set that includes polarization functions on all atoms (labeled lacv3p** in Jaguar). Spin populations obtained with the lacvp basis set are reported. Solvent effects were evaluated employing the self-consistent reaction field as implemented in Jaguar[13] together with a dielectric constant of 36.64 and a probe radius of 2.155 Å.

On the basis of previous benchmarks, an accuracy of about 3–5 kcal mol^{-1} could affect the energy profiles reported in the present investigation.[15,16] However, such an accuracy should be enough to discriminate among different reaction mechanisms.

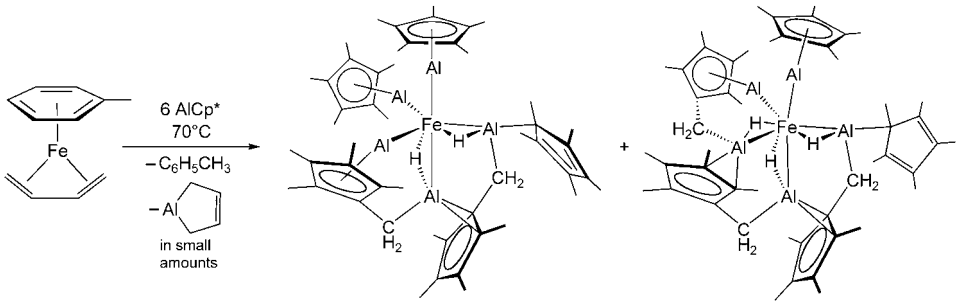
Organometallic Chemistry

C–H Activated Isomers of [M(AlCp*)$_5$] (M=Fe, Ru)**

*Tobias Steinke, Mirza Cokoja, Christian Gemel, Andreas Kempter, Andreas Krapp, Gernot Frenking, Ulrich Zenneck, and Roland A. Fischer**

Quantum mechanical calculations on the model compounds [Fe(ECH$_3$)$_5$] (E = Al, Ga, In) suggest the existence of the homoleptic, trigonal-bipyramidal d^8 metal complexes of the exotic ligands E^{I}R (R = C(SiMe$_3$)$_3$, Cp*; Cp* = C$_5$Me$_5$).[1] The M–E bonds are strong and determined by coulomb interactions, whereas the π-acceptor properties are weak for E^{I}R if R = Cp*, but considerably stronger for alkyl substituents R.[2] However, only the d^{10} complexes [M(E^{I}R)$_4$] (M = Ni, Pd, Pt) are known, which can be considered as analogues of [Ni(CO)$_4$] or [M(PR$_3$)$_4$], highlighting the similarity of the ligands E^{I}R to CO or phosphines.[3] Furthermore, clusters [M$_a$(ECp*)$_b$] have been reported, which also contain tetrahedrally coordinated Pd or Pt centers.[4] While numerous reports on [(CO)$_4$Fe(AlCp*)] and other related, CO-substituted complexes exist,[5,6] the question as to what is the limit for the coordination number n in the homoleptic compound [M(E^{I}R)$_n$], is still unanswered: is $n = 5$ possible, perhaps also $n = 6$, or even more? Does the steric demand of ECp* (Tolman angle of 112° for E = Ga[7]) hinder the stability of [M(ECp*)$_n$] with $n > 4$? Recently we could show by the structural characterization of [(CO)$_3$M(ECp*)$_3$] (M = Mo, W; E = Al, Ga), that the coordination of three ECp* ligands is possible in a facial geometry.[8] Thus we concentrated our attention on complexes of the type [Fe(AlCp*)$_n$] and chose [Fe(η^6-toluene)(η^4-1,3-butadiene)] as the Fe^0 source for the introduction of AlCp*.[9]

If a red suspension of [Fe(η^6-toluene)(η^4-1,3-butadiene)] and six equivalents of AlCp* in toluene is heated to 80 °C (Scheme 1), an orange solution is rapidly formed. The ^{1}H NMR spectroscopic data point to a mixture of two products in the ratio of 3:1, neither of which has the structure [Fe(AlCp*)$_5$]! Characteristic highfield resonance signals (δ = −18 to −20 ppm) and the complexity of the Cp* signals in the aliphatic region suggest a C–H activation of the methyl groups. Compound **1a** can be isolated from a toluene solution of the product mixture by crystallization at −30 °C for a few minutes (yield 35 %). The yellow, prismatic crystals do not contain any **1b** (by ^{1}H NMR spectroscopy). Recrystallization of this sample gave single crystals of **1a**. Crystallization of the mother liquor over a longer period of time increases the amount of **1b** in the solid. Pure **1b** could not be isolated. Repeated fractional crystallization leads to defined yellow



Scheme 1. Preparation of **1a** and **1b**, isomers of the hypothetical compound [Fe(AlCp*)$_5$] (relative amounts in percent according to ^{1}H NMR spectroscopy data).

single crystals (isolated yield ca. 5 %) containing **1a** (50 %) and **1b** (50 %) (NMR spectroscopy). Pure **1a** does not give **1b** on heating in toluene to 110 °C for several hours.

X-Ray analysis of **1a** confirms the composition suggested by NMR spectroscopy and elemental analysis (Figure 1). Two CH_3 groups of two different Cp* rings (on Al3 and Al4) are C–H activated. The methylene moieties (C30 und C39) are slightly bent out of the ring plane (ca. 15°) and bound two the adjacent Al atoms Al4 and Al5. Thus, a tridentate chelate ring {(η^1-Cp*Al)-CH$_2$-(η^2-C$_5$Me$_4$Al)-CH$_2$-(η^5-C$_5$Me$_4$)Al} is formed. The coordination environment of the Fe center can be described as either distorted trigonal-bipyramidal or distorted square pyramidal. The atoms Fe, Al1, Al2, and Al4 are almost coplanar (angular sum 359.03°), whereas the "axial" positions Al3 and Al5 (Al3-Fe-Al5 160.09(5)°) are bent towards Al2 and Al4 owing to the bridge Fe1-H2-Al5. The bridging atoms H1 and H2 could be localized and were

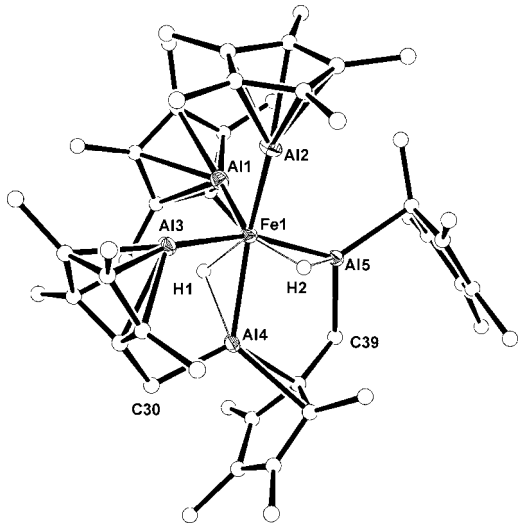

Figure 1. Molecular structure of **1a** (ORTEP plot, thermal ellipsoids set at 50% probability for Fe and Al. The C atoms were depicted isotropcally for clarity. Hydrogen atoms are omitted for clarity except H1 and H2). Selected bond lengths [Å] and angles [°]: Fe1-Al1 2.2124(15), Fe1-Al2 2.2419(15), Fe1-Al3 2.2404(15), Fe1-Al4 2.3686(15), Fe1-Al5 2.3272(14), Fe1-H1 1.59(8), Al4-H1 1.88(8), Fe1-H2 1.46(7), Al5-H2 1.89(7), Al4-C30 2.030(5), Al5-C39 1.990(4), $Cp^*_{centroid}$-Al1 1.914, $Cp^*_{centroid}$-Al3 1.891; Al1-Fe1-Al2 90.44(6), Al1-Fe1-Al3 108.83(6), Al1-Fe1-Al4 118.07(6), Al1-Fe1-Al5 88.02(5), Al2-Fe1-Al3 84.78(6), Al2-Fe1-Al4 150.52(6), Al2-Fe1-Al5 106.21(6), Al3-Fe1-Al4 79.19(5), Al3-Fe1-Al5 160.09(5), Al4-Fe1-Al5 83.55(5), $Cp^*_{centroid}$-Al1-Fe1 161.00, $Cp^*_{centroid}$-Al2-Fe1 172.22, $Cp^*_{centroid}$-Al3-Fe1 149.43, Al1-Fe1-Al2-Al4 165.9(5).

freely refined: Fe1–H1 1.59(8), Fe1–H2 1.46(7), Al4–H1 1.88(8), Al5–H2 1.89(7) Å. No other complexes with Fe-H-Al motifs are known for comparison. However, typical Fe-H-Fe bond lengths are 1.5–1.8 Å[10] and the Al–H bond in **1a** is very similar to that in [Ni(AlCp*)$_3$(HAlCp*Ph)] (Al–H 1.76(3) Å).[11] The Fe–Al bond lengths correlate to the formal oxidation states of the aluminum centers, Al^I for AlCp* and Al^{III} for the fragments [HAl(Cp*)(CH$_2$C$_5$Me$_4$)]. The Fe–Al^I distances (Al1, Al2, and Al3) are in between 2.2124(15) and 2.2419(15) Å, whereas the Fe–Al^{III} distances (Al4 and Al5) are elongated by about 10 pm owing to the higher coordination number and the different electronic situation (2.3272(14) and 2.3686(15) Å).

The ^{1}H NMR spectrum of **1a** in C$_6$D$_6$ (298 K) shows two intense singlets at $\delta = 2.20$ (15H) and 1.82 ppm (30H) representing the fluxional C$_5$Me$_5$ groups at Al5 (η^1-Cp*) and Al1 and Al2 (η^5-Cp*), respectively. The methyl groups of both activated Cp* rings give rise to four weaker signals of equal intensity at $\delta = 2.23$ (6H), 2.09 (6H), 1.88 (6H), and 1.63 ppm (6H). For the bridging CH$_2$ groups, two singlets at $\delta = 1.04$ (2H, CH$_2$) and 0.76 ppm (2H, CH$_2$) were detected. Only one signal at $\delta = -19.00$ ppm (s, 2H) was found for the two hydrogen atoms H1 and H2. However, based on the asymmetric structure of **1a** in the solid state, two resonances would be expected. Clearly a fluxional process is present. No broadening of the signals was observed in the temperature range between 25 °C and 80 °C in C$_6$D$_6$. Thus, it is unlikely that a reversible C–H bond activation is responsible for the fluxionality of the hydrides in solution. Presumably H1 and H2 rapidly exchange their position, which is also consistent with the quantum mechanical calculations. The ^{27}Al NMR spectrum has only one very broad signal at $\delta = -2.5$ ppm ([(CO)$_4$Fe(AlCp*)]: $\delta = 0.4$ ppm[5]). The other, presumably also very broad ^{27}Al resonance signals (for the Al^{III} centers), are masked by the signal of the probe head ($\delta = +66.8$ ppm).

Quantum mechanical calculations[12] show a very good agreement between the structural parameters of the optimized structure, **1aM**, and the experimentally determined structure **1a** (see Supporting Information), with one exception: The atom H1 in **1aM** is better specified as a terminal hydride according to the calculations and is even located somewhat closer to Al1 (2.103 Å) than to Al4 (2.156 Å). This result may be an indication for a very flat energy surface for the hydrogen migration, and a distinction between terminal hydrides (classical) and bridging hydrides is no longer appropriate, particularly because the structures investigated are dynamic in nature.[13]

Surprisingly, a hypothetic structure [Fe(AlCp*)$_5$] with five Fe–Al bonds and intact Cp* ligands without bridging hydrogen atoms does not represent an energetic minimum. A geometry optimization starting from a structure with local D_{3h} symmetry at Fe without symmetry restrictions leads to **1aM**, which shows no imaginary frequencies. A calculation with restricted C_s-symmetry leads to a structure with intact CH$_3$ groups but with η^1-Cp* rings, which is 22.0 kcal mol^{-1} higher in energy than the minimum. Thus, the driving force for the C–H activation is significant. An analysis of the charge distribution by the natural bond orbital (NBO) method[14] shows significant differences between terminal and bridging atoms. The methylene carbon atoms C39 (−1.06) and C30 (−1.04) bear a higher negative charge than the methyl carbons (−0.64 to −0.67). The aluminum atoms bound to C39 and C30, Al5 (+1.16) and Al4 (+1.24) therefore bear a higher positive charge than Al3 (+0.92), Al2 (+0.75), Al1 (+0.94). As expected, the atoms H1 (−0.17) and H2 (−0.16) are negatively charged and are thus definitely hydridic, whereas all other hydrogen atoms are weakly positively charged.

The molecular structure of **1b** (Scheme 1), already suggested by NMR spectroscopy, was confirmed by X-ray analysis of a mixed crystal of **1a** and **1b** (see Supporting Information). The structural solution and refinement was performed under the assumption of a disorder of both isomers over the positions in the unit cell. No superlattice reflections were observed. The molecular structures of **1a** and **1b** are very similar, but **1b** has three C–H activated Cp* rings (Al3, Al4, and Al5). Thereby the tilting angle of the Cp* ring on Al4 to the axis Al4–$Cp^*_{centroid}$ is distinctly different. Whereas in **1a** this Cp* ring coordinates in an η^5 mode to Al4, this unit can be described as η^3-Cp*Al in **1b**. Also in **1b**, the Cp*unit of the adjacent Al5 is shifted closer towards Al4 than in **1a**, leading to a short Al4–C46 distance of 2.146 Å. The structural parameters of the heavy atoms of **1a** and **1b** in the mixed crystal were not distinguishable owing to the disorder, but are very different from those of pure **1a**. For a deeper analysis of **1b**, quantum mechanical calculations (RI-BP86/SVP) were performed. Model compound **1bM** (Figure 2) represents an

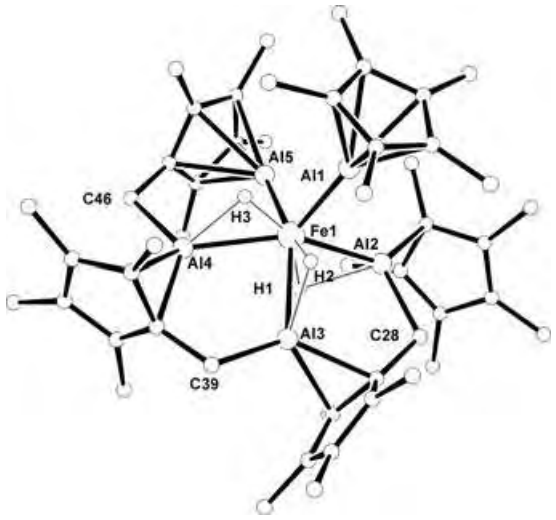

Figure 2. Calculated molecular structure **1bM**. Selected bond lengths [Å] and angles [°]: Fe1-Al1 2.223, Fe1-Al2 2.378, Fe1-Al3 2.405, Fe1-Al4 2.444, Fe1-Al5 2.263, $Cp^*_{centroid}$-Al1 1.923, $Cp^*_{centroid}$-Al5 1.893; Al1-Fe1-Al2 82.96, Al1-Fe1-Al3 119.42, Al1-Fe1-Al4 127.59, Al1-Fe1-Al5 95.10, Al2-Fe1-Al3 85.23, Al2-Fe1-Al4 149.41, Al2-Fe1-Al5 95.75, Al3-Fe1-Al4 80.41, Al3-Fe1-Al5 145.24, Al4-Fe1-Al5 81.17, $Cp^*_{centroid}$-Al1-Fe1 163.55, $Cp^*_{centroid}$-Al5- Fe1 148.97, Al1-Fe1-Al3-Al5 172.5.

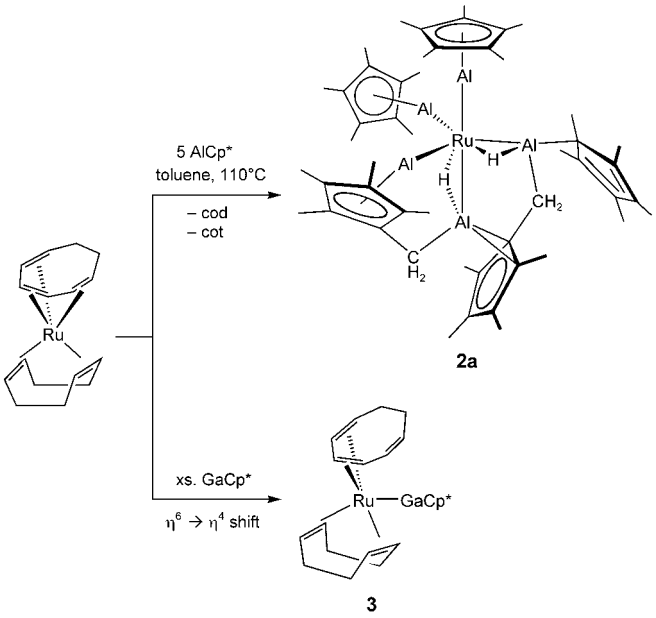

Scheme 2. Preparation of **2a** and **3**; cod = 1,5-cyclooctadiene, cot = 1,3,5-cyclooctatriene.

energetic minimum and is almost identical in energy to the doubly activated structure **1aM** (+0.16 kcal mol^{-1}).

The atoms H1, H2, and H3 bridge the bonds Fe–Al(2,3,4). The bridging CH_2 groups lead to small Al-Fe-Al angles of 80–85°, whereas the angle Al5-Fe1-Al2 (95.75°) is considerably larger. Compared to **1aM** (or **1a**), the structure of **1bM** is more distorted towards a square-pyramidal structure with Al1 in the axial position, a consequence of the three Fe-H-Al bridges. The axial ligand Al1 moves towards the open site between Al2 and Al5, leading to smaller angles Al1-Fe1-Al(2,5) (82.96 and 95.10°) in comparison to the larger angles Al1-Fe1-Al(3,4) (119.42 and 127.59°). Clearly, a fourfold activated product is unfavorable because of steric reasons. Whether a similar situation is possible in the octahedral complexes [M(AlCp*)$_6$] remains to be investigated.

The activation of AlCp* is not only restricted to [Fe(AlCp*)$_5$] (Supporting Information). [Ru(η^4-cod)(η^6-cot)][15] reacts with AlCp* (toluene, 110 °C) to give the $RuAl_5$ complex **2a** (isostructural to **1a**) in 60 % yield (Scheme 2). A complex **2b** which is analogous to **1b** could not be identified or isolated. Whereas [Fe(η^6-toluene)(η^4-1,3-butadiene)] is inert towards GaCp*, [Ru(η^4-cod)(η^6-cot)] reacts with GaCp* to give quantitatively the addition product [(η^4-cod)(η^4-cot)Ru(GaCp*)] (**3**).

The formation of [Ru(GaCp*)$_5$] or its C–H activated isomers could not be observed even with a great excess of GaCp*. InCp* is inert towards the Fe^0 and Ru^0 sources. We assume that low-coordinate intermediates [Fe(AlCp*)$_n$] ($n <$ 5) on the pathway leading to **1a** or **1b**, respectively, are responsible for the intramolecular C–H activation reactions. Thus, on reaction of [Cp*Rh(Me)$_2$(L)] (L = dmso, py; py = pyridine) and ECp* (E = Al, Ga), the zwitterionic species [Cp*Rh($C_5Me_4EMe_3$)] are formed and the complex [Cp*RhMe$_2$(ECp*)] has been isolated as an intermediate.[16a]

The intramolecular C–C bond activation proceeds at the Group 13 metal E and not at the rhodium center.[16b] Clearly, the electrophilicity of the aluminum is considerably increased on coordination of the Cp*Al unit,[1,2] which favors C–H activation and limits the availability of the compounds [M(AlCp*)$_n$]. The reaction of [$(Ph_3P)_3RuCl_2$] with six equivalents GaCp* quantitatively gives [Ru(GaCp*)$_6Cl_2$], the Cl ligands each bridging two of the Ga centers that surround the Ru^{II} center and thus blocking C–H activation reactions (see Supporting Information). This example suggests a route to[M(ECp*)$_n$] with $n \geq 6$.[17,18]

Experimental Section

1a: [Fe(η^6-toluene)(η^4-1,3-butadiene)] (0.100 g, 0.495 mmol) and [(AlCp*)$_4$] (0.478 g, 0.742 mmol) were suspended in toluene and heated to 80 °C for 2 h. After filtration of the orange solution and removal of the solvent in vacuo (25 °C, 10^{-2} Torr) from the filtrate, the yellow, microcrystalline residue was dissolved in warm toluene (6 mL) and the product crystallized at −30 °C over 2 h. Yield: 0.274 g (64 %). Pure **1a** can be isolated after a few minutes (Yield: 0.145 g, 35 %). M.p. 265 °C (decomp); ^{1}H NMR (C_6D_6, 250 MHz, 25 °C): δ = 2.23 (s, 6H, CH_3), 2.20 (s, 15H, CH_3), 2.09 (s, 6H, CH_3), 1.88 (s, 6H, CH_3), 1.82 (s, 30H, CH_3), 1.63 (s, 6H, CH_3), 1.04 (s, 2H, CH_2), 0.76 (s, 2H, CH_2), −19.00 ppm (s, 2H); ^{13}C{^{1}H} NMR (C_6D_6, 62.9 MHz, 25 °C): δ = 126.9 (C_5Me_5), 123.9 (C_5Me_5), 118.9 (C_5Me_5), 118.2 (C_5Me_5), 114.8 (C_5Me_5), 112.7 (C_5Me_5), 112.6 (C_5Me_5), 110.5 (C_5Me_5), 17.3 (CH_2), 15.1 (CH_2), 14.3 (C_5Me_5), 12.3 (C_5Me_5), 12.2 (C_5Me_5), 11.2 (C_5Me_5), 11.1 (C_5Me_5) 11.0 ppm (C_5Me_5); ^{27}Al NMR (C_6D_6, 65.2 MHz, 25 °C): δ = −2.5 ppm; elemental analysis: calcd (%) for $C_{50}H_{75}Al_5Fe$: C 69.28, H 8.72; found: C 69.43, H 8.84.

1b: Compound **1b** could not be obtained in pure form, but only as a mixed crystal together with **1a**. The volume of the mother liquor of the synthesis of **1a** described above was decreased and the concentrated solution kept at −30 °C for some time. Repeated fractional crystallization of the material obtained increased the amount of **1b** in the crystals. ^{1}H NMR (C_6D_6, 250 MHz, 25 °C): δ = 2.02 (s, 15H, CH_3), 1.77 (s, 15H, CH_3), 1.03–0.75 (m, 6H, CH_2),

−18.17 ppm (only the characteristic signals are listed, see Supporting Information).

Crystal Structure analyses (Oxford Excalibur 2 diffractometer): The structural solution and refinement was performed using the programs SHELXS-86 and SHELXL-97.[19] **1a**: $C_{50}H_{75}Al_5Fe$, M_r = 866.88, 0.30 × 0.25 × 0.15 mm, monoclinic, $P2(1)/n$, a = 10.930(3), b = 20.473(5), c = 21.400(6) Å, α = 90, β = 94.71(2), γ = 90°, V = 4772(2) Å^3, Z = 4, ρ_{calcd} = 1.206 g cm^{-3}, $\lambda(Mo_{K\alpha})$ = 0.71073 Å, T = 103(2) K, 34170 reflections measured (8437 unique), R(int) = 0.0846, $R1$ = 0.0986, $wR2(F^2)$ = 0.1752. The atoms H1 and H2 could be localized; they were taken into account for the subsequent structural refinement. **1b**: Mixed crystals of **1a**/**1b** $C_{50}H_{75}Al_5Fe$, M_r = 866.88, 0.20 × 0.15 × 0.10 mm, monoclinic, $C2/c$, a = 17.539(6), b = 16.314(5), c = 33.601(17) Å, α = 90, β = 98.61(4), γ = 90°, V = 9506(7) Å^3, Z = 8, ρ_{calcd} = 1.211 g cm^{-3}, $\lambda(Mo_{K\alpha})$ = 0.71073 Å, T = 105(2) K. 29009 reflections measured (8391 unique), R(int) = 0.0859, $R1$ = 0.1396, $wR2(F^2)$ = 0.1798. The structural solution and refinement was done under the assumption of a disorder of both isomers on the positions in the unit cell. Both parts of the disordered structure could not be freely refined (AFIX 109) and their relative amounts were determined to be: **1a** (0.51796) and **1b** (0.48204). No bridging H atoms could be localized because of the disorder. **2a**: $C_{50}H_{75}Al_5Ru$, M_r = 912.11 0.20 × 0.15 × 0.20 mm, monoclinic, $P2(1)/n$, a = 11.932(2), b = 24.352(5), c = 16.903(3) Å, α = 90, β = 96.84(3), γ = 90°, V = 4876.2(17) Å^3, Z = 4, ρ_{calcd} = 1.242 g cm^{-3}, $\lambda(Mo_{K\alpha})$ = 0.71073 Å, T = 103(2) K. 17067 reflections measured (8286 unique), R(int) = 0.0767, $R1$ = 0.1256 und $wR2(F^2)$ = 0.1157. CCDC-257541 (**1a**), CCDC-257542 (**1b**), and CCDC-257543 (**2a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

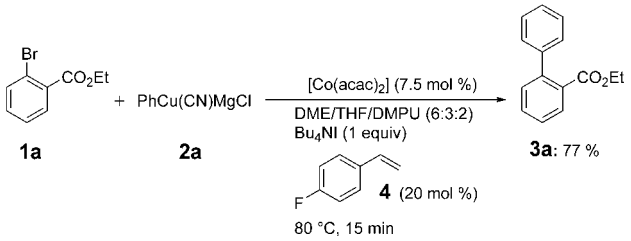
Cross-Coupling Reactions

Cobalt(II)-Catalyzed Cross-Coupling of Polyfunctional Aryl Copper Reagents with Aryl Bromides and Chlorides**

*Tobias J. Korn and Paul Knochel**

There are now a number of efficient experimental procedures available for palladium- and nickel-catalyzed cross-coupling reactions of aromatic organometallic reagents with aryl halides.[1,2] However, the high cost of palladium and the required phosphine ligands, as well as the high toxicity of nickel catalysts, led us to explore the use of alternative metals for such coupling reactions. Following the pioneering work of Kochi and co-workers and others,[3] we found recently that functionalized aryl copper reagents smoothly undergo cross-coupling with aryl iodides in the presence of $[Fe(acac)_3]$ as the catalyst.[4] In contrast to the elegant method of Fürstner and co-workers,[5] in our case only aryl iodides could be used; aryl bromides and chlorides did not react.

To extend the scope of this cross-coupling reaction, we examined other metal salts as catalysts. We reported recently the cobalt(II)-catalyzed cross-coupling of allylic chlorides with dialkyl zinc reagents[6] and of heteroaromatic chlorides with aromatic and heteroaromatic Grignard reagents.[7] Other cobalt-catalyzed reactions have also been discovered recently by the research groups of Cahiez,[8] Oshima,[9] and Gosmini.[10] Preliminary experiments showed that $[Co(acac)_2]$ catalyzes efficiently the cross-coupling of aryl copper derivatives with aryl bromides and chlorides; the reaction is therefore complementary to the recently reported iron-catalyzed process.[4] As a test reaction, we examined the coupling of ethyl 2-bromobenzoate (**1a**; 1 equiv) with the phenylcopper reagent **2a** (3 equiv),[11] which was prepared by the reaction of PhMgCl with CuCN·2 LiCl[12] in a 2:1 mixture of DME/THF at 80 °C. In the absence of the catalyst, no reaction was observed after 4 h; the desired product **3a** was only detected after 24 h.[13] When $[Co(acac)_2]$ (10 mol %) was added, a conversion of 46 % was observed after 15 min; however, the conversion increased to just 49 % within the next 4 h of reaction time. A significant improvement was observed upon the addition of Bu_4NI (3 equiv),[14] which led to a conversion of 81 % after 21 h. The addition of 4-fluorostyrene (**4**; 20 mol %), which was known to promote cross-coupling reactions,[15] was not effective alone,[16] but in combination with Bu_4NI a conversion of 100 % was reached within 21 h. The use of DMPU[17] as a cosolvent also led to a considerable rate improvement. A conversion of 100 % was now observed after 15 min at 80 °C, with the desired product **3a** formed as the sole product. Under optimized reaction conditions (**1a** (1 equiv), **2a** (1.7 equiv), $[Co(acac)_2]$ (7.5 mol %), Bu_4NI (1 equiv), **4** (20 mol %)), the ester **3a** was isolated in 77 % yield (Scheme 1).



Scheme 1. The Co^{II}-catalyzed cross-coupling reaction of **2a** with ethyl 2-bromobenzoate (**1a**) under optimized conditions. acac = acetylacetonate, DME = 1,2-dimethoxyethane, DMPU = 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone.

The additives Bu_4NI and styrene **4** were still required in the polar solvent mixture containing DMPU, as only partial conversion was observed in their absence. We studied the scope of the reaction and found that a broad range of aryl copper reagents of type **2** reacted with a variety of aryl bromides with electron-withdrawing substituents. Thus, the 4-methoxyphenylcopper reagent **2b** underwent a smooth cross-coupling reaction with **1a** at 80 °C to afford the desired biphenyl derivative **3b** in 79 % yield (Table 1, entry 2). Aryl copper species with electron-withdrawing substituents displayed lower reactivity. However, **2c** underwent the coupling with the reactive compound **1b** at 80 °C to give ketone **3c** in 62 % yield (Table 1, entry 3). Similarly, the bromo diester **1c** reacted with various aryl copper derivatives of low reactivity, such as **2d** or **2e**; in these cases the cross-coupling products **3d** and **3e** were isolated in 65 and 54 % yield, respectively (Table 1, entries 4 and 5). The heterocyclic copper reagent **2f** reacted rapidly with **1b** at 80 °C to give the substituted pyridine **3f** in 62 % yield (Table 1, entry 6). As mentioned above, aryl copper compounds with an electron-donating substituent displayed high reactivity in these cross-coupling reactions. Thus, **2b** reacted with **1b** within 1 h at room temperature (89 % yield; Table 1, entry 7). 4-Bromobenzophenone (**1d**) also underwent complete conversion at 25 °C within 7.5 h (73 % yield; Table 1, entry 8). However, 3-bromobenzophenone (**1e**) reacted only slowly in the desired cross-coupling; the expected product **3i** was obtained in 25 % yield after 24 h at room temperature (Table 1, entry 9). Interestingly, the corresponding cyano-substituted aryl copper derivatives **2g–i** reacted smoothly with **1b** to provide ketones **3j–l** in 74–90 % yield (Table 1, entries 10–12). A methyl ketone is an especially sensitive functionality, which can be readily deprotonated by numerous organometallic species. Remarkably, we found that 2-bromoacetophenone (**1f**) reacted smoothly with various aryl copper reagents to

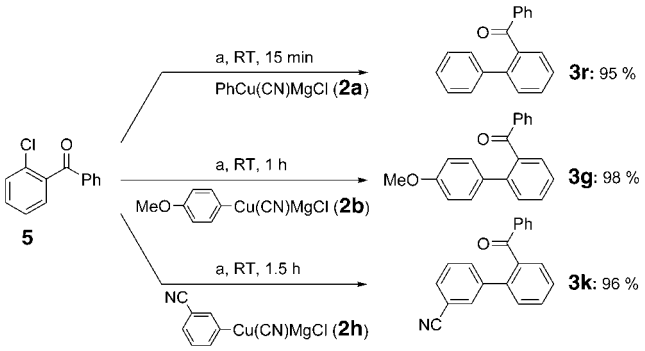
[a] The copper reagent is better represented as ArCu(CN)MgCl. [b] Yield of analytically pure product. RT = room temperature.

give the polyfunctional ketones **3m–p** in 70–90% yield (Table 1, entries 13–16). An unexpected reactivity difference was observed between the 9-phenanthrylcopper reagent **2k** and the 1-naphthylcopper reagent **2j**. Whereas **2k** reacted with **1f** within 15 min at room temperature, **2j** required a reaction time of 15 h at the same temperature (Table 1, entries 15 and 16). Finally, we found a remarkable compatibility of the reaction conditions with an aldehyde functionality. Thus, 2-bromobenzaldehyde (**1g**) reacted readily with **2a** to provide 2-phenylbenzaldehyde (**3q**) in 42% yield (Table 1, entry 17).

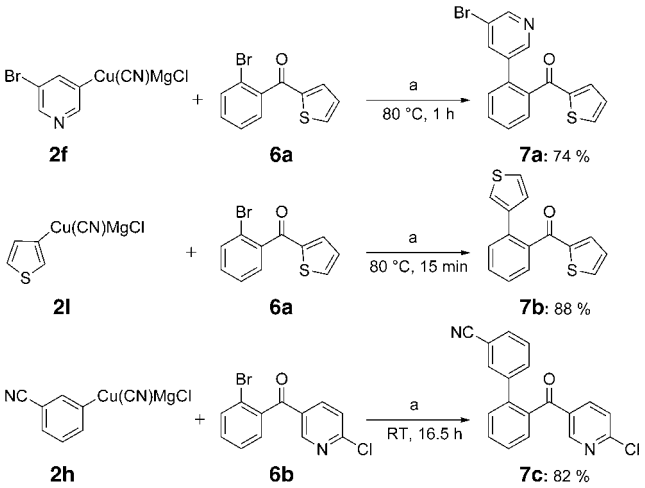
The excellent reactivity of aryl bromides with electron-withdrawing substituents led us to examine cross-coupling reactions with aryl chlorides. The reaction of 2-chlorobenzophenone (**5**) with the aryl copper compounds **2a**, **2b**, and **2h** proceeded smoothly at 25 °C within 15 min to 1.5 h under our typical reaction conditions and furnished the expected ketones **3r**, **3g**, and **3k** in almost quantitative yield (Scheme 2).

In further experiments to establish the scope of this method, we investigated the cross-coupling of bromoketones **6a**,**b** with heterocyclic substituents. An efficient cross-coupling reaction took place with **2h**, as well as with the heteroaromatic copper reagents **2f** and **2l**; the products **7a–c** were formed in 74–88% yield (Scheme 3).

In summary, we have shown that $[Co(acac)_2]$ catalyzes the cross-coupling of functionalized aryl copper reagents with a variety of chloro- and bromoaryl ketones and bromoaryl



Scheme 2. Cobalt-catalyzed cross-coupling reactions of 2-chlorobenzophenone (**5**) with aryl copper compounds: a) **5** (1 equiv), **2** (1.7 equiv), $[Co(acac)_2]$ (7.5 mol%), DME/THF/DMPU (3:2:1), **4** (20 mol%), Bu_4NI (1 equiv).



Scheme 3. Cobalt-catalyzed cross-coupling reactions of heterocycle-substituted bromoaryl ketones **6** with heteroaryl and aryl copper compounds: a) **6** (1 equiv), **2** (1.7 equiv), $[Co(acac)_2]$ (7.5 mol%), DME/THF/DMPU (3:2:1), **4** (20 mol%), Bu_4NI (1 equiv).

esters in a DME/THF/DMPU solvent mixture in the presence of the promoters 4-fluorostyrene and Bu_4NI. The reaction leads to polyfunctional biphenyl derivatives and heterocyclic analogues. The remarkable functional-group compatibility of organocopper reagents with esters, ketones, and even aldehydes should make this cross-coupling method especially attractive for multistep syntheses, as it should be possible to avoid the extensive use of protecting groups.

Experimental Section

Typical procedure: **3j**: 4-Bromobenzonitrile (309 mg, 1.70 mmol) was added to *i*PrMgCl·LiCl (1.73 mL, 1.70 mmol, 0.98 M in THF) at −20 °C in a 25-mL Schlenk tube equipped with a magnetic stirring bar and a septum. The reaction mixture was warmed to 0 °C and stirred at this temperature for 2 h. A solution of CuCN·2 LiCl (1.9 mL, 1.9 mmol, 1 M in THF) was then added, and the mixture was stirred for an additional 10 min. DME (6.0 mL), DMPU (2.0 mL), Bu_4NI (370 mg, 1.00 mmol), 4-fluorostyrene (25 mg, 0.20 mmol), $[Co(acac)_2]$ (19.3 mg, 0.075 mmol), and 2-bromobenzophenone (261 mg, 1.00 mmol) were then added, and the reaction mixture was stirred for 0.5 h at room temperature, then quenched with a saturated, aqueous solution of NH_4Cl/NH_3 (9:1; 50 mL). The organic phase was washed a second time with a saturated, aqueous solution of NH_4Cl/NH_3 (9:1; 50 mL), and the combined aqueous phases were extracted with EtOAc (3 × 40 mL). The combined organic phases were washed with brine (50 mL), dried over $MgSO_4$, and filtered, and the solvent was evaporated in vacuo. Purification by flash chromatography on silica gel (pentane/diethyl ether 4:1) furnished **3j** as a light-yellow solid (256 mg, 0.90 mmol, 90%; m.p.: 91.4–92.3 °C).

[17] Besides DMPU, 1-methyl-2-pyrrolidinone (NMP) and *N*,*N*-dimethylacetamide (DMAC) also led to a rate acceleration when used as cosolvents, but DMPU showed the strongest effect.

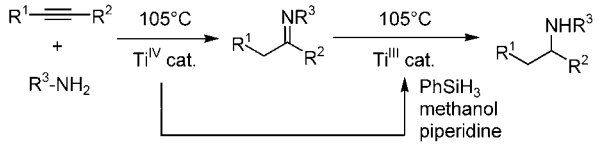
Homogeneous Catalysis

Hydroamination/Hydrosilylation Sequence Catalyzed by Titanium Complexes**

*Andreas Heutling, Frauke Pohlki, Igor Bytschkov, and Sven Doye**

Over the past few years, strategies for the one-pot synthesis of interesting target molecules that require more than one chemical transformation have gained increasing attention. In this context, the use of a single catalyst for a combination of different catalytic reactions (multifunctional catalysis) is one of the most promising approaches.[1] One way to realize a corresponding strategy is the combination of different transitions-metal-catalyzed reactions into a sequence. In this case, a single catalyst that mediates several consecutive reactions is used for the one-pot process. Each individual reaction is initiated by a change of the reaction conditions or the addition of a new reagent.[2]

During the last few years, we have been intensively involved in the development of the Ti-catalyzed hydroamination of alkynes, which converts alkynes and primary amines into imines in the presence of Ti^{IV} catalysts.[3] The corresponding imine products were usually reduced with stoichiometric amounts of $NaBH_3CN$ to give secondary amines. Herein, for the first time, we describe a sequential combination of the Ti-catalyzed hydroamination of alkynes with the Ti-catalyzed reduction of imines.[4] By this new reaction sequence, alkynes and primary amines can be converted into secondary amines in a fully catalytic one-pot protocol employing a single Ti-precatalyst (Scheme 1).[5]



Scheme 1. Ti-catalyzed hydroamination/hydrosilylation sequence.

The catalytically active species involved in the Ti-catalyzed reduction (hydrogenation, hydrosilylation) of imines is presumed to be a Ti^{III} hydride.[4b] This species is generated in situ immediately prior to the reaction from a Ti^{IV} precursor

and a reducing agent. Since a Ti^{IV} species remains in the reaction mixture obtained after a successful hydroamination of an alkyne, we assumed that this Ti^{IV} compound can also be converted into a Ti^{III}-species, which then catalyzes the reduction of the generated imine. To verify this assumption, a mixture of 1-phenylpropyne (**1**) and aniline (**2**) in toluene was heated to 105 °C for 24 h in the presence of 10 mol % $[Cp_2TiMe_2]$.[6] Subsequently, phenylsilane (3 equiv), piperidine (40 mol %), and MeOH (40 mol %)[4d] were added, and the resulting mixture was heated to 105 °C for additional 24 h.[6] After aqueous workup (decomposition of NSi compounds), the corresponding secondary amine **12a** was isolated in 85 % yield [Eq. (1), Table 1, entry 1].

With this promising result in hand, we performed a number of hydroamination/hydrosilylation sequences under identical reaction conditions employing 1-phenylpropyne (**1**) and various amines [Eq. (1), Table 1]. We found that aromatic amines (entries 1–8) gave comparable good results as long as they do not possess an *ortho* substituent. While the hydrosilylation reaction still proceeded slowly in the case of 2-methylaniline (**7**; 57 % yield after a hydrosilylation reaction time of 48 h), no successful reduction was observed when the sterically very demanding 2,6-dimethylaniline (**8**) was used. However, worse results were obtained with alkyl amines (entries 9–12). In these cases, under the employed reaction conditions, the desired secondary amines could be isolated in only modest to poor yields, even when the reaction time for the hydrosilylation was extended to 48 h.[7] Since the regioselectivity of the reaction sequence is generally determined during the hydroamination step, the ratios of the regioisomeric secondary amines are very good to excellent, as expected.[3] Additionally, two reaction sequences were performed with the *ansa* complex **22**[8] as the precatalyst (entries 5, 11). Both reactions also led to the formation of the desired secondary amines.

We also investigated the performance of various alkynes in Ti-catalyzed hydroamination/hydrosilylation sequences. For that purpose, we compared several reaction sequences employing 4-methylaniline (**5**) and the alkynes **1** and **23**–**29** [Eq. (2), Table 2]. We found that 1-phenylpropyne derivatives (**1**, **23**, **24**) and terminal alkynes (**25**–**27**) were very good substrates, while sterically more demanding alkynes such as diphenylacetylene (**28**) and 3-hexyne (**29**) gave worse results. In the case of highly reactive terminal alkynes, very good results were obtained in the presence of only 5 mol % of the catalyst. Furthermore, only short reaction times (3 h) were necessary for the hydroamination step. The observed regioselectivities were again in the expected ranges for the various substrates.[3]

Finally, we focused on intramolecular reaction sequences of aminoalkynes **37** and **38** [Eq. (3), Table 3]. In addition to $[Cp_2TiMe_2]$ and **22** we also employed the chiral catalysts [(*S*,*S*)-(ebthi)$TiMe_2$] (**41**)[4] and (*R*,*R*)-**42**[9] (ebthi = ethylene-1,2-bis(η^2-4,5,6,7-tetrahydro-1-indenyl). The expected cyclic secondary amines **39** and **40** were obtained in modest to good yields in all cases, and the products were generated in enantiomerically enriched form (up to 66 % *ee*) when [(*S*,*S*)-(ebthi)$TiMe_2$] (**41**) and (*R*,*R*)-**42** were used as precatalysts.[10,11]

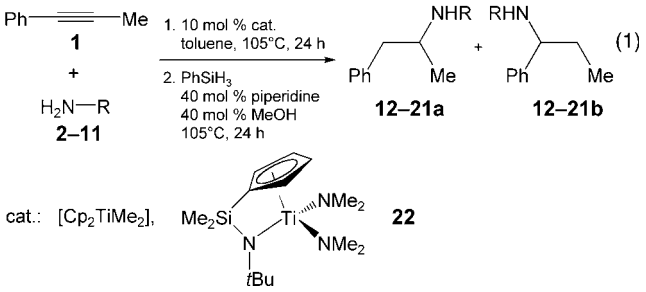

Table 1: Intermolecular Ti-catalyzed hydroamination/hydrosilylation sequence employing various amines [Eq. (1)].

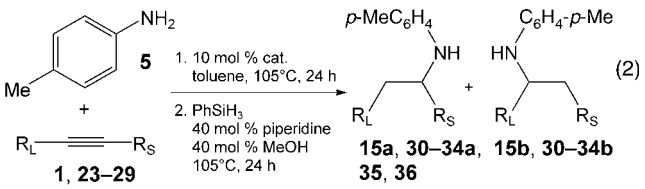
12	 **11**	$[Cp_2TiMe_2]$	11[d] (**21a**/**b**)	92:8

[a] Reaction conditions: 1) alkyne **1** (2.40 mmol), amine (2.64 mmol), $[Cp_2TiMe_2]$ (0.33 mol L^{-1} in toluene, 0.24 mmol, 10 mol %), toluene (0.28 mL), 105 °C, 24 h; 2) $PhSiH_3$ (7.20 mmol), piperidine (0.96 mmol, 40 mol %), MeOH (0.96 mmol, 40 mol %), 105 °C, 24 h. Yields refer to isolated compounds. Reaction times have not been minimized. All hydroamination reactions reached 100 % conversion. [b] GC–MS analysis prior to chromatography. [c] **22** (0.24 mmol, 10 mol %), toluene (1.0 mL). [d] The reaction time of the hydrosilylation step was 48 h.

We have shown that a sequential combination of the Ti-catalyzed hydroamination of alkynes with the Ti-catalyzed hydrosilylation of imines, which employs simple precatalysts, is an efficient and fully catalytic one-pot process for the conversion of alkynes and primary amines into secondary amines. The application of related Ti precatalysts is presently under investigation in our laboratories.



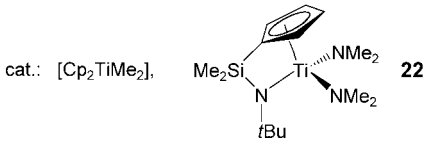


Table 2: Intermolecular Ti-catalyzed hydroamination/hydrosilylation sequence employing various alkynes [Eq. (2)].

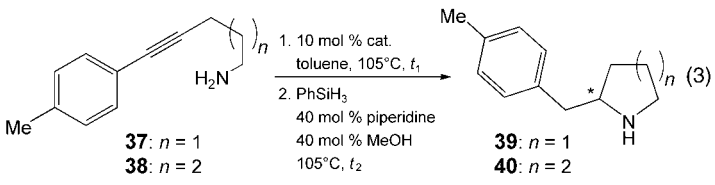
[a] Reaction conditions: 1) alkyne (2.40 mmol), amine **5** (2.64 mmol), $[Cp_2TiMe_2]$ (0.33 mol L^{-1} in toluene, 0.24 mmol, 10 mol%), toluene (0.28 mL), 105 °C, 24 h; 2) $PhSiH_3$ (7.20 mmol), piperidine (0.96 mmol, 40 mol%), MeOH (0.96 mmol, 40 mol%), 105 °C, 24 h. Yields refer to isolated compounds. Reaction times have not been minimized. All hydroamination reactions reached 100% conversion. [b] GC—MS analysis prior to chromatography. [c] The reaction time of the hydroamination step was 3 h. [d] Prior to the addition of alkyne, $[Cp_2TiMe_2]$, amine **5**, and toluene were heated to 105 °C for 90 min. [e] Reaction conducted with 5 mol% $[Cp_2TiMe_2]$, 20 mol% piperidine, and 20 mol% MeOH. [f] Reaction conducted with **22** (0.24 mmol, 10 mol%) and toluene (1.0 mL). [g] Small amounts of the imine that corresponds to amine **33b** were observed, **a**/**b** (including imine) 69:31.

Experimental Section

A Schlenk tube equipped with a Teflon stopcock and a magnetic stirring bar was charged with 1-phenylpropyne (**1**, 279 mg, 2.40 mmol), 4-methylaniline (**5**, 283 mg, 2.64 mmol), $[Cp_2TiMe_2]$ (0.72 mL, 0.33 M in toluene, 0.24 mmol, 10.0 mol%), and toluene (0.28 mL). The resulting mixture was heated to 105 °C for 24 h. The brown mixture was then cooled to room temperature, and phenylsilane (0.89 mL, 7.20 mmol), piperidine (95 μL, 96 mmol), and methanol (39 μL, 0.96 mmol) were added. The mixture was heated to 105 °C for further 24 h, cooled to room temperature, diluted with Et_2O (25 mL), and poured into 1N aqueous NaOH (25 mL). After this mixture had been stirred at 25 °C for 20 h, the organic layer was separated. The aqueous layer was extracted with Et_2O (4 × 30 mL), and the combined organic layers were dried with $MgSO_4$. After concentration under vacuum, the residue was purified by flash chromatography (SiO_2).



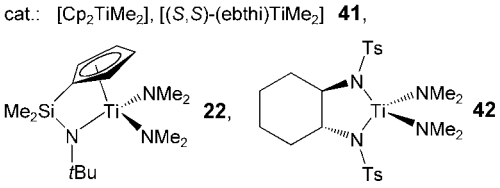


Table 3: Intramolecular Ti-catalyzed hydroamination/hydrosilylation sequence employing various aminoalkynes [Eq. (3)].

Entry	*n*	Cat.	t_1 [h]	t_2 [h]	Yield [%][a]	*ee* [%][b]

Cluster Compounds

A Molecular Silicon Cluster with a "Naked" Vertex Atom**

*David Scheschkewitz**

Silicon clusters have been the subject of intense research efforts[1] owing to the ubiquitous role of elemental silicon in a variety of electronic and optical applications, such as integrated circuits, photovoltaic cells, and optical sensors.[2] In fact, the optical properties of many silicon-based materials depend to a large extent on the presence of small- to medium-sized, partially hydrogenated clusters within the surrounding matrix of bulk silicon. Luminescence phenomena in porous silicon, for instance, have been attributed to the photoexcitation of such clusters.[3,4]

The difficulties in the structural characterization of these compounds could be circumvented by the synthesis of discrete molecular derivatives. Advances in the preparation of molecular germanium and tin clusters with "naked" (unsubstituted) vertices have been recently summarized.[5] Indeed, in the case of silicon's higher homologues a few examples have been prepared.[6] Whereas a variety of alkyl-terminated, medium-sized silicon clusters have been characterized by electron microscopic techniques,[7] small discrete molecular clusters are known only as either totally unsubstituted Zintl-type anions[8] or fully substituted deltahedral derivatives of the type Si_nR_n.[9] Theoretical studies predict interesting structural motifs for their elusive partially substituted congeners.[10]

Reductive dehalogenation of a divalent species in the presence of $GeCl_2$ had proven successful for the preparation of the germanium cluster Ge_6R_2 as reported by Power and coworkers.[6c] Unfortunately, the instability of divalent silicon compounds renders such an approach unsuitable.[11] On the other hand, the recently reported disilenides, analogues of vinyl anions, should be good precursors for multiply unsaturated silicon π systems, which could subsequently rearrange to yield the desired partially substituted clusters owing to the low stability of Si=Si double bonds. The pentadiene **2** was chosen as the initial target compound, produced by treatment of $SiCl_4$ with 2 equivalents of the lithium salt of disilenide **1** (Scheme 1).[12a] Crystallization of the complex reaction mixture yielded uniform red crystals in marginal yield (< 1%).

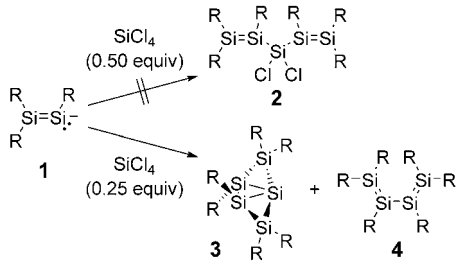

Scheme 1. Synthesis of the partially substituted silicon cluster **3** (R = Tip = 2,4,6-triisopropylphenyl).

However, a preliminary X-ray diffraction study on the crystals of mediocre quality revealed the connectivity of the partially substituted, five-vertex cluster **3** with one "naked" endohedral silicon atom.

Formation of **3** from **1** and $SiCl_4$ requires a further 2 equivalents of the disilenide **1** for reduction of the putative intermediate **2**. Indeed, the use of 4 equivalents of disilenide **1** essentially led to a 1:1 mixture of **3** and **4**, the formal oxidation product of **1** (Scheme 1). The tetrasilabutadiene **4** was identified by comparison of the ^1H and ^{29}Si NMR spectroscopic shift values with those reported in the literature.[13] Separation of the reaction mixture proved tedious, affording yields of **3** that varied between 22 and 37% of theoretical prediction.[14]

The ^{29}Si NMR spectrum shows three signals in a ratio of 2:2:1 at $\delta = 7.4$, -108.4, and -124.8 ppm. In the ^{29}Si–^1H-correlated 2D NMR spectrum only the signals at $\delta = 7.4$ and -108.4 ppm show cross-peaks to two and one aryl substituents, respectively. These findings, together with an apparent C_2 symmetry deduced from ^{13}C and ^1H NMR spectra, confirm the structural integrity of the cluster **3** in solution. Two distinct UV/Vis spectroscopic absorptions are observed at $\lambda = 365$ and 540 nm, the latter being significantly less intense.

An especially notable analytical feature of **3** was found in the EI MS data: a peak at $m/z = 1415.9$ can be assigned to Si_7Tip_6 by comparison with the calculated isotopic distribution pattern. This cluster expansion apparently takes place upon heating of the sample in the condensed phase (required for evaporation of the compound under high vacuum preceding ionization), given that no such peak was observed with milder ionization techniques. The highest mass detected by FAB MS is the molecular ion peak at $m/z = 1359.9$. This interpretation is supported by the detection of an exothermic process at 144 °C by differential scanning calorimetry of **3**. It should be noted that the hydrogenated congeners of **3** have been implied as intermediates in the chemical vapor deposition of silanes for the preparation of thin elemental silicon films.[10]

With a reproducible synthetic protocol in hand, good quality single crystals of **3** were finally obtained. X-ray crystallographic analysis (Figure 1) confirmed the structure of the partially substituted silicon cluster.[15] The distance between Si2 and Si3 (2.306(1) Å) is significantly shorter than a conventional Si–Si single bond (2.34 Å).[16] Surprisingly, the transannular distances Si2–Si5 (2.343(1) Å) and Si3–Si5 (2.337(1) Å) precisely reflect the typical Si–Si single bond length. Nevertheless, if one ignores these transannular

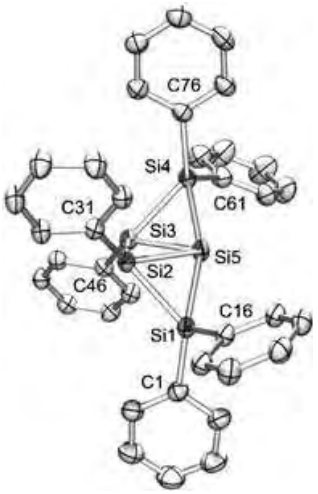

Figure 1. Molecular structure of **3** in the solid state (thermal ellipsoids at 50% probability). Isopropyl groups and protons are omitted for clarity. Selected bond lengths [Å]: Si1–Si2 2.3651(9), Si1–Si5 2.3456(9), Si2–Si3 2.3061(9), Si2–Si5 2.3430(9), Si3–Si5 2.3373(8), Si3–Si4 2.3596(9), Si4–Si5 2.3445(9), Si1–C1 1.929(2), Si1–C16 1.916(2), Si2–C31 1.917(2), Si3–C46 1.913(2), Si4–C61 1.915(2), Si4–C76 1.925(2); selected bond angles [°]: Si5-Si1-Si2 59.65(2), Si3-Si2-Si5 60.36(2), Si5-Si2-Si1 59.76(3), Si2-Si3-Si5 60.60(2), Si5-Si3-Si4 59.89(3), Si4-Si5-Si1 161.02(3).

interactions, Si2 and Si3 are only slightly pyramidal (bond-angle sums: Si2, 358.9°; Si3, 359.0°). The planes defined by Si1-Si2-C31 and Si3-Si4-C46 are almost perpendicular (torsion angle = 88.7°). The corresponding angle was determined to be 54.4° for the highly twisted disilene $(tBu_2MeSi)_2Si{=}Si(SiMetBu_2)_2$.[17]

DFT calculations at the B3LYP/6-31G(d,p) level of theory on the H-substituted parent compound **3u** were carried out to clarify the nature of the interactions that lead to the extreme distortions of **3**.[18] Interestingly, **3u** was only found to be a transition state of the ring inversion of the potential bis-homoaromatic isomer in which both silicon bridges are present on the same side of the central three-membered ring moiety.[19] The bulky substituents apparently favor **3** to an extent that the transition state becomes an energy minimum. Nonetheless, the experimental structure is reasonably well-reproduced by the calculations. Whereas the transannular distances Si5–Si2 and Si5–Si3 in **3u** are slightly longer (2.42 Å; **3**: 2.34 Å), the Si2–Si3 bond is a bit shorter (2.26 Å; **3**: 2.30 Å) than the corresponding distances in **3**. The dihedral angle H-Si2-Si3-H of 138.2° is significantly wider (**3**: C31-Si2-Si3-C46 = 112.8°) and thus is even closer to an ideal *trans* arrangement of the somewhat more pyramidal, formal sp^2-hybridized silicon centers (bond-angles sum: 354.3°).

To provide more insight into this curious bonding situation, the molecular orbitals of **3u** were calculated (Figure 2). Whereas HOMO and HOMO−1 are only separated by 0.14 eV, the difference to the next highest orbital HOMO−2 (1.34 eV) is almost ten times as large. The Heilbronner criterion for Möbius aromaticity, namely that $4n$ mobile electrons must be available, is therefore formally fulfilled.[20] Indeed, the appearance of the HOMO−1 does resemble a Möbius array, such as that calculated for *trans*-

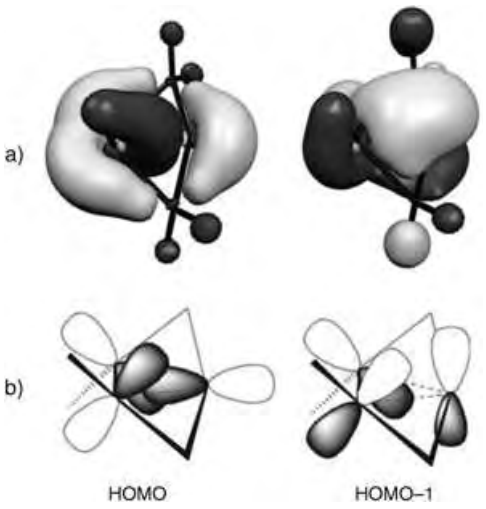

Figure 2. Molecular orbitals of **3u** as calculated at the B3LYP/6-31G-(d,p) level of theory: a) HOMO and HOMO−1, b) schematic representation of the atomic orbitals involved.

benzene.[21] The unsuccessful search for corresponding 3c-2e bonds in **3u** by NBO analysis, however, draws a picture that seemingly contradicts this interpretation of the canonical MOs. The analysis yields two degenerate orbitals with high p-character (95.26%) which are each strictly localized between two silicon atoms: Si5 and Si2, and Si5 and Si3. Therefore, an alternative description of **3** as a classical Lewis structure exclusively with 2c-2e bonds must be considered as well.

In conclusion, the first discrete partially substituted silicon cluster has been isolated and structurally characterized. Its chemical and physical features suggest that it might serve as a model for its partially hydrogenated congeners in bulk silicon materials.

Structure Elucidation

Birnbaumin A and B: Two Unusual 1-Hydroxyindole Pigments from the "Flower Pot Parasol" *Leucocoprinus birnbaumii***

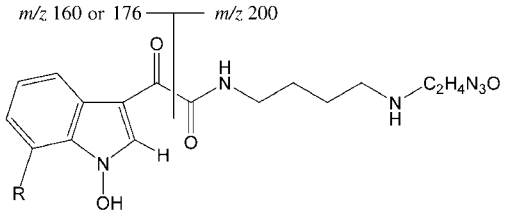
*Andrea Bartsch, Monika Bross, Peter Spiteller, Michael Spiteller, and Wolfgang Steglich**

Dedicated to Professor Timm Anke on the occasion of his 60th birthday

Occasionally the Yellow Parasol or Flower Pot Parasol (*Leucocoprinus birnbaumii* (Corda) Singer) appears in flowerpots and greenhouses, where it attracts attention because of its intense yellow color and delicate shape. It originated in the tropics and was distributed worldwide with plants and potting soil.[1] Until now, the chemical constituents of the fungus have remained unknown. Herein, we report the unusual structures of its yellow pigments, which we have named birnbaumin A and B.

To isolate the pigments, the fruit bodies were extracted carefully with methanol. Subsequent separation of the extract by preparative reversed-phase HPLC yielded birnbaumins A and B, together with L-tryptophan. Although the two pigments have similar UV/Vis spectra, the major compound, birnbaumin B, exhibits a bathochromic shift of the absorption maximum from 322 (for birnbaumin A) to 356 nm (both in MeOH). Birnbaumin A shows a $[M+H]^+$ peak in the ESI mass spectrum at m/z 361. High-resolution measurements revealed the molecular formula $C_{16}H_{20}N_6O_4$. According to ESI MS, birnbaumin B differs from birnbaumin A by an additional oxygen atom.[2] ESI MS/MS spectra of the pigments display a fragmentation of the molecules into two characteristic parts. A fragment with a peak at m/z 200 ($C_7H_{14}N_5O_2$) is common to both compounds, whereas the other fragment shows a peak at m/z 160 ($C_9H_6NO_2$) in the spectrum of birnbaumin A and at m/z 176 ($C_9H_6NO_3$) in that of birnbaumin B. The high content of Na^+ and K^+ ions detected by atom absorption spectroscopy of the samples suggests that the birnbaumins have the ability to complex metal ions.

Further insight into the structure of the birnbaumins was provided by their NMR spectra. The ^{1}H NMR spectrum ([D$_6$]DMSO; DMSO = dimethyl sulfoxide) of birnbaumin A shows signals corresponding to a 1,2-substituted benzene ring, a single hydrogen atom on an aromatic ring (at δ_H = 7.98 ppm), and a $-NHCH_2CH_2CH_2CH_2NH-$ unit. Additionally, at low field there is a sharp singlet at $\delta_H = 11.95$ ppm and a broad signal at $\delta_H = 12.32$ ppm, which we assign to OH protons. The ^{13}C NMR spectrum contains 16 signals, which correspond to four methylene and five aromatic methine groups, as well as seven quaternary carbon atoms (signals at $\delta_C = 109.8$, 121.4, 134.1, 151.4, 156.7, 161.6, and 183.8 ppm). The HMBC spectra of birnbaumin A enabled the deduction of the partial structure shown in Scheme 1, whereby an



Scheme 1. Partial structures of birnbaumins A (R = H) and B (R = OH) with the key ions observed in the ESI MS/MS spectra.

α fragmentation between the two carbonyl groups would explain the generation of the key ions with m/z 160 and 200 in the mass spectra. According to the NMR spectra and HMBC experiments, birnbaumin B contains an additional hydroxy group on the indole ring system at the 7-position, which is in agreement with the production of the fragment ions with m/z 176 and 200.

To confirm the substitution pattern, birnbaumin B was reduced with zinc in glacial acetic acid. The reductive loss of the *N*-hydroxy group causes a large shift of the 2-H signal in the ^{1}H NMR spectrum ([D$_6$]DMSO) from $\delta_H = 7.73$ to 8.59 ppm; a coupling of 2.9 Hz with the adjacent NH hydrogen atom of the indole ($\delta_H = 12.40$ ppm) also appears. Moreover, the unknown end group, $-C_2H_4N_3O$, loses its oxygen atom in the course of the reduction and is transformed by addition of two hydrogen atoms into $-C_2H_6N_3$. This transformation excludes the possibility of an amidinourea[3] or carbamoylguanidine end group. The excellent agreement of the aromatic signals of the reduction product with those of the synthetic comparison compound **1** confirms the location of the hydroxy group at the 7-position in birnbaumin B (Scheme 2).[4]

To elucidate the structure of the end group, the birnbaumins A and B were permethylated at 0 °C with diazomethane/ether in methanol to yield a dimethyl ether and a trimethyl ether, respectively. The reaction involved methylation of the hydroxy group on the nitrogen atom of the indole ($\delta_H = 12.32$ and 12.06 ppm, respectively) and the hydrogen-bonded OH group ($\delta_H = 11.95$ and 11.89 ppm, respectively), as well as of the phenol functionality in birnbaumin B. The *O*-methyl groups could be assigned by analysis of the NOESY spectra;

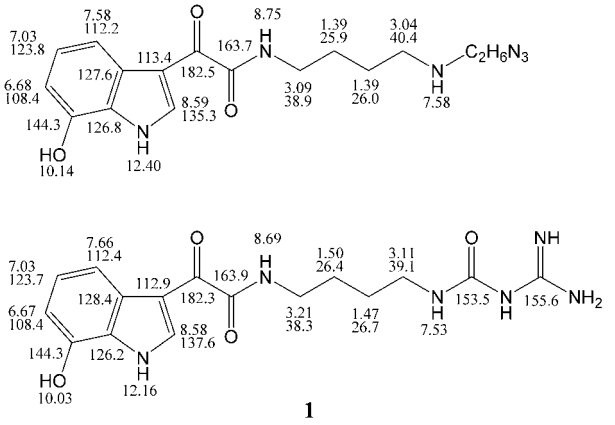
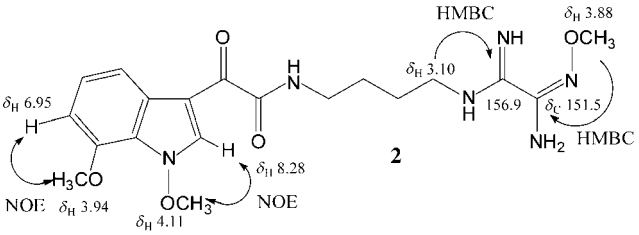


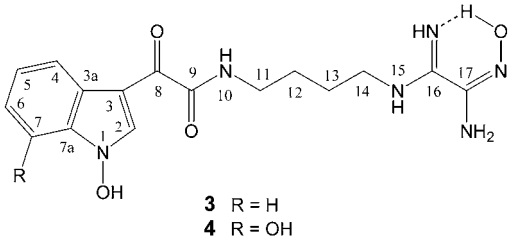
Scheme 2. Comparison of the NMR spectroscopic data (δ_H (above) and δ_C values (below, when two values are given) of reduced birnbaumin B (top) with those of the synthetic reference compound **1** (spectra recorded in [D_6]DMSO).[4]

this analysis also confirms the substitution pattern of the birnbaumins (Scheme 3). The correlation in the HMBC spectrum of the signal at $\delta_H = 3.88$ ppm for the methoxy



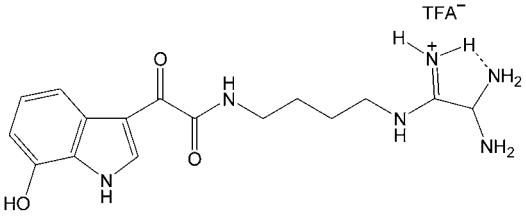
Scheme 3. Important NOE and HMBC correlations for birnbaumin B trimethyl ether (**2**; spectra recorded in [D_6]DMSO).

group positioned at the end of the side chain with the signal for an unsaturated carbon atom at $\delta_C = 151.5$ ppm is especially important, since it is consistent only with structure **2** (Scheme 3). In accordance with this deduction, the signal at $\delta_H = 3.10$ ppm for one of the terminal methylene groups shows a correlation with the carbon-atom signal at $\delta_C =$ 156.9 ppm. Analogous correlations are also observed in the spectra of birnbaumin A dimethyl ether, thus allowing the assignment of structures **3** and **4** to birnbaumins A and B. The



hydrogen bond in the terminal *N*-hydroxyamidine residue explains unambiguously the characteristic sharp singlet in the ^{1}H NMR spectra of the birnbaumins and the HMBC correlation of the OH hydrogen atom to the amidoxime carbon atom. Furthermore, the ^{1}H,^{15}N HMBC correlations for birnbaumin B are in agreement with the proposed structures (see Supporting Information).

We propose the aminal structure **5** for the reduction product, which was obtained in the form of its trifluoroacetate salt. Signals in its NMR spectra at $\delta_H = 5.27$ and $\delta_C = 58.0$ ppm indicate the presence of a methine group. The aminal group is apparently stabilized by a hydrogen bond to the adjacent amidinium functionality.



The birnbaumins are characterized by several unusual structural features. For example, to the best of our knowledge, simple *N*-hydroxyoxamidines were unknown until now, and 1-hydroxyindoles,[5] in contrast to their more stable *O*-methyl derivatives,[6] occur only rarely in nature. Similarly, only a few natural 7-hydroxyindoles have been described to date, including the coscinamides, isolated from marine sponges.[7] These indolylglyoxylic acid amides are structurally similar to birnbaumins A and B. We propose a pathway for the biosynthesis of the birnbaumins which starts from L-tryptophan, citrulline, glycine, and nitrite (see Supporting Information). Experiments to verify this hypothesis are underway.

Experimental Section

Isolation of the pigments: The fresh, deep-frozen, or lyophilized fungi were extracted on a shaker with nitrogen-saturated MeOH under the exclusion of light until complete decolorization was observed. The solvent was then evaporated under vacuum. The residue was dissolved in MeOH (HPLC-grade), prepurified on an RP-18 cartridge, and then separated by preparative HPLC (column: nucleosil 100 C-18, 7 μm, 16 × 250 mm (Macherey & Nagel); solvent A: CH_3CN/H_2O (1:9)+0.25% trifluoroacetic acid (TFA), solvent B: CH_3CN; gradient: 100% A linear in 35 min to 50% A/50% B; flow rate: 5.00 mL min^{-1}; detection: UV). The purity of the compounds was checked by analytical HPLC (column: nucleosil 100 C-18, 5 μm, 4 × 250 mm (Knauer); solvent: as above; gradient: 100% A linear in 25 min to 50% A/50% B; flow rate: 1.0 mL min^{-1}). Retention times: t_R(**4**) = 11.2 min; t_R(L-tryptophan) = 12.3 min; t_R(**3**) = 15.5 min. The pigments were stored under a nitrogen atmosphere at −20 °C. From a 42-g batch of fresh fruit bodies, 59 mg of birnbaumin A (0.14%), 228 mg of birnbaumin B (0.54%), and 58 mg of L-tryptophan (0.14%) were isolated. Yields can differ depending on the age and the condition of the fungi.

Combinatorial Catalysis

Mixtures of Configurationally Stable and Fluxional Atropisomeric Monodentate P Ligands in Asymmetric Rh-Catalyzed Olefin Hydrogenation**

Manfred T. Reetz and Xiaoguang Li*

Several years ago it was reported that monodentate phosphites,[1] phosphonites,[2] and phosphoramidites[3] derived from 2,2′-dihydroxy-1,1′-binaphthyl (BINOL) are efficient ligands in various Rh-catalyzed asymmetric olefin-hydrogenation reactions (90–99 % *ee*). These observations were surprising, because it had been accepted that chelating bidentate P ligands are generally necessary for high levels of enantioselectivity, probably due to restricted rotation in the Rh complexes. Examples of other types of monodentate P ligands are also known.[4] Preliminary mechanistic results show that two monodentate phosphites (or phosphonites) are bonded to Rh in the transition state of hydrogenation[5] when the precatalyst is $[Rh(cod)(\mathbf{1})_2]BF_4$ (cod = cycloocta-1,5-diene). Based on these results we subsequently demonstrated that the use of a mixture of two different monodentate P ligands constitutes a new and efficient approach to combinatorial asymmetric transition-metal catalysis.[6] Once a library

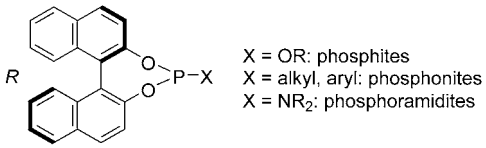
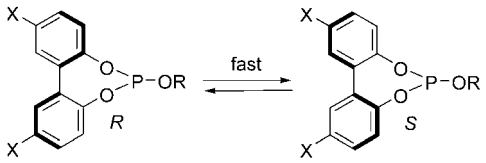
of cheap ligands has been prepared, mixtures result in high catalyst diversity and new ligands are not needed. Although each system actually contains three (pre)catalysts in an (as yet) unpredictable ratio, namely the two homocombinations $[Rh(cod)L^aL^a]BF_4$ and $[Rh(cod)L^bL^b]BF_4$, as well as the heterocombination $[Rh(cod)L^aL^b]BF_4$, enantioselectivities of 95–99% *ee* are often possible, even though the respective homocombinations in pure form result in lower enantioselectivities. Mixtures of BINOL-derived P ligands in combination with a phosphinine (phosphabenzene) or triphenylphosphine cause reversal of enantioselectivity in a few cases.[7]



1a X = OMe
b X = *t*Bu

We now show that mixtures of appropriate chiral BINOL-derived phosphonites such as (*R*)-**1b** in combination with certain achiral P ligands or configurationally fluxional atropisomeric phosphites **2** derived from the corresponding achiral biphenols are also excellent ligand systems.



2a X = H; R = CH_3
b X = H; R = CH_2Ph
c X = H; R = *t*Bu
d X = $CH(CH_3)_2$; R = CH_2Ph

Our model reaction was the Rh-catalyzed hydrogenation of β-acylamino acrylate **3a** with formation of the β-amino acid derivative **4a** [Eq. (1)][8] In addition to **2**, the achiral

3a $R^1 = R^2 = CH_3$
b $R^1 = CH_3$; $R^2 = C_2H_5$
c $R^1 = C_2H_5$; $R^2 = CH_3$
d $R^1 = n\text{-}C_3H_7$; $R^2 = C_2H_5$
e $R^1 = Ph$; $R^2 = C_2H_5$

4

phosphines PMe_3 (**5**), P*i*Pr$_3$ (**6**), and PPh_3 (**7**) as well as the achiral phosphites $P(OMe)_3$ (**8**), $P(OiPr_3)_3$ (**9**), $P(OCH_2tBu)_3$ (**10**), and $P(OPh)_3$ (**11**) were used in combination with (*R*)-**1b** (or (*R*)-**1a**). In all cases $[Rh(cod)_2]BF_4$ was treated with a 1:1 mixture of the two monodentate P ligands (Rh/ligands = 1:2) prior to hydrogenation under standard conditions.[8]

Some remarkable results are listed in Table 1. In particular, the homocombination comprising the *tert*-butylphosphonite (*R*)-**1b** alone leads to only 45% *ee* (*S*) (entry 2), whereas the heterocombination of (*R*)-**1b** and achiral **11** results in 88% *ee* (*S*) (entry 19). Selectivities higher than those obtained with the homocombinations were also observed for several other heterocombinations (entries 7, 8, 11, 16). Dramatic effects emerged when heterocombinations of phosphonite (*R*)-**1b** and configurationally labile atropisomeric phosphites **2a**, **2b**, and **2d** were used; these systems lead to enantioselectivities of 98% *ee* (*S*), 98% *ee* (*S*), and 94% *ee* (*S*), respectively (entries 20, 21, 23).

Table 1: Rh-catalyzed hydrogenation of olefin **3a**.[a] (*R*)-BINOL derivatives led to (*S*)-**4a**.

21	**1b/2b**	100	98
22	**1b/2c**	10	7
23	**1b/2d**	99	94

[a] Conditions: 60 bar H_2, CH_2Cl_2, RT, 20 h, Rh/**3a** = 1:50; L^a/L^b = 1:1; Rh/total ligands = 1:2).

A preliminary NMR study of the precatalyst system derived from (*R*)-**1b** and **2a** indicates the existence of a mixture of the two expected homocombinations $[Rh(cod)((R)\text{-}\mathbf{1b})_2]BF_4$ and $[Rh(cod)(\mathbf{2a})_2]BF_4$ in addition to the heterocombination $[Rh(cod)(R)\text{-}\mathbf{1b}(\mathbf{2a})]BF_4$ in a ratio of about 1:1:16 (plus a small amount of unidentified species). However, the situation is in fact more complicated, because those complexes containing the configurationally labile atropisomeric **2a** actually exist as fluxional diastereomers. Thus, the major component in the above mixture exists as a pair of diastereomers in equilibrium [Eq. (2)]. They interconvert so rapidly even at low temperatures that their relative amounts cannot be measured by NMR spectroscopy. In the extreme case only one diastereomeric form is present, but this is rather unlikely.

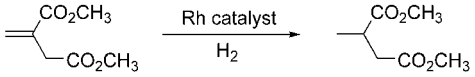
$$[Rh(cod)(R)\text{-}\mathbf{1b}(R)\text{-}\mathbf{2a}]BF_4 \rightleftharpoons [Rh(cod)(R)\text{-}\mathbf{1b}(S)\text{-}\mathbf{2a}]BF_4 \quad (2)$$

We postulate that diastereomer $[Rh(cod)(R)\text{-}\mathbf{1b}(R)\text{-}\mathbf{2a}]BF_4$ constitutes the matched case; cooperativity leads to

a higher hydrogenation rate and to enhanced enantioselectivity. To lend support to this hypothesis, we prepared and tested separately the structurally related heterocombinations composed of two BINOL-derived building blocks, namely [Rh(*R*)-**1b**(*R*)-**1a**]BF_4 and [Rh(*R*)-**1b**(*S*)-**1a**]BF_4, which are configurationally stable diastereomeric complexes. We have already shown that the former precatalyst leads to 99% *ee* (*S*),[8] and we now note that the latter is considerably less effective (40% *ee* (*S*); 84% yield). Of course, it must be remembered that these catalysts cannot be prepared in pure form; in other words, in each case it is the mixture of the two respective homocombinations and the heterocombination that defines the catalytic profile and thus determines the observed enantioselectivity.

The result of our combinatorial search[9] suggested that the heterocombination of **1b** and **2a** may be the optimal ligand system for Rh-catalyzed hydrogenations of β-acylamino acrylates in general. Therefore this combination was tested in the hydrogenation of the other substrates **3b–e** under standard conditions. Indeed, excellent results were obtained: **3b** (96% *ee* (*S*); 90% yield), **3c** (95% *ee* (*S*); 90% yield), **3d** (97% *ee* (*S*); 94% yield;), **3e** (84% *ee* (*R*); 69% yield).

Finally, we performed the hydrogenation of itaconic acid diester **12** (Rh/**12** = 1:1000; Rh/ligand = 1:2; 1.3 bar H_2; RT; 20 h) using the homocombination (*R*)-**1b**, which resulted in only 77% *ee* (*R*) [80% yield, Eq. (3)). For this reason we turned to the corresponding mixtures: The combinations (*R*)-**1b**/**2a** and (*R*)-**1b**/**11** gave essentially identical enantioselectivities (94% *ee* (*R*)) and quantitative yield.



12 **13** (3)

In summary, we have shown for the first time that in Rh-catalyzed olefin-hydrogenation, mixtures comprising a BINOL-derived P ligand in combination with an achiral P compound, or a BINOL-derived P ligand in combination with a chiral but configurationally fluxional biphenol-derived phosphite can result in high enantioselectivity. The latter system is most effective and involves two rapidly interconverting diastereomers; the presumably more reactive *R*/*R* combination shows higher activity and enantioselectivity than the diastereomeric *R*/*S* form. Apart from the theoretical interest, the present results are of practical importance because half of the ligand system is derived from cheap achiral compounds such as biphenol.[10] It remains to be seen if this combinatorial approach can be extended to other reactions and ligand types.[11,12]

Combinatorial Catalysis

The Influence of Mixtures of Monodentate Achiral Ligands on the Regioselectivity of Transition-Metal-Catalyzed Hydroformylation**

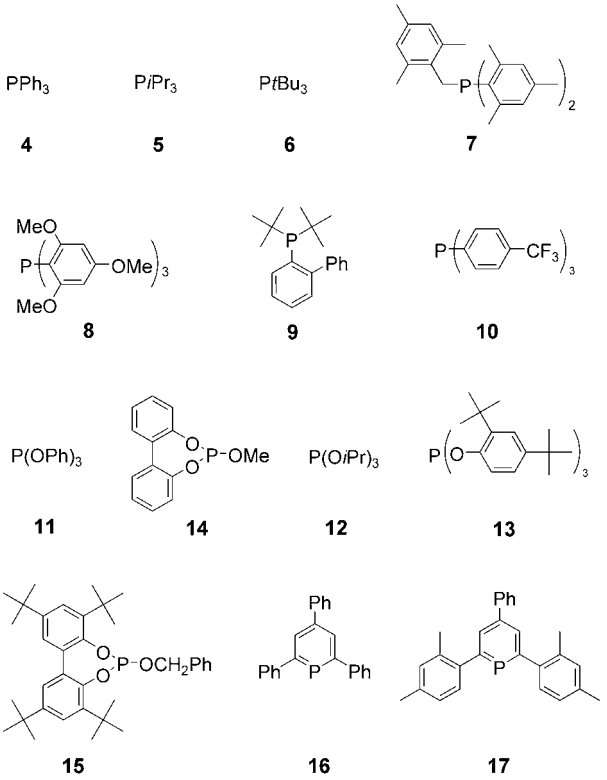
Manfred T. Reetz and Xiaoguang Li*

We recently reported that the use of a mixture of two different monodentate P ligands derived from 2,2′-dihydroxy-1,1′-binaphthyl (BINOL) in the asymmetric Rh-catalyzed hydrogenation of olefins can lead to drastically enhanced enantioselectivities relative to the performance of the corresponding pure ligand.[1,2] Since it is difficult to predict from structural considerations which combination is likely to be optimal, a combinatorial approach is necessary. In our original paper we also suggested that appropriate mixtures of achiral monodentate ligands may affect other catalytic parameters such as activity, *Z*/*E* selectivity, and/or regioselectivity in non enantioselective transformations.[1a] This possibility arises whenever the reactive metal species in the transition state of a catalytic reaction bears at least two ligands L. Thus, if ML_n is the reactive species, then $n \leq 2$. If ML_n is the precatalyst and ML_{n-1} the actual reactive species, then $n \leq 3$, etc. [Eq. (1)].

$$ML_n \rightleftharpoons ML_{n-1} + L \rightleftharpoons ML_{n-2} + L \qquad (1)$$

In the simplest case, a mixture leads to three catalysts that interconvert rapidly: the two homocombinations ML^aL^a and ML^bL^b and the heterocombination ML^aL^b. If ML^aL^b is more reactive than the two homocombinations, a new and different catalytic profile may emerge. Thus the application of ligand mixtures offers an alternative to the synthesis of new ligands.[3]

Here we illustrate this concept[4,5] by using mixtures of known monodentate P ligands to influence the regioselectivity of the Rh-catalyzed hydroformylation of *tert*-butyl methacrylate (**1**).[6] Although a vast number of achiral monodentate P ligands are potential candidates for such a study, we restricted the combinatorial search to a small library of 14 simple ligands (**4**–**17**) having different steric and electronic properties. Such parameters are known to affect the regioselectivity of hydroformylation in conventional catalyst systems with only one type of ligand (homocombinations).[7] Phosphines and phosphites have been used in hydroformylation for a long time,[7] whereas phosphinines of the type **16** and **17** were first introduced as ligands in such reactions in 1996 by Breit.[8]



In the present study $[Rh(acac)(CO)_2]$ (acac = acetylacetonate) was used as the precatalyst under typical reaction conditions (Table 1). Although not all of the theoretically possible 91 heterocombinations were tested, the 83 mixtures examined led to the discovery of some remarkable effects. It can be seen that most homocombinations lead to the preferential formation of the linear product **3** (**2**/**3** < 1). The most notable exception is phosphite **14**,[9] which leads predominantly to the branched isomer (**2**/**3** = 2.7, Table 1, entry 11). The conventional approach to increase this regioselectivity would be to prepare and test more ligands (in addition to varying other parameters). In contrast, the present method simply involves mixing ligands already on the shelf, irrespective of the performance of the homocombinations.

[a] Conditions: 60 bar $CO/H_2 = 1:1$, 50 °C, 22 h, toluene as solvent, substrate/$[Rh(acac)(CO)_2] = 200:1$, $L^a/L^b = 1:1$, Rh/total ligands = 1:2.4. [b] Hydrogenated side product.

Inspection of Table 1 reveals that the mixing process results in improved regioselectivity favoring **2** in 45 cases relative to the performance of the homocombinations.

It is of particular interest that 12 heterocombinations lead to the preferential formation of the branched product **2** (Table 1, entries 17–19, 26, 27, 35, 64, 65, 73, 92, 98, and 99), despite the fact that the corresponding homocombinations all have the opposite regioselectivity favoring the linear aldehyde **3**. This observation speaks for the catalytic role of a heteroleptic rhodium complex in which two different P ligands are bonded to the metal and not for a possibly reduced concentration of one strongly binding ligand. The most prominent heterocombination in this sense is a 1:1 mixture of triphenylphosphine (**4**) and the phosphinine **17**[8] (**2**/**3** = 8.4, Table 1, entry 27). The homocombinations of **4** and **17** lead to **2**/**3** ratios of 0.72 and 0.76, respectively (Table 1, entries 1 and 14). In some cases homocombinations of two ligands favor the branched product **2** slightly (e.g., entries 8 and 12), but the heterocombination of these two ligands enhances regioselectivity (Table 1, entry 88). Of course, in some instances the mixing of two ligands decreases regioselectivity.

Table 1 reveals another interesting phenomenon, namely that the amount of undesired side product arising from olefin hydrogenation can be influenced by the choice of the heterocombination, although the effects thus far observed are small (e.g., entries 1 and 14 vs. 27).

The selectivity in favor of the branched aldehyde **2** obtained with the heterocombination **4**/**17** was then enhanced further by varying the reaction conditions (80 bar CO/H_2 = 1:1, 40 °C, 30 h, substrate/Rh = 50:1, L^a/L^b = 1:1, Rh/total ligands = 1:2.4, toluene as solvent). This led to a **2**/**3** ratio of 20, corresponding to 95 % regioselectivity (45 % conversion). Significantly, under these conditions essentially no undesired olefin hydrogenation occurs (< 0.5 %). Previously, the highest reported regioselectivity in favor of product **2** was **2**/**3** = 1.7.[6a]

In summary, we have extended the combinatorial method of using mixtures of two chiral monodentate ligands in asymmetric transition-metal catalysis. We have shown that mixtures of achiral ligands can affect regio- and chemoselectivity. Since it is at present essentially impossible to predict which heterocombinations are likely to be effective in a given case, a combinatorial approach is required. The present study was conducted with a very small library of achiral P ligands, and we do not contend that the hits found are optimal. Moreover, a given heterocombination useful for one substrate is not necessarily effective in other cases.

In the present study the heterocombinations of ligands **4**–**17** led to only small effects in hydroformylation of styrene. The use of larger libraries encompassing a greater number of structurally different monodentate P ligands is recommended here and for other transition-metal-catalyzed reactions in which at least two monodentate ligands are bonded to the metal in the transition state. Such a combinatorial procedure provides potential catalysts with a high degree of structural diversity without the preparation of new ligands. A goal for the future is to uncover the reasons for altered regioselectivity in the hydroformylations described herein and to see if activity and/or regioselectivity of other achiral transition-metal-catalyzed processes can also be influenced by the use of mixtures of monodentate ligands.[10]

[2] Following our initial report using mixtures of BINOL-derived phosphonites and phosphites,[1a] Feringa, de Vries, et al. independently described the use of the analogous phosphoramidites: a) D. Peña, A. J. Minnaard, J. A. F. Boogers, A. H. M. de Vries, J. G. de Vries, B. L. Feringa, *Org. Biomol. Chem.* **2003**, *1*, 1087–1089; b) A. Duursma, R. Hoen, J. Schuppan, R. Hulst, A. J. Minnaard, B. L. Feringa, *Org. Lett.* **2003**, *5*, 3111–3113.

[3] A mixture of two monodentate ligands in a nonenantioselective transition-metal-catalyzed chemical transformation may also lead to other effects. For example, if the catalytic cycle involves a series of distinct consecutive events, each step may require a different ligand composition for optimal efficiency which could influence rate, regio- and chemoselectivity, and/or *Z*/*E* selectivity.

[4] In the Rh-catalyzed hydroformylation of long-chain alkenes, triphenylphosphine oxide (TPPO) is used as the ligand, but before distillation of the products triphenylphosphine is added to stabilize the Rh.[7c]

[5] Of course, additives of various types have long been used in many transition-metal-catalyzed reactions; this optimization procedure differs from the approach described herein. The idea of using two identical monodentate ligands that interact with each other through hydrogen bonding or other binding phenomenon to form a formally bidentate ligand system is also different: B. Breit, W. Seiche, *J. Am. Chem. Soc.* **2003**, *125*, 6608–6609.

Cluster Compounds

From Racemic Primary Aminoalkyl(phosphanyl)ferrocene Complexes to a Lithium–Phosphorus *closo* Cluster**

*Steffen Tschirschwitz, Peter Lönnecke, Joachim Reinhold, and Evamarie Hey-Hawkins**

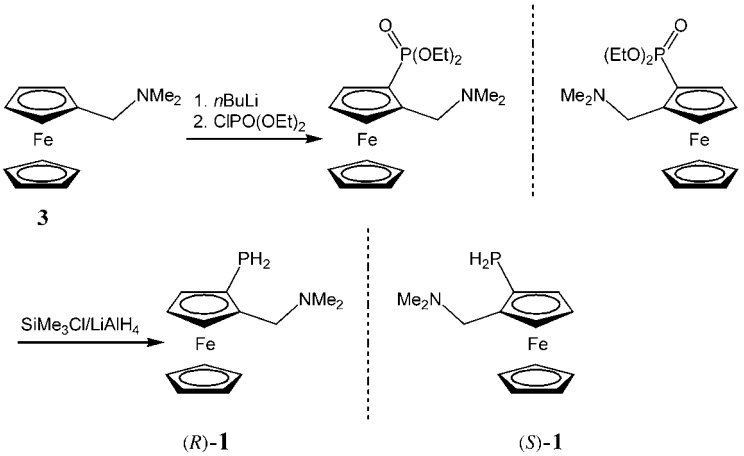
The first chiral phosphanylferrocene, (*R*)-*N*,*N*-dimethyl-1-[(*S*)-2-(diphenylphosphanyl)ferrocenyl]ethylamine ((*R*,*S*)-PPFA), was prepared by Hayashi et al.[1] in 1974 and was successfully applied in homogeneous catalysis two years later.[2] Since then a broad variety of phosphanylferrocene complexes has been synthesized and used for asymmetric reactions, such as hydrogenation, hydrosilylation, and aldol reactions.[3] Studies on the reaction mechanisms have shown that the asymmetric induction is mainly due to the planar chirality of the 1,2-disubstituted ferrocene complexes,[4] for which racemization is hardly possible.

To date only a few primary phosphanylferrocene complexes are known. Phosphanylferrocene, [Fe(η^5-C_5H_5)(η^5-$C_5H_4PH_2$)], was first prepared in 1989,[5] and 1,1′-bis(phosphanyl)ferrocene in 1994.[6] Both compounds are unstable when exposed to air and are oxidized within a few days in the solid state, and within a few seconds in solution. Primary phosphanylalkylferrocene complexes that have a methylene or ethylene bridge between the ferrocene moiety and the phosphanyl group are much more stable, these compounds include (phosphanylmethyl)ferrocene,[7] 1,1′-bis(phosphanylmethyl)ferrocene, 1,2-bis(phosphanylmethyl)ferrocene, and 1-phosphanyl-2-ferrocenylethane.[8]

The reactivity of the P–H bonds offers great synthetic potential. Reactions with carbonyl groups, alkyl and aryl halides, halogens, alkali metals, and Lewis acids are well known and provide many possibilities to produce functionalized, even chiral-phosphorus containing secondary or tertiary phosphines.[9] However, one of the most convenient methods is deprotonation of the primary phosphine by using organometallic compounds of the alkali metals as strong bases. Twofold deprotonations are also possible by this method. Especially primary silylphosphines with bulky organosilyl groups undergo such reactions affording phosphinediides that form alkali-metal–phosphorus clusters with spherical lithium–phosphorus frames.[10] Lithium phosphanides on the other hand are known as dimers or oligomers with ladder structures,[11] polymeric chains and helices of connected M–P units,[12] as well as more complex aggregates.[13]

Herein we present the syntheses of the first two chiral primary aminoalkyl(phosphanyl)ferrocene complexes: 2-(*N*,*N*-Dimethylaminomethyl)phosphanylferrocene (**1**) was obtained as a racemic mixture, and *N*,*N*-dimethyl-1-(2-phosphanylferrocenyl)ethylamine (**2**) with a d.r. of 96:4. Compound **1** readily undergoes twofold deprotonation with *n*BuLi to form the first known lithium–phosphorus cluster which has the structure and shows the electronic properties of a *closo* cluster according to Wade's rules.[14]

Primary phosphine **1** was obtained as a racemate according to Scheme 1 starting from *N*,*N*-dimethylaminomethylferrocene (**3**) in a two-step procedure in 66% overall yield. After *ortho*-lithiation, the phosphanyl group was introduced by using diethyl chlorophosphate. Reduction of the resulting phosphono compound with a 1:1 mixture of lithium aluminum hydride and chlorotrimethylsilane gave racemic **1** as a brown-red high-boiling-point liquid with a typical phosphine odor.



Scheme 1.

(*S*,*R*)-**2** was prepared similarly [Eq. (1)] with a d.r. of 96:4 (55% overall yield) starting from (*S*)-*N*,*N*-dimethyl-1-ferrocenylethylamine (**4**).

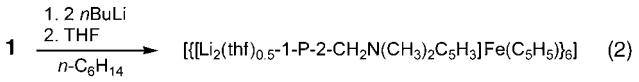
 DOI: 10.1002/anie.200462543

cenylethylamine ((*S*)-**4**).[15] The *S*,*S* diastereomer was obtained as a side product. Analogously, (*R*,*S*)-**4** was prepared in about 56% overall yield starting from (*R*)-**4** with (*R*,*R*)-**2** as a side product.

Owing to a side-group effect of the amino group, twofold deprotonation of **1** by using two equivalents of a base was comparatively easy [Eq. (2)]. The reaction occurred at room



5

temperature within a few minutes. A solution of *n*-butyllithium in *n*-hexane was added slowly to a solution of **1** in *n*-hexane. The monolithium compound precipitated immediately as a red powder, but redissolved during the addition of the second equivalent of the base with formation of the dilithium phosphinediide. Partial evaporation of the solvent gave a deep red and highly pyrophoric solid (isolated in 70% yield). A solution of the dilithium phosphinediide in THF was layered with *n*-hexane to give crystals of **5**, which were investigated by X-ray diffraction.[16] Compound **5** also precipitated upon addition of a few drops of THF to a solution of the dilithium phosphinediide in *n*-hexane.

Compound **5** forms violet hexagonal prismatic crystals. The molecular structure (Figure 1) offers some novel and unexpected characteristics. One molecule consists of six dilithium phosphinediide units. All the ferrocenyl units in one molecule are planar-chiral and have the same configuration; in the case of the depicted molecule, this is the *R* configuration (Figure 1 and Figure 2). Owing to the inversion center in the monoclinic space group *P*2/*c*, all the ferrocenyl units of the second molecule in the unit cell have *S* configuration. The phosphorus atoms of three ferrocenyl

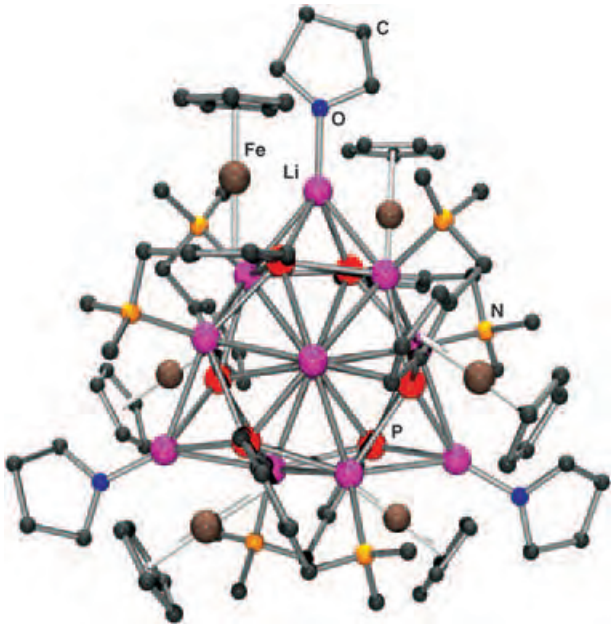


Figure 1. Molecular structure of **5**.

units and three lithium ions form a six-membered ring that has a slight chair conformation (Figure 2). Each lithium ion is additionally chelated by the dimethylamino groups of one ferrocenyl unit to form three more six-membered (Li-P-C-C-C-N) rings in a twist conformation that are anellated to the Li_3P_3 ring (Figure 2).

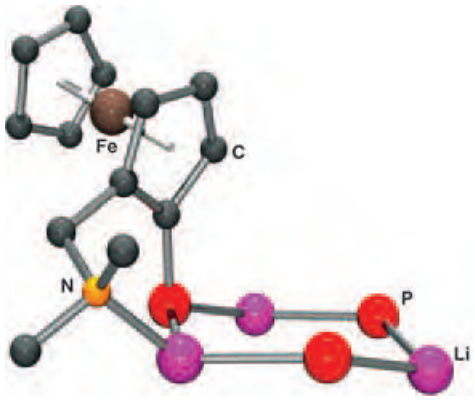

Figure 2. Fused six-membered rings in **5**.

Two of the Li_3P_3 rings are dimerized to an Li_6P_6 unit that has the structure of a distorted hexagonal antiprism in which the lithium ions have slightly distorted tetrahedral coordination geometries. Although similar structural motifs are known for lithium phosphanides and lithium amides,[17] in **5** an additional lithium ion is located in the center of the hexagonal antiprism (Figure 3) and is coordinated in a slightly distorted

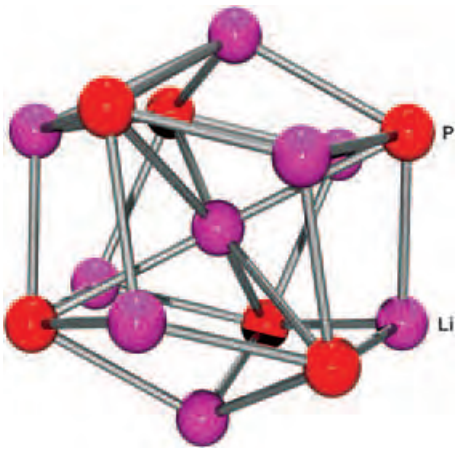

Figure 3. Li_6P_6 framework forming a distorted hexagonal antiprism with the central lithium ion and the two lithium ions capping the hexagonal faces.

octahedral fashion by the six phosphorus atoms of the Li_6P_6 unit. The central lithium ion is located on a crystallographic twofold axis. To our knowledge, **5** is the first structurally characterized lithium–phosphorus cluster with a single lithium ion in the center; alkaline-earth-metal–phosphorus clusters with alkaline-earth-metal ions in the center and

lithium–phosphorus clusters with a central Li_2O unit are known.[18]

Equally uncommon is the coordination of two additional lithium ions that cap the hexagonal faces of the Li_6P_6 antiprism (Figure 3). Owing to the shielding of these lithium ions by the ferrocenyl units they coordinate to only three phosphorus atoms and have trigonal-pyramidal coordination geometries. Three additional lithium ions are located above three of the six quadrangular Li_2P_2 faces of the distorted hexagonal Li_6P_6 antiprism. Each of these lithium ions coordinates to two phosphorus atoms and one THF molecule in a trigonal-planar fashion. Thus, the result is an $Li_{12}P_6$ cluster with 12 lithium ions and 6 ferrocenylphosphinediide units that forms an Euler deltahedron of 30 triangular planes (Figure 4).

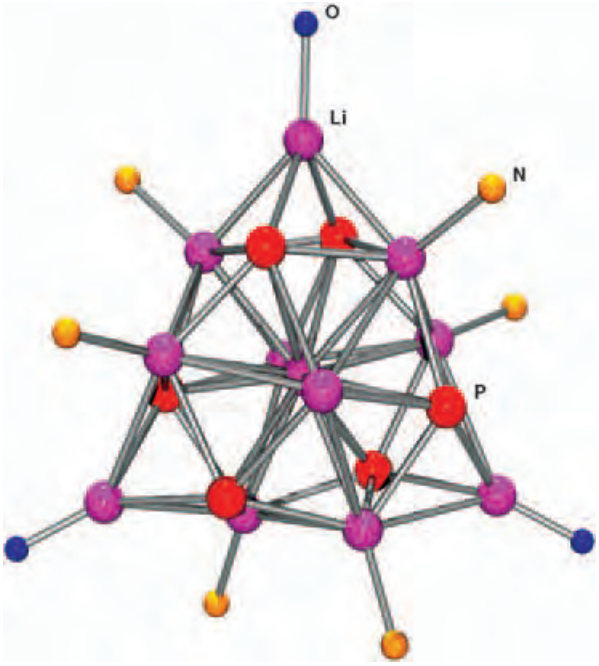

Figure 4. $Li_{12}P_6$ cluster showing all the atoms coordinating the lithium ions.

Compound **5** has the shape (30 triangular faces, $n = 17$ vertices) and electron number ($2n + 2 = 36$) of a *closo* cluster according to Wade's rules.[14] To show that **5** also has the electronic properties of a *closo* cluster, theoretical studies were carried out. To that end the $Li_{12}P_6$ cluster was considered to be composed of a 17-atom skeleton ($Li_{11}P_6$) completed by the central lithium atom. The 17 skeletal atoms occupy all of the vertices of the deltahedron. According to Wade's rule for *closo* clusters containing main-group elements, 18 (i.e., 17 + 1) skeletal bond pairs should exist. In **5**, each phosphorus atom provides four valence electrons for skeletal bonding (the fifth valence electron is involved in the terminal phosphorus–ferrocenyl bond), and each lithium atom contributes a single valence electron. This situation results in a 35-electron count, that is, one electron is missing. Usually, such an electron deficiency is compensated by a negative cluster charge. In **5**, however, the additional lithium atom in the cluster center provides the missing electron and additional stability through the electrostatic interaction between lithium and phosphorus.

To confirm this electron count, a molecular orbital (MO) calculation was performed on the model system $Li_{12}P_6H_6$, in which the terminal P–R bonds were replaced by P–H bonds (Figure 5). For this model, D_3 symmetry was adopted, which is

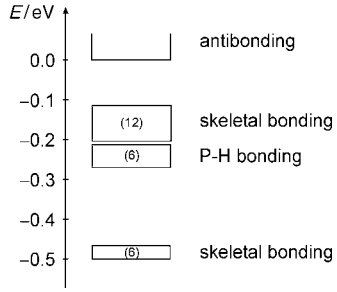

Figure 5. Number and type of molecular orbitals in various energy regions for the model compound $Li_{12}P_6H_6$ according to a DFT-B3LYP[20] calculation[21] with the minimal STO-3G basis set[22] (extended basis sets do not change the qualitative picture).

nearly that of the, albeit slightly distorted, real molecule **5**. The input structural parameters were derived as mean values from the X-ray structure. The resulting orbital energies are displayed in Figure 5. It appears that (above the core orbitals of the atoms) 24 molecular orbitals are occupied. Six of them are P–H bonding and thus not involved in skeletal bonding. The other 18 orbitals are skeletal bonding orbitals and are well separated energetically from the unoccupied antibonding orbitals; thus, the *closo* structure of the cluster is confirmed.

^{31}P and ^{7}Li NMR spectroscopy studies show that the structure of the $Li_{12}P_6$ cluster in solution is solvent-dependent. In nonpolar solvents, such as *n*-hexane, compound **5** is hardly soluble, but it dissolves when few drops of THF are added. The corresponding ^{31}P NMR spectrum shows a very broad signal at $\delta = -219$ ppm, which suggests the presence of the $Li_{12}P_6$ cluster. Upon addition of a small amount of a coordinating solvent, such as more THF, a second sharp signal at $\delta = -177.3$ ppm is observed, and, in THF alone, only this signal is observed, which we believe is due to the solvent-separated ion pairs of the dilithium phosphinediide. A similar phenomenon was revealed by ^{7}Li NMR spectroscopy investigations. A solution of **5** in *n*-hexane that contains a few drops of THF shows a broad multiplet for the $Li_{12}P_6$ cluster at $\delta =$ 0.7–5.1 ppm, this multiplet consists of several overlapping signals, and a small singlet at $\delta = 0.5$ ppm for the dilithium phosphinediide. Again the signals of the cluster decrease upon addition of THF, while the signal at $\delta = 0.5$ ppm increases. These results confirm the presence of the $Li_{12}P_6$ cluster in nonpolar solvents, while the structure is degraded in Lewis basic solvents.

Experimental Section

All procedures were performed under an inert atmosphere of pure nitrogen. The NMR spectra were recorded with an AVANCE

DRX400 spectrometer (Bruker): ^{1}H NMR (400.13 MHz): internal standard solvent, external standard TMS; ^{31}P NMR (161.9 MHz): external standard 85% H_3PO_4; ^{13}C NMR (100.16 MHz): internal standard solvent, external standard TMS; ^{7}Li NMR (155.51 MHz): internal standard solvent, external standard LiCl in D_2O. The solvents were dried and saturated with nitrogen. Compounds **3**[19] and **4**[15] were prepared by literature methods. Diethyl chlorophosphate is commercially available (ACROS Organics) and was freshly distilled before use. Elemental analyses were performed on a VARIO EL (Heraeus).

1: At room temperature *n*-butyllithium in *n*-hexane (4.8 mL, 2.05 M, 9.84 mmol, 1.2 equiv) was added to a solution of **3** (2.0 g, 8.23 mmol) in diethyl ether (20 mL). After six hours of stirring, a solution of diethyl chlorophosphate (1.7 g, 9.85 mmol, 1.2 equiv) in diethyl ether (10 mL) was added slowly at 0 °C. After a few min slow precipitation of lithium chloride was observed. After stirring overnight at room temperature, the solution was separated from the precipitate by filtration. The solvent was evaporated, and the viscous residue dried in vacuo. The reducing agent was prepared by adding a solution of chlorotrimethylsilane (2.29 g, 21.1 mmol) in THF (30 mL) to a suspension of an equimolar amount of lithium aluminum hydride (0.8 g, 21.1 mmol) in THF (10 mL) at 0 °C. The resulting suspension was stirred for 2 h at room temperature. The intermediate was dissolved in THF and slowly added to 2.5 equivalents of the reducing agent at 0 °C. After stirring overnight at room temperature, the resulting greenish suspension was hydrolyzed by slowly adding an excess of methanol (50 mL) at 0 °C. The reaction mixture was stirred for 1 h at 0 °C and then warmed to room temperature. The solvent was evaporated in vacuo, and the green-red residue extracted with *n*-pentane for 3 h. After removal of the solvent, the remaining brown-red oil was purified by fractional distillation (bath temperature: 50–60 °C, 10^{-3} mbar). The first fraction consisted mainly of residual **3**. Yield of **1**: 1.5 g (66%). ^{1}H NMR (C_6D_6): $\delta = 2.12$ (s, 6H, $N(CH_3)_2$), 3.04 (d, $^2J_{HH} = 12.0$ Hz, 1H, CH_2), 3.61 (d, $^2J_{HH} = 12.0$ Hz, 1H, CH_2), 3.72 (dd, $^1J_{PH} = 201$ Hz, $^2J_{HH} = 12.0$ Hz, 1H, PH_2), 3.86 (dd, $^1J_{PH} = 201$ Hz, $^2J_{HH} = 12.0$ Hz, 1H, PH_2), 3.90 (s, 5H, C_5H_5), 3.97 (m, 1H, C_5H_3), 4.09 (m, 1H, C_5H_3), 4.17 ppm (m, 1H, C_5H_3); ^{13}C{^{1}H} NMR (C_6D_6): $\delta = 45.0$ (s, $N(CH_3)_2$), 58.3 (d, $^3J_{CP} = 2.9$ Hz, CH_2), 66.3 (d, $^1J_{CP} = 7.6$ Hz, *i*-C1 C_5H_3), 69.2 (d, $^3J_{CP} = 3.2$ Hz, *m*-C in C_5H_3), 69.9 (s, C_5H_5), 72.9 (d, $^3J_{CP} = 2.5$ Hz, *m*-C in C_5H_3), 76.3 (d, $^2J_{CP} = 9.8$ Hz, *o*-C in C_5H_3), 89.8 ppm (d, $^2J_{CP} = 12.6$ Hz, *C*-CH_2 in C_5H_3); ^{31}P NMR (C_6D_6): $\delta = -152.2$ ppm (t, $^1J_{PH} = 200.6$ Hz); MS (FAB$^+$, 3-nitrobenzyl alcohol), *m*/*z* (%): 275 (17) $[M]^+$, 231 (100) $[M-HNMe_2]^+$, 199 (14%) $[Fe(C_5H_5)(C_5H_4CH_2)]^+$, 121 (14%) $[FeC_5H_5]^+$.

2: (*S*,*R*)-**2** was prepared analogously to **1** starting from (*S*)-**4** with a d.r. of 96:4 and an overall yield of 55%. (*R*,*S*)-**2**, was prepared similarly from (*R*)-**4** with a d.r. of 96:4 and an overall yield of 55.6%. The enantiomers (*S*,*R*)-**2** and (*R*,*S*)-**2** have identical analytical data. ^{1}H NMR (C_6D_6): $\delta = 1.18$ (d, $^3J_{HH} = 6.8$ Hz, 3H, CH_3), 2.08 (s, 6H, $N(CH_3)_2$), 3.74 (dd, $^1J_{PH} = 200$ Hz, $^2J_{HH} = 12.0$ Hz, 1H, PH_2), 3.92 (dd, $^1J_{PH} = 200$ Hz, $^2J_{HH} = 12.0$ Hz, 1H, PH_2), 3.91–4.09 ppm (m, 9H, $CH(CH_3)$, C_5H_5, C_5H_3); ^{13}C{^{1}H} NMR (C_6D_6): $\delta = 11.0$ (s, CH_3), 40.0 (s, $N(CH_3)_2$), 57.3 (d, $^3J_{CP} = 3.5$ Hz, $CH(CH_3)$), 66.3 (d, $^1J_{CP} = 6.5$ Hz, *i*-C in C_5H_3), 68.4 (d, $^3J_{CP} = 1.5$ Hz, *m*-C in C_5H_3), 69.1 (d, $^3J_{CP} = 3.1$ Hz, *m*-C in C_5H_3), 70.0 (s, C_5H_5), 75.9 (d, $^2J_{CP} = 3.2$ Hz, *o*-C in C_5H_3), 95.6 ppm (d, $^2J_{CP} = 15.2$ Hz, *C*CHMe in C_5H_3); ^{31}P NMR (C_6D_6): $\delta = -149.3$ ppm (t, $^1J_{PH} = 200.0$ Hz); MS (FAB$^+$, 3-nitrobenzylalcohol), *m*/*z* (%): 289 (17) $[M]^+$, 244 (100) $[M-HNMe_2]^+$, 186 (6) $[Fe(C_5H_5)(C_5H_5)]^+$, 121 (17) $[FeC_5H_5]^+$.

5: At 0 °C *n*-butyllithium in *n*-hexane (3.55 mL, 2.05 M, 7.28 mmol, 2 equiv) was slowly added to a solution of **1** (1.0 g, 3.64 mmol) in *n*-hexane (20 mL). Immediately after the first drop the color changed from light brown to deep red, and the monolithiated compound started to precipitate. On addition of the second equivalent of *n*-butyllithium the amount of precipitate decreased. Depending on the amount of solvent, complete dissolution could be observed. A ^{31}P NMR spectrum of the solution showed complete conversion of the starting material. After evaporation of most of the solvent, 0.73 g (70% yield) of the dilithiated compound was isolated as a red powder. The ^{31}P NMR spectrum of its THF solution showed a sharp signal at $\delta = -177.3$ ppm. Layering of the THF solution with *n*-hexane gave crystals of **5**. Crystals were also obtained by adding THF to the *n*-hexane solution of dilithiated **1**; after addition of a few drops, **5** started slowly to precipitate as an orange-red powder. More THF was added until the solid redissolved. Crystals of **5** formed slowly. In contrast to the dilithium phosphinediide, the cluster compound is hardly soluble in *n*-hexane, but soluble in a mixture of THF and *n*-hexane. ^{31}P{^{1}H} NMR: (THF): $\delta = -177.3$ ppm; (*n*-hexane/THF): $\delta = -219$ ppm (vbr); ^{7}Li NMR: (THF): $\delta = 0.5$ ppm (s); (*n*-hexane/THF): $\delta = 0.7$–5.1 ppm (m).

Cage Compounds

Rational Design of a Coordination Cage with a Trigonal-Bipyramidal Shape Constructed from 33 Building Units**

Iris M. Müller and Daniela Möller*

The rapidly growing field of supramolecular coordination chemistry can be divided into two classes according to the products formed. The polymers are already well-studied because of possible applications as new materials, heterogeneous catalysts, and ion-exchange materials.[1] The other class of supramolecular entities, discrete cage molecules, are conceived by rational design and prepared from a set of molecular building blocks that fit together such that the stoichiometry and symmetry elements of the product are predestined by the starting compounds.[2] In most of the coordination cages formed by this method the corners correspond to the metal centers, which are linked by twofold bridging ligands.[2–6] The use of building blocks that cover the faces of the cage is not as common. Triangular subunits were used to form tetrahedral, octahedral, and adamantanoid coordination cages.[2–6] Cages with lower symmetry and triangular faces have been synthesized only in the past few years.[6–10] Here we report the rational design of a coordination cage with the outer shape of a trigonal bipyramid. The characterization of an intermediate gives insight into the reaction mechanism.

To our knowledge, the formation of a trigonal bipyramid consisting of five metal centers as the corners and nine ligands as twofold connecting units (M_5L_9) has not been achieved. The reason may be the different coordination requirements of the metal centers: the equatorial centers require four coordination sites while the axial ones need only three (Figure 1 a). Nevertheless, a few systems have been reported in which the equatorial edges are not covered by ligands, and coordination cages with M_5L_6 topology resulted (Figure 1 b).[7] A related system is shown in Figure 1 c, d, in which three metal centers (depicted in gray) are coordinated by two ligands with threefold symmetry. Depending on the geometry of the central atom or atom group (usually a phenyl ring) in this ligand, a trigonal bipyramid or a trigonal-prismatic system is formed. Both types of complexes have been reported a few times.[8,9] The use of triangular subunits leads to two additional means of constructing a trigonal-bipyramidal cage (Figure 1 e, f). In the M_5L_6 system of type e again the

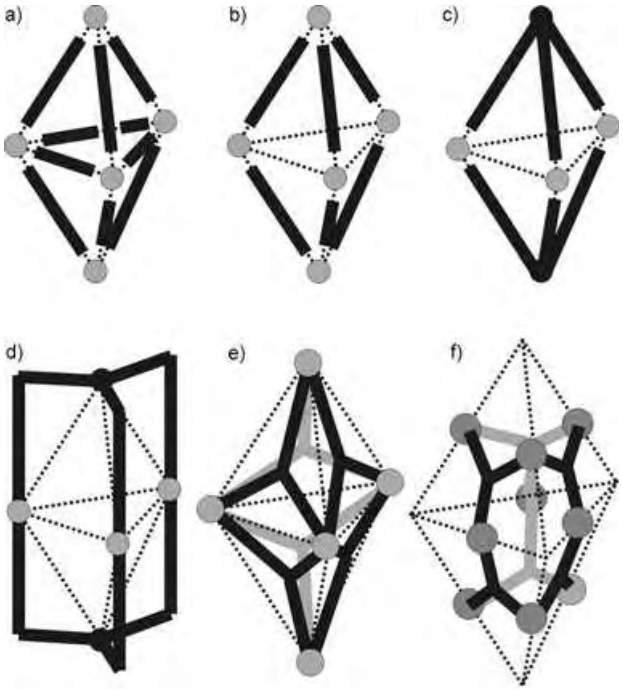

Figure 1. Schematic drawing of different trigonal-bipyramidal (tbp) cages and one related prismatic cage with different topologies; a) M_5L_9, b) M_5L_6, c) M_3L_2 (tbp), d) M_3L_2 (prismatic), e) M_5L_6, f) M_9L_6.

metal centers must adopt different coordination geometries, and again such cages have not been observed up to now. Cages in which C_3-symmetric ligands cover the six faces of the trigonal bipyramid and the metal centers represent the edges have been reported only twice. Cages with one and two metals per edge form capsules with $M_{18}L_6$ and $M_{15}L_6$ topology constructed from 24 and 21 building units, respectively.[10]

To construct larger cages with more building units, we followed this design principle, but in addition to metal centers for the linkage along the edges we used a second twofold bridging ligand. One equatorial corner in the intended trigonal bipyramid is similar to the corner in an octahedron, which we previously constructed from the ligands tris(2-hydroxybenzyl)triaminoguanidinium chloride, $[H_6L]Cl$, and sodium 5,5-diethylbarbiturate, NaHbar, which have threefold and twofold symmetry, respectively (Figure 2).[5] The obvious question is how formation of such an octahedral cage of higher symmetry can be prevented. At the corners of the octahedron close contacts between two aromatic protons were observed (2.5(2) Å).[5] The replacement of these hydrogen atoms with bulkier Br atoms should prevent the formation of the octahedral cage. Therefore, we allowed tris(5-bromo-2-hydroxybenzyl)triaminoguanidinium chloride, $[H_6Br_3L]Cl$,[11] to react with $PdCl_2$ and NaHbar under similar conditions. Dark red plates of $(Et_3NH)_6(Et_4N)_6[\{Pd_3(Br_3L)\}_6(\mu\text{-bar})_9]$ (**1**) formed; the result of the X-ray structure analysis is shown in Figure 3.[12] As expected, a trigonal bipyramid $[\{Pd_3(Br_3L)\}_6(\mu\text{-bar})_9]^{12-}$ containing a total of 33 building units was formed. Six $[Br_3L]^{5-}$ units cover the faces, and each coordinates three Pd^{2+} centers in a tridentate manner. The fourth coordination site of the square-planar metal centers is occupied by a barbiturate dianion, which bridges two adjacent faces.

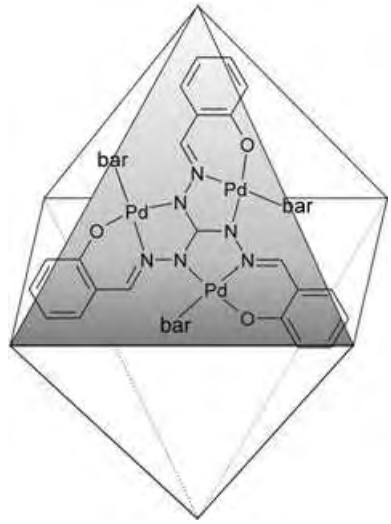

Figure 2. Schematic drawing of the octahedral cage $[(Pd_3L)_8\{\mu\text{-(bar)}\}_{12}]^{16-}$.

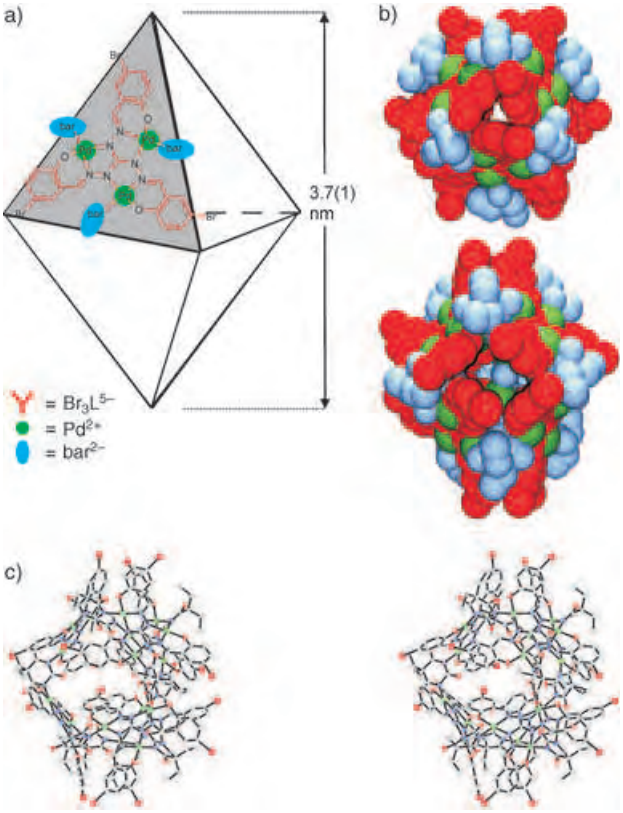

Figure 3. Crystal structure of **1**. a) Schematic drawing, b) space-filling models, and c) stereoplot (protons and counterions omitted for clarity).

The influence of the bromine atoms can be seen clearly at the corners. While at the axial corners the Br···Br distances are all equal and between 6.20(8) and 6.24(8) Å, the corners in the equatorial plane are more open with observed Br···Br distances of 5.15(8)–12.4(2) Å. The observed bond lengths

and angles in both ligands in **1** remain unchanged upon coordination, indicating that no significant distortion occurs (see Tables S1 and S2 in the Supporting Information). The cage anion in **1** is chiral; all ligands show the same screw direction of the central CN_6 core. Not surprisingly both enantiomers are present in the centrosymmetric space group *C*2/*c*. The anion in **1** has a twelvefold negative charge, and five of the counterions ($4\,Et_3NH^+$, $1\,Et_4N^+$) are present but disordered within the cage. The inside volume of the cage is estimated to be ≈ 1600 Å^3, which leaves enough space for up to 30 water molecules. Outside the cage a volume of ≈ 4500 Å^3 (or ≈ 36000 Å^3/46% of the whole unit cell) is occupied by the remaining seven cations ($2\,Et_3NH^+$, $5\,Et_4N^+$) and up to 110 disordered water molecules.

Interestingly, in addition to the dark red plates of **1** in the reaction mixture, bright red prismatic crystals of $(Et_3NH)_4(Et_4N)_4[\{Pd_3(Br_3L)\}_4(\mu\text{-bar})_4(Hbar)_4]$ (**2**) are always found. The result of their crystal structure analysis is depicted in Figure 4.[13] In one way **2** can be regarded as a tetrahedral coordination cage in which the bottom face is linked to only one and not to all three other faces. Each face is formed by a triangular $\{Pd_3(Br_3L)\}^+$ unit. The three faces that form the top of this open tetrahedron are linked by bridging bar^{2-} ligands, and the fourth face is also attached by a bridging barbiturate. In this way four Pd^{2+} centers are not involved in the linkage, and these metals each bond an $Hbar^-$ ligand at their fourth free coordination site. As a result the bottom face is not flexible but fixed in its position by strong hydrogen bonds between the protonated nitrogen atom of $Hbar^-$ and the carbonyl oxygen atom of another barbiturate ($d(N\cdots O) = 2.88(8)$ Å). The inside volume of the chiral cage is estimated to be ≈ 800 Å^3, leaving enough space for three Et_4N^+ counterions. Outside the cage a volume of ≈ 2100 Å^3 (or ≈ 4200 Å^3/31% of the whole centrosymmetric unit cell) is occupied by the remaining five cations ($1\,Et_4N^+$ and $4\,Et_3NH^+$) and roughly 40 water molecules. All bond lengths and angles in **2** fall within the expected ranges, and no significant distortions are observed (see Tables S1 and S2 in the Supporting Information).

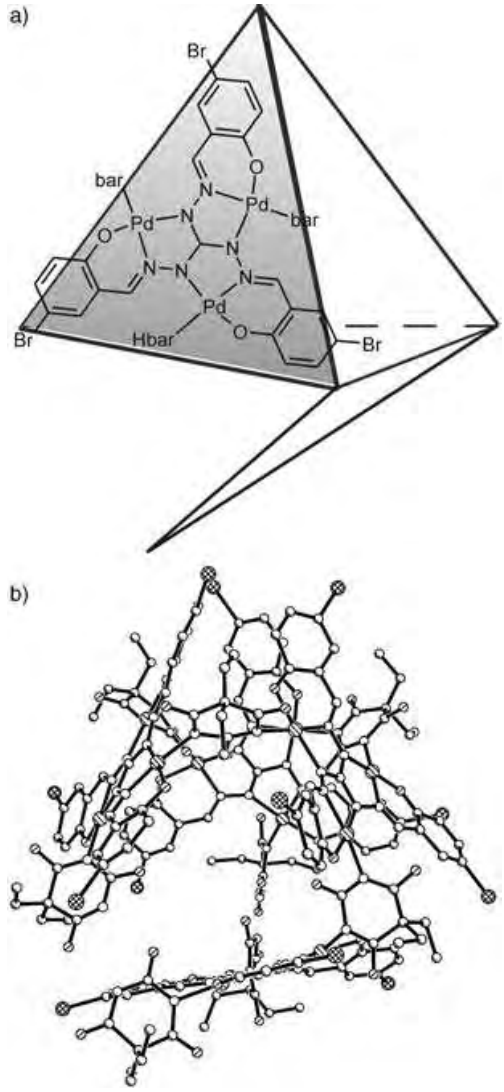

Figure 4. Crystal structure of **2**. a) Schematic drawing and b) crystal structure (protons and counterions omitted for clarity).

Cage **2** can also be seen as two-thirds of an incipient trigonal bipyramid. Only two triangular faces are missing, and all required barbiturates are already in place. Taken together with previous results, the structure of **2** provides insight into possible formation mechanism. In the first step the deprotonated ligand coordinates three square-planar metal centers. Since the free coordination sites are occupied by $Hbar^-$ ligands, the dianionic triangular building block $\{M_3(Br_3L)\}^{2-}$ results (see Figure 5a). This fragment has already been crystallized and analyzed for $M = Cu^{2+}$.[11] These units then react with each other with loss of H_2bar; this type of reaction has been confirmed under ESI conditions, again with $M = Cu^{2+}$ (see Figure 5b).[11] Linkage of three and four of these units with accompanying loss of H_2bar leads to the open trigonal pyramid and the coordination cage **2**, respectively (see Figure 5c). The subsequent introduction of two more triangular units would then lead to the formation of the trigonal bipyramid **1**.

We have succeeded in the rational, planned synthesis of the trigonal-bipyramidal coordination cage **1** with low symmetry from a set of molecular building blocks. Based on the structure of another cage compound, **2**, and previous results we suggest a possible formation mechanism.

Experimental Section

Tris(5-bromo-2-hydroxybenzyl)triaminoguanidinium chloride was prepared according to literature methods.[11] Sodium 5,5-diethylbarbiturate was purchased and used without further purification.

1 and **2**: A solution of $PdCl_2$ (48.6 mg, 0.274 mmol) and Et_4NCl (42.5 mg, 0.256 mmol) in acetonitrile (4 mL) was prepared. Solutions of tris(5-bromo-2-hydroxybenzyl)triaminoguanidinium chloride (64.7 mg, 0.0938 mmol) and sodium 5,5-diethylbarbiturate (27.6 mg, 0.134 mmol) in a mixture of acetonitrile and water (10:1, 2 mL each) were added. Then triethylamine (1 mL) was slowly diffused into the reaction mixture. After a few weeks dark red plates of **1** and red prisms of **2** formed. The two compounds were separated manually under the microscope, which resulted in lower yields of 30.8 mg (3.5×10^{-3} mmol, 23.5% relative to NaHbar) for **1** and 40.9 mg (6.5×10^{-3} mmol, 38.8% relative to NaHbar) for **2**. Elemental analyses

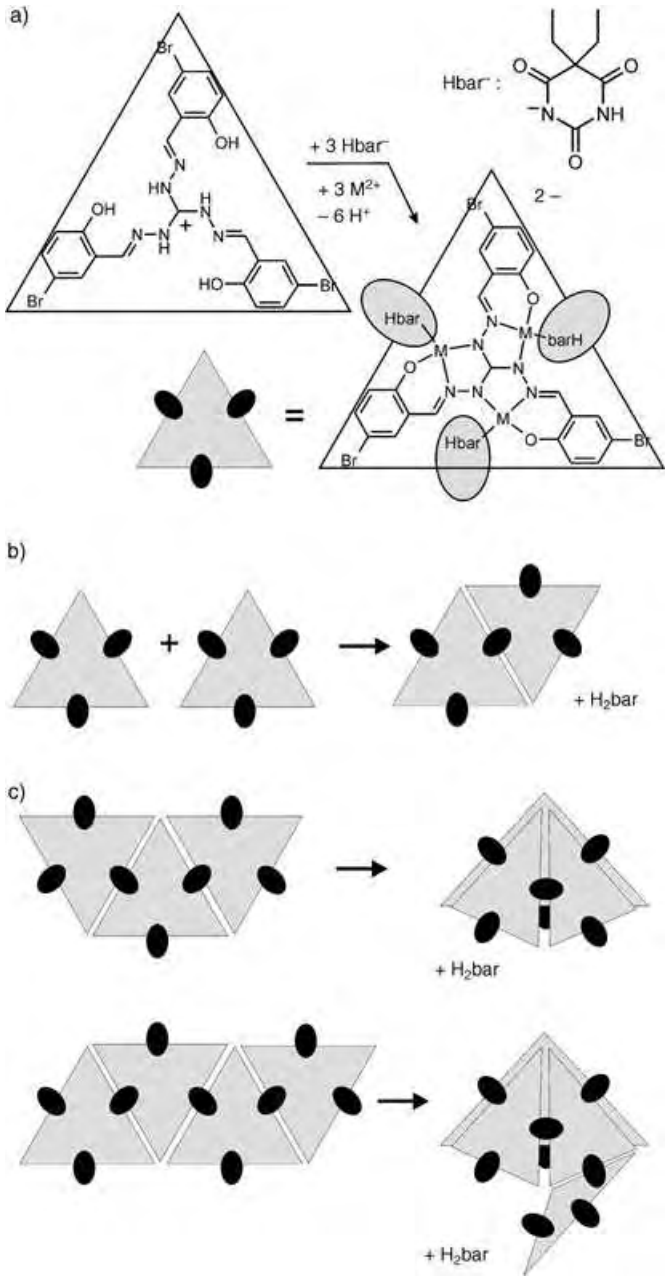

Figure 5. Possible reaction mechanism for the formation of coordination cages **1** and **2** see text for details.

[%] calcd for $C_{288}H_{378}N_{66}O_{45}Br_{18}Pd_{18}\cdot 140\,H_2O$, **1**, (11360.47): C 30.45, H 5.84, N 8.14, Pd 16.86; found: C 30.26, H 4.99, N 8.08, Pd 17.01. Elemental analyses [%] calcd for $C_{208}H_{276}N_{48}O_{36}Br_{12}Pd_{12}\cdot 30\,H_2O$, **2**, (6801.07): C 36.73, H 4.98, N 9.89, Pd 18.78; found: C 36.83, H 4.16 , N 10.02, Pd 18.45.

X-ray analysis: Intensity data were collected for **1** on a Nonius Kappa CCD ($Mo_{K\alpha}$ rotating anode) and for **2** on a Siemens SMART CCD ($Cu_{K\alpha}$ rotating anode), and in both cases the ω-scan method was employed. All data were corrected for Lorentz and polarization effects. The structures of **1** and **2** were solved by direct methods (SHELXS-97)[14] and refined by a full-matrix least-squares refinement procedure (SHELXL-97).[15] All protons were placed at geometrically estimated positions. Due to the large number of disordered counterions and solvent molecules outside the cages and the resulting low ratio of reflections to parameters, we decided to correct the X-ray data for their influence with the SQUEEZE routine in PLATON.[16] CCDC 258971–258972 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

$Ga_{10}Br_{10}$(4-*tert*-Butylpyridine)$_{10}$: A Mixed-Valent Gallium(I) Subhalide as an Intermediate during the Formation of Elemental Gallium?**

*Taike Duan, Gregor Stößer, and Hansgeorg Schnöckel**

Dedicated to Professor Gerd Becker on the occasion of his 65th birthday

Although numerous subvalent organometallic and metalloid clusters of gallium were reported in the last decade,[1] binary gallium subhalides are rare, the only exception being Ga_2X_4 species.[2] After the long known GaX_2 which is stable in aromatic solvents was shown to be a mixed-valent $Ga^+GaX_4^-$ compound,[3] many examples of donor-stabilized $Ga_2X_4(Do)_2$ (Do = donor) species could be characterized as "authentic" gallium(II) compounds.[4,5] On the way to molecular crystalline gallium(I) halides compounds only one example was known: a Ga_5Cl_7 species.[6] The first "authentic" gallium(I) compound, Ga_8I_8 (planar Ga_8 ring) was finally prepared several years ago.[7] Recently we reported the first polyhedral gallium subhalide $Ga_{24}Br_{22}$,[8] which is better described as $Ga_{12}(GaBr_2)_{10}(GaBr)_2$, in which icosahedral Ga_{12} frameworks are found both in the center and in the periphery and the mean oxidation state of gallium is only +0.92. Herein we present the compound $Ga_{10}Br_{10}$ as a further example of a gallium(I) subhalide. Similar to Ga_8I_8, the average oxidation state of the gallium atoms in this compound is +1, however, it should be interpreted as being a mixed-valent subhalide with four gallium(0), four gallium(II), and two gallium(I) atoms. The preparation, the structure, and the significance of this compound as an intermediate during the disproportionation to elemental gallium are discussed.

The co-condensation of the high-temperature molecules GaBr[9] and a solvent mixture of 4-*tert*-butylpyridine (4-*t*BuPy) and toluene (1:10) gives a dark red solution at −78 °C. The solution is concentrated at −25 °C under high vacuum and then kept at this temperature. Over several days yellowish-red platelike crystals of $Ga_{10}Br_{10}$(4-*tert*-butylpyridine)$_{10}$·4-toluene (**1**) are formed. Compound **1** is highly soluble in toluene and can also be recrystallized from this solvent. Yet the toluene solution of **1** turns pale when the temperature rises over −18 °C and above room temperature gallium metal precipitates slowly from it.[10]

The result of the X-ray structure analysis of **1**[11] is shown in Figure 1 (the data of the model compound $Ga_{10}Br_{10}(thf)_{10}$ (**1′**) determined by density functional (DFT) methods[12] are also listed). Six of the ten Ga atoms in **1** form a six-membered ring, of which two Ga atoms (Ga3 and Ga3′) are bonded to two terminal $GaBr_2$(4-*t*BuPy) entities by two-center-two electron (2c-2e) bonds; two Ga atoms are "naked", which means they are bonded only to donor molecules and other Ga atoms. The last two Ga atoms of the six-membered ring are each bonded to one Br atom and one donor molecule, therefore these atoms can be identified as gallium(I) atoms.[13]

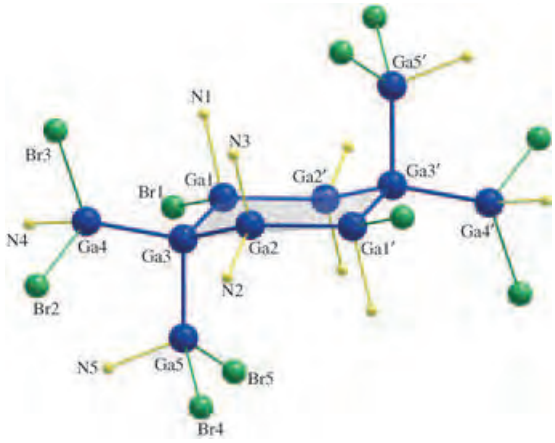

Figure 1. Results of the X-ray structure analysis of **1** (for clarity all C and H atoms are omitted) and selected bond lengths [pm] and angles [°] of **1** and the calculated model compound $Ga_{10}Br_{10}(thf)_{10}$ (**1′**; in parenthesis): Ga1-Ga2′ 249.3 (255), Ga1-Ga3 245.1 (251), Ga2-Ga3 245.6 (251), Ga3-Ga4 243.7 (250), Ga3-Ga5 244.1 (250), Ga1-Br1 249.1 (254), Ga1-N1 210.8 (216), Ga2-N2 210.4 (216), Ga2-N3 212.1 (216), Ga4-Br3 244.5 (247), Ga4-Br2 244.1 (247), Ga4-N4 208.4 (216), Ga5-Br4 241.3 (247), Ga5-Br5 243.4 (247), Ga5-N5 206.0 (216); Ga2-Ga1′-Ga3′ 119.1, Ga3-Ga2-Ga1′ 124.2, Ga2-Ga3-Ga1 106.7.

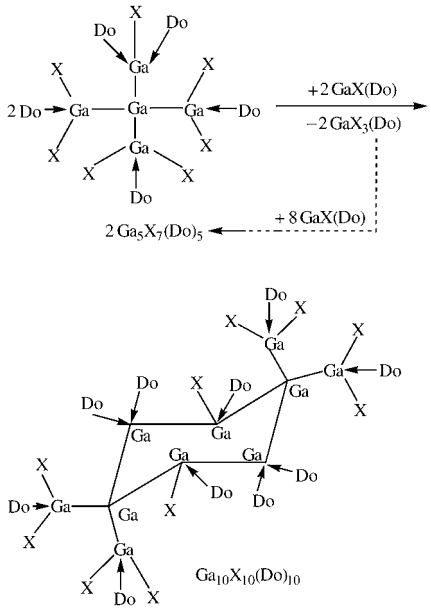
[**] The authors are grateful to Prof. Dr. Ingo Krossing for helpful discussions. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

 DOI: 10.1002/anie.200462075

The Ga–Ga bonds in the six-membered ring of **1** range from 249.3 to 245.1 pm and are, as expected, slightly longer than those to the terminal gallium atoms (243.8 pm). The Ga–Br bonds are consistent with expectations: the Ga^{I}–Br bond (Ga1 249.1 pm) is longer than the Ga^{II}–Br bonds (Ga4/Ga5 244 pm). Analogously, different Ga–N distances are also found for Ga1 (211 pm) and Ga4 (205 pm). Despite of the structural difference between **1** and $Ga_8I_8(Do)_6$, the average Ga–Ga bond length is similar in both compounds: **1** (245 pm) and Ga_8I_8 (246 pm).[6]

The structure of **1** and the necessary conditions for its synthesis indicate that the following mechanism for the formation and further reactions of **1** is plausible: Compound **1** is formed by the reaction of two Ga_5Br_7 entities[14] with excess GaBr(Do) under the elimination of $GaBr_3(Do)$ (Scheme 1). For the model compound **1′** such a reaction is



Scheme 1. The mechanism for the formation of **1** based on synthetic conditions and DFT calculations.

exothermic by $-135\ kJ\,mol^{-1}$ according to DFT calculations. The generated $GaBr_3(Do)$ molecules will be further reduced by insertion of excess GaBr(Do), and Ga_5Br_7 is formed. An analogous mechanism has been described for the formation of Al_5X_7 species.[2,15] If THF is used as donor, the reaction does not stop at **1′**; on the contrary, through the formation of additional Ga–Ga bonds and the reduction of **1** by GaBr the recently reported compound $Ga_{24}Br_{22}(thf)_{10}$ (**2**) could be formed. According to DFT calculations, the following reaction given in Equation (1) is exothermic by $-560\ kJ\,mol^{-1}$.

$$2\,Ga_{10}Br_{10}(thf)_{10}\ (\mathbf{1'}) + 5\,GaBr(thf) \rightleftharpoons Ga_{24}Br_{22}(thf)_{10}\ (\mathbf{2}) + GaBr_3(thf) + 14\,THF \quad (1)$$

Since the volatile THF released was removed by repeated evacuation during the preparation of **2**,[8] the equilibrium of Equation (1) would be clearly shifted to the right to favor the formation of the polyhedral Ga_{24} subhalide **2**. If the less volatile donor 4-*t*ert-butylpyridine[16] (b.p. 194–197 °C) instead of THF (b.p. 65–67 °C) is used and the reaction temperature is kept below −20 °C, **1** can be trapped as an intermediate during the formation of **2**. The disproportionation of **1** to **2** and finally to gallium metal and $GaBr_3$ is a chain reaction, that is, the $GaBr_3$ formed in each step reacts further with the excess GaBr species present to form Ga_5Br_7 species, which is re-introduced into the reaction cascade.

The formation of gallium metal by disproportionation is fairly restrained under −20 °C (at this temperature β-gallium and δ-gallium should be formed[1]). Probably the transformation of the puckered Ga_6 ring structure of **1** into β-gallium (planar Ga_n layers) or δ-gallium (icosahedral fragments) requires a too high activation energy. The fragmentation of **1** with the simultaneous formation of metal starts reluctantly even at −18 °C and proceeds rapidly and completely a little above room temperature. In this temperature range, however, α-gallium and liquid gallium are the stable phases. Since the topology of the Ga_6 ring in **1** is very similar to the Ga_6 framework in α-gallium (Figure 2), it seems plausible that

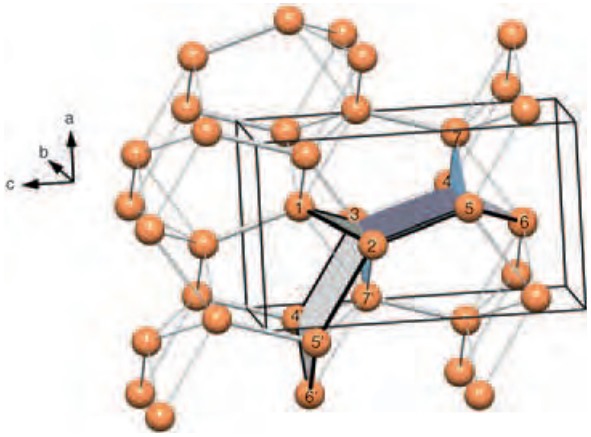


Figure 2. Ga_6 entities within α-gallium: bond lengths [pm] within the Ga_6 rings: Ga1-Ga2(Ga3)/[Ga6-Ga4(Ga5)] 279.4, Ga3-Ga4/[Ga2-Ga5] 244.8, Ga6′-Ga4′(Ga5′) 272.9, Ga4(Ga5)-Ga7/[Ga7′-Ga2(Ga3)] 272.9. The characteristic short Ga–Ga bonds (244.8 pm, for example, Ga3–Ga4) in α-gallium are highlighted; orange Ga.

the precipitation of α-gallium from **1** does not require a large activation energy. Thus, while for halides, kinetically simple insertion reactions (e.g. $4\,GaX + GaX_3 \rightarrow Ga_5X_7$) lead to their rapid disproportionation even at low temperatures and consequently to an extremely difficult isolation of the subhalides, further reactions are blocked for similar clusters protected by bulky ligands: for example, the gallium(I) compound $[Ga_6(SiPh_2Me)_8]^{2-}$ [17] with a Ga_6 framework similar to that in β-gallium does not decompose to metal even above room temperature.[18]

The isolation of **1** as an intermediate during the disproportionation of metastable GaX species in solution allows for the first time an insight into this complex process of self-organization. During this process, metalloid clusters with an increasing number of "naked" Ga^0 atoms in the core and

GaX_2 entities in the periphery grow by association, redox, and elimination reactions and could be regarded as precursors on the way to nuclei for the crystallization of the bulk metal.

Experimental Section

The high-temperature molecules GaBr (approximately, 48 mmol) were condensed together with a solvent mixture of toluene and 4-*tert*-butylpyridine (120 mL; volume ratio 10:1, ca. 1.5 equivalents of donor per Ga atom) at −196 °C.[9] The dark red solutions formed (ca. 0.41 M) are stable when kept at −78 °C. A portion (5 mL, ca. 2 mmol GaBr) of the GaBr solution was warmed from −78 °C to −20 °C overnight. The red solution was then concentrated by half at −25 °C under high vacuum and finally was kept at this temperature. During several days, yellowish-red plate crystals of $Ga_{10}Br_{10}$(4-*tert*-butylpyridine)$_{10}$·4toluene (**1**) were formed (yield: 290 mg, ca. 45 %). Compound **1** dissolves very well in toluene and can also be recrystallized from this solvent, yet it decomposes above −18 °C. Tiny single crystals of **1** were also formed directly when the GaBr solution was kept for several weeks at −78 °C and under vacuum conditions.

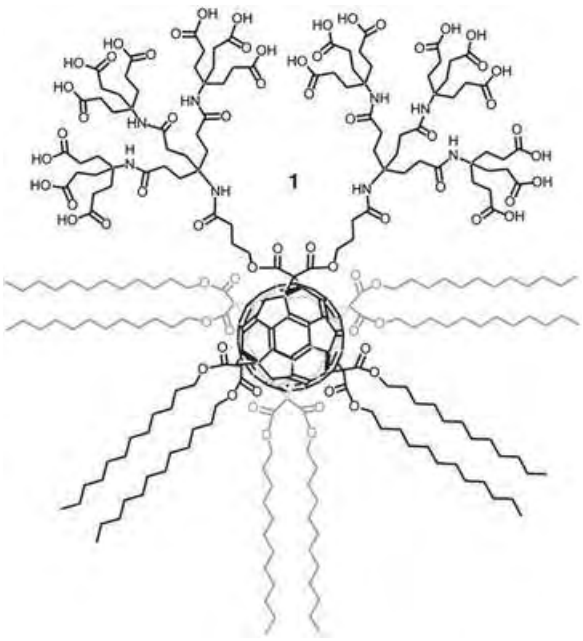
Fullerene-Based Micelles

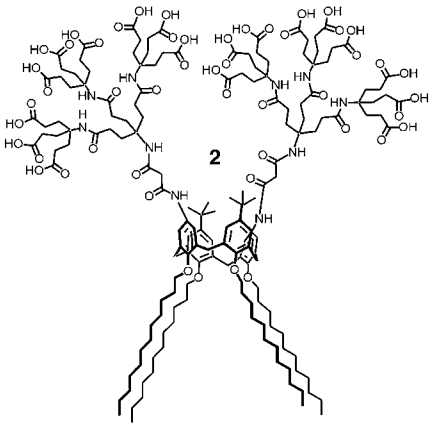
Switchable Supramolecular Organization of Structurally Defined Micelles Based on an Amphiphilic Fullerene**

Stephan Burghardt, Andreas Hirsch, Boris Schade, Kai Ludwig, and Christoph Böttcher**

Some time ago we started to investigate the synthesis and supramolecular organization of dendritic amphiphiles that contain fullerenes or calixarenes as core units.[1–3] Apart from the synthesis of structurally persistent micelles, we were particularly interested in the assembly of functionalized micelles and liposomes in order to direct the aggregation behavior of these species with an appropriate external stimulus. Results from these studies could be useful for the development of drug-delivery systems. Examples of such dendritic amphiphiles include the globular amphifullerene **1**,[1] which contains a pair of carboxy-terminated amide dendrons and five dodecyl malonate addends attached to the fullerene core in an octahedral [1:5] addition pattern, and the calixarene derivative **2**,[3] which contains analogous hydrophilic and lipophilic units. In amphiphile **1** the space required for the hydrophilic and the hydrophobic areas is balanced whereas the extended chains have free conformational mobility. This ensures a wide spectrum of energetically favorable packing motifs both for the formation of micellar structures and for extended liposomal double layers. The existence of different aggregates was confirmed by electron microscopic investigations.[2a]

By contrast, we designed amphiphile **2** as a comparatively rigid T-shaped structure[3] that does not pack to form extended ultrastructures such as liposomes. We demonstrated that the supramolecular organization of **2** yields very small and strongly bent aggregates exclusively, which are the first proven examples of structurally persistent micelles.[3] Each of these C_2-symmetrical micelles consists of exactly seven molecules of amphiphile **2**. The structure was determined by cryogenic transmission electron microscopy (cryo-TEM) and





techniques for the three-dimensional reconstruction of single particles at a resolution of 12 Å.[3]

We report here for the first time on amphiphile **3** (see the Supporting Information), whose aggregation in different supramolecular organizational forms may be switched by changing the pH (Figure 1). In principle, the aggregation behavior of amphiphilic systems may be studied under quasi-native conditions by using combined methods: ultrafast cryogenic fixation of the samples ("vitrification") and direct observation by transmission electron microscopy upon simultaneous sample cooling ($\approx$120 K). The cooling rates ($>10^4$ K s^{-1}) during sample preparation are so high that molecular reorientation (e.g. formation of ice crystals) is prevented.[5,6] Ultimately, projection images of the aggregates are obtained by microscopy and thus information about their intrinsic structure is provided.

We examined amphiphile **3** at neutral pH in water (phosphate buffer pH 7.2) by these methods and found predominantly rod-shaped aggregates with a double-layer ultrastructure (Figure 2a). The diameter of these rods is 65 ±

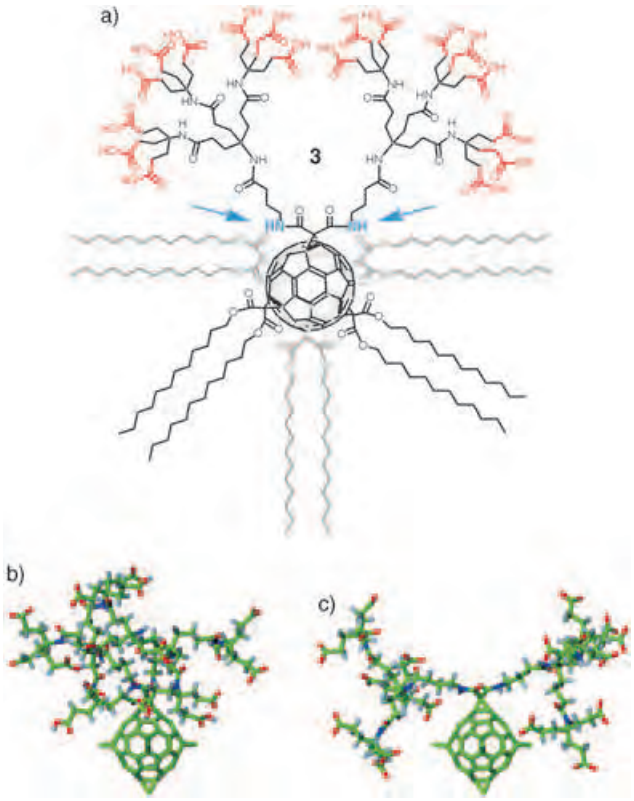

Figure 1. a) Amphiphilic fullerene dendrimer **3** with dendritic branches linked by amide bonds (blue arrow). b, c) Molecular models of differently protonated conformers of **3**, modeled with the program Tinker.[7] For clarity, the alkyl chains are not depicted. b) Dendrons partially protonated. According to earlier titration measurements on LB films, a pK_a of 7.5 is found for the chemically related dendrimer **1**.[2b] Accordingly, the simulation of **3** at pH 7.2 has been carried out by using eight negative charges (of a total of possible 18). c) Dendrons completely deprotonated (18 negative charges).

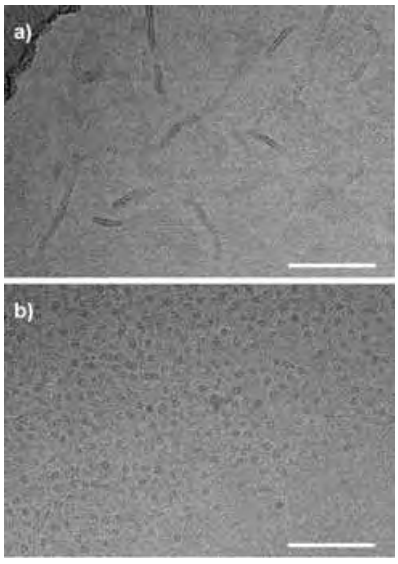

Figure 2. Representative electron micrograph showing aggregates of **3** embedded in vitrified water (scale bar: 50 Å). a) At pH 7.2 predominantly rod-shaped double-layered aggregates are found. b) At pH 9.2 exclusively globular micelles are found.

5 Å; the length is strongly variable and exceeds the diameter considerably. In addition, a few globular aggregates with a diameter of 85 ± 10 Å were found. When the pH of the neutral solution was increased to roughly 9 (borate buffer pH 9.2), those globular micelles with a diameter of 85 ± 10 Å were found exclusively (Figure 2b). Interestingly, apart from variations in diameter these globular micelles show a distinct internal structure. By analogy to our investigations on micellar structures of amphiphile **2**[3] we considered the structural motifs of the globular micelles to be an indication of structural persistence. Accordingly, each individual structure should represent a distinct spatial orientation of the aggregate. Thus, it should be possible in principle to determine the three-dimensional organization from the image data; variations in the diameters would arise from the aggregates' different orientations. By using the reconstruction techniques described earlier[3] (alignment, classification, angular reconstitution) (Figure 3a), we calculated the three-dimensional

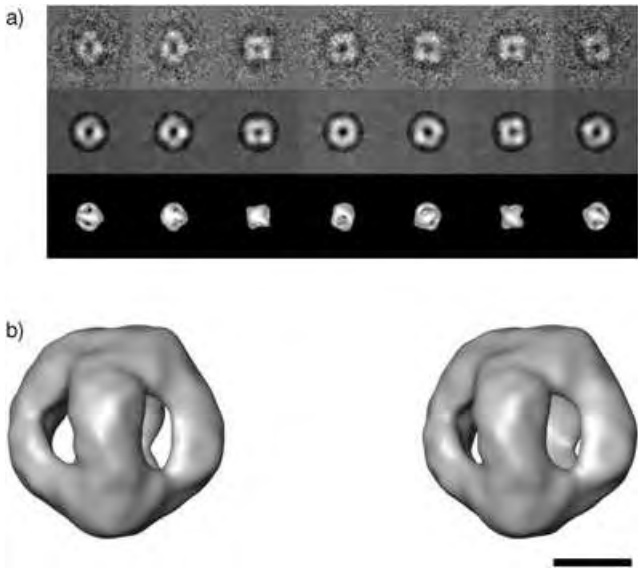

Figure 3. Three-dimensional reconstruction from electron cryogenic microscopic data of globular micelles formed by **3** at pH 9.2. a) The first row displays class sum images of micelles in various spatial orientations. Three-dimensional structural information was derived from the corresponding Euler angles at a resolution level of ≈16 Å. Back projections (second row) of the calculated volumes (third row) at identical Euler angles indicate the consistency with the experimental data. b) Stereoscopic view of the final three-dimensional reconstruction (scale bar: 25 Å).

structure for the globular micelles of **3** (Figure 3b). The successful reconstruction is evidence that the spatial molecular organization of the aggregates is identical within the achieved level of resolution (≈5000 individual aggregates were randomly extracted from the microscopic data).

To determine the possible molecular organization in the aggregates, we undertook a visual three-dimensional fitting of molecular models of **3** into the reconstructed 3D density map (Figure 4a and b). Based on a simulated conformation of **3** in its completely deprotonated form (Figure 1c) (generated with the program Tinker[7]), the globular micellar structure may be

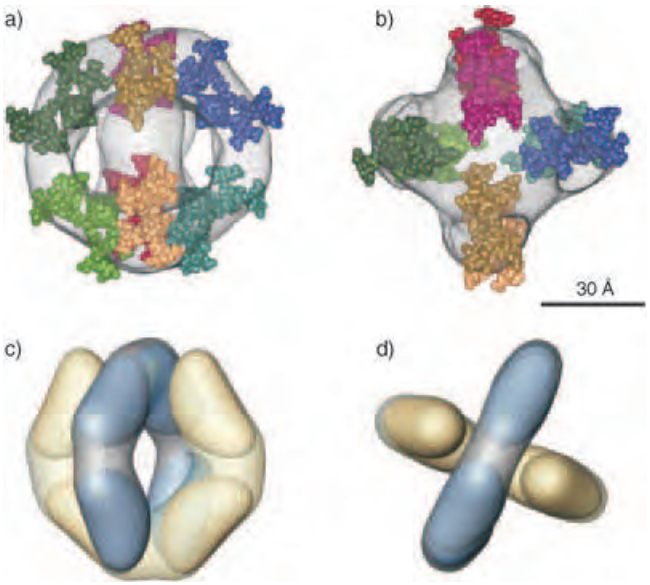

Figure 4. Interpretation of the reconstructed data. a) Eight head groups of the dendritic fullerene molecule may be fitted in a C_2-symmetrical mode into the reconstructed electron-density map. b) View of (a) tilted by 90° towards the front side. c) Schematic representation of the head-group assembly: Two planar U-shaped assemblies consisting of four molecules each (yellow and blue) are displaced by 90° along their longitudinal axes and are inserted —though not completely—into each other at their open ends. d) View of c) tilted by 90° towards the front side.

constructed from eight molecules in a C_2-symmetrical arrangement. The molecular organization of this aggregate may be described best by considering two planar U-shaped structures consisting of four molecules each. These are displaced by 90° along the longitudinal axis with respect to their open ends; however, they are not inserted completely into each other (Figure 4c and d). This molecular organization ensures a nearly spherical shape overall and thus very efficient shielding of all hydrophobic molecule parts from the aqueous environment. As was the case for the structurally persistent micelles derived from calixarene **2**, the innermost core area of the micelle formed by the hydrophobic alkyl chains is not reproduced in the reconstruction. Since individual chains do not assume a spatially defined conformation but are more or less arranged in a statistical way, this part of the aggregate is averaged out as a result of the statistical principles of the applied reconstruction method. Only the head groups, which are located easily due to the high-contrast fullerene entity, prove to be sterically persistent, thus yielding the found structural pattern.

The molecular structure of **3** encodes a supramolecular behavior representing a combination of supramolecular properties of **1** and **2**. On the one hand, and similar to **1**, the spatial demands of the hydrophilic and hydrophobic areas are well-balanced. On the other hand, and similar to **2**, the dendritic branches are linked by amide rather than ester linkages, resulting in enhanced rigidity. The significant structural change when the pH is lowered may be explained by electrostatic repulsion of the completely deprotonated carboxy groups, and enhanced solvation is a secondary effect. Accordingly, we may assume that at neutral pH the electrostatic repulsion is reduced as a consequence of partial protonation. This causes reduced solvation, which in turn leads to much closer packing as is evidenced by the smaller diameter of the rods relative to that of the globular micelles. Figure 1b shows the corresponding result of a conformational simulation of **3** in aqueous environment at neutral pH. The fact that the rod diameter is constant throughout suggests that the three-dimensional organization must be based on a circular-shaped cross-sectional area. Based on the dimensions and density profile, a double-layered molecular arrangement in a micellar cylinder can be visualized. According to this motif an appropriate radius of curvature of ca. 65 Å can be modeled by using approximately eight molecules. The corresponding model is depicted in Figure 5.

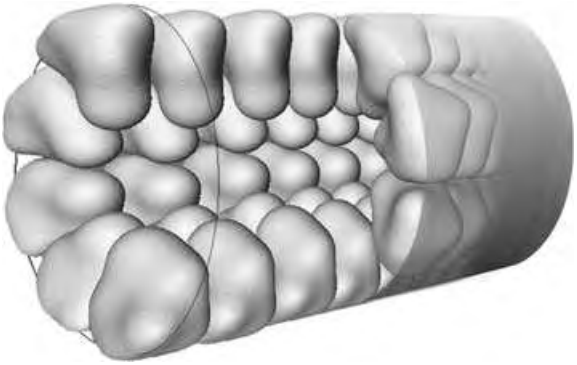

Figure 5. Proposed model of a molecular arrangement of **3** in micellar rods at neutral pH. The employed head-group volume is based on the partly protonated form shown in Figure 1b. Hydrophobic alkyl chains, which should reside at the center of the micelle, are not shown for clarity. They correspond to areas of low density in the electron microscopic images of Figure 2a.

We have demonstrated that by suitable substitution structurally persistent aggregates may be generated in a reproducible way. This opens up perspectives for the systematic investigation of the parameters responsible for aggregate formation. Fundamental investigations on the stability of the aggregates, in particular tolerance of chemical modification and functionalization of the head group, might form the basis for the synthesis of tailor-made transport systems. These may have potential for the selective deposition of drugs in living organisms.

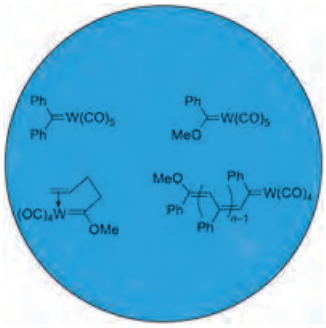
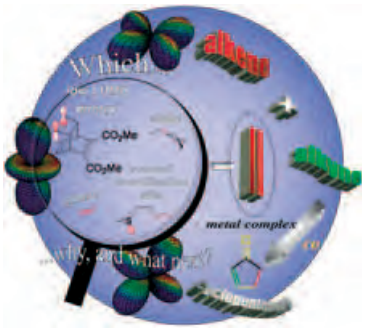
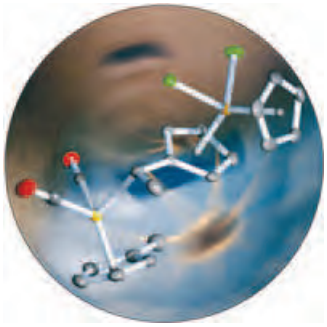
Molecular shuttles describe rotaxanes in which a key feature of the tertiary structure, the relative positions of the interlocked components, can be changed in response to an external input such as a solvent. The cover picture shows such an assembly as well as fluorescent patterns generated by stimuli-induced submolecular motion of the assembly in polymer films. For more details see the Communication by D. A. Leigh et al. on page 3062 ff. (The image of the space-shuttle launch was captured from the game SimCity 4: Rush Hour.)



Metathesis Catalysts
The Minireview by T. J. Katz on page 3010 ff. deals with metathesis catalysts: How do carbene complexes of metals in low oxidation states compare with the commonly used high-oxidation-state analogues?



Pauson–Khand Reaction
Recent advances in the intermolecular Pauson–Khand reaction point the way to an increasingly more general and versatile reaction, as detailed by S. E. Gibson and N. Mainolfi in the Review on page 3022 ff.



Metallocenes
A surprising kind of C–C coupling occurs when a Ti/Zr metallocene complex is treated with acid. G. A. Koutsantonis et al present the details of this process in their Communication on page 3038.

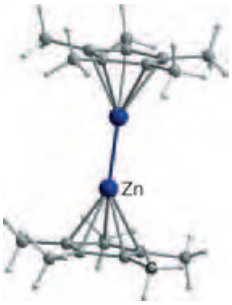
Meeting Reviews

Books

Highlights

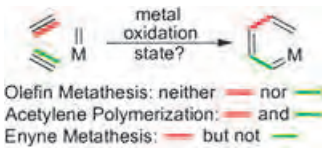
Metal-Metal Interactions

Something to zinc about: Subvalent compounds with direct metal–metal bonds have been the focus of interest for many decades. Recently the first synthesis of a molecular compound with a direct Zn–Zn bond was reported. The synthetic route, although not understood, might lead the way to other interesting compounds featuring direct metal–metal bonds, for example, of Group 2 elements.



Minireviews

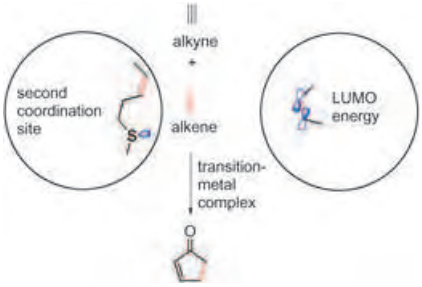
Olefin Metathesis



Highs and lows: Tungsten carbenes do not have to be in their highest oxidation state to initiate olefin metatheses, acetylene polymerizations, and enyne metatheses. Although low-oxidation-state metal carbenes are less active than those currently used, the former exhibit greater stereoselectivity and a broader substrate range.

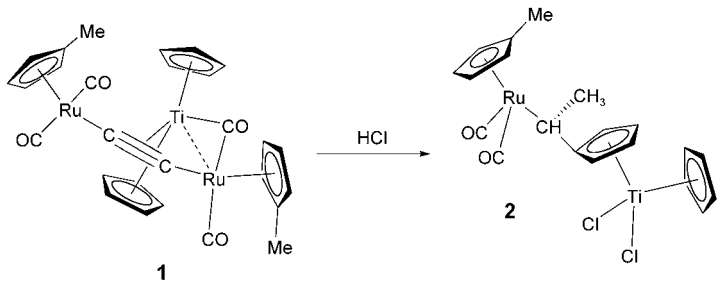
Reviews

Goodbye to the weakest link: The intermolecular Pauson–Khand reaction (see scheme) has in the past been limited by the poor reactivity and selectivity of the alkene component. Concerted efforts to broaden the scope of the intermolecular Pauson–Khand reaction are critically and comprehensively covered based on the reactivity characteristics of the alkene partners, which are used to rationalize successful and failed reactions.



Carbocycle Synthesis

Communications



Carbon ligand transfer: Compound **1** is formed with reactive metal–ligand fragments generated from Group 4 metallocene compounds. Dropwise addition of ethanolic HCl to a solution of complex **1** in toluene affords complex **2** in a carbon–carbon bond-forming transformation that is thought to be unprecedented.

Metallocene Chemistry

Even better than the real thing? As host molecules, long synthetic nanotubes may be reasonable alternatives to single-walled nanotubes. For example, calixarene-based nanotubes effectively pack into infinite tubular bundles in the solid state (see picture), and they can be easily filled with guest molecules to form stable, but reversible, encapsulation complexes.

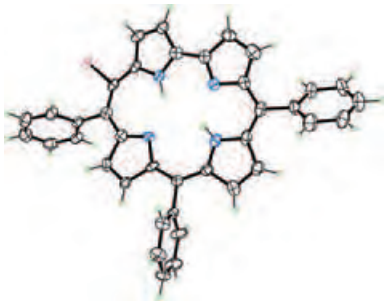
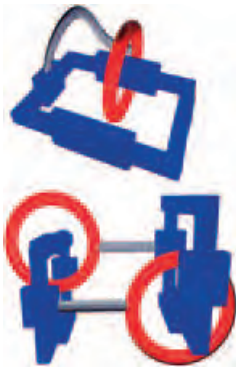
Formation of the vinylogous bridge between adjacent pyrrole rings (A and B) in the reaction of 5,10,15-triphenylcorrole with CI_4 affords the corresponding hemiporphycene (see structure; N blue, I pink, C white, H green). This approach allows a facile preparation of functionalized hemiporphycenes.

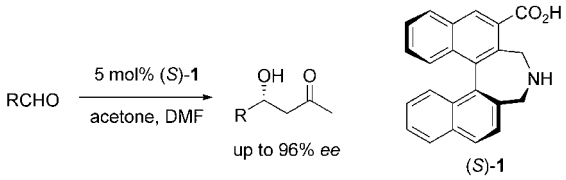


Corrole Chemistry

Raising the bar. Tethering the macrocyclic polyether to the tetracationic cyclophane in a "donor–acceptor" [2]catenane (see schematic representation) slows down the process of partial pirouetting of the crown ether around the cyclophane by a factor of 10000. This level of structural control has important consequences for the design of the next generation of molecular switches that depend on bistable "donor–acceptor" [2]catenanes.



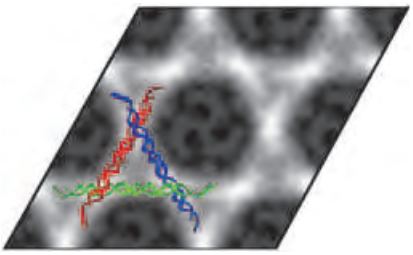
Molecular Devices



A robust binaphthyl-based amino acid ((*S*)-**1**) exhibits higher stability and selectivity than proline for the catalysis of a direct asymmetric aldol reaction between aldehydes and acetone (see scheme; DMF = *N*,*N*-dimethylformamide). Olefinic, heteroaromatic, and aromatic aldehydes were found to be suitable substrates, with the corresponding aldol adducts being obtained in good yields and excellent enantioselectivities.

Asymmetric Catalysis

Weaving with DNA: A DNA-binding protein was used to control the structure of a self-assembled 2D crystal. In the absence of protein, four oligonucleotides hybridize to form a Kagome lattice of interwoven double helices with *p*3 symmetry (see image). Addition of protein RuvA during assembly changes the symmetry and connectivity to give a DNA–protein crystal with an approximately square unit cell.

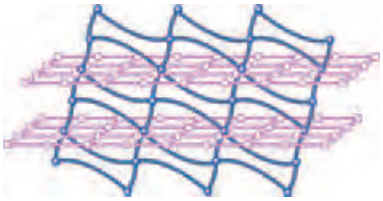


Protein–DNA Arrays

VIP

Contents

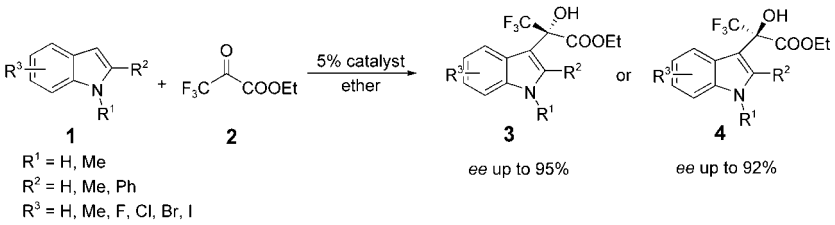
Two different types of coordination sheets made up of Co^{II} ions, 3-hydroxypicolinate, and 4,4′-bipyridine interpenetrate to form a unique molecular-based magnetic material (see picture). This material displays a low-field metamagnetic transition and spin-canted behavior.



Metamagnetism

Key prenucleation species like the open-chain tetramer and the four-membered-ring structure shown are implicated in the formation of zeolites according to density functional theory calculations. The role of the solvent and the pH value is confirmed in the control of condensation reactions, particularly those favoring the formation of cyclic structures present in many zeolite structures.

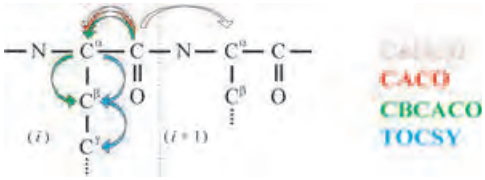
Zeolite Assembly



Readily available cinchona alkaloids have been used as organocatalysts in the highly efficient stereoselective hydroxyalkylation of heteroaromatics such as indoles with 3,3,3-trifluoropyruvate (**2**, see scheme).

High yields and *ee* values of both enantiomers of the products, depending on the catalyst used, indicate the usefulness of the developed methodology.

Organocatalysts

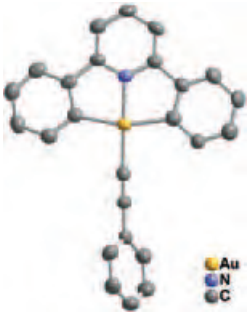


The detection of ^{13}C is now amenable to high-resolution NMR spectroscopy of proteins. A protocol for ^{13}C homonuclear decoupling in multidimensional experiments correlates carbonyl, C^{α}, and C^{β} nuclei (see picture). These techniques also allow the detection of side-chain nuclei in exclusively heteronuclear experiments, and thus the complete assignment of proteins.

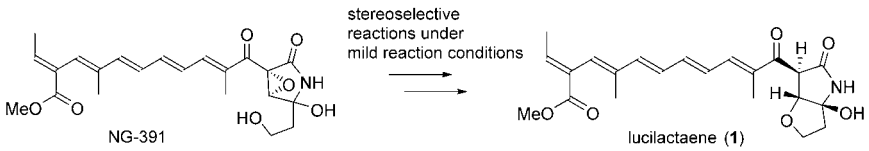
Biomolecular NMR Spectroscopy

Contents

Luminous: The Au^{III} alkynyl complexes [Au(C^N^C)(C≡CR)] [HC^N^CH = 2,6-diphenylpyridine, R = C_6H_5 (**1**), C_6H_4-Cl-*p* (**2**), C_6H_4-OCH_3-*p* (**3**), C_6H_4-NH_2-*p* (**4**); HC^N^CH = 2,6-bis(4-*tert*-butylphenyl)-pyridine, R = C_6H_5 (**5**)] were prepared, and the molecular structure of **1** was characterized (see picture). Complexes **1**–**5** display luminescence in solution and in the solid state both at low and ambient temperature.

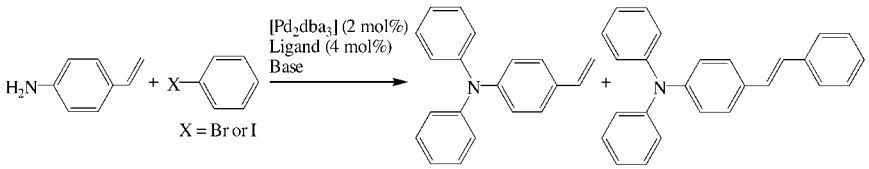


Luminescent Gold Complexes



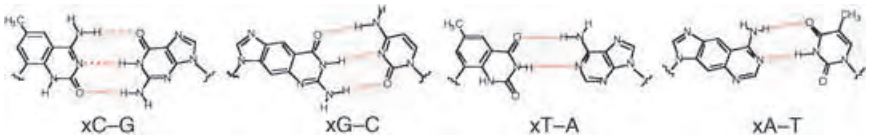
A biomimetic pathway to lucilactaene (**1**) from NG-391 has been developed which involves stereoselective reactions under very mild conditions. It was demonstrated that **1** racemizes rapidly, and the conditions under which racemization occurs were elucidated. Lucilactaene (**1**) isolated under neutral conditions is racemic, which suggests that either the natural product is racemized rapidly in the mycelia, or racemic **1** is biosynthesized.

Natural Products Synthesis



A double-amination/intermolecular-Heck-reaction sequence is used as a one-pot methodology for sequential C–N and C–C bond formations. 4-Aminostyrene was coupled with aryl bromides and aryl iodides using a [$Pd_2(dba)_3$]/proazaphosphatrane catalyst system (dba = dibenzylideneacetone; see scheme) to form *trans* 4-*N*,*N*-diaryl aminostilbene derivatives in high yields, which are comparable to those of previously reported multistep syntheses.

Arylation

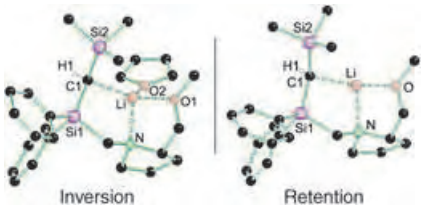


Expanding DNA: The four natural DNA nucleotides were combined with four benzo-homologous nucleotides to make self-assembling double helices (see base-paired structures). Strands of this "xDNA" form highly stable, sequence-specific duplexes with native DNA and RNA, and can expand the information capacity of DNA from a basis of four to eight characters.

Nucleic Acids

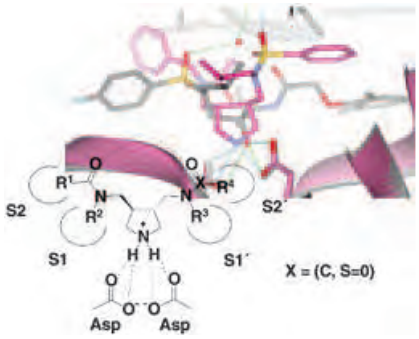
Contents

The opening or blocking of a coordination site at the lithium center (for example by attachment of THF, see picture; left) leads to diastereodivergent courses in the reactions of a highly diastereomerically enriched alkyl lithium with Me_3SnCl. At room temperature in noncoordinating solvents the reagent is configurationally stable and epimerizes in the presence of THF.



Organolithium Compounds

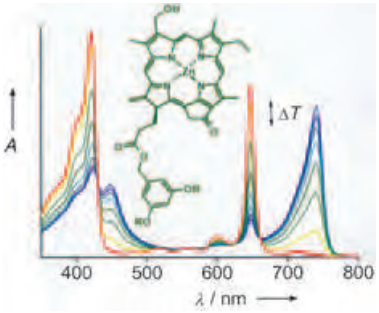
Favored entrance for the privileged. Two inhibitor structures to address the active site of aspartic proteases have been developed. They are equipped with a central hydroxysulfone unit and, alternatively, a pyrrolidine moiety and decorated with rationally designed side chains. The hydroxysulfones bind to HIV protease as expected, whereas the pyrrolidines display a surprising, previously unreported binding mode.



Structure Determination

NMR in gummi bears: What started as pure fun could open up interesting applications: stretched gelatin gels as chiral polymers can be used to distinguish enantiomeric solutes through their residual dipolar couplings. The method is demonstrated on a mixture of L- and D-alanine (see picture).

NMR Spectroscopy



Biomimetic light-harvesting antennae are made available by noncovalent polymerization of semisynthetic zinc chlorins. The excellent solubility and the prolonged stability of the zinc chlorin aggregates enables spectroscopic investigation of their reversible formation (see picture). The rod-shaped structure of these aggregates is experimentally confirmed by atomic force microscopy.

Metal-Metal Interactions

Subvalent Compounds Featuring Direct Metal–Metal Bonds: The Zn–Zn Bond in $[Cp^*_2Zn_2]$**

Andreas Schnepf and Hans-Jörg Himmel**

Keywords:
metallocenes · metal–metal bonding · subvalent compounds · zinc

Molecular compounds featuring direct metal–metal bonds have stirred up interest for many decades now, with the nature of the bonding between the two metal centers generally being the focus of attention. In recent years interest has centered on several cluster compounds of Group 13 and 14 elements with unusual bonding properties (multiple bonds or delocalized "metal-like" bonds).[1]

In the case of Group 12 elements (Zn, Cd, Hg), compounds with direct metal–metal bonds are well known for mercury, reflecting the preference of this element for a formal oxidation state of +1.[2] As to cadmium, the compounds $Cd_2(AlCl_4)_2$[3] or $Cd_2(Tp^{Me_2})_2$[4] (Tp^{Me_2} = hydrotri(3,5-dimethylpyrazolyl)borate) have direct Cd–Cd bonds. However, owing to the increased instability of the formal oxidation state +1, the $[Cd_2]^{2+}$ ion disproportionates immediately in the presence of water to give Cd and Cd^{2+}.[2]

Thus, the ability of Group 12 elements to be engaged in direct metal–metal bonding decreases dramatically from mercury to cadmium to zinc reflecting the decreasing stability of the formal oxidation state +1. On these grounds it was for some time questionable whether it would be possible to synthesize molecular compounds featuring a direct Zn–Zn bond.

With [Cp*ZnZnCp*] (**1**; Cp* = C_5Me_5), Carmona and co-workers have now synthesized the first representative of this class of compounds. As often in the case of great advances in chemistry chance played a significant role.[5] The compound was formed unexpectedly as the product of the reaction between decamethylzincocene and diethyl zinc. At room temperature a mixture between the expected zinc(II) compound [Cp*ZnEt] (**2**) and the unexpected zinc(I) compound **1** was obtained. Depending on the reaction conditions the reaction can be manipulated to lead to either **1** or **2** as a characterizable product (Scheme 1). A new route (box in Scheme 1) now allows **1** to be prepared in a few grams, opening up the possibility to study the chemistry of this fascinating compound.[6]

Compound **1** turns out to be a colorless, pyrophoric solid. The molecular structure (Figure 1) shows a central Zn_2

  DOI: 10.1002/anie.200500597

unit, with a very short Zn–Zn bond of 231 pm. Each of the zinc atoms is η^5 coordinated to one Cp* ligand with a distance between the zinc atom and the Cp* centroid of 204 pm. The Zn-Zn-$Cp^*_{centroid}$ angle amounts to 177.4°.

To exclude the possibility of the presence of hydrogen atoms bonded to the zinc atoms, for example, as hydrogen bridges between the two zinc atoms to give a [{Cp*Zn(μ-H)}$_2$] species, the compound was studied with several independent methods (NMR and IR spectroscopy and mass spectrometry). All these methods gave no sign of any additional hydrogen atoms. The absence of hydrogen bonded to the zinc atoms in **1** is supported by a comparison of the Zn–Zn distance (231 pm) with that found in the hydrogen-bridged compound [{RZn(μ-H)}$_2$] (R = HC(CMeNXyl)$_2$; Xyl = 2,6-$Me_2C_6H_3$; which has a Zn···Zn separation of 245 pm.[7] All methods therefore agree in that **1** indeed represents the first in substance isolated compound with a direct Zn–Zn bond.

The parent compound HZnZnH was previously generated and characterized in matrix isolation experiments as one of the products of the dimerization of two ZnH radicals in Ar, Ne, or H_2 matrices.[8] However, to date only the antisymmetric Zn–H stretching fundamental at 1740.3 cm^{-1} in Ar, 1746.8 cm^{-1} in Ne, and 1752.2 cm^{-1} in H_2 matrices could be detected. The Zn–Zn distance in the linear compound is approximately 238 pm according to quantum chemical (MP2) calculations,[9] a value which is in satisfying agreement with that measured (231 pm) and calculated (233 pm) for **1**. The quantum chemical calculations carried out for HZnZnH and **1** indicate a similar energy change of approximately +250 kJ mol^{-1} for dissociation into two ZnH and Zn(η^5-Cp*) radicals, respectively. Replacement of the H atoms in HZnZnH by more electronegative atoms or groups leads to a further increase of the bond energy. Hence, in FZnZnF the dissociation energy is higher by around 15 kJ mol^{-1}. However, disproportionation reactions are more important in judging the stability of the compounds. In the case of HZnZnH the calculated disproportionation in the gas phase leading to ZnH_2 molecules and Zn atoms is exothermic by approximately −31 kJ mol^{-1}. The corresponding disproportionation reactions for FZnZnF and ClZnZnCl are predicted to be endothermic (+37 and +30 kJ mol^{-1}, respectively). Unfortunately similar calculations on **1** are still missing. Nevertheless the results suggest that a careful choice of the ligands is essential to guide the reaction in the right direction.

In the light of the first synthesis of **1** the question arises whether or not it is also possible to synthesize derivatives of the compound HMgMgH on a preparative scale? These species should also feature metal–metal bonds with sufficiently high bond energy. Thus, according to calculations, dissociation of HMgMgH into two MgH radicals requires an energy of 197 kJ mol^{-1}.[10] HMgMgH and its isomer Mg(μ-H)$_2$Mg, which is approximately 63 kJ mol^{-1} higher in energy, were already sighted in matrix isolation experiments.[10] The antisymmetric Mg–H stretching fundamental in HMgMgH occurs at 1491.2 cm^{-1} (in Ar). A further problem is that gas-phase decomposition of HMgMgH into Mg_2 and H_2 was calculated to be exothermic by −24 kJ mol^{-1}. This result means that in addition to disproportionation there are other possible decomposition routes for these kind of compounds, which might complicate their stabilization. Fortunately owing to the relatively low reaction enthalpies for these decomposition processes in the case of the parent compound there is room for some hope that these decomposition reactions can be avoided by careful choice of the ligands.

Recently it was even possible to stabilize derivatives of the parent compound HGaGaH, which features a much weaker metal–metal bond.[11] Again, the parent compound HGaGaH was first generated and characterized in matrix isolation experiments.[12] The vibrational spectra of the matrix isolated molecule already indicated that the Ga–Ga bond in HGaGaH is most adequately described as a relatively weak donor–acceptor interaction between two GaH molecules. In agreement to this description the Ga–Ga bond in the *trans*-bent derivatives is with approximately 263 pm (as measured for ArGaGaAr, Ar = 2,6-$Dipp_2C_6H_3$; Dipp = 2,6-$iPr_2C_6H_3$)[11] relatively large, and fragmentation of the parent compound HGaGaH into two GaH fragments consumes an energy of around 57 kJ mol^{-1}.[13] In contrast to Mg_2H_2 and Zn_2H_2, the D_{2h} symmetric isomer Ga(μ-H)$_2$Ga is 50–60 kJ mol^{-1} more stable than the C_{2h} symmetric, *trans*-bent HGaGaH.[12]

In summary, the first synthesis of [Cp*ZnZnCp*] is a break through which will encourage the search for similar compounds, especially those of Group 2 elements. However, many questions still remain unsolved, especially with regard to the reaction pathway leading to this molecule. The analysis of the reaction mechanism would be very helpful for future attempts to synthesize similar species.[14] Because the compound can be synthesized in good yields one can expect to see a rich chemistry in the near future. The disproportionation reaction to Zn^{2+} and Zn metal (Scheme 2) possibly leads the way to zinc-rich cluster compounds, a strategy which has already been applied successfully in the case of Group 13 and 14 elements for the preparation of new metalloid cluster compounds.[1]

[14] Which species is oxidized during the reaction has to be analyzed. One possibility is that in the first step a reductive elimination takes place ($[R_2Zn] \rightarrow Zn + R-R$) leading to Zn atoms, which react in the second step with $[Cp^*_2Zn]$ in a comproportionation reaction to give **1**. The detection of ethane as a side product in the course of the reaction might indicate the involvement of radicals. However, butane would be the expected side product under assumption of the above mentioned mechanism. The influence of the steric requirements of the Cp* ligand on the reaction also has to be evaluated. That this influence cannot be neglected is clear if the reaction of $[Cp^*_2Zn]$ is compared with that of $[Cp_2Zn]$. The reaction of $[Cp_2Zn]$ with $[Et_2Zn]$ leads almost quantitatively to the half-sandwich compound [CpZnEt].[15]

Olefin Metathesis

Olefin Metatheses and Related Reactions Initiated by Carbene Derivatives of Metals in Low Oxidation States

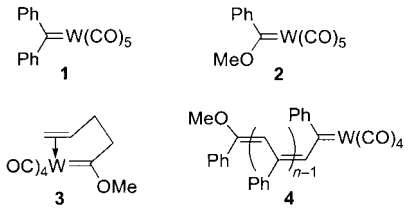
*Thomas J. Katz**

Keywords:
alkenes · alkynes · enynes · initiators · metathesis

Experiments carried out 24 years ago with tantalum carbenes have led to the much cited hypothesis that metals (other than ruthenium) must be in their highest oxidation states for their carbene derivatives to initiate olefin metatheses. The hypothesis legitimizes the uniqueness of high-oxidation-state molybdenum and tungsten carbenes as effective initiators, and it means that the Fischer tungsten carbenes that even earlier were found to initiate olefin metatheses and related transformations must be oxidized before they can be effective. The newer initiators have been termed "well-defined", the older "ill-defined". But what does the evidence show?

1. Introduction

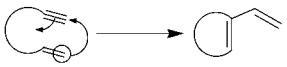
A series of experiments published in 1976 and 1977 demonstrated for the first time that isolable metal carbenes could initiate olefin metatheses.[1] Pentacarbonyl(diphenylmethylene)tungsten (**1**; Scheme 1), a compound previously



Scheme 1. Carbene initiators of olefin metathesis.

synthesized by Casey and Burkhardt[2] and at the time the most reactive metal carbene known,[3] in small amounts and at temperatures of 25 to 40 °C initiated metatheses of a variety of disubstituted cycloalkenes (cyclobutene, cyclopentene, cycloheptene, cyclooctene, and norbornene),[1c] trisubstituted cycloalkenes (1-methylcyclobutene, 1-methyl-*trans*-cyclooctene, and later 2-methylnorbornene and 1-trimethylsilylcyclobutene),[1b,e,4] 1,1-disubstituted ethylenes (2-methylpent-1-ene, 2-methylhept-1-ene),[1a] and *cis*- and *trans*-2-pentenes.[1f]

In 1980 this same metal carbene was shown to initiate polymerizations of acetylenes.[5] This was the first demonstration that isolable metal carbenes could initiate acetylene polymerizations, and in 1985 the same metal carbene was shown to initiate the enyne rearrangement [or enyne metathesis, Eq. (1)], the first demonstration of that reaction.[6]



(1)

The less-reactive pentacarbonyl(methoxyphenylmethylene)tungsten (**2**), the first metal carbene to have been isolated and characterized (by Fischer and Maasböl in 1964),[7] was also shown to initiate polymerizations of acetylenes[5] and enyne rearrangements,[6a] as well as metatheses of strained olefins.[1d]

These metal carbenes offered two significant advantages over the initiating mixtures used previously:[8] 1) the ability to avert acid-catalyzed side reactions, which previously had frustrated attempts to transform trisubstituted and 1,1-disubstituted ethylenes by metathesis;[1a,b,e] and 2) uniquely high stereoselectivity both for retention of double-bond configuration in metatheses of di-[1c,d,f,g] and trisubstituted olefins[1b,e,4] and for formation of *cis* alkenes in enyne rearrangements.[6a,9]

Despite these results, a number of recent publications assert or suggest that carbene derivatives of early transition metals initiate olefin metatheses only if the metals are in their highest oxidation states.[10,11] Because these are the oxidation states of the metals in the most effective tungsten and molybdenum carbene initiators used today[12] (but not in the even more effective ruthenium carbenes[12]), it has been proposed that for Fischer tungsten carbenes to initiate olefin metatheses they must first be oxidized to ill-defined species in

  DOI: 10.1002/anie.200462442

higher oxidation states.[10a,13] The initial compounds themselves are said[10a,b,f,14] or implied[15,16] to be ineffective. A corollary then is that high-oxidation-state tantalum [14c,17] and tungsten oxo derivatives[14c,18] were the first metal carbenes that directly initiated productive olefin metathesis. These assertions have been repeated frequently[10,13,14,16b] but never questioned. I therefore summarize herein 1) experiments demonstrating that Fischer tungsten carbenes initiate olefin metatheses, acetylene polymerizations, and enyne rearrangements; 2) evidence for the mechanisms of these transformations; 3) evidence related to the identification of well-defined initiators; and 4) possible advantages metal carbene initiators in low oxidation states might provide.

2. Fischer Tungsten Carbenes

2.1. Olefin Metatheses Initiated by Pentacarbonyl(diphenylmethylene)tungsten

As a short review was recently published of olefin metatheses, acetylene polymerizations, and enyne rearrangements initiated by Fisher metal carbenes,[1g] only orienting illustrations are provided herein. After 14–36 h in the presence of **1** (0.002–0.005 equiv) at 25–41 °C, solutions of cyclobut-, cyclopent-, cyclohept-, and cyclooctenes in toluene or benzene (≈ 3 M) were converted into the corresponding polyalkenamers in an average yield of 53 % [Eq. (2)].[1b] The number-average molecular weights ($\bar{M}_n$) of the polymers were similar, $(1.8 \pm 0.4) \times 10^5$, and their weight-average molecular weights ($\bar{M}_w$) were between 3.5×10^5 and 14×10^5. For the strained alkene norbornene, 0.0006 equivalents of the initiator sufficed, and after 18 h at room temperature (≈ 25 °C), the yield of the polymer, with $\bar{M}_n = 3.3 \times 10^5$ and $\bar{M}_w = 8.5 \times 10^5$, was 91 %.[1b,19] The number of turnovers per molecule of initiator was thus 1500 for norbornene and between 100 and 200 for the other cycloalkenes. The metatheses are not, as is sometimes asserted,[10a,c,14d] restricted to olefins that are strained.

Thomas J. Katz, born in Prague, received the BA in 1956 (Wisconsin; E. E. van Tamelen) and the PhD in 1959 (Harvard; R. B. Woodward). At Columbia University, where he has been since, he has studied new structures (10π-aromatic anions, benzvalene, prismane, pentaalkylphosphoranes, helicenes), new transformations (rhodium-catalyzed cycloaddition, enyne metathesis), and new preparative and mechanistic procedures in areas such as photocyclization, isotope effects, olefin metathesis, and enantiomer discrimination.

2.1.1. Advantages of Fischer Metal Carbenes in Olefin Metathesis

The Fischer metal carbene not only initiates these metatheses, but as the polymerization of cycloheptene shows, it can be more effective than classic initiating mixtures or [W(=CH*t*Bu)(NC_6H_3-2,6-(*i*Pr)$_2$)(O*t*Bu)$_2$]. The Fischer tungsten carbene gave *cis*-polyheptenamer (> 98 % *cis*) in 66 % yield, whereas the classical WCl_6/Et_2AlCl mixture gave the *trans* product (91 % *trans*) in 18 % yield,[20] and [W(=CH*t*Bu)(NAr)(O*t*Bu)$_2$] gave no product at all.[21]

Stereospecificity is a noteworthy attribute of these Fischer tungsten carbene initiated reactions [Eq. (2)]. The double bonds in the metathesis products are 95 ± 2 % *cis* according to infrared spectroscopic analyses and 93 ± 6 % *cis* according to ^{13}C NMR spectroscopic analyses. Figure 1 illustrates one of these analyses. There is no ^{1}H NMR signal at $\delta = 32.6$ ppm, which would have identified the presence of *trans* double bonds.[1b,21] Similarly, in the 2-butene and 3-hexene initially formed from *cis*-2-pentene, the double bonds are almost exclusively *cis* (97 % and 95 %, respectively); from *trans*-2-pentene they are largely *trans* (73 % and 83 % *trans*, respectively).[1f] In the polymer formed in quantitative yield from bicyclo[4.2.0]oct-7-ene, they are 85 % *cis*.[22] Such stereoselectivity is extraordinary. It has been achieved by classic initiators only in isolated examples of metatheses of norbornene[8a,23] and other cycloalkenes,[8a,24,25] by one carbene derivative of W^{VI} for the metathesis of 2-pentene,[26,27] and by another W^{VI} carbene for the metathesis of 2,3-dicarbomethoxynorbornadiene.[28] But the Grubbs ruthenium carbenes[29] and, with one exception,[21] the Schrock tungsten[21,30] carbenes have not led to such selectivity with olefins other than norbornene.[31]

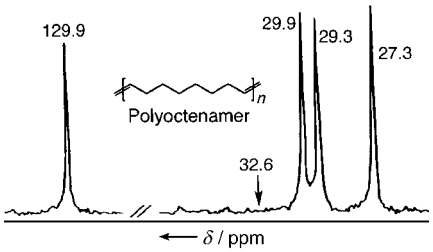

Figure 1. ^{13}C NMR spectrum (25 MHz, $CDCl_3$) of a solution of polyoctenamer prepared according to [Eq. (2)].

Pentacarbonyl(diphenylmethylene)tungsten (**1**) also initiates metatheses of trisubstituted alkenes that are cyclic and strained. In the presence of **1** (2 mol %) at 39 °C, 1-trimethylsilylcyclobutene is transformed in 80 % yield into the metathesis polymer, which within the detection limits of ^{13}C NMR spectroscopic analysis (≈ 4 %) has a perfect head-to-tail (or perfectly alternating) structure and perfect *E* ("*cis*") configuration.[4] Similarly, both 1-methyl-*trans*-cyclooctene[1e] and 2-methylnorbornene[4] give perfectly alternating polymers, the configurations of the double bonds being 76 ± 1 % *E* in the former and ≈ 60 % *Z* in the latter. 1-Methylcyclobutene,[1b] the first trisubstituted cycloalkene to be successfully polymerized by metathesis, gives, (*Z*)-"polyisoprene" (86 % *Z*;

quantitative yield) that has 90% of its units perfectly alternating.[32] Fischer metal carbene **1** also effects the exchange of methylene groups between 2-methylhept-1-ene and 2-methylpent-1-ene.[1f] Notable for all these transformations is that before they were carried out as described, no initiator was known that would bring about the metatheses of either trisubstituted or 1,1-disubstituted alkenes. The reason is that unlike **1**, all previous initiators were mixtures containing strong acids, which combine with these alkenes to form tertiary carbocations that give other products.[1a,b]

2.2. Olefin Metatheses Initiated by Other Fischer Tungsten Carbenes

Fischer metal carbenes less reactive than **1** and ineffective in initiating metatheses of many olefins are effective with olefins that are strained.[1d,4,33,34] For example, **2** (0.5 mol%) at 50°C transforms cyclobutene into *cis*-polybutenamer (90% *cis*, 60% yield) and similarly transforms other derivatives of cyclobutene as well as norbornene. The latter with 8×10^{-7} equivalents of a related initiator gave polynorbornenamer (75% *cis*, 21% yield) with $[\eta]$ (benzene, 30°C) = 3.52 dL g^{-1}.[4]

2.3. Acetylene Polymerizations

In amounts of 1–2 mol percent, both carbene complexes **1** and **2** initiate the polymerizations of acetylenes.[4,5,9,35] After 1–2 days at 50°C, the average yields of the phenyl-, methyl-, *n*-butyl-, and *tert*-butylacetylene polymers with $\bar{M}_n \approx 10^4$ were 46 ± 18%.[5] The configurations of the polymers formed when initiated by **2** were 82 ± 1% *E* (according to ^{13}C NMR spectroscopic analyses) in the case of poly(*tert*-butylacetylene) and 75 ± 10% *E* (according to infrared spectroscopic analyses) in the case of poly(phenylacetylene).[4,9] The polymerizations are slow, but the NMR spectra show that the products are notably pure.[4,5,9] Other Fischer tungsten carbenes, such as **3**, are even more reactive in polymerizing acetylenes.[36,37]

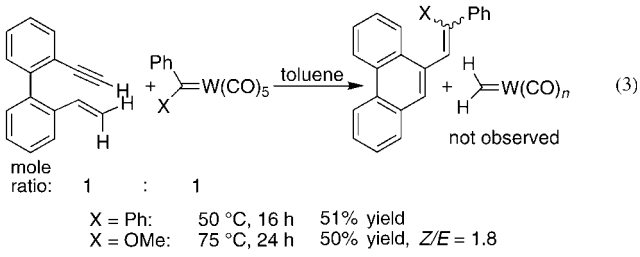
2.3.1. Advantages of Fischer Metal Carbenes in Acetylene Polymerization

Of the more recently prepared metal carbenes, [Ru(CHPh)Cl$_2$(PCy$_3$)$_2$] has not been found to polymerize any acetylenes,[38] and derivatives of [Mo(CHR)(NR″)(OR′)$_2$] polymerize only some. The latter fail, for example, with *tert*-butylacetylene.[39] In cases in which they do work,[38,40] the amounts used have been similar to or very much larger than the 1–2 mol percent of the Fischer metal carbenes used 24 years ago.

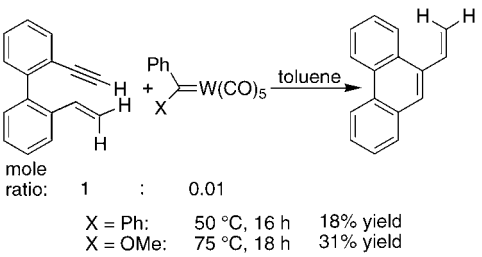
2.4. Enyne Metatheses

If, as was first suggested by Masuda,[41] the mechanism of acetylene polymerization resembles that of olefin metathesis—in simplified form if a metal carbene adds to the acetylene and is eliminated from the resulting metallacyclobutene—after metal carbene **2** has combined with *n* molecules of phenylacetylene, the product should look like structure **4**. The effect of the polymerization is to remove a stabilizing substituent,[42] the methoxy group, from the carbene center. This suggests that although **2** does not initiate metatheses of unstrained alkenes, such as 2-pentene or cyclopentene, the product **4** of its reaction with phenylacetylene, because it resembles **1**, might. In fact, when phenylacetylene in small amounts is added to a mixture of **2** and an alkene such as 2-pentene or cyclopentene, the metathesis reactions take place,[43] whereas in the absence of phenylacetylene, they do not.[44] Although the reactions are slow and low yielding, there is no question but that the addition of the acetylene actuates them. Moreover, the stereospecificities are remarkable. When the mixtures of **2** and phenylacetylene are combined with many alkenes (just as when **1** is combined with them), the double bonds in the products have the very unusual *cis* configuration: 97 ± 1% *cis* in the case of cycloheptene, 94 ± 1% *cis* in the case of cyclooctene, 95 ± 0.7% *cis* in the case of *cis*-2-pentene, and $66\%\pm8$% *cis* in the case of cyclopentene.

Related to these experiments are those in which the alkene is attached to the acetylene.[6] An example is Equation (3). Here the acetylene polymerization is terminated by an alkene after only a single cycle. Although only the phenanthrene product is observed, evidence for the presence of the other product, the methylene tungsten, is provided by similar experiments in which only small amounts of the diphenyl- or methoxyphenylmethylene tungsten reactants are used. The presumed methylene tungsten product can then compete with the diphenyl- or methoxyphenylmethylene tungsten for reaction with the enyne. The result is the enyne rearrangement [Eq. (4)].[6]

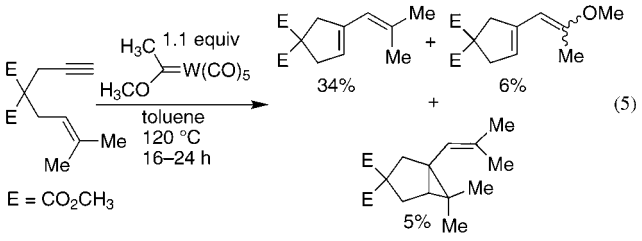


(3)



(4)

Many related experiments, one of which is summarized in Equation (5),[45] have been carried out by combining aliphatic enynes with Fischer carbene derivatives of tungsten, chromi-

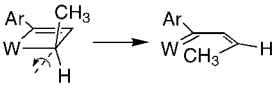


(5)

um, molybdenum, and manganese.[46a–c] These gave products analogous to those in Equations (3) and (4), as well as cyclopropanes that undoubtedly arise by a related pathway (see Section 2.5).

2.4.1. Advantages of Fischer Metal Carbenes in Enyne Metathesis

These experiments are significant not only because they demonstrated the metal-carbene-propagated enyne-metathesis reaction,[46b,c,d] but because they showed that the reaction can give the *Z* alkene with high stereoselectivity. When one of the hydrogen atoms of the methylene group of the starting material in Equation (4) is replaced by a methyl group, the propylidene group in the resulting product has the *cis* configuration (95% *cis* when the initiator is **1**, 78% *cis* when **2**).[6] The mechanistic implication is that the transformation of a metallacyclobutene into a metallabutadiene follows the path indicated in Equation (6).



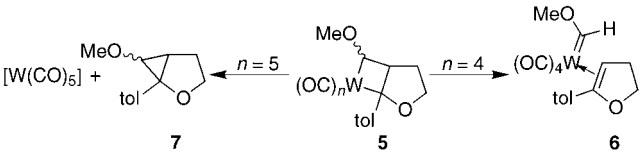
(6)

In contrast, there appears to be only one recorded example of an enyne metathesis initiated by a high-oxidation-state tungsten or molybdenum carbene.[47] There are a number of unsuccessful reactions.[47] The low-oxidation-state ruthenium carbenes have been used to great effect, but they usually give mixtures of *E* and *Z* isomers.[46d] In the presence of a ruthenium carbene plus ethylene, some alkenes give only or predominantly *E* isomers,[46d,48] but no metal carbene initiators other than the Fischer tungsten carbenes give almost pure-*Z* isomers. Remarkably, the classic olefin-metathesis initiator $MoCl_5$ combined with Ph_4Sn does also.[6b]

2.5. Evidence for the Mechanisms of These Transformations

Boiling in benzene transforms Fischer tungsten carbene [{(CH_2=$CHCH_2CH_2$)(MeO)C=}$W(CO)_5$] into **3**, by loss of CO,[49] and transforms related compounds similarly.[50] In a series of elegant mechanistic analyses, Casey et al. showed that not only do Fischer metal carbenes lose a CO ligand in this way, but to give metathesis products they *must* lose it.[51] If they do not, the metal carbenes can give cyclopropanes, but not metathesis products. Specifically, Casey et al. forced us to conclude that only when there are four carbonyl groups on the tungsten center, can **5** give the coordinatively saturated **6** (Scheme 2). When there are five carbonyl groups, it gives **7** and $[W(CO)_5]$.

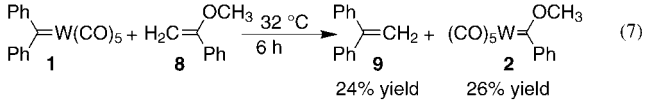
The evidence was that in benzene at 22 °C, the *cis* and *trans* isomers of [{(MeOCH=$CHCH_2CH_2$O)(*p*-tolyl)C=}-$W(CO)_5$] undergo, after an induction period, autocatalytic transformations that give mainly 2-*p*-tolyl-4,5-dihydrofuran, whereas in the presence of at least equimolar amounts of coordinating ligands (Ph_3P, CH_3CN), the kinetics are first order and none of this product is formed. Only **7** is. The explanation is that **6** is produced only when a sufficient amount of a coordinatively unsaturated tungsten, formed as a product, is available to extract CO from the starting Fischer metal carbene. If it is not available, because it has been quenched by added ligand, no dihydrofuran is produced and no autocatalysis is observed. Related experiments[50b,52] and ^{1}H NMR spectroscopic evidence for the presence of the analogue of **3**[51] support these conclusions. Casey et al. pointed out the agreement between Scheme 2 and the early



Scheme 2. The formation of products **6** and **7** from a tungsten carbene and an olefin depend on the number of ligands attached to the metal. Tol = *p*-tolyl.

observation of Fischer and Dötz[53] that CO facilitates the formation of cyclopropanes at the expense of alkenes.[51] Similarly, Casey and Cesa found, in agreement with the hypothesis, that the rates at which metal carbenes **1** and **2** exchange their carbonyl groups with isotopically labeled carbon monoxide are comparable to those of the metathesis reactions induced by the metal carbenes.[54]

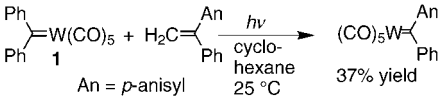
Strong evidence that Fischer metal carbenes can execute the essential step of olefin metathesis was provided by the experiment of Casey and Burkhardt [Eq. (7)].[55] Among related experiments that subsequently provided similar evidence are the following: those in which **2**, now a reactant rather than a product, combines with vinyl amines to give pentacarbonyl(aminomethylene)tungsten compounds[56] and with ethyl vinyl ether under CO or with the α,β-unsaturated esters methyl cinnamate and diethyl maleate to give cyclopropanes;[53,57] those in which the chromium analogue of **2** combines with ethyl vinyl ether or *N*-vinylpyrrolidone to give **8**;[53,58] and those in which **1** with vinyl ethers other than **8** gives either **9** or analogues of **2**.[55,59,60]



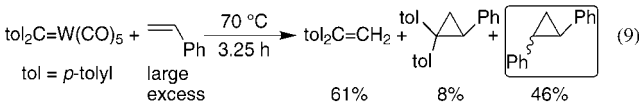
(7)

Furthermore, probably because it causes a molecule of carbon monoxide to dissociate from **1** (as it also does from **2** and from other Fischer metal carbenes),[50a,61] photoirradia-

tion brings about the exchange reaction shown in Equation (8).[62] This is a significant version of the experiment because it gives a metal carbene that has no stabilizing alkoxy group attached to the carbene center. Yet another experiment with similar significance is summarized in Equation (9): the isolation of the 1,2-diphenylcyclopropanes appears to identify a benzylidenetungsten intermediate that adds to styrene.[63]

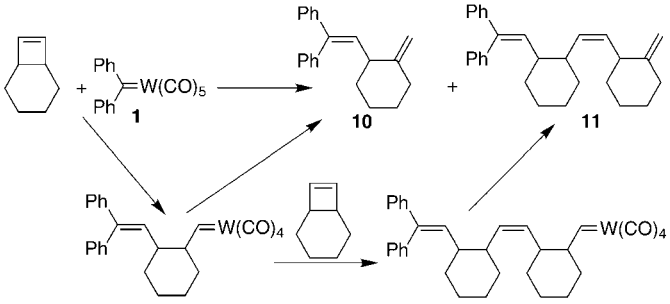


(8)



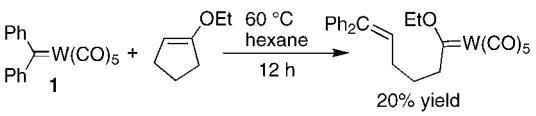
(9)

Powerful evidence for the mechanisms of initiations by Fischer metal carbenes is provided by experiments that identify a fragment of the initiator at a terminus of a ring-opening-metathesis polymerization product.[64] One is the extension of the Casey–Burkhardt experiment [Eq. (7)] shown in Equation (10).[65,66] Another, summarized in Scheme 3, yielded two materials identified as structures **10**



Scheme 3. Products of the reaction of the tungsten carbene **1** and an olefin that incorporate a fragment of the metal carbene.

and **11**, indications of the mechanistic steps in the scheme.[22,67] Another provided UV spectroscopic evidence for the presence of one diphenylmethylene unit (experimentally 0.8 units) per polymer chain in the product formed when the metathesis of 1-methyl-*trans*-cyclooctene is initiated by diphenylcarbene **1**.[1e]

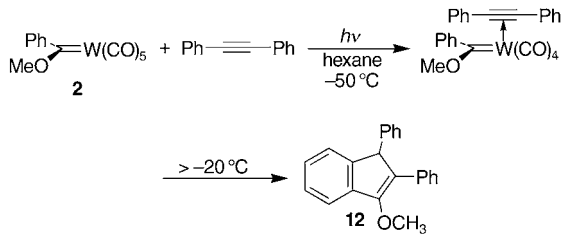


(10)

Similarly informative are the results of the experiments summarized in Equations (3) and (5) in Section 2.4. The fragments at one end of the structures formed identify how Fischer tungsten carbenes initiate enyne metatheses.

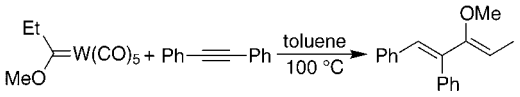
An end-group analysis also provided evidence for the related hypothesis that it is the growing acetylene polymer that initiates olefin metatheses actuated by phenylacetylene. When mixtures of this acetylene and WCl_6 initiated the polymerization of cyclopentene, a colored material was found attached to the polypentenamer formed and in an amount per chain that did not decrease when the growth of the polypentenamer chain was terminated ever earlier. The colored material (presumably polyphenylacetylene) therefore had to be attached to the initiating end of the polypentenamer chains.[68]

That Fischer metal carbenes insert into carbon–carbon multiple bonds is implied by their many stoichiometric reactions with acetylenes.[12b,69] The Dötz reaction is the best known, but Scheme 4 is cited here because it illustrates a



Scheme 4. Insertion of a tungsten carbene into diphenylacetylene.

reaction of a tungsten carbene and specifically one used in the work described above.[61a] Indene **12** is formed not only as indicated in the scheme, but also when mixtures of **2** with diphenylacetylene are heated.[61a] Similarly, other substituted acetylenes give analogous indenes.[70] The only explanations proposed involve acetylenes inserting into carbon–tungsten double bonds. The same is true for other transformations, such as the one in Equation (11).[71]



(11)

The implication of these experiments is that olefins and acetylenes insert into the carbon–metal bonds of Fischer metal carbenes, such as **1** and **2**, almost surely after a ligand is displaced from the metal. The resulting metal carbenes can combine with additional olefins and acetylenes. The consequences are olefin metatheses, acetylene polymerizations, acetylene-actuated olefin metatheses, and enyne metatheses.

3. Critique of Experiments with Fischer Metal Carbenes

3.1. Oxidation of Tungsten Carbenes

The following are reasons to question the suggestion[10a,13] that Fischer tungsten carbenes must first decompose into small amounts of high-oxidation-state alkylidene complexes before they can initiate the metathesis reactions described.

1) To carry out the experiments with **1** and **2**, solutions of the alkenes in toluene or benzene were "passed through a

column of basic alumina, degassed, and distilled from calcium hydride onto a potassium mirror and then onto pentacarbonyl(diphenylmethylene)tungsten … [then] sealed in a vacuum…"[1c] Related experiments with **3** were also carried out under vacuum.[33] The hypothesized oxidations therefore must have occurred in the absence of all but the most minuscule traces of oxidizing agents.

2) The Fischer metal carbenes are not easily decomposed or oxidized, and no significantly reactive materials have been found as products of these decompositions and oxidations.[2] The conditions described to decompose **1** were to heat it for several hours in refluxing heptane (b.p. 98 °C), whereupon it gave tetraphenylethylene, diphenylmethane, and tungsten hexacarbonyl. To oxidize it, an oxygen-saturated solution in diethyl ether was stirred under an oxygen atmosphere for 4 days to give benzophenone in 41 % yield. The methoxyphenylcarbene **2** is much more stable.[72] According to UV spectroscopic analysis, tungsten carbene **3** was unchanged after it had been heated for more than 20 times as long as it took for it to complete the metathesis of norbornene.[33]
3) The oxidation state of the tungsten does not change in the transformations summarized in Equations (7), (8), and (10) and in a related reaction.[66] These transformations mimic the essential step of olefin metatheses initiated by **1**.
4) No carbene derivative of tungsten in a higher oxidation state has yet reproduced the ability of Fischer tungsten carbenes to induce high *cis* stereospecificity in metatheses of a variety of cycloalkenes, to polymerize *tert*-butylacetylene, or to promote the metathesis of cycloheptene (see Sections 2.1.1 and 2.3.1).

Accordingly, it appears improbable that minute quantities of undetected and unspecified oxidized impurities, with properties unprecedented for oxidized species, allow Fischer metal carbenes to initiate olefin metatheses and related reactions. It also seems strange to presume that Fischer tungsten carbenes cannot propagate olefin metathesis when the most effective initiators today are carbene derivatives of Ru^{II}, which is isoelectronic with Mo^0.

3.2. Fischer Tungsten Carbenes as Chain Carriers

It is said that Fischer tungsten carbenes are unlikely to propagate metatheses because $[W(CHPh)(CO)_5]$ decomposes above −60 °C and because it does not yield metathesis products upon reaction with olefins.[10a,c] The first point is invalidated by the isolation of $[W(CHPh)(CO)_5]$ by H. Fischer et al., who handled it at room temperature,[73] and by the many transformations that seem to proceed by chain reactions even though the propagators have not been isolated. The second point contradicts Casey's conclusion,[74] summarized in Section 2.5, that the number of carbonyl ligands has to be one fewer in the propagating species than the five present in $[W(CHPh)(CO)_5]$.[75] Moreover, to exclude tungsten carbenes in low oxidation states as the propagating species in olefin metatheses seems unreasonable as they appear to be the propagating species in the enyne rearrangements discussed in Section 2.4.

3.3. Characterization of Fischer Metal Carbene Initiators

Fischer metal carbenes, it is said, do not meet criteria for an initiator to be well-defined:[10a,c,76] 1) that the propagating species either be observed in solution[16b] or be otherwise characterized;[16c] 2) that the structures of the initiators and the intermediates in the catalytic processes be essentially identical;[10c,16b] 3) that the initiators react with olefins to yield observable new carbene complexes derived from those olefins;[10c] and 4) that much of the initiator be involved in the catalytic process.[77,78]

However, as yet, no justification has been presented for these criteria, which were formulated only after the advent of recent metathesis initiators. Unexplained is why the term "initiator" should now be redefined as "well-defined initiator" and now exclude chain reactions that terminate, and why a term without previous meaning should not have been chosen for a substance that meets the new criteria.[79] Furthermore, none of the reports that provide the new definitions cite any evidence to show that the recent metathesis initiators themselves meet the new criteria. They do not seem to.

Thus in experiments with $[Mo(CH\mathit{t}Bu)(NAr)(OCMe(CF_3)_2)_2]$ (Ar = 2,6-diisopropylphenyl),[80] with $[W(CH\mathit{t}Bu)(NAr)(OCMe(CF_3)_2)_2]$,[31] and with a ruthenium carbene,[29a] only small fractions of the initiators were involved in the catalytic processes, and NMR spectra said to be those of propagating metal carbenes were detected in solution only long after the completion of the reactions in which the propagating metal carbenes were presumed to have intervened. In the experiments with $[W(CH\mathit{t}Bu)(NAr)(OCMe(CF_3)_2)_2]$, the majority of the tungsten carbene was said to have decomposed in undefined ways.[31] These results do not conform to criteria 1) and 4).

The facts are that both Fischer carbenes **1** and **2** are well-defined.[2,7,61,62,81] Their NMR, IR, UV, and mass spectra, their melting points, and their dipole moments are all defined. Their elemental compositions and molecular structures have been analyzed. They initiate olefin metatheses, acetylene polymerizations, and enyne rearrangements. The mechanisms by which they effect the initiations are compellingly made evident by experiments described in Section 2.5, which show that a ligand must be displaced from the metal, and by experiments described in Sections 2.4 and 2.5 ([Eq. (3), (5), (7), (8), (9), (10), and (11)] and Scheme 3), which identify fragments of the initiators at the termini of reaction products. The Fischer metal carbenes are not ill-defined initiators.

4. Critique of Experiments with Tantalum Carbenes

The literature on initiations by tantalum carbenes is centered on a statement repeated many times, verbatim[82] or with somewhat varied wording,[10a,c,83] that refers to the initiation of *cis*-2-pentene's metathesis by $[Ta(CH\mathit{t}Bu)Cl-$

$(OtBu)_2(PMe_3)$] and cites a preliminary communication in 1980 and a full paper in 1981:[14c,17] "This was the first time that productive metathesis of a simple olefin starting with a well-characterized carbene [or carbenoid] complex had been observed."[82] However, this initiating ability of the tantalum carbene is not described in the references cited, nor is it described anywhere else in the chemical literature.

Furthermore, experiments with this and three other tantalum carbenes are said to have demonstrated that alkoxide ligands allow, promote, encourage, or turn on the metathesis ability of tantalum carbenes.[10a,b,14a,84] *cis*-2-Pentene was the only olefin whose metathesis was mentioned, and the three other initiators were as follows: $[Ta(CHCMe_3)Cl_3(thf)_2]$, which gave a turnover of "≈ 6"; $[Ta(CHPh)Cl_3(thf)_2]$, which gave a turnover of "5–6"; and $[Ta(CHtBu)(OtBu)_3]$, which gave a turnover of "about seven".[17] Thus the basis for the statement that alkoxy substituents allow the tantalum species to function as metathesis catalysts is not strong.[85] It is weakened further by the absence of essentially any experimental details, the dissimilarity of the few mentioned,[86] and the incomplete characterization of the tantalum carbene initiators.[87,88] Six years later,[89] another tantalum carbene, which later was found to initiate the metathesis of norbornene,[89b] was said to have initiated the metathesis of 2-pentene very effectively, but there were no experimental details.

Accordingly, tantalum carbenes are known that initiate metathesis of norbornene, but there is no evidence that a well-defined and isolable tantalum carbene initiates the metathesis of any unstrained olefin.[90]

5. Summary and Outlook

There is considerable evidence that Fischer tungsten carbenes, even though their tungsten atoms are not in their highest oxidation state, initiate olefin metatheses, acetylene polymerizations, and enyne rearrangements. In contrast, members of both classes of recent initiators, $[M(CHtBu)(NAr)(OR)_2]$ (M = W or Mo) and $[Ru(CHR)Cl_2L_2]$, bring about olefin metatheses very much more quickly and with greater tolerance for accompanying functional groups. However, they do not induce the high *cis* stereoselectivity achieved by the Fischer tungsten carbenes in both olefin and enyne metatheses. Carbene derivatives of highly oxidized molybdenum or tungsten rarely initiate enyne metatheses and those of ruthenium do not initiate acetylene polymerizations. The ruthenium carbenes do initiate enyne metatheses very effectively, but their selectivities for reactions with alkenes and alkynes are usually different from those of the tungsten initiators used earlier.[91] The amounts of the initiators commonly used today are often large.[12b,d]

Thus, although the current initiators improve greatly on those discovered many years ago, further improvements should yet be possible. In searching for these, there is no reason to neglect derivatives of metals whose oxidation states are low. The differences in reactivity between the tungsten carbenes used originally and those developed more recently are similar to the differences between the currently used metal carbenes and those same metal carbenes with different ligands. If the alkoxy ligand in $[W(CHtBu)(NAr)(OR)_2]$ is $OC(CH_3)_3$ instead of $OCCH_3(CF_3)_2$,[10d,e,31] or the ligand L in $[Ru(CHR)Cl_2L_2]$ is PPh_3 instead of PCy_3,[92] the initiators are transformed from being widely effective to being effective only for the metatheses of strained olefins, such as norbornene. These differences are as great as or greater than those attributed to changes in oxidation state. Since the ligands have such large effects, the search for better initiators (e.g. those that induce high stereoselectivity) should extend beyond those classified as derivatives of Mo, W, or Re (d^0) and Ru (d^4).[93]

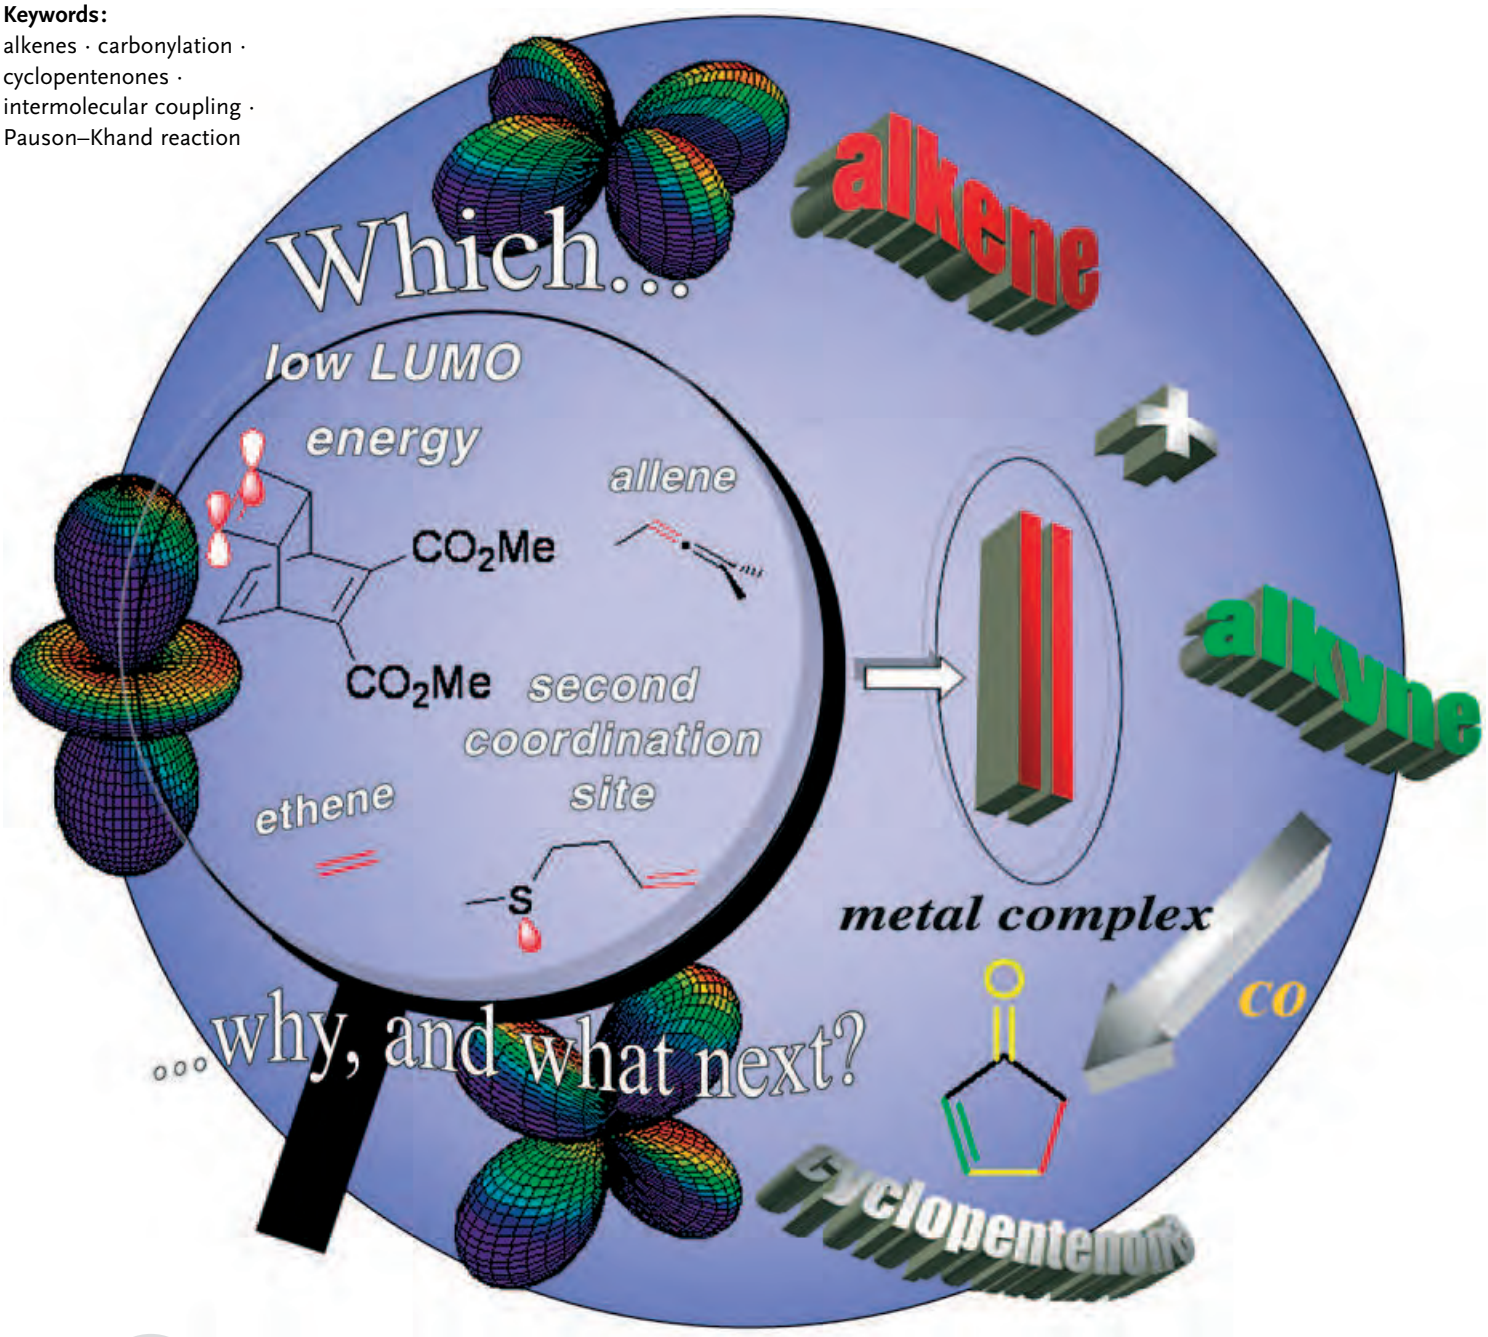
Carbocycle Synthesis

The Intermolecular Pauson–Khand Reaction

Susan E. Gibson and Nello Mainolfi*

Keywords:
alkenes · carbonylation · cyclopentenones · intermolecular coupling · Pauson–Khand reaction



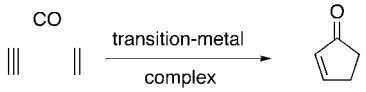
DOI: 10.1002/anie.200462235

Five membered carbocycles are important building blocks for many biologically active molecules. Moreover, substituted cyclopentenones (e.g. cyclopentenone prostaglandins) exhibit characteristic biological activity. The efficiency and atom economy of the Pauson–Khand reaction render this process potentially one of the most attractive methods for the synthesis of such compounds. Although it was discovered in its intermolecular form, the scope of the intermolecular Pauson–Khand reaction has always been limited by the poor reactivity and selectivity of the alkene component. The past decade, especially the last three years, has seen concerted efforts to broaden the scope of this reaction. In this overview, we provide a comprehensive and critical coverage of the intermolecular Pauson–Khand reaction based on the reactivity characteristics of different classes of alkenes and a rationalization of successes and misfortunes in this area.

From the Contents

1. Introduction

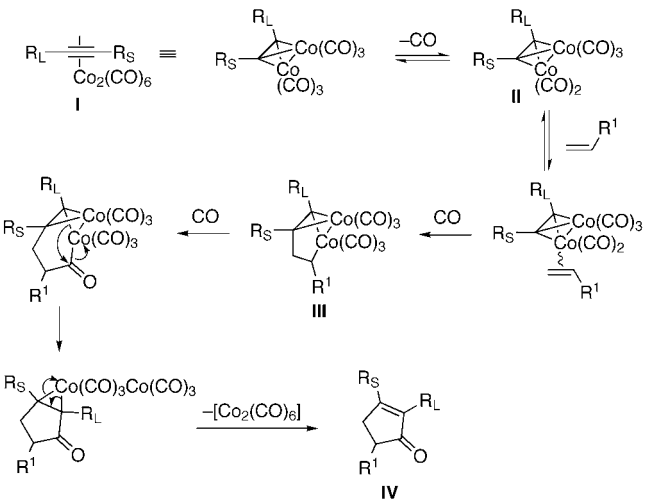
Metal-mediated reactions play an important role in our continuing search for improved ways of constructing complex molecules. For the synthesis of five-membered rings, there is surely no match for the Pauson–Khand reaction in terms of potential flexibility and atom economy. This reaction, discovered in 1971 by Pauson and Khand, [1] is a transition-metal-mediated coupling of an alkyne, an alkene, and a molecule of carbon monoxide that results in the formation of a cyclopentenone (Scheme 1).[2] Originally a cobalt carbonyl mediated process, the past decade has witnessed the introduction of new protocols based on titanium, rhodium, iridium, and ruthenium complexes. Furthermore, there are now many protocols based on transition-metal catalysts.[2g]



Scheme 1. The Pauson–Khand reaction.

The mechanism of the Pauson–Khand reaction has been the subject of extensive studies. It has proven difficult, however, to detect any intermediates beyond an initially formed hexacarbonylcobalt(0)–alkyne complex. A mechanism for the stoichiometric reaction, proposed by Magnus and co-workers in 1985, is still the generally accepted working mechanism (Scheme 2).[3] Starting from the initial hexacarbonyl complex **I**, the first step involves the loss of one CO ligand. This step, which is strongly endothermic, creates a vacant coordination site in intermediate **II**.[4] At this point the alkene coordinates with the cobalt and then inserts into a cobalt–carbon bond to form the cobaltacycle **III**. This is the step in which the regiochemical and stereochemical outcome is determined and is thought to be the rate-determining step.[5,9] The groups of Pericás,[5] Nakamura,[6] and Gimbert[7–9] have all performed elegant theoretical calculations on the role of the alkene in cobaltacycle formation, and these will be discussed in Section 3. The last two steps involve insertion of CO and reductive elimination to form the cyclopentenone **IV**.

Five-membered carbocycles are useful building blocks for the construction of complex biologically active molecules. Moreover, many cyclopentenones (e.g. cyclopentenone prostaglandins) exhibit a characteristic biological activity.[10] Although the Pauson–Khand reaction was discovered in its intermolecular form, the scope of the intermolecular reaction in synthetic projects has always been limited by the poor reactivity and selectivity of simple alkenes. Applications have been restricted to the use of strained alkenes such as



Scheme 2. The proposed mechanism for the $[Co_2(CO)_8]$-mediated Pauson–Khand reaction according to Magnus and co-workers;[3] R_L = larger group, R_S = smaller group.

norbornene, norbornadiene, and bicyclo[3.2.0]hept-6-ene, whilst the thermodynamically more favored intramolecular version has received most attention.[2]

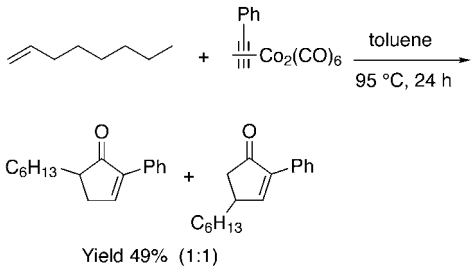
The development of efficient, versatile, environmentally friendly, and possibly asymmetric catalytic *intermolecular* systems would maximize the synthetic attractiveness of the Pauson–Khand reaction and elevate this powerful reaction to a method of choice in the synthetic planning of complex biologically active molecules.[11] The past decade, and especially the past three years, has seen concerted effort from the chemistry community to broaden the scope of the intermolecular Pauson–Khand reaction.[12] In this Review we offer a comprehensive and critical coverage of the intermolecular Pauson–Khand reaction based on the reactivity characteristics of the alkene partners. By identifying reactivity patterns for different classes of alkenes, we aim to provide an overview and rationalization of successes and misfortunes in this area.

2. Reactive Alkene Partners: A Second Coordination Site

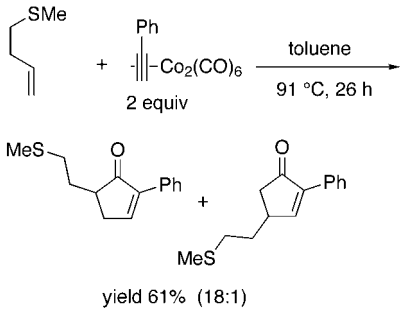
2.1. Discovery

Secondary interactions between molecules are often used to increase the rate and/or the selectivity of a reaction.[13] A preassociation of molecular partners through, for example, hydrogen bonding or Lewis acid–base interactions, is preserved during the chemical transformation and leads to a highly ordered transition state that often produces a significant enhancement in the rate and the selectivity of the reaction.

This concept was first applied to the intermolecular Pauson–Khand reaction by Krafft in 1988.[14] The use of terminal or unsymmetrically substituted alkenes usually leads to low yields and poor selectivity (Scheme 3).[2,15] Krafft and co-workers[14,16] anticipated that a heteroatom tethered to the alkene by a carbon chain would coordinate to cobalt, thus providing a bidentate complex that would lead to an increase in yield of the products and to control of the regiochemical outcome. Alkenes bearing oxygen, sulfur, and nitrogen substituents were investigated in the reaction. In contrast to alcohols and methoxymethyl ethers, which did not exhibit characteristics that would implicate heteroatom coordination,[17] sulfur and nitrogen ligands led to increased yields and excellent regiocontrol (Scheme 4).



Scheme 3. An intermolecular Pauson–Khand reaction of a terminal alkene.

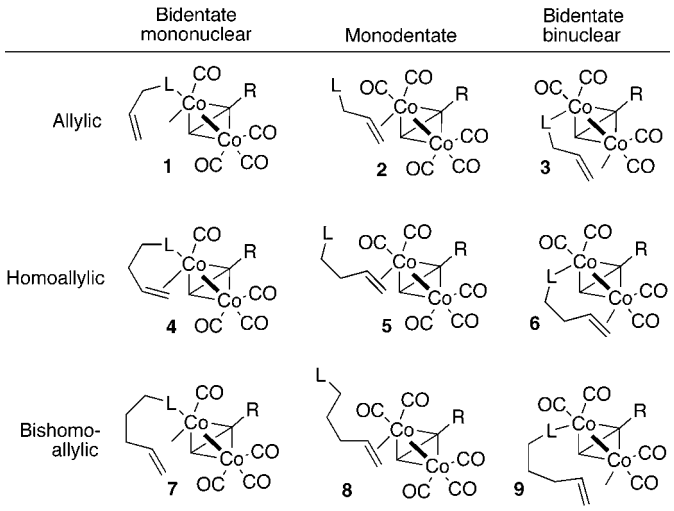


Scheme 4. An example of a substrate-directed intermolecular Pauson–Khand reaction according to Krafft and co-workers.[14]

In general allylic and bishomoallylic substrates result in poor yields and selectivities, whereas homoallylic substrates proved to be the most effective. For allylic substrates it was postulated that the tether between the heteroatom L and the alkene is too short to accommodate either a bidentate mononuclear "mode of cycloaddition" **1** (in which the heteroatom and the alkene bind to the same cobalt atom) or a bidentate binuclear "mode of cycloaddition" **3** (in which the heteroatom and the alkene each bind to different cobalt atoms) (Scheme 5). The monodentate "mode of cycloaddition" **2** (in which the heteroatom does not bind to the cobalt) is thus most likely to be the major contributor to the reaction.[18]

Sue E. Gibson obtained her first degree (1981) in Cambridge and her DPhil (1984) in Oxford (Prof. S. G. Davies). After postdoctoral studies at the ETH, Zürich (Prof. A. Eschenmoser), she lectured organic chemistry at the University of Warwick and at Imperial College, London. In 1999 she took up the Daniell Chair of Chemistry at King's College London, returning to Imperial College London and a Chair of Chemistry in 2003. Her research interests revolve around the application of transition metals in organic synthesis, especially the development and application of new asymmetric catalysts and novel chiral macrocycles.

Nello Mainolfi obtained his BSc from Queen Mary University, London, in 2001. His research project involved a new method to access substituted 2-bromophenols (Dr. Jason Eames). His PhD research (Prof. S. E. Gibson, 2001–2004) focused on the synthesis and investigations of a new class of non-racemic chiral macrocycles as ligands for asymmetric catalysis and as hosts for organic guests. He also prepared highly functionalized cyclopentenones through a new catalytic intermolecular Pauson–Khand reaction. In November 2004 he began postdoctoral studies with Prof. K. C. Nicolaou at the Scripps Research Institute.



Scheme 5. Modes of cycloaddition for the substrate-directed intermolecular Pauson–Khand reaction (L = SR or NR_2) (Krafft and co-workers[16b]).

Homoallylic substrates gave very good yields of 2,5-disubstituted cyclopentenones. Therefore, it was postulated that bidentate mononuclear complex **4** (Scheme 5) is the best "mode of cycloaddition" for these substrates (the bidentate binuclear "mode of cycloaddition" **6** would give rise to the minor regioisomer). Bishomoallylic substrates exhibit a modest enhancement in yield and regioselectivity; hence "modes" **7** and **9** (Scheme 5) may well both be operating.

Krafft and Juliano explored the concept of heteroatom-directing reactions further by using tridentate alkenes (that is, alkenes bearing two heteroatoms).[19] An in-depth study of these ligands revealed that in some of the cases examined, the second tethered directing substituent enhanced the rate of the reaction (Table 1). The significantly shorter reaction times and higher yields than those for the reaction depicted in Scheme 4 and the similar to better regioselectivities observed in the reactions (Table 1, entries 1–3), could be due to the accessibility of tridentate "modes" **11** (tridentate mononuclear) and **12** (tridentate binuclear) as well as the previously discussed bidentate "mode" **10** (Scheme 6).

Table 1: Tridentate alkenes in the substrate-directed intermolecular Pauson–Khand reaction (Krafft and Juliano[19]).

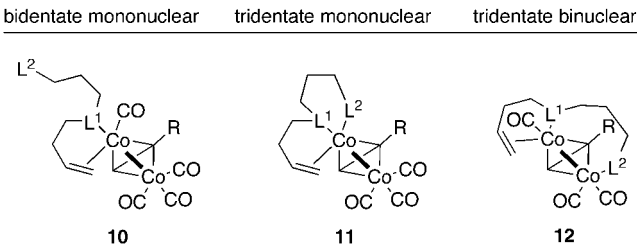
3	S	SEt	Bu	1.75	85(>40:1)

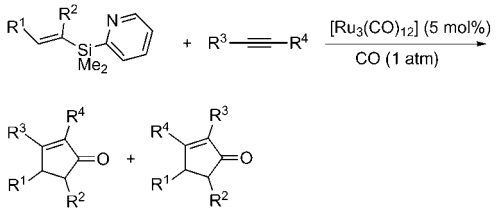


Scheme 6. Modes of cycloaddition of tridentate homoallylic substrates (Krafft and co-workers[19]).

2.2. Applications

The intermolecular Pauson–Khand reaction had to wait 10 years to benefit further from the elegant substrate-directing approach developed by Krafft and co-workers. In 2002, Itami and Yoshida reported the use of alkenyldimethyl 2-pyridylsilanes as the alkene partners for the ruthenium-catalyzed intermolecular Pauson–Khand reaction.[20] In this reaction, the pyridylsilyl group serves as a removable directing group, which facilitates the generation of desilylated cyclopentenones in moderate to excellent yields (Table 2).

Table 2: The pyridiylsilyl-directed Pauson–Khand reaction (Itami and Yoshida[20]).



Entry	R^1	R^2	R^3	R^4	Reaction conditions	Yield [%] ratio
1	H	H	Ph	Ph	xylenes, 120 °C	88
2	H	H	H	Ph	toluene, 100 °C	55 (100:0)
3	H	H	H	C_6H_{13}	toluene, 100 °C	91 (59:41)
4	C_4H_9	H	H	Ph	xylenes, 140 °C	41 (100:0)
5	H	Me	H	C_6H_{13}	xylenes, 120 °C	40 (62:38)

Dimethyl-2-pyridylvinylsilane acted as an ethene equivalent, producing cyclopentenones in good yields and selectivity when symmetrical alkynes were used (Table 2, entry 1), but moderate yields (Table 2, entry 2) or poor regioselectivities (Table 1, entry 3) when unsymmetrical alkynes were employed.

The application of β- or α-substituted vinylsilanes resulted in the completely regioselective production of substituted cyclopentenones (for R^1 and R^2), albeit in low yields and sometimes with poor alkyne selectivity (Table 2, entries 4 and 5). This work provided an excellent example of the exploitation of a second coordination site on the alkene partner and strengthens the validity of Krafft's postulated homoallylic bidentate mononuclear "mode of cycloaddition" **4** (Scheme 5).

Another study that follows the principle of substrate-directed intermolecular Pauson–Khand reactions and further

widens the scope of this method was reported in 2003.[21] In an inspiring communication,[21a] Carretero and co-workers described the use of nonracemic chiral 2-(*N*,*N*-dimethylamino)-phenyl vinyl sulfoxide as a substrate-directing alkene partner for a stoichiometric asymmetric intermolecular Pauson–Khand reaction (Table 3). After analyzing the results of their search for an active vinyl sulfoxide they concluded that the 2-(*N*,*N*-dimethylamino)phenyl substituent on the sulfoxide yielded by far the most reactive, regio-, and diastereoselective alkene. This behavior is consistent with the operation of Krafft's bidentate mononuclear "mode of cycloaddition".[21b]

Table 3: The (*o*-dimethylamino)phenylsulfinyl-directed intermolecular Pauson–Khand reaction (Carretero and co-workers[21]).

[a] TIPS = triisopropylsilyl. [b] Pressure = 10 kbar.

In this NMO-promoted (NMO = *N*-methylmorpholine *N*-oxide)[22] intermolecular Pauson–Khand reaction the presence of the bishomoallylic dimethylamino group, aided by the sulfoxide-induced polarization of the alkene (see Section 3), promotes a highly diastereoselective, completely regioselective, and reasonable yielding reaction for terminal alkynes (Table 3, entries 1–3). No reaction occurred with an internal alkyne (Table 3, entry 4), although this limitation was partially lifted by performing the reaction at high pressure (Table 3, entry 5). The reaction has been used in the shortest reported synthesis of the antibiotic (−)-pentenomycin I.[21]

This first section of the review has highlighted the synthetic relevance of the stimulating study by Krafft and co-workers on the heteroatom-directed intermolecular Pauson–Khand reaction.[14,16,19] The two recent reports by Itami and Yoshida[20] and by Carretero and co-workers,[21] which broaden the scope of this approach to new attractive alkene partners, suggest that its synthetic potential has been underestimated for a long time.

3. Reactive Alkene Partners: The LUMO Energy

3.1. Background

Milet, Gimbert, and co-workers recently published an exciting theoretical study of the reactivity of alkenes in the intermolecular Pauson–Khand reaction.[9] After analyzing the reactivity of cyclohexene, cyclopentene, and norbornene towards the hexacarbonyldicobalt(0) complex of 1-propyne they concluded that the reactivity of the alkenes in the Pauson–Khand reaction is related to the back donation of electrons from the d orbitals of the cobalt atom to the π* orbitals of the alkene. After CDA (charge decomposition analysis) calculations they discovered that for a given alkene there was an "excellent correlation between the level of back donation and the barrier to cobaltacycle formation" (which is thought to be the rate-determining step for this reaction[9]). With norbornene they discovered a greater back donation and a lower energy barrier, whereas with cyclohexene there is little back donation and a higher barrier to cobaltacycle formation. For cyclopentene the values were similar to norbornene which is consistent with experimental observations.[23] Thus it appears that the greater the back donation, the higher the reactivity of the alkene. The common component of back donation and cobaltacycle formation is the LUMO of the alkene, and the theoretical work showed that the lower the LUMO, the higher the reactivity. The authors stated that "the LUMO of a free olefin should be generally useful as a first approximation of relative reactivity." The study also notes that a correlation exists between the C=C–C angle of the alkene (cyclohexene 128°, cyclopentene 112°, norbornene 107°) and the energy level of its LUMO: the smaller the angle, the lower the LUMO energy.

In this section we review the literature of the intermolecular Pauson–Khand reaction and we rationalize the behavior of alkene partners on the basis of this study. This not only validates this exciting work but also generates a novel set of parameters for designing new Pauson–Khand substrates.

3.2. Endocyclic Alkenes

In light of the study by Milet, Gimbert, and co-workers, reports on the use of cyclopropenes as the alkene partners in the intermolecular Pauson–Khand reaction[15f,24] come as no surprise. The C=C–C angle of cyclopropene is 64.58°,[25] and hence a low-lying LUMO and high reactivity are expected. After two reports on the use of substituted cyclopropenes[15f,24a] in the intermolecular Pauson–Khand reaction, in 2001 Pericás, Riera, and co-workers used cyclopropene itself for the first time in the cobalt-mediated version of this reaction.[24b] In this NMO-promoted coupling, cyclopropene reacted with bulky terminal alkynes to give synthetically attractive bicyclo[3.1.0]hex-3-en-2-ones **13** in good to excellent yields (Table 4, entry 1). In the case of aromatic and *n*-alkyl-substituted terminal alkynes, however, the yields were poor to moderate (Table 4, entries 2–4) and the production of tricyclic ketone **14** was observed.[26]

Based on the theoretical study of Milet, Gimbert, and co-workers, cyclobutene and its derivatives, which have a C=C–C angle of 94.2°,[27] are expected to exhibit high reactivity towards alkyne metal complexes in the intermolecular Pauson–Khand reaction. In fact, there are surprisingly few reports of cyclobutene derivatives being employed in the cobalt-mediated version of this reaction.[28] They are dominated by the bicyclo[3.2.0]hept-6-ene scaffold depicted in Scheme 7 which has been the subject of several studies that reveal very good reactivity and diastereoselectivity.[28]

Table 4: The intermolecular Pauson–Khand reaction of cyclopropene with terminal alkynes (Pericás and Riera).[24b]

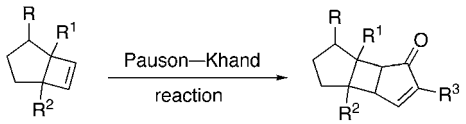

Scheme 7. The bicyclo[3.2.0]hept-6-ene scaffold in the Pauson–Khand reaction.[28]

In 2004, the use of cyclobutene derivatives was extended by our group. We reported[29] a cobalt-catalyzed intermolecular Pauson–Khand reaction of the readily available cyclobutadiene equivalent **15** (Table 5). The two-step, one-pot protocol employed a cyclobutadiene equivalent for the first time in the intermolecular Pauson–Khand reaction to provide synthetically versatile bicyclo[3.2.0]hepta-3,6-dien-2-ones **16** (Table 5, entries 1–3). A limit of this protocol is that it does not tolerate electron-withdrawing groups on the alkyne (Table 5, entry 4).

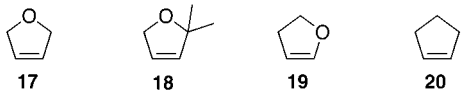
[a] TBDSM = *tert*-butyldimethylsilyl.

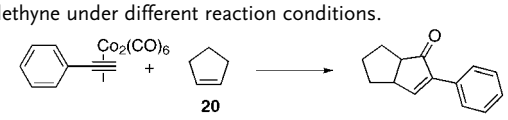
After examining cyclopropenes and cyclobutenes, our survey takes us to the cyclopentenes. The literature contains many examples of intermolecular Pauson–Khand reactions with double bonds embedded in a five-membered ring. The calculations of Milet, Gimbert, and co-workers[9] indicate that cyclopentene is activated to approximately the same extent as norbornene (the most studied alkene for this reaction). In fact, Pauson reported good reactivity for cyclopentene in his early studies of this reaction.[15a] Over the past 30 years moderate to good successes have been reported in studies on the use of 2,5-dihydrofuran **17**,[30] 2,2-dimethyl-2,5-dihydrofuran **18**,[30a] 2,3-dihydrofuran **19**,[2a,31] and cyclopentene **20**[15b,c,28f,30a,c,e–i,32,68a] (Scheme 8).



Scheme 8. Cyclopentenes used in the intermolecular Pauson–Khand reaction.

At this point it is interesting to focus on some examples in which the reactivity of the same alkene changes dramatically upon changing the reaction conditions. In the first example of the Pauson–Khand reaction of cyclopentene with phenylethyne, Pauson and Khand reported a high-temperature, moderate-yield protocol (Table 6, entry 1).[15a] A decade later Pauson and co-workers reported an improvement in the yield of this reaction when using tributylphosphine oxide as a promoter (Table 6, entry 2).[30c] A few years later, Kerr and co-workers showed that the use of an amine oxide under ultrasound conditions rendered this reaction nearly quantitative (Table 6, entry 3).[30f] In the meantime, Sugihara et al. reported the use of alkyl methyl sulfides as promoters of the Pauson–Khand reaction; under their conditions cyclopentene reacted smoothly at a relative low temperature albeit over a longer reaction time (Table 6, entry 4).[32h]

Table 6: Intermolecular Pauson–Khand reaction of cyclopentene with phenylethyne under different reaction conditions.



Entry	**20** [equiv]	Additive[a] ([equiv])	*t*, *T*	Yield [%]

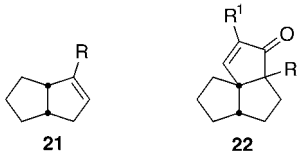
4[32h]	2.0	*n*BuSMe (5)	2 days, 35 °C	75

[a] TMANO = trimethylamine *N*-oxide.

An interesting subclass of cyclopentenes is the hexahydropentalenes **21** (Scheme 9). These undergo a double-bond shift prior to the Pauson–Khand reaction to access more-

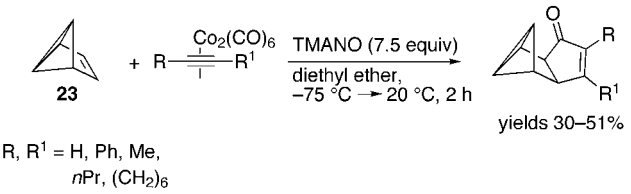


R = H (**a**), CH_3 (**b**)
$R^1 = CH_2OTBDMS$

Scheme 9. Hexahydropentalenes (**21a**)[33] and **21b**[34] and the corresponding intermolecular Pauson–Khand products **22a,b** from their reaction with a silyl-protected propargylic alcohol.

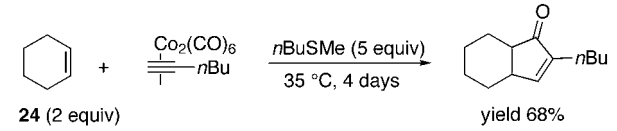
strained double bonds. Serratosa and co-workers showed[33] that the reaction of 1,2,3,3a,4,6a-hexahydropentalene (**21a**) with the hexacarbonyldicobalt(0) complex of a silyl-protected propargylic alcohol gave a single product (albeit in low yield) that corresponded to the angular fused triquinone **22a**. In an independent study Billington et al. showed that a methyl-substituted pentalene group **21b** (Scheme 9) behaved in the same way.[34] In this case the alkene shift converted a trisubstituted alkene into a tetrasubstituted alkene prior to cycloannulation.[35]

A more strained and exotic cyclopentene, benzvalene (**23**), underwent an intermolecular aminoxide-promoted Pauson–Khand reaction with moderate success (Scheme 10) in the fascinating synthesis of a $(CH)_{10}$ hydrocarbon by Christl and co-workers.[36]



Scheme 10. Intermolecular Pauson–Khand reaction of benzvalene (**23**) with alkynes (Christl and co-workers[36]).

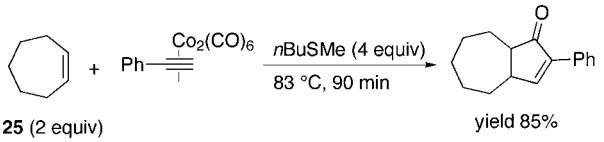
The theoretical studies of Milet, Gimbert, and co-workers supported by Pauson's experiments,[15a] reasoned that the poor reactivity of cyclohexene (3% yield with phenylethyne; C=C–C angle of 128° compared to 107° of norbornene) is due to a higher alkene LUMO which leads to a slightly endothermic binding energy value, in contrast to the exothermic binding energies of norbornene and cyclopentene.[9] Nevertheless, a good yield can be obtained from the reaction of cyclohexene **24** and 1-hexyne with a long reaction time and the use of *n*BuSMe as promoter (Scheme 11).[15f]



Scheme 11. Intermolecular Pauson–Khand reaction of cyclohexene (Sugihara et al.[15f]).

There are only a few examples of the use of cycloheptenes and cyclooctenes in the Pauson–Khand reaction. In their early studies,[15a] Pauson and Khand reported better reactivity for these two cyclic alkenes than for cyclohexene (41% for cycloheptene and 35% for cyclooctene in their reaction with phenylethyne) but not as good as for norbornene and cyclopentene. These experimental observations are also consistent with the results of Milet, Gimbert, and co-workers. Cycloheptene (C=C–C angle of 123°)[37,38] is predicted to have a lower-lying LUMO (and hence a higher reactivity) than cyclohexene (128°), but a higher-lying LUMO than norbornene (107°) and cyclopentene (112°). The same rationalization is valid for cyclooctene (C=C–C angle of 121.9°).[38]

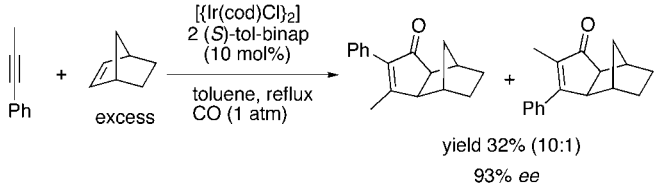
As in the case of cyclohexene, a great improvement in the yield of a reaction of cycloheptene **25** was reported,[15f] again by using *n*BuSMe as a promoter (Scheme 12). It is important to note at this point that although it has proven possible to improve reactivity by changing reaction conditions, the relative rates of reactions of different alkenes are always maintained.[39]



Scheme 12. A high-yielding intermolecular Pauson–Khand reaction of cycloheptene (Sugihara et al.[15f]).

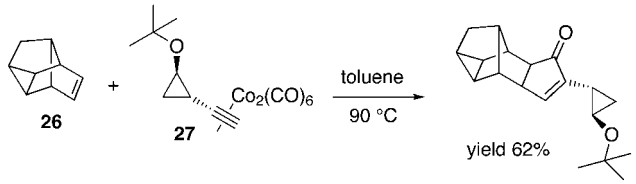
Norbornene and related systems are commonly used in the intermolecular Pauson–Khand reaction. Since the early reports of Pauson and co-workers,[23a–c] in which they showed norbornenes to be the most successful alkene partners, there have been many examples of their use in the presence of different metals and under different reaction conditions,[15b–f,30c,f,32b,g,40,68a] in the asymmetric version of the reaction,[28e,h,32d,i,41] and in heterogeneous systems.[30g–i,42] Related systems such as 8-oxabicyclo[3.2.1]octenes[28b,43] and heteroatom-containing bicyclo[2.2.1]heptenes,[28f,40b,p,42a,43c,44,45] reveal similar or slightly lower levels of reactivity. As the literature contains so many examples, we have selected just two reports, one for its current importance in the field (Scheme 13) and one for its exoticism (Scheme 14).

In 2000, Shibata used norbornene in the only catalytic enantioselective intermolecular Pauson–Khand reaction reported to date based on a chiral catalyst (Scheme 13).[41p]



Scheme 13. The only catalytic enantioselective Pauson–Khand reaction reported to date (Shibata and Takagi[41p]).

In 1993, de Meijere and co-workers [46] reported the use of deltacyclene (**26**), a norbornadiene derivative, in a cobalt-mediated intermolecular Pauson–Khand reaction with 2-alkoxy-1-ethynylcyclopropane **27** (Scheme 14). The same group reported that the fascinating cyclic diene [2.2]paracyclophane-1,9-diene (**28**) is a good alkene partner in the intermolecular Pauson–Khand reaction.[47] With a C=C–C angle of 118.7°[48] this compound would be expected to be more reactive than cyclohexene (128°), cycloheptene (123°), and cyclooctene (121.9°), but slightly less reactive than



Scheme 14. Intermolecular Pauson–Khand reaction of deltacyclene (**26**) (de Meijere and co-workers[46]).

cyclopentene (112°) and norbornene (107°). This is indeed reflected in the experimental results.[47] The reaction of diene **28** with 2 equivalents of the hexacarbonyldicobalt(0) complex of phenylethyne for 1 day gave a mixture of mono- and diannulated compounds in a moderate yields (Table 7, entry 1). The reaction of the same alkene with 2.4 equivalents of the cobalt complex of trimethylsilylethyne gave the mixture in better overall yield, but only after a longer reaction time (Table 7, entry 2). In the presence of 6 equivalents of the latter alkyne complex the reaction proceeded smoothly and gave the diannulated product in high yield as a mixture of isomers (Table 7, entry 3).

Table 7: The intermolecular Pauson–Khand reaction of [2.2]paracyclophane-1,9-diene (**28**) (de Meijere and co-workers[47]).

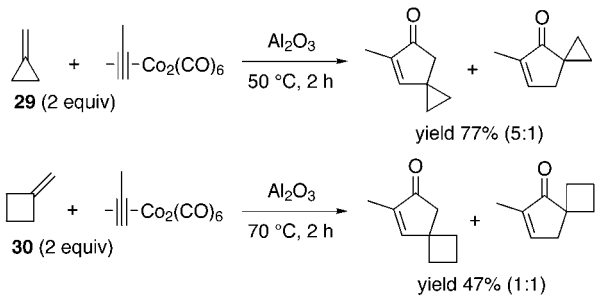
3	TMS(6)	5 days, 90 °C	0	80

[a] TMS = trimethylsilyl. [b] Yields of mono- and diannulated products.

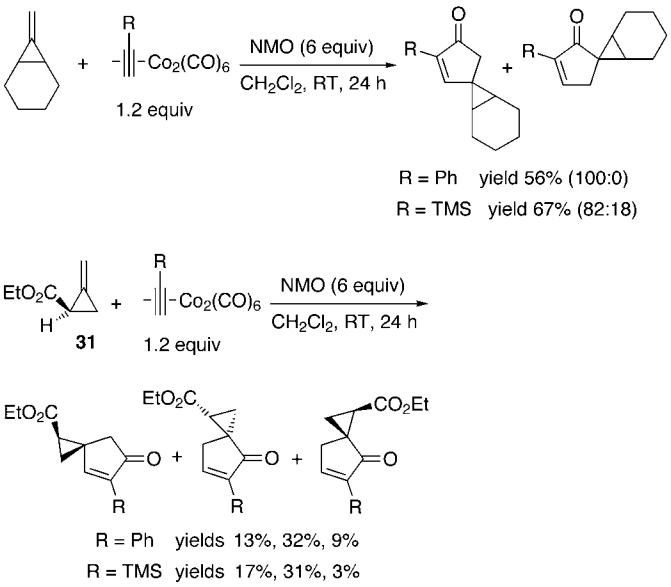
3.3. Exocyclic Alkenes

There are only a few examples of the use of exocyclic alkenes in the intermolecular Pauson–Khand reaction. Smit et al.[49] described the use of methylenecyclopropane (**29**) in a cobalt-mediated reaction under dry, absorption conditions (SiO_2, Al_2O_3, or zeolites) (Scheme 15). The strain in **29** (C–C(=C)–C angle of 63.9°[27a]) suggests a low-lying LUMO and predicts good reactivity towards alkyne complexes in the Pauson–Khand reaction. Indeed, its reaction with 2-propyne over Al_2O_3 gave a 5:1 mixture of regioisomers in very good yield after only 2 h at 50 °C (Scheme 15, top). Predictably, the use of methylenecyclobutane (**30**) (C–C(=C)–C angle of 92°[27b]), resulted in a lower yield (Scheme 15, bottom).



Scheme 15. Intermolecular Pauson–Khand reaction of methylenecyclopropane (**29**) and methylenecyclobutane (**30**) in the presence of solid adsorbents (Smit et al.[49]).

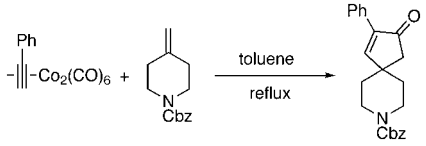
In 1996, Motherwell and co-workers[50] reported the use of functionalized alkylidene cyclopropanes in the NMO-assisted intermolecular Pauson–Khand reaction (Scheme 16). Interestingly, the presence of an ester group on the cyclopropane ring **31** not only reversed the regioselectivity of the reaction but also gave more-complex mixtures (Scheme 16, bottom).[51] An independent study of alkylidene cyclopropanes by Witulski and Gößmann[15g] with *N*-alkynyl amides as the alkyne partners gave similar yields and selectivities to those reported by Smit et al.[49] and Motherwell and co-workers.[50]



Scheme 16. Alkylidenecyclopropanes in the NMO-assisted intermolecular Pauson–Khand reaction (Motherwell and co-workers[50]).

As expected, the use of an exo methylene functionality on a six-membered ring in a thermal intermolecular Pauson–Khand reaction resulted in low yields (Table 8, entry 1).[52] However, in the presence of a large excess of the alkene (Table 8, entry 2), the desired spirocyclopentenone was produced in good yield.[53]

Table 8: Intermolecular Pauson–Khand reaction of methylene piperidines (Ishizaki, Hoshino, and co-workers[52]).

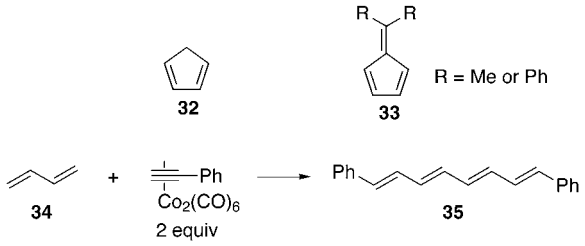


Entry	Alkene[a] [equiv]	*t* [h]	Yield [%]
1	2	5	30
2	10	3	78

CBz = benzyloxycarbonyl.

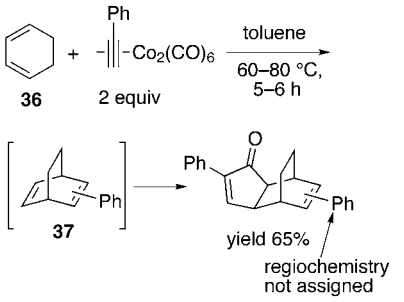
3.4. Conjugated Alkenes

Pauson and Khand examined the reactivity of conjugated alkenes in their early studies on the reaction.[54] In the case of dienes, they found that although cyclopentadiene (**32**) and fulvenes **33** reacted well,[54c] cyclohepta-1,3-diene and buta-1,3-diene (**34**) underwent a competing reaction that led to tetraenes such as **35** (hydrogen migration occurs instead of carbon monoxide insertion) (Scheme 17).[54a] They also



Scheme 17. Some conjugated dienes employed in the Pauson–Khand reaction (Pauson and co-workers[54a,c]).

observed[54b] that treatment of cyclohexa-1,3-diene (**36**; Scheme 18) with 2 equivalents of alkyne complex resulted first in a Diels–Alder reaction and subsequently in a Pauson–Khand reaction with the less-hindered alkene of the cycloadduct **37** (Scheme 18). When cyclohexa-1,4-diene was subjected to the same reaction conditions, a double-bond shift took place to yield **36**, which then entered the cascade sequence.[54b]

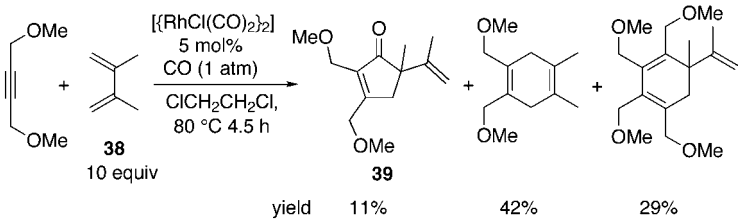


Scheme 18. A Diels–Alder/Pauson–Khand cascade reaction (Pauson and co-workers[54b]).

We believe that it is enlightening to consider these observations in the context of an extension of the hypothesis of Milet, Gimbert, and co-workers. It is known that adding conjugation to a double bond lowers the LUMO of the alkene by at least 0.5 eV.[55] Thus a conjugated diene has a lower-lying LUMO than a simple alkene, and hence should be more reactive in the Pauson–Khand reaction, if this reaction manifold can be accessed. Interestingly, a comparison of the outcome of similar reactions involving cyclopentadiene[54c] and cyclopentene[15a] suggests that the former is indeed more reactive.[56]

In 2004, Wender and co-workers have started to reveal the full potential of dienes as alkene partners in the intermolecular Pauson–Khand reaction.[57] Initially they observed that when 10 equivalents of 2,3-disubstituted-1,3-dienes such as **38** react with disubstituted alkynes in the rhodium-catalyzed intermolecular Pauson–Khand reaction at 80 °C, two other competing reactions occur: a [4+2] cycloaddition (as Pauson and co-workers observed for cyclohexadiene),[54] and a [2+2+2] coupling reaction; the desired Pauson–Khand product **39** was thus generated in low yield (Scheme 19). When the reaction was performed at 60 °C, however, a remarkable increase in selectivity was observed and led to cyclopentenones in excellent yields (Table 9, entries 1–3). Monosubstituted alkynes did not undergo cyclization.

When Pauson and co-workers investigated the reactivity of styrene **40** and its derivatives,[15a,54c,58] they discovered slightly more encouraging reactivity than with 1,3-dienes such as butadiene. Production of an unwanted coupling product still occurred through a competing pathway, but this time the Pauson–Khand product was observed. Indene (**41**), a strained version of styrene, afforded the Pauson–Khand product in improved yield (Scheme 20).[15a,54c] The two reactions showed complete regioselectivity with respect to the alkyne and the



Scheme 19. Competing [2+2+1], [4+2], and [2+2+2] couplings in the reaction of a diene with a disubstituted alkyne at 80 °C (Wender and co-workers[57]).

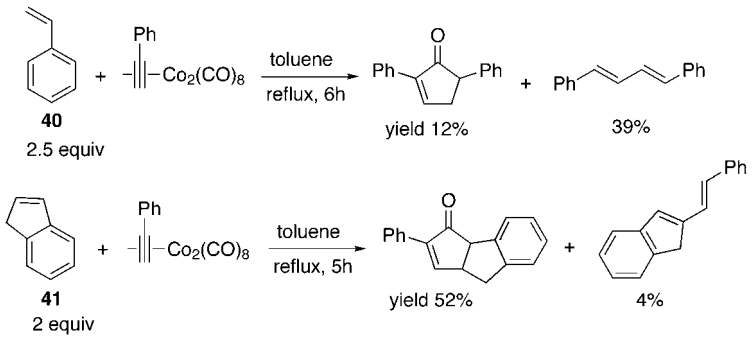
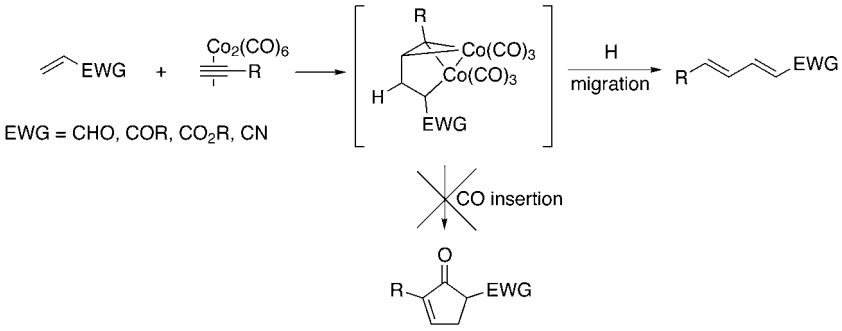


Scheme 20. Intermolecular Pauson–Khand reaction of styrene (**40**) and indene (**41**) (Pauson and Khand[15a,54c]).

alkene substituents. Although alkyne selectivity was already well-documented, the latter was noteworthy in the early years of the Pauson–Khand reaction. An explanation may be found in the polarization of the LUMO of the double bond by the arene ring which may induce the formation of the first C–C bond at the remote carbon atom of the alkene.

Control of the two observed reactivity modes of conjugated alkenes (hydrogen migration versus CO insertion) could be the key to the successful employment of a range of reactive and synthetically attractive alkene partners. The two reaction pathways can be explained in an example: The LUMO of alkenes that bear electron-withdrawing groups, for example, is very low, typically between −2 and 0 eV;[55] comparing this to the LUMO of norbornene (0.42 eV), we would expect even higher reactivity in the Pauson–Khand reaction for such alkenes. The extreme polarization of the

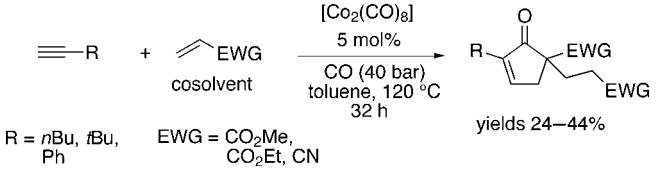


Scheme 21. Hydrogen migration (through β-hydride elimination) prevails over CO insertion in the intermolecular Pauson–Khand reaction of electron-poor alkenes. EWG = electron-withdrawing group.

double bond, however, leads to hydrogen migration and formation of dienes in preference to CO insertion and the formation of cyclopentenones (Scheme 21). In fact, reactions of members of this class of alkenes produced exclusively dienes.[59]

More recently, however, two reports on the successful employment of electron-poor alkenes have been published. In 1995, Costa and Mor[60] observed the formation of cyclopentenone products from electron-poor alkenes for the first time. Reaction of terminal alkynes and alkyl acrylates or acrylonitriles (as cosolvents) with catalytic amounts of $[Co_2(CO)_8]$ under a high pressure of CO and high temperatures forced the reactants down the CO insertion pathway and led to the isolation of cyclopentenones from a regioselective domino Pauson–Khand/Michael addition (Scheme 22).

In 1999, Cazes and co-workers reported that terminal and internal alkynes react with methyl acrylates and phenyl vinyl sulfones at lower temperatures in the stoichiometric NMO-promoted Pauson–Khand reaction.[61] They successfully exploited the anticipated high reactivity of electron-poor alkenes and suppressed the β-hydride elimination pathway by using low temperatures. In the presence of only 2 equivalents of the



Scheme 22. The domino intermolecular Pauson–Khand/Michael addition reaction of electron-poor alkenes (Costa and Mor).[60]

alkene under mild reaction conditions (facilitated by the use of an amine oxide) only cyclopentenones were isolated (Table 10). In contrast to the results of Costa and Mor,[60] internal alkynes (Table 10, entries 1–2) result in better yields than terminal alkynes (Table 10, entries 3–4). The regioselectivity described in Scheme 22 and Table 10 is consistent with polarization of the LUMO of the alkene as mentioned above for styrene.

4. Reactive Alkene Partners: Miscellaneous

4.1. Allenes

Recent advances in the application of allenes in metal-mediated or -catalyzed reactions[62] include their use as alkene partners in the intermolecular Pauson–Khand reaction. The unusual structural and electronic characteristics of allenes[63]

Table 10: The intermolecular Pauson–Khand reaction of electron-poor alkenes (Cazes and co-workers[61]).

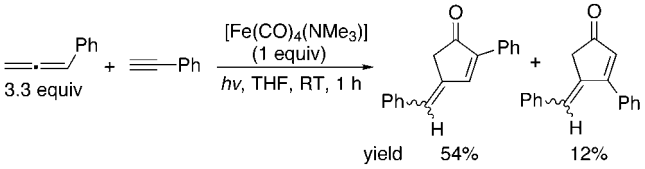
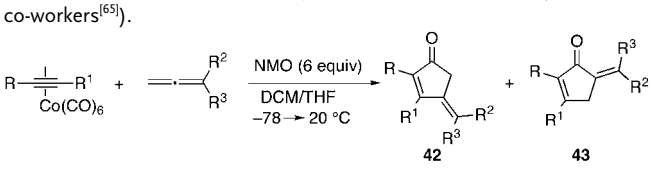
together with the limited number of literature examples available at present have rendered it difficult to classify accurately their reactivity.

The first example of the use of an allene in the Pauson–Khand reaction was reported by Pauson in his review of 1985.[2a] He reported the smooth reactivity of cyclonona-1,2-diene with alkyne metal complexes. Apart from a report from Narasaka and co-workers,[64] in which they showed that $[Fe(CO)_4(NMe_3)]$ and irradiation promote the reaction between alkynes and allenes (Scheme 23), the major contribution to this area has originated from the Cazes group. Over the past decade they have described[65] the reactivity and regioselectivity of allenes in the NMO-promoted intermolecular Pauson–Khand reaction. They showed that the reactions depend on the substitution pattern of both acetylenic and allenic partners. The presence of an electron-donating group on the allene favors the formation of cyclopentenones **42** (Table 11, entry 1),[65b] whereas an electron-withdrawing group gives a mixture of cyclopentenones **42** and **43** (Table 11, entry 2).[65b] The reactivity of allenic hydrocarbons[65c] and their reactivity with silylated alkynes[65d] were also the subjects of extensive studies.



Scheme 23. Allene–alkyne intermolecular Pauson–Khand reaction in the presence of $[Fe(CO)_4(NMe_3)]$ under irradiation (Narasaka and co-workers[64]).

Table 11: The intermolecular allenyl Pauson–Khand reaction (Cazes and co-workers[65]).



Entry	R	R^1	R^2	R^3	Yield [%] 42	43

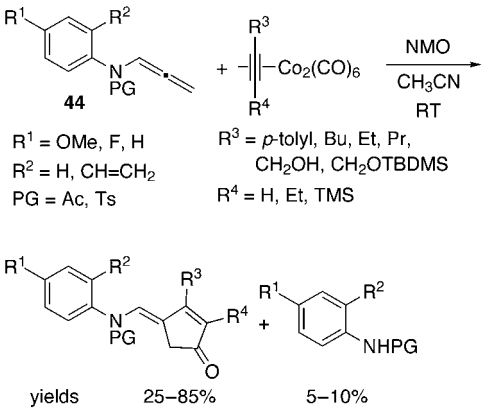
2	C_3H_7	C_3H_7	CO_2Me	H	33	14

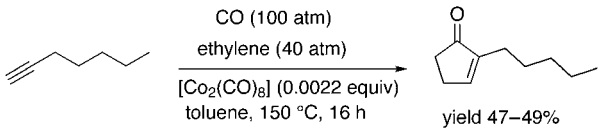
Pérez-Castells and co-workers recently observed high regio- and stereoselectivity in the reactions of allene amides **44** with alkynes in the NMO-promoted version of the reaction (Scheme 24).[66] Allenes have also been used by Witulski and Gößmann,[15g] who treated 2-methylbuta-2,3-diene with an alkynyl amide in an aminoxide-promoted intermolecular Pauson–Khand reaction, and Hailes and co-workers who used undeca-5,6-diene in a key intermolecular Pauson–Khand reaction in the synthesis of novel compounds with olfactory properties.[67]



Scheme 24. Alleneamides in the intermolecular NMO-promoted Pauson–Khand reaction (Pérez-Castells and co-workers[66]). PG = protecting group; Ts = *p*-toluenesulfonyl.

4.2. Ethene

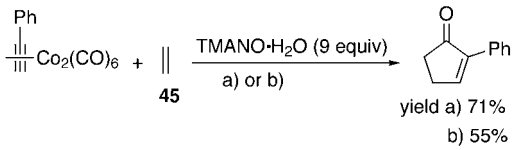
Ethene is one of the most attractive alkene partners in the Pauson–Khand reaction because of the synthetic potential of its products and it has been used since the discovery of the reaction.[2a,15a,d,30c,e,32c,40r,54a,68] However, its employment has been limited by the need for harsh reaction conditions, that is, elevated temperature and pressure. Use of the latest advances in the area such as catalysis,[68c] amine oxide promoters,[68d–f] and supercritical fluids[68g] does not remove the need to use high pressures to attain reasonable yields (Scheme 25).



Scheme 25. A catalytic Pauson–Khand reaction under high pressures of carbon monoxide and ethene (Rautenstrauch et al.[68c]).

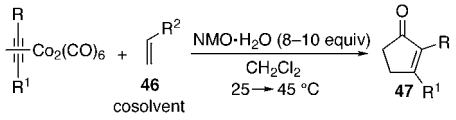
It was thus a significant development when Kerr and co-workers reported the first use of ethene at atmospheric pressure.[68d–f] They subsequently enhanced the practicality of the reaction even further through the discovery of an extremely convenient ethene equivalent for the intermolecular Pauson–Khand reaction.[69] During the synthesis of (+)-taylorione, Kerr and co-workers[68d–f] used $TMANO{\cdot}H_2O$ as a promoter for the annulation of alkyne metal complexes with ethene. Satisfactory yields were possible not only at a relatively low ethene pressure (25–35 atm) but also at atmospheric pressure (bubbling ethene) and room temperature (Scheme 26).

Later, Kerr discovered that vinyl esters behave as ethene equivalents when employed in the $NMO{\cdot}H_2O$-promoted stoichiometric intermolecular Pauson–Khand reaction (Table 12).[69] Interestingly, the poor reactivity of ethyl vinyl ethers had already been reported.[34,70] The change in reactivity between the ethers and the esters can be understood in terms of the molecular-orbital theory introduced in



Scheme 26. TMANO-promoted Pauson–Khand reaction of ethene: a) 25–35 atm, 40 °C; b) 1 atom (bubbled), room temperature; (Kerr and co-workers[68d–f]).

Table 12: Ethene equivalents **46** in the intermolecular Pauson–Khand reaction (Kerr and co-workers[69]).



Entry	R[a]	R^1	R^2 [b]	*t* [h]	Yield [%]
1	Ph	H	OAc	1	53
2	Ph	H	OBz	16	80
3	$THPOCH_2$	H	OBz	16	87
4	CH_3	CH_3	OBz	16	5

[a] THP = tetrahydropyranyl. [b] Bz = benzoyl.

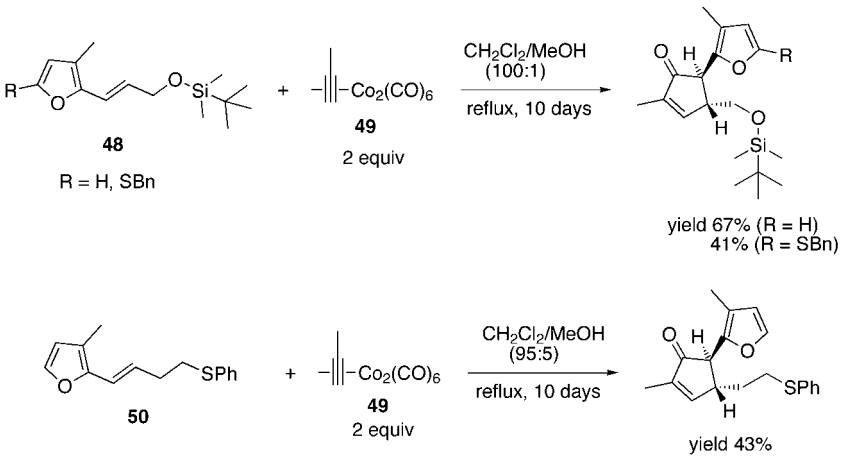
the previous section. Electron-donating groups raise the energy of the LUMO of the alkenes, thus lowering their reactivity. By converting an electron-rich vinyl ether into an electron-poor vinyl ester **46**, Kerr and co-workers not only improved the reactivity of the alkene, but also obtained the ultimate Pauson–Khand product, the deesterified cyclopentenone **47** (Table 12).[71] With this new protocol, the yields of the cyclopentenones were comparable and sometimes better than when using autoclave conditions[68d–f] (Table 12, entries 1–3). Loss of the substituent derived from the alkene may occur by the reduction of the ketone to the corresponding ketyl by low-valent cobalt species. Elimination of the ester, further reduction to the enolate, and subsequent quenching with water (contained in $NMO·H_2O$) would deliver the deesterified cyclopentenone **47**.[69b] Vinyl esters **46** showed very little reactivity towards internal alkynes, as does gaseous ethene[68] (Table 12, entry 4).

4.3. Low LUMO Energy or Coordination?

In the course of work towards the total synthesis of phorbol, Harwood and Tejera discovered that 2-furyl-substituted alkenes **48** and **50** (Scheme 27) reacted with the hexacarbonyldicobalt(0) complex of propyne **49** in good yield and regioselectivity.[72] In contrast, Pauson and co-workers showed that 2-vinylfuran reacted with phenylethyne only to produce an unwanted diene.[58a] As discussed in the previous section, this behavior is characteristic of some conjugated alkenes. In this case Harwood and Tejera showed that not only did the substituted vinyl furans **48** and **50** undergo the Pauson–Khand reaction, but also that in the case of thioether **50** the Krafft bidentate homoallylic "mode of cycloaddition" (Section 2.1, Scheme 5) was overwhelmed by the polarization of the alkene by the furyl group, thus yielding the furyl cyclopentenone as a single regioisomer.[72]

5. Summary and Outlook

We have shown how the reactivity of the alkene partners in the Pauson–Khand reaction is influenced by two major factors: the presence of other coordination sites on the alkene (Section 2) and the energy of the LUMO of the alkene (Section 3). In Section 2 it was seen that a second (and even a third) coordination site on the alkene can overcome the problems of reactivity and selectivity normally associated with the intermolecular Pauson–Khand reaction. This conclusion from a landmark study by Krafft and co-workers[14,16,19] has been underestimated for too many years, as illustrated by two recent literature reports that successfully build on this concept, and in doing so, significantly broaden the scope of the reaction.[20,21]

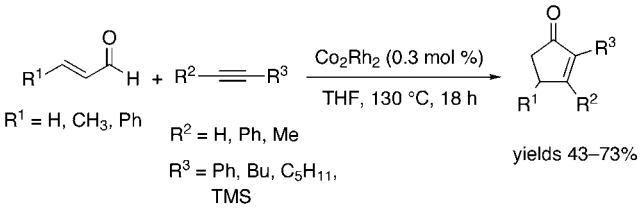


Scheme 27. The overpowering effect of the 2-furyl group in the intermolecular stoichiometric Pauson–Khand reaction (Harwood and Tejera).[72]

The second important concept is the use of the LUMO energy of the alkene to predict its relative reactivity in the Pauson–Khand reaction.[9] Our survey of intermolecular reactions in which the alkene reactivity could be rationalized with this theory has underlined the usefulness of the concept. Perhaps, more importantly, it should encourage the design and testing of many innovative Pauson–Khand substrates in the near future. As use of the intermolecular Pauson–Khand reaction in synthesis increases, it is anticipated that more examples will emerge in which electronic and coordination effects compete to determine alkene regioselectivity.

Although the journey to the perfect intermolecular Pauson–Khand reaction—efficient, versatile, environmentally friendly, asymmetric, and catalytic—is still far from over, an important step forward was very recently reported by Chung and co-workers.[73] They described a catalytic, inter-

molecular, heterogeneous (Co_2Rh_2 bimetallic nanoparticles) reaction in which an unsaturated aldehyde functions as both the alkene partner and the source of CO. It is well-documented that the reaction of aldehydes on metal surfaces releases hydrocarbons and carbon monoxide.[74,75] Chung and co-workers used this principle in the reaction of α,β-unsaturated aldehydes with terminal and internal alkynes in the presence of catalytic amounts of the nanoparticles to give cyclopentenones in moderate to good yields (Scheme 28).



Scheme 28. The catalytic intermolecular Pauson–Khand reaction with an unsaturated aldehyde as alkene and CO source (Chung and co-workers).[73]

From a personal perspective, we hope that the report of Chung and co-workers[73] together with the insight provided herein into the reactivity problems that have, to date, been associated with the intermolecular Pauson–Khand reaction will inspire efforts to widen the scope of this potentially very powerful coupling reaction.

Metallocene Chemistry

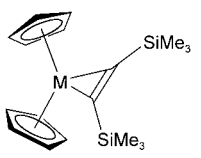
Reaction of Ruthenium Ethyne-1,2-diyl Compounds with Bis(trimethylsilyl)acetylene Complexes of Titanocene and Zirconocene: Remarkable Transfer of a C_2 Ligand**

Christopher S. Griffith, George A. Koutsantonis, Brian W. Skelton, and Allan H. White*

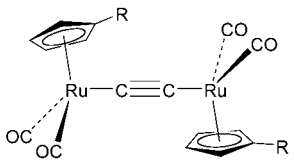
The chemistry of the metallocene bis(trimethylsilyl)alkyne complexes of Group 4 metals $[(\eta\text{-}C_5H_5)_2M\{\eta^2\text{-}C_2(SiMe_3)_2\}]$ (**1**, M = Ti; **2**, M = Zr·(thf)) has been initiated and pursued by Rosenthal and co-workers for a considerable amount of time.[1] These complexes provide fragments that react readily with a variety of unsaturated compounds. Such fragments have unstable 14-electron configurations in which the two unoccupied orbitals and single occupied orbital of the metallocene units provide a plausible explanation for the diverse chemistry exhibited by these complexes, which often form metallacycles.[1–7]

We, in turn, have been interested in the use of substrates reactive to sites of unsaturation as building blocks for the rational preparation of larger molecules from ruthenium ethyne-1,2-diyl compounds,[8–16] and viewed complexes **1** and **2**[6] as excellent candidates for this purpose. Both complexes contain a ligand that stabilizes the reactive metal center, but which is easily removed to allow access to the reactivity of the unsaturated metal. The displacement of $Me_3SiC{\equiv}CSiMe_3$ from the metal coordination spheres of complexes **1** and **2** has been exploited by Rosenthal and co-workers with a range of diynes and polyynes.[3]

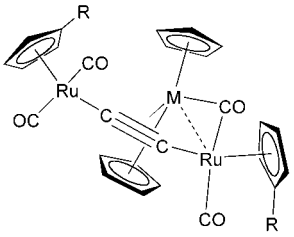
Herein we report the reaction of the ruthenium ethyne-1,2-diyl compounds $[\{Ru(CO)_2(\eta\text{-}C_5H_4R)\}_2(\mu\text{-}C_2)]$ (**3a**, R = H; **3b**, R = CH_3) with the reactive fragments "$(\eta\text{-}C_5H_5)_2M$" derived from **1** and **2**. These reactions proceeded at ambient temperatures in tetrahydrofuran to give excellent yields of the ethynediyl-coordinated metallocenes **4** and **5**. Direct in situ reaction with Group 4 metallocene dichloride and magnesium resulted in the recovery of the known compound $[RuCl(CO)_2(\eta\text{-}C_5H_5)]$ from other indeterminate products in moderate yield. The excess of complexes **1** and **2** was removed by simple hexane extraction, but no attempt was made to isolate the liberated $Me_3SiC{\equiv}CSiMe_3$. Similar reactions performed at 40–50 °C were essentially complete after ten hours with little or no decrease in yield of the complexes. Each complex exhibits similar infrared spectra with five ν(CO) absorptions, of which the absorption at $\approx$1730 cm^{-1} was assigned to the bridging carbonyl ligand between the ruthenium and Group 4 metal centers. The ^{1}H NMR spectra of the three complexes display resonances of four magnetically inequivalent cyclopentadienyl groups. The two singlet resonances attributable to the metallocene fragment in each spectrum are significantly shifted between 1.06–1.25 ppm upfield from those of **1** or **2**. The two singlet resonances assigned to the $Ru(\eta\text{-}C_5H_5)$ moieties of **4a** and **5** are shifted with respect to that observed for **3a**, one 0.06–0.11 ppm upfield, and the other 0.35–0.30 ppm downfield. Similar changes in chemical shift values relative to those of **3b** are also observed for **4b**, with the methine ring resonances at lower field appearing as four resolved singlet resonances, and with the higher field resonances appearing as a virtual triplet. Two singlet resonances at $\delta = 1.98$ and $\delta = 1.67$ ppm are assigned to the methyl protons of the two C_5H_4Me rings. Complexes **4** and **5** are moderately air-sensitive in the solid state but more so in solution, and are best handled in an inert atmosphere.



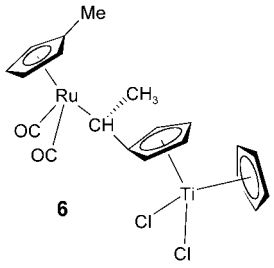
1: M = Ti
2: M = Zr • (thf)



3a: R = H
3b: R= Me



4a: M = Ti, R = H
4b: M = Ti, R= Me
5 : M = Zr, R = H



6

The ^{13}C NMR spectra measured for **4a** and **4b** contain resonances at $\delta \approx 106.0$ and $\delta \approx 105.0$ ppm, which are assigned to the titanocene moiety. The magnetic inequivalence of the $Ru(\eta\text{-}C_5H_4R)$ moieties is illustrated by the two singlet resonances at $\delta = 88.1$ and $\delta = 89.7$ ppm for **4a** and eight resolved singlet resonances at $\delta = 90.8$, 88.4, 88.0, 87.9, 86.3, 85.5, 85.3, and 85.1 ppm for **4b**. The two singlet resonances at $\delta = 114.4$ and 108.2 ppm are attributed to the *ipso* carbon atoms of the two C_5H_4Me rings. The two resonances present at $\approx$200 ppm for **4a** and **4b** are assigned to the two terminal carbonyl groups of the pendent $\{Ru(CO)_2(C_5H_4R)\}$ fragment on the basis of their chemical shifts. The resonances at $\delta =$ 203.9 and 204.4 ppm for **4a** and **4b**, respectively, are assigned to the remaining terminal carbonyl ligands coordinated to ruthenium. Downfield singlet resonances at $\delta = 305.5$ and 307.7 ppm in the spectra of **4a** and **4b**, respectively, are attributed to the bridging carbonyl group between the

titanium and ruthenium centers on the evidence of related semibridging carbonyl groups of the early/late transition metal heterobimetallic complexes $[Rh(\eta\text{-}C_5H_5)(\mu\text{-}CO)(\mu\text{-}\eta^1{:}\eta^2\text{-}CO)Zr(\eta\text{-}C_5Me_5)_2]$[17] and $[Ru(CO)(\mu\text{-}C(O)CH_2CH_2\text{-}(\eta\text{-}C_5H_4))(\mu\text{-}CO)Zr(\eta\text{-}C_5H_5)_2]$.[18] The carbon atoms of the coordinated ethyne-1,2-diyl unit are assigned to resonances at $\delta = 167.6$ and 93.7 ppm for **4a** and $\delta = 167.0$ and 101.6 ppm for **4b**. The connectivity of **4a** (Figure 1)[19] was established by X-ray single-crystal structure determination, and demonstrates the formation of an alkyne adduct of essentially "$Ti(C_5H_5)_2$" not unlike that of the starting material **1**. The most striking difference is that the ethyne-1,2-diyl moiety is coordinated in an unsymmetrical η^2 fashion to a titanocene fragment with a symmetrical bridging carbonyl group between the titanium atom and one of the ruthenium atoms. The ruthenium, titanium, and the alkynyl carbon atoms of the coordinated ethyne-1,2-diyl ligand are not strictly coplanar, but for the purpose of describing the overall geometry and connectivity of **4a**, they may be regarded as such. The Cp_1-Ti-Cp_2 angle of 130.8° is similar to that measured in several metallocene η^2-alkyne solid-state structures.[20] Coordination of the ethyne-1,2-diyl ligand is significantly distorted from the ideal η^2 coordination as observed from the measured Ti–C(1) and Ti–C(2) distances of 2.230(2) and 2.546(2) Å, respectively, and from a projection onto the $TiRu_2C_2$ plane as well. The measured C(1)–C(2) bond length of 1.229(3) Å is close to that of complex **3a** (1.19 Å), which indicates that substantial triple-bond character remains, and that the metallacyclopropene structure found for metallocene η^2-alkyne complexes[20–22] is not an appropriate description of the bonding situation present in **4a**. The unsymmetrical coordination of the C≡C unit to the titanium atom appears to be a direct result of the μ_2-η^1-CO ligand bridging the Ti and Ru(1) metal atoms. The separation of 2.9670(5) Å between the Ru(1) and Ti atoms is significantly larger than the sum of the metallic radii (2.81 Å), so that the presence of metal–metal bonding can be questioned. However, the range of Ti–Ru distances found in crystallographically characterized complexes ranges from ≈2.56 Å in complexes that contain unsupported metal–metal bonds stabilized by a trisilylsilane-based tripodal amido ligand,[23] ≈2.66 Å in $[(Me_2N)_3Ti\text{-}Ru(CO)_2(\eta\text{-}C_5H_5)]$,[24,25] and a significantly longer distance of ≈2.93 Å found in $Ti_2Ru_2S_4$ cubane-type clusters.[26] In these latter complexes it is believed that the electron-rich Ru atom participates in a dative-style donation to the electron-poor Ti atom. This variation in bond distance implies some ambiguity, and thus we represent the bonding between Ti and Ru centers in complexes **4** as dative, being supported by the electronic contribution from the bridging carbonyl ligand.

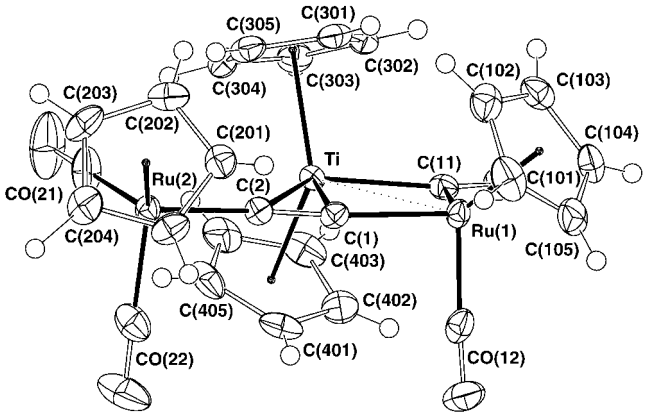

Figure 1. Molecular structure of **4a** (30% probability amplitude ellipsoids).

We were interested in the reactivity of complexes **4** and consequently conducted some reactions of those complexes with both terminal and internal alkynes, but no transformations were observed. In a manner similar to $Me_3SiC{\equiv}CSiMe_3$, the sterically encumbered ethyne-1,2-diyl ligand appears to hinder further addition of alkyne moieties to the titanium metal center, although Rosenthal and co-workers have observed varied modes of reactivity.[1,2,6]

Complex **4a** did react with carbon monoxide to afford complete transformation of the starting material with both **3a** and $[Ti(CO)_2(\eta\text{-}C_5H_5)_2]$ isolated as products. Shur and co-workers[27,28] explored the reactivity of the tolane adduct of titanocene and found that protonation of the complex by HCl/EtOH afforded *cis*-stilbene and $[TiCl_2(\eta\text{-}C_5H_5)_2]$ in essentially quantitative yield. Rosenthal and co-workers found that the Cp* ($\eta\text{-}C_5Me_5$) and ($\eta\text{-}C_5H_5$) ligands influence the reactivity of titanocene and zirconocene alkyne complexes toward water.[29] We considered protonation as a possible route to the previously unobserved ethene-1,2-diyl complexes, M-C(H)=C(H)-M and (M = $Ru(CO)_2(\eta\text{-}C_5H_4R)$). Thus, dropwise addition of ethanolic HCl to a toluene solution of complex **4b** gave the new complex **6**. The red/purple residue that remains after hexane extraction can be recrystallized to give compound **6**, $[RuTi(\mu_2\text{-}\eta^1\text{-}\eta^5\text{-}CHMe(C_5H_4))(CO)_2(\eta\text{-}C_5H_4Me)(\eta\text{-}C_5H_5)Cl_2]$, in good yield. The hexane extract of the reaction mixture afforded a pale yellow carbonyl-containing compound that has yet to be identified. Complex **6** is moderately air-sensitive in the solid state but more so in solution, and is best handled in an inert atmosphere. The spectroscopic data is consistent with the presence of at least one $\{Ru(CO)_2(\eta\text{-}C_5H_4Me)\}$ fragment. A number of likely candidate complexes, $[RuH(CO)_2(\eta\text{-}C_5H_4Me)]$, $[RuCl(CO)_2(\eta\text{-}C_5H_4Me)]$, and $[Ru(C{\equiv}CH)(CO)_2(\eta\text{-}C_5H_4Me)]$ have been discounted on the basis of their infrared and ^{1}H NMR spectra. The spectroscopic data measured for **6** is consistent with the determined single-crystal structure. The ^{1}H NMR spectrum is complicated by multiplets that are attributed to the methine protons of the substituted cyclopentadienyl ligands coordinated to ruthenium (4.99–4.91 ppm) and titanium (6.61–6.09 ppm). A singlet resonance at $\delta = 6.46$ ppm is assigned to the unsubstituted cyclopentadienyl ligand of the titanocene fragment and appears in a ratio of 5:8 to the foregoing methine resonances. The nonmethyl proton of the (CH(Me)) unit appears as a quartet ($^3J = 6.8$ Hz) at $\delta = 4.12$ ppm from coupling to the adjacent methyl protons. A doublet centered at $\delta = 1.43$ ppm displays a corresponding ^3J-coupling constant of 6.8 Hz and is assigned to the methyl protons of (CH(Me)). A singlet resonance at $\delta = 1.97$ ppm is assigned to the methyl protons of the $\eta\text{-}C_5H_4Me$ ligand. The ^{13}C NMR spectrum of **6** contains two downfield singlet resonances at $\delta = 202.6$ and

201.9 ppm, both assigned to the terminal carbonyl ligands of the {Ru(CO)$_2$(η-C$_5$H$_4$Me)} fragment. Two singlet resonances at $\delta \approx 13.0$ ppm are attributed to the methyl groups of the η-C$_5$H$_4$Me ligand and (CH(Me)) unit. A singlet resonance at $\delta = 28.5$ ppm is assigned to the tertiary carbon of the (CH(Me)) unit. Resonances assigned to the ring carbon atoms of Ru(η-C$_5$H$_4$Me) appear as four singlets between 89.9 and 88.3 ppm with a weak resonance at $\delta = 108.7$ ppm, tentatively assigned to the *ipso* carbon atom of the η-C$_5$H$_4$Me ligand. The unsubstituted η-C$_5$H$_5$ ligand of the metallocene fragment appears as a singlet resonance at $\delta =$ 119.4 ppm with four singlet resonances between 126.8 and 110.4 ppm assigned to Ti(η-C$_5$H$_4$). The corresponding *ipso* carbon gives rise to an unusual downfield singlet resonance at $\delta = 160.0$ ppm.

The structure of **6** (Figure 2)[30] is best described as a monosubstituted cyclopentadienyl titanocene dichloride fragment with a pendent {Ru(CHMe)(CO)$_2$(η-C$_5$H$_4$Me)} group.

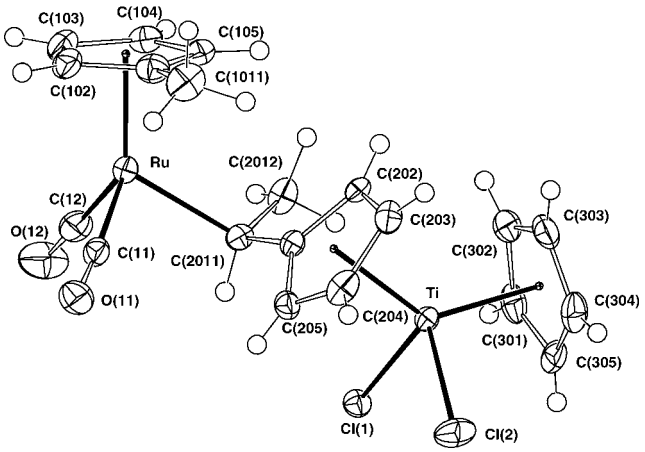

Figure 2. Molecular structure of **6** (30% probability amplitude ellipsoids).

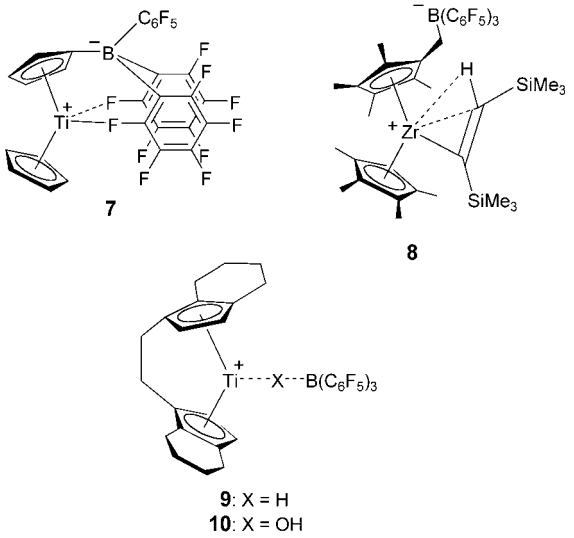
The geometry about the titanium atom is unremarkable in comparison with [TiCl$_2$(η-C$_5$H$_5$)$_2$],[31] and the geometry about the ruthenium atom is also a typical "piano stool". The measured bond length of 2.199(5) Å for Ru–C(2011) is significantly elongated from the Ru–C(sp) bond length of 2.055(2) Å for **3b**, but compares well with the average value of 2.18 Å found for the alkyl bridged diruthenium complexes, [{Ru(CO)$_2$(η-C$_5$H$_5$)}(μ-(CH$_2$)$_x$)] ($x = 1$,[32] $x = 2$,[33] $x = 5$[34]), which implies sp^3 hybridization at C(2011). This observation is supported by the C(2011)–C(2012) distance of 1.526(5) Å which is similar to other C–C (sp^3) single bond lengths and a tetrahedral geometry about C(2011). The carbon atom (C(2011)) that bridges the ruthenium and C(201) atoms is essentially coplanar with the cyclopentadienyl ring carbon atoms (C201–205) of the titanocene dichloride fragment with a measured C(2011)–C(201) distance of 1.493(5) Å, similar to the value of 1.503(6) Å determined for C(1011)–C(101) bond distance of the methyl-substituted cyclopentadienyl ring.

We believe that the formation of **6** is unprecedented. A close examination of the connectivity reveals the apparent transfer of the now fully protonated C$_2$ unit found in **4b** (originally bound in an η^2 fashion to Ti and η^1 to the two ruthenium atoms) to a Ti(η-C$_5$H$_5$) unit. Low-valence Group 4 permethyl cyclopentadienide complexes have afforded reactivity at the (η-C$_5$Me$_5$) ring by C–H activation.[35] Formation of the {(η^1:η^5-C$_5$H$_4$)(η-C$_5$H$_5$)TiCl$_2$} fragment is also not unexpected given that the protonation of the tolane adduct of titanocene gave titanocene dichloride as a product of the reaction.[27,28] The mass balance in the reaction is essentially satisfied in the yield of **6** (Ti) and presumably with the remaining ruthenium found in the unidentified complex. Given that this other product remains unidentified, any meaningful speculation on a mechanism for the formation of **6** is difficult, but it is tempting to consider that it results from the multiple protonation of the C≡C unit of complex **4b** to give the (μ^2-η^1:η^5-C(H)(CH$_3$)(C$_5$H$_4$)) ligand bridging the two metal centers with concomitant oxidation of the titanium center. At this stage, we cannot discount the insertion of ethene derived from the dehydration of EtOH. Complex **4b** does not react with ethene and is also unreactive toward water, suggesting that reaction with EtOH is also unlikely. There are other observations made by Rosenthal and coworkers in their seminal contributions, reviewed recently,[1,6] that are relevant to the discussion of a possible mechanism. First, in the reaction of **1** with B(C$_6$F$_5$)$_3$ a zwitterionic complex, **7**, containing the B(C$_6$F$_5$)$_3$ bound to the (η-C$_5$H$_5$) ring was observed with the elimination of hydrogen, 1,2-bis(trimethylsilyl)acetylene, and importantly, 1,2-bis(trimethylsilyl)ethane. Other alkyne adducts of titanocene gave



identical products. Second, in the analogous reaction of [(η-C$_5$Me$_5$)$_2$Zr(Me$_3$SiC≡CSiMe$_3$)] with B(C$_6$F$_5$)$_3$ there was no hydrogen or alkyne liberated; rather, the zwitterionic Zr^{IV} derivative, **8**, containing a σ-alkenyl ligand was isolated. Finally, the bis(trimethylsilyl)acetylene complex of *rac*-1,2-ethylene-1,1-bis(η^5-tetrahydroindenyl)titanium reacted with the Brønsted acid B(C$_6$F$_5$)$_3$·H$_2$O to give a mixture of complexes **9** and **10**. Literature precedent[36] allows the formulation of a relatively simple mechanism in which the

η^2-bound ethynediyl complex rearranges to form a bridging TiRu(μ-η^1-C≡C-Ru(CO)$_2$(η-C_5H_4R)) moiety. Subsequent hydrogen elimination from a Ti(η-C_5H_5) group leads to the formation of a bridging (μ-η^1:η^5) cyclopentadienyl ligand between the Ru and Ti atoms. Such structures are typical in organometallic chemistry and are formed by C–C homocoupling of 1,3-butadiyne and fulvene ligands. Acetylide coupling reactions[3,7,37] and cyclopentadienyl coupling reactions[6,21] are well-known in the literature. Analogous mixed heterocoupling would give either a Ru–CC–Cp unit or Ru–C(=C)–Cp intermediates, which, upon reaction with acid of the latter, lead to the observed Ru–CH(Me)–Cp moiety in **6**. Presumably, the known mobility of the C_2 group,[8,37] which we have described as bearing-like, causes discrimination between the preferred Ru–C(=C)–Cp compound over that of the Ru–CC–Cp and of Ru–CH(Me)–Cp over that of Ru–CH_2CH_2–Cp.

In spite of these observations, however, it still remains difficult to differentiate intermolecular protonation from intramolecular C–H activation. We are currently undertaking detailed isotope labeling studies that will ultimately shed light on the mechanism of formation of **6**.

In conclusion, we have compared the reactivity of our metalloalkynes, (the ruthenium ethyne-1,2-diyl complexes **3**) with that of the bulky 1,2-bis(trimethylsilyl)acetylene and found that upon coordination to titanocene, they have similar reactivity. However, upon reaction with acid, we have observed what appears to be an unprecedented transformation to give a ruthenium hydrocarbyl complex attached to titanocene dichloride. We are making a detailed examination of the reactivity of **6**, particularly with respect to its efficacy as a catalyst for the polymerization of 1-alkenes.

Experimental Section

The manipulation of oxygen- and moisture-sensitive compounds was performed under an atmosphere of high-purity argon with standard Schlenk techniques or in a dry box (Miller Howe). Infrared spectra were recorded with a Bio-Rad FTS 45 and 40 FTIR spectrometer. ^{1}H and ^{13}C NMR spectra were acquired with Varian Gemini 200 and Bruker ARX 500 spectrometers. ^{31}P NMR spectra were acquired with a Bruker ARX 500 spectrometer. ^{1}H and ^{13}C NMR spectra were referenced with respect to incompletely deuterated solvent signals. Mass spectra were obtained on a VG AutoSpec spectrometer employing a FAB ionization source in all samples unless otherwise specified. Elemental analyses were performed at The Research School of Chemistry Microanalytical Unit, Australian National University, ACT. Tetrahydrofuran was dried over sodium metal and distilled from potassium benzophenone ketyl under an atmosphere of argon. Hexanes and toluene were dried over sodium metal and distilled under an atmosphere of argon. Distilled solvents were stored over sodium or potassium mirrors until use.

4a: A solution of [Ti(η^2-$Me_3SiC{\equiv}CSiMe_3$)(η-C_5H_5)$_2$] (**1**; 42 mg, 0.121 mmol) and [{Ru(CO)$_2$(η-C_5H_5)}$_2$(μ_2-C≡C)] (**3a**; 50 mg, 0.107 mmol) in THF (20 mL) was stirred for 10 h at 50 °C. The solvent was removed in vacuo, and the dark residue was washed with *n*-hexanes (2 × 20 mL) to remove $Me_3SiC{\equiv}CSiMe_3$. Recrystallization (toluene/*n*-hexanes, −40 °C) gave dark red platelets of **4a** (58 mg, 84 %). IR (THF): $\tilde{\nu}_{CO}$ = 2032s, 1977s, 1931s, 1907w, 1733s cm^{-1}; ^{1}H NMR (C_6D_6): δ = 5.36 (s, 5H, C_5H_5Ti), 5.20 (s, 5H, C_5H_5Ti), 4.98 (s, 5H, C_5H_5Ru), 4.53 ppm (s, 5H, C_5H_5Ru); ^{13}C NMR (C_6D_6): δ = 305.5 (s, μ-CO), 203.9 (s, CO), 199.5 (s, CO), 199.2 (s, CO), 167.6 (s, (Ti)Ru*C*≡C), 106.4 (s, C_5H_5Ti), 105.1 (s, C_5H_5Ti), 93.7 (s, C≡*C*Ru(CO)$_2$(C_5H_5)), 89.7 (s, C_5H_5Ru), 88.1 ppm (s, C_5H_5Ru); elemental analysis: calcd. for $C_{26}H_{20}O_4Ru_2Ti_1$: C 48.29, H 3.12; found: C 48.19, H 2.96.

4b: A solution of [Ti(η^2-$Me_3SiC{\equiv}CSiMe_3$)(η-C_5H_5)$_2$] (**1**; 87 mg, 0.250 mmol) and [{Ru(CO)$_2$(η-C_5H_4Me)}$_2$(μ_2-C≡C)] (**3b**; 100 mg, 0.200 mmol) in THF (30 mL) was stirred for 10 h at 50 °C. The solvent was removed in vacuo, and the dark residue was washed with *n*-hexanes (2 × 20 mL) to remove $Me_3SiC{\equiv}CSiMe_3$. Recrystallization (toluene/*n*-hexanes, −40 °C sol. diff.) gave dark red crystals of **4b** (119 mg, 88 %). IR (THF): $\tilde{\nu}_{CO}$ = 2035s, 1980s, 1934s, 1907w, 1735s cm^{-1}; ^{1}H NMR (C_6D_6): δ = 5.39 (s, 5H, C_5H_5Ti), 5.24 (s, 5H, C_5H_5Ti), 4.96 (s, 1H, C_5H_4Me), 4.87 (s, 1H, C_5H_4Me), 4.84 (s, 1H, C_5H_4Me), 4.73 (s, 1H, C_5H_4Me), 4.45 (s, 1H, C_5H_4Me), 4.41 (s, 2H, C_5H_4Me), 4.37 (s, 1H, C_5H_4Me), 1.98 (s, 3H, C_5H_4*Me*), 1.67 ppm (s, 3H, C_5H_4*Me*); ^{13}C NMR (C_6D_6): δ = 307.7 (s, μ-CO), 204.4 (s, CO), 199.8 (s, CO), 199.6 (s, CO), 167.0 (s, (Ti)Ru*C*≡C), 114.4 (s, *ipso*-C), 108.2 (s, *ipso*-C), 106.5 (s, C_5H_5Ti), 105.0 (s, C_5H_5Ti), 101.6 (s, C≡*C*Ru(CO)$_2$(C_5H_5)), 90.8 (s, C_5H_4Me), 88.4 (s, *C*$_5$H$_4$Me), 88.0 (s, *C*$_5$H$_4$Me), 87.9 (s, *C*$_5$H$_4$Me), 86.8 (s, *C*$_5$H$_4$Me), 85.5 (s, *C*$_5$H$_4$Me), 85.3 (s, *C*$_5$H$_4$Me), 85.1 (s, *C*$_5$H$_4$Me), 14.0 (s, C_5H_4*Me*), 13.7 ppm (s, C_5H_4*Me*); elemental analysis: calcd. for $C_{28}H_{24}O_4Ru_2Ti_1$: C 49.86, H 3.59; found: C 49.68, H 3.56.

5: A solution of [Zr(thf)(η^2-$Me_3SiC{\equiv}CSiMe_3$)(η-C_5H_5)$_2$] (**2**; 52 mg, 0.133 mmol) and [{Ru(CO)$_2$(η-C_5H_5)}$_2$(μ_2-C≡C)] (**3a**; 50 mg, 0.107 mmol) in THF (20 mL) was stirred for 48 h at ambient temperature. The solvent was removed in vacuo and the orange residue was washed with *n*-hexanes (2 × 20 mL) to remove $Me_3SiC{\equiv}CSiMe_3$. Recrystallization (THF/*n*-hexane) gave an orange powder of **5** (38 mg, 55 %). IR (toluene): $\tilde{\nu}_{CO}$ = 2039s, 1978s, 1938s, 1909w, 1729s cm^{-1}; ^{1}H NMR (C_6D_6): δ = 5.51 (s, 5H, C_5H_5Zr), 5.36 (s, 5H, C_5H_5Zr), 4.93 (s, 5H, C_5H_5Ru(Zr)), 4.58 ppm (s, 5H, C_5H_5Ru(Zr)). The spectroscopic properties of **5** are similar to those of the Ti analogue **4a** with no indication of any other species present.

6: To a solution of [Ru_2Ti(μ_3-η^1:η^2:η^1-C≡C)(μ-CO)(CO)$_3$(η-C_5H_4Me)$_2$(η-C_5H_5)$_2$] (**4b**; 15 mg, 0.22 mmol) in toluene (10 mL) a solution of HCl/(EtOH) (0.5 mL, ≈0.006 g mL^{-1}) was added dropwise to give an immediate color change from dark to pale red. The reaction mixture was stirred for 30 min, followed by solvent removal in vacuo. The residues were washed with *n*-hexanes (50 mL) to give a yellow solution. Removal of the solvent in vacuo afforded a yellow crystalline compound, which remains unidentified (8 mg). IR (toluene): $\tilde{\nu}_{CO}$ = 2022s, 1995s cm^{-1}; ^{1}H NMR (C_6D_6): δ = 4.50 (m, 1H), 4.19 (t, 4H), 3.92 (t, 4H), 1.46 ppm (s, 6H); ^{13}C NMR (C_6D_6): δ = 197.6 (s, CO), 119.3 (s), 88.8 (s), 88.6 (s), 83.6 (s), 82.4 (s), 12.7 ppm (s); elemental analysis: found: C 38.67, H 3.48. Extraction of the remaining residues with diethyl ether (30 mL) and subsequent recrystallization (CH_2Cl_2/*n*-hexanes) gave purple rods of **6** (10 mg, 90 % with respect to Ti). IR (toluene): $\tilde{\nu}_{CO}$ = 2010s, 1957s cm^{-1}; ^{1}H NMR (CD_2Cl_2): δ = 6.61 (m, 1H, C_5H_4Ti), 6.46 (s, 5H, C_5H_5), 6.22 (m, 1H, C_5H_4Ti), 6.17 (m, 1H, C_5H_4Ti), 6.09 (m, 1H, C_5H_4Ti), 4.99–4.91 (m, 4H, C_5H_4Me), 4.12 (q, ^3J = 6.8 Hz, 1H, C*H*Me), 1.97 (s, 3H, C_5H_4*Me*), 1.43 ppm (d ^3J = 6.8 Hz, 3H, CH*Me*); ^{13}C NMR (CD_2Cl_2): δ = 202.6 (s, CO), 201.9 (s, CO), 160.0 (s, *ipso*-C(Ti)), 126.8 (s, C_5H_4Ti), 119.4 (s, unsubst. C_5H_4Ti), 110.8 (s, C_5H_4Ti), 110.4 (s, C_5H_4Ti), 108.7 (s, *ipso*-C(Ru)), 89.9 (s, C_5H_4Me), 89.4 (s, *C*$_5$H$_4$Me), 88.9 (s, *C*$_5$H$_4$Me), 88.3 (s, *C*$_5$H$_4$Me), 28.5 (s, *C*HMe), 13.4, 12.7 ppm (2 × s, C_5H_4*Me* and CH(*Me*)); MS (FAB) [*M*−(Ti(CO)(C_5H_5)Cl_2)]$^+$ *m*/*z* = 303 (100 %); experimental analysis: calcd. for $C_{20}H_{20}Cl_2O_2RuTi$: C 46.89, H 3.94; found: C 47.32, H 3.92.

Host–Guest Chemistry

Supramolecular Features of Calixarene-Based Synthetic Nanotubes**

Voltaire G. Organo, Alexander V. Leontiev, Valentina Sgarlata, H. V. Rasika Dias, and Dmitry M. Rudkevich**

Filling single-walled carbon nanotubes (SWNTs) with foreign species is a quickly emerging research area.[1] The major goal is to enforce filling materials to adopt one-dimensional morphology for nanowiring, transport, and information flow. Other potential applications include the use of SWNTs

 DOI: 10.1002/anie.200500057

as reaction vessels and gas-storage cylinders.[2] However, far-from-trivial protocols for the chemical opening of SWNTs, still not fully understood mechanisms of their filling, as well as identification of the encapsulated material are some of the problems faced in this area. Physical measurements within the interiors are also a challenge. Synthetic analogues of SWNTs have recently been introduced.[3,4] Organic synthesis offers variety of the sizes and shapes. However, most of these synthetic nanotubes are formed through self-assembly and, thus, are stable only under specific conditions. Furthermore, the stability of their encapsulation complexes is generally weak, which diminishes their capabilities as storage and transport devices and materials.

Herein, we demonstrate novel and unique features of synthetic, calixarene-based nanotubes. These nanotubes are covalently built and robust and can be prepared by conventional organic chemistry protocols. The length of the nanotubes can be controlled precisely and easily, and they effectively pack into infinite tubular bundles in the solid state. These nanotubes can also be easily filled and form kinetically and thermodynamically stable encapsulation complexes, and they can be emptied at will in a nondestructive manner. Taken together, we propose reasonable synthetic alternatives to SWNTs for filling.

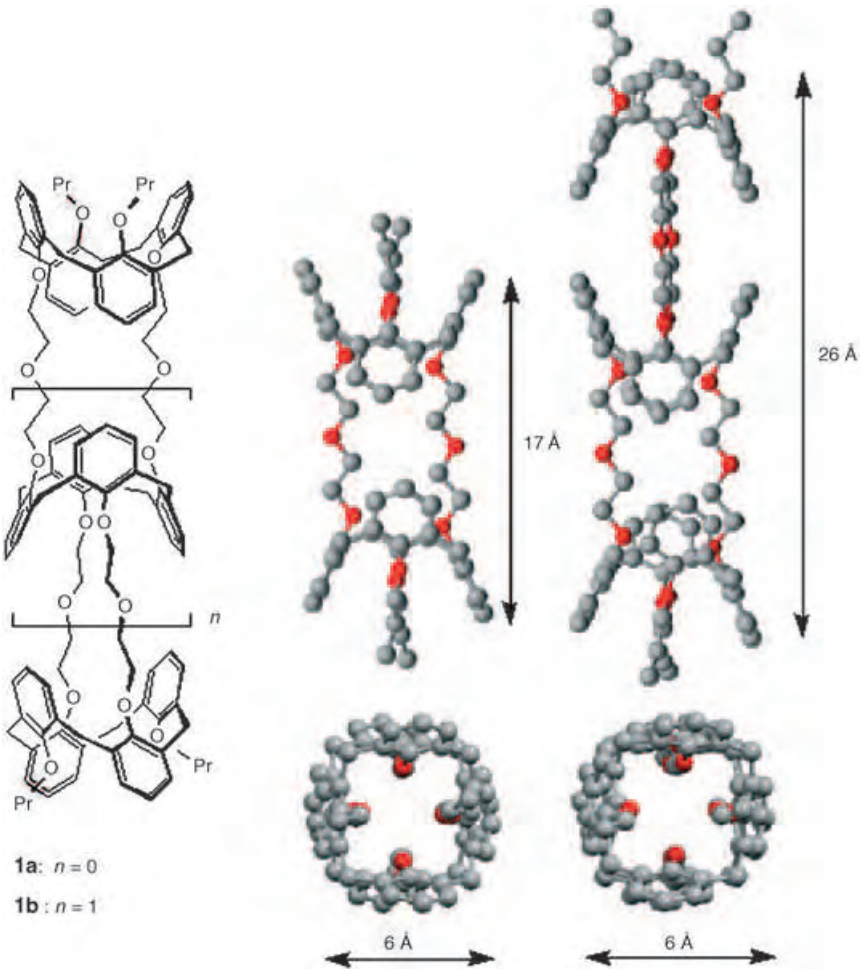

Figure 1. Left: Synthetic calixarene-based nanotubes **1a**,**b** for NO_2/N_2O_4 fixation and nitrosonium ion (NO^+) storage. Right: X-ray crystal structures of **1a**,**b** (from $CHCl_3$/MeOH; side and top views; O red, C gray). Hydrogen atoms are omitted for clarity.

Earlier we reported that simple calix[4]arenes reversibly interact with NO_2/N_2O_4 and entrap reactive nitrosonium (NO^+) cations—NO^+ is generated upon disproportionation of N_2O_4—within their π-electron-rich interiors, one per cavity.[5] Very high association constants $K_a \gg 10^6\,M^{-1}$ ($\Delta G^{295} \gg 8$ kcal mol^{-1}) for these processes were determined, and the complexes were kinetically stable. These particular properties have been used in the design of calixarene-based nanotubes **1a**,**b** (Figure 1).

The synthesis of tubes **1a**,**b** is modular (see Scheme 1 and Supporting Information). Calixarene building blocks were linked by simple, Williamson-type alkylation procedures. Alkylation of calix[4]arene diol **2a** (R = *n*Pr) with ditosylate **3** resulted in tube **1a**.[6] Reaction of diol **2b** (R = CH_2CH_2OBn) with **3** led to the formation of biscalixarene tube **4**, which has two terminal hydroxyl groups at one end. When **4** was coupled with another equivalent of ditosylate **3**, triscalixarene nanotube **1b** was isolated in 26% yield. Alternatively, nanotube **1b** could be isolated in modest yield (≈10%) from the one-step reaction of two equivalents of **3a** with tetrakisalcohol **5**. Nanotubes **1a**,**b** were characterized by high-resolution ^{1}H NMR spectroscopy and COSY and NOESY experiments, mass spectrometry, and X-ray crystallography.[7] X-ray data show that in nanotubes **1a** and **1b**, 1,3-alternate calix[4]arenes are rigidly linked with diethylene glycol bridges to form hollow cylinders with cavities of diameters of approximately 6 Å and lengths of 17 and 26 Å, respectively (Figure 1). The inner tunnels are defined by two cofacial pairs of aromatic rings oriented orthogonally along the cavity axis.

Nanotubes **1a**,**b** can be easily filled, as each calixarene unit can accommodate one NO^+ guest. Addition of excess NO_2/N_2O_4 to **1a**,**b** in tetrachloroethane in the presence of Lewis acids such as $SnCl_4$ or $BF_3{\cdot}Et_2O$ resulted in quantitative formation of nitrosonium complexes **6a**,**b** (Figure 2). Similar complexes formed when nanotubes **1a**,**b** were mixed with nitrosonium salt $NO^+SbF_6^-$ in tetrachloroethane. Adducts **6a**,**b** were identified by UV/Vis and ^{1}H NMR spectroscopy and exhibit typical features of earlier described, simpler calix[4]arene–NO^+ species.[5,8] Of particular importance is the characteristic deep purple color. The broad charge-transfer absorption bands that account for the color are observed at $\lambda_{max} \approx 550$ nm in the UV/Vis spectra. Charge transfer only occurs when NO^+ guests are tightly entrapped inside the

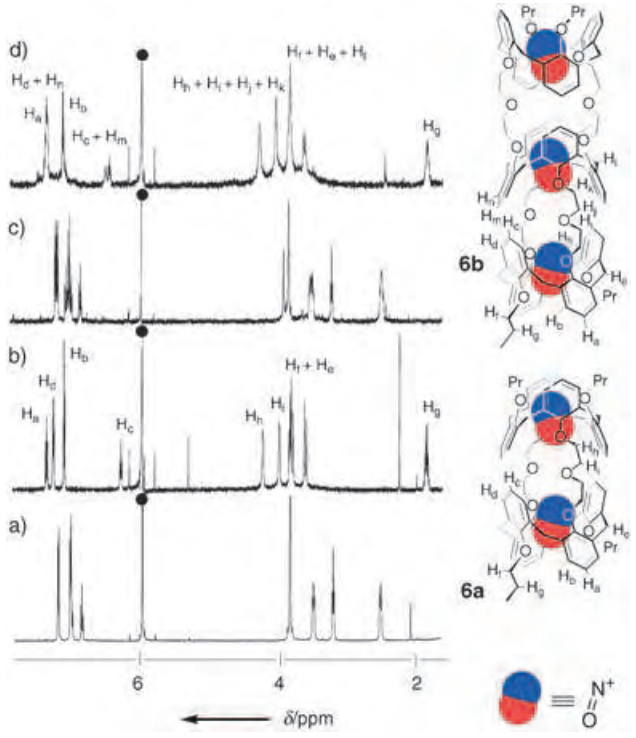

Figure 2. Partial ^{1}H NMR spectra (500 MHz, $(CDCl_2)_2$, 295 K) of a) nanotube **1a**, b) filled nanotube **6a**, c) nanotube **1b**, and d) filled nanotube **6b**. The residual solvent signals are marked with filled circles (●). The assignments were performed by COSY and NOESY experiments and supported by molecular modeling (MacroModel 7.1).

calixarene cavities.[5,8,9] Accordingly, the filling process can be monitored visually.

Upon stepwise addition of NO_2/N_2O_4 or $NO^+SbF_6^-$ in [D_2]tetrachloroethane, signals for the protons of **1a**,**b** and **6a**,**b** can be seen separately and in slow exchange by ^{1}H NMR spectroscopy. This is typical for host–guest complexes with high exchange $\Delta G^{\neq}$ barriers (>15 kcal mol^{-1}) and/or high values of association constants ($K_a > 10^6$ M^{-1}). The presence and location of the guests inside nanotubes **6a**,**b** can be deducted from conventional NMR analysis. Structural fragments that are involved in the complexation process were identified by ^{1}H NMR spectroscopy, COSY, and NOESY experiments. Although entrapped NO^+ species cannot be directly seen, chemical shifts of the methylene protons from Ar-O-CH_2 and, to a lesser extent, Ar-O-CH$_2$CH_2 and the aromatic protons are very sensitive to the encapsulation. Indeed, besides the charge transfer, strong cation–dipole interactions between the oxygen atoms of the calixarenes and the entrapped NO^+ take place.

The three signals for the protons for the propyloxy groups in **6a**,**b** appeared significantly downfield ($\Delta\delta \approx 1$ ppm) relative to empty tubes **1a**,**b** (Figure 2). This implies that two NO^+ cations are located at the ends of the nanotubes and occupy the terminal calixarene compartments. The middle calixarene in the longer tube **6b** is most probably filled as well. Downfield shifts ($\Delta\delta > 1$ ppm) of the corresponding signals for the protons of Ar-O-CH_2 and CH_2-O-CH_2 were observed for this fragment. Higher stoichiometries of NO^+ were ruled out; there is simply no room to accommodate a larger number of electrostatically repulsive cations.

According to molecular modeling studies, the nitrosonium-filled nanotubes adopt somewhat shrunken structures, with all-*gauche* conformations about the glycol C–C bonds. Such folding brings closer the aromatic rings from the neighboring calixarene units. This behavior was confirmed by NOESY for the nitrosonium-filled nonsymmetrical *O*,*O*′-dimethylated derivative of **4**. Consequently, the aromatic protons CH_c of tube **6a**, and CH_c and CH_m in tube **6b**, appear shielded and are seen somewhat upfield at $\delta \approx 6.2$–6.4 ppm (Figure 2).

Judging from the ^{1}H NMR spectra at room temperature, complexation with NO^+ does not influence the symmetry of **6a**,**b** relative to empty **1a**,**b**. Although in both cases the nonequivalence of the CH_2 protons of the calixarene methylene bridges becomes more pronounced, the number of ^{1}H NMR signals for the propyl ArOCH_2, glycol CH_2OCH_2

and $ArOCH_2$, and aromatic groups for **6a**,**b** does not change and implies that the NO^+ guests, with van der Waals dimensions of approximately 2 Å, freely rotate along the N-O axis and also tumble within the cavity.

To determine the mechanism of filling is a difficult task[1] and it remains a great challenge for SWNTs, but conventional NMR spectroscopy provides useful insights for synthetic tubes such as those prepared here. Modeling suggests that the first NO^+ ion can enter the nanotube through either its neck or one of the middle gates between the calixarenes. Upon addition of $NO^+SbF_6^-$ to tube **1a**, the intermediate half-filled 1:1 complex **1a**·NO^+ was initially observed and isolated, and the guest was found to be located between the calixarenes, within the electron-rich oxygen atoms of the crown ether.[6] The signals for the protons of the propyl Ar-O-Pr group in this complex were not shifted, which indicates that the ends of the nanotube were not occupied with NO^+. Likewise upon addition of $NO^+SbF_6^-$ to longer nanotube **1b** (at −20 °C), the intermediate partially filled species were observed. They exhibit distinct signals of all groups of protons, but the signals for the propyl Ar-O-Pr protons were not shifted downfield. These intermediate complexes were further converted into **6a**,**b** simply by addition of more NO_2/N_2O_4 or $NO^+SbF_6^-$. To avoid electrostatic repulsions, the next NO^+ ion should instead enter through the neck thus further pushing the first guest towards the end of the tube.

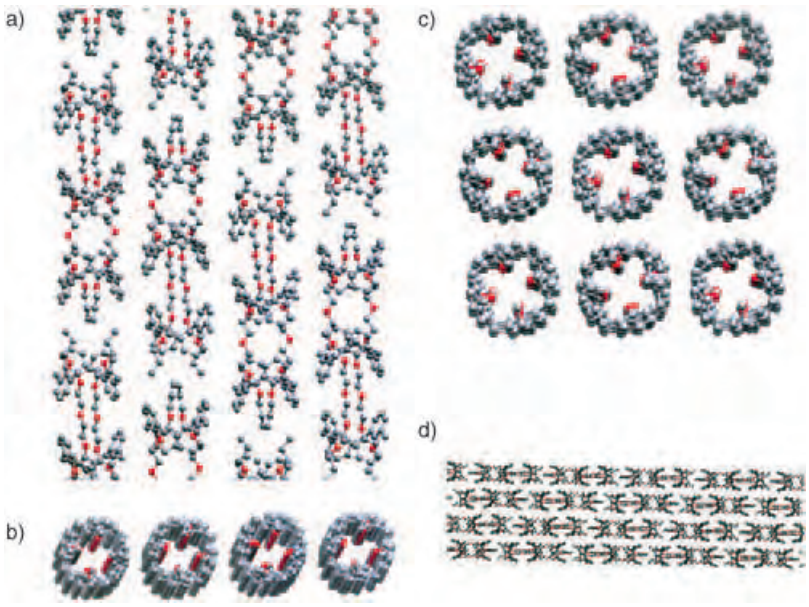

Figure 3. Side and top views of supramolecular packing of nanotube **1b** into infinite nanocylinders and the parallel stacking of neighboring nanotubes. View (d) shows the continuous tunnel of four columns of nine **1b** molecules.

Filled nanotubes **6a**,**b** are stable in anhydrous solution at room temperature for hours, but can be readily destroyed with H_2O to quantitatively regenerate free **1a**,**b** (according to ^1H NMR and UV/Vis spectral analysis). We found that the encapsulated NO^+ species can also be removed by simple addition of 18-crown-6; it is known that crown ethers form stable complexes with NO^+.[10] When 18-crown-6 ($\approx$10 equiv) was added to solutions of **6a**,**b** in [D_2]tetrachloroethane, empty nanotubes **1a**,**b** were regenerated within minutes (NMR, UV/Vis), and the deep purple color disappeared. This observation is important, as in this case foreign species are removed without decomposition and without the need to change the polarity of the solution.

Nanotube units **1a** and **1b** pack head-to-tail in straight rows to result in infinitely long cylinders. Chloroform molecules occupy the vacant spaces between the tubes. Nanotube **1b** shows a particularly appealing supramolecular structure (Figure 3) with the neighboring nanocylinders aligned parallel to each other. In each nanocylinder, molecules **1b** are twisted by 90° relative to each other, and the Ar-O-Pr propyl groups effectively occupy the voids between the adjacent molecules. In such an arrangement, the intermolecular distance between two neighboring tubes in the nanocylinder is around 6 Å, and the nanocylinders are separated from each other by about 9 Å. This supramolecular order comes with the tube length and is without precedent for conventional, shorter calixarenes. The unique linear nanostructures maximize the intermolecular van der Waals interactions in the crystal through the overall shape simplification.

In conclusion, besides SWNTs, synthetic nanotubes are now available that pack in tubular bundles and can be reversibly filled with guest molecules. At this stage only certain guests can fill the interiors, but they are charged, which is important for the design of nanowires. Given the ability of calixarenes to react with NO_x gases even in the solid state,[5,11] we will look at the flow of nitrosonium ions along the infinite nanocylinders in the solid-state bundles of **1a**,**b**. Not only would the charge be transported and detected through the changes in conductivity, but also the color of the crystals would serve as an indicator of such transport processes.[12]

[7] Crystals of suitable quality of **1a** and **1b** for X-ray studies were obtained from $CHCl_3/CH_3OH$ solutions at room temperature. The X-ray intensity data were measured at 100(2) K on a Bruker SMART APEX CCD area detector system equipped with a Oxford Cryosystems 700 Series cooler, a graphite monochromator, and a $Mo_{K\alpha}$ fine-focus sealed tube ($\lambda = 0.710\,73$ Å). The data frames were integrated with the Bruker SAINT-Plus (version 6.45) software package. Structures were solved and refined using Bruker SHELXTL (version 6.14) software package. X-ray data for **1a**·2 $CHCl_3$; $C_{78}H_{86}Cl_6O_{10}$, Monoclinic, Space group $P2_1/n$; $a = 17.9825(7)$, $b = 10.6205(4)$ Å, $c = 19.8479(7)$ Å, $\beta = 111.7390(10)°$, $V = 3521.0(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.317$ Mg m^{-3}, the hydrogen atoms were placed in idealized positions and included as riding atoms. All non-hydrogen atoms were refined anisotropically. $R1$, $wR2$ ($I > 2\sigma(I)$) = 0.0397, $wR2 = 0.1024$; $R1$, $wR2$ (all data) = 0.0465, 0.1077, GOF = 1.040. X-ray data for **1b**·4.5 $CHCl_3$; $C_{116.5}H_{124.5}Cl_{13.5}O_{16}$, Triclinic, Space group $P\bar{1}$, $a =$ 14.7634(6) Å, $b = 15.2376(6)$ Å, $c = 26.4844(11)$, Å, $\alpha =$ 75.9360(10)°, $\beta = 78.0270(10)°$, $\gamma = 80.0890(10)°$, $V =$ 5606.9(4) Å^3, $Z = 2$, $\rho_{calcd} = 1.338$ Mg m^{-3}, the hydrogen atoms were placed in idealized positions and included as riding atoms. All the chloroform molecules show severe disorder. One of the *n*-propyl groups is also disordered. These disorders were modeled reasonably well. All non-hydrogen atoms were refined anisotropically, $R1$, $wR2$ ($I > 2\sigma(I)$) = 0.0828, 0.1667; $R1$, $wR2$ (all data) = 0.1100, 0.1783, GOF = 1.105. CCDC 259477 (**1a**) and 259478 (**1b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Corrole Chemistry

Hemiporphycene from the Expansion of a Corrole Ring**

Roberto Paolesse, Sara Nardis, Manuela Stefanelli, Frank R. Fronczek, and Maria Graça H. Vicente*

Porphyrins are extensively studied macrocycles as their unique properties allow multiple and diverse applications in various fields ranging from medicine to the material sciences.[1] Interest in this type of compound has been further expanded by the discovery of porphyrin analogues,[2] that is, macrocycles which have a modified skeleton relative to that of porphyrin. Porphyrin analogues are interesting from both the theoretical and application points of view, as they are amenable to investigation of structure–property relationships as well as the rational modification of the macrocycle to suit a specific application. This approach mimics what happens in

natural systems, where iron porphyrins are used for oxygen transport and activation, while magnesium chlorins are exploited in photosynthetic systems.[3]

Among the large number of porphyrin analogues reported, corrole has received increased attention in recent years, although it was one of the first known members of this family of compounds with Johnson and Kay's studies on the synthesis of vitamin B_{12}.[4] Such renewed interest is in large part due to the peculiar behavior of this macrocycle, which is able to stabilize formal high oxidation states of coordinated metals,[5] thus opening interesting applications for metallocorrolates in catalysis.[6] The coordination chemistry of corrole is made even more intriguing by its non-innocent character as a ligand.[7]

The tumultuous increase of corrole-related papers in the last few years has been based on the definition of simple synthetic routes for the preparation of this macrocycle from commercially available precursors.[8] The synthesis of 5,10,15-triarylcorroles has opened the way to the study of the peripheral functionalization of the macrocycle,[9] which is a topic far less studied than its coordination chemistry.

We contributed to this field by studying the Vilsmeier formylation of free-base corroles. The reactivity of both the β-alkyl and *meso*-triaryl derivatives showed a peculiar and intriguing behavior.[10,11] In particular, 5,10,15-triphenylcorrole (**1**) afforded an unexpected and unprecedented *N*-ethane-bridged inner-core derivative as the major product in the presence of excess DMF (*N*,*N*-dimethylformamide). This compound is particularly intriguing and for this reason we decided to further study the reaction of 5,10,15-triphenylcorrole **1** with CI_4 to investigate whether a one-carbon-unit-bridged inner-core derivative could be similarly obtained. The reaction was carried out under conditions similar to those used for the Vilsmeier reaction, by heating in CH_2Cl_2/DMF at reflux.[12] Chromatography on silica gel afforded two green fractions: the first band, obtained in trace amount, was characterized as 5-iodo-10,15,20-triphenylporphyrin; the second fraction represented the major product of the reaction and was obtained in a yield of 30%.

The spectral characterization of this second compound showed the presence of a macrocycle, although its properties were different from those of corroles. For example, the UV/Vis absorption spectrum of the major product was porphyrin-like, with the presence of four Q bands, while the ^{1}H NMR spectrum showed the presence of different doublets for protons of the pyrrolic units which indicates that the product has a lower symmetry than **1**.[12] Solid-state X-ray analysis of a single crystal of the product[13] showed the presence of a two-carbon *meso* bridge, with the new carbon unit close to pyrrole B, and allowed us to identify the isomer as the 5-iodo-6,11,16-triphenylhemiporphycene (**2**; Figure 1). A similar triphenylhemiporphycene was reported by Callot et al. in 1995 as the serendipitous product obtained by a demetalation–metalation sequence carried out on a homoporphyrin.[14] Note, in that case the hemiporphycene was obtained from ring contraction of a homoporphyrin, whereas in the present case it results from the ring expansion of a corrole ring. Such a ring-expansion reaction is interesting from a synthetic point of view as it is possible to obtain the hemiporphycene from a triphenylcorrole precursor in a single step, whereas the rational synthesis developed by the groups of Vogel and Sessler requires a multistep approach.[15]

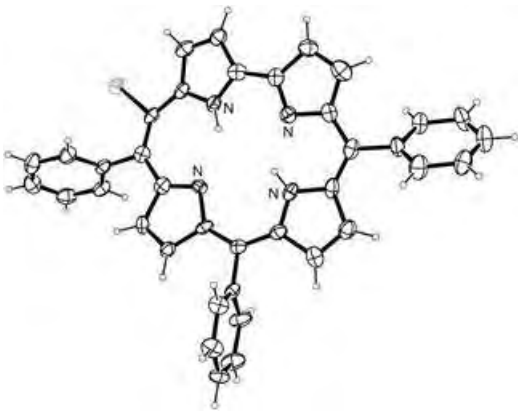

Figure 1. Crystal structure of **2** (N dark gray (labeled), I light gray, C black, H small circles).

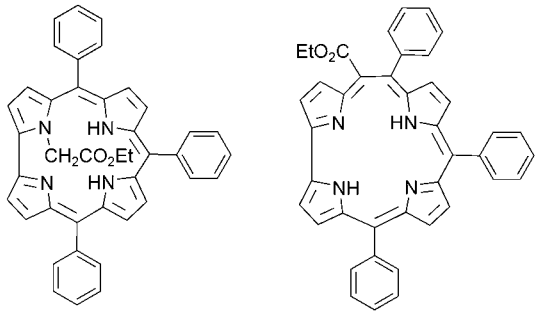
Our unexpected result led us to further investigate the plausible reaction sequence that leads to hemiporphycene **2** from the corrole ring. To verify whether the expansion of the corrole was caused by the attack of a carbenic species, we treated the triphenylcorrole **1** with ethyldiazoacetate in bromobenzene. We obtained the corresponding *N*-21-substituted corrole **3** as the major product, as well as the hemiporphycene **4**,[14] although in very low yields, among other minor reaction products.



3 **4**

Similar to the stepwise conversion of the *N*-substituted porphyrin into the corresponding homoporphyrin as reported by Callot and Tschamber in 1975,[16] the *N*-21 isomer obtained from the reaction of 5,10,15-triphenylcorrole and ethyl iodoacetate was heated at reflux in bromobenzene to afford the hemiporphycene in low yields. No hemiporphycene was obtained when the *N*-22 isomer was treated under the same conditions. These results led us to hypothesize a plausible reaction mechanism for the formation of the hemiporphycene, as shown in Figure 2.

The first step involves the formation of the *N*-substituted derivative, which can then rearrange as shown to finally give the hemiporphycene ring upon loss of HI. This novel reaction represents a facile route to the hemiporphycene ring. The

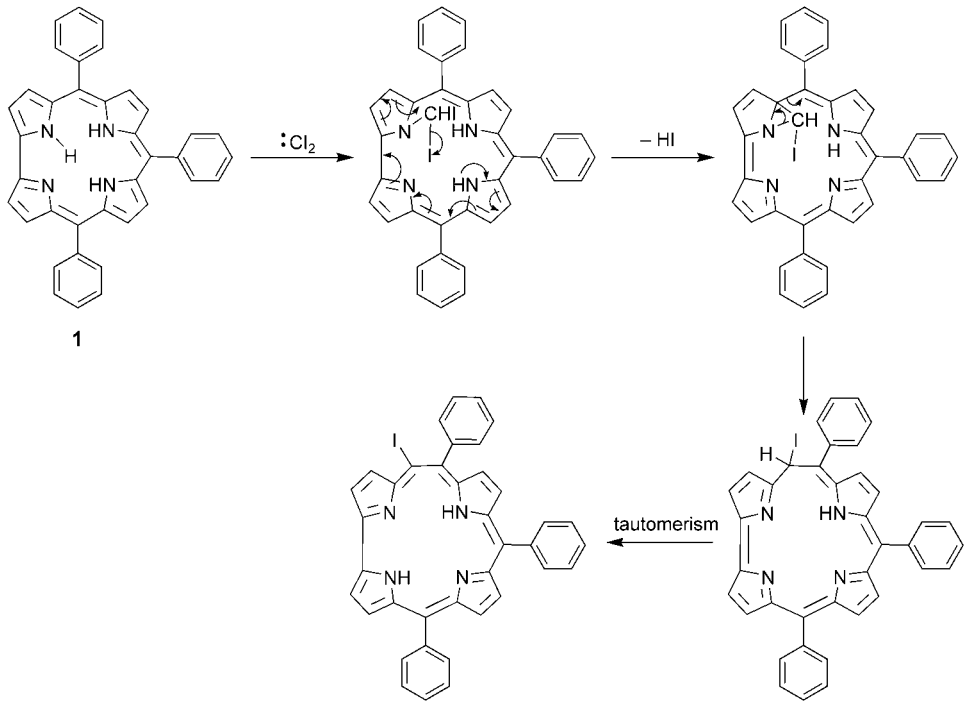


Figure 2. Proposed reaction and mechanistic pathway from **1** to **2**.

presence of an iodine atom at the vinylogous bridge offers the opportunity for further modification at this site and for exploitation of the hemiporphycene macrocycle to build more-complex molecular architectures with interesting properties for new applications.

Molecular Devices

Donor–Acceptor Pretzelanes and a Cyclic Bis[2]catenane Homologue**

*Yi Liu, Paul A. Bonvallet, Scott A. Vignon, Saeed I. Khan, and J. Fraser Stoddart**

Through its exploitation of noncovalent bonding interactions and self-assembly processes,[1] supramolecular assistance to covalent synthesis[2] has established itself as an efficient means of creating molecules with nanoscale dimensions. For two decades, researchers have harnessed the power of post-assembly covalent modification[2] to produce an array of mechanically interlocked molecular compounds,[3] some of which have been shown to behave as molecular machines[4] and switches[5] on surfaces and at interfaces, respectively. We have developed a template-directed[6] protocol for the construction of [2]catenanes[7] composed of a crown ether containing π-electron-rich aromatic ring systems and a tetracationic cyclophane comprised of two π-electron-deficient bipyridinium units. The kinetically controlled protocol relies on employing the crown ether as the template, around which the cyclophane is formed[8] from reaction of a dicationic salt with *para*-xylylene dibromide. If the crown ether is covalently tethered to this second molecule, then the resulting cyclization(s) could occur either intramolecularly and generate a pretzelane[9] or intermolecularly and generate cyclic or linear oligo/polycatenanes (Figure 1).

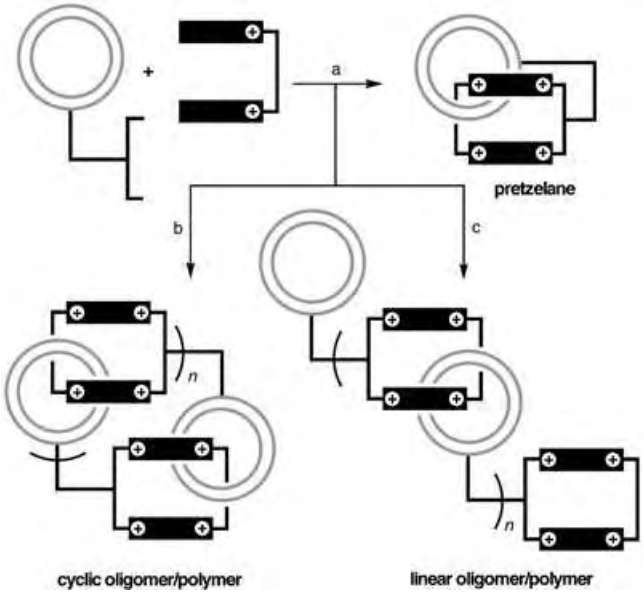

Figure 1. Graphical representations of the formation of a) a pretzelane, b) a cyclic polycatenane, and c) a linear polycatenane. The gray components are π-electron rich and the black (charged) components are π-electron deficient.

Herein, we report the synthesis of two *para*-xylylene dibromide derivatives, which have the same crown ether component[10] tethered by different linkers, and describe the outcome of their reactions with the dicationic salt. It transpires that, when the dibromide contains a longer—and more flexible—linker, a pretzelane is obtained in good yields, as suggested by (dynamic) ^{1}H NMR spectroscopic analyses in solution and confirmed by X-ray crystallographic studies in the solid state. By contrast, when the dibromide contains a shorter—and less flexible—linker, a cyclic bis[2]catenane[11] is obtained as the major product, along with lesser amounts of a pretzelane.

The synthesis of the pretzelanes **7**·4 PF_6 and **10**·4 PF_6 and the cyclic bis[2]catenane **11**·8 PF_6 are outlined in Schemes 1 and 2. Reaction of **1**,[12] which contains a symmetrically positioned carboxyl group, with an excess of **2** gave the alcohol **3**; subsequent esterification of this alcohol with another carboxylic acid derivative **4**[13] afforded the dibromide

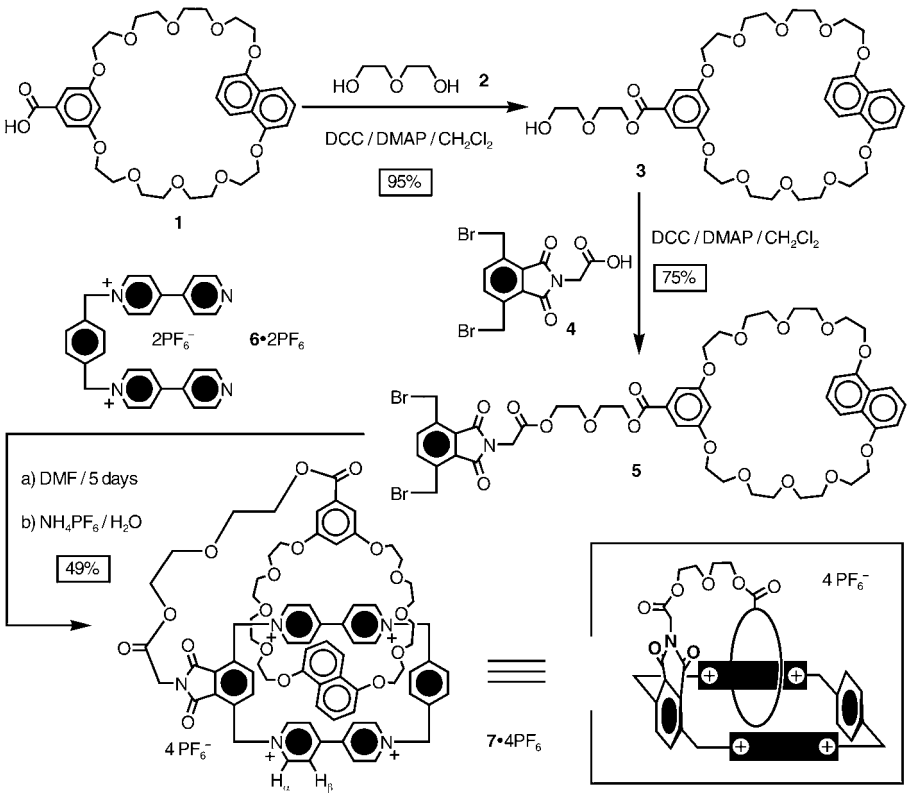
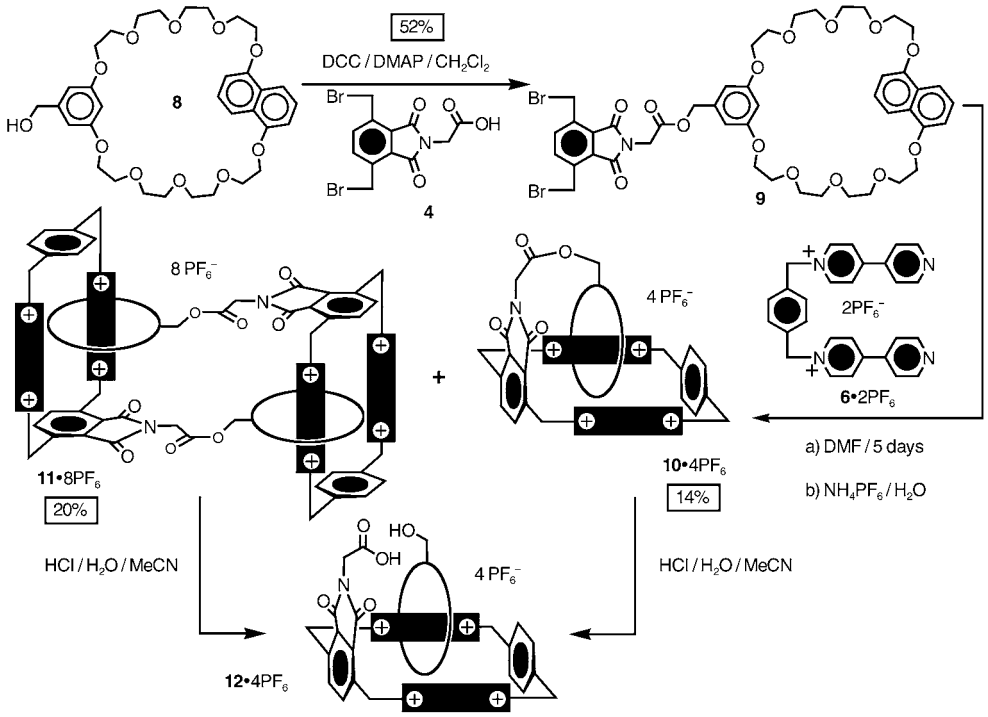


Scheme 1. The synthesis of the pretzelane **7**·4 PF_6. DCC = *N*,*N*′-dicyclohexylcarbodiimide, DMAP = 4-dimethylaminopyridine.

5 as the key intermediate. Formation of **7**·4 PF_6 was achieved in 49% yield by stirring **5** and **6**·2 PF_6[8a] in DMF (*N*,*N*′-dimethylformamide) for five days and then exchanging the counterions. In a similar fashion, the crown ether appended dibromide **9** was obtained from esterification of the crown ether **8**,[14] which carried a hydroxymethyl group, with the carboxylic acid derivative **4**. Treatment of **9** with **6**·2 PF_6 afforded a mixture of **10**·4 PF_6 and **11**·8 PF_6 in yields of 14 and 20%, respectively, after counterion exchange and column chromatography.

The pretzelane **7**·4 PF_6 contains (Figure 2) two elements of chirality, namely, planar chirality associated with the 1,5-dioxynaphthalene (DNP) ring system and helical chirality[15] arising from the relative positioning of the two interlocked rings. This helicity results from the breaking of symmetry in the tetracationic cyclophane by the phthalimido unit. It can be inverted by rotation of this phthalimido unit (process II) or by partial pirouetting of the crown ether (process III). The combination of these two chiral elements gives rise to two enantiomeric pairs of diastereoisomers. One enantiomeric pair, namely, (*pR*)-(*P*)-$\mathbf{7}^{4+}$ and (*pS*)-(*M*)-$\mathbf{7}^{4+}$, is characterized by having the oxygen atom on



Scheme 2. The synthesis of the pretzelane **10**·4 PF_6 and the cyclic bis[2]catenane **11**·8 PF_6, followed by the hydrolysis of their esters to generate the common [2]catenane **12**·4 PF_6.

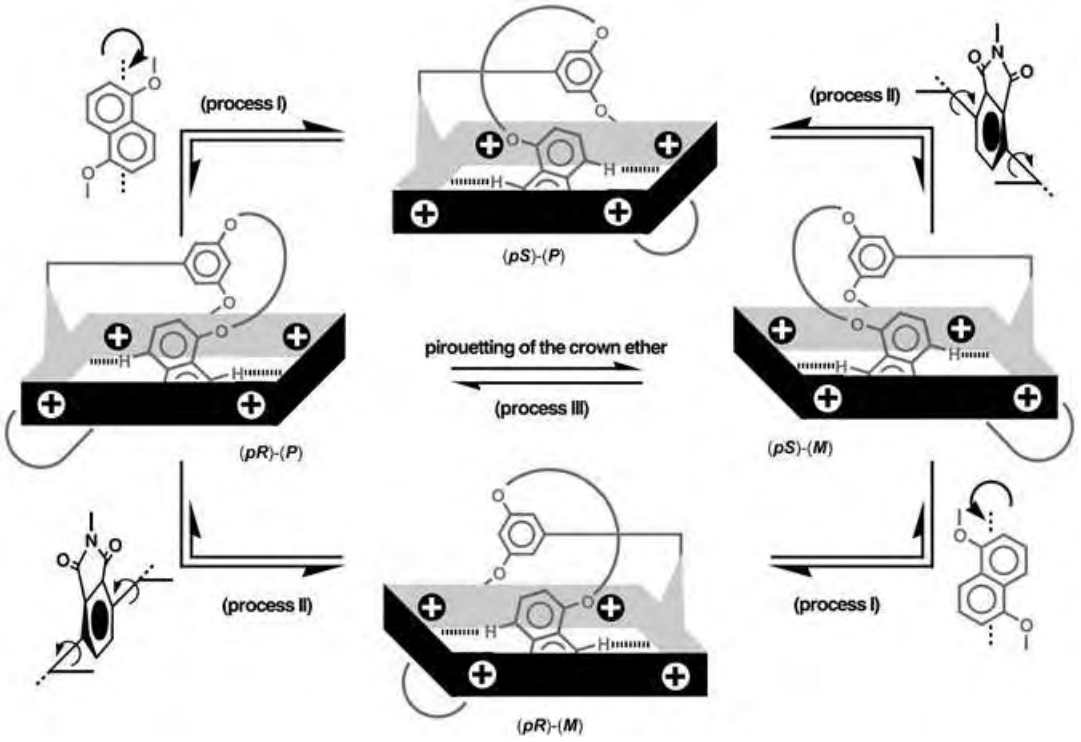


Figure 2. Graphical representations of the four possible stereoisomers of the pretzelane $\mathbf{7}^{4+}$ and the three possible dynamic processes (I, II, and III) associated with their interconversion.

the DNP ring system, which resides on the same side of the mean plane of the tetracationic cyclophane as the diimide group, pointing away from this functional group. In the case of the other enantiomeric pair, (*pS*)-(*P*)-$\mathbf{7}^{4+}$ and (*pR*)-(*M*)-$\mathbf{7}^{4+}$, this oxygen atom points toward the diimide group. Not surprisingly, the (*pR*)-(*P*) diastereoisomer is more stable than the (*pS*)-(*P*) isomer.

The X-ray structural analysis[16,17] of a single crystal obtained by vapor diffusion of $i\mathrm{Pr}_2\mathrm{O}$ into a solution of $\mathbf{7}\cdot 4\,\mathrm{PF}_6$ in MeCN identified the solid-state structure as containing an enantiomeric pair of molecules, namely, (*pR*)-(*P*)-$\mathbf{7}^{4+}$ and (*pS*)-(*M*)-$\mathbf{7}^{4+}$, and confirmed their pretzel-shaped topology (Figure 3). The tetracationic cyclophane is interlocked with the crown ether such that 1) the DNP ring system is sandwiched between the two bipyridinium units, aligned parallel to each other, with 2) one of these two units also sandwiched between the DNP ring system, also parallel, and the resorcinol ring, which is positioned alongside. The mean interplanar separations are 3.4 Å, in keeping with stabilizing π–π-stacking interactions. The conformation of the molecule is also stabilized by CH···O interactions[18] between two of the α protons on the inside bipyridinium unit and the nearby oxygen atoms in the two polyether loops of the crown ether. Furthermore, the molecular conformation is stabilized by yet another CH···O interaction between one of the oxygen atoms in the diethylene glycol linker and one of the hydrogen atoms on the appropriate methylene group at the corner of the tetracationic cyclophane. In addition, there are CH···π interactions between the naphthalene hydrogen atoms on C4 and C8 and their proximal *para*-phenylene rings. There are no discernable intermolecular stacking interactions.

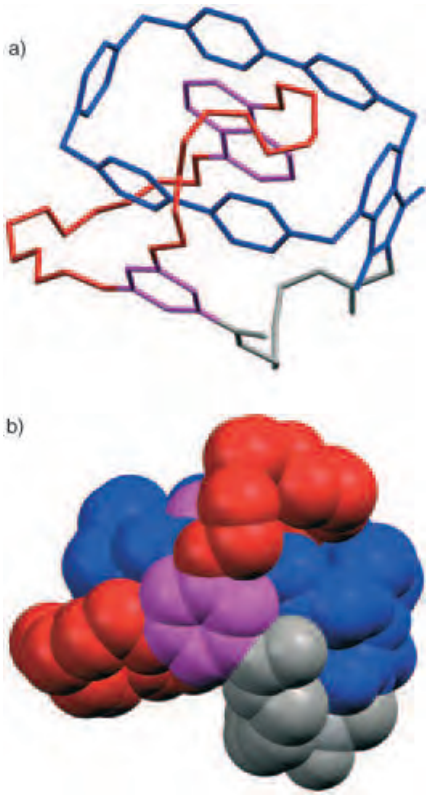

Figure 3. X-ray crystal structure of the pretzelane $\mathbf{7}^{4+}$ illustrated as a) framework and b) space-filling representations of the pretzelane. Purple: the π-donor units in the crown ether; red: the polyethylene glycol chains in the crown ether, blue: the tetracationic cyclophane; gray: the diethylene glycol chain connecting the two macrocycles.

The partial ^{1}H NMR spectrum of (Figure 4a) **7**·4 PF_6, recorded in CD_3CN, can be interpreted as a racemic modification of a single diastereoisomer. The relative stereochemistry and topology of this diastereoisomer can be

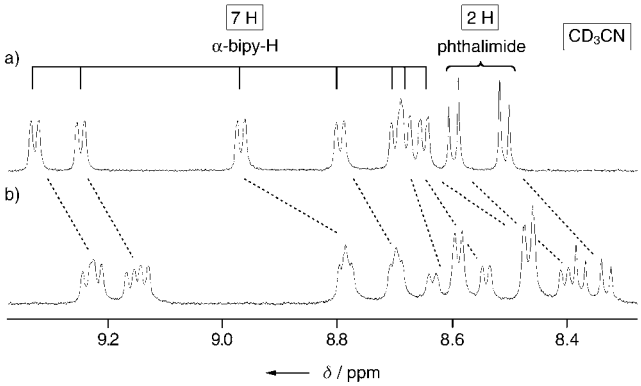

Figure 4. Partial ^{1}H NMR spectra, recorded in CD_3CN at room temperature, showing a) the signals for α-bipyridinium (bipy) and phthalimide protons in **7**·4 PF_6 and b) the change on addition of four equivalents of the chiral shift reagent Me_2NH_2·(*R*)-BINPHAT.

assigned by 2D ROESY spectroscopic analysis[19] to be the same one ((*pR*)-(*P*)-$\mathbf{7}^{4+}$/(*pS*)-(*M*)-$\mathbf{7}^{4+}$) as that observed in the solid state. The presence of these enantiomers was confirmed by recording the ^{1}H NMR spectrum (Figure 4b) in CD_3CN in the presence of a chiral shift reagent, dimethyl ammonium bis(tetrachlorobenzenediolato)mono((*R*)-[1,1′]-binaphthalenyl-2,2′-diolato)phosphate(v)[20] (Me_2NH_2·(*R*)-BINPHAT). Addition of four equivalents of Me_2NH_2·(*R*)-BINPHAT to a solution of **7**·4 PF_6 in CD_3CN results in the resonances for seven of the eight α-bipyridinium protons and the two phthalimido protons not only undergoing changes in chemical shift but also separating into two independent sets of equal intensity signals, which is commensurate with the formation of diastereoisomeric salts in approximately equal amounts.

Dynamic ^{1}H NMR spectroscopic analysis was performed on this pretzelane in CD_3SOCD_3. At room temperature, all of the protons are heterotopic and so give rise to well-resolved signals, thus indicating that any degenerate exchange processes are slow on the ^{1}H NMR timescale. Heating a CD_3SOCD_3 solution of **7**·4 PF_6 up to 120 °C (Figure 5a–d) causes the resonances[21] to begin to coalesce as a result of several site-exchange processes, including 1) reorientation (process I) of the DNP ring system outside the cyclophane's cavity, 2) a 180° rotation (process II) of the phthalimido unit about the $-CH_2ArCH_2-$ axis, and 3) pirouetting (process III) of the crown ether whereby its resorcinol unit moves from one bipyridinium unit around the tetracationic cyclophane to the other one. Since neither process I nor II are associated with degeneracy, they must occur as a pair, namely, processes I + II. The occurrence of this highly coordinated process is not unreasonable on the basis of a molecular modeling study: it suggests that the DNP ring system has to leave the cyclophane's cavity so that process II can occur.

Probe protons were chosen in $\mathbf{7}^{4+}$ to measure kinetic and thermodynamic data separately for processes I + II and

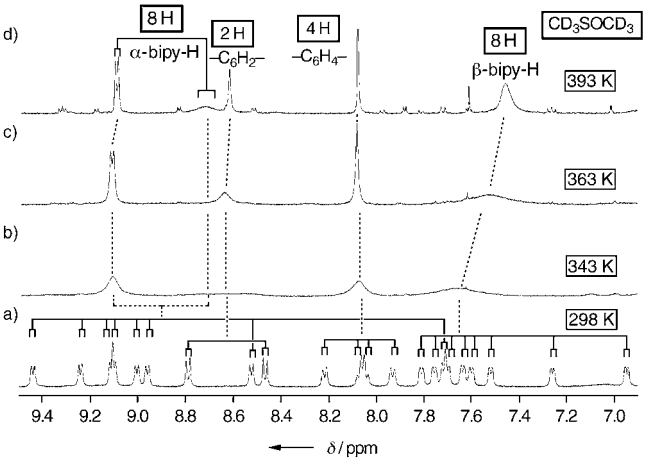

Figure 5. Partial ^{1}H NMR spectra of a solution of **7**·4 PF_6 in CD_3COCD_3 at a) 298, b) 343, c) 363, and d) 393 K, thus indicating the coalescence of the α- and β-bipyridinium protons and the phenylene protons. The unmarked, low-intensity peaks observed at 393 K are a result of decomposition of **7**·4 PF_6 at this temperature.

process III. The two diastereotopic protons on the 5-substituted resorcinol ring only undergo site exchange when processes I and II operate in tandem, while the two diastereotopic protons on the phthalimido unit experience site exchange as a result of process III. Spin-saturation transfer experiments[22] performed at 301 K on these two pairs of probe protons gave[23] ΔG values of 17.5 and 17.6 kcal mol^{-1}. The fact that these free energy barriers ($\Delta G^{\neq}$) are virtually identical (within experimental error) suggests that one process (I) is rate-limiting and that one or both of the other two processes (II and III) follow quickly.

In the case of **10**·4 PF_6 and **11**·8 PF_6, ESI mass spectrometry provided unambiguous evidence for their monomer–dimer relationship. Although they both reveal peaks at *m*/*z* 1681, 768, and 464 (Table 1), the charges carried by these ion fragments are different: the peaks for the former (**10**·4 PF_6) are singly, doubly, and triply charged, thus corresponding to the loss of one, two, and three PF_6^- ions, respectively, from a pretzelane-like constitution with a molar mass of 1826 Da, while the peaks for the latter (**11**·8 PF_6) are doubly, quadruply, and sextuply charged, thus corresponding to the loss of two, four, and six PF_6^- ions,[24] respectively, from a compound with a molar mass of 3652 Da

Table 1: Characterization[a] of **10**·4 PF_6 and **11**·8 PF_6 by ESI mass spectrometry.

[a] Data are presented as *m*/*z* ratio and (relative abundance (%)). Molecular weight and *m*/*z* values apply to the average mass of any isotope distribution and are based on a scale in which ^{12}C = 12.000.

and the constitution of a cyclic bis[2]catenane. To verify their mechanically interlocked topology, both compounds were subjected to acid-catalyzed hydrolysis of the ester linkage between the macrocyclic polyether and the tetracationic cyclophane. Heating **10**·4 PF_6 and **11**·8 PF_6 in CD_3CN/D_2O solutions at 70 °C for one day in the presence of one drop of HCl afforded a single product,[25] namely, the [2]catenane **12**·4 PF_6 in each case. These observations provide chemical proofs of the mechanically interlocked topologies of **10**·4 PF_6 and **11**·8 PF_6.

This exploratory study has established that the pretzelane topology can be generated[26] using appropriately CH···O-augmented donor–acceptor interactions as the recognition motif for templating the syntheses of dynamic pretzelanes. The fact that the barrier to enantiomerization between (*pR*)-(*P*)-**7**$^{4+}$ and (*pS*)-(*M*)-**7**$^{4+}$ is approximately 17.5 kcal mol^{-1} augurs well for introducing electrochemically switchable, metastable diastereoisomerism into bistable pretzelanes in which one of the bipyridinium units in the tetracationic cyclophane is replaced with a chemically modified one.

Experimental Section

7·4 PF_6: A solution of **5**[27] (0.45 g, 0.41 mmol) and the dicationic salt **6**·2 PF_6[8a] (0.39 g, 0.55 mmol) in DMF (10 mL) was stirred at room temperature for 5 days. Diethyl ether (200 mL) was added to the reaction mixture to ensure precipitation of the crude product. The precipitate was isolated by vacuum filtration and subjected to column chromatography on silica gel (MeOH/aqueous NH_4Cl (2 M)/$MeNO_2$, 7:2:1). Purple fractions containing the product were combined and concentrated. Solid NH_4PF_6 was added to the residue to precipitate **7**·4 PF_6 as a purple solid (0.39 g, 49 %). M.p. 195 °C (decomp); ^{1}H NMR (CD_3CN, 500 MHz, 298 K): δ = 9.27 (d, J = 6.6 Hz, 1 H), 9.19 (d, J = 6.6 Hz, 1 H), 8.88 (d, J = 6.6 Hz, 1 H), 8.73 (d, J = 6.6 Hz, 1 H), 8.65–8.59 (m, 3 H), 8.54 (d, J = 8.3 Hz, 1 H), 8.43 (d, J = 8.3 Hz, 1 H), 8.05 (d, J = 8.1 Hz, 1 H), 8.00–7.92 (m, 3 H), 7.43 (dd, J = 8.1, 2.4 Hz, 1 H), 7.41 (dd, J = 8.1, 2.4 Hz, 1 H), 7.38 (dd, J = 8.1, 2.4 Hz, 1 H), 7.36 (dd, J = 8.1, 2.4 Hz, 1 H), 7.28 (dd, J = 8.1, 2.4 Hz, 1 H), 7.27 (dd, J = 8.1, 2.4 Hz, 1 H), 7.00 (dd, J = 8.1, 2.4 Hz, 1 H), 6.95 (t, J = 1.5 Hz, 1 H), 6.81 (t, J = 1.5 Hz, 1 H), 6.67 (d, J = 13.7 Hz, 1 H), 6.62–6.60 (m, 2 H), 6.29 (d, J = 7.9 Hz, 1 H), 6.24 (d, J = 7.9 Hz, 1 H), 6.02 (t, J = 7.9 Hz, 1 H), 5.91–5.85 (m, 3 H), 5.78–5.73 (m, 4 H), 5.71 (t, J = 1.5 Hz, 1 H), 5.61 (t, J = 7.9 Hz, 1 H), 4.86 (d, J = 17.1 Hz, 1 H), 4.83 (dd, J = 12.5, 2.5 Hz, 1 H), 4.62 (dd, J = 12.5, 2.5 Hz, 1 H), 4.54 (d, J = 17.1 Hz, 1 H), 4.52–3.45 (m, 36 H), 3.29 (dd, J = 11.4, 2.5 Hz, 1 H), 3.07 (dd, J = 11.4, 2.5 Hz, 1 H), 2.50 (d, J = 8.1 Hz, 1 H), 2.44 ppm (d, J = 8.1 Hz, 1 H); MS(ESI): m/z 1783.4 $[M-PF_6]^+$, 818.9 $[M-2PF_6]^{2+}$, 497.6 $[M-3PF_6]^{3+}$; HRMS(ESI): m/z calcd for $C_{77}H_{81}N_5O_{17}P_3F_{18}$ $[M-PF_6]^+$: 1782.4547, found: 1782.4559.

10·4 PF_6 and **11**·8 PF_6: A solution of **9**[27] (0.31 g, 0.31 mmol) and **6**·2 PF_6[8a] (0.22 g, 0.31 mmol) in DMF (10 mL) was stirred at room temperature for 5 days. The solvent was removed under reduced pressure and the residue was subjected to column chromatography on silica gel. The fractions containing **10**·4 PF_6 were collected using MeOH/aqueous NH_4Cl (2 M)/$MeNO_2$ (7:2:1) as the eluent. The second set of fractions, containing **11**·8 PF_6, were collected using MeOH/aqueous NH_4Cl (2 M)/$MeNO_2$ (2:2:1) as the eluent. Solid NH_4PF_6 was added to the residues to precipitate **10**·4 PF_6 (76 mg, 14 %) and **11**·8 PF_6 (113 mg, 20 %) as brown solids.

10·4 PF_6: M.p. 232 °C (decomp); ^{1}H NMR ([D_6]DMSO, 500 MHz, 363 K): δ = 9.13–9.06 (m, 6 H), 8.69 (s, 2 H), 8.38 (br s, 2 H), 8.12 (s, 4 H), 7.83 (br s, 2 H), 7.81 (d, J = 7.9 Hz, 2 H), 7.66 (d, J = 6.6 Hz, 2 H), 7.59 (m, 4 H), 7.37 (t, J = 7.9 Hz, 2 H), 6.97 (d, J = 7.9 Hz, 2 H), 6.64 (br s, 2 H), 6.44 (s, 1 H), 6.22–5.80 (m, 8 H), 5.30–3.44 ppm (m, 36 H).

11·8 PF_6: M.p. 244 °C (decomp); ^{1}H NMR ([D_6]DMSO, 500 MHz, 363 K): δ = 9.22 (d, J = 6.4 Hz, 8 H), 9.01–8.78 (m, 8 H), 8.78 (s, 4 H), 8.17 (s, 8 H), 7.84–7.60 (m, 12 H), 7.10–6.93 (m, 4 H), 6.53 (s, 4 H), 6.35 (br s, 4 H), 6.30 (d, J = 8.3 Hz, 8 H), 5.90 (br. s, 8 H), 5.83 (br s, 4 H), 5.49 (s, 2 H), 5.34 (s, 4 H), 5.07 (s, 4 H), 4.45 (br s, 8 H), 4.28 (br s, 8 H), 4.11 (br s, 8 H), 4.01 (br s, 8 H), 3.93–3.46 (m, 32 H), 2.58 ppm (d, J = 8.3 Hz, 4 H).

[23] $\Delta G^{\neq}$ values were calculated from the rate constants k_{ex} by using the Eyring equation $\Delta G^{\neq} = R T_c \ln(k_{ex} h / k_b T_c)$, in which R is the gas constant, h is the Planck constant, and k_b is the Boltzmann constant.

[24] Furthermore, the ESI mass spectrometry of **11**·8 PF_6 also contains peaks showing the loss of three, five, and seven PF_6^- ions.

[25] The synthesis and characterization of the common [2]catenane **12**·4 PF_6 are described in the Supporting Information.

[26] A comparison of the outcomes summarized in Schemes 1 and 2 indicated that the length of the tether between the crown ether and the tetracationic cyclophane is a key parameter in determining the results of the template-directed cyclization. The longer and more flexible linker (Scheme 1) favors pretzelane formation. Higher homologues are not observed, thus reflecting the well-established fact that the entropic cost associated with generating polymeric assemblies as a result of the kinetically controlled supramolecular assistance to covalent synthesis is simply too high: small cycles are much preferred over large ones and their acyclic counterparts; see: a) R. Kramer, J.-M. Lehn, A. Marquis-Rigault, *Proc. Natl. Acad. Sci. USA* **1993**, *90*, 5394 – 5398; b) P. R. Ashton, A. N. Collins, M. C. T. Fyfe, P. T. Glink, S. Menzer, J. F. Stoddart, D. J. [27] The syntheses of **5** and **9** are described in the Supporting Information.

Asymmetric Catalysis

Design of an Axially Chiral Amino Acid with a Binaphthyl Backbone as an Organocatalyst for a Direct Asymmetric Aldol Reaction**

*Taichi Kano, Jun Takai, Osamu Tokuda, and Keiji Maruoka**

The direct catalytic asymmetric aldol reaction is one of the most fundamental transformations in organic synthesis, and several efficient asymmetric methodologies for this reaction using chiral metal catalysts[1] and organocatalysts[2–4] have recently been developed, of which catalysis by proline[2,3] and its derivatives[4] have been extensively explored. However, the reactivity and selectivity of some of these proline-catalyzed aldol reactions have serious limitations because of the difficulty in structurally modifying proline. Furthermore, a substoichiometric amount of proline is often necessary to achieve reasonable yields in the direct aldol reaction of aldehydes with acetone. Also, proline is known to react with electron-deficient aromatic aldehydes to form iminium salts, which undergo decarboxylation, even at room temperature.[5] Such degradation may induce the significant retardation of the proline-catalyzed aldol reactions. In this context, we were interested in designing an artificial amino acid catalyst **1** that would not undergo undesirable degradation through decar-

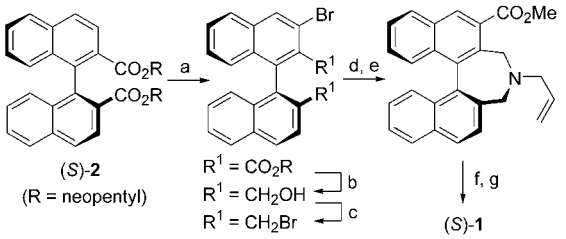
(*S*)-**1**

boxylation. Herein, we report a novel, robust amino acid catalyst **1** and its successful application to the direct asymmetric aldol reaction.

The requisite amino acid (*S*)-**1** was based on binaphthalene and prepared in a seven-step sequence from dineopentyl 1,1′-binaphthyl-2,2′-dicarboxylate ((*S*)-**2**; Scheme 1). The efficiency of this new catalyst was evaluated with the direct asymmetric aldol reaction: Reaction of 4-nitrobenzaldehyde with acetone was carried out in the



Scheme 1. Synthesis of (*S*)-**1**. Conditions: a) $Mg(TMP)_2$, THF; then Br_2; b) LAH, THF; c) BBr_3, CH_2Cl_2; d) allylamine, CH_3CN; e) 5 mol% $Pd(OAc)_2$, dppp, iPr_2NEt, CO, DMSO, MeOH; f) $Pd(OAc)_2$, PPh_3, *N*,*N*-dimethylbarbituric acid, CH_2Cl_2; g) 1 M NaOH, MeOH–THF. TMP = 2,2,6,6-tetramethylpiperidine, dppp = 1,3-bis(diphenylphosphino)propane.

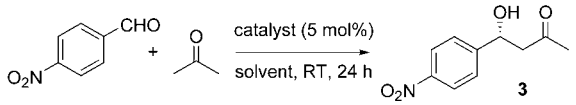
presence of 5 mol% of (*S*)-**1** at room temperature in dimethyl sulfoxide (DMSO) and the aldol adduct **3** was afforded in 70% yield and 93% *ee* (Table 1, entry 1). In contrast, the reaction with L-proline under the same reaction conditions gave **3** in low yield with moderate enantioselectivity, together with 1,3-oxazolidine **4** (48% yield based on proline) derived from proline and two equivalents of 4-nitrobenzaldehyde (entry 2). It should be noted that the formation of such a by-product was not observed with **1** because of its structural stability. We also examined the solvent effect in this reaction: Changing the solvent from DMSO to acetonitrile gave **3** in low yield with slightly higher enantioselectivity (entry 3), whereas the use of amide solvents, such as *N*-methylpyrrolidone (NMP) and *N*,*N*-dimethylformamide (DMF), gave improved yields with high enantioselectivities (entries 4 and 5).

After establishing the optimal reaction conditions, the direct asymmetric aldol reaction of other electron-deficient aldehydes with acetone was carried out (Table 2). Olefinic, heteroaromatic, and aromatic aldehydes were found to be suitable substrates, with the direct aldol reactions generally giving the corresponding aldol adducts in moderate to good yields. Furthermore, excellent enantioselectivities were observed in most cases (> 95% *ee*).

The spatial distance between the amino and carboxyl groups for (*S*)-**1** was determined by MM2 calculations using CS Chem3D, and was shown to be longer than that for L-proline (Figure 1).

In summary, we have shown that the binaphthyl-based amino acid **1** is an efficient catalyst for direct asymmetric aldol reactions of aldehydes with acetone. Most successful organic catalysts for various asymmetric reactions are derived from chiral natural products, such as amino acids and

Table 1: Direct asymmetric aldol reaction of 4-nitrobenzaldehyde with acetone catalyzed by chiral amino acids.[a]



Entry	Catalyst	Solvent	Yield [%][b]	*ee* [%][c]

Protein–DNA Arrays

Engineering a 2D Protein–DNA Crystal**

*Jonathan Malo, James C. Mitchell, Catherine Vénien-Bryan, J. Robin Harris, Holger Wille, David J. Sherratt, and Andrew J. Turberfield**

Here, we demonstrate the use of a DNA-binding protein to control the structure of a self-assembled DNA crystal. DNA self-assembly[1] has been used to create a variety of nanometer-scale objects including polyhedra,[2] simple machines,[3] two-dimensional arrays,[4] and periodic tubes.[5] Controlled construction by self-assembly is possible because the pattern of hybridization between complementary sections of oligo-

nucleotides can be predicted. Additional control can be achieved by making use of the wide range of proteins that have evolved to manipulate DNA in order to maintain and replicate genetic information. Of these, ligases and nucleases have been used during the process of DNA nanostructure fabrication and characterization to make chemical modifications to the phosphodiester backbone.[2,4a,b,d,g] Here, we report the incorporation of a bacterial recombination protein, RuvA, as an *intrinsic* component of a DNA nanostructure. By analyzing transmission electron micrographs we have produced 2D density maps (maps of transmitted electron intensity) of both RuvA–DNA and DNA-only crystals to resolutions of less than 30 Å. Both crystals are built from the same four oligonucleotides: addition of RuvA during self-assembly completely changes the lattice symmetry and connectivity. Such specially designed 2D DNA templates, used to create ordered protein arrays, may provide a tool to determine the structure of proteins that do not readily crystallize.

Our DNA arrays are built from four oligonucleotides that assemble, by hybridization of complementary sections, to form the four arms of an immobile Holliday junction (HJ)[6] shown in Figure 1 a. Each arm has a "sticky end" that consists of six unpaired bases. Each sticky end is complementary to one other; complementary sticky ends are indicated by lock-and-key symbols in Figure 1 b and e (red pairs with green, yellow pairs with blue). Hybridization of sticky ends can bind the junctions together to form an extended array. The Kagome[7] lattice shown in Figure 1 c and d consists of DNA only and is assembled by slowly cooling a stoichiometric mixture of the four oligonucleotides from 90 °C to 20 °C over 72 h. Figure 1 d shows a transmission electron micrograph of this structure, positively stained[8] with 2 % uranyl acetate. The HJs adopt a stable antiparallel χ-stacked configuration,[9] shown schematically in Figure 1 b. Pairs of arms stack coaxially to form two quasi-continuous double helices, which meet at approximately 60° in a right-handed cross. The red and orange oligonucleotides run continuously from end to end of the two double helices with largely unperturbed helical structure; the other two oligonucleotides (green and blue) cross between helices where they meet to hold the junction together. Hybridization of complementary sticky ends joins the arms of the junctions together to form extended helices. Adjacent junctions are separated by 26 base pairs or 2.5 DNA helical turns. Three sets of parallel helices are interwoven as in Kagome basketwork (Figure 1 c), with each helix woven alternately above and below others that cross at 60° and 120°. The helices must bend as they weave, which suggests a structure with kinks at the ends of the six-base sections where sticky ends overlap to reduce the resultant strain. The plane group of the crystal is $p3$ (sixfold rotational symmetry is broken by differences between the base sequences of neighboring helices that flank the hexagons and in the positions of the nicks in the DNA backbones where sticky ends overlap). A primitive unit cell contains three junctions. Only the HJ isomer shown in Figure 1 b can be incorporated into this lattice. In the other antiparallel χ-stacked isomer, in which the blue and green oligonucleotides run continuously through the junction, complementary pairs of sticky ends are on opposite rather than adjacent arms; this isomer may assemble to create a three-dimensional periodic structure.

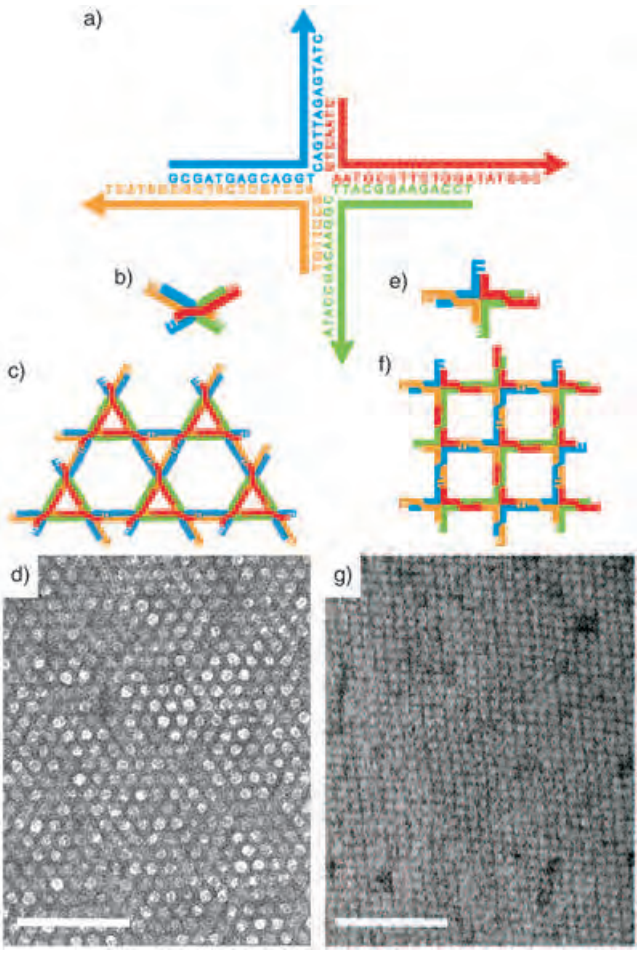

Figure 1. DNA crystals: a) The common structural unit—four oligonucleotides hybridize to form a Holliday junction (HJ) with two pairs of complementary "sticky ends". b) χ-stacked junction showing the positions of complementary sticky ends. c) Kagome lattice formed by assembly of χ-stacked junctions (for clarity, half a helical turn is shown between junctions that are, in fact, separated by 2.5 turns). d) TEM (transmission electron microscopy) image of the Kagome lattice (DNA is positively stained (dark); scale bar: 100 nm). e) Square-planar junction. f) Square lattice formed from HJs held in a square-planar configuration by protein RuvA. g) TEM image of the RuvA lattice (negatively stained: protein is lighter than background; scale bar: 100 nm).

The formation of the DNA crystal from its component oligonucleotides can be followed by measuring the decrease in A_{260}, the absorbance at 260 nm, as the mixture is slowly cooled. (A_{260} decreases as oligonucleotides hybridize.[10]) Figure 2 a shows A_{260} as a function of temperature as stoichiometric mixtures of oligonucleotides are slowly annealed and then melted. The lower pair of curves correspond to four oligonucleotides synthesized without the sticky ends that hold the junctions together. Dotted lines at 63 °C and 38 °C mark the calculated transition temperatures[11] for the assembly steps shown in Figure 2 b: first the hybridization of pairs of oligonucleotides that form the two long arms of the junction, then the coming together of these pairs to form the junction. Cooling and melting curves are overlaid, and no

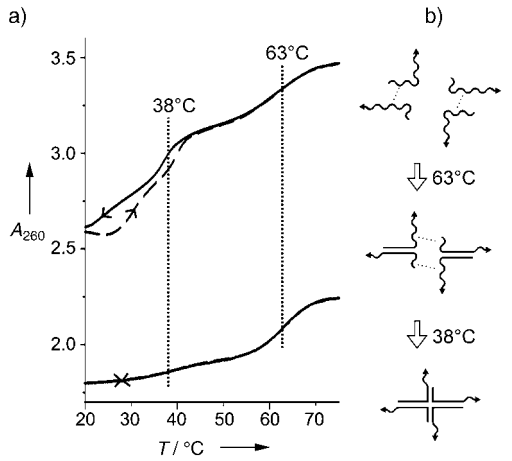

Figure 2. Monitoring self-assembly by UV/Vis absorbance spectroscopy. a) Absorbance at 260 nm (A_{260}) as a function of temperature (T) during assembly (——) and melting (-----). Hybridization is associated with a decrease in absorbance. Plots correspond to a 3 μM stoichiometric mixture of the four oligonucleotides shown in Figure 1a (upper curves) and of the same oligonucleotides with the four sticky ends removed to prevent array formation (lower curves). Rate of change of temperature: 0.1 °C min^{-1}. Dotted lines (•••••) indicate calculated transition temperatures corresponding to the assembly steps shown in part (b).

significant hysteresis is observed. The upper curves correspond to assembly and melting of the four oligonucleotides with sticky ends shown in Figure 1a. Reversible assembly of the longer arms at 63 °C is again observed, but below 42 °C there is rate-dependent hysteresis that we associate with the hybridization of sticky ends to assemble extended arrays with the structure shown in Figure 1c and d. We conclude that, as the reactants are cooled, the two more-stable pairs of oligonucleotides hybridize first then array formation begins as soon as these pairs combine to form complete junctions. This is consistent with the observation that slow cooling in the range 40–20 °C improves the size and crystalline order of the arrays, whereas slow cooling at higher temperatures does not.

The crystal shown in Figure 1f and g is made from the same four oligonucleotides to form the same HJ. In this case, however, the structure also incorporates RuvA. In vivo RuvA is part of a tripartite protein complex, the RuvABC "resolvasome",[12] which processes Holliday junctions[13] during bacterial homologous recombination. RuvA has a natural architectural role: it holds the HJ in a square-planar configuration that facilitates branch migration, driven by the ATPase RuvB,[14] and allows resolution by the endonuclease RuvC.[15] Holliday junctions are the building blocks of our DNA arrays: when RuvA binds to them during self-assembly it plays a decisive role in determining the structure and symmetry of the array. The protein is added to the cooling solution of oligonucleotides at 50 °C, at which temperature HJs have not yet formed. RuvA binds to the isolated HJs and unfolds them into a square-planar configuration[16,17] (Figure 1e). The angles between the arms are approximately 90°, the arms do not stack to form continuous helices, and the ordering of the sticky ends is different from the χ-stacked configuration (all four oligonucleotides turn at the junction to run along adjacent arms). The effect is dramatic. On further cooling the weak interactions between sticky ends assemble the units into a square lattice. In Figure 1g contrast is provided by 2% uranyl acetate which negatively stains the RuvA protein that binds each HJ.[18] The plane group of the crystal is $p1$. A primitive unit cell contains two junctions with different orientations, one of which has the major groove side upwards, and the other downwards. The connectivities of the two lattices, square and Kagome, are such that they cannot be interconverted without breaking the bonds between sticky ends that hold HJs together. Addition of RuvA at 20 °C to a ready-formed Kagome lattice does not cause detectable conversion to a square lattice.

For both crystal types, ordered domains up to 2 μm in size are observed in TEM images. Contrast between DNA or protein and background, even in the stained images shown in Figure 1d and g, is low, and the signal-to-noise ratio is limited by the need to use low electron-beam current densities to avoid damage. To obtain higher resolution structural information we have adopted two approaches to combine data from many unit cells: a process of iterative correlation mapping and averaging[19] based on the SPIDER and WEB single-particle imaging software,[20] and correction for distortion of the crystal lattice followed by reciprocal-space analysis using the MRC image-processing suite[21] designed for periodic structures. Projected density maps derived by using SPIDER are shown in Figure 3 and Figure 4 and are compared with the output of the MRC suite in the Supporting Information.

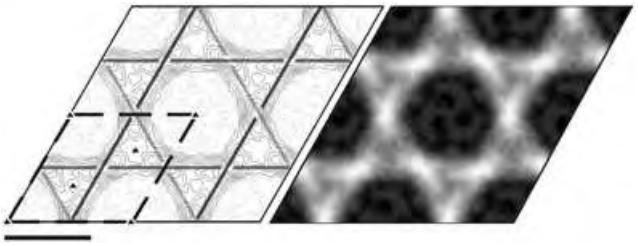

Figure 3. 2D-projected density map of a Kagome lattice composed of three interwoven DNA helices joined by χ-stacked Holliday junctions (scale bar: 10 nm). The map is derived from a negatively stained TEM image of a self-assembled DNA crystal. The contour plot and grayscale images represent the same data; woven lines indicate the positions of the helices. Dashed lines delineate a unit cell annotated with $p3$ plane group symmetry elements.

Figure 3 shows a projected density map of the DNA-only Kagome lattice. Ellipsoidal regions of high density reveal the positions of the χ-stacked HJs. The alternating orientations of the ellipses are consistent with the Kagome weaving of the helices indicated by lines in Figure 3. The distance between the junctions is 72 Å, which is 16 Å less than the contour length of the DNA duplex that joins them. We expect this distance to be shortened by strain-relieving kinks at nicks in the DNA backbone at either end of the 20 Å section that corresponds to the hybridized sticky ends. Shrinkage of the DNA caused by dehydration during grid preparation[22] may also affect this measurement.

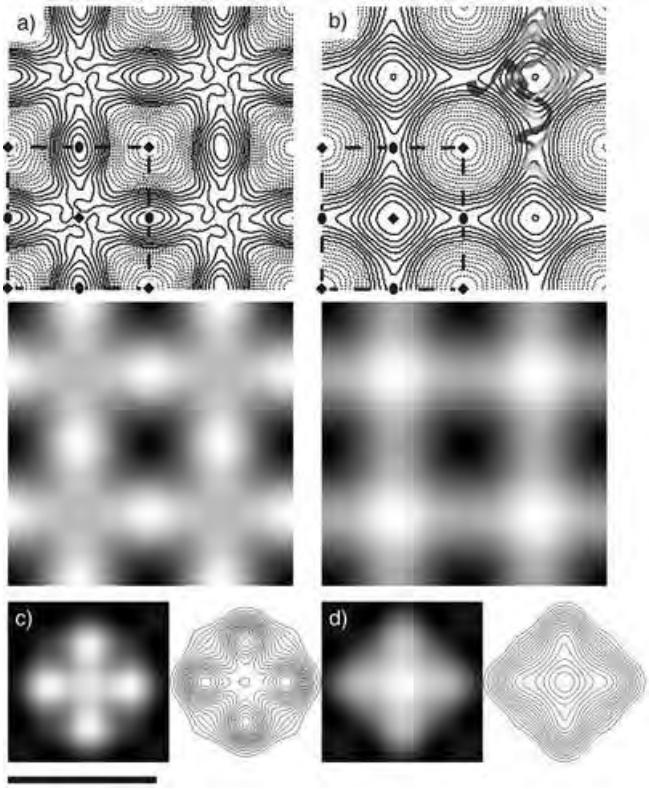

Figure 4. a, b) Projected density maps of two RuvA–DNA crystals derived from cryo-electron micrographs. Each map is represented by both a contour plot and a grayscale image. Dashed lines delineate a unit cell annotated with *p*4 plane group symmetry elements. A section of the DNA template that provides structural order is shown for illustration only. For comparison we show projection maps derived from X-ray crystal structures of Holliday junctions bound by c) a tetramer and d) an octamer of RuvA (see Supporting Information). Scale bar: 10 nm.

The protein and DNA components of the RuvA–DNA crystal shown in Figure 1g have different affinities for the uranyl acetate stain: positive staining of the DNA distorts the outline of the negatively stained RuvA complex that binds each HJ. We obtained undistorted images of this composite structure by using cryo-electron microscopy (cryo-EM) in which a thin layer of vitreous ice preserves the hydrated structure, and the image is generated by the density difference between protein and ice.[2d,23] Figure 4a and b show maps of the projected densities obtained from two RuvA–DNA crystals prepared in this way. No difference between the two differently oriented HJs in the unit cell can be resolved, so the averaged projection map has a smaller and more symmetrical unit cell than the crystal itself. The primitive unit cells of the images shown in Figure 4a and b contain one HJ and have *p*4 symmetry ($a = 95$ and 97 Å for Figure 4a and b, respectively). In Figure 4c and d, we show for comparison projected density maps derived from the X-ray crystal structures of the two known RuvA–HJ complexes, one of which incorporates a RuvA tetramer bound to one face of the junction,[16b] and the other an octamer with four molecules of RuvA bound to each face.[17] These maps have been filtered to give a resolution that is comparable to that of the cryo-EM data. The correspondence between our measured projection maps and the X-ray crystal structures is striking. We tentatively conclude that in the crystals from which the projection maps shown in Figure 4a and b were derived, which were prepared under nominally the same conditions, most HJs were bound by RuvA tetramers and octamers, respectively.

The structure of self-assembled 2D DNA crystals has previously been investigated by atomic force microscopy[4] with resolution limited to about 70 Å.[4c] To enhance the visibility of the lattice it was found necessary to add topographic features such as protruding hairpins, larger DNA domains, or streptavidin bound to biotinylated oligonucleotides,[4a,d,f,g] or to design structures with large, easily resolved gaps.[4b,c,e,h] Our micrographs demonstrate that transmission electron microscopy can provide significantly higher resolution. From computed Fourier transforms, and by comparison with the known X-ray crystal structures of the RuvA–HJ complex, we estimate the resolution of Figure 3 and Figure 4a and b to lie between 25 and 30 Å.

The use of three-dimensional DNA scaffolds[24] as templates to create artificial protein crystals for X-ray crystallography has been proposed by Seeman.[25] The structure shown in Figure 1g and Figure 4 may be regarded as a two-dimensional protein crystal whose structural order is provided by the underlying DNA scaffold rather than by interactions between protein molecules. Our density map of the RuvA–HJ complex demonstrates that a DNA-templated protein crystal can be produced with sufficient spatial order to allow measurement of protein structure. Electron microscopy of 2D crystals has achieved resolutions of 3.5 Å[26] and has the advantage that very small quantities of protein are required (typically of order 1 μg per grid). We are now working to attain higher resolution maps by improving the quality of our crystals and aim to extend the application of the DNA-scaffolding method to produce artificial crystals of other proteins, including membrane proteins that are bound to ligands attached to covalently modified oligonucleotides in a self-assembled DNA array.

Experimental Section

Purification of *E. coli* RuvA: A strain of GS566 *E. coli* that contains a RuvA-producing, ampicillin-resistant plasmid was provided by Dr. Matthew Whitby, University of Oxford. Cells were grown to OD ≈ 0.5 at 30 °C over 4 h followed by temperature-sensitive induction at 42 °C for 5 h. After lysis by sonication, purification by a series of three alternate fast-performance liquid chromatography and dialysis steps were performed to yield a solution of RuvA (80 μM, ≈ 12 mg l^{-1} of induced culture). See Supporting Information for further details.

Crystal design and assembly: Oligonucleotide sequences were designed using the program SEQUIN[27] around a symmetric sequence flanking the Holliday junction.[28] For construction of the DNA-only Kagome lattice, a stoichiometric (3 μM) mixture of the four component oligonucleotides (Sigma-Genosys; Figure 1a) was cooled from 90 °C to 20 °C over approximately 72 h in annealing buffer 1 ($MgCl_2$ (30 mM)/Tris·HCl (5 mM)/Tris acetate (20 mM)/EDTA (1 mM), pH 8.3) using a Mastercycler PCR machine (Eppendorf). The DNA–RuvA crystals were annealed using the same oligonucleotides at the same concentration in annealing buffer 2 ($MgCl_2$ (10 mM)/Tris·HCl (10 mM)/Tris acetate (40 mM)/EDTA

(1 mM), pH 8.3), also over approximately 72 h. The sample container was immersed in water in a vacuum flask, which was left to cool naturally. RuvA (24 μM) was added at 50 °C.

UV/Vis absorbance measurements: A Varian Cary 1E spectrophotometer with a 6x6 multicell-block Peltier temperature controller was used to measure the differential absorbance (A) at 260 nm between the sample, which contained a mixture of the four component oligonucleotides (3 μM) in annealing buffer 1, and a reference (only annealing buffer), both at 650 μl volume. The temperature was measured by a probe placed in a third cuvette.

Preparation of grids and electron microscopy: Specimens of the Kagome lattice were adsorbed onto 400-mesh carbon-coated copper grids and stained with 2% uranyl acetate. Electron micrographs were recorded on Kodak SO-163 film under low dose conditions using a Philips CM120 electron microscope (LMB, Oxford) at 120 kV acceleration. The defocus range was from 0.6 to 1.2 μm with a nominal magnification of ×45000. RuvA–DNA crystal specimens were applied to carbon-coated grids initially immersed in 1% tannin. These were then blotted and frozen in liquid nitrogen. Electron micrographs were recorded under low dose conditions on a JEOL 3000 electron microscope (MPI, Frankfurt) at 300 kV acceleration. The defocus range was from 0.6 to 1.2 μm with a nominal magnification of ×36000.

Image processing: Optical diffraction was used to screen and select the micrographs for crystal quality. The Kagome lattice projection map (Figure 3) was calculated from one large crystalline area ($\approx 0.6\ \mu m^2$) of an image in which the DNA was negatively stained.[18] (This image is more ordered but displays less contrast than Figure 1d in which the DNA is positively stained.[8]) The RuvA–DNA projection maps (Figure 4) were calculated using data from two separate crystals imaged under cryo-EM. Selected areas were digitized using an Optronics drum scanner (P1000) at a sampling raster of 12.5 μm that corresponds to a pixel size of 2.8 Å. A contrast transfer function (CTF) correction was applied using the CRISP software package.[29] The CTF-corrected images were processed by using correlation mapping and averaging routines[19] written for the SPIDER and WEB software packages.[20] See Supporting Information for further details.

Molecular Devices

Patterning through Controlled Submolecular Motion: Rotaxane-Based Switches and Logic Gates that Function in Solution and Polymer Films**

David A. Leigh, M. Ángeles F. Morales, Emilio M. Pérez, Jenny K. Y. Wong, Carlos G. Saiz, Alexandra M. Z. Slawin,* Adrian J. Carmichael, David M. Haddleton,* A. Manfred Brouwer,* Wybren Jan Buma,* George W. H. Wurpel, Salvador León, and Francesco Zerbetto**

The extensive use of molecular machine-like processes in biology[1] is inspiring efforts to exploit similarly well-controlled motions in functional synthetic systems.[2] Stimuli-responsive "molecular shuttles"—rotaxanes in which a key feature of the tertiary structure, the relative positions of the interlocked components, can be changed in response to an external input—constitute a basic kind of nanoscale mechanical switch,[3] capable of varying physical properties such as conductivity,[4] circular dichroism,[5] and fluorescence.[6] However, there are few examples[7] where shuttling has been demonstrated in the polymer-based media upon which many materials applications may ultimately depend, and only simple rotaxanes (not switchable molecular shuttles) have been used to create information-rich quaternary structures, such as patterned surfaces.[8] Here we report a system in which the translocation of a ring along a peptide-based thread, induced by changes in the nature of the local environment, can be used to switch the fluorescence of a rotaxane "on" or "off". Remarkably, the system not only works in solution but also in polymer films where patterns visible to the naked eye can be generated solely through controlled submolecular motion. A polymer film "INHIBIT" logic gate based on a combination of control of submolecular positioning and chemical modification (protonation) is also demonstrated.

Thread **1** consists of an anthracene fluorophore (which also acts as a "stopper") attached to a glycylglycine hydrogen-bonding binding site or "station", which, in turn, is connected to a C_{11} alkyl chain that can act as a second "solvophobic" station[9] and is terminated by a second stopper.[10] Rotaxanes **2** and **3** were prepared in 37 and 20% yields, respectively, by condensing *p*-xylylenediamine with the appropriate bis(acid chlorides) in the presence of **1** (Scheme 1).[11] Double proto-

nation of **3** with an excess of trifluoroacetic acid generated $\mathbf{3}\cdot 2H^+\cdot 2CF_3CO_2^-$. The macrocycles in **2** and $\mathbf{3}\cdot 2H^+$ contain nitrophenyl and pyridinium moieties, respectively, which are known to quench the fluorescence of anthracene through distance-dependent electron transfer.[6a,12]

A clear change in position of the rotaxane components of **2**, **3**, and $\mathbf{3}\cdot 2H^+\cdot 2CF_3CO_2^-$ between $CDCl_3$ and $[D_6]$DMSO (dimethylsulfoxide) is clearly apparent from ^{1}H NMR spectroscopy. Figure 1 shows the partial ^{1}H NMR spectra (400 MHz, 298 K) of thread **1** and rotaxane **2** in the different

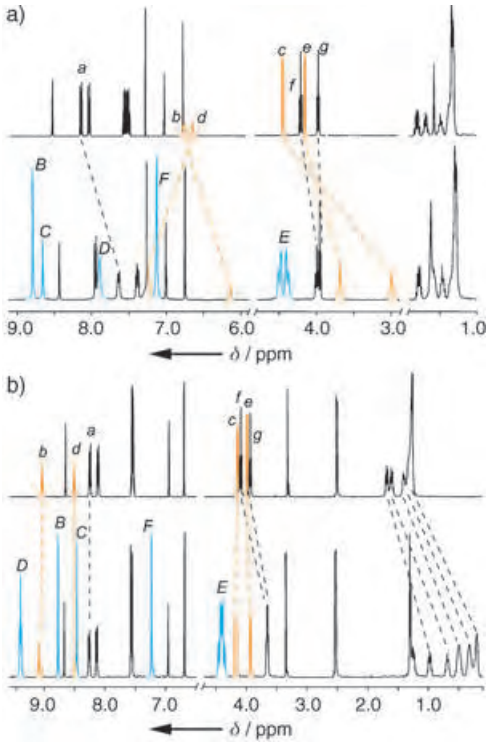

Figure 1. Partial ^{1}H NMR spectra of a) thread **1** (top) and rotaxane **2** (bottom) in $CDCl_3$, and b) thread **1** (top) and rotaxane **2** (bottom) in $[D_6]$DMSO. The assignments correspond to the lettering shown in Scheme 1 and are based on COSY and GOESY experiments (400 MHz, 298 K). In $CDCl_3$, the signals for H_c and H_e of the glycylglycine station (orange) are shielded by $\delta = 1.2$ and 0.4 ppm in the rotaxane with respect to the thread because of the aromatic rings of the macrocycle. In $[D_6]$DMSO, it is the signals that correspond to the protons of the alkyl chain that are strongly shielded, while the signals of the glycylglycine unit are essentially unchanged, which confirms the position of the macrocycle over the alkyl chain.

solvents. In $CDCl_3$ (Figure 1 a) the chemical shift differences of the glycylglycine protons between **1** and **2** indicate that the macrocycle resides principally over the peptide residue of the rotaxane.[13] The solid-state structure of a close analogue of **3** (only the non-anthracene stopper is different in **3′**) shows the macrocycle binding to the glycylglycine station through a network of intercomponent hydrogen bonds (Figure 2).[14] In contrast, in $[D_6]$DMSO (Figure 1 b) it is the signals for the protons of the alkyl chains of **2** that are shielded by up to 1.2 ppm through encapsulation by the macrocycle. The discrimination of the macrocycle for the different regions of the thread is less well expressed in solvents of polarity and hydrogen-bonding basicity that lie in-between those of $CDCl_3$ and $[D_6]$DMSO (e.g. $[D_3]$MeCN, $[D_4]$MeOH, $[D_8]$EtOAc, $[D_7]$DMF (DMF = *N*,*N*-dimethylformamide), $[D_8]$THF etc.), with smaller shifts involving more thread protons observed in the ^{1}H NMR spectra in these solvents than with $CDCl_3$ or $[D_6]$DMSO. However, the switching of the preferred translational isomer between the relatively nonpolar solvents and $[D_6]$DMSO is quite general for rotaxanes with this type of amphiphilic thread, with **3** and **3**·2 H^+·2 $CF_3CO_2^-$ exhibiting similar shift patterns to **2** (see Supporting Information).

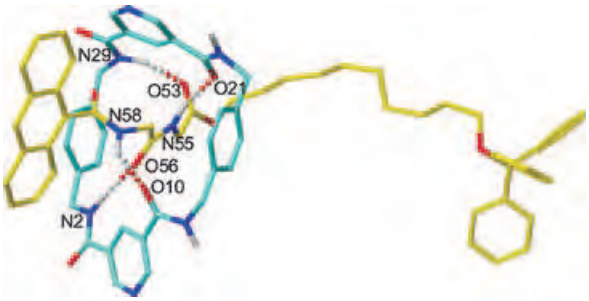

Figure 2. X-ray crystal structure[14] of **3′**, a close structural analogue of rotaxane **3** (the 3,5-di-*tert*-butylphenyl stopper in **3** is substituted for a triphenylmethyl group to give **3′**). C (macrocycle) blue, C (thread) yellow, O red, N dark blue, H white. Non-amide hydrogen atoms are omitted for clarity. Intramolecular hydrogen-bond lengths [Å] and angles [°]: N2H-O56 1.93–170.7; N58H-O10 2.16, 140.6; N55H-O21 1.96, 174.4; N29H-O53 2.03, 161.9.

The effect of the environment-induced positional change of the interlocked components on the fluorescence emission of the rotaxanes was also investigated. Fluorescence spectra ($\lambda_{ex} = 340$ nm) of 10^{-5} M solutions of rotaxanes **2** and **3**·2 H^+·2 $CF_3CO_2^-$ were recorded in benzene, CH_2Cl_2, CH_3CN, CH_3OH, DMF, DMSO, and H_2NCHO (Figure 3, Table 1). The variation in the ^{1}H NMR and fluorescence

[a] General values for the amide functional group.

spectra does not directly follow from the dielectric or hydrogen-bonding constants of the solvents, but is readily explained by considering the functional group interaction profiles (FGIP) recently introduced by Hunter (Figure 4).[15] In solvents in which the intercomponent hydrogen bonding should be strongest (benzene, CH_2Cl_2, CH_3CN) the anthracene fluorescence is virtually completely quenched, whereas in solvents with a strong solvophobic profile for alkyl chains (DMSO and NH_2CHO), UV-stimulated fluorescence is clearly visible at submicromolar concentrations. This contrasts with the trend whereby an increase in dielectric constant generally increases the efficiency of other decay pathways to result in a decrease in fluorescence intensity.[16] In fact, the very efficient quenching observed in nonpolar solvents suggests that the electron-transfer process in rotaxanes **2** and **3**·2 H^+ is close to the Marcus optimal region, where

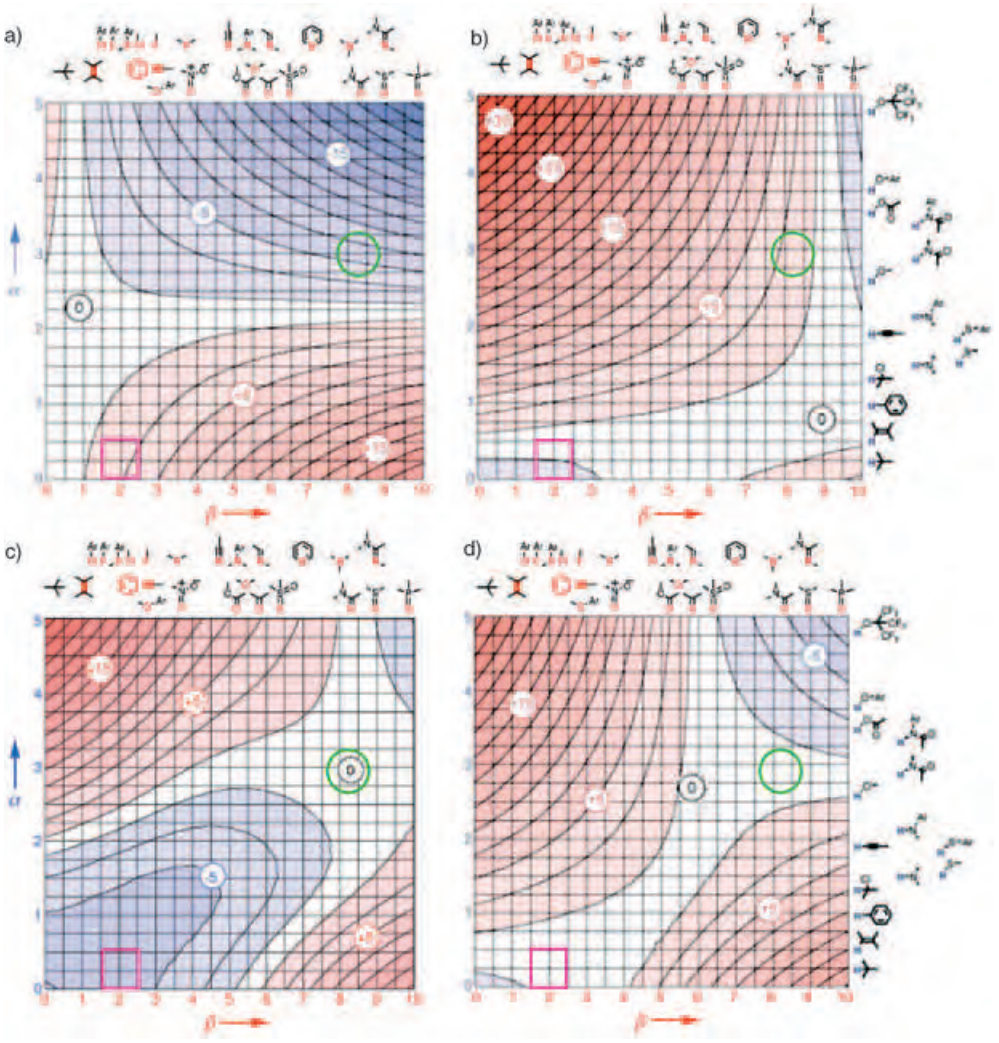

Figure 4. Functional group interaction profiles (FGIP) in a) chloroform ($\alpha_S = 2.2$, $\beta_S = 0.8$), b) DMSO ($\alpha_S = 0.8$, $\beta_S = 8.9$), c) formamide ($\alpha_S = 2.9$, $\beta_S = 8.3$),[18] and d) methanol ($\alpha_S = 0.9$ and 2.7, $\beta_S = 5.8$). Note, the FGIP of dichloromethane ($\alpha_S = 1.9$, $\beta_S = 1.1$) is very similar to that of chloroform. Blue represents a favorable interaction, and red represents an unfavorable interaction. Parts (a), (b), and (d) are reproduced with permission from Ref. [15]. The intercomponent interactions that largely determine the position and positional integrity of the macrocycle in **2**, **3**, and **3**·2 H^+·2 $CF_3CO_2^-$ are the amide–amide interaction region (highlighted with a green circle and corresponds to the peptidyl translational isomer) and the alkyl chain–phenyl ring interaction region (highlighted with a magenta square and stabilizes the alkyl translational isomer). a) Solute–solute amide–amide interactions are strongly favored and alkyl chain—phenyl ring interactions are disfavored, so we can expect the tertiary structure for the peptide-based molecular shuttles to feature the macrocycle held firmly on the peptide station by a well-defined hydrogen-bonding network, which leads to strong quenching of the anthracene fluorescence. b) Amide–amide interactions are strongly disfavored whereas alkyl chain–phenyl ring interactions in the solvent–solvent interaction dominated quadrant (bottom left) are favored, so we can expect the macrocycle to be localized on the alkyl-chain station but in a variety of positions and co-conformations owing to the general solvophobic interactions. As formamide contains both strong hydrogen-bond donors and acceptors it should display a strong solvophobic interaction in the lower left quadrant, similar to that for water. Indeed, this is the case as shown in (c), and the FGIP indicates that the solvophobic effect in NH_2CHO should be at least as strong as in DMSO, as suggested by the fluorescence measurements. d) In methanol, the amide–amide interactions are weak, but no driving force exists for alkyl-chain–phenyl-ring interactions either. So we can expect the room-temperature Boltzmann-averaged distribution to feature the macrocycle spending a significant amount of time over many positions along the entire length of the rotaxane thread; some of these conformations will lead to efficient quenching, while others do not.

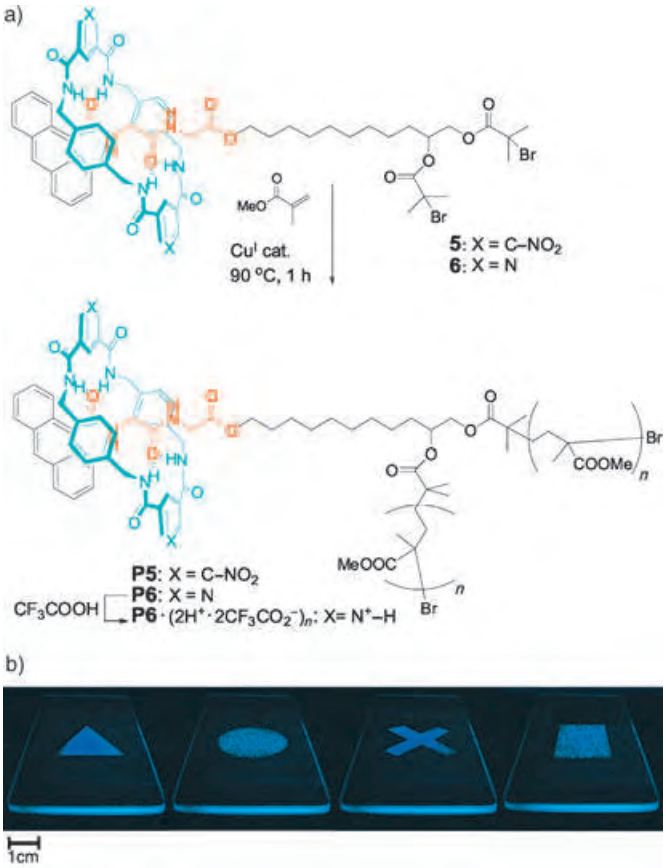
the reorganization energy is equal to the $-\Delta G$ value for electron transfer (this inference is also supported by low-temperature fluorescence spectra and thermodynamic considerations, see Supporting Information). In such circumstances the electron-transfer process is barrierless and is insensitive to the polarity of the solvent.[17] We can thus conclude that the variations in intensity observed with the different solvents is caused by the change in the relative separation of the fluorophore and quencher. Although the positioning of the macrocycle on the large alkyl-chain region would be expected to be rather poorly defined through a solvophobic effect, the ratio of fluorescence quantum yields obtained solely by the average net displacement of the macrocycle along the thread is as high as 15:1 (Table 1). This is significantly less than the 200:1 on/off ratio reported recently[6a] for a light-switchable shuttle with two discrete and well-separated hydrogen-bonding stations, but is nonetheless remarkable for such a simple system and easily visible to the naked eye (Figure 3b).

To see if the same principles could be demonstrated to work in environments that are more relevant to materials applications, we synthesized well-defined polymer analogues of **2** and **3** by transition-metal-mediated living radical polymerization (often called ATRP)[19] using methyl methacrylate as a monomer and [2]rotaxanes **5** and **6** as initiators. The resulting poly(methyl methacrylate) (PMMA)-based macromolecule [2]rotaxanes **P5** and **P6** had narrow polydispersity indices (PDI) of 1.17 and 1.14, respectively, and contained approximately 10% w/w of peptide rotaxane end-groups. ^{1}H NMR studies in $CDCl_3$ and [D_6]DMSO showed that the translational isomerism of the interlocked components of polymers **P5** and **P6** in solution exactly mirrored those of the small-molecule analogues, **2** and **3**. Thin transparent films of **P5** and **P6** on quartz slides were prepared through either conventional spin-coating techniques or by the evaporation of solutions of the polymers in dichloromethane. The resulting colorless thin films were of good optical quality and behaved in a manner independent of their method of preparation.

No fluorescence was detected when slides coated with the **P5** film were illuminated with UV light (254–350 nm), which suggests that in the nonpolar environment of the PMMA-like film the macrocycle resides over the peptide portion of the thread and efficiently quenches the anthracene fluorescence. However, although exposing the **P5**-coated slides to DMSO vapor (generated by gently warming an open beaker of the solvent in the vicinity of the film for 5 min) did not result in a noticeable change to the film under natural light, upon illumination with the UV source the characteristic blue anthracene fluorescence became apparent. Masking regions of films of **P5** from DMSO vapor with aluminum grids again produced no perceptible change under natural light, but distinctly shaped and clearly visible patterns were revealed with the UV source (Scheme 2b). The system is reversible: warming the slides to 70 °C at 0.1 Torr for 15 minutes to drive off absorbed solvent resulted in the loss of the fluorescent patterning. The behavior of **P5** implies that the environment-induced change in position of the interlocked components occurs in the polymer film just as it does in solution. This view



Scheme 2. a) Chemical structures of rotaxane initiators **5** and **6** and the corresponding PMMA-based polymers **P5**, **P6**, and **P6**·(2 H$^+$ 2 CF$_3$CO$_2^-$)$_n$. b) Images obtained by casting films of polymer **P5** on quartz slides, then covering the films with aluminum masks, and exposing the unmasked area to DMSO vapor for 5 minutes. The photographs were taken while illuminating the slides with an 8-watt Camag UV lamp (254–350 nm) and reveal representative triangle, circle, cross, and square symbols.

is supported by molecular dynamics simulations (see Supporting Information) in which close similarities are seen between the average intercomponent separation of **2** in CH_2Cl_2 and DMSO and **P5** in a solvent-free environment and with the addition of several molecules of DMSO.

The quartz slides coated with **P6** films were fluorescent when illuminated with UV light as the pyridine units of the macrocycle need to be protonated to quench the excited state of anthracene. Accordingly, when quartz slides coated with **P6** were exposed to CF_3CO_2H vapors (**P6**→ **P6**·(2 H$^+$·2 CF$_3$CO$_2^-$)$_n$) fluorescence was no longer observed. Figure 5b shows a distinct pattern of dark (nonfluorescent) bands resulting from thin films of **P6** upon exposure to CF_3CO_2H vapor through a striped aluminum mask (Figure 5a) and then illuminated with UV light. When the resulting dark strips of **P6**·(**2** H$^+$·2 CF$_3$CO$_2^-$)$_n$ were exposed to DMSO vapor through the same mask rotated by 90°, a criss-cross pattern was produced (Figure 5c) in which only segments that had been exposed to CF_3CO_2H vapor but not to DMSO vapor were dark when illuminated with the UV source, which suggest that displacement of the macrocycle

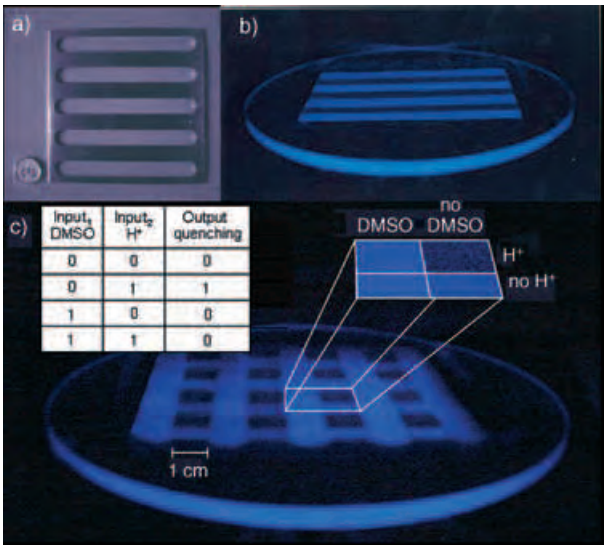


Figure 5. a) Aluminum grid used in the experiment; the coin shown for scale in the lower left corner of (a) is a UK 5 p piece. b) Pattern generated when films of **P6** were exposed to trifluoroacetic acid vapor for 5 minutes through the aluminum-grid mask. c) Criss-cross pattern obtained by rotation of the aluminum grid by 90° and exposure of the film shown in (b) to DMSO vapor for a further 5 minutes; only regions exposed to trifluoroacetic acid but not to DMSO are quenched, as shown in the magnified view. Inset: The truth table for an "INHIBIT" logic gate. The photographs of the slides were taken in the dark while illuminating with an 8-watt UV lamp (254–350 nm).

from the peptide station to the alkyl chain restores fluorescence to the exposed regions. The response of **P6** to the different combinations of two stimuli (DMSO and protons) corresponds to an "INHIBIT" Boolean logic gate.[20,21] The **P6** logic gate does not operate with full reversibility as a film, however, because although the DMSO could be removed by warming under reduced pressure (as with **P5**), the effects of the acid stimulus could not be reversed without some deterioration in the optical quality of the film. In solution, **P6** is cleanly regenerated by treatment with base, for example, triethylamine.

In conclusion, we have described a class of molecular shuttles in which translational isomerism of the components can be controlled to either permit or preclude fluorescence quenching by intercomponent electron transfer in both solution and polymer films. As the shuttling mechanism does not require a change to the covalent structure of the shuttles, the optical response can be unambiguously ascribed to changes in the relative positions of macrocycle and thread; a visible optical response from a mechanical submolecular event.[21] Although using exposure to chemical vapors as a stimulus is unlikely to be practically useful beyond sensing or, perhaps, security applications, related hydrogen-bonded shuttles can be switched in solution by using light,[23] electrochemistry,[24] changes in temperature[25] or pH,[26] and covalent-bond-forming chemical reactions.[27] The present work demonstrates that some of the switching mechanisms, properties, and logic operations established for molecular shuttles in solution can be transferred to media that are more suitable for developing materials which function through controlled submolecular motion.

[3] Most shuttling mechanisms require a concomitant—and often major—change in the rotaxane primary structure (e.g. charge, oxidation state, protonation, etc). In the absence of clear controls, attributing the changes in property to the positional displacement of components rather than the change in the electronic nature or chemical composition of the molecule is not straightforward.

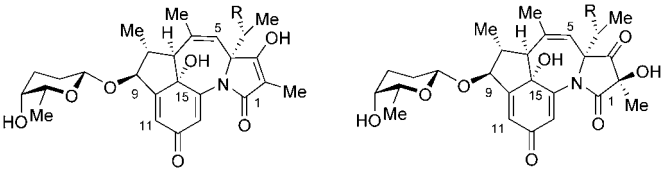
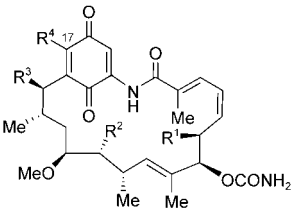
Natural Product Synthesis

Synthesis of the Tetracyclic Core of the Tetrapetalones through Transannular Oxidative [4+3] Cyclization**

*Xiang Wang and John A. Porco, Jr.**

A series of novel soybean lipoxygenase (SBL) inhibitors, tetrapetalones A–D (**1**–**4**, Scheme 1), were recently isolated





compound	R^1	R^2	R^3	R^4
macbecin (**5**)	Me	Me	OMe	H
herbimycin A (**6**)	OMe	Me	OMe	H
geldanamycin (**7**)	OMe	OH	H	OMe

Scheme 1. Chemical structures of the tetrapetalones A–D (**1**–**4**) and representative ansamycin natural products **5**–**7**.

by Komoda et al.[1] from the culture filtrate of the *Streptomyces* sp. strain USF-4727.[2] These tetrapetalones showed moderate inhibition of SBL ($IC_{50} = 190$–$360\ \mu M$ for **1**–**4**) comparable to the well-known lipoxygenase inhibitors nordihydroguaiaretic acid (NDGA, $IC_{50} = 290\ \mu M$) and kojic acid ($IC_{50} = 110\ \mu M$). The structure of tetrapetalone A (**1**) was first determined by ^1H NMR NOESY spectroscopic analysis and modified Mosher analysis,[1a] and then was subsequently revised by ^1H–^{15}N HMBC techniques, detailed NOE analysis, and chemical derivatization.[1b] The tetrapetalones B–D (**2**–**4**) were structurally characterized shortly thereafter and were shown to have similar inhibitory activities against SBL. The tetrapetalones possess an unprecedented tetracyclic skeleton bearing an appended β-rhodinosyl moiety. The unique structural feature of the tetracyclic core and its similarity to

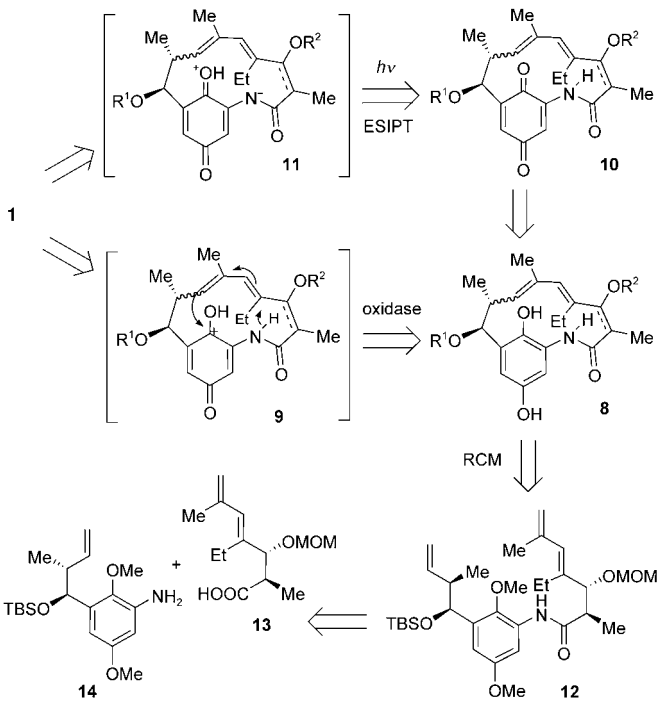
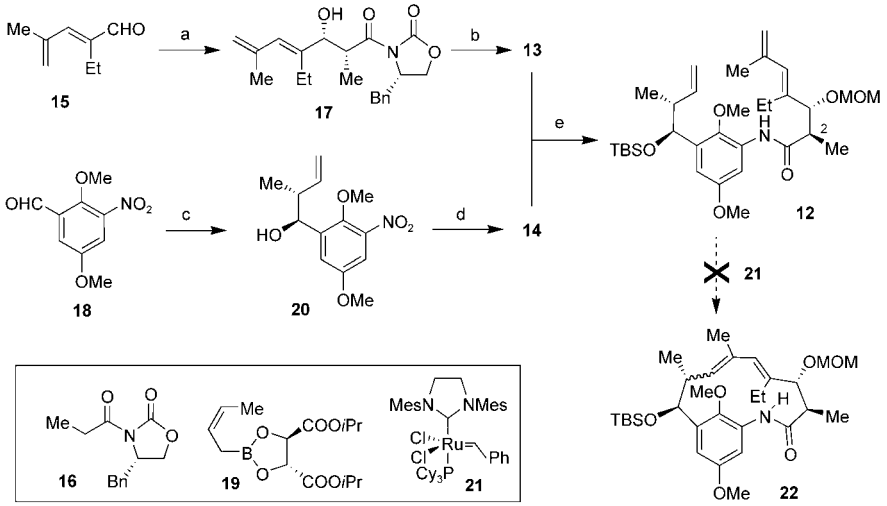
the ansamycin antibiotics[3,4] attracted our interest and prompted consideration of synthetic approaches.

The ansamycins are important antibiotics possessing antibacterial, antifungal, and antitumor activities.[5] For example, geldanamycin (**7**) has been shown to inhibit the chaperone activity of heat shock protein 90 (Hsp 90) by noncovalent binding to its ATP/ADP binding site.[6] A synthetic analogue, 17-allylamino-17-demethoxygeldanamycin, has entered phase I clinical trials.[7] The benzylic ansamycin natural products (representative members are shown in Scheme 1) vary in oxidation level from a monophenol (for example, reblastatin),[3h] hydroquinone (for example, cytotrienin A),[3f] to a benzylquinone (for example, **5**–**7**), each bearing a highly functionalized polyketide *ansa* chain. It is likely that the biosynthesis of the benzylic ansamycins involves oxidation of the aromatic core after construction of the macrolactam unit.[8] We considered whether the tetrapetalones may be derived from a macrocyclic ansamycin precursor because of structural similarities between the tetrapetalones and the ansamycins. During oxidation of hydroquinone **8**, however, the arene-derived oxonium ion **9** may be trapped by the diene fragment, which subsequently reacts with the amide nitrogen atom to form the tetracyclic skeleton of **1**–**4** (Scheme 2).[9] It is also possible that the desired quinone **10** may undergo excited-state intramolecular proton transfer (ESIPT)[10] under UV irradiation to afford dipole **11**, which further reacts with the diene fragment to form the tetracycle. To investigate these and other possible transannular[11] [4+3] cyclization processes,[12,13] we developed a retrosynthetic analysis for tetrapetalone A to target the preparation of both hydroquinone **8** and quinone **10**. We considered ring-closing metathesis (RCM)[14] of acyclic substrate **12**, which may be derived from condensation of the acid **13** and aniline **14**, as a route to develop a convergent synthetic pathway to these precursors.



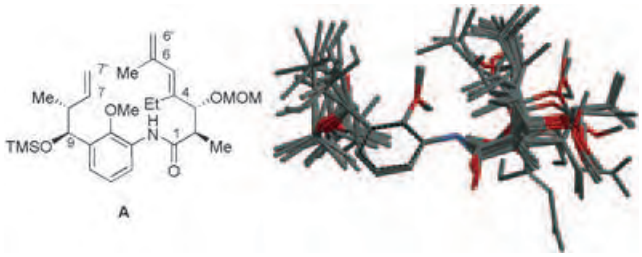
Scheme 2. Retrosynthetic analysis of tetrapetalone A (**1**). TBS = *tert*-butyldimethylsilyl. MOM = methoxymethyl.

Synthesis of the requisite diene acid **13** commenced with the Evans *syn*-aldol condensation[15] of dienal **15**[16] and chiral oxazolidinone **16** to afford chiral alcohol **17** as a single diastereomer (Scheme 3). Methoxymethyl (MOM) protection of the alcohol and hydrolysis of the chiral auxilary afforded **13** (85% yield, three steps). Asymmetric crotylation[17] of aldehyde **18**[4a] using the chiral *cis*-crotylboronate **19** derived from L-diisopropyltartrate (L-dipt) afforded chiral alcohol **20** (100% yield, single diastereomer). Silylation followed by reduction of the nitro group[18] afforded the desired aniline **14** (62% yield, two steps). Coupling of fragments **13** and **14** using *N*,*N*-bis(2-oxo-3-oxazolidinyl)phosphorodiamidic chloride (BOPCl)[19] led to epimerization of the α chiral center (C2, Scheme 3) of the amide product **12**. The use of an acid chloride proved to be feasible in the preparation of **12** (82%) without epimerization. However, treatment of acyclic triene **12** with the Grubbs second generation catalyst **21** did not produce the desired cyclic diene **22**. ^{1}H NMR spectroscopic analysis of the crude reaction mixture indicated that the ruthenium catalyst had reacted with the monosubstituted olefin, with no evidence of metathesis of the 1,1-disubstituted olefin. We believe that the 1,1-disubstituted olefin was

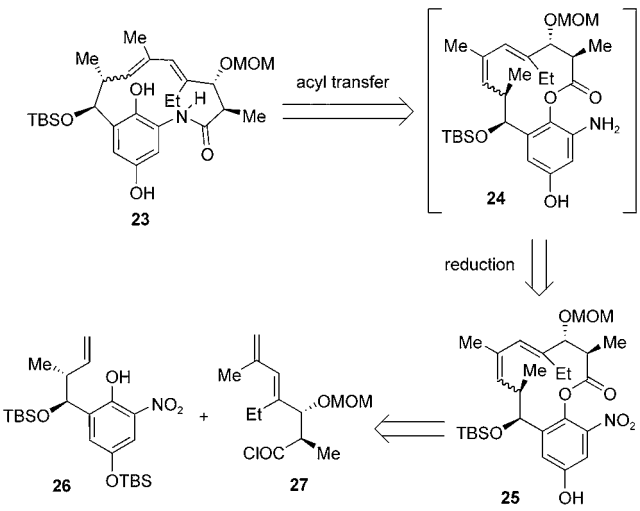


Scheme 3. RCM approach to macrolactam **22**. a) **16**, Bu_2BOTf, Et_3N, CH_2Cl_2, −78→0°C; b) 1. MOMCl, DIPEA; 2. LiOH, H_2O_2, THF, H_2O (85% yield over 3 steps); c) **19**, CH_2Cl_2, −78→25°C (100% yield); d) 1. TBSOTf, Et_3N, −78°C; 2. $NaBH_4$, S_8, THF, 65°C (62% yield over 2 steps); e) **13**, $(COCl)_2$, cat. DMF, CH_2Cl_2, 0→25°C; then **14**, Et_3N, 82% yield. MOMCl = chloromethyl methyl ether, DIPEA = diisopropylethylamine, TBSOTf = *tert*-butyldimethylsilyl triflate, DMF = *N*,*N*-dimethylformamide, Mes = mesitylene, Cy = cyclohexyl, Bn = benzyl.

unreactive in this case and that the two *meta*-substituted side chains are likely to be positioned away from each other because of "*meta* bridging" of the aromatic substituents. Therefore, the macrocyclic RCM was prohibited by both the reactivity of the olefin and the conformational strain within the substrate **12**.[4f] A conformational search on model **A** by molecular mechanics force field (MMFF) studies[20] (Scheme 4) suggested a possible rationale: the smallest



Scheme 4. Conformers of the "*meta*-bridged" acyclic model.

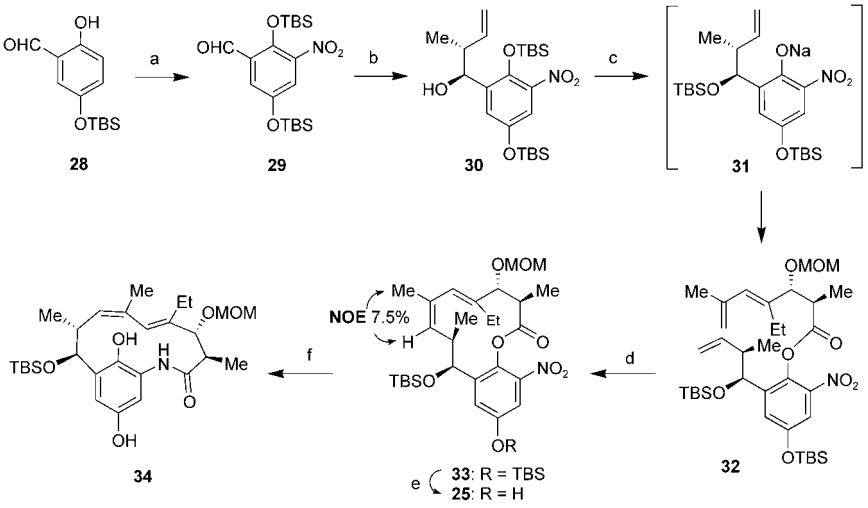


Scheme 5. Revised retrosynthetic analysis for macrolactam **23**.

distance between the C6′ and C7′ atoms is 6.2 Å among the low-energy conformers (E_{rel} = 0–5.2 kcal mol^{-1}) of model **A**. Therefore, the conformational strain of the "*meta*-bridged" framework may provide a significant barrier for macrocyclization of substrate **12**.

Since the direct macrocyclic RCM approach did not afford the desired macrocycle, we next considered that macrolactam **23** (Scheme 5) may be derived from an "*ortho*-bridged" macrolactone **24** through intramolecular acyl transfer[21] (ring expansion). Lactone **24** may be prepared from selective reduction of the nitro group of **25**, which may be obtained from nitrophenol **26** and acyl chloride **27**. A TBS group was chosen to protect the phenol of **26**, to facilitate removal at a later stage.

Synthesis of the revised C7–C15 fragment began with nitration of phenol **28**[22] followed by silylation to afford bis(silyl) ether **29** (70%, two steps; Scheme 6). Asymmetric crotylation of **29** using *cis*-crotyl boronate **19**[17] produced chiral alcohol **30** as a single diastereomer in quantitative yield. Deprotonation of the secondary alcohol of **30** using sodium hexamethyldisilazane (NaHMDS; THF, −78 °C) generated a sodium phenoxide species **31** in situ through intramolecular transfer of a silyl group.[23,24] Subsequent addition of acyl chloride **27**, Et_3N, and DMAP afforded phenol ester **32**. To our delight, triene **32** underwent smooth RCM macrocyclization to afford cyclic diene **33** after treatment with the Grubbs second generation catalyst **21** (80 °C, 30 min). NOE analysis showed that the newly formed olefin possessed a *Z* configuration. Selective desilylation of **33** (TBAF/AcOH) afforded nitrophenol **25** (85%, two steps).



Scheme 6. Synthesis of ansamycin **34**. a) 1. $Cu(NO_3)_2 \cdot 3H_2O$, Ac_2O, 0→25 °C; 2. TBSCl, Et_3N, DMF, 70% yield over 2 steps; b) **19**, CH_2Cl_2, −78→25 °C, 99% yield; c) NaHMDS, THF, −78 °C; then **27**, Et_3N, DMAP, −78→25 °C, 85% yield; d) **21**, benzene, 80 °C; e) TBAF/HOAc, THF, 0 °C, 85% yield over 2 steps; f) $Pd/CaCO_3$, Et_3N, THF, 1 atm H_2; then silica gel, EtOAc. DMAP = 4-*N*,*N*-dimethylaminopyridine, DMF = *N*,*N*-dimethylformamide; HMDS = 1,1,1,3,3,3-hexamethyldisilazane; TBAF = tetrabutylammonium fluoride.

We next evaluated conditions for the selective reduction of the aryl nitro group in the presence of the diene functionality. We found that application of standard conditions for reduction of the nitro group, such as $SnCl_2$[25] and $NaBH_4/S_8$,[18] to substrate **25** not only reduced the nitro group but also hydrolyzed the ester, and no desired macrolactam **34** was formed. The use of Pd/C[26] or $Pd/CaCO_3$[27] in a hydrogen atmosphere was found to reduce both the diene and nitro groups. However, $Pd/CaCO_3$ chemoselectively reduced the nitro group of **25** when 10% triethylamine was employed as a cosolvent. Filtration of the reaction mixture through silica gel followed by elution with EtOAc cleanly afforded the desired acyl migration product **34**. It is interesting to note that use of the Lindlar catalyst[4b] resulted in formation of trace amounts of the desired product, presumably because of the catalyst poison PbO_2 and the sensitivity of aniline **24** to the oxidant.

With hydroquinone **34** in hand, we next evaluated the crucial biomimetic transannular oxidative [4+3] cyclization.[28] Out of the possible oxidants to effect the transformation of hydroquinones to quinones, we first chose $PhI(OAc)_2$[29] for the activation of hydroquinone. After considerable experimentation, we found that hydroquinone **34** was readily oxidized, with oxidative oligomerization as a major side reaction. Addition of a dilute solution of **34** in CH_2Cl_2 to a solution of $PhI(OAc)_2$ in CH_2Cl_2 at 0 °C over 15 minutes provided tetracycle **35** (42 %, two steps; Scheme 7). The structure of **35** was determined by NOESY spectroscopic analysis as shown in Scheme 7. Three stereocenters were formed (see inset, Scheme 7), and out of these, the configurations at the C4 and C7 atoms are the same as those of the natural products **1**–**4** but the configuration at C15 is reversed (*S*).

A conformational search of substrate **34** was performed by using MMFF studies to investigate the stereochemical outcome of this highly diastereoselective transannular [4+3] cyclization.[20] The macrocycle is positioned underneath the aromatic ring in the ground-state conformer (see inset, Scheme 7), thus establishing an *S* configuration for the C15 stereocenter. Allylic strain forces the C8–H bond to be eclipsed to the C6–C5 bond, which controls the configuration at C7. Since the ground-state conformer of **34** shows that C5–C6 is *s-trans*, we believe that the transannular cyclization may, in fact, be a stepwise process. After the diene reacts with the arene-derived oxonium ion, intermediate **36** may rotate to obtain a suitable conformation for reaction with the amide nitrogen atom. Furthermore, calculations indicated that the atropisomer of the macrolactam **34** that leads to the correct configuration at C15 is approximately 4.1 kcal mol^{-1} higher in energy than the ground-state conformer (see the Supporting Information).[30]

In summary, a novel I^{III}-promoted transannular oxidative [4+3] cyclization has been developed to construct the tetracyclic skeleton of the tetrapetalones. A convergent strategy to access the macrocyclic ansamycin precursor has been developed that involves a one-pot, base-mediated silyl transfer/acylation process for fragment coupling and a tandem reduction of the nitro group/acyl transfer process for construction of the highly strained, bicyclic system. This novel strategy provides an alternative approach to the construction of macrolactams as precursors to the ansamycin antibiotics and analogues. Synthetic studies toward the total synthesis of tetrapetalone A (**1**) and development of related oxidative [4+3] cyclization processes are currently being investigated and will be reported in due course.

Iron Clusters

Coordination Chemistry of the Hexavacant Tungstophosphate $[H_2P_2W_{12}O_{48}]^{12-}$ with Fe^{III} Ions: Towards Original Structures of Increasing Size and Complexity**

*Béatrice Godin, Ya-Guang Chen, Jacqueline Vaissermann, Laurent Ruhlmann, Michel Verdaguer, and Pierre Gouzerh**

Dedicated to Professor Francis Sécheresse on the occasion of his 60th birthday

Polyoxometalates (POMs) are known to form original molecular and supramolecular structures of impressive size and complexity. This structural flexibility has been used to synthesize POMs with important chemical, biological, or physical properties.[1–3] Lacunary POMs form magnetic clusters with diverse nuclearities and original topologies.[4] The trivacant Keggin or Wells–Dawson polyoxotungstates have proven the most versatile polyoxoanion synthons for the preparation of magnetic clusters. Magnetic POMs with up to four trivacant POM subunits have been reported to date.[5,6] The largest number of first-row paramagnetic ions encapsulated in a diamagnetic POM matrix is displayed by the copper(II) polyoxotungstates $[\{(SiW_9O_{34})\{SiW_9O_{33}(OH)\}(Cu(OH))_6Cu\}_2X]^{23-}$ (X = Cl, Br) recently reported by Mialane et al.[6]

One of the goals of such studies is the search for single-molecule magnets (SMMs),[7] which are the subject of considerable interest owing to their unique physics and relevance in the development of functional nanosized materials. Their unusual properties derive from the combination of a large spin ground state with a large negative axial-type anisotropy. The current search for new SMMs is largely focused on polynuclear oxo iron[8,9] and manganese complexes.[10] Although interactions between Fe^{III} ions as well as between Mn^{III} ions, mediated by μ-oxo or μ-hydroxo bridges, are often antiferromagnetic, local ion anisotropy and particular topological arrangements can result in reasonably large spin ground states and negative *D* values. Therefore, original spin topologies and/or new SMMs can be expected from POMs with increasing size and complexity, particularly highly vacant POMs. This led us to explore the coordination chemistry of the hexavacant tungstophosphate $[H_2P_2W_{12}O_{48}]^{12-}$.

Lacunary derivatives of the Wells–Dawson anion α-$[P_2W_{18}O_{62}]^{6-}$ have been thoroughly investigated by Contant and Ciabrini,[11,12] and the related terminology (α, α_1, α_2) can be found in reference [11]. The metastable anion α-$[H_2P_2W_{12}O_{48}]^{12-}$, abbreviated as $\{P_2W_{12}\}$, could not be characterized by X-ray diffraction studies. However, its structure can be inferred from that of the condensed tetramer $[P_8W_{48}O_{184}]^{40-}$.[13] Further evidence for this structure comes from the reactions with tungstate, molybdate, and vanadate in acid media, which provide mixed tungsto-molybdo-vanadophosphates.[14] Another example of the reactivity of $\{P_2W_{12}\}$ towards d^0-transition metal ions is provided by the polyperoxo polyoxoanion $[P_2W_{12}O_{56}(NbO_2)_6]^{12-}$.[15] The reactions of $\{P_2W_{12}\}$ with lanthanides have led to the isolation of complexes that, instead of $\{P_2W_{12}\}$, contain $[P_2W_{16}O_{59}]^{16-}$ [16] or α_2-$[P_2W_{17}O_{61}]^{10-}$ [17]. In contrast, it was originally reported that $\{P_2W_{12}\}$ does not form complexes with divalent or trivalent transition-metal ions.[13] We have now succeeded in isolating several Fe^{III} and Mn^{III} complexes, and we present here our results on the $\{P_2W_{12}\}/Fe^{III}$ system.

In aqueous mixtures of lithium chloride and lithium acetate at ambient temperature, the reaction of $\{P_2W_{12}\}$ with an excess (8–14 equiv) of iron(III) chloride gives the metastable anion $[H_4P_2W_{12}Fe_9O_{56}(OAc)_7]^{6-}$ (**1**) which crystallizes as Li_2K_4-**1**·34 H_2O.[18] Upon heating in aqueous sodium acetate, **1** transforms into $[H_yP_8W_{48+x}Fe_{28-x}O_{248}]^{(84-y-3x)-}$ (**2**), which has been isolated as different salts that show slight variation in the value of *x*. A sample formulated as $Na_{16}K_{12}[H_{56}P_8W_{48}Fe_{28}O_{248}]$·ca.90 H_2O ($Na_{16}K_{12}$-**2a**·ca.90 H_2O) based on chemical analysis was obtained by heating $\{P_2W_{12}\}$ with 6 equiv of iron(III) chloride in 0.5 M sodium acetate. It was characterized by electrochemical and magnetic measurements, and by determination of the unit cell parameters. A complete X-ray diffraction study was performed on a crystal from another sample for which the formula $Na_{16}K_{10}[H_{55}P_8W_{49}Fe_{27}O_{248}]$·ca.90 H_2O ($Na_{16}K_{10}$-**2b**·ca.90 H_2O) is proposed on the basis of the structure determination. There is also some evidence of the formation of other representatives of **2** (possibly with *x* up to 4) when the Fe^{III}:$\{P_2W_{12}\}$ ratio or the pH value is lowered. However, chemical analysis and IR spectroscopy are insufficient to unequivocally determine the composition and purity of these products. When the Fe^{III}:$\{P_2W_{12}\}$ ratio is less than 4, clusters with the generalized formula $[H_yP_4W_{28+x}Fe_{8-x}O_{120}]^{(28-y-3x)-}$ (**3**) are obtained instead of **2**.[19]

The structure of **1** is shown in Figure 1. The cluster has crystallographically imposed C_2 symmetry. It derives from the hexavacant $\{P_2W_{12}\}$ anion by filling up the six vacancies with iron atoms. The substituted Wells–Dawson species $\{P_2W_{12}Fe_6\}$ thus formed supports three additional iron atoms: Two of

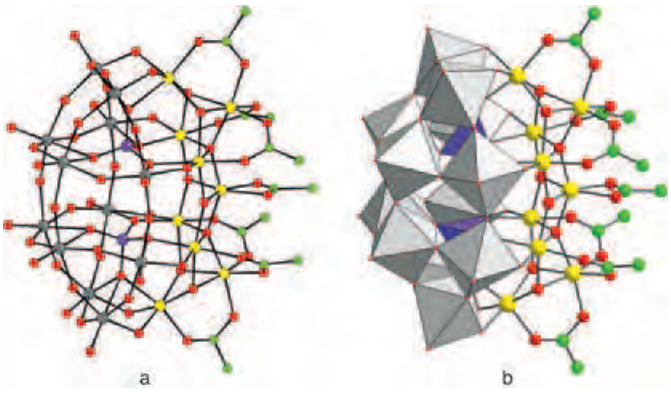

Figure 1. Ball-and-stick (a) and combined polyhedral ball-and-stick representations (b) of **1** in Li_2K_4-**1**·34 H_2O (P violet, O red, Fe yellow, W black, C green).

them are connected to three contiguous bridging oxo ligands of the $\{P_2W_{12}Fe_6\}$ subunit, while the third is connected to four bridging oxo ligands. Sixfold coordination of the Fe^{III} centers is achieved by coordination to acetate ligands. Six of the seven acetate ligands are bridging while the seventh is chelating. The Fe^{III} centers are connected through six μ_3-O and two μ_4-O units. The results of bond valence sum (BVS) calculations[20] indicate that the triply bridging oxygen atoms that do not lie in the equatorial plane are protonated. Thus the anion is formulated as $[H_4P_2W_{12}Fe_9O_{56}(OAc)_7]^{6-}$ in agreement with the results of chemical analysis. Compound **1** can be considered as bridging the gap between transition metal substituted POMs such as $[\alpha\text{-}P_2W_{15}O_{59}(FeCl)_2(FeOH_2)]^{11-}$ [21] and classic coordination clusters such as $[Fe_3O(OAc)_6(H_2O)_3]^+$.[22] Apart from the keplerates,[23a] where acetate anions act as bridging ligands for the $\{Mo_2^{V}O_4\}$ linkers, there are only a few complexes of POMs that contain acetate ligands. These include $[\gamma\text{-}SiW_{10}O_{36}(OH)Cr_2(OAc)_2(H_2O)_2]^{5-}$,[24a] $[PW_{11}O_{39}\{Rh_2(OAc)_2\}]^{5-}$,[24b] $[\{\alpha_2\text{-}P_2W_{17}O_{61}La(OAc)(H_2O)_2\}_2]^{16-}$,[17] and $[\{SiW_{11}O_{39}Ln(H_2O)(OAc)\}_2]$.[25]

The structure of **2b** is shown in Figure 2. This cluster can be viewed as a supramolecular Wells–Dawson polyoxotungstate. Each of the four $\{P_2W_{12}Fe_6\}$ subunits is connected by three Fe-O-Fe bridges to an adamantane $\{Fe_4O_6\}$ core. In addition, they are linked into pairs by three Fe-O-Fe bridges involving the three outer iron atoms. These extra bonds differentiate **2b** from the otherwise similar tetra-Keggin anion $[Nb_4O_6(\alpha\text{-}Nb_3SiW_9O_{40})_4]^{20-}$.[26] To our knowledge, there are only a few crystallographically characterized iron(III) clusters that contain an adamantane-like core: These are tetranuclear complexes with ditopic, heptadentate ligands[27] and triazacyclononane.[28]

The inner site α_2 of each Wells–Dawson subunit of **2b** is occupied either by tungsten or iron. Crystallographic refinement resulted in occupancy factors of 0.25 for W and 0.75 for Fe in this site; thus, the composition of the cluster is $\{P_8W_{49}Fe_{27}\}$. According to BVS calculations, all the Fe-O-Fe bridges are protonated, which leads to the composition $[H_{55}P_8W_{49}Fe_{27}O_{248}]^{26-}$. Only a few tetrahedral supramolecular POMs have been characterized so far. Besides the above-mentioned Nb-containing compound,[26] these include the polyoxomolybdo-europate $[Eu_4(MoO_4)(H_2O)_{16}(Mo_7O_{24})_4]^{14-}$,[29] the uranium-containing polyoxotungstate $[(UO_2)_{12}(\mu_3\text{-}O)_4(\mu_2\text{-}H_2O)_{12}(P_2W_{15}O_{56})_4]^{32-}$,[30] the tetrameric titanium(IV)-substituted Wells–Dawson polyoxotungstate $[\{Ti_3P_2W_{15}O_{57.5}(OH)_3\}_4]^{24-}$,[31] and the tetra(polyoxometalate) dendrimers $[\{P_2V_3W_{15}O_{59}(OCH_2)_3CNHCOCH_2CH_2OCH_2\}_4C]^{24-}$ [32a] and $[(SiW_{11}O_{39}GeCH_2CH_2CO_2CH_2)_4C]^{20-}$.[32b]

The cyclic voltammograms of $\{P_2W_{12}\}$, **1**, and **2a** are shown in Figure 3. The electrochemistry of $\{P_2W_{12}\}$ has been described.[33] The first reduction wave of **1** and **2a**, which is attributed to the reduction of Fe^{III} to Fe^{II}, is rather broad, particularly for **1**. However, stepwise reduction of the Fe^{III} centers is not observed, in contrast to the sandwich complexes $\alpha\beta\beta\alpha\text{-}[(Fe^{III}OH_2)_2Fe_2^{III}(X_2W_{15}O_{56})_2]^{12-}$ (X = P,[34a,b] As[34c,d]). Controlled potential coulometry under continuous argon bubbling and stirring consumes 9.3 and 27.8 electrons per molecule, respectively, for **1** at pH 3 and **2a** at pH 2. This is in satisfactory agreement with analytical and structural data. An

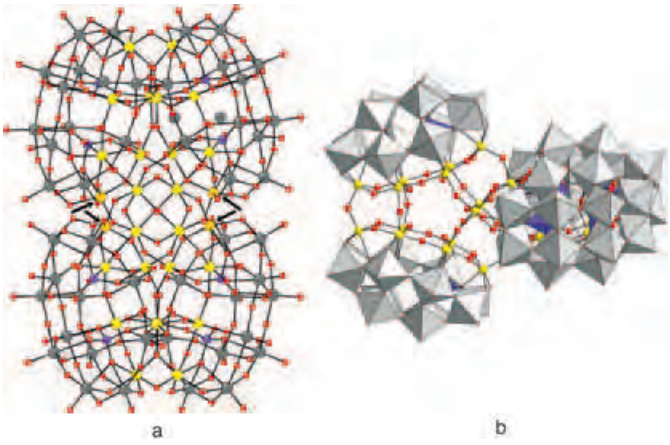

Figure 2. Ball-and-stick (a) and combined polyhedral ball-and-stick representations (b) of **2b** in $Na_{16}K_{10}$-**2b**·90 H_2O (P violet, O red, Fe yellow, W black, C green). The four inner α_2 positions (shown by the arrows) possess 75% Fe and 25% W character.

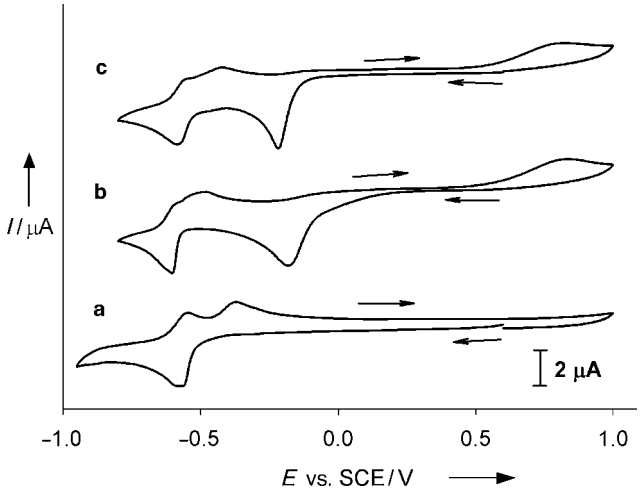

Figure 3. The cyclic voltammograms of 0.1 mM samples of $[H_2P_2W_{12}O_{48}]^{12-}$ (a), **1** (b), and **2a** (c) in 0.5 M $Li_2SO_4 + H_2SO_4$ at pH 3. The scan rate was 20 $mV\,s^{-1}$, and a glassy carbon electrode was used.

oxidation wave appears at about +0.8 V, which is attributed to the oxidation of free Fe^{II}. Demetalation of **1** and **2** upon reduction of the Fe^{III} centers parallels the behavior of multi-iron Wells–Dawson sandwich-type polyoxotungstates.[35]

The temperature dependence of the magnetization of Li_2K_4-**1**·34 H_2O was studied down to 2 K. The $\chi_M T$ product at 300 K (20 $cm^3 mol^{-1} K$) is much lower than expected for nine noninteracting Fe^{III} centers (39.4 $cm^3 mol^{-1} K$) and decreases continuously to 1.94 $cm^3 mol^{-1} K$ at 2 K. This indicates strong intramolecular antiferromagnetic coupling between the Fe^{III} centers. The magnetization was studied as a function of the applied magnetic field at 2 K: The magnetization at 50 kOe (4.2 μ_B) is consistent with a paramagnetic ground state, as expected for a cluster with an odd number of Fe^{III} centers. The magnetization data at 2 K, however, do not fit a Brillouin function for a spin $S = 5/2$, which indicates a more complex situation in the ground state. Even if the C_2 symmetry of the cluster results in a reduction in the number of nearest neighbor exchange coupling constants J in **1** to seven, the extraction of very different J values from the magnetic data is far from trivial. Accurate magnetization data, EPR characterization, and computation of the J values by density functional theory methods are in progress.[36] Magnetic studies of **2** also indicate strong antiferromagnetic coupling between the Fe^{III} centers. The residual paramagnetism in the studied sample corresponds to the presence of a species with an odd number of Fe^{III} centers, such as **2b**. Further studies are planned on this family of compounds.

In conclusion, the hexavacant tungstophosphate anion $[H_2P_2W_{12}O_{48}]^{12-}$ can accomodate six Fe^{III} centers. The $\{P_2W_{12}Fe_6\}$ species thus formed is stabilized as either **1** or **2** through further reaction with Fe^{III} centers. In addition, tungsten may substitute a part of the iron in the $\{P_2W_{12}Fe_6\}$ moiety. To our knowledge, cluster **2b**, with 27 Fe^{III} centers, is the second largest iron cluster characterized so far, being only surpassed by the $\{Mo^{VI}_{72}Fe^{III}_{30}\}$ keplerate.[23b] Manganese and nickel derivatives of $\{P_2W_{12}\}$ have been also obtained and will be reported soon.[19]

Experimental Section

1: $FeCl_3$·6 H_2O (1.21 g, 4.48 mmol) was added to a stirred solution of $K_{12}[H_2P_2W_{12}O_{48}]$·24 H_2O[12] (1.97 g, 0.50 mmol) in a mixture of 5 M LiCl (25 mL), 4 M LiOAc (9 mL), and H_2O (5 mL). The resulting mixture was stirred for 5 h and then allowed to sit. After 1 day the mixture was filtered. Dark red crystals of Li_2K_4-**1**·34 H_2O deposited from the filtrate (pH 3.7) over 1–2 d. The crystals were collected by filtration through a glass frit and washed with ice-cold water (10 mL). Yield 0.37 g (15% calculated from $\{P_2W_{12}\}$). Elemental analysis calcd (%) for $C_{14}H_{93}K_4Li_2Fe_9O_{104}P_2W_{12}$: C 3.46, K 3.21, Li 0.29, Fe 10.33, P 1.27, W 45.33; found: C 3.56, K 3.12, Li 0.33, Fe 10.13, P 1.19, W 43.37.

2: $K_{12}[H_2P_2W_{12}O_{48}]$·24 H_2O (1.0 g, 0.25 mmol) and $FeCl_3$·6 H_2O (0.405 g, 1.5 mmol) were added to a mixture of 4 M NaOAc (6 mL) and H_2O (40 mL). The resulting suspension was heated to 95 °C for 3 h and then cooled to 20 °C and filtered. Yellow-green crystals of composition $Na_{16}K_{12}$-**2a**·ca.90 H_2O deposited from the filtrate (pH 5.2) over 5 d. Yield 0.16 g (15% calculated from $\{P_2W_{12}\}$). Elemental analysis calcd (%) for $H_{238}K_{12}Fe_{28}Na_{16}O_{318}P_8W_{48}$: K 2.79, Fe 9.31, Na 2.17, P 1.47, W 52.53; found: K 2.94, Fe 9.0, Na 2.1, P 1.12, W 50.66.

The crystals thus obtained were of limited quality and only the cell parameters could be determined. Better-quality crystals, used for the crystal structure determination,[18] were obtained as follows: An aqueous solution of $Fe(ClO_4)_3$·6 H_2O (1.39 g, 3 mmol) in H_2O (10 mL) was added to a stirred suspension of $K_{12}[H_2P_2W_{12}O_{48}]$·24 H_2O (2.0 g, 0.51 mmol) in 1 M NaOAc/AcOH (20 mL, pH 6). The mixture was heated at reflux for 1 h, upon which a clear solution was obtained. The sticky solid that deposited on cooling to 20 °C was discarded and the subsequent polycrystalline fraction was recrystallized in 0.5 M NaOAc/AcOH (pH 6) to give yellow-green rods ($Na_{16}K_{10}$-**2b**·ca.90 H_2O). Both sets of crystals display similar cell parameters and IR spectra, despite small differences in the composition.

Crystal data for $Na_{16}K_{10}$-**2b**·ca.90 H_2O: Triclinic, $P\bar{1}$ (no. 2), a = 21.9605(3), b = 22.4724(5), c = 28.9946(5), α = 97.590(1), β = 94.326(1), γ = 90.813(1)°, V = 14139.0(4) Å^3, ρ_{calcd} = 4.03 g cm^{-3}, μ = 21.5 mm^{-1}, 96851 reflections (68661 unique) to 2θ = 60°, 1569

refined parameters, $R = 0.068$, $wR(F_o^2) = 0.077$ [20249 reflections with $I > 3\sigma(I)$], GOF = 1.09, $\Delta\rho_{max} = 9.92\ e\,Å^{-3}$, $\Delta\rho_{min} = -2.99\ e\,Å^{-3}$. The X-ray crystallographic data were collected at room temperature either on an Enraf-Nonius MACH3 diffractometer (**1**) or on a Bruker SMART three-circle diffractometer equipped with a CCD bidimensional detector (**2b**), both with graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). The structures were solved and refined by full-matrix least squares using CRYSTALS. Neutral-atom scattering factors were used with anomalous dispersion corrections applied. Hydrogen atoms were not included in the refinements. Both structures exhibit some disorder in the range of counterions and water molecules, as is often the case with polyoxometalates. Thus, only a limited number of cations and water molecules could be located. This resulted in rather high residual electron densities. CCDC-258626 contains the supplementary crystallographic data for Li_2K_4-**1**·34 H_2O. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Further details on the crystal structure investigation on $Na_{16}K_{10}$-**2b**·ca.90 H_2O may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (fax: (+49) 7247-808-666; e-mail: crysdata@fiz-karlsruhe.de), on quoting the depository number CSD-391310.

Zeolites

Electrochemically Controlled Ion Exchange: Proton Exchange with Sodium Zeolite Y**

*Michael J. Stephenson, Stuart M. Holmes, and Robert A. W. Dryfe**

In memory of R. J. Plaisted

Zeolites are central to a number of industrially important processes, such as catalysis, gas separation, and sorption of impurities from the solution phase.[1,2] All zeolite structures, other than the purely silicaceous series end-members, contain counterions, whose nature and position can be extremely important in the aforementioned applications. Catalytic cracking of hydrocarbons, for example, is dependent upon the introduction of protons to the zeolite structure.[3] Since zeolites are frequently synthesized in their sodium form, other counterions must be introduced through ion exchange.

Zeolite Y, which has the Faujasite structure, is a principal component of cracking catalysts because of properties such as its high thermal stability and large internal surface area with easily accessible active sites. It consists of a 3D network of 12 Si or Al atoms that form circular channels 7.4 Å in diameter with cavities 11.8 Å in diameter.[4] The as-synthesized sodium form is converted into the acidic form either by direct ion exchange with dilute mineral acids or by calcination of the ammonium ion exchanged form of the zeolite to release

ammonia.[5] Care is needed with direct ion exchange because at low pH values acid-mediated dealumination occurs followed by structural collapse.[6] To avoid these problems, the route from the ammonium ion exchanged form to acidic zeolite Y (H−Y) is preferred. Herein, we demonstrate a novel, direct method for the preparation of H−Y by electrochemically controlled proton exchange. Importantly, we believe this method, which offers enhanced control over the degree of ion exchange, is generic, and is thus applicable to other zeolite structures and the introduction of other cations.

The novel approach described herein is derived from liquid/liquid electrochemistry, in which ions can be driven from one liquid phase into an adjacent immiscible liquid phase by application of a potential across the liquid/liquid interface.[7,8] Typically, an aqueous/organic system is employed, with solvents such as nitrobenzene or 1,2-dichloroethane (DCE) used as the organic phase. The transfer of hydrophilic ions, such as Na^+, can be facilitated by the use of a complexing agent in the organic phase (for example, crown ethers). This complexing agent stabilizes the transferred ion, and in doing so lowers the required transfer potential [see Equation (1), in which the equilibrium is potential-dependent and L denotes the complexing agent].

$$Na^+_{(aq)} + L_{(org)} \rightleftharpoons [Na^+{-}L]_{(org)} \quad (1)$$

Judicious choice of the complexing agent and organic solvent allows the selective transfer of ions from multi-ion aqueous solutions; for example, small crown ethers are more selective for small ions[9] and thioethers are more selective for transition metals.[10,11] Selective ion transfer at nonpolarized liquid/liquid interfaces is utilized for specific metal extraction (for example, electrorefining and hydrometallurgy).[12] Herein, selective ion transfer at an electrified interface is used to remove unwanted ions from the exchange medium, which in turn drives the equilibrium towards further ion exchange of the zeolite with the required counterion. With reference to Equation (2), the removal of Na^+ ions from the aqueous phase will shift the ion-exchange equilibrium to the right, which increases the amount of H^+ ions in the zeolite.

$$Na^+_{(zeolite)} + H^+_{(aq)} \rightleftharpoons H^+_{(zeolite)} + Na^+_{(aq)} \quad (2)$$

This method allows excellent control over the composition of the exchange medium, and hence exerts control over the extent of ion exchange (see Figure 1 and the Experimental Section).

The exchange process within the zeolite is predicated on its ability to sequester Na^+ ions in the organic phase with dibenzo[18]crown-6 (DB18c6). The electrochemically induced transfer of Na^+ ions occurs at a lower potential than that of H^+ ions (Figure 2). The voltammetric analysis shows that the maximum current required for the transfer of Na^+ ions is observed at an applied potential difference $\Delta\varphi$ of 0.60 V, whereas the peak current for the transfer of H^+ ions is seen at $\Delta\varphi = 0.73$ V. Therefore, if $\Delta\varphi = 0.60$ V across the exchange medium/organic interface, the transfer of Na^+ ions will be favored over the transfer of H^+ ions by a factor of $\exp(zF(0.13)/RT) \approx 150$.[7] A typical time-dependent current

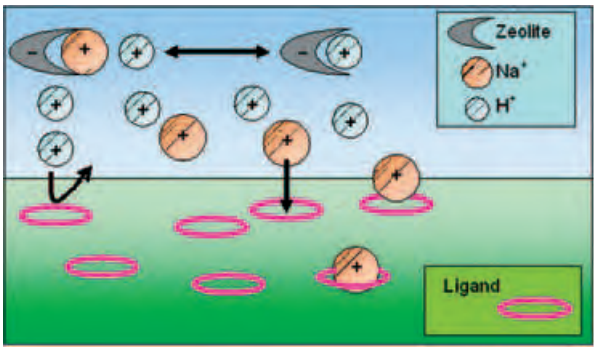

Figure 1. A schematic diagram of ion exchange in a zeolite suspended in an aqueous phase (aq) with the selective extraction of Na^+ ions into an organic phase (org), which forces the ion-exchange equilibrium [Eq. (2)] over to the right (protonated form of the zeolite).

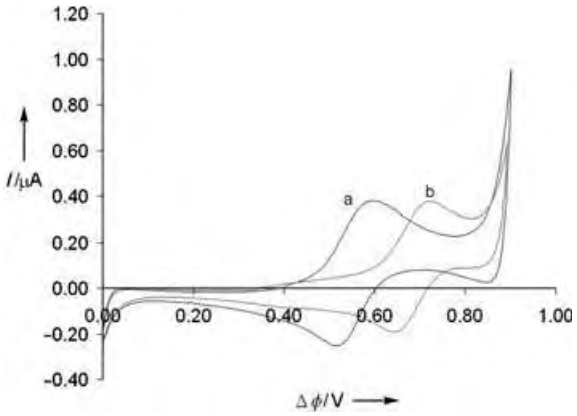

Figure 2. The cyclic-voltammetric data showing comparative transfer of Na^+ and H^+ ions facilitated by DB18c6 using a) cell 2 and b) cell 1 (see the Experimental Section) with a voltage scan rate of 0.1 Vs^{-1}.

response is shown in Figure 3 in which $\Delta\varphi = 0.60$ V across the interface. The resultant current is essentially caused by the transfer of Na^+ ions across the interface; from the magnitude of the charge passed, the amount of Na^+ ions extracted can be calculated by using Faraday's law. In this way, the removal of sodium from the exchange medium can be controlled, thus exerting control over the extent of ion exchange within the zeolite.

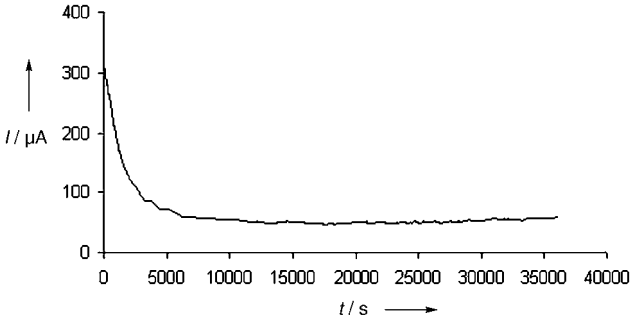

Figure 3. Chronoamperometric response of cell 3 (see the Experimental Section; X = acetic acid). The potential was stepped from 0.1 to 0.6 V and held at 0.6 V for 10 h.

The sodium and aluminum contents of the zeolite samples were then determined by inductively coupled plasma atomic emission spectroscopy (ICPAES). The proton concentration was calculated indirectly by mass balance [Eq. (3)]:

$$|H^+|_{zeo} = |AlO_2^-|_{zeo} - |Na^+|_{zeo} \quad (3)$$

The equivalent fractions of H^+ ions in the zeolite E_H, as measured experimentally, were plotted versus the charge transferred across the interface (Figure 4). The equivalent

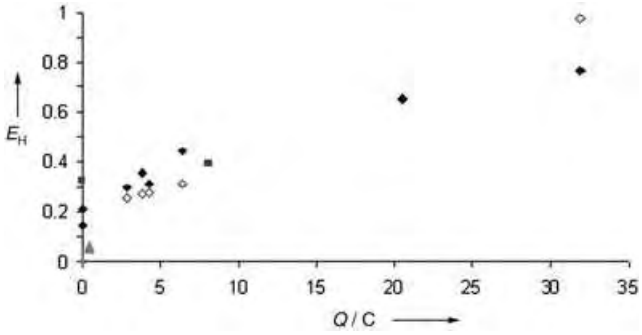

Figure 4. Graph of E_H values versus the total charged passed (Q): E_H was measured by ICPAES. Cell 3 was used (see the Experimental Section), in which X is acetic acid (filled diamonds), sulfuric acid (squares), or pure water (triangles). Data predicted by the calculations, as described in the text, are denoted with open diamonds.

fraction for ion A (E_A) was calculated with Equation (4), in which z_A is the valency of ion A, n_A is the number of moles per unit mass, and M_t is the exchange capacity of the zeolite.)

$$E_A = \frac{z_A n_A}{M_t} \quad (4)$$

The values obtained at zero Coulombs relate to the chemically exchanged samples in pure water (A), 0.02 M acetic acid (B), or 0.01 M sulfuric acid (C). These samples were left to pre-equilibrate with the zeolite for at least 14 days and were the starting points for the electrochemical experiments. Samples of type B were analyzed again after the electrochemical experiments had been completed (after approximately 2 months). For samples of type A, no proton exchange was detected after only the chemical exchange had been carried out. Subsequent electrochemical studies using pure water were hampered by resistance resulting from the aqueous phase, which made it very difficult to remove the Na^+ ions. However, partial dissociation of water allowed some H^+ ions to be incorporated, which permitted a maximum of $E_H = 0.07$ to be obtained. Note that no cations, other than H^+ ions, were present in any of the aqueous phases of the cell. For samples of type C, $E_H = 0.33$ after the chemical exchange and increased to 0.39 after 8 C of Na^+ ions had been removed from the exchange medium. For the samples of type B, $E_H = 0.15$–0.20 after the chemical exchange, which is lower than the level achieved with the sulfuric acid sample (C) and is attributed to the partial dissociation of acetic acid. However, the use of a sulfuric acid solution (C; pH = 2) might have a detrimental effect on the zeolite structure through dealumination.[13] The acetic acid solution was found to be well suited to these studies because it was sufficiently conductive to be used as an electrolyte, but was not too acidic; acted as a good source of H^+ ions; and behaved as a buffer, because it is a weak acid, giving a constant pH value of approximately 4. Figure 4 shows that there is a significant increase in the extent of the proton exchange, with increasing charge being passed. The E_H value rose to 0.77 after 32 C of Na^+ ions were extracted from the exchange medium; it is likely that this value could be improved with continual removal of Na^+ ions.

In the above experiments, it was assumed that the ion exchange was being chemically driven by transferring unwanted Na^+ ions from the exchange medium into the organic phase [Eq. (1)], which then shifts the ion-exchange equilibrium to the right [Eq. (2)]. It is conceivable that the application of an electric field at the interface may alter the ion-exchange equilibrium or remove ions directly from the zeolite; if this effect is significant, then the extent of the ion exchange will differ from that of the isotherm based just on the chemical ion-exchange process. An attempt was made to predict the extent of the ion exchange using the corrected selectivity quotient for the chemical equilibrium and the changes measured in the composition of the exchange media after electrochemical removal of the Na^+ ions (Figure 4). These predictions were then compared to the experimentally derived zeolite compositions (see the Supporting Information). The experimental values of E_H are slightly greater in most cases than the predicted values, which suggests that an electrochemical enhancement of the ion-exchange process occurs. The predicted value at 32 C is greater than the experimental value; this difference is probably because the transfer of H^+ ions begins to contribute significantly to the charge transfer at this point. At higher levels of proton exchange, the exchange medium contains a very low concentration of Na^+ ions and the selectivity of the transfer of Na^+ ions decreases, which means significant transfer of H^+ ions occurs with the transfer of Na^+ ions. However, the calculations are approximate as the corrected selectivity quotients only allow for the nonideality of the solution[13–15] and not the zeolite and only the aluminum and sodium contents are known as they are measured directly. A more accurate calculation based on the electrochemically enhanced exchange of copper ions in NaY is underway, in which both the outgoing and incoming ions can be measured directly.

The structural integrity of the samples after either chemical exchange or electrochemically enhanced ion exchange was assessed by X-ray diffraction (XRD) and N_2 sorption/desorption measurements. Exposure of samples to acid (types B and C) did not lead to the formation of amorphous regions in the XRD patterns or to any significant loss of crystallinity. The N_2 sorption isotherms showed no evidence of hysteresis, thus indicating that no secondary pore system had been formed. Secondary pores may develop with acid-induced degradation.[16] For type B samples, Barrett–Joyner–Halenda (BJH) calculations[17] of the pore-size distribution showed no significant change relative to the fresh sample. However, type C samples developed some pores

approximately 100 Å in diameter following two weeks of exposure to acid. Brunauer–Emmett–Teller (BET) surface-area measurements revealed an approximate decrease in the internal surface area for the chemically exchanged samples of type C, compared to the fresh sample after two weeks of exposure to sulfuric acid; $E_H = 0.3$ after two weeks. For type B samples, both the extent of the ion exchange and the change in the surface area were small following two weeks of exposure to acetic acid. However, extraction of 2.8 C of charge from this sample caused the E_H value to rise to 0.3. Significantly, the amount of H^+ ions needed to achieve this rise could be introduced into the sample with a decreased level of concomitant change (ca. 10%) in the surface area, as measured by BET studies, compared to the type C samples.

In summary, ion exchange can be readily controlled in microporous materials through the use of electrified interfaces: protons can be incorporated into these materials using weak acids, without the need for repeated washing. Therefore, this method is very useful for zeolites that are pH sensitive. We are currently applying this technique to zeolites with high aluminum contents, that is, NaA and NaX. This new method is very effective at removing small concentrations of unwanted ions from exchange media, and so is able to complete the exchange more efficiently than repeated washing. The exchange of ions with poor selectivity also benefits from this method, as small traces of unwanted counterions can be removed and there is no need to continually refresh the exchange medium; furthermore, the direct ion exchange of preformed membranes that are sensitive to thermal treatment is allowed. This phenomenon has been found to be useful in the final stages of copper(II) ion exchange with NaY. In addition, judiciously chosen complexing agents allow the electrochemically enhanced ion exchange of nearly every possible combination of ions. The tertiary Li^+/Ca^{2+}/NaX system is also currently being studied. The preliminary data reported herein suggest that the electrochemically enhanced ion-exchange process yields greater ion exchange than would be expected from just a chemical exchange.

Experimental Section

Method: The zeolite powder (2.5 wt% NaY; Crossfield Chemicals, Warrington, UK) was suspended in the aqueous phase of the cell (cells 1–3). The Na^+ ion content of the as-purchased zeolite sample was greater than 98%; the remaining ions were protons. ICPAES analysis was performed on the fresh sample, the level of the initial proton impurities was below the experimental error of ICPAES. The water/DCE interface was supported within a polyethylene terephthalate "track-etched" membrane (0.1 μm pore diameter; Osmonics Inc., Livermore, CA, USA). The organic phase electrolyte in all cases was bis(triphenylphosphoranylidene) ammonium tetrakis(pentafluoro)phenylborate (BTPPA $TPBF_{20}$). The water/DCE interface was polarized using a four-electrode potentiostat (Autolab PGSTAT 100; Eco-chemie, Utrecht, Netherlands). The organic phase was stirred at 4 Hz with a magnetic stirring device; other cell details have been reported previously.[18] For these experiments, the organic solution was renewed every 10 h. Typical currents were approximately 50 μA, which could be increased by using a higher interfacial area and/or by stirring both phases. The experiments were performed at ambient laboratory temperature (293(±)2 K).

The electrochemical cells used can be written as:

Cell 1

$Ag_{(S)} \,|\, AgTPB_{(S)} \,|\, 0.02\,\text{M}$ $BTPPATPBF_{20}$, $1 \times 10^{-3}\,\text{M}$ $DB18c6_{(DCE)} \,||\, 0.01\,\text{M}$ $H_2SO_{4(aq)} \,|\, Ag_2SO_{4(S)} \,|\, Ag_{(S)}$

Cell 2

$Ag_{(S)} \,|\, AgTPB_{(S)} \,|\, 0.02\,\text{M}$ $BTPPATPBF_{20}$, $1 \times 10^{-3}\,\text{M}$ $DB18c6_{(DCE)} \,||\, 0.01\,\text{M}$ H_2SO_4, $0.01\,\text{M}$ $Na_2SO_{4(aq)} \,|\, Ag_2SO_{4(S)} \,|\, Ag_{(S)}$

Cell 3

Metamagnetism

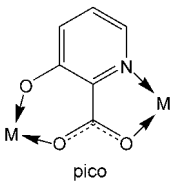
Spin Canting and Metamagnetism in a 3D Homometallic Molecular Material Constructed by Interpenetration of Two Kinds of Cobalt(II)-Coordination-Polymer Sheets**

*Ming-Hua Zeng, Wei-Xiong Zhang, Xian-Zhong Sun, and Xiao-Ming Chen**

Molecular magnetism—such as ferromagnetic, ferrimagnetic, and antiferromagnetic long-range ordering properties at low temperatures—has been observed for many transition-metal complexes.[1] In contrast, only a few magnetically ordered complexes exhibit metamagnetic phase transitions,[1b,c] and most of them are heterometallic[2] or homometallic compounds[3] or metal-radical materials[4] that display low dimensionality (one- or two-dimensional structures). In particular, homometallic three-dimensional metamagnets have only been documented in several azide-bridged complexes[5] and metal phosphonates[6] or metal carboxylates.[7]

Complicated magnetic anisotropy has significant influence on the bulk magnetic properties.[8,9] Furthermore, there is a close relationship to metamagnets, which are antiferromagnets with a strong anisotropy (without a spin-flop phase) and a net magnetic moment.[9] It is well known that a pure 1D system cannot present long-range magnetic ordering at $T \neq 0$ K.[8] Only interchain interactions can lead to ordering with spontaneous magnetization, and in a 2D system long-range ordering occurs only in the Ising limit.[9] Coupling of the magnetic ordering is a consequence of the 3D structure. So far the design of polynuclear metal complexes and extended networks with predictable magnetic properties is still a challenge in the field of molecular magnetism.[1] A great deal of work is required to understand the structural factors that govern the exchange coupling between paramagnetic centers, since such a relationship is complex and so far remains elusive.[1,8]

Recently we reported synthetic approaches to homometallic coordination polymers of different dimensionalities that show weak ferromagnetic or ferrimagnetic behavior.[10] Now we have used 3-hydroxypicolinate (pico)[11] as a bischelating ligand to construct alternating chains of metal ions. Similar to phenyleneoxamate,[2a] pico should be able to mediate electronic effects between paramagnetic metal ions,[12] and may favor antiferromagnetic coupling through the *anti–anti* carboxylate bridges.[7d] Owing to the predictable lack of compensation of the individual spin moments through the bridging and asymmetrical exchanging mode of pico ligands, weakly ferromagnetic 1D chains may be created.[9,12] Employment of additional bridging 4,4′-bipyridine (4,4′-bpy) ligands can further interconnect these chains into a 2D structure, which may lead to stabilization of the magnetic ordering.[9] Clearly, the key structural or electronic characteristics control the resulting magnetic ground states and result in modulated bulk magnetic properties.[9,12] Hydrothermal treatment of Co^{II} ions and the organic ligands provided $[Co_4(pico)_4(4,4'\text{-bpy})_3(H_2O)_2]_n \cdot 2nH_2O$ (**1**), a 3D network consisting of two different, interpenetrating 2D neutral polymers. With strong anisotropy from single ions arranged in the chains, sheets, and finally the 3D structure, **1** exhibits spin canting and typical metamagnetism.



Crystal-structure determination by X-ray crystallography showed that each of the four Co^{II} ions in the asymmetric unit of **1** is located in a distorted octahedron. Atom Co1 is coordinated by two O,N-chelating sites of two pico ligands and two 4,4′-bpy ligands, whereas Co2 is coordinated by two O,O′-chelating sites of two pico ligands and two 4,4′-bpy ligands (Figure 1, left). The two kinds of Co^{II} ions are alternatively bridged by pico ligands to form A-type zigzag chains $[Co_2(pico)_2(H_2O)_2]_n$ (Co1···Co2 5.638(1) Å). These chains are further interlinked through 4,4′-bpy ligands into A-type sheets $[Co_2(pico)_2(4,4'\text{-bpy})(H_2O)_2]_n$ (Co···Co 11.220(2) Å), in which the pair of pyridyl groups in each 4,4′-bpy ligand is significantly twisted with a dihedral angle of about 16° (Figure 2a). The curved conformation of the 4,4′-bpy ligands in the corrugated sheets leads to the existence of two kinds of meshes (atom–atom distance ca. 11.2 × 7.3, 11.2 × 3.5 Å).

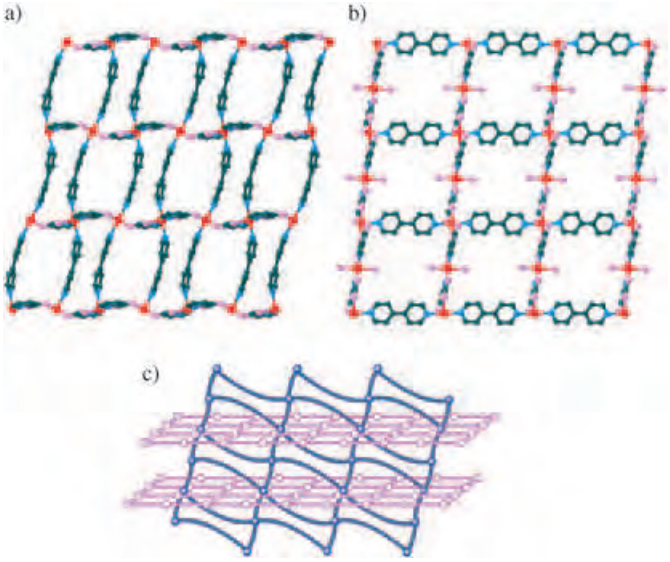

Figure 2. Views of the a) A-type and b) B-type sheets found in **1** (C green, N blue, O pink, Co red). c) A schematic representation of the interpenetrated sheets (A-type sheet blue, B-type sheet pink).

two O,O′-chelating sites of two pico ligands and two 4,4′-bpy ligands (Figure 1, right). The pico ligands alternatively bridge Co^{II} ions to form B-type zigzag chains $[Co_2(pico)_2]_n$ (Co3···Co4 5.804(1) Å), which are further bridged by the 4,4′-bpy ligands into B-type sheets $[Co_2(pico)_2(4,4'\text{-bpy})_2]_n$ (Figure 2b; Co···Co 11.538(2) Å). This results in a square net with a uniform mesh size (atom–atom distance ca. 11.5 × 11.6 Å) different than that in the A-type sheets.

Interestingly, the two types of sheets are interpenetrated in a parallel/diagonal inclined fashion with the bigger windows of the A-type nets enclosing the 4,4′-bpy rods of the B-type nets. In addition the windows of the B-type nets contain the nodes (B chain) of the A-type nets in a 1:1 ratio.[13] This leads to a unique, compact, 3D extended network (Figure 2c and Supporting Information), featuring a strong structural anisotropy (from single-ion anisotropy to anisotropic chains, sheets, and the final 3D structure).[8,9]

Hydrogen-bonding interactions are present between the sheets. The lattice water molecules participate in moderately strong hydrogen bonds with the pico oxygen atoms in the A-type chains (O–H···O 2.828, 3.005 Å; see Supporting Information). The aqua oxygen atoms O2w in the B-type chains form strong hydrogen bonds with the pico O2 and O3 atoms in the A-type chains of the adjacent sheets (2.711, 2.728 Å; see Supporting Information). Strong edge-to-face aromatic interactions (3.56 Å) also exist between adjacent 4,4′-bpy groups of different sheets. Although the 2D→3D parallel or inclined interpenetration of layers is not very unusual, the intertwining of different sheets is extremely rare in both inorganic and coordination polymer chemistry.[13] Complex **1** is the first example of the inclined interpenetration of two types of sheets with different composites that have the same topology (4,4-net).

The magnetic susceptibility of **1** was measured in the 2–320-K range at 100 Oe by using a polycrystalline powder sample (Figure 3a). The temperature dependence of the

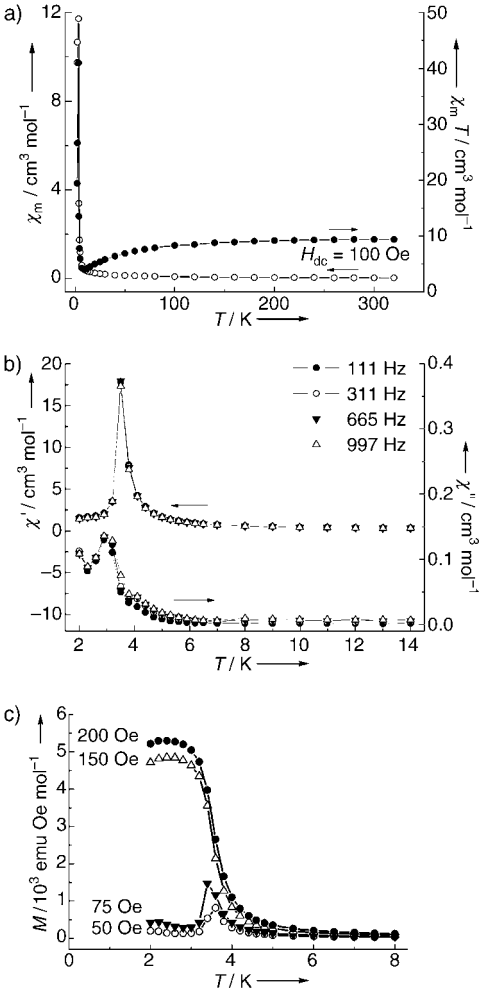

Figure 3. a) Plot of $\chi_M T$ versus T for **1**. The field strength used was $H = 100$ Oe per $\{Co^{II}\}_4$. b) The temperature dependence of the in-phase (χ') and the out-of-phase (χ'') ac magnetic susceptibilities for **1**. c) Plot of magnetization M versus T at 50, 75, 150, and 200 Oe for **1**.

reciprocal susceptibility (χ_M^{-1}) above 20 K follows the Curie–Weiss law with a Weiss constant θ of −20.4 K, thus indicating an overall strong antiferromagnetic interaction and/or spin–orbital coupling between the Co^{II} ions. The value of $\chi_M T$ at 300 K is 9.37 emu K mol^{-1} and thus higher than the spin-only value of 7.49 emu K mol^{-1} expected for four magnetically isolated high-spin Co^{II} ions. The product $\chi_M T$ first decreases smoothly to a rounded minimum of 4.03 emu K mol^{-1} at 9.0 K, then increases rapidly to a very high and sharp maximum of 41.0 emu K mol^{-1} at 3.5 K (characteristic of a magnetic long-range ordering), and finally decreases more rapidly on further cooling. The behavior above 3.5 K is characteristic of a canted antiferromagnetic chain, and that below 3.5 K may be attributed to interchain antiferromagnetic interactions and/or the saturation effect.[3]

The temperature dependence of the ac susceptibility measured in a field of 6 Oe shows the same features (Figure 3b). The maximum of χ' observed at $T_c = 3.5$ K, in agreement with the above results, confirms the occurrence of a phase transition. The absence of an out-of-phase signal (χ'') at this temperature points to a long-range antiferromagnetic

order. However, the imaginary component χ'' presents a peak at 3.0 K, which is the signature of a magnetized state, thus indicating that a partly canted antiferromagnetic structure exists below this temperature.[7a] No frequency dependence of these transitions is observed.

The temperature dependence of the magnetization of **1** at various fields is shown in Figure 3c. For applied fields below 100 Oe, the field-cooled (FC) curves present a maximum at 3.5 K, thus indicating that some interlayer antiferromagnetic interactions are operative. However, a magnetic field above 150 Oe is sufficient to overcome these weak interactions, and **1** presents a field-induced transition from an antiferromagnetic to a ferromagnetic-like state.[2–4,9] The magnetization was also measured in the range of 2–30 K (see Supporting Information). The field-cooled magnetization (FCM), measured under an applied field of 10 G, increases rapidly on cooling to 3.5 K and then diminishes. The zero-field-cooled magnetization (ZFCM) shows a maximum at 3.5 K and decreases rapidly as the temperature is further increased. This behavior implies metamagnetic ordering.[2–4,9]

Interestingly, in the *M*–*H* curve of **1** around the transition temperatures and magnetic hysteresis (Figure 4a), the magnetization curves for different temperatures below the transition temperature exhibit a sigmoidal shape with a common crossing point for $H = 160$ Oe; the 2.5-K isotherm indicates clearly that the saturation is not reached even with 70 kOe ($M = 4.35\,N\mu_B$; N = Avogadro number, μ_B = Bohr magneton). The low-field magnetization presents a small butterfly-shaped hysteresis with a metamagnetic-like transition around 160 Oe (Figure 4b), in agreement with the *FC* results. All these facts clearly confirm a metamagnetic behavior of **1** with a critical temperature T_c of 3.5 K and a critical field H_c of about 160 Oe. This reversal involves an increase of around 0.8 μ_B per Co_4 unit.

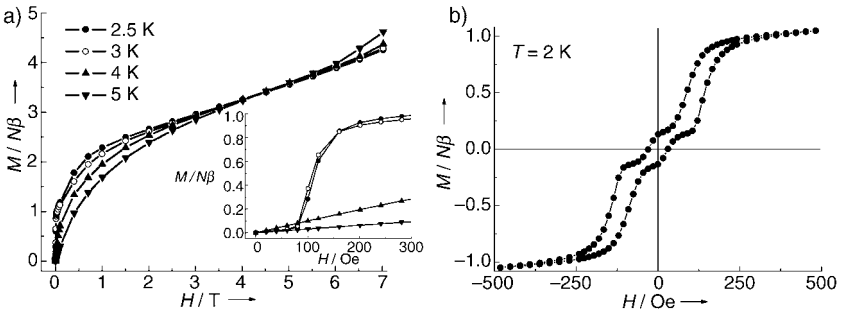

Figure 4. Plots of a) the first magnetization at 2–5 K (the inset shows the detail in a low field (0–300 Oe) at 2–5 K) and b) the hysteresis loop at 2 K.

All the structural factors in **1** diminish the antiferromagnetic interaction to a greater extent to favor the ferromagnetic interaction observed.[9] The magneto–structural correlation indicates that there exists a strong structural anisotropy in **1** and, consequently, anisotropy in competitions between the exchange interactions of the 3D motif, which result in a typical metamagnetism. The antiferromagnetic interactions operate between Co^{II} ions of adjacent sheets, possibly through electrostatic (dipolar) interactions and hydrogen bonding between the interpenetrated adjacent sheets.[3,13] The reason why the transition fields are so low in **1** is not yet clear, but the contribution of the substantial hydrogen bonding and dipolar interaction between the interpenetrated sheets and of the conjugated bridging ligands, as well as spin canting in the crystal lattice, may play a role in this phenomenon.[3,4,8]

In conclusion, the bridging pico ligand can be used to prepare a molecular-based magnetic material constructed by unusual interpenetration of two types of coordination sheets, which leads to a beautiful low-field metamagnetic transition and spin-canted behavior. This work demonstrates the importance of the crystal engineering of coordination polymers in the field of molecular-based magnetic materials.

Experimental Section

Synthesis: In a typical experiment, H_2pico (0.139 g, 1 mmol) in an aqueous solution (6 mL) of NaOH (0.080 g, 2 mmol) was mixed with 4,4′-bpy (0.117 g, 0.75 mmol) in EtOH (2 mL); the mixture was then added to an aqueous solution (2 mL) of $Co(NO_3)_2{\cdot}6H_2O$ (0.291 g, 1 mmol). The new mixture was placed in a 23-mL Teflon-lined autoclave and heated at 160 °C for 160 h. The autoclave was then cooled over a period of 12 h at a rate of 5 K h^{-1}. Orange crystals of **1** were collected by filtration, washed with water, and dried in air. Phase-pure **1** was obtained by manual separation (final yield: 185 mg, 56% based on Co). C,H,N analyses of **1**: calcd (%): C 48.96, H 3.35, N 10.57; found: C 48.94, H 3.38, N 10.52. IR (KBr disk): $\tilde{\nu} = 3391$ m, 1585 vs, 1533 vs, 1465 m, 1248 m, 810 m, 713 m, 624 cm^{-1} m.

Crystal data for **1**: $M_r = 662.36$, triclinic, space group $P\bar{1}$, $a = 11.275(2)$, $b = 11.538(2)$, $c = 11.609(2)$ Å, $\alpha = 80.181(3)°$, $\beta = 71.909(3)°$, $\gamma = 73.148(2)°$, $V = 1368.5(3)$ $Å^3$, $T = 293$ K, $Z = 2$, $\rho_{calcd} = 1.930$ g cm^{-3}; of 5267 unique reflections, 4005 were observed with $I \geq 2\sigma(I)$. Crystal size: $0.27 \times 0.19 \times 0.14$ mm^3. The structure was solved by direct methods and refined by the full-matrix least-squares method on F^2 using SHELXTL.[14] Structural plots were generated with OLEX.[15] Refinement of 385 variables with anisotropic thermal parameters for all non-hydrogen atoms gave $R1 = 0.0619$, $Rw2 = 0.1152$, and $S = 1.075$. CCDC-253952 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Magnetic measurements: The magnetic measurements were carried out with Quantum Design SQUID MPMS XL-7 instruments. The diamagnetism of the sample and sample holder were taken into account.

Zeolite Assembly

Oligomerization and Cyclization Processes in the Nucleation of Microporous Silicas**

Miguel J. Mora-Fonz, C. Richard A. Catlow, and Dewi W. Lewis**

The nucleation and growth of zeolites and other microporous solids continues to pose many questions.[1,2] Whilst the general features of self-assembly through condensation polymerization are understood for siliceous systems, the conditions under which both natural and synthetic zeolites form render such a complex process extremely difficult to characterize experimentally. Thus, whilst the species initially present in silicate gels can be characterized by NMR spectroscopy with some certainty,[3,4] their charge state is more difficult to probe.[5] Similarly, although scattering methods can be used to tentatively identify larger (possibly nucleation) species,[6,7] the relative stability and lifetime of the smallest clusters, significant in zeolitic structures, such as four-membered rings, remain unclear. Furthermore, in the postnucleation regime, there is much debate as to which species are responsible for crystal growth: small oligomers or larger subunits. Indeed, it has been suggested that the growth of silicalite-1 (MFI zeolite) is controlled by a unique nanocluster,[8] although there is some debate about this proposal.[9] Moreover, characterization of zeolite surfaces suggests that much smaller units are responsible for surface growth.[10]

Here, we describe quantum chemical calculations that model some of the species present prior to nucleation and attempt to examine the pathways by which such key species may form and hence rationalize the assembly of zeolitic structures. In particular, we discuss the factors that drive the condensation polymerization of silicate oligomers and that favor the cyclization of such species: pH and solvent.

In the past decade there have been a number of computational studies of model structures involved in the nucleation process of silicates. Structures and energies for small clusters containing up to five silicon atoms were obtained by Pereira et al.[11,12] One conclusion that can be drawn from these results is that linear silicate species are favored over cyclic structures—a situation not conducive to the formation of zeolitic structures but instead one that favors the formation of amorphous silicates.[11] These early calculations were performed using a local DFT method and considered only neutral species, although solvation effects were included using the COSMO method.[13] The roles of water and organic templates in prenucleation gels were studied by Lewis et al.[14] and Catlow et al.[15] by more approximate molecular mechan-

ics methods. They identified key roles for template molecules—preventing the collapse of large hydrophobic silicate clusters to more dense structures—and for charge interactions between anionic silicates and templating cations—maintaining intimate cluster–template interactions.

The formation of small cyclic species can be considered as central to the nucleation and growth of siliceous zeolites, since four-, five, and six-membered rings dominate such structures. However, as we have seen, ab initio calculations suggested that linear silicate oligomers are favored.[11] Herein we attempt to answer the following key questions: how does the cyclization process occur and what is the role of pH and solvation in forming such prenucleation species?

Details of the methods used are described in the Experimental Section and result from a systematic survey of available methods and tools. Further details of our evaluations will be published elsewhere, where the methods chosen will be shown to provide a good and self-consistent description of the geometry and energetics of these silicate systems. For example, trends in the successive deprotonation energies of monomeric and dimeric species are quantitatively reproduced.[16]

Experimentally, high pH is required for condensation reactions to occur: under such conditions the dominant silicate species will be anionic.[5] The basic reaction is given in Equation (1); further deprotonation gives $H_2SiO_4^{2-}$ and so

$$Si(OH)_4 + OH^- \rightarrow (OH)_3SiO^- + H_2O \quad (1)$$

on, and is also possible with larger oligomers. For some of the small clusters present in the first stages of nucleation, we have calculated the relative stability of the various possible anionic species in both the gas phase and in solution (modeled by the COSMO solvation model; Table 1). The results show that it is thermodynamically favorable for an OH^- ion to deprotonate the monomeric species to form the monocharged anion $(OH)_3SiO^-$, both in the gas phase and in solution. Further deprotonation is, however, significantly less favorable, suggesting that such species will be present in lower concentrations and will likely be highly reactive.

The change in free energy for the removal of a single proton by OH^- in the gas phase is quite large for all the linear oligomers considered; however, this value is reduced by a factor of three or four when a description of the solvent is included in the reaction. The role of the solvent is even more important for the second deprotonation. This emphasizes the important role of the water in stabilizing multiply charged anions, which is key in the condensation reactions and considered next. Whilst some of the free energies of deprotonation in our solvation model remain positive, they are clearly significantly lower than the corresponding gas-phase results. We estimate that our model may overestimate these energies by at most $\approx 25\ kJ\,mol^{-1}$ based on a comparison with experimental equilibrium constants for the deprotonation of $Si(OH)_4$.[17] Such an offset can be attributed to many factors such as solvation and dilution, which we are currently investigating further.[16].

We therefore limit ourselves to a semiquantitative discussion of the reaction energetics and compare only relative energies, which we expect to be reasonably accurate for all the species considered. We also note that, as yet, these calculations do not consider interactions with charge-balancing cations, for example, H_3O^+ and Na^+, nor with organic templating agents. However, the presence of such species is likely to increase the stability of the more deprotonated species.

We now consider the condensation reactions of some of these clusters, both neutral and charged, again in the gas phase and in the presence of the solvation model (Figure 1, Table 2). The simplest condensation reaction, that of the dimerization of silicic acid [Eq. (2)] is found to be favorable in

$$2\,Si(OH)_4 \rightarrow (OH)_3SiOSi(OH)_3 + H_2O \quad (2)$$

the gas phase for both neutral and charged species. However, when solvation is included, the free energy of the reaction is significantly less favorable for the neutral species than when charged species are considered. Similar trends are also observed for the condensation of larger oligomers. Our results, therefore, highlight the role of pH, which is also observed experimentally, in driving the initial polymerization processes to give these small oligomers. However, the reaction of two $Si(OH)_3O^-$ species ($M^- + M^-$) is very unfavorable, suggesting that stabilization of such species by cationic species or mechanisms for rearrangement by means of proton transfer will be significant. But it should also be noted that very high pH is not conducive to zeolite nucleation.[18]

Thus, our calculated condensation energies show how dimers, trimers, and larger oligomers can be readily formed, as in experiment, but only when the model includes a description of an aqueous medium at high pH. In particular, we note that condensation of neutral species is strongly disfavored beyond the formation of the dimer. Thus, at low

Table 1: Calculated Gibbs free energies [$kJ\,mol^{-1}$] for the deprotonation of silica species in the gas phase and in solution. The ΔG value is given for the formation of the deprotonated species from the reaction of its parent species with OH^-; water is the other product.[a]

[a] Codes used: M = monomer, D = dimer, Tr = timer, 3r = 3-ring, T = tetramer, 4r = 4-ring, P = pentamer, 5r = 5-ring, 6r = 6-ring, H = hexamer. The charge of the deprotonated species is given by the usual superscript. Thus, for example, the first entry is the deprotonation of a neutral monomer, $Si(OH)_4$ (M in our notation) by reaction with OH^- to give $(OH_3)SiO^-$ (M^- in our notation) and H_2O.

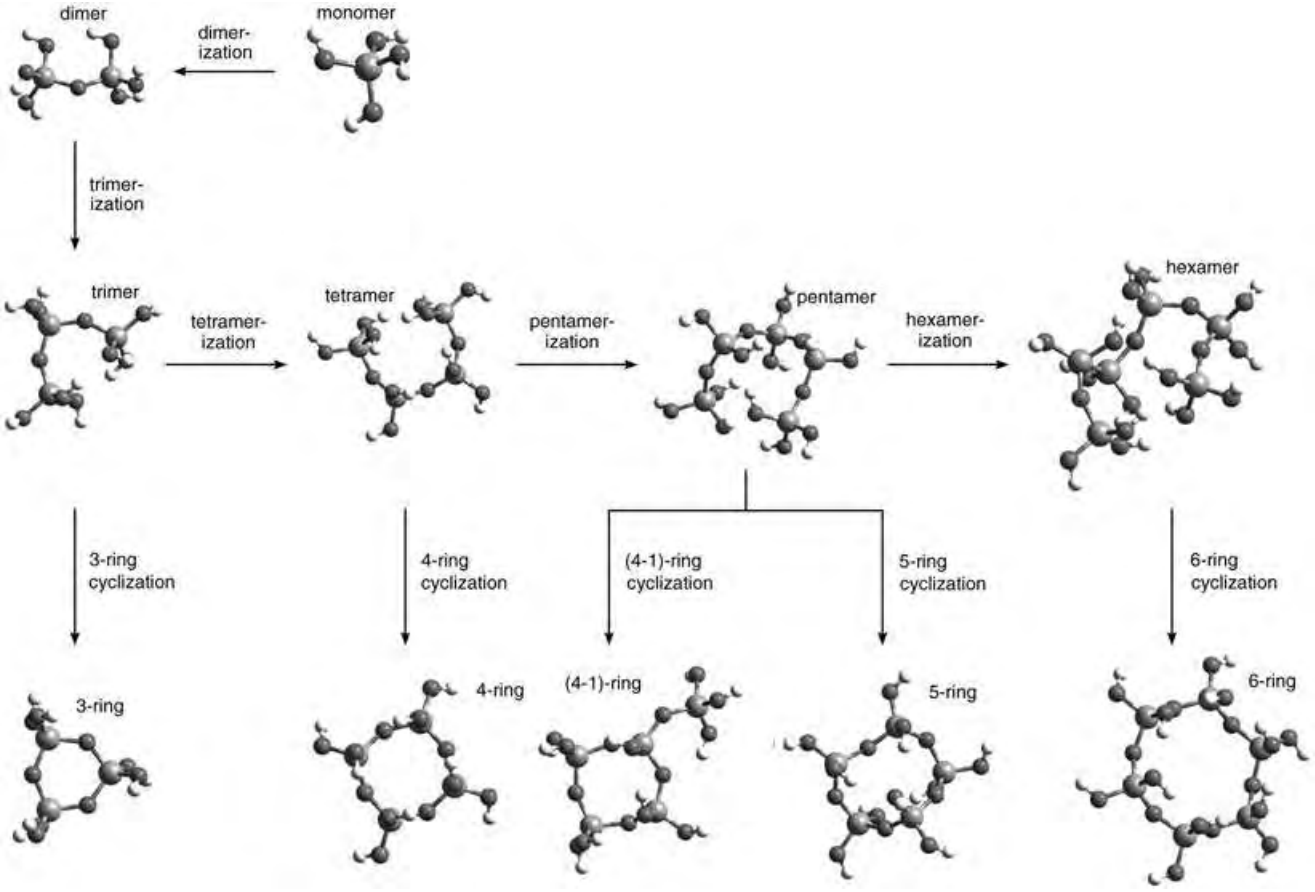

Figure 1. Condensation reactions for silicate clusters from monomer to hexameric species. For linear growth (e.g. tetramerization) the values are for the reaction of a silicate species with a monomeric species to give water as a product. For internal condensations leading to rings the other product is also water. The species codes are given in Table 1.

Table 2: Calculated energies [kJ mol^{-1}] for the condensation reactions depicted in Figure 1 forming silicate clusters from monomeric to hexameric species. For linear growth (e.g. tetramerization) the values are for the reaction of a silicate species with a monomeric species to give water as a product. For internal condensations leading to rings the other product is also water. The species codes are given in Table 1.

pH, where anionic species are less prevalent, polymerization is inhibited. We also note that for the trimerization reaction (and for the formation of higher oligomers) the dominant contribution to the free energy is a favorable change in enthalpy, which overcomes the adverse negative change in entropy.

Once trimers are formed, however, there is also the possibility of internal condensation to form rings, key zeolitic structural units. The lowest energy conformation for the trimer is almost cyclic, suggestive of an easy route for internal condensation to form a three-membered ring. Indeed, all our results suggest that the formation of a three-membered ring is

likely, in accordance with NMR experiments where this cluster is observed.[8] However, the seeming ease of 3-ring formation raises the question of the role of this species in nucleation and subsequent growth processes, since these rings are extremely rare in siliceous zeolites. However, we should note that the formation of a linear tetramer from the trimer is more favorable than the closure of the 3-ring when doubly charged trimers are considered, in other words, those likely to be present at higher pH. Furthermore, the overall formation energy of a four-membered ring by means of the reaction of the more likely 3-ring species (i.e. charged) with a monomer is favorable. For example, the free energies of formation of a 4-ring (in solvation) from an anionic 3-ring with monomer and anionic monomer are -37 and $-42\ kJ\,mol^{-1}$ respectively, whilst the reaction of a dianionic 3-ring and an anionic monomer (giving a trianionic 4-ring) is also exergonic by $11\ kJ\,mol^{-1}$. In contrast, the reopening of 4-rings by reaction with further monomers is strongly unfavorable. We are currently investigating the activation barrier to trimer cyclization and also routes for subsequent ring opening. It is also of note that cyclization processes are favored by the entropic contribution.

As with the trimer, the tetramer can either polymerize further or form a ring. The free energy released, in each of the charge states considered, clearly indicates that cyclization is strongly preferred over further linear growth. Given the prevalence of the 4-ring in so many zeolite structures, we might expect its formation and stability to be very significant in zeolite nucleation and growth. We might also expect the process of (any) cyclization reaction to be kinetically favored, as it is unimolecular. Clearly we also need to consider reaction barriers, calculation of which are now underway.[16] Again, we note that ring formation is favorable, with little variation in Gibbs energy, in a number of charge states. However, the formation of neutral 4-rings is unlikely, not due to the energetics of the cyclization itself, but rather since neutral tetramers are unlikely to be present. In contrast, there is significant variation in the reaction free energies for further addition of silicate species (giving a pentamer), depending on the exact charge state.

Thus, from a consideration of the energetics of the reactions determined here, for formation of species up to tetramers, we would expect a large population of dimers, 3-rings, and 4-rings, primarily singly and doubly charged. However, further linear polymerization will be competing with condensation onto these smaller species, particularly the 4-ring. Thus, whilst formation of larger linear oligomers remains energetically favored, we do not expect such species to be present in large amounts, owing to the other, even more favored, competing processes. Indeed, internal cyclization of a pentamer is more likely to lead to the formation of a 4-1 unit rather than the 5-ring, in excellent agreement with experiment, where the former species is considered to be present, with little evidence of the formation of the 5-ring.[3] Similarly, the 6-ring is unlikely to form as a solution species (from a linear hexamer), since internal cyclization to form smaller rings is more favorable.

From these initial calculations we can draw a number of conclusions and inferences. Firstly, we find excellent agreement between the overall energetics of the processes considered and the experimental observations of small oligomers in solution. We find a pH dependence for polymerization and the formation of small rings. Thus, we may conclude, tentatively, that the methods selected, in which solvation is included (albeit as a continuum) and pH is treated by considering anionic silicate species, give a reasonable description of the system. Future work will establish whether more sophisticated (and necessarily more expensive) models are required: for example, the inclusion of explicit water to describe the mechanism of condensation and the solvation of counter ions such as Na^+. Secondly, the formation of cyclic fragments is clearly favored—in agreement with experiment and with the expectation of the formation of zeolite-like nucleation species. Furthermore, the cyclization is driven by high pH—again well-known experimentally in silicate chemistry.[19,20] It is therefore unlikely that larger noncyclic oligomers play a significant role in either nucleation or crystal growth. Hence, growth is much more likely to occur by condensation of relatively small units, particularly those that lead to rings, in either nucleation species or in subsequent surface growth. We note that there is clear evidence that surfaces with complete (small) rings are prevalent from both high-resolution transmission electron microscopy and computational studies of siliceous zeolite surfaces.[21] Thirdly, it is clear that large single (>5- and even 5-) rings are not formed as free species in solution, although bridged species need to be considered, and result from the condensation of smaller units.

We are now considering larger species that are expected to form in solution (such as double-4-rings) and the mechanisms by which they may form (for example, double-6-rings can be constructed from 4-rings). Similarly, we are considering the reaction barriers for growth condensations and internal condensations. We believe that such studies will provide insight into the mechanisms of nucleation, assist the interpretation of experimental studies of nucleation phenomena, and also contribute to our understanding of subsequent crystal growth of siliceous zeolites.

Experimental Section

Theoretical method: All the calculations were performed using DMOL^3, version 2.2,[22,23] using a numeric DNP basis set. All final structures were optimized using the BLYP functional. Water was considered by means of the COSMO solvation approach[13,24] and gas-phase structures were subsequently reoptimized in the presence of the solvation model. To avoid bias (as many of the fragments were taken initially from zeolite crystal structures) and to avoid local minima, a simulated annealing strategy was adopted to search for the lowest energy structures. Structures were subjected to a quantum molecular dynamics simulation run at 700 K for 3000 steps of 0.46 fs, using a low-cost basis set and the PWC functional. The final structure from such runs was then optimized at the BLYP/DNP level, first in the gas phase and then in COSMO. The Gibbs free energy was calculated by standard statistical mechanical methods; a temperature of 450 K was assumed, which is typical of zeolite synthesis.

Organocatalysts

Highly Enantioselective Organocatalytic Hydroxyalkylation of Indoles with Ethyl Trifluoropyruvate**

Dedicated to Professor George A. Olah

Over the years, the application of organofluorine compounds has received extensive attention in the pharmaceutical industry and in materials science owing to the unique properties of fluorinated compounds.[1] Trifluoromethylated compounds are particularly interesting as the strong electron-withdrawing effect of the CF_3 group leads to exceptional properties. These molecules are frequently applied as drugs or chiral resolution agents as examples.[1,2] Despite the numerous methodologies, the synthesis of trifluoromethylated compounds are still in great demand.[3] The Friedel–Crafts alkylation of aromatic compounds with activated carbonyl compounds is one of the most important C–C bond-forming reactions.[4] Despite its importance, the number of asymmetric Friedel–Crafts reactions is limited and mostly based on the use of chiral Lewis acids.[5] A recently developed organocatalytic Friedel–Crafts alkylation reaction represents an important addition to this field.[6]

Herein, we describe the first highly enantioselective organocatalytic Friedel–Crafts hydroxyalkylation reaction. We demonstrate that with the application of pseudoenantiomeric cinchona alkaloids as catalysts in the reaction of substituted indoles and ethyl 3,3,3-trifluoropyruvate, the synthesis of both enantiomeric products is possible (Scheme 1).

Scheme 1. Synthesis of chiral 3,3,3-trifluoro-2-(indol-3-yl)-2-hydroxylpropionic acid esters through catalysis by cinchona alkaloids. R^1 = H, Me; R^2 = H, Me, Ph; R^3 = H, Me, F, Cl, Br, I.

The target compounds are related to the well-known Mosher's acid,[2] and many of them have recently been synthesized as racemic mixtures by a superacid-catalyzed process.[7] In another recent attempt, a chiral copper(II)–bisoxazoline complex was used as a catalyst in the reaction of activated aromatics and ethyl 3,3,3-trifluoropyruvate and yielded the *S* enantiomer of the products.[8] Our present approach is based on the interaction between **2** and chiral alcohols including cinchona alkaloids.[9] By using these auxiliaries, a chiral intermediate can be obtained which can induce effective enantiodifferentiation in an organocatalytic process that is free of Lewis acids.[10] Cinchona alkaloids are very effective catalysts in many areas of asymmetric synthesis, such as chiral-base or phase-transfer catalysis, and organometallic reactions.[11] However, there are no data available concerning their use as chiral auxiliaries in Friedel–Crafts-type reactions. Our above hypothesis was tested in the reaction of indole (**1a**) and **2** with several optically active alcohols (e.g. menthol, α-methyl and α-trifluoromethyl benzyl alcohols) and aminoalcohols (e.g. prolinols, hydroxyprolines), including cinchona alkaloids and some of their derivatives (see Table 1), as chiral auxiliaries.

Cinchona alkaloids were found to be excellent catalysts for the test reaction, while the other chiral auxiliaries resulted in both poor yields and enantioselectivities of the products. As such, cinchona alkaloids were selected for further studies. After optimizing the reaction conditions (solvent, temperature, cinchona/trifluoropyruvate/indole ratios), the activity and selectivity of cinchona derivatives were compared. The optimized conditions and summarized results are shown in Table 2.

Table 2 shows that cinchonidine (CD) was the best catalyst towards the formation of **3a**, while cinchonine (CN) gave the highest yield and *ee* value for **4a**. Both catalysts provided excellent yields and enantioselectivities (up to 99% yield, 95% *ee*) in providing the opposite enantiomers. The initial reaction rates indicate that the application of cinchona alkaloids as catalysts significantly increases the reaction rates; in the case of CD the hydroxyalkylation takes place with rates that are more than two orders of magnitude higher than in the absence of catalyst. This observation unambiguously indicates that the enantiodifferentiation is a kinetic phenomenon in this reaction. Furthermore, the data obtained with *O*- and *N*-substituted cinchona derivatives clearly demonstrate that both the nitrogen atom of the quinuclidine ring and the 9-hydroxyl group play a vital role in the enantiodifferentiation. Blocking any of these two moieties results in very low enantioselectivities. On

[a] Isolated yields. [b] Average of five parallel reactions.

Results of Table 3 indicate that both enantiomers of the products can be synthesized with high yields and enantioselectivities by appropriate selection of the catalyst. As a limitation of the approach it is worth mentioning that 1-methyl-indole derivatives ($R^1 = Me$) always gave good yields, but only racemic mixtures of products. It was also observed that the substituent in the 2-position of indole also played a crucial role. When R^2 is a relatively small group (2-Me-indole), the *ee* value of the product decreases to 75% (from 95%) with CD and 64% (from 90%) with CN. When R^2 is bulkier (2-Ph-indole), enantiodifferentiation is not observed and a racemic mixture of products is obtained.

Although it is premature to provide a detailed mechanistic explanation at this level, the major observations regarding the mechanism are as follows: 1) The indole NH, cinchona 9-OH, and quinuclidine N groups cannot be blocked; 2) Substituents in the 2-position of aromatics hinder or block enantiodifferentiation; 3) ^{19}F NMR investigations, in agreement with the literature,[9] clearly showed that **2** forms hemiketals with cinchona alkaloids through the 9-hydroxyl group. Such intermediates, however, are not effective electrophiles. The reaction of the hemiketal (prepared from a 1:1 mixture of **2** and CD) and indole gave low *ee* values in an extremely slow reaction (64% yield after 20 h, 47% *ee*); 4) The enantiodifferentiation is a kinetic phenomenon in this system (see reaction rate data in Table 2). We propose that the alkaloid forms a weak hydrogen-bonded complex with indole and then anchors **2** to form an active hydrogen-bonded intermediate. Thus the alkaloid provides a chiral environment and also activates the electrophilic carbonyl group of **2**.

In conclusion, an unprecedented cinchona alkaloid catalyzed, highly enantioselective organocatalytic Friedel–Crafts hydroxyalkylation of indole derivatives has been developed. Besides the isolation of products in high yields and enantioselectivities, the major advantages of the process are that the reactions are clean and fast and that commercially available economic catalysts can provide both enantiomers of the products, as desired. The application of this new method carries the potential of also being extended to several other reactions.

Biomolecular NMR Spectroscopy

Complete Assignment of Heteronuclear Protein Resonances by Protonless NMR Spectroscopy**

Wolfgang Bermel, Ivano Bertini, Luminita Duma, Isabella C. Felli, Lyndon Emsley, Roberta Pierattelli, and Paul R. Vasos*

The complete assignment of the resonances of a protein is key to the determination of its solution structure by NMR spectroscopy and for the study of protein–protein and protein–ligand interactions. The proton-based assignment strategy usually starts with the correlation of individual resonances of each amino acid residue through scalar connectivities followed by linking them one after the other.[1,2] Although many different triple-resonance NMR spectroscopy experiments have been designed for full assignments,[2] spectral overlap can still lead to ambiguities. This poses a significant limiting factor in the cases of large and/or paramagnetic biomolecules.[3]

After the pioneering report of ^{13}C NMR spin-system assignments of ^{13}C-enriched *Anabaena* 7120 ferredoxin by Markley and co-workers,[4] heteronuclear NMR spectroscopy experiments were progressively abandoned in favor of ^{1}H-detection experiments. However, as was recently pointed out, heteronuclear NMR spectroscopy decreases the effect of detrimental transverse relaxation, which is typical of large or paramagnetic proteins.[5–17] For this reason, several heteronuclear NMR spectroscopy experiments for backbone assignment have been proposed for fully ^{13}C- and ^{15}N-enriched proteins.[13,14,17] Furthermore, backbone sequence-specific assignment by the recently-designed CANCO experiment has also been reported.[18] We present herein an extension of the set of *exclusively heteronuclear* experiments to protein side chain resonances for the complete heteronuclear assignment of a protein. With a novel CBCACO experiment the carbonyl carbon (CO) is linked to the C^{β} and to the C^{α} nuclei; the connection to the rest of the amino acid side chain is achieved through a ^{13}C–^{13}C TOCSY experiment with C^{α} detection. In these experiments, we have successfully implemented spin-state selection methods for the removal of signal splitting in the acquisition dimension which is caused by multiple ^{13}C–^{13}C scalar couplings. This makes ^{13}C detection an amenable tool for high-resolution NMR spectroscopy. The proposed assignment strategy is summarized in Figure 1. A

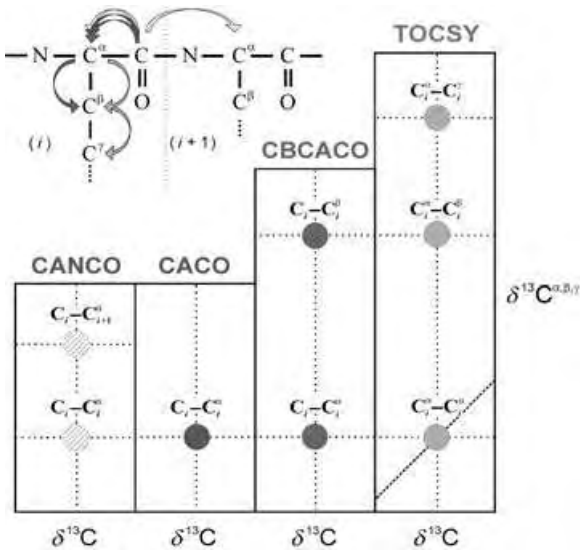

Figure 1. Illustration of the assignment procedure for ^{13}C NMR spectroscopy experiments. The assignment starts with analysis of the CACO experiment, which provides the correlation between the carbonyl carbon (CO) and the C^{α} nuclei of each amino acid. The spin-system assignment is extended to the C^{β} nuclei with the CBCACO experiment, and the process is completed with the TOCSY experiment, which provides correlation between the C^{α} and the other carbon nuclei of the amino acid side chain. The amino acid spin systems are finally assigned in a sequence-specific manner with the aid of a CANCO experiment,[18] which provides the correlation of each CO to the two neighboring C^{α} nuclei.

detailed description of CBCACO and other novel experiments presented herein are provided in the Supporting Information.

Figure 2c shows the 2D version of the CBCACO spectrum recorded with isotopically enriched (70% ^{2}H, 98% ^{13}C and ^{15}N), reduced human Cu,Zn superoxide dismutase (SOD),[19] a dimeric protein of $M_W = 32000$. The 55-Hz CO line splitting due to the C^{α}–CO scalar coupling is removed by separation of the two multiplet components with the in-phase/anti-phase (IPAP) scheme,[20,21] followed by their recombination to increase the sensitivity of the spectrum[22] (Supporting Information). Upon comparison with the IPAP–CACO spectrum (Figure 2a), the additional cross-peaks in the IPAP–CBCACO spectrum allow identification of the types of amino acid groups present in the protein on the basis of the chemical shift of C^{β}.[23] Moreover, the resolution is enhanced through the chemical-shift dispersion of C^{β} resonances ($\approx$70 ppm), which are larger than those of C^{α} ($\approx$35 ppm). Notably, this single spectrum reveals all C^{α} and C^{β} signals that have been previously assigned.[24] Furthermore, the correlations of carbonyl and carboxylate nuclei of Asp, Asn, Glu, and Gln residues, which may be important in the study of surface properties in protein–protein interactions, are easily assigned, as they are observed in a specific region of the spectrum (centered at $\omega_2 = 180$ ppm and $\omega_1 = 35$ ppm). The IPAP–CBCACO experiment is designed for easy expansion

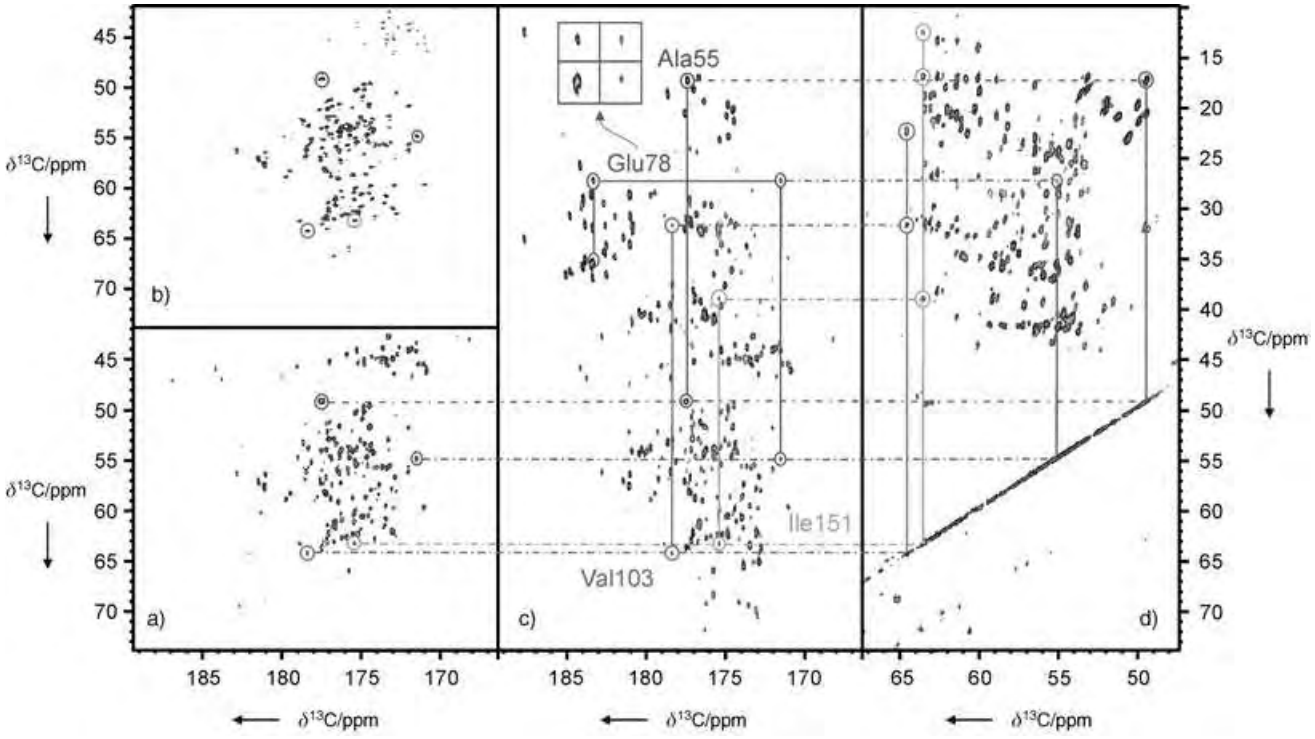

Figure 2. a) IPAP–CACO spectrum, b) DIPAP–COCA spectrum, c) 2D version (^{13}CO–$^{13}C^{\alpha/\beta}$) of the IPAP–CBCACO spectrum, and d) ^{13}C–^{13}C DIPAP–TOCSY spectrum recorded at 298 K with reduced Cu,Zn SOD (70% ^{2}H, 98% ^{13}C and ^{15}N) on a Bruker Avance NMR spectrometer (16.4 T, 700.06 MHz for ^{1}H, 176.03 MHz for ^{13}C) equipped with a ^{13}C-{^{1}H,^{15}N}TXO probe head. Chemical shifts were referenced to external 2,2-dimethyl-2-silapentane-5-sulfonic acid. The protein sample (2 mM) was prepared as previously reported[38] in phosphate buffer (20 mM, pH 5.0). The direct links between the different correlations in the spectra of panels a), c), and d) are reported for four different amino acid types. For comparison, panel b) shows the DIPAP–COCA spectrum rotated by 90°; the connectivities shown in panel a) are circled as well. The inset in panel c) shows an expansion of the four cross-peaks present in the IPAP–CBCACO spectrum for Glu78. For the spectra in panel a) and c), matrices of 1024×128 and 1024×192 complex points, respectively, in the ^{13}CO and $^{13}C^{\alpha/\beta}$ dimensions were acquired with 256 transients per increment and a recycle delay of 1.25 s; ^{1}H, ^{2}H, and ^{15}N were decoupled during the whole sequence. For each time increment in the indirect dimension, two FIDs were stored separately, one each for the anti-phase and in-phase components. The FIDs were then added and subtracted to separate the two multiplet components. These were then shifted to the center of the original multiplet by ($J_{CO-C^{\alpha}}$/2) Hz and again added to obtain a singlet.[22] Prior to Fourier transformation, an expansion to 2048×512 by linear prediction in the indirect dimension, together with zero filling and squared-sine-multiplication functions shifted by $\pi/4$ were applied in the t_2 and t_1 dimensions. For the spectrum in panel b) a matrix of 1024×96 complex points in the $^{13}C^{\alpha}$ and ^{13}CO dimensions was acquired, with 256 transients per increment and a recycle delay of 1.25 s; ^{1}H, ^{2}H, and ^{15}N were decoupled during the whole sequence. For each time increment in the indirect dimension, four FIDs were stored separately, and the resulting submatrices were added and subtracted in pairs to separate the four multiplet components, and then shifted by ($\pm J_{CO-C^{\alpha}}$/2) Hz and ($\pm J_{C^{\alpha}-C^{\beta}}$/2) Hz and added again to obtain a singlet.[22] Prior to Fourier transformation, an expansion to 2048×512 by linear prediction in the indirect dimension, together with zero filling and squared-sine-multiplication functions shifted by $\pi/4$ were applied in the t_2 and t_1 dimensions. For spectrum in panel d) a matrix of 1024×256 complex points was acquired, with 256 transients per increment and a recycle delay of 1.25 s; ^{1}H, ^{2}H, and ^{15}N were decoupled during the whole sequence, except during the DIPSI-3[39] spin lock of 23 ms. The processing of data for the four DIPAP submatrices was performed as described for panel b). Prior to Fourier transformation, an expansion of 2048×512 with zero filling and squared-sine-multiplication functions shifted by $\pi/4$ and $\pi/2$ were applied in the t_2 and t_1 dimensions, respectively.

into a 3D version by evolving the C^{α} chemical shift in the third dimension.

The IPAP filter can be implemented in a CBCACO experiment without introducing additional delays and it offers a gain in sensitivity with respect to other methods of *J*-coupling suppression.[*] The IPAP filter can, of course, be easily included in the CACO experiment.[**]

The extension of heteronuclear assignments through a ^{13}C–^{13}C TOCSY experiment[11,15] is conveniently performed by detection of the C^{α} resonances, which experience splitting from the coupling of the C^{α} nuclei to both the CO and the C^{β} nuclei. Therefore, a double IPAP (DIPAP) scheme[28] was implemented to remove the double splitting present on the C^{α} signal. As nuclear relaxation is a dominant limitation in complex pulse sequences, we succeeded in merging the two IPAP blocks into a single short building block. An example of C^{α} detection is provided by the DIPAP–COCA spectrum recorded on the same SOD sample (Figure 2b) at 16.4 T. It is nearly identical to the IPAP–CACO spectrum (Figure 2a) in terms of resolution and number of signals, except for signals that do not show the secondary coupling such as those of Gly residues. Furthermore, C^{α} detection is expected to be better than the detection of CO at high fields, as CO relaxation is dominated by the chemical-shift anisotropy (CSA) interaction that increases with the square of the magnetic field.[29,30] The detailed pulse sequence is reported in the Supporting Information.

Figure 2b shows that the DIPAP building block is quite effective. It allows one to successfully record highly resolved ^{13}C–^{13}C TOCSY spectra, as shown in Figure 2d. In the present case, the DIPAP–TOCSY experiment allowed a significant extension of the assignments for SOD[24] (expected C' and C^{α}, 100%; C^{β}, 98%; C^{γ}, 93%; C^{δ}, 89%; C^{ε}, 82%; side-chain CO, 100%).[***]

The same set of experiments was performed on a sample of ^{13}C,^{15}N-enriched oncomodulin (2.5 mM), a small Ca-binding protein of $M_W = 11\,500$. This enabled the assignment of all the resonances already obtained by standard ^{1}H-based NMR spectroscopy.[31] With this method of spin-state-selective detection, the assignments were expanded to almost all complete spin systems that were expected on the basis of the protein primary sequence (expected C', C^{α} and C^{β}, 100%; C^{γ} and C^{δ}, 98%; C^{ε}, 73%; side-chain CO, 100%;).[***]

In conclusion, the data presented herein show that removal of ^{13}C–^{13}C splitting in the acquisition dimension creates a significant step forward in direct-detection-^{13}C NMR spectroscopy and opens new prospects in the resolution of biomolecular NMR spectroscopic data. Indeed, there are a large number of experiments that could benefit from the present approach, including 3D experiments that are important to reduce spectral overlap typical of large molecules. Notably, a 3D-IPAP–CBCACO experiment on a sample of oncomodulin (2.5 mM) requires 16 scans, which is not an unreasonably long duration in comparison with standard proton-based 3D experiments at the same field. Similarly, the DIPAP–TOCSY experiment is highly sensitive and an optimal data set can be obtained in less than 24 h. The ^{13}C–^{13}C experiments presented herein can thus be included in any standard biomolecular NMR spectroscopy protocol for structure determination.

The measurement of ^{13}C–^{13}C couplings to determine residual dipolar couplings for the purposes of structure determination[32] can be performed by analysis of the individual submatrices obtained in the IPAP and DIPAP experiments, even if the resolution is still not ideal. Simultaneous decoupling of the different nuclei limits the effective RF field strength available for each nucleus as well as the duration of the acquisition time. Care should be taken to minimize overheating the sample during experiments. ^{13}C homodecoupling[10] is no longer necessary, making these experiments possible with any standard NMR spectrometer equipped for triple resonance experiments. The increase in sensitivity expected with the use of cryogenic technology in probe design, which is not yet fully exploited in ^{13}C NMR spectroscopy, will further assist in the establishment of direct-detection ^{13}C NMR as a routine technique for protein investigations and also for samples that are more dilute than those used in the experiments reported herein.

These experiments are also advantageous to the study of unfolded, highly mobile, and exchangeable systems in which the broadening of the NH signals cannot be recovered through the TROSY approach. In general, direct-detection ^{13}C NMR experiments are the only source of information for cases in which the ^{1}H resonances are broadened beyond detection through relaxation or exchange effects. Finally, ^{13}C NMR spectroscopy is the appropriate solution to paramagnetic relaxation as has been previously shown;[10,16] indeed this has been proven in studies of lanthanide-substituted oncomodulin, as a continuation of this research. In this case, a number of structural restraints based on paramagnetism are also available for solution-structure determination.[12,33–37]

[*] Several methods have been proposed to remove *J* splitting from the acquisition dimension, such as band-selective homodecoupling,[10] maximum entropy reconstruction,[25] and other post-acquisition methods.[26] We propose the method based on spin-state-selective schemes with the IPAP sequence[20,21] as an example, because it provides the best signal-to-noise ratio (S/N) in comparison with other methods (not shown). The gain in S/N compared with the most intense component of the coupled spectrum is close to that theoretically expected of SQRT(2), owing to the uniform *J*-coupling values found in ^{13}C signals. For band-selective homodecoupling, the lower S/N obtained results mainly from the higher intrinsic level of noise introduced by the acquisition method, rather than from unsatisfactory decoupling efficiency. Maximum entropy reconstruction apparently gives higher signal than the homodecoupled and nondecoupled spectra which comes at the expense of a nonuniform noise that surrounds the reconstructed peaks if the *J* coupling is not exactly matched.[25]

[**] Similarly, a S^3E filter[27] can be used, which is an even more compact way to obtain spin-state selection. The corresponding sequence and spectrum are reported in the Supporting Information.

[***] In the case of aromatic amino acids, an additional experiment is necessary to conveniently assign the aromatic ring carbon nuclei that resonate around 130 ppm.[23]

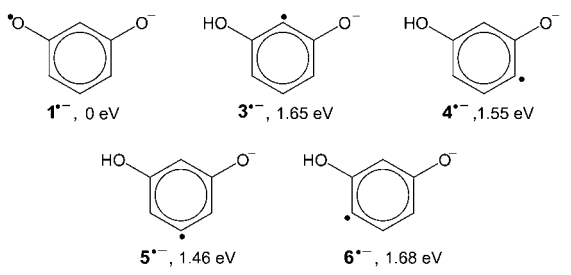
ducted by Fort et al.[4] predict a $^3B_2$ ground state of neutral **1**. The first excited singlet state ($^1B_2$) also has a biradicaloid structure and has been calculated to be 0.4 eV higher in energy.[7] There have been attempts to prepare derivatives of *meta*-benzoquinone, but probably due to the suggested rapid decarbonylation, none of the substituted *meta*-benzoquinones has been isolated so far.[8–10] This work reports the generation of *meta*-benzoquinone by means of neutralization–reionization (NR) mass spectrometry, a technique proved efficient for the generation and characterization of elusive molecules.[11,12]

Neutralization–reionization mass spectrometry consists of three steps. First, an ion of the desired structure is generated in the gas phase. Next, the mass-selected ion is neutralized in high-energy collision with an appropriate gas and all remaining charged species are deflected. In the third step, the beam of neutral species—the parent molecule and its fragments—is reionized in a second time-delayed collision to facilitate mass analysis, detection, and structural characterization based on the fragmentation pattern. As amply demonstrated,[11,12] in an ideal case an NR experiment is a convenient means for the generation and detection of otherwise hardly accessible neutral molecules. However, a conventional NR spectrum contains not only signals indicative for the neutral target molecule, rather it constitutes a superposition of fragmentations of neutral and ionic species involved in the sequential collision events. The problem of extracting the desired information specific to the neutral molecule in question has been addressed by several approaches,[11,13] of which the neutral and ion decomposition difference (NIDD) method[14] is applied here.

The first step towards *meta*-benzoquinone concerns the generation of a suitable ionic precursor.[15] The present study is confined to the corresponding anion, because experiments with the molecular cation $\mathbf{1}^{\bullet+}$ are considered ambiguous as far as the ion structure is concerned due to facile Wagner–Meerwein and other rearrangements in cationic species.[18] The anion $\mathbf{1}^{\bullet-}$ (Scheme 1) is generated by chemical ionization of resorcinol (1,3-dihydroxybenzene) using N_2O as reagent gas, where ionization of the latter provides $O^{\bullet-}$, which serves as the ionizing agent. Formation of $\mathbf{1}^{\bullet-}$ requires the elimination of both hydrogen atoms from the hydroxy groups of the precursor; of course, the singly deprotonated ion $C_6H_5O_2^-$ is observed as well. However, hydrogen may also be abstracted from the ring carbons, which would then lead to the putative anions $\mathbf{3}^{\bullet-}$–$\mathbf{6}^{\bullet-}$ (Scheme 1). According to B3LYP calculations,[19] these tautomers are about 1.5 eV higher in energy than $\mathbf{1}^{\bullet-}$. Therefore, the contribution of ring-deprotonated isomers is very likely to be small—if there is any—compared to $\mathbf{1}^{\bullet-}$. Abstraction of both hydrogen atoms from C–H bonds only as well as ring-opening would lead to anions with even considerably higher relative energies; these structures are therefore not considered any further in the discussion.



Scheme 1. Various isomers of $C_6H_4O_2^{\bullet-}$ and their energies $E_{0K} = E_{tot} + E_{ZPV}$ relative to $\mathbf{1}^{\bullet-}$; $E_{tot}(\mathbf{1}^{\bullet-}) = -381.628204$ Hartree, E_{ZPV} (zero-point vibration energy) $(\mathbf{1}^{\bullet-}) = 0.081688$ Hartree.

The connectivity of the $C_6H_4O_2^{\bullet-}$ anion generated from resorcinol was examined by recording its metastable ion (MI) and collisional activation (CA) mass spectra (Figure 1). The

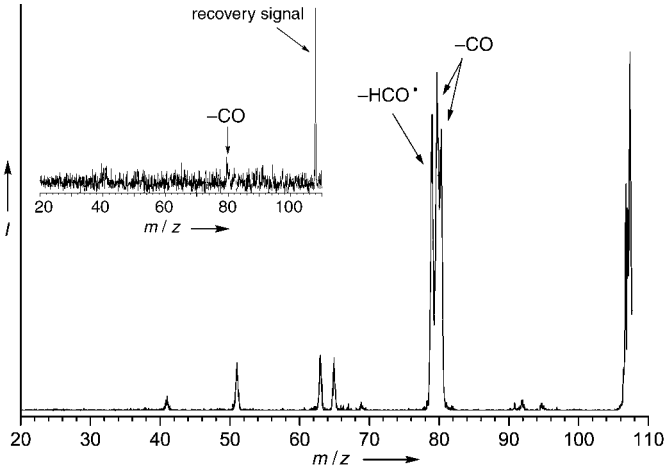


Figure 1. CA mass spectrum of $C_6H_4O_2^{\bullet-}$ generated by chemical ionization of resorcinol using N_2O as a reagent gas. The inset shows the $^-NR^-$ mass spectrum of $C_6H_4O_2^{\bullet-}$.

most dominant feature in both spectra corresponds to the loss of carbon monoxide with a characteristic peak shape that indicates a significant reverse activation barrier. The kinetic energy release associated with this process is estimated as 0.53 eV from the horn-to-horn distance of the composite peak in an energy-resolved experiment.[23] However, as the fragmentation pattern in the CA spectrum cannot be associated unambiguously with a particular connectivity of the parent ion, the CA and charge reversal ($^-CR^+$) spectra of $C_6H_4O_2^{\bullet-}$ generated by chemical ionization of $(O\text{-D})_2$- resorcinol[24,25] and 1,3-bis(trimethylsilyloxy)benzene, respectively, were acquired as well; N_2O was used as reagent gas. If mixtures of isomers were formed, the relative populations of isomers should be precursor-dependent and hence lead to differences in the spectra. Experimentally, the CA and $^-CR^+$ spectra of $C_6H_4O_2^{\bullet-}$ generated from resorcinol, its $(O\text{-D})_2$ analogue, and 1,3-bis(trimethylsilyloxy)benzene are identical within experimental uncertainty. Thus, we conclude that only the most stable isomer $\mathbf{1}^{\bullet-}$ is formed, irrespective of the precursor employed. Even if other isomers were generated initially,[26] the experimental findings imply that isomerization to $\mathbf{1}^{\bullet-}$ must have occurred either inside the ion source or within the time elapsed during mass selection (ca. 25 μs). The eventual isomerization to other benzoquinone isomers, that is, *ortho* and *para* isomers, is excluded on the basis of different CA as well as $^-CR^+$ spectra of the respective anions (see the

Supporting Information). Specifically, the base peak in the $^{-}CR^{+}$ spectrum of *para*-benzoquinone, the thermodynamically most stable isomer, corresponds to C_2H_2 elimination (*m*/*z* 82). This fragmentation is completely missing in the $^{-}CR^{+}$ spectra of either *ortho* or *meta* isomer. On the other hand, the $^{-}CR^{+}$ spectrum of *meta*-benzoquinone anion shows intense loss of $C_3H_3^{\bullet}$ (*m*/*z* 69), which is missing in the spectra of the two other isomers. Therefore, the occurrence of skeletal rearrangements leading to the formation of a mixture of benzoquinone isomers can certainly be ruled out.[27] Accordingly, the experimental results imply that $\mathbf{1}^{\bullet-}$ serves as the major, if not exclusive, contributor to the beam of mass-selected $C_6H_4O_2^{\bullet-}$ ions.

Collisional neutralization by electron transfer at keV energies is considered to occur on the femtosecond timescale as a vertical process and is thus governed by Franck–Condon factors.[11–13] The efficiency of the transition between an ion and the corresponding neutral counterpart together with the associated amount of internal excitation can be estimated from the difference of the vertical and adiabatic energies ($\Delta E_{v/a}$) of the corresponding transitions (Scheme 2). Generation of triplet ground state of *meta*-benzoquinone ($^3B_2$) from the anion $\mathbf{1}^{\bullet-}$ is associated with a calculated $\Delta E_{v/a}(\mathbf{1}^{\bullet-}/^3\mathbf{1})$ of 0.12 eV; likewise, $\Delta E_{v/a}(\mathbf{1}^{\bullet-}/^1\mathbf{1}) = 0.20$ eV results for the formation of singlet $^1B_2$ (Scheme 2).[28] These rather small values suggest favorable Franck–Condon factors for electron detachment from $\mathbf{1}^{\bullet-}$. The probability of $\mathbf{1}^{\bullet-}$ to survive an NR sequence has been probed by a $^{-}NR^{-}$ experiment.[17] Despite a rather poor signal-to-noise ratio, the $^{-}NR^{-}$ spectrum of $\mathbf{1}^{\bullet-}$ clearly shows the recovery ion as the major signal (inset in Figure 1). In agreement with the theoretical predictions, neutral *meta*-benzoquinone (**1**) can thus be generated from its anion without undergoing complete dissociation during the time interval of about 1 μs required for the passage from the neutralization to the reionization cell, which defines a minimum lifetime of **1**.

The $^{-}NR^{+}$ spectrum (Figure 2a) differs largely from the $^{-}NR^{-}$ spectrum (Figure 1, inset) in that extensive fragmentation processes are observed, for which two explanations can be put forward. First, the ionization cross sections for fragments formed at the neutral stage differ substantially for reionization to anions and reionization to cations.[29] Secondly, excessive fragmentation often takes place at the cationic stage which is also reflected in the charge-reversal spectrum ($^{-}CR^{+}$, Figure 2b).[30] Information about fragmentations of the neutral molecules can be extracted from a comparison of the $^{-}NR^{+}$ signals, resulting as a superposition of fragmentations of both, ions and neutrals, with the $^{-}CR^{+}$ spectrum, in which mostly fragmentations of ionic species are sampled.[13,14] In the resulting $^{-}NIDD^{+}$ spectrum, positive signals are due to fragmentations occurring at the neutral stage, while negative signals originate from preferential decompositions of ionic species. According to Figure 2c, the most intense fragmentation of neutral **1** is associated with loss of carbon monoxide concomitant with generation of cyclopentadienone, which is then reionized (*m*/*z* 80). Formation of cyclopentadienone is further supported by the positive $^{-}NIDD^{+}$ signal of a subsequent CO loss, which implies the generation of C_4H_4 (*m*/*z* 52);[31] the latter can further lose molecular hydrogen under NR conditions (*m*/*z* 50).[32]

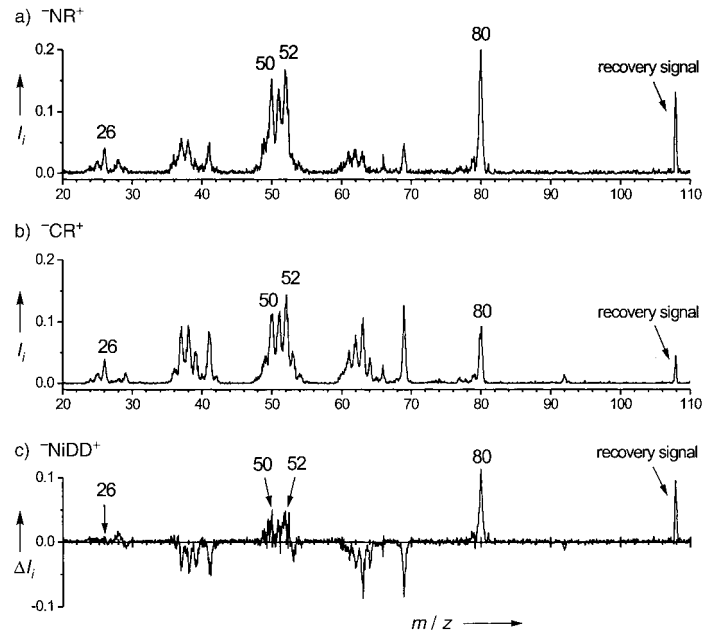

Figure 2. a) $^{-}NR^{+}$ ($\Sigma I_i = 1$), b) $^{-}CR^{+}$ ($\Sigma I_i = 1$), and c) $^{-}NIDD^{+}$ ($\Sigma I_i = 0$) mass spectra of $C_6H_4O_2^{\bullet-}$ ($\mathbf{1}^{\bullet-}$) generated by chemical ionization of resorcinol using N_2O as reagent gas.

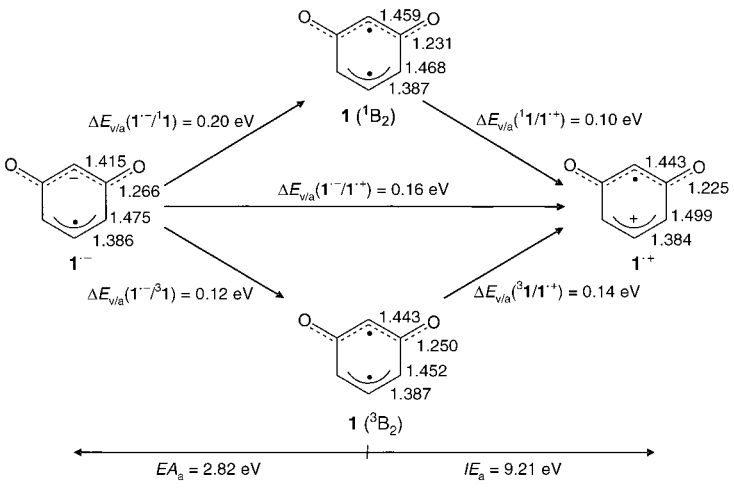
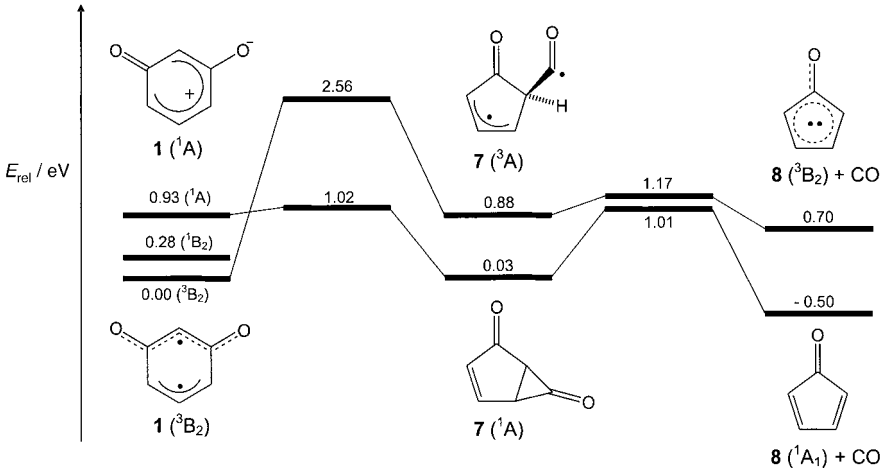


Scheme 2. Redox energies relevant in the neutralization–reionization and charge-reversal experiments. Relative energies and bond lengths [Å] were obtained from calculations.[19]

To corroborate the experimental findings, we also considered the reaction pathway for CO loss from *meta*-benzoquinone (**1**) computationally (Scheme 3). For the triplet ground state **1** ($^3B_2$), the rate-determining barrier is quite significant (2.56 eV), and decarbonylation to afford triplet cyclopentadienone is endothermic. On the singlet surface, however, the initial barrier is much lower ($E_{rel} = 1.02$ eV) and the asymptote **8** + CO is lower in energy than **1** ($^3B_2$).



Scheme 3. Calculated reaction pathways for the decarbonylation of the singlet and triplet states of *meta*-benzoquinone (**1**). Energies are given at 0 K and related to $\mathbf{1}(^3B_2)$; $E_{tot}(^3\mathbf{1}) = -381.524990$ Hartree, $E_{ZPV}(^3\mathbf{1}) = 0.0822234$ Hartree).

Accordingly, decarbonylation of **1** ($^3B_2$) can be assisted by a spin change along the reaction coordinate.[33]

In conclusion, the elusive *meta*-benzoquinone (**1**) has been generated in the gas phase by means of neutralization–reionization mass spectrometry. The main fragmentation channel of the neutral molecule leads to loss of carbon monoxide concomitant with cyclopentadienone as the most probable product. The present experimental and theoretical results pose no fundamental objections against the generation of *meta*-benzoquinone under different conditions. Matrix isolation of this molecule, which appears feasible, could then provide the ultimate spectroscopic characteristics of **1**.

[9] Oxidation of resorcinol with KIO_3 was reported to produce a "dirty yellow solid" which was assigned as a quinone based on its chemical behavior.[10] However, neither precise details of the reaction conditions and yields nor spectroscopic data were provided; the major interest in ref. [10] was the reaction kinetics. Further, we note that the reported melting points of the isolated solid (120–121 °C) and its mono-2,4-dinitrophenylhydrazone (185–187 °C) are close to the corresponding values of *para*-benzoquinone and its hydrazone derivative, respectively (115 °C and 186 °C, respectively). Several attempts in our laboratory to reproduce the reported procedure failed and instead led to iodoresorcinols as well as phenol-coupling products; *para*-benzoquinone was not even detected as a by-product.

[15] The experiments were performed with a modified VG ZAB/HF/AMD four-sector mass spectrometer of BEBE configuration (B stands for magnetic and E for electric sector).[16] $\mathbf{1}^{\bullet-}$ was generated by negative-ion chemical ionization of resorcinol, 1,3-bis(trimethylsiloxy)benzene, and 1,3-dimethoxybenzene, using N_2O as reagent gas, accelerated to a kinetic energy of 8 keV and mass-selected by means of B(1)/E(1). The structure of the anion was probed by its metastable ion and collisional activation (CA) mass spectra. To this end, the unimolecular fragmentations of anions and their fragmentations upon collision with helium (80 % transmission, *T*), respectively, in the field-free region preceding the second magnet (3rd FFR) were recorded by scanning B(2). NR and charge reversal (CR) spectra were obtained by using a tandem of differentially pumped collision cells located in the 3rd FFR equipped with a deflector placed in between the cells. For NR experiments, both cells were filled (80 % *T*) by appropriate gases (O_2/Xe in $^-NR^-$ and O_2/O_2 in $^-NR^+$, respectively)[17] and the deflector was switched on. For $^-CR^+$ experiments, only the first cell was filled with O_2 (80 % *T*) and the deflector was grounded. Usually 10–50 scans were averaged to improve the signal-to-noise ratio, and the final data were derived from two to six independent measurements.

[17] According to the charge states of the projectile and recovery ions, the NR spectra are denoted as $^+NR^+$, $^+NR^-$, $^-NR^+$, and $^-NR^-$, as suggested by: A. W. McMahon, S. K. Chowdhury, A. G. Harrison, *Org. Mass Spectrom.* **1989**, *24*, 620.
[18] D. Kuck, *Int. J. Mass Spectrom.* **2002**, *213*, 101.
[19] The calculations were performed using the density functional method B3LYP[20] in conjunction with 6-311 + G(2d,p) basis sets as implemented in Gaussian 98.[21] For all optimized structures, a frequency analysis was performed in order to assign them as genuine minima or transition structures and to determine the zero-point vibrational energies (E_{ZPV}). All transition structures were characterized by intrinsic reaction coordinate calculations.[22] The calculations of the anions $\mathbf{1}^{\bullet-}$ and $\mathbf{3}^{\bullet-}$–$\mathbf{6}^{\bullet-}$ were restricted to doublet states. The energies given in Schemes 1–3 are obtained as $E_{0K} = E_{tot} + E_{ZPV}$.

[24] The hydrogen atoms of the hydroxy groups of resorcinol were exchanged by its reaction with CH_3OD at room temperature. Due to facile keto–enol tautomerization, the sample contains also a small amount of D_3-resorcinol (< 4 %).
[25] The $^{-}CR^{+}$ spectra of O-deprotonated nonlabeled and O-bisdeuterated resorcinol (*m*/*z* 109 and 110, respectively) show characteristic losses of O$^{\bullet}$ atoms and OH$^{\bullet}$ and OD$^{\bullet}$ groups, respectively. Instead, the $^{-}CR^{+}$ spectrum of $C_6H_4O_2^{\bullet -}$ (Figure 2b) shows only the loss of O$^{\bullet}$ atom, which is yet further evidence for the suggested connectivity of $C_6H_4O_2^{\bullet -}$, rather than ring-deprotonated forms.
[26] In the studies of *meta*-xylylene, the radical anion $\mathbf{2}^{\bullet -}$ was generated by hydrogen abstraction from *meta*-xylene with $O^{\bullet -}$.[2] The authors claim generation of 75 % of desired *meta*-xylylene and 25 % of anions with one of the hydrogen atoms eliminated from the ring.
[27] In the context of a possible contribution of the ring-deprotonated isomers $\mathbf{3}^{\bullet -}$–$\mathbf{6}^{\bullet -}$, it is also worth mentioning that generation of *para*-benzoquinone anion by CI from either *para*-benzoquinone or hydroquinone leads to identical $C_6H_4O_2^{\bullet -}$ ions.
[28] The results for the $^1B_2$ state should be taken with some caution because the description of an open-shell singlet state with single reference methods, like B3LYP, inevitably encounters spin-contamination by the triplet state.

Synthetic Methods

1,3-Dipolar Cycloadditions of Carbonyl Ylides to Aldimines: A Three-Component Approach to *syn*-α-Hydroxy-β-amino Esters**

*Staffan Torssell, Marcel Kienle, and Peter Somfai**

The β-amino alcohol and α-hydroxy-β-amino acid moieties are found in a large variety of biologically important compounds and natural products[1] as well as in a growing number of ligands and chiral auxiliaries for asymmetric synthesis.[2] Existing synthetic routes towards enantiopure *vic*-amino alcohols have traditionally relied on derivatization of the chiral pool of amino acids for the most part; however, there is an inherent limitation of accessible targets.[3] Considerable efforts have been made in developing asymmetric routes to β-amino alcohols to circumvent these drawbacks; these can be divided into two strategically different approaches.[4] Most commonly, the amino alcohol functionality is introduced into a pre-existing carbon skeleton, and this can be accomplished by Sharpless aminohydroxylation[5] or by ring opening of epoxides[4,6,7] or aziridines[4,7,8] with appropriate nucleophiles. More effectively, the amino alcohol moiety can be constructed by concomitant formation of a new carbon–carbon bond and two vicinal stereogenic centers in a single step. This approach has been realized by addition of glycine-derived enolates to aldehydes to yield *anti*-β-amino alcohols[1b,9] or by addition of α-alkoxy enolates to aldimines in a Mannich-type reaction.[1a,10] Although several methods are currently available for the stereo- and enantioselective formation of *vic*-amino alcohols, there is clearly a demand for simple and efficient entries to this interesting class of substance.

It was envisioned that *vic*-amino alcohols **A** could be obtained by hydrolysis of the corresponding oxazolidines **B**, and that these heterocycles could be prepared from the 1,3-dipolar cycloaddition of a carbonyl ylide **C** to an imine **D** (Scheme 1).[11] The carbonyl ylide **C**, in turn, could be prepared from insertion of the carbene derived from **E** into aldehyde **F**. Herein, we report the realization of this strategy by detailing the first example of such a three-component protocol for the synthesis of *syn*-α-hydroxy-β-amino esters and its application to the asymmetric synthesis of the C13 taxol side chain.

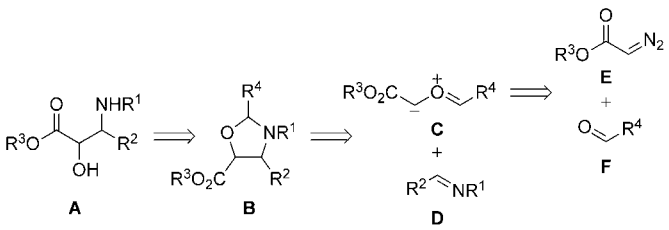
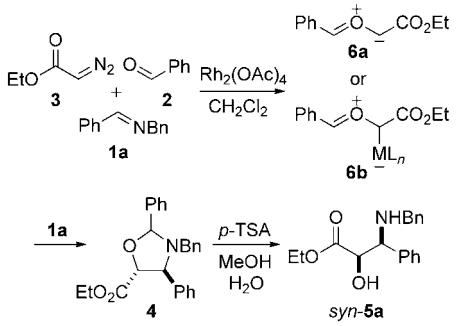


Scheme 1. Retrosynthetic analysis of the α-hydroxy-β-amino ester synthesis.

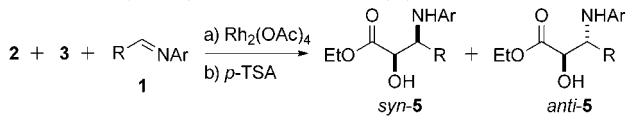
Initially, a mixture of benzylidenebenzylamine (**1a**), benzaldehyde (**2**), and $Rh_2(OAc)_4$ in CH_2Cl_2 was stirred at room temperature (Scheme 2). Addition of ethyl diazoacetate (EDA; **3**) over 1 h at room temperature afforded the desired cycloadduct **4**, which yielded *vic*-amino alcohol **5a** (*syn*/*anti* 93:7) in 82% yield (*syn*; Table 1, entry 1) on hydrolysis.[12] The relative stereochemistry of **5a** was verified by its conversion into the corresponding oxazolidinone by ^{1}H NMR spectroscopic analysis of the relevant coupling constants.[13]



Scheme 2. 1,3-Dipolar cycloaddition to benzylidenebenzylamine. *p*-TSA = *para*-toluenesulfonic acid, Bn = benzyl.

With the reaction conditions established, it was of interest to optimize the key components of the reaction. First, the choice of metal catalyst was examined. $Cu(OTf)_2$ is known to be a suitable catalyst for the decomposition of **3**, but unfortunately this only led to recovery of **1a** (entry 2), probably because of coordination of the metal to the basic imine nitrogen atom with concomitant inhibition of the carbenoid formation.[11c,d,14] Next, the substituent on the imine was varied to investigate if this would influence the reaction outcome. When using imine **1b**, which was derived from aniline and **2**, a complex reaction mixture was obtained with no trace of the desired product (entry 3), whereas attempts with **1c** gave only recovered starting material (entry 4). Aldehyde **2** could be exchanged for other aromatic aldehydes, but this did not improve the reaction outcome so the remaining experiments were performed with **2**. The performances of other aldimines under the optimized reaction conditions are summarized in Table 1. In all cases, the reaction proceeded cleanly to provide the desired *syn*-α-hydroxy-β-amino ester in high yield and excellent diastereoselectivity.[15] Several benzylidenebenzylamine derivatives containing electron-withdrawing (entries 5–8) or electron-donating substituents (entries 9–11) in the *meta* or *para*-positions gave comparable yields and diastereoselectivities irrespective of the steric or electronic properties of the aryl substituent. The furfural-derived imine **1k** afforded the corresponding product **5k** in high yield and diastereoselectivity (entry 12), which is of interest as the furan moiety can be readily derivatized into several useful functional groups. The reaction of ethyl glyoxalate imine (**1l**) gave *syn*-β-hydroxyaspartate (**5l**), a potent blocker of glutamate transporters,[16] in high yield and good diastereoselectivity (entry 13), thus indicating that the reaction is not only restricted to aromatic imines and the scope of the transformation can be widened.

Table 1: 1,3-Dipolar cycloaddition of carbonyl ylides to aldimines.[a]



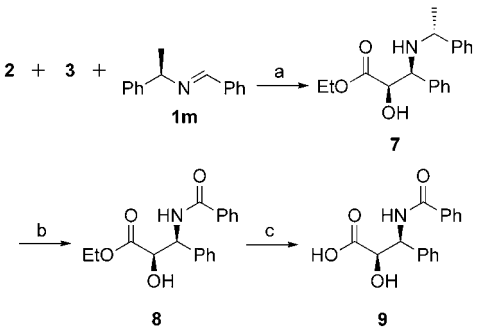
Entry	**1** (R/Ar)	d.r. (*syn*/*anti*)[b]	Yield of *syn*-**5** [%][c]
1	**a** (Ph/Bn)	93:7	**a** (82)
2[d]	**a** (Ph/Bn)	N.A.	**a** (0)[e]
3	**b** (Ph/Ph)	N.A.	**b** (0)[f]
4	**c** (Ph/4-$MeOC_6H_4$)	N.A.	**c** (0)[e]
5[g]	**d** (4-$NO_2C_6H_4$/Bn)	91:9	**d** (61)
6	**e** (4-ClC_6H_4/Bn)	98:2	**e** (75)
7	**f** (4-FC_6H_4/Bn)	97:3	**f** (78)
8	**g** (4-$MeOC_6H_4$/Bn)	98:2	**g** (77)
9	**h** (4-MeC_6H_4/Bn)	97:3	**h** (87)
10[g]	**i** (4-$MeOC_6H_4$/Bn)	94:6	**i** (78)
11	**j** (2-naphthyl/Bn)	98:2	**j** (83)
12[g,h]	**k** (2-furyl/Bn)	92:8	**k** (75)
13[g,h]	**l** (CO_2Et/Bn)	83:17	**l** (64)

[a] The reaction was carried out with imine **1** (1.0 equiv), benzaldehyde (1.5 equiv), $Rh_2(OAc)_4$ (2.0 mol%), and powdered 4-Å molecular sieves in CH_2Cl_2 at RT with addition of ethyl diazoacetate (1.5 equiv) over 1 h. Hydrolysis was performed with *p*-TSA (2 equiv) in MeOH/H_2O (95:5). [b] Determined by NMR spectroscopic analysis of the crude product; *syn* and *anti* diastereoisomers were separated with flash chromatography. [c] Yield of isolated product. [d] $Cu(OTf)_2$ (5 mol%) in THF. [e] Only imine and hydrolyzed imine. [f] Complex mixture of by-products. [g] Addition time = 10 h. [h] 0 °C. N.A. = not available.

The mechanism of the reaction proceeds through a chemoselective insertion of the metallocarbene into benzaldehyde to form either a metal-free[11a,17a] **6a** or a metal-associated ylide[17] **6b**, both of which can then undergo a 1,3-dipolar cycloaddition with the aldimine yielding the *trans*-substituted oxazolidine **4**, which can then be hydrolyzed to the corresponding *syn*-α-hydroxy-β-amino ester **5** (Scheme 2). To ascertain if ylide **6** is metal-associated, the generation of the ylide and its subsequent reaction with imine **1a** was performed with $[Rh_2(hfb)_4]$ (hfb = heptafluorobutyrate) and $[Rh_2\{(S)\text{-dosp}\}_4]$ ((*S*)-dosp = (*S*)-*N*-dodecylbenzenesulfonyl prolinate), respectively. When $[Rh_2(hfb)_4]$ was used, **5a** was obtained in only 13% yield with lower diastereoselectivity (*syn*/*anti* = 88:12 compared to entry 1, Table 1), whereas with $[Rh_2\{(S)\text{-dosp}\}_4]$ **5a** was obtained in 62% yield with excellent diastereoselectivity (*syn*/*anti* = 94:6) and modest enantiose-

lectivity (24% *ee*). These preliminary results support the formation of a metal-associated ylide in this case. It is interesting to note that no products derived from the formation of azomethine ylides, by combination of **1** with **3**, was observed in these reactions.[11c,d]

It was also of interest to develop an asymmetric protocol for the synthesis of enantiomerically enriched *syn*-α-hydroxy-β-amino esters and to apply it to the synthesis of the taxol C13 side chain **9** (Scheme 3),[5,18] which is known to be important



Scheme 3. Asymmetric synthesis of the C13 side chain of taxol. Reagents and conditions: a) 1) $Rh_2(OAc)_4$ (2 mol%), 4-Å molecular sieves, CH_2Cl_2, 0°C; 2) *p*-TSA, MeOH/H_2O (95:5), RT (77%, 2 steps, d.r. 8:1:1); b) 1) H_2, [$Pd(OH)_2$], EtOH, 3 M HCl, RT; 2) PhCOCl, $NaHCO_3$, EtOAc, 0°C (77% over 2 steps); c) LiOH·H_2O, THF/MeOH/H_2O (10:5:4), RT (89%).

for the antitumor activity of taxol.[18] Initial attempts with (−)-8-phenylmenthyl diazoacetate[19] as the carbene source with **1a** and **2** gave none of the desired product. Gratifyingly, however, reaction of the enantiomerically pure imine **1m**, derived from (+)-α-methylbenzylamine, with **2** and **3** gave the desired *syn*-amino alcohol **7** in good yield (77%) and selectivity (*syn*/*syn*/*anti* = 8:1:1) after hydrolysis (Scheme 3). Compound **7** was readily isolated from the two minor isomers by flash chromatography, and subsequent catalytic hydrogenolysis of this compound followed by benzoylation under Schotten–Baumann conditions afforded amide **8** (77% yield, two steps). Finally, hydrolysis of **8** using LiOH yielded the taxol side chain **9** as a white solid in five steps and an overall yield of 42%. Analytical data of **9** were in good agreement with previously reported data.[5,18]

In conclusion, we have developed an efficient protocol for the synthesis of *syn*-β-amino alcohols and *syn*-α-hydroxy-β-amino acid derivatives based on a highly diastereoselective three-component coupling of imines, benzaldehyde, and EDA. The methodology was applied to a short enantioselective synthesis of the C13 side chain of taxol.

Semiconductors

Photonic Crystals with Thermally Switchable Stop Bands Fabricated from Se@Ag_2Se Spherical Colloids**

*Unyong Jeong and Younan Xia**

Self-assembly of monodispersed spherical colloids into highly ordered lattices has attracted considerable attention due to the potential use of these periodic structures as photonic crystals.[1] Despite intensive study on this subject, the building blocks available to form long-range ordered lattices have been mainly limited to polymer latexes and silica beads.[2] To obtain wider photonic band gaps by increasing the contrast in refractive index, processing materials with refractive indices greater than 2 into monodispersed spherical colloids is of the utmost necessity.[3] Although a number of semiconductors (e.g., ZnS, CdS, and TiO_2) with relatively high refractive indices have been recently synthesized as monodispersed spheres and then crystallized into 3D opaline lattices with strong stop bands in the visible region,[4] the diversity of materials still needs to be greatly expanded to fully capitalize on the advantages and exploit the potential brought by the large contrast in refractive index. Very recently, we developed a solution-phase method for the large-scale production of monodispersed amorphous selenium (*a*-Se) spherical colloids with readily controllable sizes.[5] Herein we demonstrate that the high reactivity of Se towards Ag atoms could be used to generate monodispersed spherical colloids consisting of *a*-Se cores and Ag_2Se shells. More interestingly, the reversible phase transition associated with Ag_2Se provides a new platform for fabricating photonic crystals with thermally switchable stop bands.

As a semiconductor with a narrow band gap, Ag_2Se has a range of interesting and useful properties. It undergoes a phase transition at 133 °C with a remarkable change in the electronic property.[6] The low-temperature β-phase crystallizes in an orthorhombic lattice and acts as a semiconductor. It is a good candidate for thermoelectric applications due to its low lattice thermal conductivity ($\approx 5\ mW\,cm^{-1}\,K$), high electrical conductivity ($\approx 2000\ S\,cm^{-1}$), and hence a relatively large Seebeck coefficient (about $-150\ \mu V\,K^{-1}$).[7] It was also demonstrated that slight changes in stoichiometry to $Ag_{2+\delta}Se$ (in the same orthorhombic lattice) can induce appreciable magnetoresistance.[8] An explanation to account for this property considers the existence of small silver clusters in the crystal lattice.[9] Nonstoichiometric solids have also been reported to exist in tetragonal, face-centered cubic (fcc), monoclinic, or triclinic structures at room temperature.[10] Recently, Alivisatos and co-workers reported the use of a cation-exchange reaction to transform Ag_2Se nanocrystals into CdSe without causing any change to the morphology.[11] The high-temperature phase, α-Ag_2Se, has a body-centered cubic (bcc) structure and is a good superionic conductor as a result of the high mobility of silver cations and the low activation energy for diffusion and conduction.[12] The polymorphic transition between the β- and α-phases has been shown to be reversible.

We note that photonic crystals with tunable stop bands have been exploited as sensors to detect and monitor the variation in temperature, strain, and concentration of a chemical or biochemical species.[13–16] Recently, our group also demonstrated color writing and printing by embedding photonic crystals in elastomeric matrices.[17] The essence of this research is to take advantage of the reversible, polymorphic transition of a solid material to fabricate photonic crystals with stop bands that can be reversibly switched between two spectral positions. Such a system can potentially serve as an optical switch or a thermally printable medium.

It has been demonstrated that β-Ag_2Se nanowires could be produced by reacting nanowires of trigonal selenium (*t*-Se, serving as a chemical template) with $AgNO_3$ in an aqueous solution at room temperature [Eq. (1)].[18] In this particular

$$3\,Se_{(s)} + 6\,Ag^{+}_{(aq)} + 3\,H_2O \rightarrow 2\,Ag_2Se_{(s)} + Ag_2SeO_{3(s)} + 6\,H^{+}_{(aq)} \quad (1)$$

route, the formation of monoclinic Ag_2SeO_3 as a by-product was inevitable.

Herein we wish to report a new process, in which $AgNO_3$ is reduced by ethylene glycol to generate Ag atoms that further react with spherical colloids of *a*-Se to form monodispersed colloids consisting of *a*-Se cores and β-Ag_2Se shells. The *a*-Se colloids with smooth surfaces and controllable sizes are, in turn, synthesized by using a chemical solution-phase method based on the reduction of selenious acid with excessive hydrazine in ethylene glycol.[5] After residual hydrazine has been removed, $AgNO_3$ dissolved in ethylene glycol is added to generate *a*-Se@Ag_2Se core–shell colloids.

The extent of conversion from *a*-Se to Ag_2Se can be controlled by adjusting the molar ratio of $AgNO_3$ to *a*-Se.

The formation of Ag_2Se was first confirmed by powder X-ray diffraction (XRD, Philips PW-1710 diffractometer). As shown in Figure 1 A, the as-synthesized colloids of *a*-Se

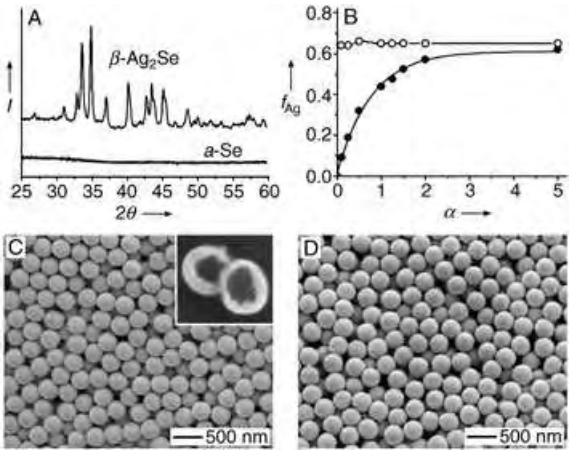

Figure 1. A) XRD patterns taken from the as-synthesized *a*-Se and *a*-Se@Ag_2Se colloids (with $f_{Ag} = 0.32$). All peaks were indexed to orthorhombic β-Ag_2Se. B) Plots showing how f_{Ag} of the core–shell colloids changed as the molar ratio (α) of $AgNO_3$ to Se varied. Solid circles and open circles represent f_{Ag} values measured by using EDX before and after removal of the Se cores with hydrazine, respectively. C) SEM image of core–shell colloids synthesized with $\alpha = 0.5$. The inset shows a SEM image of two broken colloids after the *a*-Se cores had been dissolved with hydrazine. D) SEM image of another batch of core–shell colloids synthesized with $\alpha = 2.0$.

displayed no diffraction peak in the entire 2θ range from 25 to 60°, which indicates an amorphous structure. The XRD pattern taken from the product (synthesized with a molar ratio of 0.5 $AgNO_3$ to 1.0 Se) matched the orthorhombic lattice of β-Ag_2Se (lattice constants: $a = 4.33$, $b = 7.06$, $c = 7.76$ Å). The XRD patterns were essentially the same regardless of the ratio of $AgNO_3$ to Se involved in the synthesis. It is worth mentioning that no impurity such as Ag_2SeO_3 was detected in the as-synthesized product; this lack of impurity is because ethylene glycol was able to reduce Ag^+ cations to Ag atoms, which then diffused quickly into the lattice of *a*-Se to generate β-Ag_2Se as the sole product [Eq. (2)].

$$2\,Ag + Se \rightarrow Ag_2Se \qquad (2)$$

For the as-obtained core–shell colloids, we used energy-dispersive X-ray spectra (EDX, Genesis 2000, EDAX Inc., Mahwah, NJ) to determine the elemental composition, or the atomic fraction of silver (f_{Ag}). To improve the signal-to-noise ratio and thus obtain reliable data, we used a thick slab (≈ 6 μm) of the colloid sample deposited on a silicon wafer in combination with a beam spot of > 100 μm^2. EDX peaks that corresponded to the L shell of Ag and Se were employed for all quantitative analyses. Figure 1 B shows the change in f_{Ag} (solid circles) with increasing molar ratio of $AgNO_3$ to Se ($\alpha = [AgNO_3]/[Se]$) and demonstrates a monotonic increase as α changed from 0 to 5. To determine the atomic fraction of Ag in the shells only, the Se cores were selectively removed by immersing the sample in hydrazine for 18 h. As the Ag_2Se shells were polycrystalline, the Se cores were slowly etched away by hydrazine through the grain boundaries. The atomic fractions of Ag for the etched samples are presented as open circles in Figure 1 B; essentially the same value ($\approx 65\%$) was obtained regardless of the α value. This percentage matches the stoichiometry of Ag_2Se, which indicates that the Ag_2Se shells were very pure. The plots also show that the *a*-Se colloids can only be completely converted into Ag_2Se when the molar ratio of $AgNO_3$ to Se is higher than 5.

Figure 1 C and D show scanning electron microscopy (SEM, Siron XL, FEI, Hillsboro, OR) images of two typical samples obtained at different molar ratios of $AgNO_3$ to Se: 0.5:1 and 2:1. As with the *a*-Se colloids, the core–shell particles were spherical, monodispersed, and had featureless surfaces. The inset in Figure 1 C gives a SEM image of the same sample after the unconverted *a*-Se cores had been selectively removed by extraction with hydrazine. On the basis of both SEM and XRD results, we concluded that the as-obtained products were composed of Se cores (amorphous) and β-Ag_2Se shells (polycrystalline). Once the f_{Ag} value of a sample had been determined by EDX, both the shell thickness and the dimensional change involved in this template-engaged reaction was estimated. For instance, the calculated diameter and shell thickness of the colloids displayed in Figure 1 C are 310 and 22 nm, respectively, which are in good agreement with the results from TEM studies. The derivation of these values is provided as Supporting Information, together with experimental results.

Both Se and Ag_2Se transform into different phases as the temperature is raised from room temperature to about 150 °C: Se undergoes a transition from amorphous to trigonal phase at 31 °C whereas Ag_2Se has a phase transition (from β to α) around 133 °C. We have followed the phase transitions of both cores and shells with XRD. In a typical experiment, a thick film (≈ 1 mm) was cast on a glass slide from an aqueous suspension of core–shell colloids and dried in air. The sample was annealed at various temperatures ranging from room temperature to 150 °C with increasing steps of ≈ 10 °C. The sample was annealed at each set temperature for 10 min and then quenched by placing it on a cold metal plate. XRD measurements were taken immediately after quenching and were completed within 10 min. Figure 2 shows XRD patterns taken from the same sample as that given in Figure 1 D ($f_{Ag} = 0.56$). The diffraction pattern at room temperature was similar to that shown in Figure 1 A, although different values of f_{Ag} were involved. After the sample had been annealed at 110 °C, a small new peak (indicated by the asterisk in Figure 2) appeared at $2\theta = 28.5°$, which corresponds to the (101) diffraction of *t*-Se. After the sample had been annealed at 150 °C, the peaks associated with β-Ag_2Se mostly disappeared and a characteristic peak of α-Ag_2Se (with a bcc structure) appeared at $2\theta = 35.2°$ (indicated by the triangular in Figure 2); this peak was indexed to the (200) diffraction. The sample reverted to the β-Ag_2Se structure when it was cooled slowly to 110 °C. It is worth pointing out that the peak from *t*-Se remained the same in the β↔α transition for the

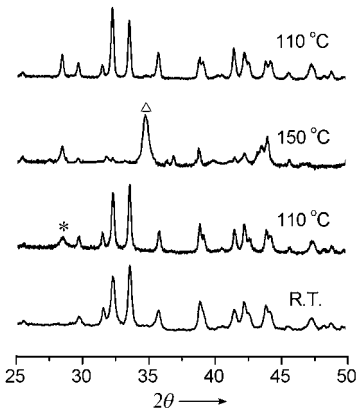

Figure 2. XRD patterns taken from a sample of Se@Ag_2Se core–shell colloids at room temperature, which were then heated to 110 and 150 °C, followed by cooling to 110 °C. The sample was annealed at each temperature for 10 min and quenched on a cold metal plate and XRD measurement was taken within 10 min. ⋆ and △ represent the peaks for *t*-Se and α-Ag_2Se, respectively.

Ag_2Se shells. These results indicate that the Se core was well preserved inside the Ag_2Se shell as the sample underwent thermal annealing. The XRD results confirm that the phase transition between orthorhombic and bcc structure for the Ag_2Se shells is reversible. SEM studies also showed that the spherical shape of these core–shell colloids was maintained through multiple cycles of such phase transitions when $f_{Ag} = 0.56$. In comparison, the shells with $f_{Ag} = 0.32$ were broken in the annealing process and the Se leaked from the shells and aggregated into large, irregular structures.

The thermally reversible transition between two different states for the Ag_2Se shells implies that these core–shell colloids could be used as building blocks to fabricate photonic crystals with reversibly switchable stop bands. To this end, we have crystallized core–shell colloids ($f_{Ag} = 0.56$) into 3D opaline lattices on glass substrates by using a previously reported method.[19] Figure 3 shows the cross-sectional SEM images of a typical sample, which displays an fcc structure with its {111} planes oriented parallel to the surface of the supporting substrate. Figure 3 A shows an image of the as-obtained sample, and Figure 3 B shows the same sample after it had been annealed at 150 °C for 10 min, then quenched to room temperature by placing it on a cold metal plate. Even though the core–shell colloids went through two phase transitions from *a*-Se to *t*-Se and from β-Ag_2Se to α-Ag_2Se, the spherical shape of the colloids and the long-range order of the lattice were both essentially retained. As long as the Se cores did not leak out (or if they were removed in advance), the phase transition between β- and α-Ag_2Se could go through many cycles of heating and cooling without causing significant changes to the opaline lattices.

Figure 4 shows the near-IR reflection spectra taken from an opaline lattice assembled from core–shell colloids with $f_{Ag} = 0.56$. The spectra were recorded by using a fiber-optic spectrometer (NIR-128, Control Development, South Bend, IN) with an incident and detection angle of 10° from the normal to the surface. The opaline lattice was annealed at various temperatures up to 150 °C with a step increase of

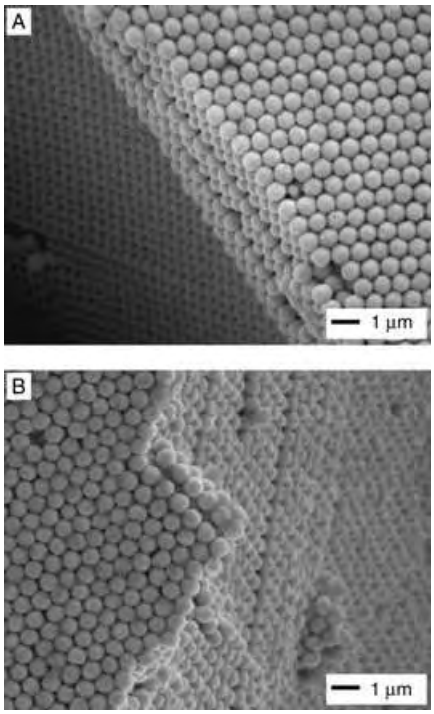

Figure 3. A) Cross-sectional SEM image of an opaline lattice assembled from *a*-Se@Ag_2Se colloids with $f_{Ag} = 0.56$. B) The same sample, after it had been annealed at 150 °C for 10 min.

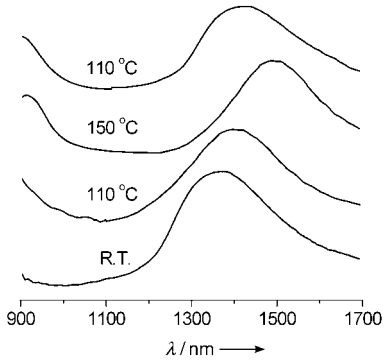

Figure 4. Reflection spectra in the near-IR region taken from an opaline lattice consisting of Se@Ag_2Se core–shell colloids with $f_{Ag} = 0.56$. The temperature was increased from room temperature to 110 and 150 °C, and then reduced to 110 °C. After the sample had been annealed at each temperature for 10 min, it was quenched to preserve the high-temperature phases.

10 °C. After annealing for 10 min at each temperature, the sample was quenched (by placing it on a cold metal plate) to preserve the high-temperature phases. We did not observe any significant change in the peak position until 70 °C. When the annealing temperature was increased to 80 °C, the peak suddenly red-shifted to 1392 nm and then showed little change as the temperature was further raised to 130 °C. This change was attributed to the increase in the refractive index when the cores were converted from *a*-Se into *t*-Se. In the range of 130–140 °C, the peak was red-shifted again to 1497 nm as the Ag_2Se shells underwent a transition from

the β- to the α-phase. The peak shifted back to 1415 nm when the sample was annealed at 110 °C, and then quenched to room temperature.

The observed reflectance peaks and shifts can be explained on the basis of the Bragg diffraction equation. The refractive index of β-Ag_2Se was obtained by plotting the data reported for the UV/Vis region[20] and fitting them with the first-order Sellmeier equation (Eq. (3)),[21] in which $A =$

$$n^2(\lambda) = A + B[\lambda^2/(\lambda^2 - C)] \quad (3)$$

5.20, $B = 3.62$, and $C = 0.13$; and the unit for λ is μm. From this equation, the refractive index of β-Ag_2Se was calculated as 2.98 at $\lambda = 2$ μm. The Moss relationship, $n^4 E_g = 95$,[22] could not be applied to this system as the value of the band gap (E_g) of β-Ag_2Se is still being disputed. The reported values, −0.17,[23] 1.33,[24] 1.58,[25] and 2.17 eV,[26] would suggest very different refractive indices: 4.86, 2.90, 2.88, and 2.44, respectively. The volume fraction of the shell and the core were calculated (see the Supporting Information). For core–shell colloids with $f_{Ag} = 0.56$, the volume fraction of the core (X_{core}) was 23 %. The dielectric constant of the core–shell colloids was calculated by assuming a linear relationship between the dielectric constant and the volume fraction [Eq. (4)].[27] With

$$n = n_{core} X_{core} + n_{shell}(1 - X_{core}) \quad (4)$$

the reported refractive index of 2.45 for *a*-Se,[28] a value of 2.86 was obtained for the refractive index of core–shell colloids with $f_{Ag} = 0.56$.

Based on the assumption of a closely packed structure (26 % air), the reflectance peak centered at ≈1365 nm for the sample annealed at room temperature was assigned to the diffraction from (111) lattice planes. From the Bragg diffraction equation,[29] the peak position was calculated as 1358 nm with a refractive index of 2.86 for the core–shell colloids. The higher refractive index of *t*-Se (2.8 at 2 μm versus 2.45 for *a*-Se)[30] increased the refractive index of the core–shell particles to 2.94. This increase in refractive index led to a red shift for the (111) peak to ≈1395 nm, which matched the experimental result. After the sample had been annealed at 150 °C, the (111) diffraction peak was further shifted to ≈1497 nm and a new peak appeared at ≈919 nm. The red shift was induced by the phase transition from β- to α-Ag_2Se, that is, from a semiconductor to a superionic state. From the peak position of the (111) plane, the refractive index of α-Ag_2Se was estimated to be 3.26. This refractive index could be used to assign the peak at ≈919 nm as the diffraction from (220) lattice planes (calculation: 916 nm). The Moss relationship[22] predicted a band-gap energy of 0.84 eV for α-Ag_2Se, which is much lower than that of β-Ag_2Se obtained from our refractive index value (1.20 eV). Note that the band gap of α-Ag_2Se is still in the range of semiconductors. The increase in conductivity accompanying the transition from the β- to the α-phase mainly results from the enhanced mobility of the Ag cations. When the sample was cooled down to 110 °C, the diffraction peaks were recovered with some slight thermal hysteresis: 1415 nm for the (111) diffraction and below 900 nm for the (220) diffraction. The peaks did not shift anymore when the sample was annealed again at temperatures below 110 °C, which suggests that the phase transition between *a*-Se and *t*-Se was irreversible.

This study focuses on how thermally induced polymorphic transitions can lead to changes in the photonic band gap. Photonic crystals with a band gap in the visible region can serve as photonic papers, which is one of the primary uses for core–shell colloids. For example, a phase transition of the photonic crystals can be induced in a confined region with the aid of a laser and subsequent quenching to room temperature can preserve the kinetically trapped patterns. These altered regions will diffract light of longer wavelengths than will do other regions, thus enabling colored patterns to be recorded. If the photonic crystals are annealed at an elevated temperature, the patterns can be readily erased. In addition, the electrical conductivity of β-Ag_2Se ($\approx 2000\ S\,cm^{-1}$) is exceptionally high relative to those of other semiconductors.[7] This value can be further increased to $\approx 6000\ S\,cm^{-1}$ in the α-Ag_2Se phase.[7c] These unique properties will make the *a*-Se@Ag_2Se core–shell colloids potentially useful in thermoelectric applications.

In summary, we have exploited the high reactivity of *a*-Se towards Ag atoms to produce core–shell spherical colloids in the form of *a*-Se@Ag_2Se. Upon heating, the cores and shells change phase from *a*-Se to *t*-Se and from β-Ag_2Se to α-Ag_2Se, respectively. When the shells were sufficiently thick (55 nm, or with $f_{Ag} = 0.56$), the core–shell colloids maintained their spherical shape while undergoing multiple cycles of phase transitions between β-Ag_2Se and α-Ag_2Se. This feature has been used to fabricate photonic crystals with thermally switchable stop bands.

Experimental Section

In a typical synthesis, hydrazine hydrate (55 % N_2H_4; Aldrich) in ethylene glycol (0.35 M, 80 mL) was added to pure ethylene glycol (400 mL; J. T. Baker) in a 1000-mL Erlenmeyer flask. After the mixture had been stirred for 10 min, H_2SeO_3 (Aldrich, 99.99 %) in ethylene glycol (0.07 M, 80 mL) was introduced and the reaction was allowed to proceed for 2 h. As hydrazine can also reduce $AgNO_3$ to Ag nanoparticles and agglomerates, all remaining hydrazine in the suspension of *a*-Se colloids was removed by vacuum distillation before $AgNO_3$ was added to the reaction system. To form Ag_2Se, a solution of poly(vinylpyrrolidone) (PVP; 15 mL, $\bar{M}_w = 55\,000$, 3 g per 200 mL; Aldrich) in ethylene glycol was added at room temperature to the *a*-Se that had been suspended in ethylene glycol (30 mL). Adding a solution of $AgNO_3$ (Aldrich, 99.9 %) in ethylene glycol to this suspension resulted in a change from red to dark brown then dark blue as the ratio between $AgNO_3$ and *a*-Se increased. The reaction mixture was diluted with water (100 mL) and the core–shell colloids were collected by centrifugation. To remove ethylene glycol and excess PVP, the product was again diluted with water (100 mL) and separated by centrifugation. This washing cycle was repeated several times before the product was dried in air. The colloids were stable in air and did not aggregate.

Gas Sensors

Organic–Inorganic Hybrid Sol–Gel Materials Incorporating Functionalized Cobalt(III) Corroles for the Selective Detection of CO**

Jean-Michel Barbe, Gabriel Canard, Stéphane Brandès, and Roger Guilard**

Corroles and their metal derivatives continue to attract increasing interest because of their potential applications in many fields[1–3] and because of the development of new straightforward and powerful syntheses.[4–9] For example, it is now possible to functionalize the corrole macrocycle at the *meso* positions with several groups,[9,10] thus allowing it be anchored on various solid supports. Nanostructured organic–inorganic hybrid materials have also been developed, and these offer the possibility to incorporate many different organic chelates and complexes into their framework.[11–14] Moreover, immobilized complexes within the material are expected to be more stable than analogous isolated com-

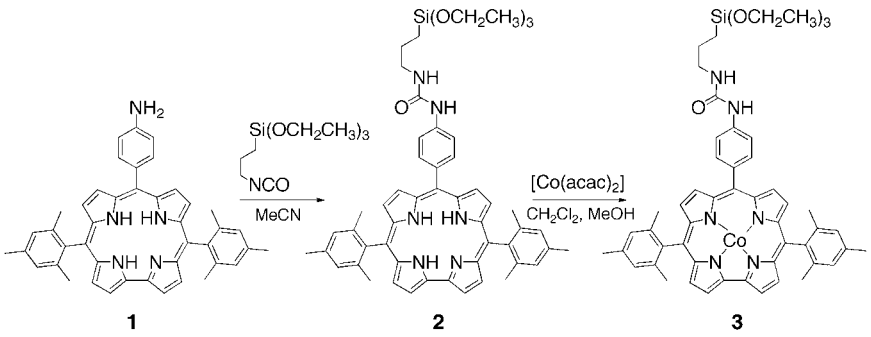
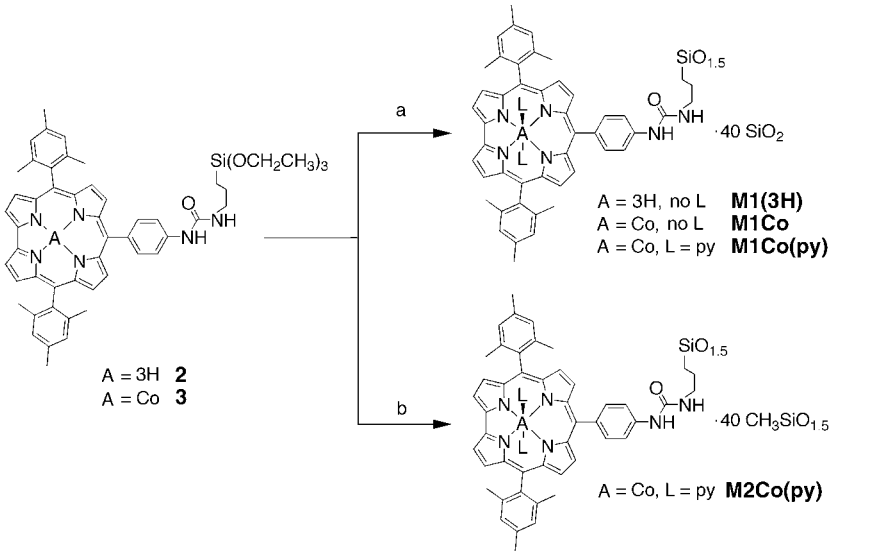
plexes. Therefore, applications in different fields such as catalysis,[15] optical sensors,[16,17] and metal-ion separation processes, especially for transition metals,[18] heavy metals,[19,20] and actinides,[21] have been developed. Many examples of gas separation devices with hybrid organic–inorganic membranes based on a gas-diffusion process have been described,[22–24] but only a few examples of gas separation through the formation of chemical bonds between gas molecules and solid supports are known;[14,25] gas-detection studies with hybrid organic–inorganic materials are also rare.[17,26]

We recently reported the high affinity and infinite selectivity of cobalt(III) corroles for CO over O_2 and N_2.[27] Hybrid xerogels are able to combine the textural and the structural properties of the inorganic matrix such that the gas-binding properties of immobilized Co^{III} corroles can be tuned. Furthermore, the incorporation of these Co complexes in a solid inorganic network stabilizes the active species and the resulting materials are well adapted to the preparation of powders, fibers, or thin films. Unusual adsorption properties may arise by combining the intrinsic reactivity of the metallo–organic complex with the properties of the inorganic framework[28] as the arrangement of the organic moieties gives rise to short-range organization.[29,30] In this regard, corrole macrocycles were immobilized, for the first time, in a silica matrix through one Si–C covalent bond. The anchoring of one hydrolysable $-Si(OEt)_3$ terminal group to the corrole allowed the preparation of hybrid materials through a sol–gel process. Herein, we describe the synthesis, physicochemical characterization, and adsorption properties of these materials.



Scheme 1. Synthesis of the alkoxysilylated corrole precursors.



Scheme 2. Preparation of the materials: a) 40 equiv TEOS, distilled H_2O, TBAF, THF (with or without pyridine); b) 40 equiv MTEOS, distilled H_2O, TBAF, py, THF. L = axial pyridine ligand.

Complex **3** was prepared in two steps starting from corrole **1** (Scheme 1).[31] The reaction of 3-(triethoxysilyl)propyl isocyanate on **1** led to the formation of **2** in 4 days with a yield of 68%. Metalation of the free base **2** with cobalt(II) acetylacetonate afforded the precursor **3** in 96% yield (Scheme 1). These derivatives were characterized by ^{1}H NMR and UV/Vis spectroscopies, MALDI-TOF MS, and elemental analysis (see the Supporting Information).

Two types of materials were made: **M1** was prepared by co-polycondensation of **2** or **3** with 40 equivalents of tetraethoxysilane (TEOS); **M2** was prepared by co-polycondensation of **3** with 40 equivalents of methyltriethoxysilane (MTEOS; Scheme 2).[31] In the case of **M1**, the gelation process was performed at room temperature in THF by adding a stoichiometric amount of distilled water to the reaction mixture in the presence of tetrabutylammonium fluoride (TBAF, 1 mol% with respect to silicon) as catalyst. Under these conditions, **M1(3H)** and **M1Co**, which were obtained from **2** and **3**, respectively, gelled rapidly and the resulting monolithic gels were aged for 7 days. Upon addition of an excess of pyridine (py) during the gelation reaction of **3** with TEOS, **M1Co(py)** was synthesized (see Scheme 2 and the Supporting Information). The sol–gel process was further explored by treating the alkoxysilylated metallocorrole precursor **3** with 40 equivalents of MTEOS to prepare homogeneous molecular materials with enhanced stability of the cobalt(III) corrole in a moist atmosphere. A 14-day procedure led to the formation of **M2Co(py)** from a mixture of **3**, MTEOS, distilled water, a large excess of pyridine, and a catalytic amount of TBAF (5 mol% with respect to Si) at room temperature (Scheme 2). A larger TBAF/Si ratio was needed to initiate the sol–gel reaction for the formation of **M2Co(py)** than was needed for **M1Co(py)**.

The axial positions of the Co ion were protected during the sol–gel process by pyridine. The challenge was to make the Co^{III} coordination sites available for CO binding after removal of the pyridine ligands and to create a cavity for optimal accessibility of the gas. Thus, this protective method prevents inactivation of cobalt(III) corrole sites that occurs

through coordination of free silanol and siloxane groups on the material surface. The interaction of the cobalt ions with these groups cannot occur in **M2Co(py)** as there are mainly methyl groups present at the surface of the material.

The analytical and spectroscopic data for the silylated precursors and the hybrid xerogels are consistent with the structures presented in Scheme 2 and demonstrate that the corrole is incorporated into the solids. The metallocorrole concentration in the materials was deduced from elemental analyses (see the Supporting Information). For **M1Co**, the presence of the organic functional moieties in the mesopores and the condensation rate of the solids were evidenced by their ^{29}Si CP/MAS NMR spectra exhibiting one set of resonances at $\delta = -58$ and -63 ppm for the hybrid parts T^2 ($CSi[(OSi)_2OH]$) and T^3 ($CSi[(OSi)_3]$) substructures, respectively, and by the presence of a second set of resonances at $\delta = -101$ and -110 ppm corresponding to Q^3 ($Si[(OSi)_3OH]$) and Q^4 ($Si[(OSi)_4]$) inorganic substructures. Although the ^{29}Si CPMAS/NMR spectra could not be analyzed quantitatively, evidence of the major T^3 and Q^3 substructures was in accordance with a high condensation level for the solids.[32] Conversely, for **M2Co(py)**, only one sharp signal for the T^3 substructure was observed at $\delta = -66$ ppm, which is indicative of a polycondensed solid. The absence of signals between $\delta = -90$ ppm and -110 ppm suggests that no Si–C bond cleavage occured during the hydrolysis–polycondensation process.

The electronic spectra in the diffuse reflectance mode for **M1Co(py)** and **M1Co** materials resemble those of Co^{III} corroles in solution, with a single Soret band near 400 nm and very broad Q bands (500–650 nm; see the Supporting Information). These results indicate that the coordinating pyridine molecules are removed when the materials are put under vacuum. Conversely, the spectrum of **M2Co(py)** exhibits a new band close to 620 nm, which is characteristic of a hexacoordinated cobalt(III) corrole with two pyridine ligands.[33] Therefore, severe conditions are needed to remove pyridine molecules from **M2Co(py)**.

The surface area and pore diameters of the xerogels were determined by using nitrogen adsorption experiments according to BET and BJH calculations.[34,35] In general, the specific area is an important physical criteria for controlling accessibility of the gas molecules to the active sites. The texture of the free-base and cobalt(III) corrole materials obtained by co-gelation with TEOS was neither highly dependent on the presence of the metal in the macrocycle nor on the use of the protecting base. Thus, the surface areas of **M1(3H)**, **M1Co**, and **M1Co(py)** range between 450 and 520 $m^2 g^{-1}$. The N_2 adsorption/desorption isotherms of these samples were of type II with no hysteresis loop, which is characteristic of macroporous materials.[36] In contrast, the **M2Co(py)** xerogel prepared with MTEOS was almost nonporous (12 $m^2 g^{-1}$), even when more drastic aging conditions were used.

The CO adsorption was investigated concomitantly with O_2 and N_2 adsorption measurements to determine the selectivity of the materials towards CO versus O_2 and N_2. The equilibrium constant related to the CO binding affinity K_i and the adsorption capacity V_i ($i = N_2$ or O_2) was calculated by considering two different adsorption processes: selective chemisorption on the Co^{III} ion and nonselective physisorption resulting from dissolution and diffusion of the gas into the solid material.[27] The experimental isotherms corresponding to the CO adsorption were thus analyzed by using a model based on three Langmuir-type isotherms [Eq. (1)] and the N_2 and O_2 isotherms with a single Langmuir-type isotherm model [Eq. (2)].

$$V_{CO} = \frac{V_1 K_1 P}{1 + K_1 P} + \frac{V_2 K_2 P}{1 + K_2 P} + K_3 P \quad (1)$$

$$V_{i_{tot}} = \frac{V_i K_i P}{1 + K_i P} \quad (2)$$

An example of the CO adsorption adjustment by the isotherm model for **M1Co(py)** is given in Figure 1 along with experimental isotherms related to O_2 and N_2 adsorption. The main data relating to the CO adsorption for the four materials are reported in Table 1.

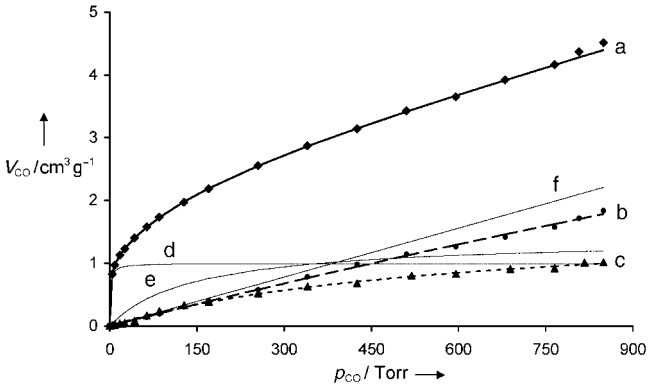


Figure 1. a) CO, b) N_2, and c) O_2 adsorption isotherms for **M1Co(py)** recorded at 293 K; d), e), and f) represent the first, second, and third components, respectively, of the calculated isotherms for CO adsorption (see [Eq. (1)].

Table 1: Experimental and calculated CO adsorption data for the xerogels

Material	V_{CO}[a] [$cm^3 g^{-1}$]	V_1 [$cm^3 g^{-1}$]	$(P_{1/2})_1$[b] [Torr]	V_2 [$cm^3 g^{-1}$]	$(P_{1/2})_2$[b] [Torr]	$K_3 \times 10^3$ [$Torr^{-1}$]	[Co][c] [$mmol g^{-1}$]	% CO[d]
M1(3H)	0.84	2.42	895	–	–	–	–	–
M1Co	5.92	0.54	1.12	0.75	138	6.19	0.186	31

M2Co(py)	3.06	1.30	0.40	0.58	73	1.61	0.219	38

[a] Experimental volume adsorbed at 760 Torr. [b] $(P_{1/2})_i = 1/K_i$. [c] Concentration of cobalt in the materials. [d] Percentage of active sites calculated from $V_1 + V_2$ and [Co].

For CO adsorption, the first two Langmuir components are related to the chemisorption of CO on accessible cobalt(III) corroles located at the surface of the material (K_1) and on less accessible complexes inside the solid (K_2), K_1 being by far larger than K_2. Physisorption of CO on the solid is given by a third component (K_3). Figure 1 clearly shows that the N_2 (b) and O_2 (c) adsorptions correspond to physisorption of the

gases on the porous material ($P_{1/2}^{N_2 \text{ or } O_2} > 500$ Torr) as well as the third component of the CO experimental adsorption isotherm curve. Another key feature is the selectivity of the CO adsorption compared to those of O_2 and N_2. Indeed, these values, which are calculated from $(P_{1/2})_1^{O_2 \text{ or } N_2}/(P_{1/2})_1^{CO}$, are about 470 and 5600 for CO/O_2 and CO/N_2 respectively. These significant values represent the adsorption phenomenon at a very low partial pressure of CO and therefore at a very low CO content. However, from a chemical point of view, the CO/O_2 and CO/N_2 selectivities are infinite as O_2 and N_2 cannot bind to the Co^{III} ion.[27] Such an attribute is significant for a CO gas detector to be used under ambient conditions.

The adsorption of CO by **M1(3H)** (Table 1 and the Supporting Information) is very low and results only from physisorption on the solid. This is not surprising as **M1(3H)** incorporates a free-base corrole, therefore no chemisorption of CO can occur. Furthermore, it is clear that the introduction of pyridine during the gelation process significantly increases the accessibility of the Co^{III} sites as demonstrated by the higher V_1 and lower $(P_{1/2})_1$ values for **M1Co(py)** and **M2Co(py)** compared with **M1Co** (see Table 1). Moreover, the use of MTEOS instead of TEOS induces an important decrease in the physisorption of CO, which is reflected by a lower K_3 value (Table 1) while maintaining a high accessibility of the metallocorroles, as shown by the low V_2 value with respect to V_1. Thus, a large surface area is not a prerequisite for a material that is very reactive towards CO.

In conclusion, very high affinities for CO compared with O_2 and N_2 were obtained for Co^{III} corroles incorporated into silica matrices. The sol–gel process led to new organic–inorganic hybrid composite materials. By this flexible process, devices with different shapes might be prepared, such as thin films coated on a solid support through a gelation reaction. This development facilitates the elaboration of a gas sensor and enhances the long-term stability of the device.

Luminescent Gold Complexes

Luminescent Gold(III) Alkynyl Complexes: Synthesis, Structural Characterization, and Luminescence Properties**

Vivian Wing-Wah Yam, Keith Man-Chung Wong, Ling-Ling Hung, and Nianyong Zhu*

C_6H_4-Cl-*p* (**2**)
C_6H_4-OCH_3-*p* (**3**)
C_6H_4-NH_2-*p* (**4**)
R' = *t*Bu; R = C_6H_5 (**5**)

Scheme 1.

In contrast to the related gold(I)[1–3] and the isoelectronic platinum(II) compounds,[4,5] which are known to show rich luminescence properties, luminescent gold(III) compounds are rare, with very few exceptions that emit at room temperature in solution.[6] The reasons for the lack of luminescence in gold(III) species are probably the presence of low-energy d–d ligand field (LF) states and the electrophilicity of the gold(III) center. The presence of a nonemissive low-lying d–d state would quench the luminescence excited state by thermal equilibration or energy transfer.[7] Coupling of strong σ-donating alkynyl ligands to gold(III) should render the metal center more electron rich, with the additional advantage of raising the energy of the d–d states, which would result in enhanced luminescence by increasing the chances of populating the emissive state for the construction of luminescent organometallic materials. Despite the fact that alkynyl complexes of gold(I)[3] and the isoelectronic platinum(II)[5] are known and have been shown to display rich photoluminescence properties, to our surprise, alkynyl complexes of gold(III) are extremely rare.[8] Although there is increasing interest in the use of gold(III) compounds for catalysis of organic synthetic reactions of alkynes,[9] the chemistry of gold(III) alkynyls is essentially unexplored and underdeveloped, and their luminescence properties are virtually unknown.

Herein we describe the synthesis of a novel series of biscyclometalated gold(III) alkynyl complexes [Au(C^N^C)(C≡CR)] [HC^N^CH = 2,6-diphenylpyridine, R = C_6H_5 (**1**), C_6H_4-Cl-*p* (**2**), C_6H_4-OCH_3-*p* (**3**), C_6H_4-NH_2-*p* (**4**); HC^N^CH = 2,6-bis(4-*tert*-butylphenyl)pyridine, R = C_6H_5 (**5**)], which are the first of their kind (Scheme 1). The molecular structure of **1** was determined by X-ray crystallography. The photophysical properties of **1**–**5** were also studied.

Unlike most other gold(III) compounds, which exhibit luminescence only at low temperature or are nonemissive, complexes **1**–**5** display luminescence in various media at both low and ambient temperature.

Figure 1 shows the crystal structure of **1**, in which the gold(III) center adopts a distorted square-planar coordination geometry with C(9)-Au(1)-C(25) and N(1)-Au(1)-C(1) angles of 162.0(3) and 178.5(3)°, respectively, as is characteristic of d^8 metal complexes. The C^N^C ligand and the gold(III) center are essentially coplanar, with the plane lying at a dihedral angle of 64.97° with respect to the ethynylbenzene moiety. The bond lengths about the gold(III) center and the C^N^C

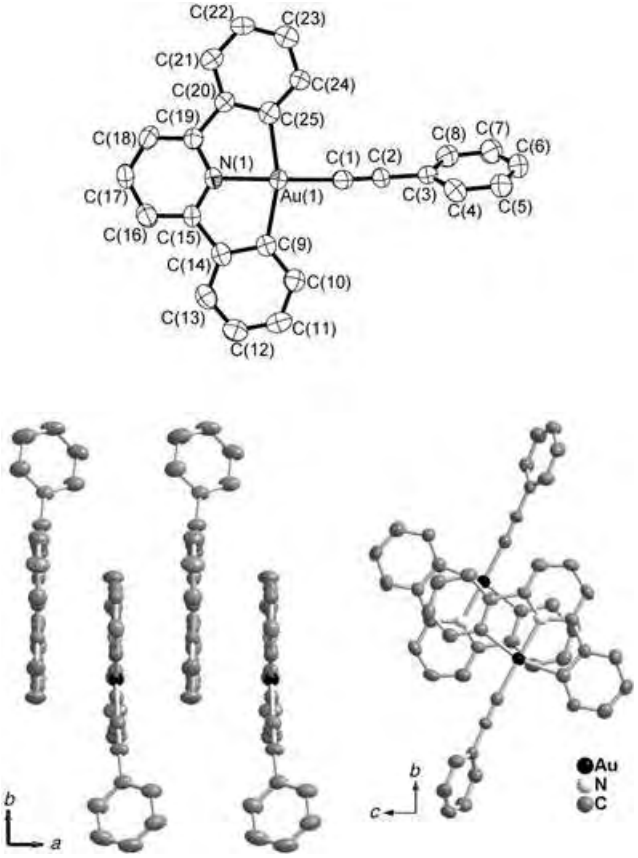

Figure 1. Top: Crystal structure of **1** with atomic numbering scheme. Hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at the 40% probability level. Selected bond lengths [Å] and angles [°]: Au(1)–C(1) 1.979(7), Au(1)–C(9) 2.073(7), Au(1)–C(25) 2.071(7), Au(1)–N(1) 1.999(5), C(1)–C(2) 1.185(9); C(9)-Au(1)-C(25) 162.0(3), N(1)-Au(1)-C(1) 178.5(3), Au(1)-C(1)-C(2) 176.6(7), C(1)-C(2)-C(3) 177.6(9). Bottom: Crystal packing showing the π···π stacking arrangement in different views.

ligand [Au(1)–C(9) 2.073(7), Au(1)–C(25) 2.071(7), Au(1)–N(1) 1.999(5) Å] are similar to the Au–C and Au–N distances in related gold(III) bis-cyclometalated complexes[10] and are also comparable to the Pt–C and Pt–N distances in analogous platinum(II) complexes.[5c–f] The Au–C(1) and C(1)–C(2) bond lengths of 1.979(7) and 1.185(9) Å, respectively, as well as the Au(1)-C(1)-C(2) bond angle of 176.6(7)° are comparable to those found in gold(I) alkynyl[3] and analogous platinum(II) alkynyl complexes.[5c–f] The shortest Au···Au distance of 5.003(1) Å indicates the absence of significant Au···Au interaction. However, the crystal packing of **1** (Figure 1) reveals the presence of partially staggered [Au^{III}-C^N^C] units with interplanar distances of 3.384 Å between the adjacent C^N^C ligands, suggestive of the presence of aromatic π···π stacking interactions.

All complexes exhibit an intense absorption band at 312–323 nm and a moderately intense vibronic-structured absorption band at 362–412 nm in dichloromethane. The photophysical data of **1**–**5** are collected in Table 1, and the electronic absorption spectra of **1**, **4**, and **5** are shown in Figure 2. The vibrational progressional spacings of 1310–1380 cm^{-1} in the lower energy absorption band correspond to the skeletal vibrational frequency of the C^N^C ligand. The absorption energy was found to be rather insensitive to the nature of the alkynyl ligand. In addition, the observation of similar absorption bands for the chloro counterpart [Au(C^N^C)Cl] is suggestive of the lack of involvement of the alkynyl ligands in this transition. In view of this, and the nonreducing nature of gold(III), such low-energy absorptions are assigned as metal-perturbed intraligand (IL) π–π* transition of the C^N^C ligand, involving some charge transfer from the phenyl moiety to the pyridyl unit. This is further supported by the lower absorption energy of **5** compared to **1** with the same alkynyl ligand. The observation of a lower energy metal-perturbed IL π–π* transition in **5** is ascribed to the better electron-donating properties of the *tert*-butyl group on the phenyl rings, which raises the energy of the HOMO localized on the phenyl ring and thus narrows the gap between the HOMO and the pyridine-localized LUMO. Similar assignments were also suggested for other related gold(III) complexes.[10] Interestingly, an additional shoulder was observed in the electronic absorption spectrum of **4** at about 415 nm (Figure 2). Since the alkynyl ligand with an electron-rich amino substituent has better electron-donating ability, the presence of a low-lying alkynyl-to-diarylpyridine

[a] In dichloromethane at 298 K. [b] Luminescence quantum yield, measured at room temperature with $[Ru(bpy)_3]^{2+}$ as standard. [c] Vibronic-structured emission band. [d] Prepared by vacuum deposition. [e] In CH_2Cl_2/EtOH/MeOH (1:40:10). [f] Double-exponential decay.

ligand-to-ligand charge-transfer (LLCT) transition is possible. Thus, the low-energy absorptions in **4** are assigned as an admixture of intraligand (IL) π–π*(C^N^C)/LLCT π(C≡C-C_6H_4-NH_2-*p*)→π*(C^N^C) transitions.

Unlike most other gold(III) compounds, which are non-emissive or only show luminescence at low temperature, **1**–**5** display intense luminescence at 468–611 nm in solution on excitation at $\lambda \geq 360$ nm at room temperature (Table 1). This supports the idea that introduction of strong σ-donating alkynyl ligands into gold(III) compounds would enhance the luminescence properties by increasing the d–d splitting, as opposed to the observation of emission only in low-temperature glasses of the chloro analogue [Au(C^N^C)Cl].[10] The long-lived emission with lifetimes in the microsecond range is suggestive of a triplet parentage. In general, the emission energies of the compounds were found to be rather insensitive to the nature of the alkynyl ligands. A vibronic-structured emission band with band maximum at around 480 nm was observed for **1**–**3** and **5** in dichloromethane at room temperature (Figure 3). The vibrational progressional spacings of

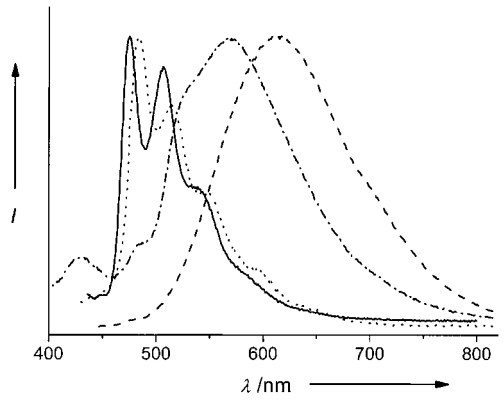

Figure 3. Normalized emission spectra of **1** (——), **4** (----), **5** (••••) in degassed CH_2Cl_2 and **1** in the solid state (thin film, –•–•) at 298 K.

about 1300 cm^{-1} are in line with the C=C and C=N stretching frequencies of the tridentate ligand, indicative of the involvement of the tridentate ligand in the excited state origin. The luminescence is assigned as originating from a metal-perturbed IL ^{3}[π-π*] state of the tridentate C^N^C ligand. Similar to the low-energy absorption band in the electronic absorption studies, **5** emits at lower energy than **1**, since the electron-rich *tert*-butyl groups on the phenyl rings of the C^N^C ligand in **5** lead to a higher energy phenyl-localized HOMO and hence a lower energy ^{3}[π-π*] excited state. In contrast to **1**–**3** and **5**, which show a vibronic-structured emission band in dichloromethane, **4** exhibits a structureless emission band at 611 nm even in dilute solution (5×10^{-6} mol dm^{-3}; Figure 3). On the basis of the energetically higher lying π(C≡C-C_6H_4-NH_2-*p*) orbital, the lower energy emission band in **4** is tentatively assigned as derived from an LLCT ^{3}[π(C≡C-C_6H_4-NH_2-*p*)→π*(C^N^C)] excited state. It is noteworthy that the emission spectra of **1**–**5** in the solid state show a low-energy structureless band at 550–585 nm (Figure 3). The red shift of the solid-state emission relative to that in solution is attributed to dimeric or excimeric emission arising from the π···π stacking of the C^N^C ligand, probably due to the ordered packing of the molecules in the solid state, as supported by the observation of such π···π stacking in the crystal packing of **1** (Figure 1).

Experimental Section

Complexes **1**–**5** were synthesized by reaction of [Au(C^N^C)Cl] with various terminal alkynes in the presence of a catalytic amount of copper(I) iodide in triethylamine and dichloromethane. Pale yellow crystals were obtained by slow diffusion of diethyl ether vapor into a dichloromethane solution of the complexes after column chromatography on silica gel with dichloromethane as eluent. **1**: Yield: 88%. ^{1}H NMR (300 MHz, CH_2Cl_2, 298 K, relative to Me_4Si): $\delta = 8.04$ (dd, $J = 7.4$, 1.0 Hz, 2H, C^N^C), 7.92 (t, $J = 8.0$ Hz, 1H, C^N^C), 7.62 (m, 4H, C^N^C and C_6H_5), 7.54 (d, $J = 8.0$ Hz, 2H, C^N^C), 7.26–7.44 ppm (m, 7H, C^N^C and C_6H_5); positive EI-MS: *m/z*: 527 $[M]^+$; IR (KBr): $\tilde{\nu} = 2147$ cm^{-1} ν(C≡C); elemental analysis (%) calcd for $C_{25}H_{16}NAu$ (found): C 56.93 (56.57), H 3.04 (3.05), N 2.66 (2.66). **2**: Yield: 85%. ^{1}H NMR (300 MHz, CH_2Cl_2, 298 K, Me_4Si): $\delta = 8.00$ (dd, $J = 7.2$, 1.0 Hz, 2H, C^N^C), 7.90 (t, $J = 8.0$ Hz, 1H, C^N^C), 7.50–7.60 (m, 6H, C^N^C and C_6H_4), 7.25–7.42 ppm (m, 6H, C^N^C and C_6H_4); positive EI-MS: *m/z*: 562 $[M]^+$; IR (KBr): $\tilde{\nu} = 2157$ cm^{-1} ν(C≡C); elemental analysis (%) calcd for $C_{25}H_{15}NClAu \cdot 0.5\,H_2O$ (found): C 52.59 (52.85), H 2.80 (2.66), N 2.45 (2.40). **3**: Yield: 86%. ^{1}H NMR (400 MHz, CH_2Cl_2, 298 K, Me_4Si): $\delta = 8.02$ (dd, $J = 7.6$, 1.0 Hz, 2H, C^N^C), 7.90 (t, $J = 8.0$ Hz, 1H, C^N^C), 7.60 (dd, $J = 7.6$, 1.0 Hz, 2H, C^N^C), 7.50–7.56 (m, 4H, C^N^C and C_6H_4), 7.40 (dt, $J = 7.3$, 1.3 Hz, 2H, C^N^C), 7.27 (dt, $J = 7.3$, 1.3 Hz, 2H, C^N^C), 6.91 (d, $J = 8.9$ Hz, 2H, C_6H_4), 3.88 ppm (s, 3H, OCH_3); positive EI-MS: *m/z*: 557 $[M]^+$; IR (KBr): $\tilde{\nu} = 2157$ cm^{-1} ν(C≡C); elemental analysis (%) calcd for $C_{26}H_{18}NOAu \cdot 0.5\,H_2O$ (found): C 55.12 (55.15), H 3.36 (3.28), N 2.47 (2.48). **4**: Yield: 80%. ^{1}H NMR (300 MHz, CH_2Cl_2, 298 K, Me_4Si): $\delta = 8.07$ (dd, $J = 7.4$, 1.0 Hz, 2H, C^N^C), 7.92 (t, $J = 8.0$ Hz, 1H, C^N^C), 7.65 (dd, $J = 7.4$, 1.0 Hz, 2H, C^N^C), 7.56 (d, $J = 8.0$ Hz, 2H, C^N^C), 7.39–7.45 (m, 4H, C^N^C and C_6H_4), 7.30 (dt, $J = 7.5$, 1.3 Hz, 2H, C^N^C), 6.67 (d, $J = 8.6$ Hz, 2H, C_6H_4), 3.84 ppm (s, 2H, NH_2); positive EI-MS: *m/z*: 542 $[M]^+$; IR (KBr): $\tilde{\nu} = 2143$ cm^{-1} ν(C≡C); elemental analysis (%) calcd for $C_{25}H_{17}N_2Au \cdot 0.5\,H_2O$ (found): C 54.45 (54.59), H 3.27 (3.13), N 5.08 (5.04). **5**: Yield: 85%. ^{1}H NMR (400 MHz, CH_2Cl_2, 298 K, Me_4Si): $\delta = 8.18$ (d, $J = 2.0$ Hz, 2H, C^N^C), 7.86 (t, $J = 8.0$ Hz, 1H, C^N^C), 7.60 (d, $J = 7.6$ Hz, 2H, C_6H_5), 7.56 (d, $J = 8.0$ Hz, 2H, C^N^C), 7.46 (d, $J = 8$ Hz, 2H, C^N^C), 7.35 (m, 5H, C^N^C and C_6H_5), 1.39 (s, 9H, *t*Bu), 1.53 ppm (s, 18H, *t*Bu); positive EI-MS: *m/z*: 640 $[M]^+$; IR (KBr): $\tilde{\nu} = 2149$ cm^{-1} ν(C≡C); elemental analysis calcd for $C_{33}H_{32}NAu \cdot 0.5\,H_2O$ (found): C 61.11 (61.02), H 5.09 (5.08), N 2.16 (2.17).

Crystal data for **1**: $C_{25}H_{16}AuN$, $M_r = 527.35$, crystal dimensions $0.4 \times 0.2 \times 0.2$ mm, orthorhombic, space group $P2_12_12_1$, $a = 6.735(1)$, $b = 14.265(3)$, $c = 19.583(4)$ Å, $V = 1881.4(6)$ $Å^3$, $Z = 4$, $\rho_{calcd} = 1.862$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 7.827$ mm^{-1}, $F(000) = 1008$, $T = 253$ K. Final $R = 0.0262$, $wR = 0.0555$ with $I > 2\sigma(I)$; $R = 0.0339$, $wR = 0.0569$ for all data; GOF = 0.925 for 244 parameters and a total of 10500 reflections, of which 3283 were independent ($R_{int} = 0.0377$). MAR diffractometer, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å); collection range $2\theta_{max} = 50.62°$ with 3° oscillation step of ϕ, 300 s exposure time, and scanner distance of 120 mm. 54 images were collected. Natural Products Synthesis

Determination by Asymmetric Total Synthesis of the Absolute Configuration of Lucilactaene, a Cell-Cycle Inhibitor in p53-Transfected Cancer Cells**

*Junichiro Yamaguchi, Hideaki Kakeya, Takao Uno, Mitsuru Shoji, Hiroyuki Osada, and Yujiro Hayashi**

The tumor-suppressor gene p53 is involved in important cellular events, such as cell-cycle control and apoptosis.[1] The p53 gene is lost or mutated in many types of human tumors. Small molecules that induce cell-cycle arrest or apoptosis in a p53-independent manner or allow mutant p53 to alter a conformationally active form of p53 may be good candidates for treating various types of cancers.[2] Recently we isolated lucilactaene (**1**), which arrests cell-cycle progression in the G1 phase at the nonpermissive temperature of 37 °C in Hl299/tsp53 cells, from *Fusarium* sp. RK97-94.[3] Lucilactaene (**1**) is a synthetically challenging molecule because of its rare hexahydro-3a-hydroxy-5-oxo-2*H*-furo[3,2-b]pyrrol-6-yl ring system and its substituted and conjugated *E*,*E*,*E*,*E*,*E* pentaene moiety, which is unstable to acid, base, and light.

Along with lucilactaene (**1**), we isolated a known neuronal-cell-protecting compound, NG-391 (**2**),[4] which possesses the same pentaene portion but a different γ-lactam moiety, and which is probably biosynthesized from the same intermediate as **1**.[3] These natural products **1** and **2** are close structural relatives of fusarins A and C,[5] nonmutagenic metabolites of *Fusarium moniliforme*. Though the biosynthetic pathways that lead to **1** and **2** remain unclear, the following is a plausible pathway based on the proposed biosynthetic route to fusarin C:[5] The fully elaborated polyketide reacts with homoserine aldehyde by an intramolecular Knoevenagel reaction to form the unmodified 1,5-dihydropyrrol-2-one **3**, a possible common key intermediate of **1** and **2**, after cleavage of the thioester (NADPH reduction) and condensation (Scheme 1). In the case of NG-391 (**2**), the remaining steps are epoxidation and oxidation to form the hemiaminal, either by ether hydroxylation α to the nitrogen atom or oxidation to an imine and addition of water (the

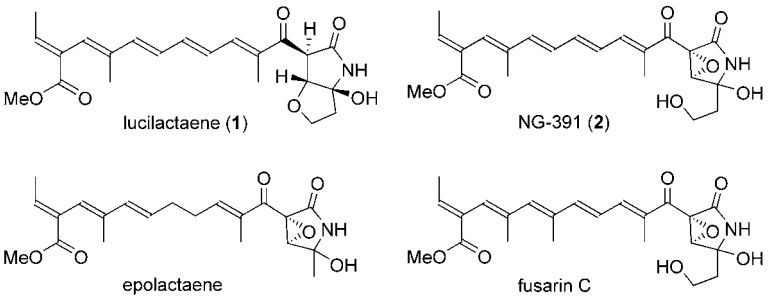
  DOI: 10.1002/anie.200500060

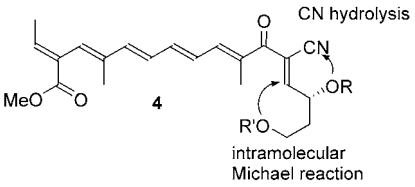


reactions might occur in the reverse order). In the case of lucilactaene (**1**), an intramolecular Michael reaction and oxidation to form the hemiaminal are the remaining reactions (again the order of reactions might be reversed). Another possibility for the biosynthesis of **1** is via **2** through intramolecular epoxide-ring opening by the primary hydroxy group, followed by reduction.

A similar side chain is also found in epolactaene, a neuritogenic compound isolated from the fungal strain *Penicillium* sp. BM-1689-P.[6] Clarification of the structure–activity relationships of lucilactaene (**1**), NG-391 (**2**), epolactaene, and their derivatives is highly desirable for elucidating their mechanism of action. We completed the first total syntheses of **2**[7] and epolactaene,[8] and developed a biologically more potent molecule, epolactaene tertiary butyl ester (ETB).[9] Recently, we revealed that both epolactaene and ETB bind to human Hsp60 and inhibit Hsp60 chaperon activity in vitro and in cultured cells,[9] whereas Kobayashi and co-workers reported that epolactaene is an inhibitor of mammalian topoisomerases α and β in vitro.[10]

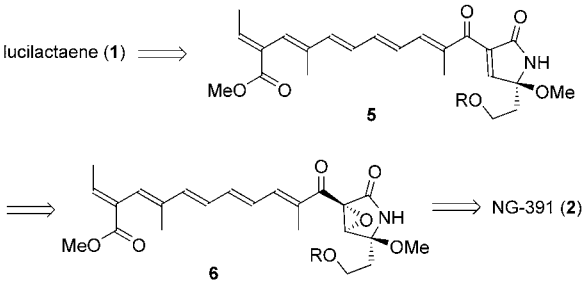
The absolute configuration of NG-391 (**2**) was determined by us by asymmetric total synthesis.[7] The optical rotation of lucilactaene (**1**) is zero in two different solvents (methanol and chloroform), which indicates the possibility that **1** is racemic. That **1** should be racemic appears strange when one considers its structural resemblance with **2**. Because of the interesting biological properties of **1**, its lability, and its rare structure, and because of the puzzle concerning its absolute configuration, we have investigated its asymmetric total synthesis by a biomimetic route.

On the basis of the proposed biosynthetic pathway, we planned to synthesize **1** from the key intermediate **4**, which corresponds to the key biosynthetic intermediate **3**. We had already synthesized **2** from **4**.[7] The remaining steps from **4** to lucilactaene (**1**) would be hydrolysis of the nitrile group, an intramolecular Michael reaction with the hydroxy group (R′ = H) as the nucleophile, and functional-group transformations (Scheme 2). However, all attempts, including changing of the order in which the reactions were carried out, were unsuccessful.



Scheme 2. Proposed synthetic approach to lucilactaene from **4**.

We therefore considered an approach to **1** from NG-391 (**2**)[7] (Scheme 3). The formation of methyl ether **6**, followed by reductive removal of the epoxide to give an alkene **5**, an intramolecular Michael reaction, and deprotection would afford lucilactaene (**1**). For this approach to be successful the reactions would have to proceed under mild conditions to avoid decomposition of the labile pentaene moiety. Methyl ether formation and the Michael reaction must proceed with



Scheme 3. Retrosynthetic analysis of lucilactaene.

high diastereoselectivity for **1** to be generated with high enantiomeric excess.

The methyl ether was formed stereoselectively by the treatment of **2** with a catalytic amount of $TsOH{\cdot}H_2O$ in MeOH to afford β-methoxide **7** as a single isomer in which methanol had captured the acyliminium ion intermediate from the opposite face to that occupied by the epoxide (Scheme 4).[11] The next planned transformation was the reductive removal of the epoxide. Although SmI_2 is known to convert α,β-epoxyketones into α,β-unsaturated ketones,[12] in this case reductive demethoxylation is faster than epoxide removal. When epoxylactam **7** was treated with SmI_2, a 5-(2-hydroxyethyl)-2-pyrrolidone derivative was formed. After some experimentation, it was found that the protecting group on the nitrogen atom of the amide affects the reactivity of the compound towards reductive demethoxylation. Thus, **7** was treated with Boc_2O in the presence of triethylamine and a catalytic amount of DMAP to give the bis-Boc-protected derivative **8** in 69% yield over two steps. The reductive removal of the epoxide with SmI_2 (2 equiv) now proceeded efficiently at low temperature without affecting the methoxy group to afford **9** in 75% yield. The two Boc protecting groups were then removed by treatment with CF_3CO_2H (TFA) in CH_2Cl_2 at room temperature, whereupon a spontaneous Michael reaction and the conversion of the methyl ether into a hydroxy group gave lucilactaene (**1**) in 28% yield, along with lucilactaene methyl ether (**10**) in 55% yield. Synthetic **1** exhibited identical spectroscopic properties to those of the natural product (^1H NMR, ^{13}C NMR, IR).

The optical rotation of this synthetic lucilactaene (**1**) was zero, identical to that of the isolated natural product and markedly different to that of **10** ($[\alpha]_D$ +36.6 ($c = 0.17$, MeOH)). Lucilactaene methyl ether (**10**) can also be converted into **1** in 60% yield by treatment with TFA in CH_2Cl_2; again the optical rotation of the product is zero. The large difference in optical rotation between **1** and its methyl ether **10** strongly suggests that the lucilactaene (**1**) formed is racemic. If racemization occurs during the synthesis, it must be during the final treatment with acid. To better understand the facile racemization of **1**, the synthesis of optically pure **1** was investigated.

To avoid possible racemization, the final cleavage of the hemiaminal protecting group should be conducted under neutral conditions. To this end we developed a novel deprotection method. When NG-391 (**2**) was treated with $PhSeCH_2CH_2OH$[13] in the presence of a catalytic amount of $TsOH{\cdot}H_2O$ in CH_2Cl_2 for 3 h at room temperature, phenylselenylethyl ether **11** was formed in 31% yield as a single isomer; **2** was recovered in 67% yield (Scheme 5). Although decomposition occurred upon longer treatment of **2** with acid, the repeated exposure of recovered **2** to acid led to its conversion into **11** in a high overall yield of 94%. Both the amide and the hydroxy groups were protected with Boc_2O to afford **12** in 73% yield. The sequence of steps involving reductive removal of the epoxide with SmI_2, removal of the Boc groups, and the Michael reaction proceeded as efficiently as for the methyl ether derivative **8** to afford the bicyclic compound **14** as a single isomer in 36% yield over two steps. The transformation of the 2-phenylselenylethoxy group into a hydroxy group could be carried out under mild reaction conditions in three novel steps: 1) The oxidation of the selenide to the selenoxide, which was isolated in good yield, proceeded smoothly at low temperature on treatment with dimethyldioxirane (DMD),[14] without affecting the pentaene moiety. 2) The elimination of benzeneselenenic acid occurred at 60 °C in the presence of dabco to provide vinyl ether **16**.[15] 3) Final oxidative removal of the vinyl substituent was performed under neutral conditions by the use of DMD at low temperature (−78 °C) to afford lucilactaene (**1**) in 56% yield from **15** *in optically pure form* ($[\alpha]_D$ +39.5 ($c = 0.10$, MeOH)).[16]

It is clear from the asymmetric total synthesis that isolated natural lucilactaene (**1**) is racemic. The facile racemization raises another question: There is the possibility that natural **1** is optically active but that racemization proceeds during the purification process. To investigate this possibility, it was necessary to isolate **1** under nonracemizing conditions. We

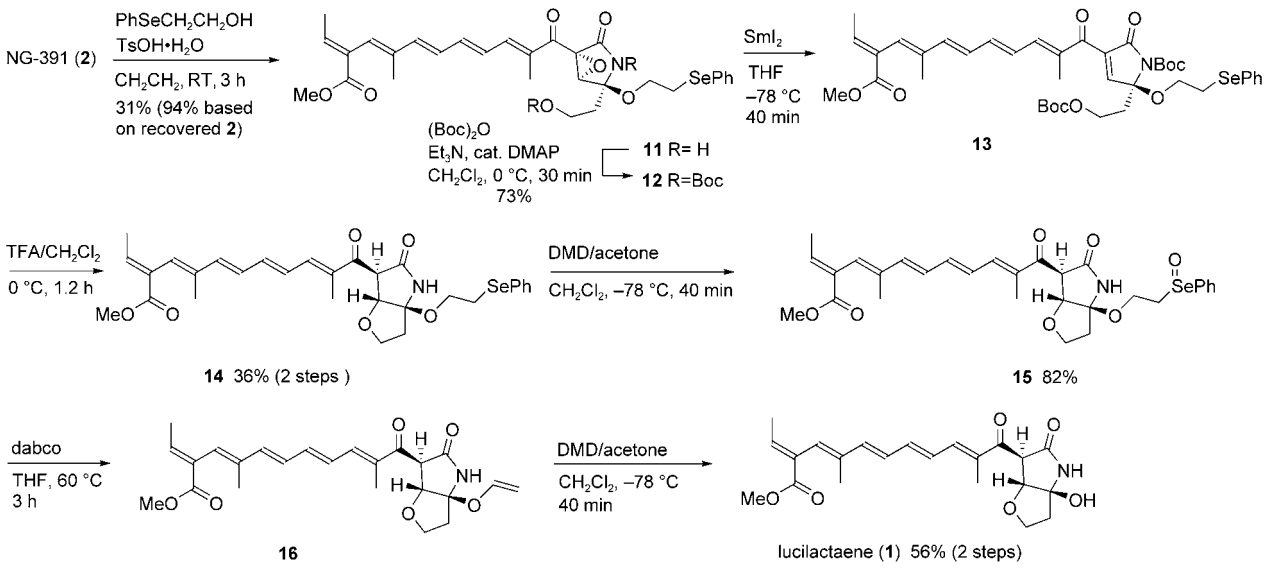

Scheme 5. Synthesis of optically pure lucilactaene; dabco = 1,4-diazabicyclo[2.2.2]octane.

chose to use bicycle **17** as a model compound to establish such conditions.

Optically pure **17**, prepared by the same method as that used for **1**, was treated with various reagents, and after a certain period of time the optical purity of the recovered **17** was measured by HPLC analysis on a chiral phase; the results are summarized in Table 1. Under weakly acidic or basic conditions, for example, in the presence of PPTS in MeOH or NEt_3 in CH_2Cl_2, no racemization was observed. However, racemization occurred when **17** was treated with TFA/CH_2Cl_2 or K_2CO_3 in MeOH. It was also confirmed that no racemization occurred in the medium in which the fermentation was carried out. These results indicate that the purification of lucilactaene (**1**) should be performed under nearly neutral, mild reaction conditions. The racemization might occur via intermediates such as **18** or **19**, which arise from a reversible retro-Michael reaction, followed by acyliminium ion formation or keto–amide formation, though the order of the reactions might be different (Scheme 6).

As information about the racemization under a variety of conditions had been obtained, the production profile of lucilactaene (**1**) by *Fusarium* sp. RK97-94 was investigated further. All experiments were performed as rapidly as possible, with the temperature and pH value controlled carefully. The ethyl acetate extracts of the broth (supernatant) and the mycelia, which were obtained by centrifugation, were prepared under mild conditions at pH 7.0. The production profile of **1** in the broth is summarized in Table 2. The optical purity of **1** in the broth was very low (ca. 10% *ee*) throughout the fermentation. Moreover, the lucilactaene (**1**) in the mycelia was also nearly racemic (data not shown).

As shown in Scheme 1, lucilactaene (**1**) and NG-391 (**2**) may be biosynthesized from the same intermediate **3**. Epoxidation and oxidation to form the hemiaminal produce **2**; these two reactions proceed in this order, as **2** would otherwise be racemic. The absolute configura-

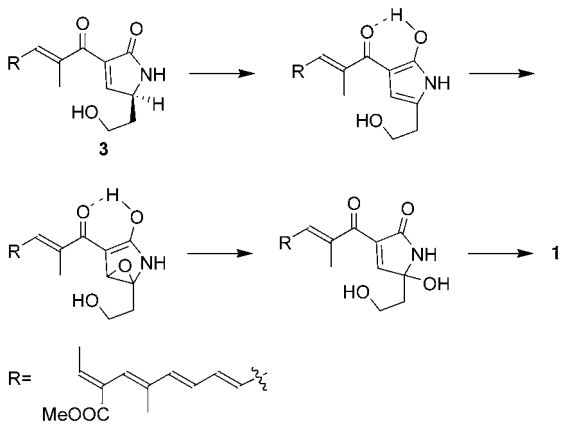
tion of the epoxide can also be explained reasonably as arising from the selective epoxidation from the opposite face to that with the hydroxyethyl substituent. In the synthesis of **1**, a Michael reaction and oxidation to form the hemiaminal are the remaining steps. Should the Michael reaction be the first step, then we suspect that racemization must occur during the subsequent oxidation step, because the internal Michael addition is a spontaneous reaction, as demonstrated for the synthetic conversion of **13** into **14** without racemization. That is, there is an acidic moiety in the enzyme responsible for this oxidation which causes racemization. If oxidation is the first step, a subsequent racemization process is conceivable (Scheme 7): Intermediate **3** may undergo tautomerism to a



Scheme 7. Possible racemization mechanism in the biosynthesis of lucilactaene.

2-hydroxypyrrole derivative, which could undergo epoxidation and isomerization. Racemization could occur via the achiral pyrrole tautomer. A subsequent Michael reaction would then afford racemic lucilactaene (**1**).

In summary, the labile natural product lucilactaene (**1**), which readily undergoes racemization, has been synthesized for the first time in optically pure form via a biomimetic pathway. The conditions under which racemization occurs were elucidated during this total synthesis. The careful isolation of lucilactaene (**1**) from both the broth and the mycelia under neutral, nonracemizing conditions demonstrated that the isolable natural product is in fact itself racemic. This total synthesis, which enabled verification of the absolute configuration of **1**, has several noteworthy features: All the reactions from NG-391 (**2**) are mild enough not to affect the labile *E*,*E*,*E*,*E*,*E* pentaene moiety; ether formation from **2** to **7** and **11** and the intramolecular Michael reaction from **9** to **10** or from **13** to **14** are both highly stereoselective; the reductive removal of the epoxide with SmI_2 without effecting demethoxylation, and the deprotection of a hemiaminal under neutral, oxidative conditions via vinyl ether **16** by using a newly developed phenylselenylethyl protecting group, are also useful transformations. Detailed biological studies on both enantiomers of lucilactaene are underway, the results of which will be reported in due course.

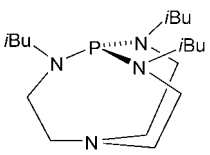
Arylation

One-Pot Sequential N and C Arylations: An Efficient Methodology for the Synthesis of *trans* 4-*N*,*N*-Diaryl Aminostilbenes**

*Mecheril V. Nandakumar and John G. Verkade**

N,*N*-Diaryl aminostilbenes and *N*,*N*-diaryl aminostyrenes are versatile compounds that have found exciting applications in the field of photochemistry; most of these compounds are patented and they are widely used as electro-photographic photoconductors and photoreceptors.[1] Recent reports have demonstrated, for example, that these compounds can exhibit an amino-conjugation effect in their fluorescence enhancement spectra[2] and can act as ionophores for transition metals,[3] and have several other applications.[4] The synthetic routes to these compounds begin from aniline and the corresponding aryl halides through a three-step process involving an Ullmann/Vilsmeier/Wittig[5] reaction sequence or from triphenylamine through a Vilsmeir/Wittig/palladium-catalyzed arylation sequence.[6] Recently, the synthesis of *trans* 4-*N*,*N*-diaryl aminostilbenes from the corresponding halostilbenes or aminostilbenes by palladium-catalyzed amination reactions has also been reported.[2,3]

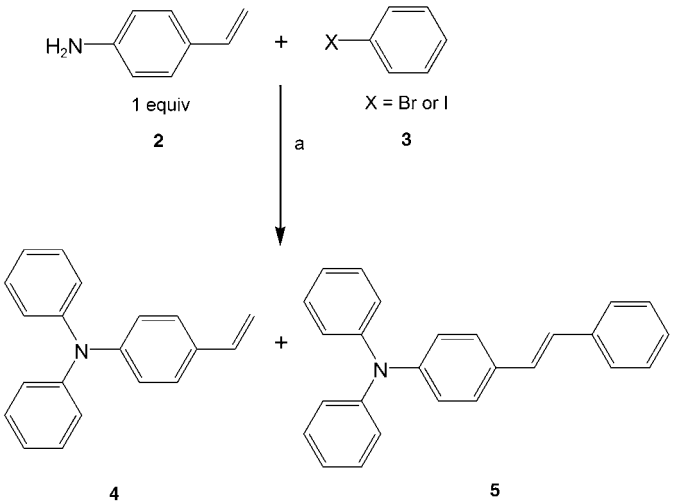
Palladium-catalyzed cross-coupling reactions, facilitated by a variety of ligands, are exceedingly powerful and reliable methods for C–C[7] and C–heteroatom[8] bond formations and have a vast number of applications in the pharmaceutical,[9] dye,[10] agriculture,[11] and polymer[12] industries. In recent years, our studies of commercially available proazaphosphatranes,[13] such as **1**, which were first synthesized by us, have shown them to be efficient ligands in palladium-catalyzed N arylations[14] and the Suzuki[15] and Stille[16] couplings. The substrates for these coupling reactions included aryl chlorides, which encompassed electron-poor, neutral, and electron-rich examples. Moreover, proazaphosphatranes can also function as strong non-ionic stoichiometric bases that facilitate a variety of useful organic transformations.[17]



1

Herein, we report a one-pot synthesis of *trans* 4-*N*,*N*-diaryl aminostilbenes from commercially available starting materials using a double Buchwald–Hartwig amination/intermolecular Heck reaction sequence in the presence of $[Pd_2(dba)_3]$/**1** (dba = dibenzylideneacetone) as the catalytic system. Recently, transition-metal-catalyzed sequential C–C and C–heteroatom bond-forming reactions have attracted synthetic chemists because of their ability to facilitate the formation of more than one bond in a one-pot reaction. Reports of palladium-catalyzed amination/intramolecular cyclization reaction sequences for the synthesis of indole derivatives[18] illustrate the importance of such coupling reactions. A one-pot two-catalyst synthesis of 1,3-diphenylindazoles using a combination of copper-catalyzed N-arylation and palladium-catalyzed C-arylation reactions has also been reported.[19] To the best of our knowledge, a one-pot double amination/intermolecular Heck reaction sequence has not been described to date. Herein, we present the preliminary results of such a one-pot protocol.

Our studies commenced with the coupling of 4-aminostyrene with bromobenzene under the conditions given in Scheme 1. Optimization studies were carried out (Table 1),



Scheme 1. a) $[Pd_2(dba)_3]$ (2 mol%), **1** (4 mol%), NaO*t*Bu (3.5 equiv), aryl halide (3.2 equiv), dry toluene (10 mL), under argon atmosphere.

and it was initially found that when the reaction was carried out at 60 °C with ligand **1** over 3 h (entry 1), the only coupling observed was a double amination (product **4**); the Heck reaction required a minimum of 110 °C for the protocol to be efficient (entry 3). When iodobenzene was used instead, the Heck reaction occurred at 100 °C (entries 7 and 8) but faster conversion was realized at 110 °C (entry 9). In addition, other phosphines, such as davephos (2-dicyclohexylphosphino-2′-(*N*,*N*-dimethylamino)biphenyl), tBu_3P, and *rac*-binap (2,2′-

[a] Yield of isolated product. [b] Reported yield for a two-step, two-pot synthesis.[2]

bis(diphenylphosphino)-1,1′-binapthyl), were found to be inefficient ligands (entries 4–6 and 10–12).

Next, we examined the coupling of a variety of aryl bromides and iodides with 4-aminostyrene to test the generality of this methodology (Table 2). The major products formed were *trans N*,*N*-diaryl aminostilbenes **5**, except when 4-bromoanisole and 3-bromoanisole were the substrates (entries 5 and 6, respectively). The yields of **5** from 4-bromotoluene and 4-iodotoluene as the substrates (entries 1 and 9, respectively) were similar to those reported previously,[20] whereas the yields of **5** from 4-bromoanisole and 4-iodoanisole were poor (entries 5 and 8). On the other hand, the yields of **5** from 4-bromotoluene and 4-iodotoluene (entries 1 and 9) were superior to the overall yield (55%) from a three-step procedure involving an Ullmann/Vilsmeier/Wittig reaction series.[20,21] All other products derived from this reaction series have not been previously reported (entries 2–4, 6 and 7).

It is evident from the results of optimization experiments given in Table 1 that the reaction pathway to **5** is a double amination followed by an intermolecular Heck reaction. As the amination reactions were completed within 3 h at 60°C and the Heck reactions required an elevated temperature and a longer reaction time, we were able to utilize this difference in coupling activity for the one-pot synthesis of **5** with two identical aryl groups at the nitrogen atom and a different one at the opposite terminus of **5** (Scheme 2). The first step of this one-pot procedure afforded the bisamination product in three hours, as monitored by TLC. The addition of 4-bromotoluene (1.2 equiv) in the second step afforded **6a** in very good yield. Reaction of 4-aminostyrene with 4-bromoanisole and bromobenzene under the same conditions gave the analogous product **6b** in moderate yield (Scheme 2). Our yield of **6a** (86%) is comparable to that reported in a patented procedure (89%) involving the single-step reaction of 4-methyldiethylbenzylphosphonate with 4-*N*,*N*-diphenylaminobenzaldehyde.[22a] However, our yield of **6a** is substantially better than the yield achieved through a Wittig reaction of 4-methylbenzyltriphenylphosphonium chloride with the aforementioned aldehyde (72%)[22a] and the overall yield (46%) of a previously reported three-step synthesis.[22bc] Although **6b** has been reported previously, no yield was given.[1]

In a similar manner, unsymmetrically *N*-substituted diaryl aminostilbenes **7a,b** were synthesized in very good yields by using aryl iodides instead of aryl bromides

Table 2: One-pot double amination/intermolecular Heck reactions of 4-aminostyrene with aryl bromides and aryl iodides.

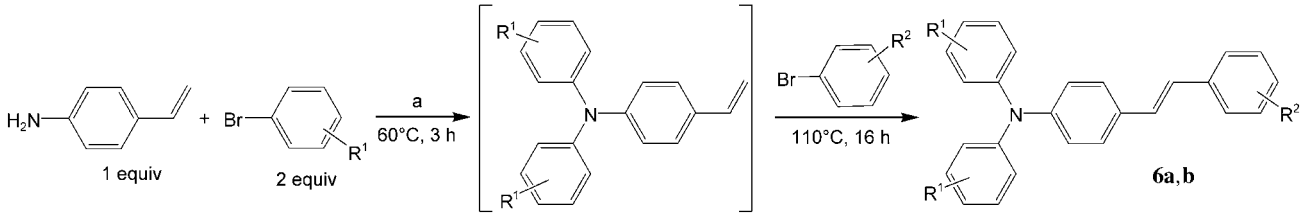
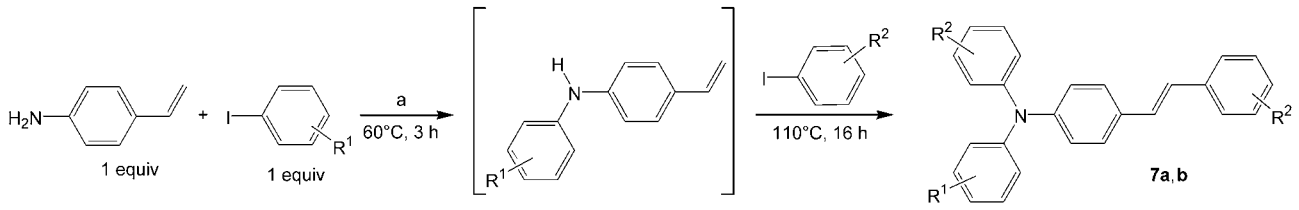
[a] Yield of isolated product. Reaction conditions: $[Pd_2(dba)_3]$ (2 mol%), **1** (4 mol%), NaO*t*Bu (3.5 equiv), aryl halides (3.2 equiv), dry toluene (10 mL), 110°C, 16 h, under argon atmosphere. [b] Reported yield.[20]



Scheme 2. a) $[Pd_2(dba)_3]$ (2 mol%), **1** (4 mol%), NaO*t*Bu (3.5 equiv), dry toluene (10 mL), in an argon atmosphere. **6a**, $R^1 = H$, $R^2 = CH_3$ (86%); **6b**, $R^1 = 4\text{-OMe}$, $R^2 = H$ (60%).



Scheme 3. a) $[Pd_2(dba)_3]$ (2 mol%), **1** (4 mol%), NaO*t*Bu (3.5 equiv), dry toluene (10 mL), in an argon atmosphere. **7a**, $R^1 = CH_3$, $R^2 = H$ (78%); **7b**, $R^1 = 4$-OMe, $R^2 = H$ (79%).

(Scheme 3). Our yield of 78% for **7a** is lower than that of a previously reported synthesis involving the reaction of 4-(*N*-(4-methylphenyl)-*N*-phenylamino)benzaldehyde and diethylbenzylphosphonate (91%).[1] It should be noted that this higher yield was achieved in a single reaction involving two reactants, one of which required prior synthesis. When this requirement is taken into consideration, the overall yield is 50%[21] compared with our yield of 78% from a one-pot procedure. Although **7b** has been reported previously, no yield was given.[1]

In summary, we have developed a novel one-pot methodology for the synthesis of *trans* 4-*N*,*N*-diaryl aminostilbenes **5**, which hitherto have always been synthesized in multipot processes. It is also of note that: 1) the same catalyst system is used for both the amination and the intermolecular Heck coupling in a loading that is quite low (2 mol% of $[Pd_2(dba)_3]$ and 4 mol% of the ligand); 2) ligand **1** is superior to others in our protocol and is commercially available; 3) selective coupling of aryl halides with the nitrogen atom and the double bond of the styrenyl substrate can be achieved in a one-pot reaction by merely adding aryl halides sequentially at different temperatures. This strategy has significant potential for the design and synthesis of many complex molecules and for combinatorial libraries in which moieties with both C–N and C–C bonds are present; 4) higher overall yields than those reported previously have been achieved; 5) the reduction in the number of steps in such syntheses permit these types of transformations to be potentially more economical and environmentally friendly. Studies are under way with heteroaryl halides and additional aryl halides (including chlorides) as reagents in the methodology reported herein and will be reported in due course.

Nucleic Acids

Assembly of the Complete Eight-Base Artificial Genetic Helix, xDNA, and Its Interaction with the Natural Genetic System**

*Jianmin Gao, Haibo Liu, and Eric T. Kool**

Much recent research has focused on the design of new base pairs that function in natural DNA.[1–11] Beyond this, a few recent studies have begun to explore the possibility of replacing *all* the base pairs of DNA, an approach which may eventually lead to entirely new genetic systems.[12–22] In addition to testing the limits of human-designed biological systems, such work might shed new light on the influence of base pairs on the storage and transfer of genetic information in DNA. Moreover, the resulting DNA-like molecules may be useful as experimental probes of physical interactions in enzyme active sites and at protein–DNA interfaces.

Toward these ends, a recent report described the pairing of benzo-homologated forms of adenine (xA) and thymine (xT) with natural thymine and adenine, respectively, to form a right-handed helical complex with a diameter approximately 2.4 Å larger than that of natural DNA.[12] The study revealed that in some cases these expanded DNA (xDNA) duplexes are more stable than the analogous sequence of natural DNA. Another report described the preparation and properties of the analogously expanded forms of cytosine and guanosine (xC and xG) as well.[16] All four expanded nucleobases were found to be inherently fluorescent, which makes them potentially applicable as biophysical tools.

The combination of the four natural bases with their four expanded analogues—potentially yielding an eight-base artificial pairing system—has not been tested; this is of interest in part because of the large information storage and processing potential of such a molecular system.[23–28] Furthermore, the concept of interfacing the artificial xDNA genetic system with the natural one is intriguing, as the larger helices may have enhanced stability and inherent fluorescence. Targeting natural DNA or RNA sequences would require combination of the full set of four xDNA bases on one strand, which has not yet been explored. With these possibilities in mind, we describe herein the first studies of the full set of xDNA genetic building blocks.

We employed previously described methods to prepare the four xDNA deoxyribosides (Figure 1) as suitably protected phosphoramidite derivatives.[12,16,29] These were incorporated into a number of oligomeric sequences for testing helical assembly properties. Sequences contained the eight bases xC, xG, xA, xT, C, G, A, and T in various combinations (Table 1 and Supporting Information). The stability of the resulting helices was evaluated by optically monitored thermal denaturation; curve fitting and concentration studies were used to derive estimates of free energy (Supporting Information). Buffers contained Na·PIPES (10 mM, pH 7.0), Na^+ (100 mM) and Mg^{2+} (10 mM). CD spectra of putative helices (and DNA controls) were also recorded (Supporting Information).

The initial results with four different eight-base contexts revealed stable self-assembly into bimolecular complexes. Table 1 shows data for these first sequences. The thermal melting experiments revealed apparent all-or-none melting behavior and sigmoidal transitions that are similar in shape to those of the corresponding DNA control helices, but with generally higher transition temperatures (T_m) (Figure 2). The three strongest xDNA complexes gave increases in T_m (12–21 °C) as well as in estimated free energy (2.3–3.0 kcal mol^{-1} at 37 °C) relative to the native DNA helices. These three sequences include two cases in which xDNA bases were scattered on both strands, and one in which they were present on one strand only. The remaining sequence context (Figure 2d) also restricted the xDNA bases to one strand, but was further specialized, as purine and pyrimidine bases were segregated to opposite ends of each strand. Thermal stability in this case was slightly (2.9 °C) lower than that of the corresponding native DNA sequence, and the estimated free energy fell within experimental error of the control. The stoichiometry of the complexes was tested with mixing experiments in which the molar ratios of strand pairs were varied in regular increments. Plots for three of the sequence contexts are available in the Supporting Information; changes in absorbance for the fourth sequence were too small to yield reliable data. The results for the three plots gave strand stoichiometry values of 0.50:0.50, 0.45:0.55, and 0.49:0.51. Thus the data were most consistent with a double-stranded stoichiometry in all three complexes. However, as the hyper- and hypochromicity values were small, the stoichiometric assignments should be considered preliminary.

The success of the natural DNA genetic system rests not only in its ability to form double helices, but importantly, in its

[a] Benzo-homologated bases are represented in boldface; native DNA controls are shown for each sequence; entries 5 and 6: xDNA–RNA duplexes in which the RNA strand bases are italicized. Conditions: NaCl (100 mM), $MgCl_2$ (10 mM), and Na·PIPES (10 mM, pH 7.0). All DNA and xDNA sequences are 3′-phosphorylated (omitted for clarity). [b] Oligonucleotide concentration = 5.0 μM. [c] Averages of values from van't Hoff and curve-fitting methods.

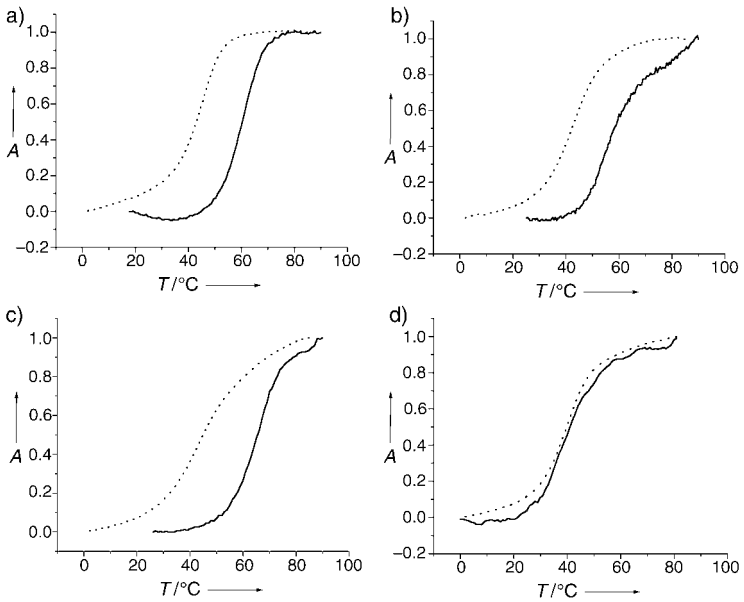

Figure 2. Normalized thermal denaturation plots for four different expanded DNA duplexes: a) d(xAxTCAxCTxGxTGCp)·d(xGxCACxAGxTxGATp) versus d(ATCACTGTGCp)·d(GCACAGTGATp); b) d(xAxCxGxTxTxAxGxTxCxGp)·d(CGACTAACGTp) versus d(ACGTTAGTCGp)·d(CGACTAACGTp); c) d(xTGxTAxCxGCxAxGTp)·d(xACTxGCGxTAxCAp) versus d(TGTACGCAGTp)·d(ACTGCGTACAp); d) d(xTxCxTxTxCxGxGxAxAxGp)·d(CTTCCGAAGAp) versus d(TCTTCGGAAGp)·d(CTTCCGAAGAp) for which the xDNA data were smoothed from five adjacent points to minimize noise from the small change in absorbance. Experimental conditions for data from both xDNA (——) and natural DNA (----): oligonucleotide (5 μM), NaCl (100 mM), $MgCl_2$ (10 mM), Na·PIPES buffer (10 mM, pH 7.0).

ability to do so with high specificity in sequence recognition. Thus it was of interest to test whether expanded-diameter xDNA helices could also exhibit sequence discrimination. This was done by evaluating the thermal stability of all possible natural-base mismatches of the four expanded bases. Figure 3 shows data from the analysis of all four matched pairs and the twelve possible mismatches. The same set of measurements were taken with native DNA as a control, so that a direct comparison of base-mismatch selectivities could

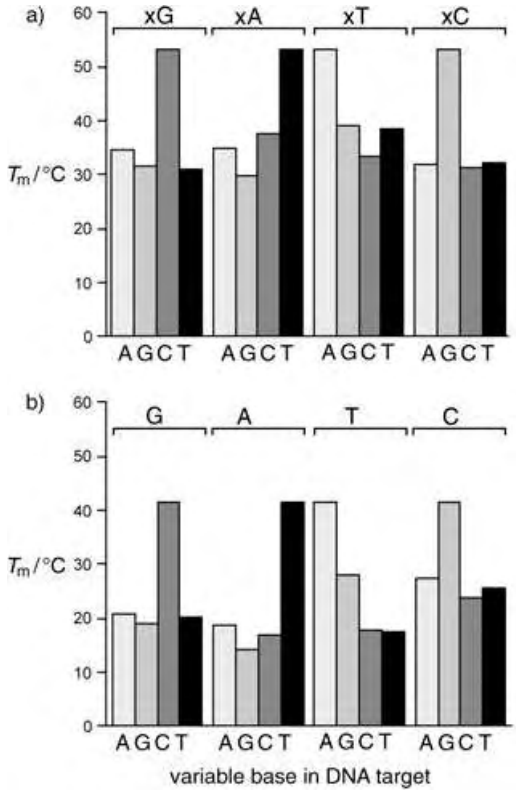

Figure 3. Histograms showing similar sequence selectivity for a) xDNA and b) native DNA of analogous sequence. Thermal melting temperatures are shown for singly mismatched and matched sequences in the context of a decamer duplex. (Details and conditions provided in Supporting Information).

be made (numerical data available in Supporting Information).

The results show that the four xDNA bases have surprisingly similar mismatch selectivity as natural DNA. Remarkably, the overall profiles of relative selectivities of xDNA had almost the same shape as those of native DNA double helices (Figure 3), which indicates that the two have similar mismatch preferences. The data show T_m values that are decreased by 13.9–23.4 °C for single xDNA mismatches, which are nearly the same as the respective decreased T_m range of 13.6–24.5 °C for mismatched bases in natural DNA. Therefore, oligonucleotide strands composed entirely of the four xDNA bases can recognize naturally structured DNA with high sequence selectivity and with high affinity.

In a search for evidence of helicity, CD was performed on all four double-stranded xDNA complexes (sequences shown in Table 1) in addition to the analogous DNA sequences as a comparison (Supporting Information). The xDNA spectra were clearly different from those of the control DNA, and also varied from sequence to sequence. Because the benzo-expanded DNA bases are electronically different from natural nucleobases, the excitonic interactions with stacked neighbors are different. However, CD spectra did reveal induced chirality in the xDNA that is consistent with helical complexes. An early structural study of a two-base xDNA system showed right-handed helicity,[17] which suggests that the present complexes also likely adopt a right-handed form. The variability in the xDNA spectra may arise from the fact that the sequences are complex: there are 64 possible nearest neighbors in this eight-base system (compared with only 16 in DNA). Thus these short xDNA sequences vary much more than native DNA in nearest-neighbor composition, which results in different electronic interactions.

Finally, full xDNA strands were tested for their ability to bind complementary RNA sequences. This was tested preliminarily in two all-xDNA strand contexts (Table 1, entries 5 and 6). Note that incorporation of the expanded bases into both strands of the duplexes was not possible, as "xRNA" nucleosides are not yet available. Representative denaturation curves for the xDNA–RNA complexes are given in the Supporting Information. The data showed clearly that both xDNA strands formed the predicted complexes with the decamer RNA target strands. In one case the xDNA–RNA complex was slightly more stable than the analogous DNA–RNA control, with an increase in T_m of 5.2 °C. In the other context, the thermal stabilities of the xDNA–RNA and DNA–RNA complexes were equal. Overall, the xDNA–RNA complexes were less stable than xDNA–DNA complexes (Table 1), which suggests that the expanded helices may prefer a B-like over an A-like helical conformation.

To our knowledge, this is the first report of a new genetic form that encodes as many as eight fundamental units of information. Previous studies from other research groups have focused on new hydrogen-bonded base pairs that are designed to function within the context of the natural genetic system.[1,5] Such artificial pairs, of which isoC–isoG and kappa–pi are examples, have been shown to pair selectively in naturally structured oligonucleotides.[30] Recent experiments with DNA polymerases have shown that such pairs may be replicated with sufficient selectivity to function properly in PCR amplifications.[31] The work reported herein is distinct from that precedent in two primary ways: first, all the current size-expanded base pairs adopt a structure that differs from the natural purine–pyrimidine base-pair structure, and second, the system presented herein is designed in its entirety, whereas the previous systems were meant to function in the natural context.

The current experiments illustrate a way for the xDNA artificial genetic system to interface with the natural biological genetic system. In the design of xDNA, the large base homologs can either be distributed among both strands (to yield the eight-base system described above), or they can be segregated into one of the two strands. In the latter scenario, the non-expanded strand is composed of natural DNA or RNA. The present results have confirmed for the first time that xDNA can recognize natural DNA and RNA in a sequence-dependent manner.

Finally, the eight-base xDNA design may lend itself to the storage and transfer of high-density information. Recent experiments have shown that natural DNA can be useful in encoding structural and computational information in designed nanostructures, computing systems, and machines.[23–28,32–39] The sequence complexity of natural DNA scales with 4^n, in which n = sequence length, whereas that of xDNA scales with 8^n. Thus the information density of xDNA is 2^n greater; for example, there are 262144 possible

hexamer sequences of xDNA, and only 4096 hexamer sequences of DNA. This high information density may be useful for data encryption and processing,[23–28] and in assembled structural designs of greater complexity than can be generated with DNA.

Experimental Section

The deoxynucleoside phosphoramidite derivatives of the four benzo-homologated nucleosides were prepared as described previously.[16,29] For synthesis of oligomers, the eight nucleosides described herein (Figure 1) were incorporated into oligonucleotides with automated solid-phase methods. All xDNA and DNA control sequences contained a 3′ phosphate group to avoid the need for eight different support resins, and were prepared with a "3′-phosphate-ON" controlled-pore glass support (Glen Research). Oligonucleotides were synthesized on an Applied Biosystems 392 DNA/RNA synthesizer in the trityl-off mode with standard β-cyanoethylphosphoramidite chemistry. Prolonged coupling times were used, which gave average stepwise yields of $>93\%$ by trityl monitoring. After synthesis, oligonucleotides were deprotected and removed from solid supports in the conventional manner. Oligomer products were purified by HPLC and quantified by UV/Vis absorption. Molar extinction coefficients were calculated by the nearest-neighbor method,[40] and those for oligonucleotides containing artificial residues were calculated by adding the extinction coefficient of the artificial nucleoside to the that of the core duplex. Previous reports have confirmed that the four modified xDNA nucleotides can be incorporated intact into oligonucleotides.[12,14,16] To confirm this for our work, we characterized two sequences by MALDI-TOF mass spectrometry: one with all four modified bases and the other with all eight bases, and the expected masses were observed. RNA oligonucleotides were purchased from Dharmacon. They were deprotected according to the manufacturer's protocol, then purified with denaturing preparative gel electrophoresis.

Thermal denaturation studies were conducted with sample concentrations that ranged between 1 and 40 μM in volumes of 1 mL in NaCl (100 mM), $MgCl_2$ (10 mM), and Na·PIPES (10 mM, pH 7.0). Solutions were then heated at 90 °C for 5 min and annealed by slow cooling to room temperature and then to 0 °C. Melting studies were carried out in teflon-capped quartz cells (path length = 1 cm) under N_2 atmosphere on a UV/Vis spectrophotometer (Varian Cary 1) equipped with a Peltier temperature controller. Absorbance was monitored at $\lambda = 320$ nm (xDNA) or $\lambda = 260$ nm (control DNA) during a temperature increase from 5 to 90 °C at a rate of 0.5 °C min^{-1}.

Melting temperatures (T_m) were determined by computer fit (Meltwin 3.5) of the first derivative of absorbance with respect to $1/T$. Uncertainty of T_m is estimated at ± 0.5 °C based on repetitions of experiments. Free energy values were estimated with two methods: 1) computer-fitting denaturation data with an algorithm that employs linear sloping baselines by using the two-state approximation for melting, and 2) van't Hoff thermodynamic parameters derived from linear plots of $1/T_m$ as a function of $\ln(C_T)$ by measuring T_m at varied concentrations (C_T = total DNA concentration). Values shown are averages from these two methods. They should be considered preliminary estimates only, as they rely on the assumption of a constant heat capacity (Cp) value,[41] which is not known to be the case for xDNA.

Cluster Compounds

Polyhedral Vanadium Oxide Cages: Infrared Spectra of Cluster Anions and Size-Induced d Electron Localization**

Knut R. Asmis, Gabriele Santambrogio, Mathias Brümmer, and Joachim Sauer**

The size-dependent properties of transition metal oxide clusters have been intensely studied not only because of interest in this peculiar state of matter, but also because of their relevance as building blocks for nanostructured materials. Vanadium oxides, in particular, are important in supported catalysts,[1] as cathode materials in lithium batteries,[2] in bolometric detectors,[3] and as ferromagnetic nanotubes.[4] While the structural characterization of vanadium oxide clusters deposited on surfaces[5] has reached atomic resolution, it remains a major experimental challenge in the gas phase.[6] Infrared photodissociation[7] paired with quantum chemistry is currently the most generally applicable approach for cluster ions even though it requires intense and tunable infrared radiation sources. Below 2000 cm^{-1}, in the fingerprint region of metal oxide clusters, only free-electron lasers meet these demands.[8]

Herein we report the first experimental infrared spectra of transition metal oxide cluster anions in the gas phase. We combine infrared multiple photon dissociation (IRMPD) spectroscopy with density functional theory (DFT) to characterize the geometric and electronic structures of a representative series of vanadium oxide cluster anions, $(V_2O_5)_n^-$ ($n = 2$, 3, or 4).[9] Compelling evidence is produced that these anions have the polyhedral cage structures that have been predicted before, but have eluded spectroscopic detection until now.[10,11] Evidence is also found for a size-induced localization of the extra electron in this series of anions.

The IRMPD spectra of mass-selected $V_4O_{10}^-$, $V_6O_{15}^-$, and $V_8O_{20}^-$ are shown on the left in Figure 1. They were measured by irradiating vibrationally cold, mass-selected parent ions with intense, tunable IR radiation from the free-electron laser FELIX[12] and monitoring the mass-selected fragment ion yield as a function of laser wavelength. Only when the radiation is resonant with a fundamental vibrational transition can the cluster ions absorb photons, thereby initiating a sequential multiphoton absorption process[13] which leads to heating of the cluster ion and eventually to photodissociation. The simplicity of the $V_4O_{10}^-$ spectrum is striking and immediately suggests a structure of higher symmetry with degenerate transitions. The dominant feature is a single, rather narrow intense band at 990 cm^{-1}. Based on our previous measurements on vanadium oxide cluster cations it is assigned to a vanadyl stretching mode.[14] The weaker signal below 750 cm^{-1} is attributed to a V–O–V stretch. The IRMPD spectrum of $V_8O_{20}^-$ is markedly different. While the vanadyl band stays nearly unchanged, a new band, much broader and roughly four times stronger than the vanadyl band, is observed centered at 870 cm^{-1}. The appearance of the $V_6O_{15}^-$ spectrum is intermediate between the spectra described above. An intense vanadyl band, somewhat broader and red-shifted, is followed by a four times less intense band at 830 cm^{-1}. No signal is observed below 700 cm^{-1} for the two larger clusters.

To understand these vibrational spectra we performed DFT calculations (B3LYP functional[15,16]) of cluster geometries and vibrational spectra (see Figure 1). All three anions are open-shell systems with a single unpaired electron. For $V_4O_{10}^-$ we find a tetragonal D_{2d} structure (**1**) which is minimally Jahn–Teller distorted from the T_d structure. Each vanadium atom is fourfold coordinated, forming one short V=O bond (159 pm) and three V–O bonds (181 pm). The four symmetry-equivalent vanadyl bond stretches combine to give three IR-active b_2 and e modes, which are quasi-degenerate and explain the single intense vanadyl band in the IRMPD spectrum. The six symmetric V–O–V bond stretches also give rise to three IR-active e and b_2 modes (629 and 609 cm^{-1}, respectively), and they have a cumulative oscillator strength that is about 1/3 that of the vanadyl bands, in good agreement with experiment. The modes resulting from the six antisym-

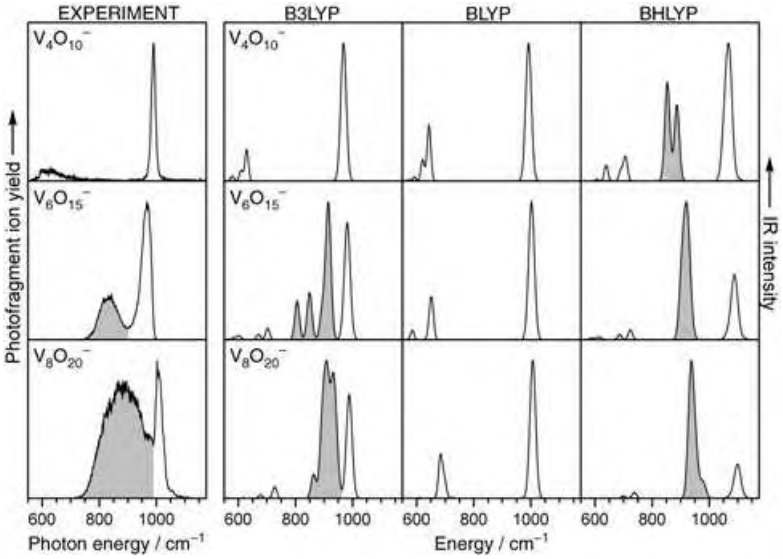

Figure 1. Experimental and simulated vibrational spectra of vanadium oxide cluster anions in the region of the V–O and V=O bond stretch modes. IRMPD spectra (left) of $V_4O_{10}^-$, $V_6O_{15}^-$, and $V_8O_{20}^-$ were measured from 550 to 1175 cm^{-1} by monitoring the dominant fragmentation channel, which leads to the formation of $V_3O_8^-$, $V_4O_{10}^-$, and $V_4O_{10}^-$, respectively. Simulated spectra (right) were obtained from scaled harmonic frequencies and oscillator strengths employing the B3LYP, BLYP, and BHLYP functionals. The calculated stick spectra were convoluted for better comparison with the experiment. Gray shaded peaks indicate localization of the unpaired d electron (see text).

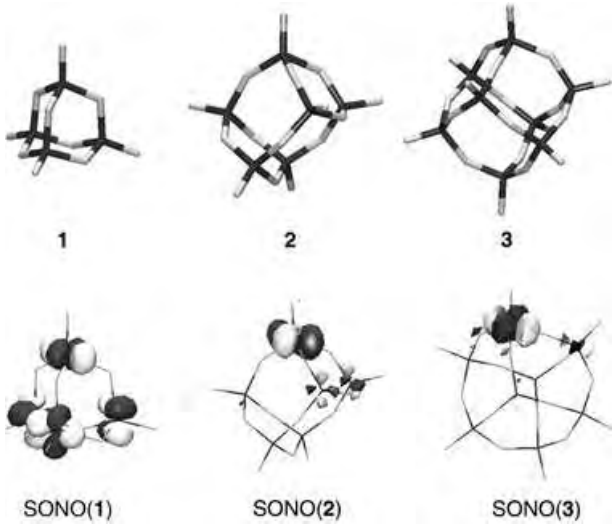
metric V–O–V bond stretches are below 600 cm^{-1} and have vanishingly low intensities.



In $V_4O_{10}^-$ the unpaired electron is completely delocalized over d-states of all four vanadium sites, as illustrated by its singly-occupied natural orbital SONO(**1**). In contrast, in the larger anions the unpaired electron is localized at a single vanadium site, which lowers the symmetry of their structures to C_s. For $V_6O_{15}^-$ and $V_8O_{20}^-$ we find the distorted trigonal prism and cube structures **2** and **3**. Their singly occupied natural orbitals, SONO(**2**) and SONO(**3**), reflect the localization of the unpaired electron. Compared to $V_4O_{10}^-$, the average V–O(–V) bond distances in $V_8O_{20}^-$ are longer at the electron localization site (189 pm), but shorter at the other sites (177–178 pm), while the V=O bond distances are similar and not affected by the localization. Unlike the closed-shell neutral parent compounds, the D_{3h} structure (trigonal prism) of $V_6O_{15}^-$ and the D_{2d} structure (cube) of $V_8O_{20}^-$ are higher-order saddle points that are 45 and 21 kJ mol^{-1}, respectively, above the ground state. For both $V_6O_{15}^-$ and $V_8O_{20}^-$ first-order saddle points with C_{2v} symmetry are found 9.8 and 8.7 kJ mol^{-1}, respectively, above the ground state. They represent transition structures for the interconversion of two equivalent C_s-minimum structures and have the additional electron delocalized over two sites.

The effects of symmetry breaking are directly observed in the vibrational spectra of these species (indicated by the gray-shaded area in Figure 1). Upon localization of the unpaired electron intense V–O–V stretch transitions appear at around 100–200 cm^{-1} below the strong vanadyl band, which replace the weak V–O–V feature more than 350 cm^{-1} below the vanadyl band in the spectrum of the delocalized case ($V_4O_{10}^-$). The calculated ratio of the cumulative oscillator strengths of the V–O–V modes and the V=O modes is 3.3 for $V_8O_{20}^-$ and 0.3 for $V_4O_{10}^-$; these values compare well to the experimental values of 4.4 and 0.4 respectively. The vanadyl modes are not affected by the electron localization and therefore their position and width remain nearly unchanged. Comparison with the experimental infrared spectra confirms the general predictions of the B3LYP model, in particular the pronounced, qualitative changes upon electron localization when the size of the cluster is increased.[17]

Figure 1 shows not only the B3LYP results discussed so far, but also the results of DFT calculations with the BLYP[16,18] and BHLYP[16,19] functionals. The increasing admixture of Fock exchange (0, 20, and 50% in BLYP, B3LYP, and BHLYP, respectively) leads to an increasing tendency for symmetry breaking.[20–22] BHLYP (right column in Figure 1) yields localization of the unpaired electron for all three cage-type anions, and also for $V_4O_{10}^-$. Consequently, the calculated BHLYP spectrum of $V_4O_{10}^-$ shows additional bands between 800 and 900 cm^{-1} that are absent from the experimental spectrum. In contrast, BLYP predicts delocalization of the unpaired electron for all three cage-type anions studied and C_{2v} and D_{2d} structures become the ground states of $V_6O_{15}^-$ and $V_8O_{20}^-$, respectively. All three BLYP spectra show no bands between 750 and 950 cm^{-1}, which is in clear contrast with the experimental spectra of $V_6O_{15}^-$ and $V_8O_{20}^-$. In summary, Figure 1 shows that only B3LYP reproduces correctly the transition from symmetric (delocalized) to broken-symmetry (localized) structures when passing from $V_4O_{10}^-$ to $V_6O_{15}^-$ in this series of $(V_2O_5)_n^-$ cluster anions.

Figure 2 compares the gas-phase IRMPD spectrum of $V_8O_{20}^-$ with the electron energy loss spectrum of a V_2O_5

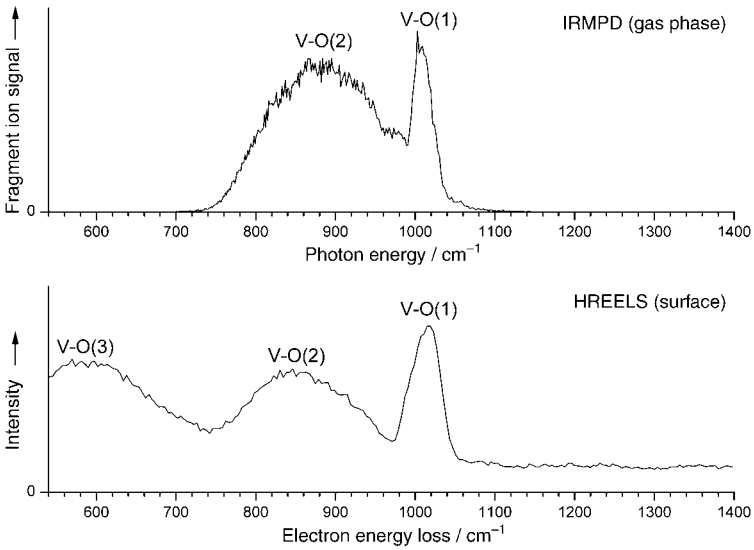


Figure 2. Vibrational spectra of different forms of vanadium oxide: The IRMPD spectrum of the gas-phase cluster anion $V_8O_{20}^-$ (top) and the spectrum of a freshly cleaved 001 surface of V_2O_5 (bottom), measured by high resolution electron energy loss spectroscopy (see text).

surface,[23] which also probes vibrational states. The spectra are surprisingly similar in the region above 740 cm^{-1}, with both displaying two bands of similar width and relative intensity. Their assignment is identical, that is, to vibrational modes of singly and doubly coordinated oxygen atoms. The third broad band of the surface spectrum is not observed in the gas phase. This can easily be rationalized because this band is assigned[11,24] to triply coordinated oxygen sites, which do not exist in the $V_8O_{20}^-$ cluster anion. Hence, the vibrational spectra reflect clearly the common (V=O and V–O–V bonds) and the discriminating (triply coordinated O) structural features of gas-phase clusters and solid surfaces.[25,26]

In this communication the polyhedral cage structures of $(V_2O_5)_n^-$ clusters ($n = 2$, 3, 4) have been identified spectroscopically for the first time by IRMPD spectroscopy. We have also found evidence for size-dependent charge localization in these clusters. Symmetry-breaking localization is observed in many other chemical systems for the reverse process—creation of an electron hole.[21] For example, the electron hole created in quartz when doped with Al is not delocalized over all four oxygen sites of the AlO_4 defect site, but localized at one oxygen only.[22] The proper description of electron (hole) localization phenomena by DFT depends on the functional used. In the present case we use the measured IRMPD spectra as the criteria for selecting the proper functional and find that only B3LYP has the right admixture of Fock exchange to reproduce the size-dependent change from delocalized to localized d electron states in vanadium oxide cages correctly. Even though the largest cluster anion studied here, $V_8O_{20}^-$, is still rather small, it reveals some striking similarities with the properties of a vanadium oxide single-crystal surface, making it an interesting gas-phase model for surface adsorption and reactivity studies.

Experimental Section

The present experiments were carried out on a previously described tandem mass spectrometer–ion trap system.[27] Vanadium oxide clusters were prepared by pulsed laser vaporization of a vanadium rod in the presence of O_2 seeded in He. The beam of negative ions was collimated and mass-selected by a quadrupole mass filter. Mass-selected cluster ions were accumulated and cooled to 15 K in a linear radio-frequency ion trap. IR photodissociation spectra were obtained by photoexcitation of the trapped cold ions with pulsed radiation from the FELIX,[12] and subsequent monitoring of the mass-selective ion yield. A FELIX bandwidth (RMS) of less than 0.3% of the central wavelength and pulse energies up to 60 mJ per macropulse were used.

Unrestricted Kohn–Sham calculations were performed with TURBOMOLE.[28] Triple-zeta valence plus polarization basis sets (TZVP) were applied.[29] Harmonic vibrational frequencies were obtained from second analytic derivatives[30] and were scaled using standard procedures (see Supporting Information).

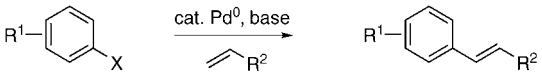
Oxidative Heck Reaction

Palladium-Catalyzed Intermolecular Alkenylation of Indoles by Solvent-Controlled Regioselective C–H Functionalization**

*Neil P. Grimster, Carolyn Gauntlett, Christopher R. A. Godfrey, and Matthew J. Gaunt**

Over the past three decades the Heck reaction has become one of the most fundamental metal-catalyzed C–C bond-forming processes for the synthesis of complex molecules.[1] It has had a huge impact on organic synthesis despite the disadvantage that the overall coupling of the two fragments requires two discrete activation steps: 1) the formation of an aryl or vinyl halide and 2) the palladium(0)-catalyzed union of the reaction partners [Eq. (1)]. A direct oxidative Heck

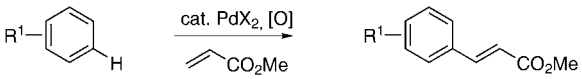
Conventional Heck reaction



(1)

reaction would bypass the need for preactivated reaction partners and lead to a more efficient process. To this end, Fujiwara, Moritani et al. developed an efficient coupling of arenes and activated alkenes through an oxidative palladium(II)-catalyzed process, and this transformation has found widespread use in synthesis [Eq. (2)].[2]

Fujiwara–Moritani oxidative Heck reaction



(2)

We are interested in the development of catalytic processes that exploit selective and controllable C–H functionalization[3] to elaborate simple aromatic compounds to useful products. The catalytic functionalization of aromatic heterocycles is an important transformation, and methods for the synthesis and elaboration of indoles in particular have received significant attention.[4] The indole motif is a ubiquitous feature of alkaloid and peptide natural products and represents an important structural element for the pharmaceutical industry. As a result, many useful and practical processes exist for the modification of the indole structure, and, as previously mentioned, metal-catalyzed coupling reactions are of particular utility, although these methods often require a prefunctionalized indole unit for each elaboration.[4,5] Surprisingly, the development of an oxidative C3 alkenylation of free (NH) indoles has received little attention,[6] and to the best of our knowledge there is no example of an intermolecular oxidative C2 alkenylation of a free (NH) indole.[7] Nor is there a method to select between the two positions of the important fundamental motif. Herein we describe a general direct oxidative Heck reaction that exploits a novel, selective, solvent-controlled, palladium-catalyzed C–H functionalization of free (NH) indoles and leads to the elaboration of the heteroaromatic core at either the 2- or the 3-position [Eq. (3)].

The natural reactivity of indole suggested that palladation and Heck coupling would take place preferentially at the 3-

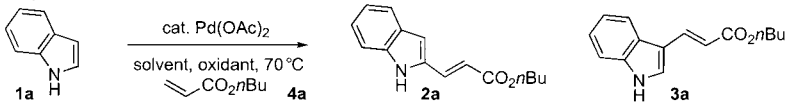
 DOI: 10.1002/anie.200500468

position.[6] However, we speculated that it might be possible to control the selectivity of the reaction by the use of different solvents and additives. Fundamental to this hypothesis was the knowledge that the migration of groups from the 3- to the 2-position of indole has been observed in the alkylation of 3-substituted indoles (Scheme 1).[8] By analogy, we anticipated that a migration of the C3–PdX bond to the 2-position would enable a complementary C–H functionalization process.

We began by screening the reaction between indole (**1a**, R^1 = H) and *n*-butyl acrylate (**4a**) in the presence of $Pd(OAc)_2$ as a catalyst with a variety of solvents and $Cu(OAc)_2$ as the oxidant.[9] Reactions in polar solvents gave exclusively the C3-functionalized indoles **3a** (Table 1, entries 1–2), except when 1,4-dioxane was used (Table 1, entry 3), in which case no reaction was observed, perhaps because of the insolubility of $Cu(OAc)_2$ in this solvent. The use of *tert*-butyl benzoyl peroxide (*t*BuOOBz) as the soluble reoxidizing agent, however, led to a reaction in 1,4-dioxane, but with a surprising reversal of selectivity to produce a 2:1 mixture of the C2- and C3-substituted indoles **2a** and **3a**, respectively (Table 1, entry 4). Careful monitoring of the reaction showed that **3a** predominated at the beginning of the reaction with **2a** only starting to form as the reaction proceeded. Benzoic acid is produced as a result of the reoxidation of Pd^0 by *t*BuOOBz, and it was believed that the increasing concentration of acid may be responsible for the switch in selectivity as the reaction progresses. This hypothesis was supported by the result of the reaction in DMF/AcOH, which led to a 1:1 mixture of isomers (Table 1, entry 5), whereas only **3a** was formed in DMF alone. To our delight, the use of AcOH as a cosolvent with 1,4-dioxane led to a 7:1 ratio of **2a**:**3a** (Table 1, entry 6) and demonstrated that the regioselectivity of palladium-catalyzed indole alkenylation could be controlled.

Further optimization showed that the use of DMSO as a cosolvent with DMF improved the yield of **3a** (Table 1, entry 7), thus suggesting that DMSO may prevent the precipitation of Pd^0 in the reaction mixture prior to reoxidation.[10a] Although no further improvements to the C2 functionalization reaction were made,[11] we found that the use of MeCN/AcOH switched the selectivity back in favor of the 3-position (Table 1, entry 8), as did the addition of DMSO to the reaction in 1,4-dioxane/AcOH (Table 1, entry 9).[10b] It is remarkable that the addition of a polar coordinating cosolvent seems to promote a total switch in the selectivity of the reaction, and investigations into the nature of this selectivity are ongoing.

Table 1: Optimization studies for indole functionalization.[a]



Entry	Catalyst loading [%]	Oxidant (equiv)	Solvent (*v*/*v*)	Yield of **2**+**3** [%][b]	**3a**/**2a**
1	10	$Cu(OAc)_2$ (1.8)	DMF	54	>95:5
2	10	$Cu(OAc)_2$ (1.8)	DMSO	66	>95:5
3	10	$Cu(OAc)_2$ (1.8)	1,4-dioxane	n.r.	–
4	10	*t*BuOOBz (0.9)	1,4-dioxane	48	1:2

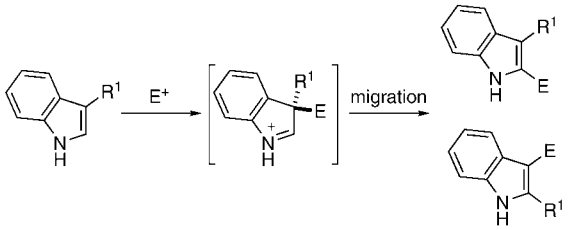
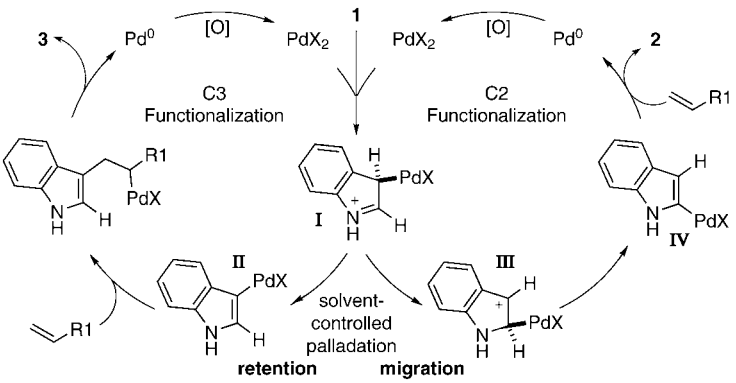


Scheme 1. Electrophilic attack on indoles.

Although at this stage we can not be certain of the mechanism of this process, we propose plausible pathways for the two reactions in Scheme 2. Palladation at C3 is thought to occur via intermediate **I**, and following rearomatization to **II** a Heck-type reaction forms the C3-functionalized indole **3**. Under neutral conditions, the acetate ion formed from the attack of indole on $Pd(OAc)_2$ will readily remove a proton from **I** to form the C3-palladated species **II**. In contrast, under acidic reaction conditions we propose that this deprotonation would be slowed, which could allow a migration of the C3–PdX bond in **I** to the highly activated 2-position of the iminium intermediate to give intermediate **III** and ultimately **IV**.[12] The effect of the cosolvent, as well as the presence of



Scheme 2. Proposed mechanism of C–H functionalization.

AcOH, is also important since the results in Table 1 suggest that strongly coordinating solvents (DMSO, MeCN) override any effect that the presence of acid may have, thus leading to C3 selectivity. However, with weakly coordinating 1,4-dioxane as a solvent the proposed migration still appears to be facile, even without the addition of acid, thus leading to the C2-functionalized indole **2** as the major isomer. It is also possible that the C3 palladation is reversible, and that the intermediate derived from C2 palladation is ultimately formed prior to coupling. In this case the C2-palladated species must be thermodynamically more stable and the rate of insertion into the alkene slow. Mechanistic investigations are currently underway, and these results will be reported in due course.

Table 2 shows that a range of indoles and alkenes participate in the regioselective oxidative coupling reaction. Importantly, free (NH) indoles are suitable substrates for this process. The C3-functionalization process worked well for electron-deficient alkenes, such as **4a–d**, which reacted with **1a** to form indoles **3a–d** in good yield. Indole phosphonate **3e** could also be generated from vinyl phosphonate **4e** in good yield. The reaction of **1a** with lactone **4f** produced a mixture of alkenyl indole regioisomers **3f** (1:1) in 66% combined yield. The non-activated alkenes styrene (**4g**) and cyclohexene (**4h**) reacted with **1a** to form the corresponding indoles **3g** and **3h** (after hydrogenation) in good yield. The *N*-methyl indole derivative **1b** reacted with **4a** to form **3i** in 75% yield, and 5-nitroindole **1c** was smoothly converted into **3j** in 76% yield. Of particular note was the use of 5-bromoindole (**1d**); the highly versatile product **3k** was isolated in 75% yield with the aryl bromide moiety intact. Thus, this first general method for the direct oxidative Heck coupling at C3 of free (NH) indoles can be applied to a range of indoles and alkenes.

Table 2: Regioselective C3 functionalization of indoles.

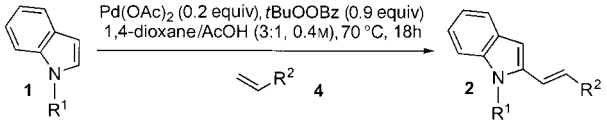
[a] Only the C3-functionalized isomer was produced. [b] Yields of products after purification. [c] A 1:1 mixture of isomers was produced. [d] **4e**: 5 equivalents. [e] **1a**: 2 equivalents, **4g**: 1 equivalent. [f] **4h**: 10 equivalents used because of its volatility; yield after hydrogenation.

We next turned our attention to the development of the corresponding catalytic C2 alkenylation. When the reactions were performed with dioxane/AcOH as the solvent (Table 1, entry 6) the regioselectivity of the oxidative process was switched in favor of reaction at the 2-position (Table 3). However, the yields were generally lower in these cases, presumably as a result of competitive oxidative decomposition of indole **1a** and the product **2** under these reaction conditions. Nevertheless, indole alkenylation occurred selectively at the C2 position with all substrates tested, in generally good yields for this type of transformation. Interestingly, the use of *N*-methylindole (**1b**) resulted in no alkenylation at either C2 or C3 under these conditions, thus highlighting a potentially crucial role of the free NH moiety in these reactions.

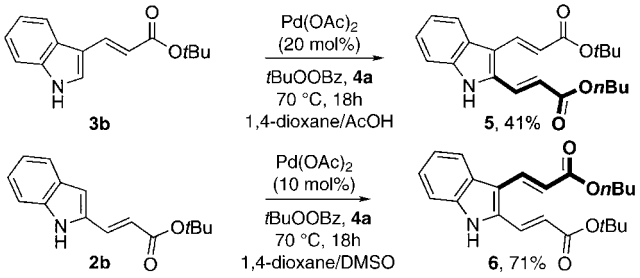
It was also possible to further derivatize the indole products through C–H functionalization (Scheme 3). Indole **3b** reacted with **4a** to form **5** in a moderate 41% yield as the

Table 3: Regioselective C2 functionalization of indoles.



Entry	Alkene		Indole	Product[a]		Yield [%][b]
1		**4a**	$R^1 = H$ **1a**		**2a**	51[c]
2		**4b**	$R^1 = H$ **1a**		**2b**	57
3		**4c**	$R^1 = H$ **1a**		**2c**	34
4		**4e**	$R^1 = H$ **1a**		**2e**	51
5		**4a**	$R^1 = Me$ **1b**		**2i**	n.r.

[a] Only the C2-functionalized isomer was produced. [b] Yields of products after purification. [c] A 7:1 mixture of **2**/**3** was produced; 51% is the yield of isolated **2a**.



Scheme 3. Formation of bis(alkenyl)indoles.

sole product, whereas indole **2b** was converted into diene **6** in 71% yield through reaction with **4a** in 1,4-dioxane/DMSO. This strategy thus allows the selective installation of substituents at either position in any order and provides access to highly functionalized indoles by catalytic methods.

In summary, we have developed a general method for the selective intermolecular alkenylation of indoles through a palladium-catalyzed C–H functionalization reaction. The nature of the solvent determines the regioselectivity of the reaction, so that the alkenylation can be directed to either the 2- or the 3-position of free (NH) indoles. This discovery could have important consequences for the selective elaboration of other heteroaromatic core structures. Current efforts are directed towards the improvement of the efficiency and scope of the reaction, a more detailed mechanistic investigation, and application to other types of heteroaromatic compounds.

Experimental Section

General procedure for C3 alkenylation: Palladium acetate (0.1 equiv) was added to a mixture of the alkene (2 equiv), copper(II) acetate (1.8 equiv), and the indole (1 equiv) in DMF/DMSO (9:1, 0.4 M), and the reaction mixture was stirred at 70 °C. After 18 h the reaction mixture was cooled to room temperature and partitioned between water and ethyl acetate, then filtered through a plug of celite. The layers were separated, and the organic layer was washed with aqueous saturated brine solution, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. Purification by flash chromatography afforded the C3-alkenylated indole.

General procedure for C2-alkenylation: Palladium acetate (0.2 equiv) was added to a mixture of the alkene (2 equiv), *t*BuOOBz (0.9 equiv), and the indole (1 equiv) in 1,4-dioxane/AcOH (3:1, 0.4 M), and the reaction mixture was stirred at 70 °C. After 18 h the reaction mixture was cooled to room temperature and neutralized with aqueous sodium hydrogen carbonate solution, diluted with ethyl acetate, and filtered through a plug of celite. The layers were separated, and the organic layer was washed with aqueous sodium hydrogen carbonate solution and aqueous saturated brine solution, dried over $MgSO_4$, filtered, and concentrated under reduced pressure. Purification by flash chromatography afforded the C2-alkenylated indole.

Transition-Metal Complexes

The Myth of Cyanide Always Being a Strong-Field Ligand: Synthesis and Structural Characterization of Homoleptic $S = 2$ Pentacyanochromate(II), $[Cr^{II}(CN)_5]^{3-}$, and Nonacyanodichromate(II), $[Cr^{II}_2(CN)_9]^{5-}$**

*Kendric J. Nelson, Ian D. Giles, William W. Shum, Atta M. Arif, and Joel S. Miller**

Dedicated to Harry B. Gray

Crystal field theory has provided detailed insight into the structure, spectroscopic, and magnetic properties of transition-metal coordination complexes since its inception. The empirical genesis of the spectrochemical series, which identifies strong π-acceptor ligands as strong-field ligands, is understood on the basis of molecular orbital theory. Cyanide is deeply entrenched as being a strong-field ligand, as revealed by low-spin ground states for its homoleptic complexes: for example, $[M(CN)_6]^{n-}$ ($n = 2$, 3, 4)[1] and $[M^{II}(CN)_5]^{3-}$ (M = Co, Ni).[2] Furthermore, they do not violate the $18e^-$ rule by exceeding 18 electrons about the metal center M. The only high-spin example is the unusual $13e^-$ $S = 5/2$ complex $[Mn^{II}(CN)_4]^{2-}$,[3] which being tetrahedral has a substantially reduced crystal-field stabilization energy, Δ, of $^4/_9$ the value expected for the $17e^-$ $S = 1/2$ complex $[Mn^{II}(CN)_6]^{4-}$. As part of our ongoing studies toward molecule-based magnets,[4] we sought to prepare Prussian blue structured magnets based upon $[Cr^{II}(CN)_6]^{4-}$ for comparison with those derived from $[Cr^{III}(CN)_6]^{3-}$, which magnetically order at temperatures as high as 100 °C (approximately).[5]

$K_4[Cr^{II}(CN)_6]$ has been prepared from aqueous media, but owing to the lability of the d^4 Cr^{II} state, excess cyanide is required in solution. Despite undergoing a Jahn–Teller distortion, $16e^-$ $K_4[Cr^{II}(CN)_6]$ is low-spin $S = 1$. Owing to the need for excess cyanide, aqueous routes to Prussian blue structured materials would be unproductive, so we sought a nonaqueous source of $[Cr^{II}(CN)_6]^{4-}$ and targeted $(NEt_4)_4[Cr^{II}(CN)_6]$. The reaction of either $Cr^{II}_2(OAc)_4$[6] or $[Cr^{II}(MeCN)_4(BF_4)_2]$[7] with as much as a twofold excess of NEt_4CN in MeCN led to dark purple block crystals of composition $(NEt_4)_3[Cr^{II}(CN)_5]\cdot MeCN\cdot{}^1/_8\,THF$ (**1**). In the solid state **1** exhibits a broad $\nu_{C\equiv N}$ absorption at 2086 cm^{-1} (half-width at half height: 9.2 cm^{-1}, see Figure 1). This is comparable to 2080 cm^{-1} reported for $[Co^{II}(CN)_5]^{3-}$,[8] but differs from the absorptions at 2095 (m), 2111 (vs), and 2123 cm^{-1} (vs) reported for $[Ni^{II}(CN)_5]^{3-}$,[9] and is higher in energy than the broad $\nu_{C\equiv N}$ absorption at 2020 cm^{-1} observed for $K_4[Cr^{II}(CN)_6]$.[10] The electronic spectrum (5000–30000 cm^{-1}) of a solution of $(NEt_4)_3[Cr^{II}(CN)_5]$ (1.30 mM) in MeCN comprises an absorption at 22120 cm^{-1} ($\lambda = 452$ nm, $\varepsilon = 122\,M^{-1}cm^{-1}$; Figure 1). However, **1** does not obey Beer's

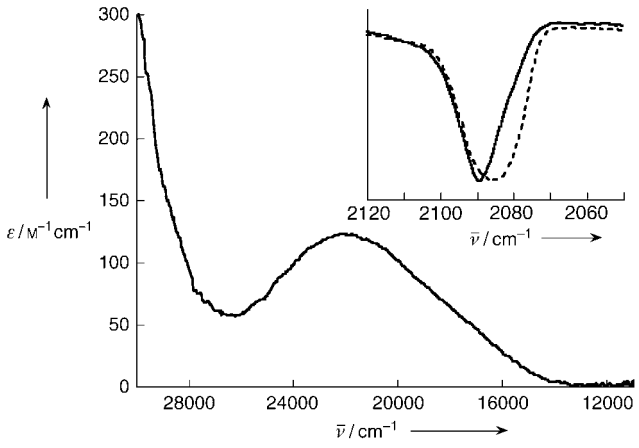

Figure 1. Electronic absorption spectrum of $(NEt_4)_3[Cr^{II}(CN)_5]$ (1.30 mM in MeCN). Inset: $\nu_{C\equiv N}$ vibrational spectra of $(NEt_4)_3[Cr^{II}(CN)_5]$ (-----) and $(NEt_4)_8[Cr^{II}(CN)_5][Cr^{II}_2(CN)_9]$ (——) in KBr.

 DOI: 10.1002/anie.200462763

law, as the electronic absorption spectrum of the solution changes as a function of cyanide concentration (the details of this equilibrium are under investigation).

The asymmetric unit cell[11] contains four $[Cr^{II}(CN)_5]^{3-}$ units (Figure 2), twelve Et_4N^+ cations, as well as four molecules of MeCN and half a molecule of THF of solvation, which arises from the diffusion of THF into a solution of **1** in MeCN to obtain the crystals. Each Cr^{II} center is pentacoordinate, with both square-pyramidal and distorted trigonal bipyramid structures present. The low barrier for interconversion between the limiting square-pyramidal and trigonal bipyramid five-coordinate structures leads to the formation of several local structures,[12] as has been reported for $[Ni^{II}(CN)_5]^{3-}$ even within the same unit cell.[13] For the square-pyramidal structures the apical Cr–C bond lengths range from 2.229(5) to 2.238(6) Å (av 2.23 Å) and the basal Cr–C bond lengths range from 2.110(7) to 2.135(5) Å (av 2.12 Å). The C_{apical}-Cr-C_{basal} angle ranges from 93.6(2) to 108.2(3)° (av 99.0°), and the *trans* C_{basal}-Cr-C_{basal} angle ranges from 155.9(2) to 166.9(2)° (av 161.9°). The Cr atom lies 0.33 Å above the plane formed by the four basal carbon atoms. These values are similar to those found for $[M^{II}(CN)_5]^{3-}$ (M = Co, Ni; see Table 1),[14] except that the Cr–C bonds are the longest, as expected for an early first-row transition metal. In the distorted trigonal bipyramidal structure the axial Cr–C bond lengths range from 2.094(6) to 2.118(6) Å (av 2.11 Å) while the equatorial Cr–C bond lengths range from 2.113(6) to 2.188(5) Å (av 2.15 Å). The axial Cr–C bonds are shorter than the equatorial Cr–C bonds, as reported for the distorted trigonal bipyramidal $[Ni^{II}(CN)_5]^{3-}$ structure.[13]

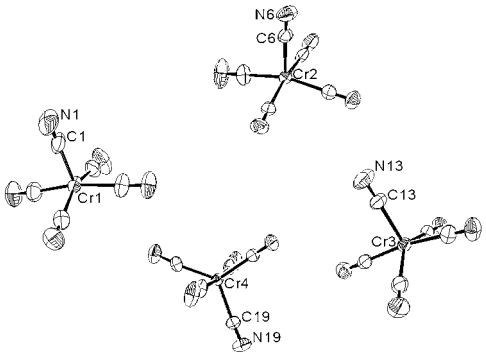

Figure 2. ORTEP labeling diagram of $(NEt_4)_3[Cr^{II}(CN)_5]\cdot MeCN\cdot{}^1/_8\,THF$ (**1**; 50% probability level; cations and solvent molecules are omitted for clarity).

Owing to formation of solely the pentacyanide complex even in the presence of excess cyanide ion, the reaction was carried out with 5 equivalents of CN^- per Cr^{II} ion, and dark brown needlelike crystals of $(NEt_4)_8[Cr^{II}(CN)_5][Cr^{II}_2(CN)_9]\cdot 2\,MeCN$ (**2**) were isolated. In the solid state **2** exhibits a broad $\nu_{C\equiv N}$ absorption at 2090 cm^{-1} (half-width at half height: 6.9 cm^{-1}), which is comparable to that observed for $(NEt_4)_3[Cr^{II}(CN)_5]$ (Figure 1). Furthermore, similar to $(NEt_4)_3[Cr^{II}(CN)_5]$, **2** also does not obey Beer's law (the details of this equilibrium are also under investigation).

The asymmetric unit cell[15] of **2** contains one $[Cr^{II}(CN)_5]^{3-}$ unit, one $[Cr_2^{II}(CN)_9]^{5-}$ unit (see Figure 3), eight Et_4N^+ cations, and two molecules of MeCN of solvation. Each Cr^{II} center is pentacoordinate, with a distorted square-pyramidal local C_{4v} symmetry. The Cr center in the distorted square-pyramidal $[Cr^{II}(CN)_5]^{3-}$ unit lies 0.40 Å above the plane formed by the four basal carbon atoms, and the apical Cr–C bond length is 2.23 Å, while the average basal Cr–C bond length is 2.12 Å. $[Cr^{II}_2(CN)_9]^{5-}$ is composed of two square-pyramidal $[Cr^{II}(CN)_4]^{2-}$ moieties bridged by a cyanide ion. The bridging cyanide is disordered, with average Cr–C and Cr–N bond lengths of 2.20 Å observed. The Cr center lies 0.37 Å above the plane formed by the four basal carbon atoms, and the basal Cr–C bond length is 2.13 Å on average. To the best of our knowledge, this structural motif has not been previously reported.

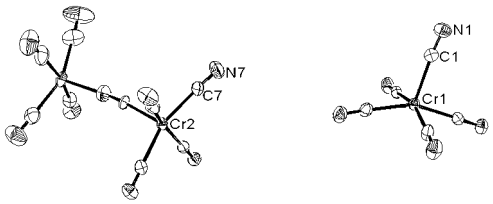

Figure 3. ORTEP labeling diagram of $(NEt_4)_8[Cr^{II}(CN)_5]$-$[Cr^{II}_2(CN)_9]\cdot 2\,MeCN$ (**2**; 50% probability level; cations and solvent molecules are omitted for clarity).

The magnetic susceptibility, χ, was measured for both $(NEt_4)_3[Cr^{II}(CN)_5]$ and $(NEt_4)_8[Cr^{II}(CN)_5][Cr^{II}_2(CN)_9]$ from 5 to 300 K. $(NEt_4)_3[Cr^{II}(CN)_5]$ has an effective room temper-

ature magnetic moment, $\mu_{eff} = (8\chi T)^{1/2}$, of 4.90 μ_B (corrected for temperature-independent paramagnetism (TIP); see Figure 4). This value significantly exceeds the expected spin-only moment of 2.83 μ_B for $S = 1$ low-speed Cr^{II}, but it is in

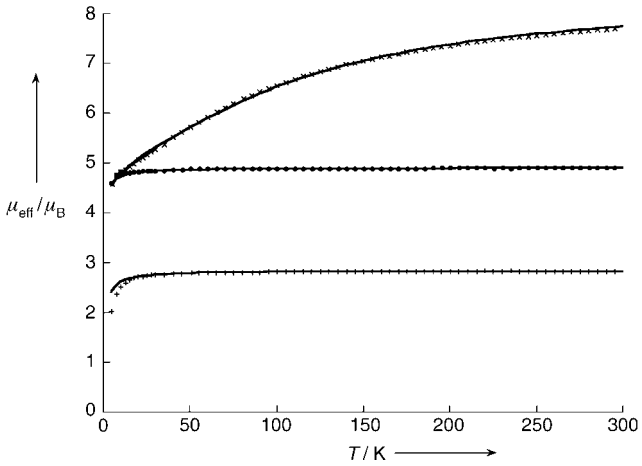

Figure 4. Temperature dependence of the effective magnetic moment, $\mu_{eff} = (8\chi T)^{1/2}$, of $K_4[Cr^{II}(CN)_6]$ (+), $(NEt_4)_3[Cr^{II}(CN)_5]$ (●), and $(NEt_4)_8[Cr^{II}(CN)_5][Cr^{II}_2(CN)_9]$ (×). The solid lines are fits, as discussed in the text.

excellent agreement with the expected spin-only value of 4.90 μ_B for $S = 2$ high-spin Cr^{II}. Above 5 K, $\chi(T)$ could be fitted to the Curie–Weiss expression, $\chi \propto (T-\theta)^{-1}$, with $g = 2.00$, $\theta = -0.79$ K, and a TIP value of 50×10^{-6} emu mol^{-1}. In contrast, the room temperature μ_{eff} value for $K_4[Cr^{II}(CN)_6]$ is 2.82 μ_B (corrected for TIP). Above 5 K, $\chi(T)$ could also be fitted to the Curie–Weiss expression with $g = 2.00$, $\theta = -1.9$ K, and a TIP value of 150×10^{-6} emu mol^{-1} (Figure 4). The room temperature μ_{eff} value is consistent with the low-spin $S = 1$ ground state previously reported.[16] Hence, $[Cr^{II}(CN)_5]^{3-}$ is a rare example of a high-spin homoleptic cyanide complex.

The magnetic behavior of $(NEt_4)_8[Cr^{II}(CN)_5][Cr^{II}_2(CN)_9]$ is more complex (Figure 4) as a result of contributions from $[Cr^{II}(CN)_5]^{3-}$ and dinuclear $[Cr^{II}_2(CN)_9]^{5-}$. The observed data can be modeled with an $S = 2$ Curie–Weiss expression and a Bleaney–Bower-like $S = 2$ term,[17] with $g = 2.00$, $J/k = -19.1$ K, $\theta = -0.79$ K, and a TIP value of 150×10^{-6} emu mol^{-1}. Hence, **2** exhibits moderate intradimer antiferromagnetic coupling of -19.1 K (-13.3 cm^{-1}), and the nonet excited state lies 266 cm^{-1} (0.76 kcal mol^{-1}) above the singlet ground state.

Formation of $[Cr^{II}(CN)_5]^{3-}$ and $[Cr^{II}_2(CN)_9]^{5-}$, but not the sought $(NEt_4)_4[Cr^{II}(CN)_6]$, is quite surprising as $K_4[Cr^{II}(CN)_6]$ as well as $Na_4[Cr^{II}(CN)_6]$ are known low-spin octahedral compounds.[10,18] Furthermore, why does $(NEt_4)_3[Cr^{II}(CN)_5]$, but not $(NEt_4)_4[Cr^{II}(CN)_6]$, form in the presence of excess cyanide? We attribute the formation of $[Cr^{II}(CN)_5]^{3-}$ to the initial formation of $[Cr^{II}(CN)_6]^{4-}$, which is expected to have a reduced $\Delta(Cr^{II})$ value with respect to $\Delta(Cr^{III})$ and which makes a high-spin state more accessible. High-spin $t_{2g}^3e_g^1$ $[Cr^{II}(CN)_6]^{4-}$ would have an electron in an antibonding orbital that weakens the Cr^{II}–C bonds and destabilizes the system, and when the large tetranegative charge is considered—although, $(NEt_4)_4[Fe^{II}(CN)_6]$ is known to have a shorter M–C bond[19]—loss of a cyanide ion is favored to form the observed $[Cr^{II}(CN)_5]^{3-}$ species. Presumably $A_4[Cr^{II}(CN)_6]$ (A = Na, K) is stabilized through electrostatic interactions between the alkali-metal cation (and water molecules) and the nitrogen centers of the cyanide units.

Experimental Section

1: In a DryBox (< 0.5 ppm O_2) $Cr^{II}_2(OAc)_4$ (274.8 mg, 0.8078 mmol) was dissolved in deoxygenated MeCN (50 mL) to give an orange–red solution, which was then added dropwise to a stirring colorless solution of NEt_4CN (1.510 g, 9.563 mmol) in MeCN (50 mL). After stirring for 30 min, the dark purple solution was filtered and concentrated to 20 mL under reduced pressure. Dark purple crystalline blocks were obtained by diffusion of THF (yield: 62%) and characterized by single-crystal X-ray diffraction. The crystallographic sample was maintained in contact with the mother liquor to prevent solvent loss. Thermogravimetric analysis showed the sample was stable up to 160 °C and could be desolvated at lower temperatures (i.e. heating at 110 °C under reduced pressure) to form the desolvated $(NEt_4)_3[Cr^{II}(CN)_5]$. Selected IR data (KBr): $\tilde{\nu} = 2986$ (s), 2950 (m), 2892 (w), 2086 (s), 1488 (s), 1461 (s), 1396 (s), 1375 (w), 1311 (w), 1186 (m), 1175 (s), 1080 (w), 1055 (w), 1035 (m), 1005 (s), 787 cm^{-1} (s).

2: $Cr^{II}_2(OAc)_4$ (55.94 mg, 0.1644 mmol) dissolved in MeCN (20 mL) was added dropwise to a solution of NEt_4CN (256.3 mg, 1.640 mmol) in MeCN (20 mL). After stirring for 30 min, the reddish purple solution was filtered and concentrated to 15 mL under reduced pressure. Brown needlelike crystals were obtained by diffusion of THF (yield: 24%) and characterized by single-crystal X-ray diffraction. The crystallographic sample was maintained in contact with the mother liquor to prevent solvent loss. Selected IR data (KBr): $\tilde{\nu} =$ 2986 (s), 2949 (m), 2894 (w), 2248 (w), 2090 (s), 1484 (s), 1461 (s), 1396 (s), 1377 (w), 1310 (w), 1185 (m), 1175 (s), 1080 (w), 1057 (w), 1036 (m), 1005 (s), 789 cm^{-1} (s).

[11] Crystal data for $(NEt_4)_3[Cr^{II}(CN)_5]\cdot MeCN\cdot{}^1/_8 THF$ (**1**): $C_{126}H_{256}Cr_4N_{36}O_{0.5}$ triclinic, space group: $P\bar{1}$, $a = 17.8172(3)$ Å,

$b = 20.8318(6)$ Å, $c = 21.5756(5)$ Å, $\alpha = 87.6399(9)°$, $\beta = 84.4486(13)°$, $\gamma = 71.9031(14)°$, $V = 7575.7(3)$ Å^3, $Z = 2$, $T = 150$ K, $\rho_{calcd} = 1.092$ Mg m^{-3}. The structure was solved by a combination of direct methods and heavy atoms using SIR 97. All non-hydrogen atoms were refined with anisotropic displacement coefficients. Hydrogen atoms were assigned isotropic displacement coefficients $U(H) = 1.2\,U(C)$ or $1.5\,U(C_{Me})$, and their coordinates were allowed to ride on their respective carbons using SHELXL97. The asymmetric unit contains four $[Cr(CN)_5]^{3-}$ and twelve $[NEt_4]^+$ units, as well as four molecules of acetonitrile and half a molecule of tetrahydrofuran. Most of the cations and half of the acetonitrile units exhibit orientation disorder (50:50). Only one anion, $[Cr^{II}(CN)_5]^{3-}$, of the asymmetric unit exhibits orientation disorder in one of the cyanide ligands (C18–N18 and C18′–N18′) on atom Cr4 (50:50). This is not surprising as both square-pyramidal and distorted trigonal bipyramid structures are present in the unit cell. The weighting scheme employed was $w = 1/[\sigma^2(F_o^2) + (0.1366P)^2 + 10.5826P]$, where $P = (F_o^2 + 2F_c^2)/3$. The refinement converged to $R1 = 0.0842$, $wR2 = 0.218$, and $S = 1.036$ for 16467 reflections with $1 > 2\sigma(I)$, and $R1 = 0.1396$, $wR2 = 0.2649$, and $S = 1.036$ for 26638 unique reflections and 1831 parameters. The maximum Δ/σ value in the final cycle of the least-squares treatment was zero, and the residual peaks on the final difference-Fourier map ranged from -0.504 to 1.677 e$^-$ Å^{-3}.

[15] Crystal data for $(NEt_4)_8[Cr^{II}(CN)_5][Cr_2^{II}(CN)_9]\cdot 2MeCN$ (**2**): $C_{82}H_{166}Cr_3N_{24}$ triclinic, space group: $P\bar{1}$, $a = 10.2618(2)$ Å, $b = 22.4902(5)$ Å, $c = 23.4526(4)$ Å, $\alpha = 114.5636(8)°$, $\beta = 90.3961(11)°$, $\gamma = 101.8783(10)°$, $V = 4791.3(2)$ Å^3, $Z = 2$, $T = 150$ K, $\rho_{calcd} = 1.140$ Mg m^{-3}. The structure was solved by a combination of direct methods and heavy atoms using SIR 97. All non-hydrogen atoms were refined with anisotropic displacement coefficients. Hydrogen atoms were assigned isotropic displacement coefficients $U(H) = 1.2\,U(C)$ or $1.5\,U(C_{Me})$, and their coordinates were allowed to ride on their respective carbons using SHELXL97. There are two distinctly different anions, $[Cr^{II}(CN)_5]^{3-}$ and $[Cr_2^{II}(CN)_9]^{5-}$. Three out of the eight $(NEt_4)^+$ cations exhibit unequal (67:33) orientation disorder. The asymmetric unit contains two noncoordinating molecules of acetonitrile. The weighting scheme employed was $w = 1/[\sigma^2(F_o^2) + (0.0944P)^2 + 4.5597P]$ where $P = (F_o^2 + 2F_c^2)/3$. The refinement converged to $R1 = 0.0671$, $wR2 = 0.1662$, and $S = 1.019$ for 14333 reflections with $1 > 2\sigma(I)$, and $R1 = 0.1131$, $wR2 = 0.1971$, and $S = 1.019$ for 21857 unique reflections and 1138 parameters. The maximum Δ/σ value in the final cycle of the least-squares treatment was zero, and the residual peaks on the final difference-Fourier map ranged from -0.595 to 1.286 e$^-$ Å^{-3}. CCDC-253631 (**1**) and 257172 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

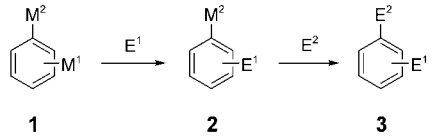
Boron–Magnesium Reagents

Preparation and Selective Reactions of Mixed Bimetallic Aromatic and Heteroaromatic Boron–Magnesium Reagents**

*Oliver Baron and Paul Knochel**

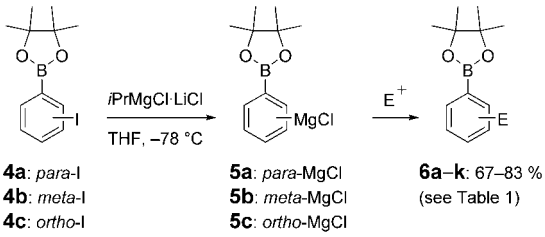
Dedicated to Professor Peter Stanetty on the occasion of his 60th birthday

The selective functionalization of aryl and heteroaryl compounds is an important synthetic task. The resulting polyfunctional (hetero)aryl derivatives are often essential building blocks in the synthesis of pharmaceuticals, agrochemicals, and new organic materials.[1] We envisaged that bimetallic[2] aromatic derivatives of type **1**, which bear two metal-centered substituents of distinctly different reactivity, would be useful reagents. Their stepwise reaction with two electrophiles E^1 and E^2 would provide products of type **2** and **3** (Scheme 1).



Scheme 1. Reactivity of bimetallic aryl derivates.

Unfortunately, the reaction of *para*-iodoboronic ester **4a**[3] with *i*PrMgCl afforded only the corresponding isopropylboronate, which results from the attack of the Grignard reagent at the boronic ester functionality. However, the reaction with the new reagent *i*PrMgCl·LiCl[4] (−78 °C, 2 h) furnished the desired magnesiated boronic ester **5a**, which reacted with a variety of electrophiles to provide boronic esters of type **6** in good yields (Scheme 2, Table 1). Thus, the reaction of **5a** with allylic bromides in the presence of a catalytic amount of CuCN·2 LiCl[5] furnished the expected allylated boronic esters **6a** and **6b** in 77 and 67 % yield, respectively (Table 1, entries 1 and 2). Acylation reactions proceeded best when the Grignard reagents **5a** and **5b** were transmetalated stoichiometrically with CuCN·2 LiCl. Both aliphatic and aromatic acid chlorides reacted smoothly to give the keto-substituted boronic esters **6c**, **6d**, and **6i** in 72, 73, and 71 % yield, respectively (Table 1, entries 3, 4, and 9). The magnesiated



Scheme 2. Synthesis of boronic esters of type **6** by the treatment of magnesiated boronic esters **5** with electrophiles.

boronic esters **5a–b** also added directly to benzaldehyde to provide the hydroxy-substituted boronic esters **6e** and **6h** in 83 and 71 % yield, respectively (Table 1, entries 5 and 8). The boronic ester cuprates underwent a smooth addition–elimination reaction with 3-iodocyclohexenones to furnish the expected β-substituted unsaturated ketones **6f** (78 %), **6g** (79 %), and **6j** (76 %; Table 1, entries 6, 7, and 10). Preliminary experiments showed that the *ortho*-magnesiated phenylboronic ester **5c** displayed a lower reactivity towards electrophiles. However, its allylation gave the boronic ester **6k** in 71 % yield (Table 1, entry 11).

By using the readily available heterocyclic diiodides **7**,[6] **8**,[7] and **9**,[8] it was possible to prepare the iodoheteroaryl boronic esters **11** (76 %), **12** (76 %), and **13** (81 %) by an I/Mg exchange followed by treatment with the dioxaborolane **10** (Scheme 3). These boronic esters were readily converted by treatment with *i*PrMgCl·LiCl at −78 °C into the related magnesiated species **14–16**, which reacted with various electrophiles as found for the magnesiated carbocyclic boronic esters. Thus, the copper(I)-catalyzed allylation of **14** and **16** provided the allylated heterocyclic boronic esters **17a** and **17c** in 83 and 91 % yield, respectively (Table 2, entries 1 and 3). Transmetalation of the magnesiated 2-indolyl boronic ester **15** with CuCN·2 LiCl, followed by treatment with

propionyl chloride, furnished the keto-substituted indolyl boronic ester **17b** in 81% yield (Table 2, entry 2). The reaction of magnesiated species **16** with benzaldehyde gave the corresponding alcohol directly in 78% yield (Table 2, entry 4).

All new polyfunctional boronic esters underwent smooth Suzuki cross-coupling reactions. Thus, boronic ester **6h** (Table 1, entry 8) reacted readily with 4-bromobenzonitrile in the presence of [$PdCl_2$(dppf)] (5 mol%; dppf = 1,1′-bis(diphenylphosphanyl)ferrocene)[9] and K_2CO_3 (3 equiv) in THF at 60 °C (9 h) to give the cross-coupling product **18** in 92% yield (Scheme 4). In a convenient one-pot procedure, the iodoboronic ester **4a** was treated first with *i*PrMgCl·LiCl (−78 °C, 2 h) and then with benzaldehyde to provide the magnesium alcoholate **19**, which was submitted directly to Suzuki cross-coupling conditions.[8] This sequence afforded the terphenyl derivative **20**, which was isolated in 73% yield (Scheme 4). Similarly, magnesiation of the *meta*-substituted iodoboronic ester **4b**, transmetalation with CuCN·2 LiCl, and treatment with 3-iodo-2-methylcyclohexenone led to the polyfunctional boronic ester **21**, which reacted with 4-bromoisoquinoline under palladium catalysis to provide the heterocyclic product **22** in 52% overall yield (Scheme 4).

In summary, we have prepared magnesiated aryl and heteroaryl boronic esters by an I/Mg exchange. These reagents provided access to a broad array of polyfunctional boronic esters, which underwent smooth Suzuki cross-coupling reactions. Further extensions of this methodology are currently being studied in our laboratories.

Experimental Section

Typical procedure: Synthesis of **12**: *i*PrMgCl (1.48 mL, 1.3 mmol, 0.88 M in THF) was added dropwise over 5 min to a solution at −78 °C of **8** (0.611 g, 1.2 mmol) in THF (8 mL) in a dry, argon-flushed 25-mL Schlenk tube equipped with a magnetic stirring bar and a septum. The reaction mixture was stirred at this temperature for 2 h, until completion of the I/Mg exchange was detected by GC analysis of reaction aliquots, then **10** (0.158 g, 1.0 mmol) was added. The resulting mixture was allowed to warm to room temperature and stirred until full conversion into the boronic ester **12** was indicated by GC analysis. The reaction mixture was then quenched with a small amount of a saturated, aqueous solution of NH_4Cl and extracted with Et_2O (4 × 10 mL), and the extracts were dried over Na_2SO_4. After filtration, the solvent was evaporated in vacuo. Recrystallization from CH_2Cl_2 yielded **12** (387 mg, 76%) as a colorless solid.

Synthesis of **17b**: *i*PrMgCl·LiCl (1.46 mL, 1.4 mmol, 0.96 M in THF) was added dropwise over 15 min to a solution at −78 °C of **12** (0.611 g, 1.2 mmol) in THF (25 mL) in a dry, argon-flushed 100-mL

Organolithium Compounds

A Highly Diastereomerically Enriched, Silyl-Substituted Alkyl Lithium, Configurationally Stable at Room Temperature**

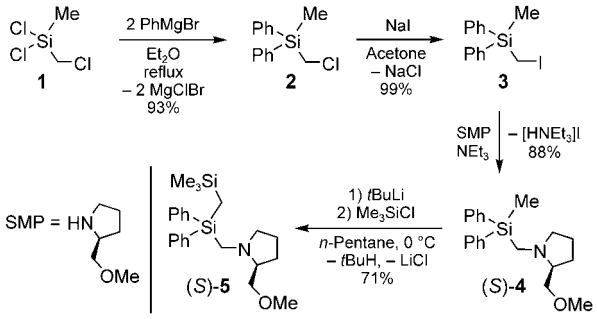
Carsten Strohmann, Bors C. Abele, Klaus Lehmen, and Daniel Schildbach*

Dedicated to Professor Johann Weis on the occasion of his 60th Birthday

Over the last 20 years, a number of enantiomerically and diastereomerically enriched[1] alkyl lithium compounds have been reported.[2,3] For most of the compounds the configuration of the metalated stereogenic carbon center is only stable at low temperatures (−78 °C). However, more recently, corresponding compounds have been synthesized which have proved to be configurationally stable for a few minutes at higher temperatures, including examples from Hoppe et al. and from our own group.[2,4,5] In a few cases the absolute configuration of the alkyl lithium and the reaction products have been determined unambiguously by single-crystal X-ray structural analysis,[6] which allows conclusions that are free from speculation to be drawn on the stereochemical course of the reaction of the alkyl lithium with electrophilic reaction partners. We recently described the highly stereoselective lithiation of an (aminomethyl)benzylsilane, the molecular structure of the corresponding alkyl lithium compound, and the stereochemical course of its reactions.[5,6g,7]

We now report the synthesis of the highly diastereomerically enriched silyl-substituted alkyl lithium compound (*R*,*S*)-**6**, its different structures in the solid state, determined on crystals from coordinating and non-coordinating solvent mixtures, and the diastereodivergent stereochemical course of the reactions of (*R*,*S*)-**6** with chlorotrimethylstannane in relation to the solvent used. Diastereodivergent reactions of alkyl lithium compounds by variation of the electrophile have already been described, however a control of the stereochemical course of the reaction by choice of solvent is to our knowledge unknown.

The synthesis of the starting compound, the optically active (aminomethyl)[(trimethylsilyl)methyl]silane (*S*)-**5**, occurs in good yields in four steps starting from dichloro(chloromethyl)silane **1**. A chlorine–iodine exchange by a Finkelstein reaction is necessary in the second step for the introduction of the optically active amine (*S*)-2-(methoxymethyl)pyrrolidine (SMP; Scheme 1).



Scheme 1. Synthesis of the starting compound (*S*)-**5**. For full experimental details see the Supporting Information.

The lithiation of (*S*)-**5** occurred in the first case by reaction with *sec*-butyllithium in toluene/cyclohexane over 30 days at −80 °C (Schema 2, path 1). After warming to room temperature and being left to stand for 60 min the mixture was cooled to −90 °C and treated with chlorotrimethylstannane (Me_3SnCl reacts rapidly as a selective trapping reagent even at low temperatures). The ^1H NMR spectra of the crude product **7** showed a diastereomeric ratio d.r. = 91:9 for the tin compound (Scheme 2). The absolute configuration of the main stereoisomer (*R*,*S*)-**7** was determined by derivatization to the ammonium stannate $[Ph_2\{(Me_3Si)(Me_3Sn)CH\}SiCH_2N(H)C_6H_{12}O][Me_3SnCl_2]$ ((*R*,*S*)-**8**) and subsequent single-crystal X-ray analysis.[8]

If the described procedure of lithiation and substitution was carried out in toluene/cyclohexane but after the addition of *sec*-butyllithium warming to room temperature was carried out within only 5 min, the tin compounds were formed with a diastereomeric ratio of only d.r. = 63:37 (Scheme 2, path 2). This diastereomeric relationship was not influenced by the standing time of the lithium compound (*R*,*S*)-**6** at room temperature, since the reactions of the lithium compound with the electrophile both immediately after warming to room temperature and after 60 min standing time at room temperature gave the same result. It follows from this result that the diastereomeric ratio of the lithium compound **6** is dependent almost exclusively upon the conditions of the deprotonation (kinetically controlled diastereotopos-differentiating deprotonation). In addition, it can be deduced that the configuration at the stereogenic, metalated carbon center of (*R*,*S*)-**6** is stable for at least 60 min at room temperature (Scheme 2).

We made a striking observation on the stereochemical course of the lithiation–substitution sequence when it was carried out in a toluene/cyclohexane/THF mixture under otherwise identical conditions (Scheme 2, path 3). The single-crystal X-ray structural analysis of the two alkyl lithium compounds (*R*,*S*)-**6** and (*R*,*S*)-**6**·THF do indeed show in each case an *R* configured metalated carbon center (Figures 1 and 2). The ^1H NMR spectroscopic investigation of the crude product of the reaction of (*R*,*S*)-**6**·THF with chlorotrimethyl-

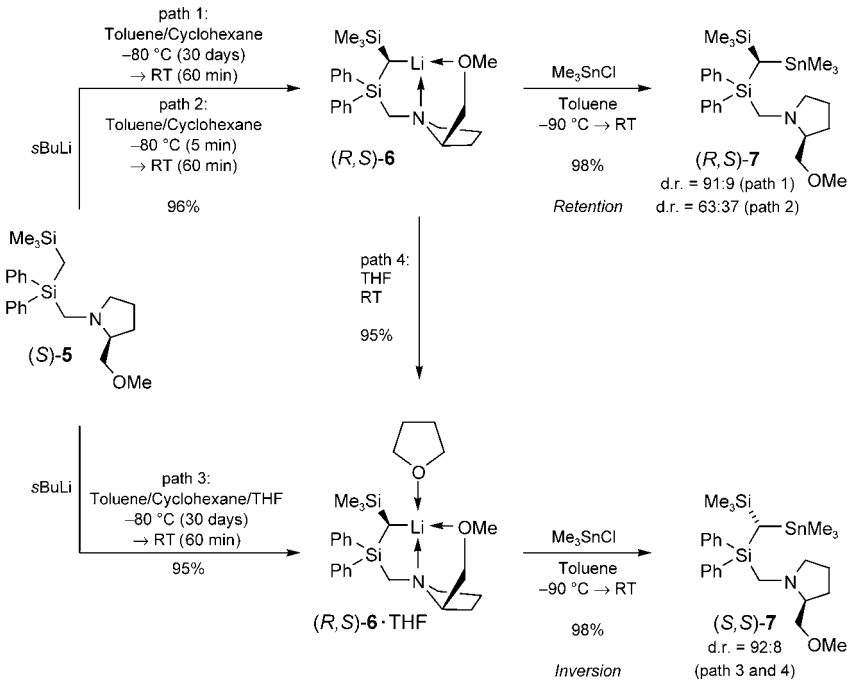

Scheme 2. Lithiation of (*S*)-**5** and diastereodivergent reaction pathway. For full experimental details see the Supporting Information.

stannane shows, however, a diastereomeric ratio of d.r. = 92:8 for the tin compound formed in favor of the (*S*,*S*)-**7** diastereomer. Thus the substitution with (*R*,*S*)-**6** in the presence of THF occurs with inversion of the configuration, whereas in the noncoordinating toluene/cyclohexane mixture retention of configuration is observed. Moreover, the addition of a few drops of THF to the only slightly diastereomerically enriched sample of (*R*,*S*)-**6** (d.r. = 63:37) at room temperature in an analogous trapping reaction at −90 °C also produces the tin compound (*S*,*S*)-**7** with d.r. = 92:8 (Scheme 2, path 4). Thus, this fourth form of the reaction is a thermodynamically controlled epimerization at room temperature. Reactions of isolated (*R*,*S*)-**6** in toluene and (*R*,*S*)-**6**·THF in THF gave the same results.

The molecular structures of (*R*,*S*)-**6** (Figure 1) and (*R*,*S*)-**6**·THF (Figure 2) were determined by single-crystal X-ray structural analysis. The stereochemical homogeneity of the samples was confirmed in that identical lattice constants were obtained for each of ten randomly chosen crystals.[8] Both (*R*,*S*)-**6** and (*R*,*S*)-**6**·THF crystallize as monomers with only one C–Li contact of 2.176(6) ((*R*,*S*)-**6**) and 2.195(8) Å ((*R*,*S*)-**6**·THF). Both molecules have an *R* configuration at the metalated carbon center C1. The lithium centers show in each case a contact to the metalated carbon center C1 and are also coordinated by both a nitrogen and oxygen center of the SMP ligand. A fourth coordination site on the lithium in (*R*,*S*)-**6**·THF is occupied by a THF molecule from the solvent, whereas in the case of (*R*,*S*)-**6** short contacts to the hydrogen atoms H3b (2.281 Å) and H3c (2.014 Å) of a methyl group of the neighboring molecule are observed with formal formation of a coordination polymer. Common to both structures are short Si1–C1 and Si2–C1 bonds of between 1.789 and 1.808 Å, which result from the polarization-induced charge stabilization by the silicon centers (α effect). The sum of the angles of 348.2 and 345.6° for the "carbanionic units" of (*R*,*S*)-**6** and (*R*,*S*)-**6**·THF show a pyramidalization of the metalated center, which is illustrated by the Si1-C1-Si2 bond angles of 127.2(2) and 125.6(2)°. In (*R*,*S*)-**6** the shortest contact involving the lithium center (1.970(7) Å) is to the oxygen atom of the SMP handle. In (*R*,*S*)-**6**·THF the shortest Li–O contact of 1.955(8) Å is to the coordinated THF molecule, the distance to the oxygen atom of the SMP handle is increased to 2.079(8) Å.

Whereas (*R*,*S*)-**6** is the result of a kinetically controlled diastereotopos-differentiating deprotonation, (*R*,*S*)-**6**·THF can be formed in a thermodynamically controlled epimerization at room temperature. Examination of the C1–Li bond axis shows that in the stereoisomer (*R*,*S*)-**6**·THF, the trimethylsilyl group and the THF molecule distance themselves spatially from each other and the crystallized

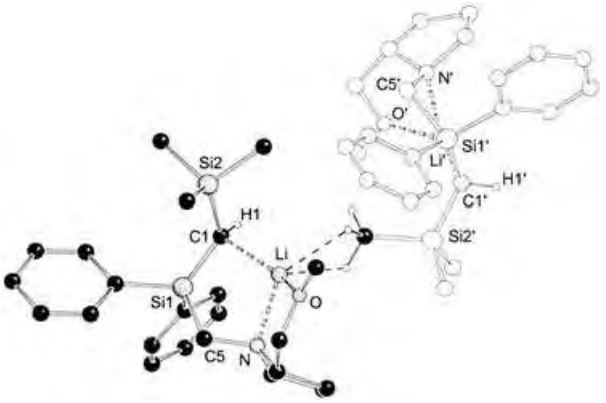

Figure 1. Molecular structure of compound (*R*,*S*)-**6** (Schakal representation).[9a] Selected bond lengths [Å] and angles [°]: Si1-C1 1.800(4), Si2-C1 1.808(4), Li-C1 2.176(6), N-Li 2.098(7), O-Li 1.970(7); C1-Si1-C5 109.7(2).

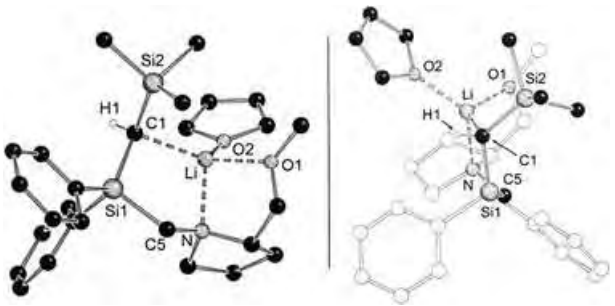

Figure 2. Molecular structure of compound (*R*,*S*)-**6**·THF (left), detail representation (right; Schakal representation).[9a] Selected bond lengths [Å] and angles [°]: Si1-C1 1.789(4), Si2-C1 1.797(4), Li-C1 2.195(8), N-Li 2.106(7), O1-Li 2.079(8), O2-Li 1.955(8); C1-Si1-C5 109.6(2).

diastereomer thus represents the thermodynamically most stable isomer (Figure 2 right). A quantum chemical estimation of the relative energies of (*R*,*S*)-**6**·THF and (*S*,*S*)-**6**·THF at the B3LYP/6-31+G(d) level shows an energetic preference for (*R*,*S*)-**6**·THF over (*S*,*S*)-**6**·THF of 8 kJ mol^{-1}, which corresponds to the trend found experimentally.[10]

The ^{13}C NMR spectrum of (*R*,*S*)-**6**·THF in [D$_6$]benzene at room temperature shows only one set of signals in which a quartet with $^{1}J_{^{13}C,^{7}Li} = 16.0$ Hz is observed for the metalated carbon center (Figure 3). The line shape of the quartet is

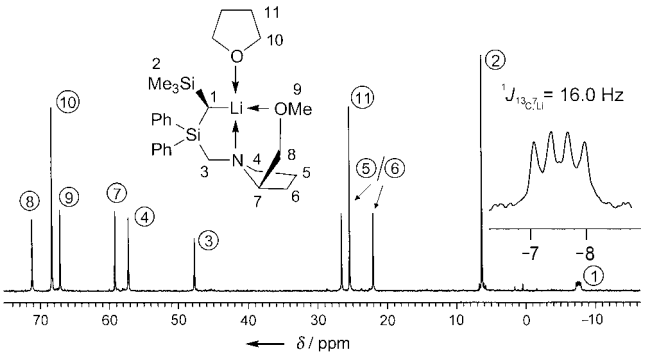

Figure 3. Section from the ^{13}C NMR spectrum of (*R*,*S*)-**6**·THF in [D$_6$]benzene at room temperature.

produced by superimposition of the ^{13}C–^{7}Li coupling pattern with the ^{13}C–^{6}Li coupling pattern. This result suggests the presence of **6** as a monomer in solution with the lithium center static on the NMR time scale at room temperature. NMR spectroscopy studies by Fraenkel and Reich in polar solvents, usually THF, show that inversion barriers which play a role in the racemization of chelated alkyl lithium compounds lie in an energy range of 18–80 kJ mol^{-1},[11], however an SMP handle allows particularly strong chelation. Thus, fixation of the lithium center in THF and the high stability of the configuration in nonpolar solvents for (*S*)-**5** are not surprising.

In contrast a ^{13}C–^{7}Li coupling could not be resolved for (*R*,*S*)-**6** in [D$_8$]toluene, neither at room temperature nor between 20 and −50 °C. Owing to the high quadrupole moment of ^{7}Li (nuclear spin $I = {}^{3}/_{2}$) corresponding couplings are not always observed, even in "frozen" exchange processes. Through the shortening of the carbon–lithium contact during a reduction in temperature, the resolution of the C–Li coupling, which is caused by the increasing quadrupole interaction, becomes worse and the coupling pattern often disappears again.[12] The same effect is observed in low-temperature ^{13}C NMR spectroscopy investigations with (*R*,*S*)-**6**·THF in [D$_8$]toluene, in which a strong broadening of the signal for the metalated carbon center is observed with falling temperature.

How can the experimentally observed stereochemical course be explained? In the case of a coordinated donor molecule, as in (*R*,*S*)-**6**·THF, it emerges that a rear attack of the electrophile with inversion of configuration is possible. This possibility is also shown by visualization of (*R*,*S*)-**6**·THF (optimized at the B3LYP/6-31+G(d) level) with the corresponding HOMO (the orbital coefficients at C1 are almost equally large; Figure 4). In contrast, with a free coordination site, substitution with retention of configuration is conceivable after precoordination at the formally triply coordinated

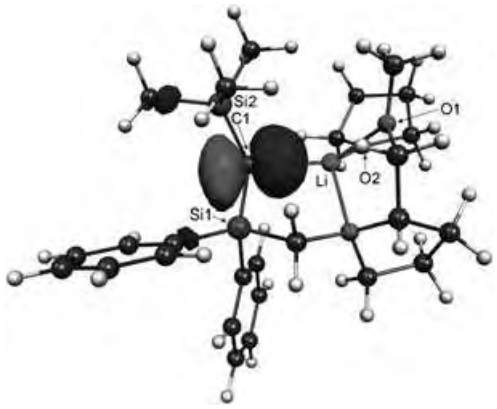

Figure 4. B3LYP/6-31+G(d)-optimized structure of (*R*,*S*)-**6**·THF and visualization of the highest occupied molecular orbital (Molekel representation; [9b] the numbering corresponds to that in Figure 1).

lithium center in solution (just as high selectivities in deprotonations can be explained by complex-induced proximity effects (CIPE)).[13] Thus the choice of solvent, and with it the coordination sphere of the lithium center, decides the stereochemical course of the reaction of (*R*,*S*)-**6** with the electrophile Me$_3$SnCl.

Our studies show that the choice of the solvent can have a considerable effect on the (stereochemical) reaction behavior of an alkyl lithium. Therefore only an unambiguous experimental determination of the absolute configuration can form the basis for an explanation of the stereochemical course of the reaction of diastereomerically enriched alkyl lithium compounds. Quantum mechanical methods can be of assistance in comparing the mechanisms involved. The next question is whether this observation in our system (*R*,*S*)-**6** can be confirmed by reactions with other electrophiles.

[1] In general we refer to the stereogenic metalated carbon center when we speak of "enantiomerically enriched" alkyl lithium compounds, however, compounds of this type are in fact diastereomerically enriched alkyl lithium compounds.

Structure Determination

An Old Target Revisited: Two New Privileged Skeletons and an Unexpected Binding Mode For HIV-Protease Inhibitors**

*Edgar Specker, Jark Böttcher, Hauke Lilie, Andreas Heine, Andreas Schoop, Gerhard Müller, Nils Griebenow, and Gerhard Klebe**

HIV protease is probably the most vigorously studied enzymatic target for therapeutic intervention in the short history of structure-based drug design.[1] For over a decade, attempts to find new efficient inhibitors have attracted and absorbed the curiosity, talents, and energy of many scientists.[2] No other protein has been scrutinized as often in crystal structures of protein–ligand complexes; in the publicly available Protein Data Bank more than 200 individual structures have been deposited.[3] As a result of these impressive efforts, nine approved drugs have been launched that improve both the quality of life and life expectancy for an increasing number of HIV-infected patients.[4] However, the initial euphoria surrounding these major achievements has decreased due to the occurrence of viral resistance to the prescribed therapy based on these drugs.[5] As a consequence, novel inhibitors with alternative frameworks are being sought to circumvent resistance development.

Can we expect any new inhibitory principles to be discovered in the case of such an exhaustively studied member of the aspartyl protease family? In an attempt to develop novel privileged building blocks to address the conserved binding epitope of aspartyl protease, we have designed and synthesized two novel parent structures, the aminohydroxysulfones and pyrrolidinemethaneamines. Both skeletons were designed to address, across the entire family of aspartyl proteases, the conserved catalytic diad and the peptide recognition motif, which features the proteases for proper recognition and arrest of their substrates. Furthermore, both skeletons were designed with the impetus to give easy access to multiple decorations using side chains tailored to systematically explore and specifically address the various substrate recognition pockets exhibited by this class of proteases.

Up to now a plethora of privileged building blocks have been incorporated successfully into HIV-protease inhibitors (Figure 1). The first generation of inhibitors comprises motifs

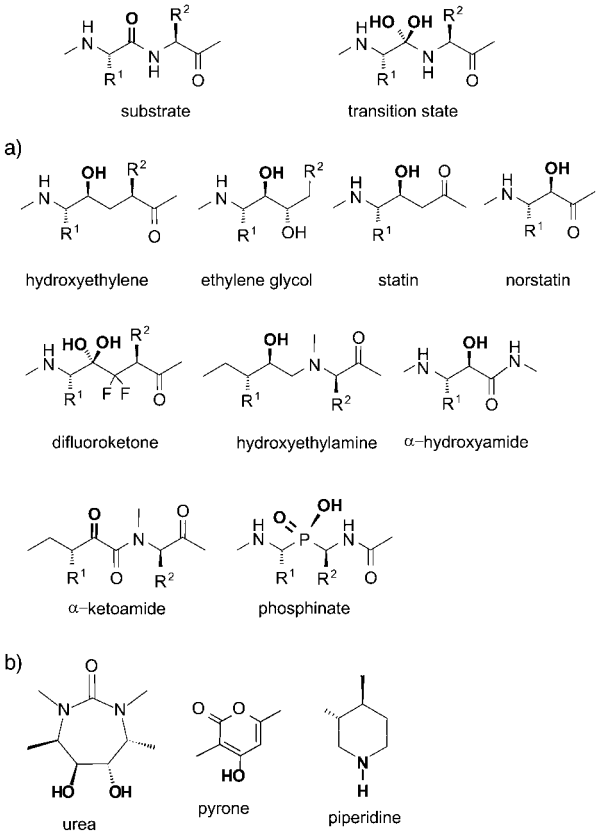

Figure 1. Privileged skeletons frequently used to address the conserved catalytic center in aspartyl protease. a) Classical transition-state analogues usually incorporated into peptidomimetics; b) newly discovered scaffolds that address aspartyl proteases, in particular HIV protease.

classified as transition-state analogues, which closely resemble the tetrahedral intermediate formed along the reaction pathway. The second generation of lead compounds departed from closely imitating the transition state, and they frequently tried to incorporate the position of the structural water.[6,7] This water mediates in case of the substrate analogue inhibitors the protein–ligand interaction. In the late 1990s researchers at Roche discovered by screening studies the piperidine moiety as a novel privileged skeleton for addressing the catalytic center of aspartyl proteases.[8]

Our rational design of the aminohydroxysulfones was inspired by four skeletons of already known inhibitors targeting distinct aspartyl proteases (Scheme 1). Our aminohydroxysulfones are derived from the hydroxyethyleneamine core of the HIV-protease inhibitor amprenavir (**1**),[9] by replacing the *sec*-butyl-substituted nitrogen atom in the α-

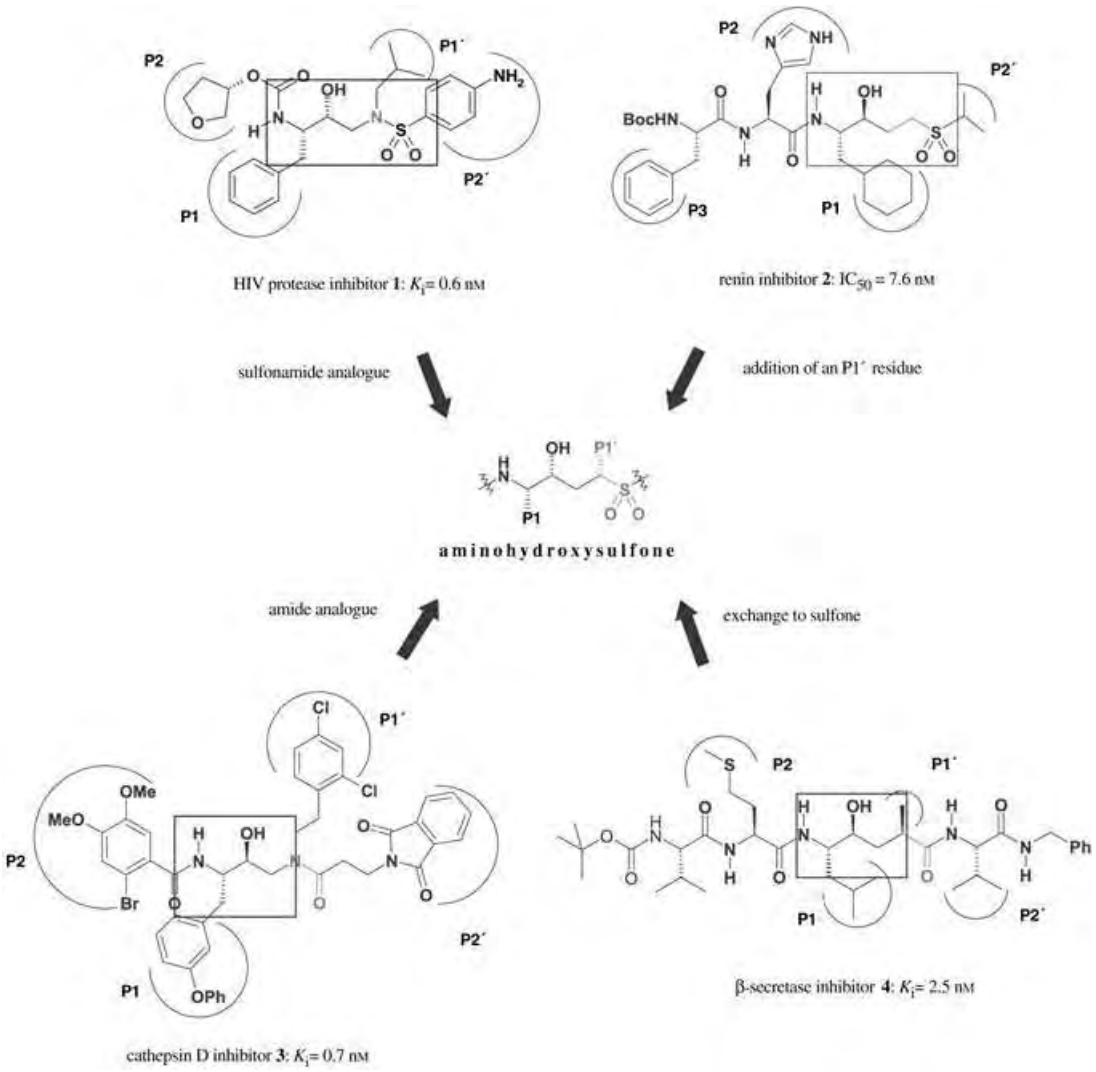

Scheme 1. Design of the aminohydroxysulfones based on the structural elements of known aspartyl protease inhibitors.

position with a carbon atom. The related sulfone core of the renin inhibitor **2**[10] lacks a substitution in α-position to address the P1′ pocket. In the aminohydroxysulfones the central scaffolds of the cathepsin D inhibitor **3**[11] and the β-secretase inhibitor **4**[12] are changed from an amide bond and a keto group, respectively, to a methylenesulfone moiety. To assess the potential of the aminohydroxysulfones as novel lead structures for the inhibition of aspartyl proteases, we decorated the central core with the previously optimized substituents found in the inhibitors **1**–**4**, which address the S2–S2′ subsites.

In our design of the novel pyrrolidinemethaneamines we intended to combine two key structural elements present in the classical peptidomimetic substrate-analogue inhibitors such as pepstatin (**5**, Scheme 2)[13,14] and the newly discovered type of cyclic amines (see Figure 1) to directly address the pivotal position between both catalytic aspartates.

The hydroxy group of statin directly coordinates to the two opposing aspartic acids. We decided to replace this privileged core fragment by a pyrrolidine moiety capable of being symmetrically extended towards the C- and N-terminal subsites by using molecular scaffolds frequently incorporated into substrate-analogue inhibitors. As apparent from the multiple crystal structures with such peptidomimetics (e.g. pepstatin **5**, Scheme 2), important hydrogen bonds are formed by the peptide-like backbone of the inhibitor to the flap regions of these proteases. In the case of HIV protease, this contact is mediated by a water molecule in hydrogen bonds with the amide functions of Ile A50 and Ile B50; for cathepsin D the inhibitor is directly hydrogen-bonded to the amide functions of Gly 79 and Asp 87. To evaluate the inhibitory potential of the new pyrrolidinemethaneamines we decorated the central pyrrolidine moiety with side chains already optimized for the HIV-protease inhibitor amprenavir (**1**). Diastereoselective syntheses yielded racemic mixtures of the designed target compounds. The synthesis and characterization of the new inhibitors will be described elsewhere.

In the series of aminohydroxysulfones the racemate of **6** (Figure 2) exhibited a K_i value of 80 nM for HIV-protease inhibition. Resolution of the racemic mixture revealed the more potent enantiomer to have a K_i value of 45 nM. To validate whether the binding of **6** follows the initial design

Figure 3a shows the binding mode of the more potent enantiomer, (*S*,*R*,*S*)-**6**, superimposed with the complex of amprenavir (**1**). The latter inhibitor served as one of the references in our design concept. Both inhibitors bind with their central OH group between the two aspartates, and either their carbonyl or sulfonyl groups form hydrogen bonds to the structural water of the protease. The S1 pocket (Leu A23, Pro A81, Val A82, Ile A84) is occupied nearly identically by the benzyl and bromobenzyl moieties in **1** and **6**, respectively. The bulky *meta*-bromine substituent in **6** extends into the adjacent solvent environment, thus not provoking any induced-fit adaptations. Similarly the S2′ subsite accommodates the *para*-aminophenyl (**1**) and the *para*-fluorophenyl (**6**) groups in nearly indistinguishable fashion. However, the fluorine substituent in **6** cannot form a hydrogen bond with the adjacent Asp 30 as is observed in the complex with **1**. The *sec*-butyl substituents at the amino group of **1** and on the α-C atom of the sulfone group of **6** orient their terminal methyl groups in very similar fashion into the S1′ site (Leu A23, Gly A27, Ile B81, Val B82, Ile B84) and achieve comparable occupancy. The two inhibitors differ in the size of their substitutents hosted in the S2 subsite (Ala B28, Val B32, Ile B47, Ile A50). Amprenavir (**1**) exhibits a terminal tetrahy-

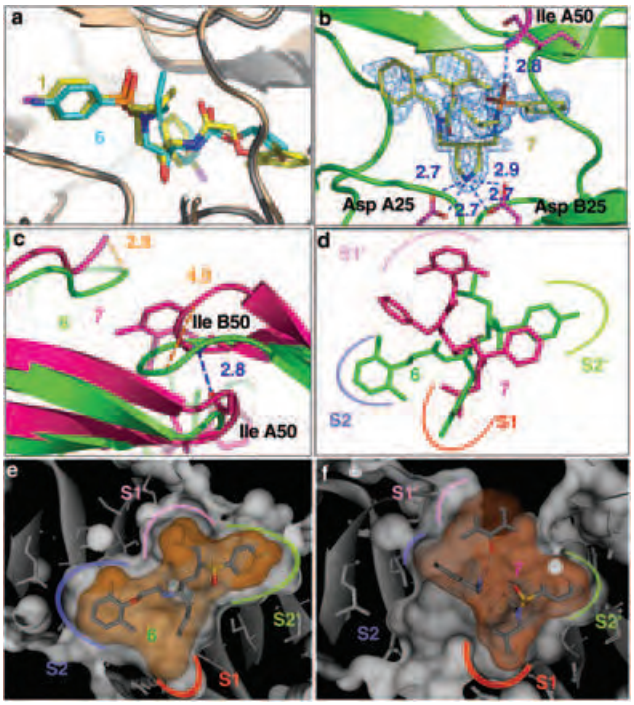

Figure 3. a) Superposition of the binding mode of (*S*,*R*,*S*)-**6** with the structure of **1** in complex with HIV1 protease. b) Binding mode of **7** with the protease showing the pyrrolidino nitrogen in the pivotal position between the two aspartates; the difference electron density (contour level 1σ) is indicated as blue chicken wire. c) Superposition of the complex of **6** and **7** depicting the strong distortion of the flap region for the latter complex. d) Ligands **6** and **7** are mutually aligned to show the addressing of subsites S2–S2′ of the protease. Sections of the complex with **6** (e) and **7** (f) showing the occupation of S2 to S2′ by the side chains of the inhibitor; protein surface in white, ligand surface in orange.

drofuran moiety, whereas **6** is decorated with a 2,6-dimethylphenoxy portion. The latter sterically more demanding substituent requires more space in the S2 pocket[15] and extends beyond the region filled by **1** into the bordering solvent. Nevertheless, it achieves a better occupation of this subpocket. Despite these differences, both complexes show hardly any conformational differences and no induced-fit adaptations of the enzyme.

The aminohydroxysulfone moiety of **6**, developed from a rather conservative design concept from already known inhibitors, exhibits the expected binding mode. The 75-fold decrease in affinity relative to that of amprenavir is supposedly due to the bromine atom of the *meta*-bromobenzyl portion, which remains partly exposed to solvent in the bound state. This incomplete desolvation is possibly detrimental to binding. Furthermore, most likely the close contact of the *para*-aminophenyl moiety in **1** is more favorable than the short distance of the negatively polarized *para*-fluorophenyl group in **6** to the carboxy group of Asp30.

While our rather conservative design of the aminohydroxysulfone template closely resembles the underlying parent substrate structure of an extended peptide chain with protruding side chains, the pyrrolidinemethaneamine core exhibits little if any structural resemblance to a peptide. Docking suggested the binding to be similar to that of the classical substrate-like inhibitors; however, significant crowding in the central region was indicated. Among the derivatives synthesized, **7** (Figure 2), specifically decorated to address HIV protease, shows a K_i value of 1.5 μM as a racemate. Cocrystallization of HIV protease with racemic **7** revealed that the *R*,*R* enantiomer binds to the enzyme (Table 1). As expected, the nitrogen atom of the pyrrolidine ring, likely protonated in the bound state, occupies the pivotal position between the two aspartates. As expected, it is a perfect substitute for the hydroxy group of, for example, **6** (Figure 3b). Even though the side chains of (*R*,*R*)-**7** are similar to those of (*S*,*R*,*S*)-**6**, the pyrrolidine-based inhibitor adopts a new and surprising binding mode. First of all, it repells the structural water from the binding site and forms one direct hydrogen bond to the backbone NH of Ile A50 with one of its sulfoxy oxygens. The carbonyl group of the amide functionality remains unsatisfied without forming any further polar contacts to the enzyme. As a consequence, the NH backbone functionality of Ile B50 finds a hydrogen-bonding partner in the carbonyl group of the amide bond of Ile A50 of the neighboring polymer chain. This additional contact to the neighboring flap loop stabilizes the dimer in the flap region. Possibly this surprising further hydrogen bond is a surrogate for the missing contact originally formed by the bridging structural water which has been repelled from the complex. This unusual geometry of the flap parallels a significant distortion (up to 4.9 Å) of the polymer chain in this region compared to, for example, the complex formed with **6** (Figure 3c).

The decorating side chains of **7** were designed to address, like **6**, the four subsites S2–S2′. However, the overall orientation of the inhibitor in the complex is rotated relative that of **6**. To some extent similarity in the occupation of the S1 and S2′ subsites (Figure 3d–f) can be recognized. The S1 pocket (Leu A23, Val A82, Val A84, Gly B48, Gly B49) accommodates the *sec*-butyl group of **7** and the *meta*-bromobenzyl moiety of **6** in a similar fashion. Likewise, the phenylsulfonamide substitutent is hosted by the S2′ pocket (Ala A28, Val A32, Ile A84, Ile B50). In case of **6**, this site is filled by the *para*-fluorophenyl group. The remaining two decorations, the *N*-benzyl- and dimethylphenoxy group, are placed next to each other; they extensively occupy the S1′ pocket and penetrate into the bordering solvent environment. The *N*-benzyl substituent barely permeates into the S2 pocket, which remains virtually unoccupied. The site accommodating the latter two side chains of **7** is bound by the residues Ile A50, Val B32, Ile B47, Ile B54, Thr B80, Pro B81, Val B82, and Ile B84.

Interestingly enough **6** and **7** crystallize in two distinct space groups, $P2_12_12$ and $P2_12_12_1$, respectively. Accordingly, it is questionable whether the observed differences are provoked by crystal packing. However, in structures of other complexes found in either space groups, distortions of the flap region similar to that observed for **7** were not observed. Next, we compared the size of the ligand-surface portion that is buried upon complex formation.[16] For **1** and **6** 95% of the ligand surface is in close contact with the protein, whereas for **7** only 85% of the surface is buried upon complexation. This

significantly smaller value for **7** is in agreement with the solvent exposure of the bulky dimethylphenoxy moiety in S1′. The latter extends with one of its faces significantly into the neighboring solvent area; inhibitor **6** places a short *sec*-butyl group into this pocket largely avoiding solvent exposure.

Two new skeletons have been discovered to successfully address the conserved binding motif of aspartyl proteases: the aminohydroxysulfones and the pyrrolidinemethanamines. Crystal structure analyses of the new privileged scaffolds decorated with side chains intended for HIV-protease inhibition reveal their binding modes. The binding mode of the aminohydroxysulfone was not surprising. However, the pyrrolidine derivative adopts a surprising and rather unexpected binding mode. Detailed analysis of its bound conformation and the contacts formed with the protein will provide further insights to explain the adopted binding mode. Furthermore, it will guide the structure-based optimization of this new inhibitor skeleton to improve its binding affinity. Supposedly, the new inhibitor skeleton also provides challenging opportunities to combat resistance. The new type of inhibitor achieves good inhibition although one subsite is left virtually unoccupied. Thus, the virus has at least one less option for mutational adaptation. Furthermore, the induced perturbation in the flap region also occurs in an area most likely out of range for the virus to mutate without significant loss in functionality of its protease.

The present study is a lesson in drug design. The binding mode of **6**,[17] derived by a rather conservative design concept, was correctly predicted including the assignment of stereocenters. Side chains transferred from other potent inhibitors were actually found in the expected subsites. The opposite has to be conceived for **7**. In rational design of **7** the hydroxy function in the transition-state analogue was correctly replaced by a pyrrolidino nitrogen. Furthermore, the inhibitor was equipped symmetrically with two polar acceptor groups to address the flap water. However, this water is repelled from the complex. The side chains were selected analogously to those of **6**, but they actually accommodate different subsites. It has to be admitted that design and docking were unable to predict the correct binding mode. Nevertheless, a potent class of ligands has been created. While the binding geometry of the heterocyclic scaffolds matches the prediction, the mounted side chains deviate substantially from the expected orientation. Without crystallography we would never have detected this discrepancy. With some good luck, an elaborate and tediously collected, however nonconclusive structure–activity relationship could have been indicative. This clearly points to the limits of computer design and stresses the importance of experiments. Only if both go hand in hand, can successful structure-based design be accomplished. The two novel scaffolds can be added to the toolbox of medicinal chemistry. They meet the stringent definition of privileged structures: they address the target family-wide molecular recognition commonalities and simultaneously offer a modular chemistry for peripheral decoration with required special orientation.

NMR Spectroscopy

Stretched Gelatin Gels as Chiral Alignment Media for the Discrimination of Enantiomers by NMR Spectroscopy**

*Kyryl Kobzar, Horst Kessler, and Burkhard Luy**

Verification of the enantiomeric purity of a product and measurement of enantiomeric excess is an everyday problem in modern organic chemistry. Therefore, the development of a convenient method of measurement for this purpose is desirable. Classical NMR spectroscopic techniques that discriminate enantiomers depend on chiral auxiliaries such as chiral derivatizing agents, lanthanide chiral-shift reagents, and chiral solvating agents.[1,2] These methods work only for functionalized chiral molecules of interest that can interact with the auxiliaries to build detectable diastereomeric compounds or adducts. In contrast, chiral orienting media permit enantiomer discrimination through the differential ordering effect of enantiomers within the chiral phase.[3,4] Therefore, even compounds that lack polar groups, such as saturated chiral hydrocarbons[5] and even prochiral elements in symmetrical molecules,[6,7] can be distinguished by NMR spectroscopy in such media.

So far, only surfactant bilayers,[8–10] various chiral liquid-crystalline media,[11–15] and achiral liquid crystals with chiral cages[16] have been reported to be suitable for enantiomeric discrimination. Such media are usually difficult to prepare and operate only within certain temperature ranges. Furthermore, their induced orientation depends on the strength of the magnetic field. In contrast, covalently cross-linked, stretched-polymer gels[17–19] are relatively easy to handle and provide field-independent orientation.

The aim of the studies presented herein was to obtain partial alignments in stretched chiral gels. Gelatin in the form of *gummibärchen* (the famous German sweets) was used for the initial proof of principle that alignment is possible with this kind of polymer. In further experiments we were able to show that stretched gelatin gels as chiral alignment media not only make it possible to obtain structural information through residual dipolar couplings,[20,21] but also provide a way to discriminate between enantiomers and to measure enantiomeric excess. Gelatin therefore represents a new subtype of alignment media: polymer gels in which the spatial structure is almost solely stabilized by hydrogen bonds.

Gummibärchen were swollen in deionized water to about twice their original dimensions (Figure 1) and subsequently cut into roughly cylindrical shapes. They were then dried on a glass capillary and inserted into NMR tubes with D_2O. After equilibration for two days, deuterium NMR spectra were acquired with a clearly visible quadrupolar splitting in the range of $\approx$20 Hz (Figure 2A).

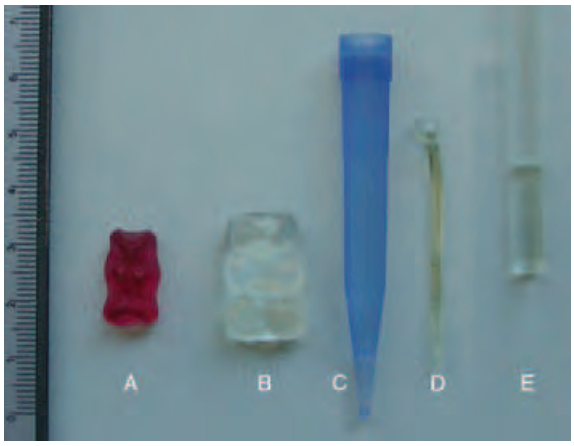

Figure 1. Various stages of the preparation of stretched gelatin samples: A) gummibärchen; B) gummibärchen swollen in water; C) gelatin gel (10%) prepared in a pipette tip; D) gel after drying in the pipette tip; E) equilibrated gelatin sample with a D_2O deuterium splitting of 117 Hz (Figure 2B); left: centimeter scale.

After this successful proof that partial alignment is possible with gelatin-based gels, further experiments with household gelatin were conducted. Heated gelatin solution ($\approx$10% w/v) was poured into a standard pipette tip with a sealed end and dried for eight weeks under refrigeration (Figure 1). From this, solid sticks with diameters of $\approx$1.9 mm and uniform appearance were collected, put into NMR tubes, and subjected to constrained swelling by direct addition of D_2O in a procedure similar to that described earlier for polystyrene sticks.[19] After swelling for a couple of days and a single solvent exchange to wash out unwanted substances, the gel showed a quadrupolar splitting for D_2O of 117 Hz at 25°C (Figure 2B). A mixture of L-alanine (30 mg) and D-alanine (25 mg; 9% *ee*) was added to the sample and allowed to diffuse into the gel. Although its spatial structure is largely stabilized by hydrogen bonds, the gel, in the presence of polar solutes over a two-month period, exhibited no change in the deuterium quadrupolar splitting of the solvent. A specially designed *J*-coupling experiment (Figure 3) was acquired that allowed separation of the two enantiomers.

In principle, any order-dependent NMR interaction can be used for the distinction of enantiomers. So far, mostly 1D[3,4,10,11,13,14,16,24–30] and 2D[4,5,31–33] ^{2}H NMR spectra of non-isotopically enriched samples have been reported in which use was made of the difference in residual quadrupolar couplings in chiral orienting media. However, the low natural abundance of deuterium nuclei requires either long acquisition times or the use of deuterated compounds.

Recently, *J*-coupling spectroscopy on ^{1}H[31] and ^{13}C[34] nuclei was proposed as an alternative technique in which the different residual dipolar couplings (RDCs) of enantiomers lead to distinguishable NMR spectroscopic signals. However, the lower limit of alignment in known liquid-

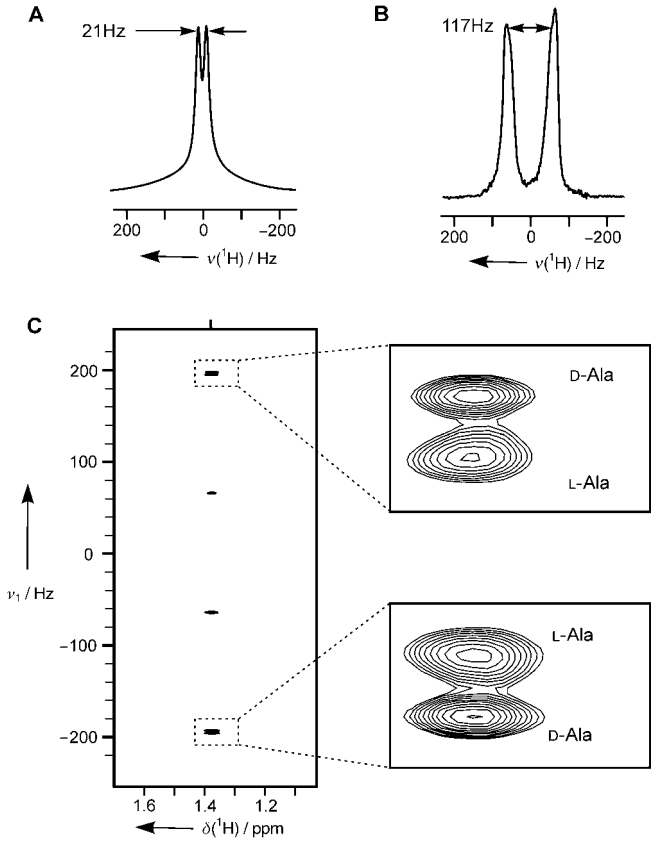

Figure 2. NMR spectra acquired on stretched gelatin samples: A) ^{2}H NMR spectrum of a stretched gummibärchen sample swollen in D_2O; B) ^{2}H NMR spectrum of a sample of household gelatin (see text for details); C) ^{1}H,^{13}C-BIRD^{d,X}-*J*-coupling spectrum of L-Ala/D-Ala (1.2:1): the two enantiomers can be clearly distinguished. The spectrum was acquired with the sequence described in Figure 3 with 2048 t_1 increments and processed in both dimensions in phase-sensitive mode.

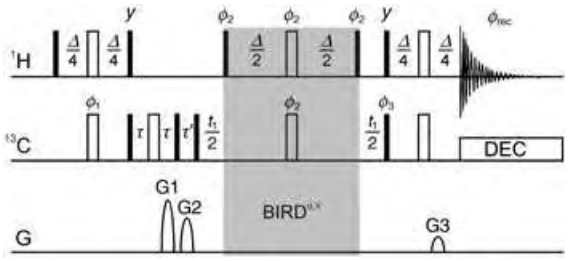

Figure 3. ^{1}H,^{13}C-BIRD^{d,X}-*J*-coupling experiment for the phase-sensitive, high-resolution detection of single-bond ($D_{CH}+{}^1J_{CH}$) couplings. 90° and 180° pulses are indicated by black and white bars, respectively. Unless otherwise indicated, the pulses are *x*-phase. Phase cycles are $\phi_1 = y, y, y, y, -y, -y, -y, -y$; $\phi_2 = x, x, -x, -x$; $\phi_3 = x, -x$; $\phi_{rec} = x, -x, x, -x, -x, x, -x, x$. Delays: $\Delta = 1/({}^1J_{CH}+D_{CH})$, τ and τ' are delays for gradient application (1.2 ms). The ratio of gradient strengths are G1:G2:G3 = 80:30:20.1. The BIRD^{d,X} element for suppression of long-range ^{1}H,^{13}C-couplings is shaded gray. Phase-sensitive absorption (States-TPPI) is possible by cycling ϕ_1. Alternatively, simple t_1-incrementation can be applied with the processing procedure described previously in references [22, 23].

crystalline media results in considerable RDCs that can easily reach the size of $^1J_{CH}$-coupling constants,[35] which therefore limits one to very basic NMR spectroscopic experiments with known disadvantages: ^{1}H *J*-coupling spectra are not phase-sensitive and broadened line widths from ^{1}H,^{1}H-RDCs lead to spectra that in many cases are hardly interpretable. Directly detected ^{13}C *J*-coupling spectra, on the other hand, have the disadvantage of a low signal-to-noise ratio.

In contrast, stretched gels with relatively weak induced alignments permit the use of conventional heteronuclear pulse-sequence building blocks, as the condition $D_{CH} \ll {}^1J_{CH}$ can be easily fulfilled. We were therefore able to design a ^{1}H-excited and detected ^{13}C,^{1}H-correlated pulse sequence with an additional BIRD^{d,X} element[36] for the suppression of long-range ^{13}C,^{1}H scalar and dipolar couplings (Figure 3). This experiment has acceptable sensitivity. Phase-sensitive detection and decreased cross-peak multiplicity decrease the signal width in the indirect dimension sufficiently to separate very small differences in single-bond D_{CH} coupling constants.

The pulse sequence applied to the mixture of L-alanine/D-alanine (1.2:1) diffused in a stretched gelatin gel gave two multiplets for the β-CH_3 groups with a well-resolved difference in outer *J*-multiplet components of 2.5 Hz (Figure 2C). A control experiment with a sample prepared with L-alanine revealed only one signal at the same position as the stronger component of the mixed sample. This is clear evidence that the difference of the D_{CH} RDCs of the enantiomers in chiral stretched gelatin is the origin of the split signal (data not shown). The spectrum of the enantiomeric mixture is so well-resolved that by cross-peak integration, an enantiomeric excess of $7 \pm 5\,\%$ was obtained which is very close to the expected value. Notably, the observed signal intensity is dependent not only on the concentration of a single enantiomer, but also on the efficiency of coherence transfer via scalar and dipolar couplings with the function: $\sin^2(\pi[{}^1J_{CH}+D_{CH}]\Delta/2)\cos(\pi[{}^1J_{CH}+D_{CH}]\Delta)$. For the case shown in Figure 2C this leads to a very low systematic error of less than 0.3 % *ee*.

We have shown the usefulness of gelatin gels for the partial alignment of molecules in aqueous environments. They form three-dimensional networks of polypeptide chains from the partial renaturation of native collagen,[37] which eliminates the need for any added cross-linking agent to connect the polymer chains, as is the case for other gels used for the same purpose.[17–19,38–40] Interestingly, this polymer structure, which is held together almost solely through a network of hydrogen bonds, is able to withstand the forces present in the constrained swollen gels. However, household gelatin gels are generally not stable at temperatures above $\approx 35\,°C$,[37] and the chemical stability of stretched gels with respect to solutes must be studied in greater detail. At neutral pH values and at room temperature, our samples did not change alignment properties after more than two months.

Chiral alignment media lead to the differential orientation of enantiomers and therefore allow discrimination of enantiomeric mixtures by NMR spectroscopy.[4] To our knowledge, gelatin is the first chiral alignment medium that combines the possibility of enantiomeric resolution with the advantages of partial alignment through mechanical stretching. The easily scalable alignment reported herein holds potential for the

application of more sophisticated pulse sequences with greater sensitivity and decreased signal width due to reduced multiplet patterns. The combination of chiral gel-based alignment media, field-independent alignment, and field-independent *J*-coupling-based measurement techniques may eventually allow these measurements to be taken on low-field, low-cost NMR spectrometers, as long as chemical-shift resolution is not necessary.

This approach toward enantiomeric resolution is not limited to gelatin polymers and is probably transferable to other chiral gels or achiral gels with chiral cages, which would permit enantiomer discrimination in nonaqueous solutions as well.

Reversible Self-Organization of Semisynthetic Zinc Chlorins into Well-Defined Rod Antennae**

*Valerie Huber, Martin Katterle, Marina Lysetska, and Frank Würthner**

Dedicated to Professor Franz Effenberger on the occasion of his 75th birthday

The light-harvesting rod-shaped antennae in the chlorosomes of green phototrophic bacteria (e.g. *Chloroflexus aurantiacus*) are one of the most fascinating examples of self-organized functional assemblies. In contrast to other plant or bacterial light-harvesting systems, chlorosome antennae solely consist

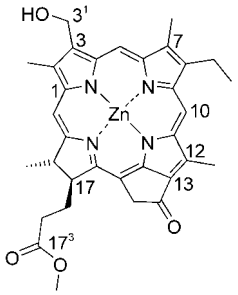
 DOI: 10.1002/anie.200462762

of bacteriochlorophylls (BChl) and do not require any protein to control their self-organization. Holzwarth, Schaffner, Tamiaki, and co-workers have investigated these natural systems and developed a simple model compound **1** for the main constituents, namely BChl *c*, of these light-harvesting antennae.[1]

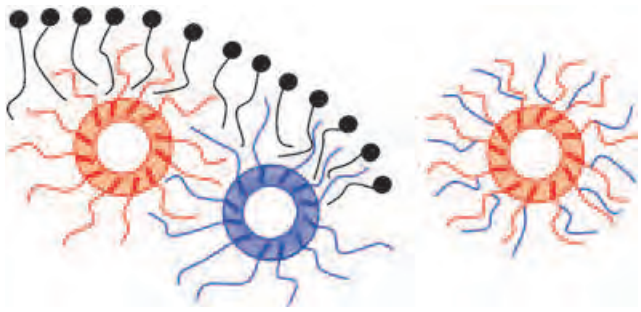


1

Both BChl *c* and the model compound **1** self-organize in nonpolar solvents, such as *n*-hexane, into extended dye aggregates which exhibit the highest exciton diffusion length of all dye assemblies reported to date.[2] This property is of fundamental importance for the high efficiency of the light-harvesting antennae in chlorosomes of green bacteria and instructive for the design of organic solar cells.

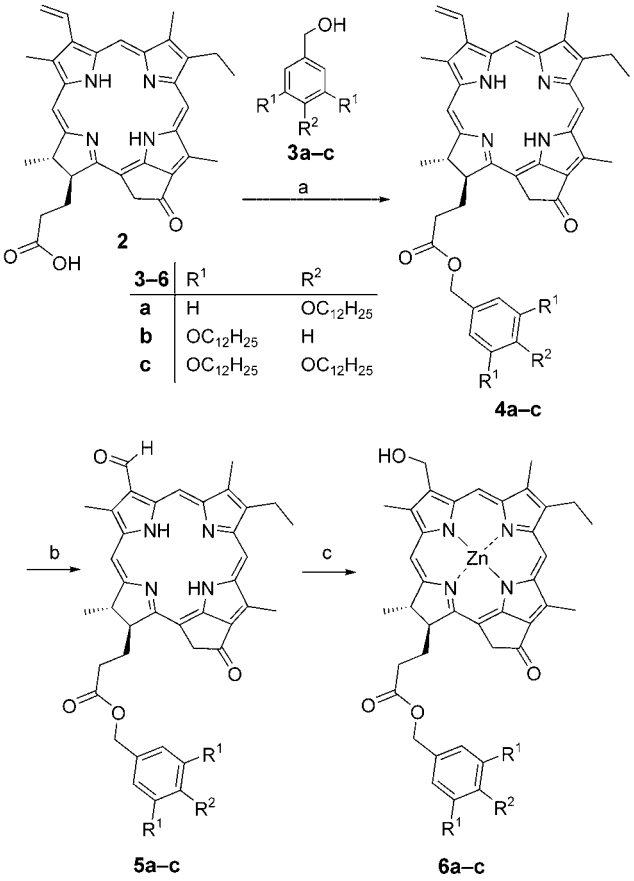
The micelle-type aggregates of BChl *c* and its model compound **1** are prone to further macroscopic aggregation in solution leading to precipitation of less-defined agglomerates.[3] Thus, it is difficult to handle these compounds and to deduce their structure–function relationships. Herein we introduce compounds developed on the basis of **1** which self-organize into well-defined rod aggregates of excellent solubility. The formation of these aggregates is completely reversible and can be triggered simply by variation of solvent polarity. Hence, for the first time an easy to use biomimetic antennae model for the more complex natural systems is made available.

Scheme 1 illustrates our strategy for the design of highly soluble artificial rod-shaped antennae which do not agglomerate. In natural chlorosome systems, each chlorin unit contains only one nonpolar chain (e.g. farnesyl).[1b] The rod aggregates formed by self-organization of these chlorins are surrounded by neighboring rod aggregates as well as by a lipid monolayer membrane covering the chlorosome. In both cases the neighboring alkyl chains interpenetrate and thereby accomplish a "fusion" which holds the aggregate together.[4] Consequently, isolated BChl *c* dissolved in water or organic solvents tend to agglomerate. In contrast, increasing the number of alkyl chains in 17^3 position of the chlorin unit should lead to highly soluble rod aggregates in the form of cylindrical micelles with a significantly reduced propensity for agglomeration. For the evaluation of this concept, the zinc chlorins **6a–c** containing one (**6a**), two (**6b**), or three (**6c**) alkyl chains were prepared. These new biomimetic compounds may be helpful for the structural elucidation of the natural antennae aggregates, and also provide spectroscopically uniform functional structures.



Scheme 1. Left: Model of a chlorosome: Lipid monolayer (black), rod aggregates of BChl *c* containing one nonpolar side chain per chlorin unit (red and blue). Right: Isolated rod aggregate in solution containing two nonpolar side chains per chlorin unit (compare **6b**).

The zinc chlorins were synthesized by derivatization of Chl *a* which was extracted from the algae *Spirulina maxima*.[5] Scheme 2 shows the synthesis of the desired zinc chlorins **6a–c** starting with the pheophorbide **2**, which was obtained from Chl *a*.[6]

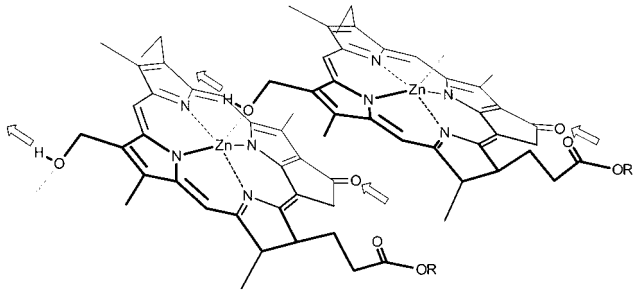


Scheme 2. a) DCC, DMAP, DPTS, *N*-ethyldiisopropylamine, CH_2Cl_2, RT, 3 h, 40–61 %; b) OsO_4, $NaIO_4$, AcOH, THF/H_2O, RT, 5 h, 80–98 %; c) $BH_3(t\text{Bu})NH_2$, THF, RT, 4 h; $Zn(OAc)_2$, MeOH, RT, 3 h, 60–85 %. DCC = dicyclohexylcarbodiimide, DMAP = 4-dimethylaminopyridine, DPTS = 4-dimethylaminopyridinium-*p*-toluenesulfonate.

The carboxylic acid in 17^3 position of 13^2-demethoxycarbonylmethylpheophorbide *a* (**2**) was esterified with the alcohols **3a–c** by activation with DCC, DMAP, DPTS, and *N*-ethyldiisopropylamine in dichloromethane. Oxidative cleavage of the 3^1 vinyl group of **4a–c** by osmium tetroxide and sodium periodate afforded the respective formyl derivates **5a–c**. The formyl group in **5a–c** was selectively reduced with borane *tert*-butylamine to the alcohol, and the desired zinc

chlorins **6a–c** were obtained by subsequent addition of a methanolic solution of zinc acetate.[7,8]

Characteristic for the dye aggregates in chlorosomes of *Chloroflexus aurantiacus* and for the in vitro aggregates of BChl *c* is a bathochromic shift of the Q_y band with respect to the corresponding absorption in the monomer.[1b] This red shift can be ascribed to the interaction between metallochlorins which is comparable to that in Scheibe aggregates (J-aggregates).[9] Three structural characteristics of metallochlorins are important for the formation of tubular J-aggregates:[3] A central metal ion for the coordination with the oxygen atom of the 3^1 hydroxy group, an extended π system for effective π–π interactions, and hydrogen-bond donor (3^1 OH) and hydrogen-bond acceptor (13^1 keto) groups. The first two interactions mentioned above lead to a slipped type of π–π stacking as in the case of J-aggregates (see Scheme 3), whereas hydrogen bonding induces the tubular



Scheme 3. Interactions between zinc chlorins **6a–c**. Zn—O coordination bonds that direct J-type stacks are marked in gray. Hydrogen bonds that connect these stacks to give tubes are shown by arrows.

structure in which all the alkyl chains are oriented towards the outside (inverse cylinder micelle).[10] Like BChl *c*, the zinc chlorins **6a–c** also have these structural characteristics and, thus, their Q_y-band should also be bathochromically shifted because of J-aggregate formation. Indeed, for the zinc chlorins **6a–c** the characteristic red shift of the Q_y-band from 648 nm to 742 nm was observed as the UV/Vis spectra show (Figure 1). Also characteristic is the very small Stokes

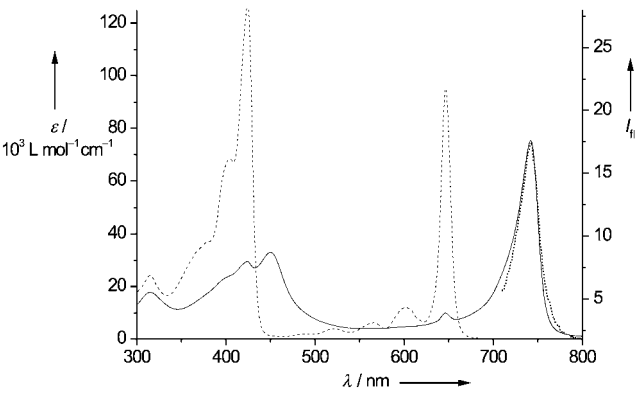


Figure 1. UV/Vis spectra of **6b**. Monomer dissolved in THF, $c = 2.3 \times 10^{-5}$ mol L^{-1} (-----); aggregate dissolved in hexane with <1% THF, $c = 4.6 \times 10^{-5}$ mol L^{-1} (——). Fluorescence spectrum ($\lambda_{ex} = 690$ nm) of **6b** dissolved in hexane with <1% THF (••••).

shift (<1 nm) which indicates resonance fluorescence behavior of J-aggregates of the zinc chlorins **6a–c** (see fluorescence spectrum in Figure 1).

In contrast to model compound **1**, both zinc chlorins **6b** and **c** with two and three alkyl chains, respectively, form in nonpolar solvents, soluble aggregates that are stable for a prolonged time. As expected from our concept, at least two alkyl chains are necessary to enable good solubility, since zinc chlorin **6a** as well as model compound **1** agglomerate within hours to days and finally precipitate (Figure 2).

Figure 2. Color and solubility of zinc chlorin **6b** in THF (left) and in heptane with 1% THF after 8 days (right) compared to that of model compound **1** (middle, also in heptane with 1% THF after 8 days).

To gain more insight into the aggregation process, zinc chlorin **6b** was dissolved in di-*n*-butyl ether and heptane (20:80) and temperature-dependent (15–95 °C) UV/Vis spectroscopic measurements were performed. Preliminary experiments showed that a steady state is achieved after about 1 h at lower temperatures; therefore, the samples were equilibrated for 1.5 h prior to each measurement. The variable temperature UV/Vis absorption studies have revealed that with increasing temperature, the Q_y-band of aggregates at 742 nm decreases and accordingly the monomer band of chlorins at 648 nm increases (Figure 3). On subsequent cooling of the sample, the Q_y-band of the aggregate is completely recovered, demonstrating the reversibility of aggregate formation. The fact that no precipitation was observed on warming or on cooling indicates that the aggregate structures of zinc chlorins are thermodynamically stable and, thus, they differ from numerous other self-organized dye aggregates.[11] As can been seen in the inset of Figure 3, the absorption versus temperature (*A* vs. *T*) plot provides sigmoidal curves with a melting temperature of about 60 °C for the aggregates of zinc chlorin **6b**. The dissociation of the aggregates can also be induced by addition of small amounts of protic solvents, such as methanol, which weaken hydrogen bonding as well as coordinative interactions (Scheme 3).

A distinct feature for natural BChl *c* rod aggregates is, besides bathochromic shift of the long-wavelength UV/Vis absorption bands, an induced circular dichroism (CD) effect. This effect occurs on chiral excitonic coupling of transition

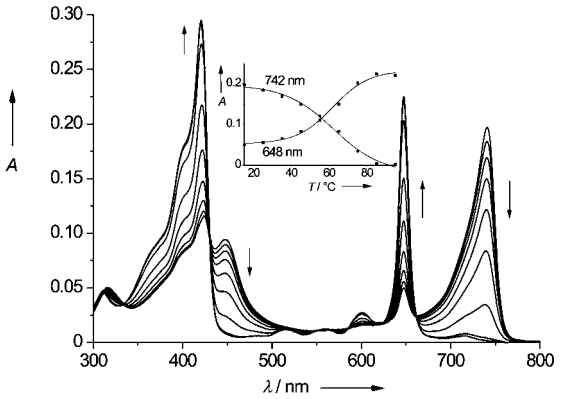

Figure 3. Temperature-dependent UV/Vis spectra of **6b** in di-*n*-butyl ether/heptane (20:80; $c = 3 \times 10^{-6}$ mol L^{-1}). Initial temperature 15 °C, increased successively by 10 °C in 1.5 h intervals up to 95 °C; arrows indicate changes upon increasing temperature. Inset: the decrease of the Q_y-band of aggregates at 742 nm and the increase of the monomer band at 648 nm upon increasing temperature.

dipole moments and consists of two bands with opposite signs (exciton couplet).[12] Surprisingly, different CD spectra of isolated chlorosomes and in vitro generated aggregates of BChl *c* have been reported.[2,13] Griebenow et al. have categorized the observed CD spectra into three types (type I: the sign of the CD curve changes from positive at shorter wavelengths to negative at longer wavelengths [+/−], type II: opposite behavior to type I [−/+], and the mixed-type: [−/+/−]).[14] In a theoretical approach, Holzwarth and co-workers proposed that the different types of CD spectra result from a size effect.[15] According to this approach, at an aggregate length of more than 30 molecules of BChl *c*, the type II converts into the mixed-type. On the other hand, previously mentioned uncontrolled agglomeration of in vitro aggregates of BChl *c* and **1** could lead to artifacts in CD spectra. Therefore, it is interesting to note that zinc chlorin **6b** exhibits an exciton couplet, which is very similar to that of the model compound **1**. This exciton couplet reversibly arises and disappears on temperature change (see Figure 4) and does not undergo any time-dependent changes at a particular temperature.

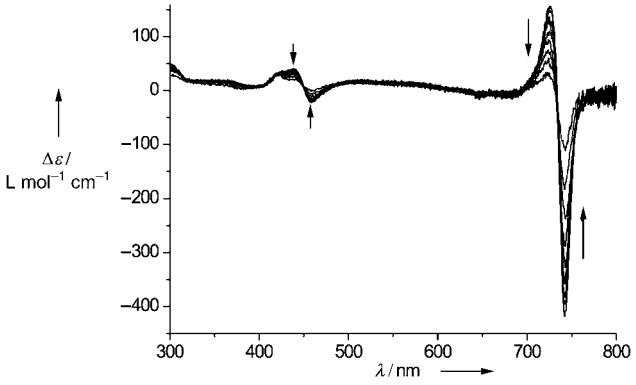

Figure 4. Temperature-dependent (15–95 °C) CD spectra of **6b** ($c = 1 \times 10^{-5}$ mol L^{-1}) in di-*n*-butyl ether/heptane (20:80). The temperature was increased in 10 °C intervals after 1.5 h equilibration time; arrows indicate changes upon increasing temperature.

The data presented reveal that the aggregates of zinc chlorins **6b** and **c** have spectral properties comparable to those of the natural light-harvesting systems in chlorosomes. Encouraged by these results, atomic force microscopy (AFM) studies were carried out to elucidate the structural properties of **6b** and **c**. Figure 5a shows an AFM image of a sample,

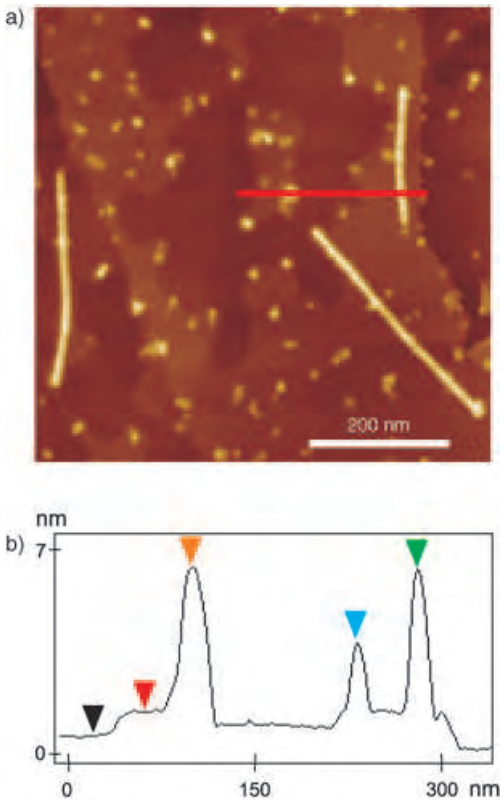

Figure 5. a) AFM image in tapping mode of **6b**. The sample was prepared by spin-coating of a solution of **6b** ($c = 4.6 \times 10^{-5}$ mol L^{-1}) in hexane/THF (100:1) onto HOPG and measured in air. b) Profile of the red line in (a), details are given in the text.

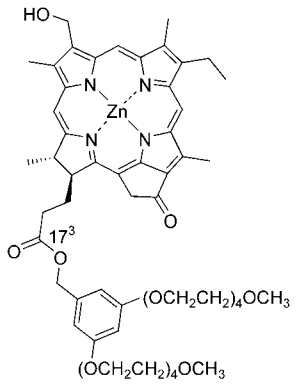
which was prepared by spin-coating of a solution of **6b** in hexane/THF onto HOPG (highly ordered pyrolytic graphite). As can be seen in this image, zinc chlorin **6b** self-organizes into rigid rods. The length of the rods is 300 ± 97 nm and the height is 5.8 ± 0.4 nm (vertical distance between the black and green triangle, Figure 5b). It is remarkable that all the observed rod-like antennae are isolated. This structural behavior corroborates our concept illustrated in Scheme 1. The measured height of about 6 nm of these biomimetic zinc chlorin aggregates is in agreement with electron microscopy data of the BChl *c* rod aggregates in chlorosomes (*Chloroflexus aurantiacus*)[16] and also comply with the tubular model postulated by Holzwarth and Schaffner.[10] Spectroscopic data and theoretical calculations[10,15] already suggested the presence of rod-shaped structures, but now, by AFM measurements, microscopic evidence is obtained for the first time for the supramolecular organization of this class of chromophores.

Besides rod-shaped structures, smaller (3.1 ± 0.6 nm in height, vertical distance between the black and blue triangle,

Figure 5b) and bigger (5.6 ± 0.7 nm in height, vertical distance between the black and orange triangle) globular objects are visible in the AFM image shown in Figure 5. Future studies should clarify, whether these globular micelle structures are caused by preparation process of the sample or if they already co-exist with the rod aggregate in solution. Furthermore, a molecular monolayer of 0.5 ± 0.1 nm thickness (vertical distance between the black and red triangle, Figure 5b) is visible on HOPG surface, which may indicate the self-organization of zinc chlorin **6b** monomers induced by the graphite surface.

Preliminary experiments indicate that our strategy demonstrated in Scheme 2 can also be applied to prepare rod aggregates of zinc chlorins in water, since the Q_y-band of zinc chlorin **7** (in water/THF 100:1) is also red-shifted from 648 nm to 744 nm. Further investigations with this compound are in progress.



7

In summary, with the newly developed compounds **6b** and **6c**, zinc chlorins are made available whose self-organized rod-shaped antennae exhibit excellent solubility in nonpolar solvents. This favorable property enabled spectroscopic investigations that confirm the reversible formation of these biological important dye assemblies. For the first time AFM enabled isolated rod aggregates to be observed whose diameter is in good agreement with electron microscopic data of BChl *c* aggregates in chlorosomes.

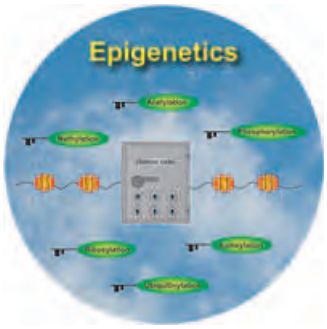
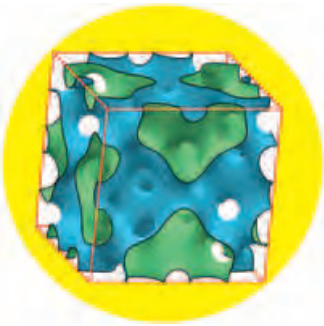
Reactions "on water" offer ease of product isolation and may be substantially faster than the same reactions performed in organic solvents. The cover picture shows the time course of an ene reaction between (*S*)-β-pinene and diethyl azodicarboxylate performed on water. The insoluble reactants float on water, whereas the product descends under the water layer and is isolated as a colorless oil. For more details on these reactions, see the Communication by K. B. Sharpless and co-workers on page 3275 ff.



Epigenetics
A. Giannis and co-workers delve into the secrets of the histone code in their Review on page 3186. What influence do histones have on the activation and inactivation of gene sequences?

Crystal Growth
Two growth processes, habit formation and branching growth, determine the crystal shape of electrochemically generated Cu_2O crystals. In their Communication on page 3218 ff., K.-S. Choi and M. J. Siegfried explain how these processes can be controlled.



Mesoporous Materials
The mesoporous silica superstructure SBA-1 was studied to obtain a formulation in terms of curvature, which is important for surfactant structures and the mechanism of formation of inorganic replicas. The results are presented by M. W. Anderson and co-workers on page 3243 ff.

News

Books

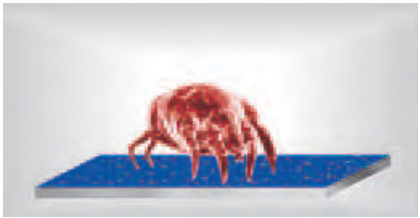
Highlights

Fullerenes

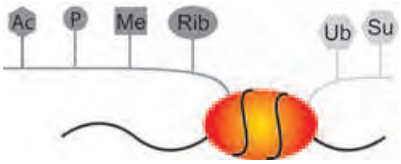
Breaking with convention: In the textbook aromatic annulenes the p orbitals are oriented perpendicular to the ring plane. In trannulenes the p orbitals form a cyclic, conjugated π system within the ring plane (see scheme). This concept of "in-plane" aromaticity was first recognized in 1979, and now representative compounds have been synthesized. The all-*trans* configuration of the annulene ring is stabilized by a fullerene framework, and the novel physicochemical properties of trannulenes open new opportunities for the design of light-harvesting compounds.

Combinatorial Chemistry

Decoding technology: Besides mainstream applications in transcription profiling, DNA microarrays are currently being explored as tools for the deconvolution of synthetic libraries. Current examples include the discovery of a new type of organic reaction and the screening of peptide nucleic acid encoded inhibitor libraries to investigate new proteolytic activities from dust mite extracts (see picture).

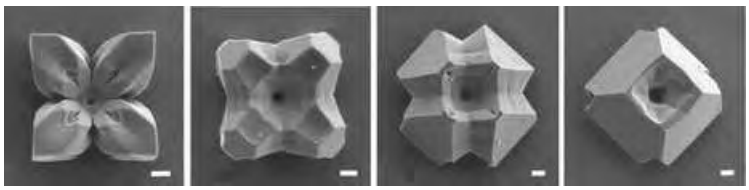


Reviews

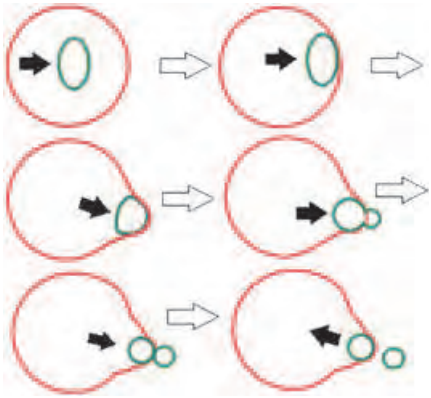


Wrapped around the finger! It has been known for a long time that histones organize the structure of cellular DNA. The news, however, is that histones are also able to influence elementary DNA-dependent processes. The type and number of specific histone modifications (examples rendered in gray) determine in advance if and when a gene is transcribed. The first modulators of histone-modifying enzymes have already become promising drugs.

Communications



A new level of programmability and freedom in directing the crystal growth of cuprous oxide was demonstrated by controlling the degree of branching and crystal habit in a systematic manner during electrodeposition. Examples of Cu_2O crystals in which these features were directed by rationally designing a growth condition and growth history are shown (scale bar = 1 μm).



Cooperation of mother and daughter vesicles, which are self-assembled from an ill-defined hyperbranched copolymer, leads to fission of the daughter membrane in a cytomimetic process (see picture; red: mother vesicle, green: daughter vesicle). This is the first example of giant polymer vesicles (5–200 μm) being used as model membranes.

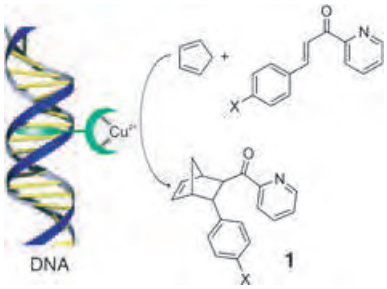
Crystallization of the thermodynamically metastable β glycine is explained on the basis of its growth at the opposite poles of the crystal (see graph) and by considering the structure of the relevant surfaces of the three polymorphs and their interactions with solvent molecules.

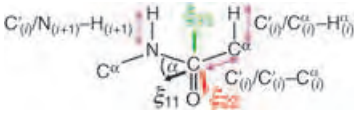
Crystal Growth



A twist in catalysis! The chirality of DNA is transferred directly to a Diels–Alder reaction by using a DNA-tethered catalyst. A catalytically active copper complex with achiral ligands self-assembles with DNA to give products with up to 90% *ee*, as is the case for the *exo* isomer of product **1**.

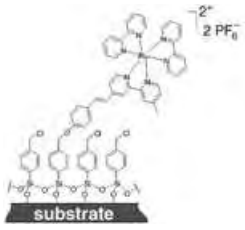
Asymmetric Catalysis

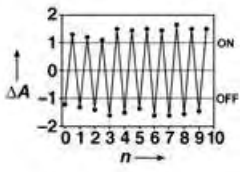
Cross-correlated relaxation (CCR) can be used to describe the structure and dynamics of biomolecules (see picture). By combining theoretical and experimental techniques in the study of proteins, for example, it is possible to acquire detailed information concerning the local anisotropic motion of the peptide plane



from a single cross-correlation: the C′/N–H CCR rate.

NMR Spectroscopy



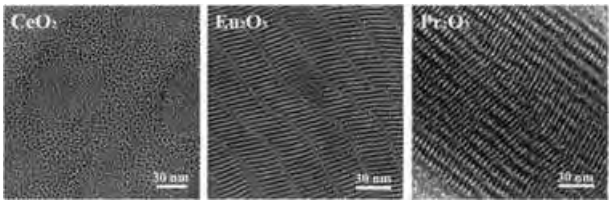


Don't forget to write! Electrochemical charge storage in a ruthenium-based monolayer on a hydrophilic substrate (for example, indium tin oxide coated glass) produces redox switching of the optical properties of the system (see picture).

This read/write process can be carried out at low voltage in air and monitored by UV/Vis spectrophotometry. This makes the monolayer system a suitable candidate for nonvolatile memory devices.

Molecular Devices

Contents

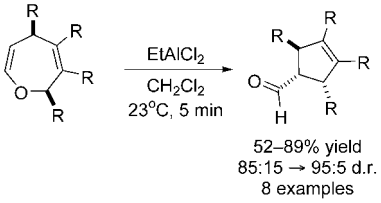


Thermolysis of benzoylacetonate complexes proved successful in the synthesis of rare-earth oxide nanocrystals. CeO_2 nanopolyhedra, Eu_2O_3 nanodisks, and Pr_2O_3 nanoplates display 2D ordering on copper grids (see figure), and the former two show interesting optical properties arising from surface-modification effects.

Nanocrystals

Hydrogen bonding and π–π interactions are the driving forces for the self-assembly of a diamide organogelator into nanotubes in organic solution. Freeze-fracture electron microscopy (see image) and small angle neutron scattering studies show the tubes have a diameter of (24.2 ± 0.3) nm with a wall thickness of (3.3 ± 0.4) nm and an aspect ratio of 1:50 or higher.

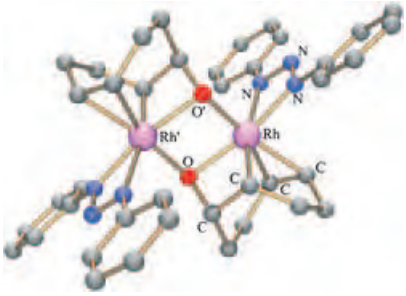
Self-Assembly



A room-temperature diastereoselective [1,3] rearrangement results from treatment of 2,5-dihydrooxepins with $EtAlCl_2$ (see scheme). A modular synthesis of dihydrooxepins allows substituents to be incorporated at any position on the ring, which means that various polysubstituted cyclopentenes can be prepared through this Lewis acid mediated [1,3] ring contraction.

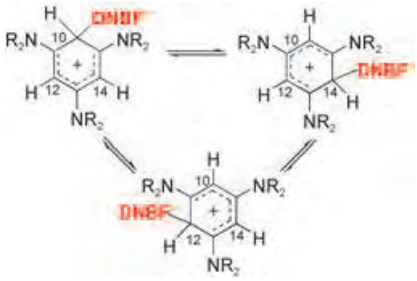
Synthetic Methods

Ready cleavage of dioxygen and its selective insertion into Rh–alkene bonds occurs in the presence of $[\{Rh(PhN_3Ph)(C_8H_{12})\}_n]$ ($n = 1$ and 2). The structure of the resulting dirhodadioxetane complex (see picture) and kinetic measurements support a dimetallic mechanism for this process that occurs with 100% atom economy.



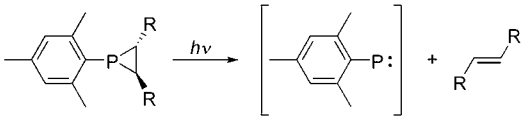
O–O Activation

Contents



Proposal accepted: NMR experiments have shown unequivocally that the previously only proposed zwitterionic carbon–carbon Meisenheimer–Wheland complexes are formed in the reaction of 4,6-dinitrobenzofuroxan (DNBF) with 1,3,5-tris(*N*,*N*-dialkylamino)benzenes. Increasing the temperature results in a rapid exchange between three homomeric forms of the complex (see scheme; NR_2 = piperidyl, morpholinyl, pyrrolidinyl).

Reactive Intermediates

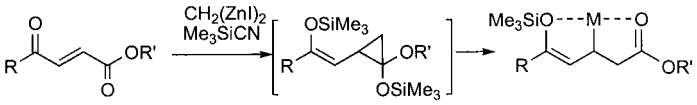


1 R = Me
2 R = H

3

Monitoring the cleavage of phosphiranes **1** and **2** by using a variety of low-temperature and time-resolved spectroscopic techniques has shown that triplet mesitylphosphinidene (**3**) is the principal product of this photolytic reaction (see scheme). Results obtained by using laser flash photolysis show that **3** is readily quenched by reactive π systems.

Radicals



1 **2**

Enolate–homoenolate equivalents 1 can be prepared in one step by the title reaction. They act as functionalized *Z*-γ-siloxyallyl zinc reagents **2** by undergoing ring opening in the presence of a Lewis acid. Addition of **2** to tosylimines gives *vic*-amino alcohols with high diastereoselectivity, presumably due to a fixed conformation resulting from coordination of the metal atom.

Organozinc Reagents

Disguise tactics: Peptide–polymer hybrid nanotubes are constructed in which self-assembled cyclic peptides govern the structure, and a synthetic polymer coating determines the surface chemistry. Formation of the latter is initiated in situ from preorganized peptide building blocks. The picture shows an AFM image of nanotubes on a silicon wafer.

Trannulenes with "In-Plane" Aromaticity: Candidates for Harvesting Light Energy**

*Glenn A. Burley**

Keywords:
annulenes · aromaticity · fullerenes · trannulenes

Dedicated to Paul von Ragué Schleyer on the occasion of his 75th birthday

Annulenes are defined as cyclic conjugated polyenes with their ring size indicated by a numerical prefix (e.g. [6]annulene for benzene).[1] Annulenes adhering to Hückel's $4n+2$ π-electron rule are termed aromatic.[2] Up until 2001 all experimentally observed annulenes comprised C–C double bonds with either an all-*cis* (such as benzene) or a *cis,trans* configuration (for example [10]annulene). In these annulenes the p orbitals are oriented perpendicular to the annulene ring plane (Figure 1 a).

Conversely, trannulenes (annulenes in which the C–C double bonds in the ring are exclusively of *trans* configuration) (e.g. **1**, Figure 2), have a completely different the p-orbitals orientation: they lie parallel to the ring plane (Figure 1 b).[3,4] This p-orbital overlap pattern, termed "in-plane" aromaticity, was predicted as early as 1979 by Schleyer et al. in a publication describing the 3,5-didehydrophenyl cation, the first double-aromatic system.[5] To support the existence of trannulenes, which are higher energy annulene isomers, Schleyer et al. elegantly predicted that a supporting molecular framework such as a dodecahedrapentaene (**2**, Figure 2) would provide a suitable three-dimensional setting for such "in-plane" aromaticity.[4]

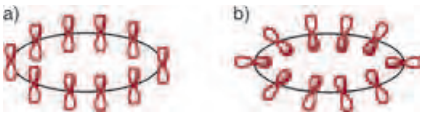

Figure 1. Visualization of the orbital overlap in a) conventional annulenes where the overlap is perpendicular to the ring plane, and in b) trannulenes where the overlap is parallel to the ring plane ("in-plane" aromaticity). This situation should not to be confused with that in [4*n*] Möbius systems, which are aromatic structures with enforced phase discontinuity. Möbius aromatic systems have been regarded as a combination of normal annulenic conjugation (a) and belt-shaped conjugation (b).[19]

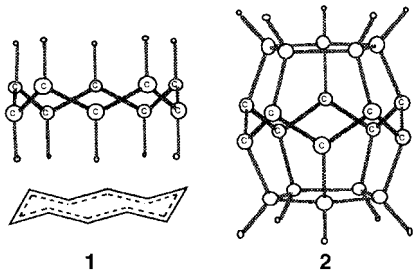

Figure 2. The [10]trannulenes: all-*trans*-cyclodecapentaene (**1**) and the central unit of dodecahedrapentaene (**2**) as computed by Schleyer et al. to be energy minima at the B3LYP/6-31G* level.[3]

The serendipitous realization of the first trannulene structure **3** by Taylor et al. (Figure 3) proved to fulfil Schleyer's theoretical predictions.[6] Indeed, **3** comprised an [18]trannulene within a three-dimensional [60]fullerene framework. The most notable structural feature of trannulene **3** is the presence of an 18π trannulene belt formed as a result of a threefold S_N2'' nucleophilic displacement of the three outermost fluorine atoms of $C_{60}F_{18}$ by the tertiary carbanion derived from diethyl bromomalonate.[6,7] Additionally, a central aromatic benzenoid ring (present in the $C_{60}F_{18}$ starting structure) is retained within the fluorinated region, and a nonplanar triphenylene substructure is formed within the nonfluorinated region, yielding a new type of double-aromatic system.[8]

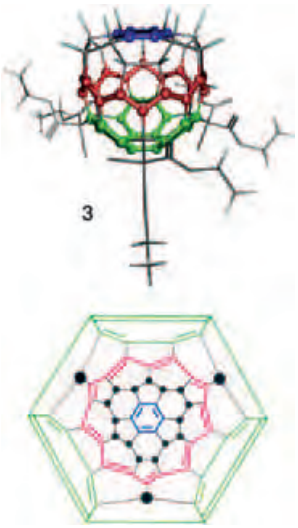

Figure 3. Top: X-ray crystal of trannulene **3**, which is prepared from the reaction of $C_{60}F_{18}$ and the carbanion of diethyl bromomalonate.[6] The [18]trannulene ring is depicted in red, the central benzene ring in blue, and the triphenylene substructure in green. Bottom: Schlegel diagram of **3**. Large black circles mark the site of functionalization (diethyl bromomalonate), whereas the smaller black circles represent fluorine atoms.

Computational investigations concerning the p-orbital arrangement and aromaticity of **3** further complemented Schleyer's theoretical predictions. Both the experimental (**3**) and theoretical (**2**) trannulenes adhere to Hückel's rule. On the basis of magnetic properties (magnetic diatropicity),[9,10] structure (small

C–C bond alternation of the trannulene substructure),[6] and stability (more stable than other known fluorofullerenes) considerations,[11] these trannulene structures are indeed aromatic.

Recently the trannulene family has welcomed two new members. The drum-shaped $C_{60}Cl_{30}$ **4** reported by Troshin et al.[12] displays an equatorial trannulene belt flanked by two benzenoid substructures situated at the poles of the fullerene (Figure 4). Equally impressive is the unexpected discovery of a mild preparative route to a nonhalogenated trannulene by sixfold alkylation of the C_{60}^{6-} anion.[*] The resulting trannulene **5** discovered by Chiang et al. comprises a central trannulene belt flanked by two highly distorted triphenylene units (Figure 5).[14]

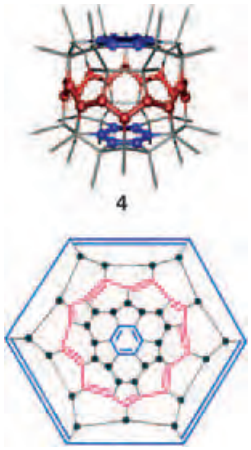

Figure 4. Top: X-ray crystal structure of trannulene **4**, which is prepared by the reaction of C_{60} with $SbCl_5$ at 220–250 °C.[12] The [18]trannulene ring is depicted in red, and the benzenoid structures are depicted in blue. Bottom: Schlegel diagram of **4**. The small black circles represent chlorine atoms.

Currently a total of three trannulenes have been discovered. Trannulenes **3**–**5** arise from three distinct preparative routes and exhibit three distinct topologies and π-conjugated substructures, which will most likely transcribe into quite distinct and tunable physicochemical properties. For example, the presence of an [18]trannulene moiety in the nonhalogenated trannulene **5** leads to significant absorptions in the near-IR region ($\lambda_{max} = 760$ and 850 nm), although the first reduction potential ($E_1^{Red} = -0.49$ V vs. Ag/AgCl) remains similar to that of [60]fullerene.[14] The presence of fifteen fluorine atoms in trannulene **3** results in a blue shift of the absorption spectrum ($\lambda_{max} = 612$ and 658 nm) and a dramatic increase in electron affinity, resulting in an anodic shift of the first reduction potential ($E_1^{Red} = -0.05$ V vs. SCE).[9,11,15,16] Although limited physicochemical data has been reported for chlorotrannulene **4**, the presence of thirty chlorine atoms in close proximity to the trannulene ring would most probably cause an even greater increase in electron affinity relative to that of **3** and **5**. The dark-orange color of **4** is an initial indicator of a more dramatic blue-shift compared with that of fluorofullerene **3**.

Hence the potential tunability of the physicochemical properties along with the low reorganization energy of the [60]fullerene cage makes these structures potential electron-acceptors for harvesting light energy.[17] Indeed the first donor–acceptor dyad comprising a fluorofullerene trannulene confirmed the ability of these remarkable molecules to accept a charged entity and store the resultant excitation energy in a long-lived charge-separated state.[15] Recent investigations have also demonstrated that the photophysics of a trannulene dyad series can be tuned from electron transfer to energy transfer as a function of the photoactive substituent, thus providing an additional level of molecular tailoring for specific applications.[18] Additionally, the mild conditions required for the preparation of trannulenes **3** and **5** will allow the incorporation of further functionalities through derivatization of the addends, thereby enabling these systems to be used as modular building blocks.

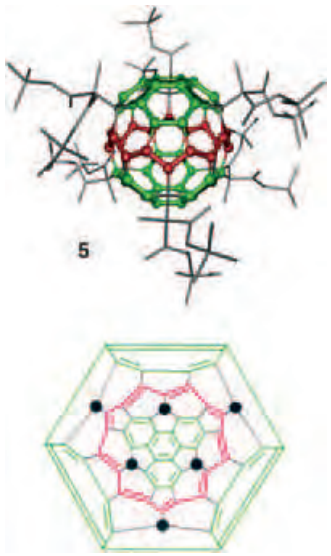

Figure 5. Top: X-ray crystal structure of trannulene **5**, which is prepared by the reaction of C_{60}^{6-} with diethyl 2-bromo-2-methylmalonate.[14] The [18]trannulene ring is depicted in red and the triphenylene substructure in green. Bottom: Schlegel diagram of **4**. The large black circles mark the sites of functionalization.

Synthetic organic chemists have now synthesized the first trannulenes, which were predicted by Schleyer et al.[4] The discoveries that followed have led to new branches of both fullerenes and of organic chemistry, and it is likely that the coming years will bring forth numerous derivatives and trannulene types exhibiting fascinating topologies and novel physicochemical properties.

[*] The C_{60}^{6-} anion is a three-dimensional aromatic species as judged by its large NICS value of −48.7.[13]

Combinatorial Chemistry

DNA Microarrays as Decoding Tools in Combinatorial Chemistry and Chemical Biology**

*Marina Lovrinovic and Christof M. Niemeyer**

Keywords:
combinatorial chemistry · DNA · immobilization · microarrays · proteins

Over the last few years, laterally microstructured arrays of DNA[1] and protein probes[2–4] have been developed as tools for high-throughput experimentation in biomedical research. These devices have the advantage of spatial addressability of the probes and require only small amounts of analyte. The development of protein microarrays is still obstructed by the intrinsic instability of many proteins, which leads to the loss of functionality during their automated deposition onto chemically activated surfaces. However, the application of DNA arrays is almost routine nowadays, as they are chemically stable and are often available off-the-shelf through academic and commercial suppliers. Hence, the application of DNA microarrays toward investigations of gene expression by quantitation of mRNA levels under variable environmental conditions offers a well-established approach in the fundamental and industrial research of biological systems.[5] In addition to these mainstream applications of DNA chips in genomics, alternative uses of these devices as tools for decoding combinatorial libraries in chemistry and chemical biology are currently emerging.

Figure 1. DNA-directed immobilization of DNA–protein conjugates with surface-bound capture oligomers of a DNA microarray.

As an example, DNA arrays can be used as programmed matrices for the site-selective immobilization of DNA oligomer-tagged proteins and small molecules (Figure 1). This approach, termed DNA-directed immobilization (DDI), offers a chemically mild procedure for the site-selective, highly parallel, and reversible attachment of protein libraries to solid supports.[6] As a particular advantage, the proteins retain their biological activity because they are attached to the surface through a short double-stranded DNA linker rather than being directly fixed at the surface by multiple covalent or noncovalent contacts, which may restrict their conformational freedom and could lead to (partial) denaturation of tertiary structure.[6b] The advantage of the DDI method for the fabrication of protein microarrays has been demonstrated for antibodies,[6c,f,g] receptors[6d] and enzymes.[6b,i]

Winssinger and co-workers have applied the principle of nucleic acid-directed immobilization to the screening of small-molecule libraries for compounds that bind to protein targets.[7–10] The technology is based on peptide nucleic acid (PNA)-encoded small-molecule probes, which are accessible through solid-phase combinatorial syntheses (Figure 2). The small-molecule portion of the probe is designed to bind to proteins in a mechanism-dependent manner, therefore discriminating between active proteins and proteins that are present in a latent or inactive form. The PNA portion of the probes functions as a code for the synthetic history of the small-molecule portion, and therefore permits deconvolution of the probe through hybridization at an oligonucleotide microarray. Array-based deconvolution allows the simultaneous analysis of multiple probes in a miniaturized format and has the potential of screening up to 400000 probes in a solution volume of less than 300 μL. The initial validation of this approach was carried out with specific inhibitor probes whose design was based on the peptide substrate specificity of known proteases, such as cathepsins[7] and caspase.[8]

Recently, this methodology was applied to the discovery of new proteolytic activities in dust mite extracts.[10] House dust mites are a major source of allergens and contribute to the increased incidence of allergenic diseases such as bronchial asthma. Some of these allergens have protease activity, which has long been known to produce an allergic response. To elucidate the cellular mechanisms behind the development

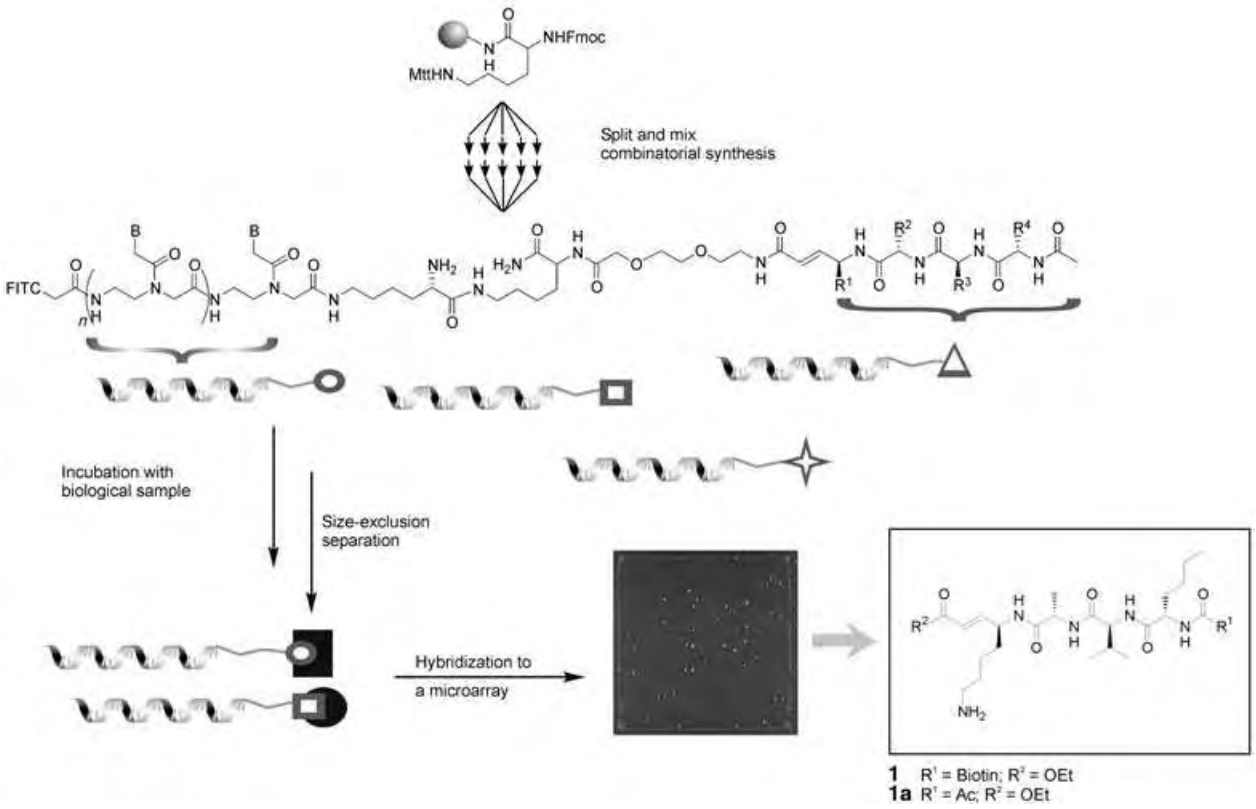

Figure 2. Synthesis and deconvolution of a PNA-encoded library (adapted from Ref. [10]). The fluorescein isothiocyanate (FITC) group enables fluorescence detection of the binding of all members of the library to the spatially encoded DNA array. Mtt = 4-methyltrityl; Fmoc = 9-fluorenylmethoxycarbonyl.

of allergies, it is essential to profile the activity of the proteases involved.

To this end, a 4000-member PNA-encoded tetrapeptide inhibitor library designed to target cysteine proteases was synthesized by combinatorial split-and-mix synthesis (Figure 2). The library was incubated with dust mite lysate, and the unbound probes were subsequently separated by spin filtration through a 30-kDa molecular weight cut-off filter. The retained samples that contained the protein-bound probes were hybridized to an oligonucleotide array containing capture oligomers for all members of the PNA-encoded inhibitor library. Fluorescence imaging allowed the identification of tetrapeptides that had bound to protease targets. Active inhibitors contained lysine and norleucine at position P1 and alanine at position P2 (Figure 2). Positions P3 and P4 of the inhibitor appeared to be less important for target binding; the most striking feature was that compounds with histidine, phenylalanine, or proline at position P3 were completely inactive as inhibitors. The probe with the highest intensity on the microarray had the inhibitor sequence Nle-Val-Ala-Lys (P1–P4). This probe (compound **1** in Figure 2) was re-synthesized with a biotinylated linker to isolate and identify the interacting proteins. Following incubation of **1** with the dust mite lysate, the probe and proteins attached to it were captured with streptavidin and the proteins were sequenced my mass spectrometry.

Two major proteins, Derp1 and Derp10 were identified. Derp1 is a 25-kDa protein homologous to the papain family of cysteine proteases, and Derp10 is a 33-kDa protein that is homologous to tropomyosin. Isolated Derp1 was then prepared from house mite fecal pellets by immunoaffinity chromatography by using an immobilized monoclonal antibody, and its substrate specificity was profiled with the tetrapeptide substrate library in a positional scanning format. The results confirmed that the major substrate specificity determinant for Derp1 is in the P2 position for the alanine residue. Moreover, a slight preference of Derp1 for basic amino acids in positions P1 and P3 was observed, as well as a preference for aliphatic amino acids such as isoleucine, proline, valine, leucine, and norleucine in position P4. Finally, the authors demonstrated the phenotypic relevance of Derp1 function in allergy progression by the inhibition of cleavage of CD25 (the α chain of the interleukin 2 cell-surface receptor) from T-cells with the tetrapeptide inhibitor **1a**.[9]

In a related approach, Melkko et al. used DNA-encoded self-assembling chemical (ESAC) libraries for the facile identification of small molecules that bind macromolecular targets.[11] In this case, libraries of organic molecules linked to individual DNA oligomers were assembled with DNA strands that contain complementary sequence stretches, thereby providing a code associated with each organic moiety. After incubation of the ESAC libraries with a protein of interest attached to a solid support and removal of unbound mate-

rials, the coding sequences of the selected compounds were decoded with a DNA microarray. Repetition of the selection cycle led to the affinity maturation of compounds that bind human serum albumin and bovine carbonic anhydrase with dissociation constants in the nanomolar range.[11]

The above examples impressively demonstrate how DNA microarrays can be used for the decoding of nucleic acid encoded small-molecule libraries. Hu et al. have recently applied DNA microarrays to the high-throughput screening of expressed enzyme libraries (Figure 3).[12] Their strategy, termed "Expression Display", is based on the ribosome-display technique, which allows the in-vitro expression of proteins in a cell-free translation reaction. The resulting polypeptides are thereby tagged with their own coding mRNAs.[13] The proteins were expressed from a cDNA library containing 384 different open-reading frames (ORFs) from yeast, four of which encoded known protein tyrosine phosphatases (PTPs), through in-vitro transcription and translation (steps 1 and 2 in Figure 3). The resulting library of ribosomal complexes was incubated with the activity-based probe **2** that had been immobilized on streptavidin magnetic beads, and which specifically and irreversibly binds PTPs (step 3). The mRNA was eluted and reverse-transcribed to generate the corresponding fluorescently labeled cDNA. The resulting cDNA library was then hybridized to the decoding DNA microarray (containing 384 cDNAs) for the parallel identification of functional PTPs. Positives were identified by the location of fluorescent spots on the array (Figure 3). Indeed, microarray analysis revealed the selective detection of the four PTPs from the library, which also contained ORFs for other enzyme classes (proteases, kinases, oxidoreductases) and nonenzyme proteins. Hence, this example of combining activity-based probes and array-based high-throughput identification suggests that it should be possible to screen thousands of proteins, all in a single reaction without the need for parallel cloning, expression, purification, and characterization of individual proteins.[12]

DNA microarrays have also been used recently in synthetic organic chemistry as a selection tool for the discovery of a new type of chemical reaction: the Pd-catalyzed carbon-carbon bond-forming reaction that generates an enone from an alkyne and alkene (Figure 4).[14] To this end, Liu and co-workers, whose work is focused on the development of DNA-templated organic syntheses,[15] prepared two pools of DNA-linked small-molecule substrates, each of which contains 12 different potentially reactive functional groups covalently linked to either the 5′- (pool A) or 3′-end (pool B) of an oligonucleotide. Pool A oligomers contain a "coding region" that uniquely identifies the substrate as well as one of 12 different "annealing regions". Pool B oligomers also contain a "coding region" which encodes the substrate and complements one of the 12 annealing regions in pool A (Figure 4a).

When pools A and B are combined in a single aqueous solution at nanomolar concentrations, specific Watson–Crick base-pairing assembles the compounds into 12×12 discrete pairs of substrates, which experience effective concentrations in the millimolar range. Substrates linked to noncomplementary oligomers experience nanomolar solution concentrations and hence do not react with each other at a significant rate. To allow the separation of reactive pairs, each substrate of pool B was covalently linked to its corresponding oligomer by a linker containing a biotin group and a cleavable disulfide bond (Figure 4b). After incubation under a set of chosen reaction conditions, the disulfide bonds were cleaved and the biotin group remained covalently linked only to pool A compounds after a bond-forming reaction between pool A and pool B substrates had occurred. Avidin affinity selection of the resulting solution separated biotinylated from non-biotinylated compounds. Reactive substrate pairs were then amplified by PCR. Because PCR amplification is extremely sensitive, femtomole quantities of substrate were sufficient for the entire reaction discovery process.

As both pools each contained 12 substrates, 144 different DNA-linked substrates of pool A were prepared to encode all heterocoupling combinations. Furthermore, DNA-linked substrates

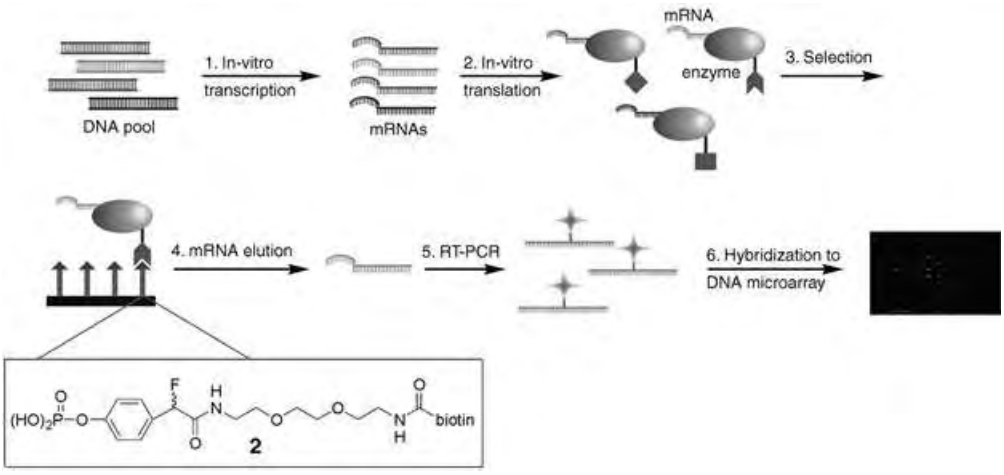

Figure 3. Expression display of an enzyme library (RT = reverse transcription). Also shown is the structure of the protein tyrosine phosphatase (PTP)-specific activity-dependent probe **2** (adapted from Ref. [12]).

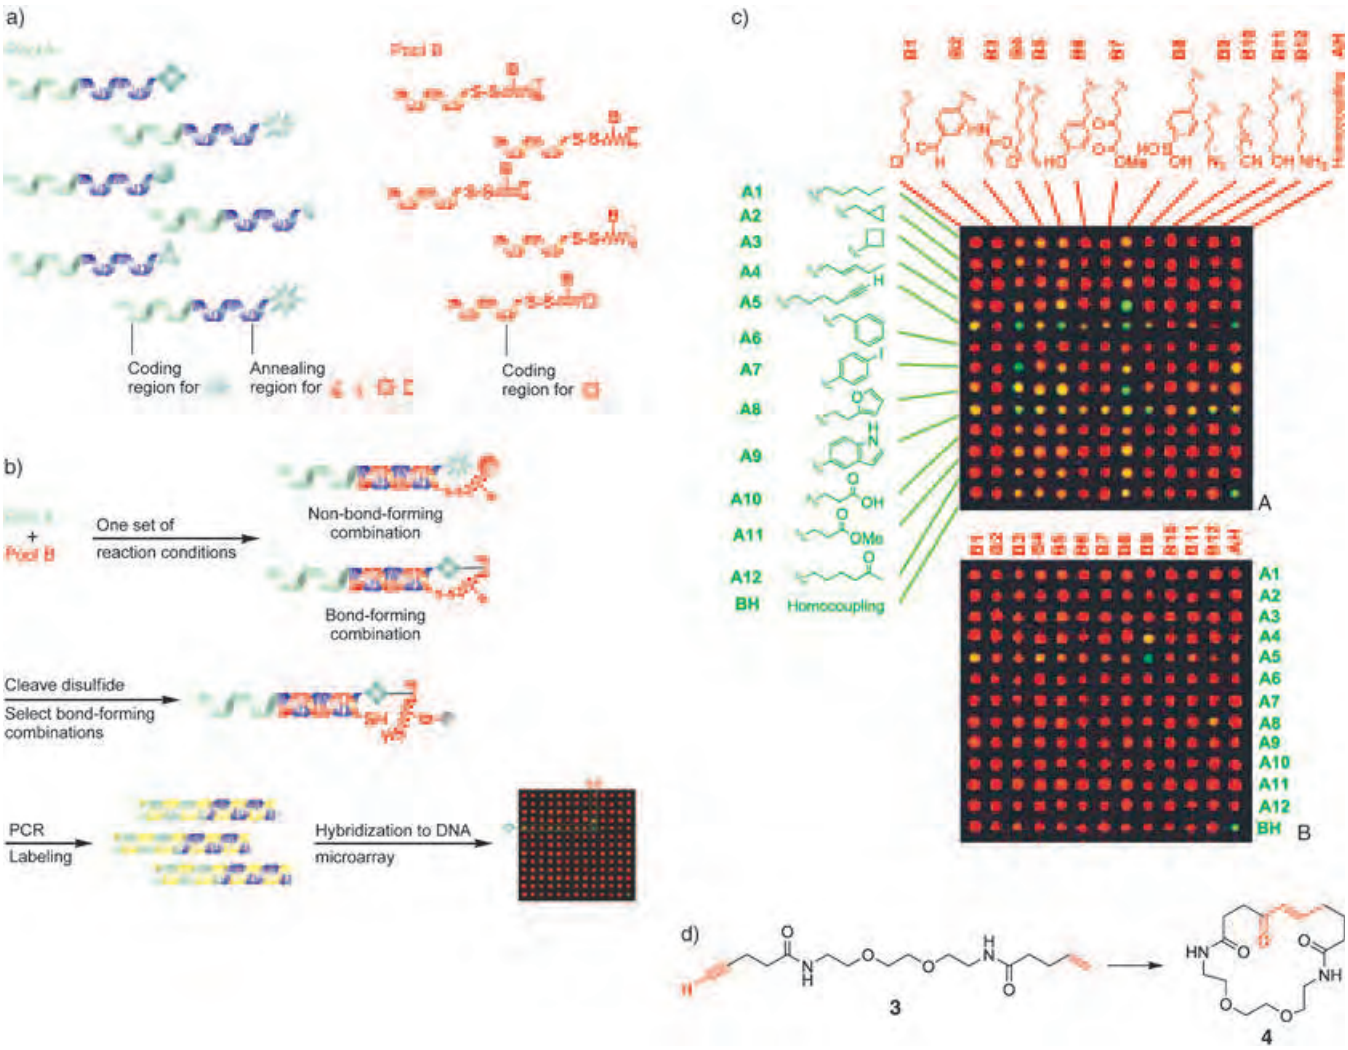

Figure 4. Discovery of a new type of chemical reaction that takes advantage of DNA-templated reactions (adapted from Ref. [14], array data reproduced with kind permission).

that encoded for the homocoupling of any of the 24 different substrates were prepared, bringing the total number of unique substrate combinations to 168. Although this approach required the preparation of a large number of DNA-linked substrates, these are typically synthesized at the nanomole-scale, and therefore, provide sufficient material for more than 1000 reaction discovery processes.

To enable a semiquantitative analysis of bond-forming efficiency, the mixture of the two pools A and B was amplified twice by PCR. Prior to bond formation and selection, PCR was carried out with Cy5-labeled primers while the post-selection mixture was amplified with Cy3-labelled primers. Equal amounts of the two PCR products were combined and hybridized to the DNA array containing all possible sequence combinations. The ratios of Cy3 (green) to Cy5 (red) fluorescence was determined for all array locations, and spots with green/red fluorescence ratios above 1.5 were considered positive. A pre-quantified internal standard (bottom right corner of the array in Figure 4c) was used as a positive control and as a reference to compare different arrays.

Initial validation tests were carried out with the known reaction between an alkyne (A5) and an azide (B9) in the presence of Cu^{I}. The observation of a single green spot (green/red ratio = 8.5) indicated the feasibility of the reaction discovery method (bottom array in Figure 4c). Similarly, the selection for bond formation after treatment of the pools with EDC/NHS (EDC = 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, NHS = *N*-hydroxysuccinimide) led to the formation of a single positive spot, indicating a reaction between the amine (B12) and the carboxylic acid (A10) compound (green/red ratio = 15.6). After the successful "rediscovery" of known bond-forming reactions, the authors then examined the reactivity of the library in the presence of Pd^{II}. The first reaction, carried out for one hour at 37 °C, led to five strong positives (A7 + B3, A5 + B3, A4 + B8, A5 + B5, and A5 homocoupling), in addition to five weaker positives (A9 + B3, A8 + B3, A8 + B8, A5 + B8, and A5 + B9; top array in Figure 4c). The 10 putative bond-forming reactions were then examined in separate DNA-templated reactions, and gel electrophoretic analysis indicated that all five strong positives and three of the weak positives indeed

corresponded to authentic DNA-templated reactions, whereas two weak positives (A9 + B3 and A5 + B9) showed little or no product formation.

Repetition of the selection experiment under more stringent conditions (20 min at 25 °C) decreased the number of positive signals and suggested that Pd^{II}-mediated carbon-carbon bond formation between the terminal alkyne (A5) and terminal alkene (B5) proceeds efficiently to generate an enone product. For the detailed investigation of this reaction in a non-DNA-templated version, small-molecule substrate **3** was synthesized and subjected to intramolecular cyclization to yield enone **4** in the presence of Pd^{II}. It was observed that this macrocyclization occurs at the milligram scale with Na_2PdCl_4 (5 mol %) in the presence of 1 equivalent $CuCl_2$ in various solvents with yields larger than 90 %. Hence, the discovery of this alkyne–alkene coupling reaction indicates the value of searching a large number of substrate combinations for unexpected reactions. The authors anticipate that similar schemes will lead to the discovery of additional bond-forming reactions between simple and relatively unreactive functional groups.[14]

In conclusion, these examples demonstrate the versatility of DNA microarrays as tools for the decoding of complex libraries of DNA-tagged small-molecules[16] as well as biomolecular compounds. These developments have been made feasible through the extraordinary physicochemical stability of nucleic acids, their availability by solid-phase synthesis, and the resulting steady progress in DNA array technologies over the past 15 years. Although DNA chips have since become routine tools, many problems have yet to be solved, for instance, the accurate prediction and quantitation of hybridization efficiencies of individual probes. Far more challenging, however, is the extension of applications similar to those described herein to protein microarrays. This may allow even deeper insight into biological systems on a proteome-wide scale. Owing to the exquisite and delicate architecture of nature's universal tools, however, steps toward this goal will surely constitute a fascinating research area for creative chemical biologists in the near future.

Gene Regulation

Epigenetics—An Epicenter of Gene Regulation: Histones and Histone-Modifying Enzymes

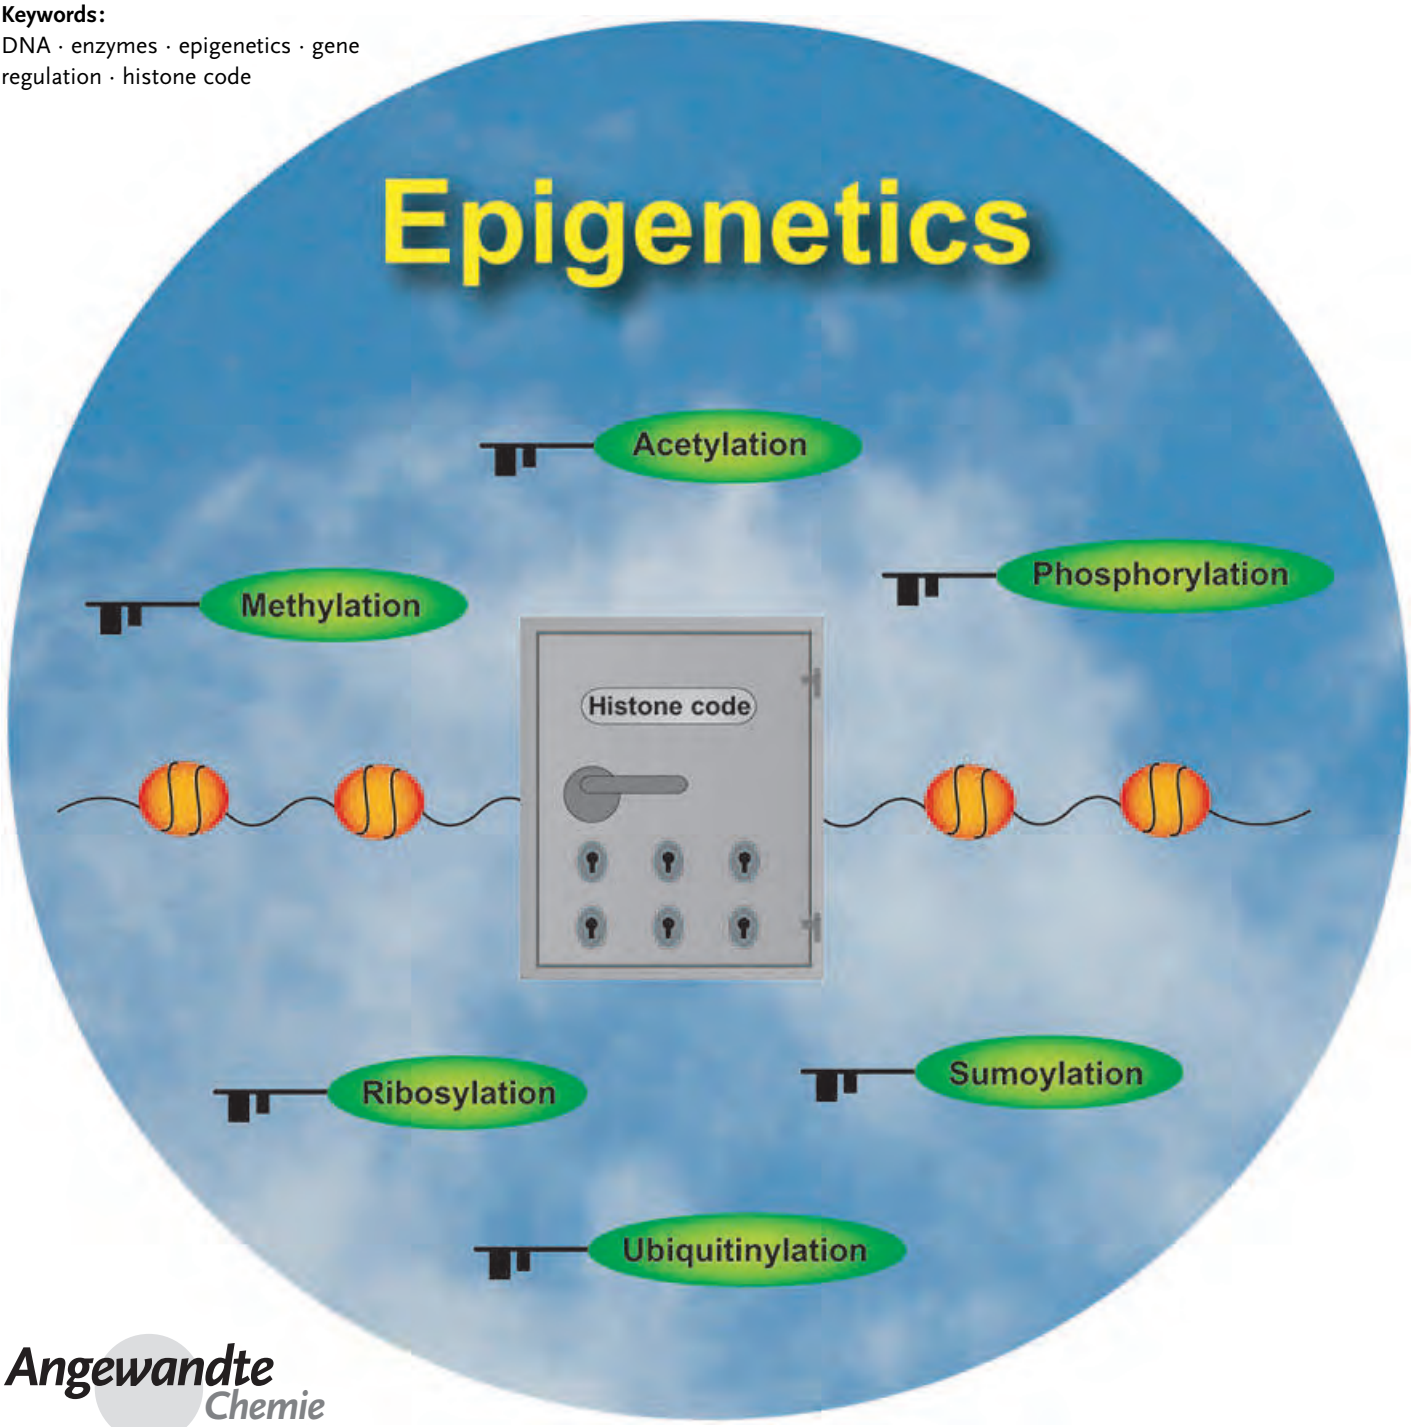
DNA · enzymes · epigenetics · gene regulation · histone code



DOI: 10.1002/anie.200461346

The treatment of cancer through the development of new therapies is one of the most important challenges of our time. The decoding of the human genome has yielded important insights into the molecular basis of physical disorders, and in most cases a connection between failures in specific genes and the resulting clinical symptoms can be made. The modulation of epigenetic mechanisms enables, by definition, the alteration of cellular phenotype without altering the genotype. The information content of a single gene can be crucial or harmful, but the prerequisite for a cellular effect is active gene transcription. To this end, epigenetic mechanisms play a very important role, and the transcription of a given gene is directly influenced by the modification pattern of the surrounding histone proteins as well as the methylation pattern of the DNA. These processes are effected by different enzymes which can be directly influenced through the development of specific modulators. Of course, all genetic information is written as a four-character code in DNA. However, epigenetics describes the art of reading between the lines.

From the Contents

1. Introduction

The entire genetic information of an organism is extremely heterogeneous when it comes to the expression of single genes. Whereas some genes are transcribed frequently, other areas of the genome are silenced. As genetic information is highly regulated and organized, it is possible to change the phenotype of a cell without altering its genotype. This is done by epigenetic mechanisms, which operate in advance of actual gene transcription events and are encoded in various patterns of DNA methylation and histone modification.

1.1. The Histone Code Hypothesis

In the nucleus of a cell, the eukaryotic genome is condensed into structures of higher order called chromatin. The fundamental repeating unit of chromatin is the nucleosome,[1] in which 145–147 DNA base pairs are wrapped left-handed around a core histone protein, which consists of two of each of the four histone protein subunits: H2A, H2B, H3 and H4.[2] The linker histone H1 completes the nucleosome and allows the condensation of this fundamental unit to structures of higher order, which are visible under the microscope as chromosomes during metaphase of the cell cycle. The structure of each core histone is essentially a globular domain;[3] only the highly conserved amino termini of the histone proteins are presented as flexible chains at the surface of the nucleosome, where they are frequent targets for various posttranslational modifications.[4,5] Such modifications include the acetylation of specific lysine residues by histone acetyltransferases (HATs), the methylation of lysine and arginine residues by histone methyltransferases (HMTs), and the phosphorylation of specific serine groups by histone kinases (HKs). Further histone modifications include the attachment of ubiquitin (Ub), small ubiquitin-like modifiers (SUMOs), and poly(ADP-ribose) (PAR) units (Figure 1).

Furthermore, enzymes responsible for the cleavage of some histone modifications, such as histone deacetylases (HDACs), histone phosphatases (PPs), ubiquitin hydrolases (Ubps) and poly(ADP-ribose)glycohydrolases (PARGs), have already been identified.[6–8] Particularly in the case of histone H3, it was shown that its posttranslational modifications are closely related to fundamental cellular events like the activation and repression of transcription.[9] In general, acetylation of H3 at lysine 14 (H3-K14), phosphorylation of serine 10 (H3-S10), and methylation of H3-K4 lead to transcriptional activation. In contrast, the repression of certain genes is linked to deacetylation of H3-K14 and methylation of H3-K9.[10,11]

These modifications mutually affect each other in many cases to generate specific, well-regulated patterns (Figure 2). In yeast, for example, phosphorylation of H3-S10 by the histone kinase Snf1 facilitates the yGcn5-mediated acetylation of H3-K14.[12] On the other hand, methylation of H3-K9 is directly dependent on a second modification: if H3-S10 is phosphorylated, methylation of H3-K9 by the histone methyltransferase SUV39 is blocked; these effects are conversely related as well.[13] From these observations came the histone code hypothesis: the various modifications made to one or more histone termini act in a combinatorial and sequence-dependent manner to yield specific downstream events; these modifications are therefore used as a cellular vocabulary for the regulation of different transcription-based processes.[14]

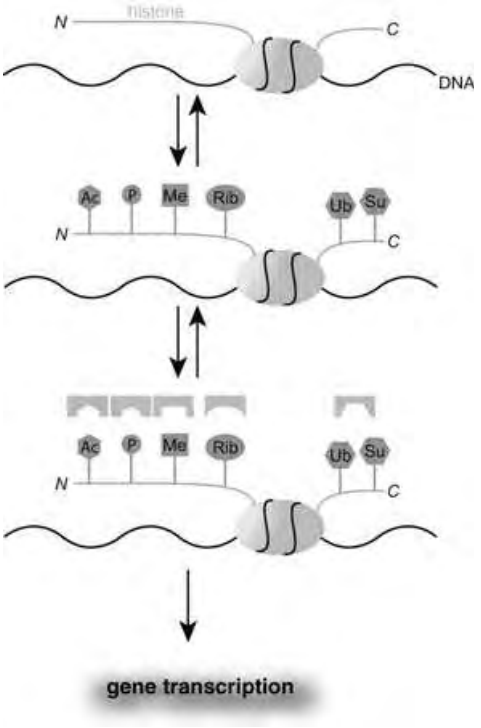

Figure 1. The formation of specific modification patterns at the histone termini results in the recruitment of regulatory units that translate the histone code into specific downstream events.

One way to read this language is through the recruitment of regulatory proteins with certain protein modules, which can recognize one or more histone modifications within a specific context. The acetylation of H3-K14 is a signal for the binding of proteins that possess a bromo domain, which is able to recognize acetylated lysine residues, and which is present in proteins such as Swi2/Snf, TAFII250, and Gcn5.[15] Swi2/Snf is responsible for the partial ATP-dependent opening of the chromatin structure, which makes the DNA more accessible to transcription machinery. Methylated lysine residues are bound by proteins equipped with a chromo domain. The heterochromatin-associated protein 1 (HP1) for example, belongs to the group of chromo domain-containing proteins that specifically interact with methylated H3-K9. This process is linked to the silencing of genes.[10]

Histone proteins not only fulfill the structural requirements of DNA, but also serve as a matrix for the establishment of a code that regulates its accessibility. This observation has moved the postulated histone code into the center of attention within the scientific community. It is an important starting point for the development of new therapies for diseases that are caused by abnormalities in the complexly regulated epigenetic network.[16]

Changing the epigenetic code through the development of small molecules that can modulate the properties of histone-modifying enzymes is an important challenge that could lead to the prevention of oncogene transcription and the activation of tumor repressors, which can induce apoptosis in tumor cells, force them to undergo cell-cycle arrest, or force their transition into differentiation. This article describes the known histone modifications and discusses the possible applications of modulators of histone-modifying enzymes in the fields of biology and medicine.

2. Histone Acetylation

Histone acetylation is one of the best understood histone modifications and takes place at the ε-

Markus Biel was born in Karlsruhe in 1973. He studied chemistry at the University of Karlsruhe and received his diploma in 2000. As a PhD student in the research group of Prof. A. Giannis, he moved from Karlsruhe to the Institute of Organic Chemistry of the University of Leipzig in 2002. He is engaged in the synthesis and biological evaluation of inhibitors of histone acetyltransferase and modulators of protein palmitoylation.

Veit Wascholowski was born in Braunschweig in 1975. He studied chemistry at the University of Karlsruhe and completed his diploma in 2000. Since that time he has been carrying out PhD studies in the research group of Prof. A. Giannis, first at Karlsruhe and since 2002 at the University of Leipzig. His field of interest is problems in chemical biology. He is therefore engaged in the synthesis and biological evaluation of new ceramide analogues and modulators of apoptosis.

amino groups of conserved lysine residues.[17] The highly regulated activities of HATs and HDACs are responsible for the control of specific acetylation levels.[18] One of the earliest discoveries in this context is that histones within the expanded, actively transcribed regions of chromatin (euchromatin) are acetylated to a higher degree than those in condensed regions (heterochromatin), which are not accessible to the transcription machinery.[19,20] This effect, that the temporary extent of gene transcription depends on its position with respect to accessible or inaccessible chromatin surroundings is called position effect variegation (PEV).[10,21–23] Genes that encode products which suppress PEV (and hence transcription) belong to the *su(var)* (suppressors of variegation) group, of which the products HDAC and HP1 are members.[24,25] In contrast, products of members of the *e(var)* (enhancers of variegation) gene group, such as the HATs, are PEV modulators that enhance variegation.[26,27]

2.1. Histone Acetyltransferases (HATs)

Many known transcription factors possess an intrinsic HAT activity.[28] These proteins are grouped into different enzyme family classes through sequence homologies and similarities in their biological functions (Table 1).[29]

Table 1: HAT families and functions of selected members.

HAT	organism	function
GNAT family		
Gcn5	yeast, human	coactivator
PCAF	human	coactivator
Elp3	yeast	elongation
ATF-2	yeast, human	activator
MYST family		
MOZ	human	coactivator
Ybf2/Sas3	yeast	elongation
Sas2	yeast	silencing
Tip60	human	DNA-repair, apoptosis
Esa1	yeast	cell cycle progression
MOF	fruit fly	dosage compensation[a]
CBP/p300 family	worm, human	global coactivator

[a] dosage compensation: a regulatory process to ensure that female and male organisms have the same amount of X-chromosome products.

Athanassios Giannis was born in Drama, Greece in 1954. From 1972 to 1980 he studied chemistry, and from 1978 to 1988, medicine at the University of Bonn. After his diploma work with Prof. M. T. Reetz, he completed his PhD on the synthesis of C-glycosides with Prof. K. Sandhoff in 1986. In 1992 he received his university lectureship in Organic Chemistry and Biochemistry; in 1997 he was appointed Professor at the University of Karlsruhe. He has been a full Professor of Organic Chemistry and Natural Products Chemistry at the University of Leipzig since May of 2002. His focus is in angiogenesis, apoptosis, epigenetic mechanisms, and signal transduction; he is researching new antitumor agents.

The GNAT family includes a relatively small number of HATs. In addition to a C-terminal catalytic HAT domain of ≈160 residues, each member possesses a bromo domain for specific interaction with acetylated lysine groups.[30–32] Members of the CBP/p300 family are less substrate-specific and serve more as global modulators of transcription.[33] They each have a 500-residue catalytic HAT domain, a bromo domain, and a cysteine-rich motif, which likely facilitates protein–protein interactions.[34] Members of the MYST family are involved in a much broader range of biological processes.[35–38] They have a 250-amino acid catalytic domain that includes a zinc-binding region, a cysteine-rich motif, and an N-terminal chromo domain for the specific recognition of methylated lysine groups.[39,40] In addition to these three main HAT groups, there are over a dozen proteins also known to have acetyltransferase activity.[41]

Histone acetyltransferases are always present in the form of large multiprotein complexes in vivo, which serves to control substrate selectivity.[42] In yeast, for example, the HAT yGcn5 is part of the multiprotein complexes Ada and SAGA.[43] Together with the proteins Ada2 and Ada3, the catalytic subunit is formed.[44] Recombinant Gcn5 is able to acetylate free histones, but the modification of native, nucleosomal histones usually succeeds only under the control of the large multiprotein complex. It directs the substrate selectivity and specificity of HAT activity. Free Gcn5 acetylates histone proteins chiefly at H3-K14, whereas within the Ada complex Gcn5 accepts H3 lysine residues 9, 14, and 18 as substrates.[45] Furthermore, complex formation regulates HAT function in transcription processes. Depending on the specific complex formed, HATs are recruited to certain promoter regions through interactions with different activators, which leads to the acetylation of surrounding histones and subsequent induction of transcription. Establishment of such activator contact in yeast is mediated by the protein Tra1, which is part of the SAGA and NuA4 complexes.[46,47] The human homologue TRAP is present in the complexes STAGA[48] and Tip60,[49] where it mediates contact with the cell-cycle-regulating protein c-Myc and with the E2F family of transcriptional activators.[50,51]

Ultimately, such an assembly of functional units leads to the transcription of the gene of interest. The regulation of the human interferon (IFN)-β gene is a good example (Figure 3). Following viral infection, the progressive acetylation of histones near the IFN-β gene promoter can be observed.[52] The enhancer region, upstream of the gene, binds a multiprotein complex that includes three transcription factors (NF-κB, IRFs, ATF-2/c-Jun) and a scaffold protein (HMG I(Y)).[53] This so-called enhanceosome recruits the HAT Gcn5, which acetylates H4-K8 and H3-K9. Furthermore, a prerequisite for the acetylation at H3-K14 is the phosphorylation of H3-S10 by an unknown kinase. This developed histone code ultimately activates transcription by the subsequent binding of the transcription complexes SWI/SNF and TFIID through their bromo domains.[54] The acetylation at H4-K8 is necessary for binding SWI/SNF, whereas acetylation at H3-K9 and H3-K14 is essential for recruiting the transcription factor TFIID. Both results support the existence of the postulated histone code.[55]

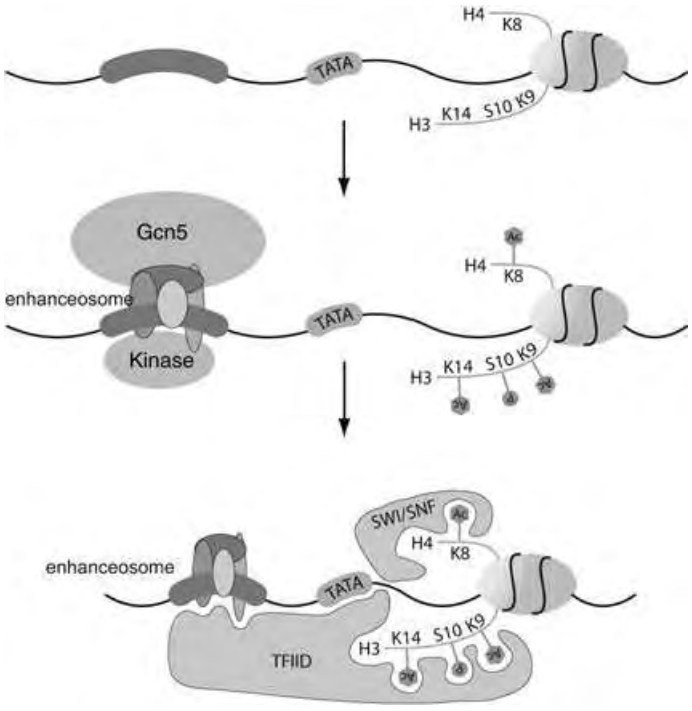

Figure 3. The transcription of the human interferon-β genes as an example of the control of transcription through specific histone acetylation. Following viral infection, a multiprotein complex (enhanceosome) is formed at the enhancer region and recruits the HAT Gcn5, which acetylates H4-K8 and H3-K9. After phosphorylation of H3-S10 by an unknown kinase, Gcn5 also acetylates H3-K14. The written histone code leads to the accumulation of the transcription complexes SWI/SNF and TFIID. Both proteins possess the requisite bromo domains for this interaction. Moreover, TFIID contacts both the TATA-box element of the DNA and the enhanceosome.

The influence of HATs on chromatin-dependent events such as transcription suggests that other DNA-based mechanisms could be influenced by HAT activity as well.[56] Examples include cell-cycle progression,[57–61] DNA recombination,[62,63] and DNA repair and apoptosis.[49] Furthermore, HATs influence DNA replication[59], elongation,[64,65] and the transcriptional silencing of genes.[66,67] Some HATs also recognize protein substrates other than histones. For example, p300 acetylates the tumor suppressor protein p53,[68–70] and therefore affects its ability to interact with DNA. Acetylation also modulates the activity of general transcription factors like TFIIβ and TFIIF,[71] the DNA-binding transcription factors GATA-1,[72] GATA-3,[73] ELKF,[74] MyoD,[75] E2F,[76] cMyb,[77] and dTCF,[78] as well as the chromatin-associated proteins HMG(Y),[79] HMG-14,[80] HMG-17,[81] CDP/cut,[82] and HIV Tat.[83] Therefore, acetylation is analogous to phosphorylation, which is an important tool in controlling the activity of kinase-mediated signal-transduction cascades.

Owing to the broad presence of HATs in different biological processes, there are some diseases which are caused by dysfunctional, mutated HATs. The Rubinstein–Taybi syndrome was first mentioned in 1957, and six years later Rubinstein and Taybi described a study of seven children with wide thumbs, broad, large toes, typical face courses, and retarded mental development. This disorder is the result of a mutation in the *crebbp* gene, which encodes the histone acetyltransferase CBP.[84,85]

A characteristic of human leukemia is chromosomal translocation, which leads to the expression of fusion proteins. Such proteins exhibit altered properties from their wild-type counterparts, and the transcription of genes, controlled by an abnormal HAT fusion protein, functions incorrectly. For example, in acute myelogenous leukemia (AML),[36,86] the amino terminus of CBP is fused with the MOZ protein—a HAT of the MYST family—and the resulting fusion protein is rendered useless.

2.1.1. *Structure and Catalytic Mechanism of the HAT Gcn5*

The results of kinetic studies[87–90] show that the acetylation mechanism of Gcn5 proceeds via a ternary complex of histone H3, enzyme, and acetyl-CoA.[91] As a result, the acetyl group is transferred directly to the amino group of the lysine residue without the formation of an acetylated enzyme intermediate. The central enzyme core domain is responsible for catalysis and acetyl-CoA binding, whereas the N- and C-terminal segments appear to be necessary for the interaction with the histone substrate.

X-ray crystallographic structure analysis[92–96] shows that the pantothen chain and the pyrophosphate groups are responsible for the binding of acetyl-CoA, whereas the adenine base does not make a considerable contribution. The H3 substrate of Gcn5 from *tetrahymena* (*t*Gcn5) binds in a groove above the core domain, and is flanked on both sides by the C- and N-terminal protein chains. Most of the contacts are present along the H3 backbone, whereby three quarters are on K14 and the five residues in the C-terminal direction, which narrows the H3 recognition motif down to GKXP. Furthermore, Glu 122 is a highly conserved basic group in *t*Gcn5 which has hydrophobic surroundings and is close to a region of negative electrostatic potential. This results in an increased pK_a value for Glu 122, and facilitates the binding of the positively charged lysine residue. The water molecule between Glu 122 and the protonated amino group of K14 is held in place by a hydrogen bond to the backbone amide of Val 123 and the hydroxy function of Tyr 160. During catalysis Glu 122 deprotonates the ammonium function of H3-K14 and enables a direct attack of the ideally positioned acetyl-CoA (Figure 4). The tetrahedral intermediate is stabilized by a hydrogen bond to the backbone amide of Leu 126 and decomposes under release of the desired products.

2.1.2. *Modulators of HAT Activity*

The first reports of selective peptide inhibitors of the HATs p300 and PCAF were published in 2000.[97–99] They were designed as disubstrate analogues of H3 and acetyl-CoA. The observed mode of inhibition reflects the substrate specificity of the particular HAT studied. Whereas p300 was inhibited by the structurally simple Lys-CoA (**1**), sufficient inhibition of the more specific PCAF was possible only with the 20-amino acid peptide H3-CoA-20 (**2**; Figure 5). The most crucial disadvantages of these inhibitors are their low cell permeability and metabolic instability, which decreases their suitability for investigations in vivo.[100] In 2003, anacardic acid (**3**) was identified as a HAT inhibitor through a broad

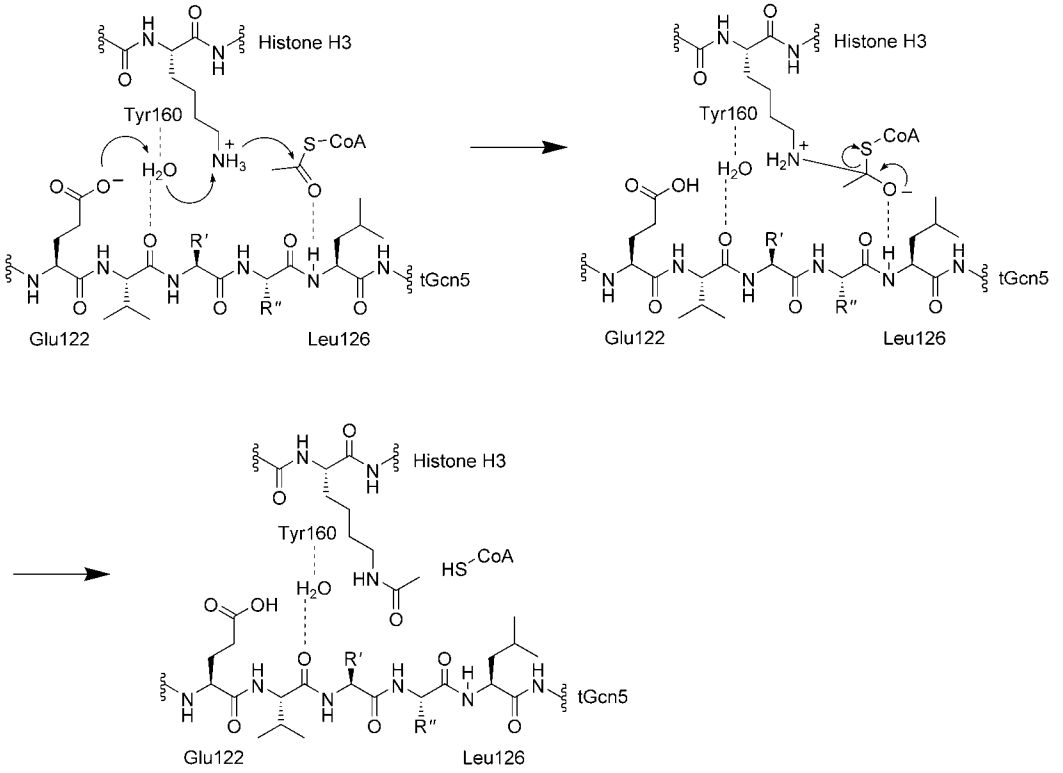

Figure 4. Catalytic mechanism of the HAT *t*Gcn5: Glu122 serves as a general base and supports nucleophilic attack of the ε-amino function of the lysine residue on the precoordinated acetyl-CoA. The transition state is stabilized through the amide function of Leu126 and decomposes with the release of CoASH and the acetylated lysine product (derived from [94]).

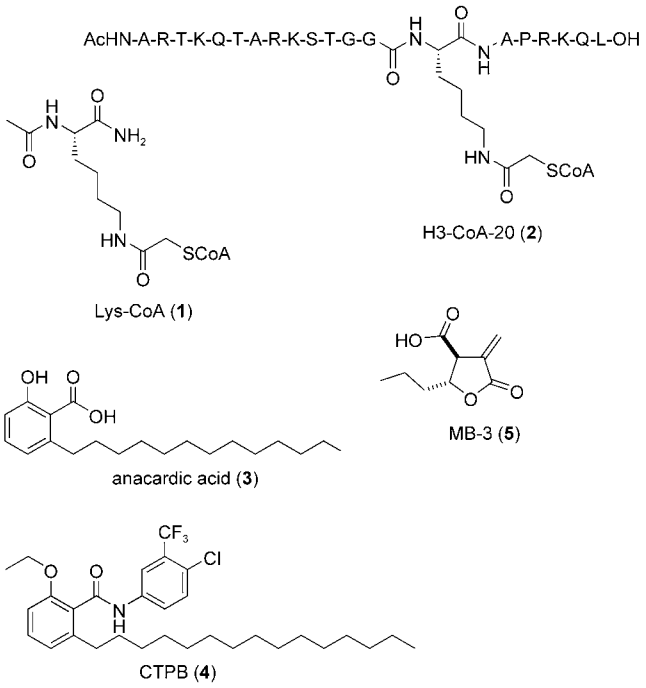

Figure 5. Modulators of the HATs: Lys-CoA (**1**) is a bisubstrate analogue and inhibits the HAT p300, whereas the peptide H3-CoA-20 (**2**) is described as an inhibitor of PCAF. Anacardic acid (**3**) inhibits both p300 and PCAF, whereas the amide derivative CTBP (**4**) represents an activator of the enzyme. MB-3 (**5**) is a small, cell-permeable inhibitor of the human Gcn5.

screen of plant extracts with antitumor activity.[101] This was the first report of a small-molecule inhibitor of the HATs p300 and PCAF. Interestingly, amidation of the carboxylic acid group leads to compound **4**, which is an activator of p300. Anacardic acid had been previously identified as an inhibitor of DNA polymerase β,[102] and therefore the biological selectivity could be limited.

In the meantime, our group developed MB-3 (**5**),[103] a small, cell-permeable inhibitor of the human Gcn5 which is based structurally on the α-methylene-γ-butyrolactone motif—a common substructure element in many natural products.[104] This privileged structure had been previously used for the design of an inhibitor for fatty acid synthase,[105] another enzyme involved in the transfer of acetyl-CoA. The development of MB-3 was brought about by the appropriate derivatization of the basic butyrolactone motif without the arbitrary screening of large compound libraries. Interestingly, the length of the aliphatic side chain is crucial for biological activity.

Alongside these efforts, nature has already developed ways to modulate HAT activity. For example, the activity of CBP/p300 is regulated through different posttranslational modifications.[106] The stimulation of CBP through phosphorylation by cycline E/CDK2 facilitates the progression of the cell through S-phase.[107] Phosphorylation within another region of the enzyme (the GF-box) allows binding of the transcription factor AP1,[108] whereas methylation within the CREB-binding domain decreases CPB affinity for the

phosphorylated CREB protein.[109] Moreover, after sumoylation (Section 6), p300 is able to interact with HDAC6.[110]

2.2. Histone Deacetylases (HDACs)

As a part of multiprotein complexes, HDACs catalyze the cleavage of acetyl functions from proteins, particularly from histones.[111] The importance of these enzymes is underscored by their evolutionary conservation from insects to humans.[112] So far, 18 different HDACs have been identified and divided into three distinct enzyme classes.[113] Enzymes of class I are originally derived from the yeast HDAC yRPD3. In humans, the HDACs 1, 2, 3, 8 and 11 are members of class I,[114] as they share the same compact structure and are expressed in the nuclei of most cell lines and tissue types.[115] Class II enzymes are expressed in a small number of cell types and are homologous to yHFA1. In contrast to class I HDACs, the subcellular location of class II HDACs is not limited to the nucleus; they are also present in cytoplasm.[113,116] Both classes have a highly conserved catalytic domain of 390 amino acids, but differ in overall composition and size. Mechanistically, the hydrolytic cleavage of the acetyl function proceeds through the activation of a water molecule by a zinc ion in the active site.[117] Class III enzymes (sirtuins) share a common ancestry with the yeast transcription repressor Sir2 (silent information regulator 2), and are subdivided into five classes.[118] Members share a common active site of 275 amino acids, and employ nicotinamide adenine dinucleotide (NAD^+) as a cofactor necessary for catalysis.[119] Moreover, class III HDACs possess two CXXC motifs (zinc-finger domains) and at least one hydrophobic region (leucine zipper) which facilitate protein–protein and protein–DNA interactions.[118,120]

2.2.1. Class I and Class II HDACs

The deacetylation of histones leads to closed chromatin structures, which are no longer accessible to the transcription machinery. To mediate this type of gene silencing, HDACs must be recruited to different promoter regions, as they cannot interact directly with DNA or associated histone proteins.[121,122] For this reason, HDACs are always part of protein complexes, which bind to specified regions of DNA (Figure 6).

In some cases, HDACs are recruited to the DNA through complex formation with different transcription factors. For example, HDAC1 associates with YY1,[123] whereas HDACs 4, 5, 7, and 9 bind to the MEF family of transcription factors, which interact with specific promoter regions and therefore transport the enzymes to their proper areas of action.[124] The HAT p300 and HDAC4 compete for the same binding site of MEF2. The transcription factor can therefore function either as a repressor or as an activator of gene expression, depending on the enzyme bound. The switch in activity is calcium dependent; the MEF2 binding site on HDAC4 overlaps with that of calmodulin. If the intracellular

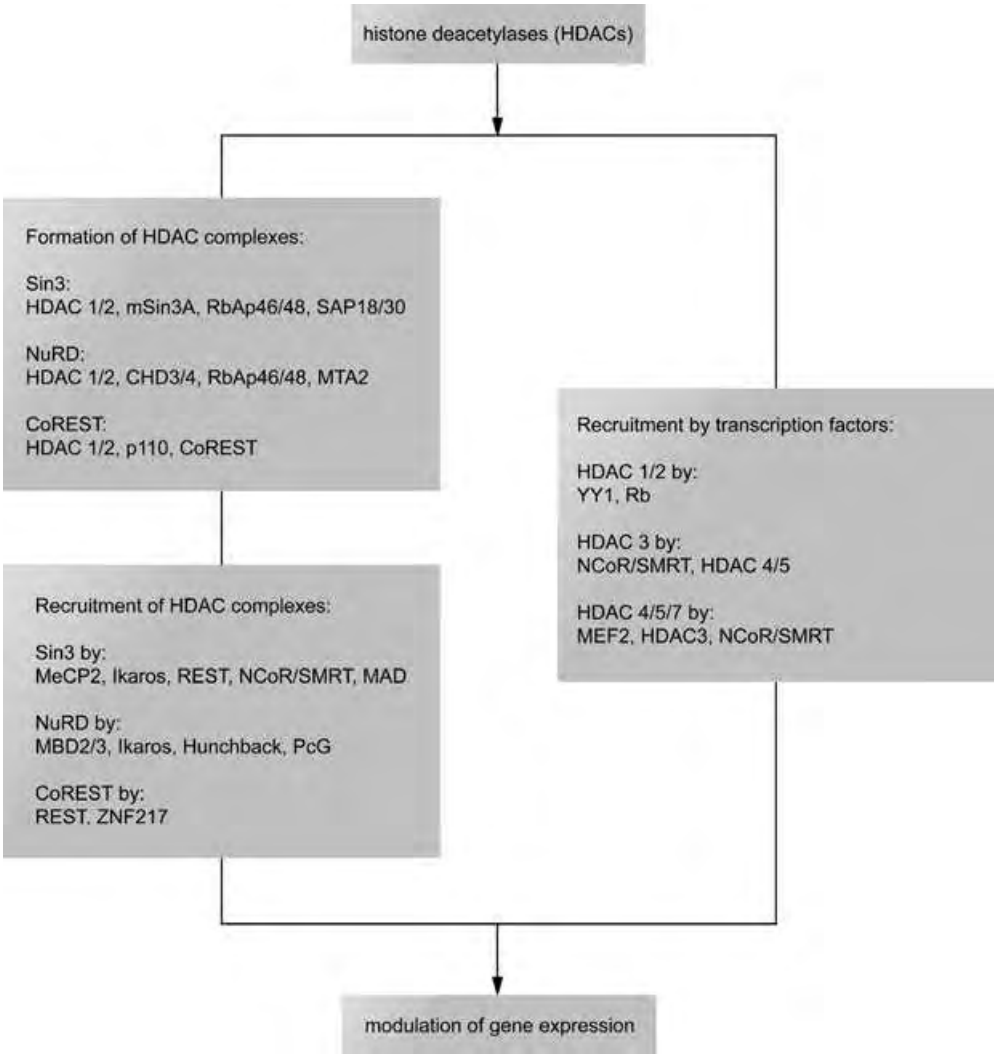

Figure 6. HDACs form complexes with other proteins to fulfill their biological functions. For example, HDAC1 and HDAC2 form the Sin3 complex with mSin3A, RpAp46/48, and SAP18/30. This is recruited to the DNA by MeCP2 and leads to silencing of the target gene. The same is true for the NuRD and CoREST complexes. In addition, HDACs are able to interact directly with transcription factors like YY1, MEF2, and the nuclear corepressor NCoR, as well as with other HDACs.

calcium level favors calmodulin binding to HDAC4, the enzyme loses its ability to interact with MEF2. In that case the transcription factor recruits p300 and gene expression is activated through acetylation of chromatin.[124] Moreover, HDAC4 as well as HDAC5 and HDAC7 possess three 14-3-3 binding sites, which can be phosphorylated at specific serine residues. Phosphorylation interrupts the HDAC–MEF contact and enables the binding of 14-3-3 proteins. As a result, the HDAC is transported from the nucleus to the cytoplasm, where the enzyme is inactive. Also in this case, p300 binds to the MEF2 transcription factor and activates gene expression.[124] Furthermore, the association of HDAC4 with Erk1 and Erk2, and the observation that activation of the Ras–MAPK pathway increases the localization of deacetylases in the nucleus are important hints that there could be cross-talk between the two pathways.[125]

There are other examples in which HDACs are able to bind transcription factors only as members of protein complexes. For HDAC1 and HDAC2, the complexes Sin3,[126,127] NuRD[128] and CoREST[129–131] have been characterized. Sin3, for example, consists of HDACs1/2 and the histone-binding proteins RpAp46/48, which together form the core complex, which is also a substructure element of the NuRD complex. The Sin3 complex also includes the stabilizers SAP18, SAP30, and mSin3A, which mediate the interactions with many DNA-binding proteins and direct the complex to specific DNA regions.

The fundamental structure[117] of the HDAC classes I and II consists of a single domain that is structurally related to the class of the open α/β hydrolases. A deep, tubular pocket widens into an internal cavity that houses the enzyme active site. Whereas the channel-like structure is lined with numerous hydrophobic amino acids, the active site is able to coordinate the central zinc ion through several polar histidine and aspartate residues. The catalytic mechanism[112] shows similarities to other metallo- and serine proteases: the carbonyl oxygen of the acetyl function coordinates to the zinc ion and is positioned in close proximity to a water molecule, which is activated for nucleophilic attack at the carbonyl group by interaction with the zinc ion (Figure 7). The tetrahedral oxyanion intermediate is probably stabilized through an interaction with the zinc ion and a hydrogen bond to a neighboring tyrosine group. After the spontaneous decomposition of this intermediate, the desired products are released, and a new catalytic cycle can start.

In 1976 the natural product trichostatin A (TSA, **6**) (Figure 8) was isolated from *Streptomyces hygroscopicus* and identified as a fungistatic antibiotic.[132] After approximately 20 years, it was also identified as a potent inhibitor of class I and class II HDACs ($K_i = 3.4$ nM).[133] Before that time, short-chain fatty acids such as the antiepilepsy drug valproic acid (**14**) and phenyl butyrate (**15**) were characterized as weak inhibitors of HDACs, with IC_{50} values in the millimolar range.[134,135] In contrast, hydroxamic acid derivatives like TSA (**6**), SAHA (**7**), and CBHA (**8**) inhibit HDACs at nanomolar concentrations, and are distinguished by longer half-lives and better bioavailability.

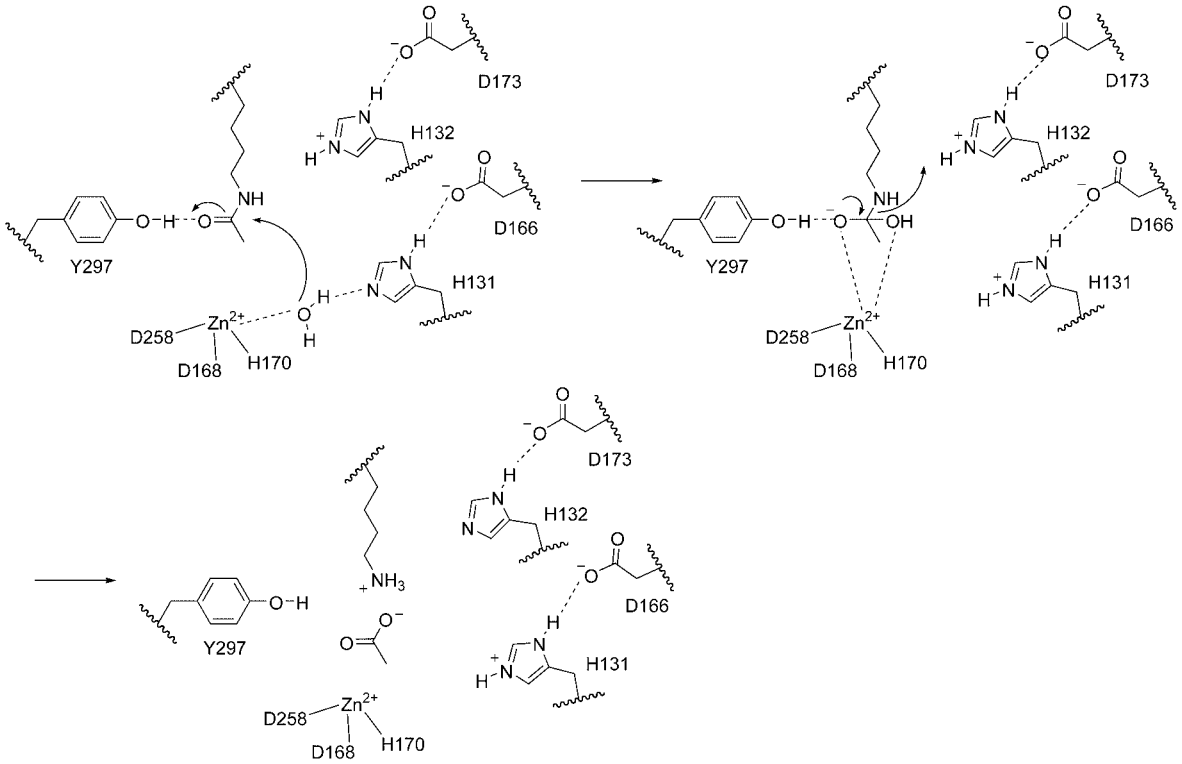

Figure 7. Catalytic mechanism of class I and II HDACs: the acetylated substrate is activated by the interaction with the hydroxy function of Y297. Meanwhile, the nucleophilic strength of the water molecule, which is necessary for amide hydrolysis, is increased through both the central zinc ion and the basic system, H131–D166. The oxyanion forms a hydrogen bond to Y297 and is coordinated by the central zinc ion to stabilize the tetrahedral intermediate. The proton required for the decomposition of the intermediate is provided by the system, H132–D173.

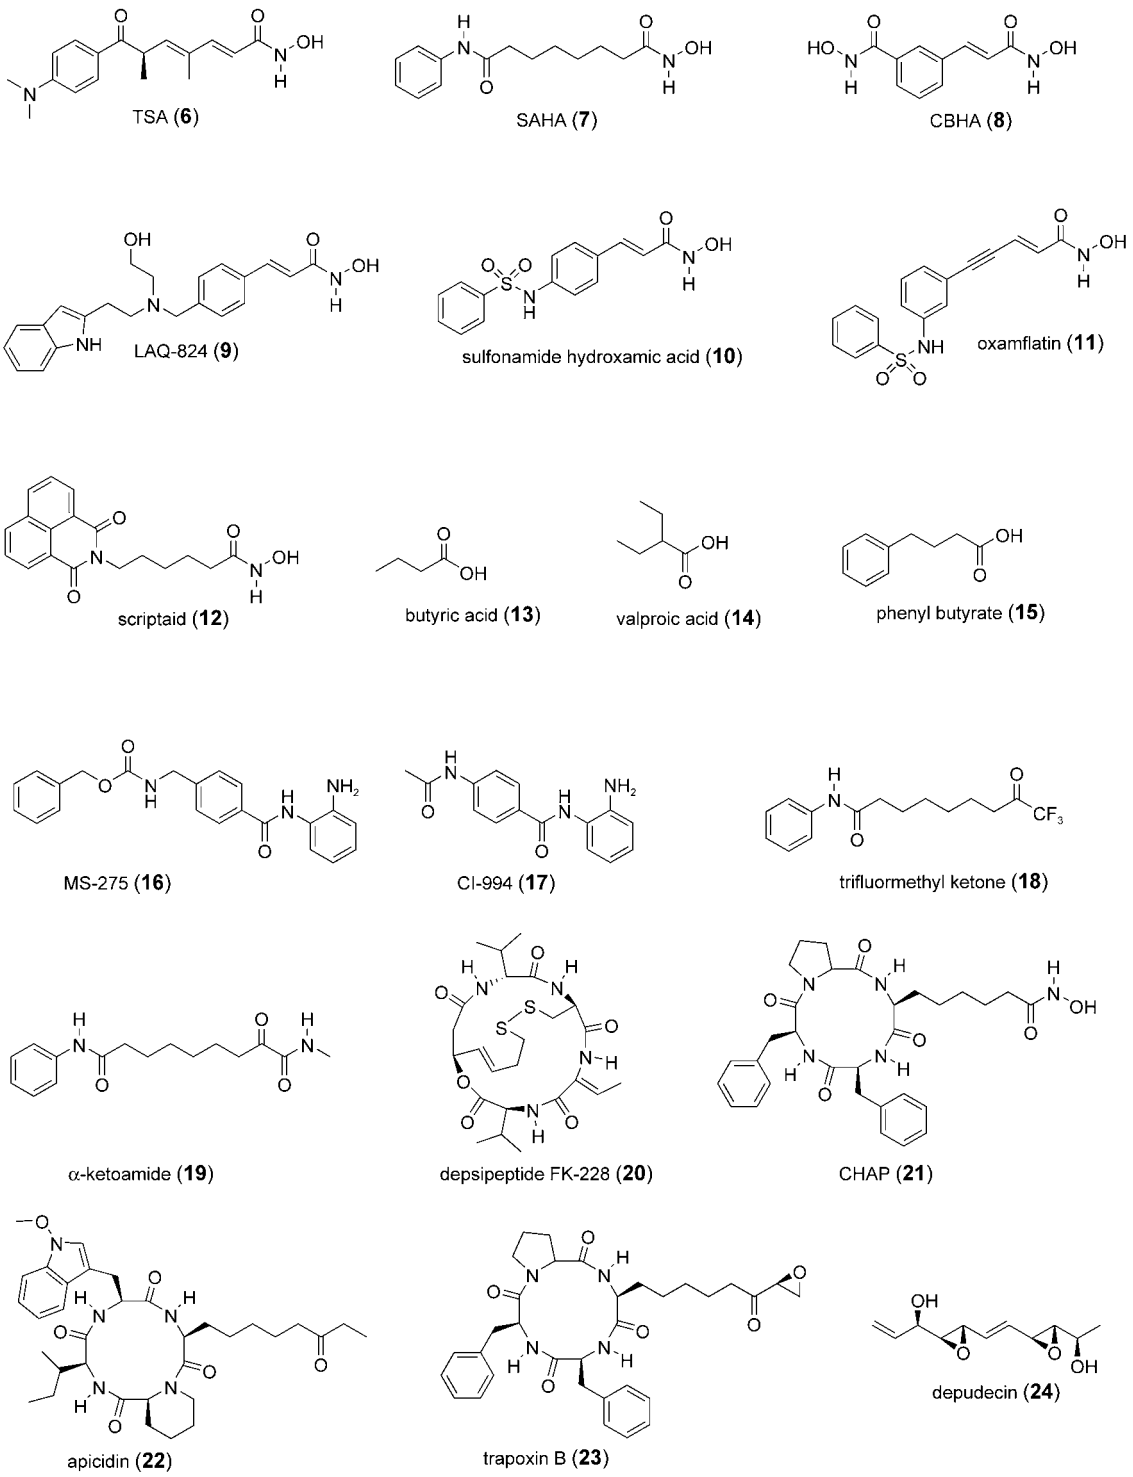

Figure 8. Examples of identified HDAC inhibitors, which can be grouped into five different structural classes: hydroxamates, **6**–**12**; aliphatic acids, **13**–**15**; benzamides, **16**–**17**; electrophilic ketones, **18**–**19**; cyclic tetrapeptides, **20**–**23**; and other molecules like **24**.

The potency of this class of inhibitors is explained by the X-ray crystallographic structure of HDAC cocrystallized with TSA,[117] as an almost perfect active-site fit is observed: the terminal hydroxamic acid function efficiently coordinates the catalytically essential zinc ion of the active site (Figure 9). As expected, trichostatic acid, the carboxylic acid analogue of TSA is biologically inactive.[136]

The aliphatic chain of TSA enables numerous van der Waals contacts with the hydrophobic residues of the tubular channel of the HDAC enzymes. The aromatic component of TSA mimics the amino acids that surround the lysine group in the natural substrate, and also acts as a surface element that caps and effectively closes the channel to the active site. This information served as a basis for the development of new

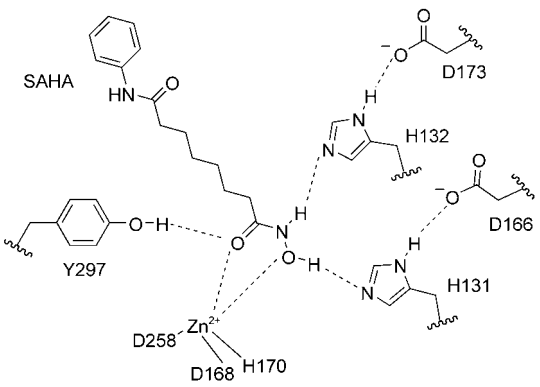

Figure 9. SAHA (**7**), a simple derivative of TSA, shows a perfect interaction with the central amino acid residues of the HDAC active site.

inhibitors that share the fundamental structure of TSA (surface element–aliphatic chain–complexing group), and provided detailed insight into the mode of inhibition through the study of structure–activity relationships (SAR).[137,138]

In addition to the hydroxamic acids, other HDAC-inhibiting compounds such as phenylenediamines (MS-275, **16**) and epoxides (trapoxin A, **23**) are well-known. Whereas the length of the aliphatic chain is limited to five or six carbon atoms (in **6** and **7**), isosteric substitution with an appropriate aromatic system (as in **8**) is allowed.[139–143] The cap should be a small, planar group (in **6**) or a tetrapeptidic structure as in apicidin (**22**); structure type affects inhibitory activity. For example, a compound with a small, planar cap and a carboxylic acid group as the functional unit leads to an ineffective inhibitor, whereas the same molecule with a cyclic tetrapeptide as a surface element is potent.[139,140] If the stereochemistry of TSA is changed, it is rendered completely inactive.[136,144] The synthetic hybrid CHAP (**21**), which has hydroxamic acid as a functional unit and a tetrapeptide as a cap structure, is a potent inhibitor at nanomolar concentrations.[145,140] Furthermore, some natural products, like depudecin (**24**), do not fit the structural motif of TSA, yet are moderately active HDAC inhibitors.[146–148]

To evaluate the biological functions of each and every HDAC enzyme, it is important to identify new and selective inhibitors. Most HDACs possess a highly conserved catalytic domain, but have a certain variation among the amino acids that do not directly interact with TSA. For this reason, a specific modulation of the capping structure enables access to selective inhibitors.[112] The sense of this strategy is the fact that HDAC6 is not inhibited by compounds with cyclic peptides as surface elements. The most pronounced differences between HDAC6 and the other HDACs lie in the vicinity of Tyr91, which is located at the entrance of the tubular channel and interacts directly with the cap portion of TSA.

The reason for the continued search for improved HDAC inhibitors is their potential use as tumor therapeutics. Although histone acetylation plays a global role in the regulation of gene expression, HDAC inhibitors only affect the transcription of a small subset of genes that are associated with the control of cell growth.[149] The explanation for such a small range of action could be attributed to the fact that according to the model of the histone code, other types of covalent histone modifications could also affect transcription.[8] In addition to histone deacetylation, histone methylation also directs gene silencing, which is not blocked by the application of HDAC inhibitors. The same principle applies to DNA methylation (Section 3.1.2).[150]

Nevertheless, HDAC inhibitors are able to stop the proliferation of leukemias and solid tumors, and can induce cell differentiation. The molecular basis for this has, until now, been only partially understood.[138,151–154] In most tumor cells, HDAC inhibitors activate transcription of the CDK inhibitor WAF1 (p21, coded by CDKN1A).[155] Moreover, the inhibition of different cyclins as well as the hypophosphorylation of the retinoblastoma tumor-suppressor protein Rb results in the inhibition of S-phase progression and subsequently in a cell-cycle arrest at G1.[156] This blocks apoptosis and directs the cell to differentiation. Tumor cells that show no G1 arrest after the application of HDAC inhibitors (for example, cells that lack CDKN1A)[157,158] replicate their DNA to the double set of chromosomes and pass into apoptosis.[159–162] One explanation for this phenomenon could be that the hyperacetylation of histones disturbs the centromere and kinetochore functions during cell-cycle progression, which would result in different lethal dysfunctions. In contrast, normal cells induce a G2 checkpoint after treatment with HDAC inhibitors, which leads to a cell-cycle arrest with less toxicity (Figure 10).[159]

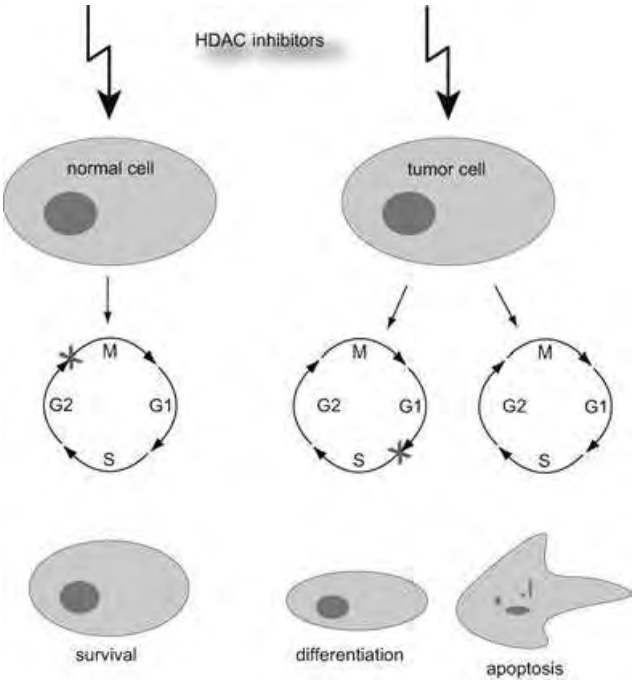

Figure 10. Biological effects of HDAC inhibitors: in normal cells, the application of HDAC inhibitors leads to the induction of a G2 checkpoint, which results in cell-cycle arrest with less toxicity. Under the influence of HDAC inhibitors, many tumor cells increase transcription of the CDK inhibitor WAF1, which leads to a cell-cycle arrest at G1 and directs the cell into differentiation. Cells that do not respond with an arrest at G1 replicate their DNA and induce apoptosis.

The treatment of various tumor cells with HDAC inhibitors induces apoptosis.[152,156,160,161,163] The inhibitors activate both the extrinsic and intrinsic apoptotic signaling pathways. For example, apicidin (**22**) and CBHA (**8**) stimulate expression of the death receptor CD95 and its ligand CD95L.[161,162] Furthermore, after the application of HDAC inhibitors, an increase in the expression of pro-apoptotic Bcl2 proteins (BAX/BAK) and a decrease of anti-apoptotic factors can be observed.[154,164,165] Both pathways result in the activation of caspases.

Beyond this, HDAC inhibitors show further antitumor activities, such as the enhanced transcription of genes that encode MHC I and MHC II to stimulate immune cell recognition and activation.[166–169] Furthermore, TSA (**6**) inhibits the expression of VEGF, which is normally induced by hypoxia, thereby preventing angiogenesis.[170]

These investigations show that HDAC inhibitors are potent antitumor agents, which exhibit only minimal side effects. For this reason they represent a dramatic change in the treatment of cancer diseases. Already, the potent HDAC inhibitors SAHA (**7**), the depsipeptide FK-228 (**20**), MS-275 (**16**), and LAQ-824 (**9**) have shown promising results in phases I and II of clinical trials.

2.2.2. *Class III HDACs: Sirtuins*

The namesake of all sirtuins is the silent information repressor 2 (Sir2) of yeast, a NAD^+-dependent histone deacetylase that is not subject to inhibition by TSA.[118,171] Initial analyses indicated that the enzyme uses a stoichiometric quantity of NAD^+ for the removal of acetyl groups from acetylated lysine residues. The NAD^+ group typically serves as a redox cofactor in biological systems, but in the case of Sir2 it is used as an acetyl group acceptor after hydrolysis of the nicotinamide moiety.[172] Detailed structural studies have shown that Sir2 possess a central core domain with a Rossman fold at both ends and a flexible zinc-binding motif. These structural elements are linked through a series of loops that form a cleft in the central region of the core domain. The acetylated lysine substrate and the NAD^+ cosubstrate bind at opposite sides of this cleft.[173–176]

The X-ray crystallographic structure of the Sir2 homologue of *Saccharomyces cerevisiae* (yHst2), cocrystallized with acetylated H4 and a stable NAD^+ analogue in which the ribose ring is replaced with a 2,3-dihydroxycyclopentane group (carba-NAD^+), has shed new light on the catalytic mechanism of the class III enzymes (Figure 11).[177] Based on this structural information, it is likely that nicotinamide is hydrolyzed in an initial step, and that the resulting oxycation intermediate is stabilized by a water molecule coordinated to Asn116. In a second step, the activated ribose is subject to nucleophilic attack by the carbonyl oxygen of the acetyl lysine function, and the resulting imine-like intermediate is captured by a second nucleophilic attack by the ribose 2′-OH group, facilitated by His135. Subsequent hydrolysis of the acetal-analogue structure gives free lysine and 2′-*O*-acetyl-ADP-ribose. This reaction is made possible by a water molecule coordinatively fixed at Asn116, with the participation of protonated His135. During catalysis, the ribose ring of the cosubstrate and the highly conserved β1-α2 loop of the enzyme clearly change their positions.

Sir2 is associated with the silencing of certain genes.[178] In the case of ySir2p, there are three different regions in the yeast genome that are mainly subject to silencing: those adjacent to the telomeres, regions of ribosomal DNA (rDNA), and regions of the silent mating-type loci.[179] To fulfill these functions, Sir2 is present in two different complexes.[179] The complex Sir2/Sir3/Sir4 (SIR-complex) is responsible for silencing at the telomeres, and could play an important role in the formation of heterochromatin.[180] A

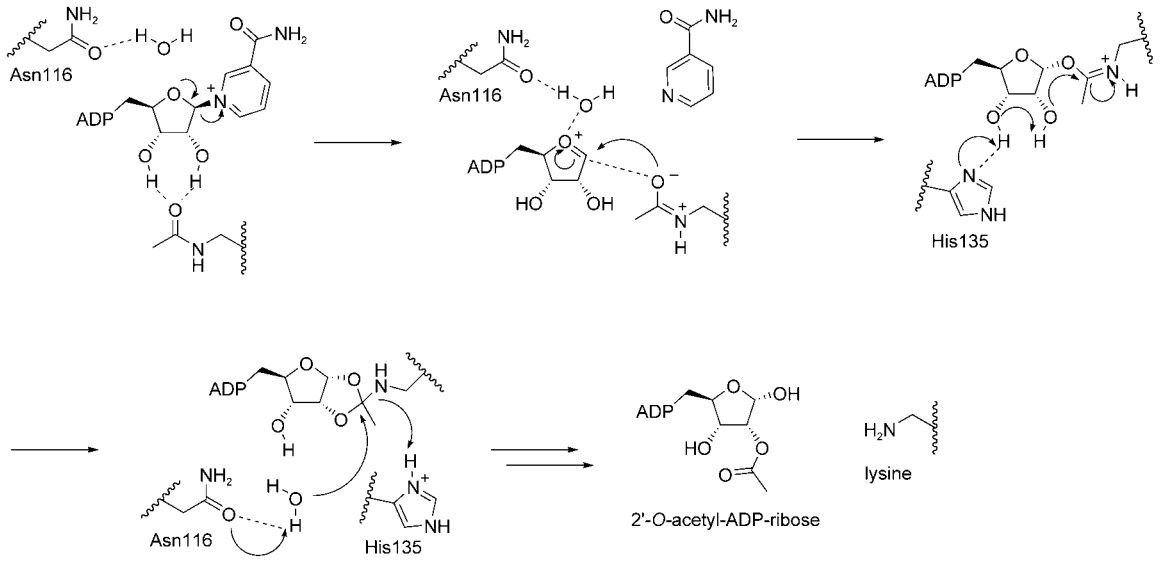

Figure 11. Catalytic mechanism of sirtuins: as the acetyl lysine substrate is precoordinated at both hydroxy functions of the ribose group, the nicotinamide unit is cleaved through the influence of a water molecule, which is coordinatively fixed at Asn116, and stabilizes the ribose oxycation intermediate. The nucleophilic attack of acetyl lysine forms a imine-analogue structure, which is trapped by a second nucleophilic attack of the 2′-OH-ribose function, mediated by His135. After hydrolysis, lysine and 2′-*O*-acetyl-ADP-ribose are released.

deletion of Sir3 or Sir4 results in truncated telomeres and misdirected mitosis, whereas the overexpression of Sir4 leads to the extension of telomeres (Figure 12).[180]

The other complex, Sir2/Net1/Cdc14, is responsible for the formation of closed chromatin structures at regions of ribosomal DNA (rDNA).[179] There are approximately 100–200 copies of genes that encode rRNA. The multiple repeats in DNA sequence enables a splicing process which forms extrachromosomal circles (ERCs), which are toxic and shorten the lifespan of a cell.[191] This effect can be demonstrated by the artificial introduction of ERCs. In contrast, lifespan can be increased by the introduction of an additional copy of Sir2, as silencing of the rDNA region represses the formation of toxic ERCs.[192] Surprisingly, in many organisms the restriction of glucose also increases lifespan.[193] An explanation for this is the direct link between Sir2 activity and the concentration of NAD^+, which reflects the metabolic state of a cell.[194] A low glucose intake leads to a decrease in metabolic activity and therefore to the oxidation of NADH to NAD^+. An increased NAD^+ concentration gives rise to enhanced Sir2 activity, and as a result, the increased silencing of rDNA represses the formation of toxic ERCs. As a control experiment in yeast has shown, a mutation in the NAD^+ biosynthetic pathway decreases lifespan, which can be reversed neither by a mutation in the glucose metabolic pathway, nor by Sir2.[194]

Small-molecule modulators of the sirtuins are absolutely required for investigations of the biological functions of these enzymes with a chemical–genetic approach. The first reported sirtuin inhibitor was a nonhydrolyzable NAD^+ analogue that is cell impermeable and of limited utility.[172] Schreiber and coworkers identified sirtinol (**25**) as an inhibitor with a central 2-hydroxy-1-naphthol unit that is necessary and sufficient for inhibition (Figure 13).[193] A recent screen of a 6000-com-

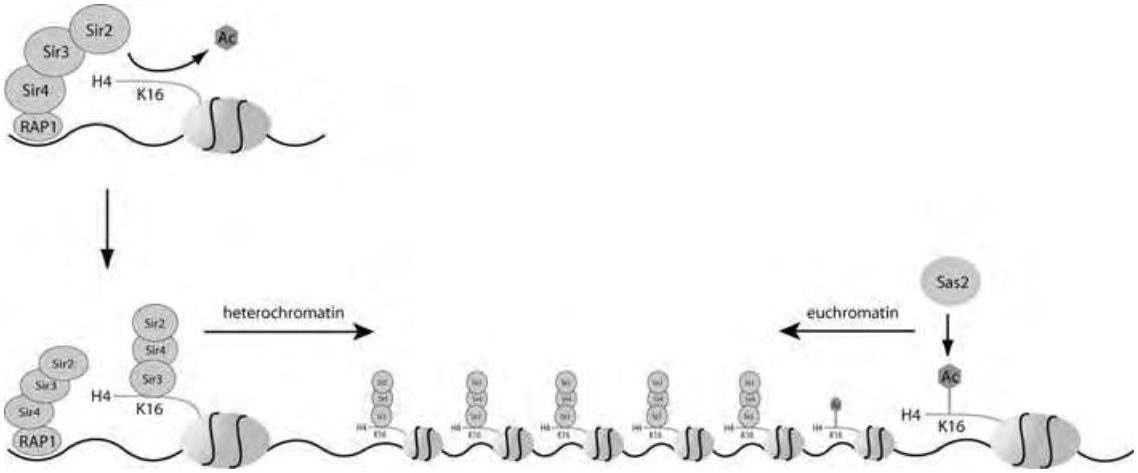

Figure 12. Sir2-mediated gene silencing at the telomeres: the DNA binding protein Rap1 recruits the HDACs Sir4, Sir3, and Sir2.[181–184] Sir2 subsequently deacetylates the closest histone H4 at K16, which creates an available site for the formation of another sirtuin complex, and the cycle can repeat again.[185–187] The spread of heterochromatin in this manner is countered by a second process mediated by the HAT Sas2, which is responsible for the active acetylation of H4-K16.[188–190] The degree of heterochromatin extension at the telomere regions is determined by the equilibrium of these opposing processes.

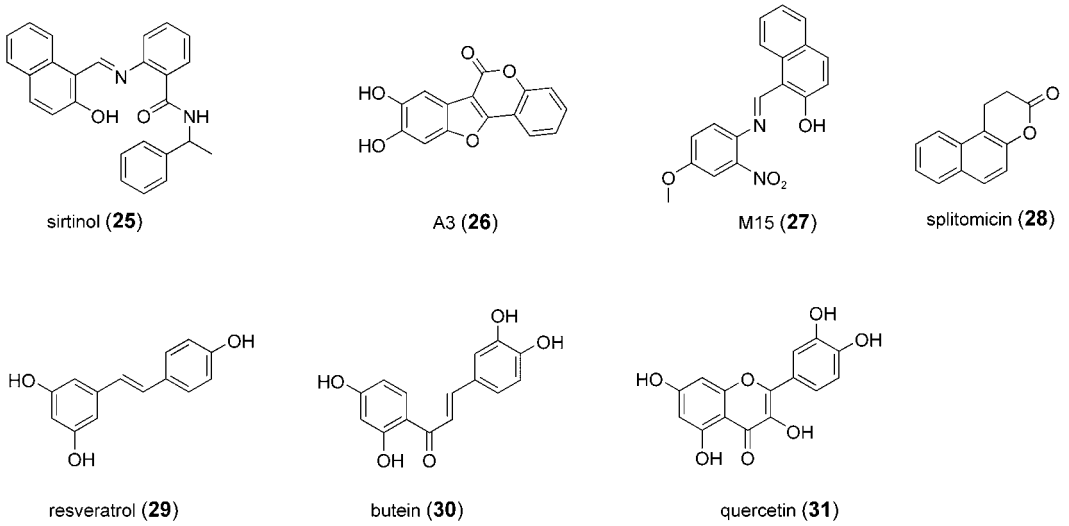

Figure 13. Modulators of sirtuins: sirtinol (**25**), A3 (**26**), M15 (**27**), and splitomicin (**28**) are sirtuin inhibitors, whereas resveratrol (**29**), butein (**30**), and the flavone derivative quercetin (**31**) are activators of these enzymes.

pound library identified splitomicin (**28**) as an inhibitor of Sir2, effective at micromolar concentrations. Splitomicin has a hydrolysis-sensitive lactone, which is crucial for biological activity.[195] Moreover, with resveratrol (3,5,4′-trihydroxy-(*E*)-stilbene, **29**) a potent stimulator of sirtuins was discovered.[196] Resveratrol is an ingredient of red wine that belongs to the group of secondary plant metabolites.[197] With the chalcone derivative butein (**30**) and the flavone derivative quercetin (**31**), other members of the family of sirtuin activating compounds (STACS) were identified, but shown to be less effective than resveratrol.

3. Histone Methylation

Although histone methylation was discovered over 30 years ago, only quite recently was it pushed into the center of scientific attention as an important part of gene regulation.[198] Since 2000, many histone methyltransferases (HMTs) have been identified, and the interactions among histone modifications have been characterized.[199,200]

Specific methylation of lysine residues is known to occur on histone H3 at K4, K9, K27, K36, K79 and on histone H4 at K20. Arginine methylation takes place within the tails of histone H3 at R2, R17, R26 and histone H4 at R3. Furthermore, the N-terminus of H1 is methylated at lysine residues[201] and the methylation of nonhistone proteins has been documented as well.[202,203]

Histone methylation is a stable epigenetic mark that does not alter the overall charge of the histone tails. However, with increasing methylation (Figure 14)[8] comes an increase in basicity, hydrophobicity, and an influence on the affinity for anionic molecules like DNA.[204,205] HMTs display remarkable specificity in the level of methylation they catalyze, and the latest findings suggest that this could have functional significance in transcription.[206]

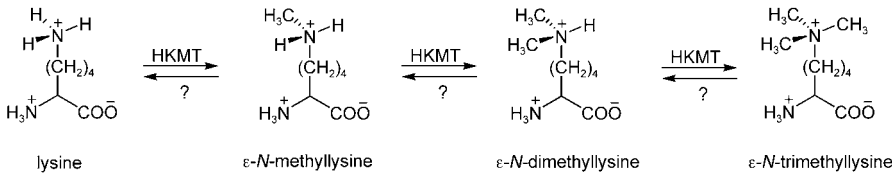

Figure 14. Structure of lysine and its methylated derivatives: HKMT = histone lysine methyltransferase; ? = unknown demethylating mechanism.

Similar to histone acetylation, histone methylation can modulate histone interaction with DNA and chromatin-associated proteins, which results in an alteration of nucleosomal structures and functions, and ultimately contributes to different biological processes.[207]

3.1. Histone Lysine Methyltransferases (HKMTs)

In 2000, SUV39 from *Drosophila* was identified as the first histone lysine methyltransferase, which is specific for H3-K9.[13] HKMTs use *S*-adenosylmethionine (SAM) as a cofactor.[207] Interestingly, the cofactor-binding region is unrelated to the classical SAM-binding folds of DNA- and arginine methyltransferases.[208]

The HKMT catalytic motif was mapped to an evolutionarily conserved, globular domain of approximately 130 amino acid residues, termed the SET domain after the three *Drosophila* genes involved in epigenetic processes (*s*u(var)3-9, *e*nhancer-of-zeste, and *t*rithorax). Cysteine-rich regions of higher sequence variation (PRE-SET- or POST-SET-domains) flank the SET domain, and are required for enzyme activity.[200,208,209] Close inspection of the SET domains has identified three specific, highly conserved amino acids (Asn241, His242, and Tyr283) that influence enzyme activity.[208,210–212] Also, mutation of Asn241 affects the binding of the SAM cofactor.[208]

To date, over 300 proteins have been identified that contain SET domains,[199] and which can be grouped into four major classes: SUV39, SET1, SET2, und RIZ-SET. Their classification is based foremost on sequence similarity between the SET domains and secondarily on their relationship to SET domains in the yeast *S. cerevisiae*.[200,213] Furthermore, each enzyme family shows other common structural features, such as bromo-, chromo-, PRE-SET- and POST-SET domains; it appears that all of them have the same substrate specificity.[200,208,209]

Only the SUV39 family possesses a PRE-SET and a chromo domain, which does not bind methylated H3-K9. However, it is possible that it recognizes other methylated lysine residues or proteins.[200] Such differences in the binding specificity of chromo domains have been observed in other proteins and it is possible that the methylation level regulates binding preferences.[214,215] The methyltransferase MLL, a SET1 family member, has a bromo domain and a methyl-binding domain (MBD).[216] Also, the SET2 family member ASH1 possesses a bromo domain and can associate with the CBP acetyltransferase, as MLL (Section 2.1).[217,218]

The members of the retinoblastoma-interacting zinc finger family (RIZ-family) are transcriptional regulators. They control differentiation, and are involved in various cancers.[200,219–222] To date, no known RIZ proteins possess methyltransferase activity.

In the meantime, X-ray crystallographic structure data are available for HKMTs such as Dim-5,[210] Clr4,[223] LSMT,[212] as well as four separate SET7/9 structures in different configurations.[211,224–226] Not all SET proteins are HKMTs, but they may represent evolutionary deactivated HKMTs.[10,209]

In 2002, the first non-SET HKMT was identified, termed Dot1. It exhibits specificity for H3-K79.[227] For this reason, HKMTs should not be classified by sequence homology, but instead on the basis of epigenetic criteria regarding their histone specificity (Table 2). At this point it is not known how different HKMTs control their catalysis of mono-, di-, and trimethylation, and in which way this varied substitution pattern correlates with transcription.[228]

[b] E(Z) methylates H3-K9 in the native complex as well.[255] [c] also known as SET 8.[253c]

3.1.1. *Histone Methylation and Gene Repression (H3-K9, H3-K27, H4-K20)*

The histone position H3-K9 seems to be of particular significance for epigenetic modification, as it is a site for both acetylation and methylation. Euchromatin or heterochromatin is formed depending on the type of modification. Also, methylation at H3-K27 and H4-K20 mediates gene repression, such as X-chromosome inactivation.

The histone binding protein HP1 (heterochromatin-associated protein 1) plays an essential role in epigenetic silencing through the formation of heterochromatin. This conserved process is based on the functional cooperation between HDACs, HKMTs and HP1 (Figure 15). After methylation of H3-K9 by SUV39, the transcriptional repressor HP1 (a product of the second *su(var)* gene, Su(var)2-5) binds through selective recognition by its chromo domain.[214,215,256] The HP1 protein possesses two highly conserved regions: the chromo- and the chromo-shadow domains.[257] With its chromo domain, HP1 recognizes and binds methylated H3-K9, whereas the chromo-shadow domain may be responsible for other protein interactions, such as that with SUV39.[256–259] More H3-K9 methylation events are caused by this interaction, and HP1 mediates the propagation of heterochromatin by spreading over wide chromosomal ranges.[260]

It has been shown in yeast as well, that the recruitment of HP1 to centromeric heterochromatin by the SUV39 homologue Clr4 is necessary for transcriptional silencing.[215,240c] Until now, it has not been known how HP1 generates highly compact chromatin structures and functions as a transcriptional repressor.[10,261] One possible mechanism for the propagation of heterochromatin is the dimerization of HP1 through chromo-shadow domain interactions.[207]

Several reports have shown that the methylation of H3-K9 and H3-K27 correlates with X-chromosome inactivation (Xi).[262–266] In this process, the recruitment of HP1 does not occur. It seems that Xi is established by an RNA-dependent process in which an Ezh2 complex is recruited for subsequent methylation of H3-K9 and H3-K27.[247a,255,266–272] However, the significance of histone methylation and Xi awaits clarification. Likewise, RNA is also involved in the propagation of heterochromatin. It could create binding sites for HMTs, or mediate the formation of higher order chromatin structures.[273,274] The acetylation of H3-K9 and H3-K14, as well as the phosphorylation of H3-S10 generally prevent the formation of heterochromatin (Section 1.1).[13,240c,275]

As mentioned above, the specific methylation of H3 creates docking sites for repressor proteins, which ultimately recruit a core repressor complex. However, the process that dictates specific gene repression by HKMTs, including the methylation of H3-K9, H3-K27, and H4-K20, is not as well-characterized. For example, the polycomb (PC) protein binds specifically to methylated H3-K27 with its chromo domain. This results in the specific formation of an active polycomb repressor complex.[247a,255,269,276–278]

Another example of transcriptional repression at euchromatic regions is the retinoblastoma (Rb) protein, which recruits the repressive SUV39/HP1 complex to the genes that control the cell cycle like cyclin E (Figure 16).[259,279,280] Cyclin E is necessary for regulation of the G1/S-phase transition in the cell cycle. Downregulation of Rb leads to cell proliferation and may be involved in tumor growth.[281]

In this case, Rb is recruited to promoters through its interaction with the cell-cycle regulatory, DNA-specific-binding protein E2F.[282,283] SUV39 subsequently binds, the appropriate H3 tails are methylated, and HP1 is localized to these specific promoters. In this manner, HP1 mediates the repression of transcription without the formation of heterochromatin.

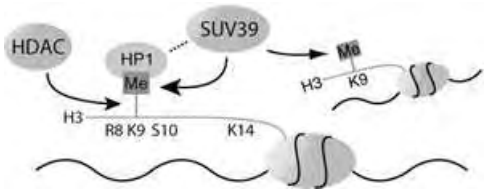

Figure 15. Gene silencing through histone methylation: deacetylation at H3-K9 by specific HDACs is necessary for subsequent methylation by HKMT activity, such as that of SUV39. HP1 selectively recognizes methylated H3-K9. The propagation of heterochromatin and gene repression is mediated by HP1 recruitment of SUV39 and additional H3-K9 methylation.

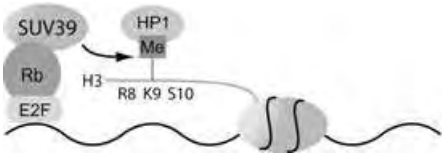

Figure 16. Histone methylation and transcriptional repression: E2F/Rb localize the histone lysine methyltransferase SUV39 at specific promoter sequences, and HP1 initiates transcriptional repression at euchromatin.

Mutation of the Rb protein disrupts the association of Rb and SUV39, the cyclin E promoter is undermethylated at H3-K9, and as a result, HP1 is not associated with the cyclin E promoter.[259] These results highlight the fact that specific methylation at H3-K9 around certain promoter regions occurs through the mediation of repressor proteins like Rb. This process is probably HDAC-dependent for deacetylation of H3-K9 prior to its methylation.[13,237b,284]

Also unclear is the role of HP1. If SUV39 is necessary for the repression of cyclin E and other Rb-regulated genes like dihydrofolate reductase (DHFR) promoters, HP1 binding is assumed to be the repressive event.[242,279] One possible mechanism could be that HP1 recruits other regulators to the promoter to mediate silencing; indeed, HP1 has been shown to associate with deacetylases and ATPases.[257] Alternatively, HP1 may protect methylated H3-K9 sites from catabolism by a demethylase activity that has yet to be characterized. If HP1 is involved in silencing of cyclin E, then its association with the promoter would have to be transient, as cyclin E is activated during S-phase. This association may be controlled by phosphorylation events, as HP1 is known to be highly phosphorylated.[258] However, the phosphorylation of Rb may disrupt the association with SUV39, so that other kinases may be involved.[279] As a result of phosphorylation, E2F is released and transcription is activated.[285] HP1 is not only involved in the regulation of Rb-dependent genes, but also associates with several transcriptional regulators,[257] such as the Ikaros protein[286,287] and the KRAB-associated protein 1 (KAP1).[288–290]

Another histone methylation that correlates with transcriptional repression is the methylation of H4-K20. In *Drosophila* this specific methylation is carried out by the HKMT PRSet7, and corresponds to condensed chromosomal regions.[253a,b,291] Furthermore, studies in vitro and in vivo have shown that methylation at H4-K20 inhibits the acetylation of H4-K16, which is a mark for the hyperactive male X chromosome in *Drosophila*,[292] and transcriptionally active chromatin in human cells.[293] Further investigations are necessary, as H4-K20 can be present in mono-, di-, and trimethylated states.[294]

3.1.2. Histone and DNA Methylation

The aberrant DNA methylation of promoter regions seems to be contribute substantially to tumorigenesis.[295–299] This could result from methylation errors that occur during DNA replication, de novo DNA methylation events, and faulty DNA-repair processes.[300] Enzymatic DNA methylation at the C5 position of cytosine residues leads directly to gene silencing, yet the fundamentals of this process remain unknown.

A recent observation in the fungus *Neurospora crassa* led to the discovery that DNA methylation is dependent on specific histone methylation events,[301,302] and a similar finding was also reported in *Arabidopsis thaliana*.[303] In *N. crassa* a methyltransferase specific for H3-K9 (Dim-5) was identified, and determined to be necessary for DNA methylation and gene silencing.[241a]

SUV39 and G9a were also reported in to be in connection with DNA methylation.[304–307] Furthermore, it is known that DNA methyltransferases (DNMTs) can associate with HP1 homologues.[303,308–310] In an initial stage, Dim-5 trimethylates[311] H3-K9, and HP1 binds through its chromo domain. Next, HP1 recruits additional DNMTs[312,313] to chromatin which methylate DNA. It was shown recently that trimethylated H3-K9[311] and HP1[314] are essential for DNA methylation in *N. crassa*. HP1 may act as an adapter between histone and DNA methylation.

A further phase in these gene-silencing processes involves the recruitment of methyl-binding proteins (MBPs), which contain an MBD domain that recognizes methylated DNA. Like MeCP2, MBPs subsequently recruit HDACs, which deacetylate lysine tails and make the substrate accessible for further methylation events (Section 2.2.1).[315–318] Recently it has been shown both in vitro and in vivo that MeCP2 is able to not only recruit HDACs, but also a histone methyltransferase, which is specific for methylation of H3-K9.[319] The identity of this recruited HKMT is not yet known, but MBP also interacts with the Suv39h1-HP1 complex.[320] Mutations in the gene sequences that code for MeCP2 lead to Rett syndrome, which is characterized by mental disabilities in young girls.[321–323] It is remarkable that such mutations do not cause a global gene derepression; the effect is limited to neuronal genes which explains the corresponding pathology.[324,325]

Furthermore, there are reports of methyltransferases that possess MBD domains for the recognition of methylated DNA, such as the human SETDB1 and its murine homologue ESET.[315] Likewise, SETDB1 is involved in H3-K9 methylation during DNA replication.[326] A new HKMT, SMYD3 has been identified, which recognizes and binds specific DNA sequences.[327] Surprisingly, DNMTs are able to associate in vitro and in vivo with H3-K9-specific HKMTs, such as Suv39h1. As a result, further histone methylations are possible.[308] These continual cycles of histone and DNA methylation lead to gene silencing (Figure 17).[200]

Interestingly, this connection between the methylation of DNA and that of H3-K9 has not been observed in other species, such as *S. cerevisiae*.[10,328] This implies that the connection between histone methylation and that of DNA may not apply to all organisms. In the fruit fly *Drosophila*

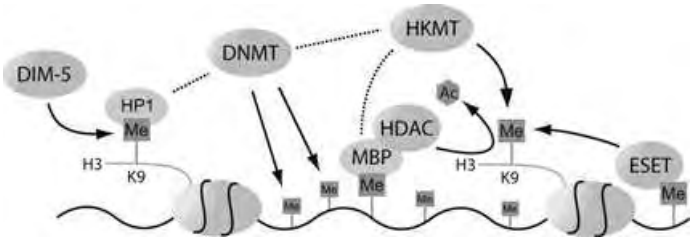

Figure 17. The complex interplay of histone and DNA methylation: after binding of HP1 at methylated H3-K9, DNA methyltransferases (DNMTs) are recruited, which subsequently methylate DNA. MBP proteins recognize this DNA methylation und recruit HDACs, which deacetylate additional histones for subsequent methylation by HKMTs equipped with methyl-binding domains, like ESET. Recent results show that MBP proteins and DNMTs are able to recruit histone-lysine methyltransferases.

melanogaster and in the yeast *Schizosaccharomyces pombe*, regions of DNA methylation have not been observed, yet these organisms do have signaling pathways that operate through histone methylation.[240] In such cases, gene silencing is associated with histone deacetylation, histone methylation, and the binding of repressor proteins, such as HP1.[214,215,240,258]

The combination of enhanced histone and DNA methylation may also occur to silence one of the two copies of the X chromosome in female mammals.[301]

Inhibitors of DNA methylation rapidly reactivate the expression of genes that have undergone epigenetic silencing, particularly if this silencing has occurred in a pathological situation. The DNA methylation inhibitors 5-azacytidine[329] (5-aza-CR, **32**), and 5-aza-2′-deoxycytidine[330] (5-aza-CdR, **33**) induce gene expression and differentiation in cultured cells.[331,332] However, a disadvantage of these azanucleosides is their instability in aqueous solution. In addition, they are toxic and not orally active. For this reason, more potent analogues 5-fluoro-2′-deoxycytidine[333] (FCDR, **34**) and zebularine[334] (**35**) were developed (Figure 18).[335]

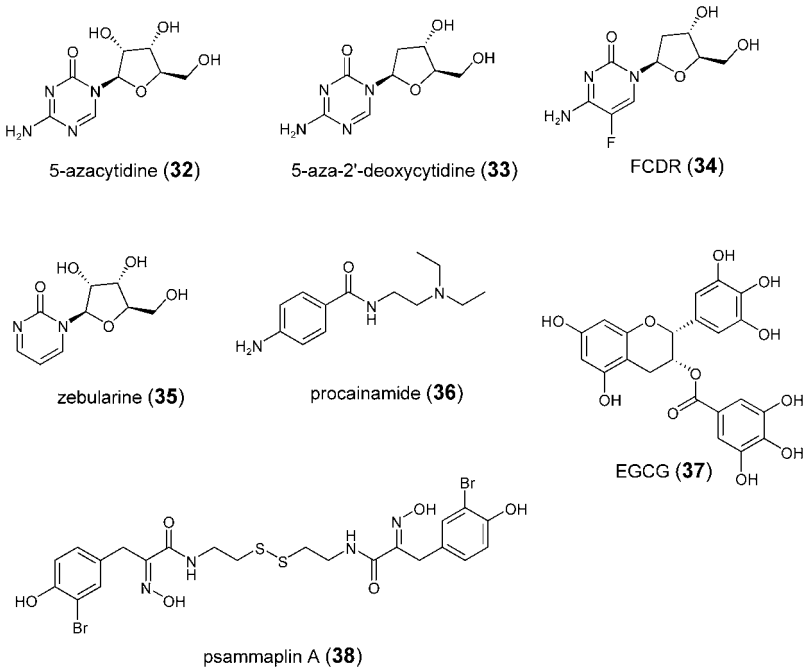

Figure 18. Structures of DNA methylation inhibitors: 5-azacytidine (5-aza-CR, **32**); 5-aza-2′-deoxycytidine (5-aza-CdR, **33**); 5-fluoro-2′-deoxycytidine (FCDR, **34**); zebularine (**35**); procainamide[336] (**36**); epigallocatechin[337] (EGCG, **37**); und psammaplin A[338] (**38**).

The fact that epigenetic silencing is almost universally associated with histone deacetylation resulted in the development of combination therapies, in which inhibitors of both HDAC and DNA methylation are present; this shows remarkable success against tumor cells.[339–343] A recent study with mice demonstrated a strong synergy between 5-aza-CdR (**33**) and the HDAC inhibitor, phenyl butyrate (**15**; Figure 8).[344] Combination preparations of **33** and HDAC inhibitors are now in clinical trials (Section 2.2.1).[16]

3.1.3. Histone Methylation and Activated Transcription (H3-K4, H3-K36, H3-K79)

Transcriptionally active euchromatin is methylated at three positions: H3-K4, H3-K36, and H3-K79. Furthermore, the methylation level at H3-K4 appears to play an important role.[199] Methylation of H3-K4 by Set7/9 impairs the Suv39h1-mediated methylation of H3-K9, and thereby the formation of heterochromatin is hindered (Figure 19).[232b] Moreover, the binding of the histone deacetylase repression complex NuRD (Section 2.2.1) to H3 is precluded by methylation at H3-K4.[345] Dimethylation at H3-K4 may serve as a global epigenetic mark in euchromatin and mediates these general mechanisms, whereas trimethylation at H3-K4 correlates with activated transcription.[228,346] Interestingly, SET7/9 catalyzes only the monomethylation of H3-K4[224,225] and ySet1 mediates only the di- and trimethylations.[228] Methylations at H3-K4 are correlated with euchromatin and activated transcription.[347,348] This is additionally supported by acetylation at H3-K9. Furthermore, the methylation of H3-K4 is highly conserved evolutionarily; methylation of H3-K4 in heterochromatin has not yet been observed.[349,350]

Similarly, Dot1-mediated methylation of H3-K79 can block the development of heterochromatin,[250] a process in which sirtuins are involved (Section 2.2.2).[227,252] On the other hand, sirtuin binding impairs Dot1-mediated methylation of H3-K79.[250,252]

The synthesis of mRNA in eukaryotic organisms is a highly regulated key biological process. Various studies have shown that histone methylation at H3-K4, H3-K36, and H3-K79 by specific HKMTs is functionally linked to RNA polymerase II (RNAP II) and transcriptional elongation.[351–355]

It seems clear that methylation of H3-K4 and H3-K9 corresponds to different biological events. However, there are forms of HKMT, such as a truncated version of the *Drosophila* Ash1 HKMT, which methylate both H3-K4 and H3-K9.[231a,232a] This particular type of dual modification may result in the induction of genes which are normally repressed.[199] More investigations are nec-

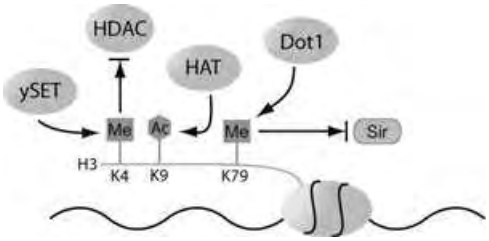

Figure 19. Histone methylation and activated transcription: both H3-K4 methylation and H3-K9 acetylation result in activated transcription. Methylation at H3-K79 by Dot1 also blocks Sir-mediated silencing.

essary for a clearer explanation of this unusual methylation pattern.

3.2. Histone Arginine Methyltransferases (HRMTs)

Methylation of arginine groups occurs on histone H3 at R2, R17, R26 and on H4 at R3. The arginine guanidino function can be either mono- or dimethylated (Figure 20). For this, HRMTs are grouped into two major enzyme classes.

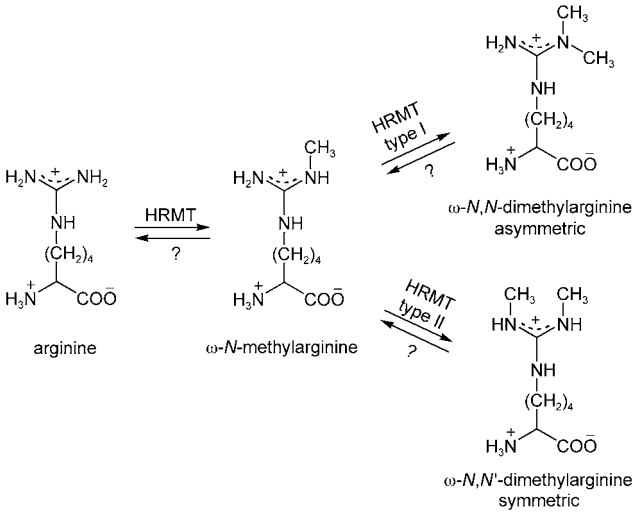

Figure 20. The structure of arginine and its methylated derivatives: HRMT = histone arginine methyltransferase; ? = unknown demethylating mechanism.

Type I enzymes catalyze the formation of symmetric ω-N^G,$N^{G'}$-dimethylarginine tails, whereas the type II enzymes catalyze the formation of asymmetric ω-N^G,N^G-dimethylarginine tails.

At this point, seven mammalian protein arginine methyltransferases (PRMTs) have been identified, and all of them share a highly conserved catalytic domain (Table 3). Nine *Drosophila* arginine methyltransferases (DARTs) have been identified in that organism.

Table 3: Known histone arginine methyltransferases (HRMTs).[200] [a]

HRMT[b]	specificity	type of methylation
PRMT1[363–365]	H4-R3	asymmetric
PRMT4/CARM1[366,367]	H3-R2, H3-R17, H3-R26	asymmetric
PRMT5/JBP1[368,369]	H2A, H4	symmetric

[a] PRMT2 is not identified as an enzyme;[8,356] PRMT3,[357–359] 6,[360] and 7[361,362] are not known as HRMTs. [b] PRMT = protein arginine N-methyltransferase; CARM = coactivator-associated arginine methyltransferase; JBP = Janus kinase-binding protein.

In contrast to histone lysine methyltransferases, PRMTs bear few domains beside the catalytic domain. PRMT3 possesses a zinc-finger structure and PRMT2 has a SH3 domain, which may be responsible for substrate specificity.[200] Nonhistone proteins are also methylated at arginine residues,[356] and are involved in signal transduction,[370–373] mRNA splicing,[374,375] RNA transport[376–378] and mediate protein–protein interactions.[379]

Furthermore, methylation of an arginine residue of the HAT CBP/p300 by PRMT4/CARM1 has been identified in vivo. This event blocks the association of CBP/p300 with the CREB transcription factor and therefore influences transcriptional regulation (Section 2.1.1).[109]

The arginine methyltransferase CARM1/PRMT4 specifically methylates H3-R2, H3-R17 and H3-R26 in vitro, and is a coactivator of nuclear receptors.[366,367,380] PRMT1 methylates H4-R3 in vivo,[364,381] yet the corresponding target promoters have not yet been identified. PRMT5 has a preference for H2A and H4 in vitro, but the region of methylation remains unknown.[200] Furthermore, methylation at H4-R3 enhances the subsequent acetylation of H4.[381] Both arginine methylation and histone acetylation are histone modifications that give rise to transcriptional activation.

In 2004, the first arginine methyltransferase inhibitor, AMI-1 (**39**), was identified that does not influence histone lysine methylation (Figure 21).[382] Moreover, AMI-1 is cell-

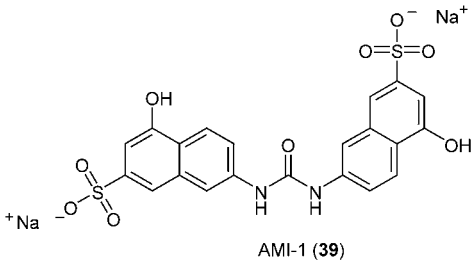

Figure 21. Structure of the specific PRMT inhibitor AMI-1 (**39**).

permeable and appears to interact with the HRMT substrate binding site. Recently, AMI-1 was described as a selective HIV-1 reverse transcriptase inhibitor; this study also demonstrated that this compound is not cytotoxic.[383] In this context, eight more inhibitors and two activators of PRMTs were identified. However, their selectivities against PRMT isoforms are varied.[382]

3.3. Histone Demethylation

As repressive histone methylation occurs at both heterochromatin and euchromatin, the stability of this modification comes into question. Under thermodynamic conditions, methylation is much more stable than acetylation or phosphorylation. The latter two are cleavable by HDACs and phosphatases (PPs) and are thus reversible. Active histone demethylases (HDMases) are as yet unknown. In 2002, a HAT was identified whose N-terminal domain has sequence similarity to an enzyme superfamily in which SAM is used as a cofactor in radical reactions. Based on this similarity, a radical-dependent demethylating activity was postulated.[384] Indeed, demethylases with nonhistone substrates have been

identified.[385–387] Such enzyme activity results in the production of formaldehyde. Thus, the demethylation process probably occurs through an oxidative mechanism.[388]

Repeated cycles of DNA replication may effectively dilute histone methylation.[10,207] An alternative mechanism for decreasing methylation density is through the replacement of methylated histones with unmodified forms, such as histone variants.[389] Another potential demethylating event is the proteolytic cleavage of histone N-termini, which has been observed in *Tetrahymena*.[10,201] Ubiquitinylation could also take part in histone demethylation.[10,390]

Recently, a demethylating mechanism for arginine groups in histones was described. The peptidylarginine deiminase 4 (PAD4/PADI4)[391] can catalyze the conversion of both mono- and unmethylated arginine groups to citrulline in vitro and in vivo. Dimethylated histone arginine residues are not substrates of PAD4/PADI4 and are therefore not demethylated. Whether citrulline-modified histones elicit any effect on chromatin structure, or if they are recognized and bound by other proteins are questions that should be explored.[392–394] However, a specific demethylating mechanism has yet to be identified, and thus continued research in this area is necessary.

4. Histone Phosphorylation

Histone phosphorylation was initially reported in the 1960s.[395] Since that time, phosphorylation has been shown to occur on all histones. Important phosphorylation sites such as H3-S10 and H3-S28 were identified to be involved in cell-cycle processes during mitosis[396,397] and meiosis, as well as in transcriptional gene activation during interphase, although these fundamental cell-cycle processes elicit opposite effects toward the structure of chromatin. Furthermore, all phosphorylated serine residues are located within the highly conserved amino acid sequence, Ala-Arg-Lys-Ser (ARKS).[398]

4.1. H3 Phosphorylation in Mitosis and Meiosis

Phosphorylation at H3-S10 is involved in chromosomal condensation and cell division during mitosis and meiosis.[6,397] H3-S28[399] and H3-T11[400] have also been identified as mitosis-specific phosphorylation sites. It remains unknown whether these modifications are causally linked. Histone phosphorylation is also necessary for chromosome condensation in mammals[401] and in *T. thermophila*.[396]

Phosphorylation of H3-S10 begins during the late G2/M-phase transition at pericentric heterochromatin and spreads throughout the genome until late prophase.[402,403] Ultimately this is followed by general dephosphorylation during the progression through cell division to telophase.[397]

Mitotic phosphorylation at H3-S10 is mediated by members of the aurora kinase family, such as Ipl1 kinase in yeast and nematodes,[404] aurora B in *Drosophila*,[405] and aurora B (and A) in mammals.[406] The aurora B kinases are also involved in mitotic phosphorylation at H3-S28[407] and are regarded as the true H3-S10 kinases, as their subcellular localization[408] seems better suited than that of aurora A, which is a centromeric protein.[409] These kinases are also thought to be required for the proper recruitment of the condensin complex and assembly of the mitotic spindle.[405]

The balance of the phosphorylation level, as well as the exact chromosomal condensation during cell division is mediated by type 1 phosphatases (PP1).[404,410–412] A set of data indicate that phosphorylation of H3 is not essential during mitosis/meiosis,[413–416] and the role of this is increasingly under controversy.[417] It is possible that H3 phosphorylation is not directly involved in chromosome condensation, but instead plays an indirect role in the complex mechanisms of chromosomal rearrangement.[417]

4.2. H3 Phosphorylation during Transcription

In mammals, histone phosphorylation is involved in the transcriptional activation of immediate early-response genes, such as *c-fos*, *c-myc*, and *c-jun* during interphase.[417–420] These genes are directly linked to signaling cascades, without a requirement for the biosynthesis of new proteins.[398] This stimulus-dependent H3 phosphorylation is fast, transient, and concerns only a particular group of genes. In addition, these phosphorylated H3 histones are susceptible to hyperacetylation,[421] which links both modifications during the activation of transcription through a MAP kinase signaling cascade.[422–424] Therefore, this cascade not only phosphorylates transcription factors and coactivators, but histones as well.[425] However, other signaling cascades are present which may be involved in the activation of immediate early-response genes, like the Janus kinase/signal transducer and activator of transcription (JAK/STAT)[426] or the nuclear factor κB (NF-κB).[427] Studies with relatively specific MAP kinase inhibitors and other inhibitors have shown that in mammals, H3 phosphorylation is mediated by the ERK or p38 MAP kinase pathways, depending on the nature of the stimulus, but is not mediated through the JNK/SAPK pathway.[423,424,428,429]

Although these two signaling pathways are involved in phosphorylation, histone phosphorylation is effected by downstream kinases and not by MAP kinases themselves. In this case, kinases of the RSK[430–432] and MSK families[428,433,434] may be activated,[398] yet it appears that the latter family represents those designated for H3 phosphorylation.[398,434,435] MSK1/2 are localized in the nucleus and are activated by both the ERK and the p38 MAP kinase pathways (Figure 22).[436] Furthermore, studies in vitro have shown that MSK1 phosphorylates H3 with a much higher efficiency than RSK1/2.[398] Mutations in RSK2 are found in the human genetic disease known as the Coffin–Lowry syndrome, which has the same clinical symptoms as Rubinstein–Taybi syndrome (Section 2.1).[437,438] Other histone kinases linked to transcription have been identified, such as Snf1,[12] PKB/Akt,[439,440] and IKB kinase-α (IKK-α).[441,442]

The stimulation-dependent phosphorylation of H3-S28 by a MAP kinase has been described.[434,443,444] However, a direct link between phosphorylation at H3-S28 and activated tran-

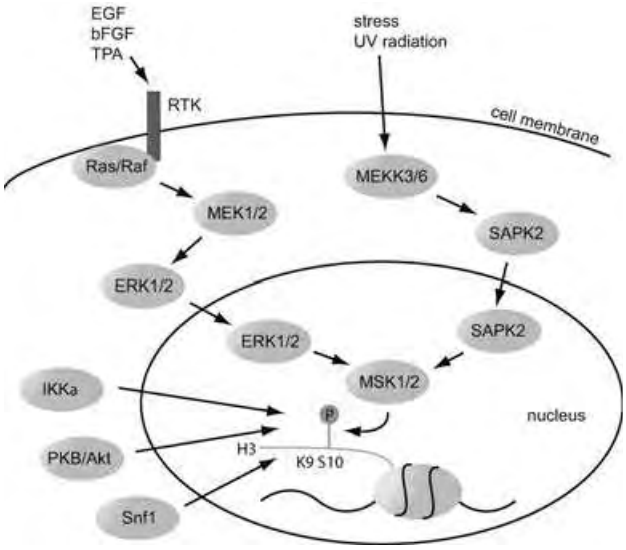

Figure 22. Signaling pathways that lead to H3-S10 phosphorylation and gene expression: activation of the MAP-kinase cascade or the p38 cascade by mitogens, growth factors, stress, or UV irradiation leads to the activation of MSK1/2 kinases, which phosphorylate H3-S10 and result in the activation of genes, such as *c-fos* and *c-jun*. The activation of IKK-α, PKB/Akt and Snf1 is also possible with subsequent H3-S10 phosphorylation. EGF = epidermal growth factor; ERK = extracellular signal-regulated kinase; FGF = fibroblast growth factor; IKKα = IKB Kinase-α; MEK = mitogen-activated protein kinase; MEKK = mitogen-activated protein kinase/ERK kinase kinase; MSK = mitogen- and stress-response kinase; PKB = protein kinase B; Raf = ras-activated factor; RAS = rat sarcoma; RKT = receptor tyrosine kinase; SAPK = stress-activated protein kinase; Snf1 = sucrose non-fermented 1; TPA = 12-*O*-tetradecanoylphorbol-13-acetate.

scription has not yet been established. [398] The H3-S10 residue is located in a region of the protein that is also subject to other modifications. For example, H3-K9 and H3-K14 can be acetylated, which normally correlates with active transcription. On the other hand, methylation at H3-K9 leads to the formation of heterochromatin and gene silencing. Experiments performed in vitro and in vivo support this conclusion of such a mutual interaction (Section 1.1).[445]

4.3. Phosphorylation and Acetylation

Phosphorylation and acetylation of histones are both linked to the activation of transcription. Antibody-based experiments have shown that the dually modified H3 isoform is present in vivo.[275,446] Precisely what role this functional interrelationship of these two modifications plays remains unclear; two models have been proposed: the synergistic model and the parallel-independent model.

4.3.1. Synergistic Model

Experiments conducted in vitro reveal that the HAT yGcn5 shows a preference for binding to phosphorylated H3-S10.[275,446,447] The crystal structure data of Gcn5 from yeast[447] and *Tetrahymena*[96] has allowed the identification of essential amino acid interactions. The yeast version (yGcn5) has a six- to tenfold higher substrate specificity for H3-S10.[275,447] This enhanced substrate specificity is the result of a higher K_M value and a k_{cat} value that is relatively unchanged, which shows that phosphorylation at H3-S10 enhances the binding affinity of yGcn5 rather than its catalytic turnover.

Promoters of MAP-kinase-activated genes, such as *c-fos*, are populated by acetylated and phosphorylated H3 histones.[275] Together, both modifications elicit a synergistic effect in which the MAP signaling pathway leads to phosphorylation at H3-S10. This phosphorylated serine group is then preferentially bound by Gcn5, which acetylates H3-K14 and induces transcriptional activation (Figure 23).[447]

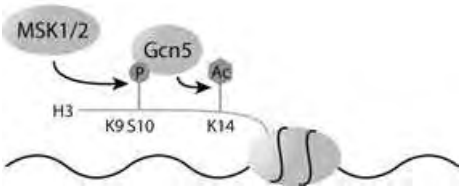

Figure 23. Synergistic model: MSK1/2 phosphorylates H3-S10, which increases the binding affinity for Gcn5. Once bound, the HAT activity of Gcn5 results in the acetylation of H3-K14, which activates transcription.

In contrast, chromatin immunoprecipitation (ChIP) assays for several yeast promoters have shown that Gcn5 acetylates all available sites of H3, except K14.[448] Furthermore, Gcn5 in the native SAGA complex (Section 2.1) exhibits preference for H3 neither in its phosphorylated nor nonphosphorylated states.[449] A possible explanation for this difference could be that the subunits of SAGA mediate binding.

4.3.2 Parallel-Independent Model

The stimulation of mouse fibroblasts with EGF leads to phosphorylation and acetylation of H3. However, both modifications occur independently of each other.[446] This shows that phosphorylation at H3-S10 is not an inevitable signal for a subsequent acetylation at K14. Analysis of the induction of *c-jun* genes supports this finding.[450] MAP-kinase-dependent phosphorylation at H3 was also identified in active, previously acetylated regions of gene expression. Acetylation is a dynamic process that is kept in balance by the action of HATs and HDACs (Figure 24).[450]

Phosphorylation of H3 is dramatically decreased by mutations in MSK kinases or by the inhibition of MSK1/2, whereas histone acetylation in these gene regions remains relatively unaffected.[434,451,452] This supports the model that in some cases the presence of a modification is not required for additional histone modifications.

The genome-wide distribution of histone H3-K14 acetylation and H3-S10 phosphorylation during the heat shock response were examined in *Drosophila*.[453] Thermal stress leads to the global inactivation of transcription and to the induction of genes that are involved in heat shock.[454,455] These results suggest that the genomic distribution of acetylation on histones H3 and H4 remains more or less

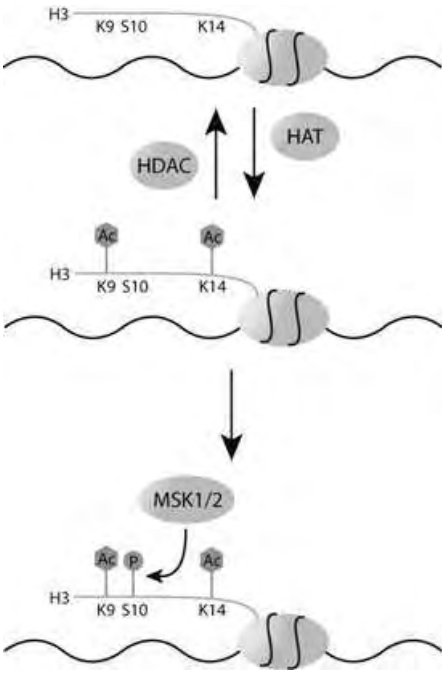

Figure 24. Parallel-independent model: acetylation at H3-K9 and H3-K14 is maintained by an equilibrium established by the activities of HATs and HDACs. MSK1/2 phosphorylates a previously acetylated histone H3 tail at K9 and K14. This results in activated transcription.

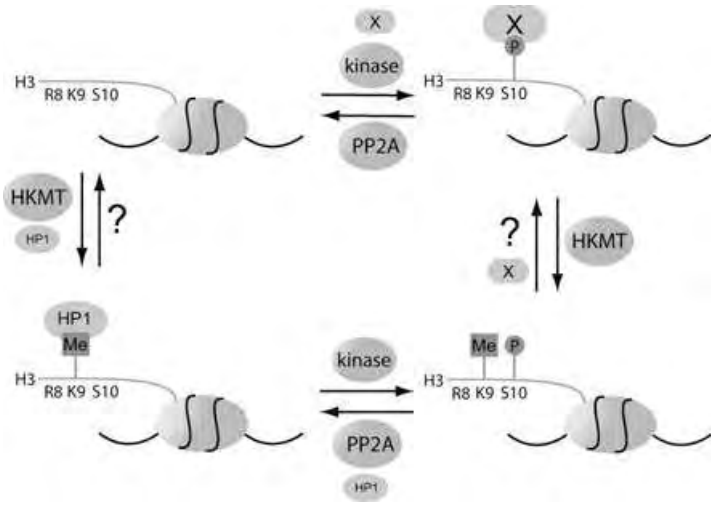

Figure 25. Binary switch hypothesis: posttranslational modification of histones results in the recruitment of effector proteins, like HP1 and X. Additional modifications in close proximity to an existing modification, such as HKMT-directed methylation at H3-K9, leads to loss of the effector protein and the associated biological effect. ? = unknown demethylating mechanism, PP2A = protein phosphatase type 2, X = postulated phosphorylation binding protein.

static. However, the distribution of histone phosphorylation changes dramatically and is only detected at those regions that contain actively transcribed heat shock genes. The kinase responsible has not yet been identified, but a possible candidate is Jil-1, a new tandem kinase with some similarity to members of the human MSK kinase family.[456–458]

The results show that in *Drosophila*, histone phosphorylation is intimately linked to transcriptional activation and the presence of acetylated histones may not necessarily denote regions of actively transcribed genes.[459]

4.4. Phosphorylation and Methylation

How are cells able to change a repressive modification, such as the methylation of H3-K9, to reach an activated state of transcription? The binary switch hypothesis is based on the observation that most repressive methylation events at H3 are adjacent to serine or threonine residues.[445] This concept postulates that phosphorylation blocks the binding of repressive proteins that normally recognize histone methylation. This is supported through the coexistence of methylation and phosphorylation in HeLa cells.[445] The phosphorylation at H3-S10 blocks the kinetically controlled binding of HP1 at H3-K9[260,460] and allows other enzymes, like HATs, to acetylate other sites to override the repressed state. In addition, the repressed state is quickly recovered by dynamic dephosphorylation (Figure 25). Another possibility is that phosphorylation creates binding sites for several enzymes, such as demethylases that have not yet been identified, which demethylate H3-K9. Subsequent acetylation at this position would then be possible. However, all these proposals remain hypothetical and must be demonstrated experimentally.

If this concept is correct, other combinations of modifications, such as acetylation/phosphorylation and ubiquitinylation/phosphorylation, could extend the potential pattern of the histone code.

4.5. Histone Dephosphorylation

The presence of kinase–phosphatase pairs that maintain proper phosphorylation levels during mitosis leads to the proposal that similar mechanisms are also present in the processes of transcriptional activation and inactivation. After heat shock in *Drosophila*, the transcriptional activation of heat shock genes is accompanied by the de-novo phosphorylation of H3-S10, whereas this modification disappears from the rest of the genome. Treatment of cells with phosphatase type 2 (PP2A) inhibitors, or mutations in genes that code for PP2A decrease the dephoshorylation of H3. This demonstrates that gene expression during heat shock depends on the phosphorylation level of H3, which may be regulated through changes in PP2A activity.[461]

5. Histone Ubiquitinylation

Ubiquitin (Ub) is a highly conserved protein of 76 amino acids. Its name reflects the broad presence of Ub in all eukaryotic cells.[462] The covalent attachment of Ub to other proteins was observed 30 years ago with histones.[463] The exact purpose of this modification is still under investigation. In most cases, ubiquitinylation serves as a mark for the proteolytic, ATP-dependent degradation of proteins by the

proteasome.[464] In this process, several Ub units are transferred to the target protein by a succession of three enzymatic steps.[465] Through ATP hydrolysis, the ubiquitin-activating enzyme E1 binds the C-terminus of Ub as a reactive thioester and subsequently catalyzes the transfer of the activated Ub protein to the ubiquitin-conjugating enzyme E2 in a transesterification reaction. The ubiquitin ligase E3 next transfers the Ub group from E2 to the ε-amino function of a lysine residue in the target protein to generate a new isopeptide bond. At position 48, Ub itself possess an internal lysine residue with which the catalytic bond-forming cascade is repeated, and several Ub units can be bound as a chain at the target protein.[466]

There are many hints that ubiquitinylation is more than a simple mark for the degradation of useless or defective proteins. Like phosphorylation, it serves as a signal for various cellular processes[467,468] and plays an important role in cell-cycle regulation, transcription, signal transduction, DNA repair, endocytosis, apoptosis, and the immune response.[468] In 2004, Chiechanover, Hershko, and Rose received the Nobel prize in chemistry for their fundamental contributions to ubiquitinylation research.

The histone protein H2B is monoubiquitinylated at the highly conserved Lys123 residue in the C-terminal region.[469,470] This particular modification is not linked to proteasome-directed degradation; instead, it is most likely an additional letter in the alphabet of the histone code.[471] The attachment of the Ub moiety follows the aforementioned enzymatic cascade: the ubiquitin-conjugating enzyme E2 was identified as Rad6 and Ubc2,[472] whereas Bre1 was found to serve as the Ub ligase E3.[473–476] Additionally, the so-called PAF complex is also associated with H2B ubiquitinylation.[477] Rad6 (E2) is recruited to a specific promoter region by Bre1 (E3), whereas the PAF complex regulates the activity of Rad6 during the monoubiquitinylation of H2B.[478]

Although the information coded through histone ubiquitinylation is not yet fully understood, it is clear that this modification is equally as important as the other letters of the histone code. Like acetylation, ubiquitinylation is a dynamic process,[479–482] and 17 different Ub hydrolases (UBPs) have been identified in yeast.[483] Furthermore, Ubp8 represents a stoichiometric subunit of the SAGA complex[484] and this is one of the reasons for describing this enzyme in the context of other histone-modifying enzymes.

Recently, it was demonstrated that ubiquitinylation of H2B influences the methylation of H3: deletion of the *rad6* gene or an appropriate mutation in the H2B ubiquitinylation sequence prevents methylation of H3-K4 and H3-K79, which is normally catalyzed by Set1 and Dot1.[227,229a,b,252,388,485–488] The ubiquitinylated histone could be bound by HMTs with a special ubiquitin-interacting domain,[489–491] which has been identified in numerous other factors. Furthermore, PAF is not only necessary for H2B ubiquitinylation, but is also decisive for the methylation at H3-K4 and H3-K79.[352] Methylation at lysine side chains will take place only if the PAF complex activates Rad6/Bre1 for monoubiquitinylation at H2B.[352] In this manner, ubiquitinylation of H2B is a regulating element for the methylation of H3-K4 and H3-K79, and preserves transcriptionally active euchromatin (Figure 26).

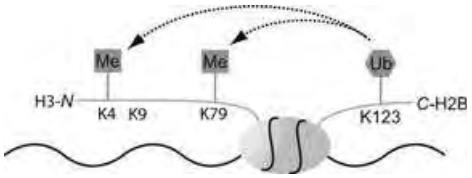

Figure 26. Ubiquitinylation of H2B-K123 influences histone methylation at H3-K4 and H3-K79.

6. Histone Sumoylation

The abbreviation SUMO (small ubiquitin-like modifier) designates a group of small proteins that are related to Ub through secondary and tertiary structure elements.[492] Their mechanism of attachment to target proteins is also similar to that of Ub. A SUMO-activating enzyme E1 (SAE1/SAE2) binds SUMO with concomitant ATP hydrolysis as a reactive thioester, which is transesterified to the SUMO-conjugating enzyme E2 (Ubc9). The last step is likely to be the transfer of the SUMO group from E2 to the ε-amino function of a lysine residue by the action of a ligase E3.[493]

Ub and SUMO proteins differ substantially in their primary structures, with a sequence homology of only 18%. This results in a completely different surface charge distribution. Furthermore, sumoylation does not represent a mark for the degradation of proteins.[494] Examples of the large group of sumoylated proteins[495] are p53 and H4. The histone is not modified at the usual consensus sequence, γ-Lys-X-Glu (γ = bulky hydrophobic amino acid; X = any amino acid).

Whereas histone ubiquitinylation is generally linked with active chromatin, there is increasing evidence that sumoylation elicits a contrary effect.[496] For example, the expression of a reporter is decreased by the SUMO-conjugating enzyme Ubc9. A simultaneous decrease in H3 acetylation and a significant increase of the heterochromatin-associated protein HP1, which is directly linked to gene silencing, can be observed.[496] From these results, a model has been developed to describe the mode of action of sumoylation.[497] As the acetylation of histone proteins increases, so does the sumoylation of H4. This serves as a signal for the termination of gene expression that had been originally induced through acetylation. The recruitment of HDAC activity clears the acetylated position for subsequent methylation, and allows the binding of the repressor protein HP1. The extent to which histone sumoylation actually plays a fundamental role must be clarified through future investigations. Some results show that sumoylation has a more indirect influence on these processes. In the case of p300/CREB, the acetyltransferase itself is sumoylated, and shows a stronger binding to HDAC6.[110] Another example is the transcription factor Elk-1; its sumoylation leads to the recruitment of HDAC activity to the Elk-1 promoter. The subsequent decrease in histone acetylation results in the repression of transcription.[498]

7. Histone Poly-ADP-Ribosylation

Like numerous other proteins, histones are modified by the successive attachment of anionic ADP-ribose monomers to generate poly(ADP-ribose) (PAR) chains (Figure 27).[499] Seven different PARPs (PAR polymerases) have been identified in mammals, from which PARP-1 is preferably expressed.[500]

From a mechanistic point of view, PARP-1 catalyzes the transfer of ADP-ribose units from the donor NAD^+ to an acceptor protein.[501] The first unit is attached to the carboxyl group of a glutamic or aspartic acid residue by an ester bond, whereas additional ADP-ribose units extend the chain through glycosidic bonds with the hydroxy function of the preceding ribose molecule. This is the same manner with which linear or branched polymers of up to 200 units are generated. The *parp-1* gene is highly conserved and codes for an N-terminal double zinc finger DNA binding domain, a central automodification domain, and a C-terminal NAD^+-binding domain.[502]

Like the sirtuins, which are NAD^+-dependent, PARP-1 is sensitive to the physiological state of a cell. Moreover, the activity of the enzyme is regulated by an allosteric mechanism.[503] The binding of DNA, especially damaged DNA, increases the activity. PARP-1 is also able to interact with two DNA helices simultaneously; it is therefore likely that the enzyme binds at locations where DNA exits the nucleosome. Moreover, PARP-1 activity is increased through the interaction of the automodification domain with transcription factors like YY1, which are able to bind DNA.[504] In contrast, an automodification in this region of PARP-1 inhibits DNA binding and ADP-ribosyltransferase activity.[503]

The influence of PARP-1 on the regulation of transcription processes is based on two important mechanisms: first, PAR modification of histones leads to an altered chromatin structure;[505] second, PARP-1 facilitates the binding of other factors to DNA in many cases, which activates transcription through the formation of a enhanceosome. Highly inducible genes are good examples of this.[506] The expression of heat shock proteins and the induction of immune system genes depends heavily on PARP-1 activity. In general, areas of high transcriptional activity or regions of decondensed chromatin are those with a high probability for the presence of PARP-1. However, there are some examples to the contrary:[507] PARP-1 is necessary for chromatin condensation and transcription repression. It appears that the effect of PARP-1 on chromatin structure depends on the neighboring chromatin. Whereas genes with euchromosomal surroundings, like *hsp70*, are activated by PARP-1, the same enzyme represses genes with a heterochromatin environment, such as *copia*.[507]

Under physiological conditions PAR modification is reversible[508] and its cleavage occurs rapidly after termination of the stimulus. PAR polymers, induced by heat shock, show a complete turnover within 25 minutes after termination of induction.[506] The reason for this is the presence of a specific poly(ADP-ribose) glycohydrolase (PARG). The activity of this enzyme seems to be proportional to the length of the polymer substrate.

The inclusion of PARP-1 into the group of chromatin-modifying enzymes is justified by some similarities to HATs, for example.[509] PARP-1 affects various DNA-based processes like transcription, replication, and DNA repair; it also participates directly in the assembly of transcription complexes at enhancers and promoters.[510] In addition, the PAR modification is part of a synergism that is typical for the histone code: nucleosomes can be modified simultaneously by acetyl groups and PAR residues.[511]

8. Conclusion

The length of the DNA of the human genome in its free, double helical form is approximately one meter. To be stably compressed for storage in cell nuclei, it must be organized into a structure of higher order. At the same time, this condensation naturally restricts accessibility to the DNA. However, nature uses this restriction very effectively as a way to regulate transcription. Histone proteins and nucleosomes are necessary for the generation of DNA structures of higher order and furthermore, they serve as templates to establish the histone code, an epigenetic mechanism for the regulation of transcription. The various histone modifications are analogous to a repertoire of letters, whose mutual dependence and influence on each other creates a sort of grammar. The fundamental establishment of the histone code is brought

about by the different enzyme families involved: HATs, HDACs, HMTs, HKs, and PPs, as well as the enzymes that control ubiquitinylation, sumoylation, and PAR modification. Despite the growing knowledge concerning the histone code, a abundance of questions still remain. Particularly, histone methylation, which is an important component of transcriptional regulation and the direction of other cellular processes, is not yet well-understood. The contradictory biological outputs of methylation at different lysine and arginine residues of the histones are also of emerging importance. The publication of some HMT crystallographic structure information should be a sufficient impetus for the development of chemical tools to assist in the study of these processes. Imitations of natural structures, for example, through bisubstrate analogues or simple peptide mimetics[512] could be the first steps in this approach.

The same type of exploration is necessary for the HATs. To date, the entire scope of their biological properties and interactions is only partially understood after the development of the first enzyme modulators; additional modulators will be helpful for further investigations. The different families of histone acetyltransferases and histone deacetylases mediate different biological processes. Therefore, the use of special modulators to selectively address these enzymes would be very helpful. Histone demethylation remains a topic that awaits clarification altogether.

In principle, the development of modulators of histone-modifying enzymes would enable the urgently-needed decoding of the histone code and, above all, the control of this code from the outside. This would enable the development of new therapies and new drugs for the treatment of tumors. This is supported by the fact that some HDAC inhibitors, in combination with inhibitors of DNA methylation, are already in clinical trials.

The investigation of epigenetic mechanisms is an important and new area of biomedical research. The development of the necessary modulators for epigenetic systems requires the active participation of chemistry. A clarification of the molecular details of epigenetic mechanisms will lead to a better understanding of pathological processes and will enable the development of completely new therapeutic drugs and concepts. Those in the fields of bioorganic and medicinal chemistry should recognize this as one of their most important research tasks.

Addendum (April 22, 2005)

During the printing of this Review, some important papers have been published in the area of epigenetics.

The dogma that histone methylation is irreversible has now been disproved with the identification of lysine-specific histone demethylase (LSD1), also known as KIAA0601.[513] LSD1 is a FAD-dependent amine oxidase that is able to specifically demethylate mono- and dimethylated H3-K4 in an oxidative manner.[514] LSD1 is associated with the CoREST repressor complex and represses transcription.[513] In this way, histone methylation is a dynamic process like histone acetylation or phosphorylation.

The type-II methyltransferase PRMT7 is specific for histones H2A and H4.[515] Analyses for the control of HKMT product specificity has been investigated.[516]

H3-T3 is an additional mitosis-specific phosphorylation mark, and the specific kinase for this is haspin.[517]

Ultraviolet B radiation (UVB) induces the phosphorylation of H3-S10 which is mediated by a Fyn kinase.[518] However, the phosphorylation of H3-S28 is mediated by MLTK-α (mixed-lineage kinase-like mitogen-activated protein triple kinase-α).[519]

With curcumin, another specific inhibitor of the histone acetyltransferase CBP has been identified.[520]

The ubiquitin hydrolase Ubp8 represents a new functional module within the SAGA multiprotein complex that is involved in gene regulation through the deubiquitinylation of H2B.[521]

Another report describes that the ubiquitin hydrolase Ubp10 targets H2B as substrate for deubiquitinylation, which helps to localize Sir2 to the telomeres.[522]

There is evidence that PARP-1 functions as both a structural component of chromatin and as a modulator of chromatin structure through its intrinsic enzymatic activity.[523]

Communications

A basic crystal shape is determined by habit formation and branching growth. Control of these processes leads to an enormous degree of synthetic freedom in generating crystal shapes. The vast array of architectures obtained for cuprous oxide during electrochemical growth is shown. For more details see the Communication by K.-S. Choi and M. J. Siegfried on the following pages.

Crystal Engineering

Directing the Architecture of Cuprous Oxide Crystals during Electrochemical Growth**

*Matthew J. Siegfried and Kyoung-Shin Choi**

A basic crystal shape is determined by two growth processes: habit formation and branching growth.[1–7] Crystal habit is determined by the relative order of surface energies of different crystallographic planes of a crystal.[1,2] The fastest crystal growth will occur in the direction perpendicular to the face with the highest surface energy. This results in elimination or reduction of higher energy surfaces, while lower energy surfaces increase in area. Therefore, a habit can be modified when the relative order of surface energies can be altered or when crystal growth along certain directions is selectively hindered.[3] Alternatively, branching growth is created by a diffusion effect.[4,5] When a crystal grows, ions or molecules near the surface are consumed by the growing crystal and a concentric diffusion field forms around the crystal.[6,7] This makes the apexes of a polyhedral crystal, which protrude further into the region of higher concentration, grow faster than the central parts of facets, thus forming branches. The branching growth, however, generates rough and unstable surfaces between branches that have many surface dangling bonds. This can rapidly increase the growth kinetic coefficient in these regions and compensate for the diffusion effect to result in faceting growth that develops flat and smooth faces.[4,5] Therefore, preference for branching and faceting can be altered by growth conditions that amplify or minimize the diffusion effect.

The ability to tune the shapes of materials directly relates to the ability to tune their properties and stabilities because the crystal shape dictates the interfacial atomic arrangement of the material. To date, many efforts have been made to stabilize various habits or branching growth of inorganic materials.[3,8–17] However, most earlier efforts focused on stabilizing specific forms rather than providing a strategy to systematically and freely direct the crystal morphology. Recently, we reported a methodical habit modification of electrochemically deposited Cu_2O crystals by using the pH-dependence of preferential adsorption of sodium dodecyl sulfate (SDS) on the {111} faces of Cu_2O crystals.[18] We have been specifically interested in understanding and controlling the shape-guiding processes in electrodeposition because electrodeposition allows the growth of various semiconducting and metallic crystals directly from a conducting substrate with good electrical contact, which can be easily integrated into devices. Here, we elucidate synthetic parameters that can systematically control branching or faceting growth in electrodeposition. By coupling this understanding with an ability to independently control habit, we demonstrate a new level of programmability and freedom in directing the morphology of Cu_2O crystals.

For supersaturation-based crystallization, temperature and concentration are the main factors that affect the basic shape-guiding processes. For example, in nature snow crystals can grow into thousands of different forms with varying crystal habits and degrees of branching by subtle changes in temperature and humidity.[19–25] Therefore, we first investigated the effects of the temperature of deposition and the concentration of Cu^{2+} ions on the branching or faceting growth of Cu_2O crystals on an ITO (indium tin oxide) working electrode. Figure 1 shows scanning electron microscopy (SEM) images of crystals of Cu_2O grown from the medium that stabilizes an octahedral habit (see Experimental Section for detailed conditions)[18] at varying deposition temperatures (40, 50, 60, and 70 °C) by using both potentiostatic deposition (constant potential) and galvanostatic deposition (constant current density). When potentiostatic deposition is used ($E = 0.09$ V), branching is more pronounced as the temperature increases. However, under galvanostatic deposition ($I = 0.1$ mA cm^{-2}) the degree of branching diminishes as the temperature increases. Similar conflicting trends were observed for crystals of Cu_2O deposited from a range of concentrations of Cu^{2+} ions (0.005, 0.01, 0.02, and 0.04 M; images not shown). When potentiostatic deposition was used ($E = 0.09$ V), branching was favored in a more dilute solution (≤ 0.02 M), while under galvanostatic deposition ($I = 0.1$ mA cm^{-2}), more-pronounced branching was observed as the concentration increased (≥ 0.01 M). These opposite tendencies for potentio- and galvanostatic depositions indicate

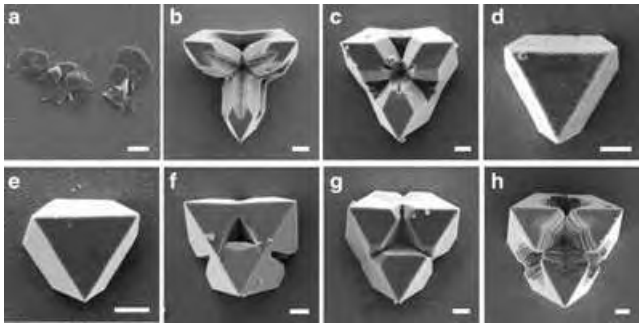

Figure 1. SEM images of octahedral Cu_2O crystals grown at varying deposition temperatures showing opposing trends of branching or faceting for potentio- and galvanostatic depositions. Potentiostatic depositions ($E = 0.09$ V) at a) 40 °C (no crystalline Cu_2O can be deposited under this condition), b) 50 °C, c) 60 °C, and d) 70 °C. Galvanostatic depositions ($I = 0.1$ mA cm^{-2}) at e) 40 °C, f) 50 °C, g) 60 °C, and h) 70 °C (scale bar = 1 μm). See Supporting Information for low-magnification SEM images that show the uniformity of crystal morphology over the electrodes.

that temperature and concentration are not the primary factors that exert homogeneous effects on branching in electrocrystallization. As the deposition temperature and the concentration of Cu^{2+} ions affect the deposition potential and current in a systematic manner, the changes in deposition potential and current caused by the variation of the temperature and concentration of Cu^{2+} ions needed to be examined in conjunction with the degree of branching.

Figure 2 shows the deposition potential and current used to deposit each crystal shown in Figure 1. In this plot, the

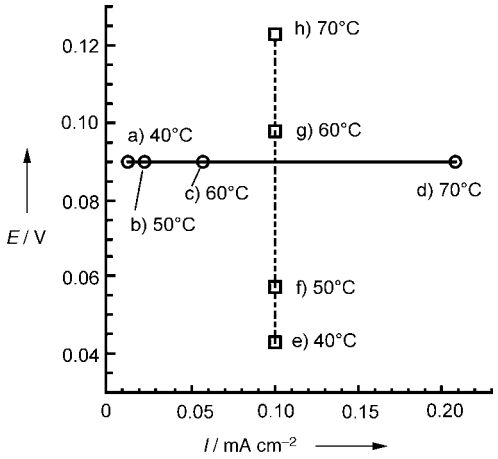

Figure 2. Plot of the deposition potential versus the current used to deposit each crystal shown in Figure 1. The effects of temperature on the deposition potential for galvanostatic deposition (-----) and the current for potentiostatic deposition (——) are clearly shown.

effect of temperature on the potentials for galvanostatic deposition and the currents for potentiostatic deposition is clearly illustrated. Generally speaking, an increase in the temperature improves the reaction kinetics and results in an increase in reaction rates, which in electrodeposition translates into an increase in deposition current. Therefore, when potentiostatic deposition is used, an increase in temperature causes an increase in deposition current (solid line in Figure 2). Accordingly, when galvanostatic deposition is used, an increase in temperature causes a decrease in the deposition potential; with a faster deposition rate, less potential (equivalent to a more positive potential for cathodic depositions) is required to keep the same level of deposition current (dashed line in Figure 2).

This understanding revealed that it was not the temperature but the deposition potential and current varied by the temperature that were directly responsible for the systematic change in the degree of branching. The most-significant branching is produced in regions of low potentials or currents (Figure 2b,h), below which no crystalline cuprous oxide can be deposited. As the overpotential or current increases (to increase the overpotential for cathodic depositions is equivalent to shifting the deposition potential toward more-negative values), the degree of branching decreases by a more-pronounced filling-in process to seal the gaps between the branches (Figure 2c,f,g). When the potential and current values reach $I = 0.2\ mA\,cm^{-2}$ and $V = 0.05\ V$ (Figure 2d,e), crystals grow as perfectly faceted polyhedra with no sign of branching. An identical trend was observed for the experiments with varying concentrations of Cu^{2+}; an increase in Cu^{2+} concentration causes an increase in deposition current for the potentiostatic deposition while causing a decrease in the deposition potential for the galvanostatic deposition. This observation again confirms that it is the changes in potential and current caused by the variation of concentration of Cu^{2+} that affect the degree of branching in a consistent manner.

On the basis of this realization, we attempted to control the preferences for branching or faceting solely by manipulating the deposition potential and current. Figure 3 shows

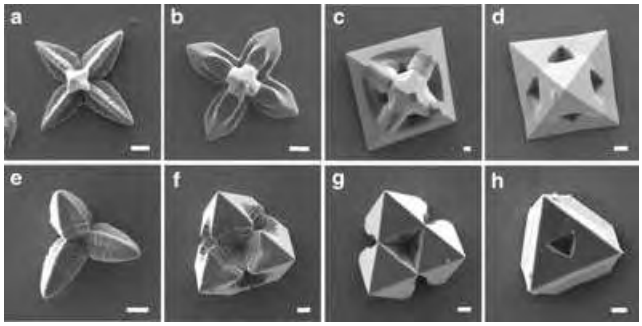

Figure 3. SEM images of deposited octahedral Cu_2O crystals that display systematically varying degrees of branching with (100) planes parallel to the substrate (a–d) and with (111) planes parallel to the substrate (e–h; scale bar = 1 μm). These crystals were obtained at a constant temperature (60 °C) and concentration of Cu^{2+} (0.02 M) and by applying deposition conditions of $0.10\ mA\,cm^{-2} \le I \le 0.12\ mA\,cm^{-2}$ and $0.08\ V \le E \le 0.12\ V$.

branched crystals obtained under constant temperature (60 °C) and concentration of Cu^{2+} (0.02 M) by applying deposition conditions that were identified from Figure 2 to induce branching growth ($0.10\ mA\,cm^{-2} \le I \le 0.12\ mA\,cm^{-2}$ and $0.08\ V \le E \le 0.12\ V$). Various stages of branching and filling-in processes were captured by finely tuning the conditions, modes (i.e. galvano- or potentiostatic), and times of deposition. All the deposition conditions we have investigated and their effect on branching and faceting are summarized in Figure 4, which composes a well-defined potential–current (I vs. V) diagram for faceting and branching growth. The degree of branching in the branching region diminishes gradually as the potential and current move toward the border of the faceting region.

This tendency for branching and faceting is quite the opposite of what one would normally expect for electrodeposition in which only the concentration of the species to be reduced creates a diffusion-limited condition. For example, dendrite or branching growth of metals will most likely occur at a high potential or deposition rate owing to a rapid depletion of M^{n+} ions near the growing crystals ($M^{n+} + n\,e^- \leftrightarrow M^0$). However, deposition of Cu_2O is quite unique in that it involves two distinctive processes for crystallization: reduction of Cu^{2+} ions ($Cu^{2+} + e^- \leftrightarrow Cu^+$, $E^0 = 0.153\ V$) and precipitation of Cu^+ ions ($2\,Cu^+ + H_2O \leftrightarrow Cu_2O + 2\,H^+$, $\log(Cu^+) = -0.84 - pH$; (Cu^+) = activity of Cu^+ ion).[26] Therefore, changes in concentrations of Cu^+

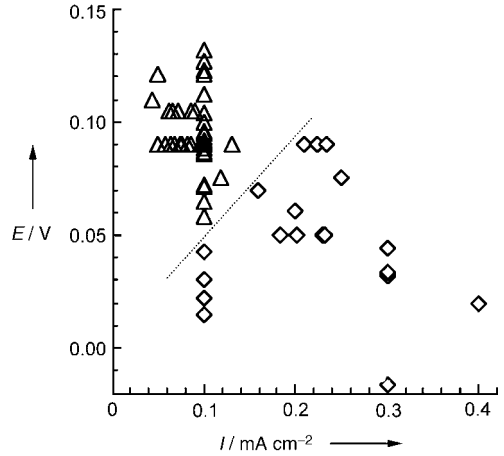

Figure 4. A deposition potential–current diagram summarizing the effect of electrochemical conditions on branching (△) and faceting (◇) growth. The electrochemical conditions plotted here were obtained either by directly adjusting the potential or current or by changing them indirectly through variation of temperature and concentrations of Cu^{2+} ion. The medium that stabilizes an octahedral habit was exclusively used to collect the data shown here.

and H^+ as well as Cu^{2+} and the site of reduction or deposition need to be studied in conjunction with changes in deposition potential and current to understand branching or faceting growth of Cu_2O crystals. More experiments are currently being carried out to derive a precise mechanism for branching in regions of low potential or current.

All the crystals discussed up to this point display the same octahedral habit as the degree of branching was independently controlled from habit. By combining the deposition conditions identified in Figure 4 with chemical conditions to regulate crystal habit (see Experimental Section for detailed compositions of media),[18] simultaneous manipulation of habit and branching become possible. Figure 5a–c show the results of branching control performed in a medium that stabilizes the {100} faces of Cu_2O crystals and, therefore, a cubic habit. Conversely, Figure 5d shows branched crystals obtained by using a medium that precisely tunes the growth ratio, R (the growth rate along the ⟨100⟩ direction/growth rate along the ⟨111⟩ direction), to obtain a truncated octahedral habit as the final morphology.[18,27] To the best of our knowledge, this level of synthetic freedom and programmability in controlling both the degree of branching and habit has not previously been demonstrated for any semiconducting system.

More complexity can be introduced to the architecture of Cu_2O crystals when different media are used for the branching and filling-in processes. This strategy mimics the growth of snow crystals in nature that leads to thousands of unique crystal morphologies. When developing snow crystals fall from the sky, they pass through many atmospheric regions of varying humidity and temperature. As each region has different preferences for habit and branching, the journey of snow crystals creates complexity in their growth history and, therefore, complexity in their final morphologies.[19,25] Electrodeposition is ideal for creating an equivalent complex growth history because the crystal growth can be paused at

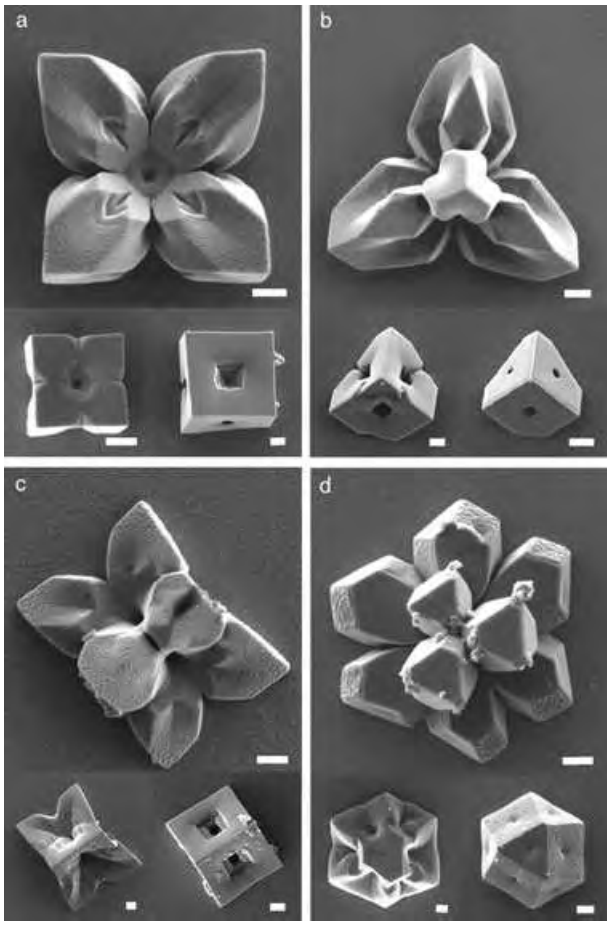

Figure 5. SEM images of branched Cu_2O crystals with varying crystal habit. Cubic crystals grown with a) (100) planes, b) (111) planes, and c) (110) planes parallel to the substrate. d) Cuboctahedral crystals with (111) planes parallel to the substrate. Insets for each image show crystals of the same habit and orientation with gradually increasing filling-in processes that are controlled by the deposition conditions identified in Figure 4 (scale bar = 1 μm). See Experimental Section for detailed compositions of the media.

any moment and resumed in a new medium. Figure 6a–c show how branched octahedral crystals transform when the filling-in process is continued in a new medium that stabilizes {100} faces. Since the initial branches are positioned to form an octahedral skeleton, a quick transition to a single cube is extremely difficult. Therefore, the tips of the branches that would otherwise become the apexes of an octahedron rapidly develop {100} faces and each branch forms its own cube and expose only {100} faces at the interfaces. Then these individual cubes eventually fuse together to form one seamless cube to attain a minimum surface energy. Figure 6d–f show the opposite case; branches were built in a medium that stabilizes cubic shapes, and the filling-in process was continued in a medium to grow octahedral crystals. Again various novel and exquisite surface patterns are generated when the crystals are forced to develop {111} faces by using branches that point to the apexes of a cube to eventually transform into a simple octahedral crystal. This observation implies endless possibilities of designing new crystal mor-

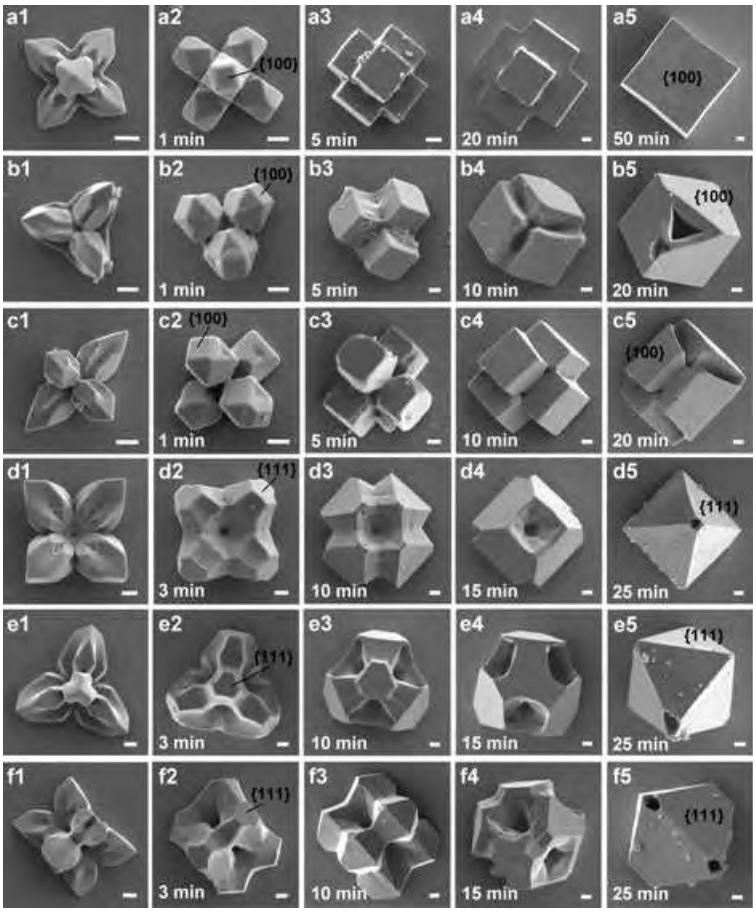

Figure 6. SEM images of novel Cu_2O crystal morphologies constructed through the addition of complex growth histories. a–c) Branched crystals were first deposited in a medium that stabilizes an octahedral habit for 3 minutes (column 1), and the filling-in process was resumed in a new medium that stabilizes a cubic habit for the time depicted in each figure (columns 2–5). d–f) Branched crystals were first deposited in a medium that stabilizes a cubic habit for 12 minutes (column 1), and the filling-in process was resumed in a new medium that stabilizes an octahedral habit for the time depicted in each figure (columns 2–5). Crystals are shown with (100) planes (a, d), (111) planes (b, e), and (110) planes (c, f) parallel to the substrate (scale bar = 1 μm). All the crystals shown here were grown under constant temperature (60 °C) and concentration of Cu^{2+} ion (0.02 M). Galvanostatic depositions of $I = 0.1$ mA cm^{-2} and 0.3 mA cm^{-2} were used for the initial branching and resumed filling processes, respectively.

phologies by combining multiple growth media and growth conditions.

In summary, we have demonstrated a methodical and simultaneous tuning of the habit and the degree of branching of Cu_2O crystals by elucidating and manipulating key conditions that control shape-guiding processes in electrocrystallization. By combining this understanding with the unique capability of electrodeposition to pause and resume crystallization at any stage, it was possible to assemble numerous unprecedented crystal architectures by rationally designing the growth conditions and growth history. The programmability and synthetic freedom demonstrated in this work will not only provide valuable information for the study of electrochemical crystal growth mechanisms[23,28,29] but also build a foundation for the study of directed crystal growth of various semiconducting crystals on a conducting substrate. These systems will be useful for a broad range of applications such as sensors, optoelectronics, and catalysis.

Experimental Section

Cu_2O crystals were prepared by cathodic deposition from aqueous solutions of 0.005–0.04 M $Cu(NO_3)_2$ ($2Cu^{2+} + H_2O + 2e^- \rightarrow Cu_2O + 2H^+$) by using a conventional three-electrode setup. For the counter electrode, 100 Å of titanium followed by 500 Å of platinum were deposited on clean glass slides by sputter-coating. ITO (sheet resistance = $15 \pm 5\ \Omega\,cm^{-2}$), purchased from Delta Techologies, Limited, was used as a working electrode. The reference electrode was Ag/AgCl in a solution of KCl (4 M), against which all potentials reported here were measured. The electrolyte used to stabilize the octahedral shape (shown in Figures 1 and 3) contains 5 wt% sodium dodecyl sulfate (SDS) as a habit modifier (pH 4.9 before the addition of SDS) to stabilize {111} faces of Cu_2O crystals. The medium used to stabilize a cubic habit (Figure 5a–c) was composed of a solution of $Cu(NO_3)_2$ (0.02 M) without SDS (pH 4.9), and the medium used to grow truncated octahedral habit (Figure 5d) was composed of a solution of $Cu(NO_3)_2$ (0.02 M) and 5 wt% SDS (the pH was adjusted to 4.3 before the addition of SDS).[18] The range of deposition conditions to promote faceting growth in a solution of Cu^{2+} (0.02 M) is $E \leq 0.07$ V and $I \geq 0.15$ mA cm^{-2} at 60 °C. Branching growth can be stabilized at $0.07\ V < E \leq 0.14$ V and $0.04\ mA\,cm^{-2} \leq I < 0.15\ mA\,cm^{-2}$ with more-significant branching induced at a more-positive potential and lower current. Both potential and current are required to be in these specific ranges to stabilize branching growth. When $E > 0.14$ V and $I < 0.04$ mA cm^{-2}, no crystalline Cu_2O can be deposited. The compositional purity of the Cu_2O crystals shown in this study was confirmed by powder X-ray diffraction, details of which are provided in the Supporting Information.

Cytomimetic Chemistry

Real-Time Membrane Fission of Giant Polymer Vesicles**

*Yongfeng Zhou and Deyue Yan**

Vesicle transformations that mimic cellular processes have become a specific topic of interest in recent years.[1] Lipid vesicles (liposomes), surfactant vesicles, and block-copolymer vesicles are conventional and useful model membranes for living cells.[2–5] Most model membranes reported are submicroscopic (20–500 nm) in nature and conclusions concerning these membranes are often based on inference rather than on direct observation. Menger and co-workers have successfully used giant vesicles (5–200 μm), which have the advantage of being microscopic and therefore visible, to directly observe real-time shape transformations of vesicles that mimic cellular morphology. They coined the term "cytomimetic chemistry" to describe the visible cell-like morphologies of giant vesicles.[6] Up to now, many interesting cell-like activities such as birth, budding, endocytosis, exocytosis, fusion, and fission have been reported in studies of cytomimetic behavior.[6–8] However, all of the vesicles that have been used so far in cytomimetic chemistry are giant liposomes, and no real-time transformations of polymer vesicles have been observed. Herein, we present work to develop the cytomimetic chemistry into the field of polymers by using giant polymer vesicles as model membranes ("cytomimetic macromolecular chemistry"). We also describe a new and sequential membrane fission process by displaying a series of high-resolution and real-time transformation images of individual vesicles.

Membrane fission is very important and common in various biological processes such as endocytosis. However, there has been little experimental work on vesicle fission that mimics cell fission at the phenomenological level. Luisi and co-workers found evidence of fission of larger vesicles by adding fresh surfactant into preformed vesicles; they called this phenomenon "the matrix effect" to stress that the pre-existing vesicles or liposomes act as a matrix for the formation of new vesicles.[2] Nolte and co-workers also detected vesicle fission by adding calcium ions into synthetic phospholipid vesicles and presented a possible mechanism.[3b] Eisenberg and co-workers also proposed a fission sequence by carefully arranging several images selected from a large number of TEM micrographs of submicroscopic block copolymer vesicles.[5c,d] The mechanisms for vesicle fission mentioned above are speculative and based on characterization data obtained from TEM and light scattering. In contrast, Döbereiner, Sackmann, and co-workers—the pioneers of cytomimetic chemistry—used optical microscopy to monitor the real-time fission of giant lipid vesicles induced by heating and osmotic deflation.[8] Kitamura also presented images of real-time fission of giant lipid vesicles induced by a laser.[9] Unfortunately, these images in are low-resolution or segmental. To understand similar behavior in living cells, it is necessary to obtain high-resolution, real-time, sequential images of individual vesicles undergoing fission. In addition, the use of giant polymer vesicles as model membranes in cytomimetic chemistry is a new and exciting area of research.

Compared with liposomes, polymer vesicles are very stabile. Eisenberg and co-workers reported a type of polymer vesicle called "crew-cut micelles", which are obtained by the self-assembly of block copolymers that have small hydrophilic fractions ($<20\,\%$) in a mixture of solvents.[5] Discher and co-workers reported another type of polymer vesicle termed "polymersomes" from block copolymers that have a hydrophilic fraction ($35\pm10\,\%$) similar to those of liposomes.[10] Very recently, we reported a new sort of polymer vesicle called "branched polymersomes". These branched polymersomes were synthesized through molecular self-assembly of an ill-defined hyperbranched copolymer, HBPO–star–PEO (HPBO is hyperbranched poly(3-ethyl-3-oxetanemethanol); PEO is polyethylene oxide), which has a higher hydrophilic fraction ($>60\,\%$) in water.[11] HBPO–star–PEO is an amphiphilic multiarm copolymer with a hydrophobic hyperbranched HBPO core and a large population of hydrophilic PEO arms.[11] Three giant polymer vesicles, HB3, HB2, and HB1, with average diameters of 4.0 μm, 22.6 μm, and 112.8 μm, respectively, were obtained[11b] The molecular self-assembly process of vesicles HB1–3 involved directly putting the polymer into stirred deionized water (polymer concen-

tration 10 mg mL^{-1}) at room temperature. HB1–3 vesicles not only have the advantages of polymer vesicles but are also visible under the microscope as are giant lipid vesicles. Thus, HB1–3 vesicles are ideal model membranes for cytomimetic chemistry.

HB2 vesicles were chosen to investigate the real-time cytomimtetic behavior under an optical microscope. Detailed structures of the HB2 molecules and vesicles are described in the Supporting Information. Membrane fission of a daughter vesicle inside a mother vesicle was observed by adding glucose to the HB2 vesicle solution (Figure 1). The daughter

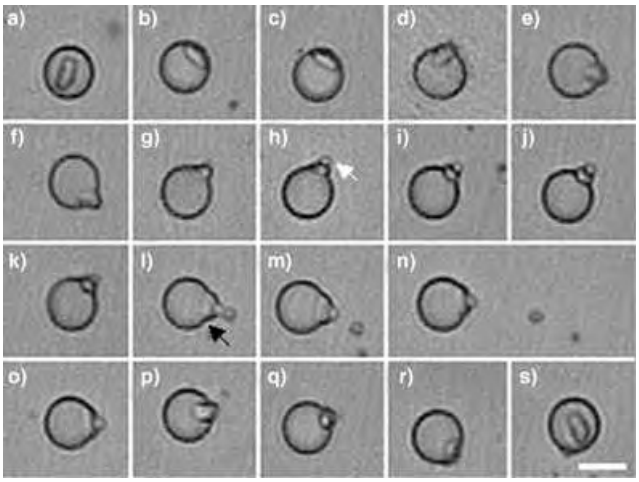

Figure 1. A series of images showing the interaction of a daughter vesicle inside its mother vesicle during fission. The scale bar represents 25 μm. The time of image (a) is set as 0, and the elapsed times for the images are 33 (b), 64 (c), 105 (d), 130 (e), 134 (f), 165 (g), 170 (h), 179 (i), 182 (j), 190 (k), 243 (l), 246 (m), 263 (n), 273 (o), 421 (p), 620 (q), 719 (r), and 920 s (s), respectively. Images (a–g), (h–o), and (p–s) are defined as the prophase, metaphase, and anaphase of fission, respectively. For the fission experiment, glucose (15 mM) was added to an aqueous solution of HB2 vesicles. After the glucose had dissolved, the sample was subjected to ultrasound for 10 min before being transferred to a culture dish for optical microscopy measurements (Leica Dmlp, TMS94) at 20°C.

vesicle underwent five fission steps: suspension inside the mother vesicle (Figure 1 a); coalescence with the mother vesicle (Figure 1 b,c); protrusion from the membrane of the mother vesicle to form a pear shape (Figure 1 d–i); fission (Figure 1 m,n); retraction into the mother vesicle (Figure 1 o–s); suspension of the daughter vesicle for several minutes until the fission cycle ends or repeats itself (Figure 1 s). We have observed one daughter vesicle inside a mother vesicle undergoing three fission cycles, with each cycle taking longer to complete than the previous. We observed at least eight vesicles displaying similar fission behavior to that shown in Figure 1.

Clearly, it is the daughter vesicle that undergoes membrane fission. Experimental evidence to support this claim comes from three sources. First, we have not observed spontaneous budding from a single vesicle without the presence of an inner daughter vesicle. Second, the sequential images (Figure 1 a–l) suggest that the daughter vesicle passes through the mother vesicle to form the pear-shaped structure (Figure 1 h–l), and it is the deformation of this structure that results in membrane fission (Figure 1 l–o). We also find that formation of a pear-shaped structure is not certain to lead to vesicle fission; sometimes the vesicles maintain the pear shape for a relatively long time without further fission. Instead, there is a gradual retraction of pear shape into the mother vesicle and the intact daughter vesicle is formed again (see the Supporting Information). The images in Figure 1 (Figure 1 a–l) combined with those in the Supporting Information confirm that the pear-shaped structure, from which the fission takes place, is formed from the daughter vesicle. The third piece of evidence comes from the change in size of the daughter vesicle before and after membrane fission. The daughter vesicle is irregular but can be regarded as quasi-ellipse. Thus, we can define the daughter vesicle in terms of the length of the major and minor axes. The major axis of the daughter vesicle before fission (≈ 7 μm) is longer than that of the daughter vesicle after fission (< 6 μm), as is the minor axis. Nevertheless, the daughter vesicle is not a regular ellipse, so it would be better to find a more precise way of comparing the volume of the vesicles. We overlapped the daughter vesicle before and after fission by using a computer program (see the Supporting Information) and the result clearly show that the size of the daughter vesicle decreased after fission.

How does the vesicle fission shown in Figure 1 take place? We believe that the osmotic pressure and the mother vesicle induce the fission. Similar to biological membranes, liposomes are semipermeable and are much more permeable to water than to glucose. It is well known that polymer vesicles are less permeable than liposomes.[5] Therefore, it is conceivable that water can easily permeate the HB2 vesicle membrane, however, permeation of glucose, a larger molecule, through the vesicle membrane is more difficult. In fact, the semipermeable membrane property of the HB1–3 vesicle has been verified by a vesicle-shrinkage experiment in another hyperosmotic solution (results not shown). So the addition of glucose greatly increases the difference in osmotic pressure between the aqueous interior of the HB2 vesicle and the bulk solution, which drives water and the daughter vesicle out of the mother vesicle.

During the fission, the daughter vesicle moves towards the mother vesicle and often part of the daughter breaks through (Figure 1 a–d). However, it does not directly penetrate the mother vesicle because of the intrinsically high stability of the polymer vesicle.[5,10] The membrane of the mother vesicle works as a tough elastic barrier, thus preventing the daughter vesicle from completely breaking out. The daughter and mother vesicles make contact and at that point the mother vesicle, driven by the movement of the daughter vesicle, deforms into a bud structure (Figure 1 e–g). A comparison of the mother vesicle before and after deformation (Figure 1 a and f; see also the Supporting Information) shows that the surface of the mother vesicle increases after forming the bud. This expansion of the membrane should lead to an increase in surface tension.[12] Figure 2 a–f shows the models to illustrate the deformation of the daughter vesicle and mother vesicle to form the bud. Details of the interaction between the mother and daughter vesicles are still under investigation in our lab and will be reported in due course.

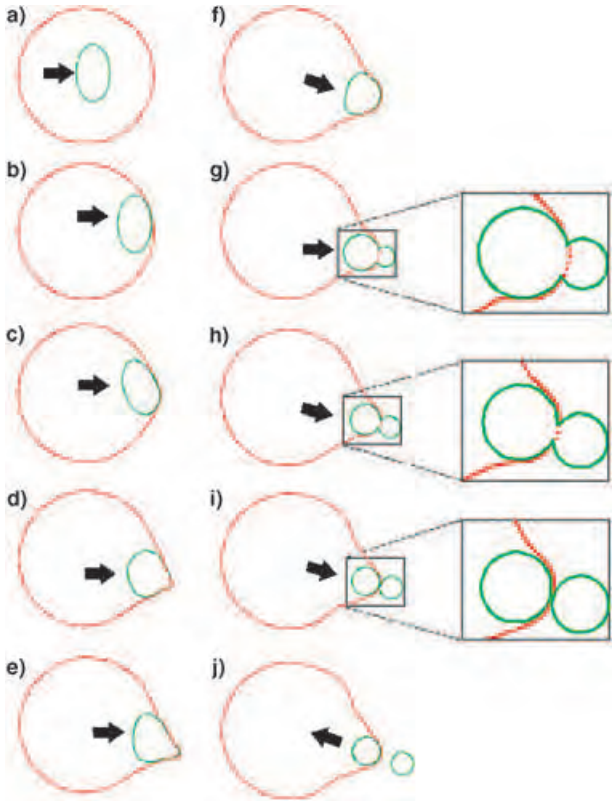

Figure 2. Models of vesicle transformations during membrane fission shown in Figure 1. The mother vesicle is in red and the daughter vesicle is in green. Black arrows show the movement of the daughter vesicle. The red dashed curves in (g) and (h) show the intersecting line resulting from the penetration of the mother vesicle by the daughter vesicle.

Figure 1 h shows an important intermediate: the partial penetration of the daughter vesicle through the mother vesicle. Figure 1 shows the mother vesicle in black and the daughter vesicle in gray. The black profiles of the vesicle image in Figure 1 a–g indicate that the daughter vesicle is enveloped by the mother vesicle during these changes in morphology. However, in Figure 1 h the gray vesicle has partly passed through the black vesicle (white arrow). From a comparison of the volume of the daughter vesicle in Figure 1 h with that in Figure 1 a, it is clear that the gray membrane located outside the black vesicle in Figure 1 h comes from the daughter vesicle. Evidently, the daughter vesicle has partly penetrated the mother vesicle by the force of osmotic pressure. It is conceivable for the daughter vesicle to break through the mother vesicle if the tension induced by the movement of the daughter has exceeded the tolerance of the mother. Further evidence of the penetrating ability of the daughter vesicle came from experiments with a higher glucose concentration (25 mM): the daughter vesicle was observed to completely pass through the mother vesicle forced by the higher osmotic pressure (see the Supporting Information). This process is similar to the birthing process reported by Menger and Gabrielson.[6b,c]

Figure 1 i–l shows the sequential deformation of the daughter vesicle inside and outside the mother vesicle. The penetration by the daughter leads to a "wound" in the mother vesicle and the mother heals the wound spontaneously.[6b,c] In addition, the daughter vesicle continues to penetrate the mother vesicle driven by osmotic pressure. Figure 2 g–i shows the possible changes of the daughter vesicle during the penetration. Figure 2 g shows that the daughter vesicle is divided into two by the mother vesicle and a neck is formed in the interface, which shapes the daughter vesicle into a pearlike structure. As the wound in the mother vesicle heals and the penetration by the daughter vesicle continues, the neck becomes narrower and narrower (Figure 2 h). Then the daughter becomes two vesicles that are in contact with each other as shown in Figure 1 l and Figure 2 i.

The strong deformation of the mother vesicle in Figure 1 l is of particular interest. Figure 1 l shows the mother vesicle at the point of greatest deformation (indicated by the black arrow; see also Figure 2 i), which leads to the large tension that retracts the part of the daughter vesicle retained inside the mother. Thus, complete fission takes place (Figures 1 m, 1 n, and 2 j). We have found that vesicle fission will only occur after the deformation of the mother and daughter vesicles has reached the state shown in Figure 1 l, which is the critical morphology for vesicle fission. The deformation of the mother vesicle decreases after releasing a small vesicle (Figure 1 m–o), the mother vesicle gradually recovers its spherical morphology (Figure 1 p–s), and the daughter vesicle is fully retracted.

Fission processes reported previously involve only one vesicle, whereas the fission described herein is new as it involves two vesicles. There is a strong interaction between mother and daughter vesicles during fission and deformation of the mother occurs with concomitant fission of the daughter. We have called this process "cooperative fission".

The "spontaneous curvature" and "area difference elasticity" models developed by Döbereiner, Sackmann, Seifert, and others have been successfully used to forecast, explain, and analyze the budding and fission of lipid vesicles.[8] The theoretical models mostly deal with a fission process that involves only one vesicle. The participation of a mother vesicle greatly increases the complexity of the studied "cooperative fission". A modified physical model that takes into account the geometrical and mechanical constraints of the mother vesicle is needed. Nevertheless, since both the theoretical and experimental results with lipid vesicles have stressed the pear structure and its importance in subsequent membrane fission, the behavior of lipid vesicles and polymer vesicles overlap here in membrane fission.

In conclusion, we have presented a novel real-time membrane fission process, called cooperative fission, by using giant polymer vesicles as model membranes. A mother vesicle with a daughter vesicle within shows a cooperative effect during membrane fission, which is caused by osmotic pressure combined with the stability of the mother polymer vesicle. Our finding extends the field of cytomimetic chemistry into polymers. These results along with previous reports on liposomes and surfactant vesicles,[2–6,8,9] lead us to the conclusion that membranes—regardless of the composition, whether they involve small molecules or macromole-

cules, whether synthetic or natural—can undergo this cytomimetic process in the absence of a protein.

Crystal Growth

Solvent Effect on Crystal Polymorphism: Why Addition of Methanol or Ethanol to Aqueous Solutions Induces the Precipitation of the Least Stable β Form of Glycine

Isabelle Weissbuch, Vladimir Yu. Torbeev, Leslie Leiserowitz,* and Meir Lahav**

Dedicated to Professor J. Michael McBride on the occasion of his 65th birthday

Crystal polymorphism, which embodies the ability of molecules to form diverse packing arrangements displaying different physical and chemical characteristics, is of paramount importance in fields such as pharmacology, solid-state chemistry, and material science.[1] However, the conditions to induce the precipitation of various (metastable) polymorphs is invariably achieved by "mix and try" methods, which are kinetically driven. Various factors should be considered in trying to understand these complex processes, for example, the formation of structured clusters in solution prior to crystallization, the structure of growing surfaces that delineate emerging nuclei, the interaction between these surfaces and the solvent, as well as solvent–solute and solute–solute interactions. Herein, we attempt to unravel some of these factors to rationalize the preferred crystallization of the β form of glycine (gly) in water–alcohol solutions as opposed to the more stable α or γ polymorphs.

The thermodynamic stability of the three polymorphs of glycine at room temperature is in the order $\gamma > \alpha > \beta$.[2–5] The α form[6] (space group $P2_1/n$), grown from supersaturated aqueous solutions (33.3 g/100 mL water) at 25 °C, has a bipyramidal habit and is composed of centrosymmetric bilayers formed by strong NH···O hydrogen-bonding interactions between cyclic hydrogen-bonded zwitterionic molecular pairs. These bilayers are related along the *b* axis by glide symmetry through weak CH···O interactions (Figure 1 a). Previous studies indicated that α-gly crystallizes primarily in aqueous solutions through hydrogen-bonded cyclic dimer growth units: Diffusion-coefficient[7] measurements of supersaturated aqueous solutions of glycine point to the formation of clusters with an average of 1.8 molecular growth units. Furthermore, atomic force microscopy (AFM) and phase interferometry microscopy measurements established that steps approximately 1 nm in size were formed, which correspond to the thickness of a glycine bilayer.[8,9] Grazing-incidence X-ray diffraction studies on growing α-gly {010}

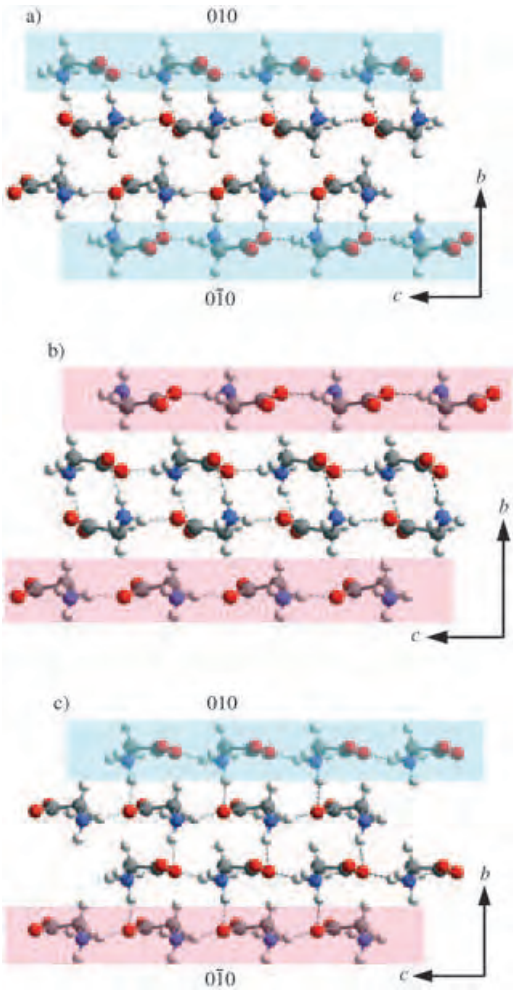

Figure 1. Packing arrangements of the a), b) α and c) β polymorphs of glycine. a), b) α-Gly exposing either weak solvent-binding C–H bonds to the solution at the (010) surface (azure) or strong solvent-binding N–H bonds to the solution at the (010) surface (pink). c) β-Gly exposing (010) "azure" and (0–10) "pink" surfaces, similar to that in α-gly, but at the two opposite poles of the crystal.

crystal faces[10] showed that the crystals primarily had exposed C–H bonds, thus indicating that glycine cyclic dimers are the growth units for α-gly formation.[9]

The first crystallization of β-gly from water–alcohol solutions was reported by Fischer.[11] The crystal structure[12,13] is polar (space group $P2_1$) and comprises hydrogen-bonded layers, which are akin to those observed in the α form, but which are interlinked by NH···O and CH···O interactions through a twofold screw-symmetry axis perpendicular to the layer plane (Figure 1c). The addition of alcohol reduces the solubility of glycine from 25.0 g/100 mL water (25 °C) to 2.65 g/100 mL solvent in 50.1 % (v/v) ethanol–water mixtures. This reduced solubility should result in an increased concentration of solvated glycine monomers relative to that of hydrogen-bonded cyclic dimers. Such behavior is apparently consistent with the preferred precipitation of β-gly from alcohol–water solutions because the crystal structure consists of hydrogen-bonded monomer units, as opposed to α-gly which comprises cyclic hydrogen-bonded pairs.

Long needles of β-gly were grown in water–ethanol mixtures containing 50, 26.1, and 10 % (v/v) ethanol and also from 1:1 water–methanol mixtures containing 4.0, 19.0, 35.9, and 5.0 g gly/100 mL solvent, respectively (Figure 2a).

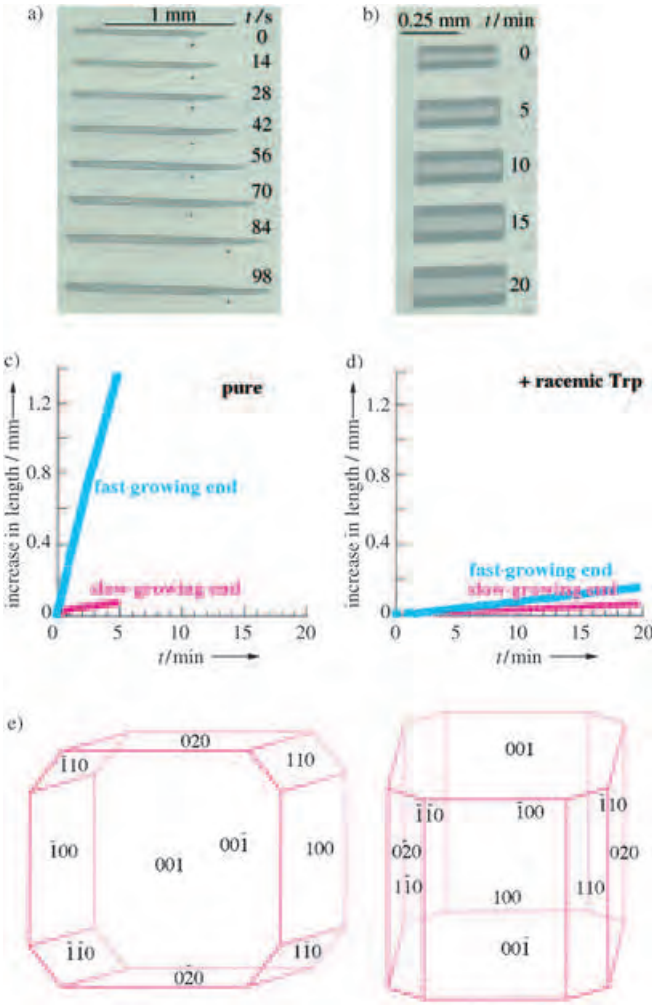

Figure 2. Photographs showing the growth of β-gly crystals in a 1:1 water–ethanol solution in a) the absence and b) the presence of 5 % (w/w) racemic Trp. c, d) Corresponding increase in length at opposite ends of the β-gly crystals. e) The theoretical growth form of β-gly viewed along the *c* and *a* axes.

Therefore, we were faced with the conundrum that the more thermodynamically stable α- and γ-gly polymorphs do not generally precipitate in aqueous solutions containing methanol or ethanol under the specified experimental conditions. We thought that an answer to this problem might be gleaned from the growth kinetics of the three polymorphs of glycine coupled with an analysis of the action of the solvent at the various crystal faces.

Growth kinetic measurements of single β-gly crystals in 1:1 water–ethanol solutions at 25 °C reveal a fast growth at one pole of the needle and a very slow growth at the opposite end (Figure 2a, c). We determined the absolute polarity[14] of

β-gly by employing "tailor-made" additives, in this case racemic tryptophane (Trp). The packing arrangement of β-gly (Figure 1c) dictates that an (*R*)-tryptophane additive may occupy the site of a glycine molecule at the end of the (010) crystal with exposed C–H bonds and subsequently retard its growth. If this end is the faster growing of the two crystal poles, tryptophane would induce the formation of short prismatic crystals, as observed experimentally (Figure 2b, d). Therefore, we conclude that β-gly grows faster at the side with exposed C–H bonds (colored azure) than at the opposite side with exposed N–H bonds (colored pink; Figure 1c). Previous studies have shown that the relative rates of growth at the opposite ends of polar crystals in polar solvents can be correlated directly with the relative rates by which solvent molecules are stripped from the opposite ends.[15–18] The faster growth rate at the β-gly pole with exposed C–H bonds is in agreement with this model; the water or alcohol solvent molecules can be attached more effectively to the slow-growing glycine surface with exposed N–H bonds through strong $OH_{sol}\cdots O_{gly}^-$ and $NH_{gly}\cdots O_{sol}$ interactions than to the fast-growing β-gly pole with exposed C–H bonds with strong $OH_{sol}\cdots O_{gly}^-$ interactions but only weak $CH_{gly}\cdots O_{sol}$ interactions. The surface of the fast- and slow-growing ends of β-gly (Figure 1c) are very similar in structure to the {010} surfaces of α-gly with either exposed C–H or N–H bonds, as shown in Figure 1a, b, respectively.[19] On the basis of the realistic assumption, which is supported by experimental evidence,[8,9] that glycine molecules in aqueous solution dock onto the crystal surface primarily as hydrogen-bonded cyclic glycine pairs, it is thought that an {010} face will expose the faster-growing surface with exposed C–H bonds to a much larger extent than the slower-growing surface with exposed N–H bonds. We anticipated that the reduced solubility of glycine in solution caused by the presence of ethanol would lead to a higher proportion of solvated glycine monomer units docking onto the α-gly {010}-surface sites with exposed N–H bonds. Thus, the time required to strip the overlying solvent molecules, prior to formation of the glycine cyclic dimer growth units and propagation of the glycine bilayer with exposed C–H bonds on its {010} surface, would lead to an overall reduction in growth rate along the $\pm b$ directions of the α-gly crystal. Indeed, the α-gly crystals obtained from a 9:1 water–ethanol solution tended to display more well developed {010} faces (Figure 3a) than crystals obtained from purely aqueous solutions. Therefore, embryonic α-crystallites would expose slow-growing {010} surfaces at higher concentrations of the alcohol in contrast to β nuclei, which has only one slow-growing polar end and so results in a preferred kinetic precipitation of the latter.

A further consequence of the pronounced effect of solvent on the crystal morphology of β-gly can be observed by comparing its needlelike habit (Figure 2a) with the regular shape resulting from the theoretical growth form (Figure 2e), which was computed by using Cerius[2] according to the attachment energy hypothesis by Hartman and Perdock.[20,21] Thus, water or alcohol as solvent impedes growth normal on the {*h*0*l*} faces of the needle crystals as a result of strong solvent attachment to these faces through $OH_{sol}\cdots O_{gly}$ and $NH_{gly}\cdots O_{sol}$ hydrogen-bonding interactions.

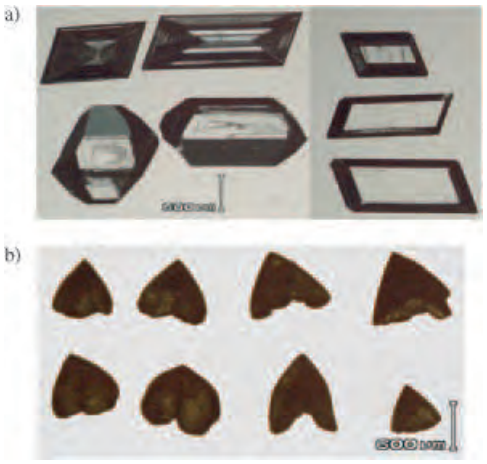

Figure 3. a) α-Gly crystals grown from 9:1 water–ethanol. b) γ-Gly crystals observed in several crystallizations from a 1:1 water–ethanol solution.

The absence of the stable γ-gly form[22] in crystals formed in alcohol–water solutions may be explained by examination of its growth properties. The polar crystal structure of γ-gly (space group $P3_1$; Figure 4), which is not composed of cyclic glycine pairs, is delineated by a (00–1) face at which CO_2^- groups emerge and capped crystal faces at the opposite end that expose NH_3^+ groups. Previous studies[23] have shown

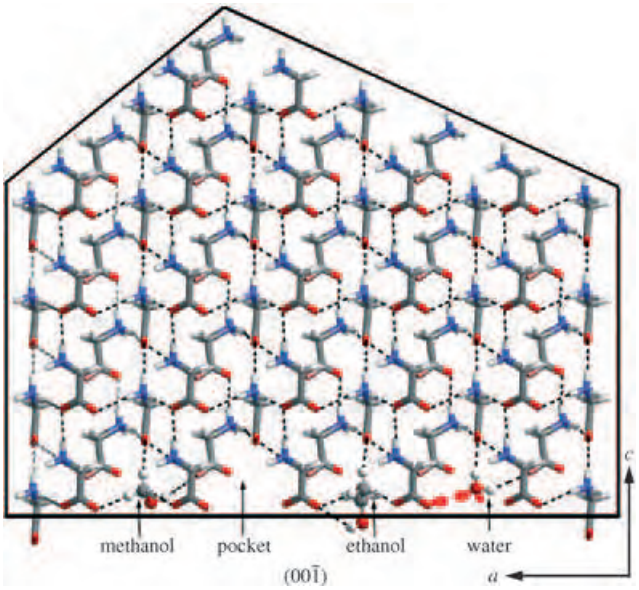

Figure 4. Packing arrangement of γ-gly showing the pockets on the fast-growing (00–1) face that are poisoned by the adsorption of ethanol and methanol molecules (shown as "balls and sticks"). In addition to the $OH_{sol}\cdots O_{gly}^-$ interaction, three $CH_{sol}\cdots O_{gly}^-$ interactions are formed that are similar in geometry to, but weaker than, the three $N{-}H_{gly}\cdots O_{gly}^-$ interactions that glycine would make. Note that a water molecule within the pocket is only weakly bound as the two possible $OH_{sol}\cdots O_{gly}^-$ hydrogen-bonding interactions would be counterbalanced by a lone-pair $O_{sol}\cdots O_{gly}^-$ repulsion (shown in red); therefore, the pocket is relatively accessible to approaching glycine molecules.

that γ-gly, grown in aqueous solutions and in the presence of auxiliaries that inhibit the crystallization of α-gly, appear as [001] needles that grow along the polar *c* axis much faster at the end of the crystal with the CO_2^- groups than at the opposite capped end. This unidirectional growth was interpreted in terms of a "relay" mechanism, according to which the corrugated face at the CO_2^- end will have ridges covered by bound water and pockets that are weakly hydrated, if at all. These pockets are then amenable to being quickly filled with NH_3^+ groups from glycine molecules that, in turn, will induce stripping of the water molecules from the ridged surfaces.[16] However, ethanol and methanol solvent molecules can reside within the pockets through $OH_{sol}\cdots O_{gly}^-$ and $CH\cdots O_{gly}^-$ hydrogen-bonding interactions, thus inhibiting growth at the CO_2^- end of the crystal (Figure 4). In several of the crystallization experiments carried out in water–ethanol mixtures, the few γ-gly crystals that were observed exhibited a morphology in keeping with the proposed inhibition by ethanol or methanol of growth along the otherwise fast-growing CO_2^- end of the crystal (Figure 2b).

In conclusion, the analysis of the growth kinetics of different polymorphs in terms of their crystal structures and solvent–surface, solute–solvent, and solute–solute interactions allows a rationale to be proposed for understanding the crystallization of kinetically controlled polymorphs.[24] Herein, focus was placed on the interplay between the various solute species[25] and solvent–surface interactions to account for the polymorph precipitated. These results also support the established model that removal of the solvent molecules is an important rate-determining step in the growth of a given face. The ideas presented herein should be relevant for understanding and controlling crystal morphology and the polymorphism of systems that form hydrogen-bonding patterns, such as amino acids, carboxylic acids, and primary and secondary amides.

Experimental Section

Crystallization experiments were performed in covered crystallizing dishes at room temperature without stirring. α-Gly crystals were grown from aqueous solutions containing 33.3 g gly/100 mL water. β-Gly crystals were grown from ethanol/water solutions (50, 26.1, and 10% ethanol (v/v)) and 50% (v/v) methanol/water solutions containing 4.0, 19.04, 35.9, and 5.0 g gly/100 mL solvent, respectively. X-ray single-crystal and powder-diffraction measurements were used to characterize the crystals. Crystals of β-gly were also grown in the absence and in the presence of racemic tryptophane in crystallizing dishes on the stage of an optical microscope with an attached digital video camera. Snapshots taken every 7 s were used to determine the growth of β-gly at both ends of the needlelike crystals by measuring on each image the increase in length at each end of the specimen crystals relative to a reference point.

Asymmetric Catalysis

DNA-Based Asymmetric Catalysis**

Gerard Roelfes and Ben L. Feringa**

The ubiquitous right-handed double helix of DNA is arguably the most elegant example of chirality in nature, yet chirality in biocatalysis is almost exclusively the domain of the enzymes encoded by DNA.[1] The direct transfer of chiral information from DNA to chemical reactions will require the use of DNA-based catalysts. In marked contrast to catalytic RNAs, which have been employed successfully in a wide range of reactions including enantioselective catalysis,[2,3] the synthetic repertoire of "DNAzymes" is still very modest.[4] The limited applicability of catalytic DNA has occasionally been attributed to the absence of the 2′-OH functional group in the sugar-phosphate backbone and the propensity for natural DNA to adopt a double-helical duplex structure, which precludes the formation of catalytically competent tertiary structures.[4] Although the catalytic power of DNA has been enhanced by the incorporation of nucleotide bases with extended functionality,[5] enantioselective catalysis based on DNA has yet to be reported. However, the reported chirality transfer from DNA in stoichiometric DNA-templated synthesis, which leads to diastereoselectivity in chemical reactions and enantioselection of chiral substrates,[6] suggests the potential of DNAzymes in asymmetric catalysis.

Herein, we demonstrate that the chirality of the DNA double helix can be transferred directly to a metal-catalyzed reaction, in the present case the copper(II)-catalyzed Diels–Alder reaction (Figure 1). This can be done by positioning a nonchiral or racemic catalyst in intimate contact with DNA and using the chiral information of the DNA double helix to generate reaction products with an excess in one of their enantiomers. These artificial DNAzymes can be generated through the propensity of small aromatic molecules to intercalate in a noncovalent, yet kinetically stable and stereoselective fashion, which enables the anchoring of metal complexes to DNA.[7] This noncovalent and modular approach allows rapid structural variation and optimization of the catalytic system.

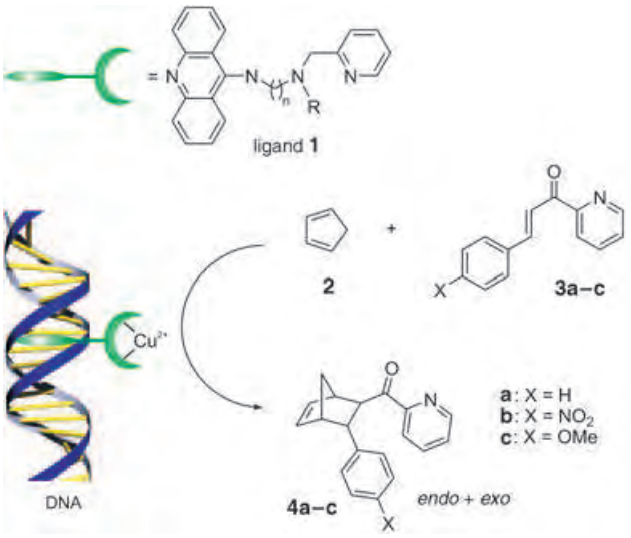

Figure 1. Schematic representation of the asymmetric Diels–Alder reaction of cyclopentadiene (**2**) with aza-chalcone **3**, catalyzed by copper complexes of ligand **1** in the presence of DNA.

The catalyst is a complex formed in situ from copper(II) with ligand **1**, which contains three key structural features: a DNA-intercalating moiety such as 9-aminoacridine, a spacer component, and a metal-binding group. The ligands were prepared in an efficient and straightforward fashion starting from monoprotected diamines (Supporting Information).[8] The copper(II) complex has a characteristic green color, with a weak UV/Vis spectroscopic absorbance at $\lambda_{max} = 620$ nm ($\varepsilon = 50\,M^{-1}cm^{-1}$) in the case of ligand **1a** (Supporting Information). This absorption, which is typical for copper di- and polyamine complexes,[9] is slightly red-shifted in the presence of DNA ($\lambda_{max} = 660$ nm). The addition of extra copper salt did not give a significant increase in this absorption. The combination of DNA with either $Cu(NO_3)_2$ or the free ligand does not have discernable features in this wavelength region, which demonstrates that DNA does not sequester the copper(II) ion from the ligand. Although complexation of these achiral ligands to copper generates chiral complexes, they are formed as a racemic mixture; thus any enantiomeric excess found in the product of the catalyzed reaction originates from DNA.[10]

The Diels–Alder reaction between cyclopentadiene (**2**) and the aza chalcone **3** in water[11] was catalyzed by copper(II) complexes of ligand **1** in the presence of salmon testes or calf thymus DNA, both of which are readily available and inexpensive. The reaction was allowed to proceed until $>80\,\%$ conversion. Product **4** was obtained as a mixture of the *endo* (major) and *exo* (minor) isomers, both with a significant enantiomeric excess, depending on the ligand used (Table 1). A series of control experiments established that the combination of ligand, copper salt, and DNA is required to obtain both efficient catalysis and enantioselectivity (Supporting Information).

[a] All experiments were carried out with salmon testes DNA under the standard conditions (see Experimental Section) unless noted otherwise. [b] Conditions: catalyst (0.18 mM), dienophile (4 mM), cyclopentadiene (34 mM). [c] Calf thymus DNA. [d] DNA = synthetic duplex $d(GACT)_2$-$(AGTC)_2$ (0.39 mM), cyclopentadiene (21 mM), buffer contained NaCl (75 mM).

The substituent R and the spacer length *n* of the ligand are crucial for both the observed enantioselectivity and the enantiopreference (that is, which enantiomer is formed in excess). A screen of ligands with a fixed spacer length ($n = 3$) revealed the importance of the R group and specifically, the requirement for it to contain an aromatic (arylmethyl) group (Supporting Information). This suggests the involvement of π–π interactions between the substituent and the dienophile, as was previously described in the case of catalysts based on amino acids.[11] The best results in the series examined were obtained for ligands with R = 1-naphthylmethyl (**1a**), for which an *endo*/*exo* ratio of 98:2 and 49% *ee* for the *endo* isomer were found (Table 1, entry 1). Comparison of these results with those from ligand with R = 2-naphthylmethyl, which did not produce any significant enantiomeric excess, demonstrates the subtlety of the interaction of the substituent of the ligand with the dienophile.

Elongation of the spacer in **1a** resulted in a rapid decrease of the enantioselectivity; for $n = 5$ (**1c**) no significant enantiomeric excess was observed (Table 1, entry 7). In contrast, a decrease in spacer length to $n = 2$ (**1d**) gave a value similar to **1a** (48% *ee*), but surprisingly of the opposite enantiomer (entry 8). These findings demonstrate that intimate contact between the DNA double helix and the catalyst is required for efficient chirality transfer. They therefore offer compelling evidence for DNA as the source of chirality in these reactions.

The special case of R = 3,5-dimethoxybenzyl gave the same enantiomer of the product in excess regardless of spacer length ($n = 2$ or 3). In the case of ligand **1f** ($n = 2$) relatively more of the *exo* isomer was formed (*endo*/*exo* = 92:8), with 37% *ee* for the *endo* and 78% *ee* for the *exo* isomer (Table 1, entry 10).

The difference in behavior of the catalyst based on ligands **1a** and **1f** is also evident from the reactions with substrates **3b** and **3c**, which contain a nitro and a methoxy group, respectively, on position 4 of the phenyl ring. Although the conversions observed with these substrates were generally lower ($\approx 50\%$) than those obtained with **3a** (a possible result of their lower solubility), similar results with **3c** and slightly lower *ee* values with **3b** were obtained with ligand **1a** (Table 1, entries 4 and 5). In contrast, the complex with ligand **1f** gave a much improved enantiomeric excess for both substrates; in the case of the methoxy-substituted substrate **3c**, up to 53 and 90% *ee* were observed for the *endo* and *exo* isomers, respectively (entry 15). These values represent the highest *ee* values obtained thus far with this system. These results provide strong evidence that the interaction of the substituent R with the dienophile is important for the stereochemical outcome of the reaction. However, the exact nature of this interaction and in particular, the differences between R = 1-naphthylmethyl and R = 3,5-dimethoxybenzyl are the subject of further study.

Neither the substrate/catalyst ratio, which could be increased to 4 mM:0.18 mM dienophile/catalyst (that is, catalyst at 4.5 mol% with respect to substrate, giving up to 22 turnover events; Table 1, entries 2 and 11) nor the source of the DNA used (salmon testes versus calf thymus DNA; entries 3 and 12) had a significant effect on the results. A small synthetic dsDNA (the self-complementary 16-mer $d(GACT)_2(AGTC)_2$) also gave a similar enantioselectivity for **1f** (entry 13), which rules out any possible residual impurity in the DNA from natural sources as influencing the catalytic reaction. Interestingly, in this case the *exo* product was favored even more.

The results presented herein demonstrate that the chirality of DNA can be transferred directly to a catalytic reaction. Despite the invariance of the chirality of the DNA employed, both enantiomers of the Diels–Alder product are accessible by a judicious choice of ligand. The key strengths of the present system are its modular nature, which together with the noncovalent binding of the catalytic moiety to DNA and the use of achiral ligands, allows rapid structural variation and optimization of catalysts for new reactions. An additional advantage of the present approach is the isolation of the product from the reaction mixture. The use of a DNA intercalator in the catalytic system creates a very tightly bound Cu–ligand–DNA complex, which remains in the aqueous phase during extraction of the products. The possibility to address specific DNA sequences in both natural and synthetic DNA, for example, by using a selective DNA binding moiety tethered to the catalyst, is particularly appealing for the future design of DNA-based catalysts.

Experimental Section

Catalytic Diels–Alder reactions: DNA-bound catalyst in buffered solution (salmon testes DNA (1.3 mg mL^{-1}), catalyst (0.3 mM, ligand/Cu^{2+} = 1.3), and MOPS (20 mM, pH 6.5))[12] was prepared by mixing salmon testes DNA (2 mg mL^{-1}) in solution with MOPS (30 mM) in a

volume of 10 mL (prepared 24 h in advance) with a solution of the preformed catalyst: $Cu(NO_3)_2$ (0.9 mM) and ligand **1a** (1.17 mM) in a volume of 5 mL. An aliquot of a stock solution of dienophile **3a** in CH_3CN (0.5 M, 30 μL) was added to a final concentration of 1 mM and the mixture was cooled to 5 °C. The reaction was started with the addition of cyclopentadiene (5 mM, 7 μL) and mixed by continuous inversion for 3 days, followed by extraction of the product with diethyl ether. After ^{1}H NMR spectroscopic analysis the percent *ee* value was determined by chiral HPLC (Daicel chiralcel-ODH column, elution with heptane/*i*PrOH 98:2). Selected products were purified by column chromatography and analyzed on an Daicel chiralpak-AD column to confirm the results obtained from analysis of the crude product.

NMR Spectroscopy

Local Structure and Anisotropic Backbone Dynamics from Cross-Correlated NMR Relaxation in Proteins**

Phineus R. L. Markwick, Remco Sprangers, and Michael Sattler**

The molecular function of biomacromolecules is determined by both their 3D structure and conformational dynamics. NMR cross-correlated relaxation (CCR) contains information about local structure and local anisotropic dynamics. CCR arises from the interference of two relaxation mechanisms such as chemical shift anisotropy (CSA) and dipole–dipole (DD) interactions, which are described by tensors in 3D space, and contains information about the relative orientation of these tensors and their correlated motion.[1–4] In this respect, CCR rates involving CSA tensors are most useful, as they sample local structure and dynamics along three orthogonal axes. Over the past few years, numerous NMR experiments have been designed to measure cross-correlated relaxation rates to determine local molecular geometry,[3,5] to study local dynamics,[6–9] and to characterize chemical-shift tensors in solution.[10–12] Different models of anisotropic local motion of the peptide plane have been discussed.[7,9,13–15]

Whereas CCR processes in principle contain an enormous amount of information, the interpretation of these relaxation rates must be treated with great care. For example, a CSA/DD relaxation process depends on many factors, including the local molecular structure, the magnitude of the CSA and orientation of the shift tensor in the fixed molecular frame, and local anisotropic dynamics.[2] To simplify this problem, the magnitude of the CSA and orientation of the shift tensor, both of which are difficult to access experimentally and theoretically, are often treated as fixed invariable parameters. Alternatively, the effect of dynamics is included through a generalized (isotropic) order parameter, which represents a considerable simplification to the complex hierarchy of internal anisotropic dynamic modes that characterize the local motion of the peptide plane. Recently, the vector fluctuations of N–H and $C'–C^{\alpha}$ bonds were monitored by studying the temperature dependence of cross-correlated relaxation rates rather than their absolute values, thereby diminishing the influence of uncertainties in CSA parameters.[9]

With extended DFT calculations, we previously found significant site-specific variations in both the magnitude of the C′ CSA (the relative magnitudes of the three principal components of the shift tensor δ_{11}, δ_{22}, and δ_{33}) and the orientation of the C′ chemical-shift tensor (with principal axes ξ_{11}, ξ_{22}, and ξ_{33}; Figure 1). We formulated a simple model for the C′ CSA, which depends only on the isotropic chemical shift, δ_{iso}.[16] The δ_{11} and δ_{33} components are ostensibly

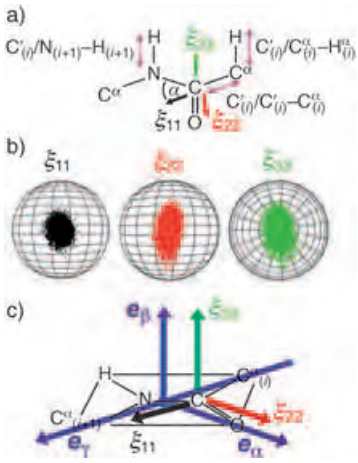

Figure 1. a) Schematic representation of the three C′ CSA/DD CCR rates studied. The average orientation of the C′ chemical-shift tensor (angle α) is also indicated (principal axes ξ_{11}, ξ_{22}, and ξ_{33}). The ξ_{33} axis lies perpendicular to the peptide plane, whereas the ξ_{11} and ξ_{22} axes lie in the peptide plane. b) Temporal fluctuations of the peptide plane of Val126 over the MD simulation. c) Representation of the average orientation of the C′ chemical-shift tensor (principal axes ξ_{11}, ξ_{22}, and ξ_{33}) and average GAF principal axes ($\boldsymbol{e}_\alpha$, $\boldsymbol{e}_\beta$, and $\boldsymbol{e}_\gamma$) in the local molecular frame.

invariable with average values of 247 ± 2 ppm and 85 ± 1 ppm, whereas the δ_{22} component varies linearly with the isotropic chemical shift ($\delta_{22} = 3\delta_{iso} - 332$ ppm). The parameterization of our CSA model[16] is notably improved in comparison with previous proposals,[17,18] and is supported by a recent analysis of experimental CCR rates, although local anisotropic motion was not explicitly considered in this study.[12] We also found that the orientation of the shift tensor is site-specific with the average α angle (the angle between ξ_{11} and the C′–N bond; Figure 1) varying from 22°–46°.[16]

Herein we combine classical molecular dynamics (MD) and extended DFT simulation methods with multidimensional NMR spectroscopy to study transverse C′ CSA/DD CCR processes. The extended DFT calculations provide an accurate representation of the C′ CSA magnitude and the orientation of the chemical-shift tensor in the fixed molecular frame. The MD simulation contains information about local anisotropic dynamics. Thus, by combining DFT and MD we can consider the relevant factors that affect the CCR rates and dissect their relative contributions.[2] Employing the Gaussian Axial Fluctuation (GAF) model,[19,20] we study local anisotropic fluctuations of the peptide plane orientation and provide an efficient method to determine these from cross-correlated relaxation.

We have measured three CSA/DD cross-correlated relaxation rates involving the carbonyl CSA: $C'_{(i)}$/ $C^{\alpha}_{(i)}$–$H^{\alpha}_{(i)}$, $C'_{(i)}$/$N_{(i+1)}$–$H_{(i+1)}$, and $C'_{(i)}$/$C'_{(i)}$–$C^{\alpha}_{(i)}$ (Figure 1) for the 55-residue Tudor domain. A CSA/DD CCR rate, $\Gamma^{(CSA/DD)}$, associated with the interference of a chemical-shift tensor centered at nucleus J and a magnetic dipole–dipole interaction between nuclei K and L is given by:[1,3,4]

$$\Gamma^{(CSA/DD)}{}_{J/K-L} = 2\,d\,c \sum_i \{\delta_{ii}\, 4J^{cc}_{ii,K-L}(0)\} \tag{1}$$

in which $d = \sqrt{(1/8)}\,(\mu_0/4\pi)\,(h/2\pi)\,\gamma_K\,\gamma_L\,\langle r^{-3}_{K\text{-}L}\rangle$ and $c = \sqrt{(1/8)}\,\gamma_J B_0$ are constant factors for the dipolar and CSA interactions, respectively (Supporting Information).[*]

The cross-correlated spectral density functions, $J^{cc}_{ii,K-L}(\omega)$, are associated with the average relative orientation and temporal correlated motion between the i^{th} principal axis of the chemical-shift tensor and the K–L dipolar interaction. Assuming time-scale separation for slow isotropic rotation diffusion with an associated correlation time, τ_c, and fast local anisotropic motion, the spectral density function can be obtained by Fourier transformation of the associated cross-correlation function as:[1,3,4]

$$J^{cc}_{ii,K-L}(\omega) = 2\int_0^{\infty} C_{ii,K-L}(t)\,cos\,\omega t\,dt \tag{2a}$$

$$C_{ii,K-L}(t) = 1/5^{(t/\tau_c)}\,C^{int}_{ii,K-L}(t) \tag{2b}$$

$$C^{int}_{ii,K-L}(t) = \langle \boldsymbol{d}_{K-L}(0)\,\xi_{ii}(t)\rangle \equiv \langle P_2\,(cos\,\theta_{ii,K-L}(t))\rangle \tag{2c}$$

The first and second terms on the right side of Equation (2b) describe the correlation functions for internal motion assuming overall isotropic tumbling, which is a reasonable assumption for the Tudor domain (the ratio of $D_{\parallel}/D_{\perp} = 1.02$). The description of anisotropic rotational diffusion involves rather complex spectral densities,[3,21] and under certain limits the influence of anisotropic rotational diffusion can be approximated.[21] The values $\boldsymbol{d}_{K-L}$ and ξ_{ii} represent the orientation of the dipole–dipole interaction (K–L) and the principal chemical-shift tensor axes, respectively. $\theta_{ii,K-L}$ is the projection angle between the dipole–dipole vector and the i^{th} principal axis of the chemical-shift tensor. Herein, the spectral density functions in Equation (1) are derived numerically from the MD simulation according to Equation (2).

The cross-correlation functions can be expressed analytically with the model-free approach,[22,23] in which the average relative orientation and amplitude of the correlated motion of the two interaction vectors is defined by a single parameter, $S^2_{ii,K-L}$, known as the order parameter (Supporting Information). In the 3D GAF model, the anisotropic order parameter $S^2_{ii,K-L}$ is described by assuming Gaussian fluctuations around three principal axes, which are rigidly attached to the peptide plane. The 3D GAF parameters for the Tudor domain (principal axes $\boldsymbol{e}_\alpha$, $\boldsymbol{e}_\beta$, and $\boldsymbol{e}_\gamma$) and the standard deviation of

[*] Note that if K = J, that is, for a CCR that involves the CSA of spin J and a dipole–dipole interaction between spins J and L, $\Gamma^{(CSA/DD)}_{J,J-L} = 2\,d\,c \sum_i \{\delta_{ii}\,(4J^{cc}_{ii,J-L}(0) + 3J^{cc}_{ii,J-L}(\omega_J)\}$.

the angular fluctuations (σ_α, σ_β, σ_γ) have been extracted from a MD trajectory.[19,20]

Figure 2a shows the correlation between the simulated [Eq. (1) and Eq. (2)] and experimental C′/C$^\alpha$–H$^\alpha$ cross-correlated relaxation rates. In general, an excellent agreement between the experimental and simulated data is observed. Deviations are found for residues in loop regions, which, apart from Asp96, exhibit a low heteronuclear {^{1}H}–^{15}N NOE (<0.65). Presumably, these differences between simulation and experiment arise from incomplete sampling of ψ angles averaged over the MD simulation. Particularly in secondary structure elements, the motion of the C′ chemical-shift tensor principal axes and the C$^\alpha$–H$^\alpha$ bond vector is highly correlated, and the associated cross-correlation functions extracted from the MD trajectory exhibit almost no decay.

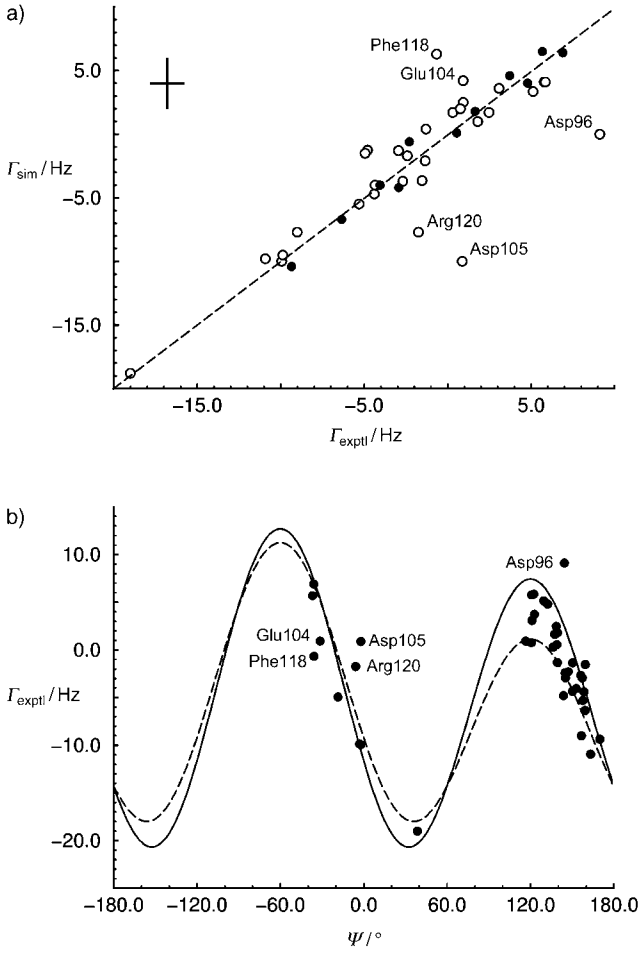

Figure 2. a) Experimental and simulated C′/C$^\alpha$–H$^\alpha$ CCR rates (Γ) for all residues in the Tudor domain excluding terminal residues and glycine residues. Filled and empty circles represent residues whose chemical-shift tensors were calculated with the extended DFT method or with the C′ CSA model, respectively. Under the model, the orientation of the shift tensor was fixed with $\alpha = 34°$. For five residues (labeled) the correlation between experiment and theory is poor. Each of these residues is in a loop region and, except for Asp96, exhibits a low heteronuclear {^{1}H}–^{15}N NOE (<0.65). b) Experimental C′/C$^\alpha$–H$^\alpha$ CCR rates plotted with respect to the ψ angle taken from the X-ray crystallographic structure.[34] Lines indicate the expected CCR rates assuming an C′ isotropic chemical shift of 168 ppm (-----) and 180 ppm (——). In both cases the orientation of the C′-shift tensor is fixed with $\alpha = 34°$.

This CCR process is predominantly dependent on the ψ angle, which determines the average orientation between the principal axes of the C′ shift tensor and the C$^\alpha$–H$^\alpha$ bond vector.[24–27] However, as can be observed in Figure 2b, site-specific variations of the C′ chemical-shift tensor also have an effect on the resulting relaxation rates, particularly when $60° < \psi < 180°$ for residues in β sheet secondary structure elements. Considering all residues studied in the Tudor domain, observed CCR rates vary between $-19.0\ s^{-1}$ and $+9.0\ s^{-1}$. The effect of C′ CSA variations causes a change in the relaxation rate of up to $7\ s^{-1}$ (25% of the total observed range), whereas the effect of dynamics (in secondary structure elements) only produces a change in the CCR rate of up to $2\ s^{-1}$ (7% variation). The orientation of the C′ chemical-shift tensor relative to the peptide plane has a small effect on the relaxation rate ($<3\ s^{-1}$) and is observed only in α-helical regions (Supporting Information).

This analysis indicates that when C′/C$^\alpha$–H$^\alpha$ CSA/DD CCR rates are used for refining the backbone angle ψ in secondary structure elements,[27,28] local dynamics has only a small effect on the measured rates. However, site-specific variations of the C′ CSA should clearly be taken into account. This can be addressed easily with the CSA model based on the isotropic C′ chemical shift.[16]

The C′/N–H CCR process depends predominantly on the C′ CSA (the magnitude of the δ_{22} component) and local anisotropic dynamics. This is highlighted in Figure 3, in which experimental and simulated CCR rates are compared with a fixed shift tensor[29] (Figure 3a) and our site-specific shift tensor[16] (Figure 3b); each case presents the simulated results with and without the inclusion of dynamics. On average, the ω angle is $180° \pm 5°$ in all residues studied, and such small variations in this angle have a negligible effect on the relaxation rates. Similarly, variations in the orientation of the C′-shift tensor in the fixed molecular frame (the α angle) have a very small effect on this CCR process (Supporting

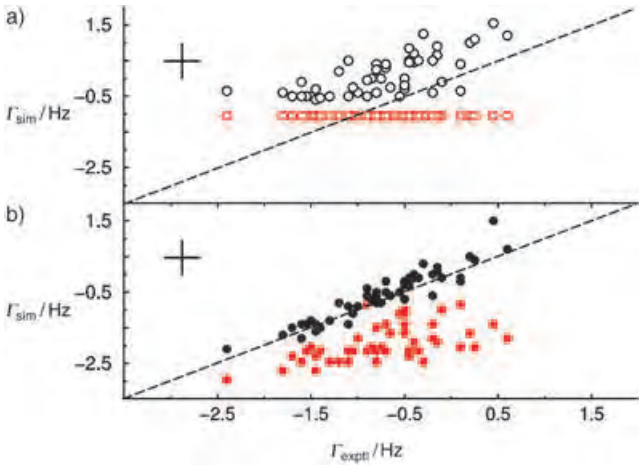

Figure 3. a) Experimental and simulated C′/N–H CCR rates assuming a fixed invariant C′ CSA[29] excluding (red ○) and including (black ○) the effect of local anisotropic dynamics. b) Experimental and simulated C′/N–H CCR rates with the site-specific C′-shift tensor excluding (red ●) and including (black ●) the effect of local anisotropic dynamics. In all cases a N–H bond length of 1.02 Å is employed, and the orientation of the C′ chemical-shift tensor is fixed with $\alpha = 34°$.

Information). This relaxation rate has been used previously to characterize local anisotropic dynamics—that of the peptide plane.[8,30] The analysis presented herein strongly argues that site-specific CSA variations have to be considered before extracting dynamic parameters from this CCR rate, as discussed below.

Experimental and simulated C′/C′–C$^{\alpha}$ cross-correlated relaxation rates for the 12 carbonyl groups studied with our extended DFT procedure are shown in Figure 4. This CCR

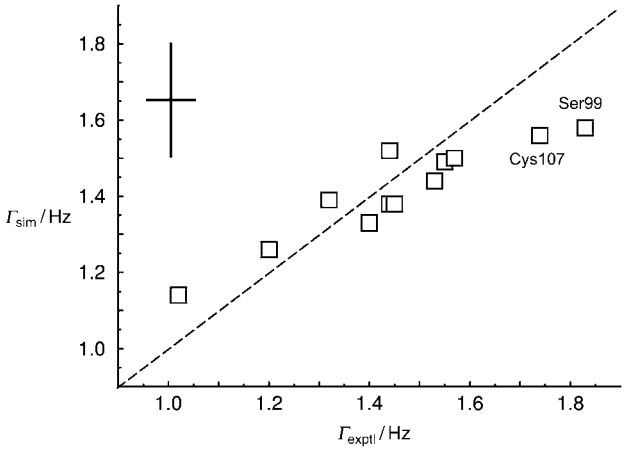

Figure 4. Correlation between experimental and simulated C′/C′–C$^{\alpha}$ CCR rates for the 12 residues studied with the extended DFT chemical-shift calculation.[16] The C′/C′–C$^{\alpha}$ CCR rate depends strongly on the orientation of the chemical-shift tensor (the α angle). Large CCR rates such as those of Ser99 and Cys107 are observed when the α angle is very large (>42°). Unfortunately, it is difficult to accurately estimate the magnitude of the site-specific α angle. The α angle of each residue is therefore obtained directly from the DFT calculations.

process depends primarily on the orientation of the shift tensor in the molecular frame. A change in the α angle alone (Figure 1) from 20° to 50° causes a change in the C′/C′–C$^{\alpha}$ CCR rate of 0.6 s^{-1}, which covers the range of relaxation rates measured. Local anisotropic dynamics leads to variations that change the relaxation rate by up to 0.30 s^{-1} (50% of the total observed range). The variation in the carbonyl CSA can cause a change in the relaxation rate of up to 0.15 s^{-1} (25% of the total range). Therefore, local anisotropic dynamics contributes only partially to the observed variations in this CCR rate, and variations in the α angle have to be considered.

For C′/N–H and C′/C′–C$^{\alpha}$ CCR processes, local anisotropic motion of the peptide plane has a considerable effect on the observed relaxation rates. To further investigate the effect of local anisotropic motion on these CCR processes, we employed the 3D GAF model of Brüschweiler and coworkers.[20] This model is particularly useful, as it describes the motion of the peptide plane in terms of physically meaningful geometrical parameters. For all residues in the Tudor domain we found that the principal axis $\boldsymbol{e}_{\beta}$ sits perpendicular to the peptide plane and the $\boldsymbol{e}_{\gamma}$ axis lies at an angle of 36°–40° relative to the C′–N bond. The 3D GAF principal axes of rotation are therefore almost exactly co-oriented with the average DFT calculated principal axes of the C′-shift tensor in the fixed peptide frame (Figure 1). The standard deviations of amplitude fluctuations (σ_{α}, σ_{β}) over the MD trajectory of 10 ns change very little from residue to residue, with average values in the β-sheet regions (6±2°, 4.5±2°), in the 3_{10} helix (5±2°, 4±2°) and in the loop regions (11°±3°, 8°±3°). A significantly larger variation was observed in the fluctuation of σ_{γ} from 9° to 17° in the secondary structure elements and up to 25° in the more flexible loop regions. These results are similar to a previous analysis of ubiquitin based on a set of autocorrelated relaxation rates.[15]

Through simplification of the 3D GAF model to an effective 1D GAF model, in which $\sigma_{\alpha}=\sigma_{\beta}=5°\equiv\sigma_{\alpha\beta}$ (the global average value for all residues in secondary structure elements) and by using the average orientation of the 3D GAF principal rotation axes, we have calculated the effect of the variation of σ_{γ} on the C′/N–H CCR rate. The resulting 2D CCR map (Figure 5), which includes the effect of site-specific

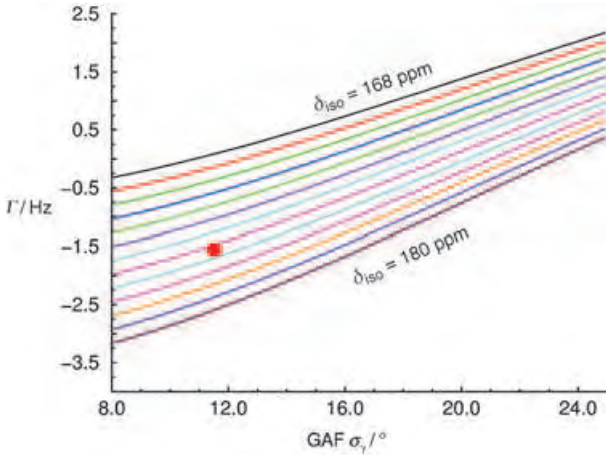

Figure 5. A 2D CCR map for C′/N–H CCR. From top to bottom, the isotropic C′ chemical shift varies from 168 to 180 ppm with lines drawn every 1 ppm; $\sigma_{\alpha\beta}$ is fixed at 5°. For a given C′/N–H CCR rate, the corresponding σ_{γ} can be extracted from the 2D map, as shown for Val126 (δ_{iso} = 175.3 ppm; C′/N–H CCR rate = −1.6 Hz).

C′ CSA variations, allows the accurate estimation of σ_{γ} from a given experimental C′/N–H CCR rate. As shown in detail in the Supporting Information, variations in the orientation of the C′-shift tensor and $\sigma_{\alpha\beta}$ generally have a negligible effect on this CCR process. The resulting σ_{γ} amplitude fluctuations correlate very well with the autocorrelated ^{15}N order parameter calculated from ^{15}N relaxation data with TENSOR2[31] (Figure 6). This important result demonstrates that the different relaxation rates provide a consistent description of the local anisotropic dynamics. This observation also argues that out-of-plane motion of the N–H bond vector[9,32] does not have a strong effect on these relaxation rates.[*] Given the larger amplitude of σ_{γ} compared with $\sigma_{\alpha\beta}$, our GAF analysis is

[*] In fact, this is indicated by comparing C′/N–H cross-correlated order parameters calculated numerically from the MD simulation [Eq. (1) and Eq. (2)] with the order parameters extracted from the 3D GAF analysis of the same simulation. The difference in the numerically calculated order parameters (which include N–H out-of-plane motion) and the 3D GAF order parameters (which do not sense N–H out-of-plane motion) is less than 0.03, resulting in a negligible change in the associated CCR rates.

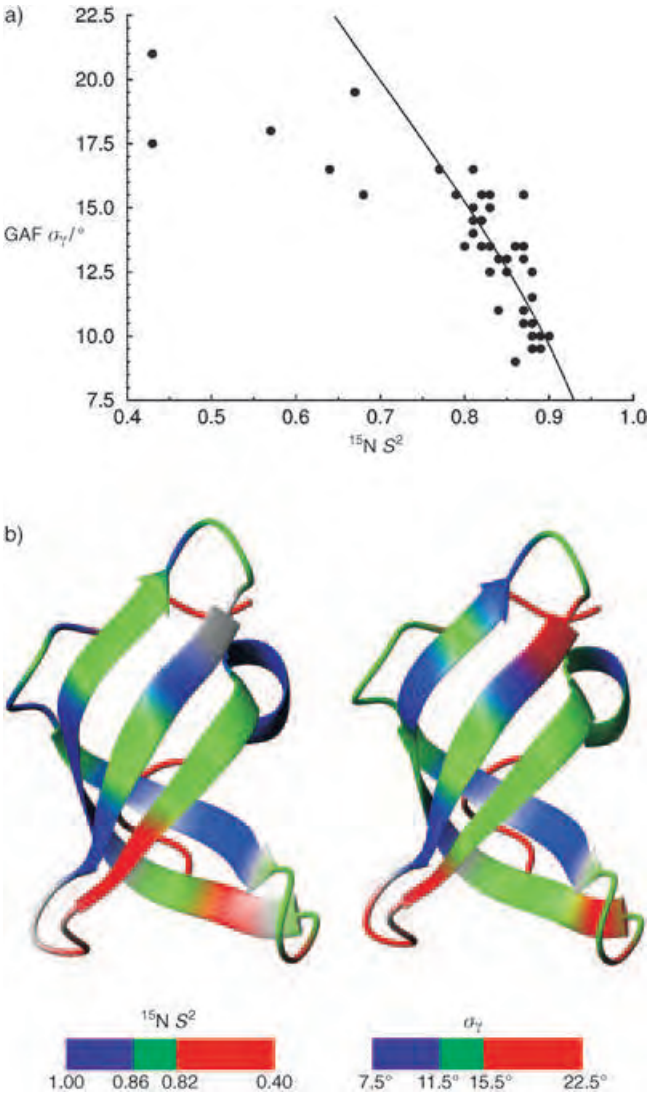

Figure 6. a) Correlation between the order parameter S^2 extracted from ^{15}N autorelaxation rates and σ_γ, which is extracted from the analysis of C′/N–H cross-correlated relaxation data. Assuming that $\sigma_\alpha = \sigma_\beta = 5°$, the theoretically expected correlation[19,20] is indicated by the solid line. For residues in secondary structure elements with the ^{15}N order parameter $S^2 = 0.75$, the result is in good agreement with the expected correlation. For the more flexible residues in terminal loop regions, a distinct deviation is observed. This results partly from the fact that for these residues, $\sigma_{\alpha\beta}$ is much larger than 5°, and also from the fact that for these very flexible regions, the 3D GAF model breaks down. b) Representation of the variations of the ^{15}N order parameter S^2 and σ_γ visualized on the Tudor domain. Residues for which no experimental data are available are rendered in gray.

consistent with so-called crankshaft motions around the $C^\alpha_{(i)} \cdots C^\alpha_{(i+1)}$ axis (Figure 1c).[7,13–15] We have also calculated 2D CCR maps for the C′/C′–C$^\alpha$ CCR rate, which demonstrate the strong dependence of this rate on the orientation of the C′-shift tensor and variations in $\sigma_{\alpha\beta}$ (Supporting Information).

In summary, we have performed a detailed analysis of C′ CSA/DD CCR rates by combining classical MD and extended DFT simulation methods. We have found that the C′/C$^\alpha$–H$^\alpha$ CCR rate depends primarily on the local protein structure (the ψ angle), but is also affected by variations in the C′ CSA. In contrast, the C′/C′–C$^\alpha$ CCR rate strongly depends on the orientation of the carbonyl chemical-shift tensor in the fixed molecular frame and local anisotropic dynamics, but C′ CSA variations also play a role. The C′/N–H CCR rate depends principally on the carbonyl CSA (the magnitude of δ_{22}) and local anisotropic dynamics and is thus most useful for the characterization of such motions. Employing the 3D GAF model, it is possible to acquire detailed information concerning the local anisotropic motion of the peptide plane from a single cross-correlation: the C′/N–H CCR rate.

Cross-correlated relaxation processes contain a wealth of information concerning both the structure and dynamics of biomolecular systems and are exploited in the design of relaxation-optimized NMR experiments.[33] The improved description of the parameters presented herein will be useful for future studies of the characterization of local anisotropic dynamics. A dissection of the relaxation data into different contributing factors demonstrates the power of combining theoretical and experimental techniques to probe the structure and dynamics of biomacromolecules.

Molecular Devices

Electrochemical Addressing of the Optical Properties of a Monolayer on a Transparent Conducting Substrate**

*Atindra D. Shukla, Amitava Das, and Milko E. van der Boom**

Thin-film chemistry and surface engineering, in particular the generation of new molecular electronic and photonic materials, are attracting considerable interest.[1] The development of a fundamental understanding of molecular interactions, orientation, and function is essential for the formation of device-quality organic mono- and multilayers.[2] Direct control of thin-film properties might lead to a wide range of applications in molecular-based optics and electronics. For instance, low-voltage redox-active molecules may be potentially useful for the design of new monolayers for charge-storage memory devices.[3,4] These molecular-based memories, bound to Si(100), withstand operation and device-processing temperatures.[4] However, many challenges need to be addressed before such systems will become readily available. It has been very difficult to predict and to switch reversibly the monolayer properties for a given molecular building block. Much effort has been devoted to the development of molecular switches in solution,[5–7] whereas such systems immobilized on substrate surfaces is a rapidly developing field.[3,4,8–11] Recently Di Bella and co-workers reported the first example of a redox switch self-assembled on an optically transparent Pt electrode.[9] The optical properties of the thiol-based monolayers can be controlled by chemical oxidation and reduction. Herein, we demonstrate electrochemical switching of the optical properties of a ruthenium-based monolayer, which is covalently attached to a transparent conducting substrate surface.

The molecular building block consists of a tris(bipyridyl)-ruthenium module for charge storage and a phenol unit for covalent surface attachment (Figure 1). Functional thin films are formed by covalent assembly of the previously reported ruthenium-based molecular building block at an organic interface (Figure 1).[12] The siloxane-based coupling layers (CL) were prepared on freshly cleaned float glass, Si(100), and glass-coated with indium tin oxide (ITO). Substrates were treated with a dry pentane solution of *p*-chloromethylphenyltrichlorosilane (1:100, v/v) at room temperature for 30 min

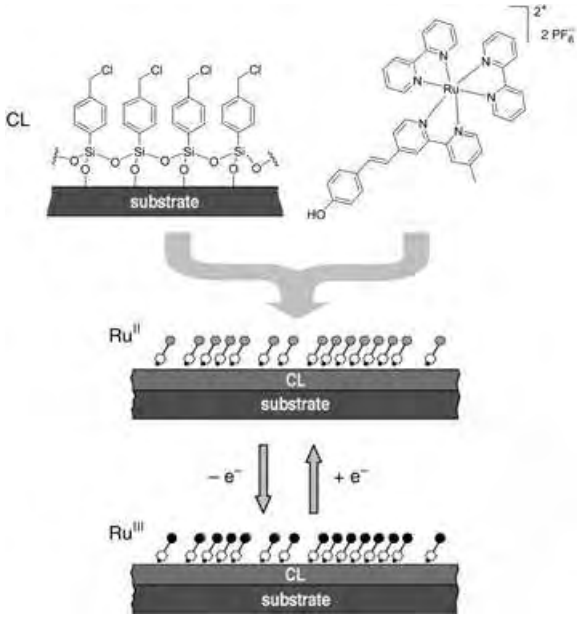

Figure 1. Formation of ruthenium-based monolayers on ITO-coated glass, glass, and silicon substrate surfaces functionalized with a chlorobenzyl-based coupling layer (CL). Electrochemical and spectroelectrochemical measurements were performed on glass coated with ITO on a single side. Monolayers were assembled only on the ITO side of the glass substrate by mechanical protection of the glass surface.

under N_2. The substrates were then thoroughly washed with copious amounts of dry pentane and dried at 115 °C for about 15 min. Subsequently, the colorless chlorobenzyl-functionalized substrates were immersed in a 2.0 mM toluene/CH_2Cl_2 (6:4, v/v) solution of the ruthenium complex, and heated for 48 h at 80 °C under N_2 by using glass pressure tubes. The resulting chromophore films were washed and sonicated (1 min) with copious amounts of CH_2Cl_2, acetone, and isopropyl alcohol, and dried under a gentle stream of N_2. Similar surface coupling reactions of benzyl halide interfaces with phenols or pyridine moieties to form ether linkages or pyridinium salts, respectively, have been reported.[13,14] The new monolayers strongly adhere to the glass and silicon substrates, are insoluble in common organic solvents, and cannot be removed by either the "Scotch-tape decohesion" test or by CO_2 snowjet cleaning.

Freshly prepared samples were characterized by a combination of semicontact atomic force microscopy (AFM), optical transmission (UV/Vis) spectrometry, X-ray photoelectron spectroscopy (XPS), electrochemistry, and spectroelectrochemistry.[14] The latter technique was used to vary and to read the optical properties of the system. XPS measurements of the Ru^{II}-based monolayer on ITO-coated glass revealed a Si/N ratio of about 1:2.1, which indicates that about 35 % of the CL molecules reacted. This is not uncommon.[15] The relatively small footprint of the CL molecules prohibits a quantitative reaction with the larger ruthenium complex. The film thickness derived from angle-resolved XPS is estimated to be 13 ± 2 Å. Semicontact AFM measurements on films grown on Si(100) substrates show an essentially smooth film surface with no evident grain boundaries. The root-mean-square surface roughness is about 0.1 nm for $1 \times 1\ \mu m^2$ scan areas (see the Supporting Information). Electrochemical measurements were performed to evaluate the redox activity of the monolayers. Figure 2 a shows the cyclic voltammograms of the monolayer on ITO-coated glass at different voltage scan rates (ν). The half-wave redox potential $E_{1/2}$ remains constant within $\nu = 100$–$1000\ mV s^{-1}$. The peak-to-peak separation (ΔE) is about 64 mV for $\nu = 500\ mV s^{-1}$. Figure 2 b shows the linear correlation of the peak current I_p versus ν. Apparently, a reversible redox process occurs involving a one-electron transfer. The ΔE value is expected to be about 60 mV for a Ru^{II}/Ru^{III} couple in solution.[16] The potential of the Ru^{II}/Ru^{III} couple $E_{1/2}$ is 0.95 V with respect to the ferrocene/ferrocenium standard.

After the initial conditioning scans, continuous cyclic voltammetry (CV) measurements show a repetitive redox behavior for at least 45 cycles. The magnitude of the ruthenium-centered oxidation current decreases slightly with the first six successive sweeps, possibly as a result of deactivation or reordering of the molecular components (Figure 3).

The UV/Vis optical absorbance measurements of the Ru^{II}-based films on glass and on ITO-coated glass substrates show a ligand-based π–π* transition band at $\lambda_{max} = 314$ nm. The low-energy metal-to-ligand charge-transfer (MLCT) band appears at $\lambda = 462$ nm. Increasing the reaction time to 72 h does not affect the intensity of these absorbance bands. In situ spectroelectrochemistry performed in air showed a

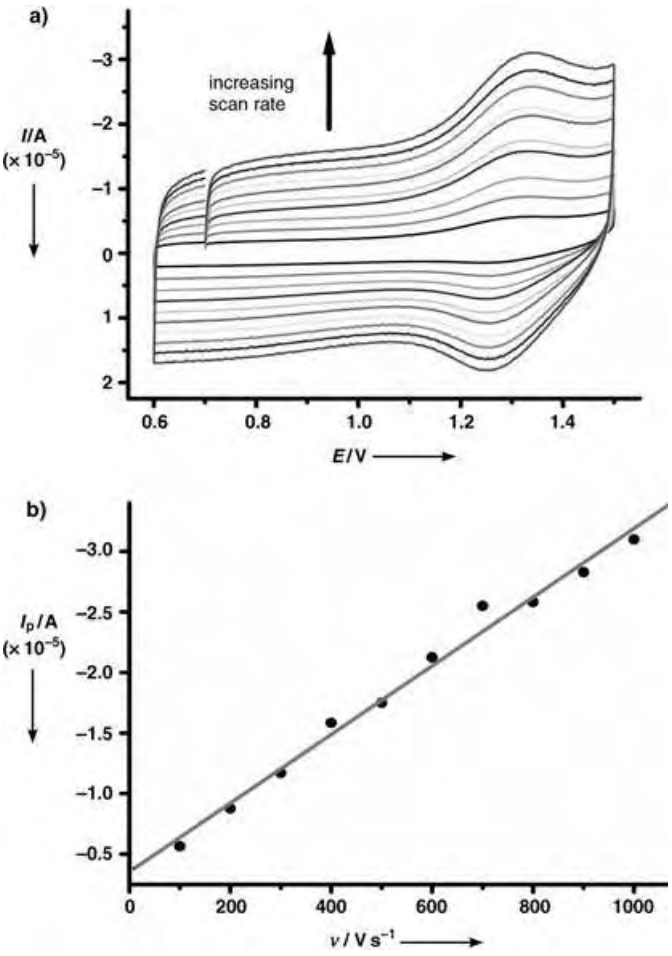

Figure 2. a) Representative cyclic voltammetric responses at different scan rates of the ruthenium-based monolayer on ITO-coated glass, which operates as the working electrode. Pt wires were used as reference and counter electrodes. The electrochemical (EC) experiments were carried out at room temperature in dry acetonitrile containing 20 mM nBu_4NPF_6 with a CHI660A potentiostat. The voltage scan rate was varied from 100 to 1000 $mV s^{-1}$ with steps of 100 $mV s^{-1}$. b) Linear correlation ($R^2 = 0.988$) of the peak current I_p versus the scan rate ν.

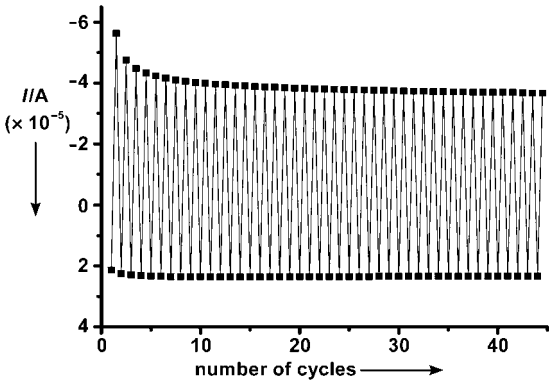

Figure 3. Representative EC redox switching as a function of redox cycles. The CV experiments were conducted at a sweep rate of 1000 $mV s^{-1}$. The lines are drawn as a guide to the eye.

significant reversible change in the intensity of the absorbance band at $\lambda_{max} = 314$ nm upon alternation of the metal

oxidation state, Ru^{II}/Ru^{III} (Figure 4). Nine repetitions of the phenomenon are shown in the inset of Figure 4; they demonstrate the possibility of optical readout of the charge storage. The MLCT band is too weak for accurate monitoring by transmission UV/Vis spectrometry.

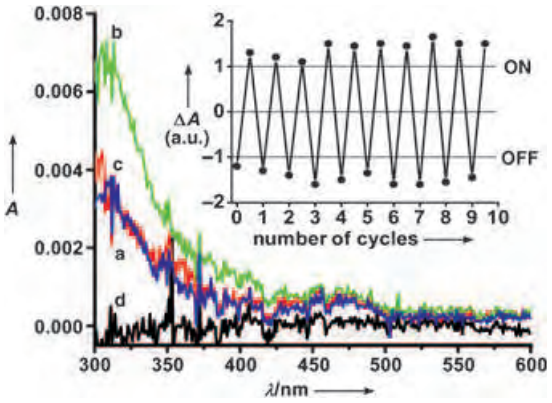

Figure 4. Absorption spectra for the optical switching of the ruthenium-based monolayer on ITO at $\lambda = 314$ nm for 10 min: a) Ru^{II}, b) Ru^{III}, c) Ru^{II}, d) baseline. The inset shows the EC on/off switching of the intensity change of the absorbance band at $\lambda = 314$ nm (ΔA, a.u.) versus the number of Ru^{II}/Ru^{III} cycles. The lines are drawn as a guide to the eye. EC oxidation was carried out by bulk electrolysis at 1.4 V, while reduction was performed at −0.1 V (20 min each). UV/Vis spectra were recorded in situ on a Cary 100 spectrophotometer after each oxidation state change.

In summary, the formation and characterization of a ruthenium-based monolayer on hydrophilic substrates, including ITO-coated glass, is described. Electrochemical variation of the metal oxidation state of the covalently surface-bound molecular building blocks triggers a reversible change in the optical properties of the ligand module. This read/write process can be carried out conveniently in air and monitored with a standard UV/Vis spectrophotometer. The low-voltage operation and the stability of the monolayer may make it a suitable candidate for nonvolatile memory devices. Extension of the scope of the work presented herein to mono- and multilayers of other metal-based chromophores, as well as to modulation of luminescence intensity and nonlinear optical responses, is in progress.

Vapochromism

Vapochromic Behavior Accompanied by Phase Transition between Charge-Polarization and Charge-Density-Wave States in a Quasi-One-Dimensional Iodine-Bridged Dinuclear Platinum Compound**

Hiroyuki Mastuzaki, Hideo Kishida, Hiroshi Okamoto,* Kouichi Takizawa, Satoshi Matsunaga, Shinya Takaishi, Hitoshi Miyasaka, Ken-ichi Sugiura, and Masahiro Yamashita*

One-dimensional (1D) materials have attracted great attention for several decades in the fields of chemistry and physics, because they exhibit characteristic optical properties that originate from 1D electronic structures as well as magnetic and transport properties.[1] Some 1D materials have been reported to show striking and reversible changes in color and/or luminescence upon exposure to volatile organic compounds and water vapor. This spectroscopic change in the presence of vapor is called vapochromism, which is a promising phenomenon for chemical-vapor-sensing devices.[2] Typical vapochromic materials are the series of compounds $[Pt(CNR)_4][Pt(CN)_4]$ ($R = p$-CN-C_6H_4-C_nH_{2n+1}; $n = 1, 2, 6, 10, 12, 14$), which are square-planar Pt^{II} compounds that form linear chains of alternating $[Pt(CNR)_4]^{2+}$ dications and $[Pt(CN)_4]^{2-}$ dianions.[2b,d] The vapochromism of these complexes is suggested to be a result of the change in the Pt···Pt distance,[2d] which is not related to instabilities of 1D electronic structures such as Peierls and spin-Peierls instabilities. Herein, we report a new type of vapochromism driven by the phase-transition characteristic of 1D electronic systems. A 1D halogen-bridged dinuclear platinum compound was studied, which displays a reversible phase transition on exposure to water vapor with a remarkable change in structural and optical properties. This compound has a 1D chain structure composed of repeating metal–metal–halogen (MMX) units, in which M = Pt and X = I, called an MMX chain.

A 1D electronic structure is formed in the MMX chain compound by the d_{z^2} orbitals of the M atoms and the p_z orbitals of the X atoms. The formal valence of M is 2.5+, and three electrons exist per two d_{z^2} orbitals. The following four charge-ordering (CO) states are theoretically expected in this system:[3]

a) -$M^{2.5+}$-$M^{2.5+}$-X-$M^{2.5+}$-$M^{2.5+}$-X-
average-valence (AV) state

b) ···M^{2+}-M^{2+}···X-M^{3+}-M^{3+}-X···
charge-density-wave (CDW) state

c) ···M^{2+}-M^{3+}-X···M^{2+}-M^{3+}-X···
charge-polarization (CP) state

d) ···M^{2+}-M^{3+}-X-M^{3+}-M^{2+}···X···
alternating charge-polarization (ACP) state

Two families of the MMX chain compounds, namely, $A'_4[Pt_2(pop)_4X]\cdot n H_2O$ ($A' = K$, NH_4; $pop = P_2O_5H_2^{2-}$; $X =$ Cl, Br)[4] and $[M_2(dta)_4I]$ ($M = Pt$, Ni; $dta = CH_3CS_2^-$),[5] were reported in the early stage of the studies. The ground state of the former was revealed to be the CDW state. For $[Pt_2(dta)_4I]$, a transition from the CP to the ACP state was suggested to occur at 80 K,[5d] while $[Ni_2(dta)_4I]$ was considered to have the AV state.[5c] The I-bridged compounds have a larger hybridization between the p orbital of the X atom and the d orbital of the M atom than the Cl- or Br-bridged compounds, so various CO states are expected to be stabilized. In preceding papers,[6,7] we reported on the synthesis of about 20 compounds of the type $A'_4[Pt_2(pop)_4I]\cdot n H_2O$ and $A''_2[Pt_2(pop)_4I]\cdot n H_2O$, with different countercations ($A' = Na$, NH_4, Rb, Cs, $C_nH_{2n+1}NH_3$, and $(C_nH_{2n+1})_2NH_2$; $A'' = NH_3(C_nH_{2n})NH_3$). We demonstrated that substitution of these compounds widely changes the Pt···I···Pt distance (d(Pt-I-Pt)) and that the electronic structures of PtPtI chains are controlled between the diamagnetic CDW and paramagnetic CP states. Moreover, we reported the pressure- and photoinduced phase transition between the CP and CDW states in $[(C_2H_5)_2NH_2]_4[Pt_2(pop)_4I]$.[7] The target material in the present study is $[NH_3(C_4H_8)NH_3]_2[Pt_2(pop)_4I]\cdot 4H_2O$ (**1**), which shows vapochromic behavior accompanied by a transition between the paramagnetic CP state and the diamagnetic CDW state.

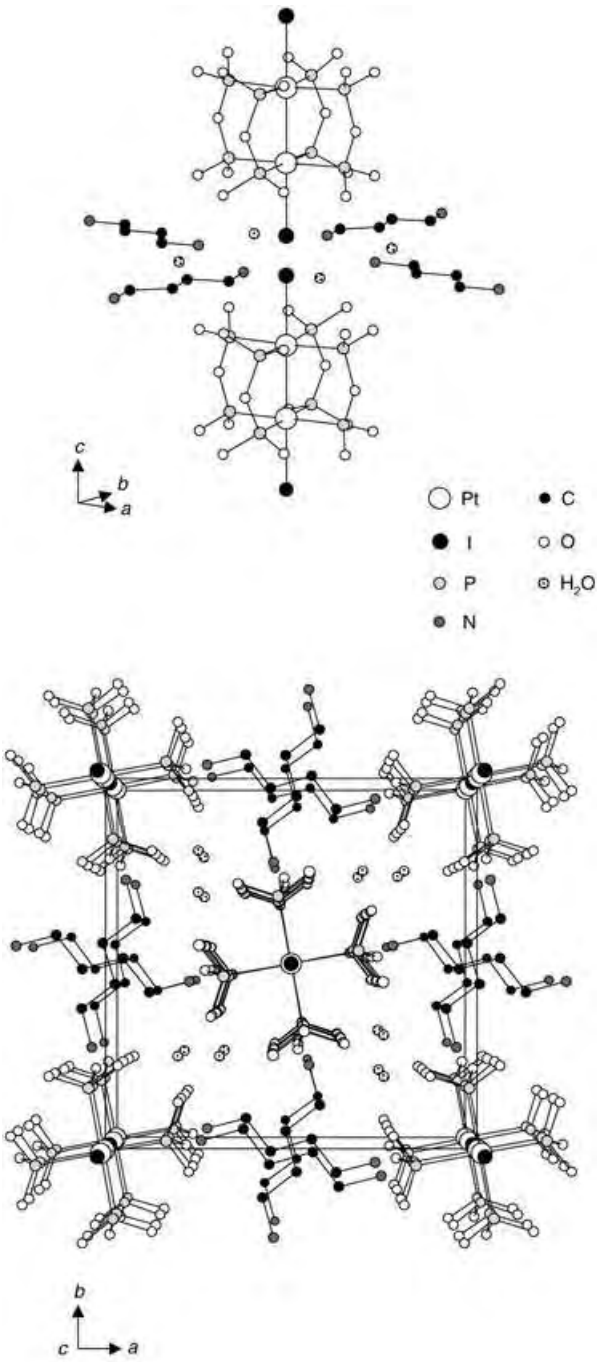

Figure 1. Crystal structure of **1**. H atoms have been omitted for clarity.

Figure 1 shows a perspective view of the crystal structure of **1** at 296 K. Two Pt atoms are linked by four pop ligands to form a $\{Pt_2(pop)_4\}$ unit. The two neighboring $\{Pt_2(pop)_4\}$ units are bridged by I ions, thus forming a PtPtI linear chain along the *c* axis. The bridging I ions are disordered with half occupancies from the midpoints between the neighboring Pt–Pt units, because the displacement of I ions is not three-dimensionally ordered. Therefore, it is difficult to determine from the X-ray structural analysis whether the ground state of **1** is the CDW or CP state. The Pt···Pt distance is 2.837 Å, which is between between that in $K_4[Pt_2^{II}(pop)_4]\cdot 2H_2O$ (2.925 Å)[8a] and that in $K_4[Pt_2^{III}(pop)_4I_2]$ (2.754 Å),[8b] and the Pt···I distance is 2.722 Å. The countercations $[NH_3(C_4H_8)NH_3]^{2+}$ are located in the spaces among the four chains and form hydrogen bonds to the pop ligands. Four H_2O molecules are also located in the spaces.

Raman spectra were measured to obtain information about the CO structure of **1**. Figure 2a shows the polarized

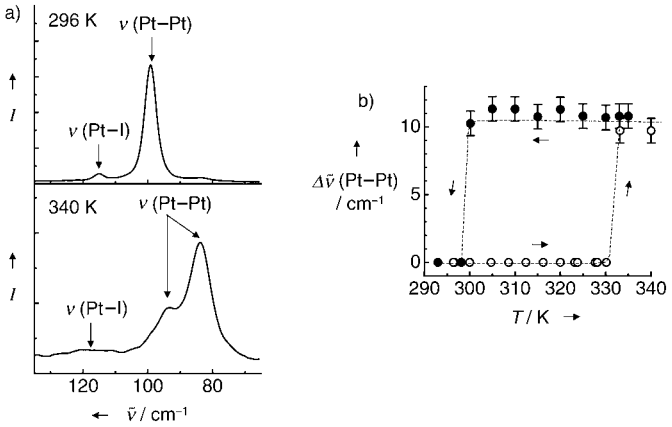

Figure 2. a) Polarized Raman spectra for the polarization of $z(x,x)z$ ($x \| c$ axis) at 296 and 340 K. b) Temperature dependence of the magnitude of splitting in the Pt–Pt stretching Raman band $\Delta\tilde{\nu}$(Pt–Pt).

Raman spectra of **1** in the usual laboratory humidity at 296 and 340 K. The strong signals at 80–100 cm^{-1} are attributed to the Pt–Pt stretching mode ν(Pt–Pt) of the Pt–Pt unit. An overtone progression of ν(Pt–Pt) up to fourth order is observed in both spectra. At 296 K, a single ν(Pt–Pt) band is observed at 98 cm^{-1}, which indicates the formation of only one kind of Pt–Pt unit. A relatively weak band is also observed at around 115 cm^{-1}. This band can be assigned to the Pt–I stretching mode, which is activated by the displacement of I ions from the midpoint between the neighboring Pt–Pt units. This fact is consistent with the crystal structure of **1** discussed above. Therefore, the ground state of **1** at 296 K can be considered as the CP state. The ν(Pt–Pt) band clearly splits into two components when the temperature is increased from 296 to 340 K, which indicates that there are two kinds of Pt–Pt units, in the present case Pt^{II}–Pt^{II} (86 cm^{-1}) and Pt^{III}–Pt^{III} (94 cm^{-1}), while the Pt–I stretching mode seems to be still activated. Therefore, the electronic phase at 340 K is reasonably classified as the CDW phase.

The temperature dependence of the magnitude of splitting in the Pt–Pt stretching Raman band $\Delta\tilde{\nu}$(Pt–Pt) is shown in Figure 2b. When heated from room temperature, $\Delta\tilde{\nu}$(Pt–Pt) remains at zero within the temperature range from 296 to 330 K but abruptly increases to about 10 cm^{-1} at 333 K. In the cooling run, $\Delta\tilde{\nu}$(Pt–Pt) does not change even at 333 K, but returns to zero at 300 K. This result indicates that the CDW phase can return to the original CP phase by cooling the crystal to room temperature. We confirmed this reversibility by repeating the heating and cooling processes several times. It should be noted that the reversibility largely depends on the humidity. In fact, the CDW phase does not recover to the CP phase on lowering the temperature in a fully dry atmosphere.

We can, however, revive the reversibility by exposing the crystal to water vapor. Thus, the reversibility is not a simple function of temperature. Further studies will be necessary to clarify how the transition between the CP and CDW phases depends on the values of temperature and humidity.

The most striking feature of **1** is that the CP-to-CDW transition is accompanied by a marked color change of the crystal. The polarized reflectivity spectra and corresponding microscope images of the sample are presented in Figure 3a.

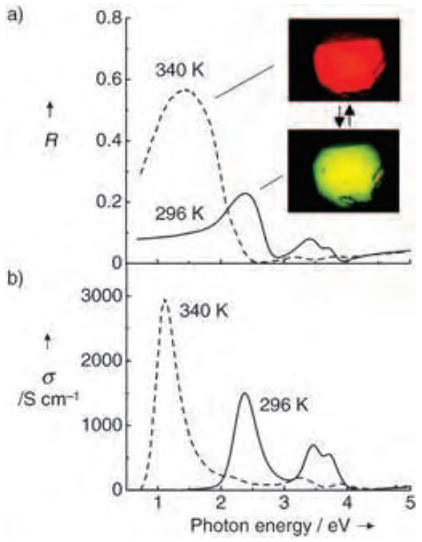

Figure 3. a) Polarized reflectivity and b) optical conductivity spectra with polarization of light parallel to the *c* axis in **1** at 296 and 340 K. The insets in (a) show the corresponding microscope images for the single crystal taken in reflection mode.

Compound **1** is yellow–green at 296 K as a result of the peak at 2.37 eV; on increasing the temperature up to about 340 K, the color changes to red–brown. This color is primarily a result of the strong reflection band from the near-infrared to the visible region. Such clear chromism is also confirmed by the optical conductivity (σ) spectra (Figure 3b). The peak energy of the lowest charge-transfer (CT) band (E_{CT}) drastically shifts from 2.37 (520 nm) to 1.12 eV (1110 nm). This spectral change is anomalously larger than that of the previously reported vapochromic materials. From a previous theoretical study on the optical excitation in the MMX chain compounds,[3c] the lowest CT band observed at 2.37 eV in the CP phase can be assigned to intradimer CT excitation from [-I···Pt^{2+}-Pt^{3+}-I···Pt^{2+}-Pt^{3+}-I-] to [-I-Pt^{3+}-Pt^{2+}···I···Pt^{2+}-Pt^{3+}-I-], while the CT band at 1.12 eV in the CDW phase is attributable to the interdimer CT band from [-I···Pt^{2+}-Pt^{2+}···I-Pt^{3+}-Pt^{3+}-I-] to [-I···Pt^{2+}-Pt^{3+}-I···Pt^{2+}-Pt^{3+}-I-]. The CP-to-CDW transition and the resultant change of the origin for the optical gap are responsible for the observed chromism. The gap energy $E_{CT} = 1.12$ eV at 340 K is nearly equal to that of other compounds in the CDW phase.[7] The *d*(Pt-I-Pt) value is relatively small in the CDW compounds compared to that in the CP compounds. Therefore, it is reasonable to consider that the observed CP-to-CDW transition is driven by the decrease in the value of *d*(Pt-I-Pt).

Thermogravimetric analysis (TGA) was performed in a dry nitrogen atmosphere to gain an insight into the mechanism of the phase transition (Figure 4). Compound **1** shows a gradual weight loss when the temperature is increased from

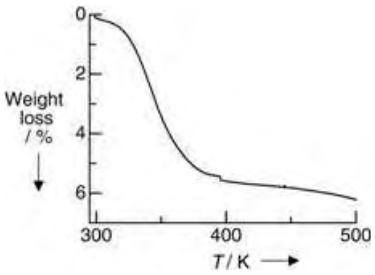

Figure 4. TGA trace of **1** under a dry nitrogen purge at 5 K min^{-1}.

room temperature, and has lost 5.450 % of its weight at 395 K. This value is in good agreement with that calculated (5.365 %) for the loss of four H_2O molecules per formula unit. The compound then shows a minor weight loss (< 0.5 %) up to approximately 500 K. There is a discrepancy in the temperature dependence of the water losses observed in TGA (Figure 4) and the valence changes observed in the Raman spectra (Figure 2b). This discrepancy is considered to be for the following reason: It is natural to consider that the water molecules near the surface of the crystal are lost more readily than those inside the crystal. The total water loss of the sample is probed in the TGA measurement, whereas the Raman spectra sensitively reflect changes in the penetration depth of the pump light (1.96 eV), which is much smaller than the thickness of the crystal (≫ 10 μm). These optical and TGA results demonstrate that the transition between the CP and CDW states is triggered by desorption and absorption of water molecules. Powder X-ray diffraction measurements were also performed to investigate the vapochromic structural changes. The diffraction pattern of **1** heated at 353 K in vacuum shows that the crystal has converted into some new, and as yet unidentified, crystal structure. Further studies will be necessary to determine the details of this structural transition.

In conclusion, we have found a novel reversible vapochromic behavior accompanied by a phase transition between the paramagnetic CP state and the diamagnetic CDW state in the MMX compound $[NH_3(C_4H_8)NH_3]_4[Pt_2(pop)_4I]\cdot 4H_2O$. The results presented here lead us to expect that the MMX chain compound is a versatile candidate for future chemical-vapor-sensing devices.

Experimental Section

The starting compounds $K_4[Pt_2(pop)_4]\cdot 2H_2O$ and $K_4[Pt_2(pop)_4I_2]$ were prepared according to the methods previously described.[4b] Single crystals of **1** were grown by the standard diffusion method using an H-shaped glass cell. Aqueous solutions (2 mL each) of $[NH_3(C_4H_8)NH_3]SO_4$ (2 mg) and of $K_4[Pt_2(pop)_4]\cdot 2H_2O$ (20 mg) and $K_4[Pt_2(pop)_4I_2]$ (20 mg) were loaded at the ends of the cell and allowed to slowly diffuse in water at room temperature. After about a week, yellow–green needle crystals were obtained. Elemental anal-

ysis (%) calcd for $C_{10}H_{48}IN_4O_{24}P_8Pt_2$: C 7.14, H 3.30, N 4.16; found: C 7.15, H 3.20, N 4.13.

X-ray structural analysis of **1** was performed by using a Rigaku RAXIS-RAPID imaging-plate diffractometer with graphite monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.7107$ Å). Crystal data for **1** at 296 K: $M_r = 1343.31$, tetragonal, space group $I4/m$, $a = 13.3474(8)$, $c = 9.8091(7)$ Å, $V = 1747.5(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.553$ g cm^{-3}, final $R = 0.0351$, $wR = 0.138$, GOF = 1.587 with $I > 3.00\sigma(I)$. CCDC-245189 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Polarized Raman spectra of **1** were measured by using a Renishaw Ramascope 1000B Raman spectrometer with a continuous-wave He–Ne laser (1.96 eV) and an optical microscope. Polarized reflectivity spectra were obtained by using a specially designed spectrometer with a 25-cm-grating monochromator and an optical microscope. TGA was carried out under a dry nitrogen atmosphere using the Rigaku Thermo plus2 TG 8120 analyzer.

Mesoporous Materials

A New Minimal Surface and the Structure of Mesoporous Silicas**

Michael W. Anderson, Chrystelle C. Egger, Gordon J. T. Tiddy, John L. Casci, and Kenneth A. Brakke*

The formation of complex inorganic superstructures in nature relies on the interaction between organic and inorganic species to direct the inorganic form away from its "usual" morphology. During synthesis the superstructures are soft and dynamic which makes a study of the nature of the ephemeral interface difficult.[1] However, the inorganic skeletons formed are stable and consequently amenable to detailed examination. In 1992 researchers at Mobil[2] and in Japan[3] made the remarkable discovery that the subtle forms of mesoscopic organization of surfactant molecules could be imprinted on oxide structures. Herein we report our studies of the structure of the surfactant-templated, cubic, mesoporous silica superstructure, SBA-1[3] and provide a formulation in terms of curvature that has important repercussions for both surfactant structures and the mechanism of formation of inorganic replicas. We establish that the crucial interface that determines the inorganic structure is between the silica and water adsorbed at the micelle surface, not between silica and surfactant, thus challenging the present synthesis mechanisms.[4] We adopt a general protocol for understanding the surface curvature and energy which could be applied widely

to the growth of inorganic structures in biology, including nonperiodic and disordered structures.

Currently there are a number of ways to address the mesophase structure of these mesoporous silicas. Terasaki and co-workers[5] adopted the direct structure elucidation approach by using electron crystallography. With this method they were able to reconstruct an electron density map directly with electron micrographs recorded along several zone axes. This has the distinct advantage that no predefined knowledge is required and that the diffraction intensities are optimized through the observation of individual particles. However, its disadvantage is that the electron density map does not easily yield clues about the synthesis mechanism. The technique is also technically very demanding and is only suitable for highly organized 3D structures that are stable in the electron microscope. It is not a routine technique and cannot be used to monitor many sample preparations, or to look at preparations in situ.

Another route, first adopted by Anderson and Alfredsson,[6] and more recently by Solovyov and co-workers,[7] and Schüth and co-workers,[8,9] involves the determination of a structural model from some known data followed by its refinement according to certain parameters, for instance, against X-ray diffraction patterns or electron micrographs. This method has the advantage that it is flexible and can be applied to a variety of preparations; the results also give information about synthesis mechanisms. The disadvantage is that the process does require input from other techniques and some prior knowledge. Also, the powder X-ray diffractogram is an average technique and as a consequence, it is important that the sample is relatively homogeneous. Herein we introduce a general mathematical approach to the modeling of mesoporous silicas, which allows easy generation of electron density maps and diffraction patterns for comparison with experimental data.

SBA-1 was synthesized in HCl (4 M) with hexadecyltriethylammonium bromide (HTEABr) as surfactant and tetraethylorthosilicate (TEOS) as a source of silica. The structure is known from electron crystallography[10] to belong to the space group $P_{m\bar{3}n}$ and consists of cages connected through windows. The corresponding surfactant phase is known as the I_1^3 (or Q^{223} referring to the space group number, or *Pm3n* as an identifier for $P_{m\bar{3}n}$[11]) phase which is a cubic, isotropic, micellar phase. Curiously, the I_1^3 phase was not observed in the phase behavior of HTEABr,[12] in which a hexagonal phase occurs at the micellar solution boundary. Consequently, we studied the phase behavior of this surfactant with a temperature-programmed penetration scan (Supporting Information). This shows that in the presence of impurities that are likely to remain from the surfactant synthesis, such as bromohexadecane, a cubic phase is induced below $\approx 32\,^{\circ}C$. Significantly, this phase occurs between the hexagonal phase and isotropic solution, which suggests a higher curvature of the micellar phase. More importantly, when HTEABr is exchanged with chloride ions to make HTEACl the penetration scan reveals the presence of three cubic mesophases. HTEACl is probably the templating agent in SBA-1 preparations owing to the large excess of chloride anions in the preparation.

The essence of our approach herein was first to build the structure essentially by hand. This requires some knowledge of the possible structures of the I_1^3 surfactant phase; some that have been discussed in the literature are illustrated in Figure 1. However, close inspection of electron micrographs

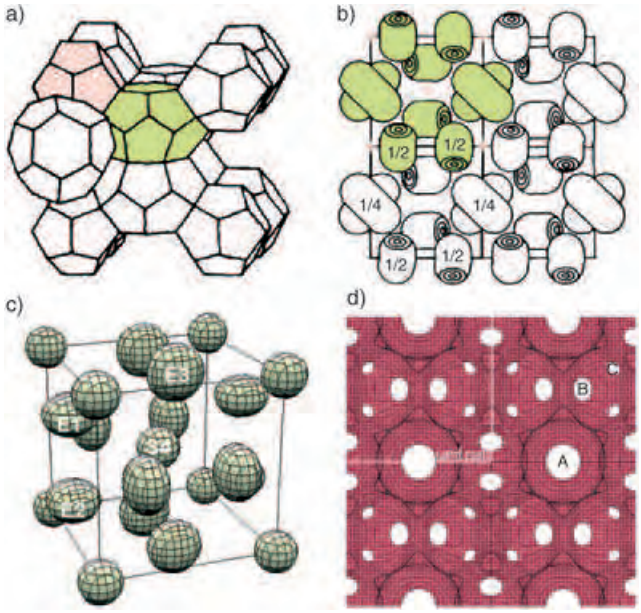

Figure 1. Various representations of the I_1^3 structure with $P_{m\bar{3}n}$ symmetry: a) model of Charvolin and Sadoc[13], which displays two polyhedra (12-hedron and 14-hedron) defining volumes that contain micelle plus associated water; b) rod-type micelles of Fontell and co-workers[14]; c) single exponential function displaying 21 micelles: 9 spherical and 12 oblate ellipsoidal, according to exponential mathematics, equivalent to model adopted by Vargas and co-workers;[15] d) continuous surface created by an exponential function as the radii of the micelles are increased, displaying the three different window types (A, B, and C) in SBA-1—2×2 unit cells viewed along [100]. To create a continuous surface, 12 extra virtual ellipsoids are placed in adjacent cells to ensure that there are no edge effects.

reported previously[10] quickly discounts the possibility of rodlike micelles as the structure-directing agent, and consequently we choose the approach of Vargas and co-workers,[15] which uses spherical and oblate ellipsoidal micelles arranged on a cubic lattice. To describe such structures, a useful and simple exponential mathematics is available to "hand build" structures, as described in detail by Jacob and Andersson,[16] and as outlined in the Experimental Section below. A remarkably good fit is produced between experimental and theoretical diffraction patterns as shown in Figure 2. However, there is some discrepancy between the calculated void volume and that determined experimentally, suggesting that the model needs further refinement. The model works well for both as-prepared and calcined samples (Supporting Information). Upon calcination the unit cell shrinks by $\approx 9\,\%$ but the relative diffraction intensity changes very little. This indicates that 1) the structure remains essentially intact, and 2) there is no need to consider an electron-density profile other than silica walls and voids. The content of the void, which will be mobile, is not a significant

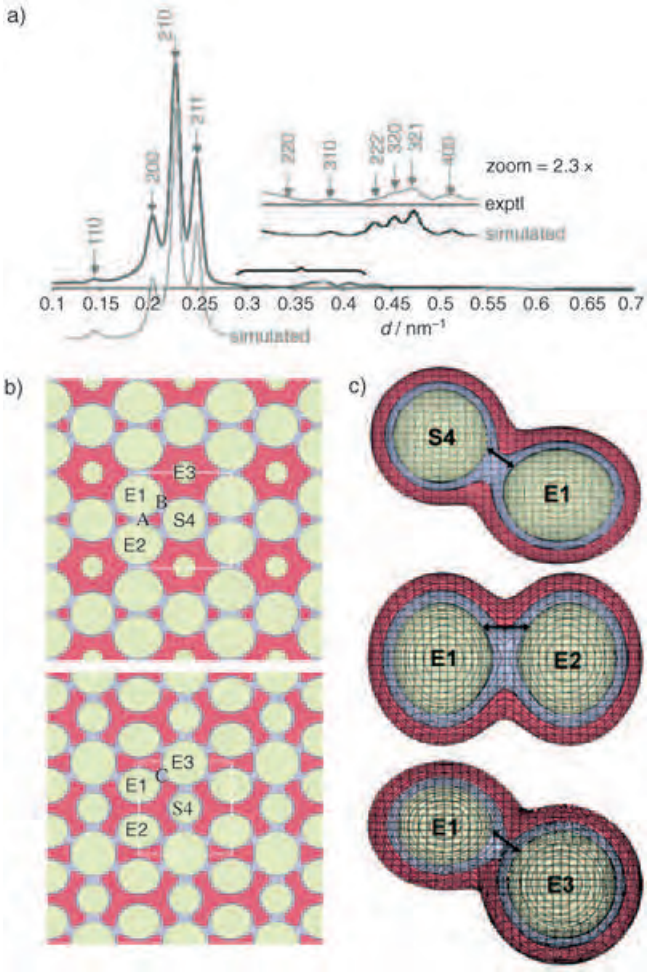

Figure 2. Calculated X-ray diffraction pattern and model from the analytical function: a) Experimental and simulated X-ray diffraction pattern for as-prepared SBA-1 with an analytical expression of $r_1 = r_2 = 0.229$ for a unit cell, for example, 19.5 Å (based on a unit cell of 85 Å) and an oblateness of 1.2; $C = 0.01$. b) Slices through the unit cell of SBA-1: red = hydroxylated silica wall structure, yellow = micellar structure, and blue = adsorbed water. The slice through the middle of the unit cell ($z = 0.5$, top) illustrates the A windows between the flat sides of two oblate ellipsoids and the B windows between a spherical and an elliptical micelle. The slice at $z = 0.375$ (bottom) shows the C windows between the tips of two ellipsoidal micelles. c) Illustration of how the window size in SBA-1 is related to the curvature in which the micelles meet, in terms of the thickness of the adsorbed water layer between the micelles; the contact angle between micelles will be different.

factor to determine the relative diffraction intensity. Nevertheless, a number of important features are immediately apparent from this approach. First, the radius of the spherical micelle must be similar to that of the short radius of the oblate ellipsoidal micelles, otherwise the [110] reflection becomes unacceptably large. This is reasonable, as these radii will both be governed by the length of the surfactant paraffin chain. Second, there is an interesting correlation between the window size and the geometry of adjacent micelles that cause the window formation. SBA-1 has three different windows and, as can be observed in Figure 1 d, the window size is greatest when the contact angle between touching micelles is smallest; alternatively, the thickness of the adsorbed water layer on the micelles which excludes the silica wall is a constant (Figure 2). This suggests mechanisms to control window size through control over the curvature of micelles.

A number of the important micellar and bicontinuous surfactant phases have been described previously in terms of infinite periodic minimal surfaces (IPMS).[17] Such surfaces are continuous in 3D space and have the property that the mean curvature at all points on the surface is zero. A number of the micellar phases have been described in this regard, but the I_1^3 structure has not yet been correlated with any known IPMS. A convenient method to explore possible IPMS structures is to use the *Surface Evolver* software from Brakke[18] which refines a surface either to minimal area or to minimal squared-mean curvature. A number of cubic IPMS have recently been explored with this approach.[19] We used this package with the "hand-built" structure as the starting point for refinement, and refined the squared-mean curvature under the constraints of defined void volume (determined from nitrogen adsorption and helium pycnometry experiments). The results are remarkable. First, without volume constraint, a new minimal surface is generated at a void volume of 55%. The surface is shown in Figure 3 and has almost exactly zero-mean curvature at every point on the surface. The surface may be characterized as a smoothed version of the analytic surface by using decreasing squared-mean curvature as a smoother. An X-ray diffraction pattern produced from such a surface is in excellent agreement with that observed experimentally. The fit is further improved by constraining the void volume to that observed experimentally (58%), and the surface produced still has close to constant and zero-mean curvature (Figure 4). In this case the surface can either be refined to constant-mean curvature or to minimal integrated-square-mean curvature. The latter approach was found to give the best agreement between experiment and simulation. The mesopore sizes are consistent with previously reported work from Terasaki and co-workers,[10] and consequently the model is consistent with X-ray diffraction, electron microscopy, and gas adsorption experiments. We have not tried to further improve the diffraction fits with the methods of Solovyov et al.,[7] as we believe that the number of variables relative to the number of fitting parameters precludes an improvement in accuracy.

This result has important repercussions for both the structure and mechanism of formation of SBA-1 and mesoporous silicas in general and also, by analogy, for the structure of surfactant mesophases. SBA-1 is formed from a low-concentration surfactant solution, which is above the critical micelle concentration (CMC) but an order of magnitude below that normally required for mesophase formation. The solution has high ionic strength which alone is not sufficient to salt out the mesophase. The precipitation only occurs in the presence of silica species. The precise nature of these silica species is unknown, although they will be positively charged at this low pH. However, the mechanism must be cooperative between the micelle species and the silica species. Before mesophase formation, the micelles must have a substantial shell formed from silica species to supply all the silica in the final product. After mesophase formation and reorganization,

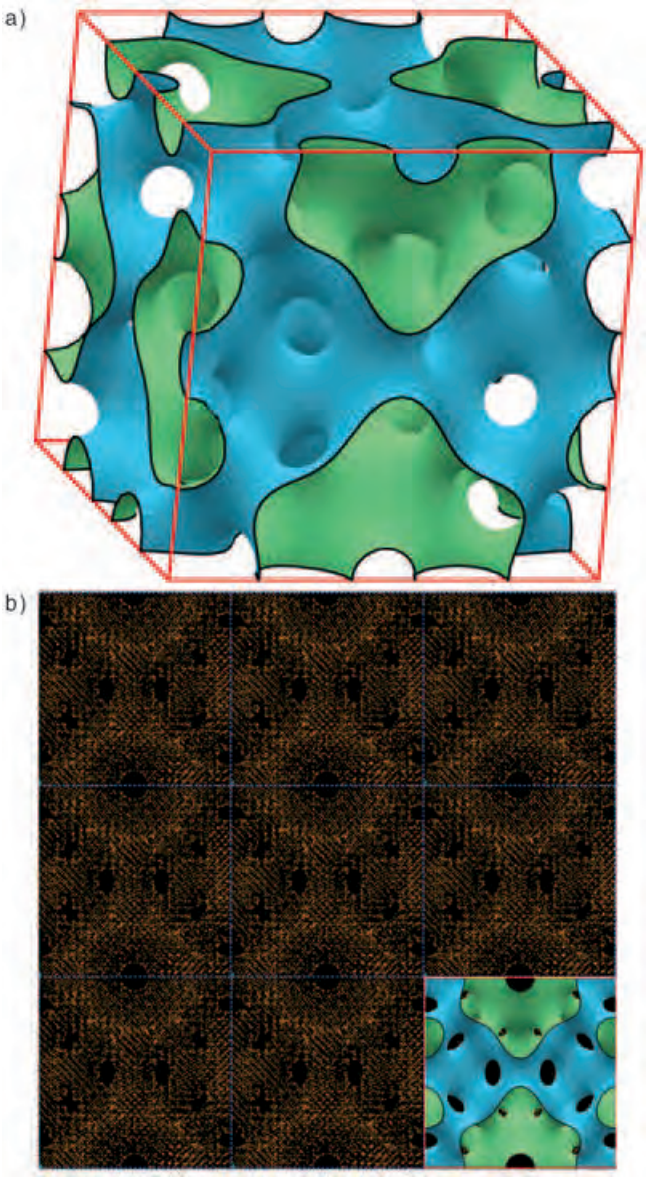

Figure 3. $P_{m\bar{3}n}$ symmetry surface with zero-mean curvature at all points: a) oblique view and b) view along [100] superimposed on 3×3 unit cells of the atomistic model used to calculate the diffraction patterns. In SBA-1 the green volume represents the inorganic hydroxylated silica wall of the material, and the blue volume contains micellar surfactant surrounded by a layer of adsorbed water. In the I_1^3 surfactant mesophase, the free water would occupy the green volume.

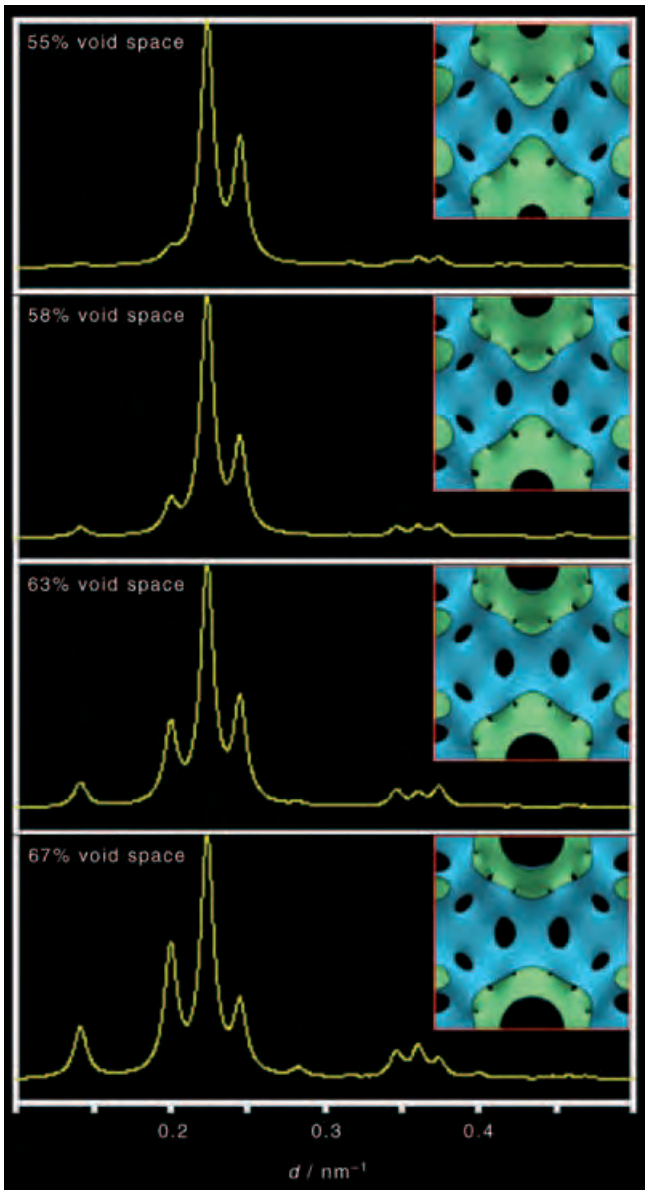

Figure 4. Calculated X-ray diffraction patterns for structures refined with *Surface Evolver*.[18] The wall volume in green is filled with uniform electron density and the void space is empty. A void volume of 55% is the surface closest to a minimal surface with near zero-mean curvature; 58% void volume represents a slightly thinner wall still, with very low curvature which most closely resembles as-prepared SBA-1.

the SBA-1 structure reveals that the silica has retracted from the micellar surface (creating windows) and that the mean curvature of the silica surface is close to zero. Yet in a micellar mesophase the mean curvature of the micelles is very large. Moreover, the Gaussian curvature (the product of the maximum and minimum curvature) of the micelles is positive, whereas the Gaussian curvature of the final structure is negative at every point. We make the assumption on geometric grounds that the micelles do not merge to form a continuous phase, as they are simply too long to be accommodated in the window region of the structure. The window sizes are less than ≈13 Å and the surfactant molecules are >20 Å, requiring a window of at least 40 Å for a bilayer (n.b.: 1) surfactant length is about 75% of all trans length; 2) the surface wrapping is complex, and therefore the notion of a bilayer is not correct, but illustrates the size that the window would need to be if the micelles were to "fuse"). Consequently, the interface of the silica is clearly not at the interface with the surfactant micelle, but at the interface with the adsorbed hydration layer surrounding the micelle (Figure 2). Although it is possible that there are other related zero-mean-curvature surfaces for such a tortuous surface, the one found fits the experimental data and is therefore a valid description for this structure in terms of curvature. As has been suggested before for other cubic

micellar mesophases (specifically Q^{225} and Q^{229}) this interface between the adsorbed water and the free water, in pure surfactant/water systems, is usually a zero-mean-curvature surface (surfaces F-RD and I-WP respectively).[17] Herein we have established, through the structure of the inorganic precipitate, that a similar picture of a high-curvature micellar structure with an adsorbed water layer extending to a zero-curvature surface and then a free water region on the other side of the surface is valid for the I_1^3 or Q^{223} structure. The silica in the structure of SBA-1, and probably many other mesoporous silica structures, develops its final form in the free water. Such a mechanism would not be inconsistent with the hexagonal MCM-41 type structure in which the surfactant is present as long rods but with substantial free water between the rods (the hexagonal phase can accommodate a larger variation in water concentration than the cubic phases). The packing constraints in the hexagonal phase would also favor thicker walls simply on geometric grounds—there is less surface area to pack the silica without thickening. As a result, there are no exclusion zones in which windows will occur, and the surfactant rods are essentially covered with silica species. Such a mechanism is, however, at substantial variance with the previously proposed mechanisms of mesoporous silica formation,[4] which rely heavily upon the direct close interaction between silica species and surfactant. We suggest this interaction is crucial only in the initial precipitation process, but the combination of other interactions is far more important to the structure of the final mesophase observed. With this general method of building structures by hand followed by curvature refinement according to experimental constraints, it should be possible to derive accurate models for all inorganic mesoporous structure types. Even disordered structures could be built, as the method of constructing surfaces by hand allows any starting arrangement and micelle shape (although this would be clearly more demanding and would require information about the nature of the disorder). The same methods can also be applied toward the growth of inorganic structures in biology.

Experimental Section

Hexadecyltriethylammonium bromide (HTEABr) was prepared by mixing 1-bromohexadecane (98%, Lancaster) and triethylamine (99%, Jansen Chimica) in absolute ethanol under reflux conditions for 24 h. Ethanol was then removed with a rotary evaporator until a white, viscous paste was obtained. The resulting gel was recrystallized by minimal addition of chloroform, then ethyl acetate until the whole solid precipitated. SBA-1 was prepared with tetraethylorthosilicate (TEOS; 98%, Aldrich) as a source of silica, HTEABr (made in-house), distilled water, and aqueous HCl (33 wt%, BDH). Molar ratios for a typical SBA-1 synthesis were HTEABr/H_20/HCl/TEOS = 1:3500:280:5. After an aging time of 1 week at 4 °C, the mixture was heated to 100 °C within 10 min for 1 h. These conditions were optimal for the generation of homogeneous stable materials that have probably reached an equilibrium as a soft solid before solidification in the final heating at 100 °C. We have established by ^{29}Si-MAS NMR spectroscopy that at these low pH conditions, cross-linking is retarded, which is consistent with the work of Brinker and Scherer.[20] Ethanol is liberated during the hydrolysis of TEOS ($\approx$1.5 wt%) but this has little influence on the processes occurring, as the ethanol resides mainly in the water. (Low ethanol levels (<1 mol dm^{-3}) are known to have only a minimal influence on CMC values, hence only a small amount of ethanol is found in the micelles.) The surfactant moiety was finally burned out by calcination at 550 °C for several hours, with a slow temperature-ramp rate (0.5 °C min^{-1}). Hand-built structures were formulated with *Mathematica* software; the atomistic structures were generated with a *Fortran* program; X-ray diffraction patterns were calculated with *Cerius II* software from Accelerys; *Mathematica* contour surfaces were translated for input into *Surface Evolver* with a *Fortran* program.

The basis for the initial hand-built structures is that a sphere can be expressed not only as $x^2+y^2+z^2=C$ but also in the exponential scale by

$$e^{-(x^2+y^2+z^2)} = C \quad (1)$$

The radius of the sphere is determined by the constant C, and the center of the sphere can be moved to any coordinate h, k, or l by the following transformation:

$$e^{-[(x-h)^2+(y-k)^2+(z-l)^2]} = C \quad (2)$$

The sphere can be elongated or squashed in any dimension to produce, for instance, an oblate ellipsoid by the following transformation:

$$e^{-[b_1(x-h)^2+b_2(y-k)^2+b_3(z-l)^2]} = C \quad (3)$$

Finally, an object with a different radius can be formed by adding a constant, a, within the exponential, thus:

$$e^{a-[b_1(x-h)^2+b_2(y-k)^2+b_3(z-l)^2)} = C \quad (4)$$

The utility of working in the exponential scale is that multiple objects can be incorporated in a single expression by adding exponential functions together (Supporting Information). Furthermore, as isolated objects approach, a continuously wrapped surface is produced with the smoothness of the wrapping governed by the value of C. Jacob and Andersson[16] have demonstrated that this approach can be extended to describe many objects with complex shape. The arrangement of micelles in the $P_{m\bar{3}n}$, I_1^3 structure is given by adding 21 objects together according to the following equation:

$$\sum_{h,k,l} e^{-\{(x-h)^2+(y-k)^2+(z-l)^2\}} + \sum_{h',k',l'} e^{|a-\{b_1(x-h')^2+b_2(y-k')^2+b_3(z-l')^2\}|} = C \quad (5)$$

and this is shown in Figure 1c. Then, by increasing the radius of the micelles relative to the unit cell size, a continuously wrapped surface is produced (Figure 1d), which represents the structure of SBA-1. To test the validity of the model, an atomistic structure of SBA-1 was produced by placing silicon atoms randomly on one side of this continuous surface; X-ray diffraction patterns were generated for varying values of the micelle radius and the degree of oblateness of the micelles.

Host–Guest Systems

Ditopic Complexation and Release of Neutral Guest Molecules by a Hydrogen-Bonded "*Endo–Exo*" Receptor

Miguel A. Mateos-Timoneda, Jessica M. C. A. Kerckhoffs, Mercedes Crego-Calama, and David N. Reinhoudt**

The highest level of sophistication in noncovalent chemistry is found in living systems, where elegant supramolecular assemblies make up the machinery that enables and supports functions important for life. The understanding of the mechanism for (bio)molecular recognition is also crucial in the development of new drugs and for the mimicry of the activity of biosystems.[1–3] The principles of biomolecular recognition[4] have successfully been extended to synthetic receptors[5] that are able to bind guest species such as cations,[6] anions,[7] or small neutral molecules.[8] The study of different degrees of complexity in the molecular recognition process is also important for the understanding of different biomolecular processes. For example, at the active site of enzymes, strict recognition of the transition state by the enzyme is required (selective *endo* recognition), whereas the initial protein–protein recognition can be more loose and flexible (nonselective *exo* recognition). Nevertheless, and to the best of our knowledge, there are no synthetic examples in the literature that exploit the diverse levels (that is, *endo/exo*, selective/nonselective) of molecular recognition encountered in nature.

Further control over the complexity of the molecular recognition process can also be achieved through the formation of multiple interactions at different areas of the host molecule, as observed at antibody–antigen interfaces,[9] as well as by the interaction of one host with two or more different guest molecules.[10] There are only a few examples of synthetic receptors capable of complexing two different types of guest molecules, usually cations and anions.[11] However, the covalent synthesis of these receptors remains elusive and time consuming because of the complexity of the functionalities needed to complex the two different types of guest. Self-assembly provides a simpler and faster way to bring together the desired functionalities for the recognition of the guest,[12] but it is necessary to avoid interfering with the required functionalities during the self-assembly of the receptor. Thus, the complexation of two (or more) different neutral guest molecules with one synthetic receptor is rare and has only been achieved in the interior of capsulelike assemblies (*endo* receptors)[13] and other cavities by using the principles of crystal engineering.[14]

Herein, we report the first (noncovalent) receptor able to act simultaneously as an *endo* and *exo* receptor for neutral molecules (Figure 1). This hydrogen-bonded receptor is able to *selectively* encapsulate a neutral noncovalent trimer in the pocket situated in between two subdomains (floors) of the receptor (*endo* complexation) while simultaneously complexing different neutral guest molecules at the periphery of the assembly (*exo* complexation), thus resembling the different degrees of complexity encountered in biorecognition.[15] The receptor is formed by the self-assembly of nine components (three calix[4]arenes dimelamines and six barbiturate/cyanurate derivatives) through 36 cooperative hydrogen bonds. The periphery of the self-assembled receptor is decorated with six pyridyl groups that are able to complex a variety of dicarboxylic acids (nonselective process) in a 1:3 fashion through two-point hydrogen-bonding interactions. The receptor can simultaneously encapsulate a noncovalent trimer of alizarin through π–π stacking interactions. This self-assembly of the receptor and the recognition processes of the guests bring together 15 molecules with total specificity. Surprisingly, the order in which these guest molecules are added is very

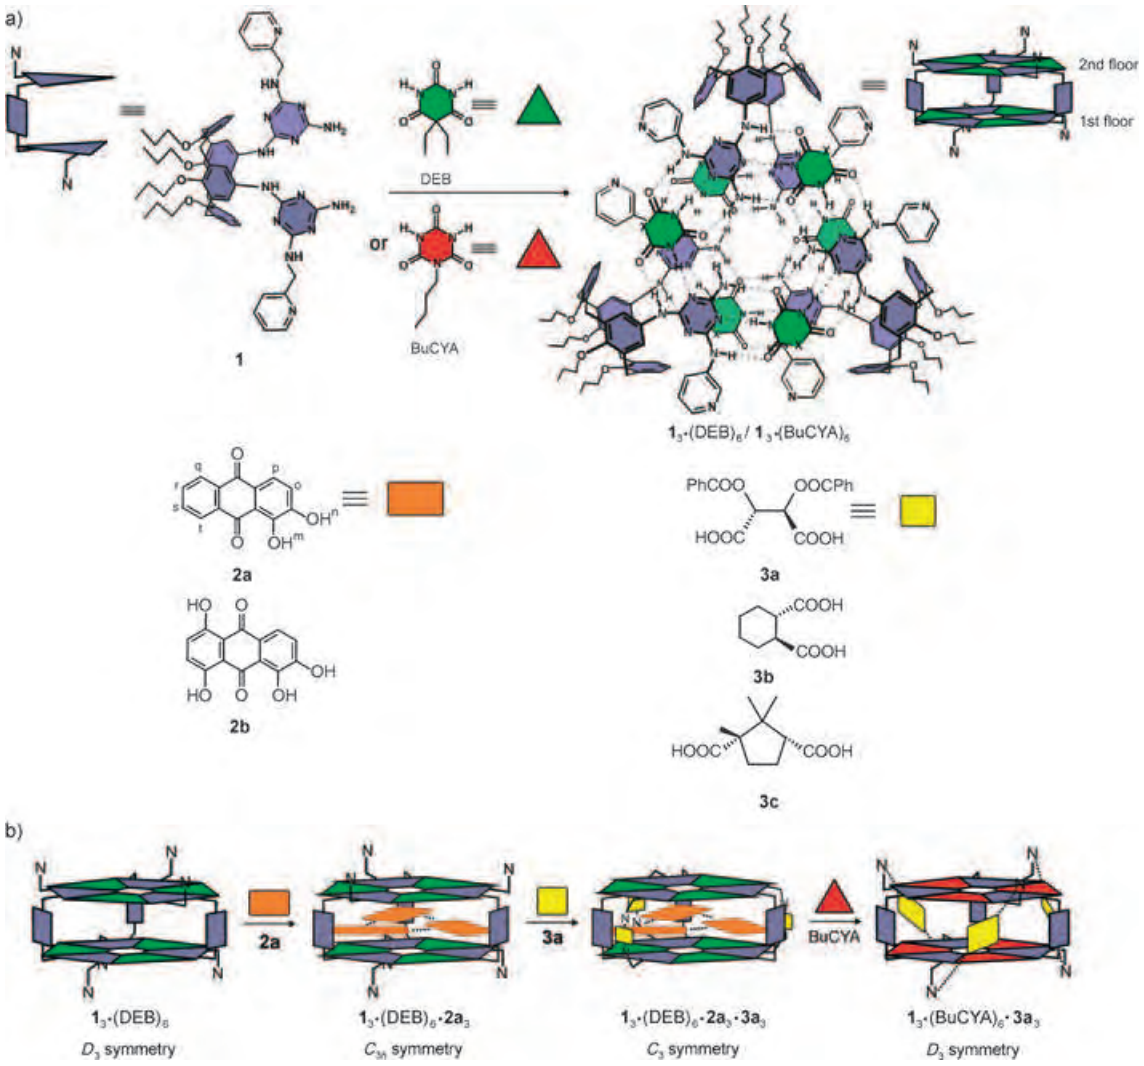

Figure 1. a) Molecular and schematic (side view) representations of the building blocks and the corresponding hydrogen-bonded assemblies $\mathbf{1}_3\cdot(DEB)_6/\mathbf{1}_3\cdot(BuCYA)_6$ and guest molecules **2a–b** and **3a–c**. b) Schematic representation of the recognition of guest **2a** and **3a** by $\mathbf{1}_3\cdot(DEB)_6/\mathbf{1}_3\cdot(BuCYA)_6$ receptors, and the release of **2a**. The corresponding symmetry of the assemblies is also given: assemblies with D_3 symmetry ($\mathbf{1}_3\cdot(DEB)_6$ and $\mathbf{1}_3\cdot(BuCYA)_6\cdot\mathbf{3a}_3$) have the two melamine rings in each calix[4]arene in a staggered orientation while these rings in assemblies with C_{3h} and C_3 symmetry ($\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ and $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$, respectively) have a parallel orientation.

important for the outcome of the recognition and encapsulation processes. Furthermore, the receptor has the ability to selectively release the guest molecules complexed in the internal cavity (when it receives the appropriate stimuli) while the guest molecules at the periphery remain complexed to the receptor.

Hydrogen-bonded receptors $\mathbf{1}_3\cdot(DEB)_6$ and $\mathbf{1}_3\cdot(BuCYA)_6$ are formed spontaneously upon mixing calix[4]arene dimelamine **1** and barbiturate (DEB) or cyanurate (BuCYA) derivatives, respectively, in a 1:2 ratio in apolar solvents (Figure 1).[16] The self-assembly process is driven by the cooperative formation of 36 hydrogen bonds, which leads to assemblies with a high thermodynamic stability, even at concentrations of 10^{-4} M. Despite the negative entropy arising from the assembly of nine components, the formation of the assembly is enthalpically driven ($\Delta H^{o} < 0$) as a result of the formation of the 36 hydrogen bonds between the complementary hydrogen-bonding arrays of **1** and DEB or BuCYA.

The first step in achieving the *endo–exo* complexation is the encapsulation of alizarin (**2a**) within the two rosette layers of the receptor. The ^{1}H NMR spectrum of a 1.0 mM solution of the hydrogen-bonded receptor $\mathbf{1}_3\cdot(DEB)_6$ in [D_8]toluene shows that nearly all the signals are shifted, both for the host assembly and for the guest molecules (Figure 2b), upon addition of three equivalents of alizarin (**2a**). For example, the signals of the NH_{DEB} protons (H^a and H^b) involved in the hydrogen-bonding array shift upfield from $\delta = 14.85$ and 14.08 to 14.43 and 13.81 ppm, respectively. Similarly, proton H^i of the 2-methylpyridine substituents of the melamine rings undergoes an upfield shift of approximately 0.5 ppm upon addition of alizarin. Molecular simulation studies (Quanta 97, CHARMm 24.0) suggest that H^i is pointing towards the center of the receptor, thus resulting in the observed upfield shift in the ^{1}H NMR spectrum. Large upfield shifts were also observed for the aromatic protons of the guest molecules **2a** (> 3.0 ppm), which indicates their encapsulation in the

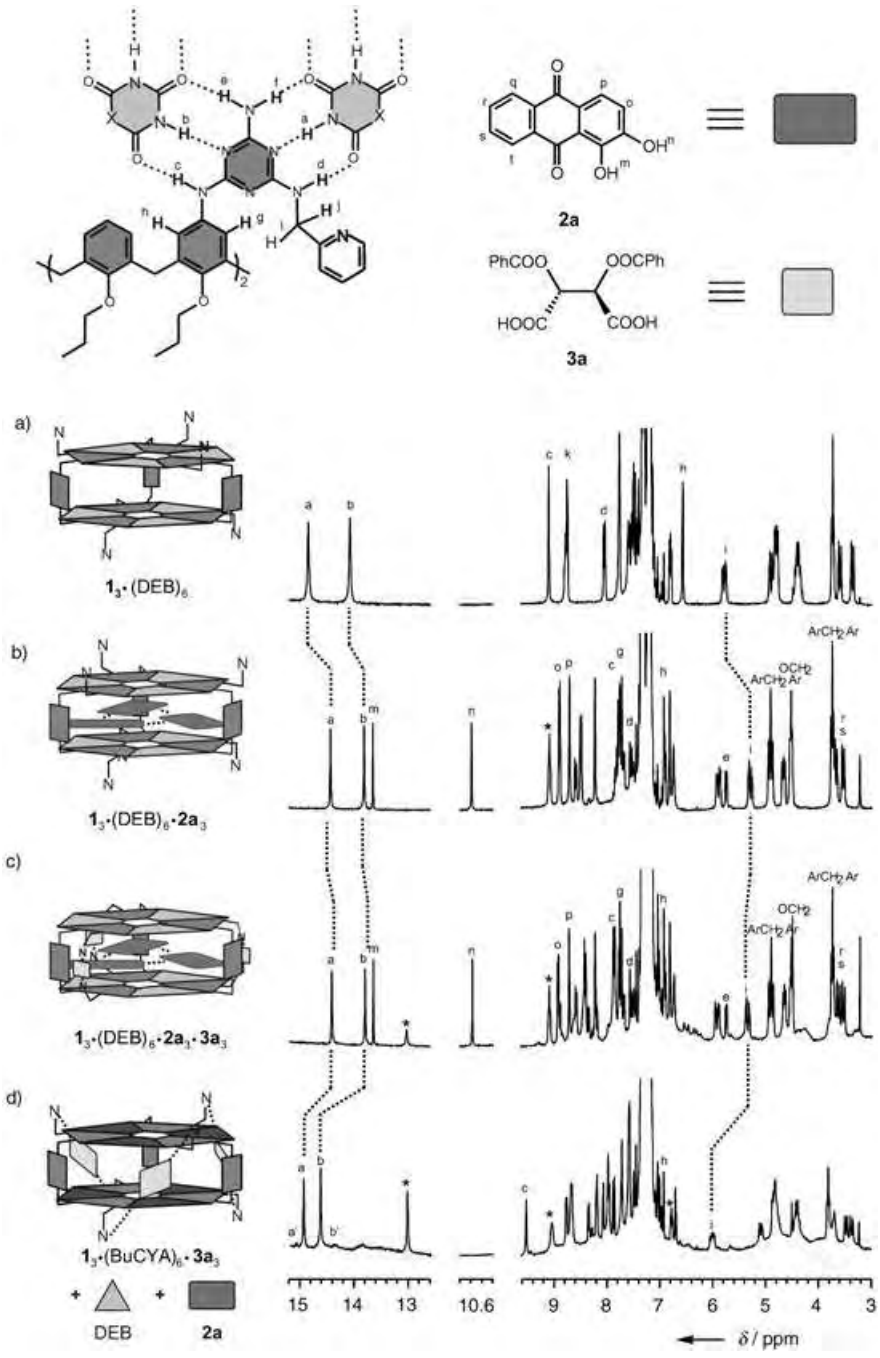

Figure 2. Parts of the ^{1}H NMR spectra (300 MHz) of a) assembly $\mathbf{1}_3\cdot(DEB)_6$ (1 mM), b) $\mathbf{1}_3\cdot(DEB)_6$ + 3 equiv **2a**, c) $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ + 3 equiv **3a**, and d) $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ + 6 equiv BuCYA. Signals marked with * belong to the free **2a**. All spectra were recorded at 298 K in [D_8]toluene.

interior of the assembly. Moreover, the downfield shift observed for alizarin hydroxyl OH^n proton ($\Delta\delta \approx 3.6$ ppm) indicates the formation of intermolecular hydrogen bonds between the carbonyl and hydroxy groups of adjacent guest molecules. These ^{1}H NMR studies shows clearly the encapsulation (*endo* complexation) of a noncovalent trimer of **2a** by receptor $\mathbf{1}_3\cdot(DEB)_6$ to give the complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$. The encapsulation of alizarin is very selective and sensitive to small structural changes. For example, no complexation was observed when protons H^q and H^t of alizarin **2a** were replaced by hydroxy groups (1,2,5,8-anthraquinone, **2b**, Figure 1).[17] The encapsulation is accompanied by a change in the symmetry of the host assembly, from D_3 to C_{3h} symmetry.[18,19]

After the encapsulation of $\mathbf{2a}_3$ in $\mathbf{1}_3\cdot(DEB)_6$ had been achieved (*endo* complexation), the role of $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ as an *exo* receptor was studied. Addition of three equivalents of dibenzoyl-D-tartaric acid (**3a**) to the complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ resulted in upfield shifts of the signals H^a and H^b from $\delta = 14.43$ and 13.81 to 14.38 and 13.76 ppm, respectively (Figure 2c). The signal for proton H^i undergoes a downfield shift of approximately 0.1 ppm. The signal of H^i at $\delta = 5.40$ ppm is indicative of the formation of hydrogen bonds between the 2-methylpyridyl substituents of the calix[4]arene dimelamine and the diacid **3a**.[20] The stoichiometry of the complexation of **3a** by $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ is not clear from these ^{1}H NMR studies. However, circular dichroism (CD) studies (data not shown) on the complexation of **3a** by receptor $\mathbf{1}_3\cdot(BuCYA)_6$ clearly showed the formation of a complex with 1:2 stoichiometry as the major species, although complexes with 1:1 and 1:3 stoichiometries were also present as minor species, probably because of steric effects or allosteric conformational changes.[21] The acids interact with the receptor through two-point interactions. These interactions are only possible "sideways", that is, each diacid interacts with both floors of the double rosette (Figure 1b), with one carboxylic acid of the guest hydrogen bonded to the pyridyl ring of the calix[4]arene dimelamine in the first floor while the other acid group of the same guest interacts with the other pyridyl group of the same calix[4]arene dimelamine (second floor).

The *exo* complexation is not very substrate selective: other diacids with different chemical structure, such as (1*R*,2*R*)-cyclohexane-1,2-dicarboxylic acid (**3b**) and (1*S*,3*R*)-camphoric acid (**3c**, Figure 1a), are also complexed in a similar fashion (data not shown).

Hence, the data show the complexation of six molecules of two different neutral guest molecules (alizarin **2a** and diacid **3a**). The hydrogen-bonded trimer $\mathbf{2a}_3$ is encapsulated in the internal cavity of the receptor $\mathbf{1}_3\cdot DEB_6$ while three molecules of guest **3a** are complexed at the periphery of the host assembly. The receptor has two different degrees of selectivity in the molecular recognition process; that is, the *endo* recognition is very selective and sensitive to the structure of the guest while the *exo* recognition is not structurally very demanding. The relative

orientation of the melamine groups (eclipsed) is preserved during the complexation of **3a** and results in the complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ with C_3 symmetry.

The controlled release of the guest molecules from the hydrogen-bonded complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ was subsequently studied.[22] Cyanurates form stronger hydrogen bonds with melamines than do barbiturates, thus allowing the exchange of DEB for BuCYA.[23] The addition of the BuCYA to the complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ results in the selective release of the hydrogen-bonded trimer $\mathbf{2a}_3$ to give the complex $\mathbf{1}_3\cdot(BuCYA)_6\cdot\mathbf{3a}_3$ in which the guest molecules at the periphery remain complexed. The release of the three guest molecules **2a** is achieved because cyanurate-based assemblies are not able to encapsulate **2a** as a result of geometrical differences between barbiturate- and cyanurate-based assemblies.[17] The release was proven by ^{1}H NMR and CD spectroscopy (Figure 2d and 3, respectively). Addition of six equivalents of BuCYA (with respect to complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$) to a solution of the complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ in [D$_8$]toluene generated a ^{1}H NMR spectrum in which all the signals of $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ had disappeared and only signals corresponding to complex $\mathbf{1}_3\cdot(BuCYA)_6\cdot\mathbf{3a}_3$ and free **2a** and DEB could be seen. For example, the signal at $\delta = 10.58$ ppm (which corresponds to OH^n when it forms intermolecular hydrogen bonds in the trimer $\mathbf{2a}_3$) is not present in the spectrum.[24] Moreover, the signals for protons H^a and H^b are split and shifted downfield from $\delta = 14.38$ and 13.76 ppm to $\delta = 14.95$ and 14.64 ppm, respectively (Figure 2d). The splitting of the signals arises from the transfer of chirality from the chiral guest (**3a**) to the assembly.[19] This induction of chirality is not complete, and therefore the two possible diastereomers (*P* and *M*) are formed.[25]

Additional proof for the complexation and selective release of guest molecules from $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ was obtained from CD spectroscopy (Figure 3). Receptor $\mathbf{1}_3\cdot(DEB)_6$ with D_3 symmetry exists as a racemic mixture of *P* and *M* enantiomers[19] and is therefore CD inactive. As mentioned earlier, the formation of the complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ is accompanied by a change in the symmetry

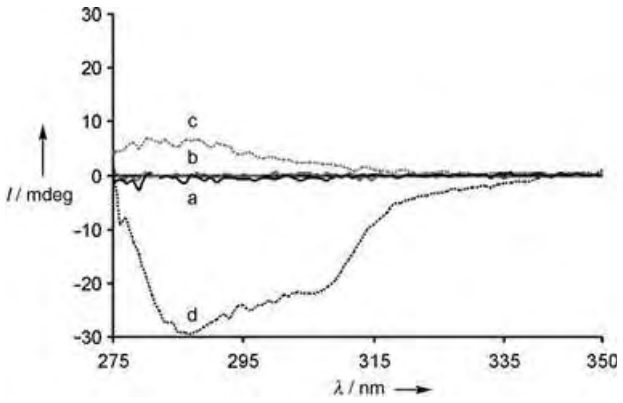

Figure 3. CD spectrum of a) $\mathbf{1}_3\cdot(DEB)_6$ (1.0 mM solution), b) $\mathbf{1}_3\cdot(DEB)_6$ + 3 equiv of **2a**, c) $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ + 3 equiv of **3a**, and d) $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ + 6 equiv of BuCYA. The spectra were recorded at 298 K in [D$_8$]toluene.

of the hydrogen-bonded receptor from D_3 to C_{3h}. In the C_{3h} symmetry, the two melamine moieties adopt an eclipsed conformation, thus resulting in an achiral complex. Addition of **3a** to $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ results in the appearance of a small CD signal (Figure 3) arising from the complexation and transfer of the chirality from **3a** to $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ which causes a change in the symmetry from C_{3h} for the complex $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3$ to C_3 for $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$.[26] Moreover, addition of BuCYA to $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ leads to a new signal in the CD spectrum. This signal is very similar to that observed in the CD spectrum of $\mathbf{1}_3\cdot(BuCYA)_6\cdot\mathbf{3a}_3$ formed by direct mixing of assembly $\mathbf{1}_3\cdot(BuCYA)_6$ and three equivalents of **3a**,[19] thus proving the release of the trimeric $\mathbf{2a}_3$ and the change of symmetry from C_3 back to D_3. In this case, the chirality of **3a** has been transferred to the complex $\mathbf{1}_3\cdot(BuCYA)_6\cdot\mathbf{3a}_3$ which results in the formation of one of the two possible diastereomeric assemblies ((P)-$\mathbf{1}_3\cdot(BuCYA)_6\cdot\mathbf{3a}_3$), and thus a signal is observed in the CD spectrum.[19]

Interestingly, changing the order in which the guest molecules **2a** and **3a** are added has a large influence on the self-assembling behavior of the system. Addition of three equivalents of **3a** directly to a solution of assembly $\mathbf{1}_3\cdot(DEB)_6$ in [D$_8$]toluene (1.0 mM) results in almost complete disassembly (only 8% remains intact) of the host assembly as can be seen by the disappearance of the signals for protons H^a and H^b in the ^{1}H NMR spectrum (Figure 4a,b). The higher acidity of the guest **3a** relative to DEB[27] possibly enables **3a** to form stronger hydrogen bonds with the calix[4]arene dimelamine building blocks **1**, thus leading to the destruction of the assembly. Nevertheless, the subsequent addition of three equivalents of **2a** to this solution results in a ^{1}H NMR spectrum that is identical to the one obtained previously when the guest molecules were added in reversed order (see Figures 2c and 4c). Thus, the host assembly is surprisingly reassembled by templation of the guest **2a** even in the presence of diacid **3a**. Moreover, the encapsulation of guest **2a** also allows the subsequent complexation of the guest **3a** in a similar fashion as described above, thus resulting in the quantitative formation $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ (Figure 4c). The reassembling of the host receptor is probably a result of the stabilizing effect of the π–π interactions between the guest **2a** and the calix[4]arene and dimelamine rings of **1**.[28] Further addition of six equivalents of BuCYA to $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ also leads to the exchange of DEB for BuCYA and release of the trimer $\mathbf{2a}_3$ (Figure 4d). The complexation of **3a** by $\mathbf{1}_3\cdot(BuCYA)_6$ after the exchange of DEB for BuCYA has also been proven by CD spectroscopy.[29]

Herein, we have demonstrated the complexation/encapsulation of two different kinds of neutral guest molecules in which perfect control is shown over the molecular recognition process at two different levels. The noncovalent host molecules $\mathbf{1}_3\cdot(DEB)_6$ display two different modes of complexation, that is, as an nonselective-*exo* receptor for three molecules of carboxylic acid **3a** at the periphery of the assembly and as an selective-*endo* receptor that templates the formation of a noncovalent hydrogen-bonded trimer of alizarin **2a** in the interior cavity of the assembly. The self-assembly of the receptor and the recognition processes bring together, using

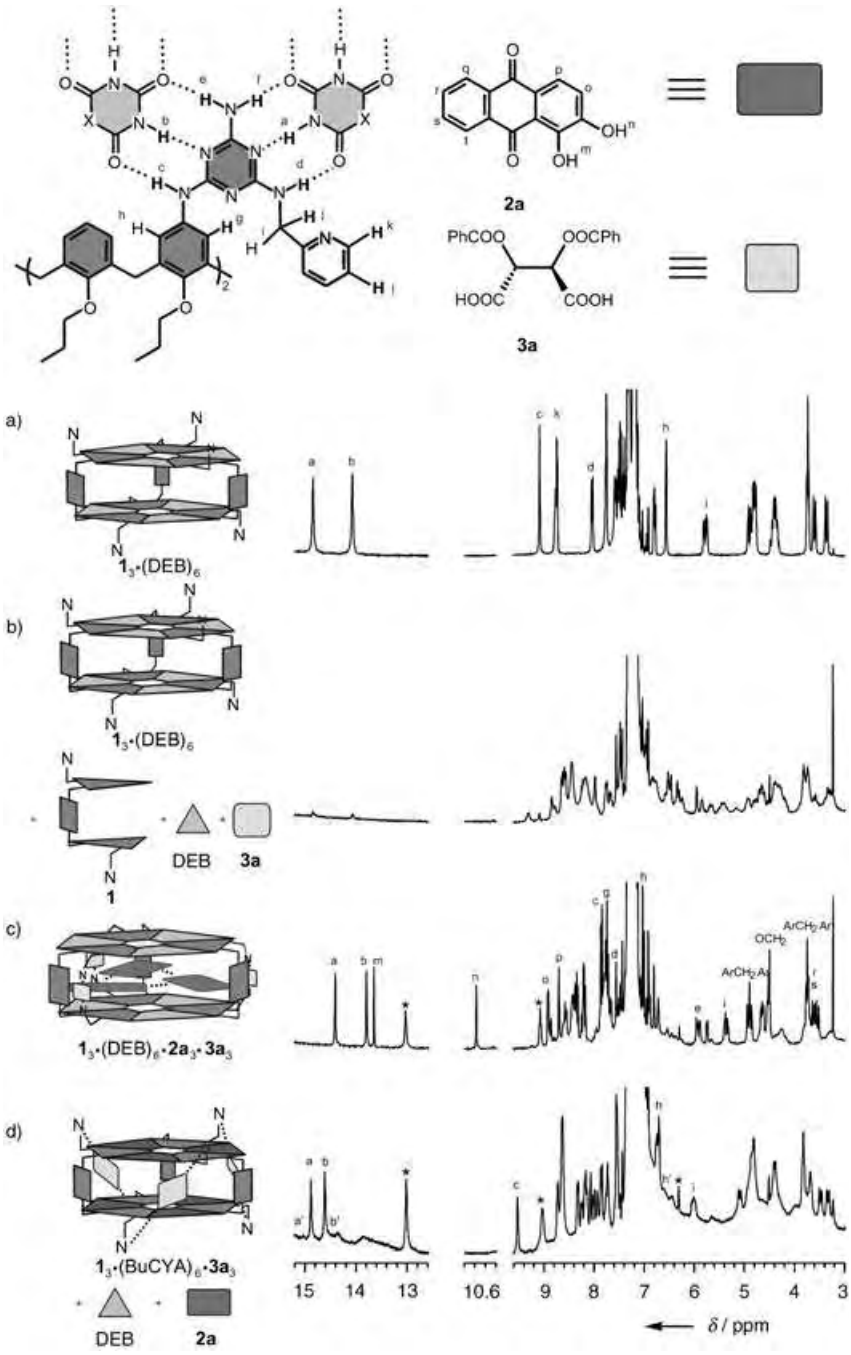

Figure 4. Parts of the ^{1}H NMR spectra (300 MHz) of a) assembly $\mathbf{1}_3\cdot(DEB)_6$ (1 mM), b) $\mathbf{1}_3\cdot(DEB)_6$ + 3 equiv **3a**, c) $\mathbf{1}_3\cdot(DEB)_6$ + 3 equiv **3a** + 3 equiv **2a**, and d) $\mathbf{1}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ + 6 equiv BuCYA. Signals marked with * belong to the free guest **2a**. All spectra were recorded at 298 K in [D_8]toluene.

the same noncovalent interactions, nine building blocks of the receptor and six guest molecules with absolute control over their spatial disposition to form the complex $\mathbf{1a}_3\cdot(DEB)_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$. Moreover, the addition of BuCYA leads to the release of the noncovalent trimer, while the other guest molecules remain complexed. It has also been demonstrated that the order in which the different building blocks are added is very important for the outcome of the self-assembly process. This observation might have important consequences for noncovalent synthesis in general.

[24] The ^{1}H NMR spectrum of the receptor complexing both $\mathbf{2a}_3$ and $\mathbf{3a}_3$ after the addition of BuCYA is similar to the ^{1}H NMR spectrum of $\mathbf{1}_3\cdot(\text{BuCYA})_6\cdot\mathbf{3a}_3$ formed by direct mixing of assembly $\mathbf{1}_3\cdot(\text{BuCYA})_6$ and three equivalents of **3a** (data not shown).

[25] In the absence of chiral auxiliary, the receptor is presented as a racemic mixture of *P* and *M* enantiomers and therefore only two signals (ca. 13–15 ppm) are expected for the NH protons of the barbiturate/cyanurate componets in the ^{1}H NMR spectrum. However, the addition of chiral diacids (D or L) leads to the formation of diastereomeric ((*P*)-D or (*M*)-L) assemblies (induction of chirality), and therefore four signals are expected, two signals for each diastereomeric receptor.

[26] The encapsulation of alizarin **2a** by assemblies bearing chiral building blocks leads to a change of symmetry from D_3 to C_3.[17] The CD spectrum of these assemblies resembles the CD spectrum obtained for complex $\mathbf{1}_3\cdot(\text{DEB})_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$.

[27] The pK_a value of DEB is 7.4 and of guest **3a** is 2.99 (see: a) R. M. C. Dawson, *Data for biochemichal research*, Clarendon Press, Oxford, **1959**; b) N. Chidambaram, D. J. Burgess, *AAPS PharmSciTech* **2000**, *2*, 1 – 11).

[28] a) C. A. Hunter, J. K. M. Sanders, *J. Am. Chem. Soc.* **1990**, *112*, 5525 – 5534; b) M. G. J. ten Cate, J. Huskens, M. Crego-Calama, D. N. Reinhoudt, *Chem. Eur. J.* **2004**, *10*, 3632 – 3639.

[29] Addition of BuCYA to $\mathbf{1}_3\cdot(\text{DEB})_6\cdot\mathbf{2a}_3\cdot\mathbf{3a}_3$ results in the appearance of a negative CD signal similar to the signal obtained by direct mixing of assembly $\mathbf{1}_3\cdot(\text{BuCYA})_6$ and three equivalents of **3a**. Thus, addition of BuCYA results in the release of the trimeric species of **2a**.

Organic Synthesis

Intermolecular Tandem Pd-Catalyzed Cross-Coupling/[4+4] and [4+2] Cycloadditions: A One-Pot, Five-Component Assembly of Bicyclo[6.4.0]dodecanes**

Phil Ho Lee and Kooyeon Lee*

Tandem reactions have long been established as efficient methods for the rapid synthesis of complex compounds starting from simple, readily available substrates in relatively few steps.[1–3] Although many intramolecular tandem reactions have been reported for constructing complex organic molecules, the corresponding highly efficient intermolecular reactions remain an important challenge for synthetic organic chemists. A range of strategies involving the sequential generation of radical and anionic species has been used for such intermolecular transformations.[4,5] However, relatively few transition-metal-catalyzed intermolecular tandem processes[6] have been developed for the synthesis of complex cyclic compounds.[7] Recently, we reported a method for the synthesis of substituted allenes, polyallenes, and unsymmetrical bis(allenes) from allenylindium reagents generated in situ.[8] With this result in hand, we envisioned that a Pd-catalyzed cascade process involving sequential cross-coupling between vinyl bromides or triflates and propargyl halides followed by [4+4] and [4+2] cycloadditions should provide structurally diverse carbocycles. Herein, we describe the development of tandem Pd-catalyzed cross-coupling/[4+4]

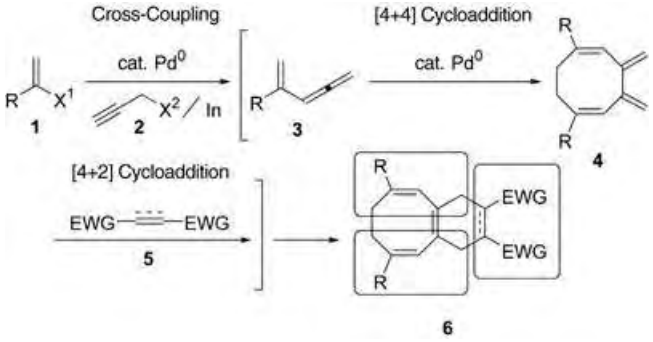
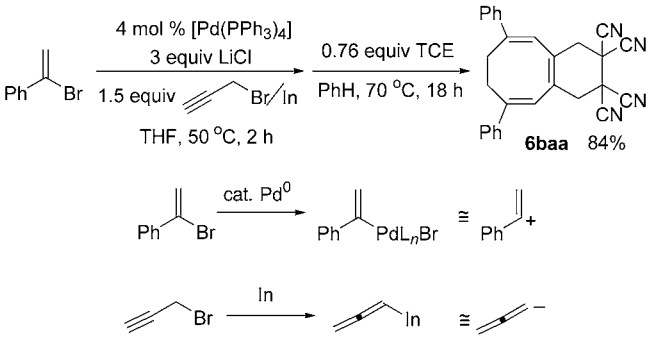
and [4+2] cycloadditions as an efficient approach to bicyclo-[6.4.0]dodecane derivatives (Scheme 1).[9]



Scheme 1. EWG = electron-withdrawing group.

The tandem process was first examined with α-bromostyrene, propargyl bromide, and tetracyanoethylene (TCE). The organoindium reagent obtained from one equivalent of indium and 1.5 equivalents of propargyl bromide was added to a solution of one equivalent of α-bromostyrene in the presence of 4 mol % of $[Pd(PPh_3)_4]$ and three equivalents of LiCl,[8,10] and the solution was stirred at 50 °C for 2 h. In the ^{1}H NMR spectrum of the crude product mixture, 3,4-dimethylene-1,6-diphenyl-1,5-cyclooctadiene (**4ba**) was observed as the major compound, thus indicating that a sequential cross-coupling/[4+4] cycloaddition had taken place to produce **4ba** in 94 % yield. Because **4ba** is a 1,3-diene, we further attempted a [4+2] cycloaddition reaction with crude **4ba**. Thus, **4ba** was treated with 1.5 equivalents of TCE (70 °C, benzene, 18 h) to afford **6baa** in 84 % yield. This transformation shows that five components can be assembled in an intermolecular cascade cross-coupling/[4+4] and [4+2] cycloaddition sequence (Scheme 2).

A Pd-catalyzed [4+4] cycloaddition reaction with a vinyl allene as the starting material was reported recently.[11] In this reaction, the vinyl allene was obtained from the reaction of 1-phenylvinylmagnesium bromide with propargyl bromide in the presence of a Pd^0 catalyst.[12] However, preparation of the vinyl allene in situ by inversion of the charge polarization of the reaction components (α-bromostyrene and propargyl bromide) was applied in the present method.



Scheme 2.

The results of several one-pot, five-component assembly reactions are summarized in Table 1. With **5b**, **5c**, **5e**, and **5g** as dienophiles, **4ba** gave bicyclo[6.4.0]dodecane derivatives in good yields (entries 2–5). Similarly, **4ba** reacted with maleimide (**5f**) to produce **6baf** in 79 % yield (entry 6). For a vast number of α-bromovinylarenes as organic electrophiles, the presence of various substituents, for example, 4-trifluoromethyl, 4-methoxy, and 2-chloro on the aromatic ring, did not affect the efficiency of the tandem reactions. The reaction also worked equally well with α-bromovinylarenes containing free hydroxy and amino groups (entries 9 and 11). Treatment of **4ga** with two equivalents of naphthoquinone afforded **6gad** in 64 % yield (entry 7). Reaction of **4da** with glyoxylic acid ethyl ester produced **6dah** in 69 % yield, and the enol triflate of 3-bromoacetophenone underwent the cascade reaction to afford **6hae** in 66 % yield (entry 12).

(α-Bromovinyl)trimethylsilane reacted with propargyl bromide to produce **4aa** in 71 % yield under the optimized conditions. Unfortunately, the desired bicyclo[6.4.0]dodecane derivative was not obtained, because of the instability of **4aa** under the conditions of the [4+2] cycloaddition reaction. With propargyl halides as nucleophilic cross-coupling partners, the presence of a methyl substituent at the α position has little effect on either the reaction rate or the product yield.[13] In the case of 3-chloro-3-methyl-1-butyne (**2b**), **4bb**, **4cb**, **4eb**, and **4gb**, with four methyl substituents on the exocyclic C=C bonds, were obtained in 63–91 % yield. However, these compounds did not undergo the [4+2] cycloaddition because of steric hindrance.

Although the mechanism of the present reaction has not been established, a possible reaction pathway is shown in

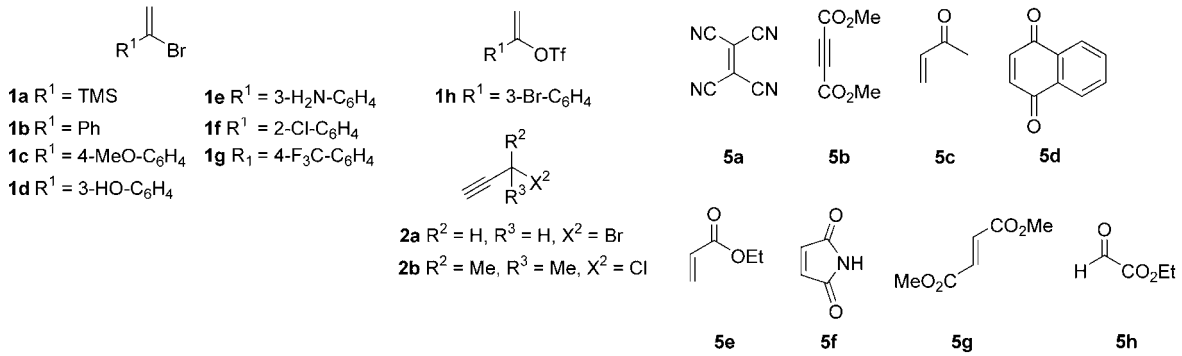


Table 1: Cascade cross-coupling/[4+4] and [4+2] cycloaddition.[a]

Entry	Reagents	Product	Yield [%][b]	Entry	Reagents	Product	Yield [%][b]	Entry	Reagents	Product	Yield [%][b]
