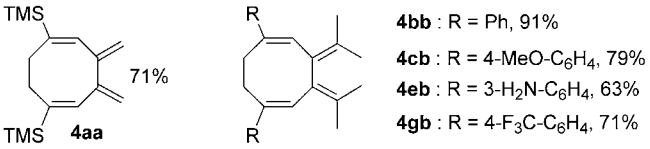
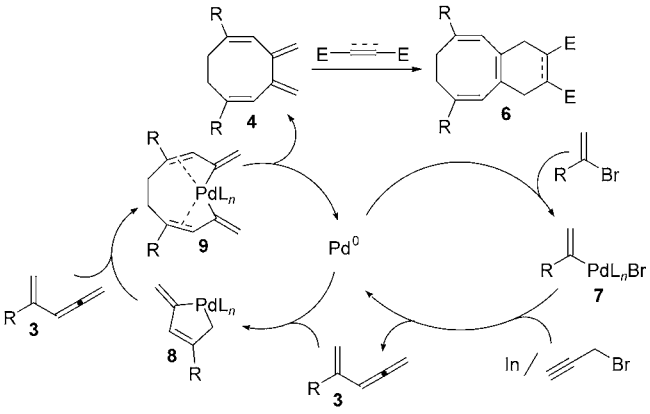
[a] Cross-coupling/[4+4] cycloaddition: Compound **1** (0.5 mmol) was treated with **2** (0.75 mmol) and indium (0.5 mmol) in THF (2 mL), in the presence of 4 mol% of $[Pd(PPh_3)_4]$ and LiCl (1.5 mmol) under N_2 at 50°C for 2 h. [4+2] Cycloaddition: Crude **4** was treated with **5** (0.38 mmol) in benzene (2 mL) at 70°C for 18 h. [b] Yield of isolated product. [c] 2.5 equiv of methyl vinyl ketone was used.





Scheme 3.

Scheme 3. Oxidative addition of the vinyl bromide to a Pd^0 complex and subsequent transmetalation with the organoindium reagent, followed by reductive elimination, affords the vinylallene **3**. Subsequent insertion of Pd^0 into the vinyl allene produces a five-membered palladacycle **8**, which reacts with another molecule of the vinyl allene to generate the di(σ-alkenyl) palladium complex **9**. Final reductive elimination would then give the 3,4-dimethylene-1,5-cyclooctadiene **4**.[8,11] [4+2] Cycloaddition of the 1,3-diene **4** with representative dienophiles produces the observed bicyclo[6.4.0]dodecane derivatives **6**.

In conclusion, this study has led to the development of a novel tandem Pd-catalyzed cross-coupling/[4+4] and [4+2] cycloaddition sequence that allows the rapid synthesis of bicyclo[6.4.0]dodecane derivatives starting from α-bromovinylarenes, propargyl bromides, and dienophiles in one reaction vessel. It is noteworthy that five components are assembled into one molecule in this procedure. In addition, the present process is one of the comparatively few examples in which a Pd^0 catalyst is simultaneously involved in two catalytic cycles.[2,3]

Experimental Section

Typical experimental procedure: **6baa**: α-Bromostyrene (**1b**, 102.0 mg, 0.5 mmol) was added at room temperature, under nitrogen, to a suspension of $[Pd(PPh_3)_4]$ (4 mol%, 23.1 mg) and lithium chloride (63.5 mg, 1.5 mmol) in dry THF (1 mL). After 15 min the allenylindium reagent, which was generated from propargyl bromide (**2a,** 80% (w/w) in toluene, 89.2 mg, 0.75 mmol) and indium (57.0 mg, 0.5 mmol) in dry THF (1 mL), was added. The solution was stirred at 50°C under nitrogen for 2 h, and then the solvent was removed under reduced pressure. A solution of tetracyanoethylene (**5a,** 48 mg, 0.38 mmol) in dry benzene (2 mL) was added to the residue. After heating at 70°C under nitrogen for 18 h, the resulting solution was quenched with saturated aqueous $NaHCO_3$. The aqueous layer was extracted with diethyl ether (3 × 20 mL), and the combined organic phases were washed with water and brine, dried with $MgSO_4$, filtered, and concentrated under reduced pressure. The residue was purified by silica-gel column chromatography with EtOAc/hexane (1:10) as eluent to produce 6,9-diphenyl-7,8-dihydro-1*H*,4*H*-benzocyclooctene-2,2,3,3-tetracarbonitrile (**6baa**; 87.0 mg, 84%). ^1H NMR (400 MHz, $CDCl_3$, 25°C, TMS): $\delta = 7.34$–7.30 (m, 10H), 5.94 (s, 2H), 3.28 (s, 4H), 2.88 ppm (s, 4H); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta =$ 147.3, 141.9, 128.6, 128.3, 126.2, 124.2, 124.0, 110.6, 37.9, 36.6,

30.4 ppm; IR (film): $\tilde{\nu}$ = 3055, 1941 cm^{-1}; HRMS (EI) calcd for $C_{28}H_{20}N_4M^+$ 412.1688; found 412.1689.

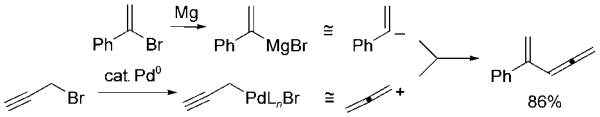
[12] When α-bromostyrene is treated with propargyl bromide in the presence of Mg and Pd^0, α-bromostyrene and propargyl bromide act as synthons of a vinyl anion and allenyl cation, respectively, to produce a vinyl allene: M. Murakami, K. Thami, Y. Ito, *Organometallics* **1999**, *18*, 1326.



[13] The use of 3-bromo-1-butyne produced the corresponding [4+4] adduct in 90% yield. The product consisted of three stereoisomers (1.3:1.0:1.3) with respect to the orientation of the two methyl groups on the exocyclic double bonds.

Nanocrystals

Rare-Earth Oxide Nanopolyhedra, Nanoplates, and Nanodisks**

Rui Si, Ya-Wen Zhang, Li-Ping You, and Chun-Hua Yan**

The synthesis of colloidal nanocrystals has attracted rapidly growing interest not only due to their remarkable size- and shape-dependent chemical and physical properties but also because of their self-assembly potential for device applications.[1–7] For the preparation of nanomaterials with desirable properties, it remains a challenge to explore robust pathways and unify principles towards the systematic manipulation of their crystal size and shape in different systems. The thermolysis of various organometallic precursors and treatment in surfactant solutions have been regarded as powerful

pathways to synthesize size- and shape-controlled nanoparticles,[1,2,5,7–19,22] nanorods,[2,6,13,14,16,20,21] and nanodisks and nanoplates[14,21–23] of metals,[2,6,8,9,11,13,22] semiconductors,[1,5,14,21] and metal oxides.[7,10,12,15–20,23]

More recently, surface-modified rare-earth compound nanocrystals have drawn more attention due to their unique properties and promising applications in, for example, UV shielding, luminescent displays, optical communication, biochemical probes, and medical diagnostics. For instance, Sato et al. obtained ZnO- and CaO-doped CeO_2 nanoparticles in water at 40 °C that show a significantly reduced catalytic activity in oxidation and excellent UV-absorption capability.[24] Haase et al. have prepared colloidal $CePO_4$:Tb/$LaPO_4$ core-shell nanoparticles in diphenyl ether at 200 °C that display green emission with a high quantum yield of 70 %,[4] and van Veggel et al. have reported the synthesis of redispersible Er^{3+}-, Nd^{3+}-, and Ho^{3+}-doped LaF_3 nanoparticles with modified near-infrared emission.[3]

However, an important family of rare-earth compounds, namely colloidal rare-earth oxide nanocrystals (other than ceria), have rarely been synthesized, possibly due to the difficulty in choosing appropriate precursor complexes.[23,25–27] Therefore, to develop a versatile route towards colloidal rare-earth oxide nanocrystals is of some urgency. We report here a novel and general synthesis of rare-earth oxide nanocrystals by thermolysis of their benzoylacetonate complexes in oleic acid/oleylamine solvents to give, depending upon the nature of the metal cations and the selective adsorption effects of the solvents employed, highly dispersible and crystalline rare-earth oxide nanopolyhedra, nanoplates, and nanodisks. Optical characterization showed that the CeO_2 nanopolyhedra and Eu_2O_3 nanodisks have interesting optical properties.

The crystal structure and morphology of the products synthesized under optimal conditions were determined by powder X-ray diffraction (XRD) and transmission electron microscopy (TEM), respectively (Table 1). All the dry, trivalent rare-earth oxides (Ln_2O_3, Ln = La–Y) have a body-centered cubic (*bcc*) structure (space group: *Ia*3), whereas dry CeO_2 has a face-centered cubic (*fcc*) structure (space group: *Fm*3*m*). Figure 1 shows the XRD patterns of four samples.

Table 1: Crystal structures and morphologies of the as-obtained rare-earth oxides synthesized by thermolysis of $Ln(BA)_3(H_2O)_2$ (Ln = La–Y) or $Ce(BA)_4$ in oleic acid (OA)/oleylamine (OM) at 250–330 °C for 20–60 min.[a]

	OA/OM	*T* [°C]	*t* [min]	Structure	Morphology
La_2O_3	1:7	330	60	*Ia*3	7 nm nanoplate
CeO_2	0	250	20	*Fm*3*m*	2.6 nm nanopolyhedron
Pr_2O_3	3:5	310	60	*Ia*3	20 nm nanoplate

Y_2O_3	3:5	310	60	*Ia*3	65 nm nanodisk

[a] Determined by powder X-ray diffraction (Rigaku D/MAX-2000, $Cu_{K\alpha}$ radiation) and transmission electron microscopy (Philips Tecnai F30, 300 kV).

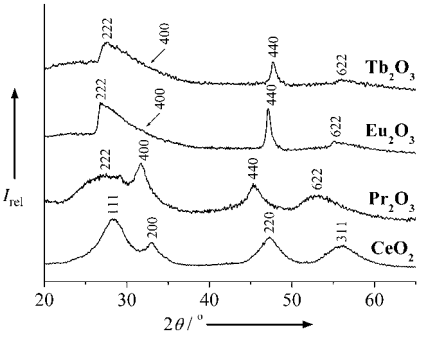

Figure 1. XRD patterns of dry CeO_2, Pr_2O_3, Eu_2O_3, and Tb_2O_3. The calculated lattice constant *a* is 5.4516(3), 11.36(1), 10.97(1), and 10.90(1) Å for CeO_2 (JCPDS: 34-0394), Pr_2O_3,[28] Eu_2O_3 (JCPDS: 34-0392), and Tb_2O_3 (JCPDS: 23-1418), respectively.

The TEM image shown in Figure 2a reveals that the as-obtained CeO_2 nanopolyhedra have a uniform size of 2.6 nm and form a two-dimensional (2D) superlattice structure on the copper grids. The HRTEM image (inset in Figure 2a) shows that each CeO_2 nanopolyhedron is a truncated octahedron enclosed by the (111) and (200) planes.[29]

Figure 2b is the TEM image of the as-obtained Eu_2O_3 redissolved in cyclohexane. Nanodisks with a diameter of about 32 nm have formed, and some of them assemble through their round surface to produce rail-like nanoarrays (see also the Supporting Information). Each slightly flexural Eu_2O_3 nanodisk comprises six (222) layers and has a thickness of 1.6 nm according to the HRTEM image of the side-surface (inset in Figure 2b). The ($\bar{4}40$) planes are perpendicular to (222), and thus the preferential growth direction of the nanodisks is [110]. Each as-obtained Eu_2O_3 nanodisk has a 2D growth structure that is confined along the [111] direction. Figure 2c displays the 2D Eu_2O_3 nanoarrays in a large area. The array axis is [111] and the distance between two adjacent nanodisks is 2.3 nm. Figure 2d shows the TEM image of the Eu_2O_3 nanocrystals redissolved in toluene/hexane (1:1); square nanoplates with a side-size of about 12 nm have formed (see also the Supporting Information). Figure 2e shows that the surface of a nanoplate is composed of the (400) and (040) planes. Each Eu_2O_3 nanoplate is constructed from four (004) layers and has a thickness of 1.0 nm, as determined from the HRTEM image of its side-surface (bottom inset in Figure 2e). The angle between the (222) and (004) planes is close to 60°, which is consistent with the calculated value. The as-obtained Eu_2O_3 nanoplate has a 2D growth structure that is confined along the [001] direction due to symmetry breaking, similar to the case of Gd_2O_3 square nanoplates.[23]

Figures 2f and g show the TEM images of the as-obtained Er_2O_3 and Pr_2O_3, respectively. Pure nanodisks with a diameter of 43 nm are present for Er_2O_3, while pure square nanoplates with a side-size of 20 nm have formed for Pr_2O_3. Figure 2h shows the 2D Pr_2O_3 nanoarrays produced on the copper grids. The array axis is [001] and the distance between two adjacent nanodisks is 2.9 nm.

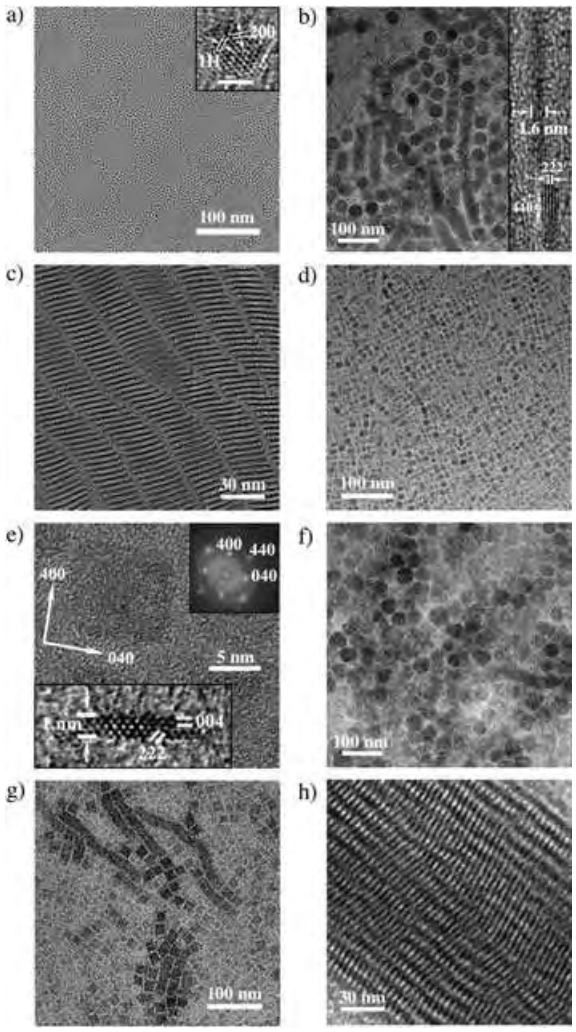

Figure 2. a) TEM image of the as-obtained CeO_2; the inset shows the HRTEM image of a CeO_2 nanopolyhedron (scale bar: 2 nm); b) TEM image of the as-obtained Eu_2O_3 redissolved in cyclohexane; the inset shows the side-surface HRTEM image of a nanodisk; c) TEM image of the 2D Eu_2O_3 nanoarrays; d) TEM image of the as-obtained Eu_2O_3 redissolved in toluene/hexane (1:1); e) The surface and side-surface HRTEM images of an Eu_2O_3 nanoplate; the inset shows the fast Fourier transformation of the surface HRTEM image; f) TEM image of the as-obtained Er_2O_3; g) TEM image of the as-obtained Pr_2O_3; h) TEM image of the 2D Pr_2O_3 nanoarrays.

The mechanism of shape-controlled synthesis of nanocrystals is currently being investigated intensively.[6,12–14,16,17,20–22] During the thermolysis of the precursor complexes the capping ligand (variety, concentration, and selective adsorption onto particular crystallographic facets) plays a critical role in the shape-control process. In our case, experiments show that oleic acid binds more strongly than oleylamine to the surface atoms of the nanocrystals, due to its higher oxophilicity. Increasing the amount of oleic acid gradually dissolved the CeO_2 and greatly improved the solubility of the Ln_2O_3 products in nonpolar solvents. Capping ligands also have distinct effects on the shape of the products formed during the crystal-growth process (Figure 3a).

The thermolysis of rare-earth benzoylacetonate complexes releases a large number of rare-earth oxide nuclei in which the oxygen comes from the chelating ligand.[5] In the *fcc* CeO_2 crystals, the density of surface atoms follows the order $\{111\} > \{100\} > \{110\}$. Generally, the face with a higher density of surface atoms is blocked by the adsorption of surfactants during the crystal growth of colloidal nanocrystals, and the growth along this facet is therefore considerably restricted. However, since oleylamine is characterized by its nonselective adsorption on these faces, the CeO_2 nuclei grow in a 3D mode to generate nanopolyhedra enclosed by both the (111) and (200) planes. The *bcc* structure of Ln_2O_3 can be derived from the *fcc* structure of CeO_2 by removing one-fourth of the oxygen atoms from specific lattice sites. The surface density of atoms in the facets of this structure follows the order $\{100\} > \{111\} > \{110\}$. The former two denser facets are selectively capped by oleic acid, which means that the nuclei grow in a 2D mode to produce nanoplates with confined (001) planes or nanodisks with confined (111) planes. The confinement effect of oleic acid on the specific facets in this case can be demonstrated in the synthesis of Eu_2O_3 nanodisks: decreasing the amount of oleic acid (OA/OM = 1:7) led to some of the Eu_2O_3 nanoparticles showing 3D growth (see Figure 3b). The shape evolution from square nanoplate (La_2O_3–Eu_2O_3) to nanodisk (Sm_2O_3–Y_2O_3) is possibly caused by the change of relative growth rate along {100} to {111} across the Ln_2O_3 series.

Further experiments showed that the size of our rare-earth oxide nanocrystals can be tuned by changing the synthetic parameters, such as the reaction time and temperature. For Eu_2O_3, for example, shortening the reaction time

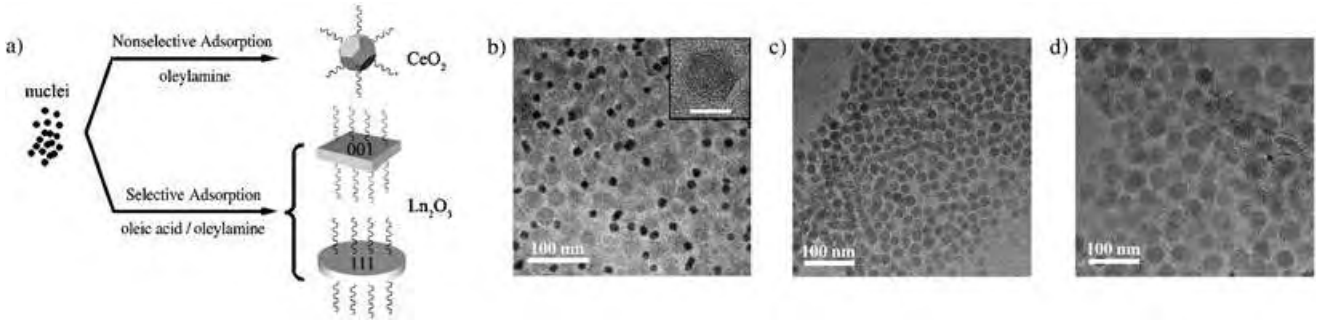

Figure 3. a) Formation of rare-earth oxide nanopolyhedra, nanoplates, and nanodisks. b)–d) TEM images of the as-obtained Eu_2O_3: b) OA/OM = 1:7, 310 °C, 1 h (inset: HRTEM image of an Eu_2O_3 nanoparticle; scale bar: 10 nm); c) OA/OM = 3:5, 310 °C, 20 min; d) OA/OM = 3:5, 330 °C, 1 h.

from 1 h to 20 min caused a decrease in the diameter of the nanodisks from 32 to 20 nm at a reaction temperature of 310 °C (Figure 3c). Upon increasing the reaction temperature from 310 to 330 °C, the size of the nanodisks increased from 32 to 41 nm with a reaction time of 1 h (Figure 3d).

Figure 4a shows the UV/Vis absorption spectrum of the colloidal CeO_2 nanopolyhedra. The spectrum exhibits a strong absorption band at about 300 nm due to the charge-transfer transition from the O 2p to the Ce 4f orbital in CeO_2. Its absorption edge is blue-shifted compared to that of the aggregated CeO_2 nanocrystals in our previous work.[30] Furthermore, the direct bandgap energy, E_d,[31] of the dispersible CeO_2 is 3.60 eV, much larger than that of the aggregated one (3.42 eV). As both CeO_2 samples have the same cubic structure and particle size (2.6 nm), the blue shift of the UV absorption observed for the present monodisperse CeO_2 nanopolyhedra must be related to a modification of the surface state by surface passivation arising from the capping oleylamine ligands.[30]

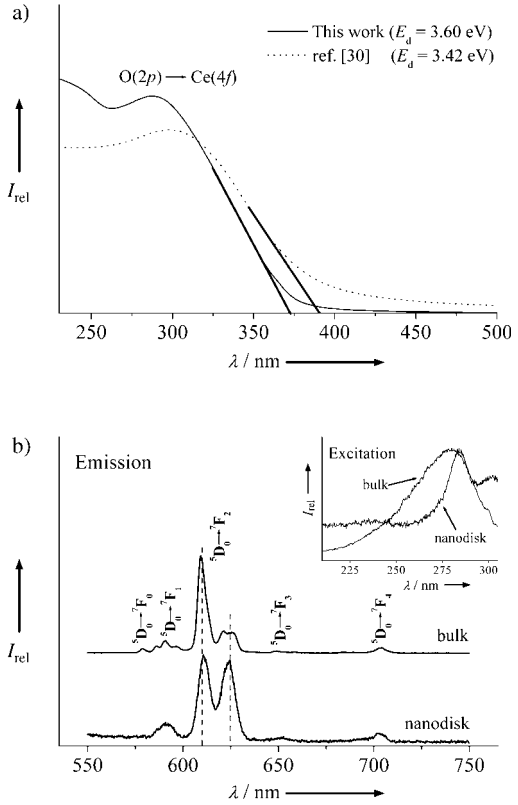

Figure 4. a) UV/Vis absorption spectra (Hitachi U-3010) of the monodisperse CeO_2 nanopolyhedra (solid line) obtained in this work and the aggregated CeO_2 ones of ref. [30] (dotted line). b) Room-temperature fluorescence emission spectra (Hitachi F-4500) of the Eu_2O_3 nanodisks and commercial Eu_2O_3 powders (λ_{ex} = 285 nm); the inset shows their excitation spectra (λ_{em} = 610 nm).

Figure 4b shows the room-temperature emission spectra of Eu_2O_3 nanodisks redissolved in cyclohexane and commercial Eu_2O_3 (99.99%) powder after excitation at a wavelength of 285 nm. The spectra are described by the $^5D_0 \rightarrow {}^7F_j$ line emissions (J = 0, 1, 2, 3, and 4) of the Eu^{3+} ion.[32] An interesting feature is that the intensity ratio of the peak at 625 nm to the peak at 610 nm is greatly enhanced in the emission spectrum of the Eu_2O_3 nanodisks compared with that of the cubic Eu_2O_3 powders. The emission spectrum of the cubic Eu_2O_3 nanodisks is very similar to that of the monoclinic Eu_2O_3 polycrystalline powders, in which the Eu^{3+} ion occupies a site of lower symmetry.[33] It is known that surface atoms, which have a lower coordination number, usually have lower symmetry than bulk ones. In the present Eu_2O_3 nanodisks, two out of six (222) planes are surface ones and thus the surface fraction of Eu^{3+} ions is very high ($> 1/3$). Therefore, this unusual spectrum is considered to result from the higher fraction of surface Eu^{3+} ions, which occupy a different symmetric site due to their lower coordination number than that of the bulk atoms in the Eu_2O_3 nanodisks.

In summary, we have demonstrated a general synthesis of dispersible rare-earth oxide nanocrystals by thermolysis of their benzoylacetonate complexes in oleic acid/oleylamine, which may represent a general route to nanocrystals of other metal oxides. Due to the selective adsorption of the capping ligands on certain cubic faces during crystal growth, nanocrystals with different morphologies, such as nanopolyhedra, nanoplates, and nanodisks, are created, which exhibit a striking ability to self-assemble into large-area nanoarrays. These novel nanometric architectures with unusual optical properties that result from surface-modification effects are expected to enrich the field of lanthanide chemistry, benefit the development of a shape-control theory for nanocrystals, and promise the fabrication of advanced rare-earth functional materials with new applications.

Experimental Section

Oleylamine (OM, Acros), oleic acid (OA, Alfa), and 1-benzoylacetone (HBA, Acros) were used as received.

Rare-earth complexes: La_2O_3, $Ce_2(CO_3)_3$, Pr_6O_{11}, Nd_2O_3, Sm_2O_3, Eu_2O_3, Gd_2O_3, Tb_4O_7, Er_2O_3, or Y_2O_3 (metal content 6 mmol) was dissolved in 40 mL of deionized water by adding HNO_3. HBA (24 mmol) was dissolved in 80 mL of ethanol by adding $NH_3{\cdot}H_2O$. The above two solutions were mixed together whilst stirring and dilute aqueous NH_3 was then added dropwise (final pH: 6–7). The solution was aged at room temperature for 12 h and then filtered. The precipitate was collected, washed with deionized water, and then dried in vacuo at 40 °C overnight. The yields of the complexes were 40–60%.

Dispersible rare-earth oxides: To obtain Ln_2O_3 (Ln = La, Pr, Nd, Sm, Eu, Gd, Tb, Er, or Y), $Ln(BA)_3(H_2O)_2$ (0.2 mmol) was added to 15 mL of OA/OM (Table 1) in a three-necked flask at room temperature. Ar was bubbled through the solution for 20 min and then the solvents were removed under vacuum at about 100 °C for 30 min. The flask was then heated to 310–330 °C at a heating rate of 20 K min^{-1} with vigorous magnetic stirring in a temperature-controlled electromantle, and was maintained at this temperature for 1 h under Ar. To obtain CeO_2, $Ce(BA)_4$ (0.5 mmol in 1 mL of OM) was injected into 15 mL of OM at 250 °C and heated for 20 min under Ar. When the reaction was complete, an excess amount of ethanol was poured into the solution at about 70 °C. The resultant mixture was centrifugally separated and the products were collected. The as-precipitated nanocrystals were washed several times with ethanol and then dried in vacuo at 70 °C overnight. The yield of nanocrystals obtained was

about 75%. The as-precipitated nanocrystals could be redissolved in nonpolar solvents such as hexane, toluene, and cyclohexane.

Self-Assembly

Self-Assembled Diamide Nanotubes in Organic Solvents**

*Nancy Díaz, François-Xavier Simon, Marc Schmutz, Michel Rawiso, Gero Decher, Jacques Jestin, and Philippe J. Mésini**

In the field of nanomaterials, high aspect ratio objects such as fibers and nanotubes are interesting since they can form 3D networklike gels, they can be effectively oriented, and can be used to transport electrons or particles in a 1D fashion. Supramolecular chemistry has proved to be very useful for building such objects. Besides carbon nanotubes and biological macromolecules, many fibrillar structures have been assembled from supramolecular self-association of small molecules.[1] The self-assembly process offers crucial advantages in the formation of gels by low-mass organic gelators,[2] such as thermoreversibility, easy processing, and high purity. However, chemical design and synthesis also permits the addition of further functionality to threadlike assemblies for applications such as biomineralization[3] and the selective binding of protein on lipidic tubes.[4] Tubular structures offer additional properties because of the presence of an inner cavity, which can be used as nanocargo devices or nanoreactors.[5] They have also been used to template inorganic tubular structures by sol–gel processes[6] and multilayered polyelectrolyte tubes upon layer-by-layer adsorption.[7]

Numerous molecules can self-assemble to form 1D objects such as ribbons or fibrils;[8] however, only a few of

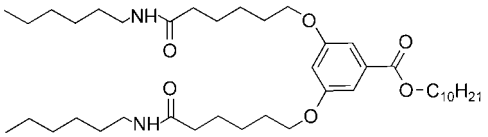
  DOI: 10.1002/anie.200500536

them form hollow tubes.[9] Some such tubes formed from lipids[10] and bile acids[11] have diameters on the order of micrometers and are polydisperse. Recent work has enabled the discovery of new self-assembled tubes, such as from sugar derivatives,[12] bolaamphiphiles,[13] lipids,[4] steroids,[14] peptides,[15] and hexabenzocoronene derivatives,[16] with diameters that fill the gap between the micrometer scale and the diameter of the carbon nanotubes (1 to 3 nm). Such tubes are always found along with helical ribbons, which are precursors to the closed tubes and were previously identified by Kunitake and co-workers.[17] These impressive objects have stimulated much theoretical work in which their assembly into ribbons that can further wind up into helical ribbons, and ultimately form tubes, was modeled.[18] In relation to the above-mentioned studies, we report a new compound, with a simple chemical structure, which is able to self-assemble into nanotubes in organic solvents. We also report the characterization of these tubes.

Many diamides self-assemble in organic solvents to form fibrillar aggregates through formation of hydrogen-bonding interactions.[19] The morphology of these aggregates is strongly influenced by the directionality of the hydrogen bonds as well as steric factors. We prepared a diamide bearing a bulky aromatic-decyl ester to study its influence on the shape of the aggregates. Compound **1** was synthesized in two



1

steps on a gram scale (see Supporting Information) and isolated as a powder that is insoluble at room temperature in most organic solvents (toluene, benzene, alkanes, methanol, ethanol) but soluble in chloroform and dichloromethane. The formation of gels at low concentration was observed when **1** was suspended in aliphatic solvents or toluene, heated until completely dissolved, and the resulting solution cooled back at 25 °C. The formation of the gel could be observed above concentrations of 0.05 wt % in cyclohexane. Gel formation is thermally reversible: heating the gel results in an isotropic sol phase. This behavior arises from the formation of aggregates through reversible bonds.

The nature of these bonds was explored by spectroscopic techniques. Examination of the **1**/cyclohexane gels by FTIR spectroscopy showed an NH stretching band at 3302 cm^{-1} (Figure 1 a) and an amide I band at 1642 cm^{-1} (Figure 1 b) characteristic of H-bonded amides. In chloroform, in which **1** is soluble at all concentrations, the IR spectra showed only an H-free NH band at 3450 cm^{-1} and a CO band at 1663 cm^{-1}. When the gels are heated from 26 to 64 °C, which is above the melting temperature of the gel (59 °C), the amide A band (Figure 1 a) at 3302 cm^{-1} and the amide I and II bands at 1642 and 1551 cm^{-1} (Figure 1 b) disappear gradually while shifted bands appear at 3457, 1660, and 1520 cm^{-1}, respectively. These bands are characteristic of H-free amides and their intensities increase with temperature. These measurements

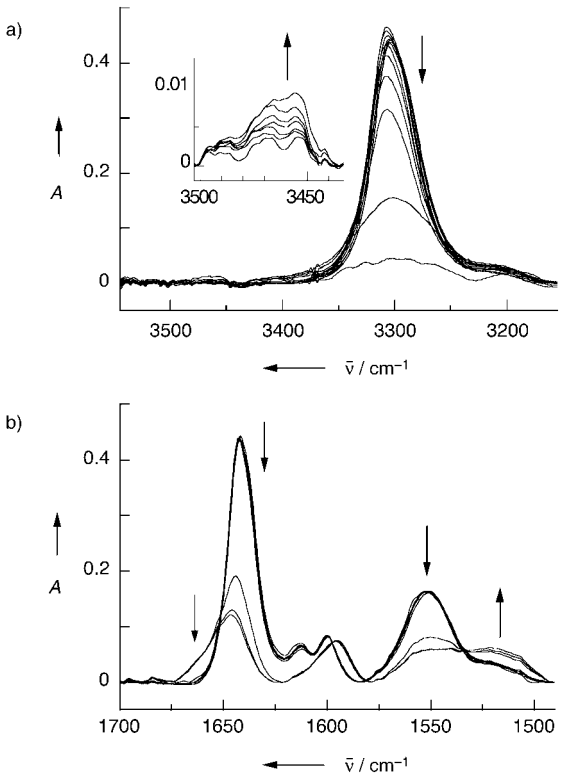


Figure 1. IR spectra of **1** gels in cyclohexane (2 wt %) at temperatures from 26 to 64 °C: a) ν_{NH} region, b) ester and amide I and II region.

confirm that hydrogen bonds between the amide groups contribute to the association process. We previously showed[20] that compounds lacking the amide groups cannot aggregate in alkane solvents. Raising the temperature of the gel also strongly affects the molecular spectra (Figure 2). For example, the absorption band at 223 nm shifts to 207 nm and the bands at 264 and 258 nm transform into a single band at 251 nm. The UV spectrum of **1** in cyclohexane at higher temperatures is similar to the spectrum in chloroform (absorption bands at 254 and 308 nm, not shown). These modifications arise from π interactions between the aromatic rings. Such interactions also contribute to the self-assembly process. The presence of marked isosbestic points in the

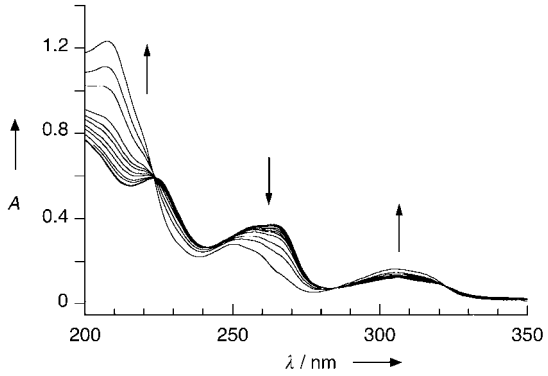

Figure 2. UV spectra of **1** gels in cyclohexane (0.3 wt %) at temperatures from 27 to 62 °C.

spectra shows that there is an equilibrium between aggregated and isolated species and that the position of this equilibrium depends on the temperature. Also, the intermediate species which lie between infinite aggregates and single molecules must have the same molar extinction coefficient. This would not be the case for the smallest aggregates, which would be expected to exhibit spectra which are different from both single molecules and larger aggregates. The stable isosbestic points, therefore, strongly suggest that the major intermediates comprise an equilibrium mixture of large aggregates.

The structure of the gels in cyclohexane has been investigated by electron microscopy (Figure 3). The gel was rapidly frozen to keep the solvent matrix in an amorphous state. Samples were fractured and Pt-shadowed (Figure 3a). Direct TEM could not be used because of the sample thickness and presence of organic solvent. This study revealed that the gels comprise cylindrical aggregates with a very large aspect ratio: their lengths are of the order of a micrometer, and their widths are about 20–30 nm with little dispersity. In a few samples the fracture occurred in a plane perpendicular to the cylinders axis, thus showing their cross-sections (Figure 3b). The white spot in the middle of the cylinder corresponds to an area that cannot be reached by the metal particles, and shows that it is lower than the surrounding rim. The cylinders are therefore hollow. The wall thickness was estimated from longitudinal fractures to be (4 ± 3) nm, the high uncertainty resulting mainly from the thickness of the evaporated metal. No branching structures were observed. Diluted solutions of **1** (below the concentration resulting in the gel) were rotary shadowed after deposition on carbon grids (Figure 3c) and found to contain mainly helical tapes. The mean diameter of those helices is (30 ± 4) nm, which lies in the same range as that of the cylinders. Tubules with helical defects can also be observed in the same solutions. They represent the last step of the self-assembly process, before the formation of the perfectly closed tubes, and emphasize again the link between the closed tubes and helical tapes. As the concentration increases, the lateral width of the helical tapes increases until the tubes are closed. In these samples, right-handed and left-handed helices are present in equal quantities, thus resulting in an overall racemic mixture. A few features structurally different to those discussed above were identified as ribbons. Their thickness was equal to that of the cylinders and they represent the first stage of tube formation.

Small-angle scattering experiments provided definitive evidence of the existence of the proposed tubular structure. The technique has been used successfully to elucidate the structure of nanotubes.[14,21] We recorded the intensities of neutron scattering by low concentration **1**/[D_{12}]cyclohexane gels in the range of $q = 0.008$–0.6 Å^{-1} (Figure 4). When interparticle correlations are negligible, the intensity scattered by a sample is given by Equation (1), in which Φ_v is the

$$I(q) = \Phi_v \, \Delta\rho^2 \, V_p \, P(q) \tag{1}$$

volume fraction of the particles, V_p is the volume of one particle (Å^3), $\Delta\rho^2$ is the contrast of the particle (cm^{-4}), and $P(q)$ is the form factor of the particle. Figure 4 represents the intensity normalized to the contrast and the volume fraction as a function of the scattering vector q.

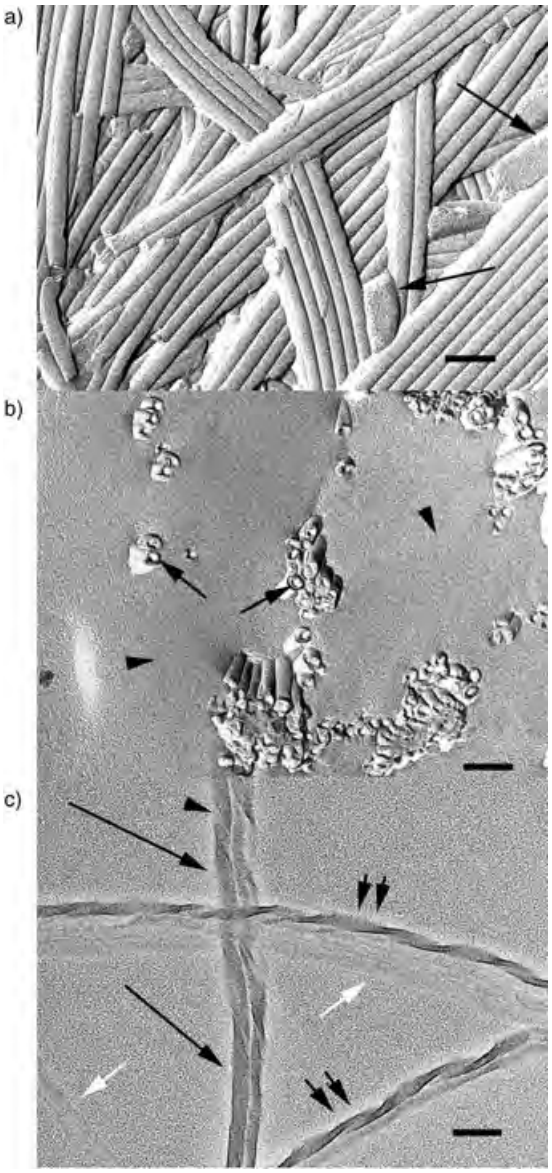

Figure 3. Electron micrographs of self-assembled **1** in cyclohexane. Scale bar is 100 nm. a) Replica of a freeze fracture of **1**-cyclohexane gels (2 wt% concentration). Diameters of the tubes approximately 25–30 nm. Arrow: solvent area. b) Same as (a) with a fracture plane nearly perpendicular to the main axis of the tubes. Arrows: sections of the tubes, which are clearly hollow. Arrowheads: amorphous solvent. c) TEM image of adsorbed diluted solution of **1** in cyclohexane (0.01 wt%) and rotary shadowed. White arrow: single tape. Double arrow: helical tape with a helical pitch of 120 nm. Long arrow: tubule showing only helical groove (arrow head).

The form factor for a long cylinder[22] can be approximated by Equation (2), where L is the length, R_o and R_i are

$$P(q) = \frac{\pi}{qL} \frac{4(R_o J_1(qR_o) - R_i J_1(qR_i))^2}{q^2(R_o^2 - R_i^2)^2} \tag{2}$$

the outer and inner radii of the cylinder, respectively, and J_1 is the Bessel function of the first order. The first factor

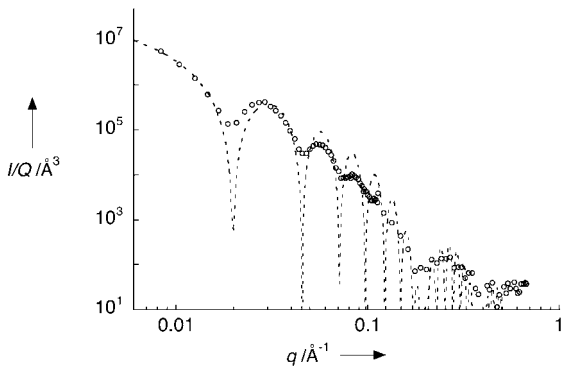

Figure 4. SANS data for **1** gels in [D_{12}]cyclohexane. ○: experimental data. -----: fit according to Equation (2): mean diameter $R_o + R_i = 242$ Å; thickness $R_o - R_i = 33$ Å.

corresponds to the form factor of the rigid rod and can be observed only at low q values, namely for $q < 1/R$. When R_o tends to R_i, which corresponds to infinitely thin hollow cylinders, the second factor in Equation (2) tends to $(J_0(qR))^2$ where J_0 represents the Bessel function of zero order. The curve exhibits a series of oscillations where the minima follow the progression of the zeros of the Bessel function of the zeroth order (ca. $3\pi/4R$, $7\pi/4R$, $11\pi/4R$ ...), which is strong evidence for hollow cylinders having a thin wall thickness. Fitting the positions of the minima and maxima enabled measurement of the mean diameter of the cylinders $2R = (R_o + R_i)$, which is equal to (24.2 ± 0.3) nm. The oscillations fit into an envelop curve that decreases and is minimal around 0.19 Å^{-1}. This envelop curve can be fitted by adjusting the thickness of the wall $R_o - R_i$, while the mean radius is kept constant. The thickness was found to be (3.3 ± 0.4) nm. The maximal length of the fully stretched molecule of **1** is estimated to be 3.6 nm by force-field calculations. The differences between the theoretical and experimental form factor may indicate a certain dispersity of tube diameters or a slight anistropy of the section.

The X-ray scattering at wide angles by the gels showed Bragg peaks (Figure 5). The spectrum confirmed that the tubes have a crystalline array, which differentiates them from micelles. Fuhrhop and co-workers also found crystalline order in self-assembled tubes of octylgluconamide.[23] Although it is not possible to establish a model for the wall structure at a molecular level, any proposed model should be coherent with the following experimental facts: the molecules are linked together by hydrogen bonds between amides and by π interactions between aromatic rings. More studies are in progress to elucidate further the inner structure of the tube wall.

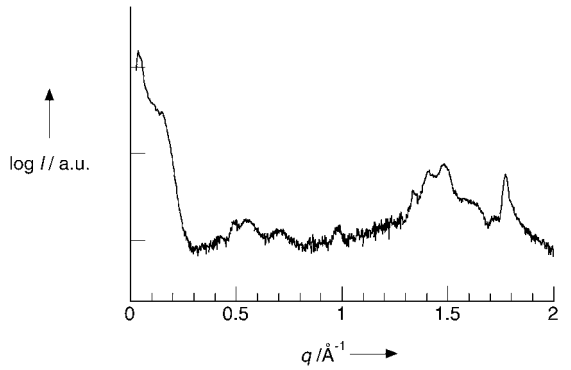

Figure 5. WAXS data of **1** gel in cyclohexane (6.4 wt%).

In summary, we have demonstrated that very simple molecules can be used to prepare well-defined nanotubes in organic solvents. The mean diameter of the tubes is (24.2 ± 0.3) nm as measured by small-angle neutron scattering studies (SANS). The interactions between molecules were assigned to hydrogen bonds between amides as well as aromatic π interactions on the basis of IR and UV spectroscopic studies. Analogues of **1** are under study to elucidate the molecular parameters that influence the shape and the size of the nanotubes.

Experimental Section

Synthesis of **1**: see the Supporting Information.

IR spectra were performed in NaCl cells on a IFS 88 apparatus equipped with a thermostated cell holder. The UV spectra were recorded on a 500 spectrometer. The neutron scattering experiments were performed at the LLB in Saclay on the PAXE spectrometer. Correction, reduction, and normalization of the data were carried out as described previously.[24] The wide-angle X-ray scattering (WAXS) experiments were carried out at the IPCMS, in Strasbourg on an Inel diffractometer, using $Cu_{K\alpha 1}$ radiation.

Freeze-fracture and electron microscopy experiments were performed as described previously for other self-associating systems.[25]

Synthetic Methods

Stereoselective Lewis Acid Mediated [1,3] Ring Contraction of 2,5-Dihydrooxepins as a Route to Polysubstituted Cyclopentenes**

*Christopher G. Nasveschuk and Tomislav Rovis**

The Diels–Alder reaction is a cornerstone of organic synthesis, and its ability to enable the production of cyclohexenes in a stereocontrolled manner is unparalleled. In contrast, no method exists for the synthesis of cyclopentanes that matches the scope and power of the Diels–Alder reaction in spite of the prevalence of these ring systems in natural products. Among numerous methods that have been used to target these cores, vinylcyclopropane ring-expansion strategies have been intensively investigated and have provided some spectacular successes.[1,2] Nevertheless, most reports result in mono- or disubstituted cyclopentanes and cyclopentenes, while approaches to polysubstituted systems are rare.[3] We were interested in addressing this deficiency and developing a diastereoselective approach to tri-, tetra-, and pentasubstituted cyclopentanes from readily available precursors, and herein we report our results.

We have previously reported the [1,3] rearrangement of vinyl acetals which proceeds through a metalloenolate and oxocarbenium ion pair.[4] To extend this concept to other stabilized cations, we initiated a program to study the [1,3] rearrangement of allylvinyl ethers that would form a metalloenolate and an allylic cation ion pair under Lewis acidic conditions. However, we were mindful that these substrates could also undergo a Lewis acid (LA) accelerated Claisen rearrangement, which if concerted, would form the [3,3] rearrangement product exclusively.[5] A number of workers have documented that the Lewis acid mediated Claisen rearrangement proceeds stepwise[6] and occasionally provides the [1,3] adduct with some selectivity.[7] To favor the [1,3] over the [3,3] product, we envisioned that a cyclic allylvinyl ether or 2,5-dihydrooxepin could provide access to densely functionalized cyclopentenes under ionizing conditions as the [3,3] rearrangement should be disfavored because of ring strain in the cyclopropane product [Eq. (1)]. We report the successful implementation of this strategy, in which a unique Lewis acid promoted ring contraction of 2,5-dihydrooxepins to cyclopentenes was used.

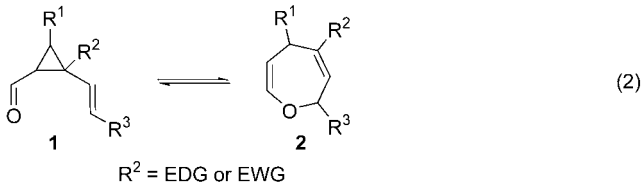
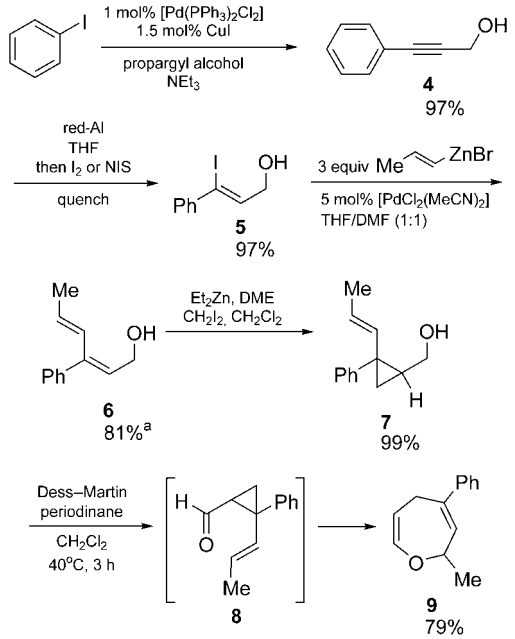
Despite their apparent complexity, 2,5-dihydrooxepins are readily prepared by a retro-Claisen reaction of the corresponding cyclopropyl aldehyde **1**, itself available by a modular approach using established methods (see below).[8,9] An equilibrium between **1** and **2** has been predicted computationally,[10] and may be shifted towards the 2,5-dihydrooxepin with π-stabilizing substituents [Eq. (2); EDG = electron-donating group, EWG = electron-withdrawing group].[9]



(2)

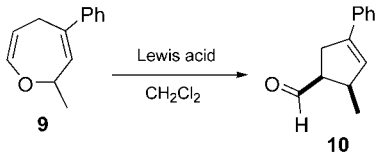
We began our investigations by developing a highly modular approach to the 2,5-dihydrooxepin skeleton. A representative synthesis is illustrated in Scheme 1. A Sonogashira cross-coupling between propargyl alcohol and aryl halides provided **4**.[11] Selective formation of the (*Z*)-vinyl iodide **5** was effected with red-Al/I_2,[12] and a Negishi coupling was then employed to insert an additional alkene.[13] A directed Simmons–Smith cyclopropanation afforded **7** in near quantitative yield as a single regioisomer.[14] We felt that **7** could be converted into **9** in a one-pot oxidation/retro-Claisen sequence and, after some optimization, it was found that 1.5 equivalents of the Dess–Martin periodinane in CH_2Cl_2 at 40 °C provided the desired 2,5-dihydrooxepin. The nature of the equilibrium meant that the unrearranged aldehyde **8** could be isolated and subsequently converted into **9** by heating overnight in toluene at 110 °C.



Scheme 1. Synthetic approach to the 2,5-dihydrooxepins.

With a convergent approach to the requisite 2,5-dihydrooxepins in hand, we began our studies on the stereoselective [1,3] ring contraction by conducting a brief screen of Lewis acids. $Cu(OTf)_2$, $TiCl_4$, and $SnCl_4$ yielded no product under a variety of conditions (Table 1, entries 1–3). In the presence of $EtAlCl_2$ (entries 4–6), the starting material was consumed with the formation of uncharacterized oligomeric products. We hypothesized that this could happen in one of two ways: 1) vinyl ether **9** could polymerize before ionization of the C–O bond or 2) the zwitterionic intermediate generated from the ionization of C–O is stable enough so that intramolecular ring closure is slower than the bimolecular reaction. Thus, cyclopentene **10** was isolated in 89% yield with 90:10 (*cis*/*trans*) selectivity (entry 7) when **9** was subjected to dilute Lewis acid at ambient temperature. We further note that slow addition of dilute 2,5-dihydrooxepin to the Lewis acid generally provides an incremental increase in selectivity (entry 8).

Table 1: Optimization of [1,3] ring contraction.



Entry	Lewis acid	Conditions	Yield [%] (*cis*/*trans*)
1	$Cu(OTf)_2$	various	NP[a]
2	$TiCl_4$	various	NP[a]
3	$SnCl_4$	various	NP[a]
4	$EtAlCl_2$	0.1 M, −78 °C, 30 min	NP[a]
5	$EtAlCl_2$	0.1 M, 23 °C, 30 min	NP[a]
6	$EtAlCl_2$	0.001 M, −78 °C, 60 min	NP[a]
7	$EtAlCl_2$	0.001 M, 23 °C, 5 min	89 (90:10)
8	$EtAlCl_2$	0.02 M, 23 °C, 5 min[b]	53 (93:7)

[a] Starting material consumed. [b] Slow addition of substrate to dilute Lewis acid. NP = no product.

We then evaluated the scope of the [1,3] ring contraction of the 2,5-dihydrooxepins. Electron-donating and electron-withdrawing groups in the *para* position of the aromatic ring are tolerated and give products in comparable yield and selectivity (Table 2, entries 1–3). Additional substitution on the dihydrooxepin unit is well-tolerated, with substrate **15** furnishing tetrasubstituted cyclopentene **16** in good selectivity. An increase in the steric bulk of the substituent from a methyl group (**9**) to a phenethyl group (**17**) or protected alcohol (**19**) results in a slight decrease in the yield and selectivity, but still provides synthetically useful amounts of product. Lastly, the use of aldehyde **21** as a substrate indicates

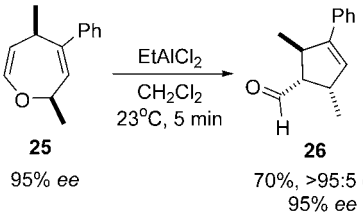
jected to the optimized reaction conditions, **26** was isolated in 70% yield and 95% *ee* [Eq. (3)]. The pre-existing stereo-



(3)

center controls the diastereoselective course of the reaction, and the observed selectivity can be rationalized by our proposed model (Figure 1). There is an interplay of minimi-

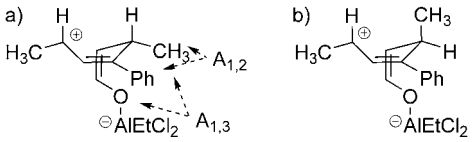


Figure 1. Proposed stereochemical model for the diastereoselective rearrangement of **25**. a) Minimization of the $A_{1,2}$ and $A_{1,3}$ strains and b) the favored model brought about by this process.

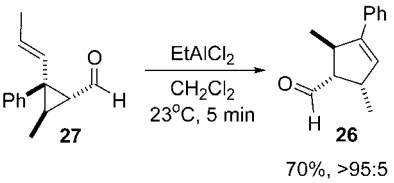
that formation of the dihydrooxepin is not necessary to achieve reaction. Furthermore, this substrate lacks the aryl stabilization evident in the other substrates, thus suggesting that aliphatic stabilization is sufficient in some cases. These disubstituted cyclopentene carboxaldehydes are readily epimerized[14] to form the *trans* diastereomer upon treatment with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU; Table 3, entries 1 and 2).

A considerable advantage of this method is the ability to introduce substitution at every position of the dihydrooxepin ring. With this approach in mind, we sought to apply the protocol of Charette et al.[15] as a means of introducing further substitutents onto the cyclopropane and affording a tetrasubstituted cyclopentene on [1,3] rearrangement. 2,5-Dihydrooxepin **25** was synthesized in an enantioenriched form using the Charette–Simmons–Smith protocol.[15] When **25** was subzation between the $A_{1,2}$ strain, between the phenyl group on the allyl cation and the adjacent methyl, and the $A_{1,3}$ strain, between the alkoxide on the enolate and the methyl group, that presumably leads to the observed levels of diastereoselectivity.

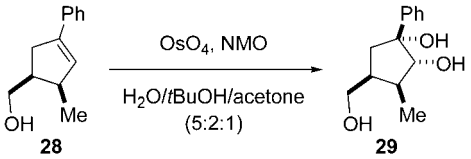
As noted above, we may also use the aldehydes as precursors for the rearrangement [Table 2, entry 7; Eq. (4)].



(4)

We suggest that this arises from the initial Lewis acid catalyzed retro-Claisen rearrangement that gives the 2,5-dihydrooxepin prior to [1,3] bond migration. Another possibility is that the Lewis acid accelerates the Claisen/retro-Claisen equilibrium so that a Curtin–Hammett situation is formed where the cyclopentene product is siphoned off from either the 2,5-dihydrooxepin or the cyclopropyl aldehyde. Although the exact mechanism at this stage remains unclear, this observation makes the overall procedure operationally simpler.

The presence of the olefin in the cyclopentene allows for further diastereoselective functionalization. We investigated one such approach and found that diastereoselective dihydroxylation produces a pentasubstituted cyclopentane in modest yield but excellent selectivity [Eq. (5), NMO = 4-methylmorphoöine *N*-oxide].[16]



(5)

In summary, we have developed a novel room-temperature Lewis acid mediated diastereoselective [1,3] ring contraction of 2,5-dihydrooxepins. Our modular approach to these seven-membered heterocycles allows for the installation of a variety of groups at every position. The reaction provides access to *cis* and *trans* cyclopentene carboxaldehydes with good selectivities, and can lead to tetrasubstituted cyclopentenes in high enantiomeric excess and diastereoselectivity.

O—O Activation

Dimetallic Dioxygen Activation Leading to a Doubly Oxygen-Bridged Dirhodium Complex**

Cristina Tejel, Miguel A. Ciriano, Eduardo Sola, M. Pilar del Río, Gustavo Ríos-Moreno, Fernando J. Lahoz, and Luis A. Oro*

Catalytic oxygenation constitutes an important method of converting readily available alkenes into chemicals with high added value. These oxygenations should preferably use the cheap and environmentally benign dioxygen as oxidant, and incorporate both oxygen atoms into the substrate molecules, thus optimizing atom economy.[1] However, with the exception of the Wacker process, such practical use of oxygen seems nowadays restricted to a few heterogeneous catalysts,[2]

although important progress towards this goal has been reported in the chemistry of soluble metal complexes.[3]

A recent review by Gal and co-workers[4] analyzes in detail the reactivity of rhodium and iridium complexes relevant to alkene oxygenation. Often, the use of peroxides as oxidants leads to facile monooxygenation reactions, through C–O bond-forming steps, to afford reactive 2-metallaoxetane intermediates.[5–7] In contrast, the more scarce C–O bond-forming reactions using dioxygen are assumed to involve the initial formation of 3-metalla-1,2-dioxolanes,[8] from which the evolution to oxygenated products seems to follow unselective routes and most often requires the presence of sacrificial reductants.[4] An exception to this inconvenient behavior has been reported for the 1,5-cyclooctadiene dianionic complex $[Ir(P_3O_9)(C_8H_{12})]^{2-}$, in which the formation of a 2-metallaoxetane intermediate from 0.5 molar equivalents of dioxygen has been suggested to be the consequence of a dimetallic O–O bond cleavage.[9] Herein we provide further evidence for the feasibility of this atom-economic dimetallic oxygenation route, by describing the facile formation of a dinuclear 2-metallaoxetane compound from dioxygen and an equilibrium mixture of the mono- and dinuclear rhodium complexes $[Rh(PhN_3Ph)(C_8H_{12})]$ ($\mathbf{1_M}$) and $[\{Rh(\mu\text{-}PhN_3Ph)(C_8H_{12})\}_2]$ ($\mathbf{1_D}$).

The bis(phenyl)triazenide rhodium(I) compound $[\{Rh(PhN_3Ph)(C_8H_{12})\}_n]$ (**1**), first reported by Knoth,[10] was easily prepared by treating $[\{Rh(\mu\text{-}OMe)(C_8H_{12})\}_2]$ with bis(phenyl)triazene in toluene. By comparison with rhodium triazenide compounds previously characterized by X-ray diffraction studies,[11] it was likely that the red solid obtained from the reaction was a dinuclear compound with bridging triazenide ligands. However, the NMR spectra of the compound dissolved in $[D_6]$benzene is indicative of an equilibrium mixture of the mono- and dinuclear complexes shown in Scheme 1. The dissociation equilibrium constant K_{eq} was estimated by NMR spectroscopic analysis to be 0.092 mol L^{-1} at 293 K.

Exposure of **1** to dioxygen in toluene at 293 K and atmospheric pressure gave the dinuclear dirhodadioxetane complex $[\{Rh(PhN_3Ph)(OC_8H_{12})\}_2]$ (**2**, Scheme 1) in 90% yield. Volumetric gas-burette measurements with O_2 indicated a consumption of 0.5 molecules of gas per atom of rhodium (0.51 ± 0.03 equiv), thus showing that all the reacting dioxygen was incorporated into **2**. The molecular structure of complex **2** (Figure 1)[12] confirms that, despite the presence of

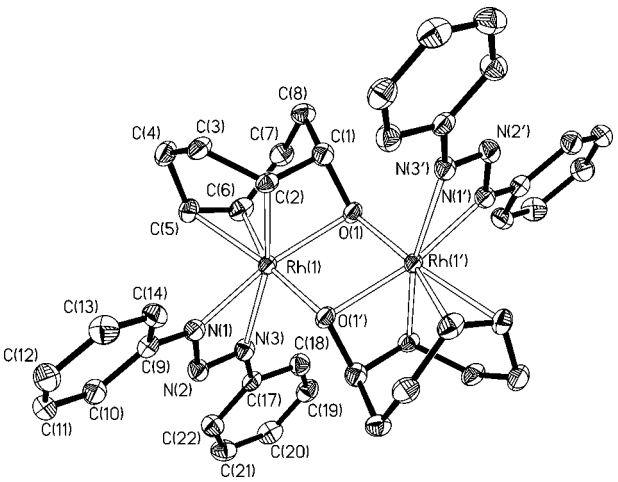

Figure 1. Solid-state structure of the dinuclear complex **2**. potentially bridging triazenide ligands, the dinuclear structure is held by bridging oxygen atoms—a feature by itself suggestive of a dimetallic activation of dioxygen. Moreover, among the few 2-metallaoxetane moieties resulting from insertion of oxygen atoms into metal–alkene bonds,[5,6,9] compound **2** constitutes the first example of a bridging one.

Complex **2** was found to be kinetically unstable in solution, slowly evolving to $[\{Rh(PhN_3Ph)(HO\text{-}C_8H_{11})\}_n]$ ($\mathbf{3_n}$, Scheme 1). The transformation was found to be complete in about three days at room temperature in dichloromethane. As confirmed by the solid-state structure shown in Figures 2 and 3,[13] the transformation involves the isomerization of the (η^2-

Bottom: Dependence of the initial reaction rates upon the initial concentration of **1** (left) and dependence of the pseudo-first-order rate constants k_{obs} upon the O_2 partial pressure (right).

κ-*O*,*C*-OC_8H_{12}) ligand of **2** into a hydroxyallyl (η^3-κ-*C*-$(HO)C_8H_{11}$) isomeric ligand (Scheme 1). Such an isomerization has been proposed to involve a metal-mediated activation of an allylic C–H bond followed by the transfer of the activated hydrogen atom to the alkoxy oxygen atom.[5,6,9]

The solid-state structure of $\mathbf{3_n}$ consists of a polymeric chain of mononuclear complexes (Figure 2) connected by Rh–O bonds (mean Rh–O(1) bond lengths 2.359(3) Å). Such bonds are long and presumably fragile, since they take place at a rhodium coordination position strongly labilized by the large *trans* effect of a σ-sp^3 carbon atom. Therefore, it seems unlikely that such a polymeric structure could remain in solution.

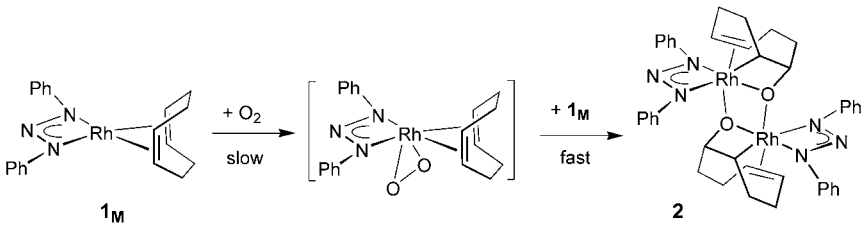
Accordingly, the NMR spectra of solutions of $\mathbf{3_n}$ are indicative of two equivalent phenyl groups, a feature hardly compatible with the polymeric structure, but likely for a potentially fluxional 16-electron Rh^{III} fragment.

The dioxygen activation reaction leading to complex **2** has been investigated kinetically by O_2-uptake experiments on solutions of **1** in toluene at 293 K. The initial concentrations of **1** in these solutions, expressed as concentrations of rhodium atoms $[Rh]_0$, were about 5×10^{-3} mol L^{-1}. At these concentrations and below, the equilibrium between $\mathbf{1_D}$ and $\mathbf{1_M}$ is greatly shifted toward the mononuclear compound, so that the concentration of $\mathbf{1_M}$ approaches a linear dependence upon that of rhodium, namely $[\mathbf{1_M}] \approx [Rh]$. In turn, that of $\mathbf{1_D}$ is better described by the expression of the equilibrium constant, namely $[\mathbf{1_D}] \approx [Rh]^2/K_{eq}$, thus depending upon the square of the rhodium concentration. Figure 4 and Table 1 shows examples for the reaction profiles obtained under constant pressure of dioxygen, which correspond well to those expected for a first-order dependence upon complex concentration. The logarithmic representation of the initial reaction rates (v_0) versus $[Rh]_0$ indicates a linear dependence, therefore confirming the mononuclear complex $\mathbf{1_M}$, rather than $\mathbf{1_D}$, to be the kinetically relevant species in this oxygenation. The dependence of the pseudo-first-order rate constants k_{obs} upon dioxygen pressure confirms that the oxygenation rate is also first order in dioxygen.

Table 1: Kinetic data for the reaction of **1** with dioxygen.

$[Rh]_0$ [$\times10^{-3}$ M]	$P(O_2)$ [bar]	v_0 [mmol O_2 s^{-1}]	k_{obs} [$\times10^{-3}$ s^{-1}]
8.48	0.97	1.56×10^{-4}	1.34
8.08	0.97	1.45×10^{-4}	1.27
6.18	0.97	1.14×10^{-4}	1.29
4.24	0.97	8.84×10^{-5}	1.28
1.94	0.97	3.76×10^{-5}	1.27
8.08	1.07	3.76×10^{-5}	1.43
8.08	0.62	3.76×10^{-5}	0.83
8.08	0.32	3.76×10^{-5}	0.37

These kinetic data discount any mechanism initiated by reaction of dioxygen with the dinuclear complex $\mathbf{1_D}$, and evidence a reaction of dioxygen with the mononuclear complex $\mathbf{1_M}$ as the most likely rate-determining step in the process (Scheme 2). This conclusion is compatible with the mechanism previously proposed by Klemperer and co-workers for the aforementioned singular example of dioxygen activation.[9] Adaptation of this proposal to our reaction in Scheme 2 would result in a mononuclear complex coordinating dioxygen, which undergoes the attack by an intact mononuclear complex ($\mathbf{1_M}$) to complete a dimetallic dioxygen cleavage. In our system, such a dimetallic activation step seems to be fast; likely as a consequence of the unsaturated character of the triazenide–rhodium complex $\mathbf{1_M}$. The coordination requirements of the Klemperer's tridentate $P_3O_9^{3-}$ ancillary ligand were proposed to favor the splitting of the



Scheme 2. Proposed mechanism for the reaction of dioxygen with **1**.

dinuclear species resulting after dioxygen activation, a feature not required in our triazenide oxygenation product, which remains dinuclear (Scheme 2).

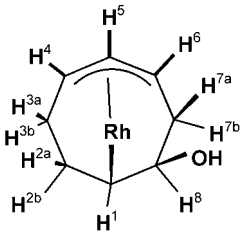
Although the above mechanism could be within the reach of other unsaturated mononuclear complexes or fragments, our preliminary investigation of rhodium compounds isoelectronic and very closely related to **1** indicates that this dioxygen activation is far from general. Actually, the complex [{Rh(μ-PhNCHNPh)(C_8H_{12})}$_2$],[13] which remains dinuclear at all concentration ranges, did not undergo reaction with dioxygen under the conditions described for **1**, while the mononuclear species [Rh(PhNC(Ph)NPh)(C_8H_{12})],[14] which does not form detectable dimers in solution, did not activate dioxygen either. These observations might suggest a correlation between the ability of unsaturated mononuclear fragments to reversibly form dinuclear species in solution and its activity in these dioxygen cleavage reactions. Whether or not this correlation exists is currently being investigated within our search for oxygenation catalysts, which can benefit from such facile, selective, and atom-economic dioxygen dimetallic activation.

Experimental Section

1: The addition of PhNNNHPh (165.7 mg, 0.84 mmol) to a yellow solution of [{Rh(μ-OMe)(cod)}$_2$] (203.4 mg, 0.42 mmol; cod = cycloocta-1,5-diene) in toluene (10 mL) produced a red solution from which a red solid precipitated in a few minutes. Hexane (5 mL) was added after 30 min to complete the precipitation of the solid. The solid was filtered under argon, washed with hexane (2 × 4 mL), and vacuum-dried. Yield: 290.8 mg (85 %). Elemental analysis (%) calcd for $C_{20}H_{22}N_3Rh$: C 58.97, H 5.44, N 10.32; found: C 59.19, H 5.34, N 10.31; ^{1}H NMR ([D$_6$]benzene, 25 °C) for $\mathbf{1_M}$: δ = 7.33 (br d, J(H,H) = 7.7 Hz, 4H), 7.14 (t, J(H,H) = 6.9 Hz, 4H) and 6.93 (tt, J(H,H) = 7.4, 1.1 Hz, 2H; C_6H_5), 4.32 (br s, 4H, =CH), 2.05 (m, 4H, CH_2^{exo}), 1.36 (q, J(H,H) = 7.9 Hz, 4H, CH_2^{endo}); for $\mathbf{1_D}$: δ = 7.77 (br s, 8H), 7.23 (t, J(H,H) = 8.3 Hz, 8H) and 7.03 (tt, J(H,H) = 7.4, 1.1 Hz, 4H; C_6H_5), 4.64 (br s, 4H) and 4.11 (br s, 4H; =CH), 2.76 (m, 4H) and 2.18 (m, 4H; CH_2^{exo}), 1.70 (q, J(H,H) = 7.7 Hz, 4H) and 1.47 (q, J(H,H) = 7.9 Hz, 4H; CH_2^{endo}); ^{13}C{^{1}H} NMR ([D$_6$]benzene, 25 °C) for $\mathbf{1_M}$: δ = 149.5 (C^{ipso}-C_6H_5), 129.2 (C^{meta}-C_6H_5), 124.1 (C^{para}-C_6H_5), 117.2 (C^{ortho}-C_6H_5), 80.3 (d, J(C,Rh) = 12 Hz, =CH), 30.6 (CH); for $\mathbf{1_D}$: δ = 152.9 (C^{ipso}-C_6H_5), 128.4 (C^{meta}-C_6H_5), 124.9 (C^{para}-C_6H_5), 124.1 (C^{ortho}-C_6H_5), 87.6 (br) and 76.8 (br; =CH), 31.1 and 30.8 (CH); MS: m/z (%): 814 (20) [M^+] ($\mathbf{1_D}$), 407 (100) [M^+] ($\mathbf{1_M}$).

2: A suspension of [{Rh(PhNNNPh)(C_8H_{12})}$_n$] (150.0 mg) in toluene (8 mL) was stirred in an oxygen atmosphere for 2 h. The initial dark red suspension evolved to an orange solution, which was concentrated to about 3 mL. Hexane (15 mL) was added to complete the precipitation of the solid, which was filtered off, washed with hexane (2 × 5 mL), and vacuum-dried. Yield: 156 mg (90 %). Elemental analysis (%) calcd for $C_{40}H_{44}N_6O_2Rh_2$: C 56.75, H 5.24, N 9.93; found: C 57.01, H 5.03, N 9.79; ^{1}H NMR ($CDCl_3$, 25 °C) (assigned from ^{1}H,^{1}H-COSY spectrum) δ = 7.47 (m, 8H, H^{ortho}-C_6H_5), 7.36 (t, J(H,H) = 7.5 Hz, 4H) and 7.32 (t, J(H,H) = 8.2 Hz, 4H; H^{meta}-C_6H_5), 7.11 (t, J(H,H) = 7.3 Hz, 2H) and 7.04 (t, J(H,H) = 7.2 Hz, 2H; H^{para}-C_6H_5), 6.25 (t, J(H,H) = 7.4 Hz, 2H) and 5.00 (m, 2H; =CH), 5.25 (t, J(H,H) = 6.9 Hz, 2H; HC-O-Rh), 4.78 (m, 2H; HC-Rh), 2.62 (m, 2H), 2.38 (m, 2H), 1.91 (m, 8H), 1.50 (m, 2H) and 0.80 (m, 2H; CH_2); ^{13}C{^{1}H} NMR ($CDCl_3$, 25 °C) δ = 149.6 and 148.4 (C^{ipso}-C_6H_5), 129.1 and 128.6 (C^{meta}-C_6H_5), 123.7 and 123.3 (C^{para}-C_6H_5), 119.2 and 117.7 (C^{ortho}-C_6H_5), 100.5 (d, J(C,Rh) = 8 Hz) and 95.7 (d, J(C,Rh) = 7 Hz; =CH), 94.6 (d, J-(C,Rh) = 2 Hz; HC-O-Rh), 33.6 (d, J(C,Rh) = 17 Hz; HC-Rh), 33.9, 27.8, 24.8 and 20.6 (CH_2); MS: m/z (%): 847 (12) [M^+], 423 (100) [(M/2)$^+$].

3: An orange solution of **2** (100 mg, 0.12 mmol) in CH_2Cl_2 (10 mL) became green over 72 h in an argon atmosphere. Concentration of the solution to about 2 mL and addition of hexane (10 mL) afforded the product as a green solid, which was separated by filtration and dried under vacuum. Yield: 70 mg (70 %). Elemental analysis (%) calcd for $C_{20}H_{22}N_3O_1Rh_1$: C 56.75, H 5.24, N 9.93; found: C 56.85, H 5.23, N 9.75; ^{1}H NMR ($CDCl_3$, 25 °C): (assigned from ^{1}H,^{1}H-COSY spectrum) δ = 7.56 (d, J(H,H) = 7.8 Hz, 4H; H^{ortho}-C_6H_5), 7.34 (t, J(H,H) = 7.8 Hz, 4H; H^{meta}-C_6H_5), 7.06 (t, J(H,H) = 7.2 Hz, 2H; H^{para}-C_6H_5), 5.15 (m, 2H; H^4 and H^6), 4.01 (t, J(H,H) = 8.7 Hz, 1H; H^5), 3.52 (m, 1H; H^1), 2.68 (m, 1H; H^8), 2.36 (d, J(H,H) = 9.0 Hz, 1H; OH), 2.03 (m, 3H; H^{2a}, H^{3a}, H^{7a}), 1.32 (m, 1H; H^{7b}), 1.27 (m, 1H; H^{3b}), 0.67 (m, 1H; H^{2b}); MS: m/z (%): 423 (100) [M^+].



Kinetic measurements: Dioxygen uptake experiments were performed in an apparatus consisting of a (7.99 mL) stainless-steel gas reservoir triply connected to a high-pressure dioxygen source, a pressure transmitter, and an electronic pressure meter/controller (EL-Press, Bronkhorst HI-TEC). The outlet of the pressure controller was connected to a 100-mL reaction flask, also connected to a Schlenk manifold to allow for manipulation of the reaction and degassing. In a typical reaction, a solution of **1** at the desired concentration in toluene was transferred to the reaction flask, degassed in vacuo over 30 s, and then exposed to dioxygen at the desired total pressure. The pressure was programmed at the computer connected to the pressure controller. The reaction flask was shaken vigorously during reaction. Consumption of dioxygen was registered as a pressure decrease in the closed reservoir, by means of the pressure transmitter, at intervals of 15 s. The pressure decrease was converted into the moles of dioxygen consumed by using the precalibrated volume of the reservoir and considering an ideal gas behavior. Initial rates were obtained through a least-square fitting of the initial 10 % of the reactions. Pseudo-first-order rate constants k_{obs} were calculated by fitting the experimental reaction profiles to exponentials. The toluene vapor pressure at the temperature of the system was considered in calculating dioxygen partial pressures.[16].

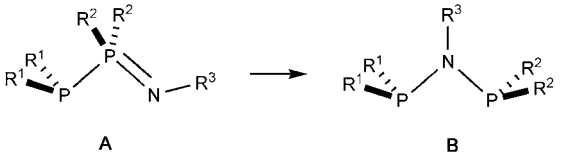
Phosphazanes

Synthesis and Solid-State Structure of a Metal Complex of a Diphosphineimine**

Leonard E. Anagho, Jamie F. Bickley, Alexander Steiner, and Lothar Stahl**

Dedicated to Professor Michael Veith on the occasion of his 60th birthday

Diphosphineimine compounds of the general structure R_2P-PR_2=NR [**A**; Eq. (1)] have been known for some time,[1] but



(1)

the pronounced tendency of these molecules to rearrange to the isomeric diphosphinoamines **B** has hampered the development of their chemistry and relegated them to structural curiosities. For example, the diphosphineimine iPr$_2$P(=N-Ph)PEt$_2$ was reported to completely rearrange to diphosphinoamine iPr$_2$P-NPh-PEt$_2$ in the presence of electrophiles or nucleophiles.[1d] Similarly, the attempted synthesis of a palladium dichloride complex of Ph_2P-PPh_2=N{C_6H_4(o-CN)} only furnished the diphosphinoamine complex *cis*-[$PdCl_2${(o-CN)C_6H_4N(PPh_2)$_2$}].[2b] Diphosphinoamines, of course, have a

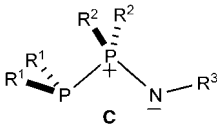
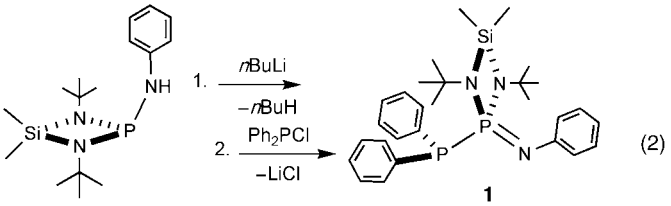
long history as ligands for transition metals and as stable molecules in their own right.[3] They have been used in late-transition-metal homogeneous polyolefin catalysis because they impart a greater stability to the complexes than the more conventional diimines.[4,5] The asymmetric diphosphineimines have both electron-donating imine and electron-accepting phosphine functionalities, as exemplified in the ylidic form **C**, which may combine the best features of diimines and diphosphines and, thus, be superior ligands. Furthermore, these hemilabile phosphorus(III)/phosphorus(V) molecules should have applications in other important catalytic transformations, such as hydroformylation and hydrogenation reactions,[6] thus making the search for stable diphosphineimines an area of interest.



C

Herein, we report the synthesis and solid-state structure of the first diphosphineimine that is kinetically stable enough to allow the isolation of a transition-metal complex. Our investigations also furnished the first solid-state structure of a diphosphineimine sulfide and of a metal complex in which the diphosphineimine has isomerized to the corresponding diphosphinoamine, thereby providing the rare opportunity to compare coordination compounds of both structural isomers.

Diphosphineimines are occasionally formed when amidophosphines are treated with halophosphines in the attempted synthesis of diphosphinoamines.[1,2] Symmetrical diphosphinediimines can also be synthesized by the oxidative coupling of amidophosphines.[7] The addition of $\{Me_2Si(\mu\text{-}NtBu)_2PNPh\}Li$ to Ph_2PCl in THF resulted in the nucleophilic attack of $\{Me_2Si(\mu\text{-}NtBu)_2PNPh\}^-$ on the phosphorus atom of Ph_2PCl to afford $Me_2Si(\mu\text{-}NtBu)_2P(=NPh)PPh_2$ (**1**) as the only phosphorus-containing product [Eq. (2)]. Treatment of



(2)

1

$(Ph_2PNPh)Li$ with $Me_2Si(\mu\text{-}NtBu)_2PCl$,[8] in contrast, gave only an intractable mixture.

A direct P–P bond in **1** was suggested by an AB pattern of doublets in the ^{31}P NMR spectrum at $\delta = 49.9$ and 44.9 ppm, respectively ($J(P,P) = 182$ Hz), but later findings showed that coupling constants of this magnitude are not diagnostic for direct P–P bonds in these systems (see below). A single-crystal X-ray analysis of the colorless product confirmed the assumed structure of **1**.

Figure 1 shows one of the two independent molecules, whose metric parameters are identical within experimental uncertainties. The P–P and P=N bonds (2.2092(7) and 1.5568(15) Å, respectively) are somewhat shorter than those of the previously characterized diphosphineimine of the type $(o\text{-}X)C_6H_4N{=}PPh_2\text{-}PPh_2$ (X = CF_3, Ph, CN) in which they

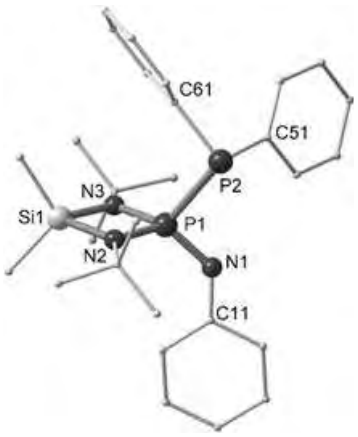


Figure 1. Solid-state structure of **1** (hydrogen atoms have been omitted). Selected bond lengths [Å] and angles [°]: P(1)-P(2) 2.2092(7), P(1)-N(1) 1.5568(15), P(1)-N(2) 1.6761(15), P(1)-N(3) 1.6804(16); N(1)-P(1)-P(2) 97.12(6), N(2)-P(1)-N(3) 86.67(8), C(61)-P(2)-P(1) 104.01(6), C(51)-P(2)-P(1) 106.44(7), C(51)-P(2)-C(61) 102.84(8).

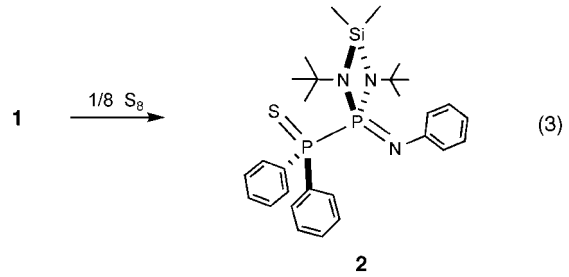
ranged from 2.2379(16) to 2.2498(18) Å and from 1.571(3) to 1.578(3) Å, respectively.[2] These bond-length contractions may be a reflection of the greater stability of **1**, which proved to be unusually thermally robust: it exhibited no tendency to decompose or rearrange to the corresponding diphosphinoamine on heating to reflux in toluene (24 hours).

Diphosphineimines are normally kinetic products that isomerize to the corresponding diphosphinoamines during attempted chemical transformations and metal coordination.[1d,2] In notable contrast, the reaction of **1** with elemental sulfur produced the colorless compound **2** as the only product [Eq. (3)]. To the best of our knowledge, this diphosphine-



(3)

2

imine sulfide is only the second of its kind to have been reported and the first to have been characterized by X-ray structural analysis.[1c]

The solid-state structure of **2** confirmed that the P–P bond had remained intact during the reaction (Figure 2). The molecule adopted a staggered conformation to minimize nonbonding interactions: the bulkiest substituent on one phosphorus atom is in a *gauche* conformation with the smallest substituents on the opposite phosphorus atom. This conformation renders **2** almost perfectly mirror-symmetric, with the phosphorus, sulfur, silicon, and nitrogen (imino) atoms all lying in a noncrystallographic mirror plane. The comparatively short P=S and P=N(imino) bonds (1.9563(8) and 1.5507(19) Å, respectively) form a torsion angle of

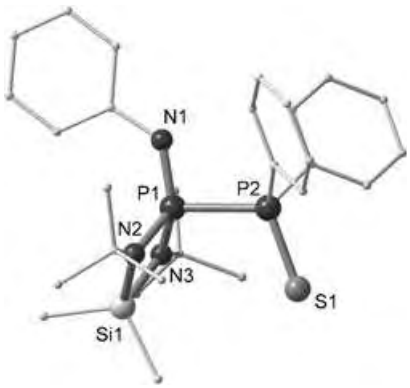


Figure 2. Solid-state structure of **2** (hydrogen atoms have been omitted). Selected bond lengths [Å] and angles [°]: P(1)-P(2) 2.2332 (7), P(1)-N(1) 1.5507(19), P(2)-S(1) 1.9563(8), P(1)-N(2) 1.6684(18), P(1)-N(3) 1.6677(17); N(1)-P(1)-P(2) 99.72(7), P(1)-P(2)-S(1) 110.71(3), N(2)-P(1)-N(3) 87.54(9), C(41)-P(2)-C(51) 103.19(10).

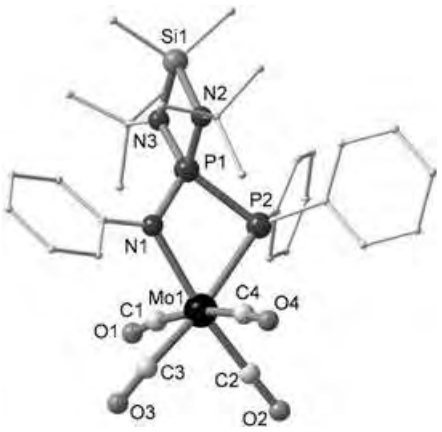

Figure 3. Solid-state structure of **3**. (Only one of the two independent molecules is shown; the toluene molecule and the hydrogen atoms have been omitted.) Selected bond lengths [Å] and angles [°]: Mo(1)-P(2) 2.4915(9), Mo(1)-N(1) 2.321(2), Mo(1)-C(1) 2.032(3), Mo(1)-C(2) 1.946(3), Mo(1)-C(3) 1.976(3), Mo(1)-C(4) 2.042(3), P(1)-P(2) 2.2362(11), P(1)-N(1) 1.599(2), P(1)-N(2) 1.661(2), P(1)-N(3) 1.669(2); N(1)-P(1)-P(2) 91.29(9), Mo(1)-N(1)-P(1) 111.16(11), Mo(1)-P(2)-P(1) 86.99(3).

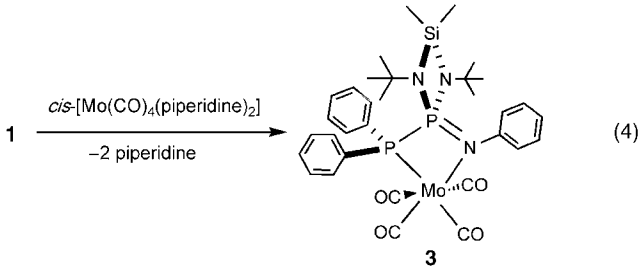
approximately 179° about the slightly elongated P–P bond (2.2332(7) Å).

Compound **1** did not isomerize on heating and oxidation, which encouraged us to explore its coordination chemistry. Treatment of **1** with *cis*-[$Mo(CO)_4$(piperidine)$_2$] in THF and heating to reflux afforded the light-yellow molybdenumtetracarbonyldiphosphineimine [**3**; Eq. (4)]. The infrared spectrum exhibited three ν(CO) bands at 2010, 1890, and 1850 cm^{-1}, respectively, as is common for many molybdenumtetracarbonyl complexes with local C_{2v} symmetry. These carbonyl stretching vibrations are lower than for most complexes of the *cis*-[$Mo(CO)_4$(PP)] type (PP refers to alkanediyl- or amine-bridged bisphosphines),[9] thus suggesting that **1** is the expected electron-rich chelating ligand.

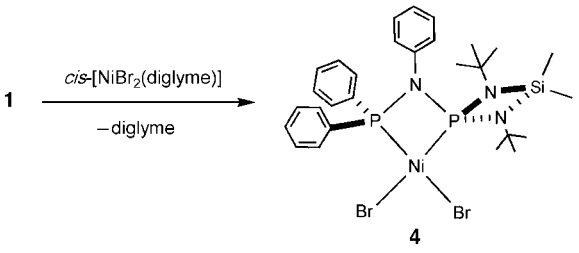


(4)

Complex **3**, which crystallizes as a monotoluene solvate with two independent molecules in the asymmetric unit, was analyzed by single-crystal X-ray analysis. The spirocyclic molecule is composed of two almost-planar four-membered rings (Figure 3), but the trapezoidal Mo-P-P-N ring is much more irregular than the rhombus of the diazasilaphosphetidine. Thus, the *cis*-configured Mo–P and Mo–N bonds are 2.4915(9) and 2.321(2) Å, respectively, while the P–P and P=N bond lengths are 2.2362(11) and 1.599(2) Å, respectively. The Mo–P bond length is similar to those in the related *cis*-[$Mo(CO)_4$(PP)] and *cis*-[$Mo(CO)_4$(PN)] complexes,[9,10] but the Mo–N and P=N bonds are rather long for an sp^2-hybridized nitrogen atom,[10] possibly because of ring strain. There is a distinct asymmetry in the Mo–CO bond lengths as the axial bonds are significantly longer than the equatorial ones. Notably, the Mo–CO bond *trans* to the best electron donor, namely the imino nitrogen atom, is the shortest one of the four Mo–CO bonds. The bond parameters within the diazasilaphosphetidine are unremarkable and similar to those in related compounds.[11]

Despite the direct P–P bond, the P–P coupling constant of **3** is only a third of the magnitude (ca. 69 Hz) as that of **1**, for reasons that are not yet clear.

Although the surprising thermal and chemical stabilities of **1** suggested that this diphosphineimine might be thermodynamically stable with respect to its isomer, its interaction with nickel salts proved otherwise. Compound **1** was treated with *cis*-[$NiBr_2$(diglyme)] (diglyme = diethyleneglycol dimethyl ether) to furnish the diphosphinoaminenickel dibromide complex **4** as the only product, even at room temperature [Eq. (5)].



(5)

The diamagnetism of the compound had indicated a square-planar coordination geometry about the nickel ion, and this arrangement was confirmed by the solid-state structure of **4** (Figure 4). The two planes defined by the nickel and phosphorus and the nickel and bromide atoms, respectively, are nearly coplanar (dihedral angle = 6°) and perpendicular to the diazasilaphosphetidine ring. Despite the dissimilar substituents on both phosphorus atoms, the Ni–P

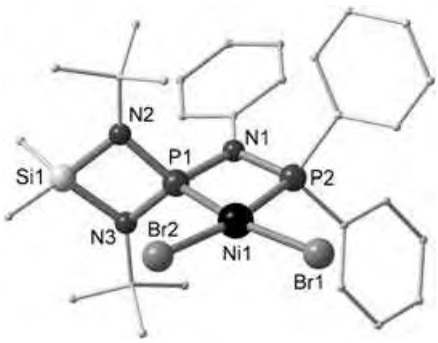


Figure 4. Solid-state structure of **4** (the THF molecule and the hydrogen atoms have been omitted). Selected bond lengths [Å] and angles [°]: Ni(1)-P(1) 2.1270(10), Ni(1)-P(2) 2.1151(10), Ni(1)-Br(1) 2.3481(6), Ni(1)-Br(2) 2.3302(6), P(1)-N(1) 1.714(3), P(2)-N(1) 1.714(3), P(1)-N(2) 1.658(3), P(1)-N(3) 1.670(3); P(1)-N(1)-P(2) 97.17(14), P(1)-Ni(1)-P(2) 74.62(4), Br(1)-Ni(1)-Br(2) 98.07(2), N(2)-P(1)-N(3) 87.67(15).

bonds are almost equidistant (the Ni–P1 and Ni–P2 bond lengths are 2.1270(10) and 2.1151(10) Å) and are slightly shorter than those in the related *cis*-[$NiBr_2${$Ar_2PN(Me)PAr_2$}] ($Ar = o$-$tBuC_6H_4$), which features symmetrical Ni–P bonds (2.1611(6) Å).[4a] This latter nickel complex, with its bulky bis(diphenylphosphine)amine ligand, was shown to be a very good polyolefin catalyst, and the more electron-rich **4** may exhibit a similar reactivity.

The ^{31}P NMR spectrum gave no indication that the isomerization of **1** had occurred as it showed two doublets at $\delta = 55.8$ and 43.9 ppm for the P1 and P2 atoms, respectively, with larger coupling constants ($J(P,P) = 137$ Hz) than those seen in **3**. Thus, ^{31}P NMR spectroscopy, which is usually considered a diagnostic tool, was neither reliable for predicting the connectivity in these phosphorus–nitrogen compounds nor did it show a correlation between the coupling constants and the P–P bond lengths. These results are in keeping with earlier studies that showed large and variable two-bond P–P coupling constants in diphosphinoamines that ranged from 15 to 665 Hz.[12]

Given the catalytic activity of nickel and the inertness of the [$Mo(CO)_4$] moiety, it is not surprising that **1** isomerized in the presence of $NiBr_2$ even at room temperature, although it was unaffected by [$Mo(CO)_4$] when they were heated together to reflux in THF. However, it is surprising that the soft {$Mo(CO)_4$} fragment is coordinated by the hard nitrogen atom, although the harder $NiBr_2$ moiety is coordinated by the soft phosphorus atoms. This disparity further underlines the kinetic control demonstrated in Equations (4) and (5). Our results also suggest that attempts to stabilize diphosphineimines with certain Group 10 metal compounds, as had been done previously, may cause isomerization instead.[2a] The ease with which **1** isomerizes in the presence of $NiBr_2$ clearly rules out its use as a diphosphineimine ligand in Group 10 metal catalysis.

In summary, the syntheses and solid-state structures of a kinetically stable diphosphineimine, its molybdenum complex, and its sulfide analogue have been reported. Whether the electronic properties or the cyclic structure of the diazasilaphosphetidine give this particular diphosphineimine its unique stability remains to be seen. The potential rewards for finding stable diphosphineimines are clear, and we are currently exploring the reaction chemistry of **1** to understand the properties of these intriguing molecules.

Experimental Section

1: A solution of $Me_2Si(\mu$-$NtBu)_2PN(H)Ph$[11a] (11.2 mmol) in hexanes (20 mL) was treated dropwise at 0 °C with *n*BuLi (11.3 mmol) in hexanes (15 mL). The reaction mixture was heated at reflux for 1 h, cooled to RT, and then treated dropwise with a solution of Ph_2PCl (11.2 mmol) in hexanes. This caused a white precipitate to form. The mixture was stirred overnight and then filtered to afford a colorless, clear solution from which colorless, rectangular crystals separated upon cooling; yield: 3.69 g (64.9 %). M.p. 170–172 °C; elemental analysis (%) calcd for $C_{28}H_{39}N_3P_2Si$: C 66.24, H 7.74, N 8.28; found: C 66.01, H 7.84, N 8.11; ^1H NMR (500.1 MHz, CD_2Cl_2, 21 °C): $\delta = 7.94$ (m, 4H, Ph), 7.37 (m, 6H, Ph), 7.15 (t, $J = 7.1$ Hz, 2H, Ph), 7.06 (d, $J = 8.1$ Hz, 2H, Ph), 6.72 (t, $J = 7.1$ Hz, 1H, Ph), 1.13 (s, 18H, *t*Bu), 0.56 (s, 3H, Me), 0.20 ppm (s, 3H, Me); $^{31}P[^1H]$ NMR (202.5 MHz, CD_2Cl_2, 21 °C): $\delta = 2.66$ (d, $J(P,P) = 182.4$ Hz), −30.82 ppm (d, $J(P,P) = 182.8$ Hz).

2: Compound **1** (0.235 g, 0.486 mmol) and elemental sulfur (0.016 g, 0.50 mmol) were dissolved in THF (20 mL), and the mixture was heated at reflux for 3 h. Following removal of THF, the ensuing white powder was dissolved in toluene to afford colorless crystals upon cooling; yield: 0.213 g (81.2 %). M.p. 202–206 °C; elemental analysis (%) calcd for $C_{28}H_{39}N_3P_2SSi$: C 62.31, H 7.28, N 7.79; found: C 61.94, H 7.35, N 7.72; ^1H NMR (500.1 MHz, C_6D_6, 21 °C): $\delta = 9.178$ (dd, $J = 12.4$, 8.0 Hz, 4H, Ph), 7.43 (d, $J = 8.3$ Hz, 2H, Ph), 7.34 (t, $J = 7.5$ Hz, 2H, Ph), 7.11 (td, $J = 8.0$, 3.2 Hz, 2H, Ph), 6.99 (t, $J = 7.4$ Hz, 2H, Ph), 6.95 (t, $J = 7.3$ Hz, 1H, Ph), 0.94 (s, 18H, *t*Bu), 0.83 (s, 3H, Me), 0.38 ppm (s, 3H, Me); $^{31}P[^1H]$ NMR (202.5 MHz, CD_2Cl_2, 21 °C): $\delta = 10.94$ (d, $J(P,P) = 238.8$ Hz), −8.40 ppm (d, $J(P,P) = 238.8$ Hz).

3: Compound **1** (0.250 g, 0.500 mmol) and *cis*-[$Mo(CO)_4$(piperidine)$_2$] (0.195 g, 0.500 mmol) were dissolved in THF (50 mL) and the mixture was heated at reflux for 3 h. A yellow powder precipitated upon cooling, which was recrystallized from toluene to afford light-yellow crystals; yield: 0.263 g (65.1 %). M.p. 176 °C (decomp); elemental analysis (%) calcd for $C_{39}H_{47}MoN_3O_4P_2Si$: C 57.99, H 5.86, N 5.20; found: C 58.04, H 5.98, N 5.34; ^1H NMR (500.1 MHz, CD_2Cl_2, 21 °C): $\delta = 8.09$ (m, 4H, Ph), 7.52 (s, 6H, Ph), 7.39 (t, $J = 7.6$ Hz, 2H, Ph), 7.22 (m, 4H, Ph), 6.91 (t, $J = 7.3$ Hz, 1H, Ph), 2.34 (s, 3H, Me), 0.84 (s, 21H, *t*Bu, Me), 0.66 ppm (s, 3H, Me); $^{31}P[^1H]$ NMR (202.5 MHz, CD_2Cl_2, 21 °C): $\delta = 49.93$ (d, $J(P,P) = 69.5$ Hz), 44.97 ppm (d, $J(P,P) = 69.0$ Hz); $^{13}C[^1H]$ NMR (CD_2Cl_2), 121.5 MHz, 21 °C): $\delta = 221.4$ (s, CO_{eq}), 218.3 (d, $J = 32.9$ Hz, CO_{eq}), 210.2 (d, $J = 8.5$ Hz, CO_{ax}), 132.8 (d, $J = 26.4$ Hz, Ph), 131.9 (s, Ph), 129.6 (s, Ph), 128.9 (s, Ph), 126.1 (s, Ph), 122.4 (s, Ph), 32.4 (s, *t*Bu), 5.0 (s, Me), 4.4 ppm (s, Me); IR (nujol): $\tilde{\nu} = 2010.4$ (s), 1889.9 (vs), 1850.4 cm^{-1} (vs).

4: A suspension of *cis*-[$NiBr_2$(diglyme)] (0.321 g, 0.912 mmol) in THF (10 mL) was treated dropwise with a solution of **1** (0.398 g, 0.816 mmol) in THF (25 mL) at RT. The ensuing orange mixture slowly turned red and was stirred overnight. The dark red–brown solution was filtered through a medium-porosity frit and stored in a freezer. Several crops of red–brown, needle-shaped crystals formed upon cooling; yield: 0.369 g (59.0 %). M.p. 273–282 °C; elemental analysis (%) calcd for $C_{32}H_{47}Br_2N_3NiOP_2Si$: C 48.15, H 5.93, N 5.26; found: C 47.91, H 5.98, N 5.23; ^1H NMR (500.1 MHz, CD_2Cl_2, 21 °C): $\delta = 8.11$ (dd, $J = 12.4$, 7.9 Hz, 4H, Ph), 7.77 (s, 2H, Ph), 7.49 (s, 4H, Ph), 7.23 (s, 4H, Ph), 7.01 (s, 3H, Ph), 3.58 (s, 4H, THF), 1.85 (s, 4H, THF) 1.50 (s, 18H, *t*Bu) 0.78 (s, 3H, Me), 0.401 ppm (s, 3H, Me);

$^{31}P\{^1H\}$ NMR (202.5 MHz, CD_2Cl_2, 21 °C): $\delta = 55.81$ (d, $J(P,P) = 137.0$ Hz), 43.88 ppm (d, $J(P,P) = 137.0$ Hz).

Crystal data for **1**, **3**, and **4** were collected on a Bruker Smart Apex CCD and those for **2** on a Stoe IPDS diffractometer using graphite monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å). The structures were solved with direct methods and refined by full-matrix least-squares against F^2 using the SHELXTL program.

Crystal data for **1**: $C_{28}H_{39}N_3P_2Si$, triclinic, space group $P\bar{1}$ (no. 2), $a = 12.1274(7)$, $b = 15.3090(9)$, $c = 16.1150(9)$ Å, $\alpha = 81.0053(11)$, $\beta = 72.7523(10)$, $\gamma = 82.8704(10)$°, $V = 2812.6(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.199$ g cm^{-3}, $T = 100$ K, $2\theta_{max} = 50$°, $\mu = 0.218$ mm^{-1}, 13774 reflections measured, of which 9783 were unique ($R_{int} = 0.0632$), final R indices: $R1 = 0.0365$, ($I > 2\sigma(I)$), $wR2 = 0.0904$ (all data).

Crystal data for **2**: $C_{28}H_{39}N_3SiP_2S$, monoclinic, space group $P2_1/n$ (no. 14), $a = 9.0459(10)$, $b = 9.7581(9)$, $c = 33.246(4)$ Å, $\beta = 93.604(13)$°, $V = 2928.8(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.224$ g cm^{-3}, $T = 200$ K, $2\theta_{max=}48$°, $\mu = 0.282$ mm^{-1}, 18452 reflections measured, of which 4522 were unique ($R_{int} = 0.0502$), final R indices: $R1 = 0.0370$ ($I > 2\sigma(I)$), $wR2 = 0.0997$ (all data).

Crystal data for **3**: $C_{39}H_{47}MoN_3O_4P_2Si$, monoclinic, space group $P2_1/n$ (no. 14), $a = 19.2663(16)$, $b = 11.4770(10)$, $c = 36.889(3)$ Å, $\beta = 103.3213(14)$°, $V = 7937.3(12)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.352$ g cm^{-3}, $T = 100$ K, $2\theta_{max} = 50$°, $\mu = 0.483$ mm^{-1}, 40213 reflections measured, of which 13998 were unique ($R_{int} = 0.0500$), final R indices: $R1 = 0.0401$ ($I > 2\sigma(I)$), $wR2 = 0.1006$ (all data).

Crystal data for **4**: $C_{32}H_{47}Br_2N_3NiOP_2Si$, monoclinic, space group $P2_1/c$ (no. 14), $a = 18.3666(13)$, $b = 12.1328(8)$, $c = 16.1095(11)$ Å, $\beta = 90.4750(14)$°, $V = 3589.7(4)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.477$ g cm^{-3}, $T = 100$ K, $2\theta_{max=}50$°, $\mu = 2.918$ mm^{-1}, 18367 reflections measured, of which 6325 were unique ($R_{int} = 0.0375$), final R indices: $R1 = 0.0351$ ($I > 2\sigma(I)$), $wR2 = 0.0859$ (all data).

CCDC-254120–254123 (**1**–**4**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Organic Chemistry

"On Water": Unique Reactivity of Organic Compounds in Aqueous Suspension**

*Sridhar Narayan, John Muldoon, M. G. Finn, Valery V. Fokin, Hartmuth C. Kolb, and K. Barry Sharpless**

Water is a desirable solvent for chemical reactions for reasons of cost, safety, and environmental concerns, and the study of organic reactions in aqueous solvents has an intriguing history.[1] Most notably, certain pericyclic reactions such as

Diels–Alder cycloadditions[2] and Claisen rearrangements[3] of hydrophobic compounds have been found to be accelerated in dilute aqueous solution. Yet, either organic cosolvents and/or substrate modifications are almost always employed in preparative-scale reactions performed in water,[1] as it is assumed that solubility is required for efficient reaction. Not only do these strategies detract from the simplicity and advantages sought from the use of water in the first place, but, as we report here, the venerable assumption "corpora non agunt nisi soluta" (substances do not interact unless dissolved) can be distinctly counterproductive.

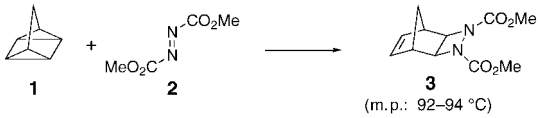
In recent years, we have focused on modular synthetic techniques that rely on a few nearly perfect reaction types.[4] In the course of this work, we have noticed that many such reactions often proceed optimally in pure water,[5] and particularly when the organic reactants are insoluble in the aqueous phase.[6] We present here several examples that illustrate a remarkable phenomenon: substantial rate acceleration when insoluble reactants are stirred in aqueous suspension, denoted here as "on water" conditions. Even when the rate acceleration is negligible, the use of water as the only supporting medium has other advantages including ease of product isolation and above all, safety, thanks to its high heat capacity[7] and unique redox stability.

In connection with our studies on the reactivity of strained olefins, we explored the preparation of 1,2-diazetidines from quadricyclane (**1**) by the $2\sigma+2\sigma+2\pi$ cycloaddition with azodicarboxylates, discovered by Lemal and co-workers.[8] The typical reaction conditions involve heating **1** with dimethyl azodicarboxylate (DMAD, **2**) in toluene or benzene at 80 °C for 24 h or longer.[8,9] In contrast, when a mixture of DMAD and quadricyclane is vigorously stirred "on water", the reaction is complete within a few minutes at ambient temperature. The corresponding neat (solvent-free) reaction of these two liquids takes nearly two days to reach completion, which shows that the rate acceleration is not the sole consequence of an increase in the effective concentration of reagents (Table 1).

As the cycloaddition of DMAD with quadricyclane demonstrates, the "on water" method consists simply of stirring the reactant(s) with water to generate an aqueous suspension. Nonpolar liquids that separate from water into a clear organic phase are ideal candidates for these reactions. Solid reactants can also be utilized, provided one reaction partner is a liquid and adequate mixing is ensured. Vigorous stirring promotes the reaction, most likely by increasing the area of surface contact between the organic and aqueous phases. The observed rate acceleration does not depend on the amount of water used, as long as sufficient water is present for clear phase separation to occur.[10] The product is isolated simply by phase separation or filtration. In cases where clear phase separation does not occur, such as in small-scale reactions, liquid–liquid extraction may be necessary.

Seeking insight into the origin of rate acceleration in the DMAD–quadricyclane cycloaddition, the reaction between **1** and **2** was carried out under a variety of conditions and the time to completion was monitored (Table 2). Under homogenous conditions, polar protic solvents accelerate the reaction, with observed reaction rates in the following order: $MeOH/H_2O$ (3:1) > MeOH > DMSO > $CH_3CN \approx CH_2Cl_2$ > EtOAc ≈ toluene.[11] This trend suggests that hydrogen bonding, charge stabilization, and dipolar effects may each be important for rate acceleration.[12] While water contributes to such properties in homogeneous mixtures, heterogeneity was crucial for observing large rate accelerations. Thus, the presence or absence of methanol in a heterogeneous reaction made little difference, but the rate slowed considerably when enough methanol was used to make the reaction homogeneous. However, heterogeneity in itself is not responsible for rate acceleration as the reaction "on" perfluorohexane was only slightly faster than the neat reaction. Interestingly, a significant solvent isotope effect was also observed: the reaction slowed noticeably when D_2O was used in place of water.

Table 1: Reaction of quadricyclane (**1**) with dimethyl azodicarboxylate (**2**).

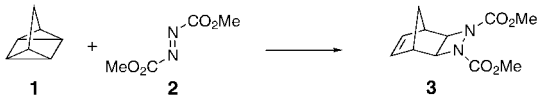


1 **2** **3** (m.p.: 92–94 °C)

Solvent	Conc. [M]	*T* [°C]	*t*	Yield [%][a]
neat	4.53[b]	0	2 h	0[c]
neat	4.53[b]	23	48 h	85
toluene	1	80	24 h	74
on H_2O	**4.53[d]**	**0**	**1.5 h**	**93**
on H_2O	**4.53[d]**	**23**	**10 min**	**82**

[a] Yields are of isolated pure products. [b] Calculated from the measured density of a 1:1 mixture of **1** and **2**. [c] No product discernible after 2 h. [d] The maximum effective concentration "on water" is assumed to be the same as that of the neat reaction.

Table 2: Reaction of quadricyclane (**1**) with dimethyl azodicarboxylate in various solvents.[a]



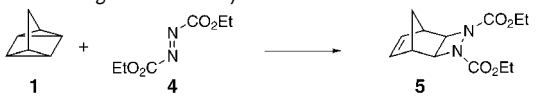
1 **2** **3**

Solvent	Conc. [M][b]	Time to completion
toluene	2	> 120 h
EtOAc	2	> 120 h
CH_3CN	2	84 h
CH_2Cl_2	2	72 h
DMSO	2	36 h
MeOH	2	18 h
neat	4.53	48 h
on D_2O	4.53	45 min
on C_6F_{14}	4.53	36 h
on H_2O	**4.53**	**10 min**
$MeOH/H_2O$ (3:1, homogeneous)	2	4 h
$MeOH/H_2O$ (1:1, heterogeneous)	4.53	10 min
$MeOH/H_2O$ (1:3, heterogeneous)	4.53	10 min

[a] Compound **3** was the only product observed in each case. [b] Concentrations of the neat and heterogeneous reactions are calculated from the measured density of a 1:1 mixture of **1** and **2**. DMSO = dimethylsulfoxide.

Acceleration of reactions "on water" is evident even when a nonpolar solvent comprises a part or most of the organic phase as shown in Table 3. Thus, the reaction of quadricyclane (**1**) with diethyl azodicarboxylate (DEAD, **4**), carried out simply by stirring a toluene solution of DEAD with **1** "on water", proceeds at a considerably higher rate than when the reaction is carried out in toluene alone.

Table 3: Cycloaddition of quadricyclane (**1**) performed with DEAD (commercial reagent in toluene) "on water".[a]



1 **4** **5**

t [h]	Conversion [%][b]	
	toluene[c]	**toluene on H_2O**[d]
3	4	**42**
6	8	**56**
17	18	**69**

[a] Isolated yield after 24 h at 23 °C: toluene, 24%; toluene "on water", 72%. [b] Determined by ^{1}H NMR spectroscopy using acetophenone as internal standard. [c] Commercial DEAD in toluene used (49%, 2.86 M). [d] As [c], except for the presence of an equal volume of water to toluene.

We have found that the high reactivity of azodicarboxylates "on water" is not limited to their cycloaddition reactions: the ene reactions of these compounds respond similarly to conditions of aqueous suspension relative to organic solution. Leblanc et al. have used the ene reaction of bis(trichloroethyl) azodicarboxylate (**7**) to achieve the allylic amination of olefins under thermal conditions.[13] In nonpolar solvents such as benzene, prolonged heating at 80 °C was reportedly required to attain useful levels of reactivity with simple olefins such as cyclohexene (**6**). In the absence of solvent, the reaction of liquid **6** and solid **7** was found to proceed at 50 °C, but still required 36 h for completion as well as the presence of excess cyclohexene. In contrast, the reaction performed "on water" was complete within eight hours at 50 °C and afforded the product in 91% yield (see Table 4). The neat reaction between **6** and **7** not only appeared to be slower, but the reaction mixture was also considerably harder to mix uniformly. In contrast, when heated to 50 °C "on water" the reaction mixture initially formed a molten organic phase, which gave way to the product as a white precipitate. In practical terms, reactions of solid components in aqueous suspension are more reproducible and convenient than in the absence of solvent, as water provides for efficient "mixing" of the reactants without the dilution cost of a true solvent. Furthermore, the effective melting point of solid reaction mixtures is noticeably lowered in the presence of water, such that a fused organic phase is often formed.

Table 4: Ene reaction of cyclohexene (**6**) with bis(trichloroethyl) azodicarboxylate (**7**) "on water".

neat	50	36[b]	62
on H_2O	**50**	**8**	**91**

[a] Data from Ref. [13]. [b] Additional **6** added after 24 h.

The notion of the special nature of water as a solvent for organic reactions began with examples of Diels–Alder reactions more than fifty years ago.[14] The first quantitative data were reported by Rideout and Breslow, who showed that Diels–Alder reactions between nonpolar compounds proceeded at much higher rates in water (dilute homogeneous solution) than in organic solvents.[15] Rate accelerations as high as 200-fold were noted in certain cases. Breslow et al. also noted the high *endo* selectivity of certain Diels–Alder reactions carried out in water, under both homogeneous and heterogeneous conditions.[16] Although rate acceleration and selectivity were ascribed primarily to hydrophobic effects, it has since been appreciated that hydrogen bonding plays an important role.[17] Ironically, much of the careful quantitative work on the process does not directly apply to synthetic chemistry, as the experiments reported by Breslow, Engberts, and others were conducted at low concentrations (mM or less) to maintain homogeneity in water, while preparative reactions usually require much higher concentrations. In a rare example of a heterogeneous process, Grieco et al. reported the Diels–Alder reaction of an acyclic diene bearing a carboxylic acid group to occur in aqueous suspension faster than in organic solution.[18] The best results were obtained in the reactions of diene carboxylate salts with various dienophiles in water, and the rate accelerations due to water were ascribed to micellar catalysis.[19] As some of these reactions were carried out under conditions similar to ours, we evaluated the effectiveness of the "on water" protocol for Diels–Alder reactions.

We performed the cycloaddition of the water-insoluble *trans*,*trans*-2,4-hexadienyl acetate (**9**) and *N*-propylmaleimide (**10**) under various conditions (Table 5). As before, a protic solvent (methanol) was better than nonprotic solvents, and

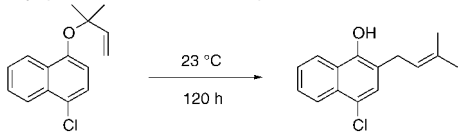
[a] Yield after chromatographic purification. Other yields are of crude products, which were >95% pure by ^{1}H NMR spectroscopy. [b] Calculated from the measured density of a 1:1 mixture of **9** and **10**.

the reaction in aqueous suspension showed substantial rate acceleration over homogeneous solution. Consistent with the results of Grieco et al.[18] and in contrast to the reaction of **1** + **2** described above, the neat Diels–Alder addition of **9** to **10** (both liquids) was approximately as fast as in water suspension.[20]

Claisen rearrangements are another significant class of reactions for which the accelerating effect of water is well-recognized.[21] The initial discovery appears to have been made during mechanistic studies of the chorismate–prephenate rearrangement, a key step in the biosynthesis of shikimic acid.[22] Brandes, Grieco, and Gajewski then performed a kinetic study on the rearrangement of an allyl vinyl ether substrate with an attached carboxylate functionality.[23] The rate of rearrangement of the carboxylate salt in water was found to be about two orders of magnitude higher than that of the methyl ester in nonpolar solvents.[24] These findings were exploited further by Grieco et al., who used the accelerating influence of water to promote difficult rearrangements.[25]

In contrast to the aliphatic Claisen rearrangements, the effect of water on the analogous aromatic Claisen rearrangement is little known.[26] We have made preliminary measurements on naphthyl ether **12**, which undergoes rearrangement at an appreciable rate even at room temperature. Table 6

Table 6: Comparison of solvents for an aromatic Claisen rearrangement (0.28–0.46 M), performed at room temperature.[a]



12 **13** (m.p.: 54–56 °C)

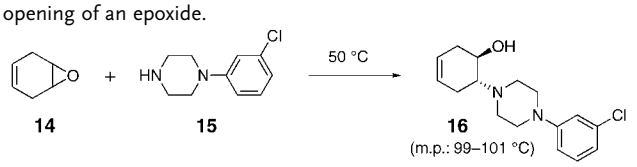
shows the effect of various solvents on this process. After five days at 23 °C, the sample of **12** in aqueous suspension had completely rearranged to **13**, while the rearrangement was considerably slower in organic solvents. The neat reaction was again closest in rate to water and required one further day to reach completion. As with Diels–Alder reactions, the "on water" protocol provides the best set of conditions in terms of efficiency, convenience, and safety, even when rate accelerations are not large.

Non-pericyclic reactions such as the opening of epoxides and aziridines with heteroatom nucleophiles also derive unique benefits from the "on water" environment. Hydrogen bonding is crucial for the activation of such electrophiles, making these ring-opening processes autocatalytic and difficult to control under neat conditions. Instead, protic solvents such as alcohols and especially alcohol/water mixtures provide good homogeneous media for these transformations.[4] Here too, we find that water alone is the medium of choice. The reactions are completed in shorter times than in other protic solvents, and the pure product often precipitates, to be isolated by simple filtration.

The reaction of cyclohexadiene monoepoxide (**14**) with *N*-(3-chlorophenyl)piperazine (**15**) is illustrative (Table 7).

Table 7: Application of the "on water" method to the nucleophilic opening of an epoxide.



14 **15** **16** (m.p.: 99–101 °C)

on H_2O	**3.88[b]**	**12**	**88**

[a] Determined by ^{1}H NMR spectroscopic analysis of the crude reaction mixture. [b] Calculated from the measured density of a 1:1 mixture of **14** and **15**.

When heated at 50 °C, the reaction "on water" was completed overnight, while the reactions in solution in ethanol or without solvent required approximately three days to reach completion. In toluene, less than 10% conversion occurred after five days at the same temperature. Thus, taking into account the concentrations of the reagents, the rates of reactions "on water" and in ethanol appeared to be approximately the same, and greater than that for the reaction performed in the absence of solvent.

Thus, a variety of reactions can be efficiently carried out in aqueous suspension, with the most dramatic effects observed for the addition of azodicarboxylates to unsaturated hydrocarbons. To the best of our knowledge, these examples represent some of the largest rate accelerations due to water observed under preparative conditions, that is, at molar concentrations. A central theme in the field of aqueous organic chemistry has been the need to promote solubility in these reactions. Clearly, solubility is not essential.

Although the reactivity phenomenon described here has immediate practical implications, its origins are presently unclear; nevertheless, a few preliminary remarks are in order. For example, it is possible that reactions "on water" actually proceed through small amounts of dissolved solutes. Rate acceleration in homogeneous aqueous solution has been attributed to a variety of effects such as hydrophobic aggregation,[2,15] cohesive energy density,[27] or ground-state destabilization.[28,29] Breslow et al. have invoked solution-phase hydrophobic effects to explain the high *endo* selectivity of certain Diels–Alder reactions in aqueous suspension and solution.[2a,16] Engberts and co-workers made a fundamental point by providing evidence that, in cycloaddition reactions, hydrophobic destabilization will have a considerably greater

impact on the ground state than on the transition state.[29,30] The importance of hydrogen bonding in the acceleration of Diels–Alder reactions in aqueous solution is supported by both experimental[31] and theoretical[32] studies.

However, it seems that many of the reactions described above are simply too fast for the acceleration to be solely due to solution-phase phenomena. In this regard, the observed requirement for heterogeneity and the finding that the rates of reactions "on water" often exceed those of the same reactions performed in the absence of solvent demand attention. Perhaps the unique properties of molecules at the macroscopic phase boundary between water and insoluble hydrophobic oils play a role.[33] The same principles that contribute to solution-phase effects may be amplified at such phase boundaries, but other factors, such as the redistribution of surface species driven by surface-tension energetics,[34] may also be relevant. We plan to keep exploring the "on water" phenomenon both for practical applications and mechanistic understanding.

[20] As both starting materials and the product are oils, the neat reaction is not prone to physical "mixing" issues, which can arise when one of the reactants is a solid. Even when mixing is not an issue, we have encountered a few cases where the reactions "on water" are two- to threefold faster than the corresponding neat reaction, although the example shown here is typical.

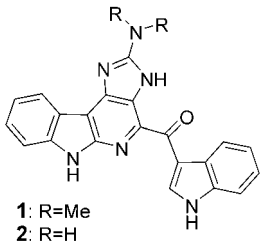
Biomimetic Synthesis

Biomimetic Synthesis of Grossularines-1**

*Fumiko Y. Miyake, Kenichi Yakushijin, and David A. Horne**

Dedicated to Professor Peter B. Dervan on the occasion of his 60th birthday

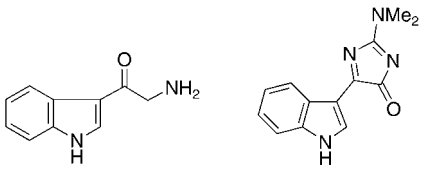
Isolated in only small amounts from the Britannia marine tunicate *Dendrodoa grossularia* (Styelidae), grossularine-1 (**1**) represents one of the more structurally intriguing members of a relatively small but potent class of α-carboline metabolites that exhibit pronounced effects against solid human tumor cell lines.[1] The limited material available from nature as well as synthetic sources, however, have hampered further investigations in vivo. Closely related to **1** is *N,N*-didesmethylgrossularine-1 (**2**) (from the Chuuk Atoll tunicate *Polycarpa aurata*) whose structure was established by X-ray crystallographic analysis.[2]



1: R=Me
2: R=H

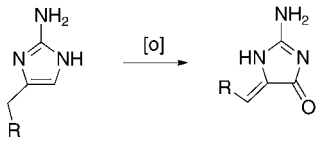
In contrast to the well-known class of β-carboline-derived natural products, grossularines represent the first examples of naturally occurring α-carbolines. Despite the promising biological activity of **1**, only one total synthesis has been completed.[3] In the approach of Hibino and co-workers, the construction of the tetracyclic pyrido[2,3-*b*]indole ring system proceeded in a linear manner through the use of Pd-catalyzed cross-coupling reactions of halogenated indoles and metallated imidazoles. A formal synthesis of **1** has been reported by Molina et al.[4] that intersects the key intermediate reported by Hibino and co-workers. Herein we describe a remarkably concise biomimetic synthesis of **1** and **2** that is based on a novel oxidative dimerization–electrocyclization sequence of 2-amino-4-(3-indolyl)imidazoles **5** and **6** derived from oxotryptamine (**3**).

Oxotryptamine (**3**) continues to serve as an important cornerstone in indole heterocyclic construction. In previous work reported by our research group, a practical procedure for the preparation of **3** was developed that avoids the use of protecting groups and DDQ oxidation, and was applied to the synthesis of various bis-indole marine natural products.[5] In a formal sense, grossularine **1** and its didesmethyl congener **2** consist of two oxotryptamine units that are linked by an oxidative coupling between the two carbon centers of the amino-bearing termini. Although such a mode of dimerization is difficult to envisage with oxotryptamine per se, the use of an electron-rich aromatic surrogate based on 2-aminoimidazoles **5** and **6** seemed plausible, particularly in view of the oxidized analogue, 2-dimethylamino-5-(3-indolyl)imidazol-4-one (**4**).[6] This derivative was co-isolated with **1** from the same tunicate. The presence of this oxidized metabolite



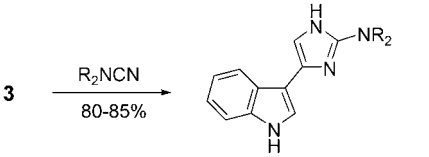
3 **4**

along with the fact that 2-aminoimidazoles are readily converted into imidazolones through oxidation [Eq. (1)],[7] suggests that 2-aminoimidazoles **5** and **6** could serve as potential biosynthetic forerunners.



(1)

The synthesis begins with the preparation of 2-aminoimidazoles **5** and **6** by using the classical cyclocondensation of α-amino carbonyl compounds and cyanamide (Scheme 1).[8] Condensation of oxotryptamine (**3**) and dimethylcyanamide in the absence of air produced 2-dimethylamino-4-(3-indolyl)imidazole (**5**).[9,10] Attempts to purify **5** as the free base by flash chromatography were unsuccessful owing to its instability; however, **5** can be obtained in relatively pure form



5: R=Me (as HCl salt)
6: R=H

  DOI: 10.1002/anie.200500055

as the hydrochloride salt. On the other hand, 2-amino-4-(3-indolyl)imidazole (**6**), which lacks the dimethyl substituent, can be secured as the free base by the condensation of **3** with cyanamide followed by chromatographic purification over silica. These findings are consistent with observations made by Snyder and co-workers during their investigations of Diels–Alder reactions of 2-aminoimidazoles, in which greater thermal and air sensitivity of 2-dimethylaminoimidazole was observed.[11]

The instability of **5** normally would not be judged very significant on its own; however, further investigation was inspired by the fact that this 2-aminoimidazole derivative is quite sensitive to air and that an oxidative coupling event could, in principle, deliver conjoined indole units as a means to potentially access the α-carboline core. We were quite surprised to find that upon exposure of **5**·HCl to a methanol solution saturated with ammonia, α-carboline **8** was produced (Scheme 2).[12] During the course of the reaction, dimer **7** partially precipitated from solution after 1 day as a dark violet solid. Collection and resubjection of **7** to the reaction conditions afforded **8**. To explain these results, one mechanistic pathway might involve initial oxidative dimerization of **5** to yield dimer **7**. Upon standing in a methanol-saturated ammonia solution, **7** undergoes an electrocyclization–aromatization event via tautomer **7a**. Oxidation of the resulting intermediate **7b** to **7c** followed by facile aminolysis results in the loss of dimethylguanidine and the formation of α-carboline **8**. The sequence is remarkably efficient, delivering **8** directly in one pot and good overall yield from **5**. Aromatic imine **8** was found to be quite stable and required fairly rigorous hydrolysis conditions to yield grossularine-1 (**1**) as a yellow solid. All spectral data of synthetic **1** were in excellent agreement with data reported for the natural product.[1]

Similarly, treatment of **6** under analogous MeOH–NH_3 conditions produced fused pentacyclic dimer **9** as a dark violet to black solid (Scheme 3). Upon further standing in MeOH–NH_3, **9** underwent aminolysis to afford imine **10**. Hydrolysis of the imine functionality of **10** gave *N*,*N*-didesmethylgrossularine-1 (**2**). Alternatively, **2** can be obtained directly from the hydrolysis of **9**. All spectral data of synthetic **2** were in excellent agreement with those reported for the natural product.[2] In noting differences between dimethylaminoimidazole **5** and its didesmethylamino analogue **6**, the precyclized desmethylamino dimer corresponding to **7** was not obtained in the case of **6**. This outcome is attributed to the greater solubility of the putative desmethyl intermediate in methanolic ammonia. In the case of **5**, the *N*,*N*-dimethylamino analogue **7c** corresponding to **9** also was not obtained. The greater propensity toward aminolysis of this putative guanidinium ion intermediate explains this result.

Although electron-rich aromatic heterocycles such as indoles are known to undergo autoxidative coupling,[13] the oxidative dimerization of 2-aminoimidazoles under simple aerobic conditions is unprecedented. The structurally and biologically significant α-carboline natural products **1** and **2** were produced in excellent overall yields with an operationally simple, three-pot sequence starting from oxotryptamine. The chemistry and brevity of this novel sequence support a plausible biogenetic con-

nection that explains these and several other structurally related members this α-carboline family.

Metallofullerenes

2D NMR Characterization of the La@C_{82} Anion**

Takahiro Tsuchiya, Takatsugu Wakahara, Yutaka Maeda, Takeshi Akasaka, Markus Waelchli, Tatsuhisa Kato, Hiroshi Okubo, Naomi Mizorogi, Kaoru Kobayashi, and Shigeru Nagase**

Endohedral metallofullerenes have attracted special interest as new spherical molecules, and intensive effort has been made to disclose their structures and electronic properties.[1] Although NMR spectroscopy is a powerful tool for elucidating the structure of a given compound,[2] its application to endohedral metallofullerenes such as La@C_{82} is very difficult because of their paramagnetic nature.[3,4] Recently, we reported the determination of the cage symmetry in paramagnetic metallofullerenes such as La@C_{82}-A(C_{2v}),[5] La@C_{82}-B(C_s),[6] Pr@C_{82}-A(C_{2v}),[7] and Ce@C_{82}-A(C_{2v})[8] by ^{13}C NMR measurements on their anionic forms [M@C_{82}]$^-$. However, it remains an important goal to verify the bond connectivity and assign the NMR lines, as this is essential for full characterization of the structures of endohedral metallofullerenes. We now report the first mapping of the bond connectivity in the carbon cage of [La@C_{82}-A]$^-$ and definitive assignment of the NMR lines by 2D INADEQUATE (incredible natural abundance double quantum transfer experiment) NMR measurements.[9–11] The bonding nature

of the carbon cage in $[La@C_{82}\text{-}A]^-$ was revealed from the carbon–carbon coupling constants $^1J_{CC}$. The position of La was also confirmed by measurements of relaxation time T_1.

Figure 1 shows the 2D INADEQUATE NMR spectrum of $[La@C_{82}\text{-}A]^-$. Two-bonded carbon atoms share a double

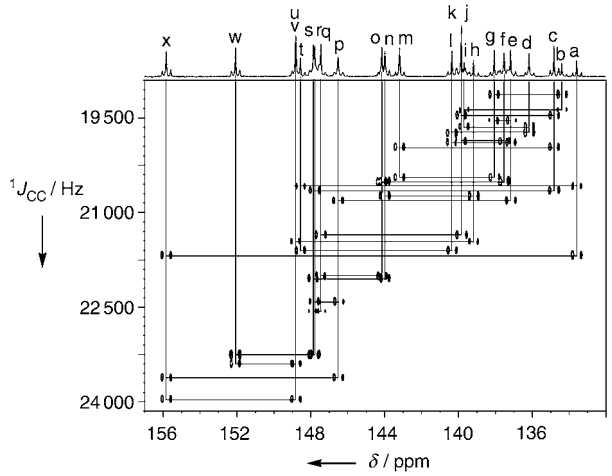

Figure 1. 2D INADEQUATE NMR spectrum of $[La@C_{82}\text{-}A]^-$.

quantum frequency in the vertical dimension, and each peak appears at the two respective chemical shifts in the horizontal dimension. To assign the 2D INADEQUATE NMR spectrum at an early stage, the ^{13}C NMR chemical shifts of $[La@C_{82}\text{-}A]^-$ were calculated at the B3LYP-GIAO/6-31G(d)//B3LYP/6-311+G(d) level. It was shown that the C atom designated no. 8 in Table 1 has the most upfield ^{13}C NMR signal. Therefore, we started the ^{13}C NMR assignment and bond

Table 1: Peak assignment and chemical shifts (δ) for the ^{13}C NMR spectrum of $[La@C_{82}]^-$.

12	c	135.1	24	j[c]	140.1

[a] Carbon atoms are numbered in order of distance from La atom. The optimized structure of $[La@C_{82}\text{-}A]^-$ was obtained at the B3LYP/6-311+G(d) level. [b] Assigned in Figure 1. [c] Half-intensity peak.

connectivity from the most upfield signal a in Figure 1, that is, from carbon no. 8. As shown in Table 1, all C atoms in $[La@C_{82}\text{-}A]^-$ are completely assigned, as the first example for fullerenes apart from C_{60}, C_{70}, and their derivatives.

In the 2D INADEQUATE NMR spectrum, each peak is split into a doublet by the relevant carbon–carbon coupling constant $^1J_{CC}$. It is well known that $^1J_{CC}$ increases with shortening bond length and increasing π-bond order.[12] The 5,6 and 6,6 ring-fusion bonds of empty fullerenes such as C_{60} and C_{70} are considered to have single- and double-bond character, respectively.[13] Figure 2a plots the C–C bond

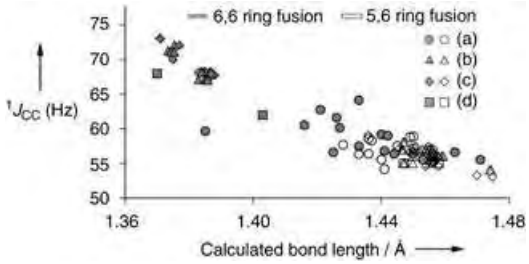

Figure 2. Plots of calculated carbon–carbon bond lengths [Å] vs $^1J_{CC}$ [Hz] for a) $[La@C_{82}\text{-}A]^-$, b) C_{60} *trans*-3 bis-adduct,[10b,c] c) C_{60} *trans*-4 bis-adduct,[10b,c] and d) C_{70}.[11b]

lengths calculated for $[La@C_{82}\text{-}A]^-$ at the B3LYP/6-311+G(d) level against the observed $^1J_{CC}$ values. To compare $[La@C_{82}\text{-}A]^-$ with empty fullerenes, the plots for *trans*-3 and *trans*-4 Bingel bis-adducts of C_{60}[10b,c] and pristine C_{70}[11b] are also shown in Figure 2b–d. For the empty fullerenes, the C–C bonds with larger $^1J_{CC}$ values and shorter calculated bonds correspond to the 6,6 ring-fusion bonds, and these plots do not overlap with those for the 5,6 ring-fusion bonds. However, the plots of 6,6 and 5,6 ring-fusion bonds for $[La@C_{82}\text{-}A]^-$ overlap with each other. In this context, it may be concluded that the 5,6 and 6,6 ring-fusion bonds in $[La@C_{82}\text{-}A]^-$ are shortened and elongated, respectively, and the classification of single- and double-bond character of $[La@C_{82}\text{-}A]^-$ is less clear than that of empty fullerenes. Shortening of the 5,6 ring-fusion bonds and the elongation of the 6,6 ring-fusion bonds were also calculated for $C_{82}(C_{2v})$ (Figure 3). However, the extent of shortening and elongation in $[La@C_{82}\text{-}A]^-$ is much larger than

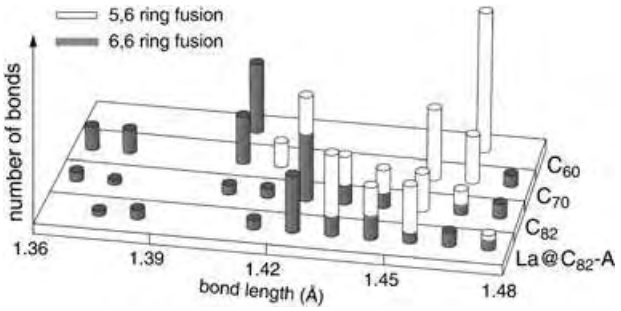

Figure 3. Histogram of 5,6 and 6,6 ring-fusion bond lengths calculated for C_{60}, C_{70}, $C_{82}(C_{2v})$, and La@C_{82}-A at the B3LYP/6-311+G(d) level.

that in pristine C_{82}, as a result of three-electron transfer from La to the LUMO and LUMO+1 of C_{82}, which have antibonding character.[4]

Important information about the position of La in $[La@C_{82}\text{-}A]^-$ is also obtainable from ^{13}C NMR measurements. Calculations on $[La@C_{82}\text{-}A]^-$ show that the C–C bonds in the vicinity of La are elongated (Figure 4) because of electron

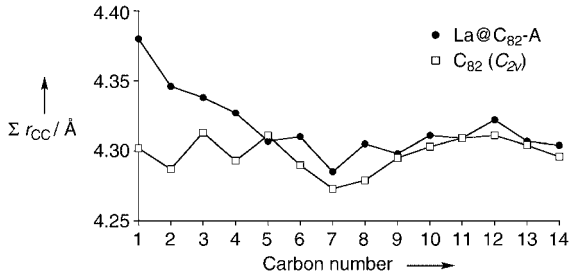

Figure 4. Plots of the sum of the calculated carbon–carbon distances to neighboring carbon atoms for $[La@C_{82}\text{-}A]^-$ and C_{82} (C_{2v}) at the B3LYP/6-311+G(d) level. Carbon atoms are numbered in order of distance from La atom, as shown in Table 1.

transfer from La to C_{82}.[4] It is known that the relaxation time T_1 governed by dipole–dipole relaxation is proportional to the sixth power of the internuclear distance.[14,15] It is noticeable that carbon no. 1 in Table 1, which is calculated to be the nearest to La in $[La@C_{82}\text{-}A]^-$, has the largest T_1 value and gives the largest value for the sum of the sixth power of the C–C bond lengths (see Supporting Information).[16] Thus, T_1 measurements support that La is located at the position predicted by calculations.[4,5]

In conclusion, the 2D INADEQUATE NMR spectrum of $[La@C_{82}\text{-}A]^-$ yields the bonding topology, coupling constants, and full assignment of the ^{13}C NMR spectrum. In other words, the 2D INADEQUATE NMR measurement can be used as an alternative method to X-ray crystallographic analysis for the structural characterization of endohedral metallofullerenes.

Experimental Section

A 13% ^{13}C-enriched $La@C_{82}$-A sample was prepared according to the reported procedure by using an arc vaporization method with a composite anode containing ^{13}C-enriched graphite and lanthanum oxide.[17] $[La@C_{82}\text{-}A]^-$ was prepared electrochemically as described before.[5] The 2D INADEQUATE NMR spectrum was measured in $[D_6]$acetone/CS_2 (1/1) at 125 MHz on a Bruker DRX 500 spectrometer with a CryoProbe system. All calculations were performed with Gaussian 03.[18]

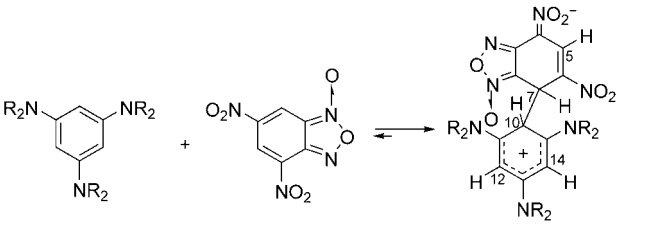
Reactive Intermediates

Evidence for Carbon–Carbon Meisenheimer–Wheland Complexes between Superelectrophilic and Supernucleophilic Carbon Reagents**

Carla Boga, Erminia Del Vecchio, Luciano Forlani, Andrea Mazzanti, and Paolo E. Todesco*

The observation, or the isolation (when it is possible), of intermediates in nucleophilic aromatic substitution[1a] (S_NAr; the so-called Meisenheimer complexes M) and in electrophilic aromatic substitution[1b,c] (the so-called Wheland complexes W) reactions is an important confirmation of the proposed mechanisms. Our interest has, in the past, focused on intermediates in the S_NAr reaction[2] and, more recently, also on electrophilic aromatic substitution reactions[3] (Wheland intermediates). Both kinds of σ complexes (M and W) have appreciable stability when a number of strong electron-withdrawing groups or electron-donating groups, respectively, are present on the aromatic ring. 4,6-Dinitrobenzofuroxan (DNBF) is a powerful carbon electrophilic reagent[4] and 1,3,5-tris(*N*,*N*-dialkylamino)benzenes are powerful carbon nucleophilic reagents.[5] Herein, we report that these couples act as superelectrophilic[6,7] and supernucleophilic reagents, thus providing evidence of a carbon–carbon coupling reaction with formation of Meisenheimer–Wheland zwitterionic complexes. This kind of adduct was, up until now, only proposed,[7] but not observed experimentally.

Addition of solutions of 1,3,5-tris(*N*-piperidyl)benzene (**1**), 1,3,5-tris(*N*-morpholinyl)benzene (**2**), or 1,3,5-tris(*N*-pyrrolidinyl)benzene (**3**) in CD_2Cl_2 to a solution of DNBF in CD_2Cl_2 at −70 °C in an NMR tube resulted in the signals of the starting materials in the ^1H NMR spectra disappearing and the appearance of new signals, which are ascribed to compounds **4**, **5**, and **6** (Scheme 1). Acidification of solutions of **4** in $[D_6]$DMSO by addition of DCl afforded a spectrum containing exclusively the signals of the starting materials, namely **1** (in a protonated form) and DNBF.



NR2 = *N*-piperidyl **1**
NR2 = *N*-morpholinyl **2**
NR2 = *N*-pyrrolidinyl **3**

DNBF

NR2 = *N*-piperidyl **4**
NR2 = *N*-morpholinyl **5**
NR2 = *N*-pyrrolidinyl **6**

Scheme 1. Reaction of 1,3,5-tris(*N*,*N*-dialkylamino)benzenes with 4,6-dinitrobenzofuroxan to produce carbon–carbon zwitterionic complexes.

Scheme 1 illustrates the observed reactions with formation of Wheland–Meisenheimer complexes **4**–**6**, whose structures are in agreement with the spectral data obtained at low temperature. Detailed analyses of the reaction products **4**–**6** by variable-temperature NMR spectroscopy revealed an unexpected behavior of these W–M compounds which deserves some special consideration. We describe herein the study carried out on compound **6** in detail; similar behavior was obtained with **4** and **5** (full spectral data for compounds **4**–**6** are shown in Tables 1 and 2).

The mixing of cooled (−70 °C) solutions of DNBF and 1,3,5-tris(*N*-pyrrolidinyl)benzene (**3**) in CD_2Cl_2 afforded a new product (**6**) immediately. The ^1H NMR spectrum of this solution (maintained at −70 °C) shows four separate signals in the range $\delta = 4.3$–5.1 ppm, three of which correspond to the three hydrogen atoms belonging to the tris(*N*-pyrrolidinyl)-benzene moiety and one ascribed to the furoxanic ring. The other hydrogen atom, which is hydrogen bonded to the furoxanic ring, was found at $\delta = 8.60$ ppm (Table 1).

Direct proton to carbon correlation (gHSQC sequence, Figure 1, left) obtained at −70 °C shows that two of the four hydrogen atoms which resonate at $\delta = 4.61$ and 4.43 ppm are connected to two carbon atoms at $\delta = 87.22$ and 88.28 ppm; these chemical shifts are in the range typical for sp^2-hybridized carbon atoms of 1,3,5-tris(*N*-pyrrolidinyl)benzene. In contrast, the two remaining proton signals ($\delta = 4.32$ and 5.00 ppm) are connected directly to carbon atoms resonating at $\delta = 45.09$ and 40.87 ppm, respectively, which is clear evidence for the sp^3 hybridization of these carbon atoms.

[a] Interchangeable assignments. [b] Broad singlet.

Proton to proton correlation obtained at −70 °C (gCOSY sequence, Figure 1, right) shows that the signal at δ = 5.00 ppm is correlated with the furoxanic hydrogen atom at δ = 8.60 ppm and to one of the three tris(*N*-pyrrolidinyl)benzene hydrogen atoms at δ = 4.32 ppm (J = 3.6 Hz).

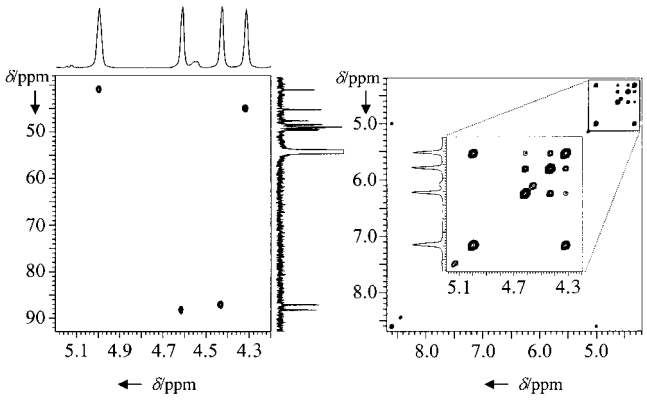

Figure 1. Left: gHSQC spectrum of compound **6** in CD_2Cl_2 at −70 °C. Right: gCOSY spectrum of compound **6** in CD_2Cl_2 at −70 °C.

All the mentioned NMR data, recorded at −70 °C, agree with a Wheland–Meisenheimer (W–M) structure that is produced in the reaction between DNBF and tris(*N*-pyrrolidinyl)benzene.[8]

In the Wheland–Meisenheimer structure (Scheme 1) C12 and C14 are sp^2 hybridized, while C10 and C7 are sp^3 hybridized, thus accounting for the two high-field ^{13}C NMR signals at δ = 45.09 and 40.87 ppm, respectively. The presence of two distinct hydrogen (and carbon) signals for the two other CH groups (C12 and C14) of the tris(*N*-pyrrolidinyl)-benzene can be easily explained because of the presence of an asymmetric carbon center (C7) and a "C_2 center" (C10);[9] under these conditions the two CH atoms are diastereotopic and thus appear as anisochronous signals in both the ^{1}H and ^{13}C NMR spectra. The same effect can be observed for the aromatic quaternary carbon atoms, which show three separated signals, and for the pyrrolidinic rings (six signals for the six α-nitrogen carbon atoms).

On raising the temperature, neither the ^{13}C nor ^{1}H NMR spectra change until −30 °C (−30 °C and −40 °C for **4** and **5**, respectively). Above −30 °C the three signals ascribed to the hydrogen atoms of the tris(*N*-pyrrolidinyl)benzene moiety show line broadening as a result of an exchange process. The signals coalesce at −1 °C and appear as a single signal at +20 °C (Figure 2). In contrast, the other signal (H7) always remains sharp.

It is worth noting that the dynamic process observed is reversible: warming the solution from −30 °C to room temperature and cooling again to −30 °C gives a spectrum that is identical to the starting one. Satisfactory line-shape simulation (Figure 2) was obtained using only one rate constant, which shows that $\Delta G^{\neq}$ is not constant with temperature and indicates that the $\Delta S^{\neq}$ value is not negligible. An accurate analysis by means of the Eyring equation[10] yields $\Delta H^{\neq} = 22.7 \pm 0.2$ kcal mol^{-1} and $\Delta S^{\neq} = 32 \pm 5$ e.u. for **6** ($\Delta H^{\neq} = 17.6 \pm 0.2$ kcal mol^{-1}, $\Delta S^{\neq} = 18 \pm 6$ e.u. for **4** and $\Delta H^{\neq} = 10.4 \pm 0.3$ kcal mol^{-1}, $\Delta S^{\neq} = 10 \pm 6$ e.u. for **5**).

The same dynamic process can also be observed in the ^{13}C NMR spectra: the coalescence of the three quaternary carbon atoms C11, C13, and C15 can be clearly seen above −30 °C, and they appear as a single line above −1 °C. However, the coalescence and the single averaged line cannot be observed for the three carbon atoms at δ = 87.22, 88.28, and 45.09 ppm because of the very large chemical shift difference between the signals (a line width of about 3 KHz is expected assuming $\Delta G^{\neq} \approx 13$ kcal mol^{-1} at room temperature). As in the proton spectra, the fourth signal, belonging to the C7 atom of the furoxanic ring, is always sharp irrespective of the temper-

[a] Interchangeable assignments. [b] Broad signals.

ature, thus showing that the furoxanic anion is still present at room temperature.[11]

Hence, the dynamic NMR data suggest the existence, above the coalescence temperature, of a Wheland–Meisenheimer complex in three homomeric structures (Scheme 2) with bonds C7/C10, C7/C12, and C7/C14 rapidly exchanging. The positive value of $\Delta S^{\neq}$ also agrees with a mechanism in which a bond involved in the W–M complex is broken. It should be noted that the activation parameters obtained for **6** are quite different from those obtained for **4** and **5**. A possible explanation can be hypothesized by considering the different steric environments involved in the W–M complexes: although the steric effects of the six-membered rings are almost the same in **4** and **5**, the smaller and more flexible five-membered rings in **6** lead to a stabilization of the W–M structure and hence affords greater $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values.

The existence of a π–π charge-transfer (CT) complex between DNBF and tris(amino)benzene derivatives could also occur, but experimental spectral data obtained for

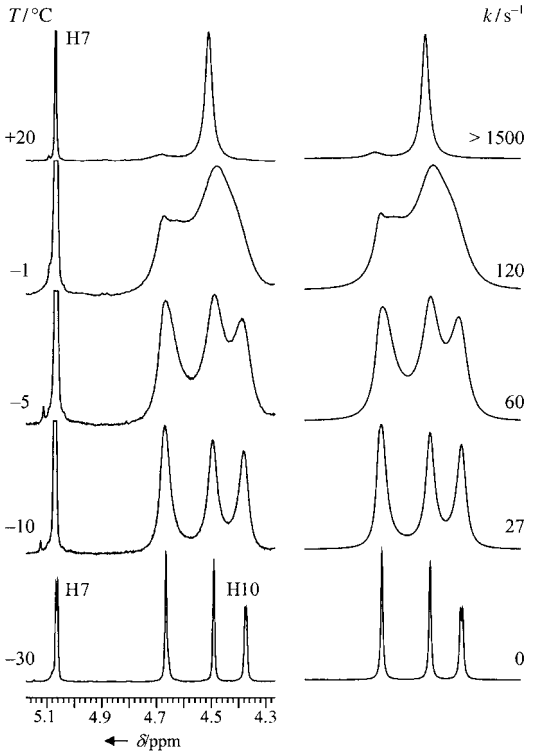

Figure 2. Left: experimental variable-temperature NMR spectra of **6**. Right: line-shape simulation obtained with the rate constant indicated. NR_2 = piperidyl, morpholinyl, pyrrolidinyl.

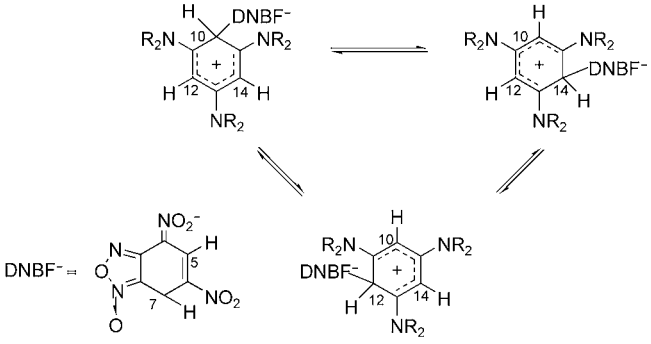

Scheme 2. Proposed interconversion pathway for the observed reversible and temperature-dependent transformation of W–M structures **4**–**6**.

compounds **4** and **6** clearly show (also at room temperature) the presence of sp^3 hybridization at the C7-position of the DNBF moiety (^{13}C NMR signal at $\delta = 40.87$ ppm). If such a CT complex existed, this carbon atom should revert back to sp^2 hybridization and hence a ^{13}C NMR signal at around $\delta =$ 90 ppm would be observed in the ^{13}C NMR spectrum at +25 °C.

In conclusion, the reaction between a superelectrophilic reagent such as DNBF and powerful carbon nucleophilic reagents such as 1,3,5-tris(*N*,*N*-dialkylamino)benzenes have given the possibility to characterize, for the first time, zwitterionic carbon–carbon Meisenheimer–Wheland complexes, whose structures were ascertained by one- and two-dimensional NMR experiments. A dynamic NMR study of these species also showed, through observation of coalescence, that increasing the temperature results in the formation of a Wheland–Meisenheimer complex in three homomeric structures with bonds C7/C10, C7/C12, and C7/C14 rapidly exchanging. Very strongly activated systems often give unexpected results, and this is the case here.

Experimental Section

Compounds **1** and **2** were prepared as reported in ref. [3]. Compound **3** was prepared in a similar manner from 1,3,5-trichlorobenzene and pyrrolidine. DNBF was prepared as reported in ref. [8]. NMR spectra were recorded on Varian Gemini 300, Mercury 400, or Inova 600 spectrometers operating at 300, 400, or 600 MHz (for ^1H NMR) or 75.46, 100.56, or 150.80 MHz (for ^{13}C NMR), respectively. Signal multiplicities were established by DEPT experiments. Chemical shifts were referenced to the solvent [($\delta = 5.30$ and 54.2 ppm for CD_2Cl_2), ($\delta = 7.27$ and 77.0 ppm for $CDCl_3$), ($\delta = 2.0$ and 0.3 ppm for CD_3CN), ($\delta = 2.6$ and 39.5 ppm for [D_6]DMSO) for ^1H and ^{13}C NMR, respectively]. The variable-temperature NMR spectra and 2D low-temperature spectra were recorded on the Inova 600 with a direct PFG Probe. The temperatures were calibrated by substituting the sample with a precision Cu/Ni thermocouple before the measurements. Complete fitting of dynamic NMR line shapes was carried out using a PC version of the DNMR-6 program.[12]

The low-temperature samples for NMR experiments were prepared directly in the NMR tube by mixing two cooled (−70 °C) solutions of DNBF (0.006 M) and **1**, **2**, or **3** (0.006 M) in CD_2Cl_2.

The behavior observed for compounds **4**–**6** on changing the temperature and the reversibility of the process was also observed in $CDCl_3$ solutions.

Mixing **1**, **2**, or **3** with DNBF in acetonitrile at low temperature (−30 °C) resulted in the precipitation of a coral-red solid. Heating the resulting solids, which were isolated by filtration, in a melting point apparatus resulted in them gradually darkening (133–140 °C, 118–125 °C, and 129–135 °C for compounds **4**–**6**, respectively) then decomposing. However, their ^1H and ^{13}C NMR spectra were identical to those obtained for compounds **4**–**6**, formed directly in an NMR tube and recorded at 25 °C.

[8] Recently, we studied the formation of σ complexes between nitrobenzofuroxans and amines and found that reaction of DNBF with 1,4-diazabicyclo[2.2.2]octane (DABCO) or piperidine affords Meisenheimer complexes which show ^{1}H NMR signals (in [D$_6$]DMSO) corresponding to protons bonded to the sp^3-hybridized C7 atom at $\delta = 6.8$ ppm and 6.2–6.4 ppm, respectively. When DNBF reacts with 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU) the positive charge is delocalized over the two nitrogen atoms, and the ^{1}H NMR signal of the proton on the sp^3-hybridized C7 atom appears at $\delta = 5.3$ ppm, which is very similar to values reported here for **4**–**6**; see C. Boga, L. Forlani, *J. Chem. Soc. Perkin Trans. 2* **2001**, 1408 – 1413.

[11] This observation also excludes the hypothesis that the starting reagents could be involved in the transition state because, if this is true, an exchange between the H7 signal of the W–M complex and the H7 signal of DNBF should be observed.

Infrared, UV/Vis, and W-band EPR Spectroscopic Characterization and Photochemistry of Triplet Mesitylphosphinidene**

Götz Bucher, Mark L. G. Borst, Andreas W. Ehlers, Koop Lammertsma, Stefano Ceola, Martina Huber, Dirk Grote, and Wolfram Sander*

Although many simple carbenes (R_2C)[1] and nitrenes (RN)[2–4] have been detected by various spectroscopic techniques, analogous phosphinidenes (RP) have not.[5–7] In sharp contrast to the abundant examples of transition-metal complexed phosphinidenes,[8–10] evidence of noncomplexed phosphinidines has remained elusive except for a recent matrix-IR study by Glatthaar and Maier[11] on H_3SiP, which was generated by the reaction of atomic silicon with phosphine, and an earlier electron paramagnetic resonance (EPR) study by Gaspar and co-workers[12] on mesitylphosphinidene (2,4,6-$Me_3C_6H_2P$; MesP; **3**), which was obtained by photolysis of *trans*-1-mesityl-2,3-dimethylphosphirane (**1**) in methylcyclohexane at $T = 77$ K (Scheme 1). No other direct experimental confirmation has been obtained for the existence of **3**.

Theoretical studies concur with the spectroscopic observation that a strongly preferred triplet ground state is predicted for aryl phosphinidene.[13,14] From the X-band

EPR spectrum, a zero-field-splitting (ZFS) parameter, D, of $|D/hc| = 3.521\ cm^{-1}$ was determined,[12] which is much larger than that for triplet phenylnitrenes ($\approx 1\ cm^{-1}$) and triplet phenylcarbenes ($\approx 0.5\ cm^{-1}$). The unusually large value of D was attributed to second-order spin–orbit contributions. Recent calculations on spin–orbit coupling in alkyl nitrenes, phosphinidenes, and arsinidenes yielded a D value of $|D/hc| = 3.46\ cm^{-1}$ for triplet methyl phosphinidene,[15] in line with the results of Gaspar and co-workers.[12] However, it should also be noted that on photolysis of more congested phosphiranes, Yoshifuji and co-workers[16] were unable to obtain an EPR signal in the reported region other than a weak signal at 5 K that was believed to be due to triplet oxygen.

We have investigated the photochemistry of **1** and **2** by using matrix-isolation spectroscopy and laser flash photolysis; herein we report EPR, infrared, and UV/Vis data that unequivocally support the formation of mesitylphosphinidene **3**.

Initially, using an X-band EPR spectrometer, we tried in vain to reproduce the EPR spectrum reported by Gaspar and co-workers.[12] Photolysis (248 nm, KrF-excimer, or 254 nm) of **2**, which was matrix-isolated in glassy methylcyclohexane ($T = 5$ K), resulted in the formation of yellow matrices but the corresponding spectra only showed strong doublet signals around $g = 2$ (g is the g factor) without EPR transitions attributable to triplet **3**. However, employing a W-band (95 GHz) EPR spectrometer, we detected a very weak signal exactly at the place predicted (4926 mT, Figure 1) for a triplet species with the ZFS parameters reported by Gaspar and co-workers; a background scan without sample showed no transitions in this spectral region.

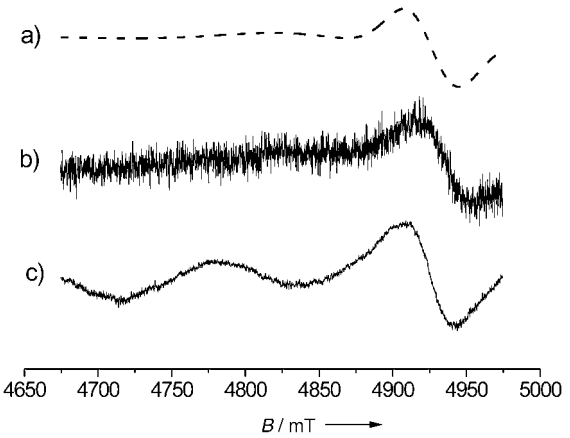

Figure 1. W-band EPR spectra of a sample of **2** in polycrystalline cyclohexane ($T = 5$ K), irradiated for 60 min with $\lambda = 254$ nm. a) Simulated spectrum. Simulation parameters: line width = 10 mT, $D = -3770.6$ mT ($|D/hc| = 3.521\ cm^{-1}$). b) Experimental spectrum obtained by sweeping the magnetic field from lower to higher values and c) from higher to lower values.

Monitoring by IR spectroscopy of the photolysis ($\lambda_{exc} =$ 254 nm, 48 h) of **1** or **2**, which were matrix-isolated in Ar at 10 K, showed slow disappearance of the phosphirane IR bands and formation of very weak new bands. Some of these bands are attributable to *trans*-2-butene (from **1**) or ethylene (from **2**), whose IR spectra were also recorded independently by matrix isolation of these alkenes. The remaining bands are assigned to triplet **3** based on a comparison with the IR spectrum calculated at the B3LYP/6-31G(d) level (Table 1).

Table 1: Calculated and experimental IR data of **3** (range 1700 to 500 cm^{-1}).

[a] Descriptions are analogous to those of the vibrations of benzene as proposed by Pitzer and Scott.[17]

When the sample was subjected to further irradiation ($\lambda_{exc} = 385$–420 nm or $\lambda_{exc} > 455$ nm, 90 min), the IR bands associated with both triplet **3** and *trans*-2-butene or ethylene disappeared, while those of the starting materials **1** or **2** partially re-emerged, together with a new set of IR bands.[18a] The new photoproduct showed a broad IR band at $\tilde{\nu} = 2261.2\ cm^{-1}$, thus indicating the presence of a P–H bond. By comparison with a calculated IR spectrum (B3LYP/6-31G(d)), the product could be identified as 1*H*,2*H*-dihydrobenzophosphete **4** (Figure 2; see also the Supporting Information).[18b] Intramolecular C–H insertion of the phosphorus center of supermesitylphosphinidene (2,4,6-*t*$Bu_3(C_6H_2)$P; Mes*P) into the *ortho*-*t*Bu group to give a phosphaindane is common[6–7] and λ^5-benzophosphetes have been reported previously.[19] The new dihydro-λ^3-benzophosphete **4**, which is energetically favored over triplet **3**, may be formed similarly or via phosphaquinone methide **5** (Scheme 2).

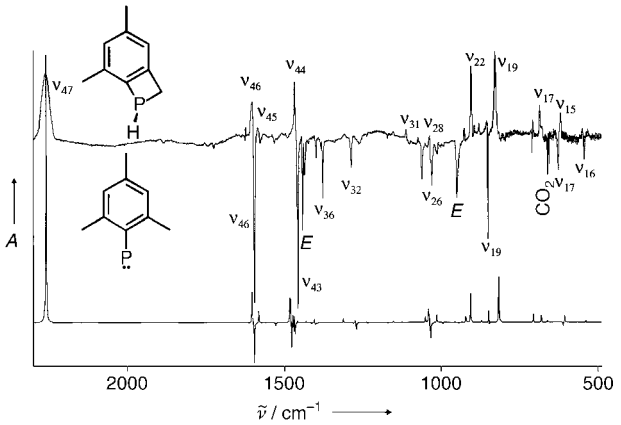

Figure 2. Top: Difference IR spectrum (Ar, 10 K) of the spectra obtained after photolysis of **2** at $\lambda_{exc} = 254$ nm (48 h) and subsequently at $\lambda_{exc} > 385$ nm (90 min). Bands pointing down disappear on photolysis at $\lambda_{exc} > 385$ nm and are attributed to a mixture of ethylene (E) and triplet **3**. The splitting of phosphinidene bands at $\tilde{\nu} = 1028.6$ and 1061.3 cm^{-1} (ν_{26}) is likely due to Fermi resonance.[18b] Several very weak bands remain unassigned. Bands pointing up are attributed to the secondary photoproduct **4** and traces of **2**. The highest intensity of the difference spectrum amounts to ca. 0.1. The assignment of a number of selected bands has been indicated by giving the transition numbers (see Tables 1 and S1). Bottom: calculated IR difference spectrum (0.97 × scaling, (U)B3LYP/6-31G(d)) of **4** minus triplet **3**.

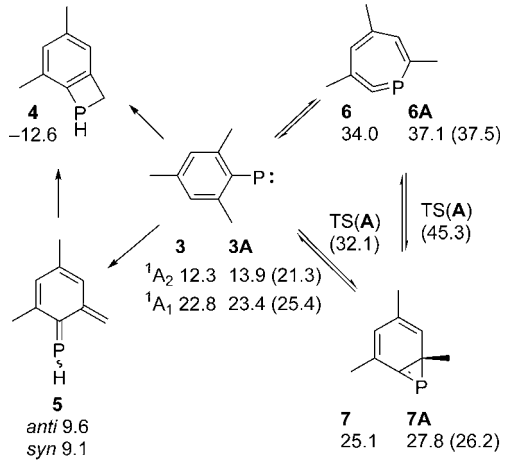

Scheme 2. B3LYP/6-31G(d) energies [kcal mol^{-1}] for the $C_9H_{11}P$ and unsubstituted C_6H_5P (**A**) isomers relative to triplet **3** and **3A**. CASPT2-(8/8)/6-31G(d) energies for **A** are given in parentheses.

The UV/Vis spectrum further supports the photochemical formation of **3** from matrix-isolated phosphiranes **1** (and **2**). Photolysis ($\lambda_{exc} = 254$ nm, 80 min, Ar, 10 K) gave rise to two new strong absorptions at $\lambda = 278$ and 292 nm, three weaker absorptions around 350, 370, and 390 nm, and a weak, broad absorption with fine structure between 420 and 470 nm. Subsequent long-wavelength photolysis ($\lambda_{exc} > 455$ nm) resulted in depletion of the absorptions at $\lambda = 278$, 292, 350, and > 420 nm, while those at $\lambda = 370$ and 390 nm initially increased in intensity (Figure 3). Extended near-UV photolysis ($\lambda_{exc} = 360$–400 nm, 2 h) resulted in bleaching of all absorptions with $\lambda > 300$ nm.

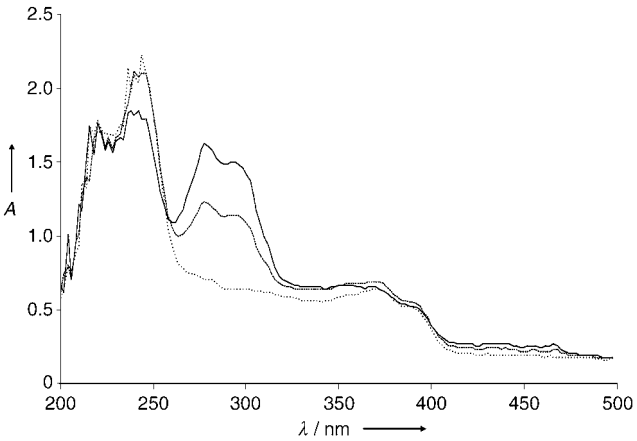

Figure 3. UV/Vis spectra (Ar, 10 K) obtained after photolysis of **1** after photolysis at $\lambda_{exc} = 254$ nm for 80 min (——), after subsequent photolysis at $\lambda_{exc} > 455$ nm for 10 min (-----), and after extended photolysis at $\lambda_{exc} > 455$ nm for 100 min (••••).

These observations are rationalized by assigning the absorptions $\lambda = 278$, 292, 350, and 420–470 nm to triplet mesitylphosphinidene **3**, and those at $\lambda = 370$ and 390 nm to a secondary photoproduct other than **4**. The UV/Vis spectrum of **3**, with a weak, structured broad band extending to $\lambda =$ 470 nm, strongly resembles the UV/Vis spectra of known triplet aryl nitrenes.[4a] The intense excitations at $\lambda = 285$, 310, 340, 415, and 440 nm calculated with time-dependent B3LYP/6-311 + G(d,p)[20] for triplet mesitylphosphinidene provide convincing evidence that triplet **3** is indeed formed upon photolysis of matrix-isolated mesitylphosphiranes **1** and **2**,[21] albeit in small yield.[22] The origin of the absorptions at 370 and 390 nm cannot be attributed to secondary photoproduct **4** because its calculated UV/Vis spectrum (TD-B3LYP/6-311 + G(d,p)) gives a longest-wavelength absorption at $\lambda_{max} =$ 255 nm. Among the compounds considered, the calculated spectrum of didehydrophosphepine **6** ($\lambda_{max} = 360$ and 385 nm) matches best the experimental data.[23,24] Formation of **6** from **3** may occur by ring enlargement, either directly,[25] or via bicyclic phosphirene **7**.[26] Borden and co-workers showed by using multiconfigurational second-order perturbation theory (CASPT2) that the ring expansion of singlet phenylphosphinidene **3A** to **6A** (via **7A**) is endothermic with sizeable barriers (Scheme 2);[27] our calculations at the B3LYP/6-31G(d) level give similar results, except for the state $^1A_2$ of the parent molecule.[28] The tentative assignment of didehydrophosphepine **6** as a minor photoproduct may appear surprising as it is the least-stable isomer of those considered, though bulky linear phospha-allenes are known.[29] However, steady-state irradiation under conditions of matrix-isolation spectroscopy frequently allows for the observation of processes that are thermodynamically unfavorable and whose outcome mostly depends on the concentration of photostationary equilibriums.

Finally, we explored the laser flash photolysis (LFP) of an argon-purged cyclohexane solution of **1** at ambient temperature with an excitation of 266 nm and nanosecond time resolution. The resulting transient spectrum (Figure 4) contained a single species with absorptions at $\lambda_{max} = 285$ nm (vs)

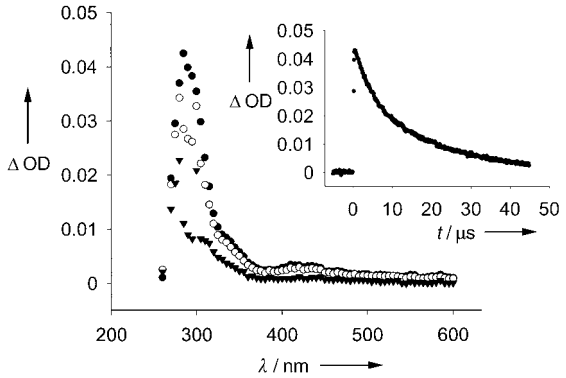

Figure 4. Transient spectra, recorded after LFP ($\lambda_{exc} = 266$ nm) of phosphirane **1** in cyclohexane under Ar atmosphere. Black circles: 470 ns after LFP, white circles: 1.7 μs after LFP, black triangles: 75 μs after LFP. Inset: transient trace, monitored at $\lambda = 285$ nm.

and 400–475 nm (broad, weak) and a lifetime $\tau = 13$ μs, which we assign to phosphinidene **3** based on the similarity with the UV/Vis spectrum of the matrix-isolated species at 10 K (Figure 3). The transient species could be quenched with oxygen,[30] and it reacted with the π-systems ethyl propiolate HC≡CCOOEt ($k_{ETP} = (7.7 \pm 1.1) \times 10^6$ L mol^{-1} s^{-1}) and tetramethylallene ($k_{TMA} = (5.0 \pm 0.8) \times 10^6$ L mol^{-1} s^{-1}, see the Supporting Information) but not with 1-hexene. This reactivity supports the formation of triplet **3**, which is expected to give an allylic triplet diradical with tetramethylallene, whereas such stabilization cannot occur with hexene as a reaction partner.

In conclusion, we have unequivocally identified triplet mesitylphosphinidene **3** as the primary reaction product in the photolytic cleavage of phosphiranes **1** and **2** by using a variety of low-temperature and time-resolved spectroscopic techniques. Under conditions of matrix isolation, **3** is formed in very low yield only, which is likely to be due to the efficient photoinduced addition of **3** to the alkene still present in the matrix cage. Upon further irradiation, **3** rearranges into 1*H*,2*H*-dihydrobenzophosphete **4**. Results obtained by using laser flash photolysis provide further support for the formation of **3**, and show that **3** will readily be quenched by reactive π-systems. Further studies on the photochemistry of **1**, **2**, and related compounds are in progress.

Experimental Section

The matrix isolation setup used in this work has been described before.[31] As light sources, a Hg low-pressure lamp ($\lambda = 254$ nm; Gräntzel, Germany) and Hg high-pressure lamps (Osram, 500 W, Oriel housing) in combination with cut-off filters were used. Argon (Messer-Griesheim, 99.999%) was used as the matrix material. Compounds **1** and **2** were synthesized according to reported procedures.[32] Deposition was performed by using the slow-spray-on technique at a sample temperature of 20 °C. *Trans*-2-butene (99%) was supplied by Matheson and deposited as 0.1%/99.9% mixture with Ar. X-band EPR-spectroscopic measurements were performed by using a Bruker Elexsys E500 EPR spectrometer with an ER077R magnet (75 mm pole cap distance) and an ER047 XG-T microwave bridge. Frozen solutions of **2** in methylcyclohexane were irradiated both within the resonator cavity ($T = 5$ K) by using a Lambda-Physik Compex 110 excimer laser operated with Kr/F_2 (248 nm, 200 mJ per pulse) or externally ($T = 77$ K) by using $\lambda = 254$ nm (Hg low-pressure lamp). W-band EPR-spectroscopic measurements employed a Bruker Elexsys E680 spectrometer. Prior to measurement, a degassed solution of **2** in cyclohexane was irradiated ($\lambda = 254$ nm, 60 min, $T = 77$ K) in a quartz capillary cooled to 77 K in a quartz dewar and transferred frozen into the precooled cryostat. Experimental parameters: frequency = 94.185061 GHz, microwave power = 15 dB, modulation amplitude = 0.1 mT, modulation frequency = 100 kHz. Simulations were performed by using the Easyspin routine[33] and all the parameters entering the simulation are given in the figure caption.

The setup used for laser flash photolysis has been described before.[34] Solutions (ca. 0.1 mM) of **1** in cyclohexane (Baker, spectroscopic grade) were purged with Ar for 20 min prior to the experiment. Tetramethylallene (Aldrich) and ethyl propiolate (Fluka) were of the highest purity commercially available and were used as received. 1-Hexene (Aldrich) was freshly distilled immediately prior to use.

All calculations were performed with Gaussian 98.[35] All geometry optimizations and frequency calculations (scaled by 0.97)[36] were performed at the (U)B3LYP/6-31G(d) level of theory. UV spectra were calculated using time-dependent density functional theory (TDDFT; B3LYP/6-311 + G(d,p)).

[21] The formation of a triplet diradical by cleavage of only one P–C bond is considered unlikely. Not only is the triplet diradical 5.2 kcal mol^{-1} less stable than triplet **3**, its calculated IR spectrum and UV spectrum do not correlate well with the experimental spectra. See the Supporting Information for details.

[22] The reversibility of the phosphirane cleavage indicates that the low yield of **3** is due to an unfavorable photostationary equilibrium rather than a very low quantum yield or pronounced filter effects.

[23] The observation of an extremely weak IR band at $\tilde{\nu} = 1723.7\ cm^{-1}$ supports the formation of **6** (C=C=P stretching mode: $\tilde{\nu}_{calcd} = 1712.9\ cm^{-1}$ (scaled by 0.97, weak).

[24] Phosphaquinone methide **5** (*anti*-**5**: $\lambda_{max,\,calcd} = 482$ nm; *syn*-**5**: $\lambda_{max,\,calcd} = 495$ nm) and bicyclic phosphirene **7** ($\lambda_{max,\,calcd} = 334$ and 494 nm) are less likely candidates.

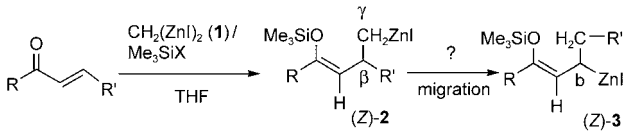
Organozinc Reagents

Preparation of Enolate–Homoenolate Species as (*Z*)-γ-Siloxyallylmetal Equivalents: Sequential 1,4-Addition of Bis(iodozincio)methane to 1,4-Dicarbonylbutenes and Cyclopropanation**

*Takaharu Hirayama, Koichiro Oshima, and Seijiro Matsubara**

gem-Dizinc reagents, which have two nucleophilic sites on a carbon atom, have been used for a variety of molecular transformations based on repetition of C–C bond formation on the same carbon atom.[1] In our series of investigations on their reactivity, we have also found that 1,4-addition of bis(iodozincio)methane (**1**) to *s-cis*-α,β-unsaturated ketones such as chalcone or phenyl 1-propenyl ketone in the presence of chlorotrimethylsilane gives (*Z*)-trimethylsilyl enol ethers of γ-iodozincioketone stereoselectively.[2] If we can force migration of the iodozincio group from the γ position to the β position stereospecifically, (*Z*)-3-siloxyallylmetal species, which are considered to be a useful synthetic tool, will become available (Scheme 1). Various 3-alkoxyallylmetal



Scheme 1. Preparation of (*Z*)-3-siloxyallylzinc species (*Z*)-**3** by 1,4-addition of bis(iodozincio)methane (**1**) via (*Z*)-**2**.

species have been reported.[3,4] As achiral 3-alkoxyallylmetal reagents which give *vic*-diols diastereoselectively by reaction with aldehyde, derivatives of B,[5] In,[6] Sn,[7] Al,[8] Fe,[9] and Cr[10] have been shown to be valuable. The corresponding optically active reagents based on Al,[11] Sn,[12] Ti,[13] and B[14] have also been applied for the enantioselective synthesis of *vic*-diols. In all cases, some limitation arises from preparation of the stereochemically defined 3-alkoxyallylmetal reagent. Using our method (Scheme 1), we can prepare diastereoselectively (*Z*)-3-alkoxyallylmetal reagents containing an additional functional group R′. Here we describe a novel method

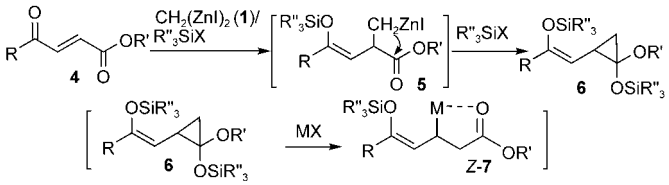
to prepare the *Z* isomers of 3-siloxyallylzinc reagents as well as their highly diastereoselective reaction with tosylimines.

To promote migration of the iodozincio group from the γ- to the β-position (i.e., (*Z*)-**2**→(*Z*)-**3** in Scheme 1), we planned to use ring opening of a cyclopropanol. As shown in Scheme 2, our approach was to prepare enolate–homoenolate

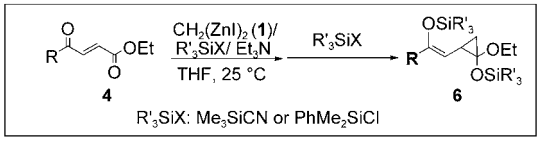


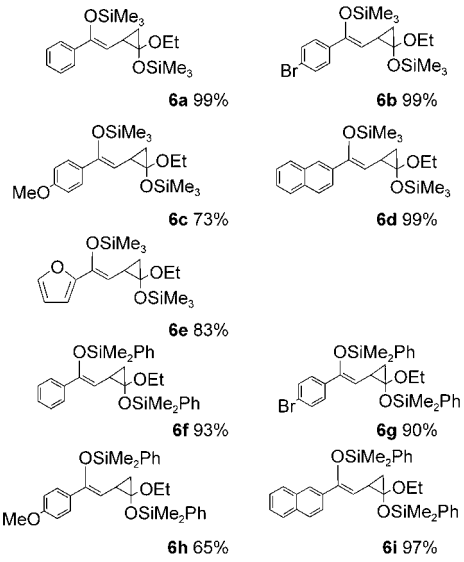
Scheme 2. Reaction concept for preparation of enolate–homoenolate equivalent **6**.

derivative **6**[15] by 1,4-addition of **1** to β-carboalkoxy α,β-unsaturated ketone **4**. The 1,4-addition of **1** to **4** in the presence of trimethylsilyl cyanide would afford the (*Z*)-trimethylsilyl enol ether of γ-iodozincio ketone **5** in situ, as shown in Scheme 2. Intramolecular nucleophilic attack on the ester group would give cyclopropane derivative **6**. This is an equivalent of enolate–homoenolate derivative (*Z*)-**7**, since 1-alkoxy-1-trialkylsiloxycyclopropane undergoes a ring-opening reaction in the presence of Lewis acid as a mediator to give a homoenolate, as reported by Nakamura.[16]

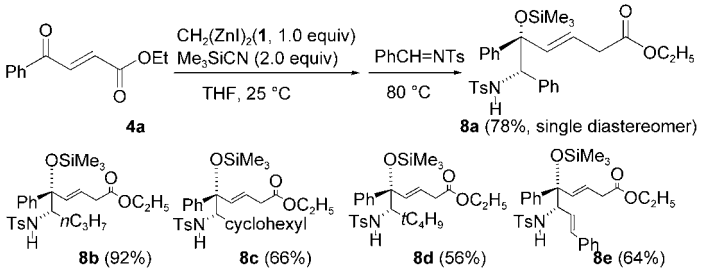
A mixture of ketoester **4a** (R = Ph, R′ = Et; 1.0 mmol), triethylamine (2.5 mmol), and trimethylsilyl cyanide (1.1 mmol) in THF was treated with **1** (1.2 mmol) at 25 °C for 5 min. Some additional trimethylsilyl cyanide (1.1 mmol) was added and the mixture was stirred for 10 min at room temperature. Triethylamine was added to prevent hydrolysis of silyl enol ether during aqueous workup. After aqueous workup, enolate–homoenolate equivalent **6a** (R = Ph, R′ = Et) was obtained in 99% yield. In the same way, enolate–homoenolate equivalents **6b–e** in Scheme 3 were obtained in good yields. When chlorodimethylphenylsilane was used as silylating reagent instead of trimethylsilyl cyanide, the corresponding phenyldimethylsilyl ether derivatives **6f–i** were obtained (Scheme 3). Products **6a–i** in Scheme 3 were obtained as equimolar mixtures of two diastereomers. Although the C=C bonds of these enol ethers were exclusively in the *Z* configuration,[17] formation of the cyclopropane ring (**5**→**6** in Scheme 2) did not proceed diastereoselectively.

Following the procedure for preparation of **6a** in Scheme 3 without addition of triethylamine, we added the tosylimine of benzaldehyde before aqueous workup and then raised the reaction temperature to 80 °C. As shown in Scheme 4, β-siloxylamine derivative **8a** was obtained as a single diastereomer after 4 h. The structure was also determined by X-ray analysis (Figure 1). The enolate–homoenolate equivalent **6a** reacted as (*Z*)-3-trimethylsiloxyallylmetal (*Z*)-**7**, since the 1-trimethylsiloxy-1-ethoxycyclopropane group in **6a** was converted to the homoenolate by the mediation of divalent zinc salts such as zinc(II) iodide and cyanide that were present in the reaction mixture. Examples





Scheme 3. Synthesis of trialkylsilyl enolate–homoenolates **6**.



Scheme 4. Reaction of enolate–homoenolate prepared from **4a** with various imines.

Figure 1. X-ray structure of **8a**.

of the reaction of **6a** with other tosylimines are also shown in Scheme 4. In all cases, the *threo*-β-siloxylamines were obtained with high diasteroselectivity.[18]

The reason for these extraordinarily high diasteroselectivities in the reaction of **6a** with imines in Scheme 4 is not clear. One possible explanation is that **6a** transforms into the β-zincioester (*Z*)-**7a**, which may have a fixed conformation due to coordination (Figure 2). If β-zincioester (*Z*)-**7a** reacts with (*E*)-tosylimine with activation by Lewis acid, as in **9**, the *threo* isomer **8a** will be a major product.

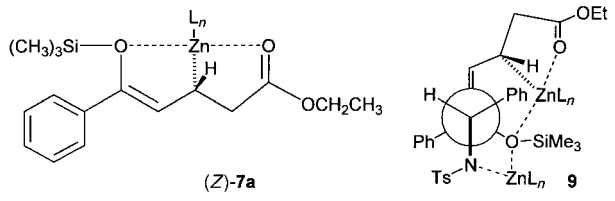


Figure 2. Proposed conformation of (*Z*)-**7a** and the transition state **9**.

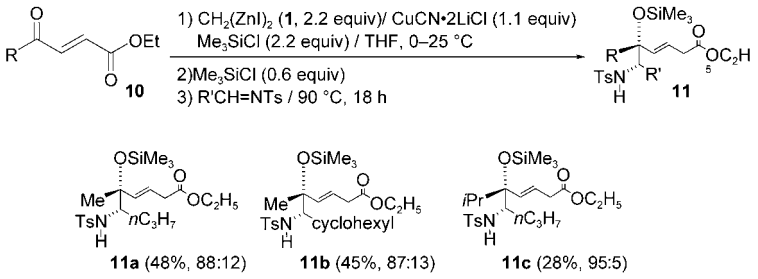
Mediation with copper salt was required for reaction of *gem*-dizinc reagent **1** with aliphatic derivatives of **4** (Scheme 5; **10**, R = alkyl). Treatment of **1** with copper salt



Scheme 5. Reaction of enolate–homoenolate prepared from aliphatic enone **10** with various imines.

in THF at −50 °C gave a copper reagent, which adds to aliphatic enone as we reported previously.[2] Treatment of **10** with the copper reagent from **1** in the presence of silylating agent gave enolate–homoenolate in situ, which added to tosylimines at 80 °C. The diastereoselectivities were inferior to those obtained with the aromatic substrates shown in Scheme 4 but were sill good.

Thus, the results allow us to propose a novel method to prepare stereochemically defined γ-siloxyallyl zinc species using 1,4-addition reactions of a *gem*-dizinc reagent. In addition, these zinc reagents add to tosylimines with high diastereoselectivity.

Experimental Section

1: A mixture of Zn (25 mmol), diiodomethane (1.0 mmol), and $PbCl_2$ (0.005 mmol) in THF (2.0 mL) was sonicated for 1 h in an ultrasonic cleaner bath under Ar. Diiodomethane (10 mmol) in THF (20 mL) was added dropwise to the mixture over 15 min at 10 °C with vigorous stirring. The mixture was stirred for 2 h at 25 °C. After the stirring was stopped, the reaction vessel was allowed to stand undisturbed for several hours. Excess zinc was separated by sedimentation. The ^{1}H NMR spectra of the obtained supernatant showed a broad singlet at −1.2 ppm at 0 °C corresponding to the methylene proton of **1**. The concentration was determined by ^{1}H NMR spectroscopy with 2,2,3,3-tetramethylbutane as an internal standard. The supernatant was used for further reaction as a solution of **1** in THF (0.4–0.5 M). In a sealed vessel, a solution of **1** can be stored at room temperature at least for two months.

6a (general procedure for **6**): A solution of **1** (0.4 M, 3.0 mL, 1.2 mmol) in THF was added dropwise to a solution of **4a** (0.2 g, 1.0 mmol), triethylamine (0.35 mL, 2.5 mmol), and trimethylsilyl cyanide (0.14 mL, 1.1 mmol) in THF (2.0 mL) at 25 °C. After the mixture had been stirred for 5 min, some additional trimethylsilyl cyanide (0.14 mL, 1.1 mmol) was added and stirring was continued for 10 min at 25 °C. Water (0.5 mL) was added to the reaction mixture at 0 °C. The mixture was extracted with diethyl ether. The combined organic layers were washed with brine and dried over anhydrous sodium sulfate. After chromatography on a short silica-gel column with hexane/ether/triethylamine as eluent, **6a** was obtained in 97% yield as a mixture of two diastereomers (55:45). These diastereomers arised from the configuration of the cyclopropane ring. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 7.42–7.48 (m, 2H), 7.26–7.31 (m, 2H), 7.19–7.24 (m, 1H), 5.08 (d, J = 9.6 Hz, 0.55H), 5.07 (d, J = 9.6 Hz, 0.45H), 3.60–3.76 (m, 2H), 2.18 (ddd, J = 6.5, 10.0, 10.0 Hz, 0.55H), 2.16 (ddd, J = 6.0, 9.6, 10.5 Hz, 0.45H), 1.39 (dd, J = 5.5, 10.5 Hz, 0.55H), 1.28 (dd, J = 5.5, 10.5 Hz, 0.45H), 1.21 (t, J = 9.0 Hz, 1.35H), 1.20 (t, J = 9.0 Hz, 1.65H), 0.88 (dd, J = 5.5, 6.0 Hz, 0.45H), 0.76 (dd, J = 5.5, 6.0 Hz, 0.55H), 0.22 (s, 5H), 0.20 ppm (s, 4H), 0.16 (s, 9H); ^{13}C NMR (125 MHz, $CDCl_3$): minor product δ = 149.6, 139.0. 128.2, 127.4, 125.2, 109.7, 89.5, 62.1, 25.4, 23.7, 22.2, 15.5, 0.94, 0.83 ppm; major product δ = 149.5, 139.0. 128.2, 127.4, 125.2, 110.0, 89.9, 61.9, 25.4, 23.7, 22.6, 15.5, 0.94, 0.83 ppm; MS (ESI): m/z: 387 [M^+($C_{19}H_{32}O_3Si_2$)+Na^+].

8b (general procedure for **8**): A solution of **1** in THF (0.4 M, 3.0 mL, 1.2 mmol) was added dropwise to a solution of **4a** (0.2 g, 1.0 mmol) and trimethylsilyl cyanide (0.14 mL, 1.1 mmol) in THF (2.0 mL) at 25 °C. After the mixture had been stirred for 5 min, trimethylsilyl cyanide (0.14 mL, 1.1 mmol) was added, and stirring was continued for 10 min at 25 °C. A solution of the *N*-tosylimine of butanal (0.27 g, 1.2 mmol) in THF (1.5 mL) was added to the mixture at 25 °C, and the mixture was warmed to 80 °C and stirred at this temperature for 5 h. The resulting mixture was cooled to 0 °C. After addition of water, the resulting mixture was extracted with ethyl acetate. The combined organic layers were washed with brine, dried over anhydrous sodium sulfate, and concentrated in vacuo. The residue was purified by column chromatography on silica gel to provide **8b** as a single diastereomer in 92% yield. Single-crystal X-ray analysis determined the stereochemistry of the product. ^{1}H NMR ($CDCl_3$): δ = 7.69 (d, J = 6.5 Hz, 2H), 7.33 (d, J = 6.5 Hz, 2H), 7.2–7.3 (m, 5H), 5.99 (d, J = 15.5 Hz, 1H), 5.76 (dt, J = 7.0, 15.5 Hz, 1H), 4.55 (d, J = 9.0 Hz, 1H), 4.14 (q, J = 7.5 Hz, 2H), 3.76 (ddd, J = 2.5, 9.0, 9.0 Hz, 1H), 3.08 (d, J = 7.0 Hz, 2H), 2.39 (s, 3H), 1.20–1.42 (m, 2H), 1.27 (t, J = 7.5 Hz, 3H), 1.06–1.19 (m, 1H), 0.85–0.95 (m, 1H), 0.71(t, J=7.0 Hz, 3H), 0.16 ppm (s, 9H); ^{13}C NMR (125 Hz, $CDCl_3$): δ = 171.5, 142.7, 142.3, 139.8, 135.8, 129.6, 128.2. 127.9, 127.8, 127.1, 126.8, 81.5, 63.7, 61.1, 38.1, 34.6, 21.7, 19.9, 14.4, 14.1, 2.2 ppm; m.p. 80.0 °C (recrystallized from CH_3CN); HRMS (FAB): m/z: calcd for $C_{27}H_{40}NO_5SiS$: 518.2396 [(M+1)$^+$]; found: 518.2405. Nanotubes

Peptide–Polymer Hybrid Nanotubes**

*Julien Couet, J. D. Jeyaprakash S. Samuel, Alexey Kopyshev, Svetlana Santer, and Markus Biesalski**

Since the discovery of carbon nanotubes,[1] there has been a growing interest in organic tubular structures with very small dimensions. The number of possible applications of these microstructures has also grown, particularly in the fields of microelectronics,[2,3] separation technology,[4] and biomedical technology.[5] There is an increased use of so-called bottom-up strategies for the design of organic nanotubes and nanofibers.[6] Some promising examples of this include the self-assembly of amphiphilic molecules (small lipids,[7] di-[8] and triblock,[9] and coil-ring-coil[10] block copolymers), polymeric foldamers,[11] as well as the self-assembly of cyclic peptides to form peptide nanotubes.[12–14]

Cyclic peptides that consist of an even number of D- and L-amino acids exhibit a pronounced tendency to self-assemble into tubular structures in which a large number of peptide subunits are held in place by intermolecular hydrogen bonds.[12–14] Through their design principle, these cyclic molecules maintain a flat conformation in which the amide functional groups lie perpendicular to the plane of the molecular ring. This allows the formation of an extended network of hydrogen bonds, preferably in an antiparallel β-sheet structure.[15] As a result of the peptide configuration, all the side-chain functional groups are located on the ring periphery. This imparts the nanotubes with a defined hollow core and enables simple access to the functional groups for modification of the surface chemistry. The side-chain functional groups of the peptide can have an influence on the formation of either single-peptide nanotubes, or higher-order 3D aggregates.[16]

Since the pioneering work by Ghadiri and co-workers,[12] such self-assembled peptide nanotubes have been applied as novel antibiotics[17] and as artificial ion channels.[18] The range of application of peptide nanotubes is determined mainly by their surface chemistry. As shown by Ghadiri and co-workers,[12–14] the surface chemistry can be tuned by individually synthesizing cyclic peptides with different primary sequences. An alternative way to adjust the surface chemistry is through the attachment of synthetic macromolecules to the surface of the structure after self-assembly, thus embedding the peptide nanotube in a polymeric shell. In this case, the structure of the resulting hybrid material is governed by both the peptide nanotube core as well as the polymeric shell, and the surface chemistry is determined by the choice of grafted synthetic macromolecules.

The assembly of cyclic peptide precursors into nanotubes with subsequent surface-induced polymerization around the nanotubes offers a novel approach toward the preparation of a large number of shape-persistent hybrid materials that are not easily accessed by any other technique. An interesting aspect of this strategy is that defined structural information can be transferred from a biologically derived module to a synthetic polymer (and vice versa).

Recently, it was shown that synthetic peptides can be modified with polymerization initiators, which can subsequently initiate reactions that link peptides into covalent polymers.[19–21] For example, such modified peptides have been used as initiators for nitroxide-mediated controlled radical polymerizations[19] and atom-transfer radical polymerizations (ATRP).[20,21]

In our work, we have taken advantage of the ability of distinct cyclic peptides to self-organize into defined tubular structures, as discussed above. In particular, we have used peptide nanotubes as structurally defined templates to prepare nanometer-sized peptide–polymer hybrid nanotubes. Figure 1 schematically outlines this approach. Cyclic peptides composed of eight amino acids that are arranged with alternating D- and L-configurations are modified with certain chemical groups at distinct side-chain positions. These groups can serve as initiation sites for controlled free-radical polymerization by the ATRP technique. The cyclic-peptide initiators self-assemble into peptide nanotubes in a fashion analogous to that described above. A subsequent polymerization reaction of *N*-isopropylacrylamide (NIPAM) in aqueous dispersion is triggered by the surface-attached initiator groups to yield a novel class of polymeric hybrid nanostructures in which the peptide core is covalently attached to a functional polymeric shell.

The process begins with a solution of the cyclic-peptide initiator in pure trifluoroacetic acid (TFA). The precursors slowly self-assemble and precipitate from solution in the form of nanotubes upon a gradual increase in the amount of water added to the TFA phase. The nanotubes can be isolated through a simple centrifugation procedure, followed by rinsing with water. The products are then characterized with respect to chemical identity, surface chemistry, internal structure, and morphology. Analysis by FTIR spectroscopy

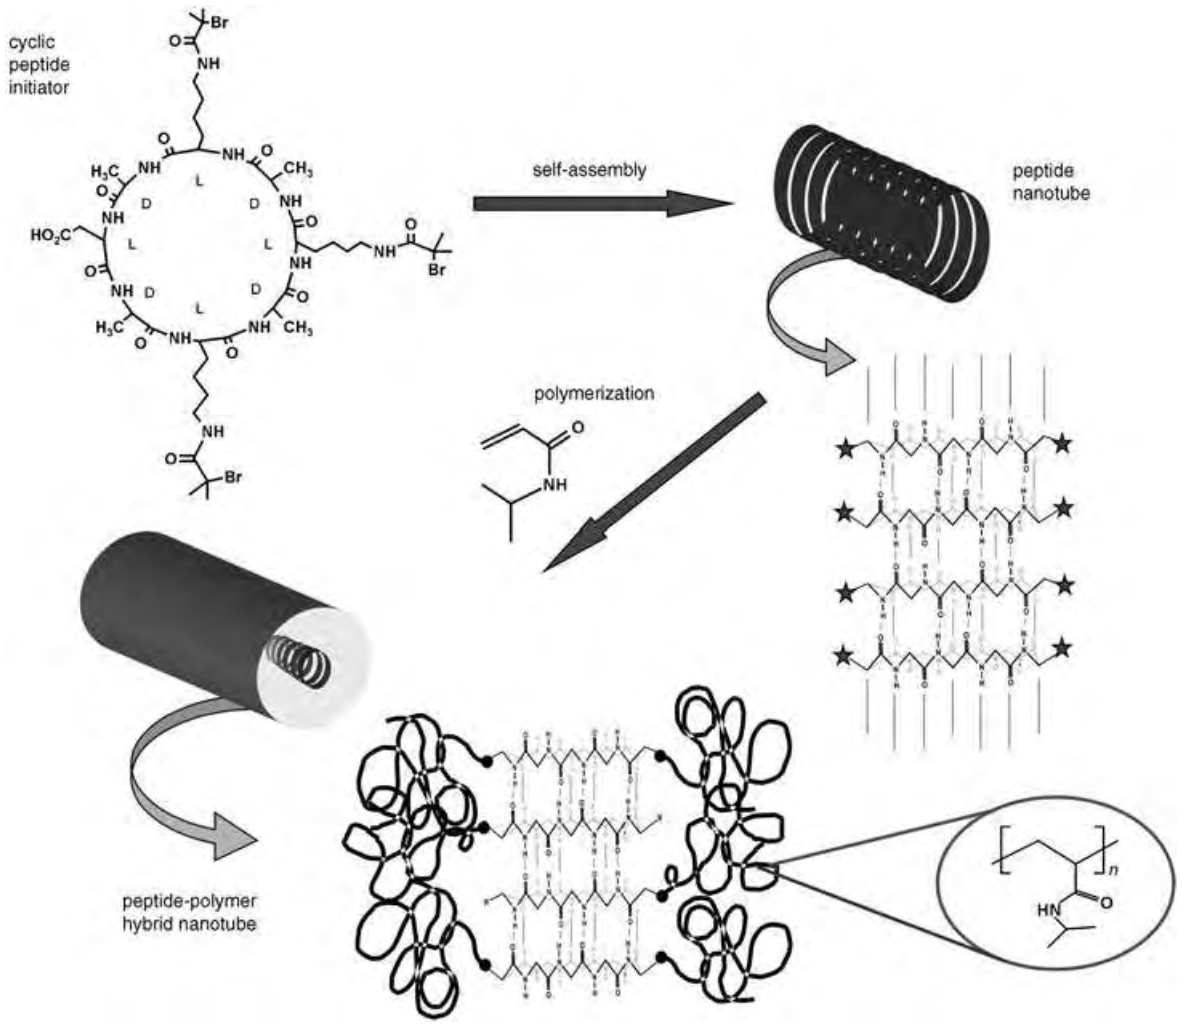

Figure 1. Schematic outline of the synthesis of peptide–polymer hybrid nanotubes. A cyclic peptide with polymerization initiator groups at distinct side chains self-assembles to form a peptide nanotube that has the initiator groups exclusively at the outer surface. A subsequent surface-initiated polymerization in the presence of NIPAM monomer coats the peptide core with a covalently bound PNIPAM polymer shell.

shows the presence of closely packed peptides that are stacked in a β-sheet structure held together through intermolecular hydrogen bonds.[22] Furthermore, X-ray photoelectron spectroscopy proves the presence of the bromine groups that are required for the nanotube surface-initiated polymerization.[22] The morphology of the cyclic-peptide nanotubes was studied by AFM and TEM. A representative AFM image of nanotubes that were drop cast from an aqueous dispersion onto a silicon wafer is shown in Figure 2. Both single nanotubes and 2D aggregates were observed on the surface. The average height of a cyclic-peptide nanotube, determined by statistical analysis of AFM cross-section data, is 1.7 ± 0.2 nm (Figure 2c). The length of the peptide nanotubes ranges between 100 and 500 nm. Both values are consistent with experimental and theoretical studies of single-peptide nanotubes consisting of eight-membered rings of D- and L-amino acids.[16] The height of the 2D fibrous aggregates, shown in Figure 2, is equal to those of single-peptide nanotubes which implies that the aggregates are most likely formed during the surface drying procedure. Clear experimental support for this is still pending, however.

The cyclic-peptide initiator nanotubes were dispersed into a mixture of water, monomer, and polymerization additives by which a surface-induced ATRP reaction was initiated at room temperature. NIPAM was chosen as the monomer, as it yields peptide–polymer nanotubes with a nontoxic polymer (PNIPAM) coating and displays interesting physical properties, such as a lower critical solution temperature. After a defined polymerization time, the cyclic-peptide–PNIPAM nanotubes were washed extensively with water to remove any physisorbed polymer generated from the transmission of surface-bound radicals to NIPAM monomers in solution.

Figure 3b shows AFM images of the cyclic-peptide–PNIPAM nanotubes adsorbed to a silicon wafer (the sample has been drop cast from aqueous solution). Notably, 2D aggregates are no longer observed; the nanotubes are present as distinct rod-shaped structures that are 80 ± 20 nm in length and 12 ± 3 nm in height as determined by the statistical analysis of more than 400 nanotubes (Figures 3c and d). A cross-section of a single polymer–peptide nanotube (Figures 3e and f) shows that the polymer shell surrounds the peptide core in a very homogeneous manner. The presence of

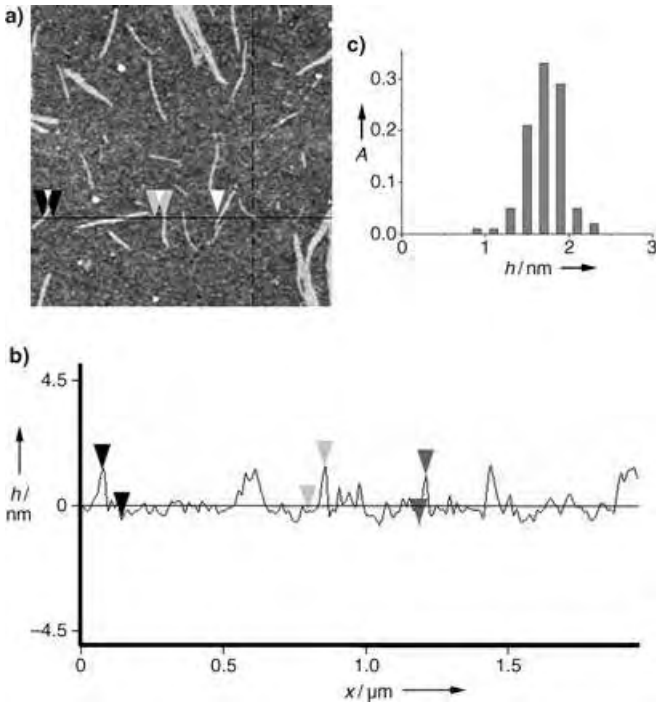

Figure 2. Analysis of the self-assembled cyclic-peptide initiator nanotubes: a) AFM image of peptide nanotubes adsorbed on a silicon wafer (scale: 2 μm; height: 5 nm); b) cross-section of the marked positions in part a); c) height distribution from the statistical analysis of adsorbed nanotubes (relative abundance *A* as a function of measured height *h*).

the PNIPAM polymer is proven by FTIR[22] spectroscopy and NMR spectroscopy. Furthermore, FTIR analysis of the cyclic-peptide–PNIPAM nanotubes suggests that the internal peptide assembly is an intact β-sheet structure.[22] Finally, as can be observed in the AFM phase image, a black halo surrounds each rodlike structure, indicative of a softer polymeric shell covering the peptide nanotube core (Figure 3a).

To demonstrate that the polymer is covalently bound to the peptides, control experiments were performed by mixing free PNIPAM polymer in solution with similar peptide nanotubes that lack initiator groups at the surface (Figure 4a). In this case the purely physisorbed macromolecules can be completely removed through simple solvent extraction. AFM analysis demonstrates that the unmodified peptide nanotubes can be recovered after solvent extraction. This indicates that the nanotubes described above consist of an assembly of covalently linked peptide–polymer hybrid molecules.

In summary, the strategy introduced herein for the design and preparation of functional peptide–polymer hybrid nanostructures allows the preparation of a novel class of nanotubes whose structure is governed primarily through the biomolecular component (peptide), and whose surface chemistry can be adjusted by the grafted synthetic polymer. AFM analysis demonstrates that the PNIPAM polymeric shell coats the peptide nanotube core in a highly homogeneous manner, and, as it is covalently attached to the cyclic peptide subunits, it cannot be removed by simple solvent extraction. Beside the peptide core, the internal structure of the polymeric shell is an

Figure 3. important factor that governs the structure of this novel class of polymeric hybrid materials. Presumably, the molar mass and the conformation of the peptide-bound polymer chains can be controlled by adjusting the appropriate polymerization conditions. Additionally, the graft density may be controlled

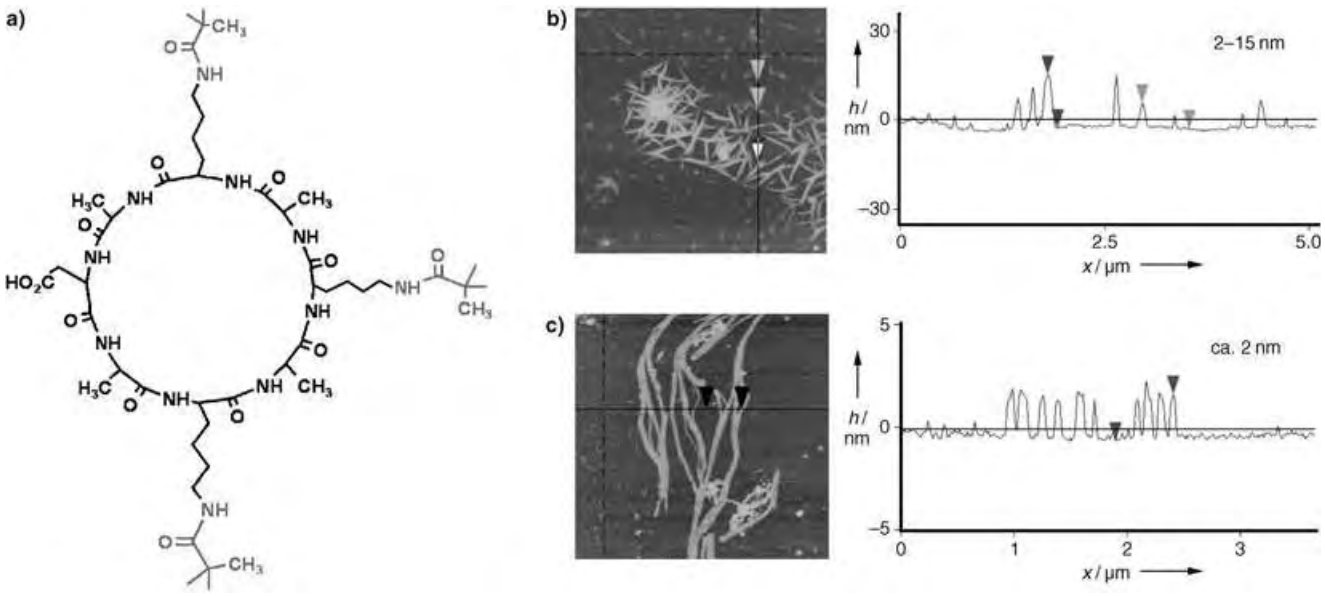

Figure 4. a) Schematic image of a cyclic peptide (CPB) that was synthesized for control experiments. It was allowed to self-assemble to form similar peptide nanotubes, which were then mixed with free PNIPAM polymer, and adsorbed to the surface of a silicon wafer, and analyzed by AFM both before and after extraction with water. b) AFM image (size: 5 μm, height: 35 nm) and cross-section analysis of polymer–CPB nanotubes before and c) after extraction with water.

by the dilution of initiator sites; systematic studies of these issues will be reported in forthcoming communications. Notably, one would expect neighboring chains to repel each other more strongly with an increase in the molecular mass and graft density of the polymers. If such forces were to overcome those that hold the cyclic-peptide subunits together, the point at which self-assembled peptide–polymer nanotubes break up into shorter aggregates may be determined. This may become a way to gain control of the length of such hybrid nanotubes.

Experimental Section

All cyclic peptides were prepared with standard Fmoc (Fmoc = 9-fluorenylmethoxycarbonyl) chemistry protocols for solid-phase peptide synthesis. Cyclization of the linear peptide (HOOC-L-Asp-(OAll)-[D-Ala-L-Lys(Mtt)]-D-Ala-NH_2) and the attachment of functional groups (the ATRP initiators) were carried out directly on the solid phase (All = allyl, Mtt = 4-methyltrityl). The cyclic peptides were cleaved from the resin and purified by recrystallization from TFA/water and preparative reversed-phase HPLC (C_{18}, CH_3CN/H_2O elution gradient). Characterization of the cyclic-peptide precursor product was carried out with ESI MS, NMR spectroscopy, and FTIR spectroscopy.[22]

Peptide nanotube surface-initiated ATRP reactions were carried out in dispersed aqueous phase similar to a recently published protocol by Kizhakkedathu and co-workers.[23] In brief, the monomer, solvent, and HMTETA (HMTETA = 1,1,4,7,10,10-hexamethyltriethylenetetramine) were mixed and degassed by repeated freeze/thaw cycles under vacuum. Subsequently, Cu^{I}, Cu^{II}, and Cu^{0} were added under frozen conditions and the reaction mixture was allowed to slowly warm to room temperature. The peptide initiator nanotubes were dispersed in an aqueous solution and added to a polymerization chamber. Polymerization was carried out at 20 ± 1.0 °C under an atmosphere of inert gas. After 90 min, the reaction was quenched by addition of excess Cu^{II} and dilution with excess water. The molar ratio of monomer/initiator was 200:1, and the monomer conversion, as determined by HPLC, was ≈ 0.7. At this point, the polymer-modified peptide nanotubes were still in a dispersed phase (the solution maintained a hazy appearance); workup could therefore be done by repeated centrifugations and extensive washings with cold water, which ensures the removal of all physisorbed macromolecules from the polymer–peptide hybrids.

The control experiment was carried out with peptide nanotubes generated from a cyclic peptide that lacks polymerization initiation groups at the surface. These reference nanotubes were mixed with free PNIPAM polymer in aqueous dispersion and analyzed by AFM without further solvent extraction. The aggregates were then repeatedly washed with water, and analyzed again by AFM for any remaining polymer physisorbed to the peptide nanotubes.

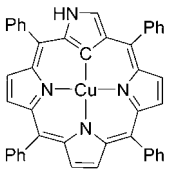
Porphyrin Complexes

Asymmetric Spin Density Distribution in the Copper(II) Complex of N-Confused Tetraphenylporphyrin: A Multifrequency Continuous-Wave and Pulse EPR Study**

*George Mitrikas, Carlos Calle, and Arthur Schweiger**

The relevance of metalloporphyrins in catalysis, biology, medicine, and materials science has been well documented during the past decades.[1] Recently, N-confused porphyrins (NCP), a new family of porphyrin isomers that contain an inverted pyrrole ring in the macrocycle connected at its α- and β′-positions, have received increased attention.[2,3] These novel artificial porphyrins exhibit unique physical and chemical properties, for instance, the ability to stabilize unusual oxidation states of metals as a result of the reactivity of the inverted pyrrole.[4]

N-confused porphyrins form stable organometallic macrocycles with transition-metal centers.[5] One of the first described is the copper(II) complex with N-confused tetraphenylporphyrin [Cu^{II}-(nctpp)] (Scheme 1).[6] This organocopper(II) species is of particular interest as a model compound in studies of the reaction mechanisms of metalloenzymes. Its properties are directly related to the electronic structure, and consequently the delocalization of the unpaired electron over the complex can be used as a probe to study the reaction mechanisms.



Scheme 1. Structure of [Cu^{II}(nctpp)].

In this communication we describe a combined multifrequency continuous-wave (CW) and pulse EPR study of [Cu^{II}(nctpp)] focusing on the elucidation of the magnetic interactions between the unpaired electron of the complex and the nitrogen donors of the porphyrin ring. Pulse EPR methods can give more detailed information than CW EPR spectroscopy about the electronic structure through an elaborate mapping of the hyperfine and nuclear quadrupole interactions.[7]

The nctpp macrocycle was prepared by the one-flask synthesis of Lindsey and co-workers.[8] The X-band EPR spectrum of [Cu^{II}(nctpp)] in frozen THF displays features that are typical for Cu^{II} complexes (Figure 1a). No ligand hyperfine structure was observed along $g_{\|}$ because of inhomogeneous broadening and strain effects related to the solvent. When the complex is magnetically diluted in zinc(II) tetra-

phenylporphyrin [Zn(tpp)] powder, a remarkably well-resolved ligand hyperfine structure is observed (Figure 1b). The low-field region of the spectrum can be accurately simulated assuming two nitrogen nuclei with hyperfine values $A_{\parallel} \approx (59 \pm 3)$ MHz and one nitrogen nucleus with $A_{\parallel} \approx (29.5 \pm 3)$ MHz (Figure 1, inset).[9] This observation is clear-cut proof that the three nitrogen donors of the porphyrin core are no longer equivalent, in contrast to the case in [Cu^{II}-(tpp)].[10]

The W-band EPR spectrum shown in Figure 1c indicates that the $\boldsymbol{g}$ matrix is axial even with the high resolution obtained at 94.3 GHz. From a simulation of this spectrum (Figure 1d) we determined the g principal values $g_{\parallel} = 2.137 \pm 0.001$ and $g_{\perp} = 2.036 \pm 0.001$, and the ^{63}Cu hyperfine couplings $|A_{\parallel}| = (379 \pm 5)$ MHz and $|A_{\perp}| = (110 \pm 20)$ MHz. The g principal values are in line with the unpaired electron being in the $d_{x^2-y^2}$ orbital but are smaller than those reported for [Cu^{II}(tpp)] ($g_{\parallel} = 2.190$, $g_{\perp} = 2.045$).[10] This observation together with the smaller copper hyperfine coupling ($|A_{\parallel}| = 615$ MHz for [Cu^{II}(tpp)]) indicates that in [Cu^{II}(nctpp)] the metal–ligand bond has a stronger covalent character than in [Cu^{II}(tpp)].

A more detailed study of the hyperfine and nuclear quadrupole couplings of the two equivalent nitrogens is provided by pulse ENDOR spectroscopy.[7] Figure 2 shows

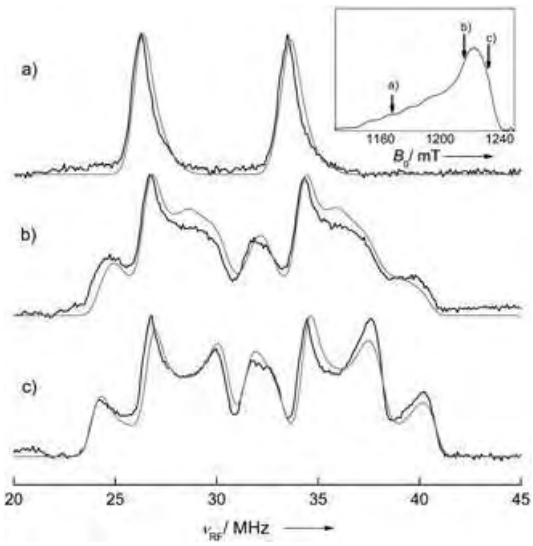

Figure 2. Q-band Davies-ENDOR spectra of [Cu^{II}(nctpp)] diluted in [Zn(tpp)] powder measured at different observer positions. Black traces: experiments; gray traces: simulations (for simulation parameters see text). Inset: FID-detected Q-band EPR spectrum ($T = 20$ K).

Davies-ENDOR spectra measured at Q-band frequencies.[11] The spectrum measured close to $g_{\parallel}$ (trace a) consists of a doublet centered at 30 MHz with the two peaks split by twice the ^{14}N Larmor frequency, $2\nu_N = 7.2$ MHz. Consequently, these two peaks are assigned to strongly coupled nitrogens with a hyperfine coupling of 60 MHz and an unresolved nuclear quadrupole interaction along this orientation. ENDOR measurements at different observer positions (Figure 2, black traces) and their spectral simulations (Figure 2, gray traces) provide the complete determination of the principal values of the hyperfine, $\boldsymbol{A}$, and nuclear quadrupole, $\boldsymbol{P}$, coupling tensors: $(A_1, A_2, A_3) = (71.5, 58.3, 59.5)$ MHz ± 0.2 MHz and $(P_1, P_2, P_3) = (-0.87, 1.00, -0.13)$ MHz ± 0.1 MHz.

The hyperfine interactions of the third ^{14}N nucleus of the porphyrin core and of the outer or "inverted" ^{14}N nucleus were studied with HYSCORE spectroscopy at Q-band. Figure 3 shows the single-crystal-like matched HYSCORE[7]

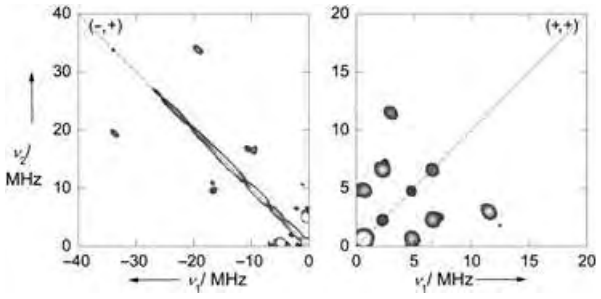

Figure 3. Matched Q-band HYSCORE spectrum of [Cu^{II}(nctpp)] diluted in [Zn(tpp)] powder; observer position at $g_{\parallel}$, $T = 20$ K. For clarity the $(-,+)$ and $(+,+)$ quadrants have different scales.

spectrum at $g_{\parallel}$. The peaks observed in the $(-,+)$ quadrant originate from strong ^{14}N interactions. The crosspeaks around $(-17, 10)$ MHz and $(-10, 17)$ MHz are assigned to single-quantum transitions, whereas the two crosspeaks at $(-33.7, 19.3)$ MHz and $(-19.3, 33.7)$ MHz are assigned to double-quantum transitions with $\Delta m_I = 2$. The latter transitions are to first order independent of the nuclear quadrupole interaction, differ by $4\nu_N = 14.4$ MHz, and are centered on the hyperfine coupling of 26.5 MHz along this orientation. HYSCORE measurements at additional observer positions (not shown here) give the following values for the hyperfine coupling tensor of the third ^{14}N nucleus of the porphyrin core: $(A_1, A_2, A_3) = (26.5, 35, 26.5)$ MHz ± 0.5 MHz.

The correlation peaks in the $(+,+)$ quadrant of the HYSCORE spectrum correspond to weak ^{14}N interactions and therefore can be assigned to the remote ^{14}N nucleus of the inverted pyrrole. The crosspeaks at (3.0, 11.5) MHz and (11.5, 3.0) MHz represent double-quantum transitions from which a hyperfine coupling of $|A_{\parallel}| = (4.3 \pm 0.2)$ MHz is estimated. In addition, the crosspeaks at (6.6, 2.3) MHz and (2.3, 6.6) MHz, as well as those at (0.7, 4.8) MHz and (4.8, 0.7) MHz are assigned to single-quantum transitions and give a nuclear quadrupole coupling of $P_3 = (0.6 \pm 0.1)$ MHz. A complete study of the magnetic parameters for this remote nitrogen nucleus will be published elsewhere.

In summary, we have shown for the first time that in [Cu^{II}(nctpp)] the three nitrogens of the porphyrin core are not equivalent, in contrast to [Cu^{II}(tpp)] where all four nitrogens are described by the same principal values of the hyperfine tensor, $(A_1, A_2, A_3) = (54.2, 42.8, 44.1)$ MHz.[10] More specifically, in [Cu^{II}(nctpp)] two of the core nitrogen nuclei are magnetically equivalent and have a considerably larger hyperfine coupling, $(A_1, A_2, A_3) = (71.5, 58.3, 59.5)$ MHz, whereas a much smaller hyperfine coupling of $(A_1, A_2, A_3) =$

(26.5, 35, 26.5) MHz is found for the third nitrogen nucleus. Thus, we conclude that the inversion of the pyrrole ring in [Cu^{II}(nctpp)] is followed by a strong asymmetric distribution of the electron spin density on the three nitrogen nuclei, demonstrating the breaking of the D_{4h} symmetry. This is in good agreement with preliminary results obtained by DFT computations.[12] On the basis of these findings it is tempting to study which other changes and special features of the electronic structure of this rare organometallic compound can be observed.

Stereoselective Reactions

Efficient 1,5-Chirality Transfer in Palladium-Catalyzed Allylic Alkylations of Chelated Amino Acid Ester Enolates**

Uli Kazmaier and Thomas Lindner*

Dedicated to Professor Franz Effenberger on the occasion of his 75th birthday

Of the palladium-catalyzed reactions, allylic alkylations are especially popular, not least because of a number of stereoselective variants.[1] In general, heteronucleophiles are used as well as symmetric stabilized carbanions such as malonates as C nucleophiles. The advantage of the latter is that in the C–C coupling step only one stereogenic center is created, that is, that in the allyl fragment. In contrast, the use of unsymmetrical nucleophiles (Nu) such as β-ketoesters[2] and imines of amino acid esters[3] in general results in mixtures of diastereomers. Therefore, most examples in the literature dealing with the stereochemical outcome of the allylic alkylation focus on 1,3-disubstituted allylic systems (Scheme 1). In reactions of substrates **A**, which form a symmetric achiral π-allyl palladium complex **B**, the stereochemical outcome can be controlled by chiral ligands (L*). In contrast, unsymmetric substrates **C** give rise to the chiral allyl complex **D**, and stereogenic information is transferred from the starting material **C** to the product **E**.[1] The only snag is the

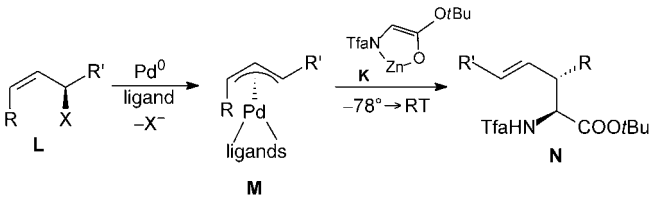
problem of regioselectivity. Especially the reaction of substrates bearing very similar substituents R and R′ results in the formation of product mixtures (**E** + **E**′).[4]

This problem is less significant with substrates **F** and **G**, which form the terminal π-allylpalladium complexes **H**, since these allyl complexes are usually attacked at the sterically least hindered position (→**I**). Therefore, for stereoselective synthesis these substrates are uninteresting, because in reactions of symmetrical nucleophiles only achiral products are obtained, while the application of unsymmetrical nucleophiles gives rise to racemic mixtures. Even the use of enantiomerically pure substrates **G** is not a solution to this problem, because the chiral information is lost nearly immediately through π-σ-π isomerization.[5] To the best of our knowledge a suitable protocol for transferring chiral information from the allyl substrate to the stereogenic center in the attacking nucleophile has not yet been reported.

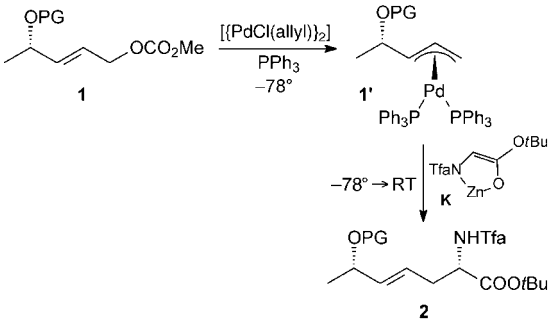
Terminal complexes such as **H** can be converted into optically active products **J** only if the nucleophilic attack can be directed towards the sterically more hindered position. According to Pfaltz et al. this goal can be reached by switching the reaction mechanism from an S_N2-type towards a more S_N1-type mechanism.[6] For example, with phosphite ligands[7] instead of phosphanes, the branched products **J** are formed preferentially. These can be obtained in an enantiomerically enriched form when chiral ligands such as phosphite oxazolines[6] and sterically demanding monophosphanes are used.[8] Other metals such as molybdenum,[9] tungsten,[10] and iridium[11] also have a higher tendency for the formation of branched product **J**. It is known that rhodium complexes in general do not undergo π-σ-π isomerization, and therefore they facilitate chirality transfer from an optically active substrate to the product **J**.[12]

Our group is investigating reactions of chelated amino acid ester enolates **K** and also their application as nucleophiles in palladium-catalyzed allylic alkylations.[13] These nucleophiles react under much milder conditions than the "standard nucleophiles". In addition, they also allow the generation of a second stereogenic center, and this generally in a highly stereoselective fashion. Because these chelated enolates already react at −78 °C, π-σ-π isomerization can be suppressed nearly completely.[14] Therefore, *Z*-configurated allyl substrates **L** can be converted into the corresponding *syn*/*anti* allyl complex **M** (without isomerization), which then is attacked by **K** regioselectively at the "*anti* position" (Scheme 2). This allows a chirality transfer from **L** to **N**. The diastereoselectivity of the formation of the allylation product **N** depends on the substituent R and increases with the decreasing bulk of R.



Scheme 2. Palladium-catalyzed allylic alkylations of chelated enolates. Tfa = trifluoroacetyl.

One might therefore expect the best selectivity for R = H. In this case only one stereogenic center is formed, and we hoped that the high selectivity of the nucleophilic attack on the allyl complex could be used for chirality transfer directly to the α-position of the amino acid formed. But with R = H the problems discussed above take effect, and the very fast π-σ-π isomerization of terminal π-allyl palladium complexes prevents chirality transfer from **L** to **N**. Therefore we focused our attention on reactions of substrates such as **1** which are easily obtained from lactic acid. We investigated the influence of the O-protecting group (PG) on the stereochemical outcome of the reaction (Scheme 3, Table 1). We chose



Scheme 3. Diastereoselective allylation of chelated enolates; see also Table 1.

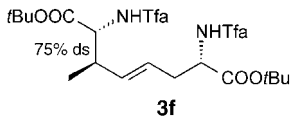
Table 1: Diastereoselective allylation of chelated enolates; see also Scheme 3.

Entry	Substrate	PG[a]	Yield [%]	ds [%][a]
1	**1a**	MOM	89	71[b]
2	**1b**	THP	96	80[b]
3	**1c**	Bn	99	87[b]
4	**1d**	TBDMS	99	84[c]
5	**1e**	TBDPS	93	96[c]
6	**1f**	Trt	–	
7	**1g**	Piv	85	93[b]

[a] MOM = methoxymethyl, THP = tetrahydropyranyl, Bn = benzyl, TBDMS = *tert*-butyldimethylsilyl, TBDPS = *tert*-butyldiphenylsilyl, Trt = trityl, Piv = pivaloyl, ds = diastereoselectivity. [b] Determined by ^{13}C NMR spectroscopy. [c] Determined by HPLC.

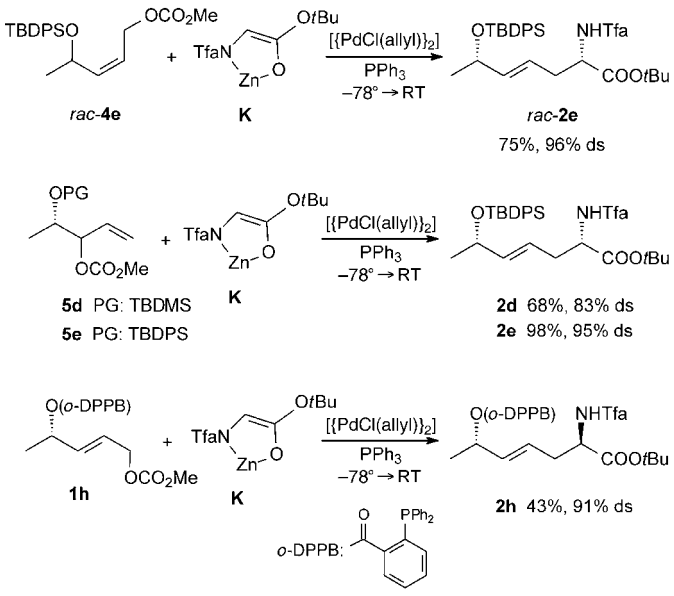
methyl carbonate as the leaving group and trifluoroacetyl-protected *tert*-butyl glycinate as the nucleophile. The yields were excellent and nearly independent of the O-protecting group used; only with the tritylated substrate (Table 1, entry 6) was no reaction observed. It seems in this case that the coordination of the palladium to the alkene is hindered for steric reasons. Apparently the coordination occurs from the face opposite to the oxygen atom, giving rise to allyl complex **1**′, which then is attacked by the chelated enolate **K** from the backside. The diastereoselectivities obtained nicely correlate with the size of the O-protecting group, which is especially significant in the switch from the TBDMS to the sterically more demanding TBDPS protecting group. The latter protecting group gave 96 % ds, an excellent result especially when one considers that this is an example of 1,5-induction.

An equally good result was obtained with the pivaloyl derivative **1g**. This substrate is quite interesting because it has two leaving groups, which should both be replaceable. The primary carbonate leaving group is the significantly more reactive one. With one equivalent of nucleophile the monosubstitution product **2f** was formed exclusively, while with 2.6 equivalents of **K** a mixture of **2f** (55%) and the disubstituted product **3f** (44%, 75% ds) in almost quantitative overall yield was obtained. In principle it should be possible to use the pivaloate group in the first step to control the configuration at the α-position of the amino acid before it is replaced in the second step by various other nucleophiles.



3f

To get an impression of how fast the π-σ-π isomerization of these terminal allyl substrates occurs, we also subjected the *Z* substrate *rac*-**4e** to the same reaction conditions (Scheme 4). As mentioned earlier, with 1,3-disubstituted substrates of type **L** (Scheme 2) the isomerization was suppressed completely.[14] If this is also true with terminal allyl complexes one might expect (Z)-**2e** as the substitution product. In contrast, *rac*-**2e** was formed with exactly the same selectivity as obtained from **1e**. This clearly indicates that in terminal π-allyl complexes the π-σ-π isomerization is even faster than the substitution with these highly reactive nucleophiles.

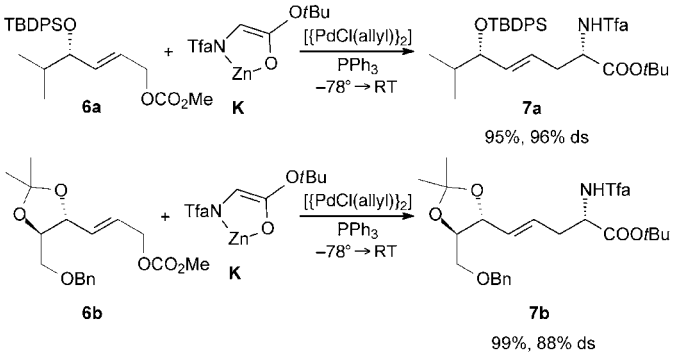


Scheme 4. Diastereoselective allylation of chelated enolates.

With this in mind one should expect that analogous substrates **5** with a secondary leaving group should provide the same substitution products, independent of the configuration of the leaving group. This is a very interesting option, because these substrates are easily accessible. Therefore we investigated the reaction of the two silyl-protected derivatives **5d** and **5e**, and indeed, the selectivities obtained were exactly the same as with the linear substrates **1d** and **1e**.

In all examples investigated so far, the *syn*-configurated product was obtained preferentially. To provide the corresponding *anti* isomer, the palladium must be coordinated to the opposite face of the alkene, in other words, the face of the O-substituent. Breit et al. reported for hydroformylation reactions that coordinating protecting groups such as the diphenylphosphanylbenzoate (*o*-dppb) are especially suitable for this purpose.[15] As illustrated with the *o*-dppb-protected substrate **1h**, such a directing effect can also be used for stereoselective allylations. By this synthetic protocol both stereoisomeric products can be obtained from one substrate (allylic alcohol) in a highly stereoselective fashion.

To test the generality of this concept we also subjected substrate **6a** (with the sterically demanding isopropyl group) and the **6b** (with a ketal protecting group) to our reaction conditions (Scheme 5). Indeed, the results were comparable to those obtained with the corresponding methyl-substituted derivatives **1**.



Scheme 5. Reactions of substituted allylic substrates.

In conclusion we could show that chelated enolates are good nucleophiles for stereoselective allylations of both 1,3-disubstituted and also terminal allylic substrates. Neither the position and configuration of the leaving group nor the olefin geometry influences on the stereochemical outcome of the reaction. This is exclusively controlled by the O-protecting group used. Further investigations are in progress.

Experimental Section

General procedure for palladium-catalyzed allylic alkylations: Hexamethyldisilazane (226 mg, 1.40 mmol) was dissolved in THF (1.5 mL) in a Schlenk flask under argon. After the solution had been cooled to −78 °C, *n*BuLi (1.6 M, 0.80 mL, 1.25 mmol) was added slowly. The reaction mixture was stirred for 20 min at this temperature, and then the cooling bath was removed and stirring was continued for further 15 min. In a second Schlenk flask *N*-trifluoroacetyl *tert*-butyl glycinate (114 mg, 0.50 mmol) was dissolved in THF (3 mL). The solution was cooled to −78 °C, before the fresh prepared lithium hexamethyldisilazanide solution was added. After 15 min a solution of dried $ZnCl_2$ (75 mg, 0.55 mmol) in THF (0.5 mL) was added, and stirring was continued for 30 min.

A solution was prepared from [{PdCl(allyl)}$_2$] (10 mg, 0.025 mmol) and PPh_3 (30 mg, 0.113 mmol) in THF (5 mL). After this solutionwas stirred for 15 min at room temperature, it was added to the chelated enolate at −78 °C. At the same temperature the allyl substrate (0.3 mmol) was added in THF (0.5 mL) before the mixture was allowed to warm to room temperature overnight. The solution was diluted with ether before 1 M $KHSO_4$ was added (NH_4Cl for ketal-protected substrates). After separation of the layers, the aqueous layer was extracted three times with ether, and the combined organic layers were dried over Na_2SO_4. The solvent was evaporated in vacuo, and the crude product was purified by flash chromatography.

Molecular Magnets

Magnetic Moments of the Endohedral Cluster Fullerenes $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$: The Role of Ligand Fields

*Manfred Wolf, Karl-Hartmut Müller, Yurii Skourski, Dieter Eckert, Petra Georgi, Matthias Krause, and Lothar Dunsch**

The electronic and magnetic properties of endohedral fullerenes $M_k@C_{2n}$ for different metals M (such as lanthanides R, Group 3 and Group 2 metals) is a current area of endohedral fullerene research.[1] The influence of the electron transfer from M to the carbon cage, the geometric structure of the $M_k@C_{2n}$, as well as the location of the metal ion(s) in the cage on the magnetic properties are commonly studied. As shown by ESR spectroscopy, photoemission or Mössbauer spectroscopy, R ions are trivalent in most cases as in $Er_k@C_{82}$ for $k = 1$ and 2[2,3] and $Dy@C_{2n}$ ($2n = 80$, 82, 84).[4] Detailed studies of the fullerene magnetization versus applied field and temperature have confirmed these results.[5–11] On the other hand europium was found to be divalent in fullerenes for $2n = 74$ or

82.[9,10] The formal valency of an ion M depends also on the number of the ions encaged: For $Sc_k@C_{82}$ ($k=1, 2, 3$) Takata et al.[12] reported scandium to be divalent for $k=1$ or 2, whereas for $k=3$ the whole trimer has a charge of $+3$, $(Sc_3)^{3+}$, that is, the formal valency of scandium is $+1$. Endohedral thulium is divalent in $Tm@C_{82}$,[13,14] whereas a $+3$ state is discussed for $Tm_2@C_{82}$.[15,16] Structural studies on $Sc_2@C_{84}$,[17] $Sc_3@C_{82}$,[12] $La@C_{82}$[18] and $Er_2@C_{82}$[3] show the metal ions in an off-center position in the cage causing a low symmetry of the fullerene. In $Sc_3@C_{82}$ the scandium ions form a (nearly) equilateral triangle.[12]

A new type of endohedral fullerene was introduced with the nitride cluster fullerenes such as $Sc_3N@C_{80}$ which are stable endohedral structures of carbon cages, and are almost as stable as empty cages. In $Sc_3N@C_{80}$, the nitrogen atom is bonded to the three scandium atoms in a triangular planar configuration.[19,20] The entire Sc_3N cluster is bonded to the C_{80} cage, the shortest Sc–C_{80} distances being of the order of 2.3 to 2.5 Å.[19,20] This bond configuration which is measured in a short-time-scale experiment may be hidden in experiments with a longer time scale. For example, ^{13}C NMR spectroscopy indicated a time-averaged structural picture of a non-interacting I_h-C_{80} cage and an isotropic Sc_3N cluster.[19] More detailed investigations revealed a complex diffusion dynamics of the encaged cluster at room temperature.[21]

The interest in endohedral fullerenes encapsulating lanthanide ions is related to the unfilled 4f shell of the lanthanide ions, which gives rise to large magnetic moments and a variety of interesting magnetic properties. Also, these materials have a great potential for applications as contrast agents for magnetic resonance or X-ray investigations, biological tracing agents, and radiopharmaceuticals.[22,23] Some of these applications are closely related to the unique magnetic properties of these materials. For the first time, we present herein a new magnetic structure for the R_3N clusters (R = Ho, Tb) in the systems $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$, and explain the unexpected values observed for the magnetic moments of the encapsulated nitride clusters. These results provide information on the interaction between the magnetic moments of rare-earth metals encapsulated in the fullerene cage. The magnetic properties are used to determine the oxidation state of R in $R_3N@C_{80}$.

By using a new preparative route[24] for nitride cluster fullerenes, $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$ were synthesized in high yields and with an outstanding selectivity. As demonstrated by HPLC analysis of the holmiumnitride fullerene soot (Figure 1), $Ho_3N@C_{80}$ is the main component in the fullerene soot and can be easily isolated by one HPLC run. Besides $Ho_3N@C_{80}$ small amounts of the endohedral structure $Ho_3N@C_{82}$ and higher cage sizes were produced. The high purity of the isolated samples is confirmed by mass spectrometric data (Figure 1, inset). The fullerenes C_{60} and C_{70} appeared as byproducts of the reaction. $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$ are large-energy-gap fullerenes having optical gaps of approximately 1.75 eV.[24] By Vis-NIR and FTIR analysis both cluster fullerenes were assigned to the carbon cage C_{80}:7 with icosahedral symmetry I_h.[24] Electron spin resonance experiments revealed that both structures are diamagnetic at room temperature.

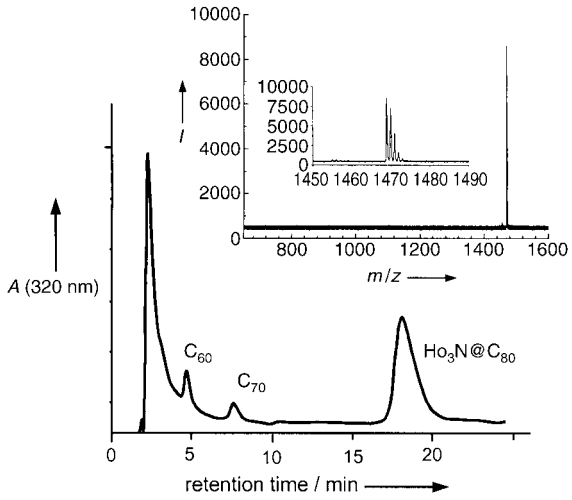

Figure 1. HPLC trace of the $Ho_3N@C_{2n}$ soot on a Buckyprep column with toluene as an eluent. The chromatogram shows the dependence of the optical absorption at $\lambda = 320$ nm on the retention time, which reveals that $Ho_3N@C_{80}$ is the main component of the soot. Inset: LD-TOF mass spectrum confirming the high purity of the $Ho_3N@C_{80}$ sample.

The results of our magnetic studies are presented in Figures 2 and 3. The field dependence of magnetization

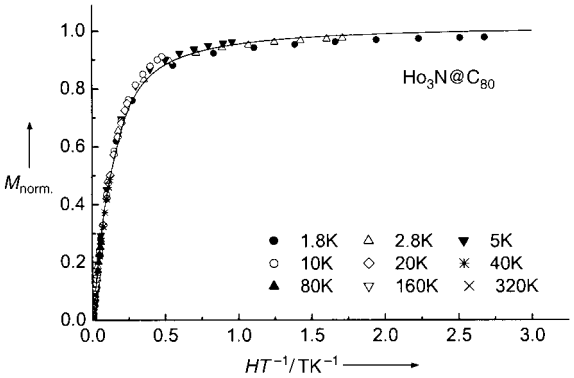

Figure 2. The experimental data $M(H,T)$ for $Ho_3N@C_{80}$ (symbols) corrected for the diamagnetic contribution and normalized to the saturation. The solid line represents the fitted Langevin function with a magnetic moment $\mu = 21\ \mu_B$.

$M(H,T)$ of $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$ was measured at various temperatures. For both structures the $M(H,T)$ data fit well with a simple dependence on only one variable, HT^{-1}, pointing to an ideal Curie paramagnetism. The observed magnetization curves can be described by the Langevin function $M(H/T) = m_s L(\mu H/k_B T)$, with μ as the moment of the fullerene molecule and k_B as the Boltzmann constant. The as determined values of μ are 21 μ_B for $Ho_3N@C_{80}$ and 17 μ_B for $Tb_3N@C_{80}$ (μ_B = Bohr's magneton). The large values of μ justify the neglect of quantum effects, that is, the description of the magnetic behavior by a Langevin function. These moments for the fullerene molecules are quite different from those of non-interacting Ho^{3+} ions (10 μ_B) or Tb^{3+} ions (9 μ_B). Also, they cannot be explained by a linear antiferromagnetic

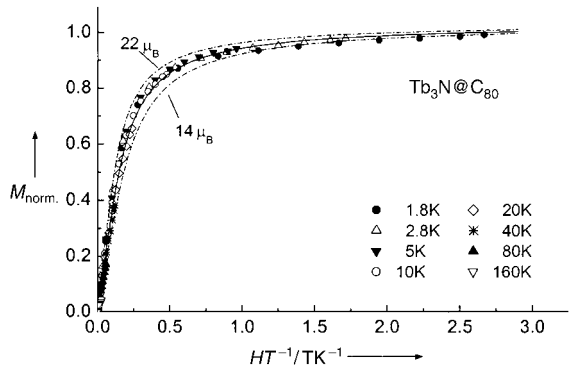

Figure 3. The experimental data $M(H,T)$ for $Tb_3N@C_{80}$ (symbols) corrected for the diamagnetic contribution and normalized to the saturation. The solid line represents the fitted Langevin function with a magnetic moment $\mu = 17\,\mu_B$. The broken lines correspond to the normalized magnetization for $\mu = 14\,\mu_B$ and $\mu = 22\,\mu_B$.

or ferromagnetic alignment of the three moments in the cages. A ferromagnetic linear alignment would result in $30\,\mu_B$ for $Ho_3N@C_{80}$ and $27\,\mu_B$ for $Tb_3N@C_{80}$.

The field and temperature dependence of the magnetization of $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$ can be understood by assuming a stable configuration of the magnetic moments the three atoms R, which is unchanged in the temperature and field range under investigation. These net magnetic moments μ do not experience any significant magnetic anisotropy. Otherwise the field and temperature dependence of magnetization would deviate from that shown in Figure 2 and Figure 3.[25,26]

A comparison with the literature data on $Sc_3@C_{82}$,[12] $Er_xSc_{3-x}@C_{80}$,[29] $Lu_3N@C_{80}$,[23] and $Sc_3N@C_{80}$[20] allows the following conclusions to be drawn: 1) the three Ho or Tb ions form a nearly equilateral triangle with one N^{3-} species in its center as shown in Figure 4a, and 2) both in $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$ each of the rare-earth ions is in the +III state. Such a charge distribution is supported by HPLC, Vis-NIR, and FTIR data.[23] On taking up six electrons the C_{80} cage attains a closed-shell like that found for $Sc_3N@C_{80}$.[19,20,27,28] No contributions of N^{3-} and $[C_{80}]^{6-}$ to the magnetic moment are expected and the magnetic behavior is governed only by the cluster $(Ho^{3+})_3N^{3-}$ or $(Tb^{3+})_3N^{3-}$. As the cage has no spin, contrary to the case of endohedral monometallofullerenes,[30] no coupling between the R magnetic moments and the cage has to be taken into account.

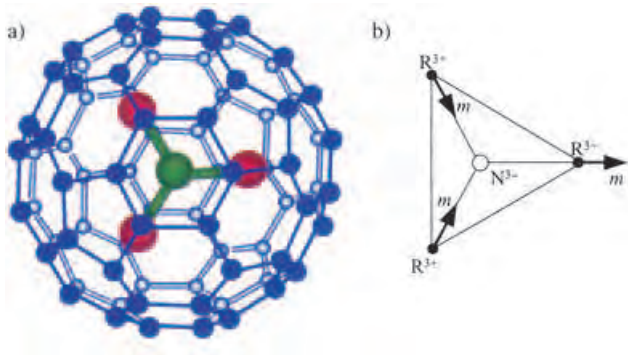

Figure 4. a) Structure of a $R_3N@C_{80}$ molecule according to ref. [18], blue: carbon, green: nitrogen, and red: rare earth atoms; b) orientation of the individual R magnetic moments m (arrows) in the R_3N cluster in $R_3N@C_{80}$ (R = Ho, Tb).

The total magnetic moments μ of $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$ do not experience any detectable magnetic anisotropy. Taking into account the diffusion dynamics of R_3N and that "static" magnetic measurements have a longer time scale than NMR spectroscopy experiments, this situation is in agreement with the current model for $Sc_3N@C_{80}$.[19–21] However, the single R ions are subjected to ligand fields resulting in a magnetic anisotropy of the individual R magnetic moments with respect to local directions within the R_3N cluster. The ligand field of the nitrogen ion in the R_3N cluster causes the preferred direction of the R magnetic moments with respect to the R–N bonds. If these R–N bonds are "magnetically easy directions" and the magnetic anisotropy caused by the ligand fields is relatively strong compared to the exchange interaction between the R magnetic moments, the direction of these moments will be "pinned" along the bond directions. For ferromagnetic exchange the configuration of the three magnetic moments is shown in Figure 4b. A vector addition of the three (classical) R magnetic moments m results in the magnitude $2\,|m|$, that is, $20\,\mu_B$ for the Ho_3N cluster and $18\,\mu_B$ for Tb_3N, which is in good agreement with the results given above. Antiferromagnetic exchange can be excluded as it would result in a vanishing total moment of the $R_3N@C_{80}$ molecule. The charge distribution of these cluster fullerenes can be formally described as $(R^{3+})_3N^{3-}@C_{80}^{6-}$. Because the N^{3-} as well as C_{80}^{6-} ions do not contribute to the magnetic moment and the R magnetic moments are shielded by a carbon cage which has a filled electron shell, $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$ do not show a finite paramagnetic Curie temperature, and magnetic hysteresis as well as differences between zero field and field cooling conditions do not occur. The vanishing (or very small) magnetic anisotropy is suggested to be related to the closed shell of the C_{80}^{6-} ion. This situation is in contrast to results on endohedral monometallofullerenes, for which the contribution of the π electron has to be taken into account.[31]

In summary, the net magnetic moments of the encaged (R_3N) trimer (R = Ho, Tb) can not be explained either by non-interacting magnetic moments from R, nor by a dominant ferromagnetic or antiferromagnetic exchange interaction between the R moments. The net moments of $21\,\mu_B$ ($Ho_3N@C_{80}$) and $17\,\mu_B$ ($Tb_3N@C_{80}$) are explained by a new model for the magnetic structure of $Ho_3N@C_{80}$ and $Tb_3N@C_{80}$, in which strong ligand fields within the (R_3N) cluster act on the ferromagnetically exchange-coupled moments of R. As a result of this combination of different types of interaction the individual R moments are not collinearly aligned but are parallel to the R–N bonds (R = Ho or Tb).

Experimental Section

The cluster fullerenes were prepared using a modified Krätschmer–Huffman arc burning method. Two modifications of this process were

applied: In a first version a solid nitrogen source was used by adding varying amounts of calcium cyanamide to the metal/graphite powder mixture. As the main and second synthetic route the concept of the reactive arc atmosphere[32] was applied to improve the ratio of trimetal nitride fullerenes to empty fullerenes. In general, graphite rods filled with a metal/graphite or metaloxide/graphite powder mixture were used. The soot of the arc burning process was soxhlet extracted with CS_2 for 20 h. After extraction non-fullerene products such as polycyclic aromatic hydrocarbons and other low molecular structures were removed from the extract by washing with acetone.

High performance liquid chromatography (HPLC) was used for fullerene purification and analysis (BuckyPrep column, Nacalai Tesque). Owing to the high content of the $R_3N@C_{80}$ structure (R = Ho or Tb) in the fullerene extract these fullerenes were isolated by a single separation step using a 4.6×250 mm BuckyPrep column. The resulting purity was over 95%.

The mass spectrometric characterization was by MALDI-TOF mass spectrometry using the Biflex II spectrometer (Bruker, Germany) and 9-nitroanthracene as the matrix. Positive and negative ions of the fullerenes were detected.

The magnetic measurements were performed on a SQUID magnetometer at temperatures T from 1.8 K to room temperature in magnetic fields H up to 5 Tesla. As the mass of the investigated samples was very small (about 60 μg in the case of $Ho_3N@C_{80}$, 40 μg for $Tb_3N@C_{80}$) the as measured magnetization values $M_{exp}(H,T)$ data revealed a remarkable diamagnetic contribution to the susceptibility, χ_{dia}, from the encapsulating glass ampoule and a two-step analysis had to be done. In a first step χ_{dia} was determined from a fit of $m_s L(\mu H/k_B T) + \chi_{dia} H$ to M_{exp}. The magnetization values $M(H,T)$ of the fullerene powder is then given by $M(H,T) = M_{exp} - \chi_{dia} H$. The final values of m_s and μ were determined by fitting $m_s L(\mu H/k_B T)$ to these $M(H,T)$ values. The very small changes in m_s and μ demonstrated the consistency of the procedure. Furthermore it is noted, that such small fullerene amounts were "smeared" over the walls of the encapsulating glass ampoule in the SQUID magnetometer. Therefore the absolute value of the magnetization of the sample could not be determined sufficiently precisely. However the dependence of the magnetization $M(H,T)$ normalized to m_s on field and temperature could be determined with an accuracy of typically 1% as confirmed by repeated measurements. Regarding μ, the fitting results have been verified by a comparison of the fitted magnetization curve with theoretical curves for assumed μ values of 22 μ_B and 14 μ_B in the case of $Tb_3N@C_{80}$ (see Figure 3).

Microbubbles

Gas-Filled Polyelectrolyte Capsules**

Dmitry G. Shchukin, Karen Köhler, Helmuth Möhwald, and Gleb B. Sukhorukov*

In the last decade material chemists have been very interested in spatially confined, engineered micro- and nanosystems containing various species (e.g., catalysts, DNA, drugs, enzymes) that are applicable in diagnostics, catalysis, therapy, and bioengineering in both aqueous and nonaqueous media. Most successful examples of such micro- and nanocontainers are liposomes,[1] micelles and microemulsions,[2–5] lipid bilayers,[6] polymer microcapsules,[7] and inorganic hosts.[8–11] The advantages of these structures are their small (and usually variable) size and low toxicity, and the controlled permeability of the microcontainer wall. In general, the inner lumen of emulsions, liposomes, capsules, etc. is composed of either solution or solid material. The only exception among the materials containing gaseous lumen are the so-called ultrasonic contrast agents[12–14] (for a survey of commercial ultrasonic contrast agents see ref. [15]). The fabrication of ultrasonic contrast agents is based on the spontaneous formation of a microbubble polydispersion in a solution containing a mixture of block copolymers or other amphiphilic materials by either shaking in a laboratory blender or, more effectively, by ultrasonic agitation.[12–15] However, the main drawbacks of such self-assembled microbubbles are their low stability in water and in salt solution (up to 10–12 h), and the difficulty in modifying their shell by introducing a desired material in order to attain additional functionality.

On the other hand, polyelectrolyte multilayers are an effective barrier to prevent or drastically decrease gas diffusion. As shown by B. Tieke, M. L. Bruening, T. J. McCarthy et al.,[16–19] poly(allylamine hydrochloride), poly(styrene sulfonate), polyacrylic acid, polyethylenimine, and poly(diallyldimethylammonium chloride) multilayers reduce the diffusion of oxygen, nitrogen, CO_2, and other gases by up to 150-fold relative to their diffusion in water, and they can be used as gas-separation membranes with good selectivity for O_2 and N_2.[17] The reduced gas permeability through polyelectrolyte multilayers is explained by the dense and rigid packing of the polyelectrolytes.[16] Thus, microcontainers built from polyelectrolyte multilayers or, at least, containing polyelectrolytes in the shell can be a good tool for gas entrapment.

Polyelectrolyte microcapsules, which are fabricated by layer-by-layer (LbL) deposition[20–22] of oppositely charged polyelectrolytes,[23] can be considered as confined microvolumes with a gaseous lumen. The main features of the polyelectrolyte capsules distinguishing them from other microcontainers are their multifunctionality and the straightforward modification of the shell on the nanometer scale. Macromolecules, drugs, fluorescent labels, and nanoparticles can be enriched in the inner volume of the capsules because of the switchable permeability of the capsule shell.[24,25] Polyelectrolyte capsules with a gaseous lumen (core) could be of interest as contrast agents for ultrasonic diagnostics, as gas-dispersing containers, as components of fuel cells, and in chemical catalysis.

Herein we describe the application of polyelectrolyte multilayers for air encapsulation and the formation of polyelectrolyte microcapsules with a gaseous interior. Our work also provides an example of LbL technology used for polyelectrolyte assembly on spherical water/air interfaces (in which the "air" core serves as the template). The resulting air-containing polyelectrolyte capsules possess all characteristics of air-in-water microemulsions; however, they are more stable and can be easily treated and transferred from one solution to another by filtration or centrifugation. Besides reduction of gas diffusion and, as a consequence, higher capsule stability, the assembled polyelectrolyte multilayers can bear additional functionality (molecular recognition, magnetic and/or fluorescent properties) providing special characteristics to the "air" capsules.

We combined the self-assembly of the gas microbubbles in aqueous media with stepwise LbL deposition of oppositely charged polyelectrolytes onto the resulting "air" core. In the first step, self-organized formation of an air microdispersion in water was performed according to a known procedure[12,13] (Figure 1a). This initial air suspension is stable for 4–5 h. Then, poly(allylamine hydrochloride) (PAH) and poly(styrene sulfonate) (PSS) layers were adsorbed in alternation starting from a positively charged PAH layer (Figure 1b,c). The resulting capsules with entrapped air are less dense than water and can be collected easily at the top of the vial (see photograph in Figure 1) upon centrifugation at low rpm (<500) or by "reverse" sedimentation. Higher rotation speeds lead to capsule coalescence and shell rupture. A more detailed description of the capsule preparation can be found in the Supporting Information.

The ζ-potential (Malvern Zetasizer 4) of the initial Tween:Span air microbubbles is slightly negative (see Figure 2a). Further electrophoretic measurements indicate the charging of the air microbubbles coated with the adsorbed polyelectrolyte multilayer upon each added layer. Figure 2a shows a drastic increase of the surface charge after deposition of the first PAH layer (≈ 50 mV) followed by alternating changes of ≈ 15 mV after each subsequent layer. In fact, there

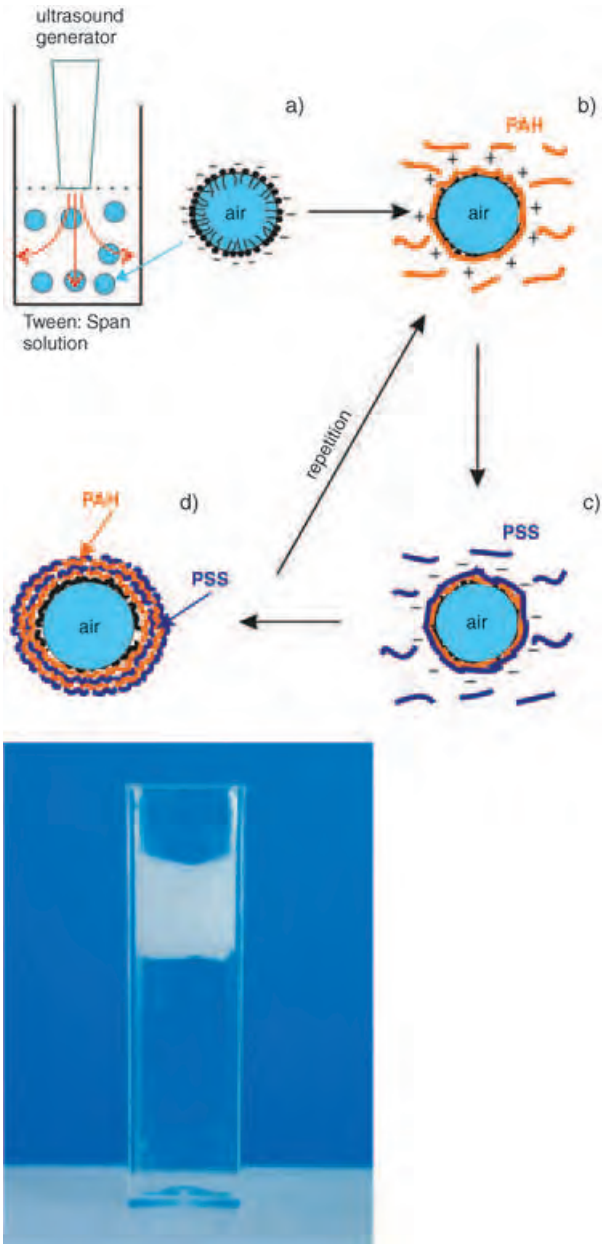

Figure 1. Schematic illustration of the formation of polyelectrolyte capsules on an "air" core. The Tween:Span mixture, which is used to form air microbubbles (a), is further stabilized by the electrostatic assembly of PAH/PSS multilayers (b–d). Bottom: a photograph of air-containing polyelectrolyte capsules in aqueous solution after centrifugation.

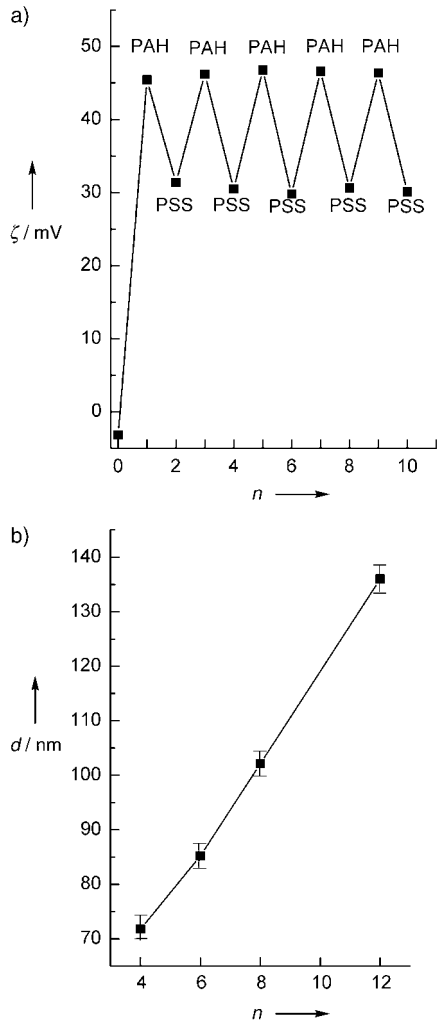

Figure 2. a) ζ-potential as a function of the number of layers, *n*, in the air-containing polyelectrolyte capsules. b) Thickness, *d*, of the capsule shell as a function of layer number (derived from AFM measurements).

is no complete recharging of the microbubble surface during the deposition of the positively and negatively charged polyelectrolytes. A possible explanation of this phenomenon is that during deposition of the first PAH layer PAH molecules deeply penetrate the initial Tween:Span shell forming a branched thick layer with an excess of positive charge inside, which cannot be completely compensated by the next PSS layer deposited onto the surface. The following PAH/PSS layers change the ζ-potential in the usual way with the same values for the assembled layers of the same evenness.

To obtain additional evidence of the growth of PAH/PSS multilayers on air microbubbles, we examined air-containing capsules with different numbers of layers by atomic force microscopy (AFM). As seen in Figure 2b, the average thickness of the capsule shell obtained from the height measurements gradually increases with the layer number in increments of about 8 nm per layer. This unambiguously confirms LbL assembly of the oppositely charged polyelectrolytes on the surface of air microbubble. However, it is not possible to study air-containing capsules with less than four layers by AFM because of their instability during drying—only polyelectrolyte debris was observed. Extrapolation of the AFM data estimates the average thickness of the first Tween:Span/PAH layer at ≈48 nm, which is six times greater than the thickness of the subsequently deposited polyelectrolyte layers and in good agreement with the drastic increase of the ζ-potential after PAH deposition onto the Tween:Span shell (Figure 2a).

The AFM image shows the continuous morphology of the shell film (Figure 3). Creases and folds resulting from capsule

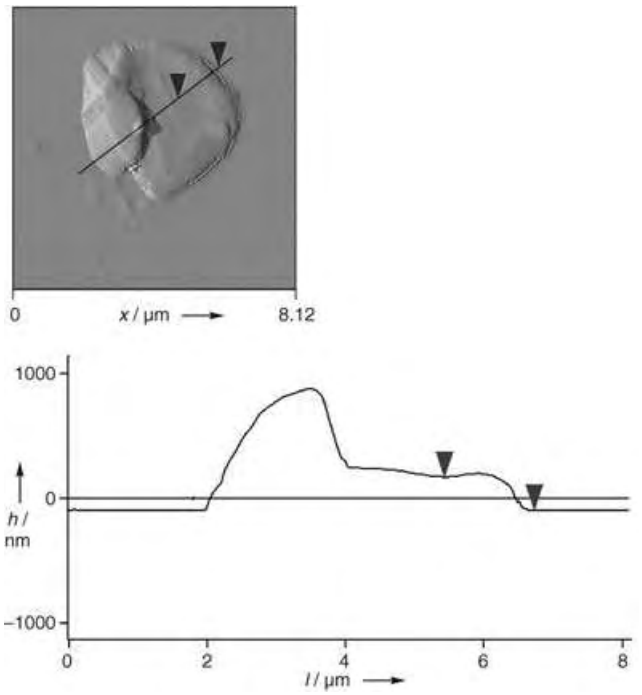

Figure 3. AFM image and height profile of an air-$(PAH/PSS)_6$ microcapsule. Vertical distance between the tip and the surface: 271.84 nm.

collapse after drying are observed, which coincide well with scanning electron microscopy observations (SEM, Figure 4a). Dried air-PAH/PSS capsules collapse to form flat structures (Figure 4a), which are rougher and bulkier than the flat structures obtained after the water-filled polyelectrolyte capsules are dried.[26] This discrepancy can be explained by different mechanisms of the capsule collapse: Shell deformation of the water-filled polyelectrolyte capsules occurs gradually as water evaporates from the capsule interior, resulting in smooth and flat films. In contrast, the air-filled capsules collapse immediately after the surrounding solution has been evaporated, forming less ordered, bulky structures.

Confocal microscopic images (Leica TCS SP, 100× oil-immersion objective) of air-containing polyelectrolyte capsules were recorded in fluorescence and transmission modes (Figure 4b,c). The capsules are polydisperse and their size varies from 1 to 20 µm; they are spherical and no aggregation is observed. Fluorescence is detected only from the capsule wall, indicating the presence of PAH labeled with fluorescein isothiocyanate (FITC) only in the shell and not in the volume. Air-containing PAH/PSS capsules can be expanded after 5 min of heating by a microscope lamp because of the high thermal expansion coefficient of the gaseous lumen (core). At elevated temperatures the shell explodes and the capsule is destroyed (Figure 5).

Raman spectra (CRM200, Witec) recorded for both the air-containing polyelectrolyte capsules and the surrounding water are shown in Figure 6a. A number of peaks observed for the polyelectrolyte capsules within the range 700–3000 cm^{-1} can be assigned to the vibration and stretching modes of PSS, Span, and Tween molecules.[27] The intensity of the broad band at 3200–3600 cm^{-1}, which corresponds to the

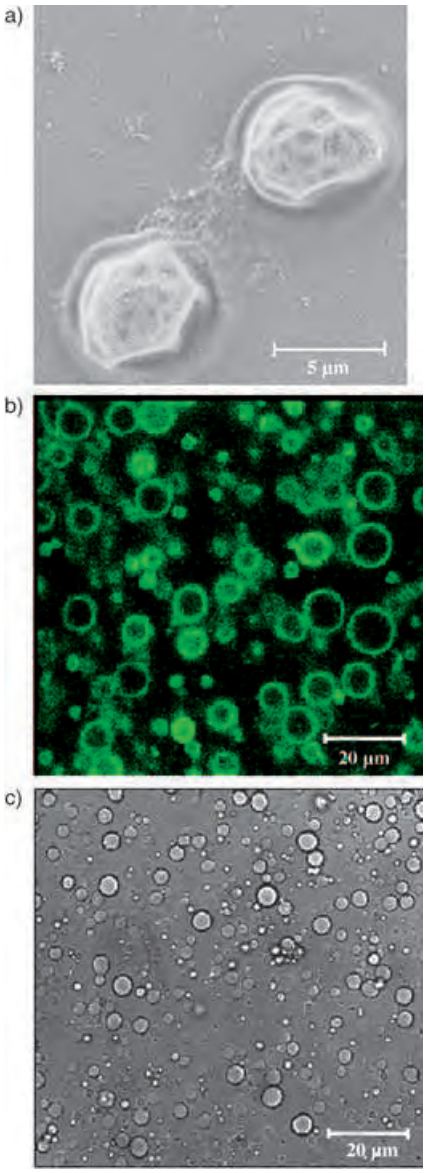

Figure 4. a) SEM image of air-$(PAH/PSS)_6$ microcapsules; b,c) confocal microscopy images of air-$(PAH/PSS)_6$ microcapsules made in FITC mode (signal from fluorescein isothiocyanate-labeled PAH) and bright-field mode, respectively.

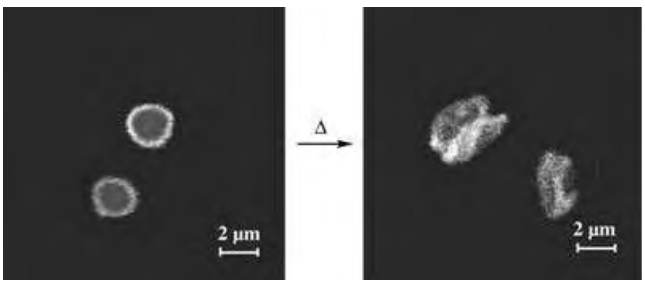

Figure 5. Confocal microscopy images of air-$(PAH/PSS)_6$ microcapsules made in FITC mode (signal from FITC-labeled PAH) before and after heating by a microscope lamp.

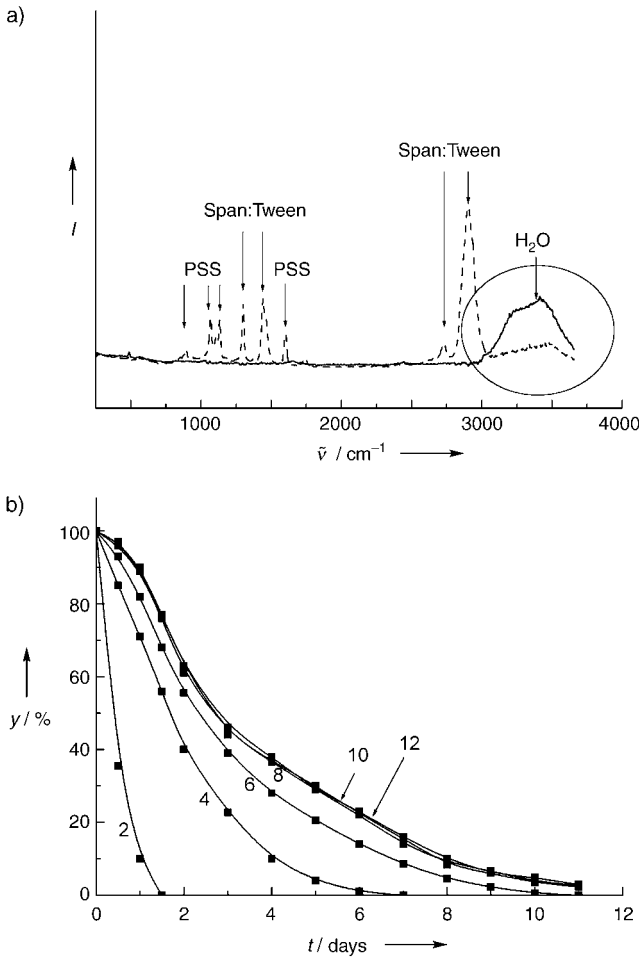

Figure 6. a) Raman confocal microscopy spectra from an air-containing polyelectrolyte capsule (dashed line) and surrounding water solution (solid line). b) Fraction *y* of intact air-containing polyelectrolyte capsule measured by counting confocal microscopy images. Numbers on the curves are the numbers of PAH and PSS layers deposited onto air microbubble.

vibration of OH groups of water, is considerably lower for polyelectrolyte capsules than for the surrounding solution. The gaseous core of the capsules does not contribute to the Raman signal at these wavenumbers, and the small intensity of the peaks observed at 3200–3600 cm^{-1} is caused by the water molecules entrapped inside the polyelectrolyte shell, which can contain up to 40 % v/v water according to Estrela-Lopis et al.[28] Hence, both confocal and Raman measurements prove the air/PAH/PSS structure of the resulting polyelectrolyte capsules.

Air-containing polyelectrolyte capsules have a higher stability against collapse in aqueous suspension than either the gas suspensions developed for ultrasonic contrasting[12–15] or the initial Span:Tween suspension. The stability of the capsules, which was estimated by confocal microscopy as the number of intact capsules after a certain time period divided by total number of capsules prepared, gradually increases with the number of polyelectrolyte layers; however, at eight or more polyelectrolyte layers the effect of the next layers becomes lower and approaches zero at 12 layers (Figure 6b). This could be associated with the looser packing of polyelectrolyte molecules at higher layer numbers accompanied by the strengthening of the first three to four layers by the following polyelectrolyte layers. The first polyelectrolyte layers are densely packed. Thus mass transfer through the shell is decreased, and consequently, the dissolution of the gaseous core in water is prevented to some extent.[29] In contrast, the last layers have a more porous structure, which has negligible influence on the gas diffusion. A similar effect of the shell thickness on the permeability properties was observed by Antipov et al.[30] for conventional "aqueous" polyelectrolyte capsules.

Electrostatic layer-by-layer assembly of polyelectrolyte multilayers was successfully accomplished on the surface of an air microbubble (core). The resulting polyelectrolyte shell stabilizes the overall air microsuspension against collapse and prevents air dissolution in water media. Air-containing poly(allylamine)/poly(styrene sulfonate) microcapsules have a wide size distribution (1–20 μm) and gaseous interior, and are stable for at least one week. These capsules have potential as contrast agents in ultrasonic diagnostics. Moreover, because of the high density gradient across the water/polyelectrolyte/air interface, air-containing polyelectrolyte capsules could be sensitive to low-power ultrasonic irradiation. This would make it feasible to use them as delivery agents capable of ultrasonically triggered remote release of the compounds entrapped within the shell of microbubbles. Additional properties could be imparted to the air-containing polyelectrolyte capsules by introducing inorganic nanoparticles (fluorescent, magnetic, bioactive) as one of the shell components (layer) or by performing a chemical reaction directly in the shell. We are currently studying ultrasonically sensitive capsules containing an air core and a polyelectrolyte shell modified by drug or metal nanoparticles.

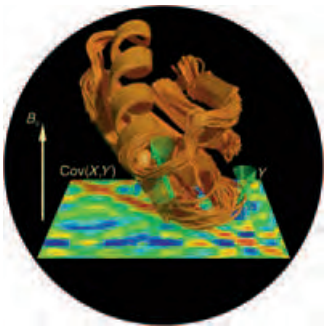
Upon thermal stimulation the two templating sulfite anions embedded in the "Trojan Horse" polyoxometalate cluster shown in the cover picture release electron "soldiers" to the cluster's surface, turning the cluster from colorless to blue (background). The formation of the mixed-valence cluster shell is commensurate with the oxidation of the sulfite to sulfate anions. More details about this coupled structural and electronic rearrangement are given in the Communication by L. Cronin et al. on page 3415 ff.

Cellulose Chemistry
In view of the strong growth in cellulose research worldwide, D. Klemm, H.-P. Fink, and co-workers take stock of the latest developments in cellulose chemistry and current perspectives on its applications in their Review on page 3358.



Molecular Dynamics Simulations
The correlated motions determined in NMR relaxation studies of protein solution structures can be consistently simulated with molecular dynamics. This technique is described in the Communication by B. de Groot and co-workers on page 3394 ff.

History of Chemistry
The Essay by E. Vaupel on page 3344 ff. covers the life and work of the Jewish chemist and industrialist Arthur Eichengrün, the father of the German cellulose acetate industry.

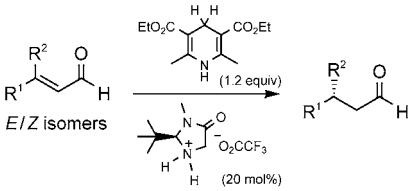
Highlights

Organocatalysis

Nature knows best: Recently developed enantioselective organocatalytic methods for the reduction of olefins under transfer-hydrogenation conditions are discussed (see scheme). The metal-free, amine-catalyzed reductions described have been inspired by the way natural systems perform reduction reactions.

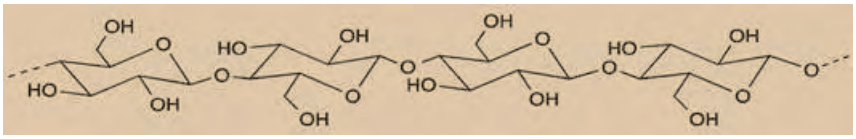


Essays

History of Chemistry

The life and achievements of the Jewish chemist and entrepreneur Arthur Eichengrün, a trailblazer in the German cellulose acetate industry, have been unjustly forgotten as a long-term consequence of National Socialism. Newly examined sources give detailed insight into his tragic biography, which was illustrative of the times.

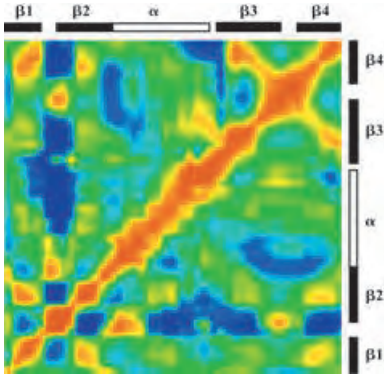
Reviews

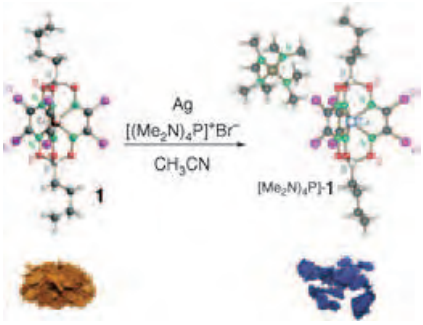


The trend toward renewable resources has led to a global renaissance of cellulose research over the past ten years. This review describes the highlights of the progress made in this area, which has provided a better understanding of the structure of cellulose derivatives, the tailoring of cellulose products, alternative production processes for cellulose regenerates, and new pathways for the formation of supramolecular architectures.

Communications

Correlated motions probed? A recently reported NMR relaxation experiment promised to probe correlated motions in proteins. However, molecular dynamics simulations imply that this is not the case. The simulations agree well with data obtained through two independent and established NMR spectroscopic methods and thus provide an alternative and consistent access to correlated protein motions (see picture) from NMR techniques.





A grip on what's inside: A clathrochelate ligand controls the oxidation state of the encapsulated cobalt ion in complex **1**. This complex can be reduced chemically in acetonitrile solution by treatment with silver in the presence of tetraalkylammonium or tetra(dimethylamido)phosphonium halides to the dark-blue reduced complex [$(NMe_2)_4$P]-**1** in high yield (see scheme).

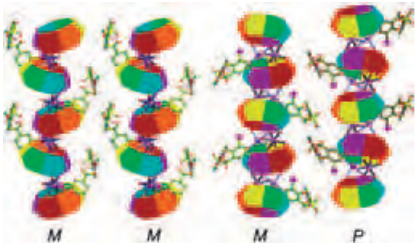
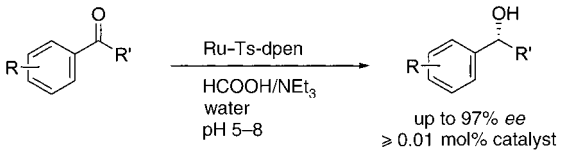
An anion-exchange strategy was used to prepare two helical structures made up of cucurbituril and asymmetric copper(II) complexes containing 8-hydroxyquinoline-5-sulfonate and 3,5-diiodosalicylate (right half of picture) or 3-iodobenzoate (left half). The shape-matching interactions between cucurbituril and the copper complexes were assisted by the iodo substituents.



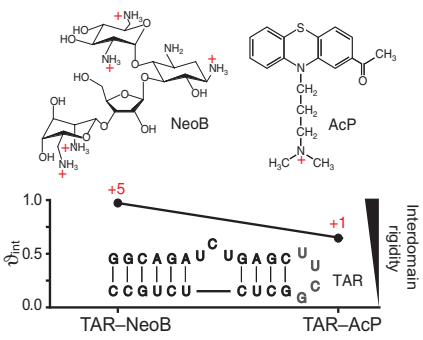
Cucurbituril Polymers



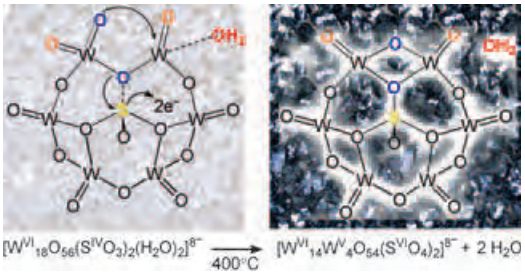
Much faster, more enantioselective, and more-productive catalysis was attained in the asymmetric transfer hydrogenation of aromatic ketones with the Noyori–Ikariya Ru–Ts-dpen catalyst in water under slightly basic conditions (see scheme). At low pH values, the reaction was much less efficient and appears to operate through a different mechanism.

Transfer Hydrogenation

The global dynamics of the TAR RNA from HIV-1 bound to two distinctly charged molecules have been characterized by NMR studies of residual dipolar couplings (see picture). While neomycin B (NeoB: +5) arrests global motions in TAR, the small organic molecule acetylpromazine (AcP: +1) does not. Results indicate that electrostatic interactions are critical for arresting global motions in RNA.



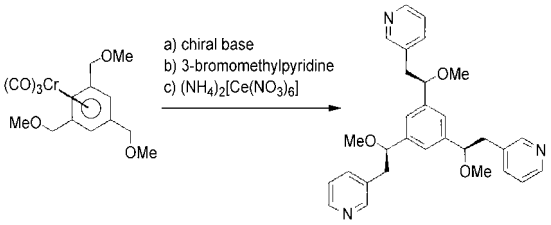
RNA Recognition



Cores and effect: Heating the cluster $[W_{18}O_{56}(SO_3)_2(H_2O)_2]^{8-}$ causes an electron transfer from the core sulfite anions to the cluster shell resulting in a color change from colorless to dark blue (see backgrounds). The electron transfer is coupled with a structural reorganization of the cluster shell and oxidation of the sulfite to sulfate anions (see scheme).

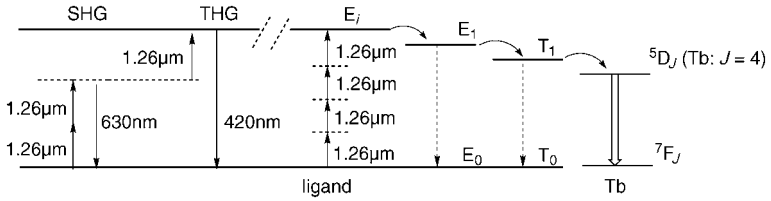
Cluster Compounds

Contents



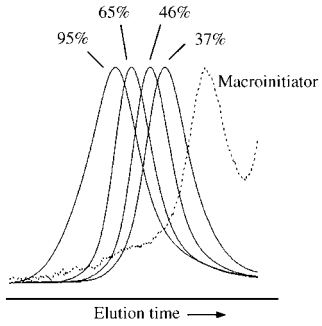
Chiral-base chemistry has been used to introduce multiple elements of chirality around an (arene)tricarbonylchromium(0) complex. Three stereogenic centers could be installed in one operation to synthesize a nonracemic chiral C_3-symmetric triphosphine and a nonracemic chiral C_3-symmetric tripyridine (see scheme).

Asymmetric Synthesis



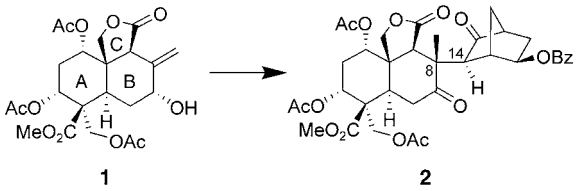
Red, green, and blue emissions are observed simultaneously for an organoterbium complex that displays remarkable multiphoton upconversion when excited by a near-infrared light source. The system undergoes two nonlinear optics processes simultaneously: second and third harmonic generation (SHG: red emission; THG: blue), and four-photon upconversion (green) for excitation at $\lambda \approx 1.26$ (see diagram).

Luminescence



A poly(vinyl acetate) macroinitiator, preformed by a cobalt-mediated technique, facilitates controlled radical polymerization of vinyl acetate (VAc) in suspension in water. The molar mass increases with monomer conversion, as demonstrated by size exclusion chromatograms (see picture), and the polydispersity remains low at 1.2–1.4. Moreover, the VAc polymerization rate is much higher in suspension than in the bulk.

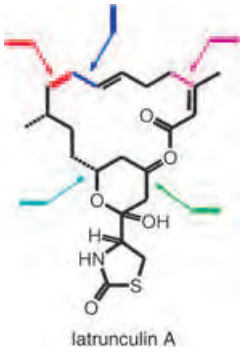
Controlled Radical Polymerization



The advanced decalin intermediate 1 was synthesized and elaborated into the potential azadirachtin precursor **2**. The challenging synthesis involved several protecting-group manipulations and coupling of **1** with an appropriate norbornene unit.

Natural Products Synthesis (1)

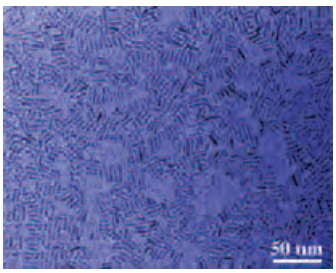
Contents



latrunculin A

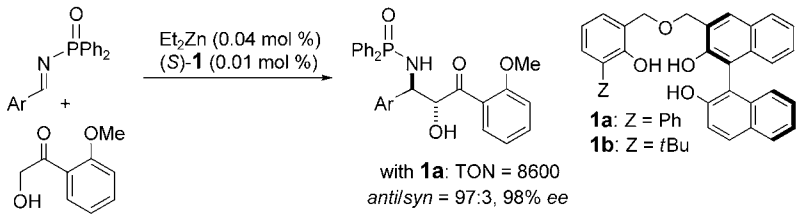
Selective actin-binding is the most prominent biochemical property of the scarce marine natural product latrunculin A (see formula). Modern metal-catalyzed C–C bond-formation reactions, including a ring-closing enyne–yne metathesis (shown in red), now open a convenient, flexible, and productive entry to this important probe molecule for chemical biology.

Natural Product Synthesis



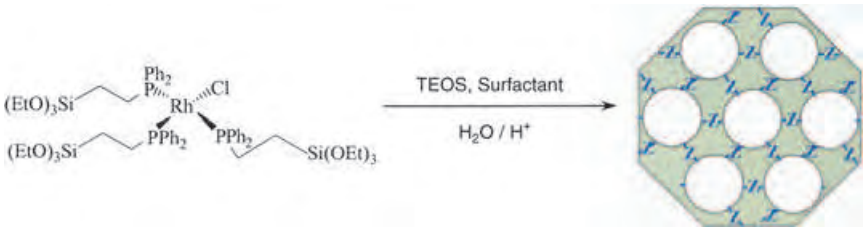
High-temperature nonhydrolytic aminolysis has been developed as an approach to monodisperse titania nanocrystals by exploiting the chemical modification of reactive titanium isopropoxide with oleic acid as the chelating ligand. Its capabilities for the anisotropic growth of highly crystalline anatase titania nanocrystals (see picture) with controlled size and shape have been demonstrated.

Nanostructures



An achiral unit is shown to be better than a chiral unit in promoting an asymmetric reaction. Non-C_2-symmetric linked-binols **1** with one chiral 1,1′-bi-2-naphthol unit and one flexible achiral unit are employed as ligands in direct catalytic asymmetric Mannich-type reactions (see scheme; TON = turnover number). With as little as 0.01 mol % of ligand **1a** and 0.04 mol % of Et_2Zn, the reaction proceeded smoothly to give the product in 98 % *ee*.

Asymmetric Catalysis



Covalently imprisoned within pore walls of mesostructured porous silica, organophosphanyl transition-metal complexes (Z, see picture) are still able to effect heterogeneous hydrogenation catalysis. The key to the synthetic protocol that leads to the well-defined metal sites lies in silylation of the material prior to extraction of the surfactant template. TEOS = tetraethylorthosilicate.

Organocatalysis

Organocatalytic Hydride Transfers: A New Concept in Asymmetric Hydrogenations

*Hans Adolfsson**

Keywords:
asymmetric catalysis · enantioselectivity · hydrogen transfer · organocatalysis · reduction

Asymmetric hydrogenation of unsaturated organic compounds, such as olefins, carbonyls, and imines, is currently becoming a standard procedure in both academic laboratories and industrial applications.[1,2] On the basis of the vast number of biologically active compounds in which a hydrogen substituent is part of the stereogenic center, it is not surprising that the development of efficient enantioselective reduction reactions has been the main focus within the area of asymmetric catalysis. The early discoveries in the 1960s by Knowles and co-workers, who revealed that chiral rhodium complexes based on the Wilkinson catalyst were able to catalyze the hydrogenation of unsaturated carboxylic acids with a slight enantiomeric excess under homogenous conditions, opened the door to an intensive hunt for more efficient and more selective catalysts.[3] A number of milestones have been reached since the initial experiments were performed, and today we are equipped with a plethora of different methods for the enantioselective reduction of unsaturated organic compounds.

Until now, all the methods developed for the reduction of organic compounds have been dominated by the use of metal catalysts surrounded by proper stereodiscriminating chiral ligands. Highly efficient catalysts based on rhodium(I) or ruthenium(II) complexes with chiral diphosphine ligands have been introduced for the enantioselective olefin reduction of enamines and unsaturated carboxylic acids with molecular hydrogen.[1,4] More recently, iridium complexes with chiral P,N ligands have been used for the enantioselective reduction of nonfunctionalized olefins.[5,6] The asymmetric reduction of ketones and imines are commonly performed by using molecular hydrogen and chiral ruthenium(II) catalysts.[4] A mild alternative for the latter reductions is to perform the reactions under hydrogen-transfer conditions.[7] Metal-catalyzed hydrogen-transfer reactions using isopropyl alcohol or formic acid as sources of hydrogen have been extensively studied during the last decade.[8] Highly enantioselective processes, in particular for the reduction of ketones, have been established using catalysts based on vicinal amino alcohols, diamines, or pseudodipeptides in combination with Ru^{II}–arene precursors.[8–10]

The common denominator in the systems described above is that the principal center of reactivity is positioned on a (transition) metal hydride or dihydride. However, a shift of this paradigm was recently made by the discovery that simple ammonium salts of secondary amines were able to catalyze the chemoselective reduction of α,β-unsaturated aldehydes in the presence of a dihydropyridine as the hydride donor.[11] In biological systems reductions are made in cascade reactions that involve metalloenzymes and organic hydride reduction cofactors such as nicotinamide adenine dinucleotide (NADH) or flavin adenine dinucleotide ($FADH_2$). Inspired by the way natural systems perform reduction reactions, List and co-workers recently reported that Hantzsch ester **1** worked as a good NADH mimic in the hydride-transfer reaction to the iminium ion formed from 2-nitrocinnamyl aldehyde **2** and a catalytic amount of dibenzylammonium trifluoroacetate (**4**; Scheme 1).[11] The reaction proved to be highly chemoselective and high yielding (94%) to afford the saturated aldehyde **3**. In a series of experiments it was shown that different ammonium salts of secondary amines, including pyrrolidine and piperidine, efficiently catalyzed the transformation. The screening of different enal substrates using catalyst **4** and the NADH mimic **1** demonstrated that mono- or disubstitution of a wide range of groups (aryl or alkyl) at the β position was tolerated and gave the corresponding saturated aldehydes in good yields. However, enals that contain an additional substituent in the α position were not reduced under these conditions. The successful results obtained when ammonium salts of cyclic secondary amines were used as catalysts indicated that chiral cyclic amines such as the com-

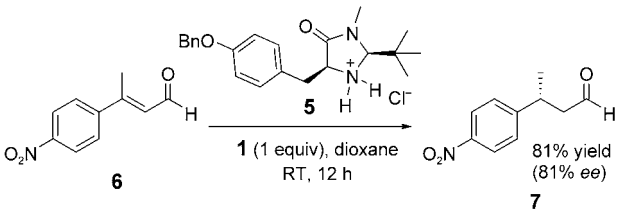
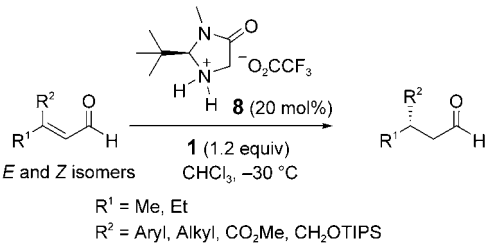
monly used organocatalyst **5**[12] would catalyze the reaction and perhaps be able to induce asymmetry in the hydride-transfer step. List and co-workers were indeed rewarded in the reduction of enal **6** by using a substoichiometric amount of the HCl salt **5** as catalyst, as product **7** was obtained in 81% yield with 81% enantiomeric excess (Scheme 2).[11] This is the first example of an enantioselective metal-free transfer hydrogenation of an olefin, and with this result yet another color was added to the constantly growing palette of organocatalyzed asymmetric reactions.[13,14]



Scheme 2. Enantioselective reduction of enal **6** catalyzed by ammonium salt **5**. Bn = benzyl.

In further studies on iminium-catalyzed asymmetric hydride transfers to olefins, the groups of MacMillan and List almost concurrently reported that β,β-disubstituted aldehydes could be reduced in good yields and with excellent enantioselectivity.[15,16] The catalysts used by both groups were based on the same imidazolidinone skeleton and differed only in the ring substituents. MacMillan and co-workers reported that superior levels of enantiomeric excess were obtained by employing the amine triflate salt **8** in chloroform at −30 °C.[15] Under these conditions a number of different trisubstituted α,β-unsaturated aldehydes were reduced in high yields (74–95%) with enantioselectivities of up to 97% *ee* (Scheme 3). Most interestingly, irregardless of whether an *E* or a *Z* olefin was used as substrate, they both converged into the same *S* enantiomer of the product. This result is in direct contrast to many metal-catalyzed hydrogenations in which the geometry of the olefin generally dictates the outcome of the reaction. The reason for the observed stereoconvergence is believed to result from a fast *E*–*Z* isomerization reaction mediated by the catalyst prior to the selective reduction of the *E* olefin.

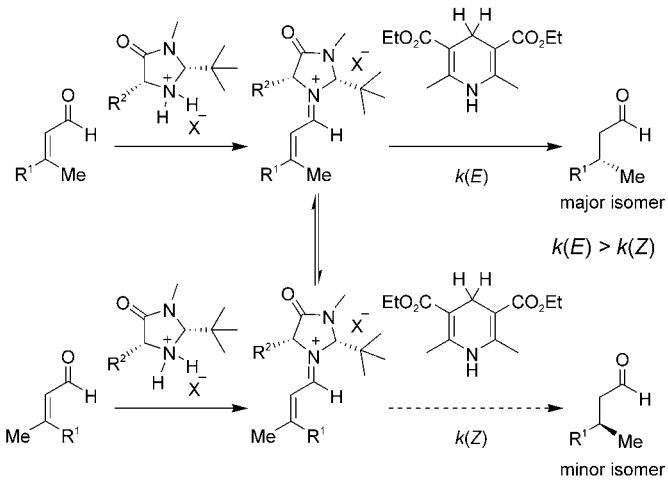


Scheme 3. Organocatalytic enantioselective transfer hydrogenation of α,β-unsaturated aldehydes. TIPS- = triisopropylsilyl.

In the report by List and co-workers, the trichloroacetate salt of a derivative of **5** (10 mol%) was used as catalyst in the reduction of different β,β-arylmethyl enals.[16] When the reaction was performed in dioxane at 13 °C using a slight excess of a modified version of **1** (1.02 equiv), the saturated aldehydes were obtained in high yields (77–90%) with enantioselectivities of up to 96%. In accordance with the results reported by MacMillan and co-workers, List's group observed similar enantioconvergence when the reduction was performed on mixtures of *E*/*Z* substrates. From a practical point of view, mixtures of *E*/*Z* isomers obtained from either Wittig-type or olefin metathesis reactions can be used directly in the reductions without initial separations. The reaction is believed to proceed by the mechanism depicted in Scheme 4.

The iminium ion is initially formed in a reaction between the imidazolidinone catalyst and the enal. Depending on the geometry of the starting olefin, *E*- and *Z*-configured ions are formed. The reason for the excellent stereoconvergence observed in the reaction is explained by a rapid interconversion of the two iminium ions prior to the rate-determining hydride attack from the dihydropyridine. The hydride ion is then selectively transferred to the *E*-configured olefin from the least sterically hindered face to produce the *S* isomer of the product.

In conclusion, List and MacMillan and their respective co-workers have opened a novel field in the area of reduction chemistry by demonstrating that asymmetric transfer-hydrogenation reactions of unsaturated aldehydes can be performed solely by organic catalysts. At its current stage, the reaction is limited to only aldehyde substrates, but it is reasonable to expect that the scope will be extended to also cover unsaturated ketones. In addition, lower catalyst loadings would make this reduction protocol even more attractive. However, the simplicity of the method in combination with the obtained high levels of enantioselectivity suggest that this method will become a standard



Scheme 4. Proposed mechanism for the organocatalytic enantioselective transfer hydrogenation of *E*/*Z* olefins.

technique for chemoselective asymmetric reductions of α,β-unsaturated aldehydes.

History of Chemistry

Arthur Eichengrün—Tribute to a Forgotten Chemist, Entrepreneur, and German Jew

*Elisabeth Vaupel**

Keywords:
aspirin · cellulose acetate · history of chemistry · pharmaceutical chemistry · plastics industry

The Jewish chemist and entrepreneur Arthur Eichengrün (1867–1949), a trailblazer in the German cellulose acetate industry, was widely known in professional circles and highly respected in both Imperial Germany and its successor, the Weimar Republic. The German Empire was indebted to him for numerous inventions and patents, some of which had considerable military value, especially during the First World War. One of the long-term consequences of the subsequent Nazi dictatorship in Germany is that Eichengrün's life and work have unjustly been forgotten. Newly examined sources from the archives of the Bayer corporation in Leverkusen and the district court in Charlottenburg, together with documents preserved by the Eichengrün family, have made it possible for the first time to reconstruct in detail key circumstances in the life of this versatile chemist—revealing a tragic story, but one illustrative of the times and important for historical research at several levels.[1]

Chemist—The Perfect Profession for a Social Climber

Arthur Eichengrün was born in 1867 into a Germany undergoing industrialization at a feverish pace. When in 1885 he elected to study chemistry it was clear that the chemical industry was on the verge of joining mechanical engineering and the electrical sector as one of the leading elements in the Imperial German economy. Especially the manufacturers of coal-tar and aniline dyes had enhanced the German chemical industry's international reputation. It was not at all unusual in this era that Eichengrün, scion of a Jewish cloth-manufacturing family from Aachen, would opt for training as a chemist.[2] A significant number of chemistry students in Imperial Germany toward the end of the 19th century were Jewish, many from families that owned textile mills, including Carl Liebermann (1842–1914) and Victor Meyer (1868–1897). Apparently it was widely appreciated that the study of chemistry, especially if directed toward chemical technology and dye chemistry, offered a singularly versatile educational platform for young people expecting someday to assume a role in the family firm. A chemical education opened for a Jew, in particular, an important door to full participation in the steady advance of the chemical industry in Germany. Despite the fact that Jews had relatively recently (1871) been granted full legal rights in all parts of the German Reich, establishing a career was still very difficult in many respects. Especially in chemistry it was possible through commercially attractive inventions and lucrative patents for one rapidly to amass a fortune, and through financial success to achieve an enviable social status.

Eichengrün decided upon training of a very practical sort and embarked on a professional career as a pharmaceutical chemist, later turning to photochemistry before finally establishing himself as a pioneer in plastics. He enrolled first at the technical institute in his hometown of Aachen, then transferred for a year to Berlin where he studied not only at the university—specifically under Prof. August Wilhelm Hofmann (1818–1892)—but also at the Charlottenburg Technical Institute. There he was taken under the wing of Carl Liebermann (1842–1914), a cousin of the painter Max Liebermann and himself a chemist with a Jewish family background. In the winter semester 1888/89 Eichengrün returned to Aachen to pursue a doctorate under Alfred Einhorn (1857–1917), who, like many of his favorite professors, was also a Jew. The young instructor Einhorn would later supervise the doctoral studies of Richard Willstätter (1872–1942), but already he was one of the rising stars in the scientific firmament. His research on the structure of cocaine, the first local anesthetic adopted by the medical profession, had, for example, attracted a considerable amount of attention.[3] Cocaine was introduced in this context in 1884 by Karl Koller (1857–1944) at the suggestion of Sigmund Freud (1856–1939), and it had opened up exciting new prospects in surgery. In particular, cocaine made it possible to perform painless operations on the eye.[4] Until 1899, technical institutes were not authorized to confer doctoral degrees, so Eichengrün could not submit his dissertation in Aachen directly but was forced instead to locate a university willing to accept the work. Einhorn helped him establish contact with Otto Fischer (1852–1932) at Erlangen, under whom Eichengrün was awarded a doctoral degree in 1890 as an "external candidate".[5] With this achievement behind him—a highly significant one in the title-hungry social world of Wilhelminic Germany—he had reached the first rung

on the social ladder, a challenging obstacle for a Jew.

In his doctoral work with Einhorn, which is noteworthy in the history of pharmacy especially for including a synthesis of the local anesthetic Novocaine, Eichengrün was pointing the way toward a new subdiscipline that was only beginning to take shape: pharmaceutical chemistry. He therefore launched his career not with one of the dye works, as might have been anticipated, but rather in the pharmaceutical industry. The first position he accepted was with the firm of C. H. Boehringer & Son in Ingelheim am Rhein, where in 1892 he was assigned the task of establishing a facility for the isolation and purification of cocaine. Cocaine preparations had become extremely interesting from an economic standpoint with the alkaloid's debut as a local anesthetic. Only a year later Eichengrün moved on, however, joining up successively with two small pharmaceutical concerns that no longer exist. The first was the recently (1888) established Balzer & Co. in Grünau near Berlin, which was in the hands of Liebermann's family, shortly thereafter, the firm of Dr. L. C. Marquardt in Beuel, a highly regarded manufacturer since 1846 of both pharmaceutical products and chemicals. The amateurish approach both companies took to research and marketing so disconcerted him, however, that Eichengrün made up his mind to seek a place instead with a large company. On January 10, 1896, he took a position with the Farbenfabrik Bayer, formerly Friedrich Bayer & Co., in Elberfeld, the forerunner of today's massive Bayer complex in Leverkusen (Figure 1). Bayer had already begun to evolve from a classical dye works into a successful producer of pharmaceuticals on the strength of a novel pain reliever, Phenacetin, introduced in 1887.[6] Eichengrün was the first chemist Bayer engaged to work exclusively in the pharmaceuticals area. He was entrusted with the further development of the new pharmaceutical research division, which in terms of personnel was already undergoing rapid expansion (Figure 2). Eichengrün's strategy for devising new drugs was as ingenious as it was simple: he kept close watch on the pharmaceutical market, noting what preparations competitors like Hoechst, Knoll, Merck, Schering, and others were introducing, at the same time monitoring the various ailments and classes of compounds in which they displayed interest.[7] He quickly latched onto promising advances, including the quest for better disinfectants during a period that witnessed the flourishing of bacteriology as well as development of new medications for treatment of the then rampant sexually transmitted diseases. Diligence, systematic research within a restricted field, sometimes the barely legitimate imitation from a patent standpoint of a competitor's product, and a healthy measure of that indispensable commodity, luck—all these played significant roles in Eichengrün's striking success as a pharmaceutical chemist.

A Pharmaceutical Patent Makes Eichengrün Rich

Among the many drugs developed and subsequently marketed by Bayer during Eichengrün's tenure there, two major successes warrant special mention. The first is the silver protein formulation Protargol (Figure 3), a disinfectant introduced for therapeutic use in 1897. This became the standard agent for treating gonorrhea (known colloquially as "tripper" ; English slang: "the clap"), at the time the most prevalent of the sexually transmitted diseases.[8] Protargol quickly replaced for this purpose the corrosive silver nitrate, and remained the classic treatment for gonorrhea for more than fifty years until the advent of sulfonamides and penicillin. With huge demand both at home and abroad, including an enormous market within the military, royalties from Protargol alone made Eichengrün a wealthy man, his social ascent of course benefiting from this financial prominence. According to the terms of his contract he

was entitled to 5% of the net profits from any patented product of which he was the sole developer, including Protargol. No other pharmaceutical discovery rewarded him as richly as Protargol. His royalties exclusively from this medication—far from the only one he devised—amounted in the year 1907 to the fantastic sum of 13309 marks, followed by 11811 marks in 1908 and 13687 marks in 1909. That was equivalent to more than twice his 1896 annual starting salary of 5000 marks, which increased by 500 marks a year such that it reached 10000 marks per annum by the time he left Bayer in 1908.[9] By way of comparison, a teacher in those days earned between 1200 and 1500 marks a year, a factory worker roughly 50 marks a month.

Eichengrün, the Intellectual Father of Aspirin

Eichengrün's name is also associated with Bayer's world-famous signature drug, the pain reliever Aspirin, even though synthesis of the active ingredient, acetylsalicylic acid, (on August 10, 1897) was not conducted by Eichengrün himself, but by his laboratory associate Felix Hoffmann (1868–1946).[10] Nevertheless, Eichengrün was probably involved in the project, since the synthesis and marketing of Aspirin certainly was the work of a team, not a single person. The inspiration behind attempting to modify the characteristics of the well-known salicylic acid through acetylation, in the hope of creating a substance more readily tolerated, probably stemmed from Eichengrün. It was actually not an especially original idea, because at that time acetylation was a favorite derivatization technique and virtually a matter of routine, a step that had already led to a host of valuable medicinal agents. For example, the important antipyretic agent Antifebrin, from Hoechst, was obtained by the acetylation of aniline. Also, in 1887 Bayer had introduced the successful antipyretic Phenacetin, prepared by acetylation of *p*-aminophenetidine, and in 1897, shortly before the key Aspirin synthesis, Bayer began supplying heroin, similarly acquired through an acetylation.[11]

Eichengrün maintained in later years—first rather casually in 1930 in the "Reichshandbuch der deutschen Gesellschaft" ("Imperial Handbook of German Society") and then quite emphatically in 1949 in the journal "Die Pharmazie"—that he had been the co-discoverer of Aspirin along with Hoffmann.[12] These claims, promulgated decades after the drug's introduction,[13] repeatedly stirred up controversy, most recently in 1999 when the British historian of pharmacy Walter Sneader confirmed Eichengrün's role in the development of the Aspirin.[14] Research in the Bayer archives has shown that Bayer's assignment of sole rights of discovery to Hoffmann was based strictly on the available documentary evidence. That the synthesis of Aspirin was in all likelihood a team effort, so in fairness the party responsible for suggesting the decisive synthetic strategy should also be identified—this argument never came into play simply because there were no relevant records to support it. Moreover, a similar lack of documentary evidence meant that nothing came of Eichengrün's further allegation that, had he not intervened, the Bayer pharmacologist Heinrich Dreser (1860–1924) would have prevented clinical testing of acetylsalicylic acid on the grounds of its supposed coronary toxicity, and only through his personal efforts to counter Dreser's rejective stance was the drug ever marketed. In summary, Eichengrün's contention that he was a co-discoverer of Aspirin, while plausible, is nowhere supported in writing.

Bayer had Eichengrün to thank not only for his role in the expansion of the pharmaceutical research division, but also for the company's diversification in the photochemical direction, a rather belated move (not further considered here), at least when compared with analogous efforts on the part of other chemical manufacturers.[15] Highlights from this phase of Eichengrün's career include the synthesis of the photographic developer Edinol and the first preparation starting from cellulose acetate of a nonflammable safety film for movies, which we revisit in some detail below. During his years with Bayer, Eichengrün submitted a total of 35 patent applications.[16] There can be no argument about his having been a versatile, inventive, bustling chemist with a sure instinct for promising research topics as well as marketable products. In reviewing his personnel files in the Bayer archives one is also struck by his business acumen as reflected in the close watch Eichengrün kept over his personal interests in negotiating with his employer.

Eichengrün's Battle for the Future of Cellulose Acetate

A crucial factor in Eichengrün's ensuing career was his work starting in 1900 with cellulose acetate, originally with the goal of providing Bayer with a foothold in artificial silk production. From that point on he increasingly fell under the spell of this substance, which although first prepared in 1865 by Paul Schützenberger (1829–1897) was largely ignored until the turn of the century.[17] In the years that followed, Eichengrün established a profile as a practitioner and empiricist dedicated wholly to the exploitation of cellulose acetate chemistry. He made no contribution whatsoever to the scientific study of cellulose itself, which went on during the 1920s especially in the laboratories of Hermann Staudinger (1881–1965) and at the Kaiser Wilhelm Institute for Fibrous Materials, founded in 1920 in Berlin-Dahlem.

Industrial interest in cellulose acetate was first kindled in 1904/05 when the American George Miles (1868–1939) and, independently, Arthur Eichengrün succeeded in preparing an acetone-soluble, plasticizable form of the material, the so-called secondary acetate, through partial saponification of the chloroform-soluble triacetate ("primary acetate"). Bayer began marketing this acetone-soluble cellulose acetate in 1905 under the tradename Cellit.[18]

Although Eichengrün actively searched for potential applications for Cellit, in every conceivable direction and always making sure that he secured appropriate patent protection, industrial-scale development posed serious problems for many years. Eichengrün's initial idea was to promote cellulose acetate as a replacement for the highly flammable cellulose nitrate in its principal applications. By contrast, the acetate could be induced to burn only with difficulty, suggesting that there should be a huge market for Cellit in the manufacture of plastics, transparent sheeting, photographic film, fibers, and lacquers. The basic idea clearly demonstrated foresight, but Eichengrün failed to reckon with what proved to be a very lengthy period of development attributable to the fact that, despite apparent similarities between cellulose nitrate and cellulose acetate, their chemical behaviors differed greatly. It was thus not possible to adapt for cellulose acetate the methods most commonly employed in cellulose nitrate processing (such as the choice of solvent, plasticizer, etc.).

A Laborious Initiation through Acetate Rayon

Eichengrün and his co-workers applied in 1904 for a patent for the dry spinning of acetate rayon. In 1907, working on the basis of this patent, the Kunstseidenfabrik Jülich attempted to initiate industrial-scale production of such a material. The project was quickly abandoned, however, despite encouraging results: the expenses were simply too great, especially given the high cost of acetic acid and problems associated with its recovery. Another drawback was the fact that no way could be found to dye the resulting acetate rayon using the coloring agents available at that time.

A commercially viable acetate rayon made its appearance only much later, in 1920, in conjunction with development by René Clavel (1886–1969), a chemist and industrialist from Basel, of the first acetate dyes. The late onset of acetate rayon production has an interesting historical origin: During the First World War, cellulose acetate was utilized extensively in the preparation of airplane lacquer (as elaborated below). When the war ended and the market for this critical defense commodity suddenly collapsed, it was essential that new products be sought to take advantage of existing manufacturing capacity. A determined quest for promising applications was thus initiated. It was this call for innovation that provided the necessary incentive for renewed attempts to commercialize acetate rayon.[19]

Visions of a Nonflammable Movie Film

Eichengrün was confident early on that his hard-to-ignite cellulose acetate could eventually evolve into a replacement for conventional nitrocellulose-based movie films, which were so highly flammable that they had been responsible for numerous theater fires. He expended considerable effort on this seminal idea during a period when he was in charge of the Bayer photo works in Düsseldorf, but his attempts were thwarted by the limited mechanical stability of cellulose acetate film relative to the nitrocellulose analogue, coupled with its greater sensitivity to water, higher cost, and poor retention of applied photochemical layers (Figure 4).[20] As in the case of acetate rayon, and for similar reasons, success in preparing a safety film based on cellulose acetate came only after the First World War, by which time Eichengrün was no longer engaged with the problem. Indeed, universal adoption of film of this type occurred only after the Second World War.[21]

In recognizing the great potential inherent in cellulose acetate, Eichengrün was years ahead of his time. Despite the problems encountered with both acetate rayon fabric and the elusive movie films he remained certain that the future for cellulose acetate was bright,

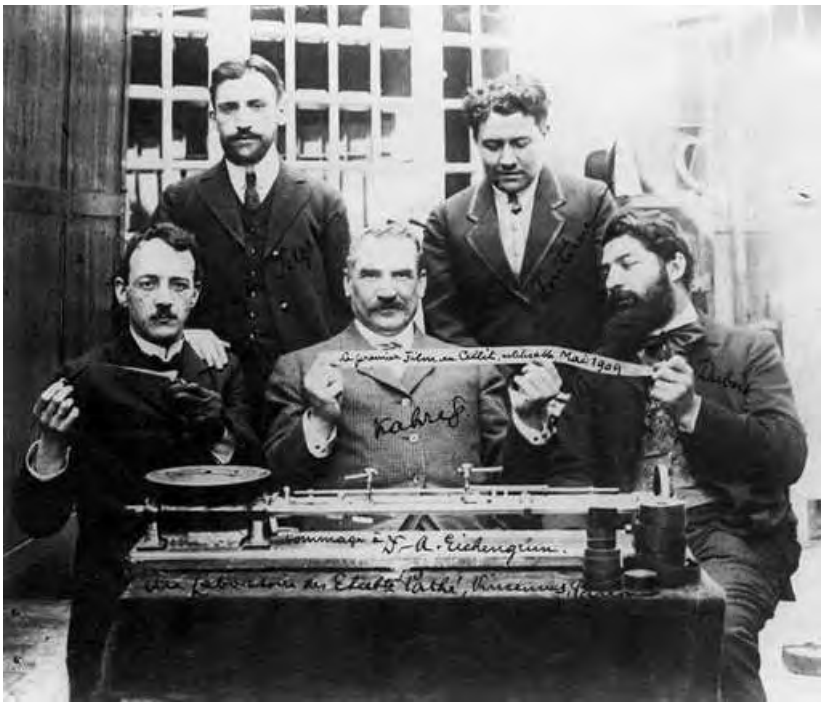

Figure 4. Tribute to Eichengrün, inventor of the first nonflammable movie film made from cellulose acetate (Cellit), which was first successfully employed in 1909 by the film company Pathé Fréres in Vincennes near Paris. Photo: Bayer-Archiv, Leverkusen.

and in fact he was critical of Bayer for not being willing to stay the course through the necessarily long phase of development, when costs would of course greatly exceed benefits. His professional frustrations were further complicated by private issues: the physically attractive Eichengrün had since 1894 been married to an American, Elizabeth Fechheimer, and was the father of four children, but he had in the meantime become involved with a Dutch woman, Madeleine Bickenbach née Mijnssen, who also was married. Even though in June of 1905 he wedded his new love, and proceeded to have two additional children with her, his turbulent private life had created a number of enemies for him in puritanical Elberfeld. The accumulating professional and personal problems culminated in his leaving Bayer at the end of 1908. Thanks to the formidable wealth he had amassed he was able to establish himself independently in Berlin with a private laboratory of his own. There he concentrated exclusively on cellulose acetate and its potential applications, still on the best of terms with his former employer. By 1915 Eichengrün's private laboratory had already evolved into what amounted to a small chemical plant with a staff of 14, and in 1919 the company, now boasting nearly 70 employees, was renamed "Cellon-Werke Dr. Arthur Eichengrün" (Figure 5).[22]

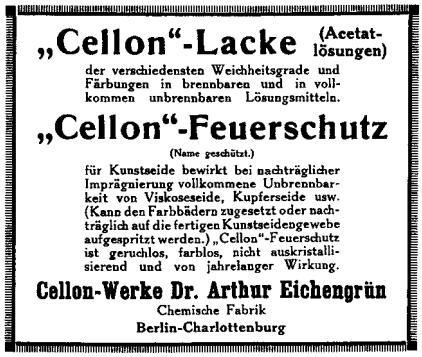

Figure 5. Advertisement for the "Cellon-Werke Dr. Arthur Eichengrün", which existed from 1919 to 1933. From: H. Stadlinger, *Das Kunstseiden-Taschenbuch*, 2nd ed., Finanz-Verlag GmbH, Berlin, **1930**, preceding p. 415.

Lacquers and Plastics as Critical War Materials

The astonishing metamorphosis of a one-man laboratory into a flourishing midsized enterprise, especially during the First World War, can be attributed above all to two of Eichengrün's inventions: cellulose-acetate lacquer and a combustion-resistant plastic, also from cellulose acetate, known as Cellon.[23] In contrast to acetate rayon and the safety film for movies, where developmental work was interrupted by the war and thus delayed for several years, the war actually served as a remarkable stimulus to the introduction of cellulose acetate in lacquers and plastics.

In the early days of aviation, airplane wings, as well as zeppelins, were covered with a linen or cotton fabric that was made water-repellant, gas-tight, and resistant to both mechanical and chemical degradation by impregnation with rubber. In 1909 Eichengrün recognized the advantages cellulose acetate lacquer might offer in this application. The lacquers he subsequently prepared not only saved weight, but they also circumvented the demand for rubber, an especially scarce commodity during wartime because it had to be imported from abroad. In the course of drying, fabric coverings that had been "cellonized" became tight as a drum, which also made the aircraft more streamlined.[24] After 1910 the rapidly expanding aviation industry became the principal consumer of cellulose acetate lacquers. Eichengrün arranged for their manufacture by the Berlin firm of Dr. Quittner & Co. using his patented process, an arrangement that proved especially lucrative during the war years. Apart from the air force, another major customer for tensioning lacquers was the navy with its fleet of zeppelins (Figure 6). Had the war not ended in 1918, Eichengrün would have been the beneficiary of yet another military contract: for the manufacture of cellulose acetate impregnated clothing as protection against the skin corrosion inflicted by the mustard gas "Lost".

Eichengrün profited from military contracts during the First World War in other contexts as well. As previously noted, cellulose acetate was useful not only in tensioning lacquers but also for plastics manufacture. The most important product of this type was known by the trade name Cellon. It had been produced since 1911 according to Eichengrün's patented method through a license agreement with the Rheinisch-Westfälische Sprengstoff AG, later known as the Dynamit-Nobel-Actien-Gesellschaft but originally Alfred Nobel & Co., located in Troisdorf near Cologne. A substantial market for this transparent, nonflammable, shatterproof plastic developed in conjunction with goggles for aviators and gas masks. The latter were in especially great demand in consequence of gas warfare. Before the advent of acrylic glass Cellon was also used in the fabrication of windows for automobiles, zeppelins, aircraft cockpits, and naval vessels.[25] For a time during the First World War there was even sporadic interest in the idea of exploiting Cellon's transparency to create a transparent airplane, which in the sky would be nearly invisible. Initially a top-secret project, the notion was eventually conceded to be technologically utopian (Figure 7).

Eichengrün's Cellon factories survived Germany's defeat in the war relatively unscathed and were not constrained by the restrictions of the Versailles Treaty, which had a devastating effect on the aircraft industry in general. This favorable outcome could be attrib-

Figure 7. A nearly invisible military aircraft with a Cellon covering, together with a plane covered as usual with cloth. The "*transparent airplane characterized by a weather-resistant covering consisting of roughly 1/10 cellulose derivative and 9/10 camphor substitute and gelatinizing agent*" was patented during World War I, but remained an object of technical utopia. Photo: Bayer-Archiv, Leverkusen.

uted in large measure to the creative entrepreneur's talent for never losing sight of civil applications for his inventions. Most of his patents were employed under licensing agreements. In his own facilities he produced only cellulose acetate lacquer, for which he had captured a significant commercial market through collaboration with subcontractors working for Berlin's electrical engineering firms, especially AEG. There was a strong demand for insulating lacquer, developed in response to wartime shortages of rubber and guttapercha.[26] Cellulose acetate also found a niche in several other relatively crisis-proof applications, such as fireproofing impregnation and substitution for plaster of Paris in the preparation of casts and related bandaging materials employed for immobilizing broken bones.[27]

Injection Molding of Thermoplastic Materials

As noted previously, Eichengrün worked closely during the period of the Weimar Republic with the Rheinisch-Westfälische-Sprengstoff AG, which had introduced to the market his plastic known as Cellon. The company actually began as a producer of nitrocellulose, primarily for gun cotton, but because of fluctuating demand for the latter (high only in wartime) they had since 1903 also been processing the material into celluloid. Gun-cotton production was abandoned entirely in 1919 in compliance with the terms of the Versailles Treaty, at which point the entire powder factory was refitted for the manufacture of plastics.[28] The company's product spectrum was limited essentially to celluloid and Cellon. This change in orientation, dictated by political circumstances, created in Germany a boom in the infant synthetic materials sector. It is thus no coincidence that the year 1919 saw Eichengrün develop a new type of synthetic, one based on cellulose acetate modified by plasticizers. This became the first thermoplastic material in synthetics history amenable to injection molding. A corresponding patent application was submitted in the same year. The preparation was marketed initially under the trade name Lonarit, but this was changed to Trolit after Eichengrün's patent was acquired by the Rheinisch-Westfälische-Sprengstoff AG.[29]

Eichengrün was responsible not only for the ground-breaking development of the first injection-molding substrate with plastic characteristics, but also for the associated processing technology. In 1919 he patented a "*device for the fabrication of moldings from cellulose esters in which the heated mass is forced under pressure through channels, with the distinctive feature that the compression mold adheres to the channel wall, within which the hot-fluid mass then solidifies to become the molded object*".[30] In other words, Eichengrün developed the first plunger-type injection-molding machine for thermoplastic materials. Based on the two Eichengrün patents referred to above, the firm of Eckert & Ziegler in Cologne became the first manufacturer of injection-molding equipment. In 1926 Eckert & Ziegler became a subsidiary of the Rheinisch-Westfälische-Sprengstoff AG, which is therefore regarded as the industrial trailblazer in the injection molding of plastics.[31] Eichengrün's achievement in perfecting both a new processing material and the associated manufacturing technology made possible the mass-production of various plastic articles on the basis of cellulose acetate, despite the fact that injection molding was initially constrained to small items in the range of 10 to 25 grams. Cellulose acetate quickly displaced celluloid in many applications, and improvements in injection-molding technology soon made it possible to produce objects in the 250–300-gram range. Injection-molded articles established an especially firm foothold in the rapidly developing electrical engineering industry, which encompassed not only civilian applications but later under the Third Reich also played a major role in arms manufacture.

"Aryanization" of the Cellon-Werke Dr. Arthur Eichengrün

The National Socialist party assumed power in Germany in January 1933. By March of that year Eichengrün had already been forced by the "Kampfbund des gewerblichen Mittelstandes" ("Fighting Union of the Industrial Middle Class") to hand over management of his company to an Aryan trustee. The Kampfbund was infamous for its especially virulent antisemitism. In 1933 (i.e.,

remarkably early) he also modified the corporate structure of the firm, transforming it into a "GmbH": the Cellon-Werke GmbH (Figure 8).[32] In the process, the Jewish-sounding name "Eichengrün" thus disappeared entirely so the enterprise would appear from the outside to be safely Aryan—a deftly arranged bit of subterfuge with the objective of keeping the firm out of Nazi hands. Eichengrün sold 51% of the company to business associates classed unambiguously as Aryans, retaining for himself the residual 49%. A board of directors made up of influential persons, some of them members of the NSDAP, was expected to shield the operation from further trespass on the part of the state.

Figure 8. Advertisement for the Cellon company after its conversion into a GmbH. Eichengrün's name no longer appears (cf. Figure 5). From: K. Mienes, *Celluloseester und Celluloseäther unter besonderer Berücksichtigung der Benzylcellulose*, Chem.-techn. Verlag Dr. Bodenbender, Berlin, **1934**, p. A VI.

Later, Eichengrün began to receive threats that after December 31, 1937 the Cellon-Werke GmbH would no longer be eligible for government contracts unless it were completely transferred into Aryan hands. Such a ban would have been catastrophic, since in the meantime the Reichsbahn (German Railroad) had become its principal client, accounting for up to 90% of total sales. In desperation he finally disposed of his remaining share in the business. The signed sales agreement, executed on January 12, 1938, predated by nine months the horrible November pogrom.[33] Thanks to this timely and rigorous Aryanization of what had been a Jewish firm, Eichengrün was able to negotiate for himself comparatively favorable terms, and also hand-select a sympathetic set of business partners. Only after November 9, 1938 did a Jew's ability to maneuver in situations like this essentially disappear altogether. Looking back, Eichengrün nevertheless recognized that he could have arranged a significantly better set of conditions had he acted even sooner: *"I would have been much better off if, when first ordered in the spring of 1933 to liquidate the Cellon works and leave them in Aryan hands, I had at once complied and stepped aside."*[34]

The Cellon-Werke GmbH was purchased by the Chemische Fabrik Dr. Joachim Wiernik & Co. AG, situated in Berlin-Waidmannslust, which on January 1, 1940 acquired the new name Diwag Chemische Fabriken AG.[35] Eichengrün maintained that Diwag always fulfilled its stated commitments "*in the most loyal way*", even though "*it was not possible to follow through*" on his aspirations to "*continue the pursuit of inventive activities in the framework of the company and with its support*".[36] Eichengrün managed to ensure, however, that he would be forced to transfer to Diwag only a portion of his patents, procedures, production techniques, and formulations. In addition, Diwag agreed to retain all personnel employed longer than ten years, including Eichengrün's son Edgar from his first marriage, who according to the terms of the Nuremberg Laws was considered only half-Jewish and, in contrast to his siblings, had foregone emigration. Eichengrün utilized his remaining freedom of action to safeguard from the National Socialists to the best of his ability the 254922 reichsmarks he received for selling the business. For example, he arranged to have Diwag set aside 92% of the money to be dispensed in the form of annual payments extending through 1955.[37] But despite these precaution his windfall quickly shrank. Commissions and legal and notary fees alone swallowed up 16000 reichsmarks. Additional outlays were required to cover compulsory tariffs imposed on all Jewish citizens in the wake of the pogrom of November 9, 1938. The sum of 125000 reichsmarks in the form of a "Jewish property tax" fell due in 1939. This particular levy, initially set at 20% of assets, was later increased to 25%. In January 1940 he was forced to pay an additional 27000 reichsmarks as an "emigrant tax for the Jewish congregation of Berlin", even though Eichengrün had officially declared his withdrawal from the Jewish community as early as September 20, 1894 and no longer regarded himself a member of the Jewish faith. Finally, in October 1940, he was obligated to surrender 83000 reichsmarks in "flight from the Reich tax". The latter was to be deposited into a blocked account, from which it could be confiscated by the tax authorities if Eichengrün were ever to leave the country. This actually transpired when he was deported to the Theresienstadt concentration camp, which technically classified as "flight" to Czechoslovakia. In other words, he was compelled to finance out of his own pocket what amounted to his kidnapping![38]

In 1933 when the Cellon-Werke was transformed into a GmbH, Eichengrün skillfully exploited a legal loophole and arranged to isolate and retain for himself a small private office and research laboratory under the name "Cellon-Werke Dr. Arthur Eichengrün". From here he supervised his remaining patents and licenses, dedicating all his consulting activities to Diwag. Put candidly, this entailed "armaments-related experiments in the interest of both the high command and the navy".[39] Eichengrün and his wife lived off royalties from the obviously numerous patents that remained his. Nevertheless, even the private office and laboratory eventually fell under National Socialist scrutiny. Using the argument that his firm was ineligible for registration under the applicable commercial statutes since it was engaged only in the exploitation of patent rights and asset administration, and neither manufactured nor marketed any products, the "Cellon-Werke Dr. Arthur Eichengrün" was expunged from the commercial register on February 3, 1942.[40]

Eichengrün failed to recognize until roughly 1938/39 how precarious his situation had become. One is left to speculate about why this might have been the case: perhaps this passionate tinkerer and inventor simply succeeded

in deluding himself, still possible because after he reorganized his firm into a GmbH in 1933 and disposed of it entirely in 1938 he was allowed to proceed largely undisturbed in his research and patent-application activities. It could also be that he believed himself immune because of the military significance of his discoveries, in conjunction with personal contacts he enjoyed with various ministries and high-ranking personalities—including his immediate neighbor, Hermann Göring (1893–1946)—and his fruitful collaboration with Diwag, a company perceived as important from a military standpoint.[41] Eichengrün was clever enough to create the impression that he and his private research laboratory were themselves indispensable on the grounds of defense contracts and various patents crucial to the military, such as that for the Cellon sheathing the navy relied on for ship propellers.[42] Despite having to pay the exorbitant Jewish property tax mentioned above, Eichengrün continued to do relatively well from a financial standpoint. Soon after November 9, 1938 he transferred all his rights from the corporate sales agreement with Diwag to his third wife, the ("Aryan") Lucie Bartsch: "*Therefore, acting on advice from lawyers, notaries, and industrialists, shortly after November 9, 1938 I conveyed my rights from the Wiernik contracts … to my wife, and a year later in Munich took the same steps in notarized form with respect to license income from various other contracts, along with all my household effects, including personal collections. … In any event, through these donations to my wife, my entire income, apart from a single contract with the Dynamit Nobel A.G., devolved upon my wife and thus came into Aryan possession and—insofar as one could foresee at the time—safe hands.*"[43]

The ever-increasing pressure of chicanery and harassment was not enough to induce Eichengrün to emigrate, even though he could have afforded to do so and most of the children from his first and second marriages had already made this choice. The staunchly apolitical Eichengrün evidently refused quite consciously to be intimidated by the Nazis. His compulsive self-assertiveness was presumably undergirded by the fact that monetary policies of the National Socialist state made emigration extremely unattractive, as he could have transferred only a fraction of his wealth abroad. But prosperity was for Eichengrün a source of great pride, a symbol of the social status he had achieved and one that could be put on display. He took pleasure in the fact that his wealth made possible a luxurious lifestyle and the acquisition of a valuable art collection (albeit one reflecting a rather conventional taste).[44] His preoccupation with social prestige was evident from the outset in a weakness for aristocratic addresses. He had long been drawn toward places where celebrities congregated. Even in the days when he worked for Bayer he resided in the same neighborhood as his superior Carl Duisberg (1861–1935), and as a young, successful Berlin industrialist he became the owner of a gorgeous villa in Berlin-Grunewald, although he was forced to sell it later when inflation ran rampant. In 1915 he acquired a vacation home on the Obersalzberg, but this too had to be sold in 1932 on account of increasingly intolerable anti-Semitic badgering.[45] After 1928 Eichengrün lived in an elegant house at Kaiserdamm 34 in Charlottenburg. In 1932 a new neighbor moved into the apartment below his: Hermann Göring, Speaker of the Reichstag (the German Parliament). In April 1933 the latter was appointed Prime Minister of Prussia, and in the following month he took over the new Imperial Aviation Ministry, from which position, in March 1935, he assumed supreme command of the Air Force, quickly ensuring its expansion. One can only speculate that, given their involvement in aviation, Eichengrün and Göring would have discussed their common interests. Both also had a fondness for luxurious surroundings, and their art collections might well have constituted another point of contact. In 1939 Göring was subjected to public pressure from comrades in the party because of what they perceived to be his unbearable domestic living situation. The result was that Eichengrün had to give up the Charlottenburg residence. After this expulsion Eichengrün was nevertheless able to afford moving for a year and a half (in 1940/41) to Munich, known as the "Capital of the [Nazi] Movement"—albeit after the "surrender of 5% of his annual income to an agency in Munich"—where he and his wife resided in the elegant Regina Palasthotel.[46] In 1941 he returned to Berlin, ultimately occupying a moderate apartment on the Pommersche Strasse in Wilmersdorf, a neighborhood that at the time was characterized by a conspicuously high proportion of Jewish residents, and where the family of his son Edgar also lived.

The ever-increasing discrimination, which in turn led to social isolation and exclusion from scientific, commercial, and civil organizations, was especially hard on someone as concerned with social acceptance as Eichengrün. "*The oppression and gradual segregation from the world of the living, and above all the transformation of good friends and scientific acquaintances into utterly indifferent and in some cases hostile figures, as well as the things one was forced to suffer in everyday life, cannot be depicted in words*", he wrote in retrospect.[47] He regarded the state's intrusion into his opulent lifestyle as especially discriminating, namely the confiscation of what had become for him cherished status symbols. For example, since September 20, 1939 it had been illegal for Jews to possess radio; they would simply be appropriated by the state with no compensation whatsoever, so Eichengrün was forced to relinquish his costly and beloved Telefunken receiver. He was equally bitter about the obligatory sale of his eight-cylinder Ford—he who had once been a proud member of the Automobile Club of Germany. There was really no choice, because since the end of 1938 Jews were not allowed to own or operate motor vehicles.[48] In the past he had also been a member of the prestigious Motor Yacht Club of Germany, but again he was compelled to sell his stately motor vessel with its American motor.

Eichengrün was deeply alarmed when he learned of the first deportations of Jewish citizens from Baden and the Palatinate under a decree issued on October 15, 1940. Report of this catastrophe triggered desperate efforts on his part to counter his escalating loss of rights on account of his "Jewishness". In a traumatic letter he appealed to Dr. Paul Müller (1876–1945), managing director of Dynamit Nobel in Troisdorf,

the company that produced his Cellon plastic (a substance of critical importance to the military) and was exploiting as well 15 additional Eichengrün patents relevant to armaments manufacture under the Third Reich, above all ones concerning the injection-molding process and related substrates. Referring explicitly to both earlier and current personal inventions with wartime relevance, he pleaded for support of his application for recognition under the terms of the Nuremberg Laws as a "citizen" despite his Jewish heritage. Quite remarkably, exceptions were sometimes granted to provisions of the German Nationality Act of September 15, 1935 so long as these were seen to be "in the interest of the public at large".[49] Full-blooded Jews or others practicing Judaism ("Geltungsjuden") could therefore under certain circumstances be declared "first-degree half-castes" or even "German-blooded". In seeking exemption from the Nationality Act, an applicant would normally attempt to demonstrate either a special set of skills and significance or else meritorious service on behalf of the fatherland, appending references solicited from persons or institutions of lofty stature and reputation within the Nazi state. What follow are several quotes (in translation) selected from Eichengrün's February 1941 letter to Paul Müller. For purposes of clarity it is worth noting that at this point Eichengrün had already been expelled from his residence on the Kaiserdamm in Charlottenburg and was living in the Regina Palasthotel in Munich:

"*As you know, I have been living here in Munich for the past year and a half. … I was supposed to be expelled from the hotel some time ago; the corresponding order from the local 'District Office for Aryanization' [Gaustelle für Arisierung] was subsequently withdrawn, however, and I have stayed here unmolested. … We recently learned in confidence from an absolutely reliable source that in the very near future the same sort of action will be initiated in Munich as … in Baden. My wife has succeeded in presenting the situation to a highly placed party official and supplying him above all with information regarding my contributions to commerce, aviation, and the four-year plan, and to the acquisition of foreign currency, as well as my current activities. The gentleman displayed increasing interest, and offered the following advice: 'Travel to Berlin and arrange to contact responsible parties in both the Ministry of Aviation and the Ministry of Economics. But first secure letters or testimonials from leading figures in industry, in particular from I.G. [Farben] if possible. These letters must state that Dr. E. in nearly 50 years of service has achieved a record of exceptional merit in the most diverse aspects of industrial chemistry, that the author of the letter is familiar with the benefits Dr. E.'s inventions have brought the German economy, and that one also anticipates additional benefits from his recent work. German industry would be incapable of understanding it if such a man were to be pulled from his path, and sees it of the greatest importance that he be permitted to pursue without hindrance or limitations his current projects, which have already led to several patent applications and are in some cases already undergoing tests in industrial settings.' … This is almost word-for-word the view expressed by the high party official in question. It follows that the sword of Damocles hovering over my head can only be restrained by the intervention of industry, in part through reference to the value and somewhat unusual current state of development of my inventions (e.g., acetate rayon, the injection-molding process, Cellit) and in part—and apparently this is regarded as extremely important—to the work I am pursuing at the moment and successes it may produce. … I therefore believe it would not be a wasted effort if you were to direct such a letter—which must of course contain references to applications of Cellon for the army and to the significance of the injection-molding technique (for the four-year plan)—to the Ministry of Economics. … I hope you will not be offended by my calling upon you in an unusual matter like this. I know that it is not appreciated when one deals in a friendly way with someone like me, and I realize that a great many in industry and science who once knew and valued me would take offense at such an unreasonable request. But you have always displayed such a friendly disposition toward me that I am confident you will help me. This has to do not simply with a courtesy or an ordinary favor for a friend, but rather with actual life or death. Because I will never allow myself to be carried away alive, so if this solitary open passageway involving a letter of exemption is closed off, I am left only with the bitter end.*"[50]

Eichengrün's petition to be exempted from the provisions of the German Nationality Act, had it been approved, would at least have conferred upon him the status of "provisional citizen" (i.e., that of a "Jewish half-caste"), and in an ideal case even that of full citizenship (i.e., one of "German blood"), thereby screening him from further persecution. But it was denied, even though leading representatives of IG Farben interceded on his behalf. Eichengrün remained a Jew in the sense of the Nuremberg Laws, and thus retained the inferior status of a "German national", who was denied essential rights of citizenship.

Denunciation and Deportation to Theresienstadt

In August 1941 Eichengrün submitted another application for the granting of an exception. It had to do with the status of his marriage to his third wife, Lucie Bartsch, an "Aryan". This time Eichengrün was more fortunate in his quest. The Minister of the Interior recognized his June 4, 1942 marriage as "privileged", even though being childless it would actually have qualified only as a simple "mixed marriage" under the laws of the National Socialists.[51] This "privileged mixed marriage" provided Eichengrün with a certain, although shaky, measure of protection; in most cases the Jewish partner escaped deportation.

After the autumn of 1942 the situation for mixed German–Jewish families and half-castes deteriorated dramatically. Early in 1943 threats were issued that Jewish partners in German–Jewish mixed marriages were also to be deported and included in the "final solution".[52] This applied especially to Berlin, the city with the most people in that category. Instead of evacuating all Jews with German partners as a single group, the tactic adopted was to charge each individual Jew in a mixed marriage insofar as possible with an alleged

breach of the law; given the hundreds of interdictions to which Jews were subject it was not difficult to identify some piece of trivia that could be exaggerated into a crime. The person in question was then taken into "protective custody" and deported to a concentration camp. In this final stage of persecution of the Jews, Eichengrün, supposedly protected by his "privileged mixed marriage", also became one of the victims of the Nazi regime. In October 1942 Eichengrün was denounced before the prosecutor's office by Dr. Georg Klauer, at that time Director of the German Patent Office and known for his rigorous application of anti-Semitic law. On the basis of Klauer's denunciation he was accused of submitting two letters to the Patent Office, dated December 1941 and January 1942, that lacked the obligatory name "Israel" in the signature, a label which had been mandatory for Jews since January 1, 1939. Through an "embezzled signature" he had thus "fraudulently attempted to accrue the honors conferred upon an inventor".[53] Eichengrün protested that neither case had involved a personal signature, but rather the official designation for his private office and laboratory, "Cellon-Werke Dr. Arthur Eichengrün", which continued to be listed in the official commercial registry until February 2, 1942. Company names were explicitly excluded from the requirement of the obligatory name "Israel", but he was nevertheless arrested, ordered to serve a prison sentence, and deported in May 1944 to Theresienstadt. His wife actually made matters worse, in that her plea for release of her husband was unfortunately submitted on company stationery from the "Cellon-Werke Dr. Arthur Eichengrün", a nonexistent entity since February 1942. The rule of law no longer being in force in Germany, her plea for mercy was ignored.

Eichengrün remained in Theresienstadt until the liberation of the concentration camp by the Red Army. Despite his advanced age and his being a diabetic he survived the confinement, though visibly weakened, with little bodily harm (Figure 9). When the war ended he returned to Berlin, where he found his home ravaged and plundered. Yet his drive was unbroken. In his new home he set up a makeshift laboratory

Figure 9. Eichengrün after his release from the concentration camp. Photo: E. Eichengrün, Königswinter.

in which he improved some of his old formulations and developed new ones. For example, based on his experiences in Theresienstadt he devised an agent against bed bugs.

Friends and colleagues went out of their way after 1945 to see that belated honors were bestowed on Eichengrün as "compensation" for the injustices he had suffered. Thus, at the initiative of Rudolf Pummerer (1882–1973), once a student of Willstätter, the University of Erlangen in August 1946 commemorated the award of his doctoral degree, six years later than would have been customary. The archives of the University of Erlangen include the revealing annotation that this commemoration of the 50th anniversary of a degree conferral was observed in 1946 rather than 1940 because Eichengrün's Jewish faith would have made a timely ceremony impossible.[54]

Eichengrün was a victim of National Socialism at several levels, even though the stepwise "Aryanization" of his firm was somewhat atypical, and quite remarkably he successively defended his art collection from the Nazis' grasp. Although especially in the early 1930s he managed to soften somewhat the blows from constant escalation of the anti-Semitic decrees through adroit and clever tactics, probably with the help of numerous opportune warnings and scraps of information, in the long run it made little difference. Today he is largely unknown by those in the plastics industry, and his name is an unfamiliar one even among acknowledged historians of chemistry and pharmacy. This is due not only to his having as a practitioner, inventor, and industrialist left less of an imprint on scientific history than colleagues whose contributions were in the more theoretical aspects of science. His consignment to oblivion is instead largely an outcome of the most dismal chapter in German history.

I wish to express my deep appreciation to Prof. Dr. Dr. h.c. Fritz Eiden, Munich, and Prof. Dr. Otto Krätz, Starnberg, for supplementary information, suggestions, and many informative discussions. With respect to acquiring archival material I am much indebted to Ernst Eichengrün, Königswinter, Ulrich Chaussy, Munich, Dr. Jost Lemmerich, Berlin, and the staff of the Bayer Archives in Leverkusen.

In this essay on the history of his department it is noteworthy that Eichengrün makes no claim to a role in the synthesis of Aspirin, whereas he discusses his other pharmaceutical discoveries in detail. That he began to publicize his contribution to the Aspirin synthesis specifically in 1930 could be accounted for by his increasing persecution as a Jew, which forced him in self-defense to cite all his accomplishments in as much detail as possible.

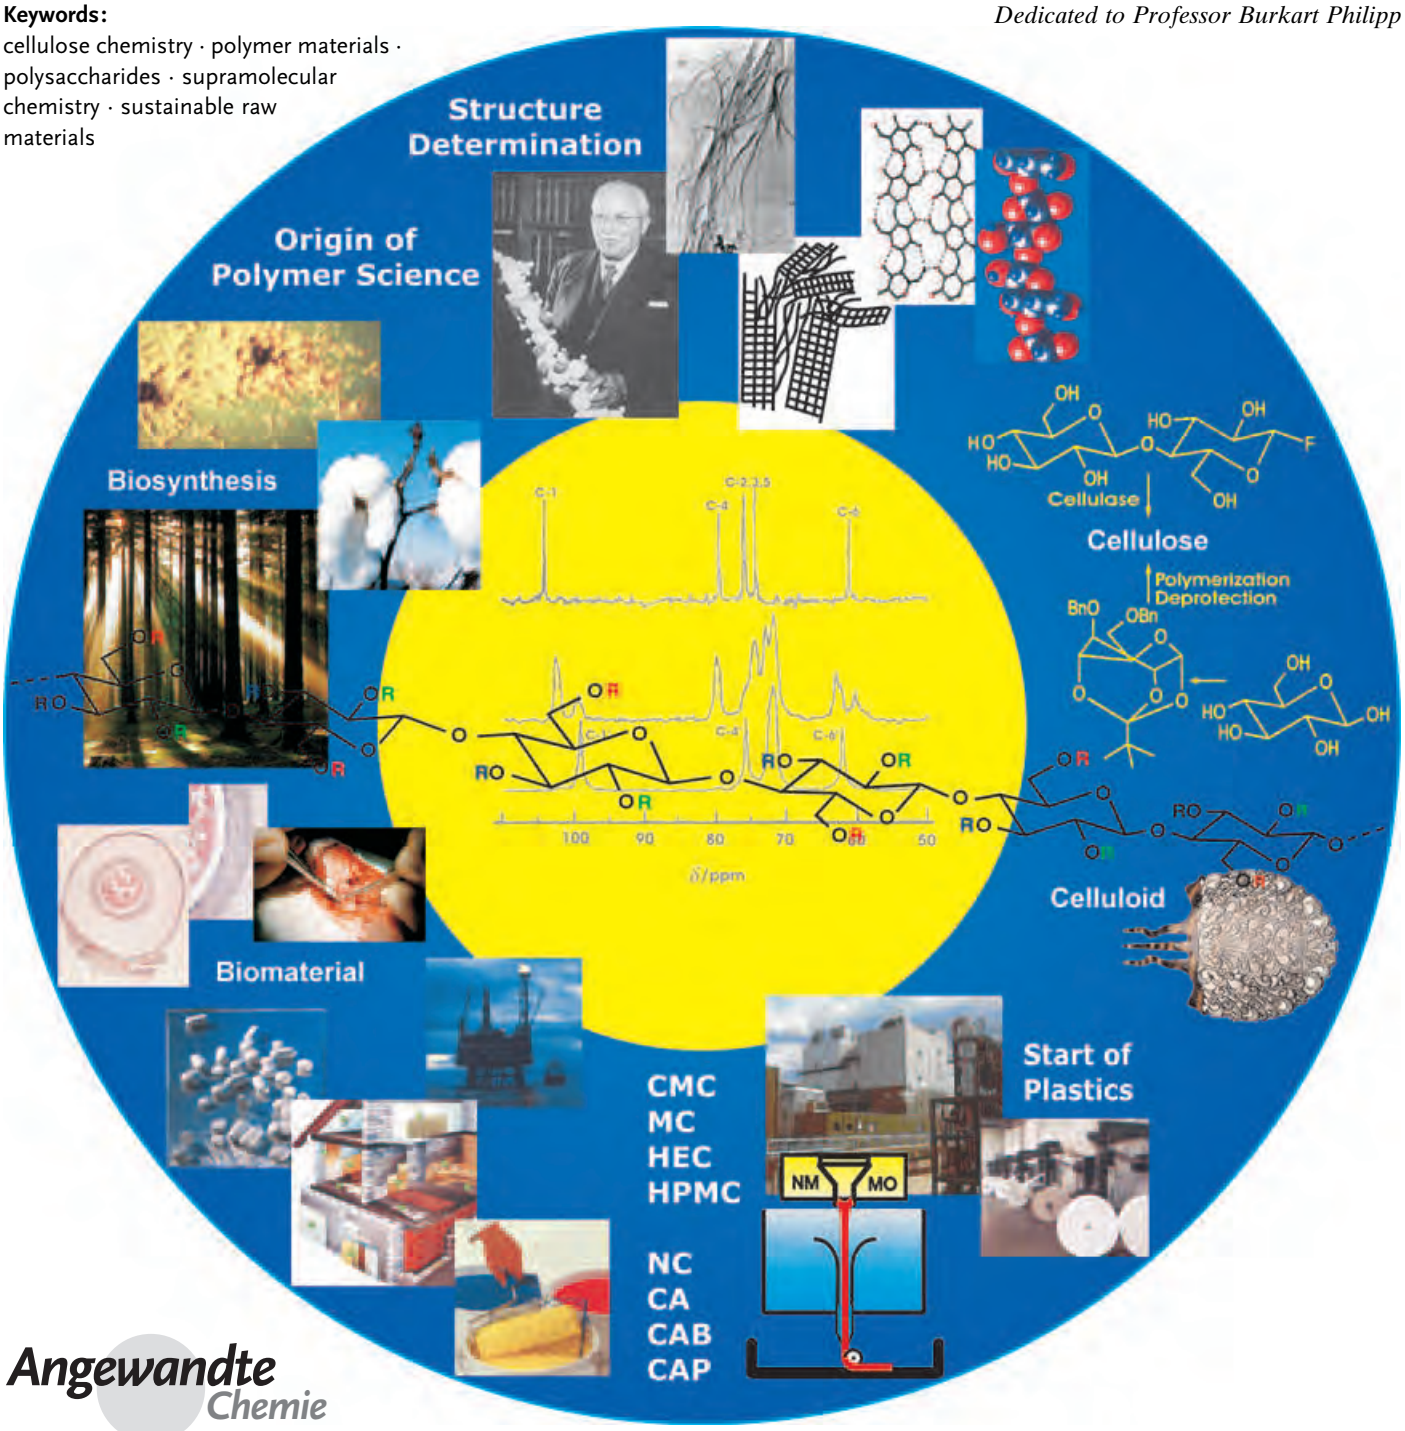
Polymer Science

Cellulose: Fascinating Biopolymer and Sustainable Raw Material

Dieter Klemm, Brigitte Heublein, Hans-Peter Fink,* and Andreas Bohn*

Keywords:
cellulose chemistry · polymer materials · polysaccharides · supramolecular chemistry · sustainable raw materials

Dedicated to Professor Burkart Philipp



DOI: 10.1002/anie.200460587

As the most important skeletal component in plants, the polysaccharide cellulose is an almost inexhaustible polymeric raw material with fascinating structure and properties. Formed by the repeated connection of D-glucose building blocks, the highly functionalized, linear stiff-chain homopolymer is characterized by its hydrophilicity, chirality, biodegradability, broad chemical modifying capacity, and its formation of versatile semicrystalline fiber morphologies. In view of the considerable increase in interdisciplinary cellulose research and product development over the past decade worldwide, this paper assembles the current knowledge in the structure and chemistry of cellulose, and in the development of innovative cellulose esters and ethers for coatings, films, membranes, building materials, drilling techniques, pharmaceuticals, and foodstuffs. New frontiers, including environmentally friendly cellulose fiber technologies, bacterial cellulose biomaterials, and in-vitro syntheses of cellulose are highlighted together with future aims, strategies, and perspectives of cellulose research and its applications.

From the Contents

1. Introduction

In 1838 the French chemist Anselme Payen described a resistant fibrous solid that remains behind after treatment of various plant tissues with acids and ammonia, and after subsequent extraction with water, alcohol, and ether.[1] He determined the molecular formula to be $C_6H_{10}O_5$ by elemental analysis, and observed the isomerism with starch. The term "cellulose" for this plant constituent was first used in 1839 in a report of the French academy on the work of Payen.[2]

Thousands of years prior to the discovery of the "sugar of the plant cell wall", cellulose was used in the form of wood, cotton, and other plant fibers as an energy source, for building materials, and for clothing. Since the Egyptian papyri, a considerable part of human culture has been shaped by cellulose materials.

As a chemical raw material, cellulose has been used for about 150 years. The formation of cellulose nitrate by reaction with nitric acid[3] and the corresponding technical synthesis of the first thermoplastic polymer material called celluloid (camphor used as plasticizer) by the Hyatt Manufacturing Company in 1870 demonstrated that new materials could be produced on an industrial scale by the chemical modification of cellulose.[4] With this knowledge came an increased use of synthetic fibers based on wood cellulose, instead of native cellulose fibers, for textiles and technical products. The first example herein is the production of regenerate cellulose filaments by spinning a solution of cellulose in a mixture of copper(II) hydroxide and aqueous ammonia, in which tetraamminecopper(II) hydroxide (cuprammonium hydroxide) $[Cu(NH_3)_4](OH)_2$ is formed,[5] followed by the currently most important large-scale technical process in fiber production, the viscose process.[6] In this process, cellulose is transformed into cellulose xanthogenate (see Scheme 16 and Figure 18) followed by spinning its solution in aqueous sodium hydroxide (viscose).

From the current point of view, cellulose is the most common organic polymer, representing about 1.5×10^{12} tons of the total annual biomass production, and is considered an almost inexhaustible source of raw material for the increasing demand for environmentally friendly and biocompatible products.[7] Wood pulp remains the most important raw material source for the processing of cellulose, most of which is used for the production of paper and cardboard. Approximately 2% ($\approx$3.2 million tons in 2003) were used for the production of cellulose regenerate fibers and films, as well as for the synthesis of a large number of cellulose esters and ethers. Such cellulose derivatives produced on an industrial scale (see Schemes 16 and 17 in Section 4) are used for coatings, laminates, optical films and sorption media, as well as for property-determining additives in building materials, pharmaceuticals, foodstuffs, and cosmetics. In the field of synthetic fibers, the Lyocell process made an industrial breakthrough as an environmentally friendly alternative to the viscose process, whereby cellulose is regenerated from

solution in *N*-methylmorpholine-*N*-oxide (NMMO) monohydrate by spinning (Section 5). Numerous new applications of cellulose take advantage of its biocompatibility and chirality for the immobilization of proteins,[8] antibodies,[9] and heparin,[10] and for the separation of enantiomeric molecules[11] as well as the formation of cellulose composites with synthetic polymers and biopolymers.[12]

The fascination of the cellulose biopolymer is a result of its specific structure, which is described in more detail in the following section. The fusion of both carbohydrate and polymer chemistry in a macromolecule composed of repeating glucose units generates surprising specificity and impressively diverse architectures, reactivities and functions. In contrast to carbohydrates of low molar mass, the reactions and properties of cellulose are determined by intermolecular interactions, cross-linking reactions, chain lengths, chain-length distribution, and by the distribution of functional groups on the repeating units and along the polymer chains. Cellulose differs from synthetic polymers by virtue of its distinct polyfunctionality, its high chain stiffness, and its sensitivity toward the hydrolysis and oxidation of the chain-forming acetal groups, which determine its chemistry and handling.

The elucidation of the polymeric structure of cellulose can be traced back to 1920 with the pioneering work of Hermann Staudinger.[13] Through acetylation and deacetylation of cellulose, he recognized that its structure does not merely consist of an aggregation of D-glucose units. Rather, the glucose units were found to be linked to each other covalently to form long molecular chains. This, along with Staudinger's research with other chain molecules, marked the discovery of the polymeric state of molecules and of the corresponding reactions that are unique to polymers and represents the origin of polymer science.

Figure 1 shows the molecular structure of cellulose as a carbohydrate polymer generated from repeating β-D-glucopyranose molecules that are covalently linked through acetal functions between the equatorial OH group of C4 and the C1 carbon atom (β-1,4-glucan), which is, in principle, the manner in which cellulose is biogenetically formed. As a result, cellulose is an extensive, linear-chain polymer with a large number of hydroxy groups (three per anhydroglucose (AGU) unit) present in the thermodynamically preferred $^4C_1$ conformation. To accommodate the preferred bond angles of the acetal oxygen bridges, every second AGU ring is rotated 180° in the plane. In this manner, two adjacent structural units define the disaccharide cellobiose.

The chain length of cellulose expressed in the number of constituent AGUs (degree of polymerization, DP) varies with the origin and treatment of the raw material. In case of wood

Dieter Klemm received his master's degree (diploma) in 1964 from the University of Jena, and received his PhD in 1968 from work in the stereospecific synthesis of nitrogen-containing steroids conducted with Prof. G. Drefahl at the Institute of Organic Chemistry. He obtained his habilitation in 1977 after conducting research in synthetic polymer chemistry with H.-H. Hörhold. After work in the pharmaceutical industry and initial activities in polysaccharides as a university lecturer, he has been a professor of organic chemistry at the University of Jena since 1987. He is associate editor of the journal Cellulose and columnist of Polymer News. In 2004 he became the first German scientist to receive the Anselme Payen Award of the American Chemical Society for contributions to the development of new cellulose-based materials.

Brigitte Heublein studied chemistry at the Friedrich Schiller University of Jena and received her master's degree (diploma) in 1969 with her investigations of cationic polymerization of vinyl monomers. She received her PhD in 1974 from research into the control of cationic polymerizations of vinyl monomers with Prof. G. Heublein at the Institute of Organic and Macromolecular Chemistry, and was associated with that research group until 1989. Since 1990 she has been working in organic natural products and polysaccharide chemistry under the direction of Prof. D. Klemm.

Hans-Peter Fink studied physics at Rostock University, where he received his diploma in 1973 and his PhD in 1977 under Prof. G. Becherer on X-ray diffraction analysis of glass ceramics. Between 1975 and 1992 he worked at the Institute for Polymer Chemistry in Teltow–Seehof, conducting structural investigations of cellulose which was also the topic of his habilitation (1991, Rostock University). He has been employed at the Fraunhofer Institute for Applied Polymer Research since its foundation in 1992, and he currently heads the Division of Natural Polymers of the Institute. He has been awarded repeatedly for his contributions to the field of cellulose research, most recently in 2002, with the Jisuke Hayashi Award of the Cellulose Society of Japan.

Andreas Bohn studied mineralogy at the universities of Münster and Berlin, where he graduated in 1994 from the Hahn–Meitner Institute with a diploma thesis on X-ray and neutron scattering investigations of the structure of proton conductors. Since 1995 he has been working in the department of structure characterization at the Fraunhofer Institute for Applied Polymer Research in Teltow and Potsdam (Golm). In 2000 he received his PhD degree with a thesis on X-ray diffraction investigations of the structure and orientation of bacterial cellulose and regenerated cellulose films. He has since headed the group of X-ray structure characterization at the Institute.

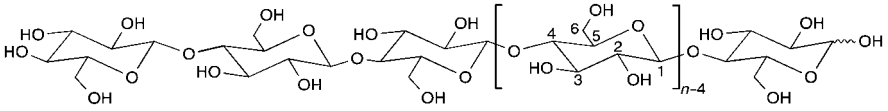

Figure 1. Molecular structure of cellulose (n = DP, degree of polymerization).

pulp, the values are typically 300 and 1700. Cotton and other plant fibers have DP values in the 800–10000 range, depending on treatment; similar DP values are observed in bacterial cellulose. Regenerate fibers from cellulose contain 250–500 repeating units per chain. By acid treatment and cellulase-catalyzed hydrolysis, cellulose can be quantitatively decomposed to D-glucose. Partial chain degradation yields powdery cellulose substrates of the microcrystalline cellulose type[14] (such as Avicel) with DP values between 150 and 300. A β(1→4) linked glucan with 20–30 repeating units offers all properties of cellulose.[15]

The cellulose chain consists at one end of a D-glucose unit with an original C4-OH group (the nonreducing end); the other end is terminated with an original C1-OH group, which is in equilibrium with the aldehyde structure (the reducing end). Technical celluloses, such as bleached wood pulp, contain additional carbonyl and carboxy groups as a result of the isolation and purification processes that play a significant role in the processing of cellulose.[16]

The molecular structure imparts cellulose with its characteristic properties: hydrophilicity, chirality, degradability, and broad chemical variability initiated by the high donor reactivity of the OH groups (Section 3). It is also the basis for extensive hydrogen bond networks, which give cellulose a multitude of partially crystalline fiber structures and morphologies (Section 2). The properties of cellulose are therefore determined by a defined hierarchical order in supramolecular structure and organization.

Scheme 1 presents the four different pathways by which cellulose is accessed today. As described above, the dominant pathway is the production of cellulose from plants. In the seed hairs of cotton, cellulose is available in almost pure form. In contrast, wood cellulose forms a native composite material with lignin and other polysaccharides (hemicelluloses) from which it is isolated by large-scale chemical pulping, separation, and purification processes.

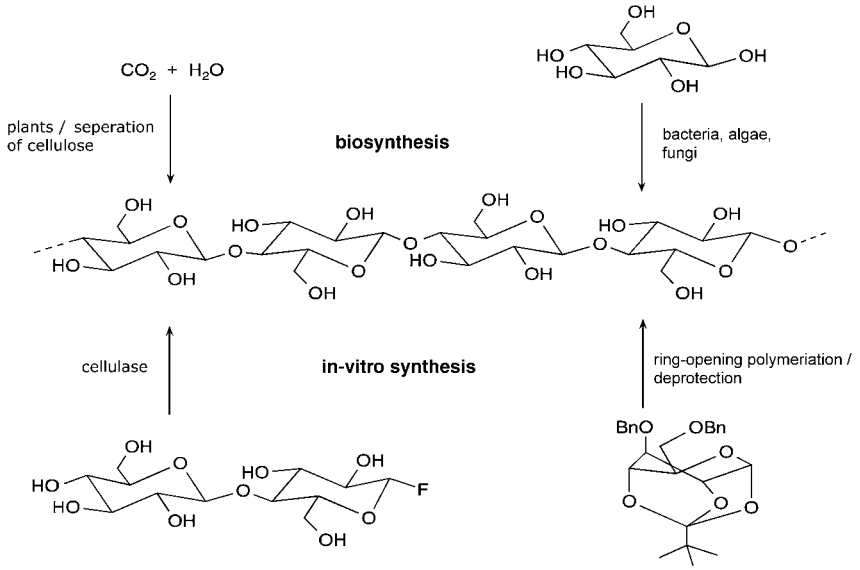
Apart from plants, certain bacteria, algae, and fungi produce cellulose as well. Because of their specific supramolecular structures, these cellulose forms are frequently used as model substances for further research on cellulose structure, crystallinity, and reactivity, as well as for the development of new materials and biomaterials (Section 6). On this basis, the biosynthesis of cellulose has been investigated in detail over the past decades.[17] Therefore, it is known that the biosynthesis of cellulose has been part of the life cycle of cyanobacteria for over 3.5 billion years.[18]

The synthesis of cellulose in vitro should be highlighted as an additional important development in recent years.[15] The first reported cellulase-catalyzed formation of cellulose was based on cellobiosyl fluoride,[19] and the first chemosynthesis was carried out through a ring-opening polymerization of substituted D-glucose pivalate moieties, followed by deprotection (Section 7).[20]

A considerable stimulation of scientific and technological research in the field of cellulose has been triggered over the past 10 years in response to the growing global importance in renewable resources and environmentally compatible materials. With its foundations in the knowledge contained in monographs, books and review articles,[21] this review presents important current developments and discusses the aims, strategies, and perspectives in the field of cellulose. The topics highlighted herein were chosen for their current importance to the field of cellulose research and the nature of the innovative impetus associated with a given development; their selection reflects the experience of the authors. Thus, a collection of current cellulose research and development has been created that combines discussions of structure, synthesis, innovative products, and new frontiers in an updated contribution to the scientific literature.

2. Structure and Properties of Cellulose in the Solid State and in Solution

The hierarchical structure of cellulose, formed by the hydrogen bond network between hydroxy groups, has been the subject of intense research for more than 100 years, marked with frequent controversy over results and a consistent supply of new insight.[22] Directly from the beginning, progress was closely connected with the introduction and continued development of structure-analysis methods, such as X-ray diffraction, electron microscopy, high-resolution ^{13}C solid state NMR spectroscopy, and neutron diffraction



Scheme 1. Principle pathways to cellulose formation.

analysis. A detailed analysis and modeling of the various structural levels of cellulose is essential for synthetic reaction procedures, and for the controlled structure formation and properties of cellulose-based chemical products (man-made cellulosics).

2.1. Solid-State Structures of Native Cellulose

As shown in the molecular structure represented in Figure 1, the hydroxy groups of β-1,4-glucan cellulose are placed at positions C2 and C3 (secondary, equatorial) as well as C6 (primary). The CH_2OH side group is arranged in a *trans-gauche* (*tg*) position relative to the O5–C5 and C4–C5 bonds. As a result of the supramolecular structure of cellulose, the solid state is represented by areas of both high order (crystalline) and low order (amorphous).

2.1.1. Crystal Structure

As a first approximation, the crystal structure of native cellulose (cellulose I) determined by X-ray diffraction can be described by a monoclinic unit cell (space group $P2_1$) which contains two cellulose chains in a parallel orientation with a twofold screw axis.[23] In the 1980s, ^{13}C-CP/MAS NMR spectroscopy was used in the initial discovery that native cellulose is present in two different crystalline cellulose I modifications (I_α and I_β), which can be found alongside each other; the I_α/I_β ratio depends on the origin of the cellulose.[24] Investigations with electron microbeam diffraction[25] and combined X-ray and neutron diffraction[26] recently revealed the corresponding crystalline structures to have triclinic (I_α) and monoclinic (I_β) unit cells. Figure 2 shows a schematic representation of the I_β crystal structure. In the side view (Figure 2b) of the central chains of a unit cell, two intramolecular, chain-stiffening hydrogen bonds are revealed. Notably, one of the most recent reports on the I_β structure[27] describes different conformations for neighboring chains as well as different H-bonding systems inside neighboring molecular layers.

Apart from the thermodynamically less stable cellulose I, cellulose may occur in other crystal structures (cellulose II, III, and IV),[21] of which cellulose II (Figure 2) is the most stable structure of technical relevance. It can be formed from cellulose I by treatment with aqueous sodium hydroxide (mercerization) or by dissolution of the cellulose and

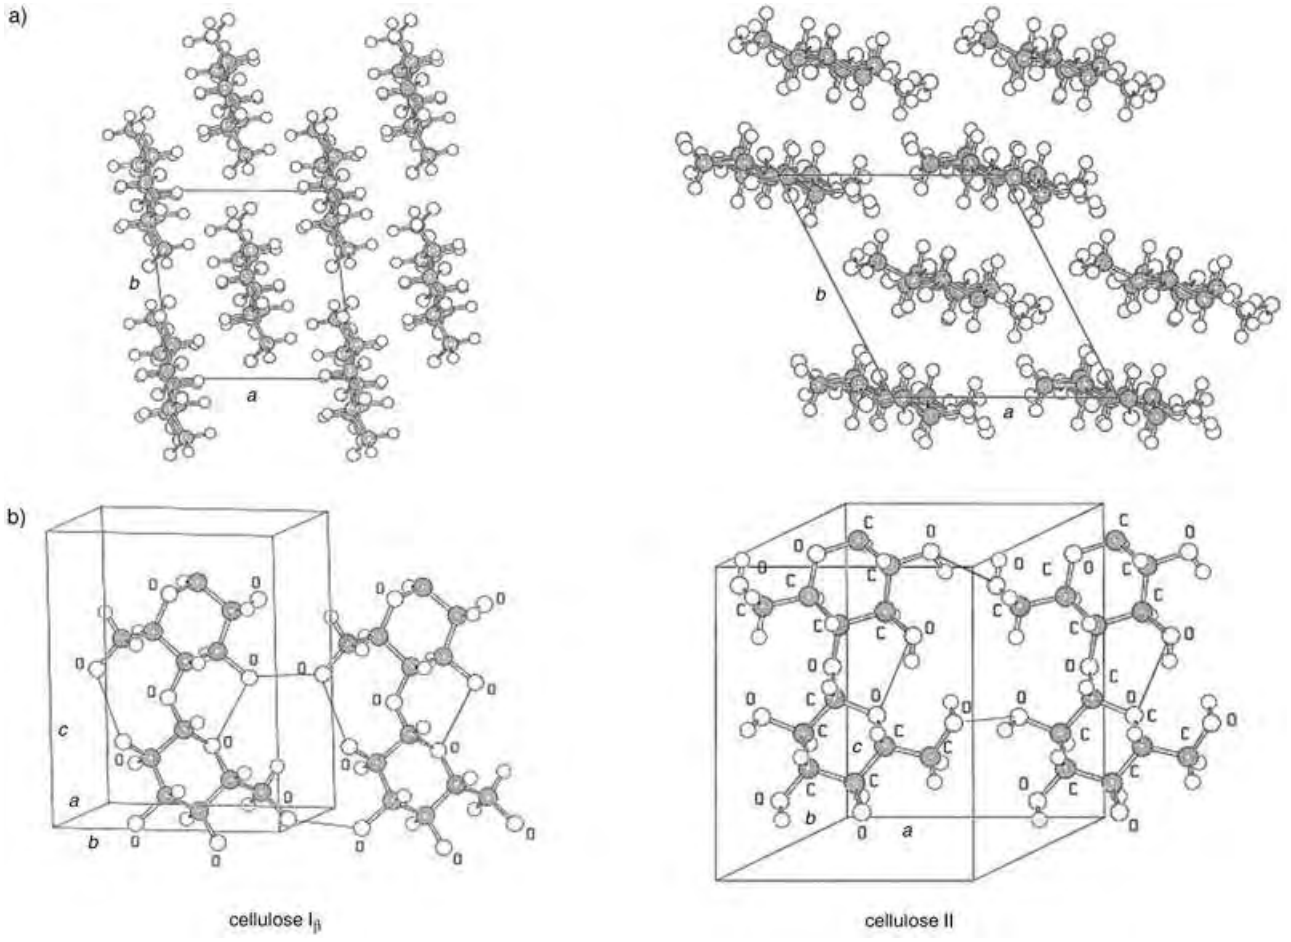


Figure 2. Crystal structures of cellulose I_β and cellulose II: a) projection of the unit cell (UC) along the *a*–*b* plane; b) projection of the UC parallel to the (100) lattice plane (cellulose I) and the (010) lattice plane (cellulose II).[22c]

subsequent precipitation/regeneration, as is done in the formation of fiber and film. This monoclinic crystal structure[28] with two antiparallel chains in the unit cell is characterized by the specific unit cell geometry with a modified H-bonding system. The alkalization of cellulose is of considerable importance to commercial-scale cellulose production as a method for increasing the reactivity (activation) of subsequent reactions as well as for the mercerization of cotton. Depending on the concentration of lye, the temperature, and mechanical load, it is possible to convert cellulose I into various crystalline alkali forms, each with a different crystal structure and variable NaOH and water content.[29] All forms will then convert into crystalline "hydrato cellulose" (water cellulose) during washout, and to cellulose II through drying (Figure 3). It is not yet understood how the parallel chain arrangement of cellulose I undergoes transition into the antiparallel orientation of cellulose II without an intermediate dispersion of cellulose molecules.

There are currently only a few reports on the structure of noncrystalline random cellulose chain segments.[30] More knowledge in this area is required, as these structure elements have a significant influence on the accessibility and reactivity of cellulose, as well as on the properties of man-made cellulose fibers.

2.1.2. *Morphology*

The biological function and numerous applications of cellulose are based on its distinct fiber morphology. The morphological hierarchy is defined by elementary fibrils, microfibrils, and microfibrillar bands.[31] The lateral dimensions of these structural units are between 1.5 and 3.5 nm (elementary fibrils), between 10 and 30 nm (microfibrils), and on the order of 100 nm (microfibrillar bands). The length of the microfibrils is on the order of several hundred nm. Figure 4 shows electron micrographs of the fibrillar structure of samples of varying origin; a structural model of an initially hydrated bacterial cellulose sample is shown in Figure 28 (Section 6.1).

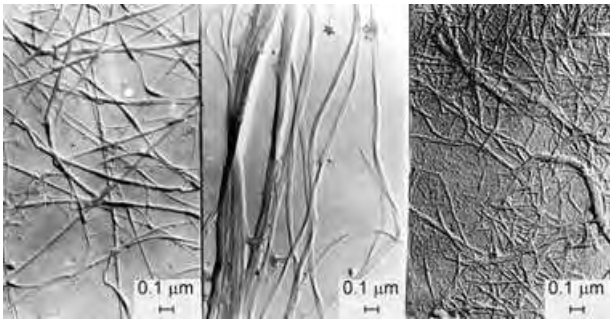

Figure 4. Electron micrographs of cellulosic microfibrils of varying origins:[32] left, *Valonia* spp. (algae) cellulose; center, cotton linters; right, spruce sulfite pulps.

The fringed fibrillar model with crystalline regions of varying dimensions (crystallites) and noncrystalline regions has proven successful for the description of the structure of microfibrils and the partial crystalline structure of cellulose in connection with the reactivity of this polymer[29c] (Figure 5).

The degree of crystallinity of cellulose and the dimensions of the crystallites have been the subject of extensive investigations for many years;[33] some results of X-ray diffraction measurements of native celluloses have been compiled in

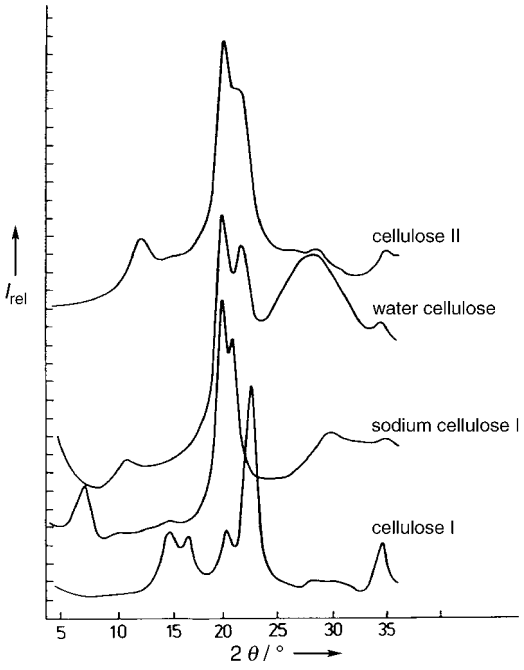

Figure 3. X-ray wide-angle scattering curves of cellulose modifications formed during alkalization and regeneration[29c] (I_{rel} = relative intensity, 2θ = diffraction angle).

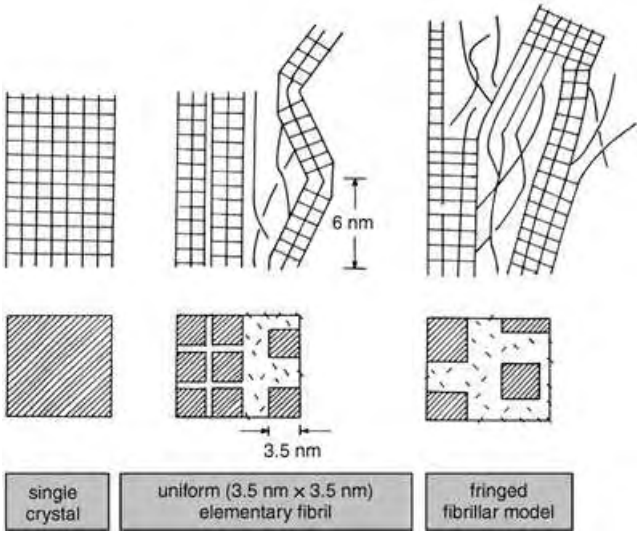

Figure 5. Various models of the supramolecular structure of cellulose microfibrils.[29c]

Table 1: Degrees of crystallinity (x_c), crystallite sizes ($D_{(hkl)}$), and lateral dimensions (d) of microfibrils of native celluloses

Cellulose Source	x_c [%]	crystallite sizes [nm]			d [nm]
		$D_{(1\bar{1}0)}$	$D_{(110)}$	$D_{(020)}$	
algal cellulose	>80%	10.1	9.7	8.9	10–35
bacterial cellulose	65–79	5.3	6.5	5.7	4–7
cotton linters	56–65	4.7	5.4	6.0	7–9
ramie	44–47	4.6		5.0	3–12
flax	44 (56)[a]	4–5	4–5	4–5	3–18
hemp	44 (59)[a]	3–5	3–5	3–5	3–18
dissolving pulp	43–56			4.1–4.7	10–30

[a] Degree of crystallinity relative to cellulose.

Table 1. The corresponding values of regenerated cellulose in the form of filaments and films are given in Table 4 (Section 5.5.1).

Notably, the lateral crystallite dimensions of regenerated cellulose (cellulose II) are in the range of ≈4–5 nm regardless of the production process (Table 4), whereas in native celluloses, values of up to 20 nm have been observed. The reasons for the formation of nearly uniform cross-sectional dimensions of these cellulose II crystallites from different structure-forming processes still have to be clarified.

The pore structure can be considered the counterpart to the fibril morphology of cellulose. It is considerably important for the accessibility in chemical reactions and enzymatic degradation.[34] The controlled variation of pore structures enables cellulose products to meet the needs of a wide range of applications, from highly specialized membrane and carrier materials to consumer goods, such as nonwovens[35] with excellent absorption properties.

2.1.3. *Growth Architectures and Material Design*

As the skeletal component in all plants, cellulose is organized in a cellular hierarchical structure. In combination with the accompanying substances hemicelluloses, lignin, and pectin, this structure leads to the extraordinary properties of native composite materials, such as wood, cotton, flax, and hemp. Figure 6 schematically illustrates the cell walls of cotton and wood with differently structured layers, in which the secondary cell-wall layer S2 contains the main quantity of cellulose.

The cellulose molecules organized in the cell walls in the form of microfibrils have characteristic orientations (helix angles), which differ as a function of the cell wall layer, and according to the plant type as well. Figure 7 shows X-ray fiber diffraction patterns of cotton and bast fibers (flax, hemp, and jute), which reflect the different average orientations of the crystalline spectra of these natural fibers.

The lower orientation of the cellulose microfibrils in cotton fibers (helix angle ≈18°) gives rise to a smaller module of elasticity and a higher elongation at breakage compared with bast fibers, which have a much higher microfibril orientation (helix angle ≈4°–5°) and fiber strength. The adaptation of the mechanical properties of wood to environmental conditions through corresponding helix angles is fascinating, and has yet to be rivaled in technical composite materials.[37] However, it is already possible to adapt the parameters of cellulosic man-made fibers to user requirements through a targeted influence on the orientation (with particular respect to the noncrystalline chain segments). It is therefore possible to develop man-made cellulose fibers similar to cotton with low orientation (high elongation), and technical fibers with high orientation and a high modulus of elasticity, similar to bast fibers.

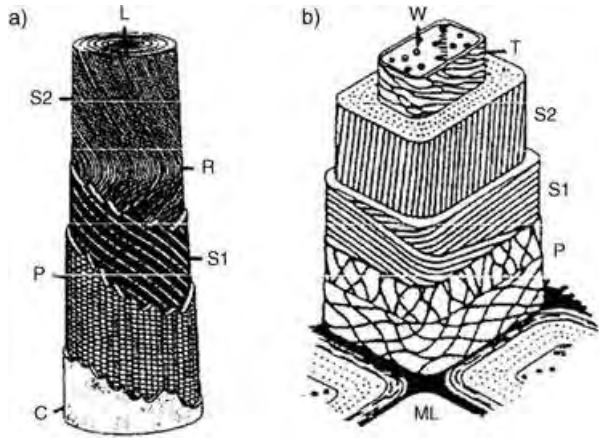

Figure 6. Structural design of plant cell walls exemplified by a) cotton and b) wood fibers:[21b] C = cuticula layer, L = lumen, ML = middle lamella, P = primary cell wall layer, R = reversing point, S1 = secondary cell wall layer 1, S2 = secondary cell wall layer 2, *T* = tertiary cell wall, W = wart layer.

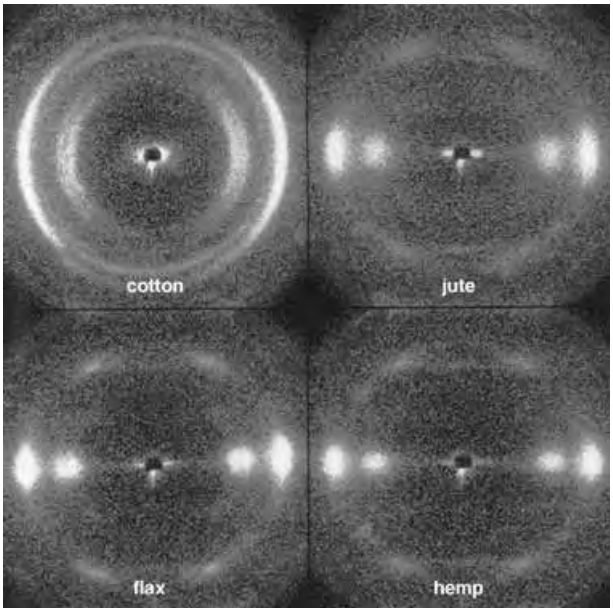

Figure 7. X-ray fiber diagrams of various natural cellulosic fibers.[36]

2.2. *Solution Structures of Cellulose and Cellulose Derivatives*

An understanding of the structure of cellulose and cellulose derivatives in solution is not only a matter of scientific interest, but has great practical importance as well.

Examples include the shaping of cellulose from spinning solutions,[38] modification of the synthesis of cellulose derivatives (Section 3) and the properties of water-soluble cellulose ethers (Section 4), which all are dependent on the solution structure. For this reason, questions regarding the structure of cellulose in solution have been the subject of intense research and discussion over the past decades. According to Schurz,[38a] a differentiation is made initially between molecularly dispersed and network solutions, to which a portion of gel particles may be added. Figure 8 illustrates suggested models of the different solution states of cellulose derivatives, which may depend on the type of solvent, polymer concentration, chain length distribution, and the type, pattern, and degree of cellulose substitution.

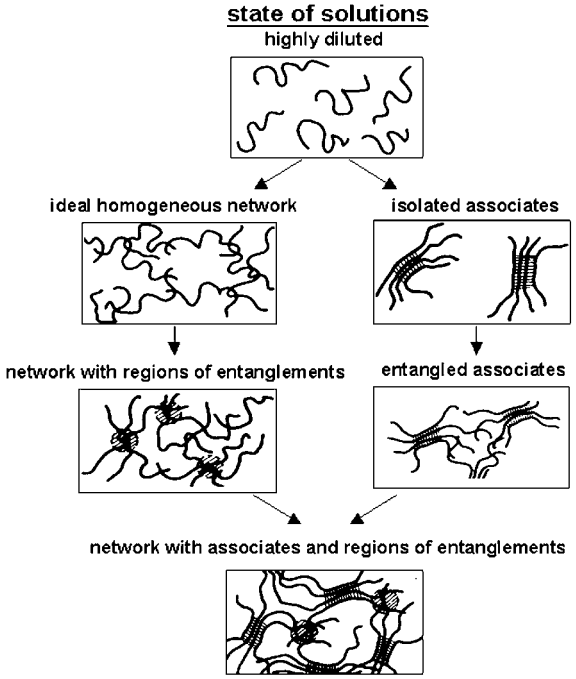

Figure 8. Scheme of the potential dissolution states of cellulose.[38a]

As a rule, cellulose derivatives with free OH groups are not molecularly dispersible. Investigations with partially substituted cellulose carbanilates and benzoates revealed, however, that aggregate-free solutions can occur through specific polymer–solvent (e.g. DMF) interactions.[39] On the other hand, completely substituted products (such as cellulose tricarbanilates) can be molecularly soluble or, owing to strong intermolecular interactions, insoluble as is the case with trimethylsilyl cellulose with DS 3.0.

Whereas highly diluted solutions have been used for fundamental research of solution structures, applied practices, such as the viscous process, employ concentrated systems with polymer concentrations of 8–12%, which are described as network solutions with gel-particle portion in accordance with model assumptions.[38b,c] Apart from rheological examinations, gel-particle characterizations are also normally carried out to determine the quality of a given spinning solution.[38]

Over the past few years the research group of Burchard, in particular, has carried out extensive fundamental research into the structure of cellulose and cellulose derivatives in solution by means of static and dynamic light scattering.[40] With regioselective modified cellulose ethers, new insight was gained into the entropy effect during the dissolution of cellulose derivatives (Section 3.2.3).[39,40]

The initial research results on the solution state of cellulose in *N*-methylmorpholine-*N*-oxide (NMMO) monohydrate as a technically relevant system (Section 5) substantiate the presence of bimodal molecule aggregations with up to 1000 chains, which can be attributed to incomplete dissolution of crystal structures of the starting cellulose material.[41] In the first approximation, the average number of molecules in the smaller aggregates corresponds to that of crystallites (50–100), whereas the average number of molecules in larger aggregates correlates with the number of molecules found in a microfibril (250–1000).[42] In a ternary solvent system composed of NMMO, water, and diethylenetriamine [bis-(2-aminoethyl)-amine], cellulose is molecularly soluble within a temperature range of 25–60 °C. Therefore, the average molar mass and other properties of the dissolved molecules could be determined by means of light scattering.[43]

2.3. Liquid-Crystalline Cellulose Structures

Owing to chain stiffness, cellulose and certain cellulose derivatives in solutions of higher concentration may form cholesteric (chiral-nematic) structures. Since the discovery of the lyotropic liquid-crystalline state of hydroxypropyl cellulose in water,[44] a multitude of cellulose derivatives were found, which produce lyotropic or thermotropic liquid-crystalline phases.[45] Chiral-nematic films and gels are formed from the solutions. The influence of the solvent and of the chain stiffness on the pitch and handedness of the chiral-nematic structures was examined.[46]

Regioselectively substituted (position 2, 3 or 6 of the AGU) cellulose phenylurethanes with F, Cl, or CH_3 groups in the phenyl ring form lyotropic liquid-crystalline mesophases in highly concentrated solutions, the structure and optical properties of which depend strongly on the site of substitution, as well as on the concentration and temperature of the solution.[46] The photo-cross-linking of cellulose-(3-chlorophenyl)-urethanes in mixtures with acrylate monomers produces semi-interpenetrating polymer networks, which can change their selective reflection under compression.[47] Cellulose urethanes with azo-dye substituents and acrylates of hydroxypropyl cellulose are other well-analyzed lyotropic liquid-crystalline cellulose products. The latter form gels in water through photo-cross-linking, and their resulting color is determined by the water content.[47] The optical properties that can be controlled by the pitch of cholesteric phases open up important fields of application, such as color pigments in car paints and as copy protection color for document papers.

Liquid-crystalline states of unsubstituted cellulose are significant with particular respect to new spinning methods and the production of high-performance fibers. Suitable

solvents for this include NMMO, a mixture of trifluoroacetic acid and chlorinated alkanes, DMA/LiCl, ammonium rhodanide in liquid ammonia,[48] and concentrated phosphoric acid. However, any spinning process based in these liquid-crystalline systems has yet to gain industrial acceptance. The cellulose concentrations in NMMO used in the Lyocell process are below the liquid-crystalline phase range (Section 5).

Recently, developments appear to have emerged in conjunction with the possible production of chiral-nematic suspensions from cellulose crystallites or microfibrils.[46a]

3. Cellulose Chemistry: New Syntheses, Products and Supramolecular Architectures

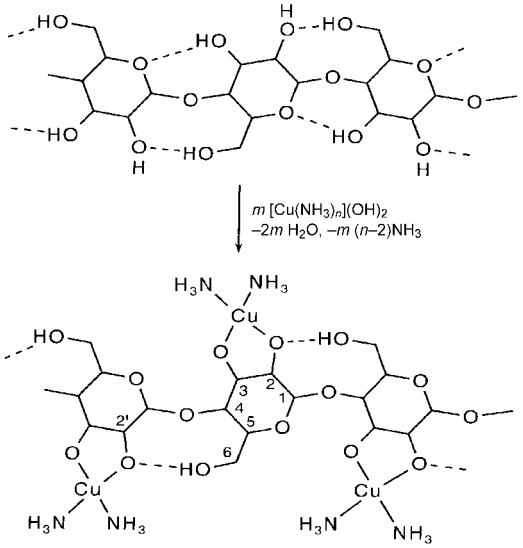
3.1. Specific Features of the Reactions of Cellulose

The insolubility of cellulose in water and in most organic solvents caused by its supramolecular structure is the reason behind the fact that all commercially available products are currently produced through reactions of cellulose in the solid, or more or less swollen state (heterogeneous reactions).[49] Because each repeating unit of cellulose has three hydroxy groups available for reaction, and the stability of the chain-forming acetal groups toward various reagents, oxygen, and mechanical and thermal load is limited, additional questions emerge over substituent distribution in the product and over chain degradation during synthesis.

In case of heterogeneous reactions, the accessibility and reactivity of the OH groups are clearly determined by hydrogen bond-breaking activation steps (through alkaline compounds such as NaOH, Section 2.1.1)[50] and by interaction with the reaction media (e.g. swelling).[51] Thus, the "linear" transfer of the typical reactions of organic chemistry to cellulose is not easily done. However, the control of cellulose activation and of the type of heterogeneous reaction permits effective synthesis of cellulose products with desired degrees of reaction, reproducible substitution patterns, and targeted properties at both the laboratory and production scales. There remain important aspects of the synthesis procedure that are understood only partially. Therefore, a lot of experience and the right "feeling" are still required in cellulose syntheses.

Through the use of specific cellulose solvents,[21a] which disrupt hydrogen bonds and thus dissolve the adducts formed, the influence of the supramolecular structure of cellulose on the reaction procedure is eliminated almost completely. In this context, a solution of LiCl in DMA (DMA/LiCl) is one of the most important solvent systems for cellulose in organic syntheses[52] as well as for analytical purposes.[53] The structure of this binary medium, the mechanism of dissolution, the influence of water on the dissolving activity, and the state of dissolution of cellulose have been investigated in detail.[40,54]

Over the past few years, it was demonstrated that tetrabutylammonium fluoride trihydrate in DMSO (DMSO/TBAF) effectively dissolves cellulose and is very useful for homogeneous syntheses.[55] Fundamental progress has also been made in the classical field of metal-containing cellulose solvents like cuprammonium hydroxide.[56] In doing so, the solution structure of cellulose in this copper-containing medium was elucidated (Scheme 2).[53]

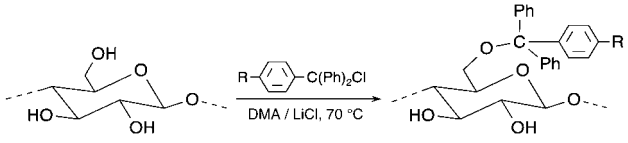


Scheme 2. Complex formation of cellulose in cuprammonium hydroxide.[53]

Extensive preparative work on the laboratory scale has been carried out over the past 20 years with cellulose solvent systems. As a result, new types of cellulose derivatives have been synthesized and the knowledge of reaction mechanisms, reaction control, structure–property relationships (solubility, film formation, stability), and structure analysis has been increased.[57] Until now, it has not been possible to transfer the homogeneous reactions to technical scale, as the handling of aprotic dipolar media and salt components poses an obstacle.

Of course, partially substituted soluble cellulose derivatives are also good substrates for reactions under homogeneous conditions (see Sections 3.2.1 and 3.2.4 as well).[58] Cellulose ethers have proven particularly useful as intermediates and regioselective protecting groups. Typical examples include trityl,[59] methoxy-substituted trityl,[60,61] bulky silyl (Section 3.2.3), as well as allyl and benzyl ethers.[62] Table 2 contains example data for trityl protecting groups.[60]

Table 2: Trityl and methoxytrityl ethers as O6-selective protecting groups.

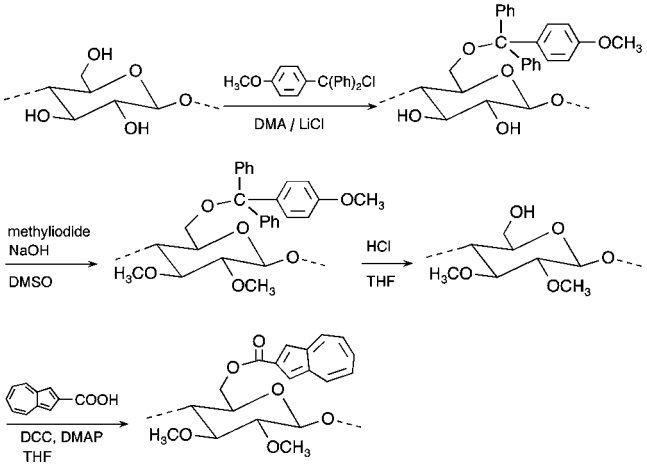


Polymer R	t [h]	DS 6	3	2	Σ
H	48	0.96	0.01	0.13	1.10
OCH_3	4	0.97	0.00	0.06	1.03
OCH_3	48	0.96	0.00	0.10	1.06

Limited chain degradation can be accepted in most reactions of cellulose without loss of the product properties, if chain lengths beyond the convergence range of the material parameters are not obtained. Transformation of cellulose with phenyl isocyanate (carbanilation) and silylation (Section 3.2.3) take place without chain degradation, for example.[58]

3.2. New Cellulose Products and Selective Syntheses

The wide range of preparative and structure-analytical studies over the past 10 years includes characterization of the donor–acceptor properties of cellulose substrates and derivatives by means of solvatochromic EDA complexes[63] and investigations of cellulose thiosulfates and self-assembling derivatives.[64] Part of this work also includes studies of celluloses with reduced functionality (at O2 and O3 as ether-protected substrates for subsequent reactions at C6-OH groups)[61] as well as cellulose products with covalently fixed dyes (e.g. azulene carboxylic acid ester) and their optoelectronic properties[65] (Scheme 3).



Scheme 3. 2,3-Methyl ether as a regioselective control element in the formation of celluloses with optoelectronic properties.

Products of current research include specifically modified cellulose derivatives for applications in enantioselective chromatography[66] and as biomaterials,[67] as are new types of cellulose products produced by acylysis and "retrosynthesis".[68] There are also reports of structure change and modification of cellulose in low-temperature salt melts/ionic solvents,[69] structure analysis of cellulose and substituted cellulose derivatives,[70] and determination of the polymer dynamics of cellulose derivatives in solution by dielectric relaxation spectroscopy.[71] The viscoelastic and rheo-optical properties of water-soluble cellulose derivatives and their ultrasonic degradation to smaller units with well-defined molar masses has also been investigated.[72]

A special challenge for synthetic work are the selective reactions of the OH groups of the repeating cellulose units and along the polymer chains. This problem is, of course, typical in polysaccharide chemistry. Horton and Yalpani have presented pioneering work in this area.[73] Results with the regiochemistry of cellulose are also the subject of review articles.[74]

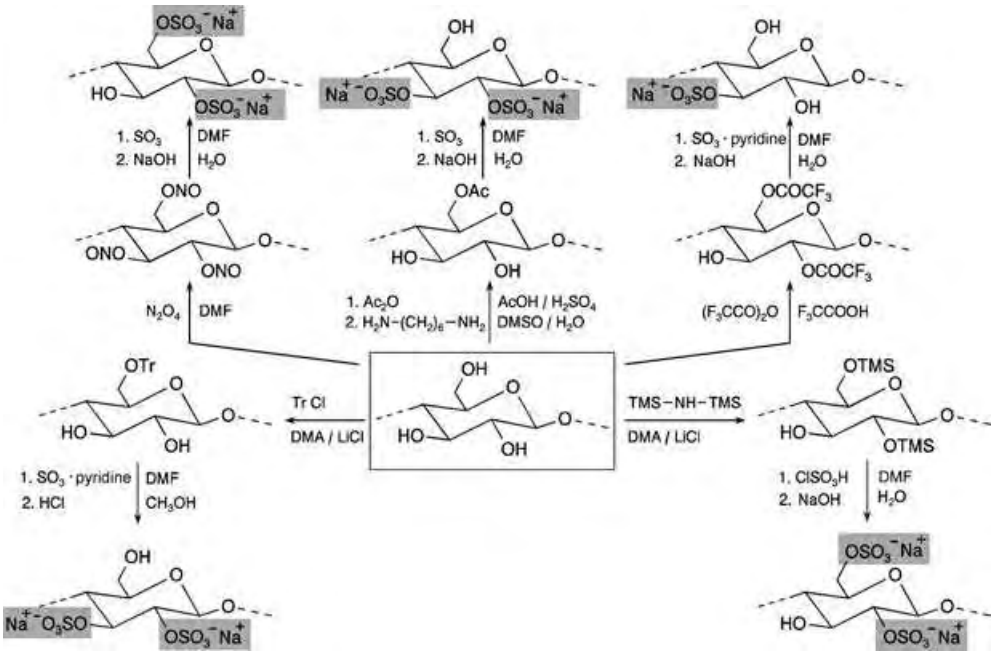
The difference in reactivity between the primary hydroxy group at C6 (highly accessible) and the secondary hydroxy group at C2 (highly acidic and in close proximity to the acetal function) is exploited for selective reactions of cellulose, but is overshadowed by the hydrogen bridge networks described in Section 2. Furthermore, AGUs can be activated along the cellulose chains in a manner to favor reaction preferentially at certain chain segments ("reactive microstructures"). At the laboratory scale, regioselective syntheses of cellulose products are particularly successful with protecting group techniques and the selective involvement of OH groups in discrete solvation and activation states, by specific downstream reactions, by enzymatic transformations of reactive cellulose derivatives, and by chemosynthesis with functionalized glucose as starting material.

Cellulose derivatives with functionalization patterns of high uniformity are important not only for comparison with statistically modified celluloses, but are particularly important as products with new properties and applications. Their importance also lies with respect to questions that remain open about the solution structure of cellulose derivatives and for the design of supramolecular architectures (Section 3.3). Typical examples include 6-*O*- and 2,3-di-*O*-acetyl-6-*O*-triphenylmethylcellulose,[75] 2,6-di-*O*-thexyldimethylsilylcellulose, and 3-*O*-alkylcelluloses,[76] as well as methyl ethers regioselectively modified with fluorescent benzyl ether groups.[77]

3.2.1. Progress in the Synthesis of Cellulose Esters

During the past decade, cellulose sulfates have undergone intense investigation,[21a] as their water-soluble sodium salts offer excellent rheological and gel-forming properties, which has increased their importance as film-forming materials, anionic polyelectrolytes, and biologically active polymers. In view of this application potential, cellulose sulfates are also mentioned in Scheme 16, Section 4, although they have not been used technically to a large extent. One priority with these products has also been the synthesis of cellulose sulfates with a regioselective distribution of substituents, which is possible by sulfation of cellulose ester and cellulose ether intermediates, including the use of protecting groups.[21a,78]

Scheme 4 highlights typical examples of this. For cellulose nitrites and trimethylsilyl ethers, sulfation takes place through the substitution of these functional groups. In the cases of acetate, trifluoroacetate, and trityl ether, sulfation occurs by transformation of the free OH groups. The acetate route proceeds through the selective diamine-catalyzed hydrolysis of cellulose triacetate to the preferentially formed 6-acetate intermediate. The regioselectivities illustrated in Scheme 4 are supported by published DS (degree of substitution) data.[21a] Whereas the reversibility of the direct sulfation of cellulose leads to a statistic distribution along the polymer chain, regioselective sulfations are successful with partially protected precursors, which render inputs irreversible, and

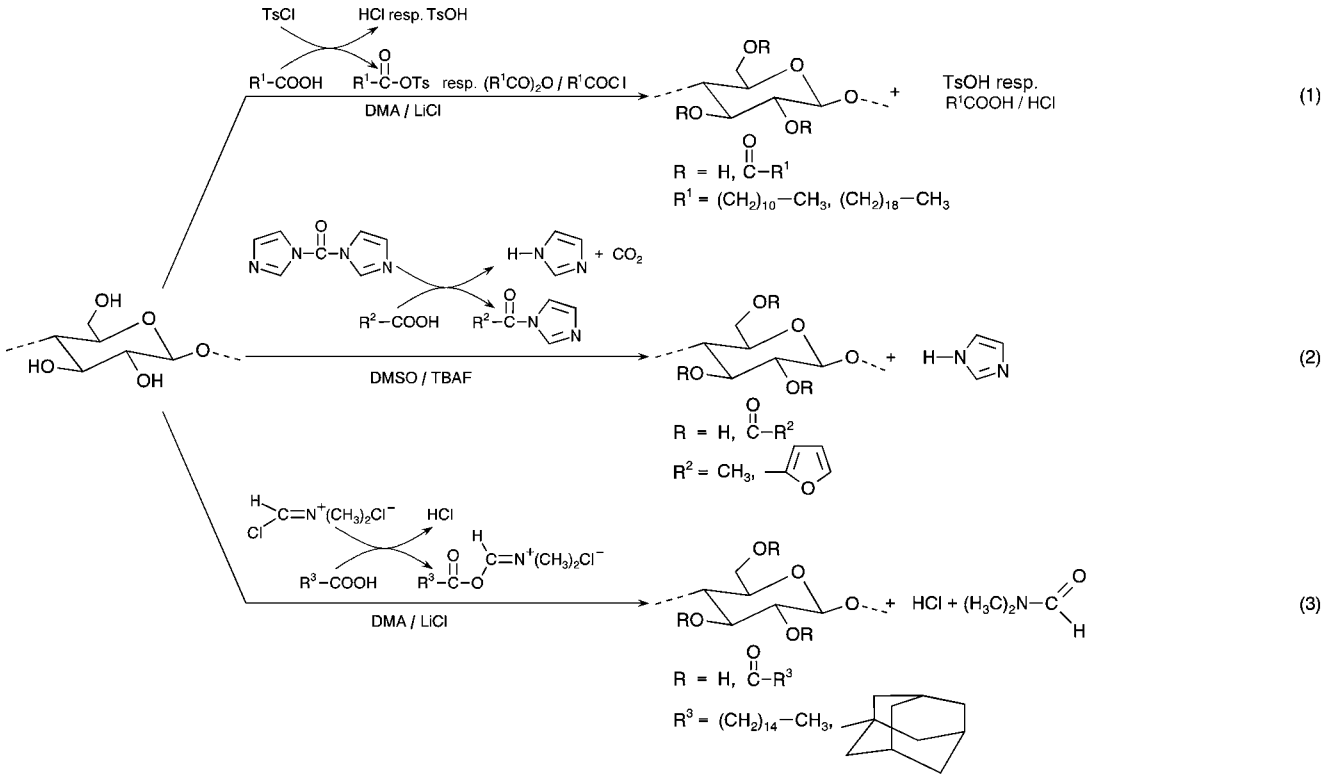


Scheme 4. Synthesis pathways to cellulose sulfates with regioselective distribution of ionic groups.

result from kinetically controlled reactions. A further option toward regioselectivity involves the conversion of reactive intermediates.

In view of their thermoplastic behavior and self-organization, cellulose esters of long-chain carboxylic acids were systematically studied.[79] In this context, composites and nanocomposites of cellulose and its derivatives with lignin as well as supramolecular architectures play an important role as natural composite wood substitute materials.[79] Cellulose esters of aliphatic, aromatic, bulky, and functionalized carboxylic acids are available through the activation of free acids in situ with tosyl chloride, *N*,*N*′-carbonyldiimidazole, and iminium chloride under homogeneous acylation with DMA/LiCl or DMSO/TBAF. From this, a wide range in the degree of substitution, various substituent distributions, and interesting properties (bioactivity, thermal and dissolution behavior) are possible (Scheme 5).[80]

The successful deacetylation of cellulose acetates (CAs) by means of acetyl esterases was recently reported.[81] Regioselectively C6-substituted CAs with a low degree of substitution (DS) can be produced by enzymes of the carbohydrate esterase (CE) family 1. Esterases of the CE 5 family lead to regioselectively 3,6-di-*O*-acetylated CAs, whereas the regioselective modification at position 3 is possible with CE 4 enzymes. Systematic investigations dem-



Scheme 5. Esterification of cellulose by the in-situ activation of the carboxylic acid by (1) tosyl chloride, (2) *N*,*N*′-carbonyldiimidazole, and (3) iminium chloride.

onstrate that the distribution of acetate groups within the AGU and along the cellulose chains of the starting acetates influences the effect of the enzymes. Acetate groups at position 2 are particularly active. The acetylase of *Aspergillus niger* catalyzes preferential deacetylation of cellulose acetate (CA) to form a product that is C6-acetylated along the polymer chain.[81a,82]

3.2.2. Cellulose Ethers with Nonstatistical Substituent Distribution along the Chains

Blocklike carboxymethyl celluloses (CMCs)[83] can be created by using the concept of reactive structure fractions.[84] This term was applied to activated noncrystalline areas of cellulose, which by treatment with low concentrations of aqueous sodium hydroxide, permit a selective attack on the alkylation reagent. This connection exploits the fact that the activation of the cellulose by aqueous sodium hydroxide is dependent on the concentration of base and on the lateral dimensions of the ordered areas. Therefore, with appropriate concentrations of base, noncrystalline chain segments can react in a blocklike manner. Another possible route to CMCs with unconventional substituent distributions is through the derivatization of cellulose in reactive microstructures, which are formed by induced-phase separation.[80a] In this case, NaOH used for activation is added in the form of anhydrous particles to a solution of cellulose in DMA/LiCl, which initiates a phase separation under gel formation. At the solution–particle interface, active cellulose is regenerated (reactive microstructures) in the chain segments with sodium monochloroacetate to give CMCs with DS values up to 2.2 in one reaction step. Structure analysis of these CMC products revealed a distribution of substituents that deviates significantly from statistical prediction.[80a]

The phase-separation principle can also be extended to other solvent systems (DMSO, TBAF, and NMMO), various cellulose intermediates (CA and TMSC; Figure 9), as well as other cellulose ether syntheses (Figure 10). In all cases, blocklike functionalization patterns occur and thus the formation of products with new properties. The curves

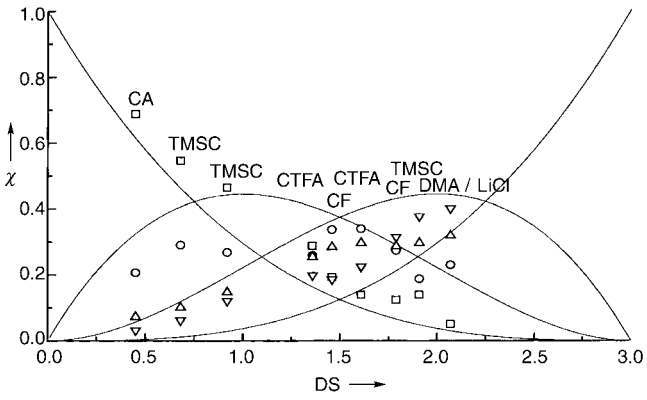


Figure 9. Mole fractions χ of glucose (○), mono-*O*-carboxymethyl glucoses (□), di-*O*-carboxymethyl glucoses (△), and 2,3,6-tri-*O*-carboxymethylglucose (▽) in hydrolyzed carboxymethyl cellulose samples as a function of the degree of substitution (DS) determined by HPLC. Starting from cellulose acetate (CA), trimethylsilyl cellulose (TMSC), cellulose trifluoroacetate (CTFA), cellulose formate (CF), and cellulose dissolved in DMA/LiCl, the polymers were synthesized by induced-phase separation.[80a]

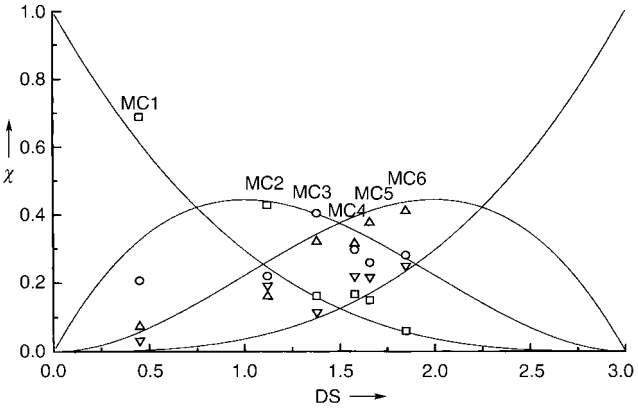

Figure 10. Mole fractions χ of glucose (○), mono-*O*-methyl glucoses (□), di-*O*-methyl glucoses (△), and 2,3,6-tri-*O*-methylglucose (▽) in hydrolyzed methyl cellulose (MC) samples as a function of the degree of substitution (DS) determined by HPLC.[80a]

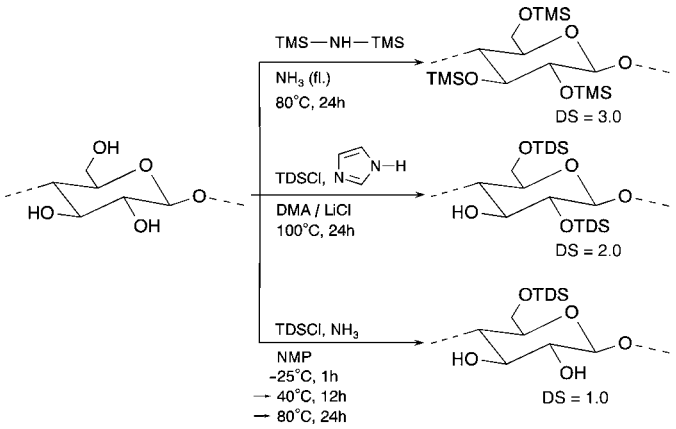
presented in the Figures correspond to the molar fractions, which were calculated by a simplified statistical model by Spurlin.[80e] This model is based on the assumption of uniform reactivity between the OH groups of C2, C3 and C6, independent of the DS value already present. Whereas the mole fractions of heterogeneously synthesized cellulose ethers agree with model calculations,[80f] the mole fractions of samples produced by induced-phase separation deviate from this model. In all cases, the portion of unsubstituted and trisubstituted AGUs is extremely high. The resulting blocklike functionalization pattern is also reflected in the new properties of these products. The partial DS values of positions 2, 3 and 6 of the carboxymethyl celluloses can be calculated from the ^{1}H NMR spectra of the carboxymethyl glucoses obtained by chain degradation.[80f]

3.2.3. Silyl Celluloses

The silylation of polar protic groups (such as OH) with chlorosilanes and silazanes leads to silyl ethers which are characterized by a remarkable increase in thermal stability, lipophilic behavior and a lack of hydrogen bonds. Owing to the simple cleavage of the silyl ethers under acidic conditions, or through nucleophilic attack, they can be used as selective protecting groups in organic synthesis.[85] Therefore, the introduction of silyl groups and the properties of silyl ethers are very attractive in carbohydrate and polysaccharide chemistry.

The silylation of cellulose has been known for about 50 years.[86] During the last decade, it proved to be a suitable way to prepare silyl celluloses for the formation of supramolecular structures (Section 3.3.1) and to differentiate between the three OH groups of the AGU in regioselective syntheses with silicon-containing protecting groups.[87,88]

As shown in Scheme 6, trimethylsilylation with hexamethyldisilazane (HMDS) in liquid ammonia results in a complete conversion of all hydroxy groups to form 2,3,6-tri-*O*-trimethylsilyl cellulose with a DS value of 3.0.[89] The



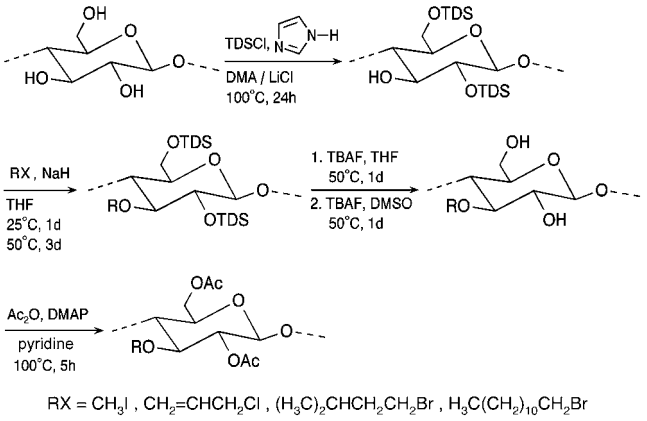
Scheme 6. Various reactivities of the hydroxy groups of cellulose during silylation.

activation of the cellulose with liquid ammonia takes about 30 min. In this process, the accessibility of the OH groups reaches such degree that the rate of silylation (with saccharin as catalyst)[88b,c] follows first-order kinetics up to 50%, although the reaction takes place heterogeneously at the suspended cellulose. During the silylation and desilylation reactions described below, no degradation of the cellulose chain occurs.[88]

If the OH groups are made accessible by dissolving the polymer in DMA/LiCl (homogeneous reaction) and if the synthesis takes place in the presence of imidazole, the bulky silylation reagent thexyldimethylchlorosilane (TDSCl) will lead to complete silylation at O6 and O2 (DS value = 2.0), which means that the primary and the most reactive secondary OH groups are converted.[90] If silyl ether formation starts with the same reagent in cellulose suspension in aprotic dipolar media such as *N*-methylpyrrolidone (NMP), which contain gaseous ammonia, a specific solution state of the silyl cellulose is observed after silylation of all primary C6-OH groups, and after evaporation of the ammonia at about 40 °C. This state does not permit any further reaction of the secondary hydroxy groups, even in cases of large reagent excess, increased temperature, and very long reaction times.[88a]

Structure analysis of the regioselectively substituted silyl celluloses has been particularly successful with 2D NMR spectroscopy after methylation of all free OH groups, complete desilylation, and acetylation of all OH functions created (Scheme 7).[88a] Such analysis is also possible after a simplified analogous process in which acetylation is carried out on the hydroxy groups not converted during the silylation.

Through this complex sample preparation, a remarkable improvement in spectral resolution is observed. In this manner, the structure of 2,6-di-*O*-TDS cellulose could be determined by NMR spectroscopy of 2,6-di-*O*-acetyl-3-*O*-

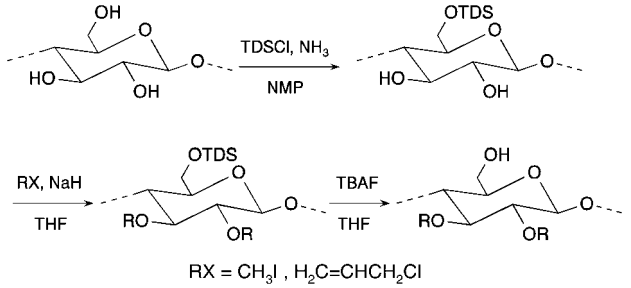


Scheme 7. Synthesis of 3-*O*-ethers of cellulose from 2,6-di-*O*-thexyldimethylsilylcellulose.

methyl cellulose. Likewise, the structure of 6-*O*-TDS cellulose was determined with 2,3-di-*O*-acetyl-6-*O*-TDS cellulose under spectroscopic analysis. An exact correlation between the signals and the protons of the AGU can made with the resultant cross-peaks. The downfield signal shifts of H-2 (4.94 ppm) and H-3 (4.58 ppm) verify the subsequent acetylation of the secondary OH groups. The methylene protons of the AGU reveal a typical high-field shift of H-6a (3.64 ppm) and H-6b (3.14 ppm) as a result of O6 silylation.[88a]

A permethylation analysis was carried out in parallel, with chain degradation of the methylated samples by aqueous trifluoroacetic acid and HPLC analysis of the methyl glucoses.[91] Furthermore, analysis of the silicon content in a classical manner by the elementary analysis of SiO_2 has proven to be very useful and reliable.

The desilylation of cellulose silyl ethers can lead to completely desilylated cellulose regenerates (films, particles, and filaments), to partially silylated celluloses with an alternative distribution of silyl groups,[89b,c] or to regioselectively substituted cellulose derivatives by using the protecting group technique.[90] Typical examples are the syntheses of 3- and 2,3-alkyl ethers of cellulose (Scheme 7 and 8).



Scheme 8. Synthesis of 2,3-di-*O*-alkylcelluloses by the protecting group techniques.

The structure of these regioselectively functionalized celluloses can be determined by ^{13}C NMR spectroscopy (Figure 11), 2D ^{1}H–^{1}H and ^{1}H–^{13}C techniques (Figure 12) and COSY-DQF spectra (Figure 13). ^{1}H NMR spectroscopy requires the acetylation of the free OH groups.

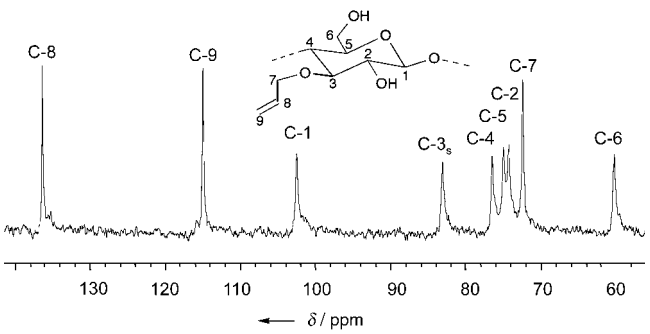


Figure 11. ^{13}C NMR spectrum of 3-*O*-allyl cellulose in [D_6]DMSO at 60 °C.[88a]

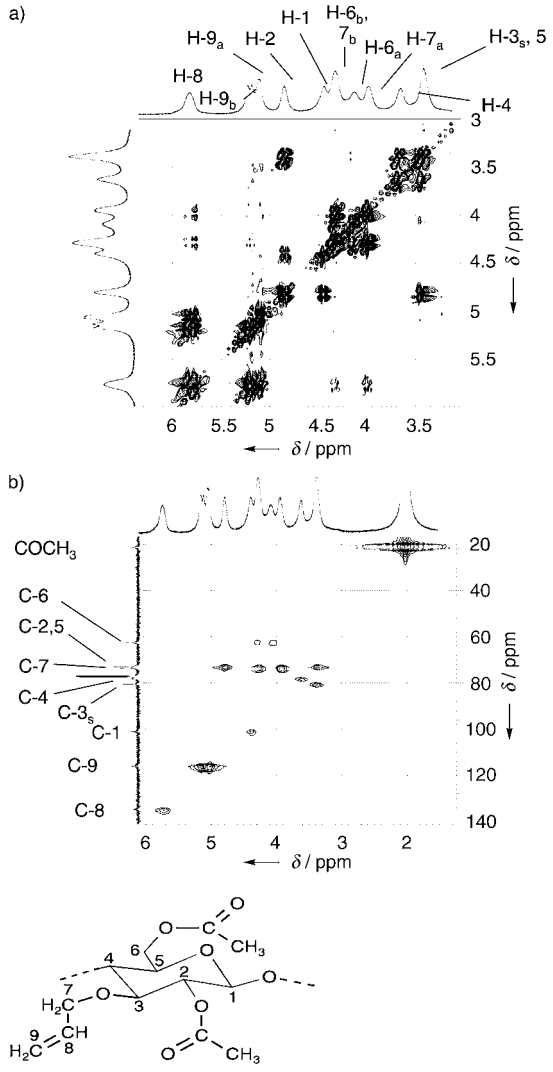

Figure 12. a) ^{1}H–^{1}H NMR spectrum and b) ^{1}H–^{13}C-HMQC measurement of 3-*O*-allyl-2,6-di-*O*-acetylcellulose in $CDCl_3$ at 40 °C.[88a]

Regular selectively functionalized celluloses are important for gaining new insight into the solubility and solution structure of cellulose derivatives. The use of aliphatic O3 cellulose ethers with various alkyl group lengths, it was demonstrated that short alkyl residues (e.g. pentyl) at the stiff cellulose backbone leads to insolubility, whereas long alkyl chains (e.g. dodecyl) result in molecularly soluble products. Together with other facts, these results indicate that entropic effects affect solubility to a much greater extent than enthalpic factors that have been considered in the interpretation of the solvation effects up to this point in time.[39,40,76]

3.2.4. *Cellulose Sulfonates*

The synthesis of organosulfonic acid esters (sulfonates) by simple esterification of the OH groups of cellulose with the corresponding sulfonic acid chlorides or anhydrides is an effective way to attach (in contrast to all cellulose derivatives important up to now) nucleofuge groups to cellulose. The cellulose sulfonates therefore open a wide range of substituted products, which are not available through the conventional methods of "O chemistry" of cellulose (that is, attack of the O atom donor of the OH groups to electrophiles). Moreover, they also have interesting polymeric and material properties, creating new fields of application.[92]

The most frequently synthesized and used cellulose sulfonates are the *p*-toluenesulfonates (tosylates) followed by the methanesulfonates (mesylates), *p*-bromobenzenesulfonates (brosylates), and trifluoromethanesulfonates (triflates). The current knowledge of the synthesis, properties, and subsequent reactions of the cellulose sulfonates is subject of a review.[93]

The synthesis of cellulose sulfonates (Scheme 9) has been previously carried out in suspension (heterogeneous). The homogeneous esterification is successful in solutions of cellulose in DMA/LiCl. In this case, the preparation of cellulose tosylate can be optimized to an extent that permits control of the DS value and the formation of polymers that are free of by-products. At temperatures of +7 °C, for example, cellulose tosylate with a maximum DS value of 2.3 can be synthesized with tosyl chloride in the presence of triethylamine, which can also be controlled by the molar ratio of tosyl chloride/AGU of the cellulose. Scheme 10 demonstrates examples of important downstream reactions of cellulose tosylate.

3.2.5. *Aminocelluloses*

The term aminocellulose refers to aminodeoxy derivatives that bear the nitrogen function directly on the cellulose skeleton, in contrast to the well-known amino acid esters and amino ethers of cellulose.[21a] Corresponding halogen derivatives and sulfonates are typical starting materials for the synthesis of aminodeoxycelluloses.

Cellulose derivatives with amino anchor groups for the immobilization of enzymes and other proteins were obtained through a specific structural design based on cellulose tosylates. In a typical example, cellulose tosylate (DS = 2.3) reacts with 1,4-phenylenediamine (PDA) in DMSO at 100 °C in the presence of TEA[94] (Scheme 11).

To ensure the S_N2 alkylation of only one of the PDA amino groups in homogeneous solution, and to obtain colorless products, a molar ratio of 9:1 PDA/AGU was used. Under these conditions, PDA cellulose is formed with

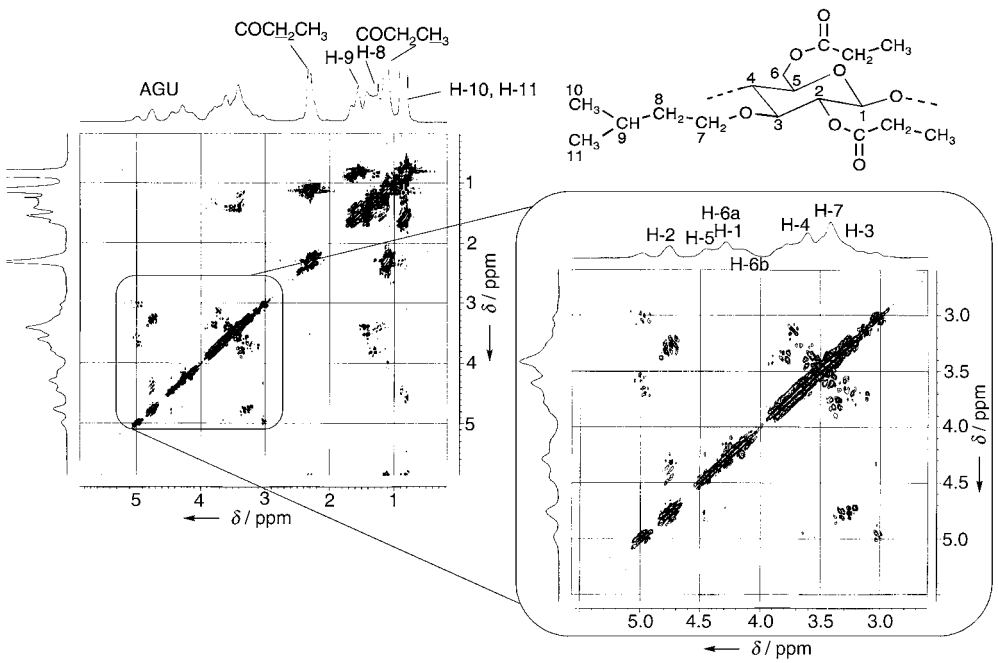

Figure 13. COSY-DQF spectrum of 3-*O*-isopentyl-2,6-di-*O*-propionyl cellulose in $CDCl_3$ at 40 °C.[88a]

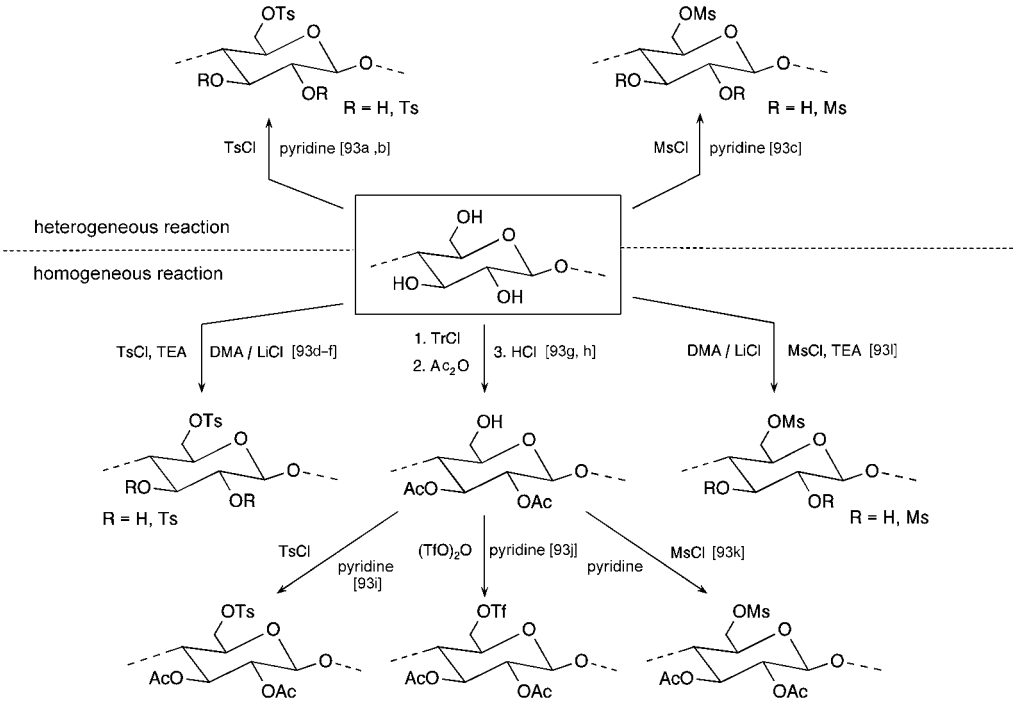


Scheme 9. Synthesis routes for cellulose sulfonates.[93]

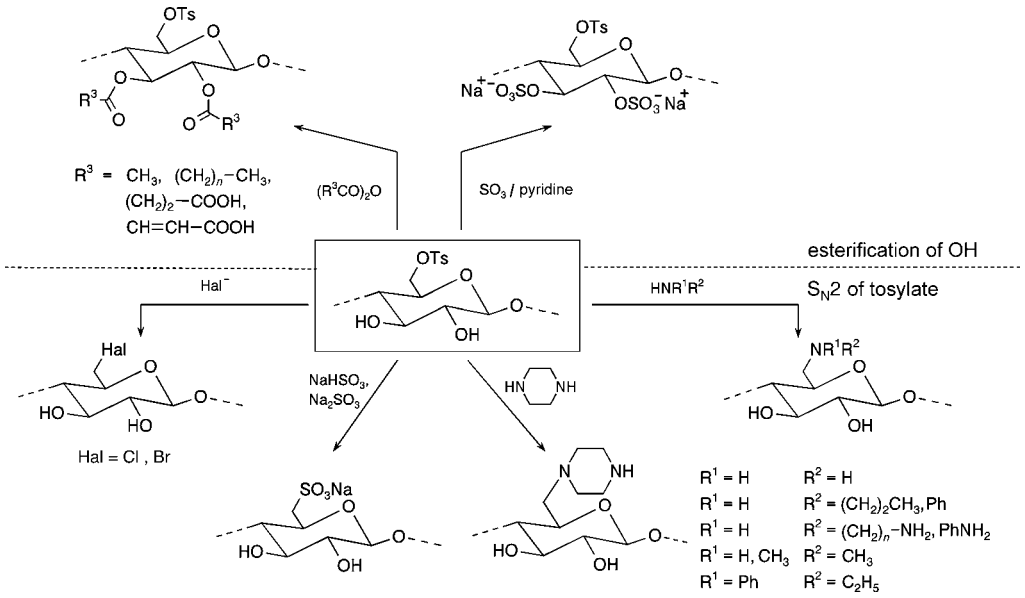
$DS_{PDA} = 0.75$ and $DS_{tosylate} = 1.30$. The ^{13}C NMR spectroscopic data reveal that the transformation occurs at the 6-tosylate group of the starting polymer. The remaining secondary tosylate groups assist in the solubility and film formation of the product.

The PDA celluloses are suitable polymer carriers for the immobilization of enzymes with, for example, glutaraldehyde, diazo coupling, or ascorbic acid, and for the combined fixation of redox-active dyes by oxidative coupling (Figure 14). The potential of PDA cellulose films was investigated by the immobilization of oxidoreductases, such as glucose oxidase, peroxidase, and lactate oxidase. High enzyme activities of 206 mU cm^{-2} were obtained during the immobilization of peroxidase with glutaraldehyde, for example.[95] These properties of PDA celluloses have triggered broad investigations on the application of such aminocelluloses as polymer supports in fiber-optical biosensors.[96]

In comparison, aliphatic diamino groups can be introduced into cellulose with diaminoalkanes (H_2N–$(CH_2)_n$–NH_2; $n = 2, 4, 8, 12$) (Scheme 12),[97] by using the S_N2 reaction of cellulose tosylate derivatives (2,3-benzoate, 2,3-carbanilate, and 2,3-methyl ether). Aminocellulose carbanilates produced from 1,2-diaminoethane and 1,4-diaminobutane with $DS_{amin} < 0.4$ are soluble in DMA and DMSO, for example, and the corresponding 2,3-methoxy derivatives are soluble in water, ethanol, and DMSO. Figure 15 shows a typical ^{13}C NMR spectrum of 6-(4-aminobutyl)-6-deoxy-2,3-di-*O*-methyl aminocellulose in D_2O in part b) compared with the spectrum of the starting tosylate in part a).

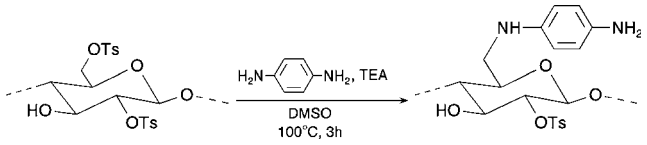
The films formed from these solutions are suitable for the immobilization of enzymes. In this manner, glucose oxidase was immobilized onto an aminocellulose carbanilate ($DS_{aminobutyl} = 0.49$, $DS_{carbanilate} = 0.58$, $DS_{tosylate} = 0.08$) with an activity of 205 mU cm^{-2} by using benzoquinone as the immobilizing reagent.[97] Aminocelluloses of araliphatic diamines have also been used as enzyme supports.[98]

The synthesis of aminocelluloses based on aliphatic monoamines has been known for a long time, as the following examples illustrate. After the initial investigations between 1978 and 1980,[99a,b] the reaction of cellulose tosylates with monoamines was investigated systematically.[99c–e] Open questions were primarily with regard to the inhibition of crosslinking by multiple reactions of the amine, the extent of aminolysis reactions of the toluene sulfonic acid ester under



Scheme 10. Subsequent reactions of cellulose tosylate.[93]

the regeneration of OH groups, as well as the selective conversion of primary and secondary tosylate groups. Tosyl cellulose with DS values of 0.1 to 1.1 synthesized under homogeneous reaction conditions reacts with methylamine to form the corresponding methylaminocellulose with comparable degrees of substitution. These cellulose derivatives are to be used as adsorbents for the extracorporeal purification of blood.[99f] Long-chain aliphatic amines can be introduced by the same methods (Scheme 13).[100]



Scheme 11. Synthesis of PDA-cellulose by reaction of cellulose tosylate with 1,4-phenylenediamine (PDA).

3.3. Supramolecular Architectures

The past 10 years of cellulose research have also been characterized by expanding activity in the design of the supramolecular structure of cellulose derivatives. As a molecular basis in this respect, regioselectively functionalized celluloses have become very important. Preparative and application-oriented work has led to the formation of colloidal superstructures through selective topochemical reactions on crystallites formed by acid-catalyzed hydrolytically degraded cellulose,[101] for example, and to the formation of ultrathin layers of phosphorylated cellulose derivatives on metal surfaces.[102] The following examples are given to illustrate other routes to the formation of supramolecular cellulose architectures and their properties.

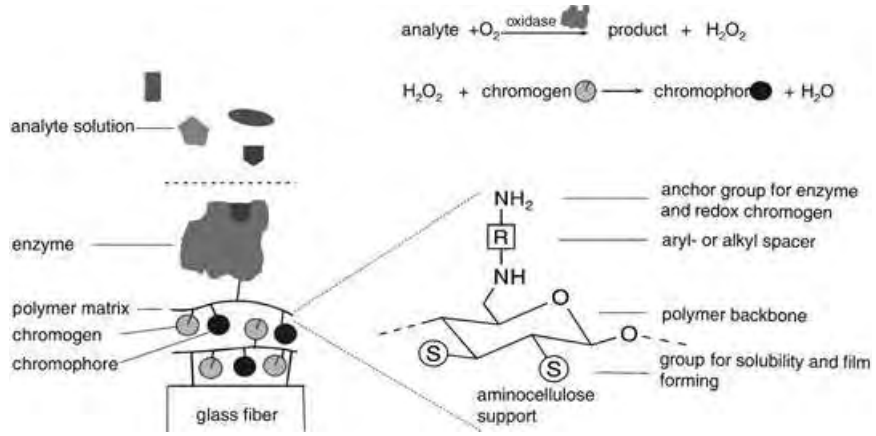


Figure 14. Scheme of an enzyme sensor and structural elements of the aminocellulose support.

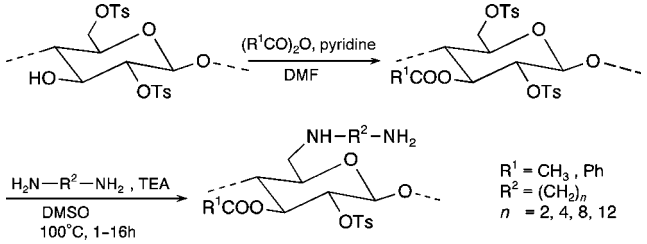
3.3.1. Hair–Rod Nanocomposites

Ultrathin mono- and multilayer systems of high order can be constructed with the Langmuir–Blodgett technique from isopentyl cellulose (DS = 2.9), [5-(9-anthrylmethoxy)pentyl]-isopentyl cellulose ($DS_{isopentyl} = 2.8$, $DS_{anthryl} = 0.1$), fumarate-modified isopentyl cellulose, and trimethylsilyl celluloses (DS > 2.5) (Figure 16).[103]

The architecture of these layers is best described by the embedding of molecular rods—in this case, the cellulose polymer backbone—into the matrix of the side-group segments (ether substituents; hair–rod polymers). By subsequent reactions (photo-cross-linking and cycloaddition) or the



Scheme 12. Aminocelluloses synthesized from aliphatic diamines and cellulose tosylate.

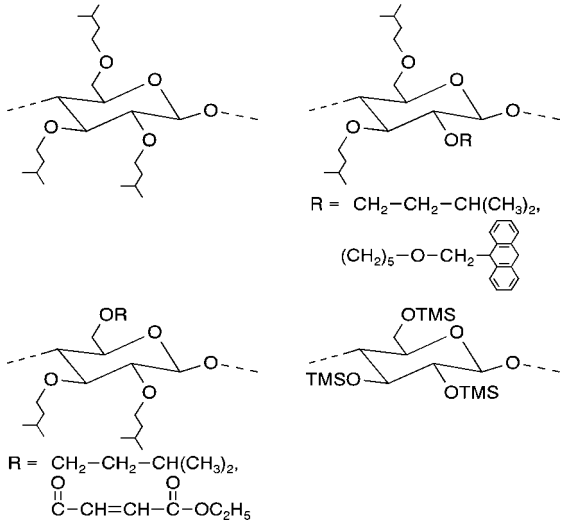

Figure 16. Typical hair–rod cellulose ethers for the construction of nanostructured layers.

regeneration of cellulose through acidic hydrolysis of the TMS-cellulose layers, 3D networks and ultrathin cellulose layers are formed.[104] The latter are important as insoluble and stable hydrophilic films for the adsorption of dyes as well as of synthetic and biogenic polymers. By subsequent introduction of succinate groups into the cellulose films, this behavior can be further amplified.[105] Therefore, ultrathin cellulose layers are very good substrates for diagnostic and analytical purposes. Corresponding 2D cellulose architectures are used for the design of structured ultrathin peptide layers and their use in neurophysiologic growth studies.[106]

3.3.2. NTA Cellulose Films for Protein Fixation

During the course of investigations on the interaction of cellulose and cellulose derivatives with proteins, it was possible to covalently bind nitrilotriacetic acid (NTA) groups onto cellulose.[107a] NTA-cellulose forms thin films on glass substrates from solution in DMSO, which enables a stoichiometric binding of nickel to the NTA substituents upon incubation with an aqueous solution of $NiSO_4$. Treatment of these films with solutions of histidine and fluorescently labeled model proteins, followed by a thorough rinsing to wash away unbound protein yields model protein that is specifically bound to the Ni-NTA groups of cellulose, as substantiated by inverse microscopy. Proteins can then be eluted from the surface by treatment with an imidazole solution (1M).

Figure 17 illustrates the principle assembly of the cellulose–protein complex, containing two histidine units bound at the NTA-modified cellulose film through a Ni^{2+} ion. The

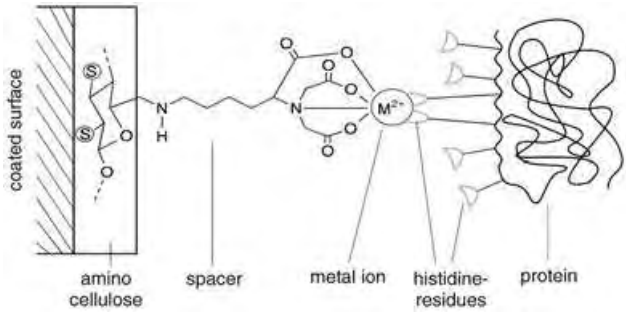

Figure 17. Schematic representation of the immobilization of histidine and fluorescently labeled proteins onto nitrilotriacetic acid (NTA)-modified aminocellulose films by metal complexes (M = Ni, S = control element for solubility and film formation).

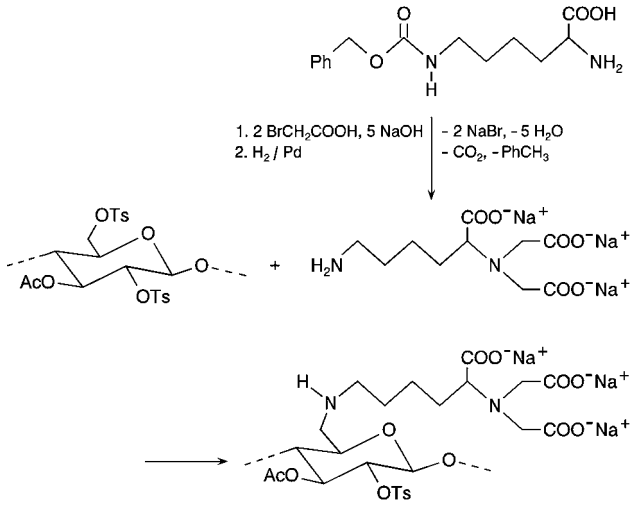
synthesis of the cellulose support involved dissolution of cellulose (DP = 800) in DMA/LiCl and tosylation with tosyl chloride in the presence of triethylamine (DS: 1.2–2.0). To introduce the NTA groups, a corresponding H_2N-terminal derivative was prepared. Starting with N_ε-benzyloxycarbonyl-L-lysine, the N_α position was dicarboxymethylated, the protecting group was removed from the N_ε position and persilylated with trimethylchlorosilane in toluol in the presence of triethylamine (for the separation of by-products and improvement of the following S_N2 reaction). In reaction

with the cellulose tosylate in a DMSO/toluene mixture, the nitrilotriacetic acid derivative was synthesized in 24 h at 90 °C (Scheme 14). The His_6 (6 histidine units) and fluorescently labeled model protein were synthesized according to published methods.[107b]



Scheme 14. Synthesis of nitrilotriacetic acid (NTA)-modified aminocellulose.

3.3.3. *Monolayers of Reactive Cellulose Derivatives*

By addition of tetrathionate to 6-*O*-(3-allyloxy-2-hydroxy)-propylcellulose, water-soluble thiosulfates of cellulose can be synthesized to form dense monolayers with a thickness of 4 ± 1 nm on gold surfaces by chemisorption.[108] These layers have been characterized by ellipsometry, AFM, FTIR- and X-ray photoelectron spectroscopy, as well as contact-angle measurements. These investigations have revealed that the thiosulfate groups are homolytically cleaved, and stable gold thiolate anchor groups are formed via thioradical intermediates. The interaction of these cellulose derivatives immobilized on gold surfaces with proteins was investigated. Cellulose thiosulfates of water-soluble carboxymethyl celluloses were included in this work (Scheme 15).

In summary, it was shown that self-assembled monolayers (SAMs) of cellulose derivatives with reactive groups can be synthesized rapidly and with uniform quality. Biomolecules can be linked to these SAMs directly, with controlled density, and with only a small amount of nonspecific interactions. Such SAMs are therefore a suitable platform for the study of molecular recognition on surfaces and for the development of biosensors.

4. Innovative Commercial Esters and Ethers of Cellulose

Cellulose esters of inorganic and organic acids (Scheme 16) as well as cellulose ethers (Scheme 17) were pioneer compounds of cellulose chemistry, and remain the most important technical derivatives of cellulose.[4,21a,d,109] Present developments are therefore aimed at a more detailed understanding of the structure–property relationships, an improved adaptation of these cellulose products to specific and new applications, and to the decreased use of chemicals from an economical and ecological perspective. Continuous investments into the improvement of technical syntheses (pilot and production plants), into sophisticated analysis, and into improved testing methods determine the course of these developments.

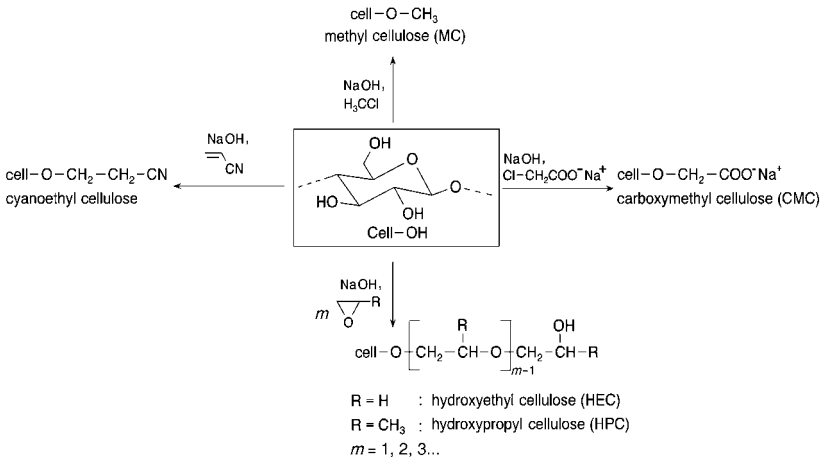

Scheme 17. Examples of commercial cellulose ethers.

acetate (CA), cellulose acetate propionate (CAP) and cellulose acetate butyrate (CAB) are the most important classical and solvent-based cellulose esters of the coating industry.

To decrease the amount of organic solvents used in coating systems, there has been an increased development over the past few years of high solid-content coatings, water-based coatings, powder coatings, and radiation-curable polymers as key elements in new technologies. These technologies now meet the requirements of commercial products as well. In view of the EU directive on volatile organic compounds (VOC), solvent-based lacquers are under special scrutiny. In the case of nitrocellulose (NC) lacquers, the aim is to retain these solvent-containing lacquers as powerful alternatives within the provisions of the EU directive through the establishment of a solvent management system.[111a]

Various concepts were pursued in the development of water-based cellulose ester coatings. Notable examples include the use of conventional as well as high hydroxy group-containing esters in water, the introduction of carboxy groups by radical-initiated graft copolymerization,[112] acylation with dicarboxylic acid anhydrides, and the esterification of carboxymethyl cellulose (Table 3). As the complex structures of these commercial products cannot be characterized completely in many cases, the functional groups are listed without information about their distributions along the polymer. The DS values of the various residues are used for product descriptions. A cellulose acetate butyrate succinate is thus characterized with $DS_{acetate} = 0.09$, $DS_{butyrate} = 1.94$, $DS_{OH} = 0.58$ and $DS_{succinate} = 0.38$. Radiation-curable coatings are synthesized from common cellulose esters by introduction of polymerizable and cross-linkable functionalities (Table 3).

In the field of controlled-release systems, cellulose ester is in an excellent position as a result of its established process and application safety, its readiness toward chemical modifications, and its good handling properties.[110a] New systems were therefore developed on this basis as enteric coatings, hydrophobic matrices, and semipermeable membranes for applications in pharmacy, agriculture, and cosmetics.

4.1.2. Composites, Films, and Membranes

Since the commercial production of celluloid, the classical application of cellulose esters has been as thermoplastic materials, and is currently under intense advancement for the creation of high-performance materials that are based on renewable resources.[110a] Topics include the production of

Table 3: Examples of water-based and radiation-curable cellulose ester coatings.

cellulose acetate propionate (CAP)		H	H_3CCO	H_3CCH_2CO	cellulose acetate propionate (CAP)		H	H_3CCO	H_3CCH_2CO	$OCCH{=}CHCOOH$

long-chain cellulose esters and the development of blends with other polymers. Cellulose esters are widely used in composites and laminates as binder, filler, and laminate layers. In combination with natural fibers, they can be used to some extent as composites from sustainable raw materials with good biodegradability.

Cellulose ester films have been used in large quantities as optical media by virtue of their very good mechanical and optical properties and ease of accessibility.[110a] Although other products with a favorable balance of performance and cost have partially replaced cellulose esters in this field, cellulose acetates in particular continue to be an excellent material for photographic films owing to their excellent properties. The development of LCDs were a result of innovations in this field.

An additional domain of cellulose esters is their use as membranes and other separation media.[110a] Cellulose nitrate and cellulose acetate were the first materials to be fabricated into useful membranes. Today, cellulose esters are used in all techniques of separation. Their applications concern water supply, food and beverage processing, as well as applications in medicine and in bioscience research. They cover the entire filtration spectrum from particle-, micro- and ultrafiltration up to nano- and hyperfiltration (reverse osmosis). Superabsorbers are also a form of sorption media in the broadest sense, characterized by their high swelling and water retention capacities and insolubility (through cross-linking).[110b]

4.2. Developments in the Field of Cellulose Ethers[111]

The synthesis of cellulose ethers is an important aspect of commercial cellulose derivatization. The production of methylcellulose (MC) was described for the first time in 1905, followed by other nonionic alkyl ethers of cellulose in 1912, and of carboxymethyl cellulose (CMC) and hydroxyethyl cellulose (HEC) after 1920. Shortly thereafter, the industrial production of these most important cellulose ethers was started.

They have the outstanding properties good solubility and high chemical stability, and are toxicologically innocuous. The especially important matter of water solubility can be controlled to a certain extent by the constitution and combination of the ether groups, the degree of substitution, and the distribution of substituents. Cellulose ethers are processed in a dissolved or highly swollen state. They are the dominant polymers in numerous industrial applications and in convenience goods for matters in which consistency in the quality of aqueous media and water-containing systems is required.

Etherification of cellulose on the industrial scale is performed in aqueous alkaline media in which cellulose is present in a highly swollen state. The dominant approach for this process is O-alkylation with alkyl halides according to Williamson; other approaches include epoxide addition and Michael addition of reagents with activated double bonds. Scheme 17 highlights some typical examples. In contrast to methyl cellulose, carboxymethyl cellulose, and hydroxyalkyl cellulose, the commercial importance of cyanoethyl cellulose remains limited to a few special applications: as an additive in the paper and textile industry, and in the formation of membranes.

4.2.1. Cellulose Ethers for Drilling Technologies and Building Materials[111a]

The use of cellulose ethers as additives to drilling fluids for consistency control is of considerable importance to the drilling of wells for mineral oil, natural gas, and water. Drilling fluids supplemented with cellulose ethers keep rock dust in suspension, cool the drilling head, and stabilize the bore.

Another significant core business in which cellulose ethers are used is the building materials market, which involves a multitude of tailor-made versions of methylhydroxyethyl (MHEC) and methylhydroxypropyl celluloses (MHPC) that control the rheology and processing of plaster systems. As additives that are admixed to the mortar in the range of 0.02–0.70% by mass, they make up a market share of about 90%. Cellulose ether permits the silo transport and machine processing of dry mortar as well as the effective handling of gypsum plasters, knifing fillers, tile adhesives, and joint fillers. They determine the water requirement, the water-retaining power, and the development of consistency in plaster systems.

4.2.2. Pharmaceuticals, Cosmetics, and the Food Market[111a]

In addition to carboxymethyl cellulose, high-purity hydroxypropylmethyl cellulose (HPMC) was synthesized and introduced onto the market for this demanding area of application. HPMC binds water, has good stability in freeze/thaw cycles, mediates the viscosity of liquids, and is odorless and tasteless. In products of this kind, purity and permanent quality play a critical role, as their production must adhere to GMP standards.

Carboxymethyl cellulose is used as a stabilizer in beverages. It has improved the consistency, texture and storage quality of milk products, and ensures that the solids added are kept in suspension. It is also used to stabilize whey-based beverages.

5. Regenerated Cellulose: Environmentally Friendly Technologies on the Advance

5.1. Present Situation

The most important segment by volume in the chemical–technical processing of cellulose is represented by products made of regenerated cellulose (man-made cellulosics), which primarily include regenerated fibers, but also films, membranes, and sponges. At an annual world production of about 2.2 million tons (2002), the viscose method,[113] well over 100 years old, still dominates production methods in which pulp with CS_2 is converted into cellulose xanthogenate as a metastable intermediate. The xanthogenate is soluble in aqueous sodium hydroxide, and can be formed as a viscose solution in a wet process. After precipitation of the shaped

product, the substituent is cleaved off, and high-purity cellulose is regenerated. Viscose fibers (Rayon) have excellent properties for a broad product range, from wet-strength cottonlike textile fibers (Modal fibers) to technical fibers in the form of cord (Rayon) for use in high-performance tires. Viscose technology is still in use today for film (cellophane) production, which is particularly important for food casing products.

The viscose route, however, is technologically complex (see processing scheme in Figure 18), requires highest-quality dissolving pulp, and leads to problematic environmental loads from the use of CS_2, heavy metal compounds (in the precipitation process), and resultant by-products. To decrease emissions and to meet the environmental standards, different methods can be applied.

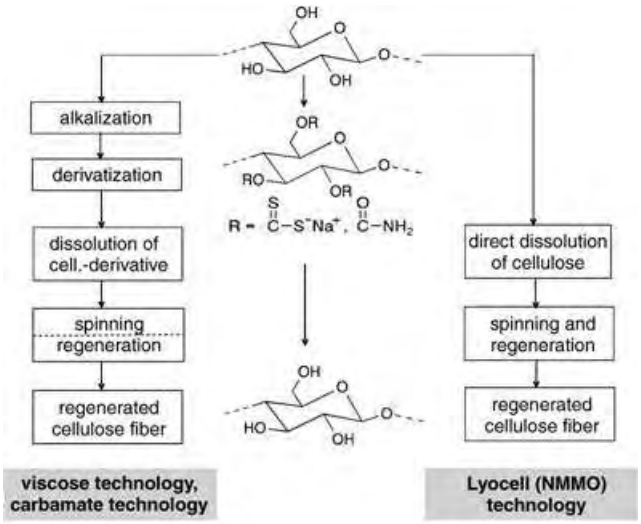

Figure 18. Process principles in regenerated cellulose technologies: left, derivate methods; right, direct methods.

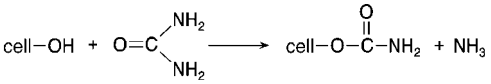
The first (and rather unspectacular) variant to this end is to improve the existing viscose production by optimizing the consumption of chemicals, with particular regard to minimizing the use of CS_2.[114] This variant also includes the refitting of exhaust gas and waste water cleaning equipment, which has been implemented continuously in the viscose industries in western Europe, where today the emissions either meet or lie below the threshold values in place.[115] It is advantageous that existing facilities can still be used for the production of highly sophisticated types of fiber that have been introduced to the market. The increased cost of viscose technology incurred by the purification of exhaust gas and waste water is a disadvantage that must be weighed against the product advantages, in particular, in case of the installation of new production capacities.

Alternate processing technologies should be simpler than the viscose process, and environmentally hazardous materials and side products in general must be avoided (Figure 18). An alternate derivatization method that has been developed to commercial maturity without the use of sulfur-containing compounds, but that retains the viscose spinning technology, is the CarbaCell process,[116] in which a new reaction variant employs urea to convert cellulose into cellulose carbamate, which can be subsequently processed on existing viscose spinning systems.

The direct dissolution and shaping of cellulose without derivatization is possible with copper ammonia technology,[117] which originated as a very early spinning route of cellulose (Cupro silk, Cuprophane). It is rarely used anymore, as it poses environmental hazards. Among others, it has been suggested that the dissolution and shaping of cellulose could be carried out by DMA/LiCl or zinc chloride and in aqueous solution with NaOH (CELSOL process),[118] or phosphoric acid as a direct solvent to spin high-strength cellulose filaments.[119] However, the most advanced development took place beginning in the 1980s with a process based on the NMMO monohydrate solvent system, which was taken to commercial maturity and which made the current industrial breakthrough known as the Lyocell process.[120] This process offers the potential for a revolutionary development in cellulose processing, as it is comparatively simple (Figure 18) and is practically free from emissions as almost all the solvent involved is recovered.

5.2. The CarbaCell Process

The starting point of this development is founded in previous studies[121] of the transformation of cellulose with urea (after urea breakdown) to form cellulose carbamate (Scheme 18), which is soluble and shapeable in sodium



Scheme 18. Formation of cellulose carbamate by transformation of cellulose with urea.

hydroxide solution. The patented CarbaCell technology is based on a synthesis of the cellulose carbamate in xylene as a transfer medium.[116] The technical sequence is similar to the viscose method (Figure 18). The starting cellulose material is initially alkalized and pre-ripened (partial chain degradation); in the synthesis stage it is subsequently derivatized and dissolved in sodium hydroxide solution. The spinning solution is filtered and deaerated prior to wet spinning in an acidic precipitation bath, followed by a salt-containing alkaline decomposition bath for the hydrolysis of the carbamate groups at elevated temperature. The structural changes of the cellulose during processing are clearly illustrated in Figure 19 with ^{13}C-CP/MAS solid-state NMR spectra.

Depending on the derivatization procedure, the transformation of the alkalized cellulose with urea leads to structures that are similar to the cellulose modifications II and IV, and that have either blocklike or statistic distributions of the substituents along the cellulose chain.[38e] Apart from

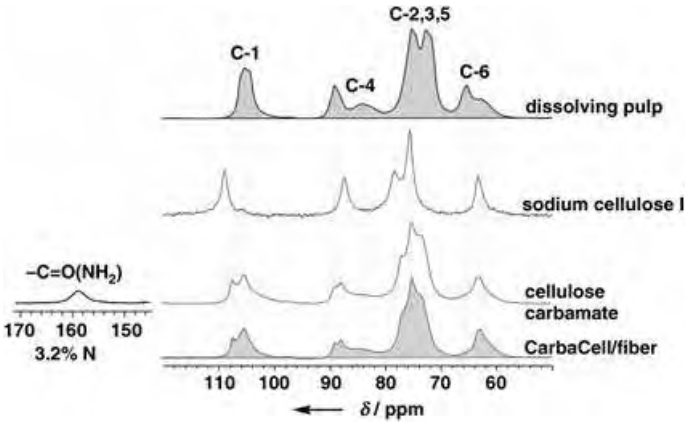


Figure 19. Structural changes of cellulose in the carbamate process as observed with ^{13}C-CP/MAS NMR spectroscopy.[122]

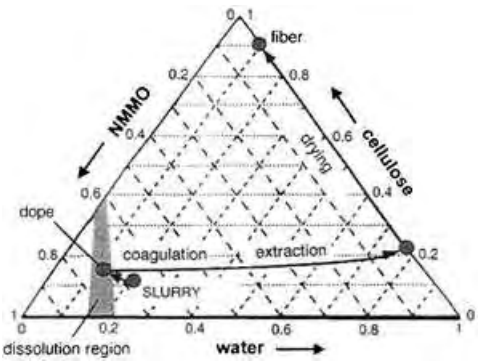

Figure 20. Phase diagram: cellulose/NMMO/water.[124a]

the use of the innocuous urea as a substitute for the toxic CS_2, the advantage of the carbamate process is that the cellulose carbamate is relatively stable at room temperature, which permits storage times of more than a year without loss of quality. Thus, the synthesis of cellulose carbamate can be carried out on a large scale in a central location, from which products can then be shipped to decentralized facilities for processing (such as spinning factories). Industrial tests have shown that cellulose carbamate can be processed without any problems on viscose spinning machines. Despite the advantages of the carbamate process, which could possibly be used for other products such as high-absorbent nonwovens, hollow fibers, sponges, and carpet cleaners, industrial cellulose carbamate production sites have not yet been established.

5.3. The NMMO (Lyocell) Process

Owing to its strong N–O dipole, *N*-methylmorpholine-*N*-oxide (NMMO) in combination with water can dissolve cellulose without prior activation or derivatization. With a water content of 13.3 % by mass and a decreased melting point of about 74 °C, NMMO monohydrate is significant as a solvent, from a technical standpoint, compared with pure NMMO. The breakthrough of this system for technical applications came with the introduction of stabilizers such as propylgallate, which suppresses the radical separation of the NMMO and scission of the cellulose chain at the required processing temperatures.[123] Solutions with cellulose content of up to 23 % can be produced starting with the dispersion of conventional cellulose in NMMO with a high water content (such as 50 %). Subsequent concentration of the suspension at higher temperature until the NMMO monohydrate composition is made permits dissolution of the cellulose. In the ternary phase diagram of Figure 20, the path of the cellulose during the solutions production and the technological stages of the NMMO processes (cf. Figure 18) can be followed.

The shaping of the cellulose/NMMO/water solution into fibers takes place at temperatures between 80 and 120 °C, at which the semiliquid system (dope), with a cellulose content of 8–23 %, is extruded from a nozzle over an air gap with a length of 10–250 mm into an aqueous precipitation bath. There, the cellulose precipitates almost instantaneously. In a closed circle, the industrial recovery of NMMO is 99.6–99.7 % from the precipitation bath, with its upgrade and cleaning by an ion-exchange process. In the dry jet/wet-spinning process, any deformation in the region of the nozzle and the following air gap section elicits a significant influence on structure formation (particularly the orientation state) of the thread and its resulting properties. The fundamentals of crystallization and structure formation of the cellulose after precipitation from NMMO solutions were initially analyzed by Chanzy and co-workers,[125] and Dubé and co-workers.[126] A list of the extensive literature concerning the structure formation of cellulose regenerated materials made from NMMO solutions available since the seminal work is given in Ref. [42]

Compared with conventional viscose fibers, today's generation of commercial Lyocell fibers spun from NMMO solution have outstanding properties in certain respects, such as strength in both wet and dry states, modulus of elasticity, sorption behavior, wearing properties, gloss, and touch. However, the distinct wet fibrillation behavior is predominantly disadvantageous, and its suppression still requires additional processing, such as subsequent cross-linking steps (Section 5.5).

The fact that the cellulose/NMMO/water solution can be deformed in the nozzle and the air gap, similar to a melt, opened up the initial possibility to produce cellulose films in a blow-extrusion process[127] (basic sketch in Figure 21). Spun fleeces (melt-blown nonwovens) [128] can also be manufactured analogously to synthetic polymers (polyethylene, polypropylene, and polyethyleneterephthalate) shaped from melt. The blown-film process permits the setting of longitudinal and transverse properties by means of the corresponding orientation states, a feature still not feasible in this manner for cellulose films, on the one hand. On the other hand, the morphology and pore structure of the film can be influenced by the subsequent precipitation process, which is not possible in melt-extruded films from synthetic polymers. This results in versatile application possibilities for the blown films from cellulose, which range from packaging materials and food casings, to dialysis membranes.

Another advantage of the NMMO process is that less expensive cellulose of lower purity (higher hemicellulose

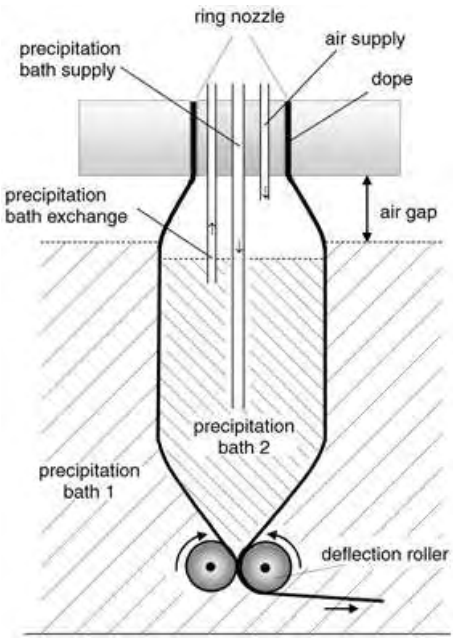

Figure 21. Basic sketch on blow-extrusion of cellulose films made from NMMO solution.

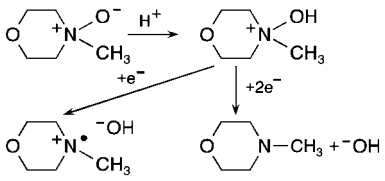
content) can be used; this is a significant benefit for the development and production of melt-blown nonwovens.[128] The pioneering significance of the cellulose/NMMO/water system is also made clear by the fact that apart from classical fibers and films, numerous new products can be produced, thus opening a gigantic field of application for the sustainable polymer raw material cellulose. Developments are currently in progress, including lyophane membranes for water purification,[124b] precursor filaments for carbon fibers,[129] and cellulose-based functional materials[130] such as conductive and piezoelectric fibers, ceramic hollow fibers, pearl cellulose for encapsulation, and highly porous materials for various applications.

Special emphasis must also be placed on the fact that through the industrially applied Lyocell fiber process and the emission-free technical NMMO recovery system developed in this field, a significant drawback to the previous cellulose technologies has been removed. This achievement was acknowledged by awarding the Austrian company Lenzing AG the EU Environmental Award 2000 for the Lyocell process.

5.4. The Chemistry of the NMMO/Cellulose System

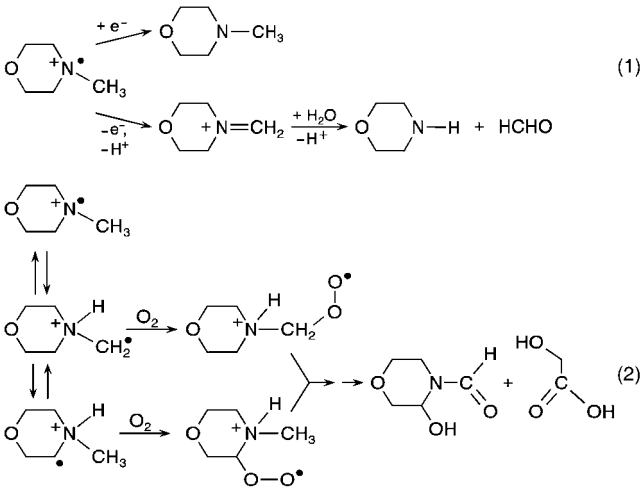
Like all amine-*N*-oxides, NMMO is well-known as an oxidizing agent in organic chemistry. Therefore, its application in an industrial process is not unproblematic. Against this background, systematic and detailed investigations on the chemistry of NMMO were carried out in a series of studies.[131a]

All homolytic reactions of NMMO start with cleavage of the N–O bond with formation of aminium (aminyl) radicals (Scheme 19). In the absence of oxygen, these radicals undergo



Scheme 19. Homolytic and heterolytic bond cleavage of *N*-methylmorpholine-*N*-oxide (NMMO).[131a]

disproportionation or react in redox processes that finally produce *N*-methylmorpholine, morpholine, and formaldehyde (Scheme 20, top). These processes are induced by transition metal ions. In the presence of oxygen, the radicals react with the latter (Scheme 20, top).



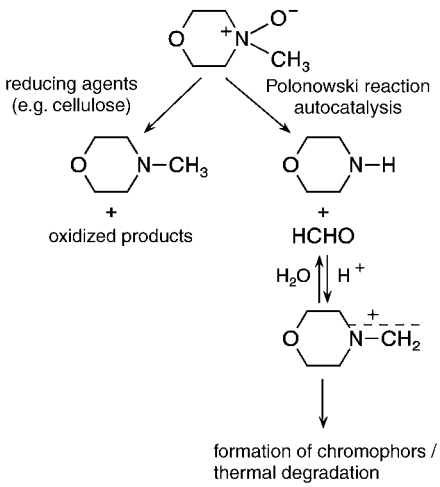
Scheme 20. Reactions in the NMMO/cellulose system starting from the aminyl radicals; products of redox processes in the (1) absence and (2) presence of oxygen.[131a]

The heterolytic reactions in NMMO solution proceed either by reductive deoxygenation of NMMO, which produces *N*-methylmorpholine with concomitant oxidation of reductants such as cellulose, or by the formation of morpholine and formaldehyde by Polonowski-type reactions in intramolecular redox processes (Scheme 21). A third pathway induced by carbenium-iminium ions as an autocatalytic process can cause the quantitative decomposition of NMMO.

The current knowledge of the potential reactions in the cellulose/NMMO/water solvent system is of considerable significance for the safe and economically effective production of cellulose fibers according to the aminoxide process. The strict exclusion of heavy metals such as copper, even at the smallest concentrations, as well as a tightly controlled temperature system are basic safety requirements.

5.5. Structures and Properties of Cellulose Regenerate Fibers and Films

The high stage of development and the vast range of today's viscose products are founded on decades of research



Scheme 21. Reductive deoxygenation and carbenium-iminium ion formation in the NMMO/cellulose system.[131a]

efforts. It results from a largely empirical understanding of the complicated processes of cellulose derivative structure formation from solution which have not always been published, and which are mastered today only by a few specialists in industry and research institutes. The development of new, possibly superior products manufactured through application of the latest environmentally compatible technologies can be realized only through a comparatively thorough understanding of the structure formation process and the connections between manufacturing conditions, structures, and properties. The differences between viscose, carbamate, and Lyocell fibers based on different structure formation conditions are described below. From this, the targets of the structure–property relationships of new products can be derived.

5.5.1. *Cellulose Regenerate Fibers*

Electron micrographs of ultrathin sections of the various regenerate fibers reveal that textile viscose fibers have a lobed cross-section and a skin–core morphology, whereas the round to oval cross-sectional shapes and the homogeneous morphologies of carbamate and Lyocell fibers are distinctly different, and are similar to each other (Figure 22). In the latter case, it is apparent that a fast "hard" precipitation takes place without hydrolysis of the carbamate groups, whereas the precipitation conditions of the viscose process are "softer"; the precipitation, the substituent removal, as well as the transport of the reaction products during regeneration take

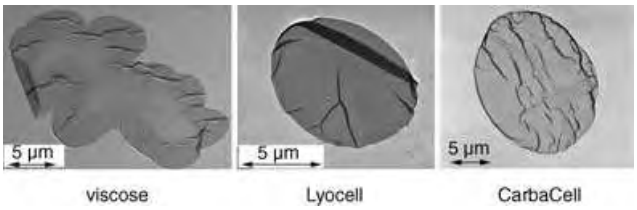


Figure 22. TEM images of cross-sections of various kinds of cellulosic fibers.

Table 4: Degrees of crystallinity (x_c) and crystallite sizes ($D_{(hkl)}$) of regenerated cellulose fibers.

Fiber Type		x_c [%]	$D_{1\bar{1}0}$ [nm]	D_{110} [nm]	D_{004} [nm]
viscose		27–31			
	technical yarn		6.6	3.9	9.7
	textile yarn		5.1	4.5	9.8
Lyocell	filament	35	4.4	3.3	17.5
carbamate	filament	34–43	3.6–4.1	4.1–5.3	10.0–12.4

place as competing processes. Table 4 shows that the degrees of crystallinity (WAXS, Ruland–Vonk method)[132] for carbamate and Lyocell fibers range between 35 and 40 %, above the respective value for viscose fibers of lower crystallinity (≈30 %). A comparison of the crystallite dimensions, also determined by X-ray diffraction and given in Table 4, demonstrates that the Lyocell fiber has narrower and particularly longer crystallites (in the fiber direction).

Distinct differences between the types of fibers are also revealed in their state of orientation, which has significant influence on the mechanical properties. Figure 23 compares the overall orientation (f_t; obtained by birefringence measurements), the orientation of the crystalline ranges (f_c; X-ray

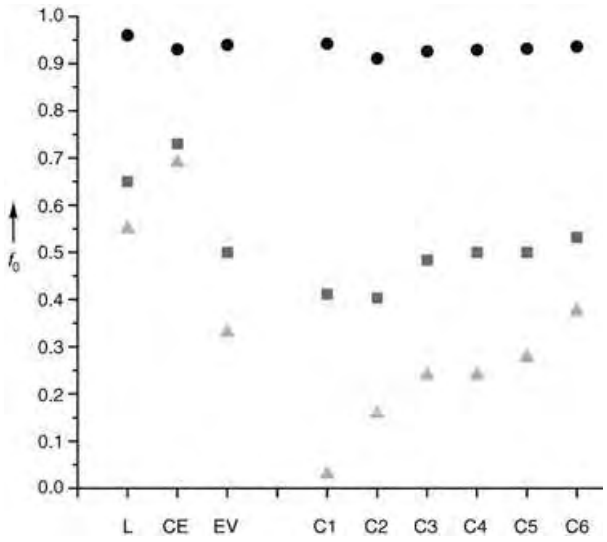

Figure 23. Orientation parameters of different cellulose regenerate fibers:[122] orientation factor, f_o; overall orientation, f_t (■); orientation of crystalline ranges, f_c (●); orientation of noncrystalline chain segments, f_a (▲); fiber types: Lyocell, L; CordEnka, CE; EnkaViskose, EV; Carbamate, C1–C6.

diffraction), as well as the orientation factors calculated for the noncrystalline chain segments (f_a) of commercial fibers and a number of development patterns from the carbamate program.

It is clear that the stiff and fibrillating behavior of the Lyocell fibers is caused by their high orientation in the noncrystalline regions—similar to technical fibers—the lowering of which in combination with a decrease in the degree of crystallinity was, and still is, a central task in the continued development of Lyocell fibers. In the development of

carbamate fibers, however, the problem was to increase the low orientation of the noncrystalline chain segments at the beginning. This problem has been solved in the meantime; today carbamate fibers can be produced with an orientation state and property profile almost identical to those of viscose.

The decrease of crystallinity and orientation of Lyocell fibers is possible by a "softer" precipitation in alcoholic baths. Fibers with a firm, highly oriented core and a soft, non-fibrillating shell can be produced through a two-stage precipitation in alcohol and water (Figure 24).[133]

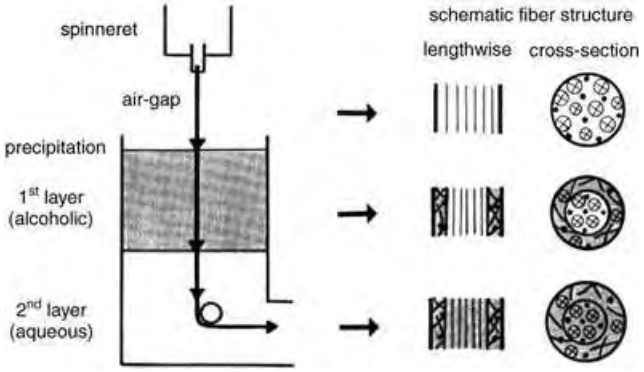

Figure 24. Basic sketch of the double-bath precipitation for Lyocell fibers with a core–shell structure.

This example demonstrates, that knowledge of fiber structures and an understanding of the structure-forming process are important prerequisites for the development of products with the desired properties. A wide range of alternate possibilities for influencing fiber structure and properties, including the downstream cross-linking of molecules in the fiber, can be found in the patent literature. The full potential capacity for such process control, however, has certainly not yet been tapped by the methods currently in use. Therefore, a more thorough understanding of these structure-forming processes is urgently required.

5.5.2. Blown Films Made of Cellulose

As with Lyocell fibers, the precipitation process, which in this case includes inner and outer precipitation baths (see basic sketch, Figure 21), offers considerable possibilities to influence the morphology and pore structure of the product films. Symmetrical (identical precipitation baths inside and outside) and asymmetrical (different precipitation baths inside and outside) film structures can be produced without difficulty (Figure 25). Compared with cellophane and cuprophane films on the market, blown films produced according to the Lyocell process have somewhat lower degrees of crystallinity ($\approx 40\,\%$) and only slightly smaller lateral crystallite dimensions.

An advantage of the blow-extrusion process, which can be transferred to cellulose films as well, is the ability to control the orientation in the machine direction and transverse

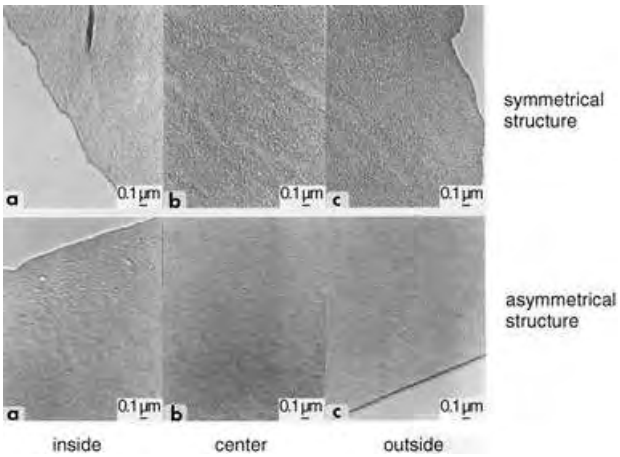

Figure 25. TEM micrographs of symmetrical and asymmetrical structures of blown films.

direction without any problems by means of the draw-down and blow-up ratio. Figure 26 shows the X-ray pole figures in a uniplanar orientation of the $(1\bar{1}0)$ lattice plane, whereby suitably adjusted draw-down and blow-up ratios[127] can be used to produce different orientation states up to almost balanced films (compare longitudinal and transverse strength values of Figure 26).

The orientation distribution of the crystallite longitudinal axis (chain direction) in the film plane can be approximated with the (110) pole figures. Figure 27 shows the corresponding distribution functions of the longitudinal chain axis of differently produced blown films (BF7, 10, and 13) in comparison with commercial cellophane and cuprophane, which substantiates the control possibilities described. It should be emphasized as well that the mechanical properties of the blown films are superior to those of conventional products, and that the separating properties of Lyocell-based films, such as the dialysis and flow rates, are outstanding as a result of their pore structures.[124a]

6. Bacterial Cellulose as a Model Compound and High-Performance Material

6.1. Formation and Structure

The biosynthesis of cellulose takes place not only in plants, but, as already mentioned in Section 1, also in bacteria (such as *Acetobacter*, *Acanthamoeba*, and *Achromobacter* spp.), algae (*Valonia, Chaetamorpha* spp.), and fungi.[134] The formation of cellulose by laboratory bacterial cultures is an interesting and attractive access to pure cellulose for both organic and polymer chemists. By selecting the substrates, cultivation conditions, various additives, and finally the bacterial strain, it is possible to control the molar mass, the molar mass distribution, and the supramolecular structure. Thus it is possible to control important cellulose properties, and also the course of biosynthesis (e.g. kinetics, yield, and other metabolic products).

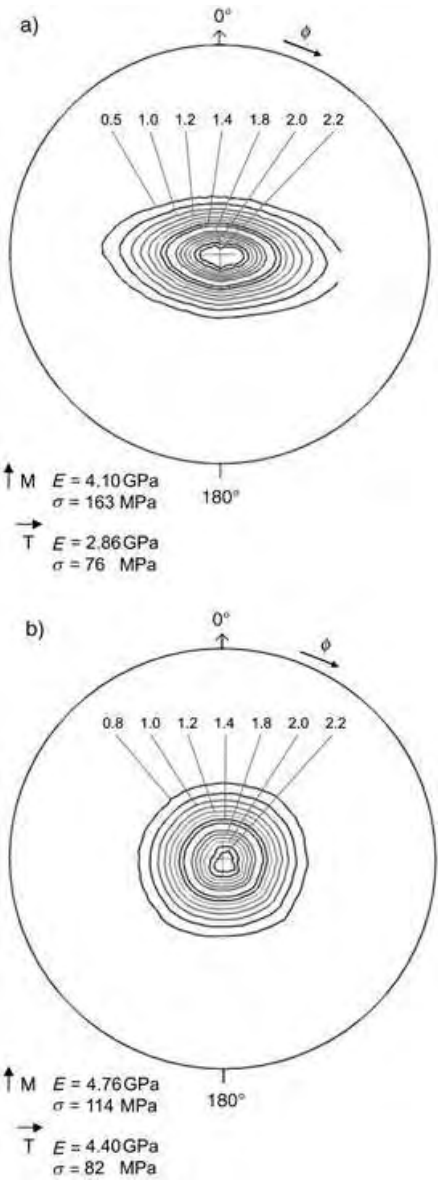

Figure 26. (1$\bar{1}$0) Pole figures and mechanical properties of differently produced cellulose blown films: a) draw-down in machine direction larger than transverse (BF7); b) drawing balanced in longitudinal and transverse direction (BF13).

Amongst the cellulose-forming bacteria, *Acetobacter* strains (reclassified as the genus *Gluconacetobacter*) are especially suitable for the production and investigation of cellulose. These gram-negative and strictly aerobic bacteria form ellipsoidal, straight, or slightly bent rods in the size range of 0.6–0.8 × 1.0–4.0 μm. They are not pathogenic and are commonly found on naturally grown fruits and in fruit products. Strains of the *Acetobacter xylinus* species produce extracellular cellulose that is easily isolated as fiber material. Under static immersed cultivation conditions, a biofilm of varying thickness (fleece) is produced which helps the colonized bacteria to maintain a high oxygen content near the surface, and which serves as a protective barrier against drying, natural enemies, and radiation.

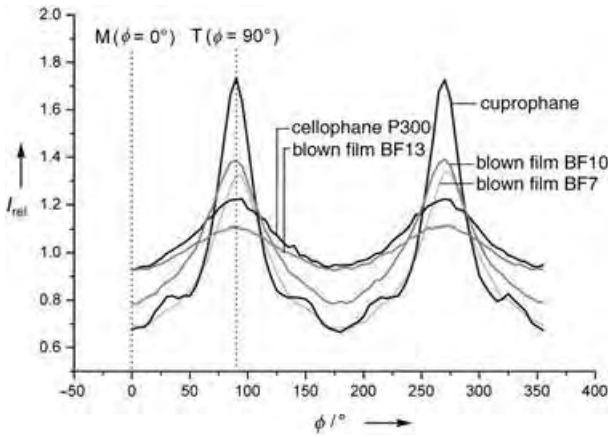

Figure 27. Orientation of the cellulose chains in the film plane (ϕ scan of the (110) pole figure at $\chi = 85°$).

The metabolic products of *A. xylinus* were initially described by A. J. Brown in 1886.[135] He identified a gelatinous mass, formed on the culture solution during the course of vinegar fermentation as cellulose. Thanks to systematic and comprehensive research over the past decades,[17] recent knowledge about the formation and structure of bacterial cellulose is extensive. Moreover, this work is an important part of research investigations of the integration of biotechnological synthesis methods in polysaccharide chemistry and the development of cellulose products with new properties and application potentials.

The synthesis of the bacterial cellulose occurs between the outer and plasma membranes of the cell by a cellulose-synthesizing complex (terminal complex) starting with uridine diphosphate glucose (UDP glucose).[136] This complex is associated with bacterial cell surface pores, which have a diameter of about 3.5 nm. Cellulose synthase catalyzes the addition of UDP glucose to the end of the growing cellulose chain, which exits the cell as an elementary fibril, and then forms a 3D network with other elementary fibrils through formation of microfibrils and ribbons.[136] Crystallization and polymerization of the elementary fibrils are closely linked. One single cell can convert over 100 glucose molecules into cellulose per hour. As the culture medium contains millions of bacteria, the polymer is synthesized practically "before your eyes". The details of the polymerization catalyzed by cellulose synthase have been the subject of controversy.[137] The latest studies seem to indicate that the β-(1→4) linkage starts with the formation of cellobiose as an intermediate at a dual UDP glucose binding site.

A detailed model of the structure (Figure 28) of the bacterial cellulose of *A. xylinus* (strain NCIB 8034) in a never-dried state was determined by synchrotron X-ray diffraction experiments and studies carried out by electron microscopy.[138] Anhydrous units (nanofibrils) with cross-sectional dimensions in the nm range appear hydrated as a whole, and are aggregated to flat microfibrils with a width of 70–150 nm. This model was basically substantiated by means of small-angle X-ray diffraction, and was expanded by the fact

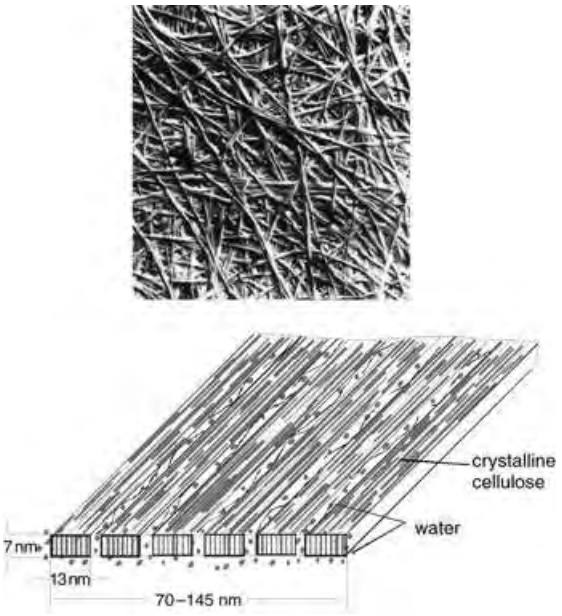

Figure 28. SEM image of dried bacterial cellulose (top) and model of an initially hydrated bacterial cellulose microfibril (bottom).

that a shell of noncrystalline cellulose chains passes around neighboring microfibrils to produce a microfibril band with a width of about 500 nm.[139] After drying, the initially wet and highly swollen cellulose fleece becomes a uniplanar oriented foil with microfibrils partially twisted around the longitudinal axis (Figure 28) which consist of $\approx 80\%$ I_α cellulose.

6.2. Properties and Applications

Although identical to cellulose of plant origin in terms of molecular formula, bacterial cellulose is quite different. The degree of polymerization is very high, with DP values of 2000–8000. Crystallinity is also high, with values of 60–90%. Bacterial cellulose is characterized by its high purity (no association with accompanying substances like hemicelluloses, lignin, or pectin) and by an extremely high water content of 90% or more. Upon complete removal of water by air drying, the bacterial cellulose will only rehydrate to the same low extent as that of plant celluloses after re-exposure to water: about 6%. After gentle freeze-drying, however, it can absorb up to 70% of the original water content by re-swelling.[140a] Through a stepwise exchange of water for other solvents, it is possible to introduce methanol, acetone, or *n*-hexane, for example, at the same volume as water in bacterial cellulose, while maintaining the hollow space and network structure.[140a]

Bacterial cellulose highly swollen with water gives well-resolved ^{13}C NMR spectra without additional pretreatment with conventional techniques (CP/MAS) of solid-state NMR spectroscopy.[138,140a,d,e] Figure 29 shows a typical example. Detailed NMR spectroscopic examinations of bacterial cellulose and of its biosynthetic route were carried out by using ^{13}C-labeled D-glucose.[141a]

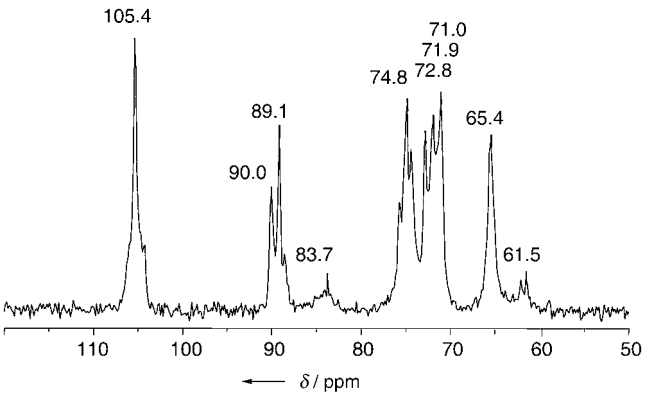

Figure 29. ^{13}C-CP/MAS NMR spectrum of a purified never-dried bacterial cellulose fleece (swelling agent: water).[140a,e]

Because of its crystalline nano- and microfibril structure, bacterial cellulose has excellent mechanical properties[142] (Table 5). It is therefore well-suited as a reinforcing agent for paper and fibers made from glass, carbon, phenol resin, and silicon at small quantities (5%). Owing to the high modulus of elasticity in combination with a large internal loss factor, it is also a superior material for headphone and loudspeaker membranes (Sony Corp.).

Table 5: Mechanical properties of bacterial cellulose and other organic layer materials (from Gilbert[142]).

Material	Young's Modulus [GPa]	Tensile Strength [MPa]	Elongation [%]
bacterial cellulose (BC)	15–35	200–300	1.5–2.0
polypropylene (PP)	1–1.5	30–40	100–600
polyethylene terephthalate (PET)	3–4	50–70	50–300
cellophane	2–3	20–100	15–40

Over the past few years, there has been an increased interest in commercial applications of bacterial cellulose. Important examples include supports for proteins, cell cultures and microorganisms, products for temporary skin and tissue replacement (Biofill, Bioprocess, and Gengiflex), calorie-free food such as Coco de Nata, and additives in the production of lattices and paper. These activities are accompanied by the isolation of new bacterial strains, genetic modifications, and a wide variation of all laboratory culture parameters.[143]

6.3. Biotechnological Synthesis of Blood Vessels from Dextrose

The investigations described below required for the formation, characterization and application of innovative biomaterials for surgery[140] have taken advantage of the powerful *A. xylinus* AX5 strain as a particularly suitable "cellulose factory in the laboratory".[140a] As shown in Figure 30, this strain produces water-soluble D-glucose (dex-

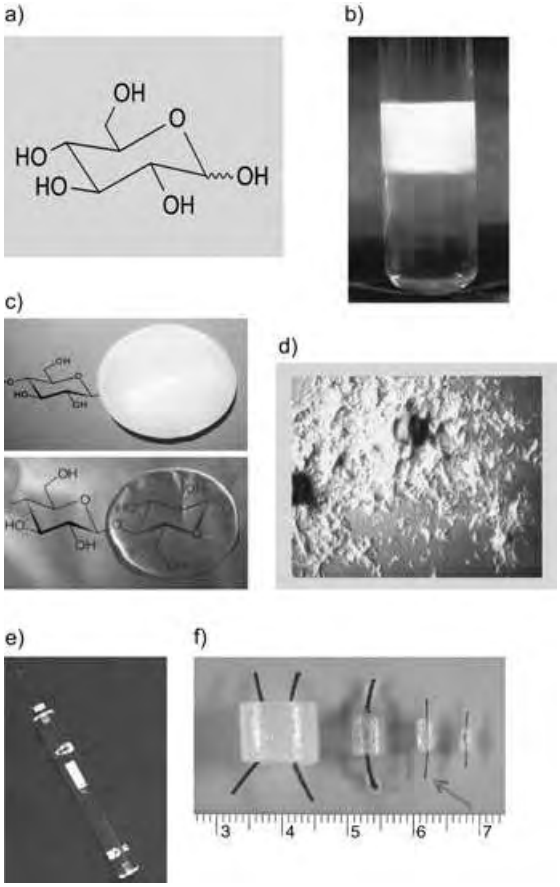

Figure 30. Biotechnological synthesis of bacterial cellulose of varying design: a) substrate D-glucose; b) static culture with cellulose fleece at the interface between Schramm–Hestrin culture medium and air after eight days of cultivation at 28 °C; c) never-dried (top) and completely air dried (bottom) cellulose fleece viewed from the top; d) colony of an *Acetobacter xylinus* strain; e) glass matrix for shaping the bacterial cellulose directly in the culture medium with cellulose tubes formed (see Figure 31); f) cellulose tubes of different dimensions after removal from the matrix and purification (arrow: implants for experimental microsurgery; scale values in cm).[140a]

trose) in static culture with the conventional Schramm–Hestrin culture medium[140a] within eight days, with a yield of 40 % cellulose in the form of a high swollen fleece at the interface between the culture medium and air.

Thus it was demonstrated that bacterial cellulose can be suitably shaped for application during biosynthesis. With the patented matrix reservoir technology developed for this purpose, it is possible to synthesize the cellulose in the shape of formed hollow bodies directly in the culture medium without subsequent treatment.[144] Figure 31 shows a schematic diagram of the cultivation vessel, in which the glass matrix is immersed in a larger volume of nutrient solution. The tube-shaped bacterial cellulose is produced in the nutrient medium which has entered between the outer and inner matrices, and is supplied with oxygen by a second opening to the air space.

The cellulose tubes (brand name BASYC, Bacterial Synthesized Cellulose) formed biotechnologically in this way were investigated for their application as a new type of

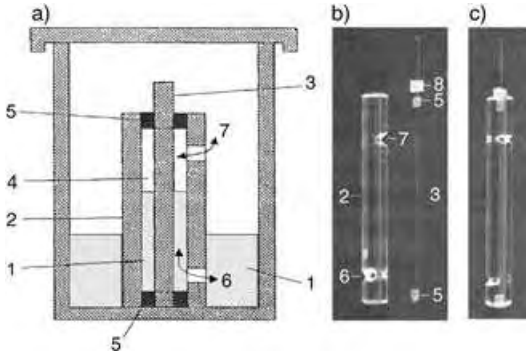

Figure 31. Matrix reservoir cultivation technique for the production of shaped bacterial cellulose (BASYC): a) basic sketch; b) example of the building units of a glass matrix: (1) Schramm–Hestrin culture medium in the reservoir and within the matrix, (2) outer matrix, (3) inner matrix, (4) cultivation space between outer and inner matrix, (5) spacer, (6) opening to the reservoir, (7) opening to the air, (8) stopper; c) ready-to-use matrix.[140a]

biomaterial for microsurgery in a cooperative effort between physicians, biologists and chemists.[140c] Tubular implants with an internal diameter of less than 3 mm were used (Figure 30 f, arrow). This application is derived from new microsurgical techniques that can repair nerves and blood vessels by sutures in a very small diameter range with optical equipment. The well-known synthetic implant materials from the surgery of larger vessels made of polytetrafluoroethylene, polyethylene terephthalate, polyethylene, and polyurethane have been insufficient for the requirements of microsurgery, often resulting in thromboses.

The wall of the BASYC tubes consist of the bacterial cellulose loaded with water at 90 % or greater in the nanofiber network, as described above. The hollow spaces of the BASYC material transport water, monovalent ions, and small molecules, but not biopolymers or corpuscular blood constituents. The stored water not only stabilizes the cellulose network, it also contributes to the tissue and hemocompatibility of BASYC.

For the BASYC vessel implants, the low roughness of the inner surface (feature variations of ≈ 15 nm) is especially significant, and can be obtained with the matrix-reservoir technique. This degree of roughness is within the order of magnitude of that for typical blood vessels in rats. BASYC tubes also meet other significant demands for microvessel replacement: they have a constant shape, are sufficiently stable against internal and external pressure, are flexible and elastic, and are capable of handling a tight microsurgical suture. Figure 32 a shows an example of the microsurgical work with shaped cellulose material. Results of investigations of the microsurgery of nerves and vessels of the rat as an experimental model are shown in Figure 32 b–f.

Upon dissection of the *nervus ischiadicus* and subsequent reconnection by a microsurgical suture, a protective cover (cuff) of BASYC prevents connective tissue from growing into the nerve gap, and favors the adhesion of the fascicles, which facilitates early regeneration of the nerve and a rapid return of muscle function. The good incorporation of bacterial cellulose-forming connective tissue and new blood

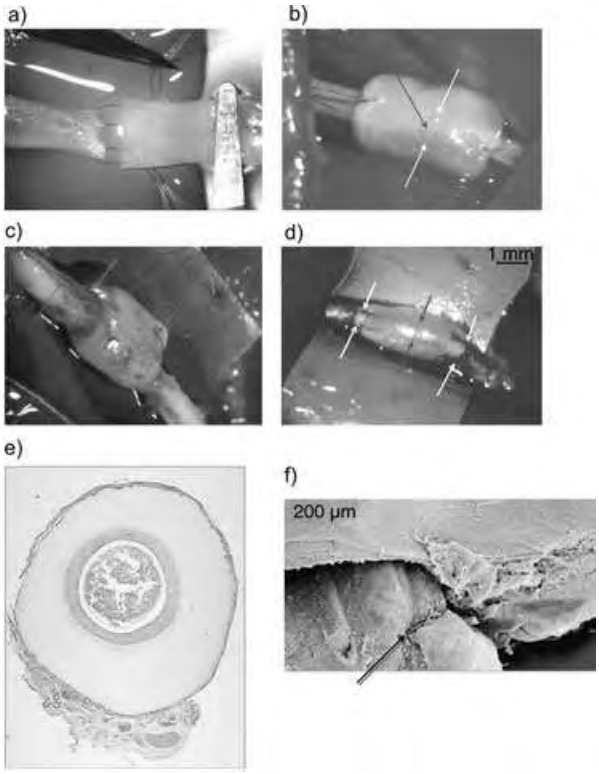

Figure 32. Application of bacterial cellulose tubes (BASYC) for training in microsurgical techniques and for animal experimental microsurgery on nerves and vessels: a) end-in-end connection (anastomosis) of BASYC tubes; b) *nervus ischiadicus* of the rat directly after operation of the dissected nerve (white arrows: anastomosis, black arrow: suture) with BASYC protective cover; c) operating field 10 weeks after the nerve dissection (arrows: new connective tissue and new blood vessels); d) BASYC implant in the carotid artery of the rat directly after operation (white arrows: anastomosis, black arrows: free blood flow, visible through the cellulose tube); e) cross-section of the middle part of a BASYC implant from the carotid artery of the rat after four weeks of residence time in the body as a histological preparation (cf. text); f) SEM image of a longitudinally cut BASYC implant with a homogeneous surface in the cellulose (left) and natural vessel region (arrow: remaining suture material). Magnification: 10×: (a, b, c); 6×: (d); and 32×: (e).[140c]

vessels on the surface of the protective cover is worthy of particular emphasis.

Upon reconnection of a dissected carotid artery (in a rat model) with a BASYC tube, the internal surface of the BASYC material becomes completely covered by an endothelial cell layer after a residence time of four weeks, as determined by histological examination of the preparation along with a specific test for endothelial cells (Figure 32e). Blood remnants can be found in the lumen. As observed by electron microscopy, the complete colonization of the BASYC region with endothelial cells covering both parts of the suture (Figure 32f) can be substantiated. Apparently, the BASYC material is a good substrate for the anchoring of autologous cells.

Upon coverage of longitudinally cleaved tubes with bovine endothelial cells in cell culture tests, a distinct sprouting of the initially spherical cells takes place within 24 h. Electron microscopy shows that the resulting filaments barely differ from the fibers of bacterial cellulose (Figure 33). This structure apparently also benefits the rapid endothelial colonization of BASYC.

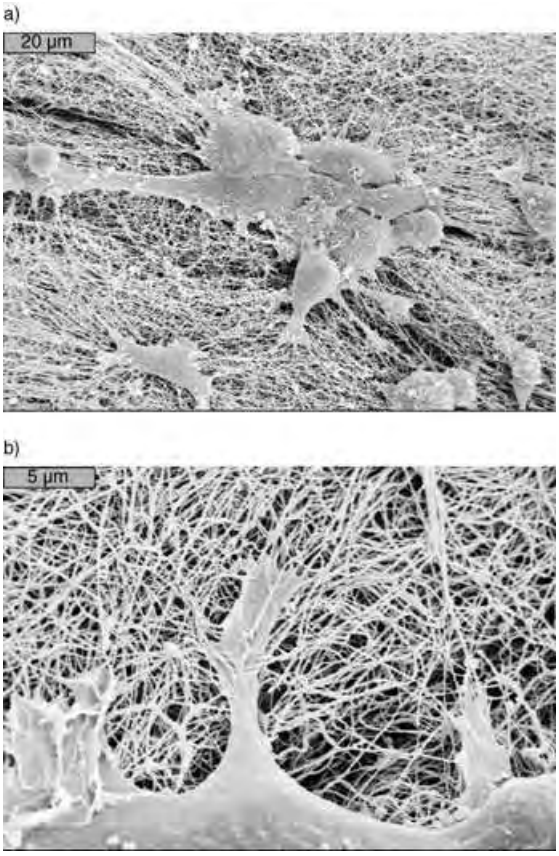

Figure 33. Scanning electron microscopy of the growth of bovine endothelial cells on a BASYC surface 24 h after spreading: a) overview; b) section at 4× enlargement.[140c]

Notably, further investigations have shown that BASYC microvessel implants can be applied toward vessels under low or high pressure, and that in all cases, thromboses were never observed.

6.4. Bacterial Cellulose for Veterinary Medicine and Cosmetics

The supramolecular structure of bacterial cellulose depends on the method of formation applied. Apart from the methods employed in static cultures and by the matrix-reservoir technique described above, an optimized surface cultivation of *A. xylinus* has been developed.[145] This cultivation system overcomes the transport barrier at the interface between nutrient solution and air for the introduction of the necessary nutrients (carbon and nitrogen sources, inorganic salts, and oxygen) as well as for the removal of the products formed by spraying a substrate aerosol directly on the surface of the immersed culture without causing a mechanical impairment. The cellulose layers of about 10 cm thickness

thus obtained are tested and respectively used for veterinary and cosmetic applications.[146]

7. In-Vitro Syntheses: Ways to New Horizons

The synthesis of a polysaccharide requires frequently repeated glycosylations, including the total control of the configuration at the anomer C atom and of the regioselectivity of the reacting hydroxy group. For this reason, it has only been within the past few years that cellulose could be produced synthetically.

7.1. Enzyme-Catalyzed Cellulose Structure

After many attempts to synthesize cellulose outside organisms, Kobayashi and co-workers[19b] succeeded in 1992 with the enzymatic polymerization of β-cellobiosyl fluoride in the presence of purified cellulase as catalyst in an acetonitrile/buffer solution at 30 °C. Cellulose with a yield of 54 % and a DP value of 22 was formed. The polymer structure as determined by ^{13}C and ^{1}H NMR spectroscopy corresponds well with that of natural cellulose.

Scheme 22 demonstrates that this in-vitro synthesis principle can also be extended to the preparation of amylose and chitin.[19] In continuation of this synthesis work, the in-vitro formation of crystalline cellulose I in an optimized solution system with purified cellulase has been described for the first time.[19d] The generation of this thermodynamically less stable allomorph had been known up to this point in living cells only.

7.2. Ring-Opening Polymerization of Glucose Derivatives

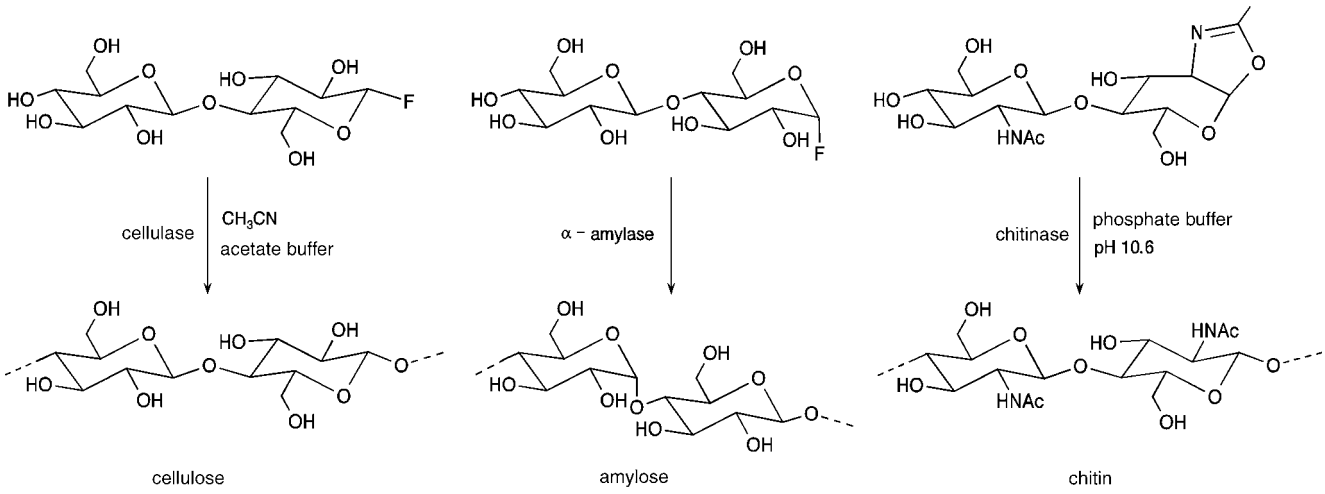
By stepwise synthesis[147] and particularly by cationic ring-opening polymerization of glucose orthoesters, cellulose was synthesized in a purely chemical manner by Nakatsubo and Kamitakahara in 1996 for the first time.[20] Starting with 3-*O*-benzyl-α-D-glucopyranose-1,2,4-orthopivalates with different groups at position 6, cellulose (after deprotection) is accessible according Scheme 23, as well as regioselectively substituted cellulose derivatives.

Scheme 24 shows the corresponding synthesis of uniform methyl celluloses. The DP values of these celluloses are in the range of 20–50. The influence of the glucose substituents on the regio- and stereochemistry of the polymerization could be identified and optimized through systematic work, as well as the availability of the glucose derivatives required and the deprotection chemistry of the product.[148]

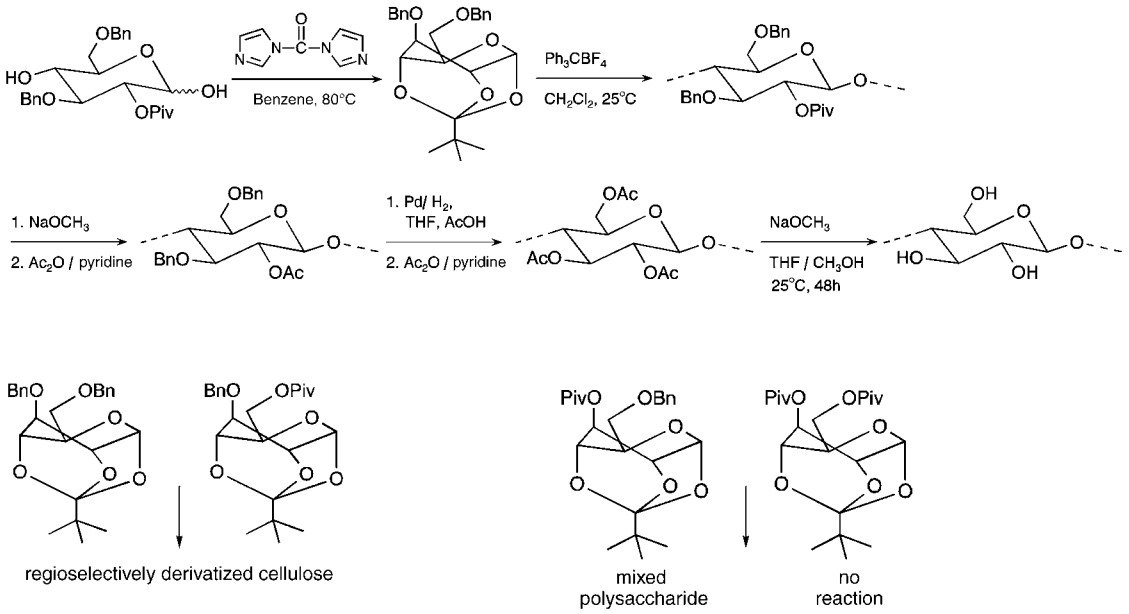
8. Summary and Outlook

Science and technology continue to move toward renewable raw materials and more environmentally friendly and sustainable resources and processes. Cellulose, cellulose derivatives, and polysaccharides as a whole are of growing importance in the development and application of polymer materials. This progression has triggered a distinct renaissance of cellulose research and application all over the world over the past 10 years. In this context, it has been essential to increase the current knowledge of organic and polymer chemistries as well as in the chemistry of low-molecular-weight carbohydrates and other polysaccharides in the basic and application-oriented work in the field of cellulose. Moreover, it has been important to intensify the interdisciplinary interactions between biology, physics, pharmacy, medicine, and the wood industry and chemical engineering.

In consequence of this expanding development, groundbreaking insight has been gained on the complex structure of cellulose and cellulose derivatives in the solid state and in solution, on cellulose reactivity, reaction control, and selective syntheses, and regarding supramolecular structure formation as well as the biosynthesis and in-vitro synthesis of cellulose. This includes the rapid development of polysaccharide instrumental analysis and a deeper understanding of the relation between reaction conditions, product structure, and application-oriented properties. Thus, it has been possible to develop new types of cellulose esters and ethers as "polymers



Scheme 22. Enzyme-catalyzed in-vitro synthesis of cellulose and related polysaccharides.



Scheme 23. Chemosynthesis of cellulose by ring-opening polymerization of 3,6-di-*O*-benzyl-α-D-glucopyranose-1,2,4-orthopivalate and the influence of substituents at positions 2 and 3 on the course of the reaction.

of the future", for example, toward a wide range of high-quality applications on the industrial scale, which have been established in the market. Fundamental research on the cellulose/NMMO/water system has led to a novel, environmentally friendly technology (Lyocell process) for the production of cellulose regenerate products, which has revolutionized the processing of cellulose, and has at least partially removed the previous disadvantages in comparison with the process steps in the production of synthetic polymers.

All signs and symptoms seem to indicate that the impressive rate of development in the field of cellulose will continue or will even accelerate. The establishment of centers of excellence, new pilot, process, and production plants, the expansion of large-scale technical products, a close cooperation of fundamental and applied research, as well as an effective international cooperation of scientists and facilities are distinct evidence of this fact. New insight into the processes of wood pulping and overall wood processing, into the production of cellulose from other plants as well as into the analysis of cellulose products will help to ensures that the quality, variety of products, and ecological acceptance of the starting materials will grow, along with the consistent ecological orientation of industrial cellulose chemistry.

Fundamental changes regarding the access to cellulose as a raw material are predictable because of the fast growth in understanding cellulose biosynthesis. Indeed, efforts are being made to purify and sequence cellulose synthase and associated proteins to generate a reproducible cell-free system capable of generating crystalline cellulose. By introducing genes to modify cellulose biosynthesis in important cellulose-forming organisms (trees, cotton crops, and bacteria), it should be possible to tailor various types of cellulose for pulp, paper, building materials, textiles, and other fields of application.

If cellulose-forming bacteria could be cultivated on a large technical scale, the requirement of cellulose could be satisfied entirely by this source in the future.

The aim of this paper is to demonstrate the current state of development in the field of cellulose research and application through examples. It should be also pointed out that cellulose as a natural product belongs to the polymers, which hold an impressive future potential for fundamental knowledge as

well as for large-scale production in a wide range of applications.

Glossary

AGU	anhydroglucose unit
BF	blow film
CMC	carboxymethyl cellulose
CA	cellulose acetate
CAB	cellulose acetate butyrate
CAP	cellulose acetate propionate
CE	carbohydrate esterase
CF	cellulose formate
CTFA	cellulose trifluoracetate
DCC	dicyclohexylcarbodiimide
DP	degree of polymerization
DS	degree of substitution
HEC	hydroxyethyl cellulose
HMDS	hexamethyldisilazane
HPC	hydroxypropyl cellulose
HPMC	hydroxypropylmethyl cellulose
MC	methyl cellulose
Ms	mesyl
NC	nitrocellulose
NMMO	*N*-methylmorpholine-*N*-oxide
NMP	*N*-methylpyrrolidone
NTA	nitrilotrieacetic acid
PDA	1,4-phenylenediamine
Piv	pivalate
TDS	thexyldimethylsilyl
TEA	Triethylamine
Thexyl	1,2-dimethyl-butyl-1
TMS	trimethylsilyl
TMSC	trimethylsilyl cellulose
Tr	triphenylmethyl, Trityl
Ts	tosyl
Tf	triflyl
UDP	uridine diphosphate

We gratefully acknowledge the Deutsche Forschungsgemeinschaft for the financial support of the Priority Program "Cellulose and Cellulose Derivatives—Molecular and Supramolecular Structure Design" from 1996 to 2002 as well as for the support by the Fachagentur Nachwachsende Rohstoffe and the German Federal Ministries BUEL and BMBF. A lot of the work described herein was carried out on this basis. Moreover, we express our gratitude for the effective and helpful cooperation with the colleagues in these programs as well as for the stimulating interaction with Professor Dieter Schumann (Clinic of Maxillofacial and Plastic Surgery, University of Jena), Professor Wolfgang Glasser (Virginia Polytechnic Institute, Blacksburg, USA), Professor R. Malcolm Brown (University of Texas, Austin, USA), and Professor Fumiaki Nakatsubo (Kyoto University, Kyoto, Japan). We thank Wolff Cellulosics GmbH (Germany), the German subsidiaries of the Acordis-Group, Lenzing AG (Austria), and Eastman Chemicals Company (Kingsport, TN, USA) for the trusting cooperation and for the versatile information on commercial products and processes.

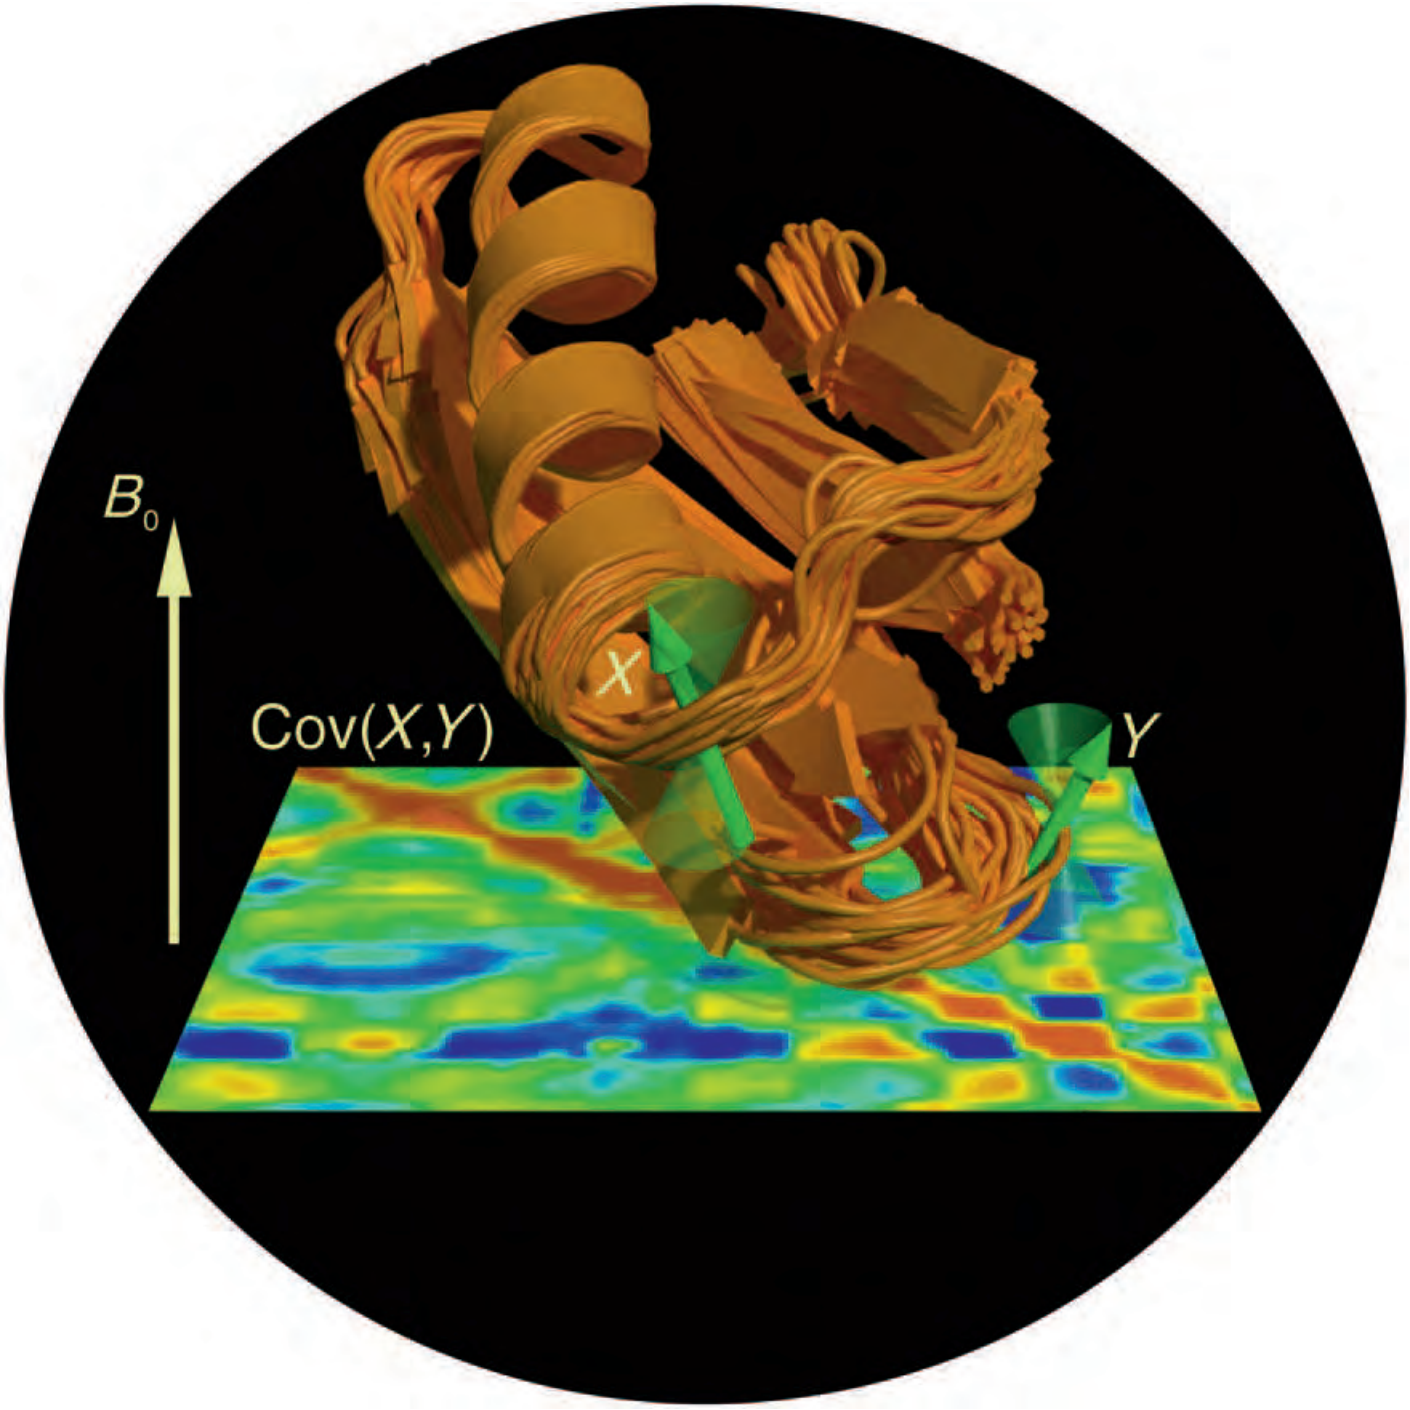
Communications



Correlated motions can be accurately extracted from molecular dynamics (MD) simulations that are compatible with the measured NMR spectroscopic data (NOE and order parameters) for two different proteins (Cov: covariance matrix). B. de Groot and co-workers discuss the results of MD simulations on a fragment of protein G in their Communication on the following pages.

Molecular Dynamics Simulations

Molecular Dynamics Simulations of Protein G Challenge NMR-Derived Correlated Backbone Motions**

*Oliver F. Lange, Helmut Grubmüller, and Bert L. de Groot**

Protein function is fundamentally linked to underlying structural and molecular dynamics.[1] Many biological functions such as enzymatic activity and ligand binding are controlled or even realized through conformational motions,[2] which are typically collective in nature, as is the case with allosteric effects and domain motions.[3] Conformational motions determine energetics, kinetics, and the strength of thermodynamic driving forces through conformational entropy.[4–6]

NMR relaxation studies provide a powerful and established method to gain experimental access to fast protein dynamics in atomic detail.[7–9] Model-free analysis of NMR relaxation times, in particular, yields generalized order parameters for individual bond vectors[10] which allows the extraction of information about flexibility and timescales of the motions of individual backbone sites[11] and side chains.[12] Until recently, however, NMR relaxation experiments could only probe the flexibility of individual bond vectors, whereas correlated motions could not be probed. A recently proposed method by Mayer et al.[13] promises to overcome this limitation by measuring the covariation of backbone motion by NMR relaxation studies. Specifically, the authors "propose a general approach to the detection of correlated changes in internal protein motions, which are expected to reflect the underlying influence of correlated dynamics".[13] In this approach, NMR relaxation data for a small domain of protein G were obtained for 10 mutants at the same sequence position. The resulting perturbations were reported to cause changes in the measured order parameters, which were recorded for each individual residue. For many residue pairs, these changes are significantly correlated (Figure 1a), which led the authors to suggest that the observed covariances reflect underlying correlated atomic motions.[13] Whether and how the measured covariations actually reflect correlated atomic motion cannot be resolved by experiment alone, which prevents the direct atomistic interpretation of these types of measurements. To address this issue, we present sub-microsecond molecular dynamics (MD) simulations which, together with the NMR experimental data, provide a comprehensive picture of the correlated atomic dynamics of the protein G domain.

We carried out two MD simulations of the B1 domain of protein G, with lengths of 100 and 200 ns, referred to as MD1 and MD2, respectively. Correlations of atomic motions were quantified by correlation matrices calculated from the MD simulations. Figure 1c shows correlation matrices obtained from MD1 (above the diagonal) and MD2 (below the diagonal). The similarity of the two matrices shows that the computed correlations are largely well-converged. Full convergence is not reached for residues 37–42, which constitute the loop that connects the α helix with the β3 strand. Closer inspection revealed long timescale contributions to the loop dynamics. However, the relevant sub-microsecond timescale probed by NMR relaxation experiments[14] is well-sampled in our simulations.

The matrix is dominated by strong correlations between neighboring residues, and appears as a band along the diagonal. The broad region of high correlation between residues 22 and 38 is caused by the 1–4 contacts of the central α helix. The two bands of high correlation perpendicular to the diagonal result from the contacts between different strands of the four-stranded β sheet. Strong correlations and anticorrelations are also found between residues 10–15 of the first hairpin loop and the rest of the molecule. They are caused by a kinking-out motion of the turn between strands β1 and β2 together with part of the β sheet. This motion, hinged around residues 8 and 15, is the main contribution to the principal collective motion (Figure 2), as revealed by principal component analysis.[15,16]

To test for a direct connection between the covariation of NMR order parameters and the computed correlated atomic motion observed in the simulation, we compared the computed correlation matrices (Figure 1c) with the S^2- and the τ_e-based covariation matrices derived by Mayer et al.[13] (Figure 1a). Overall, the level of correspondence is low. The only feature shared with the MD simulations is the band of anticorrelated motion between residues 10–14, which is present in the experimental results derived from covariations in τ_e order parameters, but which is not observed in the S^2-derived correlations. Apart from this detail, the overall lack of similarity is striking. The nature of this discrepancy deserves closer inspection.

An important question is whether the MD simulations describe atomic motions with sufficient accuracy. Potential artifacts include force-field inaccuracies and convergence problems. Therefore, we compared the root mean squared fluctuations (RMSF) of the two MD trajectories (MD1 and MD2) with the RMSF of a structural ensemble of the B1 domain of protein G obtained from NMR spectroscopic NOE data[17] (PDB entry 3gb1, Experimental Section). The RMSF profiles obtained form the MD simulation agree well with the NOE ensemble (Figure 3). Moreover, the correlation matrices obtained from the simulations (Figure 1c) are in good agreement with that obtained from the NOE ensemble (Figure 1b). These agreements between the simulation- and NOE-derived results are quantified by correlation coefficients of 0.77 and 0.81 for MD1 and MD2, respectively. In

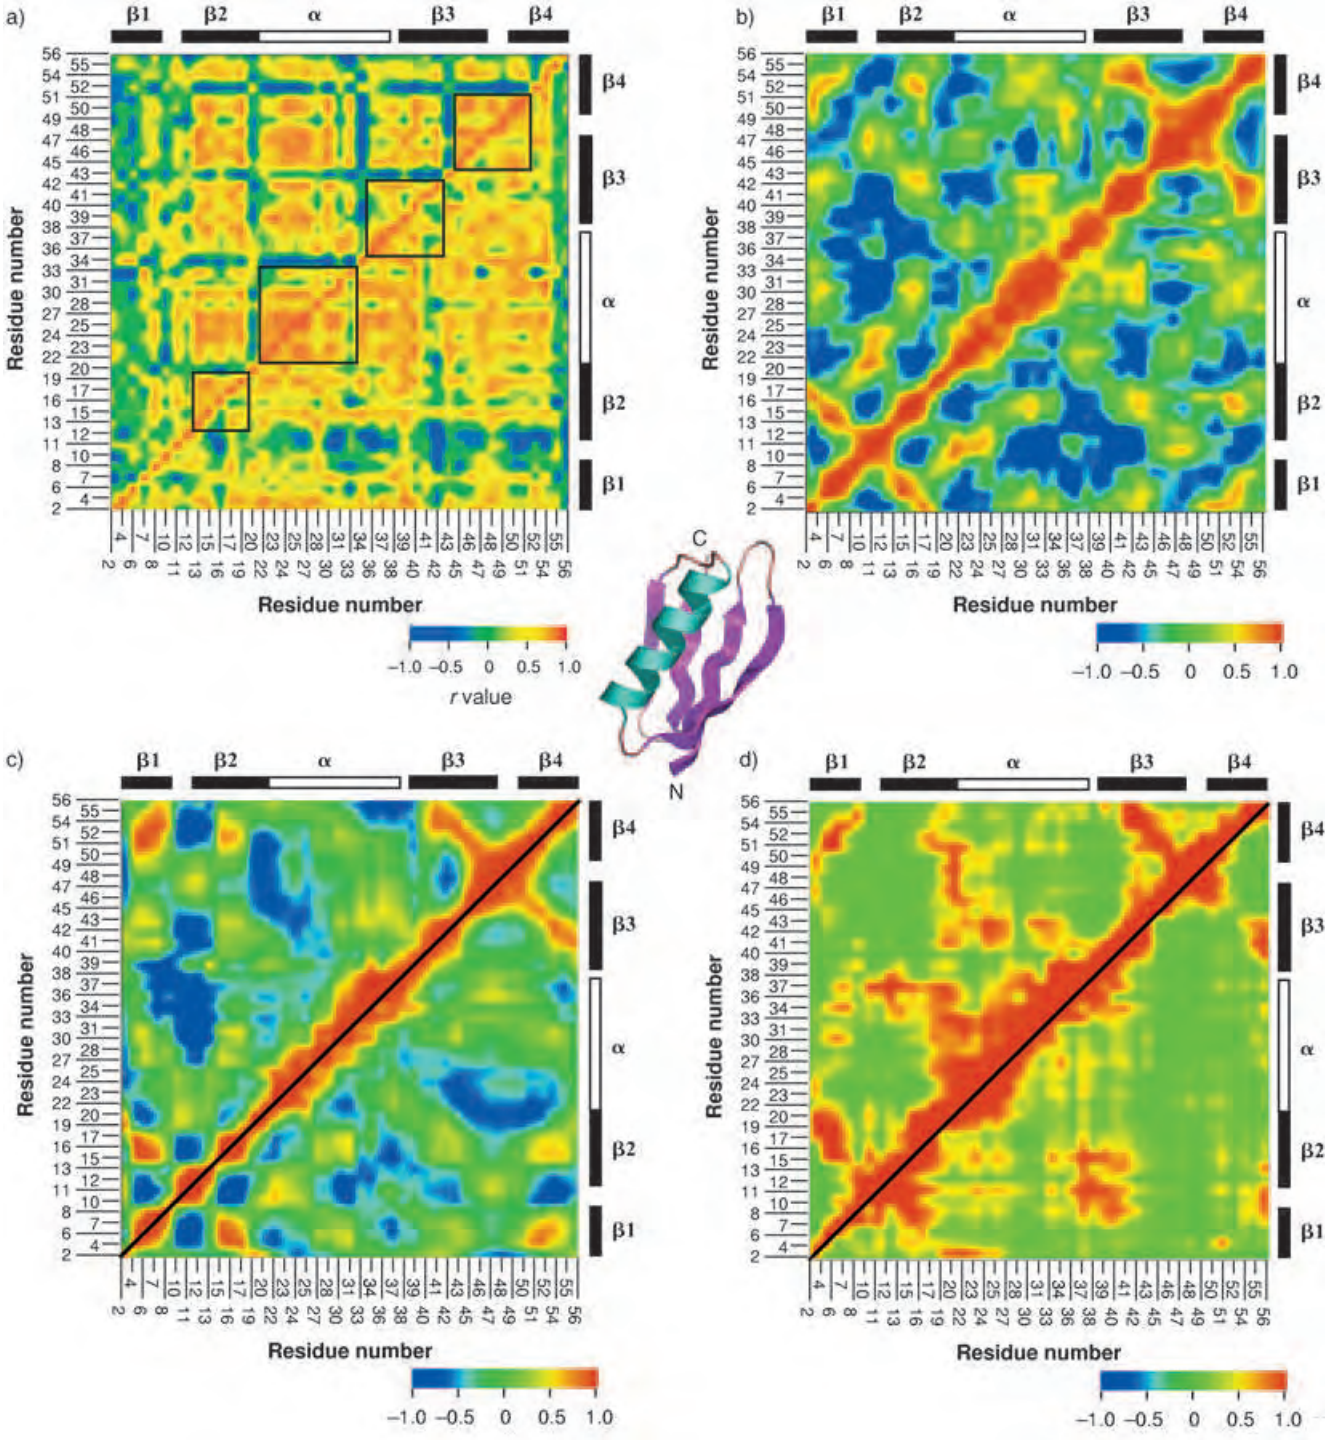

Figure 1. Correlation matrices from NMR experiments and MD calculations. a) Correlation matrices taken with permission from Mayer et al.;[13] data for S^2 covariations are shown above the diagonal, whereas those for τ_e covariations are shown below the diagonal (the black boxes are irrelevant for the present discussion). b) Correlation matrix computed from an NMR–NOE structural ensemble. c) Correlation matrices computed from MD simulations. The correlations computed from MD1 are shown above the diagonal; correlations derived from MD2 are below the diagonal. d) Generalized correlations computed from MD2 (above the diagonal); correlations computed for N–H vector motions (below the diagonal). The simulated B1 domain of protein G is depicted in the center.

contrast, the correlation coefficients between all of these matrices and the covariance matrix computed from order parameters (Figure 1a) are much smaller: 0.06 and 0.04 for the two MD matrices, and 0.05 for the NOE matrices. The good agreement between MD and the NOE ensemble in terms of the atomic fluctuations and particularly their correlations makes it unlikely that the discrepancy with the covariance matrix obtained from order parameters is caused

Figure 2. Main collective motion of the B1 domain of protein G as revealed by the principal component analysis described in the text.

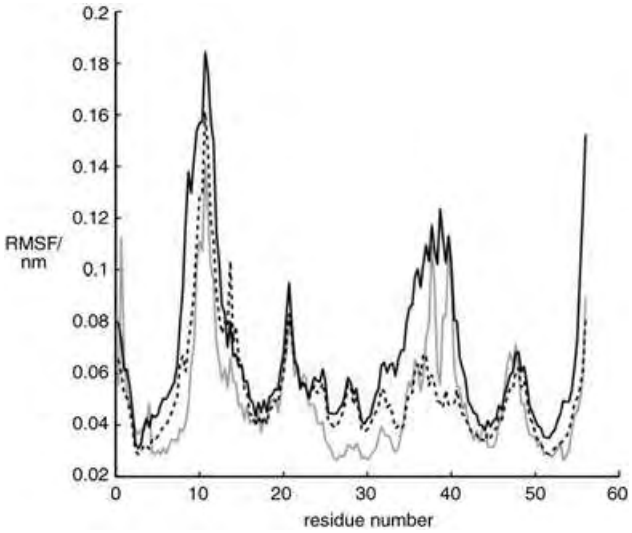

Figure 3. RMSF of backbone atoms observed in the NMR ensemble (gray line), and RMSF computed from the two different MD trajectories (MD1, ——; MD2, -----): the positions of the major RMSF peaks agree well with the experimental data. The fluctuations of the largest motion (residues 8–15) and of the α helix are slightly overestimated by the MD simulations but overall, the flexibility of the remaining regions of the molecule is well-reproduced.

by simulation artifacts. That this agreement is not just anecdotal is indicated by a correlation coefficient of 0.82 for the NOE and MD covariance matrix obtained for a different protein, ubiquitin (Supporting Information), and by a correlation coefficient of 0.8 obtained with a different NMR data set for protein G (PDB entry 1gb1).

Because order parameters form the basis for the covariances determined by Mayer et al., it is necessary to check if the motions probed by order parameters are accurately described by the MD simulations as well. To this end, we compared the experimentally obtained order parameters[18] for protein G with those computed from the MD trajectories (Figure 4a). Within the error bars, the simulations agree with each other as well as with the measured order parameters. The inset of Figure 4 shows that most differences between the observed and computed order parameters are below 0.1 with

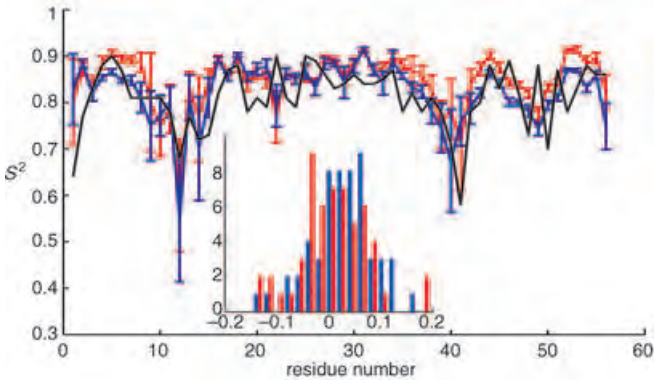

Figure 4. Comparison of the generalized order parameters (S^2) between the MD simulations and the NMR data set.[18] Computed order parameters (in color) with error bars are compared with experimentally observed order parameters (black). Inset: histogram of the order parameter differences between the MD data sets and the experimental results.

few outliers below 0.2. Overall, the agreement is good and is in line with earlier observations.[19–22]

We therefore conclude that the simulations provide a comprehensive and accurate picture of the correlated atomic motion within the protein G domain that is consistent with the available experimental data. The remaining unexplained discrepancy with the covariances derived from NMR experimental order parameters suggests that these two quantities are, in fact, not directly related. Comparison of all elements of the MD correlation matrix with the respective covariations of NMR order parameters as a scatter plot (Figure 5a) confirms this finding. Furthermore, the absence of any detectable structure in this plot suggests the absence of any relation to this measure of linearly correlated atomic motion.

At this point, it is important to note that the correlation coefficients as used in the matrices shown in Figures 1b and 1c, although widely used, detect only part of all possible correlated atomic motions. For instance, two atoms oscillating with a $\pi/2$ phase shift will give rise to a vanishing correlation matrix element $\langle \sin(\omega t)\sin(\omega t+\pi/2)\rangle = 0$, and thus, this highly correlated motion would not be detected. This simple example shows that the results discussed so far do not rule out the possibility that the measured covariations of NMR order parameters relate to such "hidden" correlated motions. To detect those as well, we employed a second, more general correlation measure derived from information theory.

To this end, we consider the information S_i contained within the motion of each individual atom i as well as the joint information $S_{i,j}$ contained within the (possibly correlated) motion of each pair of atoms i and j. As any type of correlation, hidden or not, will decrease $S_{i,j}$ with respect to $S_i + S_j$, the excess $C_{i,j} = S_i + S_j - S_{i,j}$ serves as a generalized and very sensitive measure to detect all correlations within atomic motions. We note that an equivalent formulation of the same method would rest on the fact that only for statistically independent data sets X and Y, their joint probability is given by $P(X,Y) = P(X)\,P(Y)$. For the calculation of the information contents from MD trajectories, see the Supporting Information and Ref. [34].

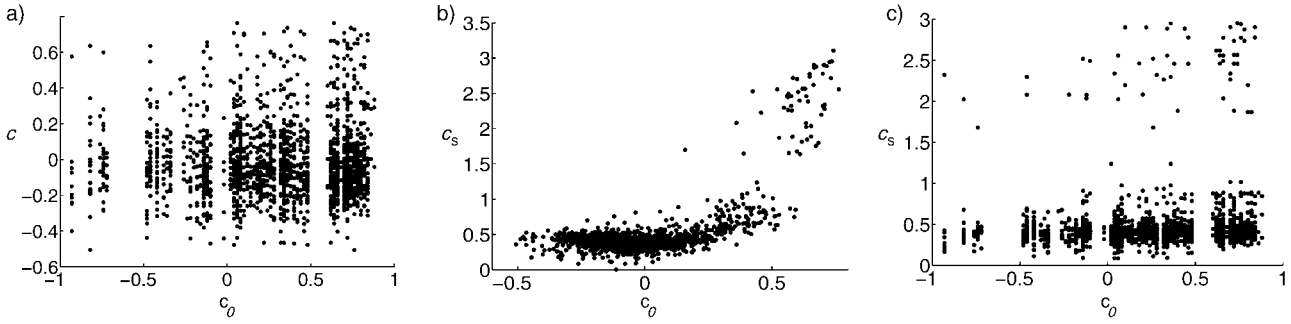

Figure 5. Scatter plots of covariation and correlation matrix elements in which two of the correlation matrices shown in Figure 1 are compared; each point represents the two different correlations obtained with the respective methods for the same residue pair. a) Correlations obtained from MD simulation *c*, as depicted in Figure 1 c, are plotted against the covariations of order parameters c_0, shown in Figure 1 a. b) Generalized correlations c_S (Figure 1 d) obtained from the MD simulation are plotted against c_0 (Figure 1 c), the correlations obtained from MD simulation in the established way. c) Generalized correlations c_S (Figure 1 d) computed from simulation MD2 plotted against measured covariations of order parameters c_0 (Figure 1 a).

Figure 1 d (above the diagonal) shows the obtained generalized correlation matrix. Although the overall structure appears similar, minor but significant differences to the linear Pearson correlation matrix (Figure 1 c) are observed, which result from the "hidden" correlations now detected by the information theoretical approach. Quantitative comparison of the Pearson matrix elements with the generalized elements (Figure 5 b) confirms that the two measures are related (with a correlation coefficient of 0.65). In contrast, no such relation is observed to the covariances derived from the NMR order parameters (Figure 5 c; correlation coefficient 0.07), which suggests that no significant information on correlated atomic motion in Cartesian space is contained within these NMR spectroscopic data.

It might be argued that a more direct comparison between MD and NMR data would rest on an analysis of the correlation in the orientational fluctuations of N–H bond vectors, which are probed by the NMR order parameters, rather than on the Cartesian coordinates. However, these fluctuations are already included within the generalized correlation measure described above and hence, similar results are expected. Figure 1 d (below the diagonal) shows that this is indeed the case as quantified by the low correlation coefficient of 0.05 between N–H vector fluctuations in MD and the covariances derived from the NMR order parameters.

In summary, we have demonstrated that for two different proteins, correlated motions can be accurately extracted from MD simulations that are compatible with the measured NMR data (NOE and order parameters). However, the correlated atomic motions described by our sub-microsecond MD simulations of the B1 domain of protein G are unrelated to covariations derived from order parameters, even though different measures of correlated motion have been applied. The obtained agreement with independent NMR spectroscopic NOE data and with N–H order parameters provides strong evidence that the simulations accurately describe the atomic motions and their correlations at the experimentally relevant timescale. This is further supported by the good qualitative agreement with the results of recently published residual dipolar coupling experiments.[23] Taken together, the results render it unlikely that the observed covariances in measured order parameters reflect the underlying influence of the correlated atomic dynamics for the wild-type protein. Instead, we speculate that the measured covariances are caused by correlated structural changes that result from the introduced point mutations, which in turn, affect the atomic mobilities. In this framework, the experiments would probe remarkably correlated structural plasticities rather than correlated atomic motions. Further simulations of all 10 mutants studied will therefore be required to test this hypothesis and to structurally characterize the properties of this proposed nonlocal plasticity.

Experimental Section

MD simulations were started from the crystal structure of the B1 domain of streptococcal protein G[24] (PDB entry 1PGB). Simulations were carried out with the OPLS all-atom force field.[25] The protein was solvated in 4651 TIP4P water molecules. Four sodium ions were added to the simulation system to compensate for the net negative charge of the protein. The total system size comprised 19463 atoms. The simulation was carried out in a cubic box with a minimal distance between solute and box edge of 0.8 nm. Periodic boundary conditions were used. All MD simulations were carried out with the Gromacs simulation suite.[26] LINCS and Settle[27,28] were applied to constrain covalent bond lengths, allowing an integration step of 2 fs. Electrostatic interactions were calculated with the particle-mesh Ewald method.[29] The temperature was kept constant by separately coupling ($\tau = 0.1$ ps) the peptide and solvent to an external temperature bath.[30] The pressure was kept constant by weak isotropic coupling ($\tau = 1.0$ ps) to a pressure bath.[30] Simulations were run for 100 ns (MD1) and 200 ns (MD2).

An NMR–NOE structure ensemble of 30 structures was generated with the standard simulated annealing protocol in CNS,[31] applying the NOE distance bounds as available from the PDB entry 3GB1.[32] In short, individual structures were generated by slow cooling from high-temperature simulations starting from an extended structure and different sets of starting velocities. Each annealing cycle consisted of 15 ps of torsion-angle MD at high temperature (50000 K) followed by an annealing phase (15 ps) to zero temperature with torsion-angle MD and an annealing phase (15 ps) with Cartesian dynamics from 2000 to 0 K. Finally, each structure was energy-minimized by 10 cycles of 200 steepest-decent steps. Default parameters for the scaling of the individual energy terms were used, including the NOE energy term.

To analyze the data in the molecular coordinate frame, all structures were fitted to the backbone of the crystal structure. RMSF for each ensemble were calculated as $RMSF_i = \sqrt{\langle r_i^2 \rangle}$, in which r_i is the distance of the i^{th} C^α atom from its average position, and the $\langle\,\rangle$ denote the average over the whole trajectory with snapshots recorded every picosecond. The correlation matrices were computed as $C_{i,j} = \langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle / (\langle \mathbf{x}_i^2 \rangle \langle \mathbf{x}_j^2 \rangle)^{1/2}$, in which $\mathbf{x}_i$ and $\mathbf{x}_j$ are difference vectors between the i^{th} and j^{th} C^α atom, respectively, and their average positions in the molecule-fixed frame. To enhance visibility of small differences, the correlations were weighted by the sigmoidal function $W(x) = 2/[1 + \exp(-\lambda x)] - 1$, with $\lambda = 5.5$ before plotting. The enhancement coefficient λ was set as strong as possible under the constraint that only statistically significant fluctuations become apparent.

Order parameters S^2 were defined as the asymptotic value of internal correlation functions.[10] The internal correlation function $C_{int}(t)$ of the N–H bond vector motion is given by $C_{int}(t) = \langle P_2(\cos\chi(t)) \rangle$, where $\chi(t)$ is the angle between the internuclear vectors $r(t)$ and $r(0)$, and r is measured in the molecule-fixed frame. $P_2(x) = (3x^2 - 1)/2$ denotes the second Legendre polynomial. Fluctuations in the internuclear separation were not included, because the length of all covalent bonds were fixed by LINCS[27] throughout the simulation. It has been shown previously that the effect of such constraints on order parameters calculated from simulations is negligible.[33]

To estimate statistical errors in the obtained order parameters, the MD trajectories were divided into N fragments of length 1 ns each. For each fragment s, internal correlation functions $C_{int}^{s,i}(t)$ were computed for each bond vector i with snapshots taken every picosecond. Parameters $\chi_{s,i}$ were computed as the average from 480 to 500 ps of the internal correlation function $C_{int}^{s,i}(t)$. The order parameter of bond vector k was computed as the mean of $\chi_{s,i}$ over all the fragments, that is $S_i^2 = (\sum_s^N \chi_s^i)/N$, with the error bars given by:

$$\Delta S_i^2 = \frac{1}{\sqrt{N(N-1)}} \left[\sum_s^N \chi_{s,i}^2 - \left(\sum_t^N \chi_{t,i} \right)^2 \right]^{1/2} \quad (1)$$

The results do not change significantly if the fragmentation length is changed from 1 ns to longer time intervals (data not shown).

To obtain the generalized correlation measure $C_{i,j} = S_i + S_j - S_{i,j}$ between the C^α atoms i and j, we computed for all atom pairs (i,j) the information S_i of the motion of atom i in its $d = 3$ dimensional configurational space as well as the information $S_{i,j}$ of the combined motion of atoms i and j in their $d = 6$ dimensional configurational space. Herein, only a sketch of the approach is given; for details, see the Supporting Information and Ref. [34].

Our approach is based on a combination of kernel density estimation and nearest-neighbor estimation. For every snapshot k of the trajectory, an effective neighbor distance σ_s is determined by requiring $T = \sum_t^N e^{(\mathbf{x}_t - \mathbf{x}_s)^2/(2\sigma_s^2)}$ for a given and fixed $T = 20$. In this case, N denotes the number of snapshots, and values of $\mathbf{x}$ represent vectors in the d dimensional configurational space considered. This isotropic averaging over local snapshots typically suffers from highly anisotropic configurational space densities, that is, drastically differing widths of the configurational snapshot ensemble in different directions. Particularly problematic and inaccurate were those directions for which the widths are smaller than σ_s. We therefore treated those l_s narrow directions separately by a Gaussian-derived estimate $S_G = 1/2 \sum_{h=1}^{l_s} \log \lambda_h^s$, which is particularly suitable for those small-amplitude degrees of freedom of width $\lambda_{h=1\ldots l_s}^s$, respectively. Taken together, the information was computed by:

$$S = \frac{\log N}{N} - \frac{1}{N} \sum_{s=1}^{N} (\log \alpha(d - l_s) - (d - l_s) \log \sigma_s - S_G) \quad (2)$$

in which $\alpha(d_s)$ denotes a proportionality factor dependent on the local dimension $d_s = d - l_s$, which relates the nearest-neighbor statistics σ_s to the information measure S. We used 10000 snapshots taken every 20 ps from trajectory MD2 for this analysis.

The correlations in the motion of N–H bond vectors were computed by applying the generalized correlation measure to pairs of the normalized internuclear vectors rather than to pairs of atomic positions.

Coordination Compounds

Tuning a Metal's Oxidation State: The Potential of Clathrochelate Systems**

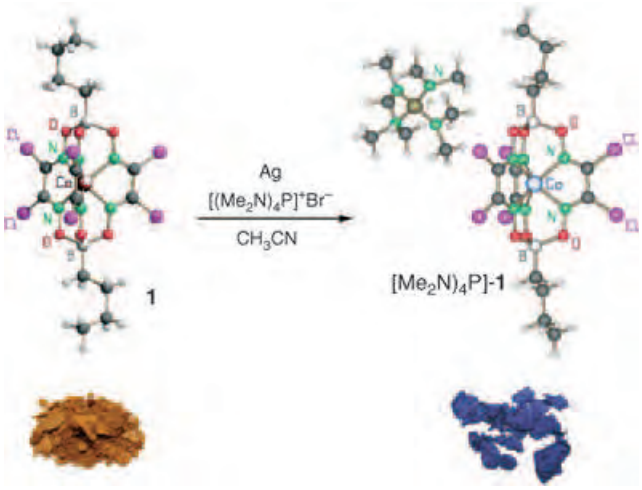
Yan Z. Voloshin, Oleg A. Varzatskii, Ivan I. Vorontsov, and Mikhail Yu. Antipin*

"Oxidation state" is one of most fundamental concepts in chemistry. The stabilization of previously unknown or unusual oxidation states of metal ions allows us to obtain results that are important both for theoretical inorganic chemistry and for the design of new molecular electronic devices, electrochromic materials, and electron-storage systems.

Complexes with a metal ion encapsulated in a three-dimensional macropolycyclic ligand cavity have undoubted promise in stabilizing unusual oxidation states of such caged ions. This is due to the fact that an encapsulated and coordinatively saturated metal ion is completely isolated from environmental factors (in particular, effects of solvation and additional coordination that exclude occurrence of redox processes by bridge mechanisms). The size of a three-dimensional ligand cavity may be controlled by changing the nature of the capping and chelating fragments of the macropolycyclic framework, and donor atoms (groups) that are optimal for stabilization of a desired electronic configuration of this ion may be chosen.[1]

Varying the substituents on a clathrochelate framework is thought to be a new and unique opportunity to stabilize unusual oxidation states of an encapsulated metal ion: although the apical substituents in the capping fragments of the same type affect the electronic characteristics of ligand donor atoms (and, therefore, the encapsulated metal ion) to a very minor extent,[2] the influence of electron-donating (electron-withdrawing) substituents in chelate (ribbed) fragments with a system of conjugated π-bonds may prove to be crucial.[3] We suppose that the electron-withdrawing substituents in such fragments of a clathrochelate ligand stabilize the lowest oxidation states of an encapsulated metal ion. A new approach to the synthesis of cobalt(I) complexes uses a macrobicyclic hexachloride ligand with six strongly electron-withdrawing substituents in chelating π-conjugated α-dioximate fragments. The template condensation of dichloroglyoxime with the corresponding boron-containing Lewis acid on a Co^{2+} ion matrix leads to formation of the brown *n*-butylborane-capped hexachloride cobalt(II) clathrochelate [Co{$(Cl_2Gm)_3(Bn\text{-}C_4H_9)_2$}] (**1**) in high yield (Gm = glyoxime).

We were unable to oxidize, either chemically or electrochemically, the clathrochelate **1** to the corresponding cobalt(III) complex (the process is irreversible and is accompanied by destruction of the clathrochelate structure), but **1** easily undergoes a chemical reduction in acetonitrile solution with silver in the presence of tetraalkylammonium or tetra(dimethylamido)phosphonium halides to produce the dark-blue complex $\mathbf{1}^-$ in high yield (Scheme 1). Analogous reductions



Scheme 1. Reduction of cobalt(II) clathrochelate **1** affords cobalt(I) clathrochelate $[(NMe_2)_4P]$-**1**.

were also carried out for phenylboronic and fluoroboronic hexachloride cobalt(II) clathrochelates. The resulting tetraalkylammonium and tetra(dimethylamido)phosphonium salts of clathrochelate anions with an encapsulated Co^+ ion proved to be air-stable as solid for several months.

The X-ray crystallography data for **1** and $[(NMe_2)_4P]$-**1** indicate that the Co–N distance changes very little on passing from a cobalt(II) clathrochelate **1** to a cobalt(I) clathrochelate anion $\mathbf{1}^-$ (1.984(1) vs. 2.003(3) Å, respectively), as is the case for the previously studied pair $[Co^{II}(bipy)_3]^{2+}/[Co^{I}(bipy)_3]^+$ (2.128 vs. 2.11(2) Å[4]; bipy = 2,2′-bipyridyl) due to an appreciable contribution of Co^I-to-cage charge transfer (πd→π*cage back donation). However, the Co–N distance in the synthesized clathrochelate complexes with a rigid cage framework, as in the case of macrobicyclic iron(II) compounds,[1] is substantially shorter than that in their nonmacrocyclic analogs.[4]

The coordination polyhedra of nonmacrocyclic tris-diiminate complexes and their clathrochelate analogs are also appreciably different: cobalt(II) and cobalt(I) tris-bipyridinates display a trigonal-antiprismatic (TAP) configuration

with distortion angles φ (in passing from TAP ($\varphi = 60°$) to a trigonal prism (TP; $\varphi = 0°$)) of 44.9° and 45.2°, respectively, whereas the geometry of the cage complexes obtained is close to the value for a TP (φ value of 7.8° and 1.3° for cobalt(II) and cobalt(I) cages, respectively). Such a geometry in the case of macrobicyclic systems is due to the large ionic (Shannon) radius of the Co^{2+} ion, which fits the cavity size of the TAP clathrochelate ligand poorly. A change in the ligand geometry from TAP, characteristic of cobalt(III) clathrochelates,[1] to TP leads to an increase in the cavity size, and this facilitates encapsulation of the Co^{2+} ion. A further rotary–translationary extension of the clathrochelate framework permits the encapsulation of a Co^{+} ion with a higher Shannon radius.

It should also be emphasized that the Co^{2+} ion is shifted (by 0.3 Å) from the cavity center towards one of the three chelating fragments (probably due to the structural Jahn–Teller effect for a low-spin d^7 configuration: according to the magnetic susceptibility data for **1**, $\mu_{eff} = 1.55\ \mu_B$ and $S = 1/2$). On the other hand, the clathrochelate of the Co^{+} ion (d^8 configuration) is a high-spin complex ($\mu_{eff} = 2.85\ \mu_B$ and $S = 1$). The X-band EPR spectrum of **1** recorded at 10 K for a powdered sample of an isostructural diamagnetic iron(II) clathrochelate containing the same ligand that was doped with 1% of **1** shows the strong anisotropy of the *g*-factor as well as the hyperfine coupling constant. This spectrum can be described in terms of an $S = 1/2$ spin doublet interacting with a single ^{59}Co nucleus ($I = 7/2$, natural abundance 100%) and is typical of low-spin d^7 systems.[5] The EPR spectral parameters are $g_x = 2.252$, $g_y = 2.070$, and $g_z = 1.984$ and $A_{xx} = 125 \times 10^{-4}$, $A_{yy} = 9 \times 10^{-4}$, and $A_{zz} = 50 \times 10^{-4}\ cm^{-1}$. We failed to observe the EPR spectra of paramagnetic complexes $\mathbf{1}^-$ down to 4 K because of both the long spin–lattice relaxation time and the magnitude and sign of the spin–orbital interaction and their ligand-field symmetry.[6] On the other hand, the absence of EPR signals undoubtedly excludes the formation of organic radicals (i.e., the reduced cage).

XPS was used to directly probe the cobalt ion oxidation states in **1** and $\mathbf{1}^-$. For this ion there is a noticeable (0.9 eV) decrease in the $Co\,2p_{3/2}$ binding energy in $\mathbf{1}^-$ (main peak at 780.8 eV) compared to **1** (main peak at 781.7 eV).

The UV/vis spectra of these clathrochelates in solution are different (Figure 1): the spectrum of the dark-blue solution of $\mathbf{1}^-$ contains two intense bands at $\lambda = 544$ ($\varepsilon = 6.6 \times 10^3\ mol^{-1}\,L\,cm^{-1}$) and 680 nm ($\varepsilon = 8.0 \times 10^3$), whereas the brown color of **1** is determined by two less-intense bands at $\lambda = 421$ ($\varepsilon = 640$) and 468 nm ($\varepsilon = 1550$). The intense bands in the visible spectra of cobalt(I) complexes with azomethine ligands were assigned in earlier studies[7] to charge-transfer bands (first of all to MLCT bands).

The electrochemical behavior of $\mathbf{1}^-$ in dichloromethane solution is characterized by two consecutive oxidations. The first wave, at $E_{1/2} = -440$ mV, is reversible on both glassy carbon and Pt electrodes: the Tomeš criterion value, which was determined from the cyclic voltammogram on a Pt ultramicroelectrode, is equal to 60 mV, and the ratio of peak currents for direct (anodic) and reverse (cathodic) waves on a glassy carbon electrode is close to 1. This process is assigned to a metal-based $Co^{+/2+}$ redox couple. The second wave, which is observed at higher potential ($E_{1/2} = 630$ mV), is most probably irreversible since the Tomeš criterion value is 130 mV and the above-mentioned ratio is less than 1. This process is assigned to the $Co^{2+/3+}$ redox couple.

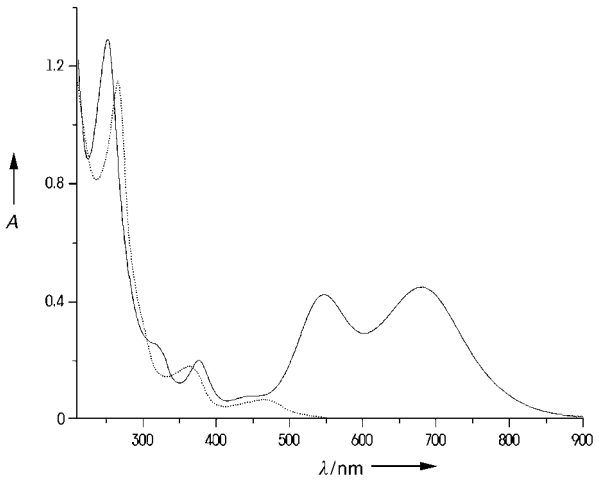

Figure 1. UV/vis spectra of acetonitrile solutions of **1** (••••) and $[(NMe_2)_4P]$-**1** (——) at the same concentrations.

The cobalt(II) clathrochelate can be both irreversibly oxidized and reversibly reduced electrochemically. The location and shape of the reduction wave for this complex coincide with the first oxidation wave for the cobalt(I) compound. The oxidation wave for **1** coincides with the second oxidation wave for $\mathbf{1}^-$.

Our results suggest wider possibilities for the stabilization of the lowest and highest (including unusual and previously unknown) oxidation states by introducing electron-withdrawing (in particular, halide, alkoxy and aryloxy) and electron-donating (especially amine) substituents in the chelating fragments of a macrobicyclic ligand.

Experimental Section

Single crystals of complexes **1** and $[(NMe_2)_4P]$-**1** were grown at room temperature from benzene/isooctane and dichloromethane/benzene mixtures, respectively.

Crystallographic measurements were performed at 110 K (**1**) and 120 K ($[(NMe_2)_4P]$-**1**) with a Bruker SMART 1 K CCD area detector using $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å).[8] Reflection intensities were integrated with SAINT software[8] and corrected by a semi-empirical method (SADABS program).[9] The structures were solved by direct methods and refined by full-matrix least-squares in the anisotropic approximation for non-hydrogen atoms using SHELXTL.[10] The position of the hydrogen atoms was calculated geometrically and refined using the riding model with isotropic temperature factors $U_{iso} = n\,U_{eq}(C)$, where $n = 1.5$ for methyl groups and 1.2 for the other ones and U_{eq} is the equivalent isotropic displacement parameter of the corresponding pivot carbon atoms.

Crystal data for **1**: $C_{14}H_{18}B_2Cl_6CoN_6O_6$, $M_r = 659.59$, monoclinic, space group $C2/c$, $a = 17.347(4)$, $b = 8.102(2)$, $c = 17.172(3)$ Å, $\beta = 91.936(4)°$, $V = 2411.9(8)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.816\ g\,cm^{-3}$, $2\theta_{max} = 50.0°$, 11685 unique data, $R_1 = 0.0466$, $R_w = 0.1311$.Crystal data for $[(NMe_2)_4P]$-**1**: $C_{28}H_{48}B_2Cl_6CoN_{10}O_6P$, $M_r = 944.98$, monoclinic, space group $P2_1/c$, $a = 15.405(2)$, $b = 12.381(2)$, $c = 22.627(3)$ Å, $\beta = 102.162(3)°$, $V = 4218.6(9)$ Å^3, $\rho_{calcd} = 1.488\ g\,cm^{-3}$, $2\theta_{max} = 54.1°$, 9152 unique data, $R_1 = 0.0539$, $R_w = 0.1364$. CCDC-213266 (**1**) and -213265 ($[(NMe_2)_4P]$-**1**) contain the supplementary crystallographic

data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Cucurbituril Polymers

Iodine-Assisted Assembly of Helical Coordination Polymers of Cucurbituril and Asymmetric Copper(II) Complexes**

Feng Zhang, Tatsuo Yajima, Yi-Zhi Li, Guo-Zheng Xu, Hui-Lan Chen, Qi-Tao Liu,* and Osamu Yamauchi**

Iodine has long been paid considerable attention for its fascinating chemical behavior[1,2] and biological essentiality.[3] The use of iodine as electrical conductor in the synthesis of donor–acceptor charge-transfer materials is well known.[4] In recent years, iodine in various forms has found applications in catalysis[5] as well as the creation of novel structures[6] and materials.[7] When covalently bound to an aromatic ring, iodine and other halogen atoms are versatile, assembly-organizing factors that direct extended networks[8,9] and induce helical aggregation of copper(II) complexes.[9,10] Furthermore, iodine is an essential element and plays an important role in the life processes of mammals and most vertebrates by forming the iodophenol moieties of thyroid hormones, growth hormones that function by binding to nuclear receptors.[11–13] The effect of the iodo substituent on these biological events has yet to be understood.

Cucurbituril (CB6) is a pumpkin-shaped macrocyclic compound synthesized by acid-catalyzed condensation of glycoluril and formaldehyde.[14] It is composed of six symmetrically arranged glycoluril units covalently linked by twelve methylene bridges to form a rigid, annular, hollow cavitand with two highly polar carbonyl openings.[15] CB6 has

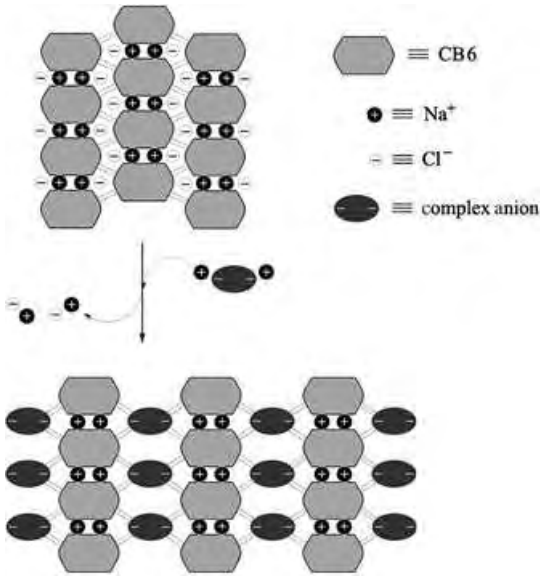
Cucurbituril (CB6)

received much interest in the last two decades as synthetic receptor[16–22] and has found discrete uses in inclusion catalysis,[20] interlocked architectures,[21] and functional molecular devices.[22] The guest-binding properties and inclusion mechanisms of CB6 have been investigated in detail.[16,18] Recently, various CB6 homologues, CB7 and CB8 in particular,[23] have been used for the development of functional molecular devices.[17c,24]

To date, investigations of the weak interactions leading to CB6-mediated molecular assembly are still lacking. The chemical behavior of the convex-shaped outer walls of CB6 and its homologues remains unknown and needs to be explored for the development of novel structures and functional materials incorporating cucurbiturils with transition metal complexes. CB6 can form more stable complexes with alkali metal ions[18] than with transition metal ions,[19g] and thus drives the assembly of alkali metal one-dimensional coordination polymers through wall-to-wall, shape-matching interactions of CB6.[19c,d] A negatively charged transition metal complex with aromatic moieties can bind to a positively charged CB6–alkali metal complex in aqueous solution and compete with CB6 self-recognition. This leads to a hybrid assembly of the CB6–alkali metal coordination polymer incorporating the transition metal complex.



Scheme 1. Schematic representation of the anion-exchange strategy involving CB6 self-recognition (top) and CB6–ligand recognition (bottom).

Herein we report two novel helical structures that are synthesized by an anion-exchange strategy based on asymmetric, shape-matching recognition (Scheme 1). The anionic copper(II) complexes $[Cu(I_2sal)(Hqs)]^{2-}$ and $[Cu(Ibz)(Hqs)Cl]^{2-}$ (I_2sal = 3,5-diiodosalicylate, Ibz = 3-iodobenzoate, Hqs = 8-hydroxyquinoline-5-sulfonate) display a four-coordinate N_1O_3 and a five-coordinate N_1O_3Cl asymmetric structure, respectively, and are recognized by the cationic CB6–sodium(I) 1D coordination polymer. According to the structures of the two molecular assemblies, the convex-shaped glycoluril backbones of CB6 exhibit a much higher affinity to the iodoaromatic moieties of the copper(II) complexes than to the other CB6 units. This results in formation of the helical 1D polymer arrays with the assistance of the iodo substituents.

Compound **1** was isolated as rod-shaped colorless crystals from an aqueous NaCl solution of CB6. A dilute 1:1:1:1 mixture of **1** with Cu^{II}, Hqs, and I_2sal or Ibz in aqueous NaCl solution afforded complexes **2** or **3** as prismatic or needle-shaped green crystals (see the Experimental Section). The structures of **1**–**3** were determined by X-ray crystallography.[25]

$[Na_4(CB6)_2(H_2O)_{16}]Cl_4 \cdot 6H_2O$ **1**

$[Na_2(CB6)(H_2O)_2][Cu(I_2sal)(Hqs)] \cdot 6.5H_2O$ **2**

$[Na_2(CB6)(H_2O)_2][Cu(Ibz)(Hqs)Cl] \cdot 5.5H_2O$ **3**

In the crystal structure of **1**, the CB6 molecules display C_{2h} symmetry and are connected by twofold O(1)-Na^I-O(1) coordination linkages to form a linear 1D polymer (Figure 1a). The CB6 molecules in **2** and **3** are asymmetric in the presence of the complex anions. They are connected by asymmetric $O_{\mu2}$(water)–Na^I dinuclear clusters with formation of O–Na chelates for one of the carbonyl openings and one Na(1)-$O(12)_{\mu2}$-Na(2) bridging and two O–Na coordination bonds for the other. The resulting 1D polymers in **2** and **3** exhibit a zig-zag, folded helical conformation; neighboring CB6 molecules in the same polymer are in close contact with each other (Figure 1b,c). The closest distances between the carbonyl O(3) atom of the glycoluril unit G3 and the carbonyl C(12) atom of unit G6 are 3.07 and 3.13 Å, with corresponding CB6–CB6 tilting angles of 31.1° and 32.6° for **2** and **3**, respectively.

The 1D polymer in **2** exists as a pair of helical enantiomers, and the enantiomeric CB6 molecules of the *P* and *M* helices bind with the corresponding enantiomeric $[Cu(I_2sal)(Hqs)]^{2-}$ anions along the same $P2_1$ axis through asymmetric shape-matching interactions between the aromatic moieties of $Cu(I_2sal)(Hqs)$ and the outer walls of the CB6 molecules. The 1D polymer in **3**, on the other hand, exists only as an *M*-type helix, whose CB6 molecules are closely contacted by the $[Cu(Ibz)(Hqs)Cl]^{2-}$ anions through *P*-type helical shape-matching accommodation. The complex anions of **2** and **3** assume a rigid skew-bent conformation connected by asymmetric Cu^{II} ion centers with a distorted square-planar coordination geometry for $[Cu(I_2sal)(Hqs)]^{2-}$ and a distorted square-pyramidal coordination geometry for $[Cu(Ibz)(Hqs)Cl]^{2-}$ (Figure 2); the dihedral angles between the

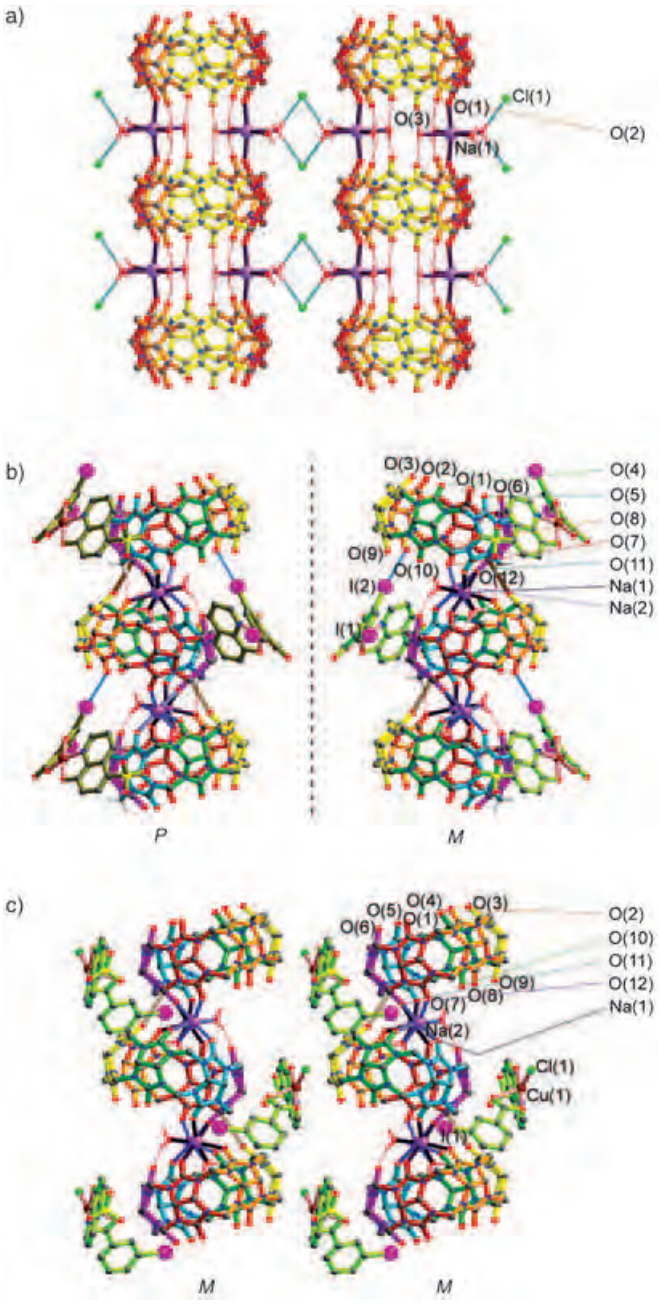


Figure 1. Ball-and-stick representations for the linear 1D-polymer in **1** (a) and the helical 1D polymers in **2** (b) and **3** (c) with the asymmetric glycoluril units G1–G6 (G1 red, G2 orange, G3 yellow, G4 green, G5 cyan, G6 purple).[26]

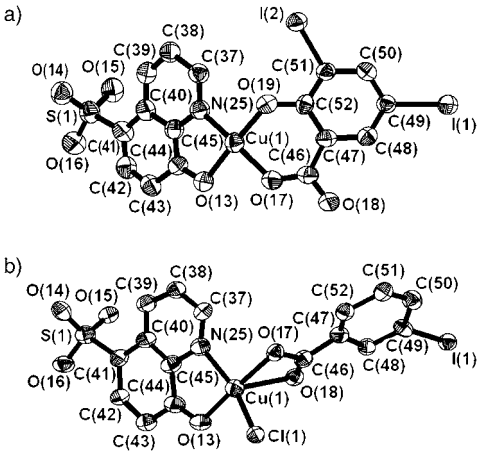

Figure 2. ORTEP views of a) $[Cu(I_2sal)(Hqs)]^{2-}$ in **2** and b) $[Cu(Ibz)(Hqs)Cl]^{2-}$ in **3** with the thermal ellipsoids at the 50% probability level.[26]

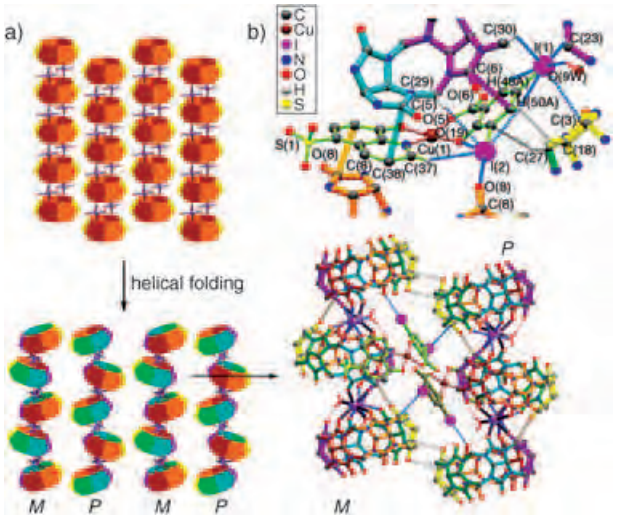

Figure 3. a) Schematic representation of the polymer 2D layer in **1**, the 2D open-cavity framework in **2** (left), and the structure for the accommodation of $Cu(I_2sal)(Hqs)$ into the homocenter-symmetric open cavity (lower right). b) The host–guest shape-matching mode in **2** involving I–O, I–C, and I–H weak interactions.[26]

coordinated aromatic rings are 130.3 and 106.1°, respectively. It is these discrete and properly skew-bent conformations that allow the asymmetric shape-matching and thus result in the discrete helical structures (Figures 3 and 4). The skew-bent conformations are reminiscent of that of thyroid hormones, whose inner and outer phenol rings are asymmetrically bridged by an ether oxygen atom instead of the Cu^{II} ion of the complexes presented here.[3b]

In complex **2**, the positively charged *P* and *M* polymer helices are alternately packed with opposite orientations (Figure 3a) and assembled as a two-dimensional layer structure with open cavities. Each cavity is composed of the half walls of three CB6 enantiomer pairs through shape-matching interactions between the G3 semi-glycoluril rings of two CB6 enantiomer pairs with a ring–ring distance of 3.29 Å. Most importantly, each open cavity holds homocenter symmetry, tightly accommodating a pair of $[Cu(I_2sal)(Hqs)]^{2-}$ enantiomers in the same symmetry. To our knowledge, this is the first example of a helical enantiomeric host–guest assembly constructed from an asymmetric transition metal complex anion (guest) and the outer walls of CB6 molecules within the cavity-forming cation aggregates (host) through asymmetric shape-matching interactions.

The skew-bent form of $[Cu(I_2sal)(Hqs)]^{2-}$ in **2** is arranged in such a way that the inward I_2sal and Hqs ring faces fit to the semi-glycoluril rings of units G6 and G5, respectively, of the same CB6 molecule. The outward I_2sal and Hqs ring faces

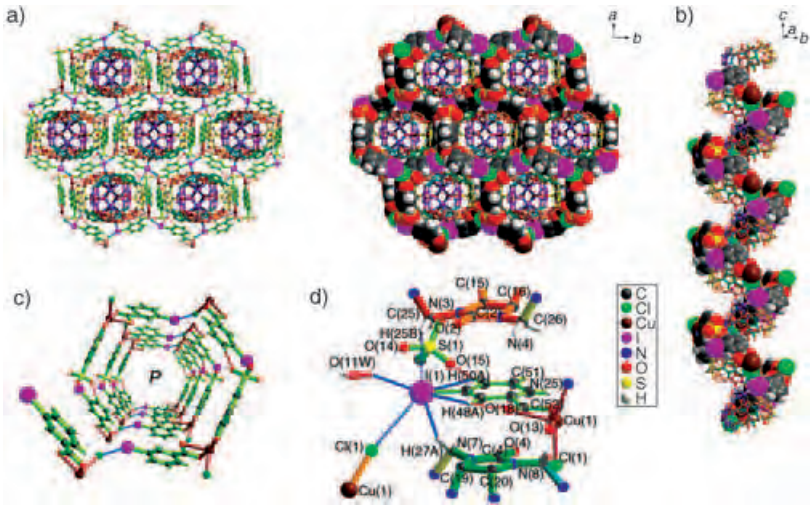

Figure 4. a) Top views for the helical inclusion structure of **3**. b) Side view for the complex anion-wrapped polymer helix in **3**. c) Top view for the *P*-type anionic helical net channel. d) Representation of the asymmetric shape-matching mode of Ibz to G2 (orange) and G4 (green) involving I–H and I–Cl weak interactions.[26]

contact with the semi-glycoluril rings of units G3 and G2, respectively, of the CB6 molecules in the neighboring polymers (Figure 3b). The inward G6–I_2sal and G5–Hqs and outward Hqs–G2 matching pairs form face-to-face π–π stacking interactions, with closest ring–ring distances of 3.38, 3.47, and 3.43 Å and ring–ring tilting angles of 19.6, 5.9, and 5.8°, respectively. In contrast, the outward I_2sal–G3 matching pair is achieved by complementary iodine–G3 ring charge transfer and C–H···π interactions between a G3 hydrogen atom and the I_2sal ring. This places the I_2sal and G3 rings in edge-to-edge contact with a closest ring–ring distance and angle of 3.50 Å and 15.7°.

In **3**, unique helical polymer-inclusion assembly by the $[Cu(Ibz)(Hqs)Cl]^{2-}$ anion is achieved with formation of helical networks (Figure 4). The complex anion is arranged leaning toward the corresponding hinge site of the polymer helix, with the inward Ibz and Hqs ring faces contacting the semi-glycoluril rings of units G2 and G6, respectively, of the neighboring CB6 molecules. The outward Ibz and Hqs ring faces close to G4 and G3, respectively, of the CB6 molecules in the neighboring polymer (Figure 1c and 4d). The closest ring–ring distances are 3.67, 3.46, 3.60, and 3.44 Å, respectively, for the G2–Ibz, G6–Hqs, Ibz–G4, and Hqs–G3 matching pairs with corresponding ring–ring angles of 3.3, 4.6, 1.5, and 4.2°, indicating face-to-face π–π stacking interactions.

The same striking point for compounds **2** and **3** is the assembly-assisting role of the iodo substituents, whose multiple weak interactions with CB6 amplify the asymmetry and enhance the stability of the asymmetric shape-matching interactions. In **2**, the iodo substituents are involved in multiple hydrogen-bonding interactions with the G6 methine and the hydrogen atoms of the C(29) and C(30) methylene groups as well as charge-transfer interactions with the ureido G2 oxygen and G3 carbon atoms (Figure 3b). The interatomic distances for I(1)–C(3), I(2)–O(8), and I–H(23A, 30A, 9WA, 29B, 37A) are 3.78, 3.34, and 3.25–3.30 Å, respectively, and thus all lie within the corresponding van der Waals distances[27] of 3.85, 3.55, and 3.35 Å, respectively. The interatomic distances involving the iodo substituent in **3** (Figure 4d), that is, I(1)–H(25B) (2.98 Å) and I(1)–H(27A) (3.07 Å), are distinctly shorter than the van der Waals distance for I–H. All these distances are comparable with those previously observed for other systems (I–C 3.63–3.82, I–O 3.08–3.37, I–H 2.85–3.20 Å)[9] and some thyroactive species (I–O 2.99–3.45 Å).[3c] In addition, the iodo substituent in **3** also contacts the coordinated Cl^- anion within the van der Waals distance and favors the hydrogen-bonding interaction of its *ortho*-hydrogen atom with the sulfonate oxygen atom of Hqs (O···C 3.37, O···H 2.39 Å; ∢O···H–C 176.2°). These results suggest that the iodine atoms of coordinated I_2sal and Ibz may play an important role in the formation of **2** and **3** by serving as an efficient asymmetric weak-binding knot and template.

In conclusion we present two novel helical structures established by iodine-assisted asymmetric shape-matching interactions between the convex outer walls of CB6 and the aromatic moieties of asymmetric copper(II) complexes. The synthetic strategy may also be suitable for other hybrid structures and the construction of cucurbiturils incorporating various transition metal complexes. Our results suggest that the iodo substituent may exert a profound effect on its covalently bound aromatic moiety in specific asymmetric recognition to a given structural environment through selective shape-matching interactions. The observed structural change due to the interactions between CB6 and the iodophenol moiety may suggest the possible function of thyroid hormones as an iodine-assisted asymmetric template in the hormone–receptor binding switches inducing the biologically active conformation of the receptor.

Experimental Section

CB6 was synthesized following a literature procedure[15] and obtained as a white powder in 40–45% yield after drying at 110°C. Elemental analysis calcd for $(C_{36}H_{36}N_{24}O_{12})\cdot 9H_2O$ [%]: C 37.31, H 4.70, N 29.01; found: C 37.68, H 4.84, N 28.70; ^{1}H NMR (Bruker, 500 MHz, in D_2O): $\delta = 5.65$ (s, CH), 5.74 (d, CHH), 4.38 ppm (d, CHH).

1: A solution of CB6 (0.5 mmol) in 0.2 M aqueous NaCl was concentrated to near saturation followed by slow vapor diffusion of ethanol into the solution at room temperature for one week. The colorless rod-shaped crystals were dried in air at room temperature (60–70% yield). Elemental analysis calcd for $(C_{72}H_{104}N_{48}Na_4O_{40})Cl_4\cdot 6H_2O$ [%]: C 32.96, H 4.46, N 25.62; found: C 33.12, H 4.32, N 25.76.

2: Compound **1** (0.05 mmol) was dissolved in 0.2 M aqueous NaCl and the solution was added dropwise to an aqueous 1:1:1 mixture of $CuCl_2$, I_2sal, and Hqs (0.05 mmol) at pH 6 under stirring. Slow evaporation of the filtrate over two weeks provided prismatic green crystals of **2** (40–50% yield based on CB6). Elemental analysis calcd for $(C_{52}H_{47}N_{25}I_2SNa_2O_{21}Cu)\cdot 6.5H_2O$ [%]: C 33.39, H 3.23, N 18.72; found: C 33.67, H 3.02, N 18.90.

3: Compound **3** was prepared in a similar manner to **2** with Ibz in place of I_2sal. Slow evaporation of the filtrate for two weeks provided needle-shaped green crystals of **3** (40–50% yield based on CB6). Elemental analysis calcd for $(C_{52}H_{49}N_{25}O_{20}SICuClNa_2)\cdot 5.5H_2O$ [%]: C 35.75, H 3.46, N 20.04; found: C 36.07, H 3.09, N 20.25.

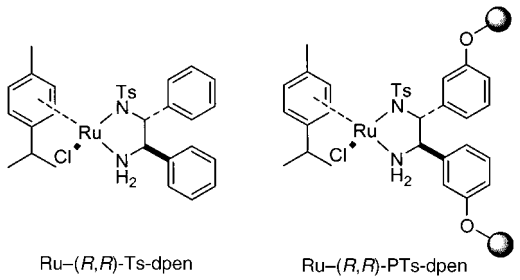
Transfer Hydrogenation

Insight into and Practical Application of pH-Controlled Asymmetric Transfer Hydrogenation of Aromatic Ketones in Water**

*Xiaofeng Wu, Xiaoguang Li, Frank King, and Jianliang Xiao**

Dedicated to Professor Ryoji Noyori

Catalysis in water represents a major area of intense research in modern chemistry.[1] Water is inexpensive, readily available, and environmentally benign, and is thus an ideal solvent for chemical reactions. We recently reported that asymmetric transfer hydrogenation of aromatic ketones with the Ru–(*R*,*R*)-Ts-dpen catalyst (Ts-dpen = *N*-(*p*-toluenesulfonyl)-1,2-diphenylethylenediamine) or its polymer-supported analogue



Ru–(*R*,*R*)-Ts-dpen Ru–(*R*,*R*)-PTs-dpen

Ru–(*R*,*R*)-PTs-dpen (PTs-dpen = poly(ethylene glycol)-supported Ts-dpen) can be considerably accelerated by using water as solvent and in the case of Ru–(*R*,*R*)-PTs-dpen, the catalyst was recycled more than 10 times without loss of enantioselectivity.[2,3] The reducing agent used in those studies was HCOONa. To our surprise, when the often-used HCOOH–NEt_3 azeotrope was adopted as reductant for the same reaction in water, a much slower reaction was observed. This prompted us to investigate whether the reaction was affected by the pH value of the solution. Although Benyei and Joó reported that the rate of transfer hydrogenation of benzaldehyde by aqueous HCOONa with a water-soluble

Ru^{II}–phosphine catalyst is independent of the pH value of the solution under basic conditions,[4] recent work from Ogo et al. revealed a strong pH dependence in the rate of the reduction of ketones by HCOONa with $[(\eta^6\text{-}C_6M_6)Ru(bpy)(H_2O)]^{2+}$ (bpy = bipyridyl) in water.[5] However, there appear to be no reported studies on how the pH values may affect asymmetric transfer hydrogenation in aqueous media.

Asymmetric transfer hydrogenation of ketones is a powerful alternative to asymmetric hydrogenation for the production of chiral alcohols.[6] Among the various chiral catalysts reported, the most notable is the Ru–Ts-dpen catalyst developed by Noyori, Ikariya, Hashiguchi, and co-workers.[7] This catalyst and the related variants have been successfully applied by Noyori, Ikariya, and others to a wide range of prochiral ketones and imines.[3,7–9] The reaction is most often performed in 2-propanol or the HCOOH–NEt_3 azeotropic mixture; they act as both solvents and hydrogen sources. However, the transfer hydrogenation under such conditions tends to be sluggish, accompanied with low productivity. We herein report that asymmetric transfer hydrogenation with the Noyori–Ikariya catalyst is pH dependent and can be effected in faster rates, with little compromise on enantioselectivities, by a smaller amount of HCOOH–NEt_3 in water. Our preliminary observations concerning why the reduction is pH dependent are also presented.

Following on from our finding that aromatic ketones can be reduced more rapidly by HCOONa in water than in HCOOH–NEt_3 with the Ru–Ts-dpen catalyst,[2] we wondered whether similar acceleration in rates could be achieved with the azeotrope in water as solvent. We set out by examining the asymmetric transfer hydrogenation of acetophenone to 1-phenylethanol. As before,[2a] the precatalyst was generated by treating (*R*,*R*)-Ts-dpen (0.012 mmol) with $[\{RuCl_2(p\text{-cymene})\}_2]$ (0.005 mmol) in water (1 mL) at 40 °C for 1 h, and the reduction started by introducing the HCOOH–NEt_3 azeotrope (1.0 mL; molar ratio HCOOH/NEt_3 = 2.5:1) and acetophenone with a substrate/catalyst (S/C) ratio of 100:1. Surprisingly, less than 2% conversion was observed after reduction at 40 °C for 1 h; the conversion rose to 98% after a prolonged time of 12 h. This is in stark contrast to the observation made with HCOONa in water, under which the ketone was fully converted into (*R*)-1-phenylethanol in 1 h albeit with a lower enantioselectivity (94 vs. 97% *ee*). The most discernable difference between the two systems was the pH value of the solution. The pH value of the azeotrope–water system was 3 at the beginning of the reaction; the aqueous HCOONa solution was far more basic (pH 7). Thus the question arose: Was the reaction rate affected by pH values, and if so, could the reduction be accelerated by adjusting the pH value?

To address this issue, we measured the initial rates of the reduction of acetophenone (1.0 mmol) in water (0.5 mL) at various initial solution pH values by adjusting the HCOOH/NEt_3 molar ratios; the total solution volume remained constant at 1.0 mL, however. Figure 1 shows the initial turnover frequency (TOF) as a function of the starting pH values. Our speculations were confirmed as the reaction barely took place at low pH values; it accelerated at pH 3.9, with the acceleration slowing down at approximately pH 4.8.

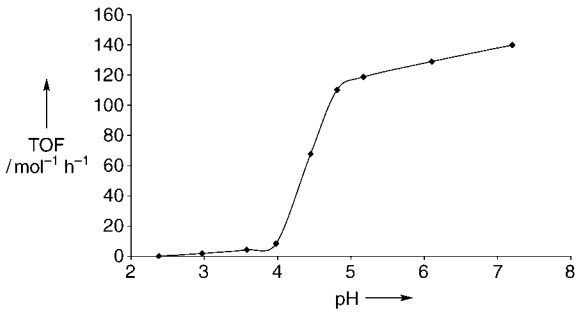

Figure 1. Initial TOF against initial solution pH values for the reduction of acetophenone (1 M, assuming the solution is homogeneous) by HCOOH–NEt_3 in water (1 mL total volume) with Ru–(*R*,*R*)-Ts-dpen at 40 °C. The initial pH values were determined by varying the HCOOH/NEt_3 molar ratios from 4.6:1.0 to 0.37:1.0.

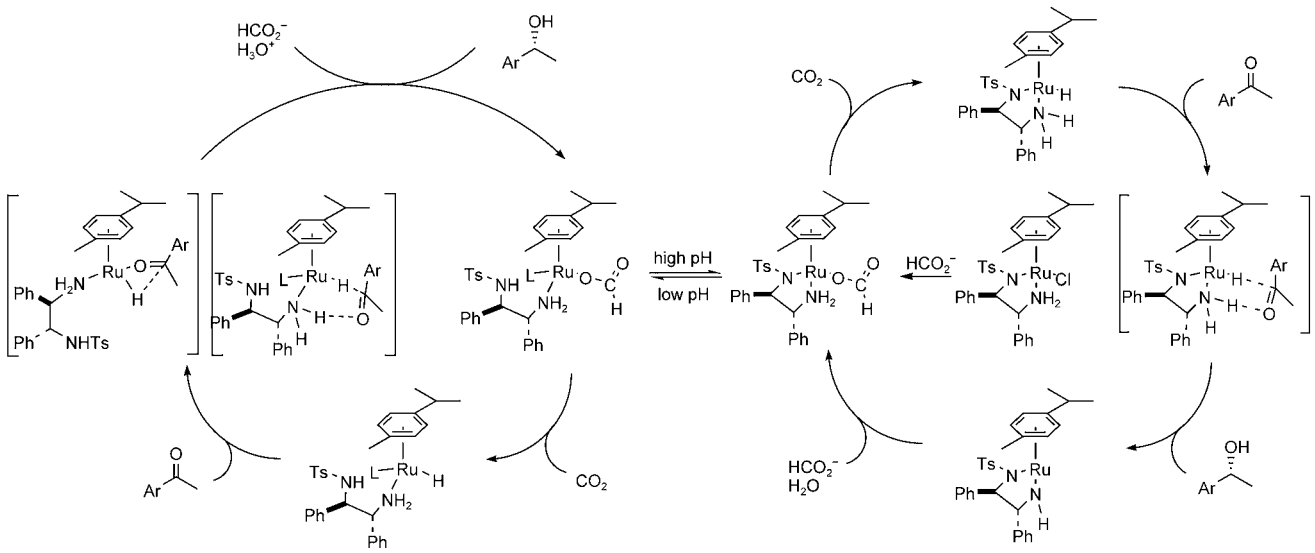
The rate appeared to level off at pH > 7. However, examination of the effect of a further pH increase on the rate was difficult under the chosen conditions. The aforementioned $[(\eta^6\text{-}C_6M_6)Ru(bpy)(H_2O)]^{2+}$ resulted in a decreased rate at pH > 6 in the reduction of ketones.[5] This was attributed to the formation of a Ru^{II}–OH complex by deprotonation of a coordinated H_2O. The less significant effect of higher pH on the reduction in this case may stem from the higher basicity of Ts-dpen than that of bipyridine.[10]

The higher rates at pH values greater than 4 could be due to the increased concentration of $HCOO^-$. At pH > 4, HCOOH ($pK_a = 3.6$) exists predominately as $HCOO^-$, which is needed to form the ruthenium formato complex (Scheme 1, see below). This would be in line with our previous report that the rate of the reduction of acetophenone by HCOONa increases with the formate concentration in water when [formate] < 5 M.[2a] However, there appears to be no correlation of TOF with $[HCOO^-]$ in this study. Thus, for example, the initial TOF increased 8 times when the initial pH value changed from 4.0 to 4.5; the corresponding change in the calculated initial $[HCOO^-]$ was only from 3.1 to 2.9 M, suggesting that the observed TOF–pH correlation cannot simply be ascribed to the variation in formate concentration.

To address the issue raised above further, we followed the reduction of acetophenone starting at pH 2.3. As can be seen from Figure 2, the reduction barely occurred before the pH value increased to approximately 3.5, which seems to support the notion that the reduction is governed by the concentration of formate. The observed increase in solution pH with time is a consequence of the decomposition of HCOOH by Ru–Ts-dpen and its consumption in the reduction of the ketone. The decomposition gave rise to CO_2 and H_2, as shown by MS in the absence of ketone. However, the most surprising observation is that the enantioselectivity varied with the pH value as well (Figure 2). This observation suggests that there might be a competing pathway in operation under acidic conditions, which is less selective than that at higher pH values and becomes insignificant under basic conditions. A similar change in *ee* values with time was noticed by Carmona, Oro, Joó, and co-workers, but the cause was less clear.[11]

The observed change in reaction rates with solution pH values suggests that the rates can be modulated by the pH.



Scheme 1. Proposed catalytic cycles for the reduction of ketones under acidic and basic conditions. L may be a water molecule.

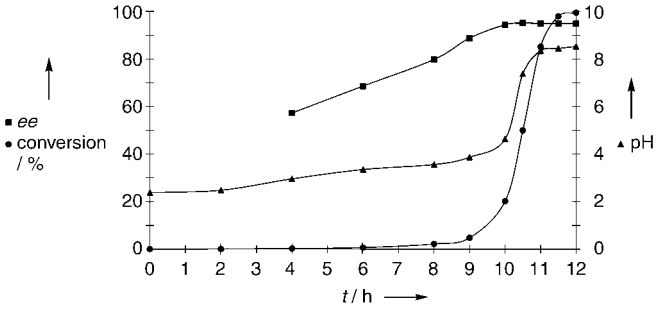


Figure 2. Graph of conversion (●), enantioselectivity (■), and pH (▲) versus time for the reduction of acetophenone (1 M) by HCOOH–NEt_3 (initial molar ratio: 4.6:1.0; 0.5 mL) in water (0.5 mL) with Ru–(*R*,*R*)-Ts-dpen at 40 °C.

This is indeed the case. Thus, as illustrated in Figure 3, the reduction of acetophenone could be rapidly initiated by raising the pH value by simple adding NEt_3 and suppressed by adding HCOOH. The reversible rise and fall in rates against

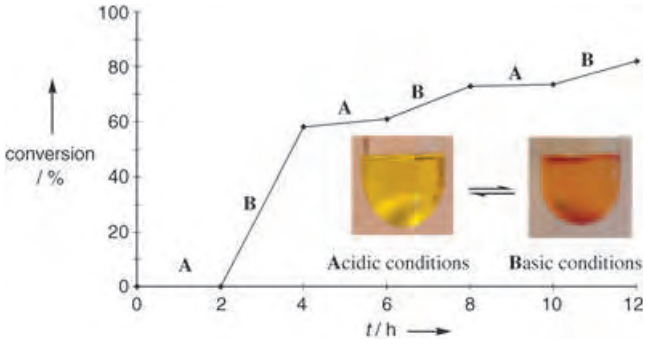

Figure 3. Graph of conversion versus time for the reduction of acetophenone (1 M) by HCOOH–NEt_3 in water (1:1 initial volume ratio, 0.5 mL water) with Ru–(*R*,*R*)-Ts-dpen at 40 °C. In regions A the initial HCOOH/NEt_3 molar ratio was maintained at 4.6:1.0 (pH 2.8), whereas in regions B HCOOH/NEt_3 = 2.3:1.0 (pH 3.7).

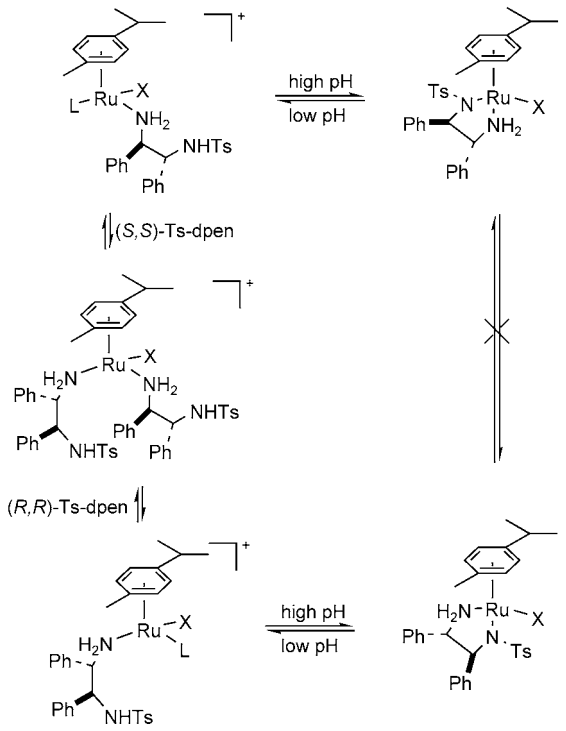
pH may partly result from the fluctuation of formate concentration; but there could be another explanation, that is, there may exist two interchangeable catalytic pathways, with their proportion determined by solution pH. Consistent with this, the aqueous solution changed color reversibly; the solution was yellow under acidic conditions and orange under basic conditions (Figure 3).

Taken the above observations together, we propose that the Ru–Ts-dpen catalyst operates through two catalytic cycles (Scheme 1). The cycle under basic conditions follows the concerted mechanism proposed by Noyori et al.,[12,13] whereas that at low pH values starts with the protonation of the coordinated Ts-dpen. The low rates and low *ee* values in the latter case can be interpreted as resulting from the conventional, stepwise reduction of ketones[12b,14] and/or from a similar concerted mechanism with a less-well-organized transition state. The Ru^{II}–Cl precatalyst is probably hydrolyzed with displacement of the chloride by water,[15] thus explaining its solubility in water. The question concerning which nitrogen atom is protonated is not yet clear but may be addressed from the following observations. The pK_a value of the amido nitrogen group in Ts-dpen has been measured to be 7.4,[10] and a lanthanide complex that contains a related NTs unit (pK_a = 6.4) has been shown to undergo a pH-dependent on-and-off process.[16] It is also known that the amino chelate rings in Ru^{II}–en (en = ethylenediamine) complexes are stable under conditions that are far more acidic than those used in this study.[17] Furthermore, the Ru^{II}–NTs bond is longer than the Ru^{II}–NH_2 bond in the precatalyst.[18] These observations suggest that the amido rather than the amino nitrogen atom is protonated.

If the (*R*,*R*)-Ts-dpen ligand is protonated under acidic conditions, introduction of the opposite enantiomer, (*S*,*S*)-Ts-dpen, to the solution could be expected to generate a mixture of Ru–(*R*,*R*)-Ts-dpen and Ru–(*S*,*S*)-Ts-dpen and lead to a racemic product. Furthermore, the ligand substitution process should be pH dependent, as the chelating effect of (*R*,*R*)-Ts-dpen would come into play at higher pH values (Scheme 2).



Scheme 2. Proposed ligand substitution as a function of pH. X may be a hydride or formate.

This is indeed the case, as shown in Figure 4 for the reduction of acetophenone. Thus, the addition of (*S*,*S*)-Ts-dpen (1 equiv) into an aqueous solution containing Ru–(*R*,*R*)-Ts-dpen (pH 4.6) lowered the enantioselectivity dramatically from the initial value of 98% *ee* at 5% conversion to 5% *ee* when the reaction was complete (Figure 4a). This corresponds to an *ee* value of 5% for the reduction upon the introduction of (*S*,*S*)-Ts-dpen and indicates that the subsequent reduction was virtually non-enantioselective. In sharp contrast, no significant effects on either the rate or *ee* values were noticed when the same ligand was introduced at a higher pH value of 7.7 (Figure 4b). These kinetic profiles are similar to those observed without the additional ligand, suggesting that the active catalytic species in the presence of additional (*S*,*S*)-Ts-dpen are the same Ru–(*R*,*R*)- or (*S*,*S*)-Ts-dpen complex. Further evidence in support of the mechanism is seen in the reaction by adding bipyridine, which inhibited the reduction of acetophenone only under acidic conditions.

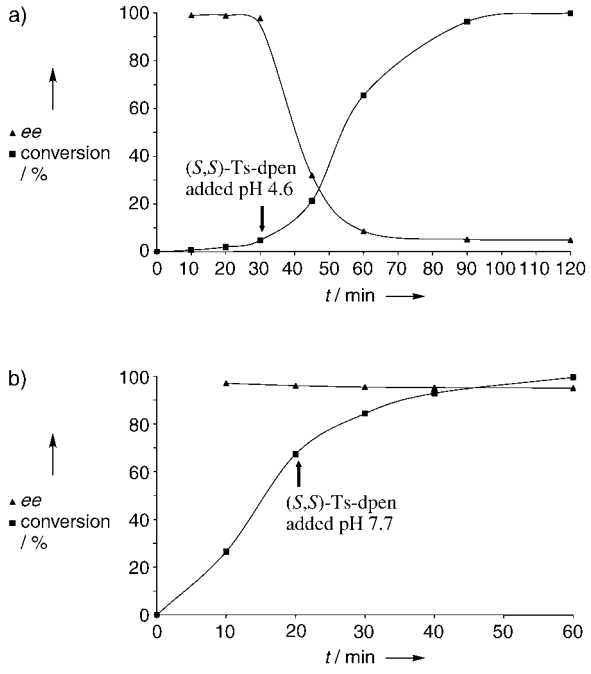


Figure 4. Effect of (*S*,*S*)-Ts-dpen (1 equiv added at the pH indicated) on the conversion (■) and enantioselectivity (▲) of the reduction of acetophenone (1 M) by HCOOH–NEt_3 in water (1:1 volume ratio) with Ru–(*R*,*R*)-Ts-dpen at 40°C. The initial HCOOH/NEt_3 molar ratio was 2.3:1.0 (a) and 0.7:1.0 (b).

With these findings in hand, it was then easy to address the issue of slow reaction rates faced when combining the HCOOH–NEt_3 azeotrope with water.[19] Thus, instead of simply adding the azeotrope mixture to water, we used an aqueous solution of HCOOH and NEt_3, in which the amine acted as a pH modulator, thus ensuring that the pH value of the solution was maintained between 5 and 8 during any reduction. Under such conditions, aromatic ketones could be reduced with Ru–(*R*,*R*)-Ts-dpen to secondary alcohols in water at much faster rates and with little loss in enantioselectivities; some examples are given in Table 1. In comparison with the original conditions described by Noyori and coworkers,[7a] the current method affords similar conversions and *ee* values in much shorter times by using much smaller amounts of HCOOH and NEt_3.

Table 1: Asymmetric transfer hydrogenation of ketones by HCOOH–Et_3N with Ru–(*R*,*R*)-Ts-dpen in water.[a]

Ketones	*t* [h]	Conversion [%][b]	*ee* [%][b]
acetophenone	1.5	100	97
4′-fluoroacetophenone	1.5	100	92
4′-trifluoromethylacetophenone	1.3	100	95
4-acetylbenzonitrile	1.5	99	89
4′-nitroacetophenone	2	>99	85
4′-methoxyacetophenone	5	>99	97
3′-methoxyacetophenone	2.5	99	95
4-acetylpyridine	2	>99	96
2-acetylthiophene	2	>99	96
4′-methylpropiophenone	3	99	92

[a] The reactions were carried out in a mixture of H_2O (0.5 mL) and HCOOH–Et_3N (0.5 mL; molar ratio 1.2:1.0; initial pH 5) at 40°C, with ketone (1 mmol) at a S/C ratio of 100:1. [b] Determined by GC. The configuration of the alcohol was *R*.

One of the limitations of the Ru–Ts-dpen catalyst and related variants was their low productivity, with most applications having S/C ratios of ≈200:1.[7–9] This limitation can now be effectively circumvented by employing the current method. As is seen from Table 2, by controlling the pH to a range of 5–8 by simply adjusting the HCOOH/NEt_3 ratios, aromatic ketones can be readily reduced at S/C ratios of 1000:1–10000:1 in water to afford the chiral alcohols with little compromise in enantioselectivities.

Table 2: Asymmetric transfer hydrogenation of ketones in water at higher S/C ratios.[a]

Ketones	S/C	*t* [h]	Conversion [%][b]	*ee* [%][b]
Acetophenone	1000	9	>99	96
4′-chloroacetophenone	1000	11	>99	93
4′-methoxyacetophenone	1000	32	99	95
2-acetylfuran	1000	8	>99	96
2′-acetonaphthone	1000	11	>99	95
acetophenone	5000[c]	57	98	96
acetophenone	10000[d]	110	98	94

[a] The reactions were carried out in a mixture of H_2O (2.5 mL) and HCOOH–Et_3N (2.5 mL; 1.2:1.0) at 40 °C with 10 mmol of ketone at pH 5–8. [b] Determined by GC analysis. The configuration of the alcohol was *R*. [c] The volume of the mixture of water and HCOOH–Et_3N was 10 mL (1:1 volume ratio); ketone: 50 mmol. [d] Water (10 mL), HCOOH (initially 5 mL), Et_3N (20 mL), and ketone (0.1 mol) were used.

In summary, the results presented herein demonstrate that aqueous-phase asymmetric transfer hydrogenation of aromatic ketones by formic acid with the Noyori–Ikariya Ru–Ts-dpen catalyst is modulated by the solution pH. By controlling the pH value, much faster rates and higher turnover numbers in conjunction with excellent *ee* values can be delivered. Evidence is presented that suggests that there may be two competing catalytic cycles, and hence the reaction rates and enantioselectivities are a function of solution pH values.

Experimental Section

$[\{RuCl_2(p\text{-cymene})\}_2]$ (3.1 mg, 0.005 mmol) and (*R,R*)-Ts-dpen (4.4 mg, 0.012 mmol) were dissolved in degassed water (0.5 mL). After stirring at 40 °C for 1 h, HCOOH (0.13 mL, 3.3 mmol), Et_3N (0.37 mL, 2.7 mmol), and acetophenone (120 mg, 1.0 mmol) were added to the solution. Following degassing three times, the mixture was allowed to react at 40 °C for a certain period of time. The workup was the same as before[2] and the product was analyzed by GC (Chrompack Chirasil-Dex CB column).

The reduction at S/C = 10000:1 was carried out as follows: After preparation of the precatalyst in water (10 mL), HCOOH (5 mL, 0.13 mol), Et_3N (20 mL, 0.14 mol), and acetophenone (12 g, 0.10 mol) were introduced. The reaction was conducted in a way similar to that above, except that during the reduction HCOOH was periodically added to keep the pH value between 5 and 8.

The reduction could also be performed in the absence of water. An example under comparable conditions is given here. The catalyst was prepared in a similar way in degassed HCOOH–NEt_3 (1 mL; molar ratio = 0.9:1). The reduction started with the introduction of acetophenone (120 mg, 1 mmol; S/C = 100:1) and resulted in a complete reaction at 40 °C in 7 h with 97 % *ee*.

[19] In neat HCOOH–NEt_3, the reduction was faster when the HCOOH/NEt_3 ratio decreased, but slower than that in the aqueous solution (see Experimental Section).

RNA Recognition

Evidence that Electrostatic Interactions Dictate the Ligand-Induced Arrest of RNA Global Flexibility**

*Stephen W. Pitt, Qi Zhang, Dinshaw J. Patel, and Hashim M. Al-Hashimi**

Arresting flexibility to prevent RNA from undergoing functionally important conformational transitions is an established strategy for developing RNA-targeting therapeutics.[1] To understand the role of RNA flexibility in adaptive recognition[2] is also important for the rational design of small molecules that bind their RNA target with high affinity and specificity.[3] Yet few studies have quantitatively examined how RNA-binding therapeutics affect the flexibility of their RNA targets. As a result, little is known about the RNA–ligand interactions that are important for arresting different types of RNA functional flexibility. Here, we provide direct evidence by using NMR residual dipolar couplings (RDCs)[4] that electrostatic interactions play a primary role in dictating the degree to which small molecules arrest global motions in RNA.

The transactivation response element (TAR) RNA from HIV-1 (Figure 1a) is a primary RNA target for developing anti-HIV therapeutics[5] and its molecular flexibility is implicated in its function. Upon binding to its cognate target, the transactivator protein (Tat), TAR undergoes large conformational changes that involve reorientation of two helical domains from a bent to a coaxially aligned state.[6] By using RDCs, we previously reported evidence for significant interdomain flexibility in free TAR which may play a direct role in mediating the conformational changes in TAR that accompany Tat recognition.[7a,b] We also demonstrated that Mg^{2+} or the ligand mimic of Tat, argininamide, can bind TAR and completely arrest these interdomain motions.[7c,d]

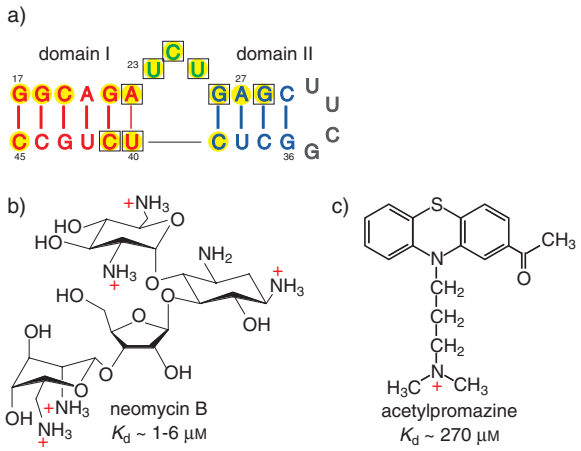

Figure 1. a) Secondary structure of TAR (transactivation response element) RNA in which the wild-type loop is replaced by a UUCG counterpart. The highlighted residues undergo $\Delta\delta > 0.1$ ppm changes in ^{1}H NMR chemical shifts upon binding to neomycin B (yellow) and acetylpromazine (□). b, c) Structures and TAR-dissociation constants (K_d) for neomycin B (b; NeoB)[9,11] and acetylpromazine (c; AcP).[14]

The RDC methodology and TAR provide a unique opportunity to examine RNA–ligand interactions that are particularly important for arresting a general class of RNA motions, which involve global reorientation of helical domains. Numerous studies on RNA–aminoglycoside recognition have demonstrated that electrostatic interactions between cationic groups on the ligand and regions of high negative-charge density in the RNA can contribute significantly to aminoglycoside-binding affinities and specificities.[8] As global motions in RNA originate from local mobility in the negatively charged backbone and as functional groups from many residues can be involved in forming pockets of high negative-charge density in RNA, we reasoned that similar electrostatic interactions are also likely to be important for arresting RNA global motions.

To examine this hypothesis, we employed RDC NMR methodology to characterize the conformational dynamics of TAR when it is bound to two molecules that have different electrostatic charges: the aminoglycoside neomycin B (NeoB),[9] which bears five positively charged ammonium groups, and the small organic molecule acetylpromazine (AcP),[10] which carries a single positive charge (Figure 1b,c). Both NeoB and AcP bind TAR and inhibit its interaction with Tat.[9,10] A previously reported NOE-based NMR spectroscopic study of the structure of the TAR–NeoB complex[11] showed that NeoB binds TAR in the minor groove and stabilizes a coaxially stacked conformation similar to that observed for TAR bound to Tat peptides and Arg (arginine).[6a,b,d] In contrast, the NMR-determined structure of the TAR–AcP complex indicates that AcP induces minor changes in the conformation of TAR and that it binds a cavity at the interdomain interface.[12] Both NMR studies did not report on the global dynamics of TAR in the ligand-bound state.

Supporting information for this article (correlation plots for RDCs measured in two different experiments; measured and back-calculated RDCs; impact of choice of RDCs on order tensor analysis; table of measured RDCs) is available on the WWW under http://www.angewandte.org or from the author.

  DOI: 10.1002/anie.200500075

Shown in Figure 2 are the RDC-derived best-fit generalized degrees of order (ϑ)[13] determined for each domain in the two TAR complexes. The generalized degree of order describes the degree of alignment experienced by each domain which should be identical if the domains are held rigid relative to one another.[13] Results are shown when different input domain structures were used in the order tensor calculations, including idealized A-form helices generated by using Insight II (Molecular Simulations Inc.) and the previous NOE-based NMR spectroscopically determined structures of TAR–NeoB (pdb 1QD3)[11] and TAR–AcP (pdb 1LVJ).[12] Also shown are the values of the root-mean-square deviation (rmsd) between measured and back-calculated RDC values which provide a measure of agreement between a domain structure and measured RDC values.

In the structure determined from NMR spectroscopic studies, NeoB induces local distortions in domain I.[11] Accordingly, most NMR models for domain I in TAR–NeoB yield rmsd values that are lower than the idealized A-form helix (Figure 2a). More importantly, the ϑ value determined for the two domains in TAR–NeoB are similar, particularly for domains that yield the lowest rmsd values (Figure 2a). The best-fit ϑ_{int} value ($\vartheta_{domain\,I}/\vartheta_{domain\,II}$),[13] which provides a measure of interdomain motional amplitudes, is close to unity ($\vartheta_{int} = 0.94$) and thus indicates that NeoB arrests interdomain motions in TAR (Figure 2c). Remarkably, this is not the case for TAR bound to AcP. As previously observed for free TAR,[7a] the ϑ value for domain I is significantly smaller than that for domain II (Figure 2b), and the best-fit ϑ_{int} value (0.69) for TAR–AcP is only slightly higher than that previously reported for free TAR (0.59; Figure 2c). The low ϑ_{int} value for TAR–AcP cannot be attributed to errors in the input domain structures because the best-fit domains yield rmsd values that are equal to or smaller than the experimental uncertainty in the RDC values (see Figure 2b and Supporting Information) and because low ϑ_{int} values are observed independent of both input domain structure (Figure 2b) and RDCs (see Supporting Information). The low ϑ_{int} value for TAR–AcP could arise from fast exchange between free and AcP-bound TAR states. On the basis of the concentrations of TAR ($\approx$1 mM) and AcP ($\approx$2 mM) used in the RDC measurements and the binding constant (K_a) of $K_a \approx 270$ μm,[14] approximately 81% of TAR is computed to be in the bound state. If a population-weighted average of free and bound ϑ_{int} values is assumed (although, strictly, averages over RDCs should be considered), then a similar population-corrected ϑ_{int} value for TAR–AcP of 0.71 is obtained. In agreement with this analysis, an ϑ_{int} value of 0.71 was determined for molar ratios of about 1:5 for TAR/AcP in which the bound state is approximately 94% populated (data not shown). Rather, the low ϑ_{int} value determined for TAR–AcP argues that unlike NeoB, AcP only marginally arrests global motions in TAR.

In Figure 2d, we compare the average domain–domain orientations determined for TAR–NeoB and TAR–AcP by using RDCs with counterparts determined previously for free TAR[7a] and TAR bound to Mg^{2+}[7c] and Arg.[7d] The more coaxially stacked TAR–NeoB conformation is similar to those of TAR–Arg and TAR–Mg, whereas TAR–AcP is very similar to free TAR. The RDC-derived global conformations for TAR–NeoB and TAR–AcP are also in excellent agreement with the corresponding results of NOE-based structural NMR studies (Figure 2e).[11,12]

Our results allude to a correlation between the average domain–domain orientation of TAR and dynamics with bent interdomain alignments being more globally flexible than their coaxially stacked counterparts (Figure 2c,d). Furthermore, all of the ligands that arrest global motions in TAR

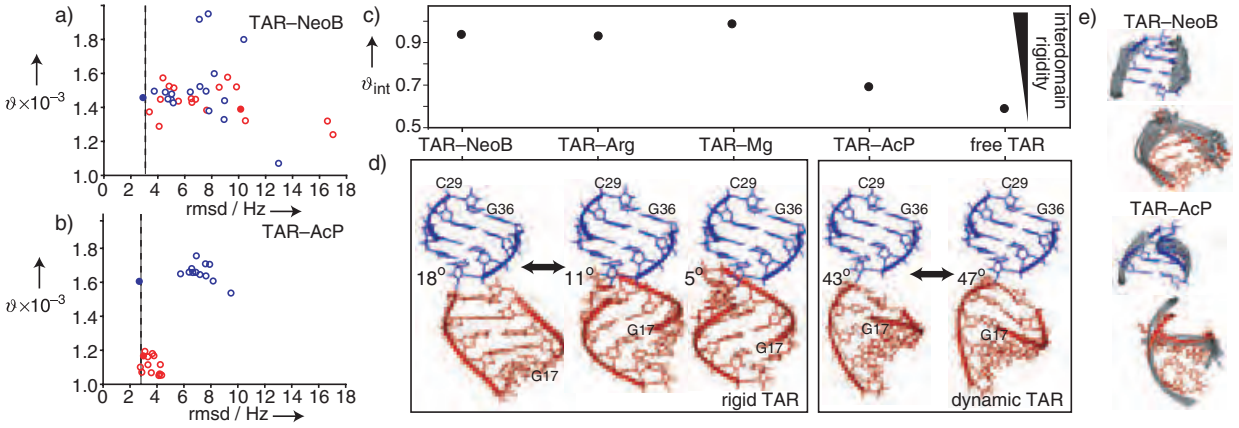

Figure 2. The global structural dynamics of TAR–NeoB and TAR–AcP. The best-fit generalized degree of order (ϑ) for domains I and II in a) TAR–NeoB and b) TAR–AcP as a function of the root-mean-square deviation (rmsd) between measured residual dipolar couplings (RDCs) and values back-calculated by using the best-fit order tensor (red unfilled circle: domain I NMR models; red filled circle: domain I idealized; blue unfilled circle: domain II NMR models; blue filled circle: domain II idealized). The experimental uncertainty (rmsd) in RDCs (see Supporting Information) is indicated by a dashed vertical line. c) The internal generalized degree of order, $\vartheta_{int} = \vartheta_{domain\,I}/\vartheta_{domain\,II}$, determined for TAR–NeoB and TAR–AcP and a comparison with previous values determined for free TAR,[7a] TAR–Mg,[7c] and TAR–Arg.[7d] d) The best-fit relative domain orientation in TAR–NeoB and TAR–AcP determined by superimposing order tensor frames and a comparison with free TAR,[7a] TAR—Mg,[7c] and TAR–Arg.[7d] Domain II (blue) is superimposed and the best-fit interhelical angle is shown next to each structure. The residues for the bulge are not shown. The estimated uncertainty in the interhelical angle is less than $\pm 6°$. e) Comparison of the RDC-derived interdomain alignment (red and blue) with structures as determined by NOE-based NMR spectroscopy (in gray) of TAR–NeoB (pdb 1QD3) and TAR–AcP (pdb 1LVJ).

(NeoB, Arg, and Mg^{2+}) are known to be involved in intermolecular electrostatic interactions. In the structure determined from NMR studies,[11] the five positively charged amino groups in NeoB are in close proximity to many backbone phosphate groups of TAR and other electronegative groups that belong to domains I and II and the bulge (U-C-U). The positively charged guanidinium group of Arg interacts with phosphate groups in domain I (A22) and the bulge (U23) as well as basic electronegative groups in domain II (G26).[6a,b,d] Recent studies indicate that two Arg ligands may be involved in electrostatic interactions with two regions of negative-charge density in TAR.[15] The crystal structure of TAR in the presence of Mg^{2+} and Ca^{2+} shows a network of inner- and outer-sphere interactions between three divalent ions and functional groups that span domains I (A22) and II (G26, A27, and G28) as well as the bulge (U23, C24, U25).[6e] In sharp contrast, the structure determined from NMR studies of TAR–AcP indicates that the RNA–ligand intermolecular contacts primarily involve stacking and hydrophobic interactions between the three-membered ring and base moieties in the bulge and neighboring residues.[12] There is also evidence that the aliphatic side chain that harbors the single positive charge is flexible and protrudes in and out of the TAR binding pocket.[14]

Our results can therefore be rationalized in part on the basis of electrostatic interactions between negatively charged pockets in TAR that can be formed by backbone phosphate groups as well as other sugar/base electronegative groups and cationic groups in the ligand. Such interactions can uniquely stabilize the negatively charged backbone that is responsible for activating global motions in TAR and/or allow simultaneous clamping interactions with electronegative groups that belong to residues that span the interdomain interface. In TAR, formation of such negatively charged pockets appears to require a degree of coaxial stacking which likely serves to bring backbone phosphates and other electronegative groups in the bulge and neighboring residues into spatial proximity.[15] In this manner, electrostatic interactions may simultaneously arrest global motions and stabilize coaxially aligned conformations of TAR.

To our knowledge, the results reported here for TAR–AcP represent the first example in which global motions are observed in an RNA complex. This illustrates how ligand binding in itself is not sufficient for arresting RNA global motions, even if the RNA-binding site is at a critical junction that intersperses helical domains. Our results also indicate that electrostatic interactions offer one approach for stabilizing the global alignment of RNA domains that are separated by flexible linkers. The RDC approach presented in this work provides insight into such dynamical features underlying RNA–small-molecule recognition that are critical to rational drug design and that are not available from static three-dimensional structures.

Experimental Section

Uniformly $^{15}N/^{13}C$-labeled TAR was prepared by in vitro transcription. Samples for NMR studies contained TAR ($\approx$1.0 mM), sodium phosphate (15 mM), sodium sulfate (25 mM), and EDTA (ethylenediaminetetraacetic acid, 0.1 mM) at pH 6.0–6.2. The samples of TAR–NeoB and TAR–AcP also contained NeoB (2 mM, MP Biomedical Inc.) or AcP (2 mM, Research Diagnostics), respectively. Identical samples that contained Pf1 phage ($\approx$25 mg mL^{-1}, ASLA Ltd) were also prepared for NMR studies.[16] NMR spectroscopy experiments were recorded at 600 MHz at 25 °C. One-bond RDCs for C1′–H1′, C2–H2, C5–H5, C6–H6, C8–H8, N1–H1, and N3–H3 were measured twice by using experiments that yield splittings along either the direct (^{1}H) and indirect ($^{13}C/^{15}N$) dimension, as previously described.[7d] Average RDC values were used whenever possible. Order tensors were computed using ORDERTEN SVD[17a] and REDCAT.[17b] A total of 20/18 and 21/19 RDCs were measured in domains I/II in TAR–NeoB and TAR–AcP, respectively. In all cases, RDCs from terminal residues G17 and C45 in domain I were omitted from analysis to avoid complications resulting from end-fraying effects. For NMR models of TAR–AcP, five RDC interactions from G18 and C44 had to be omitted owing to differences between the secondary structure of domain I in the two TAR constructs.

Cluster Compounds

Confined Electron-Transfer Reactions within a Molecular Metal Oxide "Trojan Horse"**

*De-Liang Long, Hamera Abbas, Paul Kögerler, and Leroy Cronin**

Dedicated to Professor Xin-Quan Xin on the occasion of his 70th birthday.

Heteropolyoxometalates (HPOMs) are molecular metal oxide clusters characterized by a vast structural diversity,[1] rich electrochemistry,[2] and versatile catalytic activities.[3] HPOMs frequently are derived from archetypal metal oxide cages of the general composition $(MO_3)_x$ (M = Mo, W) that incorporate structurally vital tetrahedral anions (e.g., $[SO_4]^{2-}$, $[PO_4]^{3-}$, $[SiO_4]^{4-}$). Yet since the first structural elucidation of the archetypal Keggin HPOM $[(MO_3)_{12}PO_4]^{3-}$ in 1933, and after many thousands of publications on developments in the HPOM area,[4–6] the role of the central template in these exceptionally stable molecules has primarily remained a structural one.[6]

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

One particularly interesting family of HPOMs is based on the very stable Dawson structural type ($[M_{18}O_{54}(XO_4)_2]^{m-}$; M = Mo or W, X = main-group element) which contains two tetrahedral anions and a metal oxide framework structure $(MO_3)_{18}$. This class of HPOM cluster was first structurally characterized fifty years ago and since then the subject of many hundreds of papers.[2,7] We are interested in the design of new fundamental types of isopolyoxometalates[8,9] as well as non-conventional HPOM clusters[10] that incorporate two pyramidal anions,[11] similar to the Dawson archetype, as such clusters may exhibit unprecedented properties arising from the intramolecular electronic interactions between the encapsulated anions, thus providing a novel route to manipulate the physical properties of the $\{M_{18}\}$ Dawson-type clusters.

In an attempt to develop internally switchable molecular clusters based on polyoxometalates, we have recently discovered the sulfite-based Dawson-type polyoxomolybdates α- and β-$[Mo^{VI}{}_{18}O_{54}(SO_3)_2]^{4-}$ (**1a** and **1b**, respectively). They incorporate two adjacent sulfite anions in a configuration causing a short, yet non-bonding intramolecular S···S interaction between the sulfite anions and exhibit unusual reversible thermochromic properties over the temperature range 77 to 500 K.[10] In an extension of this work we succeeded in synthesizing the first two examples of polyoxotungstate clusters incorporating the sulfite anion,[12] $[W^{VI}{}_{18}O_{54}(SO_3)_2]^{4-}$ (**2a**), the isostructural tungstate analogue to **1a**, and $[W^{VI}{}_{18}O_{56}(SO_3)_2(H_2O)_2]^{8-}$ (**3a**; see Figure 1). They were isolated as $(Bu_4N)_4[W^{VI}{}_{18}O_{54}(SO_3)_2]$ (**2**) and $K_7Na[W^{VI}{}_{18}O_{56}(SO_3)_2(H_2O)_2]\cdot 20H_2O$ (**3**) and characterized by single crystal X-ray structure analysis,[13] elemental analysis, IR and UV-Vis spectroscopy, bond valence sum (BVS) and DFT calculations.[14]

Interestingly, **3a** has a curious structure including two terminal water ligands which is unknown for closed-shell HPOM clusters of any type.[15] Moreover, **3** also demonstrates unprecedented electronic properties: the cluster anion **3a**, $[W_{18}O_{56}(SO_3)_2(H_2O)_2]^{8-}$, undergoes a unique electron-transfer reaction when heated, in which a structural re-arrangement allows the two embedded pyramidal sulfite ($S^{IV}O_3^{2-}$) anions to release up to four electrons (analogous to the "soldiers" hidden inside the "Trojan Horse") to the surface of the cluster generating the sulfate-based, deep blue, mixed-valence cluster $[W_{18}O_{54}(SO_4)_2]^{8-}$. Although electron-transfer reactions and structural rearrangements are very well known for HPOMs,[6] this is the first example of a coupled structural-rearrangement and electron-transfer process, whereby the electrons are "released" from the core of the cluster. It is also the first example of a fully characterized unimolecular reaction involving an HPOM.

To fully explore and understand these properties we must consider the structural differences between the cluster anions **2a** and **3a**. The structures of both clusters consist of two $\{W_9(SO_3)\}$ halves which contain six equatorial and three capping metal positions. The two halves are joined by linking each of the six equatorial metal atoms of each half together through six bridging oxo ligands (Figure 1 and Figure 2). The key structural differences between these two cluster families are primarily based on the relative orientation of their two sulfite groups (Figure 2) whereby the base of the pyramid

 DOI: 10.1002/anie.200500541

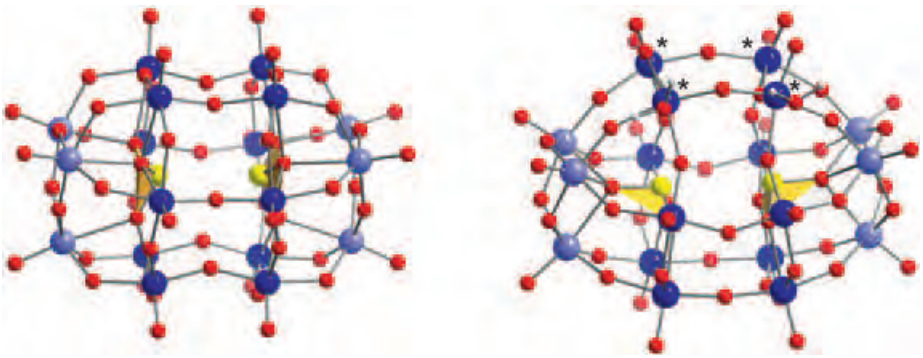

Figure 1. Ball-and-stick representations of the structures of the D_{3h}-symmetric α-$[W_{18}O_{54}(SO_3)_2]^{4-}$ (**2a**, left) and the C_{2v}-symmetric $[W_{18}O_{56}(SO_3)_2(H_2O)_2]^{8-}$ (**3a**, right) cluster anions; light blue spheres represent capping $\{W_3\}$, dark blue spheres represent equatorial $\{W_6\}$, red O, gray H, yellow S. Yellow polyhedra represent the pyramidal SO_3 units and emphasize their different relative orientations within each framework; * marks tungsten units that are not coordinated to the sulfite groups and thus have two terminal oxo ligands.

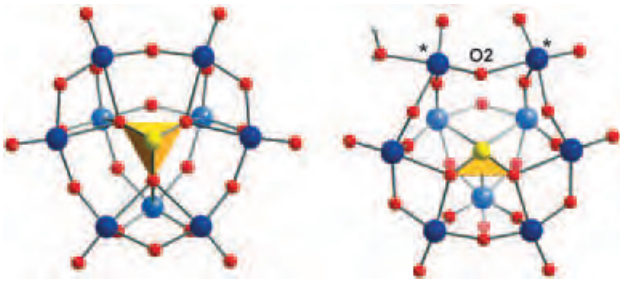

Figure 2. Schematic comparison of the SO_3 coordination mode in **2a** (left) and **3a** (right). Only one $\{W_9(SO_3)\}$ half is shown, viewed along the long axis of the cluster. Colors are as in Figure 1.

formed by the trigonal-pyramidal SO_3 group in **2a** is centrally aligned and binds to all nine metal centers of each $\{W_9(SO_3)\}$ fragment, whereas in compound **3a** the SO_3 pyramids are tilted so that only seven of the nine metal centers of each $\{W_9(SO_3)\}$ fragment are connected.

This arrangement leaves four neighboring equatorial tungsten positions in **3a** uncoordinated to the templating sulfite groups and thereby reduces the overall molecular symmetry from D_{3h} (**1a** and **2a**) to C_{2v} with the loss of a number of mirror planes and the C_3 axis for **3a**. The significantly different orientations of the sulfite ions in **3a** compared to **1a** and **2a** is also reflected by the S···S distance of 3.61(2) Å in **3a** which is significantly longer than the distance of 3.19(1) Å in **2a** and 3.27(1) Å in **1a**.

The second major structural difference between **2a** and **3a** lies in the number of terminal oxo ligands present in each cluster type. All of the metal atoms present in **2a** (as well as in **1a**) only support one terminal oxo ligand that is not shared by other metal atoms, however cluster **3a** contains four tungsten units (labeled as W* in Figures 1 and 2), each with two terminal ligands. This situation arises because these four tungsten units are not bonded to the embedded sulfite groups. The two terminal ligands and four bridging μ_2-oxo (O^{2-}) ligands per W* center complete a slightly distorted octahedral coordination geometry. Structural analysis (including bond valence sum analysis) reveals that while two of the four unique W* centers each have two terminal oxo ligands (W=O ca. 1.7 Å), the other two W* centers each have one terminal oxo ligand and one terminal water ligand (W=O ca. 1.7 Å and W–OH_2 ca. 2.2 Å). There is a slight disorder but the presence of two water ligands and two oxo ligands is confirmed by the average bond valence sums as well as chemical and thermal analysis. Furthermore the bridging oxo group (O2 in Figure 2) between the two W* positions of a $\{W_9(SO_3)\}$ half is now folded into the cluster and points towards the vacant site of the SO_3 pyramid with a O2···S distance of 2.96(2) Å, whereas the equivalent position in **1a** and **2a** points outwards.

The structure of **3a** is already prearranged for an internal reorganization and a concurrent internal redox reaction, in which the encapsulated sulfite anions act as embedded reducing agents, and are oxidized to sulfate when heated to over 400 °C. In the course of this reaction a maximum of four electrons could be transferred to the metal oxide framework, causing the color change from colorless ($\{W^{VI}_{18}\}$) to blue ($\{W^{VI}_{14}W^{V}_{4}\}$). The overall reaction is accompanied by the release of the two coordinated water ligands from the W* centers. Because the reduction of the metal oxide shell by four electrons is balanced by the internal oxidation of the two sulfite anions (to sulfate groups), the overall charge of the cluster remains identical to give $[W^{VI}_{14}W^{V}_{4}O_{54}(SO_4)_2]^{8-}$ (**4a**). The reaction can be summarized as shown in Equation (1).

$$[W^{VI}_{18}O_{56}(S^{IV}O_3)_2(H_2O)_2]^{8-} \rightarrow \alpha\text{-}[W^{VI}_{14}W^{V}_{4}O_{54}(S^{VI}O_4)_2]^{8-} + 2\,H_2O \quad (1)$$

This reaction mechanism is confirmed by a variety of experiments which includes the observation of the loss of two water molecules at 400 °C, indicated in the IR spectrum and quantified by thermogravimetric analysis (TGA). The formation of the two sulfate moieties is shown by the IR and Raman spectra (emergence of an additional band at 650 cm^{-1}, attributed to sulfate) and in differential scanning calorimetry (DSC) traces, a sharp exothermic process associated with the onset of the internal redox reaction and the formation of sulfate at ca. 400 °C (Figure 3).

Analysis of compound **4** ($K_7Na[W_{18}O_{54}(SO_4)_2]$) also confirms its formula, and the four-electron reduced polyoxotungstate shell which is also indicated by the transformation of colorless **3** into deep blue **4**. This data also confirms that **4a** is not protonated, which is confirmed by the loss of the H(-O) signal in solid-state ^1H magic angle spinning (MAS) NMR spectrum. Given the unambiguous analytical data for the formation of **4** it is unfortunate that crystals suitable for single-crystal X-ray diffraction could not be obtained and that it is exceptionally reactive, but **4** is stable for many weeks if sealed in an evacuated glass tube. However, we are able to confidently suggest that the mixed-valence framework of the

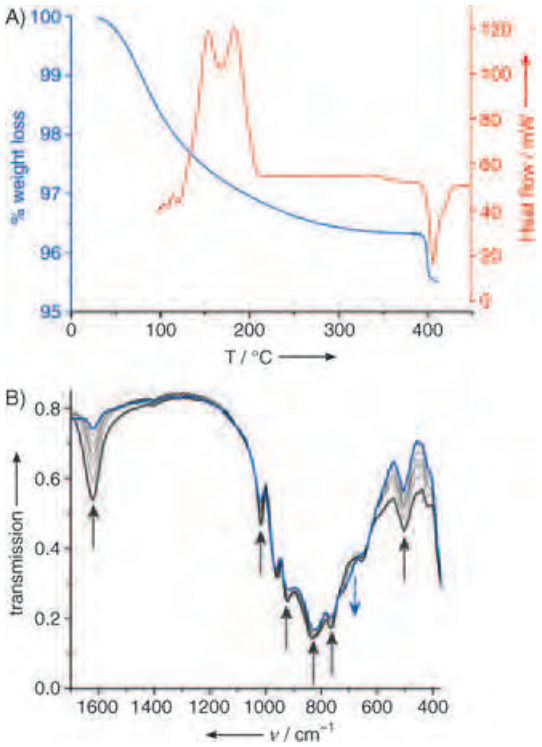

Figure 3. A) TGA (blue line) and DSC (red line) results. B) the IR spectrum of **3** (dark gray line) and the product **4** (blue line). Arrows indicate the changes going from **3** to **4**. The weight loss of just under 0.9% at 400°C correlates with the loss of two water molecules. The exothermic peak in the DSC curve at 400°C is consistent with the formation of the sulfate groups.

product α-$[W_{18}O_{54}(SO_4)_2]^{8-}$ (**4a**) is equivalent to the fully oxidized framework of the conventional sulfate-based Dawson cluster α-$[W_{18}O_{54}(SO_4)_2]^{4-}$ (**5a**), which can be synthesized by the reaction of tungstate in the presence of sulfate anions.[16] This structural hypothesis follows from a comparison of the structure of the cluster anion **5a** with that of the starting species **3a**. Overlaying the two structures reveals that the positions of all the tungsten and sulfur centers are identical to within 0.30(2) Å. We therefore hypothesize that the frameworks of the reduced product **4a** and oxidized **5a** are virtually isostructural; this idea is also supported by the fact that almost all other $\{M_{18}\}$ clusters with tetrahedral templates (over 80 are reported) display the same metal oxide framework geometry and may only differ in the relative orientation of the capping $\{M_3\}$ units giving several isomeric possibilities.

To examine this hypothesis, the preliminary energetic features of a pathway for the reaction in Equation (1) can be established from ab initio density functional theory (DFT) calculations.[14] Owing to the complexity of the system, the complete energy hyper-surface cannot be obtained and we thus used an approximate transition state. This transition-state geometry was obtained from geometrical arguments by interpolation between the atomic coordinates in **3a** and **5a**. Although the results can only be interpreted semi-quantitatively, they agree with the existence of a substantial activation barrier requiring heating and a subsequent exothermic step. The energy difference between **3a** and the transition state (plus two water molecules), that is, the reaction state representing the thermodynamic barrier, is approximately 200 kJ mol^{-1}, while the step from the transition state to the final state is characterized by an energy gain of approximately 450 kJ mol^{-1}, rendering the final state (**4a** + 2 H_2O) around 250 kJ mol^{-1} more stable than **3a**. The energy release during the exothermic process at 400°C (when **3** transforms to **4**) measured using DSC (288 kJ mol^{-1}) coincides within 15% with the theoretical result. This comparison therefore provides a striking link between theory and experiment.[17] The initial step of the reaction in Equation (1) requires movement of some of the terminal and bridging oxygen ligands of the W1 and W2 centers (Figure 4). First, the O1, O2 (both blue) and the O3, O4 (orange) positions shown in Figure 4A and 4B rotate clockwise about the central tungsten atoms through the transition state (Figure 4A, center) until the terminal O1 (bound to W1) position is within bonding distance of W2 and

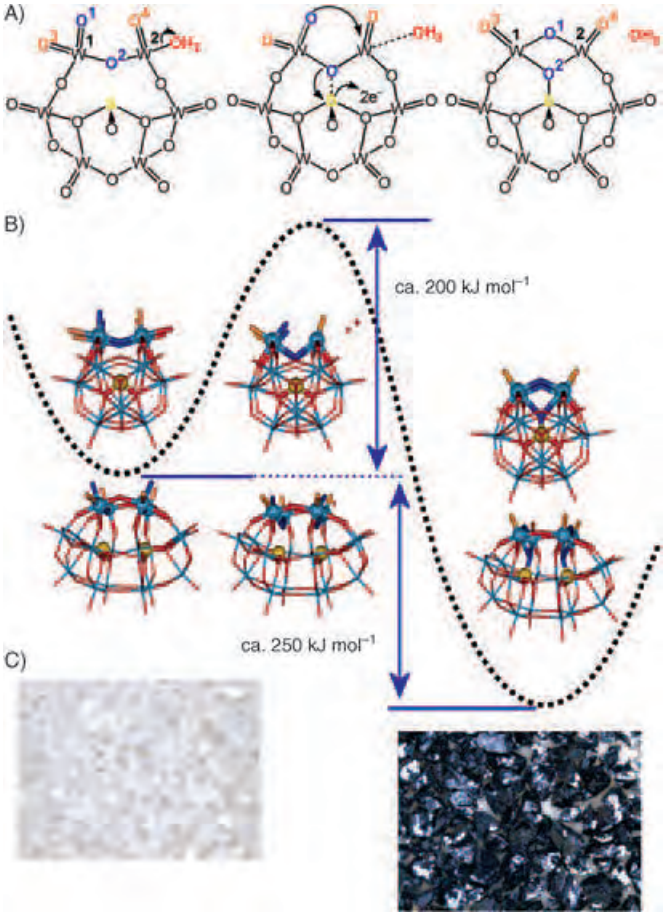

Figure 4. A) Scheme illustrating the proposed reaction mechanism. For clarity only the equatorial cluster "belts" and the central sulfur position of a $\{W_9(SO_3)\}$ fragment are shown. B) The structures of the cluster reactant **3a**, the transition state, and the product **4a** are shown and are superimposed on the suggested energy pathway (both a top view and side view of the clusters are shown for clarity with the red O, light blue W, yellow S). A common color scheme is used in (A) and (B) for the oxygen atoms that move during the transformation. C) Photographs of the crystals of the reactant **3** (colorless; left) and the product **4** (blue; right).

the bridging O2 center moving towards the sulfur atom reaches bonding distance with this center.

As can be seen in Figure 4A and 4B, the oxygen trajectories during the transformation are extremely (O1 $\Delta = 1.8$ Å; 66°), (O2 $\Delta = 1.5$ Å; 37°), (O3 $\Delta = 1.2$ Å; 30°), (O4 $\Delta = 1.2$ Å; 37°). Finally, as the bond is being made between O1 and W2 the *trans*-positioned water ligand on W2 is cleaved off (an animation of this transformation, generated by the interpolation of the coordinates between **3a** and **5a**, is present in the Supporting Information).

In conclusion, the enclosure of sulfite anions with a "correct" orientation in an HPOM cluster shell transforms these anions from "innocent" structural templates to electronically reactive, functional units. The sulfite ions can now release electrons to the cluster shell upon activation by heat (the sulfite groups in cluster **3a** are "activated" whereas those in **2a** are not). Therefore this new class of "activated" metal oxide cluster shows promise for the development of novel functional metal oxides, and **3a** is the first characterized inorganic cluster to undergo a concerted reaction in which a unimolecular process is characterized by a coupled structural and electronic rearrangement. Although the transformation of **3** to **4** does not appear reversible we will seek to extend this system, for example, by the replacement of the water groups for other ligands.

Experimental Section

2: $Na_2WO_4{\cdot}2H_2O$ (6.6 g, 20 mmol) and Na_2SO_3 (2.4 g, 19 mmol) were dissolved in water (25 mL). Hydrochloric acid (37%, 5 mL) was added to the stirred solution and the pH value of the solution was adjusted to 1.9 using diluted hydrochloric acid. The solution was then heated under reflux for 72 h. After cooling, the solution was added to a solution of Bu_4NBr (6.0 g, 18.6 mmol) in water (200 mL). A white precipitate was collected by centrifuging, washed with water and ethanol, and dried in vacuum. Recrystallization of the solid in acetonitrile afforded cream yellow crystals of **2** (yield 2.3 g, 39%). IR (KBr disk): $\tilde{\nu} = 3434$, 2961, 2873, 1625, 1482, 1379, 1151, 1105, 993, 915, 877, 779 cm^{-1}; elemental analysis (%) calcd for $C_{64}H_{144}W_{18}N_4O_{60}S_2$: C 14.5, H 2.7, N 1.1, W 62.4; found: C 14.2, H 2.6, N 1.2, W 63.0.

3: Compound **3** was produced in the same procedure as **2** except that in the final step solid KCl (5.0 g, 67 mmol) was added to the reaction mixture instead of a Bu_4NBr solution and the mixture was stirred for 2 h to yield a white precipitate, which was collected and then recrystallized in minimum water (ca. 140 mL) with the addition of KCl (2 g) and drops of diluted hydrochloric acid to keep the pH value at 2.0. After the solution was concentrated to about 100 mL (by evaporation in air), the colorless crystals of **3** were collected (yield 2.3 g, 41%). IR (KBr disk): $\tilde{\nu} = 3434$, 1623, 1017, 917, 800 cm^{-1}; elemental analysis (%) calcd for $H_{44}K_7NaO_{84}S_2W_{18}$: K 5.4, Na 0.45, W 65.4%; found: K 4.8, Na 0.40, W 66.1. The purity of the bulk phases was confirmed by powder diffraction.

[17] Other characteristic electronic properties support the suggested reaction pathway as well: A gradual transfer of charge density from the sulfite groups in the initial state **3a** to the tungsten positions in the final state is reflected by a continuous decrease in the HOMO–LUMO energy gap and a gradual decrease of the tungsten partial atomic net charges. In the final product, the four electrons are delocalized over all 18 tungsten positions, resulting in nearly uniform Löwdin partial charges (with standard deviations of 2%). Throughout the series, the Löwdin charges of the sulfur positions successively increase from 0.173 (**3a**) to 0.186 (transition state) to 0.198 (final product), a pattern corresponding to the oxidation of the sulfite groups.

Biosensors

AFM-Tip-Integrated Amperometric Microbiosensors: High-Resolution Imaging of Membrane Transport**

Angelika Kueng, Christine Kranz, Alois Lugstein, Emmerich Bertagnolli, and Boris Mizaikoff*

The mapping of molecular transport across membranes at the single-cell level is one of the major challenges in cell physiology. Miniaturized biosensors offer many advantages by combining the selectivity of biological recognition with well-established principles of transduction. To date, the combination of biosensing with atomic force microscopy (AFM) is mainly based on the mass-sensitive detection of binding events that change the deflection of a cantilever which is surface-modified with immobilized bioreceptors. Many biochemically relevant processes are based on the electrochemical conversion of molecules; therefore, techniques for obtaining laterally resolved information on coupled oxidation–reduction processes with correlation in space and time are of particular interest.[1] Scanning electrochemical microscopy (SECM) has proven to be a versatile tool for spatially resolved measurements of molecular transport across porous membranes.[2–4] Spatially resolved electrochemical information on interface processes is provided by combining electroanalytical techniques with the principle of scanning a microelectrode in close vicinity across the sample surface.[5] Few applications of miniaturized scanning biosensors combined with SECM are described in the literature.[6,7] A main limitation is the achievable lateral resolution, which is not comparable to that of AFM or consistent with the targeted imaging of membrane-transport processes at a molecular level.

A major step toward overcoming these limitations was recently made with the integration of micro- and nanoelectrodes into AFM tips.[8,9] An electroactive area with defined geometry, which is recessed from the apex of an AFM tip (Figure 1a and b), allows integration of SECM[10–12] functionality into AFM by correlating the current measured at the integrated electrode with the topographical information obtained by the AFM tip. These combined AFM–SECM probes retain the integrity of both techniques, and can be applied in dynamic-mode operation at soft biological samples.[13]

Herein, well-established protocols for the immobilization of biological recognition elements, such as enzymes, are applied to integrate micro- and nanobiosensors into AFM tips. The defined electrode geometry and the employed immobilization techniques result in a confined immobilization of the biological recognition element at the electrode surface. Enzymatic conversion of electroactive and -inactive species generated at the sample surface is possible by the immobilization of enzymes through self-assembled thiol monolayers with reactive headgroups[14] (Figure 1b(B)) or polymer-film entrapment[15,16] (Figure 1b(A)). Hence, simultaneous imaging of surface morphology and biologically relevant analytes involved in surface processes significantly extends the applicability of this technology. This integrated approach, along with the high sensitivity and fast response time of amperometric micro- and nanobiosensors, provides the spatial and temporal resolution for the investigation of cellular processes at the nanometer scale.

A synthetic model was selected to mimic glucose transport through cellular membranes. The high-resolution mapping of glucose membrane transport was carried out by immobilizing glucose oxidase at the surface of the AFM-tip-integrated electrode by electrochemically induced, localized precipitation of enzyme-containing polymer suspensions.[15] Glucose biosensors fabricated with this technology exhibit excellent sensitivity, response time, reproducibility, and long-term stability.

Enzymes can be immobilized at the surface of the scanning-probe tip-integrated electrode through self-assembled thiol monolayers with functionalized headgroups (A) or through electrochemical deposition of enzyme-containing polymer films (B). c) Schematic cross section of the experimental setup for imaging glucose transport through a porous membrane during simultaneous AFM mapping.

transport with AFM-tip-integrated glucose biosensors. Images were recorded in AFM dynamic mode,[17] a prerequisite for the investigation of soft biological samples, and in SECM generation/collection (G/C) mode.[12] In G/C operation, the current response arises from an electroactive species generated at the sample surface. The integrated electrode or microbiosensor acts as a sensor that establishes concentration profiles of individual species near the sample surface. The signal traces in Figure 1c schematically illustrate schematically the expected qualitative height and current signals recorded with the bifunctional probe scanned in the x direction above a synthetic membrane with 200-nm pores. As the reshaped AFM tip is imaging the pores, which corresponds to a decrease in the height signal, glucose is diffusing through the pores toward the immobilized glucose oxidase layer, which catalyzes the conversion of glucose into gluconolactone. The corresponding reactions are summarized in Figure 2a. The resulting current measured at the integrated electrode arises from the oxidation of the enzymatically generated by-product H_2O_2, which is oxidized at the electrode surface at a bias voltage of 650 mV versus Ag/AgCl. Therefore, the current signal increases during imaging of the pores as a result of glucose diffusion from the donor into the receptor compartment.

Prior to application, the AFM-tip-integrated enzyme electrodes were characterized in an electrochemical cell by constant-potential amperometry. The calibration function obtained for the AFM-tip-integrated glucose biosensor is shown in Figure 2b and exhibits adequate linearity with an R^2 value of 0.9889 in the concentration range of 0.5–2.5 mM glucose in aqueous solution.

Simultaneously recorded AFM topography (Figure 2c) and SECM current images in the presence (Figure 2d) and absence (Figure 2f) of glucose in the donor compartment, and exemplary line scans of the height and current response (Figure 2e) are also presented. The current recorded at the AFM-tip-integrated glucose biosensor during the imaging of the pores increases as a result of the localized production of H_2O_2. The glucose signal response in the electrochemical image corresponds to the topography measured simultaneously with the AFM tip. The SECM current image of the porous membrane represents a contour map of the glucose concentration after emergence of the aqueous solution of

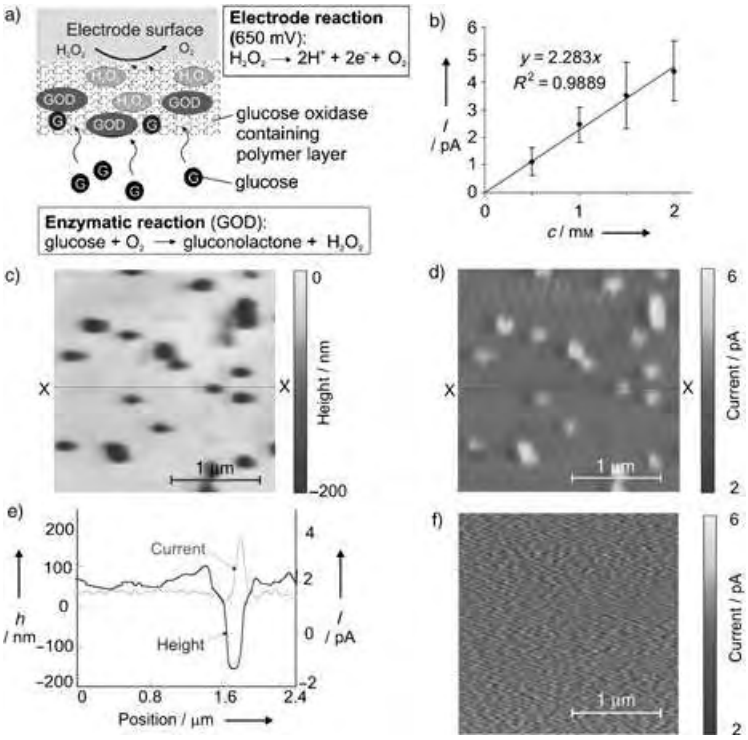

Figure 2. a) Reactions for glucose detection with a biosensor based on glucose oxidase (GOD). b) Glucose calibration of an AFM-tip-integrated biosensor (edge length: 800 nm) fabricated by entrapment of glucose oxidase within a polymer film. Simultaneously recorded c) height and d) current images of glucose diffusion through a porous polycarbonate membrane (pore size: 200 nm); images recorded in AFM dynamic mode. e) Exemplary corresponding line scans of height and current. f) Current image recorded without glucose in the donor compartment.

glucose from the membrane pore and free diffusion into the receptor-compartment solution. As is evident in the control experiment, the measured current is negligible without glucose in the donor compartment (Figure 2 f).

Quantification of the current signal obtained requires precise knowledge of the electrode geometry and the absolute distance between the electrochemical probe and the sample surface, which is provided by the bifunctional AFM–SECM probes. Furthermore, by applying a simple single-pore model previously described for the analysis of SECM images at membranes,[2,18] the flux of glucose away from the pore opening is assumed to be dominated by radial diffusion in the absence of an appreciable convective flow. The glucose transport rate can be obtained by assuming that the pore opening is hemispherical and solving the continuity equation by using Fick's law at appropriate boundary conditions.[19–22]

The concentration profile $C(r)$ at a radius r above the hemispherical pore opening can be described by Equation (1), where C_S represents the concentration of the molecule at the surface of the pore opening. Earlier results demonstrated that the radial divergence of the diffusive flux from a microscopic pore, regardless of its real shape, results in the pore appearing as if it were hemispherical in shape.[19] For a disk-shaped pore with radius a, the radius of the corresponding hemispherical pore r_0 can be described by Equation (2).

$$C(r) = (r_0/r)C_S \quad (1)$$

$$r_0 = 2a/\pi \quad (2)$$

On the basis of this approach, the theoretical glucose concentration at a distance (r) of 310 nm, which corresponds to the reshaped AFM tip height, above a pore opening with a radius of 100 nm (a) is estimated to be 0.62 mM for a 3 mM glucose solution. The evaluation of the current response in the SECM image (Figure 2 d) results in an average peak current of 1.5 ± 0.3 pA. According to the linear regression of the glucose calibration obtained at the AFM-tip-integrated electrode (Figure 2 b), the measured glucose concentration is estimated to be 0.66 ± 0.13 mM. This semiquantitative value corresponds well to the theoretically estimated concentration of 0.62 mM.

To demonstrate the versatility of the proposed technique for a wider range of applications, horseradish peroxidase (HRP) was immobilized at the surface of an AFM-tip-integrated electrode through self-assembled thiol monolayers with reactive headgroups (Figure 1 b (B)).[14] Simultaneously recorded topographical (AFM-tip) and electrochemical (substrate-generated) images were obtained by immobilizing a peroxidase layer at the surface of an AFM-tip-integrated electrode. The reactions involved are shown schematically in Figure 3. The peroxidase activity was imaged in the tip-generation/substrate-collection mode of SECM (see Figure 3 a) during AFM contact-mode operation. At the AFM-tip-integrated electrode, the enzyme-catalyzed reduction of H_2O_2 involves ferrocene methanol (Fc) as an electron donor. Ferrocenium methanol (Fc^+, which contains Fe^{2+}), the electroactive by-product of the HRP-catalyzed reaction,

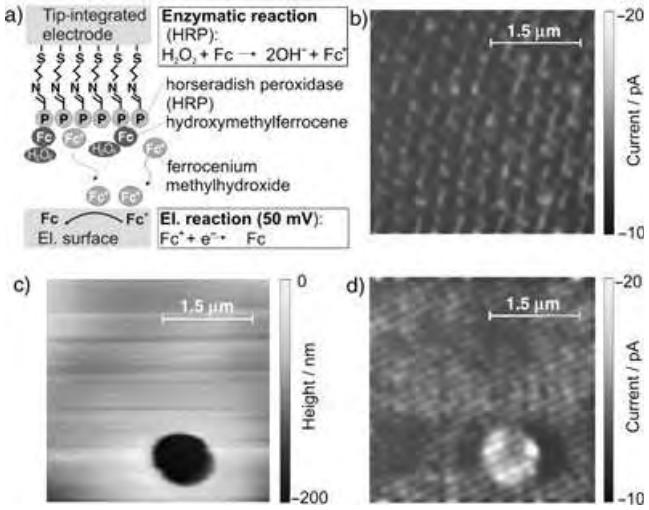

Figure 3. a) Reactions and detection scheme of the experiment in the tip-generation/substrate-collection mode for imaging with an AFM-tip-integrated biosensor based on horseradish peroxidase (HRP). Topographical information and tip-integrated peroxidase activity is recorded simultaneously by contact-mode AFM operation. The current measured at the microelectrode array reflects the enzyme activity of the HRP biosensor integrated into the AFM tip. Top view of the height (c) and simultaneously recorded current in the presence (d) and absence (b) of H_2O_2 in solution. El. = electrode.

diffuses to the biased sample surface, which comprises a microstructured electrode array where Fc^+ is reduced at a selected potential not amenable to any other species in solution. The simultaneously obtained topography of an individual microstructured disk electrode and the local (electro)chemical activity are shown in Figure 3 c and 3 d, respectively. Comparison with the control experiment in the absence of H_2O_2 (Figure 3 b) demonstrates the successful application of tip-integrated enzyme layers in bifunctional SECM–AFM probes for SECM tip generation/substrate collection.

AFM-tip-integrated imaging biosensors are a promising concept that combine the advantages of high selectivity provided by amperometric microbiosensors with high-resolution scanning probe microscopy based on microfabricated multifuntional scanning probes. High reproducibility of the fabrication process and the size of the integrated sensors in the micro- to nanodomain make them a versatile tool for future applications in probing a wide range of biologically relevant processes at a cellular level. The presented technology provides a concept for the simultaneous detection of surface morphology and (electro)chemical activity with high selectivity and high lateral resolution, on the basis of this concept of "imaging nanobiosensors". Accurate positioning and scanning of nanobiosensors at a defined distance above the sample surface provides quantitative kinetic parameters with high lateral and temporal resolution. Given the flexibility of the technology, there is considerable scope for the extended use of multifunctional scanning probes for a wide range of biological specimens and processes.

Experimental Section

AFM-tip-integrated gold electrodes (thickness of the gold layer: 100 nm, parylene C insulation layer: 800 nm) were fabricated and characterized as previously described.[8,9] All measurements were carried out with a Pico Plus AFM (Molecular Imaging, Tempe, AZ). The output signal of the bipotentiostat (A-832, CH Instruments, Austin, TX) was read at an additional AD/DA channel offered by the AFM instrument. The faradaic current recorded at the integrated electrode was obtained simultaneously with the topographical information provided by the reshaped AFM tip.

Imaging of glucose membrane transport with an AFM-tip-integrated biosensor based on glucose oxidase: The AFM–SECM tip used for imaging glucose diffusion through the synthetic porous membrane had an edge length of 800 nm and a reshaped tip height of 310 nm. Selective electrode-surface modification was performed by the pH-shift-induced polymerization of enzyme-containing films.[15] For polymer-film formation, a potential-pulse profile (2200 mV for 0.2 s, 800 mV for 1 s, and 0 mV for 5 s versus Ag/AgCl) was applied for one cycle, which led to the formation of an enzyme-containing polymer layer selectively deposited on the electrode surface.

Calibration of the tip-integrated biosensor was carried out by constant-potential amperometry by using a bipotentiostat (A832, CH Instruments, Austin, TX) and an electrochemical cell equipped with a Pt counter electrode and an Ag/AgCl reference electrode containing 10 mL of phosphate-buffered saline (PBS) solution at pH 7.4. The enzyme-modified electrode was operated at a potential of 650 mV versus Ag/AgCl to oxidize the H_2O_2 formed during the reaction catalyzed by glucose oxidase. After the current signal reached a steady-state value, aliquots of a glucose standard solution (0.2 M) were injected and the increase in current was monitored.

To study glucose membrane transport, a porous polycarbonate membrane (200-nm pore size, Osmonics Inc., Minnetonka, MN) was mounted in a custom-built vertical diffusion cell that separated aqueous solutions in the donor and receptor compartments (see Figure 1c). Measurements were performed in PBS solution (pH 7.4). The donor solution (bottom) contained glucose (3 mM). All measurements were carried out in a three-electrode setup with an Ag/AgCl reference electrode and a platinum-wire counter electrode at room temperature. The integrated biosensor was biased at a potential of 650 mV to oxidize evolving H_2O_2. Scan area: 2450 × 2450 nm, scan rate: 1 line s^{-1}, drive frequency: 32 kHz, tip potential: 650 mV versus Ag/AgCl.

Imaging with an AFM-tip integrated biosensor based on horseradish peroxidase: The AFM–SECM tip (edge length: 860 nm, tip height: 410 nm) was cleaned in H_2SO_4/H_2O_2 (70:30 v/v) for 30 s, rinsed three times with water, and then immediately immersed in cystaminium dichloride (0.1M in acetate buffer; pH 5.5) for 30 min. After rinsing the probe five times with deionized water, HRP (1 mg) in phosphate buffer (100 μL, pH 7.0) containing 2.5% (v/v) glutaraldehyde was immobilized on the integrated gold electrode for 2 h. The probe was thoroughly rinsed with buffer solution several times, and the sample was stored at 4 °C prior to use.

The AFM–SECM experiment was carried out in AFM contact and SECM tip-generation/substrate-collection modes in ferrocene methanol (Fc, 2 mmol) in phosphate buffer (0.1M, pH 7.0) with KCl (0.1M) as the electrolyte in the presence and absence of the enzymatic substrate H_2O_2 (0.5 mmol). The microstructured gold sample (Quantifoil Micro Tools, Jena, Germany) was biased at a potential of 50 mV versus Ag/AgCl to reduce ferrocenium methanol (Fc^+). Scan area: 4 × 4 μm, scan rate: 1 line s^{-1}.

Supported Catalysts

Heterotrimetallic RuMnMn Species on a Hydrotalcite Surface as Highly Efficient Heterogeneous Catalysts for Liquid-Phase Oxidation of Alcohols with Molecular Oxygen**

*Kohki Ebitani, Ken Motokura, Tomoo Mizugaki, and Kiyotomi Kaneda**

The creation of a well-defined, active metal site on a solid surface not only opens up an avenue to materials that boost catalytic performance but also aids an understanding of the molecular basis of heterogeneous catalysis.[1] Modifying the coordination sphere of a metal species with other metals as ligands, which is a basic approach in organometallic and bioinorganic chemistry,[2] is also being applied to heterogeneous catalysis[3] because of the potential of performing unique catalytic reactions based on cooperation between diverse metals within a regular arrangement. In addition, this allows local compositional modeling for the strong metal–support interactions (SMSI) seen in supported metal catalysts.[4]

Hydrotalcite (HT), which is a layered, mixed hydroxide of Mg and Al,[5] has received attention as a material for advanced heterogeneous catalysts[6,7] because of the cation-exchange ability of the Brucite layer, the anion-exchange ability of the interlayer, its adjustable surface basicity, and adsorption capacity. Recently, we created a monomeric Ru^{IV}-OH species on the HT (Ru/HT) surface by adsorption which turned out to be an excellent heterogeneous catalyst for the one-pot synthesis of α-alkylated nitriles by a Ru-catalyzed alcohol oxidation coupled with a base-promoted aldol reaction.[7d] As part of our ongoing project on the functionalization of supported Ru catalysts to achieve environmentally friendly ("green") organic syntheses, we present a novel HT-bound heterotrimetallic $Ru^{IV}Mn^{IV}Mn^{IV}$ species that has been structurally characterized on the atomic scale by X-ray absorption spectroscopy.[8] This material is an excellent solid catalyst for liquid-phase alcohol oxidation under mild conditions. This protocol to create a supported mixed-metal species can provide catalytically active compounds that are uniform in composition and distribution on a solid surface by applying concepts from coordination chemistry, and bridges the gap between homogeneous and heterogeneous catalysis.[9]

We obtained well-defined, heterotrimetallic RuMnMn species on the HT surface ($RuMn_2$/HT) by immobilizing Mn cations onto Ru/HT. The Ru/HT was prepared by treating HT with an aqueous solution of $RuCl_3 \cdot n\,H_2O$.[7d] The retention of the HT interlayer distance (3.0 Å), as shown by XRD (X-ray diffraction),[10] indicated that both metal species are accommodated on the HT surface. The K-edge XANES (X-ray absorption near-edge structure) spectrum of the Ru and Mn of $RuMn_2$/HT reveals that the surface Ru and Mn cations are in the oxidation state +IV. In the Fourier transformation of the Ru K-edge k^3-weighted EXAFS (extended X-ray absorption fine structure) spectrum of $RuMn_2$/HT (Figure 1b) a peak near 3.5 Å, corresponding to the contiguous Ru sites (Ru–O–Ru),[11] was barely detected.

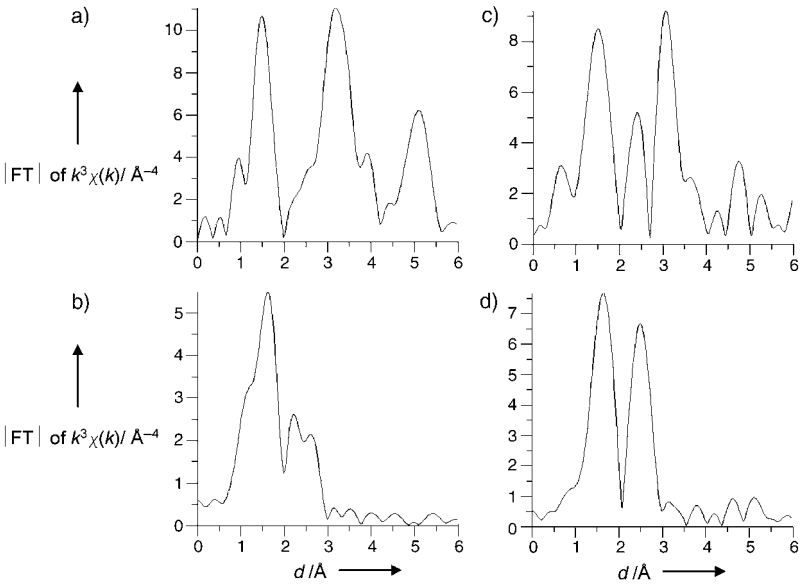

Figure 1. Fourier transformation (FT) of the k^3-weighted K-edge EXAFS spectrum of a) RuO_2, b) $RuMn_2$/HT (Ru K-edge), c) β-MnO_2, and d) $RuMn_2$/HT (Mn K-edge). The phase shift was not corrected.

The coordination number (CN), distance (R), and Debye–Waller factor ($\Delta\sigma$) of the Ru–O, Ru–Mg, and Ru–Mn bonds, as estimated by a curve-fitting analysis,[8] are listed in Table 1. The Ru^{IV} species of $RuMn_2$/HT are surrounded by six oxygen atoms with different bond distances. The shortest Ru–O bond was assigned to a Ru^{IV}–OH moiety.[12] Two bonds of Ru–Mg and Ru–Mn shells, with CNs of 0.9 and 1.9, respectively, prove that the Ru^{IV} species is in the vicinity of the Mg cation within the Brucite-like sheets and two Mn cations on the HT surface. Furthermore, a Mn–Mn shell with a distance of 2.32 Å and CN of 1.1 shows the formation of dimeric Mn^{IV} cation species.[13]

The above results show a $Ru^{IV}Mn^{IV}Mn^{IV}$ trimetallic species on the HT surface, as shown in Figure 2, in which dimeric Mn–Mn species are connected to a single Ru^{IV} cation through OH groups and water. To our knowledge, this is the first report of the preparation of heterotrimetallic species

Table 2: Oxidation of benzyl alcohol (**1**) in the presence of various Ru catalysts under 1 atm O_2.[a]

Entry	Catalyst	Conv. [%][b]	Yield [%][b]
1	$RuMn_2$/HT	100	99
2	reuse 1[c]	100	99
3	reuse 2[c]	100	98
4	reuse 3[c]	100	99
5	Ru/HT	66	66
6	Ru/Al_2O_3[d]	56	55
7	$RuO_2 \cdot n H_2O$	5	4
8	Mn_2/HT[e]	0	0
9	HT	0	0

[a] Reaction conditions: catalyst (3 mol% Ru), benzyl alcohol (1 mmol), toluene (5 mL), 60°C, 1 atm O_2, 1 h. [b] Conversions and yields were determined by GC analysis using an internal standard method based on benzyl alcohol. [c] Catalyst recovered and reused. [d] Prepared by the reported procedure.[15c] [e] 6 mol% Mn.

consisting of metal cations on a support involving metal oxide and metal hydroxides,[14] whereas the preparation of supported heterobimetallic or metal alloy species have been reported.[3] Adjusting the basicity of the hydroxy groups around the Ru^{IV} cation, produced by reaction of the surface OH groups of HT with $RuCl_3$ species,[7d] brought about selective immobilization of Mn cations in the vicinity of the Ru species to give the unique $Ru^{IV}Mn^{IV}Mn^{IV}$ sites.

The catalytic ability of the RuMnMn species was explored in the oxidation of alcohol with O_2 at atmospheric pressure (Table 2).[15,16] The trimetallic $RuMn_2$/HT shows a higher catalytic activity than Ru/HT,[7d] Ru/Al_2O_3,[15c,e] and RuO_2,[15a] which are typical heterogeneous Ru catalysts for the oxidation of benzyl alcohol (**1**).[17] Benzyl alcohol was oxidized to benzaldehyde (**2**) quantitatively within 1 h in the presence of the $RuMn_2$/HT catalyst.[18]

The initial turnover frequency based on Ru for $RuMn_2$/HT (140 h^{-1}) is almost five times larger than that for Ru/HT. On a 10-mmol scale oxidation of **1** in the presence of 0.1 mol% Ru, the turnover number based on Ru reached 840 at 90°C. Moreover, the high catalytic ability of $RuMn_2$/HT was demonstrated by the quantitative oxidation of **1** within 10 h, even at 40°C.

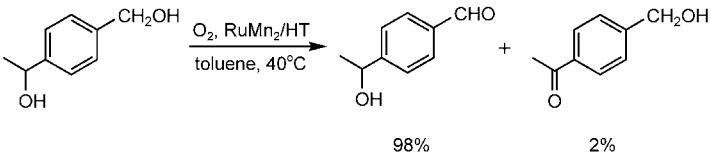
As displayed in Table 3, the $RuMn_2$/HT catalyst selectively oxidizes a wide variety of alcohols. Primary and secondary benzylic alcohols are converted into the corresponding carbonyl compounds in high yield (entries 1–3). The catalysis is also chemoselective; $RuMn_2$/HT preferentially oxidizes primary over secondary hydroxy groups, as shown by the selective oxidation of 1-[(4′-hydroxymethyl)phenyl]ethanol to 1-[(4′-formyl)phenyl]ethanol in 98% yield (Scheme 1).

In the case of cyclopropyl(phenyl)methanol, the hydroxy group was oxidized without cleavage of the cyclopropyl ring

Table 3: Oxidation of various alcohols catalyzed by $RuMn_2$/HT in the presence of O_2.[a]

Entry	Alcohol	Product	*t* [h]	Conv. [%]	Yield [%][b]
1	Benzyl alcohol (**1**)	Benzaldehyde (**2**)	1	100	99
2	1-Phenylethanol	Acetophenone	3.5	100	92
3	Benzhydrol	Benzophenone	2	94	93
4	Cyclopropyl(phenyl)methanol	Cyclopropyl phenyl ketone	6	100	99
5	Cinnamyl alcohol	Cinnamaldehyde	1.5	100	97
6	(2-Hydroxymethyl)thiophene	2-Thiophenecarboxaldehyde	2	100	89
7	2-Aminobenzyl alcohol	2-Aminobenzaldehyde	21	100	100

[a] Reaction conditions: catalyst (2 mol% Ru), alcohol (1 mmol), toluene (5 mL), 60°C, O_2 flow. [b] Yields were calculated based on alcohols.



Scheme 1. Selective oxidation of primary hydroxy groups by $RuMn_2$/HT catalyst.

(entry 4). Oxidation of cinnamyl alcohol proceeded smoothly without affecting the carbon–carbon double bond (entry 5). Furthermore, $RuMn_2$/HT effectively catalyzes the oxidation of (2-hydroxymethyl)thiophene, a heteroaromatic alcohol, to 2-thiophenecarboxaldehyde, in high yield (entry 6), and the oxidation of 2-aminobenzyl alcohol to 2-aminobenzaldehyde, quantitatively (entry 7), in contrast to the homogeneous Pd and Ru complexes.[16]

The spent $RuMn_2$/HT catalyst could be readily separated from the reaction mixture by filtration. The EXAFS spectrum of the recovered $RuMn_2$/HT catalyst confirmed retention of the original RuMnMn structure, and ICP (inductively coupled plasma) analysis of the filtrate indicated no leaching of Ru and Mn species during the oxidation. The $RuMn_2$/HT catalyst could be reused while maintaining the same high catalytic activity and selectivity (Table 2, entries 2–4). When the catalyst was removed at about 50% conversion of the alcohol, no further oxidation was detected in the filtrate after 3 h under 1 atm O_2 which shows that the present alcohol oxidations proceed at the interface between the catalyst surface and the liquid phase.

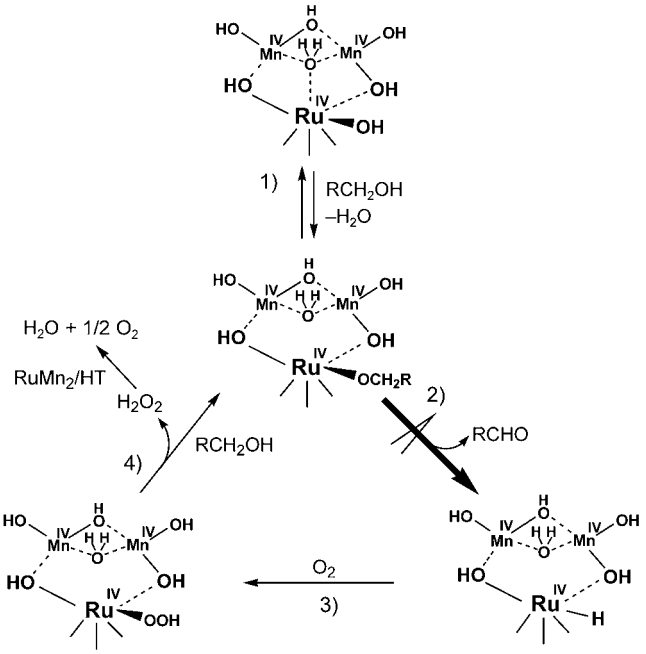
To the best of our knowledge, $RuMn_2$/HT is the most effective, environmentally benign Ru catalyst for the oxidation of benzylic and aromatic allylic alcohols in the liquid phase[15,16c,d,19] with the advantages of 1) high catalytic activity, even with O_2 at 1 atm as the sole oxidant, 2) wide applicability to alcohols, including those containing heteroatoms, 3) simple preparation and work-up procedures, and 4) reusability as a solid catalyst.

The Mn cations in the RuMnMn species evidently play a pivotal role in improving the Ru-catalyzed alcohol oxidation since Mn_2/HT does not catalyze the reaction (Table 2, entry 8). We have proposed a catalytic cycle for the alcohol oxidation (Scheme 2)[20] that proceeds via a ruthenium alkoxide intermediate, which undergoes β-hydrogen elimination to produce the carbonyl compound and a ruthenium hydride species, as observed by IR spectroscopy.[10] Reaction of this hydride with O_2 and subsequent ligand-exchange with the alcohol completes the catalytic cycle.[15b,c]

A rate equation based on a Michaelis–Menten-type model[21] for this proposed mechanism [Eq. (1)] agrees well with the kinetic data.

$$\mathrm{Ru{-}OH + RCH_2OH} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{[Ru{-}OCH_2R]} \xrightarrow{k_2} \mathrm{Ru{-}H + RCHO} \qquad (1)$$

For the $RuMn_2$/HT-catalyzed oxidation of **1**, K_M and k_2 were calculated to be 2.96 mM and 0.047 s^{-1}, respectively, at 60 °C. The rate constant (k_2) of β-hydrogen elimination from the ruthenium alkoxide intermediate is therefore almost twice that for the Mn-free Ru/HT. The β-hydrogen elimination is considered as the rate-determining step in the overall alcohol oxidation from the primary kinetic isotope effect in the competitive oxidation of **1** and $C_6D_5CD_2OH$ (4.2).[15b,e] Thus, the Mn cations in the heterotrimetallic sites facilitate β-hydrogen elimination from the ruthenium alkoxide intermediate. Removing the water molecule that binds the Ru and Mn cations improves the situation of the Ru species during β-hydrogen elimination by, for example, producing a coordinately unsaturated Ru site.[16c]



Scheme 2. A proposed mechanism for the oxidation of a primary alcohol by trimetallic RuMnMn sites.

For the secondary alcohol 1-phenylethanol, K_M and k_2 were found to be 133 mM and 0.026 s^{-1}, respectively, at 60 °C. Importantly, the K_M value is significantly greater than that for the oxidation of **1**, which is reflected in the preferential oxidation of primary hydroxy groups by this species.[22] The formation of metal alkoxide intermediates of primary alcohols is favored over secondary alcohols in the ligand-exchange step.[23]

In summary, a robust heterotrimetallic $Ru^{IV}Mn^{IV}Mn^{IV}$ species coordinated to a hydrotalcite surface as a macroligand facilitates the highly efficient aerobic oxidation of alcohols. Such cooperative action among high-valence metal cations in a heterometallic species on a solid surface provides a unique protocol for the preparation of functionalized heterogeneous catalysts for environmentally benign organic syntheses.[24] Ongoing efforts are focused on creating high-valence Ru cation species, that is, Ru^{VI} and Ru^{VII}, based on the redox interaction within a heterometallic site for highly efficient epoxidation and dihydroxylation reactions of alkenes with molecular oxygen.

Experimental Section

Ru/HT[7d] was treated with an aqueous solution of $MnCl_2{\cdot}4H_2O$ to afford $RuMn_2$/HT.[10] Elemental analysis (%) calcd for $Ru_{0.071}Mn_{0.142}/Mg_6Al_2(OH)_{16}CO_3$: Ru 1.03, Mn 1.12, Mg 21.0, Al, 8.14; found: Ru 1.05, Mn 1.20, Mg 21.4, Al 7.9.

The X-ray absorption spectra were recorded at the BL01B1 beamline in SPring-8 of JASRI, Japan (2003B0944-UXa-np and 2004A489-NXa-np) and at the BL-10B beamline of PF at KEK, Japan (2001G143 and 2002G102). The data were reduced using computer

systems at the Data Processing Center of Kyoto University according to a previously reported procedure.[25]

[17] See the Supporting Information for typical time courses for the oxidation of **1**.

[18] A control experiment was performed using benzaldehyde in the presence of $RuMn_2$/HT and water at 60 °C in toluene under oxygen. Benzaldehyde was quantitatively recovered showing that it is not oxidized further under these conditions. See Supporting Information.

[19] $RuMn_2$/HT is highly effective for the oxidation of benzylic and aromatic allylic alcohols, but not for primary aliphatic alcohols; the oxidation of 1-octanol with $RuMn_2$/HT (2 mol-% Ru) afforded octanal in 62% yield at 60 °C after 5 h. A CoCeRu trimetallic catalyst shows a high activity for the aerobic oxidation of primary aliphatic alcohols: H.-B. Ji, T. Mizugaki, K. Ebitani, K. Kaneda, *Tetrahedron Lett.* **2002**, *43*, 7179; K. Ebitani, H.-B. Ji, T. Mizugaki, K. Kaneda, *J. Mol. Catal. A* **2004**, *212*, 161.

[20] 1) The addition of a radical scavenger (2,6-di-*tert*-butyl-*p*-cresol) did not affect the rate of the oxidation. 2) Treatment of $RuMn_2$/HT with **1** under argon afforded an IR signal of a Ru–H species at 2120 cm^{-1}.[10,16d] This species disappeared upon exposure to O_2. 3) During the oxidation of **1**, the ratio of O_2 consumed to **2** was 1:2.

[21] R. W. Missen, C. A. Mims, B. A. Saville, *Introduction to Chemical Reaction Engineering and Kinetics*, Wiley, New York, **1999**. The initial rate of oxidation of **1** is proportional to the amount of $RuMn_2$/HT and independent of the oxygen pressure.

[22] If the second step in Equation (1) is the rate-determining step, the K_M value can be regarded as a dissociation equilibrium constant (k_{-1}/k_1) of the first step. See ref. [21].

[23] A similarly high chemoselectivity for primary alcohols has been observed in the $Zr(OAc)_2$-catalyzed oxidation of alcohols: K. Kaneda, Y. Kawanishi, S. Teranishi, *Chem. Lett.* **1984**, 1481.

Enzymes

Synthesis of Luciferyl Coenzyme A: A Bioluminescent Substrate for Firefly Luciferase in the Presence of AMP**

*Hugo Fraga, Rui Fontes, and Joaquim C. G. Esteves da Silva**

Firefly luciferase (EC 1.13.12.7) is an oxidoreductase that catalyzes the bioluminescent reaction of luciferin (LH_2), ATP, and oxygen [Eq. (1) and (2)].[1,2] Research has been focused

$$LH_2 + ATP\text{-}Mg \rightleftharpoons LH_2\text{-}AMP + PPi \quad (1)$$

$$LH_2\text{-}AMP + O_2 \rightarrow Oxyluciferin + AMP + CO_2 + h\nu \quad (2)$$

on the clarification of the mechanism behind light emission, and as a consequence of its high quantum yield,[3] this reaction was defined as a model for the optimization of chemiluminescence systems.[4] The applications of firefly luciferase reactions range from ATP determination to the standard use of the *luc* gene in molecular biology.[5–7]

McElroy et al.[8] described the similarities between the mechanism of firefly luciferase reactions [Eq. (1)–(4)] and

$$LH_2\text{-}AMP + CoA \rightleftharpoons LH_2\text{-}CoA + AMP \quad (3)$$

$$L\text{-}AMP + CoA \rightleftharpoons L\text{-}CoA + AMP \quad (4)$$

those of the acyl-CoA synthetases [Eq. (5) and (6)]. This

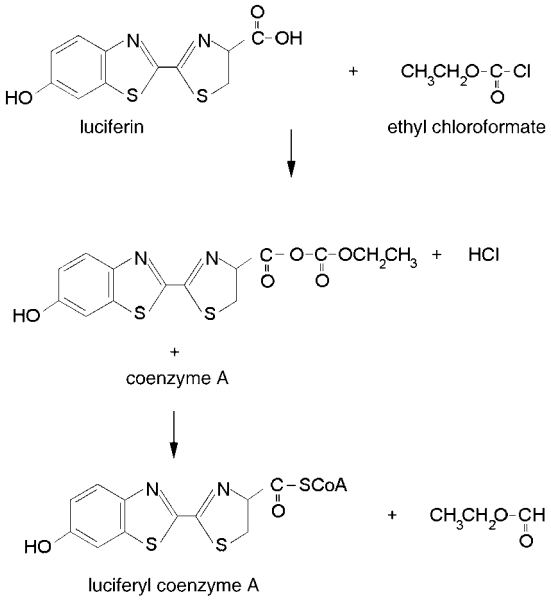
$$fatty\ acid + ATP\text{-}Mg \rightleftharpoons acyl\text{-}AMP + PPi \quad (5)$$

$$acyl\text{-}AMP + CoA \rightleftharpoons acyl\text{-}CoA + AMP \quad (6)$$

relationship was supported by the luciferase formation of the intermediate luciferyl adenylate (LH_2-AMP) and the production of dehydroluciferyl coenzyme A (L-CoA) from dehydroluciferyl adenylate (L-AMP); the latter compound is an oxidation product of LH_2-AMP (Supporting Information). Since then, several experimental observations have provided support for the McElroy hypothesis: the synthesis of dinucleoside polyphosphates (observed in acyl-CoA synthetases),[9] the high primary degree of sequence identity with rat long chain acyl-CoA synthetase (35.8%),[10] and recently the ability of luciferase to catalyze directly acyl-CoA formation [Eq. (5) and (6)].[11]

Herein we report the chemical synthesis and characterization of a new product in the firefly luciferase mechanism, namely, luciferyl coenzyme A (LH_2-CoA). The luciferase-catalyzed formation of LH_2-CoA from LH_2-AMP and coenzyme A [Eq. (3)] in anoxic media was recently advanced.[12] In that work, however, the unequivocal characterization of the enzymatically produced compound was not performed owing to the low catalytic activity that made the isolation of the formed compound impractical.

The chemical synthesis methodology employed in this work to obtain LH_2-CoA was based on the procedures of Simon and Shemin and of Wieland and Rueff (Scheme 1),[13,14] in which an acid anhydride is allowed to



Scheme 1. Chemical synthesis of LH_2-CoA.

react with a thiol in cold aqueous solution. As luciferin anhydride is not readily available, a mixed anhydride obtained from luciferin and ethyl chloroformate was used (Scheme 1).[15] By using this synthetic scheme we synthesized LH_2-CoA and confirmed its identity as the firefly luciferase product, which has already been detected.[12]

The formation of acyl-CoA catalyzed by acyl-CoA synthetases is readily reversible,[16] and the same was observed in the case of the luciferase-catalyzed formation of L-CoA.[2,17] Both the reverse and direct reactions occur through the same adenylated intermediates: L-AMP and acyl-AMP for luciferase and acyl-CoA synthetases, respectively [Eq. (4) and (6)]. In the case of LH_2-CoA, the corresponding adenylate is LH_2-AMP, which is also the direct intermediate in the bioluminescent reaction [Eq. (2) and (3)].

If Equation (3) could be reversed, luciferase would catalyze the conversion of AMP and LH_2-CoA into LH_2-AMP. This adenylate in the presence of oxygen would be oxidized to oxyluciferin, the light emitter. This hypothesis was

 DOI: 10.1002/anie.200462934

confirmed by the observed light production when LH_2-CoA and AMP were mixed in the presence of firefly luciferase (Figure 1). No light was emitted in the controls performed with LH_2-CoA and without AMP injection, thus confirming that the conversion of this compound into LH_2-AMP is essential for light emission.

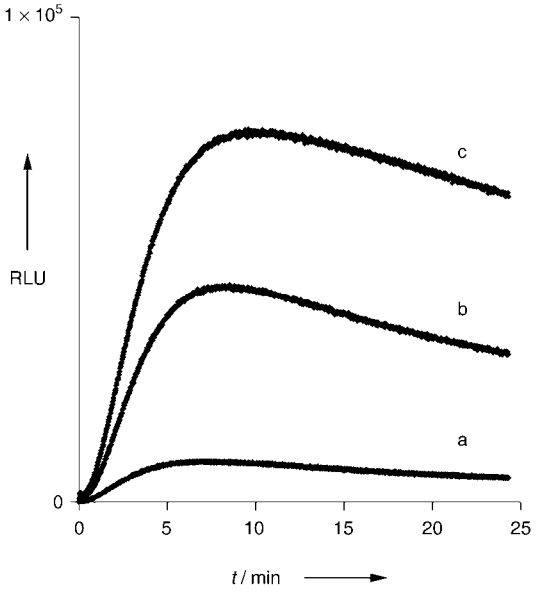

Figure 1. Bioluminescence from LH_2-CoA and AMP. The reaction mixtures contained purified and desalted LH_2-CoA (4 mM), EDTA (10 mM), hepes pH 7.5 (50 mM), and luciferase (0.04 mg protein mL^{-1}) in a final volume of 100 μL. The reactions were initiated with the injection of AMP. Curves a, b and c correspond to 62.5, 250, and 500 μM AMP, respectively (final concentrations).

The synthesized LH_2-CoA was purified but still contained traces of LH_2 as contaminant. In the presence of LH_2 any residual ATP would generate light through the direct adenylation of LH_2 [Eq. (1) and (2)]. To confirm that bioluminescence resulted from LH_2-CoA and AMP, the assays were supplemented with EDTA (10 mM). The presence of EDTA in this relatively high concentration prevented any possibility of direct adenylation because this process is Mg^{2+} dependent [Eq. (1)].[1,2]

The light emitted during the assay time was directly proportional to the concentration of AMP (up to 500 μM, Figure 2). Under our experimental conditions, that is, in the presence of 10 mM EDTA, the response obtained with ATP (5 mM, the highest AMP concentration used) was negligible (less than 5%).

The kinetic profile of LH_2-CoA + AMP bioluminescence (Figure 1) was markedly different from the flash profile of the LH_2 + ATP-Mg^{2+} (classic) bioluminescent reaction. In LH_2-CoA + AMP bioluminescence the rate of light production increased with incubation time, reaching a maximum at 10–20 min. Slow rise time patterns have already been described for LH_2-AMP analogues and luciferase mutants.[18]

As we have worked with native enzyme, and LH_2-AMP is a common intermediate in LH_2-CoA + AMP and classic bioluminescence, we deduce that the light profile obtained should be a consequence of the slow kinetics of the reaction of formation of LH_2-AMP from LH_2-CoA and AMP [Eq. (3)].

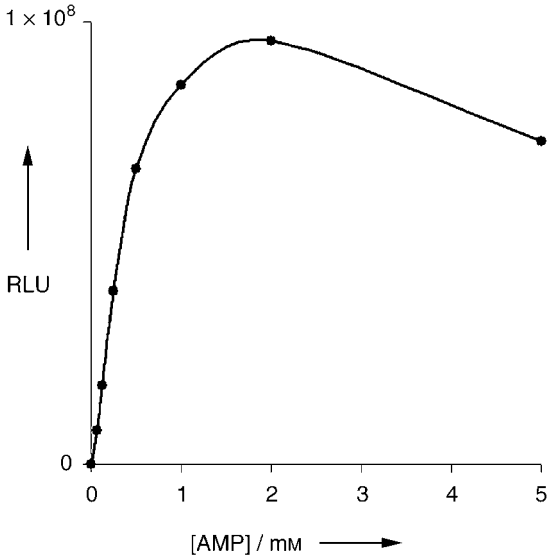

Figure 2. Total light output during the assay time (25 min) as a function of added AMP.

We had previously observed that the conversion of LH_2-AMP into LH_2-CoA is a relatively slow process.[12]

The identification of a new bioluminescent substrate for luciferase opens perspectives for the development of new bioanalytical methodologies for AMP detection. Moreover, the results presented herein are strong evidence for an evolutionary relationship between luciferase and acyl-CoA synthetases. From Equations (1)–(6) it is clear that if we exclude the light-production reaction [Eq. (2)], the mechanisms presented by firefly luciferase are in all ways similar to those of this class of enzymes.

Experimental Section

A stock solution of commercial luciferase (L8506) was prepared by dissolving the lyophilized powder (15 mg lyophilisate mL^{-1}) in hepes pH 7.5 (500 mM; 15 mg lyophilisate mL^{-1}) and stored at −20 °C. A stock solution of EDTA was prepared in hepes pH 7.5 (500 mM). Firefly luciferin, firefly luciferase, AMP, ATP, coenzyme A, EDTA, and hepes were purchased from Sigma, ethyl chloroformate from Aldrich, and triethylamine from Fluka.

Identification of enzyme-produced LH_2-CoA: The reaction mixture (15 μL) for the luciferase (Lase) synthesis of LH_2-CoA used ATP (1 mM), LH_2 (30 μM), coenzyme A (1 mM), $MgCl_2$ (2 mM), hepes pH 7.5 (100 mM), and Lase (1 mg protein mL^{-1}). All the solutions were prepared and kept under N_2. The reaction was initiated by the addition of Lase and was performed at ambient temperature. After 30 min of incubation, the enzyme reaction was stopped by the addition of aqueous methanol (15 μL; 66% v/v), centrifuged (13400 rpm, 2 min), and the supernatant was analyzed by reversed-phase HPLC. The chromatographic system consisted of a HP-1100 isocratic pump, a Rheodyne manual injection valve, a Chromolith C18 (Merck) column, and a Unicam Crystal 250 UV/Vis diode array detector. The eluent was an aqueous solution of 20% methanol, 4 mM phosphate buffer (pH 7.0), and the flux rate was set to 1 mL min^{-1}. Although a different order of elution could be obtained by using other phosphate buffer concentrations, under the above conditions LH_2-CoA (12 min) eluted after LH_2 (7 min). The spectra obtained for LH_2-CoA was similar to that reported previously,[12] with maxima at 262 and 340 nm ($A_{260}/A_{340} = 1.15:1$); see Supporting Information.

Chemical synthesis of luciferyl coenzyme A: The synthesis of luciferyl coenzyme A was based on previously reported methods for acyl-CoA thioester preparation.[13–15] LH_2 (50 mg, 0.178 mmol) in THF (15 mL) was mixed with triethylamine (25 μL, 0.178 mmol) at 0 °C. Ethyl chloroformate (17 μL, 0.178 mmol) was then added, and the mixture was left at 0 °C for 30 min. The volume of the reaction mixture was reduced to a half under a stream of N_2, and a mixture of coenzyme A (68.7 mg; 0.09 mmol) and $NaHCO_3$ (20 mg) in THF/H_2O (2:1; 10 mL) was added. The pH value was maintained at 7.5–8. After stirring for 30 minutes the reaction mixture was analyzed by reversed-phase HPLC as described for the identification of enzyme-produced LH_2-CoA. This system allowed the resolution of reactants and products, and the reaction was monitored at regular time intervals until no more LH_2-CoA formation was observed (120 min).

The retention time observed for the chemically synthesized compound was the same as that observed with enzyme-produced LH_2-CoA (Supporting Information). The THF was evaporated, and the aqueous solution was acidified to pH 3–4 by the addition of small amounts of a cation-exchange resin (Amberlite IR-120-H^+). The resin was removed by filtration, and the filtrate was extracted with diethyl ether (2×20 mL) to remove unconverted LH_2. The aqueous phase and organic phase were analyzed by reversed-phase HPLC, and as expected, no LH_2-CoA was detected in the diethyl ether.

The aqueous phase was lyophilized and a green fluorescent powder was obtained. LH_2-CoA was purified by reversed-phase HPLC by using a Supelco semipreparative column (LC-18, 25 cm × 10 mm, 5 μm) with a solution of methanol (40%) and phosphate buffer (11–15 mM; pH 7.0) as eluent; the flux rate was set to 3 mL min^{-1}. MALDI TOF analysis of purified LH_2-CoA was performed at RIAIDT, Unidad de Espectroscopia de Masas, Santiago de Compostela, Spain, and confirmed the calculated mass for $C_{32}H_{42}N_9O_{18}P_3S_3$, $M_w = 1029.842$ g mol^{-1} (Supporting Information). Prior to MS analysis and bioluminescence assays, LH_2-CoA solutions were desalted by using a ZipTip from Millipore; the phosphate content on the treated sample was verified by a variation of the molybdate method.[19] Purified LH_2-CoA stored at −20 °C was stable during the period of the bioluminescent assays (2 weeks), as confirmed by reversed-phase HPLC.

Bioluminescence from LH_2-CoA and AMP: The bioluminescence tests were performed in a homemade luminometer by using a Hammamatsu HCL35 photomultiplier tube. The reaction mixtures contained purified and desalted LH_2-CoA (4 μM), EDTA (10 mM), hepes pH 7.5 (50 mM), and luciferase (0.04 mg protein mL^{-1}); final volume: 100 μL. The reactions were initiated with the injection of AMP. The assays were carried out in duplicate, and control assays with water and ATP (5 mM, with and without EDTA (10 mM)) were also performed. Light was measured for 25 minutes with integrations at 1-s intervals.

recently.[2] At the time of our report on $[Mn(tda)(bipy)]_n$ (**1**) (tda = thiodiacetate = $S(CH_2COO)_2^{2-}$; bipy = 2,2′-bipyridine),[2] the only other known examples either lacked detailed structural information ($[Mn_2(C_3F_7CO_2)_4(bipy)_2]$[3]) or had not been deposited in the Cambridge Structural Database[4] ($[Mn_2(Ph_2XCCO_2)_4(quinoline)_2]$;[5] X = H, Me). Another example, $[Mn_2(\mu\text{-}OOCtBu)_4\{OC(tBu)OHNEt_3\}_2]$, has appeared recently.[6] In **1**, the bimetallic $\{Mn_2(\mu\text{-carboxylate})_4\}$ units, completed by two terminal bipy ligands and interconnected by pairs of CH_2SCH_2 spacers, form linear chains which further organize into a supramolecular structure through noncovalent interactions.[7,8] Copper acetate itself and other metal carboxylate synthons often generate metal-organic frameworks (MOF) through coordinative bonds,[7] whereas the overall architecture of **1** stems from the interactions between the 1D polymeric chains. In fact, the bipy ligands of adjacent chains, which are all parallel to each other, are π-stacked in a gearlike arrangement with the formation of compacted 2D sheets. In order to understand better the correlations between the geometry of the building blocks and the given supramolecular structure, we have tried to combine the Mn–tda unit with other N-donor chelating ligands.

X-ray studies of complexes obtained with 1,10-phenanthroline[9] and 4,4′-dimethoxy-2,2′-bipyridine showed that they are not isostructural with **1**, possibly because of the steric requirements of the different ligands (see the Supporting Information). To minimize these, we selected the ligands 4,4′-dimethyl-2,2′-bipyridine (4,4′-Me_2bipy) and 5,5′-dimethyl-2,2′-bipyridine (5,5′-Me_2bipy), which contain a pair of the smallest alkyl substituents, CH_3 groups, that are not adjacent to the N donors. The synthetic procedure was maintained as close as possible to that of **1**: we treated each of the above ligands with $[Mn(tda)(H_2O)]_n$ (**2**), which is obtainable in good yields by the reaction of aerobic aqueous solutions of $MnCl_2$ with a 1:1 mixture of Na_2CO_3 and thiodiacetic acid.[2] Two new compounds were crystallized that, like **1**, exhibit a 1:1:1 ratio of Mn, tda, and the N-chelate. From X-ray analyses, both products were shown to be one-dimensional polymers of formula $[\{Mn(N\text{-}N)\}_2(\mu\text{-}tda)_2(\mu\text{-}H_2O)]_n$ (N-N = 4,4′-Me_2bipy, **3**; 5,5′-Me_2bipy, **4**), formed by binuclear units with a core different from that of copper acetate. Both compounds exhibit antiferromagnetic behavior (see the Supporting Information for details). The estimated value of J ($5.5 \pm 0.1\ cm^{-1}$) matches those of other binuclear Mn^{II} species with structures similar to **3** and **4** (i.e., similar local coordination, Mn–Mn separation, and a unique Mn–O–Mn bridge).[10–12] The larger J value found for **1** ($8.2\ cm^{-1}$)[2] indicates that the exchange interaction is more efficient with four rather than two *syn-syn* carboxylato and one μ-H_2O bridges.[13]

As shown in Figure 1,[14] the structure of **3** (that of **4** is similar, see the Supporting Information) consists of extended ribbons formed by binuclear Mn_2 units linked through pairs of CH_2SCH_2 spacers. In contrast to **1**, two of the four carboxylate groups coordinated to the Mn_2 unit adopt monodentate coordination to each metal atom, thereby affording an unprecedented bridging mode (μ_3-κ^1(O),κ^1(O′)-κ^1(O″)) for the tda ligand. In the binuclear core, a bridging water molecule (O9) forms two strong hydrogen bonds with the uncoordinated oxygen atoms of the two monodentate carboxylate groups (the contacts O2···O9 and O6′···O9 are 2.547 and 2.561 Å, respectively). Finally, two terminal Me_2bipy ligands, which are now almost orthogonal to each other (dihedral angle 72°) rather than parallel, complete a pseudo-octahedral geometry at each metal. With respect to **1**, the loss of the trigonal-prismatic coordination (TP) does not affect the Mn···Mn separation, which remains nonbonding (3.581(1) Å and 3.502(1) Å, in **3** and **1**, respectively). The arrangement $[\{M(\kappa^1\text{-}OOCR)L_2\}_2(\mu\text{-}OOCR)_2(\mu\text{-}H_2O)]$ (L_2 = two monodentate N-donor ligands or a bidentate one) is common for divalent metal ions,[15] and includes four manganese examples.[10,11,16] One of these, which contains the ligand 4,4′-Me_2bipy,[11] has been proposed as a model for the active site of dimanganese enzymes.[17]

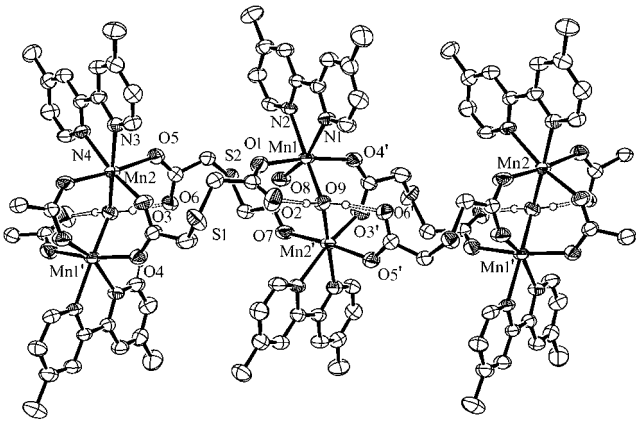

Figure 1. ORTEP drawing of polymer **3** propagated along the *y* axis. The H atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Mn1–O1 2.203(4), Mn1–O8 2.113(4), Mn1–O4′ 2.166(3), Mn1–O9 2.218(3), Mn2–O3 2.140(3), Mn2–O5 2.182(4), Mn2′–O7 2.136(4), Mn2′–O9 2.234(4), Mn1···Mn2′ 3.581(1); Mn1-O9-Mn2′ 107.1(2). The symbol ′ corresponds to the transformation $-x+{}^1/_2, y+{}^1/_2, -z+{}^1/_2$.

The fact that the structure of **1** differs from those of **3** and **4** seems attributable to the methyl substituents on the bipyridine ligand in **3** and **4**. As highlighted before,[2] the threading of the ribbons in **1** stems from a head-to-tail interpenetration of the parallel bipy ligands and the formation of extended 2D sheets. The degree of π-stacking is definitely more compact here than that described for similar systems.[18] In this respect, the interaction mode between the bipy ligands in **3** and **4** is evidently different from that in **1** (see the Supporting Information). First, the nonparallel disposition of the two bipy ligands in each binuclear unit determines the presence of an extended 3D packing rather than 2D sheets. Moreover, the presence of methyl substituents does not allow the same degree of interpenetration between the parallel bipy ligands of adjacent chains. The loss of compactness with respect to **1** is confirmed by the lower crystal densities of **3** and **4**, in spite of their 10% larger molecular weights (1.520, 1.540, and $1.705\ g\,cm^{-3}$ for **3**, **4**, and **1**, respectively). The different situation can be qualitatively appreciated by looking at the projections of two facing bipy ligands down their normal vectors (Figure 2).

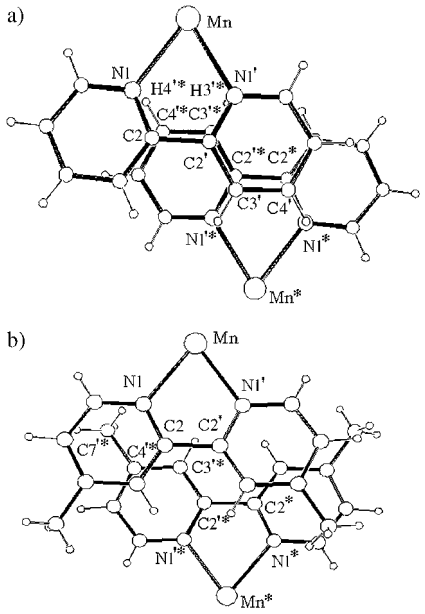

Figure 2. Comparative projections of the facing {Mn(bipy)} and {Mn(4,4′-Me_2bipy)} fragments in **1** (a) and **3** (b) down axes perpendicular to the bipy ligands. The atom of the bipy skeleton are indicated by standard labeling (the applied symmetry operations (*) are: $-x$, $1-y$, $1-z$ and $-x+{}^1/_2$, $-y+{}^1/_2$, $-z$ for compounds **1** and **3**, respectively).

In **1**, five C–C bonds of two stacked bipy ligands are mutually eclipsed, as are seven C–H bonds. Conversely, a slippage of the two projected ligands in **3** elongates the separation between the symmetry-related Mn atoms by about 0.4 Å with respect to **1**. This avoids a shortened contact between one CH_3 group and the coordination sphere of the facing metal atom (e.g., the atom Mn and the group at C7′* in **3**). If, in the lattice of **1**, the H4′* atom was replaced by a CH_3 group, the latter would clash with the coordination sphere of the facing Mn atom (contacts <2 Å). Another aspect of the bipy geometry in **1** is the 10° twisting of the two six-membered rings around the connecting C2–C2′ bond. As a consequence, the contacts between the eclipsing atoms N1/H4′* and N1′/H3′* (and their symmetry equivalents) are significantly shorter (3.15 and 3.45 Å) than the separation of the bipy mean squares planes (4.01 Å). Although not exceptionally short, the latter N···H distances suggest that an important contribution to the overall stacking originates from the four π–σ interactions between the H atoms and the p_π-orbitals of the N atoms for any pair of bipy ligands.[18] Finally, another possible contribution to the compactness of the interpenetrating ribbons in **1** may be due to a residual interaction between the thioether sulfur atom and a bipy C–H bond (3.32 Å). Conversely, the slippage in **3** minimizes such a hydrogen bonding (if any), since the S···H–C separation increases to 3.71 Å.

Comparative DFT calculations were performed for the discrete binuclear units of **1** and **3**, with no methyl substituents in either case. The optimized geometry of $[Mn_2(OOCH)_2(bipy)_2(\mu\text{-}OOCH)_2(\mu\text{-}H_2O)]$ (**3a**) satisfactorily reproduces that of the building block in **3**, including the two quasi-orthogonal bipy ligands (84°). The $[Mn_2(\mu\text{-}OOCH)_4(bipy)_2]$ unit was first optimized by imposing D_{2h} symmetry (model **1a**). The computed parameters are sufficiently similar to those of the actual compound **1** (see the Supporting Information), but the number of imaginary frequencies suggested that **1a** is not a minimum. A new optimization without symmetry constraints provided an actual minimum, **1b**, with a different coordination geometry. In particular, the local coordination at the Mn atoms is no longer TP but almost octahedral (one of the O–Mn–O angles opens to 166°), and the terminal bipy ligands are far from being coplanar (dihedral angle of about 66°). Energetically, **1b** is more stable than **1a** by only 1.2 kcal mol^{-1}, a result which is consistent with the zero crystal-field stabilization energy for d^5 high-spin metal systems and their facile and subtle adaptation to alternative coordination environments.[19] In contrast, the comparison of the energies associated with **3a** and **1a** is very significant as the former species is more stable with respect to the system **1a** + H_2O by as much as 20.4 kcal mol^{-1}. While the entropic factor should favor separated components, complex **3a** must receive a considerable amount of stabilization from the intramolecular hydrogen bonding between water and free carboxylate oxygen atoms. Since the structure of **3** is not experimentally observed in the presence of the bipy ligand, the formation of complex **1** can only be caused by more-energetic noncovalent interactions between the coordination polymers.

In conclusion, this study provides evidence that the noncovalent interactions between coordination polymers in a supramolecular system can ultimately affect the primary structure of the metallic building blocks. In general, metallic building blocks are used in supramolecular chemistry to generate specific directional patterns, while the present case reverses such a paradigm. In fact, the geometry of the building block adapts to support the most-stabilized supramolecular architecture.

Experimental Section

3: A solution of **2**[2] (0.113 g, 0.5 mmol) in 20 mL of water was treated with a solution of 4,4′-Me_2bipy (0.092 g, 0.5 mmol) in 20 mL of ethanol. The mixture was heated at 90 °C for 2 h and then it was concentrated to a volume of 15 mL. The resultant solution was filtered and yellow crystals of **3** suitable for single-crystal X-ray structure analysis were obtained after slow evaporation of the solvent at ambient temperature for several days. Yield: 0.12 g (60 %). IR (Nujol mull on NaCl plates): $\tilde{\nu}=3588$–3249 (br), 1970 (br, m), 1619 (s), 1553 (s), 1528 (s), 1486 (m), 1454 (s), 1397 (s), 1306 (m), 1289 (w), 1236 (m), 1209 (s), 1166 (w), 1130 (w), 1096 (w), 1037 (w), 1012 (s), 936 (m), 919 (m), 887 (m), 843 (w), 830 (s), 792 (m), 767 (w), 718 (w), 686 (s), 675 (s), 665 (m) cm^{-1}. Elemental analysis (%) calcd for $C_{16}H_{17}MnN_2O_{4.5}S$: C 48.49, H 4.32, N 7.07; found C 47.90, H 4.26, N 6.80.

Complex **4** was obtained by a similar synthetic procedure as yellow crystals (0.17 g, 82 % yield). IR (Nujol mull on NaCl plates): $\tilde{\nu}=3029$ (br, s), 1970 (br, m), 1615 (s), 1569 (s), 1526 (s), 1499 (s), 1484 (s), 1446 (s), 1387 (s), 1319 (m), 1245 (m), 1234 (m), 1212 (s), 1181 (m), 1164 (m), 1153 (m), 1089 (m), 1043 (s), 990 (w), 953 (w), 938 (m), 892 (m), 843 (m), 832 (m), 810 (w), 793 (m), 771 (m), 734 (m), 670 (s), 648 (m) cm^{-1}. Elemental analysis (%) calcd for $C_{16}H_{17}MnN_2O_{4.5}S$: C 48.49, H 4.32, N 7.07, S 8.09; found C 48.38, H 4.18, N 7.15, S 8.13.

The geometries of the complexes $[Mn_2(\mu\text{-}OOCH)_4(bipy)_2]$ (**1a** and **1b**) and $[Mn_2(OOCH)_2(bipy)_2(\mu\text{-}OOCH)_2(\mu\text{-}H_2O)]$ (**3a**) were

computed by density functional calculations at the unrestricted BP86[20] level of theory using the 6-31G* basis set. The multiplicity was imposed to $S=5$, in agreement with the experimental data recorded at room temperature. Vibrational frequency calculations by diagonalization of the analytically computed Hessian were carried out for all models. Structures **1b** and **3a** (both optimized without symmetry constraints) correspond to real minima in the potential-energy surface. Conversely, **1a** (imposed D_{2h} symmetry) is characterized by six imaginary frequencies that involve displacement of some atoms in order to break the imposed symmetry (all of them smaller than 60 cm^{-1}). For the energy differences, single-point calculation on the previously optimized structures were carried out with the 6-311+G** basis set. All calculations were performed with the Gaussian 98 package of programs.[21]

Asymmetric Synthesis

Introduction of Multiple Elements of Chirality around an Aromatic Core and an Approach to Enantiomerically Pure C_3-Symmetric Ligands

M. Paola Castaldi, Susan E. Gibson, Matthew Rudd, and Andrew J. P. White*

Nonracemic chiral ligands that possess planar chirality and C_2 and C_3 symmetry have delivered excellent results in the field of asymmetric catalysis.[1–4] In particular, the application of ligands that possess C_3 symmetry in asymmetric catalysis is currently attracting interest, despite the challenges associated with the synthesis of such ligands.[5–8] Having discovered a chiral-base-mediated reaction that efficiently generates a single stereogenic center,[9] we wondered whether this reaction could be used to generate multiple stereocenters in a one-pot reaction, and thus create ligands with some of the more synthetically challenging configurations that perform so well in asymmetric catalysis. The results of our study are presented herein, and their potential application in the field of ligand synthesis is illustrated by the synthesis of a C_3-symmetric

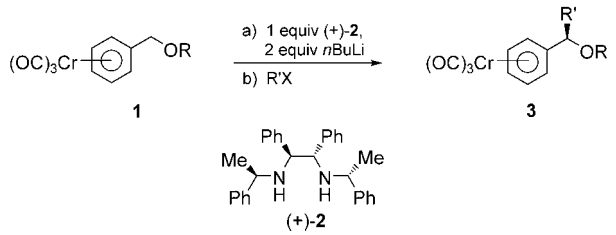
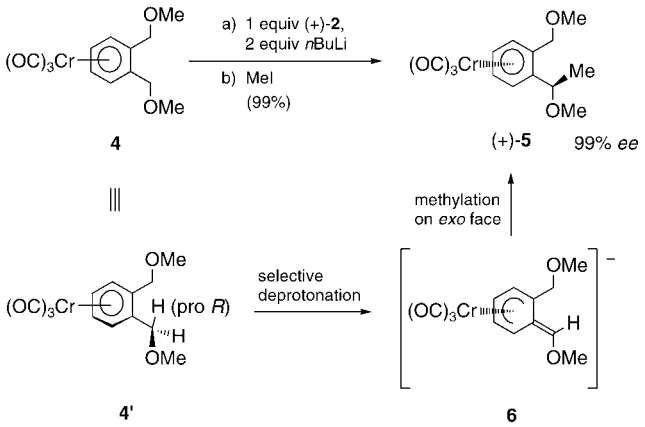
enantiomerically pure triphosphine and a C_3-symmetric enantiomerically pure tripyridine.

Tricarbonylchromium(0) complexes of alkyl benzyl ethers, such as **1**, give chiral ether complexes **3** in high yield and enantiomeric excess upon treatment with *n*-butyllithium and a chiral diamine **2** followed by an electrophile (Scheme 1).[9] The enantiomer (+)-(*R*,*S*,*S*,*R*)-**2**,[10] which is derived from (*R*)-α-methylbenzylamine, leads to an *R* configuration at the new stereocenter, presumably because the base will preferentially abstract the pro-*R* benzylic proton.



Scheme 1. Use of a chiral diamide to create a single stereocenter.

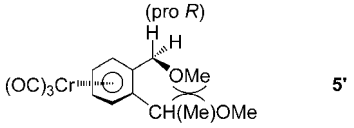
Our first experiment to determine whether this reaction could be used more than once on a single aromatic core was performed with a tricarbonylchromium(0) complex of a 1,2-disubstituted arene. As shown in Scheme 2, complex **4** was



Scheme 2. Creation of central and planar chirality by selective alkylation.

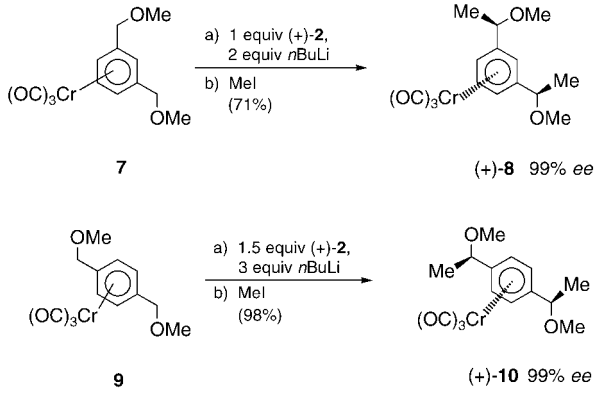
used with iodomethane as a model for the electrophile.[11] Reaction of **4** with one equivalent of diamine (+)-**2** (the *R*,*S*,*S*,*R* enantiomer) and two equivalents of *n*-butyllithium followed by quenching with iodomethane gave one monomethylated species in 99% yield and with 99% *ee*, as determined by HPLC analysis.[12,13]

The selective monomethylation of **4** can be explained as follows: first, it was assumed that the two methoxymethyl substituents adopt conformations that minimize their steric interactions. It was apparent that the pro-*R* proton in **4** (indicated in structure **4′**) is the most accessible of the four benzylic protons to the base because removal of benzylic protons is favored by an antiperiplanar relationship between the proton and the tricarbonylchromium(0) unit,[14] and the chiral base (*R*,*S*,*S*,*R* configuration) is known to selectively remove pro-*R* protons. Thus, deprotonation leads to anion **6**, which is subsequently methylated on its *exo* face (that is, antiperiplanar to the tricarbonylchromium(0) unit) to give the monomethylated product (+)-**5**. Further methylation is disfavored as the conformation that would place the remaining pro-*R* proton antiperiplanar to the tricarbonylchromium(0) unit gives rise to severe steric interactions between the two groups attached to the arene ring, as illustrated by structure **5′**. Thus, although the desired multiple selective alkylation did



not occur with this substrate, the chiral base did differentiate between the four hydrogen atoms and the monomethylation of the resulting anion generated an enantiomerically pure product with not only central chirality at one of the benzylic sites but also planar chirality that arises from the two different substituents on the chromium-complexed arene ring.

In contrast to the monomethylation described above, the treatment of complex **7**,[15] which is derived from 1,3-benzenedimethanol, with one equivalent of diamine (+)-**2** and two equivalents of *n*-butyllithium followed by quenching of the reaction with iodomethane gave a dimethylated product in 71% yield and with 99% *ee* (Scheme 3), as

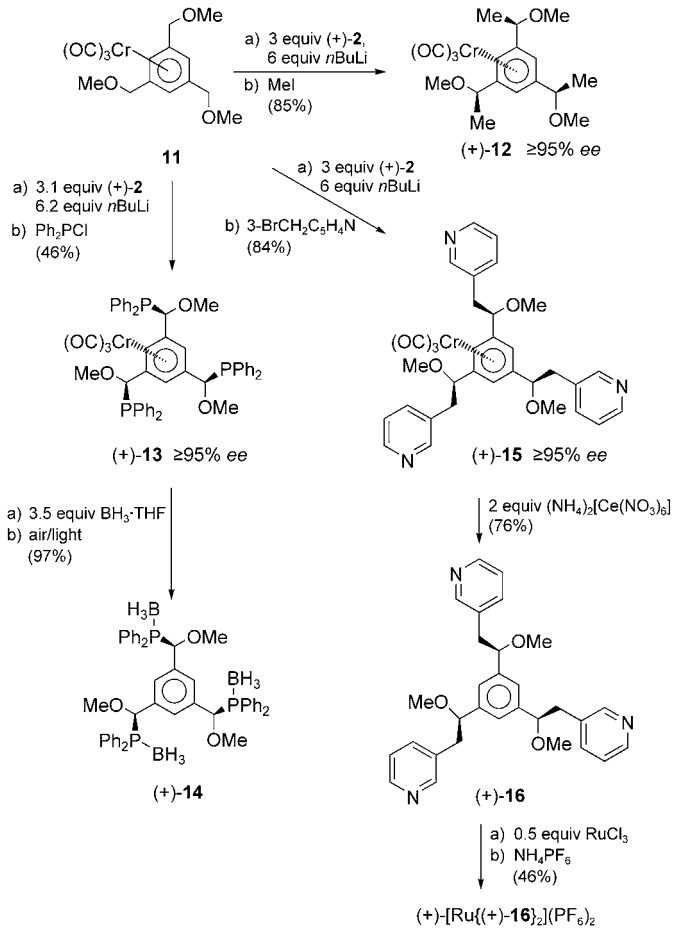


Scheme 3. Creation of two stereocenters by using a chiral diamide.

determined by HPLC analysis. In this case, the two pro-*R* hydrogen atoms can readily adopt an antiperiplanar relationship to the tricarbonylchromium(0) unit, so that both are cleanly removed by the chiral base. Quenching of the resulting dianion leads to the dimethylated product (+)-**8**. It was anticipated that the use of electrophiles that contain groups such as phosphines and subsequent removal of the tricarbonylchromium(0) unit (see below) would provide rapid access to enantiomerically pure C_2-symmetric pincer ligands.[16] The 1,4-disubstituted complex **9** behaved in a similar manner to the 1,3-disubstituted complex **7** (Scheme 3). In this case, the yield and the enantiomeric excess of the C_2-

symmetric product (+)-**10** were optimized by using 1.5 equivalents of diamine **2** and 3 equivalents of *n*-butyllithium.[17]

To determine whether three stereoselective alkylations could be carried out in a one-pot reaction, we turned our attention to the 1,3,5-trisubstituted complex **11**.[18] After optimization of the reaction conditions with the iodomethane quench, it was found that three chiral centers could be installed to give the complex (+)-**12** in good yield and with high enantioselectivity (Scheme 4).



Scheme 4. Creation of three stereocenters by using a chiral diamide.

To demonstrate the potential of the reactions described above for the preparation of structurally distinct ligands for application in asymmetric catalysis, we introduced phosphine and pyridine moieties into the electrophile and applied the resulting compounds to the most challenging reaction in which the model electrophile had been used: the trifunctionalization of **11**. Pleasingly, when chlorodiphenylphosphane was used as the electrophile in the reaction of **11**, the C_3-symmetrical triphosphine (+)-**13** was formed in reasonable yield and with high enantiomeric excess (Scheme 4 and Figure 1). Similarly, when the reaction was quenched with 3-bromomethylpyridine, the C_3-symmetric tripyridine (+)-**15** was prepared in very good yield and with high enantiomeric excess.[19] The subsequent oxidative removal of the tricarbonylchromium(0) unit proceeded smoothly to give enantiomerically pure products (+)-**14** and (+)-**16**. Heating (+)-**16** with $RuCl_3$ followed by anion exchange gave (+)-[Ru{(+)-**16**}$_2$](PF$_6$)$_2$, which is the first example of a structurally characterized chiral bis(tripyridyl)ruthenium complex (Figure 2).

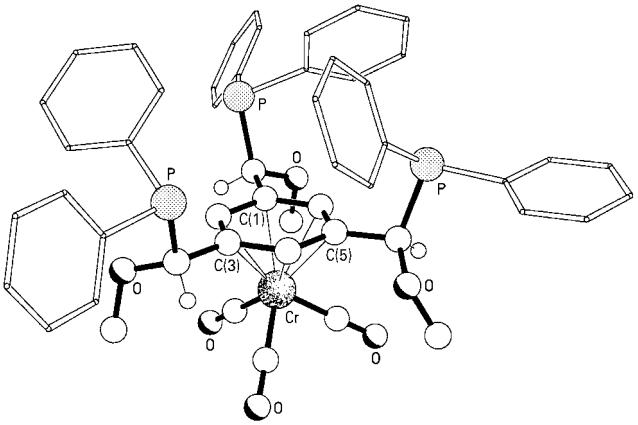


Figure 1. The molecular structure of (+)-**13**.[20]

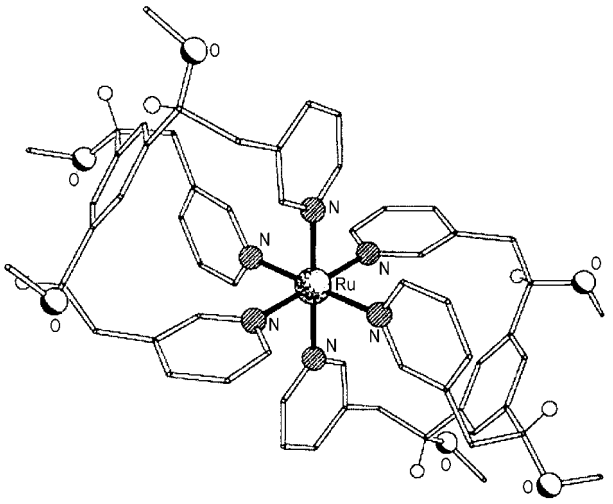

Figure 2. The molecular structure of (+)-[Ru{(+)-**16**}$_2$](PF$_6$)$_2$.[21]

In summary, we have demonstrated that chiral bases can be used to readily generate a range of stereochemical arrays around an aromatic core. Initial experiments reveal that replacement of the model electrophile that was used as a quench with other electrophiles that can introduce important donor groups, such as phosphanes and pyridines, leads to structurally distinct enantiomerically pure chiral ligands. Finally, the reactions described may also be applied to the synthesis of chiral cores of organometallic and organic dendrimers.

Experimental Section

(+)-**13**: *n*-Butyllithium (1.49 mL, 2.50 M in hexanes, 3.72 mmol, 6.2 equiv) was added dropwise to a stirred solution of diamine **2** (208 mg, 1.86 mmol, 3.1 equiv) in dry THF (100 mL) at −78 °C. The

solution was then allowed to warm to room temperature over a period of 30 min to allow the formation of a diamide. The resulting deep-red solution was cooled to −78 °C, and a solution of lithium chloride (80 mg, 1.86 mmol, 3.1 equiv; dried with a heat gun) in THF (10 mL) was added through a cannula. The reaction mixture was stirred for a further 5 min before a precooled solution (−78 °C) of **11** (208 mg, 0.6 mmol, 1.0 equiv) in THF (10 mL) was introduced dropwise through a short cannula. Stirring was continued for a period of 60 min before chlorodiphenylphosphane (0.99 mL, 5.4 mmol, 9.0 equiv) was added in one portion through a syringe. The reaction was then stirred for 1 h at −78 °C followed by a further 2 h at −40 °C before methanol (2 mL) was added and the solvent removed in vacuo. Purification of the residue by flash column chromatography on silica gel (hexane/diethyl ether, 99:1–90:10) afforded (+)-**13** (253 mg, 0.28 mmol, 47 % yield) as a yellow solid. The enantiomeric excess was determined by HPLC analysis (chiralcel OD-H; *n*-hexane/2-propanol, 99.6:0.4, 1.0 $cm^3 min^{-1}$, 330 nm); *S* enantiomer: t_R = 12.5 min (minor); *R* enantiomer: t_R = 20.6 min (major): ≥ 95 % *ee*; $[\alpha]_D^{20} = +226.9$ ($c = 0.67$, CH_2Cl_2); m.p. 155–157 °C; ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 3.43$ (s, 9H; OCH_3), 4.75 (d, $J = 4.7$ Hz, 3H; $CHPPh_2$), 5.54 (s, 3H; $C_{Cr}H$), 7.28–7.40 (m, 24H; PPh_2), 7.46–7.51 ppm (m, 6H; PPh_2); ^{31}P NMR (202 MHz, $CDCl_3$): $\delta = 13.38$ ppm (PPh_2); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 61.0$ (OCH_3), 83.6 (d, J = 24 Hz; $CHPPh_2$), 89.8 (d, $J = 10$ Hz; $C_{Cr}H$), 107.2 (d, $J = 19$ Hz; $C_{Cr}CHPPh_2$), 128.3–128.5 (m; C_{Ar}), 128.9, 129.5 (C_{Ar}), 132.2 (d, J = 15 Hz; C_{Ar}), 133.2 (d, $J = 19$ Hz; C_{Ar}), 135.2 (d, $J = 20$ Hz; C_{Ar}), 135.9 (d, $J = 15$ Hz; C_{Ar}), 233.6 ppm (CO); IR ($\tilde{\nu}_{max}$, CH_2Cl_2): 1967 (CO), 1882 (CO) cm^{-1}; MS(FAB): *m/z* (%): 898 (72) [M^+], 814 (100) [M^+−3 CO], 629 (38) [M^+−3 CO−PPh_2]; elemental analysis (%) calcd for $C_{51}H_{45}O_6P_3Cr$ (898.833): C 68.15, H 5.05; found: C 68.15, H 4.96.

Luminescence

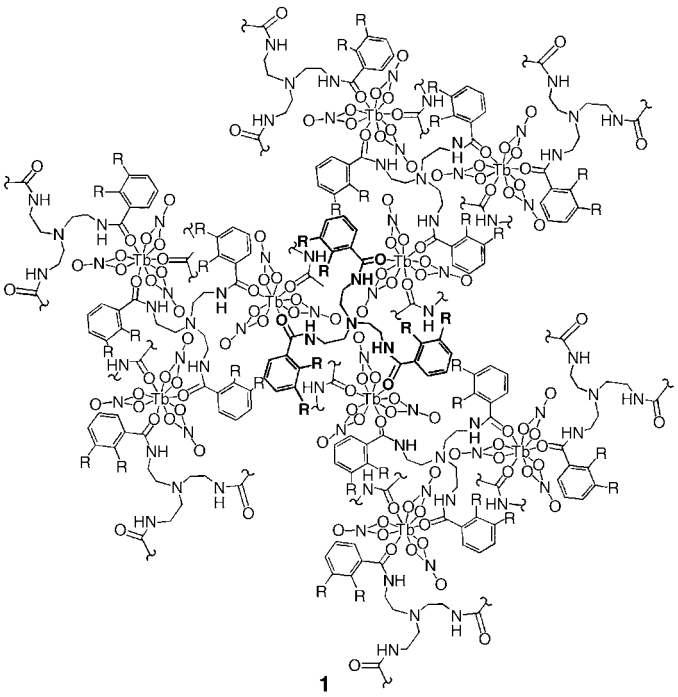
Simultaneous Observation of Green Multiphoton Upconversion and Red and Blue NLO Processes from Polymeric Terbium(III) Complexes**

Ka-Leung Wong, Ga-Lai Law, Wai-Ming Kwok, Wing-Tak Wong, and David Lee Phillips**

Photoexcitation at a certain wavelength in the near-infrared (NIR) region followed by luminescence at a shorter wavelength in the visible domain is called near-infrared-to-visible photon upconversion. This is a rather unusual process as low-energy photons are "converted" into higher energy photons: two or three photons of NIR light are required to generate one photon of visible light.[1] Nonlinear optics (NLO) is another mechanism that can lead to the generation of light at a frequency that is either twice or integral-multiples of the incident light.[2] The phenomena of two- or three-photon upconversion, and second or third harmonic generation (SHG or THG) on organic materials have received considerable attention since fluorescence detection became popular in applications such as photodynamic therapy, optical data storage, and microfabrication.[3]

Multiphoton excitation allows molecules that typically absorb in the UV region to be excited with red or NIR light. The photoluminescence processes from organolanthanide complexes are usually induced by an organic chromophoric ligand that absorbs incident light and transfers its resultant excitation energy to the lanthanide ion.[4] Until now, only a few multiphoton processes in organolanthanide complexes have been observed owing to the limitations of experimental measurements.[5] Although there have been reports on lanthanide complexes that display second harmonic generation, these have been limited and focused only on glassy doped lanthanide materials.[6] In recent years, our group[7] and others[8] have investigated several high-order multiphoton processes from organic ligands and metal complexes. Herein we report, to the best of our knowledge, the first observation of rare multiphoton upconversion emission from a lanthanide complex as well as SHG and THG transmission phenomena, which occur simultaneously from the same excitation source in the IR region at $\lambda \approx 1.26$ and 1.34 μm.

The N-tripodal ligand **L** was treated with terbium nitrate to give the complex $[Tb(\mathbf{L})(NO_3)_3]$ (**1**, see Figure 1), which is



1

Figure 1. Polymeric structure of complex **1**. Ligand **L** is highlighted in bold at the center of the structure. R = OCH_3.

thermally stable up to 300 °C, as shown by thermogravimetric analysis (see Supporting Information). Single crystals of **1** were isolated through the slow evaporation of a solution of **1** in THF/MeCN at room temperature over a few days. The crystal structure of **1** was determined by X-ray crystallography and is shown in Figure 2. The coordination geometry of the metal center in **1** can be described as a tricapped trigonal prism, in which each Tb^{3+} ion is coordinated by three carbonyl (amide) groups from three separate but identical tripodal ligands, and doubly coordinated by three nitrate ions. Upon complexation, the tripodal ligand adopts a polymetallic dendritic form, as the branches contain oxygen groups for binding with lanthanide ions. The ensemble of the tripodal ligand and its connectivity with the lanthanide ion, which itself is preorganized as a result of its coordination to three chromophores, forms a metallodendrimer. The metal takes on a "metal as ligand, metal as complex" approach in this dendritic architecture.[8]

Complex **1** exhibits both strong linear and nonlinear luminescence at room temperature and acts as the gain medium. The chromophores and complexes are known to absorb two or more photons ($\lambda_{ex} = 650$ and 800 nm) and be excited to higher energy states with further energy transfer to the terbium center to produce green f–f emission (Figure 3a).[7] Ligand **L** shows upconversion emission in the blue region ($S_1 \rightarrow S_0$) upon three-photon absorption at $\lambda \approx 800$ nm and four-photon absorption at $\lambda \approx 1.26$ μm (see Supporting

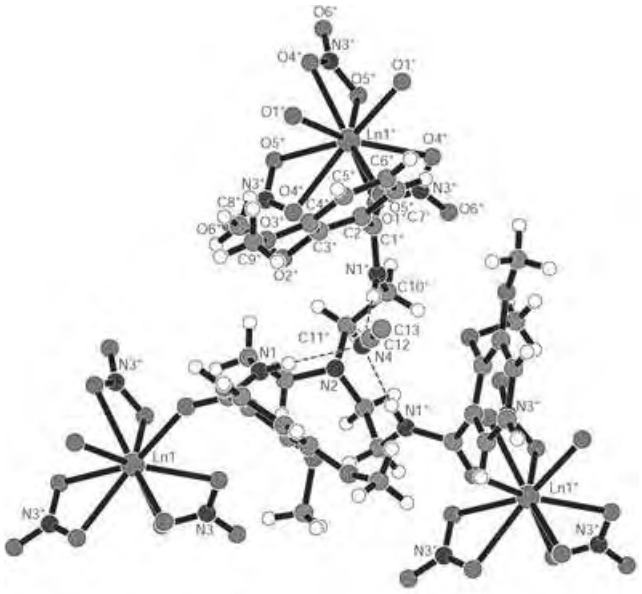

Figure 2. ORTEP drawing of **1** (Ln = Tb) and **2** (Ln = Gd).

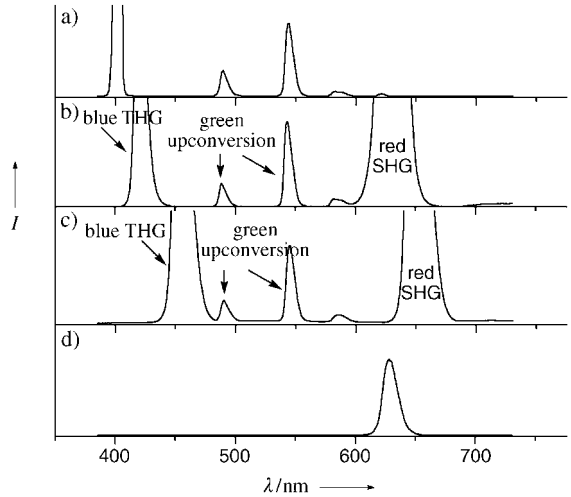

Figure 3. Spectra of the upconversion ($\lambda_{em} = 545$ nm, $^5D_4 \rightarrow {}^7F_5$) and NLO emissions produced upon multiphoton absorption in complex **1**: a) Three-photon upconversion ($\lambda_{ex} = 800$ nm); b, c) simultaneous green four-photon upconversion and red SHG and blue THG processes upon excitation at $\lambda \approx 1.26$ μm (b) and $\lambda \approx 1.34$ μm (c) with a NIR irradiation source; d) SHG spectrum of urea, which was used as the standard, upon excitation at $\lambda \approx 1.26$ μm with the NIR irradiation source.

Information). Complex **1** exhibits a strong multiphoton absorption when excited by ultrashort laser pulses at $\lambda \approx 1.26$ μm to produce the green structured upconversion emission bands of **1** that arise from the f–f transitions of the $^5D_4 \rightarrow {}^7F_J$ ($J = 6$–3) states of terbium. This upconversion process occurs simultaneously with two other nonlinear processes, namely SHG and THG, to generate two additional colors, blue and red, under the same excitation process in the NIR region (Figure 3b). Furthermore, by adjusting the wavelength and intensity of the source, the second and third color elements can be continuously tuned around $\lambda \approx 1.34$ μm, while the green upconversion is still detected (Figure 3c). From the observed behavior, the complexes seem to be extremely wavelength-sensitive and provide an effective tunable system. The red SHG effect can be visually observed as it is the more dominant process, however, a suitable filter can be used to cut-off the red SHG emission while the green upconversion and blue THG are still observed.

The ligand and complex appeared to have no linear absorption in the spectral range from 400 nm to 1.34 μm. However, the blue and green upconversion luminescence from both the ligand and the lanthanide complex can be seen under excitation at $\lambda = 1.26$ and ≈ 1.34 μm when generated by a Ti:sapphire laser. The chromophore absorbs at $\lambda \approx 330$ nm (30303 cm^{-1}), [7] which indicates that the absorption of at least four photons is required for upconversion upon excitation at $\lambda \approx 1.26$ μm (7937 cm^{-1}) and ≈ 1.34 μm (7462 cm^{-1}), whereas for the ligand the accumulation of more than three photons is needed upon excitation at $\lambda \approx 1.34$ μm to reach its lowest emitting state for upconversion emission. The Soga equation[9] is used in auxiliary to verify these SHG, THG, and upconversion processes (Figure 4a–d). The gradients

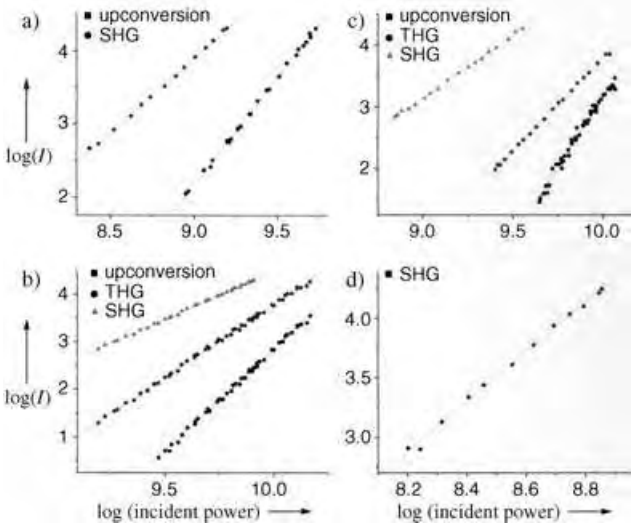

Figure 4. Power dependence of the emission intensities of a) three-photon upconversion ($\lambda_{ex} = 800$ nm) and b), c) four-photon upconversion ($^5D_4 \rightarrow {}^7F_5$), SHG, and THG processes in **1** upon excitation at $\lambda \approx 1.26$ μm (b) and $\lambda \approx 1.34$ μm (c); d) spectrum of SHG of urea as standard ($\lambda_{ex} \approx 1.26$ μm).

obtained for logarithmic plots of incident power versus intensity are 4.28 (Figure 4b, $\lambda_{ex} = 1.26$ μm) and 4.51 (Figure 4c, $\lambda_{ex} = 1.34$ μm). These double-logarithmic representations are therefore in good agreement with the multiphoton-upconversion processes, while the slopes in Figure 4b and c for the THG and SHG processes are 3 and 2, respectively, in the region of $\lambda \approx 1.26$ and ≈ 1.34 μm and agree with the theoretical values of photons needed.

The suggested energy-transfer diagram for the various multi-NLO processes of the Tb complex **1** is shown in Figure 5. For upconversion: First, the energy provided from either a visible or NIR pulse promotes the ligand from the ground state S_0 to a higher energy excited singlet state S_i after absorption of four photons. Then, the electrons in S_i return to

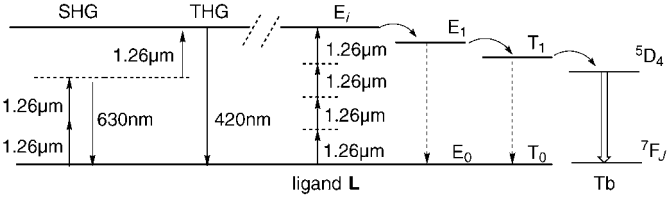

Figure 5. The proposed energy-transfer diagram for the various processes (four-photon upconversion, SHG, THG) in **1**. E_i is a higher energy singlet excited state; E_1 is the radiative lower energy singlet excited state; T_1 is the lowest energy triplet excited state; E_0 and T_0 both refer to the ground state. Linear arrows indicate radiative energy-transfer processes; curly arrows represent nonradiative energy-transfer processes.

the lowest energy excited singlet state S_1 and further, through intersystem crossing, to the lowest energy triplet excited state T_1. This mechanism was further supported by the energies of the S_1 and T_1 states determined for the Gd complex [Gd(**L**)-$(NO_3)_3$] (**2**).[4a,10] As a result of the ligand being attached to a heavy-metal ion such as terbium, the rate of intersystem crossing ($S_1 \rightarrow T_1$) is enhanced.[11] Finally, the electrons from the ligand T_1 state transfer their excess energy to Tb^{III} through either nonresonant phonon-assisted energy transfer or resonant energy transfer, which leads to promotion of Tb^{III} to the $^5D_4$ state. Finally, Tb^{III} relaxes to the ground-state ^7F_J configuration and emits its characteristic green luminescence. Meanwhile, the mechanism for the two other NLO processes involves direct accumulation of two or three photons for SHG and THG, respectively, to result in the two other emissions (red and blue) in the visible region (Figure 5).

We previously reported crystallographic details for a ligand that is similar to **L** but differs in its mode of coordination to Tb to consequently give rise to a different center of symmetry. Only green multiphoton upconversion was observed in that particular system (see Supporting Information). Therefore, the geometry and symmetry of the complex, as controlled by the configuration of coordination of the chromophore to Tb, together with the exceptional properties of the chromophore bring about this unique multiphoton process.

In summary, we have reported tunable second and third harmonic generation with simultaneous indirect multiphoton-upconversion-sensitized luminescence processes in a terbium complex. This phenomenon occurs when the Tb^{III} center has an appropriate symmetry center and is sensitized with a suitable organic ligand. Complex **1** appears to be a very good system for multiple-photon nonlinear photoluminescence and may be useful in future designs of new multiphoton materials. The novel simultaneous multiphoton processes described here may allow the further development of organolanthanide complexes as probe molecules.

Experimental Section

N-[2-(bis{2-[(2,3-dimethoxybenzoyl)amino]ethyl}-amino)ethyl]-2,3-dimethoxybenzamide (**L**) was prepared according to a reported method.[12]

1: $Tb(NO_3)_3 \cdot 6H_2O$ (47 mmol) and **L** (141 mmol) were dissolved in methanol (15 mL), and the mixture was allowed to heat at reflux for 24 h to give complex **1** (62%). Single crystals of **1** were obtained by slow evaporation of a solution of **1** in THF/MeCN. Elemental analysis: calcd for $C_{33}H_{42}N_7O_{18}Tb$: C 40.28, H 4.27, N 9.97; found: C 40.29, H 4.26, N 9.96; FAB-MS: *m/z*: 797 $[M-3NO_3]^+$, 645 $[M-3NO_3-Tb]^+$. Crystal data for **1**·MeCN: $C_{35}H_{45}N_8O_{18}Tb$, $M=1024.71$, trigonal, $P3c1$, $a=10.877(1)$, $c=21.360(2)$ Å, $V=2188.5(3)$ Å^3, $T=298$ K, $Z=2$, $\mu(Mo_{K\alpha})=16.94$ cm^{-1}, 13728 reflections measured, 1960 unique, 1468 observed reflections [$I>1.5\sigma(I)$] were used in all of the calculations, $R=0.0977$, $R_w=0.0822$. Although the crystal data were not of high quality, the crystal structure is essentially isomorphous with the Gd complex **2** and other complexes of **L** with the middle members of the lanthanide series.

2: $Gd(NO_3)_3 \cdot 6H_2O$ (47 mmol) and **L** (141 mmol) were dissolved in methanol (15 mL), and the mixture was heated at reflux for 24 h to give **2** (66%). Single crystals of **2** were obtained by slow evaporation of a solution of **2** in THF/MeCN. Elemental analysis: calcd for $C_{35}H_{45}N_7O_{18}Gd$: C 41.06, H 4.40, N 9.57; found: C 41.08, H 4.41, N 9.58; FAB-MS: *m/z*: 792 $[M-3NO_3]^+$, 643 $[M-3NO_3-Gd]^+$. Crystal data for **2**·MeCN: $C_{35}H_{45}N_7O_{18}Gd$, $M=1023.03$, trigonal, $P3c1$, $a=10.885(1)$, $c=21.403(2)$ Å, $V=2196.1(3)$ Å^3, $T=298$ K, $Z=2$, $\mu(Mo_{K\alpha})=15.95$ cm^{-1}, 13901 reflections measured, 1497 unique, 1468 observed reflections with [$I>2\sigma(I)$] were used in all of the calculations, $R=0.0963$, $R_w=0.0871$. CCDC 258846 (**1**) and 258847 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

The 800-nm pump source was generated from the fundamental of a femtosecond mode-locked Ti:Sapphire laser system (output beam: ≈150-fs duration and 1-kHz repetition rate). The 1.26–1.34 μm pump wavelengths were generated from a homebuilt optical parametric amplifier, which was pumped by the SHG of the 800-nm femtosecond pulses.[13] The lasers were focused to a spot size of ca. 50 μm by means of a lens ($f=10$ cm) onto the sample. The emitting light was collected with a backscattering configuration into a 0.5-m spectrograph and detected by a liquid-nitrogen-cooled CCD detector.

Controlled Radical Polymerization

Effective Cobalt Mediation of the Radical Polymerization of Vinyl Acetate in Suspension**

*Antoine Debuigne, Jean-Raphaël Caille, Christophe Detrembleur, and Robert Jérôme**

Controlled radical polymerization (CRP)[1] is a common technique for the synthesis of (co)polymers with well-defined molecular parameters (M_n, M_w/M_n), reactive end groups, composition, and architecture. Radical polymerization of a variety of monomers can be controlled by three mechanisms: nitroxide-mediated polymerization (NMP),[2] atom-transfer radical polymerization (ATRP),[3] and radical addition/fragmentation chain-transfer (RAFT).[4] However, control of the radical polymerization of vinyl acetate remains a concern, even though substantial progress by degenerative chain transfer,[5] ATRP,[6,7] and RAFT based on xanthates[8,9] and dithiocarbamates[10] has been reported. Additional effort needs to be devoted to this issue, because vinyl acetate can be polymerized only by a radical process and poly(vinyl acetate) (PVAc) is widely used, for example, as precursor of the water-soluble and otherwise inaccessible poly(vinyl alcohol).[11] Therefore, molecular engineering of PVAc and development of suitable techniques are of utmost importance for the production of novel polymeric materials.

Controlled radical polymerization is most often carried out in bulk or in solution in organic solvents. However, the use of water as dispersion medium may have a number of advantages, including better control of heat transfer, absence of volatile organic solvents, fast polymerization, and possibly high monomer conversion and production of high molar mass polymers. For all these reasons, ever-increasing attention is being paid to the extension of CRP to heterogeneous polymerization techniques, that is, suspension, emulsion, and miniemulsion polymerization.[12–14]

Recently, we reported a system based on cobalt acetylacetonate [$Co(acac)_2$] that imparts control to the radical polymerization of vinyl acetate initiated by 2,2′-azobis(4-methoxy-2,4-dimethyl valeronitrile), V-70, in the bulk at 30 °C.[15] The molar mass of poly(vinyl acetate) indeed changes linearly with monomer conversion, in good agreement with the predicted values (Table 1, entry 1). Moreover, the polydispersity is as low as 1.2. These observations are consistent with a mechanism based on reversible addition of the growing radicals to the cobalt complex and establishment of an equilibrium between alkylcobalt(III) and cobalt(II) complexes, that is, the dormant and the active species, respectively (Scheme 1). A similar mechanism was previously proposed for acrylate polymerization mediated by cobalt porphyrin[16–18] and cobaloxime complexes.[19]

Because of the advantages of using water as a continuous phase, cobalt-mediated radical polymerization of vinyl acetate was tentatively conducted in suspension in water. Therefore, in addition to [$Co(acac)_2$] and V-70, water and a poly(vinyl alcohol-*co*-vinyl acetate) dispersant (0.16 wt% in water) were added to vinyl acetate to give a dispersion in water of the azo initiator (V-70) and the monomer (Scheme 2). Under these conditions, the cobalt-mediated radical polymerization of vinyl acetate remains controlled, as assessed by the clear increase of the molar mass with monomer conversion (Table 1, entry 2). In parallel, the polydispersity increases rapidly with monomer conversion (from 1.3 to 2.35), and the experimental molar masses exceed the theoretical values calculated from the [VAc]/[$Co(acac)_2$] molar ratio, which indicates a loss of control as the polymerization progresses. The poor solubility of the [$Co(acac)_2$] complex in the organic phase (vinyl acetate) is thought to be the reason for the low polymerization efficiency ($M_{n,theor}$/

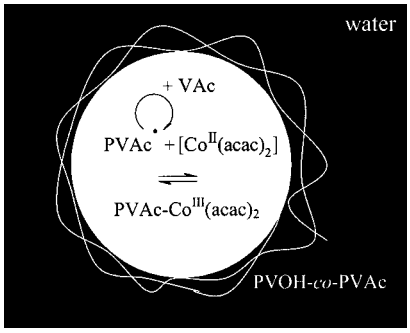

Scheme 2. Equilibrium between dormant and active species within vinyl acetate droplets in suspension polymerization.

$M_{n,SEC}$). The partition coefficient of the cobalt complex between vinyl acetate and water was determined by weighing the solid residue left by each liquid phase after decantation. The concentration of $[Co(acac)_2]$ in water was ten times higher than in the monomer, consistent with the color of the aqueous phase, which had the typical purple color of $[Co(acac)_2]$. That only a small part of the cobalt complex is available in the monomer droplets is confirmed by the polymerization kinetics. Plots of $\ln([M]_0/[M])$ versus time are shown in Figure 1 for bulk and suspension CRP of vinyl acetate. The induction period is much shorter for suspension polymerization (3 h) than for bulk polymerization (19 h). Because this period is the time required for the growing radicals to add to the cobalt complex with formation of dormant species (Scheme 1), the shorter induction time qualitatively agrees with the smaller amount of cobalt in the monomer phase in suspension polymerization.

To increase the polymerization efficiency and to restrict the extent of irreversible termination, the concentration of the cobalt complex in the organic phase must be increased to increase the amount of dormant species (Scheme 2). For this purpose, suspension polymerization of vinyl acetate was initiated by a poly(vinyl acetate) macroinitiator, end-capped by $[Co^{III}(acac)_2]$ and preformed in the bulk, in the presence of the cobalt complex and V-70, at low monomer conversion. This prereacted mixture, which consists of poly(vinyl acetate) chains in unconverted monomer, was merely poured

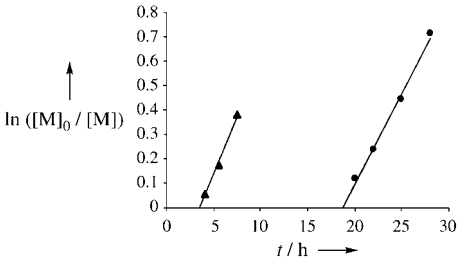

Figure 1. Plot of $\ln([M]_0/[M])$ versus time for the vinyl acetate polymerization initiated by V-70 in the presence of $[Co(acac)_2]$ at 30 °C in bulk (●) and in suspension in water (▲) (Table 1).

into an aqueous solution of poly(vinyl alcohol-*co*-vinyl acetate) under vigorous stirring at 30 °C. According to this strategy, the $[Co(acac)_2]$ complex, covalently bonded as an end group to the dormant chains, is located in the vinyl acetate droplets, that is, where it must be present to efficiently mediate the polymerization. This technique was tested at two $[VAc]/[Co(acac)_2]$ molar ratios (Table 2). Under these conditions, the molar mass increases with reaction time, and the molar mass distribution is rather narrow ($M_w/M_n = 1.2$–1.4), even at high monomer conversion (90%; Table 2, Figure 2). As expected, compared to suspension polymerization in the presence of $[Co(acac)_2]$, the use of a PVAc-$Co(acac)_2$ macroinitiator results in a much higher efficiency ($M_{n,theor}/M_{n,SEC} \approx 0.7$; see entry 2 in Table 1 and data in Table 2). Dependence of the molar mass on monomer conversion is linear, and the molecular weight of PVAc is dictated by the $[VAc]/[PVAc\text{-}Co(acac)_2]$ molar ratio, as is the case for a controlled process. Figure 3 illustrates the shift of the size exclusion chromatogram with polymerization time. Importantly, very high molecular weight PVAc with a rather low polydispersity ($M_{n,SEC} = 100000$ g mol^{-1}, $M_w/M_n = 1.40$, Table 2, entry 2) can be prepared. Moreover, the cobalt-mediated polymerization of vinyl acetate in suspension is very fast at low temperature (30 °C) and is quasicomplete 2 h after addition of the prereaction mixture to the aqueous solution of dispersant. Indeed, the slope of monomer conversion versus time

PVOH-*co*-PVAc in water (0.16 wt%). 1) 22 h of prepolymerization in bulk, [VAc]/[Co] 542:1. 2) 14 h of prepolymerization in bulk, [VAc]/[Co] 1084:1. [b] t_0: time of addition of the prepolymerized VAc to a PVOH-*co*-PVAc aqueous solution, VAc/H_2O 2.5:3 (v/v). [c] Monomer conversion was determined gravimetrically after removal of the unconverted monomer in vacuo. [d] Determined by SEC with PS calibration. [e] $M_{n,theor} = ([M]_0/[Co]_0) \times M_{mono} \times$ conv.

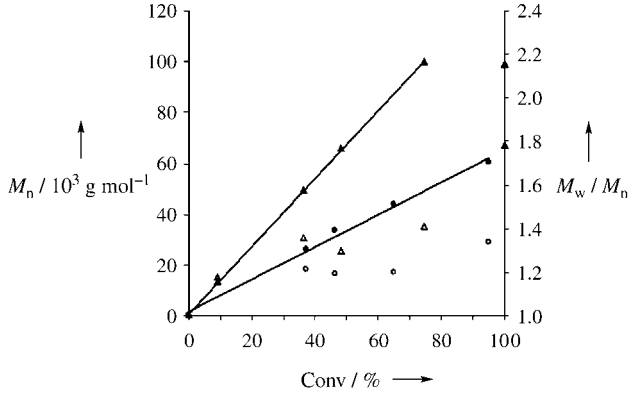

Figure 2. Dependence of M_n (filled symbols) and M_w/M_n (open symbols) on monomer conversion for VAc polymerization initiated at 30 °C by a low molar mass poly(vinyl acetate) macroinitiator in suspension in water (Table 2). VAc/H_2O = 5:6 (v/v), PVOH-*co*-PVAc in water (0.16 wt%). ●: $M_{n,SEC}$ for [Co(acac)$_2$]/[V-70]/[VAc] 1:3.25:542; ▲: $M_{n,SEC}$ for [Co(acac)$_2$]/[V-70]/[VAc] 1:3.25:1084; ○: M_w/M_n for [Co(acac)$_2$]/[V-70]/[VAc] 1:3.25:542; △: M_w/M_n for [Co(acac)$_2$]/[V-70]/[VAc] 1:3.25:1084.

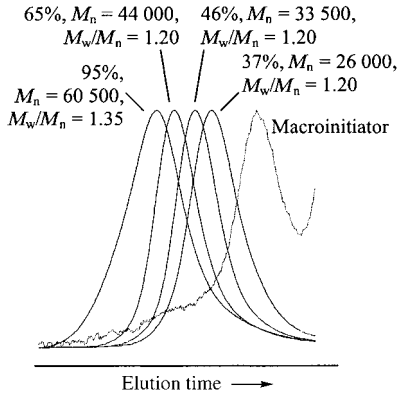

Figure 3. Size exclusion chromatograms for poly(vinyl acetate) initiated by PVAc oligomers end-capped by [Co(acac)$_2$] at 30 °C in the presence of water and PVOH-*co*-PVAc (0.16 wt%) as stabilizer. [Co(acac)$_2$]/[V-70]/[VAc] 1:3.25:542 (Table 2, entry 1).

increases drastically when the prepolymerized medium is poured into water (Figure 4). This spectacular increase in polymerization rate may be attributed to the diffusion of [Co(acac)$_2$] from the monomer droplets to the aqueous phase, which induces a shift of the equilibrium towards the active species (Scheme 2). Finally, poly(vinyl acetate) beads, with a diameter in the millimeter range, are obtained at high monomer conversion, as observed by optical microscopy (Figure 5).

For the first time, the radical polymerization of vinyl acetate can be easily controlled in suspension in water to give poly(vinyl acetate) with predictable molecular weight and low polydispersity up to very high molecular weight and high monomer conversion. Because the reactivity of vinyl acetate is comparable to that

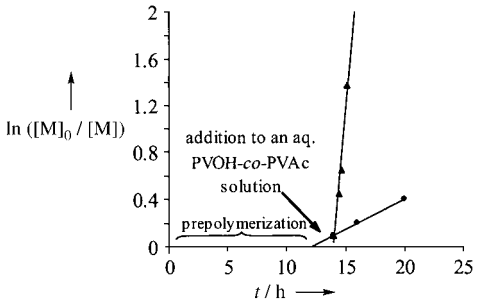

Figure 4. Conversion versus time for VAc bulk polymerization initiated by V-70 in the presence of [Co(acac)$_2$] at 30 °C (●) on addition of the polymerization medium at 10% conversion to an aqueous solution of PVOH-*co*-PVAc (▲; Table 2, entry 2). [Co(acac)$_2$]/[V-70]/[VAc] 1:3.25:1084.

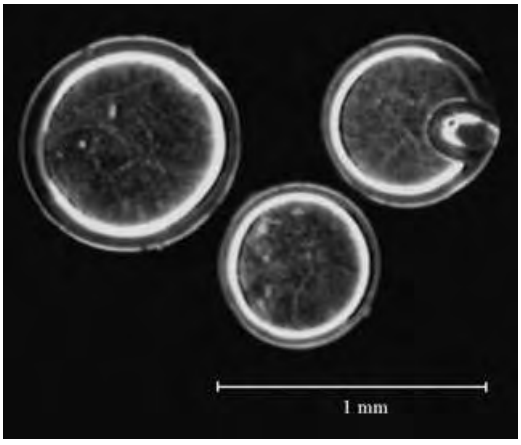

Figure 5. Poly(vinyl acetate) beads prepared by cobalt-mediated polymerization of VAc initiated by a low molar mass PVAc macroinitiator in the presence of water and a PVOH-*co*-PVAc dispersant at 30 °C (Table 2, entry 1, 95%).

of vinyl chloride, this new process will be extended to the radical polymerization of vinyl chloride in the near future.

Experimental Section

Materials: Vinyl acetate (>99%, Acros) was dried over calcium hydride, degassed by several freeze/thaw cycles, distilled under reduced pressure, and stored under argon. Doubly distilled water was degassed by several freeze/thaw cycles. Cobalt(II) acetylacetonate ($[Co(acac)_2]$, >98%, Merck), poly(vinyl alcohol-*co*-vinyl acetate) (72.5% hydrolyzed, Alcotex), and 2,2′-azobis(4-methoxy-2,4-dimethyl valeronitrile) (V-70, Wakko) were used as received. Size exclusion chromatography (SEC) was carried out in THF (flow rate: 1 mL min^{-1}) at 40°C with a Waters 600 liquid chromatograph equipped with a 410 refractive-index detector and styragel columns (four columns HP PL gel 5 μL 10^5 Å, 10^4 Å, 10^3 Å, 10^2 Å). Polystyrene (PS) standards were used for calibration. The molar mass of PVAc determined by SEC with PS calibration was in good agreement with that determined by ^{1}H NMR whenever the α end group of the initiator ($-OCH_3$ at $\delta = 3.13$ ppm) could be observed and compared to the $-CHOCOCH_3$ proton at $\delta = 4.8$ ppm of the monomer unit. An optical microscope (Zeiss) was used to observe the PVAc beads.

Cobalt-mediated radical polymerization of vinyl acetate in the bulk: $[Co(acac)_2]$ (25.7 mg, 10^{-4} mol) and V-70 (100 mg, 3.25×10^{-4} mol) were added to a glass tube capped by a three-way stopcock. The reactor was purged by three vacuum/argon cycles before addition of vinyl acetate (5 mL, 542×10^{-4} mol). The reaction mixture was heated in an oil bath thermostatically controlled at 30°C. No polymerization occurred for a few hours, after which the viscosity increased. Samples were withdrawn at different reaction times, and the vinyl acetate conversion was determined by weighing the polymer collected on removal of the unconverted monomer in vacuo at 50°C.

Cobalt-mediated radical polymerization of vinyl acetate in suspension in water: $[Co(acac)_2]$ (78 mg, 3×10^{-4} mol) and V-70 (300 mg, 9.75×10^{-4} mol) were added to a glass tube capped by a three-way stopcock. The reactor was purged by three vacuum/argon cycles before vinyl acetate (15 mL, 1626×10^{-4} mol) was added. Then known volumes (2.5 mL) of the purple reaction mixture were added to a degassed aqueous solution of PVOH-*co*-PVAc (3 mL, 0.16 wt%) in several round-bottom flasks, previously purged by argon and containing a magnetic stirrer. All these flasks were heated in an oil bath thermostatically controlled at 30°C with vigorous stirring (1000 rpm). Samples were taken from the flasks at different reaction times, the monomer conversion was determined gravimetrically as descibed above, taking into account the amount of water and stabilizer.

Cobalt-mediated radical polymerization of vinyl acetate initiated by a PVAc macroinitiator in suspension in water: $[Co(acac)_2]$ (78 mg, 3×10^{-4} mol) and V-70 (300 mg, 9.75×10^{-4} mol) were added to a glass tube capped by a three-way stopcock. The reactor was purged by three vacuum/argon cycles before vinyl acetate (15 mL, 1626×10^{-4} mol) was added. The flask was heated to 30°C for a few hours, during which the color turned green-brown. Samples (2.5 mL) of this reaction mixture were added to a degassed aqueous solution of PVOH-*co*-PVAc (3 mL, 0.16 wt%) in several round-bottom flasks, previously purged with argon. All these flasks were heated in an oil bath thermostatically controlled at 30°C with vigorous stirring (1000 rpm). At high monomer conversion, PVAc beads were collected by filtration, washed with water, and dried in vacuo.

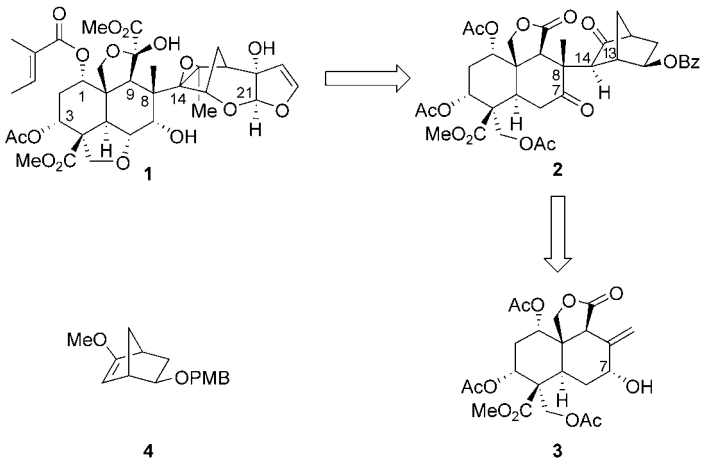
Natural Products Synthesis (1)

Studies toward the Synthesis of Azadirachtin, Part 1: Total Synthesis of a Fully Functionalized ABC Ring Framework and Coupling with a Norbornene Domain**

K. C. Nicolaou, Pradip K. Sasmal, A. J. Roecker, Xiao-Wen Sun, Sunil Mandal, and Antonella Converso*

We recently embarked on a program directed towards the total synthesis of azadirachtin (**1**, Scheme 1), the remarkable



Scheme 1. Retrosynthetic analysis of azadirachtin (**1**).

antifeedant agent isolated from the Neem tree[1] and currently in use as an insecticide.[2] Our radical-based approach towards this unusually challenging target molecule (see Scheme 1) was validated by a number of model studies,[3–5] which, however, left much to be desired in terms of functionalities on the crowded decalin system of the natural product. Herein we report the total synthesis of a fully functionalized ABC decalin intermediate **3** and its coupling with a suitable norbornene system **4** to afford a C7–C13 linked product, which was elaborated into the advanced intermediate **2** and whose structural disposition might allow its eventual conversion into azadirachtin (**1**). In the following Communication in this issue,[6] we describe both the total synthesis and semisynthesis of a different decalin intermediate and its elaboration into a close precursor of the target molecule, as well as some interesting reactions made possible by the special proximity effects that uniquely characterize the azadirachtin structural motif.[7]

According to our previously disclosed strategy,[3–5] azadirachtin (**1**) was to be approached through a path marked by key intermediates such as **2**, **3**, and **4** as retrosynthetically outlined in Scheme 1. Crucial to the success of such a plan is the availability of fully functionalized advanced decalin systems such as **3**, which have the potential to yield azadirachtin upon coupling with norbornene derivatives such as **4** followed by appropriate elaboration.

The fundamental strategy for the synthesis of the norbornene precursor **4** has already been reported in a previous Communication.[5] The construction of the fully functionalized decalin system **3** in its enantiomerically pure form is depicted in Scheme 2. Thus, starting from enantiopure compound **5**,[5] ketone **6** was produced by dibenzylation (for abbreviations and conditions, see legends in schemes) followed by desilylation and Swern oxidation of the resulting secondary alcohol. Ketone **6** was then converted into enone **7** in 81% overall yield for the three-step sequence with a regioselectivity of approximately 10:1. Subsequent functionalization of **7** by Mander carboxylation[8] followed by aldol reaction of the resulting β-ketoester with paraformaldehyde in the presence of $Yb(OTf)_3$ led to the corresponding hydroxyester, whose hydroxy group was protected as a TBS ether (69% yield for three steps). Subsequent epoxidation of the enone moiety of the so-obtained intermediate by TBHP in the presence of triton B furnished, stereoselectively, epoxide **8** in 87% yield. The required 1,3-diaxial diol system within the growing substrate was established first by regioselective opening of the epoxide moiety of **8** (91% yield) with PhSeNa (generated in situ from PhSeSePh and $NaBH_4$)[9] and then stereoselective reduction ($NaBH_4$) of the intermediate hydroxyketone to afford the desired compound **9** in 63% yield. Selective removal of the TBS group, peracetylation, debenzylation, and finally, regioselective monoprotection of the primary alcohol of the resulting diol as a TES ether yielded alcohol **10** in 74% yield over four steps. The hydroxy compound **10** was then oxidized with DMP, and the resulting ketone was olefinated with $Ph_3P=CH_2$ prior to removal of the TES group in the presence of catalytic DDQ.[10] The primary alcohol was then oxidized to the corresponding aldehyde **11** (once again with DMP) in 65% overall yield over the four steps. The targeted coupling partner **3** was finally obtained from the latter intermediate **11** in 48% overall yield,[11] by the following sequence: 1) oxidation with $NaClO_2$, 2) exposure to ethanolic HCl (0.5 M), and 3) allylic oxidation with SeO_2 and TBHP.

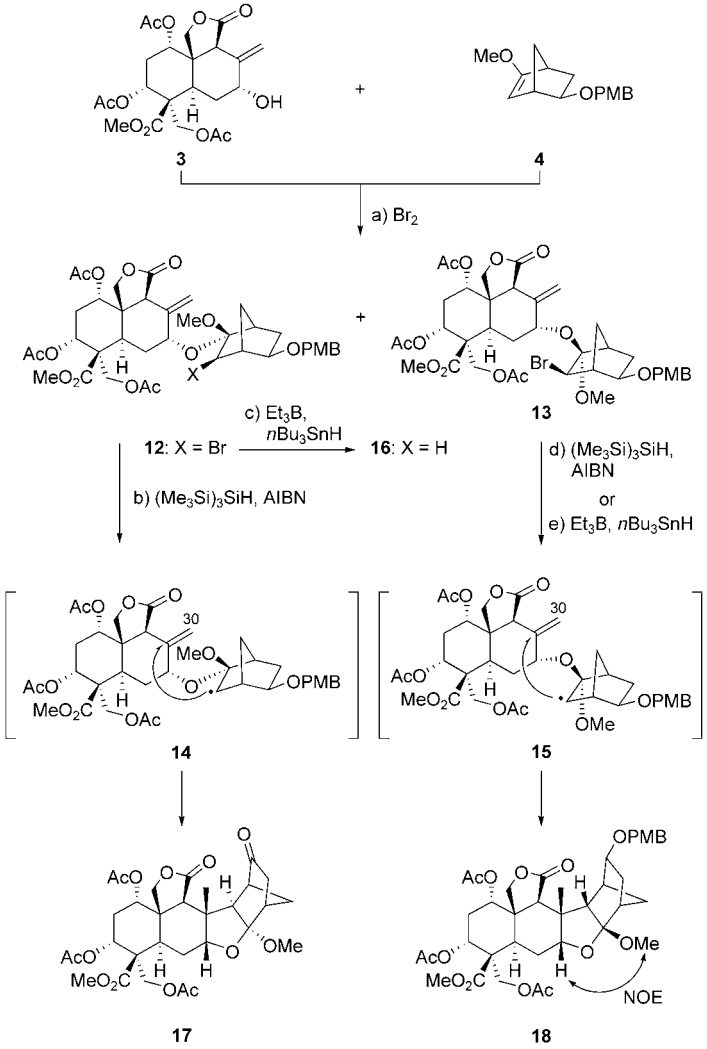
With **3** in hand, we were now poised to test the key bromoketalization[12] reaction between this substrate and norbornene enol ether **4**, a reaction that had shown rather capricious behavior during our previous model studies. Upon considerable experimentation, it was found that the optimum conditions for this coupling required addition of Br_2 to norbornene derivative **4** in CH_2Cl_2 at −78 °C followed by the sequential addition of *N*,*N*-dimethylaniline and allylic alcohol **3**, and warming slowly to 0 °C. Chromatographic resolution of the rather complex mixture of products led to the isolation and characterization of two diastereomeric bromoketals (ca. 1:1 ratio, 80 % combined yield), whose NMR spectroscopic analysis revealed structures **12** and **13** (Scheme 3). The ratio of the two isomers was found to be dependent on reaction time, temperature, and, apparently, on the steric environment around the attacking allylic alcohol moiety, since previous[4,5] and subsequent[6] experiments with other decalin allylic alcohol substrates led to different results. Scheme 4 provides a possible explanation for these results by invoking an oxonium ion intermediate **4b** derived from the rupture of the initially formed bromonium ion **4a** as the temperature is raised to 0 °C. Attack on oxonium ion **4b** from the *exo* face is now possible, and leads to the formation of the *epi*-C13 bromoketal (azadirachtin numbering) **4d** (Scheme 4) or **13** (Scheme 3).

Both bromoketals **12** and **13** were subjected to radical cyclization conditions[13] to afford the desired hexacyclic products **17** and **18** (Table 1) in 70 and 76 % yield, respectively (Scheme 3). The structures and stereochemistries of **17** and **18** were unambiguously assigned by NMR spectroscopy (^{1}H,^{13}C-COSY, ROESY, and HMQC). Interestingly, only compound **13** generated the desired polycycle **18** upon treatment with nBu$_3$SnH–Et$_3$B[14] at room temperature, whereas compound **12** gave, exclusively, reduction to **16**. This observation suggests that, while the radical formed from **12** (i.e. **14**) requires higher temperature to access the appropriate transition state for ring closure, the radical obtained from **13** resides in a more privileged position to attain the required transition state for cyclization, which apparently takes place even at ambient temperature.

Interestingly, the primary radicals initially formed from **14** and **15** only undergo the 5-*exo*-trig mode of ring closure. The alternative 6-*endo*-trig mode of reaction is also available in principle and, indeed, is observed with other substrates, as we shall describe in more detail in the following Communication in this issue.[6] In the present instance the secondary radical thus formed through the action of $(Me_3Si)_3SiH$–AIBN undergoes ring closure, leading to a primary radical, which in turn undergoes an intramolecular 1,5-H shift (see 30-H (azadirachtin numbering) in structures **14** and **15**) to afford ketone **17**, in the case of **14**, or undergoes an intermolecular quench to yield PMB ether **18** in the case of **15**.

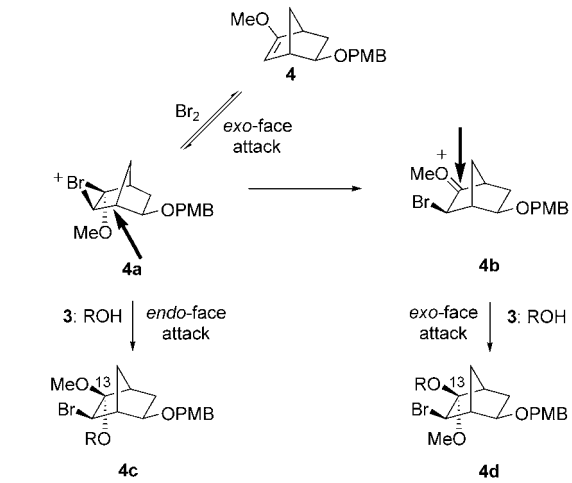
The stereochemistry of the newly generated stereogenic centers within **18** was confirmed by ^{1}H NMR NOE studies (see Scheme 3). As further proof of its structure, compound **17** was also constructed from the previously synthesized[5] intermediate **19** as shown in Scheme 5. Thus, **19** was converted into compound **20** by protection as a BOM ether, desilylation, and oxidation under Swern conditions. Regioselective unsa-



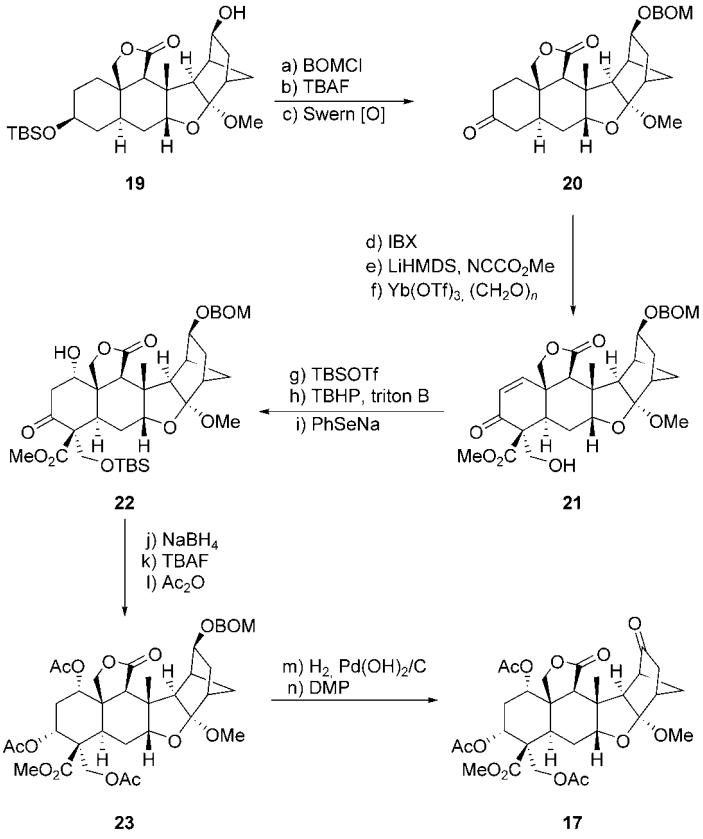
Scheme 3. Coupling of decalin system **3** with norbornene derivative **4** and synthesis of hexacyclic compounds **17** and **18**. Reagents and conditions: a) Br_2 (1.5 equiv), *N*,*N*-dimethylaniline (2.0 equiv), **4** (2.0 equiv), CH_2Cl_2, −78 °C, 10 min; then **3**, −78→0 °C over 2 h, 0 °C, 1 h, **12** (38%) and **13** (42%); b) $(Me_3Si)_3SiH$ (2.0 equiv), AIBN (1.0 equiv), toluene (0.007 M), 110 °C, 30 min, 70%; c) Et_3B (5.0 equiv), nBu_3SnH (5.0 equiv), CH_2Cl_2, 25 °C, 1 h, 80%; d) $(Me_3Si)_3SiH$ (2.0 equiv), AIBN (1.0 equiv), toluene (0.007 M), 110 °C, 30 min, 76%; e) Et_3B (5.0 equiv), nBu_3SnH (5.0 equiv), CH_2Cl_2, 25 °C, 1 h, 80%. AIBN = 2,2′-azobisisobutyronitrile.

turation of ketone **20** with IBX,[15] followed by sequential treatment with LiHDMS/$NCCO_2Me$ and $Yb(OTf)_3/(CH_2O)_n$, furnished hydroxyenone **21**, whose protection with TBS, stereoselective epoxidation, and reductive epoxide opening (PhSeNa, 81% over two steps) led to β-hydroxyketone **22**. Following stereoselective reduction (30%) of **22** with $NaBH_4$, desilylation and then peracetylation of the resulting triol afforded triacetate **23**. Finally, hydrogenolysis of the BOM protecting group from intermediate **23** followed by oxidation with DMP furnished the desired hexacyclic ketone **17**, whose spectroscopic and chromatographic properties matched those of a sample obtained from the more convergent and expedient route depicted in Scheme 3.

In the final phase of this study, it was important to demonstrate the cleavage of the temporary bridge that was so

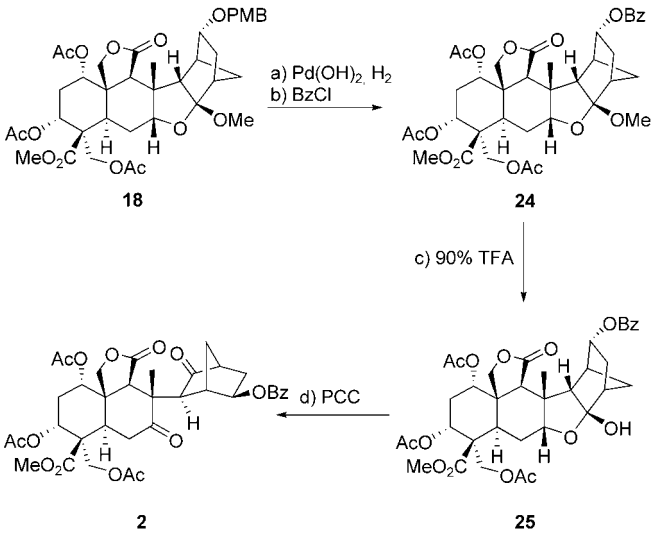


Scheme 4. Proposed mechanism for bromoketalization of **3** and **4**.



Scheme 5. Construction of hexacyclic compound **17** from **19**. Reagents and conditions: a) BOMCl (5.0 equiv), iPr_2NEt (10 equiv), DMF, 40 °C, 24 h, 96%; b) TBAF (2.0 equiv), THF, 25 °C, 12 h, 94%; c) $(COCl)_2$ (2.0 equiv), DMSO (3.0 equiv), Et_3N (4.0 equiv), −78→25 °C, CH_2Cl_2, 1 h, 74%; d) IBX (1.5 equiv), DMSO, 65 °C, 36 h, 75%; e) LiHMDS (1.5 equiv), $NCCO_2Me$ (1.2 equiv), HMPA (1.5 equiv), THF, −78 °C, 3 h, 65%; f) $(CH_2O)_n$ (5.0 equiv), $Yb(OTf)_3$ (2.0 equiv), THF, 25 °C, 1 h, 72%; g) TBSOTf (1.1 equiv), 2,6-lutidine (2.0 equiv), CH_2Cl_2, −78 °C, 1 h, 90%; h) triton B (2.0 equiv), aqueous TBHP (70%; 10 equiv), THF, 25 °C, 16 h; i) PhSeNa (3.0 equiv), EtOH, 25 °C, 4 h, 81% over two steps; j) $NaBH_4$ (8.0 equiv), THF, 25 °C, 30 min, 30%; k) TBAF (1.5 equiv), THF, 0→25 °C, 1 h; l) Ac_2O (6.0 equiv), Et_3N (10 equiv), DMAP (0.4 equiv), CH_2Cl_2, 25 °C, 6 h, 80% over two steps; m) $Pd(OH)_2/C$ (20%; 10 wt%), H_2 (1 atm), EtOH, 25 °C, 1 h; n) DMP (2.0 equiv), CH_2Cl_2, 0→25 °C, 2 h, 90% over two steps. BOM = benzyloxymethyl, IBX = *o*-iodoxybenzoic acid, HMPA = hexamethylphosphoramide.

instrumental in forming the challenging C8–C14 bond as a prelude to further advances toward azadirachtin. Towards this end, the hexacyclic compound **18** was first converted into the benzoate **24** (by protecting-group exchange through hydrogenolysis and benzoylation) and followed by hydrolysis to hemiketal **25** in 75% overall yield (Scheme 6). Finally, hemiketal **25** was oxidized with PCC to afford diketone **2** (Table 1) in 80% yield. Diastereomer **17** has not, as yet, been advanced further.



Scheme 6. Conversion of hexacyclic compound **18** into advanced pentacyclic intermediate **2**. Reagents and conditions: a) $Pd(OH)_2/C$ (20%; 10 wt%), H_2 (1 atm), EtOH, 25 °C, 1 h; b) BzCl (3.0 equiv), Et_3N (6.0 equiv), DMAP (0.1 equiv), CH_2Cl_2, 0→25 °C, 4 h; c) aqueous TFA (90%), 65 °C, 3 h, 75% over three steps; d) PCC (15 equiv), DCE, 65 °C, 16 h, 80%. Bz = benzoyl, TFA = trifluoroacetic acid, PCC = pyridinium chlorochromate, DCE = 1,2-dichloroethane.

The described chemistry provides solutions to a number of challenges posed by the decalin domain of azadirachtin (**1**) and brings the realization of the synthesis of this molecule within close range. In the following Communication in this issue,[6] we describe further studies that place this goal even closer, but from a different angle.

Studies toward the Synthesis of Azadirachtin, Part 2: Construction of Fully Functionalized ABCD Ring Frameworks and Unusual Intramolecular Reactions Induced by Close-Proximity Effects**

K. C. Nicolaou, Pradip K. Sasmal, Theocharis V. Koftis, Antonella Converso, Eriketi Loizidou, Florian Kaiser, A. J. Roecker, Constantinos C. Dellios, Xiao-Wen Sun, and Goran Petrovic*

In the preceding Communication in this issue[1] we described the total synthesis of a potential decalin precursor to azadirachtin (**1**),[2] its coupling to a suitable norbornene fragment **4** (Scheme 1), and the elaboration of the product to an advanced intermediate along the path to this synthetic target. Herein we report the total synthesis and semisynthesis from azadirachtin of a more advanced decalin system **3**, its coupling to the same norbornene fragment **4**, and the elaboration of the resulting product to an advanced intermediate for the total synthesis of azadirachtin (Scheme 1). This report also includes a number of unusual reactions induced by proximity effects and special steric factors highlighting the unique characteristics of the azadirachtin scaffold.

Having successfully synthesized tricyclic decalin system **5**, (Scheme 1) and explored its chemistry toward azadirachtin (**1**) as described in the preceding Communication,[1] we turned our attention to the more advanced tetracyclic decalin precursor **3**, which bears the tetrahydrofuran ring system of **1** within its structure. Our plan to synthesize the targeted intermediate **3** required key building block **6** (Scheme 2) as

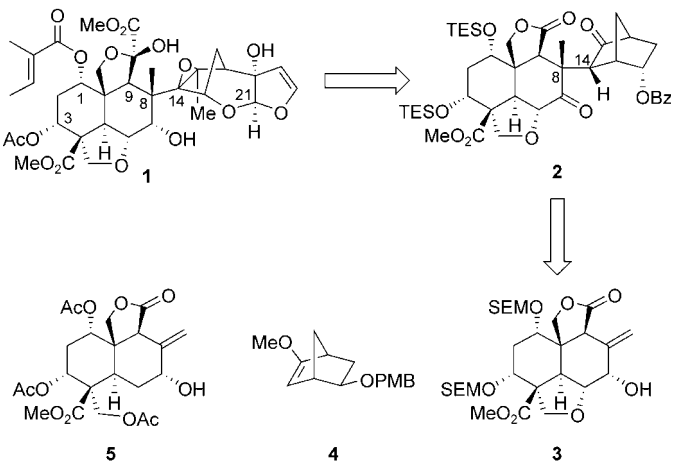
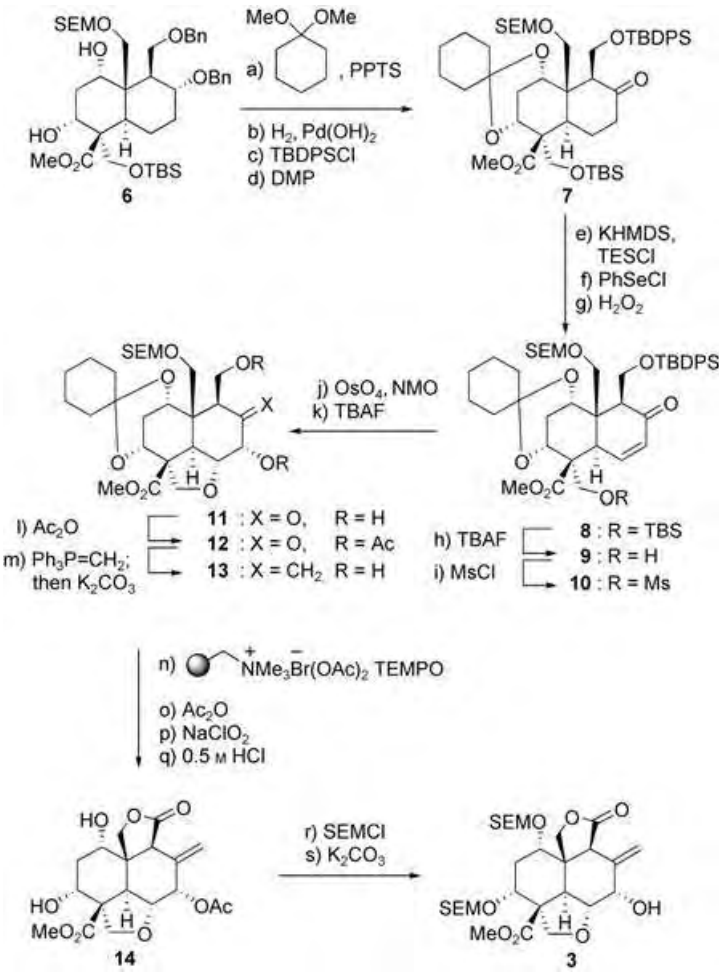


Scheme 1. Structure of azadirachtin (**1**) and possible precursors **3** and **5**.

the starting point, a compound that had been encountered as an enantiopure substance in our previous expeditions.[1] This diol **6** was first protected as a cyclohexanone ketal, the two benzyl protecting groups were cleaved, the resulting primary hydroxy group was selectively silylated, and finally the remaining secondary alcohol was oxidized with DMP to afford ketone **7** in 58% overall yield. Compound **7** was then converted into enone **8** by the standard, three-step protocol in 95% overall yield and thence into mesylate **10** via hydroxy compound **9** by desilylation followed by mesylation of the primary alcohol. The OsO_4–NMO-induced dihydroxylation of enone **10** proceeded stereoselectively from the less-hindered α face and was accompanied by internal S_N2-type mesylate displacement, affording the expected tetrahydrofuran derivative in 95% yield over two steps. Desilylation of the latter intermediate with TBAF furnished dihydroxyketone **11** in 96% yield. This substance was then converted into the exocyclic olefin **13** via its diacetate **12** (95%) by a Wittig reaction with $Ph_3P{=}CH_2$ (93%) followed by deacetylation with K_2CO_3 in MeOH (92%). This three-step process was adopted after encountering difficulties with the attempted, but failed, direct olefination of **11**. The primary alcohol of diol **13** was selectively oxidized to the corresponding hydroxyaldehyde through a TEMPO-catalyzed oxidation procedure (75%).[3] The remaining secondary hydroxy function was protected as an acetoxy group, and the aldehyde moiety was further oxidized to the acetate carboxylic acid. Exposure of the latter to 0.5 M ethanolic HCl gave the dihydroxylactone **14** through cleavage of both the ketal and the silyl protecting groups and ring closure (69% overall yield). Lactone **14** crystallized from CH_2Cl_2/hexanes as colorless crystals (m.p. 240–241 °C) and X-ray crystallographic analysis[4] confirmed the ring framework and stereochemical features of this compound (Figure 1). Finally, protection of both free hydroxy groups within **14** with SEMCl (89% yield) followed by treatment with K_2CO_3 in MeOH led to the coveted hydroxylactone **3** in 99% yield.



Scheme 2. Total synthesis of hydroxylactone **3**. Having completed the construction of hydroxylactone **3**, we then contemplated obtaining this same key intermediate

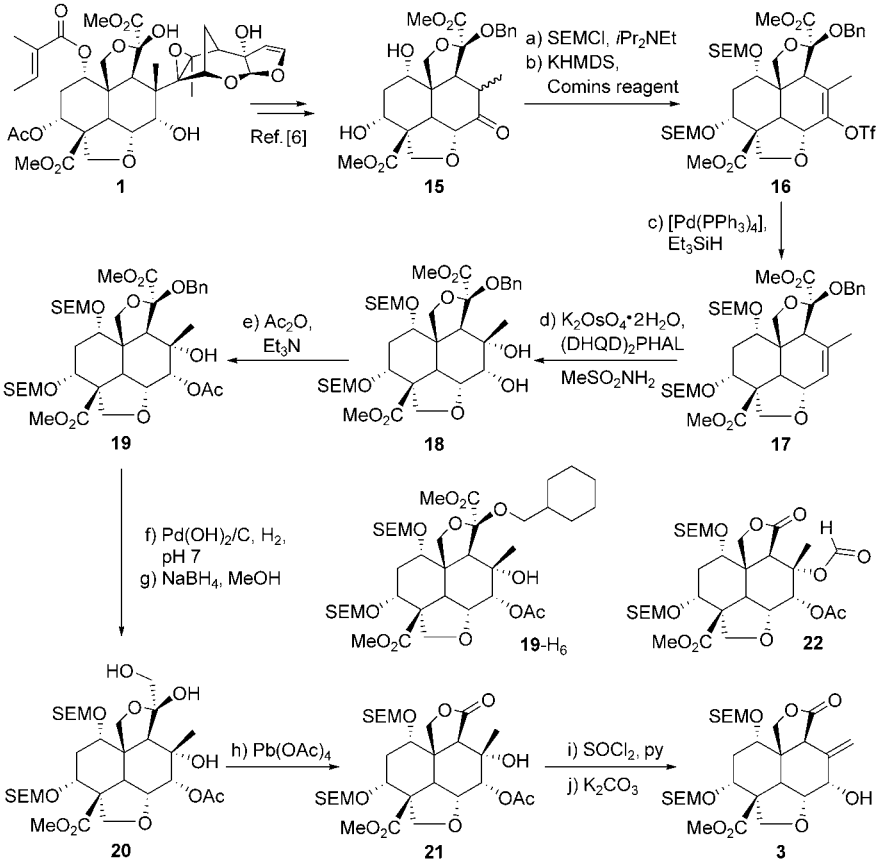
from the natural product **1** through semisynthesis. The aim of the degradation exercise of azadirachtin (**1**) to this key decalin fragment was not only to enrich our supplies of the target compound **2** for the purposes of our total synthesis efforts, but also to discover certain, unexpected or suspected, intricacies of the azadirachtin molecule that may be either of general interest or prove to be of some use in aiding our sail towards the natural product. In our search for an expedient route to **3** from **1** we made use of the work of Ley and coworkers,[5–7] who developed a four-step degradation sequence from **1** to **15**,[6] the tetracyclic compound that served as a beachhead for our expeditions (Scheme 3). Thus, the two hydroxy groups within **15** were protected as SEM ethers by reaction with SEMCl in the presence of iPr$_2$NEt, and the resulting bis-SEM-protected ketone was converted into olefin **17** by a regioselective transformation into the corresponding triflate **16** and then reduction of the latter compound with Et$_3$SiH in the presence of [Pd(PPh$_3$)$_4$] (47% overall yield for three steps). Manual molecular modeling suggested the α face of the double bond of **17** as the more accessible site, and this bias was greatly enhanced by the asymmetric dihydroxylation of this compound with K_2OsO_4 and (DHQD)$_2$PHAL in the presence of $MeSO_2NH_2$ in 96% yield, leading to 1,2-diol **18** as the exclusive product. Landing an acetate group on the secondary alcohol of **18** proved trivial, as treatment of this compound with Ac$_2$O, DMAP and Et$_3$N furnished monoacetate **19** (98% yield) as expected. Debenzylation of compound **19** required carefully controlled conditions (10% Pd(OH)$_2$/C, MeOH-H$_2$O, pH 7, H$_2$), otherwise an unusual reaction took place, namely the reduction of the benzene ring to afford the corresponding cyclohexylmethyl ether derivative **19**-H$_6$ (10% Pd(OH)$_2$/C, EtOH, H$_2$, 98% yield, **23**/**19**-H$_6$ ≈ 2.6:1). The origin of this remarkable mode of reactivity of benzyl ether derivative **19** remains unknown. Facilitated by the neighboring hydroxy group, the reduction with NaBH$_4$ of the carbomethoxy group of the debenzylation product derived from **19** proceeded smoothly to afford triol **20** in good yield. The Pb(OAc)$_4$-induced cleavage of the 1,2-diol system within **20** gave γ-lactone **21** in 70% overall yield from **19** for the three steps. Finally, exposure of **21** to SOCl$_2$ in the presence of pyridine led to the corresponding exocyclic olefin, which was treated with K$_2$CO$_3$ to give the targeted allylic alcohol **3** in 85% overall yield.



Scheme 3. Semisynthesis of hydroxylactone fragment **3** from **1**. Reagents and conditions: a) SEMCl (6.0 equiv), iPr$_2$NEt (12 equiv), nBu$_4$NI (4.0 equiv), CHCl$_3$, 60 °C, 8 h, 89%; b) Comins reagent (2.0 equiv), KHMDS (0.5 M in toluene, 2.0 equiv), THF, −78 °C, 30 min, 56%; c) [Pd(PPh$_3$)$_4$] (0.2 equiv), Et$_3$SiH (3.0 equiv), LiCl (3.0 equiv), DMF, 55 °C, 24 h, 95%; d) K_2OsO_4·H$_2$O (0.2 equiv), (DHQD)$_2$PHAL (0.5 equiv), K$_3$Fe(CN)$_6$ (3.0 equiv), $MeSO_2NH_2$ (1.0 equiv), K$_2$CO$_3$ (3.0 equiv), tBuOH/H$_2$O (3:2), 2 h, 96%; e) Ac$_2$O (5.0 equiv), Et$_3$N (10 equiv), DMAP (1.0 equiv), CH$_2$Cl$_2$, 0→25 °C, 8 h, 98%; f) Pd(OH)$_2$/C (1:1 w/w), H$_2$O/MeOH (1:2), pH 7, H$_2$, 25 °C, 2 h; g) NaBH$_4$ (10 equiv), MeOH, 0→25 °C, 4 h; h) Pb(OAc)$_4$ (2.0 equiv), CH$_2$Cl$_2$, 0 °C, 2 h, 70% over three steps; i) SOCl$_2$ (20 equiv), py, 0→25 °C, 8 h, 86%; j) K$_2$CO$_3$ (10 equiv), MeOH, 25 °C, 2 h, 99%. Comins reagent = 2-[*N*,*N*-bis(trifluoromethylsulfonyl)amino]-5-chloropyridine, DMF = *N*,*N*-dimethylformamide, (DHQD)$_2$PHAL = 1,4-bis(9-*O*-dihydroquinidinyl)phthalazine, py = pyridine.

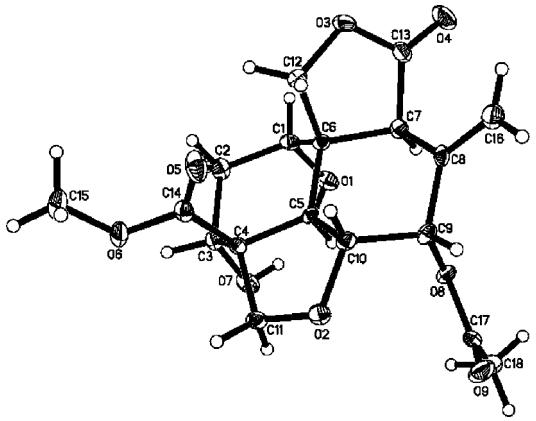


Figure 1. ORTEP drawing of **14** at the 30% probability level.

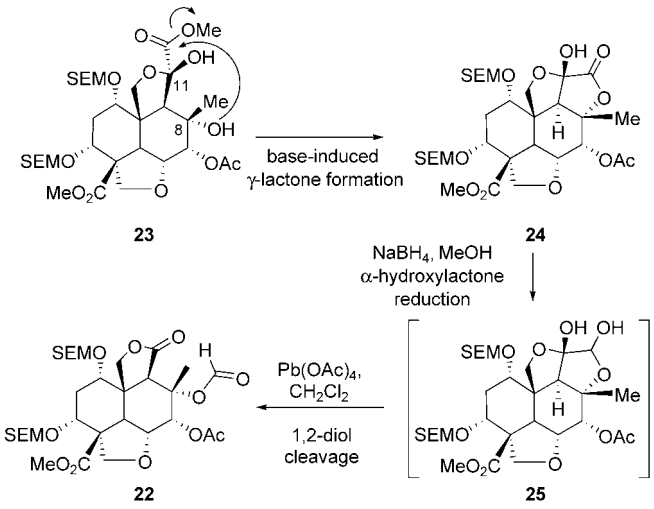
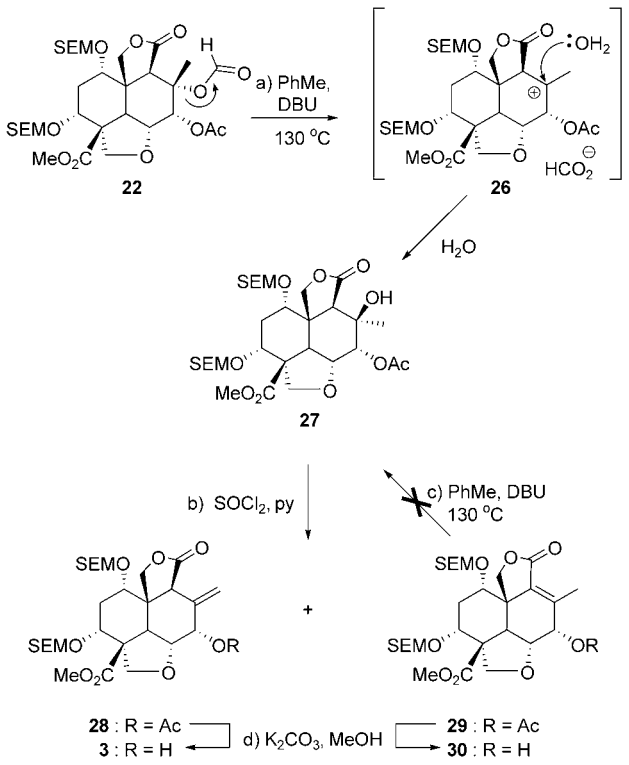
En route to allylic alcohol **3** from compound **19**, a noteworthy reaction was observed which led to a number of subsequent developments of equal interest. When the crude reaction mixture from hydrogenation of **19** was subjected to the intended reduction of the methyl ester with NaBH$_4$ followed by 1,2-diol cleavage with Pb(OAc)$_4$ on a large scale, the γ-lactone formate **22** was obtained, together with the desired γ-lactone alcohol **21** in approximately equimolar amounts and good overall yield. As shown in Scheme 4, we



Scheme 4. An unexpected $Pb(OAc)_4$-induced carbonyl migration and preparation of formate **22**. Reagents and conditions: $NaBH_4$ (10 equiv), MeOH, 0 °C→25 °C, 30 min; then $Pb(OAc)_4$ (10 equiv), CH_2Cl_2, 0→25 °C, 2 h, 95% over three steps.



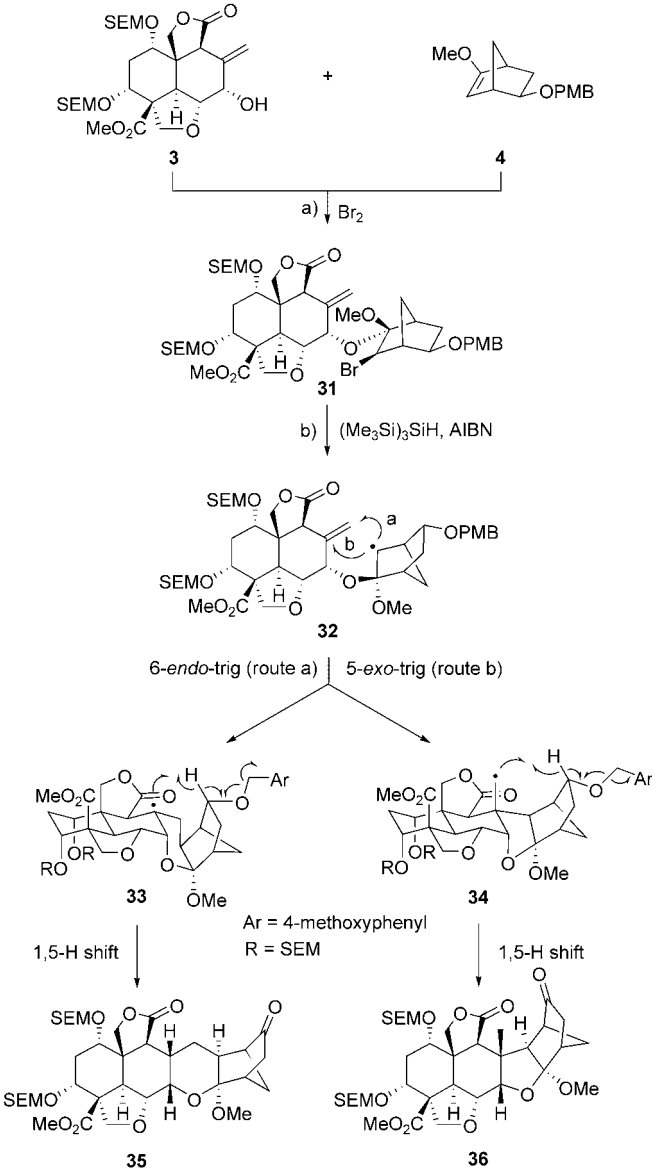
Scheme 5. An unexpected, DBU-induced inversion of configuration and preparation of 8-*epi* hydroxy compound **27** and allylic acetates **28** and **29**. Reagents and conditions: a) DBU (20 equiv), toluene, reflux, 4 h, 70%; b) $SOCl_2$ (20 equiv), py, 0→25 °C, 8 h, 71%; c) DBU (20 equiv), toluene, reflux, 10 h; d) K_2CO_3 (10 equiv), MeOH, 25 °C, 2 h, 99%. DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

hypothesized that this rather unusual outcome might be due to the propensity of the incipient diol **23** to form pentacyclic lactone **24** by attack of the C8 tertiary hydroxy group at the neighboring C11-carbomethoxy moiety with subsequent expulsion of a molecule of MeOH. Exposure of **24** to $NaBH_4$ would then result in the C11-OH-assisted reduction of the newly formed γ-lactone ring, yielding bis-hemiketal **25**, which could be oxidatively cleaved in the next step by $Pb(OAc)_4$ to give the observed formate lactone **22**. In support of this hypothesis we synthesized the postulated intermediate **24** from **23** and converted it exclusively into formate **22** by the proposed two-step sequence in 95% overall yield.

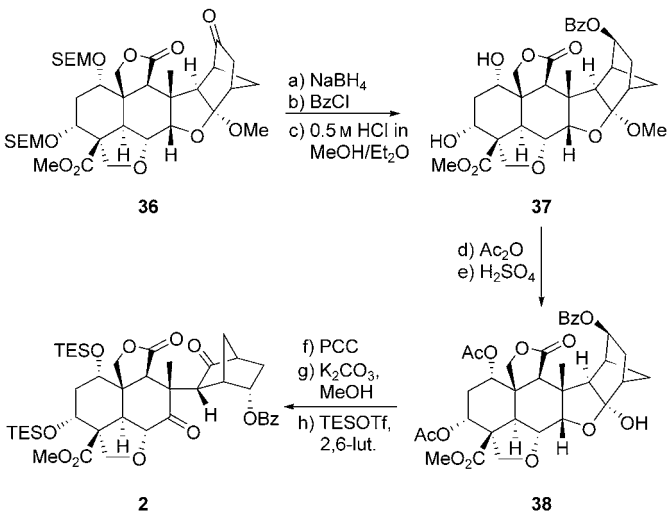
The fortuitous availability of formate **22** inspired a potential entry into the α,β-unsaturated γ-lactone series of decalin fragments (e.g. compound **30**, Scheme 5) as possible partners in coupling reactions with the norbornene-type precursors of azadirachtin (e.g. **4**). Thus, **22** was heated in refluxing toluene in the presence of DBU in the hope that the α,β-unsaturated lactone **29** would be obtained by elimination of the formate ester group (see Scheme 5). Instead, however, compound **27** was observed as the only product (70%). This C8-inverted tertiary alcohol **27** is presumably the product of ionization of the formate group to carbocation **26** followed by its immediate quenching by traces of moisture present in the reaction medium (**22**→**26**→**27**, Scheme 5). The nonpolar nature of the solvent employed (toluene) accounts for the observed inversion of configuration at C8, the tight ion pair formed between the decalin cationic domain and the leaving formate anion ensuring total blockade of the already hindered decalin α face. An alternative plausible mechanism, namely that involving stereoselective conjugate addition of water to an initially formed α,β-unsaturated γ-lactone (i.e. **29**, the compound targeted in the first place), has been ruled out by the failure of **29** to undergo addition of water upon exposure to the same reaction conditions. Unexpected as it was, the C8-*epi* alcohol **27** offers the only point of entry found so far, even after considerable experimentation, into the α,β-unsaturated γ-lactone series of decalin fragments. This was converted into **29** by exposure to $SOCl_2$ in the presence of pyridine in a reaction that also produced the exocyclic olefinic acetate **28** in a combined yield of 71% (**28**/**29** ≈ 2:1). Allylic alcohols **3** and **30**, obtained by treatment of this mixture with K_2CO_3 in MeOH, were conveniently separated by silica gel chromatography.

Allylic alcohol **3**, which was now available through two different routes, was then subjected to bromoketalization with norbornene derivative **4** under the conditions described in the preceding Communication[1] and remarkably afforded a single bromoketal **31** in 76% yield (Scheme 6).[10] It is interesting to recall that the bromoketalization of the previously employed decalin substrate **5**, which lacks the tetrahydrofuran system, led to a mixture of two diastereomeric bromoketals in approximately 1:1 ratio.[1] From this contrast, it is apparent that the distribution of the two isomers in these reactions is dictated not only by the reaction time and temperature, but also, and most profoundly, by the nature of the decalin partner.[8]

It was again found that $(Me_3Si)_3SiH$ served as an excellent H-atom donor in the radical-based cyclization of bromoketal **31**, yielding heptacyclic compounds **35** and **36** (Table 1) in 32 and 42% yield, respectively.[9] In this case, the secondary radical **32**, initially generated from **31**, underwent both the 6-*endo*-trig and the 5-*exo*-trig modes of ring closure,[8] thus leading to the tertiary and primary radicals **33** and **34**. These,



Scheme 6. Bromoketalization of hydroxylactone **3** with norbornene derivative **4** and elaboration of the product into **35** and **36**. Reagents and conditions: a) Br_2 (1.5 equiv), *N*,*N*-dimethylaniline (2.0 equiv), K_2CO_3 (10 equiv), **4** (2.0 equiv), CH_2Cl_2, −78 °C, 10 min; then **3**, −78→0 °C over 2 h, 0 °C, 1 h, 76%; b) $(Me_3Si)_3SiH$ (2.0 equiv), AIBN (1.0 equiv), toluene (0.007 M), 110 °C, 30 min, **35** (32%) **36** (42%); AIBN = 2,2′-azobisisobutyronitrile.

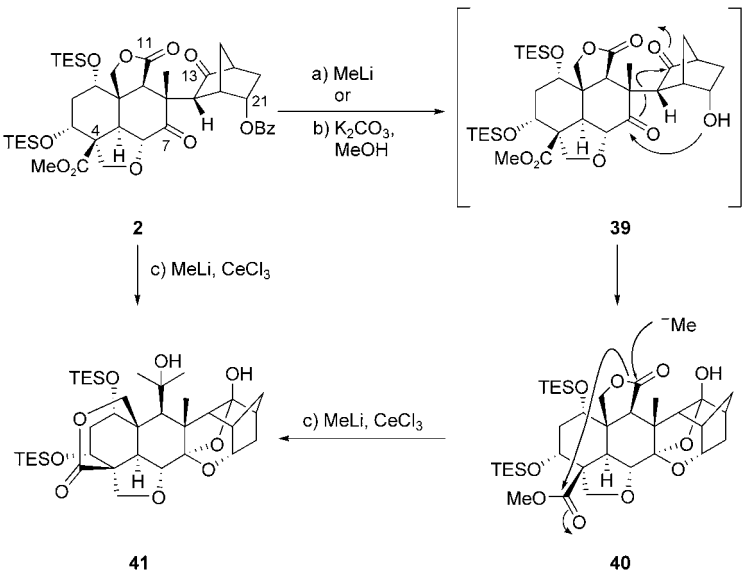


Scheme 7. Conversion of heptacyclic compound **36** into advanced system **2**. Reagents and conditions: a) $NaBH_4$ (5.0 equiv), MeOH, 0 °C, 15 min, 88%; b) BzCl (7.0 equiv), DMAP (5.0 equiv), pyridine, 60 °C, 5 h; c) 0.5 M HCl, MeOH/Et_2O (1:1), 0→25 °C, 6 h, 72% over two steps; d) Ac_2O (8.0 equiv), Et_3N (12 equiv), DMAP (0.4 equiv), CH_2Cl_2, 0→25 °C, 6 h, 79%; e) H_2SO_4 (5.0 equiv), CH_2Cl_2, 0 °C, 30 min; f) PCC (15 equiv), DCE, 65 °C, 16 h, 60% over two steps; g) K_2CO_3 (10 equiv), MeOH, 25 °C, 30 min; h) TESOTf (10 equiv), 2,6-lutidine (20 equiv), CH_2Cl_2, −78→25 °C, 24 h, 62% over two steps. Bz = benzoyl, PCC = pyridinium chlorochromate, DCE = 1,2-dichloroethane, OTf = trifluoromethanesulfonate.

in turn, undergo a 1,5-H shift (as shown in Scheme 6), to afford ketones **35** and **36**, respectively, upon oxidative cleavage of the PMB ether group. This behavior again reveals the controlling power of the decalin system in deciding the fate of these chemical species.

From the two intermediates **35** and **36**, only the latter is potentially productive in the campaign towards azadirachtin. To this end, we needed to demonstrate the facile cleavage of the temporary bridge that enabled the formation of the crucial C8–C14 bond in the first place. The heptacyclic ketone **36** (Scheme 7) was reduced with $NaBH_4$ in MeOH, exclusively from the *exo* side, to afford the corresponding alcohol, which was benzoylated and then desilylated under acidic conditions to furnish dihydroxy benzoate **37** in 63% overall yield. Exposure of diol **37** to Ac_2O, Et_3N, and DMAP gave the corresponding bisacetate (79% yield), which was subsequently converted into hemiketal **38**. Finally, oxidation of **38** with PCC, cleavage of the acetate group, and TES protection furnished diketone **2** (Table 1) in 37% yield for the four steps.

In the course of our drive towards azadirachtin (**1**), we became keenly, and sometimes painfully, aware of the unique behavior of this natural product due to the oxygen-rich nature of its skeleton and the close proximity of its numerous functional groups. In addition to the above-mentioned incidents, we consider it of interest to reveal one more example that speaks to this point. Scheme 8 shows the outcome of the reaction of diketone **2** with MeLi. It became apparent that initial loss of the benzoyl protecting group at C21 unmasked the secondary alcohol function, which was then in a position to attack the C7 carbonyl group, presumably forming a hemiketal. The existence of the latter compound was evidently transient under the reaction conditions, as a further ring closure ensued, this time on the C13 carbonyl carbon atom, to give the highly congested cagelike ketal/hemiketal **40** in 72% overall yield. Lactone **40** did not constitute the end of the journey in this cascade in the presence of $CeCl_3$. In this case, further attack by MeLi at the C11 lactone carbonyl function produced a free primary alcohol group, which was then able to reach across the decalin system to attack the C4 carbomethoxy residue to generate a second lactone ring with the expulsion of a methoxy group, furnishing, upon further addition of MeLi, the impressively



Scheme 8. Intriguing cascade sequences with azadirachtin-type scaffolds. Reagents and conditions: a) MeLi (5.0 equiv), Et_2O, −78 °C, 2 h, 72%; b) K_2CO_3 (10 equiv), MeOH, 25 °C, 36 h, 91%; c) MeLi (5.0 equiv), $CeCl_3$ (5.0 equiv), Et_2O, 0 °C, 8 h, 80%.

compact polycycle **41** in 80% overall yield from **2**. The stable ketal/hemiketal **40** was also the exclusive product (91% yield) of the reaction of benzoate **2** with K_2CO_3 in MeOH.

The described chemistry represents our most recent and important advancements toward the total synthesis of azadirachtin (**1**) and at the same time reveals some of the inner intricacies of this uniquely crowded and highly functionalized molecular architecture. Further progress towards congeners of azadirachtin is sure to be frustrated or facilitated by these intricacies.

Polymer Films

Environmentally Stable Super Water-Repellent Poly(alkylpyrrole) Films**

Hu Yan, Kazutomo Kurogi, Hiroyuki Mayama, and Kaoru Tsujii**

It is well-known that the wettability of a solid surface by a liquid is governed by two factors: a chemical component and a geometric component of the solid surface.[1] Super liquid repellency is crucially important in daily life and in industry. Several kinds of super water- or oil-repellent surfaces with contact angles larger than 150° have been realized by a combination of chemical and geometric approaches.[2–12] The main approach for the chemical factor is a coating of fluorinated compounds with low surface energy, whereas the geometric factor is governed by the formation of fractal or rough surface structures.

In nature the leaves of some plants, such as the lotus, show super water repellency only by the geometric factor.[13] The surface of the leaf is geometrically a fractal, but chemically is a wax composed mainly of fatty acid esters and alcohols. The legs of water striders also show super water repellency by the geometric factor only.[14]

The alkylketene dimer (AKD) surface, which geometrically is a fractal with a dimension of 2.29 but chemically is just a wax, is only one artificial super water-repellent surface with a large contact angle, in this case 174°.[2,3] A series of studies on the AKD fractal structures provide much insight into the theoretical origins of the super water repellency that occurs in nature in plant leaves or insects. The AKD surface, however, has the drawback of poor durability from the standpoint of practical applications. The AKD surface is environmentally weak, mainly because it is soluble in organic solvents and its melting point is as low as 67 °C.[3] Therefore, creation of environmentally stable super water-repellent surfaces which do not contain any fluorinated compounds but are geometrically rough or fractal structures is crucially significant, from both the academic and practical aspects.

Conductive polymers have attracted great attention because of their unique electrical properties and the easy synthesis of film-shaped products coupled with good thermal stability.[15–17] Therefore, the synthetic methods are well-established.[18,19] Conventionally, conductive polymers are electrochemically synthesized as films with various surface features according to the reaction conditions.[19] Therefore, in principle, conductive polymer films with a fractal structure or rough morphology are easily synthesized by simple optimization of the reaction conditions. Kossmehl et al. reported poly(2,2′-bithienyl-5,5′-diyl) (PBT) layers, which were synthesized by an electrochemical method and showed super water repellency and good thermal stability.[20,21] Herein, we report on super water-repellent poly(alkylpyrrole) films (contact angle larger than 150°), which showed excellent environmental stability to both temperature and organic solvents or oils.

The electrochemical polymerization of alkylpyrrole was performed in a beaker by using two electrodes (Figure 1; see

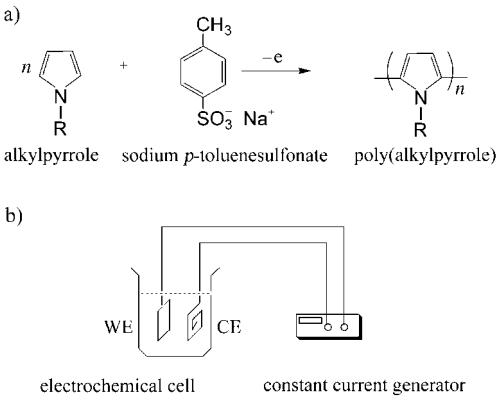

Figure 1. a) Chemical structures of monomeric alkylpyrrole, sodium *p*-toluenesulfonate electrolyte, and the polymer produced; b) setup of the electrochemical synthesis (WE = working electrode, CE = counter electrode).

Experimental Section). Figure 2 shows the poly(alkylpyrrole) film that was electrochemically synthesized with 1-*n*-octadecylpyrrole and sodium *p*-toluenesulfonate as monomer and electrolyte, respectively. "Needle"-like poly(alkylpyrrole) structures grew perpendicularly to the surface of the indium tin oxide (ITO) electrode. Thousands of the poly(alkylpyrrole) needles, which were approximately 5 μm in diameter and 40 μm in length, were arrayed in an orderly manner on the surface of the ITO electrode. The needle-shaped array is similar to an array of polyacrylonitrile nanofibrils previously reported by Feng et al.[8] However, these nanofibril arrays were fabricated by using a template. The surface of the array of polyacrylonitrile nanofibrils showed super water repellency, with a contact angle larger than 150°. Martin et al. first reported the template-guided electrochemical synthesis of an array of polypyrrole microtubes by using a porous poly-

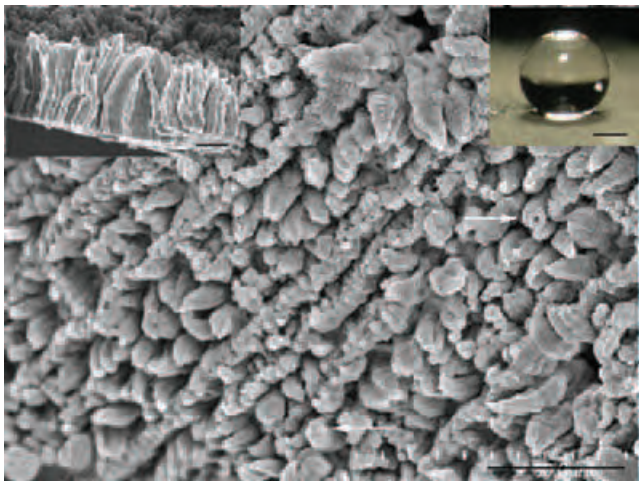

Figure 2. Scanning electron microscopic (SEM) image of the super water-repellent poly(alkylpyrrole) film (scale bar: 15 μm). Left inset: SEM image of the cross section of the film (bar: 15 μm). Right inset: digital camera image of a water droplet on the film (bar: 500 μm). The synthetic conditions were as follows: 1-*n*-octadecylpyrrole/*p*-toluenesulfonate (10:1 molar ratio); 1-*n*-octadecylpyrrole (0.005 mol dm^{-3}); reaction time, 60 min; applied voltage, 22.5 V; working electrode, ITO glass.

carbonate membrane as a template.[22] In the work described herein, the poly(alkylpyrrole) array grew without any template and, on close inspection, the single needle-like poly(alkylpyrrole) structures may be microtubes (arrows in Figure 2). Qiu et al. previously reported that microtube-like polypyrrole is formed in the electrochemical polymerization of pyrrole without template materials.[23] Recently Yan et al. also independently reported the formation of polypyrrole microtubes during the electrochemical polymerization of pyrrole without a template.[24–26] However, in these two cases, the microtubes do not array in an orderly and dense fashion, and the diameters and lengths are much larger than those reported herein.[22–25] Therefore, we believe that our work is the first to show an array of needle-like or capped microtubes of conductive polymer that was electrochemically synthesized without a template. The features of the array indicate that it should show super water repellency in principle, as in the case of polyacrylonitrile nanofibrils.[9] Furthermore, the array should show high stability to heating and organic solvents, because conductive polymers normally consist of long-range-conjugated aromatic rings which are thermally stable and poorly soluble in the usual organic solvents.[19]

Actually, the surface of the poly(alkylpyrrole) film showed super water repellency with a contact angle larger than 150° (right inset of Figure 2). The surface of a cross section of the poly(alkylpyrrole) film was subjected to a preliminary analysis by a box counting method,[2,3] and was found to be a fractal with a dimension of 2.23 (left inset of Figure 2).

The reaction conditions such as concentration and molar ratio of the reactants, applied voltage, reaction time, and working electrode significantly influence the surface structure, that is, the water repellency of the poly(alkylpyrrole) film. Detailed results will be reported elsewhere.

The influence of treatment temperature on the wettability was systematically investigated to evaluate the thermal stability of the films in terms of contact angle to water (Figure 3). The contact angle of the film was nearly constant

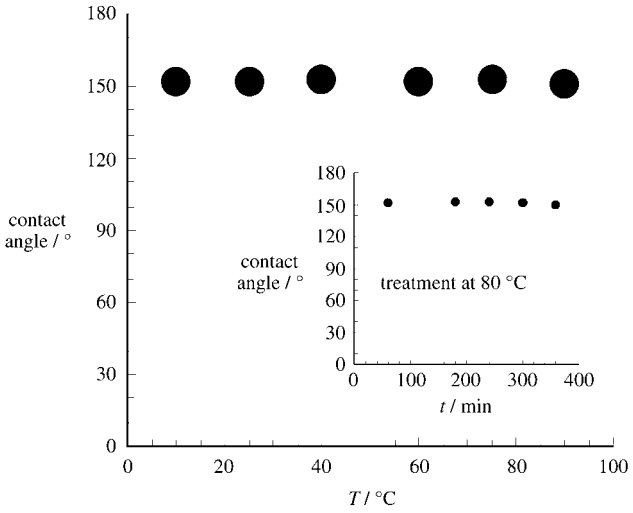

Figure 3. Thermal stability of the super water-repellent poly(alkylpyrrole) film treated at various temperatures for 2 h. The inset shows the thermal stability of a film treated at 80 °C for various treatment times.

even when the temperature was increased. The inset of Figure 3 shows the effects of the treatment time at 80 °C on the film. Similarly, the contact angle of the film was also nearly constant when the treatment time was increased. Poly(alkylpyrrole) is one of the conductive polymers that usually consist of aromatic rings and conjugated π bonds on the main polymer chain. Therefore, the polymer has enough thermal stability of chemical composition in the experimental range of temperature and treatment time. The needle-like shape of the poly(alkylpyrrole) structures may also have high thermal stability, similar to the case of polypyrrole microtubes.[26] We consider that the high thermal stability of the film in terms of contact angle can be explained by the thermally stable chemical and geometric factors (see Supporting Information).

Similarly, the influence of treatment with organic solvents and oils on the wettability was systematically investigated to evaluate the durability of the films to these substances in terms of contact angle to water. Figure 4 shows the effects of various organic solvents and oils on the water repellency of the film. The contact angle of the film did not change even after treatment. On the basis of the dark color of the film, the poly(alkylpyrrole) could be a doped conductive polymer, which usually consists of conjugated π bonds with π electrons that are delocalized on the main polymer chains.[19] Doped conductive polymers are normally insoluble in any organic solvents.[19] Therefore, the film has sufficient durability of chemical composition and morphology when treated with organic solvents and oils. We consider that the durability of the film in terms of contact angle can also be explained by the highly stable chemical and geometric factors.

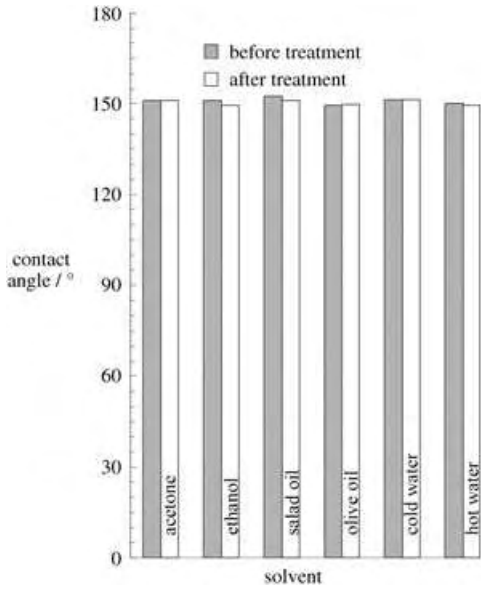

Figure 4. Durability of the super water-repellent poly(alkylpyrrole) film on treatment with organic solvent and oil. See text for the treatment conditions.

In conclusion, we have succeeded in the electrochemical synthesis of super water-repellent poly(alkylpyrrole) films with a contact angle larger than 150°. The SEM images show that the surface of the film consists of a perpendicular alignment of thousands of "needle"-like poly(alkylpyrrole) structures. On the basis of a preliminary analysis by a box counting method, the surface was considered to be a fractal with a dimension of 2.23. In contrast to AKD, the super water-repellent poly(alkylpyrrole) films had excellent environmental stability to both heating and organic solvent treatments in terms of the contact angle to water. These results may be of considerable significance as both fundamental and industrial guiding principles. Moreover, the feature of the film which consists of a vertical alignment of needle-like conductive polymer can be extended to nanotechnological or biotechnological applications, such as electronic devices[22] and substrates for cell culture.[27]

Experimental Section

Synthesis of poly(alkylpyrrole) films: The electrochemical synthesis was performed in a two-electrode cell containing an acetonitrile solution of alkylpyrrole and sodium *p*-toluenesulfonate, by using a constant-current generator (Yokogawa programmable DC source) at room temperature (Figure 1). The alkylpyrrole chosen was 1-*n*-octadecylpyrrole. Synthesis was carried out under the following conditions: working electrode, ITO glass; 1-*n*-octadecylpyrrole (5 mmol); sodium *p*-toluenesulfonate (0.5 mmol); applied voltage, 22.5 V; reaction time, 60 min. The films obtained were extensively washed with acetonitrile to eliminate reactants, and finally dried overnight at room temperature under reduced pressure. The reaction conditions were optimized in terms of contact angle of the film to water by changing the concentrations and molar ratios of alkylpyrrole and sodium *p*-toluenesulfonate, and the applied voltage, time, and working electrode.

Environmental stability of the films in terms of contact angle: Thermal stability was evaluated by treating the films at various temperatures for 2 hours. After the thermal treatments the contact angles were measured at room temperature. The treatment at 80 °C, however, was carried out for various treatment times. The durability to organic solvents or oils was evaluated by immersing the films in an organic solvent and then drying at 80 °C under a reduced pressure. The oils were placed on the films, which were then washed with acetone and finally dried as above. The contact angle was measured on the dried films.

SEM and contact angle measurements: Scanning electron microscopy (SEM) of the films was carried out with a field-emission SEM (Hitachi S-5200) after covering them with a thin layer of sputtered alloy of gold and palladium. The contact angles of the films to water droplets ($\approx$1 mm in diameter) were measured with an optical contact angle meter (Kyowa DropMaster) at room temperature and humidity.

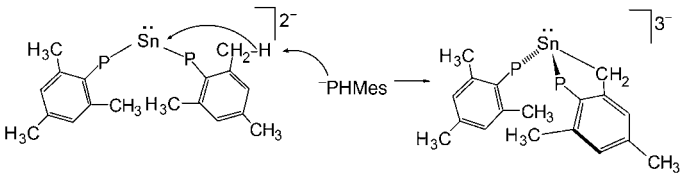
P,N Ligands

Quadruple Deprotonation of 2-Aminophenylphosphane with a p-Block-Metal/Alkali-Metal Base**

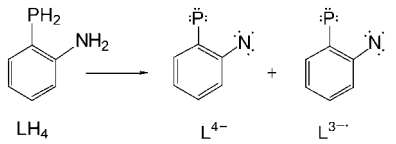
Felipe García, Simon M. Humphrey, Richard A. Kowenicki, Eric J. L. McInnes, Christopher M. Pask, Mary McPartlin, Jeremy M. Rawson, Matthew L. Stead, Anthony D. Woods, and Dominic S. Wright**

The application of superbases, such as the well-known Schlosser base consisting of *t*BuOK and RLi, in the deprotonation of organic substrates is well established.[1] Recently, Mulvey investigated the structural chemistry and applications of related mixed-metal amide reagents.[2] These species show remarkable activity and specificity in their reactions with aromatic hydrocarbons and ferrocene (Cp_2Fe; Cp = cyclopentadienyl).[3,4] For example, the treatment of Cp_2Fe with a mixture of iPr_2NH/Bu_2Mg and *n*BuNa results in a double 1,3-deprotonation of the two Cp rings.[3] We recently observed that the stepwise reaction of $MesPH_2$ (Mes = 2,4,6-$Me_3C_6H_2$) with BnNa (Bn = benzyl) and $[Sn(NMe_2)_2]$ results in the unusual stannate ion $[Sn(2\text{-}CH_2\text{-}4,6\text{-}Me_2C_6H_2)(PMes)]^{3-}$, which arises from the intermolecular deprotonation of a methyl group (Scheme 1).[5] We wanted to examine the activity of this type of p-block-metal/alkali metal reaction



Scheme 1. Formation of $[Sn(2\text{-}CH_2\text{-}4,6\text{-}Me_2C_6H_2)(PMes)]^{3-}$ through intermolecular *ortho* deprotonation of a C–H bond.

system further because this Sn^{II}/BnNa system effectively acts as a superbase and there is a close relationship between this C–H activation reaction and activation reactions mediated by transition metals.[6] Herein, we present the observation that the reaction of 2-aminophenylphosphane (1-PH_2-2-$NH_2C_6H_4$) with *n*BuLi (1 equiv) followed by the addition of $[Sn(NMe_2)_2]$ (1 equiv) results in remarkable quadruple deprotonation of the ligand (Scheme 2) and generates the unusual paramagnetic Sn^{II}-centered cage $[\{[Sn(L)(NMe_2)Li(thf)][Sn(L)Li(thf)_3]Sn\}_2]$ (**1**) containing L^{4-} and $L^{3-\cdot}$ ions (L = ligand; see the Experimental Section).



Scheme 2. The deprotonation of LH_4 by $[Sn(NMe_2)_2]$/*n*BuLi. LH_4 = 1-PH_2-2-$NH_2C_6H_4$, L = ligand.

No N–H or P–H stretching bands are found in the IR spectrum of solid **1**, thus showing that the NH_2 and PH_2 groups of the ligand have been completely deprotonated. As far as we can gauge, neither $[Sn(NMe_2)_2]$ nor *n*BuLi alone will cause deprotonation to this extent. The surprising paramagnetic character of **1** was indicated initially by ^1H and ^{31}P NMR spectroscopic studies: only a broad resonance in the aromatic region appears in the ^1H NMR spectrum at room temperature, and a very broad singlet appears at approximately $\delta = 10$–15 ppm in the $^{31}P\{^1H\}$ NMR spectrum. Compound **1** in the solid state exhibits a strong signal in the EPR spectrum at both the X and K bands (Figure 1). The spectral width is identical at both frequencies, which means that this signal can not be interpreted as a rhombic set of *g* values. Therefore, we attempted to simulate the spectra on the basis of 1) hyperfine coupling in which the two unpaired electrons are independent of each other and 2) hyperfine coupling with an exchange interaction (a biradical system). It was not possible to reproduce the relative intensities of the transitions by assuming coupling to ^{31}P or $^{117,119}Sn$ nuclei[7] for any set of parameters that were tried (including the number of nuclei), nor was it possible to simulate the spectra on the basis of a biradical system with coupling to these isotopes or the

  DOI: 10.1002/anie.200500340

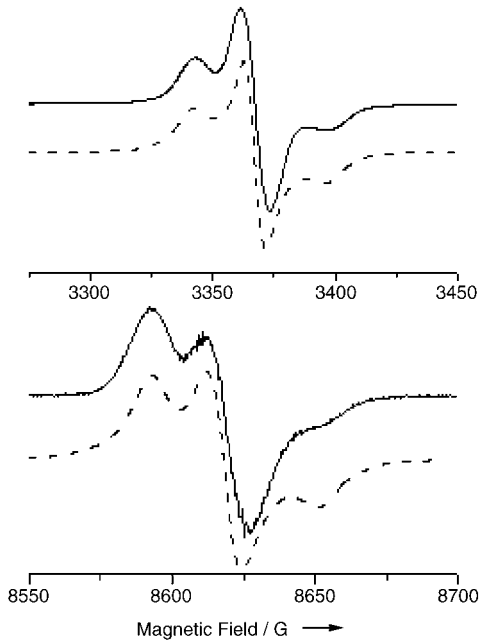

Figure 1. Experimental (solid lines) and simulated (from parameters in the text; dashed lines) EPR spectra of a powdered sample of **1** at 295 K; top: at the X band (9.448 GHz) and bottom: at the K band (24.167 GHz).

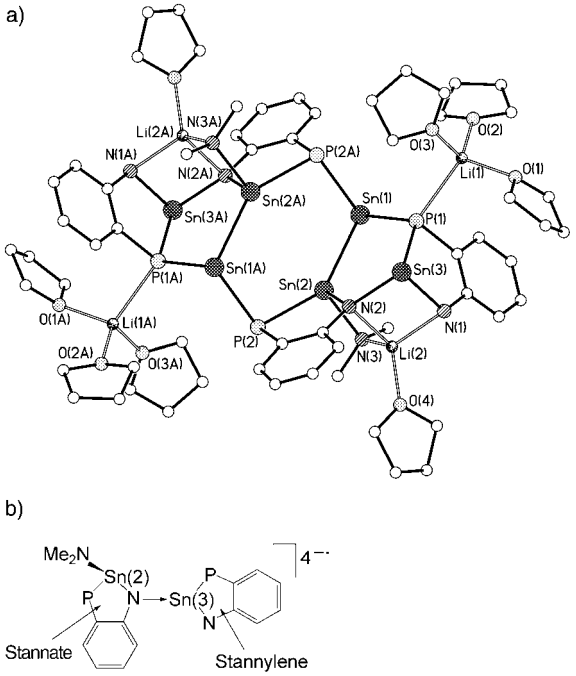

Figure 2. a) Molecular structure of **1**. Hydrogen atoms and lattice-bound THF molecules have been omitted for clarity; disorder of the THF molecules is not shown. Selected bond lengths [Å] and angles [°]: Sn(1)–P(1) 2.603(4), Sn(1)–P(2A) 2.607(4), Sn(1)–Sn(2) 2.885(1), Sn(2)–N(2) 2.10(1), Sn(2)–N(3) 2.18(1), Sn(3)–N(1) 2.18(1), Sn(3)–N(2) 2.17(1), Sn(3)–P(1) 2.566(4), Li(1)–P(1) 2.56(3), Li(2)–N 2.00(3)–2.14(3); angles about Sn(1): 86.21(9)–103.58(9), Sn(2): 88.4(3)–145.9(1), Sn(3): 81.0(3)–99.7(3). b) Schematic representation of the stannate/stannylene $[Sn_2(L)_2(NMe_2)]^{4-}$ ion of **1**.

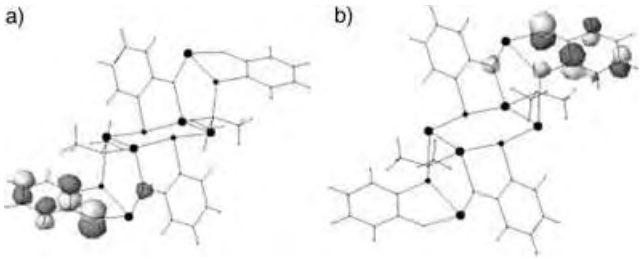

Figure 3. Representation of the semiempirical component PM5-derived frontier MOs of **1**, which illustrates their ligand-based π character: a) the HOMO and b) the LUMO. Large spheres = Sn atoms, small spheres = P atoms.

^{14}N isotope. The only good simulations were obtained by assuming coupling of each unpaired electron to a single ^{14}N nucleus (with no interaction between the two unpaired electrons) with the parameters $g_{x,y} = 2.004$, $g_z = 2.002$, $A_z = 27 \times 10^{-4}\ cm^{-1}$, and $A_{x,y}$ held at an arbitrarily small value of $1x10^{-4}\ cm^{-1}$. The $A_z(^{14}N)$ value places an upper limit of approximately 45% on the unpaired electron density in the 2p orbital of the N atom. The lack of resolution of the ^{31}P nuclei coupling in the EPR spectrum suggests that this coupling constant is smaller than the experimentally obtained linewidths (ca. 10 G).

The low-temperature X-ray crystal structural analysis of **1**[8] (combined with the previous spectroscopic data) shows that the complex consists of centrosymmetric molecules with the formula $[\{[Sn(L)(NMe_2)Li(thf)][Sn(L)Li(thf)_3]Sn\}_2]$ (Figure 2a). Consistent with the main conclusion drawn from the EPR studies, semiempirical calculations on the $[Sn_6(L)_4(NMe_2)_2]^{4-}$ ion of **1** (see Figure 3, in which the tris-THF-solvated Li^+ ions and the THF solvation have been omitted) show that the frontier orbitals are ligand based (85%) rather than Sn based.[9] Furthermore, the majority of the spin density is found on the nitrogen centers of the ligands located at the periphery of the cage (as indicated in Figure 3). The calculated spin density of 30% on the nitrogen centers of these ligands is in good agreement with the upper estimate of 45% based on EPR studies. Interestingly, the spin densities on the nitrogen and phosphorus centers of the ligands within the central portion of the molecule are an order of magnitude less (no greater than 5%). This distribution explains why the complex behaves as a biradical, in which there is no interaction between the unpaired electrons. The major deduction drawn from the spectroscopic and molecular orbital (MO) studies is that to attain electronic neutrality the hexanuclear Sn_6 arrangement of **1** must consist of six Sn^{II} centers together with two tetraanions L^{4-} and two radical trianions $L^{3-\cdot}$, as well as two NMe_2 groups, rather than the potential metal-centered alternative consisting of two Sn^{III} and four Sn^{II} ions and four L^{4-} ions.

The biradical arrangement of **1** consists of two symmetry-related stannylene/stannate fragments (Figure 2b) that are connected by two Sn^{II} centers within the central $(Sn_2P)_2$ ring of **1** through Sn–Sn and Sn–P bonds. The Sn–Sn bonds within the $(Sn_2P)_2$ ring (Sn(2)–Sn(1) = 2.885(1) Å) are best described as dative bonds between eight-electron stannate

(donor) and Sn^{II} centers (acceptor). These bonds are considerably shorter than the dative Sn–Sn bonds in $[ArSn^{II}\rightarrow Sn^{II}\{1,8\text{-}(NR)_2C_{10}H_6\}]$ ($Ar = 2,6\text{-}(Me_2N)_2C_6H_3$; Sn–Sn = 3.087(2) Å),[10] but similar in length to the bonds in the most closely related species $[(Me_3Si)_3Sn^{II}\rightarrow Sn^{II}\{2\text{-}[(Me_3Si)_2C]C_5H_4N\}]$ (Sn–Sn = 2.8689(5) Å).[11] The Sn–P and Sn–N bond lengths (2.497(4)–2.607(4) and 2.10(1)–2.18(1) Å, respectively) are within the range observed for structurally characterized Sn^{II}–P and Sn^{II}–N compounds.[12] The shortest of the Sn–P and Sn–N bond lengths in **1** are in the {Sn(N–C⋯C–P)} chelate rings, with Sn(1)–P bonds (mean = 2.605(4) Å) being the longest bonds of this type in the structure. This Sn(1) centre has a highly distorted pyramidal geometry (range of angles about Sn(1) = 86.21(9)–103.58(9)°), which is similar to that found at the stannylene center Sn(3) (range = 81.0(3)–99.7(3)°). The neutrality of the molecular arrangement of **1** is completed by four Li^+ ions that are located at the periphery of the cage. The $Li(1)(thf)_3$ center is bonded to a P atom (Li(1)–P(1) = 2.56(3) Å), and the Li(2)(thf) center is coordinated by three N centers of the core (Li(2)–N = 2.00(3)–2.14(3) Å).

Although symmetrical N-heterocyclic germylenes,[13] silylenes,[14] and stannylenes[15] have been studied extensively in the past decade, and noncyclic N–Sn–O and N–Sn–C stannylenes are known,[16,17] the N,P-stannylene arrangement found in **1** is unique for a heterocyclic species. To the best of our knowledge, the extent of the deprotonation observed in this study is without precedent for a simple organic acid when treated with a base in solution. The deprotonation of both the NH_2 and PH_2 groups of 2-aminophenylphosphane is particularly dramatic bearing in mind the large negative charge that develops in the resulting L^{4-} and $L^{3-\cdot}$ ions. The results reported herein show that multiple deprotonation of organic acids by mixed alkali-metal organometallic/p-block-metal dimethylamide reagents is a promising area for future study.

Experimental Section

*n*BuLi (3.1 mL, 1.6 mol L^{-1} in hexanes, 5.0 mmol) was added to 2-aminophenylphosphane (0.47 mL, 5.0 mmol) in THF (20 mL) was carried out at −78 °C. The reaction mixture was warmed to room temperature and stirred for 4 h to yield a red solution. The reaction mixture was then cooled to −78 °C, and $[Sn(NMe_2)_2]$ (1.10 g, 5.0 mmol) was added as a solution in THF (10 mL). The reaction mixture was warmed to room temperature and stirred for 16 h to yield a dark-red solution. The solvent was reduced in volume to 5–10 mL and filtered. Complex **1** (0.20 g, 10% yield based on Sn) was crystallized from the filtrate at −30 °C (ca. 1 week). IR (nujol): $\tilde{\nu}$ = 1583 (m), 1020 (s), 816 (m), 765 (w), 735 cm^{-1} (m); ^1H NMR (25 °C, 500.16 MHz, $[D_8]$THF): $\delta = 7.5$–5.7 (collection of overlapping multiplets), 3.50 (m, -CH_2-, THF), 1.70 ppm (m, -CH_2-O, THF) the aromatic resonances were not resolved when the temperature was lowered to −80 °C; ^{31}P NMR (25 °C, 161.975 MHz, $[D_8]$THF, reference: 85% H_3PO_4/D_2O): δ = 10–15 ppm (v br s); elemental analysis (%) calcd for $C_{64}H_{100}Li_4N_6O_9P_4Sn_6$: C 37.7, H 4.8, N 4.4, P 5.9; found C 39.2, H 5.1, N 4.3, P 6.3. The X-ray crystallographic analysis of **1** was carried out on batches of crystals from two separate reactions to confirm the reproducibility and consistency of the product obtained. Although the yield of **1** is low, the paramagnetic nature of the other products of this reaction that are present in solution made it impossible to obtain further NMR spectroscopic data on them (through, the absence of crystalline material). However, other products may well be expected if one bears in mind that the 1:1:1 reaction stoichiometry of nBuLi/$[Sn(NMe_2)_2]$/LH_4 is different from the observed stoichiometry of the components in **1**.

Data were collected on a Nonius KappaCCD diffractometer. Of a total of 14976 reflections collected, 4813 were unique (R_{int} = 0.151). The structure was solved by direct methods and refined by full-matrix least-squares on F^2 (G. M. Sheldrick, *SHELX-97*, Göttingen, Germany, **1997**). Final $R1 = 0.079$ ($I > 2\sigma(I)$) and $wR2 = 0.213$ (all data). CCDC-261960 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.
[9] Single-point semiempirical calculations were performed by using MOPAC implemented through the quantum cache version 5.0 (Fujitsu). PM5 parameters were employed on the assumption of an RHF state (neglecting electron–electron correlation). This process yielded a near-degenerate pair of singly occupied MOs with an energy separation of 0.056 eV (5.4 kJ mol^{-1}). These MOs comprise the in-phase and out-of-phase combinations ($\sqrt{2}$-($\Phi_a \pm \Phi_b$)) of the frontier MOs depicted in Figure 3, which were calculated from a closed-shell configuration. Further SCF calculations confirmed that the structure is a minimum on the potential-energy surface.

Inverse Crown Compounds

Selective *Meta*-Deprotonation of Toluene by Using Alkali-Metal-Mediated Magnesiation**

Prokopis C. Andrikopoulos, David R. Armstrong, David V. Graham, Eva Hevia, Alan R. Kennedy, Robert E. Mulvey, Charles T. O'Hara, and Christine Talmard*

Deprotonative metalation, whereby a proton is substituted by a metal cation to transform a parent organic compound to a more reactive metallic intermediate, which, in turn, can be used to transfer the organic fragment to another molecule, is one of the fundamental synthetic tools that chemists employ to construct compounds.[1] Thus this indispensable tool is put to labor on a daily basis in laboratories across the world, both in academia, for general synthesis, and in industry, for the manufacture of fine chemicals and pharmaceuticals. With polyatomic organic compounds containing two or more hydrogen atoms, there is often a requirement to be selective in choosing the specific hydrogen atom to be removed to generate the desired organic fragment. Owing largely to their polar nature, alkali-metal alkyl ("RM") and amide ("R_2NM") compounds, especially those of lithium, are often the best reagents for effecting deprotonative metalation, but there are limits to their selectivity.[2,3]

A primary source of aromatic compounds, alkylbenzenes, typified by toluene, offer several sites for metalation: the alkyl side chain or the *ortho*, *meta*, or *para* ring sites.[4] However, in practice, toluene is almost exclusively metalated on the CH_3 substituent by common reagents such as BuLi-(tmeda) (tmeda is *N*,*N*,*N*′,*N*′-tetramethylethylenediamine), BuNa, or BuK.[5–7] This situation follows conventional wisdom as the newly formed benzyl "carbanion" ($PhCH_2^-$) is resonance stabilized, and thus in these mainstream monometallic systems it is the most thermodynamically stable of the four isomers possible when a proton is abstracted from toluene. All of the relevant studies hitherto have achieved metalation at kinetic ring sites to only a very minor, synthetically useless, extent, and anyway this is usually followed by isomerization to the thermodynamic benzyl structure. For this reason, metalation reactions of toluene have had a limited scope of usefulness within organic synthesis. Given this background, chemists will be surprised to learn that it is now possible to reverse this order of thermodynamic stability in favor of ring as opposed to methyl deprotonation of toluene by using a special synergic (bimetallic)[8] approach. Moreover, this approach enables regioselective metalation at the *meta* position, to contrast with the normal *ortho*-, *para*-directing effect that the methyl group of toluene exerts in reactions such as electrophilic aromatic substitution. Thus we report the selective *meta* deprotonation of toluene in the mixed sodium–magnesium amido complex [(tmeda)Na(μ-$C_6H_4CH_3$)(μ-tmp)Mg(tmp)] (**1**; where tmp is 2,2,6,6-tetramethylpiperidide). We describe the synthesis and characterization of **1**, as well as reporting the results of theoretical calculations on model compounds, which can offer an explanation for this unexpected *meta* selectivity.

As part of a study working towards the development of new mixed-metal amide-based reagents which can display remarkable synergic reactivities, we recently introduced the bimetallic sodium-magnesium monoalkyl bisamido complex [(tmeda)Na(μ-Bu)(μ-tmp)Mg(tmp)] (**2**).[9] This new reagent is best prepared by combining the individual monometallic alkyl compounds and treating the mixture with equimolar amounts of the parent cyclic amine tmp(H) and the chelating auxiliary tmeda (Scheme 1). In this way **2** is produced in near-quantitative yields in a pure, crystalline form ideal for synthetic utilization. We anticipated that **2** could have special Brønsted basic properties as it has a number of characteristics of different existing bases, but all combined within a single molecule: these include bulky amide ligands (as in Li(tmp)), a strongly nucleophilic alkyl ligand (as in BuLi or BuNa) but one within a unique sterically hindered environment, a mixed-metal mixed-anion set (as in the Lochmann–Schlosser, lithium carbon potassium alkoxide (LICKOR) superbases), and a diamine molecule known to activate alkali metal reagents in many reactions.[1] Furthermore, **2** is soluble in many common organic solvents (such as hydrocarbons). Its

Scheme 1. Synthesis of the bimetallic base **2** and its reaction with toluene to form **1**.

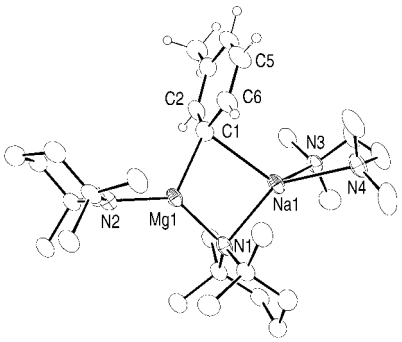

Figure 1. Molecular structure of **1**. Hydrogen atoms, apart from those of the tolyl group, are omitted for clarity.

deprotonative ability was first demonstrated with benzene, which was readily converted into $C_6H_5^-$ within the product [(tmeda)Na(μ-C_6H_5)(μ-tmp)Mg(tmp)] (**3**).[9] Regioselectivity was not an issue in this case. Deprotonation of toluene (Scheme 1) also proved straightforward, by simply adding it to a hexane solution of **2** and heating the mixture to reflux. The solid product of the reaction was colorless, crystalline **1** (58% yield), the formation of which was accompanied by butane gas evolution. When the reaction was repeated using a stoichiometric amount of toluene instead of a tenfold excess, **1** was still obtained in a 30% yield. Characterized by both ^1H and ^{13}C NMR spectroscopic studies (recorded in [D_6]benzene solution), **1** displays a pattern in the aromatic region of the ^1H NMR spectrum (a singlet, two doublets, and a triplet) consistent with *meta*-deprotonated toluene (i.e., corresponding to the *ortho**-, *ortho*/*para*-, and *meta*-hydrogen atoms respectively). This assignment is confirmed by the presence of the CH_3 resonance of toluene and the absence of a benzylic CH_2 resonance. Furthermore, there is no sign of other possible regioisomers of metalated toluene, each of which, if present, would give rise to distinctive resonance patterns in the aromatic region. The spectra also reveal that at ambient temperature both types of tmp ligand are equivalent and that the tmeda coligand remains coordinated to the sodium center. It should be noted that in the absence of tmeda, a 1:1:3 mixture of BuNa, Bu_2Mg, and tmp(H), thought to generate "[{tmp(H)}Na(Bu)$(tmp)_2$Mg]" in situ,[9] reacts with toluene to give [$(tmp)_6Na_4Mg_2${C_6H_3(Me)}][10] in which toluene is dideprotonated in the 2,5-positions. The low yield of this product and the new discovery of **1**, suggests that this twofold deprotonation is a subsequent reaction effected by strong heating, which probably involves intramolecular deprotonation of a monodeprotonated toluene species and elimination of $Mg(tmp)_2$ as the Na:Mg ratio changes from 1:1 in **1** to 2:1 in the other product.

X-ray crystallographic studies established the molecular structure of **1** (Figure 1).[11] A four-element NaNMgC ring, with a mixed tmp/$C_6H_4CH_3$ bridging ligand set, forms the central feature of the structure, which is completed by a terminal tmp on magnesium and a bidentate attached tmeda on sodium. Thus its basic connectivity is the same as that in **2** and **3**, with only the identity of the carbon bridge changing ($C_6H_4CH_3$ in **1**, Bu in **2**, C_6H_5 in **3**). In **1** (as in **3**), the central NaNMgC ring is essentially planar (sum of endocyclic bond angles, 359.94°), whereas in **2** there is a deviation from planarity (corresponding sum, 356.33°). This distinction reflects the aromatic/aliphatic nature of the carbon bridge and its hybridization (sp^2/sp^3, on discounting the long contacts to Na). In forming a short, strong bond to the *meta*-C1 atom (2.197(5) Å), close to coplanarity with the tolyl ring plane (as shown by the Mg1C1C6C5 torsion angle, −168.9(4)°), the Mg1 atom in **1** in effect refills the position vacated by the abstracted proton. This result implies intriguingly that the metalation reaction is formally a magnesiation as opposed to a sodiation, which runs counter to the normal reactivity order of organomagnesium versus organosodium compounds (i.e., that organosodium compounds are orders of magnitude more reactive).[12] Contrary to the parallel orientation of Mg1, Na1 lies almost perpendicular to the tolyl ring plane (Na1-C1-Mg1 bond angle, 80.78(16)°). The shortest Na1-tolyl contact is to the *meta* C1 (2.681(5) Å), where most of the negative charge resides, but the proximate C atoms also lie close by (Na1-C6, 3.147(5)Å; Na1-C2, 3.333(5) Å). This bonding distinction between magnesium and sodium with respect to the deprotonated substrate, signifying more σ character for magnesium and more π character for sodium, is also found in inverse crown complexes.[13,14]

The origin of this unexpected *meta* selectivity was probed by theoretical calculations. Preliminary geometry optimizations on all molecules were performed at the Hartree–Fock level, using the 6-13G* basis set, then the optimized structure so obtained was re-refined at the density functional theory (DFT) level, employing the B3LYP method and the 6-311G** basis set.[13] The reaction between **2** and toluene to give **1** (Scheme 1) was calculated to be exothermic by 8.21 kcal mol^{-1}. Four regioisomers of the model compound [Na(μ-tolyl)(μ-tmp)Mg(tmp)] (**1A**–**1D**; Figure 2), where tolyl represents a toluene molecule singly deprotonated in the *ortho* (**1A**), *meta* (**1B**), *para* (**1C**), or *methyl* (**1D**) positions, were examined. Consistent with the experimental structure of **1**, the most stable theoretical structure is calculated to be the *meta* isomer **1B** (relative energy, 0.00 kcal mol^{-1}). The next lowest energy structure is the *para* isomer **1C** (at +2.35 kcal mol^{-1}) followed by the *ortho* isomer **1A** (at 5.12 kcal mol^{-1}). Somewhat surprisingly, the least stable structure of all is the benzyl isomer **1D**, which is 7.77 kcal mol^{-1} less stable than **1B**. Comparing the dimensions of **1B** and **1D**, it is clear that the major contribution to the energetic preference for **1B** lies not in Mg–C σ bonding but in

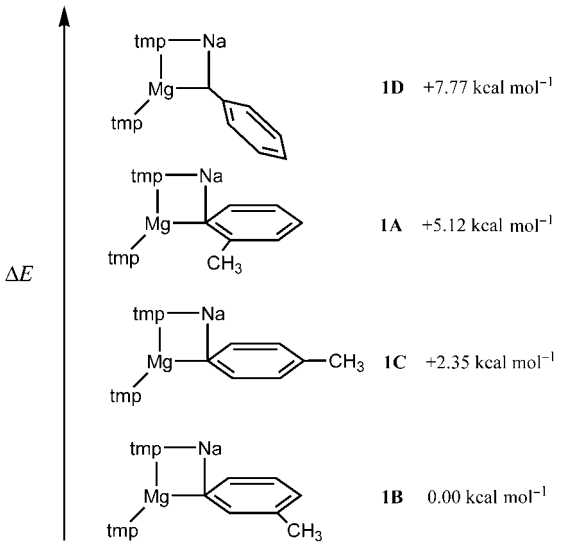

Figure 2. The theoretical structures **1A**–**1D**, in order of decreasing stability.

Na–C π interactions: thus the Mg–C bond in **1B** (2.232 Å) is only modestly shorter than that in **1D** (2.279 Å); but whereas **1B** displays several short-to-medium length Na–C π interactions (2.453 Å, 2.915 Å, and 2.960 Å to *meta*, *para*, and *ortho* C atoms, respectively), the orientation of the benzyl ring in **1D** is such that there are no Na–C π contacts below 4.8 Å (the Na–C benzylic bond length is 2.475 Å). While each individual Na–C π interaction in **1B** may be weak, collectively they must contribute significantly to its overall stability. Hence the normal order of thermodynamic stability of toluene metalation products (side-chain isomer > ring-site isomer) has been reversed by using this special bimetallic approach. When tmeda is included in the calculations, the benzyl isomer is still less stable than the *meta* isomer, but by a reduced margin ($+1.99$ kcal mol^{-1}); also the *para* isomer is fractionally more stable than the *meta* isomer (relative energies, 0.00 and $+0.05$ kcal mol^{-1}, respectively). However, *meta*-deprotonation has also been observed in tmeda-free solutions in the synthesis of the dideprotonated complex $[Na_4Mg_2(C_6H_3CH_3)(tmp)_6]$, so the tmeda-free models **1A**–**1D** probably provide a reasonable guide to the experimental reaction. Noting that conventional magnesium bases are generally too weak to metalate toluene, this new synergic mixed-metal methodology that opens a direct route to *meta*-substituted toluenes,[15,16] is perhaps best regarded as alkali-metal-mediated magnesiation, a new form of magnesiation with greatly enhanced basic powers.[17]

To test its ability to be intercepted by electrophiles, **1** was treated with three molar equivalents of trimethylsilyl triflate in [D$_6$]benzene solution. A white precipitate formed instantaneously, and was removed by filtration. A ^{1}H NMR spectrum of the filtrate showed that **1** had converted essentially quantitatively into trimethyl *meta*-tolylsilane, as established by comparison with an authentic sample of trimethyl *meta*-tolylsilane.[16] This promising result confirms that **1** should be an excellent precursor to *meta*-substituted tolyl compounds.

Experimental Section

All reactions were carried out under a protective argon atmosphere.

1: Freshly prepared [(tmeda)Na(μ-Bu)(μ-tmp)Mg(tmp)] (**2**) (1.0 g, 2 mmol) was dissolved in hexane (10 mL). Next toluene (2 mL; 20 mmol) was added and the pale yellow solution obtained was heated to reflux for 90 min. The flask containing the resulting light orange solution was placed in a Dewar flask of hot water and allowed to cool slowly to room temperature affording colorless crystals of **1** (yield, 0.62 g, 58 %). ^{1}H NMR (400 MHz, 25 °C, [D$_6$]benzene): $\delta = 7.75$ (H_{ortho*}, C_6H_4-CH_3), 7.62 (H_{para}, C_6H_4-CH_3), 7.10 (H_{meta}, C_6H_4-CH_3), 6.92 (H_{ortho}, C_6H_4-CH_3), 2.19 (CH_3, C_6H_4-CH_3), 1.90 (m, 4H, tmp), 1.64 (s, 24H, CH_3, tmp), 1.56 (s, 12H, CH_3, tmeda), 1.48 (m, 4H, CH_2, tmeda), 1.35 ppm (m, 8H, tmp); ^{13}C{^{1}H} NMR (100.63 MHz, 25 °C, [D$_6$]benzene): $\delta = 172.83$ (Mg-C_{meta*}), 142.29 (C_{ortho*}), 137.48 (C_{para}), 135.76 (C_{ipso}), 127.04 (C_{meta}), 126.13 (C_{ortho}), 57.23 (CH_2, tmeda), 52.60 (N-*C*, tmp), 46.26 (CH_3, tmeda), 42.71 (tmp), 36.24 (CH_3, tmp), 22.45 (CH_3, C_6H_4-CH_3), 20.70 ppm (tmp).

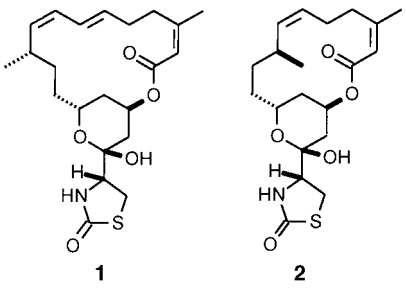
Natural Product Synthesis

Concise and Practical Synthesis of Latrunculin A by Ring-Closing Enyne–Yne Metathesis**

Alois Fürstner and Laurent Turet*

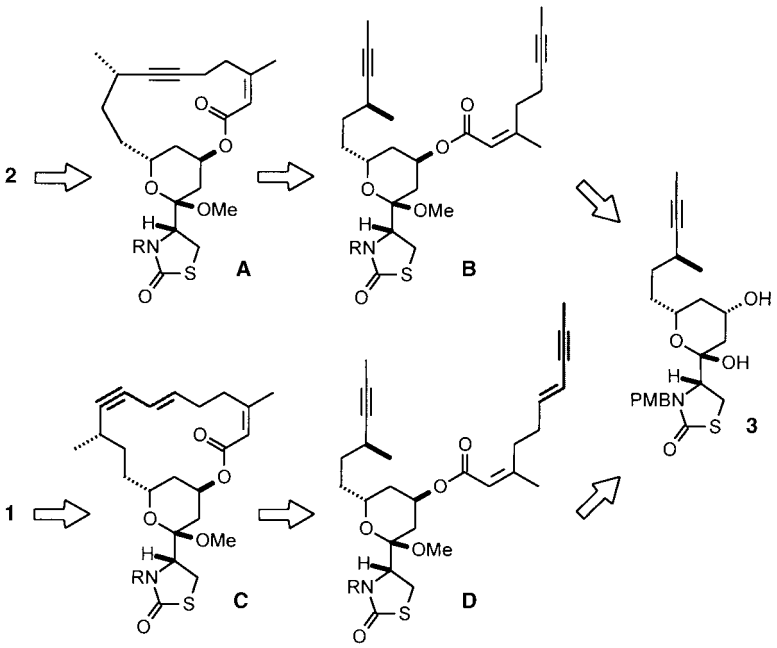
Incubation of eukaryotic cells with micromolar concentrations of the marine natural product latrunculin A (**1**) or its ring-contracted congener



latrunculin B (**2**) results in a selective perturbation or even complete disruption of the actin cytoskeleton.[1,2] Thereby, the potency and rapid onset of action are highly reminiscent of genetic knockout experiments, and thus allow study of the many biological properties of actin by what might be considered a prototype "chemical genetics" approach.[3] This crucial and highly complex subcellular protein network determines the shape and mechanical properties of the cells and is responsible for motility processes as fundamental as exo- and endocytosis. The recent discovery of an actin-dependent checkpoint in mitosis also relied on the use of **1**, thus increasing the interest in this and related probe molecules even further.[4]

It is hardly surprising, therefore, that this family of scarce macrolides has also attracted the interest of the synthetic community to culminate in three successful total synthesis campaigns.[5–7] In this context, we reported an efficient route to latrunculin B (**2**) based upon the use of ring-closing alkyne metathesis (RCAM)[8,9] for the formation of the macrocycle.[7] Although this approach is inherently flexible and should therefore be amenable to the synthesis of all other members of this series, two important aspects deserved further consideration before it was adapted to the total synthesis of the parent compound **1**.

While access to **2** relies on a regular RCAM reaction[8,9] of a properly protected diyne of type **B** to cycloalkyne **A** followed by Lindlar reduction, the envisaged extension of this strategy to the synthesis of **1** implies a metathetic event between an alkyne and a conjugated enyne (**D**→**C**, Scheme 1). Only if this transformation occurs strictly chemoselectively at the triple bonds without affecting the adjacent olefin[10] might latrunculin A come into reach. Such alkyne-selective enyne–yne metathesis reactions were disclosed only recently and have never been used in a similarly complex setting.[11] Moreover, as the resulting products are necessarily strained, the efficiency of this reaction strongly depends on the ring size formed, with the smallest successful example reported to date comprising 18 ring atoms.[11] It was therefore by no means clear if this methodology was applicable to the



Scheme 1. Retrosynthetic analyses of latrunculin A and B which both converge to the common building block **3**. PMB = *para*-methoxybenzyl.

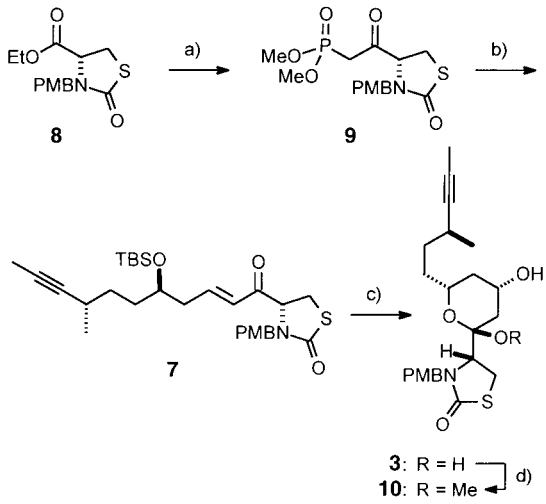
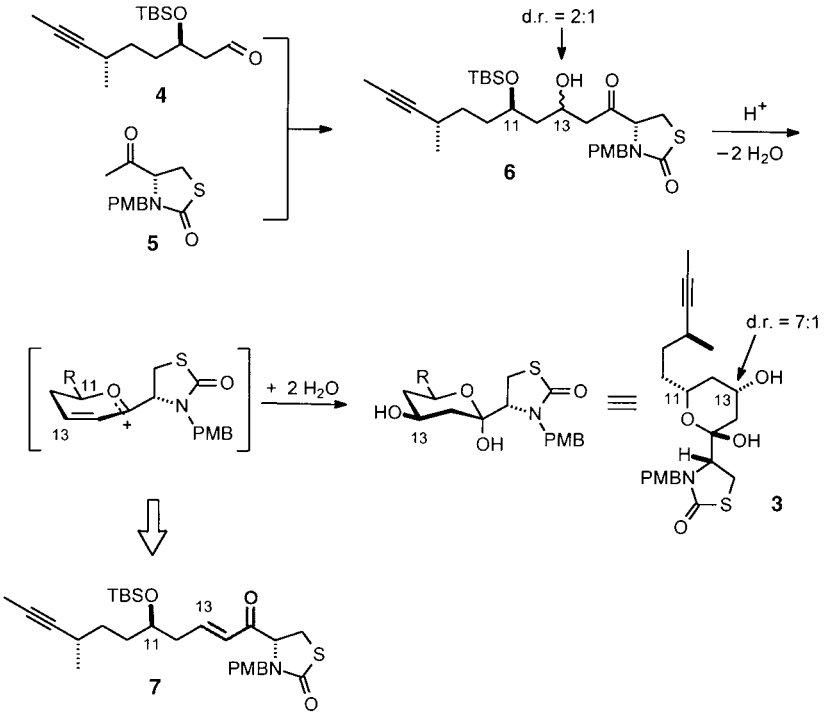
stereoselective formation of the diene moiety of **1** which is embedded into the 16-membered ring of a rigid bicyclic skeleton.

The second aspect that deserves further consideration is of practical relevance. While compound **3** as the key building block en route to **2** can also be used for the total synthesis of **1** (see Scheme 1), its preparation relies on an aldol reaction which is not fully satisfactory. Specifically, exposure of aldehyde **4** to the titanium enolate derived from ketone **5** at −78 °C provides product **6** as an inseparable 2:1 mixture of the corresponding diastereomers (Scheme 2).[7] This mixture equilibrates to a more favorable ≈7:1 ratio of isomeric hemiketals on acid-catalyzed cleavage of the O-TBS group at C-11 (latrunculin B numbering), most likely by a retro-Michael/Michael manifold that involves a transient oxocarbenium ion.[7,12] If this mechanistic hypothesis is correct, however, it might be possible to obtain **3** also from the α,β-unsaturated ketone **7** by protonation and addition of water through a sterically and stereoelectronically preferred equatorial trajectory. It seemed lucrative to pursue this idea as it



Scheme 3. Improved synthesis of the key building block **3**: a) $(MeO)_2P(O)CH_3$, *n*BuLi, THF, −78 °C, 60%; b) $Ba(OH)_2 \cdot 8H_2O$ (activated at 140 °C), THF, aldehyde **4**, 75%; c) aq. HCl, THF, 63%; d) MeOH, camphorsulfonic acid (cat.), quantitative.

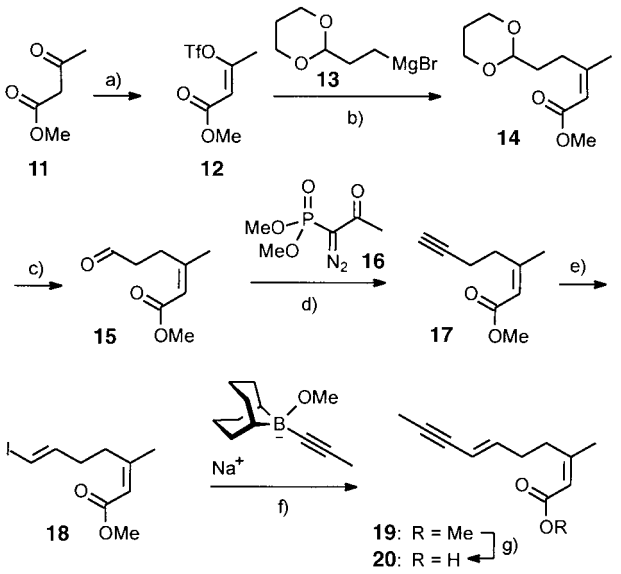


Scheme 2. Established aldol route to the key building block **3** and rationale for the stereochemical equilibration observed upon hemiketal formation. TBS = *tert*-butyldimethylsilyl.

may allow us to replace the somewhat capricious aldol reaction by a simple olefination, which requires neither the handling of sensitive compounds nor the use of low temperatures and should therefore be much more robust, practical, and scaleable.

As shown in Scheme 3, this strategy turned out highly rewarding. Thus, reaction of ester **8** (derived from cysteine in two high-yielding steps)[7] with deprotonated $(MeO)_2P(O)CH_3$ afforded ketophosphonate **9**, ready for condensation with aldehyde **4** (obtained in multigram quantities from (+)-citronellene in seven steps, as previously described).[7] After some experimentation it was found that this Horner–Wadsworth–Emmons reaction proceeded best when activated $Ba(OH)_2$ was used as the base.[13] Exposure of the resulting alkene **7** to aqueous HCl gave the desired hydrated hemiketal **3** in approximately 9:1 ratio; the individual isomers were separable after transformation into the corresponding methyl glycosides **10**. Importantly, this outcome does not only corroborate the proposed equilibration mechanism (see Scheme 2) but also opens a convenient route to this essential building block.

The required acid part was obtained from enol triflate **12**[14] by using iron-catalyzed cross-coupling chemistry previously developed in our laboratory (Scheme 4).[15,16] To this end, substrate **12** was treated with the commercially available organomagnesium reagent **13** in the presence of $[Fe(acac)_3]$ as a cheap and benign precatalyst to give product **14** on a multigram scale.[17] Cleavage of the acetal, conversion of the resulting aldehyde **15** into the corresponding alkyne **17** with the aid of the Ohira–Bestmann reagent **16**,[18] followed by hydrozirconation/iodination[19] provided the desired alkenyl iodide **18** as a single isomer.[20] Conversion of this compound into enyne **19** turned out to be surprisingly difficult, and only the "9-methoxy-9-BBN" variant of the Suzuki reaction (9-MeO-9-BBN, MeC≡CNa, $[Pd(PPh_3)_4]$ catalyst), as previously described by our group, gave satisfactory and reproducible results.[21] Enyne **19** was saponified with KOH in aqueous THF, whereas other bases commonly used for ester hydrolyses led to the decomposition of the material and/or partial epimerization of its *Z*-configured enoate moiety.



Scheme 4. Preparation of the acid part: a) (1) NaH, CH_2Cl_2; (2) Tf_2O, 82%; b) Grignard reagent **13**, [Fe(acac)$_3$] (15 mol%), −30°C, THF, 67–83%; c) aq. HCOOH, reflux; d) reagent **16**, K_2CO_3, MeOH, 80% (over both steps); e) [$Cp_2Zr(H)Cl$], CH_2Cl_2, then I_2, 56%; f) 9-MeO-9-BBN, NaC≡CMe, [$Pd(PPh_3)_4$] (5 mol%), THF, reflux, 77%; g) KOH, aq. THF, 82%. Tf = trifluoromethanesulfonyl, acac = acetylacetonate, Cp = cyclopentadienyl, BBN = borabicyclo[3.3.1]nonane.

Coupling of the fragments now in hand required the consecutive formation of triflate **21** and substitution with the sodium salt of acid **20** (see Scheme 5). All attempts to perform this esterification under Mitsunobu conditions were unrewarding. We were pleased to note that the resulting product **22** underwent productive enyne–yne metathesis to give the desired product **23** in the presence of catalytic amounts of [Mo{N(*t*Bu)(Ar)}$_3$] (**26**), activated in situ with CH_2Cl_2 as previously described.[22,23] This success, however, was thwarted by our inability to cleave the remaining N-PMB group from the thiazolidinone ring with either 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) or cerium ammonium nitrate (CAN). Although we were apprehensive that this step might be problematic,[24] it seemed likely that the high ring strain of the cyclic enyne **23** promotes its degradation by rendering the single-electron oxidation of this reactive entity more facile than the cleavage of the PMB group.

To test this hypothesis, cleavage of the N-PMB group prior to ring closure was attempted. It was gratifying to note that this change in the order of events paved the way to the target. Thus, treatment of the acyclic enyne **22** with CAN afforded product **24** in acceptable yield. Although this compound could not be cyclized owing to the known incompatibility of complex **26** with N-unprotected amides,[22] conversion into the Teoc derivative **25** allowed the crucial enyne–yne metathesis to proceed with rigorous chemoselectivity at the triple bonds to form the highly strained 16-membered cyclic product **27** in 70% yield. Not only is this the smallest ring size ever to be formed by ring-closing enyne–yne metathesis[11] but the compatibility with the dense and diverse array of functional groups also attests to the excellent application profile of this emerging methodology. *Z*-Selective semihydrogenation of the triple bond in **27** with Lindlar's catalyst in the presence of a large excess of quinoline to suppress overreduction followed by consecutive cleavage of the Teoc group and the methyl glycoside in **28** under standard conditions furnished latrunculin A (**1**). The spectroscopic and analytical data for the product were in excellent agreement with those already reported.[1,5,6]

In summary, a concise and efficient synthesis of the strongly actin-binding marine natural product latrunculin A has been achieved. The chosen route features the first successful implementation of a ring-closing enyne–yne metathesis reaction into a total synthesis and is largely catalysis-based overall. Furthermore, a practical solution for the preparation of the key intermediate **3** has been developed that clearly surpasses prior art. As this building block can also serve as a convenient platform for the preparation of non-natural analogues of both **1** and **2**, we are now in a favorable position for a synthesis-driven evaluation of the still largely unknown structure–activity profile of this important class of bioactive macrolides. Our investigations along these lines will be reported shortly.

Nanostructures

Aminolysis Route to Monodisperse Titania Nanorods with Tunable Aspect Ratio**

*Zhihua Zhang, Xinhua Zhong, Shuhua Liu, Dongfei Li, and Mingyong Han**

Nanocrystalline titanium dioxide (titania) has been investigated extensively, as it plays a prominent role in fundamental studies and has both potential and demonstrated applications in solar energy conversion,[1] photocatalysis,[2] photochromic devices,[3] and gas sensing.[4,5] Among the three natural crystalline forms of titanium dioxide (anatase, brookite, and rutile), rutile is the most stable phase, whereas anatase has superior optoelectronic and photochemical properties.[6] There have been a number of recent reports on the preparation of nanoscaled anatase titania in the form of nanoparticles, nanorods, nanowires, and nanotubes for significantly increasing its specific surface area and delocalization of carriers, which may enhance the performance of this material in highly efficient sensors, photocatalysts, and photovoltaic cells as compared with planar solids or powders.[5,7] To realize these promising high-performance applications, the various nanosized titanias and their derivatives must also fulfill a wide variety of requirements in terms of particle size, size distribution, shape and morphology, crystallinity, and phase purity. The current challenge is to control and tailor all these parameters and properties simultaneously in one synthetic approach or process.

Among the various synthetic routes developed in the last decades, the most general and versatile solution-phase synthetic strategy is based on the hydrolysis and condensation of titanium alkoxides to create nanosized titania with diameters that range from a few tens to several hundreds of nanometers.[8] Owing to extreme moisture or water sensitivity, in most cases, the very fast hydrolytic process at low temperature yields amorphous products with polydisperse size and mixed phases, and subsequent hydrothermal processing or calcination is necessary to induce crystallization. The high reactivity of tetrafunctional titanium alkoxides $Ti(OR)_4$ can be chemically modified by using carboxylic acids such as oleic acid as chelating ligands to decrease the number of TiOR groups available for violent hydrolysis by ligand substitution/exchange.[9] Chemical modification can decrease precursor reactivity and yield more controllable hydrolysis and condensation processes under mild reflux. Volatile water is maintained in a closed system at an elevated temperature of 80–100 °C, and long aging times of 6–12 h or more are required to promote further hydrolysis and improve crystallization of the final nanoproducts. Until now, an alternative high-temperature nonhydrolytic strategy was still preferred to make highly crystalline nanoparticles[10] because the amorphous form is usually inactive in various light-responsive properties such as photocatalysis.[11] The main conventional nonhydrolytic routes reported involve the elimination reaction between titanium tetrachloride and oxygen-donor molecules such as titanium alkoxides and organic ethers which yield environmentally unfavorable, volatile alkyl chlorides or hydrogen chloride. The fast formation of nanosized titania may also limit systematic morphological control in the presence of organic surfactants. Therefore, it is useful to explore and design new preparative reactions to avoid the existing specific problems encountered in conventional hydrolytic or nonhydrolytic routes.

Herein we present a novel high-temperature, nonhydrolytic synthetic approach to anatase titania nanocrystals. It was developed on the basis of a well-known ester aminolysis reaction that involves the nucleophilic attack of an amine group on the carbonyl carbon atom of titanium carboxylate derivatives[12] and the chemical modification of reactive molecular precursors with OLA as the chelating ligand. The high-temperature aminolysis of titanium carboxylate (titanium oleate) complexes can be well-controlled by using high-boiling long-chain oleylamine rather than volatile water. In addition to the preparation of size-tunable anatase TiO_2 nanodots, the "greener" aminolysis route can also provide much better control of the anisotropic growth and can be used

to readily prepare monodisperse anatase TiO_2 nanorods with tunable length and diameter. An added benefit is that anatase TiO_2 nanorods can also be used as ideal host matrices for the preparation of transparent dilute magnetic oxides that have promising applications such as magneto-optical devices.[13]

A mixture of titanium isopropoxide (TIP; 1 mmol) and oleic acid (OLA; 5 mmol) was used to generate OLA complexes of titanium at 80 °C in 1-octadecene (ODE; 6 mL), followed by the injection of a predetermined amount of oleylamine (OA; 1–10 mmol) at 260 °C to give various nanosized TiO_2 preparations. TiO_2 nanorods were characterized by TEM (Figure 1 a–c); their length depends on the amount of OA used. When the OA content was increased from 1 to 2 to 3 mmol, monodisperse TiO_2 nanorods with lengths of 12, 30, and 16 nm were obtained, respectively, all with a diameter of about 2 nm. The use of OA at 4 mmol in the presence of the unchanged molar ratio of TIP (1 mmol) and OLA (5 mmol), spherical TiO_2 nanoparticles of $\approx$2.3 nm in diameter were obtained (Figure 1 d). Large excesses of OA only generate white titania precipitate. The high-resolution TEM image of a single nanorod (16 nm) shows the single-crystalline structure (Figure 1 c, inset). The lattice spacing of 0.35 nm corresponds to the *d* spacing between adjacent (101) crystallographic planes of anatase TiO_2 nanorods. The as-synthesized anatase nanorods were elongated along the [001] direction; the long axis of the nanorods is parallel to the [001] direction. These surface-capped nanorods can be well-spaced on the copper grid, and some of them are self-assembled with identical distance between them, as shown in Figure 1 a–c. The XRD patterns show a pure anatase phase without other titanium oxide polymorphs (Figure 2). The (004) diffraction peak becomes much stronger and sharper with an increase in length of the nanorods, whereas other peaks remain similar in shape and intensity. The strong peak intensity and narrow width of the ⟨004⟩ reflection and relatively lower intensity and broader width for the other reflections indicate preferred anisotropic growth along the *c* axis of the anatase lattice.

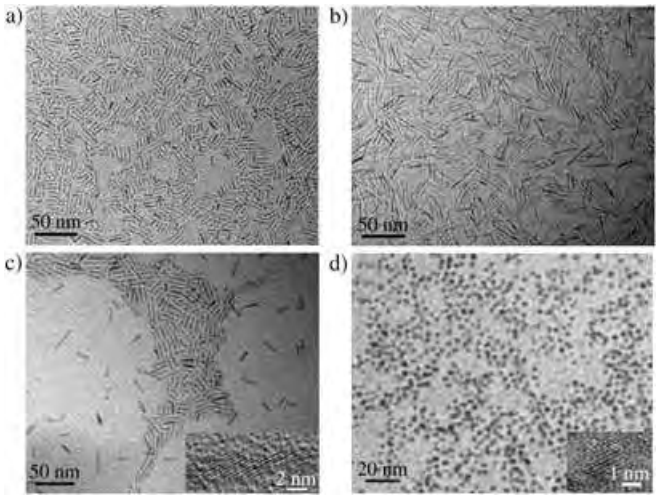

Figure 1. TEM images of length-tunable TiO_2 nanorods with lengths of a) 12, b) 30, and c) 16 nm, prepared at 260 °C with 1, 2, and 3 mmol of OA, respectively; the molar ratio of TIP (1 mmol) and OLA (5 mmol) was kept unchanged. d) TEM image of TiO_2 nanodots of 2.3 nm obtained at 260 °C with 4 mmol OA; the molar ratio of TIP and OLA was kept as described for parts a)–c). Inset in part c): HR-TEM image of a single titania nanorod (16 nm).

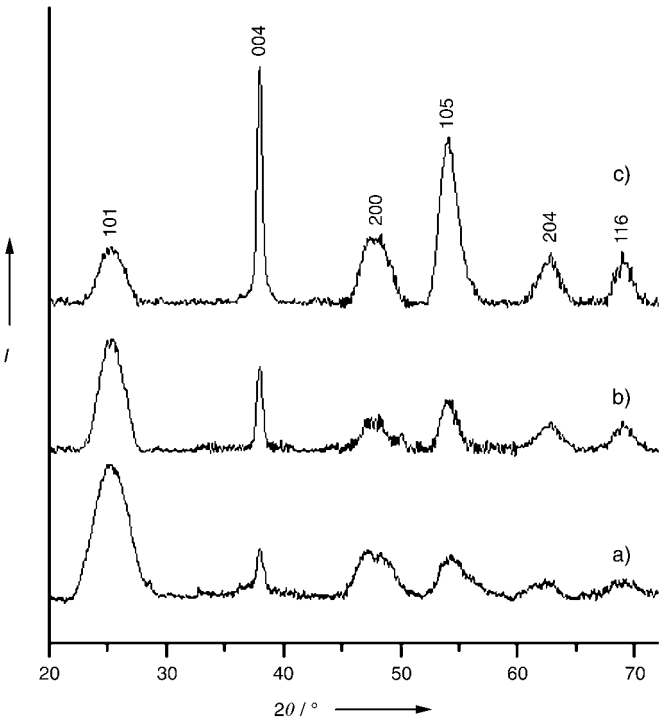

Figure 2. Powder XRD patterns of TiO_2 samples: a) spherical particles of diameter 2.3 nm (molar ratio TIP/OLA/OA = 1:5:4); b) 16-nm nanorods (molar ratio TIP/OLA/OA = 1:5:3); c) 30-nm nanorods (molar ratio TIP/OLA/OA = 1:5:2).

To elucidate the mechanism of titania nanorod formation, we investigated the respective roles of OA and OLA in the noncoordinating ODE system under the optimized conditions for preparing 30-nm titania nanorods with a TIP/OLA/OA molar ratio of 1:5:2. Interestingly, when either OLA or OA is used alone, TiO_2 cannot be obtained even at 260 °C. This observation indicates a synergistic effect of OA and OLA in generating titania nanorods. As reported in the literature, TIP ($Ti(OiPr)_4$) can readily react with OLA ($C_{17}H_{33}COOH$) to generate yellow OLA–titanium complexes $(C_{17}H_{33}COO)_xTi(OiPr)_{4-x}$ at 80 °C in which one or more isopropoxide groups is replaced with an oleate ligand with concomitant release of isopropyl alcohol.[9,14] Although heating the resulting titanium carboxylates at 260 °C does not produce TiO_2, the subsequent injection of a predetermined amount of OA ($C_{18}H_{35}NH_2$) can "decompose" it to form monodisperse anatase titania nanorods. We note that similar reaction systems were also used for the preparation of metal oxide or chalcogenide nanoparticles such as Fe_2O_3, Fe_3O_4, $MnFe_2O_4$, $CoFe_2O_4$, and ZnSe with fatty acid as a stabilization/coordination reagent, and primary amine as an efficient activation reagent to accelerate the formation of nanoparticles.[15]

The mechanism of formation of nanosized TiO_2 was further studied systematically by FTIR spectroscopy. Figures 3 a and b show the FTIR spectra of pure OLA and the mixture of TIP (1 mmol) and OLA (2 mmol) after 20 min at

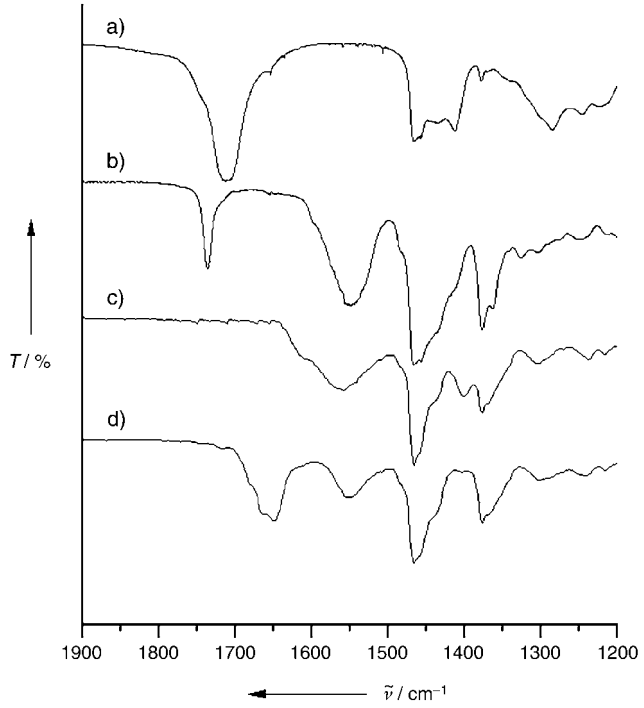

Figure 3. FTIR spectra of a) OLA; b) a mixture of OLA and TIP after treatment at 80 °C; c) the same mixture after washing with acetone and hexane; d) the mixture after further aminolysis to generate nanosized TiO_2.

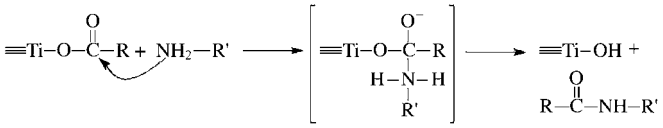
80 °C. A characteristic C=O stretching band of OLA appears at 1710 cm^{-1} in Figure 3a. The disappearance of the free C=O stretching band at 1710 cm^{-1} in Figure 3b shows that OLA reacts completely with TIP (or excludes the presence of unionized OLA). The resulting oleate anion ($C_{17}H_{33}COO^-$) is expected to show asymmetric and symmetric COO^- stretching bands at $\approx$1565 and $\approx$1434 cm^{-1}, respectively, as were observed in titanium acetate.[16–18] The latter is normally more difficult to locate as a result of its overlap with C–H bending vibrations at 1467, 1450, and 1375 cm^{-1} (attributed to symmetric CH_2, asymmetric CH_3, and symmetric CH_3 in oleate (or OLA), respectively).[16] In our case, the new strong band at $\approx$1555 cm^{-1}, attributed to the asymmetric stretching vibration of carboxylate anions, indicates the coordination of OLA to titanium centers to form titanium oleate complexes by ligand exchange/substitution.[16]

The characteristic C=O stretching vibration of isopropyl oleate at 1736 cm^{-1} in Figure 3b is clearly distinguished from that of titanium oleate complexes. The by-product, isopropyl oleate, was generated either by nonhydrolytic elimination/condensation of unstable carboxylatotitanium alkoxide $(C_{17}H_{33}COO)_xTi(OiPr)_{4-x}$, which can remove some of the oleate and isopropoxide ligands together, or a slow esterification reaction between the reactant OLA and the released isopropyl alcohol. Figure 3c shows the FTIR spectrum of the reaction mixture of OLA with TIP after washing with hexane/acetone (1:1) to remove isopropyl oleate for further reaction. As a result, only the asymmetric COO^- stretching frequency at $\approx$1560 cm^{-1} appeared after the complete removal of isopropyl oleate from the reaction system. Further reaction was carried out at 260 °C for 20 min after the injection of 2 mmol of OA into the reaction mixture. In comparison with Figure 3c, the new stretching vibrations at 1651 and 1550 cm^{-1} in Figure 3d are attributed to different carbonyl stretches in single-substituted amide, which is discussed further below. Almost the same evidence was also obtained when acetic acid was used to replace OLA to prepare titania particles (Supporting Information). The above results indicate that the carbonyl groups of titanium carboxylate precursors can undergo nucleophilic attack by OA to form amides, as opposed to water, which attacks the highly electron-deficient/electrophilic Ti^{IV} center and thus hydrolyzes titanium alkoxides. This process is similar to the conventional aminolysis reaction of organic esters.[12] The conventional aminolysis mechanism of esters may resemble an S_N2 reaction with a tetrahedral transition state or intermediate, which requires a nucleophile ($R'NH_2$) to collide with the electropositive carbonyl carbon in the ester to form an organic amide ($RC(O)NHR'$). In our case, the resulting tetrafunctional titanium carboxylate (titanium oleate) complexes $(C_{17}H_{33}COO)_xTi(OiPr)_{4-x}$ were aminolyzed by OA to form unstable hydroxyalkoxides $(C_{17}H_{33}COO)_{x-1}Ti(OH)(OiPr)_{4-x}$ via a tetrahedral transition state through nucleophilic attack by OA on the carbonyl carbon atom of titanium oleate complexes (Scheme 1). Consequently, the subsequent polycondensation reaction of the resulting hydroxylated titanium precursors produces extensive Ti–O–Ti networks covalently capped with carboxylates.[19]



Scheme 1. Aminolysis reaction between titanium carboxylate complexes and primary amine.

During the growth of TiO_2 nanocrystals, as (001) planes have higher surface energy or are more chemically reactive than others,[20] carboxylate groups coordinated to (001) faces could be more easily aminolyzed under the attack of OA and form or extend the Ti–O–Ti network along the [001] direction. Less reactive titanium carboxylate precursors are also helpful in maintaining high monomer concentrations in the reaction solution for elongated growth of titania nanocrystals, as has been suggested.[21] Various amounts of OLA were used to optimize the preparation conditions of titania nanorods, and more than 4 mmol of OLA was necessary to prepare soluble TiO_2 nanocrystals in the noncoordinating ODE system. It was also observed that upon increasing the amount of OA from 1 to 2 mmol, the length of the resulting monodisperse titania nanorods increased from 12 to 30 nm. However, with the further increase of OA content to 3 mmol, nanorod length was decreased to 16 nm, which indicates suppression of anisotropic growth at higher OA contents. Finally, only spherical nanoparticles were formed when 4 mmol of OA was used, and aggregated particles were produced when $\gg$5 mmol of OA was used; this indicates the

decreased stabilization that results from the consumption of surface-coordinated oleate ligands on particle surfaces. Moreover, the increased OA content can accelerate the aminolysis reaction to form nanoparticles.

Although monodisperse TiO_2 nanocrystals with a tunable aspect ratio ranging from 1 to 13 (nanodots to nanorods) have been prepared, the resulting length-tunable TiO_2 nanocrystals have only a very small diameter of $\approx$2.0 nm, a result of the tight binding of OLA on the titania surface, which restrains its growth.[9,10c] To prepare diameter-tunable TiO_2 nanorods, a weaker capping agent, cetyltrimethylammonium bromide (CTAB), was used to decrease/balance the strong binding affinity of OLA on the anatase surface. With 1 mmol of TIP, 1 mmol of OA, and 5 mmol of OLA, only very narrow TiO_2 nanorods of diameter $\approx$2.0 nm were obtained (Figure 1a). By introducing larger amounts of CTAB and maintaining a similar TIP/OA/OLA molar ratio, larger, diameter-tunable TiO_2 nanorods of 2.9, 3.8, and 4.6 nm (Figure 4a–c) were produced under optimized conditions. From the above results, it is now known that higher OA content is required to prepare TiO_2 nanodots (Figure 1d). Hence, to prepare larger TiO_2 nanodots, an larger amount of CTAB and a smaller amount of OLA were used to balance the stabilization of nanoparticles while retaining the TIP/OA molar ratio of 1:3. Thus, size-tunable TiO_2 nanodots of 2.3, 3.0, 4.2, and 6.0 nm were prepared under various reaction conditions (Figure 1d and Figure 4c–d). In comparison with bulk anatase titania (3.2 eV), a blue-shift of the absorption onset of anatase titania nanodots was observed. The blue-shift increased with decreasing size of the particles, which exhibit size-dependent optical properties (Supporting Information).

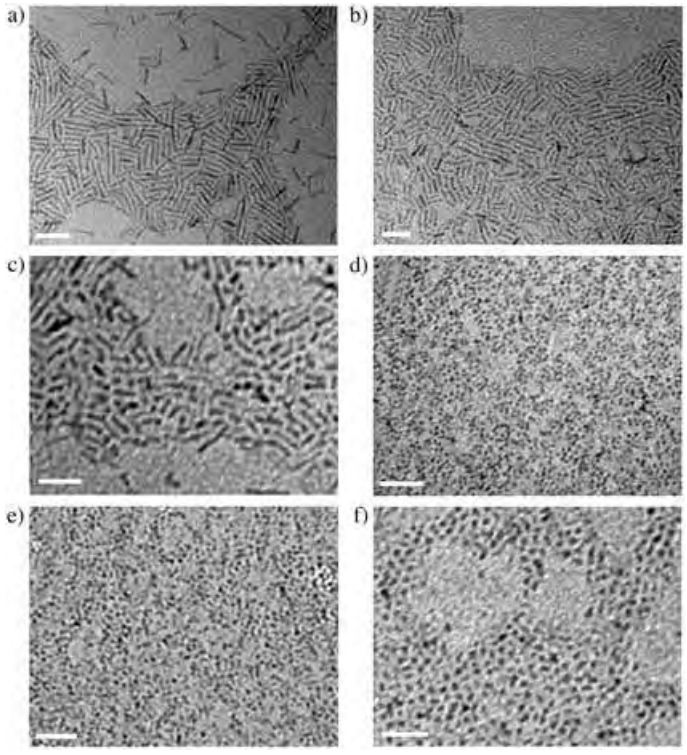


Figure 4. TEM images of diameter-tunable TiO_2 nanorods of length a) 2.9, b) 3.8, and c) 4.6 nm and size-tunable TiO_2 nanodots of size d) 3.0, e) 4.2, and f) 6.0 nm, prepared at different TIP/OA/OLA/CTAB molar ratios and temperatures (1 mmol of TIP was used for all the preparations): a) 1:1:5:3, 260°C; b) 1:1:5:6, 260°C; c) 1:1:4:6, 280°C; d) 1:3:5:3, 260°C; e) 1:3:4:5, 260°C; f) 1:3:3:5, 300°C. Scale bar: 50 nm.

In conclusion, a high-temperature nonhydrolytic aminolysis approach has been developed, and its capability to produce highly crystalline, monodisperse anatase nanocrystals with controlled size and shape in a reasonable size range was demonstrated. By combining the advantage of chemical modification of reactive titanium isopropoxide by oleic acid, the high-temperature aminolysis reaction of titanium oleate complexes with decreased reactivity can be controlled very well for the anisotropic growth of titania nanorods with high-boiling-point oleylamine rather than volatile water. Weaker CTAB ligands were further used to balance the strong binding affinity of OLA ligands for producing larger titania nanodots and thicker titania nanorods. The aminolysis route is much greener because, unlike conventional nonhydrolytic routes, it does not form environmentally unfavorable, volatile alkyl chlorides or hydrogen chloride. In addition to the preparation of size-tunable anatase titania nanodots ranging from 2.3 to 6.0 nm, the "greener" aminolysis route can also provide much better control of anisotropic growth and allows ready preparation of monodisperse titania nanorods with tunable lengths and diameters that range between 2.3–30 nm and 2.0–4.6 nm, respectively. Meanwhile, our synthetic method has been extended further for the preparation of various oxide nanocrystals (e.g., ZrO_2) from different carboxylate precursors.

Experimental Section

Titanium isopropoxide (98%, Acros), oleic acid (90%, Aldrich), oleylamine (70%, Aldrich), octylamine (99%, Aldrich), 1-octadecene (90%, Aldrich), cetyltrimethylammonium bromide (99%, Acros), hexane (99%, Tedia), and acetone (HPLC grade, Tedia) were used as received. All experiments were carried out by standard oxygen-free techniques under nitrogen flow.

In a typical preparation of length-tunable TiO_2 nanorods with a diameter of $\approx$2.0 nm, OLA (1.6 mL, 5 mmol) in 1-ODE (6 mL) was dried and degassed at 80°C in a 50-mL three-neck flask for 1 h. Then TIP (0.3 mL, 1 mmol) was injected into the mixed solution and heated for 20 min. The solution gradually turned from colorless to a pale yellow, indicating the formation of titanium carboxylate complexes. Gaseous isopropyl alcohol was rapidly released while the mixture was heated at 260°C for 10 min. The aminolysis reaction was then initiated by rapid injection of a predetermined amount of OA ranging from 1 to 4 mmol (0.32–1.28 mL) with vigorous stirring. After 1 h, the resulting solution was allowed to cool to room temperature. The resulting crude solution of TiO_2 nanorods was diluted with hexane (10 mL) followed by precipitation with acetone (20 mL). The crude product was recovered by centrifugation, dispersed in hexane (20 mL), and subjected to a second round of purification. The white powders obtained can be redispersed easily in nonpolar solvents such as hexane, toluene, and chloroform for further characterization. For the preparation of diameter-tunable TiO_2 nanorods and size-tunable TiO_2 nanodots, a certain amount of CTAB was mixed with OLA in 1-ODE, and the mixture was dried and degassed for 1 h. Then TIP (0.3 mL, 1 mmol) was injected into the mixed solution, which was heated for 20 min. The remaining procedure is identical to that described above, but with different experimental parameters as

appropriate. TIP (0.3 mL, 1 mmol) was used for all the above preparations.

Powder XRD was performed with a Siemens D5005 X-ray powder diffractometer. XRD samples were prepared by dropping the a TiO_2 nanocrystal solution onto a silicon (100) wafer and drying at room temperature. TEM and HR TEM images were obtained with a JEOL 1010 and a Philips 3010 operating at accelerating voltages of 100 and 300 kV, respectively. TEM samples were prepared by placing a drop of a nanorod solution in hexane onto Formvar carbon-coated copper grids and drying in a desiccator. FTIR spectra were recorded with a FTS 165 Bio-Rad FTIR spectrophotometer in the range of 4000–400 cm^{-1} with KBr plates.

Asymmetric Catalysis

Non-C_2-Symmetric, Chirally Economical, and Readily Tunable Linked-binols: Design and Application in a Direct Catalytic Asymmetric Mannich-Type Reaction**

Takamasa Yoshida, Hiroyuki Morimoto, Naoya Kumagai, Shigeki Matsunaga, and Masakatsu Shibasaki**

Asymmetric catalysis employing chiral metal complexes is one of the most general and flexible methods in asymmetric synthesis.[1] In the development of asymmetric metal catalysts for highly enantioselective and reactive reactions, the design of chiral ligands for the metal center is of key importance: the activity and selectivity of the metal centers can be tuned by chiral ligands. A delicate balance between the steric and electronic properties of the catalyst determines the reaction efficiency. Thus, a chiral ligand with a readily tuneable framework is desirable.[2]

We recently reported the preparation of a series of chiral ligands termed "linked-binols" (**1a**–**c**; Scheme 1).[3,4] These linked-binols consist of two chiral 1,1′-bi-2-naphthol units connected at the 3 and 3″-positions by a flexible linker containing one heteroatom. Linked-binols often provide a better chiral environment than 1,1′-bi-2-naphthol (**2**;

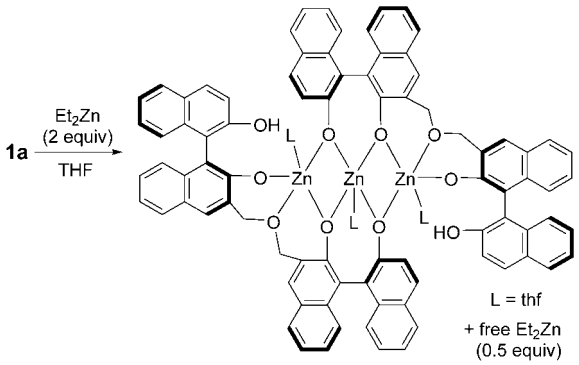
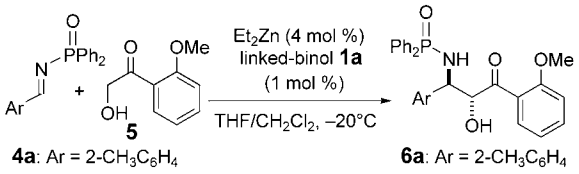


Scheme 2. Structure of a Zn/**1a** (3:2) complex.



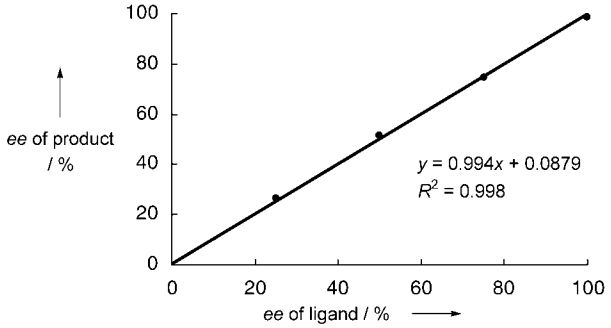


Figure 1. Linear relationship between Mannich-adduct **6a** and (*S*,*S*)-linked-binol **1a** observed in a direct Mannich-type reaction of **4a** with **5**.

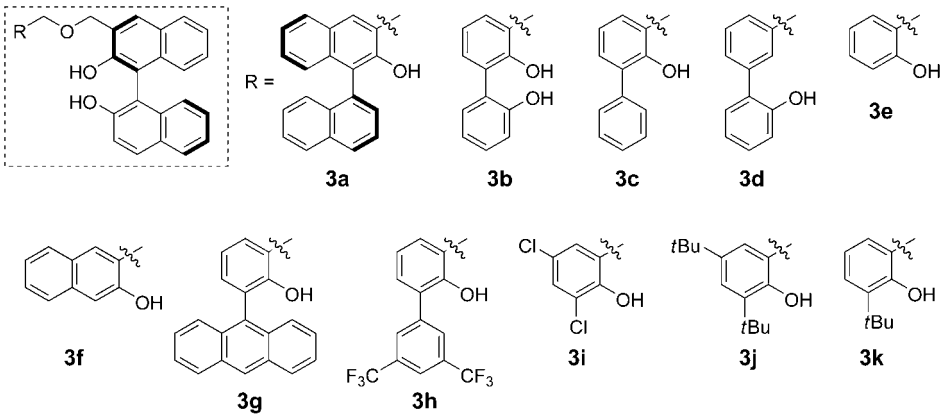
Scheme 1), as was demonstrated in various catalytic asymmetric reactions, such as epoxide openings,[3a] a direct aldol reaction,[5] Michael reactions,[6,7] and direct Mannich-type reactions.[8] Although they are conformationally rigid, two chiral binaphthyl units seem essential to provide an efficient chiral environment for high enantioselectivity; however, they also impose severe limitations on ligand design. So far, the properties of linked-binol complexes could only be tuned by changing the heteroatom of the linker (**1a–c**).[3] Electronic and steric modifications of the binaphthyl moiety is tedious and lengthy because of the presence of two chiral units. Thus, improving the performance of ligands with the original linked-binol framework in catalytic reactions is a formidable challenge. For example, many steps are required when modifying the electronic properties by preparing 6,6′,6″,6‴-tetrasubstituted C_2-symmetric linked-binols. A simple, more flexible strategy is required to overcome this intrinsic dilemma and tune the properties of linked-binols. Herein, we report a readily tuneable, non-C_2-symmetric linked-binol **3** with only one chiral 1,1′-bi-2-naphthol unit and one flexible achiral unit (Scheme 1).[9] On the basis of our mechanistic studies on the Et_2Zn/linked-binol **1a** catalytic system, new ligands were designed and evaluated in direct catalytic asymmetric Mannich-type reactions. The introduction of an achiral unit was not only economical in terms of chirality[10] but also afforded comparable enantioselectivity and a much higher reaction rate than the original linked-binol **1a** with two chiral 1,1′-bi-2-naphthol units.

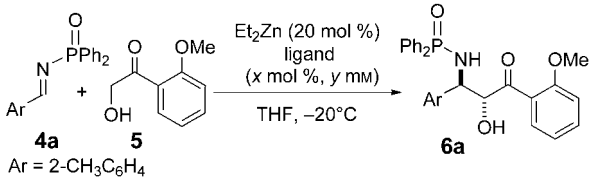
For the design and evaluation of the new linked-binols, a Et_2Zn/**1a** complex was used for reference because its structure and reactivity had been previously studied. The structure of the Zn/**1a** (3:2) precatalyst, prepared from Et_2Zn/**1a** (2:1; Scheme 2), was determined by X-ray crystallographic, NMR spectroscopic, and ESI mass-spectrometric analysis.[11] In the Zn/**1a** (3:2) complex, neither of the linked-binol units had a C_2-symmetric environment and one of the phenolic OH groups remained unchanged, even in the presence of a slight excess of Et_2Zn. On the other hand, there was a linear relationship between the enantiomeric excess of product **6a** and that of the chiral ligand **1a** used in the Mannich-type reaction of diphenylphosphanoylimine (**4a**) and hydroxyketone **5** (Figure 1).[12] The structure of the Zn/**1a** (3:2) complex (Scheme 2) and the results shown in Figure 1 suggested that 1) C_2 symmetry in linked-binol **1a** is not important, 2) one phenolic OH group is not required, and 3) a homochiral complex is more favorable than a heterochiral complex. We hypothesized that one of the chiral binaphthol units could be replaced with an achiral unit, such as an atropisomeric biphenol or an achiral phenol derivative. Chirality should be then transferred to the flexible achiral unit on complexation with a zinc center, and a similar chiral environment should be obtained with a ligand that was economical in terms of chirality.

The structures of ligands **3a–k** are shown in Scheme 3.[13] The catalytic potential of these ligands was evaluated in a direct asymmetric Mannich-type reaction of imine **4a** and hydroxyketone **5** using 5 mol% of ligand **3** and 20 mol% of Et_2Zn at −20°C in THF/CH_2Cl_2 ([imine] = 150 mM, [**3**] = 7.5 mM). When the original ligand **1a** was used, the reaction was completed within 1 h and the Mannich adduct **6a** was obtained in 99% yield with *anti*/*syn* selectivity of 98:2 in >99% *ee* (Table 1, entry 1). A control experiment with 10 mol% of binol **2** had a much lower reaction rate and



Scheme 3. Structures of non-C_2-symmetric (*S*)-linked-binol derivatives **3a–k** containing one achiral unit and one chiral binaphthol unit.

Table 1: Catalytic asymmetric Mannich-type reaction using various chiral ligands (**1a**, **2**, and **3a–k**).

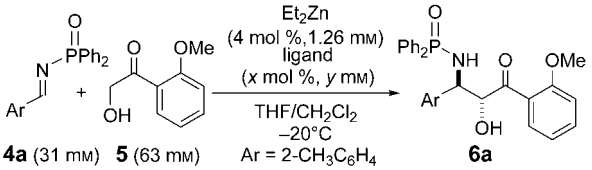


Entry	Ligand (mol%)	[Ligand] [mM]	*t* [h]	Yield [%]	*anti*/*syn*	*ee* [%]
1	**1a** (5)	7.5	1	99	97:3	>99
2	**2** (10)	15	68	85	87:13	24
3	**3a** (5)	7.5	1	99	94:6	99
4	**3b** (5)	7.5	1	98	98:2	98
5	**3c** (5)	7.5	1	99	97:3	99
6	**3d** (5)	7.5	23	74	91:9	9
7	**3e** (5)	7.5	11	92	95:5	90
8	**3f** (5)	7.5	5	93	95:5	87
9	**3g** (5)	7.5	1	98	96:4	99
10	**3h** (5)	7.5	1	95	98:2	98
11	**3i** (5)	7.5	1	94	98:2	98
12	**3j** (5)	7.5	1	96	98:2	98
13	**3k** (5)	7.5	1	95	98:2	98

ee value (68 h, 24% *ee*; entry 2). Ligand **3a**, which lacks one phenolic OH group, gave results similar to those obtained with **1a** (entry 3). Ligand **3b** with an atropisomeric biphenol unit was also efficient (entry 4), thus suggesting that the chirality of the biphenol unit was controlled by complexation with the zinc center.[14] Even an achiral unit, such as **3c**, gave excellent results (1 h, 99% yield, 99% *ee*; entry 5), whereas ligand **3d**, which has a phenolic OH group in the 2′-position, had a low reaction rate and poor enantioselectivity (23 h, 74% yield, 9% *ee*; entry 6). Ligands **3e** and **3f** also produced unsatisfactory yields and modest enantioselectivities (entries 7 and 8). The results shown in entries 5–8 imply that both the phenolic OH group at the proper position and a substituent on the aromatic ring are required. To evaluate the effects of substituents on the phenol ring, ligands **3g–k** were used, and all of them showed a high reactivity and enantioselectivity (entries 9–15). The achiral units in ligands **3i–k** were readily accessible from commercially available salicylic aldehyde derivatives.[15]

Although many ligands in Scheme 3 gave high enantioselectivities (Table 1), it was difficult to compare their performance precisely in terms of reaction rate. Generally, catalyst concentration becomes rather low when catalyst loading is reduced to <0.1 mol% because of substrate-solubility limitations. Thus, high turnover frequencies (TOF) and turnover numbers (TON) under dilute conditions are required to lower the catalyst loading. To evaluate the ligands quantitatively, the reaction for each ligand was monitored under dilute conditions ([imine] = 31 mM, [**3**] = 0.31 mM, 1 mol%; Table 2 and Figure 2). The initial rate of the reaction with each ligand (**1a**, **2**, and **3a–k**) is summarized in Table 2, and the profiles of the reactions with ligands **1a**, **2**, **3c**, **3j**, and **3k** are shown in Figure 2.[16] It is of note that many ligands with achiral units (shown in Scheme 3) gave a better reaction rate than the original linked-binol **1a** that contained two chiral units (initial

Table 2: Initial reaction rate with various chiral ligands (**1a**, **2**, and **3a–k**) under dilute conditions.



Entry	Ligand (mol%)	[Ligand] [mM]	Initial rate [mM min^{-1}]
1	**1a** (1)	0.31	0.199
2	**2** (2)	0.62	0.015
3	**3a** (1)	0.31	0.333
4	**3b** (1)	0.31	0.354
5	**3c** (1)	0.31	0.696
6	**3d** (1)	0.31	0.019
7	**3e** (1)	0.31	0.096
8	**3f** (1)	0.31	0.135
9	**3g** (1)	0.31	0.375
10	**3h** (1)	0.31	0.455
11	**3i** (1)	0.31	0.435
12	**3j** (1)	0.31	0.742
13	**3k** (1)	0.31	0.848

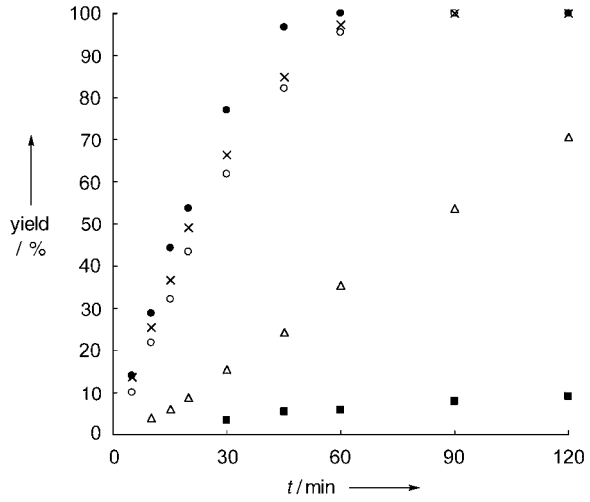


Figure 2. Reaction profiles with chiral ligands: **1a** (△ = 0.31 mM), **2** (■ = 0.62 mM), **3c** (○ = 0.31 mM), **3j** (× = 0.31 mM), and **3k** (● = 0.31 mM).

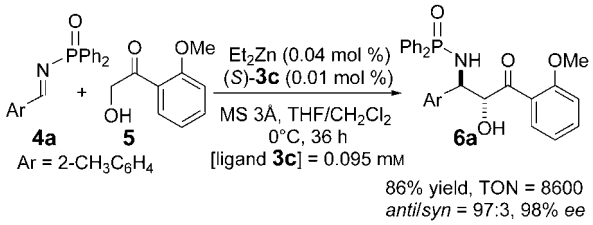
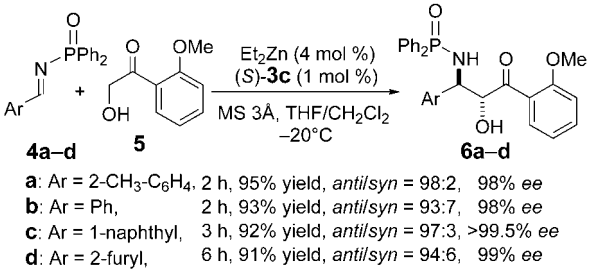
rate = 0.199 mM min^{-1}). Ligands **3j** and **3k** with electron-donating *t*Bu groups gave the highest reaction rates (**3j** = 0.742 mM min^{-1}, **3k** = 0.848 mM min^{-1}), and ligand **3c** also produced a comparable reaction rate (**3c** = 0.696 mM min^{-1}). Ligand **3g**, with a bulky aromatic substituent, had lower reactivity than **3c** but higher reactivity than **1a**. An electron-withdrawing group also had a lower reaction rate (**3h** and **3i**). These results suggested that an appropriate group at the *ortho* position of the phenolic OH group and a relatively less acidic phenolic OH group were suitable substituents on the ligands for the present Mannich-type reaction. These results demonstrated the usefulness of the present strategy to sterically and electronically fine-tune complexes of metal and linked-binols.

The utility of ligand **3c** was further demonstrated, as shown in Schemes 4 and 5. The catalyst loading for **3c** was successfully lowered: the Mannich-type reaction proceeded smoothly with as little as 0.01 mol% of **3c**, with the product being afforded in good yield and selectivity at 0 °C after 36 h (86%, 98% *ee*, TON = 8600; this is the highest TON value achieved in the catalytic asymmetric Mannich-type reaction so far.[17,18]) The reaction proceeded smoothly even with low concentrations of the ligand ([**3c**] = 0.095 mM). The broad substrate range of ligand **3c** is also summarized in Scheme 5.

Although a Et_2Zn/ligand stoichiometry of 4:1 was used for the Mannich-type reaction, characterization of the reaction



Scheme 4. Catalytic asymmetric Mannich-type reaction using 0.01 mol% of **3c**. MS 3 Å = molecular sieves (3 Å).



Scheme 5. Catalytic asymmetric Mannich-type reaction of imines **4a–d** using **3c**.

mixture was difficult for both **1a** and **3c**. Thus, we investigated the structures of precatalysts of a Et_2Zn/ligand mixture in a 2:1 ratio for a preliminary evaluation of the properties of **3c** relative to **1a**.[19] The complex formed in the Et_2Zn/**3c** (2:1) mixture was confirmed to be similar to that in the Et_2Zn/**1a** (2:1) mixture (Zn/**1a** = 3:2; Scheme 2) by ESI mass-spectrometric analysis. The ESIMS spectrum of the Et_2Zn/**3c** (2:1) mixture showed major peaks at *m*/*z* 1183–1194,[20] which correspond to a Zn/**3c** (3:2) complex. The ^{1}H and ^{13}C NMR spectroscopic analysis of the Et_2Zn/**3c** (2:1) mixture indicated eight different benzylic protons and four benzylic carbon atoms,[20] thus suggesting that the Zn/**3c** (3:2) complex does not have C_2 symmetry, and that two molecules of **3c** were differentially involved, possibly in a head-to-tail fashion. Further investigations to determine the structure of the Zn/**3c** complex unequivocally are ongoing. Although the structure of the actual active species formed under the reaction conditions is not clear at the moment, we speculate that the coordination site at the zinc center would be sterically less crowded in the Zn/**3c** complex than in the Zn/**1a** complex, thus accelerating the rate-limiting exchange step[21] between the product and ketone **5** to regenerate the Zn/ligand/ketone complex. Further mechanistic studies are in progress.

In summary, we have developed readily tuneable, economical in terms of chirality, non-C_2-symmetric linked-binol derivatives. The new design overcomes the drawbacks inherent in the original C_2-symmetric ligand **1a** with two chiral binaphthol units. The present strategy has been useful to fine-tune metal/linked-binol complexes in a direct catalytic asymmetric Mannich-type reaction. Further application of these new sterically and electronically tuneable ligands to other asymmetric reactions, in which the original linked-binol **1a** produced unsatisfactory results, is currently ongoing.

[13] For the synthesis and spectra of ligands **3a–k**, see the Supporting Information.

[14] The initial reaction rate of the Mannich-type reaction with a *meso*-linked-binol derivative prepared from (*S*)-binol and (*R*)-binol units was estimated relative to that of (*S*,*S*)-linked-binol **1a**. A similar initial reaction rate was observed for **1a** and the *meso*-linked-binol. The chirality of ligand **3b** should be controlled by (*S*)-biphenol-(*S*)-binol on complexation with the zinc center because the pseudo-*meso*-(*R*)-biphenol-(*S*)-binol-type complex would afford products in low enantiomeric excess.

[15] In terms of cost efficiency, **3b** and **3c** are also superior to **1a**: 2,2′-biphenol (500 g; Aldrich) and 2-phenylphenol (500 g; Aldrich).

[16] The reaction profiles with other ligands are summarized in the Supporting Information.

[18] The best TON was achieved using 0.02 mol% of **1a** ([ligand **1a**] = 0.21 mM, TON = 4900)[8b]; however, the concentration of **1a** had to be >0.2 mM to promote the reaction efficiently. Under similar conditions given in Scheme 2 ([ligand **1a**] = 0.1 mM, 0.01 mol%), TON < 4000.

[19] In the present Mannich-type reaction, the ratio of Et_2Zn/ligand (**1a** or **3c**) did not affect enantioselectivity. Et_2Zn/**1a** (2 mol% of **1a**): 2:1 (>99% *ee*, d.r. 98:2, 2 h, >95% yield), 3:1 (>99% *ee*, d.r. 98:2, 1 h, >95% yield), 4:1 (>99% *ee*, d.r. 98:2, 1 h, >95% yield); Et_2Zn/**3c** (2 mol% of **3c**): 2:1 (99% *ee*, d.r. 99:1, 1 h, >95% yield), 3:1 (98% *ee*, d.r. 98:2, 1 h, >95% yield), 4:1 (98% *ee*, d.r. 98:2, 1 h, >95% yield); thus, we assumed that a similar active species formed under these reaction conditions, and that the structural information obtained with Et_2Zn/ligand (2:1) would give some insight into the properties of **3c**.

[20] ESI mass spectra as well as the ^1H NMR and ^{13}C NMR spectra of Et_2Zn/**3c** (2:1) are given in the Supporting Information. The ESI mass-spectrometric analysis showed several signals that correspond to the Zn/**3c** (3:2) trinuclear complex, depending on the natural-isotope distribution pattern of zinc.

[21] The rate-limiting step of the Mannich-type reaction of **4a** with **5** was determined to be a catalyst-turnover step by kinetic studies on the initial rate; see Ref. [8b]

Mesoporous Materials

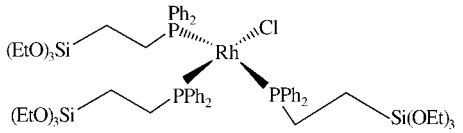
Organometallic Chemistry Inside the Pore Walls of Mesostructured Silica Materials**

Véronique Dufaud, France Beauchesne, and Laurent Bonneviot**

Recently a new class of porous organic–inorganic hybrid materials was prepared through the surfactant-templated polycondensation of bridged silsesquioxane organic molecules. These new materials, which are also referred to as periodic mesoporous organosilicas (PMOs), are unique as their channel walls contain both inorganic and organic fragments.[1] These fragments are uniformly distributed within the framework by covalent bonding of two or more terminal silyl groups, which leaves the void space unoccupied after template removal. This new approach extends the field of mesoporous materials into the chemistry of channel walls. Through choice or design of the organic functionality, one may create new materials that have truly unique properties and behaviors. These embedded fragments are readily accessible for chemical reaction, thus opening the possibility of using such materials as catalysts.[2]

Herein, we report the development of new methodologies for the preparation of inorganic–organometallic hybrid materials in which the organometallic complexes, which are structurally well defined at the molecular level, are integrated within the pore walls of highly ordered mesostructured silicas. This integration of the complex into the solid, rather than the grafting of a complex to the surface, should reduce some of the problems commonly associated with supported homogeneous systems, notably, catalyst leaching, pore blockage, and distribution inhomogeneity.

The first step in the accomplishment of this goal was the synthesis of an organometallic precursor that had multiple polycondensable organosiloxane functionalized donor ligands.[3] The rhodium organophosphine complex **1** was chosen to provide a wide range of potential catalytic applications (e.g., hydrogenation, hydroformylation).



1

We wished to use this precursor directly in the synthesis of a hybrid MCM-type silica by cohydrolysis and polycondensation of **1** with tetraethylorthosilicate (TEOS) in the presence of cetyltrimethylammonium bromide (CTAB) as a structure-directing agent (SDA), but this precursor (and indeed, many catalytically interesting transition-metal complexes) was insoluble in water and unlikely to be stable under the classical aqueous basic conditions of this process.[4] Thus, we adapted the condensation reaction under the mild, acidic conditions reported by Stucky and co-workers (which led to the formation of SBA-3 mesostructured silicas)[5] to add an organic cosolvent, acetonitrile,[6] to better dissolve the transition-metal complex. Various combinations of **1**, TEOS, water, acetonitrile, CTAB, and HCl were attempted. The best results were obtained with 7.5 % wt acetonitrile, which led to materials that had a rhodium content of up to a 2 % wt in a highly ordered solid and contained the structure-directing agent CTAB in the channels.[7]

To render the organometallic sites of the as-made solid accessible, the surfactant template was removed by extraction.[8] It was found that if the extraction was performed directly on the as-made materials, all the structural order was lost. This instability, which is likely to be a consequence of the low temperature at which the condensation reaction was performed, disappeared when the as-made material was first silylated with $(CH_3)_3SiCl$ or $(CH_3)_2SiCl_2$ before the CTAB was extracted.[9]

The solids thus obtained were characterized by methods appropriate to molecular species (e.g., solid-state ^{13}C, ^{31}P, and ^{29}Si NMR spectroscopy, IR spectroscopy, and elemental analysis) as well as techniques more commonly associated with the characterization of mesoporous solids (nitrogen sorption isotherms, powder X-ray diffraction (XRD), thermogravimetric analysis (TGA), transmission electron microscopy (TEM), and energy dispersive X-ray (EDX) analysis). The characterization of one material (**2**, lot 1), which had been silylated with $(CH_3)_3SiCl$ and was shown by microanalysis to have 1.7 % wt Rh is presented below.

Mesoscopic order within **2** was shown to have been maintained after extraction of the SDA. The powder XRD pattern of **2** showed three clear peaks in the 2θ range of 1–10°, which is characteristic of 2D hexagonal ordered mesophases, with the d(10) spacing changing from 30 to 37 Å because of extraction of the template (Figure 1).[10] At this stage, the IR spectrum of **2** showed very little absorption in the 3000–2800 cm^{-1} range, thus indicating that the SDA had been removed.

Ordering was also clearly evident in the TEM image of **2** (Figure 2). Long-range ordering of the channels was observed with a spacing periodicity of approximately 3 nm. The TEM/EDX data were also important as they showed that metal complexes were localized in well-ordered phases of the solid

and the ligand-to-metal ratio (i.e., the P/Rh ratio) of the molecular precursor was maintained at 3 ± 0.3 (see the Supporting Information). This observation was confirmed over a large number of sample areas of the surface that was tested. Note that the elemental analysis of a sample of material on the milligram scale showed a P/Rh ratio of 2.96.[11]

The ^{31}P cross-polarization magic-angle spinning (CP-MAS) NMR spectroscopy showed a single signal at $\delta = 40.4$ ppm, which corresponds to a coordinated phosphine ligand. The ^{13}C CP-MAS NMR spectrum exhibited all of the aryl and alkyl resonances for the phosphine ligand as well as a strong signal at $\delta = -1.0$ ppm associated with the methyl of $(CH_3)_3Si-$ fragment, but no significant signal that could be associated with the CTAB template molecule was present. The ^{13}C CP-MAS NMR spectrum also showed evidence of a trace of the ethoxy fragment of the molecular precursor, which would indicate that some of the ethoxysilane was incompletely condensed. In the ^{29}Si CP-MAS NMR spectrum, the presence of T^2 and T^3 sites, as indicated by signals at $\delta = -60$ and 67.4 ppm, suggests that the precursor is not simply encapsulated but rather integrated into the silica network. Other signals were also observed in the $\delta = -90$ to -115 ppm spectral region (silica Q sites) and at $\delta = 15$ ppm ($(CH_3)_3Si-$ fragment).[12]

The TGA profile showed four regions of weight loss.[13] At temperatures up to about 100 °C, weight loss was accompanied by an endothermic differential thermal analysis (DTA) peak, which was presumably because of desorption of water. A second region of weight loss followed at temperatures between 200 and 550 °C, which, may be considered n inspection of the first derivative of the profile as a peak centered at 360 °C and a shoulder at around 460 °C, both arising from the decomposition and desorption of volatile organic species. The embedded complex is thermally stable up to 200 °C. The weight loss taken between 200 and 460 °C, and attributed to the ligand, is in good agreement with the metal loading and the stoichiometry of the molecular precursor. Above 460 °C, the weight loss is mainly because of the decomposition of the trimethylsilyl groups and accounts for approximately two $(CH_3)_3Si-$ fragments per rhodium atom. Further weight loss occurred at temperatures above 650 °C, which is probably because of the condensation of silanols of the silica framework.

The results of the analysis of the adsorption–desorption isotherms and the pore-size-distribution curves of the extracted unmodified and rhodium-modified materials are shown in Figure 3. Both samples show a type IV isotherm, which is characteristic of mesoporous solids. Relatively

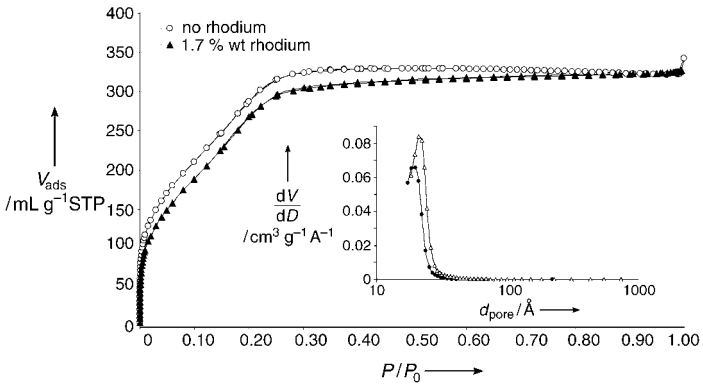

Figure 3. Nitrogen adsorption–desorption isotherms and pore-size distributions (from the Barret–Joiner–Halenda (BJH) calculations) of unmodified and rhodium-modified SBA-3 silicas.

narrow pore–diameter distributions were observed for both materials and the average pore diameter did not vary significantly between the two samples (2.0–2.2 nm), which would seem to indicate that the rhodium had indeed been incorporated into the walls of the silica rather than remaining in the pores or the channels. The Brunauer–Emmett–Teller (BET) specific surface area measured for the rhodium-modified material ($930\ m^2 g^{-1}$) was also quite similar to that of the unmodified analogue ($1090\ m^2 g^{-1}$).[14]

Thus, we have a material in which intact triphosphanylrhodium chloride fragments have been covalently bound to the silica framework without the overall porosity or the degree of order of the material being affected. The complexes seem to be homogeneously distributed and embedded in the channel walls. The question remained whether the metal-containing sites of **2** were accessible for catalytic chemical reactions and

whether the rhodium complex would exhibit typical behavior associated with its homogeneous analogue.

The catalytic activity of several hybrid materials for hydrogenation was evaluated by using substrates of varying steric encumbrance and compared to the activity of a homogeneous catalyst, [$RhCl(PPh_3)_3$]. Among the materials tested were two different lots of a model system prepared by postsynthetic grafting of precursor **1** onto calcined SBA-15 silica **3**. Results obtained for the catalytic tests are given in Table 1.

Table 1: Hydrogenation of alkenes by different rhodium-based catalysts.[a]

Substrate	Catalyst	% wt Rh[b]	Substrate/Rh	Conv [%]	TOF [h^{-1}]
styrene	**3**	0.8	7600	85	2150
	2	0.7	8500	93	2650
cyclohexene	**3**	0.8	7550	100	2590
	2	0.7	8560	100	2850
acrolein	**3**	0.8	7500	4	97
	2	0.7	8890	4	104
crotonaldehyde	**3**	1.1	5500	≈7[c]	20[c]
	2	1.7	3400	≈5[c]	9[c]
styrene	[$RhCl(PPh_3)_3$]	3.5×10^{-4} M solution	6600	75[d]	3300[d]

[a] Conditions: $P(H_2)=20$ bar, 70 °C, 3 h in benzene. TOF = turnover frequency, conv = conversion. [b] From elemental analysis. [c] 19 h. [d] Homogeneous catalysis, 1.5 h.

In all cases, the modified SBA-3 materials, including **2**, exhibited similar activity to that of model system **3**; thus, it is clear that the rhodium centers are available for catalysis. Indeed, for styrene hydrogenation, the activity is in the same range as that observed for the homogeneous complex. Furthermore, catalytic activity was observed even for the more hindered double bonds of cyclohexene and crotonaldehyde (see Table 1. The chemoselectivity (100%) of the catalyst for the carbon–carbon double bond in α,β-unsaturated aldehydes is the same as that reported for the homogeneous catalyst.[15] Limited attempts at recycling the catalyst have shown that catalytic activity is undiminished over several cycles, but more rigorous testing is needed.

In summary, we have developed a new synthetic protocol that allows the incorporation of phosphine-ligated transition-metal complexes into SBA-3 type silicas without significant loss of the mesoscopic order of the silica framework or the coordination environment and catalytic activity of the transition-metal complex. Key novel aspects of the protocol are the use of acetonitrile as a cosolvent, the acidic conditions, the relatively low temperatures, and silylation of the material prior to extraction of the SDA. The method has been successfully extended to incorporate other siloxy organophosphanyl transition-metal complexes into hybrid materials, notably those of platinum and palladium. The evaluation of these materials, in terms of activity and stability, for a variety of catalytic applications is ongoing.

[6] In a typical procedure, CTAB was first dissolved in water, HCl, and half of the amount of acetonitrile used in the gel composition. TEOS was then prehydrolyzed over 15 min at room temperature prior to the addition of the organometallic precursor that had been dissolved in the remaining portion of acetonitrile. The resulting solution was stirred for 3 h at room temperature. The solid product was collected by filtration, washed with water, and dried under vacuum overnight at 25 °C.

[7] Optimized molar composition: TEOS 1; H_2O 120; CH_3CN 4.3; HCl 9.2; CTAB 0.12. When a siloxane-containing transition-metal complex is used, the calculation of the molar composition is based on the total number of condensable silicon centers, from TEOS and the complex.

[8] The template was removed from the as-made material by batch extraction with dry ethanol at 50 °C for 2 h. Three extraction cycles were necessary to complete the process.

[9] The postsilylation reaction was performed in dry toluene at 50 °C for 1 h using either $(CH_3)_3SiCl$ or $(CH_3)_2SiCl_2$ as the silylating agents.

[10] The expansion of the structure upon silylation and extraction, indicated by the increase of the d(10) spacing is likely to be related to the decreased degree of hydrogen-bonding interactions between the surface hydroxy groups, which leads to a partial release of the internal surface tension.

[11] Elemental analysis: 1.5% wt P and 1.7% wt Rh.

Natural Product Synthesis

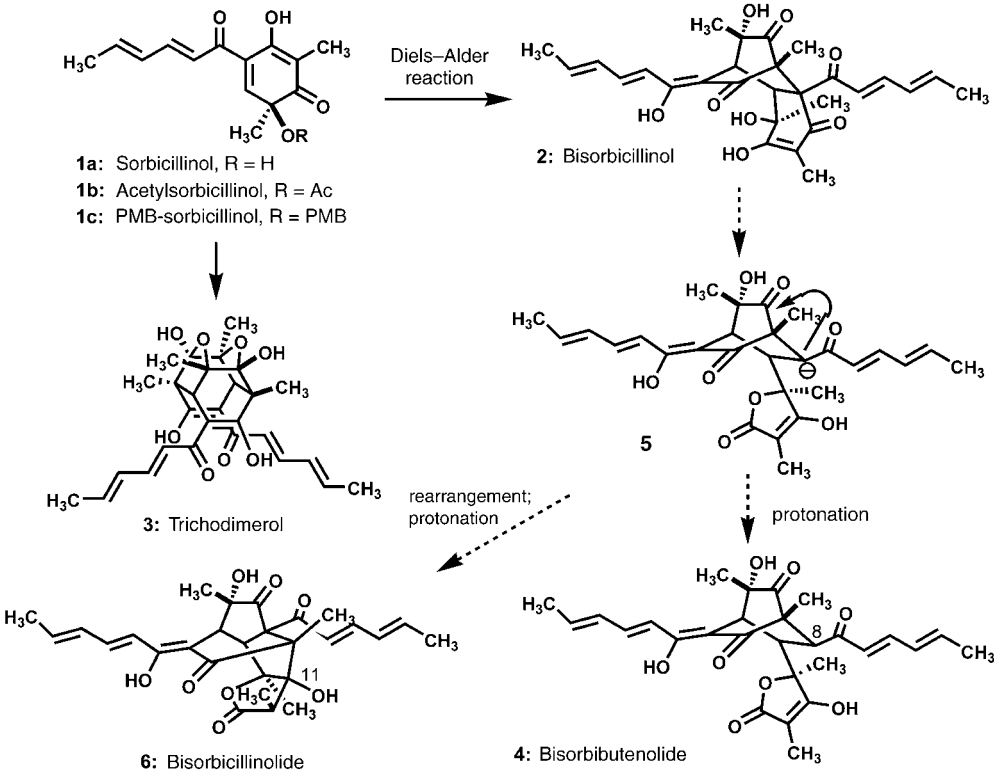
Catalytic Enantioselective Total Syntheses of Bisorbicillinolide, Bisorbicillinol, and Bisorbibutenolide**

*Ran Hong, Yonggang Chen, and Li Deng**

Dedicated to Professor Eric N. Jacobsen

The remarkable structural complexity and broad range of interesting biological activitiesis of bisorbicillinoids have made them attractive synthetic targets. Although structurally diverse, it was postulated that bisorbicillinoids were biosynthetically generated from a common intermediate, sorbicillinol (**1a**), through several fascinating and chemically distinct dimerizations of **1a** (Scheme 1).[1,2] This notion was confirmed in pioneering synthetic studies of bisorbicillinoids by the research groups of Corey and Nicolaou that culminated in the successful biomimetic total syntheses of bisorbicillinol (**2**) and trichodimerol (**3**) through a [4+2] dimerization and a Michael reaction/ketalization dimerization, respectively.[1,2] Furthermore, the Corey and Nicolaou groups showed that dimerization of optically active sorbicillinol (**1a**), prepared by hydrolysis of the optically active 6-acetylsorbicillinol (**1b**; obtained through preparative HPLC resolution of its racemic counterpart), led to the formation of **2** and **3** in the optically active form.[2a,d] Nicolaou et al. also demonstrated that bisorbicillinol (**2**) could be converted into bisorbibutenolide (**4**),[2c,d] thus supporting the proposal of Abe et al. that bisorbicillinol (**2**) is a biosynthetic precursor to other more structurally complex bisorbicillinoids.[3] Although Abe et al. postulated that intermediate **5**, which is formed during the conversion of **2** into **4**, could also give rise to bisorbicillinolide (**6**),[3b] the total synthesis of **6**, in either its racemic or optically active form, has not yet been reported.

These inspiring synthetic studies underscored the importance of developing a highly enantioselective synthesis of sorbicillinol derivatives (**1**). The presence of a single heteroatom-substituted quaternary stereocenter and densely packed sensitive functionalities apparently render this task highly challenging, as no enantioselective total synthesis of any member of the bisorbicillinoids has been reported.[4] Herein, we describe a catalytic, enantioselective, and flexible synthesis of sorbicillinol derivatives **1** and the enantioselective total syntheses of bisorbicillinolide (**6**), bisorbicillinol (**2**), and bisorbibutenolide (**4**).



Scheme 1. Selected bisorbicillinoids and the biosynthesis hypothesis.

Our synthetic plan, outlined in Scheme 2 featured a catalyst-controlled enantioselective construction of the het-

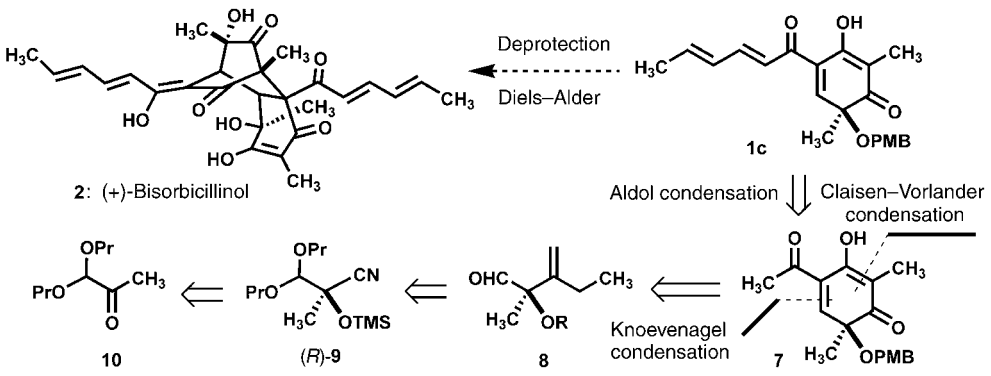


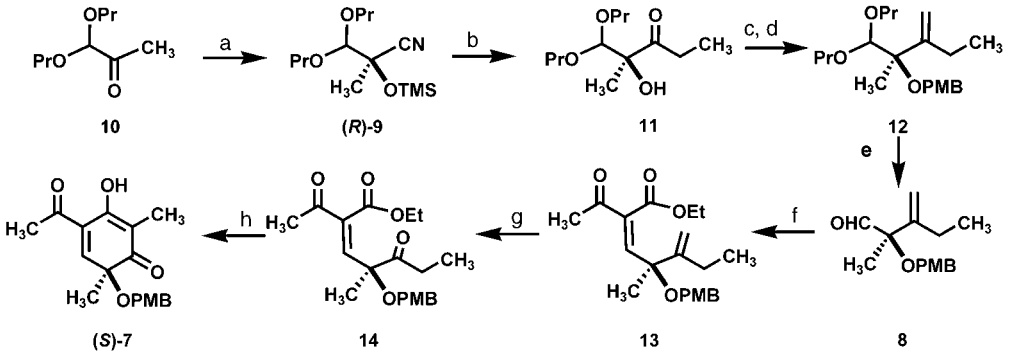
Scheme 2. Retrosynthetic analysis of bisorbicillinol (**2**). TMS = trimethylsilyl.

eroatom-substituted quaternary stereocenter in sorbicillinol derivative **1c**. Considering the sensitive nature of the dienone side chain,[5] we planned to introduce it at a later stage in our synthesis of **1c**. We envisaged that quinol **7** could be derived from aldehyde **8** through a Knoevenagel condensation and a subsequent Claisen–Vorländer condensation.[6] Aldehyde **8** could be prepared from cyanohydrin (*R*)-**9**, which was prepared in 92% *ee* and quantitative yield on a multigram scale by a modified cinchona alkaloid catalyzed enantioselective cyanosilylation of acetal ketone **10** (Scheme 3).[7]

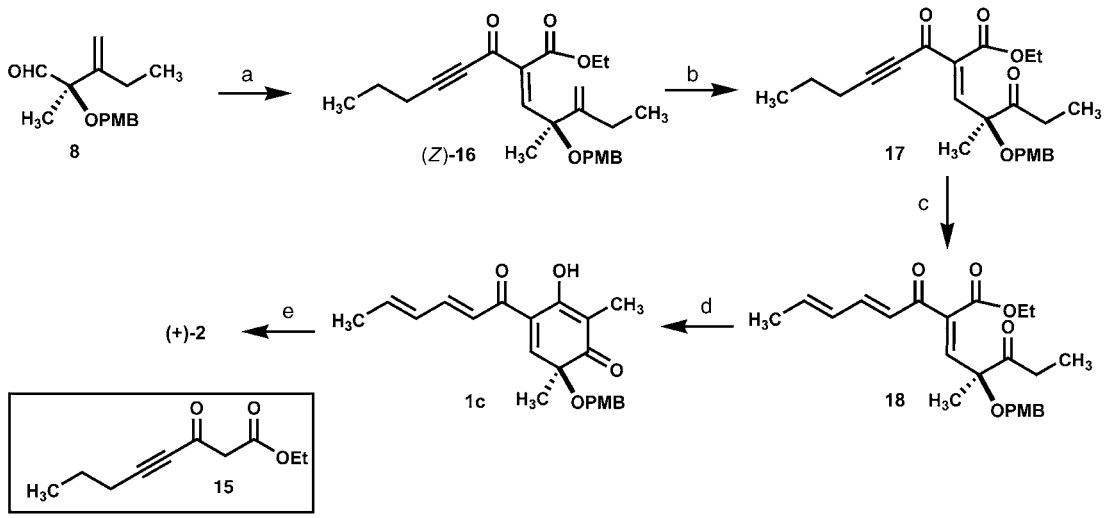
The addition of Grignard reagent EtMgBr to the optically active cyanohydrin **9** in THF/Et_2O proceeded smoothly to form α-hydroxy ketone **11** in nearly quantitative yield (Scheme 3).[8] After masking the ketone as a methylene group through a Wittig olefination,[9] the tertiary alcohol was protected as a *para*-methoxybenzyl (PMB) ether to furnish **12**.[10] The acetal group of **12** was readily hydrolyzed in excellent yield with aqueous HCl to provide aldehyde **8**, which was required for the critical Knoevenagel condensation. A modification of the procedure developed by Lehnert[11] was used for the $TiCl_4$-promoted Knoevenagel condensation of aldehyde **8** with ethyl acetoacetate, which proceeded to generate **13** as a 7:1 mixture of isomers (*Z*/*E*). The desired *Z* isomer was isolated in 85% yield. Ozonolysis in the presence of pyridine at −72 °C provided diketone ester **14** in 80% yield.[12] Gratifyingly, the Claisen–Vorländer condensation with NaOH in dry dimethyl sulfoxide (DMSO) furnished the PMB-protected chiral quinol **7** in 67% yield.

Having secured an eight-step enantioselective route for the construction of the chiral quinol ring, we turned our attention to the installation of the dienone side chain to form the PMB-protected sorbicillinol **1c**. Unfortunately, all attempts to accomplish this task through either an aldol condensation or a two-step sequence[5b] of allylation followed by dehydrogenation were unsuccessful because of the propensity of **7** to undergo decomposition under basic conditions. We then began to explore an alternative strategy involving the introduction of all the carbon atoms required for the construction of sorbicillinol derivatives **1** before the formation of the quinol ring. We envisaged using the readily accessible ynone ester **15**[13] instead of ethyl acetoacetate for the Knoevenagel condensation (Scheme 4) with subsequent isomerization of the alkynone to a dienone.

The Knoevenagel condensation of **15** with aldehyde **8** proceeded in the presence of *N*-methylmorpholine (NMM)[11b] with exceedingly high Z selectivity ($Z/E > 50{:}1$) to afford **16** in 93% yield. Following the ozonolysis of **16**, the isomerization of ynone **17** to dienone **18** was accomplished in 92% yield with a modified Trost–Lu protocol[14] utilizing palladium acetate and tri-*p*-tolylphosphine. The outcome of the Claisen–Vorländer cyclization of **18** depended critically on the base used for the generation of the enolate, as **18** readily underwent decomposition with either lithium diisopropylamide (LDA) or NaH, whereas no reaction occurred with lithium bis(trimethylsilyl)amide (LiHMDS) or sodium bis(trimethylsilyl)amide (NaHMDS). After numerous experi-



Scheme 3. Conditions: a) TMSCN, $(DHQ)_2AQN$ (2 mol%), $CHCl_3$, 100%, 92% *ee*; b) EtMgBr, Et_2O/THF (4:1), 98%; c) Ph_3PCH_3Br, $Et(Me)_2COK$, benzene, 82%; d) PMBOC(=NH)CCl_3, TfOH (cat.), Et_2O, 92% (based on the recovered starting material); e) 3 N HCl (aq), acetone, 90%; f) ethyl acetoacetate, $TiCl_4$, pyridine, THF, 85%; g) ozone, pyridine, CH_2Cl_2, 80%; h) NaOH, DMSO, 67%. $(DHQ)_2AQN$ = 1,4-bis(dihydroquinyl)anthraquinone, TfO = trifluoromethanesulfonate; PMB = *para*-methoxybenzyl.



Scheme 4. Conditions: a) **15**, $TiCl_4$, NMM, THF, 93%; b) ozone, pyridine, CH_2Cl_2, 99%; c) $Pd(OAc)_2$ (cat.), *p*-tol_3P, benzene, 92%; d) Ph_3COH, KH, THF, 90%; e) TFA, CH_2Cl_2, 54%. tol = tolyl.

ments, we found that the cyclization proceeded cleanly with Ph_3COK to afford PMB-protected sorbicillinol **1c** in 90% yield. Treatment of **1c** with trifluoroacetic acid (TFA) at room temperature[15] accomplished the removal of the PMB group and the [4+2] dimerization of the resulting sorbicillinol **1a** in one pot to afford (+)-bisorbicillinol (**2**) in 54% yield after isolation. The conversion of (+)-**2** into (+)-**4** following the procedure reported by Nicolaou et al.[2c,d] allowed us to complete an 11-step enantioselective synthesis of **4** in 15% overall yield.[16,17]

In light of the proposal by Abe et al. that bisorbicillinol (**2**) is the possible biosynthetic precursor for bisorbicillinolide (**6**),[3b] we attempted the conversion of synthetic (+)-**2** into (+)-**6**. We were pleased to observe that (+)-**2**, on standing in methanol for 48 hours, rearranged to give (+)-**6** and (+)-**4** as a 4:1 mixture, which after isolation gave these compounds in 64% and 10% yield, respectively (Scheme 5). Thus, the first total synthesis of bisorbicillinolide (**6**) was completed.[16,17]

In conclusion, the first enantioselective total syntheses of bisorbicillinolide (**6**), bisorbicillinol (**2**), and bisorbibutenolide (**4**) have been accomplished in 10/11 steps and 12–19% overall yields by using a modified cinchona alkaloid catalyzed cyanosilylation as the stereochemistry-defining step.[18] Moreover, the rearrangement of **2** into **6** sheds light on the biosynthesis of **6**. Further exploration of the potential for modified cinchona alkaloid catalyzed enantioselective ketone cyanosilylations in target-oriented synthesis are now underway. These investigations are being carried out in the context of asymmetric total syntheses of other complex natural products and biosynthetically related analogues of chiral quinols **7** or sorbicillinol derivatives **1**.

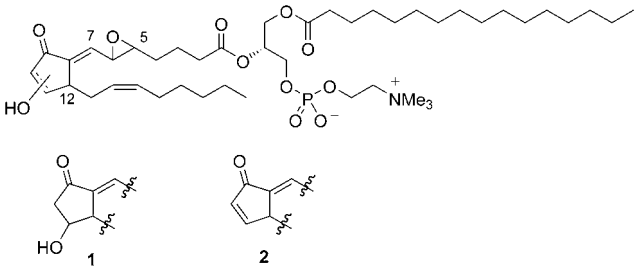
[18] The absolute configuration of cyanohydrin **9** has been determined to be *R*;[7] consequently, the current asymmetric syntheses with (*R*)-**9** as an intermediate provide direct experimental evidence confirming the previous assignment of the absolute configurations for (+)-**2**, (+)-**4**, and (+)-**6** based on their biosynthesis hypothesis (see the Supporting Information).

Natural Product Synthesis

Total Synthesis of 2-(5,6-Epoxyisoprostane A_2)phosphorylcholine and Elucidation of the Relative Configuration of the Isoprostane Moiety**

*Hukum P. Acharya and Yuichi Kobayashi**

1-Palmitoyl-2-(5,6-epoxyisoprostane E_2)-*sn*-glycero-3-phosphorylcholine (**1**) and the related molecule **2** with 5,6-epoxyisoprostane A_2 at the *sn*-2 position (Scheme 1) are



Scheme 1. Aortic oxidation products of 2-arachidonoylphosphorylcholine.

oxidation products of 1-palmitoyl-2-arachidonoyl-*sn*-glycero-3-phosphorylcholine (PAPC)[1] that are found in interleukin-1β-stimulated human aortic endothelial cells (HAEC) and in mildly oxidized low-density lipoproteins (ox-LDL).[2] These molecules stimulate HAEC to release interleukin-8 and monocyte chemotactic protein-1. The monocytes activated by these chemokines[2,3] enter the vessel wall, where they initiate and cause the progression of atherosclerotic lesion.[3,4] The whole structures of **1** and **2**, and in particular the vinyl epoxide moiety of the isoprostane unit, are important for this activity.[5]

In contrast to the considerable progress made in the biological study of these compounds, the structures of the epoxyisoprostane parts of **1** and **2** had not been elucidated fully. Thus, although the connectivities and geometries of the epoxy and Δ^{14} olefinic moieties had been determined unambiguously by ^{1}H NMR spectroscopy and mass spectrometry,[1] the *E* geometry of the Δ^7 alkene and the relative configura-

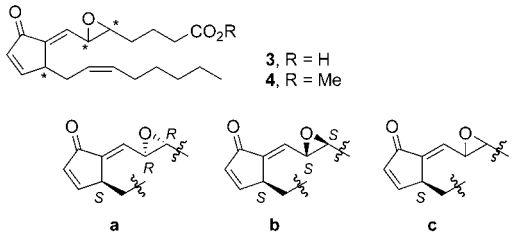
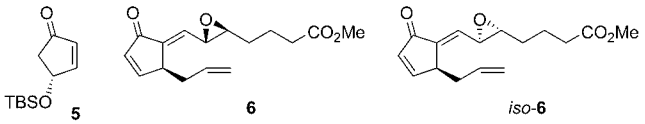
 DOI: 10.1002/anie.200500534

tion of the epoxy moiety and C12 were assigned for **2** by analogy with a structurally related compound.[6] Whereas it is believed that the configuration of the glycerol moiety of compounds **1** and **2** is the same as in *sn*-glycerol-3-phosphate, there was no information about the configuration of the 4 (for **1**) or 3 (for **2**) stereocenters in the respective isoprostane moieties. As **2** is the dehydration product of **1** and was isolated with **1** from the same origin, it seems reasonable to assume that the epoxyisoprostane portions of **1** and **2** share the same configuration at C5, C6, C12, and the Δ^7 olefin. Consequently, we chose to synthesize the epoxyisoprostane A_2 **3**—that is, the cyclopentenone-containing carboxylic acid constituent of compound **2**—to elucidate the relative configuration (Scheme 2).[7]



Scheme 2. 5,6-Epoxyisoprostanes A_2 that we have synthesized.

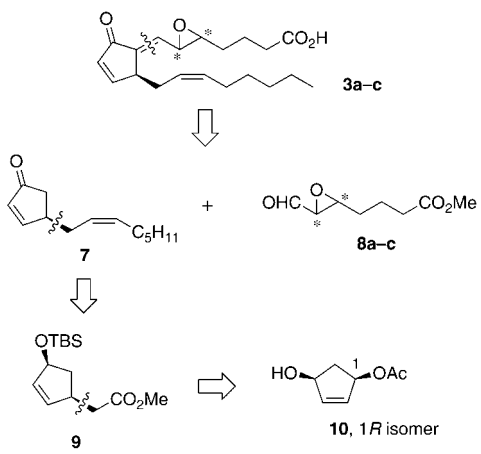
Methyl ester **6**, with a similar structure to acid **3**, was synthesized by Jung et al. by a three-component coupling strategy[8] starting from enone **5** (TBS = *tert*-butyldimethylsilyl). The same relative configuration as in **6** was assigned to **2**



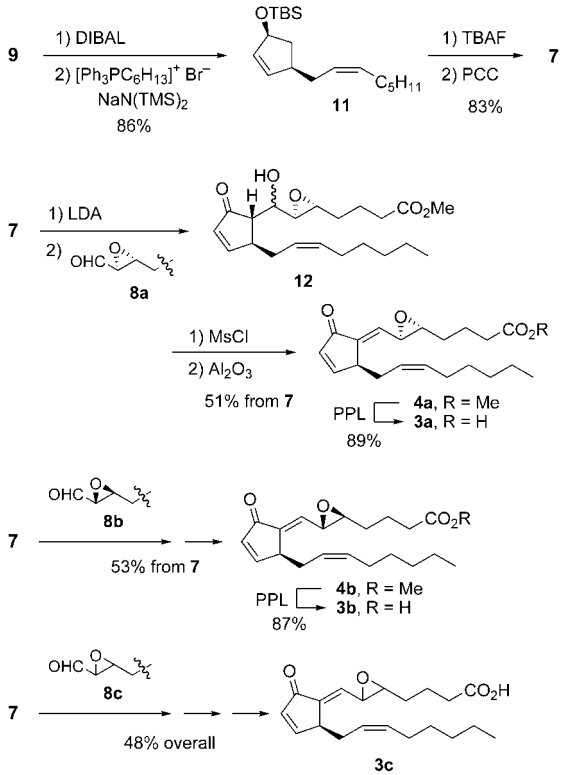
(i.e., **2b**) by comparison of their ^{1}H NMR spectra.[6] The results reported in the following prove that this assignment was wrong—the error having occurred mostly because Jung et al. did not include the isomer *iso*-**6** in their study—and that the natural product **2** either has the stereostructure **2a** or is the enantiomer of **14**.

Our approach to the epoxyisoprostane A_2 stereoisomers **3a–c**, which involves the combination of enone **7** and epoxyaldehydes **8a–c** in an aldol reaction, is summarized in Scheme 3. First, ester **9** was synthesized on a multigram scale from the TBS ether of **10**[9] (> 95% *ee*) through a palladium-catalyzed reaction with dimethyl malonate/*t*BuOK followed by decarboxylation,[10] and was converted into olefin **11** stereoselectively by reduction with DIBAL and subsequent Wittig reaction of the resulting aldehyde in 86% yield (Scheme 4). The silyl group was removed with TBAF, and oxidation of the resulting alcohol with PCC afforded **7** in 83% yield.

The aldol reaction of **7** with the epoxyaldehyde **8a**[11] afforded **12** as a mixture of the *anti* and *syn* aldol products. Without separation, the mixture was converted into the corresponding mesylate, which was exposed to Al_2O_3[12] to



Scheme 3. Retrosynthetic analysis of **3**.



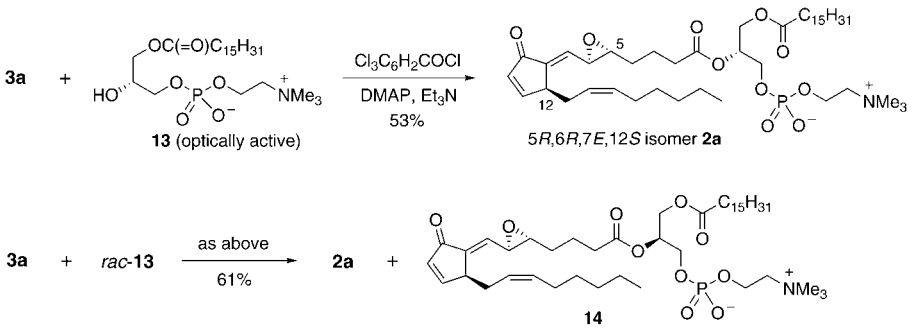
Scheme 4. Stereoselective synthesis of **3a**, **3b**, and **3c** via enone **7**. DIBAL = diisobutylaluminum hydride, LDA = lithium diisopropylamide, Ms = methanesulfonyl, TBAF = tetrabutylammonium fluoride, TMS = trimethylsilyl, PCC = pyridinium chlorochromate.

produce the 7*E* alkene–methyl ester **4a** in 51% yield from **7**.[13] No signal was observed for the hydrogen atom at C7 of the *Z* isomer in the expected 0.5–1-ppm upfield region.[14] Finally, the hydrolysis of **4a** with porcine pancreatic lipase (PPL) furnished epoxyisoprostane **3a** in 89% yield. Similarly, the aldol reaction of **7** with epoxyaldehyde **8b**[11] followed by hydrolysis with PPL afforded **3b** in 46% yield from **7**. The diastereomeric mixture **3c** (a 1:1 mixture of **3a** and **3b**) was synthesized from **7** and the racemic epoxide **8c**.

Expanded ^{1}H NMR spectra of **3a**, **3b**, **3c** (a 2:3 mixture of **3a** and **3b**), [15] and natural **3** that include the signals for the diagnostic 7-H atom ($\delta = 6.1$–6.2 ppm) and the less variable 10-H atom ($\delta = 6.3$–6.4 ppm) are presented in Figure 1.[16,17] For comparison, the spectrum of the analogue **6** is also sketched, but in two possible ways, since the chemical shift of residual $CHCl_3$ ($\delta = 7.24$ or 7.26 ppm) in $CDCl_3$, which was used as the reference, is not reported. The observed baseline separation of the signals for the 7-H atom in **3a** and **3b**, and the negligible drift in the chemical shifts for 7-H and 10-H of **3a** and **3b** in the mixture **3c**, show the high reliability of this method for the elucidation. Clearly, the spectrum of **3a** is coincident with that of natural **3**, thus allowing the determination of the 5*R**,6*R**,12*S** relative configuration and the 7*E* olefin geometry for natural **3**. This configuration is different from that assigned by analogy with the analogue **6**.[6]

Finally, the synthesis of the isoprostane phosphorylcholine **2a** was investigated. From the methods available for the synthesis of phospholipids,[18,19] we chose the direct esterification of **3a** with 1-palmitoyl-2-lyso-PC (**13**; PC = phosphorylcholine) since the reagents or conditions established for the other methods seemed incompatible with **3a**. Unfortunately, an attempted esterification of **3a** and the lyso-PC **13** with the standard reagent (DCC/DMAP)[19] did not take place even upon treatment at elevated temperatures for several days.[20] However, the treatment of **3a** and **13** with the Yamaguchi reagent[21,22] in CH_2Cl_2[23] at room temperature for 36 h afforded **2a** in 53% yield after chromatography on silica gel to obtain a mixture of **2a** and DMAP, and then reversed-phase chromatography to separate the mixture (Scheme 5).

According to the literature, the formation of **2** in vivo from 1-palmitoyl-2-arachidonoyl-PC may be a non-enzymatic process;[2,5] therefore, **2** is probably a diastereomeric mixture



Scheme 5. Synthesis of two diastereomers of **2**. DMAP = 4-dimethylaminopyridine.

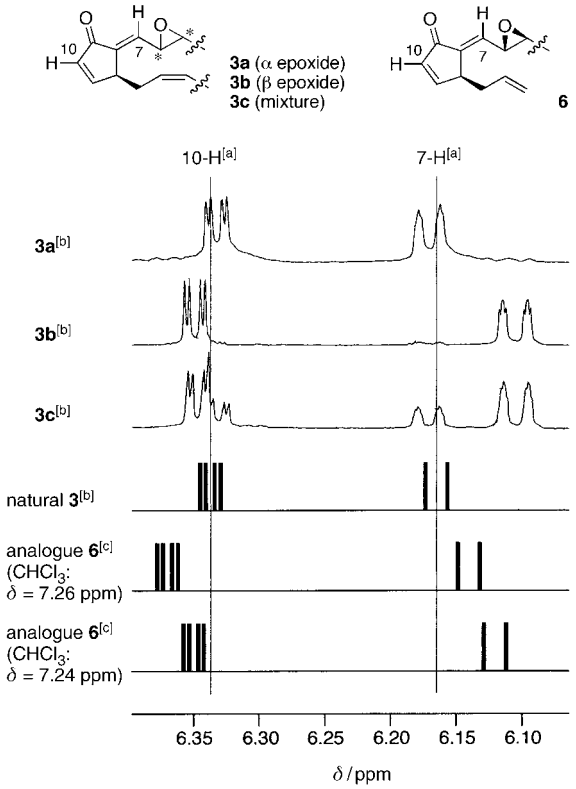


Figure 1. Expanded ^{1}H NMR spectra (500 MHz, $CDCl_3$) of **3a–c**, natural **3**, and the analogue **6**. [a] Reference lines that cross the center of the signals for natural **3**. [b] As residual $CHCl_3$, used as a reference in the ^{1}H NMR spectrum (500 MHz) of natural **3**, is set at $\delta = 7.24$ ppm, the spectra of **3a**, **3b**, and **3c** were referenced in the same way. [c] As the chemical shift of $CHCl_3$ is not reported, two spectra of **6** are represented in which it is assumed that the signal for $CHCl_3$ is observed at $\delta = 7.26$ or 7.24 ppm in the original spectrum.

in which both possible substituents derived from the carboxylic acids **3a** and *ent*-**3a** are present at the *sn*-2 position. To obtain spectroscopic and chromatographic information about the diastereomer derived from *ent*-**3a**, the condensation of **3a** and *rac*-**13**[24] was carried out under the above conditions to synthesize **2a** and **14**, the latter of which is the enantiomer of the compound in question. The mixture (**2a** and **14**), produced in 61% yield, was inseparable by TLC and column chromatography. Furthermore, the ^{1}H NMR (500 MHz) spectrum of the mixture was superimposable on that of pure **2a**.

In conclusion, we have established the relative configuration of the epoxyisoprostane component of **2** as **3a**. Moreover, **2a** was successfully constructed from **3a** and 1-palmitoyl lyso-PC (**13**) by using the Yamaguchi reagent. The present method would also be applicable to the synthesis of the regioisomers of **2** that were described recently.[5] We believe that the biological study of atherosclerosis will be spurred by the stereodefinition of 2-(5,6-epoxyisoprostane A_2)phosphorylcholine.

[13] The Al_2O_3-assisted elimination generally produces the thermodynamically stable alkene (see reference [10] and the references cited therein).

[14] a) G. L. Bundy, D. R. Morton, D. C. Peterson, E. E. Nishizawa, W. L. Miller, *J. Med. Chem.* **1983**, *26*, 790 – 799; b) S. Sugiura, T. Toru, T. Tanaka, A. Hazato, N. Okamura, K. Bannai, K. Manabe, S. Kurozumi, R. Noyori, *Chem. Pharm. Bull.* **1984**, *32*, 4658 – 4661; c) J. Zhu, J.-Y. Yang, A. J. H. Klunder, Z.-Y. Liu, B. Zwanenburg, *Tetrahedron* **1995**, *51*, 5847 – 5870.

[15] This 2:3 mixture of diastereomers was synthesized by another sequence of reactions: 1) aldol reaction of **7** with $MeO_2C(CH_2)_3CH{=}CHCHO$; 2) epoxidation of the resulting *anti* aldol product with *t*BuOOH/$Ti(OiPr)_4$; 3) mesylation; 4) elimination of the mesylate group with Al_2O_3.

[16] The ^{1}H NMR spectra of **3a**, **3b**, and **3c** were recorded under identical conditions to those reported[1] for natural **3** (500 MHz, $CDCl_3$, residual $CHCl_3$ set at $\delta = 7.24$ instead of 7.26 ppm).

[17] The exposure of **3a** to silica gel afforded lactone **I**, whose signals in the ^{1}H NMR spectrum overlap with another diagnostic multiplet at $\delta = 2.5$–2.7 ppm; therefore we used the clearly resolved region $\delta = 6.0$–6.2 ppm for the assignment. Furthermore, the signals for the lactone can be seen in the reported spectrum of **3**[1] at $\delta \approx 4.40$ and 4.80 ppm as the isolated signals and at $\delta = 6.35$ and 7.55 ppm as shoulders. Compound **I** is probably formed by epoxide-ring opening by H_2O under weakly acidic conditions (silica gel and/or DCl in $CDCl_3$) and subsequent lactonization of the resulting diol.

[23] Because of the low solubility of the lyso-PC, toluene, the standard solvent for the Yamaguchi reaction, was not used.

[24] Prepared from racemic glycidol according to a literature method; see reference [19b].

Natural Product Synthesis

Total Synthesis of (+)-Dactylolide through an Efficient Sequential Peterson Olefination and Prins Cyclization Reaction**

*Danielle L. Aubele, Shuangyi Wan, and Paul E. Floreancig**

Dedicated to Professor Peter Dervan on the occasion of his 60th birthday

Dactylolide (**1**, Figure 1) is a bicyclic macrolactone that was isolated from the Vanuatu sponge *Dactylospongia* in 2001 by Riccio and co-workers.[1] While dactylolide is moderately cytotoxic toward L1210 (lymphatic leukemia) and SK-OV-3 (ovarian cancer) cells, causing 63% and 40% growth inhibition, respectively, at 3.2 $\mu g\,mL^{-1}$ (8.3 μM), the structurally related natural product zampanolide (**2**)[2] shows significantly greater cytotoxic activity, with IC_{50} values of 1–5 nM against several cell lines. Upon completing the syntheses of **1** and **2**,[3] Smith et al. concluded, on the basis of optical rotation data, that the common macrolide cores of these compounds have opposite absolute configurations. The incongruence in optical rotations between natural ($[\alpha]_D = +30°$, $c = 1$, MeOH) and synthetic ($[\alpha]_D = +235°$, $c = 0.52$, MeOH[3] or $-128°$, $c = 0.39$, MeOH, antipode[4]) dactylolide, however, preclude a firm conclusion regarding its absolute stereochemistry. Hoye and Hu's demonstration[4] that dactylolide can be converted into zampanolide through an aza-aldol addition shows that both compounds can be accessed through a common strategy, provided the route can be used to access either enantiomer. Herein, we report a convergent and efficient route to dactylolide that employs an acetal linkage to fuse two complex fragments and a Prins reaction that proceeds under remarkably mild conditions to form the methylene tetrahydropyran group. In this sequence stereogenicity is derived from asymmetric catalysts that are readily available as either enantiomer, which makes the route also applicable to the synthesis of zampanolide.

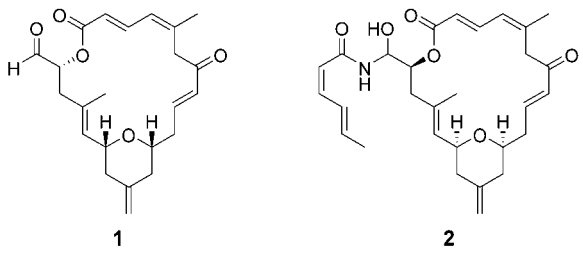

Figure 1. (+)-Dactylolide and (−)-zampanolide.

We established two key objectives for the synthesis of dactylolide (Figure 2): to maximize convergency by coupling two functionalized subunits at a reasonably late stage in the sequence, and to minimize the number of carbon–carbon bond-forming reactions. We postulated that the former objective could result from the union of two advanced fragments through an acetal linkage.[5] This somewhat underutilized approach to increasing molecular complexity is quite attractive in both the efficiency of the coupling and the capacity for acetals to serve as precursors for structurally diverse ethers. We envisioned asymmetric vinylogous Mukaiyama aldol reactions[6] to be effective vehicles for achieving the latter objective. Thus **1** can be accessed from diol **3**, which, in turn, results from transposed allylic alcohol **4** (Figure 2). Acetal **5**, prepared through the union of **6** and **7**, serves as the precursor for the methylene tetrahydropyran. We recently reported[7] that acetals of this general structure undergo Prins reactions under very mild conditions, with promotion of the process in water by Lewis acid surfactant catalysts.[8] Sequences that employ catalytic, asymmetric vinylogous Mukaiyama aldol reactions can be designed to access **6** and **7** from *p*-methoxybenzyloxyacetaldehyde and 2-butynol, respectively.

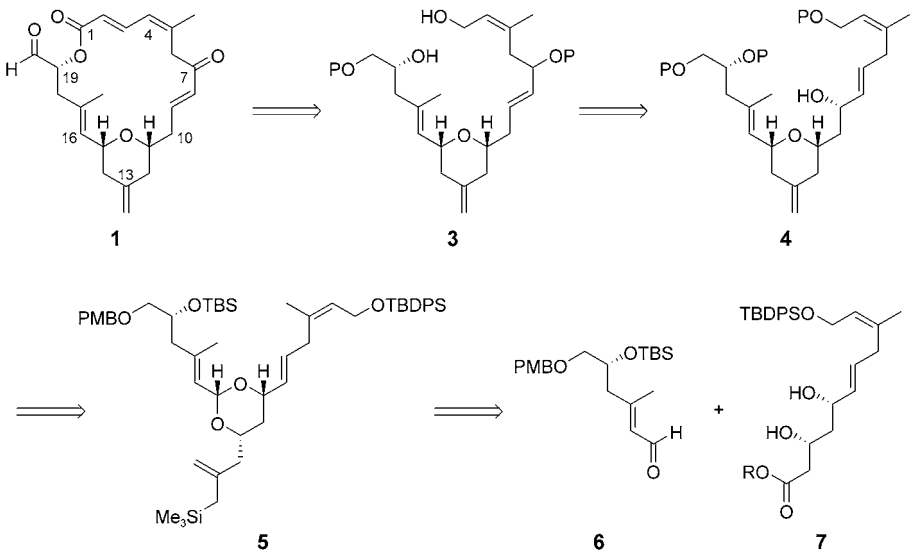

Figure 2. Retrosynthetic analysis of dactylolide. P = protecting group, PMB = *p*-methoxybenzyl, TBS = *tert*-butyldimethylsilyl, TBDPS = *tert*-butyldiphenylsilyl.

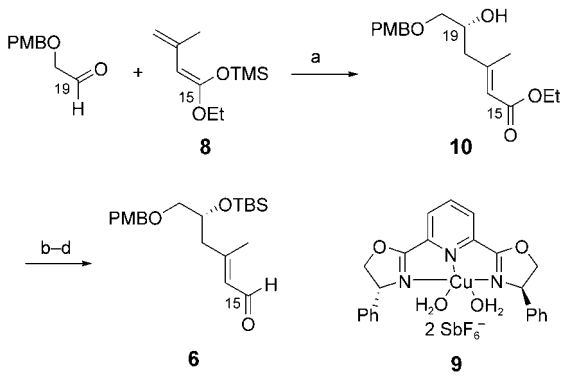
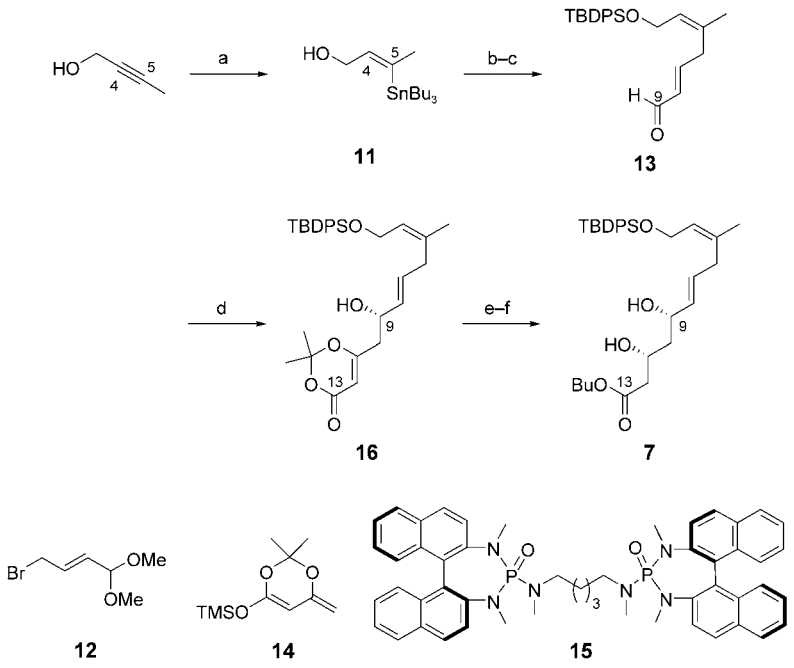
The synthesis of **6** (Scheme 1) requires a high level of control over both the stereocenter at C19 and the geometry of the trisubstituted alkene. Our route to **6** follows the sequence devised by Evans et al. in their synthesis of callipeltoside.[9]



Scheme 1. a) **9**, CH_2Cl_2, −78 °C, 82 %, 95 % *ee*; b) TBSCl, imidazole, DMF, 89 %; c) $LiAlH_4$, Et_2O; d) MnO_2, CH_2Cl_2, 80 %, 2 steps. DMF = *N*,*N*-dimethylformamide.

Condensation of silyl ketene acetal **8** with *p*-methoxybenzyloxyacetaldehyde in the presence of Cu·pybox catalyst **9**[10] provided **10** in 82 % yield and 95 % *ee*, with the alkene formed as a single isomer. Conversion of **10** into **6** proceeded through a straightforward three-step sequence of protection, reduction, and oxidation.

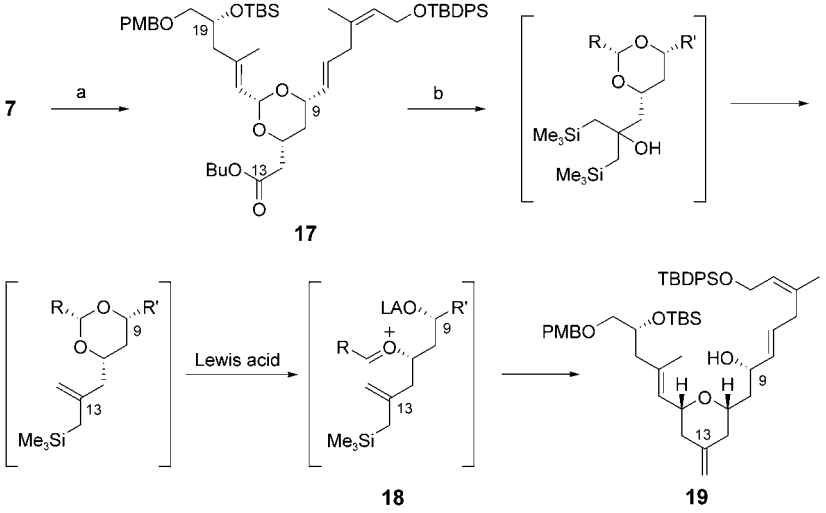
As an entry into **7** (Scheme 2), the geometry of the $\Delta^{4,5}$-trisubstituted olefin was set through a hydroalumination reaction of 2-butynol with Red-Al[11] followed by quenching with Bu_3SnCl to form vinyl stannane **11** in 93 % yield. Following protection of the primary hydroxyl group, palladium-mediated coupling[12] with bromide **12**[13] and acetal hydrolysis in situ provided enal **13** in 80 % yield. To the best of our knowledge, this is the first report of **12** serving as an electrophilic surrogate for crotonaldehyde in a cross-coupling reaction. The absence of a chelating group in **13** precluded the use of the Cu·pybox complex as a promoter of aldol chemistry. Therefore we utilized Denmark's bisphosphoramide catalytic system **15**[14] and $SiCl_4$ to effect coupling between **13** and ketene acetal **14** to yield alcohol **16** in 93 % *ee* and 67 % yield at 83 % conversion (83 % yield based on recovered starting material). Notably, this reaction proceeded with even higher selectivity than the corresponding reaction with cinnamaldehyde that was reported in the original manuscript,[15] which suggests that this catalyst is well suited for applications in the synthesis of complex molecules. Thermolysis of **16** in BuOH followed by *syn*-reduction of the resulting keto ester with Et_2BOMe and $NaBH_4$[16] completed the synthesis of diol **7**.



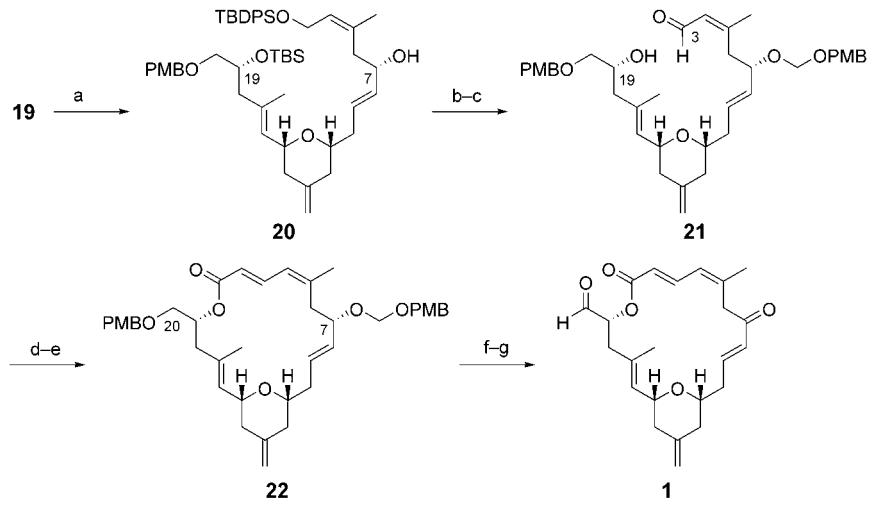
Scheme 2. a) Red-Al, THF, then Bu_3SnCl, 93 %; b) TBDPSCl, imidazole, DMF, 87 %; c) **12**, $[(CH_3CN)_2PdCl_2]$, PPh_3, $CHCl_3$, 65 °C, then HCO_2H, CH_2Cl_2, 80 %; d) **15**, $SiCl_4$, **14**, CH_2Cl_2, −78 °C, 67 % at 83 % conversion, 93 % *ee*; e) *n*BuOH, reflux, 74 %; f) Et_2BOMe, $NaBH_4$, THF, −78 °C, 83 %. Red-Al = sodium bis(2-methoxyethoxy)aluminumhydride.

Formation of the acetal linkage between **6** and **7** (Scheme 3) through standard acid catalysis was complicated by competitive isomerization of the trisubstituted alkene in the enal. Conversion of **7** into its bis-trimethylsilyl ether and coupling with **6** using Noyori's TMSOTf-mediated protocol,[17] however, provided acetal **17** in high yield and without isomerization. In preparation for the Prins reaction, we subjected **17** to excess $TMSCH_2MgCl$ and $CeCl_3$ followed by an acidic workup.[18] To our surprise the major product isolated from this reaction was methylene tetrahydropyran **19**, the desired subunit of dactylolide, which resulted from allylsilane formation, followed by acetal ionization to provide oxocarbenium ion **18**, and cyclization. After conducting a series of experiments designed to elucidate the initiator for the Prins reaction, we concluded that weakly Lewis acidic cerium salts are not completely removed in the aqueous workup and initiate ionization and cyclization upon evaporation of the organic solvent. While this process was quite direct, the yields proved to be irreproducible. A more reliable protocol for this transformation was devised in which the addition of alkylcerium was quenched with aqueous $NaHCO_3$ and a solution of the resulting crude tertiary alcohol in CH_2Cl_2 was subjected to pyridinium triflate and $MgSO_4$ to effect a sequential Peterson olefination and Prins cyclization. This remarkably mild process routinely provided **19** in 75 % yield from **17**. The desiccant and the non-nucleophilic triflate ion were both necessary to promote cyclization without causing protodesilylation of the allylsilane. Although acetal ionization can occur to form two oxocarbenium ions, **18** can proceed through a kinetically facile 6-*endo* pathway while cyclization through the alternative ion would proceed through a less favorable 8-*endo* pathway. Therefore the observed selectivity strongly suggests that cyclization is the product-determining step rather than ionization.[19]

Transposition of the C9 allylic alcohol that was formed in the Prins reaction was required to complete the synthesis of dactylolide (Scheme 4) and was achieved through conversion of the hydroxyl group of **19**



Scheme 3. a) (1) TMSCl, imidazole, DMAP, DMF; (2) **6**, TMSOTf, CH_2Cl_2, −78 °C, 83 %; b) 1) Me_3SiCH_2MgCl, $CeCl_3$, THF, −78 °C→RT; 2) Py·HOTf, $MgSO_4$, CH_2Cl_2, 75 %. TMS = trimethylsilyl, DMAP = 4-dimethylaminopyridine, Tf = trifluoromethanesulfonyl, Py (py) = pyridine, LA = Lewis acid.



Scheme 4. a) (1) PhSeCN, Bu_3P, THF; (2) H_2O_2, py, THF, −30 °C, 62 %; b) (1) $PMBOCH_2Cl$, iPr_2NEt, CH_2Cl_2; (2) HF·Py, py, THF, 80 %; c) $PhI(OAc)_2$, TEMPO, CH_2Cl_2, 87 %; d) Diethylphosphonoacetic acid, DCC, DMAP, CH_2Cl_2, 95 %; e) NaHMDS, THF, −78 →0 °C, 73 %; f) DDQ, CH_2Cl_2, buffer (pH 7), 63 % (14 % C7 ketone); g) Dess–Martin periodinane, CH_2Cl_2, 77 %. TEMPO = 2,2,6,6-tetramethylpiperidinyl-1-oxyl, DCC = dicyclohexyl carbodiimide, HMDS = hexamethyldisilazide, DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

into a selenide with PhSeCN and Bu_3P[20], with no complication from the S_N2' pathway. Oxidation of the crude selenide with H_2O_2 in the presence of pyridine induced a selenium variant[21] of the Mislow–Evans rearrangement[22] to provide allylic alcohol **20** in 62 % yield over the two-step sequence.[23] While the stereochemical outcome of this reaction was not rigorously established, mechanistic analogy[24] strongly suggests that the nascent alcohol is oriented as shown in Scheme 4. Attempts to form the PMB ether of the hydroxyl group at C7 under basic (NaH, PMBCl, NaI) or acidic ($PMBOC(NH)CCl_3$, $BF_3{\cdot}OEt_2$, or TfOH) conditions resulted in low conversions and significant decomposition. Formation of the *p*-methoxybenzyloxymethyl ether[25] ($PMBOCH_2Cl$, iPr_2NEt), however, proceeded much more efficiently. Desilylation of the resulting ether with Py·HF yielded the C3,C19 diol in 80 % yield from **20**. Selective oxidation of the primary allylic C3 alcohol with TEMPO and $PhI(OAc)_2$[26] formed aldehyde **21** in 87 % yield. Macrolactone formation was most conveniently accomplished through an intramolecular Horner–Emmons reaction, a parallel of Smith's approach[3] to this system. Acylation of the hydroxyl group at C19 with diethylphosphonoacetic acid and DCC provided the corresponding phosphonoacetate, which, upon deprotonation with NaHMDS, engaged in an intramolecular condensation reaction to provide macrolactone **22** in 73 % yield from **21**. The synthesis was completed by an oxidative cleavage of both protecting groups with DDQ. This process provided the C7,C20 diol along with variable amounts of the C7 ketone. The allylic oxidation proved to be inconsequential as the following step was a double oxidation of the diol with the Dess–Martin periodinane[27] to provide dactylolide in 77 % yield ($[\alpha]_D = +163°$, $c = 0.29$, MeOH).

In summary, we have reported an efficient total synthesis of dactylolide. Key steps in the sequence include two enantioselective vinylogous Mukaiyama reactions, fragment coupling through acetal formation, a sequential Peterson olefination/Prins cyclization reaction that proceeds under very mild conditions, and a Mislow–Evans rearrangement to effect the transposition of an allylic alcohol. The linear sequence was kept as brief as possible by minimizing carbon–carbon bond-forming reactions and employing a convergent approach. As both antipodes of the catalysts that were used to establish stereogenicity are available, this sequence is also applicable to the synthesis of zampanolide through the use of Hoye's aza-aldol reaction.

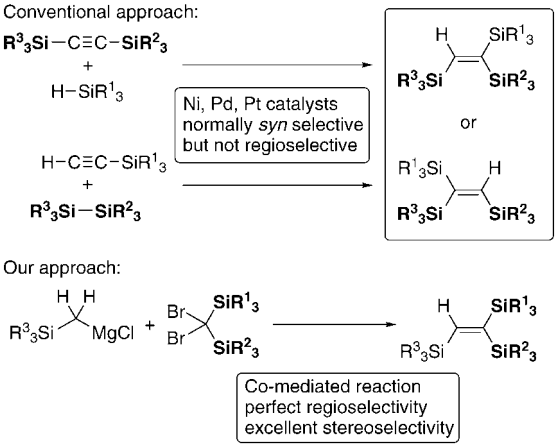
Silyl Ethenes

Regio- and Stereoselective Approach to 1,2-Di- and 1,1,2-Trisilylethenes by Cobalt-Mediated Reaction of Silyl-Substituted Dibromomethanes with Silylmethylmagnesium Reagents**

*Hirohisa Ohmiya, Hideki Yorimitsu, and Koichiro Oshima**

Vinylsilanes are useful organometallic reagents in organic synthesis because the C(sp^2)–Si bonds undergo numerous transformations.[1] Multiply silylated ethenes are thus likely to represent platforms for a variety of highly substituted ethenes. Moreover, multiply silylated ethenes themselves attract considerable attention from the viewpoint of structural organic chemistry.[2] Despite their importance, there is a limited number of access routes to multiply silylated ethenes. Hydrosilylation of silylacetylenes[3] and bissilylation of acetylenes[4] are most convenient procedures.[5] Scheme 1 (top)



Scheme 1. Conventional and novel approaches toward 1,2-di- and 1,1,2-trisilylethenes.

shows representative approaches, for instance, to trisilylethenes with three different silyl groups. However, difficulties are often encountered in such synthetic strategies in terms of regioselectivity and the occurrence of several side reactions.

During the course of our studies into cobalt-mediated reactions of organic halides with Grignard reagents,[6] we

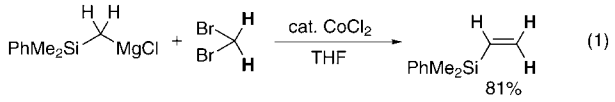
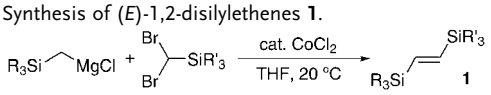
serendipitously found that the reaction of dibromomethane with dimethyl(phenyl)silylmethylmagnesium chloride in the presence of a cobalt salt provided dimethyl(phenyl)vinylsilane in excellent yield [Eq. (1)]. This observation encouraged us to explore the potential of silylated dibromomethanes[7] as precursors for multiply silylated ethenes (Scheme 1, bottom). Herein we report an inherently regioselective and, fortunately, stereoselective preparation of 1,2-di- and 1,1,2-trisilylethenes by means of a cobalt salt, thus creating a novel approach toward multiply silylated ethenes.[8,9]



(1)

After optimization of reaction conditions, the synthesis of 1,2-disilylethene proved to require cobalt(II) chloride (10 mol%) and a Grignard reagent (3 equiv). THF was the solvent of choice, while ether, dioxane, and HMPA were far inferior. The best results were found at a reaction temperature of 20 °C. Table 1 summarizes the syntheses of various 1,2-disilylethenes. All the reactions resulted in the exclusive formation of (*E*)-1,2-disilylethenes **1** in high yields. The steric hindrance of the silyl groups such as $MePh_2Si$ and $tBuMe_2Si$ had virtually no adverse influence on the synthesis. Interestingly, isopropoxy- and allyl-substituted silylmethyl Grignard reagents participated in this reaction.

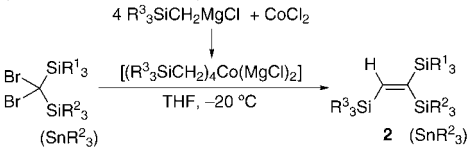
Table 1: Synthesis of (*E*)-1,2-disilylethenes **1**.



Entry	R_3Si	R′Si	**1**	Yield [%]
1	Me_3Si	Me_2PhSi	**a**	87
2	Me_3Si	$MePh_2Si$	**b**	86
3	Me_3Si	$tBuMe_2Si$	**c**	70
4	Me_2PhSi	Me_3Si	**a**	90
5	Me_2PhSi	Me_2PhSi	**d**	78
6	$(iPrO)Me_2Si$	Me_2PhSi	**e**	88
7	$(CH_2{=}CHCH_2)Me_2Si$	Me_2PhSi	**f**	79

The high efficiency of this method prompted us to examine dibromodisilylmethanes as starting materials. Contrary to our expectation, the catalytic conditions did not give satisfactory results. Instead, stoichiometric use of a cobaltate reagent $[(R^3{}_3SiCH_2)_4Co(MgCl)_2]$,[10,11] prepared from Co^{II} chloride and a Grignard reagent (4 equiv), allowed the efficient synthesis of 1,1,2-trisilylethenes (Table 2). The reactions of $(Me_3Si)_2CBr_2$ proceeded smoothly to afford **2a** and **2b** in good yields (Table 2, entries 1 and 2). The bulkier $MePh_2Si$- and $tBuMe_2Si$-substituted precursors were also converted into **2** in reasonable yields (Table 2, entries 3–7). The reactions were clean, and the main by-products were $(R^1{}_3Si)(R^2{}_3Si)C(H)Br$, $(R^1{}_3Si)(R^2{}_3Si)CH_2$, and $(R^1{}_3Si)(R^2{}_3Si)C{=}CH_2$, which were readily separated from the desired products by size-exclusion chromatography (see below). Gratifyingly, treatment of unsymmetrically substituted dibromodisilylmethanes under similar conditions yielded (*E*)-**2e**–**2g** with three different silyl groups stereoselectively (Table 2, entries 5–7). The reaction of a dibromosilylstannylmethane furnished the corresponding (*Z*)-1,2-disilyl-1-stannylethene **2h** with good stereoselectivity (Table 2, entry 8). There are few facile methods for the stereo- and regioselective synthesis of ethenes with different Group 14 metal substituents. Unfortunately, the attempted synthesis of tetrasilylethene from $(R_3Si)_2CBr_2$ and $(R_3Si)_2CHMgCl$ did not succeed.

Table 2: Synthesis of 1,1,2-trisilylethenes **2**.



Entry	$R^1{}_3Si$	$R^2{}_3Si$	$R^3{}_3Si$	**2**	Yield [%]	*E*/*Z*

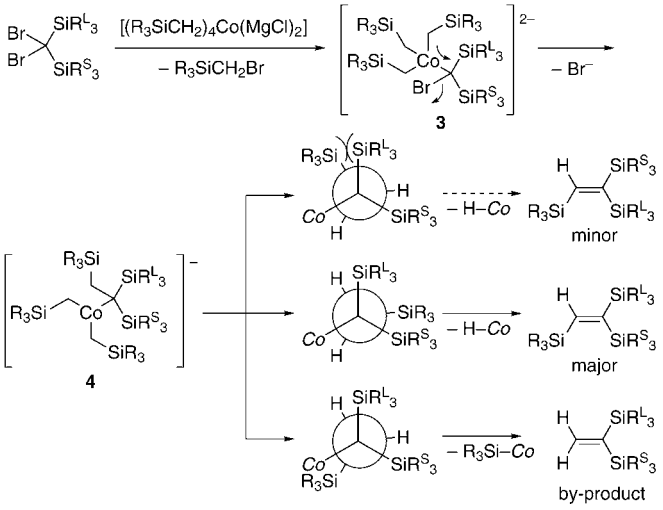
We propose a mechanism for the stoichiometric reaction as shown in Scheme 2. Halogen–cobalt exchange initially takes place to produce intermediate **3**. One of the silylmethyl groups on the cobalt center migrates to generate **4** with concomitant liberation of bromide.[12] β-Hydride elimination finalizes the formation of 1,1,2-trisilylethene **2**. The major *E* stereoisomers in Table 2 would originate from the more stable eclipsed conformer upon β-hydride elimination. The formation of the by-product $(R^1{}_3Si)(R^2{}_3Si)C{=}CH_2$ can stem from β-silyl elimination.[13]



Scheme 2. Proposed mechanism for the formation of 1,1,2-trisilylethenes in the presence of stoichiometric amounts of the cobaltate complex.

In summary, we have developed a novel method for the synthesis of 1,2-di- and 1,1,2-trisilylethenes in a regio- and stereoselective manner. The products are not only useful as precursors for various alkenes but are also structurally interesting. Further improvement of this strategy will allow access to a wide range of ethenes that are multifariously substituted with Group 14 metals.

Experimental Section

General procedure (**1a**): Anhydrous cobalt(II) chloride (6.5 mg, 0.05 mmol) was placed in a 20-mL reaction flask and heated with a hair dryer in vacuo for 2 min. After the cobalt salt turned blue, anhydrous THF (3.0 mL) was added under argon. The mixture was stirred for 3 min at room temperature. Dibromo(dimethyl(phenyl)-silyl)methane (154 mg, 0.50 mmol) and a solution of trimethylsilyl-methylmagnesium chloride in diethyl ether (1.0 M; 1.5 mL, 1.5 mmol) were successively added dropwise to the reaction mixture at 0 °C. While the Grignard reagent was being added, the mixture turned brown. After being stirred for 1 h at 20 °C, the reaction mixture was poured into water. The product was extracted with hexane (2 × 20 mL). The combined organic layer was dried over sodium sulfate and concentrated. Purification of the crude oil by silica-gel column chromatography (hexane) provided the corresponding (*E*)-1,2-di-silylethene **1a** (102 mg, 0.43 mmol) in 87 % yield.

2b: Anhydrous cobalt(II) chloride (97.5 mg, 0.75 mmol) was placed in a 30-mL reaction flask and dried in vacuo for 2 min. Anhydrous THF (5.0 mL) was added under argon, and the mixture was stirred for 3 min at room temperature. A solution of dimethyl-(phenyl)silylmethylmagnesium chloride in diethyl ether (0.95 M; 3.16 mL, 3.0 mmol) was added dropwise to the reaction mixture at −20 °C. After the mixture was stirred for 15 min at −20 °C, dibromobis(trimethylsilyl)methane (159 mg, 0.50 mmol) was added dropwise to the reaction mixture at −20 °C. After being stirred for an additional 1 h at −20 °C, the reaction mixture was poured into water. The product was extracted with hexane (2 × 20 mL). The combined organic layer was dried over sodium sulfate and concentrated. Silica-gel column chromatography (hexane) followed by gel-permeation chromatography (toluene, to remove by-products described above) provided the corresponding 1,1,2-trisilylethene **2b** (111 mg, 0.36 mmol) in 73 % yield.

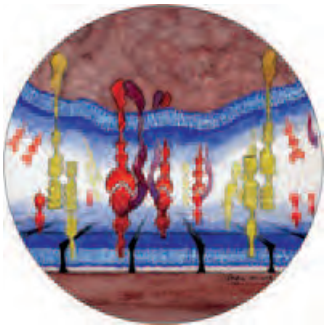
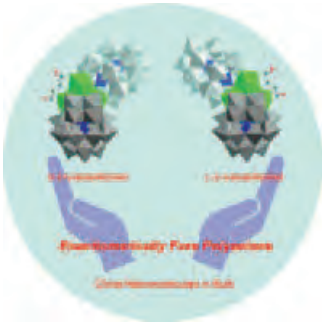
Cover Picture

Rolf Schiffmann, Andreas Heine, Gerhard Klebe, and Christian D. P. Klein*

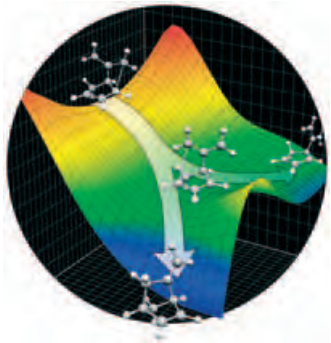
Metalloenzymes are often studied in the presence of unphysiologically high concentrations of metal ions. This situation may lead to artifacts in assays if the binding of an inhibitor is made possible through additional metal ions; such compounds would appear highly potent in vitro, but may not possess activity in vivo. In their Communication on page 3620 ff., C. D. P. Klein and co-workers describe this effect with the enzyme methionine aminopeptidase as an example. (Mouse image provided by the U.S. National Park Service.)



Surface Chemistry of Membranes
The interactions between neighboring membranes that lead to the formation of protein patterns perform important biological functions. In his Review on page 3524 ff. J. T. Groves discusses these processes through the use of model systems and measurement techniques.



Chirality Transfer
A small organic molecule can transfer chirality to a large polyoxometalate cluster. How this transfer occurs is reported by C. L. Hill and co-workers in their Communication on page 3540 ff.



Reaction Mechanisms
K. N. Houk and co-workers describe computational studies of the thermal rearrangement of 6-methylenebicyclo[3.2.0]hept-2-ene in their Communication on page 3548 ff. The results suggest a bifurcation of reaction trajectories which explains the product ratios observed.

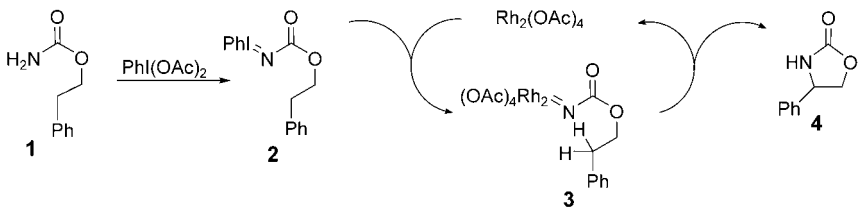
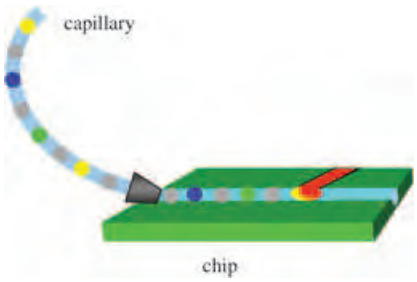
Highlights

C–H Aminations



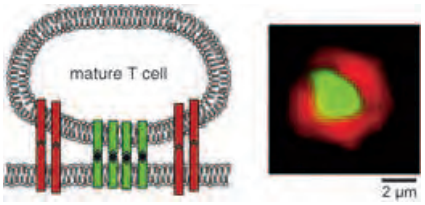
C–N bond formation by nitrene-induced C–H amination is an elegant class of reaction (see scheme). The Highlight describes how such intramolecular processes are catalytic with transition metals and display enantioselectivity to provide a powerful synthetic tool ideally suited to the synthesis of natural products.

Lab on a Chip



Chipping in for microlabs: A capillary with segmented sample droplets was coupled to a microfluidic chip for the high-throughput screening of samples on the nanoliter scale. A three-phase system was developed for the segmentation; the sample droplets are surrounded by a fluorinated carrier fluid and additionally separated by gas bubbles. The ultimate goal in this area of research is a pocket-sized laboratory.

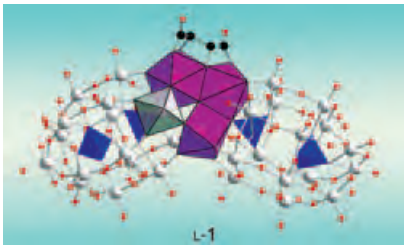
Reviews



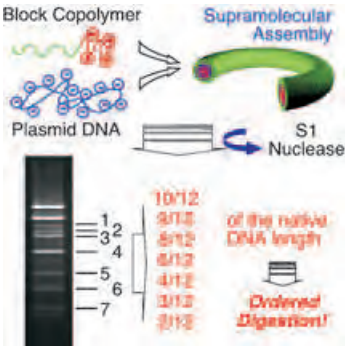
Informative patterns: Cell membranes can respond to chemical interactions with the surface in ways not seen with inorganic materials. One example is the formation of a spatial pattern at membrane junctions during intercellular signaling. The formation of such a pattern in immunological synapses (see picture; right: fluorescence image) is examined in this Review through the use of model systems and imaging technologies.

Communications

Small but influential: Chirality transfer from a small chiral organic unit (D- or L-tartrate) to a very large metal–oxide framework is demonstrated by the enantiomerically pure, nonracemizing polytungstates D- or L-**1** (see picture, the central part is shown in polyhedral form; purple Zr, gray W, blue P, black C, red O). The tartrate unit determines the absolute configuration of the inorganic moiety, offering a new method to control the chirality of polyoxoanions.



Split into seven sizes: Highly ordered cleavage of supercoiled plasmid DNA by S1 nuclease was accomplished through DNA complexation with water-soluble cationic block copolymers (see schematic representation). The results provide insights into the mechanisms of endogenous protein-induced modification of DNA and into the design of artificial restriction enzymes through the supramolecular assembly of synthetic macromolecules.



For the USA and Canada:
ANGEWANDTE CHEMIE International Edition (ISSN 1433-7851) is published weekly by Wiley-VCH PO Box 191161, D 69451 Weinheim, Germany. Air freight and mailing in the USA by Publications Expediting Inc. 200 Meacham Ave., Elmont, NY 11003. Periodicals postage paid at Jamaica NY 11431. US POSTMASTER: send address changes to *Angewandte Chemie*, Wiley-VCH, 111 River Street, Hoboken, NJ 07030. Annual subscription price for institutions: US$ 4948.00/4498.00 (valid for print and electronic / print or electronic delivery); for individuals who are personal members of a national chemical society, or whose institution already subscribes, or who are retired or self-employed consultants, print only: US$ 394.00. Postage and handling charges included. All Wiley-VCH prices are exclusive VAT.

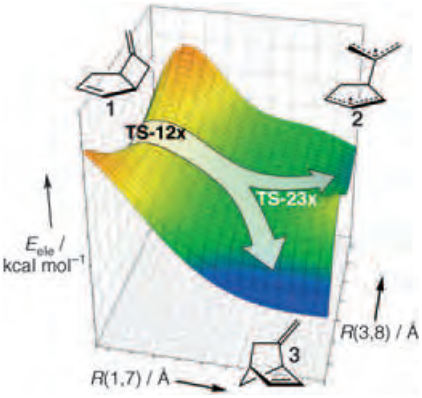
WILEY InterScience® DISCOVER SOMETHING GREAT

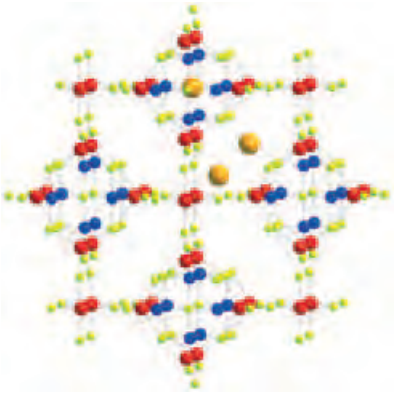
WILEY-VCH

11951404_gu

Deuterium labeling experiments on the rearrangement of methylenebicycloalkene **1** to **3** show stereoselectivity despite the intermediacy of a stabilized diradical structure **2**. A theoretical model built from computational studies explains the observed product ratios. Stereoselectivity among [3,3] (minor) products implicates an unusual bifurcation of reaction trajectories after the initial bond-breaking transition state.



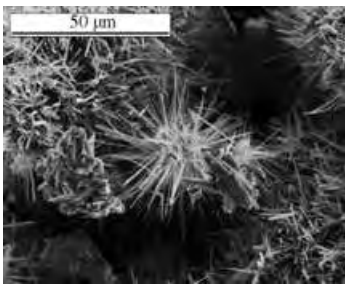
Reaction Dynamics



Like zeolites, $K_6Sn[Zn_4Sn_4S_{17}]$ (see structure) has remarkable ion-exchange properties and forms $CsK_5Sn[Zn_4Sn_4S_{17}]$ and $RbK_5Sn[Zn_4Sn_4S_{17}]$ in the presence of the Cs^+ and Rb^+ ions, respectively. These compounds have an open framework comprising $[Zn_4Sn_4S_{17}]^{10-}$ clusters linked by Sn^{4+} centers and are remarkably stable. One-fifth of the K^+ ions play an important templating role in stabilizing the framework. Zn blue, Sn red, S yellow, K orange.

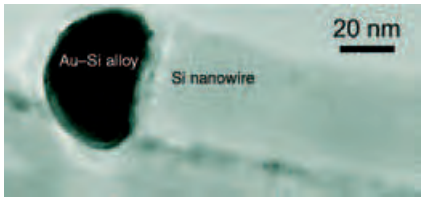
Ion Exchange

Group 5 telluride nanostructures have been grown through chemical vapor transport from the elements. The novel nanostructured chalcogenide Nb_3Te_4 (a cluster of Nb_3Te_4 nanowires is pictured) is the first example of this type of nanowire grown with a pseudo-1D structural basis. The wires are single crystalline with longitudinal axes aligned along the crystallographic *c* axis. The nanowires are metallic but do not exhibit superconductivity above 1.8 K.



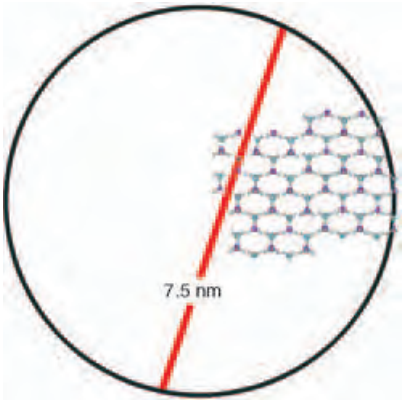
Nanostructures

Contents



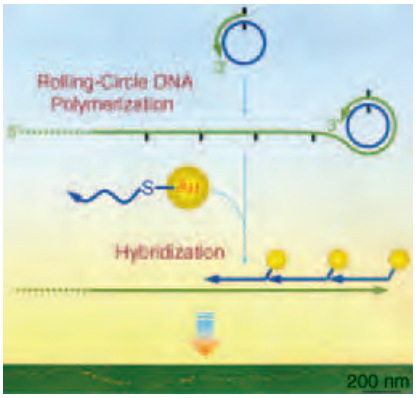
Under pressure! The synthesis of crystalline silicon nanowires can be carried out in organic solvents at reaction temperatures of up to 450–500°C under high-pressure conditions. Gold particles are used as seeds, and organosilanes are employed as the silicon source. The decomposition chemistry of the organosilanes determines the quality of the nanowires formed (see picture of an Si nanowire with an Si/Au tip).

Nanostructures



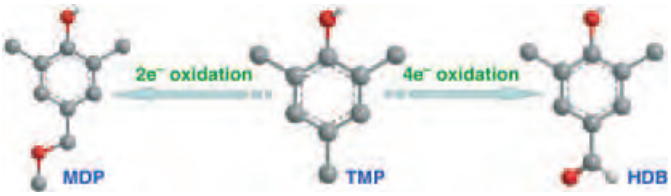
Hydrogen-rich materials infused in nanoscaffolds offer a promising approach to on-board hydrogen storage. A mesoporous scaffold decreases the temperature for hydrogen release from ammonia borane (AB), a conventional hydrogen-storage material, to below 80 °C and leads to an increase in the purity of the hydrogen released. (See schematic representation of a hydrogen-bonded AB network in the cross-section of a single pore.)

Hydrogen Storage



Strands of gold: Extended one-dimensional arrays of gold nanoparticles up to 4 μm long can be assembled by hybridization between thiolated DNA/nanoparticle 1:1 conjugates and long DNA templates, which were prepared by rolling-circle polymerization (see picture). The linear self-assembled structures could link the nanometric properties of materials with the convenience of micrometric manipulation.

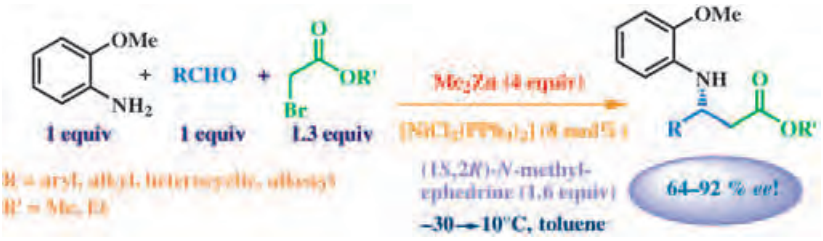
Nanoparticle Arrays



An environmentally friendly procedure has been developed for the oxidation of 2,4,6-trimethylphenol (TMP) at the *para* C_{sp^3}–H bond. Upon reaction with H_2O_2 in the presence of catalytic amounts of Cu^{II} and neocuproine in methanol at 65 °C, 4-(methoxymethyl)-2,6-dimethylphenol (MDP) or 4-hydroxy-3,5-dimethylbenzaldehyde (HDB) is formed (see reaction).

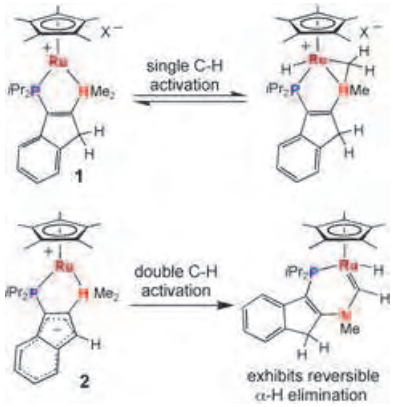
C–H Activation

Contents



A key to molecular diversity is the preparation of new frameworks in multicomponent condensations of three or more reactants. A new highly enantioselective one-pot, three-component, nickel-catalyzed, imino-Reformatsky reaction affords β-amino esters with 64–92% *ee* (see scheme). The simplicity and broad scope of our method provide a practical access to useful building blocks.

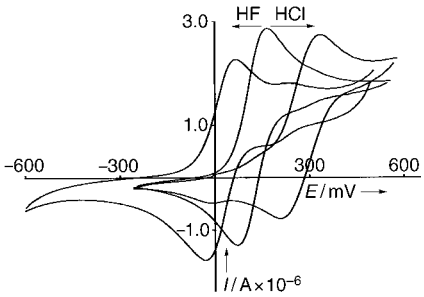
Multicomponent Reactions



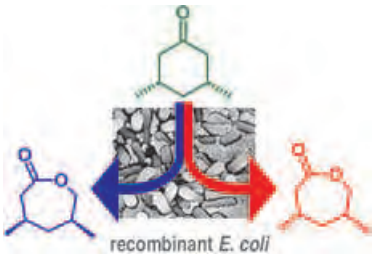
A masked variant of the first coordinatively unsaturated [Cp*Ru(κ²-*P*,*N*)]⁺ cation (**1**) is reported, which has proven capable of single intramolecular C–H activation. In contrast, the isostructural zwitterionic complex **2** apparently rearranges to a hydridocarbene by way of a remarkably facile, ligand-assisted double C–H bond activation process (see scheme).

C–H Activation

Appropriate linking of Lewis acidic and Lewis basic components—in this case boronic acid and tertiary amine functionalities—allows the construction of a robust organometallic receptor capable of selectively binding hydrogen fluoride. This system can differentiate between exposure to HF and to related acids, such as HCl, by providing opposing electrochemical responses (see picture).



Sensors



The identification of enzyme pairs with overlapping substrate specificity and enantiocomplementary transformations is a key challenge in biocatalysis. Enantio- and regiodivergent Baeyer–Villiger oxidations were successfully carried out by using a small library of recombinant *Escherichia coli* strains expressing monooxygenases of various microbial origin (see picture). The clustering of enzymes based on stereopreference is in good agreement with phylogenetic similarity.

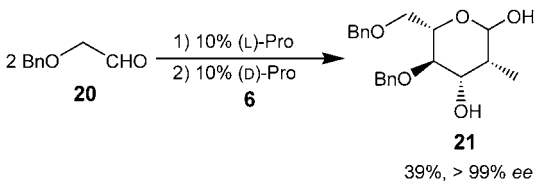
Amino Acids—Valuable Organocatalysts in Carbohydrate Synthesis

Angew. Chem. Int. Ed. **2005**, *44*

DOI 10.1002/anie.200462873

In this Highlight, the reaction scheme for a proline-catalyzed carbohydrate synthesis was rendered incorrectly at the bottom of Scheme 4. The correct Scheme is shown, and the sentence that begins at the bottom of the first column on page 2188 should read: "For example, the 2-methyl-2-deoxymannose derivative **21** was obtained as a single stereoisomer from α-benzyloxyacetaldehyde (**20**) and propionaldehyde (**6**)."

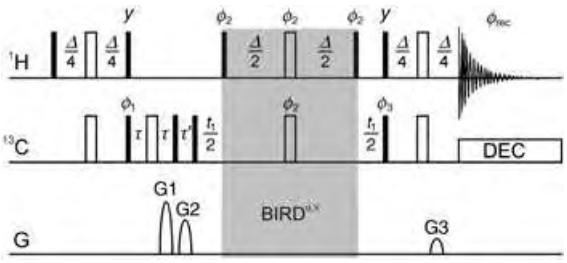


Stretched Gelatin Gels as Chiral Alignment Media for the Discrimination of Enantiomers by NMR Spectroscopy

Angew. Chem. Int. Ed. **2005**, *44*

DOI 10.1002/anie.200462736

In Figure 3 of this Communication, the label for ϕ_1 was positioned incorrectly. The correct figure is shown here.



Swiss Delight: Bürgenstock 2005**

Martin Oestreich*

Spectacular Bürgenstock, a haven of tranquility almost 1000 meters above Lake Lucerne, is the traditional venue for the EUCHEM Conference on Stereochemistry. Under the presidency of Alain Krief (Université de Namur) some 140 junior and senior chemists from academia and industry met for the 40th anniversary of the "Bürgenstock Conference" in April.

The president and the organizing committee [Hans-Beat Bürgi (Universität Bern), François Diederich (ETH Zürich), E. Peter Kündig (Université de Genève), and Klaus Müller (F. Hoffmann-LaRoche)] provided a well-balanced interdisciplinary program of 14 invited lectures and three poster sessions including five selected short oral communications each as appetizers. As a special teaser, the program was only revealed to the participants upon arrival!

The scientific portion commenced with a guided tour by Jonathan Clayden (University of Manchester) through synthetic and stereochemical aspects of amide chemistry. The asymmetric metallation of amides coupled with spontaneous dearomatizing cyclization is the key step in his enantioselective total synthesis of kanoid amino acids. Another focus of his research group is the use of sterically hindered and thus atropisomeric aromatic amides as stereochemical controllers. With this system, it is possible to impart remote stereocontrol over the impressive distance of more than 20(!) bond lengths (**1**→**2**; Scheme 1).

Charles Mioskowski (Université Louis Pasteur) reported on the high-throughput screening of catalysts for enantioselective carbonyl reduction (benzoyl formic acid → mandelic acid) with competitive enzyme immunoassays. The enantiomeric excess was determined by measuring the concentration of one enantiomer with an enantiospecific antibody. In the second part of his talk, he discussed the synthesis of the bis(pulvinic acid) norbadione A and its complexation of radioactive cesium-137 in comparison with related pulvinic acids. In the evening lecture, David E. Cane (Brown University) presented the detailed synthetic and enzymological elucidation of polyketide biosynthesis, namely that of the broad-spectrum antibiotic erythromycin A. A direct study of enzyme-mediated polyketide chain elongation clarified the conversion of acetate and propionate building blocks into macrolides.

Guy C. Lloyd-Jones (University of Bristol) gave an excellent talk on isotopic "hidden" desymmetrization as a stereochemical probe in transition-metal-catalyzed processes. Realized through the site-specific introduction of stable isotopes (^{2}H or ^{13}C), this technology was successfully applied to the mechanistic elucidation of palladium- and molybdenum-catalyzed asymmetric alkylation reactions. By using isotopic labeling, his research group has also shed light on the ruthenium-catalyzed enyne metathesis, which likely follows an "yne-then-ene" rather than an "ene-then-yne" pathway. Continuing the theme of catalysis, yet from an entirely different angle, Keiji Maruoka (Kyoto University) described the evolution of structurally simple but powerful quaternary ammonium salts as chiral phase-transfer catalysts. The application of such organocatalysts (**5**, Scheme 2)—some of which are now commercially available—to the asymmetric alkylation of α-amino acid derivatives permits the preparation of important unnatural secondary and tertiary α-amino acids (**3** → **4**; Scheme 2). Among other transformations, these catalysts also promote highly enantio- and diastereoselective direct aldol reactions.

Baptized a "Zn-ing Mg-ician", Paul Knochel (Universität München) presented a selection of novel Grignard reagents with distinctly graduated reactivity for the halogen–magnesium exchange at unsaturated carbon centers. With this methodology at hand, a plethora of functionalized magnesium organometallic compounds are now accessible and have been subsequently

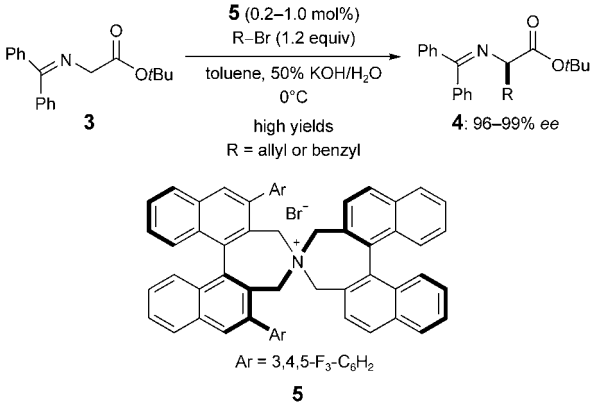
[**] 40th EUCHEM Conference on Stereochemistry, sponsored by the European Association for Chemical and Molecular Sciences (EuCheMS), Bürgenstock (Switzerland), April 16–22, 2005.

  DOI: 10.1002/anie.200501433



Scheme 2. Asymmetric phase-transfer catalysis.

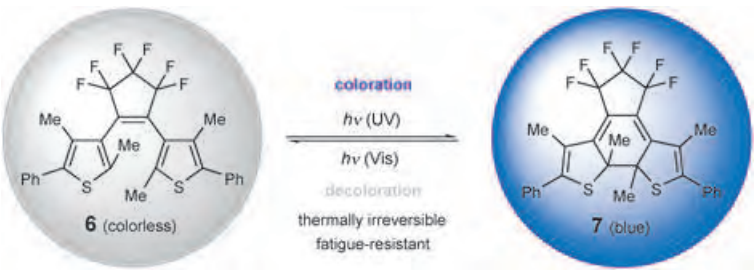
implemented in cross-coupling reactions.

The third day kicked off with a talk by Ian A. Wilson (The Scripps Research Institute) about studies of antibody–antigen complexes with X-ray crystallography. As an example, insight has been gained into the recognition of HIV-1 proteins which could advance efforts toward an effective HIV-1 vaccine. An informative historical background on the Spanish flu epidemic of 1918 served as an introduction for his approach toward answering the question of why this particular avian influenza was so disastrous. In an instructive talk, Thomas Carell (Universität München) focused on genome maintenance systems and the molecular machinery involved in recognizing and repairing oxidative and photoinduced lesions. Synthetic and crystallographic efforts have shed light on the mechanisms that counteract such DNA damage.

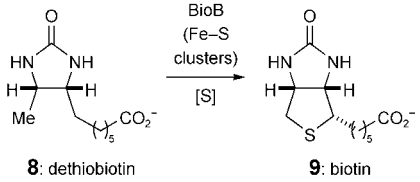
The morning session of the following day was devoted to organic molecules as functional materials. Klaus Müllen (MPI Mainz) enticed his audience into the aesthetic electronic world of two- and three-dimensional benzenes: rods, discs, spheres, and dendrimers. Later, Masahiro Irie (Kyushu University) gave a fascinating talk on photochromism "spiced up" with several experiments demonstrating the reversible photochemical transformation of two defined, thermally stable compounds (**6** ⇄ **7**; Scheme 3). The application of photochromic reactions in solution and in solid state, even at a molecular level, provides opportunities for the design of optoelectronic devices.

Catherine L. Drennan (MIT) reported on the (structural) elucidation of vitamin biosynthesis by AdoMet (*S*-adenosyl-L-methionine) radical metalloproteins such as biotin synthase (BioB) (**8** → **9**; Scheme 4). She also emphasized the substantial role of bifunctional carbon monoxide dehydrogenase/acetyl-CoA synthase (CODH/ACS) in the global carbon cycle and presented insight into the mechanisms of carbon dioxide fixation.

The final morning session was opened by Mikiko Sodeoka (Tohoku University) in a presentation of her efforts toward the development of selective inhibitors of protein phosphatases and necrotic cell death. The understanding of the mode of action of these inhibitors was supported through structure–activity relationships. With the unique polycyclic structures of the phomoidrides (**10**; Figure 1) as a starting point, John L. Wood (Yale University) told an intriguing story about the interplay of target-oriented synthesis and the occasionally serendipitous discovery of novel reactions.



Scheme 3. A photochromic reaction.



Scheme 4. Biotin synthase-catalyzed insertion of sulfur.

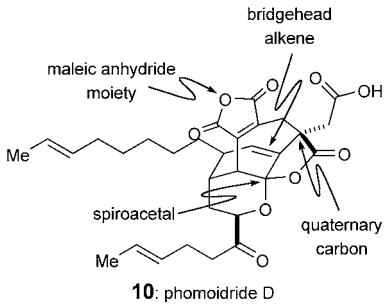


Figure 1. Synthetic challenges in **10**.

The privilege of the final scientific talk was granted to David A. Evans (Harvard University). In a highly scholarly talk on asymmetric Lewis acid catalysis employing chiral bis(oxazoline) (box) and bis(oxazolinyl)pyridine (pybox) metal complexes, he delineated the importance of the metal center (the inorganic chemist's perspective) besides ligand design (the organic chemist's perspective). As tidbits, several elegant applications of novel methodologies in natural product synthesis were also included.

On the entertaining side, an "enchanting" Koji Nakanishi (Columbia University) performed as a magician with some of the invited speakers as victims of his magic. The final words belonged to Klaus Müller who improvised an amusing, not-so-serious summary of the week.

The perfect blend of scientific exchange and recreation had again set the stage for an extraordinarily pleasant experience. The president and the "four gnomes of Bürgenstock" (C&EN, April 11, 2005) organized a flawless conference. If there had been a downside, it was the weather; when Alain Krief handed the baton to president-elect Bernhard Kräutler (Universität Innsbruck), he roguishly selected an umbrella!

C–H Aminations

Recent Advances in Catalytic Intramolecular C–H Aminations

Huw M. L. Davies and Matthew S. Long*

Keywords:
amination · C–H activation · insertion · synthetic methods · transition metals

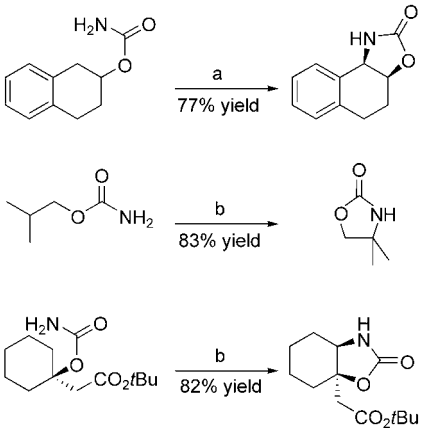
Installation of an amine functionality is a fundamental operation in organic synthesis and can, of course, be performed in many ways, but ultimately the majority of methods involve reaction of a nitrogen-based nucleophile with an electrophilic carbon center. From a strategic standpoint, the preparation of amines by amination of C–H bonds would be an extremely attractive alternative [Eq. (1)].[1] Pioneering work by Breslow

(1)

and Gellman in the 1980s demonstrated that the metal-catalyzed reaction of tosylimidophenyliodinane (TsN=IPh, tosyl (Ts) = *p*-toluenesulfonyl) generated metal nitrenes that were capable of aminating cyclohexane.[2] In recent years considerable advances have been made in the development of this chemistry into a generally useful C–H amination process by using improved catalysts and protocols in which readily available amines or amides are used as the starting substrates. This report highlights these advances and illustrates the elegant applications of the amination of C–H bonds in total synthesis.

One of the drawbacks with the early methods of amination of C–H bonds was the requirement of preforming the rather labile aryliodinane intermediates.[1] Recently, the groups of Che[3] and Du Bois[4] independently reported that the formation of aryliodinanes and the insertion of metallonitrenoids into C–H bonds can be conducted in a one-pot procedure. While Che and co-workers initially focused on intermolecular reactions,[3] Espino and Du Bois demonstrated that carbamates are efficiently converted into the corresponding oxazolidinones through an intramolecular nitrenoid C–H insertion pathway.[4] Initially the primary carbamate **1** is oxidized to the corresponding iodoimine **2**, which is in turn decomposed by a dirhodium complex to generate the metallonitrene **3**; this reactive intermediate then undergoes a C–H insertion event to furnish the cyclic product **4** and releases the rhodium complex to continue the catalytic cycle (Scheme 1).

The intramolecular reactions may exhibit impressive levels of stereo- and regiocontrol. The formation of five-membered rings is strongly favored, and the nitrenoid will preferentially insert into an activated benzylic site over an alkyl site. More-hindered methine C–H bonds are also amenable to insertion by the nitrenoid. In all the examples reported, the cyclic carbamates are generated with *syn* diastereoselectivity and with retention of stereochemistry at the insertion site (Scheme 2).



Scheme 2. a) $PhI(OAc)_2$, $Rh_2(tpa)_4$ (5 mol%), MgO, CH_2Cl_2, 40 °C; b) $PhI(OAc)_2$, $Rh_2(OAc)_4$ (5 mol%), MgO, CH_2Cl_2, 40 °C. tpa = triphenylacetate.

When sulfamate esters such as **5** are used as substrates, six-membered-ring formation is favored and results in the selective formation of 1,2,3-oxathiazinane-2,2-dioxide heterocycles **6**.[5] In general the reactions are high yielding and proceed with elevated levels of diastereoselectivity (Scheme 3).[6]

A very elegant expansion of the synthetic utility of the intramolecular amination reaction has been insertion reactions into ethereal C–H bonds.[7] Du Bois and co-workers have exploited this reactivity to prepare cyclic sulfamates **7**–**10** that are then used as iminium ion equivalents. Upon treatment

with a suitable Lewis acid, the cyclic iminium ion formed can undergo attack from nucleophiles such as zinc acetylides, allyl silanes, and silyl enol ethers to form the elaborated 1,3-amino alcohols **11**–**14**. The nucleophilic additions appear to proceed through a well-ordered transition state, and the majority of examples presented exhibit good levels of diastereoselectivity (Scheme 4).[7,8]

Improved catalysts are required for further enhancement of C–H amination chemistry. Du Bois and co-workers originally used rhodium(II) acetate and rhodium triphenylacetate (tpa) as catalysts and found that regio- and diastereocontol was influenced by the catalysts, but neither was effective when low catalyst loadings were used. Inspired by the bridged dirhodium catalysts developed for carbenoid chemistry,[9] a second-generation catalyst $Rh_2(esp)_4$ (**15**, esp = α,α,α′,α′-tetramethyl-1,3-benzenedipropionate)[10] was designed which was capable of much higher turnover numbers (Scheme 5). Furthermore, this catalyst was effective in intermolecular reactions.

Che and co-workers have used manganese– and ruthenium–porphyrin catalysts for their amination reactions. In their original studies on intermolecular aminations with preformed iodinanes, catalyst turnover numbers as high as 2600 were reported.[2] More recently Che and co-workers have investigated intramolecular C–H insertion reactions of sulfamate esters using ruthenium–porphyrin complexes as catalysts. Interestingly five-membered-ring formation will take place in systems in which there is an activated C–H bond available for insertion, as exemplified by the formation of **19** from **18**. When a chiral porphyrin was employed, the insertions proceeded with impressive levels of enantioselectivity (Scheme 6).[11]

The intramolecular insertion reactions of nitrenoids into C–H bonds as described above provide an attractive alternative to conventional methods of amine formation. Furthermore, the protocols are practical and tolerant of many different functional groups, therefore it is not surprising that they have been elegantly exploited in natural product synthesis. In their synthesis of tetrodotoxin in 2003, Hinman and Du Bois used the carbamate-based nitrenoid C–H insertion to form a pivotal C–N bond in **20** in a stereospecific fashion.[12] The sulfamate ester variant of this chemistry was showcased in the synthesis of the bromopyrrole alkaloids manzacidin A and C. A nitrenoid insertion was used early in the synthesis to stereospecifically set up the secondary amine in **21** which was subsequently converted into the cyclic amidine (Scheme 7).[6]

In conclusion, the advances made in performing and controlling nitrene-induced C–H amination reactions have provided a reliable and viable alterna-

analytical methods · high-throughput screening · lab on a chip · microfluidics · microreactors

In analogy to miniaturization in microelectronics, the integration of chemical processes on chips, where chemical reactions are performed in microchannels and -cavities, is currently the focus of significant research efforts. The ambitious aim is to shrink chemical laboratories to "lab-on-a-chip" systems. The development of technologies and miniaturized components like reactors and valves in order to realize such a handheld laboratory is currently a very active research area. In this context microfluidics is of particular importance as microfluidic channels play a major role as central elements of miniaturized labs in analogy to the conducting paths in microelectronics. Microfluidic channels are utilized for transport, mixing, and separation of reagents on the nanoliter scale. While tremendous progress has been made in the miniaturization of individual construction units of potential lab chips, interfacing such tiny devices to the macroscopic world is still a big challenge.

Zheng und Ismagilov[1] reported recently a straightforward and economic approach for handling and transfering a large number of samples on the nanoliter scale into basic microfluidic systems for subsequent screening assays. For this purpose aqueous samples several nanoliters in volume are introduced into a capillary using immiscible phases as spacers to form a sample array. While in classical flow injection analyses (FIA) air bubbles are used to separate a series of samples, Zheng and Ismagilov describe a three-phase liquid/liquid/gas system. An array of different aqueous samples is generated inside a capillary, while the sample plugs are surrounded by a fluorinated carrier fluid and additionally separated by gas bubbles (Figure 1).

Figure 1. An array of differently colored aqueous samples separated by air bubbles (dark segments) in a capillary filled with a fluorocarbon.

Zheng and Ismagilov report that such three-phase systems are much more robust than the classical two-phase gas/liquid[2] and liquid/liquid systems.[3] This reduces coalescence and carry-over of samples more efficiently. Preloaded capillaries are even suitable for long-term storage of samples on the nanoliter scale.

Such segmented flows, whereby aqueous sample droplets are floating in a hydrophobic liquid, are especially attractive in mircrofluidics, as reagents can be mixed within a droplet and simultaneously sample dispersion is minimized.[4] The mixing of compounds in microfluidic channels is challenging because of the low Reynolds numbers and the corresponding laminar flows. Significant research efforts have been devoted to solving this problem, for example, by the development of micromixers.[5]

By coupling a capillary to a microfluidic chip, Zheng and Ismagilov performed simple chemical reactions with the sample array. For this purpose the preformed samples are introduced into a microfluidic system with a T-junction, where they meet a reagent stream (Figure 2). In this type of microreactor, which has already been described in detail for two-phase systems,[6] the sample droplets merge with the reagent solution without distortion of the segmented flow. The reagent concentrations can be adjusted easily by regulating the flow rates.

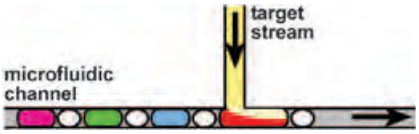

Figure 2. Schematic drawing of sample zones merging with a reagent solution in a microfluidic chip.

This technique was illustrated with two examples. In one case an assay was performed in which a set of enzymes was screened for phosphatase activity using fluorescein diphosphate as a fluorogenic substrate. An array of protein samples (≈15 nL), preloaded in a capillary as described above, was merged with the reagent solution at the T-junction. The presence of a phosphatase could be evident from the fluorescence of the hydrolyzed substrate (see Figure 3).

In a second example this approach was successfully utilized for screening a single protein against multiple crystal-

lization agents. For this purpose an additional outlet capillary was coupled to the chip in order to collect the segmented crystallization solutions. Such glass capillaries are much better suited for time-consuming crystallization experiments than the solvent-permeable polydimethylsiloxane (PDMS) chips.[7]

Microfluidic chips prepared from PDMS appear to be well suited for coupling with capillaries and adapters owing to the elasticity of the material. It would be very attractive to extend this concept also to chips manufactured from glass or fused silica, which are considered the materials of choice for future chip laboratories because of their excellent chemical resistance and optical properties.

Segmented flow is not optimal for more complex chip laboratories since successive operations would require a homogeneous one-phase flow. In classical flow injection analyses, bubble gates are used for that purpose. Hibara et al.[8] have recently described a corresponding microfluidic system for the removal of air bubbles in aqueous flows that is based on channel segments with different hydrophobicity. In this approach, gas bubbles are removed utilizing hydrophobic channels, while the aqueous phase is guided into hydrophilic channels. The application of this approach to the system described by Zheng and Ismagilov could allow online coupling of succeeding analytical steps like electrophoresis. This would be a promising step toward the goal of a "lab on a chip".

Surfaces create an environment in which multiple forces conspire together to yield a wealth of complex chemical processes. This is especially true of cell membranes, whose fluidity and flexibility enables responsive feedback with surface chemical interactions in ways not generally seen with inorganic materials. Spatial pattern formation of cell-surface proteins at intermembrane junctions provides many beautiful examples of these phenomena, and is also emerging as a functional aspect of intercellular signaling. Correspondingly, the study of interactions of cell-membrane surfaces is attracting significant attention from cell biologists and physical chemists alike. This convergence is fueled be recent, exquisite observations of protein pattern formation events within living immunological synapses along with parallel advances in membrane reconstitution, manipulation, and imaging technologies.

From the Contents

1. Introduction

The ability of cells to transmit signals to each other is an essential aspect of all multicellular life. Thousands of membrane-associated receptors and signaling molecules transduce signals between cells, and much attention has been directed toward understanding the chemical interactions between the receptors and ligands. However, in many cases, the properties of individual binding events have proven insufficient to account for the remarkable behavior exhibited by these proteins in living cells. Collective protein–protein interactions and the formation of molecular clusters have been widely implicated in signal transduction, and account for a first level of cooperativity.[1–6] More recently, coordinated rearrangement of cell-membrane receptors into distinctive patterns is emerging as a broadly significant theme of intercellular signaling. Hallmark examples are provided by the immunological synapses, which have been discovered over the last few years at junctions between a variety of immune cells and their respective target cells.[7–15] Spatial patterns of proteins within the junction develop as populations of receptors on one cell membrane interact with their cognate ligands on the apposed cell membrane. The emergent patterns can extend to several micrometers, thus transcending direct protein–protein contact interactions, and exhibit strong correlations with the ensuing intracellular signaling and effector functions.

Geometrical confinement on molecular length scales, which is inherent to intercellular junctions, has profound consequences on the biochemical reactions that take place in these spaces. In the case of the immunological synapses, protein patterns result from intimate cooperativity between both inter- and intramembrane protein binding, membrane mechanical constraints, and cytoskeletal rearrangements, which lead to lateral sorting of proteins within their respective fluid membranes.[16–18] A distinctive feature of the intermembrane junction environment is that driving forces for pattern assembly can arise without direct binding interactions among proteins. For example, bending constraints from the membrane impose an effectively repulsive interaction on receptor–ligand complexes with different preferred intermembrane spacing. Correspondingly, the effective kinetic rate for the formation of another receptor–ligand complex in the vicinity of one of similar size is enhanced by the pre-positioning of the membranes. This type of reaction feedback loop is capable of driving the formation of a rich array of patterns at intermembrane junctions.[19–23] Alternatively, preferential association with a particular membrane phase domain (raft[140]) can lead to colocalization. The generality of these types of forces suggests that tendencies towards spatial pattern formation are likely to have a wide-ranging influence within intercellular junctions.

Reaction-driven formation of spatial patterns is a widespread physical phenomenon with important implications outside of biological systems, such as in heterogeneous catalysis.[24–26] However, the complexity of pattern-forming reaction phenomena within living systems is unparalleled. Dramatic advances in unraveling the molecular aspects of cellular signaling systems, such as the immunological synapse, create distinct opportunities for highly quantitative experimental and computational investigations of the physical mechanisms underlying the elaborate signaling events that occur in live cell membranes.

In this Review recent developments in the study of physical mechanisms of signal transduction at intercellular junctions are summarized. The immunological synapses are emphasized as examples, which may reveal general themes of collective signaling interactions at intercellular junctions. These are discussed from a physical perspective and in the context of developing quantitative interpretations. Experimental model membrane systems and measurement techniques that address the hierarchical cooperativity of interactions among populations of signaling molecules at intermembrane junctions are highlighted.

2. Spatial Patterns and Cell Signaling

2.1. Intercellular Synapses

A critical role of the immune system is to identify and destroy those cells that have become infected by a pathogen or have entered into some other form of aberrant life cycle. One class of immune cells that perform this surveillance are the T lymphocytes (T cells). These cells are the front-line of the adaptive immune system and their activation primarily occurs through interaction of T-cell receptors (TCRs) on the T cell with major histocompatibility complex proteins (MHC) that display peptide fragments on the surface of antigen-presenting cells (APCs). A variety of signals can be transduced depending on the nature of these interactions. For example, the recognition of peptide/MHC (pMHC) by TCRs on activated cytotoxic $CD8^+$ T cells induces killing of the target cell. In contrast, recognition of self-pMHC on APCs in the thymus by TCRs on thymocytes (immature T cells) results in destruction of the autoreactive thymocytes by apoptosis. Failure of this thymic selection process leads to autoimmune disease. Rheumatoid arthritis, multiple sclerosis, and psoriasis can all be traced to faulty signaling at T-cell synapses

T cells execute their recognition processes through formation of an immunological synapse with the target cell.[10,11,13–15,17,27–31] Numerous recent observations have revealed precisely organized and dynamic patterns of receptors and signaling molecules within the synapse[7–9,32–35] (Figure 1). Immunological synapses are not restricted to T cells: natural killer (NK) cells, which play a key role in the innate immune response, also form a rich collection of synaptic patterns during interactions with target cells. While the focus of this Review is restricted to T cells, many of the themes described have also been observed at NK cell synapses.[10]

In the case of the synapse of a mature T cell, the preferred geometry for sustained signaling consists of a central supramolecular activation cluster (c-SMAC), with dimensions of 1–3 μm, in which TCR–pMHC complexes accumulate. Other co-stimulatory molecules on the T-cell surface, including CD28 and cytotoxic T-lymphocyte antigen 4 (CTLA4), become enriched within the c-SMAC along with their shared cognate ligands, B7-1 and B7-2, on the APC surface. The c-SMAC is surrounded by a peripheral ring, which is populated by complexes between leukocyte function associated antigen 1 (LFA1) on the T cell and intercellular adhesion molecule 1 (ICAM1) on the APC (Figure 1 a). This structure, known as the periferal supramolecular activation cluster (p-SMAC), is also enriched with larger co-stimulatory molecules including CD2 and its ligand (CD48) on the T cell and APC, respectively. The size of the TCR–pMHC complexes fixes the intermembrane spacing within the c-SMAC at about 15 nm. The larger LFA1–ICAM1 complexes (ca. 40 nm) force the apposed membranes into a wider spacing within the peripheral ring of adhesion molecules. Ultimately, an elaborate interplay of co-stimulatory, adhesion, and signaling molecules[31,36–39] together with cytoskeletal attachments[18,40–42] and lipid rafts[43–46] becomes organized within immunological synapses.

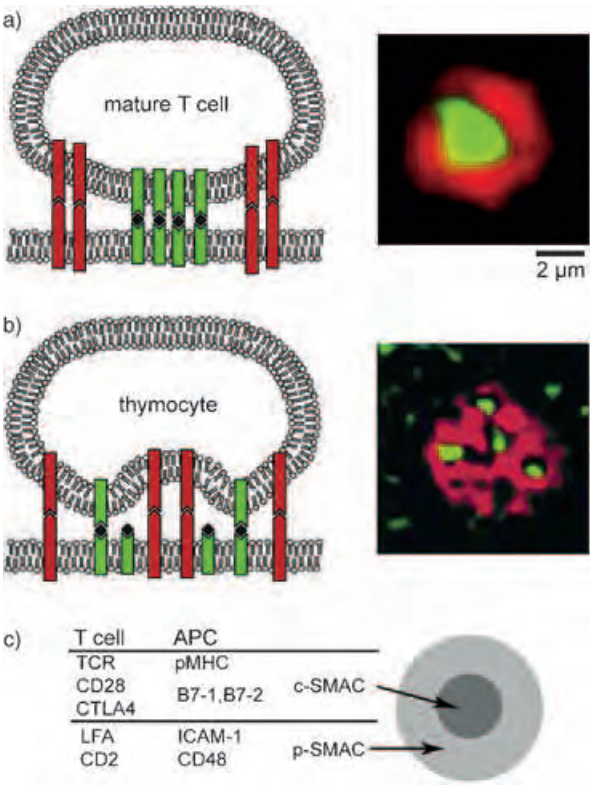

Figure 1. Synaptic patterns in different immune cell types: Schematic representations (left) and fluorescence images of live cells (right). a) Synapse of a mature T cell with TCR–peptide/MHC (green) in the center (c-SMAC) and LFA1–ICAM1 (red) at the periphery (p-SMAC). The fluorescence image is taken from ref. [8]. b) Schematic representation and fluorescence image of a thymocyte synapse (same color scheme as in (a)). The fluorescence image is taken from ref. [48]. c) Schematic representation of the molecular anatomy of a synapse of a mature T cell.

Thymocyte–APC interactions involve the same primary receptor–ligand pairs described above for the synapse of mature T cells, however their spatial organization is different. No c-SMAC forms at thymocyte–APC synapses. Instead, multifocal accumulations of TCR–pMHC condense and effervesce within a sea of LFA1–ICAM1 complexes[47,48] (Figure 1 b). A thermodynamic origin to the differing patterns, based on TCR expression levels, has been proposed[49] (see Section 2.2). However, the extent to which the differ-

Jay T. Groves received a BS in physics and chemistry from Tufts University (USA), followed by a PhD in biophysics from Stanford University. He then spent a year as a Visiting Scholar at Academia Sinica, in Taipei, Taiwan before returning to the USA to be the Division Director's Fellow at Lawrence Berkeley National Laboratory. In 2001 he joined the faculty of the Chemistry Department at the University of California, Berkeley. His research interests focus on the physical chemistry of lipid membranes, and the organizational principles these structures impose on living molecular systems.

ential patterns of proteins observed in mature T-cell and thymocyte synapses contribute to their differing cellular responses to TCR activation is not resolved.

Information regarding the structural organization of the immunological synapses described above was obtained through a variety of optical and electron imaging techniques. Protein patterns have been observed by imaging fluorescently labeled proteins in living cells[7,9,34,47] and in hybrid synapses formed from live cells and supported membranes.[8,48,50] Topographical patterns of intermembrane spacing within live immunological synapses have been imaged in hybrid synapses formed between live cells and supported membranes by using reflection interference contrast microscopy (RICM).[8] Measurements of intermembrane spacing in synapses between two living cells have also been obtained from electron microscopy images of two-dimensional slices made perpendicular to the synaptic interface.[51,52]

The immunological synapses are likely to have multiple functions that have varying degrees of importance for different cell–cell interactions. The synapse-forming process (see below) offers multiple possibilities for the inhibition and regulation of the assembly of a mature synaptic pattern. Once a synapse is formed, the increased concentration of TCR in the c-SMAC can increase the rate of TCR triggering, at least initially. Increased down-regulation of TCR in the c-SMAC can also occur, ultimately leading to reduced signaling. It has been proposed that the mature synaptic pattern serves as a mechanism to balance TCR signaling and degradation.[53] In addition to signaling, the structure of the immunological synapse may play a role in effector function by directing the secretion of cytokine or lytic granules towards the target cell.[54]

Immunological synapses can be corrupted by pathogens. Human immunodeficiency virus (HIV) and human T-cell lymphotropic virus type 1 (HTLV-1) have both been recently observed to take advantage of the concentration of targeted receptors and confined geometry of the synapse to facilitate cell to cell transmission.[55–57] Prion proteins also appear to spread from the immune to the nervous system at neuro-immunological synapses.[58,59]

Early stages of synaptogenesis and postsynaptic partner recognition in the central nervous system represent a similar task to that confronted by immune cells during surveillance. Recent results provide mounting evidence for common motifs between synapses in the nervous and immune systems.[12,51] For example, important proteins including MHC,[60] agrin,[61,62] and neuropilin-1[63,64] have recently been found to play functional roles in synapses from both systems.

2.2. Physical Driving Forces

Active transport by the cytoskeleton plays a key role in pattern formation at immunological synapses, and is one of the first activities triggered by signaling from the T-cell receptor.[18,40–42] The TCR starts to be transported towards the center of the forming synapse within moments of the first interaction with antigenic pMHC. Transport velocities ranging from 0.04–0.1 $\mu m s^{-1}$ have been measured by three dimensional fluorescence tracking microscopy.[65] The TCRs interact with the actin cytoskeleton directly through the TCRζ chain and the cytoskeletal regulator Vav.[66,67] Blocking active cytoskeletal transport, for example, with an actin polymerization inhibitor such as cytochalasin D, disrupts the formation of synapse in T cells.[8] As the TCRs accumulate in the c-SMAC, various adhesion and co-stimulatory molecules, including LFA1, are excluded from this central region and begin to form the encircling p-SMAC. It has been reported that the microtubule organization center (MTOC) is anchored to the membrane at the p-SMAC,[68] thus suggesting a mechanism in which this tubulin-based scaffold may be coordinated with the function of the actin cytoskeleton during formation of the synapse. Furthermore, treatment of cells with the potent microtubule inhibitor nocodazole interferes with TCR activation, thus providing additional support for a functional role of the MTOC in synapse signaling.[69]

In addition to providing various driving forces to create protein patterns within the immunological synapse, there is emerging evidence that the cytoskeleton plays multiple regulatory roles. For example, sustained accumulation of actin in the T-cell synapse depends both on the concentration of the agonist pMHC and engagement of co-stimulatory receptors CD28 or LFA1.[70] Signals from co-stimulatory molecules may thus regulate the formation of the large-scale protein pattern through their influence over the dynamics of the actin cytoskeleton. The cytoskeleton may also exert a regulatory role over synapse function mediated by the ezrin-radixin-moesin (ERM) proteins.[71] The ERM proteins act as general cross-linkers between the cortical actin filament network and the plasma membrane,[72] and are known to be involved in the T-cell immunological synapse.[73] Early stages of TCR signaling can trigger inactivation of the ERM proteins. This results in a partial disanchoring of the cortical actin cytoskeleton and seems to lead to more efficient formation of a T-cell/APC conjugate. How these multifarious roles for the cytoskeleton are integrated and what types of feedback mechanisms regulate these processes are currently open questions.

Membrane-governed self-assembly mechanisms have also been implicated in the formation of synapses. The size disparity between the various receptor–ligand complexes that form within T-cell synapses defines a specific topographical variation of the intermembrane spacing.[74] This has been observed directly in live T-cell synapses by electron microscopy[51,52] and RICM;[8] the membrane topography shown schematically on the left of Figure 1 is based on these observations. Once topographical structures begin to form at intermembrane junctions, other cell surface molecules can then be driven indirectly into spatial patterns by a size-exclusion effect. Evidence of a functional role for size-based sorting has been provided by a set of experiments in which genetic elongation of the extracellular domain of CD48 (a co-stimulatory ligand on the APC) was shown to disrupt its natural ability to augment antigen recognition by T cells.[75]

Mechanical constraints on the membrane provide the driving force for size-based protein sorting at intermembrane junctions. The interplay between protein organization and

membrane shape during the assembly of the synaptic pattern has been investigated using theoretical models for the collective interaction between populations of cell surface receptors and ligands in apposed membranes.[19–21,49,76,77] Receptor–ligand binding can be modeled as a reaction-diffusion process, which can be described mathematically by Smoluchowski equations. In this representation, receptor–ligand binding is characterized by the rates of association (on) and dissociation (off). The receptors and ligands are free to diffuse within the two-dimensional plane of their respective membranes. The effective local reaction rate between cognate receptor–ligand pairs depends on their local concentrations, the appropriate association rate, the local intermembrane spacing, and the size of the complex. A distinguishing feature of this modeling strategy is its incorporation of the evolving topography of the intermembrane junction. The energy content of the membrane shape is calculated by including contributions from membrane bending and stretching as well as contributions from distortions caused by formation of the receptor–ligand complex. The time evolution of the membrane shape is then coupled to the reaction-diffusion equations using a time-dependent Landau–Ginzburg equation. In this way, the intimate feedback between protein binding and membrane shape can be explored.

A notable feature of the immunological synapses is the characteristic transformation in the pattern that occurs as the synapse matures. The initial state of the helper T cell synapse consists of an outer ring of TCR–pMHC surrounding a central concentration of LFA1–ICAM1 complexes. The initial state of the cytotoxic T-cell synapse is less well organized. As signaling progresses, both types of T-cell synapse undergo a rearrangement process during which TCR and pMHC relocate to the c-SMAC while LFA1 and ICAM1 migrate to the periphery. Numerous other molecules on the cell surface are also sorted during this process. Calculations, based on measured values of protein binding kinetics, membrane bending rigidity and elasticity, and the size of the protein complexes, predict pattern reorganization with remarkable spatial and temporal resemblance to that observed in live T-cell synapses (Figure 2). The top two rows of images illustrate the sequential formation of a hybrid immunological synapse between a live cell and a supported membrane.[8] The top row contains RICM images, which reveal the changing topography of the junction. Brighter intensities in the RICM image correspond to regions where the intermembrane spacing is greater. The second row depicts a series of superimposed fluorescence images, which illustrate the distribution of MHC (green) and ICAM (red) in the junction. The lower three rows illustrate the topography, MHC, and ICAM profiles resulting from calculations according to the membrane-coupled reaction-diffusion modeling strategy mentioned above.[19] Although modeling studies suggest that membrane-mediated forces could drive pattern formation without directed transport by the cytoskeleton, it is important to note that mechanical properties of the cell membrane are significantly influenced by the cytoskeleton.[78] Thus, indirect influence from the cytoskeleton is inescapable. Furthermore, certain aspects of pattern formation may require a directed push by the cytoskeleton to occur.[21]

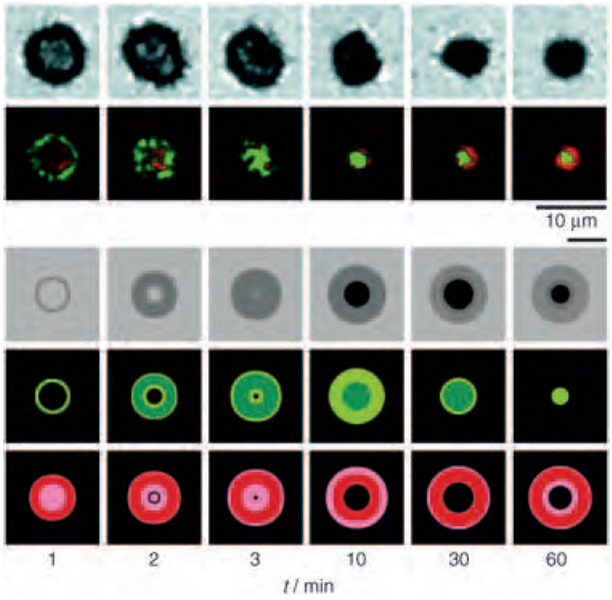

Figure 2. Time series of RICM images (top row) and superimposed fluorescence images (second row) tracking the formation of a synapse between an immunological T cell with a supported membrane displaying ICAM (red) and MHC (green). The data were taken from ref. [8]. The lower three rows illustrate the calculated topography and the MHC and ICAM patterns. For the calculated patterns of protein concentration illustrated in rows 4 and 5, regions with protein concentrations below the average are colored black, while protein-enriched regions are colored with progressively darker shades of green (MHC) or red (ICAM). Contrast optimization of the fluorescence data (row 2) produces a similar effect.

Irrespective of the role of the cytoskeleton, the membrane-governed tendencies to form patterns under non-equilibrium conditions constitute a set of forces that globally influence proteins on the cell surface. These membrane-mediated forces are similarly inescapable and will ultimately contribute to the overall organization of proteins within the synapse. For example, suppose that the actin cytoskeleton and the MTOC establish a pattern of membrane topography at an intercellular junction through a coordinated effort. This topography will then produce membrane-mediated driving forces that will influence the spatial organization of molecules not bound to the cytoskeleton. Cytoskeleton- and membrane-mediated mechanisms of spatial organization thus become inextricably coupled within an intercellular junction. The development of quantitative interpretations of the mechanisms of signal transduction between cells will likely require an inclusive treatment of both membrane and cytoskeletal effects.

Membrane-mediated forces exhibit an intrinsic sensitivity to the kinetics of protein binding. This results from the basic fact that the motion of a bound intermembrane protein complex is greatly hindered by the undulating topography of the junction. In order for a complex to move laterally within the membrane, the intermembrane spacing must comply. No corresponding hindrance affects unbound cell-surface proteins (Figure 3). The reaction-diffusion dynamics of protein organization can thus exhibit a greater sensitivity to reaction

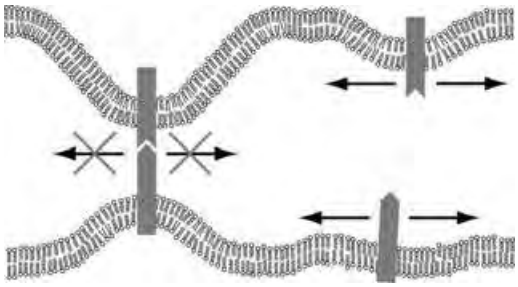

Figure 3. The lateral diffusion constraint experienced by intermembrane protein complexes. Topographical variations of the membrane hinder lateral motion unless the adjacent intermembrane spacing is comparable to the complex size. Uncomplexed proteins, in contrast, diffuse freely in their respective membranes.

kinetics than to diffusion kinetics. The extent to which the kinetics of protein binding influence pattern formation through membrane-mediated reaction-diffusion processes in the T-cell synapse is not clear. However, comprehensive analysis of biological data relating protein-binding kinetics to cell activation yields interesting correlations with calculated pattern-forming tendencies. Protein-binding kinetics that, according to the model, lead to formation of a mature synaptic pattern correlate strongly with activation of helper T cells. In contrast, no correlation is seen between pattern-forming tendencies and target cell lysis by cytotoxic T cells. This observation may reflect the multiple types of signals, and signaling mechanisms, that traverse the immunological synapse.[76] Modeling studies have also suggested that the dynamic multifocal synapses involved in thymocyte selection can result from low TCR expression and thermal fluctuations of the membrane. A possible mechanism by which TCR expression levels in thymocytes could be used to mediate differential signaling through the same molecules involved in T-cell activation is implied.[49] Interplay between the chemical kinetics of protein binding and membrane constraints at intercellular junctions produces a rich source of pattern-forming tendencies. These collective driving forces exhibit pronounced sensitivity to protein-binding kinetics and offer a mechanism for signal amplification.

The membrane-mediated forces described above result primarily from mechanical bending effects. Another class of forces originating from the membranes can result from lateral phase separation tendencies within the membrane.[79] These much-discussed raft structures are implicated in numerous signal-transduction processes,[80,81] including the T-cell synapse.[43,44,82,83] Whereas the physical chemistry of the separation of immiscible phases in lipid bilayer mixtures can be understood with a high degree of quantitative precision,[84,85] a similarly quantitative interpretation of phase-separation phenomena in living cell membranes remains elusive. With respect to the mechanical membrane bending effects discussed above, phase-separated membrane domains could exert substantial influences, and developing effective methods for considering these processes in the context of the topographical bending of the membrane and cytoskeletal interactions is important.

It is compelling to hypothesize that spatial patterns of molecules at intercellular junctions collectively convey information that supersedes the mere summation of individual signaling contributions. In addition to the immunological synapses, there exists substantive evidence of correlations between the spatial arrangement of receptor proteins and signaling activity in bacterial chemoreception,[5] intigrin signaling,[3] extra cellular matrix (ECM) cell adhesion,[4] and the ubiquitous cell-membrane raft domains.[80,86] However, the degree to which spatial patterns actually convey a supernumerary quantity of information remains an open question.

3. Experimental Model Systems

3.1. Hybrid Synapses Formed from Cells and Supported Membranes

A remarkable and fortuitous characteristic of lipid membranes is the tendency of lipid bilayer vesicles to spontaneously assemble into a single, continuous lipid membrane on an appropriate substrate (e.g., silicon oxide or various polymeric materials).[87,88] This vesicle fusion process is general. A vast collection of different membrane compositions, including charged phospholipids, glycolipids, membrane-linked proteins (e.g., by glycosylphosphatidylinositol (GPI) linkers), transmembrane proteins, and even phase-separated membrane rafts can be deposited under essentially identical conditions.[89] The orientation of the membranes is preserved during the fusion process.[90] Biological function can also be preserved, as beautifully illustrated by the observation of the formation of an active immunological synapse between supported membranes and living T cells. A schematic illustration of this hybrid synapse is illustrated in Figure 4. In fact,

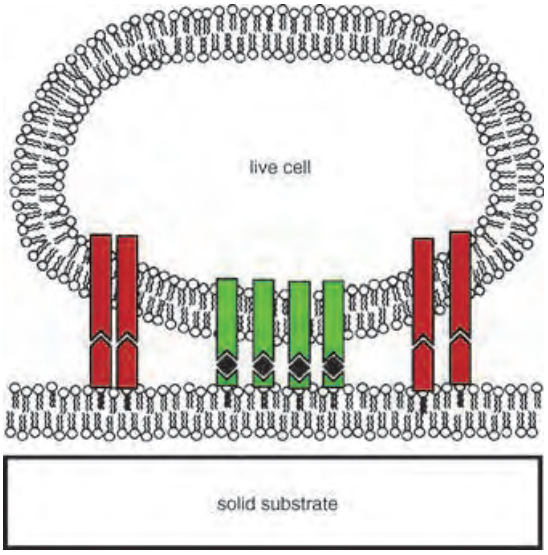

Figure 4. Schematic representation of a hybrid synapse formed from live cells and a supported membrane. In this example, the cognate ligands for receptors on the cell surface are displayed in the supported membrane in the GPI-linked form.

the highest resolution dynamic images of synapse formation in T cells have been obtained using supported membranes in place of live APCs.[8,50] The images in Figure 1a and 1b were both obtained from synapses with a supported membrane. In these examples, mature T cells (1a)[8] or thymocytes (1b)[48] form immunological synapses with supported membranes displaying membrane-linked forms of pMHC and ICAM1. A critical feature of supported membranes, which enables formation of a hybrid synapse, is the free lateral diffusivity of lipids and membrane-linked proteins. Supported bilayers are typically separated from the solid substrate by a film of water about 1 nm thick[91–93] and retain many of the properties of free membranes, including lateral fluidity. The fluidity acts over a long range, with mobile components of both leaflets of the bilayer diffusing freely over the entire surface of the substrate.[94]

A pivotal realization in the development of supported membrane technology was that barriers to lateral diffusion can be imposed on the supported membrane and used to partition it into corrals or other well-defined geometrically constrained configurations. Partitioning can be achieved by assembling membranes on prepatterned supports created by micro- or nanolithographic processes (e.g., photolithography, microcontact printing, or electron beam lithography).[95–101] In all cases, lipids and mobile proteins exhibit uninterrupted diffusion within the membrane, while at the same time there is no intermixing across barriers. The advantage of this general strategy of patterning membranes on surfaces is that it makes use of lithographic processing techniques, which have been developed extensively for the semiconductor industry, to achieve spatial control down to about 10 nm (the limit of state-of-the-art electron beam lithography). A fluorescence image of a supported membrane on a patterned substrate is depicted in Figure 5. This substrate was patterned with concentric hexagonal lines of chrome, 100 nm wide and spaced by 1 μm. Fluorescent probes in the membrane have been spot photobleached; the fluorescence recovery patterns illustrate the restricted diffusive connectivity within the supported membrane.

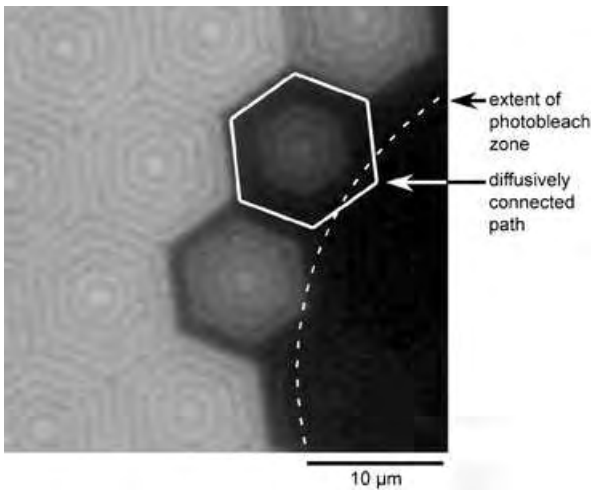

Figure 5. Fluorescence recovery after a photobleaching (FRAP) experiment on a substrate-partitioned supported membrane. The substrate is patterned by electron beam lithography. A diffracted image of the underlying chrome lines can be seen faintly in the fluorescence image. A supported membrane coats exposed regions of the underlying silica substrate and flows freely within diffusively connected regions, thus giving rise to the fluorescence recovery pattern seen here. This pattern is in diffusive equilibrium. (The image was supplied by K. Mossman.)

The formation of such hybrid synapses enables spatial restrictions of protein mobility and position to be imposed on living cell systems. An inherent requirement of this type of cellular dissection is the use of substrate patterns with subcellular (nanometer) length scales. New methods of membrane patterning that combine scanning probe lithography (SPL) with substrate diffusion barrier grids fabricated by electron beam lithography are extending fluid membrane patterning capabilities into the sub-micrometer range.[102]

Membranes can be deposited onto silica microbeads in much the same way that supported membranes are formed on monolithic substrates.[91,103,104] This format facilitates introduction of signaling molecules bound to the membrane surface to preexisting cell cultures. In one recent implementation, for example, a GPI-linked form of the postsynaptic cell-surface protein neuroligin-1 was displayed on membrane-coated microbeads. The functionalized beads were then introduced into a culture of primary hippocampal nerve cells. Through its interactions with β-neurexin on the neuronal cell surface, neuroligin-1 displayed on membrane-coated beads was able to induce preliminary stages of synaptogenesis in the neurons (Figure 6). The activity of the neuroligin-1 appeared to require display within a membrane environment, thus suggesting that surface rearrangements of this protein are required for its function.

3.2. Cell-Free Systems

There is significant interest in the development of entirely cell-free model systems to facilitate precise analysis of reaction processes at intermembrane junctions. Model intermembrane junctions, in which both membranes are reconstituted, have been created with supported membranes by several methods. Junctions can be formed by allowing intact giant unilamellar vesicles (GUVs) to interact with supported membranes. The use of RICM[105] to image the nanometer-scale topography of membrane junctions produced in this way has revealed a variety of phenomena, including coexistence of multiple adhesion states.[106–109] An alternative method of forming supported intermembrane junctions employs a combination of Langmuir–Blodgett and Langmuir–Schaeffer monolayer-transfer techniques. Two membranes are deposited onto a solid substrate by successive transfer of four monolayers from an air–water interface. This process has the advantage of uniformly coating a large surface area with a planar membrane, and has proven useful for neutron reflectivity studies.[110,111] Limitations of the Langmuir method include the difficulty of working with transmembrane proteins and an intrinsic requirement of intermembrane adhesion to achieve monolayer transfer; this precludes direct formation of weakly adhering junction states (described below). A third type of intermembrane junction can be formed by rupture of GUVs onto supported membranes. This technique produces

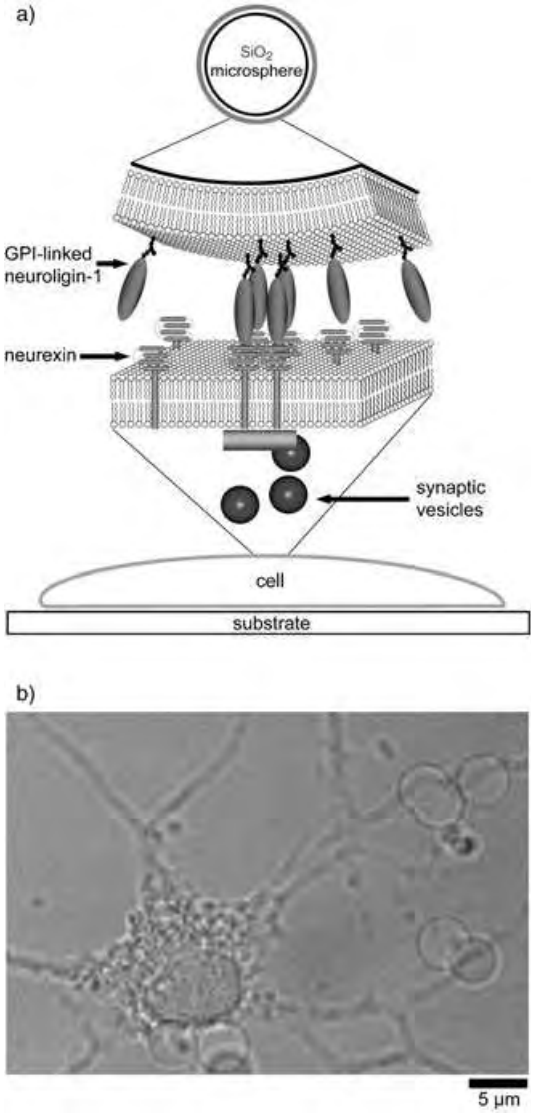

Figure 6. a) Schematic representation of a membrane-coated bead displaying a GPI-linked form of neuroligin-1. Neuroligin-1 binds its cognate receptor β-neurexin on the neuronal cell surface and triggers early stages of synaptogenesis. b) Bright field phase contrast image illustrating interactions between membrane-coated beads and primary neurons. (The image was supplied by M. Baksh and S. Pautot.)

planar junctions, with typical sizes of 10–50 μm, which exhibit multiple adhesion states and are well suited to optical and scanning probe imaging techniques.[112–115] This type of supported membrane junction has proven useful in the study of membrane-mediated reorganization of proteins into patterned states,[23] and is discussed further in Section 4.2 in the context of membrane topographical imaging.

Membrane–membrane interactions can also be characterized by examining the colloidal behavior of a population of membrane-coated beads.[116,117] The behavior of a colloidal system is driven by the potential for the interaction between pairs of particles. In the case of membrane-derivatized silica beads, this potential is dominated by membrane–membrane interactions. Hence, the phase behavior of the entire system is responsive to details of the interaction between the membranes. For example, the binding of a protein to a membrane-associated ligand at densities as low as 10^{-4} monolayer has been observed to trigger a phase transition. A typical colloidal phase transition triggered by protein binding to ligands on the membrane surface is depicted in Figure 7. The assay is

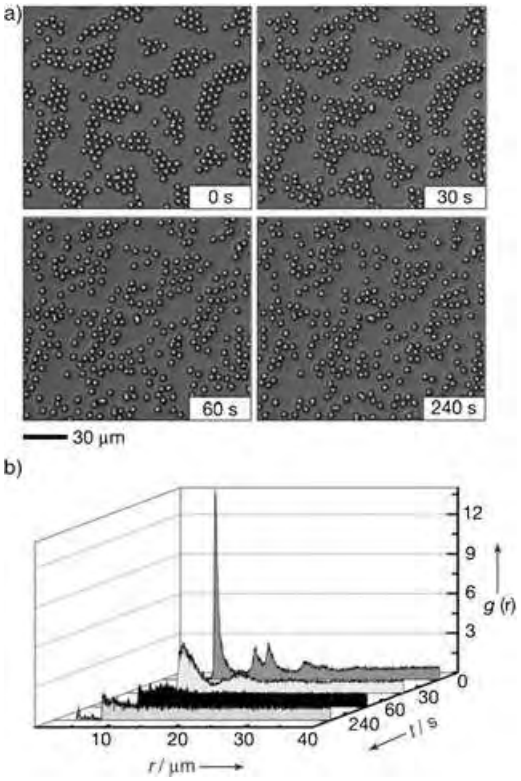

Figure 7. Colloidal phase transition of membrane-coated beads triggered by protein binding. a) Time sequence of images depicting the transition from a condensed to a dispersed colloidal phase, triggered by the addition of protein (5 $\mu g\,ml^{-1}$ final concentration IgG antibody specific to a membrane surface ligand). Transitions were triggered only when the appropriate ligand was also incorporated into the membrane. b) Corresponding plots of $g(r)$ for the time sequence in (a). Adapted from ref. [116].

performed by dispersing membrane-derivatized beads underwater, where they settle under gravity onto the underlying substrate and form a two-dimensional colloid. The beads exhibit free lateral diffusion and the system behaves as an ergodic fluid. For highly sensitive assays, the membrane composition is tuned so that the colloid weakly condenses (first picture in Figure 7a). The condensed distribution is dynamic, with individual beads continuously "evaporating" and recondensing into clusters. However, the overall structure is invariant. Quantitative analysis of the colloidal phases is performed by extracting the pair distribution function $g(r)$.

More than one type of membrane-coated bead can be mixed using fluorescent labels to enable them to be distinguished. In such a binary colloid format, interactions between membrane-associated proteins can be characterized by analysis of the colloid distribution. The distribution function for heterogeneous pairs, which counts the relative positions of beads of different type, can provide a measure of the

interaction strength between the different membrane compositions. This relatively high-throughput strategy of characterizing intermembrane protein-binding affinities could be of utility for the acquisition of large quantities of protein-binding data relevant to intercellular adhesion and signaling events.

4. Imaging Techniques

4.1. Dynamic Fluorescence Microscopy

Fluorescence microscopy is an extremely useful technique for resolving both static and dynamic aspects of molecular organization in membranes. Direct imaging of the fluorescence from probe molecules linked to membrane components of interest immediately offers lateral resolution of compositional variations to the diffraction limit. Quantitative analysis of fluorescence intensity changes within a three-dimensional volume has been used to monitor the flux of green fluorescent protein (GFP) labelled TCR into the c-SMAC during formation of the immunological synapse.[65] A similar type of strategy has been used in an elegant series of experiments to count, molecule by molecule, the amount of agonist pMHC in a T-cell synapse.[118] This information was then correlated with intracellular signaling activity to demonstrate that a single agonist pMHC ligand can trigger transient TCR signaling. Even more interestingly, blocking the co-stimulatory molecule CD4 substantially reduced the sensitivity of TCR signaling, thus suggesting a role for this molecule in signal amplification. These experiments demonstrate the enormous molecular detail with which aspects of signal transduction at immunological synapses can now be observed. Signaling was monitored by a conventional strategy using a calcium-sensitive fluorescent probe (fura-2AM), which was loaded into the T cell. Individual pMHC agonists were labeled with the phycobiliprotein phycoerythrin. Phycoerythrin is an approximately 240-kDa protein with about 34 fluorophores, which make it an extremely bright single molecule that can be tracked by confocal microscopy.

Single-molecule tracking is now being applied by a number of research groups to image molecular motions during formation of the synapse by using total internal reflection fluorescence (TIRF) microscopy. In the objective lens version of TIRF microscopy, a laser is focused off-center onto the back focal plane of an extremely high numerical aperture objective (e.g., NA = 1.45). The beam is then collimated by the objective lens and emerges at a glancing angle. As the beam meets the sample, it is totally internally reflected off of the coverslip/aqueous interface. Only an evanescent field penetrates the sample to excite fluorophores within a thin layer of 50–100 nm from the coverslip interface. This is an ideal configuration for imaging molecules in synapses formed with supported membranes. The extremely low fluorescence background provided by TIRF allows facile observation of single fluorophore probes, and is expected to greatly extend the applicability of single-molecule observations within hybrid synapses. An example of the set-up and representative diffusion tracks from single molecules in a supported membrane are illustrated in Figure 8a and 8b.

Another useful probe of molecular mobility is fluorescence correlation spectroscopy (FCS). Originally developed in the 1970s,[119] FCS has lately undergone a renaissance with the advent of fast hardware correlators, sensitive avalanche photodiodes (APDs), and extremely high NA objectives.[120–125] In applying FCS to membrane systems, a laser is typically focused to a diffraction-limited waist (< 0.5 μm) by a high aperture objective. The diffusion of fluorophores into and out of the excitation volume produces intensity fluctuations that are temporally correlated (Figure 8c and 8d). Analysis of the correlation data yields information about the diffusion of fluorophores within the excitation volume. Cross-correlations between signals from different color fluorophores can reveal specific molecular interactions. This type of observation can be particularly useful in resolving the specific sequences of molecular interactions occurring in the immunological synapses. Again, the simplified configuration provided by hybrid synapses formed from live cells and supported membranes is likely to be of high utility.

4.2. Topographical Imaging

The importance of geometrical constraints within the immunological synapse underscores the need for imaging methods capable of resolving nanometer-scale topography at intermembrane junctions. Two recent fluorescence imaging techniques enable real-time topographical imaging of intermembrane junctions with sub-nanometer precision. Intermembrane fluorescence resonance energy transfer (FRET) is exquisitely sensitive for membrane spacings up to 10 nm. Optical interferometry is most useful beyond this range. Reflection interference contrast microscopy (RICM) has been the dominant method of imaging topographical features of membranes near surfaces for over a decade[105–108,126–129] (for a recent review see ref. [109]). More recently, fluorescence interference contrast microscopy (FLIC) has emerged as a powerful alternative to RICM.[112,114,130,131] Applications of intermembrane FRET and FLIC imaging to resolve membrane topography are described below. A detailed review of the optics and implementation of these techniques is presented elsewhere.[132]

FRET occurs between membranes which have been doped with complementary fluorescent probes when the intermembrane spacing is comparable to the Förster distance for the probe pair (ca. 5 nm). Quantitative analysis of FRET efficiency provides measurement of intermembrane spacing with sub-nanometer precision.[112,113] A general schematic representation for interpretation of intermembrane FRET is depicted in Figure 9. The rate k_T of nonradiative energy transfer from a donor to a population of acceptors, which are distributed in an offset plane, is given by Equation (1).

$$k_T = \frac{\sigma\pi R_0^6}{2\tau_D z^4} \quad (1)$$

σ is the concentration of acceptor molecules, R_0 is the Förster distance (5 nm for the Texas Red/NBD pair[133]), τ_D is

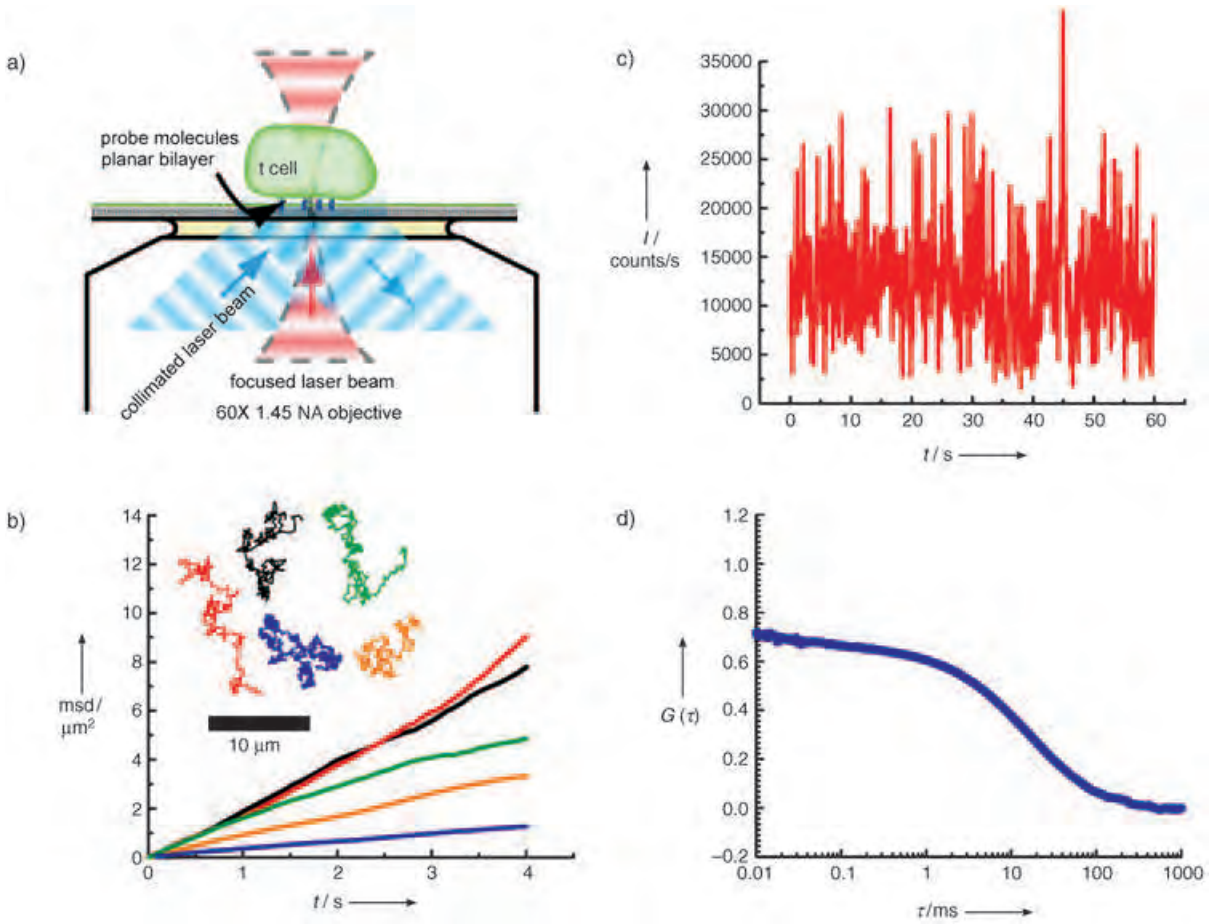

Figure 8. a) A combined system for TIRF and FCS microscopy. The collimated TIRF excitation (blue) emerges from the objective at a glancing angle and experiences total internal reflection at the coverslip/sample interface where it produces an evanescent field at the surface. The FCS excitation (red) is tightly focused on the sample interface. b) Characteristic diffusion tracks of a single molecule observed by TIRF microscopy, together with plots of the mean-square displacements (msd) of fluorescently labeled proteins bound to a supported membrane. c) Temporal fluorescence intensity fluctuations observed with focused excitation (FCS mode) reveal movements of fluorescently labeled antibodies bound to a supported membrane. Fluctuations are produced as the molecules diffuse into and out of the excitation spot. d) Autocorrelation of the intensity fluctuations can be used to quantify molecular motion. (The image was supplied by M. Forstner and A. Demond.)

the fluorescence lifetime of the donor in the absence of acceptors, and z is the distance between the donor and the plane of acceptors. Two leaflets of the bilayer membrane result in two planes of acceptors, separated from each other by about 4 nm. The NBD chromophore on the commonly used, tail-labeled NBDPC (1-palmitoyl-2-[12-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino]dodecanoyl]-*sn*-glycerol-3-phosphocholine) preferentially localizes in the glycerol/upper chain region of the membrane;[134] it can be taken to occupy a single plane for analysis. The total FRET efficiency E is obtained by summing up the different transfer pathways, denoted in Equation (2) with primes. Analysis of FRET efficiency using Equations (1) and (2) directly provides the distance between the planes of the probe molecules.

$$E = \frac{k'_T + k''_T}{k'_T + k''_T + 1/\tau_D} \qquad (2)$$

Quantitative measurements of FRET efficiency are fit to calculations, based on Equation (2), to determine the average intermembrane fluorophore spacing z. Calculated FRET efficiency curves are plotted against the measured efficiencies in Figure 9. These results indicate the average spacings to be 3.5, 4.6, and 6.7 nm for the PI, G_{M1}, and G_{M1}-cholera toxin junctions, respectively (PI = phosphatidylinositol, G_{M1} = Galβ1-3GalNAcβ1-4(NeuAcα2-3)Galβ1-4Glcβ1-1′-ceramide). An estimate of $R_0 = 5$ nm for the Texas Red/NBD pair is used[133] and an interleaflet probe separation distance of 4 nm was estimated for the Texas Red/DPPE bilayer. No adjustments were made for the two planes of the donor since there is evidence suggesting that negatively charged probes can be substantially enriched in the upper leaflet of supported membranes formed by fusion of small unilamellar vesicles.[135] The absolute values of these distance determinations are sensitive to the estimates of R_0 and, to a lesser extent, to interleaflet spacing. However, the relative distances obtained are accurate. For example, X-ray diffraction analysis of osmotically stressed multibilayers indicate that G_{M1} extends 1.2 nm above the surface of the phosphatidylcholine membrane;[136] we determine a difference of 1.1 nm in membrane

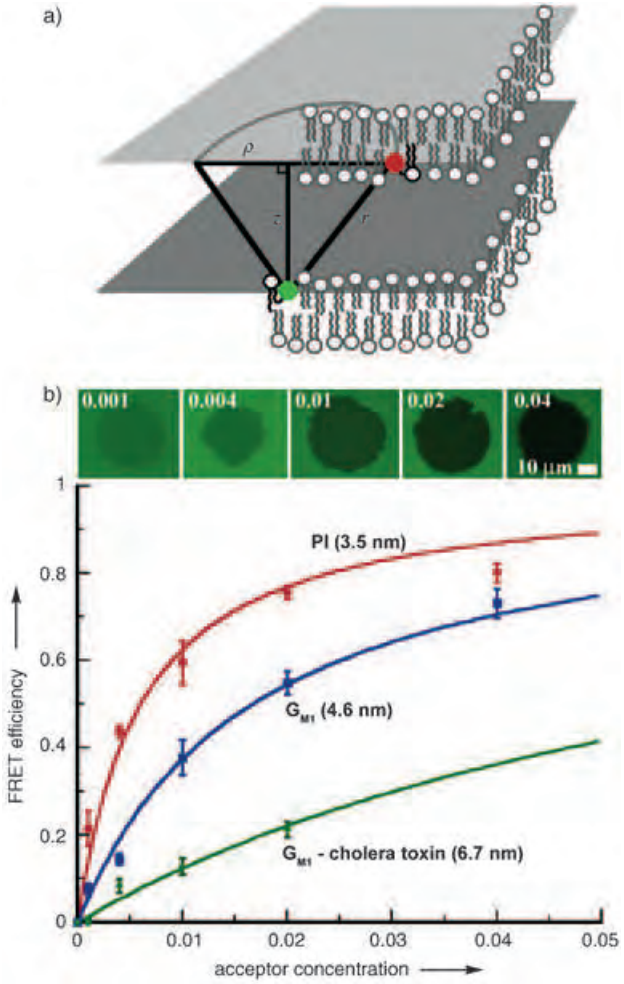

Figure 9. a) Schematic representation illustrating intermembrane FRET. A single probe molecule in one membrane can, in general, transfer resonance energy with one of multiple probes in the apposed membrane. This leads to a fourth power dependence of FRET efficiency on *z*, in contrast to the canonical sixth power dependence generally encountered for one-to-one molecular FRET between a donor and acceptor. b) FRET efficiency data for PI, G_{M1}, and G_{M1}-cholera toxin membrane junctions. The sequence of images depicts FRET data from PI junctions for each of the acceptor (Texas Red/DPPE, mole fraction σ; DPPE = *N*-(Texas Red sulfonyl)-1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine) concentration shown. Solid curves represent calculations based on Equation (2) with intermembrane separation distances (*z*) as labeled. Adapted from ref. [113].

spacing induced by G_{M1}, relative to the PI/DMPC membrane junctions (DMPC = dimyristoylphosphatidylcholine). The height of 3.2 nm determined from intermembrane FRET for the G_{M1}-cholera toxin complex is in direct agreement with structural information from X-ray crystallography data.[137] Although the highest resolution measurement of intermembrane spacing is achieved by quantifying FRET efficiency at a variety of acceptor concentrations, intermembrane FRET can be used in imaging mode with a single acceptor concentration. FRET is an intrinsically short range (10 nm) phenomenon, which cannot be used to resolve larger scale topographical features.

Measurements of intermembrane spacings beyond the range of FRET can be achieved using FLIC microscopy.[112,114,130,131] This technique exploits the spatial variation of the intensity within an optical standing wave to modulate the fluorescence intensity of probes as a function of their position along the optical axis, which is perpendicular to the interface in this configuration. A schematic representation of

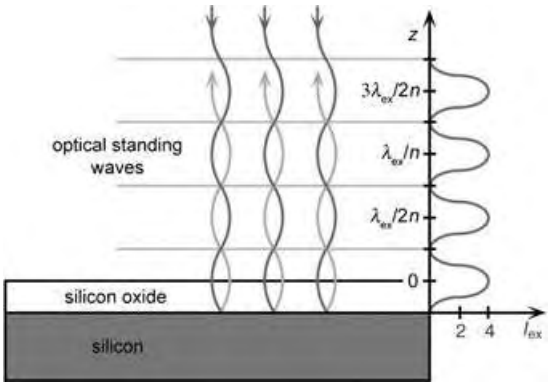

Figure 10. Schematic representation of a FLIC set-up using an oxidized silicon wafer as the substrate. Reflection off of the silicon/silicon oxide interface produces counter-propagating waves of the excitation light, which set up a standing wave of spatially varying optical intensity. The pattern of the excitation intensity exhibits a $\lambda/2$ spatial periodicity, and is plotted along the right vertical axis. Emitted fluorescence also experiences a photon self-interference effect (not shown) which is superimposed on the excitation pattern.

the set up on an oxidized silicon wafer is depicted in Figure 10. The primary optical reflection occurs at the interface between the silicon and silicon oxide. The oxide layer provides a controllable spacer, which allows the relevant features of the system to be positioned optimally with respect to the standing wave. A 60-nm thick oxide layer is useful for proteins at supported membrane interfaces. FLIC microscopy achieves nanometer resolution and can resolve topographical structures extending hundreds of nanometers from the primary plane. FLIC intensity images can be easily deconvolved into three-dimensional topography data using the simplified relation for fluorescence intensity I_F [Eq. (3)].

$$I_F \propto \left((1-r_f)^2 + 4\,r_f \sin^2\left(\frac{\phi_{ex}}{2}\right)\right)\left((1-r_f)^2 + 4\,r_f \sin^2\left(\frac{\phi_{em}}{2}\right)\right) \qquad (3)$$

This Equation is derived from basic optical principles.[138] ϕ_{ex} and ϕ_{em} are given by $(4\pi/\lambda_{ex})(n_w z + n_o z_o)$ and $(4\pi/\lambda_{em})(n_w z + n_o z_o)$, respectively. Indices of refraction for water (1.33) and silicon oxide (1.46) are represented by n_w and n_0, z is the height above the oxide surface, and z_o is the oxide thickness. The excitation and emission wavelengths λ_{ex} and λ_{em} are 560 and 645 nm when the Texas Red fluorophore is used. The reflection coefficient of the silicon/silicon oxide interface (0.46 at 645 nm) is represented by r_f. This approximation has a maximum error of about 2 nm over the distance range of typical experiments involving supported membrane junctions (5–75 nm); more involved calculations include the angular spread of incident and collected light as well as spectral bandwidth.[115,130–132]

Examples of the use of FLIC microscopy to resolve membrane topography at supported membrane junctions are illustrated in Figures 11 and 12. A notable feature of the upper membrane in a supported membrane junction is the existence of two distinctly different states of adhesion to the lower bilayer membrane. The first, referred to as type 1, is characterized by uniform intermembrane FRET, which indicates intermembrane distances of a few nanometers. In the second state (type 2), large intermembrane spacings (ca. 50 nm) are maintained by a balance between Helfrich (entropic) repulsion[139] and occasional adhesion sites that pin the two membranes together. No intermembrane FRET is visible in type 2 junctions; however, FLIC reveals large-scale thermal undulations. Schematic representations, FLIC images, and reconstructed surface topography maps for examples of the two junction types are illustrated in Figure 11. FLIC is easily performed in real time, thus allowing dynamic observations of membrane topographical fluctuations. The type 2 junction illustrated in Figure 11 exhibits fluctuations with amplitudes of approximately 4 nm root-mean-square, a lateral spatial correlation length of about 340 nm, and a correlation time of about 1 s. All values were determined by FLIC imaging.[114]

The combination of FLIC with conventional fluorescence imaging (and FRET) can be used to acquire highly detailed three-dimensional information about the organization of proteins and lipids at intermembrane junctions. Observations of an intermembrane junction, in which membrane-bound antibody proteins in the junction become organized into patterns as a result of adhesive interactions between the two membranes, are illustrated in Figure 12. A FLIC image of

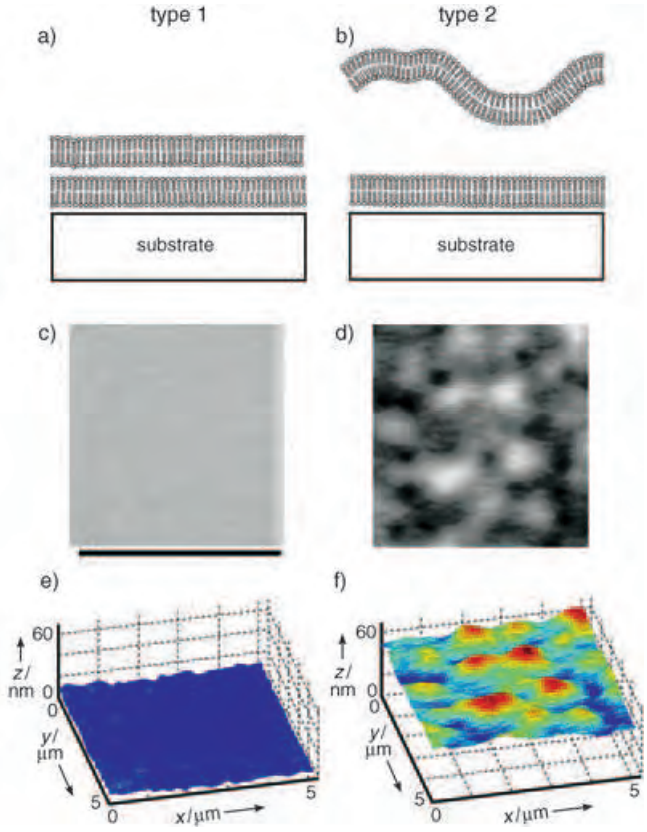

Figure 11. Type 1 (a) and type 2 (b) junctions. The corresponding FLIC images and topographical maps [computed from Eq. (3)]) are plotted in (c)–(f). The topography of type 2 junctions is dynamic, and fluctuates randomly with a characteristic temporal correlation time of about 1 s. (The image was supplied by Y. Kaizuka.)

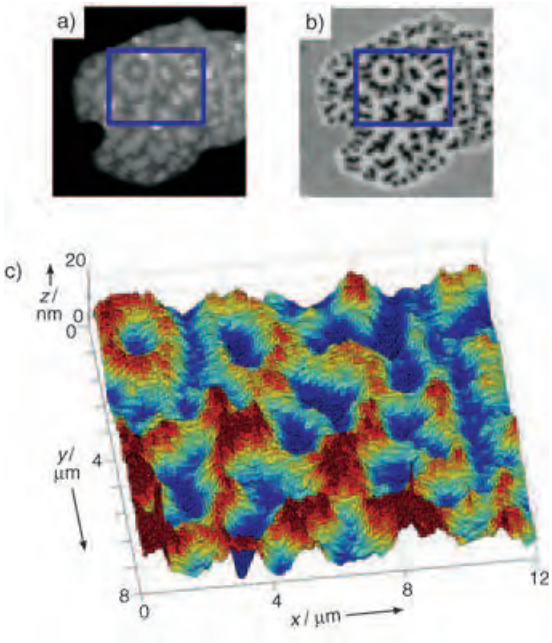

Figure 12. A supported intermembrane junction in which antibodies are bound to the lower membrane. A FLIC image of the upper membrane (a) reveals topographical features that reflect the distribution of fluorescently labeled antibodies (b) in the junction. c) Topographical map of the marked inset region of the junction. The topography of this protein intermembrane junction is static. (The image was supplied by R. Parthasarathy.)

probes in the upper membrane is depicted in Figure 12a, while direct fluorescence imaging of the antibodies is shown in Figure 12b. A topography map, computed from the FLIC data in Figure 12a, is plotted in Figure 12C. The membrane-bound antibodies diffuse freely on the membrane surface outside of the junction. The antibody is corralled into patterns in the junction, and loses much of its lateral mobility. Antibody mobility can be characterized by fluorescence recovery after photobleaching (FRAP), single-molecule tracking, or FCS. The topography map indicates that the hills and valleys of this junction have a height difference of about 12 nm, which is about the size of an antibody. The conformation of the membrane thus follows the topography of the interface, and therefore, this can be categorized as a type 1 junction. The topography of the protein intermembrane junction shown in Figure 12 is static in time, in contrast to the type 2 junction illustrated in Figure 11. FLIC imaging is instrumental in making these types of distinctions. Intermembrane FRET has been used to additionally confirm that valleys observed in the upper membrane of the protein intermembrane junction descend to within a few nanometers of the lower membrane.[115] The combined use of intermem-

brane FRET can increase the absolute resolution of FLIC by helping to break some of the degeneracy inherent to interference imaging techniques.

5. Conclusion and Outlook

The surfaces of cell membranes present a highly dynamic and responsive environment in which convergence of chemical and mechanical forces produces a rich collection of reaction processes. The natural fluidity and flexibility of membranes provides mechanisms for them to respond to chemical interactions in ways not generally seen with inorganic materials. Highly cooperative reaction processes, which combine chemical binding events with spatial pattern formation, are emerging as general themes among cell–cell interactions. The immunological synapses, discussed briefly here, represent the best resolved examples of such phenomena at the present time. As such, interactions between immune cells are attractive for highly quantitative investigations aimed at developing a physicochemical understanding of the underlying mechanisms that drive and regulate these events. Such studies of immunological synapses may further reveal mechanistic paradigms common to many intercellular signaling processes. Indeed, the physical characteristics of immune cell junctions are likely to be shared by intermembrane junctions in general. The parallel application of new imaging and manipulation techniques to reconstituted membrane systems and hybrid synapses represents a promising convergence of physical chemistry and cell biology. The blending of ideas and observations one can expect from this situation may well help to expose some of the secrets as to how molecules come to life.

I would like to thank the many students, postdoctoral fellows, and colleagues who have contributed to these projects. Financial support has been provided by the National Institutes of Health (NIH), the Department of Energy (DOE), the National Science Foundation (NSF), the Burroughs Wellcome Fund, The Searle Scholars Program, the Beckman Foundation, and the Hellman Family Faculty Fund. The watercolor art in this Review was created by Dr. Raghuveer Parthasarathy.

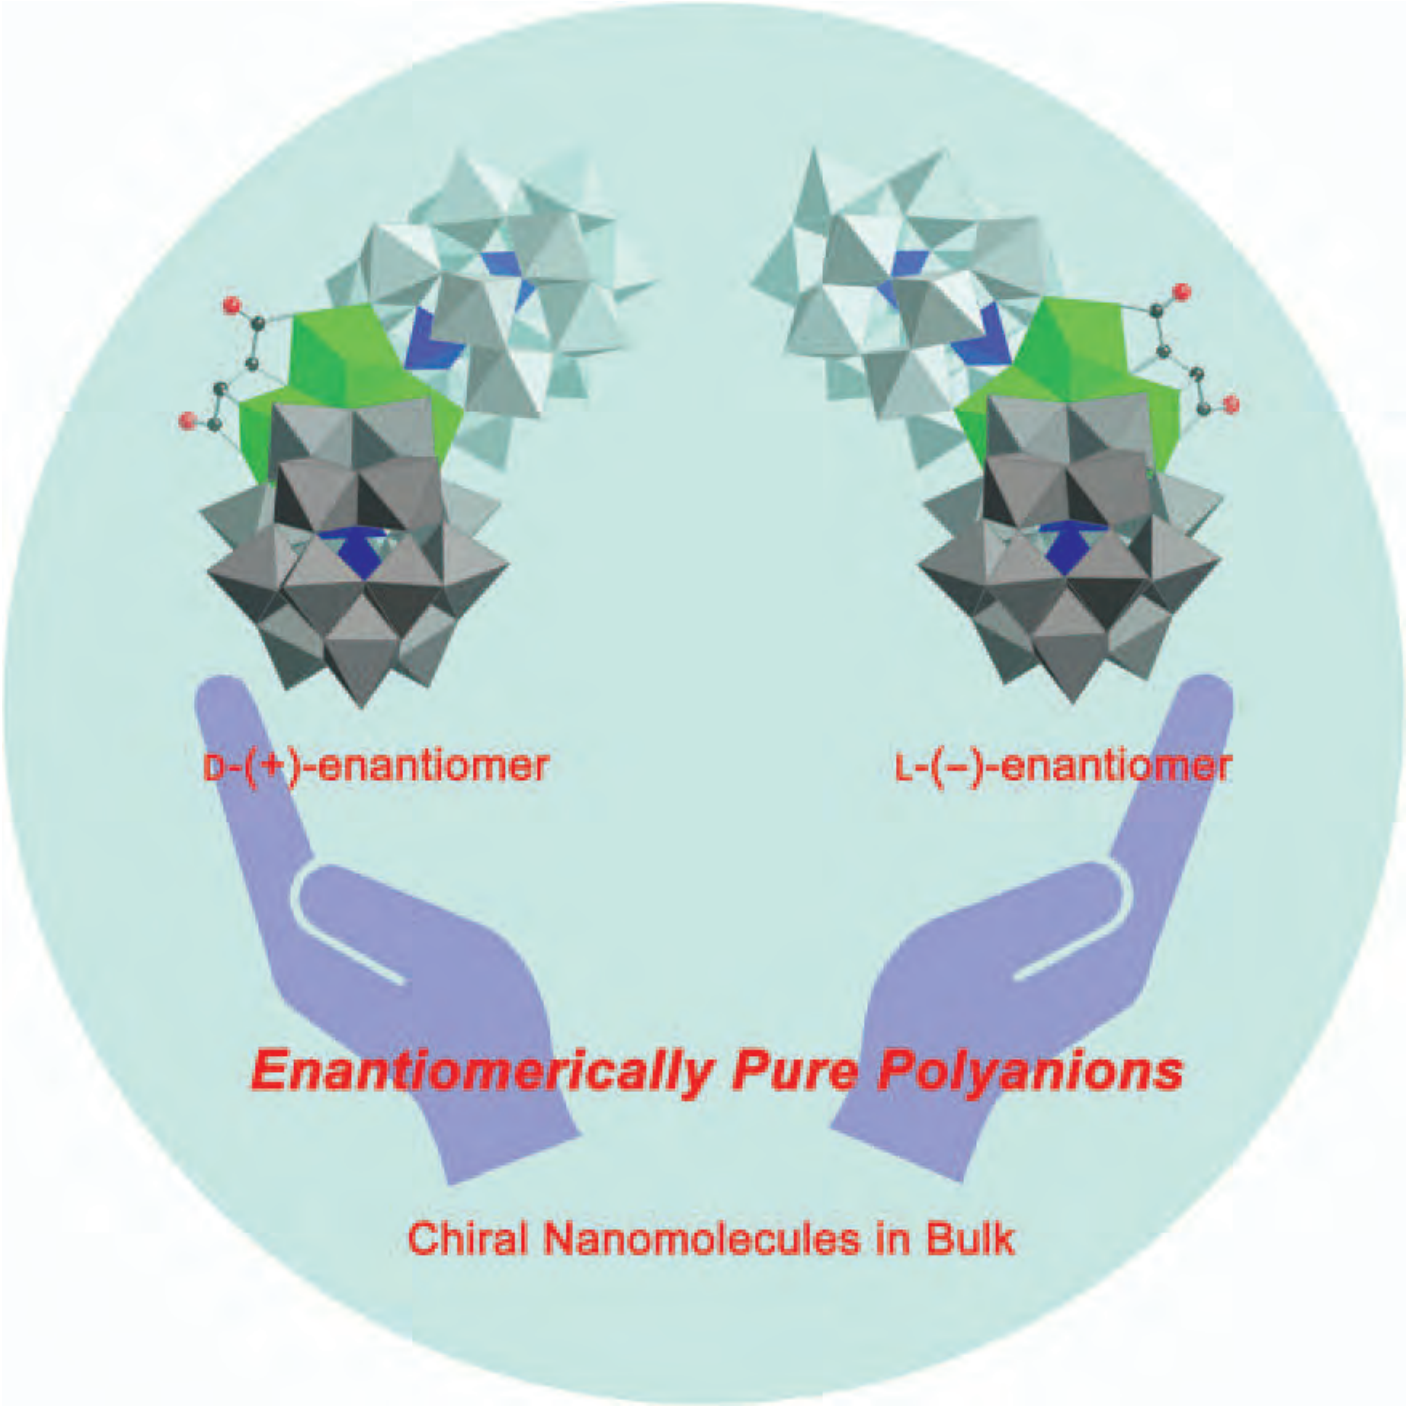
Communications



The amplification and transfer of chirality from a small organic natural product, tartrate, to a large multinanometer polytungstate is demonstrated. This strategy affords nonlabile, readily separable, and pure enantiomers of the polytungstates. For more information of this promising approach see the Communication by C. L. Hill and co-workers on the following pages.

Chirality Transfer

Enantiomerically Pure Polytungstates: Chirality Transfer through Zirconium Coordination Centers to Nanosized Inorganic Clusters**

*Xikui Fang, Travis M. Anderson, and Craig L. Hill**

Stable, nanometer-sized enantiomerically pure polyoxoanions could lead to useful chiral materials ranging from microporous solids and inorganic pharmaceuticals to catalysts for homogeneous asymmetric oxidation. However, chirality has been largely unexplored in polyoxometalate (POM) systems.[1] Most POMs with chiral structures undergo rapid racemization in solution, and racemic mixtures are usually seen in solution as well as in the solid state. Typically in crystals the two enantiomers coexist in the same unit cell, related to each other by a crystallographically imposed inversion center.[2] Although Pfeiffer effects have been demonstrated with a wide range of racemic POM systems, the chiral resolution of the enantiomers is frequently complicated by their solubility, lability, and structural similarity.[3,4] Three different synthetic routes to enantiopure POMs in the solid state have been reported. First, hydrothermal synthesis can produce solid inorganic materials with helical characters.[5] One example is the vanadium phosphate complex, $[(CH_3)_2NH_2]K_4[V_{10}O_{10}(H_2O)_2(OH)_4(PO_4)_7]\cdot 4H_2O$, with a chiral interpenetrating double helix of Zubieta and coworkers.[5a] Second, reactions of a few polymolybdates and chiral amino acids afford chiral POMs.[6] A recent study by Kortz et al. demonstrated that the bound amino acids are probably labile in solution, based on NMR spectroscopy and X-ray studies (weak bonding, approximately 2.3 Å, between the Mo and carboxylate O atoms).[6b] Therefore it is not surprising that the chirality of these complexes is largely localized on the amino acid moieties. Third, counterions can play a critical role in determining the solid-state structures of POMs, and, in some cases, cause achiral POMs to crystallize in chiral space groups.[7] Sometimes crystallization of racemic bulk solids can lead to chiral crystals.[8] However, there is no report of chiroptical activity in the solution-state for such enantiopure POM systems. Realization of an intrinsically chiral and configurationally stable POM should afford enantioselective catalytic properties and enhanced biological activities.[9] Furthermore, the control of chiral induction is an important component of the larger goal of effectively managing and utilizing chirogenic phenomena.

Herein we report the synthesis and characterization of chiral, nonracemizing, enantiomerically pure polyoxotungstates, L-**1** and D-**1** prepared in bulk. Significantly, strong

$\{[\alpha\text{-}P_2W_{15}O_{55}(H_2O)]Zr_3(\mu_3\text{-}O)(H_2O)(\text{L-tartH})[\alpha\text{-}P_2W_{16}O_{59}]\}^{15-}$ L-**1**

$\{[\alpha\text{-}P_2W_{15}O_{55}(H_2O)]Zr_3(\mu_3\text{-}O)(H_2O)(\text{D-tartH})[\alpha\text{-}P_2W_{16}O_{59}]\}^{15-}$ D-**1**

chiroptical effects are manifested by the POM units as a result of chirality transfer from a far smaller enantiopure organic molecule, L- or D-tartaric acid ($HO_2CCH(OH)CH(OH)CO_2H$; L-tartH$_4$ or D-tartH$_4$). Both enantiomeric complexes have been characterized by elemental analysis, ^{31}P NMR, IR, and UV/Vis spectroscopy, in addition to the single-crystal X-ray structure analysis on the L enantiomer, and their solution chiroptical properties have been demonstrated by circular dichroism (CD) spectroscopy.

The synthetic approach involves recognition between an achiral host and chiral (nonracemic) guest molecule to produce a chiral microenvironment on the achiral host, a phenomenon revealed by induced circular dichroism (ICD).[10] This straightforward strategy, outlined in Figure 1,

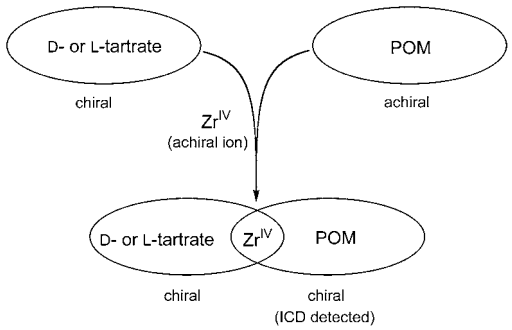

Figure 1. The interaction between D- or L-tartrate and the achiral POM unit through the coordinated Zr^{IV} ions.

relies on the "recognition" between α-$[P_2W_{15}O_{56}]^{12-}$ (**2**), an achiral lacunary Wells–Dawson POM unit of C_{3v} symmetry, and the simple C_2-symmetric D- or L-tartrate ligand.[11] Given the electrostatic repulsion between **2** and tartrate, a positively charged mediator is needed for chirality transfer. The Zr^{IV} ion, is well suited for this task because it has both high charge density and coordination flexibility.[12,13] In the systems reported herein, the Zr^{IV} ions transmit chirality from the chiral tartrate to the polytungstate units by binding strongly to both.

This approach facilitates the crystallization of L-**1** in the chiral orthorhombic space group $P2_12_12_1$, with only one enantiomer present in the unit cell ($Z = 4$). Crystallization in a chiral space group is a rare but ideal starting point for the generation of chiral materials. The structure of L-**1** consists of two units of **2** bridged by a central fragment containing three Zr^{IV} centers and one W^{VI} center (Figure 2a). All three zirconium atoms are nonequivalent and form a triangular unit sharing a coplanar μ_3-oxo oxygen atom. One of the zirconium atoms, Zr3, serves as a "hinge" between the two α-$[P_2W_{15}O_{56}]^{12-}$ units, while the other two zirconium ions (Zr1

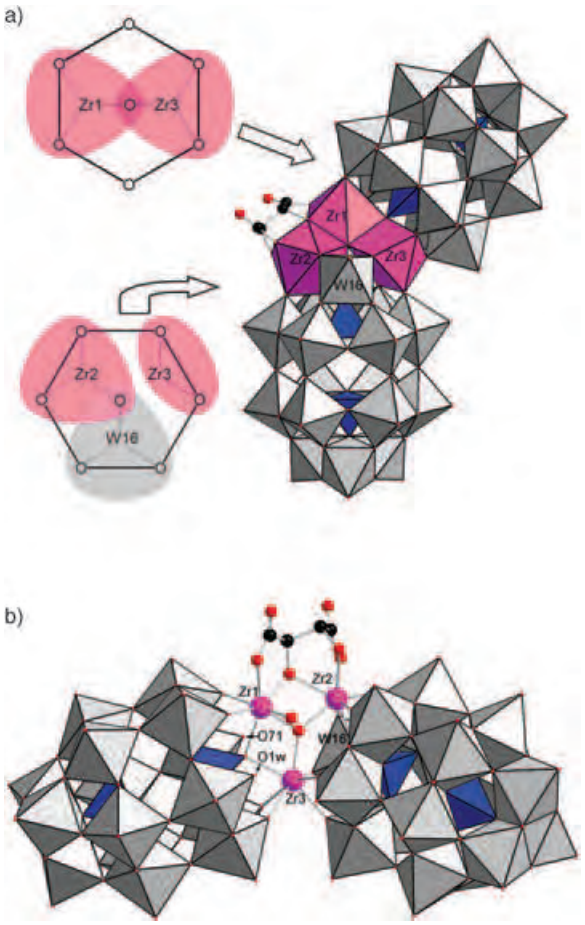

Figure 2. The structure of L-**1**. a) A combination ball-and-stick/polyhedral representation of L-**1** with the metal–oxide framework in polyhedral notation and the L-tart ligand in ball-and-stick notation; gray W, blue P, purple Zr, black C, red O. The hexagons illustrate the coordination between substituted Zr or W sites with the seven terminal oxygen atoms in the vacant positions of the polytungstate moieties. b) A side view of L-**1** showing the three Zr centers as well as the L-tart ligand in ball-and-stick representation.

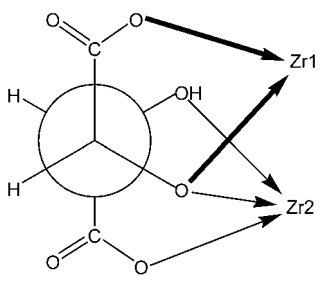
and Zr2) are bridged by the L-tart unit, by chelation through both the hydroxy and carboxy groups in an unusual η^2:μ_1:μ_2:μ_1:μ_1 fashion (Scheme 1).[14] Bond valence sum calculations reveal that one of two "hydroxy" oxygen atoms on L-tart remains protonated while the other, which bridges the two Zr centers, does not. The asymmetric protonation reduces the local symmetry of the L-tart unit from C_2 to C_1. This mixed protonation state is very rarely observed in metal tartrate



Scheme 1. The coordination environment of the L-tart ligand in L-**1**.

complexes,[14a] and is likely a key factor in providing the strong complexation between L-tart and the large metal–oxide framework. This complexation in turn dictates the configurational stability of L-**1**. In other words, the protonation state of the L-tart hydroxy groups adjusts in response to rearrangements in the coordination sphere of the zirconium ions caused by the ligation of **2**. Simultaneously the chelating L-tart maintains the enhanced complexation ability provided by the vicinal hydroxy oxygen atoms.

Two of the three vacant positions in the bottom α-$[P_2W_{15}O_{56}]^{12-}$ (**2**) unit shown in Figure 2a are occupied by zirconium ions, Zr2 and Zr3, and each bridges a pair of adjacent corner-sharing W octahedra in **2**. A tungsten atom (W16) is located in the third position, presumably from the decomposition of **2** in the acidic solution. In contrast, the top unit of **2** remains coordinatively unsaturated, which provides an energetically favorable coordination geometry about the zirconium ions (see the hexagonal schematics in Figure 2a). The top unit is rotated with respect to the bottom unit about the central rotation axis running through the two P atoms by about 60° such that only two vacant positions are occupied in a diagonal fashion by two zirconium ions, Zr1 and Zr3. This leaves two of the seven "ligating" oxygen atoms of **2** uncoordinated. Thus the entire framework of L-**1** exhibits no local symmetry in either the organic or inorganic moieties. The asymmetry of the L-tart ligand is extended to the POM structure by the zirconium ions, making L-**1** a topologically chiral species. It is also of note that the two uncoordinated terminal oxygen atoms in the top **2** unit mentioned above are also different from one another in L-**1** (Figure 2b). One of them is replaced by an aqua ligand O1w (W–OH_2 ca. 2.25 Å) while the other atom (O71) remains unprotonated (W=O ca. 1.76 Å).

The ^{31}P NMR (162 MHz, D_2O) spectrum of L-**1** shows four signals ($\delta = -6.29$, -6.62, -12.88, and -13.83 ppm) and the spectrum remains unchanged for several weeks, indicating that the C_1 symmetry exhibited by the solid-state structure (Figure 2) exists and persists in solution. These spectral data also preclude the presence of any diastereomers. The chirality of L-**1** is also demonstrated unambiguously by its solution-state optical properties. This optically active complex shows a negative optical rotation in contrast to the free L-(+)-tartaric acid precursor. As seen in Figure 3, the profile of the CD spectrum of L-(−)-**1** is totally different from that of its precursor, L-tartaric acid (Figure 3, inset), which only shows a single negative Cotton effect at 214 nm. In the long-wavelength spectral region where L-(−)-**1** is CD-active (above 240 nm; vertical dashed line in the inset), L-tartaric acid is almost CD silent. In contrast, L-(−)-**1** exhibits strong Cotton effects up to 350 nm, the spectral region where the characteristic oxygen-to-tungsten charge-transfer bands of both plenary and the lacunary Wells–Dawson polyanions occur.[15] These results clearly show the ICD in the metal–oxide cluster moiety. Recently, a systematic study of intrinsic circular dichroism in L-tartaric acid and its salts established that the magnitude ($\Delta\varepsilon$) of their CD spectra never exceeds 5 $dm^3 mol^{-1} cm^{-1}$ in the absorption region below 220 nm.[16] In contrast, the observed high ICD intensity for L-(−)-**1** suggests a moderately strong induced chirality. Thus the

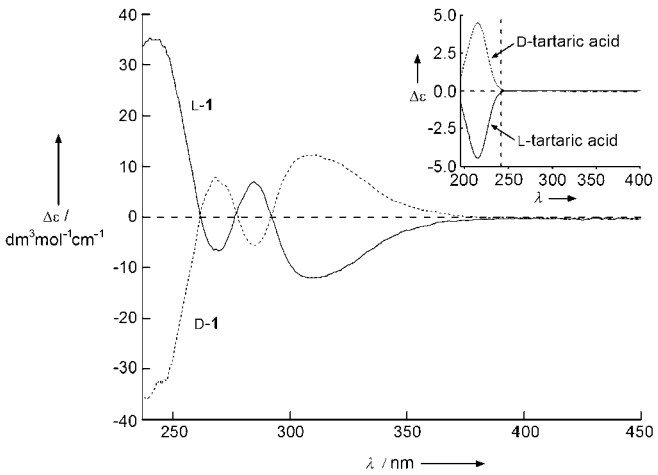


Figure 3. CD spectra of both the L-(−)- and D-(+)-enantiomers of **1** and their precursors, L-(+)- and D-(−)-tartaric acids (inset, the same scale units apply) as aqueous solutions. See text for details.

asymmetric arrangement of the zirconium ions in the substituted positions and the lowering of symmetry on the POM ligands facilitate transfer of chirality from L-tart to the POM, and the induced optical activity in **1** is quite pronounced. There is no detectable change in optical activity of L-(−)-**1** with time, again indicating no racemization of the enantiomeric complex in solution.

Significantly, the other enantiomer of the complex, D-**1**, can be prepared from the unnatural D-tartaric acid under synthetic conditions otherwise identical to those used in the preparation of L-**1**, and it exhibits the same physical and spectroscopic properties as L-**1** except for the chiroptical behavior. Although we were not able to obtain diffraction-quality crystals of D-**1**, the mirror-symmetrical CD spectra for L-(−)-**1** and D-(+)-**1** (Figure 3) confirm they are enantiomers of one another.

In conclusion, we have prepared and purified both enantiomers of a polytungstate. Chirality from a small organic ligand, tartrate, can be transferred to a much larger (ca. 2 × 1 × 1 nm) metal–oxide cluster through high-coordinate zirconium centers. The metal-substituted POM units in the two enantiomers show significant induced circular dichroism. The complexes are stable with respect to racemization, other rearrangements, and decomposition, a key point for applications in catalysis, material science, and applied biology.

Experimental Section

Preparation of $[(CH_3)_2NH_2]_{15}$(L-**1**)·25 H_2O: $ZrO(NO_3)_2$·6 H_2O (0.24 g, 0.7 mmol) was dissolved in H_2O (15 mL). L-Tartaric acid (0.105 g, 0.7 mmol) was then added to the stirred solution, resulting in a slurry. Solid $Na_{12}[\alpha\text{-}P_2W_{15}O_{56}]\cdot 18H_2O$[17] (1.00 g, 0.23 mmol) was added to the mixture in one portion with vigorous stirring. After 30 min at room temperature, a clear solution resulted to which dimethylamine hydrochloride (0.4 g, 5 mmol) was added. The solution was then heated to 70 °C for 15 min. Slow evaporation of the solution produced needle-like crystals after 24 h (yield 0.51 g, 49.5 %). Elemental analysis: calcd Zr 2.96, P 1.34, W 61.55; found Zr 3.08, P 1.40, W 63.38. $[(CH_3)_2NH_2]_{15}$(D-**1**)·29 H_2O was prepared in the same way except that D-tartaric acid was used instead of L-tartaric acid (yield 0.48 g, 46.4 %). Elemental analysis: calcd Zr 2.93, P 1.33, W 61.07; found Zr 3.01, P 1.42, W 60.25. The number of crystal water molecules was determined by thermogravimetric analysis (TGA).

X-ray analysis and crystal data for L-(−)-**1**, $[(CH_3)_2NH_2]_{15}\{[\alpha\text{-}P_2W_{15}O_{55}(H_2O)]Zr_3(\mu_3\text{-}O)(H_2O)(\text{L-tartH})[\alpha\text{-}P_2W_{16}O_{59}]\}\cdot 18H_2O$: colorless needles, crystal size $0.20\times0.04\times0.02$ mm^3, $C_{34}H_{161}N_{15}O_{141}P_4W_{31}Zr_3$, $M_r = 9133.27$, orthorhombic crystal system, space group $P2_12_12_1$ (No. 19), $a = 13.431(3)$, $b = 33.897(7)$, $c = 34.892(7)$ Å, $V = 15885(6)$ Å^3, $Z = 4$; $\rho_{calcd} = 3.674$ g cm^{-3}; $\mu(Mo_{K\alpha}) = 22.679$ mm^{-1}; $1.62 \le \theta \le 28.32°$. Data were collected with a Bruker SMART-APEX CCD sealed tube diffractometer with graphite monochromated $Mo_{K\alpha}$ ($\lambda = 0.71073$ Å) radiation. Data were measured using a series of combinations of ϕ and ω scans with 30 s frame exposures and 0.3° frames widths. The structure was solved by direct methods and refined by full-matrix least-squares against F^2 of all data using SHELXTL software. Hydrogen atoms, except for the water hydrogen atoms, were included in calculated positions and assigned isotropic thermal parameters, riding on their parent carbon, oxygen or nitrogen atoms. The refinement converges with $R_1 = 0.0941$ and $wR_2 = 0.2247$ for 8472 reflections with $I > 2\sigma(I)$. The Flack parameter = 0.06(2) indicates the correct absolute configuration. Max/min residual electron density 8.782/−3.863 e Å^{-3}. The highest residual peaks are all associated with W atoms. CCDC 257975 (L-(−)-**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

1: ^{31}P NMR (162 MHz, D_2O): $\delta = -6.29$, -6.62, -12.88, -13.83 ppm; IR (KBr pellet, metal–oxygen stretching region): $\tilde{\nu} =$ 1086 (s), 1054 (sh), 1017 (m), 943 (s), 912 (s), 760 (s), 697 cm^{-1} (sh). The IR region for the tartrate ligand is not informative owing to its weak absorbance and overlap with that of the dimethyl ammonium countercations. L-(−)-**1**: $[\alpha]_D^{20} = -2.2$ ($c = 1.0$ in H_2O); $[M]_D = -200.9$; UV/Vis (H_2O, 2.2×10^{-6} M): λ_{max} (ε_{max}) = 196 (3.8×10^5), 280 nm (7.2×10^4, sh); CD (H_2O, $c = 2.2\times10^{-4}$ M, 0.1 cm cell): 241 ($\theta = 25.1$, $\Delta\varepsilon = 35.3$), 270 ($\theta = -4.8$, $\Delta\varepsilon = -6.7$), 285 ($\theta = 4.9$, $\Delta\varepsilon = 6.9$), 309 nm ($\theta = -8.6$, $\Delta\varepsilon = -12.0$). D-(+)-**1**: $[\alpha]_D^{20} = 2.0$ ($c = 1.0$ in H_2O); $[M]_D = 183.9$; UV/Vis (H_2O, 2.2×10^{-6} M): λ_{max} (ε_{max}) = 196 (4.1×10^5), 280 nm (7.8×10^4, sh); CD (H_2O, $c = 2.3\times10^{-4}$ M, 0.1 cm cell): 239 ($\theta = -27.0$, $\Delta\varepsilon = -36.0$), 268 ($\theta = 5.9$, $\Delta\varepsilon = 7.9$), 285 ($\theta = -4.2$, $\Delta\varepsilon = -5.7$), 312 nm ($\theta = 9.2$, $\Delta\varepsilon = 12.1$).

Circular dichroism spectra were measured using a JASCO J-715 spectropolarimeter with 1 mm path-length cells. Spectra were collected between 190 and 600 nm, with a step size of 0.5 nm and at a speed of 50 nm min^{-1}. Three spectra were recorded and averaged automatically by the instrument. Optical rotations were measured on a Perkin Elmer 341 digital polarimeter with a 10 cm path-length cell.

[3] The Pfeiffer effect refers to the observation of induced circular dichroism (CD) signals for a configurationally labile chirality when the equilibrium between the enantiomers is shifted in presence of a chiral ligand. See: P. Pfeiffer, K. Quehl, *Ber. Dtsch. Chem. Ges. A* **1931**, *64*, 2667; Pfeiffer effects in polyanion systems: a) J. F. Garvey, M. T. Pope, *Inorg. Chem.* **1978**, *17*, 1115; b) K. Nomiya, R. Kobayashi, M. Miwa, *Bull. Chem. Soc. Jpn.* **1983**, *56*, 3505. Since a Pfeiffer effect necessarily involves optical enrichment of polyanions under equilibrium conditions, this effect, alone, can not lead to isolation of bulk enantiomerically pure complexes, one goal and achievement of the present work.

DNA Cleavage

A Synthetic Block Copolymer Regulates S1 Nuclease Fragmentation of Supercoiled Plasmid DNA**

*Kensuke Osada, Yuichi Yamasaki, Satoshi Katayose, and Kazunori Kataoka**

The materials chemistry and physics of block copolymer supramolecular assembly continue to receive considerable attention in the construction of higher-ordered architectures with unique morphologies and functions.[1–10] Of particular

interest is the exploitation of the spatial order intrinsic to block copolymers for the amplification or modulation of molecular recognition processes by using integrated multisite interactions as well as a distinct spatial matching. Herein we report an unprecedented finding that DNA supramolecular assembly with the synthetic block copolymer poly(ethylene glycol)-*b*-poly(L-lysine) (PEG-PLL)[6,11–14] modulates supercoiled plasmid DNA into a particular structure. The incorporated DNA within the assembly is cleaved into seven distinct regular fragments by S1 nuclease, an enzyme known to cleave single-stranded DNA. The seven characteristic DNA fragments were of well-defined molecular sizes; in each case these were 10/12, 9/12, 8/12, 6/12, 4/12, 3/12, and 2/12 of the original plasmid length (Figure 1). It is notable that the cleaved sites

Figure 1. Regulated fragmentation of plasmid DNAs complexed with PEG-PLL by the S1 nuclease: a) Gel electrophoresis results. Lane 1: marker DNA; lane 2: pBR322 (4363 bp); lane 3: pGL3-Luc (5256 bp); lane 4: ColE1 (6646 bp). OC = relaxed open circular DNA, Lnr = linearized DNA. b) Length of the obtained fragments and size ratio of them to the native DNA. The size ratio of each fragment from three plasmid DNAs is represented as a fraction in the right-hand column.

are located just outside of protein-coding regions, a fact which simultaneously indicates that the S1 nuclease cuts out genes from DNA.

The block copolymer used in this study comprises a cationic PLL segment, which is the plasmid-binding portion, and a nonionic PEG segment, which forms a hydrophilic and hydrated palisade surrounding the ion-paired complex between PLL and plasmid DNA (see the Supporting Information). This allows to obtain a water-soluble nanoscale assembly (100-nm size) without precipitation. The size-specific plasmid DNA cleavage by S1 nuclease was observed at an acidic pH value of 4.9 for the complex, particularly in a unit molar ratio (amino group/phosphate) of 1.0. As seen in lane 2 of Figure 1a, pBR322 DNA is cut into seven distinct fragments (as listed in Figure 1b). This regular fragmentation was not specific only for pBR322 but seems common for other plasmids. Surprisingly, the other plasmids, pGL3-Luc and ColE1, when complexed with PEG-PLL, were also cut into seven fragments of the same fractions when measured against each original plasmid (Figure 1a, lanes 3 and 4, and Figure 1b). The consistency of the fragmentation results clearly indicates the systematic cleavage of plasmid DNA at well-defined intervals. It should be noted that this regular cleavage of plasmid DNA complexed with PEG-PLL is only observed for the supercoiled DNA form. Relaxed open circular DNA, prepared by treatment with topoisomerase I, also formed stable complexes with PEG-PLL but exhibited no sensitivity to S1 nuclease (data not shown). Additionally, a complex with linear plasmid DNA, prepared by treatment with a restriction enzyme (EcoRI) having a unique recognition site on the plasmid, was smoothly degraded to oligo-DNA pieces in a nonspecific manner (data not shown). The observed differences in S1 nuclease sensitivity to plasmid isomer constructs suggest that topological features of the block copolymer–DNA supramolecular complex influence the enzymatic fragmentation process.

Polyion complex formation between DNA and cationic compounds is known to induce a coil–globule transition, thereby resulting in condensed complexes with ordered morphologies, mainly in toroidal or rod-like forms.[14–18] Consistent with this, charge-neutralizing DNA complexation with PEG-PLL produces a detectable transition from an expanded DNA superhelix into a compact state, as confirmed by static and dynamic light scattering[13] as well as by direct observation with fluorescence microscopy.[18] Although the structural details of the condensed plasmid in this complex have not yet been clarified, significant structural features are probably present in the supercoiled double-stranded DNA upon polyion-induced condensation. Constrained structural order (or regular disorder) in the double-stranded DNA structure might be regularly repeated in this polyion-induced condensation process. This would permit the DNA to adopt particular structures that compensate for the structural constraints accompanying conformation transitions during complexation. Consequently, these specific disordered sites in the condensed DNA strands may preferentially promote S1 nuclease attack, thereby resulting in the observed regular DNA fragmentation.

Supercoiled DNA associated with poly(L-lysine) homopolymer with degrees of polymerization (DP) of 19 and 260 exhibited only nonspecific S1 nuclease degradation without any ordered cleavage, as shown by a smeared electrophoresis gel stain (data not shown). This indicates that polyion complexation alone is not sufficient and that the PEG segment in the block copolymer plays a crucial role in regulating the nuclease sensitivity in addition to promoting the complex solution stability. Inter- or intramolecular steric repulsion of hydrated PEG segments may contribute to the modulated structure of plasmid DNA.

The sensitivity of single-strand-cleavage endonucleases like S1 nuclease against naked plasmid DNAs has been investigated since the 1980s.[19–22] The naked DNAs are first nicked and then linearized. The cleavage sites are cruciform loops, which are adopted by short inverted repeat (palindrome) sequences in the topologically stressed double helix.

Formation of the hairpin-loop structure relieves the topological strain in double-stranded circular DNA molecules. These inverted repeats, separated by nonrepetitious sections of DNA, are specifically cleaved by single-strand-specific nucleases at the center of each hairpin loop. Torsional stress of negative supercoiling of plasmid DNA occasionally induces a kink in the DNA strand with an acute angle. The high susceptibility of palindrome sequences to S1 nuclease digestion led us to assume that the regular fragmentation seen here in the system with the PEG-PLL/plasmid DNA (pDNA) complex might be a result of selective digestion at the cruciform loop regularly induced in the condensed DNA strands. To get an insight into this assumed mechanism, inverted repeats larger than five continuous sequences are picked up from three plasmids (pBR322, pGL3-Luc, and ColE1) by using computer analysis.[23] Neighboring smaller palindromes separated by one or two nonrepetitious sections of DNA were also taken into consideration. It is to be expected that hairpin stability will be directly proportional to stem length but inversely proportional to loop length. The inverted sequences were marked from four to one according to the hairpin stability, as summarized in Figure 2a as a function of base number. Obviously, there are quite a few palindrome sequences. Denaturation of the DNA double strand is necessary for transformation from the normal interstrand base pairing to the intrastrand base pairing of the cruciform structure. The binding energy of the A–T (adenine–thymine) pair is lower than that of the G–C (guanine–cytosine) pair, because two hydrogen bonds are contributing to the pairing between A and T while three contribute between G and C. Thus, the composition of A–T pairs within the palindrome sequences was also examined (Figure 2b). Refinement according to palindrome size and A–T composition allowed the extraction of several sites as candidates for S1 nuclease recognition; these are indicated as dotted lines in Figure 2a and b and as slashes in the pDNA maps (Figure 2d). By use of these refined sites, combinations satisfying the regular fragments were surveyed by consideration of fragment lengths, since two sites on the circular plasmid DNA must be cleaved (for example, 3/12+9/12 = 12/12). Consequently, combinations of cleavage sites yielding the seven DNA sizes were acquired for all three plasmid DNAs

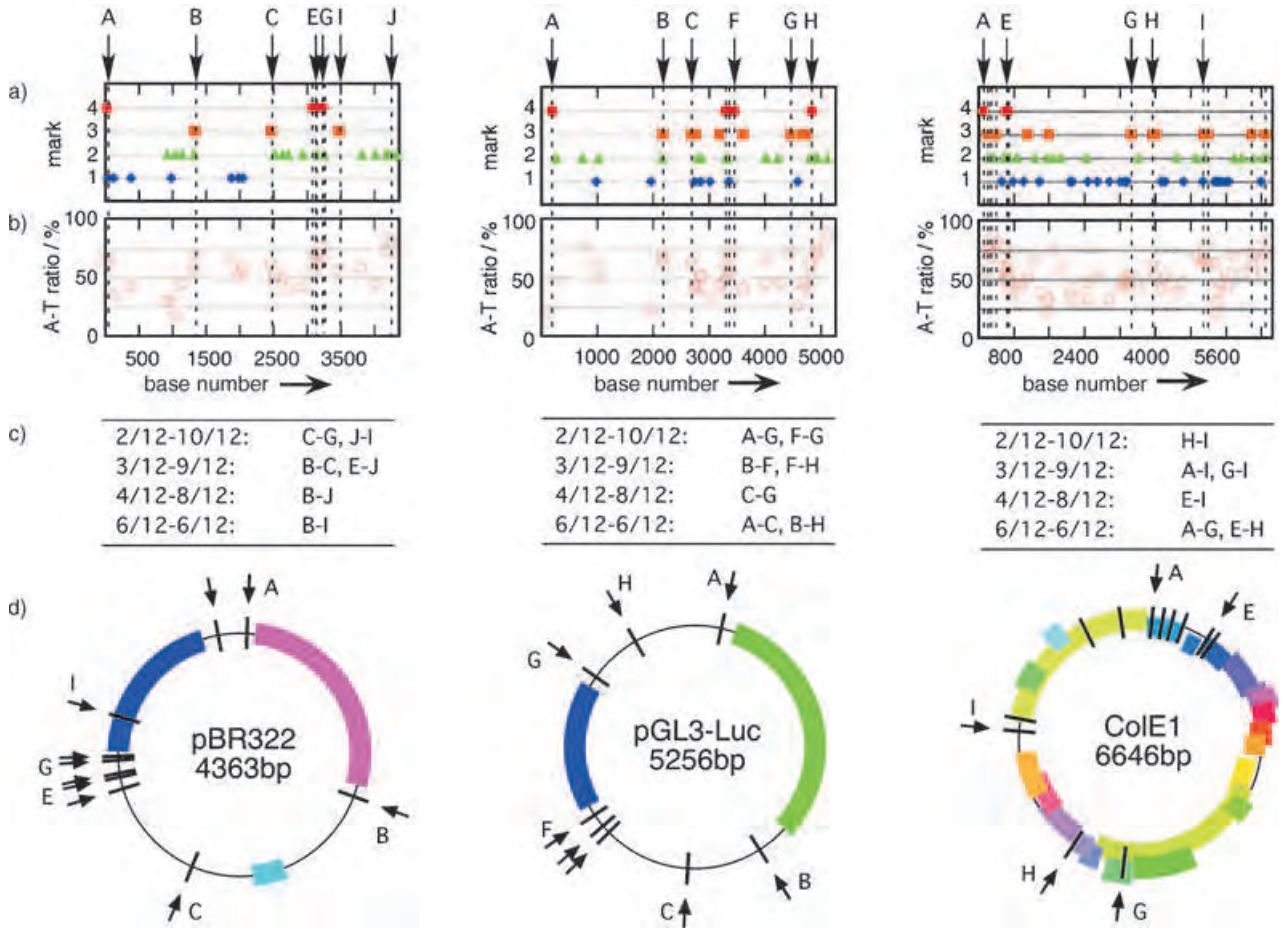

Figure 2. Palindrome maps and protein codes of the three plasmid DNAs pBR322 (left), pGL3-Luc (middle), and ColE1 (right). a) Cruciform stability by the size of inverted repeats. Higher mark numbers indicate higher cruciform stability. b) Percentage A–T composition in the considered palindrome sequences as a function of base number in the plasmid DNAs. Here, base 1 was defined as the recognition site of the EcoR1 restriction enzyme. The dotted lines in panels (a) and (b) indicate refined digestion sites as evaluated from the panels. The combinations of cleavage sites that satisfy the seven-piece fragmentation pattern are summarized in (c). Those evaluated cleavage sites are shown as arrows with capital letters in panels (a) and (d); in addition, correlation between the protein-coding regions and proposed cleavage sites is shown in (d).

(listed in Figure 2c) and those sites are indicated as arrows in Figure 2a and d. The regular fragmentation can be explained by assuming that the cruciform structures regularly induced in the DNA by complexation with the PEG-PLL block copolymer are digested by the single-strand-recognition endonuclease.

Obviously, development of the extruded cruciform structure requires definite stress. The cruciform formation in the naked pDNA is known to be driven by the torsional stress of negative supercoiling.[22] In the complex of pDNA with PEG-PLL, the stress of condensation by the polycation further amplified the torsional stress of the supercoiled conformation, so that the cruciform may be developed in multiple sites. It should be noted that the charge ratio of 1.0 is indeed a critical point in the pDNA transition from extended state to condensed state. The ethidium bromide exclusion assay showed an abrupt decrease in the relative fluorescence, which indicates condensation of DNA molecules, at a charge ratio range of around 1.0 (see the Supporting Information). Additionally, the transition of DNA shape is confirmed by direct observation with atomic force microscopy (Figure 3). Apparently, complex shapes at the charge ratio of 1.0 comprise preferentially condensed rod and toroid conformations.

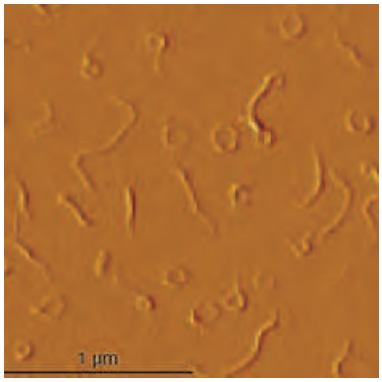

Figure 3. AFM image of plasmid DNA (pGL3-Luc) complexed with the PEG-PLL block copolymer at a charge ratio of 1.0. The image was taken in the amplitude mode for the complex after equilibration in solution for 24 hours. A scale bar is included in the figure.

Furthermore, the potential cleavage site (palindrome site) and protein-coding region have a very interesting correlation, in that the former is located just outside of the latter, as can be clearly seen in Figure 2d. It is worth mentioning that this is commonly observed among the three examined plasmids. This correlation is most distinctive in the ColE1 plasmid, which has various protein codes (Figure 2d). The fact that the selected inverted repeats are located just in the gap or at the terminus of various coding regions suggests that the cruciform structure may substantially contribute to the regulation of gene expression[21] and is most likely to be a landmark for DNA-binding proteins. It should be noted that hypersensitivity of structured DNA to S1 nuclease has been observed in regions of transcriptionally active genes in chromatin.[24] DNA breakage by S1 nuclease is observed in apoptotic cells[25] and also more in mitotic chromosomes than chromosomes in interphase cells.[26] This may be a reflection of the differences of stress under such circumstances. The cruciform structural motifs must be to regulate the binding of proteins, nucleases, promoters, or transcription factors; the full function remains to be determined. Yet, the potential for designing synthetic polymer constructs that reliably alter or mimic these supramolecular structures or for imparting new features of molecular recognition by using the materials of unconventional biopolymer complexes, as demonstrated here, is exciting.

In conclusion, we have demonstrated that the size-specific cleavage of plasmid DNA by S1 nuclease can be mediated by condensed complexes of plasmids with synthetic block copolymers without any sequence-specific binding. The recognition site is probably the cruciform structure induced by DNA complexation with the block copolymer. This means that DNA inherently retains sequences that can transform its secondary structure by certain stimuli and the synthetic polymer reveals the functional structure by complexation. The observed unique sensitivity of PEG-PLL/pDNA complexes to S1 nuclease should provide an insight into the mechanisms of endogenous protein-induced modification of DNA and into the design of artificial restriction enzymes and gene-exploring systems through supramolecular assembly of synthetic macromolecular materials.

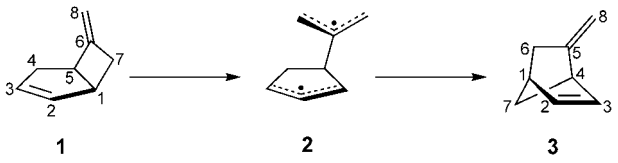
Reaction Dynamics

Dynamic Effects on [3,3] and [1,3] Shifts of 6-Methylenebicyclo[3.2.0]hept-2-ene**

Christopher P. Suhrada, Cenk Selçuki, Maja Nendel, Carina Cannizzaro, K. N. Houk, Peter-Jürgen Rissing, Dirk Baumann, and Dieter Hasselmann**

Dedicated to Professor Wolfgang Kirmse on the occasion of his 75th birthday

The controversies over concerted versus stepwise diradical mechanisms of potentially pericyclic reactions have subsided with improvements in the understanding of stereoselectivity in thermal rearrangements that involve modestly stabilized diradical intermediates. The thermal rearrangements of vinylcyclopropanes[1] and vinylcyclobutanes,[2] including bicyclo[3.2.0]hept-2-ene,[3] involve diradical intermediates that lack a deep potential energy well, and their outcomes deviate from statistical predictions. The thermal rearrangement of 6-methylenebicyclo[3.2.0]hept-2-ene (**1**) to 5-methylenenorbornene (**3**) is more intriguing, as it yields a nonrandom distribution of products despite the stabilizing effect of the 6-methylene substituent on the intermediate **2**.



Dideuterio labeling has revealed a preference for [1,3] over [3,3] shifts,[4] and the stereochemistry observed with methyl labels has led to the hypothesis that diradical intermediates do not equilibrate rotationally before collapsing to form the bicyclic products.[5] New experimental studies of monodeuterated species currently show modest levels of both regio- and stereoselectivity (Table 1),[6] and DFT and ab initio calculations provide a theoretical framework for understanding these results.

Table 1: Deuterium label distribution in product **3** from the thermolysis of 7*x*-, 8*E*-, and 8*Z*-**1**, extrapolated to $t = 0$ min.

Educt	6*x*-**3**	6*n*-**3**	8*E*-**3**	8*Z*-**3**
7*x*-**1**	0.37	0.20	0.22	0.21
8*E*-**1**	0.13	0.23	0.64	–
8*Z*-**1**	0.24	0.14	–	0.62

UB3LYP and CASSCF calculations indicate that two modes of C1–C7 cleavage produce stereoisomeric diallyl intermediates **2** from **1** (Figure 1). The favored transition state, **TS-12n**, moves C7 toward C3 and places the 7*x* substituent in an *E* configuration. In contrast, **TS-12x** moves C7 away from C3 and puts the 7*x* substituent in the *Z* position. The preference (1.8 kcal mol^{-1}; CASPT2//UB3LYP) for **TS-12n** over **TS-12x** is analogous to torquoselectivity in electro-

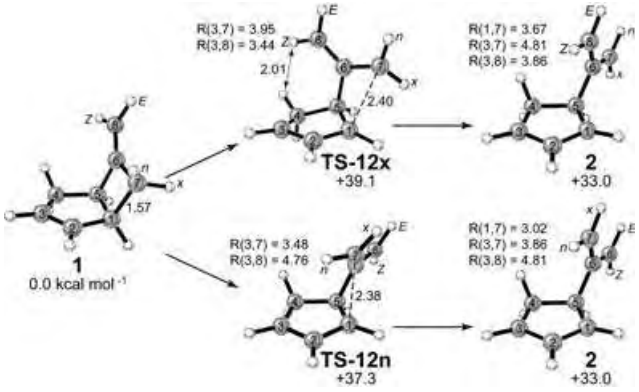


Figure 1. Two transition states for bond breaking lead to stereoisomeric diallyl intermediates **2**. Structures shown are (U)B3LYP-optimized with selected bond distances indicated in angstroms. Enthalpy values (CASPT2//UB3LYP), in kcal mol^{-1} relative to that of **1**, are listed below each structure label.

cyclic ring openings;[7] the favored structure minimizes closed-shell repulsion and maximizes hyperconjugation between the orbitals of the breaking C1–C7 σ bond and the C2–C3 π bond. Also, **TS-12x** brings the 8*Z* hydrogen atom into close proximity with the one in the 4-*cis* position.

The diradical **2** lies 4.3 kcal mol^{-1} below **TS-12n**. Once formed, **2** can isomerize by rotation about the C5–C6 bond with a calculated barrier of only 2.4 kcal mol^{-1} (**TS-22**, Figure 2). This motion exchanges the positions of C7 and C8. Allylic stabilization preserves the pseudo-*E*/*Z* configuration of C7 and C8 substituents during the lifetime of the intermediate; barriers for rotation about C6–C7 and C6–C8 are calculated to be ≈12–13 kcal mol^{-1} higher than those that separate **2** from the product **3**.

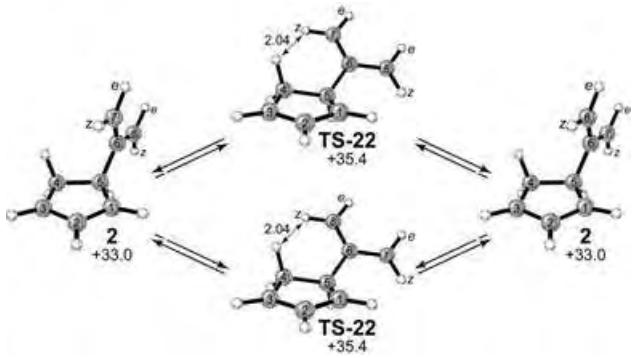

Figure 2. Rotation about C5–C6 exchanges the position of proximal and distal allyl termini, yet the pseudo-*E*/*Z* configuration of substituents is preserved. Structures shown are (U)B3LYP-optimized with selected bond distances indicated in angstroms. Enthalpy values (CASPT2//UB3LYP), in kcal mol^{-1} relative to that of **1**, are listed below each structure label.

In analogy to the bond-breaking step, the formation of a new bond at C3 can occur in two different stereochemical senses (Figure 3). Both transition states involve the formation of a bond between C3 and the proximal allyl terminus in **2**.[8] From a given intermediate **2**, the two products **3** that can be formed are thus epimers with respect to the substituents on that carbon. **TS-23n** is favored slightly and places the pseudo-*E* substituent in the 6*x* position in the product; **TS-23x** places the same substituent in the 6*n* position.

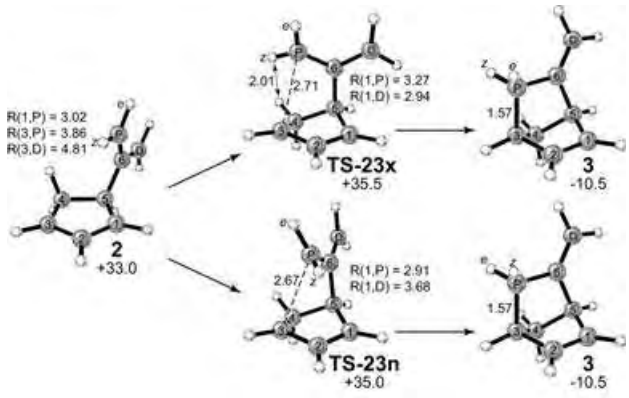

Figure 3. Two cyclization routes form epimeric products from a given intermediate **2**. Structures shown are (U)B3LYP-optimized with selected bond distances indicated in angstroms. Enthalpy values (CASPT2//UB3LYP), in kcal mol^{-1} relative to that of **1**, are listed below each structure label.

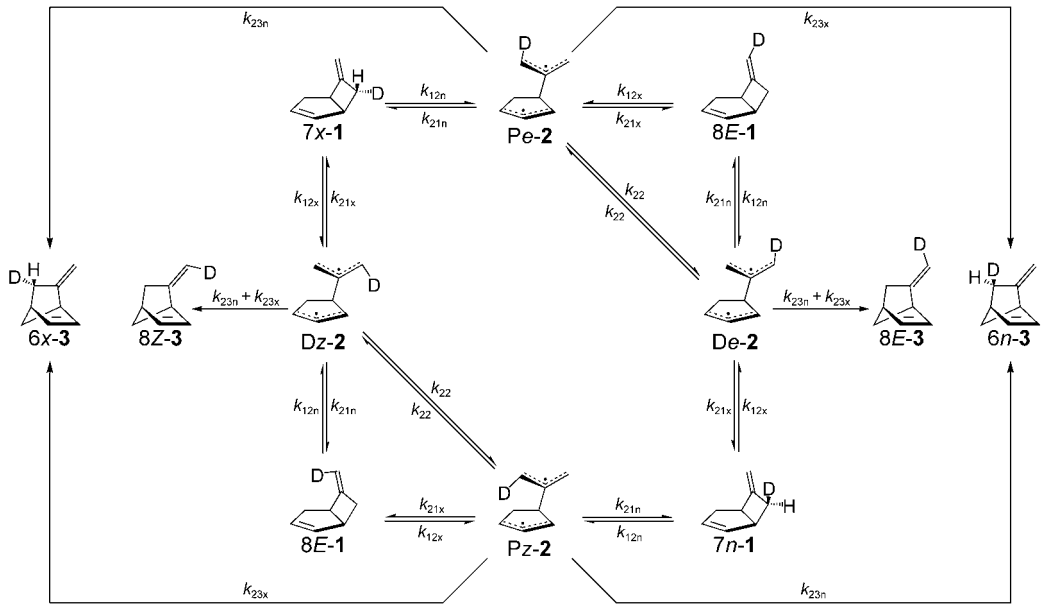
TS-23n and **TS-23x** lie only 2.0 and 2.5 kcal mol^{-1} above **2**, respectively. Compared with 2.4 kcal mol^{-1} for **TS-22**, this suggests that cyclization competes with conformational isomerization in the intermediate, and therefore a majority of products will come from an intermediate in the conformation in which it is initially formed.

These pathways imply the kinetic model outlined in Scheme 1 for a single-labeled system. For comparison with the experimental zero-time data, reversions from **2** to **1** may



Scheme 1. Stepwise kinetic model for rearrangements of **1** bearing a single deuterium label on C7 or C8.

be ignored,[9] and the relative yield of products can be computed based on three independent parameters, related to k_{12n} versus k_{12x}, and k_{23n} versus k_{23x} versus k_{22} (Supporting Information).

With the model in Scheme 1 and the selectivity parameters from CASPT2//UB3LYP transition-state energies, calculations predict the product distribution listed in Table 2, Column 2. The major products of both experiments are correctly identified, although the minor product ratios deviate from experiment markedly.

Table 2: Product distributions from experiment, CASPT2//UB3LYP calculations, and least-squares fits of two theoretical models to the experimental data. Corresponding kinetic parameters and relative TS energies are listed along with predicted product distributions.[a]

	Experiment	CASPT2//UB3LYP (fully stepwise)	Least-squares fit (fully stepwise)	Least-squares fit (stepwise plus concerted [3s,3s])

Fraction direct **TS-12x** to [3*s*,3*s*]-**3**	–	–	–	0.808
$\Delta\Delta G^{\ddagger}_{(\text{TS-12x}-\text{TS-12n})}$	–	+1.8	+1.0	+1.3
$\Delta\Delta G^{\ddagger}_{(\text{TS-22}-\text{TS-23n})}$	–	+0.4	+0.7	+0.9
$\Delta\Delta G^{\ddagger}_{(\text{TS-23x}-\text{TS-23n})}$	–	+0.5	+0.2	+0.6

[a] For CASPT2//UB3LYP, relative TS energies ($\Delta\Delta H^{\ddagger}$) give parameters that produce the product distribution. Least-squares fits produce both kinetic parameters and expected values for the product distribution; relative TS energies are calculated from the kinetic parameters thus obtained. [b] The 8*E*-**1** and 8*Z*-**1** experiments are redundant under all models considered, excluding isotope effects. For this reason, they have been averaged for comparison and fit to theory to simplify the analysis and not to assign the two 8-*d*-**1** experiments undue weight in comparison with the single 7-*d*-**1** experiment. For example, the entry for 8*E*-**1**→6*n*-**3** is actually the average of experimental proportion in which 8*E*-**1** forms 6*n*-**3**, and 8*Z*-**1** forms 6*x*-**3**. [c] $R^2=\Sigma(\gamma_{\text{predicted}}-\gamma_{\text{expt}})^2/\Sigma(\gamma_{\text{expt}}-\gamma_{\text{random}})^2$ in which γ_{random} represents the hypothetical nonselective product distribution: $\gamma_{\text{random}}=0.25$ for each product except the [1,3] product in the 8-*d*-**1** experiment, for which $\gamma_{\text{random}}=0.50$. Although the CASPT2//UB3LYP prediction does not involve a fit to experiment, the R^2 analysis is applied for comparison with the least-squares results.

We have also worked backward from the experimental result by means of a least-squares fit, to determine what combination of relative rates would lead to the observed outcome. Such a fit produces selectivity parameters and a corresponding expected product distribution, shown in Column 3 of Table 2. The fit parameters match the experimental outcome more closely, despite the fact that they differ only slightly from the CASPT2//UB3LYP predictions. However, closer inspection shows that the fit still does not reproduce the experimental result satisfactorily in all cases. For instance, the ratio among [3,3] products from 8-*d*-**1** (i.e., 8*E*-**1** and 8*Z*-**1**) is reversed, whereas the proportion of [1*r*,3*s*] products in the 7*x*-**1** experiment is higher than it should be.

The problem is solved by incorporating a concerted Cope pathway into the stepwise model. The addition of a corresponding fourth selectivity parameter, described below, improves the fit from $R^2=0.628$ to $R^2=0.969$ (Table 2, Column 4). The goodness of fit alone is evidence to support the presence of such a pathway, yet how can this be reconciled theoretically? Examination of the potential energy surface of the reaction gives clues to what may be happening.[10] Preliminary single-point energy calculations prompted us to suspect that a CASPT2//UB3LYP treatment[11] would give the most accurate representation of the PES shape (Figure 4a). At this level of theory, the **TS-12x** saddle point lies at a low value of R(3,8), and the transition vector has a component in the negative R(3,8) direction. At the same time, the flattening of the diradical potential energy well shifts **TS-23x** toward larger values of R(3,8), positioning it almost directly in front of **TS-12x**. Thus situated, one can easily envision how **TS-23x** might bifurcate the ensemble of trajectories passing over **TS-12x**, sending them either to intermediate **2** or to the product **3** (Figure 4b).[12]

According to this model, **TS-12x** is populated based on its relative free energy, as before. After the transition state, that population is divided into two portions according to a new parameter. One portion goes to **2** and a statistical distribution of products from there, and the other produces [3*s*,3*s*]-**3** directly. The relative TS energies corresponding to this fit are listed in Table 2 and agree reasonably well with CASPT2//UB3LYP values. As for the additional parameter, the fit suggests that $81\pm16\%$ of the **TS-12x** trajectories (16% of the total product distribution) go directly to **3**.

Having obtained an adequate quantitative fit between theory and experiment, we consider the fact that the experimental [1,3]/[3,3] ratio is subject to a large positional secondary isotope effect, outside of probable error limits: [1,3]/[3,3] = 58:42 from 7*x*-**1** but 63:37 from 8*E*-**1** or 8*Z*-**1** (see also Reference [4]). This remains puzzling: although our calculations predict reasonable isotope effects for the various rate constants in Scheme 1, their combined effect (60:40 from 7*x*-**1** versus 61:39 from 8-*d*-**1**) is much smaller than what is experimentally observed.

In summary, experiments and calculations reported herein establish how [1,3] versus [3,3] and [1*i*,3*s*] versus [1*r*,3*s*] preferences may arise in a strictly stepwise reaction as a result of stereoelectronic effects on the breakage and formation of bonds, along with incomplete conformational equilibration among intermediate diradicals. Whereas much of the observed selectivity can be explained by a fully stepwise, statistical model, we find that there is also a role for a formally concerted Cope pathway in the form of a nonstatistical post-

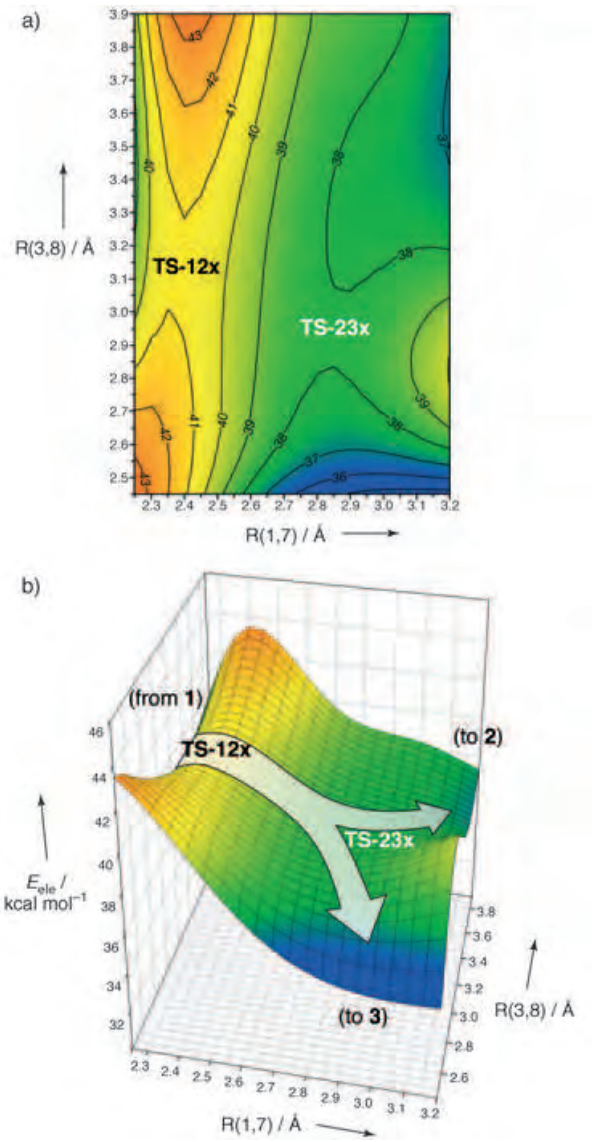

Figure 4. a) Two-dimensional projection of the potential energy surface for the rearrangement of **1** to **3**. The plot was mapped with CASPT2 single-point energy calculations on UB3LYP constrained-optimized structures at intervals of 0.05 Å in the coordinates R(1,7) and R(3,8), the bond-breakage and formation distances, respectively, for a [3,3] shift. Energy contours are marked in kcal mol^{-1}, relative to **1**. b) Three-dimensional representation of plot in part a) that schematically illustrates the concept of bifurcation of **TS-12x** reaction trajectories by **TS-23x**.

transition-state bifurcation. Dynamic simulations may yield additional insight into this process.

Experimental Section

The preparation of 7*x*-, 8*E*-, and 8*Z*-**1** is described in the Supporting Information. Thermolyses were carried out in the gas phase at 220 °C in a 20-L reaction flask at 1 to 3 mbar. *n*-Nonane served as an internal standard and *n*-hexane as collision partner. Samples were taken after approximately 20 %, 40 %, 60 %, and 80 % structural isomerization of starting material. Besides **3**, the only products observed were isotopomers of **1**. Ratios of individual isotopomers were determined by ^{2}H NMR spectroscopy (61.4 MHz) after separation of structural isomers by vapor-phase gas chromatography. Isotopomeric ratios were extrapolated to a thermolysis time $t = 0$ (Table 1).

Structures of **1** and **3**, as well as that of the intervening diradical **2** and associated transition species were optimized with both UB3LYP/6-31G(d) and (6,6)CASSCF/6-31G(d) in Gaussian 98.[13] (6,6)CASPT2/6-31G(d) single-point energies were calculated for both sets of stationary points in MOLCAS.[14] Kinetic isotope effects were calculated in the program Quiver[15] based on UB3LYP/6-31G(d) frequency data.

[8] It is immediately evident that **TS-23n** forms a bond from C3 to the *proximal* allyl terminus. Although it appears feasible that **TS-23x** might involve rotation of the *distal* allyl carbon past C4 and into bonding distance with C3, IRC calculations show that this is not the case: the bond is formed to the proximal carbon in **TS-23x** as well as **TS-23n**.
[9] Although isotopomers of the educt **1** begin to accumulate with time, their effect on the distribution of labels in the product **3** vanishes upon extrapolation to $t = 0$. Examination of **1** at high levels of conversion shows a preponderance of the starting isotopomer, indicating that educt isomerization is slow in comparison with product formation. Regardless of its magnitude, the rate k_{21} is the same for all intermediates **2**, and therefore may be ignored in the computation of label distribution in product **3**.
[10] A transition state for a concerted [3*s*,3*s*] reaction, as well as one for a concerted [1*i*,3*s*] process, can be located with RB3LYP/6-31G(d) (Supporting Information), but these saddle points are only artifacts of the restricted formalism, and they disappear at the UB3LYP level.
[11] A CASPT2 single-point energy calculation was performed on each of the UB3LYP constrained-optimized structures used to construct the UB3LYP surface.
[12] A PES involving a post-TS bifurcation between a Cope pathway and formation of an allylic-stabilized diradical intermediate has been discussed in the case of an acyclic allenic triene: S. L.

Ion Exchange

$\{Sn[Zn_4Sn_4S_{17}]\}^{6-}$: A Robust Open Framework Based on Metal-Linked Penta-Supertetrahedral $[Zn_4Sn_4S_{17}]^{10-}$ Clusters with Ion-Exchange Properties**

*Manolis J. Manos, Ratnasabapathy G. Iyer, Eric Quarez, J. H. Liao, and Mercouri G. Kanatzidis**

The huge diversity in structure and pore size encountered in open-framework aluminosilicate zeolite materials is not yet reflected in sulfide and chalcogenide compounds. Interest in chalcogenides with open frameworks, however, is growing, and progress towards developing this important class of materials has been steady in the past decade.[1–3] Because of the wider chemical and bonding flexibility, in principle, chalcogenides can be even more diverse in composition and structure than zeolites. In addition, they can uniquely combine properties of zeolitic micropores—exploited in solid-acid, ion-exchange, and absorption materials—with properties of semiconductors that provide the basis of electronic, optical, and photonic applications.

Some chalcogenides with open frameworks are based on so-called supertetrahedral clusters, denoted as T*n* (*n* is the number of metal layers).[2c] Other frameworks are based on different units that range from simple tetrahedra to so-called penta-supertetrahedral clusters denoted as P*n*.[1a,2a,2b] Recently the family of compounds featuring $A_{10}[M_4M'_4S_{17}]$ ($A = K$, Cs; $M = Zn$, Cd, Fe, Co; $M' = Sn$, Ge)[4] and $A'[Sn_4M^{II}_4Se_{17}]$ ($A' = [K_{10}(H_2O)_{16}(CH_3OH)_{0.5}]$, $[K_{22}(H_2O)_7(CH_3OH)_{18}](SnSe_4)_3$; $[K_{36}Cl(H_2O)_{11}(CH_3OH)_{32}]$; $[K_6(H_2O)_3]$; $M^{II} = Co$, Zn, Mn, Cd, Hg)[5,6b] was shown to have discrete supertetrahedral clusters that belong to the penta-supertetrahedral series P*n*.[1a,2a,2b] This cluster type is an assembly of four $\{MQ_4\}$ (T1) and one $\{QM_4\}$ (anti-T1) structural units, in which M is the metal ion and Q is the chalcogen atom (see Figure 1a). The $[M_4M'_4S_{17}]^{10-}$ clusters have four terminal S atoms, which are potential binding sites to other clusters or metal centers, and can thus serve as building blocks for framework materials. However, to date no pertinent reports regarding such systems have appeared even though frameworks consisting of the partially destroyed P1 selenido clusters $[Cd_4Sn_3Se_{13}]^{6-}$ and $[Hg_4Sn_3Se_{13}]^{6-}$ were recently reported.[6]

Herein we describe $A_{5-x}K_{1+x}Sn[Zn_4Sn_4S_{17}]$ ($A = K^+$, Rb^+, Cs^+; $x = 0,4,5$), the first examples of compounds consisting of intact $[Zn_4Sn_4S_{17}]^{10-}$ clusters linked with Sn^{4+} centers. They feature a new type of open framework and have excellent chemical stability. Furthermore, we report the surprising finding that one-fifth of the K^+ ions play an important templating role in stabilizing the framework. The A^+ ions fill relatively large voids and exhibit remarkably facile ion-exchange properties similar to those of small-pore zeolites.

The synthesis of $K_6Sn[Zn_4Sn_4S_{17}]$[7] (**1**) was carried out by using the alkali polychalcogenide flux method,[8] with a K_2S/S ratio of 1:8–1:10 (that is, in a flux of relatively low basicity). For reasons that will become apparent below, we also succeeded in isolating the isostructural $CsK_5Sn[Zn_4Sn_4S_{17}]$ (**2**) and $RbK_5Sn[Zn_4Sn_4S_{17}]$ (**3**).[9]

Compound **1** crystallizes in the tetragonal acentric $I\bar{4}m2$ space group.[10] The noncentrosymmetric character of **1** is apparent when one looks at the (010) projection of the unit cell (Figure 1b). The critical building unit of **1** is the $[Zn_4Sn_4S_{17}]^{10-}$ cluster, which features a central tetrahedral $\{Zn_4S\}^{6+}$ core capped with four tridentate $\{SnS_4\}^{4-}$ fragments (see Figure 1a). To form the 3D framework, the cluster uses all four terminal S atoms to coordinate to four linking Sn atoms (Sn1), which in turn bind to four clusters (Figure 1c). This creates a full diamondlike framework with a zinc-blende (ZnS) topology (Figure 1d). Fourfold inversion rotation axes (-4) pass through the Sn1 atoms and the intracluster S1 atoms of the structure (Figure 1c).

The connection of tetrahedral chalcogenide clusters with metal linkers is a rational way to build open-framework compounds, yet it is still a relatively uncommon structural feature among the known crystalline examples. Generally in the latter compounds, the clusters tend to link by sharing terminal chalcogen atoms (μ_2-S or μ_2-Se). An exception to this is the $(Me_4N)_2[MGe_4Q_{10}]$ ($M = Mn$, Fe, Co, Zn, Cd) and

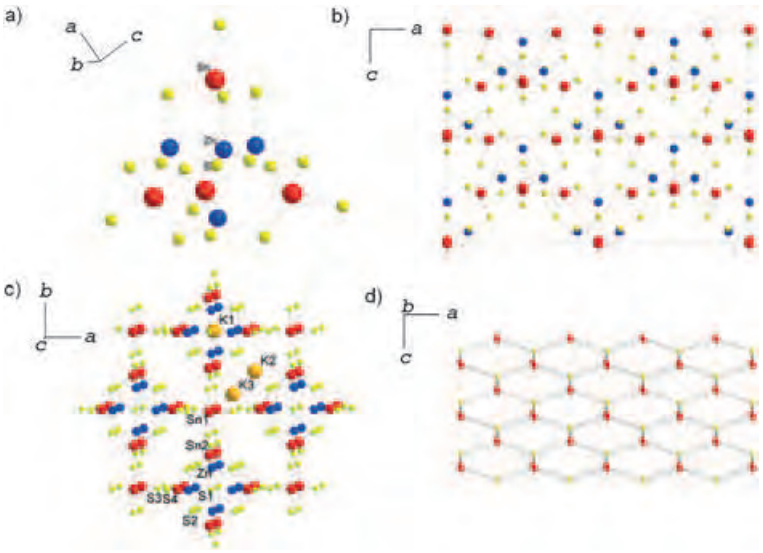

Figure 1. a) The $[Zn_4Sn_4S_{17}]^{10-}$ P1 cluster. b) A [010] projection showing the absence of a center of symmetry in the structure of compound **1**. Yellow, red, and blue balls represent S, Sn, and Zn atoms, respectively. K ions were removed for clarity. c) The $\{Sn[Zn_4Sn_4S_{17}]\}^{6-}$ framework viewed down the *c* axis. For clarity, K3 is shown in only one of the several subsites that are partially occupied by this ion. Selected distances [Å] and angles [°]: Sn1-S3 2.397(2), Sn2-S4 2.342, Sn-S2 2.3497(16), Sn2-S3 2.428(2), Zn-S1 2.3287(9), Zn-S2 2.3369(15), Zn-S4 2.353(2), K1-S2 3.4460(16), K2-S4 3.3637(15), K2-S2 3.145(2), K3-S3 3.791(3), K3-S4 3.253(5), Sn(1)-S(2)-Sn(2) 104.42(9). d) Skeletal version of the structure of $\{Sn[Zn_4Sn_4S_{17}]\}^{6-}$ depicting the topological relationship to diamond. The yellow balls are $[Zn_4Sn_4S_{17}]^{10-}$ clusters, and red balls are linking Sn atoms (Sn1).

$A_n[MGe_4Se_{10}]\cdot m\,H_2O$ (A = Rb, Cs; M = Ag: $n=3$, $m=2$; M = Mn: $n=2$, $m=3$) families, which feature adamantane clusters linked by tetrahedral M^{2+} centers.[11,12]

The most prominent aspect of the framework we describe here is the nature of the open space available in it. There are two types of large cavities: one that accommodates the K2 atoms and one that accommodates the K3 atoms. The K3 cavity is larger and both are indicated in Figure 2a, b. Out of the six K atoms in the formula, one atom is accommodated in site K1, one atom is in site K3, and four atoms are in site K2. K1 is in a tight eight-coordinate square-prismatic environment of S atoms. The K1–S2 bond length is 3.446(2) Å. Atoms K1, K2, and K3 occupy different environments in the tunnel network. K3 is in the largest cavity with a diameter of ≈9.7 Å and K2 is in the next largest cavity with a diameter of ≈6 Å. The atoms in the K3 site were modeled with several split subsites over the cavity.[14]

We can obtain a better understanding of the empty space in the $\{Sn[Zn_4Sn_4S_{17}]\}^{6-}$ framework if we plot the isosurface[13] that lies between the framework atoms and the voids (see Figure 2c, d). From this perspective, the relative size, shape, and interconnection of the cavities are revealed. It is apparent from these plots that the tunnel network in the structure is three-dimensional with a diamondlike topology similar to the topology of the filled space. Each cavity is not spherical but square and "pancake" in shape with the short dimension being parallel to the tetragonal *c* axis, Figure 2c, d. The two types of cavities (K2 and K3) communicate through narrow passages that are only ≈2 Å wide. This feature accounts for the observed selectivity in the ion-exchange properties observed for this framework (see below).

The K1 site seems to be an exact fit for this framework (see Figure 2c), and the role of this atom seems pivotal to the stability of the structure. This aspect was suggested by the results of experiments aimed at preparing analogues with larger alkali atoms such as $Rb_6Sn[Zn_4Sn_4S_{17}]$ and $Cs_6Sn[Zn_4Sn_4S_{17}]$; the experiments did not succeed. This lack of success implied that a K atom might be needed to occupy a K1 site to stabilize the framework. Conversely, the large cavities of K2 and K3 suggested that the K^+ ions are potentially very mobile and that it might be possible to replace them with larger Rb^+ or Cs^+ ions. Indeed compounds **2**, **3**, $Rb_5KSn[Zn_4Sn_4S_{17}]$ (**4**), and $(A_{5-x}K_x)KSn[Zn_4Sn_4S_{17}]$ (A = Rb, Cs) are all possible and can be prepared by high-temperature solid-state synthesis as well as topotactic ion-exchange reactions at room temperature.

A refinement of the crystal structures of **2** and **3** showed unequivocally that the K1 and K2 sites are occupied exclusively by K atoms. The largest site of K3 is occupied exclusively by Rb^+ and Cs^+ cations. However, refinement of the structure of the ion-exchanged material **4** showed that only K1

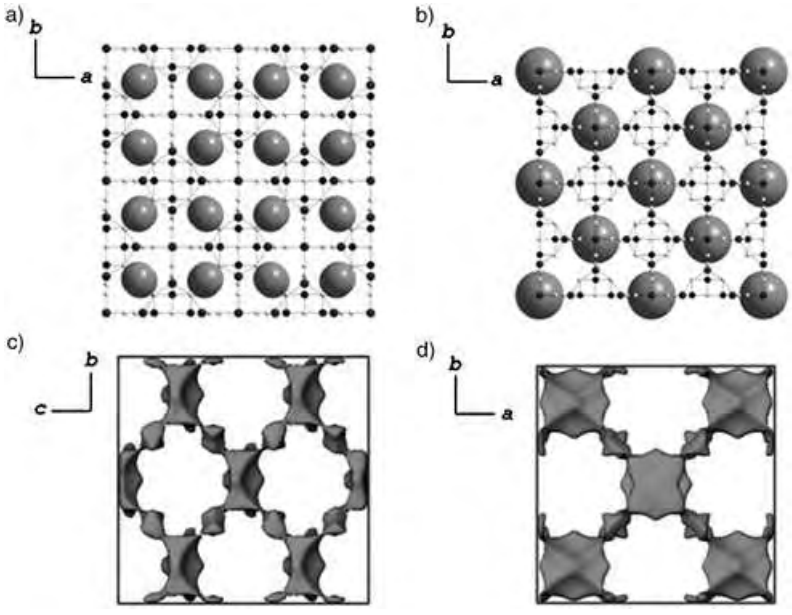

Figure 2. a) A [010] projection of the structure of **1** with the K2 sites represented by oversized spheres to show the available space around them. The diameter of the cavity hosting K2 is ≈6.0 Å. b) The same projection with the K3 sites now shown as oversized spheres. The diameter of the cavity hosting the K3 atoms is ≈9 Å. c) Depiction of the void space in $\{Sn[Zn_4Sn_4S_{17}]\}^{6-}$ viewed down the [100] direction of the isosurface representing the atom-free space in $\{KSn[Zn_4Sn_4S_{17}]\}^{5-}$ (2 Å from the van der Waals radius). d) The isosurface viewed down the [001] direction. The cavities containing the K3 atoms are square shaped "pancakes", whereas the cavities hosting the K2 atoms serve as connecting channels between the pancake-shaped cavities.

remains intact after ion-exchange (see below). Furthermore, analogues of **1** with larger metal ions, such as Hg^{2+} and Cd^{2+}, or with selenium analogues could not be isolated, possibly because they create larger K1 cavities thereby destabilizing the structure.[15] Because of these results, we are tempted to view the K1 site as a major reason for the stability of this structure type and likely to play the role of template. In this context and because it does not seem to be exchangeable, K1 must be considered as part of the framework whereas K2 and K3 are extraframework ions.

Since the extraframework K^+ ions are loosely bound, they are readily exchanged for other types of ions in solution. Complete ion exchange was achieved in a single-step reaction by stirring compound **1** in water for a few hours at room temperature with excess RbI and CsI.[16] The powder X-ray diffraction (XRD) patterns of compound **1** and those of the ion-exchanged material **4** are almost identical with the exception of a small shift of the diffraction peaks to lower 2θ angles (as expected) in the pattern of compound **4** (see Figure 3a, b). Energy-dispersive spectroscopy (EDS) analysis of the exchanged material was consistent with the formula of $Rb_5KSn_5Zn_4S_{17}$.

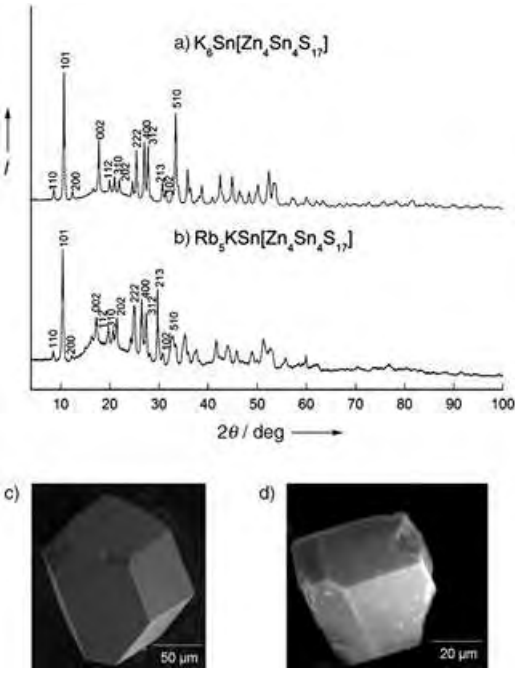

Figure 3. XRD ($Cu_{K\alpha}$ radiation) diagrams (with indexing of selected reflections) of: a) pristine $K_6Sn[Zn_4Sn_4S_{17}]$ and b) ion-exchanged $Rb_5KSn[Zn_4Sn_4S_{17}]$. c) SEM images of a single crystal of pristine $K_6Sn[Zn_4Sn_4S_{17}]$. d) A single crystal of ion-exchanged $Rb_5KSn[Zn_4Sn_4S_{17}]$.

Even whole single crystals of compound **1** can be ion-exchanged to give compound **4**,[17] which could be characterized by single-crystal X-ray diffraction. Figure 3c,d depicts typical well-formed crystals of pristine and ion-exchanged material. Crystallographic analysis on such a single crystal confirmed the replacement of only five of the K atoms (K2 and K3 from the large cavities),[18] whereas the K1 site remained totally unaffected. Again this result is consistent with the view that K1 may be necessary to form the $\{Sn[Zn_4Sn_4S_{17}]\}^{6-}$ framework.

The pale-yellow compound **1** and the analogues **2** and **3** show an optical energy gap of ≈ 2.87 eV, which indicates that they are semiconductors with wide band gaps. They also have high optical transparency to electromagnetic radiation, which begins from 2.87 eV and extends down to 0.30 eV as determined from combined IR–near-IR–UV/Vis spectroscopy. The high transparency and the noncentrosymmetric lattice of **1** prompted us to check for possible nonlinear optical (NLO) behavior. We note that the crystal structures of compounds **1**–**4** have the same topology and belong to the same point group $-42m$ as that of $AgGaS_2$. The latter has attained special interest for middle- and deep-IR applications due to its large NLO coefficients and high transmission in the IR region.[19] By using a pulsed Nd-YAG laser on polycrystalline samples of **1**, we observed the presence of a second harmonic generation (SHG) signal. More quantitative experiments are needed, however, to fully assess the NLO behavior of **1**–**4** materials.

In conclusion, $\{Sn[Zn_4Sn_4S_{17}]\}^{6-}$ is the first extended framework based on supertetrahedral $[M_4M'_4S_{17}]^{10-}$ clusters (P1) linked through metal ions. The compound is an ion-exchange material with properties reminiscent of those of small-pore zeolites. We are currently investigating the ion-exchange properties in more detail and the possibility of synthesizing mesostructured open frameworks by using discrete soluble P1 chalcogenide clusters and various metal linkers.[20]

[7] $K_6Sn[Zn_4Sn_4S_{17}]$ (**1**): A mixture of Sn (0.5 mmol), Zn (0.4 mmol), K_2S (1 mmol), and S (8 mmol) was sealed under vacuum ($\approx 10^{-4}$ torr) in a 9-mm silica tube, heated ($\approx 40\,^{\circ}C\,h^{-1}$) to 400 °C for 96 h, and then cooled to 25 °C at a rate of $6\,^{\circ}C\,h^{-1}$. The excess flux was removed with *N*,*N*-dimethylformamide (DMF) to reveal a mixture of pale yellow polyhedral crystals of **1** and orange crystals of $K_2Sn_2S_5$. In some preparations, the product contained a small quantity of S_8, which could be removed by washing with CS_2. Treating the mixture of **1** and $K_2Sn_2S_5$ with aqueous K_2CO_3 (pH 9–10) completely dissolved the ternary phase, and pure compound **1** was obtained (yield ≈30–60%). EDS analysis on several crystals of **1** gave an average composition of $K_{5.6}Sn_{5.2}Zn_4S_{17.2}$.

[14] The split-occupancy sites and possible rattling of these ions inside the cages explains the much higher thermal-displacement parameters of K3 and K2 relative to that of K1.

[15] Reactions aiming to form $K_6Sn[M_4Sn_4S_{17}]$ analogues ($M = Hg^{2+}$, Cd^{2+}, Co^{2+}, Fe^{2+}) or the Se analogue of **1** led to other quaternary and ternary phases. However, compounds with Sn atoms partially replaced by Ge, or Zn atoms partially replaced by other divalent atoms (such as Hg^{2+} or Cd^{2+}) have been isolated, and these results will be published elsewhere. Efforts to prepare $K_6Ge[Zn_4Ge_4S_{17}]$ resulted instead in $K_{10}Zn_4Ge_4S_{17}$.[4]

[16] Interestingly, the material exhibits selectivity against Li and Na ions. In water these have a strongly held hydration sphere that prevents the large hydrated ions from entering the structure. Preliminary ion-exchange experiments of compound **1** with CsCl at room temperature showed that only one K^+ ion can be exchanged by one Cs^+ ion. Crystallographic analysis of the exchanged material showed that only the K3 ions were exchanged with Cs ions.

[17] A typical ion-exchange experimental route for the preparation of compound **4** is as follows: An excess of solid RbI (0.2 mmol) was added to a suspension of compound **1** (0.01 mmol) in water (20 mL). The mixture was stirred for ≈12 h. Then, the yellowish-white crystalline material was isolated by filtration, washed several times with water, acetone, and ether (in this order), and dried in air.

[18] $Rb_5KSn_5Zn_4S_{17}$ (ion-exchanged), space group $I\bar{4}m2$, $a = 13.8354(10)$, $c = 9.8893(9)$ Å, $V = 1893.0(3)$, $Z = 2$, $R1(F) = 0.0793$, $wR2(F^2) = 0.1519$. Further details on the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (fax: (+49) 7247-808-666; e-mail: crysdata@fiz-karlsruhe.de), on quoting the depository number CSD-415017.

Nanostructures

Metallic Nanowires of Nb_3Te_4: A Nanostructured Chalcogenide**

Hannah K. Edwards, Pamela A. Salyer, Martin J. Roe, Gavin S. Walker, Paul D. Brown, and Duncan H. Gregory**

Since the discovery of carbon nanotubes,[1] there has been a sharp growth in the research of carbon nanostructures and, latterly, inorganic nanotubes and wires. The promise of a greater breadth of chemical and physical properties from inorganic nanostructures over their carbon counterparts has led to a proactive search for inorganic compounds with the capacity to be synthesized as nanowires or nanotubes. This evolving area of nanomaterials chemistry promises novel

properties through the transition from the bulk phase to the nanoscale and the introduction of additional design elements for materials, such as quantum confinement. The first inorganic nanotubes were synthesized by Tenne[2] and many new inorganic nanostructures have been produced since through a small number of increasingly understood synthetic methods.[3] By far the largest and most-studied family of these inorganic nanostructures is the transition-metal chalcogenides. This family is dominated by the dichalcogenides MX_2 (M = Group 4–6 metals, Re; X = S, Se, Te),[2–4] whose component layers of MX_6 polyhedra, which are separated by van der Waals interactions, are conducive to the rolling or scrolling required for the formation of nanotubes or wires (similar to the "dangling bonds" in graphene layers).[5] Only two nanostructured niobium chalcogenides are known, NbS_2[6] and $NbSe_2$.[7] Additionally, nanoscaled $NbSe_3$ has also been obtained after being physically cleaved from larger crystals.[8] Furthermore, and perhaps surprisingly, only one example of a metal telluride nanomaterial has been reported so far, the dichalcogenide $MoTe_2$.[9] Herein, we report the first example of a new class of inorganic nanowire, the telluride Nb_3Te_4. The niobium telluride is unique among the nanostructured chalcogenides in terms of its stoichiometry and, crucially, its structure. In contrast to the dichalcogenides, this 3:4 nanostructured compound is the first to be grown that is derived from a 1D bulk structure. The ensuing electronic properties of such nanowires can be inferred directly from the 1D crystal structure of the material.

Niobium telluride nanowires were synthesized at elevated temperature by direct chemical vapor transport (CVT) from the respective elemental powders in a sealed system (see the Experimental Section). The transition of the starting material from an intimate mixture of powders to nanostructured product was followed (ex situ) by powder X-ray diffraction (PXD; Figure 1). Elemental Nb and Te react after 1 h at 900 °C to form $NbTe_2$ (**1**; Figure 2a), which converts into Nb_3Te_4 (**2**) after 1 week. Both the Nb/Te phases are present at the intermediate times of 4 h, 1 day, and 3 days. Material held at 900 °C for 1 h and then annealed at 1160 °C for 2 days also converts from $NbTe_2$ into Nb_3Te_4 (**3**). Secondary electron (SE) images from scanning electron microscopy (SEM) show well-defined particles for **1** and **2**, as opposed to clusters of nanowires for **3**. Hexagonal lattice parameters of $a =$ 10.665(5) and $c = 3.643(2)$ Å were obtained for **3** from PXD data, which were in excellent agreement with previously reported single-crystal data.[10] The nanowires grow out from a central core as "sea-urchin-like" clusters (Figure 2b) with lengths of the order of 30 μm. Energy-dispersive X-ray spectroscopy (EDX) analysis yielded an Nb/Te atomic ratio of 43:57 (3:4), which is consistent with Nb_3Te_4 and in agreement with the PXD data. Furthermore, back-scattered electron (BSE) imaging indicated a lack of high contrast between the wires, thus suggesting the sample composition to be relatively constant throughout.

X-ray photoelectron spectroscopy (XPS) analysis of **3** yielded a Nb/Te elemental ratio of 0.762:1, again in close agreement with the expected ratio of 0.75:1 for Nb_3Te_4. Furthermore, high-resolution spectra gave binding energies (BEs) of 202.9 and 572.7 eV for the Nb and Te centers in **3**, concomitant with BEs in Nb_3Te_4 of 202.8 and 572.6 eV, respectively.[11] Additional oxide peaks at 206.8 and 576.3 eV were in excellent agreement with the ternary oxides

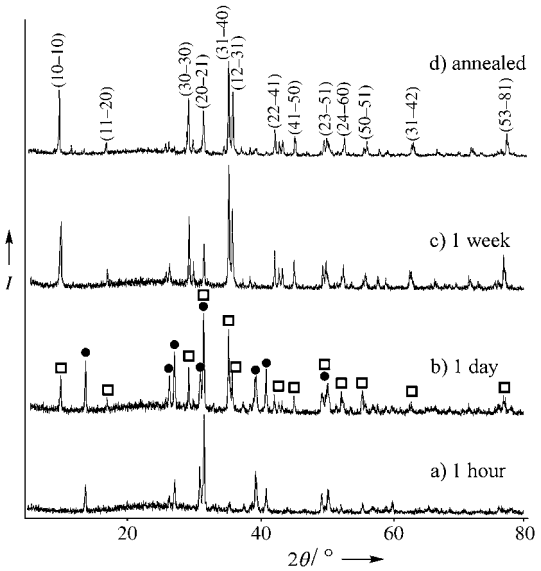

Figure 1. XRD patterns of samples sintered at 900 °C after a) 1 h (**1**), b) 24 h, and c) 1 week (**2**) showing the gradual transformation of **1** (solid circles) into **2** (open squares). These samples did not contain nanowires. d) XRD pattern of **1** sintered for 1 h at 900 °C followed by annealing at 1160 °C for 2 days. The resulting sample **3** was composed of clusters of nanowires. (Major peaks are indicated with indices.)

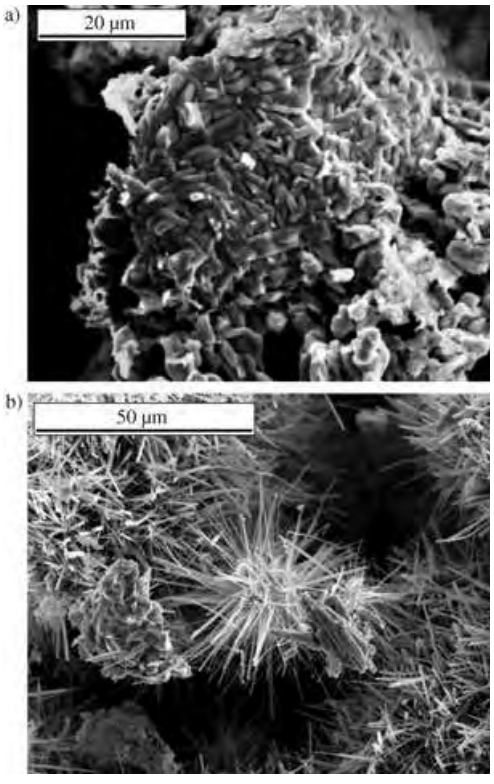

Figure 2. SEM micrographs of a) $NbTe_2$ particles after 1 h at 900 °C and b) a cluster of Nb_3Te_4 nanowires. The nanowires emanate from larger core particles of Nb_3Te_4.

$Nb_2Te_3O_{11}$ and $Nb_2Te_4O_{13}$ (where the BEs for the Nb and Te centers are 207.0 and 576.1 eV, respectively),[12] thus suggesting some surface oxidation of the telluride that probably occurred during postsynthetic handling. Similar oxide-layer phenomena are observed with nanotubes of NbS_2.[6b]

Transmission electron microscopy (TEM) analysis revealed the wires are straight with diameters of 50 nm–1 μm (Figure 3). The nanowires exhibit bundled structures, as

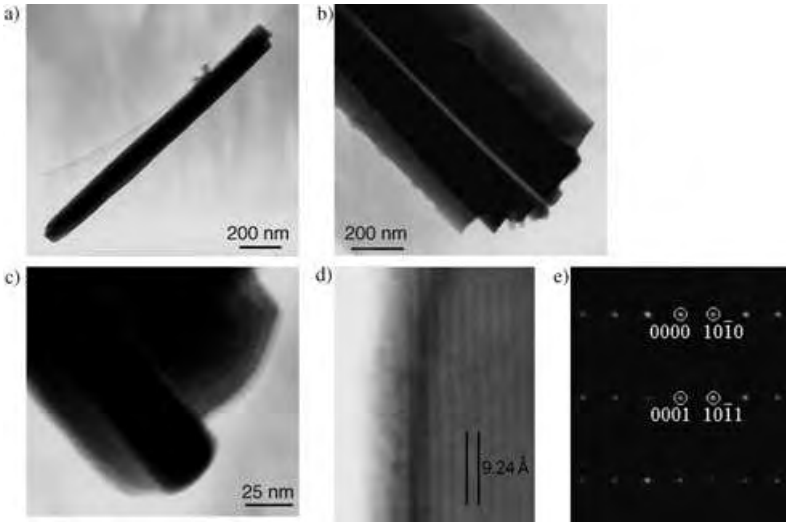

Figure 3. TEM images and SAED patterns of the Nb_3Te_4 nanowires. a) TEM image of a single nanowire. b) TEM image of bundled nanowires. c) High-magnification TEM image of rounded nanowire ends illustrating the amorphous surface layer found on some wires. (d, e) TEM image and corresponding [1−210] SAED pattern of the (10−10) lattice fringes of a Nb_3Te_4 nanowire.

if composed of many smaller filaments. Similar bundles are observed with NbS_2 and WS_2, for example,[6a,13] although for the telluride, selected-area electron diffraction (SAED) studies confirmed the presence of single crystalline wires, thus suggesting a cooperative growth mechanism. Many wires were found to have rounded ends. The indexing of the nanowire SAED patterns was consistent with the hexagonal $P6_3/m$ structure of Nb_3Te_4[10] and the indexing from PXD. TEM also showed the presence of a thin (< 5 nm) surface layer of amorphous material covering the ends and sides of some wires, which is consistent with the surface oxidation indicated by XPS. The combined PXD, XPS, and SAED results indicate that the wires have a Nb_3Te_4 core with a surface oxide layer of niobium(v) tellurate. High-resolution electron microscopy (HREM)/SAED revealed that Nb_3Te_4 wires grow with the [0001] direction parallel to the long axis of the wire. The orientation of the Nb_3Te_4 planes was also confirmed by measuring the lattice fringes (Figure 3d). The corresponding SAED pattern of projection [1−210] is shown in Figure 3e, where the plane spacings of 9.24 Å correspond to the (10−10) (i.e., 100) planes of Nb_3Te_4 (9.2414 Å).[10] This orientation leads to Nb−Nb chains and open channels running parallel to the long axis of the wire (Figure 4).

Separated wires from **3** display weak, temperature-independent magnetism between 1.8 and 300 K, which is characteristic of a Pauli paramagnet. The bulk material is reported to be a 1D metal and a superconductor (from electrical resistivity measurements) at approximately 2 K.[14] However, no anomaly in the specific heat was observed until 0.5 K and no Meissner effect is seen above 1.4 K.[15] Our results for Nb_3Te_4 nanowires concur with these earlier findings, thus suggesting that the wires are metallic but not superconducting above 1.8 K.

Although a precise growth mechanism has not yet been established, it is evident from investigating the heating regimes that the annealing process is fundamental to the growth of the nanowires. The elements first react to form $NbTe_2$ crystallites, which then transform to Nb_3Te_4 nanowires at 1160 °C. Elemental Te has a melting point of 449.5 °C,[16] and hence should be molten during the initial reaction step. It is considered that a CVT process subsequently occurs at elevated temperature to yield Nb_3Te_4 nanowires from the gas phase which then seed and nucleate outward from an initial core of material. This model is reinforced by SE images showing the characteristic sea-urchin-like form (Figure 2b). SE observations also indicate the formation of hollow-core particles which is consistent with mass transport from the inside to the outside. It is worth noting that transformation from $NbTe_2$ to Nb_3Te_4 should proceed through the loss of Te, but no Te-containing phases, other than Nb_3Te_4, were detected in the products by PXD. Indexing of the $NbTe_2$ phase reveals contraction along the *c* axis (i.e., between the Nb−Te layers) relative to the reported parameters,[17] thus suggesting that the initial telluride formed is $Nb_{1+x}Te_2$, by analogy to $Nb_{1+x}S_2$ and, for example, $V_{1+x}Te_2$.[18,19] This ditelluride phase is a subject of our further investigations.

The crystallographic orientation of the wires show that the growth direction is along the hexagonal *c* axis. Nb_3Te_4 has a large *a* value (10.671 Å) and small *c* value (3.647 Å). The growth direction of inorganic nanotubes and wires is commonly along that of the shortest lattice parameter. Nb_3Te_4 wires are consistent in this respect: they grow with their

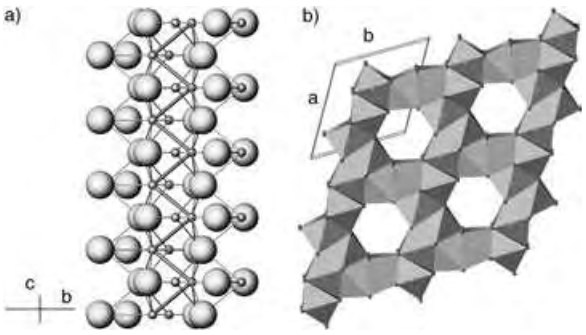

Figure 4. a) Crystal structure of Nb_3Te_4 to illustrate the Nb−Nb zigzag chains running parallel to the *c* axis (small spheres indicate Nb; larger spheres Te) and b) a polyhedral representation in the *a*–*b* plane, which shows the Nb-centred edge-sharing octahedra and open channels that also lie parallel to the *c* axis.

[00*l*] planes perpendicular to the long axis of the wire. Hence, this growth direction is distinct from chalcogenide nanowires that take a 2D structural basis (smaller *a* and larger *c* axis).[2,4] It is of key importance to the physical properties of the nanowires that the long axis of the wire is also in the same direction as the shortest Nb–Nb bond; infinite zigzag Nb chains run along the *c* axis. The intrachain Nb–Nb bond length is 2.973 Å, (Nb metal, Nb–Nb = 2.86 Å),[20] whereas the interchain Nb–Nb bond is much longer at 3.854 Å.[5] Anisotropic conduction along the *c* axis in large single crystals of Nb_3Te_4 was verified through resistivity and magnetoresistance experiments.[14b,21] Nb chains are able to carry charge linearly and are decoupled by the intervening Te atoms. This behavior should be mirrored at the nanoscale, thus inviting compositional and structural modification through substitution (of Te and/or Nb atoms) and intercalation ($M_xNb(Ta)_3X_4$); for example, the isostructural $Nb_3S(Se)_4$ and intercalates with M = In, Hg, Tl, and Cu, in which $0 < x \leq 1$[22] are known bulk materials. Hence, there is a real prospect of designing a new family of 1D-derived nanowires exhibiting metallic conduction, charge-density wave phenomena, superconductivity, or fast ionic transport. A systematic study of the growth and properties of such a family is currently underway.

In summary, we have synthesized metallic nanowires of Nb_3Te_4 for the first time by a high-temperature CVT process. This novel 1D system offers a promising basis for a new family of tailored nanostructured functional materials.

Experimental Section

Nb_3Te_4 nanowires were prepared from ground mixtures of niobium (99.9%, Aldrich) and tellurium powders (99.99%, Alfa; molar ratio = 3:4) in a nitrogen-filled recirculating glove box. The mixtures were initially heated in evacuated (approximately 10^{-3} mbar) 12-mm diameter sealed silica ampoules to 900 °C for between 1 h and 1 week. After quenching the ampoules in air, the ampoules were subsequently annealed at 1160 °C for 2 days. The resulting low-density black powder was characterized by PXD (Philips X'Pert θ-2θ diffractometer; $Cu_{K\alpha}$ radiation), SEM (JEOL 6400 SEM with an Oxford Instruments ISIS EDX system), XPS (VG Scientific Escalab Mark II spectrometer using $Al_{K\alpha}$ radiation at an anode potential of 10 kV and a filament emission current of 20 mA), and TEM (JEOL 2000fx TEM with an ISIS EDX system) for nanoscale imaging and SAED studies. Samples for analysis by SEM and XPS were prepared by depositing powder on to a carbon tab of sufficient thickness to prevent detection of the underlying carbon. Samples for TEM analysis were prepared by sonicating the powders in acetone for 3 min and then transfering drops of the suspension by pipette onto holey carbon-film Cu grids. Samples for SQUID (superconducting quantum interference device) analysis were prepared in similar a manner to separate the nanowires from any residual powder and were then loaded into gelatine capsules. Magnetic measurements were performed using a quantum design MPMS 5T SQUID susceptometer under a field of 1 Oe between 1.8 and 300 K.

Molecular Targeting

Photo-Cross-Linked Small-Molecule Affinity Matrix for Facilitating Forward and Reverse Chemical Genetics**

*Naoki Kanoh, Kaori Honda, Siro Simizu, Makoto Muroi, and Hiroyuki Osada**

Affinity purification of small-molecule binding protein has been one of the most important techniques in forward chemical genetics (Figure 1a).[1,2] Once hit compound(s) which induce a specific phenotype in a cellular system are identified, the next step is to identify the molecular target. Thus, derivatization of the small molecules and structure–activity relationship studies are conducted to prepare tagged probes (for example, biotin conjugates) that can be used in a pull-down assay. Many targets of biologically important drugs have been discovered or identified by using this technique.[3–6] However, it remains challenging and time-consuming to derivatize small molecules without a loss in biological activity, and an easy-to-use, universal approach would be of great benefit in this context.

Affinity purification can also be used in reverse chemical genetics[7] for other purposes (Figure 1b). In vitro binding assays including small-molecule microarrays have been used to identify small-molecule ligands for proteins of interest. Although these techniques have led to the successful identification of ligand candidates, they do not provide information about the specificity of the ligand–protein interaction. If the ligand could be immobilized on an affinity matrix in a manner that was independent of the functional groups present, pull-down experiments and competitive binding assays using this matrix could be used to confirm whether or not an interaction is specific. We have looked for a rapid and general approach for the immobilization of small molecules on an affinity matrix to enhance the forward and reverse chemical genetics approaches described above.

Recently, we reported a coupling method that enables the introduction of a variety of small molecules onto glass slides through a photoaffinity reaction.[8] By using this method, aryl

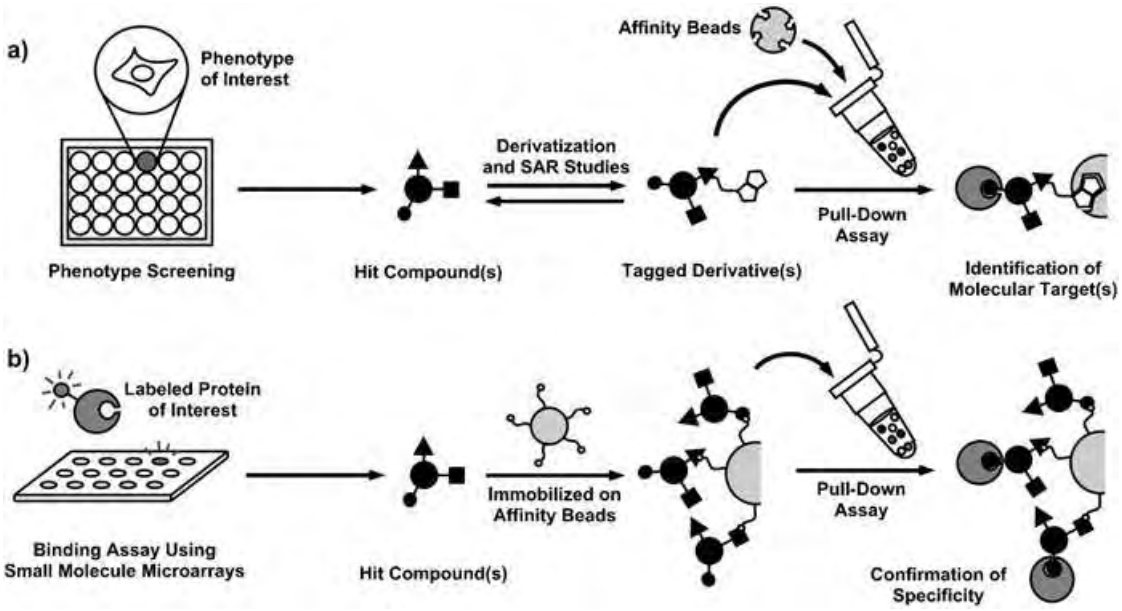

Figure 1. Affinity purification of small-molecule binding proteins in forward and reverse chemical genetics studies.

diazirine groups covalently attached to glass slides are transformed upon irradiation with UV light into highly reactive carbenes, which in turn bind to or insert irreversibly into a proximal small molecule in a manner that is independent of the functional groups.[9] This method, referred to as photo-cross-linking, has proven useful in the construction of small-molecule microarrays.[10] It is expected that a similar chemical approach could be used to introduce small molecules onto affinity gel, such as onto agarose beads. To test this hypothesis a photoaffinity linker **1** was introduced on agarose beads to prepare photoaffinity-linker-coated (PALC) agarose beads **3**, and the photo-cross-linking of complex small molecules onto **3** was demonstrated.

The preparation of **3** and the immobilization of small molecules on **3** were performed in a straightforward manner

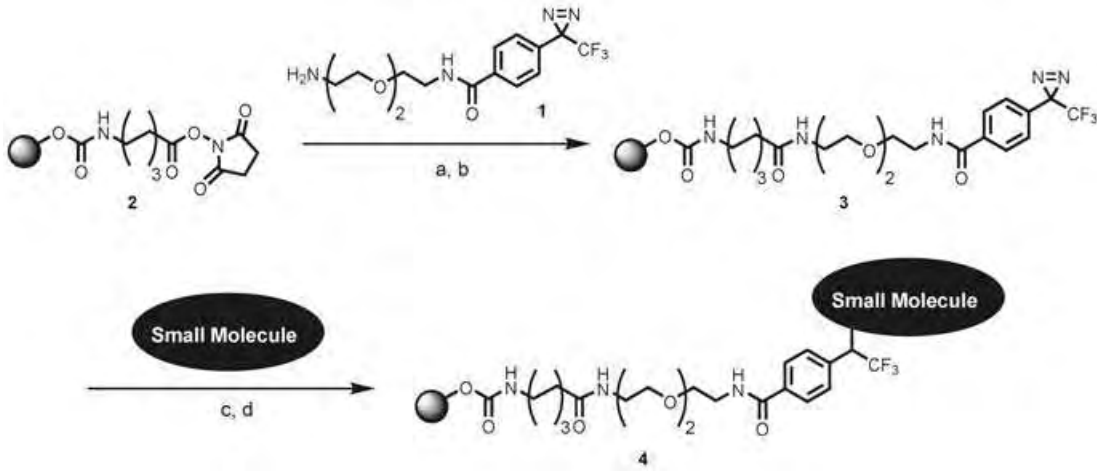

Scheme 1. Preparation of PALC agarose beads and photo-cross-linking of a small molecule. Reagents and conditions: a) **1**, $NaHCO_3$, NaCl, H_2O/dioxane (1:1), RT, 2 h; b) 1.0 M aq ethanolamine, RT, 1 h; c) 10 mM methanolic solution of small molecules, drying; d) irradiation at 365 nm, 4 J cm^{-2}; washing with organic solvent and water.

(Scheme 1). Activated CH sepharose 4B beads (Amersham Bioscience, Uppsala, Sweden; **2**) were first coupled with the photoaffinity linker **1**, and the beads were then blocked with 1.0 M aqueous ethanolamine, by using a solid-state coupling approach, to give **3**. Introduction of the photoaffinity linker **1** on the beads **2** was confirmed by high-resolution solid-state ^{19}F NMR measurements of **3** ($\delta = -65.9$ ppm, ArCF_3). To immobilize structurally diverse small molecules on **3** a methanolic solution of a small molecule was premixed with **3**, and then the mixture was concentrated and dried in vacuo. The dried beads were exposed to UV light (365 nm, 4 J cm^{-2}) from a UV cross-linker, and then washed thoroughly with methanol and water.

Figure 2 shows that the immobilization of the fluorescent rhodamine B depended on the photoaffinity linker **1** and irradiation with UV light: when agarose beads (sepharose CL-6B, Amersham Bioscience, Uppsala, Sweden) were irradiated in the presence of rhodamine B and then washed, no fluorescence was detected by fluorescence microscopy (Figure 2b). Fluorescence was observed only on PALC beads which had been irradiated in the presence of rhodamine B and then washed (Figure 2d). No fluorescence was observed on the beads in the absence of UV irradiation (Figure 2f). These results suggest that the photo-cross-linking strategy could be applied not only in studies using glass slides but also in assays with agarose beads.

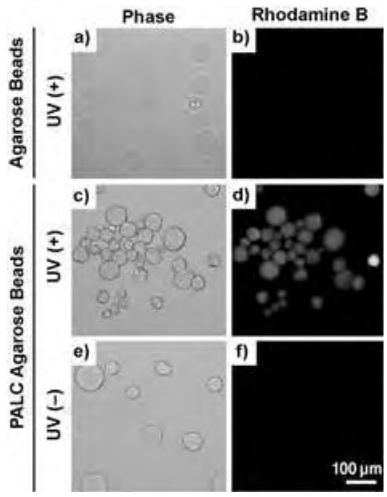

Figure 2. Observation of beads with immobilized rhodamine B by microscopy. Agarose beads and PALC agarose beads were mixed with rhodamine B and dried in vacuo. After incubation of the beads with or without irradiation, they were washed with methanol and water, and were observed under a microscope in the phase-contrast (a, c, e) or fluorescence mode (b, d, f).

To validate the binding ability of small molecules that had been photo-cross-linked on affinity beads with their target proteins we used the immunosuppressive drugs cyclosporin A (CsA) and FK506 (FK) as model ligands. CsA and FK are known to bind to the cellular targets cyclophilin A[11] and FKBP12,[3] respectively. In the specific case of CsA, photo-cross-linking with 4-benzoylbenzoic acid in solution[12] and a site-selective free-radical reaction on an appropriately protected CsA derivative[13] have been reported. Both molecules were photo-cross-linked on **3**, as shown in Scheme 1. The resulting CsA beads were incubated with the cell lysates of an *E. coli* BL21(DE3)pLysS strain over-expressing GST-cyclophilin A (GST-CypA), and the FK beads were incubated with the same *E. coli* strain, but which over-expressed $(His)_6$-FKBP12 (Figure 3a). First, we were able to identify a protein band of approximately 40 kDa that co-precipitated with the CsA beads (Lane 1). To determine the specificity of this interaction we examined whether or not CsA could compete for the binding of the CsA beads to the 40-kDa protein. The binding of CsA beads to the 40-kDa protein was found to be completely blocked by the addition of 10 and 100 μM CsA (Lanes 2 and 3), although no change in binding was observed in a control experiment using DMSO (Lane 4). The 40-kDa protein was reactive with an *anti*-GST antibody, thus indicating that the protein was GST-CypA (Figure 3b, left panel).

We were also able to identify a band of approximately 16 kDa (Figure 3a, Lane 6) that was reactive with an *anti*-$(His)_6$ antibody (Figure 3b, right panel); binding between the FK beads and the 16 kDa protein was blocked by a dose-

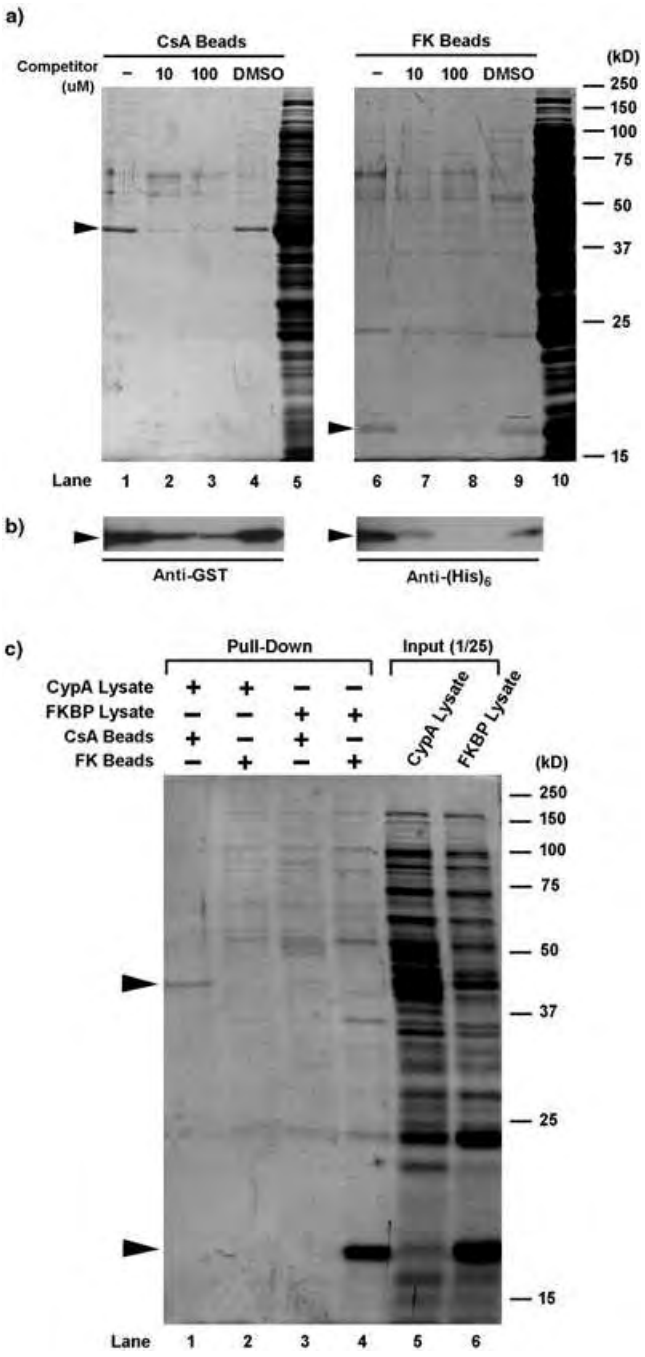

Figure 3. Detection of binding proteins for small-molecule-immobilized beads. Cell lysates of *E. coli* over-expressing GST-CypA or $(His)_6$-FKBP12 (namely, CypA lysate or FK lysate) were incubated with or without competitor. CsA beads or FK beads were then added to absorb the binding proteins. After the beads had been washed with the incubation buffer they were resuspended in SDS sample buffer, heated, and subjected to SDS-PAGE. The gels were visualized by CBB staining. a) Competition experiments. Lanes 1–4: CypA lysate plus CsA beads with CsA as a competitor; Lane 5: CypA lysate (loading control); Lanes 6–9: FK lysate plus FK beads with FK as a competitor; Lane 10: FK lysate (loading control). b) Western blot analysis. Protein bound specifically to the CsA beads was reactive to *anti*-GST antibody (left panel). Protein bound specifically to the FK beads was reactive with an *anti*-(His)6 antibody (right panel). c) Cross-experiments. Lane 1: CypA lysate plus CsA beads; Lane 2: CypA lysate plus FK beads; Lane 3: FK lysate plus CsA beads; Lane 4: FK lysate plus FK beads; Lane 5: CypA lysate (loading control); Lane 6: FK lysate (loading control).

dependent competition by the addition of FK506 (Figure 3a, Lanes 7 and 8). These results demonstrated that the protein was $(His)_6$-FKBP12 and also that the binding was specific.

The specificity of the interactions between a photo-cross-linked drug and immunophilin was further confirmed by cross-experiments (Figure 3c). Briefly, GST-CypA and $(His)_6$-FKBP12 did not co-precipitate with the FK and CsA beads, respectively (Lanes 2 and 3).

The next issue to be addressed was whether the photo-cross-linked affinity beads would be able to both purify the over-expressed proteins and also identify the cellular target(s) of the immobilized ligand. To address this question we incubated the CsA beads with Jurkat cell lysate, and the co-precipitated proteins were analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE, Figure 4a). This procedure led to the detection of a protein band of approximately 20 kDa by Coumassie Brilliant Blue (CBB)

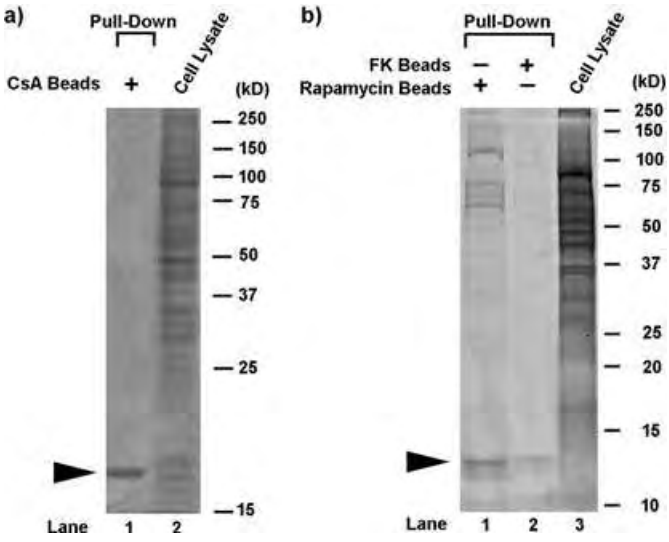

Figure 4. Detection of CsA-, FK-, and rapamycin-binding protein from the Jurkat cell lysate. The Jurkat cell lysate was first incubated with beads on which each of the small molecules were immobilized (CsA for Lane 1 of (a); rapamycin for Lane 1 of (b); FK for Lane 2 of (b)). The beads were then washed with lysis buffer containing 0.3% triton X-100, resuspended in SDS sample buffer, heated, and subjected to SDS-PAGE. The gels were visualized with CBB staining. The arrowheads indicate the bands which disappeared on addition of the respective small molecules (10 μM).

staining (Lane 1). To identify the protein the protein-containing region was excised and digested on SDS-polyacrylamide gel, and the resulting peptides were extracted and analyzed by MALDI-TOF MS (Supporting Information). The protein was identified from peptide mass fingerprinting (PMF) using the Mascot search program (Matrix science Inc., USA) and the Swiss-Prot database as human cyclophilin A with a protein score of 125—a score of greater than 52 is considered significant ($p < 0.05$). Besides being successful in the case of CsA beads, we also succeeded in purifying a human FKBP12 from Jurkat cell lysate by using both the FK beads and beads on which rapamycin was photo-cross-linked (Figure 4b).[14]

In summary, we have prepared PALC beads and demonstrated that photo-cross-linked small-molecule agarose beads can be used to identify and purify the binding protein. It was of note that complex small molecules such as FK506, rapamycin, and cyclosporin A could be introduced on the affinity matrix by using a uniform and straightforward procedure. Although the present procedure can not be applied to small molecules that degrade upon UV irradiation, technologies aimed at immobilizing ligands on an affinity matrix in a functional-group-independent manner are expected to facilitate the identification of molecular targets of small molecules in forward chemical genetics, and is also considered potentially useful for the confirmation of specificity between small molecules and proteins of interest in the field of reverse chemical genetics.

Nanostructure Synthesis

Synthesis of Ultrathin Zinc Nanowires and Nanotubes by Vapor Transport**

*Xiaogang Wen, Yueping Fang, and Shihe Yang**

One of the most important challenges in the synthesis of nanowire materials is the control of size and morphology.[1,2] With regards to metallic nanowires, most studies have so far concentrated on gold and silver nanowires,[3–6] while less has been reported about their zinc counterparts. Ultrathin zinc wires are expected to display intriguing properties, such as metal–insulator transitions and 1D superconductivity. The magnetoresistance and thermopower of zinc-nanowire composites in insulating matrices were studied by Wu and coworkers,[7] who found that zinc nanowires with a diameter of 15 nm are metallic, whereas smaller nanowires show weak 1D localization with resistivity proportional to $T^{-1/2}$. The thermopower of zinc nanowires with a diameter of 4 nm was found to saturate at −130 μV/K. However, the structural details of the embedded zinc nanowires have not been investigated. Zinc nanowires may also be a good template to form 1D nanostructures of other important materials, such as ZnO, ZnS, and Cu.[8,9] Zinc nanowires and nanotubes with core/shell structures of Zn/ZnO and Zn/ZnS were usually prepared from ZnO[10–12] or ZnS[13–15] as precursors by a vapor–solid (VS) process. Recently, Peng et al. reported the synthesis of zinc nanofibers with diameters of 50–200 nm by evaporation of pure zinc powders.[16] Also, zinc nanowires have been prepared by electrochemical etching in HF solution.[17] Until now, however, the synthesis of discrete, ultrathin (< 10 nm) zinc nanowires and nanotubes had not been reported, although 6-nm-wide ZnO nanobelts have been described recently.[18] Herein, and to the best of our knowledge, we report the first synthesis of discrete zinc nanowires and nanotubes, with diameters of several nanometers, by a VS process using zinc foil as the precursor. The key to our success is the use of H_2O and NH_3 as molecular directing agents.

To synthesize zinc nanowires, the evaporation temperature was fixed at 900 °C, as lower temperatures (below 750 °C) failed to yield any zinc-based products. Figure 1 a shows an X-ray diffraction (XRD) pattern of as-prepared zinc nanowires. All of the observed signals for the sample match very well with those of hexagonal zinc ($a = 2.665$, $c = 4.947$ Å,

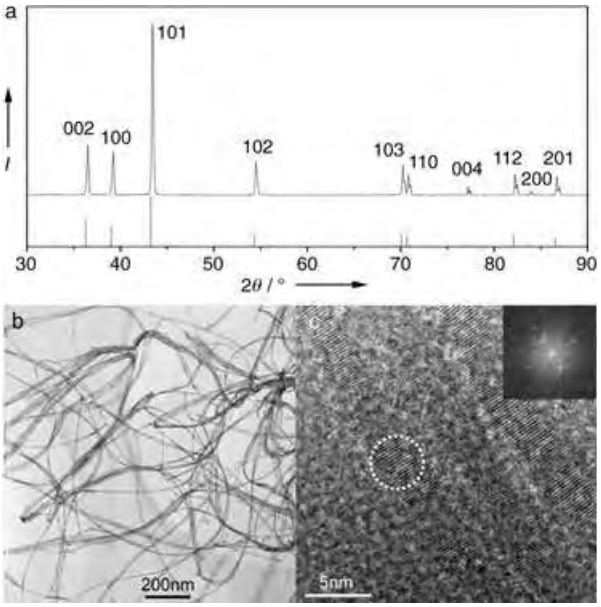

Figure 1. a) XRD pattern of the zinc nanowires prepared by the vapor-transport method, b) a typical TEM image of zinc nanowires prepared in an NH_3 atmosphere, and c) HRTEM image of three parallel zinc nanowires (the inset shows the corresponding FFT pattern of the sample indicated by the white dotted circle in the main panel). The zinc nanowires were deposited at 190–250 °C.

obtained from the JCPDS 04-0831 card), which indicates that the nanowires consist predominantly of pure zinc. Shown in Figure 1 b is a typical transmission electron microscopy (TEM) image of the zinc nanowires deposited over a temperature range of 190–250 °C, with a flow of N_2 of 20 sccm (standard cubic centimeters per minute) for carrying NH_3 (with a trace amount of residual water, $H_2O/NH_3 \approx 1{:}20$). The zinc nanowires have a uniform diameter of 3–8 nm (average diameter ≈ 5 nm) along its entire length, which is up to tens of micrometers. Some of the nanowires are bundled together. Figure 1 c shows a high-resolution TEM (HRTEM) image of three parallel zinc nanowires. The nanowires are 3–4 nm in diameter with excellent uniformity. Clear fringes perpendicular to the nanowire axis can be seen with an interplanar spacing of 0.25 nm in accordance with the distance between the (002) crystal planes, which suggests that the zinc nanowires grow along the [001] direction, that is, along the direction of the *c* axis of hexagonal zinc. This observation is also reflected in the fast Fourier transform (FFT) pattern (inset, Figure 1 c) of the area indicated by a white dotted circle in the main panel.

The products deposited in regions of different temperature of the furnace have different sizes and morphologies, as demonstrated by their TEM images (see the Supporting Information). The products formed in the 200 °C region are uniform, ultrathin nanowires with a diameter of 3–8 nm. In the 150 °C region, although thin nanowires of several nanometers in diameter can still be found, much thicker nanowires (50–70 nm) are found abundantly in a more twisted form. Finally, when the deposition temperature is 100 °C, the nanowires become even thicker (90–100 nm in diameter) and, moreover, these twisted nanowires are tangled together to form a network structure. Note that although the nanowires thicken as the deposition temperature decreases, they all have a pure hexagonal structure based on XRD and energy dispersive X-ray (EDX) analyses. Oxidized surface layers (ZnO) were not identified in these nanowires by HRTEM.

When the ammonia solution was replaced by pure water, ultrathin zinc nanotubes, rather than nanowires, were obtained as shown in Figure 2. In this experiment, the water

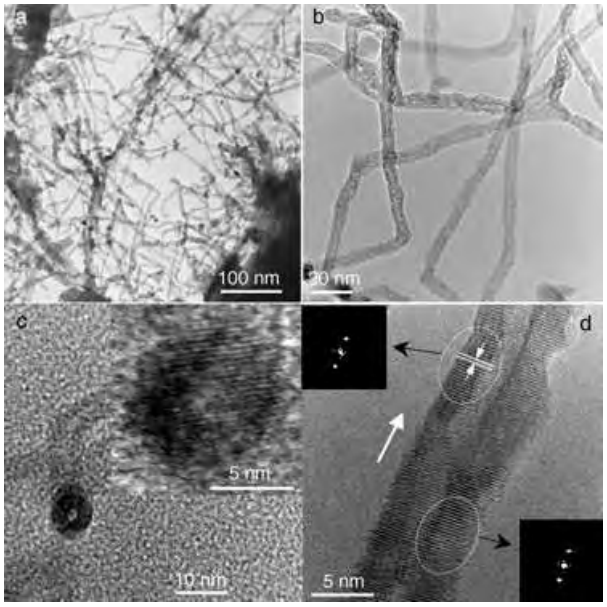

Figure 2. TEM images of zinc nanotubes synthesized in a water-vapor atmosphere. a) Low magnification, b) higher magnification, c) cross-sectional view of a tube end (the inset shows a HRTEM image), and d) HRTEM image of a single zinc nanotube (the insets show the FFT patterns from regions enclosed by the white dashed ellipsoids in the main panel).

vapor was transported into the reaction tube by N_2 through a sealed water bubble aeration setup. Figure 2 a is a low-magnification TEM image of the as-prepared zinc nanotubes, which have a uniform diameter (5–8 nm) along their length (several hundred nanometers to several micrometers) and are mostly open-ended. A higher magnification TEM image is shown in Figure 2 b and reveals the tubular structure more clearly. The inner diameters of the nanotubes are about 1–2 nm and the wall thicknesses are about 2–3 nm. The nanotubes are not very smooth on either the inner or outer surfaces. Although the 1D structure is generally tubelike, the zinc tubes are not completely continuous and the inner channels are often blocked. Figure 2 c highlights the end of a single nanotube so that the cross section can be seen directly. The nanotube appears to have a circular cross section; the diameter of the inner tube is 1.5 nm and the wall thickness is 3.0 nm. From the HRTEM image of the tip of the zinc nanotube in the inset of Figure 2 c, well-defined fringes with a spacing of approximately 0.27 nm can be seen and correspond to double the spacing between the (110) crystal planes ($d_{110} = 0.133$ nm). Consequently, the cross-sectional plane of the nanotube is the *ab* plane of hexagonal zinc, which suggests

that the growth direction of the nanotube is [001], similar to that for the zinc nanowires. Figure 2d shows a higher magnification HRTEM image of a single zinc nanotube. The tubelike structure is seen more clearly, and fringes spaced by approximately 0.25 nm are found to lie perpendicular to the tube axis, which confirms the [001] growth direction of the nanotube. As can be seen from the inset of Figure 2d, the FFTs of both side walls (enclosed by white dotted ellipsoids in the main panel) display the same spotted pattern and indicate the same crystal structure with the length of the nanotube extending along the [001] direction.

When only pure N_2 was used as the carrier gas, zinc nanowires could not be obtained. Instead, most of the products were well-defined polyhedral microparticles and XRD data indicate that the products are still pure zinc (see the Supporting Information). The microparticles deposited on an aluminum-foil substrate have a uniform size of 3–5 μm. Higher magnification scanning electron microscopy (SEM) images indicate that the particles have faceted morphologies that range from hexagonal columns (major) to polyhedra (minor; see the Supporting Information).

For comparison, the vapor–liquid–solid (VLS) approach was also explored to synthesize zinc nanowires. A small piece of lead foil (placed in the high-temperature region together with the zinc foils) was chosen as a catalyst as it has an appropriate melting point (325 °C). N_2/NH_3 was used as the carrier gas, while the other conditions were kept the same. Indeed, zinc nanowires could also be produced by the VLS process as shown in Figure 3. Most of the nanowires are

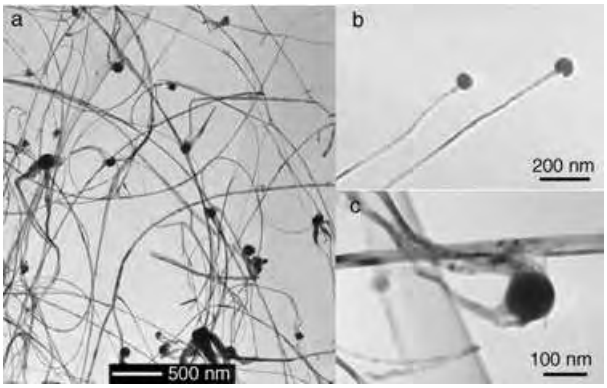

Figure 3. Zinc nanowires prepared by the VLS process. a) A typical TEM image, b) at higher magnification, and c) at even higher magnification to show that several zinc nanowires grow from one catalytic lead nanoparticle.

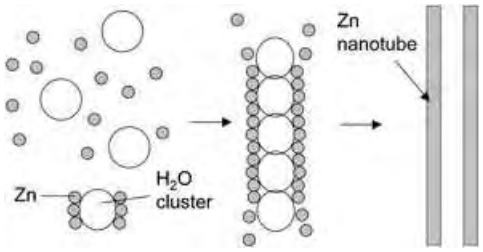
capped by a nanoparticle on their tips (see Figure 3a), as expected for the VLS process. The tips can be seen more clearly in Figure 3b. EDX analysis confirmed that the nanoparticles comprise lead and that the nanowires consist purely of zinc. Interestingly, the diameter of the zinc nanowires here (15–25 nm), although a little larger than the diameter of the nanowires prepared by the VS method, is much smaller than that of the lead nanoparticles (50–60 nm). The fact that thin zinc nanowires can also be formed on large lead nanodroplets by the VLS process is perhaps because of the confining effect of ammonia. In some cases, several zinc nanowires share a common, relatively large catalytic nanoparticle ($\approx$100 nm; Figure 3c), which suggests that this nanoparticle can provide nucleation sites for the growth of several nanowires simultaneously. The zinc nanowires prepared by the VLS method are obtained in a higher yield than those prepared without the lead catalyst, but they are less uniform and have a larger diameter probably as a result of the non-uniform and large sizes of the lead nanoparticles.

Presumably, the formation of the zinc nanowires in the absence of a catalyst is through a vapor–solid (VS) process. The zinc precursor was evaporated at high temperature (900 °C), and the vapor was transferred to the deposition region (200 °C) by carrier gas. On the basis of the data presented above, the size and morphology of the products are mainly controlled by the temperature of evaporation and deposition, and the composition of the carrier gas. A higher evaporation temperature ensures the formation of a sufficient density of zinc atoms or clusters for nucleation as well as a large temperature gradient favorable for the growth of zinc nanowires. At higher deposition temperatures the growth is relatively slow, whereas at lower temperatures the growth is faster. These temperature effects, when considered together with appropriate compositions of carrier gas, can be exploited so that ultrathin nanowires can be synthesized at high temperatures and thicker nanowires at low temperatures.

Here, the carrier gas appears to be the most important factor and is, in fact, essential to controlling the synthesis of the nanowires. The coordination of NH_3 and H_2O molecules to zinc atoms and clusters at the temperature region in which the nanowire deposition occurs plays a particularly important role. In this way, they act as capping agents to promote anisotropic growth of the nanowires. Specifically, the preferential adsorption of NH_3 and H_2O on the surfaces of the zinc nanowire, other than at the tips, has the effect of restraining the radial, but not the axial, growth so that 1D growth is facilitated. It is not surprising that such a molecularly directed growth yields nanowires that are much thinner than those from the VLS process. For the synthesis of zinc nanotubes in a water-vapor atmosphere, water clusters form much more easily through hydrogen-bonding interactions than ammonia clusters in the deposition region and so may act as templates for the nucleation of zinc. Such a zinc-shell structure that is supported by a core of water clusters may eventually evolve into a tubelike structure with open ends as a result of morphological developments of the water-cluster template (Scheme 1). The soft and dynamic nature of the water-cluster



Scheme 1. A schematic representation of a possible mechanism for the formation of zinc nanotubes in the presence of water vapor.

template may explain the observed imperfect structure of the zinc nanotubes. A clearer understanding of the growth mechanisms of the nanowires and nanotubes requires more-detailed studies.

In summary, ultrathin zinc nanowires and nanotubes have been synthesized by both VS and VLS processes with pure zinc. The composition of the carrier gas is the key to controlling the size and morphology of the nanoproducts. Zinc nanowire crystals with diameters as small as 3 nm (average diameter ≈ 5 nm) could be synthesized in an ammonia atmosphere. Furthermore, when water vapor was used instead of ammonia, zinc nanotubes were obtained that are characterized by an inner diameter of 1–2 nm and a wall thickness of 2–3 nm. Our study highlights the essential role of small polar molecules, the adsorption of which modifies the kinetics of crystal growth and thus directs the 1D growth of zinc. Ultrathin metallic nanowires and nanotubes, with sizes that approach the Fermi wavelength, offer new opportunities to explore the effects of size on the transport and photonic properties of these materials and promise a wide range of applications in nanotechnology.

Experimental Section

The experimental setup consisted of a horizontal tube furnace (120 × 10 cm), a quartz tube (100 × 5 cm), and a gas-flow control system. Zinc foils (10 × 10 × 0.1 mm^3; 99.9% purity, Aldrich) were washed with absolute ethanol twice before loading onto a quartz substrate, which was positioned at the end of the quartz tube. A piece of aluminum foil or a quartz slide was positioned at the opening end of the quartz tube to serve as a product deposition substrate. The quartz tube was then mounted in the middle of the tube furnace. A flow of high-purity nitrogen (> 99.995%) was introduced into the quartz tube through a sealed container containing a diluted aqueous solution of ammonia (6.0 M) or pure water at a fast rate (about 200 sccm) for 40 min to remove air from the system. Afterwards, the N_2 flow was adjusted to 20 sccm and the tube furnace was heated to 900 °C at a rate of 30 °C min^{-1}. After heating at this temperature for 5 h, the system was allowed to cool unaided to room temperature and black products were obtained. XRD analyses were carried out on a Philips PW 1830 X-ray diffractometer with a 1.5405-Å $Cu_{K\alpha}$ rotating anode point source operated at 40 kV and 40 mA. Kβ radiation was eliminated with a nickel filter. TEM measurements were performed on Philips CM20 and JEOL 2010F transmission electron microscopes with an accelerating voltage of 200 kV. SEM images were observed with a JEOL 6300F microscope at an accelerating voltage of 15 kV.

Photocatalysis

Visible-Light-Induced H_2 Evolution from an Aqueous Solution Containing Sulfide and Sulfite over a ZnS–$CuInS_2$–$AgInS_2$ Solid-Solution Photocatalyst**

*Issei Tsuji, Hideki Kato, and Akihiko Kudo**

The photocatalytic splitting of water to generate H_2 and O_2 has attracted attention as a clean energy system. An important feature of this system is that it does not require complicated devices: the photocatalysts are simply placed in water, irradiated with sunlight, and then hydrogen is produced by a photocatalytic reaction. This water-splitting reaction does not depend on fossil fuels, and is therefore an ideal method to produce clean hydrogen fuel. The reaction is also attractive from the viewpoint of achieving an artificial

photosynthesis, which converts light into chemical energy. Many active photocatalysts for splitting water under UV irradiation have been reported. In particular, the NiO-loaded $NaTaO_3$:La photocatalyst showed extremely high activity, and the quantum yield amounted to 56% at 270 nm.[1] However, photocatalysts with wide band gaps (3 eV or above) do not absorb visible light, which is a large part of the solar spectrum. It is indispensable to develop highly active photocatalysts with a visible-light response.

A Pt-loaded CdS photocatalyst showed high activity for the evolution of hydrogen from aqueous solutions containing S^{2-} and SO_3^{2-} ions as sacrificial electron donors, under visible-light irradiation, even though most sulfide photocatalysts are unstable during the water-splitting reaction.[2–4] The sacrificial reagents make up half of the water-splitting reaction and they are routinely used as a test to make sure that the photocatalytic materials can reduce H_2O to H_2. Sacrificial electron donors that irreversibly consume photogenerated holes may promote hydrogen evolution. If the reaction could be turned into a practical application for the production of hydrogen gas from by-products such as hydrogen sulfide and sulfur dioxide, which are emitted in hydrogenation and flue-gas desulfurization processes at chemical plants, it would be especially interesting in light of current energy and environmental concerns.[5,6]

Photocatalysts driven by visible light that show high activity for hydrogen evolution, with the exception of the Pt-loaded CdS photocatalyst, have not been investigated until recently. We have succeeded in developing several photocatalysts that are driven by visible light by doping transition-metal ions such as Ni^{2+} and Cu^{2+}, as well as Pb^{2+} into ZnS, which is a highly active photocatalyst for hydrogen evolution under UV/Vis irradiation, even without the presence of a Pt co-catalyst.[7–11] Specifically, Ni- and Cu-doped ZnS photocatalysts showed a high activity for hydrogen evolution without the presence of any co-catalysts, and their apparent quantum yields were 1.3 and 3.7%, respectively, at 420 nm. We also developed solid-solution photocatalysts between ZnS (wide band gap) and $MInS_2$ (M = Cu, Ag; narrow band gap). The energy structures of the solid solutions were controllable by the change in their compositions. At 420 nm, the apparent quantum yields of Pt-loaded $(AgIn)_{0.22}Zn_{1.56}S_2$ (band gap 2.3 eV) and Pt-loaded $(CuIn)_{0.09}Zn_{1.82}S_2$ (band gap 2.3 eV) amounted to 20% and 13%, respectively.[12,13]

We have recently found that the $ZnS–CuInS_2–AgInS_2$ solid solution was a highly active photocatalyst that exhibited an absorption band over a wider wavelength range than $ZnS–AgInS_2$ and $ZnS–CuInS_2$ solid solutions. Herein, we report the evolution of hydrogen over a Ru-loaded $ZnS–CuInS_2–AgInS_2$ solid solution photocatalyst under visible-light irradiation. We also demonstrate hydrogen production under solar-light irradiation (air mass (AM) = 1.5).

Figure 1 shows X-ray diffraction patterns of the previously reported solid solution photocatalysts $(CuIn)_{0.09}Zn_{1.82}S_2$ (**1**) and $(AgIn)_{0.22}Zn_{1.56}S_2$ (**2**) and the solid solution $(CuAg)_{0.15}In_{0.3}Zn_{1.4}S_2$ (**3**). The crystal structure of the solid solution **1** between ZnS and $CuInS_2$ was a zinc-blende, low-temperature phase of ZnS (Figure 1a). The solid solution **2** between ZnS and $AgInS_2$ exhibited the wurtzite structure of a high-temperature phase of ZnS (Figure 1b). For **3**, which can be regarded as a solid solution of three sulfides ($ZnS–AgInS_2–CuInS_2$), diffraction patterns similar to those of both zinc-blende and wurtzite were obtained. The main peaks indicated the presence of zinc blende along with a negligible amount of unidentified impurities. The diffraction peaks of (111) and (222) planes were relatively intensive, thus indicating an anisotropic shape of the powder.

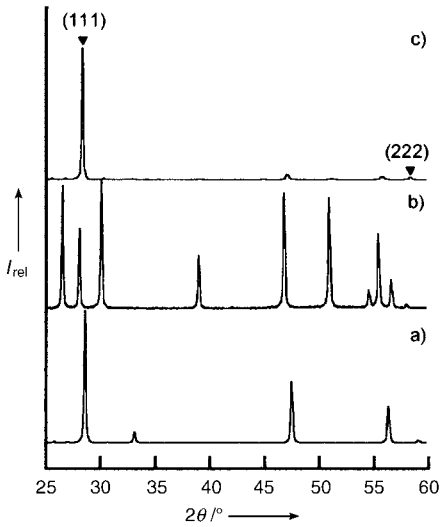

Figure 1. X-ray diffraction patterns (XRD) of the solid solution **1** (a), **2** (b), and **3** (c).

Figure 2 shows SEM images of the solid solution **3**. The small particles were about 200 nm in size (Figure 2a), and the average particle size of the solid solution was relatively small compared with those of the solid-solution photocatalysts **1** and **2** (several micrometers). Some of these small particles were platelike. Extremely large Plate-shaped particles, such as that shown in Figure 2b, were also observed in relatively large numbers. Therefore, we suggest that the anisotropy in

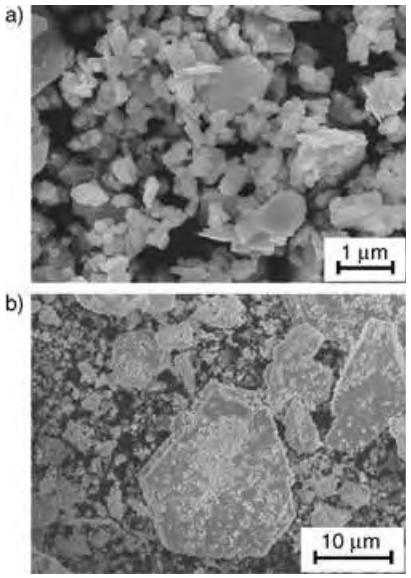

Figure 2. SEM images of solid solution **3**.

the XRD pattern is due to the presence of such particles. The surface area of the solid solution was 3.3 $m^2 g^{-1}$.

Figure 3 shows diffuse reflection spectra of the solid solutions and ZnS. The ZnS photocatalyst with a wide band gap (3.5 eV) had an UV absorption band. Unlike ZnS, the

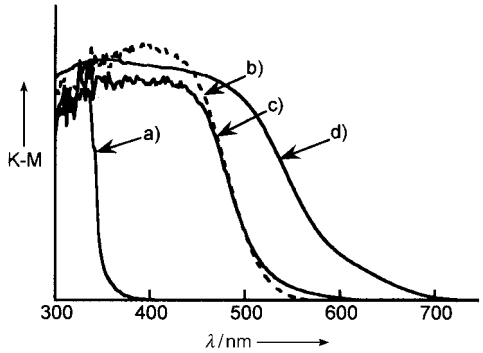

Figure 3. Diffuse reflection spectra of ZnS (a) and the solid solutions **1** (b), **2** (c), and **3** (d). K–M = diffuse reflection spectra converted into absorbance by the Kubelka–Munk method (arbitrary units).

solid solutions of ZnS and $MInS_2$ (M = Cu, Ag) had visible-light absorption bands; those bands with steep edges were due to band-gap transitions. The solid solutions **1** and **2** were able to use visible light up to 500 nm and thus the estimated band-gap energies are 2.4 eV. The absorption edge of the solid solution **3** was at a longer wavelength than those of other solid solutions. The color of the powder of **3** was dark orange. Taking into account the efficient use of visible light in a large part of the solar spectrum, we believe that this solid solution, with its long wavelength absorption band, is an attractive photocatalyst for hydrogen evolution.

When a Ru co-catalyst was loaded, the solid solution **3** effected hydrogen evolution under visible-light irradiation. The rate of hydrogen evolution was extremely high (2.3 mmol h^{-1}) under irradiation from a 300-W Xe lamp with a 420 nm cut-off filter. The optimized photocatalytic activities of the solid solutions **1** and **2** were 0.94 mmol h^{-1} and 1.16 mmol h^{-1}, respectively. The solid solution **3** produced hydrogen more efficiently than the solid solutions **1** and **2**. Vigorous evolution of hydrogen bubbles was observed over the photocatalyst particles irradiated with visible light.

Figure 4 shows H_2 evolution under simulated sunlight irradiation (AM 1.5) from an aqueous solution containing the sacrificial reagents SO_3^{2-} and S^{2-} over a Ru-loaded $(CuAg)_{0.15}In_{0.3}Zn_{1.4}S_2$ (**3**) solid-solution photocatalyst. Even under these conditions, the photocatalyst produced hydrogen gas efficiently. The initial rate of hydrogen evolution was 8.2 L $m^{-2} h^{-1}$, which was estimated from the irradiated area (33 cm^2). Although a slight deactivation was observed during the photocatalytic reaction, the activity remained comparatively stable over 20 h when the reaction solution was replaced periodically with fresh solution. As there were no significant changes in the XRD patterns of the catalyst before and after the reaction, we conclude that the slight deactivation was due to a change in the surface state and/or poisoning by products. The solid solution showed higher activity than

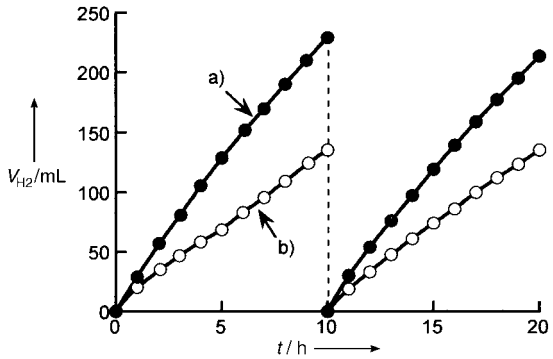

Figure 4. Photocatalytic H_2 evolution from an aqueous K_2SO_3 (0.25 mol L^{-1}) Na_2S (0.35 mol L^{-1}) solution (150 mL) under simulated sunlight irradiation over solid solution photocatalyst **3** loaded with 0.75 wt% Ru (a) and the Pt-black-loaded (2 wt%) CdS photocatalyst (b). Catalyst: 0.3 g; solar simulator: 300-W Xe short arc lamp with an AM-1.5 filter; reaction cell: top-window pyrex cell; irradiated area: 33 cm^2.

the well-known Pt-loaded CdS photocatalyst with wurtzite structure under the same reaction conditions (Figure 4). Its activity was also higher than that of the previously reported Pt-loaded $(AgIn)_{0.22}Zn_{1.56}S_2$ (**2**) solid solution photocatalyst (3.3 L $m^{-2} h^{-1}$).[12]

Figure 5 shows an action spectrum for hydrogen evolution from an aqueous solution containing K_2SO_3 and Na_2S over a Ru-loaded $(CuAg)_{0.15}In_{0.3}Zn_{1.4}S_2$ (**3**) photocatalyst. The onset

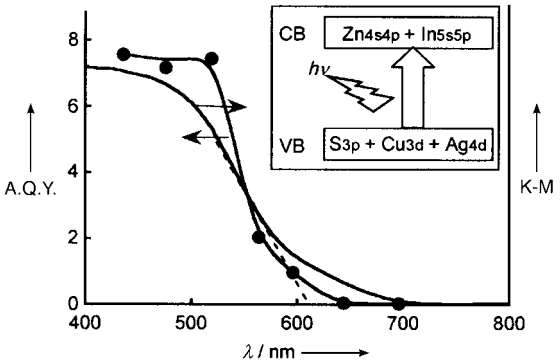

Figure 5. Action spectrum of H_2 evolution from an aqueous K_2SO_3 (0.25 mol L^{-1}) Na_2S (0.35 mol L^{-1}) solution (150 mL) over the solid solution **3** loaded with 0.75 wt% Ru. Catalyst: 0.3 g; light source: 300-W Xe lamp with cut-off and band-pass filters; reaction cell: top-window Pyrex cell. A.Q.Y. = apparent quantum yield. K–M = diffuse reflection spectra converted into absorbance by the Kubelka–Munk method (arbitrary units).

of the action spectrum "hydrogen evolution" agreed approximately with onset of the diffuse reflection spectrum. It was revealed that the visible-light response for hydrogen evolution was due to a band-gap transition between the valence and conduction bands; this band gap and thus the transition could be altered by making a solid solution. The visible-light response might be derived from the contribution of Cu 3d, Ag 4d, and S 3p orbitals to the valence band and that of In 5s5p and Zn 4s4p orbitals to the conduction band, respectively, as

in the cases of the $ZnS–AgInS_2$ and $ZnS–CuInS_2$ solid solutions. Hydrogen did not evolve through absorption of light in the region around 650–700 nm. This result indicates that a visible-light absorption band, which might be due to impurities and defects, was not responsible for the photocatalytic reaction. The comparatively high average quantum yield of 7.4% was obtained under monochromatic irradiation at 440, 480, and 520 nm.

In summary, we report that a $ZnS–CuInS_2–AgInS_2$ solid solution **3** is a highly active photocatalyst for the evolution of hydrogen under visible-light irradiation from an aqueous solution containing sulfide and sulfite. The activity of the solid solution that contained Cu and Ag atoms was higher than that of the previously reported $ZnS–MInS_2$ (M = Cu or Ag) solid solutions **1** and **2**. Although the quantum yield of the $ZnS–CuInS_2–AgInS_2$ solid solution was lower than that of the $ZnS–MInS_2$ (M = Cu or Ag) solid-solution photocatalysts, the former had higher activity when irradiated from a solar simulator. A sulfide photocatalyst that is able to produce hydrogen efficiently, even under solar-light irradiation would be an attractive functional material. Although it has not yet reached the level that it has a practical use, if quantum yields and activities can be further improved, this series of solid solutions could be used in photocatalytic hydrogen production.

Experimental Section

3: An aqueous solution of $Zn(NO_3)_2{\cdot}6H_2O$ (Wako Pure Chemicals; 99.0%), $AgNO_3$ (Tanaka Kikinzoku; 99.8%), and $In(NO_3)_3{\cdot}3.6H_2O$ (Kojundo Chemical; 99.9%) was purged with N_2 gas. An excess ($\approx$10%) of $In(NO_3)_3$, was added to the solution, followed by CuCl, freshly prepared by reduction of $CuCl_2{\cdot}2H_2O$ (Wako Pure Chemicals; 99.0%) with metallic Cu. Purging the reaction mixture with H_2S gas resulted in a grayish brown precipitate. The mixture was stirred for 15 h, washed with deionized water, and dried in air. The obtained powder was sealed in a quartz ampoule together with a small quantity of sulfur (about 1 wt%). The sealed ampoule was evacuated and heated over the course of 20 h to 600 °C and held at this temperature for 2 h. The phase of the product was confirmed by X-ray diffraction (Rigaku; MiniFlex). Surface areas were determined by BET (Brunauer–Emmett–Teller) measurement (Coulter; SA3100). Diffuse reflection spectra were obtained with a UV/Vis/NIR spectrometer (Jasco; Ubest U-570) and were converted from reflection to absorbance by the Kubelka–Munk method. Photocatalyst powders were observed by scanning electron microscopy (JEOL: JSM-6700F).

Photocatalytic reactions were conducted in a gas-closed circulation system. The photocatalyst powder (0.3 g) was dispersed by a magnetic stirrer in an aqueous solution (150 mL) containing K_2SO_3 and Na_2S as electron donors in a pyrex cell with a window on the top. The mixture was irradiated with visible light ($\lambda \geq 420$ nm) through a cut-off filter (HOYA; L42) from a 300-W Xe lamp (ILC technology; CERMAX LX-300). Ru co-catalyst was loaded by a photodeposition method in situ. An appropriate amount of $(NH_4)_2RuCl_6$ (Wako Pure Chemicals) was dissolved in an aqueous K_2SO_3 solution, the photocatalyst powder was added and the aqueous solution was irradiated under visible light for 20–30 min; subsequently, Na_2S was added into the solution. The optimum amount of the co-catalyst was about 0.7 wt%. Hydrogen production was measured by using on-line gas chromatography (Shimadzu; GC-8A, MS-5 A column, TCD, Ar carrier). The apparent quantum yields defined by Equation (1) were measured by using combined band-pass (Kenko) and cut-off (HOYA) filters, and a photodiode (OPHIRA: PD300-UV head and NOVA power monitor).

$$\text{A.Q.Y. } [\%] = \frac{\text{number of reacted electrons}}{\text{number of incident photons}} \times 100 = \frac{\text{number of evolved } H_2 \text{ molecules} \times 2}{\text{number of incident photons}} \times 100 \quad (1)$$

A solar simulator (YAMASHITA DENSO; YSS-80QA) was also used to test the photocatalytic reaction (AM 1.5). In this case, the amount of hydrogen gas evolved was determined by a volumetric measurement.

Self-Assembly

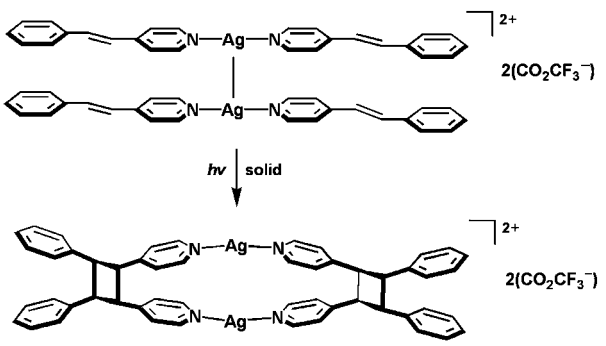
A Single-Crystal-to-Single-Crystal Transformation Mediated by Argentophilic Forces Converts a Finite Metal Complex into an Infinite Coordination Network**

*Qianli Chu, Dale C. Swenson, and Leonard R. MacGillivray**

Transition-metal ions play a prominent role in mediating chemical reactions, a central paradigm being catalysis.[1] The d orbitals of such ions are sources of directional bonding that organize substrates for stereocontrolled reactions that give molecular and polymeric products that cannot be obtained in the absence of the metal. Whereas a variety of transition-metal ions have been used to mediate chemical reactivity in the liquid phase,[1] such broad applicability to mediate reactivity in the organic solid state, particularly for the well-studied [2+2] photodimerization,[2] has not been realized.[3–8] In addition to forces that assemble molecules into strict geometries for stereocontrolled reactions, such ions can provide properties (e.g. color), and other components (e.g. counterions), that may be altered by the ensuing reaction that occurs within such solids.[4b,8]

Herein, we report the use of a transition-metal ion, in the form of Ag^I,[9] which mediates a [2+2] photodimerization in the solid state. Specifically, argentophilic forces, in the form of Ag···Ag interactions,[10] are used to guide stacking[11] of olefins in the dinuclear complex $[Ag_2(4\text{-stilbz})_4][CO_2CF_3]_2$ (**1**; where 4-stilbz = *trans*-1-(4-pyridyl)-2-(phenyl)ethylene) for a regiocontrolled head-to-head [2+2] photodimerization (Scheme 1). We show that the reaction occurs in 100% yield by a rare single-crystal-to-single-crystal (SCSC) transformation that, in addition to carbon–carbon single-bond making, involves breaking and formation of Ag···Ag and Ag···C interactions, respectively. Remarkably, the formation and breakage of the covalent and noncovalent bonds are accompanied by long-range movement of the Ag^I ions and rotation of the carboxylate ions,[12] which result in the finite dinuclear complex being converted into an infinite, one-dimensional (1D) coordination network. This study represents the first case in which a closed-shell d^{10} metal cation has been used to direct a reaction in the crystalline state.

Interactions between closed-shell d^{10} metal ions have been used to construct supramolecular assemblies[13] that exhibit host–guest, photophysical, and electrical properties.[14] For Ag^I, such Ag···Ag, or argentophilic, forces are evoked at separations < 3.4 Å, although separations up to 3.8 Å have been cited.[14] These separations fall within the distance criterion of Schmidt for a [2+2] a photodimerization in a solid.[2] Moreover, the ability of the Ag^I ion to engage in argentophilic forces, coupled with a tendency of the ion to exhibit linear coordination,[14] prompted us to investigate whether it would be possible to utilize Ag^I ions to guide the stacking of olefins in the solid state for a [2+2] photoreaction.[15]



Scheme 1.

Reaction of a solution of $AgCO_2CF_3$ in acetonitrile with 4-stilbz afforded large colorless plates of **1** upon slow evaporation. The formulation of **1** was confirmed by ^{1}H NMR spectroscopy, as well as powder and single-crystal X-ray diffraction data.

Perspective views of **1** are shown in Figure 1. The metal and organic components have assembled to form a dinuclear complex sustained by an Ag···Ag force (Ag···Ag distance: 3.41 Å; Figure 1a).[16] The primary coordination sphere of the Ag^I ion is based on a T-shaped geometry that involves two *transoid* nitrogen atoms of two 4-pyridyl groups of two olefins and a single oxygen atom of a carboxylate ion (Figure 1a, inset). The olefins that span the Ag···Ag interaction lie approximately parallel, the pyridine units participating in offset, face-to-face π–π interactions (pyridine centroid–centroid distances 3.62 Å). The carboxylate group is twisted orthogonal to the stacked olefins such that each $-CF_3$ group points away from the metal complex. As a consequence of the assembly process, the C=C bonds, which are disordered (occupancies: site A 0.89(1); site B 0.11(1)) and adopt a criss-cross arrangement,[17] are separated by 3.82 Å. This distance satisfies the distance criterion for [2+2] photoreaction in a solid.[2] The complex self-assembles to form 1D quadruple π-stacked arrays (Figure 1b), which are canted at 60° (Figure 1c), with neighboring olefins offset and separated by 4.22 Å (C···C distances [Å]: C(21)···C(22)a 4.22, C(22)···C(21)a 4.22, C(21)···C(21)a 3.91, C(22)···C(22)a 4.87; a: $1.5-x$, $0.5-y$, $-z$).

To test whether the olefins are photoactive, either single crystals or a powdered crystalline sample of **1** was exposed to UV radiation (broadband Hg lamp) for 18 h. As shown in Figure 2, a ^{1}H NMR spectrum (solvent: [D$_6$]DMSO) of photoreacted **1** reveals that the olefins reacted to give *rctt*-

Selected interatomic distances [Å] and angles [°]: Ag1-N1 2.161(3), Ag1-N2 2.149(3), Ag1-O1 2.583(4), C8···C21 3.82, C8···C22 3.79, C9···C21 4.11, C9···C22 4.23; O1-Ag1-N1 94.7(1), N1-Ag1-N2 165.3(1), O1-Ag1-N2 98.1(1).

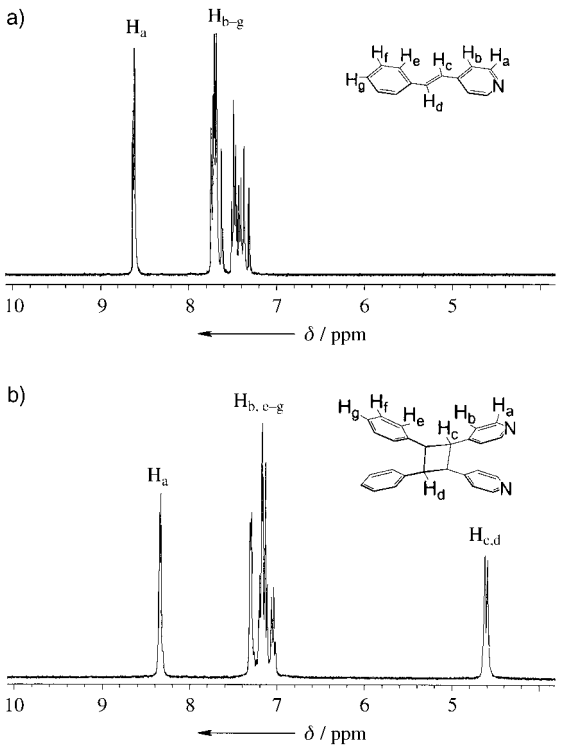

Figure 2. ^{1}H NMR spectra: a) **1** before photoreaction and b) **2** after photoreaction.

1,2-bis(4-pyridyl)-3,4-bis(phenyl)cyclobutane (4-pyr-ph-cb) in 100 % yield. The formation of the photoproduct is shown by the disappearance of the signals of the olefinic protons ($\delta = 7.50$ ppm) and the emergence of signals for the cyclobutane protons ($\delta = 4.60$ ppm). Optical microscopy revealed that the transparency and shape of the single crystals remained intact during the photoreaction, which suggested that the reaction occurred by a SCSC transformation.

An X-ray diffraction analysis of photoreacted **1** confirms that the reaction occurred by a SCSC transformation. As shown in Figure 3, the olefins of **1** reacted to give head-to-head 4-pyr-ph-cb in $[Ag_2(4\text{-pyr-ph-cb})_2][(CO_2CF_3)_2]$ (**2**) in quantitative yield (Figure 3a). The photoproduct adopts two orientations, with the cyclobutane ring of **2** exhibiting site occupancies different than that of the olefins of **1** (occupancies: site A 0.60; site B 0.40). These occupancies are consistent with the C=C bonds of the olefins undergoing a pedal-like motion in **1**[17] prior to the photoreaction.

The generation of 4-pyr-ph-cb is accompanied by major repositioning[12] of the Ag^{I} and carboxylate ions. Specifically, each Ag^{I} ion has moved approximately 1.16 Å (Ag···Ag distance in **2**: 5.73 Å) in a direction approximately parallel to the newly formed C–C bonds,[12a] while each carboxylate ion has undergone an approximate 90° rotation such that each $-CF_3$ group is oriented approximately perpendicular to the pyridyl groups (Figure 3b). Despite such long-range movement and rotation, the Ag–N and Ag–O bonds remain intact. In particular, the nitrogen and oxygen atoms form a trigonal planar coordination geometry around each Ag^{I} ion, with each metal atom lying approximately 0.37 Å out of the plane of the donor atoms.

An important consequence of the movement and rotation of the ions is that Ag···C interactions[18] (Ag···C(phenyl) distances: Ag(1)···C9C 2.63 Å) have formed between each repositioned Ag^{I} ion and a *para*-carbon atom of a phenyl group of a neighboring photoproduct (Figure 3c and inset). These forces link adjacent complexes of **2** to give a linear coordination polymer.[8] The Ag···C forces of the newly formed coordination polymer compare favorably to those networks with aromatics (e.g. cyclophanes) as donor ligands.[18] In the case of **2**, the photodimerization has, in effect, forced the Ag···Ag interactions[10] to break and the Ag···C interactions to form,[18] which, in turn, has resulted in the 1D geometry of the olefins of **1** being captured,[19] through coordination bonds, within the 1D polymer of **2**. To our knowledge, the photoconversion **1** into **2** represents the first case in which a finite metal complex has been transformed into an infinite coordination network in the solid state by a [2+2] photoreaction.[20,21]

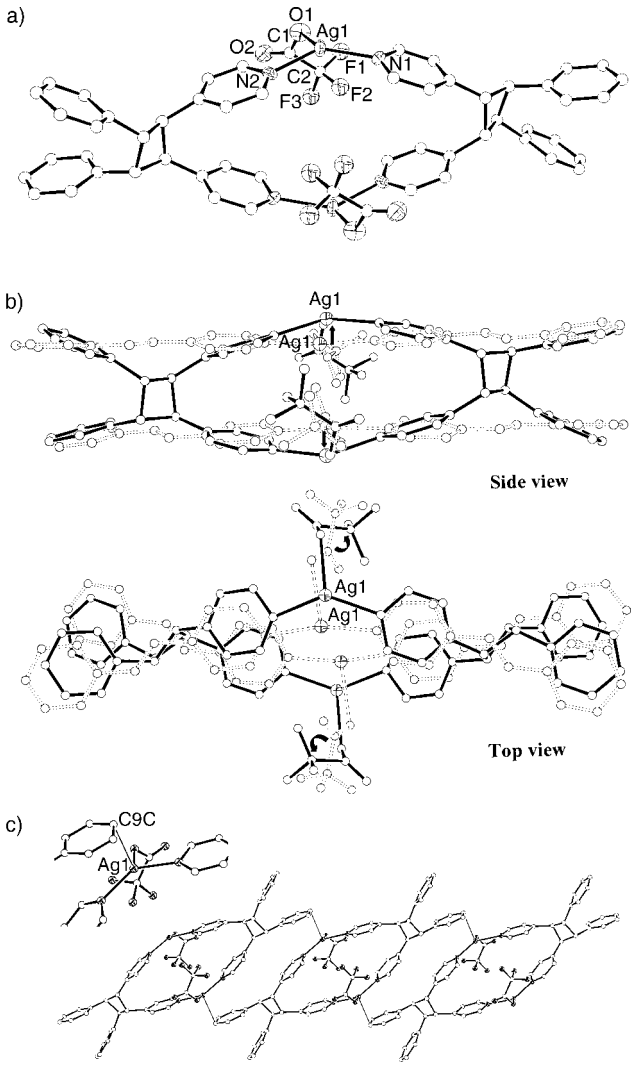

Figure 3. X-ray crystal structure of **2**: a) ORTEP view of the dinuclear assembly, thermal ellipsoids set at 30 % probability. b) overlay views of **2** (solid) and **1** (dashed) (arrows indicate movement of Ag^{I} atoms and carboxylate ions), c) newly formed 1D coordination polymer (inset: coordination environment of the Ag^{I} ion). Selected interatomic distances [Å] and angles [°]: Ag1-N1 2.22(1), Ag1-N2 2.27(1), Ag1-O1 2.44(2); N1-Ag1-N2 136(1), N1-Ag1-O1 112(2), N2-Ag1-O1 104(2).

Herein, we have revealed that argentophilic forces involving Ag^{I} ions can guide the stacking of olefins in the solid state for a regiospecific [2+2] photodimerization. The olefins assembled in a geometry that converts a finite metal complex into an 1D coordination network by a SCSC transformation.[8] Based these observations, we are now determining the reliability of using Ag···Ag interactions to direct reactivity in the solid state and plan to expand the reactants to olefins of increasing structural complexity.[11] That a finite complex can be converted into an infinite network by using a photodimerization and pyridyl units—chemical reactivity and ligands common to organic solid-state chemistry[2,22]—suggests this approach may also provide an entry to solids with properties that may be deliberately modified using photoresponsive building units.[25]

Experimental Section

Preparation of **1**: 4-stilbz was prepared according to a published procedure.[23] $AgCO_2CF_3$ was commercially available. Compound **1** was obtained by evaporation of a solution of 4-stilbz (0.100 g, 0.55 mmol) and $AgCO_2CF_3$ (0.061 g, 0.28 mmol) in acetonitrile (2.0 mL).

Solid-state photoreactions: UV irradiation of either single crystals or powdered crystalline **1** (500 W Hg lamp) over 18 h resulted in 100 % conversion of 4-stilbz to 4-pyr-ph-cb. The irradiation experiments were performed by placing either single crystals or finely ground samples of **1** between two pyrex plates and turning the sample in 9 h intervals to ensure uniform irradiation. ^{1}H NMR for **1** (300 MHz, [D$_6$]DMSO): $\delta = 8.62$ (dd, 4H), 7.50 (m, 18H); ^{1}H NMR for **2** (300 MHz, [D$_6$]DMSO): $\delta = 8.44$ (dd, 4H), 7.30 (m, 14H), 4.60 ppm (m, 4H).

X-ray crystallography: Crystal data for **1**: monoclinic, C2/c, $a =$ 22.048(2), $b = 13.156(2)$, $c = 17.9566(2)$ Å, $\beta = 98.44(1)°$, $V =$ 5152(1) Å^3, $Z = 4$, $\rho_{calcd} = 1.50$ g cm^{-3}, $R_1 = 0.051$ for 3965 reflections with $I > 2\sigma(I)$. Crystal data for **2**: monoclinic, *C*2/*c*, $a = 21.544(2)$, $b =$ 13.548(1), $c = 17.694(2)$ Å, $\beta = 99.00(1)°$, $V = 5101(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.52$ g cm^{-3}, $R_1 = 0.096$ for 1977 reflections with $I > 2\sigma(I)$. All crystal data were measured on a Nonius KappaCCD single-crystal X-ray diffractometer. All non-hydrogen atoms of **1** were refined with anisotropic thermal parameters except the atoms of the low-occupancy site of the disordered olefin. These atoms were given isotropic thermal parameters that were restrained to be similar to the U_{iso} of the corresponding atom on the high-occupancy site of the disordered ligand. The conformation of the low-occupancy site was restrained to be the same as that of the high-occupancy site. The occupancies refined to 0.89(1) (A) and 0.11(1) (B). The carboxylate ion displayed highly anisotropic thermal motion and was modeled as disordered for the final cycles of refinement. The disordered sites were restrained to have the same conformation and corresponding atoms were given the same anisotropic thermal parameters (i.e. U(O1) = U(O1′), U(C1) = U(C1′)…). The occupancies refined to 0.59(1) (A) and 0.41(1) (B). Upon reaction, the single crystal of **2** fractured into several highly mosaic single-crystal domains. The data from one of these single-crystal domains were successfully indexed and integrated. An examination of zonal precession syntheses indicated minimal interference from other single-crystal domains. Owing to the high degree of mosaicity, data above 37.5° 2θ were excluded from the refinement as there were essentially no data above background levels in this shell. The reaction product was disordered (the cyclobutane can form in one of two orientations yielding two chemically equivalent complexes with partial occupancy) and the occupancies converged to and were fixed at 0.60 (A) to 0.40 (B). The limited data set limited the refinement model. The Ag and O atoms, as well as the N atoms, were refined with anisotropic thermal parameters while all other atoms were refined with isotropic thermal parameters. The pyridyl rings of the photoproduct were treated as rigid groups. The equivalent N atoms (N1A, N1B…) from each disordered site were found in close proximity and were given the same anisotropic thermal parameters. For the remaining atoms, chemically equivalent disorder atom sites (C1A, C1B; C2A, C2B…) were given the same isotropic thermal parameter. The carboxylate groups were disordered and were restrained to exhibit the same conformation. The thermal parameters for O1 were restrained by the rigid bond restraint to the thermal parameters of the Ag atom for the final cycles of refinement. The bond lengths and angles described above refer to the major occupied sites. All crystallographic calculations were conducted using SHELXL-97.[24] CCDC-261658 (**1**) and CCDC-261660 (**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge

Nanostructures

The Role of Precursor-Decomposition Kinetics in Silicon-Nanowire Synthesis in Organic Solvents**

*Doh C. Lee, Tobias Hanrath, and Brian A. Korgel**

The "bottom-up" chemical synthesis of semiconductor nanowires has been developed as an alternative strategy to conventional lithographic patterning for the preparation of functional nanostructures suitable for applications such as logic gates,[1] memory devices,[2] light-emitting devices,[3] sensors,[4] and photonic circuits.[5,6] Nanowire growth by the vapor–liquid–solid (VLS) mechanism has been very successful for a variety of different materials, including Group IV, Group II–VI, and Group III–V semiconductors,[7–12] and metal oxides.[13] These nanowires are in many ways like macromolecules, as they can be suspended in solvents and deposited on substrates or mixed with polymers as composites. Ideally, the aim is to synthesize nanowires by solution chemistry and move away from slow and expensive gas-phase chemical vapor deposition (CVD).

The colloidal synthesis of Si nanomaterials is extremely challenging and represents to some extent a "holy grail" in solution-based nanomaterials chemistry. In 2000, we showed that crystalline Si nanowires could be synthesized in solution by using Au nanocrystals as seeds to lower the crystallization barrier and promote crystalline nanowire growth.[14] By pressurizing the organic solvent, reaction temperatures exceeding the Au/Si eutectic temperature (363 °C) could be reached[15] and "VLS-like" nanowire growth could be promoted. We refer to this nanowire-growth mechanism as supercritical fluid–liquid–solid (SFLS) synthesis.[16]

In hindsight, we were very lucky to stumble across diphenylsilane as a suitable Si precursor for the synthesis. Very little is known about the chemistry of the relevant silanes (that is, aryl- and alkyl-substituted silanes and trisilane) in pressurized solvents at high temperature, and as we show herein, other potential precursors that would appear to be obvious choices fail completely. In fact, we have found that the SFLS process is very sensitive to the precursor-decomposition kinetics, and careful tuning of this process is required to optimize the nanowire quality and prevent unwanted homogeneous Si-particle nucleation. Herein, we report on the relationship between the silane decomposition chemistry and the quality of the Si nanowires produced by SFLS by using Au-nanocrystal seeds.

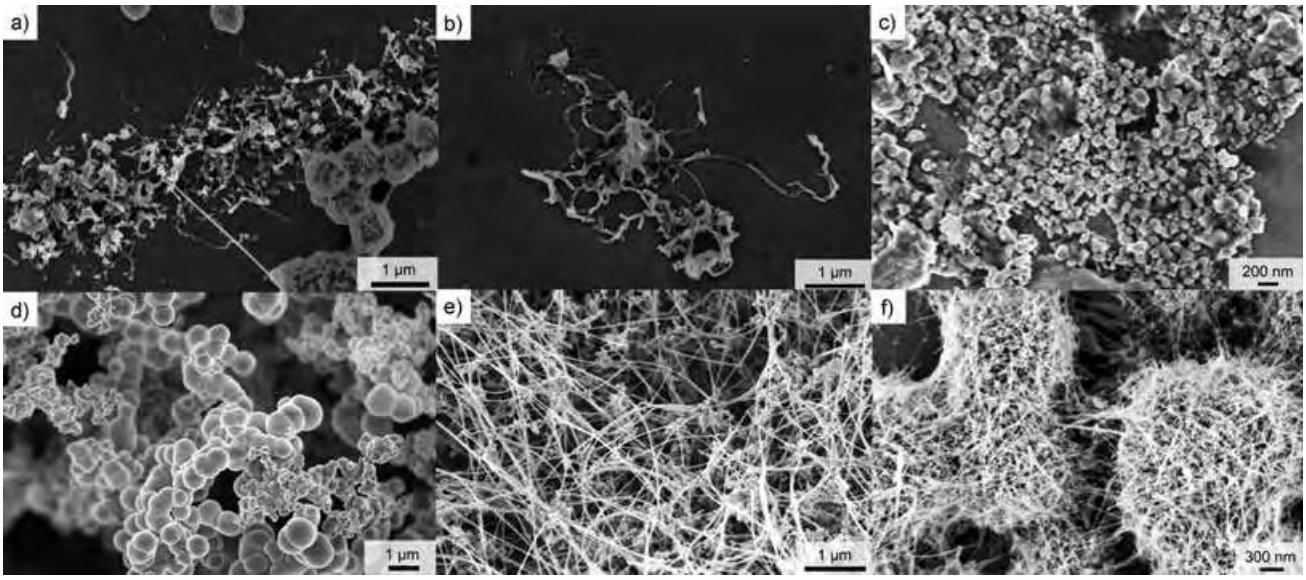

Figure 1. HRSEM images of the reaction products obtained from a) octylsilane, b) diethylsilane, c) tetraethylsilane, d) trisilane, e) phenylsilane, and f) diphenylsilane injected into hexane at 450 °C, approximately 7.2 MPa, and a concentration of 350 mM. The reactions were carried out for 5 min with a Au/Si molar ratio of 1:1000.

Figure 1 shows scanning electron microscopy (SEM) images of the solid product obtained from six different Si precursors injected into anhydrous hexane at 450 °C and 7.2 MPa with dodecanethiol-coated Au nanocrystals with an average diameter of approximately 4 nm. The silane concentration in each case was 350 mM with a Au/Si molar ratio of 1:1000, and the reactions were carried out for 5 min. The

images in Figure 1 show the products obtained from the alkyl silanes octylsilane, diethylsilane, and tetraethylsilane (Figure 1 a–c, respectively). In all cases, the nanowire was formed in extremely low yield or not at all. Only the monosubstituted alkyl silane, octylsilane, produced a measurable amount of crystalline Si nanowires, but in miniscule yield and with large amounts of oligomeric silicon- and carbon-containing impurities. The multisubstituted alkyl silanes, diethylsilane and tetraethylsilane, did not produce any crystalline nanowires, only curly amorphous wires in the case of diethylsilane and amorphous particulates in the case of tetraethylsilane. It appears that the Si–H bond is relatively reactive and labile, but homolytic cleavage of the alkyl Si–C bond is too slow to provide sufficient Si atoms for the Au-seed particles to sustain crystalline nanowire growth.

Trisilane is very reactive and decomposes rapidly at temperatures above 350 °C to produce silicon in nearly 100 % yield.[17] However, trisilane does not form Si nanowires in the presence of the Au nanocrystals. The reaction produces micrometer-sized amorphous Si colloids (Figure 1 d); surprisingly, the same product was obtained in the absence of Au nanocrystals.[18] Unlike the alkyl or aryl silane precursors, trisilane can undergo thermolysis through heterogeneous insertion at hydrogen-terminated sites on Si surfaces, which is a process that can lead to rapid particle formation once amorphous Si colloids have nucleated.[19] Furthermore, the Si–Si bonds in trisilane are very stable and do not dissociate at the typical SFLS reaction temperatures of approximately 450–500 °C. Therefore, dehydrogenation of trisilane at these reaction temperatures leaves a "bare" Si trimer, which appears not to dissolve in the Au-nanocrystal seeds. Trisilane can also be deposited on the sidewalls of any nanowires that have not fully formed to give rise to a thick amorphous coating. The alkyl silanes are not sufficiently reactive to produce high-quality crystalline nanowires by Au-seeded SFLS and trisilane is too reactive, which leads to the homogeneous particle formation of amorphous Si structures.

Aryl silanes exhibit suitable reactivity for the formation of high-quality nanowires. Figure 1 e,f shows the Si products obtained from phenylsilane and diphenylsilane: Both precursors yield large quantities of Si nanowires as the primary reaction product. As shown in Figure 2, the nanowires formed by using diphenylsilane as the precursor are crystalline with a diamond cubic structure and few defects. The alkyl- and aryl-substituted organosilanes exhibit qualitatively different reactivities at approximately 450 °C. The Si–C bonds in the alkyl-substituted silanes have lower dissociation enthalpies than those in the aryl-substituted silanes;[20,21] however, the aryl-substituted silanes can undergo disproportionation reactions of the type shown in Scheme 1, and therefore the aryl group is a more reactive substituent under the nanowire growth conditions.[22,23] Although the exact details of the disproportionation reactions have not been well-studied,[24] the mechanism appears to be associative and involves the exchange of a hydrogen atom and a phenyl group. The resonance effect of the benzene ring lowers the activation energy for the disproportionation reaction, whereas the alkyl group does not give rise to a resonance effect.[23] The alkyl-substituted silanes can only decompose by homolytic dissociation, which is very slow at these temperatures; however, the aryl silanes undergo a series

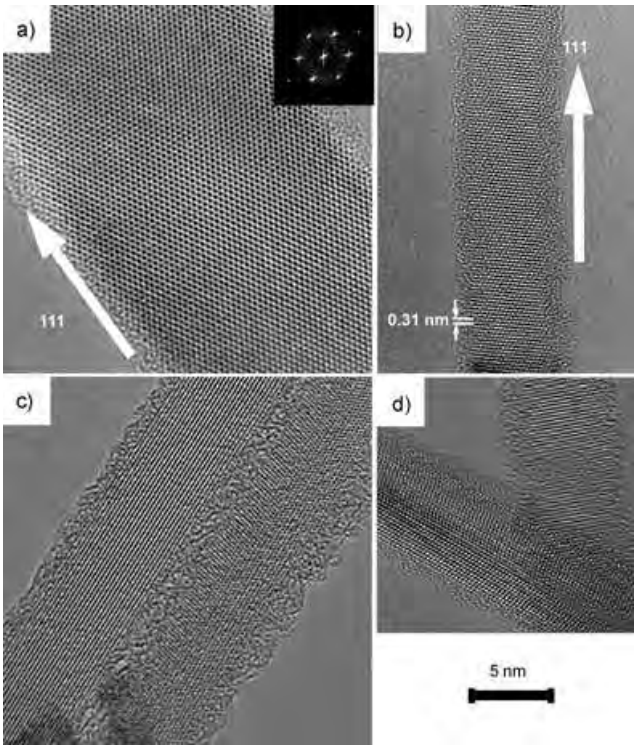

Figure 2. High-resolution TEM (HRTEM) images of Si nanowires produced by SFLS from Au nanocrystals and diphenylsilane at 450 °C. Under these conditions, SFLS yields predominantly ⟨111⟩-oriented nanowires, as shown in (a) and (b); however, limited numbers of ⟨110⟩- and ⟨211⟩-oriented nanowires are also found with diameters smaller than 10 nm (c, d). The fast Fourier transforms (FFTs) of the image in (a) are shown in the inset.

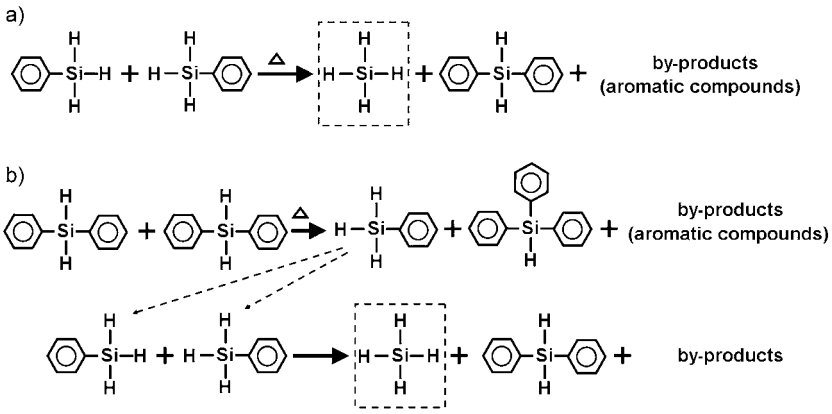

Scheme 1. Bimolecular disproportionation of a) phenylsilane and b) diphenylsilane. Silane decomposes at temperatures above approximately 350 °C to produce Si atoms.

of disproportionation reactions that yield silane and tetraphenylsilane as the final reaction products. Tetraphenylsilane is very stable and does not decompose below 500 °C,[24,25] and silane decomposes to silicon at approximately 350 °C.[26] On the basis of this proposed mechanism, silane generated in situ during the reaction promotes nanowire growth.

As expected from the proposed disproportionation mechanism for the decomposition of the aryl silanes, reactants with higher phenyl substitution give the product in lower yields. As shown in Scheme 1, phenylsilane requires only one disproportionation step to form silane, in contrast to diphenylsilane, which requires two consecutive reactions. Phenylsilane was found to lead to higher product yields than diphenylsilane. High-resolution SEM (HRSEM) analysis of the Si nanowires produced from diphenylsilane at 500 °C also showed that a significantly greater amount of carbonaceous by-products formed relative to those produced from phenylsilane. Perhaps because of its additional phenyl moiety, diphenylsilane exhibits an increased likelihood to form carbonaceous by-products as well as nanowires. For both diphenylsilane and phenylsilane, there appears to be a "threshold" concentration (approximately 120 mM for phenylsilane) below which little or no nanowire product is formed.

Figure 3 shows HRSEM images of the reaction products synthesized from phenylsilane (Figure 3a–c) and diphenylsilane (Figure 3d–e) at different reaction temperatures between 400 and 500 °C. When the synthesis was performed at 350 °C—just below the bulk-phase Si/Au eutectic temperature (363 °C)—from either phenylsilane or diphenylsilane, no significant quantities of solid product were yielded (the results are not shown). In the reactions carried out at just above the eutectic temperature (400 °C), nanowires did not form and only particulate materials that were poorly defined in structure, and so could not be clearly observed by HRSEM, were formed. This result is in stark contrast to the Au-nanocrystal-promoted SFLS synthesis of Ge nanowires, which are routinely grown at 385 °C in very high quality.[27] Since the Au/Ge system exhibits a similar eutectic temperature to that of the Au/Si system (361 °C),[27] similar results for the Si nanowires would be expected. The significantly lower growth temperature of the Ge nanowires appears to be directly related to the higher reactivity of the aryl germanes relative to the aryl silanes; therefore, the slow precursor-degradation kinetics appear to limit the Si-nanowire growth at temperatures just above the Au/Si eutectic temperature. The reaction temperature must reach approximately 450 °C

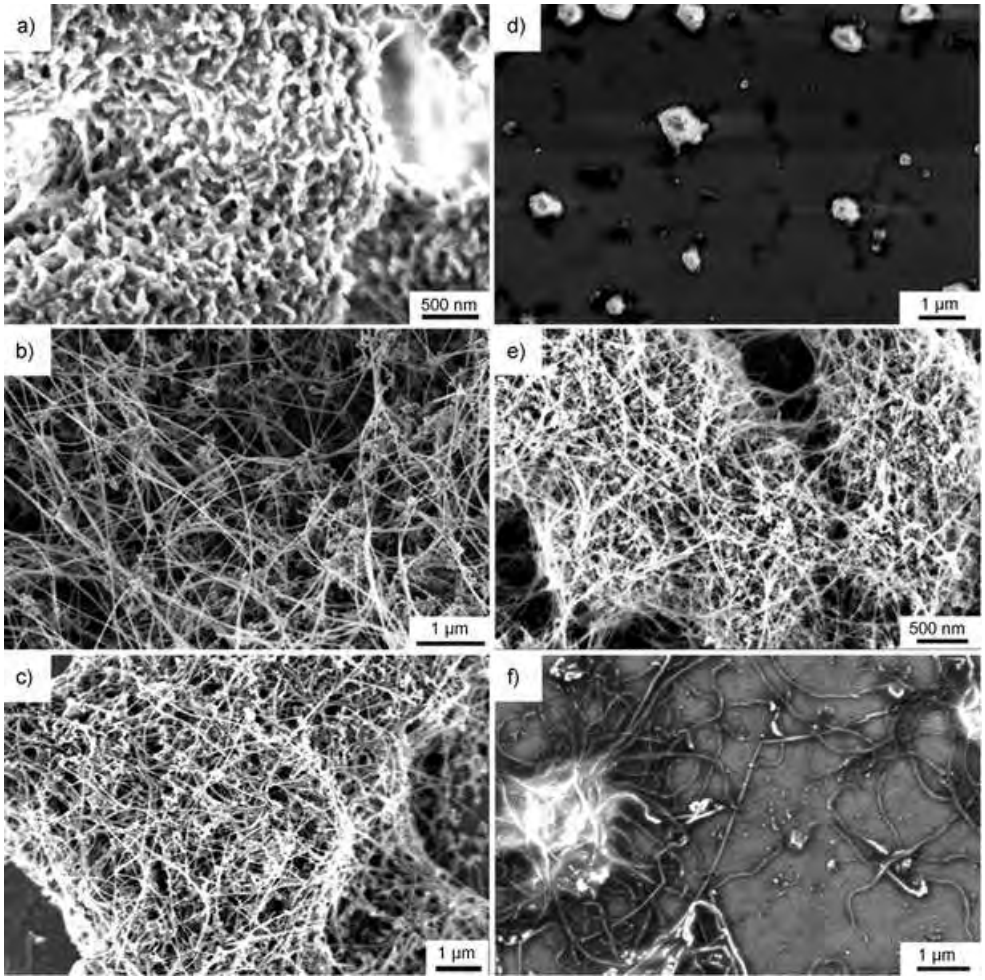

Figure 3. HRSEM images of the Si product obtained from phenylsilane (a–c) or diphenylsilane (d–f) in hexane at 400 °C (a, d), at 450 °C (b, e), and at 500 °C (c, f). For both precursors, reaction temperatures of at least 450 °C are required to form nanowires.

for high-quality crystalline Si nanowires to be produced. However, further increases in reaction temperature do not improve the nanowire growth: Phenylsilane produces nanowires at 500 °C but with a relatively high proportion of carbon-containing amorphous Si by-products, and reactions at temperatures higher than 500 °C result in significant pyrolysis of hexane.

As shown in Figures 2 and 4, ⟨111⟩ is the predominant growth direction for Si nanowires synthesized at 450 °C from

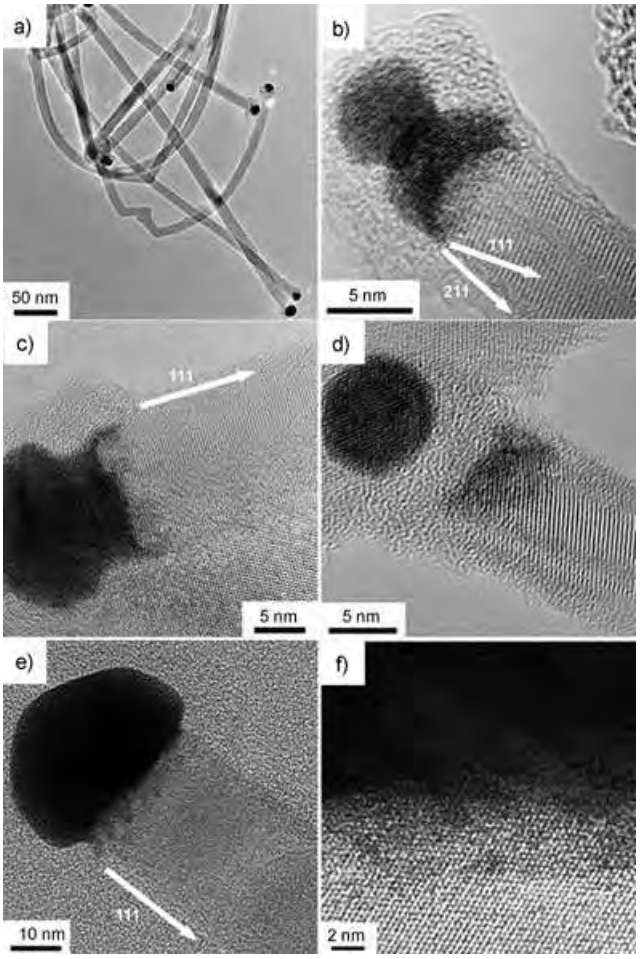

Figure 4. HRTEM images of Au-seed particles at Si-nanowire tips. a) HRTEM image of several nanowires with Au tips. b) The "curved" Au/Si interface of a ⟨211⟩-oriented nanowire. c) Au tip at the end of a ⟨111⟩-oriented Si nanowire. d) A nanowire that was exposed for two months to air that has oxidized at the Au/Si interface and the nanowire surface. e) Au tip at the end of a ⟨111⟩-oriented Si nanowire. f) The interface at the Au tip in (e) at a greater magnification of 1 000 000×.

Au nanocrystals and either phenylsilane or diphenylsilane. A few nanowires could be found with ⟨110⟩ or ⟨112⟩ growth directions. The preference for the ⟨111⟩ growth direction in the Si nanowires is consistent with Si whiskers grown in the gas phase by Au-seeded VLS at similar reaction temperatures.[28] Transmission electron microscopy (TEM) imaging of the Au/Si tip of the nanowires grown by SFLS reveals a flat, atomically abrupt interface with a Si (111) surface. Nanowires with ⟨112⟩ or ⟨110⟩ growth directions do not exhibit this flat cross-sectional interface (Figure 4b) but possess "curved" interfaces instead that appear to undergo reconstruction to form flat Si (111)/Au interfaces at the tip, as observed by Wu et al.[29] for Si nanowires grown by Au-seeded VLS with ⟨110⟩ orientation. The influence of the liquid–crystal interface and the fact that the Si (111)/Au interface exhibits the lowest free energy relative to other possible interfaces has been well-established from early work on Si whiskers.[28] The stability of the Si (111)/Au interface is further confirmed by our observations of a migrating Si/Au interface when it is exposed to the electron beam in TEM. Long exposure time of the Si/Au interface to the electron beam results in the generation of sufficient thermal energy for the Au interface to migrate approximately 14 nm into the nanowire (Figure 5). The

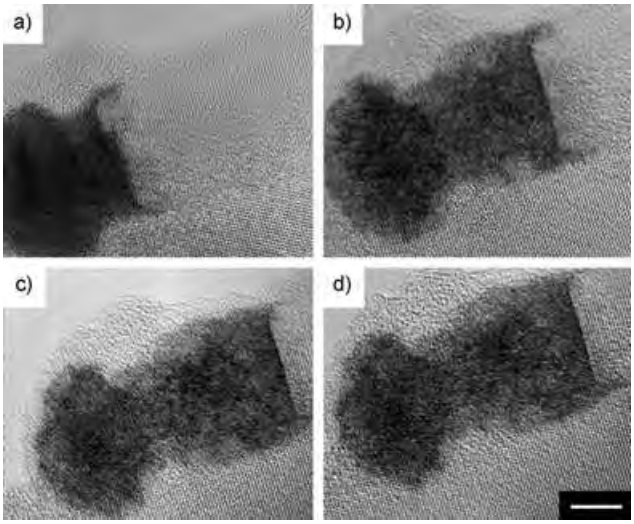

Figure 5. Au tip at the end of a Si nanowire exposed to a converged electron beam at 200 kV after a) 0, b) 1.5, c) 3, and d) 4.5 min. The Au interface migrates into the Si nanowire until it penetrates by approximately 14 nm. The nanowire maintains the sharp {111} interface at the Au/Si tip. Scale bar: 5 nm.

interface remains sharp and atomically smooth despite this progression. Compare this interfacial structure to the curved Au/SiO_2 interface that forms at the tip of a Si nanowire after two months of exposure to air (Figure 4d). The difference in the interfacial energy of the Au/SiO_2 interface relative to the Au/Si interface is reflected in the qualitatively different structures formed.

In summary, aryl silanes are effective precursors for the growth of crystalline Si nanowires by Au-nanocrystal-seeded SFLS, whereas alkyl silanes and trisilane are not. The quality of the Si product is related directly to the decomposition chemistry of the precursor: The precursor must be sufficiently reactive to saturate the Au-nanocrystal seeds with Si atoms and promote nanowire growth, but not so reactive that homogeneous particle nucleation and sidewall deposition overcome the metal-particle-directed crystallization. To put these findings into perspective, low-melting-point metals, such as In and Bi, have recently been used successfully as seeds to lower the metal/semiconductor eutectic temperature to below 300 °C and enable conventional solvents to be used

in the VLS method for the growth of nanowires composed of materials such as GaAs,[30] InN,[31] and CdSe.[32] For silicon nanowires, germanium nanowires, and carbon nanotubes,[33] however, the use of low-melting-point metals to lower the eutectic temperature is not a viable option because of the limited precursor reactivity for Group IV materials—even silane barely decomposes at approximately 350 °C.[21] Therefore, despite the technical challenges of high-pressure and high-temperature conditions, SFLS has an important role as a general synthetic technique for the synthesis of Group IV semiconductor nanowires.

Experimental Section

All silicon precursors (phenylsilane (Aldrich), diphenylsilane (Gelest), octylsilane (Gelest), diethylsilane (Aldrich), tetraethylsilane (Adlrich), and trisilane (Gelest)) were stored in an inert nitrogen atmosphere and were used without purification. The alkanethiol-capped Au nanocrystals were prepared according to established methods.[34] Stock solutions of the Si precursors and Au nanocrystals were prepared in anhydrous hexane in a nitrogen-filled glove box prior to injection into the reactor system.

Nanowire synthesis: The reactor system consisted of a 10-mL Ti grade-2 reaction cell, pressurized by using an HPLC pump and heated in a brass heating block.[27] The temperature was monitored with a thermocouple (Omega) that was placed on the wall of the heating block connected to a temperature controller. To help with sample collection after the reaction had been completed, an oxidized Si wafer placed inside the reactor was used as a deposition substrate (6.3 × 1.0 cm). The reactor cell was filled with anhydrous, oxygen-free hexane and sealed in a nitrogen-purged glove box. The reactor cell was connected to the high-pressure assembly and heated to the desired reaction temperature at a pressure of approximately 5.5 MPa before injection of the silane/Au nanocrystal mixture into the cell from a 500-μL HPLC injection loop. All the reactions were carried out for 5 min before careful immersion of the cell into an ice–water bath to quench the reaction. The cell was cooled to room temperature before opening. Care must be exercised when opening the reactor as it could still be under high pressure! The deposition substrate was carefully removed with sharp-edged tweezers, and the remaining product on the inner reactor walls was extracted with hexane and mild sonication. The reaction products were stored under nitrogen to minimize surface oxidation.

Characterization methods: HRSEM images were obtained on a field-emission LEO 1530 scanning electron microscope operated at an accelerating voltage of 2–3-kV. HRTEM was performed with a JEOL 2010F operated at an accelerating voltage of 200-kV. For TEM, the samples prepared by dispersion in chloroform with brief sonication followed by drop-casting on a lacey carbon grid (Electron Microscopy Sciences, LC200-Cu, Mesh 200). The nanowires were sufficiently long to stretch across the lacey carbon grid to provide a vacuum background for the HRTEM images. FFTs of the TEM images were obtained by using digital micrograph (Gatan) software.

Hydrogen Storage

Nanoscaffold Mediates Hydrogen Release and the Reactivity of Ammonia Borane**

*Anna Gutowska, Liyu Li, Yongsoon Shin, Chongmin M. Wang, Xiaohong S. Li, John C. Linehan, R. Scott Smith, Bruce D. Kay, Benjamin Schmid, Wendy Shaw, Maciej Gutowski, and Tom Autrey**

The increasing demand for clean energy sources that do not add more carbon dioxide and other pollutants to the environment has resulted in increased attention worldwide to the possibilities of a "hydrogen economy" as a long-term solution for a secure energy future based on potentially renewable resources.[1–3] Some of the greatest challenges are the discovery and development of new on-board hydrogen-storage materials and catalysts for fuel-cell-powered vehicles. New materials that store both high gravimetric ($\geq 90\ gm\,H_2\,kg^{-1}$) and high volumetric ($\geq 82\ gm\,H_2\,L^{-1}$) densities of hydrogen that can be delivered at temperatures between −20 and 85 °C are needed by the year 2015.[4] The volumetric constraints eliminate from consideration pressurized hydrogen systems and guide towards the development of solid storage materials.[5] There are several broad classes of solid hydrogen-storage materials that are currently being investigated as potential on-board storage materials: 1) metal materials, hydrides (e.g., MgH_2),[6] imides (e.g., $LiNH_2$),[7] and organic frameworks (e.g., Zn_4O(1,4-benezenedicarboxylate)),[8] 2) complex hydrides (e.g., $NaAlH_4$),[9] and 3) carbon materials (e.g., carbon nanofibers,[10] single-wall carbon nanotubes).[11] The most thoroughly studied complex hydride, $NaAlH_4$, has been shown to release hydrogen at 110 °C when doped with Ti;[12] however, the kinetics are very slow and hydrogen-storage densities are too low ($56\ gm\,H_2\,kg^{-1}$) to meet long-term targets. The temperatures for H_2 release from carbon materials are too low, and the reported storage densities are controversial.[13] The hydrolysis of metal hydrides is being explored, but the unfavorable thermodynamics for regeneration of the spent material prevents their widespread application. For example, the reaction $NaBH_4 + 4\,H_2O \rightarrow NaB(OH)_4 + 4\,H_2$ is exothermic by $-250\ kJ\,mol^{-1}$. Reaction enthalpy for hydrogen loss is an important property since near-thermoneutral thermodynamics will be critical for materials for reversible H_2 storage. To date, few of these materials meet the long-term gravimetric requirements and provide rapid hydrogen release at temperatures between −20 and 85 °C; thus, new materials and novel approaches are needed. Herein we show that the kinetics of hydrogen release are significantly enhanced at low temperatures for a new hybrid material, ammonia borane infused in nanoporous silica, and that the hydrogen purity is increased. These findings suggest that hydrogen-rich materials infused in nanoscaffolds offer a most promising approach to on-board hydrogen storage.

Chemical hydrogen-storage materials that release H_2 by thermolysis without generating CO_2 may offer an attractive alternative to other systems studied. For example, the NH_xBH_x family of compounds[14] should provide favorable gravimetric densities of 245, 196, 140, and 75 $gm\,H_2\,kg^{-1}$ for $x = 4$, 3, 2, and 1, respectively. As the NB unit is isoelectronic with CC, these materials are viewed as inorganic analogues of hydrocarbons. However, NH_xBH_x compounds are solids rather than gases at ambient temperature because of their greater polarity and stronger intermolecular interactions relative to organic analogues. The inherent polarity results from the different electronegativities of the B and N atoms: 2.0 and 3.0, respectively.[15] As solids, they provide far more favorable volumetric densities than do the corresponding gaseous hydrocarbons. The two hydrogen-rich materials ammonium borohydride (NH_4BH_4) and ammonia borane (NH_3BH_3) were first prepared in the mid-1950s as part of the US government's program to develop boron-based jet fuels. NH_4BH_4 evolves hydrogen slowly at temperatures above −40 °C and thus is too unstable for applications at room temperature.[16] On the other hand, ammonia borane (AB) is a stable solid at room temperature and requires external heating to release H_2. AB decomposes upon melting at 114 °C with the vigorous bubbling of H_2 gas, or alternatively the hydrogen from AB can be released from the solid material at temperatures below 100 °C, albeit at significantly lower rates.[17] The thermal decomposition of NH_3BH_3 at temperatures below 100 °C yields H_2 and a complex polyaminoborane-like material $-(NH_2BH_2)_n-$ (PAB).[18] At temperatures above 150 °C the PAB decomposes to yield a second equivalent of H_2, concurrent with the formation of a further oxidized polyiminoborane-like material $-(NHBH)_n-$ (PIB) and borazine (c-$(NHBH)_3$).[19] The latter is an inorganic analogue of benzene that is highly undesirable in the H_2 feed.

Recent computational results indicate that the NH_xBH_x molecules also display favorable thermodynamics: All four consecutive steps of hydrogen release from NH_xBH_x for $x =$ 4–1 are thermoneutral to within $40\ kJ\,mol^{-1}$.[14,20] These theoretical results are supported by experimental work that shows that the reaction enthalpy for H_2 loss from NH_3BH_3 is only moderately exothermic ($\Delta H_{rxn} = -21\ kJ\,mol^{-1}$).[21] The

Schubert (US Borax) for helpful discussions.

  DOI: 10.1002/anie.200462602

low reaction exothermicity of AB thermolysis is in significant contrast to hydrolysis pathways of boron-based hydrogen-storage materials. Given the approximate thermoneutrality of thermolysis accompanied by relatively low temperatures for H_2 release, AB is a strong candidate for on-board hydrogen storage. However, although AB exceeds targets for volumetric and gravimetric density for a hydrogen-storage material, three additional physical obstacles must be overcome: 1) The rates of H_2 release at temperatures below 85 °C must be increased, 2) borazine formation must be prevented, and 3) reversibility must be demonstrated.

There are reports that nanophase metal hydrides show enhanced kinetics for reversible hydrogen storage relative to the bulk materials.[22–24] However, after a few hydriding/dehydriding cycles the kinetic enhancement is diminished for some materials, as they lose nanophase structure.[25] Herein we suggest that a nanophase scaffold loaded with a hydrogen-rich material may provide an attractive option to preserve the nanoscale dimensions through several hydriding/dehydriding cycles. To demonstrate the effect of a nanophase scaffold on hydrogen release we use a high-surface-area mesoporous silica material loaded with AB as a model system. Three notable observations are described in this work: 1) increased rates of H_2 release, 2) modifications of the nonvolatile polymeric products that lead to a change in the thermodynamics of hydrogen release, and 3) minimized formation of borazine.

Mesoporous silica materials have an extremely high surface area and a highly ordered pore structure, which give them the appearance of nanochanneled silica scaffolds.[26] The mesoporous silica material used in this work, SBA-15, which was prepared according to a literature procedure,[27] is shown in Figure 1. The SBA-15 was loaded with AB by dosing the silica scaffold with a saturated methanolic solution of AB. Because of the porous nature of the silica scaffold, the internal channels of SBA-15 were filled rapidly by a capillary action directly upon exposure. The sample was dried under vacuum to remove the methanol and produce the SBA-15 coated with AB (1:1 by weight). Attempts to observe AB coated on the pores of SBA-15 by transmission electron microscopy (TEM) in ultramicrotome cross-sectional slices of the sample were not successful as a result of the weak scattering of electrons by the light elements B and N; however, electron dispersive spectrometry (EDS) of the microtome samples showed the presence of both elements B and N. Further evidence for the embedded material was inferred from BET measurements that show that the SBA-15 surface area is reduced from 900 $m^2 gm^{-1}$ before coating to $< 50\ m^2 gm^{-1}$ after coating.

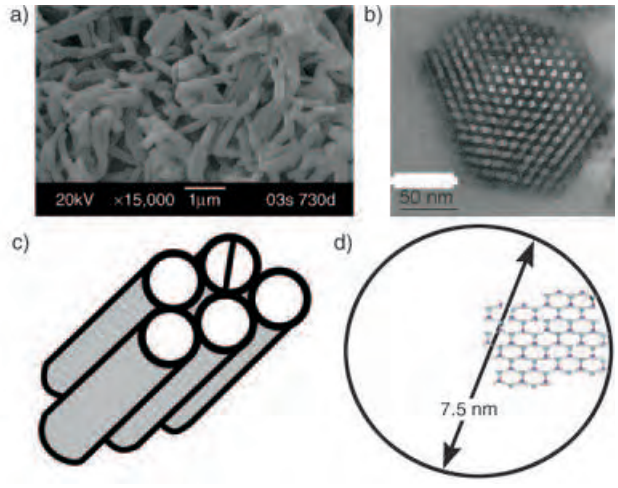

Figure 1. Schematic representation of AB in SBA-15, from the micro- to the nanoscale: a) SEM image of mesoporous silica; average particle size: 1 μm × 0.2 μm, surface area: ≈900 $m^2 gm^{-1}$, porous volume: 1.2 $mL g^{-1}$; b) TEM ultratome cross-sectional image of SBA-15 showing porous channels; c) schematic representation of parallel channels in SBA-15; pore diameter: 7.5 nm; d) schematic representation of a hydrogen-bonded AB network in the cross-section of a single pore.

Temperature-programmed desorption mass spectrometry (TPD/MS) was used to compare the temperature profiles of volatile products (H_2, borazine) released from neat AB and AB in the SBA-15 scaffold (Figure 2). Two peaks for neat AB

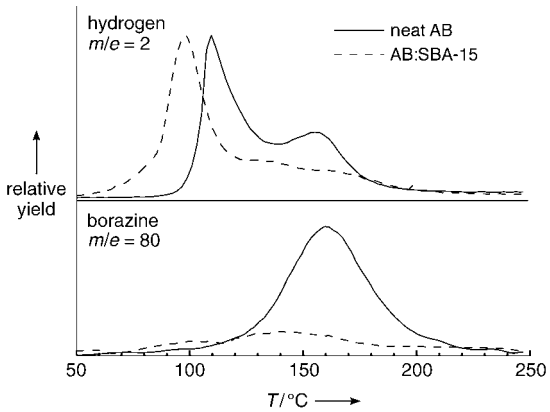

Figure 2. TPD/MS (1 °C min^{-1}) of volatile products generated by heating neat ammonia borane (solid line) and AB:SBA-15 (dashed line); $m/e = 2$ (H_2) and $m/e = 80$ (borazine, *c*-$(NHBH)_3$). The value $m/e = 2$ (H_2) is normalized to the area under the curve for neat ammonia borane (solid line). The corresponding scalar was used to normalize the $m/e = 80$ borazine data for AB:SBA-15.

at approximately 110 and 155 °C correspond to the release of the first equivalent of hydrogen with the formation of PAB, and the release of the second equivalent of hydrogen with the formation of PIB, respectively. There are two notable effects resulting from the nanostructure of AB in the SBA-15 scaffold: First, the temperature threshold for H_2 release ($m/e = 2$) is notably lower than the temperature threshold for neat AB, which is indicative of an enhanced rate of H_2 release. Second, the yield of the borazine side product ($m/e = 80$) is significantly lower than for neat AB. Solid-state ^{11}B NMR spectroscopy was used to analyze the nonvolatile products from neat AB and AB:SBA-15 to see if the borazine became entrapped within the mesoporous scaffold. However, no ^{11}B signal for borazine was observed, thus indicating that borazine is not likely to be trapped in the scaffold. Because borazine is not observed as a volatile product in the TPD/MS experiment and not detected by solid-state NMR spectroscopy, the mesoporous scaffold appears to affect the decomposition pathways of AB that lead to hydrogen formation.

Furthermore, if the PAB and PIB polymeric decomposition products formed in the SBA-15 scaffold do not form the more stabilized cyclization products, there may be a measurable difference between the reaction enthalpies for H_2 loss from AB:SBA-15 and neat AB.

Differential scanning calorimetry (DSC) experiments were used to quantify both the thermodynamics and kinetics for the release of the first equivalent of H_2 from neat AB and AB:SBA-15. Integration of the area under an isothermal DSC curve provides the enthalpy of reaction for H_2 release (ΔH_{rxn}). The enthalpy for H_2 loss from neat AB ($\Delta H_{rxn} = -21 \pm 1\ kJ\,mol^{-1}$) is in excellent agreement with the literature value for neat AB.[21] However, we find that the loss of H_2 from the AB in the scaffold is significantly less exothermic ($\Delta H_{rxn} = -1 \pm 1\ kJ\,mol^{-1}$). The difference in the observed ΔH_{rxn} for the release of H_2 from AB in the scaffold suggests that the nonvolatile products formed in the scaffold might be different from the nonvolatile products formed upon the release of H_2 from bulk AB. This hypothesis was confirmed by analysis of the ^{11}B NMR spectra of the nonvolatile products. After heating the 1:1 AB:SBA-15 mixture for 90 min at 85 °C only one resonance was observed (at $\delta = -23$ ppm), which we assign to PAB. On the other hand, after neat AB had been heated for 90 min at 85 °C three additional boron resonances were observed, as well as the PAB resonance.[28] The formation of the additional boron-containing products from neat AB must then contribute to the greater reaction exothermicity. The observation of a less exothermic enthalpy of reaction for H_2 loss from AB in the scaffold is important. As hydrogen loss becomes less exothermic, the reverse reaction, hydrogen uptake, becomes more favorable at a given pressure and temperature. The difference in the equilibrium between AB and PAB+H_2 in the neat material and the scaffold can be estimated from the van 't Hoff equation.[29] The experimental $\Delta\Delta H_{rxn}$ of 20 kJ mol^{-1} for H_2 loss from AB in the scaffold compared to H_2 loss from neat AB corresponds to a >4600-fold difference in pressure at room temperature!

The time dependence of H_2 release from neat AB at 80 °C and AB:SBA-15 at 50 °C is shown in Figure 3. The reaction exhibits sigmoidal kinetic behavior, and the extent of reaction (dashed curves) is indicative of an autocatalytic mechanism of hydrogen release.[30] The point ● on the integrated curve marks the half-life for hydrogen release. This analysis yields $t_{1/2} = 290$ min for the neat AB at 80 °C. The half-life for the 1:1 AB:SBA-15 sample at 80 °C could not be measured because the H_2 is released before the sample has reached this temperature ($t_{1/2} < 10$ min). However, if the temperature is decreased to 50 °C a baseline is observed for the AB:SBA-15 sample, and the kinetic analysis of the data results in a $t_{1/2}$ value of 85 min at 50 °C. Analysis of the integrated DSC data for various temperatures provides the half-life for hydrogen release as a function of temperature. Arrhenius treatment of this temperature-dependent rate data is shown in Figure 4. In both cases (neat AB and AB:SBA-15) a straight line is obtained; the gradient gives the apparent activation energy for hydrogen loss. These results suggest that the barrier for H_2 release from AB in the scaffold ($E_a \approx 67 \pm 5\ kJ\,mol^{-1}$) is significantly lower than the barrier for H_2 release from neat AB ($E_a \approx 184 \pm 5\ kJ\,mol^{-1}$). This large difference in activation energy manifests itself in a greater than 300-fold enhancement in the H_2-evolution rate at 70 °C. This result is important because one could potentially use the waste heat from a PEM (proton-exchange membrane) fuel cell (≈85 °C) to provide the heat to the hydrogen-storage media to drive hydrogen release.

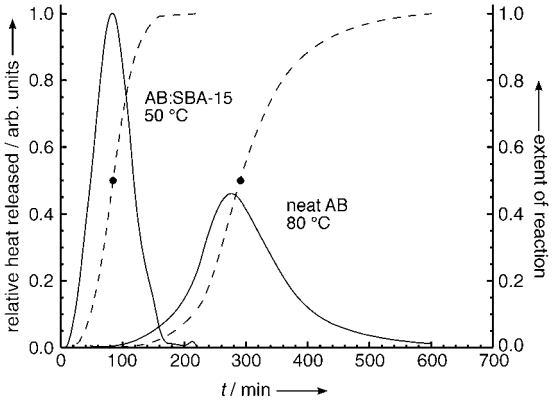

Figure 3. Scaled exotherms (solid lines) from isothermal DSC experiments that show the time-dependent release of H_2 from AB and AB:SBA-15 (1:1 wt/wt). The area under the curve for neat AB corresponds to $\Delta H_{rxn} = -21$ kJ mol^{-1}, and the area under the curve for AB:SBA-15 corresponds to $\Delta H_{rxn} = -1$ kJ mol^{-1}. The release of hydrogen from AB proceeds at a more rapid rate and at lower temperatures in SBA-15. The dashed line (——) is the integrated signal intensity; (●) is the point at which the reaction is 50% complete.

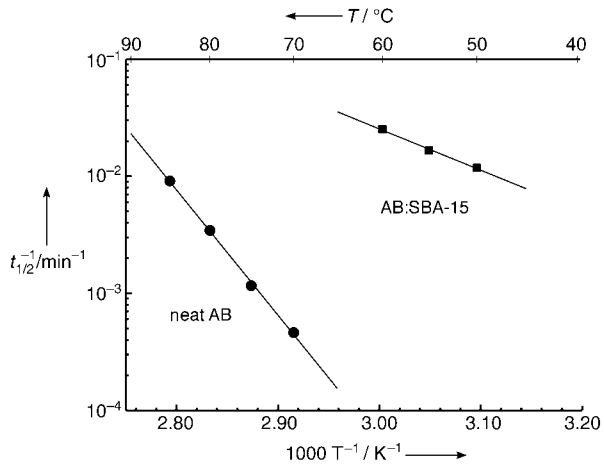

Figure 4. Arrhenius treatment of the temperature-dependent rate data yields a straight line with a gradient that is proportional to the apparent activation energy for hydrogen loss from neat AB (●; $E_a \approx$ 184 kJ mol^{-1}) or AB in the scaffold (■; $E_a \approx 67$ kJ mol^{-1}).

To our knowledge this is the first report of the use of an external agent (highly porous silica) to enhance the properties of a solid-state hydrogen-storage material. Coating the hydrogen-rich material AB within the mesoporus silica SBA-15 leads to: 1) suppression of borazine release, 2) modification of the enthalpy of the decomposition, and 3) lowering of the activation barrier for the loss of H_2. The enforced nanostructural geometry of the AB embedded in the scaffold may result in defect sites that initiate the dehydropolymeri-

zation reaction at lower temperatures. Alternatively, interfacial catalysis by the terminal SiO–H groups within the silica scaffold may result in the catalysis of the thermolysis of AB and control of the product distribution. These possibilities will be explored in forthcoming studies. The results for AB in the mesoporous silica are notable in themselves. We believe, however, that mesoporous materials may improve the kinetics and thermodynamics of hydrogen release from other materials, such as hydrogenated metal nitrides and imides or $LiBH_4$. For example, it has recently been reported that SiO_2 powder lowers the onset temperature for hydrogen release from $LiBH_4$.[31] The high surface area of SBA-15 would probably have very similar benefits and could enhance the kinetics for rehydriding, as the $LiBH_4$ would be confined to a nanophase structure.

Experimental Section

SBA-15 synthesis: Hexagonally ordered mesoporous silica (SBA-15) was prepared according to published procedures.[32] In a typical preparation of mesoporous silica with pores of 100 Å in diameter, pluronic P123 ($\bar{M}_W = 5800$; 12.0 g) was dissolved in 2 M HCl (360 mL) at 40 °C. Tetraethylorthosilicate (TEOS; 25.5 g) was added to the resulting milky solution, which was then stirred for 18 h at the same temperature. The mixture was transferred into a teflon-lined autoclave and heated at 100 °C for 24 h without stirring. The white precipitate was filtered, dried in air, and finally calcined at 550 °C for 6 h.

Preparation of AB:SBA-15: A solution of AB (50 mg) in methanol (300 μL) was added to a sample of SBA-15 (50 mg). The methanolic solution appeared to fill the internal channels of the mesoporous scaffold through a capillary action. The "wet" SBA-15 was dried under vacuum to produce a sample with an internal coating of ammonia borane (approximately 1:1 AB to SBA-15 by weight).

TEM: A thin section of the specimen was prepared for high-resolution TEM (HRTEM) by standard epoxy embedding followed by ultramicrotoming to a thickness of less than 50 nm. The HRTEM analysis was carried out with a Jeol JEM 2010 microscope with a specified point-to-point resolution of 0.194 nm. The operating voltage of the microscope was 200 keV. All images were recorded digitally with a slow-scan CCD camera (image size: 1024 × 1024 pixels), and image processing was carried out by using a digital micrograph (Gatan).

DSC/TPD/MS: DSC analyses were performed by using a Netzsch STA 409 TGA/DSC and a Pfeiffer QMS300 MS or a Setaram C80 calorimeter. The TPD/MS data for $m/e = 2$ (H_2) and $m/e = 80$ (borazine) were obtained by monitoring the off-gas with a heated fused (200 °C) silica capillary (a 1-m silanized fused silica capillary, 0.1 mm ID) attached to the top of the Netzsch instrument. The MS uses a standard electron impact ionization detector. The MS scanning rate was 12 s for a range of 1 to 100 amu. To obtain the relative yields of hydrogen and borazine, samples of AB (6.2 mg) and SBA-15:AB (1:1 wt/wt; 6.2 mg) were weighed into a Pt crucible for back-to-back experiments. The area under the SBA-15:AB curve was multiplied by a factor of two to provide a direct comparison for H_2 and borazine release from neat AB and AB embedded into the SBA-15 scaffold. A thermal ramp of 1 °C min^{-1} from room temperature to 200 °C with an argon flow of 20 $cm^3 min^{-1}$ were used in our analysis.

^{11}B NMR spectroscopy: Spectra of amino borane samples were recorded on a Varian Unity Inova spectrometer operating at a ^1H frequency of 800 MHz with a 4-mm 3-Ch Doty MAS probe. For the Bloch decay experiment a 200-kHz sweep width, a 5-μs 90°-pulse for ^{11}B (with and without ≈30 kHz decoupling), and a pulse delay of 5 s were used. Samples were spun at 15 kHz then cooled to 10–20 °C, and 128 scans were collected for each spectrum.

[28] The 800-MHz solid-state NMR spectrum is available as Supporting Information. Observed ^{11}B resonances: AB:SBA-15

(one signal, $\delta = -23$ ppm), neat AB (four signals, $\delta = -6$, -12, -23, -37 ppm).

[29] van 't Hoff equation: $\ln(p_{eq}/p^{o}_{eq}) = \Delta H/RT - \Delta S/R$. The difference in hydrogen overpressure can be calculated from $\Delta\Delta H$ of H_2 loss from AB bulk and AB in the scaffold. $\Delta\ln(p_{eq}/p^{o}_{eq}) = \Delta\Delta H/RT - \Delta\Delta S/R$. $\Delta\Delta S = 0$, $\Delta\Delta H = 20\ kJ\,mol^{-1}$, then $p_{eq}(AB)/p_{eq}(AB{:}SBA\text{-}15) = 4667$. As $\Delta H \approx 0$ in the scaffold, the pressure required for H_2 uptake by the spent AB is the pressure required to overcome the entropy of formation of the gaseous H_2. Reversibility processes will be addressed in a subsequent publication.

Nanoparticle Arrays

DNA-Encoded Self-Assembly of Gold Nanoparticles into One-Dimensional Arrays**

*Zhaoxiang Deng, Ye Tian, Seung-Hyun Lee, Alexander E. Ribbe, and Chengde Mao**

DNA-templated material assemblies usually fall into two categories: nonspecific electrostatic (or intercalative)[1] and sequence-specific assemblies.[2–5] The latter take advantage of the Watson–Crick base pairing and can assemble materials into well-defined structures by DNA-based molecular recognition. This approach is promising in controlling both the complexity and regularity of nanostructures. In previous work this approach was used to build small assemblies of gold nanoparticles (AuNPs).[3] The basic scheme is to hybridize mono-DNA-functionalized AuNPs with template-DNA strands to form the desired structures. It is conceivable to integrate this strategy with more extended and complicated DNA nanostructures[2,6] for nanoparticle assembly. One immediate challenge is to build large arrays by DNA-encoded self-assembly of AuNPs into well-extended micrometers-long one-dimensional (1D) arrays. The resulting linear structures could potentially link the nanometric properties of materials with the convenience of micrometric maneuverability.

Rolling-circle DNA polymerization is well-suited for the preparation of long, repetitive DNA single strands as templates for nanoparticle assembly. During the polymerization, a DNA polymerase uses a short (less than 100 bases long), circularized, single DNA strand as a template to synthesize long (more than 10000 bases), linear, tandemly repetitive single DNA strands under isothermal conditions.[7] This technique has found important applications in gene detection.[7c] Here, we use the products of rolling-circle polymerization to assemble AuNPs into extended 1D arrays up to 4 μm long.

Figure 1 illustrates our strategy to assemble micrometers-long AuNP arrays: 1) functionalization of 5-nm AuNPs with DNA 1 (with a 5′ thiol group) to form a 1:1 AuNP/DNA 1 conjugate (AuDNA 1); 2) rolling-circle polymerization[7] to synthesize template DNA ($\mathbf{T}_{long}$) with a large number of repeats complementary to DNA 1; and 3) hybridization of AuDNA 1 with $\mathbf{T}_{long}$ to form micrometers-long AuNP assemblies.

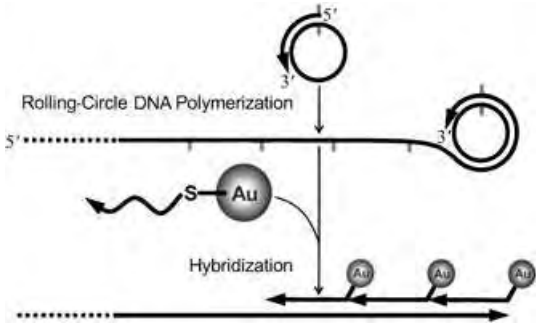

Figure 1. Synthesis of an extended gold nanoparticle array by combining DNA-encoded self-assembly and rolling-circle polymerization of DNA.

The reported methods[3] for synthesizing AuDNA 1 were adopted. The 53-base-long thiolated DNA 1 was first incubated with phosphine-capped 5-nm AuNPs in buffer 1 (see the Experimental Section) for over 3 h. Then, the AuDNA 1 conjugates were isolated by 3 % agarose gel electrophoresis in 10–20 % yields. Dark-red bands in the agarose gel corresponding to AuDNA 1 were easily determined (see the Supporting Information) by comparing the gel patterns to a pure AuNP band or by observing the evolution of the gel patterns while gradually increasing the amount of thiolated DNA 1 in the AuNP solution.

Before the assembly of micrometers-long AuNP arrays, we tested this scheme in the formation of smaller structures containing three to six AuNPs. Template-DNA strands ($\mathbf{T}_n$, $n = 3$–6, where n denotes the number of repeats in the template strands and each repeat is complementary to DNA 1) were prepared by ligation and purified by polyacrylamide gel electrophoresis (PAGE; 6 %, denaturing conditions). AuDNA 1 and the corresponding template strand were

The AFM study was carried out in Purdue Laboratory for Chemical Nanotechnology (PLCN). We thank Prof. A. Ivanisevic for use of an AFM in some cases. EM imaging was conducted at Purdue electron microscopy consortium.

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

  DOI: 10.1002/anie.200463096

then mixed together in buffer 1 at different ratios, and an AuDNA 1/$\mathbf{T}_n$ molar ratio of 1:0.5 (in terms of the repeats) was finally chosen to produce the desired AuNP assemblies, since the excess of AuDNA 1 could compensate its slightly decreased hybridization ability. The AuNP assemblies were isolated by gel electrophoresis (3% agarose), eluted into buffer 2, and analyzed by transmission electron microscopy (TEM). The TEM images and statistical analyses in Figure 2 and Table 1 clearly show the formation of the desired structures in high yields.

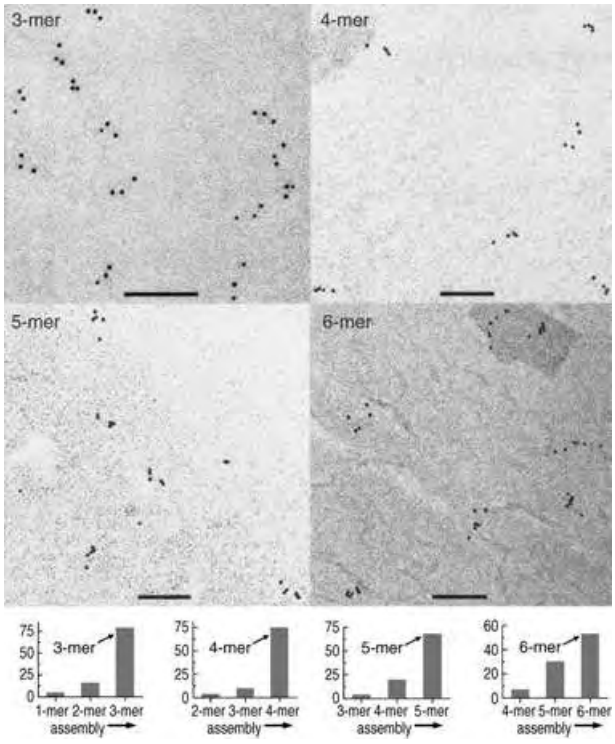

Figure 2. TEM images and statistical column charts showing the highly efficient assembly of gold nanoparticles into 3-, 4-, 5-, and 6-mers; all scale bars correspond to 100 nm.

Table 1: Typical yields for the AuNP assemblies from 3- to 6-mer obtained by TEM image analysis.[a]

	3-mer	4-mer	5-mer	6-mer
Counts of AuNPs [N_T]	619	345	466	660
Yield [%]	79	75	67.5	53

[a] N_T is the total number of observed AuNPs in the TEM images. The yield is defined as N_A/N_T, where N_A is the total number of AuNPs within the desired assembly. Particles located close to the edges of the TEM images were excluded.

The interparticle spacings of the AuNP assemblies were analyzed from the TEM images. To avoid the confusion in finding the correct particle pairs, only assemblies with easily distinguishable linear structures were chosen for the measurements. The results showed a center-to-center interparticle distance of (18.5 ± 6.9) nm (see the Supporting Information), consistent with the theoretical value of 18.0 nm for a 53-base-long DNA duplex. The observed interparticle distances had quite a wide distribution, which ranged from 6.1 to 33.9 nm. We attributed the spacing variation to the strong particle–particle and particle–substrate affinities, the bending, stretching, or partial unzipping of the DNA duplex during sample preparation, the flexibility of the linkage part between DNA and the AuNPs, and the 5-nm diameter of the AuNPs.[3b]

The synthesis of micrometers-long DNA template ($\mathbf{T}_{long}$) is key to the formation of extended AuNP arrays but is usually difficult. We solved this issue by rolling-circle DNA synthesis,[7] which used a circularized DNA 1 as the template, a 12-base-long DNA 2 as the primer, and a Phi29 DNA polymerase. The polymerization product ($\mathbf{T}_{long}$) contains many copies of the DNA 1 complement. $\mathbf{T}_{long}$ migrated very slowly in 1% agarose gel (Figure 3a) and is at least thousands

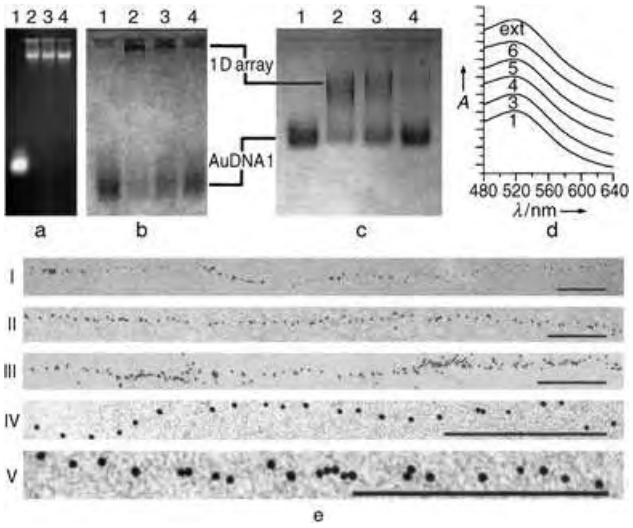

Figure 3. a) Agarose gel (1%) electrophoresis for the rolling-circle-synthesized products; lane 1: 53-base cDNA1, lanes 2–4: polymerized products obtained in different synthesis batches, which indicate good consistency. b, c) Agarose gel (b: 3%, c: 0.5%) electrophoresis of the extended 1D AuNP assembly; lane 1: AuDNA1, lanes 2–4: products obtained in 1:1, 1:0.5, and 1:0.25 ratios. d) Optical absorbance of the 1- (AuDNA1), 3-, 4-, 5-, and 6-mers and the extended (ext) 1D structure. e) TEM images of the extended 1D structures; (IV) and (V) are close-up views of part of the wires in (I) and (II); all scale bars are equivalent to 200 nm.

of bases long, with reference to a 100-base-pair DNA ladder (see the Supporting Information). The high-molecular-weight fraction was sliced from the gel, electrically eluted, precipitated from ethanol, and redispersed in doubly distilled H_2O (ddH_2O). The extended 1D arrays were prepared by combining AuDNA 1 and $\mathbf{T}_{long}$ at different ratios and annealing from 95 to 4 °C in buffer 1. The resulting aggregates were too large to migrate into a 3% agarose gel (Figure 3b), but they ran well in a 0.5% gel (Figure 3c). The aggregates at a ratio of 1:0.5 (AuDNA 1:repeat of $\mathbf{T}_{long}$) migrated slightly slower than those at a ratio of 1:1, which indicates that there were some unpaired segments on the template and thus an excess of

AuDNA 1 could improve the DNA hybridization. The aggregates at a ratio of 1:0.25 migrated the same as those at a ratio of 1:0.5, which implies that the template was saturated and thus incorporation of more particles was impossible. A ratio of 1:0.5 was chosen for the synthesis of the micrometers-long AuNP arrays.

Large-area atomic force microscopy (AFM), TEM, and field-emission scanning electron microscopy (FESEM) images showed 1D arrays of AuNPs up to 4 μm long aligned in a parallel fashion on TEM grids and silicon-wafer substrates (see the Supporting Information). The AuNP arrays could reach several micrometers in length, so it is reasonable to assume that the fluidic flow created during removal of the solution droplet could cause the long assemblies to be stretched and aligned. As shown in Figure 3e, the AuNPs were either well-separated within the appropriately stretched parts of the wires or entangled and coalesced on other parts. The visible absorbance spectra of the extended arrays and the 3- to 6-mers (Figure 3d) show no significant differences with that of AuDNA 1, in agreement with the large interparticle distances expected for a 53-base-pair DNA spacer.

In conclusion, we have successfully prepared extended 1D arrays of gold nanoparticles by combining rolling-circle polymerization and DNA-encoded self-assembly. The arrays obtained can dissolve in water and form a stable homogeneous solution, which enables subsequent modifications and easy manipulation. These results are an important step forward in obtaining extended nanoparticle arrays in a precise and controllable manner, which may help build structures with versatile functionalities. One of our further research goals is to design and fabricate more rigid and hierarchically complicated structures extending to one, two, or even three dimensions and to explore any potentially emerging physical properties.

Experimental Section

Buffer solutions: TBE buffer: tris(hydroxymethyl)aminomethane (Tris, 89 mM), ethylenediaminetetraacetate (EDTA, 2 mM), and boric acid (89 mM), pH 8.0. Buffer 1: 1:1 TBE + sodium chloride (0.2 M). Buffer 2: 1:1 TBE + sodium acetate (NaAc, 0.1 M). NEB Phi29 polymerase reaction buffer: Tris-HCl (50 mM), magnesium chloride (10 mM), ammonium sulfate (10 mM), and dithiothreitol (DTT, 4 mM).

Synthesis of $\mathbf{T}_n$ ($n = 3$–6): For the preparation of DNA templates $\mathbf{T}_n$, cDNA 1, a DNA strand complementary to DNA 1, was designed to leave four-base sticky ends at both sides of the duplex with DNA 1 that allow the formation of a ladder of duplexes. The corresponding templates were obtained by ligating cDNA 1 in the above product mixtures with a T4 DNA ligase (New England Biolabs, Inc., NEB). The 3- to 6-mers of cDNA 1 were then purified from a 6% denaturing polyacrylamide gel. DNA 1: 5′GAGTAGACCGTGCATCATGGACTAACCAGTGACCGCATCGGACAGCAGCCTGA3′; cDNA 1: 5′ACTCTCAGGCTGCTGTCCGATGCGGTCACTGGTTAGTCCATGATGCACGGTCT3′.

Rolling-circle synthesis of $\mathbf{T}_{long}$: Rolling-circle polymerization was conducted in solution (20 μL) at 37 °C for 90 min. The reaction was stopped by heating at 65 °C for 10 min. The reaction mixture contained 53-base-long circularized DNA 1 (0.1 μg), 12-base primer DNA 2 (5′CCATGATGCACG3′; 0.023 μg), Phi29 DNA polymerase (New England Biolabs, Inc., NEB; 5–10 units), NEB Phi29 polymerase reaction buffer, dNTP mix (1 mM), and BSA (0.1 mg mL^{-1}). The polymerization product was then dialyzed against ddH_2O for 16 h to remove salts and the dNTP monomers. The dialyzed sample was loaded onto 1% agarose gel containing ethidium bromide (0.5 μg mL^{-1}). For electrophoresis, the running buffer was half as concentrated as the TBE buffer and is designated 0.5 × TBE. The major band of the product (see the Supporting Information) was sliced and sealed into a dialysis membrane tube filled with 0.5 × TBE buffer. The product was electrically eluted from the gel block, extracted with butanol, precipitated with ethanol, and finally dispersed in ddH_2O (100 μL). The purified product was quantitated by measuring its UV absorbance at 260 nm. Typically, 3–5 μg of the $\mathbf{T}_{long}$ template was obtained.

Phosphine-capped gold nanoparticles (AuNPs): AuNPs (Ted Pella, Redding, CA; 5 nm) were stabilized by complexation with bis(*para*-sulfonatophenyl)phenylphosphine dihydrate dipotassium salt (salt 1, Strem Chemicals, Newburyport, MA). Typically, salt 1 (2 mg) was added to the AuNP solution (10 mL), and the mixture was shaken at 22 °C overnight. The AuNPs were then precipitated by adding solid sodium chloride until the color turned blue. After centrifugation, the supernatant was carefully removed with a pipette, and the AuNP precipitate was redispersed in ddH_2O to a concentration of 1–4 μmol, as estimated from the optical absorbance at 520 nm (1 OD equals 0.083 μmol for 5-nm AuNPs).

AuDNA 1: Thiolated DNA 1 and phosphine-protected AuNPs (1–4 μM) were mixed in buffer 1 at a molar ratio of 1:1 (estimated by optical absorbance). The mixture was incubated at 22 °C for over 3 h. The product containing AuNPs conjugated with different numbers of DNA 1 appeared as a series of dark-red bands in a 3% agarose gel with 0.5 × TBE as running buffer. The sample band corresponding to AuDNA 1 was sliced from the gel and sealed in a dialysis membrane tube prefilled with 0.5 × TBE buffer. AuDNA 1 was then electrically eluted into the dialysis tube, and the inner tubing buffer was carefully collected.

AuNP assemblies: Purified AuDNA 1 (0.3–0.8 μM based on the absorbance of AuNPs at 520 nm) was mixed with DNA templates at molar ratios (AuDNA 1:repeat of the template) of 1:1, 1:0.5, and 1:0.25. The mixtures were incubated in buffer 1: 95 °C (1 min), 65 °C (5 min), 50 °C (10 min), 37 °C (20 min), 22 °C (20 min), and 4 °C (20 min). The products were separated by electrophoresis on 3 or 0.5% agarose gel with buffer 2 as the running buffer. The ratios corresponding to the highest yields of the desired products were chosen, and the expected product bands were electrically eluted into buffer 2 and kept at 4 °C.

Microscopic analyses: 1) The TEM sample was prepared by dropping sample solution (5 μL) onto a carbon-coated TEM grid (400 mesh, EMS Inc.). After 1 min, the solution was wicked from the edge of the grid with a piece of paper. TEM images were taken with a Philips CM-10 transmission electron microscope operated at 80 kV in the bright-field mode. 2) The sample on a silicon wafer for AFM and FESEM imaging was prepared by spotting sample solution (5 μL) onto the silicon substrate. The drop was blown off after 1 min by compressed air and the surface of the wafer was washed once with aqueous magnesium acetate solution (2 mM, 30 μL). The sample was first checked with a Nanoscope IIIa multimode atomic force microscope operated in the tapping mode in air, and then subjected to imaging with a Hitachi S-4800 FESEM operated at 1 kV.

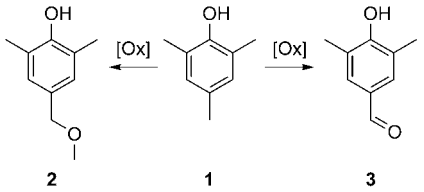
C–H Activation

Copper-Mediated Selective Oxidation of a C–H Bond**

*Christophe Boldron, Patrick Gamez, Duncan M. Tooke, Anthony L. Spek, and Jan Reedijk**

Substituted hydroxybenzaldehydes are important feedstock materials for the pharmaceutical and perfume industries.[1,2] These compounds are commonly made by the selective oxidation of aromatic methyl groups. However, this chemical reaction is difficult and often proceeds to the carboxylic acid derivative. Thus, 4-hydroxy-3,5-dimethylbenzaldehyde (HDB) is a valuable intermediate, especially for the preparation of drugs.[3–5] A number of synthetic routes to HDB starting from 2,4,6-trimethylphenol (TMP) involving stoichiometric amounts or an excess of oxidant are known.[6–10] So far, the only catalytic oxidation of TMP to HDB was achieved by Takehira and co-workers.[11–14]

Copper-containing enzymes, such as vanillyl alcohol oxidase[15] or laccase[16] can selectively produce the aromatic aldehyde functional group from a methyl group. We report here a bioinspired Cu^{II}/neocuproine system to perform the selective *para*-formylation of mesitol [Eq. (1)]. The reaction



2 1 3 (1)

of TMP (**1**) with $[CuCl_2(neo)_x]$ (neo = neocuproine = 2,9-dimethylphenanthroline) and sodium methoxide as cocatalyst in methanol at room temperature leads to the formation of 4-(methoxymethyl)-2,6-dimethylphenol (**2**, MDP) and/or HDB (**3**), depending on the experimental conditions (Table 1).

Without neocuproine no oxidation products were observed (entry 1); neo is thus necessary for the reaction to proceed, most likely to increase the oxidation potential of the

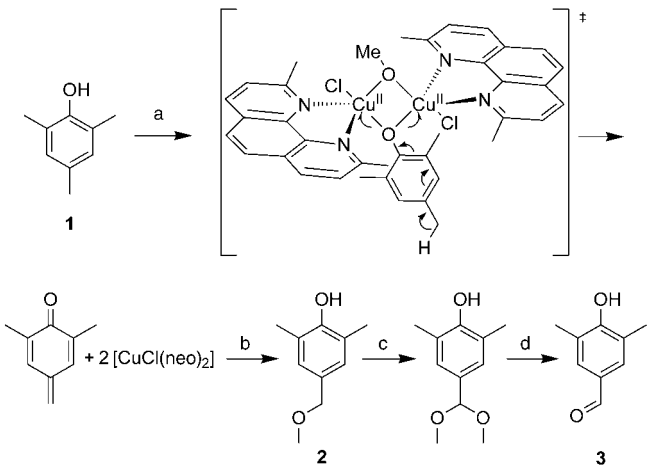
[a] [Ox] = [$CuCl_2$(neo)$_x$] + NaOMe; see the Supporting Information for the experimental procedure. [b] The yields (±5%) were determined by ^{1}H NMR spectroscopy after a reaction time of 30 min. [c] No products of over-oxidation could be detected; HDB was isolated in 85% yield. [d] Isolated in 69% yield. [e] Optimized catalytic reactions performed at 65°C under argon with H_2O_2. The yields (±5%) were determined by ^{1}H NMR spectroscopy using 1,2,4,5-tetrabromobenzene as an internal standard. [f] After a reaction time of 6 h. [g] After a reaction time of 12 h.

Cu^{II}/Cu^{I} pair. The neo ligand is indeed a highly specific bidentate ligand for Cu^{I} species, while its affinity towards Cu^{II} species is known to be low.[17,18] The bis-neocuproine copper(I) complex $[Cu(neo)_2]^+$ is extremely stable due to the presence of *ortho*-methyl groups, which strongly stabilize the tetrahedral geometry of Cu^{I} ions, thereby preventing their reoxidation to Cu^{II}. The driving force of the reaction is thus the more facile reduction of copper(II) ions owing to the affinity of neo for copper(I) species (see the Supporting Information). This is confirmed when neo is replaced by the sterically far less crowded 2,2′-bipyridine, as the resulting copper complex is inactive.

The amount of TMP used in the reaction was then varied. When 2 or 1 equiv of TMP per Cu^{II}/neo were used, total conversion of the substrate could not be achieved (Table 1, entries 2 and 3). The oxidation reactions exclusively led to the formation of MDP in 29% and 51% yield, respectively. These results are in accordance with the fact that the formation of MDP is a two-electron process. If 0.5 equiv of TMP is allowed to react with 1 equiv of Cu^{II}/neo, both MDP and HDB are produced (entry 4). The quantitative formation of the benzaldehyde derivative HDB was achieved with a TMP/Cu ratio of 0.25 (four-electron oxidation; entry 5). A series of experiments was subsequently carried out to improve the selectivity towards the methoxymethyl derivative. This study showed that very good selectivities in MDP could only be reached when moderate amounts of the basic cocatalyst were used along with one equivalent of neo per copper ion. For instance, the *para*-methoxymethyl compound could be produced in 82% yield in the presence of 0.75 equiv of NaOMe instead of 1 equiv (entry 6).

Based on the active site found in enzymes containing the type-3 copper site, a dinuclear copper species bridged by a phenolate and a methoxide is proposed as the key intermediate of the reaction (Scheme 1). The *para*-benzylic proton is activated through the coordination of the phenolate to the metal ions. Deprotonated TMP reduces each Cu^{II} to Cu^{I}. This $2e^-$ transfer induces the polarization of the benzylic C–H bond, which results in a rearrangement of the aromatic ring to a quinone methide. The nucleophilic addition of methanol to the quinone methide leads to the formation of the *para*-methoxymethyl derivative MDP. A second step ($2e^-$ oxidation/MeOH) yields a ketal compound, which has been detected by ^{1}H NMR spectroscopy in the crude mixture after evaporation of the solvent. Hydrolysis during the work-up affords HDB. The same result was observed when argon was used in place of air, suggesting that molecular oxygen is not involved in the C–O bond formation.

To further study the reaction mechanism and detect the proposed active species, attempts were made to crystallize a key intermediate. Reaction of a DMF/MeOH (9:1) solution of sodium pentafluorophenoxide (1 equiv)—a phenolate that is inactive towards oxidation—and neo (2 equiv) with $CuCl_2$ (2 equiv), NaOMe (1.2 equiv), and acetonitrile yields diamond-shaped green crystals suitable for X-ray diffraction (see the Supporting Information). A PLATON[19] representation of the molecular structure of this compound is depicted in Figure 1. As previously postulated by several authors, [20] a dinuclear copper(II) species bridged by both a methoxide and a pentafluorophenoxide is obtained. To the best of our knowledge, this is the first crystallographic evidence of a self-assembled, mixed μ-methoxo-μ-phenoxo-bridged dinuclear copper complex with a mononucleating nonbridging ligand, namely, neocuproine. This structure is in total agreement with the proposed active species for the reaction described above.



Scheme 1. Proposed reaction mechanism for the stoichiometric formation of MDP (**2**) and HDB (**3**) from TMP (**1**). a) NaOMe (2 equiv), $CuCl_2$ (2 equiv), neo (4 equiv), MeOH; b) MeOH; c) $2e^-$ oxidation: NaOMe (2 equiv), $CuCl_2$ (2 equiv), neo (4 equiv), MeOH; d) H_2O.

The investigation was then focused on performing this oxidation with catalytic amounts of the Cu^{II}/neo complex. This would provide an environmentally friendly and economically favorable system for industrial application. This mech-

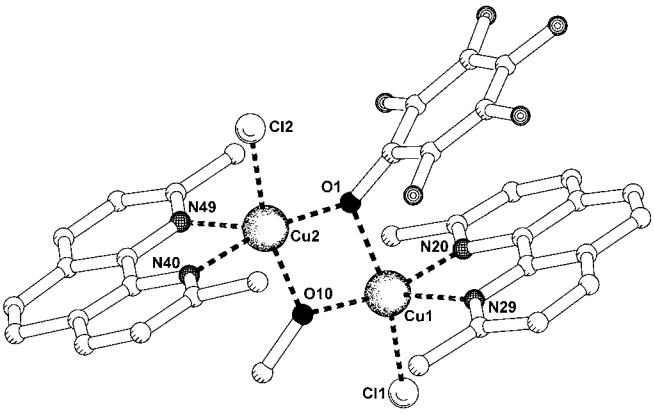


Figure 1. Molecular structure of $[Cu_2Cl_2(neo)_2(\mu\text{-}CH_3O)(\mu\text{-}C_6F_5O)]$. Selected bond lengths [Å] and angles [°]: Cu1–O1 2.066(7), Cu1–O10 1.950(6), Cu1–Cl1 2.276(3), Cu1–N20 2.025(8), Cu1–N29 2.270(9), Cu1–Cu2 3.137(8), Cu2–O1 1.947(6), Cu2–O10 1.966(7), Cu2–Cl2 2.265(3), Cu2–N40 2.043(8), Cu2–N49 2.256(8); Cu1-O1-Cu2 102.8(3), Cu1-O10-Cu2 106.4(3). See also the Supporting Information.

anism would imply the reoxidation of the Cu^{I} species, which a priori seems to be unlikely due to the very high stability of the $[Cu(neo)_2]^+$ cation. For this purpose, only 1 equiv of neo was used per Cu^{II} ion, as we anticipated a more facile reoxidation of the resulting Cu^{I} complex $[Cu(neo)]^+$. The first logical procedure was to perform the catalytic reaction in air, or in pure dioxygen, and heat the reaction mixture to promote the Cu^{I} oxidation. Only one catalytic cycle can be completed under these experimental conditions, suggesting that molecular oxygen is not strong enough to achieve the Cu^{I} reoxidation. To overcome this difficulty, hydrogen peroxide, an activated form of dioxygen, was successfully used as oxidant, and the experimental conditions were optimized. Thus, 0.14 equiv of $[CuCl_2(neo)]$, in the presence of 2 equiv of H_2O_2 and 0.3 equiv of NaOMe as basic cocatalyst, could catalyze the quantitative formylation of 1 equiv of TMP after 6 h (Table 1, entry 7). The selective oxidation was performed under argon and refluxing methanol. The controlled production of MDP could be carried out using a smaller amount of neo (0.035 equiv instead of 0.105 equiv; entries 7 and 8). Most likely, the presence of less ligand leads to the formation of different active species, allowing the isolation of the intermediate product **2**. No effective catalytic method for preparing MDP has yet been reported. Therefore, the synthetic procedure described here is the first effective catalytic preparation of MDP.

In conclusion, a new environmentally friendly, high-yielding procedure has been developed for the *para* C_{sp^3}-H oxidation of TMP. This compound can be selectively oxidized to form either MDP or HDB, two valuable industrial compounds. A key reaction intermediate, a self-assembled μ-methoxo-μ-phenoxo-bridged dinuclear copper complex involving a mononucleating ligand, was isolated and structurally characterized. This dicopper complex suggests the participation of bimetallic active species in the catalytic cycle as well as the nucleophilic attack of a methanolate anion to the bis-alkoxo-bridged complex. The substrate scope for this catalytic oxidation reaction is currently being investigated.

Selenenylation

Asymmetric Carboselenenylation Reaction of Alkenes with Aromatic Compounds**

Kazuki Okamoto, Yoshiaki Nishibayashi, Sakae Uemura, and Akio Toshimitsu**

Asymmetric functionalization of simple alkenes is one of the most attractive subjects in organic synthesis. A variety of asymmetric reactions such as epoxidation,[1] dihydroxylation,[2] aminohydroxylation,[3] hydroboration,[4] hydrosilylation,[5] cyclopropanation,[6] and carbonylation[7] have been reported for the introduction of new functional groups into alkene substrates to produce optically active compounds. The stereoselective addition of electrophilic reagents to simple alkenes is another versatile approach to provide synthetically useful compounds that bear various functionalized groups.[8,9] Recently, electrophilic selenium reagents with optically active moieties have been successfully employed in a number of stereoselective additions to simple alkenes.[10] Typically, the stereoselective selenenylation of simple alkenes with heteroatom-centered nucleophiles such as alcohols, nitriles, oximes, and azides gave the corresponding functionalized organoselenium compounds with high diastereoselectivity.[11,12] In all cases, the selenenylation proceeds via chiral episelenonium ions as key intermediates, which then undergo a ring-opening reaction by nucleophilic attack.

We recently reported the stereospecific reactions of chiral episelenonium ions generated from optically active (β-arylseleno)ethyl alcohols with carbon-centered nucleophiles such as alkenyl silyl ethers, trimethylsilyl cyanide, allyltrimethylsilane, and aromatic compounds.[13] This result prompted us to investigate the asymmetric carboselenenylation reaction of simple alkenes with carbon-centered nucleophiles. We describe herein the first example of the asymmetric carboselenenylation reaction of simple alkenes with aromatic compounds by using an optically active electrophilic selenium reagent.[14]

Treatment of an optically active areneselenenyl trifluoromethanesulfonate (triflate) **1a** (which is generated in situ from the reaction of a diaryl diselenide **2a** with bromine and silver triflate) with excess (*E*)-β-methylstyrene (**3a**) at −78 °C for 10 min in dichloromethane in the presence of molecular sieves (4 Å) and then with 2-methylfuran (**4a**) at −78 °C for 2 h gave 2-(1-phenyl-2-arylselenopropyl)-5-methylfuran (**5a**) in 73% yield with 91:9 d.r. (Scheme 1). Typical results are shown in Table 1. The presence of the 4-Å molecular sieves is essential to obtain **5a** in high yields (Table 1, entries 1–3). In fact, in the absence of the 4-Å molecular sieves, the yield of **5a** decreased, with an increase in the amount of 1-phenyl-2-aryleselenopropanol (**6**) (Table 1, entry 4). The compound **6** is considered to be formed by nucleophilic attack of adventitious water at the episelenonium ion intermediate. The use of a smaller amount of **3a** decreased the yield of **5a**

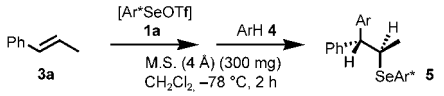
  DOI: 10.1002/anie.200500573

(Table 1, entry 5). A high diastereoselectivity was only attained by the use of **1a**. When other C_2-symmetric areneselenenyl triflates bearing two ethoxy groups (**1b**)[15] and two benzyloxy groups (**1c**) were used instead of **1a**, a lower diastereoselectivity of the product and no formation of the product were observed, respectively. Although extremely high diastereoselectivities were reported in the selenenylation of **3a** with heteroatom-centered nucleophiles such as alcohols by using a variety of active areneselenenyl triflates (Scheme 2, **1d**–**1f**),[11,12h] these areneselenenyl triflates did not work effectively in this carboselenenylation reaction. Detailed results are given in the Supporting Information.

The asymmetric carboselenenylation reactions of **3a** with other furans **4b**–**4d** by using **1a** as an optically active electrophilic selenium reagent under similar reaction conditions gave the corresponding alkylated furans **5b**–**5d** in good yields with high diastereoselectivity (Table 2). In the reaction with furan (**4b**), the product **5b** was obtained in slightly lower yield (Table 2, entry 1). Other heterocyclic aromatic compounds such as 2-methylthiophene (**4e**) and *N*-methylpyrrole (**4f**) can be alkylated at the α position of the heterocyclic rings. In both cases, high diastereoselectivities (91:9 and 89:11 d.r., respectively) were attained (Table 2, entries 4 and 5). Unfortunately, no reaction occurred when *N*-methylindole was used as a heterocyclic aromatic compound. Not only heterocyclic aromatic compounds but also electron-rich benzene derivatives can be used in this asymmetric carboselenenylation reaction. The best diastereoselectivity was found in the reaction of **3a** with 1,3,5-trimethoxybenzene (**4i**), and the corresponding alkyl substituted derivative was formed with 95:5 d.r. (Table 2, entry 8). Recrystallization of the mixture from methanol gave only the major diastereoisomer in pure form. The molecular structure of the major diastereoisomer of **5i** was unambiguously determined by X-ray crystallographic analysis (see Supporting Information).[16] In contrast to the good reactivity of *N*,*N*-dimethylaniline (**4j**) and azulene (**4k**) (Table 2, entries 9 and 10), no reaction proceeded when anisole (**4g**) and 1,4-dimethoxybenzene (**4h**) were used as benzene derivatives (Table 2, entries 6 and 7).

Table 2: Asymmetric carboselenenylation reaction of (*E*)-β-methylstyrene (**3a**) with aromatic compound (**4**) by using **1a**.[a]



Entry	ArH (**4**)		Product (**5**)		Yield[%][b]	d.r.[c]

[a] All the reactions of **3a** (2.00 mmol) with **4** (1.00 mmol) in the presence of **1a** (0.20 mmol) were carried out at −78 °C for 2 h. [b] Yield of isolated product. [c] Determined by ^{1}H NMR.

The asymmetric carboselenenylation reaction of other alkenes (**3**) was investigated next (Table 3). The introduction of a *p*-fluoro or *p*-phenyl substituent in the aromatic ring of β-methylstyrene slightly increased the diastereoselectivity (Table 3, entries 1 and 2). On the other hand, a slightly lower diastereoselectivity was attained in the reaction of *p*-methyl-(*E*)-β-methylstyrene (**3d**) (Table 3, entry 3). The introduction of a chloro substituent in the aromatic ring decreased the reactivity (Table 3, entries 4 and 5). Furthermore, the reaction of 2-((*E*)-1-propenyl)naphthalene (**3g**) proceeded smoothly to give the corresponding alkylated furan (**5q**) in good yield with 87:13 d.r. (Table 3, entry 6). Although the reason is not known, the presence of 4-Å molecular sieves decreased both the reactivity and the

8		**3i**		**5s**	45	78:22
9		**3j**	**5t**	0	–
10		**3k**	**5u**	0	–

[a] All the reactions of **3** (2.00 mmol) with **4a** (1.00 mmol) in the presence of **1a** (0.20 mmol) were carried out at −78 °C for 2 h. [b] Yield of isolated product. [c] Determined by ^{1}H NMR. [d] In the absence of 4-Å molecular sieves.

diastereoselectivity of the reaction of α-methylstyrene (**3h**) (Table 3, entry 7). A lower diastereoselectivity was observed when styrene (**3i**) was used as an alkene (Table 3, entry 8). A similar trend of lower diastereoselectivity in the cases of **3h** and **3i** has been observed in the asymmetric oxyselenenylation with methanol by using **1b**.[15] Unfortunately, no reaction occurred in the reactions of aliphatic alkenes such as 1-octene (**3j**) and 3,3-dimethylbutene (**3k**).

The stereochemistry of the major diastereoisomer of **5i** (*R* configuration at the benzylic position) indicates that **3a** undergoes *Si*-face attack by the chiral areneselenium moiety (Figure 1). This stereoselective approach is supported by previous theoretical studies with density-functional calculations on the transition states by using **1a**.[17] Separately, we confirmed that the reductive cleavage of a chiral arylselenium moiety of **5j** (90:10 d.r.) with Bu_3SnH in the presence of a catalytic amount of AIBN in toluene at reflux for 6 h afforded optically active 1-(*N*,*N*-dimethylaminophenyl)-1-phenylpropane (**7**) in quantitative yield with 90:10 d.r. (HPLC) (Scheme 3). This result indicates that the removal of the arylselenium moiety in **5** proceeded without loss of optical purity at the benzylic position.

In summary, we have developed an asymmetric carboselenenylation reaction of simple alkenes with aromatic compounds by using a C_2-symmetric areneselenenyl triflate. The carbon–carbon bond-forming reaction proceeds with high diastereoselectivity. This reaction is a convenient procedure for the preparation of chiral hydrocarbons that bear an aryl moiety at the stereogenic carbon atom and can be considered as a new type of asymmetric Friedel–Crafts alkylation reaction of aromatic compounds with alkenes. Further work is aimed at the elucidation of the reaction mechanism in detail and broadening the scope of the asymmetric reaction.

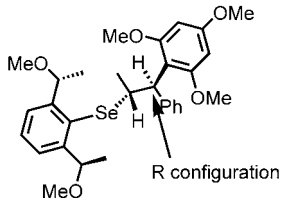

Figure 1. Stereochemistry of the major diastereoisomer of **5i**.

Experimental Section

5a: Molecular sieves (4 Å) (300 mg) and a solution of bromine (0.12 mmol) in CCl_4 (0.12 mL) were added to a solution of diselenide **2a** (54.4 mg, 0.10 mmol, > 99 % *ee*) in CH_2Cl_2 (4.0 mL) at −78 °C. After 30 min, silver triflate (61.7 mg, 0.24 mmol) was added. The resulting heterogeneous mixture was stirred at −78 °C for 30 min. *(E)*-β-Methylstyrene (**3a**) (236.4 mg, 2.00 mmol) was then added to the mixture at −78 °C followed by 2-methylfuran (**4a**) (81.2 mg, 1.00 mmol). The mixture was stirred for 2 h, quenched with saturated aqueous $NaHCO_3$ at −78 °C, and extracted with CH_2Cl_2. The combined organic layers were dried over $MgSO_4$ and concentrated. The residue was purified by silica-gel chromatography to give **5a** as a colorless oil (68.4 mg, 0.145 mmol, 73 % yield, 91:9 d.r.). The diastereoisomers could not be separated by flash chromatography. The diastereoselectivity does not change during the purification. The ratio of two diastereoisomers was determined by ^{1}H NMR and ^{77}Se NMR; ^{1}H NMR ($CDCl_3$, 400 MHz): major diastereoisomer: δ = 1.24 (d, J = 6.8 Hz, 3H), 1.39 (d, J = 6.4 Hz, 6H), 2.26 (s, 3H), 3.12 (s, 6H), 3.74 (dq, J = 10 and 6.8 Hz, 1H), 4.06 (d, J = 10 Hz, 1H), 5.13 (q,

$J = 6.4$ Hz, 2H), 5.86 (d, $J = 3.2$ Hz, 1H), 6.03 (d, $J = 3.2$ Hz, 1H), 7.27–7.46 ppm (m, 8H); minor diastereoisomer: $\delta = 3.83$ (dq, $J = 8.8$ and 6.4 Hz, 1H), 4.11 ppm (d, $J = 8.8$ Hz, 1H); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 100 MHz): major diastereoisomer: $\delta = 13.7$, 20.6, 24.2, 44.3, 52.4, 56.3, 78.4, 105.9, 107.5, 125.2, 127.2, 128.1, 128.3, 128.5, 129.7, 140.6, 148.3, 151.2, 153.0 ppm; $^{77}Se\{^1H\}$ NMR ($CDCl_3$, 76 MHz): major diastereoisomer: $\delta = 236.9$ ppm (s); minor diastereoisomer: $\delta = 236.3$ ppm (s). Elemental analysis: calcd for $C_{26}H_{32}O_3Se$: C 66.23, H 6.84; found: C 66.31, H 6.92.

intensively in recent years. The elementary reaction can be written as Equation (1):

$$S + h\nu \rightarrow S^* \rightarrow S^+ + e^-_{surf}(TiO_2) \rightarrow S^+ + e^-_{CB\ or\ trap}(TiO_2) \quad (1)$$

In this process the dye linked covalently to the TiO_2 through a carboxy group is excited from the ground state S to the excited state S*. The excited dye molecule then acts as an electron donor, and transfers an electron to the surface states and subsequently to the conduction band of colloidal TiO_2. A high quantum efficiency for the conversion of light energy into electricity in dye-sensitized solar cells requires the fast injection of electrons combined with a very slow back transfer of electrons.[1–11] Charge recombination associated with dye-sensitized TiO_2 systems has been rationalized in terms of the inverted Marcus region, where the recombination rate is slowed because of a highly exergonic reaction.[12–14]

The charge-separated state is one of the key intermediates in the photosensitization of electron transfer across the semiconductor/solution interface. The electron in the conduction band reverts to the ground state by recombination, or is trapped on an interior Ti^{3+} ion. The dye molecule remains as the radical cation, which is composed of the charge-separated state and the trapped electron within the TiO_2 particle. Time-resolved EPR (TREPR) spectroscopy has been applied successfully to obtain precise information on transient paramagnetic species. In nanocrystalline TiO_2 particles where bidentate ligands were used as electron donors, polarized EPR spectra originating from a limited distribution of geometries were interpreted by the fixed relative orientation of the magnetic tensor corresponding to the trapped electron and trapped hole.[15] Herein, we report the observation of charge-separated states of TiO_2 nanoparticles sensitized with xanthene dye. We determined the distances between the electron and the dye radical cation as well as their relative orientations by analysis of spin-polarized EPR spectra.

Colloidal TiO_2 particles were prepared by controlled hydrolysis of $TiCl_4$ at 2 °C and further dialysis of the sol.[16] The mean particle size was determined to be about 22 nm by dynamic light scattering studies. The two xanthene dyes (fluorescein (FL) and dichlorofluorescein (FL-Cl_2)) used in the experiments were obtained from Tokyo Kasei and were purified by recrystallization from ethanol before use. The output (coumarin 480, 485 nm) of a dye laser (Lumonics, HD300) pumped by an excimer laser (Lambda Physik COMPex 102) was used for excitation of FL and FL-Cl_2. The detection system for the TREPR signal has been described elsewhere.[17] A helium-flow cryostat (Oxford ESR900) was utilized for measurements at low temperatures.

Spin-polarized EPR spectra were observed after excitation with visible light of xanthene dyes adsorbed on colloidal TiO_2 (Figure 1). The polarization patterns (EAE), where A and E denote the enhanced absorption and emission of microwaves, respectively, were essentially identical for the two dye/TiO_2 systems. These results indicate that the precursor state responsible for injection of electrons into the TiO_2 nanoparticle has the same spin multiplicity in the two cases. Since the quantum yields of intersystem crossing in these dyes are very small, electron injection can be expected to occur from the excited singlet precursor state.[18] The polarized signals in each canonical magnetic field decayed with the same rate (approximately $1.0 \times 10^6\ s^{-1}$), with the phase of the polarization maintaining the EAE pattern during the decay.

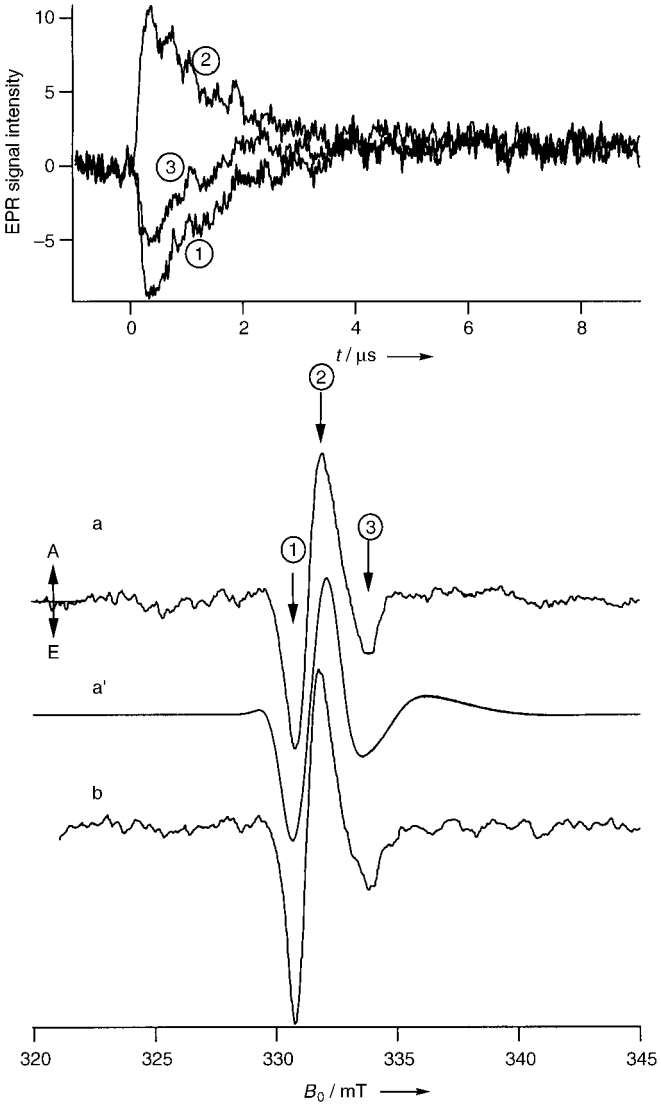

Figure 1. Top: temporal behavior of the polarization at different magnetic fields. Bottom: Time-resolved EPR spectra of FL (a) and FL-Cl_2 (b) adsorbed on colloidal TiO_2 nanoparticles observed at 500 ns after excitation with a laser pulse with a wavelength of 485 nm at 30 K, and the simulated spectrum (a').

The polarized spectra can be readily interpreted in terms of the polarization mechanism of the spin-correlated radical pair (SCRP), where coherent spin singlet/triplet mixing takes place within the radical pair.[19–22] For the calculation we assumed an axial symmetric **g** tensor ($g_\parallel = 1.958$ and $g_\perp = 1.988$) for the trapped electron on TiO_2 and isotropic g values for the dye radical cations.[23] From consideration of the contribution from unresolved hyperfine interactions, an anisotropy of the line widths, $\Delta H_\parallel = 0.8$ and $\Delta H_\perp = 0.3$ mT, was also assumed for the trapped electron. However, isotropic

line widths were used for the dye radical cations because of the expected significant delocalization of the unpaired electron. Exchange (J_{SS}) and dipolar (D_{SS}) interactions were the parameters used for simulation of the observed SCRP signals. D_{SS} is given by $D_{SS}R^3 = -2.786\ \mathrm{mT\,nm^3}$, in which R is the separation of the two unpaired electrons in the molecular center if a point dipole approximation is assumed. According to empirical estimates of the exchange coupling, the value of J_{SS} is negligible compared to the dipolar coupling for distances larger than 1.5 nm.[24–26]

We first calculated the spectrum under the assumption that the dye radical cation is distributed randomly on the surface of TiO_2. However, the observed spectral patterns could not be reproduced satisfactorily. As the local symmetry of the magnetic interactions of a trapped electron on a TiO_2 colloidal nanoparticle is highly anisotropic, the relative orientation between the **g** tensor of the trapped electron and the dipolar tensor of the electron–hole (dye radical cation) pair should be taken into account. In addition, the spin dynamics in the radical pair can also influence the polarization pattern. Unfortunately, the recombination rate of the radical pair at cryogenic temperatures has not been determined. We assumed for the calculation that the recombination rate of the singlet radical pair was of the same order as the polarization decay. The calculated SCRP spectra with different angles ϕ between the **g** tensor of the trapped electron and the dipolar tensor ($\mathbf{Z_d}$) are shown in Figure 2. The EAE polarization patterns were obtained when the angle was set between 90 and 100°. J_{SS} and D_{SS} values corresponding to a distance of 1.6 nm between two unpaired electrons were used for the calculation. The calculated results assuming positive values of J_{SS} are shown in Figure 2. The spectral widths were not significantly affected beyond a radical separation of 1.5 nm, because the small magnetic interaction between two unpaired electrons becomes almost equivalent to the line width. Thus, from the present analysis, we found the separation of the two unpaired electrons was greater than 1.5 nm. Since the size of the dye molecules is known, the trapped electron can be said to be localized at about 0.5 nm from the surface.

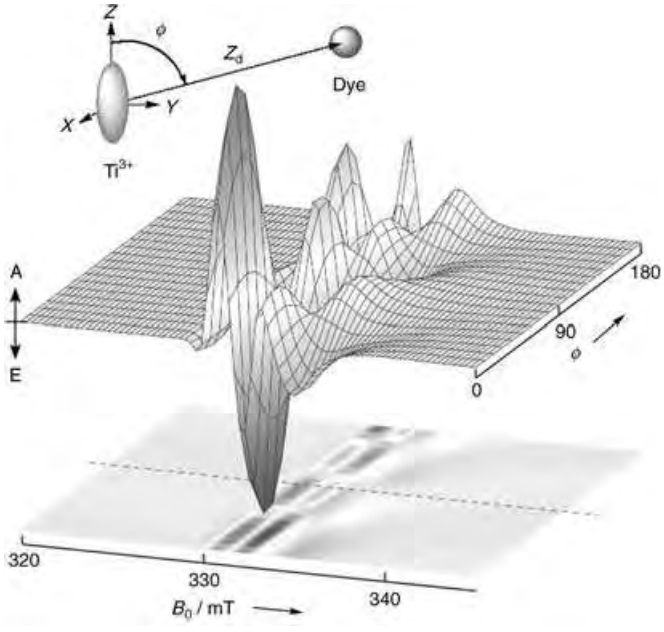

Figure 2. Calculated EPR spectra with different angles between the **g** tensor of the trapped electron and the dipolar tensor of the charge-separated state. The parameters used in the calculation are described in the text.

We obtained the simulated spectra of FL as shown in Figure 1a′ by using the same parameters (J_{SS}, D_{SS}, ϕ, and **g** tensor of the trapped electron). The spectrum observed in the FL-Cl_2/TiO_2 system was also reproduced by using essentially identical parameters. The deviation from the observed spectra can be ascribed to the distribution of dye molecules around ϕ on the TiO_2 colloidal semiconductor. To obtain the best fit of the observed EPR spectra we assumed a positive sign for the exchange interaction. As mentioned above, slow back electron transfer to the dye ground state occurs in the Marcus inverted region where recombination is slowed because of a large change in the free energy of the reaction. The sign of the exchange interaction between the radical pairs is determined by the charge-transfer interaction between the radical ion pair state and the nearby charge-recombined state.[27,28] The locally excited triplet state in the singlet precursor reaction systems effectively perturbs the radical ion pair states because of the small energy difference. The triplet radical ion pair state is selectively stabilized by perturbation from the locally excited triplet state through the electronic coupling, thus leading to positive J values.

The recombination rates for xanthene dye/TiO_2 systems were reported to range from several picoseconds up to microseconds and even milliseconds.[1–11] Colloidal TiO_2 particles had previously been shown to have a crystal structure corresponding to that of anatase.[29] The negatively charged dye molecule reacts with a positively charged Ti-hydroxy group and becomes bound to the Ti atom through formation of a bidentate surface complex. The electron injected from the excited dye molecule recombines through a geminate recombination pathway, but is also trapped in states (assigned to interior Ti^{3+} ions having D_{2d} symmetry) lying below the edge of the conduction band of the TiO_2 nanoparticle. A distribution of energetically different trap sites for the electron and its environments could be responsible for such recombination kinetics. The polarized EPR spectrum is observed at timescales of the order of a microsecond or shorter. In the analysis of the SCRP signal of the xanthene dye/TiO_2 system the relative orientations of the **g** tensor of the trapped electron and the vector of the dipole–dipole interaction between two unpaired electrons are fixed regardless of the expected uniform adsorption of the dye molecules on the surface of the TiO_2 nanoparticle. The observed polarized spectra were well-reproduced at an angle of around 90° between the **g** tensor of the electron and the dipolar tensor. This finding indicates that electron transfer across the semiconductor surface occurs with high orientational selectivity with respect to the radical stabilized on the xanthene dyes. As a result, an anisotropic orientation between the trapped electron and the hole is realized in the microsecond-scale interval after the injection of electrons. The relative orientation of trapped electrons versus cationic

dyes as reported here may correspond to a residual distribution that remains after most of the recombination events have already occurred on a much shorter time scale (femtoseconds to picoseconds) than corresponds to the time resolution of the present experiment.

In conclusion, we have observed polarized EPR spectra of xanthene dyes adsorbed on colloidal TiO_2 at low temperatures upon excitation with pulses of visible light. The SCRP polarization mechanism was adopted to analyze the polarization patterns and line shapes in detail. The positive sign of the exchange interaction of the radical pair was ascribed to charge recombination in the Marcus inverted region. The relative orientation of the magnetic tensor of the trapped electron and the dye radical cation is fixed, thus leading to orientational selectivity in electron transfer across the semiconductor nanoparticle.

Molecular Dynamics

The Importance of Molecular Vibrations: The Sign Change of the Optical Rotation of Methyloxirane**

Kenneth Ruud and Riccardo Zanasi*

Since the publication of the first measurement of the optical rotation of (*S*)-methyloxirane in the gas phase by Müller et al.[1] there has been much theoretical interest in the optical rotation of this molecule. To a large extent, this is because it has proven very difficult to obtain the correct sign of the optical rotation of this molecule at the experimental wavelength of 355 nm in theoretical calculations.[2–4] Several coupled-cluster investigations,[3,4] such as the highly correlated CC3 approach which includes triple excitation corrections, all predict a negative optical rotation for (*S*)-methyloxirane at the experimental wavelength of 355 nm. The geometry dependence of the property is important, but the

  DOI: 10.1002/anie.200500642

use of different geometries[4] has not been sufficient to reproduce the experimental sign of the optical rotation at 355 nm.

DFT/B3LYP calculations provided a positive optical rotation at 355 nm, in agreement with experiment.[2,3] However, Tam et al.[3] argue that this result is a consequence of the incorrect prediction by the B3LYP functional of the energy for the excitation to the lowest Rydberg state, which is too low compared to experimental values because of the well-known limitations of common density functionals in reproducing the correct asymptotic limit for diffuse excited states.[5,6] The too low excitation energy leads to an unphysically strong dispersion of the optical rotation in the vicinity of electronic excitations, which occurs at too long wavelengths, and thus incorrectly increases and changes the sign of the optical rotation calculated at the DFT/B3LYP level of theory.

It was suggested in the coupled-cluster studies that the observed discrepancy between theory and experiment may be a result of vibrational effects. There has only been one study of zero-point vibrational effects on optical rotation in the literature,[7] which also included an examination of the zero-point vibrational corrections to (*S*)-methyloxirane. It was shown that zero-point vibrational corrections could be quite sizeable in comparison to the electronic contribution. However, at 589 nm and at the Hartree–Fock level of theory, the calculated zero-point vibrational correction was only 3.6 deg dm^{-1} g^{-1} mL, which was not enough to change the sign of the calculated CCSD or CC3 optical rotation.

Herein, we present calculations of the zero-point vibrational corrections of the optical rotation of (*S*)-methyloxirane at the DFT/B3LYP level of theory, with both 589 and 355 nm as the wavelength for the incident light. The zero-point vibrational corrections are calculated by using a computational method described previously.[7–9] The use of the B3LYP functional should give us some understanding of the importance of electron correlation effects,[10] although we keep in mind the potential problems of B3LYP calculations at 355 nm that result from the too low excitation energy. Our results were obtained using the aug-cc-pVDZ and aug-cc-pVTZ basis sets,[11,12] and are collected in Table 1.

Notably, the dispersion is also very strong for the zero-point vibrational corrections to the optical rotation, and these corrections are 18.6 (48.1) and 2.1 (10.7) at 355 and 589 nm, respectively, when calculated using the aug-cc-pVDZ (aug-cc-pVTZ) basis set. There is also a large difference in the zero-point vibrational correction calculated at the double- (DZ) and triple-zeta (TZ) levels of theory, which is primarily a result of the change in sign of the anharmonic contribution. In our approach, the anharmonic contribution arises from a shift in the molecular geometry, and is related to the cubic force field of the molecule.[8,9] When going from the DZ to the TZ basis set, the changes in the cubic force lead to a change of direction of the rotation of the methyl group, and thus to a change of the sign of the anharmonic term. The DFT/B3LYP results at the aug-cc-pVDZ level are in good agreement with our previous Hartree–Fock results at 589 nm (3.6).[7]

The vibrationally averaged optical rotation calculated at the B3LYP/aug-cc-pVTZ level of theory now appears quite meaningless, as it is much too large at 355 nm and has the wrong sign at 589 nm. However, if we combine our zero-point vibrational corrections (obtained with the aug-cc-pVTZ basis set) with the best correlated data for the optical rotation (the CC3 results of Kongsted et al.[4]), we find that their value for the equilibrium-geometry optical rotation of −23.2 at 355 nm leads to a vibrationally averaged optical rotation of 24.9, whereas at 589 nm their equilibrium-geometry optical rotation of −17.7 leads to a vibrationally averaged optical rotation of −7.0 when combined with our calculated zero-point vibrational correction (see Table 1). The experimental data at 589 nm were obtained in solution and were extrapolated to −26.9 in the innocuous solvent cyclohexane. Calculations show that the effects of a dielectric medium are to make the optical rotation more negative.[4]

Table 1: Calculated and experimental optical rotations of (*S*)-methyloxirane.[a]

λ [nm]	$[\alpha]_\lambda^e$	$[\alpha]_\lambda^{eff}-[\alpha]_\lambda^e$	$\langle[\alpha]_\lambda^{(2)}\rangle^{eff}$	$\langle[\alpha]_\lambda\rangle^{ZPV}$	$\langle[\alpha]_\lambda\rangle$	Exp.[1]

[a] The optical rotation at the equilibrium geometry $[\alpha]_\lambda^e$, the anharmonic zero-point vibrational correction ($[\alpha]_\lambda^{eff}-[\alpha]_\lambda^e$), the harmonic vibrational correction $\langle[\alpha]_\lambda^{(2)}\rangle^{eff}$, the total zero-point vibrational correction $\langle[\alpha]_\lambda\rangle^{ZPV}$, and the vibrationally averaged optical rotation $\langle[\alpha]_\lambda\rangle$ were calculated at the B3LYP level of theory with two different basis sets. All results reported in units of deg dm^{-1} g^{-1} mL. [b] For the gas phase. [c] Cyclohexane solution. [d] Using the CC3 results[4] for the equilibrium-geometry optical rotation, and the B3LYP/aug-cc-pVTZ results reported herein for the vibrational correction.

The sensitivity of our calculated vibrational corrections to the quality of the basis (and in practice to the quality of the anharmonic force field), and the rather dramatic consequence this has for the vibrational corrections to the optical rotation of methyloxirane, highlights the inadequacy of a local-mode approximation to such a freely rotating methyl group. We might therefore expect that our anharmonic contribution may be too large. Furthermore, although there is no strict correlation between the dispersion dependence of the vibrational correction and the electronic contribution to the property, the dependence on dispersion may be exaggerated in our vibrational corrections by the too low B3LYP excitation energies. Still, even if our vibrational corrections are somewhat large, we believe an even more accurate calculation of the vibrational correction will leave our conclusion unchanged and lead to an improved agreement with experiment.

In conclusion, the observed change of sign of the optical rotation of (*S*)-methyloxirane when going from a wavelength of 589 to 355 nm is a result of the vibrational corrections to these properties. Our approach has inherent limitations because of the too low excitation energies predicted by the DFT/B3LYP level of theory, and the inadequacy of a local-

mode approximation in modeling the contributions to the optical rotation that result from the rotation of the methyl group. However, we believe that our results and conclusions will not be overturned by a more accurate calculation. The apparent success of DFT/B3LYP in obtaining the correct sign of the optical rotation at 355 nm[2,3] is shown to be fortuitous, in agreement with earlier observations.[3,4]

Self-Assembled Monolayers

Side-by-Side Patterning of Multiple Alkanethiolate Monolayers on Gold by Edge-Spreading Lithography**

*Matthias Geissler, Joseph M. McLellan, Jingyi Chen, and Younan Xia**

The ability to generate multicomponent patterns of high chemical and structural complexity is central to many scientific areas, including the fabrication of DNA arrays for monitoring gene expression,[1] the development of novel displays,[2] and the study of surface-related phenomena such as wetting, nucleation, and adhesion.[3] The methodology of patterning can vary depending on the type of materials involved and the resolution that needs to be achieved. Techniques such as photolithography,[1b] inkjet printing,[4] and microcontact printing,[5] as well as scanning probes,[6] can be used to introduce multiple functionalities at a surface with spatial control. Several of these techniques have reached high levels of maturity and sophistication, but the procedures often involve a number of lithographic steps, which necessitates alignment between them. This drawback has spurred the search for extended or alternative patterning methodologies. In a recent approach, Ryan et al. used a photomask that transmitted different wavelengths in different areas in combination with a monolayer of a photosensitive alkanethiol on gold.[7] Another approach suggested by Tien et al. involved the use of a multilevel polydimethylsiloxane (PDMS) stamp to fabricate aligned patterns of proteins on substrates.[8] For the same purpose, Delamarche and co-workers introduced a method called affinity contact printing, which employs the specific recognition between target proteins and their complementary binding partners on a PDMS stamp.[9] As recently demonstrated by Whitesides and co-workers,[10] the parallel patterning of multiple polymers, proteins, or cells with microfluidic systems might be straightforward, even though these methods are generally limited to the fabrication of simple and continuous patterns that result from constraints imposed by the channel geometries.

Herein, we describe an approach for patterning multiple self-assembled monolayers (SAMs) of alkanethiolates on

gold in a simple and convenient way without the need for alignment steps. We rely on the recently introduced technique of edge-spreading lithography (ESL).[11] The concept behind ESL is fairly simple: alkanethiol molecules are delivered from a PDMS stamp onto a coinage-metal substrate by the surface of a relief structure. Our previous studies only established the patterning of just one type of monolayer, but we now extend this technique to the side-by-side patterning of multiple SAMs by successive printing steps. We used monodispersed silica beads as the guides because: a) they are commercially available in a wide range of sizes; b) they can readily assemble into ordered two-dimensional (2D) arrays over relatively large areas; c) they are inert to most organic solvents and are mechanically more robust than most polymer beads of equivalent size; d) their hydrophilic surfaces support the spreading of thiols; and e) they can be easily removed from the substrate by sonication without leaving any notable residues on the surface. Figure 1 shows a schematic illustration of our approach in its simplest form, that is, the side-by-side patterning of two monolayers. A planar PDMS stamp was inked with an alkanethiol such as sulfanylhexadecanoic acid (SHA, $HS(CH_2)_{15}COOH$), and printed onto silica beads (1.6 μm diameter) deposited on a thin film of gold. Upon reaching the surface of the gold, the molecules formed a SAM around the circular footprint of each bead. As long as the supply of molecules was maintained through contact between the stamp and the array, the area of the SAM expanded radially by reactive spreading.[11,12] In a second step of ESL another thiol, such as eicosanethiol (ECT, $HS(CH_2)_{19}CH_3$), was printed in the same way to form a SAM that nucleated at the edges of the SHA monolayer rings. Once the stamp was removed and the beads were lifted off, a monolayer pattern of concentric rings was observed by lateral force microscopy (LFM).[13]

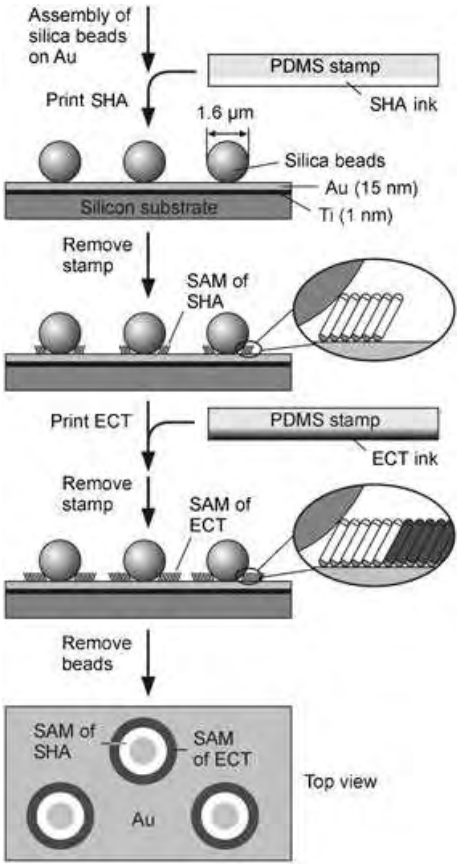

Figure 1. Schematic illustration of the ESL procedure used for side-by-side patterning of SHA and ECT monolayer rings on a gold substrate. The process involves two successive prints that are performed on a 2D array of silica beads supported on a thin film of gold. In the first step, SHA molecules (white) are guided from a planar stamp to the gold surface where they assemble into a monolayer, as directed by the circular footprint of each bead and lateral spreading. In the second step, ECT molecules (black) are applied in a similar fashion, thus forming a SAM that emerges from the edges of the SHA monolayer. Removal of the beads yields an array of concentric rings of SHA and ECT SAMs on the surface.

The functional groups involved in our experiments yield strong differences in contrast when imaged by LFM, as demonstrated by the control experiments shown in Figures 2a and b. The carboxy-terminated SAM appears bright as a result of the relatively strong adhesion forces between the COOH groups and the polar surface of the silicon nitride tip employed for our measurements.[14] Conversely, the methyl-terminated regions interact more weakly with the tip, which results in a darker appearance under LFM.[14] Figure 2c shows the result of a successive ESL experiment as described above. The resultant pattern was an array of concentric rings with an hexagonal arrangement in which the SHA and ECT portions were resolved clearly, both having a width on the order of

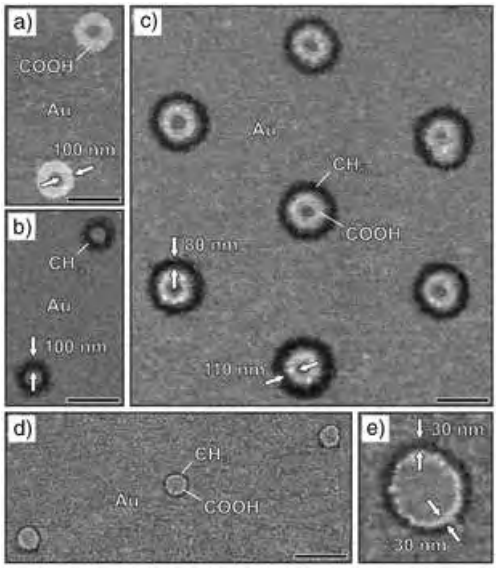

Figure 2. LFM images of carboxy- and methyl-terminated thiolate monolayer rings that were patterned on gold by ESL using SHA and ECT with 1.6-μm-diameter silica beads as guides. The COOH group appears bright, whereas the CH_3 group appears dark, as confirmed by reference measurements (a, b). These rings have a width of ≈100 nm, which was achieved with 1.0-mM ink solutions and a printing time of 1 min. c) Hexagonal array of concentric rings with well-resolved monolayer rings of 80- and 110-nm width. In this case, the printing times were 1 and 2.5 min for SHA and ECT, respectively. A decrease in the concentration of thiol in the ink to 0.1 mM along with contact times of 50 s and 2 min were key to confining the line width to 30 nm and below (d, e). All scale bars correspond to 500 nm.

100 nm. We used this approach to investigate the lower limits of resolution by decreasing the concentration of thiol molecules in the ink and the printing time. Figures 2d and e reveal striking results: the line widths were reduced to 30 nm and less without compromising the contrast or accuracy of the rings. It was difficult to elucidate the integrity of the SAMs on the molecular level, but if a close packing arrangement and a lattice constant of 0.501 nm[15] were assumed, the width of these rings corresponds to about 60 molecules. In principle, further reduction of the line width should be possible, although there may be several obstacles for both fabrication and analysis.

To demonstrate the versatility of our approach we added another alkanethiol, 12-hydroxydodecanethiol (HDDT, $HS(CH_2)_{12}OH$), and increased the number of successive prints from two to three (Figure 3). The use of HDDT proved advantageous since the resulting SAM appears gray in the LFM image, thus providing a sufficient contrast to both SHA and ECT monolayers. Insertion of the HDDT printing step inbetween those for SHA and ECT resulted in a concentric triple-ring system with high structural definition (Figure 3a). The width of each monolayer ring could be varied independently by tuning both the concentration of the ink and the printing time (Figure 3b). Furthermore, the SAMs could be arranged in any order (Figures 3c and d); switching of the printing order did not have any adverse effect on the appearance of the SAMs under LFM for the majority of samples. The monolayers shown in Figure 3 involve only three types of thiols and just a few of their possible combinations, but increasing the number of successive prints or adding more thiols to the process should be straightforward provided that suitable compounds are selected.[16]

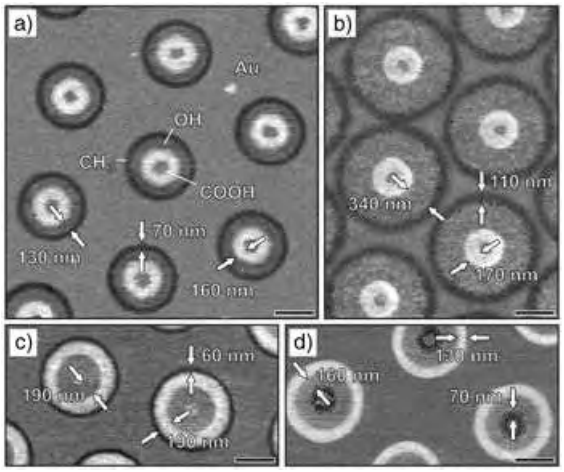

Figure 3. LFM images of concentric rings of carboxy- (bright), hydroxy- (gray), and methyl-terminated (dark) thiolate monolayers on gold. a) The rings were fabricated under the following conditions: 1 min for SHA, 1.5 min for HDDT, and 3 min for ECT. b) An increase in the printing times for HDDT and ECT to 3.5 and 4 min, respectively, resulted in wider rings for these two monolayers. c, d) The position of each monolayer in the concentric structure could be varied by changing the printing order. The pattern in (c) was generated by printing HDDT for 1.5 min, followed by printing of SHA and ECT for 3 min each. The sample shown in (d) was prepared by printing both ECT and HDDT for 1 min, and SHA for 2 min. All scale bars correspond to 500 nm.

To increase the versatility of our approach further, we explored the inclusion of non-thiol-based inks in the ESL experiments. Figure 4 illustrates one demonstration, in which 1-octadecylamine (ODA, $H_2N(CH_2)_{17}CH_3$) was selected as the non-thiol compound in conjunction with SHA and ECT. Amines can form monolayers on gold surfaces, but the stability of these layers is much lower than that of their thiol counterparts.[17] We deposited 2.3-μm silica beads on 30 nm of gold and made three successive prints (Figure 4a). After lift-off, the gold was etched in an aqueous solution containing both Fe^{3+} ions and thiourea.[18] Inspection of the etched sample by scanning electron microscopy (SEM) showed the presence of concentric gold rings on the substrate which were separated by a distinct, well-defined gap (Figure 4b). This

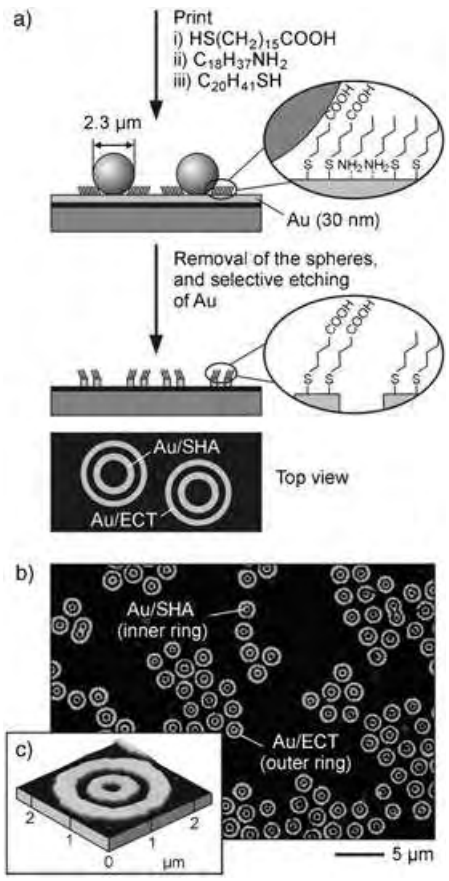

Figure 4. Fabrication of concentric gold rings by ESL and selective etching. The procedure depicted in (a) involves a 2D array of silica beads and an alkyl amine monolayer sandwiched between two concentric rings of thiolate SAMs. The amine monolayer has dual functions: it largely resists the adsorption of thiols while providing sufficient transparency during wet etching of the gold. b) SEM image showing an array of concentric gold rings that were fabricated with 2.3-μm-diameter silica beads and contact times of 1.5 min for SHA, 4 min for ODA, and 7 min for ECT. c) AFM image of the 3D topography of a pair of concentric gold rings. The gap between the two rings is 250 nm wide. The widths of the inner and outer rings are 260 and 340 nm, respectively.

finding reveals two characteristics of the ODA film: it was dense enough to resist the displacement by ECT molecules during ESL, but unlike the thiol monolayers, it was not sufficiently robust to protect the underlying gold from etching. Both the order and density of the array were low in this example, although the contrast and accuracy that could be achieved for individual rings were excellent as depicted by the atomic force microscopy (AFM) image in Figure 4c. Similar results were not obtained when ODA was replaced with either 1-octadecanol ($HO(CH_2)_{17}CH_3$) or *n*-octadecane (CH_3-$(CH_2)_{16}CH_3$). It is probable that in both these cases the interaction between the molecules and the gold surface was too weak, such that adequate monolayers were not formed. These findings highlight some of the possible limitations of this technique.

In summary, we have extended ESL from a novel microfabrication technique to a versatile tool capable of patterning multiple alkanethiolate SAMs on gold at the sub-100-nm scale without any need for alignment. Well-defined concentric rings of monolayers were achieved by using 2D arrays of silica beads as guides in successive printing steps with a planar PDMS stamp. While the width of the rings could be varied between 30 and 340 nm, the most attractive feature of this technique is its flexibility in the print order of the different alkanethiols—a finding that was quite surprising. When a non-thiol ink was incorporated, we demonstrated fabrication of concentric gold rings by a combination of successive prints and selective wet etching. The 2D arrays of silica beads served as a convenient model system for these initial demonstrations; however, the technique should be extendable to guides comprising other materials (for example, polymers, oxides, or metals) and with different geometries.[11a] Modification of the SAMs shown here, backfilling, or the use of other functional inks may also be helpful in further increasing the chemical complexity of the patterns.

Experimental Section

Gold substrates were prepared by e-beam evaporation (SEC 6000, CHA Industries) of 15 nm of gold (99.999%, Kurt J. Lesker Company) onto a silicon wafer (Montco Silicon Technologies) that had been primed with 1 nm of titanium (99.995%, Kurt J. Lesker Company) to promote adhesion between the gold film and the silicon substrate. The gold-coated wafer was then cut into smaller pieces ($\approx$1 cm^2), which were subjected to an air plasma treatment (Harrick Scientific Corp.) for 1 min to remove possible organic contaminants. Monodispersed silica beads were purchased from Duke Scientific (1.6 ± 0.06 μm) and from Bangs Laboratories (2.3 ± 0.1 μm). The commercial samples were diluted with deionized (DI) water to give suspensions containing $\approx$0.15 wt% of beads. A drop of the bead suspension was placed onto a freshly prepared gold substrate, and a 2D array was formed by capillary interaction while the water slowly evaporated.

Planar PDMS slabs were prepared from Sylgard 184 (Dow Corning) by curing the mixed prepolymers of PDMS on a flat polystyrene surface (Falcon 1001 petri dish, Becton Dickinson Labware) in an oven at 60°C for $\approx$20 h. The slabs were cut into pieces ($\approx$1 cm^2) which were used as stamps for inking and printing. Sulfanylhexadecanoic acid (Aldrich) was purified by recrystallization from toluene (Fisher Scientific). Eicosanethiol (Robinson Brothers Ltd.) was used as received. Hydroxydodecanethiol was kindly provided by Prof. G. M. Whitesides at Harvard University. Octadecylamine was from Aldrich; octadecanol and octadecane were both from Fluka, and used without further purification. In all examples, except for the high-resolution experiments, ethanolic solutions (1.0 mM) of these compounds provided the inks. Stamps were inked by covering one side entirely with the ink solution for 1 min, then dried with a stream of air, and placed by hand onto a colloidal array for various times. After each print, samples were allowed to rest for several minutes before further processing. Lift-off was accomplished by sonication in DI water for $\approx$1 min. Gold was etched in a solution of $Fe(NO_3)_3$ (20 mM, Fisher Scientific) and thiourea (30 mM, Acros Organics) in DI water at room temperature with gentle stirring. After removal from the etch bath, the samples were rinsed with DI water and dried in a stream of air.

AFM measurements were performed with a multimode Nanoscope III atomic force microscope (Veeco Instruments), operated under ambient conditions and in the contact mode to record both friction and height simultaneously. All measurements were conducted by using silicon nitride cantilevers (Veeco) with spring constants ranging from 0.06 to 0.58 $N\,m^{-1}$. SEM images were obtained with a Siron XL field-emission microscope (FEI Company) operated at an acceleration voltage of 5.0 kV. The width of the ring patterns was determined with an image analysis program (Image Tool 3.0, UTHSCSA).

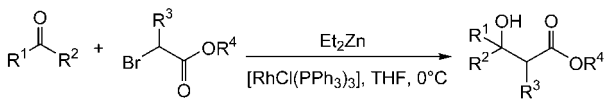
Multicomponent Reactions

Highly Enantioselective One-Pot, Three-Component Imino-Reformatsky Reaction**

Pier Giorgio Cozzi and Eleonora Rivalta*

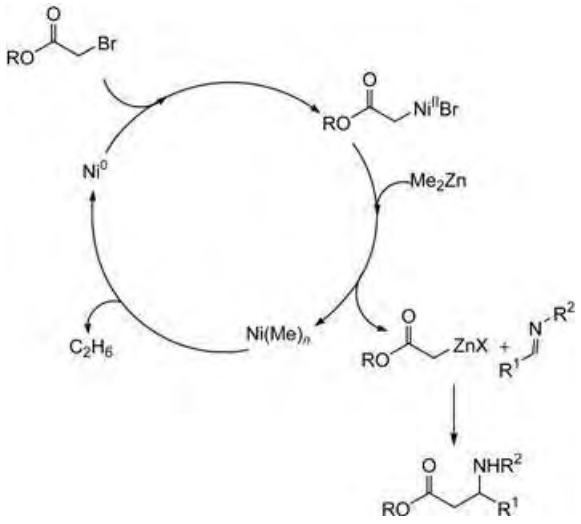
The Reformatsky reaction,[1] discovered more than 115 years ago, is still widely used in synthesis.[2] High functional-group tolerance and the in situ preparation of the reagent have contributed to its success. The reagent is prepared by the activation of zinc metal through a variety of different methods.[3] Recently, renewed interest in the catalytic redox reaction[4] has positively influenced further studies in the field.[5] Honda and co-workers have developed a new, interesting variant of the Reformatsky reaction, which uses Et_2Zn and $[RhCl(PPh_3)_3]$ in catalytic amounts (Scheme 1).[6]

Imines are suitable substrates for the Reformatsky reaction, and the so-called imino-Reformatsky reaction was first described by Gilman 60 years ago.[7] Although the use of this reaction in synthesis has great potential, it can be problematic, as a mixture of β-aminoesters and β-lactams is generally obtained. Recently, this problem was solved by using imines derived from 2-methoxyaniline.[8] In view of the increasing importance of β-amino acids as valuable synthetic tools[9] we were attracted by the interesting work published by Adrian and co-workers,[8b] who presented an efficient, nickel-catalyzed Reformatsky-type three-component condensation that combines aldehyde, 2-methoxyaniline, and a bromocarbonyl reagent (esters, ketones, and amides) in a one-pot reaction. The method was successfully applied on the micro- and macroscale and to combinatorial synthesis. Herein, we present the first practical one-pot three-component enantioselective imino-Reformatsky reaction, which is based on the use of *N*-methylephedrine as a cheap and recoverable chiral ligand.[10]



Scheme 1. Rhodium-catalyzed Reformatsky reaction developed by Honda and co-workers.

The efficient three-component Reformatsky reaction developed by Adrian and co-workers[8b] uses Me_2Zn in the presence of a catalytic amount of inexpensive $[NiCl_2(PPh_3)_2]$.[11] On the basis of detailed electrochemical study by Périchon, Sibille, and co-workers,[12] a reasonable mechanistic picture was presented by Adrian and co-workers. The mechanism involved the reduction of the Ni^{II} complex to a Ni^0 complex, oxidative addition of the bromoester to the Ni^0 complex, and a Ni^{II}/Zn^{II} exchange, which leads to an organozinc Reformatsky reagent. The proposed catalytic cycle (Scheme 2) was our starting point in developing an enantioselective variant. We reasoned that, contrary to other nickel-catalyzed[13] processes, a chiral ligand able to coordinate nickel was not crucial to transmit chiral information. Instead, we decided to surround the zinc enolate formed by transmetalation and the chelating imine with a chiral ligand able to coordinate zinc. Carreira and co-workers have developed a



Scheme 2. Catalytic cycle for the imino-Reformatsky reaction mediated by nickel.

very efficient and simple method based on the use of *N*-methylephedrine for the addition of acetylides to aldehydes,[14] and Tan et al. have used *N*-alkylephedrine derivatives to add zinc acetylides to a ketone precursor of the anti-HIV drug efavirenz.[15] *N*-Methylephedrine can be considered as a privileged ligand[16] for zinc derivatives. For this reason we explored the Me_2Zn-mediated one-pot three-component imino-Reformatsky reaction with *N*-methylephedrine[17] as the chiral ligand. Me_2Zn plays several important roles in the reaction: a) Me_2Zn is the dehydrating agent responsible for the formation of the imine in situ; b) Me_2Zn can reduce the Ni^{II} salt to Ni^0; c) Me_2Zn reacts with the incipient nickel enolate to form the reactive zinc enolate; and, finally, d) Me_2Zn can coordinate *N*-methylephedrine, the amino alcohol used as a chiral ligand. We have chosen the imine obtained in situ from 2-methoxyaniline and *p*-chlorobenzaldehyde as a model substrate, in conjunction with different bromoacetates, Ni^{II} salts in catalytic amounts, and *N*-methylephedrine. We adjusted the protocol developed by Adrian and Snapper[8b] to investigate several experimental conditions of our process in detail (Table 1). In light of its multiple roles in this reaction, 4 equivalents of Me_2Zn was used. To ensure good enantiomeric excess, 1.5–1.6 equivalents of *N*-methylephedrine were employed in our process (Table 1, entries 2–5). *N*-methylephedrine can easily be separated from the adducts by acidic workup and recovered after extraction of the aqueous alkaline layer. The two solvents tested in the model reaction, CH_2Cl_2 and toluene, gave comparable results.[18] The crucial difference that determines the choice of solvent concerns the use of the nickel catalyst. $[NiCl_2(PPh_3)_2]$ is soluble in CH_2Cl_2 but is poorly soluble in toluene. We have also used $[Ni(acac)_2]$ hydrate, which is poorly soluble in both solvents. To compare results and guarantee reproducibility, we decided to add Ni^{II} salts as a solid to the reaction mixture containing Me_2Zn, imine, bromoester, and *N*-methylephedrine (see Supporting Information for details), at the indicated reaction temperature. The Ni^{II} salts are quickly dissolved in the reaction mixture and initiate the catalytic cycle. The $[RhCl(PPh_3)_3]$ complex also promotes the reaction, although the product was isolated with lower *ee* values than those obtained in the presence of nickel complexes (Table 1, entry 6). We also examined the enantiomeric excess attained in the model reaction with different bromoesters. Apart from the hindered *tert*-butyl bromoacetate (Table 1, entry 14), which gave a lower *ee* value than the others, similar enantiomeric excesses were attained with all type of esters examined.[19] Toluene was chosen as the solvent owing to the slightly better results obtained, and the scope of the reaction was investigated.

In Table 2 we report the results collected with different aldehydes. The reaction shows broad scope, since aromatic, aliphatic, unsaturated, and heterocyclic aldehydes are reactive and result in good to excellent enantioselectivites (up to 92% *ee*). Yields were generally only moderate, but no by-products were isolated. Better yield was obtained by increasing the reaction temperature, but at the expense of enantiomeric excess. We optimized the reaction temperature with all the different aldehydes so as to reach a compromise between yield and enantiomeric excess. Notably, α,β-unsaturated aldehydes are good reaction partners in this reaction and also lead to good enantiomeric excess.[20] The absolute configuration of the products obtained with (1*S*,2*R*)-*N*-methylephedrine as a chiral ligand was established in the case of aliphatic and aromatic aldehydes (isopropyl and phenyl), as shown in Scheme 3, following the general procedure of deprotection of 2-methoxyamines, developed by Josephsohn, Snapper, and Hoveyda (see Supporting Information for details).[21]

In conclusion, we have developed the first practical and highly efficient, enantioselective[22] one-pot three-component imino-Reformatsky reaction, which gives β-aminoesters in moderate to good

[a] All the reactions were carried out at 0°C for 3 h in the presence of *N*-methylephedrine (1.6 equiv) and the Ni^{II} salt (7.5–8 mol%). [b] Yield of isolated product after chromatographic purification. [c] Determined by HPLC analysis (see Supporting Information for details). [d] *N*-methylephedrine: 1 equiv. [e] $[NiCl_2(PPh_3)_2]$ was added as a solution in CH_2Cl_2 as reported by Adrian and co-workers.[8b] [f] The Ni^{II} salt was added as solid to the reaction mixture. [g] *N*-methylephedrine: 1.8 equiv. [h] *N*-methylephedrine: 2 equiv. [i] Wilkinson catalyst, $[RhCl(PPh_3)_3]$, (5 mol%) was used and added as a solution in CH_2Cl_2.[8b] The reaction was stirred for 13 h at 0°C. [j] Recycling experiment: *N*-methylephedrine, recovered from the reaction, was dried under high vacuum for 3 h. The crude *N*-methylephedrine containing 2-methoxyaniline (10%) (checked by NMR and ES-MS) was used in another model reaction without any purification. The reaction was performed at −10°C for 14 h with $[NiCl_2(PPh_3)_2]$ (8 mol%).

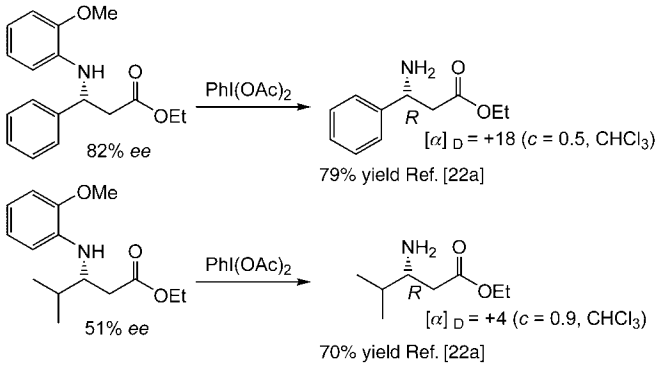
[a] All the reactions were performed at the indicated temperature with *N*-methylephedrine (1.6 equiv) as a chiral ligand (see Supporting Information for experimental details).[b] Yield of isolated product after flash chromatography. [c] Determined by chiral HPLC analysis (Chiralcel OD column). [d] The reaction was slowly allowed to reach 0°C in 3–4 h before quenching. [e] A solution of Et_2Zn in toluene (1 M; 4 equiv) was used. GC–MS analysis performed on the crude reaction mixture after quenching revealed the presence of less than 5% of by-product derived from the attack of the ethyl on the imine. [f] The reaction was performed with the preformed purified imine in the presence of Me_2Zn (3 equiv) and *N*-methylephedrine (1 equiv) as chiral ligand.



Scheme 3. Correlation of aromatic and aliphatic β-aminoesters with known compounds.

yields. The reaction uses an inexpensive nickel salt, bromoesters, and *N*-methylephedrine as a chiral ligand. The chiral auxiliary, *N*-methylephedrine, is completely recovered after workup of the reaction and could be recycled (Table 1, entry 15).[23] The imines are prepared in situ, in the same reaction flask, and Me_2Zn is used as a dehydrating agent. More importantly, the reaction shows broad scope, since aromatic, heterocyclic, aliphatic and unsaturated aldehydes are suitable substrates for the reaction. We believe that the enantioselectivity (64–92% *ee*) can be improved as many other inexpensive homochiral aminoalcohols are available.[24] Further studies of this reaction are in progress in our laboratory and will be reported in due course.

C–H Activation

Coordinatively Unsaturated Cationic and Zwitterionic [Cp*Ru(κ^2-*P,N*)] Complexes: Ligand-Assisted Double-Geminal C–H Bond Activation and Reversible α-H Elimination at Ruthenium**

*Matthew A. Rankin, Robert McDonald, Michael J. Ferguson, and Mark Stradiotto**

The catalytic cleavage and functionalization of an otherwise unactivated C–H bond within the ligand sphere of a coordinatively unsaturated transition-metal complex is developing into a practical synthetic methodology, despite the inherent difficulty associated with breaking such robust σ bonds.[1] In contrast, the activation of multiple C–H bonds on a single substrate has proven to be a significantly greater challenge; stoichiometric transformations of this type are still uncommon and examples in which this reactivity has been incorporated into useful catalytic cycles are few.[1,2] Given the central role that multiple C–H bond activation processes could play in the functionalization of hydrocarbons and other relatively unreactive molecules, we are targeting new classes

of reactive transition-metal complexes that are designed to effect one or more C–H bond activation steps. On the basis of the propensity of late-transition-metal cations for C–H activation,[3] and the desirable reactivity characteristics commonly associated with P,N ligation,[4] one facet of our research targets coordinatively unsaturated cations supported by κ^2-*P,N*-ligated 1-P*i*Pr$_2$-2-NMe$_2$-indene (**1a**[H]) or 2-NMe$_2$-3-P*i*Pr$_2$-indene (**1b**[H]), as well as structurally related zwitterionic complexes that feature κ^2-*P,N*-ligated 2-NMe$_2$-3-P*i*Pr$_2$-indenide (**1**) in which the ten-π-electron indenide unit functions as a sequestered anionic charge reservoir.[5] We view these coordinatively unsaturated zwitterions as particularly attractive candidates for multiple C–H activation, since the anionic backbone in **1** is poised to accept a proton from a formally cationic metal center following an initial C–H bond activation step, thereby re-establishing coordinative unsaturation at the reactive metal center and enabling subsequent C–H activation processes. As part of this study, we identified the 16-electron cation [Cp*Ru(κ^2-*P,N*-**1b**[H])]$^+$ and the coordinatively unsaturated zwitterion [Cp*Ru(κ^2-*P,N*-**1**)] as important targets (Cp* = η^5-C$_5$Me$_5$); whereas 16-electron complexes of the type [Cp*RuL$_2$]$^+$X$^-$ (L = N- or P-donor fragments) have proven to be effective in the activation of C–H bonds, related P,N-ligated cations have yet to be isolated.[6,7] Herein, we report the preparation of a masked source of [Cp*Ru(κ^2-*P,N*-**1b**[H])]$^+$ that exhibits reversible C–H activation. We also report the facile isomerization of the putative zwitterion [Cp*Ru(κ^2-*P,N*-**1**)] to a [Cp*Ru(H)(κ^2-*P,C*)] hydridocarbene complex in an apparent double-geminal C–H bond activation process that is enabled by the proton-accepting ability of the indenide unit in **1**. Dynamic NMR spectroscopic and reactivity studies involving this hydridocarbene species provide compelling evidence for what appears to be the first documented interconversion of Ru(H)=CH and Ru–CH$_2$ fragments by reversible α-H elimination.

The addition of 0.25 equivalents of [(Cp*RuCl)$_4$] to **1a**[H] afforded **2a**, which was isolated in 92% yield (Scheme 1);[8] treatment of **2a** with NEt$_3$ resulted in a clean isomerization to **2b**. In the pursuit of the 16-electron cation [Cp*Ru(κ^2-*P,N*-**1b**[H])]$^+$ (**3**), complex **2b** was treated with Li(Et$_2$O)$_{2.5}$B(C$_6$F$_5$)$_4$. After 1.5 h, ^{31}P NMR spectroscopic analysis of the reaction mixture confirmed the consumption of **2b** ($\delta_{^{31}P}$ = 54.0 ppm) and the appearance of a single product ($\delta_{^{31}P}$ = 82.3 ppm), which was isolated in 83% yield as a pale-yellow solid. Elemental analysis data obtained from this solid were found to be consistent with **3**, but X-ray diffraction analysis allowed for the identification of this complex as the isomeric C–H activation product **4** (Figure 1),[8b,c] which exhibits

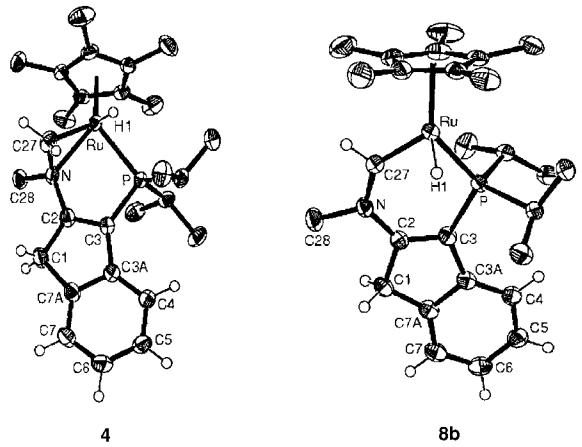

Figure 1. ORTEP diagrams for **4** and **8b** shown with 50% displacement ellipsoids; selected hydrogen atoms and the B(C$_6$F$_5$)$_4^-$ counteranion in **4** have been omitted for clarity. Selected bond lengths [Å] and angles [°]: **4**: Ru–P 2.3094(4), Ru–N 2.136(1), Ru–C27 2.071(2), P–C3 1.809(2), N–C2 1.441(2), N–C27 1.433(2), N–C28 1.484(2), C1–C2 1.503(2), C2–C3 1.336(2); P-Ru-N 82.26(4), Ru-P-C3 101.90(5), Ru-N-C27 67.67(9), Ru-N-C2 116.6(1), Ru-C27-N 72.55(9); **8b**: Ru–P 2.2374(7), Ru···N 3.05, Ru–C27 1.886(2), P–C3 1.812(2), N–C2 1.384(3), N–C27 1.374(3), N–C28 1.475(3), C1–C2 1.512(3), C2–C3 1.362(3); Ru-P-C3 112.74(9), C2-N-C27 123.5(2), C2-N-C28 117.1(2), C27-N-C28 119.4(2), N-C2-C3 129.3(2), P-C3-C2 122.7(2), Ru-C27-N 138.3(2).

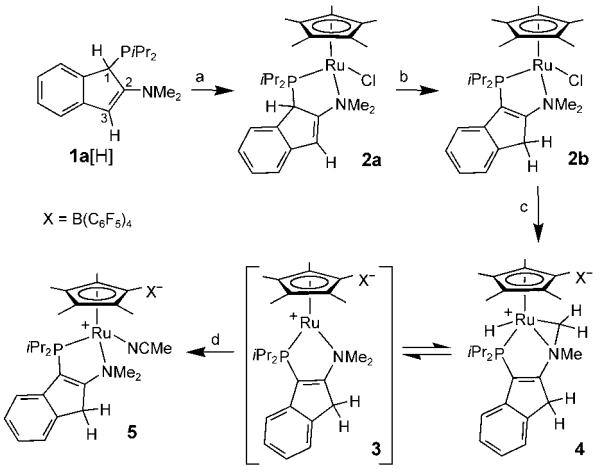
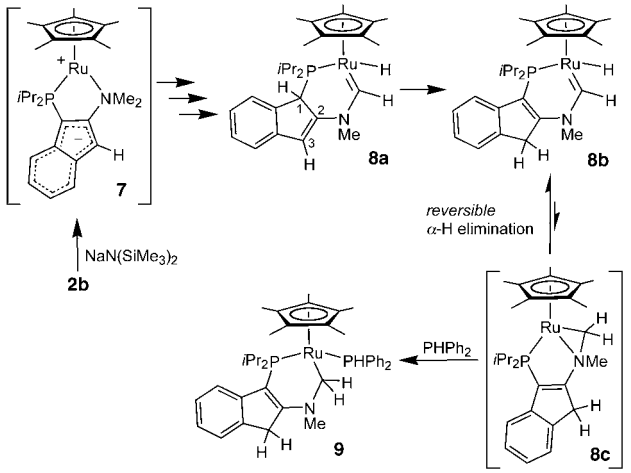


Scheme 1. Synthesis and reactivity of the masked [Cp*Ru(κ^2-*P,N*)]$^+$ complex **4**. Reagents: a) 0.25 [(Cp*RuCl)$_4$]; b) NEt$_3$; c) Li(Et$_2$O)$_{2.5}$B(C$_6$F$_5$)$_4$; d) MeCN.

interatomic distances in keeping with an aza-ruthenacyclopropane ring.[9] Notably, the ^{1}H and ^{13}C NMR spectra of **4** (300 K) in solution are not consistent with the rigid structure depicted in Figure 1.[8a] The effective mirror-plane symmetry, as well as the low-frequency and broadened ^{1}H NMR resonance of NMe$_2$ (δ = 0.95 ppm, $\Delta\nu_{1/2}$ = 20.3 Hz; cf. $\Delta\nu_{1/2}$ = 4.5 Hz for C$_5$Me$_5$ in **4**), suggest a reversible C–H oxidative addition process involving the NMe$_2$ unit of **4** in which the metalated and free N-C-H fragments exchange rapidly on the NMR timescale at 300 K.[10] On lowering the temperature from 300 to 178 K, the ^{1}H NMR spectra of **4** become increasingly complex and downfield signals attributable to non-metalated NMe groups emerge, thus suggesting a slowing of the aforementioned exchange process. However, neither low-frequency ^{1}H NMR signals attributable to Ru–H or agostic Ru-H-CH$_2$ units, nor new ^{31}P NMR resonances were detected over this temperature range. The apparent reversibility of the intramolecular C–H activation process leading to **4** suggests that this complex could serve as a masked source of

the coordinatively unsaturated target cation **3**. Indeed, treatment of **4** with CH_3CN cleanly yields **3**·CH_3CN (**5**),[11a] and as such we are currently assessing the intermolecular C–H bond activating abilities of **4**.

In an effort to prepare [Cp*Ru(κ^2-*P*,*N*-**1**)] (**7**), a zwitterionic analogue of **3**, compound **2b** was treated with $NaN(SiMe_3)_2$ in toluene at ambient temperature (Scheme 2);



Scheme 2. Synthesis and reactivity of the hydridocarbene complex **8b**.

^{31}P NMR spectroscopic analysis of the reaction mixture after 24 hours indicated the clean conversion into a single product ($\delta_{^{31}P} = 78.2$ ppm), which was isolated as an orange powder in 84% yield. Elemental analysis data for this powder were in keeping with **7**, but further characterization revealed this material to be the isomeric double-geminal C–H bond activation product **8b**. The identification of **8b** as a hydridocarbene complex was based in part on the observation of ^1H NMR signals at $\delta = 12.1$ and -12.4 ppm, as well as a ^{13}C NMR resonance at $\delta = 244.1$ ppm; the structure of **8b** was subsequently confirmed by X-ray diffraction analysis (Figure 1).[8b,d] The contracted Ru–C27 (1.886(2) Å) and N–C27 (1.374(3) Å) distances in **8b** are comparable to some other N-stabilized Ru=C fragments.[12b–d] These interatomic distances, the short N–C2 distance (1.384(3) Å; cf. N–C28 1.475(3) Å), and the planarity of the nitrogen center are all indicative of significant π-bonding interactions in **8b** extending from the Ru=C fragment through to the indene backbone.

In monitoring the progress of the reaction, the consumption of **2b** was confirmed after 20 minutes, with the ^{31}P NMR spectrum displaying new signals at $\delta = 67.8$ (possibly corresponding to **7**) and 112.6 ppm (**8a**; ratio ≈ 1:8). After 1 hour, only the resonance at $\delta = 112.6$ ppm was detected, and the features observed in the ^1H NMR spectrum allowed for the tentative assignment of **8a** as the allylic isomer of **8b**.[11b] Over the ensuing 23 hours, **8a** evolved into **8b** in the absence of detectable intermediates. These observations are consistent with the mechanism outlined in Scheme 2,[11c] in which the transiently formed zwitterion **7** undergoes an intramolecular C–H activation process to yield a zwitterionic relative of **4**.[11d] Regioselective proton transfer from ruthenium to the indenide ligand backbone regenerates a coordinatively unsaturated alkylruthenium complex that undergoes a second C–H activation step (α-H elimination) to yield **8a**, which isomerizes to **8b**.[13] The facile rearrangement of **7** to **8b** is remarkable, since double-geminal C–H bond activation to give a Ru=C complex is rare and invariably requires extended heating and loss of a small molecule to facilitate the reaction.[12]

In exploring the reactivity of **8b**, we observed that treatment with $PHPh_2$ provided **9**, a product that can be viewed as an adduct of a 16-electron alkylruthenium species; perhaps the most striking feature in the crystal structure of **9** is the elongated Ru–CH_2 distance (2.124(2) Å) relative to the Ru=C unit in **8b**.[8b,e] The formation of **9** provided indirect evidence of the dynamic interconversion of Ru(H)=CH and Ru–CH_2 fragments (as in **8b** and **8c**[11e]) by reversible α-H elimination. In contrast to the well-established reversibility of β-H eliminations, reversible α-H elimination is rare,[14] and to the best of our knowledge the latter process involving ruthenium has not been documented previously.

Data from 1D- and 2D-exchange spectroscopic (EXSY) ^1H NMR experiments provide definitive spectroscopic evidence for the operation of reversible α-H eliminations involving **8b**.[8a] In the case of ^1H EXSY experiments, irradiation of either the Ru(*H*)=CH or the Ru(H)=C*H* signal in **8b** results in significant positively-phased enhancement of the other resonance, indicating that these two sites are undergoing chemical exchange. Similarly, the ^1H-^1H EXSY spectrum of **8b** exhibits positively-phased off-diagonal exchange cross-peaks that connect the two Ru(*H*)=C*H* environments. The observation of reversible α-H elimination involving ruthenium is significant, as the interconversion of Ru=C and Ru–alkyl species by this mechanism may play a role in the transmutation of olefin metathesis and hydrogenation catalysts in situ.[15]

In conclusion, we have prepared and isolated a masked variant of the first coordinatively unsaturated [Cp*Ru(κ^2-*P*,*N*)]$^+$ complex, which has proven to be capable of *single* C–H bond activation. By comparison, the putative zwitterion **7** exhibits much more aggressive reactivity with C–H bonds to yield a hydridocarbene by way of a remarkably facile *double* C–H activation process that is enabled by the proton-accepting ability of the ancillary ligand **1**; moreover, an NMR investigation of this hydridocarbene has revealed a reversible α-H elimination process previously undocumented for ruthenium. We are currently developing more cyclometalation-resistant analogues of **7**, with the aim of exploiting the proton-accepting function of **1** in the establishment of new and synthetically useful intermolecular multiple C–H bond activation processes.

Sensors

Selective Electrochemical Detection of Hydrogen Fluoride by Ambiphilic Ferrocene Derivatives**

Christopher Bresner, Simon Aldridge, Ian A. Fallis,* Cameron Jones, and Li-Ling Ooi*

The selective detection of specific anions or whole acids/metal salts (HX or MX) in the presence of potentially competitive contaminants represents a fundamental chemical challenge for applications, for example, in sensor devices and in separation technologies.[1–4] In the former case, such a process typically involves recognition of both anionic and cationic components, accompanied by an appropriate reporter response.[2,3] Within this sphere, the detection of hydrogen fluoride represents a particularly timely goal, given its industrial use and its well-documented liberation in the hydrolysis of the fluorinated G-type chemical warfare agents (CWAs).[4–7] Given the low ambient levels of volatile fluorides, a potential sensor for airborne Sarin or Soman utilizes HF as the target analyte.

Selective binding of the fluoride anion by Lewis acid receptors based on boronic acid/ester has been reported by a number of groups.[4,8,9] Furthermore, significant electrochemical shifts have been shown to accompany the binding event for systems incorporating directly linked receptor and ferrocene components.[8a,b,d] Given the selective detection of fluoride demonstrated for these systems, we wondered whether incorporation of a suitable Lewis basic component within an appropriate molecular framework might facilitate selective HF recognition, either by binding of an intact HF

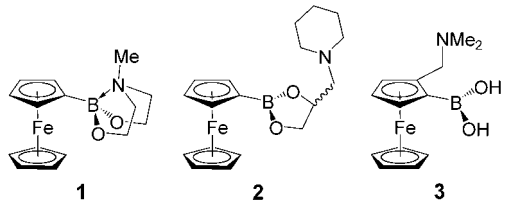
entity or distinct H^+ and F^- components. With this in mind, we set out to examine the response to hydrogen fluoride exposure of the mixed Lewis acid/Lewis base systems **1**–**3**.



The compounds chosen sought to probe the stability of different molecular architectures to HF and to further examine the effect (if any) of the intramolecular N→B interaction in the H–F bond breaking process.

Compounds **1** and **2** can be synthesized by a one-pot process from $FcBBr_2$ [Fc = (η^5-C_5H_5)Fe(η^5-C_5H_4)][10] and one equivalent of the appropriate reagent, that is, $(Me_3SiOCH_2CH_2)_2NMe$ for **1** and *rac*-$(C_5H_{10}N)CH_2CH$-(OLi)CH(OLi) for **2**. The structure of **1** was corroborated by single-crystal X-ray diffraction (Figure 1), which also

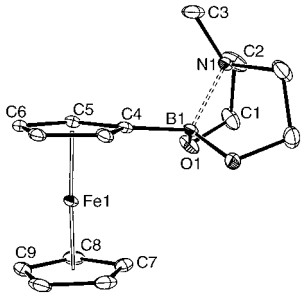


Figure 1. Molecular structure of $FcB(OCH_2CH_2)_2NMe$ (**1**) with ORTEP ellipsoids set at the 50% probability level; hydrogen atoms are omitted for clarity. Relevant bond lengths [Å] and angles [°]: Fe1-$Cp_{centroid}$ 1.649(2), Fe1-$C_5H_4BRR'_{centroid}$ 1.645(2), B1-N1 1.735(3), B1-O1 1.443(2), B1-C4 1.595(4); B1-C4-$C_5H_4BRR'_{centroid}$ 176.3(1).

confirmed the presence of an intramolecular N→B bond (1.735(3) Å).[11] Although suitable single crystals of **2** were not forthcoming, the three-coordinate nature of the boron center was implied by the ^{11}B NMR chemical shift ($\delta_B = 32.3$ ppm) and the ferrocene-based oxidation potential ($E_{1/2} = -0.5$ mV (96 mV)[12]), which are characteristic of this type of pendant boryl function [for comparison, $\delta_B = 34.1$ ppm, $E_{1/2} = +116.0$ mV (80 mV) for $FcBO_2C_2H_2Ph_2$ (three-coordinate boron)[13] and $\delta_B = 13.4$ ppm, $E_{1/2} = -190.5$ mV (85 mV) for **1** (four-coordinate boron)].

The NMR spectroscopic and electrochemical (CV) monitoring of the reactions of **1** and **2** with hydrogen fluoride (as the collidine complex 2,4,6-trimethylpyridine·$(HF)_{1.5}$) showed that the reaction requires three equivalents of HF to be driven to completion, and that a common ferrocene- and boron-containing product is formed in each case [quartet $\delta_B = 3.7$ ppm, $J_{BF} = 49.8$ Hz; $E_{1/2} = -320$ mV (75 mV)]. For the reaction with **1**, crystallographic investigation of the product revealed that this is the $[FcBF_3]^-$ anion,[14] isolated in this case as the $[(HOCH_2CH_2)_2N(H)Me]^+$ salt (**4**, Figure 2).

Given that **4** is formed by rupture of the boronic ester linkages in **1**, it is clear that the design of an ambiphilic

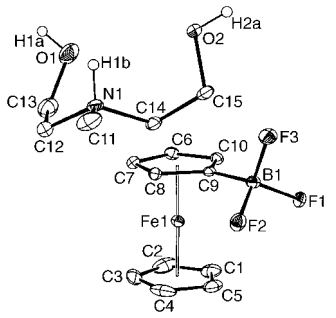

Figure 2. Molecular structure of $[(HOCH_2CH_2)_2N(H)Me][FcBF_3]$ (**4**) with ORTEP ellipsoids set at the 50% probability level; hydrogen atoms (except those attached to O1, O2, and N1) are omitted for clarity. Relevant bond lengths [Å] and angles [°]: Fe1-$Cp_{centroid}$ 1.648(3), Fe1-$C_5H_4BRR'_{centroid}$ 1.644(3), B1-F1 1.435(3), B1-F2 1.423(3), B1-F3 1.405(4), B1-C9 1.590(4); B1-C9-$C_5H_4BF_{3\,centroid}$ 179.6(2).

receptor system that survives exposure to HF necessitates the avoidance of structurally significant B–O bonds. Consequently, we have examined the whole acid sensing properties of 2-(*N*,*N*-dimethylaminomethyl)ferrocene boronic acid (**3**), a compound which was originally reported by Marr et al.,[15] and which has, for example, also been investigated by Shinkai and by Norrild and Søtofte as a carbohydrate sensor.[16] Tethering of the Lewis acidic and Lewis basic components to the cyclopentadienyl ring through B–C and N–C bonds allows isolation of an intact, charge-neutral HF host–guest complex.

In practice, the reaction of **3** with three equivalents of HF in acetonitrile leads to the isolation of the zwitterionic species [(η^5-C_5H_5)Fe{η^5-$C_5H_3(BF_3)(CH_2NMe_2H)$}] (**5**) in about 68% yield. The structure of **5** has been elucidated from spectroscopic and X-ray diffraction measurements and reveals—in addition to substitution of the two boronic acid OH groups by fluorine atoms[17]—the binding of a single equivalent of HF (Figure 3). The residual intramolecular H···F interaction is

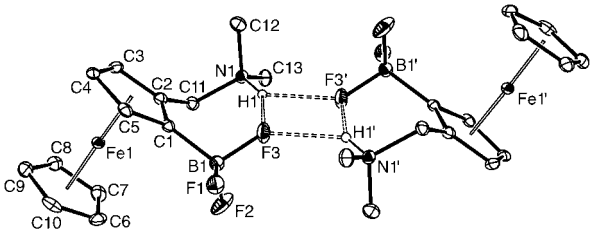

Figure 3. Hydrogen-bonded dimeric structure of [(η^5-C_5H_5)Fe{η^5-C_5H_3-$(BF_3)(CH_2NMe_2H)$}] (**5**) in the solid state with ORTEP ellipsoids set at the 50% probability level; hydrogen atoms (except that attached to N1 and N1′) are omitted for clarity. Relevant bond lengths [Å] and angles [°]: Fe1-$Cp_{centroid}$ 1.643(5), Fe1-$C_5H_3BF_{3\,centroid}$ 1.640(5), B1-C1 1.600(6), B1-F1 1.413(5), B1-F2 1.382(5), B1-F3 1.431(5), F3-H1 2.204, F3-H1′ 2.124, N1-H1 0.930, N1-F3 2.996(4), N1-F3′ 2.854(3); B1-C1-$C_5H_3CBF_{3\,centroid}$ 176.6(3), N1-H1-F3 142.5, N1-H1-F3′ 134.4.

relatively weak, as evidenced by a separation of 2.204 Å (0.92 Å for gaseous HF),[18] and is best viewed as an ionic hydrogen bond between the BF_3^- and NMe_2H^+ fragments.[19] In the solid state these hydrogen-bonded units are linked through additional intermolecular H···F interactions (2.124 Å) into centrosymmetric dimers.

The key feature of whole acid binding by **3** is its selectivity for HF over other acids. This can not only be demonstrated electrochemically, but also results in distinct *opposing* responses for HF and, for example, HCl. Thus, the voltammograms for **3** and **5** reveal a cathodic shift of −80 mV on HF binding [$E_{1/2} = +37.5$ mV (85 mV) for **3** and −43 mV (75 mV) for **5**; Figure 4, top]. The oxidation potential for **5** is markedly

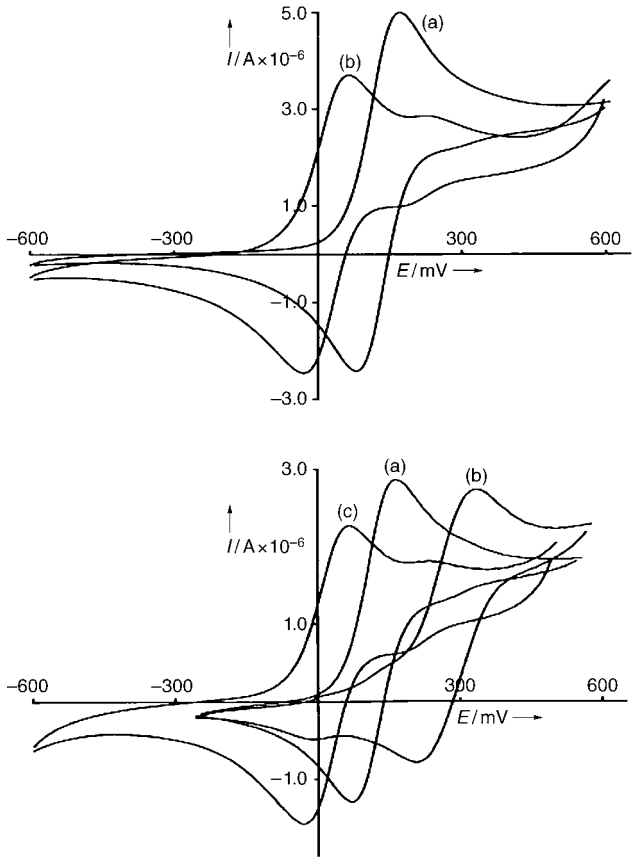

Figure 4. Top: Cyclic voltammograms of **3** (a) and of **5** (b). Bottom: Cyclic voltammograms of **3** (a), of **3** after addition of HCl (b), and of **3** after subsequent addition of nBu$_4$NF (c).

less negative than that for $[FcBF_3]^-$ [$E_{1/2} = -320$ mV (75 mV)], reflecting the overall charge neutrality of **5**. However, the net cathodic shift (with respect to **3**) is consistent with transformation of a three-coordinate electron-withdrawing boronic acid group into a net electron-donating four-coordinate boronate.[20] An entirely different electrochemical response is observed on addition of excess HCl to **3** (Figure 4, bottom). Here a significant anodic shift (+149.5 mV) is observed, and this (together with the lack of any discernable shift in the ^{11}B NMR spectrum of **3** on addition of HCl) is consistent with protonation of the amine functionality, but with no significant Lewis base coordination at the boron center. The identification of this species as cationic $[(\eta^5\text{-}C_5H_5)Fe\{\eta^5\text{-}C_5H_3[B(OH)_2](CH_2NMe_2H)\}]^+$ is given further credence by the addition of excess fluoride. This leads to an upfield shift in the ^{11}B NMR resonance (to $\delta_B = 3.0$ ppm) and to a CV trace that is essentially identical to that measured for an authentic sample of **5**. Thus it would appear that the opposing senses of the electrochemical shifts observed for **3** with HF and HCl[*] reflect the intrinsic selectivity of the boronic acid moiety for fluoride.[4,8]

In conclusion, it has been demonstrated that by avoiding structurally significant B–O bonds it is possible to construct robust organometallic receptor systems capable of selectively binding hydrogen fluoride. Such a system has been shown to be capable of differentiating between exposure to HF and exposure to related acids (such as HCl) by providing opposing electrochemical responses. This in turn can be related to the much stronger affinity of fluoride for boronic acid/ester receptors compared to other conjugate bases such as chloride.

Experimental Section

Details of the preparation and characterization of **1** and **2**, details of the reaction of **1** with HF, and characterizing data for **4** are included in the Supporting Information.

5: To **3** (24.4 mg, 0.085 mmol) in acetonitrile (ca. 20 cm^3) was added 2,4,6-trimethylpyridine·$(HF)_{1.5}$, (3 equiv of HF), and the reaction mixture was stirred for 20 min. Monitoring by ^{11}B NMR spectroscopy indicated complete conversion into a single product. Cannula filtration followed by cooling to −30 °C yielded **5** as a yellow-orange solid (yield: 18.0 mg, 68.4 %). ^{1}H NMR ([D$_3$]acetonitrile, 300 MHz, 20 °C): $\delta = 2.57$ (s, 3H, NCH_3), 2.83 (s, 3H, NCH_3), 3.75 (d $J = 13$ Hz, 1H, CH_2N), 4.08 (s, 5H, C_5H_5), 4.15 (m, 3H, C_5H_3), 4.55 (d $J = 13$ Hz, 1H, CH_2N), 6.98 ppm (v br s, 1H, NH). ^{13}C NMR ([D$_3$]acetonitrile, 76 MHz, 20 °C): $\delta = 40.7$ (br, NCH_3), 43.3 (br, NCH_3), 60.0 (NCH_2), 68.7 (CH of C_5H_5), 68.4, 70.6, 73.8 (CH of C_5H_3), 77.6 ppm (C-bound quaternary of C_5H_3), B-bound quaternary of C_5H_3 not observed. ^{11}B NMR ([D$_3$]acetonitrile, 96 MHz, 21 °C): $\delta =$ 3.0 ppm (q, $J_{B\text{-}F} = 49$ Hz). ^{19}F NMR ([D$_3$]acetonitrile, 283 MHz, 21 °C): $\delta = -133.9$ ppm (q, $J_{F\text{-}B} = 49$ Hz). IR (KBr disk): $\tilde{\nu} = 3174$ s (NH), 1489 w, 1473 w, 1448 w, 1388 m, 1297 w, 1248 w, 1187 m, 1165 w, 1139 m, 1102 s, 1035 s, 1009 s, 946 s, 921 s, 890 m, 853 m, 813 s, 757 w cm^{-1}. MS(EI): $[M-HF]^+ = 291$ (75 %), calcd 291.0683, found 291.0685; $[M-HF-NMe_2]^+ = 247$ (100 %), calcd 247.0185, found 247.0186.

For the crystal structure determinations of **1**, **4**, and **5** a suitable crystal was covered in predried mineral oil and mounted on an Enraf-Nonius Kappa CCD diffractometer at 150(2) K. Crystal data for **1** ($C_{15}H_{20}BFeNO_2$): orthorhombic, space group *Pnma*, $a = 12.522(3)$, $b = 10.602(2)$, $c = 10.421(2)$ Å, $V = 1383.5(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.503$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 1.089$ mm^{-1}; 8254 unique reflections were collected ($3.2 < \theta < 27.5°$); final R factor $R_1 = 0.034$. Crystal data for **4** ($C_{15}H_{23}BF_3FeNO_2$): monoclinic, space group $P2_1/n$, $a = 5.8490(1)$, $b =$

[*] That the response of **3** towards HCl is typical of other inorganic and organic acids (i.e., that there is little or no interaction of the conjugate anion with the boronate moiety) has been shown for related systems[8d] and can be demonstrated explicitly for **3** by cyclic voltammetry. Exposure of **3** to other sources of fluoride (e.g. KF/[18]crown-6) is accompanied by an electrochemical response (a cathodic shift of about 450 mV in MeCN) typical of fluoride coordination to the boron center[8d,13] but with no significant interaction of the tertiary amine function with the cation (K^+).

8.6140(2), $c = 32.1360(9)$ Å, $\beta = 92.210(1)°$, $V = 1617.9(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.531$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 0.970$ mm^{-1}; 3667 unique reflections were collected ($3.0 < \theta < 27.5°$); final R factor: $R_1 = 0.047$. Crystal data for **5** ($C_{13}H_{17}BF_3FeN$): monoclinic, space group $P2_1/a$, $a = 11.6268(5)$, $b = 7.3492(4)$, $c = 15.7888(7)$ Å, $\beta = 104.684(3)°$, $V = 1305.1(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.583$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 1.174$ mm^{-1}; 2982 unique reflections were collected ($3.1 < \theta < 27.5°$); final R factor: $R_1 = 0.056$. CCDC 263113 (**1**), CCDC 263114 (**4**), and CCDC 263115 (**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Biotransformations

Family Clustering of Baeyer–Villiger Monooxygenases Based on Protein Sequence and Stereopreference**

Marko D. Mihovilovic, Florian Rudroff, Birgit Grötzl, Peter Kapitan, Radka Snajdrova, Joanna Rydz, and Robert Mach*

Since its discovery by Adolf von Baeyer and Victor Villiger in 1899,[1] the oxidation process later named after the two scientists has become a powerful tool in synthesis to break carbon–carbon bonds in an oxygen-insertion process.[2] The regiochemistry of the reaction is governed by predictable

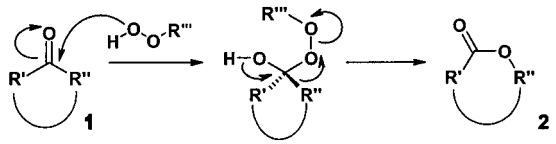
conformational, steric, and electronic effects,[3] and the rearrangement process of the tetrahedral peroxo Criegee intermediate proceeds with strict retention of configuration.[4] These factors are key prerequisites for performing the Baeyer–Villiger oxidation in an enantioselective manner.

The conversion of cyclic ketones into optically pure lactones (Scheme 1), in particular, allows access to highly



Scheme 1. Baeyer–Villiger oxidation of cyclic ketones **1** to form lactones **2**.

flexible compounds as platforms for the subsequent synthesis of bioactive compounds and natural products. Consequently, enantioselective Baeyer–Villiger oxidations have become a highly active field in asymmetric chemistry in recent years.[5] Currently, two major strategies are being developed with implementation of the "green-chemistry" concept aimed at sustainable, environmentally benign, and atom-efficient processes. Metal-based, de novo designed chiral catalysts have been continuously improved and are becoming promising candidates for industrial-scale applications.[6] By taking advantage of the vast catalytic repertoire of enzymes in nature, biocatalysis offers alternative entities for stereoselective oxidation processes with molecular oxygen utilized as the oxidant.[7] An increasing number of flavin-containing Baeyer–Villiger monooxygenases (BVMOs) have been identified during the past decade, and several such proteins display a remarkably broad acceptance profile for nonnatural substrates.[8]

Our approach to overcome some of the BVMO limitations, which have hampered the widespread utilization of oxidizing enzymes by synthetic chemists, utilizes living whole cells that are genetically engineered to express the required protein in high concentration.[9] This concept simplifies the problem of cofactor recycling, which arises because BVMOs require nicotinamide adenine dinucleotide (phosphate) in the reduced form (NAD(P)H) in the initial step of the catalytic cycle.[10] In addition, the tedious process of protein isolation is overcome and enzyme stability is not a limiting factor. As a result of the genetic modifications, the overexpressed BVMO becomes the major fraction in the organism's proteome, and side reactions by competing enzymes can be essentially avoided. This strategy was successfully optimized[11] and scaled up in pilot-plant industrial fermentation facilities[12] very recently.

The second major challenge in biocatalysis in general is the aspect of enantiodivergence. Artificial catalytic entities can be readily tailored to produce antipodal forms of the required products by inverting the chirality of the inducing ligand field. This strategy cannot be transferred to biotransformations, as there is no efficient process available to yield D-amino acid based proteins. Consequently, the identification and characterization of enzymes with overlapping substrate specificity that yield antipodal products is a key issue for the further implementation of biocatalytic methods in synthetic chemistry.

Recently, we and others have observed the formation of antipodal lactones by some representatives of the BVMO enzyme family.[13] This study compares the stereopreference, with respect to enantio- and regiodivergence, of cyclohexanone (CH) and cyclopentanone (CP) monooxygenases originating from *Acinetobacter* ($CHMO_{Acineto}$),[14] *Arthrobacter* ($CHMO_{Arthro}$),[15] *Brachymonas* ($CHMO_{Brachy}$),[16] *Brevibacterium* ($CHMO_{Brevi1}$, $CHMO_{Brevi2}$),[17] *Comamonas* ($CPMO_{Coma}$),[18] and *Rhodococcus* ($CHMO_{Rhodo1}$, $CHMO_{Rhodo2}$)[15] species in recombinant whole-cell-mediated Baeyer–Villiger oxidations with *Escherichia coli* as the host organism.

Initially, desymmetrization of prochiral ketones **1a–i** to the corresponding lactones **2a–i**, in part potential precursors in natural product synthesis, was investigated (Table 1). In a series of monocyclic ketones with prochiral substitution patterns, a significant clustering into two groups was observed: while the majority of BVMOs ("CHMO type") gave (−)-**2a–d** and (+)-**2e** lactones, $CPMO_{Coma}$ and $CHMO_{Brevi2}$ ("CPMO type") gave the antipodal products with moderate to excellent enantiomeric excess. This general trend is only violated by the enzyme $CHMO_{Brevi1}$, which displays the stereopreference of a CHMO-type BVMO but does not accept 4,4-disubstituted ketone **1c**. As observed previously for similar hydroxy compounds,[19] the oxidation of **1c** does not yield the expected seven-membered-ring lactone but rearranges under biotransformation conditions to give the more stable five-membered-ring system.

The enantiodivergent trend in biooxidation was also observed for fused bicycloketones **1f–h**. Generally, moderate to excellent stereoselectivity was obtained upon biooxidation with CHMO-type enzymes. CPMO-type BVMOs gave lactones with chirality consistent with the two-enzyme-groups hypothesis but with lower selectivity for **2f**.

Bridged bicyclo precursor **1i** is only oxidized by CPMO-type enzymes to form lactone **2i**. Together with previous studies of classical kinetic resolutions,[20] this is to some extent an exception of the hypothesis of stereodivergent biotransformations. However, the clearly differentiated substrate acceptance again supports the classification of the studied BVMOs into two groups.

Representatives of this enzyme library exhibited superior enantioselectivities for desymmetrizations with all ketones compared to those observed in previously reported bacterial BVMO oxidations. The potential of enantiodivergent biocatalysts with overlapping substrate acceptance for natural product synthesis is demonstrated by accessing various indole alkaloids such as alloyohimbane[21] from (−)-**2h** and antirhine[22] from the antipodal (+)-**2h**.

Intrigued by the significantly different behavior of the two BVMO clusters in the desymmetrization reactions, we investigated the regiodivergent transformation of fused ketones bearing a cyclobutanone structural motif (Scheme 2). This conversion is considered to be one of the "benchmark" reactions for asymmetric Baeyer–Villiger oxidations[23] and

3 **4** **5**

Scheme 2. Regiodivergent Baeyer–Villiger oxidation of fused ketone **3** to "normal lactone" **4** and "abnormal lactone" **5**.

has been studied in detail with $CHMO_{Acineto}$.[24] Racemic compound **3** is transformed into two types of regioisomeric lactones in a resolution process: migration of the more-substituted carbon atom generates the expected "normal" lactone **4**, while "abnormal" lactone **5** is formed by migration of the less-substituted carbon atom.

Again, we observed a divergent trend for the two enzyme groups (Table 2).[25] CHMO-type proteins displayed a clean resolution that led to the formation of regioisomeric lactones **4** and **5** in approximately 1:1 ratio and with high optical purities. By contrast, $CPMO_{Coma}$ and $CHMO_{Brevi2}$ (CPMO-type enzymes) yielded predominantly "normal" lactone **4** in nearly racemic form. Trace amounts of "abnormal" product **5** were obtained in good enantiomeric excess.

To rationalize this significantly different biocatalytic activity, we compared the results from the biooxidations with sequence-analysis data for the genes and proteins of all eight BVMOs. While only minor correlation was observed on the DNA level of the structural genes, a significant trend in enzyme similarity was found at the amino acid level. Phylogenetic tree analysis of the representatives of the BVMO enzyme family vis-à-vis a remote reference sequence also resulted in clustering into two groups, which to a high degree reflected the reaction profiles of the biocatalysts (Figure 1). $CPMO_{Coma}$ and $CHMO_{Brevi2}$ form a distinctly different cluster while the other six enzymes form the

[a] Combined yields are given for the mixture of **4** and **5** after single flash column chromatography. [b] Ratio and *ee* values were determined by chiral-phase gas chromatography.

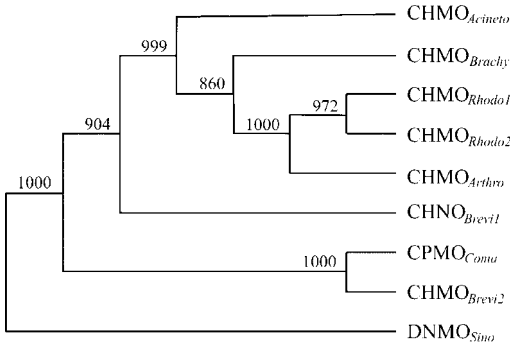

Figure 1. Phylogenetic tree of BVMOs originating from *Acinetobacter*, *Arthrobacter*, *Brachymonas*, *Brevibacterium*, *Comamonas*, and *Rhodococcus* species with the N^4-diaminopropane monooxygenase from *Sinorhizobium meliloti* (DNMO$_{Sino}$) as the outgroup (1000 bootstraps).

"CHMO-type" group. CHMO$_{Brevi1}$ is located at the borderline of the two clusters closer to the CHMO group, a fact which again agrees with its stereopreference and slightly modified substrate-acceptance profile.

A related phylogenetic tree analysis with biomolecular interpretation has been reported previously for a large general set of monooxygenases.[26] However, we consider our results to be the first connection of primary protein sequence with biocatalyst performance for BVMOs.

When the alignment of protein sequences of BVMOs included in this study is compared with the recently described point mutations in CHMO$_{Acineto}$,[27] two striking similarities can be identified. The Leu 143 Phe mutation exactly follows the separation in the two main enzyme groups. The CPMO type in both cases has a phenylalanine, whereas the CHMO type, with the exception of CHMO$_{Brevi1}$, has a leucine residue in this position, a fact again that reflects the borderline position of the latter enzyme. Phenylalanine is conserved in position 432 throughout the studied sequences with two exceptions: CHMO$_{Brevi1}$ and CHMO$_{Arthro}$. The Phe 432 Tyr mutation exactly mimics the amino acid composition of CHMO$_{Brevi1}$ at this position. This mutation has been indicated to significantly increase stereoselectivity and, interestingly, a similar trend was observed in this study.

Recently, the first X-ray structure for a moderately related BVMO from an extremophilic microorganism was solved.[28] This work gave valuable suggestions for the molecular mechanism of the enzymatic oxidation. However, the enzyme structure was determined in the absence of NADPH and no cocrystallization with a substrate is available, so far. As the authors suggest that the protein undergoes extensive conformational changes in the biocatalytic cycle, further conclusions for distant members of the BVMO family, such as those included in this study, seem rather speculative. However, when we consider the information together with recent results in modifying the enantioselectivity of CHMO$_{Acineto}$ by random mutagenesis,[27] we can begin to identify BVMO regions with major impact on biocatalytic behavior and stereopreference. Further structural and biotransformation studies on BVMOs more closely related to the two clusters outlined herein and on a larger set of ketones—currently being addressed in our laboratory—seem necessary for the development of a comprehensive and predictive model for this enzyme family to successfully expand the biocatalytic armament in the field of Baeyer–Villiger oxidations.

EPR Spectroscopy

Anisotropic Hyperfine Interaction in the Manganese(III) Hexaaqua Ion

Itana Krivokapič, Chris Noble, Søren Klitgaard, Philip Tregenna-Piggott, Høgni Weihe,* and Anne-Laure Barra*

The manganese(III) ion is ubiquitous among chemical systems that exhibit intriguing biological and physical properties, ranging from photosystem II and superoxide dismutase to the celebrated single-molecule magnet Mn_{12}. It is for this reason that complexes and clusters of the manganese(III) ion are widely recognized as the delicicae of high-field electron paramagnetic resonance (EPR) spectroscopists,[1] the fact that they invariably yield good-quality spectra being but a secondary consideration.[2–7]

Hitherto, the spatial property of the hyperfine interaction between the $S = 2$ electronic spin and the $I = 5/2$ nuclear spin in any chemically relevant manganese(III) compound has escaped observation. There are two fundamental reasons why knowledge of the hyperfine interaction energies is important. First, the magnitude and sign of the anisotropy relate directly to the manganese(III) coordination sphere. Secondly, the hyperfine interaction has been demonstrated to be instrumental in quantum tunneling of the magnetization in single-molecule magnets.[8,9]

In an EPR study of manganese(III) superoxide dismutase,[2] the hyperfine splittings were resolved and compared to those documented for a photo-oxidation product of manganese(III) in the high-affinity site of photosystem II. Consistency was found between the observed hyperfine splitting and the sign of the zero-field-splitting parameter in the two systems. However, these experiments were confined to X-band parallel-mode experiments, which can determine just one component of the hyperfine interaction matrix. Information concerning the spatial property of the hyperfine interaction matrix requires the use of higher frequencies, as shown in a study of manganese(III)-doped rutile.[12]

In this communication we report single-crystal and powder EPR spectra of the $[Mn(H_2O)_6]^{3+}$ ion at high fields and multiple frequencies. To minimize line broadening due to spin–spin dipolar interactions, the $[Mn(H_2O)_6]^{3+}$ ion was doped into the diamagnetic cesium gallium alum, $Cs[Ga(H_2O)_6](SO_4)_2 \cdot 6H_2O$, thus enabling the precise determination of the metal hyperfine interaction parameters.

Pale orange–red crystals of this sample were grown at 0 °C from a saturated 6 M sulfuric acid solution of the cesium gallium alum that contained 1 % cesium manganese alum. A trace of the corresponding chromium(III) alum was also added. The EPR lines of $[Cr(OH_2)_6]^{3+}$ were readily identified and were useful for crystal alignment.

The single-crystal EPR spectra exhibited several magnetically nonequivalent species, reflecting the space group of the host and the propensity of the $[Mn(OH_2)_6]^{3+}$ ion to distort along a Jahn–Teller active coordinate. There are four tervalent cations in the cubic unit cell, each occupying a site of S_6 symmetry on one of the four unique threefold axes of the unit cell. In addition, at low temperatures the $[Mn(OH_2)_6]^{3+}$ ion is expected to be locked into one of the three possible tetragonally elongated structures that results from the Jahn–Teller interaction. Such a distortion is clearly identified in the neat cesium manganese alum, which undergoes a phase transition from cubic to orthorhombic at 156 K. In the low-temperature phase, the metal ion is situated on a site with point symmetry C_i.[14] A total of twelve magnetically nonequivalent species is therefore anticipated for cesium gallium alum doped with manganese(III) ions, and the principal axes of the various interaction tensors are expected to be aligned close to the Mn–O bonds. Since the vectors of the Mn–O bonds are very closely aligned with the pseudo-crystallographic fourfold axes of the cubic unit cell, the

spectra are expected to simplify when the external magnetic field is aligned along one of these axes.

This expectation is, indeed, found to be the case. Figure 1 shows a 190-GHz spectrum taken between 0 and 6 T and obtained with the magnetic field parallel to a crystallographic

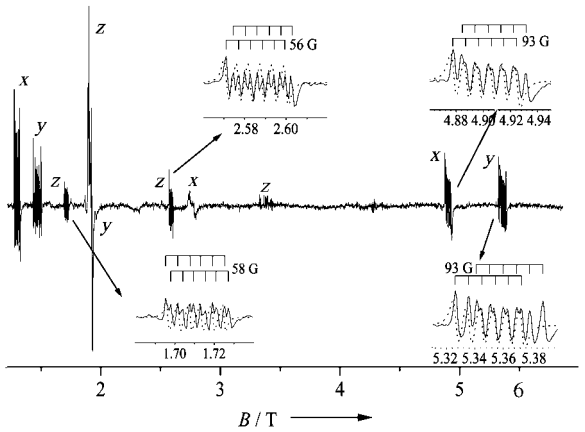

Figure 1. Single-crystal 190-GHz spectrum of the manganese(III) ion in cesium gallium alum obtained at 5 K with the magnetic field vector parallel to a crystallographic fourfold axis. Transitions corresponding to the magnetic field that is parallel to the molecular *x*, *y*, or *z* axis are designated accordingly. The inserts show the spacing between the hyperfine components of the least-complicated features in the spectrum. The simulated[10] spectra (dotted lines in the inserts) were calculated with the spin Hamiltonian parameters given in Equation (3).

fourfold axis. The spectrum exhibits several electronic transitions, each being split into a sextet due to the hyperfine interaction. Two types of sextets are identified in the spectrum: one in which the separation between neighboring lines is 92–93 Gauss; the other in which this splitting is 56–58 Gauss. Each electronic transition is doubled but this doubling is not found in the powder spectra, representative examples of which are shown in Figure 2. Therefore, the doubling must be due to either crystal twinning, a small misalignment when orienting the crystal, or a result of magnetically nonequivalent $[Mn(OH_2)_6]^{3+}$ ions that differ in terms of the orientation of the threefold axes for the sites on which they lie. Rotation of the magnetic field less than 10° away from the fourfold axis has the effect of rendering all sites magnetically nonequivalent, and the complexity of the spectrum increases enormously. The smaller hyperfine splitting of 57 Gauss appears again in the parallel-mode X-band spectra shown in Figure 3. The overlap of lines arising from magnetically nonequivalent species can be seen clearly, as the crystal is rotated in the {110} plane, away from the fourfold axis.

The hyperfine lines in the single-crystal spectra in Figures 1 and 3 were interpreted in terms of a spin Hamiltonian for $(S,I) = (2, 5/2)$.[11] In Equation (1), the five first terms describe the zero-field splittings, and the remaining lines describe the Zeeman energy and the hyperfine interaction.

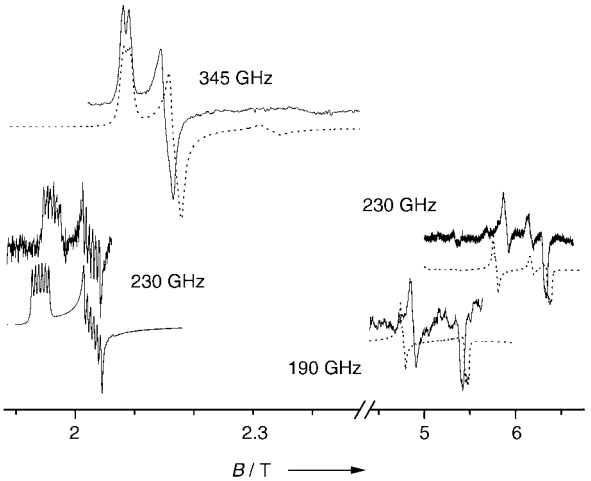

Figure 2. The strongest features (upper traces) in the EPR spectra of a powdered sample of the manganese(III) hexaaqua ion in cesium gallium alum. The frequencies used are designated. Only the field ranges 1.9–2.5 T and 4.5–6.7 T are shown. The separation between the hyperfine components of the low-field 230-GHz spectrum is 93 ± 1 Gauss. The simulated spectra (lower traces) are calculated with the parameters obtained from the single-crystal spectra [Eq. (3)]. All simulated spectra are obtained by using the same bandwidth (70 G) for each hyperfine line.

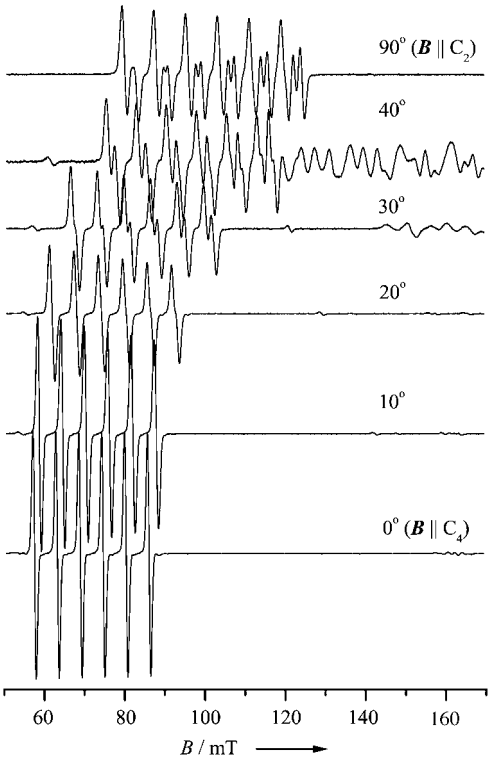

Figure 3. Single-crystal parallel-mode X-band spectra recorded with the magnetic field in the (110) crystallographic plane. The frequencies varied between 9.3107 and 9.3114 GHz. The angle indicated for each spectrum designates the angle between the crystallographic fourfold axis and the vector of the magnetic field. The separation between the hyperfine components in the low-field portion of the six spectra is 57, 58, 61, 66, 75, and 80 Gauss going from the bottom trace to the top.

$$\begin{aligned}\hat{\mathscr{H}} =& D(\hat{S}_z^2-2) + E(\hat{S}_x^2-\hat{S}_y^2)\\ &+B_4^4\frac{1}{2}[\hat{S}_+^4+\hat{S}_-^4] + B_0^4[35\hat{S}_z^4-155\hat{S}_z^2+72]\\ &+B_2^4\frac{1}{4}[(7\hat{S}_z^2\text{-}11)(\hat{S}_+^2+\hat{S}_-^2)+(\hat{S}_+^2+\hat{S}_-^2)(7\hat{S}_z^2-11)]\\ &+\mu_B(g_x B_x \hat{S}_x + g_y B_y \hat{S}_y + g_z B_z \hat{S}_z)\\ &+A_x \hat{S}_x \hat{I}_x + A_y \hat{S}_y \hat{I}_y + A_z \hat{S}_z \hat{I}_z\end{aligned} \quad (1)$$

The lines in the spectrum of Figure 1 as well as the low-angle lines in Figure 3 were assigned to specific transitions of this spin system, and the spin Hamiltonian parameters of Equation (1) were obtained by minimizing χ^2 in Equation (2). N is the number of observations; $B_{i,\mathrm{obs}}$ and $B_{i,\mathrm{calc}}$ are the observed and calculated ith resonance magnetic field, respectively. σ_i is an uncertainty associated with the ith observation and was set to a fraction of the bandwidth for most of the observations.

$$\chi^2 = \sum_{i=1}^{N} \frac{(B_{i,\mathrm{obs}}-B_{i,\mathrm{calc}})^2}{\sigma_i^2} \quad (2)$$

By using a total of 84 resonance magnetic fields in the fit and setting $g_x = g_y$ as well as $A_x = A_y$ as directly suggested by the experimental data (Figure 1), we were able to obtain the parameter values listed in Equation (3).

$$\begin{aligned}D &= -4.514(1)\ \mathrm{cm}^{-1}\\ E &= -0.161(5)\ \mathrm{cm}^{-1}\\ B_0^4 &= -0.0041(5)\ \mathrm{cm}^{-1}\\ B_2^4 &= -0.00014(5)\ \mathrm{cm}^{-1}\\ B_4^4 &= -0.00577(7)\ \mathrm{cm}^{-1}\\ g_x &= g_y = 2.000(1)\\ g_z &= 1.9844(6)\\ A_x &= A_y = -0.0087(2)\ \mathrm{cm}^{-1}\\ A_z &= -0.00531(5)\ \mathrm{cm}^{-1}\end{aligned} \quad (3)$$

These parameter values were then used to reproduce the powder spectra in Figure 2. The agreement is certainly acceptable. In reference [3] values for D and $|E|$ of $-4.491(7)\ \mathrm{cm}^{-1}$ and $0.248\ \mathrm{cm}^{-1}$, respectively, were derived from an EPR study of $Cs[Mn(OD_2)_6](SO_4)_2\cdot 6H_2O$, with a small but significant change in these parameters noted upon hydrogen-for-deuterium isotopic substitution. Note that the value of the orthorhombic zero-field splitting parameter E is slightly larger in magnitude than that determined for the diluted alum in the present study. The discrepancy is primarily a result of the large linewidths obtained for the undiluted alum, which made an inclusion of the fourth-order zero-field splitting parameters unwarranted. The parameters E and B_4^4 are somewhat negatively correlated, and a precise definition requires data from a range of frequencies, including X-band measurements, which are tractable only if the EPR linewidths are sufficiently narrow. The similar values of D suggests that the structure and bonding in the $[Mn(OD_2)_6]^{3+}$ is similar in the two systems.

With the choice of $E<0$ we see that the fourth-order spin Hamiltonian parameters B_0^4, B_2^4, and B_4^4 are all found to be negative, which was also found to be the case for $[Mn(cyclam)Br_2]Br$.[6] (cyclam = 1,4,8,11-tetraazacyclotetradecane). An analysis of this result, however, is not relevant in the present context and will not be discussed here.

The g values, with $g_x, g_y > g_z$, conform to what is expected for an elongated coordination sphere. According to a previous report, the relation $g_x - g_z = 2\zeta/3\Delta_{T_2}$ holds.[15] In this equation, ζ is the spin–orbit coupling parameter, and Δ_{T_2} is the energy separation between the ground-spin quintet and the $^5T_2$ (O notation) excited term. Using the experimentally determined $\Delta_{T_2} = 21\,400\ \mathrm{cm}^{-1}$[3] we find $\zeta = 223\ \mathrm{cm}^{-1}$, which corresponds to 63% of the free-ion value. In Equation (3), we have explicitly set the values of the hyperfine splitting constants as negative. The fit cannot discriminate between the possible sign combinations of these parameters. However, based on other arguments, presented below, we conclude that the parameters are negative.

The angular variation of the resonance magnetic fields as well as the angular variation of the separation between the hyperfine splitting components in Figure 3 is very well described by the effective spin Hamiltonian with $S=\frac{1}{2}$ for a non-Kramers doublet involving only the $+2$ and -2 M_S components in Equation (4), in which θ is the angle between the magnetic field vector and the elongation axis of the coordination sphere.

$$\hat{\mathscr{H}}_{\mathrm{approx}} = b\hat{S}_x + \mu_B g_z' \hat{S}_z B\cos\theta + A_z' \hat{S}_z \hat{I}_z \quad (4)$$

The parameters b, g_z', and A_z' of this effective Hamiltonian are related to those of Equation (1). It can be shown that to the second order in the perturbation theory, the zero-field splitting b of the two components is given by Equation (5).

$$b = 24B_4^4 + \frac{(\sqrt{6}E+\sqrt{54}B_2^4)^2}{2D-30B_0^4} \quad (5)$$

With the parameter values determined above, we see that the first and second term on the right-hand side of the equation have the same sign and are comparable in magnitude. The effective g_z' factor and the effective hyperfine splitting constant A_z' are related to g_z and A_z by Equations (6) and (7).

$$g_z' = 4g_z \quad (6)$$

$$A_z' = 4A_z \quad (7)$$

The effective Hamiltonian Equation (4) is applicable when the $|\pm 2\rangle$ components are well isolated from the remaining components of the spin quintet and when $h\nu > b$, ν being the spectrometer frequency, which is the case here. Using Equation (4) to interpret the spectra in Figure 3 only confirms Equations (6) and (7) and gives $|b| = 0.172\ \mathrm{cm}^{-1}$, which is in reasonable agreement with the value calculated from the formula for the second-order perturbation theory, Equation (5), $b = -0.156\ \mathrm{cm}^{-1}$. With the Hamiltonian Equation (4) the separation between neighboring hyperfine lines is,

to a good approximation, given by Equation (8).

$$B_r(M_I)-B_r(M_I-1) \approx \frac{A'_z}{g'_z \mu_B \cos\theta} \quad (8)$$

The experimental hyperfine line separations of the spectra in Figure 3 are reproduced within 1 Gauss by Equation (8).

For the tetragonally elongated coordination sphere, the relations in Equations (9) and (10) can be derived for the hyperfine coupling constants.[2,15]

$$A_z = P\left(\frac{1}{7}-\kappa-\frac{2\zeta}{\Delta_{T_2}}\right) = P\left(\frac{1}{7}-\kappa+(g_z-2.0023)\right) \quad (9)$$

$$A_x = A_y = P\left(-\frac{1}{14}-\kappa-\frac{\zeta}{2\Delta_{T_2}}\right) = P\left(-\frac{1}{14}-\kappa+(g_x-2.0023)\right) \quad (10)$$

The parameter κ for manganese(III) has been determined to be approximately 0.5.[12] Hence the term in parentheses becomes negative and we conclude that both hyperfine coupling constants are negative because the parameter P for ^{55}Mn is positive. Using Equations (9) and (10) together with the experimentally determined A values and the deviation of the g values from the free-electron g value, we obtain $P = 0.0170\ cm^{-1}$ and $\kappa = 0.43$. P depends on the expectation value $\langle r^{-3}\rangle$, as does the spin–orbit coupling parameter ζ; therefore, it can be expected to be related to the free-ion value in a similar way as the spin–orbit coupling parameter is related to the free-ion value. This is indeed the case; the free-ion value of P for manganese(III) has been calculated to $0.0212\ cm^{-1}$, and our value for the manganese(III) hexaaqua ion corresponds to 80% of this free-ion value, which is in good agreement with the spin–orbit coupling reduction (see above). In comparison, for rutile: Mn^{3+} $P = 0.0140\ cm^{-1}$. The average metal–oxygen bond length in rutile and $[Mn(H_2O)_6]^{3+}$ is 1.956 Å and 1.994 Å, respectively.[13,14] As shorter bond lengths are associated with stronger overlaps between metal- and oxygen-centered orbitals it is also expected that $P(\text{rutile}) < P([Mn(H_2O)_6]^{3+})$. By the same token, P is expected to be further reduced for a metal center that is surrounded by donors softer than oxygen.

In summary, we have presented the first observation and interpretation of the anisotropic hyperfine interaction in a chemically relevant monomeric complex that contains the manganese(III) ion. The hyperfine interaction parameters are related to more fundamental parameters such as the spin–orbit coupling parameter, as well as excited-state energies obtained from the absorption spectrum, which has been analyzed in detail. Basically, the analyses performed here are based on ligand–field theory, which offers a consistent description of the situation. A comprehensive treatment requires that Jahn–Teller coupling be considered explicitly, as dynamic effects can have profound effect on all the orbital electronic operators. This will be the topic of a paper currently in preparation.

Bonding Analysis

Direct Estimate of the Conjugative and Hyperconjugative Stabilization in Diynes, Dienes, and Related Compounds**

*Daniel Cappel, Sandor Tüllmann, Andreas Krapp, and Gernot Frenking**

Compounds with conjugated double bonds such as 1,3-butadiene are energetically stabilized through π interactions. Kistiakowsky et al. suggested in 1936 that the energetic consequences can be assessed by stepwise hydrogenation first to 1-butene and then to butane [Eq. (1)].[1] The first step is

(1)

3.8 kcal mol^{-1} less exothermic (calculated value at G3 level 3.7 kcal mol^{-1})[2] than the second step, which according to Kistiakowsky et al. indicates the strength of the π conjugation in 1,3-butadiene. 1,3-Butadiyne has two pairs of conjugating double bonds and should have stronger conjugative stabilization than 1,3-butadiene, which has only one pair. A recent publication by Rogers et al. reported that the conjugation in the former compound is zero, because the stepwise hydrogenation of 1,3-butadiyne yields nearly equally exothermic values [Eq. (2)].[3]

(2)

The results of Rogers et al.[3] have been confirmed in a recent publication of Jarowski et al.[4] But their divergent interpretation sparked renewed discussion.[5] Jarowski et al. pointed out that hyperconjugation plays an important role in the thermodynamics of the hydrogenation reactions, which was not considered by Rogers et al. Hyperconjugation has recently been suggested to be the driving force for the staggered equilibrium conformation of ethane, but the claim was not undisputed.[6] Jarowski et al.[4] estimated the strength of the hyperconjugation by comparing the calculated and experimental heats of hydrogenation of ethylene and 1-butene with the values for acetylene and 1-butyne. This shows that the hyperconjugative stabilization of acetylene by an ethyl group is 2.5–3.0 kcal mol^{-1} higher than the stabilization of ethylene by an ethyl substituent. A similar result was obtained using isodesmic reactions [Eqs. (3), (4)], which

(3)

(4)

suggest that hyperconjugative stabilization of a triple bond is roughly twice as high as the stabilization of a double bond. The calculated energies for the reactions in Equations (5) and

(5)

(6), which employ virtual intermediates in which hyperconjugation is eliminated, indicate that the conjugation in 1,3-butadiyne is now even slightly stronger (9.6 kcal mol^{-1})[7] than

(6)

in 1,3-butadiene (8.5 kcal mol^{-1}). This is in agreement with previous theoretical investigations.[8,9]

The studies by Rogers et al.[3] and by Jarowski et al.[4] are based on the suggestion of Kistiakowsky[1] to correlate reaction energies with conjugative stabilization, and the latter work modified the original proposal by considering hyperconjugation. Jarowski et al.[4] pointed out that comparisons of heats of hydrogenation evaluate not only conjugative effects but also other structural and electronic differences between the conjugated molecule and its hydrogenated products. We note that the absolute values of the conjugative stabilization given by Equations (5) and (6) are very different from the data of Equations (1) and (2). It would be helpful if a direct estimate of the intrinsic conjugative stabilization in 1,3-butadiene and 1,3-butadiyne could be made based on a well-defined quantum chemical partitioning of the interaction energy. An attempt was published in 1979 by Kollmar, who calculated the resonance stabilization of 1,3-butadiyne (19 kcal mol^{-1}) to be nearly twice that of 1,3-butadiene (9.7 kcal mol^{-1}); this is in agreement with the chemical intuition that two conjugative π systems should be twice as strong as one system.[9] Kollmar's values come from calculations of the two molecules with hypothetical reference systems having nonresonating acetylene and ethylene units. It would be more useful if the actual $^{\cdot}C{\equiv}CH$ and $^{\cdot}HC{=}CH_2$ fragments would be used for an estimate of the conjugative stabilization.

Here we report on an energy decomposition analysis (EDA)[10] of the C–C interactions in 1,3-butadiene, 1,3-butadiyne, and related systems which allows a direct estimate of the intrinsic conjugative and hyperconjugative stabilization that arises from the mixing between the occupied and vacant orbitals of the conjugating fragments. EDA has proven to give important information about the nature of the bonding in main-group[11] and transition-metal compounds.[12] Since the method has been described in detail previously[10–12] we shall

describe the concept only briefly. In EDA, bond formation between the interacting fragments is divided into three steps, which can be interpreted in a plausible way. In the first step the fragments, which are calculated with the frozen geometry of the entire molecule, are superimposed without electronic relaxation; this yields the quasiclassical electrostatic attraction ΔE_{elstat}. In the second step the product wave function becomes antisymmetrized and renormalized, which gives the repulsive term ΔE_{Pauli}, termed Pauli repulsion. In the third step the molecular orbitals relax to their final form to yield the stabilizing orbital interaction ΔE_{orb}. The latter term can be divided into contributions of orbitals having different symmetry which is crucial for this study. The sum of the three terms $\Delta E_{elstat} + \Delta E_{Pauli} + \Delta E_{orb}$ gives the total interaction energy ΔE_{int}. Note that the latter is not the same as the bond dissociation energy, because the relaxation of the fragments is not considered in ΔE_{int}.

Table 1 gives the EDA results[13] of the calculated molecules. In all cases a central C–C single bond connects the interacting fragments, which are calculated in the electronic doublet state with the unpaired electron in a σ orbital. As expected, the C–C bond in 1,3-butadiyne has a much larger interaction energy ($\Delta E_{int} = -176.0$ kcal mol^{-1}) than in 1,3-butadiene ($\Delta E_{int} = -128.5$ kcal mol^{-1}). The electrostatic character[14] of the former bond is smaller (33.9%) than that of the latter (42.8%). The largest contribution to the C–C attraction in both molecules comes from the orbital term ΔE_{orb}. The partitioning of the C–C orbital interactions in σ and π bonding shows that σ bonding is stronger. We note that the strength of σ bonding in 1,3-butadiene ($\Delta E_{\sigma} = -207.5$ kcal mol^{-1}) is greater than in 1,3-butadiyne ($\Delta E_{\sigma} = -178.3$ kcal mol^{-1}). This is because σ bonding in 1,3-butadiyne involves only the C–C σ bond, while σ bonding in 1,3-butadiene has additional contributions from the hyperconjugative interactions of the C–H and terminal C–C bonds. Thus, σ bonding in 1,3-butadiyne comes from only the C–C mixing of the 2s and 2p(σ) atomic orbitals (AOs) of carbon, while the σ bonding in 1,3-butadiene comes not only from the 2s and 2p(σ) orbitals but also from the in-plane 2p(π_{II}) AO of carbon and the 1s AO of hydrogen. Consequently, the total value of the attractive orbital interactions in 1,3-butadiene is slightly larger ($\Delta E_{orb} = -227.0$ kcal mol^{-1}) than in 1,3-butadiyne ($\Delta E_{orb} = -223.3$ kcal mol^{-1}). The electrostatic attraction in 1,3-butadiene ($\Delta E_{elstat} = -169.9$ kcal mol^{-1}) is also larger than in 1,3-butadiyne ($\Delta E_{elstat} = -114.6$ kcal mol^{-1}), although the central C–C bond in the former is longer (1.453 Å) than in the latter (1.361 Å). This is because the unpaired electron in the $^{\bullet}HC{=}CH_2$ fragment is in a (formally) sp^2-hybridized orbital, which is more diffuse and thus has a higher density at the carbon nucleus of the other fragment than the unpaired electron in the more compact sp orbital of $^{\bullet}C{\equiv}CH$.

The most important results of our analysis are the calculated values for ΔE_{π}, which are a direct measure of the π conjugation in 1,3-butadiyne and 1,3-butadiene. Table 1 shows that the conjugative stabilization in the former molecule ($\Delta E_{\pi} = -45.0$ kcal mol^{-1}) is more than twice that calculated for the latter species ($\Delta E_{\pi} = -19.5$ kcal mol^{-1}). This is a reasonable result because the conjugation of the two π systems in 1,3-butadiyne takes place at a shorter C–C distance than in 1,3-butadiene.

How strong is the hyperconjugation in 1-butyne and 1-butene? The hyperconjugation of the multiple bonds in these molecules with the p(π) orbitals of the adjacent carbon atoms involve C–H and C–C bonds. To address the question whether C–H or C–C bonds are better hyperconjugative donors or acceptors, we first analyzed the C–C bonding

Table 1: Results of the energy decomposition analysis at the BP86/TZ2P level. Energy values in kcal mol^{-1}.

[a] The percentages in parentheses give the contribution to the total attractive interactions $\Delta E_{elstat} + \Delta E_{orb}$. [b] The percentages in parentheses give the contribution to the orbital interactions ΔE_{orb}. [c] $\Delta E = \Delta E_{int} + \Delta E_{prep}$. [d] There is a small contribution of 0.6 kcal mol^{-1} from orbitals having δ symmetry.

situations in propyne $HC{\equiv}CCH_3$ and its trimethyl-substituted derivative 3,3-dimethyl-1-butyne $HC{\equiv}CCMe_3$. Table 1 shows that hyperconjugation of the C–H bonds in the former molecule is rather strong ($\Delta E_\pi = -20.1$ kcal mol^{-1}). The hyperconjugative stabilization in $HC{\equiv}CCMe_3$ is even slightly larger ($\Delta E_\pi = -20.6$ kcal mol^{-1}), although the C–C bond is a bit longer than in propyne. This means that C–C bonds stabilize multiple bonds through hyperconjugation better than C–H bonds. It is interesting to note that the hyperconjugative stabilization of the degenerate π systems in $HC{\equiv}CCH_3$ and $HC{\equiv}CCMe_3$ is even slightly stronger than the conjugative stabilization in 1,3-butadiene (−19.5 kcal mol^{-1}), which has nearly the same central C–C bond length (1.453 Å) as the former species (1.456 Å and 1.469 Å).

We also calculated the hyperconjugation in propene $H_2C{=}CHCH_3$ and its trimethyl-substituted derivative $H_2C{=}CHCMe_3$. The calculated ΔE_π values (Table 1) for the former molecule ($\Delta E_\pi = -9.3$ kcal mol^{-1}) and the latter species ($\Delta E_\pi = -9.5$ kcal mol^{-1}) suggest that the hyperconjugative stabilization of C–H and C–C bonds with olefinic double bonds is half as strong as that of C≡C triple bonds. This is reasonable because alkynes have two π components but alkenes have only one π component. The stabilization of the C–C bonds are again slightly larger than that of the C–H bonds.

Hyperconjugation involves donation from the occupied π orbitals of the multiple bonds into the vacant π* orbitals of the CH_3 or CMe_3 groups and backdonation from occupied π orbitals of CH_3 or CMe_3 into π* orbitals of the multiple bonds. Which of the two contributions is stronger? We estimated the strength of the π→π* donation and backdonation separately by carrying out EDA calculations on propene and propyne where the vacant π* orbitals of either fragment were deleted. The results show that both contributions are important for the hyperconjugation but that the backdonation from the π orbitals of CH_3 into the π* orbitals of the multiple bonds is stronger than the donation. In propene the calculated value for the π-orbital donation $\pi(H_2C{=}CH){\rightarrow}\pi^*(CH_3)$ becomes $\Delta E_\pi = -4.0$ kcal mol^{-1} when the virtual π orbitals in the $H_2C{=}CH^{\bullet}$ fragment are deleted, while the $\pi^*(H_2C{=}CH){\leftarrow}\pi(CH_3)$ π backdonation becomes $\Delta E_\pi = -6.0$ kcal mol^{-1} after deletion of the virtual π orbitals in the $CH_3^{\bullet}$ fragment. In the same fashion we found that the π-orbital donation $\pi(HC{\equiv}CH){\rightarrow}\pi^*(CH_3)$ becomes $\Delta E_\pi = -9.3$ kcal mol^{-1} after deletion of the π* orbitals of $HC{\equiv}CH^{\bullet}$, while the $\pi^*(HC{\equiv}CH){\leftarrow}\pi(CH_3)$ backdonation becomes $\Delta E_\pi = -12.8$ kcal mol^{-1} when the π* orbitals of $CH_3^{\bullet}$ are deleted.

We also calculated the conjugative stabilization between a triple and a double bond in but-1-en-3-yne $H_2C{=}CH{-}C{\equiv}CH$. Table 1 shows that the π-bonding contribution to the central C–C bonding ($\Delta E_\pi = -20.5$ kcal mol^{-1}), which involves only one π component of the triple bond, is slightly stronger than the π conjugation in 1,3-butadiene ($\Delta E_\pi = -19.5$ kcal mol^{-1}); this can be explained by the shorter C–C distance in the former compound. We finally calculated the strength of the hyperconjugation in ethane and 2,2,3,3-tetramethylbutane. The doubly degenerate C–C hyperconjugation in the latter compound ($\Delta E_\pi = -11.6$ kcal mol^{-1}) is slightly stronger than the degenerate C–H hyperconjugation in the former species ($\Delta E_\pi = -10.0$ kcal mol^{-1}).

In summary, EDA calculations show that the intrinsic conjugative stabilization arising from the π–π* interactions in 1,3-butadiyne is approximately twice as strong as that in 1,3-butadiene. Hyperconjugation of C–H and C–C bonds with multiple bonds is quite strong. The hyperconjugation is roughly half as strong as π conjugation between two multiple bonds. The hyperconjugation of C–C bonds is slightly stronger than hyperconjugation of C–H bonds.

Metalloenzyme Inhibitors

Metal Ions as Cofactors for the Binding of Inhibitors to Methionine Aminopeptidase: A Critical View of the Relevance of In Vitro Metalloenzyme Assays**

*Rolf Schiffmann, Andreas Heine, Gerhard Klebe, and Christian D. P. Klein**

Methionine aminopeptidases (MetAPs) are highly conserved, ubiquitous metalloproteases that remove the N-terminal starter methionine residue from nascent polypeptide chains. Inhibitors of MetAPs can have numerous biological effects and are consequently under development for a variety of therapies, including anticancer,[1,2] anti-infective,[3] and anti-arthritis[4] drugs. Previous X-ray crystallographic analyses have resulted in a number of reported MetAP structures, including those of the human type II[5] and *Escherichia coli* enzymes.[6] All MetAPs share the "pita bread" folding motif. The active sites of the known MetAPs are very similar; all contain identical metal-chelating residues (2 × Asp, 2 × Glu, 1 × His) that coordinate two adjacent metal ions. These metal ions, in turn, activate a water molecule for nucleophilic attack on the N-terminal methionine amide bond of the peptide substrate. For experiments in vitro, cobalt(II) is most commonly used as the MetAP cofactor, as the resulting dicobalt enzyme has the highest catalytic activity.

We have conducted molecular dynamics studies[7,8] and virtual screening procedures with an emphasis on the MetAP from *E. coli* in pursuit of a rational design approach for MetAP inhibitors. A careful preparation of the active site with particular consideration of the water molecules bound to the two cobalt ions preceded the virtual screening runs. Among the most promising virtual screening hits, we identified thiabendazole (**1**), a frequently used antifungal and antiparasitic compound. The inhibitory activity of this compound against *E. coli* MetAP[6] was consequently tested with a published[9] in vitro assay method (Table 1). As is the case with all other known in vitro assay methods for MetAP, an excess of cobalt was present in the buffer to afford sufficient enzymatic activity.

We found thiabendazole (**1**) to be active in the upper nanomolar range, binding to *E. coli* MetAP with a K_i value of 0.4 μM. The subsequent use of **1** as the lead compound for structural modifications yielded more potent inhibitors based on the benzimidazole scaffold.[11] Because MetAP is an essential enzyme in all cells, we expected that **1** and particularly its more potent analogues would have an antibacterial effect against *E. coli*. However, all compounds were inactive against the growth of *E. coli* at concentrations up to 1 mM. This result, which was reminiscent of similar observations with a structurally distinct and even more potent class of MetAP inhibitors,[3] was initially attributed to insufficient compound uptake into the bacterial cell. To create a reliable basis for further rational drug design efforts, *E. coli* MetAP was crystallized with and without the inhibitor, and the resulting 3D structures were determined by X-ray diffraction at a resolution of 1.6 Å.

Table 1: Noncovalent inhibitors of MetAP.

	 Thiabendazole (**1**)	 **2** (Luo et al.[3])	 **3** (Douangamath et al.[10])
Structure of MetAP complex	This work (PDB code 1YVM)	This work[12]	Ref. [10]
Affinity towards MetAP	$K_i = 0.4$ μM (*E. coli*)	$IC_{50} = 5$ μM (*E. coli*)	$IC_{50} = 16$ μM (*S. aureus*)

Based on the virtual screening results, we assumed that thiabendazole (**1**) was localized in close proximity to the two cobalt ions deep in the active site of *E. coli* MetAP. Complexes between **1** and metal ions are known to form, and we expected the inhibitor to interact with the two metal cations of the active site. It therefore came as a complete surprise to find the inhibitor at the entrance of the active site, not bound to the "regular" cobalt ions at all, but rather to an additional cobalt ion, which is not present in the ligand-free structure. The binding mode is depicted in Figure 1. The

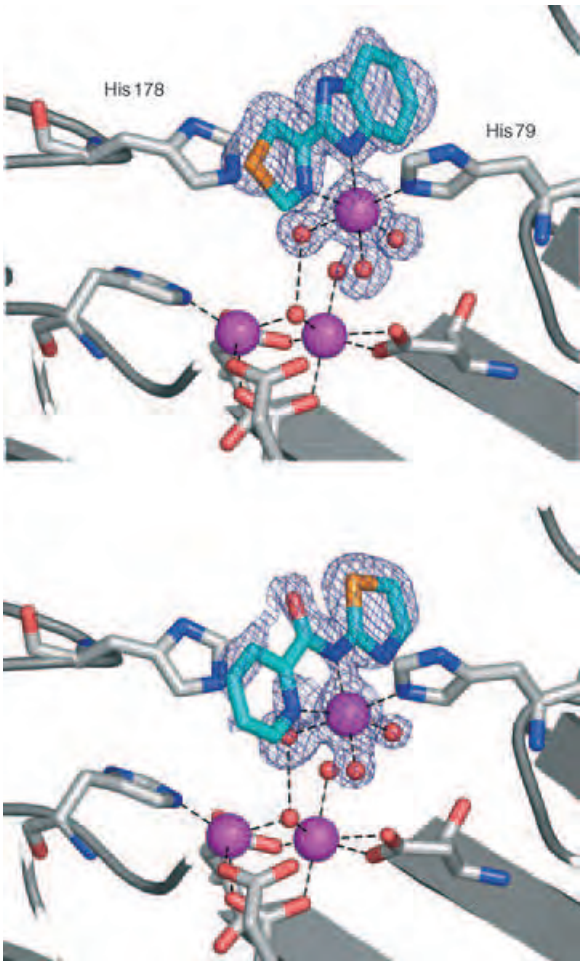

Figure 1. Electron density of thiabendazole (**1**, top) and compound **2** (bottom) near the active site of *E. coli* MetAP. The $2F_o-F_c$ electron density is contoured at 1 σ and shown within a radius of 1.5 Å around the inhibitor, the auxiliary cobalt ion, and the complexing water molecules. (C = turquoise, Co = magenta, N = blue, O = red, S = yellow.)

auxiliary cobalt ion is complexed in a nearly perfect octahedral geometry by two nitrogen atoms of thiabendazole, one histidine nitrogen atom (His79), and three water molecules.

Additionally, we determined the 3D structure of *E. coli* MetAP in complex with the lead compound **2**, which has been previously identified by Luo et al.[3] to a resolution of 1.6 Å. Through its pyridine and amide nitrogen atoms, this compound likewise binds an auxiliary cobalt ion that interacts with His79 and three water molecules at the entrance of the active site.[12] It is possible that the thiazole nitrogen atom, which is located 2.5 Å from the water molecule opposite the pyridine nitrogen atom and about 3 Å from the cobalt ion, also contributes to the stabilization of this complex.

The auxiliary cobalt ion at His79 is not present in enzyme preparations crystallized in the absence of ligand. This has been shown by the previous work of Lowther et al.,[6] and was confirmed by our determination of the structure of the ligand-free enzyme under otherwise identical conditions.

During the course of this work, Douangamath and co-workers[10] reported another MetAP inhibitor class, including **3**, and the binding modes of these compounds to *Staphylococcus aureus* MetAP. Remarkably, compound **3** and a close structural analogue also bind to an additional cobalt ion that is not present in the ligand-free active site. In contrast to the *E. coli* MetAP complexes with **1** and **2** reported herein, the auxiliary cobalt ion is not bound to His79, but rather to His178, and the inhibitors make additional interactions with the "regular" cobalt ions in the active site. Notably, the authors also described a potent inhibitor whose binding is not mediated by an auxiliary cobalt ion.

Three research groups have independently developed structurally distinct inhibitors of MetAPs (with considerable potency in vitro) which share the common feature of binding through auxiliary metal ions. The observation of ternary complexes that including additional cations must clearly be attributed to the high concentration of free metal ions in the in vitro assay; this certainly does not reflect the conditions in a living cell, as has already been pointed out by Douangamath and co-workers.[10] The inhibitors are therefore—most likely—not useful for therapeutic or other in-vivo use.

One may suggest that the problem could easily be solved by lowering the concentration of the metal cofactor in the assay buffer. This is not a viable solution, as MetAPs and many other therapeutically relevant metalloenzymes require high metal concentrations (usually in the range of 1 μM to 1 mM) to be active in vitro. However, the concentration of unbound transition metal ions in living cells is several orders of magnitude lower.[13]

Several conclusions can be drawn from these results. First, it is evident that structural information about the enzyme–inhibitor complex is of crucial importance for the understanding of in vitro assay results. Compounds **1**–**3** have been used as starting points for structure–activity studies, although it must now be assumed that they do not bind MetAP under physiological conditions. Their inactivity in vivo has been incorrectly attributed to insufficient pharmacokinetic properties.

Second, these findings call for more cautious interpretation of in vitro assay results, particularly in the field of metalloenzymes. It seems advisable to judge potential lead compounds not only with respect to pharmacokinetic properties ($\log P$, molecular weight, hydrogen bonding), but also under the perspective of their capacity for binding small inorganic ions. This would prevent the generation of meaningless in vitro assay results. It would also help to avoid investments in experimental substances that have unacceptable pharmacokinetic properties brought about by the binding of metals and other inorganic ions from foodstuffs and nutritional supplements in the gastrointestinal tract. A filtering algorithm that identifies adjacent heteroatoms that are prone to form complexes with inorganic cations should be straightforward to design. Such a tool may be easily implemented within the computer programs that are in current use for the handling of compound databases and for the selection of compounds to be used in virtual or experimental high-throughput screening.

In 1998, Katz et al.[14] proposed the deliberate use of auxiliary zinc ions to increase the binding affinity of serine protease inhibitors. To our knowledge, this group was the first

to describe ligand binding mediated by transition metal ions. The results presented herein may be interpreted similarly; analogous to Katz et al., we might suggest the design of transition metal cofactor-dependent compounds with increased affinity for the enzyme in vitro. However, recent findings on zinc homeostasis[13] indicate that the concentration of free zinc ions in the cell is too low to be used for this purpose, and it must be assumed that this is even more pertinent for other, less inert (redox active) cations such as cobalt. In contrast, it may be possible to use more abundant and inert cations such as calcium and magnesium as mediators for ligand binding. Notably, this would allow the coupling of ligand–receptor interactions to the intracellular concentration of these ions, which (especially calcium) play a major role in many signal-transduction processes. The design of specific high-affinity ligands that make ternary complexes with selected cations and biological target molecules, however, will be a challenging task.

Experimental Section

Crystallization and structure determination: Recombinant eMetAP (Arg175Gln to remove a secondary thrombin cleavage site within a surface loop) was overexpressed in *E. coli* strain BL21(DE3) and purified as previously reported.[2]

Crystals were grown with a slight modification in the conditions described before.[15] In brief, freshly prepared enzyme was kept in buffer containing HEPES (25 mM, pH 6.8), KCl (25 mM), NaCl (100 mM), $CoCl_2$ (1 mM), and methionine (15 mM). Crystals of the Co^{II}-containing enzyme were obtained overnight at 22 °C by vapor diffusion in 20-μL sitting drops after mixing the protein solution in buffer (13.5 mg mL^{-1}) to which *n*-octanoylsucrose (Calbiochem-Novabiochem Corp., La Jolla, CA) was added (final concentration = 48.8 mM), at a ratio of 1:1 with well solutions (500 μL) containing PEG 4000 (24–33 %), HEPES (0.1M, pH 7.1) and fresh $CoCl_2$ (2 mM).

Crystals of the thiabendazole complex were obtained by incubating the enzyme (13.5 mg mL^{-1}) in *n*-octanoylsucrose (49.8 mM) at room temperature for 5 min with a solution of the inhibitor dissolved in DMSO. The final inhibitor/enzyme ratio was 5:1 (DMSO, 1 %; *n*-octanoylsucrose, 48.8 mM) after mixing the preformed complex with well solution: PEG 4000 (24–33 %), HEPES (0.1M, pH 7.1) and $CoCl_2$ (2 mM).

The data set was collected on a Rigaku/MSC rotating anode generator (RU300) operated at 50 kV and 90 mA equipped with an R-axis 4++ imaging-plate detector. 360 frames with $\delta_\phi = 0.5°$ at a detector distance of 100 mm were collected at −170 °C with 18 % glycerol in mother liquor as cryoprotectant.

For compound **2**, the inhibitor/enzyme ratio was 2.5:1 and the well solution contained 4-mM $CoCl_2$. The data set was collected with an R-axis 4 imaging-plate detector under the conditions and parameters mentioned above and consisted of 240 frames.

Data were processed and scaled with the program HKL2000.[16] The MetAP structure published by Lowther and coworkers (PDB code 2MAT) was used without the cobalt atoms and water molecules as a starting model for molecular replacement in PHASER[17] followed by a rigid-body refinement in CNS.[18] Initial refinement was continued in CNS by using positional and slow-cooling protocols followed by restrained *B*-value refinement. Refinement was then continued with SHELXL97.[19] At least 20 cycles of conjugate gradient minimization with restraints on bond distances, angles, and *B* values were performed for each refinement step. In the final stages, hydrogen atoms were placed in calculated positions without the use of additional parameters. Intermittent cycles of model building were done with the program O.[20]

The coordinates have been deposited in the PDB (http://www.rcsb.org/pdb/) with access code 1YVM. All images were created with PYMOL.[21] 3D structures were checked and Ramachandran plots were generated with Procheck.[22]

[12] There was clear density for the auxiliary cobalt ion and the two water molecules in the same position as in the structure with thiabendazole. Additional density suggests the position of the planar ligand that could coordinate through its nitrogen atoms to the Co ion. However, multiple binding modes cannot be entirely ruled out, as the electron density is somewhat ambiguous and only clearly visible for a part of the ligand. The structure was therefore not deposited in the protein data bank.

Chiral Molecules

Isotopic Chirality and Molecular Parity Violation**

Robert Berger, Guido Laubender, Martin Quack, Achim Sieben, Jürgen Stohner, and Martin Willeke*

Dedicated to Richard N. Zare on the occasion of his 65th birthday

Studies of isotope effects have a long tradition in providing fundamental insights into molecular spectroscopy and reaction dynamics,[1,2] usually dealt with theoretically on the basis of the electromagnetic interaction that is parity conserving, i.e. remains unchanged under space inversion at the origin.[3–5] Isotope effects are frequently caused by mass differences of the isotopes. There are also isotope effects due to the different nuclear spins of the isotopes,[6] and, in principle, isotope effects can arise independent of mass and spin because of symmetry restrictions on the molecular wavefunction leading to different symmetry selection rules for different isotopomers.[7] Here we report the first quantitative investigations of a new isotope effect, which leads to a ground-state energy difference $\Delta_{pv}E \approx \Delta_{pv}H_0^0/N_A$ for the enantiomers of molecules that are isotopically chiral, i.e. chiral only by isotopic substitution (Figure 1). This parity-violating isotope effect arises from the electroweak interaction between electrons and nucleons, mediated by the Z-boson, and thus depends upon nucleonic composition. Our calculations are of interest in relation to efforts of measuring $\Delta_{pv}E$ in enantiomers,[5,8] and they are also important for the fundamental understanding of isotope effects and molecular chirality. The present work opens a new avenue in this field by providing quantitative calculations on such chiral isotopomers in the framework of electroweak quantum chemistry[9] including the weak nuclear force. Since recent theoretical approaches predict absolute values of $\Delta_{pv}E$ that can be orders of magnitude larger[9–12] than anticipated on the basis of earlier calculations,[14,15] there is new hope that accurate measurements and calculations, particularly for molecules with light atoms, will provide additional insights into the standard model of high-energy physics.[5,16] We refer here to recent articles with extensive further references.[4,5,10,12]

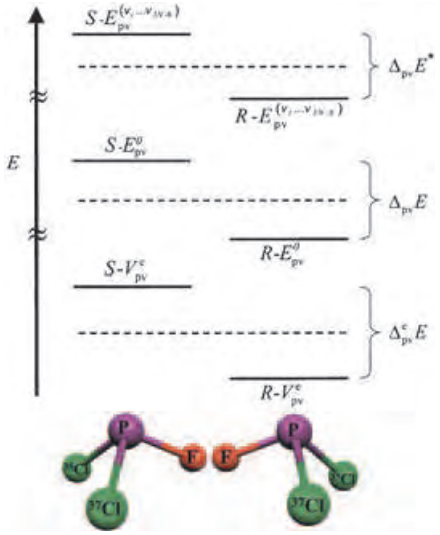

Figure 1. Scheme showing all quantities of interest as explained in the text. For the example $PF^{35}Cl^{37}Cl$ the relative magnitudes of the various $\Delta_{pv}E$ values are to scale, with $\Delta_{pv}E^*$ for the case $v_i=1$ for all i, but the comparison with much larger zero-point and vibrational excitation energies is, of course, not to scale. The magnitude of the reaction enthalpy for the stereomutation reaction $S=R$ is $|\Delta_{pv}H_0^0| \approx N_A|\Delta_{pv}E| = 3.3\times10^{-13}$ J mol^{-1} (at 0 K).

In this context we address and answer the following questions:

1. How large is $\Delta_{pv}E$ in isotopically chiral systems compared to "ordinary" enantiomers?
2. Is $\Delta_{pv}E$ dominated here by the parity-violating potential at the equilibrium geometry or by vibrationally averaging the parity-violating potential?
3. How does vibrational excitation change $\Delta_{pv}E$ (i.e. $\Delta_{pv}E^*$) in such systems compared to "ordinary" enantiomers where this question was addressed previously?[17]

The answers to these questions will help in planning future experiments possibly including isotopic enantiomers. We study the phosphane derivatives PHDX (X = F,^{35}Cl,^{37}Cl,^{79}Br,^{81}Br) and $P^{35}Cl^{37}ClY$ (Y = F,H,D) with these goals in mind. While isotopic chirality has been considered for some time,[3,18–20] as an isotope effect through variation of

identity and mass of the isotopes, our work provides the first quantitative predictions of $\Delta_{pv}E$ resulting from the parity-violating isotope effect.

Figure 1 illustrates the quantities of interest. *R*-V^e_{pv} and *S*-V^e_{pv} refer to the parity-violating potentials at the Born–Oppenheimer (BO) equilibrium geometries of the *R* and *S* enantiomers. Because of the antisymmetry of the parity-violating potential with respect to space inversion,[5] the absolute magnitude of the difference $|\Delta^e_{pv}E|$ is just twice the absolute magnitude of each of the two potentials. Adding the zero-point vibrational energy and the average parity-violating potentials in the vibrational ground states to the BO parity-conserving potentials gives the ground state energy levels including parity violation for both enantiomers (*R*-E^0_{pv}, *S*-E^0_{pv}). Their difference corresponds to the in principle measurable ground state energy difference (if tunneling is negligible) or to the reaction enthalpy at 0 K $|R\text{-}E^0_{pv} - S\text{-}E^0_{pv}| = |\Delta_{pv}E| \approx |\Delta_r H^0_0/N_A|$ (the sign depends on the convention for the directed stereomutation reaction between *R* and *S*). Finally a similar definition applies to excited vibrational states $(v_1 \ldots v_{3N-6})$ of the chiral molecule, which occur as closely spaced doublets of levels for the two enantiomers with the parity-violating splitting $|\Delta_{pv}E^*(v_1 \ldots v_{3N-6})| = |R\text{-}E^{v_1 \ldots v_{3N-6}}_{pv} - S\text{-}E^{v_1 \ldots v_{3N-6}}_{pv}|$ provided that this splitting is much larger than the hypothetical tunneling splitting for the parity-conserving case but much smaller than the separation of vibrational levels.[3,8]

The parity-violating potentials were calculated within our multiconfiguration linear response (MC-LR) approach to electroweak quantum chemistry,[11] here within the random-phase approximation (RPA). The approximate parity-violating Hamiltonian in SI units is given in Equation (1).[10,11,17]

$$\hat{H}_{pv} = \frac{\pi G_F}{h m_e c\sqrt{2}} \sum_{A=1}^{N} Q_w(A) \sum_{i=1}^{n} [\hat{\vec{p}}_i \cdot \hat{\vec{s}}_i, \delta^3(\vec{r}_i - \vec{r}_A)]_+ \quad (1)$$

Here, G_F (Fermi constant) is $2.222527 \times 10^{-14}\, E_h a_0^3 = 1.43586 \times 10^{-62}\,\mathrm{J\,m^3}$ (Hartree energy E_h and Bohr radius a_0), m_e is the electron mass, h is Planck's constant, and c is the speed of light in vacuum. $\hat{\vec{p}}_i$ and $\hat{\vec{s}}_i$ are the linear momentum and spin operator of the electron i, and $\vec{r}_i$ denotes its position. $\vec{r}_A$ is the position vector of nucleus A. δ^3 represents the three-dimensional Dirac delta distribution and $[.,.]_+$ the anticommutator. The strength of the resulting effect is related to the numbers of protons Z_A and neutrons N_A in the nucleus A, which enter the Hamiltonian by means of the electroweak charge [Eq. (2)].

$$Q_w(A) = Z_A(1 - 4\sin^2\theta_w) - N_A \quad (2)$$

Here, θ_w is the Weinberg angle; we used $\sin^2\theta_w = 0.2319$ in our calculations. The electroweak charge Q_w differs for the various isotopes leading to the new parity-violating isotope effect discussed here. We first focus on the parity-violating potential energy at the equilibrium geometries of the electronic ground states V^e_{pv} (and $|\Delta^e_{pv}E| = |2V^e_{pv}|$). The results reported in Table 1 for V^e_{pv} correspond to the *R* configuration of the molecules **1**–**10**. A negative value of V^e_{pv} indicates a stabilization of the given structure, while the corresponding mirror image is destabilized by the same amount. The absolute values of V^e_{pv} of systems that are chiral due to substitution with different chlorine isotopes (**6**–**8**) are remarkably large, whereas the effect due to a deuteration (**1**–**5**) is two to three orders of magnitude smaller. This can be understood from the parity-violating operator $\hat{H}_{pv}$ given in Equation (1), which describes effectively a contact-like interaction between each electron and each nucleus, depending on the weak nuclear charge $Q_w(A)$ [Eq. (2)]. The parity-violating potential arises as a sum of contributions from the various nuclei, where typically the heavier nuclei dominate.[10] Therefore, simple deuteration results in an absolute value of V^e_{pv} that is small compared to systems that are chiral with different chlorine isotopes. We report in Table 1 also V^e_{pv} for the "ordinary" chiral systems $P^{79}Br^{35}ClF$ (**10**) and $PH^{35}ClF$ (**9**). For the isotopically chiral molecules $PH^{35}Cl^{37}Cl$ and $P^{35}Cl^{37}ClF$ the parity-violating potential is about one order of magnitude smaller than for the "ordinary" chiral molecule PHClF. This can be understood by the electroweak charges of ^{35}Cl and ^{37}Cl ($Q_w = -16.8$ vs -18.8) differing by about 10%. For the isotopically chiral systems one would thus expect a

[a] $V^e_{pv}/(hc)$ is the parity-violating potential calculated at the equilibrium geometry of the parity-conserving Born–Oppenheimer potential. All geometry optimizations and one-dimensional (1D) cuts through the parity-conserving potential energy hypersurface were carried out on the level of second order Møller–Plesset perturbation theory (MP2) within the frozen core approximation using Gaussian 98.[26] $E^0_{pv}/(hc)$ is the parity-violating potential averaged over the ground vibrational state as explained in the text. From the quantities given it is possible to calculate the parity-violating energy differences $|\Delta^e_{pv}E| = |2V^e_{pv}|$ and $|\Delta_{pv}E| = |2E^0_{pv}|$ (see text and refs. [11,17] for methods and basis sets). Parity-violating potentials were calculated with our modification[11] of the Dalton program.[27]

decrease of V_{pv}^{e} by an order of magnitude; one notes that for the symmetric equilibrium geometry of $PF^{35}Cl_2$ the atomic contributions to V_{pv}^{e} for the two ^{35}Cl nuclei are of exactly the same "normal" magnitude but cancel because of their different sign. In $PF^{35}Cl^{37}Cl$ a difference of about 10% remains with respect to exact cancellation. For a normal asymmetric molecule like PHFCl such a partial cancellation is not expected systematically and V_{pv}^{e} is an order of magnitude larger. H–D substitution leads to a large relative change of the electroweak charge but to little change in the parity-violating potentials simply because neither H nor D contribute much to V_{pv}^{e}. This explains the small parity-violating potentials with H/D isotopic chirality in Table 1. For isotopically chiral CHDTOH[20] we have discussed that those nuclei that lie in the C_s symmetry plane of the corresponding achiral isotopomers do not contribute to the parity-violating potential V_{pv}^{e}. Thus, the values of V_{pv}^{e} for $PHD^{35}Cl$ and $PHD^{37}Cl$ are identical (as also for the pairs $PH^{35}Cl^{37}Cl$(**6**)/$PD^{35}Cl^{37}Cl$(**7**) and $PHD^{79}Br$(**4**)/$PHD^{81}Br$(**5**)).

Isotopic substitution, however, does not only influence the parity-violating potential at the equilibrium structure, it also modifies the molecular motion and changes the average ground state geometry of a molecule.[17] It is, for instance, well known that the average X–D bond lengths are shorter than the average X–H bond lengths (see refs. [3,21] for a discussion of CH_4 including its potentially chiral isotopomers). To include this effect in the calculation of $\Delta_{pv}E$ we described the vibrational problem in the separable anharmonic adiabatic approximation (SAAA[17]). Our methods of calculation have been described in detail in refs. [11,17], and we have checked by test calculations that the nonseparable coupling in $V_{pv}(q_i)$ as a function of the reduced normal coordinates q_i is of minor importance.[17] We are allowed to talk of a measurable $\Delta_{pv}E$,[5,8] as it is much larger than the tunneling splitting. The latter was roughly estimated for **2** as 10^{-23} cm^{-1} to 10^{-20} cm^{-1} using a simple WKB method. For the other compounds[22] the tunneling splitting should be even smaller because of the higher inversion barrier or larger tunneling mass (see ref. [23] and references therein). With the parity-violating potential $V_{pv}(q_i)$ and the vibrational wavefunction $\Psi_i^{v_i}$ we calculated the expectation value $\langle E_{pv}\rangle_i^{v_i}$ of the parity-violating energy for the ith mode excited with v_i quanta [Eq. (3)].[17] Figure 2 illustrates this for (*R*)-PHDF.

$$\langle E_{pv}\rangle_i^{v_i} = \langle \Psi_i^{v_i} | V_{pv}(q_i) | \Psi_i^{v_i} \rangle \qquad (3)$$

Within the SAAA[17] we obtain the parity-violating energy $E_{pv}^{(v_1,\ldots,v_{3N-6})}$ for a vibrational state with vibrational quantum numbers v_i according to Equation (4).

$$E_{pv}^{(v_1,\ldots,v_{3N-6})} = \langle \prod_i^{3N-6} \Psi_i^{v_i} | V_{pv}^{e} + \sum_{i=1}^{3N-6} \Delta V_{pv}(q_i) | \prod_i^{3N-6} \Psi_i^{v_i} \rangle$$
$$= \sum_i^{3N-6} \langle E_{pv}\rangle_i^{v_i} - (3N-7)\, V_{pv}^{e} \qquad (4)$$

We use E_{pv}^{0} as the abbreviation for the ground state value with $v_i = 0$ for all i. The ground state parity-violating energy difference can be calculated as $|\Delta_{pv}E| = |2E_{pv}^{0}|$ or for excited states as $|\Delta_{pv}E^*| = |2E_{pv}^{(v_1,\ldots,v_{3N-6})}|$. We applied the procedure illustrated for (*R*)-PHDF to all compounds **1**–**10**. The results for E_{pv}^{0} are given in the third column of Table 1. For compounds **6**–**10** E_{pv}^{0} is similar to V_{pv}^{e}, whereas for **1**–**5**, which are chiral due to single deuteration, E_{pv}^{0} is up to three orders of magnitude larger than V_{pv}^{e}. The strong vibrational dependence for **1**–**5** opens up the possibility of increasing or decreasing the parity-violating energy by selected excitation of fundamentals.[17] For (*R*)-PHDF excitation with one quantum in ν_6 for instance leads to $E_{pv}^{(0,0,0,0,0,1)} = 9.90 \times 10^{-15}$ cm^{-1} (positive), whereas an excitation of ν_4 with one quantum results in $E_{pv}^{(0,0,0,1,0,0)} = -1.22 \times 10^{-14}$ cm^{-1} (negative). Simultaneous excitation of both modes leads to substantial compensation, with $E_{pv}^{(0,0,0,1,0,1)} = -8.57 \times 10^{-16}$ cm^{-1}. In (*R*)-$P^{35}Cl^{37}ClF$, however, the parity-violating energy is predicted to depend less upon vibrational excitation. At some stage the nonseparable, anharmonic effects will certainly become important and can be accounted for.[17]

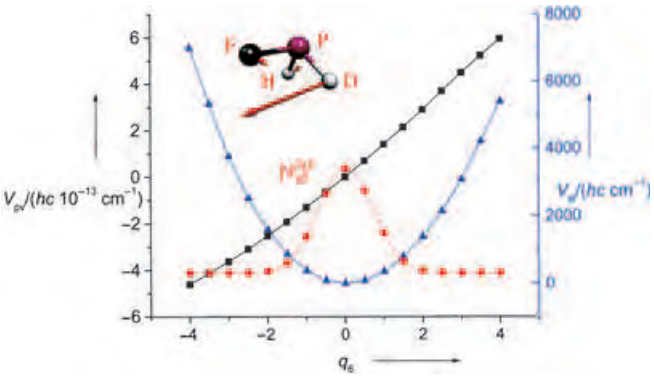

Figure 2. The one-dimensional cut through the parity-conserving potential energy hypersurface (MP2/6-311G(d,p)) of (*R*)-PHDF along the reduced normal coordinate q_6 (triangles, ordinate on the right). The displacement vectors of q_6 are indicated for the different atoms. We show no scale for the probability density $|\Psi_6^0|^2$ (circles), but the scale may be defined by its maximum value (0.28) of $|\Psi_6^0|^2$ in the figure. The squares (ordinate on the left) represent the parity-violating potential (RPA/6-311G(d,p)) along q_6.

We conclude that chirality caused by intermediate-mass isotopes can give rise to relatively large absolute values of the parity-violating energy difference $\Delta_{pv}E$. For **1**–**5**, which are chiral due to deuteration, the vibrational averaging is important for $\Delta_{pv}E$. The absolute value of the vibrationally averaged parity-violating ground state energy difference for **4**–**5** is more than two orders of magnitude larger than $\Delta_{pv}^{e}E$ at the equilibrium structure. For **6**–**10** $\Delta_{pv}^{e}E$ and $\Delta_{pv}E$ differ by less than 15%, and their absolute values are only about an order of magnitude smaller than those obtained for "ordinary" chiral molecules with similar elemental composition. These results suggest that compounds that are chiral by isotopic substitution are well-suited candidates for theoretical and experimental work on molecular parity violation. Whereas detection of parity-violating effects in the frequency domain[24] may not be feasible for a compound such as $P^{35}Cl^{37}ClF$, the time $t = h/(2\Delta_{pv}E)$ for a transition between parity eigenstates induced by the parity-violating energy difference $\Delta_{pv}E$ would correspond to about 600 s with an

initial time-dependent signal for the change of parity being perhaps realistic on a millisecond timescale (see ref. [8] for such experiments and ref. [25] for a preliminary conference account of spectroscopic work in relation to parity violation in isotopically chiral $P^{35}Cl^{37}ClF$).

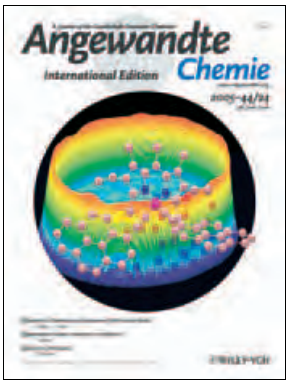
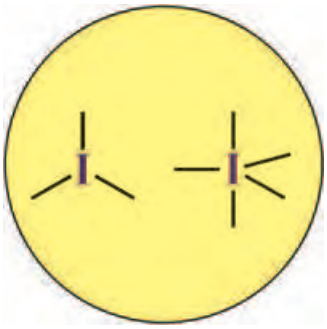
Cover Picture

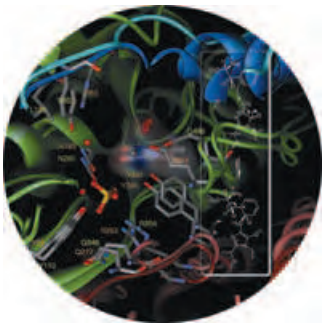


Gilles Ulrich,* Christine Goze, Massimo Guardigli, Aldo Roda, and Raymond Ziessel*

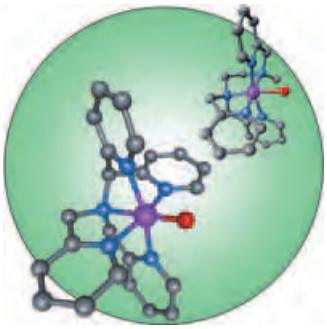
An energy-cascade device is created by linking ethynylpyrene fragments to boron centers. The cover picture shows such a Bodipyrene dye in which irradiation of the pyrene moiety gives a virtual Stokes shift of 10000 cm^{-1}. The background shows a 3D plot of a fluorescence well containing femtomolar amounts of labeled biomaterial. In their Communication on page 3694 ff., G. Ulrich, R. Ziessel, and co-workers describe how biomolecules can be labeled with these dyes, which are very promising for fluorescence imaging.



Hypervalent Iodine Compounds
In his Minireview on page 3656 ff., T. Wirth describes recent advances and trends in hypervalent iodine chemistry. The stability and versatility of these compounds has opened the route to new applications in organic synthesis.



Enzyme Mechanisms
Lyases catalyze the removal of the nonacidic β protons of histidine and phenylalanine with the release of ammonia. In their Review on page 3668 ff., J. Rétey and L. Poppe summarize the latest findings that have led to revision of the long-accepted reaction mechanism.



Oxoiron(IV) Complexes
Structural insight obtained through a combination of X-ray crystallography, NMR spectroscopy, and DFT calculations of novel oxoiron(IV) complexes with pentadentate aza ligands is discussed by L. Que, Jr., C. J. Cramer, and co-workers in their Communication on page 3690 ff.

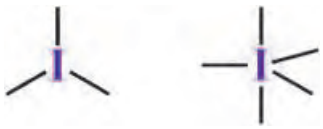
Supramolecular Chemistry

Welcome to the superbowl! The coupling of five resorcinarene-based compounds affords the covalent bowl-shaped analogues of hydrogen-bonded hexameric capsular assemblies (see picture). Such molecules offer stability, solubility, and functionality beyond those of their non-covalent cousins, and provide interesting insight into intracavity reactions, molecular transport, and complexation processes.

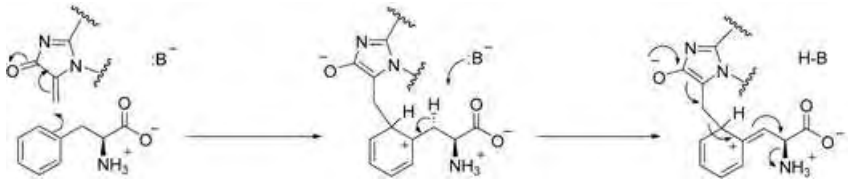
Minireviews

I^{III} and I^{V} Reagents

New reagents and reactions show the potential of hypervalent iodine compounds in organic synthesis: The understanding of the structures and reactivities of iodine(III) and iodine(V) compounds forms the basis for novel synthetic strategies and their application in the synthesis of complex natural products.



Reviews

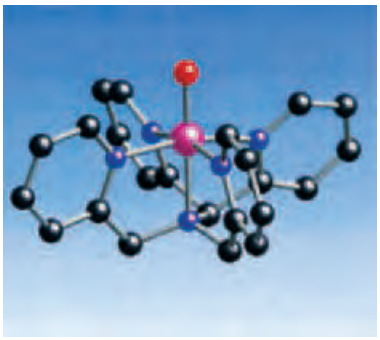


In the enzymatic superelectrophile 5-methylene-3,4-dihydroimidazol-4-one (MIO), delocalization of the lone pair of electrons on the nitrogen atom into the Michael system is prohibited for stereoelectronic reasons, and nucleophilic attack at the exocyclic double bond makes the ring aromatic. The MIO group in histidine and phenylalanine ammonia-lyases activates a β hydrogen atom of the corresponding amino acid and facilitates the elimination of ammonia (see scheme).

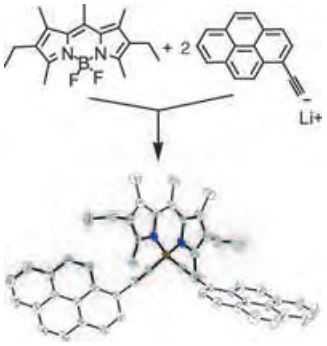
Enzyme Mechanisms

Communications

Stabilizing the oxoiron(IV) unit: From a combination of X-ray crystallography, NMR spectroscopy, and DFT calculations, the relative thermal stabilities of two oxoiron(IV) complexes with pentaaza ligands, such as that shown in the picture, can be ascribed to the number of pyridine rings that are oriented parallel to the Fe=O bond. (Fe pink, N blue, O red, C black.)



Oxoiron(IV) Complexes



All aglow: A new class of highly luminescent dyes is built by the attachment of a pyrene fragment to the boron center of a boradiazaindacene moiety through an ethynyl unit (see scheme). Very efficient energy transfer from the pyrene to the indacene center produces virtual large Stokes shifts, which are maintained, along with strong luminescence ($\Phi = 32$–$45\,\%$) when the dyes are attached to proteins such as bovine serum albumin.

Fluorescence Imaging

For the USA and Canada:
ANGEWANDTE CHEMIE International Edition (ISSN 1433-7851) is published weekly by Wiley-VCH PO Box 191161, D 69451 Weinheim, Germany. Air freight and mailing in the USA by Publications Expediting Inc. 200 Meacham Ave., Elmont, NY 11003. Periodicals postage paid at Jamaica NY 11431. US POSTMASTER: send address changes to *Angewandte Chemie*, Wiley-VCH, 111 River Street, Hoboken, NJ 07030. Annual subscription price for institutions: US$ 4948.00/4498.00 (valid for print and electronic / print or electronic delivery); for individuals who are personal members of a national chemical society, or whose institution already subscribes, or who are retired or self-employed consultants, print only: US$ 394.00. Postage and handling charges included. All Wiley-VCH prices are exclusive VAT.

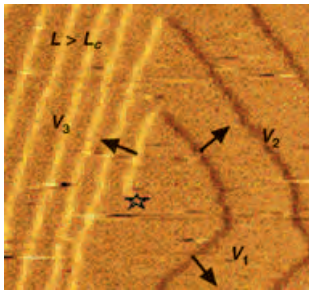
WILEY InterScience® DISCOVER SOMETHING GREAT

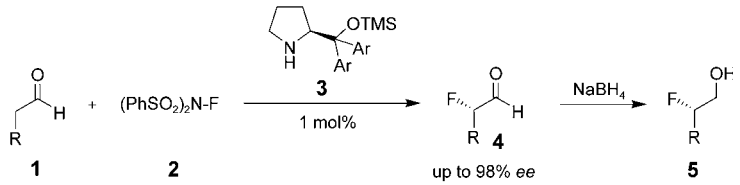
WILEY-VCH

16131412_gu



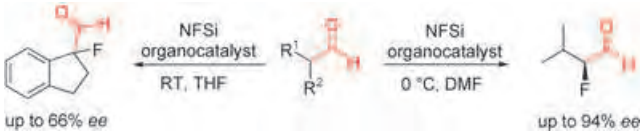
The critical length and density of the steps, rather than step morphology and velocity of deposition, are useful for understanding the effectiveness of the additive molecules in modifying the crystallization kinetics in biomineralization. This biological control stems from a change in solid–solution interfacial energies, which delays the formation of active steps on the growing crystal face (see picture).

Crystal Growth



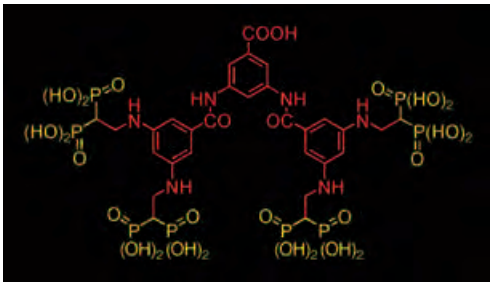
An easy protocol has been developed for the formation of stereogenic carbon–fluorine centers by the organocatalytic asymmetric α-fluorination of aldehydes **1**. The 2-fluoroaldehydes **4** are formed with **2** as the fluorinating agent and only 1 mol% of a sterically demanding silylated prolinol **3** as catalyst. The 2-fluoroaldehydes are subsequently reduced to the corresponding alcohols **5** without loss of enantiomeric excess.

Enantioselective Fluorination



Linear and branched aldehydes are asymmetrically α-fluorinated with L-proline- and pyrrolidine-based organocatalysts (see scheme; NFSi: *N*-fluorobenzenesulfonamide). In the first case, yields and enantioselectivities were high; in the second, the yields remained high and the enantioselectivities were moderate. Significantly, linear aldehydes were only monofluorinated.

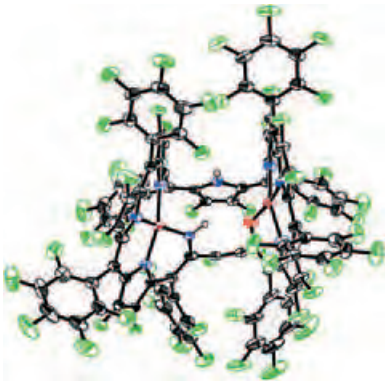
Enantioselective Fluorination



Close to the bone: A dendritic molecule that contains four bone-seeking bisphosphonic acid groups (see picture) has been prepared for targeting proteins to bone tissue. The tetra(bisphosphonic acid) molecule provides a high density of bisphosphonic acid groups per attachment site at the protein and will aid the design of bone-seeking proteins with minimal modification.

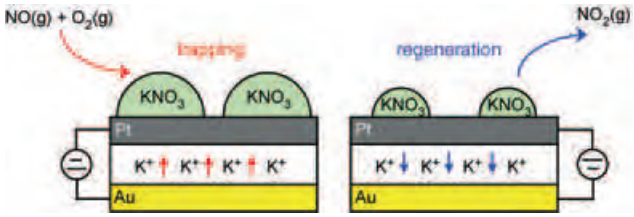
Bioorganic Chemistry

Contents



Metallooctaphyrin complexes: Dimetalation of perfluorinated [36]octaphyrin with copper(II) results in the hydrolytic ring opening of one of the pyrrole rings (see structure), whereas with silver ions perfluorinated [36]octaphyrin and *meso*-pentafluorophenyl-substituted [36]octaphyrin gave disilver(I) complexes of [34]octaphyrin.

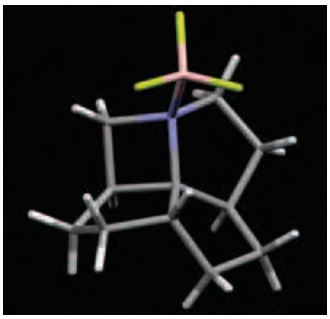
Metalloporphyrinoids



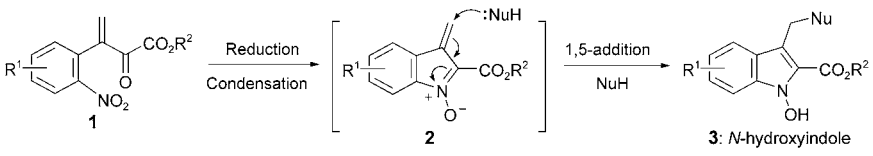
Fort NOx: The principle of an NO_x trap based on the use of solid alkali-metal-ion conductors is demonstrated. The trap efficiently stores NO_x and subsequently releases mainly NO_2 under isothermal conditions (see scheme); this is relevant to the abatement of nitrogen oxides in the exhaust gases of fuel-efficient automotive engines.

Chemical Traps

An unprecedented skeletal reorganization initially hindered a concise route based on a tandem [4+2]/[3+2] nitroalkene cycloaddition for the synthesis of the strained title compound. Conditions to suppress the observed dyotropic rearrangement were developed, and X-ray crystallographic analysis of the BF_3 derivative (see picture) of the azafenestrane revealed significant planarization around the central carbon atom.



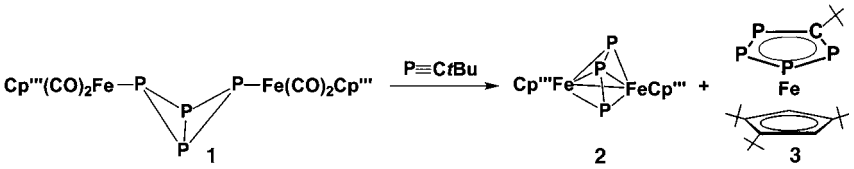
Strained Polycycles



Generation (1→2) and trapping (2→3) of the fleeting α,β-unsaturated nitrone system **2** leads to the rare, biologically important *N*-hydroxyindole **3** in synthetically useful yields. This structural motif is found within the molecule of the antibiotic nocathiacin I.

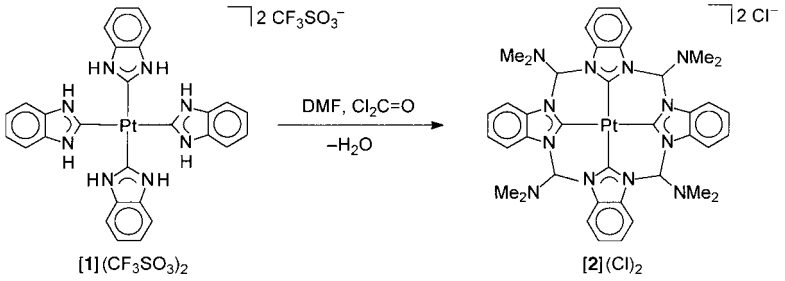
Indole Synthesis

Contents



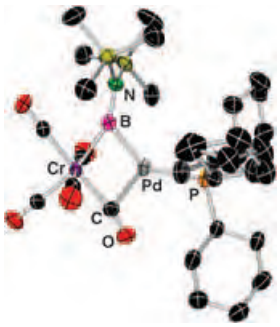
Different faces of phosphorus chemistry: The reaction of the bicyclotetraphosphine complex **1** with *t*BuC≡P leads to the first 1,2,3,4-tetraphosphaferrocene complex **2** and an allylic P_3-bridged complex **3**. $Cp''' = \eta^5\text{-}C_5H_2tBu_3$.

Polyphosphorus Ligands



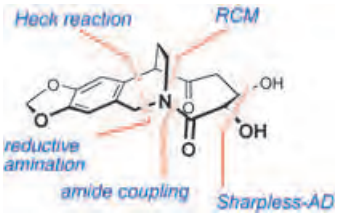
A template-controlled reaction cascade starting from $[Pt(PMe_3)_4](CF_3SO_3)_2$ and 2-azidophenyl isocyanide yields the tetracarbene complex $[\mathbf{1}](CF_3SO_3)_2$. The four NH,NH-stabilized carbene ligands in $[\mathbf{1}]^{2+}$ can be bridged at the metal template by reaction with *N*,*N*-dimethylformamide (DMF) and diphosgene to give the coordinated cyclic tetracarbene ligand with crown ether topology in complex $[\mathbf{2}](Cl)_2$.

Carbene Complexes



The heat is on: In the first instance of thermal reactivity of the terminal borylenes $[(OC)_5M{=}B{=}N(SiMe_3)_2]$ (M = Cr, W), the new heterodinuclear complexes $[(OC)_4M(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (see structure; M = Cr) are synthesized. The compounds feature a semibridging borylene ligand and, by virtue of the dative Pd—B bonding interaction, represent the only examples of terminal borylene species stabilized by a transition-metal base.

Borylene Complexes



The unusual [5.3.2]bicyclic structure of the insecticidal *Amaryllidaceae* alkaloids cripowellins A and B has been synthesized for the first time by a sequence of Sharpless dihydroxylation, ring-closing metathesis (RCM), and intramolecular Heck reaction (see scheme). The asymmetric synthesis of the 1-*epi* aglycon proceeds with virtually complete diastereo- and enantioselectivity (≥ 98 % *de*, ≥ 98 % *ee*) in 13 steps and an overall yield of 5.6 %.

Supramolecular Chemistry

Very Large Container Molecules

*Kari Rissanen**

Keywords:
calixarenes · cavitands · host–guest chemistry · resorcinarenes

Vase- or bowl-shaped molecules, which are synthetically challenging targets as well as objects with aesthetic structural symmetry, attract the attention of both synthetic and structural chemists alike. Many vase- or bowl-shaped molecules have been reported, but it was not until the discovery and utilization of calixarenes and resorcinarenes that these molecular objects were recognized as intriguing synthetic targets or structurally elegant compounds. With the birth of calixarene (derived from the Latin word *calix* for vase) and resorcinarene chemistry these vase-shaped molecules were brought to the front row in modern chemistry. Seminal work by Gutsche[1] on calixarenes and by Cram[2] on cyclophanes and resorcinares (Figure 1) gave new insight into functional vase- and bowl-shaped molecules which, in turn, was one of the seeds to the birth of supramolecular chemistry and chemistry "beyond the molecule".[3]

Calixarenes, with their four phenolic OH groups, are the more flexible of the two families of compounds, yet they remain easy to functionalize on either the upper or lower rim, or on both.[1] The octaphenolic resorcinares allow intramolecular rigidification by attachment of a bridge, typically through bis-*O*-alkylation, between adjacent aromatic rings to give rigid bowl-shaped cavitands.[2] When properly functionalized, the rigid cavitand is a unique structural building block on the way to larger dimeric capsulelike molecules, namely carcerends.[2] The synthesis of carcerands requires a suitable guest molecule that remains incarcerated inside the dimeric covalent molecule. By suitable modulation of the synthesis sequence, one or two of the cavitand-connecting bridges can be omitted to lead to hemicarcerands from which the incarcerated guest can be released. The resorcinarene-based cavitands, carcerands, and hemicarcerands have a very limited bowl size which is dictated by the size and conformation of the inner 16-membered cyclophane ring.

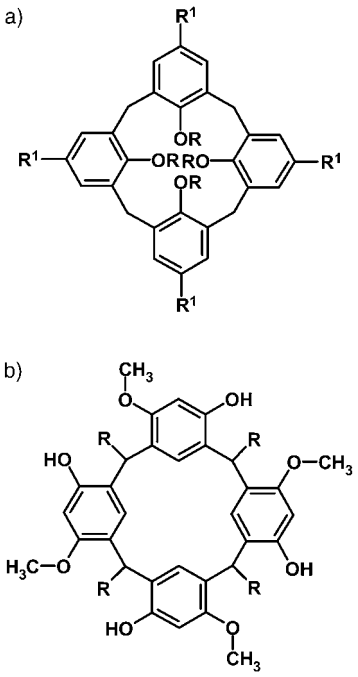

Figure 1. The structures of a) calixarene and b) resorcinarene.

In the latter half of the 1990s, two different approaches to increase the volume of the bowl or container were developed. As the extension of the carcerend "wall" was not synthetically rewarding, Harrison[4] and Dalcanale[5] and their respective co-workers used self-organization and metal coordination to bridge two cavitand halves into dimeric capsular structures to form so-called coordination cages. This approach resulted in much larger container molecules constructed from two cavitand halves. The second approach, which was synthetically more simplistic, was reported by MacGillivray and Atwood in 1997 with the crystal structure of a very large self-assembling hydrogen-bonded hexameric assembly (Figure 2a) that consisted of six core resorcinarene units and eight water molecules.[6] The pyrogallarene analogue of the hexameric assembly, prepared from pyrogallol (1,2,3-trihydroxybenzene) instead of resorcinol (1,3-dihydroxybenzene), was later reported by Mattay and co-workers.[7]

These extraordinary noncovalent spherical assemblies have volumes of about 1400 Å^3, which is truly a very large intracavity volume. Their noncovalent synthesis, which utilizes self-assembly, offers unsurpassed ease of preparation. However, what is gained in the synthesis is lost in the stability of the assembly. As the assembly is typically constructed from multiple weak hydrogen-bonding interactions, its stability is often very weak in competing hydrogen-bonding solvents (e.g. water, dimethylsulfoxide, *N*,*N*-dimethylformamide) while its solubility in organic solvents is often limited. These features prevent the use of these assemblies in further applications, however, their relative insolubility in organic media often enhances recrystallization of the assemblies and makes possible the determination of their crystal structures. The formation, guest-exchange properties, and stabilities of these large self-assembling hydro-

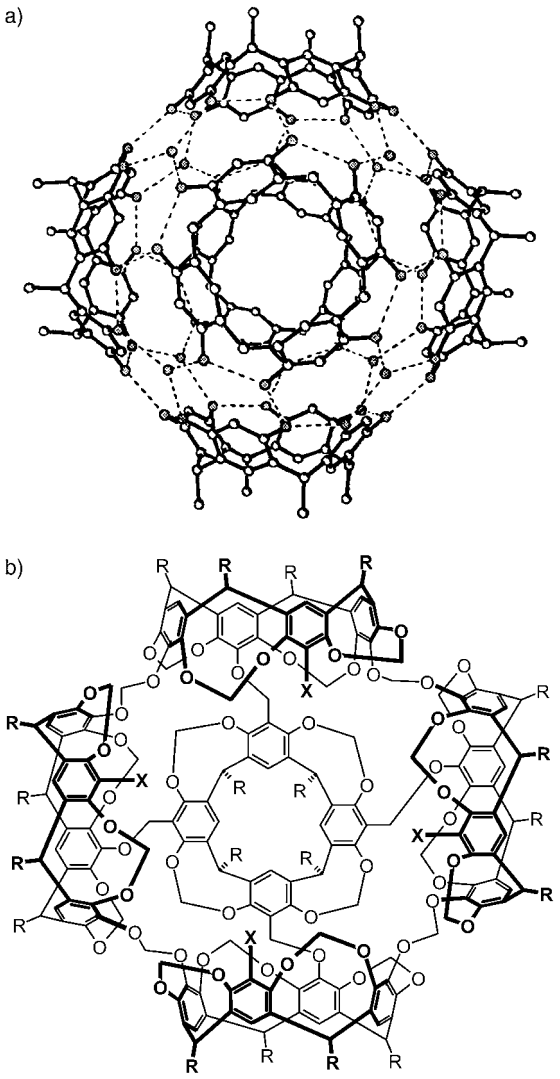

Figure 2. a) The hexameric hydrogen-bonded resorcinarene assembly by MacGillivray and Atwood[6] (oxygen atoms are shaded), and b) the covalent resorcinarene pentamer by Sherburn and co-workers[12] (R = pentyl, X = H, Br).

gen-bonded dimeric, tetrameric, and hexameric assemblies have been studied and reported extensively by the groups of Rebek,[8] Atwood,[9] Cohen,[10] and Kaifer.[11]

Covalent cousins of the very large hydrogen-bonded capsular assemblies described above were recently reported by Sherburn and co-workers,[12] and, indeed, their studies on "superbowls" have opened a new chapter on very large container molecules. They used a multistep regioselective protection/deprotection strategy to combine five resorcinare molecules into one very large covalent container molecule: a superbowl. One unique resorcinare acts as the platform on which four other equivalent resorcinares are covalently attached as "walls" (Figure 2).

Their work started with a retrosynthetic analysis of the target pentaresorcinarene molecule. A multitude of covalent connections between the five components were required, and careful inspection of the various target molecule models led Sherburn and co-workers to employ classical carcerand linkers, $-OCH_2O-$, between the walls and $-CH_2O-$ linkers between the platform and the walls. This combination allowed the necessary flexibility to form the interbowl bonds, while preventing holes in the superbowl structure that were large enough for the entry and exit of all but the smallest of guest molecules.

The multistep synthetic route[12] to the pentaresorcinarene started from an *n*-pentyl-footed tetrabromocavitand, which upon chemo- and regioselective double lithium–bromine exchange with *n*BuLi gave the A,C-dibromodiol. Protection of the dibromodiol as the bis-methoxymethyl (MOM) ether $(MOM)_2$-A,C-$(Br)_2$, followed by selective single lithium–bromine exchange, boronate ester formation, and oxidative hydrolysis gave the required unsymmetrically functionalized diprotected bromoalcohol cavitand $(MOM)_2$-(Br)-(OH), which yielded the corresponding bis-methoxymethyl phenol $(MOM)_2$-(H)-(OH) upon reductive debromination. Combination of four molar equivalents of the $(MOM)_2$-(Br)-(OH) cavitand (or its debrominated analogue $(MOM)_2$-(H)-(OH)) with a tetrabromomethyl cavitand, which acts as the platform of the pentaresorcinarene, resulted in the multiply MOM-protected tetrabromopentamer (or its debrominated analogue, respectively). Subsequent hydrolysis of the eight MOM ether groups of the pentamers led to the respective octaol. The final "wall-closure" step was performed by using a standard resorcinarene-to-cavitand method.[12]

The X-ray crystal structure of Sherburn's covalent tetrabrominated pentamer[12] is strikingly similar to that of MacGillivray and Atwood's hydrogen-bonded hexamer[6] (Figure 3). However, this is not surprising as both structures comprise resorcinarenes with similar spatial orientations.

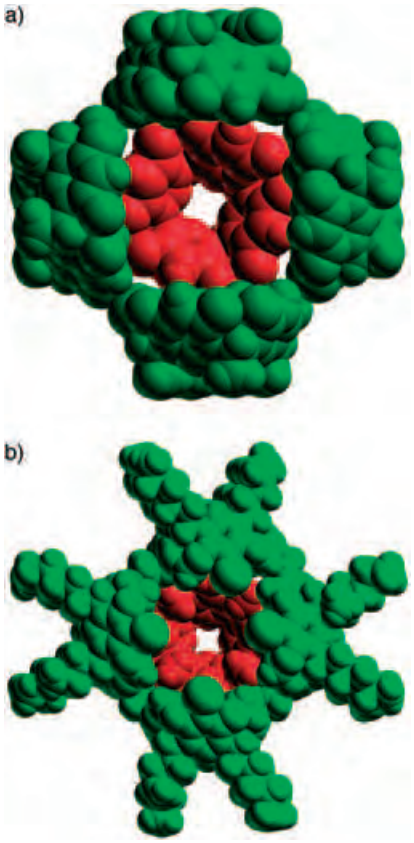

Figure 3. X-ray crystal structures of a) the hydrogen-bonded hexameric assembly[6] with one of the resorcinarene units removed, and b) the covalent tetrabrominated pentamer.[12] (Solvent molecules are omitted from both structures; green wall, red platform).

The hexamer described by MacGillivray and Atwood has a slightly larger intracavity volume (ca. 1375 Å^3) relative to that of the covalent pentamer (ca. 1050 Å^3). If we take into account the different constitutions of the structures, that is, a hexamer versus a pentamer, the intracavity volumes are essentially the same (1375 Å^3/6 = 229 Å^3 per monomer; 1050 Å^3/5 = 210 Å^3 per mono-

mer). The X-ray crystal structure of the pentamer with the bromine substituents shows a slightly unsymmetrical cavity aperture of approximately 10 Å, whereas in the hydrogenated analogue the aperture is slightly bigger. The hydrogenated analogue binds tetra-*n*-hexylammonium ions with a complexation constant of approximately $460\,\text{M}^{-1}$ for the 1:1 host–guest association, but under similar conditions the brominated pentamer did not show any binding of tetraalkylammonium ions. Thus the size of the cavity aperture, as well as the presence of large bromine substituents on the rim, appear to be crucial for the association process.

Despite its weak complexation ability, the covalent resorcinare pentamer provides an entry to very large container molecules. The covalent approach developed by Sherburn and co-workers offers molecules that display considerably greater stability, structural variation, functional group tolerance, and solubility in organic solvents. This example of how to construct very large covalent container molecules can and will lead to more robust nanosized objects for intracavity reactions (however, product inhibition has to be solved first), catalysis, and transport. In particular, encapsulation of drugs and their delivery is a stimulating possibility: On the basis of this seminal work by Sherburn and co-workers[12] it is easy to visualize very large covalent but hydrolyzable container molecules that can be decomposed under specific conditions to release the drug into a specific target organ or cell. Also a nonhydrolyzable covalent pentamer with a removable cap (attached to the pentamer through a combination of hydrogen bonds and one covalent bond, or with hydrolyzable bonds) offers intriguing possibilities for the controlled release of the guest. These features are not offered by solely hydrogen-bonded systems.

Hypervalent Iodine Chemistry in Synthesis: Scope and New Directions

*Thomas Wirth**

Keywords:
hypervalent compounds · iodine · oxidations · rearrangements · total synthesis

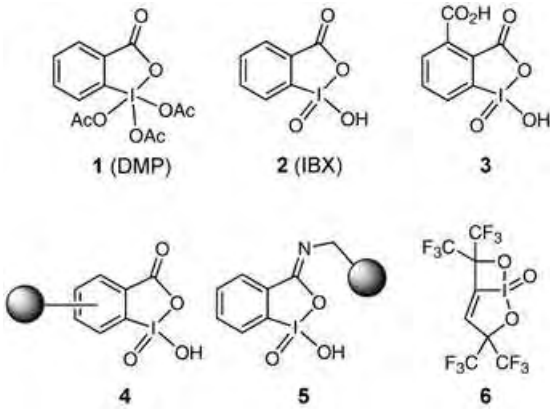
The impressive development of hypervalent iodine chemistry in recent years is reflected by the number of publications in this area. Although the synthesis of the first hypervalent iodine compound dates back more than 100 years, the investigation of the reactivities of these compounds and their efficient use as metal-free reagents in organic synthesis is still ongoing. This contribution summarizes recent achievements and highlights key findings and developments that will influence future research and lead to novel applications of hypervalent iodine reagents in synthesis.

1. Introduction

Organic molecules bearing hypervalent iodine moieties have been transformed from laboratory curiosities to useful and routinely employed reagents in organic synthesis. Several reagents in which the oxidation state of the iodine atom is not −1 are now routinely accessible and, not surprisingly, several aspects of their chemistry have been reviewed recently.[1] It is therefore not the purpose of this article to summarize all efforts in this area comprehensively; instead, a rather select number of important developments during the last couple of years are emphasized, and their significance for synthetic chemistry is highlighted.

2. Oxidations

The facile oxidation of alcohols to the corresponding carbonyl compounds is one of the prominent features of hypervalent iodine compounds appreciated by many synthetic chemists.[2] Iodine(v) compounds such as the Dess–Martin periodinane (DMP; **1**) and *ortho*-iodoxybenzoic acid (IBX; **2**) are known to be explosive reagents, but the simple one-step oxidation of 2-iodobenzoic acid to IBX with oxone[3] has made it a quite popular reagent,[4] despite its low solubility in most organic solvents. Reactions must usually be carried out in DMSO at slightly elevated temperatures. IBX (**2**) can be used in DMSO at room temperature to synthesize α-aminoaldehydes from the corresponding amino-alcohols without racemization,[5] but a survey of other solvents and reaction conditions looks promising.[6] The perceived disadvantage of **2** being an almost insoluble reagent in ethyl acetate or dichloromethane is turned into an advantage as the reagent and by-products can be completely removed simply by filtration.



The use of IBX (**2**) in ethyl acetate led to a high-yielding procedure for the oxidation of 1,2-dihydronaphthols to the corresponding naphthols.[7] But other protocols and reagents have also been developed to overcome some initial preparative limitations. More-soluble derivatives such as **3**[8] and completely insoluble polymer-bound IBX reagents **4**[9] have been prepared. Whereas first attempts focused on the syn-

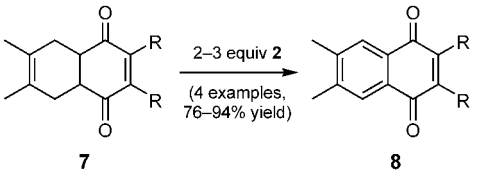
thesis of reagents **4** with a polymer linkage to the aromatic core of the IBX reagent, recent developments exploit the oxidative properties of the IBX amides **5** introduced by Zhdankin and co-workers.[10,11] The synthesis of polymer-bound IBX amides **5** is much shorter and can lead to reagents with similar efficiency.[12]

The replacement of DMSO as the common solvent for oxidations with IBX (**2**) with ionic liquids such as $[bmim]^+X^-$ (bmim = 1-butyl-3-methylimidazolium; $X^- = Cl^-$, Br^-, PF_6^-)[13] have dramatically improved the applicability of this reagent. Although the soluble derivative **3** and polymer-bound reagents **4** and **5** seem to be limited to the oxidation of alcohols to their carbonyl counterparts, the replacement of DMSO with an ionic liquid was found to allow the introduction of an α,β-unsaturation in carbonyl compounds, as initially reported by Nicolaou.[14] Although the synthesis of the tetracoordinate 1,2-iodoxetane-1-oxide **6** is quite elaborate, the compound has been successfully used as an oxidant for alcohols.[15] This recent example elegantly demonstrates that even hypervalent iodine compounds with aliphatic substituents can be prepared and that further developments along these lines can be expected. The dehydrogenation of carbonyl compounds can also be efficiently used for the synthesis of quinones, and even the IBX-mediated aromatization of polycyclic compounds **7** to form **8** proceeds in good yields (Scheme 1).[16]



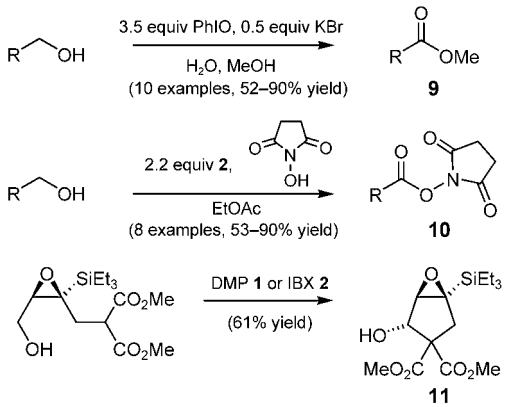
Scheme 1. Aromatization of polycyclic compounds.

The area of carbon–heteroatom bond oxidation is still dominated by the iodine(v) reagents mentioned above, but iodine(III) reagents continue to increase in importance as non-explosive and readily available reagents for such oxidations. Several of these reagents can now be synthesized under solvent-free conditions, and even some subsequent transformations have been performed as solid-state reactions with high efficiency.[17] It is difficult to oxidize aliphatic alcohols with reagents such as (diacetoxyiodo)benzene, but catalytic amounts of TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxyl)[18] facilitate such reactions. Depending on the reaction conditions, primary alcohols can be oxidized to the corresponding aldehydes[18] or to carboxylic acids[19] without affecting neighboring stereogenic centers. The racemization-free preparation of epoxyaldehydes or amino acid derivatives was achieved, and this method has already found its way into several natural product syntheses.[20]

Oxidations in the presence of metal complexes are possible:[21] Chiral Mn(salen) complexes with (diacetoxyiodo)benzene as cooxidant have been used for efficient racemic resolutions of secondary alcohols.[22] Several of these reactions use water as the partial or sole solvent, and hence the hydrolysis of (diacetoxyiodo)benzene to iodosylbenzene, which is known to occur under alkaline conditions, cannot be excluded. Kita and co-workers developed conditions to oxidize alcohols in water[23] with iodosylbenzene together with KBr, and exclusive oxidation of alcohols to carboxylic acids was observed.[24] The mild reaction conditions and the broad functional-group tolerance of hypervalent iodine reagents have led to the development of sequential transformations involving an oxidation step. There is no need to isolate and purify potentially unstable intermediates; this is especially useful when stereogenic centers are present in the α position to the newly generated carbonyl group.

Oxidations with iodosylbenzene and KBr in aqueous methanol instead of water leads to the formation of the corresponding methyl esters **9**.[25] In a similar process, IBX-mediated oxidations of alcohols (or aldehydes) were carried out in the presence of *N*-hydroxysuccinimide and the corresponding *N*-hydroxysuccinimide esters **10** were obtained in good yields.[26] The oxidation of propargylic alcohols with IBX (**2**) to the corresponding unstable aldehydes can be performed in the presence of acetamidine, and pyrimidines are obtained directly in a one-pot process.[27] Intramolecular reactions are also possible, for example, oxidative cyclizations to highly functionalized cyclopentanols **11** (Scheme 2).[28]

Hypervalent iodine reagents have also proven to be mild oxidants for phenolic substrates. Spirocyclizations of various compounds have been studied extensively.[29] Domino oxidation/Diels–Alder reactions are also versatile sequences,[30] as

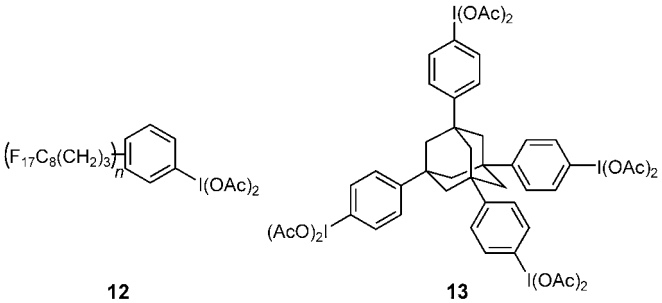


Scheme 2. Oxidations with hypervalent iodine compounds followed by subsequent transformations in the one-pot synthesis of esters or carbocycles.

Thomas Wirth received his Diplom from the University of Bonn in 1989 and his PhD from the Technical University of Berlin (S. Blechert, 1992). After a postdoctoral stay with K. Fuji at Kyoto University as a JSPS fellow 1992/93, he started his independent research on stereoselective oxidation reactions (University of Basel, B. Giese) and obtained his habilitation in 1999. He was a visiting professor at the University of Toronto (1999), Chuo University in Tokyo (2000), and Osaka University (2004). He was awarded the Werner Prize from the New Swiss Chemical Society in 2000.

shown in studies towards the synthesis of tashironin[31] or in oxidations followed by radical cyclization reactions to generate bicyclic compounds.[32]

In all these oxidations stoichiometric amounts of an iodoarene are generated as a by-product. To facilitate the purification of the product and to achieve an easy separation from the iodoarene, polystyrene-bound versions[33] of (diacetoxy)iodobenzene have been prepared and used with similar efficiency in the reactions mentioned above.[24,25,34] The synthesis of fluorous hypervalent iodine compounds such as **12** also allows easy recovery and recycling of the reduced



12 **13**

reagent through extraction into a fluorous organic phase.[35] Similar ease of separation was reported in reactions with the adamantane derivative **13**, in which case the reduced compound can be easily recovered and reoxidized.[36]

Analogously to the oxidation of a carbon–oxygen single bond, secondary amines can be oxidized with IBX (**2**). A series of amines **14** were oxidized to the corresponding imines **15** efficiently.[37] Other hypervalent iodine reagents such as the alkylperoxy-λ^3-iodane **16** are also suitable for this transformation.[38] Mechanistic investigations indicate that both **2** and **16** serve as single-electron-transfer reagents in this reaction. Under certain reaction conditions, compounds containing a carbon–nitrogen double bond (e.g. aldoximes **17**) have been oxidized to the corresponding nitrile oxides **18**, which are trapped in a 1,3-dipolar cycloaddition to form isoxazolines **19** (Scheme 3).[39]

The synthesis of diazo compounds by oxidation of hydrazone derivatives **20** was reported recently.[37,40] Silyl-protected hydrazones **20** are oxidized with (difluoroiodo)-benzene in situ to the corresponding diazo compounds **21**, which then react with carboxylic acids to form the corresponding esters **22**.[40] The main advantage of this elaborate esterification is the wide applicability to a range of labile substrates. The oxidation of the nitrogen–nitrogen bonds in 2-pyridylhydrazones led to the formation of the corresponding triazolopyridines, compounds with remarkably high antibacterial activities.[41] The oxidation of hydrazones to diazo compounds of type **21** in the presence of thioketones results in the high-yielding formation of thioepoxides, which are precursors for sterically hindered tetrasubstituted alkenes.[42]

3. Formation of Carbon–Carbon Bonds

Reactions leading to the formation of carbon–carbon bonds are important applications of hypervalent iodine reagents. These reactions proceed either through reactive intermediates such as radicals or carbocations, or they are ligand-coupling reactions mediated by trivalent iodine derivatives. The oxidative coupling of appropriately substituted phenol derivatives has been developed into a powerful tool for the synthesis of polycyclic compounds. Kita and coworkers recently showed that this reaction can be used successfully as a key step in the synthesis of complex natural products. They found that intermediate **23** could only be cyclized with R = CH_2OTBS (but not with R = CO_2Me) in the presence of [bis(trifluoroacetoxy)iodo]benzene and MK10 as a solid acid additive. After optimization of the diastereoselectivity of the spirocyclization to **24** by a variation of the protecting groups, this reaction was key to the first diastereoselective synthesis of discorhabdin A (Scheme 4).[43]

A combination of [bis(trifluoroacetoxy)iodo]benzene and heteropoly acids (e.g. $H_3[PW_{12}O_{40}]$) were recently used as efficient reagent combinations for intramolecular oxidative coupling reactions in the synthesis of spirodienone alkaloids such as morphinandienone and neospirinedienone.[44] The

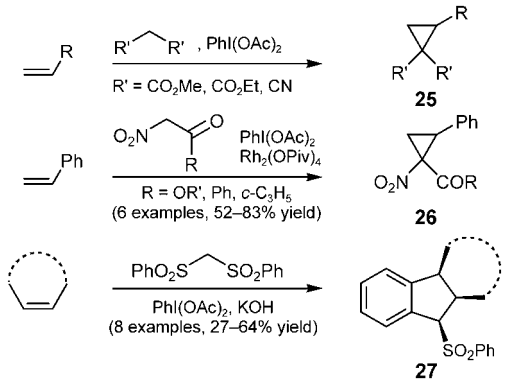
Scheme 4. Hypervalent iodine mediated spirocyclization in the total synthesis of discorhabdin A.

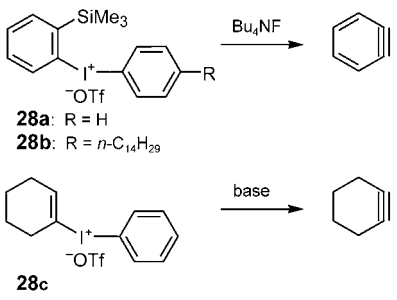
established combination of [bis(trifluoroacetoxy)iodo]benzene and boron trifluoro etherate proved to be efficient in the synthesis of aporphine alkaloids such as glaucine.[45] These reactions are believed to be initiated by a SET (single-electron transfer) to the electron-rich aromatic moiety. This concept has now been extended to couple 3-alkylthiophenes to give the corresponding 2,2′-bithiophene derivatives in moderate yields.[46] Whereas the oxidative coupling reactions initiated by a SET lead to radical cations as intermediates, mechanistic investigations revealed that radicals are not involved in aryl transfer in ligand-coupling reactions of trivalent iodine derivatives.[47]

Although the generation of iodonium ylides as carbene precursors in cyclopropanation reactions is known, more-efficient routes for the cyclopropanation of alkenes involve carbene precursors with two acceptor substituents. Malonic acid derivatives can be employed to synthesize cyclopropanes **25**,[48] and α-nitro carbonyl compounds have been successfully added under rhodium catalysis to generate compounds **26** as versatile precursors for cyclopropane amino acids.[49] Iodonium ylides derived from bis(phenylsulfonyl)methane can also be used for insertion reactions into the C–H bonds of alkenes. This reaction has been used to functionalize pyrroles[50] and flavones.[51] Reactions of unfunctionalized alkenes can lead to subsequent extrusion of sulfur dioxide and to the formation of functionalized indanes such as **27** (Scheme 5).[52]

The generation of benzynes by using silylated hypervalent iodine compounds such as **28a** is known and was recently



Scheme 5. Synthesis of cyclopropane and indane derivatives with hypervalent iodine reagents. Ts = *p*-toluenesulfonyl.

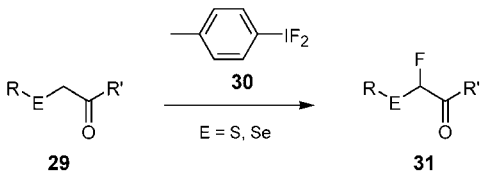


Scheme 6. Generation of benzyne and cyclohexyne from suitable hypervalent iodine precursors. Piv = pivaloyl.

optimized by the introduction of more-soluble compounds **28b** (Scheme 6), which led to a better performance in subsequent Diels–Alder reactions.[53] Similar precursors such as **28c** were recently used for the generation of cyclohexyne intermediates, and the elimination/addition mechanism was established by kinetic deuterium isotope studies.[54]

4. Formation of Carbon–Heteroatom Bonds and Heteroatom–Heteroatom Bonds

The use of hypervalent iodine reagents for the formation of carbon–heteroatom and heteroatom–heteroatom bonds is well established, and a wide range of substrates have been used in these transformations. The functionalization of carbonyl compounds at the α position is still under intensive investigation. Different types of halogenations have been reported with (difluoroiodo)arene and (dichloroiodo)arene derivatives as very powerful reagents. Advances in the preparation of organofluorine compounds by using hypervalent iodine reagents were extensively reviewed recently.[55] The selective introduction of fluorine atoms is possible under mild and neutral conditions in the presence of *p*-(difluoroiodo)toluene (**30**) as a stable and safe reagent. Various improved methods for the synthesis of **30** were reported recently,[56,57] but new hypervalent difluoroiodo derivatives have also been synthesized.[58] The fluorination of sulfur-substituted esters or amides **29** (E = S) has been investigated intensively, and the reaction proceeds through a sulfur-Pummerer-reaction to yield **31**.[59] Depending on the reaction conditions, difluorination or oxidation to the sulfoxides occurs, whereas the corresponding selenium substrates **29** (E = Se) only yield monofluorinated products **31** (Scheme 7).[57]

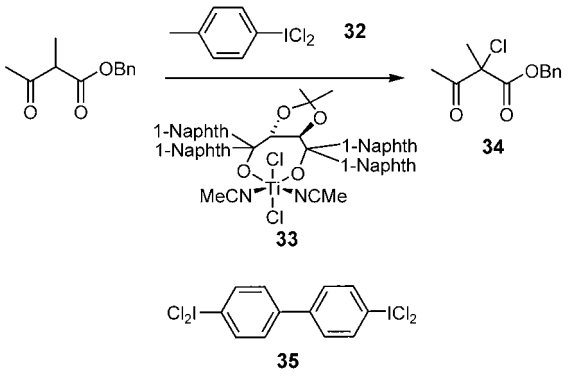


Scheme 7. Fluorination of sulfur- or selenium-substituted esters or amides.

p-(Difluoroiodo)toluene (**30**) can also be used to fluorinate β-dicarbonyl compounds. Hara et al. showed that the addition of a hazardous HF–amine complex, as described earlier,[60] is not necessary.[61] The combination of pyridinium polyhydrogen fluoride (Olah reagent) with either (diacetoxyiodo)benzene or [bis(trifluoroacetoxy)iodo]benzene is, however, necessary for an efficient *ipso*-fluorination of *para*-substituted phenols.[62] A similar reagent combination is necessary for the fluorinative ring expansion of cyclic iodo ethers (**69**→**70**; see Scheme 19 in Section 5).[63]

Catalytic asymmetric halogenation reactions are still rare. *p*-(Dichloroiodo)toluene (**32**) was recently used in combination with a titanium–taddol catalyst **33** for stereoselective chlorinations of 1,3-diketone derivatives and led to products

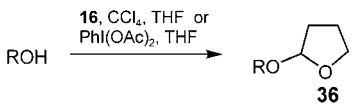
such as **34** with up to 70% *ee* Scheme 8.[64] This enantioselectivity is slightly lower than that attained when using *N*-chlorosuccinimide as the chlorinating agent in similar reactions.[65] The recently reported biphenyl derivative **35** might



Scheme 8. Catalytic approach to stereoselective chlorination with hypervalent dichloroiodo derivatives. Naphth = naphthyl.

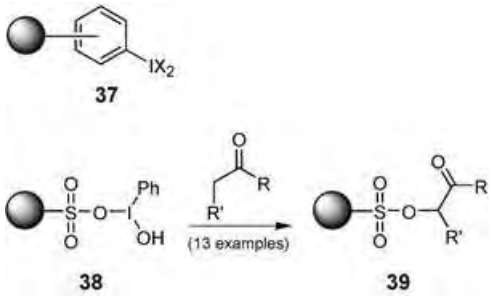
be advantageous in such reactions.[66] Although the stereoselectivities are only moderate, the transfer of ligands X from the great number of known compounds of the type $ArIX_2$ to enolizable substrates by using a stereoselective catalytic protocol is very promising. The main challenge in the development of such transformations will be the efficient suppression of the uncatalyzed background reaction between the hypervalent iodine reagent and the substrate. A two-step approach for the halogenation of enolizable substrates has been reported as well. Microwave-induced α tosylation with [hydroxy(tosyloxy)iodo]benzene followed by treatment with magnesium halides led to an efficient synthesis of the corresponding α-halocarbonyl compounds.[67]

The direct reaction of hypervalent iodine reagents with enolizable substrates has been the focus of a series of other publications. The introduction of oxygen functionalities α to carbonyl groups is well established and is being used advantageously in natural product synthesis.[68] The activation of the 2-position of tetrahydrofurans with hypervalent iodine compounds has been investigated, and processes for the protection of alcohols as tetrahydrofuranyl ethers **36** have been developed by using peroxyiodane **16** in combination with carbon tetrachloride in a radical process[69] or with (diacetoxyiodo)benzene through an ionic mechanism Scheme 9.[70] A similar reaction has also been observed with alkenyl or alkynyl iodanes to oxidize tetrahydrofuran.[71] Also tetrahydrothiophene derivatives can be employed in a similar process for the synthesis of thionucleosides.[72]



Scheme 9. Protection of alcohols as THF acetals with hypervalent iodine compounds.

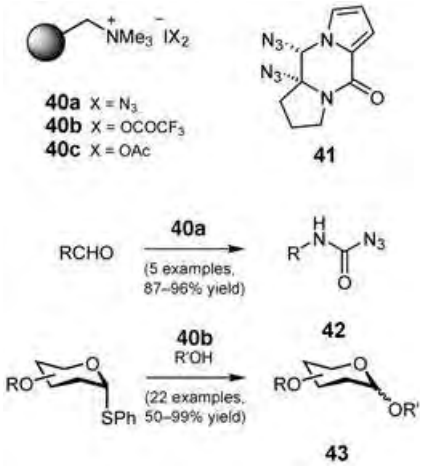
The synthesis of polymer-bound hypervalent iodine reagents[33c] such as **37** is already well established, and many reports indicate an efficiency almost similar to that of their soluble counterparts. The reactions of the novel polymer-bound compounds **38** with enolizable substrates yield polymer-bound products **39** (Scheme 10), which can be used in



Scheme 10. Novel polymer-supported hypervalent iodine reagents in synthesis.

various subsequent reactions, from simple substitutions to the elaborate syntheses of heterocyclic compounds.[73] For example, reactions of **39** with thioamides led to the formation of thiazoles in good yields.[74]

Polymer-bound reagents **40** were developed by Kirschning and co-workers (Scheme 11).[78,79] The diazide **40a** is a safe

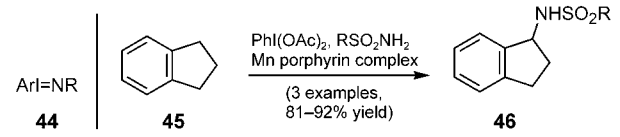


Scheme 11. Azidations and related reactions with polymer-supported hypervalent iodine reagents **40a–c**.

reagent for reactions with azide anions or azidyl radicals. The *syn* diazidation of a double bond with **40a** was used as a key step in the preparation of **41** in the synthesis of (±)-dibromophakellstatin.[75] The reaction of **40a** with aldehydes allowed the synthesis of carbamoyl azides **42** via the corresponding acyl azides in good yields.[76] The polymer-supported azide **40a** have also been used for the azidonation of benzyl ethers and are a safe alternative to IN_3. Furthermore, the diazide based on **37** ($X = N_3$) was used successfully in the synthesis of organotellurophosphanes.[77] Reagent **40b** was used for the activation of thioglycosides in the synthesis

of 2-desoxyglycoconjugates **43**,[78] and **40c** can be employed in iodoacylation reactions.[79]

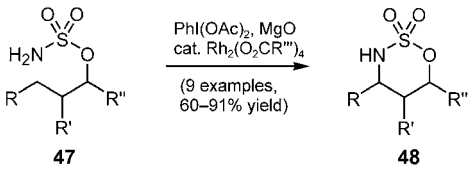
The introduction of nitrogen functions into organic molecules with hypervalent iodine compounds is carried out with iminoiodanes **44** rather than with azide-based reagents. Many processes such as metal-catalyzed aziridinations of alkenes rely on the capability of these reagents to serve as useful nitrene precursors.[80] Unfortunately, these reagents **44** are sometimes difficult to prepare owing to their thermal sensitivity, and some have even been claimed to be explosive.[81] Recently, one-pot procedures were developed starting from easily accessible hypervalent iodine compounds and appropriate nitrogen sources. A mixture of (diacetoxyiodo)-benzene and sulfonamides were used in manganese or ruthenium porphyrin catalyzed aziridations of alkenes or amidations of the benzylic position of hydrocarbons such as indane (**45**) as shown in the reaction to give **46** Scheme 12.[82]



Scheme 12. Activation of C–H bonds in hypervalent iodine mediated aminations.

Similar combinations of iodosylbenzene (PhI=O) and sulfonamides or sulfonimidamides can be used for the generation of iminoiodanes in situ and have been applied to copper-catalyzed aziridinations of alkenes.[48b,83] Other nucleophiles such as sulfur trioxide can be used together with iodosylbenzene for the direct formation of cyclic sulfates from alkenes.[84]

Although rhodium catalysts are known to be efficient in C–H insertion reactions, they have rarely been used together with hypervalent iodine compounds. Du Bois and co-workers have developed procedures for aminations through selective C–H bond oxidation. Carbamates[85] and sulfamate esters **47**[86] can be efficiently cyclized to products **48** under rhodium catalysis (Scheme 13). Because (diacetoxyiodo)benzene is

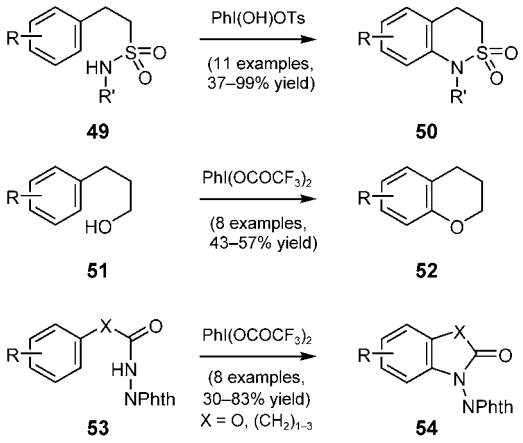


Scheme 13. Activation of C–H bonds in rhodium-catalyzed cyclization reactions.

used as oxidant, a base such as magnesium oxide is necessary to scavenge the generated acetic acid. New catalysts[87] are now allowing intermolecular C–H insertions, and combinations with subsequent transformations[88] have expanded the scope of this transformation.

Similar reaction conditions have been employed in aziridinations of alkenes in inter- and intramolecular reactions. The proposed mechanism involves the formation of an iminoiodane followed by rhodium-catalyzed C–H insertion or aziridination, which can be followed by nucleophilic ring-opening. Recent stereochemical results indicate that the addition of the metallonitrene might also proceed in a stepwise fashion without the formation of an aziridine intermediate, and in some cases the reaction even proceeds without the rhodium catalyst.[89]

Under different reaction conditions, the aziridinations of alkenes with a combination of (diacetoxyiodo)benzene and *N*-aminophthalimide can also proceed without metal catalysts.[90] The direct formation of carbon–heteroatom bonds by replacing C–H bonds of aromatic compounds has been used for the synthesis of various target molecules. The reactions of electron-rich arenes might proceed through a SET mechanism, but others have been shown to involve an ionic pathway. Various functional groups in combination with various hypervalent iodine reagents have been used to effect aromatic substitution. Depending on the reaction conditions and on the substitution pattern of the aromatic moiety, spiro compounds can be obtained by *ipso* cyclization, especially with 4-methoxy or 4-halo substitutents on the aromatic moiety.[91] This principle has also been applied to the synthesis of a muscarinic M_1 receptor antagonist.[92] Products of such initial spirocyclizations are likely to be intermediates in the reaction to products **50**, **52**, and **54** (Scheme 14). Sulfonamides **49**

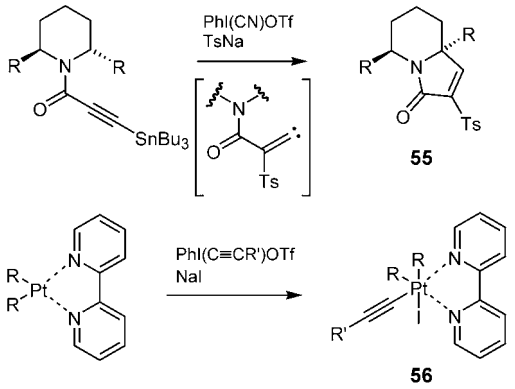


Scheme 14. Cyclizations of aromatic compounds in heterocycle synthesis. NPhth = phthalimidoyl.

undergo cyclization to form the corresponding 2,1-benzothiazine compounds **50** and the highest yields are attained with [hydroxy(tosyloxy)iodo]benzene as reagent.[93] However, polymer-supported reagents have been investigated as well.[94] Alcohols **51** are direct precursors for the chroman derivatives **52**,[95] whereas the acylimino phthalimides **53** can be cyclized to give a variety of different substituted lactams **54**.[96]

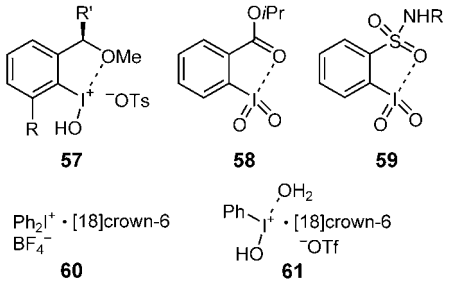
The chemistry of alkynyl(aryl)iodonium compounds is manifold, and their preparation usually involves a ligand-exchange reaction of the corresponding alkynyl stannane. Several new approaches for their synthesis have been developed, including ligand exchange of silylated alkynes[97] or from alkynyl boronates[98] as precursors; polymer-supported reagents[99] have also been synthesized. They are powerful

and versatile carbene precursors in natural product synthesis[100] which was recently demonstrated in the preparation of **55** as a key intermediate in the synthesis of halichlorine Scheme 15.[101] Alkynyl(aryl)iodonium compounds are frequently used for insertion reactions into heteroatom–hydrogen bonds for heterocycle synthesis.[102] These reagents were recently used in the alkynylation of metal complexes. The reaction with diorganoplatinum(II) complexes provides a general route for the synthesis of alkynylplatinum(IV) complexes **56**[103] as well as iridium(III)–σ-alkynyl complexes in high yields (Scheme 15).[104]



Scheme 15. Alkynyl iodo compounds in cyclizations via carbene intermediates (top) and in the synthesis of metal complexes (bottom). Tf = trifluoromethanesulfonyl.

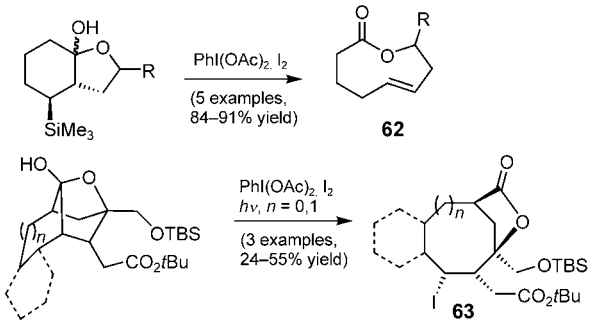
The stabilization of hypervalent iodine moieties by intramolecular coordination has led to the development of chiral reagents such as **57**;[105] recently IBX esters **58** were reported



as reagents for the selective oxidation of sulfides to sulfoxides.[106] Several sulfamide derivatives **59** have also been prepared and evaluated in oxidation reactions.[107] Recent work by Ochiai et al. has shown that intermolecular stabilization of the hypervalent iodine moiety using [18]crown-6 can be used to form complexes **60**[108] or **61**,[109] which show interesting reactivities as they can be used for reactions in aqueous solvents.

5. Fragmentations and Rearrangements

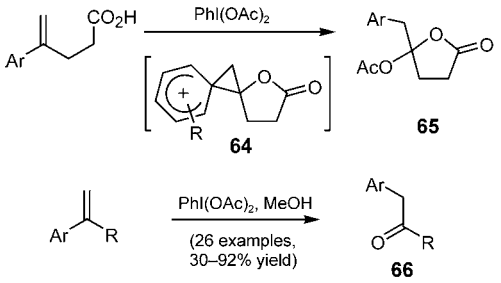
The use of hypervalent iodine reagents in the fragmentation of tertiary cyclopropanol systems is already established and was reviewed recently.[110] The oxidative fragmentation of hemiacetals has been applied to the synthesis of functionalized medium-sized ring systems by using a combination of (diacetoxyiodo)benzene and iodine. This reaction is believed to proceed through a radical pathway by β scission of the corresponding alkoxy radicals. Medium-sized lactones **62**[111] or, with photochemical assistance, cycloheptane or cyclooctane derivatives **63** have been obtained (Scheme 16).[112]



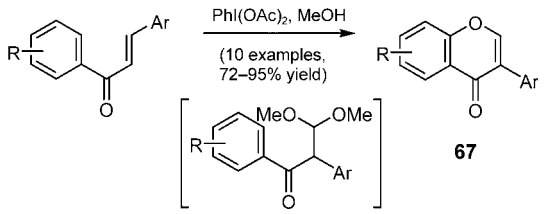
Scheme 16. Oxidative fragmentations in the synthesis of medium-sized ring systems.

The property of hypervalent iodine compounds to react as electrophilic reagents followed by the exploitation of their excellent leaving-group character has been used in various rearrangements for the synthesis of functionalized molecules. Their use in Hofmann-type rearrangements is well established, and the intermediate isocyanate has been used for the synthesis of heterocycles.[113] This reaction has now been extended to peptide chemistry in water, thus allowing the efficient rearrangement of *N*-protected glutamine to diaminobutyric acid derivatives, which have been used successfully for the synthesis of polymyxin B heptapeptide.[114] Treatment of aryl-substituted alkenes with hypervalent iodine compounds can lead to the formation of intermediates that can be stabilized by the aryl substituent via phenonium ions such as **64**; a rearrangement might occur. Internal nucleophiles lead to cyclized products **65**,[115] and external nucleophiles such as methanol/water result in the corresponding ketones **66** (Scheme 17).[116]

Similar intermediates might be involved in the rearrangement of chalcones. This reaction was used recently for the efficient synthesis of isoflavones **67** in a one-pot reaction (Scheme 18).[117]

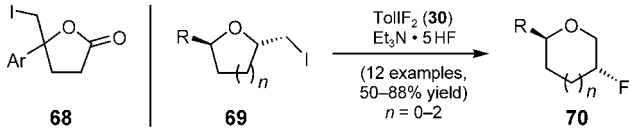


Scheme 17. Rearrangements of aryl alkenes via phenonium ion intermediates.



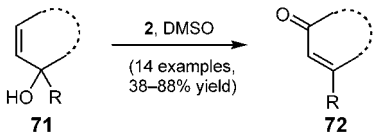
Scheme 18. Rearrangement–cyclization sequence for isoflavone synthesis.

The generation of a hypervalent iodine moiety as a leaving group has been explored with various substrates. Iodolactone **68**[118] can be oxidized to the diacetoxyiodo derivative, which then rearranges via phenonium ion **64** to compound **65**.[115] Iodoethers **69** are readily obtained from the corresponding unsaturated alcohols by an iodocyclization reaction.[119] Treatment of **69** with (difluoroiodo)toluene (**30**) leads to difluorination of the iodine atom and finally to rearranged ring-expanded cyclic ethers **70** in good yield (Scheme 19).[120]



Scheme 19. Oxidative ring expansion with fluorination.

An oxidative rearrangement of allylic tertiary alcohols **71** has only precedence in organochromium chemistry. Iwabuchi and co-workers showed that IBX (**2**) in DMSO can be used for efficient rearrangement to the α,β-unsaturated carbonyl compounds **72** (Scheme 20); this process is compatible with a variety of protecting groups.[121]



Scheme 20. IBX-controlled oxidative rearrangement of allylic alcohols.

6. Summary and Outlook

The great advantages of hypervalent iodine compounds, for example, their low toxicity compared with heavy-metal reagents, mild reaction conditions, fast accessibility of a large variety of reagents, and easy handling have led to their increased use in synthesis. This Mini-review will hopefully stimulate the application of hypervalent iodine reagents in synthesis, and the discovery of new transformations with these compounds will surely be the basis for different and improved synthetic strategies and concepts.

I thank my co-workers for their excellent contributions, Professor H. Sasai for his hospitality during my stay at Osaka University in autumn 2004 where parts of this review were written, and Dr. B. Linclau, Southampton University, for a preprint.

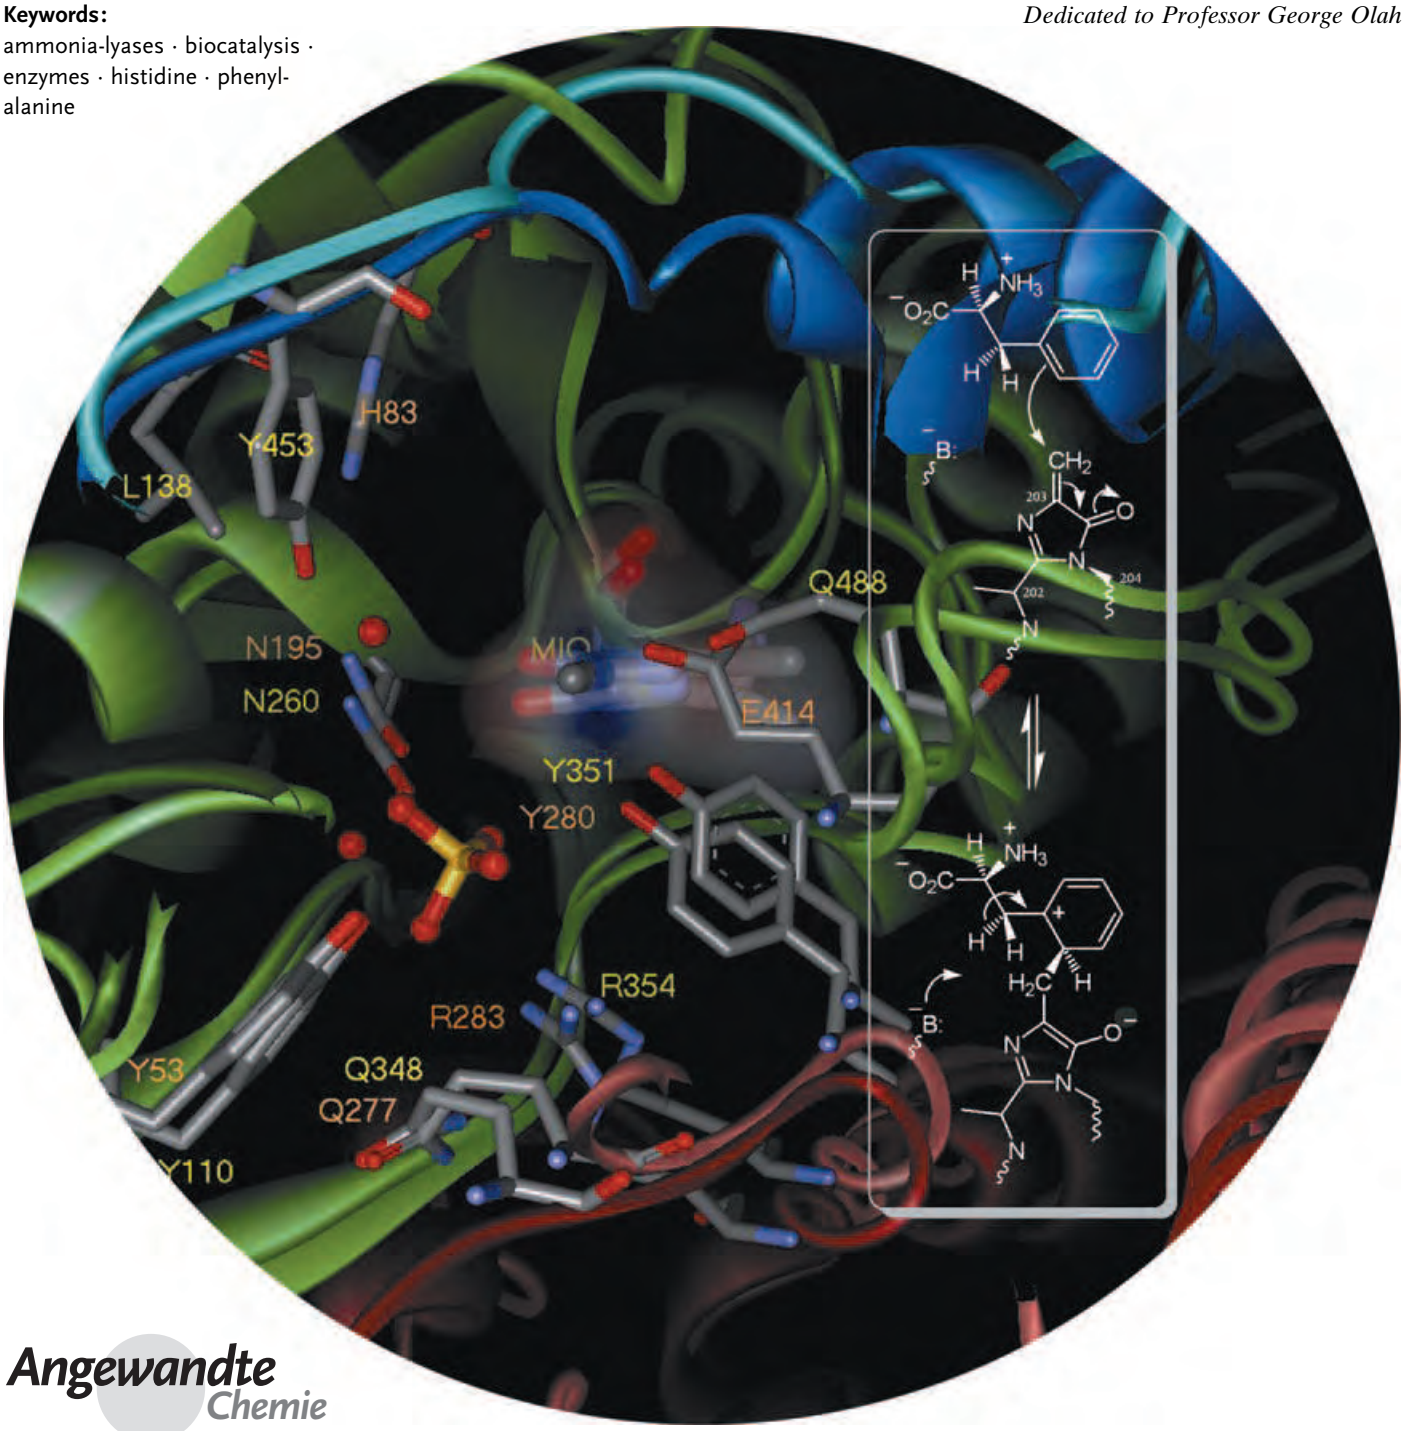
Enzyme Mechanisms

Friedel–Crafts-Type Mechanism for the Enzymatic Elimination of Ammonia from Histidine and Phenylalanine

*László Poppe and János Rétey**

Keywords:
ammonia-lyases · biocatalysis · enzymes · histidine · phenylalanine

Dedicated to Professor George Olah



DOI: 10.1002/anie.200461377

The surprisingly high catalytic activity and selectivity of enzymes stem from their ability to both accelerate the target reaction and suppress competitive reaction pathways that may even be dominant in the absence of enzymes. For example, histidine and phenylalanine ammonia-lyases (HAL and PAL) trigger the abstraction of the nonacidic β protons of these amino acids while leaving the much more acidic ammonium hydrogen atoms untouched. Both ammonia-lyases have a catalytically important electrophilic group, which was believed to be dehydroalanine for 30 years but has now been revealed by X-ray crystallography and UV spectroscopy to be a highly electrophilic 5-methylene-3,5-dihydroimidazol-4-one (MIO) group. Experiments suggest that the reaction is initiated by the electrophilic attack of MIO on the aromatic ring of the substrate. This incomplete Friedel–Crafts-type reaction leads to the activation of a β proton and its stereospecific abstraction, followed by the elimination of ammonia and regeneration of the MIO group. The plausibility of such a mechanism is supported by a synthetic model. The application of the PAL reaction in the biocatalytic synthesis of enantiomerically pure α-amino β-aryl propionates from aryl acrylates is also discussed.

From the Contents

1. Introduction

Almost all biochemical processes are catalyzed by enzymes. Reactions for which nonenzymatic analogues exist can be accelerated by a factor of up to 10^{20} by these biocatalysts. Even more challenging for the biochemist are enzyme-mediated transformations that would never occur in the absence of the enzyme, because either the corresponding substrates are completely stable under most conditions or alternative reactions are much faster. It has been proposed that enzymes not only catalyze certain transformations but also suppress alternative, competing reactions. This activity is especially important in cases in which highly reactive intermediates are involved, but is a general property of enzymes which leads to a high reaction selectivity. For this ability of enzymes to suppress competing reactions the term "negative catalysis" has been coined.[1] Some proteins function exclusively as negative catalysts. For example, hemoglobin and myoglobin bind dioxygen reversibly at their heme iron (Fe^{II}) center and prevent its oxidation to Fe^{III}, which occurs spontaneously in free heme.

To generate highly reactive intermediates, the activation of relatively stable substrates is required; examples are reactions that involve radical intermediates. Radical initiators include adenosylcobalamin[1–3] (coenzyme B_{12}) and S-adenosylmethionine (SAM) in combination with iron–sulfur clusters.[4] Both are protected forms of the 5′-deoxyadenosyl radical, which can be generated by the corresponding enzymes.

Another method of substrate activation involves the action of electrophiles. As the side chains of all proteinogenic amino acids contain only nucleophilic groups, cofactors or post-translationally modified side chains are required for electrophilic catalysis. The role of the electrophilic cofactor pyridoxal phosphate in amino acid metabolism has been known for a long time.[5] More recently, a number of post-translational modifications were discovered that transform nucleophilic groups into electrophilic groups (Table 1).

Serine, whose OH group is an important nucleophile in many enzymatic reactions, can be transformed into a pyruvyl group.[6] The pyruvyl enzymes catalyze similar reactions to those in which pyridoxal phosphate is used. As they only occur in certain bacteria, one can speculate that the pyruvyl group was the evolutionary precursor of pyridoxal phosphate. Another modification involves the internal tripeptide Ala-Ser-Gly and leads to the very strong electrophile 5-methylene-3,5-dihydroimidazol-4-one (MIO). The corresponding enzymes are the topic of this Review. Another recently discovered modification of serine or cysteine side chains leads to formylglycine, which occurs in prokaryotic and eukaryotic aryl sulfatases.[7] Further modifications affect the aromatic

Table 1: Conversion of nucleophilic amino acid side chains into electrophiles by post-translational modifications.

Precursor	Electrophilic prosthetic group	Enzyme
serine	pyruvate	histidine decarboxylase, SAM decarboxylase
serine or cysteine	MIO	histidine ammonia-lyase (HAL), phenylalanine ammonia-lyase (PAL)
serine or cysteine	formylglycine	prokaryotic or eukaryotic aryl sulfatases
tyrosine	dopaquinone	

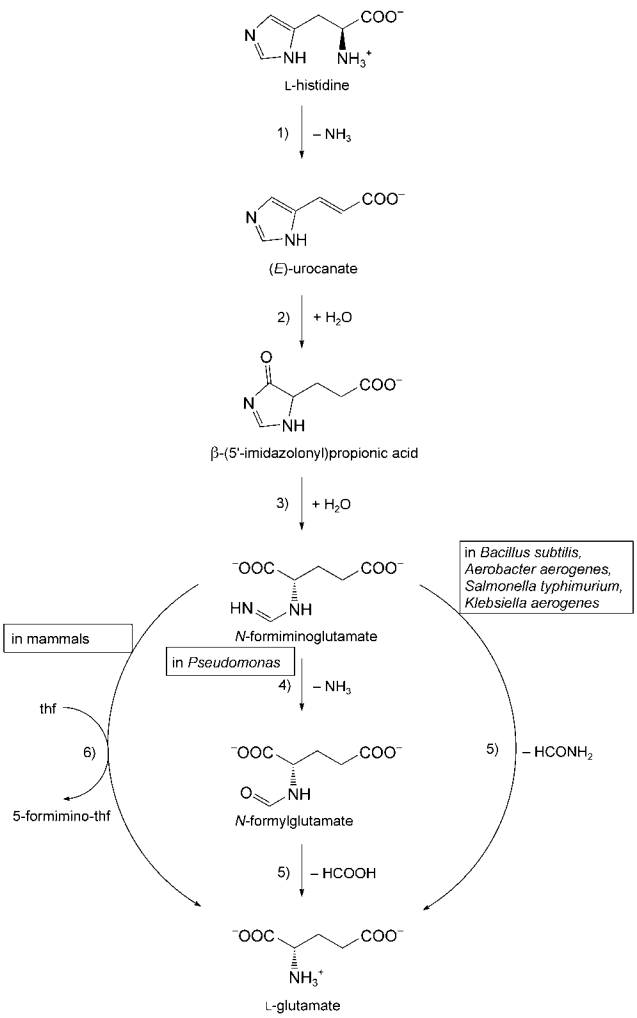
amino acids tyrosine and tryptophan, which are oxidized to quinones. The mechanism of action of quinoenzymes is attracting a great deal of attention.[8]

Finally, the modification of lysine to pyrrolysine was discovered recently.[9] It was first proposed that a specific lysyl-tRNA is modified at the 6-amino group through the formation of an amide with 4*R*,5*R* 4-substituted pyrroline-5-carboxylic acid.[10] A more recent report stated that pyrrolysine is formed before the binding to tRNA occurs.[11] The codon of the resulting pyrrolysyl-tRNA is the stop codon UAG. Precedence for such a pretranslational modification is the formation of selenocysteinyl-tRNA from a specific seryl-tRNA.[12]

2. HAL in Histidine Metabolism

Whereas the catabolism of most amino acids starts with transamination to the corresponding 2-keto acid, histidine is degraded in a different way. The first step of histidine metabolism consists of the elimination of ammonia catalyzed by histidine ammonia-lyase (HAL; Scheme 1). The product, (*E*)-urocanate, is further processed to imidazolonepropionate, a transformation catalyzed by urocanase (urocanate hydratase, imidazolonepropionate hydrolase).

Each subunit of this enzyme contains a tightly bound NAD^+ molecule, which functions as an electrophile and forms a covalent adduct with the imidazole ring of the substrate.[13]



Scheme 1. Degradation pathway of histidine in various organisms; enzymes involved: 1) histidine ammonia-lyase, 2) urocanase, 3) imidazolonepropionate hydrolase, 4) formiminoglutamate hydrolase, 5) *N*-formylglutamate aminohydrolase, 6) glutamate formiminotransferase. thf = tetrahydrofolate.

The result is an "umpolung", which is followed by the addition of water to form 4-hydroxyimidazolylpropionate.[13] This compound tautomerizes spontaneously to racemic imidazolonepropionate. The next step is catalyzed by imidazo-

László Poppe graduated as a chemical engineer from Budapest University of Technology and Economics (BUTE) and completed his PhD in 1987 with L. Novák on pheromone synthesis and biocatalysis. He was a research fellow at the Central Research Institute for Chemistry of the Hungarian Academy of Sciences before becoming a research professor at BUTE in 2001. He also spent over a year (1991–1992) as an Alexander von Humboldt Fellow with J. Rétey at the Universität Karlsruhe. His areas of interest are the stereoselective synthesis of biologically active compounds, biocatalysis, and enzyme mechanisms.

János Rétey studied chemistry at the ETH Zürich and completed his PhD on the stereospecificity of oxidoreductases in 1963 with V. Prelog. After postdoctoral periods with F. Lynen (München) and D. Arigoni (ETH Zürich) he became a lecturer at the ETH Zürich. In 1972 he moved as Professor of Biochemistry to the Universität Karlsruhe. His research interests include the mechanisms and stereospecificity of enzyme reactions, synthetic enzyme models, bioorganic and bioinorganic chemistry, and the investigation of enzyme structures by molecular biological methods.

lonepropionate hydrolase, which is enantioselective for the *S* substrate. As imidazolonepropionate racemizes spontaneously, the result is a kinetic resolution that leads quantitatively to (*S*)-formiminoglutamate. The formimino group may be removed in one or two steps, depending on the organism. In mammals it is transferred to tetrahydrofolate by glutamate formiminotransferase. In certain bacteria, such as *Bacillus subtilis*,[14] *Klebsiella aerogenes*,[15] and *Salmonella typhimurium*,[16] hydrolysis to formamide occurs; in *Pseudomonas* spp.,[17] hydrolysis first to formylglutamate then, in a second step, to formate and glutamate takes place. Histidinaemia, a rare but usually lethal disease in humans, is caused by a defect in HAL.[18]

Urocanate is a component of human sweat and protects the skin from UV radiation. When exposed to UV radiation, the *E* form of urocanate is converted into the *Z* form, which can initiate an immunosuppressive process.[19] Urocanase deficiency in the liver is believed to be a cause of mental retardation.[20] The recently elucidated structure of urocanase is consistent with the previously proposed mechanism.[21]

The genes of *Pseudomonas putida* that code for HAL (*hutH*) and urocanase (*hutU*) have been cloned and sequenced.[22] The HAL sequences from human, rat, and murine tissues are also described in the literature.[23]

In certain bacteria the structural and regulatory genes that code for the enzymes of the histidine utilization pathways are clustered in the *hut* operon (Figure 1).[24] For example, in

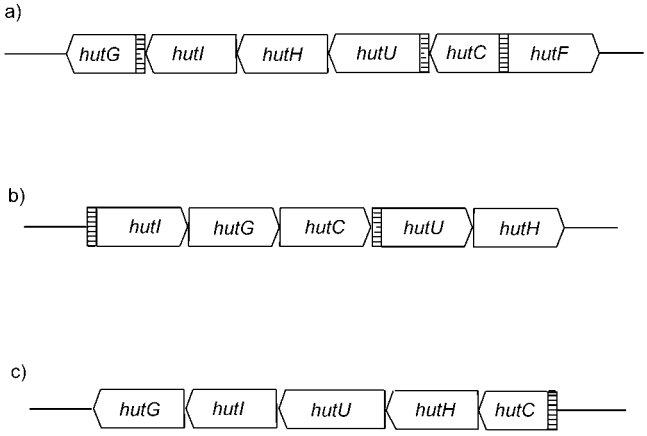


Figure 1. Structure and regulation of histidine utilization (*hut*) operons in a) *P. putida*, b) *Klebsiella aerogenes* and *Salmonella typhimurium*, c) *Bacillus subtilis*. Promotors are marked as shaded boxes; the gene boxes indicate the direction of transcription.

P. putida the *hut* operon has six open reading frames and four regions whose transcription is regulated by three promotors. The three structural genes, *hutU*, *hutH*, and *hutI*, are negatively regulated by a promoter–repressor system. The expression of all three genes is induced by urocanate, not by histidine. Therefore, a basal expression of HAL is necessary. Interestingly, transcription by *hutF* occurs in the opposite direction to transcription by the other genes. The organization of the *hut* operon in other bacteria is different from that in *P. putida*.[24] Only *P. putida* possesses *hutF*, which codes for formylglutamate amidohydrolase.[14,24a,b]

3. PAL in Plant and Fungal Metabolism

Phenylalanine can be degraded in two different ways, depending on the organism. Whereas in animals and most bacteria transformation to the corresponding 2-keto acid is the initial step, in plants,[25] fungi,[26] and at least one bacterium[27] the initial step is the elimination of ammonia catalyzed by phenylalanine ammonia-lyase (PAL).[28] The product of the elimination reaction is (*E*)-cinnamate, which is the precursor of a large number of plant metabolites, including lignin, coumarins, and flavonoids.[25] Lignin is the major constituent of wood; the flavonoids are the colorful components of many flowers (Figure 2). By genetic modification it was possible to alter lignin or flavonoid levels and thus flower color.[29] PAL lies at the branching point between the primary and secondary metabolism of plants, which makes it a target for herbicides.[30,31]

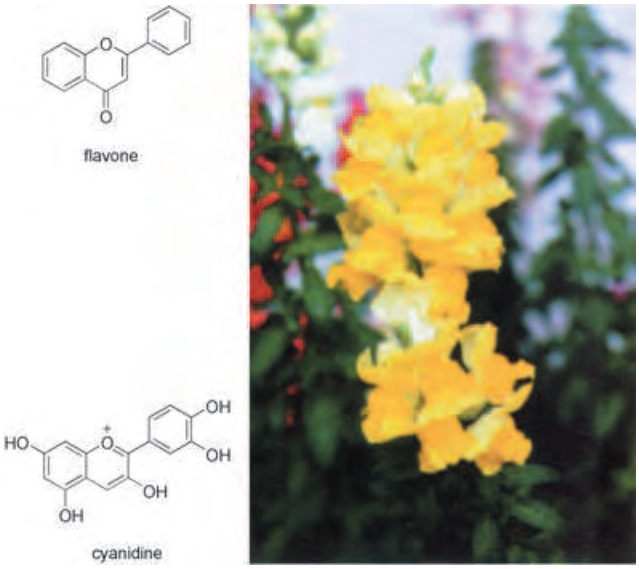

Figure 2. Colors of the plant world: anthocyanins (flavonoid pigments).

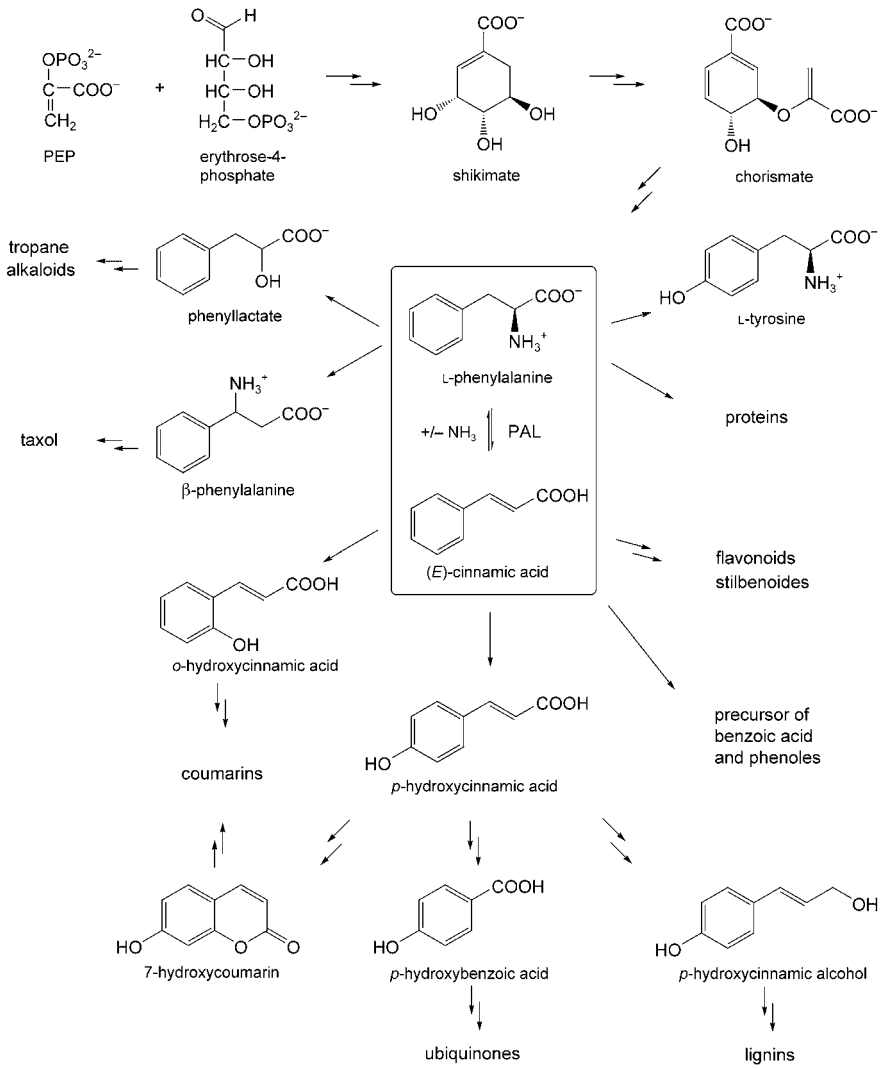
The metabolism of phenylalanine in plants is shown in Scheme 2. The biosynthesis of phenylalanine follows the well-known shikimate pathway.[31a] Hydroxylation at the *para* position leads to tyrosine, another essential amino acid. Rearrangement through the action of a 2,3-aminomutase affords β-phenylalanine, which is a precursor of taxol, an important anticancer agent.[32] The hydroxylation of (*E*)-cinnamic acid, the immediate product of the PAL reaction, can take place at either the *ortho* or the *para* position and leads to coumarins or 4-hydroxybenzoic acid, respectively. The latter is a building block of ubiquinone.[33,34]

In some plants, substituted coumaric acids can be converted into the corresponding coenzyme A esters. Feruloyl-CoA, for example, is transformed by hydroxycinnamoyl-CoA hydratase/lyase.[34] This mechanistically interesting reaction consists of the addition of water to the Michael system, followed by a retroaldol cleavage to give vanillin, an



Scheme 2. Metabolism of L-phenylalanine.

important flavor substance, which is eventually oxidized to vanillic acid.

A partially purified PAL from *Rhodotorula glutinis* (also known as *Rhodosporidium toruloides*) is commercially available.[35] It is the most thoroughly investigated fungal PAL enzyme.[26] Recently, the isolation and properties of PAL from *Streptomyces maritimus* were also described.[27] This is the only bacterial PAL known to date. It is involved in the biosynthesis of the antibiotic enterocin via (*E*)-cinnamate and benzoyl-CoA. The rarity of PAL in bacteria may be explained by the absence of phenylpropanoids in these species. On the other hand, (*E*)-cinnamate may be the precursor of some specific bacterial products. A similar case is the discovery of tyrosine ammonia-lyase (TAL) in *Rhodobacter capsulatus*.[36] The recombinant enzyme reacts 150 times faster with tyrosine than with phenylalanine and corresponds to an alternative pathway to *p*-coumaryl-CoA. It is involved in the biosynthesis of the photoactive yellow protein chromophore of this bacterium.

4. Mechanism of the HAL and PAL Reactions

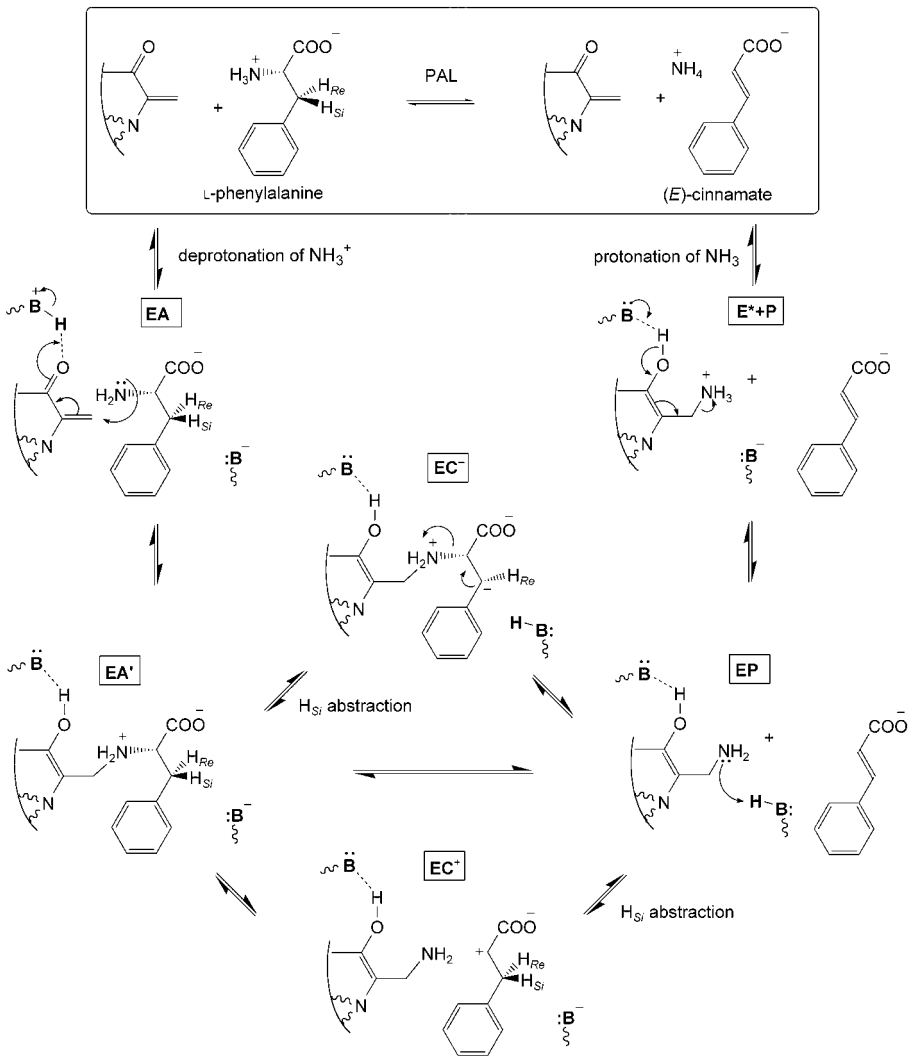
4.1 Early Mechanistic Proposals for HAL and PAL: Discovery of a Catalytically Important Electrophilic Group

After the elucidation of the structure of urocanic acid by Hunter in 1912,[37] its intermediacy in the histidine degradation pathway was proposed. Cell-free systems from various organisms were able to transform histidine into glutamate. Edlbacher named such systems "histidases".[38] Later the name histidase was restricted to one of the component enzymes, which catalyzes the conversion of histidine into urocanic acid and ammonia. Tabor and Mehler described the purification of the enzyme from *P. putida* in 1954;[17a] the partial characterization of the enzyme was described by Peterkofsky.[39]

A mechanism for the HAL reaction was first proposed in 1967 by Abeles and coworkers,[40] who found that histidase contains a catalytically essential electrophilic group. Evidence for the presence of this group was the inhibition of HAL by strong nucleophiles, such as KCN, CH_3NO_2, and $NaBH_4$. When the radioactively labeled inhibitors $[^{14}C]CN^-$[41] and $[^3H]NaBH_4$[42] were used, total hydrolysis of the inhibited protein afforded [^{14}C]aspartate and [^{3}H]alanine, respectively. From these results it was concluded that the prosthetic electrophile is dehydroalanine, which behaves as a Michael acceptor. It was suggested that the amino group of the substrate reacts with the dehydroalanine residue, whereby the leaving ability of the now positively charged ammonium group would be enhanced.[40] In the following this mechanism is referred to as the E_1cB mechanism.

Although the E_1cB mechanism via the EC^- state (see Scheme 3) does not explain how the nonacidic β proton of histidine can be abstracted by an enzymatic base, it has been accepted by most enzymologists for almost 30 years. Moreover, the same mechanism was also assumed for the PAL reaction,[28,43] in which the existence of dehydroalanine had been indicated by similar experiments to those described for HAL.[40]

The E_1cB mechanism for the PAL reaction is illustrated in Scheme 3. In the first step the α ammonium group of phenylalanine must be deprotonated, which enables a nucleophilic addition to the prosthetic electrophile to occur. In this way a secondary ammonium group is formed. From this point three pathways are possible.[43] By the E_1cB mechanism, H_{Si} abstraction would lead to a benzylic carbanion (EC^-), whereas by an E_1 mechanism cleavage of the N–C^α bond would result in an α carbocation (EC^+). However, the occurrence of both intermediates is unlikely because the



Scheme 3. Mechanism of the PAL reaction, as proposed by Hanson and Havir (1970)[28] and modified by Hermes et al. (1985).[43] The states EA, EA′, EC^-, EC^+, EP, and E*+P are depicted according to the proposal of Hermes et al.

pK_a value for the abstraction of a benzylic proton is more than 40, and the carbocation α to the carboxy group is also too high in energy. Although the following steps would be chemically plausible, both reaction pathways are improbable because of the high-energy intermediates involved. As a third alternative, a concerted reaction (E_2 mechanism) that leads directly from the EA′ state to the EP state was also considered.[43]

In a thorough kinetic analysis of the PAL reaction, Hermes et al. measured kinetic isotope effects for [^{15}N]- and [3-$^2H_2$]phenylalanine and concluded that the mechanism is not concerted.[43] (For further details of the studies with isotope-labeled substrates, see Section 6.2). The difficulty in abstracting the nonacidic β proton is also discussed by Hermes et al.,[43] but no solution to this chemical challenge is offered. Nevertheless, the kinetic ^{15}N-isotope effect of ≈1% is interpreted in favor of the addition of the amino group to the prosthetic dehydroalanine residue.

A further mechanistically relevant observation was interpreted in the same sense. In 1962, Peterkofsky reported that in the presence of radiolabeled urocanate a substantial portion of the radioactivity was found in histidine, whereas [^{15}N]ammonia was not incorporated.[39] This observation indicated the involvement of a relatively stable amino enzyme intermediate, which could revert to histidine in the presence of [^{14}C]urocanate. These results seemed to support the formerly accepted E_1cB mechanism, as it was believed that the amino group was covalently bound to the enzymatic electrophile.[40,43] A convincing alternative explanation for Peterkofsky's results is presented in Section 4.2.

Although according to Hermes et al.[43] both the concerted (E_2) and the carbonium-ion (E_1) mechanisms are ruled out on the basis of double-kinetic-isotope-effect measurements, we also considered this possibility. A positively charged ammonium ion is known to enhance the acidity of the neighboring hydrogen atoms.[44] Such an effect may be significant in the enzymatic elimination of ammonia from aspartate and 3-methylaspartate. However, in these substrates the β hydrogen atom is activated additionally by the neighboring carboxy group. It is therefore not surprising that the corresponding enzymes aspartase and methylaspartase do not have a prosthetic electrophile, as revealed by the determination of their crystal structures.[45–48] Moreover, these two ammonia-lyases belong to the enolase superfamily, as concluded on the basis of their sequence similarity and structure, which suggests that in a first step a proton is removed from position 3. Thus, the reaction is not concerted as was originally believed.

In the last 10 years, no results that support the E_1cB mechanism have been published. Although the E_1cB mechanism is favored on the basis of modeling studies in a recent publication that describes the first X-ray crystal structure of PAL,[49a] a more recently published X-ray crystal structure of higher resolution[49b] supports another mechanism, which is discussed in Section 4.2.

4.2. An Alternative Mechanistic Proposal: Friedel–Crafts Attack by the Prosthetic Electrophile

As discussed in the previous section, the main problem with the "old" E_1cB mechanism for ammonia-lyase-catalyzed

reactions is that it does not explain the abstraction of the nonacidic β protons by the enzymatic base. The pK_a value for the abstraction of the benzylic protons is above 40,[50] so that an extremely strong base would be required to abstract them under harsh conditions, for example, at high temperature. At the same time, the much more acidic ammonium hydrogen atoms should remain untouched, as the positive charge is required for the ammonium group to retain its leaving ability. In the so-called Hofmann degradation of the second type, the trimethylammonium group cannot lose its positive charge even under harsh basic conditions.

The experimental basis for the postulation of an alternative mechanism emerged in an indirect way. It originated in the search for the precursor of the prosthetic dehydroalanine residue. It was known that dehydroalanine can be formed by the dehydration of serine either in vitro or during the biosynthesis of the lantibiotics.[51] After some controversy[22a,52] the question was solved by specific mutations of serine residues that are conserved in a number of HAL and PAL sequences.[53] The mutation of Ser143 in HAL from *P. putida*[54] and Ser202[*] in PAL from parsley (*Petroselinum crispum*)[55] to alanine led to a decrease in the activity of the enzyme by a factor of more than 1000 (Table 2).[55] The

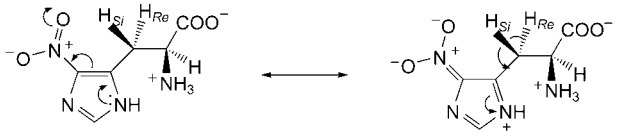
Table 2: Comparison of the kinetic constants of HALs isolated from *Pseudomonas* ATCC 11299b and *P. putida*, and mutant enzymes expressed in *E. coli* BL21(DE3).[54]

HAL-derivative source	K_m [mM]	V_{max} [U mg^{-1}]
wild-type *Pseudomonas* ATCC 11299b	4.0	28
wild-type *Pseudomonas putida*	5.3	25
recombinant wild-type *E. coli*	3.6	25
recombinant mutant S112A	4.9	26
recombinant mutant S143A	7.5	0.021
recombinant mutant S393A	3.6	20
recombinant mutant S418A	3.5	22

mutation of other conserved serine residues had little or no effect on the activity. This result identified the two serine residues mentioned as the precursors of the catalytically essential dehydroalanine residue. Interestingly, the mutation of the essential serine residue to cysteine led to fully active wild-type enzyme.[56] It can be concluded that the post-translational modification can remove either water or SH_2, but in a site-specific manner.[56]

After obtaining these results, we turned to the question of the role of dehydroalanine in the reaction mechanism. A literature search helped to solve the problem. Klee et al.[57] found that 5-nitrohistidine is also a substrate of HAL. Moreover, whereas β-dideuterated histidine showed a kinetic isotope effect of 1.5–2.0, no such effect was observed for β-dideuterated 5-nitrohistidine.[57] The explanation for this difference is illustrated in Scheme 4: The presence of the nitro group leads to a decrease in the electron density of the imidazole ring and thus to an increase in the acidity of the

[*] This residue is Ser203 in the sequence of PAL from *P. crispum* (P24481) in the SWISS-PROT database.



Scheme 4. Activation of the β hydrogen atoms by the nitro group of 5-nitro-L-histidine, a substrate of HAL.

β hydrogen atoms. As a consequence, the abstraction of the β proton is no longer the rate-determining step, and no kinetic isotope effect is observed.

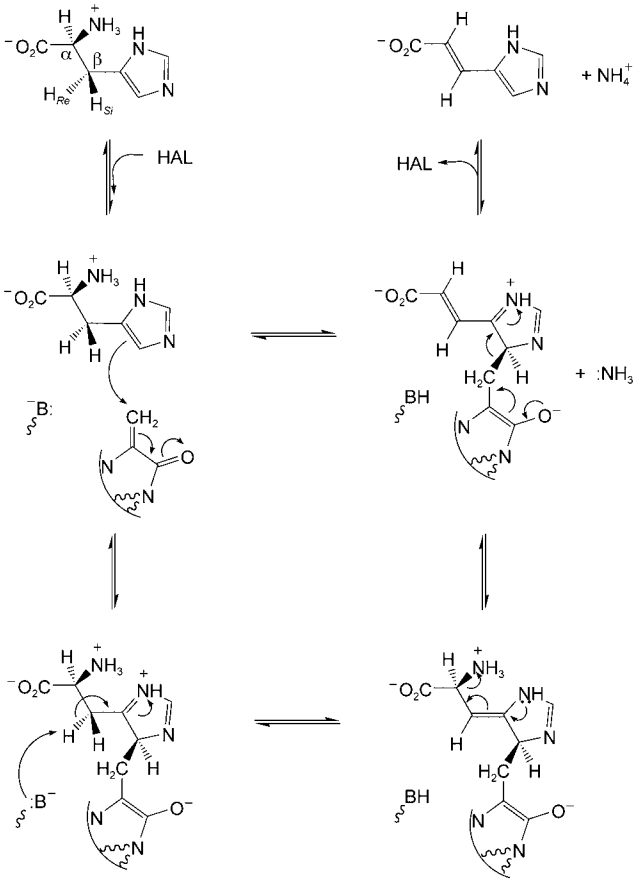
This result suggested that the function of the prosthetic dehydroalanine residue may be similar to that of the nitro group, namely, the acidification of the β hydrogen atom. To test this idea, the activity of 5-nitrohistidine was measured both with wild-type HAL and with HAL derivatives mutated at Ser143 or inactivated by treatment with $NaBH_4$.[58] The reaction rate is practically independent of the HAL derivative used. In other words, the presence of the nitro group makes the prosthetic electrophile unnecessary. A further conclusion is that the nitro group and the prosthetic electrophile do in fact have the same function, namely, the acidification of the β hydrogen atom.

This conclusion and the precedent for electrophilic attack at the imidazole ring in the urocanase reaction[13] led to the proposal of an alternative mechanism, which is depicted in Scheme 5.[58] Attack at the imidazole ring of histidine by the prosthetic electrophile creates a similar situation to the presence of the nitro substituent and facilitates the abstraction of H_{Re}[59] by the enzymatic base. The ammonium group is then cleaved as ammonia, and, in a final step, the fragmentation of the adduct gives urocanate and regenerates the prosthetic group.[58]

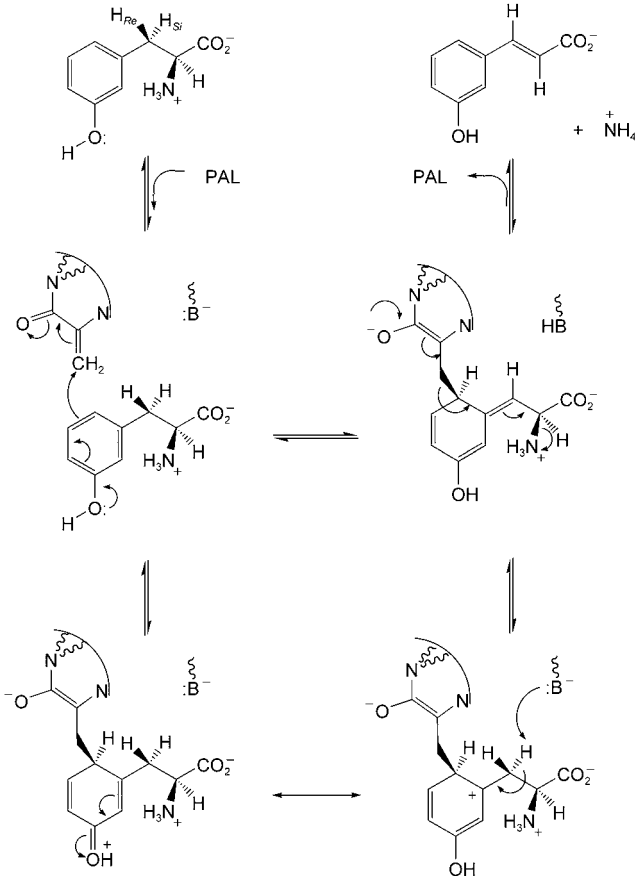
Such a mechanism is less plausible for the PAL reaction, as the phenyl ring is not as electron rich as the imidazole ring. Through the attack by the prosthetic electrophile, the aromaticity would be lost at least transiently, which is unfavorable energetically. This would be the first biological Friedel–Crafts reaction.[60] However, a number of experiments supported such a mechanism for the PAL reaction.[61] In analogous experiments to those described for HAL, the PAL mutants Ser202Ala and Ser202Thr reacted much faster with 4-nitrophenylalanine than with the unsubstituted substrate ($k_{cat} < 20$).[61]

PALs from various sources also accept tyrosine as a substrate, but react with it at a much lower rate ($k_{cat} < 50$). If the Friedel–Crafts-type attack plays a role in the mechanism, then *m*-tyrosine should be a much better substrate, as is indeed the case. Recombinant PAL from parsley even reacts with *m*-tyrosine 10–20% faster than with L-phenylalanine. The proposed mechanism is illustrated in Scheme 6.[61]

More recently, the chemical feasibility of the electrophile-assisted elimination of ammonia was demonstrated with a chemical model.[62] One portion of the model compound mimicked the essential parts of the substrate (phenylalanine), and another portion mimicked the electrophilic Michael acceptor (MIO) in a sterically appropriate position (Scheme 7).



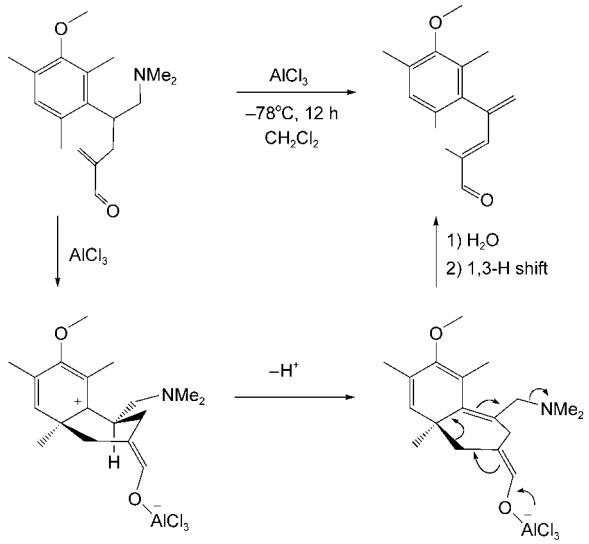
Scheme 5. Alternative mechanism for the HAl reaction.[58]



Scheme 6. Mechanism of the PAL reaction with *m*-tyrosine as the substrate, assuming a Friedel–Crafts-like attack.

The following measures were taken to facilitate the reaction: a) The reaction was carried out in an intramolecular fashion, b) a methoxy group was introduced to enhance the nucleophilicity of the phenyl ring at the position of attack, and c) the electrophilicity of the Michael acceptor was enhanced by using an α,β-unsaturated aldehyde instead of the corresponding amide. Under Friedel–Crafts conditions ($BF_3{\cdot}Et_2O$ or $AlCl_3$) two diastereomeric tricyclic compounds were isolated in excellent yields, but no trace of the product that would arise from the elimination of dimethylamine was detected. Evidently, the competing abstraction of a proton from the ring, accompanied by rearomatization and completion of the substitution, suppressed the abstraction of the benzylic proton. PAL prevents the abstraction of a ring proton by excluding bases from the hydrophobic pocket which the phenyl group occupies. Therefore, we had to take a further measure to mimic this "negative catalysis". When we substituted the hydrogen atoms on the phenyl ring for methyl groups (Scheme 7) the completion of the Friedel–Crafts substitution was prevented, and we could isolate the desired elimination product.[62]

Evidence for the active role of the phenyl ring in the process was provided by deactivating the phenyl ring, either by removing the methoxy group or by exchanging it for a nitro group. In these cases no elimination products were detected.[62]



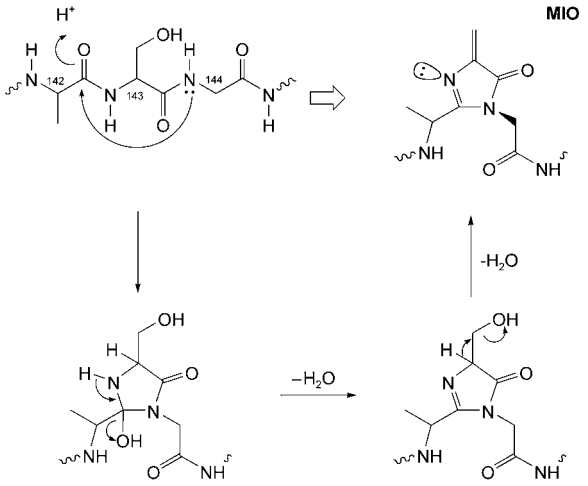
Scheme 7. Synthetic model system for modeling the PAL reaction.

4.3. Discovery of 5-Methylene-3,5-dihydroimidazol-4-one (MIO) as the Prosthetic Electrophile of HAL and PAL

The prerequisite for site-directed mutation in HAL and PAL was the cloning and heterologous expression of both enzymes. Success was first achieved with HAL. The expres-

sion of its gene from *P. putida* in *E. coli* by using the pT7-7 expression vector yielded about 100 mg of the pure enzyme from 1 L of overnight culture of the recombinant bacteria. The access to gram quantities of pure HAL facilitated its crystallization.[58] However, the crystal structure could only be solved after the mutation of a solvent-exposed cysteine residue to alanine.[63b]

HAL from *P. putida* had been characterized previously by biochemical methods.[52] The X-ray structure at a resolution of 2.1 Å confirmed that it is a homotetramer and also led to an unexpected result, namely, that the prosthetic electrophile is not dehydroalanine but MIO.[64] MIO can be regarded as a modified dehydroalanine residue and is formed post-translationally by cyclization followed by the elimination of two water molecules from the inner tripeptide Ala142-Ser143-Gly144 (Scheme 8).



Scheme 8. Formation of the MIO group in HAL by post-translational modification.

MIO is the only catalytically important protein-derived cofactor with such a heterocyclic structure. An example of a noncatalytic species is the fluorophore of the green fluorescent protein. This fluorophore also has an MIO structure, but the exocyclic methylene group has a *p*-hydroxyphenyl substituent.[65]

As catalytically active HAL is also formed in an in vitro translation system, the information for the biosynthesis of MIO must be in the amino acid sequence and hence in the folding of the polypeptide chain.[66] The homotetramer exhibits D_2 symmetry and consists mainly of α helices (Figure 3). Each subunit can be subdivided into two domains. The N-terminal domain is globular with eight helices and four short β strands; the C-terminal domain consists of five long, nearly parallel α helices surrounded by six other helices.[64]

In each active center (identified by the presence of the MIO groups) there are amino acid residues from three subunits (Figure 4). The importance of these active-site amino acids for catalysis is supported by mutational analysis. The much higher electrophilicity of MIO relative to dehydroalanine makes the Friedel–Crafts attack at the aromatic ring feasible.[52]

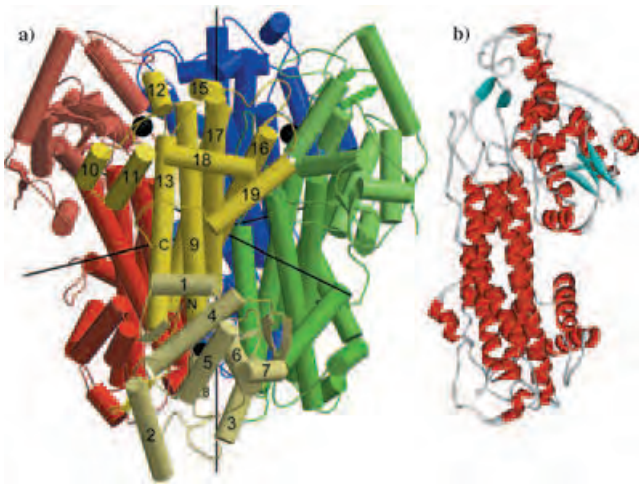


Figure 3. X-ray crystal structure of the homotetramer of HAL (a) and one subunit (b).[64]

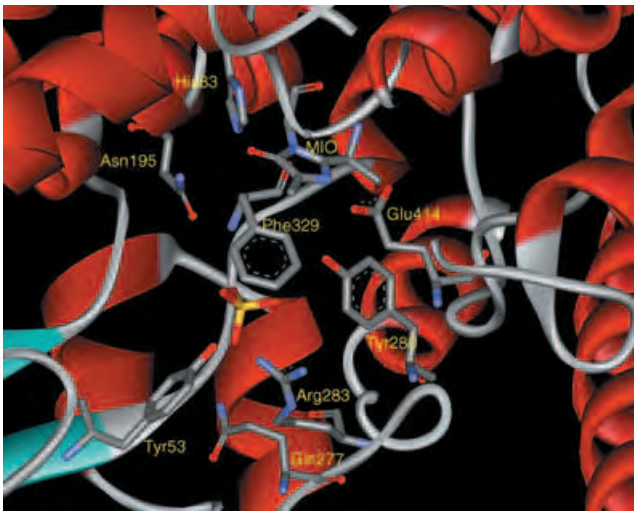

Figure 4. Substrate-free active site of HAL.

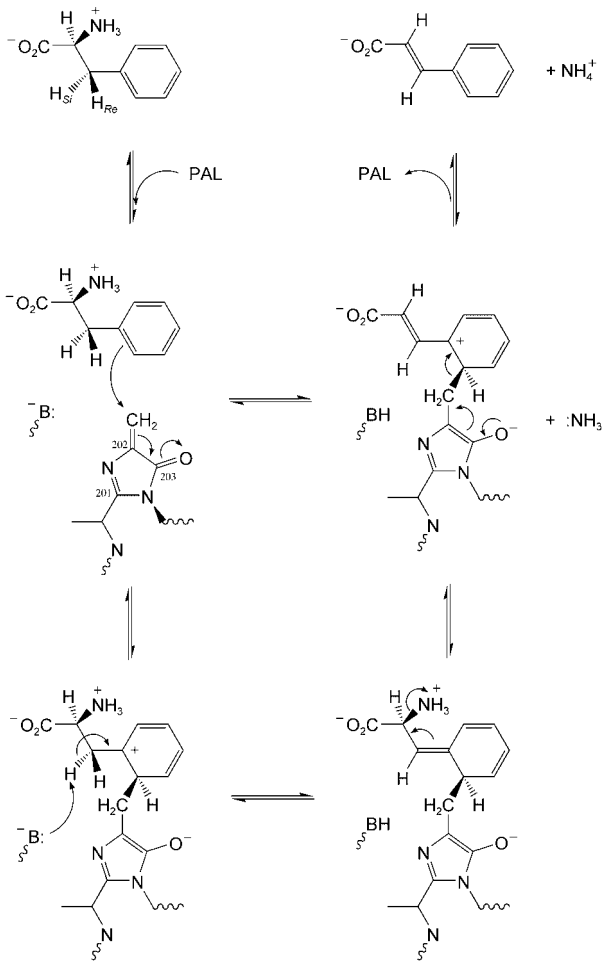
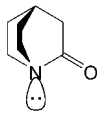
In MIO, the delocalization of the lone pairs of electrons on the nitrogen atoms into the Michael system is prevented. In the case of the sp^2-hybridized nitrogen atom the orbital of the lone pair of electrons is orthogonal to the π orbitals of the α,β-unsaturated carbonyl system, and in the case of the sp^3-hybridized nitrogen atom the $sp^3 \rightarrow sp^2$ transition is prevented by the fold of the polypeptide chain. However, the barrier to this transition is not excessively high.[67] Moreover, the attack of a nucleophile at the exocyclic double bond renders the imidazole ring aromatic, which compensates for the transient loss of aromaticity of the imidazolyl or phenyl group of the substrate.

The mechanism of the PAL reaction initiated by a Friedel–Crafts attack is shown in Scheme 9. An example of a lone pair of electrons on a nitrogen atom that is prevented from undergoing delocalization into an adjacent carbonyl group is provided by quinuclidone (Scheme 10), which does not behave as a lactam, but as a ketoamine.



Scheme 9. Mechanism of the PAL reaction involving a Friedel–Crafts-type attack of the MIO group on the phenyl moiety of L-phenylalanine.



Scheme 10. Structure of quinuclidone.

In 1970, Klee reported a shoulder at about 315 nm in the UV spectrum of HAL, but no explanation for its occurrence could be offered at that time.[68] The idea emerged that the cross-conjugated system of MIO could be responsible for the shoulder. We recorded UV difference spectra of HAL and PAL mutants that do not contain the MIO group and the corresponding wild-type enzymes. In both cases a distinct absorption maximum (λ_{max}) was observed at 308 nm (Figure 5).[69] This method has also been used by others to show the presence of MIO.[70]

The very recently published X-ray crystal structures of PAL from *Rhodosporidium toruloides*[49a] and parsley[49b] further confirm the presence of MIO.

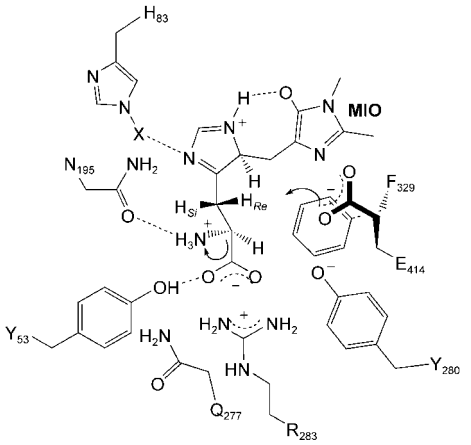
5. The Active Sites of HAL and PAL

5.1 Identification of Active-Site Amino Acids by Site-Directed Mutagenesis

The amino acids in the active site of HAL were identified by X-ray crystal-structure analysis.[64,71] In Scheme 11 the relative positions of these amino acids are shown, together with the substrate modeled into the active site.[72] All mutations were carried out on the Cys273Ala mutant, which had been used for the X-ray crystal-structure analysis. The k_{cat} value of this mutant was about 5 times lower than that of wild-type HAL, whereas its K_m value was 4.5 times higher. The kinetic constants of several mutants are listed in Table 3.[72] The importance of Glu414 was highlighted by the decrease in the k_{cat} value for the Glu414Ala mutant by a factor of 21000. The likely function of this residue is the abstraction of the H_{Re} proton from the substrate as the enzymatic base. As can be seen from Scheme 11, Glu414 is assisted in the abstraction of H_{Re} by Tyr280 on a neighboring subunit. On the basis of the structure of cysteine-inhibited HAL, Baedeker and Schulz postulated a different mechanism, by which Tyr280 abstracts H_{Re} with assistance from Glu414.[67] There are arguments in



Scheme 11. Model of the active site of HAL with the substrate arranged according to the Friedel–Crafts-like mechanism.[74]

Table 3: Kinetic constants of active-site mutants of C273A HAL.[72]

Mutation in C273A HAL	K_m [mM]	k_{cat} [s^{-1}]	$k_{cat,C273A}/k_{cat,mut}$

[a] $k_{cat,C273A}/k_{cat,wt} = 0.21$.

favor of both suggestions. The fact that the HAL mutant Glu144Ala shows a greater loss of activity than Tyr280Phe relative to the wild-type enzyme would support the former view,[64,72] whereas the observation that Gln488 occupies a position in PAL analogous to Glu144 in HAL, but that Tyr351 is conserved, speaks for the second view.

A large decrease in k_{cat} was also observed for the mutant His83Leu. His83 is most likely involved in the binding of the imidazole ring of the substrate. The distance (4.15 Å) suggests that the binding occurs through a water molecule or a hydronium ion. Although in the X-ray crystal structure no metal ion is observed, it has been found that Zn^{2+}, Mn^{2+}, and similar metal ions increase the activity of HAL.[73] We suggest that the species represented with an "X" in Scheme 11 could be either a hydronium or a metal ion. The guanidino group of Arg283 is the counter ion of the carboxylate group of the histidine substrate and can be substituted for Lys with a relatively small loss of activity. However, its substitution by Ile, a neutral amino acid, leads to a large decrease in the k_{cat} value. An even larger loss of activity is observed for the mutation Tyr53→Phe. Tyr53 interacts with the carboxylate group of the substrate and may play a role in the abstraction and binding of the α amino group. Tyr53 may also be responsible for the stability of the amino enzyme intermediate,[39] possibly with the assistance of Asn195, whose substitution for Ala causes a 1000-fold decrease in k_{cat}. Somewhat controversial is the effect of the mutation Phe329→Ala. One research group[72] found a 100-fold decrease in activity, whereas another[67] found a 2500-fold decrease. Phe329 is conserved in all members of the HAL/PAL family and in the second model[67] interacts with the imidazolyl group of the substrate. It is postulated that the phenyl group of Phe329 is required to induce MIO formation by steric compression. The mutant Phe329Gly leads to an inactive HAL protein which does not contain MIO,[71] whereas the mutant Phe329Ala formed the MIO group but showed very low activity.

To elucidate the role of the active-site amino acids of PAL it was necessary to resort to its high sequence homology with HAL, which allowed modeling of the active site of PAL (see also Section 5.2). On the basis of this model and the kinetic constants of a number of PAL mutants (Table 4), functions of the active-site residues could be proposed.[74] All except two amino acids are found to occupy almost identical positions. His83 and Glu414 in HAL are exchanged for Leu138 and Gln488, respectively, in PAL.

In an attempt to transform PAL into HAL, the PAL mutants Leu138His and Gln488Glu were prepared, as well as the double mutant Leu138His/Gln488Glu.[74,75] Whereas for the single mutants the k_{cat} values decreased only slightly, the double mutant was 145 times less active than wild-type PAL (Table 4). More dramatic was the change in the K_m values for

Table 4: Kinetic constants of active-site mutants of PAL.[74]

Mutation in wt-PAL	K_m [mM]	k_{cat} [s^{-1}]	$k_{cat,wt}/k_{cat,mut}$

the Leu138His mutants. These values are more than 100 times higher than that for the wild-type enzyme, thus supporting the view that Leu138 is part of the hydrophobic binding pocket that harbors the phenyl group of the substrate. Because of the relatively strong adhesion of the phenyl group to this hydrophobic environment, the rate-limiting step in the PAL reaction is the release of the product, (*E*)-cinnamate. Therefore, in contrast to the HAL reaction, no primary kinetic deuterium-isotope effect is observed in the PAL reaction.[43] Recently, it was shown that with the mutant Leu138His the release of the product is faster and a kinetic deuterium-isotope effect ($k_H/k_D = 2.3$) is observed.[75] The assumption that the PAL double mutant Leu138His/Gln488Glu would

behave like HAL was only partially endorsed. Whereas the K_m value for histidine was similar to that with HAL, the k_{cat} value was 8000 times lower. It seems that amino acid residues other than those in the active site also affect the reaction rate.

The largest loss of activity was found with the PAL mutant Tyr110Phe. Tyr110 in PAL is thought to have the same function as Tyr53 in HAL, but it seems to be even more important. Similarly, Asn260 and Tyr348 in PAL correspond to Asn195 and Tyr280 in HAL and probably have the same important functions. In this case the phenolate form of Tyr348 is definitely the enzymatic base that abstracts the β H_{Si} proton of the substrate.[76] Arg354 and Phe400 in PAL correspond to Arg283 and Phe329 in HAL, and their mutations affect the kinetic constants of the two enzymes to a similar extent.[74]

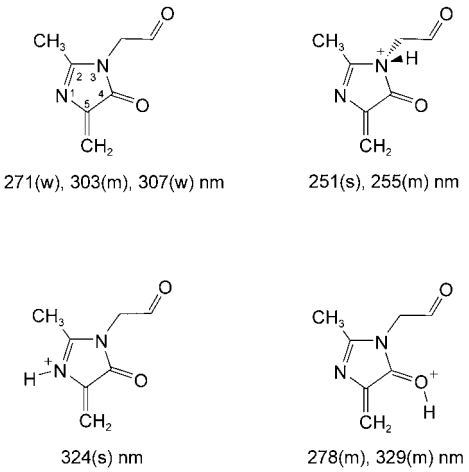
Another interesting difference between HAL and PAL is found with the mutants Ser143Thr and Ser203Thr. Although practically inactive, the HAL mutant Ser143Thr shows a maximum at 305 nm in the UV difference spectrum versus the MIO-free mutant Ser143Ala, whereas no such absorption maximum is observed in a similar experiment with the Ser203Thr mutant of PAL. These results indicate that the HAL mutant Ser143Thr still forms the MIO structure but that the corresponding PAL mutant does not. The exchange of the two other amino acid residues directly involved in MIO formation to give HAL mutants Ala142Ser and Gly144Val led to decreased V_{max} values (by a factor of 6 and 44, respectively), but these effects are less dramatic.[77] Other mutations at the same positions (Ala142Gly, Ala142Asp, and Gly144Ala) resulted in moderate loss of activity. No activity at all was reported for the HAL mutant Asp145Ala.[67]

5.2. Modeling the Active Sites of HAL and PAL

Molecular modeling was applied as a complementary tool for the interpretation of the enzyme kinetic data from reactions with HAL and PAL mutants modified at active-site residues. Thus, a histidine molecule was modeled into the X-ray crystal structure of HAL[64] with its amino group at binding distance from the exocyclic methylene carbon atom of MIO and its carboxylate near the guanidino group of Arg283′.[67] Inspection of this arrangement revealed that there is no strong base near the β hydrogen atom of the substrate and no specific binding site for the imidazole ring of histidine, thus suggesting that direct ammonia abstraction is not compatible with the experimental structure.

However, the experimental HAL structure[64] was found to be compatible with a Friedel–Crafts attack of the MIO group at the aromatic ring of the substrate.[58,61,64] Two slightly different substrate-binding models have been described for HAL.[64,71,72] In the first model,[64,72] the imidazole ring of histidine is positioned close to Leu146 and thus "below" the MIO group. In the second, later, proposal[67] the imidazole ring is positioned "above" MIO and interacts with Phe329. Both models are consistent with the functions of the amino acid residues at the active site as concluded from mutational experiments, and both rationalize the experimental finding that urocanate is released before ammonia.[39]

The electronic spectra of a truncated MIO model were calculated at the PM3 level of theory and used to estimate the degree of polarization of the MIO moiety in the substrate-free state of HAL (Scheme 12).[72] The calculated absorption



Scheme 12. A model compound for nonprotonated MIO and its singly protonated forms; the calculated UV absorption maxima are given.

maxima at $\lambda = 303$ and 307 nm for the nonprotonated MIO model were in good agreement with the experimentally determined maximum at about $\lambda = 308$ nm in the UV difference spectrum of HAL. Calculated UV spectra for MIO structures fully protonated at the carbonyl oxygen atom, at N1, or at N3 were significantly different, thus indicating that MIO is not polarized significantly in substrate-free HAL.

To investigate the functions of the active-site residues of PAL, the X-ray structure of HAL was used as a template for homology modeling of the PAL structure (Figure 6).[74] In agreement with biochemical data, PAL was modeled as homotetramer (Figure 6, right). The model revealed that catalytically important residues are located at highly isosteric positions within two distinct regions of the protein chains in both HAL and PAL.

In the region of the active site, the PAL model closely resembles the X-ray crystal structure of HAL (Figure 7). All the active-site residues in the PAL model occupy positions that would be expected on the basis of comparison with the HAL sequence and structure. Moreover, the model constructed for the PAL from *Petroselinum crispum*[86] (*Pc*-PAL; Figure 6, right) shows excellent similarity with the recently published X-ray crystal structures of the PAL from *Rhodosporidium toruloides*[49a] (*Rt*-PAL; Figure 6, middle column; PDB codes for *Rt*-PAL: 1T6J and 1T6P) and *Pc*-PAL.[49b]

Interestingly, the residues His137 and Gln138 at the active site of *Rt*-PAL are replaced by Phe140 and Leu141 in the *Pc*-PAL model. This difference stems from differences in the sequences of the two PALs in this region rather than errors in the modeling of *Pc*-PAL. Moreover, the loop 105–123, which contains the catalytically important Tyr110 residue, is not present in the *Rt*-PAL structure.[49a] The absence of this loop can lead to the ambiguous arrangement of the substrate when modeling within this structure.

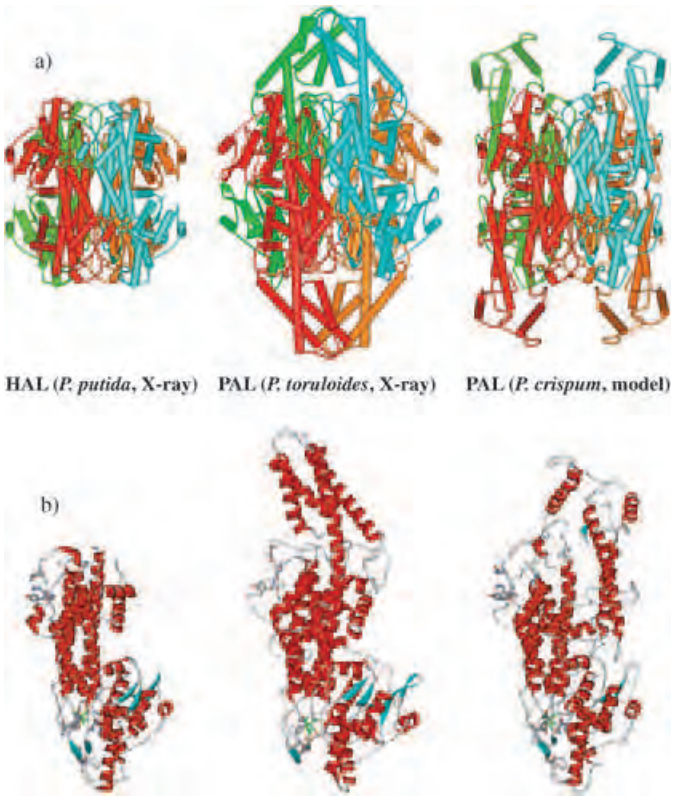


Figure 6. Comparison of the X-ray crystal structures of HAL (from *Pseudomonas putida*)[64] and PAL (from *Rhodosporidium toruloides*)[49a] with the homology model of PAL (from *Petroselinum crispum*):[86] a) tetrameric structures; b) single subunits (the catalytically important residues are shown as stick models; moieties containing MIO prosthetic groups are colored green).

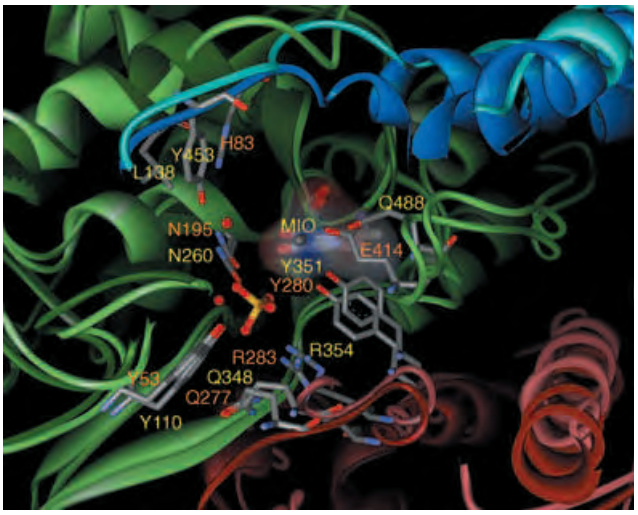

Figure 7. Model of the substrate-free active site of PAL (from *P. crispum*)[86] superimposed on the active site of HAL (from *P. putida*)[64] The lighter colors (yellow labels; light-blue, light-green, and light-red ribbons) indicate the PAL model; the darker colors (orange labels, blue, green, and red ribbons) indicate the HAL structure.

The modeling of a σ-complex-like intermediate (Figure 8a) and the product-binding state with (*E*)-cinnamate

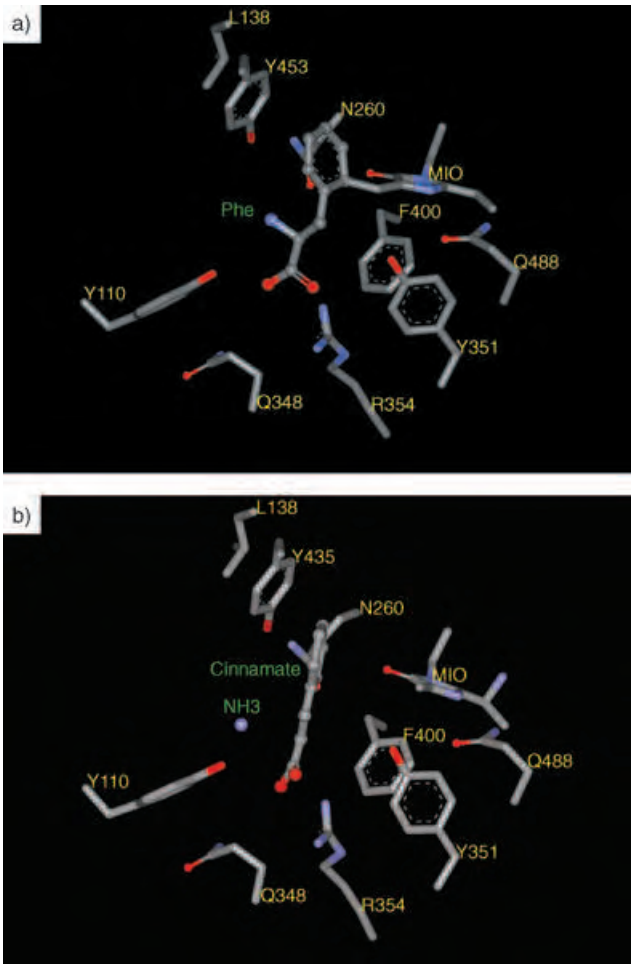

Figure 8. Models of the cationic intermediate (a) and product-binding states (b) at the PAL active site according to the Friedel–Crafts-like mechanism.

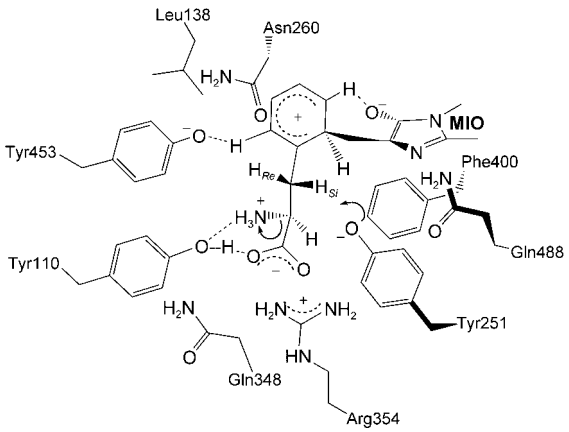
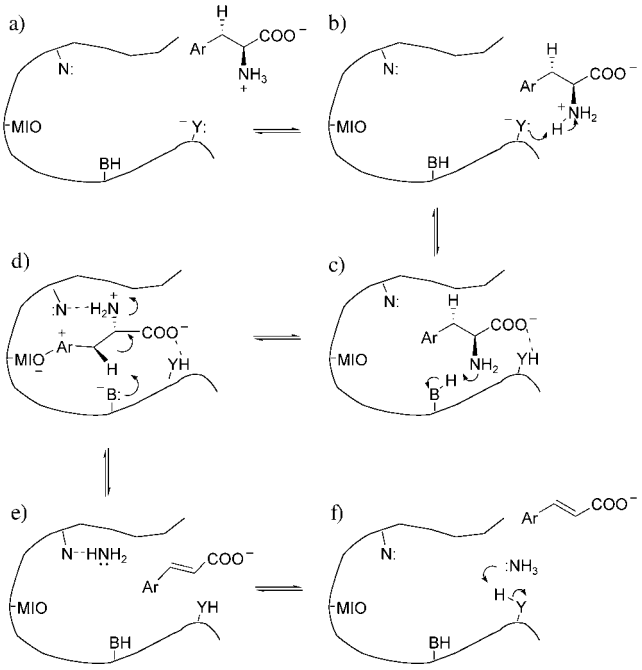
plus ammonia (Figure 8b) at the active site of *Pc*-PAL provided more information about the catalytic functions of the amino acid residues (Scheme 13).

A common feature of the tetrameric HAL and PAL structures is that a tyrosine residue (Tyr53 in HAL and



Scheme 13. Proposed catalytic roles of the active-site residues on the basis of the model of PAL.[86]

Tyr110 in PAL) is located at the edge of the channel through which the substrate can enter or the product be released from the active site. Mutations of Tyr to Phe at these positions lead to a dramatic decrease in catalytic activity (Scheme 14).[74] The existence of this narrow channel may account for the experimental finding[39,74] that after the elimination the product (*E*)-cinnamate is released first (Scheme 14e), followed by the ammonia in the form of an ammonium ion (Scheme 14f).



Scheme 14. Proposed mode of substrate binding (a–c), elimination (d), and release of the product (e, f) in HAL and PAL, assuming a Friedel–Crafts-like mechanism.

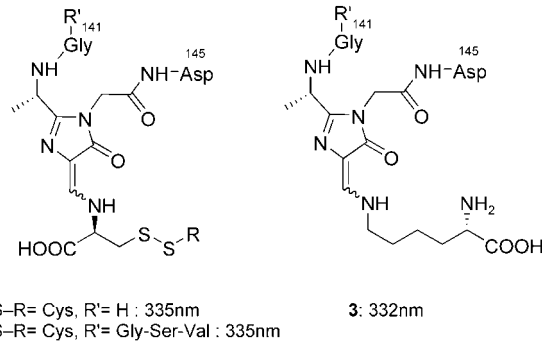
6. HAL and PAL Inhibitors and Alternative Substrates

6.1. Inhibition of HAL by Cysteine

Among the inhibitors of HAL, L-cysteine is the most interesting, because its behavior provided clues as to the reaction mechanism.[58] Inhibition by cysteine is reversible at neutral pH and under anaerobic conditions, but irreversible above pH 10.5 and in the presence of oxygen. An absorption occurs at about $\lambda = 340$ nm, the intensity of which is proportional to the degree of inhibition.[68b]

The first proposals for the structure of the chromophore generated had been made before MIO was discovered as the prosthetic group of HAL.[78] Soon after the discovery of the MIO group[64] two research groups described the structure and proposed mechanisms for its formation.[79] In both cases it was assumed that the thiolate group of cysteine reacts as a nucleophile with MIO, which is consistent with our previous proposal.[58,78b] The follwing arguments favor the attack of the thiolate group: 1) L-Cysteine and L-homocysteine but no other nonaromatic amino acids act as inhibitors, and 2) the thiol groups of the two inhibitors are positioned at the correct distance to attack MIO (relative to the 5-position of the imidazole ring of histidine).

To isolate the chromophore that absorbs at $\lambda = 335$–340 nm, the inhibited HAL protein was denatured and partially digested with pronases. After separation of the peptides produced, those that contained the chromophore were identified and characterized spectroscopically. Although the oligopeptides described in the two reports differed in length, they both contained the same chromophore structure (**1** and **2** in Scheme 15).[79] Viewed superficially, this finding



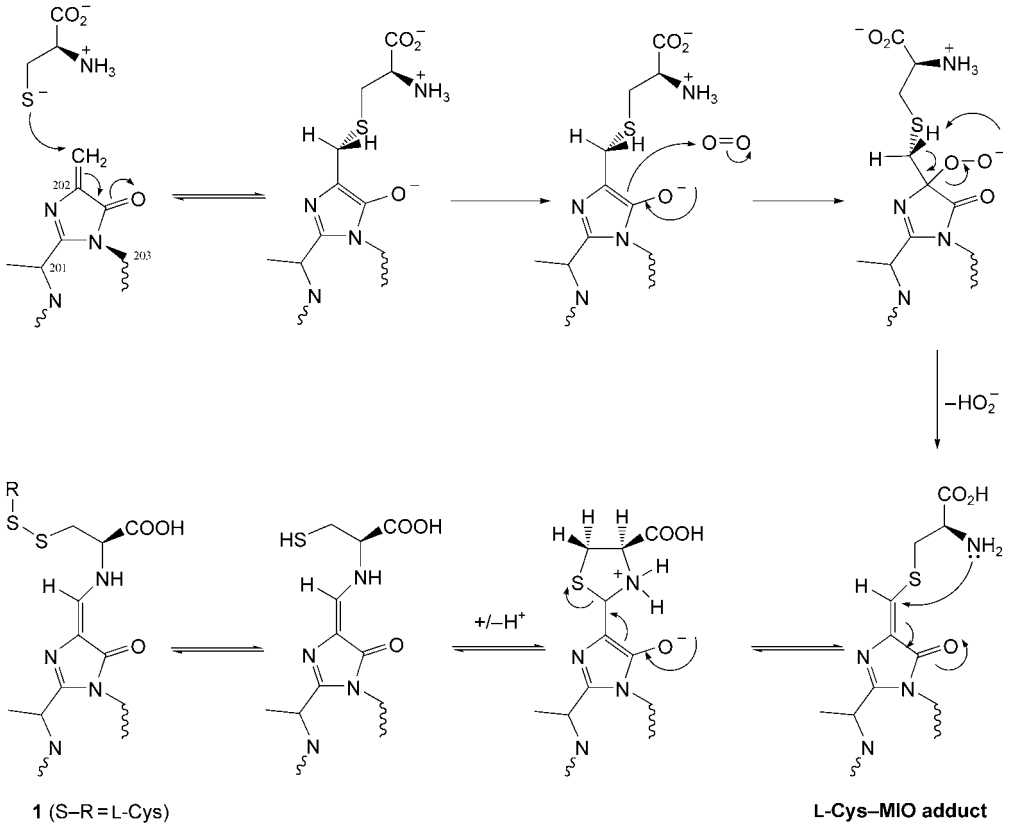
1: S–R= Cys, R'= H : 335nm
2: S–R= Cys, R'= Gly-Ser-Val : 335nm
3: 332nm

Scheme 15. Chromophore groups in the isolated oligopeptides after treatment of the HAL protein with L-cysteine or after reaction with L-lysine followed by proteolytic digestion.

supports the previously favored mechanism, in which the α amino group of histidine is the nucleophile that reacts with MIO.[28,41–43] However, both research groups believe that the isolated chromophore is the product of a rearrangement, as illustrated in Scheme 16.[79] The initial addition of the thiolate group of cysteine to MIO affords a highly nucleophilic enolate, which, like in the photorespiration by the enzyme ribulose-1,5-bisphosphate carboxylase (rubisco),[80] reacts with dioxygen to give a peroxide anion. A vinylogous thioester formed in an electrocyclic reaction coupled with a 1,3-H shift from a C atom to an O atom then undergoes intramolecular aminolysis followed by disulfide formation with a further cysteine molecule.

The postulated rearrangement was supported by the observation of other proteolysis products. Merkel isolated the adduct from lysine and MIO as the main product (**3** in Scheme 15).[79a,c] Evidently the initially formed vinylogous thioester had undergone an intermolecular aminolysis with the ε amino group of lysine molecules present in the lysate as the products of extensive proteolysis. This explanation is consistent with the observation that the inhibited but intact protein shows an absorption maximum at $\lambda = 338$ nm, whereas for the isolated cysteine adduct $\lambda_{max} = 335$ nm was found, and for the lysine adduct $\lambda_{max} = 332$ nm.[79a,c]

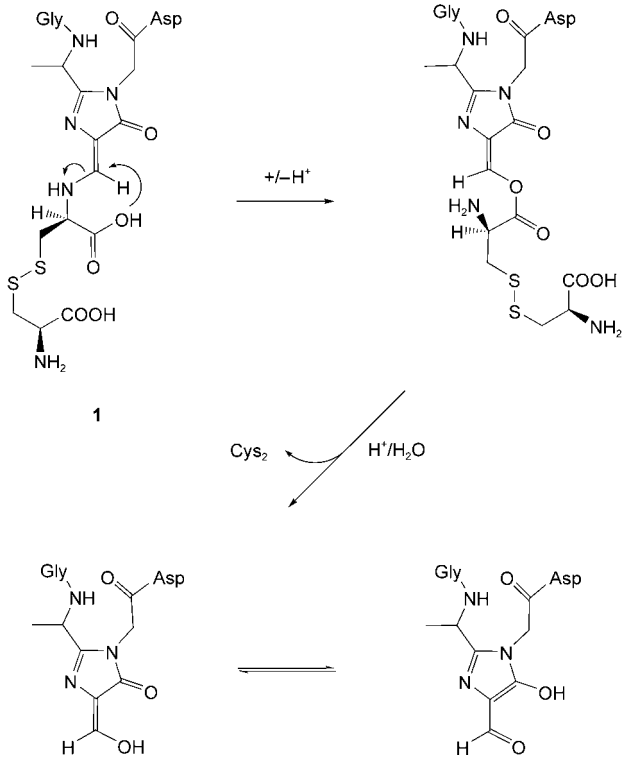
The isolated pure peptide containing the chromophore that absorbs at $\lambda = 335$ nm was slightly unstable to chromatography on a reversed-phase column under acidic conditions, as manifested by a smaller extra peak in the elution diagram. This degradation product was also isolated and characterized spectroscopically. From the spectral data (UV, NMR, MS) its



Scheme 16. Proposed mode of addition of L-cysteine to MIO followed by oxidation and rearrangement.

chromophore was identified as an MIO group with a hydroxy substituent on the exocyclic methylene group. The compound forms two tautomers and is reductone-like, like vitamin C. Its absorption maximum occurs at 310 nm, very close to that of MIO ($\lambda_{max} = 308$ nm). A possible mechanism for the formation of this degradation product involves a further rearrangement followed by ester hydrolysis (Scheme 17).[79a,c]

When L-[^{35}S]cysteine was used as an inhibitor of HAL, it was incorporated into the peptide containing the chromophore that absorbs at $\lambda = 335$ nm.[79a,c] This finding seems to contradict previous results.[68b,78a] A plausible explanation for this deviation could be that in the earlier studies the initially formed chromophore had already been converted into products devoid of cysteine. Recently, the X-ray crystal structure of the cysteine-inhibited HAL was determined, but the cysteine moiety was not observed despite very high resolution.[67] As the crystals had been prepared several months before they were submitted to X-ray crystallographic examination, rearrangement of the chromophore might have occurred, so that it was no longer possible to localize the cysteine unit.

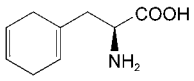


Scheme 17. Degradation of the chromophore **1** upon hydrolysis.

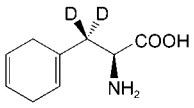
6.2. The Behavior of Substrate Analogues and Kinetic Isotope Effects in the PAL Reaction

In recent years a number of research groups have examined the above issues and interpreted the results in

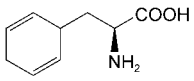
favor of the Friedel–Crafts-type mechanism.[81–83,94] However, before the new mechanism was proposed some relevant publications had appeared,[43,84] in which 2,5-dihydrophenylalanine (**4**, Scheme 18) was identified as a moderately good



2,5-dihydrophenylalanine, **4**



β-$^2H_2$-2,5-dihydrophenylalanine, **5**



1,4-dihydrophenylalanine, **6**

Scheme 18. Partially hydrogenated phenylalanine derivatives for the kinetic investigation of the PAL reaction.

substrate of PAL. In contrast to phenylalanine, the 3,3′-dideutero derivative **5** exhibited a primary kinetic isotope effect of about 2, thus indicating that the deprotonation is partially rate limiting.[43] It seems that the activation of the βH_{Si} hydrogen atom is less efficient in this substrate analogue, but still possible through the electrophilic attack of MIO at the double bond next to the side chain. No activation of the β hydrogen atoms is expected, however, in 1,4-dihydrophenylalanine (**6**). It was discovered that the Birch reduction of L-phenylalanine affords, beside 2,5-dihydrophenylalanine as the main product, some 1,4-dihydro-L-phenylalanine.[81] As expected, this compound was not a substrate for PAL but showed weak inhibitory properties.

On the assumption that the most difficult step in the PAL reaction is the Friedel–Crafts-type attack with concomitant dearomatization of the phenyl ring, it was anticipated that the substitution of the phenyl group for the nonaromatic cyclooctatetraenyl group could facilitate the reaction. Racemic cyclooctatetraenylalanine, however, showed a very low V_{max} value (0.6% of the value for L-phenylalanine).[85] A possible explanation for the low reactivity of this compound is that the different size and nonplanar geometry of the cyclooctatetraene ring may make the electrophilic attack by MIO more difficult.

Another interesting aspect is the synergistic inhibition of PAL by various phenols with glycine. Although glycine alone does not inhibit PAL at all and the phenols are only very weak inhibitors, together in 1:1 ratio they act as strong inhibitors.[83,94] For example, the combination *m*-cresol/glycine could be seen to correspond to *m*-tyrosine, which is an excellent substrate of PAL. *m*-Cresol and glycine together inhibit PAL competitively with a K_i value of 0.89 mM, which is more than twenty times lower than that observed for glycine or *m*-cresol alone.[94] Alunni et al.[83] analyzed this synergistic inhibition systematically and found that the pair phenol/glycine showed the strongest inhibition ($K_i = 0.014$ mM), whereas the pair *p*-cresol/glycine hardly inhibited PAL at all. Except for the pair *m*-cresol/glycine, all other pairs showed mixed inhibition.

The kinetic isotope effect was also studied with phenylalanine labeled with deuterium or tritium on the phenyl ring. Gloge et al. found a conventional secondary kinetic isotope effect of 1.09 ± 0.01 on the overall reaction rate with [$^2H_5$]phenylalanine.[94] Since a deuterated carbon atom changes its hybridization from sp^2 to sp^3 in the first putative chemical step, an inverse secondary isotope effect should be expected. However, this effect may be overcompensated by the influence of the four other deuterium atoms on the phenyl ring.

Lewandowicz et al. confirmed the normal secondary kinetic isotope effect with [$^2H_5$]phenylalanine through competitive methods, i.e. determination of the enrichment of the deuterated material in the unconverted substrate.[82] The obtained k_H/k_D value of 1.13 ± 0.02 was similar to that described by Gloge et al. (1.09 ± 0.01).[94] Lewandowicz et al. also measured secondary kinetic tritium-isotope effects with phenylalanine labeled with tritium at the *ortho* position of the phenyl group.[82] The isotope effect showed a strong dependence on the reaction progress. For the first 5% conversion the k_H/k_T value was 0.85; it then reached the normal value and was about 1.15 at 20% conversion. The authors interpreted these results in favor of the Friedel–Crafts-type mechanism. Simple semiempirical calculations supported this interpretation. It was concluded that with [$^2H_5$]phenylalanine both the Hanson/Havir and the Friedel–Crafts-type mechanism should give a conventional secondary kinetic deuterium-isotope effect, but that the k_H/k_T value should be higher for the latter.

6.3. *N*-Methylated L-Phenylalanines in the PAL Reaction

N-Methyl-L-phenylalanine, *N*-methyl-4-nitro-L-phenylalanine, and *N*,*N*-dimethyl-4-nitro-L-phenylalanine were investigated as substrates or inhibitors of PAL from *Petroselinum crispum*.[86] Although *N*-methyl-L-phenylalanine was a moderate substrate ($K_m = 6.6$ mM, $k_{cat} = 0.22\ s^{-1}$), no reverse reaction was observed with methylamine and (*E*)-cinnamate. The K_m value for ammonia in the reverse reaction with (*E*)-cinnamate was determined to be 4.4 M at pH 8.8 and 2.6 M at pH 10. *N*-Methyl-4-nitro-L-phenylalanine and *N*,*N*-dimethyl-4-nitro-L-phenylalanine did not act as substrates but instead showed strong inhibitory effects ($K_i = 130$ and 8 nM, respectively).[86] This finding can be better interpreted in terms of the Friedel–Crafts-type mechanism than with the Hanson/Havir mechanism.[28]

Molecular modeling of *N*-methyl- and *N*,*N*-dimethyl-4-nitro-L-phenylalanine in the orientation that corresponds to the Friedel–Crafts-type mechanism[86] into the active site of PAL[74] demonstrated that the nitrated aromatic rings fit well into the apolar binding pocket. On the other hand, the increased gas-phase proton affinities of *N*-methyl- and *N*,*N*-dimethyl-L-phenylalanine relative to that of L-phenylalanine[87] indicate that the *N*-methylamino and *N*,*N*-dimethylamino moieties might be more strongly bound than the nonmethylated groups. Moreover, if the 4-nitro moiety on the

aromatic ring hinders the addition to MIO, the *N*-methylated group will remain anchored to Tyr100, thus keeping the β H_{Si} hydrogen atom[76] far from the enzymatic base Tyr348. These effects may together account for the strong inhibition.

In contrast, if one considers that 4-nitro-L-phenylalanine reacts with both wild-type PAL and the MIO-free mutant Ser202Ala,[61] and that *N*-methyl-L-phenylalanine is a moderate substrate for wild-type PAL,[86] a faster reaction would be expected by the E_1cB route for 4-nitro-*N*-methyl-L-phenylalanine. An electron-withdrawing group at 4-position of the phenyl ring would facilitate the deprotonation from the EA′ state (Scheme 3) and also stabilize the developing carbanion in the EC state.

7. Use of the Reverse HAL and PAL Reactions in Biocatalysis

The synthesis of enantiomerically pure natural amino acids and their non-natural derivatives and analogues is an important goal in synthetic chemistry. For example, the pharmacophores of protease inhibitors, an extremely important class of pharmaceuticals against HIV, influenza, and human cytomegalovirus, have a phenylalanine-like architecture.

As the ammonia-lyase reactions proceed by the stereodestructive elimination of ammonia from L-amino acids, the D-amino acids could in principal be produced by the enantioselective removal of the corresponding L-amino acids from the racemate. However, the stereoconstructive nature of the reverse reaction (the enantioselective addition of ammonia to α,β-unsaturated acids) made this approach more attractive for the preparation of amino acids by biotransformations.[88]

The reversibility of the HAL reaction was recognized about four decades ago.[89] Under extreme reaction conditions (4M NH_4OH, pH 10) HAL can catalyze the reverse (amination) reaction in vitro.[90] The synthetic utility of HAL is quite restricted, because it reacts with only a limited number of analogues, such as 5-nitrohistidine and 5- or 2-fluorohistidines.[57,91] However, it was recently reported that HAL can be used for the production of a wider selection of aromatic L-amino acids from the corresponding acrylic acid derivatives.[92]

More than 20 years ago it was recognized that PAL also catalyzes the enantioselective addition of ammonia to aryl acrylic acids when the ammonia concentration is increased to 5M.[93] Furthermore, L-phenylalanine ammonia-lyase tolerates a broader, more structurally diverse range of substrates than HAL, while strictly maintaining the enantioselectivity of the ammonia addition. This broader substrate tolerance—in addition to the demand for structures derived from phenylalanine in protease inhibitors—makes PAL a valuable tool for the preparation of enantiomerically pure amino acids from achiral acrylate precursors. Methods for PAL-catalyzed biotransformations have been elaborated for the enantioselective synthesis of all pyridinylalanine isomers,[94] 5-pyrimidinylalanine and several fluoro- and chlorophenylalanines,[85,95] and other substituted aryl alanines[85] (Table 5). Various aryl alanines were prepared in enantiomerically pure form (>99% *ee*) by PAL catalysis in moderate to almost quantitative yields.

Table 5: Synthesis of enantiomerically pure L-phenylalanine analogues by PAL catalysis.

With the whole cells of *Rhodotorula graminis* as the PAL source, no reaction was observed when 4-chloro-, 3,4-dichloro-, 2,4,6-trichloro-, 4-bromo-, 4-methyl-, 4-formyl-, 4-amino-, 4-nitro-, or 2-hydroxyphenylacrylate, naphth-2-ylacrylate, or furan-3-ylacrylate were tested as substrates.[95] However, when the differences between *Pc*-PAL and *Rt*-PAL in the active site region are considered (see Section 5.2), it seems reasonable that there may be slight differences in the substrate tolerance of yeast and plant PAL enzymes.

More recently, a PAL enzyme of plant origin was found to be a useful reagent for the asymmetric synthesis of non-natural amino acids.[96] PAL can also be catalytically active in organic solvents, such as *n*-octanol.[97]

Enzymes can not only be used for synthetic processes as single biocatalysts. Combinatorial biosynthetic approaches can also be designed for the synthesis of natural products and for the construction of libraries of non-natural analogues of natural products. The usefulness of this strategy was demonstrated with synthesis of the chalcones naringenin and pinocembrin from L-tyrosine and L-phenylalanine, respectively, by recombinant *E. coli* with an artificial gene cluster assembled from the PAL gene of the yeast *Rhodotorula rubra* and the genes that code for chalcone isomerase and chalcone synthase of other organisms.[98]

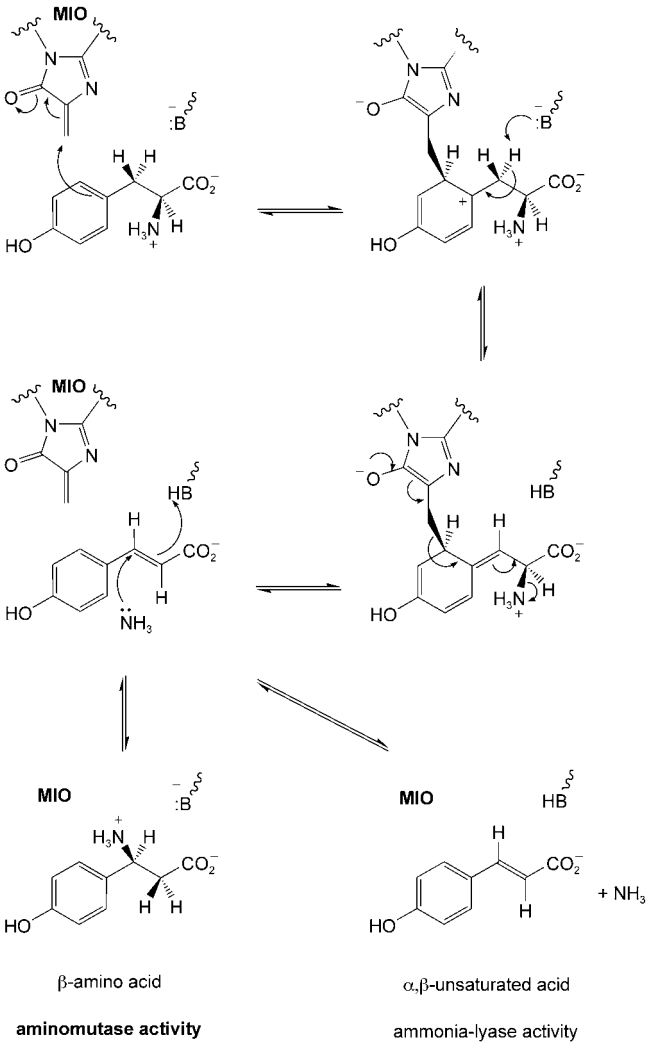
8. Tyrosine 2,3-aminomutase: Another MIO Enzyme

A number of ammonia-lyases[88] and aminomutases use different cofactors and mechanisms. Ethanolamine ammonia-lyase, for example, is dependent on coenzyme B_{12}, as is β-lysine 5,6-aminomutase.[3] Both enzymes have radical intermediates. α-Lysine 2,3-aminomutase is a radical SAM (S-adenosyl-L-methionine) enzyme;[4] aspartate and methylaspartate ammonia-lyases do not require a cofactor.

Until recently HAL and PAL were the only enzymes known to contain the MIO group. Christenson et al. discovered another enzyme, tyrosine 2,3-aminomutase,[70] which contains the MIO group and uses a similar mechanism to that of HAL and PAL. The enzyme is produced by *Streptomyces globisporus*, and its product, (*S*)-β-tyrosine, is believed to be a precursor of the antibiotic C-1027, which shows potent anticancer and antimicrobial activity.[99] One portion of C-1027 is (*S*)-3-chloro-4,5-dihydroxy-β-phenylalanine, which is most likely formed from (*S*)-β-tyrosine, as 3,4-dihydroxyphenylalanine and 3-chlorophenylalanine are poor substrates of the isolated mutase.[70] The gene that codes for the mutase was isolated from *S. globisporus*, overexpressed in *E. coli*, and shown to have a high sequence homology with the HAL/PAL enzyme family.

Evidence for the presence of an MIO group in tyrosine 2,3-aminomutase has been provided in several ways: 1) The mutation of serine to alanine in the inner-peptide sequence Ala152Ser153Gly154 reduces the k_{cat}/K_m value by a factor of 640; 2) the UV difference spectrum between the wild-type enzyme and its Ser153Ala mutant shows an absorption maximum at ~310 nm; 3) nucleophiles such as $NaBH_4$ or KCN inhibit the mutase, but preincubation with L-tyrosine or 4-hydroxycinnamate protect the enzyme from inhibition; 4) the optimum pH value for the mutase reaction is about 8.8, similar to those for the HAL and PAL reactions.

Further mechanistic studies revealed that 4-hydroxycinnamate is an intermediate in the mutase reaction and that it is released slowly as a by-product of the reaction. In other words, tyrosine 2,3-aminomutase also displays ammonia-lyase activity. Normally, the mutase does not release the ammonia formed at the active site, but adds it to the intermediate 4-hydroxycinnamate at the β position. This second step is a Michael addition to a α,β-unsaturated acid derivative, and therefore the easier part of the overall reaction.[70] Interestingly, the mutase also exhibits β-tyrosine racemase activity, but α-tyrosine is not racemized. Thus, the readdition of ammonia to the Michael system is reversible and not enantiospecific. A mechanism for the L-tyrosine 2,3-aminomutase reaction is illustrated in Scheme 19.



Scheme 19. Proposed mechanism of action of L-tyrosine 2,3-aminomutase.[70]

The question arises as to whether there are still undiscovered MIO enzymes. Several mechanistic devices exist for the activation of the inert β position of carboxylic acids. Highly reactive radical species, such as 5′-deoxyadenosyl and glycyl radicals, can abstract protons from inert positions to form an activated substrate radical which can react further under enzymatic control.[1] Electrophilic activation is an alternative in all cases in which there is an aromatic ring at the adjacent position. There are a few examples for which it has still not been established definitively whether a radical or an electrophilic activation mechanism operates.

9. Conclusions and Outlook

Herein we have reviewed the elucidation of the mechanism by which the chemically difficult elimination of ammonia from histidine and phenylalanine is catalyzed by the corresponding ammonia-lyases HAL and PAL. These enzymes use the recently discovered superelectrophilic prosthetic group 5-methylene-3,5-dihydroimidazol-4-one to activate the nonacidic β hydrogen atoms of their substrates by a Friedel–Crafts-type attack at the aromatic ring. In the σ-complex generated, proton abstraction from the ring is prevented by excluding any bases in the binding pocket of the enzyme. Instead, the exocyclic proton is abstracted by an appropriately positioned enzymatic base. The exocyclic double bond formed in this way is the prerequisite for a concomitant process that involves the elimination of ammonia, rearomatization, and fragmentation. The MIO group is thereby regenerated, and the product, (*E*)-urocanate or (*E*)-cinnamate, is formed.

The above mechanism is supported by the results of several biochemical studies, as well as by the X-ray crystal structures of HAL and PAL, and modeling studies. Before these discoveries it was believed for thirty years that the prosthetic electrophile was dehydroalanine and that the α-NH_2 group of the substrate added to this Michael acceptor. This "old" mechanism was unsatisfactory for several reasons. It did not explain how the nonacidic β proton ($pK_a > 40$) could be abstracted by an enzymatic base, or why most amino acids do not inhibit HAL, but L-cysteine and L-homocysteine do. Finally, dehydroalanine itself is not a good Michael receptor, because the delocalization of the lone pair of electrons on the nitrogen atom decreases its electrophilicity.

Since the publication of the "new" mechanism and in particular of the X-ray crystal structure of HAL, a number of research groups have reported results that support the Friedel–Crafts-type mechanism, and no arguments against it have been published.

Recently, a new bacterial MIO enzyme with tyrosine 2,3-amino-mutase activity was discovered. We look forward to the discovery of further MIO enzymes.

We thank Dr. Csaba Paizs for his help with the preparation of the manuscript. J.R. thanks his former students for their enthusiastic involvement in the MIO project: Dr. Andreas Gloge, Dr. Birgid Langer (formerly Schuster), Dr. Martin Langer, Dr. Dietrich Merkel, Dr. Gaby Morlock, Dr. Andrea Pauling, Dr. Gunhild Reck, Dr. Dagmar Röther, Dr. Alexander Skolaut, Dr. Sandra Viergutz, and Dr. Karl-Heinz Weber. J.R. also thanks Professor Georg E. Schulz, Dr. Torsten F. Schwede, and Dr. Mathias Baedeker for the fruitful collaboration on the X-ray crystal structure of HAL and for a plasmid of the modified PAL gene.

We are grateful to Professor Nicholas Amrhein and Professor Klaus Hahlbrock, who gave us the antibody against PAL and the PAL gene from parsley, respectively. The excellent technical assistance of Ingrid Merkler and Stefanie Vollmer is also greatfully acknowledged.

The research at Karlsruhe was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Land Baden-Württemberg. L.P. thanks the Alexander von Humboldt Foundation for a fellowship and OTKA (T-048854) for financial support.

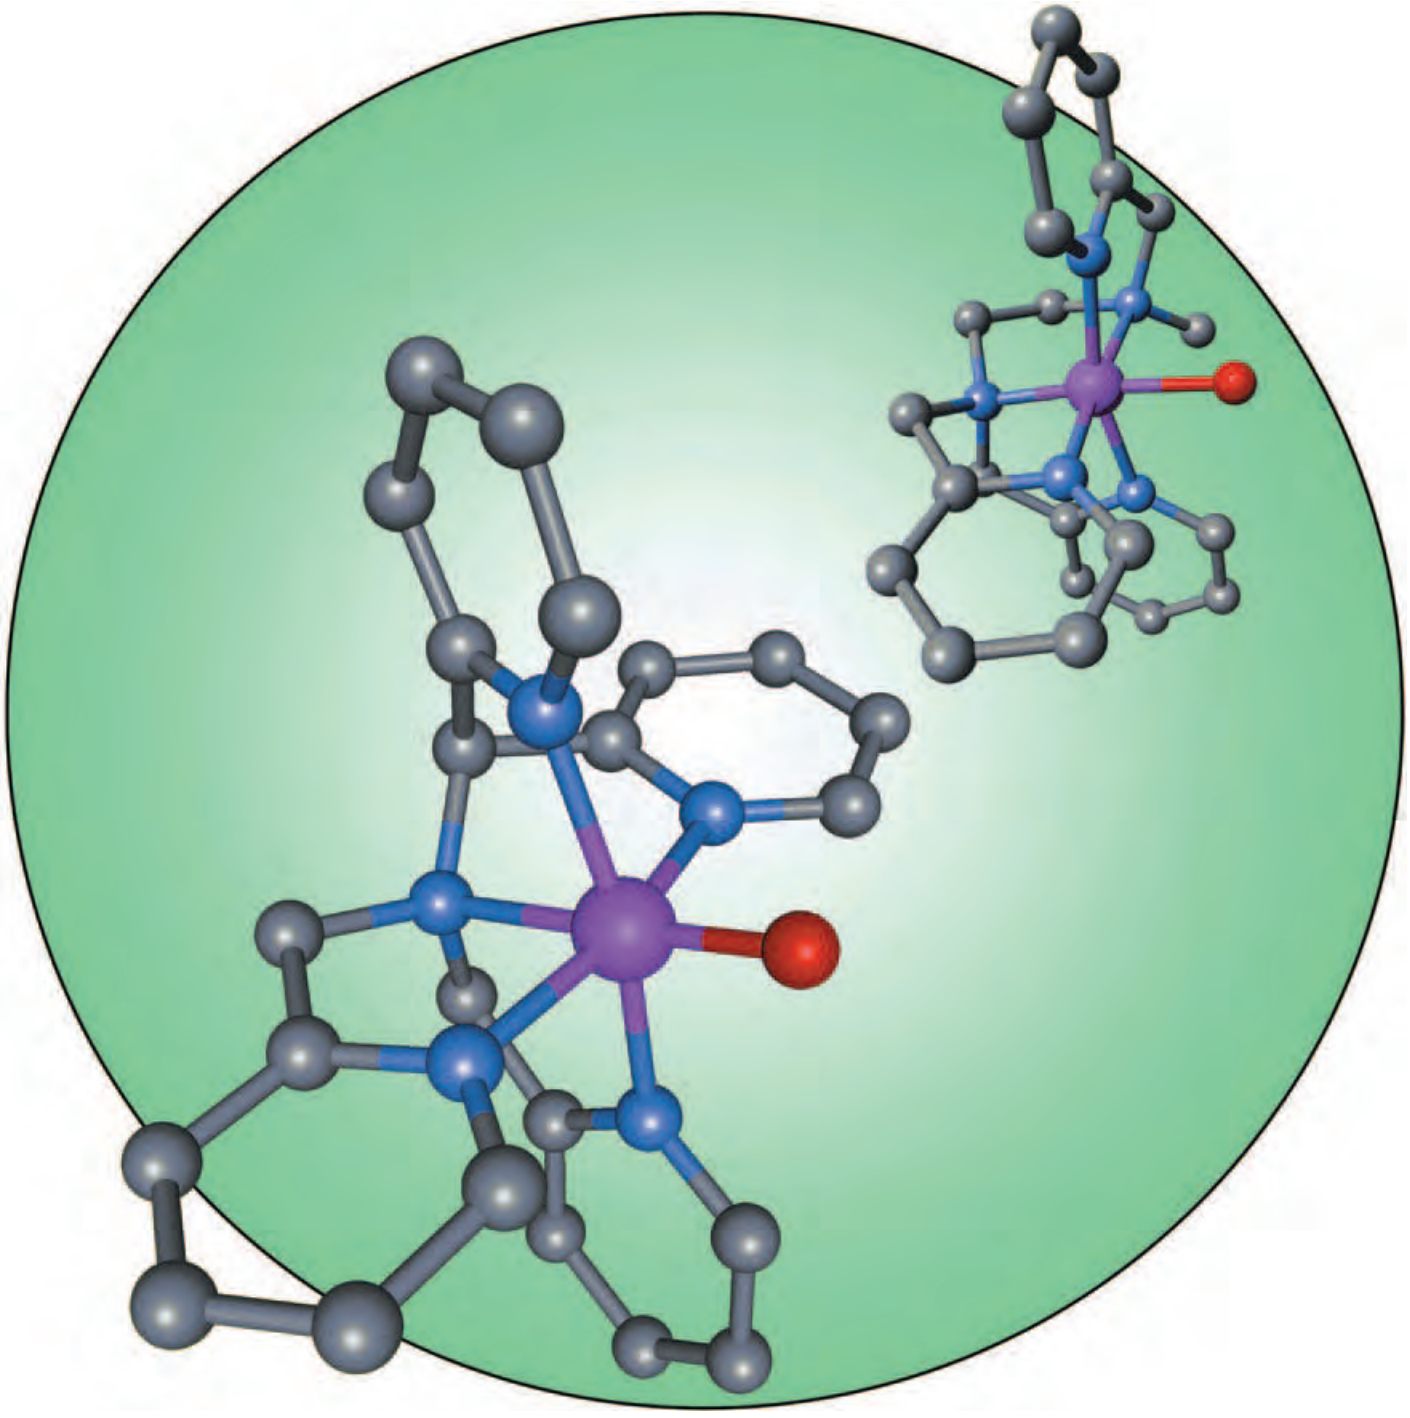
Communications



The structures of recently discovered non-heme oxoiron(IV) complexes of two pentadentate ligands have been deduced, one by X-ray crystallography and the other by ^{1}H NMR spectroscopy. Detailed experimental and theoretical studies are described by L. Que, Jr., C. J. Cramer et al. on the following pages.

  DOI: 10.1002/anie.200500485

Oxoiron(IV) Complexes

Structures of Nonheme Oxoiron(IV) Complexes from X-ray Crystallography, NMR Spectroscopy, and DFT Calculations**

Eric J. Klinker, József Kaizer, William W. Brennessel, Nathaniel L. Woodrum, Christopher J. Cramer, and Lawrence Que, Jr.**

Oxoiron(IV) species are frequently invoked as reactive intermediates in the oxygen-activation mechanisms of mononuclear nonheme iron enzymes.[1] In 2003, the trapping of the first nonheme oxoiron(IV) intermediate in the reaction of O_2 with the 2-oxoglutarate-dependent enzyme TauD, which was complexed with 2-oxoglutarate and its substrate taurine, was reported.[2–5] Contemporaneously, the first examples of well-characterized synthetic oxoiron(IV) complexes with nonheme ligand environments were also described.[6,7] The presumably reactive oxoiron(IV) units could be stabilized sufficiently by tetraaza ligands such as macrocyclic tetramethylcyclam (TMC) and tripodal tris(2-pyridylmethyl)amine (TPA) to allow their spectroscopic characterization at low temperature. In the case of the TMC complex, its considerable stability allowed it to be crystallized and its structure to be determined by X-ray crystallography. These results represented the first high-resolution structural data for any oxoiron(IV) complex, heme or nonheme. Subsequently it was found that the oxoiron(IV) unit could also be generated from precursor iron(II) complexes of pentadentate pentaaza ligands such as *N*,*N*-bis(2-pyridylmethyl)-*N*-bis(2-pyridyl)methylamine (N4Py) and *N*-benzyl-*N*,*N*′,*N*′-tris(2-pyridylmethyl)-1,2-diaminoethane (Bn-TPEN) by treatment with a peracid or PhIO. In fact, $[Fe^{IV}(O)(N4Py)]^{2+}$ (**1**) and $[Fe^{IV}(O)(Bn\text{-}TPEN)]^{2+}$ (**2**) could be produced in high yields at room temperature by reaction with excess solid iodosylbenzene in CH_3CN to afford solutions with significant thermal stability.[8] Herein, we report insight into the structures of **1** and **2** obtained from a combination of X-ray crystallography, NMR spectroscopy, and DFT (density functional theory) calculations, and their relative thermal stabilities.

Complexes **1** and **2** exhibit half-lives of approximately 60 and 6 h, respectively, at room temperature. The greater thermal stability of **1** allowed the isolation of single crystals for X-ray crystal structural analysis (Figure 1) to provide only the second high-resolution structure of an oxoiron(IV) complex. The X-ray crystal structure of **1** shows an Fe–O bond length of 1.639(5) Å, a value that is essentially identical to the length of 1.646(3) Å reported for the analogous bond in $[Fe(O)(TMC)(NCCH_3)](SO_3CF_3)_2$ (**3**).[6] Trans to the oxo ligand in **1** is the amine nitrogen atom that holds the pentadentate ligand together, with an Fe–N1 bond length of 2.033(8) Å, the longest metal–ligand bond in the molecule. The O1, Fe, and N1 atoms are nearly colinear with an O1-Fe-N1 angle of 178.6(3)°. Coordinated in the equatorial plane are the four pyridine nitrogen atoms, whose rings are aligned parallel to the Fe–O axis, and the iron atom lies 0.252 Å above the plane subtended by these four pyridyl nitrogen atoms towards the oxo ligand. Interestingly, the equatorial Fe–N bond lengths are on average 1.957(5) Å; these bonds are shorter than the corresponding equatorial bonds in **3** by 0.1 Å and reflect the stronger bonding ability of a pyridine moiety relative to a tertiary amine.

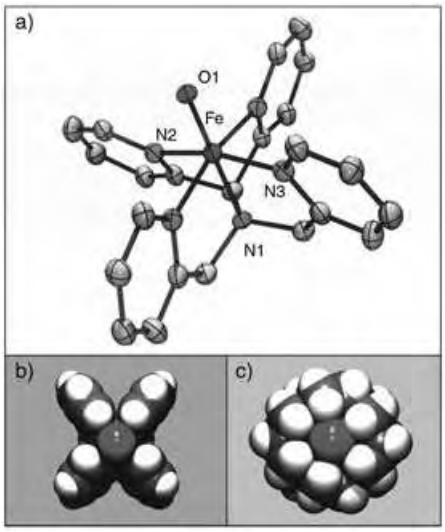


Figure 1. Molecular structure of **1** (a) and top views of space-filling models of **1** (b) and **3** (c). Metal–ligand bond lengths [Å] for **1**: Fe–O 1.639(5), Fe–N1 2.033(8), Fe–N2 1.964(5), Fe–N3 1.949(5).

Figures 1b and c compare the top views of space-filling models of **1** and **3** and reveal a large difference in the accessibility of the oxoiron unit in the two complexes. Whereas the hydrogen atoms of the TMC macrocycle nestle nicely around the oxo atom in **3** and restrict access,[6] the oxo group in **1** is much more exposed not only from the top of the molecule but also along channels that form between adjacent pyridine rings. This difference may rationalize the relative reactivities of the two complexes. While **3** is quite inert toward hydrocarbon substrates, at room temperature **1** can attack C–H bonds as strong as those in cyclohexane.[6,8]

Single crystals of **2** have not yet been isolated, so its structure must be deduced by alternative means. A recent EXAFS (extended X-ray absorption fine spectrum) study[9] revealed the presence of a short Fe–O bond of 1.67 Å and Fe–N bond lengths that average 2.00 Å, as expected, but no insight was gained into how the pentadentate ligand wraps around the metal center. The flexibility of the ligand requires three conformational isomers, if we neglect enantiomers, to be considered (Figure 2). Isomer **A** contains two pyridine rings that eclipse the Fe–O axis and a third that is perpendicular to it, as found in the structure of the iron(II) precursor.[9] In isomer **B** one ring eclipses the Fe–O axis and two are perpendicular to it, whereas in isomer **C** two rings are perpendicular to the Fe–O axis and the other is coordinated trans to the oxygen atom.

We found ^{1}H NMR spectroscopy to be a very useful technique to probe the structures of the nonheme oxoiron(IV) complexes, and the spectra of **1** and **2** are shown in Figure 3. The $S = 1$ iron(IV) centers of **1** and **2** have favorable electronic relaxation properties that give rise to relatively sharp and well-resolved, paramagnetically shifted proton resonances that span 200 ppm. The number of signals observed for **1** is consistent with the presence of mirror symmetry, as established from the solid-state structure. Two sets of pyridine resonances (β, β′, and γ) can be readily identified by a COSY experiment (see Supporting Information). The shift pattern for the protons of the pyridine rings is unique for the low-spin iron(IV) center, with one β proton shifted downfield and the β′ proton shifted upfield. In iron(II) and iron(III) pyridine complexes, both β protons are typically shifted downfield with comparable paramagnetic shifts.[10,11]

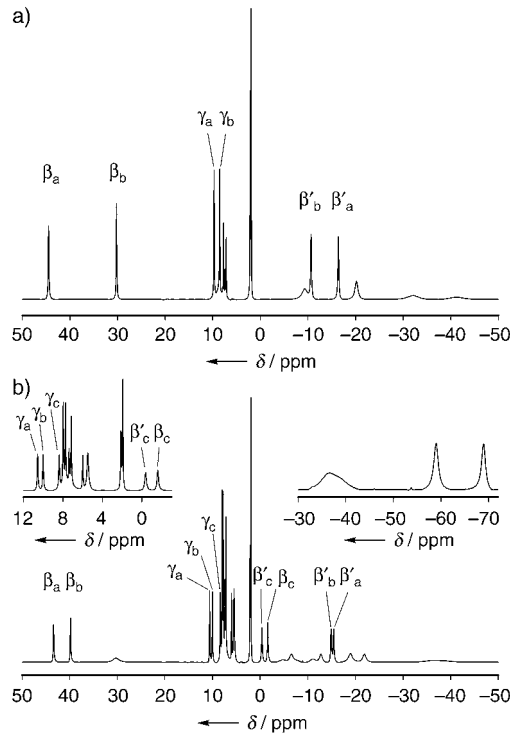

Figure 3. ^{1}H NMR spectra of **1** (a) and **2** (b, and insets) in CD_3CN. Peaks from pyridine ring protons are assigned based on cross peaks identified in COSY spectra. The left inset shows the expanded region near $\delta = 0$ ppm (0.5×) for **2** and reveals the third set of pyridine ring protons, while the right inset shows the $-30 > \delta > -75$ ppm region (10×) of **2**.

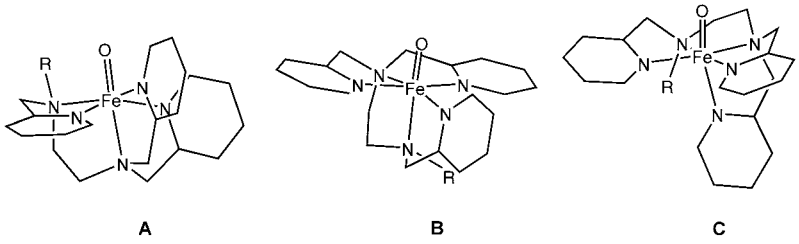

Figure 2. The three possible isomers (**A**–**C**) of $[Fe^{IV}(O)(R\text{-TPEN})]^{2+}$ complexes. R = Bn or Me.

Not surprisingly, the ^{1}H NMR spectrum of **2** is more complex as a result of the lower symmetry of this complex. Two sets of pyridine β, γ, and β′ protons are readily identified from their COSY cross peaks (see Supporting Information) and found at chemical shifts that are comparable to those found for **1**. Their integrations indicate that these peaks account for only two of the three pyridine rings in the complex. Examination of a second COSY spectrum with a narrower spectral width (see Supporting Information) reveals the β, γ, and β′ protons of the third pyridine. These protons exhibit smaller paramagnetic shifts and have a distinct shift pattern in which both β and β′ peaks are shifted upfield and the peak for the γ proton is shifted downfield. The spectrum of the corresponding 5-Me-Bn-TPEN complex **4** shows the disappearance of the β'_c proton, thereby leading us to assign the c set of pyridine protons to the unique pyridine on the Bn-TPEN ligand.

The presence of a pyridine ring with a unique shift pattern in **2** suggests that the Bn-TPEN ligand adopts a wrapping mode that corresponds to isomer **A** (Figure 2). The two pyridines that display similar shift patterns to those found in **1** would correspond to the two that are parallel to the Fe–O axis, while the pyridine that lies perpendicular to the Fe–O axis would give rise to the unusual shift pattern. The difference in their paramagnetic shifts can be easily rationalized by the fact that these pyridines must interact differently with iron d orbitals that have differing amounts of unpaired spin density.

To provide a theoretical foundation upon which to interpret our observations, DFT calculations were carried out to assess the relative energies of the three possible isomers of **2** (Figure 2). Of several models examined, the pure density functional BPW91 model provided an optimized structure for **1** that agreed well with crystallographic data (0.0957 Å root-mean-square deviation over all heavy atoms; see Supporting Information for results using all functionals). Primarily on this basis, BPW91 was chosen for the study of **2**. Table 1 provides Fe–O bond lengths and relative energies for all optimized structures and spin states. The triplet state is

Table 1: Relative BPW91 energies (E [kcal mol^{-1}]) for **2A**–**C** and Fe–ligand bond lengths (Å; for $S=1$ isomers only).[a]

	1[b]	**2A**	**2B**	**2C**
E ($S=1$)[c]		0.0	5.3	12.5
E ($S=2$)[c]		16.6	19.0	
Fe-O	1.639	1.640	1.643	1.645
Fe-N1	2.082 (amine, ax)	2.078 (amine)	2.010 (amine)	2.051 (amine)
Fe-N2	1.976 (py $\parallel$)	2.022 (py $\perp$)	2.040 (py $\perp$)	2.058 (py $\perp$)
Fe-N3	1.983 (py $\parallel$)	1.976 (py $\parallel$)	1.976 (py $\parallel$)	2.042 (py $\perp$)
Fe-N4		1.990 (py $\parallel$)	2.002 (py $\perp$)	2.104 (py, ax)
Fe-N5		2.132 (amine, ax)	2.191 (amine, ax)	2.004 (amine)
Fe-N_{av}	2.000	2.040	2.044	2.052

[a] See Supporting Information for Cartesian coordinates of the geometry-optimized structures of the three isomers **2A**–**C**. [b] Crystallographic bond lengths for **1** included for comparison. [c] Energy for the $S=1$ state of isomer **2A** set to zero. py = pyridine, ax = axial.

favored over the pentet state in each of the two lower-energy isomers (the pentet was not converged for isomer **C**), and all further discussion refers only to triplet states.

Of the three isomers of **2**, **A** is predicted to be lowest in energy, with isomers **B** and **C** lying 5.3 and 12.5 kcal mol^{-1} higher in energy, respectively.[12] When the iron atom is removed and the relative energies of the frozen ligands are computed at the same level of theory, the relative energies of **A**, **B**, and **C** are found to be 1.0, 0.0, and 2.4 kcal mol^{-1}, respectively. Thus, the relative energies of the iron complexes do not derive from differences in steric energy in the supporting ligand but rather from interactions of the ligand with the Fe=O moiety.

Examination of the data in Table 1 suggests that the metal–ligand bond lengths rationalize the relative stabilities of the three isomers of **2**. Equatorial pyridine ligands aligned parallel to the Fe=O axis always have shorter Fe–N bonds than those aligned perpendicular to the Fe=O axis. This shorter distance contributes to the ability of parallel pyridines to stabilize the high-valent iron center through electron donation better than perpendicular pyridines, as judged by second-order perturbation theory in the natural bond orbital (NBO) basis. [13,14] The difference in Fe–N bond lengths is easily explained by the greater steric demand of the α hydrogen atoms of the pyridines that lie perpendicular to the Fe=O axis. Thus, among the three isomers of **2**, the most stable isomer **A** has one pyridine ring perpendicular and two rings parallel to the Fe=O axis to give rise to an average bond length of 2.040 Å over all Fe–N bonds. The less-stable isomers, by contrast, both contain *two* perpendicular equatorial pyridines, with the remaining ring either parallel (**B**) or trans to the oxo atom (**C**). These differences give rise to average Fe–N bond lengths of 2.044 and 2.052 Å, respectively. For comparison, all four of the pyridine rings in the N4Py complex **1** are oriented parallel to the Fe=O axis with an average Fe–N bond length of 2.00 Å and thereby it achieves maximum stabilization among the four structures. Not surprisingly, the half-life of **1** is an order of magnitude greater than that of **2**.

In summary, we have gained structural insight into novel oxoiron(IV) complexes with pentadentate pentaaza ligands by a combination of X-ray crystallography, NMR spectroscopy, and DFT calculations. The X-ray structure of **1** establishes the metrical parameters for this complex and shows the expected ligand topology in which all four pyridines are oriented approximately parallel to the Fe=O axis. In the absence of a crystal structure for **2**, NMR spectral data and DFT calculations clearly favor **2A** as the most stable isomer. We thus conclude that pyridine rings aligned parallel to the Fe=O bond contribute significantly to the stability of the oxoiron(IV) unit and allow such complexes to be observed at room temperature.

Experimental Section

Complexes **1** and **2** were generated from their respective iron(II) precursors following reported procedures,[8] while the generation of **4** followed a similar protocol. The synthesis for the precursor to **4**, [(5-Me-Bn-TPEN)Fe^{II}(OSO_2CF_3)](SO_3CF_3), is described in the Supporting Information.

^{1}H NMR spectra were recorded on a Varian Inova VI-500 spectrometer at ambient temperature, with reported ^{1}H NMR chemical shifts (δ [ppm]) referenced to residual solvent peaks. The COSY spectrum for **1** was collected using 256 points in t_1 with a spectral width of 54.3 kHz and a delay of 30 ms. The COSY spectra for **2** were collected using 256 points in t_1 with spectral widths of 47.8 and 19.7 kHz and a delay of 30 ms.

X-ray crystal structure data for **1**: Blue needles were isolated upon layering pentane on a solution of **1** in acetonitrile: $C_{27}H_{27}Cl_2FeN_7O_9$, monoclinic, space group Cm, $a=11.955(4)$, $b=17.954(5)$, $c=7.084(2)$ Å, $\beta=93.708(5)°$, $V=1517.3(8)$ Å^3, $Z=2$, $\rho_{calcd}=1.577$ g cm^{-3}, crystal dimensions: $0.32\times0.12\times0.04$ mm^3; Bruker CCD diffractometer; $Mo_{K\alpha}$ radiation, 173(2) K; $2\theta_{max}=50.1°$, 5606 reflections, 2669 independent ($R_{int}=0.0454$), direct methods; multiscan absorption correction ($\mu=0.739$ mm^{-1}); refinement (on F^2) with SHELXTL-Plus (version 5.10), 301 parameters, 126 restraints, $R_1=0.0499$ ($I>2\sigma$) and wR_2 (all data) = 0.1178, GOF = 1.046, max/min residual electron density: 0.435/−0.211 e Å^{-3}. CCDC 261401 (**1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. See Supporting Information for additional experimental details.

Computational Methods: The molecular geometry of [Fe(O)(N4Py)]$^{2+}$ ($S=1$) was optimized at the unrestricted BLYP,[15,16] BPW91,[16,17] BP86,[15,18,19] BP86-VWN5,[15,19,20] B3LYP,[15,16,19] B3PW91,[15,17] B3P86,[15,19,20] and BHANDH[15] levels using the LACVP*[21–23] effective core potential on iron and the 6-31G**[24–29] basis set on all other atoms. The BPW91 model was found to provide good agreement with the known crystal structure and was chosen on this basis for modeling Fe(Me-TPEN) (in Me-TPEN, the benzyl group of Bn-TPEN is replaced by a methyl group). Three conformers of Fe(Me-TPEN) were optimized at this level for the $S=1$ spin state, and in the two lowest energy cases for the $S=2$ spin state. All structures were verified as minima by computation of analytical vibrational frequencies. Calculations were performed using Jaguar 5.0[30] and Jaguar NBO Version 5.0.[31]

Fluorescence Imaging

Pyrromethene Dialkynyl Borane Complexes for "Cascatelle" Energy Transfer and Protein Labeling**

Gilles Ulrich, Christine Goze, Massimo Guardigli, Aldo Roda, and Raymond Ziessel**

The design of strongly luminescent probes is a thriving subject which finds applications in electroluminescent devices and fluorescence technology.[1,2] Fluorescent labels and probes have found widespread uses in biomedicine, polymer science, and sensor chemistry.[3,4] One of the most promising classes of dyes is that of cyanines stabilized with BF_2 fragments, such as 4,4-difluoro-4-bora-3a,4a-diaza-s-indacene (Bodipy) derivatives.[5] These non-ionic, stable molecules have exceptional optical and luminescence properties,[6] and a wide range of dyes have been engineered by modification of the pyrrole substituents.[7] To date, chemical modification of the BF_2 fragment with ethynylaryl modules has rarely been attempted.[8]

Frequently encountered deficiencies in the use of Bodipy derivatives are the small Stokes shifts ($\Delta\lambda \approx 600\ cm^{-1}$) between the lowest energy absorption band and the emission band, and the quenching of their fluorescence on conjugation to proteins.[5] Larger Stokes shifts would be advantageous in simplifying simultaneous excitation and emission detection, since background interferences are reduced and wide-band excitation and emission filters may be used, thus increasing the intensity of the fluorescence signal. Also desirable is the enhancement of this signal intensity by incorporation of a chromophore active in the region 350–370 nm where Bodipy species do not absorb, pyrene is an example of such a chromophore.[9]

Herein, we describe an elegant method for increasing the Stokes shift of Bodipy derivatives and minimizing fluorescence quenching after bioconjugation. This approach involves functionalization of the Bodipy core by binding ethynylpyrene entities directly to the boron center. Irradiation of the pyrene chromophore results in exclusive emission from the Bodipy core as a result of efficient intramolecular energy

  DOI: 10.1002/anie.200500808

transfer, so that these new dyes function as a small cascade device or "cascatelle". Further functionalization enables ready attachment of the dyes to biopolymers such as proteins.

While trigonal alkynylboranes are well-known,[10] tetrahedral species are rare[11] and herein we describe the first such compounds in which two ethynyl units are bound to the boron center of a bora-indacene (Figure 1). The syntheses of **1** and **2** involve the displacement of fluoride from boron by 4-lithioethynyltoluene and 1-lithioethynylpyrene, respectively. Both compounds are obtained in satisfactory yield (**1** 62%, **2** 30%), and have been characterized by chemical analyses, full spectroscopic measurements, and crystal structure determinations.

The structure determinations (Figure 1) show an almost exact tetrahedral geometry for the sterically congested boron atoms. In both, the N-B-N angle is 106°, while the C-B-C angle for **1** is 115° and for **2** is 111°. The B–C and C≡C bonds fall in the ranges 1.58–1.60 Å and 1.18–1.20 Å, respectively. The B–C distances are longer than those of trigonal tris(3,3-dimethyl-1-butynyl)borane but similar to those in its tetrahedral pyridine adduct.[12]

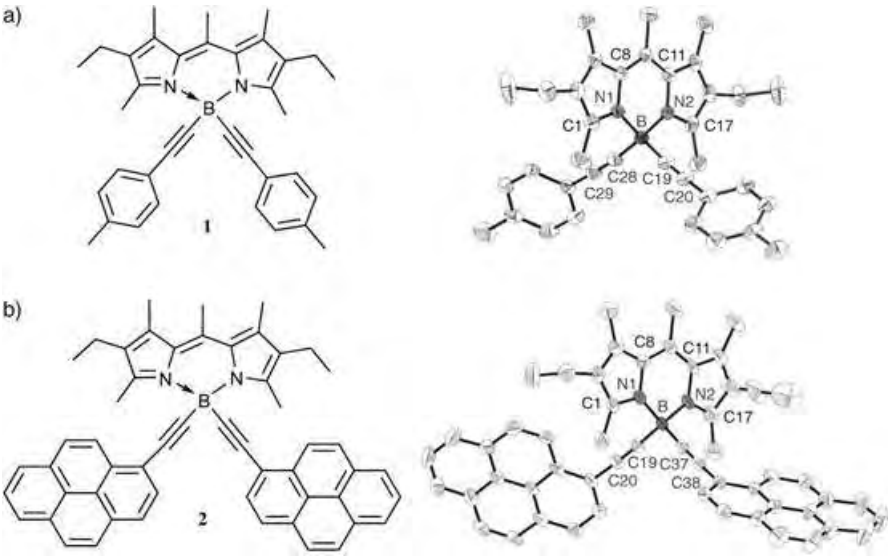

Figure 1. Structures of **1** (a) and **2** (b). Selected bond lengths [Å] and angles [°]: for **1** B-C28 1.589, B-C19 1.595, B-N1 1.562, B-N2 1.557, C28-C29 1.206, C19-C20 1.204, N1-C1 1.350, N1-C8 1.403, N2-C17 1.351, N2-C11 1.401; C28-B-C19 114.76, C28-B-N2 108.67, N1-B-N2 106.05, N2-B-C19 109.62. For **2** B-C19 1.603, B-C37 1.585, B-N1 1.563, B-N2 1.565, C20-C19 1.187, C37-C38 1.194, N1-C1 1.352, N1-C8 1.402, N2-C17 1.344, N2-C11 1.403; C19-B-C37 111.61, C19-B-N1 108.18, N1-B-N2 105.89, N2-B-C37 109.64, N2-B-C19 110.99.

The electronic absorption spectra of **1** and **2** reflect the presence of the separate Bodipy and ethynylaryl units (Figure 2). A strong band at 516 nm is attributed to the $S_0 \rightarrow S_1$ Bodipy transition, while a second weaker and broader band at 371 nm (clearly seen in Figure 2a) is typical of the $S_0 \rightarrow S_2$ transition.[13,14] Peaks observed at higher energies may be confidently assigned to the spin-allowed π–π* transitions of the ethynyl ($\lambda \approx 320$ nm) and toluyl ($\lambda \approx 265$ nm) groups (Figure 2). For **2**, a strong absorption at 330–370 nm, partially overlapping the $S_0 \rightarrow S_2$ Bodipy transition, is assigned to the ethynylpyrene unit.[9] The spectroscopic data are summarized in Table 1.

When excited at 516 nm, both **1** and **2** emit strongly, with high fluorescence quantum yields, in the region 535–540 nm. The radiative rate constants have values close to 1.5×10^8 s^{-1}. For **2**, excitation in the pyrene absorption band did not lead to pyrene emission but instead to emission characteristic of the indacene core. The fluorescence excitation spectrum matches the absorption spectrum, indicating that there is an efficient energy transfer from the pyrene to the Bodipy moiety. The quantum yield measurements are consistent with an efficiency close to 100% for this transfer. The result is that there are virtual Stokes shifts of approximately 10^4 cm^{-1}.

To devise a means of grafting these highly fluorescent units onto biopolymers, we synthesized an indacene derivative bearing an iodophenyl substituent on the *meso* position. Substitution of the iodine by a carboxybutylethynyl unit ultimately led to the activated ester **3d** (Scheme 1), which was expected to be reactive towards protein amino acid side-chain nucleophiles such as the terminal amino group of lysine (Scheme 1).[16]

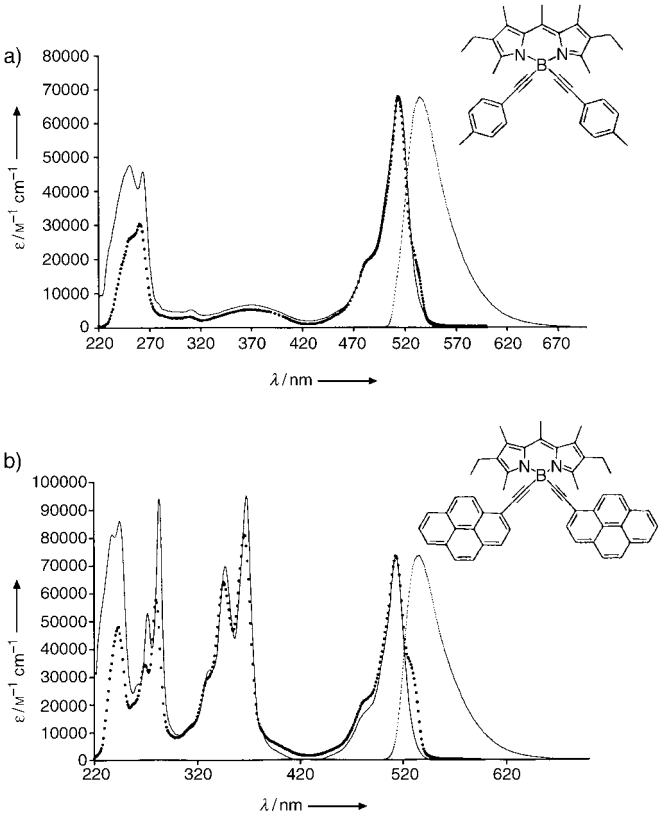

Figure 2. Absorption (——), emission (-----), and fluorescence excitation spectra (•••••) for compounds **1** (a) and **2** (b) in dichloromethane solution. Emission spectra were obtained upon excitation in the ethynyltoluyl moiety absorption (252 nm) for **1** and in the ethynylpyrene moiety absorption (371 nm) for **2**, while fluorescence excitation spectra were measured upon emission at 535 nm.

Table 1: Spectroscopic[a] data at 298 K for the new compounds.

succimimide (NHS) esters.[17] Indeed, it proved possible to attach multiple fluorescent tags to BSA using **3d** in various label/protein ratios (ranging from 2:1 to 10:1), in a 1:1 (v/v) water/DMSO solution. Characterization of the conjugates in terms of label/protein molar ratio was performed by means of UV/Vis absorption spectroscopy, under the assumption that the absorption spectra of the conjugates are the sum of the absorption spectra of BSA and the Bodipy dye and that these spectra coincide with those of the free BSA and **3e**, respectively (Figure 3).

The experimentally determined label/protein molar ratios of the conjugates were in good agreement with the label/protein molar ratio used in the conjugation reaction (Table 2), indicating a high reaction yield. These BSA conjugates essentially maintain the spectroscopic characteristics of the model compound **3e** (Scheme 1 and Table 1). The fluorescence emission of aqueous solutions of the conjugates shows maximum intensity at 544 nm (Figure 4), being slightly red-shifted in comparison to that of compound **3e** in dichloromethane. All the protein conjugates remain strongly fluorescent, with an efficiency of energy transfer from the ethynylpyrene chromophore to the indacene moiety similar to that found for **3e** (see Figure 3). The efficiency of the energy transfer from the pyrene to the indacene moiety drops for **3e** and the labeled BSA conjugates when compared to that of **3b**, which has an ester function. This drop is likely to be due to the presence of the amide function in **3e** and the labeled conjugates which provides a non-radiative channel for the deactivation process.[18]

The fluorescence quantum yield decreases slightly with the increase in the degree of labeling of the conjugates,

The demonstration of the suitability of derivative **3d** for protein labeling and the evaluation of the spectroscopic properties of its protein conjugates were performed using bovine serum albumin (BSA) as a model protein which has 59 lysine residues that can potentially react with *N*-hydroxy-

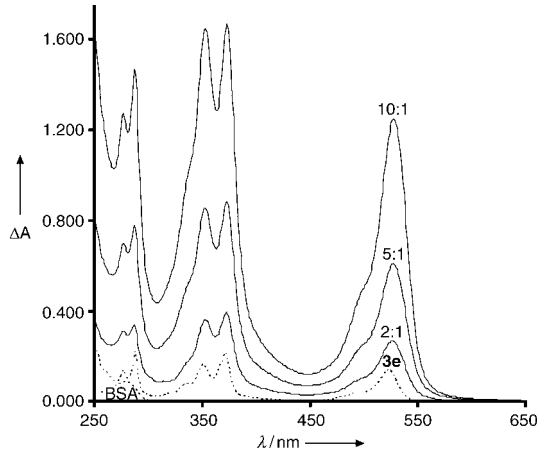

Figure 3. UV/Vis absorption spectra of the BSA conjugates of **3d** in water at a concentration of about 2.3×10^{-6} M and the BSA:**3d** ratios indicated; for comparison, the absorption spectra of BSA in water and of **3e** in dichloromethane at the same concentration are also shown (•••••).

Table 2: Label/protein molar ratios evaluated by UV/Vis spectroscopy and fluorescence properties of the BSA conjugates of **3d** in aqueous solution.

Conjugate	Label/protein molar ratio[a]	ϕ_F [b] [%]	η [c] [%]
2:1	1.9–1.8:1	75[d], 45[e]	61
5:1	4.3–5.2:1	63[d], 38[e]	61
10:1	8.9–9.9:1	49[d], 32[e]	67

[a] The values are the label/protein molar ratios of the conjugates evaluated from the absorption at 528 nm and from the comparison of the absorption of the conjugate at 280 nm with those of free BSA and **3d**. [b] Determined using rhodamine 6G ($\phi_F = 0.76$ in water[15]) as reference. [c] Efficiency of the energy transfer from the ethynyltoluyl or ethynylpyrene chromophore to the indacene moiety, calculated by dividing the quantum yield found by excitation in the chromophores by those found by excitation in the indacene moiety. [d] Upon excitation in the indacene moiety absorption at 528 nm. [e] Upon excitation in the ethynylpyrene chromophore absorption at 370 nm.

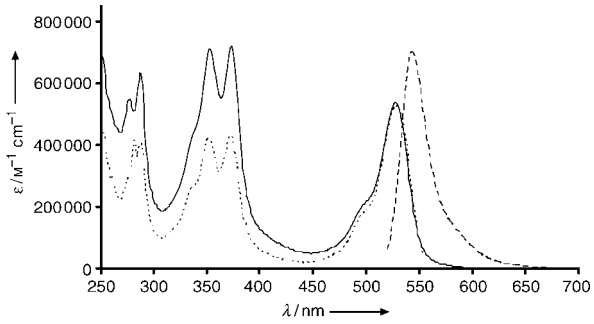

Figure 4. Absorption (——) and emission (-----) spectra of the 10:1 BSA conjugate of **3d** in water solution recorded upon excitation in the ethynylpyrene moiety absorption at 370 nm, and the fluorescence excitation spectra (••••) measured upon emission at 544 nm.

indicating a slight degree of self-quenching. However, the overall fluorescence intensity of the conjugates, as evaluated on the basis of their molar extinction coefficients and fluorescence quantum yields, still increases with the degree of labeling (Figure 5 and Table 2).

To compare the performance of the new Bodipy derivative with that of conventional fluorescent labels, fluorescence-imaging experiments were conducted. Figure 5 shows fluorescence images of spots containing the same amount of the BSA conjugates of **3d** or a fluorescein-labeled rabbit immunoglobulin G (IgG) with a 2.3:1 fluorescein/antibody labeling ratio (the fluorescein-labeled IgG and the 2:1 conjugate spots thus contain comparable amounts of fluorescent label molecules). The comparison of the fluorescence intensities of the spots indicates that, upon excitation in the UV spectral region, the BSA conjugates of **3d** are more efficient emitters than the fluorescein-labeled immunoglobulin (Figure 5a). The fluorescence emission of the BSA conjugates is stronger than that of the fluorescein-labeled IgG even when the latter is measured using fluorescein-specific excitation and emission filters (Figure 5b); the BSA conjugates are only weakly fluorescent using fluorescein filters because such filters do not match the absorption and emission bands of **3d**). This observation demonstrates that the peculiar absorption and emission properties of **3d** could be successfully exploited also using the conventional excitation sources used in fluorescence microscopy, such as mercury arc lamps. Indeed, their most intense emission line of such lamps (365–366 nm) is close to the maximum of the absorption band of the ethynylpyrene chromophore, whereas fluorescein has only a weak absorption at this wavelength.

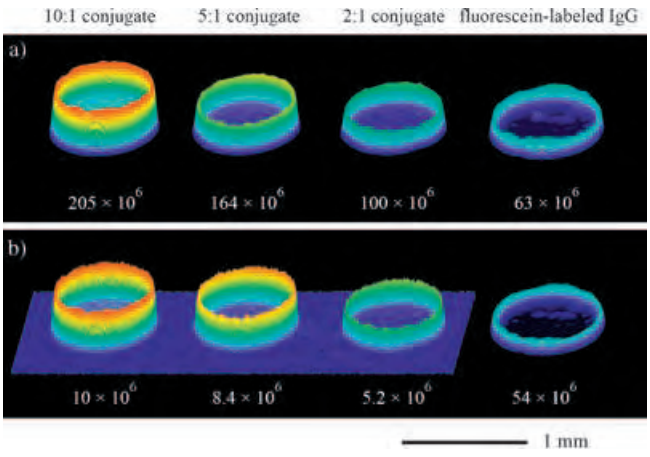

Figure 5. Pseudocolored 3D plots of fluorescence images of spots (diameter ≈ 800 μm) containing approximately 5×10^{-15} mol of the BSA conjugates of **3d** or a fluorescein-labeled rabbit immunoglobulin G. Spots were obtained using a manual microarrayer device, which employs an array of pins to transfer small volumes (ca. 3 nL) of solution onto microscope glass slides. Images were acquired with a standard epifluorescence microscope using either a) a wide-band UV excitation filter and a visible light emission filter or b) fluorescein-specific excitation and emission filters (because of their relatively low intensity, the images of BSA conjugate spots in (b) are shown using a different intensity scale). The images represent the actual fluorescence intensity of each spot, evaluated by integrating the signal over the whole spot area and expressed in arbitrary units.

The key feature of the present molecular design is the introduction of a supplementary chromophore linked by an ethynyl bridge to a tetrahedral boron atom. Such "Bodipyrene" dyes have three outstanding features: 1) relative ease of synthesis; 2) very large Stokes shifts resulting from an efficient, spin-allowed energy transfer from the excited pyrene subunit to the emitting state of the indacene center (a "cascatelle" process); 3) convenient functionalization to introduce an activated ester group suitable for grafting the dye to biopolymers. Very importantly, attachment of the dyes to a protein appears to produce only minor quenching effects and the singular other properties of the dyes are maintained. Fluorescence-imaging microscopy shows that these new labels are considerably superior to conventional fluorophores. The notion of a cascatelle process, clearly substantiated by the present work, is open to many avenues of development, leading to possibilities such as the multichromatic patterning of biomaterials using a single excitation source.

Crystal Growth

Control of Biomineralization Dynamics by Interfacial Energies**

*Ruikang Tang, Molly Darragh, Christine A. Orme, Xiangying Guan, John R. Hoyer, and George H. Nancollas**

The constructive interaction of an inorganic crystal phase with an organic matrix results in the formation of composite biomaterials that have an exceptional appearance and remarkable physical properties.[1–4] During this process, living organisms may make use of peptides and proteins to deterministically modify nucleation, growth kinetics, surface morphology, and facet stability.[5–7] This control can range from the most specific binding of protein or macromolecular functional groups, to a nonspecific control, in which the species in solution change the thermodynamic driving force of crystallization.[6–8] It is generally agreed that proteins which are most active in the mediation of biologically directed mineral growth contain acidic amino acid residues, specifically, regions rich in carboxylates that interact with mineral surfaces to influence both the crystal morphologies and rates of formation.[7,9–11]

The mechanisms of biomineralization have been the subject of extensive discussion. A widely accepted view is that the organic matrix or the other molecules control the crystal structure by epitaxial matching.[6,8] Another suggestion is that the adsorption of additives does not occur on crystal faces but rather on dislocation lines for crystal growth or dissolution, which influences their morphology and rates of movement.[11,12] In this step-control model, the altered crystal shape is the result of dynamic processes, and the resulting crystal geometries are based on these modified surface steps. Herein, we report on a new mechanism based on modifications that result from a change of solid–solution interfacial energies. In this third mechanism, the adsorption of structure-controlling molecules may not influence the step dynamics.

A constant composition (CC) method sensitive to changes at the nanomolar level provides reliable rates of crystal growth,[13] and the development of in situ fluid atomic force microscopy (AFM) enables the visualization of these processes in real time. Brushite (dicalcium phosphate dihydrate, $CaHPO_4{\cdot}2H_2O$) is one of the more important mineral phases that has frequently been invoked as a precursor phase in the biological formation of apatite.[14] It is readily crystallized from aqueous solutions and has been found in developing bone, immature dentins, and even in renal stones.[15] It is also a good model system for biominerals as it is very stable with respect to structural rearrangements and the crystals are large enough to be employed as substrates for dynamic AFM examination. Citric acid, $HOOC(CH_2)_2CH(COOH)(CH_2)_2COOH$, a carboxylate-rich molecule, is often considered as a model system for more complicated naturally occurring proteins.[11] Deficiencies of urinary citrate predispose one to renal stone formation.[16] We expect that the general trends found for this model brushite–citrate system will also hold for the other crystallizing biominerals.

Figure 1 shows typical CC curves for brushite growth in the absence and presence of citrate. The normalized brushite-growth rate R in the absence of an additive is almost unchanged at citrate concentrations below 1.0×10^{-6} M ($R = 4.20\pm0.15\times10^{-5}\,\mathrm{mol\,m^{-2}\,min^{-1}}$). However, the rate is reduced by about 50% ($R = 2.08\pm0.05\times10^{-5}\,\mathrm{mol\,m^{-2}\,min^{-1}}$) in the presence of 2.1×10^{-6} M citrate, and the degree of inhibition increases with increasing citrate concentration to $0.22\pm0.01\times10^{-5}\,\mathrm{mol\,m^{-2}\,min^{-1}}$ or 95% inhibition at a citrate concentration of 1.0×10^{-5} M. A further increase in citrate concentration does not change the CC growth curves, which suggests that the maximum degree of inhibition by citrate is about 95%. It is important to note that as the ratios of calcium

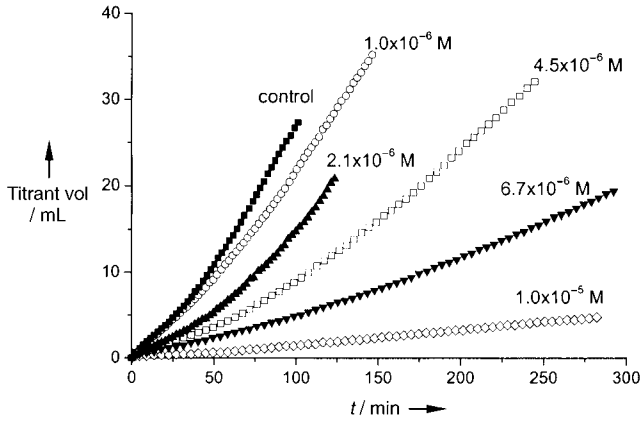

Figure 1. CC growth curves of brushite in the presence of citrate. The relative supersaturation with respect to brushite (σ) was 0.250; the pH value and ionic strength were 5.60 and 0.15 M, respectively; the curves have been normalized to the same seed mass of 10.0 mg. The growth rates are calculated from the gradient of these CC curves.

to citrate in the reaction solutions are always greater than 800, changes in the calcium concentration as a result of the formation of calcium citrate complexes can be ruled out. Thus, citrate effectively retards the growth of brushite crystals.

Typical platelike brushite crystals with smooth (010) surfaces served as suitable substrates for AFM (the Miller indices (*hkl*) denote a single plane and [*uvw*] specify a unique vector direction). In common with observations of other solution-based crystals growing near equilibrium,[11,12,17–19] parallel in situ AFM experiments, made under the same conditions as those for the CC experiments, show that brushite crystals in pure solutions grow on atomic steps generated at complex dislocation hillocks (Figure 2). These are triangular in shape with crystallographically distinct steps along the [101], [201], and [001] directions (Figure 2). In pure supersaturated solution, they have anisotropic spreading velocities in the order $[101] \approx [001] > [201]$, which is also reflected by the different terrace spacings between the growing steps.[11]

Qiu et al. and Orme et al. have proposed that the modification of biological mineralization (step control) is a result of additive binding at step edges to change the step velocities and morphologies.[11,12] However, in the present study of brushite biomineralization, neither the step morphology (Figure 2) nor the kinetics are affected by the presence of citrate even though it has been recognized as an effective inhibitor. At each of the citrate concentrations examined, neither defect nor the loss of defined direction for any of the three steps is observed in the AFM investigations performed in situ. Furthermore, the velocities of all three steps are not significantly changed in the presence of citrate (Figure 3). It is interesting that such a decrease in the crystal growth rate and change of crystal habit would be attributed conventionally to a decrease in step-spreading speed,[11,12] thus emphasizing that the pinned defects on the steps are consequences of the specific binding/adsorption of additives with resulting growth modification. Although the measured step velocities are not perfectly constant, the maximum variation is only about 10%. Nevertheless, in the parallel CC experiments, the bulk inhibition reaches more than 50%, so the conventional understanding of growth inhibition in terms of reduced step velocity does not apply.

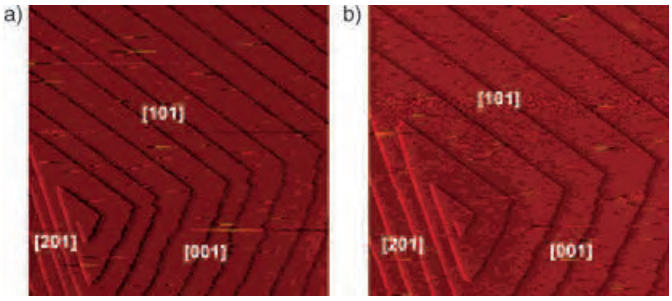

Figure 2. AFM frames of a growing (010)-brushite face: a) in the absence of citrate; b) in the presence of citrate. Introduction of citrate molecules reduces the brushite growth rate by changing the terrace spacing between the growth steps rather than the morphology or velocity of the steps, which results in a marked decrease of the step density on the growing surface.

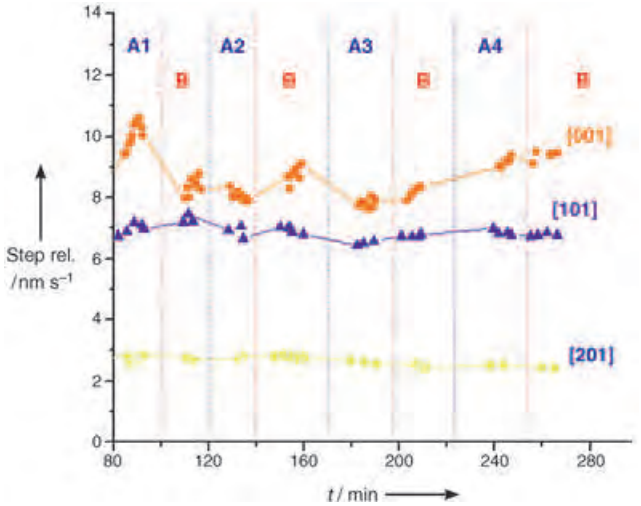

Figure 3. Evolution of the velocities of all three steps for crystals grown in solutions with and without citrate. All experimental conditions were kept constant, and there was no change in the spreading rates of steps in the absence and presence of citrate. The vertical red dotted lines indicate the time at which the crystals were exposed to a pure growth solution supersaturated with calcium phosphate (marked as B areas), while the blue dotted lines indicate the times at which the growth solutions contained citrate. In areas A1, A2, A3, and A4, the citrate concentrations were 1.0×10^{-6}, 5.0×10^{-6}, 1.0×10^{-5}, and 2.0×10^{-5} M, respectively.

It is noteworthy that citrate dramatically decreases the step density, especially for the [101] and [001] steps (Figure 2). It is well-known that the bulk growth rate R depends not only upon the step velocity but also upon the step density.[17–19] R is dominated by the two fastest growth steps ([101] and [001] steps), and the decrease in step density accounts for the observed inhibition in the bulk CC seeded growth experiments. Thus, the retardant effect is attributed to a decrease of step velocity. However, these modifications in step density are

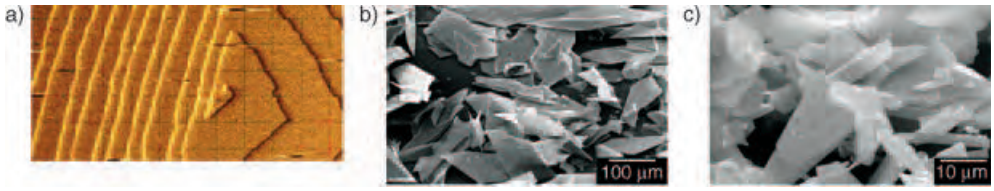

Figure 4. a) AFM image shows that inhibition effects (decreasing step density) are anisotropic; increasing citrate concentration (5.0×10^{-5} M) results in density reductions of fast growth steps [101] and [001], which are much more significant than that of the slow growth step [201]. In bulk crystallization experiments, the morphologies of grown brushite crystallites change from typical platelike (b) to rodlike (c) at high citrate concentrations (1.0×10^{-5} M) as a result of this anisotropic modification.

anisotropic; the ratio of [101] or [001] step spacings to those of [201] increases with increasing citrate (Figure 4a), which implies that the inhibition order is $[101]\approx[001]>[201]$. It follows that although [201] steps have the lowest growth rate in the control experiments, they are much less influenced by the presence of citrate than the [101] and [100] steps. With increasing citrate concentration and greater inhibition on [001] and [101] steps, the growth of [201] steps eventually dominates. At higher concentrations of citrate (1.0×10^{-5} M), the effective growth in the [001] and [101] directions decreases markedly and, as expected, the typical platelike brushite crystallites become rodlike (Figure 4b,c). The much lower inhibitory influence on the [201] steps also explains why citrate cannot fully inhibit brushite CC growth rates. Our results are in general agreement with the essential role of step modification in biomineralization. However, there is one important new feature: the results clearly show that biological systems may use step density rather than step velocity to change mineralization rates by modifying step energies while the velocity and morphology are virtually unchanged.

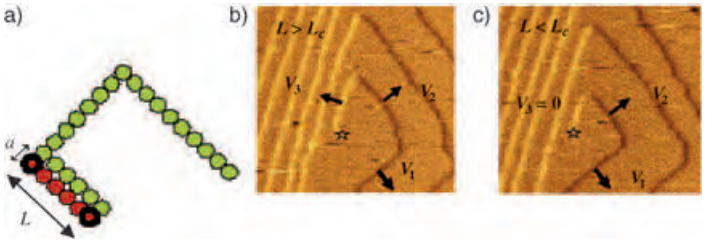

Figure 5. a) Enlargement of a dislocation source; the green represents the original step while the orange represents the new growth. The images in b) and c) show that the critical length is the minimum length at which the step will begin growing outward and the following step will begin growing. Adding biological additives such as citrate, and thus altering the energetics of the crystal formation, can in turn alter the shape of the crystal. The dislocation source on brushite surface is marked with a star.

Crystal growth in solution occurs at surface dislocations, which provide constant sources of steps.[17] Two terms that determine whether a step will grow or dissolve are related to the solution supersaturation S and the free energy of the step edge. The total change in free energy of the system is given by Equation (1). Here, n is the number of growth units adsorbing

$$\Delta G = -n\,\Delta\mu + 2a\gamma_{step} \qquad (1)$$

to the surface and $\Delta\mu$ is the change in chemical potential per growth unit during this phase transformation ($\Delta\mu \propto \ln S$). The second term relates the free energy of the step edge γ_{step} and the diameter a of the newly added growth units. The diagram (Figure 5a) shows the relationship between n and the step length such that $n = L/a$. The addition of molecules to a step becomes favorable at the point at which $\Delta G \leq 0$. Solving for L gives the critical length L_C, the length at which the step will begin growing outward and the following step will develop (Figure 5b,c). The spontaneous step growth does not occur until L_C is reached; rather, it will remain stationary or dissolve with no contribution to the growth rate. In this way, the mass of a brushite crystal increases as calcium and phosphate ions are deposited along steps on the crystal surfaces. These steps grow by spiraling outward from the dislocation sources on the surface. The relationship between terrace widths for the steps and the critical length L_C has been discussed.[18,19] Figure 2b suggests that citrate increases L_C, and in turn increases the period of time that it takes for a dislocation to create new step edges (this conclusion is supported by the nucleation study described below). As the step velocity is not inhibited by citrate, the terrace widths become larger and the step density is decreased on the growing (010) brushite surfaces. In Equation (1), when the supersaturation is kept constant, the only variable that can influence the value of L_C is the step energy, γ_{step}. It follows that γ_{step} is modified by the presence of citrate in the solution.

To further test this model, we have measured the interfacial tensions of brushite surfaces in the solutions by using a thin-layer wicking (TLW) method.[20] As predicted, the results, which are summarized in Table 1, show that the adsorption of citrate increases the interfacial energy γ_{SL} of brushite. In terms of an isotropic model γ_{step}, the mean value for all crystal-plane-step energies can be considered to be a

Table 1: Influence of citrate on brushite interfacial tension γ_{SL}. The increasing surface tension values and induction times (τ) in supersaturated brushite solutions with increasing citrate concentration are in agreement with Equation (3).

	γ_{SL} [mJ m^{-2}]	$\tau_\sigma = 0.450$ [min]
Control	4.53	≈400
2.0×10^{-6} M citrate	5.96	≈560
5.0×10^{-6} M citrate	7.06	≈760
1.0×10^{-5} M citrate	8.87	≈1100

function of γ_{SL}. In an analogous relationship between γ_{step} and L_C for steps at the microscopic level, the Kelvin–Gibbs equation [Eq. (2)] expresses the dependence, on a macro-

$$r^* = \frac{2\gamma_{SL}\,\Omega}{kT\ln S} \tag{2}$$

scopic scale, of the energy of formation of nucleated droplets of minimum radius r^* (assuming spherical shape) and surface tension γ_{SL}. In Equation (2), Ω is the volume occupied by each growth unit. It implies that spontaneous crystallization does not occur in bulk until critical conditions are reached, or the driving force (supersaturation) is sufficiently high. Rather, a metastable equilibrium condition persists during an "induction period" τ prior to crystal formation. If the simplifying assumption is made that τ is essentially concerned with classical nucleation, we can use Equation (3), in which, C_1 and

$$\ln\tau \propto \left[C_1 + C_2\frac{\gamma_{SL}^3}{k^3\,T^3\,(\ln S)^2}\right] \tag{3}$$

C_2 are independent constants. Equation (3) shows that the increase of the interfacial tension γ_{SL} following the introduction of citrate results in the inhibition of brushite growth and increase of the induction time.

Mann et al. suggested that the interaction of carboxyl groups with Ca^{2+} ions may increase the local concentration of a carboxylated additive in the vicinity of these cations, thereby lowering the energy barrier for nucleation and inducing the precipitation of calcium salts, such as calcium oxalate and calcite, in the "modified" supersaturated solutions.[1,6,8] In contrast, the CC nucleation results in the present study show that citrate dramatically increases the induction times and nucleation is retarded (Figure 6). The data in Table 1 further confirm the relationship between the induction time and surface tension as a function of citrate concentration. The data support the suggestion that citrate

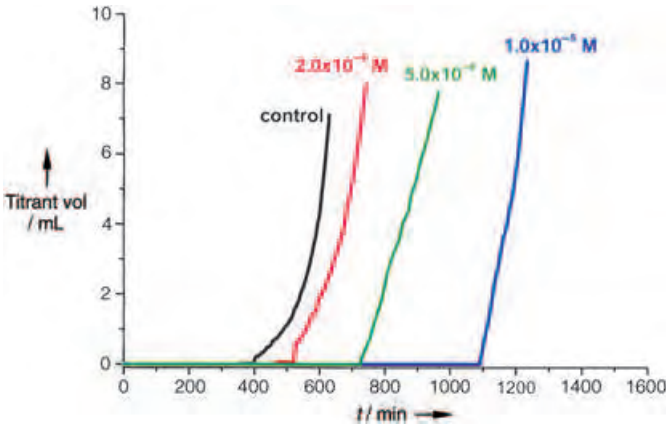

Figure 6. CC nucleation studies of brushite at different citrate concentrations. Although the carboxylate-rich molecules may bind to calcium ions in the solution to result in higher local concentrations near these molecules, the nucleation of brushite is not promoted by the mechanism of epitaxial control as suggested by Mann et al.[6,8] Instead, the longer nucleation induction times in the presence of citrate indicate that this carboxylate-rich compound is a nucleation inhibitor.

delays the formation of active step sources and increases the time for the formation of critical one-dimensional steps. In this process, interfacial energetic control plays the most important role as it can modify the critical conditions directly, as described by Equations (2) and (3). It is also well known that solution properties, such as surface tension, can be changed by the adsorption of additives. Although additives such as simple inorganic ions are unable to bind to the precipitated solid surfaces by an "epitaxial fit" or incorporate into the crystal lattice, the crystallization and morphology of the resulting crystals can be altered by these foreign additives. However, the interfacial energetic control can provide an interesting explanation of these modified crystallizations.

Our results suggest that the addition of biological growth modifiers alters mineral surface energies, thus changing the critical step length and delaying the formation of active steps for crystal growth. In bulk crystallization, these effects are manifested by longer induction times and delayed nucleation. We also conclude that the alteration of crystal habit may be because of the anisotropic modification of step densities in different growth directions and consequently changes of crystal geometry. These conclusions emphasize the importance of interfacial energies in biomineralization and their effect on critical step length. Approaches involving surface–step adsorption, for example by using a Langmuir model, may be misleading. This finding will be important for improving our understanding of the mechanisms of biomineralization.

Experimental Section

Constant composition for bulk-crystallization studies: This method can mimic in vivo biologically stabilized conditions for crystallization. Titrant solutions are added to maintain constant concentrations of the reaction solution during the experiments, and the kinetic growth results can be calculated from the addition rates of the titrant. Crystallization experiments were performed in double-walled Pyrex vessels with magnetic stirring (450 rpm). The supersaturated reaction solutions (200 mL) were prepared by mixing calcium chloride and potassium dihydrogen phosphate with sodium chloride to maintain the physiological ionic strength, $I = 0.15\ \mathrm{mol\,L^{-1}}$. The pH value was adjusted to 5.60 ± 0.01 with 0.1 M KOH solution. For experiments in the presence of additive, citrate solutions (1.00×10^{-4} or 1.00×10^{-3} M) were added prior to pH adjustment. Nitrogen presaturated with water vapor at 37 °C was passed through the reaction solutions to exclude carbon dioxide. The growth reactions were initiated by the introduction of brushite seed crystallites (10.0 mg); no seed was used for the CC nucleation experiments. Titrant addition was potentiometrically controlled using glass (Orion 91–01) and Ag/AgCl reference electrodes (Orion 900100). During crystallization, the electrode potential was constantly compared with a preset value, and the difference, or error signal, activated two motor-driven titrant burettes to maintain a constant thermodynamic driving force. Concentrations of the titrant solutions which were used to compensate reaction solutions for growth are given by Equations (4a) and (4b) for titrant burette no. 1 and Equations (5a) and (5b) for titrant burette no. 2. Here, W and T

$$T_{CaCl_2} = 2\,W_{CaCl_2} + C_{eff} \tag{4a}$$

$$T_{NaCl} = 2\,W_{NaCl} - 2\,C_{eff} \tag{4b}$$

$$T_{KH_2PO_4} = 2\,W_{KH_2PO_4} + C_{eff} \tag{5a}$$

$$T_{KOH} = 2\,W_{KOH} + 2\,W_{KOH} \tag{5b}$$

are the total concentrations in the reaction solutions and titrants, respectively, and C_{eff} is the effective titrant concentration with respect to brushite. During the reactions, slurry samples were periodically withdrawn and filtered, and the solutions were analyzed for calcium and phosphate. The total concentrations of calcium and phosphate remained constant to within $\pm 1.5\,\%$ during the experiments.

The growth flux rate R is calculated by using Equation (6), in

$$R = \frac{C_{eff}}{A_T}\frac{dV}{dt} \tag{6}$$

which C_{eff}, the effective titrant concentration with respect to brushite, indicates the molar amount of growth per liter of added titrants, dV/dt is the gradient of the CC titrant curves, and A_T is the surface area. The initial value of A_T was calculated from the specific surface area of the seed crystals, which was determined by Brunauer–Emmett–Teller (BET) nitrogen adsorption, and subsequent values were estimated from the growth model for brushite. Growth rates were calculated from the first 20 minutes of the reaction.

For the nucleation tests, the induction time τ was determined directly from the beginning of a steady and continuous addition of titrant solutions by CC.

Solution speciation and supersaturation: The supersaturation S and relative supersaturation σ are given by Equation (7), in which IP

$$\sigma = S - 1 = \left[\frac{IP}{K_s}\right]^{1/2} - 1 \tag{7}$$

is the ionic activity product, and the solubility activity product of brushite K_s is 2.36×10^{-5}. Solution speciation calculations were made by using the extended Debye–Hückel equation proposed by Davies[21] from mass balance expressions for total calcium and total phosphate with appropriate equilibrium constants by successive approximation for the ionic strength.

In situ atomic force microscopy: AFM images were collected in contact mode with a Digital Instruments Nanoscope III instrument. All images were acquired in height and deflection modes by using the lowest tip force possible to reduce the tip–surface interaction. The brushite seed crystal was anchored inside the fluid cell, and supersaturated solutions (identical to the CC reaction solutions) were passed through it while the images were taken.

Scanning electron microscopy (SEM): Samples under vacuum were sputter-coated with a thin carbon deposit to provide conductivity and then examined with a field-emission SEM (Hitachi S-4000), typically at 20 or 30 KeV.

Enantioselective Fluorination

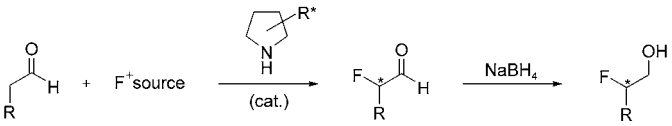
Enantioselective Formation of Stereogenic Carbon–Fluorine Centers by a Simple Catalytic Method**

*Mauro Marigo, Doris Fielenbach, Alan Braunton, Anne Kjærsgaard, and Karl Anker Jørgensen**

The unique properties of fluorinated molecules have led to the wide interest in these compounds in organic syntheses, medicinal and agricultural chemistry, as well as materials sciences.[1] This interest has been manifested in the enormous number of publications relating to organofluorine compounds.[2] In this context, structures in which the fluorine atom is attached to a chiral center are gaining increasing importance. Despite this great interest, there is still no simple and direct catalytic method to obtain optically active fluorinated compounds.[3] The development of stable electrophilic fluorine sources such as Selectfluor, 1-fluoropyridinium salts, and *N*-fluorodibenzenesulfonimide (NFSI) has marked an important milestone for the realization of these reaction types.[4] As a consequence, the first examples of catalytic enantioselective fluorinations of β-keto esters that apply both metal- and organocatalytic approaches were reported.[5,6] Recently, these methods were also applied toward the synthesis of chiral fluorinated β-keto phosphonates.[7]

To our knowledge, no enantioselective catalytic method for the direct α-fluorination of aldehydes has been described. Recently, asymmetric carbon–heteroatom bond formation reactions that proceed via enamine intermediates were reported in which chiral secondary amines are used as catalysts.[8–11] These procedures also showed promise for application toward fluorination reactions. So far, the only access to α-fluorinated aldehydes uses a chiral auxiliary strategy that involves a multistep process.[12] The authors state that the resulting α-fluorinated products decompose rapidly on silica and as a result, they must be derivatized directly from the crude mixture.

Herein we present a new and easy access to stereogenic carbon–fluorine centers through the direct enantioselective α-fluorination of aldehydes with an organocatalytic approach. The general reaction is shown below, including the functionalization of α-fluorinated aldehydes in situ to optically active α-fluoroalcohols, which are important organic compounds[1] and which have found direct use in liquid crystal compositions.[13]



As fluorine is the most electronegative element, the reaction conditions must be chosen carefully under the following terms: 1) *N*-fluorination of the catalyst is likely; therefore, the α-fluorination reaction must be faster than this process. 2) Undesired racemization and difluorination events must be rigorously avoided. Taking these considerations into account, we started our screening experiments with catalysts that had been previously applied with success in asymmetric C–Cl[10b,c] and C–S[11] bond formation reactions. The results of the screening in which 3-phenylpropanal (**1a**) was used as substrate with the commercially available NFSI (**2**) as the fluorinating reagent are presented in Table 1.

The use of L-proline (**4a**), L-prolinamide (**4b**), and the C_2-symmetric catalyst **5** gave low yields and moderate enantioselectivities (Table 1, entries 1–3). This behavior was not a surprise, as the chemical and physical properties of fluorine amplify some of the problems that are encountered in the related chlorination reaction. Because of the high electronegativity of fluorine, the catalyst easily forms enamine

Table 1: Screening of catalysts and reaction conditions for the α-fluorination of 3-phenylpropanal (**1a**) with NFSI (**2**) as F^+ ion source.[a]

species with both the starting material and the fluorinated product. The enhanced acidity of the α proton in the fluorinated product even favors its enamine formation, as discussed below. Furthermore, in contrast to the chlorination reaction, the small fluorine atom does not contribute to an added steric shielding that would disfavor the enamine equilibrium. This second enamine formation causes either difluorination or racemization.

Use of the silylated prolinol derivative **6** as a catalyst significantly improved the conversion and enantioselectivity of the reaction (Table 1, entry 4). NMR spectroscopy studies revealed that the catalyst is slowly desilylated upon mixing with NFSI. The desilylated **6** shows very low catalytic activity (10% conversion after 20 h and 61% *ee*). Therefore, the low conversion was caused by inactivation of the catalyst. We rationalized that the solvent could influence the reaction rate and deprotection of the catalyst. Acetonitrile still did not lead to full conversion, because of catalyst degradation (entry 5). However, an improvement was observed with methyl-*tert*-butyl ether (MTBE); all reactions performed in this solvent showed complete consumption of NFSI, but a significant amount of the difluorinated product was formed as well. Lowering the amount of catalyst to 5 mol% decreased the difluorination problem. Finally, the use of only 1 mol% of catalyst **6** and an excess of the aldehyde **1a** resulted in more than 90% yield of the monofluorinated product within 2 h (entry 10). Performing the reaction on a larger scale (10 mmol) allowed us to further decrease the catalyst loading to only 0.25 mmol%. Furthermore, 90% conversion was obtained, maintaining the enantioselectivity of 93% *ee* after 8 h reaction time (entry 11). Other commercially available F^+ ion sources such as Selectfluor turned out to be unsuitable for the reaction, as the silylated catalyst **6** is immediately deprotected in the presence of the BF_4^- counterion.

With these optimized conditions in hand, the general scope of the reaction was probed by application to a series of aldehydes. As mentioned above, α-fluorinated aldehydes easily decompose on silica gel.[12] Notably, α-fluoroaldehydes are more volatile than the starting compounds. The formation of α-fluorinated aldehydes was confirmed by GC–MS and NMR spectroscopic analysis of the crude reaction mixtures. The α-fluoroaldehydes **3a**, **3d–f**, and **3h** were reduced directly to the resulting β-fluoroalcohols without loss of enantiomeric excess, and the isolated yields given in Table 2 confirm the high conversion in the organocatalytic enantioselective fluorination step. For the volatile substrates **1b**, **1c** and **1g**, yields were calculated according to GC analysis of the crude reaction mixtures before reduction to the β-fluoroalcohols. The results are presented in Table 2.

For all examples in which a variety of different R substituents were evaluated, excellent enantioselectivities of more than 91% *ee* were obtained, and the enantioenriched products were formed in good yields with only 1 mol% of catalyst **6** (Table 2). In the case of substrate **1a** in reaction with 20 mol% of the catalyst, more than 90% of the catalyst could be recovered after flash chromatography.

The absolute configuration of the β-fluoroalcohols was determined to be *S* by comparison of their optical rotation values with those reported in the literature.[14] The stereochemical outcome of the reaction can be explained by the formation of an *E*-configured enamine, where the sterically demanding substituent of the pyrrolidine ring shields the *Re* face of the enamine.

Table 2: Organocatalytic enantioselective α-fluorination of aldehydes by NFSI, catalyzed by **6** (1 mol%).[a]

[a] Compound **2** (0.25 mmol) was added to a mixture of **1** (0.38 mmol) and **6** (0.0025 mmol) in MTBE (0.5 mL) at room temperature for the stated period of time; Ad = adamantyl; Bn = benzyl; Cy = cyclohexyl. [b] Percent *ee* values were determined by GC or HPLC on a chiral phase; see Supporting Information for separation conditions. [c] Yields were based on GC analysis of the crude mixtures before reduction owing to the volatility of the products. [d] Isolated yields of the alcohol after reduction with $NaBH_4$. [e] 1.1 equiv NFSI; 1 equiv aldehyde.

This hypothesis is confirmed by a model based on DFT calculations of the optimized enamine intermediate at the B3LYP/6-31G(d) level of theory.[15] The lowest-energy structure of the enamine intermediate is presented in Figure 1. The

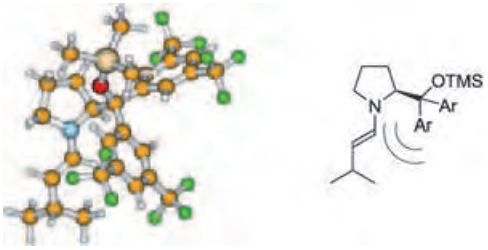

Figure 1. DFT-calculated model of the optimized structure of the enamine formed by isovaleraldehyde and catalyst **6**; Ar = Ph-3,5-$(CF_3)_2$.

intermediate structure shows that one of the 3,5-di(trifluoromethyl)phenyl groups covers the *Re* face of the enamine. As a consequence, the electrophilic F^+ ion attack occurs from the *Si* face, providing excellent enantioselectivities. This model is in agreement with our experimental observations.

The high configurative stability of the α-fluorinated products observed under the reaction conditions is a surprising phenomenon, especially as difluorination is also observed under certain reaction conditions. Figure 2 illustrates our theory to explain such stability of the optically active products. As shown in Figure 1, one of the 3,5-di(trifluoromethyl)phenyl groups points towards the reactive center of the enamine **A**. In the preferably formed (*S*,*S*)-**B** imminium ion, the remaining hydrogen atom is situated in between the

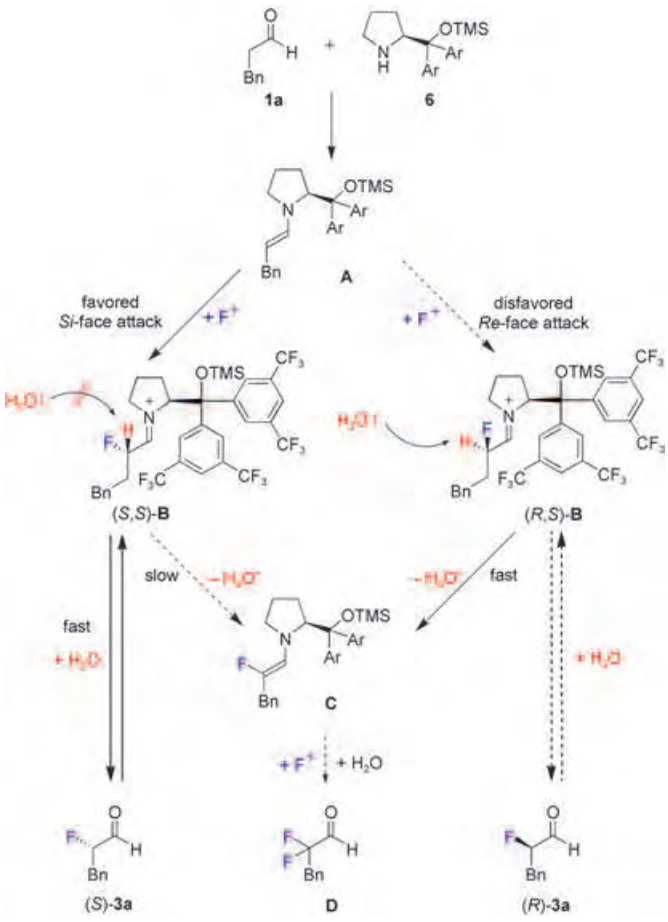

Figure 2. Explanation of the observed configurative stability of the α-fluorinated aldehydes under the reaction conditions in accordance with kinetic resolution experiments; Ar = Ph-3,5-$(CF_3)_2$.

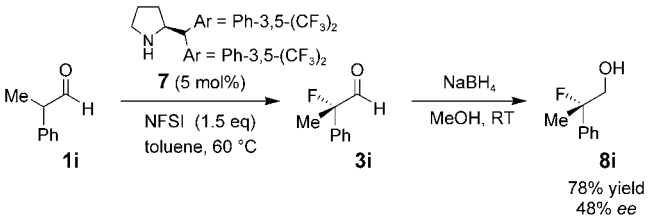
fluorine atom and the shielding substituent of the catalyst. This hydrogen atom is thus placed in a sort of hydrophobic pocket, which prevents its abstraction as a proton from nucleophilic attack by a water molecule. On the other hand, in the disfavored (*R*,*S*)-**B** intermediate, the hydrogen atom is placed on the open *Si* face and can be easily abstracted to form enamine intermediate **C**. We envisaged that a kinetic resolution experiment could support this hypothesis: a racemic mixture of α-fluoroaldehyde **3a** was slowly converted (20% in 4 h) to the difluorinated product **D** in the presence of 0.5 equiv NFSI (**2**) and 1 mol% of the catalyst **6**. This experiment clearly revealed that (*R*)-**3a** was consumed faster than (*S*)-**3a** and was supported by an enantiomeric excess of the latter of 20% *ee*. This observation supports our proposal of an embedded proton in the favored (*S*,*S*)-**B** intermediate in the enantiomeric reaction.

We have extended the scope of the reaction to the formation of quaternary stereocenters. A modified protocol was developed for the branched aldehyde **1i**. The sterically encumbered substrate required a sterically less-demanding catalyst and higher temperatures to keep the reaction rate high. With 5 mol% of catalyst **7** in a reaction performed at 60 °C, the β-fluoroalcohol product **8i** was generated in 78% yield with 48% *ee*.



Besides the in-situ reduction to alcohols, other direct transformations that proceed without epimerization, for example, the HWE olefination, are described in the literature.[8]

In summary, a simple method for the formation of stereogenic carbon–fluorine bonds through a direct, catalytic α-fluorination of aldehydes has been developed. A range of aldehydes can be directly fluorinated in the α position in good yields and with excellent enantioselectivities. The use of NFSI as a stable, easily handled, and commercially available electrophilic fluorine source in combination with the advantages of organocatalysis affords this simple protocol. Moreover, 1 mol% of a sterically encumbered chiral pyrrolidine derivative that is easily accessible in four steps from L-proline was sufficient for obtaining good to high yields and high enantioselectivities. It should be pointed out that optically active α-fluorinated aldehydes are unstable on silica gel and are more volatile than the starting compounds. Thus, the optically active α-fluorinated aldehydes were directly reduced to the corresponding α-fluorinated alcohols, without loss of enantioselectivity. We believe that this procedure represents an important new organocatalytic reaction and a significant improvement of existing methods, and that it will find intensive use in the synthesis and application of optically active fluorine compounds. Enantioselective Fluorination

Direct Asymmetric α-Fluorination of Aldehydes**

*Derek D. Steiner, Nobuyuki Mase, and Carlos F. Barbas, III**

Organic molecules containing fluorine have attracted much attention because they show distinctive characteristics in comparison with their parent compounds owing to the unique C–F bond.[1] Substitution of hydrogen by fluorine is often considered isosteric and the high C–F bond strength generally protects fluorine from metabolic transformations. In addition, as fluorine has the ability to function as a hydrogen bond acceptor, fluorine-substituted bioactive compounds are useful analogues and probes of hydrogen bonding characteristics. The selective formation of carbon-fluorine bonds under mild conditions is thus a highly desirable methodology, especially in medicinal chemistry.[2] Previous approaches toward asymmetric fluorination relied on stoichiometric amounts of chiral fluorinating reagents[3] or chiral auxiliaries.[4] More recently, the catalytic asymmetric fluorination of β-keto esters with titanium and palladium as Lewis acids was reported.[5]

α-Fluoro aldehydes have been characterized as unstable compounds that generally decompose upon purification. As a result, their syntheses have been very limited. Synthesis of α-fluoro aldehydes was first reported by Middleton and Bingham, who treated silyl enol ethers with trifluoromethyl hypofluorite (CF_3OF).[6] Subsequently, enolate methodologies that use commercially available electrophilic fluorinating reagents such as NFSi (*N*-fluorobenzenesulfonamide; **5**) and Selectfluor (F-TEDA-BF_4 or 1-chloromethyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate); **3**) have

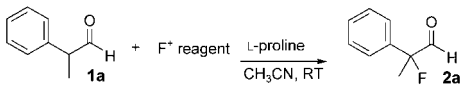
been employed to produce α-fluoro carbonyls.[7] Although there is an extensive body of research on the α-fluorination of carbonyls, there are no examples of direct asymmetric fluorinations of aldehydes. Herein, we report the first examples of direct α-fluorinations with asymmetric induction.

Proline and its analogues have been found to be excellent catalysts in asymmetric aldol,[8] Mannich,[9] and α-chlorination[10] reactions of carbonyls. Our early work in fluorine chemistry focused on the use of α-fluoro carbonyl compounds as nucleophiles in reactions catalyzed by enzymes,[11] catalytic antibodies,[12] and organocatalysts[13] in asymmetric aldol reactions and, in one case, the Mannich reaction.[14] The asymmetric α-fluorination of aldehydes is based on the same principles of organocatalysis that we used in our first Michael, aldol, and Mannich catalytic asymmetric aldehyde addition reactions.[15]Initial screening of electrophilic fluorinating reagents was done with L-proline and 2-phenylpropionaldehyde (**1a**) in acetonitrile at room temperature (Table 1).

Table 1: Comparison of N–F reagents for direct α-fluorination of aldehydes.[a]



Entry	N–F Reagent		*t*	Yield [%][b]	*ee* [%][c]
1		**3**	24 h	87	4
2		**4**	24 h	90	0
3		**5**	24 h	87	25
4		**6**	5 d	NR	–
5		**7**	5 d	7	12

[a] N–F reagent (1.2 equiv) was added to a mixture of aldehyde and catalyst at ambient temperature. [b] All isolated yields determined after aqueous workup. [c] Enantiomeric excess determined by chiral GLC analysis (Bodman γ-TA).

2-Phenylpropionaldehyde was chosen for screening because of its excellent reactivity and because the product is unable to racemize, as it has no proton alpha to the aldehyde. It was found that NFSi (**5**) was the only fluorinating reagent to provide any enantioselectivity in a reasonable time period. Commercially available fluorinating reagents Selectfluor (**3**) and Accufluor (**4**) were employed, but afforded 4 and 0% *ee* respectively. The pyridinium fluoride reagents **6** and **7** were minimally reactive, and thus gave very low yields. Therefore, NFSi (**5**) was used for subsequent reactions.

Following this selection of an electrophilic fluorinating reagent, a solvent screen was undertaken. Acetonitrile is a standard reaction solvent used in electrophilic fluorination. Acetonitrile (Table 2, entry 1, 87% conversion, 25% *ee*) was adequate, but tetrahydrofuran, dimethylformamide (DMF), 1,4-dioxane, and methanol all provided the product in higher yield. Interestingly, THF afforded both the best selectivity and highest chemical yield (Table 2, entry 4, 94% conversion, 28% *ee*). DMSO has a mildly exothermic reaction with NFSi, possibly explaining the poor aldehyde fluorination in this medium.

Table 2: Effect of solvent on organocatalyzed α-fluorination.

15	[bmim]BF_4[d]	56	19

[a] Conversion measured by ^{1}H NMR spectroscopy of the crude reaction mixture and correlated to GC, owing to high volatility of products. [b] Enantiomeric excess determined by chiral GLC analysis (Bodman γ-TA). [c] NMP = *N*-methylpyrrolidinone. [d] BMIM = 1-butyl-3-methylimidizolium.

It is important to note that α-fluorinated aldehydes are generally not stable under column purification or distillation conditions, and that the addition of an α-fluorine significantly increases the volatility relative to that of the starting aldehyde.[16] These characteristics of α-fluorinated aldehydes make them difficult substrates to manipulate. To optimize the fluorination reaction with branched aldehydes, **1a** was subjected to a catalyst screen with NFSi as the electrophilic fluorinating reagent and THF as a standard solvent (Table 3). The silylated L-prolinol derivative **9c**, with the sterically demanding triisopropylsilyl (TIPS) group, provided the highest enantioselectivity (44% *ee*, 90% yield), although the reaction yield was much improved with the proline-derived tetrazole catalyst **11** (38% *ee*, 98% yield).

We next examined the organocatalytic asymmetric fluorination of straight-chain aldehydes. These aldehydes are prone to self-react under organocatalysis to yield self-aldol products. Decyl aldehyde (**1b**), which is slow to form the self-aldol product and which has a high boiling point, was chosen as a general aldehyde for reaction optimization (Table 4). The initial fluorination reactions of decyl aldehyde were monitored by ^{1}H NMR and ^{19}F NMR spectroscopy in $CDCl_3$, CD_3CN and [D_7]DMF. All reactions reached completion after approximately 30 minutes. Also, after initial α-fluoro decyl

[a] Yield measured by ^{1}H NMR spectroscopy of the crude reaction mixture and correlated to GC, owing to high volatility of products. [b] Enantiomeric excess determined by chiral GLC analysis (Bodman γ-TA). [c] Opposite enantiomer from that obtained with other catalysts. [d] Stoichiometric amount of pyrrolidine.

aldehyde formation (^{19}F NMR (CD_3CN): $\delta = -200.2$ ppm) the $CDCl_3$ and CD_3CN reactions showed steady formation of α,α-difluoro product (^{19}F NMR (CD_3CN): $\delta = -115.2$ ppm).[17] Subsequent reactions with THF also gave the α,α-difluoro product. Therefore, DMF, which inhibited formation of the α,α-difluoro product, was employed throughout the catalyst screening with linear aldehydes.

Interestingly, imidazolidinone catalysts **14a** and **14b** (Table 4, entry 5) provided the desired product with the highest enantioselectivities. Catalyst **14a** was used in a sub-stoichiometric amount, yet in repeated reactions would not progress beyond 65% completion. The highest optical purity was obtained with catalyst **14b** (30% conversion, 88% *ee*). Use of the hydrochloric, trifluoroacetic or 5-methyltetrazole salts of **14a** and **14b** resulted in diminished enantioselectivity and no enhancement in turnover. Lowering the reaction temperature to −20°C inhibited the reactivity greatly, without increasing the enantioselectivity. Conversely, raising the temperature to room temperature resulted in an increased formation of side products, presumably self-aldol products.

To determine the scope of the reaction, we subjected a series of aldehydes to the optimized conditions (Table 5). Generally, **14b** catalyzed the direct asymmetric α-fluorination of linear aldehydes with good to excellent yields (Table 5, entries 1–6) and with enantioselectivities ranging from 86% for 2-fluoro-1-octanal (**2e**) (Table 5, entry 4) to 96% for 2-fluoro-isovaleraldehyde (**2c**) (Table 5, entry 1). Linear aldehydes were transformed with the highest enantioselectivity when reacted with equimolar imidazolidinone **14b** as a chiral promoter at 4°C in DMF. The absolute stereochemistry was confirmed for several compounds: **2e** was reduced to 2-fluoro-1-octanol with sodium borohydride,[18] 2-fluoro-2-phenylpropionaldehyde (**2a**) was oxidized to the corresponding carboxylic acid,[19] and (*S*)-(−)-2-fluoro-isovaleraldehyde (**2c**) is known in the literature.[20] In each case, the optical rotation of the compounds prepared compared favorably with the literature values reported. These results are all consistent with the assignment of an *S* configuration to the fluorinated aldehydes and are in agreement with a *Si*-face approach of the electrophile. The *Re* face of the enamine is shielded by the sterically demanding benzyl and 2,2-dimethyl substituents of

Table 5: Direct organocatalytic enantioselective α-fluorination of aldehydes.[a]

[a] Reaction conditions for linear aldehydes (entries 1–6): 4 °C in DMF with stoichiometric amounts of chiral promoter **14b**; branched aldehydes (entries 7 and 8): room temperature in THF with 30 mol% catalyst. [b] Yield measured by ^{1}H NMR spectroscopy of the crude reaction mixture and correlated to GC, owing to high volatility of products. [c] Enantiomeric excess determined by chiral GLC analysis (Bodman γ-TA). [d] Yield and enantiomeric excess determined by chiral HPLC of the corresponding hydrazone derivative with Daicel CHIRALCEL OD-R.

the catalysts. Similar models have been proposed with sterically demanding enamine catalysts.[21]

Our methodology was extended to branched aldehydes **2h** and **2a** (Table 5, entries 7 and 8) to show the broad scope of this reaction. With L-proline (**8a**), silylated prolinol derivative **9c**, and proline-derived tetrazole **11** as catalysts for the formation of chiral quaternary α-fluoro aldehydes, excellent yields of up to 98% were attained, albeit with moderate enantioselectivities of up to 66%. Reactions of branched aldehydes were carried out at room temperature in THF with 30 mol% catalyst. The reaction rate was greatly enhanced when **11** was used with branched aldehyde substrates, although **9c** provided products with higher enantioselectivity. Catalyst **8a** gave excellent yields, but had diminished enantioselectivity and slow reaction times.

In summary, we have developed an organocatalytic α-fluorination reaction for branched aldehydes that delivers optically active quaternary α-fluoroaldehydes in high yield and with moderate enantioselectivity. In conjunction, we have developed a highly enantioselective direct mono α-fluorination reaction of linear aldehydes employing imidazolidinones as chiral promoters. The chiral α-fluoroaldehydes that can now be readily prepared are versatile synthons and should find considerable utility. This new methodology complements our previous studies in fluorine chemistry that used fluorine-containing ketones as nucleophiles in enamine-based addition reactions, and extends the chemistry of aldehydes in a significant way.[22]

Bioorganic Chemistry

A Dendritic Tetra(bisphosphonic acid) for Improved Targeting of Proteins to Bone**

*Geeti Bansal, Jennifer E. I. Wright, Cezary Kucharski, and Hasan Uludağ**

Protein-based therapeutic agents are being actively pursued for the treatment of skeletal diseases.[1] As endogenous regulators of cellular activity, proteins have the potential to modulate cellular activity at skeletal sites to obtain a desired tissue response. For example, protein-based cytokines that can stimulate the formation of new bone or inhibit the cell activity that is responsible for bone loss will be beneficial for the treatment of diseases such as osteoporosis and arthritis. Despite the demonstrated efficacy of several proteins in preclinical disease models,[2] the clinical entry of most proteins has been hampered as a result of undesired side effects at extraskeletal sites. As systemically administered proteins are not naturally targeted to skeletal tissue, the desired efficacy is achieved only at exuberant doses of the protein by nonspecific deposition at skeletal tissues. In this case, pharmacological activity at extraskeletal sites becomes unacceptable. If proteins could be engineered to exhibit a strong affinity for bone, then systemic administration would allow delivery of the proteins selectively to the skeletal sites.

Bone affinity can be imparted to a molecule by chemical modification with bisphosphonic acids (BPs), a class of compounds with exceptionally high affinity for the bone mineral hydroxyapatite (HA). Bisphosphonic acids are chemical analogues of endogenous pyrophosphate in which the central, hydrolytically labile P-O-P linkage has been replaced by the hydrolysis-resistant P-C-P bond. Intravenous administration of molecules that contain bisphosphonic acid groups results in significant deposition (20–50% of injected dose) of the molecules at bone tissue.[3,4] The exceptional affinity of bisphosphonic acid derivatives for minerals has been utilized to deliver radiopharmaceutical and imaging agents to skeletal tissue.[5,6] To target proteins to bone, we devised conjugation schemes by which 1-amino-1,1-diphosphonic acid (aminoBP)[7] and 2-(3-mercapto-propylsulfanyl)-ethyl-1,1-bisphosphonic acid (SH-BP)[8] were conjugated to proteins

with heterofunctional linkers in aqueous medium.[9–14] The affinity of proteins for hydroxyapatite in vitro was shown to be proportional to the extent of conjugation of the bisphosphonic acid groups.[9,12,14] Intraosseous injection of the aminoBP conjugates confirmed the high affinity in vivo of the conjugates for bone[10] as well as their capability to "seek" bone tissue after systemic injection in rats.[11] The length of the tether between the bisphosphonic acid derivative and the protein was found to be an important factor for the affinity of the conjugates to minerals: conjugates with shorter tethers displayed a higher mineral affinity than those with longer tethers.[13] A higher density of the bisphosphonic acid ligand at the vicinity of proteins was postulated for the beneficial effect of shorter tethers. On the basis of these observations, the ideal approach to target bone would rely on creating a high density of bisphosphonic acids on proteins through short tethers. To this end, we have prepared a new dendritic molecule composed of four bisphosphonic acid moieties linked through a benzene ring (**8**, COOH-4BP; Scheme 1). This compound should provide a higher density of bisphosphonic acid groups on the proteins as four BP units are attached per protein site, unlike the conventional approach that relies on one-to-one linkage (Scheme 2). A carboxylic acid moiety was also incorporated into **8** to allow its conjugation to proteins through a short (zero carbon atom) tether using carbodiimide chemistry (Scheme 2).

The synthesis of COOH-4BP (**8**) is outlined in Scheme 1. Tetraethyl methylenebisphosphonate (**1**; 4 mmol) was converted into tetraethyl ethylidenebisphosphonate (**3**) by reaction, first, with formaldehyde (20 mmol) in diethylamine (0.42 mL) according to the method of Degenhardt and Burdsell to give the intermediate tetraethyl 2-methoxyethylene-bisphosphonate (**2**).[15] Methanol was removed from **2** by adding a catalytic amount of *p*-toluenesulfonic acid monohydrate to a solution of **2** in toluene and then heating the mixture at reflux with a Soxhlet apparatus (CaH_2) to give **3**, which was purified by chromatography on silica gel (60–270 mesh; 4:1 $CHCl_3$/hexane as eluent). Meanwhile, 3,5-bis(3,5-dinitrobenzoylamino)benzoic acid (**6**) was prepared from a mixture of 3,5-diaminobenzoic acid (**4**; 19.7 mmol) and 3,5-dinitrobenzoyl chloride (**5**; 43.4 mmol) in *N*,*N*-dimethylacetamide and was then reduced to 3,5-bis(3,5-diaminobenzoylamino)benzoic acid (**7**) with H_2 and 10% Pd/C.[16] Then compound **3** (1.6 mmol) was coupled to the amine moieties of **7** (0.4 mmol) by an anti-Markovnikov reaction in THF (15 mL) at 60 °C for 5 hours to give 3,5-bis[3,5-di(ethylamino-2,2-tetraethylbisphosphonate)benzoylamino]benzoic acid. After removal of the solvent, the residue was dissolved in CH_2Cl_2 and the phosphonate esters were hydrolyzed with bromotrimethylsilane ($BrSi(CH_3)_3$)[15] for 48 hours to afford the dendritic tetra(bisphosphonic acid) **8** (Scheme 1).[17]

Bovine serum albumin (BSA) served as the model protein for conjugation of the bisphosphonic acid derivative. Acid **8** was activated by treating equimolar concentrations (0–20 mM) of NHS and EDC in MES (morpholinoethanesulfonic acid) buffer (0.1M, pH 4.5) for 45 minutes. The activated acid **8** (0.15–1.25 mM) was then incubated with BSA (5 mg mL^{-1}) in MES buffer for 3 hours, after which time the unreacted components were removed by dialysis against 0.2 M carbonate buffer (pH 10; ×4) and deionized water (×2). The dialyzed samples were further purified by gel permeation chromatography (Bio-Rad P2 gel-fine; 18 × 1.2 cm^2 column) with deionized water as eluent. Samples of BSA mixed with **8** in the absence of EDC/NHS as well as BSA conjugated to SH-BP[14] served as controls. These control samples were purified by dialysis only. All conjugates were analyzed for an average

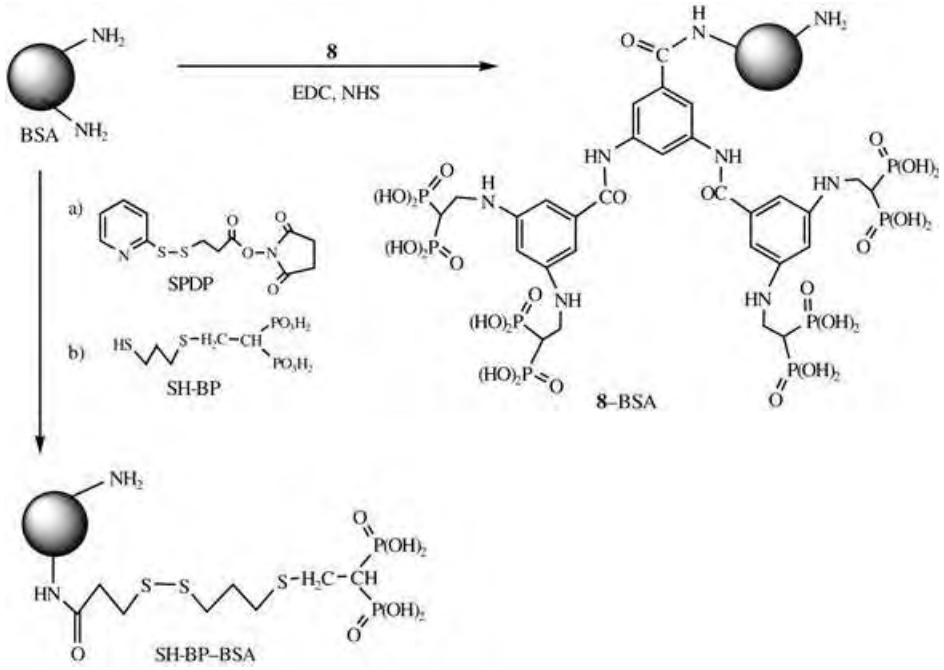

Scheme 2. Conjugation of **8** (COOH-4BP) and SH-BP to model protein BSA. EDC = 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, NHS = *N*-hydroxysuccinimide, SPDP = *N*-succinimidyl 3-(2-pyridyldithio)propionate.

number of bisphosphonic acid substituents (i.e. the number of BP groups attached per BSA) by using the Bradford assay for protein concentrations[18] and the Ames assay[19] for phosphate concentrations.

SDS-PAGE (sodium dodecylsulfate–polyacrylamide-gel electrophoresis) analysis of the obtained proteins indicated the migration of protein as single bands, which confirmed a lack of protein–protein linking during the conjugation reactions (data not shown). The number of bisphosphonic acid substituents for a representative set of **8**–BSA conjugates ([EDC] = [NHS] = 0–20 mM; [**8**] = 1.25 mM) are summarized in Figure 1 a. The control sample of BSA ([EDC] = [NHS] = 0 mM) revealed 0.8 molecules of **8** per BSA protein which presumably represents the extent of free COOH-4BP (**8**) not removed by dialysis (or gel chromatography). The conjugates

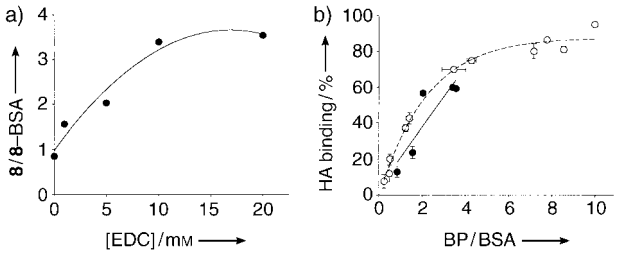

Figure 1. a) Number of tetra(bisphosphonic acid) substituents **8** per BSA conjugate upon coupling **8** (1.25 mM) to BSA in the presence of equimolar quantities of EDC and NHS ([EDC] = [NHS] = 0–20 mM). b) Correlation between the number of bisphosphonic acid (BP) substituents per BSA protein conjugate (mean ± SD) and the percentage binding to hydroxyapatite (HA; mean ± SD) in phosphate buffer (100 mM). Note the linear increase in the percentage binding of the conjugates at low numbers of BP groups for both SH-BP–BSA (○) and **8**–BSA (●). See Ref. [9] for details about the methods.

8–BSA showed an increasing efficiency of conjugation (up to 3.6 molecules of **8** per BSA) as the concentration of EDC and NHS was increased (Figure 1 a). The binding of the conjugates to hydroxyapatite was assessed in phosphate buffer (100 mM, pH 7.4), which was previously optimized for investigating such protein–HA binding.[7] Figure 1 b summarizes the relationship between the binding of the conjugates to hydroxyapatite and the conjugation efficiency (that is, the number of bisphosphonic acid groups per BSA) for SH-BP–BSA and **8**–BSA. Both conjugates exhibited an increased level of binding to hydroxyapatite as a function of conjugation efficiency. Whereas a plateau in the percentage binding to hydroxyapatite was evident with SH-BP–BSA, no such plateau was seen for **8**–BSA, partly as a result of our inability to obtain more than 3.6 bisphosphonic acid groups per BSA (two other independent reactions did not yield higher numbers of bisphosphonic acid substituents). This excellent correlation between the conjugation efficiency and the affinity for hydroxyapatite was in accord with the results obtained previously for aminoBP and SH-BP conjugations with hydroxyapatite.[9,14]

The conjugates were then analyzed for binding to hydroxyapatite and bone in the presence of serum proteins. Fresh bone matrix was obtained from Sprague–Dawley rats,[9] and the serum proteins originated from tissue-culture grade adult bovine serum. The use of bone matrix and serum proteins in the binding medium provides more stringent conditions for an assessment of binding and better represents the situation in vivo. The BSA conjugates for this analysis had similar levels of substitution by bisphosphonic acids: 3.4 and 3.6 for SH-BP–BSA and **8**–BSA, respectively. Owing to the presence of serum, ^{125}I-labeled conjugates were used for this analysis and were added to unlabeled (cold) proteins to give

approximately 10^6 cpm (counts per minute) at a concentration of 0.1 mg mL^{-1} protein (hot/cold = 1:100).[9] In 30 and 60% serum media, both conjugates exhibited a higher level of binding to hydroxyapatite than unmodified BSA (Figure 2a).

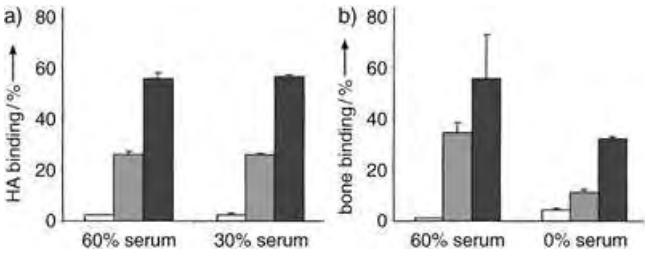

Figure 2. Percentage binding of BSA protein (□) and its conjugates (SH-BP–BSA ■, **8**–BSA ■) to a) HA and b) bone in serum-containing media (200 mM phosphate buffer). For both binding matrices, **8**–BSA gave the highest extent of binding, followed by SH-BP—BSA, while only a low level of binding was observed with the control (BSA protein) under all conditions. See Ref. [9] for details about the methods.

Conjugates prepared with **8** exhibited a higher level of binding to hydroxyapatite relative to SH-BP–BSA, despite the same number of bisphosphonic acid substituents. A similar result was obtained when hydroxyapatite was replaced by bone as the binding matrix (Figure 2b), with the **8**–BSA conjugate exhibiting superior levels of binding than the SH-BP–BSA conjugate.

Finally, the ability of these two conjugates to target bone was evaluated in rats. The ^{125}I-labeled conjugates (as above) were injected intravenously through the tail vein and bone (femora and tibiae), and deposition of the proteins was assessed by explanting the bones and determining the counts in these tissues. The depositions of the control BSA and the SH-BP–BSA conjugate at the bone were similar at both femora and tibia, which indicates a lack of targeting by the SH-BP–BSA conjugate (Figure 3). The presence of approximately 3.4 bisphosphonic acid substituents per BSA protein was not expected to impart a strong affinity to bone, as our previous studies required around 10 bisphosphonic acid groups per BSA for successful bone-targeting.[11] However,

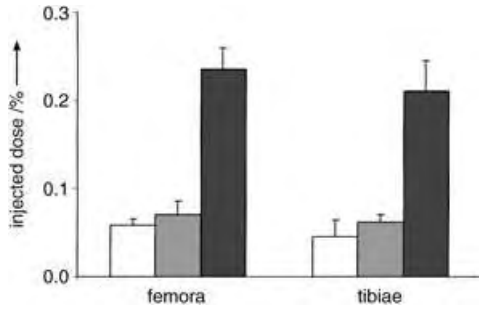

Figure 3. Delivery of BSA (control; □), SH-BP–BSA (■), and **8**–BSA (■) to femora and tibiae after intravenous injection in Sprague–Dawley rats ($n = 3$ per group). Bone-targeting was assessed one day after injection. Note the lack of bone-targeting by the SH-BP–BSA conjugate (i.e. similar to BSA) and the significantly improved bone-targeting by **8**–BSA. See Ref. [11] for details about the methods.

conjugate **8**–BSA, with a similar extent of bisphosphonic acid substituents, gave 4.1- and 4.7-fold higher delivery (relative to control BSA) at the femora and tibiae, respectively (Figure 3). A similar result was obtained in a repeat study in which the control BSA and **8**–BSA were injected subcutaneously: delivery increased by 3.7- (femora) and 3.4-fold (tibiae) as a result of conjugation of **8** (data not shown).

In conclusion, we have reported the synthesis of a novel, dendritic tetra(bisphosphonic acid) **8**. The synthesized molecule is introduced through a minimal tether length at the attachment site and provides a high density of bisphosphonic acid groups per protein site modified. Dendritic **8** gave higher numbers of total bisphosphonic acid groups attached per protein relative to SH-BP conjugates and exhibited its intended effect, namely bone-targeting, at a lower extent of protein modification which is an important consideration for maintaining the pharmacological activity of proteins when they are derivatized with bone-seeking ligands. The studies reported here should further stimulate the efforts to design "bone-seeking" proteins with minimal degree of modification.

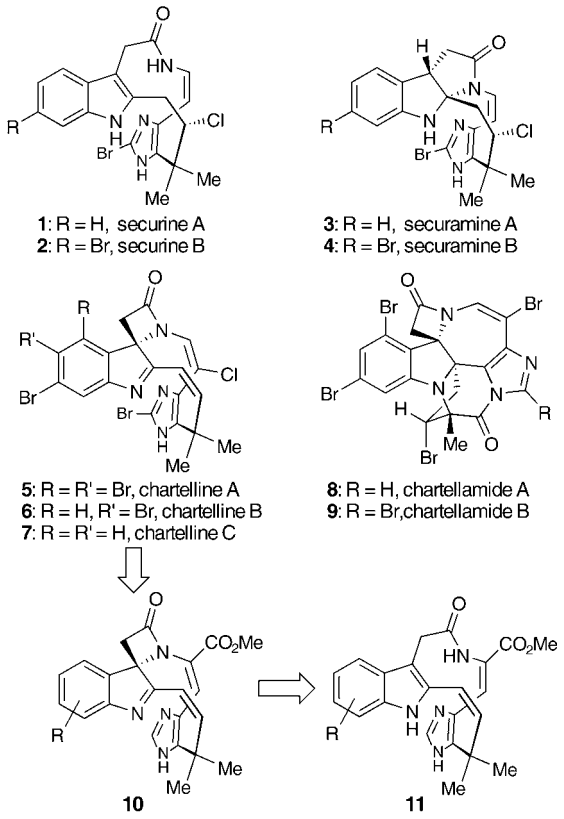
Natural Product Synthesis

A Remarkable Ring Contraction En Route to the Chartelline Alkaloids**

Phil S. Baran, Ryan A. Shenvi, and Christos A. Mitsos*

Marine fauna continually produce molecules endowed with potent bioactivities and extraordinary structures.[1] The securines (**1**, **2**), securamines (**3**, **4**), chartellines (**5**–**7**), and chartellamides (**8**, **9**; Scheme 1) are members of a structurally unique class of natural products that were isolated by Christophersen and co-workers from the bryozoa *Chartella papyracea* and *Securiflustra securifrons*.[2] They contain an interesting arrangement of various heterocyclic entities that are wound around a prenyl unit and adorned with halogen atoms. With such a dense array of sensitive and exotic functionalities, such as spiro-β-lactam, indolenine, chloroenamide, and 2-bromoimidazole units, it is understandable why no member of this family has yet succumbed to total synthesis since their isolation over two decades ago.[3]



Scheme 1. Structures of the chartellines, chartellamides, securines, and securamines, and the retrosynthetic analysis of the carbocyclic skeleton.

The belief that macrocyclic constructs such as **10** and **11** would behave differently than their individual heterocyclic subunits was central to our synthetic plan. Specifically, late-stage chemo- and regioselective halogenations and a bromine-induced rearrangement of **11** to **10** were planned. The presence of extensive halogen substitution in these natural products perhaps suggests that many of the biotransformations that create such complex polycyclic structures are indeed accomplished with electrophilic sources of bromine and chlorine; it is this hypothesis that inspired the current approach. However, there are no examples for such a ring contraction of a pyrroloindoline unit and ample precedent that suggests its failure (Scheme 2).[4] Pyrroloindoline intermediates of type **A** have not been known to undergo ring contraction to strained spiro systems of type **B** (see Scheme 2). Furthermore, an indolenine, such as **C**, can be rapidly hydrated (**D**) and undergo a 1,2-shift to an oxindole (**E**).[5] Notwithstanding this bleak outlook, we hypothesized that π stacking and conformational effects in the macrocycle **11** would provide sufficient driving force for a bromine-induced ring contraction to yield **10** (via an intermediate of type **A**). Herein, we present the successful execution of this approach, which resulted in a short and practical route to the

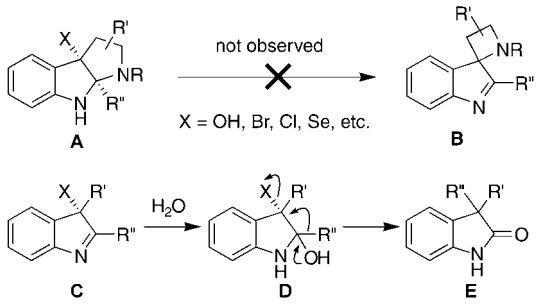


Scheme 2. The known reactivity profile of oxidized indoles suggests that the proposed rearrangement (**11**→**10**) is unlikely to occur.

carbocyclic skeleton of the chartelline, securine, and securamine alkaloid families.

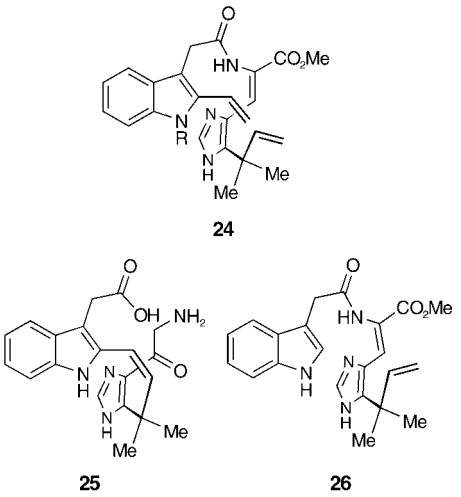
The synthetic pathway to **10** is outlined in Scheme 3. Thus, treatment of the readily available serine-derivative **12** with prenylmagnesium bromide furnished α-amino ketone **13** which could be easily transformed into imidazole **14** in 84% yield via an imidazoline-2-thione intermediate.[6] The corresponding primary alcohol of **14** has been previously synthesized in nine steps[7] and was used in the total synthesis of the anticancer agents phenylahistin and aurantiamine and libraries that were based upon these compounds.[7,8] In preparation for linking the imidazole and indole subunits, it was necessary to convert the vinyl group of **14** into an alkynyl group. This conversion was carried out by the Johnson–Lemieux oxidation of **14** to the corresponding aldehyde followed by treatment with reagent **15**, developed by Ohira and Bestmann and co-workers,[9] to furnish alkyne **16** in 63% yield. The coupling of **16** and 2-bromoindole **17**[10] was accomplished by employing the method of Sonogashira et al. for a copper-accelerated[11] Heck alkyne synthesis[12] to afford **18** in 71% yield. Subsequent hydrogenation to the *cis* olefin,[13] removal of the TBS protecting group, and MnO_2-mediated oxidation of the resulting alcohol led to the crystalline aldehyde **19** (m.p. 50–55 °C, CH_2Cl_2/hexanes), whose markedly folded structure was discerned through X-ray crystallography (see Scheme 3 for the ORTEP representation). After a number of abortive attempts, the reliable Horner–Wadsworth–Emmons reaction finally emerged as an effective means to mediate the macro-

NBS (1.0 equiv), $KHCO_3$ (20 equiv), THF/H_2O, 35 min, 88% from **22**. TBS = *tert*-butyldimethylsilyl , KNCS = potassium thiocyanate, Boc = *tert*-butoxycarbonyl, DME = 1,2-dimethoxyethane, TBAF = tetra butylammonium fluoride, BOPCl = bis(2-oxo-3-oxazolidinyl)phosphinic chloride, DIPEA = diisopropylethylamine, NBS = *N*-bromosuccinimide.

cyclization.[14] Aldehyde **19** was primed for this reaction through saponification with LiOH and coupling with amine **20**[15] in the presence of BOPCl to furnish phosphonate **21** in 86% yield. Macrocyclization under the conditions developed by Masamune, Roush, and co-workers[16] produced macrocycle **22** in 75% yield and set the stage for the critical rearrangement.

Macrocycle **22** was converted into the chartelline skeleton **10** in 88% yield and in a single operation by simple thermolytic removal of the Boc protecting group in **22** (180 °C, no solvent)[17] followed by treatment of the resulting free indole (**11**, Scheme 1) with NBS and aqueous $KHCO_3$. The structure of this crystalline substance (m.p. 190–220 °C (decomp; CH_3CN)) was verified by X-ray crystallographic analysis (see Scheme 3 for the ORTEP representation). Although we speculate that the reaction proceeds through intermediate **23**, several degenerate pathways to **10** could also be envisaged.

As alluded to above, a number of unanticipated roadblocks were encountered during our efforts to accomplish macrocyclization. Some of these experiences are briefly summarized in Scheme 4, with the resistance of **24** to undergo ring-closing metathesis, the failure of a seemingly simple macrolactamization (**25**), and the refusal of **26** to take part in a Heck-type[18] ring closure.



Scheme 4. Selected dead-end routes to the chartelline, securamine, and securine carbocyclic skeletons.

Notable aspects of the approach described herein include synthetic efficacy (approximately 19% overall yield and 10 steps); rapid access to the carbocyclic skeletons of the chartelline, securine, and securamine alkaloids; and a remarkable ring contraction (**22**→**10**) that proceeds in high yield, despite the inherent ring strain of the β-lactam unit and an abundance of discouraging literature precedent (Scheme 2). The distinctive architecture of the chartelline alkaloids inspired this approach, and it is possible that a similar strategy is employed in nature to forge the intriguing spiro-β-lactam ring in the chartellines from securine-like structures. Completion of the total synthesis of the chartellines and related alkaloids will be reported shortly.[19]

Main Group Chemistry

Telluradistibirane and Telluradibismirane: Three-Membered Heterocycles of Heavier Main Group Elements**

*Takahiro Sasamori, Eiko Mieda, Nobuhiro Takeda, and Norihiro Tokitoh**

The chemistry of three-membered heterocycles has been widely explored in organic chemistry from the viewpoint of their unique structures and properties, which are attributed to their strained skeletons.[1,2] Although numerous papers have been published on the theory, preparation, and applications of three-membered heterocycles containing one heteroatom such as nitrogen, oxygen, or sulfur, only very few examples of three-membered ring compounds containing heavier chalcogen atoms such as selenium or tellurium have appeared to date.[3] In addition, three-membered ring systems composed of three heavier heteroatoms are also scarce, most likely owing to the instability of these systems. To synthesize such three-membered heterocycles that incorporate selenium or tellurium together with other heavier heteroatoms in their skeletons, one effective method should be the chalcogenation of highly reactive heavier double-bond compounds by formal [2+1] cycloaddition reactions. In the case of heavier Group 14 elements, selenadimetalliranes and telluradimetalliranes (Ch-M-M three-membered ring compounds; Ch = Se, Te, M = Si, Sn) have been successfully synthesized by chalcogenation reactions of the corresponding kinetically stabilized dimetallenes (M=M double-bond compounds) using elemental chalcogens.[4] There has also been much interest in doubly bonded compounds between heavier Group 15 elements, that is, heavier congeners of azo compounds. We synthesized a series of kinetically stabilized distibene (ArSb=SbAr)[5,6] and dibismuthene (ArBi=BiAr)[5,7] compounds by using 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl (Tbt) and 2,6-bis[bis(trimethylsilyl)methyl]-4-[tris(trimethylsilyl)methyl]phenyl (Bbt) groups as effective steric protection groups. However, whereas no tellurirane containing two heavier Group 15 elements was obtained from the tellurization reaction of BbtP=PBbt using elemental Te or (nBu)$_3$P=Te,[8] selenadiphosphiranes[8,9] and a selenadistibirane[10] were synthesized by the selenization reaction of the corresponding diphosphene (Mes*P=PMes* (Mes* = 2,4,6-tri-*tert*-butylphenyl), BbtP=PBbt, etc.) and distibene (BbtSb=SbBbt), respectively. Herein, we report the tellurization reaction of the kinetically stabilized distibene BbtSb=SbBbt (**1**) and dibismuthene BbtBi=BiBbt (**2**), which led to the formation of novel three-membered heterocycles, that is, the first stable telluradistibirane and telluradibismirane, respectively.

The reaction of BbtBi=BiBbt (**2**, 30 mg, 0.02 mmol), which was readily prepared by reductive coupling of BbtBiBr$_2$ with Mg in almost quantitative yield,[5] with an excess amount of elemental tellurium (26 mg, 10 equiv) in [D$_6$]benzene solution was performed in the hope of generating a telluradibismirane derivative. After heating the mixture at 60 °C for 72 h, then at 80 °C for 72 h, and finally at 100 °C for 72 h, **2** disappeared completely as judged by the ^{1}H NMR spectra. However, not the desired telluradibismirane but only the ditelluride **3** (Bbt-Te-Te-Bbt) was obtained (12 mg, 42 %) as green crystals after purification by GPLC. The structure of **3** was determined by spectroscopic data (^{1}H, ^{13}C, ^{125}Te NMR, FAB-MS) and X-ray crystallographic analysis.[11] Although mechanism for the formation of **3** is not clear at present, **3** was most likely generated by over-tellurization of **2** under severe conditions such as heating at 60–100 °C, which would be required to dissolving elemental tellurium in benzene.

Since nBu$_3$P=Te has been known to function as a tellurization reagent under mild conditions,[12] we selected nBu$_3$P=Te as an alternative tellurium source for the tellurization of **1** and **2**. When a solution of **2** (49 mg, 0.03 mmol) in benzene (2.0 mL) was mixed with two equivalents of nBu$_3$P=Te (23 mg, 0.06 mmol) at room temperature, telluradibismirane **5**, in the form of an insoluble brown powder, precipitated from the reaction mixture (Scheme 1). After the suspension

Tokitoh), who is grateful to the von Humboldt Stiftung for their generosity and to Prof. Reinhard Schmutzler and Prof. Wolf-Walther du Mont for their warm hospitality.

 DOI: 10.1002/anie.200462122

was left to stand for 2 h, **5** was isolated as a pure material by filtration followed by washing with hexane (23.3 mg, 0.013 mmol, 43%). In this case, the tellurization reaction of **2** occurred at room temperature probably due to the fact that nBu$_3$P=Te is more soluble than elemental tellurium. In addition, no ditelluride **3** was observed in the ^{1}H NMR spectrum of the crude mixture. Distibene **1** was also tellurized by this method, giving the corresponding telluradistibirane **4**. Treatment of **1** with nBu$_3$P=Te under conditions similar to those applied to **2** afforded **4** as an orange powder in 50% yield. Three-membered ring compounds were obtained by the tellurization reaction of **1** and **2**, in contrast to the case of sulfurization reactions of **1**, which resulted in the formation of corresponding four-, five-, and six-membered ring compounds.[13] The formation of **4** and **5** is worthy of note not only as the synthesis of new members of three-membered heterocycles, but also as a new finding on the reactivity of distibenes and dibismuthenes toward the tellurization reaction.

The telluradistibirane **4** was found to be thermally stable in [D$_6$]benzene solution up to 140°C, and showed satisfactory ^{1}H and ^{13}C NMR spectral data. In addition, no change was observed in [D$_6$]benzene solution at 60°C under photoirradiation with a 100-W high-pressure Hg lamp. Although the telluradibismirane **5** was stable under ambient conditions, heating a solution of **5** in [D$_6$]benzene at 80°C for 1 h afforded a trace amount of ditelluride **3**. After the solution was heated at 100°C for 1 h, **5**, **2**, and **3** were observed in the ratio of 1:0.2:0.1. Additional heating of the solution at 110°C for 1 h gave an unidentified compound (**X**) together with **2** and **3** as the final products in a ratio of **X**:**2**:**3** = 1:2:2 as judged by ^{1}H NMR spectroscopy. Unfortunately, the reaction mechanism and the structure of the final product for the decomposition process of **5** are still unclear owing to the instability of compound **X** during the purification procedure. On the other hand, ^{125}Te NMR spectra of **4** measured in [D$_8$]toluene show a signal at $\delta = -622.3$ ppm within an upfield region, which is characteristic of such three-membered ring compounds. For example, some telluradisilirane ($\delta_{Te} = -784$ ppm)[4a] and telluradistannirane ($\delta_{Te} = -903$ ppm)[4b] derivatives were reported to show their ^{125}Te NMR signals in an up-field region, similar to the case of **4**. In addition, the ^{125}Te NMR chemical shift of dimesityltelluradistibirane (**6**), a model compound for **4**, was computed as $\delta = -700$ ppm by a GIAO calculation, which supports the experimentally observed chemical shift of **4**. Unfortunately, no signal was observed in the ^{125}Te NMR spectrum of **5** probably due to considerable peak broadening caused by the adjacent two bismuth atoms having nuclear spins of 9/2.

The molecular structures of **4** and **5** were determined by X-ray crystallographic analysis.[14] The structure of telluradibismirane **5** is shown in Figure 1 as a representative. The selected bond lengths and angles of **4** and **5** are depicted in Figure 2 together with the optimized structural parameters of model compounds, dimesityltelluradistibirane (**6**) and dimesityltelluradibismirane (**7**).[15] In both **4** and **5**, the two Bbt groups are oriented *trans* with regard to the central three-membered rings. The tellurirane skeletons of **4** and **5** are almost isosceles triangles with bond lengths (**4**: Sb–Sb

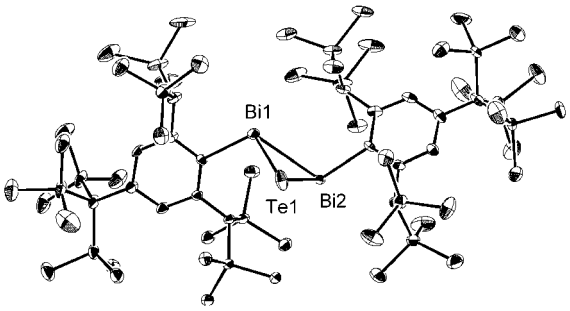

Figure 1. Molecular structure of **5** (ORTEP drawing; thermal ellipsoid plot (50% probability)).

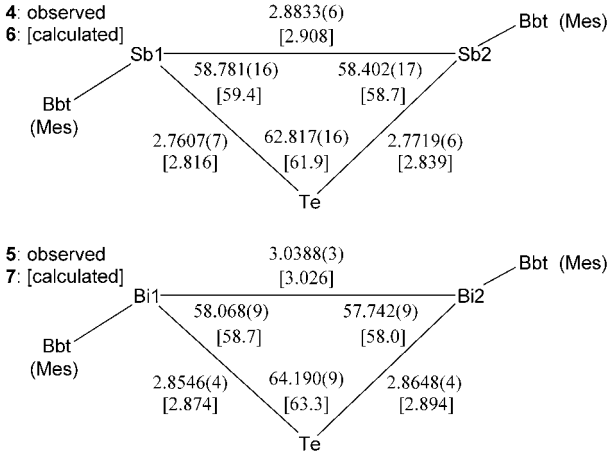

Figure 2. Selected bond lengths [Å] and bond angles [°] of **4** and **5**. Values in braces are calculated structural parameters for Mes-substituted model compounds **6** and **7**.

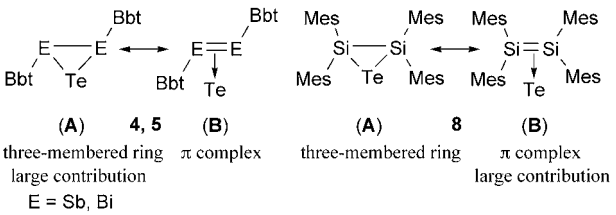
2.8833(6), Sb–Te 2.7607(7), 2.7719(6); **5**: Bi–Bi 3.0388(3), Bi–Te 2.8546(4), 2.8648(4) Å) that are comparable with previously reported values for the respective single bonds.[16] In addition, calculated structural parameters obtained by structural optimization (B3LYP) for the model compounds **6** and **7** supported the experimentally observed values obtained for the central three-membered-ring skeletons of **4** and **5**. These experimental and theoretical studies on the structures of **4** and **5** indicate that the telluradistibirane and telluradibismirane feature three-membered-ring character (**A**) rather than the π-complex character (**B**) as shown in Scheme 2. Interestingly, the telluradisilirane **8**, which is reported to be obtained by the reaction of Mes$_2$Si=SiMes$_2$ with elemental tellurium, features π-complex character (**B**) rather than the three-membered-ring character (**A**).[4a] It should be noted



Scheme 2. Structures of telluriranes.

that the structural features of the corresponding tellurirane derivatives of heavier Group 15 elements differ from those of heavier group 14 elements.

In summary, we have synthesized the first stable telluradistibirane, **4**, and telluradibismirane, **5**, by a tellurization reaction of the reactive double-bond systems, BbtSb=SbBbt and BbtBi=BiBbt, by using $(n\mathrm{Bu})_3\mathrm{P}{=}\mathrm{Te}$ as a tellurization reagent. We have demonstrated here that telluradistibirane and telluradibismirane derivatives, which are three-membered ring compounds composed of much heavier elements, Sb, Bi, and Te, can be isolated without any oligomerization by using an appropriate steric protecting group and synthetic method. Further investigation of the physical and chemical properties of the newly obtained three-membered ring systems **4** and **5** is currently in progress.

Experimental Section

4: Addition of $n\mathrm{Bu}_3\mathrm{P}{=}\mathrm{Te}$ (33 mg, 0.10 mmol) to a solution of **1** (70.4 mg, 0.05 mmol) in benzene (2 mL) at room temperature, led to the immediate precipitation of an orange powder. After the reaction mixture had been left to stand for 2 h, telluradistibirane **4** was separated by filtration, and then further purified by GPLC (40 mg, 0.025 mmol, 50 %). **4**: orange crystals, m.p. 161 °C (decomp); ^{1}H NMR (300 MHz, [D$_6$]benzene): $\delta = 0.33$ (s, 54 H), 0.36 (s, 36 H), 0.37 (s, 36 H), 2.87 (s, 4 H), 6.96 ppm (s, 4 H); ^{13}C NMR (75 MHz, [D$_6$]benzene): $\delta = 2.09$ (q), 2.28 (q), 5.65 (q), 22.21 (s), 37.69 (d), 126.90 (d), 138.33 (s), 145.83 (s), 150.88 ppm (s); ^{125}Te NMR (94 MHz, [D$_8$]toluene): $\delta = -622.3$ ppm; UV/Vis (hexane): λ_{max} (ε) = 458 (680), 390 (3100), 346 nm (8500); HRMS (FAB): m/z: 1619.4440([M+H]$^+$), calcd for $C_{60}H_{135}{}^{121}Sb_2Si_{14}{}^{130}Te$ ([M+H]$^+$): 1619.4472; elemental analysis calcd (%) for $C_{60}H_{134}Sb_2Si_{14}Te$: C 44.48, H 8.34; found: C 44.23, H 8.23.

5: $n\mathrm{Bu}_3\mathrm{P}{=}\mathrm{Te}$ (23 mg, 0.06 mmol) was added to a solution of **2** (49.0 mg, 0.03 mmol) in benzene (2 mL) at room temperature. The color of the reaction mixture immediately changed to dark brown. After the resulting suspension had been stirred for 2 h, the reaction mixture was filtered, and the residue was washed with hexane (20 mL) to afford brown crystals of telluradibismirane **5** (23.3 mg, 0.013 mmol, 43 %). **5**: brown crystals, m.p. 156 °C (decomp); ^{1}H NMR (400 MHz, [D$_6$]benzene): $\delta = 0.33$ (s, 36 H), 0.34 (s, 54 H), 0.36 (s, 36 H), 2.29 (s, 4 H), 7.20 ppm (s, 4 H); ^{13}C NMR (100 MHz, [D$_6$]benzene): $\delta = 2.31$ (q), 2.41 (q), 5.65 (q), 22.10 (s), 43.15 (d), 126.54 (d), 145.08 (s), 151.68 (s), 161.38 ppm (s); UV/Vis (hexane): λ_{max} (ε) = 521 (2100), 450 (3200), 338 nm (18700); HRMS (FAB): m/z: 1795.6004 ([M+H]$^+$), calcd for $C_{60}H_{135}Bi_2Si_{14}{}^{130}Te$ ([M+H]$^+$): 1795.6004; elemental analysis calcd (%) for $C_{60}H_{134}Bi_2Si_{14}$ Te: C 40.16, H 7.53; found: C 40.12, H 7.48.

Nanoparticles

Radical Mechanism of a Place-Exchange Reaction of Au Nanoparticles**

*Petre Ionita, Bruce C. Gilbert, and Victor Chechik**

The exchange reaction shown in Equation (1) is a convenient method to prepare functionalized metal nanoparticles, and its

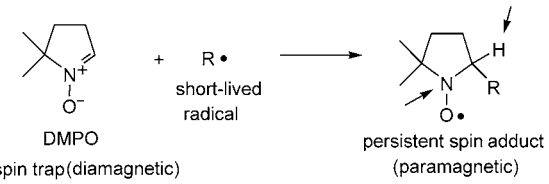
(1)

mechanism has been studied by several research groups.[1–3] Murray and co-workers carried out detailed kinetic studies on the exchange of thiol-protecting groups on Au particles with other thiols.[4,5] The exchange was shown to be an associative (bimolecular) process, with both the incoming ligand and Au nanoparticles participating in the rate-determining step. As well as by evidence from kinetic studies, this mechanism is supported by the sensitivity of the place-exchange reaction to the electronic effects of the incoming ligand. The fact that the reaction is facilitated under oxidizing conditions, for example, in an electrochemical cell or in the presence of oxygen, is particularly intriguing.[6] To explain the apparent catalytic effect of oxidizing reagents, it was tentatively proposed that Au^{I} thiolates could act as reaction intermediates.

Recently, we applied a spin-labeling method to study an exchange reaction with disulfides.[7] We found with EPR spectroscopy that Au nanoparticles protected with weakly bound ligands (for example, phosphines or amines) undergo a rapid place-exchange reaction with disulfides. The S–S bond in the disulfide is broken during the reaction, and the two branches of the disulfide molecule do not adsorb adjacent to each other on the Au surface.[7,8]

We noticed, however, that although spin-labeled disulfides are very stable under exchange-reaction conditions, the EPR signal of the parent (spin-labeled) thiol decays rapidly during the reaction. The apparent destruction of the spin label (a nitroxide group) is most likely brought about by a redox reaction that involves either Au ions or organic free radicals. To detect the possible formation of free radicals during the exchange reaction of triphenylphosphane-protected Au nanoparticles with alkanethiols, we performed a series of EPR spin-trapping experiments.

The spin-trapping technique used in this study relies on the fast addition (trapping) of short-lived radicals to the diamagnetic spin trap DMPO (5,5-dimethyl-4,5-dihydro-3*H*-pyrrole-*N*-oxide). The product of such an addition is a persistent free radical, with a lifetime that is long enough that it can be detected by direct EPR measurements (Scheme 1).[9]



Scheme 1. Spin trapping of short-lived radicals by DMPO.

An important feature of the DMPO spin adducts is the sensitivity of the hyperfine coupling constants of the unpaired electron in the adduct with the hydrogen and nitrogen atoms (shown by arrows in Scheme 1) to the chemical composition of the short-lived radical. The EPR spectra of the spin adducts, therefore, provide useful information about the structure of the original radical.

In a typical spin-trapping experiment, a solution of *n*-butanethiol (2.5×10^{-3} M) in toluene/CH_2Cl_2 (4:1, *v*/*v*) was added to a mixture of triphenylphosphane-protected Au nanoparticles ($1.25–10 \times 10^{-4}$ M) and DMPO ($1.25–5 \times 10^{-2}$ M) in the same solvent mixture. The formation of spin adducts in the reaction mixture was monitored by EPR spectroscopic analysis.

A strong EPR signal was observed immediately after mixing (Figure 1a). Analysis of the hyperfine splitting allowed us to assign its structure to the spin adduct of DMPO and butanethiol radical $C_4H_9S^{\bullet}$ (Table 1). The spectrum was also identical to that of an authentic spin adduct

DMPO–H	14.88[a] (14.83)[b]	19.32[a] (19.27)[b]	19.32[a] (19.27)[b]

[a] Observed during exchange reaction. [b] Observed on oxidation with PbO_2. [c] Previously reported values (toluene).[9]

DMPO–SC_4H_9 prepared by the oxidation of butanethiol with lead dioxide (Figure 1, Table 1). The exact amount of the spin adduct formed varied, but double integration of the EPR spectra revealed that the amount of the spin adduct accounted for 3–12 % of the amount of butanethiol used in the reaction. Importantly, no EPR signal was observed if the reaction was carried out in the absence of oxygen (for example, in an argon atmosphere).

As well as by the trapping of free radicals, the spin adducts can sometimes form by two alternative reactions,[10,11] namely, the Forrester–Hepburn mechanism (nucleophilic addition followed by oxidation) and the Eberson mechanism (inverse spin-trapping; Equations (2) and (3), respectively).

$$\mathrm{DMPO} + \mathrm{Nu}^- \rightarrow \mathrm{DMPO{-}Nu}^- \xrightarrow{\mathrm{ox}} \mathrm{DMPO{-}Nu}^{\cdot} \quad (2)$$

$$\mathrm{DMPO} \xrightarrow{\mathrm{ox}} \mathrm{DMPO}^{+\cdot} \xrightarrow{\mathrm{Nu}^-} \mathrm{DMPO{-}Nu}^{\cdot} \quad (3)$$

To test if the spin adducts are formed by the reaction given in Equation (2), we studied the nucleophilic addition of butanethiol to the DMPO spin trap under exchange-reaction conditions. NMR spectroscopic experiments showed the absence of a Michael addition on the reaction timescale. The Eberson mechanism can also be ruled out, as we observed no EPR signal with a control reaction mixture of the DMPO spin trap with Au nanoparticles in the presence of oxygen. This lack of a signal implies that the spin trap can not be oxidized under the reaction conditions.

We conclude, therefore, that the observed spin adducts are formed by trapping of the parent short-lived radicals formed during the exchange reaction. As the relative amount of the observed spin adduct was quite high (up to 12 % of the added alkanethiol, see above), the radical pathway must play a key role in the mechanism of the exchange reaction.

A likely route to RS$^{\cdot}$ radicals is the Au-nanoparticle-catalyzed oxidation of RSH with molecular oxygen. This mechanism is consistent with the fact that no radicals are formed when the exchange reaction is carried out in an inert atmosphere, and with reports that exchange reactions are significantly slower in the absence of air (confirmed by our own control experiments with alkanethiols and triphenylphosphane-protected Au nanoparticles). The oxidation of thiols is further supported by the formation of alkane disulfides (as observed by NMR spectroscopic analysis) when the exchange reaction is carried out in the absence of the spin trap.

To test the feasibility of such a mechanism, we set out to explore whether Au nanoparticles can catalyze the air oxidation of organic compounds. Indeed, the addition of *tert*-butyl hydroperoxide or sodium borohydride to a mixture of phosphine-protected Au nanoparticles and DMPO in air led to intense EPR spectra of the corresponding spin adducts of DMPO with *t*BuOO$^{\cdot}$ and H$^{\cdot}$ radicals (Figure 2). The structure

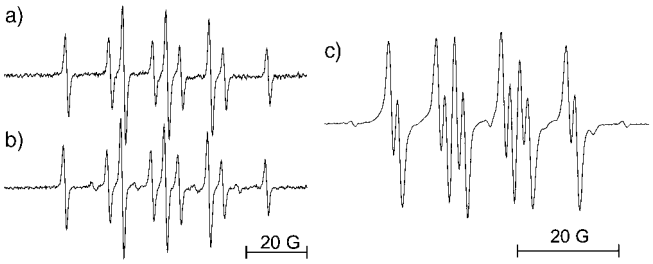

Figure 2. EPR spectra of the spin adducts DMPO–H produced by a) Au-nanoparticle-catalyzed oxidation of BH_4^- with air and b) oxidation of BH_4^- with PbO_2. c) EPR spectrum of DMPO–OO*t*Bu produced by nanoparticle-catalyzed oxidation of *t*BuOOH with air.

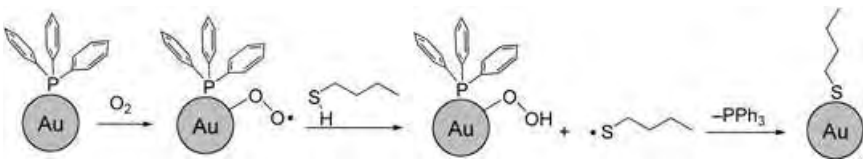
of the H$^{\cdot}$ adduct was confirmed by comparison with an authentic radical generated by the oxidation of $NaBH_4$ with PbO_2 (Figure 2, Table 1). The peroxide adduct was identified by comparison with previously reported data (Table 1).[9] No radicals were detected in the absence of Au nanoparticles or air. These experiments confirmed the oxidizing power of the mixture of Au nanoparticles and air.

On the basis of our findings, we propose a mechanism for the exchange reaction (Scheme 2). The reaction starts with the adsorption of oxygen on the phosphine-protected nanoparticle surface to form an active catalyst. This superoxide-type species then abstracts a hydrogen atom from the incoming ligand (alkanethiol) to form a sulfur-centred radical, which is then successfully trapped with DMPO. We speculate that in the absence of the spin traps, the sulfur-centred



Scheme 2. Proposed mechanism of radical formation.

radicals rapidly replace the outgoing ligands (triphenylphosphane) from the Au surface.

This mechanism is consistent with several features of previously reported exchange reactions.[12,13] Meisel and co-workers described the oxidation of 4-amino-2,2,6,6-tetramethylpiperidine-1-oxyl (4-amino-tempo) to 4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl (4-oxo-tempo) with Au nanoparticles in the presence of oxygen.[14] The authors proposed that this reaction included Au nanoparticle mediated electron transfer from the NH_2 group to oxygen (to form a hydroperoxide radical), in a similar process to the mechanism given in Scheme 2. The electrocatalytic reduction of oxygen on Au nanoparticles was also reported by Murray and co-workers.[15]

Interestingly, we were unable to trap free radicals when the exchange reaction was carried out with thiol-protected Au nanoparticles. This failure to trap radicals could result from a number of factors, including the relatively slow kinetics of exchange reactions that involve thiol-protected nanoparticles, or the reduction of radicals by the outgoing ligand. There is, however, some indirect evidence for the involvement of free radicals in the reactions of thiol-protected Au nanoparticles, for example, the suppression of the exchange reaction in the absence of oxygen, the destruction of the nitroxide spin labels during the exchange of thiols with Au nanoparticles, and the oxidation of 4-amino-tempo (see above). It is, therefore, likely that at least some features of the proposed mechanism are quite general and not restricted to the phosphine-protected nanoparticles.

In conclusion, we have shown that the exchange reaction of phosphine-protected Au nanoparticles with alkanethiols in air proceeds by a free-radical pathway. Oxidation of the alkanethiols by molecular oxygen adsorbed on the nanoparticles is proposed as the key step in these reactions. The feasibility of such a reaction is demonstrated by the Au-nanoparticle-catalyzed oxidation of BH_4^- and *t*BuOOH with air.

Aqueous Foams

Aqueous Foams Stabilized Solely by Silica Nanoparticles**

Bernard P. Binks and Tommy S. Horozov*

Foams occur as end products or during the processing of products in a wide range of areas including the detergent, food, and cosmetic industries. They are mixtures of immiscible fluids in which a vapor phase is dispersed as millimeter-sized bubbles in the continuous phase of a liquid.[1] To prevent collapse of the foam, surfactants or proteins are usually added whose molecules cover the liquid/vapor interfaces. Small solid particles exhibit some similarities with such molecules by adsorbing at interfaces and acting as excellent emulsifiers of oil and water.[2] However, the use of small solid particles in stabilizing aqueous foams in air–water–particle systems in the absence of any other surface-active substance has not been demonstrated previously. Here we describe the preparation and stability of aqueous foams stabilized solely by nanoparticles of silica that exhibit different extents of hydrophobicity. By using a novel dispersion method, suitably hydrophobic particles can be dispersed in water and very stable foams can be formed in which aggregates of particles adsorb at the surfaces of micrometer-sized bubbles.

Certain small solid particles have been used in conjunction with surfactant molecules, which they adsorb at fluid/fluid interfaces, to either stabilize or destabilize drops in emulsions and bubbles in foams.[2] It is only recently, however, that their precise role is being elucidated in surfactant-free systems. Unlike surfactant molecules, most colloidal particles, although surface-active, are not amphiphilic. The exceptions

  DOI: 10.1002/anie.200462470

are so-called Janus particles, in which two separated regions of different wettability exist on the surface of a given particle. Such particles are both surface-active and amphiphilic.[2] The particles used in this work are not amphiphilic, but are homogeneously coated. In contrast to surfactant molecules, adsorption of solid particles to fluid/liquid interfaces does not change the interfacial tension.[3] A key parameter that affects adsorption appears to be the contact angle, θ (measured through water), that particles exhibit at the interface. The angle θ increases with the hydrophobicity of the particle. If θ is large enough, particles prefer to stay in air (or oil) rather than in water. However, if adsorbed, they are strongly held at the fluid interface. The energy ΔG required to remove a small spherical particle of radius r from an air/water surface is at a maximum at $\theta = 90°$.[2] It can be shown that for the particles used here for which $r \approx 10^{-7}$ m and $\theta = 90°$, ΔG is several orders of magnitude greater than the thermal energy. Hence, the particles are practically irreversibly adsorbed, in marked contrast to surfactant molecules that adsorb and desorb reversibly.

The well-documented flotation method relies on the attachment of mineral particles to air bubbles by adding to the slurry surface-active molecules as frothing agents and collectors.[4] Only two examples have been reported in which particles are employed as foam stabilizers in water-containing systems. Wilson[5] utilized relatively large, charged polystyrene latex particles (several μm) and varied the pH and the concentrations of salt and added surfactant to optimize foaming. These results indicate that θ approaches 90° for systems that display high foamability and stability. Sun and Gao[6] used particles (diameter $d \geq 1$ μm) of either teflon, polyethylene, or polyvinylchloride, but needed to add 20–40 wt% of ethanol to the aqueous dispersions to obtain a foam in sufficient quantity and of reasonable stability. Similarly, air-in-liquid metal (e.g. Al) foams are thought to be stabilized by ceramic particles such as SiC, but the underlying physics is not understood and surface-active impurities are commonly present.[7]

We show here the effect of the inherent hydrophobicity of silica nanoparticles on their ability to stabilize aqueous foams. Particles of intermediate hydrophobicity act as emulsifiers of oil and water by the formation of close-packed adsorbed layers at interfaces, which prevents coalescence of droplets.[8] They also adsorb around air bubbles and drastically slow down or halt completely the transfer of gas between them.[9] Hydrophilic silica particles contain surface silanol groups that react with silanizing agents to impart hydrophobicity. The latter is quantified in terms of the residual content of SiOH, which varies here from 100 to 14%. On the basis of a simple theory for predicting the contact angle that a particle exhibits at an air/water surface when the surface-energy components of the solid are known,[10] we calculate that $\theta = 13°$ for the most hydrophilic silica particles and $\theta = 84°$ for the most hydrophobic ones used here (see inset in Figure 1). In acknowledgement of the fact that more hydrophobic particles are required to adsorb for foam stabilization, we prepare foams either with particles initially in air or by dispersing them in water with the aid of ethanol, which is deliberately removed *before* the foaming tests.

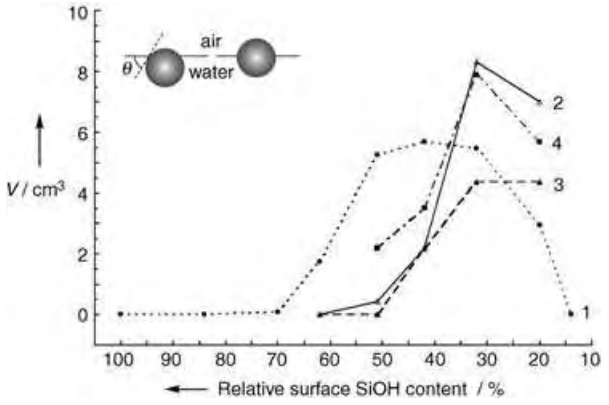

Figure 1. Volume of foam (V) produced at room temperature from 7 cm³ of water in the presence of fumed silica nanoparticles of different hydrophobicity (given as the percentage of SiOH on their surfaces) at 3 wt/v% (hand-shaken, 1) and 0.86 wt/v% (homogenized, 2–4). The conditions and time delays after the formation of the foam are 1) no salt, 0 and 1 h (----), 2) no salt, 10 s (——), 3) no salt, 27 h (– – –), and 4) 8.5 mM NaCl, 13.5 h (–•–•). The inset shows schematically the position of a particle at an air–water surface if hydrophilic (high % SiOH, left) or more hydrophobic (low % SiOH, right).

Figure 1 shows the volume of foam produced as a function of the hydrophobicity of the nanoparticles under different conditions. In the absence of salt and for hand-shaken systems (3 wt/v% particles initially in air, curve 1) no foam is formed for hydrophilic (≥ 70% SiOH) or very hydrophobic particles (14% SiOH, dry powder remained on water surface), but the foamability increases progressively for particles of intermediate hydrophobicity. These foams contain approximately 30% water when formed and are subsequently very stable to collapse. An alternative method is to disperse the particles in a solution of water/ethanol, which allows the more hydrophobic particles to become wetted, then to remove the ethanol by repeated sedimentation–redispersion cycles in pure water, and aerate the dispersion by using an Ultra Turrax homogenizer. The initial volume of foam in this case (0.86 wt/v% particles, curve 2) shows a more pronounced maximum with respect to the hydrophobicity of the particles, with the most effective being those that contain 32% SiOH.

The foams obtained with 32 and 20% SiOH are wet and even after a long time contain around 60% water. They are very stable to collapse. The decrease in their volume is a result of water drainage and bubble compaction, but not to loss of air (Figure 1, curve 3, 27 h). This is also evident in Figure 2 in which photographs of the vessels for particles of different hydrophobicities (% SiOH, given) are shown at 10 minutes (upper) and 13.5 hours (lower) after homogenization. For particles with a surface content of SiOH of greater than 42%, it can be seen that they reside mainly in the water phase (cloudy) with little foam, whereas for particles with 32 and 20% SiOH they are located entirely within the white, creamy foam that envelopes the air bubbles. The size of the bubbles decreases progressively with an increase in hydrophobicity of the particles.

The stability of the foam prepared with particles that contain 32% SiOH was measured by using the Dispersion Stability Analyzer 24 (DiStA 24)[11] and compared to that of

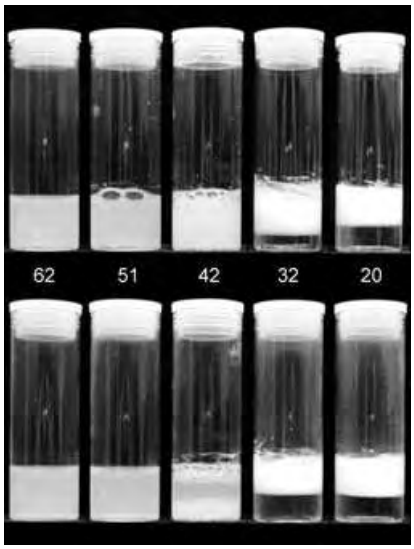

Figure 2. Appearance of vessels at room temperature at 10 minutes (upper) and 13.5 h (lower) after homogenization of aqueous dispersions containing 0.86 wt/v% silica particles (of different hydrophobicities, given as the percentage of SiOH (62, 51, 42, 32, and 20%) on their surfaces) in pure water.

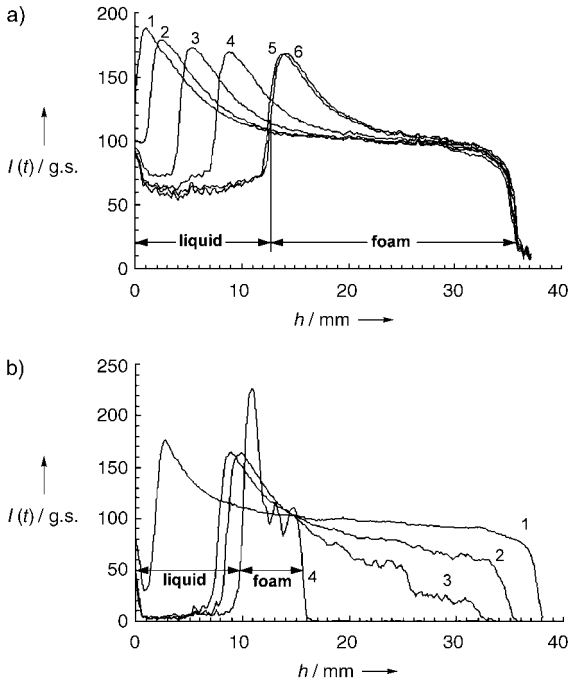

Figure 3. Vertical profiles (versus height, *h*) of scattered light in gray-scale (g.s.) units measured using DiStA 24 at 25 °C at different times after generation of the foam by homogenization: a) with 1 wt/v% silica particles in pure water containing 32% SiOH on their surfaces: 1) 30 s, 2) 10.5 min, 3) 31 min, 4) 1 h, 5) 24 h, and 6) 62 h; b) with 5.8 wt% aqueous SDS: 1) 36 s, 2) 10.6 min, 3) 31 min, and 4) 18 h.

foams made with the popular surfactant sodium dodecyl sulphate (SDS). This analyzer uses a scanner to take side images of the foam at preset time intervals. The images are automatically analyzed, and the vertical profile of light scattered from the sample is obtained. The destructive processes that occur in the foam can be detected and monitored well before it is possible to observe them with the naked eye.

The vertical profiles of the scattered light intensity are shown in Figure 3 for the silica-stabilized foam (part a) and that stabilized by the surfactant (part b) at different times after formation of the foam. In both cases the intensity of the light close to the bottom of the sample decreases with time, while the maximum light intensity shifts upwards. These changes are a result of the drainage of water from between the bubbles in the foam, with a clear serum appearing at the bottom in contact with a concentrated foam at the top (see Figure 2). In the case of the particle-stabilized foam, this drainage takes place relatively slowly and is over after several hours. By contrast, the fast drainage of water out of the foam in the surfactant-stabilized case (few minutes) leads to a significant shift upwards of the intensity maximum and a drastic decrease in the intensity in the upper part of the profile. The collapse of the foam is accompanied by the appearance of local maxima and minima. Such changes in the light intensity are a direct consequence of coarsening of the foam as a result of both bubble coalescence and disproportionation. Adsorbed particles clearly prevent the occurrence of both of these phenomena.

Optical microscope images of bubbles in foams stabilized by particles with 32% SiOH, in the presence and absence of salt, are given in Figure 4a–c. Distinct nonspherical bubbles, with diameters of 5–50 μm, are a feature of these systems. Their surfaces are rough as a result of ripples. Similar ripples have been observed in the case of a planar air/water monolayer of silica nanoparticles after compression (Figure 4d) which suggests that the bubbles are covered with dense particle layers compressed to a high surface pressure that is close to the surface tension of water (71.9 $mN\,m^{-1}$).[12]

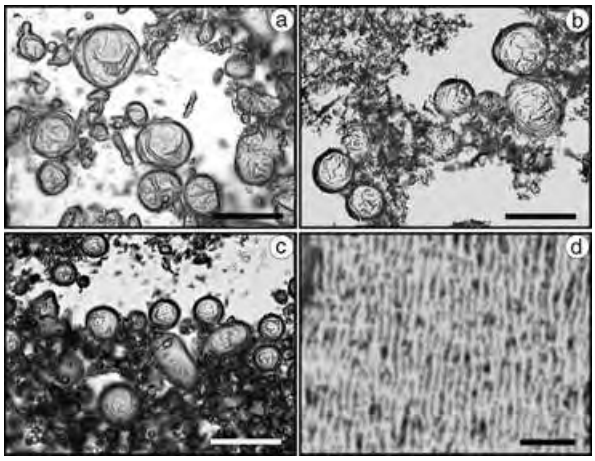

Figure 4. Optical microscopy images of aqueous foams stabilized by silica nanoparticles that contain 32% SiOH on their surfaces. Conditions and time after formation by homogenization: a) no salt, 3 wt/v% particles, 40 h, b) 8.5 mM NaCl, 0.86 wt/v% particles, 5 min, and c) 1 M NaCl, 0.37 wt/v% particles, 5 min. Also shown in d) is the image of a planar monolayer of silica nanoparticles (with 50% SiOH) at the air–water surface after compression to a surface pressure of 70 $mN\,m^{-1}$. The corrugations are parallel to the trough barriers. All scale bars: 50 μm.

Stable bubbles are probably formed by coalescence between smaller bubbles that are covered with dilute particle layers during homogenization.[13] As the bubble area decreases, excess particles cannot be released as they are irreversibly adsorbed and so the surface corrugates to increase in area. As silica particles in water and bare air–water surfaces are negatively charged, it is anticipated that addition of salt to water should enhance the transfer of particles to the surface by reducing the energy barrier to adsorption.[14] It may also increase their contact angle as hydrophobicity increases, with both of these factors leading to improved stabilization of the foam. Indeed, this is the case as seen in Figure 1 (curve 4) and in Figure 5, in which even a small amount of electrolyte

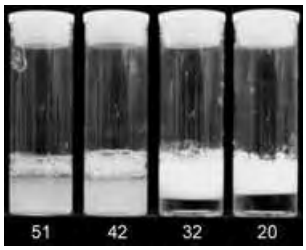

Figure 5. Appearance of vessels at room temperature in systems containing 0.86 wt/v% silica nanoparticles of different hydrophobicity (given as the percentage SiOH) in 8.5 mM NaCl at $t = 13.5$ h after formation of the foam by homogenization. Note that particles reside mainly in water for SiOH contents of 51 and 42%, but are entirely within the foam for SiOH contents of 32 and 20%.

(8.5 mM) improves both the foamability and foam stability. Particles that are initially relatively hydrophilic (42 and 51% SiOH) can now stabilize foams to a higher extent than in the absence of salt (compare with Figure 2).

Nanoparticles are effective foaming agents of air and water, and by controlling their hydrophobicity, foams that are completely stable to collapse, coalescence, and disproportionation can be prepared. We plan to investigate further the influence of pH and the concentration of salt in these systems. Manipulation of the behavior of particles adsorbed at fluid interfaces in this way enables the development of a novel range of foams for use in food, detergent, and cosmetic formulations.[15]

Experimental Section

Methods: Fumed silica particles of primary diameter 20–50 nm and surface area 200 $m^2 g^{-1}$ were supplied by Wacker-Chemie. During preparation, some particles fuse irreversibly to form aggregates (few hundred nm) of particles. The different hydrophobic grades were obtained after silanization of hydrophilic silica with dichlorodimethylsilane.[8] Their surface content of silanol varied from 100 to 14%. Water was passed through a reverse osmosis unit and then a Milli-Q reagent system—its pH value was 5.6 owing to dissolved CO_2. The salt used was NaCl (99.9% pure) from Prolabo. Foams were prepared in sample tubes (inner diameter:2.5 cm, height:7.5 cm) either by shaking by hand the system of powdered particles resting on 7 cm^3 of water (20 s, frequency:5 Hz) or by aerating the same volume of an aqueous dispersion of particles by using an Ultra Turrax homogeniser (Janke & Kunkel) with a 1.8-cm-diameter head operating at 11000 rpm for 3 minutes (6 × 30 s with 30 s rest periods). In the latter, the powders were wet with ethanol, then mixed with water to give a suspension that contained < 2 wt% ethanol. The ethanol was removed by repeated sedimentation–redispersion cycles in pure water to attain less than 10^{-4} wt% residual ethanol. Photographs of the vessels were taken with a Kodak DX4330 digital camera. The surfactant-stabilized foam was formed by homogenizing 5 cm^3 of an aqueous solution of SDS (Lancaster, 99%) at 8000 rpm for 1 minute. The stability of the foams was measured with the automated Dispersion Stability Analyser 24 developed recently.[11] An optical microscope (Nikon Optiphot-2) was used to observe the structure around and between the bubbles in the foams. A planar monolayer at the air–water surface was formed by the spreading of a dispersion of silica particles in chloroform and compressing in a Langmuir trough. The images were captured by the same microscope in reflected light.

[13] We anticipate that the fumed silica particles will aggregate in bulk and that the extent of aggregation may depend on the hydrophobicity of the particle and the concentration of the electrolyte. Whether discrete primary particles or aggregates of particles, or both, adsorb around air bubbles is not known, but work to determine this is in progress. One consequence of particle aggregation is the increased viscosity of the aqueous phase (gelling) which results in slower drainage of foam films and increased stability of the foam.

Metalloporphyrinoids

Dicopper and Disilver Complexes of Octaphyrin(1.1.1.1.1.1.1.1): Reversible Hydrolytic Cleavage of the Pyrrolic Ring to a Keto–Imine**

*Soji Shimizu, Yasuo Tanaka, Katsuyuki Youfu, and Atsuhiro Osuka**

Of the various expanded porphyrins developed in recent years,[1] octaphyrins hold a unique position in view of their dynamic figure-of-eight conformations as well as their ability to coordinate two metal ions,[2] while some octaphyrins are known to be planar and aromatic.[3] Curiously, the metalation of figure-of-eight octaphyrins is often accompanied by rather unexpected skeletal rearrangements.[4] Vogel et al. revealed an interesting equilibrium of the dipalladium complex of octaphyrin(1.1.1.0.1.1.1.0) and its bis-spiro derivative, and isolated the dinickel complex of a spirodicorrole upon metalation of dioxooctaphyrin(1.1.1.0.1.1.1.0).[5] Both processes involved large skeletal rearrangements. We also reported that complexation of [36]octaphyrin(1.1.1.1.1.1.1.1) **1** with copper provided the dicopper(II) complex **2**, which underwent a quantitative thermal splitting reaction into two copper(II) porphyrins, **3**, through an unprecedented metathesis that involved the scission and formation of at least two carbon–carbon bonds.[6] This reaction is thought to be driven by severe distortion of the complex **2**. Herein, we report the dimetalation of perfluorinated [36]octaphyrin(1.1.1.1.1.1.1.1) **4**[7] with copper(II) ions which leads to unusual hydrolytic ring opening of one pyrrole ring to give the keto–imine form. We also report facile dimetalations of **1** and **4** with silver ions to quantitatively provide figure-of-eight disilver complexes.

A solution of **4** in CH_2Cl_2 was stirred with $Cu(OAc)_2$ (50 equiv) and NaOAc for 6 hours at room temperature to provide two dicopper complexes, **5** and **6**, in respective yields of 58 and 14%. The parent-ion peak in the ESI-TOF (electrospray ionization/time of flight) mass spectrum for complex **5** was observed at $m/z = 2375$ ($[M-H]^-$), which is 16 mass units larger than the expected mass of a dicopper complex (see Table 1). The absorption spectrum of **5** comprises a broad band at 396 nm and a less intense band at 699 nm and is significantly different from that of **4** (Figure 1). The crystal structure of **5** was determined by single crystal X-ray diffraction analysis and is shown in Figure 2.[8] The complex exhibits a bent U-shaped ellipsoidal conformation, in which one pyrrole ring is hydrolytically cleaved to give a keto–imine. One of the two copper ions (Cu1) is bound to the keto-carbonyl oxygen atom (O1) and the nitrogen atoms of the nearby tripyrrolic subunit, while Cu2 is bound to the imine nitrogen atom (N5) and the nearby second tripyyrolic subunit. The coordination-bond lengths are in the range of 1.92–2.02 Å, and the distance between the two Cu ions is 5.41 Å.

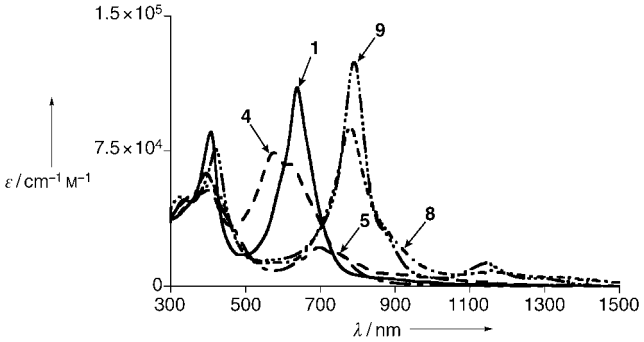

Figure 1. UV/Vis absorption spectra of **1** and **4**, and complexes **5**, **8**, and **9** in CH_2Cl_2.

Coordination features of the two copper ions in **5** are likely closer to a square-planar geometry than the highly distorted structure of **2**. The mean planes defined by Cu1, N2, N3, and N4, and by Cu2, N6, N7, and N8, are relatively flat and almost parallel to each other. The ligating carbonyl oxygen atom O1 and imine nitrogen atom N5 are somewhat deviated from these planes (O1 by 0.8 Å; N5 by 1.2 Å). Interestingly, **5** was quantitatively demetalated to give **4** upon treatment with trifluoroacetic acid and H_2SO_4 with concomitant recyclization of the keto–imine unit to the pyrrole ring. Measurement of the magnetic susceptibility (χ) by SQUID revealed that the copper ions in **5** were both present as paramagnetic d^9 forms

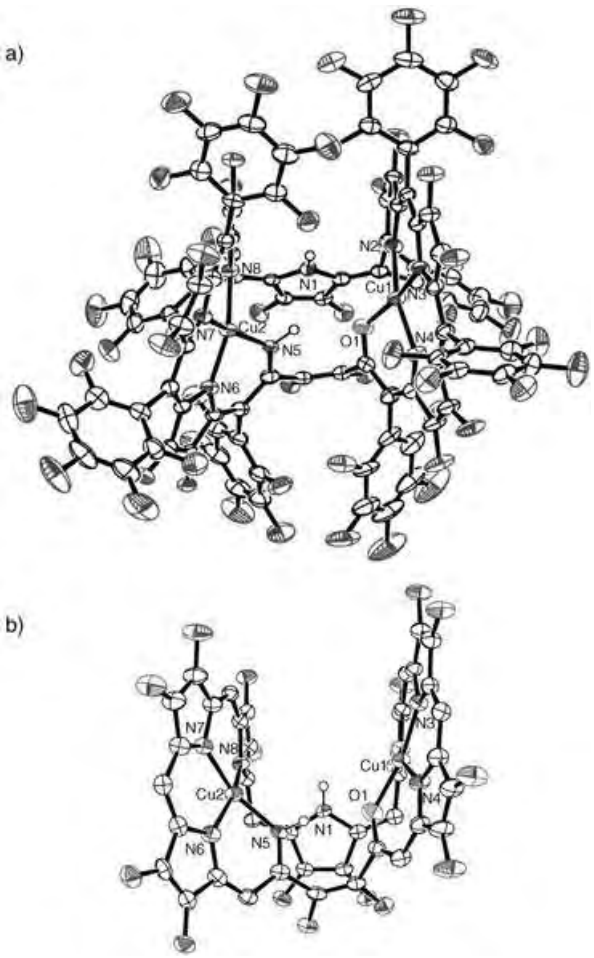

Figure 2. X-ray crystal structure of **5**: a) top view and b) side view. The thermal ellipsoids are scaled to the 50% probability level. Solvent molecules are omitted in the top view while *meso*-pentafluorophenyl substituents are also omitted in the side view for clarity.

of Cu^{II} ($\chi_p T=0.81$ emu K mol^{-1} at room temperature), in accord with the crystal structure.[9]

The minor product **6** exhibits an absorption spectrum that is quite similar to that of **2** (see Supporting Information), and its high-resolution ESI-MS spectrum showed a peak for the molecular ion at $m/z=2357.7978$ (calcd for $C_{88}N_8F_{56}Cu_2=2357.7938$) with the expected isotopic peak pattern. Although efforts to obtain suitable crystals of **6** for X-ray analysis were unsuccessful, these data suggest that **6** is a dicopper complex that adopts a figure-of-eight structure, similar to **2**. Upon heating complex **6** in solution, it underwent hydrolysis to give **5** with concomitant decomposition, whereas, interestingly, thermolysis of **6** in the solid state led to its splitting into perfluorinated Cu^{II} porphyrin **7**.[10] One possible route to **5** may be through initial formation of **6** followed by subsequent hydrolytic ring opening of one pyrrole ring, facilitated by the strongly electron-deficient nature of the perfluorinated macrocycle in **6**.

Among the transition-metal salts tested, we found that complexation of **1** and **4** with salts of silver(I), a heavier congener of copper, proceeded smoothly without any rearrangement of the macrocyclic ring, in sharp contrast to

dimetalation with copper, to provide disilver(I) complexes. A solution of **1** in a mixture of $CHCl_3$ and methanol (3:1) was heated at reflux in the presence of AgOAc (10 equiv) for 15 minutes. Disilver complex **8** was obtained as a blue solid in 98% yield. The parent-ion peak for this complex appeared at $m/z = 2158$ (M^-; calcd for $C_{88}H_{16}N_8F_{40}Ag_2 = 2158$) in the ESI-TOF mass spectrum (see Table 1). The structure of **8** was revealed by single-crystal X-ray diffraction analysis (Figure 3)

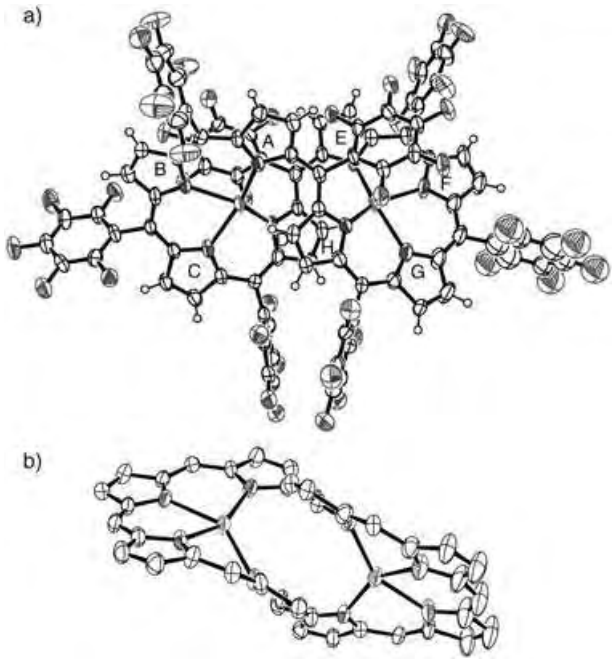

Figure 3. X-ray crystal structure of **8**: a) top view and b) side view. The thermal ellipsoids are scaled to the 50% probability level. Solvent molecules are omitted in the top view while *meso*-pentafluorophenyl substituents and β-hydrogen atoms are also omitted in the side view for clarity.

to adopt a near-C_2-symmetric figure-of-eight conformation, in which two silver ions are each bound within porphyrin-like hemicyclic cavities with Ag–N bond distances in the range of 2.27–2.37 Å.[11] Tripyrrolic units consisting of pyrroles A, B, and C, and E, F, and G are relatively flat, while pyrroles D and H are tilted by 33 and 43°, respectively, from these planes. As a consequence, the structure of **8** is rather distorted from square-planar geometry, but the extent of this distortion is modest relative to **2**. Interestingly, pentafluorophenyl substituents at the crossing *meso* position lie just over the silver atoms in parallel with the tripyrrolic units, with an interplanar distance of approximately 3.2 Å, while pyrroles D and H are placed below silver ions with Ag–βC distances of 2.89 and 2.87 Å, respectively. Relative to the structures of silver complexes of porphyrins and porphyrinoids,[12] relatively long Ag–N distances lead to the assignment of **8** as a disilver(I) complex of [34]octaphyrin(1.1.1.1.1.1.1.1).

In accord with this assignment, the ^{1}H NMR spectrum of **8** revealed eight sharp signals for the peripheral β protons of which seven signals were observed as doublets in the range of $\delta = 7.98$–6.26 ppm and one signal was observed at $\delta =$ 5.64 ppm as a double-doublet. The observed double-doublet signal cannot be explained by considering only proton–proton coupling, but can be accounted for in terms of additional through-space coupling with the proximal Ag^I ion as the Ag^I ion ($I = 1/2$) is placed close to the β-CH protons of pyrroles D and H (see Supporting Information). In the ^{19}F NMR spectrum of **8**, the peaks from the *ortho* and *meta* fluorine atoms that are close to the Ag^I ions are split similarly.[13] While the absorption spectrum of **1** displayed a broad Soret-like band at 638 nm, the spectrum of **8** displayed Soret-like bands at 408 and 780 nm and a Q-like band at 1151 nm, probably reflecting the 34-π-electron system of the macrocycle. As an excess of AgOAc was needed for complete metalation, the initial step may be silver(I)-promoted oxidation of [36]octaphyrin to [34]octaphyrin, which then may bind two Ag^I ions inside the porphyrin-like hemi-macrocycles.

In an analogous manner, treatment of **4** with CF_3COOAg (10 equiv) in a mixture of CH_2Cl_2 and methanol (10:1) for 40 minutes at room temperature provided almost quantitatively the disilver complex **9** as a dark green solid. Complex **9** displayed its parent-ion peak at $m/z = 2445$ [M^-] in the ESI-TOF mass spectrum and its ^{19}F NMR spectrum revealed sharp signals, which indicate its diamagnetic nature and a C_2-symmetric structure in solution (see Table 1). The absorption spectrum of **9** displayed bands at 422 and 791 nm and Q-band-like bands at 1143 and 1287 nm (Figure 1). The final structural confirmation of **9** was provided by single-crystal X-ray analysis.[14] As shown in Figure 4, complex **9** has a figure-of-eight conformation in the solid state which is quite similar to that of **8**. Pyrrole rings D and H are located below the silver

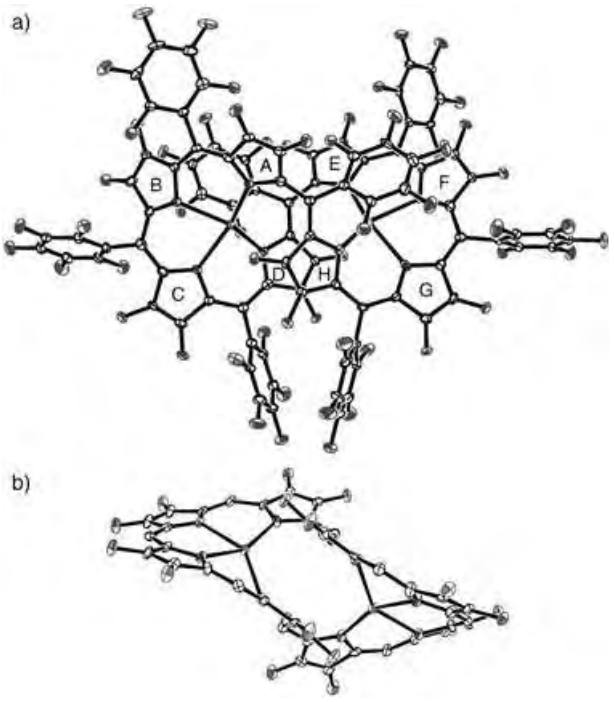

Figure 4. X-ray crystal structure of **9**: a) top view and b) side view. The thermal ellipsoids are scaled to the 50% probability level. Solvent molecules are omitted in the top view while *meso*-pentafluorophenyl substituents are also omitted in the side view for clarity.

ions on the opposite hemi-macrocycle with their pyrrolic β-fluorine atoms close to the silver ion, while the pentafluorophenyl substituents at the *meso* positions between pyrroles D and E and between pyrroles A and H also lie close to the silver ions. These structural features lead to through-space coupling of the related fluorine atoms with silver ions.[15] The Ag–N bond distances are in the range of 2.27–2.40 Å. We thus assigned complex **9** as a disilver(I) complex of perfluorinated [34]octaphyrin.

Despite the figure-of-eight structures that are similar to that of **2**, both disilver complexes **8** and **9** are thermally stable and do not exhibit any splitting reactivity, as observed for **2**. A major reason for the absence of thermal splitting reactivity may be the 34-π-electron systems of **8** and **9** which rationally preclude splitting into two 18-π-electron porphyrins. We thus attempted the reduction of **8** and **9** with $NaBH_4$ which caused spontaneous demetalation of the complexes to provide the respective free-base [38]octaphyrins.

In summary, metalation of the perfluorinated octaphyrin **4** with copper resulted in the formation of the dicopper complex **5** with an unprecedented concomitant hydrolytic ring opening of one of the pyrrole units. The octaphyrin framework was restored by demetalation with TFA and H_2SO_4. In contrast, metalation of both octaphyrin **1** and **4** with silver proceeded with initial two-electron oxidation of the ligands to give twisted figure-of-eight disilver(I) complexes of [34]octaphyrins that are thermally very stable. The structures and properties of dimetal complexes of octaphyrins are diverse and depend on the individual properties of the metal ion and the ligand, and they hail great potential for expanded porphyrins, which are actively pursued in our laboratory.

Chemical Traps

An Electrochemically Driven and Electrochemically Regenerated NO_x Trap**

*Norman MacLeod, Federico J. Williams, Mintcho S. Tikhov, and Richard M. Lambert**

Absorption traps are used in a wide variety of different applications to prevent potentially harmful chemicals from entering the environment and/or from coming into contact with sensitive downstream equipment. Many of the materials in use cannot be regenerated so that concerns relating to sustainable usage and environmentally acceptable disposal are important; in other cases, regeneration can only be accomplished with relative difficulty. Herein we describe a new principle that can be used to address both these issues.

A key application where chemical traps have found widespread use is in the control of NO_x emissions generated by fuel-efficient automotive engines which, by reducing the atmospheric CO_2 burden, can significantly mitigate the impact of road transport on global warming. Unfortunately, such engines produce much higher concentrations of nitrogen oxides (NO_x) than conventional gasoline engines[1] with attendant adverse impact on human health and the environment.[2] As a consequence, conventional "three-way" catalytic converters are inadequate and a post-converter NO_x trap is required. These traps consist of an alkaline-earth component (usually barium) that is able to store NO_x species as various nitrates and nitrites under the oxygen-rich conditions typical of "lean" engine operation. Precious metals, usually platinum, are also used as they aid in the uptake of NO_x by providing sites for the adsorption and catalytic oxidation of NO to NO_2. To restore the trap the engine is momentarily switched to "rich operation", generating a large concentration of reducing species that cause reduction of the adsorbed nitrate/nitrite species to nitrogen thus regenerating the active $BaO/BaCO_3$ component. A disadvantage of this procedure is that relatively high temperatures (≈ 900 K) are required for complete regeneration. Although the current generation of NO_x traps is very effective when run under these conditions, a number of significant problems remain, especially the need for regular high-temperature excursions, the requirement of periodic rich engine operation (which partially defeats the object of lean operation), and susceptibility to poisoning by sulfur compounds present in the fuel.

Herein we report a novel electrochemically driven NO_x trap that can operate effectively over a range of temperatures and can be regenerated as required in a controlled manner, without the requirement for temperature excursions or changes in gas-phase composition. Although NO_x trapping is used herein to illustrate the technique, the general method employed could be applicable in a wide variety of different applications, including, for example, removal oxides of carbon and sulfur. The trap consists of a thin porous layer of a precious metal (Pt, Pd, or Rh) deposited onto the surface of a solid electrolyte wafer that is biased to deliver the active species to the metal surface where it encounters the adsorbed NO_x. We used sodium and potassium ionic conductors although a variety of other solid electrolytes could be used, depending on the application.

NO_x-trapping and trap-regeneration measurements were performed in a well-mixed microreactor operated at atmospheric pressure and described in detail elsewhere.[3] X-ray photoelectron spectroscopy (XPS) measurements were carried out with a VG ADES 400 spectrometer system[4] and in situ infrared spectroscopy measurements were performed with a Perkin Elmer GX2000 spectrometer utilizing a Harrick Refractor Reactor specular reflection accessory.

The performance of the trap is illustrated in Figure 1 which shows the effects of 1) electrochemically trapping NO_x

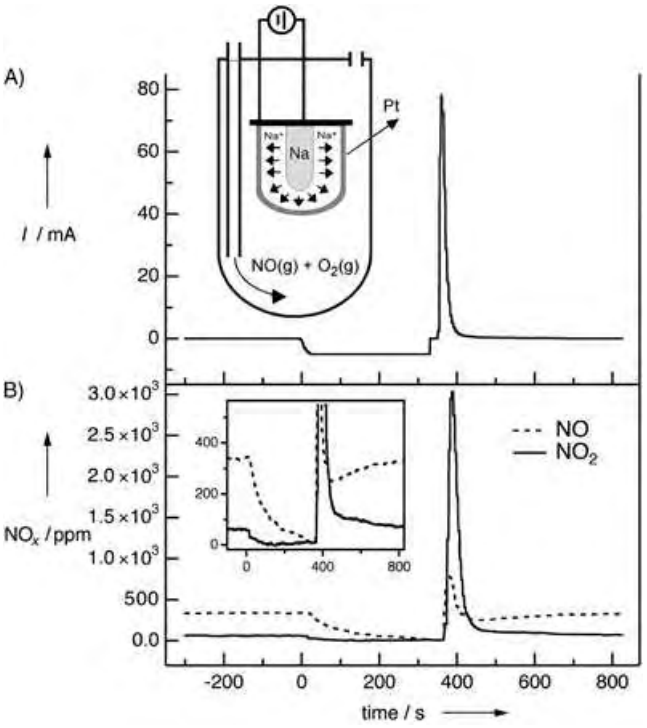

Figure 1. Trapping and regeneration carried out with a Pt|Na–β″alumina|Na electrochemical cell as shown in the inset of (A). A) Variations in the galvanic current passed through the trap and B) the composition of the exit gas. The counter electrode (metallic sodium) is not in contact with the gas atmosphere. Gas feed was 400 ppm NO_x + 5% O_2 at 150 mL min^{-1} at 573 K. Initial reactant feed at open circuit, negative current imposed at $t = 0$ (A) resulting in electrochemical pumping of sodium towards the Pt electrode and NO_x trapping from the gas phase (B). Inset in (B) shows gas-phase composition over 0–800 s interval in more detail. Reversing the current decomposes the trapped nitroxy species resulting in the desorption of mainly NO_2.

and subsequent 2) trap regeneration with release of (mainly) NO_2. Initially, under open circuit conditions with trap at 573 K, the exit gas composition (identical to the inlet gas composition) was 340 ppm NO, 60 ppm NO_2 and 5% O_2. These concentrations are representative of lean-burn engine exhaust. At $t=0$ a constant current of -5 mA (4.2×10^{-4} A cm^{-2}, ca. 10 V) was applied between the counter and working electrodes, by means of a galvanostat, driving sodium ions to the surface of the porous platinum film where they were discharged at the three-phase boundary ($Na^+ + e^- \rightarrow$ Na) the sodium then reacted with ambient gas, trapping NO_x. Within approximately 10 s of current application the exit concentration of NO_x from the reactor declined reaching a value of 15 ppm after 300 s of current flow which corresponds to 95.5% removal of NO_x and essentially 100% suppression of NO_2. (Note that in our experiment the apparent time dependence of NO_x uptake is entirely determined by the mean residence time of gas molecules in the trap (ca. 60 s) and not by the intrinsic rate of trapping). The trap was then switched to open circuit for 15 s after which it was polarized in the opposite sense. This resulted in a current spike of approximately $+80$ mA (6.7×10^{-3} A cm^{-2}) which correlated with a very large release of NO_x which consisted principally of NO_2 accompanied by a small quantity of NO. This feature is important because NO_2 is much more reactive than NO towards the reductant species present in engine exhaust (CO, H_2, hydrocarbons).[5] Its production during trap regeneration is therefore an additional advantage because it implies much more efficient conversion of stored NO_x into N_2, hence cleaner operation, under practical conditions. Integration of the current/time curves in Figure 1 showed that the amounts of sodium pumped to/from the trap during the trapping/regeneration cycle were equal—that is, there is no loss of Na during operation. The nitrogen balance obtained by integrating the NO_x curves (N trapped during NO_x uptake versus N desorbed during regeneration) closed within 4%. This behavior was reproducible and repeated in a number of separate experiments.

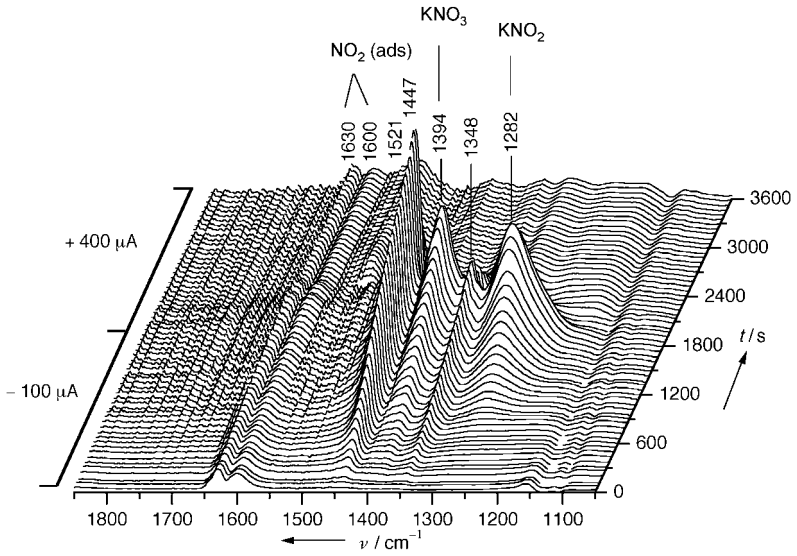

Figure 2. In situ reflectance infrared spectroscopy measurements determine the nature of the nitroxy species resulting from NO_x trapping. Experiments were performed using a Pd | K–β″alumina | Au cell with 400 ppm NO_x + 5% O_2, 150 mL min^{-1}, at 423 K. A negative current traps NO_x; a positive current decomposes the surface compounds, restoring the initial condition.

To investigate the nature of the species generated by NO_x uptake a separate set of experiments was performed under very similar conditions using an in situ reflectance infrared spectroscopy cell. The data presented in Figure 2 were obtained with a palladium metal film deposited onto a K–β″Al_2O_3 electrolyte wafer, spectra were recorded every 60 s with currents of -100 μA and $+400$ μA being used to drive K^+ ions to and from the metal surface, respectively. Prior to current application (spectrum at $t=0$ in Figure 2), bands were observed at 1630 and 1600 cm^{-1}, which are characteristic of adsorbed NO_2 on palladium sites.[6] Following current application, two bands developed ($t=180$ s) at 1447 cm^{-1} and 1348 cm^{-1}. The ratio of their intensities was constant indicating that they were due to the same chemical species. On the basis of the observed frequencies these bands are assigned to the symmetric and asymmetric stretches of a highly dispersed potassium nitrite species.[6] Subsequently, a band appeared at 1394 cm^{-1} which may be confidently assigned to bulk-like KNO_3,[6] indicating the onset of three-dimensional growth of nitrate crystallites on the palladium surface. Finally, ($t=$ 900 s) a band appeared at 1282 cm^{-1} which may be assigned to bulk-like KNO_2.[6]

After 1800 s the current direction was reversed ($I=$ 400 μA), thus pumping potassium ions away from the surface. This change resulted in a rapid decline in the intensity of all the bands between 1200 and 1500 cm^{-1}, directly demonstrating the electrochemically induced decomposition of the various nitrate/nitrite species. Clearly, the evolution of surface species with amount of charge passed is in very good accord with variations in gas composition at the trap exit. (The small remaining feature at 1521 cm^{-1} is assigned to residual nitrate on the palladium surface.)

Further confirmation of the electrochemically induced formation and destruction of NO_x-storing surface species and of their chemical identity was obtained by ex situ XPS (Figure 3). The pumping of Na to and from the Pt surface and the concomitant accumulation and destruction, respectively, of alkali metal nitrate and nitrite are clearly apparent.[7] Thus the XPS findings are in complete agreement with the trapping/regeneration behavior and the in situ IR results. Note that the spectroscopic measurements called for compact samples and as a result truly reversible alkali metal counter electrodes were impractical. Although irreversible in the strict sense, the Au electrodes employed behaved reversibly over many cycles because in any given experiment the extent of alkali depletion of the bulk electrolyte was negligible and was restored when the current was reversed.

Optimization of trap design, for example to improve gas throughput and active trapping surface area, are important practical issues that remain to be addressed—however these are beyond the aim of this report. Our object was to demonstrate a novel concept: a solid-state electrochemical device that operates at modest temperatures, stores NO_x very

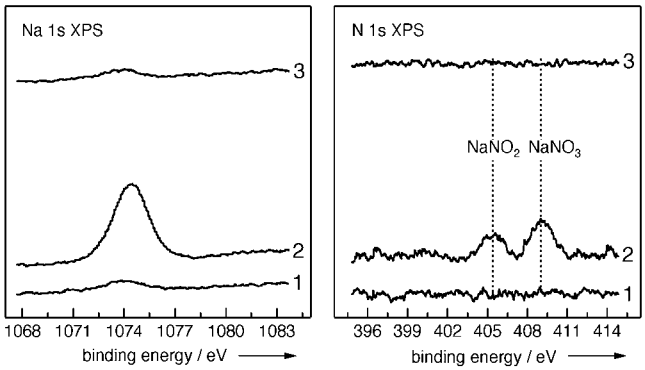

Figure 3. Na 1s (left) and N 1s (right) XP spectra obtained using a Pt | Na–β″alumina | Au cell after exposing the Pt electrode to a reactive gas atmosphere (0.1% NO + 5% O_2 at 473 K) under open circuit conditions (spectra 1), after pumping Na to the Pt electrode (spectra 2), and after pumping Na away from the Pt electrode (spectra 3).

effectively, and can be efficiently regenerated isothermally. In terms of practical application, the stability of an electrochemical trap device against long-term degradation by water vapor in the gas stream represents a materials issue that would have to be solved. In this regard K–β″aluminas are significantly more stable in the presence of water vapor than Na–β″aluminas. For example, they survive long periods at 900 K/15% humidity/atmospheric-pressure conditions that are more severe than those that would be encountered in the application envisaged here.[8] Moreover, NASICON-type alkali metal ion conducting ceramics, an alternative class of materials that could be used, exhibit transport properties that are independent of water vapor pressure and can have good stability in wet atmospheres.[9]

Conventional NO_x traps have a storage capacity of approximately 1 g NO/litre of trap volume before regeneration is necessary. Our trap had an effective volume of 3×10^{-3} litre and the data presented in Figure 1 correspond to storage of 0.13 g NO/litre of trap volume over the course of this experiment. A $NaNO_3$ film of 60 nm thickness (readily attainable with our system) equates to a maximum theoretical trapping capacity of 1 g NO/litre so that the achievable trapping capacity should be at least as good as that with conventional traps.

fusion configurations, variable planarization of the central carbon atom results, thus giving chemists a tool with which to probe one of the cornerstone theories of organic chemistry.[3] Unfortunately, unsubstituted fenestranes are low-molecular-weight hydrocarbons, and therefore crystallization for single-crystal analysis and quantification of the distortions to the central carbon atom is difficult.[4] By substituting a nitrogen

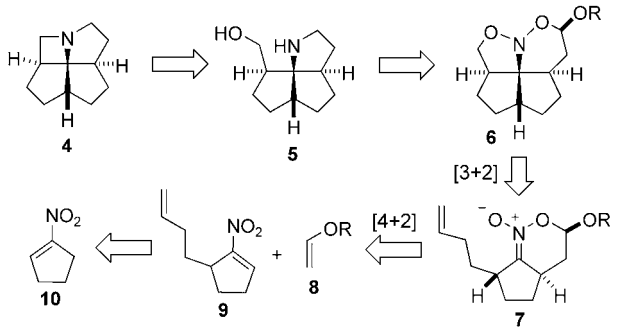
atom for one of the external bridgehead carbons, new opportunities for X-ray crystallographic analysis exist.

We recently reported the first synthesis of a 1-azafenestrane, *cis*,*cis*,*cis*,*cis*-[5.5.5.5]-1-azafenestrane·BH_3 (**2**),[5] which featured the tandem [4+2]/[3+2] cycloaddition[6] of nitrocyclopentene **3** as the key step. Although the tandem cycloaddition allows for rapid and stereoselective formation of the required skeleton, problematic steps in the synthesis of nitroalkene **3** led to a poor overall yield of azafenestrane **2** (18 steps, 0.02% overall yield). Furthermore, azafenestrane **2** displayed only modest planarizing distortions to the central carbon atom.[7] Therefore, an efficient route to an even more strained azafenestrane was sought, and the successful realization of that goal is described herein.

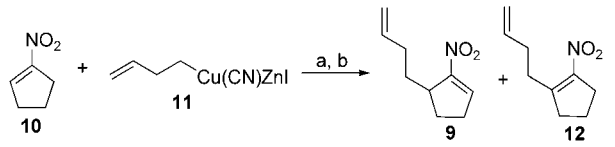
Contraction of one of the pyrrolizidine five-membered rings in azafenestrane **2** should lead to increased planarization of the central carbon atom.[8] Retrosynthetic analysis for *cis*,*cis*,*cis*,*cis*-[5.5.5.4]-1-azafenestrane (**4**) is presented in Scheme 2. The azetidine ring in **4** should be formed through



Scheme 2. Retrosynthetic analysis for *cis*,*cis*,*cis*,*cis*-[5.5.5.4]-1-azafenestrane (**4**).

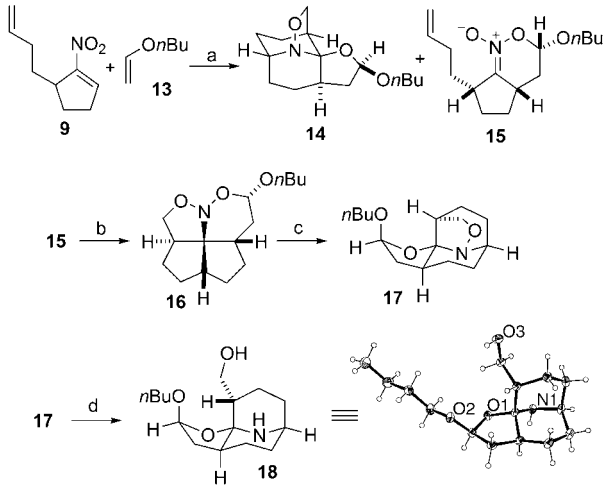
an irreversible intramolecular displacement of an activated alcohol **5**, which is derived from nitroso acetal **6** through hydrogenolysis. This reduction involves two N–O-bond cleavages and a reductive amination to form the pyrrolidine ring in a single operation. Nitroso acetal **6** is the direct product of tandem inter-/intramolecular [4+2]/[3+2] cycloaddition of nitroalkene **9** and a suitable vinyl ether. Presumably, vinyl ether **8** would approach from the less hindered side of the nitroalkene (opposite the tethered olefin) to give an *anti* relationship between the hydrogen atoms at the ring-fusion sites in nitronate **7**. An *exo*-fold, [3+2] cycloaddition[9] with the unactivated dipolarophile[10] would then set the remaining two stereogenic centers (final ring fusion and central carbon atom) in the required sense for the all-*cis* azafenestrane skeleton. The required 5-butenyl-1-nitrocyclopentene **9** would be available from 1-nitrocyclopentene (**10**) through 1,4-addition followed by regeneration of the nitroalkene.

A route analogous to that reported for nitroalkene **3** involving nitroallylation[11] was first investigated for the synthesis of **9**. Although the desired target was obtained, a very poor overall yield for the sequence prompted the development of a more efficient synthesis (Scheme 3). Treatment of 1-nitrocyclopentene (**10**)[12] with 3-butenylcyanozinc cuprate **11**,[13] followed by trapping of the resulting nitronate[14] with phenylselenyl bromide, provided a mixture of nitroselenides. Upon oxidation, *syn* selenoxide elimination gave the desired nitroalkene **9**, along with its double-bond isomer **12** (**9**/**12**, 2:1) in 78% combined yield from 1-nitrocyclopentene. All attempts at chromatographic separation of the two nitroalkenes were unsuccessful. Ultimately, the most efficient way to separate the two nitroalkenes was simply to carry out the next step of the azafenestrane synthesis with the mixture of compounds. Trimethylaluminum-promoted [4+2] cycloaddition of trisubstituted nitroalkene **9** with various vinyl ethers takes place in less than one hour at −78 °C and leaves tetrasubstituted nitroalkene **12** unreacted.



Scheme 3. a) THF, 0 °C, 1 h, then PhSeBr, 0 °C→RT, 1 h; b) H_2O_2, THF, 0 °C→RT, 30 min (78% from **10**; **9**/**12** 2:1).

Treatment of nitroalkene **9** (Scheme 4) with *n*-butyl vinyl ether in the presence of trimethylaluminum was expected to provide nitroso acetal **6** (Scheme 2, R = *n*-butyl), the product

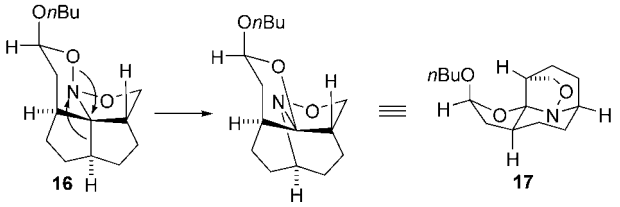


Scheme 4. a) $AlMe_3$, CH_2Cl_2, −78 °C, 30 min (48% **14**, 36% **15**); b) K_2CO_3, toluene, reflux, 2 h; c) SiO_2, room temperature; d) H_2 (26 atm), Raney Ni, MeOH, 14 h (46% from **15**). ORTEP-3 plot of **18** (30% thermal ellipsoids).

of tandem [4+2]/[3+2] cycloaddition. However, the major product of the reaction was compound **14**, which contains an azabicyclononane ring system and two five-membered rings! The minor [4+2] cycloadduct **15** derived from *endo* approach of *n*-butyl vinyl ether from the same face as the tethered dipolarophile was also isolated. The structure of aminal **14** was established from studies carried out with the minor cycloadduct **15**: Thermal intramolecular [3+2] cycloaddition of nitronate **15** with its tethered dipolarophile in refluxing toluene gave nitroso acetal **16**. However, upon purification with silica gel, a new product, **17**, which is a diastereomer of aminal **14**, was formed. The structure of **17**, and by analogy

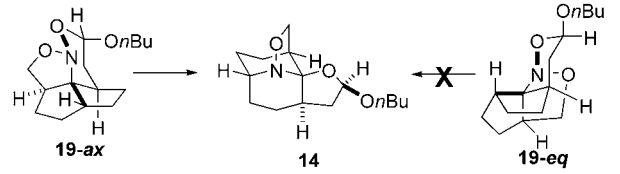
that of its diastereomer **14**, was confirmed by X-ray crystallographic analysis[15] of hydrogenation product **18**, in which the only N–O bond has been cleaved.

This novel rearrangement that converts nitroso acetal **16** into aminal **17** involves breaking both an N–O bond and a C–C bond with formation of a C–O bond and a C–N bond (Scheme 5). Analysis of the 3D structure of nitroso acetal **16** clearly shows the two breaking bonds in near-perfect antiperiplanar alignment. The ensuing transposition, known as a dyotropic rearrangement,[16] can take place readily to give the rearranged product **17**.[17]



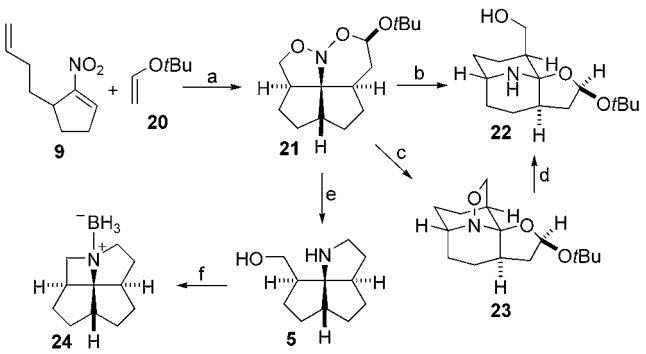
Scheme 5. Dyotropic rearrangement of nitroso acetal **16**.

Although this unexpected dyotropic rearrangement is mechanistically intriguing and potentially useful synthetically, its occurrence in the formation of the major product under the conditions employed for the tandem cycloaddition reaction precludes formation of the desired amino alcohol **5**. However, from conformational analysis of nitroso acetal **19** (the product of tandem [4+2]/[3+2] cycloaddition with approach of the dienophile from the opposite side to that occupied by the tethered dipolarophile, and the precursor to aminal **14**), a means to prevent the rearrangement became apparent (Scheme 6). The 1,2-oxazine ring in nitroso acetal **19-*ax*** adopts a chair conformation, which places the butyloxy group in an (anomerically stabilized) axial orientation. This conformation exhibits the required stereoelectronic alignment of the two migrating bonds (bold); thus the rearrangement takes place readily to give aminal **14**. However, in a second low-energy conformation, depicted in structure **19-*eq***, a chair flip has occurred, and the migrating bonds (bold) are no longer in alignment. By favoring this conformation, the rearrangement should be suppressed, and hydrogenolysis might provide the desired tricyclic amino alcohol **5**. Calculations[18] suggest that the two conformers are very close in energy. A nitroso acetal derived from a bulkier vinyl ether might favor the equatorial conformer and consequently deter or prevent the undesired dyotropic rearrangement.



Scheme 6. Conformations of nitroso acetal **19**.

In the event, tandem cycloaddition of *tert*-butyl vinyl ether with nitroalkene **9** promoted by trimethylaluminum (Scheme 7) led to formation of nitroso acetal **21** with no rearrangement under the reaction conditions, thus providing support for the proposed hypothesis. The crude reaction mixture contained, in a 2:1 ratio, nitroso acetal **21** (*endo* approach of the dienophile from the side opposite the tethered dipolarophile) and the minor nitronate (*endo* approach of the dienophile from the same side as the dipolarophile), which does not undergo spontaneous [3+2] cycloaddition. Purification of nitroso acetal **21** on silica gel did lead to partial rearrangement to aminal **23**; however, chromatography on basic alumina provided **21** in 67% yield.



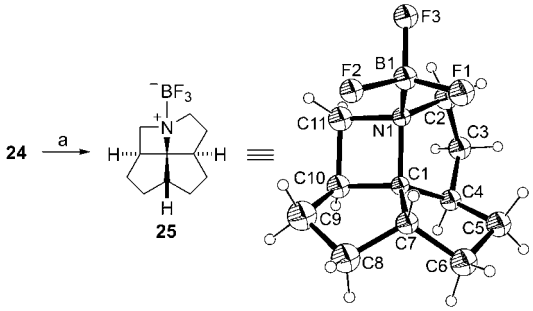
Scheme 7. a) $AlMe_3$, CH_2Cl_2, −78 °C, 1 h, purification on Al_2O_3 (67%); b) H_2 (1 atm), Raney Ni, MeOH, (94%); c) MeOH, 3 h, room temperature, (70%); d) H_2 (26 atm), Raney Ni, MeOH, room temperature, 15 h, (98%); e) H_2 (26 atm), Raney Ni, 10% H_2O-saturated EtOAc in EtOAc (0.25 M), 20 h, (85%); f) PPh_3, diisopropyl azodicarboxylate (DIAD), CH_2Cl_2, 0 °C, 40 min, then BH_3·THF, −78 °C→RT, 1 h (87%).

With nitroso acetal **21** in hand, we were poised to complete the synthesis in short order. Unfortunately, standard hydrogenolysis conditions (H_2, Raney Ni, MeOH) provided the reduced, rearranged product **22**, with no sign of the desired amino alcohol. An investigation of reaction conditions uncovered the fact that protic solvents induced the dyotropic rearrangement. In fact, simply stirring nitroso acetal **21** in methanol at room temperature provided aminal **23** in good yield. Consequently, new hydrogenation conditions had to be developed that would allow reduction of nitroso acetal **21** without promoting the rearrangement. Attempts to carry out the hydrogenation in nonprotic, dry solvents were unsuccessful; however, rearrangement did not take place under these conditions. In the end, it was discovered that by adding a controlled amount of water in the form of water-saturated ethyl acetate (10% in dry ethyl acetate) to the reaction mixture, the desired hydrogenolysis took place to give amino alcohol **5** while still suppressing the rearrangement.

At the outset of the synthesis, the formation of the azetidine ring from amino alcohol **5** was believed to be the most challenging step of the proposed route. However, simple treatment of **5** under Mitsunobu[19] coupling conditions led to formation of the desired azafenestrane, which was efficiently isolated as its borane complex *cis*,*cis*,*cis*,*cis*-[5.5.5.4]-1-azafenestrane·BH_3 (**24**) in 87% yield.[20] The availability of **24** from 5-butenyl-1-nitrocyclopentene **9** in only three steps and 50% overall yield demonstrates the power of the tandem

nitroalkene cycloaddition reaction for rapidly building molecular complexity.

To quantify the planarizing distortions at the central carbon atom in **24**, X-ray crystallographic analysis is required. Although the azafenestrane–borane adduct is a crystalline solid, crystals suitable for X-ray diffraction could not be obtained.[21] Fortunately, simple treatment of **24** with boron trifluoride etherate promoted an exchange to give the crystalline BF_3 adduct **25** (Scheme 8). Cooling of a warm, saturated solution of **25** in hexane to room temperature gave crystals of a quality suitable for X-ray crystallographic



Scheme 8. a) $BF_3{\cdot}OEt_2$, room temperature. ORTEP-3 plot of **25** (form 1, 30% thermal spheres).

analysis that formed in an unambiguous[22] space group $P2_1/n$.[23] The two most populated crystal forms in the disordered model exhibit similar planarization as defined by the angles around the central carbon atom; form 1: N1-C1-C7 119.8(7)° and C4-C1-C10 120.7(8)°, form 2: N1-C1-C7 119.2(8)° and C4-C1-C10 121.2(10)°. The degree of distortion agrees well with calculated values for the corresponding parent hydrocarbon.[2] Ab initio DFT calculations predict that the strain energy of azafenestrane **4** is 17.8-kcal mol^{-1} higher than that of the previously synthesized *cis*,*cis*,*cis*,*cis*-[5.5.5.5]-1-azafenestrane.[24]

In conclusion, the synthesis of *cis*,*cis*,*cis*,*cis*-[5.5.5.4]-1-azafenestrane·BH_3 (**24**) was completed efficiently in five steps and 26% overall yield from 1-nitrocyclopentene by using a tandem [4+2]/[3+2] cycloaddition of a nitroalkene as the key step. Along the way, an unprecedented dyotropic rearrangement was discovered that converts nitroso acetals into tetracyclic aminals. The rearrangement is controlled by the conformation of the six-membered ring in the nitroso acetal precursors. By utilizing a bulky vinyl ether and developing new hydrogenation conditions, the rearrangement was suppressed, thus allowing the synthesis of the desired azafenestrane. The [5.5.5.4]-1-azafenestrane was analyzed by X-ray crystallography as its BF_3 adduct to quantify the planarizing distortion around the central carbon atom. Efforts toward even more strained azafenestranes, as well as investigations into the reported dyotropic rearrangement and its use in synthesis, are currently underway.

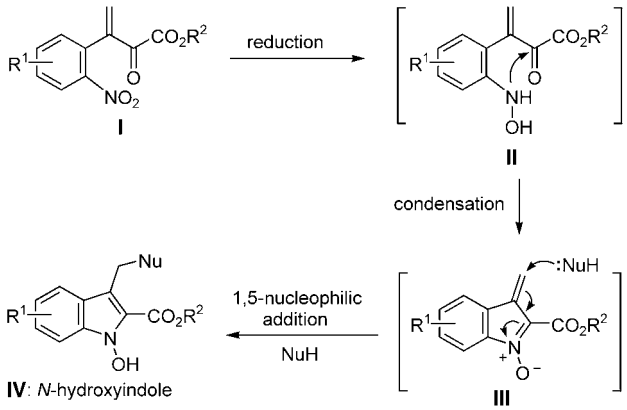
Indole Synthesis

Construction of Substituted *N*-Hydroxyindoles: Synthesis of a Nocathiacin I Model System**

K. C. Nicolaou, Sang Hyup Lee, Anthony A. Estrada, and Mark Zak*

Rare as they appear to be in nature, *N*-hydroxyindoles are intriguing chemical entities as they may play important biological roles and serve as useful synthetic building blocks.[1,2] One of the most impressive naturally-occurring molecules that features this unit is the recently discovered nocathiacin I (**1**), an antibiotic isolated from *Nocardia sp.* (ATCC-202099)[3] and the fungus *Amicolaptosis sp.*[4] Compound **1** exhibits strikingly potent activity in vitro and in vivo against Gram-positive bacteria.[3a,4] Given the complex structure of this antibiotic and the prominent position of a highly substituted *N*-hydroxyindole motif within its structure, as well as the lack of general methods for the construction of such systems, we deemed the development of suitable synthetic methodologies in this area as an important goal. Herein we report a new synthetic technology for the construction of substituted *N*-hydroxyindoles **2** from simple aromatic precursors and its application to the synthesis of a nocathiacin I model system **3**, which contains this unusual molecular framework.

Scheme 1 depicts the general concept for the construction of *N*-hydroxyindoles formulated on the basis of relevant precedents.[2] Thus, selective reduction of nitro ketoester **I**



Scheme 1. General scheme for the construction of substituted *N*-hydroxyindoles **IV**.

under appropriate conditions to hydroxylamine **II** was expected to initiate an intramolecular condensation with the carbonyl group, leading to the α,β-unsaturated nitrone system **III**, whose capture with nucleophiles would deliver the desired substituted *N*-hydroxyindoles **IV**.

The required starting material for these studies, nitro ketoester **6**, was readily prepared by standard chemistry[2c,5,6] in two steps from aromatic compound **4** via intermediate **5** (Scheme 2). Schemes 3 and 4 summarize the initial results of this study and demonstrate the feasibility of this plan under two different sets of experimental conditions. Thus, addition

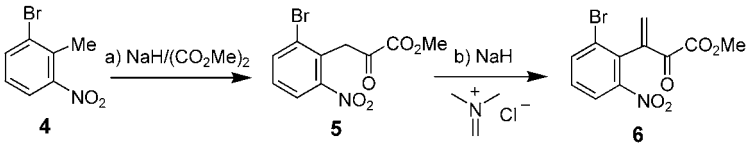
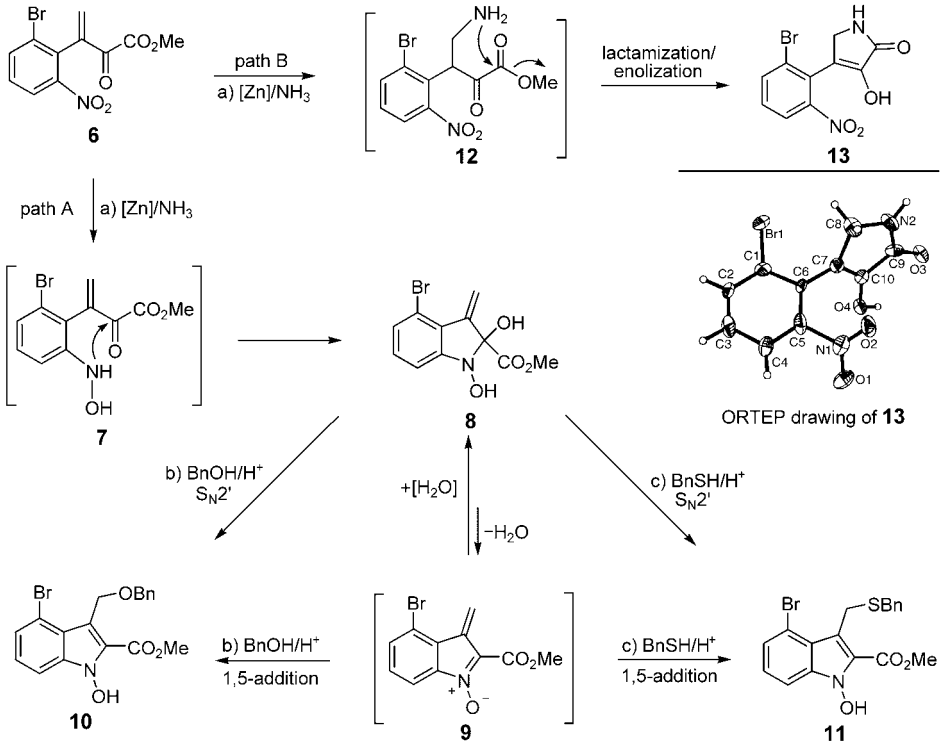


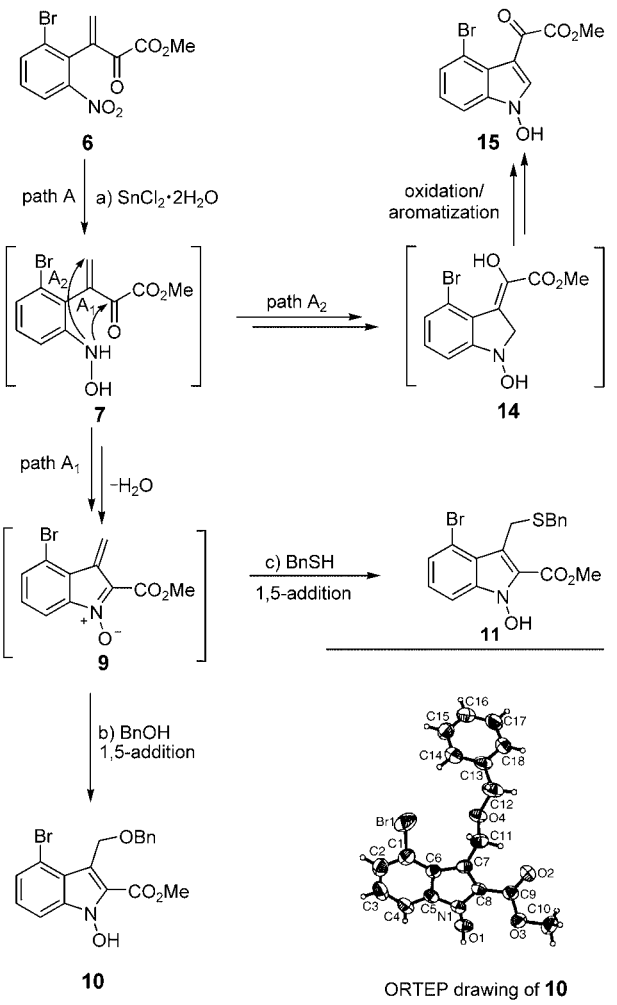
Scheme 2. Synthesis of nitro ketoester **6**. Reagents and conditions: a) NaH (4.0 equiv), $(CO_2Me)_2$ (5.0 equiv), DMF, 0 °C, 1 h; then 25 °C, 18 h, 60%; b) NaH (1.1 equiv), $CH_2{=}N^+Me_2Cl^-$ (3.0 equiv), THF, 0 °C, 1 h; then 25 °C, 12 h, 80%. DMF = *N*,*N*-dimethylformamide.

of activated zinc [Zn][2b] (prepared from zinc dust, 1,2-dibromoethane, and TMSCl) in THF to a solution of **6** and NH_4Cl in THF at 25 °C (Scheme 3) resulted in the formation of *N*-hydroxyindoline derivative **8** (56%; Table 2) along with small amounts of hydroxylactam **13** (10%) whose structure was proven beyond doubt through X-ray crystallographic analysis[7] (see ORTEP drawing, Scheme 3). These observations can be explained by invoking ring closure of the initially formed hydroxylamine **7**, leading to *N*-hydroxy tertiary alcohol **8** (path A; Scheme 3), and 1,4-addition of NH_3 to unreduced starting material **6** followed by lactamization and enolization of the initially formed amino ester **12** to form **13** (path B; Scheme 3). The *N*-hydroxy tertiary alcohol **8** was found to be rather labile, losing a molecule of water to generate nitrone **9** whose isolation remains elusive, although its presence can be surmised by TLC and NMR spectroscopy as well as through trapping by a variety of nucleophiles. Indeed, **8** reacted with benzyl alcohol or phenylmethanethiol in DME at 40 °C in the presence of *p*TsOH to afford *N*-hydroxyindoles **10** (55%; Table 2) and **11** (90%), respectively. These *N*-hydroxyindole-forming reactions are assumed to proceed either directly from *N*-hydroxy tertiary alcohol **8** by S_N2'-type displacement or by 1,5-addition to the initially formed nitrone **9**, or through both mechanistic pathways. These results are in contrast to those of Myers and Herzon[2b] in which the products obtained by 1,5-addition to a sterically congested α,β-unsaturated nitrone proved unstable to isolation, readily reverting back to the starting material.

In an effort to find a more direct access to the desired *N*-hydroxyindoles, a second protocol involving $SnCl_2$ as a reducing agent[2c,e] was explored. According to this method, **6** was treated with $SnCl_2{\cdot}2H_2O$ (2.2 equiv) and benzyl alcohol or phenylmethanethiol (benzyl mercaptan, 5.0 equiv) in DME in the presence of 4-Å molecular sieves at 40 °C for 1–1.5 h, circumstances that led, through path A_1, directly to the formation of adducts **10** (60%, see ORTEP drawing[7]) or **11** (55%), respectively (Scheme 4). These conditions were arrived at after a systematic investigation in which benzyl alcohol was used as the nucleophile, whereby the effects of solvent, temperature, time, amount of water, and stoichiometry were examined. The absence of the *N*-hydroxy tertiary alcohol **8** from the reaction mixture under these conditions is presumably due to its fleeting nature under the reaction



Scheme 3. Zn/NH_4Cl-induced generation and trapping of α,β-unsaturated nitrone **9** to form *N*-hydroxyindoles. Reagents and conditions: a) Zn dust (4.9 equiv), $BrCH_2CH_2Br$ (0.33 equiv), THF, reflux, 1 h; then cool to 25 °C; then TMSCl (0.2 equiv); and then a mixture of aqueous NH_4Cl (1.0 N; 2.2 equiv) and **6** (1.0 equiv), 25 °C, 15 min, **8** (56%), **13** (10%); b) **8** (1.0 equiv), *p*TsOH (3.0 equiv), molecular sieves (4 Å; 20 wt%), BnOH (5.0 equiv), DME, 40 °C, 3 h, **10** (55%); c) **8** (1.0 equiv), *p*TsOH (3.0 equiv), molecular sieves (4 Å; 20 wt%), BnSH (5.0 equiv), DME, 40 °C, 1 h, **11** (90%). TMS = trimethylsilyl; *p*TsOH = *p*-toluenesulfonic acid; Bn = benzyl; DME = 1,2-dimethoxyethane. ORTEP drawing of **13** drawn at the 50% probability level.



Scheme 4. $SnCl_2 \cdot 2H_2O$-induced generation and trapping of α,β-unsaturated nitrone **9** to form *N*-hydroxyindoles. Reagents and conditions: a, b) $SnCl_2 \cdot 2H_2O$ (2.2 equiv), molecular sieves (4 Å; 20 wt%), BnOH (5.0 equiv), **6** (1.0 equiv), DME, 40°C, 1.5 h, **10** (60%), **15** (17%); a, c) $SnCl_2 \cdot 2H_2O$ (2.2 equiv), molecular sieves (4 Å; 20 wt%), BnSH (5.0 equiv), **6** (1.0 equiv), DME, 40°C, 1 h, **11** (55%), **15** (15%). ORTEP drawing of **10** drawn at the 50% probability level.

conditions (acidic), which promote its conversion into nitrone **9** and/or its trapping by the nucleophile. The $SnCl_2$-promoted reaction, however, also yields ketoester *N*-hydroxyindole **15** in small amounts (15–17%). This byproduct presumably arises from the initially generated hydroxylamine **7** through path A_2, which involves intramolecular 1,4-addition followed by oxidation/aromatization of the resulting enolic species **14** (Scheme 4). An alternative mechanism for the generation of **15** may involve the nitroso intermediate (formed by partial reduction of **6**) or its hydrated counterpart, which could undergo, through its nitrogen atom, intramolecular addition to the neighboring Michael acceptor; this event may then be followed by rearrangement (or elimination of H_2O) to the observed compound **15**.

To explore the generality and scope of the developed reaction, a number of nucleophiles were employed to capture the labile nitrone (**9** or its hydrated form **8**) under the direct $SnCl_2 \cdot 2H_2O$ conditions. The results are shown in Table 1. Thus, both primary and secondary alcohols enter the reaction smoothly, affording good yields of the expected substituted *N*-hydroxyindoles (compounds **10** and **16–18**; Table 1, entries 1–4). The somewhat modest yields in these and the other reactions listed in Table 1 are presumably a consequence of a competing pathway through which the *N*-hydroxy group of one molecule of **8** or **7** reacts as a nucleophile to trap another of these species, thus leading to oligomeric materials. In fact, a dimer of **8** was detected by mass spectrometry. Besides hydroxy-bearing nucleophiles, thiols (Table 1, entries 5–8) and amines (Table 1, entries 9 and

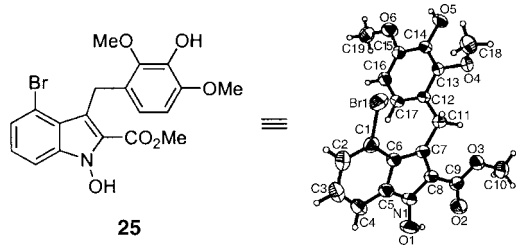
[a] Reactions were carried out on a 0.06–0.10-mmol scale in anhydrous DME (concentration: 0.12–0.16 M) and the products were purified by PTLC (silica gel). [b] Yields of isolated products. [c] $SnCl_2 \cdot 2H_2O$ (3 equiv).

10) also participated in this reaction to furnish *S*-substituted *N*-hydroxyindoles **11** and **19–21** and *N*′-substituted *N*-hydroxyindoles **22** and **23**, respectively. Interestingly, phenols react as carbon nucleophiles in this process and form carbon–carbon rather than carbon–oxygen bonds to give compounds **24** and **25** (Table 1, entries 11 and 12). Compound **25** (Table 2) was recrystallized from acetonitrile and its structure was confirmed by X-ray crystallographic analysis[7] (Figure 1).



25

Figure 1. ORTEP drawing of compound **25** drawn at the 50% probability level.

Despite the presently unknown origins of this rather special and exclusive reactivity of phenolic nucleophiles towards these reactive species (i.e. **8** and/or **9**), its potential in delivering novel molecular diversity remains considerable and warrants further exploration.

Having developed this technology, we then proceeded to apply it to the synthesis of the nocathiacin I model system **3**, which contains the *N*-hydroxyindole structural motif and one of the thiazole rings of the natural product. Scheme 5 outlines the successful execution of this explorative study. Thus, the

previously synthesized thiazole derivative **26**[8] was partially deprotected by controlled exposure to TFA in $MeOH/CH_2Cl_2$ at 25 °C to afford hydroxy Boc-protected amine **27** in 68 % yield. Coupling of the latter compound with **8** in the presence of *p*TsOH in DME at 40 °C then resulted in the formation of *N*-hydroxyindole model system **3** (Table 2) in 44 % yield (unoptimized).[9]

Besides possibly facilitating the total synthesis of nocathiacin I (**1**), the described new synthetic technology may find numerous applications in synthetic endeavors directed towards polyfunctional *N*-hydroxyindoles and other biologically interesting molecules.

DNA Structures

Drastic Effect of a Single Base Difference between Human and *Tetrahymena* Telomere Sequences on Their Structures under Molecular Crowding Conditions**

*Daisuke Miyoshi, Hisae Karimata, and Naoki Sugimoto**

G-rich sequences, which are abundant throughout the genomes of most organisms, can fold into G-quadruplexes. There is little direct evidence for the formation of G-quadruplexes in vivo,[1] but there is growing interest in their potential roles in many biological systems.[2] In addition, various functional molecules can form G-quadruplex structures in vitro.[3] G-rich sequences have extraordinary structural polymorphism that depends on the sequence and the environmental conditions.[4] Importantly, the polymorphic nature of the G-quadruplexes makes them a promising nanomolecular material, because a regulated structural transition between different types of G-quadruplexes can provide the basis for switchable molecular devices.[5] Moreover, the G-rich sequences are attracting interest as functional elements in molecular electronics.[6] Therefore, regulation of the polymorphic nature of the G-quadruplex presents a novel methodology for both developing molecular devices in vitro and controlling biological phenomena in vivo.

Changes in the environmental conditions can result in various structural changes of nucleic acids,[7] especially G-quadruplexes. For example, we reported that structural transitions between antiparallel and parallel G-quadruplexes, and between duplex and quadruplex, are induced by molecular crowding,[8] which is a critical environmental factor affecting the structure of biomacromolecules.[9] The effect of molecular crowding on the structures and functions of biomacromolecules has been examined because living cells are inherently molecularly crowded environments that contain a wide variety of biomolecules. For example, the total biomolecule concentration in *Escherichia coli* is in the range of 300 to 400 $g L^{-1}$.[9] This value is different from the typical biomolecule concentrations ($< 1 g L^{-1}$) generally used for

in vitro experiments. However, only a few systematic experimental studies of G-quadruplex structures under molecular crowding conditions have been reported.[8] Herein we present evidence that molecular crowding induces drastically different structures in the G-quadruplexes formed by *Tetrahymena* (Tet) and human (Hum) telomere sequences. These sequence motifs differ by only one base, which indicates that the single mutation in the telomere sequence is crucial for the regulation of its polymorphic nature and, therefore, its potential biological functions and material properties.

Figure 1 shows the circular dichroism (CD) spectra of samples (50 μmol L^{-1}) of four telomere DNA sequences (sites where Tet and Hum differ are underlined): intermolecular

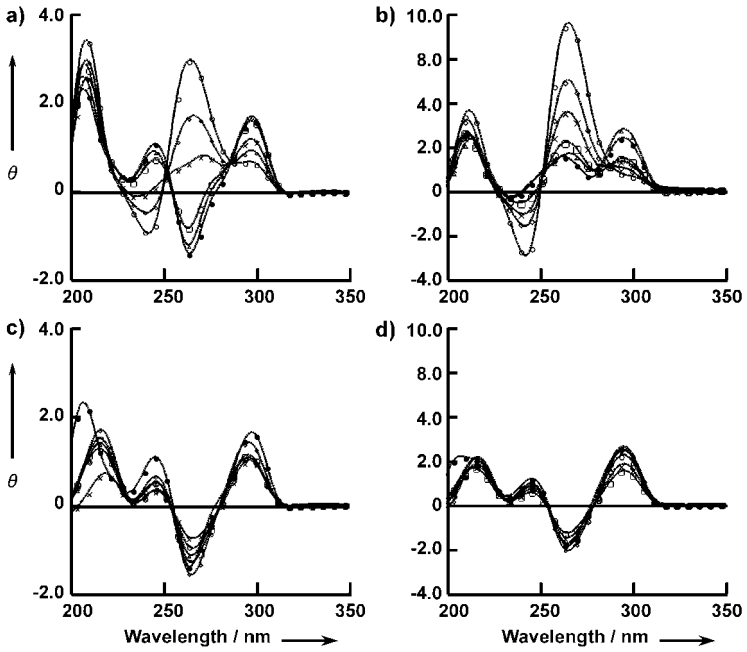

Figure 1. CD spectra (θ in 10^5 deg cm^2 $dmol^{-1}$) of samples of inter-Tet (a), intra-Tet (b), inter-Hum (c), and intra-Hum (d) at 4 °C without (●) and with 40 wt% cosolute. Cosolutes include ethylene glycol (△), diethylene glycol (□), triethylene glycol (×), PEG 200 (◇), and PEG 2000 (○).

Tetrahymena (inter-Tet; d[$TGG_3T_2\underline{G}G_3T$]; Figure 1a), intramolecular *Tetrahymena* (intra-Tet; d[$T_2G(G_3T_2\underline{G})_3G$]; Figure 1b), intermolecular human (inter-Hum; d[$TAG_3T_2\underline{A}G_3T$]; Figure 1c), and intramolecular human (intra-Hum; d[$(G_3T_2\underline{A})_3G_3$]; Figure 1d). CD measurements were carried out with and without a cosolute.[10] Polyethylene glycol (PEG) and its related small molecules are commonly used as cosolutes in aqueous solution to mimic molecular crowding conditions, because they do not react with nucleotides and a variety of molecular weights are available.[8–10] Except for intra-Tet, the CD spectra of the telomere sequences in the absence of cosolute have positive and negative peaks at 295 and 265 nm, respectively, which indicates that these telomere sequences fold into antiparallel G-quadruplexes.[8,11] Intermolecular *Oxytricha* (inter-Oxy; d[$G_4T_4G_4$]) and intramolecular *Oxytricha* (intra-Oxy; d[$(G_4T_4)_3G_4$)]) telomere sequences also show an antiparallel structure in the absence of the cosolute (see the Supporting Information). However, the CD spectrum of intra-Tet has positive peaks at 295 and 260 nm in the absence of cosolute, thus indicating a mixture of parallel and antiparallel G-quadruplexes.[8,11] These results are consistent with those of previous reports that describe the structure of these telomere sequences.[12]

Surprisingly, the CD spectra in the presence of cosolutes with various molecular weights reveal that, under crowding conditions, a single G-to-A replacement in the loops affects the entire telomere structure. Specifically, the CD spectra of inter-Tet and intra-Tet in the presence of higher-molecular-weight cosolutes have a positive peak at approximately 260 nm and a shoulder near 295 nm. In contrast, the CD spectra of inter-Hum and intra-Hum do not change under these conditions. This finding indicates that the *Tetrahymena* but not the human telomere DNA undergoes a structural transition from an antiparallel to a parallel G-quadruplex in the presence of higher-molecular-weight cosolutes such as PEG 2000. Furthermore, the CD spectra of inter-Oxy, intra-Oxy, d[$(T_3G_4)_4$], d[$(G_3T_3)_3G_3$], d[$(G_4T_2)_3G_4$], and d[$(T_2AG_3)_4$] in the presence and absence of the cosolute demonstrated that these telomere sequences, except d[$(T_2AG_3)_4$], undergo the structural transition by adding the cosolute (see the Supporting Information). These telomere sequences have different molecularities (intermolecular or intramolecular), sequence lengths, and numbers of G-quartets (guanine plane), nucleotides in the loop, and extra nucleotides at the termini, which indicates that these factors are not important participants in the transition. Therefore, the single base difference between human and *Tetrahymena* telomere sequences critically affects the entire structure of the telomere DNA. However, the CD spectra suggest that the cosolutes cause a more dramatic shift to a parallel G-quadruplex for inter-Tet (Figure 1a) than for intra-Tet (Figure 1b).

Phan et al.[12a,b] reported the solution structure of inter-Tet in the presence of Na^+ ions and of inter-Hum in the presence of K^+ ions. Inter-Tet forms two antiparallel dimeric G-quadruplexes with different positions of the loops. Inter-Hum also has two different structures: a dimeric parallel G-quadruplex with loops located in the grooves (propeller structure) and a dimeric antiparallel G-quadruplex with loops located on the G-tetrad planes. Wang and Patel[12c,d] reported that intra-Tet and intra-Hum form intramolecular antiparallel G-quadruplexes with Na^+ ions. Parkinson et al.[13] used X-ray crystallography to show that the inter-Hum and intra-Hum form dimeric and monomeric propeller-type parallel G-quadruplex structures in the presence of K^+ ions, although the human telomere sequences used in their study were slightly different from those used here. On the basis of these structural studies, one can conclude that inter-Tet and intra-Tet fold into antiparallel G-quadruplexes in the presence of Na^+ ions. Inter-Hum and intra-Hum can fold into dimeric and monomeric antiparallel G-quadruplexes, respectively, in the presence of Na^+ ions and

can potentially fold into propeller-type parallel G-quadruplexes as a monomer and dimer, respectively.

The excluded volume, one of the factors of molecular crowding,[9] can induce the association of monomers into multimeric complexes.[9,14] For example, monomeric and dimeric antiparallel G-quadruplexes can associate into multistranded G-wires.[8] Inter-Tet and intra-Tet likely underwent this structural transition because their parallel structure must be either four- or multistranded, such as in a G-wire structure (Figure 2). Inter-Hum and intra-Hum, however, could not

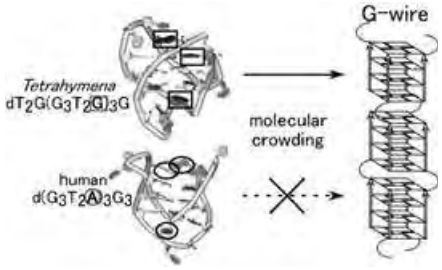

Figure 2. Schematic illustration of the structures of intra-Tet and intra-Hum in dilute and molecular crowding conditions. G (□) and A (○) correspond to the single-mutation sites.

undergo the antiparallel-to-parallel transition under conditions of molecular crowding because the parallel structures form propeller-type G-quadruplexes, which may have excluded volumes larger than that of the antiparallel G-quadruplex.[12,13] In addition, the thermodynamic properties of intra-Tet and intra-Hum in the presence and absence of 40 wt% PEG200 were examined by using UV melting curves monitored at 295 nm. The melting temperatures (T_m) of intra-Tet were 70.4 and 62.0 °C, respectively, whereas these T_m values for intra-Hum were 65.0 and 60.8 °C, respectively. Therefore, a larger stabilization of intra-Tet by the cosolutes may induce the structural transition.

To further verify the formation of the G-wire structure, we performed native gel electrophoresis on a 10% polyacrylamide gel.[15] Figure 3a shows the migration of intra-Tet and intra-Hum in the presence of 0 to 40 wt% PEG2000. The migration pattern of intra-Tet is typical for a G-wire (indicated by asterisks).[16] Furthermore, the ratio of intra-Tet migrating at the top of the gel increased as the concentration of PEG2000 was increased (indicated by arrows). In denaturing gel electrophoresis, the band at the top of the gel with intra-Tet samples disappeared, and another moderately migrating band appeared (arrow in Figure 3b). All of these results indicate that the band observed at the top of the native gel for intra-Tet samples corresponds to a highly ordered G-wire complex, whereas intra-Hum remains as a compact intramolecular G-quadruplex structure even in the presence of 40 wt% PEG2000. This concept is further confirmed by the CD spectra, which show that titration with PEG2000 causes a structural transition from an antiparallel G-quadruplex to a parallel-oriented G-quadruplex of intra-Tet but

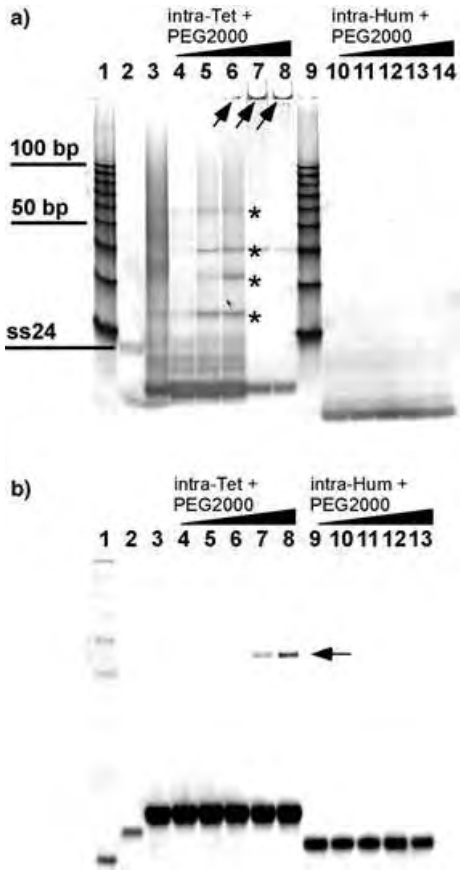

Figure 3. a) Native gel electrophoresis of intra-Tet and intra-Hum in the absence and presence of PEG2000. See the Experimental Section for details. Lanes 1 and 9: 10-bp DNA ladder; lane 2: single-stranded 24-mer DNA; lane 3: inter-Tet with Mg^{2+} and spermidine; lanes 4–8: intra-Tet in the presence of 0, 10, 20, 30, and 40 wt% PEG2000, respectively; lanes 10–14: intra-Hum in the presence of 0, 10, 20, 30, and 40 wt% PEG2000, respectively. b) Denaturing gel electrophoresis of intra-Tet and intra-Hum in the absence and presence of PEG2000. See the Experimental Section for details. Lane 1: 10-base DNA ladder; lane 2: single-stranded 24-mer DNA; lane 3: inter-Tet with Mg^{2+} and spermidine; lanes 4–8: intra-Tet in the presence of 0, 10, 20, 30, and 40 wt% PEG2000, respectively; lanes 9–13: intra-Hum in the presence of 0, 10, 20, 30, and 40 wt% PEG2000, respectively.

not intra-Hum (Figure 4). The CD spectrum of intra-Tet in the presence of 40 wt% PEG2000 (○) in Figure 4a) has a

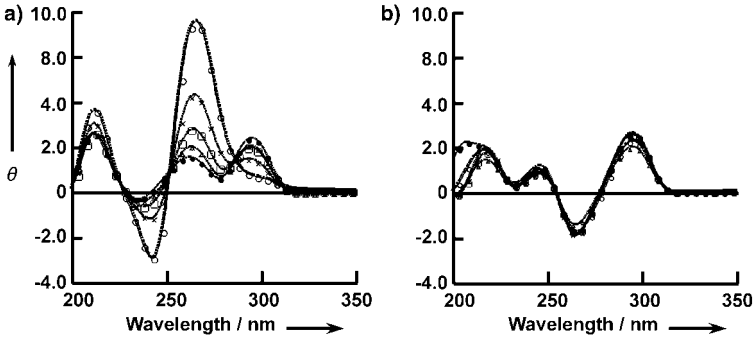

Figure 4. CD spectra of samples of intra-Tet (a) and intra-Hum (b) at 4 °C without (●) or with 10 (△), 20 (□), 30 (×), or 40 wt% (○) PEG2000.

small shoulder around 295 nm, which indicates that the antiparallel G-quadruplex still remains in this condition. This shoulder may correspond to the remaining band present in the antiparallel G-quadruplex of intra-Tet (Figure 3a). In addition, the migration of inter-Tet in the presence of Mg^{2+} ions and spermidine (lane 3 in Figure 3a), where there is a high potential for the formation of G-wires,[16] shows a very diffuse band, and lanes 4 to 8 provide some evidence of discrete retarded complexes. Therefore, the migration of intra-Tet in the presence of PEG 2000 shows a higher-ordered and, thus, a longer G-wire structure. Finally, although it is difficult to prepare homogeneous G-wires, they can be obtained by cutting out the band in the denaturing gel.

In summary, we have demonstrated that a single G-to-A substitution in the loops of telomere sequences leads to drastically different structures. Under molecular crowding conditions, *Tetrahymena* telomere sequences fold into very long, highly ordered G-wires, whereas human telomere sequences fold into antiparallel G-quadruplexes. Further studies are required, such as on the effect of monovalent cations on the structure of the telomere sequences under molecular crowding conditions. However, the results reported here indicate that a single mutation in the telomere sequence is a critical factor affecting the polymorphic nature of the G-quadruplex and, therefore, of telomere function in cell-like conditions.

Apart from the biological aspects, there is growing interest in G-rich sequences as functional elements in molecular electronics.[6,17] A theoretical study suggested that the G-wire structure is promising for nanoscale biomolecular electronics because of its highly order structure.[18] However, its electrical properties have not yet been described because of the difficulty in creating and controlling the G-wire structure. Herein, we have described the control of the G-wire structure by a single mutation and by adjusting the solution conditions. These findings make it possible to measure electrical transport through G-wires.

Experimental Section

All cosolutes were purchased from Wako Pure Chemical Co. Ltd. (Japan) and used without further purification. Oligonucleotides were synthesized, purified, and confirmed as described elsewhere.[19] The DNA samples were heated to 80 °C, gently cooled at a rate of 2.0 K min^{-1}, and incubated overnight at 4 °C.

CD spectra of DNA samples (50 μmol L^{-1} total strand concentration) were obtained by using a J-820 spectropolarimeter (JASCO Co. Ltd., Japan) with a 0.1-cm-path-length quartz cell. CD measurements were carried out in a buffer containing NaCl (100 mmol L^{-1}), Na_2HPO_4 (10 mmol L^{-1}), and ethylenediaminetetraacetic acid disodium salt (Na_2EDTA, 1 mmol L^{-1}, pH 7.0) with or without cosolutes at the desired temperature. It was possible to induce the formation of G-wires by inter-Tet and intra-Tet by adding a cosolute and without heating. In this study, however, to ensure that the structures reached equilibrium, CD spectra were recorded after heating and slow cooling to 4 °C followed by an overnight incubation.

UV melting curves for DNA samples (50 μmol L^{-1} total strand concentration) were recorded at 295 nm[20] by using a Shimadzu UV-1700 instrument (Shimadzu Co. Ltd., Japan) with a 0.1-cm-path-length quartz cell. The measurements were carried out at 4 °C in a buffer containing NaCl (100 mmol L^{-1}), Na_2HPO_4 (10 mmol L^{-1}), and Na_2EDTA (1 mmol L^{-1}, pH 7.0) with or without cosolutes. Before measurements were made, the DNA samples were heated, cooled, and incubated to allow them to equilibrate, as described above. The samples were heated at 0.5 K min^{-1} to obtain the melting curves.

Native gel electrophoresis was carried out at 4 °C and 5 V cm^{-1} on a 10 % nondenaturing polyacrylamide gel in a buffer containing NaCl (100 mmol L^{-1}), Na_2HPO_4 (10 mmol L^{-1}), and Na_2EDTA (1 mmol L^{-1}, pH 7.0). Ice-cold loading buffer (2 μL, 40 % glycerol and 1 % blue dextran) was mixed with the DNA sample (2 μL, 25 μmol L^{-1}). Before measurements were made, the DNA samples were heated, cooled, and incubated to allow them to equilibrate, as described above. Denaturing gel electrophoresis was carried out using the same procedure as that for native gel electrophoresis, except that the loading buffer contained 50 % formamide and electrophoresis was performed at room temperature. Gels were stained with GelStar nucleic acid gel stain (Cambrex, ME, USA) and imaged using FLS-5100 film (Fuji Photo Film Co. Ltd., Japan).

Host–Guest Systems

Size-Selective and Reversible Encapsulation of Single Small Hydrocarbon Molecules by a Cavitand–Porphyrin Species**

*Jun Nakazawa, Jun Hagiwara, Maki Mizuki, Yuichi Shimazaki, Fumito Tani, and Yoshinori Naruta**

Small hydrocarbon molecules are subject to processes of biological isolation, sequestration, and selective reactions that are mediated by biomolecular recognition events.[1] One particularly noteworthy biological process of hydrocarbons is the enzymatic monooxygenation of methane and related small hydrocarbons.[2,3] The mechanisms through which these chemical transformations occur are of particular interest in light of their potential applicability for the development of catalysts for large-scale industrial chemical transformations.[4]

One of the major shortcomings of artificial hydrocarbon-recognition model systems is the absence of the requisite strong interactions between the host and the guest molecules. This feature of hydrocarbons makes the selective recognition processes less efficient. One of the most effective natural mechanisms for the recognition of hydrocarbons is an encapsulation process mediated by capsulelike molecules that have a hydrophobic cavity with a given shape and volume.[5] Various guest-encapsulating carcerands and related molecules have been reported.[6] These compounds typically have rigid enclosed structures and are not suitable for release or exchange of encapsulated guest molecules. For further reaction of the encapsulated guest molecules, the host requires an active site with a flexible portal for guest exchange.

Other researchers have reported host compounds with cup-shaped calix[4]arenes,[7] cavitands,[8] cyclodextrin, etc.[9] that have cavities suitable to accommodate small organic molecules in combination with a flat porphyrin, which acts both as a lid for the cavity and as a ligand for metal ions. These compounds have been demonstrated to encapsulate pyridines, imidazoles, adamantanes, etc.

In work described herein, we have designed a new cavitand–porphyrin **1** as a host compound for smaller hydrocarbons such as methane and ethane. To accommodate small guest molecules and to retain suitable flexibility of the portal, the cavitand and the porphyrin are connected by two ether linkages. With use of **1** as a host, we have successfully demonstrated size-selective and reversible encapsulation of small hydrocarbons within the host cavity.

Williamson-type coupling between A,B-type bis(chloromethyl)cavitand **3**[10] and *meso*-bis(2-hydroxyphenyl)diphenylporphyrin (**4**) (used as a mixture of four regio- and atropisomers: 5,10; 5,15; α,α; and α,β)[11] gave *syn* (**1**, 46% yield based on **3**) and *anti* (**2**, 14% yield) cavitand–porphyrin species (Supporting Information).

The structures of the two isomers were determined by ^{1}H NMR spectra as follows: The ^{1}H NMR signals of all bridged -OCH_2O- protons of the *syn* isomer **1** showed large upfield shifts relative to those of the starting cavitand **3** (H_{ao}, H_{ai}, H_{bo}, and H_{bi}: $\Delta\delta = -3.41$, -5.65, -0.52, and -2.42 ppm, respectively) owing to the large anisotropic effect of the porphyrin ring current (Supporting Information). This observation suggests that the cavitand and porphyrin moieties of **1** adopt a fully overlapping geometry and that the portal is very narrow.

We examined the encapsulation of various small hydrocarbon molecules in **1** (Figure 1). Upon exposure of CH_4 gas to a solution of **1** in $CDCl_3$, a new proton signal appeared at $\delta = -7.19$ ppm (Figure 1b), which disappeared when Ar was bubbled into the solution.[12] The large upfield shift ($\Delta\delta = -7.34$ ppm) from the signal of free methane ($\delta = 0.15$ ppm) is rationalized by anisotropic effects arising from both the cavitand and porphyrin aromatic ring systems which are

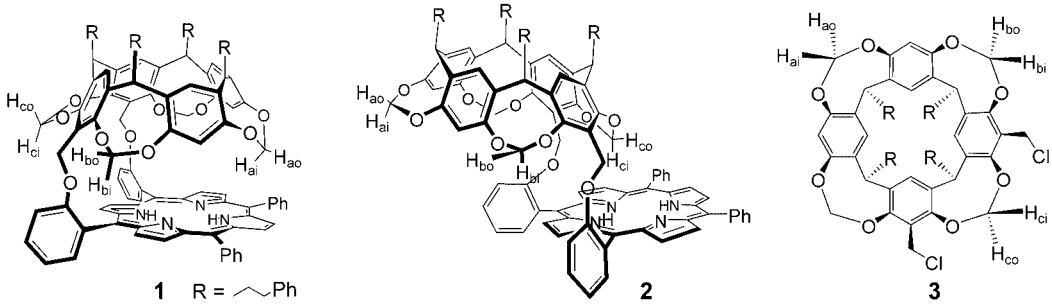

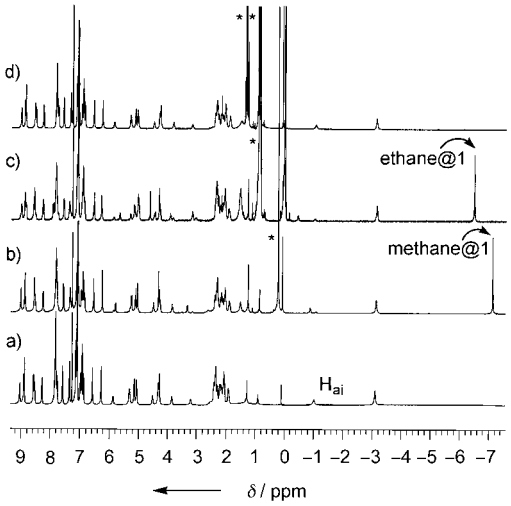

Figure 1. ^{1}H NMR spectra of **1** with hydrocarbons in $CDCl_3$ under atmospheric pressure at 25 °C. a) **1**, b) **1** with methane, c) **1** with ethane, d) **1** with propane. *Signals of the free hydrocarbons.

estimated to contribute to the upfield shift of the signal for the encapsulated molecule by $\delta = -3$–-4[5b,c,13] and $\delta = -4$–-5 ppm,[14] respectively. Thus, the signal at $\delta = -7.19$ ppm is assigned to the protons of the encapsulated methane molecule. Only one CH_4 molecule was trapped in the cavity, as confirmed by the integration ratio of the ^{1}H NMR signals. Furthermore, the solvent $CDCl_3$ is not trapped in the cavity, as confirmed by ^{13}C NMR spectroscopy.

The perfect separation of the signals corresponding to free and encapsulated methane protons indicates that the guest-exchange rate in **1** with the bulk solvent phase is slower than the ^{1}H NMR timescale. The fact that CH_4 is trapped in and purged from the cavity when CH_4 or Ar, respectively, are bubbled into the solution suggests that the portal of the cavity has enough flexibility to exchange the encapsulated guest.

Encapsulation of other small hydrocarbons in **1** was also observed, as indicated by the ^{1}H NMR chemical shifts of various encapsulated small hydrocarbons in **1** (Table 1). Ethane, ethylene, acetylene, and cyclopropane encapsulated by **1** give rise to signals upfield to those for the protons of the free hydrocarbons. However, addition of either propane or CH_2Cl_2 to the solution of **1** does not cause an upfield shift of the proton signals, indicating that **1** cannot encapsulate hydrocarbons larger than cyclopropane.

Each proton signal of the encapsulated hydrocarbon appears as a sharp singlet, thus indicating that the encapsulated hydrocarbons in the cavity of **1** are capable of free rotation.

Table 1: ^{1}H NMR chemical shifts[a] and binding constants K_{11}[b] of hydrocarbons in **1**.

Guest	δ_{free} [ppm]	$\delta_{@1}$ [ppm]	$\Delta\delta$ [ppm]	K_{11} [M^{-1}]
methane	0.15	−7.19	−7.34	81 ± 18
acetylene	1.91	−5.37	−7.28	130 ± 20
ethylene	5.39	−2.07	−7.46	49 ± 5
ethane	0.85	−6.49	−7.34	9.4 ± 1.4
cyclopropane	0.23	−6.95	−7.18	9.6 ± 2.3
propane	1.31, 0.88		–[c]	

[a] Chemical shifts relative to TMS in $CDCl_3$. [b] Conditions: [**1**] = 5 mM in $CDCl_3$ at 25 °C, 1 atm. [c] Not encapsulated.

Upon the encapsulation of hydrocarbons, the ^{1}H NMR signals of the peripheral protons of the cavitand moiety of **1** undergo a downfield shift. In particular, a remarkable downfield shift is observed for H_{ai} for the cavitand -OCH_2O- segment (Figure 1),[15] that is located closest to the porphyrin plane and which acts as a sensitive marker of the portal shape. The magnitude of this shift shows a positive correlation with guest volumes[16] (Figure 2). This is attributed to a process in which the cavitand is forced to move away from the porphyrin plane upon complexation with a guest molecule. A concomitant decrease in the porphyrin anisotropic effect accompanies this movement.

To evaluate the affinity and selectivity of guest binding of **1**, we determined the 1:1 binding constant K_{11} of the

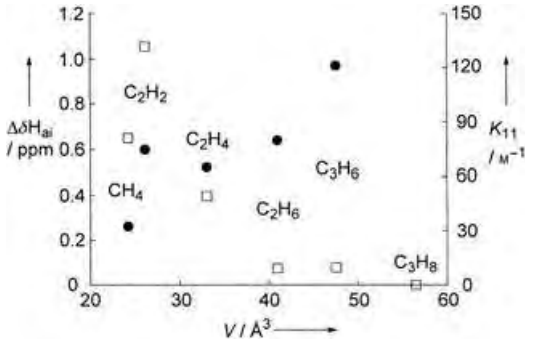

Figure 2. ^{1}H NMR chemical shift difference $\Delta\delta H_{ai}$ (●) and binding constant K_{11} (□) versus guest molecular volume *V*. $\Delta\delta H_{ai} = \delta(H_{ai}$ of hydrocarbon@**1**$) - \delta(H_{ai}$ of **1**$)$. Guest volumes (Connolly solvent-excluded volumes) were estimated according to the method described in reference [16].

hydrocarbon encapsulation. The K_{11} values are shown in Table 1. Acetylene exhibits the greatest affinity of encapsulation in the cavity, and the binding constants decrease in the following order: acetylene $\gg$ methane $>$ ethylene $\gg$ cyclopropane $\approx$ ethane. Among the saturated hydrocarbons examined in this work, large differences in K_{11} values were observed (methane/ethane/propane = 8.6:1.0:$\approx$0). The selectivity of encapsulation appears to be related to the volume and shape of the guest molecules. Figure 2 shows the plot of K_{11} versus molecular volumes[16] for various hydrocarbons. An inverse correlation is observed between K_{11} and guest volumes for most of the small hydrocarbons examined. However, the remarkable large binding constant of acetylene cannot be explained only in terms of molecular volume. Since the acetylene protons favor stronger CH/π interactions with electron-rich aromatic π systems that act as electron donors,[17] the high affinity of acetylene may be due to this attractive effect induced by the aromatic walls of the host molecule.

Prior to this work, the cavitand compound with the smallest cavity observed was the benzene-capped cavitand reported by Paek et al.[5b] This compound encapsulates a wide range of guest sizes, from methanol to tetrahydrofuran to *n*-propanol (K_{11} = 238, 14, and 3 M^{-1}, respectively, measured at −40 °C). However, **1** has an even smaller cavity and narrower portal, and shows higher selectivity for small guest molecules.

In summary, we have synthesized a new capsule-shaped host **1**, which can selectively and reversibly bind a single hydrocarbon molecule of sizes ranging from methane to cyclopropane. The binding constants are inversely correlated with the molecular volumes of the guest hydrocarbons with the exception of acetylene. Compound **1** has the smallest cavity among known cavitand compounds and the high size selectivity for small hydrocarbons reported thus far. The syntheses of metal complexes of this cavitand–porphyrin and investigations of their guest-encapsulation properties and reactivity are in progress in our laboratory.

Experimental Section

Determination of binding constants: Hydrocarbon gas was bubbled directly into the solution of **1** in $CDCl_3$ (5 mM, 0.6 mL) in an NMR tube with a gas-tight screw cap. ^{1}H NMR spectra were measured at various hydrocarbon concentrations (5–50 mM) at 25 °C. The amount of free and encapsulated hydrocarbons were determined by the integration of their proton signals relative to the host signals at δ = 7.13–6.84 ppm (20 protons). The [$\mathbf{1}_{free}$] values were estimated from the amount of trapped hydrocarbon. The 1:1 binding constants were calculated by using Equation (1).

$$K_{11} = \frac{[\text{hydrocarbon}_{@\mathbf{1}}]}{[\mathbf{1}_{free}][\text{hydrocarbon}_{free}]} \quad (1)$$

The average value and standard deviation of K_{11} were determined by ten independent measurements.

Protein Trapping

Trapping of Proteins under Physiological Conditions in a Nanopipette**

Richard W. Clarke, Samuel S. White, Dejian Zhou, Liming Ying, and David Klenerman**

Dielectrophoresis (DEP) uses the directed motion of particles caused by polarization effects in a nonuniform electric field,[1] and it has proved to be a powerful tool in performing sample sorting,[2–6] trapping,[6–8] and manipulation[6,9–11] on micrometer- and submicrometer-sized particles to date. These experiments have been largely performed in low-conductance solutions by using metal electrodes—conditions that are nonphysiological and in which damage by electrolysis is also possible. Herein, we use a nanopipette for electrodeless dielectrophoresis and show clear evidence, by using wide-field fluorescence imaging, for the reversible trapping of Alexa-488-labeled proteins (protein G and immunoglobulin G (IgG)) and also of the fluorophore alone. Our results show a dielectrophoretic concentration enhancement for these fluorophore-labeled proteins of at least a factor of 300. This concentration enhancement was shown to take place in less than a second and to be within about a factor of two of that observed with DNA. This finding opens up new possibilities for miniaturized bioanalysis.

Previous applications of DEP have focused on the separation of micrometer- and submicrometer-scale objects, such as cells,[9] viruses,[10] and colloidal particles,[12] and the manipulation and trapping of long DNA molecules.[7] More recently, DEP has been applied as a bottom-up approach to assemble functional structures by using nanosized building blocks[13–16] and submicrometer-diameter fibrils from single-wall carbon nanotubes.[17] DEP has also been utilized in separating metallic carbon nanotubes from semiconducting carbon nanotubes,[18] and evidence for the trapping of bovine serum albumin has been presented.[19] All of these studies have used metallic microelectrodes for their DEP traps. These have the advantage of flexible designs for the electrodes and a relatively low voltage being required to generate a high-field gradient on the microscale. However, there are limitations in the application of trapping by metallic DEP. Firstly, it is not compatible with biological samples, as the low-ionic-strength solutions that are used will lead to unfolding of DNA and proteins. Secondly, proteins will be easily drawn to the metal surface of the electrodes where they will become denatured. Thirdly, complex electrochemical reactions such as electrolysis may occur at the microelectrodes. These reactions not only generate gas bubbles that interfere with trapping but they may also damage the trapped molecules and degrade the electrodes. This is a particular problem at the predicted high electric fields required to trap proteins.[20] To address this problem, Chou and co-workers developed DEP traps by patterning geometrical constrictions in an insulating quartz substrate instead of the traditional metallic microelectrodes.[21] The constrictions in a microfluidic channel are used to create a high-field gradient with a local maximum; DNA was successfully trapped in this high-field region under ionic buffer conditions. Recently, we used a laser-pulled glass nanopipette filled with ionic buffer to generate a high-field gradient near the pipette tip.[22] We have shown that DNA and proteins maintain their functionality after passing through this high electric field in the pipette tip.[23] We have also probed the motion of fluorophore-labeled double- and single-stranded 40-mer DNA, a one kilobase single-stranded DNA, and a single nucleotide triphosphate (deoxycytidine 5′-triphosphate, dCTP) just inside and outside the pipette tip at different frequencies and amplitudes of applied voltages.[22] A strong trapping effect was observed during the negative half cycle for all DNA samples and also for dCTP. DNA might have been a special case for the trapping of molecules by DEP since it is a highly charged polyelectrolyte because of its phosphate backbone. Herein, we present unequivocal evidence of the reversible trapping of proteins in the nonuniform electric field generated in the tip of a nanopipette, by using fluorescence microscopy with wide-field illumination.

A schematic representation of the experimental setup is shown in Figure 1. The borosilicate glass pipettes have a 3–6° half-cone angle and an inner diameter of 100–150 nm. The pipette and bath solution contain 100–150 mM sodium chlo-

ride. An electric field is generated in the tip of the pipette on application of a voltage between the electrodes in the pipette (GE) and bath (WE). In these experiments, the pipette electrode was earthed and a voltage was applied to the bath electrode. Application of 1 V results in a maximum electric field of about $10^6\ V\,m^{-1}$ in the pipette tip.[22] We used wide-field illumination of the pipette by using an expanded 488-nm laser beam and detected the fluorescence with a CCD camera. This enabled the spatial distribution of fluorophore-labeled biomolecules in the pipette on application of different voltages to be examined.

We studied protein G and IgG labeled with multiple Alexa-488 fluorophores, and as a comparison we also studied a single-stranded 20-mer DNA labeled with a Rhodamine Green fluorophore. When certain potential differences were applied between the two electrodes, we observed fluorescence in an area close to the tip; this fluorescence is proportional to the concentration of molecules, a fact allowing us to confirm that the molecules must be trapped in this tip region. Qualitatively, all these samples showed the same trapping behavior: Figure 2 A–D shows representative wide-field images obtained at −5, −1, +1, and +5 V, respectively, with protein G in the pipette. There is weak localization at +1 V, but a clear, confined build-up of protein G occurs upon application of −5 V. Once the electric field is removed, the trapped protein molecules quickly disperse away by simple diffusion in less than a second. Figure 2 E shows a line scan along the nanopipette at −5 V: protein G is clearly localized very close to the pipette tip in a region with a full width at half maximum of (990 ± 80) nm. The observed trap is also completely reversible: when a sine wave is applied (0.5 Hz) at either 1 or 5 V, cycles of "trapping" followed by "release" are seen. Videos of this time-dependent behavior of the pipette upon application of a sine wave at 0.1 Hz with an amplitude of 1 V (Movie 1) and 5 V (Movie 2) are shown in the Supporting Information.

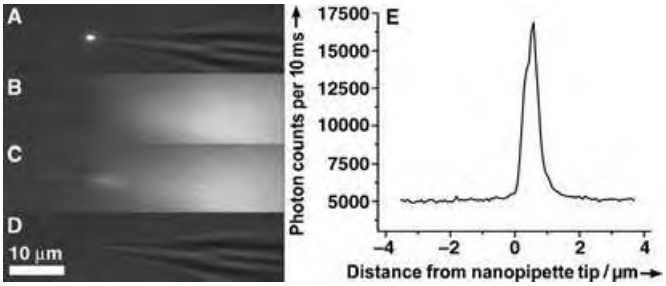

Figure 2. A)–D) Representative wide-field fluorescence images showing the dependence of protein G concentration in the nanopipette on applied voltage: A) −5, B) −1, C) +1, D) +5 V. The nanopipette was wide-field illuminated by a 7-mW laser beam at 488 nm and contained 100 nM Alexa-488-labeled protein G in PBS buffer, the same buffer solution as in the bath. Images (A) and (D) were recorded with very low background illumination to simultaneously record the pipette position and fluorescence (exposure time 10 ms). Images (B) and (C) were recorded without background illumination (exposure time 100 ms). E) Line scan along the axis of a wide-field illuminated nanopipette filled with the same solution as used for (A)–(D) and with the bath electrode at −5 V.

A representative graph of the dependence of the fluorescence intensity of the trapped protein G with applied voltage is shown in Figure 3. It is clear from the Figure that the protein G concentrates at the tip of the pipette below a voltage of −5 V. There is also a far smaller population build-up at approximately +2 V. Comparison of the fluorescence intensity at zero-applied voltage with the highest integrated fluorescence intensity allows us to estimate the concentration enhancement in the pipette tip. This value varied between pipettes, because of variation in size and taper angle, but was always in the range of 300–3000. IgG gave similar concentration enhancements.

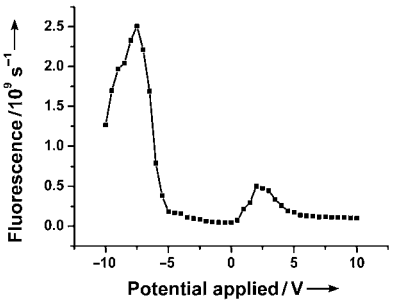

Figure 3. Integrated fluorescence response of the protein G solution in a nanopipette to applied voltage. The nanopipette tip was wide-field illuminated at 488 nm and contained 100 nM Alexa-488-labeled protein G. The intensity of the fluorescence was integrated in the same small trap region. All experiments were performed in PBS buffer, the same buffer solution as in the bath. Fluorescence data were derived from images of 1-ms time resolution and were acquired 2 s after the bath electrode changed polarity to the value indicated.

We compared the enhancement in protein G concentration with that for single-stranded 20-mer DNA in the pipette under the same experimental conditions. The DNA gave a concentration enhancement approximately two times larger than protein G (600–6000) and also showed the onset of trapping at about half the applied voltage. A video of the DNA trapping in the pipette is shown in the Supporting Information (Movie 3). Similar concentration enhancements were observed when using a DC voltage rather than an AC voltage. The number of trapped molecules did not increase significantly with time, since there is a very low rate of flow of molecules to the tip once a negative voltage has been applied to the bath electrode. To test whether the trapping was dye dependant, Alexa-647-labeled IgG was investigated. Exactly the same trapping phenomenon as with Alexa-488-labeled IgG and protein G was observed, a result indicating that the trapping of the protein is not dye specific.

We also studied the free Alexa-488 dye to determine how much the dye contributed to the observed trapping. The onset of strong trapping occurred at approximately −1.1 V—a lower amplitude of voltage than that observed with the DNA and the proteins. Another key difference is that the trap was much larger than that with either the proteins or the DNA, as shown in Figure 4. The dye trap is approximately 8 μm in length. These observations indicate that not only the dye but also the protein or DNA has an effect on the trapping voltage and the size of the trap region.

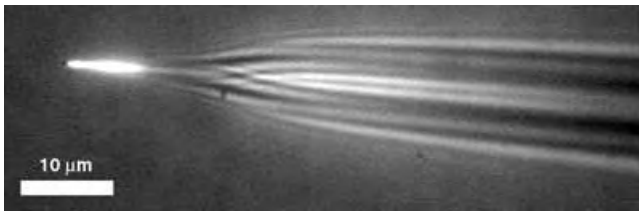

Figure 4. Fluorescence image recorded by using wide-field illumination (5.2 mW) of a nanopipette filled with 100 nM Alexa-488 dye in PBS buffer, the same buffer solution as in the bath. At −2 V there is a large dielectrophoretic concentration of dye confined to the first 8 μm of the nanopipette tip. This image was acquired with an exposure time of 1 s.

The net electric-field-induced force acting on the biomolecules in the nanopipette is a result of the combination of three components: electroosmosis, electrophoresis, and dielectrophoresis. The direction and magnitude of these forces depend on the applied voltage and the position of the molecules in the pipette. In particular, the dielectrophoretic force is proportional to the square of the electric field and will be largest at the pipette tip.[22] Here, we have applied higher voltages (up to 10 V) than we have used previously for controlled delivery (up to 400 mV) to increase the magnitude of the dielectrophoretic effect. Protein G is negatively charged under the conditions of this experiment and the contribution of electroosmotic flow is small,[22] so at a positive applied voltage the electrophoretic force and dielectrophoretic force act in the same direction to pull protein G out of the pipette tip. It appears that there is a range of voltages (1.5–3.5 V) at which some build-up of protein occurs in the tip but the protein is still able to flow out of the pipette. By contrast, on the application of a negative voltage the dielectrophoretic force opposes the electrophoretic force. Hence, close to the tip the two forces balance, and trapping can occur in a small, localized region inside the tip without any flow either to the bath solution or to the capillary electrode.

This work has demonstrated that, under the same experimental conditions, proteins can be trapped with an increase in concentration that is within a factor of two of that observed with DNA. There seems to be no theoretical basis for this observation and it was not expected. While there is clearly a contribution from the dye, there also appears to be a significant contribution from the protein as well. The observed trapping by DEP at DC or low-frequency AC voltages may reflect the contribution of the structured water molecules and counterions around the biological molecule to the dipole induced under these high electric fields, rather than the structure of the biomolecule itself. This will need further experimental and theoretical investigation.

In summary, we have shown that we can trap nanometer-sized proteins, as well as DNA, in physiological buffer. This results in concentration enhancements of at least a factor of 300, with this enhancement obtained in less than a second. Extension of this methodology to the single-molecule limit should be possible with optimization of the trap geometry, thereby allowing prolonged solution studies of individual molecules. Practically, this is a new and potentially powerful method to trap, concentrate, and manipulate both DNA and proteins. It could be used as the basis of ultrasensitive and highly miniaturized bioassays, particularly when performed in parallel in two-dimensional nanofabricated devices.

Experimental Section

The protocol in the Alexa Fluor 488 (Alexa-488) protein-labeling kit provided by Molecular Probes (USA) was employed to label rabbit IgG. Briefly, 1M freshly prepared sodium bicarbonate solution (50 μL) was added to rabbit IgG (0.5 mL, 2 mg mL^{-1}) in phosphate-buffered saline (PBS) buffer to adjust the pH value of the solution to about 8.3. The combined solution was then transferred to a vial of Alexa-488 reactive dye, and the mixture was gently stirred for 1 h at room temperature. The reaction mixture was then loaded on a purification resin column supplied with the kit, to separate the protein from the unreacted dye, and washed once with eluting buffer to give a purity of $>99\,\%$. The labeled rabbit IgG was in the first fluorescent band. The degree of labeling was determined by measuring the UV absorbance at 280 and 494 nm, by using the equations provided by Molecular Probes (USA). The average labeling was 7 Alexa-488 fluorophores per IgG molecule. HPLC-purified 20-base oligonucleotide 5′-CTATGCAGCCATTGTAGTCC-3′ (IBA, Germany) was labeled at the 3′ terminus with the fluorophore Rhodamine Green. Protein G was purchased from Molecular Probes (USA). The average labeling was 2.3 Alexa-488 fluorophores per protein G molecule.

The nanopipettes, with inner radii of around 50 nm, were made by using a laser-based pipette puller (Model P-2000, Sutter Instrument Co., USA), and a two-line program was used to pull borosilicate glass capillaries (inner diameter = 0.58, outer diameter = 1 mm), with the following parameters: Heat = 350, Fil = 3, Vel = 30, Del = 220, Pull and Heat = 330, Fil = 2, Vel = 27, Del = 180, Pull = 250.

For the pipette experiments, a 100 nM DNA, 100 nM protein, or 100 nM Alexa-488 dye solution was backfilled to the bent nanopipette by a microfiller (Microfil 34, World Precision Instruments, USA). A coverglass-bottomed dish (Willco Wells GWST-1000, Netherlands) containing buffer (2–3 mL) was used as the bath. A home-built nanomanipulation system consisting of a piezoelectric translational stage (Tritor 38, Piezosystem Jena, Germany) was used to position the nanopipette. The pipette tip was placed 5–10 μm above the dish surface. A voltage was applied to the nanopipette through two Ag/AgCl electrodes, one in the bath and the other inside the pipette, which served as the working and ground electrodes, respectively. The ion-current flow through the pipette was amplified by a high-impedance amplifier and monitored by an oscilloscope. The ion current flowing through the pipette was the same in the presence and absence of DNA or protein since the ion current is dominated by the flow of sodium and chloride ions. In addition, no ion-current reduction because of partial blocking could be detected with DNA, protein, or antibody in the pipette. Identical buffers were used both in the pipette and in the bath. For the DNA experiments, buffer (10 mM tris(hydroxymethyl)aminomethane hydrochloride (Tris-HCl), 1 mM ethylenediaminetetraacetate (EDTA), and 100 mM NaCl at pH 7.4) was used with EDTA added to remove multivalent cations in the solution. For the protein and dye experiments, a different buffer (10 mM phosphate, 150 mM NaCl, 2 mM NaN_3 at pH 7.2) was used.

A home-built wide-field fluorescence microscope was used to record images of the trapping of dye-labeled biomolecules in the nanopipette. Laser beams (488 nm, Argon ion, model 35LAP321–230, Melles Griot, USA) were spatially filtered and collimated before being sent to the microscope. A home-built fluorescence microscopy attachment was mounted to the rear port of a TE2000U optical microscope (Nikon, USA). The laser beam was focused to the back focal point of an oil immersion objective (Apochromat 60×, NA 1.45, Nikon, USA) after passing through a dichroic mirror (FITC/CY5, AHF Analysentechnik AG, Germany). Fluorescence was collected by

the same objective, filtered by a bandpass filter (535 AF45, Omega Optical, USA) and imaged onto a CCD camera (see Figure 1). The potential waveforms applied to the electrodes were created by using a function generator (Model DS345, Stanford Research Systems, USA).

All experimental data (except for Figure 4) were acquired by using a Photometrics Cascade 512B High Speed CCD camera (Roper Scientific, USA) and a PICOLO Pro 2 video capture card (Euresys Inc., USA). The data for Figure 4 were acquired by using a Watec WAT-902H CCD camera (Watec, Japan). The conversion of the raw video format into AVI format was performed by using the VirtualDub 1.4.10 program (Build 13870).

Inclusion Complexes

Ultrastable Rhodamine with Cucurbituril**

*Jyotirmayee Mohanty and Werner M. Nau**

Rhodamines are arguably the most important fluorescent dyes as shown by their classical and contemporary applications,[1–8] for example, in dye lasers, as quantum counters, as photosensitizers, for spectral calibration in fluorometers, in single-molecule detection, as imaging agents for biomolecules, for scanning confocal microscopy, in fluorescence correlation spectroscopy (FCS), and in high-throughput screening assays. The various applications are made possible through the combination of their water solubility, close-to-unity quantum yields, high extinction coefficients, and very high photostability. Rhodamine 6G (Rh6G) is the most prominent derivative and has become a prototype for many reasons,[3,4] including its photostability: the first continuous-wave dye laser, for example, was based on an aqueous solution of Rh6G containing 1.5% triton X as surfactant.[9] Efforts have been made to improve the fluorescence and lasing characteristics of rhodamines, in particular in regard to their stability towards adsorption, aggregation, and photochemical decomposition, by derivatization or use of additives.[3,7] These approaches have frequently had limited success and often sacrifice other advantageous features of the chromophore.

We now describe the development of an ultrastable rhodamine derivative through the complexation of Rh6G by cucurbit[7]uril (CB7).[10,11] The additive leads to an unprecedented long fluorescence lifetime and an exceptional supramolecular stabilization, including the suppression of undesirable aggregation, the prevention of surface adsorption, and a

substantial decrease in the quantum yield of photobleaching. These features enable the applicability of this water-soluble dye to be expanded.

Cucurbiturils are macrocyclic host molecules which can form inclusion complexes with organic guests, with the strongest complexes formed with positively charged guests.[12–14] Although their supramolecular chemistry has recently been intensively investigated, relatively few investigations have dealt with photochemical investigations such as their effect on fluorophores,[11,15–21] and their complexation behavior with classical fluorescent dyes has not yet been addressed. The addition of CB7 to solutions of Rh6G in water results in the immediate formation of a 1:1 host–guest complex (as established by Job's plots) with a high binding constant ($>50000\,\text{M}^{-1}$, by UV/Vis titration). Low concentrations of CB7 (1 mM) are therefore sufficient to ensure a virtually quantitative complexation of the fluorescent dye at the most relevant nano- to micromolar concentrations of the dye. The formation of the complex is also reflected in a decrease in the diffusion coefficient of the dye from $2.80\times10^{-6}\,\text{cm}^2\,\text{s}^{-1}$[22] to $(1.27\pm0.05)\times10^{-6}\,\text{cm}^2\,\text{s}^{-1}$, as determined by FCS. The characteristic upfield ^{1}H NMR shifts on complexation,[12,14,23] and in particular the marked change in the photophysical properties (see below), provide further evidence for the formation of an inclusion complex in which Rh6G experiences a drastically altered microenvironment. The addition of 2,3-diazabicyclo[2.2.2]oct-2-ene, which is known to form a strong inclusion complex with CB7,[11,20] leads to dissociation of the Rh6G complex through competitive binding. This result provides further experimental support that the Rh6G complex with CB7 is of the inclusion type; the size of Rh6G, however, prevents the dye from being completely immersed.

Complexation of Rh6G by CB7 (1 mM) causes a sharpening and a bathochromic shift of the absorption band (Figure 1). The latter effect is characteristic for the immersion of the guest in a less polar environment, and is similar to that observed in *n*-octanol ($\varepsilon=10.3$).[24] The shift in the fluorescence (Figure 1) is less pronounced, and the resulting smaller Stokes shift suggests that relaxation of the dye through geometrical and solvent effects is smaller, as expected for inclusion in a less polar and more-confined environment.[25] Importantly, the fluorescence quantum yield remains unchanged and close to unity (0.89 ± 0.02).[24]

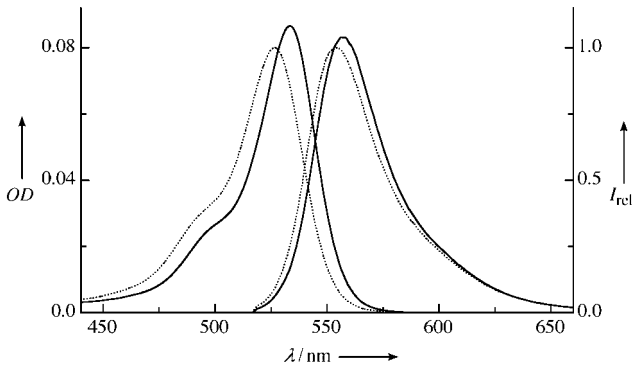

Figure 1. Absorption and fluorescence spectra of Rh6G (1 μM) in water in the absence (dotted lines) and presence (solid lines) of 1 mM CB7.

Strikingly, the fluorescence lifetime of Rh6G increases from 4.08 ± 0.03 ns in water to 4.76 ± 0.04 ns inside CB7. The latter value is the longest lifetime hitherto reported for this dye. The effect on the lifetime of Rh6G is opposite to that observed on its immersion in organic, less polar solvents, and the absolute increase is also more pronounced.[24] This special effect is related to the very low polarizability/refractive index (close to the gas phase) which a guest molecule experiences inside the CB7 cavity. We recently interpolated this low polarizability from solvatochromic effects experienced by an azo chromophore,[20,21] and the present result represents the first practically relevant example of what we have recently described as the supramolecular approach to radiative decay engineering.[21] According to the Strickler–Berg Equation,[26] the rate constant for the radiative decay of a chromophore (the ratio of the fluorescence quantum yields divided by the fluorescence lifetime) increases with the square of the refractive index, such that low environmental polarizabilities result in slower radiative decay rates and expectedly longer fluorescence lifetimes. Indeed, the rate of radiative decay decreases from $(2.18\pm0.02)\times10^8\,\text{s}^{-1}$ to $(1.87\pm0.06)\times10^8\,\text{s}^{-1}$ upon complexation of Rh6G by CB7, an observation which is in keeping with the lower polarizability inside the CB7 cavity.[20] In addition, the rate of the radiationless decay (obtained as the difference between the observed rate of fluorescence decay and the rate of radiative decay) decreases from $(2.7\pm0.1)\times10^7\,\text{s}^{-1}$ to $(2.3\pm0.1)\times10^7\,\text{s}^{-1}$ upon complexation by CB7. The slower radiationless decay of Rh6G in the CB7 complex ensures a constant fluorescence quantum yield regardless of the slower rate of radiative decay. The reduced rate of the radiationless decay can be related, among other things, to a partial protection from the bulk water, which is known to quench Rh6G fluorescence[8]—as evident by its longer fluorescence lifetime in D_2O (4.36 ns).[24,27]

The enhancement of the fluorescence lifetime of Rh6G by an additive is unique and could be of interest, for example, for assays based on fluorescence lifetimes,[28] as well as fluorescence lifetime imaging microscopy.[29] However, the addition of CB7 has benefits which go far beyond this photophysical peculiarity and are of more immediate relevance for practical use. First, CB7 reduces the photobleaching of Rh6G, a phenomenon which describes the tendency of fluorescent dyes to permanently lose their ability to fluoresce as a consequence of photon-induced chemical damage. Increasing the photostability of rhodamines either with additives or by structural modifications has remained an active field of dye research[3–5] since the photostability of a fluorescent dye is a key parameter, along with its brightness, for practical applications. This has been reinforced[3,4] in recent years by the development of single-molecule detection and scanning confocal microscopic techniques, for which chromophore stability is quintessential. Numerous additives for rhodamines have been tested to date which have in common that their photostabilizing properties are limited, that they operate either by preventing secondary photolytic steps, for example, as antioxidants to prevent oxidation, or by quenching undesired reactive triplet states, and that they have to be applied in high concentrations, which in turn may lead to undesirable fluorescence quenching effects.[3] If the use of

organic solvents or surfactants are disregarded, none of the previously recommended techniques actually involves a discrete complexation of the dye and modification of the intrinsic rate constants for the primary elementary photoprocesses like CB7 does, thus establishing the current approach as a novel strategy for photostabilization in water.[3]

The photostabilization of Rh6G by CB7 is already sizable (a factor of ca. 1.5) at low levels of irradiation ($< 1\ kW\,cm^{-2}$, photoreactor with lamps emitting visible light), but it becomes remarkably high at high levels of irradiation (ca. $10\ MW\,cm^{-2}$, 10 Hz pulsed 2nd harmonic 532 nm Nd-YAG laser excitation, ca. 0.1 J pulse energy, pulse width ca. 10 ns), where two-step two-photon decomposition dominates.[4] As is apparent from Figure 2, there is a dramatic

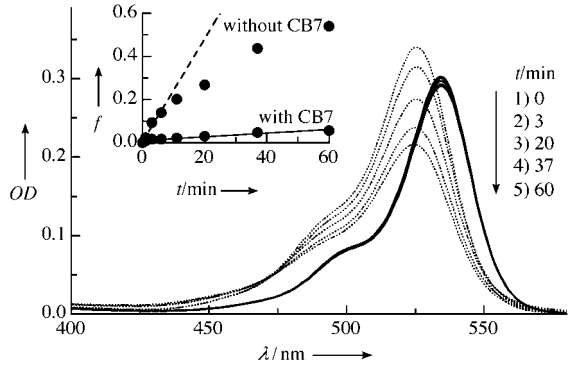

Figure 2. Photobleaching of Rh6G (ca. 4 μM) in aerated water in the absence (dotted lines) and presence (solid lines) of 1 mM CB7 followed through the decrease of the visible absorption with increasing time of pulsed 532-nm Nd-YAG laser irradiation. The inset shows the graph and correlation lines for the characteristic function $f = \log([10^{A_0}-1]/[10^{A}-1])$ versus irradiation time for the determination of the relative quantum yield of photobleaching (see Experimental Section). For the unstabilized solution, the correlation line refers to the initial 10-min time period because of the formation of absorbing photoproducts at longer times.

increase (factor of 30 ± 3) in the photostability upon addition of CB7, as quantified through absorbance-based quantum yields of photobleaching during the initial pulsed-laser photolysis period (at longer times absorbing photoproducts are formed,[25] which cause the graph to become nonlinear). The high levels of irradiation described in Figure 2 are most relevant for dye lasers, but also in scanning confocal microscopy, where irradiances of $1\ MW\,cm^{-2}$ can be reached.[4] Apparently, CB7 selectively prevents the two-step two-photon photolysis, and it does not have the common drawbacks, namely, it does not act as a quencher, does not absorb in the visible region, and consequently displays no autofluorescence. These combined properties distinguish CB7 from other stabilizing additives.[3]

The higher photostability of Rh6G is presumably caused by a combination of factors. Cucurbiturils generally provide an extremely inert reaction medium; for example, it is very resistant to oxidation and even withstands ozonolysis.[30] In addition, the fluorescent dye is quite efficiently protected from water,[11] which may further reduce intermolecular follow-up (photo)chemistry,[25] including photoionization from higher excited states relevant in the two-step two-photon decomposition.[4]

There is another benefit of using CB7 as an additive to Rh6G solutions. It improves the stability of the emission by greatly increasing the thermal stability of the dye solution by preventing unspecific adsorption to glass and plastic surfaces. This was a previously documented problem for xanthene dyes.[4] The addition of CB7 to an aqueous solution of Rh6G prevents this adsorption virtually completely, such that the dye depletion can be conveniently quantified with reference to a CB7-stabilized solution. Figure 3 shows the temporal

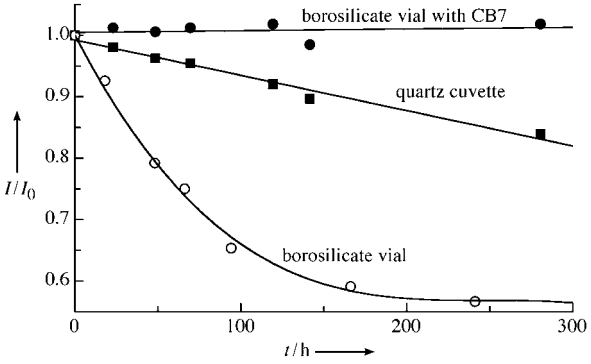

Figure 3. Temporal evolution of the fluorescence intensity of Rh6G (1 μM) in aerated water under ambient light in different sample containers.

evolution of the steady-state fluorescence intensity of aqueous Rh6G solutions stored in different sample containers under ambient conditions and daylight. The CB7-stabilized Rh6G solution (1 μM) stored in a standard sample vial showed no significant loss of fluorescence intensity over a period of several weeks. In contrast, an unstabilized solution with the same concentration of Rh6G in the same vial showed a dramatic reduction in the fluorescence intensity. Some improvement (a factor of ca. 3 after 10 days) could be achieved by using quartz cuvettes instead of borosilicate vials, but the CB7-stabilized sample excelled (Figure 3). The stabilization factor can only be estimated in these cases ($>$ 100), since the fluorescence behavior of the CB7 solution implied indefinite stability after two weeks storage, thus providing a gold standard. Additional experiments using polypropylene showed that this material was the poorest choice for handling and storage of Rh6G, unless CB7 was present; the tendency of Rh6G to adsorb to surfaces follows the order: polypropylene $\gg$ borosilicate glass $>$ quartz glass. The depletion of the dye as a result of surface adsorption was, as expected, found to be most pronounced at very relevant low concentrations of the dye since at higher concentrations a surface-area-dependent adsorption–desorption equilibrium can be attained.[4] Clearly, the addition of CB7 greatly simplifies sample handling and eliminates a number of uncertainties related to the actual dye concentration studied, irrespective of the materials used. More importantly, the increased thermal (as well as photochemical) stability of CB7-containing Rh6G solutions allows the storage of aqueous Rh6G dye solutions, in particular of very dilute (nM)

solutions, for an extended period of time. This, therefore, allows the use of water as the solvent but eliminates the need to prepare the respective aqueous solutions freshly before each experiment, for example, for spectral calibration or as a diffusion coefficient reference in FCS. The addition of high concentrations of surfactants, which are similarly known to reduce unspecific adsorption but afford microheterogeneous solutions,[4] is also avoided.

In fact, we found that the prevention of unspecific adsorption becomes indispensable in confocal microscopy experiments (FCS mode). A routine sample preparation cycle (see Experimental Section) reduced the initial fluorescence intensity, assessed through the count rate, by nearly one order of magnitude compared to an identically handled CB7-stabilized Rh6G solution—from 96 to 13 KHz (Figure 4, $t = 0$)—although the extinction coefficient of the uncomplexed

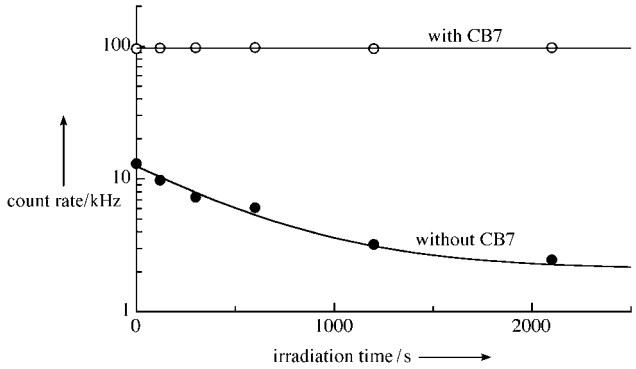

Figure 4. Dependence of the registered count rate of a Rh6G solution (10 nM) in the time course of an extended FCS measurement in a Lab-Tek 8-chambered borosilicate cover glass.

Rh6G at the employed Ar/2 laser wavelength (514 nm) is about 50% higher (Figure 1). In addition, the average number of molecules in the focal volume afforded directly by the FCS experiment decreased by a factor of 12 when CB7 was absent (from 5.6 to 0.46), thus suggesting that more than 90% of the Rh6G molecules were actually already lost during sample preparation by adsorption to the plastic and glass walls in the absence of the stabilizer. Moreover, the count rate of the unstabilized Rh6G solution continued to deplete during the course of the on-going FCS measurements, while that of the CB7-stabilized solution remained quite stable with prolonged irradiation (Figure 4, note the logarithmic scale). The count rate after 35 minutes was nearly 50 times higher with CB7, which illustrates the importance of appropriately stabilized dye solutions for long-time FCS measurements.

Finally, the formation of the supramolecular complex not only prevents surface adsorption, but also reduces adverse effects arising from aggregation of the dye, a phenomenon which comes into play at higher concentrations of dye that are relevant, for example, for dye lasers.[7,8] The addition of CB7 results ultimately in a stronger fluorescence of concentrated Rh6G solutions ($>10\,\mu M$), which in the absence of CB7 display a weaker fluorescence (and absorbance) than is extrapolated from lower concentrations as a consequence of Rh6G dimerization.[4] Addition of CB7 appears to suppress dye aggregation by selective formation of complexes containing only a single dye molecule. CB7 therefore plays an important role in breaking up fluorescent dye aggregates, thus providing an attractive alternative to the use of organic solvents or micellar solutions, the use of which is discouraged, for example, for dye lasers because of reduced dye photostability, poorer thermooptic performance, and economic as well as environmental considerations.[7,8,25] It should be noted that the photostabilization, adsorption, and FCS experiments (see above) were performed at low concentrations of the dye, where the deaggregating effect of CB7 is less important.

The concept of using a macrocyclic host to improve the solubility of Rh6G, enhance its photostability, and modify its photophysical characteristics is as simple as it is appealing. That the currently described supramolecular effects on the fluorescent properties of Rh6G are nevertheless nontrivial and critically dependent on the choice of CB7 as a unique host is readily seen by comparison with the effects of cyclodextrins as classical water-soluble hosts, which do not show the combination of desirable photophysical and photochemical effects. For example, their binding constants with Rh6G are very low, approximately only $200\,M^{-1}$,[31] such that a significant fraction of dye remains uncomplexed even in solutions saturated with host.

In summary, the addition of CB7 to aqueous solutions of Rh6G has exposed a synergistic interplay of several advantageous effects, which include high brightness, increased fluorescence lifetimes, spectral shifts, increased photostability at low and in particular high levels of irradiation, and the prevention of unspecific adsorption and dye aggregation. These factors are of interest for multiple practical applications: for dye lasers, for storing dilute Rh6G solutions, in confocal microscopy, for biomolecule labeling (note that complexation of a fluorophore by CB7 in a labeled peptide has recently been reported),[11] for high-throughput screening assays, and in PCR with fluorescence read-out. Several of these applications are currently under detailed evaluation.

Experimental Section

Rh6G was obtained from Molecular Probes and CB7 was synthesized as reported.[10,11] All measurements were made in water under air. The photolysis of Rh6G solutions with and without CB7 at high levels of irradiation were carried out by using the 2nd harmonic (532 nm) output of an Nd-YAG laser (Continuum Surelite III 10 model, 0.1 J pulse energy). The absorbance of Rh6G was monitored on a Varian Cary 4000 UV/Vis spectrophotometer parallel to an optically matched unstabilized solution. For quantification of the relative photobleaching quantum yield, the decrease in the absorbance at 532 nm (A) at different irradiation times was plotted according to the pertinent function $\log([10^{A_0}-1]/[10^{A}-1])$, and the ratio of the slopes of the plots were corrected for different extinction coefficients at the irradiation wavelength to afford the relative photobleaching quantum yields.[32] The low-irradiance photolysis was performed with 1 μM solutions in a Luzchem LZC-4V photoreactor equipped with 14 cool white fluorescent tubes, and the relative quantum yield for photobleaching in the presence of CB7 was determined accordingly, but no corrections for differential absorbance were made as a consequence of the broad-band irradiation.

The long-term storage experiments under ambient conditions were performed by monitoring the decrease in the integrated steady-state fluorescence intensity (measured on a Varian Cary Eclipse fluorometer) of the stabilized and unstabilized Rh6G solutions (1 μM) in different sample containers. For the FCS experiments on a confocal microscope (Carl Zeiss LSM 510 Meta, Confocor 2), 10 nM Rh6G solutions were obtained by diluting a freshly prepared 1 μM dye solution with water or with a 1 mM solution of CB7 in an Eppendorf polypropylene standard reaction vial, and immediately transferring a 400 μL sample volume with an Eppendorf pipette/polypropylene tip into a Lab-Tek 8-chambered borosilicate cover glass (chamber walls are polystyrene). The count rate obtained in the course of prolonged 514 nm Ar/2 laser excitation (irradiance estimated as ca. 0.1 $MW\,cm^{-2}$) was then followed over time. A control experiment demonstrated that the addition of 1 mM CB7 did not significantly enhance the background count rate in the FCS mode.

The fluorescence lifetimes of 200 nM Rh6G solutions in the presence and absence of CB7 were measured by time-correlated single-photon counting on an FLS-920 fluorometer (Edinburgh Instruments) using a H_2-flash lamp ($\lambda_{ex} = 527$ nm, $\lambda_{mon} = 552$ nm) for excitation by reconvolution of the fluorescence decay with the instrument response function. The fluorescence quantum yield of the CB7-stabilized dye was determined from integrated corrected fluorescence spectra with reference to Rh6G in water ($\Phi_f = 0.89$).[24]

[27] The fact that the lifetime of the Rh6G·CB7 complex increases also slightly when assembled in D_2O compared to H_2O (4.88 ± 0.05 versus 4.76 ± 0.04 ns) demonstrates directly that quenching by water is reduced by the supramolecular host, but not completely eliminated, presumably because the dye is too large to be fully included.

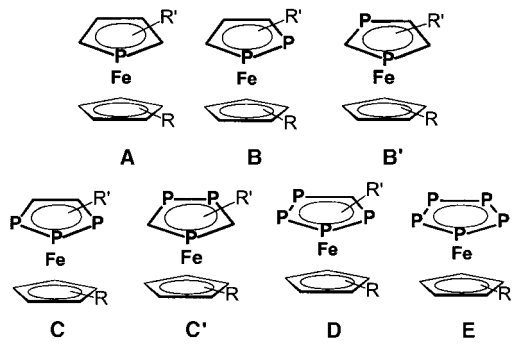
Polyphosphorus Ligands

Tetraphosphacyclopentadienyl and Triphosphaallyl Ligands in Iron Complexes**

Manfred Scheer, Shining Deng, Otto J. Scherer, and Marek Sierka*

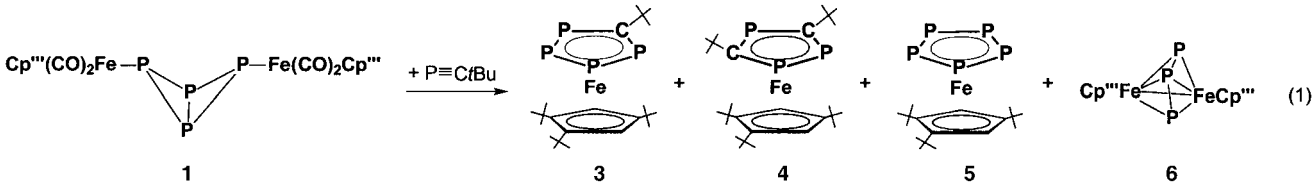
Dedicated to Professor Gerd Becker on the occasion of his 65th birthday



Since the first synthesis of $[Ti(\eta^5\text{-}P_5)_2]^{2-}$ by Ellis et al.[1] the search for decaphosphaferrocene has been a challenge in the field of phosphorus-containing complexes.[2] In addition, the lower phosphorus-containing complexes with $[(RC)_nP_{5-n}]^-$ ligands ($n = 1$–3) are of particular interest since η^5-phospholyl complexes show activity in various homogeneous catalysis applications.[3] Among the series of ferrocene complexes with $[(RC)_nP_{5-n}]^-$ ligands ($n = 0$–5) the syntheses of **A**[4] and **E**[5] have been benchmarks in the development of polyphospholyl complex chemistry.[6]

Whereas the ferrocenes of type **B**[7] as well as **B′** and **C′**[8] were synthesized later using phosphaalkyne as starting material for **B′** and **C′**, the missing 1,2,3-triphosphaferrocene **C** was only recently synthesized by Scherer et al. by the reaction of the tetraphosphabicyclobutadiene complex **1** with diphenylacetylene.[9] In the series shown, the hitherto missing complex **D** is of interest for us, since our general goal lies in the use of P_n ligand complexes as linking units for the formation of soluble supramolecular aggregates[10] as well as 1D and 2D polymers and networks.[11] Thus, we developed a synthesis for the first completely characterized 1,2,3,4-tetraphosphaferrocene complex **D** by a method using *t*BuC≡P as starting material, the results of which are reported herein.

The reaction of **1** with *t*BuC≡P leads to the desired complex in a mixture of products which have been separated by chromatography [Eq. (1); $Cp''' = \eta^5\text{-}C_5H_2tBu_3$]. In each of these thermolysis reactions a very broad signal appears at $\delta = 92$ ppm ($\omega_{1/2} = 300$ Hz) in the ^{31}P NMR spectrum, which probably represents a polymeric product. The main products isolated are complexes **4** and **3**, whereas **6** and the known *cyclo*-P_5 complex **5**[12] could only be obtained in small amounts.[13] The structure of the main products gives evidence for a P_3/P_1 fragmentation[14] of the bicyclo-tetraphosphine complex **1**, with subsequent further reaction with one or two equivalents of phosphaalkyne to give the products **3** and **4**,



1 3 4 5 6 (1)

respectively. Similar observations were made for an indanyl-substituted derivative of **1** and 1-methylcyclohexylphosphaalkyne by Scherer et al.[15]

The crystals of complexes **3** and **6** are green and those of **4** are red. The compounds are readily soluble in toluene and CH_2Cl_2 and slightly soluble in nonpolar solvents, such as *n*-pentane. The mass spectrum of each compound shows the appropriate molecular ion peak. The $^{31}P\{^1H\}$ NMR spectrum of the major product **4** shows two groups of signals of an AM_2 spin system, which is very similar to the values found in complexes of type **C′**.[8] Furthermore, the molecular structure of **4**[16] (see Supporting Information) is similar to those of other type **C′** derivatives[8] and reveals the staggered conformation of the *t*Bu groups of the five-membered rings to minimize steric repulsion. The rings are tilted by only 0.7°.

The ^{31}P NMR spectrum of the target complex **3** reveals an AA′MM′ spin system at $\delta = 122.8$ ppm for the P_M and $P_{M'}$ atoms, and at $\delta = 80.4$ ppm for the P_A and $P_{A'}$ atoms.

Complex **3** crystallizes in the monoclinic space group $P2_1/n$ with two independent molecules in the unit cell.[16] In

[**] This work was comprehensively supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The authors thank Prof. Dr. H. Sitzmann for helpful discussions about the synthesis of the starting material and Dr. E Matern for the simulation of the ^{31}P NMR spectra.

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

 DOI: 10.1002/anie.200500194

Figure 1 the top view of both molecules is shown, revealing that in the solid state both enantiomers are present, these become equivalent in solution owing to the free rotation of the five-membered rings.

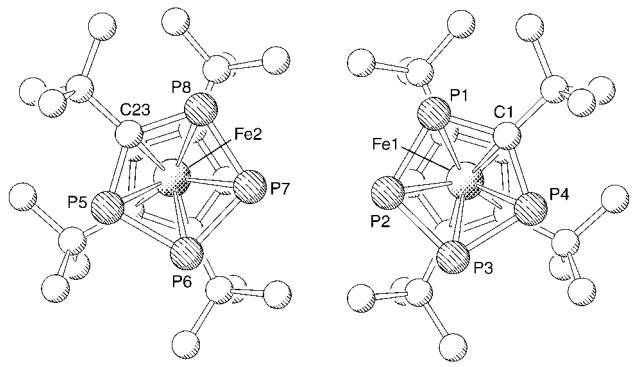

Figure 1. Top-view of the two independent molecules of **3** in the crystal structure. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: P1-C1 1.759(3), P1-P2 2.115(1), P2-P3 2.115(1), P3-P4 2.116(1), P4-C1 1.769(3), P5-C23 1.766(3), P8-C23 1.759(3), P5-P6 2.1167(13), P6-P7 2.1190(13), P7-P8 2.1152(12); P1-C1-P4 124.67(18), P1-P2-P3 104.02(5), P2-P3-P4 103.59(5), C1-P1-P2 103.75(11), C1-P4-P3 103.85(11), P5-C23-P8 125.05(17), P5-P6-P7 103.53(7), P6-P7-P8 104.03(5), C23-P5-P6 103.73(11), C23-P8-P7 103.58(11).

In the sandwich complex **3** both five-membered rings are nearly parallel (Figure 2). The tilting angles between the five-membered rings are 4.93(2)° (molecule A) and 5.24(2)° (molecule B). Since the structural data of both molecules are similar only molecule A is considered hereafter. The averaged P–C and P–P bond lengths of the tetraphospholyl ring are 1.763(3) and 2.115(1) Å, respectively, and are therefore shorter than corresponding single bonds. The P–P bonds in **3** are slightly longer than the averaged bond lengths in the *cyclo*-P_5 rings of [Cp‴Fe(η^5-P_5)] (2.079(8) Å)[12] and [Cp^{x}Fe(η^5-P_5)] (Cp^x = η^5-C_5Me_4Et) (2.096(3) Å)[17] and thus more comparable to those of the *cyclo*-P_3C_2-ring in [Cp‴Fe(η^5-$P_5C_3Ph_2$)] (av. P–C 1.775(4) Å, av. P–P 2.124(2) Å).[9] Since each of the angles in the tetraphospholyl ring of **3** deviate from 120° (av. P-P-P 102.8°, P(1)-C(1)-P(4) 127.1(19)°) the five-fold symmetry of the ring is distorted, which is similar to the situation in the P_3C_2 ring of [Cp‴Fe(η^5-$P_3C_2Ph_2$)].[9]

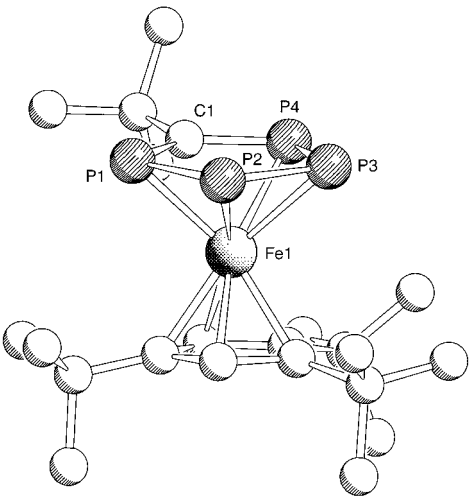

Figure 2. Molecular structure of **3** (molecule A). Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°] [molecule B]: P1-C1 1.759(3) [1.766(3)], P1-P2 2.115(1) [2.117(1)], P2-P3 2.115(1) [2.119(1)], P3-P4 2.116(1) [2.115(1)], P4-C1 1.769(3) [1.759(3)]; P4-Fe1-P3 53.36(3) [53.33(3)], C1-Fe1-P1 45.16(8) [45.48(8)], P3-Fe1-P1 89.86(3) [89.99(4)], P4-Fe1-P2 89.96(4) [89.86(3)], P3-Fe1-P2 52.94(3) [53.02(3)], C2-C1-Fe1 138.3(2) [138.2(2)].

Complex **6** contains the first triphosphaallyl unit in a binuclear complex. To date only *cyclo*-P_3 ligands[18] and organoallylic EtE_3 units (E = P, As)[19] are the only known phosphorus or allylic groups to bridge two metal centers. The molecular structure of **6**[16] (Figure 3) reveals a *cis*-orientation

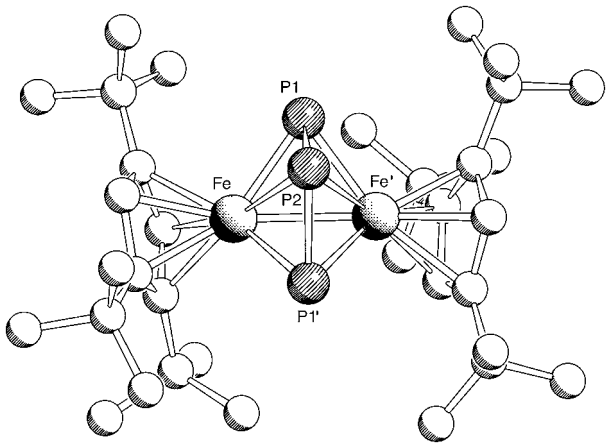

Figure 3. Molecular structure of **6**. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Fe-Fe 2.589(1), P1(1′)-P2 2.148(1), Fe-P1 2.225(1), Fe-P2 2.446(1); P1-P2-P1′ 100.71(7), Fe-P1-Fe′ 71.51(4), Fe-P2-Fe′ 63.92(4).

of the Cp‴ groups, whereas the allylic P_3 unit is directed away from the Fe–Fe axis. The P–P bond length of the allylic P_3 moiety is 2.148(1) Å and thus shorter than a single bond and slightly longer than the P–P double bond of the EtP_3 unit in [{(tripod)Co}$_2$(μ,η^3-EtP_3)] (2.110 Å; tripod = CH_3C-$(CH_2PPh_2)_3$).[19] The distance between the Fe atoms (2.589(1) Å) is in the same range as those of the various [{Cp′Fe(CO)$_2$}$_2$] complexes.[20]

Since the electronic structure of **6** was not clear upon initial inspection, we decided to carry out density functional theory (DFT) calculations. Theoretical methods have proven to be a useful tool in analyzing the structure and properties of phosphorus-containing transition-metal complexes.[1,2,21] Calculations are performed on the original complex **6** and, additionally, to analyze the steric influence of the bulky *t*Bu groups, on a model compound **6a** in which the *t*Bu groups are replaced by H atoms.

Structure optimizations of **6** and **6a** yield close lying low-spin doublet states (Table 1) with an unpaired electron delocalized over the d orbitals of both Fe atoms (see Supporting Information). Comparison of the results obtained

Table 1: Comparison of relative energies of different electronic states ΔE [kJ mol^{-1}] and selected structural parameters ([Å], [°]) for the central Fe_2P_3 unit of compounds **6a** and **6** (BP86 calculations).

	6a (C_{2v})[a]		**6** (C_2)[a]		Exp

[a] Symmetry point group.

for **6** and **6a** indicates that the steric repulsion between *t*Bu groups has an important influence on the electronic structure. For **6a** calculations yield two almost degenerate $^2A_2$ and $^2B_1$ states with the latter one being slightly less stable. These two states differ by the occupancy of the a_2 and b_1 orbitals which are composed of d_{xz} and d_{xy} orbitals of the Fe and Fe′ atoms (with both Fe atoms located on the *y* axis). The $(b_1)^2(a_2)^1$ configuration of the $^2A_2$ state facilitates a weak Fe–Fe′ bonding interaction. Promoting one electron from the b_1 to a_2 orbital results in the $^2B_1$ state ($(b_1)^1(a_2)^2$), which weakens the Fe···Fe′ interaction and facilitates the $P_3 \rightarrow$ Fe π donation. In **6** the stability of the ^2A and ^2B states, which correspond to the $^2A_2$ and $^2B_1$ states of **6a**, respectively, is reversed. The ^2A state is now less stable as a result of the stronger Fe–Fe′ interaction which results in a higher repulsion between bulky Cp‴ ligands.

To rationalize the differences between different states of **6** and **6a** we performed an atoms-in-molecules (AIM)[22] topological analysis of the electronic charge density for both systems (Figure 4; see Supporting Information). The bonding of the ^2B state of **6** is similar to the $^2B_1$ state of **6a**. However, the ^2A and $^2A_2$ states differ because of the absence of the Fe–Fe′ bond in **6** which is a result of the repulsion between bulky *t*Bu groups.

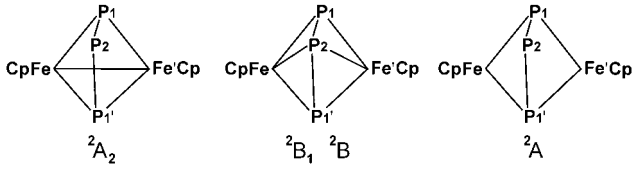

Figure 4. Bonding schemes of the compounds **6a** ($^2A_2$ and $^2B_1$ states) and **6** (^2A and ^2B states) from the AIM analysis of electronic charge densities (Cp denotes η^5-C_5H_5 in **6a** and η^5-$C_5H_2tBu_3$ in **6**).

The structure parameters calculated for the slightly less stable ^2A state of **6** are in better agreement with experimental data than those calculated for the ^2B state. Thus, the $\mu,\eta^2{:}\eta^2$-coordination of the allylic P_3 ligand is the most probable one. Results obtained for **6** and **6a** show that the weak attractive Fe···Fe′ interaction and repulsion between the bulky *t*Bu groups are two competing effects. The DFT method may not be accurate enough to properly describe the balance of the two interactions, and the energy difference between the two states is certainly within its margin for error. The delocalization of the unpaired electron over both Fe atoms is the reason that signals for an AA′X spin system are observed in the ^{31}P NMR spectrum of **6**. However, the paramagnetism might cause the large chemical shift differences in both signals, which is especially pronounced for the P1 and P1′ atoms.

In conclusion, the results have shown that the bicyclotetraphosphine complex **1** is an excellent starting material for the synthesis of novel polyphosphorus-ligand-containing metallocenes. With the synthesis of the 1,2,3,4-tetraphosphaferrocene the path has been cleared for its application in the formation of well-defined aggregates by intermolecular assembly.

Experimental Section

All manipulations were performed under an atmosphere of dry nitrogen using a glovebox and Schlenk technique. Solvents were purified and degassed by standard procedures.

*t*BuC≡P (0.223 g, 2.23 mmol) was added to a solution of **1** (1.82 g, 2.23 mmol) in toluene (150 mL) at room temperature. The reaction mixture was heated under reflux for 36 h. After removal of all volatile material in vacuum, the residue was dissolved in dichloromethane (10 mL) and transferred onto silica gel. Chromatographic work-up on a silica gel column (40 × 2.5 cm) eluting with hexane/dichloromethane (10:1) gave first a red fraction of **6**, then a green fraction of **5**, an orange-red fraction of **4**, and finally an olive-green fraction of **3**. Each product was recrystallized from *n*-hexane. A fifth band (green) contained the proposed polymeric compound mentioned in the main text. If, as in some cases, the separation was not complete after column chromatography, the separation was completed in a glovebox by thin layer chromatography (TLC) using a hexane/dichloromethane (10:1) solvent mixture.

All theoretical calculations were performed using the TURBOMOLE program package.[23] We employ the triple zeta plus polarization (TZVP) basis set on all atoms.[24] We considered BP86[25] and B3LYP[26] exchange-correlation functionals. Comparison of structural parameters calculated for **6** using both functionals (see Table 1 for BP86 and the Supporting Information for B3LYP results) shows that the BP86 provides a more reliable description. To speed up calculations with BP86 functional the Coulomb part was evaluated using the MARI-J method.[27] To confirm that a calculated structure and density are not the result of symmetry restrictions, the calculations are performed both by using symmetry and without symmetry. The most stable spin states have been found employing the pseudo Fermi smearing technique.[28] All nuclear coordinates have been fully optimized. Convergence criteria were set to 10^{-3} a.u. for the norm of the gradients and 10^{-5} a.u. for energy change. The AIM analysis was performed with the AIMPAC program.[29]

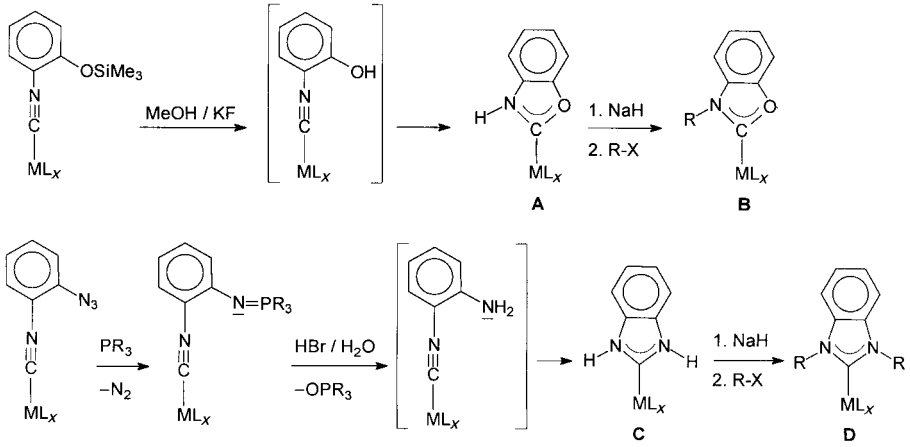
Carbene Complexes

Template Synthesis of a Coordinated Tetracarbene Ligand with Crown Ether Topology**

F. Ekkehardt Hahn, Volker Langenhahn, Thomas Lügger, Tania Pape, and Duc Le Van*

Nucleophilic attack at the carbon atom of a coordinated isocyanide is one of the oldest methods for the preparation of carbene complexes.[1] Particularly protic nucleophiles like alcohols and primary amines have been useful in this reaction. They give in good yield carbene complexes in which the carbene ligand has a H substituent at the N-position.[2] The use of functionalized isocyanides like 2-hydroxyethyl isocyanide containing both the isocyanide function and the nucleophile in the same molecule leads, when the isocyanide is coordinated to a metal center in a high oxidation state, to complexes with a heterocyclic NH,O-stabilized carbene ligand.[3]

We reported on the template-controlled cyclization of 2-hydroxyphenyl isocyanide, which was obtained from complexes containing 2-(trimethylsiloxy)phenyl isocyanide[4] by cleavage of the O–Si bond[5] (Scheme 1). The synthesis of complexes containing benzannulated NH,NH-stabilized N-heterocyclic carbene ligands was also achieved in a template synthesis.[6] In this reaction 2-azidophenyl isocyanide was used as a synthon for the unstable 2-aminophenyl isocyanide. 2-Azidophenyl isocyanide, when coordinated to a transition metal, can be activated at the azido function by a Staudinger reaction.[7] Hydrolysis of the initially obtained iminophosphorane leads to immediate cyclization and formation of the NH,NH-stabilized carbene ligand. Both the NH,O- (in **A**) and the NH,NH-stabilized carbene ligand (in **C**) are easily alkylated at the N-position to form the carbene complexes **B** and **D** (Scheme 1). The carbene ligands in complexes **A**–**C** are not stable when removed from the metal center. The template-controlled synthesis of **D** offers an alternative to the direct reaction of stable benzannulated carbene ligands[8,9] and benzimidazolium salts[10] with transition-metal complexes for the preparation of carbene complexes. Here we report on a modified cyclization reaction of coordinated 2-azidophenyl isocyanide for the synthesis of the tetracarbene complex $[\mathbf{5}](CF_3SO_3)_2$ (Scheme 2) and on a method to bridge the four NH,NH-stabilized carbene ligands in $[\mathbf{5}]^{2+}$ to give complex $[\mathbf{8}]^{2+}$, which contains a cyclic tetracarbene ligand with crown ether topology (Scheme 3).



Scheme 1. Template-controlled cyclization of β-functionalized phenyl isocyanides to give N-heterocyclic carbene ligands. $ML_x = W(CO)_5$, $Mo(CO)_5$, $Cr(CO)_5$.

The preparation of a cationic tetracarbene complex of type $[\mathbf{5}]^{2+}$ (Scheme 2) starting from a cationic square-planar tetrakis(2-azidophenyl isocyanide)metal(II) complex by a fourfold Staudinger reaction, hydrolysis, and cyclization in analogy to the preparation of **C** (Scheme 1) appears initially unproblematic. Homoleptic tetrakis(phenyl isocyanide) complexes of Pd^{II} and Pt^{II} have been described,[11] while Ni^{II} is known to polymerize isocyanides.[12] However, the preparation of complexes of type $[M(C{\equiv}N\text{-}Ar)_4]^{2+}$ starting from PdX_2 or PtX_2 (X = Cl, I) requires a tenfold excess of aryl isocyanide and yields, particularly upon stoichiometric application of the aryl isocyanide, often only the diisocyanide complexes[13] of type $[MX_2(C{\equiv}N\text{-}Ar)_2]^{2+}$. Similar results were obtained in the reaction of 2-azidophenyl isocyanide **2** with PtX_2. Contrary to this, the more nucleophilic alkyl isocyanides readily form homoleptic complexes[3e,14] with Pt^{II} and Pd^{II}.

To avoid the problems associated with the preparation of tetrakis(2-phenyl isocyanide) complexes we developed the template-controlled reaction cascade depicted in Scheme 2. First tetrakis(trimethylphosphane)platinum(II) bis(trifluoromethanesulfonate) $[\mathbf{1}](CF_3SO_3)_2$ was treated with four equivalents of ligand **2**. At first only one of the phosphine ligands is replaced by an isocyanide ligand in the formation of complex $[\mathbf{3}]^{2+}$. No further substitution takes place at this stage. The liberated phosphine ligand can attack the metal center in $[\mathbf{3}]^{2+}$ to regenerate $[\mathbf{1}]^{2+}$. An alternative reaction path is the Staudinger reaction of the liberated phosphine with the

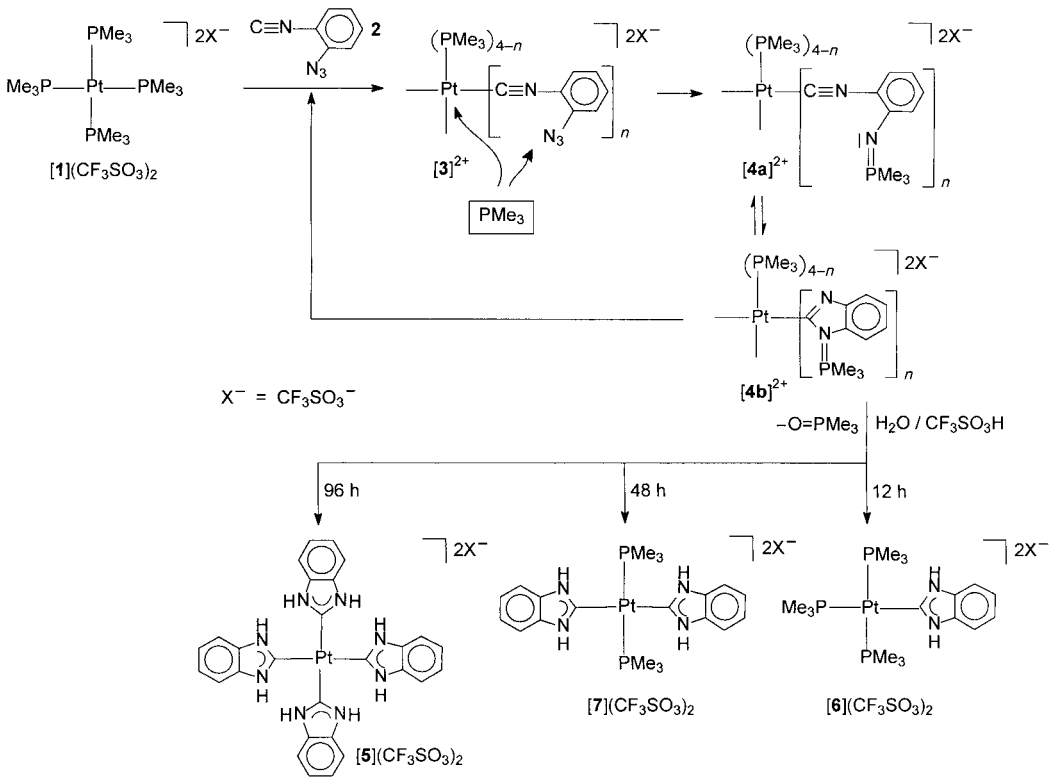

Scheme 2. Synthesis of Pt^{II} carbene complexes $[\mathbf{5}](CF_3SO_3)_2$, $[\mathbf{6}](CF_3SO_3)_2$, and $[\mathbf{7}](CF_3SO_3)_2$.

azido function of the coordinated 2-azidophenyl isocyanide. If the Staudinger reaction proceeds faster than the backreaction to $[\mathbf{1}]^{2+}$, the competitor for a coordination site at platinum (PMe_3) is consumed and irreversible liberation of N_2 gives the iminophosphorane complex $[\mathbf{4a}]^{2+}$. This reaction is indeed observed.

For electron-rich transition metals, the chemical equilibrium between the complexes with the open and cyclized forms of the iminophosphorane ligand ($[\mathbf{4a}]^{2+}/[\mathbf{4b}]^{2+}$) resides mainly on the side of the noncyclized ligand (type $[\mathbf{4a}]^{2+}$), which has been confirmed crystallographically for the $W(CO)_5$ complex (Scheme 1).[6a,15] However, the Pt^{II}-coordinated isocyanide carbon atom in $[\mathbf{4a}]^{2+}$ is much more strongly activated for the nucleophilic attack of the iminophosphorane nitrogen atom. We therefore postulate that the iminophosphorane ligand in $[\mathbf{4a}]^{2+}$ cyclizes in an intramolecular fashion to give complex $[\mathbf{4b}]^{2+}$ as the main product.[16] This would also explain the subsequent reactions. The formation of an ylide-type heterocycle in $[\mathbf{4b}]^{2+}$ leads to a strong *trans* effect. The PMe_3 ligand in *trans* position to the ylide in $[\mathbf{4b}]^{2+}$ is more labile than a PMe_3 ligand *trans* to the phenyl isocyanide in $[\mathbf{4a}]^{2+}$. Consequently, complex $[\mathbf{4b}]^{2+}$ reacts by substitution of the *trans* phosphine ligand for an isocyanide ligand **2**, which then again undergoes Staudinger reaction and cyclization. The reaction sequence substitution of a phosphine, Staudinger reaction, and cyclization proceeds a total of four times. The four cyclized iminophosphorane ligands were hydrolyzed after a total reaction time of 96 h with H_2O/CF_3SO_3H giving the tetracarbene complex $[\mathbf{5}](CF_3SO_3)_2$ in 57% yield (Scheme 2).

Complex $[\mathbf{5}](CF_3SO_3)_2$ was characterized by NMR spectroscopy and X-ray diffraction. The ^1H NMR spectrum exhibits the expected low-field resonance[6] for the amine protons at $\delta = 12.77$ ppm. The protons of the symmetrically substituted aromatic ring give rise to two multiplets at $\delta =$ 7.56 ppm and $\delta = 7.38$ ppm. The signal for the carbene carbon atom was observed in the ^{13}C NMR spectrum at $\delta =$ 168.6 ppm with pronounced platinum–carbon coupling ($^1J_{Pt\text{-}C}$=920.7 Hz), which is indicative of carbene coordination to the platinum atom.

Single crystals of $[\mathbf{5}](CF_3SO_3)_2 \cdot 4\,THF$ for a diffraction study (Figure 1)[17] were obtained by recrystallization from THF. The structure analysis shows a platinum atom on a crystallographic inversion center with almost perfect square-planar coordination of four carbene ligands. The Pt–C bond lengths (2.025(3) Å and 2.020(3) Å) fall in the range reported for Pt^{II} complexes with acyclic NH,NH-stabilized carbene ligands (2.043(9) Å and 2.041(8) Å).[14c] They are significantly shorter than those reported for the Pt^{II} complex with a six-membered N-heterocyclic NH,NH-stabilized carbene ligand.[16] One of the two unique carbene ligands in the asymmetric unit is rotated about the Pt–C bond out of the PtC_4 plane and is oriented almost perpendicular to this plane (angle between the PtC_4 plane and plane C2/N21/C21C22/N22 85.30°). The second carbene ligand is almost coplanar with the PtC_4 plane (angle between PtC_4 plane and plane C1/N11/C11C12/N12 0.73°). A similar rotation of the carbene planes relative to the ML_4 plane (83.06° and 79.84°) has been described for Pd^{II} complexes with benzannulated N-heterocyclic carbenes.[10]

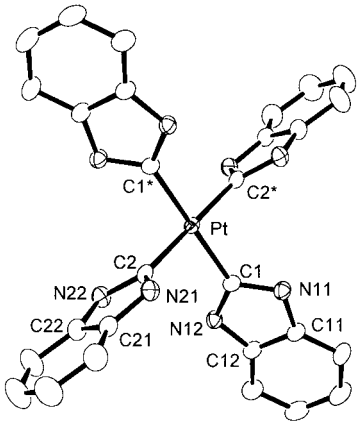

Figure 1. Molecular structure of the dication $[\mathbf{5}]^{2+}$ in crystalline $[\mathbf{5}](CF_3SO_3)_2 \cdot 4\,C_4H_8O$. The asymmetric unit contains one-half of the dication; the platinum atom resides on a crystallographic inversion center. Selected bond lengths [Å] and bond angles [°]: Pt–C1 2.025(3), Pt–C2 2.020(3), N11–C1 1.345(3), N11–C11 1.396(3), N12–C1 1.350(3), N12–C12 1.393(3); C1-Pt-C2 88.12(10), C1-Pt-C2* 91.88(10), C1-Pt-C1* 180.0, N11-C1-N12 106.0(2), N21-C2-N22 105.2(2).

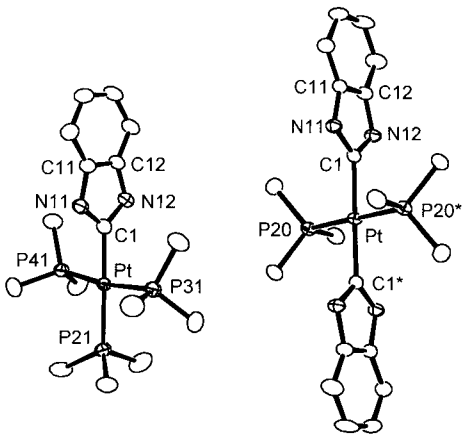

Figure 2. Molecular structures of the dications $[\mathbf{6}]^{2+}$ (left) in crystalline $[\mathbf{6}](CF_3SO_3)_2$ and $[\mathbf{7}]^{2+}$ (right) in crystalline $[\mathbf{7}](CF_3SO_3)_2 \cdot 2\,CH_3OH$. The platinum atom in dication $[\mathbf{7}]^{2+}$ resides on a crystallographic inversion center. Selected bond lengths [Å] and bond angles [°] for $[\mathbf{6}]^{2+}$: Pt–C1 2.018(4), Pt–P21 2.3309(11), Pt–P31 2.3260(10), Pt–P41 2.3262(10), N11–C1 1.346(6), N11–C11 1.395(5), N12–C1 1.344(5), N12–C12 1.397(5); C1-Pt-P21 178.79(12), C1-Pt-C31 86.11(10), C1-Pt-C41 85.89(10), P21-Pt-P31 93.46(4), P21-Pt-P41 94.58(4), P31-Pt-P41 171.63(4), N11-C1-N12 107.1(4). Selected bond lengths [Å] and bond angles [°] for $[\mathbf{7}]^{2+}$: Pt–C1 2.025(2), Pt–P20 2.3012(6), N11–C1 1.339(3), N11–C11 1.385(3), N12–C1 1.354(3), N12–C12 1.396(3); C1-Pt-C1* 180.0, P20-Pt-P20* 180.0, C1-Pt-P20 89.73(7), N11-C1-N12 106.1(2).

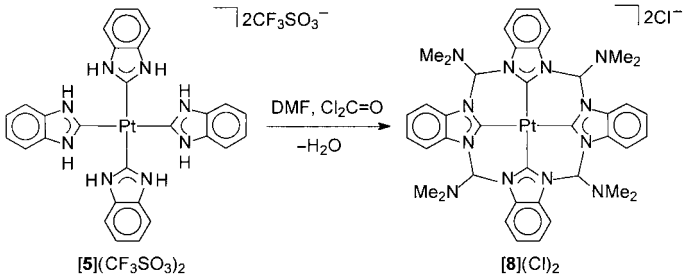
The complex dication $[\mathbf{5}]^{2+}$ is formed in a domino reaction in which each of the trimethylphosphane ligands in $[\mathbf{1}]^{2+}$ is replaced in a stepwise manner by an isocyanide ligand, which subsequently reacts with the liberated phosphine to form a cyclic iminophosphorane ligand, thereby generating the conditions for the next phosphine substitution. Because of the sensitivity of the iminophosphorane ligand towards acid, the reaction can be terminated after each cycle by addition of an acid, even before all four iminophosphorane ligands have been formed. This method was used for the preparation of the monocarbene complex $[\mathbf{6}]^{2+}$ and the *trans*-dicarbene complex $[\mathbf{7}]^{2+}$ (Scheme 2), which were isolated after hydrolysis of the reaction mixture with CF_3SO_3H/H_2O after reaction times of 12 h and 48 h, respectively. However, compounds $[\mathbf{6}](CF_3SO_3)_2$ and $[\mathbf{7}](CF_3SO_3)_2$ obtained this way were contaminated with large amounts of unreacted ligand **2** and were difficult to purify. To obtain X-ray quality crystals, we prepared complexes $[\mathbf{6}](CF_3SO_3)_2$ and $[\mathbf{7}](CF_3SO_3)_2$ again from $[\mathbf{1}](CF_3SO_3)_2$ and stoichiometric amounts of **2**.

The ^{13}C NMR spectrum of the monocarbene complex $[\mathbf{6}]^{2+}$ exhibits a resonance for the carbene carbon atom at $\delta = 167.2$ ppm, which is comparable to that observed for the carbene carbons in $[\mathbf{5}]^{2+}$. In contrast to the resonance in $[\mathbf{5}]^{2+}$ the carbene signal for $[\mathbf{6}]^{2+}$ shows $^2J_{P\text{-}C}$ coupling to the phosporous atoms in *cis* (13.4 Hz) and *trans* (115.6 Hz) positions. Two resonances for the phosphorous atoms at $\delta = -15.2$ ppm (d, Pt satellites, $^2J_{P\text{-}P} = 27.8$ Hz, $^1J_{Pt\text{-}P} = 2143.8$ Hz, 2P *cis* to carbene) and $\delta = -25.2$ (t, Pt satellites, $^2J_{P\text{-}P} = 27.8$ Hz, $^1J_{Pt\text{-}P} = 2143.4$ Hz, P *trans* to carbene) were observed in the $^{31}P\{^1H\}$ NMR spectrum. Similar observations were made for the *trans*-dicarbene complex $[\mathbf{7}]^{2+}$, where the resonance for the carbene carbon atoms appears at $\delta = 168.4$ ppm (t, Pt satellites, $^2J_{P\text{-}C} = 12.1$ Hz, $^1J_{Pt\text{-}C} = 854.5$ Hz) in the ^{13}C NMR spectrum.

Single crystals suitable for X-ray diffraction analyses of $[\mathbf{6}](CF_3SO_3)_2$ and $[\mathbf{7}](CF_3SO_3)_2 \cdot 2\,CH_3OH$ (Figure 2)[17] were obtained by recrystallization from methanol. The structure analysis of $[\mathbf{6}](CF_3SO_3)_2$ confirms that the formation of just one NH,NH-stabilized carbene ligand, i.e. the cyclic iminophosphorane precursor, is completed before a second phosphine ligand is substituted. The molecular structure of $[\mathbf{7}](CF_3SO_3)_2 \cdot 2\,CH_3OH$ shows that the second isocyanide ligand enters and cyclizes in *trans* position to the first carbene ligand.

The bonding parameters in the dications $[\mathbf{6}]^{2+}$ and $[\mathbf{7}]^{2+}$ are only marginally different from the equivalent parameters in $[\mathbf{5}]^{2+}$. Particularly the Pt–C bond lengths are independent of the type of ligand in *trans* position. Both dications are coordinated in a slightly distorted square-planar geometry; the distortions observed in $[\mathbf{6}]^{2+}$ are larger than those in $[\mathbf{7}]^{2+}$. The carbene planes in both complex cations are oriented almost perpendicular to the PtL_4 plane (angle between planes 87.35° for $[\mathbf{6}]^{2+}$ and 75.92° for $[\mathbf{7}]^{2+}$).

Attempts to connect the four NH,NH-stabilized carbene ligands in $[\mathbf{5}]^{2+}$ by deprotonation and bridging alkylation with dibromomethane or 1,2-dibromoethane to give a cyclic tetracarbene ligand were initially unsuccessful. The removal of eight NH protons from $[\mathbf{5}]^{2+}$ using NaH generates a sixfold negatively charged anion that is insoluble and unreactive in all common solvents. Highly charged intermediates are avoided in the reaction of $[\mathbf{5}]^{2+}$ with DMF, which also serves also as the solvent for the reaction. Diphosgene is also added to trap the water formed. By this method four $Me_2N\text{-}CH$ bridges are introduced between the carbene ligands, and complex $[\mathbf{8}](Cl)_2$ is formed in over 60% yield. Complex cation $[\mathbf{8}]^{2+}$ contains a cyclic tetracarbene ligand with a crown ether topology (Scheme 3).



Scheme 3. Template synthesis of $[\mathbf{8}]^{2+}$ from $[\mathbf{5}]^{2+}$.

The ^{13}C NMR spectrum of $[\mathbf{8}](Cl)_2$ (in $[D_6]$DMSO) differs only slightly from that of $[\mathbf{5}](CF_3SO_3)_2$. The bridging alkylation of the N1 and N3 positions at the carbene ligands has little effect on the chemical shift of the atoms within the heterocycle.[6] Two new resonances were observed for the carbon atoms of the bridging CH-N$(CH_3)_2$ groups.

The X-ray diffraction study (Figure 3)[17] shows complex $[\mathbf{8}]^{2+}$ to contain a platinum atom surrounded in an almost perfect square-planar fashion by four carbene carbon atoms. The Pt–C bond lengths are about 0.05 Å shorter than those in dication $[\mathbf{5}]^{2+}$. The bridges between the carbene ligands force in $[\mathbf{8}]^{2+}$, in contrast to $[\mathbf{5}]^{2+}$, the carbene planes to be almost coplanar with the PtC_4 plane (maximum angle between carbene planes and PtC_4 plane 15.6°).

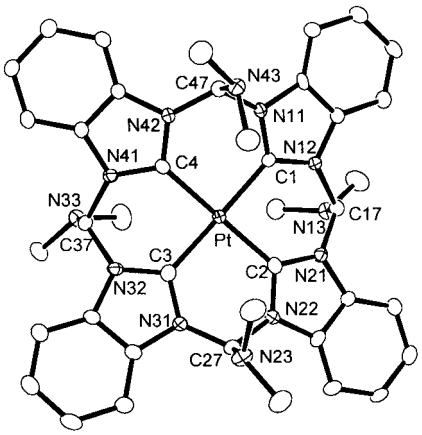


Figure 3. Molecular structure of the dication $[\mathbf{8}]^{2+}$ in crystalline $[\mathbf{8}](Cl)_2 \cdot 4\,CH_3OH$. Selected bond lengths [Å] and bond angles [°]: Pt–C1 1.980(4), Pt–C2 1.969(4), Pt–C3 1.973(4), Pt–C4 1.978(4); C1-Pt-C2 89.89(14), C1-Pt-C3 179.03(15), C1-Pt-C4 90.19(14), C2-Pt-C3 90.54(15), C2-Pt-C4 178.77(15), C3-Pt-C4 89.40(14).

We have demonstrated that the homoleptic Pt^{II} tetracarbene complex $[\mathbf{5}]^{2+}$ can be prepared from the tetrakis(trimethylphosphane)platinum(II) dication $[\mathbf{1}]^{2+}$ and 2-azidophenyl isocyanide (**2**) in a template-controlled reaction cascade. Mono- and dicarbene intermediates in this multistep reaction were also isolated. The connection of the four NH,NH-stabilized carbene ligands in $[\mathbf{5}]^{2+}$ using the sp^3 carbon atom of a CH-NMe_2 group as a bridge to yield a coordinated cyclic tetracarbene ligand was achieved by reaction of $[\mathbf{5}]^{2+}$ with DMF in the presence of diphosgene. Attempts to introduce an sp^2-hybridized bridging atom between the carbene ligands and to remove the platinum atom from the macrocycle are currently underway.

Borylene Complexes

Terminal Borylene Complexes Stabilized by a Transition-Metal Base**

Holger Braunschweig, Daniela Rais, and Katharina Uttinger*

Transition-metal carbonyl complexes constitute one of the most prominent classes of organometallic compounds, displaying a wealth of structural complexity and chemical reactivity. Carbonyl complexes are found widely in organometallic chemistry[1a] and homogeneous catalysis,[1b] for reasons that relate to the experimental accessibility of CO and its efficient, synergic binding to transition metals. In the quest for molecules that display similar properties borylenes, B–R, have been identified as excellent candidates.[2] However, the instability and consequent high reactivity of borylene as a free molecule[3] mean that transition-metal borylene complexes are challenging targets for synthetic chemists.[4]

A variety of bonding modes is available to the carbonyl ligand, ranging from terminal to different types of bridging coordination, including semi-bridging and triply bridging (μ_3).[1] Of these modes, only the terminal and symmetrical bridging modes had thus far been realized for the borylene group. Bridged borylenes, for example, $[\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2(\mu\text{-}BNMe_2)]$[5a] (**1**) or $[\{(\eta^5\text{-}C_5H_4Me)Fe(CO)\}_2(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}]$[5d] (**2**), represent the most numerous and well-studied class of borylene compounds (Scheme 1).[5] Appropriate synthetic routes to their terminal borylene counterparts were developed more recently.[6] Investigation of the chemical reactivity of compounds such as $[(OC)_5M{=}B{=}N(SiMe_3)_2]$ (M = Cr, W),[6a] revealed their remarkable stability. To date, for reactivity to be observed, photochemical activation was required, which leads to an unprecedented intermetallic borylene transfer.[6d,f]

Herein we present the first instance of thermal reactivity of the terminal borylene complexes $[(OC)_5M{=}B{=}N(SiMe_3)_2]$

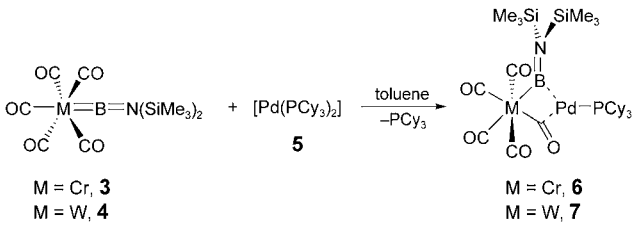
(M = Cr **3**, M = W **4**; Scheme 2).[6a] These species, upon reaction with $[Pd(PCy_3)_2]$ (**5**),[7] generate the heterodinuclear systems $[(OC)_4M(\mu\text{-}CO)\{\mu\text{-}BN(SiMe_3)_2\}Pd(PCy_3)]$ (M = Cr **6**, M = W **7**), featuring an unprecedented semi-bridging borylene ligand.



Scheme 2. Synthesis of bridged borylene complexes **6** and **7**.

All transition-metal borylenes feature carbon monoxide as an ancillary ligand.[4–6] In an attempt to expand the scope of the photochemically promoted borylene transfer as a synthetic route to electronically more diverse systems, we focused our attention on the transfer of the borylene unit to carbonyl-free complexes of the late transition metals. We chose $[Pd(PCy_3)_2]$ (**5**) because of the electron-rich but highly unsaturated nature of the palladium center, which suggested potentially high reactivity of this species in borylene transfer reactions. Indeed, when **5** was added to an equimolar amount of **3** or **4** in C_6D_6, multinuclear NMR spectroscopy revealed immediate consumption of the starting materials, prior to irradiation, and formation of new compounds, **6** or **7**, respectively, with concomitant liberation of tricyclohexylphosphine (Scheme 2).

The $^{11}B\{^1H\}$ NMR spectrum of the reaction mixture featured a broad downfield-shifted resonance signal at $\delta =$ 100 ppm for **6** and $\delta = 97$ ppm for **7** [cf. for **3**, $\delta = 92$ ppm; for **4**, $\delta = 87$ ppm],[6a] suggesting formation of bridged borylene species. A sharp singlet at $\delta = 9.8$ ppm in the $^{31}P\{^1H\}$ NMR spectra indicated the presence of noncoordinated tricyclohexylphosphine. Accordingly, we inferred that the singlets at $\delta = 34.2$ ppm (**6**) and at $\delta = 41.9$ ppm (**7**), which are the only other signals in the $^{31}P\{^1H\}$ NMR spectra, arise from a palladium complex with only one PCy_3 ligand.

The atom connectivity within the compounds was conclusively determined by performing a single-crystal X-ray diffraction study of **6** (Figure 1).[8] Pale yellow crystals were obtained upon cooling a saturated solution of the complex in toluene to −30 °C.

Compound **6** is a semi-bridging borylene complex, which also contains a semi-bridging carbonyl ligand linking the $\{(OC)_4Cr\}$ and $\{Pd(PCy_3)\}$ fragments. The Cr1–B1 bond (2.0842(18) Å) is considerably longer than that in the terminal borylene precursor **3** (1.996(6) Å)[6d] and consistent with the increased coordination number at boron, while the Pd1–B1 bond (2.0425(18) Å) is in the range (2.006(9) to 2.077(6) Å), of those reported for compounds with bonds between palladium and three-coordinate boron centers.[9]

The most intriguing structural feature of **6** relates to the almost orthogonal orientation of the bis(trimethylsilyl)amino substituent at boron with respect to the plane containing the two transition metal centers and boron (Si1-N1-B1-Pd1 91.12(15)°). Such a disposition differs significantly from that observed in other bridged borylene complexes, such as **1**[5a] and **2**[5d], for which the structural parameters are in agreement with the presence of a formally sp^2-hybridized boron atom (Scheme 1). Accordingly, assuming a formally sp^2-hybridized boron atom in **6**, the orthogonal disposition of the amino substituent would preclude any effective N–B π donation, and should result in considerable elongation of the N–B bond. However, despite the increased coordination number at boron, the B1–N1 bond (1.377(2) Å) is negligibly longer than that in terminal borylene **3** (1.353(6) Å),[6d] thus indicating a significant double bond character of the B–N linkage. These structural features suggest that the bonding mode of the borylene ligand in **6** differs significantly from that adopted in other complexes.

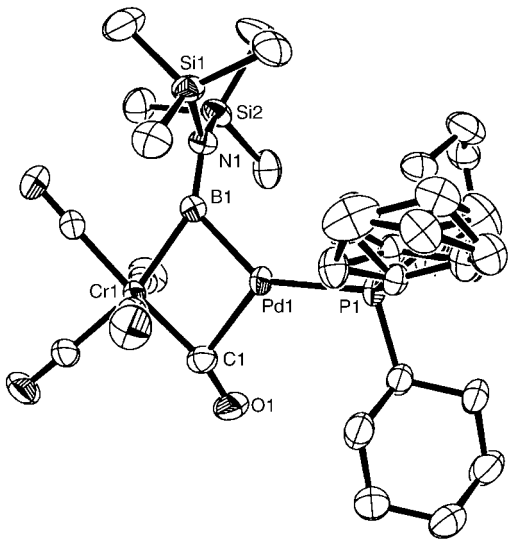


Figure 1. Molecular structure of **6**. Bond lengths [Å] and angles [°]: Pd1-B1 2.0425(18), Cr1-B1 2.0842(18), B1-N1 1.377(2), Pd1-P1 2.3470(10); N1-B1-Cr1 152.33(13), N1-B1-Pd1 128.74(12), Cr1-C1-O1 165.49(16), Pd1-C1-O1 115.20(14).

The bonding interactions that characterize **6** can be rationalized on the basis of the theoretically predicted analogy between borylene and carbon monoxide.[10] Thus, the electronically saturated chromium borylene **3** behaves as a π-acceptor ligand, while the Lewis basic palladium fragment $\{Pd(PCy_3)\}$ donates electron density into the π* orbitals of CO and the empty π orbitals of the borylene. Partial rehybridization of the carbon and boron atoms is necessary, this results in a more efficient π-acceptor capability and in CO and $B{=}N(SiMe_3)_2$ forming a pair of non-compensating semi-bridging ligands. Relevant angles for the CO moiety (Pd1-Cr1-C1(O1) 54.2°; Cr1-C1-O1 165.5°) are in accord with the classification scheme for semi-bridging carbonyl ligands developed by Crabtree.[11] The analogous values for the borylene ligand (Pd1-Cr1-B1 49.8°, Cr1-B1-N1 152.3°) have no literature precedent but are clearly intermediate between those typical of a symmetrically bridging and a terminal arrangement.

Furthermore, by virtue of the aforementioned Pd–B dative interaction, **6** is the only example of a terminal

borylene complex which is stabilized by a transition-metal center acting as a Lewis base. Only a handful of related compounds, featuring amines[6b,e] or a phosphine[5e] as stabilizing bases, are reported, none of which, however, was obtained by addition of the base to a pre-formed terminal borylene complex. Such reactivity suggests that residual Lewis acidity is unexpectedly retained by the boron atom in **3** and **4** despite the presence of the amino substituent, and testifies for the thermodynamic and kinetic stability of the Cr–B linkage in the complexes. This situation differs markedly from that, for instance, of the cationic iron species $[(\eta^5\text{-}C_5Me_5)(OC)_2Fe{=}BMes][BAr^f{}_4]$ (Mes = 2,4,6-$C_6H_2Me_3$; Ar^f = 3,5-$C_6H_3(CF_3)_2$), the chemistry of which is dominated by borylene displacement.[12]

In conclusion, we have described the first instance of thermal reactivity of a terminal borylene complex $[(OC)_5M{=}B{=}N(SiMe_3)_2]$. Upon reaction with the electron-rich $[Pd(PCy_3)_2]$ system, heterodinuclear complexes are formed in which the borylene ligand adopts a semi-bridging bonding mode, providing further empirical confirmation of its close relationship to CO.

Experimental Section

All manipulations were conducted either under an atmosphere of dry argon or in vacuo using standard Schlenk line or glove-box techniques.

6: A pale yellow solution of **5** (0.276 g, 0.413 mmol) in toluene (4 mL) was added to solid **3** (0.150 g, 0.413 mmol). Yellow crystals formed from the bright yellow solution at room temperature. The mixture was then stored at −35 °C yielding yellow crystals of **6** (0.249 g, 81 %). ^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS): δ = 1.94–1.13 (m, 33 H, Cy), 0.42 ppm (s, 18 H, $SiMe_3$); $^{13}C\{^1H\}$ NMR (101 MHz, C_6D_6, 25 °C): δ = 223.5 (d, $J_{C\text{-}P}$ = 2 Hz, CO), 223.0 (d, $J_{C\text{-}P}$ = 3 Hz, CO), 33.7 (d, $^1J_{C\text{-}P}$ = 14 Hz, C_1, Cy), 31.4 (d, $^3J_{C\text{-}P}$ = 6 Hz, $C_{3,5}$, Cy), 27.7 (d, $^2J_{C\text{-}P}$ = 11 Hz, $C_{2,6}$, Cy), 26.4 (s, C_4, Cy), 3.7 ppm (s, $SiMe_3$); $^{31}P\{^1H\}$ NMR (162 MHz, C_6D_6, 25 °C): δ = 34.2 ppm (s); $^{11}B\{^1H\}$ (64 MHz, C_6D_6, 25 °C): δ = 100 ppm (s, $\omega_{1/2}$ = 752 Hz). IR (toluene): $\tilde{\nu}$ = 2030, 1957, 1932, 1858 cm^{-1}, (C=O). Elemental Analysis (%) calcd for $C_{29}H_{51}NBCrO_5PPdSi_2$: C 46.44, H 6.85, N 1.87; found: C 46.43, H 6.80, N 1.86.

7: A pale yellow solution of **5** (0.135 g, 0.202 mmol) in toluene (4 mL) was added to solid **4** (0.100 g, 0.202 mmol). After 24 h the volume of the red solution was reduced to approximately half and the mixture was cooled to −80 °C. An orange microcrystalline solid of **7** deposited after several days. This solid was isolated and dried in vacuo (0.120 g, 67 %). ^{1}H NMR (300 MHz, C_6D_6, 25 °C, TMS): δ = 1.96–1.13 (m, 33 H, Cy), 0.42 ppm (s, 18 H, $SiMe_3$); $^{13}C\{^1H\}$ NMR (75 MHz, C_6D_6, 25 °C): δ = 203.1 (d, $^1J_{C\text{-}W}$ = 121 Hz, $J_{C\text{-}P}$ = 2 Hz, CO), 200.5 (d, $J_{C\text{-}P}$ = 3 Hz, CO), 34.0 (d, $^1J_{C\text{-}P}$ = 12 Hz, C_1, Cy), 31.4 (d, $^3J_{C\text{-}P}$ = 5 Hz, $C_{3,5}$, Cy), 27.8 (d, $^2J_{C\text{-}P}$ = 11 Hz, $C_{2,6}$, Cy), 26.4 (s, $^4J_{C\text{-}P}$ = 1 Hz, C_4, Cy), 3.9 ppm (s, $SiMe_3$); $^{31}P\{^1H\}$ NMR (121 MHz, C_6D_6, 25 °C): δ = 41.9 ppm (s); $^{11}B\{^1H\}$ (96 MHz, C_6D_6, 25 °C): δ = 97 ppm (s, $\omega_{1/2}$ = 884 Hz). IR (toluene): $\tilde{\nu}$ = 2043, 1955, 1932, 1873 cm^{-1}, (C=O). Elemental Analyses: (%) calcd for $C_{29}H_{51}NBO_5PPdSi_2W$: C 39.49, H 5.83, N 1.59; found: C 39.48, H 5.75, N 1.65.

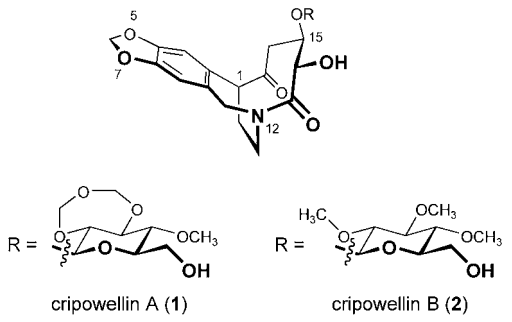
Natural Product Synthesis

Asymmetric Synthesis of the 1-*epi* Aglycon of the Cripowellins A and B**

Dieter Enders, Achim Lenzen, and Gerhard Raabe*

In 1997 researchers at Bayer AG reported on two new *Amaryllidaceae* alkaloids,[1] cripowellins A (**1**) and B (**2**), which had been isolated from the bulbs and roots of *Crinum powellii*, a popular ornamental plant in Europe.[2,3] The two compounds differ only in their glycosidic parts. The assumption that both of these sugar moieties are derived biogenically from β-D-glucose accounts for the depicted absolute stereochemistry. Their common aglycon comprises a [5.3.2]bicyclic core, a structural motif unique among the *Amaryllidaceae* alkaloids. One of both bridgehead atoms is a trisubstituted amide N atom and therefore not a stereogenic center.



In addition to their unusual structure, which contains five-, six-, seven-, nine-, and ten-membered rings, both alkaloids exhibit extraordinary biological properties. Their insecticidal activity compares well to that of natural pyrethroids—not only with regard to their strength but also their broad activity. It is important to note that mainly the aglycon seems to be responsible for their biological activity because it alone shows the same activity as the two glycosides.[2] However, practically nothing is known about the mode of action.[4] In order to clarify that and to determine structure–activity relationships, the synthesis of stereoisomers and derivatives of the cripowellins will be necessary.

Because of their unique structures and their high biological activity, Bayer AG has patented both cripowellins and some of their derivatives.[2] Their exceptional position was also recognized by experts at the Irseer conference on natural products in 1997, where cripowellin A (**1**) was voted the second most interesting new natural product.[5] Despite all this attention, a synthesis of the cripowellins, their aglycon, or one of their stereoisomers has not been described so far. This seems to be highly desirable in the light of the small quantities obtainable from natural sources.[3]

We now report on the first asymmetric synthesis of the skeleton of the cripowellins A and B in the form of their 1-*epi* aglycon **15**. Our remarkably short synthesis started with the asymmetric dihydroxylation[6] of the benzoylated allyl alcohol **3**[7,8] to give the diol **4** (Scheme 1); the 72% yield of this reaction is quite efficient when one considers the obvious problem of regioselectivity. In addition, the asymmetric induction was virtually complete (≥98% *ee*).[9] Acetonide formation and saponification of the ester functionality yielded the primary alcohol **5** in nearly quantitative yield. This alcohol was oxidized to the corresponding acid **6** in two steps, and **6** was subsequently coupled with the amine **10** (available from the reductive amination of bromopiperonal (**9**) with 3-butene-1-amine) to give the amide **7**.

According to our synthetic route a ring-closing metathesis (RCM)[10] of this amide to give the azacyclononene lactam derivative **8** was proposed to follow. The structure of the RCM precursor **7** had to be designed carefully taking into account the "problem of medium sized rings". It had to be restricted conformationally in a way which would favour the metathesis. Both the dioxolane ring[11] and the tertiary amide[12] were assumed to operate synergistically thus favoring the formation of the nine-membered ring.[13] Our assumptions were confirmed by the successful RCM. By employing Grubbs' second-generation catalyst and by performing the reaction under high dilution (1 mM), we were able to obtain **8** in a very good yield of 77%.

After that the [5.3.2]bicyclic core was supposed to be built up by means of a Heck reaction of the piperonyl moiety to the double bond.[14] After extensive studies, we finally succeeded in the selective synthesis of the two Heck products **11** and **12** (Scheme 2). Under neutral reaction conditions, we observed exclusively the formation of product **11**, which has a disubstituted *Z*-configurated double bond. Under cationic conditions, on the other hand, the reaction yielded selectively the trisubstituted olefin **12**.[15] The formation of this anti-Bredt alkene is worth mentioning because the additional ring strain in this bicyclic compound cannot be compensated by stability from the conjugation with the aromatic moiety (both are nearly perpendicular to each other). The double bond of this anti-Bredt alkene is not configurationally stable under the

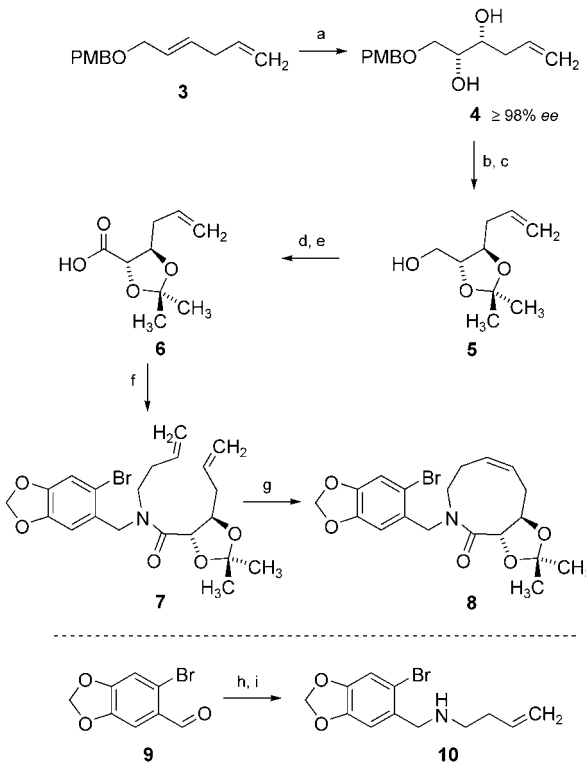
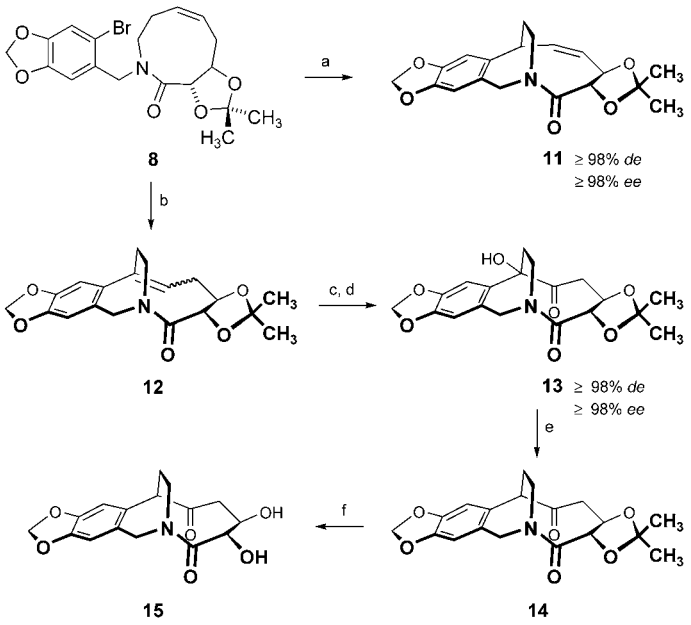


Scheme 1. Synthesis of the nine-membered-ring lactam intermediate **8**. a) AD-mix β, $K_2OsO_4 \cdot 2H_2O$ (0.006 equiv), $MeSO_2NH_2$ (1.0 equiv), *t*BuOH/H_2O (1:1), 0 °C, 2.25 h, 72%; b) 2,2-DMP, PTSA (0.05 equiv), 25 °C, 1 h; c) K_2CO_3 (1.5 equiv), MeOH, 25 °C, 2 h, 97% (two steps); d) CO_2Cl_2 (1.1 equiv), DMSO (2.3 equiv), Et_3N (5.0 equiv), CH_2Cl_2, −78→25 °C; e) $NaClO_2$ (80%, 2.5 equiv), $NaH_2PO_4 \cdot 2H_2O$ (2.0 equiv), 2-methyl-2-butene (18 equiv), acetone/H_2O (1:1), 0→25 °C, 0.5 h; f) FEP (1.2 equiv), amine **10** (1.1 equiv), Et*i*Pr_2N (3.2 equiv), CH_2Cl_2, 0→25 °C, 12 h, 66% (three steps); g) Grubbs' 2nd generation catalyst (0.1 equiv, addition in portions), CH_2Cl_2, reflux, 2.5 h, then DMSO (5.0 equiv), 25 °C, 12 h, 77%; h) 3-butene-1-amine (1.2 equiv), MS 4 Å, CH_2Cl_2, 25 °C, 12 h; i) $NaBH_4$ (1.0 equiv), MeOH, 25 °C, 2 h, 94% (two steps). 2,2-DMP = 2,2-dimethoxypropane, DMSO = dimethyl sulfoxide, FEP = 2-fluoro-1-ethyl pyridinium tetrafluoroborate, MS = molecular sieves, PMB = *p*-methoxybenzoyl, PTSA = *p*-toluenesulfonic acid.



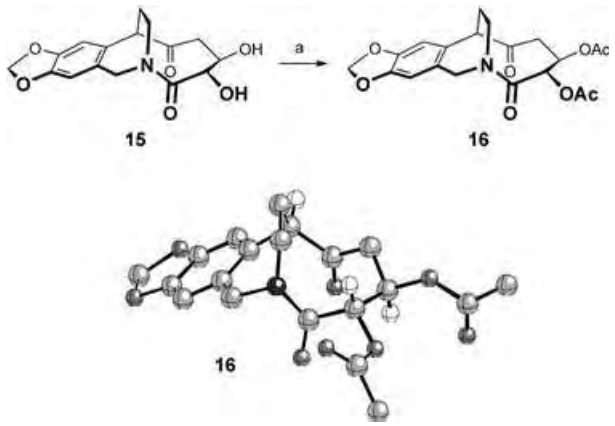
Scheme 2. Completion of the synthesis of the 1-*epi* aglycon **15** of the cripowellins A (**1**) and B (**2**). a) $Pd(OAc)_2$ (0.2 equiv), PPh_3 (0.6 equiv), Et_3N (3.5 equiv), DMF, 110 °C, 6 h, 59%; b) $Pd(OAc)_2$ (0.15 equiv), dppp (0.2 equiv), Ag_2CO_3 (3.0 equiv), toluene, 124 °C, 4 h, 59%; c) $K_2OsO_4 \cdot 2H_2O$ (0.05 equiv), NMO (97%, 3.1 equiv), acetone/H_2O (10:7), 25 °C, 3 h, then Na_2SO_3 (2.3 equiv); d) CO_2Cl_2 (2.5 equiv), DMSO (5.3 equiv), Et_3N (10.0 equiv), CH_2Cl_2, −78→25 °C, 55% (two steps); e) SmI_2 (excess, ca. 7.2 equiv), *t*BuOH (3.0 equiv), THF, 25 °C, 12 h, 99%; f) Dowex-50, H_2O, 25 °C, 4.25 h, 56%. DMF = dimethyl formamide, dppp = 1,3-bis(diphenylphosphanyl)propane, NMO = *N*-methylmorpholine *N*-oxide, THF = tetrahydrofuran.

reaction conditions employed since the *E*/*Z* ratio was observed to be time dependent.[16] To our surprise, both Heck reactions were completely diastereoselective with regard to the orientation of the ethylene bridge; we were able to isolate only compounds **11** and **12**, in which this bridge is on the upper face of the molecule.[17] To the best of our knowledge, this is the first example of a (highly diastereoselective) intramolecular Heck reaction of a highly functionalized (aza)cyclonene derivative.[18]

Olefin **11** proved to be extremely difficult to functionalize. We therefore decided to continue with the *E*/*Z* mixture of olefins **12**, which seemed to be more reasonable to us anyway because a differentiation between the olefinic C atoms was assumed to be easier (singly vs. doubly substituted). Both olefins **12** were first transformed into the α-hydroxy ketone **13** in a two-step sequence consisting of dihydroxylation and Swern oxidation. Deoxygenation of **13** with SmI_2 in the presence of *t*BuOH proceeded smoothly to give **14**.[19] The high yield of 99% in this reaction was astonishing because α-hydroxy ketones are normally not very good substrates for SmI_2-induced defunctionalizations.[20] Likewise, the stability of the acetonide-protected 1,2-diol unit is worth mentioning. In the case of carboxylates, the reductive cleavage of the α-C–O bond is commonly observed.[21] The cleavage of the acetonide protecting group in the presence of Dowex-50 finally yielded the 1-*epi* aglycon **15** of the cripowellins A (**1**) and B (**2**).

At this point we were very much interested in the spatial structure of this compound—especially with regard to the known structure of the bisacetate of cripowellin A and the biological activity of the cripowellins.[2,3] In the search for derivatives of the 1-*epi* aglycon **15** suitable for an X-ray structure analysis, we were finally rewarded by its bisacetate, **16** (Scheme 3).[22] A comparison of its crystal structure with the one obtained from the bisacetate of cripowellin A clearly shows the same spatial orientation of the keto and the lactam carbonyl groups: both are *syn* to each other and in spatial proximity. This substructure had been identified as the probable pharmacophor by researchers at Bayer AG after extensive investigations on structure–activity relationships.[4] Therefore it seems reasonable to expect the 1-*epi* aglycon **15** to be biologically active, too. Yet, this still needs to be proven by biological tests.

In summary, we report the first access to this unique [5.3.2]bicyclic skeleton of the cripowellins A (**1**) and B (**2**). Key steps in our synthesis are a highly enantioselective



Scheme 3. Synthesis and crystal structure of the bisacetylated 1-*epi* aglycon **16**. a) $Sc(OTf)_3$ (0.3 equiv), Ac_2O/CH_3CN (1:1), 25 °C, 2 h, 65 %. Tf = trifluoromethanesulfonyl.[22]

Sharpless dihydroxylation, a properly designed ring-closing metathesis, and a highly diastereoselective intramolecular Heck reaction. Considering the complexity of the target molecule, this synthesis is very short (13 steps in the longest linear sequence, 15 steps altogether; 5.6 % overall yield). In addition, the diastereo- and enantioselectivity are virtually complete ($\geq$ 98 % *de*, $\geq$ 98 % *ee*). The crystal structure of the bisacetate of the 1-*epi* aglycon **16** reveals the same spatial orientation of the ketone and the lactam carbonyl groups as in the cripowellins. Therefore one may be curious whether the 1-*epi* derivatives exhibit the same biological activity as the cripowellins and their aglycon. The 1-*epi* aglycon **15** might at least help to further clarify their hitherto unknown mode of action.[23]

Theoretical Chemistry

Exploring Polymorphism: The Case of Benzene**

Paolo Raiteri, Roman Martoňák, and Michele Parrinello*

The prediction of crystal structures from the molecular structure is of great importance for the chemical and pharmaceutical industries as well as for fundamental science, and it represents a great challenge for theoretical chemists and physicists.[1–7] An even harder task is the computational exploration of all possible polymorphs of a given compound. Crystalline benzene is a case in point: its phase diagram has been investigated for almost 40 years, but its structures have been only partially elucidated.

A small and simple molecule, benzene, has provided a challenging testing ground for many theorists in spite of its limited significance in chemical practice. Only three of the experimentally observed phases have been correctly reproduced by computer simulations.[8–13] Here, by using a novel theoretical algorithm[14] we describe that at finite temperature there are at least seven possible stable phases. Our results help to answer a number of pending questions and identify six of the experimental structures. For the seventh, with limited experimental data, we are able to propose a complete structure.

A tentative phase diagram showing all the benzene phases identified in the literature is shown in Figure 1. At room temperature X-ray and Raman scattering[15,16] have determined the existence of five phases, I, II, III, III′, and IV, but a good agreement between theory and experiment has been obtained only for the first three,[8–13] while phases III′ and IV are more controversial. It has in fact been argued that benzene III′ may be only a distortion of benzene III,[15] while benzene IV has been hypothesized as being a polymer-like compound, where new chemical bonds have been formed due to the very high pressure.[16] However, more recent far-infrared spectroscopic data support the existence of both phases as true benzene crystals.[17] Less detailed evidence is available for the remaining phases I′ and V. The former has been identified only on the basis of a discontinuity in the lattice constants as a function of temperature, and it has been suggested that the transformation benzene I→benzene I′ is a second order transition.[15] Finally, in the high-temperature region only Raman data can be called on to support of the existence of another phase, here called benzene V.[16]

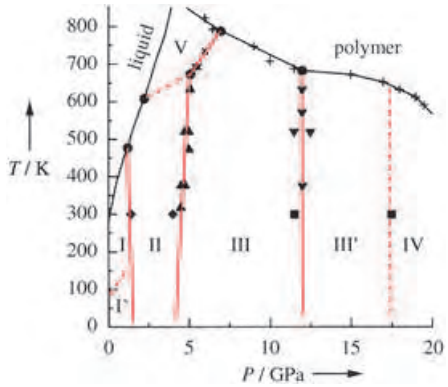

Figure 1. Proposed phase diagram of solid benzene. For phases I, II, III, III′, and IV we follow the nomenclature of ref. [15]. As a consequence phase IV of ref. [16] becomes here phase V. The liquid–solid boundary and all the points reported in the picture are taken from refs. [15,16]. Hypothetical phase boundaries are represented with dashed lines.

The practical relevance of crystal structure prediction has stimulated the development of many computational protocols,[1–7] among which the most common approach is to generate large numbers of structures and select the one with the lowest enthalpy by means of different minimization

techniques. Entropy is usually neglected or evaluated in the harmonic lattice approximation. Here we take a different approach and apply a new general method, called metadynamics,[14] where the search for stable polymorphs is guided by the Gibbs free energy, taking fully into account the role of temperature and pressure. In its application to solid–solid phase transitions, metadynamics[18] shares the basic idea of the Parrinello–Rahman technique,[19,20] where the simulation box edges act as an order parameter to favor a structural transition. The technique allows a fast and accurate exploration of the Gibbs free energy surface as a function of this order parameter. Early applications of this method to inorganic crystals have been very encouraging.[18,21]

The problem of determining all the possible polymorphs of a given compound, consisting of a search for stable or metastable crystal structures at a given temperature T and pressure P, can be formulated as a search for minima of the Gibbs free energy $G(\mathbf{h})$ in the space of a suitable order parameter, $\mathbf{h}$. In the simulation of crystals, periodic boundary conditions are commonly used, and if no defects are present, the simulation box defined by its edges a, b, and c has to be commensurate with the crystalline unit cell. Therefore, the simulation box vectors, arranged in a 3×3 matrix, $\mathbf{h}=(a,b,c)$, can be used as an order parameter that discriminates between different crystal structures in the same way as in the Parrinello–Rahman technique.[19,20] It is convenient to take the box matrix $\mathbf{h}$ as upper triangular, which effectively freezes the rotations of the box and reduces the dimensionality of the order parameter to 6. This can be easily achieved by a rotation of the simulation cell so that the a vector is aligned with the x Cartesian axis and the b vector lies in the xy Cartesian plane.

Metadynamics explores the Gibbs free energy $G(\mathbf{h})$ in the subspace of the order parameter $\mathbf{h}$ in a stepwise fashion by means of a steepest-descent-like dynamics [Eq. (1)], where δh

$$\mathbf{h}^{t+1}=\mathbf{h}^{t}+\delta h\left(\frac{\phi^{t}}{|\phi^{t}|}\right) \tag{1}$$

is the maximum allowed variation of the box dimensions. The driving force, $\phi^{t}=-\partial G^{t}/\partial\mathbf{h}$, is a gradient of the Gibbs free energy plus a time-dependent potential that discourages the system from going into previously visited configurations. This potential is obtained as a sum of Gaussians placed on all previously visited points in the space of the order parameter $\mathbf{h}$ [Eq. (2)].

$$G^{t}(\mathbf{h},t)=G(\mathbf{h})+\sum_{t'<t} W\exp\left[\frac{-(\mathbf{h}-\mathbf{h}^{t'})^{2}}{2\,\delta h^{2}}\right] \tag{2}$$

The parameters W and δh determine the resolution in energy and order parameter and can be chosen following the empirical guidelines provided in ref. [18]. The derivative of the Gibbs free energy can be calculated using Equation (3),

$$\frac{\partial G}{\partial h_{ij}}=-V[\mathbf{h}^{-1}(\mathbf{p}-P]_{ji} \tag{3}$$

where P is the external pressure and $\mathbf{p}$ is the averaged pressure tensor. The latter can easily be evaluated from molecular dynamics runs at constant $\mathbf{h}$ and temperature. Entropy is thus automatically accounted for through its volume–pressure dependence. As the dynamics proceeds, the added Gaussians modify the free energy landscape by filling the potential energy well relative to the initial crystal structure so that eventually the system must escape to a new basin of attraction, corresponding to a new crystal structure.

Each metadynamics step consists of: a) the equilibration of the system at the desired $\mathbf{h}$ and temperature, b) the calculation of the average pressure tensor $\mathbf{p}$, and c) the evolution of $\mathbf{h}$ according to Equation (1) followed by the rescaling of the atomic coordinates. Each of steps a and b consists of a 1-ps molecular dynamics run at constant temperature (300 K) and $\mathbf{h}$. The external pressure, P, is fixed at 2 GPa.

Many force fields have been developed for studying organic crystals (see, for example, refs. [22–24]). Because it is known that force fields optimized on static crystal structures may perform poorly in dynamic calculations, here we adopted the GROMOS96 force field.[25] The molecules are fully flexible and hydrogen atoms are explicitly considered. The partial atomic charges were obtained by the standard RESP[26] method and are $-0.11\,e$ for the carbon atoms and $0.11\,e$ for the hydrogen atoms. The long-range electrostatic interactions are computed with the Particle Mesh Ewald (PME) summation. The simulation supercell is replicated in space by means of the periodic boundary conditions. All the molecules in the simulation box are free to move and to find a suitable periodic arrangement without any restriction on the number of molecules in the unit cell. For the time-dependent potential we chose the Gaussian width, δh, between 2 and 3 Å and the Gaussian height, W, between 500 and 2500 kJ mol^{-1}, while the $W/\delta h^{2}$ ratio fulfills the guidelines given in ref. [18].

This method offers a number of competitive advantages over standard approaches to crystal structure prediction. At finite temperature the Gibbs free energy is much smoother than the potential energy surface at $T=0$. This eliminates most of the shallow minima, leaving only the relevant ones. Another consequence of explicitly considering a finite temperature is that we can discover phases that are stabilized by entropy. In our application to benzene, only a limited number of thermodynamically stable phases are found, some of which (benzene I and V) are unstable at $T=0$ and $P=0$. A further advantage of this method is that it can be implemented on modest computer equipment like standard PCs. In our case, a whole metadynamics run took a couple of hours on a 2-GHz Pentium IV workstation. Clearly, however, the cost of the method depends mainly on the intermolecular potential used for the MD simulations.

We tackled the problem of determining all the polymorphs of benzene assuming only the knowledge of its molecular structure. As an initial step in our procedure, we generated a periodic lattice with two molecules in the unit cell, where lattice vectors and molecular orientations were taken at random. Then we performed a pure steepest descent relaxation of the box and of the atomic coordinates using a simulation cell that contained no more than eight molecules. Once the system relaxed to an energy basin, the temperature

was raised to room temperature and a short conventional constant-pressure molecular dynamics simulation was performed. If the system so generated is unstable, the procedure was started again.

We used tens of randomly generated crystal structures as starting points for the metadynamics. Most of them have no symmetry and are highly metastable, and a few metadynamics steps were often sufficient to escape from the shallow energy basin and obtain a more stable structure, which most of the time is similar to benzene I or III. This structure was then used as a building block for larger simulation cells used in subsequent metadynamics runs. In a series of trial runs it was observed that if we chose a MD simulation cell that was too small, no structural transition was observed. On the other hand, in large MD cells stacking faults were created at low energy cost, thus preempting the crystal-to-crystal phase transition. With a cell of 192 independent molecules it was possible to observe smooth crystal-to-crystal transformations.

The structure factor F_{hkl} provides a means to monitor the occurrence of a phase transition [Eq. (4)].[18] When a pronounced change in a selected reflection of F_{hkl} was observed, the dynamics was stopped and the new structure was optimized with respect to the box edges and the internal coordinates, both at $T=0$ and at the experimental condi-

$$F_{hkl} = \sum_j e^{-i \vec{G}_{hkl} \vec{r}_j} \quad (4)$$

Table 1: Comparison of experimental[15] and theoretical data of the seven benzene polymorphs.[a]

[a] The cell lengths (*a*, *b* and *c*) are in Å, the angle β is in degrees, and the molecular volume (V_m) is in Å^3. All the crystalline phases have $\alpha=\gamma=90$. The theoretical data are computed at room temperature and experimental pressure,[15] except for benzene I′ and V, which are computed at $T=0$ K and $P=0$ GPa and $T=600$ K and $P=5$ GPa, respectively. The experimental data relative to benzene II are from ref. [11], and the experimental crystallographic assignments of benzene III′ and IV are rather tentative.[15]

tions.[15] This was the key step in the identification of the new stable structures. The space group and the number of molecules in the unit cell for the equilibrium structure were determined by the program PLATON.[27] Then we simulated the powder diffraction spectra $S(2\theta)$ for all the equilibrated structures. Comparison of the structural information and of $S(2\theta)$ with the available experimental data allowed the matching of theoretical and experimental phases. In particular, the difference in the interplanar distances is quite low ($\approx 6\,\%$), and there is a good correspondence in the relative peak heights of the $S(2\theta)$. We label the structures found by the metadynamics with the names of the experimental phases to which they correspond. A most noticeable result is that Table 1 exhausts the list of all the minima that are found by metadynamics; it is not a selection of those structures that better fit the experimental data.

Benzene I is found to be stable at room temperature, but it converts into a different structure, benzene I′, upon relaxation at 0 K. This supports the hypothesis of the existence of a such a phase suggested in ref. [15], and benzene I is an example of a phase stabilized at room temperature by an entropic contribution. The two other well-characterized phases, benzene II and III,[10,11] are also found correctly by the metadynamics. It is interesting to note that benzene II, which is stable between 2 and 5 GPa,[15] has the same packing as its inorganic analogue, borazine, at ambient pressure.[28]

Moving to the high-pressure side of the phase diagram, the metadynamics is able to answer some open questions. Benzene III′ indeed exists, and it is not a modification of benzene III as proposed in ref. [15] but a new monoclinic phase in the space group $C2/c$, which may better match the experimental data when one cell parameter and the number of molecules in the unit cell are halved. At even higher pressure, benzene IV comes into play, and we are able to determine that it belongs to the *Pbam* space group. Finally, we assign the seventh structure discovered, whose space group is $P2_1$, to benzene V. Owing to the lack of structural information the last assignment is tentative and should be confirmed by experiment; moreover, this structure appears to be unstable at pressures lower than 5 GPa. The quantitative agreement between theory and experiment decreases with increasing pressure. This is not surprising since the potential has been modeled on low-pressure data.

In view of the very delicate balance between the different energy contributions we find our results remarkably good. The accuracy of our predictions, the absence of spurious minima, and a comparison between the lattice energies computed with the GROMOS96 and with the W99 force fields (Table 2) give an a posteriori validation of the capability of the force field used. It is worth noting that the GROMOS96[25] force field was not optimized for studying crystal structures. We were able to fill the experimental gaps in the understanding of the phase diagram of benzene by determining all the stable crystal structures. This success demonstrates that our methodology is a new and powerful tool for the fast and accurate determination of the relevant polymorphs of an organic molecular crystal, and that it may help solve the problem of crystal structure prediction. The most promising aspect of our work is that it provides a workable new paradigm in which the Gibbs free energy and not the potential energy surface plays the determining role. Since in most practical applications the relevant structures are those which are stable at ambient conditions, this appears to us a major step forward. This is especially true for substances like most organic molecules for which $T = 300$ K is very close to the melting temperature. Once the thermodynamically relevant phases are found, the calculations can be further refined with the use of more accurate potentials and thus the relative enthalpy of the different phases can be determined.[11,21] By using methods of statistical mechanics it is also possible to draw a full phase diagram.[29] These extensions are, however, outside the scope of the present work.

Table 2: Lattice energies in kJ mol^{-1} for all the benzene phases that are stable at $T = 0$ and $P = 0$ computed with both the GROMOS96[25] and the W99[22] force fields.[a]

	GROMOS96	W99
II	0.00	0.00
III	0.25	0.43
III′	1.25	0.84
IV	2.07	0.37

[a] For both force fields we considered the molecules as rigid units and we minimized the energy with respect to the lattice vectors and molecular orientations. We observed that upon cooling benzene I converts into I′ for the GROMOS96 force field, while the opposite occurs for the W99 force field. The reference structure is benzene II. The atomic charges are those used for the molecular dynamics simulations.

Polyoxometalates

The Ball-Shaped Heteropolytungstates $[\{Sn(CH_3)_2(H_2O)\}_{24}\{Sn(CH_3)_2\}_{12}(A\text{-}XW_9O_{34})_{12}]^{36-}$ **

Ulrich Kortz, Firasat Hussain, and Markus Reicke*

Polyoxometalates can be considered as soluble metal-oxide fragments with an enormous structural variety and a multitude of interesting properties.[1–6] The first polyanions were reported almost two centuries ago.[7,8] Nevertheless, interest in this class of compounds is larger than ever before. The search for novel polyanions is predominantly driven by the catalytic properties of many transition-metal-substituted polyoxotungstates,[9] and by potential applications in bio- and nanotechnology.

Besides being useful, the symmetry and molecular nature of polyoxometalates are highly attractive features. Until recently, the isopolyanion $[Mo_{36}O_{112}(H_2O)_{18}]^{8-}$,[10] the heteropolyanions $[As_4W_{40}O_{140}]^{28-}$[11] and $[H_7P_8W_{48}O_{148}]^{33-}$[12] were the largest polyoxometalates reported. However, in the last couple of years we have witnessed the discovery of several polyoxometalates with truly spectacular sizes. Especially Müller et al. reported on gigantic mixed-valence polyoxomolybdate rings and spheres containing up to 368 molybdenum atoms.[13] Pope et al. reported on a polyoxotungstate with 148 tungsten atoms, $[As_{12}Ce_{16}(H_2O)_{36}W_{148}O_{524}]^{76-}$.[14] Sécheresse et al. have treated the cationic oxo-thio linker $[Mo_2O_2S_2(OH_2)_6]^{2+}$ with many different lacunary polyoxotungstates resulting in large polyanion assemblies.[15] Our group has reported a large tungstoarsenate(III) with 65 tungsten atoms which was prepared by self-condensation of the dilacunary polyanion precursor $[As_2W_{19}O_{67}(H_2O)]^{14-}$.[16] Recently we also reported on large polyoxotungstates based on titanium(IV).[17]

It is important to realize that the mechanism of formation of polyoxometalates is still not well understood and commonly described as self-assembly. Therefore it is usually not possible to design a multi-step sequence for the synthesis of a novel polyoxometalate. As a result the design of novel polyoxometalates remains a challenge.

In our search for a cationic linker which is hydrolytically stable and allows for covalent attachment of organic functional groups we identified the diorganotin group (R_2Sn^{2+}, $R = CH_3$, C_6H_5 etc.) as an interesting candidate. We have already demonstrated that this electrophile can be incorporated in lone-pair-containing polyanion precursors.[18] Furthermore, we have discovered that the two organic groups are always *trans* to each other, which allows the construction of large polyanions with unexpected geometries. Herein we report the reactivity of dimethyltindichloride with the trilacunary Keggin precursors $[A\text{-}XW_9O_{34}]^{9-}$ (X = P, As).

Interaction of $(CH_3)_2SnCl_2$ with $Na_9[A\text{-}PW_9O_{34}]$ in the ratio 3:1 in aqueous medium (pH 4) resulted in the dodecameric, ball-shaped anion $[\{Sn(CH_3)_2(H_2O)\}_{24}\{Sn(CH_3)_2\}_{12}(A\text{-}PW_9O_{34})_{12}]^{36-}$ (**1**; Figure 1 and Figure 2). We were also able to prepare the isostructural arsenic analogue $[\{Sn(CH_3)_2(H_2O)\}_{24}\{Sn(CH_3)_2\}_{12}(A\text{-}AsW_9O_{34})_{12}]^{36-}$ (**2**) by an identical procedure. Both compounds crystallized as mixed cesium–sodium salts and are in fact isomorphous.[19] Owing to the high symmetry of the solid state arrangement (space group $Im\bar{3}$), the asymmetric unit of **1** and **2** is very small and includes only five tungsten and two tin atoms (Figure 1). The spherical structure of **1** and **2** is spectacular in terms of geometry and size (diameter of ≈ 30 Å) and is unprecedented in polyoxotungstate chemistry (Figure 2 and Figure 3). This supermolecular assembly is composed of 12 trilacunary $[A\text{-}XW_9O_{34}]^{9-}$ (X = P, As) Keggin fragments which are linked by a total of 36 dimethyltin groups (12 inner $(CH_3)_2Sn^{2+}$ and 24 outer $(CH_3)_2(H_2O)Sn^{2+}$ groups) resulting in a polyanion with T_h symmetry. Note that **1** and **2** have almost 1000 atoms and a

Figure 1. Ball-and-stick representation of the asymmetric unit of **1**; green C, red O. This Figure is also representative of the As-analogue **2**, as both structures are isomorphous.

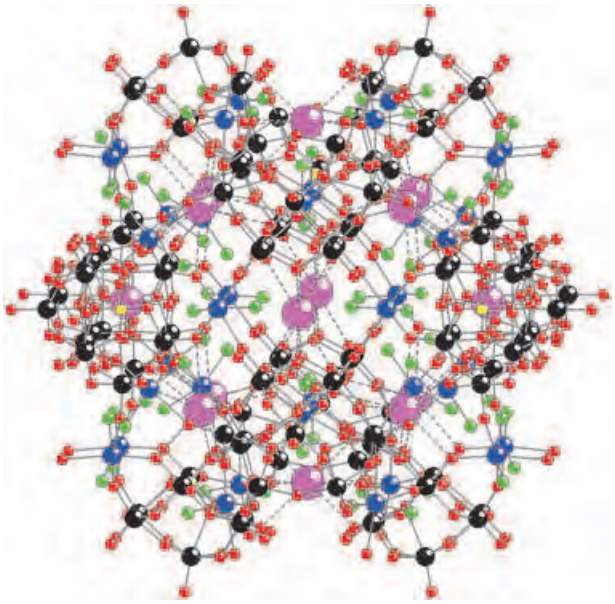

Figure 2. Ball-and-stick representation of **1** and **2** including the 14 cesium counterions. black W, blue Sn, yellow P/As, red O, green C, and purple Cs. For clarity no hydrogen atoms are shown.

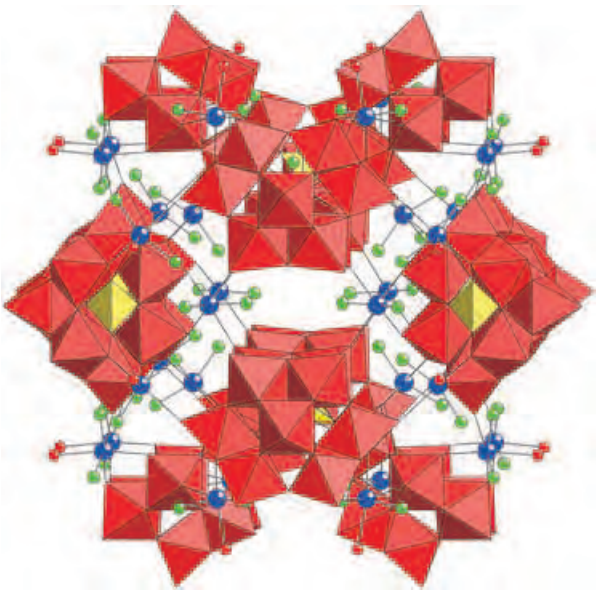

Figure 3. Polyhedral representation of **1** and **2**. The WO_6 octahedra are red and the XO_4 tetrahedra (X = P, As) are yellow, otherwise, the color scheme is the same as in Figure 2. For clarity no hydrogen or cesium atoms are shown.

molar mass of around 33 000 g mol^{-1}. In addition, 14 cesium ions are closely associated with **1** and **2** in the solid state. They are located in hydrophilic surface pockets of the spherical clusters, thereby stabilizing the assembly further (Figure 2).

Polyanions **1** and **2** are the second largest, discrete polyoxotungstates reported.[14] Furthermore, the overall shape of **1** and **2** resembles Müller's Keplerates which are highly symmetrical polyoxomolybdates.[20] This class of compounds is characterized by spherical clusters with icosahedral symmetry of the type $(pentagon)_{12}(linker)_{30}$ where the centers of the 12 pentagons describe an icosahedron and the centers of the 30 linkers an icosidodecahedron. Close inspection of the structure of **1** and **2** indicates that it is best described as a "pseudo Keplerate". Although the 12 hetero atoms (P in **1** and As in **2**) describe an almost perfect icosahedron (Figure 4), the 12 inner tin atoms do not (Figure 5). Of note is that the 24 outer tin atoms also form a highly symmetrical

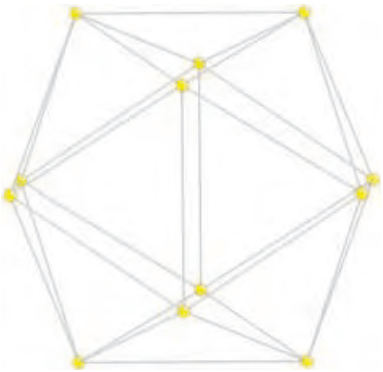

Figure 4. Representation of the icosahedron described by the hetero atoms of **1** (P) and **2** (As).

arrangement (Figure 6) as do the 14 cesium ions which describe a hexacapped cube (Figure 7). Therefore polyanions **1** and **2** exhibit some analogies with a Russian doll, but are in fact more complex as the shells have varying size, symmetry, and chemical composition. The multishell nature of **1** and **2** is nicely visible in Figure 8 (cesium ions not included for clarity).

Bond valence sum calculations (BVS) of **1** and **2** indicate that the terminal oxygen atoms attached to the 24 outer tin atoms belong to water molecules. There are no other protonation sites on **1** and **2** and therefore the charge must be −36.[21] This is fully consistent with elemental analysis, which indicated the presence of 14 cesium and 22 sodium ions. The cesium ions could be identified by X-ray diffraction, but not sodium ions which is probably a result of disorder.

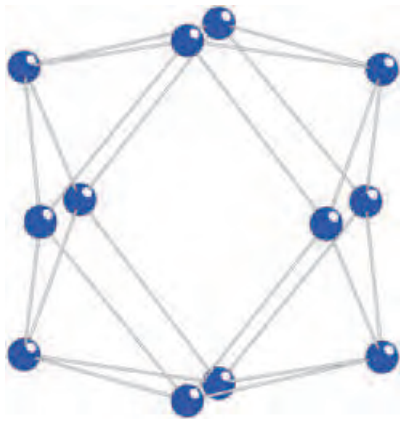

Figure 5. Representation of the polyhedron described by the 12 inner tin atoms of **1** and **2**.

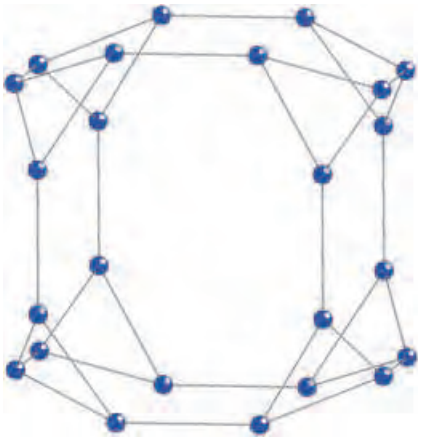

Figure 6. Representation of the polyhedron described by the 24 outer tin atoms of **1** and **2**.

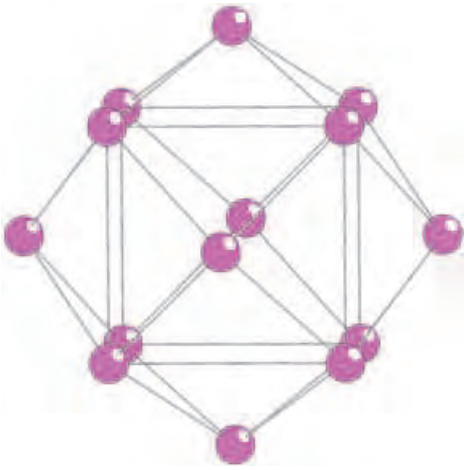

Figure 7. Representation of the hexacapped cube described by the 14 cesium ions of **1** and **2**.

The central cavity of the ball-shaped **1** and **2** has a diameter of around 8 Å and it does not contain any water molecules or ions. The pocket is actually hydrophobic because it is lined by 12 methyl groups. This hydrophobicity probably explains why polyanions **1** and **2**, which were synthesized in aqueous medium, do not contain any guests. Nevertheless, we believe that in principle small guest molecules with appropriate size and polarity can be encapsulated during formation of **1** and **2**. Furthermore, we identified hydrophobic channels (lined by methyl groups) passing through the entire structure of **1** and **2**, which could allow for loading and discharging of guest molecules even after the polyanions have been formed. In addition, the surface of **1** and **2** has 14 hydrophilic pockets, which are all occupied by cesium ions (Figure 2).

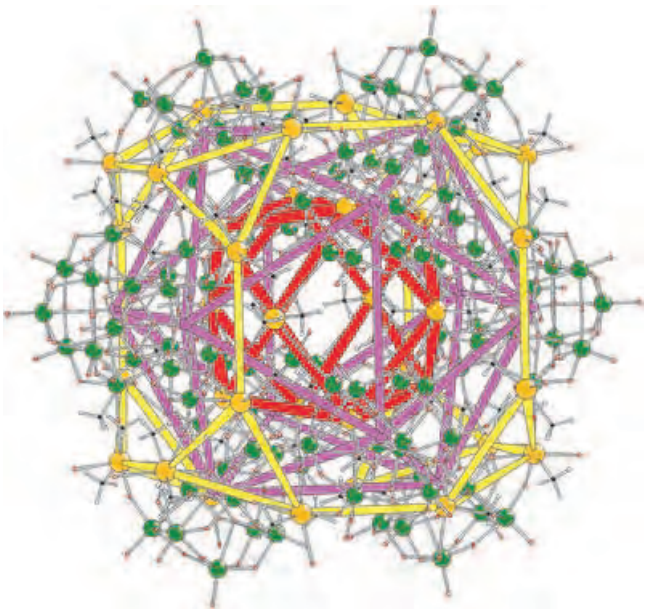

Figure 8. Ball-and-stick representation of **1** and **2** highlighting the different polyhedral shells; red 12 inner Sn atoms, purple 12 hetero atoms, yellow 24 outer Sn atoms (green spheres tungsten).

We also investigated the solution properties of **1** by multinuclear solution NMR (^{183}W, ^{119}Sn, ^{31}P, ^{13}C, ^{1}H) spectroscopy at room temperature in D_2O (400 MHz JEOL ECX instrument). The ^{183}W NMR spectrum of **1** shows two singlets at $\delta = -134.0$ and -157.9 ppm, with an intensity ratio 1:2. The ^{31}P NMR spectrum of **1** has a singlet at $\delta = -13.1$ ppm and the ^{119}Sn NMR spectrum has a singlet at $\delta = -170.8$ ppm. The ^{13}C NMR spectrum shows two signals at $\delta = 22.1$ and 8.4 ppm, with an intensity ratio 1:2 and the ^{1}H NMR spectrum shows two signals at $\delta = 1.9$ and 0.8 ppm, also with an intensity ratio 1:2. Thus for solutions of **1** we identified two types of tungsten, carbon, and hydrogen environments and, one type of phosphorus environment. The ^{183}W NMR results indicate that all 12 Keggin units are magnetically equivalent and the six belt tungsten atoms ($\delta = -157.9$ ppm) can be distinguished from the three capping tungsten atoms ($\delta = -134.0$ ppm). As expected, all 12 phosphorus atoms are fully equivalent. The NMR spectroscopy results of **2** are in good agreement with those of **1** (relative intensities in parenthesis): ^{183}W NMR: $\delta = -131.4$ (1), -139.1 ppm (2); ^{119}Sn NMR: $\delta = -228.4$ ppm; ^{13}C NMR: $\delta = 20.8$ (1), 10.3 ppm (2); ^{1}H NMR: $\delta = 2.0$ (1), 0.9 ppm (2). We do not have a good explanation why solution NMR spectroscopy does not enable the two types of tin atoms

in **1** and **2** to be distinguished which we identify in the crystal structure (Figures 1–3, 5, 6).

In summary, we have synthesized the supermolecular, spherical polyoxotungstate assemblies **1** and **2** using a simple one-pot procedure in aqueous medium. The structures of these compounds are unprecedented and allow for a multitude of studies including host–guest chemistry, ion exchange, gas storage, and use in catalysis and medicine. We have demonstrated that the dimethlytin group is a highly reactive electrophile which allows lacunary polyanion fragments to be linked in an unprecedented fashion. The resulting compounds are diamagnetic which allows multinuclear solution NMR studies to be performed, which is of major importance for medicinal applications. The fact that all tungsten centers are in the fully oxidized +VI state also allows for unequivocal determination of the charges of the product polyanions. In addition to the results we have already published (see ref. [18]) and the structure presented herein, we have several other discrete and also polymeric polyanion structures with completely unprecedented geometries. These results will be published elsewhere.

Experimental Section

$Cs_{14}Na_{22}$**1**·149 H_2O: A sample of $Na_9[A\text{-}PW_9O_{34}]$ (1.46 g, 0.600 mmol; synthesized according to ref. [22]) was added to a stirred solution of $(CH_3)_2SnCl_2$ (0.435 g, 1.98 mmol) in H_2O (20 mL). The pH value was adjusted to 4 by addition of 4 M HCl. This solution was heated to 80 °C for 1 h and then cooled to room temperature and filtered. Addition of 1.0 M CsCl solution (0.5 mL) to the colorless filtrate and slow evaporation at room temperature led to a white crystalline product after about one week. Yield: 1.3 g (69 %). IR: $\tilde{\nu}$ = 1084(s), 1070(s), 1019(m), 977(sh), 961(sh), 945(s), 928(s), 882(m), 833(s), 774(vs), 719(vs), 668(m), 640(sh), 596(w), 574(w), 520(m), 495(sh), 478(w), 465(w) cm^{-1}. Elemental analysis (%) calcd for $Cs_{14}Na_{22}$**1**·149 H_2O: Cs 5.0, Na 1.4, W 52.8, Sn 11.4, P 1.0, C 2.3, H 1.5; Found: Cs 4.6, Na 1.2, W 53.6, Sn 11.9, P 1.2, C 2.5, H 1.2.

$Cs_{14}Na_{22}$**2**·149 H_2O: The synthesis of this compound was analogous to $Cs_{14}Na_{22}$**1**·149 H_2O, but instead of $Na_9[A\text{-}PW_9O_{34}]$ we used $Na_8H[A\text{-}AsW_9O_{34}]$ (1.59 g, 0.600 mmol; synthesized according to ref. [23]) and the pH value was adjusted to 3. Yield: 1.2 g (63 %). IR: $\tilde{\nu}$ = 1015(sh), 983(sh), 951(s), 901(sh), 863(s), 840(sh), 773(s), 715(s), 658(s), 578(sh), 520(w), 484(w), 471(w), 411(m) cm^{-1}. Elemental analysis (%) calcd for $Cs_{14}Na_{22}$**2**·149 H_2O: Cs 4.9, Na 1.3, W 52.1, Sn 11.2, As 2.4, C 2.3, H 1.5; found: Cs 4.5, Na 1.2, W 53.1, Sn 11.6, As 2.6, C 2.4, H 1.6.

Elemental analyses were performed by Kanti Labs Ltd. in Mississauga, Canada.

Polyoxometalates

The Wheel-Shaped Cu_{20} Tungstophosphate $[Cu_{20}Cl(OH)_{24}(H_2O)_{12}(P_8W_{48}O_{184})]^{25-}$ Ion**

*Sib Sankar Mal and Ulrich Kortz**

Polyoxometalates are a unique class of metal-oxide clusters. This family of compounds was discovered by Berzelius many years ago, but only recently the full potential of these species has been realized.[1–2] The search for novel polyanion structures is predominantly driven by the manifold applications of these compounds in areas as diverse as catalysis, bio- and nanotechnology, medicine, and materials science.[3–9]

The structural beauty of polyoxometalates is an additional feature that has contributed to this class attracting so much attention. Especially the work of Müller et al. has resulted in discrete molecular species with spectacular sizes and symmetries. For example, they reported gigantic mixed-valence polyoxomolybdate rings and spheres containing up to 368 molybdenum atoms.[10] Pope et al. reported a polyoxotungstate with 148 tungsten atoms, $[As_{12}Ce_{16}(H_2O)_{36}W_{148}O_{524}]^{76-}$.[11]

Interestingly all of the above species were synthesized without using any polyanion precursor. It must be realized that formation of polyanions is a self-assembly process, which depends more on the reaction conditions (e.g. pH value, concentration and ratio of reagents, ionic strengths) than on the type of polyanion precursors used.

We have been interested for some time in transition-metal-substituted polyoxotungstates, especially with respect to their magnetic and electrochemical properties.[12] There is interest in the synthesis of molecular species with high spin ground states. Lately Christou et al. reported the largest molecular magnet known to date composed of 84 manganese atoms.[13] Until then the so called "Mn_{12} acetate" had probably been the most attractive species in the area of single-molecule magnets.[14] Also polyoxometalate chemistry plays a major role in this field, as it allows for a bottom-up synthesis of paramagnetic multimetal-oxo-hydroxo clusters which are encapsulated and stabilized by diamagnetic polyanion fragments.[5–8,15] The magnetic and EPR properties of such discrete clusters can be analyzed in great detail, as usually intermolecular interactions are negligibly small.[12] Nevertheless, it must be realized that routinely polyoxotungstates with only three or four transition-metal ions have been synthesized, and only a handful of systems containing five or more paramagnetic centers.[12a,b,16]

In our search for highly lacunary polyanion ligands that might be an appropriate template for significantly larger paramagnetic clusters we have focused our attention on the established crown heteropolyanion $[H_7P_8W_{48}O_{184}]^{33-}$.[17] This species is composed of four $[H_2P_2W_{12}0_{48}]^{12-}$ fragments which are linked by capping tungsten atoms resulting in a cyclic arrangement. The stability of $[H_7P_8W_{48}O_{184}]^{33-}$ in aqueous solution over an unusually large pH range (1–8) and its large central cavity (diameter of around 10 Å) are highly attractive features. We can consider $[H_7P_8W_{48}O_{184}]^{33-}$ as a superlacunary polyanion, but surprisingly this species has been largely neglected as a precursor.[18] This situation is probably because Tézé and Contant concluded in 1985 that $[H_7P_8W_{48}O_{184}]^{33-}$ "does not give complexes with divalent or trivalent transition-metal ions".[17a] Nevertheless, we decided to investigate in detail the reactivity of paramagnetic 3d metal ions with $[H_7P_8W_{48}O_{184}]^{33-}$ in aqueous medium.

Interaction of $CuCl_2$ with $K_{28}Li_5[H_7P_8W_{48}O_{184}]$ in the ratio 24:1 in aqueous medium (pH 6) resulted in the large, wheel-shaped anion $[Cu_{20}Cl(OH)_{24}(H_2O)_{12}(P_8W_{48}O_{184})]^{25-}$ (**1**; Figures 1–3. Polyanion **1** crystallized as a mixed potassium-

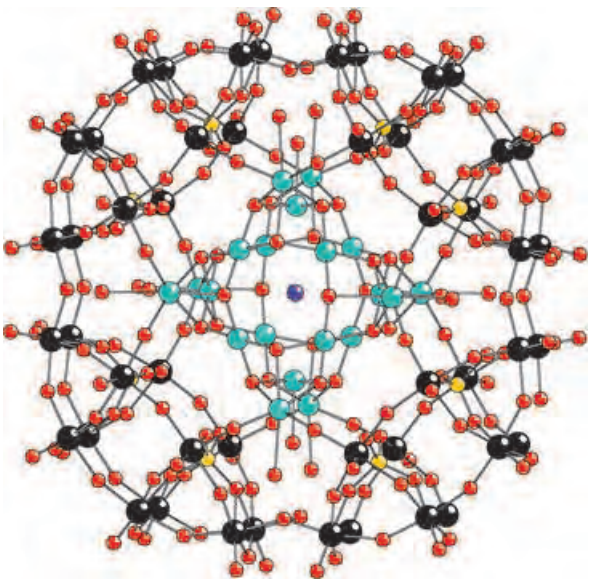

Figure 1. Ball-and stick-representation of $[Cu_{20}Cl(OH)_{24}(H_2O)_{12}(P_8W_{48}O_{184})]^{25-}$ (**1**). Black W, turquoise Cu, yellow P, violet Cl, red O.

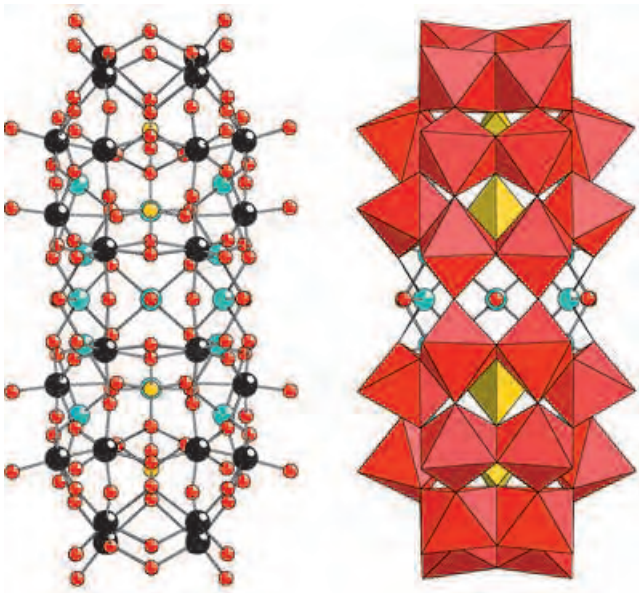

Figure 3. Side view of **1** showing ball-and-stick (left) and combined polyhedral/ball-and-stick (right) representations.

lithium salt in the tetragonal system (space group $I4/m$).[19] As a result, the asymmetric unit of **1** includes only six tungsten and three copper atoms (Figure 4).

The polyanion **1** is unprecedented in structure, size, and composition. This molecule is the first transition-metal-substituted derivative of $[H_7P_8W_{48}O_{184}]^{33-}$ and it incorporates more paramagnetic 3d metal ions than any other polyoxotungstate to date.[12a,b,16] The structure of the wheel-shaped $[H_7P_8W_{48}O_{184}]^{33-}$ precursor is maintained in **1** and the cavity is filled with a highly symmetrical copper-hydroxo cluster (Figure 1, Figure 2, and Figure 5). This structure emphasizes that the template effect plays an important role during

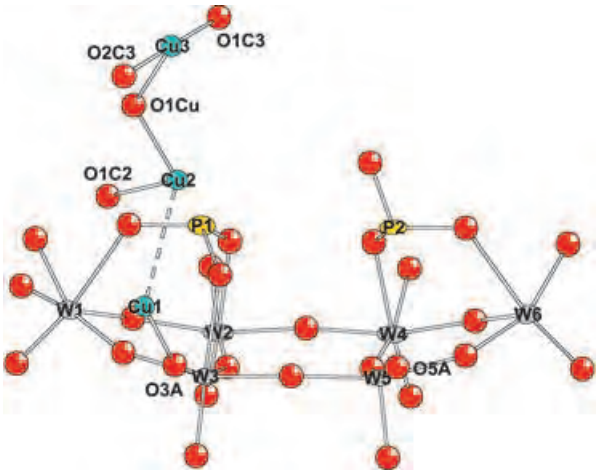

Figure 4. Ball-and-stick representation of the asymmetric unit of **1**, thermal ellipsoids shown are set at 50% probability.

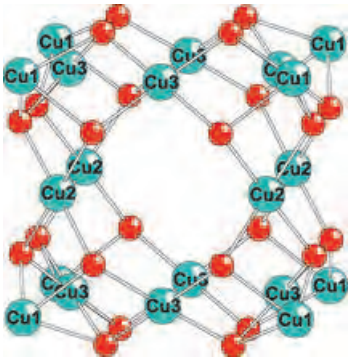

Figure 5. Ball and stick representation of the copper-hydroxo cluster in **1** showing all structurally equivalent copper atoms with the same label. Only the oxo-ligands bridging neighboring copper ions are shown.

formation of **1**. We have shown that the oxo-groups in the cavity of the tungstophosphate precursor $[H_7P_8W_{48}O_{184}]^{33-}$ do actually interact with transition-metal ions in aqueous medium, but some heating is required (see Experimental Section). Therefore, $[H_7P_8W_{48}O_{184}]^{33-}$ can indeed be considered as a superlacunary polyanion precursor and we expect that other transition-metal ions besides copper(II) can also be incorporated.

The Cu_{20} cluster in **1** is composed of only three structurally unique types of copper(II) ions (eight Cu1, four Cu2, and eight Cu3; see Figure 5). All 20 copper centers are bridged to neighboring copper ions by μ_3-oxo ligands to give a highly symmetrical, cage-like assembly. Based on bond valence sum calculations all 24 bridging oxygen atoms are monoprotonated.[20] The center of the cavity (which has a diameter of around 7 Å) is occupied by a chloride ion (Figure 1 and Figure 2). The coordination numbers and geometries of Cu1, Cu2, and Cu3 are different from each other. Cu1 is coordinated in a strongly distorted octahedral fashion and exhibits Jahn–Teller distortion with axial elongation. The equatorial plane is composed of Cu1–O3A (1.922(14) Å), Cu1–O5A (1.926(15) Å), Cu1–O2C3 (1.980(14) Å), and Cu1–O1Cu (1.986(14) Å) bonds. The two axial bonds are

Cu1–O1C3 (2.358(16) Å) and a very long bond Cu1–O5W (2.504(17) Å) to a terminal water molecule.[20] This very long bond Cu1–O5W is not shown in Figure 4 as the bond order is almost negligibly small (around 0.1), nevertheless, this bond is shown in Figures 1–3. The angle O1C3-Cu1-O5W is only 145° which reflects steric hindrance of the water ligand. Cu2 has square-pyramidal coordination geometry with two Cu2–O2C3 (1.922(14) Å) and two Cu2–O1Cu (1.925(14) Å) bonds in the equatorial plane and a long bond to a terminal water ligand, Cu2–O1C2 (2.29(3) Å).[20] Finally, Cu3 has a square-planar coordination geometry which is composed of Cu3–O1C3 (1.905(16) Å), Cu3–O1Cu (1.933(14) Å), Cu3–O1C3′ (1.947(16) Å), and Cu3–O2C3 (1.948(14) Å) bonds. The copper–copper distances in **1** are: Cu1···Cu2 2.812(3) Å, Cu1···Cu3 3.045(4) Å, and Cu1···Cu3′ 3.052(4) Å.

We also investigated the solution properties of **1** by ^{31}P NMR spectroscopy at room temperature in D_2O (400 MHz; JEOL ECX instrument). We observed a singlet at $\delta = -29.3$ ppm indicating that all eight phosphorus atoms in **1** are equivalent, which is in complete agreement with the solid-state structure (Figure 1 and Figure 2). We have not yet obtained a good ^{183}W NMR spectrum for **1** (expected are three signals of equal intensity), probably due to solubility problems.

In summary, we have synthesized a large, wheel-shaped, Cu_{20} containing polyanion by direct reaction of copper(II) ions with $[H_7P_8W_{48}O_{184}]^{33-}$. The polyanion **1** contains more paramagnetic 3d transition-metal centers than any other polyoxotungstate reported to date. Furthermore, it is stable in solution, as shown by ^{31}P NMR spectroscopy. Contrary to prior reports, we have shown that the wheel-shaped $[H_7P_8W_{48}O_{184}]^{33-}$ 1) actually does react with transition-metal ions in aqueous medium using simple, one-pot procedures, 2) is to be considered as a superlacunary polyanion precursor, 3) acts as a template which allows the construction of large transition-metal-oxo clusters, and 4) is probably also reactive towards many other electrophiles (e.g. rare earths and organotin species). We consider $[H_7P_8W_{48}O_{184}]^{33-}$ as a ligand of choice in our search for paramagnetic polyanions with high spin ground states. Currently we are investigating the magnetic, EPR, and electrochemical properties of **1** and these results will be reported elsewhere. We are also interested to see of derivatives of **1** incorporating other transition-metals besides copper(II) and other guests besides Cl^- can be isolated. In fact, we have already prepared a cobalt(II)-containing derivative with a structure different from **1**. Furthermore, the cage-like structure of **1** allows studies in host–guest chemistry, ion exchange, gas storage, catalysis and medicine to be envisaged.

Experimental Section

Preparation $K_{12}Li_{13}$**1**$\cdot 22H_2O$: A sample of $CuCl_2\cdot 2H_2O$ (0.10 g, 0.60 mmol) was dissolved in a 1M $LiCH_3COO$ buffer solution (20 mL) at pH 6.0, then $K_{28}Li_5[H_7P_8W_{48}O_{184}]\cdot 92H_2O$ (0.37 g 0.025 mmol) (synthesized according to ref [17b]) was added. This solution was heated to 80 °C for 1 h and after cooling to room temperature it was filtered. The filtrate was allowed to evaporate in an open beaker at room temperature. After 1–2 days a blue crystalline product started to appear. Evaporation was allowed to continue until the solution level had approached the solid product, which was then collected by filtration and air-dried. Yield: 0.11 g (30%). IR: $\tilde{\nu} = 1137$(sh), 1121(s), 1080(s), 1017(m), 979(sh), 951(sh), 932(s), 913(sh), 832(sh), 753(s), 681(s), 570(sh), 523(w), 470 cm^{-1}(w). Elemental analysis (%) calcd for $K_{12}Li_{13}$**1**$\cdot 22H_2O$: K 3.2, Li 0.6, W 59.2, Cu 8.5, P 1.7; found: K 3.4, Li 0.8, W 58.8, Cu 8.6, P 1.6.

Elemental analysis was performed by Kanti Labs Ltd. in Mississauga, Canada.

[18] A cerium-containing derivative of $[H_7P_8W_{48}O_{184}]^{33-}$ with the formula $[(K)Ce_6P_8W_{56}O_{208}]^{21-}$ was recently presented at a conference. M. T. Pope, *International Symposium on Nanostructures and Physicochemical Properties of Polyoxometalate Superclusters and Related Colloid Particles*, Shonan Village Center, Kanagawa, Japan, 21.-25. November 2004.

[19] Crystal data for $K_{12}Li_{13}$**1**$\cdot 22\,H_2O$: A blue block with dimensions $0.09 \times 0.07 \times 0.06\ mm^3$ was mounted on a glass fiber for indexing and intensity data collection at 153 K on a Bruker D8 SMART APEX CCD single-crystal diffractometer using $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). Of the 9102 unique reflections ($2\theta_{max} = 56.12°$), 5826 reflections ($R_{int} = 0.083$) were considered observed ($I > 2\sigma(I)$). Direct methods were used to solve the structure and to locate the tungsten and copper atoms (SHELXS-97). Then the remaining atoms were found from successive difference maps (SHELXL-97). The final cycle of refinement, including the atomic coordinates, anisotropic thermal parameters (W, Cu, P, K and Cl atoms), and isotropic thermal parameters (O atoms) converged at $R = 0.068$ and $R_w = 0.179$ ($I > 2\sigma(I)$). No lithium ions could be located crystallographically. In the final difference map the deepest hole was $-3.054\ e\,Å^{-3}$ and the highest peak $4.663\ e\,Å^{-3}$. Routine Lorentz and polarization corrections were applied and an absorption correction was performed using the SADABS program (G. M. Sheldrick, Siemens Analytical X-ray Instrument Division, Madison, WI, **1995**). Further details on the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (fax: (+49) 7247-808-666; e-mail: crysdata@fiz-karlsruhe.de), on quoting the depository number CSD-415126.
