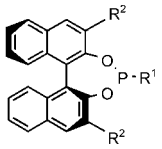
For example the use of **L1c** in combination with triphenylphosphine resulted in an enhancement of the conversion from 76 to 100% and the *ee* value from 0 to 63% (entries 5 and 6). It was observed that phosphoramidites based on 3,3′-dimethyl-2,2′-dihydroxy-1,1′-binaphthyl (3,3′-dimethylbinol) gave distinctly higher *ee* values than the phosphoramidites based on binol (entries 1–8 versus 9–16, Table 1). Piperidine-based phosphoramidite **L2c**[10] further improved the enantioselectivities. The addition of triphenylphosphine in the presence of the catalyst based on **L2c** resulted in a remarkable increase in the *ee* value from 2 to 85% (entries 13 and 14).

A screening of different phosphines was performed after further optimization of the solvent, temperature, pressure, and ligand ratio.[11] A variety of achiral alkyl phosphines and substituted aryl phosphines were tested in the rhodium-catalyzed asymmetric hydrogenation of α-methylcinnamic acid (**1**) using **L2c** (Table 2).



Substitution at the *ortho* position of triphenylphosphine increased the *ee* value significantly (entries 2 and 3), whereas substitution at the *meta* or *para* position had hardly any influence on the enantioselectivity (compare entries 2, 4, 5, 8,

and 9). Linear or branched alkyl phosphines resulted in a decrease in the rate and enantioselectivity compared to tricyclohexylphosphine **P9** (entries 10–12). Electron-donating or -withdrawing substituents on the aryl phosphines had no influence on the *ee* value (compare entries 2 with 4 and 5 as well as 8 and 9). While reactions were in general complete after 2 h, incomplete conversions were obtained with the sterically hindered phosphines **P6** and **P11** after 16 h (entries 7 and 12). In these cases, not only did the rate of the hydrogenations decrease, but the enantioselectivities also dropped dramatically.

Next the hydrogenation of a number of disubstituted acrylic acids was studied (Table 3). In all cases, full conversion

Table 3: Rhodium-catalyzed asymmetric hydrogenation of substituted acrylic acids[a],[b]

Entry	Substrate	Product	Ligand	Phosphine	*ee*[c,d] [%]

5[f]	**7**	**12**	**L2c**	**P2**	95

[a] Reaction conditions: 1 mmol substrate in 4 mL solvent with 0.01 mmol $[Rh(cod)_2]BF_4$, 0.02 mmol phosphoramidite and 0.01 mmol PPh_3. [b] Reactions were carried out for 16 h. [c] *ee* values were determined by GC or HPLC on chiral stationary phases, full conversion was obtained unless indicated otherwise. [d] In all cases the *S* enantiomer of the ligand gave the *S* enantiomer of the product.[15] [e] Conversion 98%. [f] Reaction was performed at 60°C.

of the substrates was obtained with high to excellent *ee* values. The enantioselectivity is higher when R^1 is an aromatic group than when R^1 is an alkyl group, as in tiglic acid (**3**, compare entry 3 of Table 2 with entry 1 of Table 3). Electron-donating as well as electron-withdrawing substituents at the aromatic moiety had little effect on the enantioselectivity (entry 3 versus 4, Table 3). The size of R^2 also has little influence on the enantioselectivities. Enantiomeric excesses of $\geq 97\%$ for **2** and **9** could be obtained by fine-tuning of the phosphine–phosphoramidite combination (entry 3 of Table 2 and entry 2 of Table 3).

On the basis of preliminary NMR experiments it can be concluded that the formation of a heterocomplex comprising one chiral phosphoramidite and one achiral phosphine bound to the Rh center is the predominant factor for the remarkable selectivity enhancement and high activity. The formation of a homocomplex comprising two achiral phosphines bound to the Rh center causes a non-asymmetric catalytic reaction. Using a 2:1 ratio of phosphoramidite:phosphine suppresses the formation of the latter homocomplex.

The enantioselectivities obtained here for products **2** and **12** exceed or are comparable to reported values for rhodium-catalyzed and ruthenium-catalyzed hydrogenations using chiral bidentate ligands.[5a,12,13] With the exception of five Ru complexes based on bidentate phosphine ligands, which hydrogenate substrate **3** with $\geq 95\%$ *ee*,[12f,13b,13c,14] the present system belongs to the most selective so far reported.

In conclusion, a new catalytic system, based on a mixed-ligand approach, has been developed for the rhodium-catalyzed asymmetric hydrogenation of cinnamic acid derivatives with *ee* values up to 99%. Easy variation of the chiral and achiral monodentate ligands makes it possible to screen a variety of catalytic systems in a short time. It has been shown for the first time that a catalyst complex based on a heterocombination of a chiral and an achiral monodentate ligand gives dramatically higher enantioselectivity than any of the corresponding homocomplexes.

Organocatalysis

Diphenylprolinol Silyl Ethers as Efficient Organocatalysts for the Asymmetric Michael Reaction of Aldehydes and Nitroalkenes**

Yujiro Hayashi, Hiroaki Gotoh, Takaaki Hayashi, and Mitsuru Shoji*

A subtle change in catalyst structure can sometimes improve catalytic activity dramatically, as we found in our recent study on α-aminoxylation, tandem O-nitroso aldol/Michael reactions, and Mannich reactions catalyzed by the siloxyproline **4**, a highly active proline surrogate (Scheme 1).[1] The simple

1 **2a** R = TMS **2b** R = TES **2c** R = TBS **3** **4**

Scheme 1. Organocatalysts examined in this study. TMS = trimethylsilyl, TES = triethylsilyl, TBS = *tert*-butyldimethylsilyl.

introduction of a siloxy group into the proline structure leads to an increase in the catalytic activity, thus allowing a decrease in catalyst loading and shorter reaction times, without compromising the enantioselectivity, and is accompanied by broadening of the substrate scope. This higher activity can be attributed to the increased solubility of **4** in organic solvents. The fact that the substitution of a hydroxy group for a siloxy group can dramatically affect catalytic activity prompted us to investigate other catalytic systems, and these investigations led us to the diphenylprolinol silyl ether **2**. The parent diphenyl-2-pyrrolidinemethanol (**1**, diphenylprolinol), a commercially available amino alcohol developed by Corey and co-workers, has proved to be a very useful ligand for asymmetric synthesis: *B*-alkylated oxazaborodine is a useful catalyst for the CBS reduction,[2] while an effective, asymmetric Lewis acid catalyst prepared from *B*-aryl oxazaborodine and a Brønsted acid promotes the Diels–Alder reaction of a broad range of substrates with excellent enantioselectiv-

ity[3] and also catalyzes asymmetric cyanosilylation.[4] Herein we disclose another synthetically useful feature of diphenylprolinol (**1**), the silyl ethers **2** of which were found to be exceptionally effective in the asymmetric catalysis of the Michael reaction of aldehydes and nitroalkenes.[5]

The Michael reaction of a carbon nucleophile with a nitroalkene[6] is one useful synthetic method for the preparation of nitroalkanes, which are versatile synthetic intermediates owing to the various possible transformations of the nitro group into other useful functional groups. The need for environmentally friendly and metal-free reactions has led recently to great progress in the organocatalyst-mediated Michael addition to nitroalkenes: Asymmetric Michael reactions of malonates and β-ketoesters as nucleophiles are promoted by a cinchona-alkaloid derivative[7] and a bifunctional thiourea catalyst.[8] The reactions of ketones and aldehydes as nucleophiles are catalyzed by proline,[9] pyrrolidinyltetrazole,[10] aminomethylpyrrolidine,[11] and 2,2′-bipyrrolidine.[12] Kotsuki and co-workers have developed an excellent Michael reaction of ketones with a pyrrolidine catalyst that includes pyridine as the conjugate base.[13] Recently, Wang et al. reported a highly enantio- and diastereoselective Michael reaction of aldehydes, although the catalyst loading was high (20 mol%) and an alkyl-substituted nitroalkene was a poor Michael acceptor (22% *ee*).[14] The development of more-effective asymmetric catalysts in terms of both enantioselectivity and substrate scope is desirable.

The Michael reaction of propanal and nitrostyrene was selected as a model [Eq. (1), Table 1]. The first catalyst

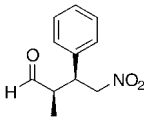
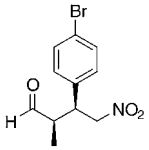
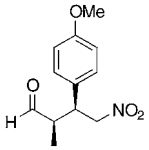
[a] Yield of isolated product. [b] Determined by ^{1}H NMR spectroscopy (400 MHz). [c] The *ee* values were determined by HPLC analysis on a chiral phase (chiralcel OD-H).

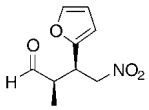
examined, proline (**3**), led to a low yield and low enantioselectivity (Table 1, entry 1). Higher enantioselectivity (75% *ee*) was observed with the siloxyproline **4**, but the yield was poor (Table 1, entry 2). Although excellent enantioselectivity (95% *ee*) was observed when diphenylprolinol (**1**) was employed, the progress of the reaction was slow, and the yield was unsatisfactory (29%) even after 24 h (Table 1, entry 3). The reactivity of the catalyst was increased dramatically, along with the enantioselectivity, when the hydroxy group in **1** was exchanged for a siloxy group. That is, the reaction was complete within 1 h at room temperature in the presence of the diphenyl siloxy proline **2a**, and the adduct was afforded in good yield (82%) and with increased enantioselectivity (99% *ee*; Table 1, entry 4). When the reaction was performed at a lower temperature (0°C), the adduct was obtained in nearly optically pure form (99% *ee*), in good yield, and also with high diastereoselectivity (*syn*/*anti* 94:6; Table 1, entry 5). The catalyst loading can be reduced to 5 mol% without compromising the enantioselectivity, but the reaction must then be carried out at room temperature, and a longer reaction time is needed. Not only the TMS-substituted compound **2a**, but also the TES and TBS derivatives **2b** and **2c** are excellent catalysts; however, the reaction becomes slower as the silyl substituent becomes bulkier. As excellent results had been obtained with the model system, the generality of the reaction was examined in detail, with the results summarized in Table 2.

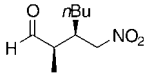
The reaction has broad applicability with respect to both the Michael acceptor and the donor; the adducts were obtained in nearly optically pure form (99% *ee*) and with excellent *syn* diastereoselectivity in most of the cases examined. Both aryl- and alkyl-substituted nitroalkenes are excellent Michael acceptors: Not only phenyl, but also electron-rich and electron-deficient aryl groups and heteroaromatic substituents can be present on the nitroalkene. Alkyl-substituted nitroalkenes, such as 1-nitro-1-hexene and 2-cyclohexyl-1-nitroethene, are also excellent Michael acceptors (Table 2, entries 5 and 6). Not only propanal, but also other linear aldehydes, such as *n*-butanal and *n*-pentanal (Table 2, entries 9 and 10), and branched aldehydes, such as isovaleraldehyde (Table 2, entries 7 and 8), can be employed successfully as the Michael donor, again to afford the adducts in nearly optically pure form. In the reaction of (*Z*)-nitrostyrene[15] with propanal, the same high levels of diastereo- and enantioselectivity were observed as those found in the reaction of the *E* isomer (Table 2, entries 1 and 11). In this reaction, the rapid isomerization of (*Z*)-nitrostyrene to the corresponding *E* isomer was observed by TLC. This method also has its limitations, however: Isobutyraldehyde was found to be a poor nucleophile; in its reaction with nitrostyrene the product was afforded with only moderate enantioselectivity (68% *ee*; Table 2, entry 12). The β,β′-disubstituted nitroolefin (*E*)-2-methyl-2-phenyl-1-nitroethene was found to be a poor Michael acceptor, with the desired adduct formed in low yield.

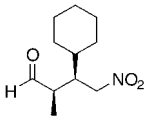


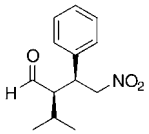


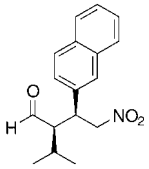


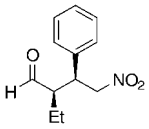


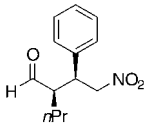


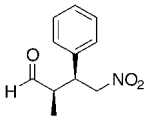


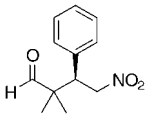












A preliminary study showed that not only nitroalkenes, but also α,β-unsaturated ketones can be employed as the Michael acceptor: 3-Phenylpropanal reacted with methyl vinyl ketone in the presence of **2a** to afford the Michael adduct[16] in 52% yield and with 97% *ee* [Eq. (2); Bn = benzyl].

[a] Yield of isolated product. [b] Determined by ^{1}H NMR spectroscopy (400 MHz). [c] The *ee* values were determined by HPLC analysis on a chiral phase (chiralpak AS-H, IA, AD-H, and chiralcel OD-H). [d] (*Z*)-Nitrostyrene was used as the Michael acceptor.

The higher reactivity of **2** relative to that of the parent compound **1** can be attributed to effective formation of the corresponding enamine without generation of the aminal, which would be formed in the case of diphenylprolinol (**1**).[5] The high diastereoselectivities and excellent enantioselectivities can be explained as follows: The *anti* enamine, with its double bond oriented away from the diphenylsiloxymethyl group, would be formed selectively and would react with nitrostyrene via an acyclic synclinal transition state proposed by Seebach and Golinski,[17] as shown in Scheme 2. In this model, an electrostatic interaction between nitro group and the nitrogen atom of the enamine would be operating.[12c] The bulky diphenylsiloxymethyl group on the pyrrolidine ring would play two important roles towards the excellent enantioselectivity: promotion of the selective formation of the *anti* enamine and selective shielding of the *Re* face of the enamine double bond.

Scheme 2. Transition-state model.

In summary, with the development of a highly enantioselective Michael reaction of aldehydes and nitroalkenes we have shown that silylation of the prolinol **1** can dramatically improve its catalytic activity. This reaction has several noteworthy features: 1) The catalyst **2** is easily prepared from commercially available diphenylprolinol in a single step, 2) a broad range of Michael acceptors (nitroalkenes) and Michael donors (aldehydes) can be used, and 3) the adducts were obtained in nearly optically pure form in almost all cases examined.

Experimental Section

Typical experimental procedure: Propanal (0.75 mL, 10 mmol) was added to a solution of nitrostyrene (154 mg, 1.0 mmol) and **2a** (34 mg, 0.1 mmol) in hexane (1.0 mL) at 0 °C. After the reaction mixture had been stirred for 5 h at that temperature, the reaction was quenched by the addition of aqueous 1N HCl. Organic materials were extracted three times with AcOEt, and the combined organic phases were dried (Na_2SO_4), concentrated, and purified by preparatory TLC (chloroform) to afford the Michael adduct (183 mg, 85%) as a clear oil: *syn*/*anti* 94:6 (by ^{1}H NMR spectroscopy of the crude mixture), 99% *ee* (by HPLC on a chiral phase: chiralcel OD-H column, $\lambda = 254$ nm, *i*PrOH/hexane 1:10, 1.0 mL min^{-1}; $t_R = 14.5$ min (minor), 19.7 min (major)).[11a]

Fullerenes

A [70]Fullerene Chloride, $C_{70}Cl_{16}$, Obtained by the Attempted Bromination of C_{70} in $TiCl_4$**

Sergey I. Troyanov and Alexey A. Popov*

The use of liquid inorganic chlorides as chlorinating agents for fullerenes resulted recently in the synthesis of several new chlorofullerenes. In addition to $C_{60}Cl_6$, which was obtained many years ago and investigated by ^{13}C NMR and IR spectroscopy,[1] four highly chlorinated [60]fullerenes, $C_{60}Cl_{24}$,[2] $C_{60}Cl_{28}$,[3] and two isomers of $C_{60}Cl_{30}$,[3,4] have been prepared and characterized by means of single-crystal X-ray crystallography and IR spectroscopy. The application of this method to the chlorination of C_{70} produced a highly chlorinated fullerene, $C_{70}Cl_{28}$, which, according to the single-crystal X-ray crystallographic study, comprised three isomers with similar structures.[5] Earlier, $C_{70}Cl_{10}$ was prepared by treating C_{70} with ICl in benzene; its addition pattern has been deduced from ^{13}C NMR spectroscopic analysis,[6a] substitution reactions,[6b] and theoretical modeling studies.[6c] Thus, the chlorination of the fullerenes under mild conditions results in "lower" chlorides, whereas the use of strong chlorinating agents at elevated temperatures produces "higher" chlorides of both [60]- and [70]fullerenes. These results raise the question as to whether "missing" intermediate chlorides could be obtained by variation of the reactants and/or reaction conditions.

Herein, we report the synthesis of such an intermediate chloride of [70]fullerene, $C_{70}Cl_{16}$, and its characterization by single-crystal X-ray crystallography, IR spectroscopy, and DFT calculations. Notably, the new fullerene chloride was obtained during an attempt to brominate C_{70} in $TiCl_4$. Typically, neat bromine (0.5 mL) was added to a solution of C_{70} (30 mg) in $TiCl_4$ (2.0 mL) in a glass ampoule. The ampoule was evacuated on cooling and sealed. A yellow crystalline precipitate formed after heating the mixture at 60–80 °C for 1–2 days. Work-up consisted of distilling off the bromine and excess $TiCl_4$ into a second section of the sealed ampoule by cooling it with liquid nitrogen. Alternatively, the ampoule was opened and the mixture was poured into 15% HCl. The yellow precipitate so formed was washed with dilute HCl and then water before removal by filtration and drying at 50 °C for

several hours. The product was stable in air for many months. Thermal decomposition occurs between 240 and 360 °C (a typical temperature range for fullerene chlorides[7]) with the evolution of chlorine and small amounts of bromine, as monitored by mass spectrometric analysis of the evolved gases.

The crystal-structure determination revealed the product had a composition of $C_{70}Cl_{16}\cdot 0.5\,Br_2$ (**1**).[8] The molecular structure of $C_{70}Cl_{16}$ shows a remarkable combination of a chlorine belt around the equator and a skew pyramidal chlorine cap at one of the poles (Figures 1 and 2). The same

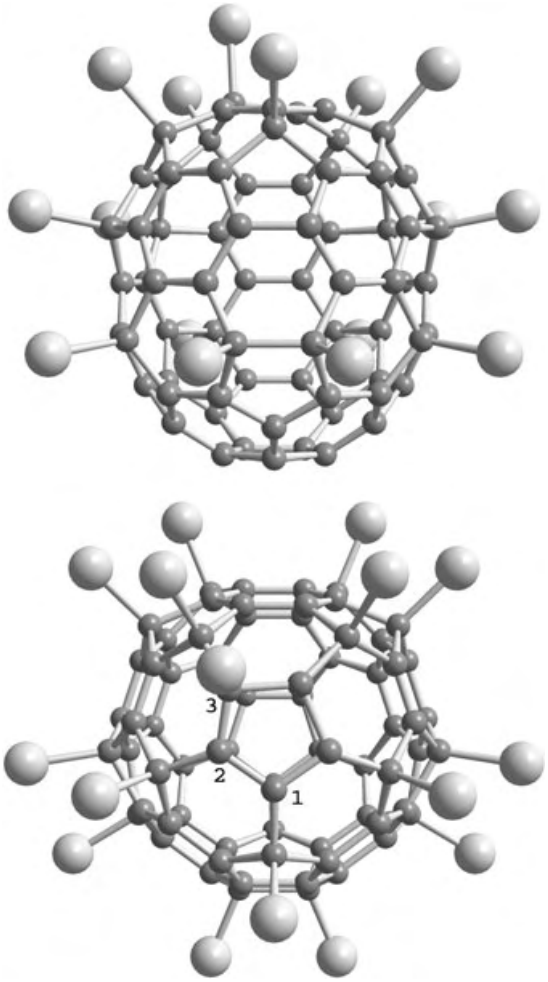

Figure 1. Side and top views of the C_1 isomer of $C_{70}Cl_{16}$.

belt of ten halogen atoms (Cl5–Cl9 in **1**) with nine 1,4 and one 1,2 X···X contacts is also present in $C_{70}Cl_{10}$[6] and $C_{70}Br_{10}$,[9] whereas a X_{10} belt without a 1,2 contact was reported recently for the $C_{70}(OO\mathit{t}Bu)_{10}$ derivative.[10] The combination of a skew pyramidal cap of six halogen atoms (Cl1–Cl4) with a cyclopentadiene fragment in the pentagon is characteristic of $C_{60}X_6$ structures with X being Cl[1] or Br.[11] A similar fragment was found in the $C_{70}(OO\mathit{t}Bu)_6$ derivative, but not on the top pentagon.[10] Both enantiomeric $C_{70}Cl_{16}$ molecules with C_1 symmetry are present in the crystal of **1**; their overlapping results in overall C_s symmetry with statistically disordered C3

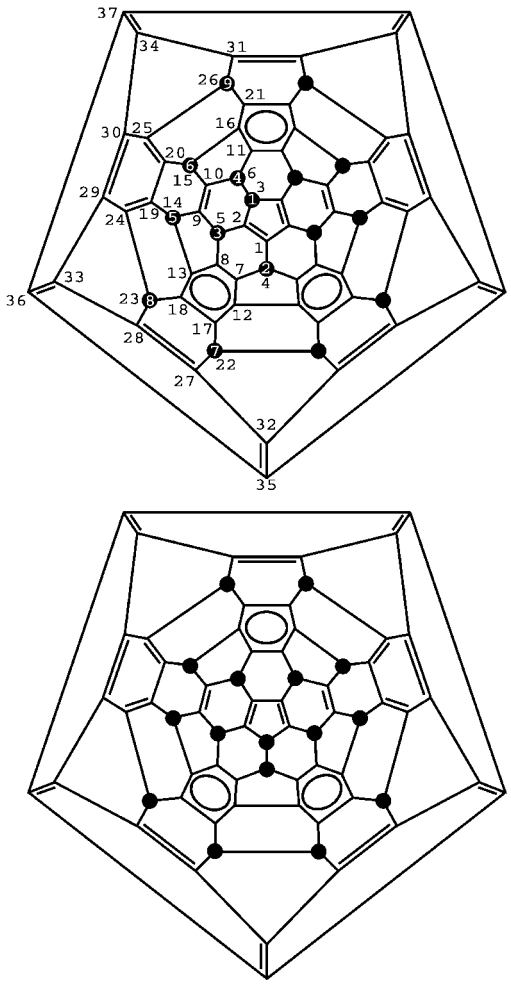

Figure 2. Schlegel diagrams for the experimentally observed C_1 (top) and C_s (bottom) isomers of $C_{70}Cl_{16}$ showing the labeling scheme for the independent C and Cl atoms. An alternative labeling with contiguous numbering for the whole molecules is given in the Supporting Information.

and Cl1 atoms. A comparison of the experimental and calculated[12] IR spectra demonstrates their close similarity (Figure 3), thus suggesting the high purity of $C_{70}Cl_{16}$ in compound **1**.

Another compound (**2**) obtained when the reaction was carried out with a larger amount of bromine had a composition of $C_{70}Cl_{16}\cdot 3\,Br_2$ according to the single-crystal X-ray analysis.[8] In spite of the poor crystal quality, the X-ray crystallographic study of **2** has unambiguously revealed the presence of two isomers of $C_{70}Cl_{16}$, namely, those with chlorinated positions at C1 (C_s) and C3 (C_1), in a ratio of approximately 3:4 (Figure 2). The IR spectrum of **2** was virtually identical to that of **1**.

Averaged experimental C–C bond lengths in **1** correspond satisfactorily to those calculated at the PBE/TZ2P level of theory.[12] The longest bond (C22–C22a) between sp^3 carbon atoms is 1.65 Å (calcd: 1.64 Å), while sp^2–sp^3 C–C bonds are shorter with an averaged value of 1.51 Å (calcd: 1.51 Å). Two independent six-membered isolated (C11-C16-C21-C21a-C16a-C11a) and nearly isolated (C7-C8-C13-C18-C17-C12)

aromatic rings are characterized by averaged C–C bond lengths of 1.39 Å (calcd: 1.40 Å). Finally, there are two isolated double C–C bonds with an average bond length of 1.34 Å (calcd: 1.34 Å). Bond lengths in the chlorinated cap region are distorted as a result of disorder in the crystal. The average C–Cl (Cl2–Cl9) bond has a length of 1.85 Å, whereas the apparent effective position of C3 (between two actual positions in each enantiomer) results in a strongly elongated C3···Cl1 distance (2.04 Å).

DFT calculations performed at the PBE/TZ2P level revealed that three isomers of $C_{70}Cl_{16}$ with different positions of the chlorinated carbon atoms in the cyclopentadiene ring on the cap are essentially isoenergetic with the relative energies of 0 (for C1), 2.8 (C3), and 7.6 kJ mol^{-1} (C2).[13] Alternative $C_{70}Cl_{16}$ structures with a cap of six chlorine atoms on the opposite pole of the cage were found to be 33–40 kJ mol^{-1} less favorable; this result may be attributed to the presence of only two benzenoid rings in their addition patterns compared to three such rings in the synthesized isomers.

It is known from our recent investigation of the bromination of [70]fullerene that even the use of liquid bromine does not result in the addition of more than ten Br atoms to the [70]fullerene cage.[9] Therefore, the formation of $C_{70}Cl_{16}$ can not be explained by two successive steps, such as bromination to give $C_{70}Br_{16}$ and halogen exchange. $TiCl_4$ itself can not chlorinate C_{70}; the solvate $C_{70}\cdot 2\,TiCl_4$ has been isolated from a solution of C_{70} in $TiCl_4$ and characterized by single-crystal X-ray crystallography.[14] Although the mechanism of the [70]fullerene chlorination by the mixture of Br_2 and $TiCl_4$ remains unclear, it can be assumed that the formation of the chloride higher than $C_{70}Cl_{10}$ results from the high Lewis acidity of $TiCl_4$. The formation of Br^+ or BrCl species in Br_2/Lewis acid systems is known to promote the electrophilic bromochlorination of olefins.[15] Clearly, $TiCl_4$ also participates in a Br/Cl exchange that results in the thermodynamically more stable chloride. The exclusive formation of chlorides as the reaction products is documented, for example, for the system $Br_2/SbCl_5$/norbornene.[16] However, bromination of C_{70} with Br_2 in molten $TiBr_4$ produced only $C_{70}Br_{10}$, possibly because of the absence of BrCl molecules in this system.

Alternatively, the reaction may proceed through a radical mechanism involving the addition of Br$^\bullet$ with subsequent Br/Cl exchange. In this case, the formation of $C_{70}Cl_{16}$ can be rationalized with a simple kinetic model,[17] when it is assumed that addition occurs in turn to the sites of maximum free valence in closed-shell molecules and of maximum spin density in the radicals; furthermore, 1,2-addition of a bulky addend (Br or Cl) is avoided unless it is necessary to quench the radical. This model successfully explains the formation of $C_{60}X_6$ and $C_{70}X_{10}$ isomers by the radical addition of bulky groups to C_{60} and C_{70}.[17] We have found by using bond orders from extended Hückel calculations that the most reactive site in $C_{70}X_{10}$ (X = Br or Cl) is C4. Further addition occurs in the sequence C5-C6-C5a-C6a until the radical $C_{70}X^{\cdot}_{15}$ is formed. The maximum spin density in $C_{70}X^{\cdot}_{15}$ is located on C1 (0.38), C3 (0.20), and C3a (0.20), whereas the spin density on the C2 and C2a sites is only 0.03. Thus, both energetic and kinetic considerations favor the experimentally observed isomers of $C_{70}Cl_{16}$.

In summary, the reaction between C_{70} and a $Br_2/TiCl_4$ mixture resulted in the isolation of the new chlorofullerene $C_{70}Cl_{16}$. X-ray crystallography elucidated the structure of two $C_{70}Cl_{16}$ isomers, which are the most stable according to theoretical calculations. Formation of these isomers was also rationalized from kinetic considerations based on the Hückel theory. This new reaction represents a promising synthetic approach for the preparation of chlorofullerenes with a level of addition that lies between that of the "lower" and "higher" fullerene chlorides.

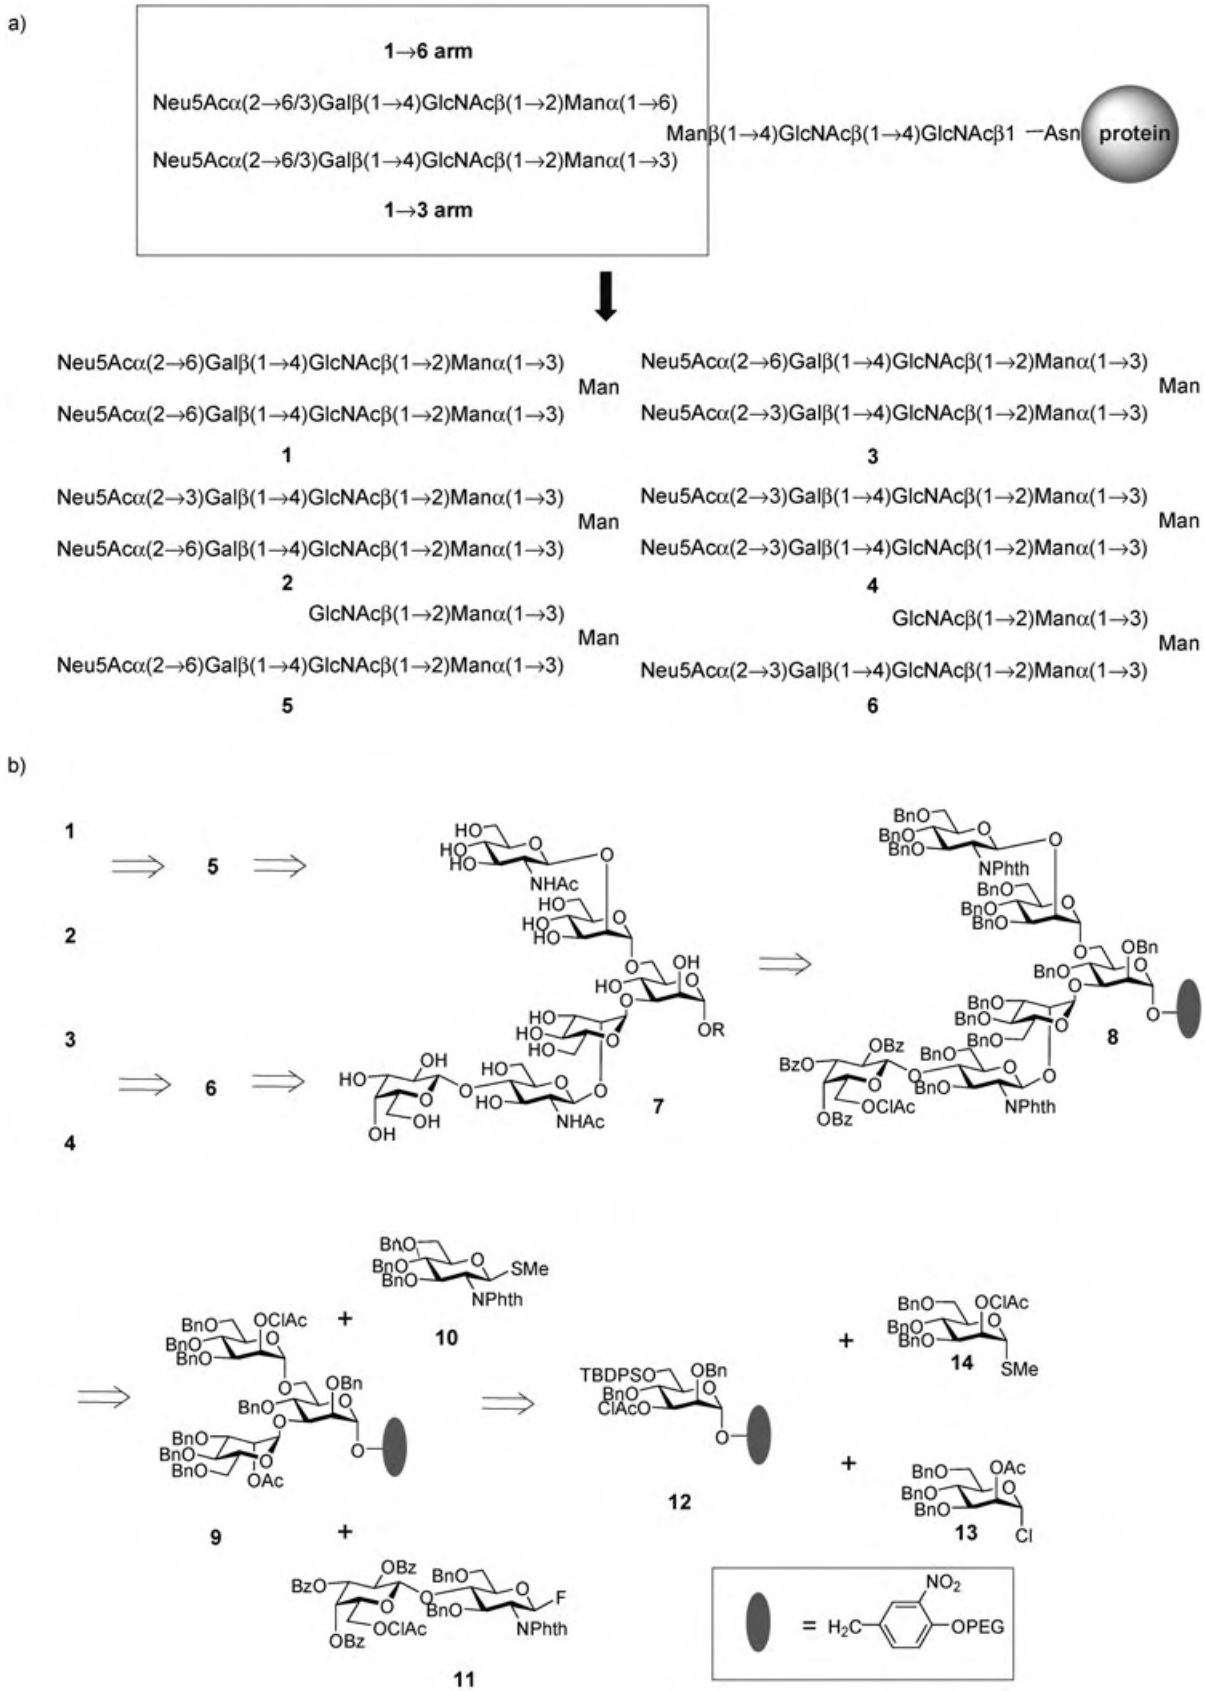
Carbohydrate Chemistry

Divergent Synthesis of Sialylated Glycan Chains: Combined Use of Polymer Support, Resin Capture–Release, and Chemoenzymatic Strategies**

*Shinya Hanashima, Shino Manabe, and Yukishige Ito**

As key constituents of cell-surface glycoproteins and glycosphingolipids, sialic acid containing glycan chains are involved in a variety of important physiological events such as cell–cell recognition, adhesion, and signal transduction.[1] It has been reported that the increased levels of sialic acid and sialyltransferase expression in tumor cells are closely related to their metastatic potential and malignancy progression.[2] Sialic acid residues of cell-surface glycoconjugates are also recognized by virulent proteins such as influenza virus hemagglutinins, which initiate the viral invasion into the host cell cytoplasm.[3] In cell-mediated immunity, the rolling of leukocytes is dependent on the levels of endothelial sialic acid.[4] Modulation of the recognition events exerted by sialylated glycans, therefore, seems promising for therapeutic purposes.[5]



Among the types of glycoprotein structures, asparagine-linked complex-type oligosaccharides (*N*-glycans) are most prominent[6] in terms of diversity as well as complexity. These *N*-glycans are often terminated with a sialic acid (Neu5Ac) residue attached to a penultimate galactose (Gal) moiety through an α(2,3) or α(2,6) linkage (Scheme 1 a). The synthesis of sialylated *N*-glycans has been reported by several groups.[7] Most notably, Unverzagt and co-workers developed chemoenzymatic routes to afford a variety of biantennary glycans.[7d,e,8] More recently, Kajihara and co-workers reported the systematic preparation of biantennary complex-type glycans and glycopeptides, starting from glycopeptides that are isolated from egg yolks as the common

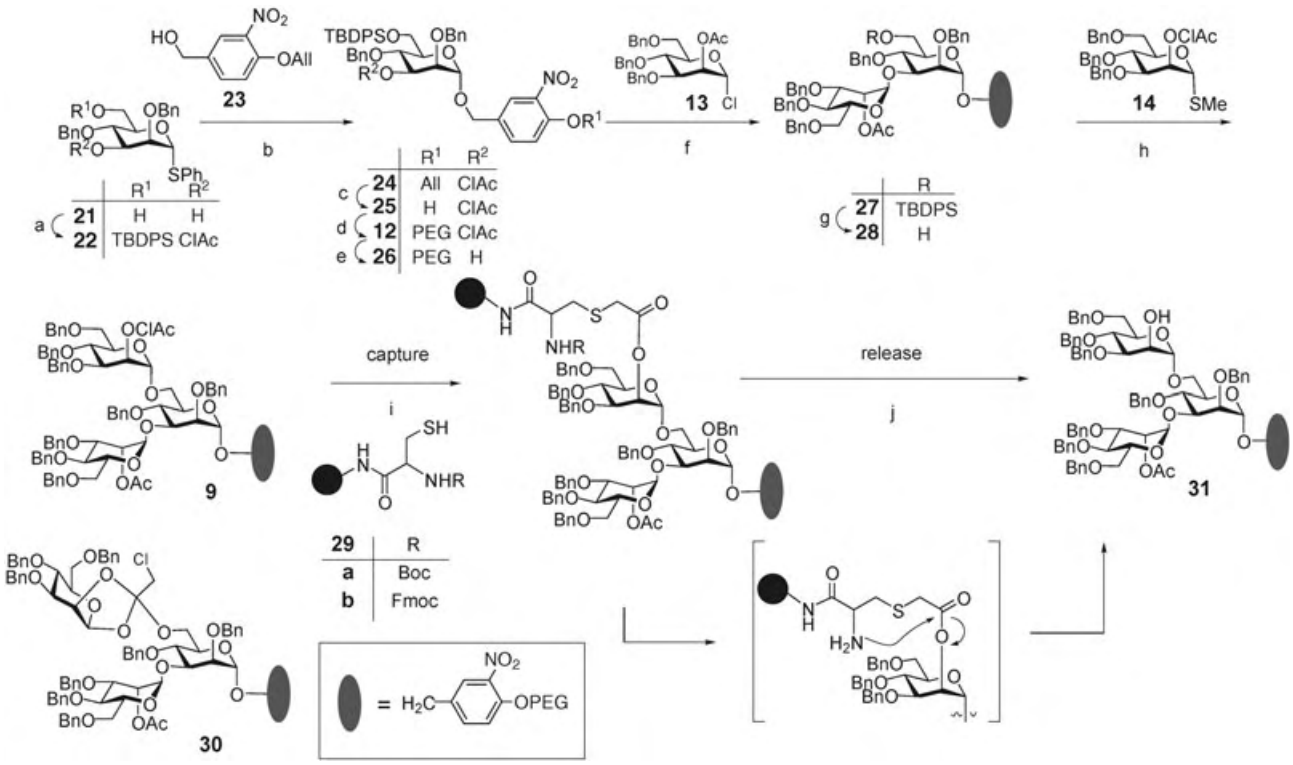
precursor.[9] In terms of chemical synthesis, the preparation of (2,6)-[7a] and (2,3)-linked disialylated *N*-glycans[7b] have been reported.

Polymer-supported synthesis is considered to be a promising technology that should facilitate, and ultimately automate, the synthesis of oligosaccharides. To date, however, there are only a few reported syntheses of branched complex structures such as sialylated *N*-glycans.[10] As part of our efforts to develop methodologies for the efficient construction of glycan chains based on soluble polymer-support technology,[11] we set out to synthesize disialylated compounds **1**–**4** as well as monosialylated saccharides **5** and **6** in a divergent manner. Low molecular weight (average $M_W \approx 750$) monomethyl polyethylene glycol (PEG) was chosen as the polymer support. For purification, the PEG-supported product can be adsorbed on silica gel, washed to remove the non-PEG supported materials (e.g. excess donor), and then retrieved by elution with polar solvents.[11e] With a unique resin capture–release purification, which uses a chloroacetyl group as the purification handle, fully assembled oligomers can be distinguished from shorter products. A nitro-modified Wang-resin-type linker, which has been shown to endure most of the typical glycosylation conditions,[12] was used.

The synthetic plan for the preparation of target glycans **1**–**6** is depicted in Scheme 1b. With hexasaccharide **7** as the common precursor, the scheme involves the use of glycosyltransferases to introduce the terminal Neu5Ac residues and penultimate Gal of the (1,6) branch. An initial glycosylation with either (2,6)- or (2,3)-sialyltransferase should provide monosialylated heptasaccharide **5** or **6**, which can then serve as substrates of sequential galactosylation–sialylation to afford **1**–**4**. Thus, simply by changing the type of glycosyltransferase, all positional isomers of $Neu5Ac_2Gal_2GlcNAc_2$-Man_3, **1** (2,6/2,6), **2** (2,3/2,6), **3** (2,6/2,3), and **4** (2,3/2,3), as well as monosialylated **5** and **6**, can be prepared from the single precursor **7**. Compound **8** was designed as a protected hexasaccharide that would be assembled from Man_3 **9**, GlcNAc **10**, and LacNAc **11** derivatives.

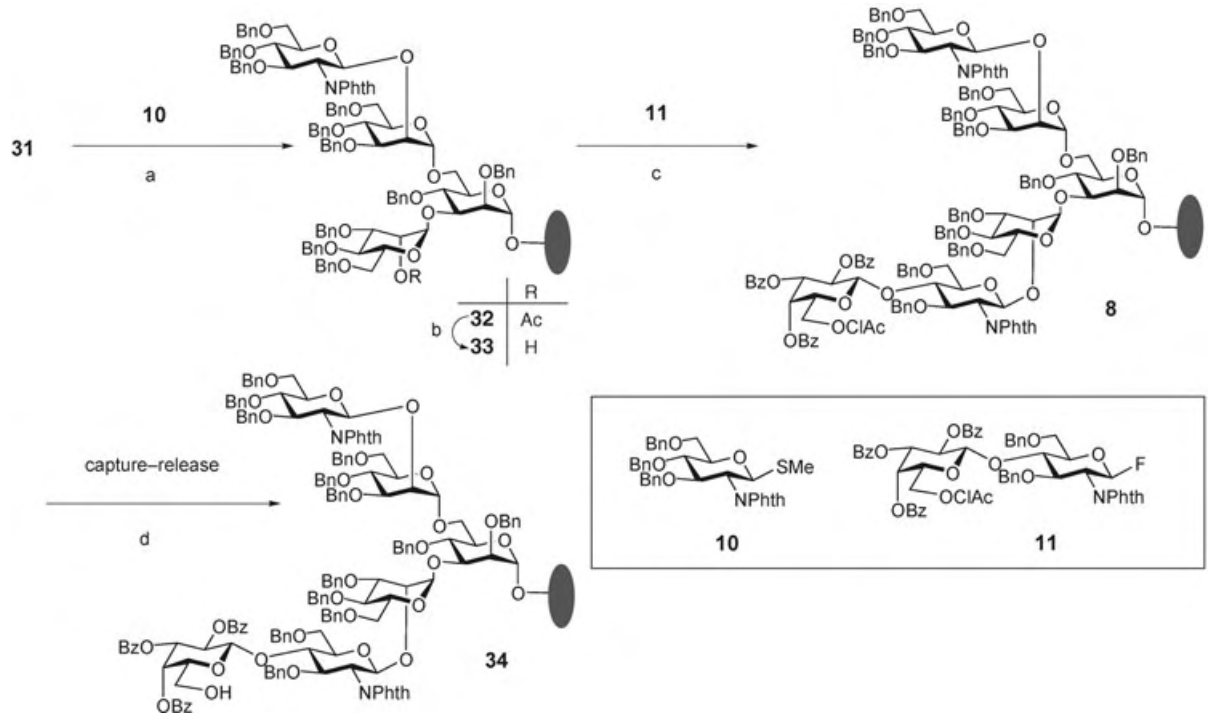
As shown in Scheme 2, lactosamine fluoride **11** was prepared from galactosyl donor **15**[13] and glucosamine component **19**.[14] Removal of the trityl group of **15** afforded **16**, which was reprotected with a chloroacetyl (ClAc) group to give **17**. Conversion of the phenylthio group to fluoride was carried out by using *N*-bromosuccinimide (NBS) and diethylaminosulfur trifluoride (DAST)[15] to afford **18** in nearly quantitative yield ($\alpha/\beta = 46{:}54$). Coupling with **19** was then conducted through activation with $[Cp_2HfCl_2]$ and AgOTf[16] in toluene to afford **20**, which was then converted into fluoride **11**.

The synthesis of the trimannose core is depicted in Scheme 3. Phenylthiomannoside **21**[17] was silylated and chloroacetylated to give **22** in 93% yield. The nitro-modified Wang-resin-type linker was introduced with **23**[18] under activation with *N*-iodosuccinimide (NIS) and triflic acid (TfOH),[19] to afford **24** in 92% yield. Removal of the allyl group afforded phenol **25**, to which PEG was introduced under standard Mitsunobu conditions to provide **12**. Following the selective deprotection with hydrazinedithiocarbonate (HDTC),[20] the resultant **26** was glycosylated sequentially



Scheme 2. Reagents and conditions: a) TFA, Et_3SiH, CH_2Cl_2, −40 °C, 96%; b) $(ClAc)_2O$, pyridine, CH_2Cl_2, 96%; c) NBS, DAST, CH_2Cl_2, 98%; d) AgOTf, $[Cp_2HfCl_2]$, molecular sieves (4 Å), toluene, 45 °C, 85%; e) NBS, DAST, CH_2Cl_2, 84%. TFA = trifluoroacetic acid, Cp = cyclopentadienyl.

with 2-*O*-Ac- and 2-*O*-ClAc-protected donors **13** and **14**. The initial glycosylation with chloride **13**[21] proceeded smoothly under standard conditions to afford disaccharide **27** with excellent purity in 98% yield,[22] then desilylation produced **28**. Subsequent glycosylation with methylthiomannoside **14**,[11d] when conducted through activation with NIS and TMSOTf (0.2–0.4 equiv) in CH_2Cl_2 (−20 °C), gave a mixture of the desired product **9** [$\delta_H = 5.18$ (d, $J = 1.7$ Hz), 4.99 ppm (d, $J = 1.7$ Hz)] and the corresponding orthoester **30** [$\delta_H =$ 5.25 (d, $J = 2.4$ Hz), 5.19 ppm (s)] in variable ratios (1:5–1:0.7). In contrast, the use of a stoichiometric amount of TfOH with NIS at low temperatures drastically suppressed formation of the orthoester and provided **9** as the major product. Capture–release purification was then carried out by using Merrifield resin loaded with *N*-protected (Boc or Fmoc) Cys (**29a**,**b**)[11d] in the presence of excess iPr_2NEt to specifically capture **9**. We found that Boc-protected **29a** was more expedient than the Fmoc-protected **29b** for the chemoselective reaction. Notably, orthoester **30** did not react under these conditions and remained in the solution phase, along with unreacted **9**. Removal of the Boc group was carried out with 10% TFA in CH_2Cl_2. Treatment with 10% piperidine in THF initiated the cyclo-release to afford product **31** (60% overall yield from **12**).



The construction of hexasaccharide **8** is shown in Scheme 4. For the elongation of the α(1,6) branch, thioglycoside **10**[23] was used as the donor to afford **32**,[22] which was deacetylated to give **33**. Reaction with LacNAc donor **11** with $[Cp_2HfCl_2]$ and AgOTf gave hexasaccharide **8** in 92% yield, which was subjected to the same capture–release purification used for **31** to afford **34** in 81% yield (from **31**).

Cleavage from the linker and global deprotection are depicted in Scheme 5. After acetylation of **34**, the nitro group was reduced to an amine function by using $Mo(CO)_6$.[24]

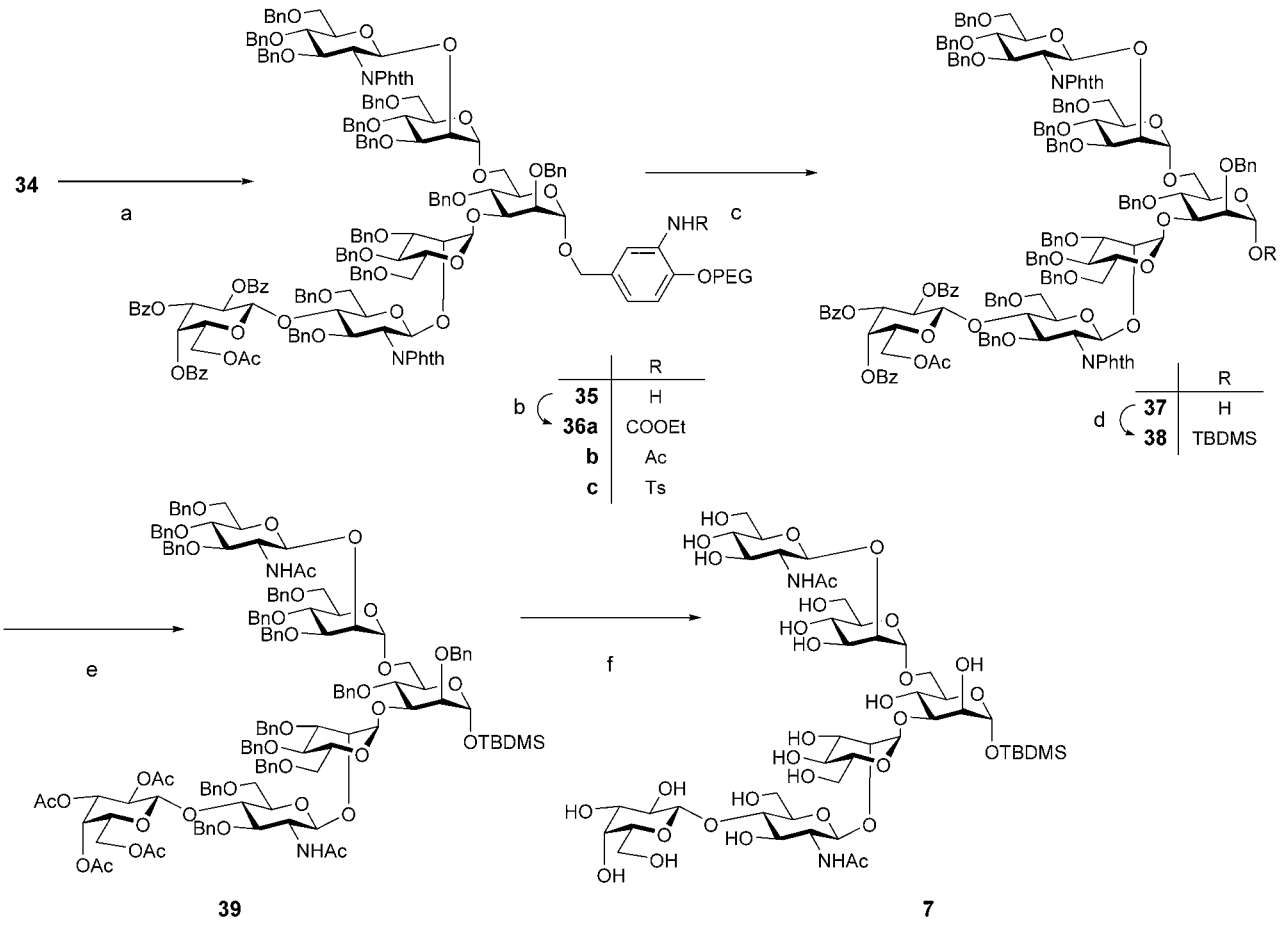
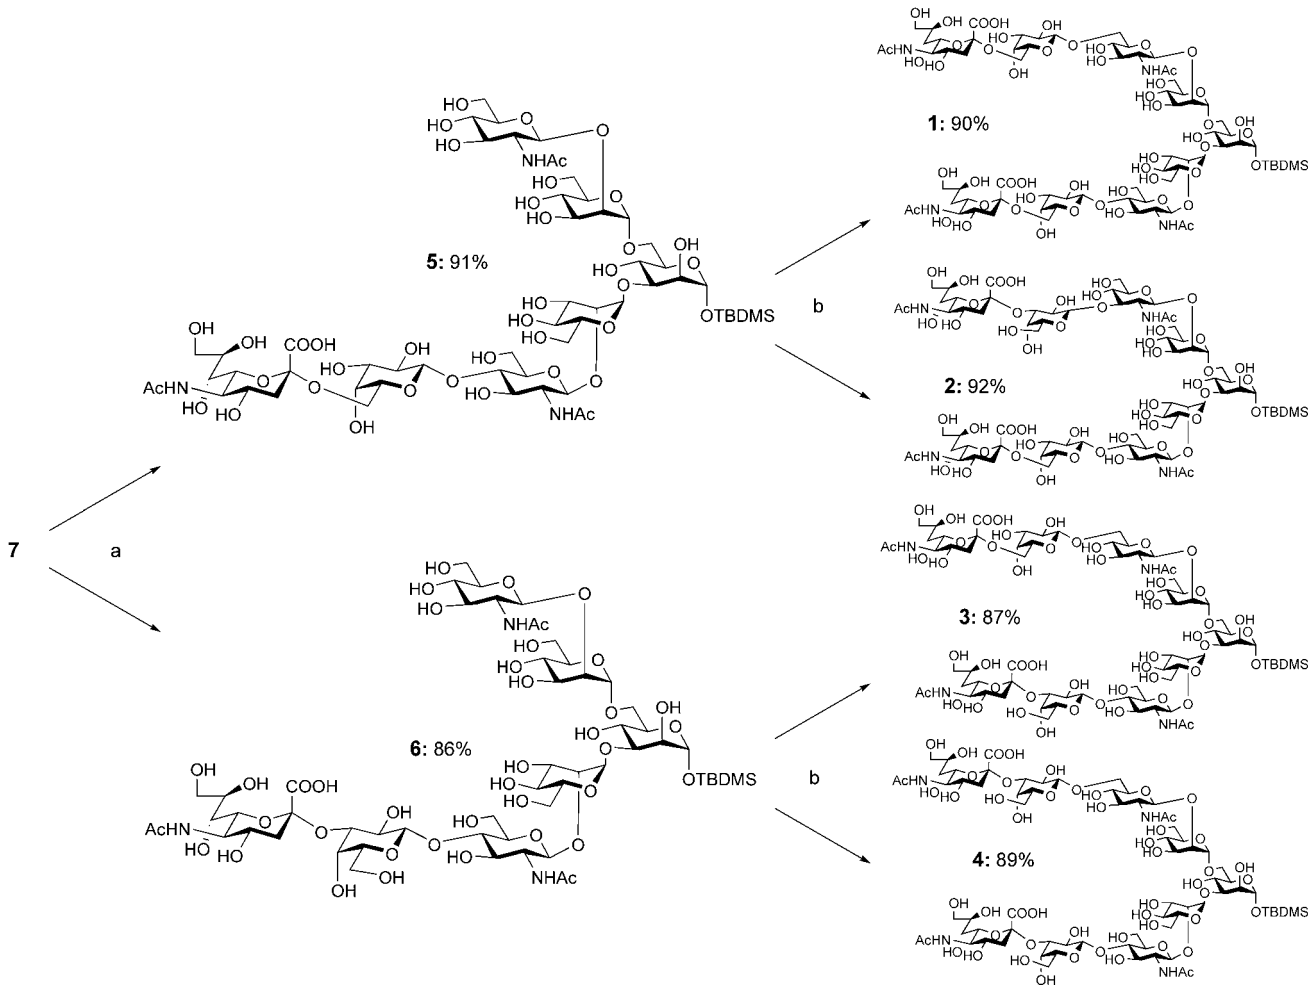


Scheme 3. Reagents and conditions: a) 1) TBDPSCl, DMAP, Et_3N, DMF; 2) $(ClAc)_2O$, pyridine, CH_2Cl_2, 93%; b) NIS, TfOH, molecular sieves (4 Å), CH_2Cl_2, 4°C, 92%; c) $[Pd(PPh_3)_4]$, Et_3SiH, AcOH, toluene, 98%; d) HO-PEG-OMe, DEAD, Ph_3P, THF, 94%; e) HDTC (0.42 M), CH_3CN, 98%; f) **13**, AgOTf, CH_2Cl_2, molecular sieves (4 Å), −20→0°C, 98%; g) HF-pyridine, THF, 98%; h) **14**, NIS, TfOH, molecular sieves (4 Å), −40°C, 94%; i) iPr_2NEt, CH_3CN/CH_2Cl_2; j) 1) 10% TFA in CH_2Cl_2, 2) 10% piperidine, THF, 60% from **12**. All = allyl, DEAD = diethyl azodicarboxylate, DMAP = 4-(*N*,*N*-dimethylamino)pyridine, DMF = dimethylformamide.

Scheme 4. Reagents and conditions: a) **10**, NIS, TfOH, molecular sieves (4 Å), CH_2Cl_2, −10→0°C, 92%; b) NaOMe (0.05 M) in MeOH/THF, 96%; c) **11**, AgOTf, $[Cp_2HfCl_2]$, toluene, molecular sieves (4 Å), −20→0°C, 92%; d) 1) **29**, iPr_2NEt, DMF, 80°C, 2) TFA (10%) in CH_2Cl_2, 3) piperidine (10%) in THF, 88% from **31**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 5. Reagents and conditions: a) 1) Ac_2O, pyridine, 2) $Mo(CO)_6$, EtOH, dichloroethane; b) EtOCOCl, iPr_2NEt, CH_2Cl_2; c) TFA (15%) in CH_2Cl_2, 88%; d) BTBSA, TBAF (0.05 equiv) in THF-NMP; e) 1) ethylenediamine, *n*BuOH, 95°C; 2) Ac_2O, pyridine, 56%; f) 1) NaOMe (0.05 M) in MeOH, 93%; 2) $Pd(OH)_2/C$ (20%), MeOH, H_2O, 92%. Ts = tosyl.

Amine **35** was then converted into ethyl carbamate **36a**, then treated with 15% TFA in CH_2Cl_2 to give **37** in 88% yield (from **34**). Interestingly, the corresponding acetyl **36b** and tosyl **36c** derivatives were more resistant to cleavage under these conditions. The liberated hydroxy group was protected as a *tert*-butyldimethylsilyl (TBDMS) ether with *N*,*O*-bis(*tert*-butyldimethylsilyl)acetamide (BTBSA) and a catalytic amount of tetrabutylammonium fluoride (TBAF)[25] in *N*-methylpyrrolidinone (NMP) to yield **38**. Following conversion of the phthalimide **38** to the acetamide **39**, the acetyl and benzyl groups were removed to afford **7**.

As several types of sialyltransferases are commercially available, and chemical sialylation is technically demanding, enzymatic glycosylation is an attractive strategy for the preparation of oligosaccharides that contain sialic acids.[26] Hexasaccharide **7** possesses a terminal LacNAc residue, which is an excellent substrate for sialyltransferases. In fact, **7** was smoothly converted into **5** and **6** with α(2,6)-*N*-sialyltransferase (EC 2.4.99.1, Toyobo) and α(2,3)-*N*-sialyltransferase (EC 2.4.99.5, Calbiochem), respectively, then subjected to sequential galactosylation/sialylation[27] to afford **1**–**4** (Scheme 6). As an example, heptasaccharide **5** was treated with β(1,4)-galactosyltransferase (EC 2.4.1.22, Toyobo) and UDP-galactose in $MnCl_2$ containing a cacodylate buffer; upon completion of the galactose transfer, α(2,6)- or α(2,3)-sialyltransferase and CMP-Neu5Ac were added to the reaction mixture to give nonasaccharides **1** and **2** in quantitative yields (CMP = cytidine-5′-monophosphoryl). Similarly, heptasaccharide **6** was used to afford nonasaccharides **3** and **4** in high yields. During the enzymatic transformations, the TBDMS group served as a hydrophobic tag that allowed product isolation by using reversed-phase solid-phase extraction cartridges.[28]

In summary, the α(2,3)- or α(2,6)-sialylated biantennary glycans **1**–**6**, which correspond to the branched portions of typical complex-type *N*-glycans, were systematically synthesized with a polymer–resin hybrid strategy and enzymatic glycosylation. By using low molecular weight (average $M_W \approx 750$) monomethyl polyethylene glycol as the polymer support, the purification procedures were simple and involved only loading on silica gel, washing to remove the non-PEG-supported materials (e.g. excess donor), then eluting with polar solvents. Introduction of sialic acid on the nonreducing ends, and of the penultimate galactose moiety on the (1,6) branch was successful with commercially available glycosyltransferases and the appropriate sugar nucleotides. The common precursor **7** was synthesized by using a soluble polymer support strategy, in which Merrifield resin loaded

Scheme 6. Enzymatic transformations of **7** to **1**–**6**: a) α2,6- or α2,3-sialyltransferase, CMP-Neu5Ac, alkaline phosphatase, BSA, cacodylate buffer (50 mM); b) 1) β1,4-galactosyltransferase, UDP-galactose, BSA, alkaline phosphatase, $MnCl_2$, cacodylate buffer (50 mM); 2) α2,6- or α2,3-sialyltransferase, CMP-Neu5Ac. UDP = uridine diphosphate.

with Boc-Cys was used for the capture–release protocol to facilitate product purification. Hexasaccharide **7** was diverged to monosialylated **5** and **6** and disialylated **1**–**4** saccharides by enzymatic glycosylation with α(2,3)- or α(2,6)-sialyltransferase and β(1,4)-galactosyltransferase.

Asymmetric Catalysis

Rhodium-Catalyzed Asymmetric 1,6-Addition of Aryl Zinc Reagents to Dienones**

Tamio Hayashi, Shohei Yamamoto, and Norihito Tokunaga*

The catalytic asymmetric 1,4-addition of organometallic reagents to electron-deficient olefins is one of the most important methods of forming stereogenic centers in carbon–carbon bond-forming reactions.[1] In this field, attention has focused on asymmetric 1,4-additions catalyzed by copper,[2,3] rhodium,[4–8] palladium,[9] and nickel[10] complexes. On the other hand, asymmetric 1,6-addition to extended conjugate systems has developed less rapidly.[11] Although several reports have appeared on diastereoselective 1,6-additions,[12] the use of a chiral catalyst for this asymmetric transformation remains to be studied. Herein, we report the first example of a catalytic asymmetric 1,6-addition to 2,4-dien-1-ones, in which a stereogenic center at the C5 position is also formed; this reaction is realized by a rhodium-catalyzed addition of aryl zinc reagents to dienones in the presence of chlorotrimethylsilane.

To investigate conjugate addition to 3-((*E*)-hexenyl)-2-cyclohexenone (**1**), several phenyl organometallic reagents that had been successfully used in rhodium-catalyzed asymmetric 1,4-addition reactions to electron-deficient alkenes[4–7] were examined for their reactivity and selectivity (Scheme 1 and Table 1). When the reaction was carried out with phenylboronic acid under reaction conditions that have been shown to be very efficient for asymmetric 1,4-additions

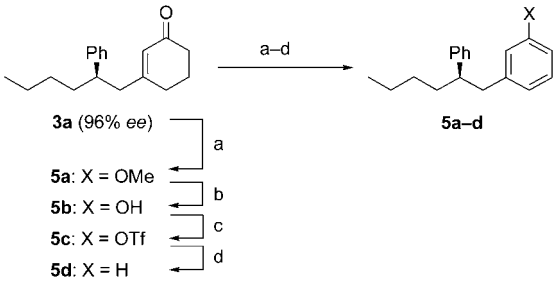
Table 1: Rhodium-catalyzed asymmetric 1,6-addition to **1** forming products **3a–e**.[a]

Entry	PhM (equiv)	Conditions[b]	Yield [%][c]	*ee* [%][d]
1	$PhB(OH)_2$ (2.5)	A	0[e]	–
2	$PhTi(OiPr)_3$ (1.6)	B	0[f]	–
3	$PhTi(OiPr)_4Li/Me_3SiCl$ (1.5/2.0)	C	78 (**3a**)	88
4	PhZnCl[g] (1.4)	D	18 (**3a**)	96
5	$PhZnCl$[g]$/Me_3SiCl$ (1.4/1.5)	D	99 (**3a**)	96
6	$PhZnX$[h]$/Me_3SiCl$ (1.4/1.5)	D	94 (**3a**)	94
7	$4\text{-}FC_6H_4ZnX$[h]$/Me_3SiCl$ (1.4/1.5)	D	90 (**3b**)	98
8	$4\text{-}MeOC_6H_4ZnCl$[g]$/Me_3SiCl$ (1.4/1.5)	D	94 (**3c**)	91
9	$3\text{-}MeOC_6H_4ZnCl$[h]$/Me_3SiCl$ (1.4/1.5)	D	86 (**3d**)	86
10	2-naphthylZnCl[h]$/Me_3SiCl$ (1.4/1.5)	D	85 (**3e**)	91

[a] The reactions were carried out with 0.30 mmol of **1** in the presence of 3 mol% of the rhodium catalyst. [b] Conditions A: [{Rh(OH)[(*S*)-binap]}$_2$], dioxane/H_2O (10:1), 50°C, 3 h. Conditions B: [{Rh(OH)[(*S*)-binap]}$_2$], THF, 30°C, 1 h; hydrolysis with dilute HCl. Conditions C: [{RhCl[(*S*)-binap]}$_2$], THF, 20°C, 0.5 h; hydrolysis with dilute HCl. Conditions D: [{RhCl[(*S*)-binap]}$_2$], THF, 20°C, 2 h; hydrolysis with dilute HCl. [c] Yield of product isolated by column chromatography on silica gel (hexane/ethyl acetate, 4:1). [d] Determined by HPLC analysis with a chiral stationary-phase column (chiralpak OJ: hexane/2-propanol, 95:5); *ee* value for *R* enantiomer. [e] Dienone **1** was recovered. [f] A 1,2-addition product **2** was formed in 70% yield. [g] Generated from ArLi and $ZnCl_2$. [h] Generated from ArMgBr and $ZnCl_2$.

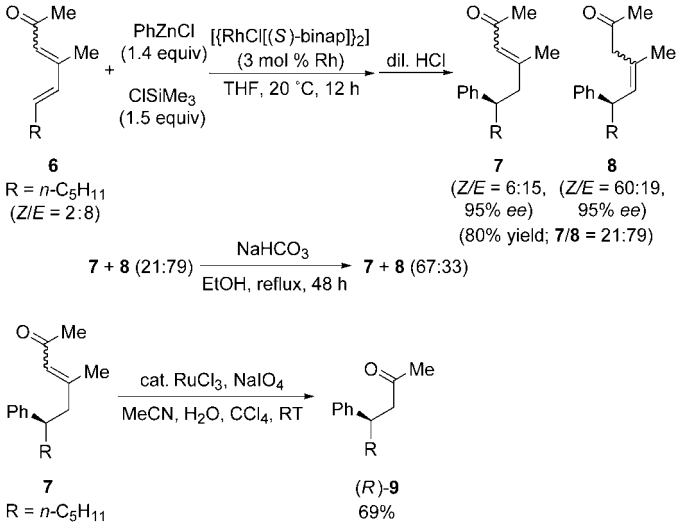
(3 mol% (Rh) of [{Rh(OH)[(*S*)-binap]}$_2$] (binap = 2,2′-bis-(diphenylphosphanyl)-1,1′-binaphthyl) as the catalyst in dioxane/H_2O (10:1) at 50°C for 3 h),[5b] the starting dienone **1** was recovered quantitatively (Table 1, entry 1). The use of the phenyltitanium reagent $PhTi(OiPr)_3$ in the presence of [{Rh(OH)[(*S*)-binap]}$_2$] in THF at 30°C, which gives titanium enolates as 1,4-addition products with high enantioselectivities from α,β-unsaturated ketones,[6a] does not react in the same way with the present substrate **1**. Instead, titanium reagent reacted to give the tertiary alcohol **2** (70% yield; Table 1, entry 2) by a noncatalyzed 1,2-addition. The lithium titanate reagent $PhTi(OiPr)_4Li$ (1.5 equiv), used in the presence of chlorotrimethylsilane (2.0 equiv) and [{RhCl[(*S*)-binap]}$_2$] (3 mol% Rh) in THF at 20°C, proved more promising.[6c] The 1,6-addition product (*R*)-3-(2-phenylhexyl)-2-cyclohexenone (**3a**) was afforded after acidic hydrolysis in 78% yield and with 88% *ee* (Table 1, entry 3). The zinc reagent PhZnCl (1.4 equiv), which has been recently found to be more efficient than boron or titanium reagents in rhodium-catalyzed asymmetric 1,4-addition reactions to enones,[7] gave the 1,6-addition product **3a** with higher enantioselectivity (96% *ee* (*R*)), although its yield was as low as 18% (Table 1, entry 4).



We have found, therefore, that chlorotrimethylsilane greatly accelerates[13] the rhodium-catalyzed 1,6-addition of aryl zinc reagents to dienone **1**. Thus, **1** was treated with PhZnCl (1.4 equiv; generated from PhLi and $ZnCl_2$ in THF) in the presence of chlorotrimethylsilane (1.5 equiv) and [{RhCl[(*S*)-binap]}$_2$] (3 mol% Rh) in THF at 20°C for 2 h, and the phenylation product (*R*)-**3a** was obtained in a quantitative yield with 96% *ee* after acidic hydrolysis (Scheme 2; Table 1, entry 5). The 1,6-addition product before hydrolysis was a 1,3-dienyl silyl ether **4** (*Z*/*E* = 4:1). The high yield of the addition product may be ascribed to the

Scheme 2. Rhodium-catalyzed asymmetric 1,6-addition of ArZnCl to dienone **1** in the presence of Me_3SiCl.

activation of **1** by the chlorosilane acting as a Lewis acid,[13] which accelerates the addition of **1** to a phenylrhodium species in the catalytic cycle (see below). The asymmetric addition of aryl zinc reagents generated from $4\text{-}FC_6H_4MgBr$, $4\text{-}MeOC_6H_4Li$, $3\text{-}MeOC_6H_4MgBr$, and 2-naphthylMgBr also gave the corresponding 1,6-addition products **3b–e**, respectively, in high yields and with high enantioselectivities (Table 1, entries 7–10). The formation of any 1,4- or 1,2-addition products was not detected in the reaction of **1** under the current conditions.



The absolute configuration of the 1,6-addition product **3a** was determined to be *R* after its conversion into (*R*)-1,2-diphenylhexane[14] (**5d**). The key step in the synthetic pathway to **5d** is the oxidation of the cyclohexenone moiety in **3a** into the methoxyphenyl group in **5a** (Scheme 3).[15]

Scheme 3. Determination of the absolute configuration of the 1,6-addition product **3a**. a) I_2, MeOH, reflux (99%); b) BBr_3, CH_2Cl_2, room temperature (90%); c) Tf_2O, pyridine, $ClCH_2CH_2Cl$, room temperature (99%); d) H_2, Pd/C, EtOH, $EtN(iPr)_2$, room temperature (86%). Tf = trifluoromethanesulfonyl.

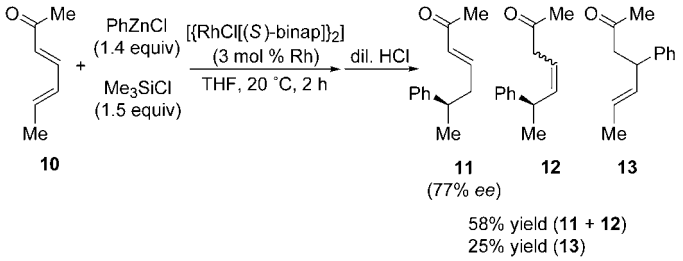
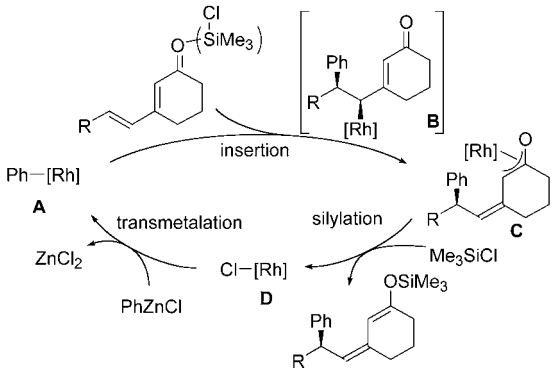
The treatment of the linear dienone 4-methylundeca-3,5-dien-2-one (**6**) with PhZnCl and chlorotrimethylsilane in the presence of the Rh/(*S*)-binap (3 mol% Rh) catalytic system also proceeded with perfect 1,6-selectivity to give the phenylation product in high yield (Scheme 4). Hydrolysis with



Scheme 4. Rhodium-catalyzed asymmetric 1,6-addition of PhZnCl to dienone **6** in the presence of Me_3SiCl.

hydrochloric acid afforded α,β-unsaturated ketone **7** and β,γ-unsaturated ketone **8** as a mixture of olefinic isomers in a ratio of 21:79. Treatment of the mixture with sodium bicarbonate in ethanol at reflux for 48 h shifted the ratio of **7**/**8** to 67:33. Both **7** and **8** were found to be *R* enantiomers in 95% *ee*. The configuration was determined by correlation with (*R*)-3-phenylnonen-2-one[5a] ((*R*)-**9**), which was obtained by oxidative cleavage of the double bond in **7**.

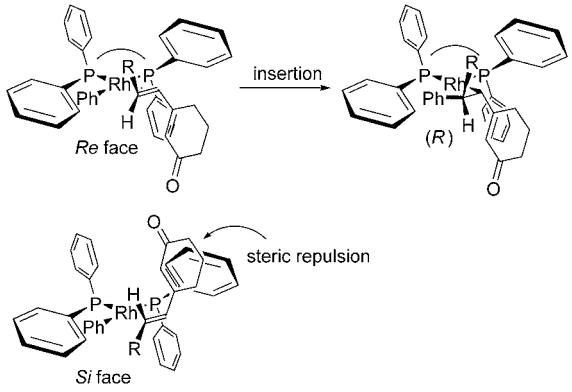


The selectivity of the 1,6-addition was not as high in the reaction of hepta-3,5-dien-2-one (**10**); the 1,4-addition product was formed as a by-product because **10** lacks a substituent at the β position. Thus, the addition of PhZnCl to **10** in the presence of chlorotrimethylsilane under similar conditions gave the 1,6-addition products **11** (77% *ee*) and **12** in a combined yield of 58% together with the 1,4-addition product **13** in 25% yield (Scheme 5).

The catalytic cycle proposed for the rhodium-catalyzed 1,4-addition of aryl titanates in the presence of chlorotrimethylsilane[6c] can be applied to the 1,6-addition of aryl zinc

Scheme 5. Rhodium-catalyzed asymmetric addition of PhZnCl to dienone **10** in the presence of Me_3SiCl.

reagents (Scheme 6), as this mechanism involves the reaction of an oxo-π-allyl rhodium intermediate with chlorosilane to afford a chlororhodium complex and a silyl enolate as the product. With a dienone as the substrate, insertion of its γ,δ-double bond into the phenyl–rhodium bond in **A** is slow



Scheme 6. The catalytic cycle for the rhodium-catalyzed 1,6-addition reaction. [Rh] = [Rh{(*S*)-binap}].

compared with the insertion of the α,β-double bond of an α,β-unsaturated ketone; therefore, insertion of the dienone γ,δ-double bond takes place more smoothly with the assistance of a chlorosilane as a Lewis acid. An alkyl rhodium intermediate **B** is formed by the insertion reaction and undergoes isomerization to a thermodynamically stable oxo-π-allyl rhodium complex **C**. A silylation reaction of **C** with chlorotrimethylsilane yields a chlororhodium species **D** and a silyl dienyl ether as the 1,6-addition product. Transmetalation between **D** and PhZnCl regenerates the phenylrhodium species **A**.

The absolute configuration *R* of the 1,6-addition product **3**, obtained with (*S*)-binap as a chiral ligand, was rationalized by using the stereochemical pathway shown in Scheme 7. At the insertion step, coordination of the γ,δ-double bond at the *Re* face is more favorable than coordination at the *Si* face because of the steric repulsions between one of the phenyl rings of the binap ligand and the cyclohexene moiety.

In summary, catalytic asymmetric 1,6-additions to 2,4-dien-1-ones has been realized with up to 98% *ee* using a chiral

Molecular Devices

Self-Assembled Monolayers of Isocyanides on Nickel Electrodes**

*Youngu Lee, Gustavo M. Morales, and Luping Yu**

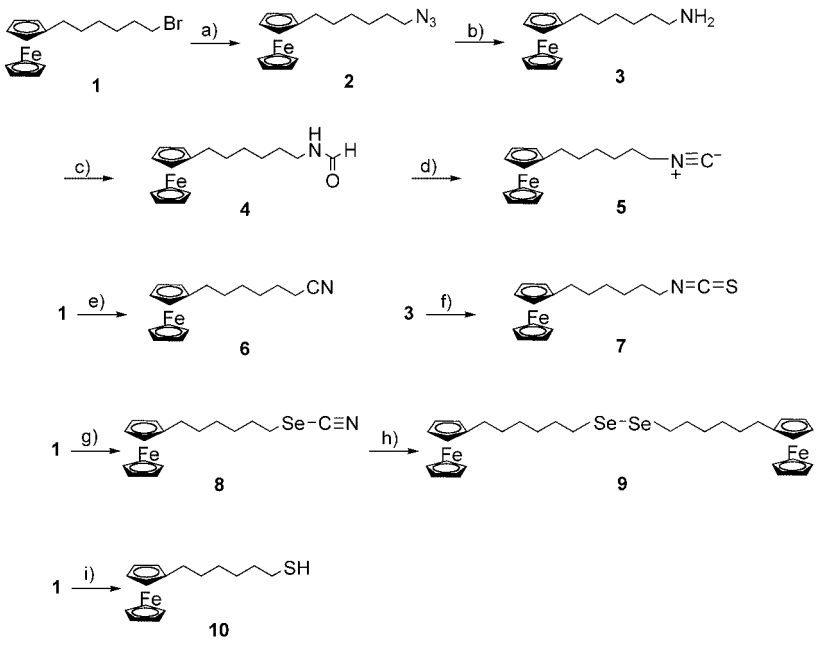
Self-assembled monolayers (SAMs) of thiols on Au(111) surfaces have been examined extensively in recent years as a platform for surface science. They have been used in a number of applications in the areas of molecular electronics and surface-property modulation.[1] In molecular electronics, SAMs of thiol on a gold substrate have been particularly useful in controlling the placement and orientation of molecular electronic components such as wires, diodes, switches, and memories. In the design of molecular electronic components, appropriate interfaces between molecules and electrodes are as crucial as the active organic molecules. To be useful, these interfaces should possess low impedance and high stability. The mismatch between the Fermi level of the electrodes and either the HOMO or LUMO level of the adsorbent molecule generally induces a contact barrier which is the source of contact impedances.[2] So far, the thiol–gold linkage has been mainly considered for composing molecular electronic devices. Gold has an advantage over other surfaces for SAM formation because of its intrinsic inertness in air and high conductivity. However, there are still several limitations of gold surfaces as the electrode for practical molecular electronic applications. Theoretical calculations predicted that the combination of sulfur and gold yields one of the highest contact barriers for charge transport.[3] It is also well-known that SAMs of thiols on gold are thermally unstable.[4] Furthermore, the stochastic behavior of thiols on gold electrodes that results from the breakage of the adsorbent molecule–metal contact have also been observed.[5] The high diffusion mobility of gold atoms makes them less attractive for practical applications because of the limited lifetime of the devices.[6] Therefore, it is meaningful to develop a new combination of chemical linkage groups—alligator clips—and metal electrodes.

Current semiconductor technology employs nickel, tungsten, and their silicon alloys as electrodes for microelectronic devices. In addition, the ferromagnetic character of Ni presents the possibility of expanding the application of such electrodes to spintronic devices.[7] Although there are various reports about the thiol–nickel interaction,[8] the thiol–nickel junction is not as good as the thiol–gold junction for molecular electronic applications. Therefore, it is necessary to develop new alligator clips for Ni substrates. According to theoretical calculations, the isocyanide–nickel junction has significant advantages over the thiol–gold junction and others because of its low charge-transport barriers.[3] There have been several examples of SAMs generated from isocyanides on Au,[9] Pt,[10] Pd,[11] Ag,[9b,12] and Cr.[13] However, the isocyanide–nickel interaction has not yet been explored except for vacuum-evaporated methyl isocyanide (CH_3NC) on Ni(100) and Ni(111) surfaces.[14]

Herein, we report the synthesis of ferrocenylalkyl isocyanides and their assembly on polycrystalline Ni surfaces. The ferrocenyl moiety was introduced as a messenger for convenient characterization of monolayers by electrochemical methods to evaluate the surface coverage and thermal stability of SAMs.[15] Additionally, the conformation and binding mode of isocyanide on Ni surfaces, which were characterized by reflection–absorption infrared (RAIR) spectroscopy, are discussed.

We synthesized the ferrocenyl-terminated isocyanide molecules **5** to test their ability to chemisorb on Ni surfaces. In addition to isocyanides, several ferrocenyl-terminated molecules containing reactive functional groups that can potentially chemisorb on Ni surfaces, such as cyanide (**6**), isothiocyanate (**7**), diselenide (**9**), and thiol (**10**), were synthesized (Scheme 1). Polycrystalline Ni surfaces were used as substrates for monolayer formation. Ni surfaces were pretreated by electrochemical reduction (−1.3 V vs. Ag/AgCl, 3 M NaCl) in an aqueous solution of $HClO_4$ (1 M) for 20 minutes prior to use, since Ni is easily oxidized on exposure to air.[8]

The molecular packing and surface coverage of the monolayers were assessed by cyclic voltammetry. Figure 1 shows cyclic voltammograms (CVs) obtained after electrochemically reduced Ni electrodes had been immersed in 0.01 M ethanolic solutions of **5**, **9**, and **10** for 48 hours. Oxidation and reduction peaks were observed at +0.47 and +0.44 V, which correspond to the oxidation and reduction of the ferrocene moiety.[15] However, Ni surfaces immersed for 48 hours in solutions of ferrocenyl-terminated molecules containing azide (**2**), amine (**3**), cyanide (**6**), and isothiocyanate (**7**) functional groups gave featureless CVs similar to those of bare electrodes. These results indicate that **5**, **9**, and **10** were successfully chemisorbed on the electrochemically reduced nickel surfaces. The charge density obtained for SAMs of **5**, **9**, and **10** are clearly different, and they follow the order of isocyanide > thiol > diselenide.



The surface coverage was calculated from the area of ferrocene redox peaks, by assuming that the surface has zero roughness and all chemisorbed molecules are electrochemically active. A surface coverage of 1×10^{-9} mol cm^{-2} was obtained from the electrodes modified by a 0.01 M ethanolic solution of **5**. This value is approximately two times larger than the reported value for a well-packed monolayer of ferrocenyl alkylthiols on gold ($4.6–8 \times 10^{-10}$ mol cm^{-2}).[15] The discrepancy for the Ni surface may arise from the rough morphology of Ni surfaces compared to that of gold (see the Supporting Information).

suggests that chemisorbed monolayers are chemically and thermodynamically stable under the given experimental conditions.

When Ni surfaces not treated reductively were used, the surface coverage was 1.9×10^{-10} mol cm^{-2}, five times lower than that of the electrochemically reduced Ni surfaces. The surface coverage of the monolayer on the nonreduced Ni surfaces decreased by over 50% of the original value after 100 repetitive scans at 0.1 V s^{-1}. The instability of the monolayers on nonreduced Ni surfaces may be a result of the weak interaction from the physisorption of isocyanides on nickel oxide rather than chemisorption.

Figure 2 shows the CVs of electrochemically reduced Ni electrodes modified with **5** at different scan rates. The peak splitting ($\Delta E_p = E_p^{ox} - E_p^{red}$) increased with increasing scan rate and was larger than that obtained under the same conditions for a monolayer of **5** on polycrystalline gold (data not shown). These phenomena are not consistent with the theory for a reversible redox couple confined to a surface.[16] However, ΔE_p approaches zero at low scan rates, as

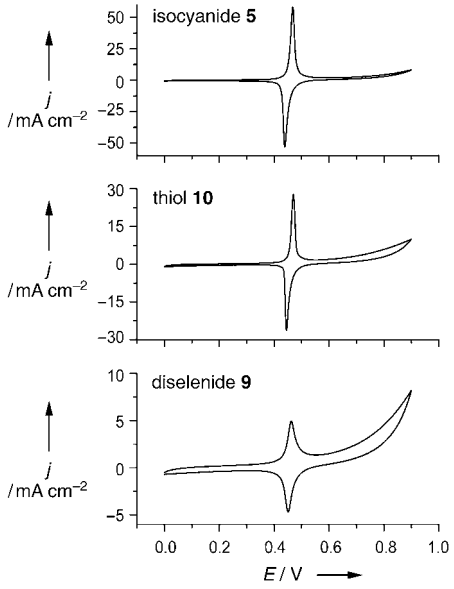

Figure 1. Cyclic voltammograms of monolayers of isocyanide **5**, diselenide **9**, and thiol **10** self-assembled on electrochemically reduced nickel surfaces. Electrolyte: 0.1 M nBu_4NPF_6 in THF. Scan rate: 0.01 V s^{-1}.

The electrochemical responses of monolayers of **5** were shown to be stable when subjected to repetitive cycling at different sweep rates. Only a small loss (5%) in the surface coverage was observed after 100 cycles at 0.2 V s^{-1}. Notably, surface coverage decreased by only 12% when monolayers of **5** were sonicated in THF for 10 minutes. This observation

expected for a reversible surface-confined redox couple. This behavior can be attributed to a slow electron transfer rate on the timescale of the experiment, where at low scan rates the redox centers remain nearly at equilibrium with the electrode surface.

Another important piece of evidence for a surface-confined faradaic reaction is the linearity between the peak current (J_p) and the scan rate (ν), as expressed by Equation (1).[16]

$$j_p = \frac{I_p}{A} = \frac{n^2F^2\Gamma\nu}{4RT} \quad (1)$$

The plot of anodic and cathodic current density against the scan rate is nearly linear at low scan rates, which indicates the existence of a surface-confined faradaic reaction (inset in Figure 2b). At faster scan rates, a deviation from the linearity was observed which is common for slow-electron-transfer kinetics (Figure 2). Along with previous CV results, this electrochemical behavior confirms the fact that a monolayer of **5** was formed on Ni surfaces.

Reflection–absorption infrared (RAIR) spectroscopy has been used to investigate the chemisorption and binding mode of SAMs on various metal surfaces.[15] Figure 3 shows the

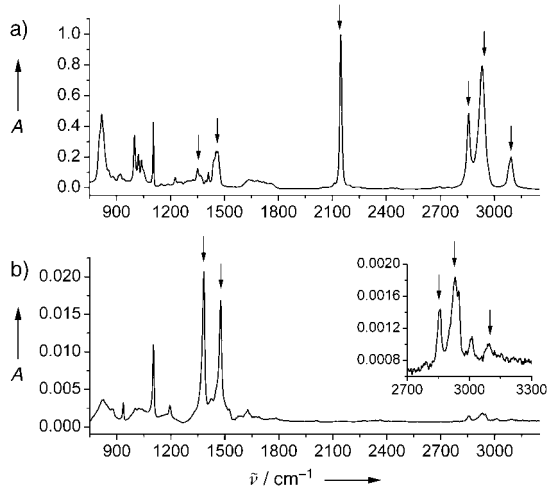

Figure 3. FTIR spectra of **5**: a) transmission on a KBr plate and b) RAIR spectra of a self-assembled monolayer on a nickel surface.

transmission (a) and RAIR (b) spectra for **5** on a KBr plate and a Ni surface, respectively. In the transmission mode, the characteristic peaks of the hydrocarbon chain and ferrocene unit of **5** appear at 2932 (C–H symmetric stretching), 2855 (C–H asymmetric stretching), 3093 (C–H stretching in ferrocene), 1464 (C–C stretching from the substituted ferrocene), and 1350 cm^{-1} (C–H bending from the substituted ferrocene; Figure 3a). These peaks are also observed in the RAIR spectrum (Figure 3b). This result clearly shows the formation of monolayers of **5** on Ni surfaces. In addition, the binding mode of isocyanides on Ni surfaces was deduced from the RAIR spectrum. While a strong peak for isocyanide stretching is observed in the transmission spectrum at 2147 cm^{-1}, the RAIR spectrum on nickel does not show the corresponding peak. In contrast, the isocyanide stretching peak of the monolayers of **5** on gold occurs at 2213 cm^{-1}. This result is in agreement with previous reports of isocyanides on gold, and the peak has been assigned to the absorption of isocyanide bonded to the metal surface through the carbon atom of the isocyanide.[9] Considering the surface selection rules for RAIR spectroscopy,[17] the absence of an isocyanide stretching peak in the RAIR spectrum suggests that the chemisorbed isocyanides are bonded through both their carbon and nitrogen atoms, and that they adopt a position parallel to the surface. This observation is consistent with previous studies of methyl isocyanide on Ni surfaces.[14a]

We examined the thermal stability by immersing Ni electrodes modified with **5** into boiling ethanol (78 °C).[18] The surface coverage (Γ) of the monolayers of **5** was monitored by cyclic voltammetry as a function of boiling time (Figure 4).

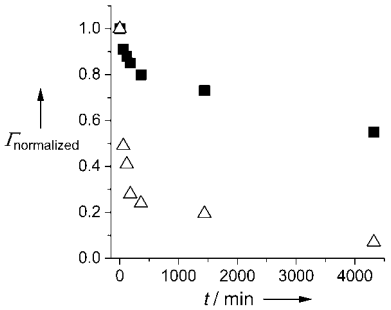

Figure 4. Thermal stability profiles of nickel–isocyanide **5** (■) and gold–thiol **10** (△) as a function of time in boiling ethanol (78 °C).

After three days in boiling ethanol, the surface coverage decreased by about 50%. Notably, SAMs of **10** on a gold surface lost over 50% of their surface coverage after one hour in boiling ethanol. The nickel–isocyanide interaction in the present study clearly shows higher thermal stability than the gold–thiol interaction. The peak shape and position in the voltammograms before and after the heating process are constant, which indicates that this experimental condition does not lead to decomposition of the isocyanide compounds on the surface.

In conclusion, ferrocenyl-terminated isocyanides were synthesized and tested for surface reaction with Ni substrates. SAMs generated from isocyanides on Ni surfaces were characterized by cyclic voltammetry and RAIR spectroscopy. It was found that SAMs of isocyanides on Ni surfaces have a parallel binding mode and high thermal stability in boiling ethanol. The results indicate the presence of strong chemisorption between isocyanides and the metallic Ni surface. This work is an indication that molecular electronic components with isocyanide groups should be synthesized so that they can be immobilized on substrates more relevant to industrial standards.

Metal–Metal Interactions

Dimerization of Indanediyl Fragments: An Alkene Analogue for Group 13?**

Michael S. Hill, Peter B. Hitchcock, and Ruti Pongtavornpinyo*

The occasionally vexed question of the potential for homonuclear multiple bonding between the heavier elements of Groups 13 and 14 continues to provoke intense interest.[1] For the wide-ranging family of Group 14 derivatives in this category, a lineage that culminated in the recent synthesis of the long-sought silicon alkyne analogue, 1,1,4,4-tetrakis[bis-(trimethylsilyl)methyl]-1,4-diisopropyl-2-tetrasilyne,[2] may be traced directly to the seminal discovery of the dimeric stannanediyl [{[$(Me_3Si)_2HC]_2Sn$}$_2$] by Lappert and co-workers.[3] All possible alkene and alkyne analogues based on a link between two Group 14 centers have since been prepared.[4] The structures of these R_2EER_2 and REER (E = Group 14 element) complexes substantiate an incremental decrease in the strength of any π-bonded component on transition from the respective planar D_{2h} and linear $D_{\infty h}$ structures. More pronounced *trans*-bent (C_{2h}) configurations (defined by the out-of-plane angle δ) are observed as the group is descended, alongside an increasing tendency of the R_2EER_2 species to dissociate to monomeric forms in solution. These observations have been attributed to the increasing stability of the lone pair of electrons in the *n*s orbital with increasing atomic number and the formation of polarized donor–acceptor interactions between the metal centers. A complementary molecular-orbital description ascribes increased nonbonding (or even antibonding) character to the b_u highest unoccupied molecular orbital (HOMO), through σ^* mixing, with increasing principal quantum number of the valence orbitals of E.[1,4]

Similar questions of multiple bond order in respect to Group 13 species have been especially problematic. The claim by Robinson and co-workers[5] of a triple-bond interaction between the Ga centers of the reduced species [$Na_2(GaC_6H_3$2,6-trip$)_2$] (trip = 2,4,6-*i*$Pr_3C_6H_2$) provoked vigorous debate,[5–13] while the subsequent work of Power and co-workers has highlighted as many contrasts as similarities within complexes maintaining contacts between formally low-valent heavier Group 13 and 14 elements.[14–16]

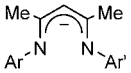
Our entry point was provided by the syntheses of the monovalent indium and thallium β-diketiminate derivatives **1** and **2**, respectively.[17] These compounds exist as well-sepa-



1: Ar = Ar' = 2,6-*i*Pr$_2$C$_6$H$_3$, E = In
2: Ar = Ar' = 2,6-*i*Pr$_2$C$_6$H$_3$, E = Tl
3: Ar = Ar' = 2,6-*i*Pr$_2$C$_6$H$_3$, E = Ga
4: Ar = Ar' = 2,6-*i*Pr$_2$C$_6$H$_3$, E = Al
5: Ar = 2,6-*i*Pr$_2$C$_6$H$_3$, Ar' =2-CH$_3$OC$_6$H$_4$, E = In
6: Ar = Ar' = 2,4,6-Me$_3$C$_6$H$_3$, E = In

rated singlet "carbene analogues" and are isostructural to the previously reported gallium and aluminum complexes, **3** and **4**, respectively.[18,19] It has been observed that variation of the overall steric demands of the bulky terphenyl ligands in combination with a low-valent gallium or indium center results in either monomeric or metal–metal-bonded species, the nuclearity of which is dictated by the size and topology of the stabilizing ligand system.[16,20] Although investigations by us suggested that an ability to isolate the two-coordinate species **1**–**4** was chiefly a product of the kinetic stability imparted by the bulky *N*-aryl 2,6-diisopropylphenyl (dipp) substituents,[17–19] we reasoned that use of substituents with decreased steric demands would similarly promote the formation of compounds with higher nuclearity. A particularly appealing target was the dimeric species, illustrated as the localized enamideimine form **I**, which may be considered as essentially isoelectronic to the stannanediyl discovered by Lappert and co-workers and other dimeric stannanediyls (Scheme 1).

Scheme 1. Generalized Sn=Sn and In=In complexes and target dimeric species **I**.

Known anions **II** and **III** were selected to provide an incremental decrease in the steric demands of the supporting ligand environment.[21] The appropriate β-imino amine pre-

II: Ar = 2,6-*i*Pr$_2$C$_6$H$_3$, Ar' = 2-CH$_3$OC$_6$H$_4$
III: Ar = Ar' = 2,4,6-Me$_3$C$_6$H$_2$

cursor was used in a synthetic route identical to that employed in the synthesis of **1**, providing facile access to In^{I} derivatives supported by **II** and **III**. Although the THF reaction solutions were somewhat photo- and thermally sensitive to depositing indium metal, rapid workup and crystallization in the dark from hexane at 5 °C provided yellow crystals of the desired In^{I} derivatives **5** and **6**. In common with the behavior of **1**, both compounds begin to decompose immediately on dissolution in aromatic solvents. Prompt acquisition of ^{1}H and ^{13}C NMR spectra in [D$_6$]benzene, however, enabled collection of data that were consistent with C_s- and C_2-symmetric structures for **5** and **6**, respectively. This solution lability to reductive decomposition has thus far restricted a thorough assessment of the nature of these species in solution. However, our appraisal of the strength of the In–In interactions present in the solid state (see below) and the analysis of Power and co-workers of the unique neutral Group 13 dimers [(2,6-dippC$_6$H$_3$M)$_2$] (M = Ga, In)[14,16] indicate that it is unlikely that anything other than transient In–In interactions persist in solution.[22]

Although crystalline samples of both complexes may be successfully manipulated for crystallographic purposes, both compounds darken because of the separation of metallic indium over the course of several days, even when stored at low temperature under N$_2$ and in the dark. These difficulties notwithstanding, the molecular structures of both compounds were determined by single-crystal X-ray diffraction studies. Although the data for **5** were of a poor quality, the structure, in common with our previously reported indium complexes bearing dipp substituents at both nitrogen donor centers, was unambiguously monomeric and contained no short In–In interactions (Figure 1). It is apparent that the presence of a single dipp group is sufficient to prevent any well-defined intermolecular contact.

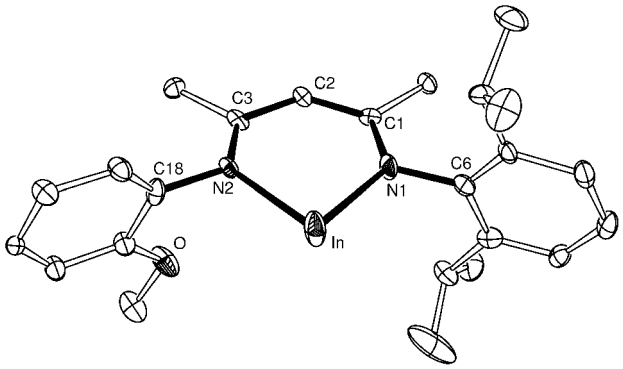


Figure 1. Structure of **5** (ORTEP plot, ellipsoids are set at 20% probability; H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: In-N1 2.277(10), In-N2 2.257(9), N1-C1 1.339(16), N1-C6 1.461(18), N2-C3 1.318(15), N2-C18 1.453(15), C1-C2 1.389(18), C2-C3 1.414(17); N1-In-N2 82.6(4), In-N1-C1 128.0(8), In-N2-C3 129.0(7), N1-C1-C2 125.1(10), C1-C2-C3 129.5(13), C2-C3-N2 125.3(12).

Further X-ray analysis of **6** provided high-quality data and revealed that replacement of both of the dipp substituents of **1** by mesityl permits dimerization through the formation of a direct In–In bond. The centrosymmetric dimer possesses approximate C_{2h} symmetry with a mutual *trans*-bent orientation of the N-chelated ligands (Figure 2). It is notable, therefore, that **6** provides the first example of a neutral dimeric Group 13 species that is formally isoelectronic to the historically significant bis(stannane)diyls. The space-filling models shown in Figure 3 emphasize the efficient encapsulation of the In–In bond axis provided by the *N*-mesityl substituents of the chelate ligands within the dimeric arrange-

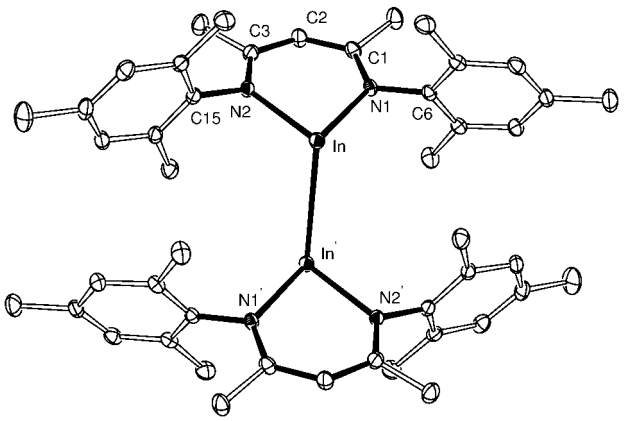

Figure 2. Structure of **6** (ORTEP plot, ellipsoids are set at 25% probability; H atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: In-N1 2.262(2), In-N2 2.256(2), In-In′ 3.1967(4), N1-C1 1.336(3), N1-C6 1.435(3), N2-C3 1.327(3), N2-C15 1.435(3), C1-C2 1.394(4), C2-C3 1.397(4); N1-In-N2 83.15(8), N1-In-In′ 110.65(6), N2-In-In′ 107.88(6), In-N1-C1 127.68(19), In-N2-C3 128.73(19), N1-C1-C2 125.1(3), C1-C2-C3 130.2(3), C2-C3-N2 124.4(3).

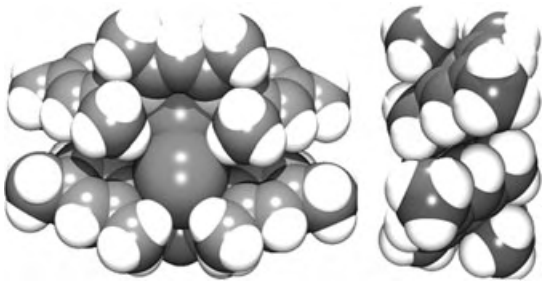

Figure 3. Space-filling (POVRAY) illustrations of **6** showing the kinetic protection of the In–In bond.

ment. The In–In distance in **6** (3.1967(4) Å) is significantly longer than that observed in the dimeric terphenyl derivative $[(2,6\text{-dipp}C_6H_3In)_2]$ (2.9786(5) Å).[16] Irrespective of the precise details of the bonding, this elongation can be interpreted in a straightforward manner as a consequence of the increased overall coordination number of the individual indium centers in **6** (three compared to two). This view is given further credence by the observation that the only other known In^I dimer features pentahapto coordination with a pentabenzylcyclopentadienyl anion and a very weak In···In interaction of 3.631(2) Å.[23] The In–In distance in **6** also lies well above the range established for typical In–In single bonds, such as those within the β-diketiminato disproportionation product $[\{\{HC[CMeN(dipp)]_2\}InCl\}_2]$ (2.8343(7) Å) and the three-coordinate indium centers of $[\{(2,4,6\text{-}i\text{Pr}_3C_6H_2)_2In\}_2]$ (2.775(2) Å), both of which feature formally divalent indium.[24,25] The β-diketiminato chelate structure is effectively planar (root-mean-square deviation of the In-N1-C1-C2-C3-N2 plane: 0.03 Å) with the result that the *trans*-bent configuration may be accurately defined by the In′-In-C2 angle of 113.02°. This represents an out-of-plane angle of 66.98° and indicates that dimerization occurs with a significantly greater degree of pyramidalization (with respect to a planar alkene-like D_{2h} structure) than that observed in the majority of homoleptic stannylenes of the general formula R_2SnSnR_2 (typically $\delta = 30$–$45°$).[1]

Dimerization has little effect on the local environment around the indium center provided by the chelated β-diketiminato ligand. The N1-In-N2 angle (83.15(8)°) is similar to the angles observed in the mononuclear compounds **1** and **5** (81.12(10) and 82.6(4)°, respectively), whereas the In–N1 and In–N2 bond lengths (2.262(2) and 2.256(2) Å, respectively) are actually the shortest observed for any indium(I) β-diketiminato chelate.[17] This latter, somewhat counterintuitive, feature occurs despite the increased coordination number of the indium centers and may be an illustration of the decreased steric demands of the chelated ligands and intrasubstituent repulsion.

We undertook DFT calculations on the dimeric model complex $[\{In[N(H)C(H)]_2CH\}_2]$ by using the B3LYP DFT and LANL2DZ pseudo potentials (and basis set) implemented in Gaussian 03.[26] The bond lengths and angles with regard to the two indium-containing fragments of the fully optimized structures are, in general, within 2% of the experimentally determined parameters. The In–In distance for the model system is, however, somewhat overestimated at 3.388 Å, as is the degree of *trans* bending indicated by the out-of-plane angle of 77.69°. The calculated molecular orbitals of this model compound do, however, reveal a qualitative insight into the In–In bonding present within **6** and provide a cogent comparison to bonding models developed for related Group 13 and 14 species. The frontier molecular-orbital diagram is presented in Figure 4 and illustrates that the

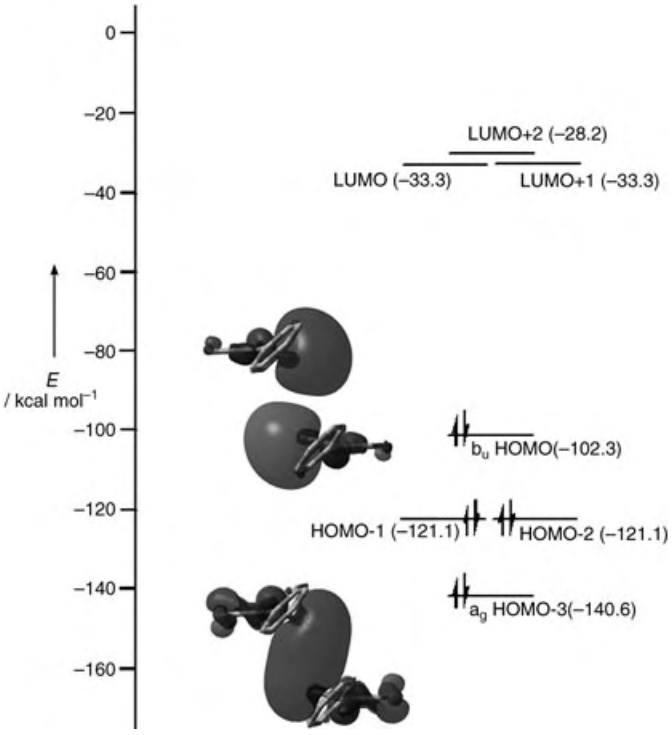

Figure 4. Calculated (B3LYP/LANDZ) frontier molecular-orbital diagram for $[\{In[(N(H)C(H)]_2CH\}_2]$ illustrating the b_u HOMO and a_g HOMO-3. LUMO = lowest unoccupied molecular orbital.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

HOMO is a b_u orbital that is nonbonding with regard to In–In contact. The degenerate HOMO-1 and -2 provide a level of π overlap between the indium centers and the nitrogen donor atoms of the chelated ligands. The HOMO-3 is an In–In σ-bonding orbital of A_g symmetry. This a_g orbital thus provides the primary bonding interaction between the metal centers. This view of the metal–metal bonding within **6** is qualitatively similar to that which has been evinced for alkene analogues of the heavier Group 14 elements and some multiply bonded gallium species.[1,9–13,27] The b_u HOMO in these cases has been variously interpreted as a "slipped" π bond or as possessing lone-pair or even antibonding character. Experimental and theoretical studies of heavier Group 14 R_2EER_2 species indicate that, despite increased lone-pair character with increased atomic mass of E, the π-bonding b_u HOMO acts to provide a minor augmentation of the overall bonding interaction between the metal centers.[1] A similar rationale has been applied to the recently completed series of REER derivatives.[4] The data presented herein and the somewhat limited literature precedents highlight some notable contrasts within Group 13. The experimental data indicate that In–In bonding with π character within **6** is feeble at best, or indeed destructive. A further calculation based on the separation of $[\{In[(N(H)C(H)]_2CH\}_2]$ into two singlet indanediyl fragments provided a bond-dissociation energy of only 2 kcal mol^{-1}. This extremely low value is commensurate with values calculated (ca. 3 kcal mol^{-1}) for the separation of the two {InH} fragments of $[In_2H_2]$ and suggests that the notion of "multiple bonding" within molecules such as **6** is fallacious if the only expectation is an augmentation of the overall bond strength.[28] The weakness of the Ga–Ga bonding within the neutral complex $[\{(2,6\text{-dipp})_2C_6H_3Ga\}_2]$ was similarly attributed to the large energy difference between the lone pair on the singlet Ga^{I} center and the p orbitals.[14] This situation is likely to be exacerbated in the current case by N–In π interactions within the planar β-diketiminato chelates and indicates that the "multiple bonding" present within **6** actually represents an overall bond order of less than unity. This view of the HOMO within homonuclear bonding in Group 13 elements has been emphasized previously by calculations carried out on the hypothetical cationic species $[MeGaGaMe]^+$.[11] In this case, removal of an electron from the b_u HOMO of [MeGaGaMe] caused a decrease of approximately 0.2 Å in the computed Ga–Ga bond length. Preliminary calculations on the $[\{In[(N(H)C(H)]_2CH\}_2]^+$ species indicated a similar and pronounced contraction of the In–In bond length to approximately 3 Å and highlighted the fact that the b_u HOMO may also possess antibonding character. Experiments to assess the validity of this hypothesis and further studies on the reactivity of these unusual species are in progress.

Experimental Section

5: Precooled THF (20 mL) was added at −78 °C to a rapidly stirred mixture of **II**-H (0.45 g, 1.25 mmol), InI (0.30 g, 1.25 mmol), and $KN(SiMe_3)_2$ (0.24 g, 1.25 mmol) in the absence of light. The reaction mixture was stirred for 3 h and allowed to warm to room temperature to produce a gray slurry. Volatiles were removed and the gray solid residue extracted with hexane (25 mL). Filtration, concentration to approximately 10 mL, and storage at 5 °C afforded bright yellow crystals suitable for X-ray analysis (0.29 g, 49 %). Elemental analysis calcd (%) for $C_{24}H_{31}InN_2O$: C 60.26, H 6.55, N 5.86; found: C 62.26, H 5.47, N 5.42 (partially decomposed in transit); ^{1}H NMR (270 MHz, [D$_6$]benzene, 25 °C): $\delta = 1.14$ (d, 6H, $^3J_{HH} = 6.9$ Hz; $CH(CH_3)_2$), 1.21 (d, 6H, $^3J_{HH} = 6.9$ Hz; $CH(CH_3)_2$), 1.75 (s, 3H; CCH_3), 1.90 (s, 3H; CCH_3), 3.20 (m, 2H, $^3J_{HH} = 6.9$ Hz; $CH(CH_3)_2$), 3.25 (s, 3H; OCH_3), 5.06 (s, 1H; C*H*), 6.50 (d, 1H; Ar*H*), 6.88–6.96 (m, 2H; Ar*H*), 7.15–7.16 ppm (m, 4H; Ar*H*); ^{13}C{^{1}H} NMR (125.8 MHz, [D$_6$]benzene): $\delta = 23.8$ ($CH(CH_3)_2$), 25.7 (CCH_3), 28.2 ($CH(CH_3)_2$), 28.6 (*C*H-$(CH_2)_2$), 55.1 (OCH_3), 98.7 (γ-*C*H), 111.8, 121.3, 123.3, 123.9, 124.5, 125.2, 125.5, 125.8, 126.7, (ArH) 142.3 (*o*-*C*(dipp)), 145.2 (*i*-C(dipp)), 155.6 (*i*-Ar-2-OCH_3), 163.6 (*C*N), 163.9 ppm (*C*N).

6: This compound was made by the same general method employing **III**-H (0.69 g, 2.07 mmol), InI (0.50 g, 2.07 mmol), and $KN(SiMe_3)_2$ (0.42 g, 2.10 mmol) to afford pale yellow rectangular crystals suitable for X-ray analysis (0.42 g, 45 %). Elemental analysis (%) calcd for $C_{46}H_{58}In_2N_4$: C 61.62, H 6.53, N 6.25; found: C 61.68, H 6.47, N 6.18; ^{1}H NMR (500 MHz, [D$_6$]benzene, 25 °C): $\delta = 1.59$ (s, 6H; CCH_3), 2.03 (s, 12H; *o*-CH_3), 2.12 (s, 6H; *p*-CH_3), 4.92 (s, 1H; C*H*), 6.76 ppm (s, 4H; *m*-Ar*H*); ^{13}C{^{1}H} NMR (125.8 MHz, [D$_6$]benzene): $\delta = 19.3$ (*o*-CH_3), 20.9 (*p*-CH_3), 23.6 (CCH_3), 98.2 (γ-*C*H), 129.5 (*m*-ArH), 133.4 (*p*-Ar), 137.4 (*o*-Ar), 146.0 (*i*-Ar), 163.4 ppm (*C*N).

Data for the X-ray structural analyses of **5** and **6** were collected on a KappaCCD diffractometer ($\lambda(Mo_{K\alpha}) = 0.71073$ Å), solved by direct methods (SHELXS-97), and refined against all F^2 using SHELXL-97) with non-hydrogen atoms anisotropic and hydrogen atoms in riding mode. An absorption correction (MULTISCAN) was applied. For **5**, the diffraction was weak and limited in extent. Crystallographic data for **5** ($C_{24}H_{31}InN_2O$) at 173(2) K: $M_r = 478.33$, crystal dimensions $0.25 \times 0.10 \times 0.05$ mm^3, orthorhombic, space group $P2_12_12$ (no. 18), $a = 11.6183(8)$, $b = 22.8982(14)$, $c = 8.7686(6)$ Å, $V = 2332.8(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.36$ Mg m^{-3}, $\mu = 1.03$ mm^{-1}; of 10481 reflections measured ($3.41 < \theta < 23.26°$), 3304 were independent ($R_{int} = 0.067$); $wR2 = 0.253$ (all data), $R1 = 0.100$ (for 2765 reflections with $I > 2\sigma(I)$), 254 parameters, GOF = 1.114. Crystallographic data for **6** ($C_{46}H_{58}In_2N_4$) at 173(2) K: $M_r = 896.6$, crystal dimensions $0.10 \times 0.10 \times 0.05$ mm^3, triclinic, space group $P\bar{1}$ (no. 2), $a = 8.6847(3)$, $b = 9.9683(3)$, $c = 13.5822(5)$ Å, $\alpha = 71.003(2)$, $\beta = 82.758(2)$, $\gamma = 81.907(2)°$, $V = 1096.67(6)$ Å^3, $Z = 1$, $\rho_{calcd} = 1.36$ Mg m^{-3}, $\mu = 1.09$ mm^{-1}; of 17033 reflections measured ($3.54 < \theta < 26.06°$), 4316 were independent ($R_{int} = 0.053$); $wR2 = 0.072$ (all data), $R1 = 0.031$ (for 3783 reflections with $I > 2\sigma(I)$), 241 parameters, GOF = 1.031. CCDC-264672 and -264673 (**5** and **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Reaction Mechanisms

Mechanistic Insight into Alcohol Oxidation by High-Valent Iron–Oxo Complexes of Heme and Nonheme Ligands**

Na Young Oh, Yumi Suh, Mi Joo Park, Mi Sook Seo, Jinheung Kim, and Wonwoo Nam**

High-valent iron–oxo species are frequently invoked as the key intermediates in the catalytic oxidation of organic substrates by heme and nonheme iron mono-oxygenases.[1,2] In the case of heme-containing enzymes such as cytochromes P450, oxoiron(IV) porphyrin π-cation radicals have been proposed as active oxidants that effect a number of oxidation reactions, which include alkane hydroxylation, olefin epoxidation, and alcohol oxidation.[1] Indeed, a number of synthetic oxoiron(IV) porphyrin π-cation radicals have been prepared and used in mechanistic studies of alkane hydroxylation and olefin epoxidation.[3] In mononuclear nonheme iron enzymes, oxoiron(IV) intermediates have been unveiled very recently in enzymatic and biomimetic reactions.[4–6] The mononuclear nonheme oxoiron(IV) species have been well-characterized with various spectroscopic techniques and with X-ray crystallography and were shown to be active in a variety of oxidation reactions such as alkane hydroxylation, olefin epoxidation, and the oxidation of sulfides and PPh_3.[4–6]

The oxidation of alcohols to the corresponding carbonyl compounds is an important chemical process in industrial and

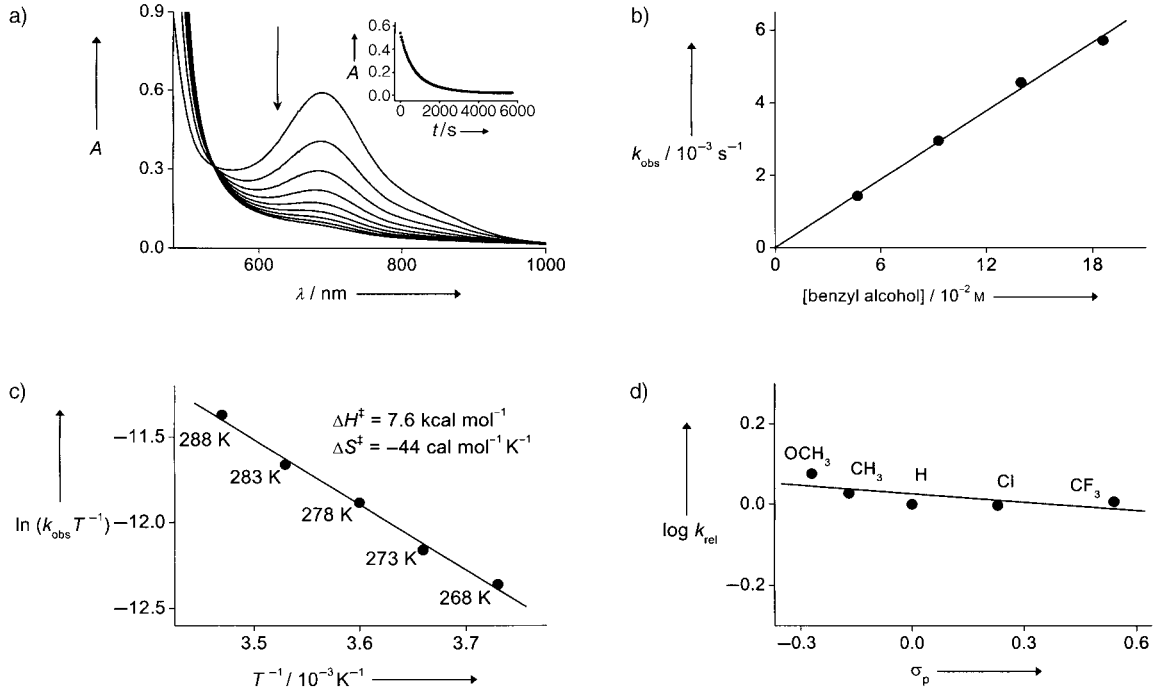
biological reactions.[7,8] Thus, tremendous effort has been devoted to developing environmentally benign catalysis and bioinspired oxidation reactions. In the latter case, the oxidation of alcohols by synthetic copper complexes has been intensively investigated as chemical models of galactose oxidase (GOase).[9,10] It has been also shown that cytochromes P450 and their model compounds are able to catalyze the oxidation of alcohols,[11,12] although mechanistic details of iron-complex-mediated alcohol oxidation have never been investigated with in situ generated intermediates of oxoiron(IV) porphyrin π-cation radicals. In the present work, we carried out alcohol oxidation reactions with spectroscopically well characterized oxoiron(IV) porphyrin π-cation radicals, $[(tdcpp)^{\bullet+}Fe^{IV}{=}O]^{+}$ (**1a**) and $[(tmp)^{\bullet+}Fe^{IV}{=}O]^{+}$ (**1b**),[13] and mononuclear nonheme oxoiron(IV) complexes, $[(tpa)Fe^{IV}{=}O]^{2+}$ (**1c**)[5b] and $[(N4Py)Fe^{IV}{=}O]^{2+}$ (**1d**)[5c] (see Scheme 1 for structures of heme and nonheme ligands).[14] To the best of our knowledge, this study provides the first mechanistic details of alcohol oxidation with oxoiron(IV) complexes generated in situ, which bear heme and nonheme ligands.

The high-valent iron–oxo complexes were prepared by using reported methods (see Supporting Information), and kinetic studies with benzyl alcohol were performed at different temperatures due to the different reactivity of the oxoiron(IV) complexes in the oxidation reactions; reaction temperatures were −100 °C for **1a**, −60 °C for **1b**, −40 °C for **1c**, and 0 °C for **1d**. Upon adding 25 equivalents of benzyl alcohol to the solutions of **1**, the intermediates reverted back to the starting iron complexes and showed pseudo-first-order decay as monitored by a UV/Vis spectrophotometer (see Figure 1a for **1d** and Supporting Information for **1a–c**). Pseudo-first-order fitting of the kinetic data allowed us to determine k_{obs} values for the reactions of **1a–d** (Table 1; k_{obs} is the observed rate constant), and product analysis of the resulting solutions with HPLC and GC revealed that benzaldehyde was produced with high yields in all of the reactions (> 70 % based on the intermediates generated; Scheme 2).

Scheme 1. Structures of heme and nonheme ligands of the iron complexes **1a–d** used in this study.

The pseudo-first-order rate constants increased proportionally with benzyl alcohol concentration, thus leading us to determine second-order rate constants (see Table 1, Figure 1b, and Supporting Information). We then determined activation enthalpy, entropy, and Gibbs energy ($\Delta H^{\neq}$, $\Delta S^{\neq}$,



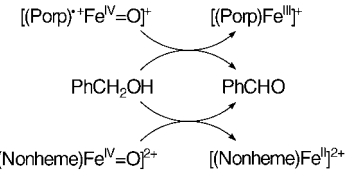


Figure 1. Reactions of **1d** with benzyl alcohols at 0 °C. a) UV/Vis spectral changes of **1d** (2 mM) upon addition of 25 equivalents of benzyl alcohol (50 mM, interval 300 s, A = absorbance). Inset shows absorbance traces monitored at 695 nm. b) Plot of k_{obs} against the concentration of benzyl alcohol to determine a second-order rate constant. c) Plot of first-order rate constants against $1/T$ to determine activation parameters. d) Hammett plot of $\log k_{rel}$ against substituent constants σ_p of benzyl alcohols. The k_{rel} values were calculated by dividing k_{obs} of *para*-X-benzyl alcohol by k_{obs} of benzyl alcohol.

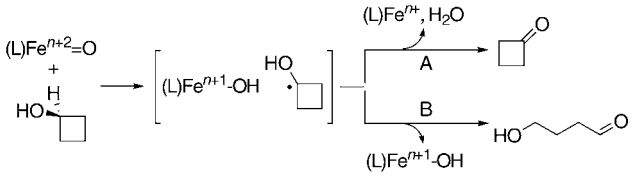
Table 1: Kinetic parameters determined in the oxidation of benzyl alcohol by oxoiron(IV) complexes of heme and nonheme ligands.[a]

Intermediate[b]	T [°C]	k_{obs} [10^{-3} s^{-1}]	k_2 [10^{-1} M^{-1} s^{-1}][c]	$\Delta G^{\neq}$ [kcal mol^{-1}][d]	k_H/k_D[e]	ρ[f]
1a	−100	6.9 ± 0.3	1.7 ± 0.2	11 ± 1	21 ± 3	−0.39
1b	−60	3.5 ± 0.2	0.84 ± 0.03	16 ± 2	> 20 [g]	−0.43
1c	−40	5.5 ± 0.3	1.2 ± 0.1	16 ± 2	58 ± 5	−0.06
1d	0	1.4 ± 0.1	0.31 ± 0.02	20 ± 2	48 ± 4	−0.07

[a] See Supporting Information for detailed reaction procedures. [b] Intermediates were prepared as described in the Supporting Information. [c] k_2 is the second-order rate constant, see Figure 1b and Supporting Information. [d] Data of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are reported in Figure 1c and Supporting Information. [e] Data of k_H and k_D are listed in Supporting Information; k_H is the rate constant obtained with $C_6H_5CH_2OH$, k_D is the rate constant obtained with $C_6D_5CD_2OH$. [f] See Figure 1d and Supporting Information. ρ = Hammett reaction constant. [g] The k_D value was similar to the natural decay of **1b**, which indicates that the k_H/k_D value should be greater than that reported. See the k_D value and the rate of natural decay of **1b** in Supporting Information.

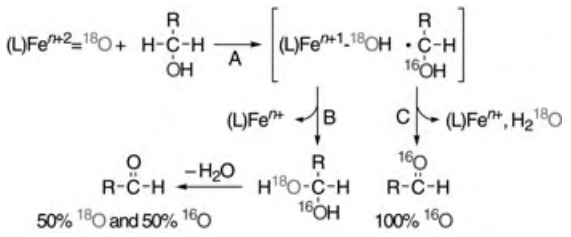


Scheme 2. Oxidation of benzyl alcohol by high-valent iron–oxo complexes of heme and nonheme ligands.

and $\Delta G^{\neq}$) for the benzyl alcohol oxidation with **1** by plotting first-order-rate constants determined at different temperatures against $1/T$ (see Table 1, Figure 1c, and Supporting Information). Taking into consideration that the reactions were performed at different temperatures, we find the kinetic and activation parameters indicate that the relative reactivities of oxoiron(IV) complexes are in the order of **1a** > **1b** > **1c** > **1d**. The greater reactivity of oxoiron(IV) porphyrin π-cation radicals compared to nonheme oxoiron(IV) complexes is rationalized with the higher oxidation state of the iron center in oxoiron(IV) porphyrin π-cation radicals (i.e., the formal oxidation states of Fe^{V} and Fe^{IV} in oxoiron(IV) porphyrin π-cation radical and nonheme oxoiron(IV) species, respectively).[15] In the case of oxoiron(IV) porphyrin π-cation radicals, it has been well documented that the reactivity of electron-deficient iron porphyrins is greater than that of electron-rich iron porphyrins.[16] It has been also shown that the reactivity of nonheme oxoiron(IV) species is dependent on the ligand architecture,[5a–c] and the results presented herein demonstrate that **1c** is more reactive than **1d** in alcohol oxidation.

The kinetics of benzyl alcohol oxidation have also been measured with [D_7]-deuterated benzyl alcohol ($C_6D_5CD_2OH$) to investigate the C–H kinetic isotope effect (KIE). The KIE values determined were large in all of the reactions (see Table 1 and Supporting Information), and such large KIE values have also been observed in GOase[17] and its models[10a,c,18] as well as in the oxidation of benzyl alcohol by high-valent ruthenium-oxo complexes[19] and hydrogen atom abstraction reactions by the iron(IV) intermediates of mono-iron Taurine/α-Ketoglutarate Dioxygenase (TauD)[4b] and diiron methane monooxygenase enzymes.[20] The large, non-classical KIE values indicate that heme and nonheme oxoiron intermediates activate alcohols exclusively by hydrogen atom abstraction from the α-CH of benzyl alcohol and that C–H bond cleavage is the rate-determining step in the alcohol oxidation.[10a,c,17–19] Consistent with this mechanism, studies with *para*-substituted benzyl alcohols reveal that the reaction rates are not greatly influenced by the electron-withdrawing and electron-donating ability of the *para* substituents and that plotting the rates as a function of σ_p of the substituents affords small Hammett ρ values (see Table 1, Figure 1d, and Supporting Information). It is of interest to note that Hammett ρ values obtained in the reactions of GOase and its model compounds are small (e.g., ≈ −0.1)[17,18] and that the Hammett ρ values of synthetic oxoiron(IV) porphyrin π-cation radicals, **1a** and **1b**, are similar to those reported in cytochrome P450 enzymes (e.g., ≈ −0.4).[11]

We then studied cyclobutanol oxidation with the oxoiron(IV) species, as the substrate has been often used as a mechanistic probe to distinguish a one-electron versus a two-electron process in alcohol oxidation by high-valent transition-metal oxidants.[21] For example, if cyclobutanone is produced predominantly, then the reaction occurs by hydrogen atom abstraction followed by an electron transfer (i.e., a two-electron process, see Scheme 3, pathway A). If a carbon



Scheme 3. Oxidation of cyclobutanol by heme and nonheme oxoiron(IV) complexes.

radical formed by hydrogen atom abstraction of cyclobutanol escapes from the solvent cage, a ring-opened product, 4-hydroxybutyraldehyde, is formed (Scheme 3, pathway B).[21a] In the present study, when the oxidation of cyclobutanol was carried out with two oxoiron(IV) complexes, **1a** and **1c**, we found that cyclobutanone was formed exclusively (80–90% yields; see Supporting Information), thus demonstrating that the alcohol oxidation by heme and nonheme oxoiron(IV) complexes proceeds by a two-electron process (Scheme 3, pathway A). A similar observation was reported in the oxidation of cyclobutanol by $Fe^{IV}O^{2+}$ in aqueous solution.[21a]

Finally, the oxidation of benzyl alcohol was carried out with an ^{18}O-labeled oxoiron(IV) complex, $[(N4Py)Fe^{IV}{=}^{18}O]^{2+}$ ([^{18}O]**1d**), to understand whether the final step of the alcohol oxidation is the dehydration of a *gem*-diol intermediate or hydride transfer in the solvent cage to yield a carbonyl

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

product (Scheme 4). We therefore prepared [^{18}O]**1d** by treating [(N4Py)Fe^{IV}=O]$^{2+}$ with $H_2{}^{18}O$ and checked the percentage of the ^{18}O isotope in [^{18}O]**1d** with electrospray ionization mass spectrometry (80% ^{18}O in [^{18}O]**1d**, see

Scheme 4. Proposed mechanism for the oxidation of alcohol by heme and nonheme oxoiron(IV) complexes.

Supporting Information).[22] Upon addition of 25 equivalents of benzyl alcohol to the solution of [^{18}O]**1d**, the intermediate reverted back to the starting [Fe^{II}(N4Py)]$^{2+}$, and product analysis with GC–MS revealed that ca. 5% of the oxygen in the benzaldehyde product derived from the oxoiron(IV) species. A control experiment, carried out by incubating benzaldehyde in $H_2{}^{18}O$ under the identical conditions, showed ca. 6% incorporation of the ^{18}O isotope from $H_2{}^{18}O$ in benzaldehyde due to solvent exchange. Based on the observation that the oxygen atom in the aldehyde product does not derive from the oxoiron(IV) complex, we conclude that the benzaldehyde product is formed by hydride transfer (Scheme 4, pathway C), not by a *gem*-diol dehydration (Scheme 4, pathway B).[21a,23]

In summary, we have reported the first example of alcohol oxidation by mononuclear nonheme oxoiron(IV) complexes. We have also reported mechanistic details of alcohol oxidation that have been investigated with in situ generated high-valent iron–oxo complexes of heme and nonheme ligands. The reactivity of heme and nonheme oxoiron(IV) complexes has been briefly compared as well. Finally, we have proposed a plausible mechanism for alcohol oxidation by heme and nonheme oxoiron(IV) intermediates, in which the oxidation of alcohols occurs by an α-CH hydrogen atom abstraction followed by electron transfer (Scheme 4, pathways A and C).

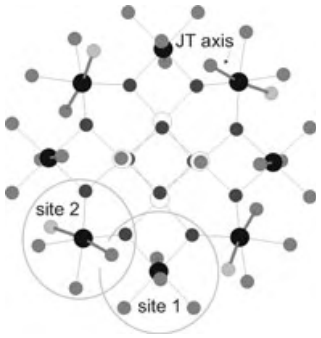

Figure 1. Structure of the core of Mn_{12}-acetate (view along the S_4 axis). For clarity only the first coordination sphere of the Mn ions is drawn. The single-ion Jahn–Teller (JT) axes are represented by thick bonds. Mn^{4+}: white, Mn^{3+}: black, μ_3-O^{2-}: dark gray, OAc: medium gray, H_2O: light gray. The two specific sites 1 and 2 are used in the data analysis and discussion.

Single-Molecule Magnets

Effect of Pressure on the Magnetic Anisotropy in the Single-Molecule Magnet Mn_{12}-Acetate: An Inelastic Neutron Scattering Study**

*Andreas Sieber, Roland Bircher, Oliver Waldmann, Graham Carver, Grégory Chaboussant, Hannu Mutka, and Hans-Ulrich Güdel**

Mn_{12}-acetate is the prototype of a class of polynuclear transition metal complexes known as single-molecule magnets (SMMs). These spin clusters exhibit new phenomena such as slow relaxation and quantum tunneling of magnetization (QTM) at low temperature,[1,2] and this discovery, about a decade ago, triggered a flurry of interdisciplinary research in physics and chemistry. Mn_{12}-acetate was the first SMM discovered, and its properties have been thoroughly studied by many different techniques. As shown in Figure 1, it is composed of a tetrahedral core of oxygen-coordinated Mn^{4+} ions, which are surrounded by a ring of eight Mn^{3+} ions with oxo and acetate coordination.[3] Dominant antiferromagnetic interactions between the Mn^{4+} and Mn^{3+} ions lead to an $S = 10$ ground state.[4] The Mn^{3+} coordination environment is Jahn–Teller-distorted; the elongated Mn–O bonds are emphasized in Figure 1. The concerted action of the resulting Mn^{3+} single-ion anisotropies leads to an overall easy-axis-type anisotropy of the $S = 10$ cluster ground state, which can be expressed by Equation (1).

$$\hat{H}_{ZFS} = D[\hat{S}_z^2 - {}^1/_3 S(S+1)] + B_4^0 \hat{O}_4^0$$
where
$$\hat{O}_4^0 = 35\hat{S}_z^4 - 30S(S+1)\hat{S}_z^2 + 25\hat{S}_z^2 - 6S(S+1) + 3S^2(S+1)^2 \quad (1)$$

As a result the $S = 10$ ground state splits in zero field into eleven $\pm M_S$ sublevels, of which $M_S = \pm 10$ are lowest in energy. An energy barrier between the plus and minus M_S sublevels is thus built up (Figure 2). Inelastic neutron scattering (INS), for which $\Delta M_S = \pm 1$ transitions are allowed, is eminently suited for the direct measurement of this splitting pattern in zero field.[5] The physical properties of Mn_{12}-acetate can be tuned by chemical variation[6,7] or by physical perturbations such as an external magnetic field or pressure.[8,9] Here we report the first spectroscopic study of the anisotropy splitting of Mn_{12}-acetate under hydrostatic pressure up to 12 kbar. From magnetization experiments it was earlier concluded that the anisotropy barrier increases with increasing pressure.[8] From the observed acceleration of the

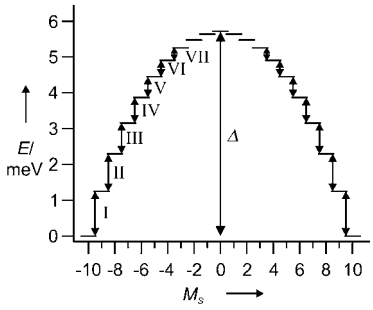

Figure 2. Axial anisotropy splitting and energy barrier Δ of the $S = 10$ ground state. The double arrows correspond to the observed $\Delta M_S = \pm 1$ INS transitions.

magnetization relaxation it was further postulated that pressure induces partial conversion of the normal, slow-relaxing (SR) Mn_{12}-acetate molecules into a faster relaxing (FR) species.[9] Since INS allows the identification and quantitative characterization of individual species, we expect to clarify and quantify these points, which are important for understanding the mechanism and structural origin of slow magnetic relaxation in Mn_{12}-acetate.

Figure 3 shows the relevant section of the 2.5 K INS spectrum of a fully deuterated sample of Mn_{12}-acetate for the full accessible pressure range, measured on IN5 at the ILL in Grenoble. At 2.5 K the only allowed INS transition is $M_S = \pm 10$ to ± 9. Besides the major peak I around 1.25 meV, we observe a weaker peak *I* around 0.92 meV. The intensity ratio of the two peaks is clearly pressure dependent, and we assign the weak peak to a minority species. Its fraction increases from 3.8% at ambient pressure to 11.1% at 5 kbar, and this conversion is reversible. Above 6 kbar the minority peak is no longer observable in our spectra, most likely due to inhomogeneous broadening and the lower signal-to-noise ratio in the high-pressure clamp cells. Furthermore, a shift of the INS peak positions to higher energies with increasing pressure is evident for both species. Figure 4 shows the pressure dependence of the INS spectrum at 23 K. At this temperature all levels are thermally populated and seven transitions (labeled I to VII in Figure 4) within the zero-field split (ZFS) $S = 10$ ground state are observed. The 5 kbar pattern was measured at four temperatures from 2.5 K to 23 K, and this allowed the peaks originating from the two different species to be identified (cf. Supporting Information). The pressure dependent peak positions of the majority and minority species are listed in Tables S1 and S2, respectively, in the Supporting Information.

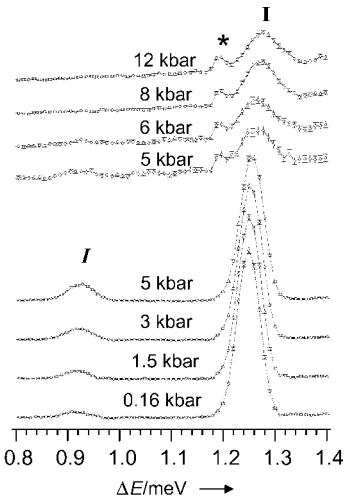

Figure 3. INS spectra at 2.5 K of Mn_{12}-acetate for the indicated pressures. The spectra correspond to the sum of all the scattering angles and are normalized to the elastic intensity. The upper four spectra were obtained with the clamp cells. The lower signal-to-noise ratios in the clamp-cell data originate from the higher background. The labels I and *I* refer to the $\pm 10 \rightarrow \pm 9$ transition (Figure 2) of the majority and minority species, respectively. The asterisk marks a spurion.

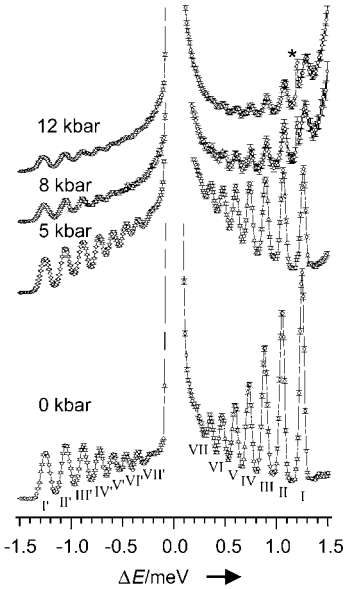

Figure 4. INS spectra at 23 K of Mn_{12}-acetate for the indicated pressures. The spectra correspond to the sum of all the scattering angles and are normalized to the elastic intensity. The lower signal-to-noise ratios at 8 and 12 kbar originate from the higher background of the clamp cells. The labeling of the peaks corresponds to the scheme adopted in Figure 2. The data at ambient pressure are taken from ref. [5]. The asterisk marks a spurion.

It is straightforward to assign the majority species in our INS spectra to the normal, SR Mn_{12}-acetate molecules with the structure shown in Figure 1. The minority species with a significantly smaller anisotropy is assigned to a FR isomer with a different structure. The observed fraction of 3.8% at ambient pressure is in good agreement with the value of 5% derived from ac susceptibility measurements.[10]

For ambient pressure the ZFS of the majority species has been studied previously in great detail by INS with higher instrumental resolution.[5] In addition to the D and B_4^0 parameters in Equation (1), it was possible to quantify two higher order terms which lead to deviations from the pattern in Figure 2. In the present study we concentrate on transitions I–IV, and these are essentially unaffected by the higher order terms and are sufficient to determine both D and B_4^0 accurately. The results of least-squares fits of the eigenvalues of Equation (1) to the experimental energies are given in Tables S1 and S2 in the Supporting Information. The variation of D as a function of pressure for both species is shown in Figure 5. In analogy to other Mn_{12} systems,[6,7] we assume an $S = 10$ ground state for the minority species, which is in good agreement with our INS data. The pressure dependence of D of the SR species is in good agreement with the values given in ref. [8]. The 2.1% increase in $|D|$ between ambient pressure and 12 kbar is significant. B_4^0 is pressure-independent within experimental accuracy, and thus this parameter was kept constant in the analysis.

D in Equation (1) can be related to the anisotropy of the individual Mn^{3+} ions by Equation (2) where the projection

$$D = 2 \sum_{i=1}^{2} a_i D_{Mn^{3+},i} (3 \cos^2 \alpha_i - 1) \qquad (2)$$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

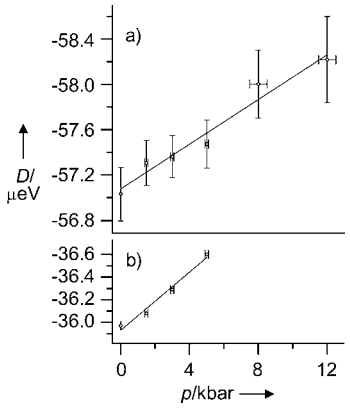

Figure 5. Variation of D as a function of hydrostatic pressure for a) the majority species and b) the minority species.

coefficient $a_i = 0.02845$[3] and α_i is the projection angle of the respective single-ion anisotropy axis (Jahn–Teller axis) on the cluster-anisotropy axis (S_4 axis). The two distinct Mn^{3+} sites with $i = 1$ and 2 (Figure 1) have values of $\alpha_1 = 11°$ and $\alpha_2 = 37°$, respectively, and thus contribute differently to D. In a recent pressure study of another SMM containing Mn^{3+}, $[Mn_4O_3Br(OAc)_3(dbm)_3]$ (dbm = dibenzoylmethane) or Mn_4 in short, $|D|$ was found to decrease by 3.8% between ambient pressure and 12 kbar.[11] This was ascribed to a tilting of the Jahn–Teller axes under pressure, which leads to a decrease in the $(3\cos^2\alpha_i - 1)$ factor in Equation (2). The situation is different in Mn_{12}-acetate, where the observed increase in $|D|$ can be explained by an increase in $|D_{Mn^{3+},i}|$. Using the angular overlap model (AOM) as in ref. [12] and assuming the same compressibility for all Mn^{3+}–O bonds ($d_{12\,kbar}/d_{0\,kbar} = 0.9975$),[11] we can calculate the pressure dependence of $D_{Mn^{3+},i}$ by scaling the AOM parameters with the Mn–O distances. Assuming constant α_i in Equation (2) (isotropic compression), we calculate an increase in $|D|$ of 2.2% between ambient pressure and 12 kbar. The excellent agreement with the experimental value of 2.1% is fortuitous, but the calculation clearly reveals that an increase in the single-ion anisotropy under pressure can explain the observed pressure dependence. As seen in Figure 5b, $|D|$ increases about twice as strongly with pressure in the minority species, but here, too, the main effect is an increase in single-ion anisotropies with increasing pressure.

For a number of Mn_{12}-acetate derivatives FR minority species have been identified and studied in detail. In all cases the activation energy for the magnetization relaxation Δ_{rel} is reduced by about 40% compared to the SR species, but with regard to the anisotropy barrier Δ (Figure 2), two different groups can be distinguished. In the first group the reduction of Δ is about an order of magnitude smaller than the reduction of Δ_{rel}.[6] This is ascribed to a switching of the Jahn–Teller axis of one of the Mn^{3+} ions on site 2 towards the μ_3-oxo bridge (Figure 1). In the second group the reduction of Δ is similar to that of Δ_{rel},[7] and a rather unusual coordination geometry (compressed octahedron) at one Mn^{3+} ion on site 2 was proposed. From our INS data we derive $\Delta = 5.75$ and 3.7 meV at ambient pressure for the SR and FR species, respectively. The reduction of Δ is thus similar to the reduction of the relaxation barrier from $\Delta_{rel} = 5.6$ meV for the SR to $\Delta_{rel} = 3.5$ meV for the FR species.[13] This would place Mn_{12}-acetate in the second group, but additional structural information on the FR species in Mn_{12}-acetate would be desirable.

High-resolution INS allows the simultaneous direct measurement of the anisotropy splitting and its pressure dependence in the $S = 10$ ground state of the two molecular species in Mn_{12}-acetate. From the INS data we clearly see a transformation of the SR into the FR species under pressure. The axial anisotropy of both species increases with increasing pressure, in striking contrast to the situation found in Mn_4, for which a decrease is observed. Apparently, there are no general rules for the pressure dependence of the axial anisotropy in SMMs, though we could provide a consistent explanation for both Mn_{12}-acetate and Mn_4.

Experimental Section

A fully deuterated, polycrystalline sample of Mn_{12}-acetate was synthesized according to ref. [14].

INS measurements were performed on the high-resolution time-of-flight spectrometer IN5 at the Institut Laue-Langevin in Grenoble, France. A neutron wavelength of $\lambda_i = 5.9$ Å (FWHM = 57 μeV) was used. Data treatment involved the calibration of the detectors with a vanadium spectrum. The time-of-flight to energy conversion and data reduction were performed with the standard program INX at the ILL.

A standard ILL continuously loaded high-pressure He gas cell, loaded with 4.3 g of Mn_{12}-acetate, was used for pressures $p = 0.16(1)$, 1.5(1), 3.0(1), and 5.0(1) kbar. For $p = 5.0(5)$, 6.0(5), and 8.0(5) kbar the standard ILL 10 kbar high-pressure clamp cell (0.6 g sample) and for $p = 12.0(5)$ kbar the standard ILL 15 kbar high-pressure clamp cell (0.4 g sample) were used with FC-75 (fluorinated hydrocarbon, 3M) as pressure-transmitting medium. An ILL orange cryostat was used for cooling.

Drug Delivery

Design, Construction, and Intracellular Activation of an Intramolecularly Self-Silenced Signal Transduction Inhibitor**

Seung-Yub Lee, Fubo Liang, Xiao-Ling Guo, Laiping Xie, Sean M. Cahill, Michael Blumenstein, Heyi Yang, David S. Lawrence, and Zhong-Yin Zhang**

The AB protein toxins are among the most potent and lethal cell death inducing agents known. This protein family includes such notorious cytotoxins as ricin, and the cholera, diphtheria, tetanus, and botulinum toxins.[1] These, and related family members, share a variety of structural and mechanistic motifs. The A polypeptide acts on a specific intracellular target in a fashion that compromises cellular viability. By contrast, the B moiety serves as a transporter that delivers the A component to the intracellular environment. In addition, the B polypeptide is typically conjoined to the A moiety through a disulfide bridge, which suppresses the biological activity of the latter. However, upon intracellular reduction of the disulfide, the A protein is released into its fully activated state.

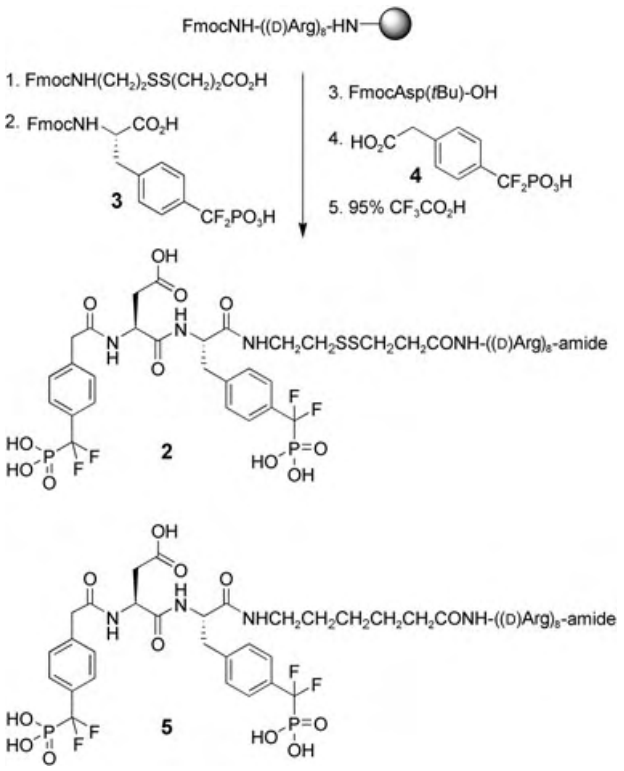
It occurred to us that the AB protein toxin mechanism by which a highly toxic, but membrane-impermeable, protein is delivered to a cell in an inert form might prove applicable to other inhibitory agents as well. We describe herein a strategy that employs a cell-penetrating peptide (CPP)[2] to 1) suppress the activity of an appended inhibitor, 2) deliver the membrane-impermeable inhibitor to the intracellular environment, and, once inside the cell, 3) release the inhibitor in its active form.

We previously described the protein tyrosine phosphatase (PTP) 1B inhibitor **1**.[3] This species is the most potent



1

(inhibitory constant, $K_i = 2.4$ nM) and selective PTP1B inhibitor (1000–10000-fold versus a panel of phosphatases) reported to date. The negatively charged aryldifluorophosphonate functional groups participate in key active-site and near-active-site interactions that are responsible for the high PTP1B potency displayed by **1**.[4] Not surprisingly, the negatively charged inhibitor is not cell-permeable.[5] We anticipated that a cell-permeable derivative of **1** could be prepared by coupling it to the CPP ((D)-Arg)$_8$ moiety to generate **2** (Scheme 1). Polycationic CPPs are widely used to transport cargo through cell membranes.[2] However, we also expected that electrostatic interactions between the positively charged CPP and the negatively charged cargo might have the desirable effect of suppressing inhibitory efficacy. Consequently, effective inhibition of PTP1B, a cytoplasmically oriented endoplasmic reticulum (ER)-embedded protein,[6] should only transpire upon release of the cargo from the CPP and only if release occurs within a PTP1B-available region of the cell. By contrast, a corresponding construct that lacks the disulfide bridge (**5**) should be unable to effectively inhibit PTP1B.

Compound **2** was directly prepared on the Rink resin by sequential coupling of eight (D)-Fmoc-Arg(Pbf) residues (Pbf = 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl), FmocNH$(CH_2)_2SS(CH_2)_2CO_2H$, compound **3**, Fmoc-Asp-(*t*Bu)OH, and compound **4** (Scheme 1).[7] Simultaneous deprotection and cleavage mediated by CF_3CO_2H furnished **2**. Compound **2** is an extraordinarily ineffective inhibitor of PTP1B, with a K_i value (8.2 μM) that is three orders of magnitude lower than that of **1**. This appears to be a consequence of intramolecular interactions between the PTP1B-directed portion of **2** and its disulfide-linked ((D)-Arg)$_8$ appendage. NMR experiments under aqueous conditions confirm that the key active-site-directed aryldifluorophosphonate moiety is engaged in through-space interactions with the ((D)-Arg)$_8$ cell-permeabilizing sequence (see Supporting Information). Furthermore, the intramolecular nature

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/anie.200462004

Scheme 1. Solid-phase synthesis of the CPP-S-S-(PTB1-B inhibitor) constructs **2** and **5**. Peptides were prepared on the Rink amide resin by using 9-fluorenylmethoxycarbonyl (Fmoc)-protected amino acids and a standard coupling protocol involving 1-hydroxybenzotriazole/2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate/*N*-methylmorpholine for the activation of acids.

enhancements in IRβ and IRS-1 phosphotyrosine levels have been reported with a PTP1B inhibitor.[5]

We performed an analogous study using a Chinese hamster oocyte (CHO) cell line transfected with an expression plasmid encoding human IR (CHO/HIRc). We previously found that compound **1** has no effect on IRβ and IRS-1 phosphotyrosine levels in this cell line, since its five negative charges render it membrane-impermeable.[5] The CHO/HIRc cell line was exposed to compounds **2** and **5** over a selected range of concentrations for 1 h and subsequently treated either with or without insulin (10 nM) for 10 min. Cell lysates were then resolved by SDS-PAGE, electrotransferred to nitrocellulose membranes, and probed with anti-pTyr antibody (Figure 1). Compound **5** has no effect on IRβ or IRS-1

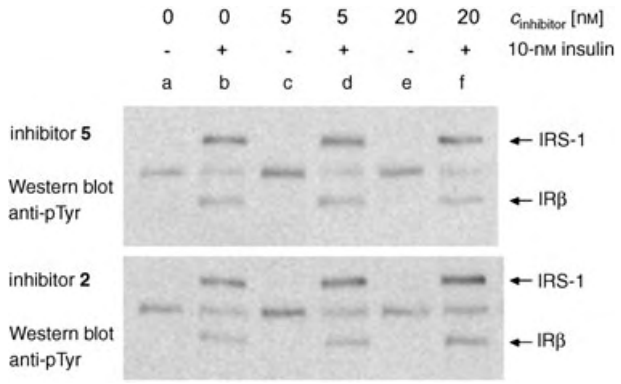


Figure 1. Effect of PTP1B inhibitors **5** (upper gel) and **2** (lower gel) on the tyrosine phosphorylation status of IRS-1 and IRβ. Lane a (no inhibitor, without insulin); lane b (no inhibitor, with insulin); lane c (5-nM **5** and **2**, without insulin); lane d (5-nM **5** and **2**, with insulin); lane e (20-nM **5** and **2**, without insulin); lane f (20-nM **5** and **2**, with insulin).

of this interaction is confirmed by the fact that the inhibitory efficacy of free **1** is not affected by added $((D)\text{-Arg})_8$ (at concentrations up to 20 μM). Finally, the masking effect of the positively charged permeabilizing sequence is due to electrostatic interactions, since a corresponding cell-permeable fatty-acid-derivatized PTP1B inhibitor is fully active.[5]

The disulfide bridge present in **2** is absent in the otherwise structurally equivalent derivative **5**. Compound **5** was synthesized in a fashion analogous to that outlined in Scheme 1 with the exception that $FmocNH(CH_2)_5CO_2H$ was employed in step 1. As expected, both compounds **2** and **5** ($K_i = 9.0$ μM) are equally poor PTP1B inhibitors under nonreducing conditions.

We determined the cellular effects of compounds **2** and **5** on insulin signaling to assess the efficacy of the delivery strategy mimicking AB protein toxins. Insulin-mediated activation of the insulin receptor (IR) produces a wide array of cellular responses, including enhanced phosphorylation of the insulin receptor β (IRβ) subunit and the insulin receptor substrate-1 (IRS-1). Previous studies have demonstrated that PTP1B serves as a negative regulator of the insulin-activated signaling pathways by catalyzing the dephosphorylation of IRβ and IRS-1.[5] For example, the antisense-mediated reduction of PTP1B in rat hepatoma cells generates a 2.3-fold and 1.5-fold increase in IRβ and IRS-1 phosphotyrosine levels, respectively.[8] In addition, significant phosphotyrosine levels, even at concentrations as high as 100 nM (data not shown). This is not surprising given that the latter concentration is 90 times lower than the in vitro K_i of **5**. By contrast, even at 5 nM, compound **2** enhances the phosphotyrosine content of IRβ and IRS-1 1.7- and 1.4-fold, respectively. An even more pronounced effect is observed at 20 nM (2.4- and 2.2-fold, respectively). These concentrations are nearly three orders of magnitude lower than the K_i value displayed by **2** under nonreducing conditions in vitro. These results are consistent with the notion that the disulfide bridge linking the PTP1B inhibitory component ($K_i = 2.4$ nM) with the CPP has been cleaved and that the liberated inhibitor has ready access to the cytoplasmically oriented protein target.

In summary, we have shown that a CPP module can be used to biochemically silence the biological activity of appended cargo.[9] This property, which is a characteristic feature of AB protein toxins, should restrict the desired biological effect to the targeted intracellular environment. We are currently investigating the scope of this approach as well as the utility of compound **2** for the treatment of diabetes and obesity.[10]

Analytical Methods

Quantification of the Cellular Uptake of Cell-Penetrating Peptides by MALDI-TOF Mass Spectrometry**

Fabienne Burlina, Sandrine Sagan, Gérard Bolbach, and Gérard Chassaing*

Cell-penetrating peptides (CPPs) are widely used to deliver biologically active molecules into cells.[1] We have successfully applied matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) to the quantification of cellular uptake of CPPs. Penetratin, which corresponds to residues 43 to 58 of the *Antennapedia* homeodomain, was one of the first small CPPs to be discovered a decade ago.[2] Many others were identified soon after: Tat-derived peptides,[3] nuclear localization sequences,[4] transportan,[5] model amphipatic peptides,[6] polybasic peptides,[7,8] amphipathic proline-rich peptides,[9] and β peptides.[10] Many studies concerning the cellular uptake efficiencies of these CPPs have been reported, most of them based on the quantification of a radioactive or a fluorescent reporter group.[11] Only one example of direct CPP quantification has been reported, based on HPLC analysis of fluorescent CPPs.[12] The results strongly differ from one study to another. For example, the ratio between intracellular and extracellular concentrations of penetratin ranges from 0.6:1.0[13] to 95.0:1.0.[14] Discrepancies observed between studies can be explained by the use of different cell types and cell treatments (fixed or unfixed cells), different methods of detection, interference of the reporter group, or inaccurate distinction between internalized and membrane-associated peptides. In some of the studies the fraction of CPP bound to the external surface of the cells is removed by washing or by enzymatic digestion.[11] In other cases discrimination between internalized and membrane-bound peptide is achieved by chemical modification of the non-internalized peptide[12] or by the use of a reduction-sensitive fluorophore.[15] We report here a novel method based on MALDI-TOF MS to measure the concentration of internalized peptide and its application to the study of three widely used CPPs: penetratin, Tat_{48-59}, and $(Arg)_9$. The concept is outlined in Figure 1.

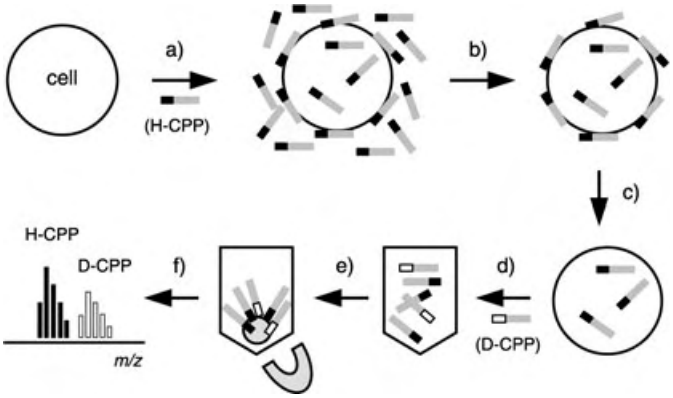

Figure 1. Quantification of CPP cellular uptake by MALDI-TOF MS. a) Cells are incubated with biotinylated non-deuterated CPP (H-CPP). b) Cells are washed. c) Membrane-bound CPP is digested by trypsin then trypsin inhibitor is added. d) A known and appropriate amount of internal standard (biotinylated deuterated CPP, D-CPP) is added, cell lysis is performed in 0.3% triton X100 and 1 M NaCl, and the sample is heated for 15 min at 100°C. e) Biotinylated peptides are captured by streptavidin-coated magnetic beads. f) Beads are washed and analyzed by MALDI-TOF MS. The ratio between the $[M+H]^+$ signal areas of H-CPP and D-CPP yields the absolute amount of internalized peptide.

Peptide quantification by MALDI-TOF MS can only be achieved by using the same peptide labeled with a stable isotope as an internal standard. Both peptides have identical chemical structure and exhibit the same efficiencies of desorption/ionization and detection. The relative intensity of the peptides $[M+H]^+$ signals therefore corresponds to the relative proportion of the peptides in the sample.[16,17] We

have previously reported a method to directly analyze by MALDI-TOF MS biotinylated peptides that were extracted from a complex mixture using streptavidin-coated magnetic beads.[18] We have now combined this technique with isotopic labeling to quantify cellular uptake of CPPs. The process of capturing the CPPs on beads enables concentration of the internalized CPP and its purification from cell lysate before MALDI-TOF MS analysis. This step is essential to facilitate detection of very small amounts of internalized CPP and also to allow distinction between the CPPs and endogenous peptides having the same molecular weight. The use of MALDI-TOF MS gives the advantage of direct detection of the peptide. Therefore, discrimination between internalized and membrane-bound peptide can be easily achieved by submitting the non-internalized peptide to a chemical or an enzymatic treatment that modifies its molecular weight. Intracellular degradation of the CPPs can also be studied. Finally, the simultaneous comparison of the cellular uptake efficiencies of several CPPs can be performed as long as the peptides have different molecular weights.

The CPPs used in this study were functionalized on their N-terminus with biotin and an isotopic tag composed either of four non-deuterated glycine residues (H-CPP, internalized) or four deuterated glycine residues (D-CPP, internal standard). The internalization experiments were performed following the protocol described in Figure 1 (see also the Supporting Information). The internal standard was submitted to the whole process of cell lysis and internalized CPP extraction to enable any degradation artefacts to be detected. Indeed this process allows the fast distinction between intracellular degradation of CPP (only H-CPP digests would be detected) and degradation of CPP occurring during sample preparation (the same H-CPP and D-CPP digests would be detected) by MALDI-TOF MS (see the Supporting Information). The conditions used for cell lysis and peptide capture were found to be particularly critical for the accuracy of the quantification. Indeed, the lysate may contain molecules that exhibit affinity for the CPPs and may thus hamper their capture by streptavidin-coated magnetic beads. This situation may lead to discrimination during capture between the internalized CPP and the internal standard since both peptides have not necessarily been exposed to the same interactions. Nucleic acids in particular were found to perturb the peptide extraction process. This problem could be overcome by treating the lysate with nucleases before peptide capture or by performing the capture in the presence of high salt concentrations. However, degradation of both the internalized peptide and the internal standard was then observed. This effect was possibly a result of the release of lysosomal enzymes during cell lysis. The addition of protease inhibitors during the whole process of peptide extraction was not sufficient to completely block degradation; this was only achieved by directly heating the cells in the lysis solution at 100 °C for 15 minutes and maintaining the samples at 4 °C for the rest of the extraction process (see the Supporting Information). In addition to protease denaturation, this heating step enables both the internal standard and the internalized CPP to associate to the same extent with lysate components and to be subsequently captured on streptavidin-coated magnetic beads with the same efficiency. After capture of the biotinylated peptides, lysate components were easily removed by using the protocol described previously for washing the beads.[18] The peptides associated with the beads were then mixed with the matrix α-cyano-4-hydroxycinnamic acid, deposited directly on the MALDI-TOF plate, and then analyzed. Spectra were averaged for statistical sampling from a few hundred laser shots recorded on different spots of the deposit. The acquisition of $[M+H]^+$ signals with the natural isotopic distribution for both H-CPP and D-CPP was the indication of a valid statistical sampling (Figure 2a and Supporting Information). The areas of the H-CPP and D-CPP $[M+H]^+$ signals, including all the isotopes, were used for the quantification. Quantification was more precise when H-CPP and D-CPP signals had similar intensities because the signal/noise ratio was then comparable for both peptides. In practice, the amount of internalized H-CPP was first evaluated by adding various known quantities of D-CPP to samples containing the internalized peptide. Quantification was then found to be feasible with our mass spectrometer for H-CPP/D-CPP signals ratios ranging from 0.2:1 to 5:1. The experiment was repeated, with the amount of D-CPP adjusted to get a signal ratio close to 1:1. Quantifications performed on different deposits of the same biological sample gave highly reproducible results (±5% variation).

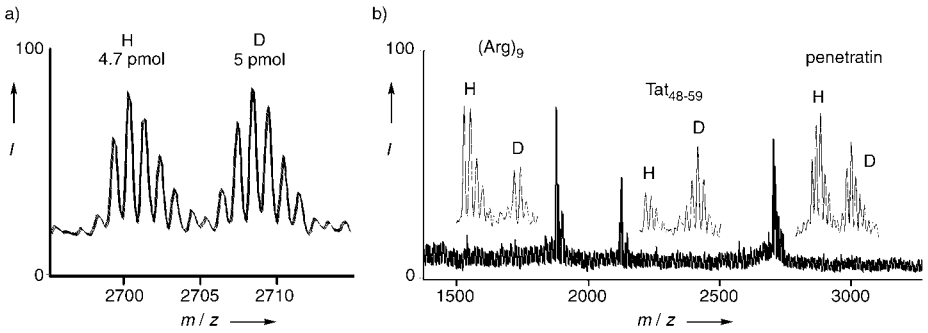

Figure 2. MALDI-TOF mass spectra obtained for internalization of a) penetratin and b) a mixture of penetratin (biotin-GGGG-RQIKIWFQNRRMKWKK-NH_2), Tat_{48-59} (biotin-GGGG-RKKRRQRRRPPQ-NH_2), and $(Arg)_9$ (biotin-GGGG-RRRRRRRRR-NH_2). H and D correspond to the $[M+H]^+$ peaks of the internalized CPPs and the internal standards, respectively.

By using this protocol we measured the intracellular concentrations of penetratin, Tat_{48-59}, and $(Arg)_9$. Each experiment was carried out by incubating 10^6 Chinese hamster ovary (CHO) cells (corresponding to a total intracellular volume of 1.5 μL) for 75 minutes at 37 °C with the CPP (7.5 μM). The highest intracellular concentration was found for $(Arg)_9$ corresponding to 4.5 ± 1 μM (average concentration ± standard deviation (± SD), $n = 10$) followed by penetratin (3.5 ± 0.8 μM, $n = 12$) and Tat_{48-59} (0.7 ± 0.2 μM, $n =$

10; Figures 2a and 3a). H-CPPs digests corresponding exclusively to cleavage at the C-terminus of basic residues were occasionally observed with low abundance. These species were likely formed by the trypsin treatment used to digest the membrane-bound H-CPP and not completely eliminated during the subsequent washing step (Figure 1). In contrast to other CPP uptake assays our mass spectrometry approach allowed the facile distinction between these false positives and the peptide fraction that was actually internalized. No other digestion products were detected (see the Supporting Information for full mass spectra). The trypsin treatment was omitted in another set of experiments aimed at evaluating the affinities of the CPPs for the cellular membrane. Depending on the CPP, the amount corresponding to the sum of internalized and membrane-bound peptide was 5 to 60 times higher than the amount of internalized peptide (Figure 3b). These results stress the importance of the trypsin digestion step combined with direct quantification of the CPP to accurately discriminate extracellular membrane-bound peptide from internalized peptide. They also show that the efficiency of CPP internalization is not directly linked to membrane affinity. Finally, the amount of internalized CPPs was measured when the cells were incubated with a mixture of the three CPPs (7.5 μM each; Figures 2b and 3a). No cell lysis during incubation was observed. The relative internalization efficiencies of the CPPs were found to be equivalent to those calculated from the single CPP incubation experiments, but lower amounts of internalized peptide were measured (Figure 3a). These data show that no competition occurs between the three CPPs and suggest that a limited number of internalization domains are available. Experiments using CPP mixtures are more applicable for screening than for absolute quantification of cellular uptake. Indeed, saturation phenomena can occur as observed with the CPP mixture used in this study. Other CPP mixtures may also lead to competition between individual peptides. Furthermore, low-intensity signals may be observed in the MALDI-TOF mass spectra for CPPs that are the most poorly internalized.

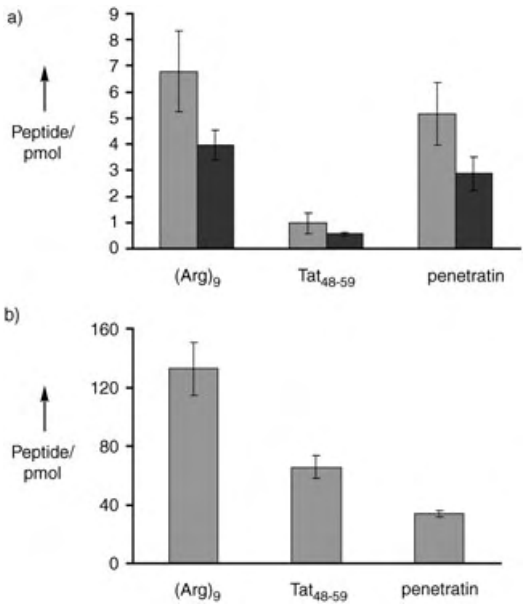

Figure 3. a) Amount of intact internalized CPP. Gray and black bars correspond to incubation of 10^6 CHO cells with each CPP independently or a mixture of the three CPPs, respectively. Each data is the average result of at least three independent experiments performed in duplicates or triplicates (±SD). Comparison of the mean differences between intracellular amounts of the three CPPs was performed with the Welch t test (populations with unequal SD) and was found significant ($p = 0.016$) between penetratin and $(Arg)_9$ and very significant ($p < 0.0001$) between penetratin or $(Arg)_9$ and Tat_{48-59}. b) Total amount of membrane-bound and internalized CPP. Data correspond to incubation of 10^6 CHO cells with each CPP independently.

In contrast to the majority of data reported in the literature for penetratin, Tat-derived peptides, and $(Arg)_9$, the intracellular CPP concentration was found in this study to be lower than the extracellular CPP concentration. Some of the high values of internalized CPP reported in the literature are likely explained by an incomplete elimination of the fraction of membrane-bound peptide. Results that closely match the ones determined in this study were obtained by fluorescence correlation microscopy, which allows unambiguous discrimination between extracellular and intracellular CPP.[13]

The detailed analysis of intracellular degradation of CPPs by using MALDI-TOF MS has been reported before.[19,20] However, compared to the method used, our procedure offers the advantage of allowing distinction between degradation occurring during sample preparation and actual intracellular degradation, with the internal standard (D-CPP) serving as a control (see the Supporting Information).

In conclusion, the method presented here enables direct quantification of CPP with unambiguous discrimination between membrane-bound and intracellular CPP. It is the first method described that allows direct comparison of internalization efficiencies using mixtures of CPPs. It is simple to use, fast, and yields highly reproducible results. The process of sample analysis on the MALDI-TOF plate lends itself to automation for the high-throughput screening of CPP libraries. The present method will provide a reliable and efficient tool for the design and optimization of new CPPs and for the study of their internalization mechanisms.

Metal Nitrides

Prediction of Novel Phases of Tantalum(V) Nitride and Tungsten(VI) Nitride That Can Be Synthesized under High Pressure and High Temperature

Peter Kroll, Timon Schröter, and Martina Peters*

The recent chemical syntheses of novel nitride compounds under high-pressure/high-temperature conditions is based on advances in instrumentation of diamond anvil cells and multi-anvil cells.[1–3] Spinel-type γ-Si_3N_4 is formed at pressures above 15 GPa and temperatures exceeding 2000 K,[4] the isotypic γ-Ge_3N_4 at pressures above 12 GPa and temperatures about 1000–1200 °C.[5] γ-P_3N_5 forms at 11 GPa and 1500 °C.[6] Hf_3N_4, for which no modification existed before, has been synthesized at 2800 K and 18 GPa and adopts the Th_3P_4-type structure. An isotypic Zr_3N_4 forms at pressures between 15.6 and 18 GPa and temperatures between 2500 and 3000 K.[7] PtN with sphalerite-type structure, the first binary nitride of the noble metals group, has been synthesized above 50 GPa and temperatures exceeding 2000 K.[8] Most recently, polymeric nitrogen with cubic structure was synthesized at temperatures above 2000 K and pressures above 110 GPa.[9] While this pure nitride compound deteriorated on expansion (reduction in pressure), all the novel binary nitrides could be quenched to ambient conditions. Some of them have or are proposed to have outstanding mechanical,[10] optical,[9] or electronic[11] properties. Herein we investigate the possible preparation of novel nitrides of tantalum and tungsten, predict the crystal structures of Ta_3N_5-II, WN_2-I, and WN_2-II, and estimate the range of pressure and temperature necessary to synthesize these new phase modifications.

The binary Ta–N system displays a rich crystal chemistry, ranging from solid solutions of nitrogen in close-packed tantalum, over compounds with a composition of approximately 1:1, and several nitrogen-rich phases up to Ta_3N_5, the most nitrogen rich tantalum(V) nitride.[12] Just recently, a new tantalum nitride with composition Ta_2N_3 adopting a bixbyite-type structure has been synthesized by plasma-enhanced chemical vapor deposition methods.[13] Our computation of the crystal structure of the experimentally observed orthorhombic modification of Ta_3N_5 with space group *Cmcm* is in excellent agreement with experimental[14,15] and recent theoretical data.[16,17] The volume of this ground-state structure, which exhibits two kinds of distorted $\{TaN_6\}$ octahedra, is 104.28 Å^3 per Ta_3N_5 unit. In search of high-pressure modifications of Ta_3N_5 we found three candidates with a denser packing of atoms and a higher average tantalum–nitrogen coordination, thus fulfilling the pressure-coordination rule:[18] A Sm_2SnS_5-type structure that contains both six- and eight-fold coordinate tantalum,[19] a U_3Se_5-type that has seven- and eight-fold coordinate tantalum,[20] and the most promising candidate we found is isostructural to U_3Te_5.[21] The orthorhombic structure of this modification (space group *Pnma*) comprises three different tantalum atoms in the unit cell, each in eighth-fold coordination to nitrogen (Figure 1). This

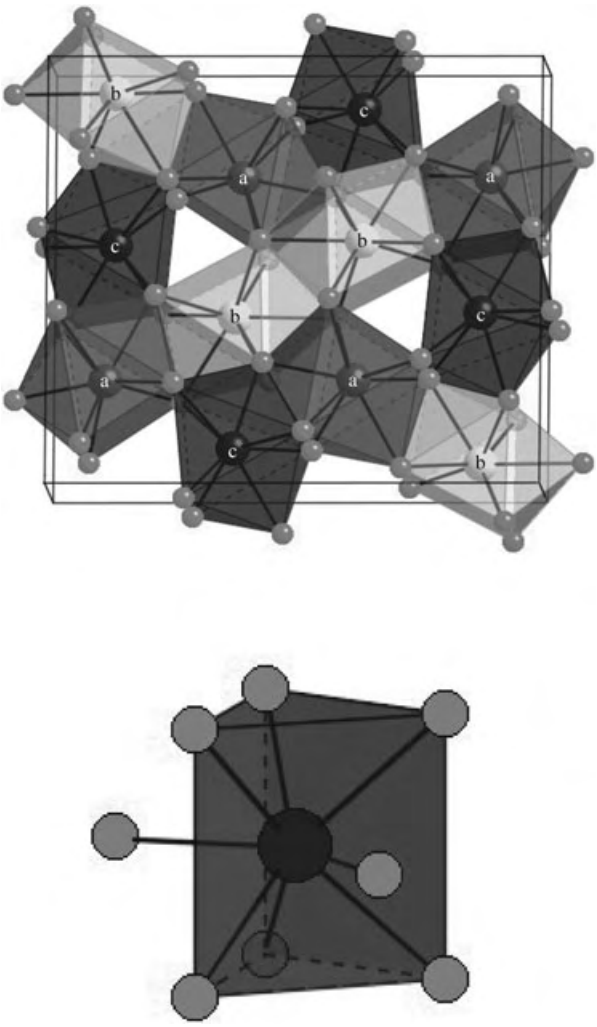

Figure 1. The U_3Te_5-type structure of Ta_3N_5-II. Top: a polyhedral view of the structure which contains three different Ta atoms (a–c: a unit cell is outlined). Bottom: A representative bicapped trigonal-prismatic environment of Ta (large circle, N small circles).

situation is similar to the coordination of hafnium in cubic Hf_3N_4, which is build up by $\{HfN_8\}$ bisdisphenoids.[7] The $\{TaN_8\}$ polyhedra, however, are bicapped trigonal prisms. The energy difference of the U_3Te_5-type polymorph of Ta_3N_5 relative to the ground state *Cmcm* structure is +1.36 eV per Ta_3N_5 unit, its volume is 78.40 Å^3 per Ta_3N_5, indicating a contraction by almost 26 %.[22]

The results of our energy–volume computations and the corresponding enthalpy–pressure phase diagram of Ta_3N_5 are shown in Figure 2. Accordingly, the *Cmcm* ground-state structure is the most stable modification of Ta_3N_5 up to 9 GPa. Above this pressure the U_3Te_5-type is favored. The

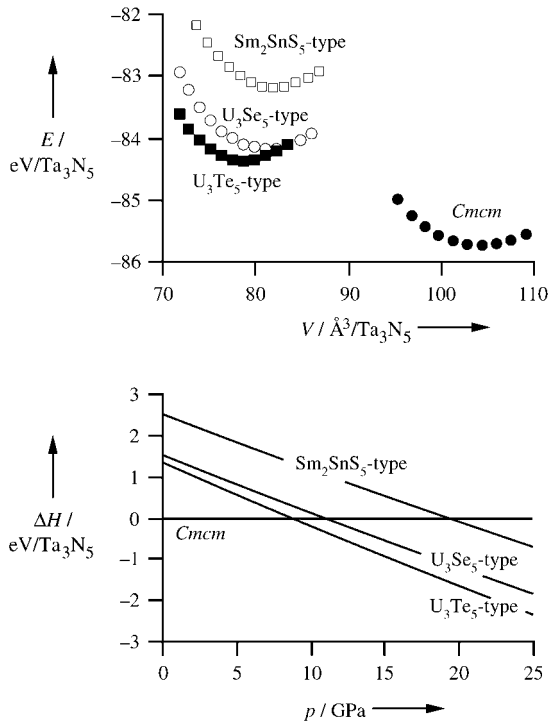

Figure 2. Energy–volume (*E*–*V*) diagram (top) and enthalpy–pressure (Δ*H*-*p*) diagram (bottom) for different phases of Ta_3N_5.

U_3Se_5- and Sm_2SnS_5-types will surpass the ground state for stability above 11 and 19 GPa, respectively, but will not outperform the U_3Te_5-type. Neglecting further entropy contributions to the free enthalpy ΔG (that is, $\Delta G \approx \Delta H$) we predict the formation of a new high-pressure modification, Ta_3N_5-II, from the ground-state structure Ta_3N_5-I at about 9 GPa. This transition will take place, because entropy differences between solid-state compounds, though present and contributing to the free enthalpy ΔG, are typically small in comparison to the much larger variation of ΔH within a few GPa of pressure (see the Methods Section for definition of ΔH).

To date, WN_2 has not been synthesized in crystalline form. For a long time is has been speculated that it would adopt a fluorite-type structure,[23] but no binary nitride of tungsten(VI) paralleling the oxide WO_3 has been produced. Nitrogen-rich WN_x thin films, with x approaching 2, however, can be produced by low-temperature deposition methods.[24,25] Our calculations suggest that WN_2, if it exists in crystalline form, may adopt the monoclinic structure of baddeleyite (m-ZrO_2, space group $P2_1/c$).[26] In this case the tungsten atoms are seven-fold coordinate in a monocapped trigonal prismatic arrangement of nitrogen atoms. We found three more seven-coordinate structures with a similar tungsten environment that are close in energy.[27] The monoclinic modification of WN_2-I ($V = 31.39$ Å^3/WN_2), however, has the lowest energy.[28] It competes with a six-coordinate brookite-type structure
(+0.07 eV/WN_2), which has a significantly larger volume of 36.13 Å^3/WN_2. Our calculations give no indication of fluorite- or pyrite-type structures appearing at high pressures. The most likely candidate we find for a high-pressure phase of WN_2 is a cotunnite-type (α-$PbCl_2$ (C23), space group *Pnma*[29]) modification. If adopted, tungsten will be nine-fold coordinated by nitrogen atoms (Figure 3). The {WN_9}

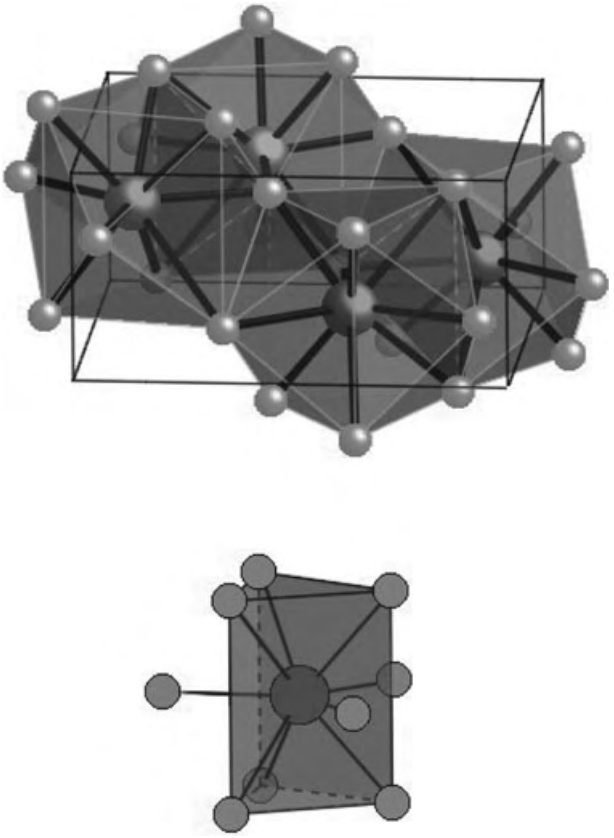

Figure 3. Cotunnite-type structure of WN_2. Top: a polyhedral view of the structure (a unit cell is outlined). Bottom: the tricapped trigonal prism {WN_9} environment (large circle W, smaller circles N).

polyhedra are tricapped trigonal prisms. The structure is more than 13% denser ($V = 27.29$ Å^3/WN_2), its energy is 0.78 eV/WN_2 higher than the proposed monoclinic ground state.[30] Energy–volume and enthalpy–pressure phase diagrams of WN_2 are displayed in Figure 4. The baddeleyite-type is the most stable modification of WN_2 up to a pressure of 34 GPa. Above this pressure it will transform into the cotunnite-type of WN_2-II.

How may the high-pressure phases of Ta_3N_5 and WN_2 be realized? In principle it is possible to start with a sample of Ta_3N_5-I and compress it to enforce its transformation into Ta_3N_5-II. Synthesizing the high-pressure phase of WN_2-II may follow a similar plan, however an amorphous sample of appropriate composition must be used. A chemical synthesis in the diamond anvil cell will start with metal platelets or cold-pressed powder pellets of the mononitrides (TaN or WN) as precursors. These are embedded in liquid nitrogen, which will act as the pressure medium, and then squeezed to the desired pressure. The starting materials are electrical conductors and can be heated with laser radiation to activate the transformation. However, it is possible that the solid nitride

compounds may decompose under development of nitrogen. For instance, Ta_3N_5 starts to decompose into TaN and nitrogen gas through a series of phases of intermediate composition at about 1000 °C at ambient pressure.[31,32]

Predicting the chemical synthesis of the new high-pressure phases, therefore, necessitates evaluating the equilibrium of the reaction $3\,TaN + N_2 \rightleftharpoons Ta_3N_5$ and $WN + \frac{1}{2}N_2 \rightleftharpoons WN_2$ as a function of pressure and temperature. To achieve this, we first calculate the enthalpy of formation ΔH as a function of pressure within density functional theory (DFT) at zero Kelvin. The phases of the products have been identified already, leaving just those of the starting materials to be found. We found the CoSn-type of ε-TaN as the phase of TaN with lowest enthalpy at ambient pressure. We compute its transition into the WC-type of ϑ-TaN to occur at about 8 GPa. This compares to shock-compression results, in which ε-TaN transforms to ϑ-TaN between 1 and 3 GPa below 1800 °C, but into a highly defective δ-TaN (NaCl-type) above 1800 °C at similar pressures.[34,33] Our choice of a reference phase of nitrogen was the ε-phase of N_2.[11] Computations for zero Kelvin suggest polymeric nitrogen may form at pressures above 55 GPa. Experimentally its formation in the cubic phase is observed at temperatures above 2.000 K and pressures above 110 GPa.[9] From this information we determine ΔH to be negative for both the formation of Ta_3N_5-I (-1.46 eV/Ta_3N_5) and Ta_3N_5-II (-0.10 eV/Ta_3N_5).

We proceed in a similar way for the tungsten–nitrogen system. A NiAs-type is identified as the ground-state structure of WN. We find no further modification of WN becoming more favorable up to 100 GPa. Our calculations then show that WN_2-I forms exothermically, $\Delta H = -0.24$ eV/WN_2. WN_2-II, on the other hand, has a positive ΔH value of $+0.53$ eV/WN_2. It requires a substantial pressure, we estimate 4 GPa, to stabilize this phase against decomposition.[35] Note that ΔH of WN_2-I, taken per atom (!), is significantly smaller than ΔH of Ta_3N_5-I. This result might indicate the difficulties in synthesizing crystalline WN_2 at ambient conditions.

At elevated temperatures the formation of gaseous nitrogen will contribute most to the free enthalpy of formation, ΔG, while the difference in entropy between the solid-state compounds contributes significantly less.[36] Therefore, we can use Equation (1) as a first order approximation to ΔG. With $\Delta_{sol}H(p)$ already determined, the free enthalpy of a gaseous species as a function of pressure and temperature is given by Equation (2) with f the fugacity of nitrogen.

$$\Delta G(p,T) = \Delta_{sol}H(p) + \Delta_{gas}G(p,T) \quad (1)$$

$$\Delta_{gas}G(p,T) = \Delta_{gas}G^0(p = 1\,\text{bar},T) + RT\,\ln\left(f/(1\,\text{bar})\right) \quad (2)$$

The first term on the right side of Equation (2), $\Delta_{gas}G^0(p{=}1\,\text{bar},T)$, is known for nitrogen to very high precision for the range 300–4000 K and tabulated in thermochemical tables.[37] The replacement of pressure by fugacity in the second term of the equation is mandatory even at moderate pressures to describe the deviation of nitrogen from ideal gas behavior. Pressure p and fugacity f are related through $f = \gamma p$, with γ the fugacity coefficient. If $\gamma = 1$, the gas has ideal behavior. A comprehensive collection of experimental data about nitrogen properties from the freezing line up to 2000 K and for pressures up to 1 GPa has been compiled by Jacobsen et al.[38] To approximate γ beyond this regime we propose two extrapolations: a conservative estimate and a more liberal expansion of γ. They provide the lower and upper boundary for the fugacity of nitrogen at high pressures. Details of both expansions are given in the Methods Section. Figure 5 shows both extrapolations used in this work in comparison to the virial expansion of Unland et al., which is based on experimental data, but valid only up to 2 GPa.[39] A value of $\ln\gamma = 20$ corresponding to a fugacity 10^6 times larger than the pressure should not come as a surprise, because it matches the measured properties of nitrogen at, for example, 300 K and 2 GPa.[38]

In Figure 6 shows the calculated phase boundary between mononitride and fully oxidized metal nitride in the pressure–temperature (p,T) phase diagrams of Ta-N and W-N. Accordingly, at 2800 K we predict the formation of Ta_3N_5-II in a diamond anvil cell at pressures above 17 GPa or above 25 GPa, depending upon which extrapolation of $\ln\gamma$ is applied. Similarly, WN_2-II can be synthesized above 31 or above 55 GPa at this temperature. Up to 34 GPa, however, WN_2-I is still favored over WN_2-II and, hence, will form instead. Once the novel high-pressure modifications have formed, they may be stabilized kinetically against transformation into the ground-state structures by a rapid quench. For WN_2-II its probable decomposition into WN and nitrogen provides an additional challenge.[40] Treating nitrogen as an ideal gas (setting $f = p$, $\ln\gamma = 1$) in the calculations yields a

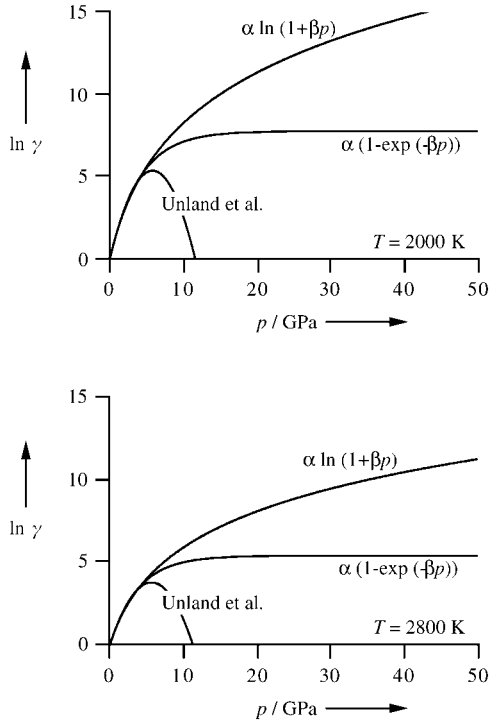

Figure 5. Plot of the logarithm of the fugacity coefficient ln γ as a function of pressure for both extrapolations used in this work in comparison to the virial expansion of Unland et al. The temperatures are typical for recent high-pressure experiments.[6,7] The (physically unrealistic) decrease of the fugacity coefficient at higher pressures in the virial expansion of Unland et al. is due to the functional form used.

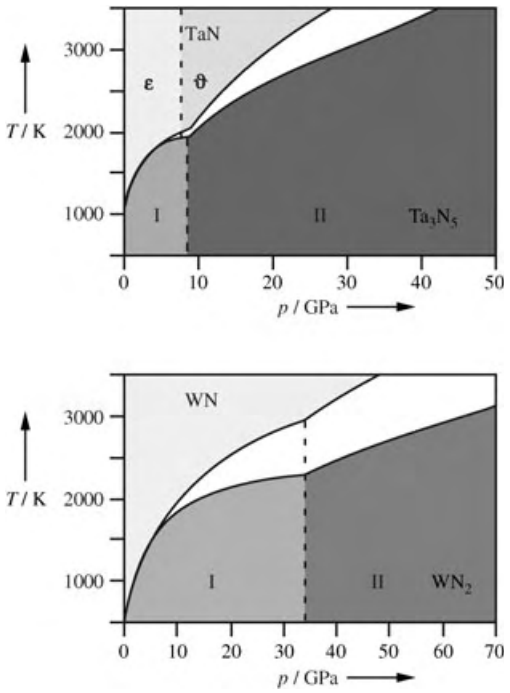

Figure 6. Phase boundary between TaN and Ta_3N_5 in the tantalum–nitrogen pressure–temperature phase diagram (top) and between WN and WN_2 in the tungsten–nitrogen pressure–temperature phase diagram (bottom). In both figures, the lower full line corresponds to the conservative expansion, the upper full line marks the more liberal estimate for the fugacity of nitrogen. Dashed lines separate phases of same composition. Gray shades indicate regions in which the respective phase is thermodynamically stable. The uncolored (white) region is the uncertainty range between the conservative and liberal expansion.

formation pressure of 44 GPa for Ta_3N_5-II at 2800 K, while WN_2-II will not form below 100 GPa. If we compare these results with our previous estimate of 22 GPa for the pressure of formation of Hf_3N_4 at this temperature[41] we notice the trend of increasing pressure needed to fully oxidize the metal when going from Group IV to Group V to Group VI. This trend can be expected for the experiment as well: Hf_3N_4 in fact forms at 18 GPa at 2800 K, which corroborates the substantial difference between fugacity and pressure.[7]

What properties may we expect from the new phases? If synthesized, the novel high-pressure phases Ta_3N_5-II and WN_2-II will not be transparent. A band-structure calculation reveals them as metallic conductors, despite the simple electron counting scheme of Ta^{+5} or W^{+6} together with N^{3-}, which leads us to expect a semiconductor. The ground-state structures, however, do have a band gap: 1.4 eV for Ta_3N_5-I and 0.4 eV for WN_2-I. The novel phases are very low-compressible materials. We calculate the bulk modulus B_0 of Ta_3N_5-II to be 378 GPa, that of the *Cmcm* ground state Ta_3N_5-I to be 265 GPa, WN_2-I has a B_0 of 318 GPa and WN_2-II of 408 GPa. These values exceed those of the high-pressure phases of spinel silicon nitride, γ-Si_3N_4 (300 GPa), and cubic hafnium nitride, Hf_3N_4 (283 GPa).[4,11]

The high-pressure modifications also show trend of increasing metal–nitrogen bond length with increasing coordination, termed the coordination–distance paradoxon.[42] The average Ta–N bond length is 2.10 Å (range: 1.96–2.28 Å) in Ta_3N_5-I, and increases about 5% to an average of 2.21 Å (range: 2.05–2.31 Å) in Ta_3N_5-II. The average W–N bond length in WN_2-I is 2.09 Å (1.87–2.22 Å), and increases to 2.19 Å (2.06–2.42 Å) in WN_2-II. This trend manifests itself in a decrease of the wave number of the principle Raman-active vibrational mode. It shifts from 900 cm^{-1} to 830 cm^{-1} in the Ta_3N_5-I to Ta_3N_5-II transition, and from 968 cm^{-1} to 797 cm^{-1} in the WN_2-I to WN_2-II transition.

In summary, we predict the novel modifications Ta_3N_5-II, WN_2-I, and WN_2-II that should be accessible by chemical synthesis at high pressures. Our assessment of the Ta–N and W–N phase diagrams is based on a combination of quantum-chemical calculations of crystal phases at high pressures and thermochemical calculations using proposed empirical relations for the fugacity of nitrogen. The *Cmcm* modification Ta_3N_5-I will undergo a structural transition into Ta_3N_5-II at 9 GPa. Using nitrogen as both pressure medium and reactant Ta_3N_5-II can be synthesized from the mononitride at pressures above 17 and 25 GPa at 2800 K. WN_2-II becomes accessible above 31 and 55 GPa at this temperature. If synthesized, this modification comprises unique $\{WN_9\}$-tricapped trigonal prisms, the highest W–N coordination in crystal chemistry. The high-pressure modifications exhibit very high bulk moduli, 378 GPa for Ta_3N_5-II and 408 GPa for WN_2-II. We conclude that nitrogen can be activated by such pressures and is capable of oxidizing tungsten to its highest oxidation state,

tungsten(VI). Investigation of the phase diagrams of Ta–N and W–N will give further substantial information on the fugacity of nitrogen at very high pressures.

Experimental Section

Our computations of crystal structures are based on density functional theory as implemented in the Vienna Ab Initio Simulation Package (VASP).[43–46] We employ the generalized gradient approximation (GGA) to compute energy differences and band structures, and rely on Blöchls projector augmented wave (PAW) method.[47,48] The local density approximation (LDA) is used for comparison and to compute the elastic properties and vibrational spectra. The pseudopotentials of the metal atoms include the d-electrons as valence states. Cut-off energy (500 eV) for the expansion of the wave function into plane waves and k-point sampling scheme are chosen to ensure that all structures are well-converged to better than 1 meV per atom. The application of pressure to the crystal structures is simulated by reducing the volume of the unit cell. With the constraint of constant volume, all other structural parameters (atomic positions and lattice parameter) are optimized and the energy calculated. This results in a energy–volume (E–V) diagram, which can be fitted with common equations of state (EOS) to access the bulk modulus B_0 and its pressure derivative B'. We calculate the pressure p by numerical differentiation of a spline fit to the E–V data and get the enthalpy H from $H = E + pV$. It is good practice to give the enthalpy difference ΔH relative to a reference (ground state) structure.

The extrapolation of the fugacity of nitrogen is based on the thermochemical data compiled by Jacobsen et al.[38] and the corresponding six-parameter virial expansion of $\ln \gamma$ by Unland et al.[39] We started with a linear extrapolation of $\ln\gamma$ for pressures beyond 3 GPa. This approach corresponds to that of Ma et al.,[49] but leads to much too unrealistic values for $\ln \gamma$. The more modest functional forms we choose are motivated by simplicity and reasonable high-pressure behavior. They have been fitted with the virial expansion and adjusted to reproduce the pressure of formation of Hf_3N_4 and Zr_3N_4. In particular, the conservative estimate is given by $\ln\gamma_l = \alpha_l(T)\,(1-\exp(-\beta_l(T)\,p))$, with virial expansions for both $\alpha_l = \alpha_1/T + \alpha_2/T^2 + \alpha_3/T^3$ and $\beta_l = \beta_0 + \beta_1/T + \beta_2/T^2$. Coefficients are: $\alpha_1 = 14.0707$, $\alpha_2 = 2.40815$, $\alpha_3 = 0.86685$, $\beta_0 = 0.29775$, $\beta_1 = -0.09503$, $\beta_2 = 0.00996$. The more liberal estimate is given by $\ln\gamma_h = \alpha_h/T\,\ln(1+\beta_h p)$. Coefficients are: $\alpha_h = 10.4583$, $\beta_h = 0.3879$. In both expansions the temperature T is given in units of 1000 K and the pressure p in GPa.

Gas-Phase Reactions

Stability of Gaseous Thallium Monofluoride as TlF^0, TlF^+, and TlF^{2+}**

Detlef Schröder, Christoph van Wüllen,* Helmut Schwarz, and Thomas M. Klapötke*

Dedicated to Professor Konrad Seppelt

As the most electronegative element, fluorine forms rather strong bonds with many elements, including metals. Accordingly, fluorine allows formation of the highest valences in the molecular compounds of several elements, for example, CoF_3, AgF_2, IrF_7, PtF_6, and AuF_5. Similarly, several multiply charged metal atoms form stronger bonds to fluorine than to any other element,[1] and even the triply charged diatomic metal fluorides TiF^{3+} and UF^{3+} are known.[2,3] However, there exist some notable exceptions such as gold(I) fluoride, which remained elusive until 1994,[4] while AuCl, AuBr, and AuI were well-characterized more than a century ago. The corresponding diatomic ion AuF^+ has a bond energy of only 0.8 eV,[5] whereas the heavier analogue gold iodide ion AuI^+ has a much stronger bond (ca. 2.6 eV).[6] Three major factors contribute to the comparably weak Au–F bonding in the cation: 1) the unfavorable overlap between the 6s orbital of gold and the $2p_\sigma$ orbital of fluorine, 2) the small polarizability of fluorine, and 3) the relativistically lowered energy of the gold 6s orbital which disfavors the ionic bonding preferred in fluorine compounds.[7]

Herein, we report a combined experimental and theoretical investigation on the stability of thallium monofluoride in different charge states $TlF^{0/+/2+}$.[8] The TlF^{2+} dication is of particular interest because the $6s^15d^{10}$ ground state of Tl^{2+} corresponds to the configuration of the neutral gold atom while the positive charge is expected to weaken the Tl–F bond and may even lead to Coulomb explosion into the singly charged atomic ions. Accordingly, the question arises about the existence and, if so, the stability of TlF^{2+} in the gas phase. It turns out, however, that the deceptively simple monocation TlF^+ poses an even bigger challenge for both experiment and theory.

Neutral thallium(I) fluoride is a colorless, hygroscopic solid. Upon heating to about 200 °C, TlF evaporates in high vacuum (10^{-6} mbar). Electron ionization (EI, 70 eV) of gaseous neutral TlF affords the following cationic species (relative abundances in brackets): TlF^+ (2%), Tl^+ (100%), TlF^{2+} (1%), and Tl^{2+} (6%); in addition, some minor signals arising from EI of the neutral dimer Tl_2F_2 are observed.[10] Considering that neutral TlF is used as a precursor,[11] the weakness of the molecular ion signal for TlF^+ upon EI indicates either an intrinsic instability of the cation or unfavorable Franck–Condon overlaps between neutral and monocationic $TlF^{0/+}$. Consistent with the argument of intrinsic instability, the mass-selected TlF^+ ion undergoes a pronounced unimolecular decomposition to afford atomic Tl^+ according to Equation (1) accompanied by a small kinetic energy release (KER) of (10 ± 4) meV.[12]

$$TlF^+ \rightarrow Tl^+ + F \qquad (1)$$

In the approximately 2-m long field-free region of the sector-field mass spectrometer used,[8,9] a fraction of about 15% of the incident TlF^+ ions entering this region undergoes metastable-ion decay, which corresponds to a unimolecular rate constant in the order of $10^4\ s^{-1}$. For a diatomic species having just one degree of freedom, the sheer magnitude of this value may appear surprising because metastable-ion decay usually only applies to a fraction between 0.1 and 1% of the incident ions.[13] We return to this aspect later in the discussion.

Upon collision of mass-selected TlF^+ ions (which have 8 keV kinetic energy) with oxygen, dissociation to afford Tl^+ prevails. Despite the large collision energy, charge stripping (CS)[14] to afford the dications TlF^{2+} and Tl^{2+} is rather inefficient; only at highest sensitivity is a small signal for TlF^{2+} observed.[15] Compared to other metal–fluoride cations for which medium to intense dication signals are formed upon CS,[2,3,16] this observation implies that either dissociation of TlF^+ is particularly facile, that the formation of TlF^{2+} is very

energy-demanding, or that TlF^{2+} undergoes rapid dissociation. Further, a composite peak is found for the Tl^+ fragment, where the abundant, narrow component is due to the process in Equation (1) and a weak, broader component can be attributed to the occurrence of charge separation according to Equation (2).[17] Thus facile dissociations of both TlF^+ and TlF^{2+} are implied.

$$TlF^{2+} \rightarrow Tl^+ + F^+ \qquad (2)$$

Unlike TlF^+, the mass-selected dication TlF^{2+} undergoes minimal unimolecular decay (< 0.1% of the incident beam), just as expected for a diatomic species in the μs regime.[13] Upon collision of mass-selected TlF^{2+} with O_2 as collision gas, fragmentation to $Tl^{2+} + F$ as well as charge exchange to afford TlF^+ and subsequently $Tl^+ + F$ are observed (Figure 1). Note that the charge-exchange products unambiguously prove

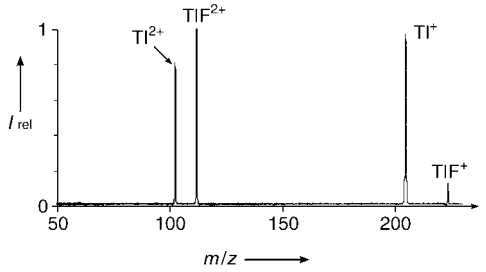

Figure 1. Charge-exchange spectrum (collision gas: O_2, 80% T) of mass-selected TlF^{2+}. Note that the precursor dication appears in the middle of the spectrum and is off-scale.

that a dication has been mass-selected in the experiment because product ions with m/z values larger than that of the parent ion can only be detected for precursor ions with $z > 1$. Quite unusual for such a charge-exchange experiment is, however, the low abundance of the TlF^+ monocation, again suggesting that dissociation of the singly charged species is facile. In spite of this feature, the experimental data presented so far still demonstrate that TlF can exist not only as a neutral compound but also in its singly and doubly charged cation states.

Further insight into the energetics of $TlF^{0/+/2+}$ is gained by high-level ab initio calculations (Table 1).[18,21] Neutral TlF ($^1\Sigma$) with $r = 2.09$ Å and $\tilde{\nu} = 472\ cm^{-1}$ is located in a deep potential-energy well with a computed dissociation energy of $D_0 = 4.57$ eV at 0 K[21] which nicely matches the experimental values available (exp. 4.58 eV).[22] In marked contrast to the substantial binding in the neutral species, the computed bond energy for the ground state of the monocation TlF^+ ($^2\Sigma$) with $r = 2.05$ Å and $\tilde{\nu} = 349\ cm^{-1}$ is only $D_0 = 0.02$ eV. Consistent with the corresponding Born–Haber cycle, the ionization energy $IE(TlF) = 10.54$ eV (exp. 10.52 eV[23]) is 4.55 eV larger than $IE(Tl) = 5.99$ eV (exp. 6.11 eV[24]). Near the minimum,

Table 1: Total energies of $TlF^{0/+/2+}$, the relevant dissociation asymptotes, and the corresponding properties derived from them.

[a] Values derived from RCCSD(T) calculations unless stated otherwise. [b] Ref. [21]. [c] Taken from ref. [24]. [d] Derived from MR-AQCC values. [e] Ref. [22] [f] Derived from the difference of the appearance energies from TlF^+ and Tl^+ upon photoionization of gaseous TlF with an experimental error of 0.05 eV. Note further that the appearance of Tl^+ may be shifted to energies slightly higher than the adiabatic value owing to the 0.1 eV barrier discussed in the text. [g] Taken from ref. [23]. [h] Derived from the combined RCCSD(T) and MR-AQCC values, see Figure 2. [i] This work; see ref. [15].

the bonding in TlF^+ can be described as a mixture of the mostly repulsive interaction of the quasi-closed shell Tl^+ (^{1}S) with F (^{2}P) and ionic contributions from the Tl^{2+} (^{2}S) + F^- (^{1}S) asymptote. With respect to the unusually low D_0 value of TlF^+, the dissociation into ground-state Tl^+ (^{1}S) + F (^{2}P) was considered in more detail.

As shown in Figure 2, the ion dissociation of TlF^+ is associated with a very modest barrier of only about 0.1 eV (precisely, 897 cm^{-1}) at a Tl–F distance of $r = 2.5$ Å. To assess

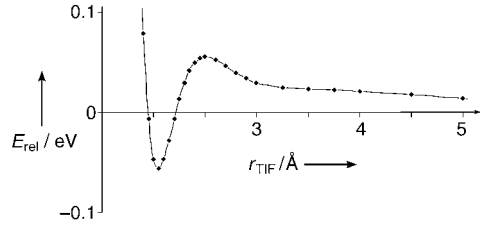

Figure 2. Computed potential-energy curve (in eV) of diatomic TlF^+.

whether or not the computed potential-energy curve is compatible with the experimentally observed metastable state of TlF^+ formed upon ionization, the one-dimensional vibrational Schrödinger equation of TlF^+ was solved. A bound vibrational state TlF^+ ($\nu = 0$) is located 173 cm^{-1} above the minimum, and two metastable states or resonances TlF^+ ($\nu = 1$) and TlF^+ ($\nu = 2$) are situated 479 cm^{-1} and 733 cm^{-1}, respectively, above the minimum. Starting from a Boltzmann distribution ($T = 500$ K) of the vibrational states of neutral TlF and assuming that EI occurs as a vertical process, the Franck–Condon factors suggest that upon ionization the bound state TlF^+ ($\nu = 0$) and the metastable states with $\nu = 1$ and $\nu = 2$ are populated with probabilities of 65, 24, and 6%, respectively; the remaining percentage directly ionizes into

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the continuum states which decay within a few vibrational periods.

The decay rates of the metastable states can be estimated within the semiclassical approximation which goes back to the seminal description of nuclear α-decay by Gamow.[25] For TlF^+ ($v=2$), a lifetime of 7 ns is thus estimated, while the lifetime of TlF^+ ($v=1$) is very large, because the energy level is only slightly above the dissociation asymptote. For the $v=2$ resonance, also a fully quantum mechanical wave-packet propagation was performed for a period of 60 ns which led to an exponential decay of TlF^+ ($v=2$) with a lifetime of 26 ns, which is consistent with the semiclassical estimate. While these values have been obtained for the rotational ground state ($J=0$), the preferentially populated rotational level at $T=500$ K is around $J=27$ and 33% of the molecules occupy rotational levels above $J=40$ and 25% above $J=45$. If the centrifugal potential corresponding to J values between 40 and 45 is added to the calculated potential-energy curve, the minimum is shifted upwards with respect to the dissociation asymptote by approximately 0.05 eV. Even more important is that the barrier height is reduced by about 15%. As a consequence, the $v=2$ resonance vanishes and the semiclassical estimate for the lifetime of $v=1$ decreases to 2×10^{-4} s for $J=40$ and 9×10^{-6} s for $J=45$. The observed metastable decay thus most likely corresponds to the decay of a rotationally excited quasi-stationary vibrational state ($v=1$), for which both the population based on the Franck–Condon factors and the decay rate are in reasonable agreement with the experimental results.

The dication TlF^{2+} ($^1\Sigma$) with $r=1.95$ Å and $\tilde{\nu}=498$ cm^{-1} is located 19.08 eV above ground state TlF^+ ($^2\Sigma$). As a consequence of the large *IE*, TlF^{2+} is a metastable dication for which decomposition with charge separation into $Tl^+ + F^+$ [Eq. (2)] is exothermic by 1.71 eV. Nevertheless, a Coulomb barrier kinetically stabilizes the dication, thereby allowing its mass spectrometric detection. Using the computed TlF^{2+} curve in conjunction with Coulomb's law, the crossing is estimated to occur at an interatomic distance of about 5 Å. From these theoretical results, the redox chemistry of $TlF^{0/+/2+}$ can be described quantitatively (Figure 3). Furthermore, note that the similar Tl–F distances in the ground states of TlF, TlF^+, and TlF^{2+} discount particularly unfavorable Franck–Condon effects in the vertical electron-transfer processes.

Given the rather weakly bound monocationic species, possible low-lying excited states of TlF^+ were considered as an alternative explanation for the observed TlF^+ species. The lowest lying excited state TlF^{+*} ($^2\Sigma$) with $r=2.20$ Å and $\tilde{\nu}=517$ cm^{-1} is located 3.65 eV above ground state TlF^+ ($^2\Sigma$). The bonding in TlF^{+*} ($^2\Sigma$) arises from the $Tl^+(^3P)+F(^2P)$ asymptote, that is, the covalent coupling of atomic fluorine and the first excited state of the metal cation, Tl^+ (^3P), which has a $6s^16p^1$ configuration and $E_{ex}=7.06$ eV (exp. 7.10 eV). The excited state TlF^{+*} ($^2\Sigma$) is located in a deep well with respect to the associated dissociation asymptote, yet is also some 3.7 eV above ground state asymptote for $Tl^+(^1S)+F(^2P)$. Thus, formation of TlF^{+*} ($^2\Sigma$) might offer an explanation for the long-lived TlF^+ molecular ion formed upon EI. Nevertheless, the experimental observations themselves disfavor this line of reasoning. If TlF^{+*} ($^2\Sigma$) were the major component of the mass-selected TlF^+ beam, its unimolecular dissociation which occurs on the μs timescale must lead to the atomic fragments in their ground state, that is, $Tl^+(^1S)+F(^2P)$, which would in turn requires the release of approximately 3.7 eV because neither Tl^+ nor F have excited states in this energy region.[24] However, the measured KER of the Tl^+ fragment is rather small. Failure to observe a significant amount of photons emitted during the ion beam's passage of the off-axis photomultiplier in the third field-free region of the instrument[8,26,27] discounts the alternative option of a radiative transition. Furthermore, even though the dication signal obtained upon CS of TlF^+ is rather weak, the *IE*(TlF^+) $\approx 19.7\pm1.1$ eV determined in energy-resolved experiments[15] is consistent with ground state TlF^+ serving as the precursor, whereas TlF^{+*} would require a significantly lower amount of energy of dication formation and should have a larger cross section.

In conclusion, diatomic TlF can exist in the three different charge states 0, +1, and +2. The neutral state shows tight binding, the monocation resides in a very shallow well, and the dication even is metastable with respect to Coulomb explosion, though the dication is kinetically stabilized. Perhaps surprising is that electron ionization of neutral TlF as well as charge exchange of metastable TlF^{2+}, both commonly considered as "harsh" methods, do allow the generation of ground state TlF^+, although this diatomic species can only survive in the lowest vibrational levels. As we have pointed out in a previous case,[28] this apparent paradox is directly associated with the small size of the system. For a polyatomic species with a large density of states, these "harsh" methods as well as the thermal energy of the precursor are very unlikely to support a well of only about 0.1 eV depth in the μs timeframe. In contrast, for small species, diatomic molecules in particular, there is a finite possibility that the rovibrational ground states might be populated despite the large energies involved in the experiments. Hence, the assumption that mass spectrometric experiments with ions having keV energies cannot sample very weakly bound species[29] is somewhat too general, and reconsideration of this aspect might be useful to resolve some current discrepancies.[30]

[8] The experiments were performed with a modified VG ZAB/HF/AMD 604 four-sector mass spectrometer of BEBE configuration (B stands for magnetic and E for electric sector).[9] The ions of interest were generated by electron ionization (EI, 70 eV) of anhydrous TlF. The ions accelerated by a potential of 8 kV were mass-selected using B(1)/E(1), and the respective mass spectra were recorded by scanning B(2). For collisional activation, helium was used as collision gas at 80% transmission (T). In the charge stripping (CS) and charge-exchange (CE) experiments,[1] oxygen was used throughout as the collision gas (80% T). Energy-resolved CS was performed with B(1)-only mass-selected ions. The attempt to detect photons emitted from metastable TlF^+ was conducted as follows: At a mass-resolution of $m/\Delta m = 2000$, the total ion current of TlF^+ in the mass region m/z 220 to 226 was measured by scanning B(1) and monitoring the cations using the off-axis detector mounted behind E(1). Next, the deflector electrode which directs the ions on the detector was switched off. If photons were emitted during the passage of the TlF^+ beam in the vicinity of the detector, these should give rise to signals at the correct m/z values of the two Tl isotopes in the B(1) scan. Even though the detector was set to maximal sensitivity, no photons could be observed.

[11] While we cannot strictly exclude that the dimeric ions $Tl_2F_n^+$ ($n = 1, 2$; see ref. [10]) may serve as precursor of the TlF^+ species formed, the low pressures applied in the ion source as well as the favorable Franck–Condon factors for the ionization of neutral TlF into low-lying cation states (see text) discount the need to include this issue in the further discussion.

[12] Ion dissociation owing to collisional activation by background gases was found to be negligible.

[15] The signal is too weak for an accurate determination of the energy demand of the CS process; only a crude value of $IE(TlF^+) \approx Q_{min} = 19.7 \pm 1.1$ eV can be extracted from experiment.

[17] From the distance between the peak maxima of the broad component, a KER of about (3 ± 1) eV can be estimated for Coulomb explosion of TlF^{2+} according to Equation (2).

[18] The calculations were performed using the MOLPRO[19] ab initio program at the RCCSD(T) and MR-AQCC levels. For thallium, we used a scalar-relativistic small-core ECP replacing 60 core electrons ([Kr]4d104f14 core) together with a 12s12p9d3f2g basis contracted to 6s6p4d3f2g.[20] For fluorine, the aug-cc-pVQZ basis set has been used. The 5s and 5p orbitals of thallium and the 1s orbital of fluorine were left uncorrelated. The MR-AQCC calculations use a reference CASSCF wave function with 13 active orbitals (full valence space covering the Tl 5d/6s/6p and F 2s/2p atomic orbitals).

[19] MOLPRO (version 2002.3) is a package of ab initio programs written by H.-J. Werner, P. J. Knowles, M. Schütz, R. Lindh, P. Celani, T. Korona, G. Rauhut, F. R. Manby, R. D. Amos, A. Arene Functionalization

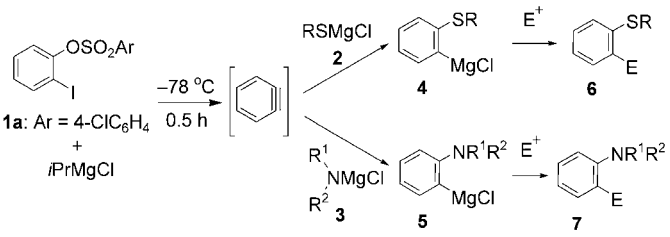
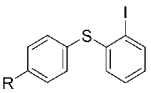
Preparation of Functionalized Aryl Magnesium Reagents by the Addition of Magnesium Aryl Thiolates and Amides to Arynes**

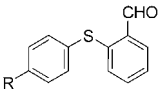


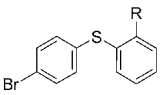
*Wenwei Lin, Ioannis Sapountzis, and Paul Knochel**

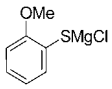
Dedicated to Professor Reinhard W. Hoffmann

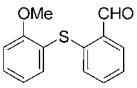
The functionalization of arenes is an important synthetic task.[1] A potential approach is the addition reaction of nucleophiles to intermediate arynes.[2] The addition of heteroatom–metal bonds (Nu–Met; Nu = OR, NR_2, SR, PR_2) to alkynes is usually a difficult process due to the high energy of the Nu–Met bond and to the high nucleophilicity of the resulting C–Met bond of the adduct, which is prone to undergo polymerization and other side reactions.[3] In the presence of a catalytic amount of a metal catalyst, various heteroatom–hydrogen bonds can be added to triple bonds.[3,4] However, in this case, the reactivity of the C–Met bond of the adduct cannot be exploited. By using a very reactive alkyne, such as an aryne,[5] the addition of nucleophiles should be facilitated and should afford useful arylmetal complexes, which should react with various electrophiles. Although the addition of various nitrogen nucleophiles to arynes has been reported,[5,6] the successful trapping of the intermediates with electrophiles has been reported in only a few cases.[7]

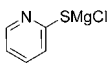


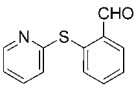


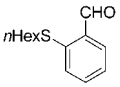


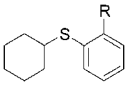












Recently we have described a new preparation of polyfunctional arynes by the elimination of 2-magnesiated diaryl sulfonates prepared from the corresponding iodides of type **1**.[8] Herein, we report the selective addition of magnesiated thiols and amines of types **2** and **3** to arynes generated by our previous procedure, providing 2-thio- and 2-amino-substituted aryl magnesium species of types **4** and **5**, respectively (Scheme 1). In contrast to previous methods,[2,5d,6] these aryl magnesium reagents can be trapped by a range of electrophiles giving rise to thioethers of type **6** and arylamines of type **7** (Table 1 and Table 2).

Thus, the addition of *i*PrMgCl (2.0 equiv) to thiophenol (1.0 equiv) in THF (−78 °C, 10 min) followed by the addition of 2-iodophenyl 4-chlorobenzenesulfonate (**1a**) (1.0 equiv; −78 °C, 0.5 h) and subsequent warming to 0 °C within 10 min led to the benzyne-addition product **4a**, which, upon quenching with iodine in THF at −78 °C, provided 2-iodophenyl

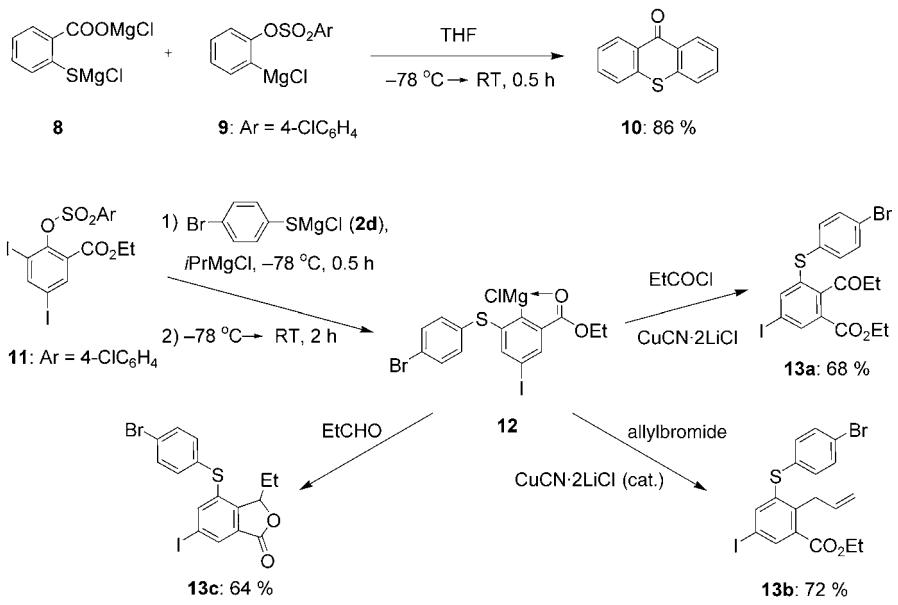
phenyl sulfide (**6a**) in 83% yield (entry 1, Table 1). Various substituted thiophenolates, such as **2b–d**, reacted as well affording after iodolysis the 2-iodophenyl thioethers **6b–d** in 82–90% yield (entries 2–4).

Similarly, the intermediate Grignard reagents were formylated with DMF (2.5 equiv, −40°C to RT, 1 h) leading to aldehydes **6e–g** in 73–78% yield (entries 5–7, Table 1). Acid chlorides (in the presence of CuCN·2 LiCl) and aldehydes were also excellent trapping agents, leading to ketones **6h–i** and to the benzylic alcohol **6j**, respectively, in 85–90% yield (entries 8–10). The *ortho*-substituted magnesium thiolate **2e** (entry 11) and the heterocyclic thiolate **2f** (entry 12) both underwent the addition reaction followed by formylation with DMF giving rise to **6k** (80% yield) and **6l** (82% yield), respectively. Aliphatic thiolates, such as **2g** and **2h**, added to benzyne under the same reaction conditions affording the functionalized alkyl aryl thioethers **6m–o** in 67–83% yield (entries 13–15).



The high strain of the generated aryne ensures a smooth addition and excellent functional-group compatibility. Thus, the reaction of the magnesium thiolate **8**, bearing a carboxy group in position 2, with the 2-magnesiated benzenesulfonate **9** provided the desired addition aryl magnesium species, which reacted intramolecularly with the carbonyl group in *ortho*-position leading to thioxanthone (**10**) in 86% yield (Scheme 2).

Interestingly, functionalized arynes displayed remarkable regioselectivity in the addition step. Thus, the polyfunctional sulfonate **11** was selectively magnesiated in the α-position to the sulfonate group (inductive activation of the *ortho*-carbon–iodine bond), and its reaction with the magnesium thiolate **2d** provided only the magnesium reagent **12**, which was stabilized by chelation. Its reaction with various electrophiles, like an acid chloride, allyl bromide in the presence of CuCN·2 LiCl, or an aldehyde, furnished the tetrasubstituted thioethers **13a–c** in 64–72% yield (Scheme 2).

Remarkably, all the previous reactions involved the conversion of the magnesium–sulfur bond of **2** into the magnesium–carbon bond in **4**. We have also examined the addition of a magnesium amide of type **3** to benzyne; this results in the conversion of a nitrogen–magnesium bond to a carbon–magnesium bond in the product **5** (Scheme 1). Thus, the reaction of magnesiated *N*-methylaniline (**3a**) with the 2-magnesiated benzenesulfonate **9** provided the desired addition product of type **5** (−78°C, 30 min, then 0°C for 10 min). After the addition of CuCN·2 LiCl and allyl bromide, the desired product **7a** was obtained in 83% yield (entry 1, Table 2). Typical electrophiles, such as benzoyl chloride, benzaldehyde, and DMF, reacted similarly furnishing the diarylamines **7b–d** in 74–85% yield (entries 2–4). Related phenyl-substituted secondary magnesium amides, such as **3b** and **3c** (entries 5–7), reacted in a similar way leading to the benzaldehyde **7e** (71% yield) and the indolines **7f** and **7g** (62–66% yield), respectively. The bulky aliphatic amide *i*Pr_2NMgCl (**3d**) was less prone to add to benzyne, and the desired product **7h** (after formylation) was obtained only in 25% yield (entry 8). Interestingly, a functionalized magnesium amide, such as **3e**, underwent the benzyne addition providing a polyfunctional aryl magnesium species, which was efficiently trapped with DMF and EtCOCl according to our standard procedure furnishing the tertiary amines **7i** (73% yield, entry 9) and **7j** (76% yield, entry 10), respectively.

During this study, we realized that the rate of addition to the aryne strongly depended on the nucleophilicity of the magnesium reagent (Nu–MgX) as noted previously by Huisgen.[5a] Thus, whereas magnesium amides are basic reagents, magnesium thiolates are more nucleophilic and therefore add more readily.[9] We anticipated that highly nucleophilic reagents, like phenylselenyl magnesium chloride **14**, would react well with benzyne. Preliminary experiments confirmed this hypothesis. Thus, the addition of **14** to **9** lead via the magnesiated intermediate **16**[10] to the products **15a** (85% yield) and **15b** (87% yield) under standard conditions (Scheme 3).

In summary, we have developed a general procedure for the thio-(seleno-) and aminomagnesiation of arynes. The resulting aryl magnesium species can be trapped with numerous electrophiles in contrast to most previously reported addition reactions. Further extensions utilizing other nucleophiles are currently underway in our laboratories.

added dropwise, and the reaction mixture was stirred for 10 min. A solution of **1a** (394 mg, 1.0 mmol) in dry THF (2 mL) was added, and the reaction mixture was stirred vigorously for 30 min at the same temperature. The resulting mixture was immediately warmed to 0 °C and stirred for 10 min. Then the reaction mixture was cooled to −40 °C, and DMF (0.20 mL, 2.5 equiv) was added. Thereafter, the reaction mixture was warmed to room temperature and stirred for 1 h. The reaction was quenched with sat. aq. NH_4Cl solution and extracted with CH_2Cl_2 (3 × 40 mL). The combined organic phases were dried over anhydrous Na_2SO_4 and filtered, and the solvent was removed by evaporation in vacuo. Purification by flash chromatography (*n*-pentane/diethyl ether 20:1) furnished the thioether **6g** as a yellow solid (220 mg, 75 %).

Preparation of **7d**: A dry and argon-flushed 25-mL Schlenk flask, equipped with a magnetic stirring bar and a septum, was charged with a solution of *N*-methylaniline (107 mg, 1.0 mmol) in dry THF (3 mL). This solution was cooled to −20 °C, *i*PrMgCl (0.94 mL, 1.0 equiv, 1.07 M in THF) was added dropwise, and the reaction mixture was stirred for 30 min. The reaction mixture was cooled to −78 °C, and *i*PrMgCl (0.94 mL, 1.0 equiv, 1.07 M in THF) was added. A solution of **1a** (394 mg, 1.0 mmol) in dry THF (2 mL) was added, and the reaction mixture was stirred vigorously for 30 min at the same temperature. The resulting mixture was immediately warmed to 0 °C and stirred for 10 min. Then, the reaction mixture was cooled to −40 °C, and DMF (0.20 mL, 2.5 equiv) was added. Thereafter, the reaction mixture was warmed to room temperature and stirred for 1 h. The reaction was quenched with sat. aq. NH_4Cl solution and extracted with CH_2Cl_2 (3 × 40 mL). The combined organic phases were dried over anhydrous Na_2SO_4 and filtered, and the solvent was removed by evaporation in vacuo. Purification by flash chromatography (*n*-pentane/diethyl ether 250:1) furnished the amino aldehyde **7d** as a yellow oil (156 mg, 74 %).

Oxygen-Rich Compounds

The Molecules AlO_2, $Al(O_2)_2$, and $Al(O_2)_3$: Experimental and Quantum-Chemical Investigations on the Oxidation of Aluminum Atoms**

*Gregor Stößer and Hansgeorg Schnöckel**

Dedicated to Professor Klaus Krogmann on the occasion of his 80th birthday

We have already mentioned the significance of peroxo- and hyperoxo complexes with unusual spin states as intermediates in oxidation processes in biology and synthetic chemistry when we reported the oxidation of AlX molecules with O_2 under matrix-isolation conditions.[1][2] The reactions of metal atoms with oxygen discussed herein also prove to be complex, since electrons are taken up stepwise by the O_2 molecules with retention of symmetry and spin rules ($O_2 \rightarrow O_2^- \rightarrow O_2^{2-}$). On the preparative scale, this process results exclusively cleavage of the O–O bond and the formation of O^{2-} ions; with metal cations these ions form particularly stable oxides, such as Al_2O_3. To investigate the primary steps of this reaction we have treated aluminum atoms with an increasing excess of O_2 in the matrix-gas argon under matrix-isolation conditions and have obtained the molecules AlO_2 (**1**), $Al(O_2)_2$ (**2**), and $Al(O_2)_3$ (**3**). These result are reported herein, while details of the spectra and the results of quantum-chemical calculations are given in the Supporting Information.

The formation of C_{2v} symmetrical AlO_2 (**1**) in solid argon from aluminum atoms with approximately 0.1 % O_2 has been reported elsewhere.[3]. In our experiments, and in agreement with the literature, we have observed the symmetrical AlO_2 vibration in the IR spectrum at 496 cm^{-1} and measured its $^{16}O/^{18}O$ shifts.[4] A new band at 1070 cm^{-1} is observed at higher O_2 concentrations in argon gas (1–3 %) after reaction of aluminum atoms, again in agreement with the literature.[5] $^{16}O/^{18}O$ substitution experiments indicate that this new band belongs to a species with four equivalent oxygen atoms.[6] As will be shown below, this species is $Al(O_2)_2$ (**2**), which is assigned the structure (D_{2d} symmetry) illustrated in Figure 1. At still higher O_2 concentrations in the matrix and finally in pure solid O_2 a band at 688 cm^{-1} is observed in the IR spectrum. This band shifts to 671 cm^{-1} in $^{18}O_2$ enriched O_2 and occurs at 679 cm^{-1} in the presence of $^{16}O/^{18}O$ species.[7] Since,

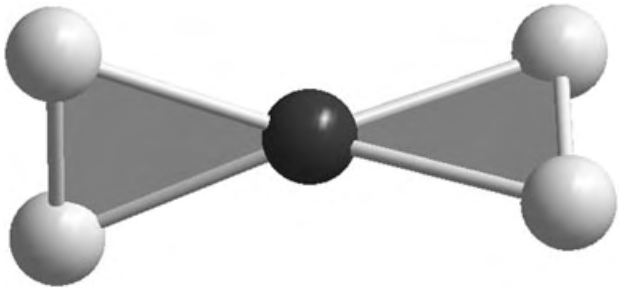

Figure 1. Minimum structure of $Al(O_2)_2$ (**2**) calculated with B3LYP/TZVPP (see Table 1).

under identical conditions, a new band appears at 1065 cm^{-1} in the Raman spectrum,[8] we have assigned these two intense bands as well as a weak signal in the Raman spectrum at 406 cm^{-1} to the molecule $Al(O_2)_3$ (**3**), whose calculated molecular structure (D_3 symmetry)is illustrated in Figure 2.

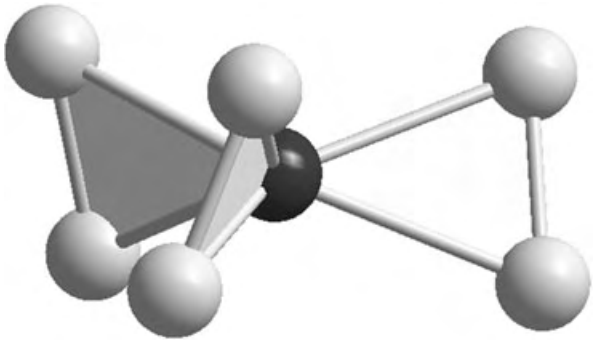

Figure 2. Minimum structure von $Al(O_2)_3$ (**3**) calculated with B3LYP/TZVPP (see Table 1).

To confirm the assignment of the cited vibrational frequencies to molecules **1**, **2**, and **3** extensive quantum-chemical calculations were carried out; these gave the Al–O and O–O distances and force constants listed in Table 1.

Table 1: Distances r [pm] and force constants f [N m^{-1}] of AlO_2 (**1**), $Al(O_2)_2$ (**2**), and $Al(O_2)_3$ (**3**) calculated with B3LYP/TZVPP.

	r_{Al-O}	r_{O-O}	f_{Al-O_2}	f_{O-O}
1	195	134	210	648
2	175	148	386	473
3	185	136	353	632

The special bond properties in **1**, its stability, and the kinetics of the conversion of its different isomers have been reported in detail recently.[9] We have been able to confirm these results according to which the observed C_{2v} hyperoxide **1** has a stability similar to that of the linear $D_{\infty h}$ isomer. Presumably the energy barrier between the two species is very high so that in our spectra only the somewhat less stable (according to calculation[9]) C_{2v} isomer is observed.[10]

For **2**, the D_{2d} isomer shown in Figure 1 is approximately 55 kJ mol^{-1} more stable than a molecule with D_{2h} symmetry. The other isomers (C_{4v} and T_d) also lie energetically much higher (266 and 329 kJ mol^{-1}, respectively). Although only one band is observed for **2**, the assignment seems to be correct since five $^{16}O/^{18}O$ shifts were observed for this band which are in very good agreement with those calculated, and indicates that there are four equivalent oxygen atoms in this molecule. Moreover, this interpretation is plausible since the bands assigned to **2** appear after the formation of **1** and prior to the formation of **3**. The special bonding situation in **2** arises because in the highest singly occupied molecular orbital (SOMO; $1a_2$, Figure 3) one electron must be shared by both

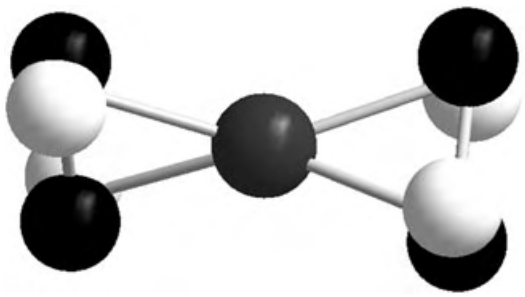

Figure 3. Graphical representation of the SOMO ($1a_2$) of $Al(O_2)_2$ (**2**).

O_2 groups, that is, compared to neutral O_2, each O_2 group is weakened because it carries an additional 1.5 electrons. Hence **2** may not be described as $O_2^-Al^{3+}O_2^{2-}$ (that is, as hyperoxide with an additional peroxo group). Thus it appears plausible that the O–O bond in **2** is weaker and the Al–O bond stronger than in **1**.

Unlike the unusual bonding relationships in **2**, those in **3** appear analogous to the bonding relationships in the recently described $XAl(O_2)_2$ species (X = F, Cl, Br),[1] which means that in **3** there are three O_2^- groups attached to the Al^{3+} ion by interactions that are predominantly ionic in character. This situation becomes especially clear through the absence of vibrational coupling between the three O_2 vibrations, since almost identical frequencies of 1158 and 1154 cm^{-1} are calculated for the E and A_1 vibrations. In this respect, as well as with the O–O and Al–O distances and also the force constants, the expected parallels to the $XAl(O_2)_2$ species emerge. The unusual spin situation in the $XAl(O_2)_2$ compounds (triplet electronic ground states) becomes even more unusual in **3** for which a quartet ground state is found. To our knowledge this is unique for molecular compounds free of transition metals.[11] Admittedly, the energy difference between the doublet and quartet states is very small. This finding and the absence of stabilization in **3** from a Jahn–Teller distortion also provide support for an essentially ionic bonding mode. In spite of the unusual bonding situations in **1**, **2**, and **3** a consistent picture emerges for the three compounds:

The following distances and force constants were calculated for the isolated ions O_2^- and O_2^{2-}: O_2^- 135 pm, 660 N m^{-1} and O_2^{2-} 163 pm, 190 N m^{-1}.[1] In comparison the force constants determined from the observed frequencies for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

1, **2**, and **3** and the calculated distances confirm that in **1** and **3** (as with the $XAl(O_2)_2$ species) the hyperoxide ions are essentially ionically bonded to the positively charged Al centers. In **2**, in agreement with the electronic situation, the O_2 bond is clearly elongated, similar to the bond an O_2^{2-} ion. On the other hand, the Al–O bond also clearly lengthens in the order $\mathbf{2} < \mathbf{3} < \mathbf{1}$, which correlates very well with the calculated Al-O_2 force constants (Table 1). These findings are illustrated in Figure 3 for the special bonding situation of compound **2**. For compound **3** and **1** this bond lengthening may be attributed to the reduced formal charge at the Al center (Al^{1+} in **1** and Al^{3+} in **3**).

The energetic ordering of the three hypervalent compounds is shown in Figure 4 and emerges from experimental

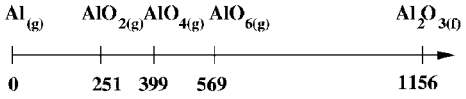

Figure 4. Energy scheme [kJ mol^{-1}] for the stepwise exothermic oxidation of Al atoms with O_2.

thermodynamic data[12] and the quantum-mechanical results obtained in this work. Relative to 1 mol aluminum atoms, in the stepwise formation of **1**, **2**, and **3** more energy is released than for any other molecular Al_xO_y compound.[13] Nevertheless, the $Al(O_2)_n$ ($n = 1, 2, 3$) molecules described herein are certainly only obtainable in measurable quantities under matrix conditions, since the formation of alumina from $Al(O_2)_3$ is favored by 587 kJ mol^{-1}

The results on the oxidation of aluminum atoms with excess O_2 reported herein demonstrate the complexity of such apparently trivial reactions. On the other hand, this process is an extreme situation, in the reverse case, that is, the reaction of excess aluminum atoms with few O_2 molecules is a more realistic model when it comes to the investigation of the primary products of oxidation, for example, on aluminum surfaces. This problem is at the center of current gas-phase investigations of Al_n clusters and their oxidation by O_2, reactions which are being studied with the aid of FT mass spectroscopy.[14]

Experimental section

A detailed description of the experimental construction used may be found in ref. [15]. Aluminum was evaporated in high vacuum (10^{-7} mbar) at 1400 K from a resistance-heated boron nitride cell and cocondensed with the matrix gas (Ar/O_2) for 2 h onto a copper block cooled to 10 K with a "closed cycle" cryostat (Leybold LB510). Each hour approximately 150 μg Al and 50 mmol matrix gas were evaporated. Isotope substitution experiments were carried out with $^{18}O_2$, a 1:1 mixture of $^{16}O_2/^{18}O_2$, and a 1:2:1 mixture of $^{16}O_2/^{16}O^{18}O/^{18}O_2$. The IR and Raman spectra were recorded immediately after sample deposition. The following chemicals were used in the matrix reactions: Al (Merck, 99.9999 %), Ar (Messer 99.999 %), $^{16}O_2$ (Messer 99.9998 %), $^{18}O_2$ (Linde 99.9998 %, isotopic purity 99 %).

The IR spectra were taken with Bruker (Karlsruhe) FTIR spectrometers, types 113v and 66v. DTGS and MCT detectors were used, the resolution was 1 cm^{-1}. Raman spectra were taken with a Dilor grating spectrometer, type 800. The Raman vibrations were excited with a argon ion laser (Coherent), the selected wave length was 458 nm.

The quantum-chemical DFT calculations (functional B3-LYP)[16] were carried out with the Turbomole program package.[17] The ab initio calculations were carried out at the CASSCF level with Dalton,[18] Gaussian 98[19] was used for calculation of the CCSD(T) energies. TZVPP basis sets were used for all calculations.[20]

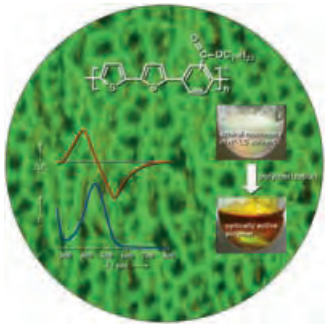
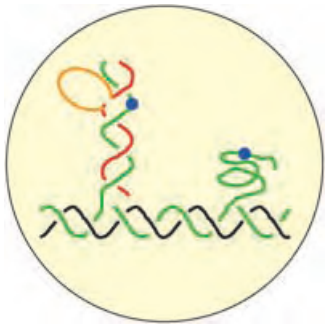
Cover Picture



Donna G. Blackmond*



The London Eye moves continuously even as passengers embark and disembark, serving as both a backdrop and a metaphor for a steady-state catalytic cycle. The theme of the Review by D. G. Blackmond on page 4302 ff. is the mechanistic study of complex catalytic reactions using reaction progress kinetic analysis. A new set of graphical tools are described that are based on reaction monitoring in situ with simple data manipulations. Photo: ArtoftheState.co.uk.

Asymmetric Catalysis
In his Minireview on page 4292 ff., J. M. Janey provides a synopsis of catalytic, enantioselective α amination and α oxygenation reactions of carbonyl compounds which provide access to important enantiomerically pure building blocks such as α-amino acids.

Liquid Crystals as Solvents
Polymerization of an achiral monomer in an inert chiral nematic liquid-crystal medium leads to optically active polybithiophene derivatives. K. Akagi and H. Goto discuss this phenomenon in their Communication on page 4322 ff.

DNA Motors
In their Communications on pages 4355 ff. and 4358 ff., C. Mao et al. and J. Bath et al., respectively, describe DNA devices that move along well-defined tracks by means of enzyme-assisted cleavage and a strand-displacement strategy.

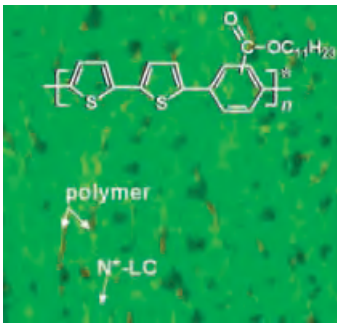
Reaction Progress Kinetic Analysis: A Powerful Methodology for Mechanistic Studies of Complex Catalytic Reactions



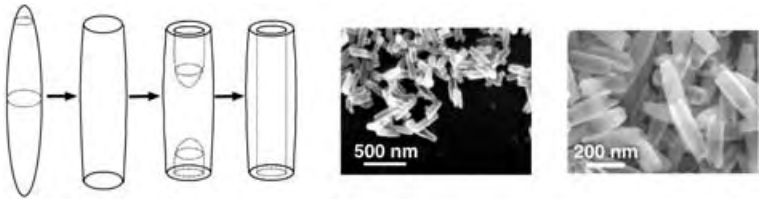
Intuitive and precise: Kinetic measurements are often considered time-intensive and routine studies required to determine concentration dependences and help distinguish between different proposed reaction mechanisms. This Review describes step by step how this can be achieved from a minimal number of experiments with the help of intuitive "graphical rate equations" (see picture) without prior mechanistic knowledge of a catalytic reaction cycle.

Communications

Chiral Polymerization

H. Goto, K. Akagi* _____ 4322 – 4328

Optically Active Conjugated Polymers Prepared from Achiral Monomers by Polycondensation in a Chiral Nematic Solvent



Contagious chirality: A chiral polymer (see image) was obtained from the polycondensation of an achiral monomer by using a chiral nematic liquid crystal (N*-LC) as an inert reaction solvent. The chirality of the polymer is thought to derive from the asymmetry produced by the chiral medium during polymerization.

In this communication, the structure of activated CH agarose 4B beads (**2**), which were purchased from Amersham Bioscience, and the following structures (**3** and **4**) in Scheme 1 were rendered incorrectly; the correct structures are shown. The authors apologize for this oversight.

Awarded...

R. R. Schmidt Receives Haworth Lectureship

Richard R. Schmidt (Universität Konstanz, Germany) is the winner of the 2005 Haworth Memorial Lectureship, which is awarded every two years by the Royal Society of Chemistry. The award is given in recognition of researchers who have made significant contributions to the field of carbohydrate chemistry. A silver medal and £500 are part of the prize. Schmidt completed his PhD studies under the direction of R. Gompper at the University of Stuttgart in 1962. His postdoctoral research was carried out in the research group of F. M. Huennekens at Scripps Research Institute in La Jolla in 1965–66. In 1969 he returned to the University of Stuttgart, where he held a professorship until 1975. Since that year he has been professor of chemistry and biochemistry at the University of Konstanz, today as professor emeritus.

R. R. Schmidt

Schmidt's research is focused on finding and improving strategies for the synthesis of biologically important oligosaccharides with the trichloroacetimidate method, which he developed. His work also involves quinone methides, polar 1,4-cycloadditions, heterocyclic 8π-electron systems, and nucleosides. His research group's efforts in the generation of carbohydrate arrays on glass slides recently appeared in *ChemBioChem*.[1] Schmidt was a member of the advisory boards of *Liebigs Annalen der Chemie* and the *European Journal of Organic Chemistry* from 1994 to 2004.

H. Kagan Receives Bower Award

Henri B. Kagan (Université Paris-Sud, France) was given the US$250000 Bower Award for Science Achievement from the Franklin Institute in Philadelphia for his outstanding work in the area of asymmetric synthesis. His achievements include the first asymmetric synthesis with circularly polarized light, the first description of a chiral "homogenous" solid-phase catalyst, and the synthesis of DIOP, a chiral bidentate diphosphine ligand which has had a significant impact in the development of asymmetric catalysis. He recently reported the in situ formation of a chiral heterobimetallic catalyst for the addition of trimethylsilyl cyanide to benzaldehyde in *Angewandte Chemie*.[2a] Kagan is a member of the academic advisory board for *Advanced Synthesis & Catalysis*, in which he recently published a review of multisubstrate screening of asymmetric catalysts.[2b]

H. Kagan

Kagan studied chemistry in Paris and received his PhD in 1960 after working with J. Jacques at the Collège de France. Afterward he joined the research group of A. Horeau at the same institution, and also worked for a year with T. Mabry at the University of Texas in Austin. In 1967 he became assistant professor at the Université Paris-Sud in Orsay, and assumed full professorship in 1973. Before retiring emeritus, he was a professor at the Institut Universitaire de France from 1993 to 1999. Kagan has been a corresponding member of the French Academy of Sciences since 1978 and a full member since 1991. He is the recipient of numerous prizes, including the August Wilhelm von Hofmann Medal of the GDCh, the Wolf Prize, and the Nagoya Medal.

L. Oro Honored

The Université de Rennes 1 in France has given Luis A. Oro (Universidad Zaragoza, Spain) an honorary doctorate in recognition of his achievements in organometallic chemistry (particularly with the transition metals rhodium, iridium, ruthenium, and osmium) and in catalysis (hydration, hydrosilylation, and C–H bond activation). The honorary title is also reflective of the healthy Spanish-French relationship in science. Oro is already a foreign member of the French Academy of Sciences.

L. Oro

Oro received his PhD in 1970 at the University of Zaragoza. Following postdoctoral work at Cambridge University, he accepted successive positions at the University of Zaragoza, the University of Madrid (Complutense), and the University of Santander. In 1982 he returned to the University of Zaragoza as professor of inorganic chemistry. Oro is the president of the Real Sociedad Española de Química, member of the advisory board for the *European Journal of Inorganic Chemistry*, and joint editor of a multivolume handbook of metal clusters.[3a] His research group recently reported on oxygen activation and the formation of a doubly oxygen-bridged dirhodium complex in *Angewandte Chemie*.[3b]

Gene Regulation

A High-Precision Switch on an RNA Message**

*Bernhard Kräutler**

Keywords:
amino acids · catabolism · gene regulation · molecular switches · RNA

In the classic view, (oligo)ribonucleotides (RNA) are molecular vehicles in high-fidelity transmission systems, through which genetic information is realized by protein expression.[1] In cellular organisms, messenger RNA (mRNA) represents a transcript of the DNA with coding and noncoding regions, and can be classified as a "conditional" molecular message: the downstream fate of the transcribed message depends on cellular constituents, and is subject to further expressional control either at the stage of its own transcription (as nascent RNA) or during translation.

Recent work has uncovered a previously unrecognized function of RNA as a regulatory component in gene expression. Direct interactions between natural RNA molecules and low molecular weight compounds were shown by Breaker and co-workers to provide a new mechanism of genetic control in metabolite-sensitive "riboswitches".[2,3] Such riboswitches contain conserved sequences and are found in the 5′-untranslated (noncoding) region of the mRNA. By an allosteric effect, the binding of a metabolite induces a switch in the DNA-transcribed mRNA between "on" and "off" states, which control subsequent processing events of the coded message. Metabolite binding riboswitches therefore adapt gene expression efficiently and directly to the molecular contents of the cell. Although they are particularly widespread among bacteria, they are not restricted to prokaryotes, but are used in eukaryotes as well.[4]

The discovery of the group of glycine-dependent bacterial riboswitches provided evidence of Nature's capacity for even more exquisite RNA-engineering:[5] glycine-dependent riboswitches represent a new type of riboswitch that consists of a tandem of two glycine-binding RNA motifs (see Figure 1 for a representation of the tandem motifs from *Bacillus subtilis*). These conserved RNA motifs, which encompass about 100–120 nucleotides each, are separated by a short stretch of RNA. The glycine-dependent riboswitches are part of the 5′-untranslated region of the *gcvT* operon, which codes for proteins that degrade glycine for energy production. In the mRNA from *B. subtilis*, the downstream (3′ direction) glycine-binding motif (aptamer II) of the tandem encompasses a putative intrinsic transcription terminator motif. In the absence of glycine, the latter is "off" and continued transcription of the message is terminated (and hence the eventual expression of the proteins involved in glycine catabolism as well). These riboswitches bind glycine at concentrations of 10–

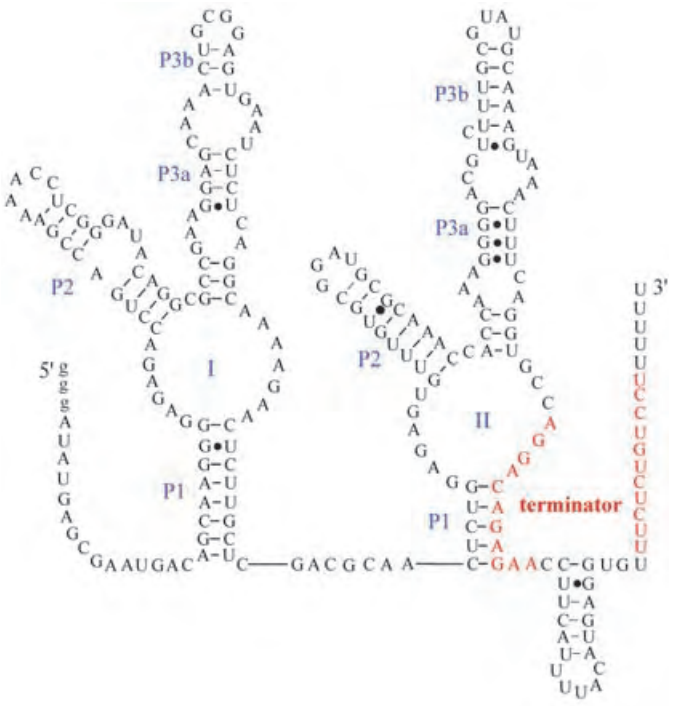

Figure 1. The glycine-binding tandem RNA motif of *Bacillus subtilis*. Hypothetical base-paired elements are indicated (P1–P3) as is the putative terminator sequence (red), rendered here in the "on" state, permitting further RNA transcription (adapted from Ref.[5]).

100 μM and with remarkable selectivity for their small molecular target, which consists of only 10 atoms. Both of the glycine aptamer motifs must be occupied by their target for disruption of the putative terminator hairpin and to bring the riboswitch into the "on" state. The tandem arrangement imparts the system with full sensitivity to glycine binding in a "digital" manner and in a narrow concentration range. Indeed, the tandem motif is highly selective and is able to discriminate very efficiently for other low molecular weight compounds, such as the glycine homologue, alanine and related amino acids.[5] These findings in vitro were shown to have relevance in vivo: when incorporated into the *B. subtilis* genome, a fusion construct coding for the glycine riboswitch upstream of a β-galactosidase reporter gene showed full transcriptional control by glycine (on the expression of β-galactosidase in this modified bacterium).

Cooperativity in glycine binding the two tandem binding motifs was studied with several RNA constructs based on the glycine binding riboswitch of *Vibrio cholerae*. With a method termed "inline probing" (which reveals metabolite-induced changes in RNA structure by monitoring alterations in the levels of spontaneous RNA cleavage) the aptamer tandem of *V. cholerae* was found to respond to glycine in the narrow concentration range of 10–100 μM, whereas a corresponding experiment with a single glycine-binding motif showed the same effect in a concentration range tenfold greater. The decrease in the dynamic range with the tandem arrangement is indicative of a significant cooperative effect for which a Hill coefficient of 1.64 was determined. Binding of glycine at one site was deduced to lead to concomitant restructuring of both binding motifs and was estimated to increase binding affinity at the other site by about 100- to 1000-fold.

The cooperative tandem glycine riboswitches thus hold a crucial regulatory position in the metabolism of these prokaryotes, which they switch precisely depending on the availability of glycine. When this simple amino acid is abundant, the glycine-bound "on"-state dominates, and proteins that are involved in the breakdown of glycine for energy (one of the major uses of glycine) are expressed (Figure 2).[1] Outside this pathway, glycine remains available as a basic anabolic component to be used primarily in amino acid biosynthesis. These microorganisms clearly depend on precise molecular sensors for the economic use of glycine: this natural "chemical" is required first of all for biosynthesis; when available in high concentration, it can also serve as a "fuel".

Cooperative binding of the small molecule glycine to the glycine riboswitches thus provides prokaryotic cells with a high-precision instrument for shifting from (exclusive) anabolic to (additional) catabolic uses of glycine. Studies of hemoglobin provided the first insight into the crucial fine-tuning of a multi-subunit enzyme and helped to uncover cooperativity in ligand binding.[1] The discovery of the glycine riboswitches shows that such cooperativity is not monopolized by proteins, but is a strategy naturally used by other modular biomolecules as well (as is the case for the noncoding regions of mRNA). Indeed, earlier work by Breaker and co-workers with artificially evolved RNA has already provided a remarkable precedence for the observation of "cooperativity" in the binding of small molecules by RNA.[6]

Whereas the structural basis for the observed cooperativity of the tandem glycine riboswitches remains to be elucidated, pioneering structural studies have provided initial insight into the intricate modes of highly selective molecular recognition by the conserved "aptamer"-regions of riboswitches. Recent crystallographic[7] and NMR spectroscopic[8] studies of adenine- and guanine-sensing mRNAs revealed the structural basis for the use of oligonucleotides in the recognition of small molecules. This work confirmed that the binding site corresponds to the central bulge of the aptamers, as had been expected from the results of mutational studies.[9] The exquisite selectivity was

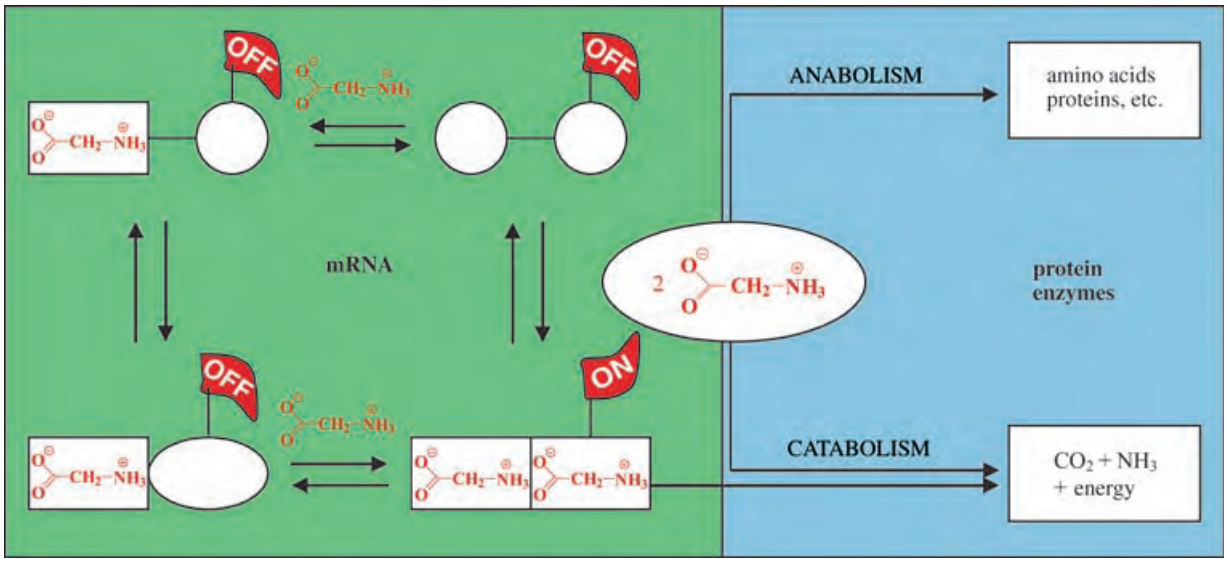

Figure 2. The glycine-dependent riboswitch, a crucial element in the regulation of glycine metabolism and subject to cooperative binding of glycine in a tandem motif.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

shown to result from specific hydrogen bonding with a strategically situated RNA base. In previous experiments in vitro, various oligomeric RNAs ("aptamers") had been already prepared which were able to recognize and selectively bind small molecules with high affinity.[10] These studies, the discovery of self-splicing RNA and natural ribozymes,[11] more recent experiments on artificial ribozymes[12] and on *retro*-riboswitches[13] promise to expand our general knowledge on the intriguing functional diversity of RNA.[14]

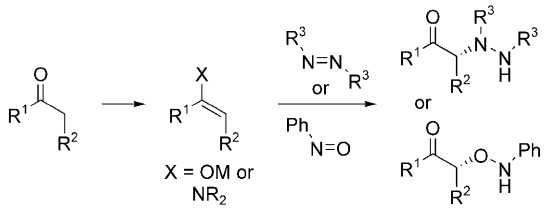
Synthetic Methods

Recent Advances in Catalytic, Enantioselective α Aminations and α Oxygenations of Carbonyl Compounds**

*Jacob M. Janey**



Keywords:
amination · asymmetric catalysis · Lewis acids · organocatalysis · synthetic methods

The direct introduction of either a nitrogen or oxygen atom adjacent to a carbonyl group in a catalytic, enantioselective manner using both chiral Lewis acid and Lewis base catalysis has been described recently. The enantiomerically enriched products of these reactions, such as α-amino acids, represent fundamental building blocks for the construction of complex natural products and other important bioactive molecules. This Minireview provides a synopsis of this ever-growing field and highlights some of the challenges that still remain.

1. Introduction

The literature concerning α amination[1] and α oxygenation[2] of ketones, aldehydes, and esters contains many examples of nonstereoselective and auxiliary-controlled methodologies. The more prominent, well-established methods of enantioselective α oxygenation include the use of Davis oxaziridine,[3] Sharpless dihydroxylation of enol ethers,[4] manganese–salen epoxidation of enol ethers,[5] and Shi epoxidation of enol ethers.[6] It is only rather recently that direct catalytic, asymmetric variants have been reported.[7] This review will focus only upon these contemporary aminations and oxygenations, although it should be noted that the catalytic, asymmetric α halogenation of carbonyls may also serve as an alternative entry to enantioenriched α-amino and α-hydroxy carbonyls.[8]

The basic reaction manifold consists of an enolate (or enamine) reacting with an electrophilic nitrogen or oxygen atom (Scheme 1). The enolate may either be preformed (such as a silyl enol ether) or generated in situ through "soft" enolization involving a Lewis acidic metal and a base. Enamines are also competent nucleophiles and form from the reversible condensation between an aldehyde or ketone and a secondary amine. The heteroatom electrophile is either an azodicarboxylate for aminations, or nitrosobenzene for both oxygenation and amination reactions, depending upon the reaction conditions.

Scheme 1. General reactivity pattern.

The reactions can be catalyzed by either chiral Lewis acids or Lewis bases. For Lewis acid catalysis, there are two modes for activation and stereochemical induction (Figure 1). The chiral Lewis acid metal complex may generate a chiral metal enolate (**A**) by either "soft" enolization of the carbonyl or by transmetalation of a preformed enolate. The chiral Lewis acid

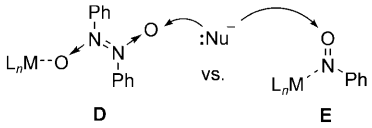
may also serve to activate the electrophile by coordination to either an oxygen or nitrogen lone pair (**B**). It is also possible that the Lewis acid complex plays both roles at once by forming a metal enolate, which may then bind to and activate the electrophile. Chiral Lewis bases catalyze these reactions by the reversible formation of a chiral enamine (**C**). The asymmetry is then transferred upon reaction between this enamine and the electrophile, followed by imine hydrolysis of the product, which allows for catalyst turnover.

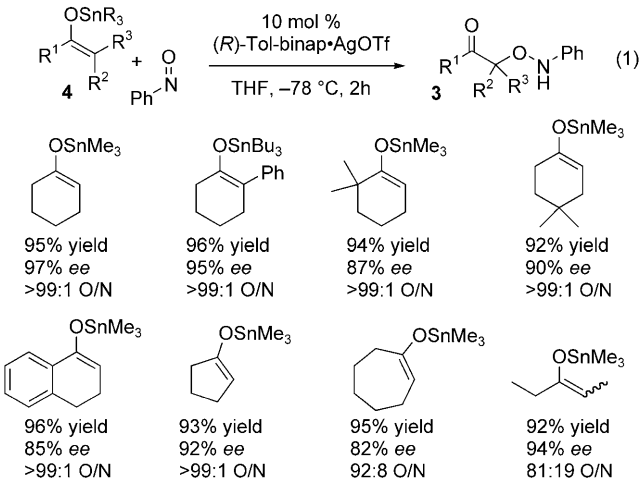
2. α Oxygenations Catalyzed by Chiral Lewis Acids



In recent years a growing number of reports have detailed the use of nitrosobenzene as a versatile electrophile for catalytic enantioselective nucleophilic additions. Nitrosobenzene can best be thought of as the nitrogen equivalent of an aldehyde in terms of reactivity and, as such, displays many of the same reactivity patterns, although with some unique and obvious deviations. Of particular note is the proclivity for nitrosobenzene to undergo nucleophilic attack at either oxygen or nitrogen. As depicted in Scheme 2, depending

Scheme 2. Divergent regioselectivity in reactions with nitrosobenzene.

upon the nature of the enolate and presence or absence of a catalyst, either the α-oxygenated or α-aminated product may emerge.[9]



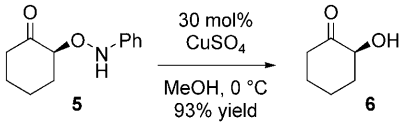
Hisashi Yamamoto and co-workers have extensively explored this "nitroso-aldol" reaction and report that tin(IV), lithium, and zinc(II) enolates, in the absence of any Lewis acid catalyst, give predominantly the aminated product **2**.[9b] In addition, morpholine-derived enamines may also generate **2**.[10] By contrast, silyl enol ethers and tin(IV) enolates in the presence of a Lewis acid give mainly the α-oxygenated product **3**. This divergent reactivity pattern is explained by the facile formation of a nitrosobenzene dimer **D** in the presence of a Lewis acid (Scheme 3). Coordination of a metal at one oxygen then favors nucleophilic attack at the other. Yamamoto et al. also considered the nitrogen coordination in monomer **E**, but ancillary evidence argues against this mode

Scheme 3. Possible modes of nucleophilic attack: a complex of the dimer (**D**) versus a complex of the monomeric nitrosobenzene (**E**).

of activation. Upon addition of Lewis acid they detected the dimer by in situ IR spectroscopy, and also a peak in the ESI mass spectra corresponded to a Lewis acid coordinated to the dimer. It should be noted that this cannot rule out monomer **E** as the actual kinetically active species in the reaction pathway. In addition to the divergent reactivity of enol ethers observed with Lewis acids, enamines may also exhibit such behavior. For example, morpholine-derived enamines give predominantly **2**, whereas pyrrolidine enamines give mainly **3**.[11] Although no explanation for this selectivity has been posited, it is known that enamines derived from pyrrolidine are orders of magnitude more nucleophilic than those from morpholine.[12]

The first Lewis acid catalyzed, enantioselective addition to nitrosobenzene was reported by Yamamoto and co-workers [Eq. (1)].[13] They report that silver(I)–binap complexes effectively catalyze the enantioselective reaction between tin(IV) enolates **4** and nitrosobenzene giving the α-oxygenated carbonyl **3** with excellent regio- and enantioselectivity for a variety of cyclic ketones (Scheme 4). Although the N–O bond

(1)



Scheme 4. α Oxygenation of tin(IV) enolates catalyzed by a silver(I)–binap complex.

of **5** is easily cleaved under a variety of hydrogenation conditions, Yamamoto et al. report that catalytic copper(II) sulfate in methanol rapidly gives the free alcohol **6** with no racemization [Eq. (2)].

Jacob Janey was born in Minnesota in 1976. He received his BS degree in chemistry from the University of Chicago in 1998, where he worked in the laboratory of Viresh H. Rawal. In 2003 he earned a PhD in organic chemistry from Harvard University under the guidance of David A. Evans. His thesis dealt with the development and application of chiral Lewis acids for ketene cycloadditions and Suga–Ibata oxazole aldol reactions. He is currently a Senior Research Chemist in the Department of Process Research at Merck & Co., Inc.

5 6 (2)

3. α Aminations Catalyzed by Chiral Lewis Acids

The O selectivity of reactions with nitrosobenzene can be completely reversed, as reported recently by Yamamoto and co-workers.[14] They detail conditions under which tin(IV) enolates **4** react with nitrosobenzene to give almost exclusively the α-amino product **2** in a catalytic, enantioselective manner [Eq. (3)]. As shown in Scheme 5, a range of cyclic

Scheme 5. α Amination of tin(IV) enolates catalyzed by a Ag_2^I-binap complex.

tin(IV) enolates react with nitrosobenzene giving **2** with uniformly high levels of both N selectivity and enantioselectivity when conducted in the presence of 10 mol% of a preformed catalyst composed of a 2:1 mixture of silver(I) triflate and (*R*)-binap. This catalyst also showed pronounced solvent effects with THF giving predominantly the oxygenated product, albeit with little enantioselectivity. For aminations, the optimal solvent was found to be ethylene glycol diethyl ether. The reactions in other diether solvents were equally N selective, although the enantioselectivity was moderate at best.

Although no model has been offered to explain why the 1:1 complex of silver(I) and binap is O selective while the 2:1 complex is N selective and gives product **2**, X-ray structures of the 1:2, 1:1, and 2:1 silver(I)–binap complexes were reported.[14] In the 2:1 structure, each phosphine of binap is coordinated to a separate Ag^I center; one of the metal centers also bears two triflates and the other bears two water molecules (Figure 2). In contrast, the 1:1 complex has a tetragonal Ag^I center bound in a chelate by both phosphines of binap in addition to the coordinated counterion (Figure 3). Based on these structures it is not immediately apparent what factors govern O versus N selectivity, as solvent appears to play an important role in this regard.

Azodicarboxylates also serve as ready electrophiles for the Lewis acid catalyzed amination reaction. In a seminal paper on this topic, David A. Evans and Scott G. Nelson[15] reported that a chiral magnesium Lewis acid complex **8** in the presence of a complimentary base will enolize aryl-substitut-

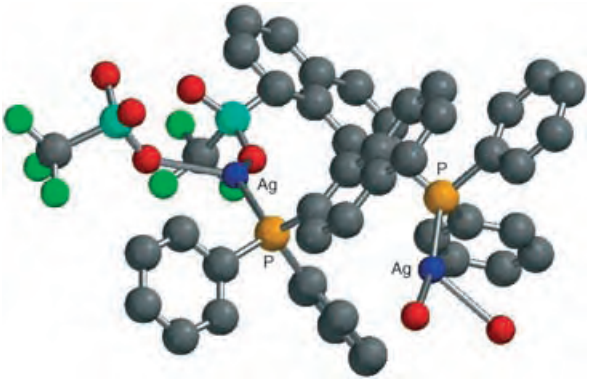

Figure 2. X-ray structure of [{Ag(OTf)}$_2${μ-(*R*)-binap}{Ag(H_2O)$_2$}]. O red, S turquoise, F green.

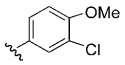
ed carboximides **7**, which are then aminated by di-*tert*-butyl azodicarboxylate [Eq. (4)]. As shown in Table 1, the catalyst provides the expected α-amino acid derivatives **9** with excellent levels of enantioselectivity and yield. The enantiomeric purity can be upgraded with a single recrystallization. It is postulated that the azodicarboxylate acts as the base for the soft enolization between Mg^{II} and **7**. A kinetic investigation indicates that the *N*-methyl-*p*-toluenesulfonamide additive acts as a weak acid to protonate the hydrazide conjugate from the Mg^{II} complex, allowing for liberation of the catalyst. The sense of asymmetric induction was rationalized based upon a chelated tetrahedral magnesium enolate where the C_2-symmetric chiral backbone of the bis(sulfonamide) ligand gears the aryl substituents to shield one face of the bound enolate.



Chiral C_2-symmetric copper(II) bis(oxazoline) Lewis acids also are capable of effecting a "soft" enolization–amination reaction [Eq. (5)].[16] The reaction proceeds quite well for a variety of α-keto esters **10** and dibenzyl azodicarboxylates catalyzed by **11** (Table 2). Since the products **12** were quite prone to racemization, the crude reaction mixture was immediately treated with L-selectride. The reaction most likely proceeds through a complex in which the distorted square-planar Cu^{II} center is chelated to the α-keto ester

enolate. The sense of asymmetric induction can be rationalized by electrophilic attack of the azodicarboxylate onto the less hindered face of the copper(II) enolate.

This type of amination reaction was extended to β-keto ester substrates (**13**) as well [Eq. (6)].[17] Once again, a C_2-symmetric copper(II)–bis(oxazoline) complex, **14**, was found to be the optimal catalyst with very low loadings (0.5 mol%). The catalyst shows exceptional levels of selectivity for a variety of cyclic and acyclic keto esters (Table 3). The proposed mechanism and model for stereoinduction is similar to that previously described: the chelating ability of the substrate explains the high levels of enantioselectivity.

Lewis acid activation of the azodicarboxylate electrophile has also been reported by Evans and co-workers.[18] They

synthesized the azodicarboxylate derivative **17**, which is capable of forming a chelate with the Cu^{II} complex **18** [Eq. (7)]. This reacts cleanly with a variety of silyl enol ethers **16** giving aminated products **19** with uniform high selectivities and yields (Table 4). Cyclic silyl enol ethers **20** are also good nucleophiles for this transformation (Scheme 6). The key to efficient catalyst turnover in this reaction was found to be the addition of CF_3CH_2OH. This alcohol additive serves to break down a hetero-Diels–Alder intermediate that binds strongly to the Cu^{II} catalyst. The rationale for the observed stereoselectivity is consistent with that seen for other reactions catalyzed by copper(II)–bis(oxazoline) complexes.[19]

Although not directly related to the aforementioned topics, Yamamoto et al. have also explored the use of arylnitroso compounds as heterodienophiles in the Diels–Alder reaction of various cyclic dienes [Eq. (8)].[20] They

(8)

report quantitative yields and excellent enantioselectivity for forming cycloadduct **22** when they use a chiral Lewis acid catalyst composed of a copper(I) hexafluorophosphate salt and the axially chiral bisphosphine (*S*)-segphos. The key to this reaction is the use of 2-nitrosopyridines **21**, as these are capable of forming a five-membered chelate with the chiral Cu^{I} catalyst. This provides a high level of organization in the transition state, thus leading to exceptional levels of stereoselectivity. The reported model to explain the stereochemical outcome of this Diels–Alder reaction with (*S*)-binap as a ligand assumes a tetrahedral Cu^{I} center with a "filled" first and third quadrant according to the mnemonic developed by Noyori (Figure 4).[21] Cycloadduct **22** can be transformed over a five-step sequence in 48% overall yield to a fully protected 1,4-amino alcohol.

4. α Oxygenations Catalyzed by Chiral Lewis Bases

Many of the aforementioned amination and oxygenation reactions relied upon pregenerated, stable metal enolates as reaction partners, but as stated in the introduction, enamines are also known to react cleanly with nitrosobenzene. Given this precedent and the burgeoning literature concerning catalysis of the aldol reaction by chiral Lewis bases by means of reversible formation of enamines, a series of reports have appeared recently which detail the use of proline to catalyze the addition of simple aldehydes and ketones to nitrosobenzene. The primary advantage of this approach is that it avoids the added step of first forming a metal enolate; in addition, proline catalysis tolerates benign reaction conditions (ambient temperature and atmosphere, wet solvents). The first reports of this methodology all appeared within three months of each other from the laboratories of Guofu Zhong, David W. C. MacMillan, and Yujiro Hayashi, and differ only in choice of solvent and the substrates examined.[22] As shown in Equation (9), enolizable aldehydes **23** with varying degrees of branching and functionality react quite well with nitrosobenzene in the presence of catalytic amounts of L-proline. Since the initial α-alkoxy aldehydes produced are oligomeric, subsequent reduction with $NaBH_4$ is necessary to give diol **24**. Table 5 shows that a variety of aldehydes, from bulky ones

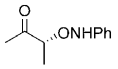
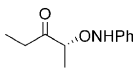
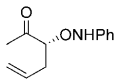
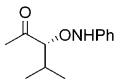
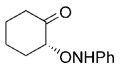
(Table 5, entry 3) to aldehydes containing other functional groups (entries 7, 8, 11, and 12), are well tolerated and produce the expected diol with excellent enantioselectivity and moderate-to-high yields. MacMillan and co-workers report that chloroform is the best solvent in terms of catalyst efficiency. They found that L-proline loadings could be dropped to 1 mol% with little loss in reaction efficiency. In other recent reports photochemically generated singlet oxygen was used as an electrophile for this transformation, albeit with moderate enantioselectivity.[23]

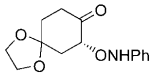


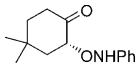


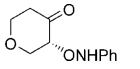


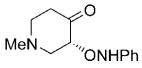












Ketones have proven to be more challenging substrates for this reaction.[24] Besides their diminished ability to reversibly form enamines with proline, they have two enolizable carbon atoms, which may compromise chemoselectivity in the oxygenation reaction. To avoid this complication, a large excess (2–10 equiv) of ketone **25** is often used and nitrosobenzene is added slowly with a syringe pump

[Eq. (10)]. This protocol prevents the formation of any C_2-symmetric diaddition products and cleanly gives **26**, although in the case of acyclic ketones (Table 6, entries 1–4) minor amounts of the regioisomer **27** arising from N addition are

Table 6: α Oxygenation of ketones catalyzed by L-proline.

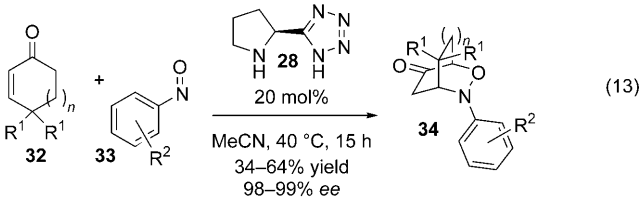
8		>99:1	53	96
9		>99:1	44	99



formed. It is also interesting to note that in the case of nonsymmetric ketones, such as entries 1, 3, and 4, it is the more substituted carbon that undergoes reaction with nitrosobenzene. Cyclic ketones (entries 5–9) are excellent substrates, giving **26** with complete regio- and stereoselectivity regardless of any substitution at the 4-position. In addition, Yamamoto et al. have described a more efficient proline–tetrazole catalyst **28**, which mediates the oxygenation of both aldehydes and ketones in high yields (65–97%) and enantioselectivities [Eq. (11)].[11] Shorter reaction times, lower catalyst loadings, and faster addition times of nitrosobenzene were reported with catalyst **28**.

The proline-catalyzed reaction has also been applied to the desymmetrization of *meso* ketones **29a** and **29b** [Eq. (12)].[24b] The degree of catalyst control is very high as both the *cis* (**30a**,**b**) and *trans* ketones (**31a**,**b**) are produced with high *ee*.

An interesting extension to this chemistry is the hetero-Diels–Alder reaction between cyclic enones and nitrosobenzene catalyzed by chiral Lewis bases.[25] A variety of 2-cyclohexene-1-ones **32** react with nitrosobenzenes **33** catalyzed by proline tetrazole **28** giving cycloadducts **34** with moderate yields and very high enantioselectivity [Eq. (13)].

This reaction appears to be insensitive to substituents at the 4-position of enones **32** and nitrosobenzene **33**. Although formally a hetero-Diels–Alder reaction, this appears to be a more stepwise process. After a typical nitroso-aldol reaction, the nitrogen undergoes a conjugate addition to the enone double bond to give the cycloadduct **34**. Attempts at reversing the regioselectivity of this reaction with silver(I) Lewis acids were unsuccessful as the oxygen is reluctant to add in a conjugate manner to the enone.

The purported mechanism of this proline-catalyzed nitroso-aldol reaction is similar to that of the proline-catalyzed aldol reaction (Figure 5).[26] The proline enamine is believed to form an organized six-membered chairlike transition state with nitrosobenzene. A hydrogen bond between the nitrogen of nitrosobenzene and the acid functionality of proline accounts for the observed facial bias. According to calculations performed by Houk and co-workers, the O-*syn* transition state, which leads to the observed major enantiomer, is favored by 3.3 kcal mol^{-1} over the O-*anti* transition state. A

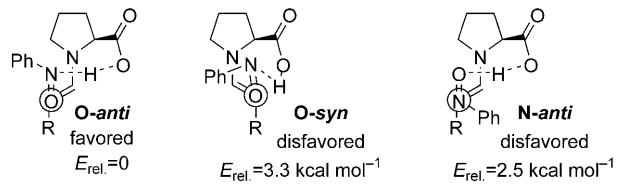


Figure 5. Possible transition state in the reaction of a proline enamine with nitrosobenzene.

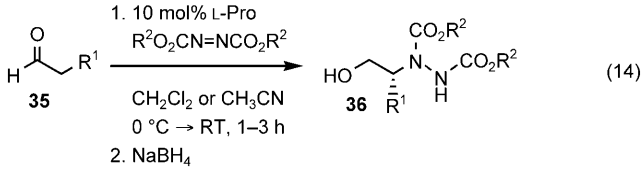
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

competing pathway that is only 2.5 kcal mol^{-1} higher in energy proceeds via the N-*anti* transition state, which gives rise to the undesired α-aminated product. Although the observed selectivities lend support to this model to explain the stereoinduction, kinetic data suggests a more complex catalytic cycle.[27] A calorimetric analysis of the reaction kinetics clearly indicates a selectivity-enhancing autoinductive process in which the rate and *ee* of the reaction increase with each cycle of the catalytic species. This implies that a product–proline adduct of some sort (either an enamine or hydrogen-bonded species) gives rise to an improved catalyst over the original, sparingly soluble proline.

5. α Aminations Catalyzed by Chiral Lewis Bases

To date, there have been no reported organocatalytic reactions of nitrosobenzene that give the product resulting from attack at nitrogen as the major product, other than the single example of a stoichiometric morpholine enamine giving the N adduct.[10] Instead, K. A. Jørgensen et al. as well as Benjamin List have reported that proline catalyzes the amination of aldehydes and ketone with azodicarboxylates (Table 7).[28] These reactions proceed with moderate-to-excellent yields and high enantioselectivity, and appear to be quite general for a variety of aldehydes and azodicarboxylates. There have also been reports that α,α-disubstituted aldehydes are competent substrates, although selectivities are moderate at best.[29]



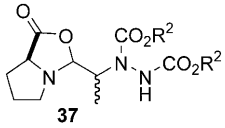


Table 7: α Amination of enolizable aldehydes catalyzed by L-proline.

Entry	R^1	R^2	Yield [%]	*ee* [%]
1	Me	Et	67	93

9	*n*Bu	Bn	94	97
10	Me	Bn	97	95
11	Bn	Bn	95	95

The mechanism for this transformation exhibits very interesting and dramatic kinetics.[30] An examination of this reaction using calorimetry reveals both a nonlinear effect and an accelerating reaction rate, which is a hallmark of an autocatalytic reaction wherein the *ee* is amplified after each catalytic cycle. It was found that adding product to the reaction mixture accelerated the reaction. In addition, premixing proline and the product gave a new catalyst (or precatalyst) species which led to a much improved reaction rate. The authors characterized an oxazolidinone (**37**) that leads to this acceleration. Although the exact role and mechanism of this "improved" catalyst is not yet known, it may serve as a solublized proline species that can enter the catalytic cycle immediately, as solid proline is only slightly soluble in organic solvents such as chloroform. It has also been proposed that the origin of autocatalysis may be the improved solubility of proline through hydrogen-bonding interactions with a matched product molecule.[30b]

A recent contribution to this area was made by K. A. Jørgensen and co-workers who report that a quinidine-derived alkaloid (β-isocupreidine, β-ICD) serves as an efficient catalyst for the α amination of α-cyanoacetates and β-dicarbonyl compounds [Eq. (15)].[31] This highly efficient reaction proceeds with 5 mol% β-ICD to give the expected product with excellent levels of enantioselectivity for a variety of aryl-substituted α-cyanoacetates and a few β-dicarbonyl compounds (Table 8 and Scheme 7). No mechanistic scenarios were offered, although given the high acidity of the substrates and the basic nature of the catalyst, an enolate with a chiral ammonium (β-ICD-H$^+$) counterion is a likely intermediate.

6. Summary and Outlook

The catalytic, asymmetric α amination and α oxygenation of carbonyl compounds represents a valuable advance in synthetic methodology. Although much progress has been made in developing this chemistry, many challenges and

questions still remain. A deeper understanding of the mechanism and the factors that govern O versus N selectivity with nitroso compounds will allow for innovation in catalyst design and make this methodology a robust and efficient way to access valuable, enantiopure building blocks with broad applicatione to the synthesis of biologically important molecules. In addition, more convenient electrophilic sources of nitrogen and oxygen along with broadened and general substrate scope would be a welcome advance. This area is developing at a rapid pace and surely further progress in both catalyst design and mechanistic insight will be forthcoming.

Reaction Kinetics

Reaction Progress Kinetic Analysis: A Powerful Methodology for Mechanistic Studies of Complex Catalytic Reactions

*Donna G. Blackmond**

Keywords:
catalysis · in situ measurements · kinetics · reaction kinetics · reaction mechanisms

In memory of Keith J. Laidler (1916–2003)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/anie.200462544

Reaction progress kinetic analysis to obtain a comprehensive picture of complex catalytic reaction behavior is described. This methodology employs in situ measurements and simple manipulations to construct a series of graphical rate equations that enable analysis of the reaction to be accomplished from a minimal number of experiments. Such an analysis helps to describe the driving forces of a reaction and may be used to help distinguish between different proposed mechanistic models. This Review describes the procedure for undertaking such analysis for any new reaction under study.

1. Introduction

Kinetic investigations of multistep organic reactions form a critical part of fundamental mechanistic studies as well as being indispensable to practical applications of organic synthesis. Such studies are aimed at providing a better understanding of reaction pathways by giving concentration dependences of reacting components as well as rate and equilibrium constants pertaining to elementary steps in the reaction network. Analysis of experimental data in multistep catalytic reactions is complicated, however, by the complexity of the reaction rate laws characteristic of these reactions, and therefore simplified means of representing the kinetic data are often sought.

One of the most important examples of such a simplifying tool is the double-reciprocal plot developed by Lineweaver and Burk. The original paper outlining this approach[1] has become the most-cited paper in the history of the *Journal of the American Chemical Society*[2] and offers a straightforward means of linearizing enzymatic reaction rates (Scheme 1)

Scheme 1. Catalytic reaction cycle for a simple enzyme-catalyzed reaction.

given by the Michaelis–Menten Equation [Eq. (1), υ = reaction rate (in M min^{-1}), υ_{max} = maximum reaction rate (in M min^{-1}), [S] = substrate concentration (in M), K_{MM} = Michaelis constant (in M)].[3] The Lineweaver–Burk Equation [Eq. (2)] turns the Michaelis–Menten Equation upside down;

$$\upsilon = \frac{\upsilon_{max}[S]}{K_{MM} + [S]} \quad (1)$$

$$\frac{1}{\upsilon} = \frac{1}{\upsilon_{max}} + \frac{K_{MM}}{\upsilon_{max}}\frac{1}{[S]} \quad (2)$$

this simple but powerful operation created an enabling graphical tool for several generations of chemists trying to make sense of experimental kinetic data in both enzymatic and nonenzymatic catalytic systems (Figure 1).[4]

Today, 70 years since the Lineweaver–Burk Equation was developed, dramatic advances both in experimental measurement techniques and in computer analysis tools provide far more accurate methods for extracting kinetic parameters in reaction systems. Reaction progress kinetic analysis is a methodology that makes use of the voluminous data sets that are now readily obtained from continuous monitoring of the entire course of a reaction. This analysis has permitted the development of a new set of enabling graphical tools that we have termed "graphical rate equations" for a new generation of chemists. Reaction progress kinetic analysis gives the same information provided by classical kinetic approaches with only a fraction of the number of separate experiments. In addition, monitoring the time evolution of the reaction can yield significant further clues about issues that can be problematic in classical experimental approaches, such as catalyst activation and deactivation, as well as substrate and product inhibition or acceleration.[5]

In its most comprehensive form, reaction progress kinetic analysis uses detailed kinetic modeling to assess quantitatively the relative likelihood of different proposed reaction

mechanisms. At the other end of the spectrum, monitoring reaction progress can provide a rapid, qualitative "fingerprint" of reaction behavior for streamlining practical exploitation of new chemistry as well as offering general insights useful for further mechanistic study. In the middle lies a graphical approach where simple manipulations applied to a series of seemingly inscrutable experimental kinetic profiles allow the "interrogation" of the data to yield a wealth of mechanistic information, while requiring only minimal mathematical prowess on the part of the analyst.

The level at which reaction progress kinetic analysis is carried out in any particular example will ultimately reflect a balance between the depth of information desired, the complexity of the reaction under study, the quality of the measured data, and the time commitment of the analyst. This Review gives an introducion to reaction progress kinetic analysis through topical experimental examples from my research group. Special emphasis will be placed on the intermediate level of data "interrogation" to help demonstrate the power of modern experimental techniques in rapid and comprehensive kinetic analysis and to illustrate the accessibility and intuitive value of this graphical approach.

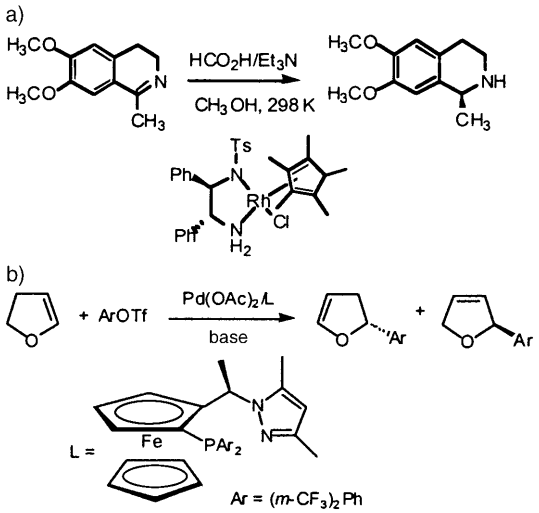
Donna G. Blackmond is a Professor in the Departments of Chemistry as well as Chemical Engineering and Chemical Technology at Imperial College (Chair of Catalysis). Previously she held appointments at the University of Hull, the Max-Planck-Institut für Kohlenforschung, the University of Pittsburgh, and Merck & Co, Inc. She was recently awarded the Arthur C. Cope Scholar Award from the American Chemical Society. Her research interests are focussed on the kinetics of organic reactions with application in pharmaceutical processes.

2. Reaction Progress Kinetic Analysis: Definition

Reaction progress kinetic analysis is faster, requires fewer experiments, can provide enhanced mechanistic detail, and is arguably more accurate than classical kinetic techniques. Why, then, have these methods not yet become common practice in studies of organic reactions? The answer to this question lies, I believe, in our general difficulty in relating the mathematics of a reaction rate law to the molecular story unfolding within a catalytic reaction system. Kinetics conjures up images of experimental drudgery, mathematical manipulations, and logarithmic graphs; chemists prefer to spend their time devising novel transformations in the laboratory. What is not generally made evident in our training in kinetics is that, rather than being a rote and rather detached method of "dotting the i's and crossing the t's" undertaken only after a mechanistic supposition has been all but confirmed by other work, kinetics and its concomitant mathematics are critical tools that can help predict how molecules undergo transformations. Furthermore, these tools can be applied each and every time a reaction is carried out—without altering the conditions under which the reaction is typically performed.

Kinetics is one of several languages for describing chemical events. Other possibilities include drawing out a reaction mechanism or construction of an energy diagram. The fact that the study of kinetics presents a "language barrier" to many chemists reflects the different ways reactions are viewed. To a synthetic chemist, a chemical reaction is characterized by the singular verdict of its outcome: yield and selectivity at the end of the reaction event are registered as numbers in a table. From a kinetic perspective, a chemical reaction is a journey narrated by the reaction rate law. While reaction progress is evident in an energy diagram with its "reaction coordinate" axis, surprisingly few chemists realize that they may envision kinetic graphs in this way. Where classical kinetic approaches provide only a bare summary of the journey that the molecules have undertaken, reaction progress kinetic analysis allows much more to be learnt by following the molecules on their journey.

3. Getting Started



The two key components required for carrying out reaction progress kinetic analysis are: 1) an in situ method of continuous and accurate experimental data collection and 2) a computational means for manipulating the data (typically a PC with a spreadsheet program, perhaps supplemented by a commercial curve-fitting package). Data collection may be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

carried out by using any method that provides an adequate and accurate response (both in signal strength and in time resolution) that is related in a known way to reaction turnover. Understanding the ways in which we manipulate the data we obtain requires that a few words are first said about the different ways in which kinetic data can be measured.

3.1. Integral Measurements

Kinetic methods that rely on a relationship between the measurable parameter and species concentration are called integral measurements because concentration is proportional to the integral of the reaction rate. For example, FTIR spectroscopic studies that follow particular vibrations of reactant or product molecules and also incorporate a chemometric analysis relate the signal intensity to temporal reactant or product concentrations (Table 1, left column). The reaction rate is obtained by differentiating the experimental concentration versus time data. Thus, with integral methods, rate is termed a "processed" parameter to the "primary" parameter of concentration or conversion of the substrate. Typically, some method of smoothing the concentration data is applied before calculating the rate to minimize the noise inherent in the derivative process.[6]

Scheme 2. Examples of reactions monitored using integral (a; see Figure 2a) and differential (b, see Figure 2b) measurements of reaction progress.

Table 1: Integral and differential measurements of reaction progress.

FTIR spectroscopy as an example of an integral measurement[a]	Reaction calorimetry as an example of a differential measurement[b]
$A = \varepsilon b c$	$\dot{q} = \Delta H_{rxn} \times \text{volume} \times \text{rate}$
$\text{rate} = \frac{dc}{dt}$	
$\text{conversion} = 1 - \frac{A}{A_0}$	$\text{conversion} = \int_{t=0}^{t=t} q(t)dt \,/\, \int_{t=0}^{t=t(\text{end})} q(t)dt$
measured parameter: conversion	measured parameter: reaction rate
processed parameter: reaction rate	processed parameter: conversion

[a] A = absorbance, c = concentration, ε = extinction coefficient, b = cell path length. [b] $\dot{q}$ = reactant heat flow, ΔH_{rxn} = heat of reaction.

3.2. Differential Measurements

Methods that measure reaction rate directly are termed differential or derivative measurements (Table 1, right column). These methods include reaction calorimetry, which measures the instantaneous heat flow of the reaction. The reaction rate is related to the heat flow q through the thermodynamic heat of reaction ΔH_{rxn}. In this case the rate is the primary measured parameter, while concentration or conversion (the processed parameters) is proportional to the integral of the rate versus the time.

3.3. A "Graphical Rate Equation"

The reaction shown in Scheme 2a is an example in which the reaction progress was monitored by using an integral method (Figure 2a).[7] Another example in which a differential method (Figure 2b) was used is the reaction shown in Scheme 2b.[8] The graphs in Figure 2 reflect the way data are collected, with time as the x-axis. However, viewing reaction progress as a function of time is not the best way to extract kinetic information from a reaction. Con-

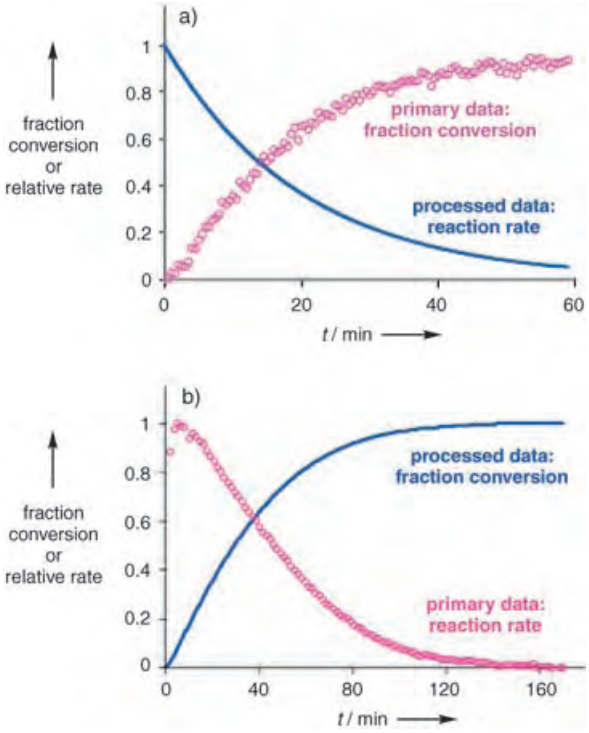


Figure 2. a) Integral (see Scheme 2a) and b) differential (see Scheme 2b) methods for monitoring reaction progress.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

sider the Michaelis–Menten rate expression [Eq. (1)] used to describe the simple mechanism shown in Scheme 1. We can see that time appears only implicitly in this expression. Instead, as with all reaction-rate expressions, the Michaelis–Menten Equation defines a relationship between *rate* and *substrate concentration*. This is where it is useful to combine the two ways in which reaction progress data are described. For any given reaction, the differential measurement can be plotted as the *y*-axis and the integral measurement as the *x*-axis, thus leaving time out of the picture. The resulting plot is termed a "graphical rate equation". Figure 3 shows such plots of rate versus substrate concentration for the two examples of Figure 2.

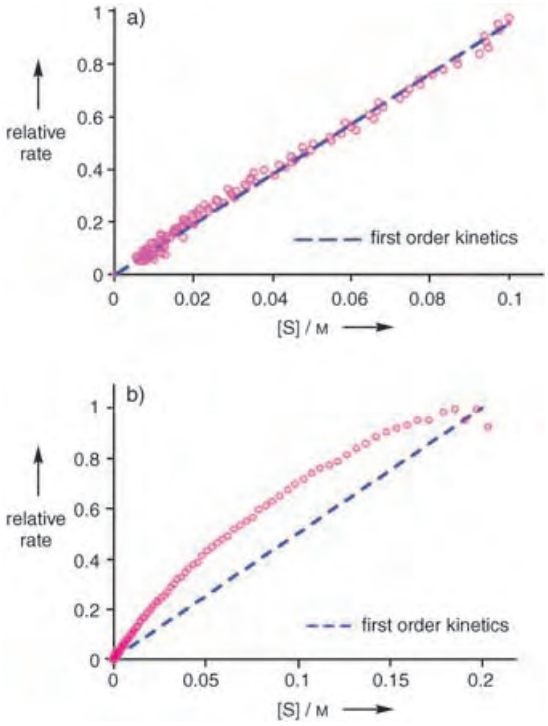

Figure 3. "Graphical rate equations" constructed from the data in Figure 2a and b.

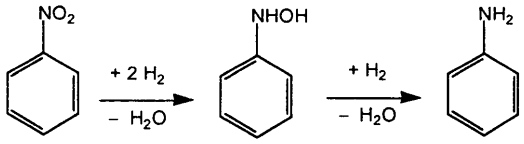
Either concentration or conversion can be used as the "integral method" *x*-axis in these plots. The fraction conversion x of the limiting substrate S is related to the concentration of the substrate by Equation (3).

$$[S] = [S]_0\,(1-x) \tag{3}$$

$$v = \frac{d[S]}{dt} = -[S]_0\,\frac{dx}{dt}$$



Although fraction conversion is often preferred, comparisons on this basis can be misleading, because a given value for fraction converted represents different substrate concentrations for experiments carried out at different initial concentrations of the limiting substrate. Notice also that plotting concentration as the *x*-axis means that the reaction progresses from right to left, because substrate concentration decreases over the course of the reaction.

The graphical rate equation is a powerful tool for probing concentration dependences. For example, the straight-line relationship in Figure 3a shows that the asymmetric transfer hydrogenation of Scheme 2a exhibits overall first-order kinetics in the concentration of the imine substrate. The curvature in the graphical rate equation in Figure 3b suggests a more complex relationship must be used to describe the enantioselective Heck coupling of Scheme 2b.

The key to the success of this graphical tool lies in the accurate construction of the graphical rate equation by obtaining sufficient high-quality data over the course of the reaction. This highlights the importance of accurate, rapid-response in situ measurement tools in reaction progress kinetic analysis.

3.4. Two (or More) In Situ Techniques are Better than One

Facile access to a range of in situ monitoring techniques makes it possible in many cases today to employ more than one such technique simultaneously. Monitoring a reaction by several orthogonal techniques[9]—methods that rely on different properties of a reacting system to monitor its progress—is a good way of checking that the desired reaction is indeed being followed. A multitechnique approach can also provide valuable mechanistic information that one technique used alone might miss. The reaction shown in Scheme 3 and the

Scheme 3. Room-temperature hydrogenation of nitrobenzene at normal pressure using a Pd/carbon catalyst (see Figure 4).

corresponding analysis shown in Figure 4 are shown as an example.[10] Hydrogenation of nitro substituents on aromatic rings using heterogeneous catalysts is a common transforma-

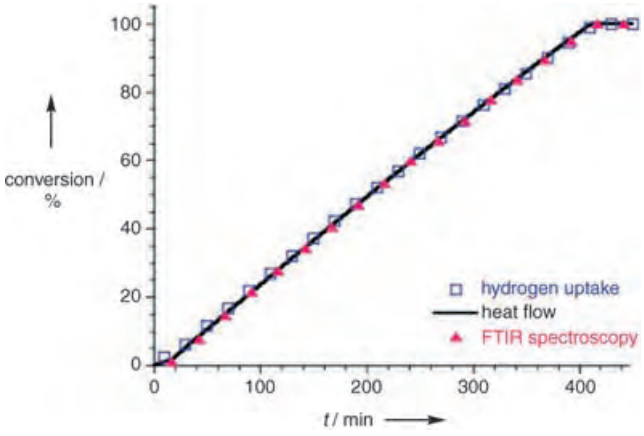


Figure 4. Reaction progress of the Pd/carbon-catalyzed hydrogenation of nitrobenzene shown in Scheme 3 as monitored by three different in situ techniques.

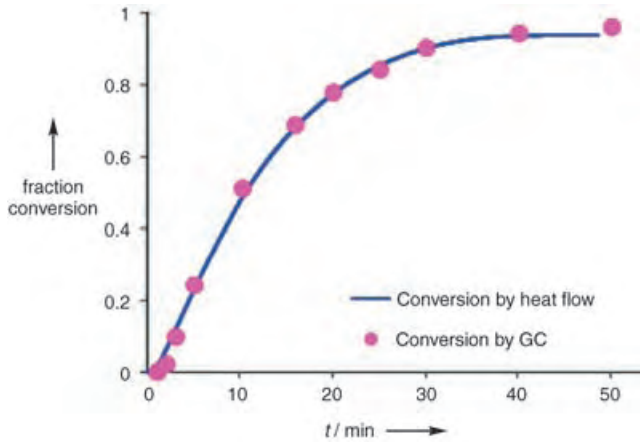
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tion in the pharmaceutical industry. The conversion of nitrobenzene, shown in Figure 4, into aniline using Pd/C is monitored by three separate in situ methods that monitor different properties of the reaction under study: FTIR spectroscopy follows the disappearance of the nitro group in the starting material; hydrogen uptake monitors the stepwise stoichiometry of the hydrogenation; and reaction calorimetry measures the thermodynamic heats in all steps of this highly exothermic reaction. Figure 4 shows clearly that the three methods are in excellent agreement. This result demonstrates that the kinetic data are accurately following the reaction in question and that any potential contribution from side reactions may be safely neglected.

Note that no discrepancy is observed between a method following the decay of the starting material and one monitoring the stoichiometry of the hydrogen uptake, although the hydrogen uptake profile differs for the first and second steps in Scheme 3. From this information it can be proposed that intermediate species, such as hydroxylamine, do not build up in solution over the course of the reaction, since all three techniques give identical information about the global reaction stoichiometry. Thus, in this case, the use of these three methods also offers additional mechanistic insight.

3.5. Calibrating the In Situ Measurement

Whatever the method or methods used to follow the progress of the reaction, it is vitally important to verify that the measurement indeed correlates with the turnover of substrate molecules to product. In most cases it is not feasible to compare the reaction progress profile with three separate measurement techniques as in the previous example. More routinely, calibration of the in situ technique is accomplished by periodic sampling of the reaction mixture over time and employing a known analytical method of assessing concentration. Figure 5 shows a comparison of conversion versus time determined from GC analysis of discrete samples and from the reaction heat flow for the example shown in Scheme 4, the copper-free Sonogashira coupling of bromoacetophenone with phenylacetylene using $[Pd(PtBu_3)_2]$ as catalyst.[11,12] Although discrete analytical sampling alone seldom provides the quantity of data required for reaction progress kinetic analysis, it serves as a check on the veracity of the in situ technique used for monitoring the reaction progress.[13]



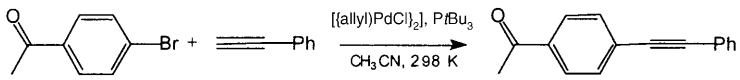


Figure 5. Fraction converted versus time for the reaction shown in Scheme 4 as monitored by reaction calorimetry and verified by GC analysis.

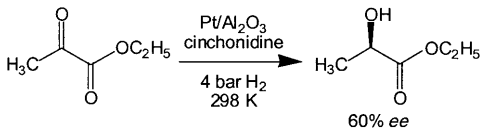
Scheme 4. Sonogashira coupling of an aryl bromide with phenylacetylene using a zero-valent Pd phosphine catalyst (see Figure 5).

3.6. Caveats



The principles and the graphical tools developed here for reaction progress kinetic analysis owe a large debt to a long history of graphical approaches in enzyme catalysis that are beyond the scope of this Review. Curve-fitting and simulation approaches as well as widely available commercial software packages that determine rate constants will not be the focus of this Review. The fact that these approaches are available but not routinely used by synthetic organic chemists studying chemical catalytic systems provides a strong rationale for the development of the approach described here.

The rate equations developed in this Review are based on the steady-state approximation. Reaction progress kinetic analysis may also be applied (with certain caveats) to stoichiometric reactions; however, this extension of the methodology is beyond the scope of the present Review. The parallel reaction cycles of asymmetric catalytic reactions are not treated here, although the simple reaction schemes given may be easily extended to these systems.

Illustrating the graphical approach described here required access to data sets for manipulation, and hence all of the data and examples discussed come from work carried out in my research group or in collaborative efforts. These data are used here without attempts at detailed mechanistic interpetation; interested readers can refer to the published papers.

4. A Simple Example of "High-Throughput Kinetics"

The asymmetric hydrogenation reaction depicted in Scheme 5 and carried out in two different solvents is used as an introductory illustration of kinetic analysis of the progress of the reaction.[14] Reaction progress, determined by an integral (Figure 6a) and by a differential (Figure 6b)

Scheme 5. Asymmetric hydrogenation of ethyl pyruvate mediated by cinchona-modified Pt/Al_2O_3.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

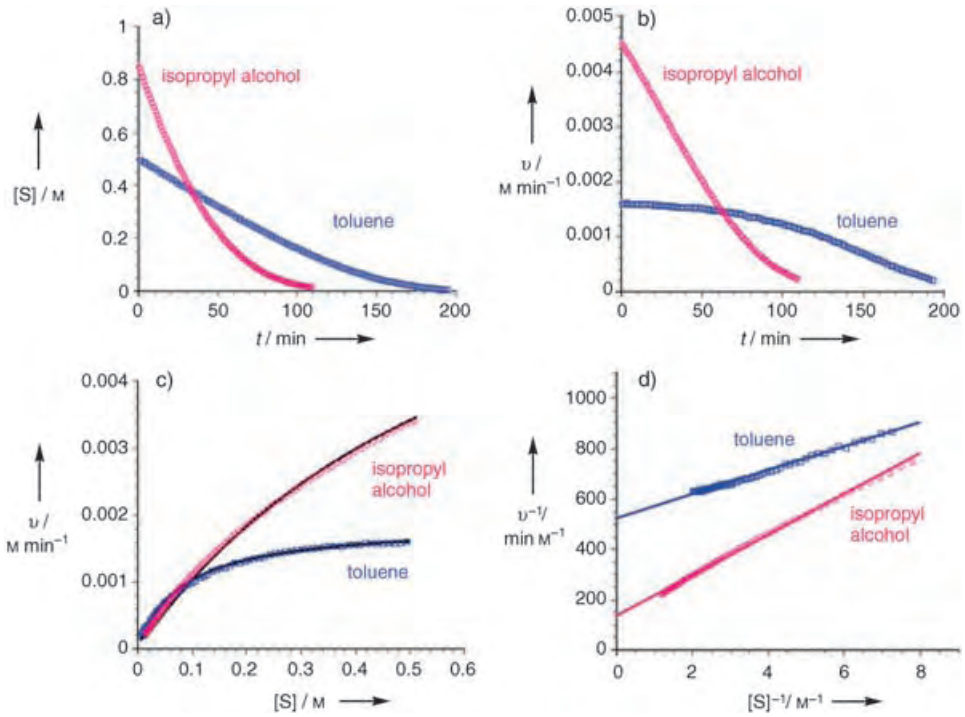


Figure 6. Kinetic analysis (by differential and integral methods) of the hydrogenation reaction shown in Scheme 5 carried out in two different solvents: a) Substrate concentration versus time (integral method). b) Reaction rate versus time (differential method). c) Rate versus substrate concentration; a fit to Equation (1) gives $\upsilon_{max} = 0.008 \pm 0.33\%$ M min^{-1}, $K_{MM} = 0.684 \pm 0.56\%$ M^{-1} (isopropyl alcohol) and $\upsilon_{max} = 0.002 \pm 0.07\%$ M min^{-1}, $K_{MM} = 0.083 \pm 0.23\%$ M^{-1} (toluene). d) Reciprocal rate versus reciprocal substrate (Lineweaver–Burk plot); a fit to Equation (2) gives $\upsilon_{max} = 0.007 \pm 0.90\%$ M min^{-1}, $K_{MM} = 0.600 \pm 1.32\%$ M^{-1} (isopropyl alcohol) and $\upsilon_{max} = 0.002 \pm 0.12\%$ M min^{-1}, $K_{MM} = 0.091 \pm 0.34\%$ M^{-1} (toluene).

method, is plotted as a function of time.[15] This example shows how the progress curves can be used to obtain both a *qualitative* comparison of the reaction's features in the two solvents as well as a *quantitative* analysis of kinetic parameters. The important point about monitoring reaction progress is that, in a single experiment, kinetic data can be obtained not only at the initial concentration of the reactant but also at every concentration between this value and that at the reaction's end. Thus, continuous monitoring of reaction progress is akin to carrying out hundreds of separate initial rate experiments.

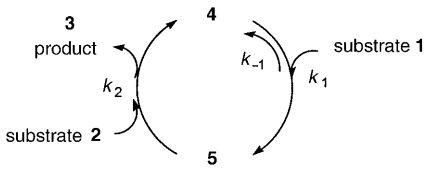
The qualitative approach allows some information to be gained before a reaction mechanism is proposed. The temporal data of Figure 6a and 6b show that the reaction is slower in toluene and appears to exhibit a greater degree of "flatness" in the progress curve relative to that in isopropyl alcohol. This observation suggests that the reaction exhibits less-positive-order kinetics in toluene than in isopropyl alcohol. Such a conclusion is even easier to reach by looking at the graphical rate equation of Figure 6c, which is constructed by combining Figure 6a and b. The closer the data are to a horizontal line, the closer the reaction is to zero-order kinetics. Thus, the reaction seems to be not-quite zero order when carried out in toluene, and not-quite first order when carried out in isopropyl alcohol.

Possible reaction mechanisms for kinetic modeling of the data need to be considered if a more quantitative approach is to be used. A good place to start for a constant-pressure hydrogenation reaction is the simple Michaelis–Menten mechanism shown in Scheme 1, with the rate constant k_2 replaced by a pseudo-first-order constant that incorporates the constant hydrogen concentration. The qualitative observations made above are indeed borne out quantitatively by the Michaelis–Menten kinetic model of Scheme 1 and Equation (1). Figure 6c shows that an excellent fit to Equation (1) is obtained for reactions in both solvents and give statistically significant values of the kinetic parameters. These parameters show that the value of K_{MM} in toluene is nearly one order of magnitude lower than it is in isopropyl alcohol. Since K_{MM} is related to the inverse of the binding constant,[16] this result suggests that much stronger catalyst–substrate binding occurs in toluene, thus confirming the pseudo-zero-order form of Equation (1) for the reaction in toluene. In isopropyl alcohol, the Michaelis–Menten Equation cannot be simplified to an integer order, thus resulting in a reaction order that lies between 0 and 1, with its value changing with [S].

These same reaction progress data may also be plotted in the time-honored Lineweaver–Burk double reciprocal plot as in Figure 6d, which shows similar values for the kinetic parameters with similar standard deviations. One advantage of the "straight-line" approach of Figure 6d is that slopes and intercepts can be extracted easily without resorting to a curve-fitting program. One drawback is that the relative values of K_{MM} in the two solvents are intuitively less easy to visualize from double-reciprocal plots of Figure 6d than they are from the direct "graphical rate equation" plots of Figure 6c.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The most important message to take away from this example is that, in this simple case, one single experiment is all that is mathematically required to develop a quantitative kinetic model of the reaction at a given pressure and temperature. The reason for this is because the experiment contained in essence hundreds of separate initial rate measurements at different substrate concentrations. In comparison to the days of labor that the classical kinetic approach would require, this is very high-throughput kinetic analysis indeed.



5. Dealing with Added Complexity

The example from the previous section (Scheme 5 and Figure 6) gives a sense of the ease with which a mechanistic model can be developed and tested by monitoring the reaction progress even in a single experiment, and it demonstrates both qualitative and quantitative approaches to reaction progress kinetic analysis. Furthermore, it illustrates the value of the "graphical rate equation" (the plot of rate versus concentration) as a visual aid in assessing concentration dependences. However, most reactions are mechanistically and experimentally much more complicated than this example.

5.1. Reactions with Two Substrates: Beyond the Lineweaver–Burk Plot

The reaction system in Scheme 1 represents the simplest case of a catalytic reaction mechanism, which in practice applies to only a very few cases—including decompositions and isomerizations, or, as already shown, hydrogenations under constant pressure. Typically, however, chemists are more interested in putting molecules together, and thus most reactions of interest will involve at least two reactant species. This means that, under synthetically relevant conditions, two separate reactant concentrations will change simultaneously over the course of the reaction.

Scheme 6 shows how the simple reaction system of Scheme 1 is modified for the case where a second substrate

Scheme 6. Mechanism for a simple reaction with two substrates and one intermediate species.

2 adds to the catalytic intermediate species **5** formed from the binding of the first substrate **1** to catalyst **4** to form the product **3**. The rate expression for this case can be written in the same form as the Michaelis–Menten relationship of Equation (1) to give Equation (4).

$$\upsilon = \frac{\upsilon_{max}\,[\mathbf{1}]}{K_{MM} + [\mathbf{1}]} \tag{4}$$

$$\upsilon_{max} = k_2\,[\mathbf{2}][\mathbf{4}]_{total},\; K_{MM} = \frac{k_{-1} + k_2\,[\mathbf{2}]}{k_1}$$

It can be seen that the kinetic parameters υ_{max} and K_{MM} have now become more complex. They are no longer constants, but instead they each incorporate a dependence on the concentration of the second substrate. A Lineweaver–Burk plot for a two-substrate reaction must be constructed from a series of experiments in which the concentration of the substrate [**2**] is held constant. It is important to emphasize that the constants obtained from this plot are only valid at that particular concentration of the second substrate. This limits the information that can be extracted from these parameters; for example, the magnitude of K_{MM} will no longer be easily related to the strength of binding of the substrate to the catalyst.

K_{MM} can be generalized—that is, the value of K_{MM} can be related back to values of the elementary step rate constants—by using a classical kinetic approach in which not one, but a series of Lineweaver–Burk plots are constructed at different constant values of [**2**]. This process will provide the relationship between K_{MM} and [**2**] that is needed to determine k_1, k_{-1}, and k_2 individually. Since each data point on each Lineweaver–Burk plot represents a separate experiment, it is clear that the classical kinetic approach to reactions involving two substrates involves even more work than it does for experiments with only one substrate.

5.2. Defining the Reaction ["Excess"]

Reaction progress kinetic analysis can help in the streamlining of the approach described above for reactions with two substrates. If the Michaelis–Menten form of the kinetic parameters is dismissed and the rate equation written out instead in terms of the elementary step rate constants, the relationship in Equation (5a) and (5b) is obtained.

$$\upsilon = \frac{k_1 k_2\,[\mathbf{1}]\,[\mathbf{2}]\,[\mathbf{4}]_{total}}{k_{-1} + k_1\,[\mathbf{1}] + k_2\,[\mathbf{2}]} \tag{5a}$$

$$\upsilon = \frac{a\,[\mathbf{1}]\,[\mathbf{2}]\,[\mathbf{4}]_{total}}{1 + b\,[\mathbf{1}] + c\,[\mathbf{2}]} \tag{5b}$$

$$a = \frac{k_1}{k_{-1}}\,k_2,\; b = \frac{k_1}{k_{-1}},\; c = \frac{k_2}{k_{-1}}$$

Equation (5b) divides both the numerator and denominator by the constant k_{-1} to give the rate equation in what is called the "one-plus" form.[17] These equations reveal that for reactions with two substrates the idea of an integer reaction order in either substrate will be at best an approximation: [**1**] and [**2**] appear in additive terms in the denominator as well as being multiplied together in the numerator. Reaction progress data can help make sense of this complex situation, without constraining one concentration to remain constant; instead conditions are employed where both [**1**] and [**2**] change over the course of the reaction.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Although [**1**] and [**2**] both change with time, the manner in which they change is linked to the reaction stoichiometry. For the reaction shown in Scheme 6, this stoichiometric "rule" says that each time one molecule of **1** is converted into one molecule of product **3**, one molecule of **2** is necessarily also converted. Here we define a parameter called the ["excess"], which is equal to the difference in the initial concentrations of the two substrates [Eq. (6)].[18]

$$[\mathbf{2}] = [\mathbf{2}]_0 - [\mathbf{1}]_0 + [\mathbf{1}] \;\Rightarrow\; [\mathbf{2}] = [\text{"excess"}] + [\mathbf{1}] \qquad (6)$$

This parameter ["excess"] has units, the same units as [**1**] and [**2**] (typically M or mM). The ["excess"] need not be a large number—such as the familiar tenfold excess used in classical kinetic experiments to approximate zero-order conditions in one substrate. The ["excess"] may be a positive number, a negative number, or zero ([“excess”] = 0 for equimolar conditions). A few important points to emphasize about this parameter ["excess"] include:

- ["excess"] gives the difference between the initial concentrations of the two substrates.
- ["excess"] does not change as the reaction progresses (for constant volume reactions).
- ["excess"] is *not* identical to either the number of equivalents or to a percentage excess concentration, both of which do change as the reaction progresses.

One of the key features of reaction progress kinetic analysis is that reactions can be carried out using synthetically relevant conditions. A synthetically reasonable value for the excess of one substrate over the other is employed, thus avoiding the synthetically unreasonable tenfold concentration differences typical of the "pseudo-zero-order" classical kinetic approach.

5.3. How ["Excess"] Helps to Streamline Kinetic Analysis

If the stoichiometric relationship of Equation (6) is substituted into the rate expression Equation (5b), the resulting rate equation is given by Equation (7). For a given set of conditions, the quantities $[\mathbf{4}]_{total}$ and ["excess"] are constant, and k_1, k_{-1}, and k_2 are constants, thus leaving [**1**] as the only variable.

$$v = a' \frac{[\text{"excess"}]\,[\mathbf{1}] + [\mathbf{1}]^2}{1 + b'\,[\mathbf{1}]}\,[\mathbf{4}]_{total} \qquad (7)$$

$$a' = \frac{k_1 k_2}{k_{-1} + k_2\,[\text{"excess"}]},\; b' = \frac{k_1 + k_2}{k_{-1} + k_2\,[\text{"excess"}]}$$

Writing the rate expression in this form highlights how the parameter ["excess"] helps deal with the conundrum of having two concentrations changing at once. Equation (7) shows that there is no need to carry out reactions where the concentration of one substrate is artificially fixed at a pseudoconstant high value over the course of the reaction. As long as the ["excess"] is known, then monitoring the concentration of *one* substrate as the reaction progresses allows the kinetics of reactions with two substrates to be assessed. And because the concentrations of each reactant need not be fixed in turn for a series of experiments probing the other substrate's concentration dependence, this process cuts down significantly on the total number of experiments that must be carried out in order to complete the kinetic analysis of a reaction.

Equation (7) allows us to illustrate two important ways in which we use the variable ["excess"] in kinetic analysis, as outlined in the next two sections.

5.3.1. Experiments Eploying the Same ["Excess"]

First, suppose several experiments are carried out with the same ["excess"] but different starting concentrations of **1** and **2**. Equation (7) illustrates that this is equivalent to carrying out the same experiment from two different starting points. This possibility becomes useful to probe reactions for complexities such as product inhibition or catalyst deactivation (see Section 7.1.2).

5.3.2. Experiments with Different ["Excess"]

Equation (7) shows that there are only two independent adjustable parameters in this rate equation, a' and b', while the reaction mechanism has three independent rate constants, k_1, k_{-1}, and k_2. This situation is analogous to having two simultaneous algebraic equations containing three unknowns, for which an infinite number of solutions exists. Suppose, however, that several experiments are carried out with different ["excess"] values. Collecting data from reactions with at least two different ["excess"] values gives an extra equation and allows a unique solution to be obtained for all three rate constants. This becomes especially important when different mechanistic models are to be tested (Sections 7.4 and 7.5).

6. Graphical Tools for Reactions with Two Substrates: Dissecting the Reaction-Rate Expression

The dependence of the reaction rate on [**1**] in Equation (7) is complex, with second-order and first-order polynomials in [**1**] appearing in the numerator and denominator, respectively. Since [**1**] and [**2**] are associated with the parameter ["excess"], it is often easier in practice to return to the rate equation in the form of Equation (5b), where both [**1**] and [**2**] appear explicitly. In this section some limiting cases of this rate equation are probed.

The denominator of Equation (5b) is comprised of three terms: one is a constant (simply the number 1) and the other two terms contain reactant concentrations [**1**] and [**2**], each multiplied by constants. It is this complexity that makes the concentration dependences of [**1**] and [**2**] nonstraightforward. The key to relating this equation to the species shown in the reaction mechanism (Scheme 6) is to probe which, if any, of the three terms in the denominator dominates the other two.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 2: Limiting cases of the rate expression given in Equation (5b) for the catalytic reaction in Scheme 6.

Dominating species (Scheme 6)	Dominating term in denominator of Eq. (5b)	Observed rate equation
5	b	$v = k_2[\mathbf{2}][\mathbf{4}]_{total}$ (8)
4	c	$v = k_1[\mathbf{1}][\mathbf{4}]_{total}$ (9)
none	all terms contribute	$v = \frac{\frac{k_1}{k_{-1}} k_2 [\mathbf{1}][\mathbf{2}][\mathbf{4}]_{total}}{1+\frac{k_1}{k_{-1}}[\mathbf{1}]+\frac{k_2}{k_{-1}}[\mathbf{2}]}$ (5b)

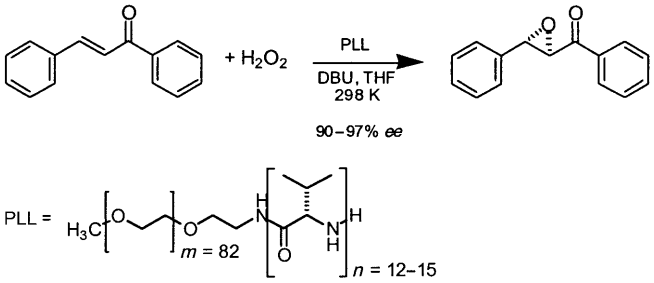
The various limiting forms of this equation are discussed below and are summarized in Table 2.

Note that the ratio given by the constant b in Equation (5b) is the equilibrium constant for the binding of substrate **1** and hence gives information about the concentration of the catalyst intermediate species **5**. If the term containing b outweighs the other denominator terms, the intermediate species **5** dominates and the slow step will be the reaction consuming this intermediate. This limiting situation is commonly termed "saturation kinetics" in species **1**. The rate equation in this case simplifies to that of Equation (8) in Table 2. A case of saturation kinetics for a reaction with only one substrate was shown in the introductory example of Section 4.0 and one for a reaction with two substrates will be shown in Section 7.2.

The constant c gives the ratio of rate constants for the two reactions of intermediate species **5:** forward to yield product **3** versus backward to reform substrate **1**. If c is large, then intermediate **5** does not build up to a significant concentration. In this case the formation of the intermediate **5** will be rate-limiting, and the unbound catalyst species **4** will be the "resting state" of the catalyst. Equation (9) in Table 2 describes this case, with an example given in Section 7.3.

It is also possible that none of the terms in the denominator dominate the rate expression. This situation is equivalent to saying that the reaction doesn't have a rate-limiting step—a circumstance more common than is typically considered; it simply means that the catalyst exists in significant amounts in both forms **4** and **5** in the system rather than opting for one particular resting state. In this case it is necessary to use the full rate Equation (5b), without simplification of the denominator, to describe the reaction (see Section 7.5).

The observed kinetics will be dictated by the reaction involving the catalytic species that dominates, as summarized in Table 2. It can be seen from this discussion that observation of integer reaction orders in catalytic reactions can hide a wealth of mechanistic information. The next few examples will demonstrate how reaction progress data can be used to help discern which, if any, of these limiting cases are applicable to the reaction under study. While we start from the form of equation (5), we will see again how the parameter ["excess"], which defines the relationship between substrates **1** and **2**, can help us gather significant mechanistic detail from a minimal number of experiments.



7. "Interrogating" the Data

The ["excess"] relationship allows a set of data pairs of ([**2**], time) points to be compiled with the data from the reaction analysis, that is, with ([**1**], time) and (rate, time) data pairs. Armed with these data, it is now possible to start constructing graphical rate equations for reactions with two substrates. A number of examples below highlight how these data can give information about catalyst behavior. It should be noted that all of the kinetic treatment described here is designed for use in experiments that are carried out under isothermal conditions where the reaction under study is dominant (that is, there are minimal side reactions).

7.1. Catalyst Instabilities

7.1.1. Induction Periods

An important consideration that is often neglected in classical kinetic approaches is the problem of induction periods in catalytic reactions. Transient behavior at the beginning of a reaction is common in chemical catalysis where reactions are often initiated by addition of a catalyst precursor, rather than a catalyst in its active form. Even when the catalyst itself is in its active form, there may be other considerations that cause data obtained at the very outset of the reaction to be suspect. The example in Scheme 7

Scheme 7. Epoxidation of chalcone by H_2O_2 in the presence of the catalyst PLL (MeO-poly(ethylene glycol)-poly-(L-leucine); see Figure 7). DBU = 1,8-diazabicyclo[5.4.0]unde-7-ene.

illustrates this for the Julià–Colonna epoxidation of 1,3-diphenylpropenone (chalcone).[19] The reaction rate versus time curve (Figure 7) shows that the rate rises for the first few minutes of the reaction, before decreasing with time in the manner expected for a reaction exhibiting positive-order kinetics in substrate concentration.[20] The inset in Figure 7 shows a plot of the graphical rate equation in the form of reaction rate versus fraction conversion of the chalcone substrate and shows that the reaction reaches about 20% conversion before the rate profile assumes positive-order kinetics. During the initial few minutes of reaction, the measured values of rate will vary dramatically with even small increments in time. For example, an initial rate measurement taken at 30 seconds would differ by a factor of 50% from one taken at 60 seconds. Such transient behavior might never be

Scheme 8. a) Heck coupling of aryl bromides. b) Hydrolytic epoxide ring opening.

detected, and misleading interpretation of kinetic data might result, if reaction-progress analysis was not available.

The potential complications of induction periods can easily be overcome when kinetic data are obtained using an in situ method for monitoring reaction progress. Most often it is the steady-state characteristics of the reaction that are of interest for our kinetic analysis. Since the reaction rate and the concentrations of the reactants are known at every point in the reaction, the data obtained during the induction period can simply be discarded and the analysis carried out by selecting only the portion of the reaction that exhibits steady-state behavior. This is what has been done in the examples in the following sections, both for graphical data "interrogation" and for detailed kinetic modeling studies.[21]

7.1.2. *Catalyst Deactivation and Product Inhibition*

A source of additional complexity in catalytic reactions arises in cases where the catalyst deactivates over time, or where the concentration of the active catalyst can be altered over the course of the reaction by substrate or product inhibition. These issues are often cited in support of the practice of carrying out initial rate measurements, to remove time-dependent properties of the reaction from consideration. Such practice may in some cases provide an ideal picture of the kinetics of the reaction; however, this picture can be quite misleading in the practical world, where reactions necessarily are carried out from beginning to end.

One of the most powerful features of reaction progress kinetic analysis is that it allows us to account for the influence of such time-dependent processes, rather than simply ignoring them. Consider the two reactions shown in Scheme 8a and 8b, for which reaction progress data are plotted in the graphical rate equation form in Figure 8a[22] and 8b,[23] respectively. Palladium-catalyzed Heck couplings of aryl halides (Scheme 8a) are commercially important carbon–carbon bond-forming reactions that are often plagued by catalyst deactivation.[24] Epoxide ring opening catalyzed by a cobalt–salen complex, as performed by Jacobsen and co-workers, offers a strikingly efficient method for the kinetic resolution of racemic epoxides (Scheme 8b).[25] These reactions are more complex than our introductory hydrogenation example, because in each case two substrate concentrations change simultaneously over the course of the reaction.

The issue of catalyst deactivation can be probed for the two reactions by carrying out two separate reactions with different starting concentrations of species **1** and **2**, but identical values of the ["excess"]. As explained in Section 5.3, two such experiments represent an identical reaction started from two different places. Thus, choosing any concentration value on either of the plots in Figure 8a and b gives data that correspond to experiments that are identical except for two things: 1) the reaction with a higher initial concentration (red curve) contains more product than that with a lower initial concentration (blue curve); and 2) the catalyst for the reaction with a higher initial concentration has completed more turnovers. By comparing the curves for the reaction progress under these conditions, it is possible to address both the influence of the presence of product and the possibility of catalyst deactivation slowing the reaction over time.

Figure 8a shows that the two curves (reaction rate versus [ArX]) fall exactly on top of one another, thus confirming that neither the presence of product nor the "extra work" done by the catalyst in the reaction shown in red had any influence on the reaction kinetics. We will return to this example later to discuss the interesting "bend" in the curves toward the end of the reaction. For now, however, it has been shown how two simple experiments effectively tell us that neither catalyst deactivation nor product inhibition is a factor in this Heck reaction.

The reaction shown in Figure 8b tells a different story. For a given epoxide concentration, a slightly higher rate was observed in the reaction indicated by the blue curve (lower initial concentration) compared to that shown in red (higher initial concentration). This result suggests that either product inhibition or catalyst deactivation influences the reaction. In this case, further experiments are required to establish which of the two effects is responsible for the lowered rate. For example, reaction product could be added to the mixture at the outset of a reaction under the conditions shown by the blue curve, and the effect on the resulting graphical rate equation observed: namely, do the new data fall on top of the blue curve, or do they fall on top of the red curve? If the curve with addition of product overlays with the blue curve, then it

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

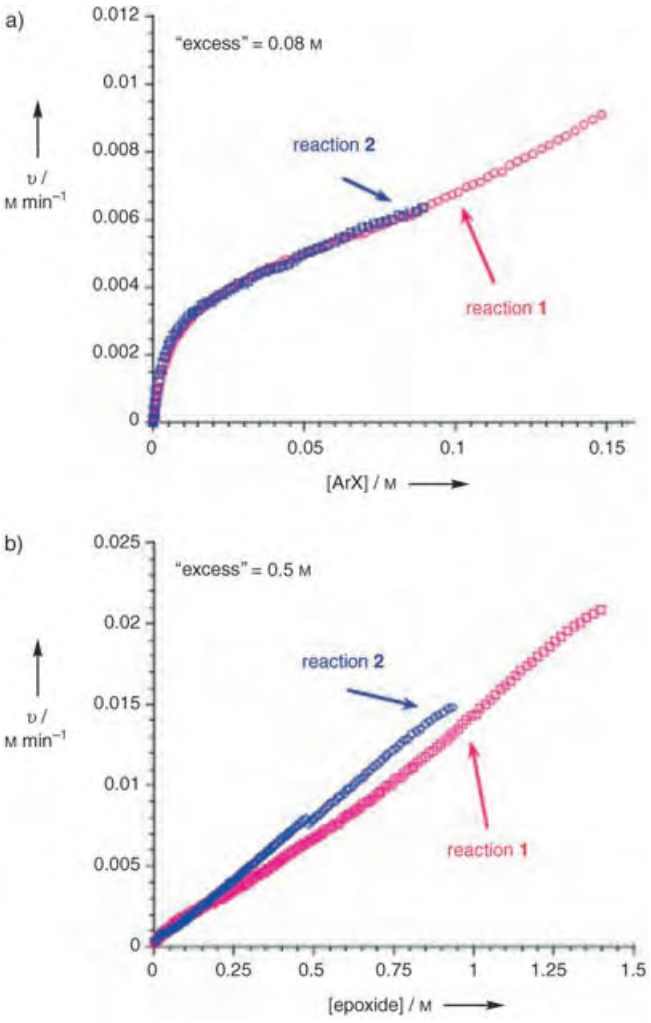

Figure 8. Probing catalyst deactivation by carrying out two reactions at the same ["excess"] but different initial substrate concentrations. a) Heck coupling using a C-N palladacycle catalyst (0.0002 M); red curve: $[ArX]_0 = 0.16$ M, $[olefin]_0 = 0.24$ M; blue curve: $[ArX]_0 = 0.12$ M, $[olefin]_0 = 0.20$ M; b) epoxide ring opening with 2 mol% [Co(salen)]; red curve: $[epoxide]_0 = 1.5$ M, $[H_2O]_0 = 2$ M; blue curve: $[epoxide]_0 = 1$ M, $[H_2O]_0 = 1.5$ M.

can be concluded that catalyst deactivation and not product inhibition is responsible—this is what was found for the reaction shown in Scheme 8b. Further experiments suggested that such deactivation was significant only at the unusually high water:epoxide ratios used in these experiments. Since the hydrolytic kinetic resolution is typically carried out at 0.55 equivalents of water (compared to the 1.3–1.5 equivalents used here), it could be concluded that catalyst deactivation would not be a factor under synthetically relevant conditions.[26]

The example shown in Figure 8b brings up an important consideration in comparing reaction progress kinetic analysis to classical kinetic approaches. Kinetic behavior may be altered when reactions are carried out under conditions significantly removed from those of practical application, as is often the case in classical kinetic approaches in which pseudoconstant concentrations of one reactant is used. The consequences of this practice of removing the catalytic reaction system from its "natural environment" are seldom addressed. Our goal is to employ the conditions under which we plan to run a reaction and allow reaction progress kinetics to help us understand how our reaction works. Kinetic analysis that studies the reacting system in its natural state provides a truer account of the journey taken by the reaction.

These two illustrations have shown how reaction progress kinetic analysis can make use of two simple experiments with identical ["excess"] to address the questions of catalyst deactivation and product inhibition. Adding a third experiment to the list (that of product addition at the start of the reaction) can generally settle these issues definitively for a given system under a given range of conditions. Initial rate measurements leave these questions unanswered; however—especially since the experimental protocol is disarmingly straightforward—it makes sense not to avoid looking for the answers.

7.2. Saturation Kinetics in a Reaction with Two Substrates

Returning to the Heck coupling example of Figure 8a, we turn our attention to the unusual bend observed in the rate curves at high conversion. This unusual shape is also evident when the data are plotted in the time domain, as in Figure 9a,[27] where in addition to the data from Figure 8a, a third reaction carried out at a different ["excess"] value is shown. For most of the reaction, the curve of rate versus [ArX] in Figure 8a is a straight line suggestive of first-order kinetics; however, this line has a non-zero y-intercept ($y = mx + b$ instead of $y = mx$). The parameter ["excess"] can be used to explain this. From the initial reactant concentrations, it can be seen that the aryl bromide is the limiting reactant in all three cases in Figure 9a. If the rate was first order in [ArX] (or [**1**]), the graphical rate equation should have had a y-intercept of zero. However, if the reaction is first order in [olefin] (or [**2**]), then the rate is given by Equation (10):

$$v = k[\mathbf{2}] = k([\text{"excess"}] + [\mathbf{1}]) \tag{10}$$

$$\text{slope} = k$$

$$y\text{–intercept} = k[\text{"excess"}]$$

This result suggests that the Heck reaction under study fits the limiting condition of Equation (8) in Table 2 and describes "saturation kinetics" in [ArX]. The resting state of the catalyst is species **5**, that is, the oxidative addition complex with the substrate. Note that the condition of saturation in a reaction with two substrates is revealed by a linear rate versus concentration curve (overall first-order kinetics), while for a reaction with only one substrate, saturation gives a horizontal line (overall zero-order kinetics) on the same plot.

This result can be corroborated with another form of the graphical rate equation. The simplified rate expression of Equation (8) is divided on both sides by the concentration of the olefin [**2**] to give Equation (11), in which the variables that are functions of time (v and [**2**]) appear as a quotient on the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

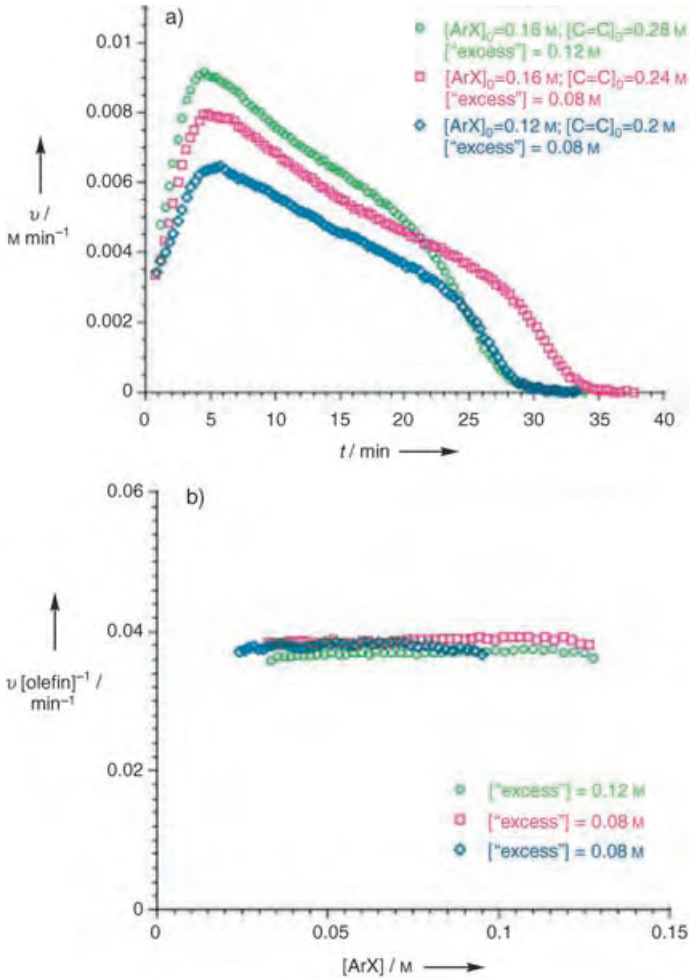

Figure 9. a) Primary data of reaction rate versus time for the Heck coupling in Scheme 8a (C,N palladacycle catalyst) carried out under three different sets of initial substrate conditions. b) A variation of the graphical rate equation for the Heck coupling derived from Figure 8a and 9a. The reaction rate divided by the corresponding olefin concentration is plotted versus aryl halide concentration [see Eq. (11)].

left side of the equation, while the quantities on the right side are constants.

$$\frac{v(t)}{[\mathbf{2}](t)} = k_2\,[\mathbf{4}]_{\text{total}} = \text{constant} \qquad (11)$$

A graphical rate equation can be made according to Equation (11) with our data from the three reactions shown in Figure 9a. This is achieved by dividing each row of a column of rate data points by its corresponding olefin concentration; Equation (11) says that a horizontal straight line could be obtained when this function is plotted versus [**1**] or [**2**] for experiments carried out at any ["excess"] value (Figure 9b).

It is evident from Figures 8, 9a, and 9b that three simple reaction experiments and two graphical rate equations have given extensive detail concerning the mechanism of this Heck coupling reaction. These plots reveal that the system suffers from neither catalyst deactivation nor product inhibition and it exhibits pseudozero order (saturation) kinetics in [ArX] and first-order kinetics in [olefin]. Such efficient mechanistic analysis from so few experiments was possible only because of the voluminous reaction progress data available for constructing the graphical rate equations.

7.3. Free Catalyst as the Resting State

Reactions following the simple mechanism in Scheme 6 can look deceptively different from one another when carried out under different conditions: changing the substrates, the catalyst, the reaction temperature, or even the relative substrate concentrations can shift the resting state of the catalyst in the cycle and thus change the observed substrate concentration dependences. An example illustrating this reconsiders this Heck reaction, but now employing the $[Pd(PtBu)_3)_2]$ catalyst that Littke and Fu have shown to be active under mild conditions.[28] Plotting the standard graphical rate equation of rate versus [ArX] for three reactions carried out at two different ["excess"] values gives a first-order relationship for rate versus [ArX], with a *y*-intercept at zero (Figure 10).[29] This result suggests that the reaction obeys the limiting form of Equation (9) (Table 2) and that the unbound catalyst is the resting state in the reaction. This indicates that the rate-limiting step is the formation of the oxidative addition Pd complex, while the addition and insertion of the olefin proceeds much faster. It can also be seen from the two experiments carried out at the same ["excess"] value that catalyst deactivation is not a problem for this catalyst under the conditions employed. Comparing Figures 10 and 8a illustrates how differently two different Pd catalysts can behave even in the same reaction.

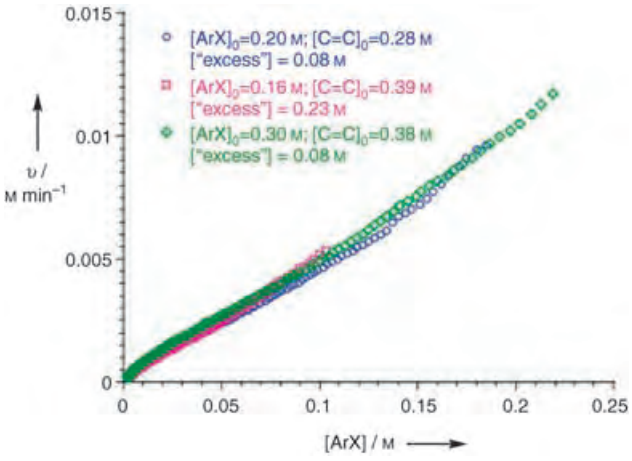

Figure 10. Standard graphical rate of reaction [Eq. (9)] for the Heck coupling shown in Scheme 8a using $[Pd(PtBu_3)_2]$ as the catalyst; the reaction was carried out at three different sets of initial concentrations of the reactants.

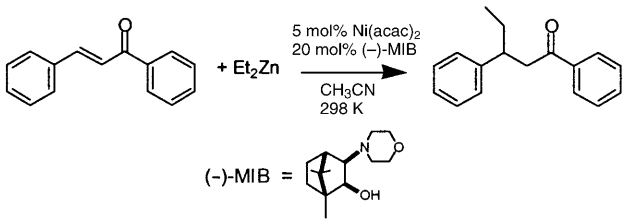

7.4. An Ambiguous Case of Catalyst Resting State

These examples have highlighted two limiting cases of the resting state of the catalyst shown in Table 2 for the reaction system of Scheme 6 with two substrates, demonstrating how

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reaction progress kinetic analysis can help in obtaining a rapid and comprehensive picture of the reaction's concentration driving forces in both cases. Reaction progress kinetic analysis can also help to sort out mechanistic details efficiently for more complicated cases that fall in between these two limits.

The reaction shown in Scheme 9,[30] the conjugate addition of diethylzinc to chalcone mediated by chiral amino alcohols

Scheme 9. Alkylation of chalcone with diethylzinc using $Ni(acac)_2$ and (−)-MIB ((2*S*)-(−)-3-*exo*-morpholinoisoborneol) as a chiral ligand (see Figure 11).

in the presence of a Ni complex, involves a complex mix of reagents. The active catalyst species itself is formed in situ, and much conjecture has been put forward about the reaction mechanism, with complicated dependences of the rate and selectivity on various reaction variables.[31] This would be a formidable test case for reaction progress kinetic analysis. The most important aspects are considered here, a detailed interpretation will be reported separately.[32]

7.4.1. *Failure of the Standard Graphical Rate Equation*

In the terminology of Scheme 6, [chalcone] can be represented by [**1**] and [Et_2Zn] by [**2**]. Three reaction progress curves of this reaction at two different ["excess"] values are shown in Figure 11 as a function of time.[33] Note that the reaction exhibits an induction period, thus suggesting that rate data at conversions less than about 20% will not give a reliable picture of the steady-state catalytic cycle. At conversions higher than this, the reaction appears to be well-behaved, and our analysis will focus on this region. Further details about the relationship between rate and reactant concentrations cannot easily be discerned from the raw reaction rate versus time data. Therefore the next step is to plot graphical rate equations.

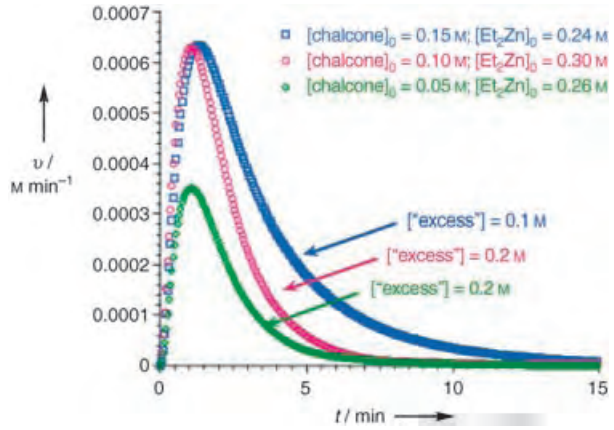

Figure 11. Primary data (reaction rate versus time) for the dialkylzinc alkylation of chalcone (see Scheme 9). The reaction was carried out under three different sets of initial substrate concentrations.

The standard graphical rate equation of rate versus [**1**] is shown in Figure 12a. The curves for the two reactions with the same value of ["excess"] fall on top of each other, which indicates that product inhibition or catalyst deactivation is not a factor in this reaction. However, the third reaction, carried out at different initial concentrations of both chalcone and diethylzinc, as well as at a different value of ["excess"], doesn't fall nicely on the other two. Indeed, it is difficult to determine any useful relationship between the substrate and the reaction rate from these plots. In this situation, the best thing to do is to try plotting other forms of the graphical rate equation.

7.4.2. *Trying Other Graphical Rate Equations: Do the Curves "Overlay"?*

New graphical rate equations can be made by "normalizing" the rate law in Equation (5b) in different ways. For instance, the rate can be divided by each substrate concentration in turn to provide a new function to plot against the other substrate concentration. This procedure gave Figure 9b in the example of the palladium-catalyzed Heck coupling, where all three curves fell on top of each other in a horizontal straight line which indicated zero-order kinetics (Section 7.2). In that case, this result was not unexpected, because it was predicted by Equation (11). In most new reactions, as in the current example, the shape of curves given by developing new graphical rate equations will not be known a priori. What is sought, then, in making these plots is a relationship – whether a straight line or some other function – that produces curves that fall on top of one another; the questions is, therefore, do the curves "overlay"?

Figure 12b and c show the plots of the graphical rate equations where the general rate equation has been divided first by the concentration of chalcone [**1**] [Eq. (12)], and then by diethylzinc [**2**] [Eq. (13)].

$$\frac{v}{[\mathbf{1}]} = \frac{a\,[\mathbf{2}]\,[\mathbf{4}]_{total}}{1 + b\,[\mathbf{1}] + c\,[\mathbf{2}]} \tag{12}$$

$$\frac{v}{[\mathbf{2}]} = \frac{a\,[\mathbf{1}]\,[\mathbf{4}]_{total}}{1 + b\,[\mathbf{1}] + c\,[\mathbf{2}]} \tag{13}$$

Both equations still appear to be complex. Indeed the plot in Figure 12b doesn't help to deconvolute the picture, because the curves don't overlay when plotted. This observation indicates that unlike the previous Heck examples, the order in [**1**] is not a simple integer; the *b* term in the denominator is not negligible in this case.

However, the curves do overlay when the data is plotted according to Equation (13). This result indicates that the data plotted according to Equation (13) versus [**1**] are independent of [**2**], since at any given [**1**] value one of the three runs has a value of [**2**] that is different from the others. This means that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

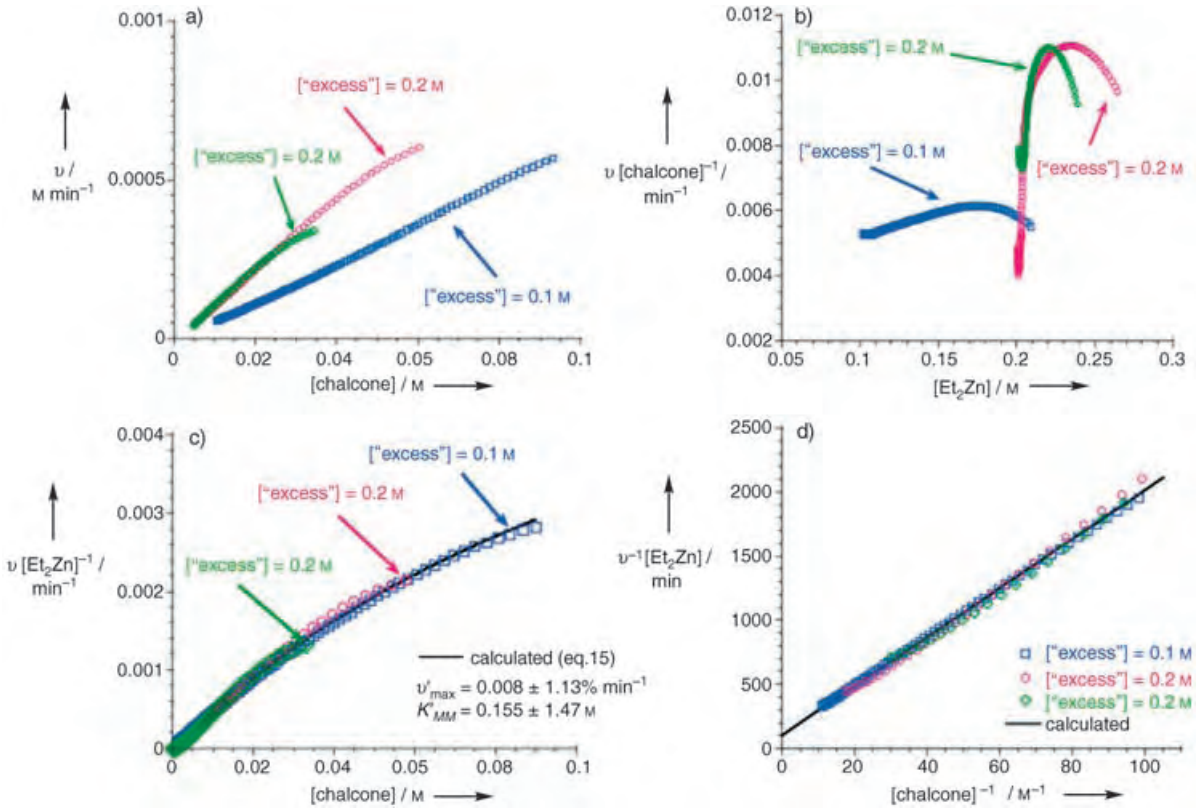

Figure 12. Graphical rate equations for the alkylation of chalcone with dialkylzinc as in Scheme 9 constructed from the primary data given in Figure 11. a) Standard graphical rate equation rate versus [**1**]. b) v/[**1**] versus [**2**]. c) v/[**2**] versus [**1**]; the solid line represents the curve fit to the modified Michaelis–Menten Equation [Eq. (15)]. d) Lineweaver–Burk plot showing the experimental data and the fit calculated according to the inverse form of Equation (15).

the right side of Equation (13) can't contain [**2**], and therefore the term c[**2**] must be small compared to the other terms. Thus Equation (13) can be simplified to Equation (14).

$$\frac{v}{[\mathbf{2}]} = \frac{a\,[\mathbf{1}]\,[\mathbf{4}]_{total}}{1 + b\,[\mathbf{1}]} \tag{14}$$

$$\frac{k_2}{k_{-1}}\,[\mathbf{2}] \ll \frac{k_1}{k_{-1}}\,[\mathbf{1}]$$

$$\frac{k_2}{k_{-1}}\,[\mathbf{2}] \ll 1$$

Equation (14) and its graphical version in Figure 12c show that this reaction exhibits overall first-order kinetics in the concentration of diethylzinc [**2**] and a saturation kinetics expression in the concentration of chalcone [**1**]. Since the plots in Figure 12c do not show a horizontal straight line, as they did in the Heck reaction (Figure 9), it can be deduced that the condition of saturation in [**1**] has not been reached under the concentrations of these conjugate addition reactions.

7.4.3. *Quantifying the Results of the Data Interrogation*

These graphical conclusions can be quantified just as in the asymmetric hydrogenation example of Figure 6 (Section 4). Equation (14) can be written in a Michaelis–Menten form [Eq. (15)] and a simple curve-fitting program applied

$$v' = \frac{v'_{max}\,[\mathbf{1}]}{K'_{MM} + [\mathbf{1}]} \tag{15}$$

$$v' = \text{“normalized rate”} = \frac{v}{[\mathbf{2}]}$$

$$v'_{max} = k_1\,k_2\,[\mathbf{4}]_{total}$$

$$K'_{MM} = \frac{k_{-1}}{k_1}$$

fitting the data in Figure 12c to Equation (15) yields the values for v_{max} and K_{MM} that are shown in the Figure.[34] Note that excellent standard deviations were obtained in these values based on the data from just three separate experiments.

The straight-line approach could instead be used with the same data by inverting Equation (15). The Lineweaver–Burk plot constructed from the same three experiments is shown in Figure 12d. The same quantitative information is available from the plot in this form.

To obtain the information on this plot from a classical kinetic approach would have required a much greater experimental effort. It would have been necessary to complete at least two separate Lineweaver–Burk plots in which data was included from two sets of reactions carried out at two different (constant) values of [**2**] while varying [**1**]. At the very

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

least, about half a dozen reactions in each set would have been needed. Reaction progress kinetic analysis allows the total number of experiments to be cut by a factor of four.

7.4.4. Turnover Frequency: Reaction Order in [Catalyst]

The reaction mechanism of Scheme 6 predicts that reaction rate will be proportional to the concentration of the catalyst. Although there are notable exceptions, most catalytic reactions do exhibit first-order behavior in the catalyst concentration. A graphical rate equation can be developed to confirm the relationship by dividing the general rate expression of Equation (5b) (reaction with two substrates) by the total catalyst concentration $[\mathbf{4}]_{total}$ [Eq. (16)]. This expression for the rate normalized by catalyst concentration is also referred to as the turnover frequency (TOF).[35]

$$\frac{\upsilon}{[\mathbf{4}]_{total}} = \mathrm{TOF} = \frac{a\,[\mathbf{1}]\,[\mathbf{2}]}{1 + b\,[\mathbf{1}] + c\,[\mathbf{2}]} \qquad (16)$$

Any two or more reactions carried out using the same ["excess"] but different catalyst concentrations may now be investigated and TOF plotted versus [**1**] (for example, chalcone). If the curves fall on top of one another, the reaction is first order in the catalyst concentration. Note that catalyst concentration is a constant for the entire reaction, and TOF is calculated by dividing each rate data point by this constant number; this is in contrast to the other graphical rate equations where each data point for the rate was divided by a quantity ([**1**] or [**2**]) that changes over the course of the reaction.

Figure 13 shows the TOF versus [chalcone] plots for two reactions shown in Scheme 9 carried out at the same ["excess"] and different concentrations of the catalyst precursor (Ni salt). Since the curves fall on top of one another, the reaction is first order in [Ni]. Note that constructing the graphical rate equation and determining the order in [catalyst] by this method requires no information about the reaction orders in [**1**] and [**2**]. As long as TOF is plotted for reactions with the same ["excess"], the key to this plot is not the shape of the profile but simply whether the curves fall on top of one another.

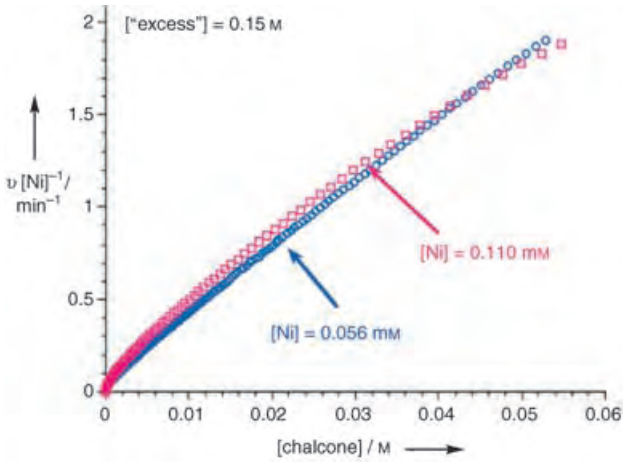

Figure 13. Graphical rate equation for turnover frequency as in Equation (16) for data from the reaction shown in Scheme 9.

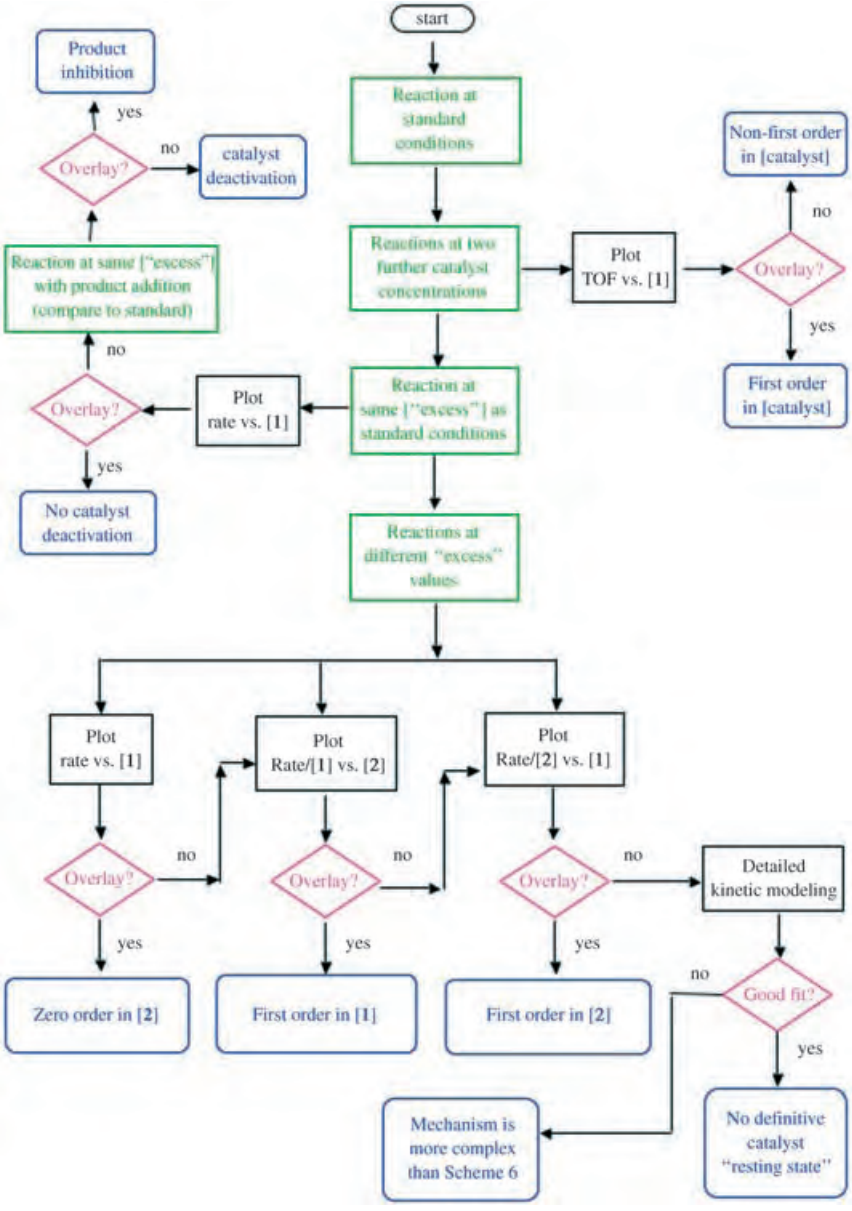
7.5. Complex Cases

In some reactions with two substrates it may be found that none of the plots of graphical rate equations result in all the curves falling on top of one another. What this means is that neither substrate exhibits an integer order and both substrate concentration terms in the denominator of the rate expression Equation (5b) make a noticeable contribution to the overall rate expression. The catalyst is almost evenly distributed between its free state **4** and intermediate **5** so that that the reaction does not exhibit a definitive rate-limiting step or resting state.[36] In such cases, the failure of the graphical approach to produce curves that overlay suggests that detailed kinetic modeling studies must be carried out to determine the values of the rate constants in the system.

7.6. Other Reaction Mechanisms

Although the discussion in this section focuses on a simple reaction with two substrates (Scheme 6), a similar approach may be applied in constructing graphical rate equations for more complicated reactions.[37] The method allows the rapid assessment of whether the concentration dependences in a particular reaction system obey simple or complex forms. Indeed, in most cases a simple series of a half-dozen separate reaction-progress experiments are all that is required to assess concentration dependences of the two substrates and the catalyst, while assessing whether the reaction exhibits catalyst deactivation or product inhibition are also important features of the reaction.

7.7. Lessons Learned



These examples illustrate several important points about reaction progress kinetic analysis. 1) Access to powerful in situ experimental tools enables new experimental protocols to be devised to collect accurate and plentiful data sets to streamline the data collection portion of the task. Understanding how the data are going to be manipulated also contributes to optimizing our experimental design. 2) Kinetics may be used to deconvolute a reaction system and even to propose new mechanistic possibilities. 3) The straightforward experimental effort and data manipulation of reaction progress kinetic analysis allows kinetics to be used at the outset of a mechanistic investigation rather than simply to confirm a mechanistic proposal.

The relationships found from the data interrogation do not depend on the mechanism shown in Scheme 6. The trends observed can be used to indicate the direction of other potential schemes, thus carrying out kinetic studies as a first—instead of a last—resort is good advice for the study of any new reaction.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

8. A Flow Chart for Kinetic Analysis of Catalytic Reaction Systems

A summary of what has been demonstrated in the examples discussed above can be illustrated by making a flow chart for the kinetic analysis of a reaction with two substrates hypothesized to follow the reaction mechanism shown in Scheme 6. Even with no proposed reaction mechanism in mind, this simple system can be used as the starting point, and the steps described in Scheme 10 can act as a guide to tackling kinetic analysis of any new reaction system. The experiments listed in the flow chart follow those described in the examples in this Review.

Scheme 10. Flow chart for carrying out kinetic analysis of a reaction with two substrates. The green boxes indicate experiments to be carried out, black boxes indicate plots to be constructed, magenta boxes are query points for determining whether manipulation of the data results in overlay between curves from reactions carried out under different conditions.

The analysis begins with the choice of a set of reaction conditions for the first experiment, including initial concentrations of substrates **1** and **2**, and catalyst concentration, at a fixed temperature that will remain constant through the series of experiments. This experiment will serve as the "standard conditions", and the experiments that follow will involve alterations in one or more of these conditions. Next the reactions can be carried out at two catalyst concentrations that are different from the standard conditions, and the graphical rate equation is plotted as turnover frequency (TOF) versus [**1**]. This helps us ascertain the order in the catalyst concentration. If the reaction is not first order in the catalyst concentration, then the simple mechanism of Scheme 1 is an imperfect description of all of the activities of the catalyst.

Next, at least one further experiment is carried out with the same value of ["excess"] as our standard conditions but different values of starting concentrations of **1** and **2**. A plot of these data in the form of the graphical rate equation of rate versus [**1**] will show whether or not the curves overlay. If they do, then catalyst deactivation or product inhibition is not a feature of these reactions. If they don't, further experiments are carried out with product addition to distinguish product inhibition from catalyst deactivation.

In the next step further reactions are carried out at values of ["excess"] different from that of the standard conditions. With these data, various graphical rate equations described in Section 7 can be tried. The goal is to find out if the data overlay in any of the different forms of the graphical rate equation and helps in determining whether the reaction exhibits simple integer order, or if it exhibits saturation kinetics in one or both of the two substrates.

If none of these plots result in overlay between the different experiments, then it is known that either the catalyst does not exhibit a definitive resting state in the mechanism of Scheme 6, or that the reaction mechanism itself is more complex. In this case, other measures must be used, including detailed quantitative kinetic modeling of the mechanism and other proposed mechanisms.

9. Summary

This Review has endeavored to illustrate the ways in which accurate in situ reaction progress data coupled with simple data manipulations can help to illuminate aspects of catalytic behavior. Particular focus has been placed on a graphical approach involving simple manipulations that aims to keep the situation close to the "story" of the molecules on their reaction pathway, without straying too far into the mathematical wilderness of quantitative kinetics. Reaction profiles hold a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

wealth of mechanistic information that we are challenged to reveal; it is hoped that the ideas discussed here will inspire chemists to begin to demand more from the data that are now so easily obtainable through in situ techniques.

[4] The Michaelis Menten rate law was conceived first by Victor Henri (V. Henri, *C. R. Hebd. Seances Acad. Sci.* **1902**, *135*, 916). A linearized form of the Michaelis–Menten Equation was published by Hanes two years before the Lineweaver–Burk paper[1] (C. S. Hanes, *Biochem. J.* **1932**, *26*, 1406). The Lineweaver–Burk and other related graphical methods are covered in detail in enzyme kinetics textbooks. For an especially lucid discussion of both the history and the use of graphical methods in general and the opportunities and limitations of such methods, see A. Cornish-Bowden, *Enzyme Kinetics*, 3rd ed., Portland, London, **2004**.
[5] Extensive graphical methods have been developed, primarily for studying enzyme kinetics, for consideration of reaction complexities such as product inhibition by using a classical kinetic approach, which entailed a concomitant increase in the number of required experiments. The textbook cited in Ref. [4] provides an excellent background to these methods.
[6] Rate may be calculated from (concentration, time) data sets by fitting the data to an arbitrary function (e.g., a 9th order polynomial) and then differentiating this function to obtain (rate, time) data. Care must be taken to insure that the fit is accurate to obtain an accurate rate profile.

[13] The use of a corroborating technique also helps check the validity of the method when the question of complications other than side reactions arises. For example, the extent of contribution to the overall signal from physical processes such as heat of mixing or heat of precipitation may be quantified by using reaction calorimetry, while by using FTIR spectroscopy the possibility of an inhomogeneous solution layer adjacent to the IR window may be explored.

[18] The concentration of **2** is strictly given by: [**2**] = ["excess"] + [**1**] + [**5**]; however, [**5**] may be neglected under typical catalytic conditions where [**5**] $\ll$ [**1**] and [**5**] $\ll$ ["excess"]. This consideration helps to set a lower limit on ["excess"]. In general, practical values of ["excess"] should be at least an order of magnitude greater than the catalyst concentration.

[21] The graphical tools described here may only be used where the steady-state approximation applies. For many catalytic reactions this rules out data at the very start of the reaction if an induction period is present (see Section 7.1.1). By definition, the steady-state approximation breaks down for the last few turnovers of the reaction, where the concentration of the catalytic intermediate species approaches that of the substrates being consumed and the parameter ["excess"] is no longer constant (see discussion in Ref. [18]). These graphical tools are generally recommended for use on reaction progress data between 15 and 85% conversion of the limiting substrate.

[35] The left side of Equation (16) has the units of inverse time, and therefore it appears the turnover frequency should have no concentration dependence. A closer examination reveals that the units of TOF are: $\text{M(substrate)} \times \text{M(catalyst)}^{-1} \times \text{time}^{-1}$. While the units of molarity cancel these are, in reality, molarities of two different substances. The right hand side of Equation (16) shows clearly that TOF exhibits a concentration dependence.

Communications

Chiral thiophene–phenylene polymers have been prepared from achiral monomers by a Stille polycondensation reaction using a chiral nematic liquid crystal as solvent. The chirality of the polymers is thought to derive from the asymmetry produced by the chiral liquid-crystalline medium during polymerization. For more details, see the Communication by H. Goto and K. Akagi on the following pages.

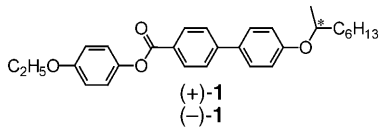
Chiral Polymerization

Optically Active Conjugated Polymers Prepared from Achiral Monomers by Polycondensation in a Chiral Nematic Solvent**



*Hiromasa Goto and Kazuo Akagi**

Asymmetric synthesis is one of the most intriguing research fields in chemistry. Methods for obtaining optically active compounds, such as enantioselective syntheses,[1] asymmetric autocatalytic reactions,[2] asymmetric autoinductions,[3] asymmetric transformations,[4] as well as absolute asymmetric reactions,[5] have been extensively studied. Many approaches to produce stable optically active polymers have also been proposed, such as the introduction of a bulky substituent to a vinyl polymer[6] or an optically active substituent to the polymer side chain,[7] and the induction of chiroptical properties.[8] The synthesis of chiral polymers in an isotropic organic solvent such as tetrahydrofuran (THF), benzene, or diethyl ether requires the use of a chiral monomer or a chiral catalyst.

Liquid crystals are unique in that they exhibit both crystal-like birefringence and fluid behavior. Chiral nematic liquid crystals (N*-LCs) have a quasi-layer structure in which the director of each layer is gradually rotated to produce helicity over several layers. Although liquid crystals exhibit fluid behavior, the crystal-like structural order of N*-LCs can effectively provide chiral order in the propagating step of a polymerization reaction, in contrast to chiral isotropic liquids. However, polymerization reactions performed in liquid-crystal media have received little attention as the liquid-crystalline phase is generally lost upon the addition of a non-liquid-crystal compound.

Helical polyacetylenes with chiroptical properties have been synthesized by using a N*-LC as the reaction medium.[9] The helical polyacetylene prepared in this way exhibited relatively stable chirality as a result of its insolubility and infusibility. In the case of chiral polybithiophene, which was prepared from achiral bithiophene by electrochemical polymerization in a N*-LC electrolyte, the polymer displayed a split Cotton effect in circular dichroism (CD) spectroscopy as well as optically active electrochromism.[10a] N*-LCs are thus considered to provide an effective chiral environment for the control of polycondensation reactions.[10] Herein, we report the use of a nematic liquid crystal as an asymmetric solvent for chiral polymerization and that successful polymerization is dependent on careful consideration of the affinity of the monomer for the N*-LC as well as its solubility therein. We selected a monomer that displays a good affinity for chiral nematic liquid crystals and prepared a stable N*-LC that is suitable for the polycondensation reaction of aromatic compounds and exhibits a chiral nematic phase at around 90 °C as the reaction solvent. The addition of the monomer and the production of the resulting polymer do not affect the liquid crystallinity of the N*-LC reaction medium in this system.

Chiral nematic liquid-crystalline compounds (+)-**1** and (−)-**1**, which comprise a three-ring core with optically active

(+)-**1**
(−)-**1**

terminal alkyl groups, were prepared as the chiral solvents for the polycondensation reactions. The chiral nematic liquid-crystal phase of these compounds is stable over a wide temperature range and remains stable upon the addition of aromatic compounds such as dibromobenzene and dibromothiophene. The phase-transition behavior of these compounds was determined by differential scanning calorimetry and polarizing optical microscopy (POM) as K 97 (72) N* 135 (133) BP (134) Iso* (K = crystal, N* = chiral nematic, BP = blue phase, Iso* = isotropic; parentheses denote the transition temperature in the cooling process). Both (+)-**1** and (−)-**1** exhibit a frustrated platelet texture of a blue phase and the oily streak texture of a chiral nematic liquid-crystal phase, as observed by POM (see Figure 1 a, b). Generally, high shear stress breaks the helical structure of the N*-LC to result in a nematic phase with no helical structure. However, chiral

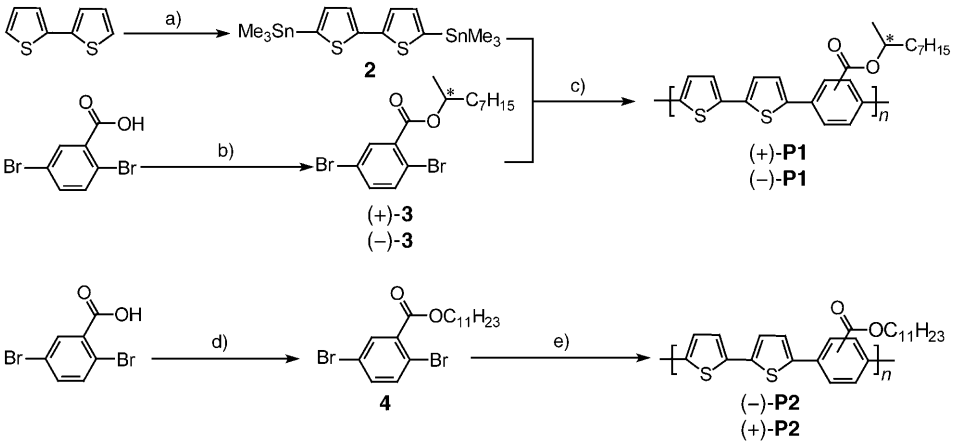
nematic liquid crystallinity was confirmed to be maintained under stirring at 80 rpm using a Teflon-coated 1-cm magnetic stirrer bar in a 1.7-cm-diameter Schlenk flask.

Two types of chiral polymer were synthesized in this study: 1) a polymer with chiral substituents prepared in an isotropic organic solvent (THF) and 2) a polymer with no chiral substituents prepared in a chiral nematic liquid crystal as solvent. The syntheses of the polymers through a C–C bond-forming Stille polycondensation reaction are shown in Scheme 1. Brominated chiral benzene derivatives **3** were treated with bis(trimethyltin)-substituted bithiophene derivative **2** in THF under an argon atmosphere in the presence of $[Pd(PPh_3)_4]$ as catalyst. After 24 h reaction, the mixture was washed with methanol and then acetone to afford the aromatic conjugated polymers with chiral substituents, (+)-**P1** (from **2** and (+)-**3**) and (−)-**P1** (from **2** and (−)-**3**).

Polymerization in the chiral nematic medium was performed by placing 1 g of **1** ((+)-**1** or (−)-**1**) in a small Schlenk flask under argon flow at 93 °C. Iridescence was confirmed due to the selective reflection of light, then **2** (0.1 g, 0.2 mmol) was added and dissolved in the medium. Achiral 2,5-dibromobenzoic acid undecyl ester (**4**; 87 mg, 0.2 mmol) was then added to the mixture and stirred at exactly 80 rpm for 30 min before the addition of a catalytic amount of $[Pd(PPh_3)_4]$ (3 mg, 0.0026 mmol) to initiate the polycondensation. Stirring was continued at 80 rpm to preserve the chiral nematic liquid crystallinity, and the temperature was maintained at exactly 93 °C during the course of the reaction. Chiral nematic liquid crystallinity was confirmed by monitoring the selective reflection of the mixture during the course of the reaction. Although the transition temperature of the chiral nematic liquid-crystalline phase may be depressed by the introduction of "impurities", namely the monomer, catalyst, or the resulting polymer, this mixture was confirmed to maintain its chiral nematic liquid-crystalline phase at 93 °C. After 24 h reaction, the visible selective reflection of the N*-LC in the reaction flask again confirmed that the chiral nematic liquid-crystalline phase was maintained in the mixture. The mixture in the Schlenk flask also gave rise to a fluorescent emission from the presence of a fluorescent polymeric product in the N*-LC solvent. Figure 1c shows the POM image of the reaction mixture at 93 °C. Polymer fractions of higher molecular weight which were insoluble in the N*-LC medium were observed as insoluble orange masses surrounded by the oily streak texture of the N*-LC.



The reaction mixture was allowed to cool to room temperature and then dissolved in a minimal amount of THF, then the solution was poured into a large volume of acetone to dissolve and completely remove **1** (N*-LC) and the fractions of low molecular weight. The product, which was insoluble in acetone, was further washed in acetone and then methanol to leave a red solid that was soluble in THF and $CHCl_3$. The polymers prepared in media (−)-**1** and (+)-**1** are abbreviated (+)-**P2** and (−)-**P2**, respectively. The directions of optical rotation of the polymers were the opposite of those of the N*-LC solvent used.

The results of both sets of polymerization reactions are summarized in Table 1. The number-average molecular weights of (+)-**P1** and (−)-**P1** are 3500 and 3200, respectively, while those of (+)-**P2** and (−)-**P2** are 7000 and 6100, respectively. The quantum efficiency (Φ) of both polymers in $CHCl_3$ was determined as 23 %.

Table 1: Results of polymerization experiments.

Polymer	Monomer	Solvent	Yield [%]	M_n[a]	M_w[b]	MWD[c]	DP[d]	Φ [%][e]

Figure 2 shows the UV/Vis absorption and CD spectra of solutions of the polymers in $CHCl_3$. Polymers (+)-**P1** and (−)-**P1** exhibit maxima (λ_{max}) at 418 nm in the UV/Vis spectrum and CD signals in the region that correspond to the

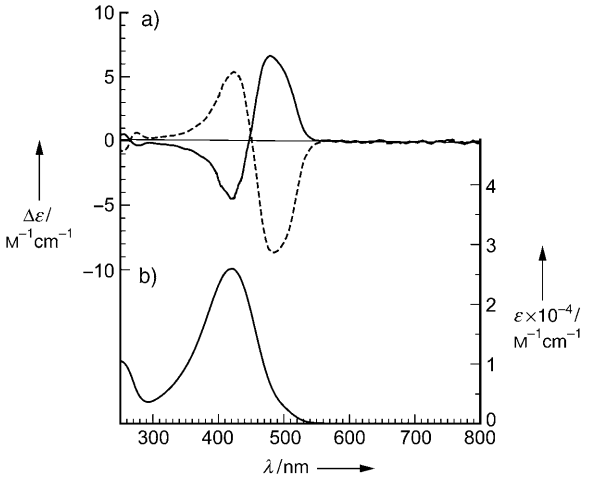

Figure 2. a) Circular dichroism and b) UV/Vis absorption spectra of (+)-**P1** (——) and (−)-**P1** (----) in $CHCl_3$.

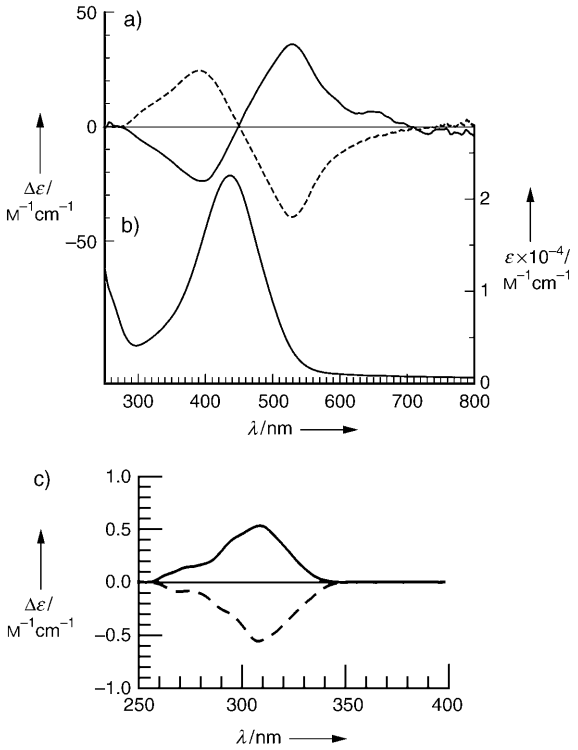

Figure 3. a) CD and b) UV/Vis spectra of (+)-**P2** (——) and (−)-**P2** (----) in $CHCl_3$. c) CD spectra of N*-LC solvents (+)-**1** (——) and (−)-**1** (----) measured as solutions in $CHCl_3$.

conjugated double bonds of the polymer main chain. They also display mirror-image, exciton-coupled, Davydov-split CD signals at two exciton levels. This splitting is not detected by absorption spectroscopy which indicates an interchain origin of the optical activity and suggests that the polymer has helical interchain organization. Such chiral aggregation of the polymer main chains bears a resemblance to the form of the N*-LC.[7b] Polymer (+)-**P1** displays a positive first and negative second Cotton effect, whereas (−)-**P1** exhibits a negative first and a positive second Cotton effect. This result indicates that the transition moments of (+)-**P1** and (−)-**P1** are clockwise and counterclockwise, respectively.[11] The polymers with chiral substituents have a stable optical activity which is attributable to a stabilization of the chiral structure of the polymer main chain by the ester groups.

Polymers (+)-**P2** and (−)-**P2**, which were prepared in the N*-LC solvent, display absorbance maxima at 436 nm that tail off toward 800 nm. The CD bands at 380 and 530 nm of solutions of the polymers in $CHCl_3$ are assigned to the bisignate exciton-coupled band associated with the absorption band at 436 nm, and a similar bisignate Cotton effect as seen for **P1** is observed (Figure 3). This result indicates that the transition moments of (+)-**P2** and (−)-**P2** are also oriented clockwise and counterclockwise, respectively. The CD spectrum of (−)-**P2** in THF has almost the same shape as that of (−)-**P2** in chloroform. The expected mirror-image relationship between (+)-**P2** and (−)-**P2** is not caused by the chiral compound that was employed as the solvent in this case because the Cotton effect of **1** is only observed at shorter wavelengths ((+)-**1**: CD ($CHCl_3$): λ_{max} ($\Delta\varepsilon$) = 308 nm (+0.53 $M^{-1}cm^{-1}$); (−)-**1**, CD ($CHCl_3$): λ_{max} ($\Delta\varepsilon$) = 308 nm (−0.55 $M^{-1}cm^{-1}$)).

The polymers **P2** prepared in the N*-LC medium have an optically active structure in isotropic solution. The chiral structure developed during polymerization was preserved even after dissolution and washing, probably as a result of the steric hindrance of the ester groups at the 2-position of the benzene rings which stabilizes the chiral structure of the polymer. To examine the origin of chirality of the polymer, a model compound of low molecular weight was prepared by a Stille reaction. 5-Trimethylstannyl-2,2′-bithiophene[12] and compound **4** were coupled in the same manner as in the preparation of (−)-**P2** to yield the bithiophene–phenylene–bithiophene compound **P3**. This model polymer exhibited no Cotton effect in the CD spectrum which implies that the axial chirality of **P3** was not produced by the N*-LC reaction medium. Thus, the optical activity of **P2** may be derived from chiral aggregation, not axial chirality. However, the optical activity of **P2** may alternatively be caused by a polymer effect such as small changes in one direction in the dihedral angle between repeat monomer units, which would also produce a Cotton effect. Also, high optical rotations in chloroform are obtained for (−)-**P2** ($[\alpha]_D^{20} = -910.1°$) and (+)-**P2** ($[\alpha]_D^{20} = 762.5°$) relative to the lower molecular weight polymers (−)-**P1** ($[\alpha]_D^{20} = -71.8°$) and (+)-**P1** ($[\alpha]_D^{20} = 88.4°$). This result suggests that the polymer effect is important in this system. Although the origin of the Cotton effect cannot be clarified completely on the basis of the results for **P3**, which exhibits neither polymer effects nor aggregation, the experimental results strongly imply that the chirality of **P2** derives from chiral aggregation rather than the helical structure of the main chain (axial chirality). However, in the helical aggregation state of the polymer, several hierarchical levels of chiral structure are plausible, including helical main-chain confor-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mations. In this case, the main chain plays a role of a virtual chiral axis.[7b]

Polymers (+)-**P1** and (−)-**P1** exhibit circularly polarized luminescence (CPL) at 500 nm in solution in chloroform, with g_{em} values of -1.1×10^{-3} and $+8.6\times10^{-4}$ at an excitation wavelength $\lambda_{ex}=380$ nm. The degree of circular polarization in the emission is defined by $g_{em}=(I_L-I_R)/[(I_L+I_R)/2]=\Delta I/I=V_{AC}/V_{DC}$, in which I denotes the intensity, subscripts L and R denote left and right, respectively, and V_{DC} and V_{AC} are the values of measured fluorescence and CPL, respectively. Polymers (+)-**P1** and (−)-**P1** display photoluminescence (PL) at 540 nm and CPL centered at 556 nm. Solutions in $CHCl_3$ of (+)-**P2** and (−)-**P2** prepared in the chiral nematic liquid-crystal medium display bisignate and opposite CPL signs ($\lambda_{ex}=380$ nm): $g_{em}=+3.17\times10^{-3}$ (at 620 nm) for (+)-**P2** and $g_{em}=-2.40\times10^{-3}$ (at 620 nm) for (−)-**P2**, as shown in Figure 4. Polymerization under vigorous stirring at 200 rpm

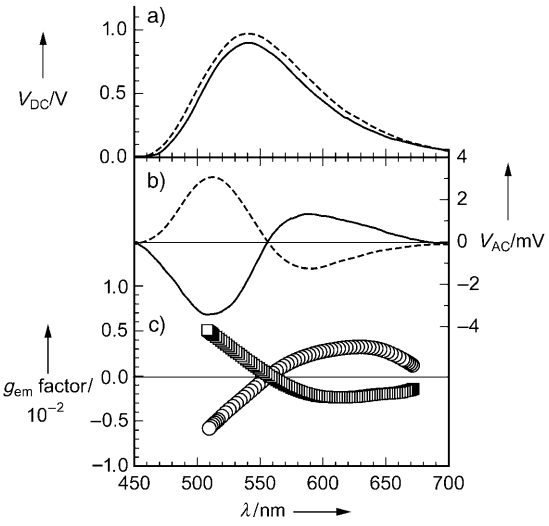

Figure 4. a) PL and b) CPL spectra, and c) g_{em} factors of (+)-**P2** (——, ○) and (−)-**P2** (-----, □) in $CHCl_3$.

produced polymers that exhibit no Cotton effect in CD measurements, which is attributable to the loss of the helical structure of the chiral nematic liquid-crystalline phase as a result of excessive shear stress and growth of the polymer in the nonhelical medium. Green et al. showed that chiral solvents such as (*R*)-2-chlorohexane can transfer chirality to the poly(*n*-hexylisocyanate) main chain of an otherwise achiral polymer.[13] In the present experiments, the chiral structure of the polymer could not be produced when the reaction solvent was in an isotropic or nonhelical state. This is probably a result of the fact that the chirality-inducing property of solvent **1** in the nonhelical state is insufficient to induce chiral aggregation of **P2**, whereas the solvent in a chiral nematic liquid-crystalline mesophase with helical architecture effectively affords a polymer with chiral structure during the polymerization process.

Heating of the chiral compounds should result in racemization as a result of the random rotation of polymer main chains and a loss of chiral aggregation. To examine this process, (−)-**P1** and (−)-**P2** were heated in cumene, a solvent of high boiling point. Optical spectra were recorded after the samples had been heated once to 150 °C and then allowed to cool to 25 °C. Heat treatment of (−)-**P1** at 150 °C for 15 min under an argon atmosphere resulted in a weakening, but not complete disappearance, of the Cotton effect. On the other hand, the intensities of the absorption bands of the polymer increased with heating, accompanied by a shift of the maxima to longer wavelengths and an increase in ε values. Figure 5

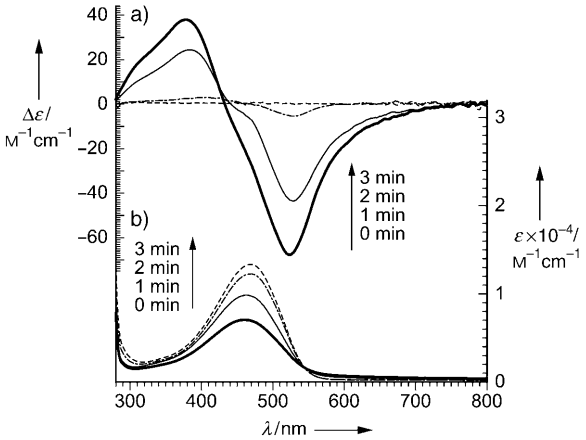

Figure 5. a) CD spectra and b) UV/Vis absorption spectra of (−)-**P2** after heating in cumene for 0, 1, 2, and 3 minutes at 150 °C. These spectra were recorded at 25 °C.

shows the UV/Vis and CD spectra of (−)-**P2** in cumene under an argon atmosphere before and after heat treatment. Heating the sample at 150 °C for 3 min can be seen to cause a shift of the absorption maxima from $\lambda=458$ to 469 nm and an increase in ε (but decrease in $\Delta\varepsilon$), along with a shift of the CD peaks to longer wavelengths. The heated sample of (−)-**P2** no longer displayed a Cotton effect, although the UV/Vis absorption intensities increased. This result is thought to reflect deaggregation of the polymer, free rotation of the main chain, and a decrease in the average dihedral angle in the main chain during heating. Random rotation of the monomer repeat unit along the polymer main chain as a result of heating is considered to improve the average coplanarity of the polymer measured at 25 °C and increase the effective conjugation length, which leads to an increase in the absorption intensity and a red shift of the absorption peaks. The change in the CD intensities of the annealed polymer in cumene is irreversible.

Figure 6 shows the PL and CPL spectra and g_{em} factors for (−)-**P2** before and after heating, with the spectra for (−)-**P2** in $CHCl_3$ shown for reference (thick line). The minima and maxima in the PL spectrum of the polymer in solution in cumene occured at longer wavelengths than in solution in $CHCl_3$, and heating reduced the intensity of the CPL. The emission peaks (minima/maxima) in the CPL spectrum also shifted slightly to longer wavelengths upon heat treatment. The g_{em} factors of (−)-**P2** also decreased upon heating. Heat treatment of (−)-**P2** at 150 °C for 3 min resulted in the loss of the CPL signal, although the polymer exhibited photoluminescence. This CPL result is suggestive of deaggregation of

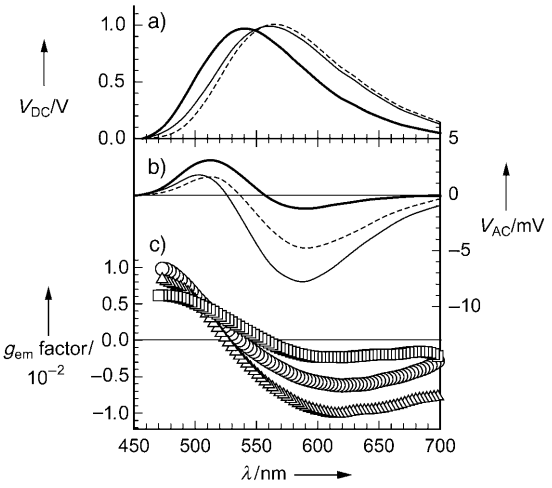

Figure 6. a) PL and b) CPL spectra, and c) g_{em} values of (−)-**P2** in $CHCl_3$ (unheated; bold line, □), in cumene (before heating; ——, △), and in cumene after heating at 150 °C for 1 min (-----, ○). These spectra were obtained at 25 °C.

the polymer and swelling in the solvent upon heating. The chirality of the polymers (+)-**P2** and (−)-**P2**, which contain no chiral substituents, is thus considered to derive from the asymmetry produced by the chiral liquid-crystal medium during polymerization. No chiral molecules reacted with the monomer during the polymerization process, and the N*-LC employed as a solvent functioned only as the reaction medium. In general, the synthesis of chiral polymers requires the introduction of a chiral substituent or the use of a chiral catalyst. The present N*-LC medium thus provides a molecular matrix with central chirality for polymerization, and growth of the polymer in this three-dimensional chiral medium results in the chiral aggregation. The chiral nematic liquid-crystal phase has a chiral helical superstructure with a long helical pitch (> 400 nm), and the small twist angle between quasi-layers of the liquid crystal at the molecular level produces a strong Cotton effect in the CD and CPL spectra of the resultant polymers. The polymerization mechanism has an affinity with the so-called "sergeant-and-soldier" system,[14] as the small asymmetric environment within the quasi-layers of the N*-LC gives consistent optical activity in the resultant polymers. In other words, the "asymmetric field effect" induces the chirality of the polymer aggregation.

In summary, a reaction medium comprised of a chiral nematic liquid crystal leads to chiral aggregation of the conjugated polymer product (as observed by CPL) during the polymerization process, and the aggregation is maintained after visual dissolution of the polymer in chloroform or THF. As enzymes (proteins) form specific stereostructures in which the spacing of the folded protein main chains produce a spatially asymmetric reaction field, the approach proposed in this study may provide a model for biological reactions such as the synthesis of biomolecules in asymmetric environments in living organisms. The results of this study also demonstrate the utility of the chemistry of reaction media.

Experimental Section

All experiments were performed under an argon atmosphere using Schlenk/vacuum line techniques. Tetrahydrofuran (THF), ethanol, acetone, and ether were distilled prior to use. High purity chloroform (Wako) was used without purification for optical measurements of the polymers. ^{1}H NMR spectra were measured in $CDCl_3$ using a Bruker AV-600 FT-NMR spectrometer. Chemical shifts are represented in parts per million downfield from tetramethylsilane (TMS) as an internal standard. Infrared spectra were measured with a JASCO FT-IR 550 spectrometer as KBr disks. Optical absorption spectra were measured in quartz cells at room temperature using a HITACHI U-2000 spectrometer. CD spectra were obtained with a JASCO J-720 spectrometer. PL and CPL measurements of the polymers were performed with a JASCO CPL 200S spectrometer. Phase-transition temperatures were determined using a TA Instrument Q-100 differential scanning calorimeter with a constant heating/cooling rate of 10 °C min^{-1}, and texture observations were made using a Nikon ECLIPS E400 POL polarizing microscope equipped with a Linkam TM 600PM heating/cooling stage. Temperature calibration of the heating stage was carried out by using DSC. The molecular weights of polymers were determined by gel permeation chromatography on a Shodex A-80 M column with a JASCO HPLC 870 UV detector using THF, with the instrument calibrated with a polystyrene standard.

Iron Oxide Nanotubes

Single-Crystalline Iron Oxide Nanotubes**

Chun-Jiang Jia, Ling-Dong Sun, Zheng-Guang Yan, Li-Ping You, Feng Luo, Xiao-Dong Han, Yu-Cheng Pang, Ze Zhang, and Chun-Hua Yan**

In recent years considerable attention has been focused on one-dimensional nanostructured materials owing to their unique physical properties and potential applications in sensors, magnetics, electric transportation, optics, and even as building blocks for nanoscale devices.[1] In particular, much effort has been devoted to the controllable synthesis of inorganic nanotubes since the discovery of carbon nanotubes in 1991.[2] The synthesis of a number of tubular materials from two-dimensional layered precursors at elevated temperatures, based on a "rolling-up" mechanism, has been reported,[3] such as BN, V_2O_5, WS_2, and $NiCl_2$. With the development of soft-chemistry synthetic methods, a low-temperature solution approach provides a facile method to produce nanotubes of lamellar compounds,[4] for example InS, Bi, and $Cu(OH)_2$. Nanotubes made from other materials,[5] such as Si, ZnS, Eu_2O_3, and GaN, which do not possess 2D layered structures, have also been prepared by employing various templates. However, except for a few examples,[5a,d] the template-assisted method has proved to be unsuitable for the formation of single-crystalline nanotubes. A mild solution strategy has been used[6] to obtain single-crystalline hexagonal prismatic Te nanotubes, but it is difficult to extend this method to the formation of other three-dimensional materials. It is therefore still a challenge to extend the fabrication of single-crystalline tubular nanostructures from lamellar to 3D materials.

Hematite (α-Fe_2O_3), the most stable iron oxide under ambient conditions, is widely used in catalysts,[7] pigments,[8] sensors,[9] and as the raw material for the synthesis of

maghemite (γ-Fe_2O_3), which is of great importance as a ferro fluid and in magnetic recording materials. Because of its excellent properties, much attention has been directed to the controlled synthesis of hematite particles. For example, Matijevic and co-workers[10] have prepared monodispersed hematite particles by forced hydrolysis of ferric ions in solution, and Kallay et al.[11] and Sugimoto et al.[12] have synthesized hematite particles with controllable shape and size by a sol–gel method. Recently, much research has been focused on the synthesis of 1D nanostructures, including nanorods,[13] nanowires,[14] nanobelts[15] of hematite, and nanotubes of magnetite,[16] owing to their potential applications in various fields. Herein, we report a rational synthesis of single-crystalline hematite nanotubes by a convenient hydrothermal method, and demonstrate a feasible, large-scale, and controllable synthesis of single-crystalline Fe_2O_3 nanostructures. A mechanism for the formation of tubular-structured hematite is proposed in accordance with the morphology investigations carried out by electron microscopy. Different from the mechanism of formation of other inorganic nanotubes reported previously, these hematite nanotubes are formed by a coordination-assisted dissolution process. The presence of phosphate ions is the crucial factor that induces the formation of a tubular structure, which results from the selective adsorption of phosphate ions on the surfaces of hematite particles and their ability to coordinate with ferric ions. Single-crystalline maghemite nanotubes are also obtained by a reduction and re-oxidation process with hematite nanotubes as precursors. This approach not only enriches iron oxide chemistry, but also provides a new strategy to synthesize single-crystalline nanotubes of non-lamellar-structured materials, which could be applicable to the synthesis of other inorganic tubular nanostructures.

The hematite products were synthesized by a solution-phase approach. In a typical experimental procedure, the nanotubes were obtained by the hydrothermal treatment of an $FeCl_3$ solution (0.02 M) in the presence of $NH_4H_2PO_4$ (7.2×10^{-4} M) at 220 °C for 48 h. The morphology of the typical hematite nanotubes obtained was studied by electron microscopy. Figure 1a shows an SEM image of the as-synthesized hematite nanotubes, with a magnified image shown in the inset. The product consists almost entirely of nanotubes with outer diameters of 90–110 nm, inner diameters of 40–80 nm, and lengths of 250–400 nm. Some of the nanotubes have one end open with the other end closed. The phase purity of the products was examined by X-ray diffraction (Figure 1b). All the peaks can be well-indexed to a pure corundum structure (space group $R\bar{3}c$) of hematite (JCPDS: 33-0664).

To provide further insight into the nanostructures of the tubes, analytical TEM investigations were also performed. Figure 2a shows an STEM image of a single hematite tube collected with a high angle annular dark field detector (HAADF) attached to a TEM. The sidewalls of the hematite nanotubes in the STEM images appear brighter as a result of the relatively large number of atoms relative to the other parts of the nanotubes. The compositional line profiles (Figure 2b) probed by energy-dispersive X-ray spectroscopy (EDS) exhibit well-correlated iron and oxygen signals across the tube walls (the arrow in Figure 2a). Figure 2c shows a typical HRTEM image of a single hematite nanotube, and the inset of this figure shows the low-resolution TEM image. The clear lattice image indicates the high crystallinity and single-crystalline nature of the hematite nanotubes. A lattice spacing of 0.460 nm for the (003) planes of the rhombohedral hematite structure along the nanotube can be readily

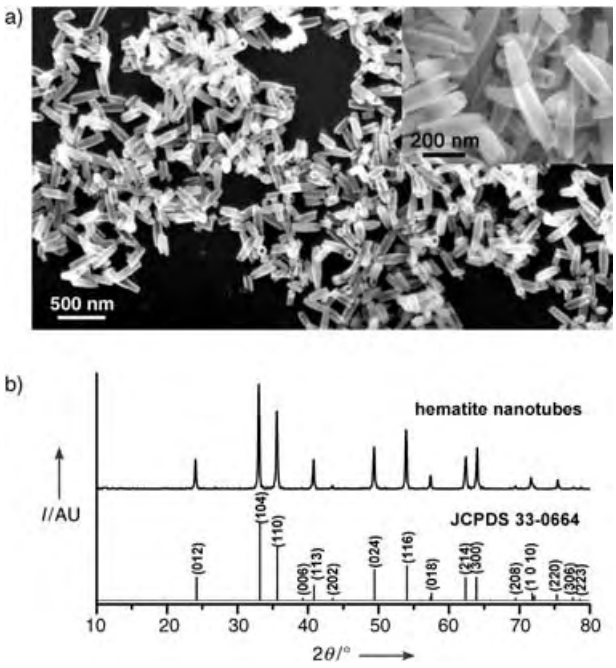

Figure 1. a) Hematite nanotubes imaged with SEM (inset: magnified view) and b) XRD pattern of the hematite nanotubes.

resolved. The selective-area electron diffraction (SAED) (Figure 2d) and HRTEM analyses reveal that the nanotubes grow along [001] (*c* axis). The (003) reflection shown in Figure 2d is often forbidden in the corundum structure of hematite, as shown in the XRD patterns (see Figure 1b). We suppose that the observation of the (003) reflection by ED is the result of a double-diffraction effect due to the strong electron scattering.[17]

For a complete view of the formation process of the hematite nanotubes and their growth mechanism, a detailed time-dependent morphology evolution study was conducted at 220 °C (Figure 3a–d). The product obtained after 2 h

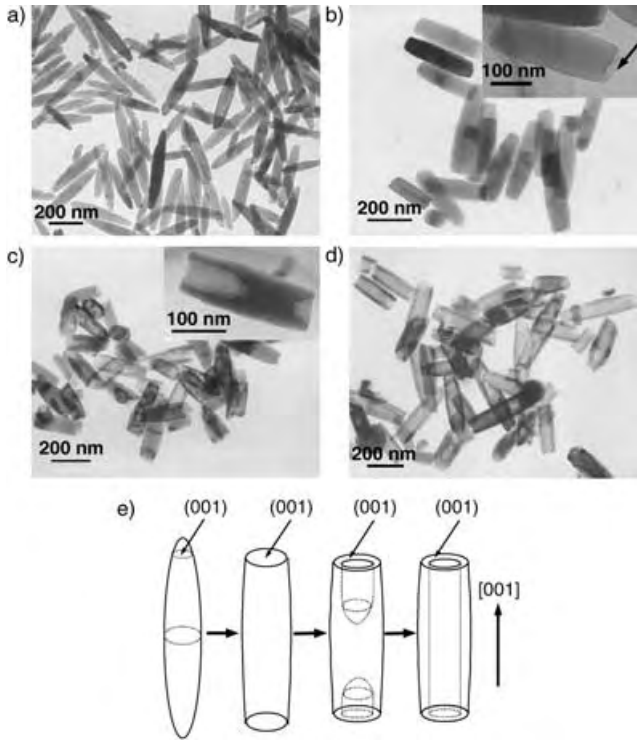

Figure 3. Morphology evolution of the hematite nanotubes with reaction time: TEM images of the products obtained at 220 °C after a) 2 h, b) 8 h, c) 12 h, and d) 48 h; e) schematic illustration of the tube-formation process.

contains spindlelike particles with a diameter of 60–70 nm and a length of 350–450 nm, as has been extensively observed in forced hydrolysis processes.[10,18] Prolonging the reaction time to 8 h gave nanorods with a diameter of about 100 nm and a length of 250–400 nm. The tips of these rods are concave, as can be observed in the inset of Figure 3b. A mixture of rodlike, tubular, and semitubular (inset of Figure 3c) nanostructures was formed after longer reaction times (12 h, Figure 3c). For reaction times of 48 h (Figure 3d), the product consists predominantly of nanotubes that are completely hollow. XRD analysis confirmed the hematite phase of all the above products. HRTEM and SAED analysis of the hematite nanorods and tubes formed at different stages (see Supporting Information) showed that they all grow along the [001] direction, which is consistent with the preferential growth direction of the spindles.

Based on the above time-dependent morphology evolution evidence, the formation process of the nanotubes can be proposed as occurring by "dissolution" of the spindlelike precursors from the tips toward the interior along the long axis, via rodlike nanocrystals and semi-nanotubes, until hollow tubes are formed (Figure 3e). The driving force is the high activity of the sharp spindle tips, which are easily attacked by the protons in acidic solution (pH 1.8). Notably, only part of the interior is dissolved during the formation of hematite nanotubes, and the dissolution is not uniform from spindle to spindle and even for a single spindle (see Figure 3b,c). Furthermore, the diameter of the final nanotubes is larger and the surface is smoother than those of the spindlelike precursors, which indicates that recrystallization on the surface also accompanies the "dissolution" process. This process is similar to that occurring in ZnO, which "etches" from the center of the hexagonal disks to form hexagonal rings.[19]

Although the formation process of the nanotubes has been deduced, the intrinsic cause of the shape transformation from spindle to tube is still unclear. The growth control of hematite nanocrystals by the adsorption of phosphate ions has been extensively studied.[10,18] Our investigations show that phosphate adsorption on the hematite surface takes place, and that these adsorbed phosphate ions cannot be removed by washing (Supporting Information).[20] The adsorption behavior of anions on oxides and hydroxides depends on the surface properties, particularly the surface hydroxy group configuration.[21] The adsorption of phosphate on hematite occurs by reaction with the singly coordinated surface hydroxy groups to form a monodentate or bidentate inner-sphere complex.[22] A hematite crystal has a rhombohedrally centered hexagonal structure of the corundum type with a close-packed lattice in which two thirds of the octahedral sites are occupied by Fe^{3+} ions (see Figure 4a). In a typical crystal unit, each Fe atom is surrounded by six O atoms, whereas each O atom is bound to four Fe atoms. Due to these characteristics of the corundum structure, the surface hydroxy group configuration of the various crystal faces of hematite is quite different.[21] For (001) planes (see Figure 4b), the surface hydroxy functions are all doubly coordinated, whereas for other planes that commonly occur at the surface of natural and artificial hematite crystals, such as the (100), (110), (012), and (104) planes, singly coordinated surface hydroxy groups are present. Therefore, the adsorption capacities and affinities for phosphate to hematite are much lower for the (001) planes than for the others,[22a] and the adsorbed phosphate will protect them from further reaction. Although previous studies[23] have shown that dissolution of hematite does not appear to take place preferentially at specific crystal faces, the selective adsorption of phosphate ions on the crystal planes parallel to the *c* axis other than (001) favors the dissolution along the *c* axis and causes the hematite tube to grow in the [001] direction.

Besides the selective adsorption of phosphate ions at different faces, the coordination effect of phosphate ions with Fe^{3+} ions is another important aspect in the formation of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

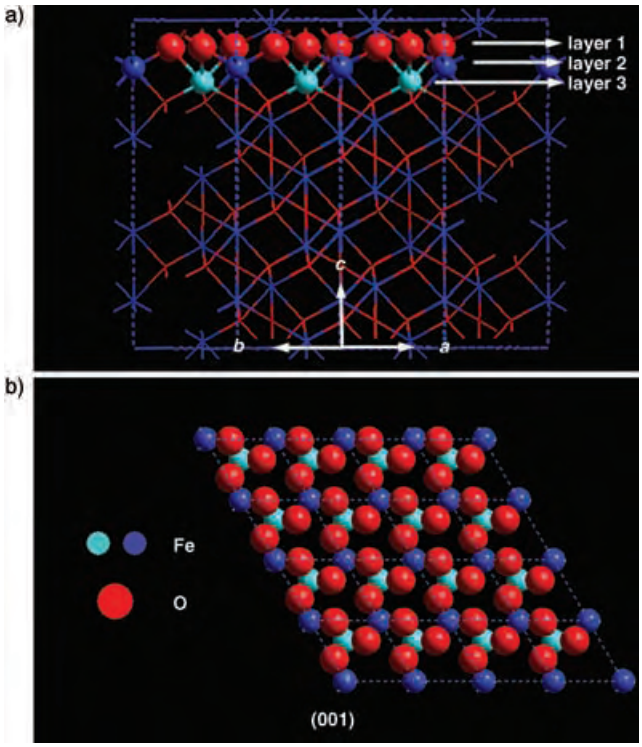

Figure 4. Schematic structures of hematite: a) crystal structure projection on the (110) plane: the repeating elemental sequence is $(O,Fe,Fe)_n$ along the *c* axis; b) crystal structure projection on the O-terminated (001) plane, in which O atoms are all doubly coordinated by Fe atoms. Compared with other planes, the adsorption capacities and affinities for phosphate are much lower for (001) owing to the absence of singly coordinated hydroxy groups.

nanotubes. As for the "dissolution" of the hematite particles, the following reactions take place:

$$Fe_2O_3 + 6\,H^+ \rightarrow 2\,Fe^{3+} + 3\,H_2O \quad (1)$$

$$Fe^{3+} + x\,H_2PO_4^- \rightarrow [Fe(H_2PO_4)_x]^{3-x} \quad (2)$$

The formation of $[Fe(H_2PO_4)_x]^{3-x}$ [Eq. (2)] forces Equation (1) toward the right-hand side and speeds up the dissolution of the hematite particles. Based on the two roles played by phosphate ions during the reaction, we have proposed a coordination-assisted dissolution process for the hematite tube formation during hydrothermal treatment of the spindle precursors in the presence of phosphate ions (see Figure 3e).

Experiments to determine the parameters, other than the reaction time, that are also important for the formation of the nanotubes were carried out. For example, their formation at temperatures lower than 220 °C is not favored as spindle nanocrystals dominate at 180 °C and only a few nanotubes form at 200 °C (Supporting Information). The phosphate ions are essential for the formation of spindlelike hematite, which is the precursor for the formation of the tubular structure. Furthermore, the concentration of phosphate ions should be maintained for the coordination-assisted dissolution process to proceed. If the concentration of phosphate ions is lower than 6.5×10^{-4} M, nanorods or only a few nanotubes are obtained instead of large amounts of nanotubes. On the other hand, a relatively large phosphate ion concentration ($> 1.0 \times 10^{-3}$ M) destroys the tubes. Under basic conditions only solid particles are obtained, and the mediation effect of phosphate ions is weak. Moreover, tubular structures are not formed due to the lack of spindle precursors, and the high pH value does not favor the dissolution. Other ions that coordinate to Fe^{3+}, like SO_4^{2-}, also lead to the "dissolution" of the spindle precursors and formation of the final tubular product. Studies on the formation of other kinds of hematite nanostructures, based on this dissolution process, are still in progress.

Maghemite, and especially its nanostructures,[24] are scientifically interesting and technologically important as a type of magnetic material. We were able to obtain maghemite nanotubes by a reduction and re-oxidation process starting with the hematite nanotubes as precursors. Figure 5a shows an SEM image of the maghemite nanotubes obtained. Compared with the corresponding hematite precursors, the size, tubular structure, and the single-crystal nature are perfectly maintained for maghemite. The XRD patterns of the maghemite nanotubes are shown in Figure 5b; all of them can be well indexed to a pure spinel structure of maghemite

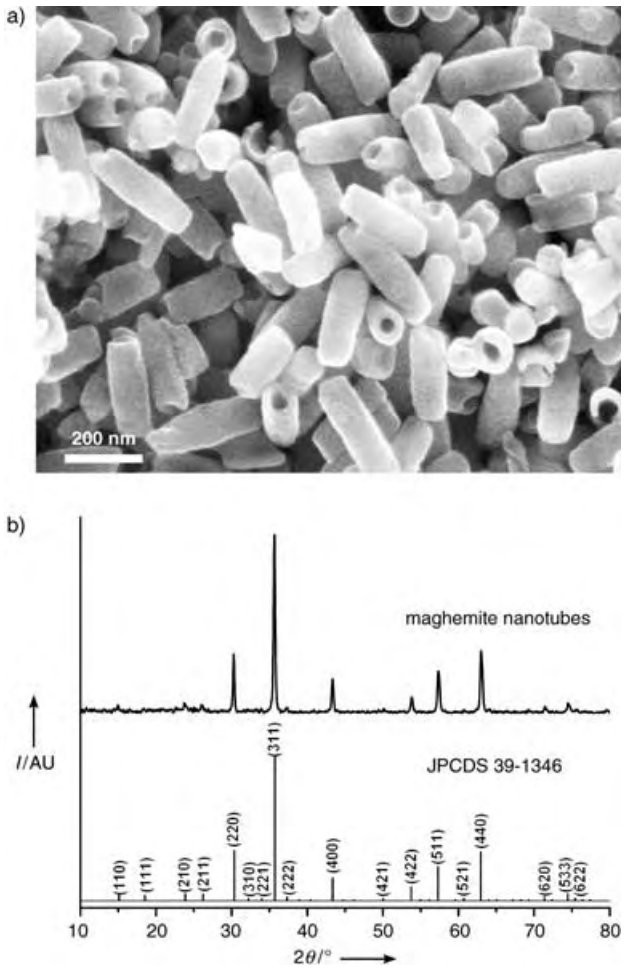

Figure 5. a) SEM image and b) XRD pattern of the maghemite nanotubes.

(JCPDS: 39-1346). The sharp peaks confirm the high crystallinity of the products. A study of the magnetic properties of these maghemite nanotubes is still in progress. Both the hematite and maghemite nanotubes provide novel structures for magnetism studies and also have potential applications for the design of novel complex structures[25] and as carriers in biomagnetic sensors, nanomedicine, and catalysis.

In summary, single-crystalline hematite nanotubes have been fabricated by a facile, one-step hydrothermal method. Various experimental conditions, including temperature, additives, pH value, and reaction time for the growth of hematite nanocrystals were investigated. Based on the evidence of electron microscope images, the formation mechanism of tubular-structured hematite has been proposed as a coordination-assisted dissolution process. The presence of phosphate ions in this process is crucial because of their different adsorption ability on the different crystal planes of hematite and a coordination effect with Fe^{3+}, which induces the preferential dissolution of the hematite spindle precursors along the long axis from the tips down to the interior. Maghemite nanotubes have also been obtained in a reduction and re-oxidation processes of these hematite precursors. These results not only enrich the tubular nanostructures of inorganic compounds, but also provide a new strategy to synthesize single-crystalline nanotubes of nonlamellar-structured materials, which could be applicable to the synthesis of other inorganic tubular nanostructures.

Experimental Section

The hematite nanotubes were fabricated by hydrothermal treatment of a mixture of $FeCl_3$ and $NH_4H_2PO_4$ solutions. In a typical experimental procedure, 3.20 mL of aqueous $FeCl_3$ solution (0.5 M) and 2.88 mL of aqueous $NH_4H_2PO_4$ solution (0.02 M) were mixed with vigorous stirring. Distilled water was then added to a final volume of 80 mL. After stirring for ten minutes, the mixture was transferred into a Teflon-lined stainless-steel autoclave with a capacity of 100 mL for hydrothermal treatment at 220 °C for 48 h. After the autoclave had cooled down to room temperature naturally, the precipitate was separated by centrifugation, washed with distilled water and absolute ethanol, and dried under vacuum at 80 °C. The parameters that are essential for the tube formation were studied by varying temperature, concentration of $NH_4H_2PO_4$, pH value, and the reaction time.

Maghemite nanotubes were obtained by a reduction and re-oxidation of the hematite nanotube precursors. The dried hematite powders were annealed in a furnace at 360 °C under a continuous hydrogen gas flow for 5 h. Then, the gas flow was stopped, the powder exposed to air, and the furnace temperature decreased to 240 °C over 2 h.

The powder XRD patterns were recorded with a Rigaku D/MAX-2000 diffractometer using Cu K_α radiation ($\lambda = 1.5418$ Å). SEM images were obtained with a DB-235 focused ion beam (FIB) system. TEM images were recorded with a JEOL 200CX transmission electron microscope at a working voltage of 160 kV. HRTEM, EDS, and STEM were performed with a Philips Tecnai F30 FEG-TEM operating at 300 kV. IR spectra were obtained with a Nicolet Magna 750 FTIR spectrometer at a resolution of 4 cm^{-1} with a Nic-Plan IR microscope.

Protein Nanoarrays

Aptamer-Directed Self-Assembly of Protein Arrays on a DNA Nanostructure**

*Yan Liu, Chenxiang Lin, Hanying Li, and Hao Yan**

DNA-based self-assembly[1] represents a versatile system for nanoscale construction due largely to the well-characterized conformation of DNA and its predictability in the formation of base pairs. The methodology of DNA self-assembly begins with the chemical synthesis of single-stranded DNA molecules that self-assemble into branched DNA motifs, known as tiles. DNA tiles can carry sticky ends that are complementary to the sticky ends of other DNA tiles; this facilitates continued assembly of the tiles into DNA lattices. Substantial progress has been made in recent years with DNA nanostructures in the construction of patterned arrays.[2–13] One promising application of DNA-based self-assembly is the use of self-assembled DNA nanostructures to direct the assembly of other macromolecular components such as proteins. DNA-templated protein arrays with predictable control at the nanometer scale could lead to single-molecule detection in proteomics studies. Individual proteins placed at unique locations on the nanoarray could be detected with single-molecule imaging techniques such as recognition imaging, in which specific antibodies are attached to the scanning probe cantilever.[14] Niemeyer has also pointed out another interesting application of precisely controlled protein assemblies in the construction of spatially well-defined multienzyme constructs.[15]

The noncovalent streptavidin–biotin interaction has been the most-explored method in the creation of streptavidin molecule networks through the modification of DNA oligonucleotides with biotin.[6,16–19] However, this method is limited in that only one type of protein–ligand interaction is present. Although other proteins can be fused with streptavidin by protein engineering, it is a tedious process, and the function of the proteins and the biotin-binding capacity of streptavidin may both be affected by the fusion. The covalent linkage of proteins to nucleic acids often relies on the use of heterobispecific cross-linkers,[20] and involves multistep chemical coupling and purification steps. Another method to covalently link proteins to oligonucleotides uses recombinant protein engineering to incorporate a cysteine residue into the protein to allow subsequent coupling to thiolated oligonucleotides by disulfide linkages.[21–23] Although attachment through covalent bonds would be ideal, the process for this has not yet been automated. To realize the potential of self-assembled DNA templates in the construction of protein nanoarrays, there is an immediate need to develop programmable methods in which DNA nanostructures are used to direct the assembly of any protein of interest.

Aptamers are DNA or RNA molecules that can be selected from random pools based on their ability to bind other molecules. Aptamers have been selected to bind other nucleic acids, proteins, small organic compounds, and even entire organisms.[24–27] Aptamers that exhibit sub-nanomolar affinities for a wide range of protein targets have been identified.[27,28] It is possible to generate a virtually unlimited number of specific ligand–aptamer pairs, so that each class of spatially displayed aptamer will interact with high affinity to its specific ligand. Cox and Ellington have reported the identification of new aptamer sequences through an automated systematic evolution of ligands by exponential enrichment (SELEX) process.[25]

Herein, we demonstrate the first use of selective DNA aptamer binding as a robust platform to link proteins to periodic sites of a self-assembled DNA array. The system employs three components: 1) a rationally designed DNA nanostructure that self-assembles into highly ordered spatial lattices by virtue of specific annealing of complementary sticky ends; 2) a DNA-docking site containing an aptamer sequence which tethers the protein of interest to the DNA lattice; and 3) the protein to be displayed on a self-assembled DNA lattice.

The DNA aptamer-directed self-assembled protein nanoarray possesses the following advantageous features: 1) the DNA tiling self-assembly is programmable: a rich set of DNA tiles and lattices with various geometries and patterns can be generated by altering the tiling design and sticky-end associations;[2–13] 2) the DNA tiles and aptamers are compatible with each other, as they are both composed of oligonucleotides; 3) new protein-binding aptamers can be generated with automated processes; 4) DNA nanostructure-displayed aptamers are not just limited to proteins, but can be extended to bind other ligand types.

To demonstrate this system, we chose the thrombin-binding aptamer (TBA). TBA is a well-characterized 15-base DNA aptamer with a consensus sequence of d(GGTTGGTGTGGTTGG) that folds into a unimolecular guanine quadruplex and binds thrombin with nanomolar affinity.[29] Thrombin is a multifunctional serine protease that

recognizes multiple macromolecular substrates and plays a key role in both coagulation and anticoagulation.

Figure 1 illustrates the use of a triple-crossover (TX) DNA tile as the template to direct the assembly of an aptamer and its subsequent organization of proteins into 1D periodic arrays. The TX tile shown is similar to another developed previously,[3,19] except that it has two DNA hairpin loops: one protrudes outward in the plane of the tile and contains the

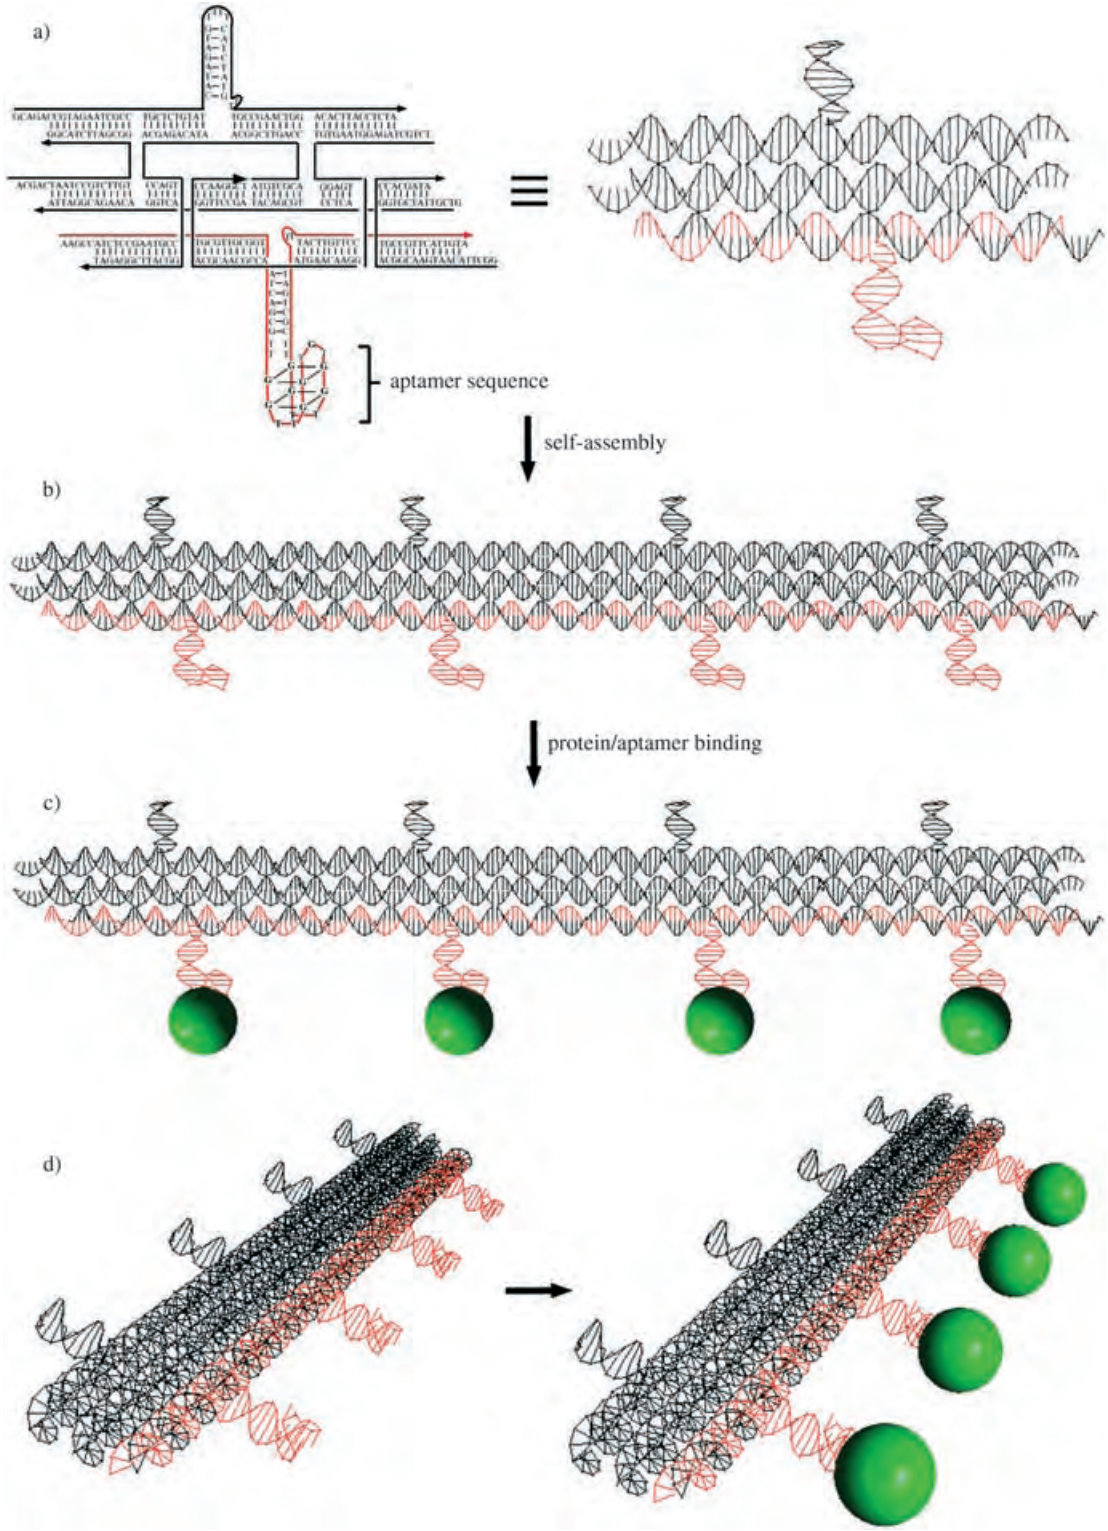

Figure 1. Aptamer-directed self-assembly of thrombin protein on a triple crossover DNA tile: a) DNA strand structure and sequence used for the self-assembly, the red strand contains the thrombin-binding aptamer sequence, which is illustrated as a G-quadruplex structure; b) the TX tiles self-assemble into linear DNA nanoarrays, in which the spacing between adjacent aptamer loops corresponds to five helical DNA turns: ≈17 nm; c) binding of thrombin (green spheres) to aptamers on the linear array leads to linear protein arrays; d) 3D rendering of the aptamer-directed self-assembly of the protein array.

aptamer sequence (in red) at the end of the stem, the other loop serves as a control; it also protrudes out of the TX tile, but does not contain the aptamer sequence. The length of the stem is arbitrary and can be adjusted as needed to place the target binding molecules in the desired positions and rotational orientations. In general, aptamers can be extended from the tile lattice regardless of their specific secondary structures. Furthermore, the DNA lattice may contain an arbitrary number of different tiles if necessary, so that the aptamers that bind proteins can be placed at every tile, every other tile, every third tile, and so on. Notably, various protein-binding tiles within the lattice may potentially be engineered to display different proteins at defined positions and orientations by virtue of the different possible combinations of aptamers and target ligands. Together, the DNA nanostructure and aptamers constitute a versatile and novel platform for the nanoarchitecture of proteins and synthetic molecules.

The dimensions of the three components used in this study are summarized below. The TX tile is approximately $6 \times 17 \times 2$ nm^3 as illustrated in Figure 1 a. The DNA aptamer stem loop is approximately 2 nm in helical diameter. A stem of 9 bp ($l \approx 3$ nm) was included to allow enough space for the thrombin to bind the aptamer. Thrombin has a molecular weight of ≈ 37 kDa, and a spherical diameter of about 3 nm.[30] Other larger target macromolecules could also be accommodated onto the lattice by varying the dimension of the tiles and the length of the stems. The TX tile self-assembles in $1 \times$ TAE/Mg^{2+} buffer (Experimental Section) into a linear array of TBA units with a periodic distance of ≈ 17 nm between two adjacent aptamers (Figure 1 b). The self-assembly of the DNA linear array is then followed by the addition of thrombin protein to the solution. Binding of thrombin to its aptamer results in a periodic linear array of thrombin molecules, illustrated by the green spheres in Figure 1 c. Figure 1 d gives a 3D view of the aptamer-directed self-assembly of thrombin protein on the 1D TX array.

Both AFM and gel electrophoresis experiments were used to demonstrate aptamer-directed self-assembly. Following formation of the 1D TX array and subsequent binding of thrombin, the preparations were examined by AFM. Figure 2 a shows an AFM height profile of the linear TX arrays before the addition of thrombin protein. Figures 2 b–d show the protein nanoarrays that result from the binding of thrombin to the periodic aptamer sites on the linear TX array. With its diameter of ≈ 3 nm, thrombin binding to the aptamer sequences generates topographical features on the mica surface that are higher than those of bare TX arrays; these are observed as regularly spaced brighter spots at the aptamer locations. The AFM images of Figures 2 b–d clearly demonstrate the regular spacing of the thrombin molecules templated on the linear TX arrays. The average distance measured between pairs of adjacent thrombin molecules along a given TX array is $\approx 18 \pm 1$ nm (Figure 3, profile 1), which is in good agreement with the designed parameters of five helical DNA turns between each adjacent aptamer pair. AFM measurements show that thrombin molecules have an average height of $\approx 2.7 \pm 0.3$ nm (Figure 3, profiles 3–6), in comparison with a height of $\approx 1.7 \pm 0.2$ nm measured across

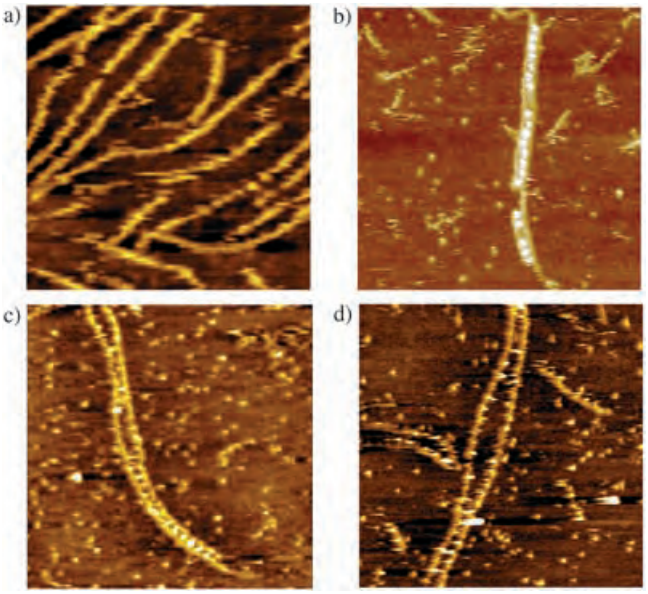

Figure 2. AFM images of the aptamer-directed self-assembly of thrombin protein linear arrays: a) 1D TX tile array with aptamer sequences prior to thrombin protein binding; b)–d) AFM images after binding of thrombin to the TX array; brighter spots correspond to thrombin proteins. Each image shows 500×500 nm^2.

the DNA segment on the array (Figure 3, profile 2). This further confirms that the periodic bumps in the lattice result from the binding of thrombin to the DNA tiles. (More distance and height profiles are available in the Supporting Information.)

Interestingly, upon binding with thrombin, the TX linear array has an inclination to form a parallel pair with the proteins sandwiched inside. One possible explanation is that each protein binds with two aptamers which brings two opposing TX tiles together. A second possibility is that the protein dimerizes under the experimental conditions, and each monomer in the dimer binds with an aptamer on the opposite side of the TX tiles, thus creating the parallel pair of the TX linear array. We believe the latter explanation is most relevant, and this conclusion is supported by several important observations: first, the average center-to-center distance between the parallel pair of DNA linear arrays is 22 ± 1 nm (Figure 3, profile 2). The width of the TX tile is ≈ 6 nm, the hairpin loop including the aptamer sequence on each TX tile is about 4–5 nm, and therefore the protein structure in the center should have a span of ≈ 7–8 nm. This spacing is consistent with the hypothesis of two protein molecules separating the DNA arrays. Secondly, some loosely bound TX pairs were also observed with alternating, closely parallel, separated sections (Figures 2 c and d). Upon careful examination of the separated parts, proteins were observed to be bound on one side but not on the other. This indicates that the linkage between the two parallel linear DNA arrays is not through a single protein molecule, but through a protein dimer. Upon examination of the X-ray crystal structure of the thrombin–aptamer complex, each thrombin molecule is observed to have two possible binding sites for the different locations of the aptamer.[30] Specifically, the G8-T9-G10

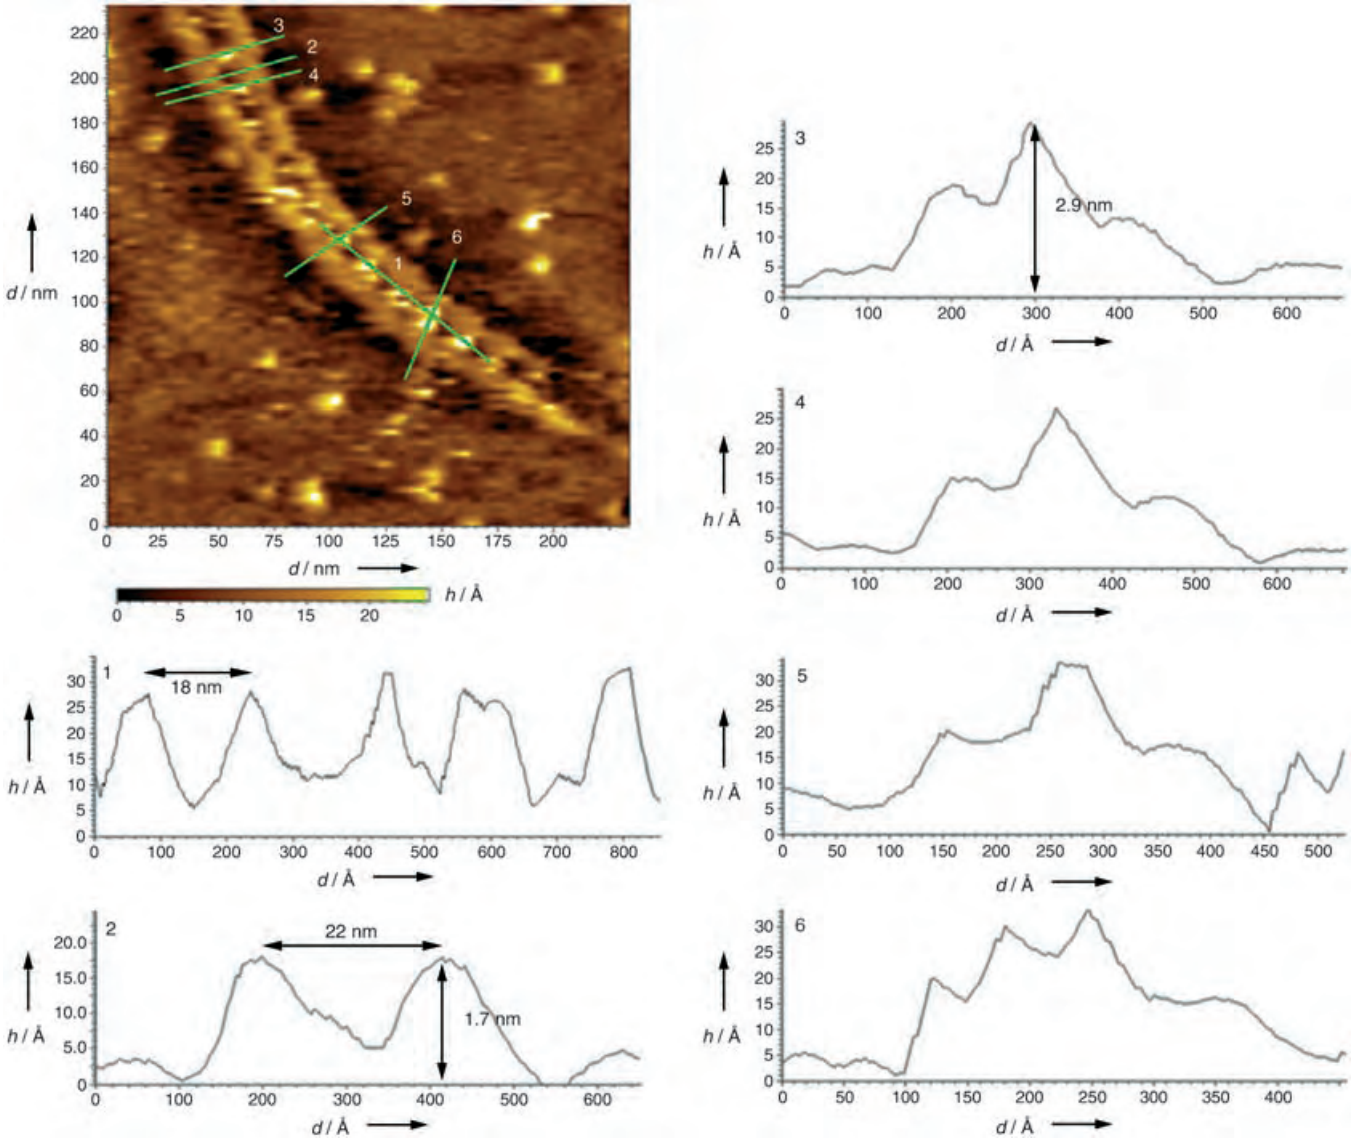

Figure 3. Analysis of the AFM data in Figure 2c (magnified): lines and numbers in the image correspond to the cross sections of the image shown in profiles 1 to 6. The periodicity of the protein molecules in the array is clearly shown (lateral distance ≈17–19 nm). The parallel pairing of the TX linear arrays show protein molecules sandwiched in between that are higher (2.5–3 nm), than the DNA tiles (≈1.7 nm). Profile 6 clearly shows two loosely bound thrombin molecules resolved by AFM. The average distance between the linear DNA arrays is ≈22 nm.

region of the aptamer binds the fibrinogen-binding site (Arg75 and Arg77), and the T13-G14-G15 region binds to the heparin-binding site (Arg101, Arg233, Lys236, Trp237, and Lys240) through both ion pairing (negatively charged phosphate on the DNA backbone with the positively charged amino acid residues on the protein) and hydrogen bonding.[30] In the crystal structure of the complex, the aptamer is squeezed in between two thrombin molecules and concurrently, one thrombin protein has two aptamer-binding sites. Although the site of primary bimolecular interaction in solution is not clear, we propose that both sites in both the aptamer and protein molecules are involved, and the dimerization of thrombin is induced by aptamer binding. Owing to the limit of AFM resolution, the geometry of dimer formation is not clear. It is possible that the two opposing TX arrays can assume parallel or antiparallel alignments.

The model proposed above is further evidenced by analysis with nondenaturing polyacrylamide gel electrophoresis. Figure 4 shows a gel image that demonstrates the concentration dependence of TX aptamer–protein binding. The sticky ends of the TX tiles were removed to allow the formation of single tile complex monomers, which are able to migrate in the gel. The isoelectric point (pI) of thrombin is 7.5, close to the pH value of the buffer. Therefore, the protein alone barely migrates in the gel. However, if bound to the negatively charged TX tile, the thrombin–aptamer complex can migrate in the gel, albeit slower than TX tile alone. Stains-all was used for gel imaging; as the protein is neutral in charge, it is not stained with the positively charged dye, whereas the DNA is well-stained.

The gel image shows that with an increase in protein concentration, at least two slower-migrating bands show up in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

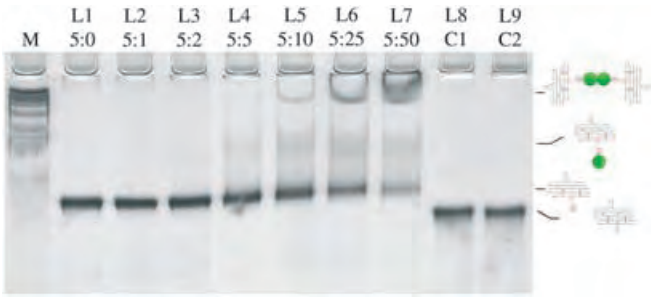

Figure 4. Nondenaturing gel electrophoresis of TX tile and TX aptamer–protein complexes. The polyacrylamide gel (10%) in 1×TAE/Mg^{2+} buffer was run at constant current (25 mA) for 48 h at 4°C. The gel was stained with Stains-all (0.1%) and destained by exposure to white light. Lane M: 100-bp DNA ladder; lane L1: TX tile alone; lanes L2–L7: consistent quantity of TX tiles (10 pmol) but an increasing amount of thrombin from 2 to 100 pmol. DNA/protein ratios are indicated for each lane. Lane L8 contains the control TX molecule without the aptamer sequence; L9 contains a mixture of the control TX and thrombin at a molar ratio of 5:10. The assignments of the bands are indicated schematically on the right-hand side.

the lane, and the intensity distribution of the bands within the lane shifts toward the slower-migrating bands. At a molar ratio of 5:1 TX tile/thrombin, the first slower-migrating band initially appears, the intensity of which increases and then levels off at a tile/protein ratio of 5:10. At a molar ratio of about 5:10, another even slower-migrating band appears; its intensity increases steadily up to the ratio of 5:50. If the aptamer–protein interaction is a one-to-one stoichiometry, only one slower-migrating band would be expected to appear. The appearance of the second slower band and its relative position in the gel indicate that this is a dimer of the TX DNA molecule with one or two protein molecules sandwiched in between. If only one protein molecule were present between each TX pair, the intensity of this band relative to the first slower-migrating band would be expected to decrease with an increase in protein concentration, yet the opposite trend is observed. We therefore conclude that two protein molecules are sandwiched between two opposing TX tiles, as indicated by the schematic representation to the right of the gel image. Lanes 8 and 9 are the controls: lane 8 contains the TX molecule without the aptamer sequence (strand structure and sequence shown in Supporting Information); it migrates slightly faster than the TX assembly with the aptamer sequence in the lane 2. Lane 9 contains a 5:10 molar ratio of the control TX tile used in lane 8 and thrombin. No slower-migrating bands are evident, which indicates that nonspecific interactions are not present between the protein and the TX tile in which the aptamer is absent. It is also notable that the fast-migrating bands show a backward shift in the lanes with the high protein concentrations, whereas the middle bands smear forward. This can be explained through an unstable interaction between the TX aptamer and the thrombin molecule in the 1:1 complex; such complexes formed in solution may break down under gel conditions. To obtain good band separation, the polyacrylamide gel (10%) was run for 48 h. The thrombin–aptamer interaction is governed not by covalent bonds, but by dynamic equilibrium. It is possible that during the long gel-running time, some complex dissociation occurs. This would result in the DNA aptamer band running in the front, but hindered, as observed, and the 1:1 protein–aptamer complex running in the middle, yet smeared.

On the other hand, the 2:2 complex (the slowest-migrating band) is apparently more stable. This phenomenon is consistent with the observation that at a molar ratio of 5:10, AFM images show that aptamers on the DNA array are mostly occupied by thrombin. Overall, dimer formation as evidenced by gel electrophoresis is consistent with the AFM imaging results.

In summary, we have demonstrated the incorporation of aptamer sequences into a rationally designed DNA nanostructure, and have successfully used the aptamer-bearing DNA nanostructure for the directed assembly of thrombin protein arrays. The results clearly show that the thrombin-binding aptamer still functions as the protein-binding moiety upon incorporation into a complex DNA nanostructure. This is encouraging, as it will open up future opportunities for the construction of nanoscale protein arrays in a programmable fashion.

The DNA tiles could be easily modified to accommodate other aptamer sequences in the construction of 2D or 3D protein arrays. Precisely controlled organization of protein molecules onto periodic 2D DNA lattices would give insight into protein structure with 2D cryoelectron diffraction microscopy. However, the ultimate resolution for obtaining structural information from spatially organized proteins will depend on the flexibility of the orientation, and the conformation of the aptamers on the DNA tiles. A recent development by Simmel and co-workers[31] involved a combination of the aptamer-directed self-assembly system with the use of fuel DNA strands to control the binding and release of thrombin proteins. In this way, the pattern of the protein nanoarray could be efficiently tuned. Also, the incorporation of previously developed DNA nanoactuators[32] into the aptamer-directed protein array would permit a change in the relative positions of proteins in real time, which could enable the study of proximity effects of protein–protein interactions. Indeed, the DNA-directed self-assembly of proteins can be used for the direct visualization of protein–protein interactions, as the spatial resolution of such interactions is greatly amplified by the patterning of the DNA structure.

Experimental Section

All DNA strands used for the work reported herein are listed in the Supporting Information. The DNA sequences were designed with the SEQUIN program.[33] DNA strands were commercially synthesized (Integrated DNA Technologies, Inc.) and purified by denaturing gel electrophoresis. Thrombin from human plasma (freeze-dried from a sodium citrate buffer) and Stains-all were purchased from Sigma-Aldrich. The TX tile complex and DNA array were formed by mixing equal quantities of each strand designed in the complex or lattice unit at a concentration of 1 μM (as estimated by OD_{260}) in 1×TAE/Mg^{2+} buffer (Tris, 40 mM; acetic acid, 20 mM; EDTA, 2 mM; and magnesium acetate, 12.5 mM; pH 8.0). The mixture was cooled slowly from 90°C to 20°C. Thrombin was reconstituted into aqueous solution by adding ultrapure water to a final protein concentration of ≈10 μM.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Nondenaturing gel electrophoresis: TX tiles were mixed with thrombin at different concentration ratios and left at room temperature for 30 min to establish binding equilibrium. Sampling aliquots were loaded onto a nondenaturing polyacrylamide gel (10%), and run at 4°C for 48 h at a constant current of 25 mA. A solution of Stains-all (0.1%) in water/formamide (45:55, v/v) was used to stain the gel. The gel was destained by exposure to white light, and the gel image was collected with a scanner.

AFM imaging: DNA lattice samples (5 μL, ≈30 nM) were dropped onto freshly cleaved mica (Ted Pella, Inc.) and left to adsorb to the surface for 3 min. Buffer (1 × TAE/Mg^{2+}) in volumes of either 30 μL or 400 μL was then added to the drops on the mica. Imaging was performed in a fluid cell in tapping mode on a Multimode NanoScope IIIa (Digital Instruments) or a Pico-Plus AFM (Molecular Imaging) with NP-S tips (Veeco, Inc.). The 3D structure of the TX tile was drawn with Strata 3D software.

Cluster Compounds

cyclo-$Ti_3[\eta^2(\mu_2\text{-}C,O)]_3$: A Side-on-Bonded Polycarbonyl Titanium Cluster with Potentially Antiaromatic Character**

Qiang Xu, Ling Jiang, and Nobuko Tsumori*

Carbon monoxide, one of the most important ligands in transition-metal chemistry from an academic and industrial viewpoint, is well known to coordinate only in the direction from the C atom to metal(s), forming terminal or bridging metal–CO bonds, in the known metal carbonyls,[1] with very few exceptions for chemisorbed CO on some transition metal

surfaces[2] and so-called four-electron-donor CO in a limited number of organometallic complexes.[3] The recently reported $Sc_2[\eta^2(\mu_2\text{-C,O})]$ is a simple homoleptic metal carbonyl with only a single side-on-bonded CO ligand,[4] whereas there has been no report thus far of a side-on-bonded polycarbonyl metal cluster. Here we report the generation, IR spectroscopic characterization, and theoretical investigation of side-on-bonded mono- and polycarbonyl titanium clusters $Ti_2(CO)_n$ ($n=1$, 2) and $Ti_3(CO)_n$ ($n=1$–3). In particular, calculations revealed the novel planar, CO side-on-bonded windmill-like *cyclo*-$Ti_3[\eta^2(\mu_2\text{-C,O})]_3$ molecule, which may have antiaromatic character.

Matrix-isolated $Ti_2(CO)_n$ ($n=1, 2$) and $Ti_3(CO)_n$ ($n=1$–3) molecules were produced by codeposition of laser-ablated Ti atoms with CO in excess argon at 7 K and were investigated by FTIR spectroscopy.[5] Recent studies, with the aid of an isotopic substitution technique, have shown that a combination of matrix-isolation IR spectroscopy and quantum chemical calculations is a powerful tool for investigating the spectrum, structure, and bonding of novel species.[6,7] The IR spectra as a function of changes in CO concentrations and laser energy are of particular interest here. At high CO concentration (0.20%) and low laser energy (4 mJ/pulse), only mononuclear species $Ti(CO)_n$ ($n=1$–6) with IR absorptions in the 1740–2040 cm^{-1} region were observed as the reaction products on sample annealing,[8] which have been previously identified.[9] At lower CO concentration (0.05%) and higher laser power (12 mJ/pulse), these mononuclear species almost disappeared, while new absorptions appeared in the 1160–1420 cm^{-1} region on sample annealing, which disappeared after broadband irradiation and did not recover upon further annealing (Figure 1 and Table 1).[8] Note that these new bands were only observed with lower CO concentration and higher laser energy than those for the mononuclear Ti carbonyls, that is, these new products involve more than one Ti atom. Since doping with CCl_4 as an electron scavenger had no effect on these bands, the products are neutral (Figure 1).

On the basis of the growth/decay characteristics as a function of changes in experimental conditions (Figure 1 and ref. [8]), the bands in the 1160–1420 cm^{-1} region can be grouped into five species. All of the absorptions exhibit the isotopic $^{12}C^{16}O/^{13}C^{16}O$ and $^{12}C^{16}O/^{12}C^{18}O$ frequency ratios characteristic of C–O stretching vibrations, but their ν_{C-O} values are anomalously lower than for terminal or bridging CO (Table 1 and Table 2). They are therefore attributed to Ti cluster carbonyls containing only side-on-bonded CO ligand(s) with extremely weakened C–O bonding, as observed for $Sc_2[\eta^2(\mu_2\text{-C,O})]$.[4] The absorptions at 1297.8 cm^{-1} (trapping sites: 1304.2 and 1293.5 cm^{-1}) and at 1253.3 cm^{-1} respectively split into doublets for the mixed $^{12}C^{16}O+^{13}C^{16}O$ and $^{12}C^{16}O+^{12}C^{18}O$ samples (Figure 2), and this indicates that only one CO subunit is involved in each molecule;[10] the former is assigned to Ti_2CO and the latter to Ti_3CO on the basis of the stepwise annealing behavior (Figure 1). The absorptions at 1334.3 cm^{-1} (site: 1324.8 cm^{-1}) and at 1189.9 cm^{-1} (sites: 1185.0 and 1181.7 cm^{-1}) respectively split into triplets with approxi-

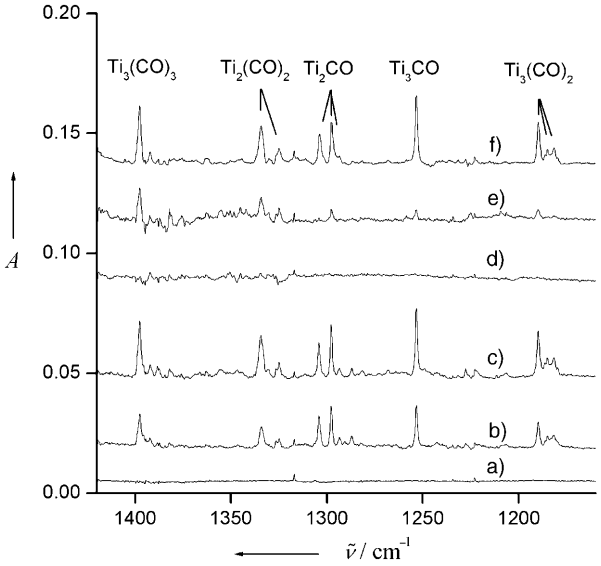

Figure 1. IR spectra in the 1420–1160 cm^{-1} region for laser-ablated Ti atoms codeposited with 0.05% CO in argon at 7 K: a) after 60 min of sample deposition, b) after annealing to 30 K, c) after annealing to 34 K, d) after 20 min of broadband irradiation, e) after annealing to 36 K, f) after doping with 0.01% CCl_4 and annealing to 34 K.

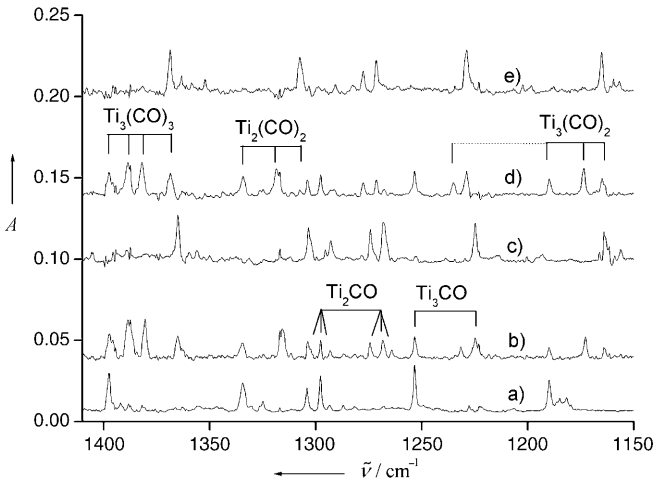

Figure 2. IR spectra in the 1420–1150 cm^{-1} region for laser-ablated Ti atoms codeposited with isotopic CO in Ar for 60 min at 7 K, followed by annealing to 34 K. a) 0.05% $^{12}C^{16}O$, b) 0.025% $^{12}C^{16}O$ + 0.025% $^{13}C^{16}O$, c) 0.05% $^{13}C^{16}O$, d) 0.025% $^{12}C^{16}O$ + 0.025% $^{12}C^{18}O$, e) 0.05% $^{12}C^{18}O$.

mately 1:2:1 relative intensities in the mixed-isotope experiments (Figure 2), that is, each mode involves two equivalent CO ligands;[10] we assign the former to the asymmetric C–O stretching of $Ti_2(CO)_2$, and the latter to $Ti_3(CO)_2$. The splitting of the highest absorption at 1397.6 cm^{-1} into a quadruplet in the mixed-isotope experiments suggests the involvement of three CO subunits.[10] Quantum chemical calculations (vide infra) indicate that this species is preferably assigned to $Ti_3(CO)_3$ rather than to $Ti_2(CO)_3$. For species containing two or three CO ligands, symmetric C–O stretching modes should be observed due to the reduced symmetry of the isotopically mixed species. The symmetric C–O stretching for each isotopomer of $Ti_2(^{12}C^{16}O)(^{13}C^{16}O)$ and $Ti_2(^{12}C^{16}O)(^{12}C^{18}O)$ overlapped with $Ti_3(CO)_3$ absorptions, and the symmetric C–O stretching modes in the mixed-isotope spectra for $Ti_3(CO)_3$ were too weak to be observed, as predicted by DFT calculations,[8] whereas an additional blue-shifted absorption was observed for the symmetric C–O stretching mode for each isotopomer of $Ti_3(^{12}C^{16}O)(^{13}C^{16}O)$ and $Ti_3(^{12}C^{16}O)(^{12}C^{18}O)$ (Table 1). With 0.05% CO all five species were observed, whereas only the CO-poorer and Ti-richer species, Ti_2CO and Ti_3CO, survived on further lowering the CO concentration to 0.02%.[8]

Density functional calculations, performed at the BP86/6-311++G(d,p) and B3LYP/6-311++G(d,p) levels[11] for the possible isomers of $Ti_2(CO)_n$ ($n=1$, 2) and $Ti_3(CO)_n$ ($n=1$–3), provide strong support to the above assignments and insight into structures and bonding. The trial calculations to test reliability gave ν_{C-O} values for linear quintet TiCO of 1889.0 (BP86) and 1971.2 cm^{-1} (B3LYP), close to the experimental value (1855.2 cm^{-1}) with scale factors (obsd/calcd frequency ratios) of 0.982 and 0.941, respectively, in good agreement with previous reports ($\nu_{C-O}=1854.4$ cm^{-1} in solid argon, 1920.0 cm^{-1} in solid neon).[9] Hereafter, mainly BP86 results are presented for discussion. The calculations show that the planar $Ti_2[\eta^2(\mu_2\text{-}C,O)]$ (**1**) molecule with a single side-on-bonded CO ligand, similar to $Sc_2[\eta^2(\mu_2\text{-}C,O)]$,[4] and the planar $Ti_2[\eta^2(\mu_2\text{-}C,O)]_2$ (**2**) molecule with two side-on-bonded CO units (Figure 3) nicely match the experimental vibrational frequencies, relative absorption intensities, and isotopic shifts for $Ti_2(CO)$ and $Ti_2(CO)_2$, respectively. The ν_{C-O} values of **1** and **2** are predicted to be 1330.9 and 1332.6 cm^{-1} (B_2), respectively, in good agreement with observations (1297.8 and 1334.3 cm^{-1}), whereas the symmetric C–O stretching mode (A_1) of **2** exhibits a much lower intensity than the antisymmetric B_2 mode (Table S1 in Supporting Information), consistent with the absence of this A_1 absorption in the IR spectra. The calculated $^{12}C^{16}O/^{13}C^{16}O$ ($^{12}C^{16}O/^{12}C^{18}O$) frequency ratios of **1** and **2** are 1.0238 (1.0222) and 1.0239 (1.0217), respectively, in accord with the observed values of 1.0233 (1.0208) and 1.0237 (1.0206) (Table 2). Our

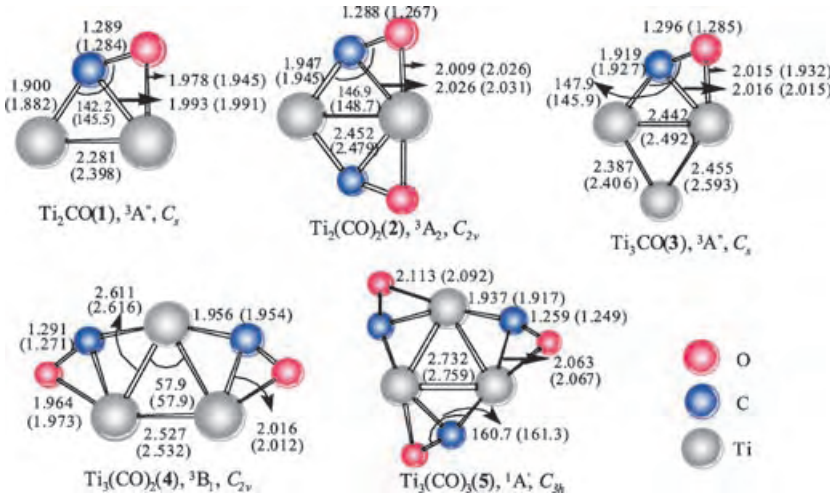

Figure 3. Optimized structures (bond lengths in Å, bond angles in degrees), electronic ground states, and point groups of the reaction products calculated at the BP86/6-311++G(d,p) and B3LYP/6-311++G(d,p) (in parentheses) levels.

BP86 calculations predict that **1** ($^3A''$, C_s, $R_{C-O}=1.289$ Å, $\nu_{C-O}=1330.9$ cm^{-1}) has a structure similar to but smaller R_{C-O} and higher ν_{C-O} than those of the analogous $Sc_2[\eta^2(\mu_2\text{-}C,O)]$ ($^1A'$, C_s, 1.320 Å, 1237.6 cm^{-1}).[4] The R_{C-O} value of **1** is larger than that of $OTi(\eta^2\text{-}CO)$ (1.246 Å).[12] In comparison with **1**, **2** [$^3A_2$, C_{2v}, 1.288 Å, 1332.6 cm^{-1} (B_2)] is predicted to have longer Ti–Ti, Ti–C, and Ti–O bonds but almost the same R_{C-O}.

For a trititanium cluster, a side-on-bonded CO ligand may have two possible coordination forms: $\eta^2(\mu_3\text{-}C,\mu_2\text{-}O)$ and $\eta^2(\mu_2\text{-}C,O)$. Our BP86 calculations show that the *cyclo*-$Ti_3[\eta^2(\mu_3\text{-}C,\mu_2\text{-}O)]$ ($^3A'$, C_s, 1.364 Å, 1099.5 cm^{-1}) and *cyclo*-$Ti_3[\eta^2(\mu_3\text{-}C,\mu_2\text{-}O)]_2$ ($^1A'$, C_{2v}, 1.371 Å, 1064.2 cm^{-1}) molecules do not fit the observations, as their calculated ν_{C-O} values are much lower than the observed frequencies for $Ti_3(CO)$ (1253.3 cm^{-1}) and $Ti_3(CO)_2$ (1189.9 cm^{-1}). Calculations at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the same level show that the planar *cyclo*-$Ti_3[\eta^2(\mu_2\text{-C,O})]$ (**3**) molecule ($^3A''$, C_s, 1.296 Å, 1302.7 cm^{-1}) and the planar *cyclo*-$Ti_3[\eta^2(\mu_2\text{-C,O})]_2$ (**4**) molecule [$^3B_1$, C_{2v}, 1.291 Å, 1316.0 cm^{-1} (B_2)] (Figure 3) fit the experimental results well (Tables 1 and 2).[8] For **4**, the calculated symmetric C–O stretching mode (A_1, 1359.8 cm^{-1}, 45 km mol^{-1}) has an intensity much lower than the antisymmetric one (B_2, 1316.0 cm^{-1}, 731 km mol^{-1}) (Table S1 in Supporting Information), in agreement with the absence of this A_1 absorption in the IR spectra. By comparing **1** with **3** and **2** with **4**, it is found that addition of the third Ti atom to Ti_2 to form a triangular Ti_3 cluster leads to the lengthening of C–O bonds, which corresponds to weakening of the C–O bond and therefore to lower ν_{C-O}, in agreement with the observations.

As a Ti cluster carrying three side-on-bonded CO ligands should be considered for the 1397.6 cm^{-1} absorption, we first performed BP86 calculations on possible isomers of $Ti_2(CO)_3$, which predict that its most stable isomer ($^3A_1$, C_{3v}) exhibits IR absorptions at 1432.1 and 1357.7 cm^{-1} with intensities of 152 and 502(×2) km mol^{-1}, respectively. The prediction does not match the observation of a single IR absorption at 1397.6 cm^{-1}, and this leads to the conclusion that $Ti_2(CO)_3$ should be excluded. Calculations at the same level revealed that the planar *cyclo*-$Ti_3[\eta^2(\mu_2\text{-C,O})]_3$ (**5**) molecule having a $^1A_1$ ground state with C_{3h} symmetry (Figure 3) nicely fits the observations for this tricarbonyl species (scale factor 0.967). Species **5** [$^1A_1$, C_{3h}, 1445.9 cm^{-1} (E′)] consists of an equilateral Ti_3 triangle with $R_{Ti-Ti} = 2.732$ Å, much longer than in the naked Ti_3 cluster[13] or in **3** or **4**, and three equivalent side-on-bonded CO units with $R_{C-O} = 1.259$ Å, the shortest among $Ti_3(CO)_n$ ($n = 1$–3), forming a planar windmill-like molecule. It lies 44.55 kcal mol^{-1} lower in energy than the planar CO-bridged *cyclo*-$Ti_3(\mu\text{-CO})_3$ molecule with D_{3h} symmetry, which has three imaginary vibrational frequencies. In addition, the cyclic $Ti_3(CO)_3$ isomer with terminally bonded CO ligands and D_{3h} symmetry exhibits no geometry convergence, and the removal of symmetry restrictions in the optimization procedure results in a nonplanar structure with C_1 symmetry [$\nu_{C-O} = 1500.5$ (734), 1450.9 (464), and 1108.2 cm^{-1} (119 km mol^{-1})], which lies 14.75 kcal mol^{-1} higher in energy than **5**. We also performed DFT calculations on other electronic states for the planar C_{3h} *cyclo*-$Ti_3[\eta^2(\mu_2\text{-C,O})]_3$ molecule and found that the triplet state exhibits no geometry convergence, and the relative triplet energy at the singlet geometry is predicted to be 9.37 kcal mol^{-1} higher. Species **5** has an $\ldots(a')^2(e')^4(e')^4(a')^2(a'')^2(e'')^4$ electronic configuration; the doubly degenerate HOMO consists of the π orbitals localized on the Ti-C-Ti subunits, and the HOMO−1 is the delocalized π orbital mainly involving the Ti_3C_3 unit (Figure 4). It is noted that the LUMO is quite low in energy (HOMO–LUMO energy gap: 13.81 kcal mol^{-1}).

Interestingly, theoretical examination of **5** reveals that this molecule may have antiaromatic character. Recently, aromaticity[14,15] has been extended by gas-phase observations to main-group metal clusters such as Al_4^{2-}, Al_4^{4-}, Si_4^{2+}, Si_4, Si_4^{2-}, Sn_6^{2-}, and Hg_4^{6-}, which have stimulated several theoretical investigations and heated discussions.[16] One of the useful approaches to the characterization of aromaticity and antiaromaticity is analysis of the nucleus-independent chemical shift (NICS) on the basis of the magnetic criterion, in which a negative NICS corresponds to aromaticity and a positive NICS to antiaromaticity.[17] Calculations on **5** at the gauge-including atomic orbital (GIAO) BP86/6-311++G(d,p) level show that the NICSs at the Ti_3 ring center and 1 Å above are 23.4 and 14.8, respectively, and thus indicate significant antiaromaticity. The corresponding values for benzene calculated at the same level are −7.7 and −10.1. Further calculations to clarify the source of the NICS value of **5** by way of current density plots and dissected NICS data are in progress and will be reported in a subsequent full paper.

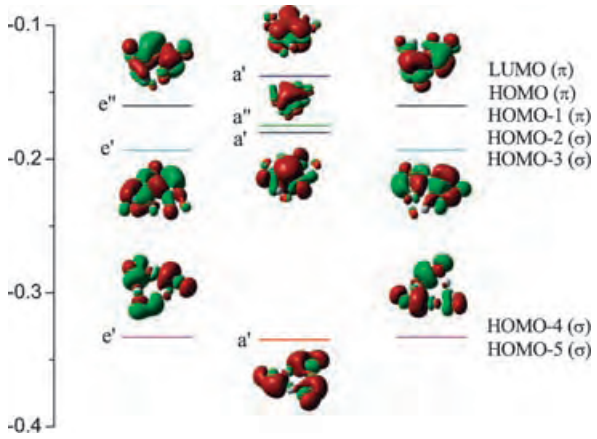

Figure 4. Molecular orbital pictures of singlet *cyclo*-$Ti_3[\eta^2(\mu_2\text{-C,O})]_3$ showing the LUMO and the HOMOs down to the fifth valence molecular orbital from the HOMO. HOMO, HOMO−3, and HOMO−4 each consist of degenerate pairs, both of which are shown here.

In summary, FTIR spectroscopy and calculations revealed the novel planar windmill-like *cyclo*-$Ti_3[\eta^2(\mu_2\text{-C,O})]_3$ molecule exhibiting antiaromatic character as a new example of transition metal cluster compounds having aromaticity or antiaromaticity. This molecule is generated, along with other side-on-bonded mono- and polycarbonyl di- and trititanium clusters, from the reaction of laser-ablated Ti atoms with CO in a solid argon matrix. All of these molecules show unusually low C–O stretching frequencies and thus represent a new class of metal carbonyls with extremely weakened C–O bonding. It is possible that further development in the concept of aromaticity and antiaromaticity in transition-metal systems, through matrix-isolation and theoretical investigations, will lead to the discovery of new classes of compounds or new insights into the electronic structures and chemical bonding of transition-metal cluster compounds.

Experimental Section

Matrix-isolation IR spectroscopy: The experimental setup for laser ablation and matrix-isolation IR spectroscopy was similar to those in previous reports.[5] Briefly, Ti atoms ablated with the Nd:YAG laser fundamental (1064 nm, 10 Hz repetition rate) were codeposited with CO in excess argon onto a CsI window at 7 K. IR spectra were recorded on a BIO-RAD FTS-6000e spectrometer at 0.5 cm^{-1} resolution by using a liquid-nitrogen-cooled HgCdTe (MCT) detector for the range of 5000–400 cm^{-1}. Samples were annealed at different temperatures and subjected to broadband irradiation ($\lambda > 250$ nm) from a high-pressure mercury arc lamp (Ushio, 100 W).

Calculations: DFT calculations were performed to predict the structures and vibrational frequencies of the observed reaction products with the Gaussian 03 program.[11] The BP86 density functional was used with 6-311++G(d,p) basis sets for C and O atoms, and the all-electron set of Wachters and Hay as modified by Gaussian 03 for Ti atoms. Geometries were fully optimized and vibrational frequencies were calculated with analytical second derivatives. Previous investigations have shown that the use of BP86 can provide reliable information for titanium carbonyls, such as IR frequencies, relative absorption intensities, and isotopic shifts.[9] For comparison, calculations were also performed with the hybrid B3LYP functional. Molecular orbitals were generated with GaussView.

Nanoreactors

Size Tuning, Functionalization, and Reactivation of Au in TiO_2 Nanoreactors**

*Jing Li and Hua Chun Zeng**

Over the past few years, there have been a significant number of new methods developed for the fabrication of core–shell structures ranging from multiphase semiconductors to metal–metal oxide nanocomposites.[1–10] Recently, the engineering of movable cores inside hollow shells has also been achieved with a silica template method and a Kirkendall-type diffusion process.[6,10] If the shell is permeable to reactants, this new type of core–shell nanostructure can be considered in a wider sense as a tiny reactor containing a movable catalyst core. As regards their applications, hydrogenation of ethylene (C_2H_4) has been conducted in Pt–CoO hollow core–shell nanostructures, and the heterogeneous catalytic activity of Pt cores has been demonstrated in the gas phase.[10] To carry out a

wider range of chemical reactions under both gaseous and liquid conditions, we note that multifunctional core–shell nanoreactors may be required in this emerging area of research. Apart from its normal role of container, for instance, a reactor (shell) itself should also be able to participate in certain chemical processes. Furthermore, a synthetic flexibility in size manipulation, functionalization, and reactivation of the catalyst (core) in a confined environment is yet to be demonstrated. Herein, we report that hollow Au–TiO_2 core–shell nanocomposites can be synthesized by using a wet chemical approach. Encouragingly, our synthetic method offers the flexibility to investigate the aforementioned exploratory subjects. In addition to the synthetic fabrication of Au–TiO_2 nanostructures, the photocatalytic activity of the core–shell nanoreactors was elucidated by desorption and/or decomposition of anchored organic molecules on the metallic cores under UV irradiation.

To test the above conceptual schemes, we conducted a series of experiments. The schematic flowchart in Figure 1

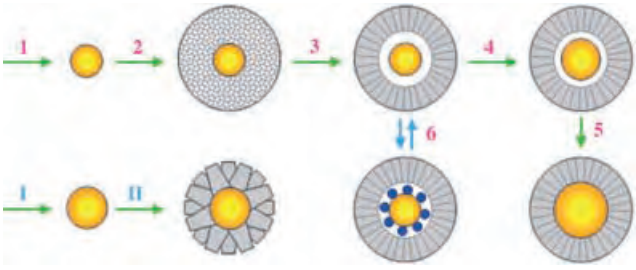

Figure 1. Schematic illustration of the three different processes investigated: fabrication of Au–TiO_2 nanoreactor and size tuning of core catalyst (steps 1–5); preparation of flowerlike Au–TiO_2 core–shell structure (steps I and II); and inclusion/removal of ionic or molecular species in an Au–TiO_2 nanoreactor (reversible steps 6). Gold cores are represented in orange/yellow, anatase TiO_2 shells in gray, and surface-anchored species in blue. Projected lines in products of steps 3–6 indicate the channels formed perpendicularly to the central space of the reactor.

illustrates some major process steps in aqueous media: 1) formation of metallic cores; 2) aggregation of TiO_2 nanocrystallites around a single metallic core; 3) evacuation of central TiO_2 crystallites by Ostwald ripening; and 4) and 5) manipulation of the metal core (that is, growth of the inside metal) to a desired size.

Figure 2 shows TEM images of the Au–TiO_2 nanoreactors fabricated through steps 1–3. For each discrete Au–TiO_2 core–shell structure, the Au catalyst core (50–150 nm) and a hollow interior can be clearly observed. The crystallites located in the central part of the TiO_2 spheres were removed during the synthesis.[11] Thus, it is understandable that intercrystallite channels must exist between the inner and outer spaces, through which ionic and/or molecular species can be transferred into or out of the nanoreactor. In addition to adjustable shell thickness and void volume through Ostwald ripening,[11,12] the size of the catalytic core can be further tuned within the nanoreactor (steps 3 and 4). In such a size manipulation, gold nutrients ($HAuCl_4$; see the Supporting Information) were first introduced into the vacant space

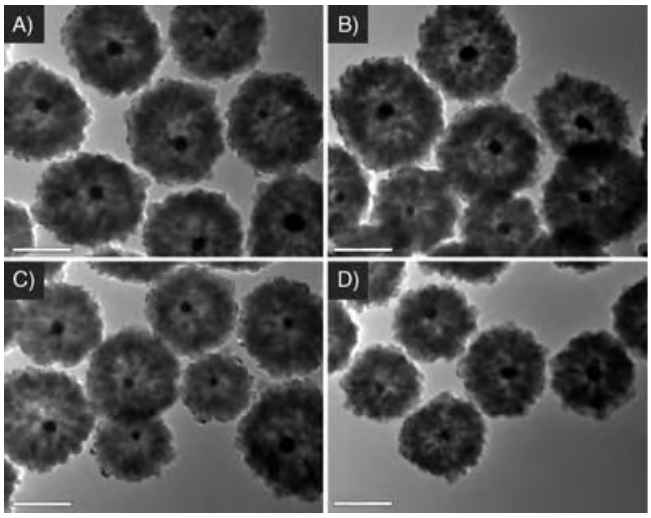

Figure 2. A)–D) TEM images of Au–TiO_2 core–shell nanoreactors with a central vacant space (prepared in step 3 of Figure 1). Experimental conditions: $HAuCl_4$ (3.1 mL, 0.32 mM) + sodium citrate solution (0.1 mL, 0.01 M) + TiF_4 (2.0 mL, 0.04 M) + H_2O to a total volume of 30.0 mL; at 180 °C for 48 h. All bar scales: 500 nm.

of the nanoreactor, and the $HAuCl_4$-soaked Au–TiO_2 nanoreactors were then placed in a solution of cetyltrimethylammonium bromide (CTAB) and ascorbic acid. It is believed that a slow interdiffusion between the $HAuCl_4$ inside the nanoreactor and the CTAB/ascorbic acid solution outside the nanoreactor would ensure a slow growth of Au cores while preventing TiO_2 shells from direct metal deposition. Furthermore, with the introduction of CTAB surfactant better-faceted Au cores can also be attained. Figure 3 shows Au–TiO_2 nanoreactors after core enlargement (Au: 150–250 nm). If $HAuCl_4$ and CTAB/ascorbic acid were premixed in the outside bulk solution, however, small Au nanoparticles would also be deposited on the outer surface of TiO_2 in addition to

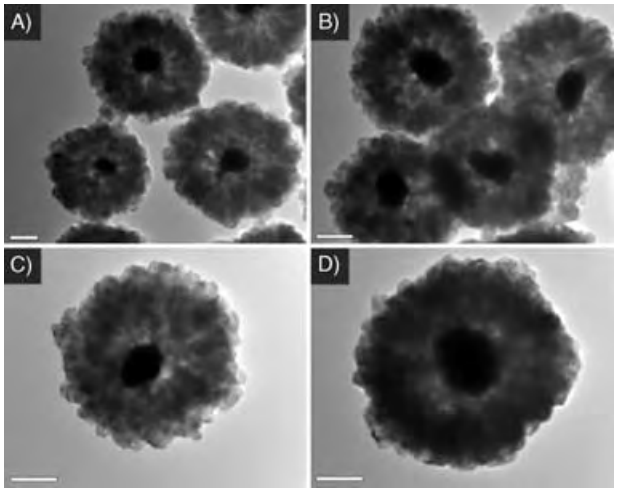

Figure 3. A)–D) TEM images of Au–TiO_2 core–shell nanoreactors after enlargement of Au cores (prepared in step 4 of Figure 1). A size-tuning experiment was carried out (see the Supporting Information); the pristine Au–TiO_2 core–shell nanoreactors used in this core tuning were those of Figure 2. All bar scales: 200 nm.

the desired core growth. In such a case, the vacant space can be filled up entirely (step 5, Figure 1; see the Supporting Information), which once again confirms the availability of communicable channels between the interior space of reactors and the exterior environment.

X-ray diffraction (XRD) investigations show that all the prepared Au–TiO_2 composite samples contain both face-centered cubic Au (space group (SG): $Fm\bar{3}m$, $a_0 = 4.078$ Å, JCPDS card No. 4-0784; see the Supporting Information) and tetragonal anatase TiO_2 (SG: $I4_1/amd$, $a_0 = 3.7852$ Å and $c_0 = 9.5139$ Å, JCPDS card No. 21-1272; see the Supporting Information). The chemical compositions of these metal–metal oxide nanocomposites were further confirmed by energy-dispersive X-ray spectroscopy (EDX). It was clearly shown that the content of Au in the size-tuned Au–TiO_2 nanoreactors increased in accordance with the enlargement of the Au cores, as evidenced in EDX elemental profiles (see the Supporting Information).

The present approach also permits other types of synthetic architecture. For example, on adding ascorbic acid to the synthesis mixture, well-faceted and much larger anatase TiO_2 crystallites were formed, which gave rise to a flowerlike Au–TiO_2 core–shell structure (steps I and II, Figure 1; see the Supporting Information). As detailed in Figure 4, the TiO_2 shell comprises only a small number of crystallites that are single-crystalline and elongated along the ⟨001⟩ directions.[11] In this case, it is likely that the ascorbic acid molecules would adsorb preferentially on certain crystal planes of TiO_2 crystallites during hydrothermal Ostwald ripening, thus resulting in larger building blocks from which the TiO_2 shell is formed. Nonetheless, this type of metal–metal oxide nanocomposite would be still very useful for new applications, such as storage of photogenerated electrons where no interior space is required.[13]

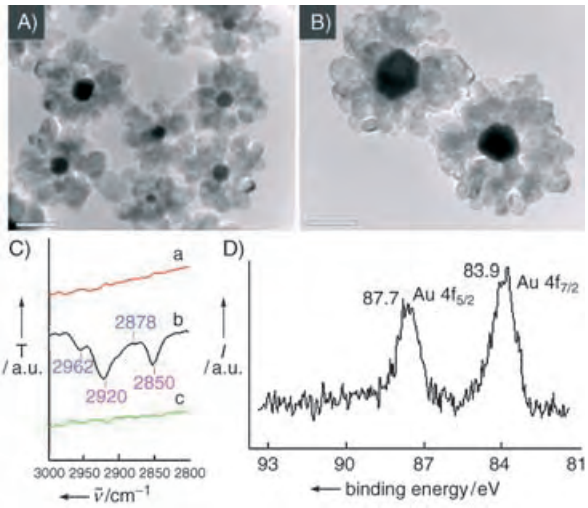

Figure 4. A, B) TEM images of flowerlike Au–TiO_2 core–shell structures (prepared in step II of Figure 1, see the Supporting Information); bar scales: 100 nm. C) FTIR spectra: a: clean Au–TiO_2; b: $C_{12}H_{25}SH$-adsorbed Au–TiO_2; and c: removal of $C_{12}H_{25}SH$ from b under UV irradiation. D) XPS spectrum of Au 4f measured for the Au–TiO_2 core–shell nanoreactors (Figure 2) after photocatalytic decomposition/desorption of adsorbed $C_{12}H_{25}SH$ molecules.

The catalytic Au cores can still be functionalized to meet targeted applications. For example, surface hydrophobicity or hydrophilicity can be attained by the introduction of alkane chains or carboxylic groups, respectively, to the Au core. Here, as a simple illustration, the straight-chain aliphatic thiol $C_{12}H_{25}SH$ was anchored on the Au surface (reversible steps 6, Figure 1). The Fourier-transform infrared (FTIR) spectra of Figure 4C show that the asymmetric and symmetric vibrational modes of C–H are located at 2920 and 2850 cm^{-1} ($\nu_{as}(CH_2)$ and $\nu_s(CH_2)$) and weaker modes at 2962 and 2878 cm^{-1} ($\nu_{as}(CH_3)$ and $\nu_s(CH_3)$), respectively, in the $C_{12}H_{25}SH$ adsorbed samples (see the Supporting Information), which indicates an all-*trans* conformation for the molecules.[14] Interestingly, after UV irradiation ($\lambda = 254$ nm, 15 h) the thiolate anions were desorbed and/or decomposed, as confirmed with both FTIR (Figure 4C) and X-ray photoelectron spectroscopy (XPS; see the Supporting Information). The Au^0 (binding energies at 87.7 and 83.9 eV, Au 4$f_{5/2}$ and 4$f_{7/2}$; Figure 4D) and TiO_2 (binding energies at 464.1 and 458.4 eV, Ti 2$p_{1/2}$ and 2$p_{3/2}$; see the Supporting Information) phases are clearly observed, whereas the signals for S over the binding energy range 160.0–170.0 eV are absent (see the Supporting Information).[14,15] This XPS observation indicates that the Au cores became clean again after removal of the anchored thiolate anions. In this process, the photogenerated holes in the valance band are likely to be responsible for the organic molecular oxidation (including the solvent used, ethanol;[16] see the Supporting Information), whereas the photogenerated electrons may transfer to the metallic core and induce reductive desorption of anionic sulfur species ($-S^{\delta-}$) from the Au surface. The reversibility of this process could be very useful for sulfur-poisoned metal catalyst regeneration in actual applications. It should also be recognized that unlike the normal Au–oxide nanocomposites (for example, Au–TiO_2) reported in literature,[17] the composite nanoreactors fabricated in the present work possess an additional function of screening reactants as a result of the presence of membrane-like shells. With this new structural feature (that is, inorganic membrane reactors), only chemical species permeable through the shell channels can access the catalytic metal cores and thus undergo metal-catalyzed reactions. In this regard, effective control of pore structure and channel size as well as chemical modification (inorganic and/or organic anchoring) of channel walls for the reactor shells would become immediate research tasks in future selective reactions. To further develop the nanoreactors, it is anticipated that higher catalytic activity could be attained with even smaller metal nanoparticles. Current research efforts are directed toward the size reduction of the reactor as well as chemical compatibility between the prepared solid materials (reactors) and solution constituents (reactants, products, and solvent media which form the reaction environment), although further exploitation appears to be challenging.

In summary, the preparation, size manipulation, functionalization, photocatalytic reactions, and reactivation of gold nanoparticles inside Au–TiO_2 nanoreactors have been dem-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

onstrated. The current approach offers a method for the synthetic fabrication of complex nanocomposites with high process flexibility. Many other catalytic reactions, in both the gaseous and liquid phase, can be conducted in this type of photosensitized metal–semiconductor nanoreactor. It is believed that higher catalytic activity and selectivity can be achieved when metal cores are trimmed down to even smaller sizes and the channel structure of the shell is better controlled.

Experimental Section

The synthesis of Au–TiO_2 core–shell nanoreactors involves a number of process steps (Figure 1). For the preparation of the starting Au-core nanoparticles, $HAuCl_4$ (3.0–4.0 mL, 0.2–0.6 mM) was mixed with sodium citrate solution (0.075–0.40 mL, 0.01M). After the solution was stirred for 3–4 h at room temperature (that is, after forming Au-seed nanoparticles, step 1, Figure 1), TiF_4 (1.0–2.0 mL, 0.04 M) and deionized water were added sequentially to a total volume of 30.0 mL. The mixture was then transferred to a Teflon-lined stainless-steel autoclave, and the hydrothermal reaction was conducted at 180 °C for 48 h in an electric oven. During this process, anatase TiO_2 crystallites were aggregated on the surface of Au cores, followed by evacuation of central TiO_2 crystallites (steps 2 and 3, Figure 1). Experiments for tuning Au cores inside TiO_2 nanoreactors were also carried out with two different methods (steps 4 and 5, Figure 1; see the Supporting Information). Flowerlike Au–TiO_2 core–shell structures without central voids (steps I and II, Figure 1) were synthesized with three different methods by varying the reagent concentrations, reaction temperature, and process time (see the Supporting Information). Adsorption and photon-assisted removal of adsorbed dodecanethiol ($C_{12}H_{25}SH$) on the interior Au cores were also conducted (see Supporting Information). The crystallographic structures of the products were determined by X-ray diffraction (XRD; Shimadzu XRD-6000, $Cu_{K\alpha}$). The spatial, morphological, and compositional studies were carried out with field-emission scanning electron microscopy and energy-dispersive X-ray spectroscopy (FESEM/EDX, JSM-6700F), transmission electron microscopy (TEM; JEM-2010F), Fourier-transform infrared spectroscopy (FTIR, KBr method; Bio-Rad FTS 135), and X-ray photoelectron spectroscopy (XPS; AXIS-Hsi, Kratos Analytical).[18,19]

Alkane Activation

Multinuclear Copper Triethanolamine Complexes as Selective Catalysts for the Peroxidative Oxidation of Alkanes under Mild Conditions**

*Alexander M. Kirillov, Maximilian N. Kopylovich, Marina V. Kirillova, Matti Haukka, M. Fátima C. Guedes da Silva, and Armando J. L. Pombeiro**

Copper species are widely found in nature and are present in many enzymes as di-, tri- or polynuclear Cu centers that catalyze selectively various oxidation reactions.[1] These reactions include the poorly characterized particulate methane monooxygenase (pMMO), which is present in methanotrophs, wherein a tri- or multinuclear Cu cluster catalyzes alkane hydroxylation and alkene epoxidation.[1f–i] Although increasing attention has been paid to the design of Cu complexes with polydentate ligands as models of copper oxidases[1a,b,2] and some mononuclear compounds have been

recognized as catalysts for alkane oxidation,[3] the use of multicopper complexes for such reactions still remains an unexplored area of research. Our main aims are to find a simple synthetic method to generate multinuclear copper complexes with *N*,*O*-polydentate ligands and to investigate the catalytic activity of these complexes for the oxidation of alkanes under mild conditions, thus extending our interest of alkane functionalization catalyzed by biologically inspired complexes from vanadium compounds, such as synthetic amavadine and its models, to copper complexes.[4]

As a polydentate ligand, we chose an ethanolamine as it is cheap, commercially available, environmentally tolerable, is of a recognized synthetic significance,[5] and its Cu complexes have not yet been applied to alkane functionalization. Cyclohexane and methane were tested as the main substrates in view of the biological interest of the latter and the significance of the oxidized products of both starting materials, that is, cyclohexanol/cyclohexanone (manufacture of adipic acid, Nylon-6,6′ and polyamide-6) from cyclohexane[6] and methanol or other oxidized species, from methane. Attempts have been made to develop processes that have advantages (e.g., higher efficiency, selectivity, simplicity, and use of milder conditions)[7] over commercial processes.[6,7a] However, of the mononuclear Cu^{I} and Cu^{II} complexes tested as catalysts for cyclohexane oxidation,[3] most provide modest yields and low selectivity,[3b,e,f] require expensive[3f,i] and environmentally unfriendly[3g] reagents and various additives,[3g,i] and/or involve complicated syntheses.[3b–d,f–i] Although the catalytic oxidation of methane under relatively mild conditions is currently a matter of a high interest,[8] reported Cu catalysts are scant and have little activity. [9]

Herein we report the easy generation and characterization of copper(II) triethanolamine (H_3tea) complexes that adopt dimeric ($[Cu_2(H_2tea)_2(C_6H_5COO)_2]\cdot 2H_2O$; **1**), trimeric ($[Cu_3(H_2tea)_2(4\text{-}OC_6H_4COO)_2(H_2O)]\cdot 4H_2O$; **2**), tetrameric ($[O\subset Cu_4(tea)_4(BOH)_4][BF_4]_2$; **3**) and polymeric structures ($[Cu_2(H_2tea)_2\{\mu\text{-}C_6H_4(COO)_2\text{-}1,4\}]_n\cdot 2n\,H_2O$; **4**) and show that they are highly selective and active catalysts for the oxidation of alkanes. The addition of different types of aromatic carboxylates or $Na[BF_4]$ to an aqueous blue solution of $Cu(NO_3)_2$, H_3tea, and NaOH provides the formation at room temperature of Cu complexes of diverse nuclearity. Hence, by adding benzoic acid, 4-hydroxybenzoic acid, $Na[BF_4]$, or terephthalic acid one obtains compounds **1**, **2**, **3**, or **4**, respectively, which are isolated as crystalline solids in good yields (76–91%) and characterized by IR and FABMS spectroscopies, elemental analysis, and X-ray crystallography (preparation procedures and characterization details are provided as Supporting Information).[10]

The molecular structure of **1** (Figure 1a) consists of centrosymmetric binuclear fragments, $[Cu_2(H_2tea)_2]^{2+}$, which are stabilized by two monodentate benzoate ligands. Each Cu center has a distorted tetragonal bipyramidal geometry and each H_2tea molecule acts as a tetradentate ligand with one bridging alkoxo group. The equatorial plane is defined by the two bridging alkoxo oxygen atoms of the H_2tea ligands, one amino nitrogen atom and one carboxylate oxygen atom.

The molecular structure of **2** (Figure 1b) consists of three metal atoms that are clustered by two oxygen bridges of two triethanolamine ligands and two carboxylate groups; the central Cu atom is an inversion center. Each lateral Cu atom is coordinated by one H_2tea ligand and the distorted square-

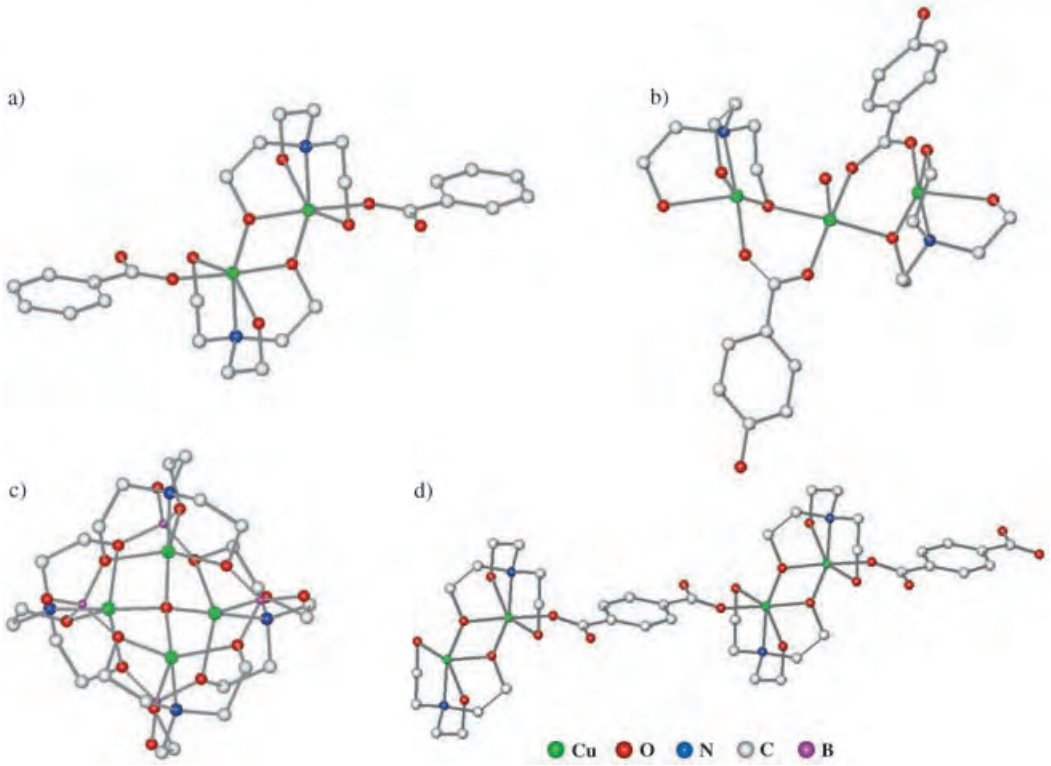

Figure 1. Ball-and-stick representation of the molecular structures of complexes **1** (a), **2** (b), $\mathbf{3}^{2+}$ (c), **4** (d) (only two dinuclear repeating units are shown). Solvent molecules, counterions, and hydrogen atoms are omitted for clarity.

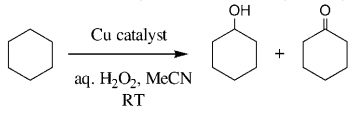
pyramidal geometry is completed by one carboxylate oxygen atom. The pentacoordinated central Cu atom binds with one water molecule (Cu–O 2.452(3) Å) that is involved in a hydrogen-bonding network with non-coordinated water molecules (see the Supporting Information). The overall positive charge is compensated by the deprotonation of OH groups on the substituted benzoate ligands. Although H_3tea as a tetradentate ligand has been extensively used to prepare polynuclear complexes,[5a,b] to our knowledge, compound **2** is the first example of a trinuclear complex with such a ligand.

Complex **3** (Figure 1c) is composed of two metallacrown ether centrosymmetric subunits $[O\subset Cu_4(tea)_4(BOH)_4]^{2+}$ and four BF_4^- counterions per unit cell, which are linked by hydrogen bonds (see the Supporting Information). Each subunit is present in the crystal as a cyclic Cu^{II} complex, in which an oxygen atom (μ_4-O) is encapsulated in the center. Four practically equivalent copper atoms (Cu–Cu separations of 3.066(3)–3.196(3) Å) are located in the corners of an almost regular tetragon. The copper pentacoordination comprises one N and three O atoms of a deprotonated triethanolamine molecule and the μ_4-O center. Eight μ_3-O centers, two from each tea ligand, are linked to four B–OH groups (formed by an unusual conversion from $[BF_4]^-$ in alkali medium), which leads to additional tetragon stabilization.

Copper(II), H_3tea, and terephthalic acid are involved in the formation of the 1D coordination polymer **4** (Figure 1d), which is constructed from unsymmetrical binuclear nodes $[Cu_2(H_2tea)_2]^{2+}$ (Cu–Cu separation of 2.905(3) Å), which has a structure similar to that of **1** and linear-type spacers. The parallel chains are arranged in neighboring layers (see the Supporting Information).

All these complexes are catalyst precursors for the oxidation of cyclohexane to cyclohexanol and cyclohexanone in acetonitrile by hydrogen peroxide in acidic medium (liquid biphasic catalysis) at room temperature (Table 1). The tri- and tetranuclear complexes **2** and **3** have evident labile sites and exhibit the highest activity with overall yields (based on cycloalkane) of up to 32% (see entries 3, 7, and 11) for a typical acid-to-catalyst molar ratio of 10:1, whereas the other complexes, **1** and **4**, required a higher amount of acid, which is conceivably to promote unsaturation of the metal centers upon ligand protonation. Turnover numbers (TONs, moles of product/mole of complex) of about 360–380 can be reached for a sufficiently high ratio of alkane to catalyst (6400).



Complexes **2** and **3** can also catalyze the peroxidative oxidation of gaseous alkanes such as methane and ethane, although less effectively than in the case of cyclohexane. For example, methanol (TON = 47, 2.2% yield) and ethanol (TON = 23, 2.1% yield) are obtained from CH_4 and C_2H_6, respectively, with catalyst **3** at 40 °C at an alkane pressure of 30 atm, a H_2O_2:catalyst molar ratio of 1000, and a HNO_3:catalyst molar ratio of 20. The use of O_2 instead of H_2O_2 results in a marked decrease in the activity which, nevertheless, can still be catalytic (e.g., TON = 4 for oxidation of methane to methanol with catalyst **3** and $p(O_2) = 2$ atm, the other conditions being similar to those given above).

The activity is dependent on the molar ratio of the peroxide to catalyst (compare entries 3–7 for **2** and entries 8–12 for **3**). Typically for cyclohexane reactions of 6 h, ratios of peroxide to catalyst ranging from 200:1 to 400:1 led to the best yields. Very high selectivity towards the formation of cyclohexanol and cyclohexanone was exhibited by these systems as no traces of any by-products were detected by GC or GC–MS analyses of the final reaction mixtures. The remarkable activity of our copper complexes is even higher than those found in amavadine and related vanadium catalysts for the same reaction.[4b] Based on mass, our Cu complexes appear to exhibit an activity that is comparable to or even higher than that of pMMO (17 nmol of ethanol per min mg of catalyst **3**; 34 nmol of methanol per min mg of catalyst **3**; or 97 nmol of cyclohexanol and cyclohexanone per min mg of catalyst **2** averaged over the reaction time versus 12–17 nmol of ethanol per min mg of protein for the enzymatic hydroxylation of ethane,[1g] which is a particularly favorable substrate).

The relevance of polydentate *N*,*O*-triethanolaminate ligands is evident in view of the much lower activity of a simple copper salt such as $Cu(NO_3)_2$ under the same reaction conditions (3–5% yield, TON ≈ 1, entries 15, 16, in the case of cyclohexane oxidation; or 0.06% yield, TON = 0.6 for the methane oxidation). This is conceivably associated with the involvement of those ligands (upon decoordination of an N or O atom) in proton-transfer steps for example among H_2O_2, oxo, and/or peroxo ligands, as suggested for some vanadium catalysts that may require particular N, O additives as cocatalysts.[4,7c,11]

The above alkane reactions appear to proceed mainly by mechanisms that involve both carbon-centered and oxygen-

Table 1: Peroxidative oxidation of cyclohexane catalyzed by complexes **1**–**4**.[a]

Entry	Catalyst	$n(H_2O_2)$/ n(catalyst)	t [h]	Yield [%][b]

centered radicals (the former upon homolysis of an alkane C–H bond) as very pronounced decreases in product yields occur when the reactions are carried out in the presence of either a carbon-radical trap such as $CBrCl_3$ or TEMPO (2,2,6,6-tetramethylpiperidin-1-oxyl) (use of the former almost completely suppresses the formation of cyclohexanol and cyclohexanone when used in excess relative to the alkane, whereas the latter leads to around 60% suppression of activity for a stoichiometric amount in relation to the alkane)[12] or an oxygen-radical trap such as Ph_2NH (activity suppression of ca. 90% for a stoichiometric amount relative to H_2O_2). BHT (2,6-di-*tert*-butyl-4-methylphenol) has a lower inhibition effect, commonly below 50%.[12]

Competitive nonradical pathways can probably occur through either 1) electrophilic attack from an oxidized metal (metal-peroxo or metal-oxo) centre to an alkane C–H bond with heterolytic cleavage of this bond to give an organocopper intermediate (R^- abstraction) as proposed[6a,8c,8g] for other metals, or 2) a concerted mechanism involving a direct insertion of an activated electrophilic oxygen atom, for example, a bridging oxygen atom, into an alkane C–H bond or through a pairwise process with C–H addition to two oxygen-atoms, as suggested for biological alkane hydroxylation by pMMO.[1g]

The higher activity of catalysts **2** and **3** might be accounted for by: 1) their lower coordination number (they are five-coordinate, whereas the others are six-coordinate); 2) the presence of a labile ligand (H_2O); 3) the expected higher stability of the multinuclear structures that have relatively close copper atoms supported by various bridging ligands (in the other complexes, only μ-ethoxy-type bridges are involved in the coordination to Cu atoms at a close distance). The last feature (3) agrees with the isolation after the reaction of the tetranuclear catalyst **3**, which maintains its high activity for further catalytic assays. Moreover, it is also consistent with the proposed involvement of three or four Cu atoms in a xylyl hydroxylation reaction in which a (μ-1,1-hydroperoxide) dicopper intermediate is further activated by a second dicopper center that acts as a Lewis acid thus promoting the electrophilic character of the hydroperoxide towards the substrate.[2e,13]

In conclusion, we have found a simple and convenient route for the formation of novel di-, tri-, tetra-, and polynuclear copper triethanolamine complexes, which can be easily prepared in high yields by using cheap, commercially available, and environmentally tolerable reagents. We have also opened up the possibility of applying such copper complexes as highly selective and active catalyst precursors for single-pot alkane oxidation at room temperature with an environmentally friendly oxidant (H_2O_2 that produces only water as by-product) towards the establishment of a powerful copper-based alkane oxidation system, which mimics pMMO and has some advantages over the current industrial synthetic processes for alcohols and ketones.

Copolymer Synthesis

Synthesis and Self-Assembly of Rod–Rod Hybrid Poly(γ-benzyl L-glutamate)-*block*-Polyisocyanide Copolymers**

Alexander Kros, Wim Jesse, Gerald A. Metselaar, and Jeroen J. L. M. Cornelissen**

Dedicated to Professor Roeland J. M. Nolte on the occasion of his 60th birthday

The synthesis and self-assembly of rod–rod block copolymers is still a pristine area in the field of polymer chemistry.[1,2] Nevertheless, it promises applications, for example, as biosensors, scaffolds for tissue engineering, and materials with new properties.[3] To our knowledge only two publications on rod–rod block copolymers have been published till now. Deming and co-workers synthesized polyleucine–poly(hydroxylated glutamate), which formed large vesicular systems in water.[4] This block copolymer was prepared by an elegant method developed by this group for the living polymerization of *N*-carboxy anhydrides of amino acids (NCAs) using a 2,2′-bipyridylnickel(0)(1,5-cyclooctadiene) [Ni(bpy)(cod)] complex as the catalyst.[5] This synthetic method enabled not only the preparation of the above system but also of a host of block polypeptides.[6] The synthesis and self-assembly of hybrid block copolymers containing a π-conjugated polymer and peptide segment was described by Jenekhe and Kong.[7] Upon changing the secondary conformation (that is, helix versus coil) of the peptide segment in a polyfluorene–poly(γ-benzyl glutamate), different types of nanosized assemblies were observed.

Cornelissen and co-workers studied the polymerization and self-assembly of isocyanopeptide polymers[8] and rod–coil block copolymers containing this peptidomimetic segment.[9] These peptide-derived polyisocyanides have unique properties that result from the intramolecular β-sheetlike hydrogen-

bonding arrays formed between the polymer side arms. The resultant macromolecules are stiffer than DNA, as determined by atomic force microscopy (AFM) studies.[10] The polymerization of isocyanides using nickel salts as a catalyst has been studied in Nolte's research group for several years.[11] From these investigations it was postulated that the polymerization of the isocyanide monomers occurs via a so-called "merry-go-round" mechanism around the central nickel atom resulting in a 4_1 (four repeat units per turn) helix, which is formed as the kinetic product. We have investigated the possibility of using the living polymerization catalyst developed by Deming,[5] which is formed by the action of NCAs on [Ni(bpy)(cod)],[5] as a catalyst for the polymerization of isocyanides. A catalyst that can be applied to two different monomers has great potential, as it allows the synthesis of a whole new class of rod–rod block copolymers with multiple structural motifs (for example, an α-helical peptide segment combined with a β-helical polyisocyanopeptide segment) and consequently unique properties. Herein, we describe the synthesis and self-assembly of hybrid block copolymers composed of a poly(γ-benzyl L-glutamate) block (PBLG) and two different polyisocyanide blocks, namely, poly((*S*)-(−)-α-methylbenzyl isocyanide) (PMBI) and poly(L-isocyanoalanyl-L-alanine methyl ester) (L,L-PIAA).

Scheme 1. Synthesis of PBLG-*block*-PMBI (**4**) and PBLG-*block*-L,L-PIAA (**5**) by a combination of *N*-carboxyanhydride ring-opening and isocyanide polymerization.

The diblock copolymers were synthesized by the nickel-catalyzed living polymerization of γ-benzyl L-glutamate *N*-carboxyanhydride (Bn-Glu NCA, **1**) according to the procedure of Deming and co-workers (Scheme 1),[5,6] followed by the addition of (*S*)-(−)-α-methylbenzyl isocyanide (MBI) or L-isocyanoalanyl-L-alanine methyl ester (L,L-IAA) to the reaction mixture. Upon addition of the isocyanide to the PBLG homopolymer with the active nickel complex still attached (intermediate **2**, Scheme 1),[5] a color change from red to yellow was observed, which indicated an alteration in the coordination sphere of the metal. From previous studies by Deming and co-workers[12] it is known that the N-terminus of the growing polypeptide chain can be terminated when **2** is treated with an electrophile. An isocyanide coordinated to a nickel(II) center is an electrophilic species. We therefore expect that the coordinated primary amine is able to react with an incoming isocyanide, likely through the temporary formation of a five-coordinate complex,[13] to yield a carbene-like initiator complex for the isocyanide polymerization.[9,11] This polymerization subsequently commences through the coordination of free monomers to the formally nickel(II) center (possibly helped by the partial dissociation of the bpy ligand) and their insertion in the growing polyisocyanide chain. More detailed experiments to elucidate the precise polymerization mechanism are currently in progress.

During polymerization of the L,L-IAA monomer, gelation of the reaction mixture was observed within minutes after addition of the isocyanide, which indicates its rapid polymerization and the formation of high-molecular-weight material. After workup, block copolymers free from residual homopolymers were isolated by selective solvent extractions. The block copolymers were characterized by ^{1}H NMR, FTIR, and CD spectroscopy and gel permeation chromatography (GPC; see the Supporting Information for details).

PBLG and the copolymers were first studied by GPC in THF, which provided direct evidence of the formation of the block copolymers. PBLG aggregates in this solvent, and thus gives rise to a broad peak.[14] The resultant block copolymer had a smaller elution volume, which indicates a higher molecular weight than the PBLG homopolymer. However, the rigid nature of the copolymers prevented calibration with standards such as polystyrene. The polymers were subsequently studied in 0.1 M LiBr in DMF at 65 °C. While PBLG is completely soluble without any aggregation in this solvent, the block copolymers did not dissolve, thus indicating the absence of any residual homopolymer. GPC analysis at 65 °C in this solvent provided the molecular weight parameters of the PBLG block isolated from a sample taken before addition of the isocyanide monomers, which allows the determination of the degree of polymerization of the block copolymers by ^{1}H NMR spectroscopy (Table 1). The degree of polymeri-

[a] Molecular weight data were obtained by GPC at 65 °C by using 0.1 M LiBr in DMF as the solvent and polystyrene standards. [b] Degree of polymerization. [c] Determined by integration of the ^{1}H NMR spectrum measured in $CDCl_3$ or CD_2Cl_2. [d] Determined by using GPC data of the PBLG block and ^{1}H NMR data of the block copolymer.

zation (DP) of the polyisocyanide block was determined by analysis of the integrals of the protons of the methyl groups in the case of L,L-PIAA, or the phenyl group in the case of PMBI, relative to the benzylic protons of the PBLG segment. Further evidence for the formation of block copolymers came from AFM studies. A relatively short contour length was observed for the polypeptide homopolymer upon deposition of the sample on mica (not shown), while significantly longer individual polymer chains could be visualized for the block copolymers (Figure 1).

Figure 1. AFM image of isolated PBLG-*block*-L,L-PIAA strands. The sample was prepared from a 0.01 g L^{-1} polymer solution in $CHCl_3$.

FTIR spectroscopic studies were carried out on films cast from a suitable solvent. A selection of the IR vibrations is given in Table 2. The PBLG homopolymer adopts a typical α-helical structure as is evident from the amide I and amide II positions. No indications were found for β-sheet secondary structures. The block copolymers showed a shoulder ($\tilde{\nu}$ = 1614 cm^{-1}) on the amide I vibration, indicative of an imine IR vibration. In the case of PBLG-*block*-PMBI, an amide I vibration was observed at 1650 cm^{-1}, showing the stability of the α-helical PBLG. A shift was observed in PBLG-*block*-L,L-PIAA, which indicates that a mixture of the PBLG α-helix and the β-sheet of L,L-PIAA was present.

Table 2: Selected IR spectroscopic data [cm^{-1}].

Polymer	$\tilde{\nu}_{\text{amide I}}$	$\tilde{\nu}_{\text{amide II}}$	$\tilde{\nu}_{\text{amide A}}$
PBLG	1650.0	1548.0	3292.0
L,L-PIAA	1657.0	1532.0	3276.0
PBLG-*block*-L,L-PIAA	1654.0	1530.3	3270.5
PBLG-*block*-PMBI	1650.0	1548.0	3291.0

CD analysis confirmed the existence of conformationally ordered block copolymers, in agreement with the FTIR studies. The helical structure of the PBLG segment gave a double minimum at 222 and 210 nm. Furthermore, the chiral polyisocyanopeptide displayed a single Cotton effect centered around ≈315 nm, which is typical for the n–π* transition of the C=N chromophores in these materials.[8] Together the FTIR and CD spectra revealed that the PBLG-*block*-L,L-PIAA has three secondary structural motifs within one macromolecule, that is, an α-helical polypeptide segment and a polyisocyanide helix with side arms organized in a parallel β-sheet, which to our knowledge is unprecedented.

Preliminary self-assembly studies were performed in organic solutions. The formation of spherical objects was observed upon fast drying of a solution of PBLG-*block*-L,L-PIAA (Figure 2). Confocal laser scanning microscopy revealed that these objects were actually polymersomes with a uniform diameter of 7.5 μm (standard deviation of 0.9 μm).[15] Slow evaporation resulted in the formation of closed films, which suggests that the polymersomes are a kinetically trapped architecture. Polarized optical microscopy studies showed that the polymers were aligned and confirmed that the polymersomes were hollow (Figure 2). However, PBLG-*block*-PMBI was unable to assemble into spheres and only formed a continuous film. The absence of the stabilizing hydrogen-bonding array along the polymeric backbone of the polyisocyanide segment in this block copolymer will likely result in a less well-defined helix, which in return will affect the self-organizing properties of the macromolecule.[3] This finding may explain why no defined aggregates are formed from PBLG-*block*-PMBI under the applied conditions.

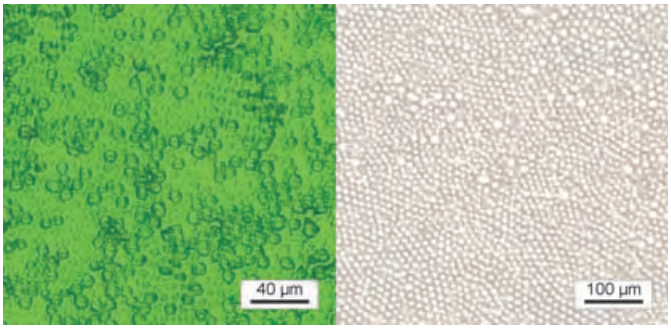

Figure 2. Confocal laser scanning (left) and optical microscope (right) images showing the typical morphologies of PBLG-*block*-L,L-PIAA. The sample was prepared by spreading drops of dilute chloroform solutions (1 mg mL^{-1}) on glass slides.

In summary, we have found a route to synthesize rigid rod–rod block copolymers comprising a peptide block and a

polyisocyanide block. These compounds assemble upon drying into ordered layers of hollow capsules with potential applications in the fields of therapeutics or biomaterials. All protected amino acids and isocyanides are in principle compatible with the block copolymer synthesis, which allows a wealth of hybrid materials to be synthesized. As the secondary structure of the polymer segments can be controlled, for example, during the synthesis or by external stimuli, it is expected that aggregate formation can also be controlled.[4,9] In-depth investigations of the self-assembly of the block copolymers and the polymerization mechanism are in progress.

Carbon Dioxide Fixation

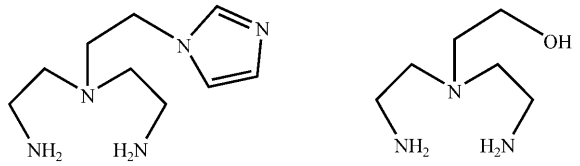
Copper(II) and Zinc(II) Complexes Can Fix Atmospheric Carbon Dioxide**

Ling-Yan Kong, Zheng-Hua Zhang, Hui-Fang Zhu, Hiroyuki Kawaguchi, Taka-aki Okamura, Mototsugu Doi, Qian Chu, Wei-Yin Sun, and Norikazu Ueyama*

In the past few decades various zinc(II) complexes with polyamine ligands have been synthesized as models of zinc(II)-containing enzymes, in particular carbonic anhydrase.[1] From these studies, zinc(II) and zinc(II)-bound hydroxides have been demonstrated to play important roles in the hydrolysis of the substrates. However, zinc(II)–polyamine complexes that can fix carbon dioxide have not been reported until recently.[2]

The chemical fixation and activation of carbon dioxide has drawn long-standing interest as excess CO_2 is an atmospheric pollutant and also because CO_2 could be used as an attractive C_1 feedstock for the preparation of useful carbon-containing compounds by the reaction of CO_2 with metal complexes.[3] So far, a great deal of research has been performed on the coordination chemistry of CO_2 and its hydration products HCO_3^- and CO_3^{2-}.[4]

The focus of our attention is the reaction of imidazole-containing ligands with a variety of metal salts.[5] Previous studies have shown that the nature of the organic ligand is crucial for determining the structure and properties of metal complexes.[6] Following this approach, we prepared a new ligand L (Scheme 1) by incorporation of an imidazole group into a polyamine ligand and report herein its copper(II) and zinc(II) complexes, which contain a network formed with the aid of CO_3^{2-}.



Treatment of a mixture of L and $M(ClO_4)_2{\cdot}6H_2O$ (M = Cu, Zn) with imidazole at pH 9 in air gave the complexes $[M_3(L)_3(\mu_3\text{-}CO_3)](ClO_4)_4{\cdot}n\,CH_3CN$ (**1a**: M = Cu, $n = 3$; **1b**:

Scheme 1. Structures of ligands L and L0.

M = Zn, $n = 1$) by slow evaporation. Subsequent crystallographic studies confirmed that **1a** and **1b** have the same framework structure, although they crystallize in a hexagonal unit cell with space group $P6_3$ and a trigonal unit cell with space group $P3c1$, respectively.[7] No imidazole or imidazolate group is found in the complex; instead, a carbonate anion is present. Complex **1b** can also be obtained by treatment of L with $Zn(ClO_4)_2 \cdot 6H_2O$ at pH 9 without addition of imidazole.

As illustrated in Figure 1a, each metal atom is coordinated by four N atoms from two different ligands L, and, in turn, each ligand L links two metal centers through its N donor atoms. It is noteworthy that three metal atoms and three ligands L form a trigonal M_3L_3 21-membered ring with a metal–metal separation of 9.24 Å in **1a** and 9.15 Å in **1b**. These trigonal rings are further linked by the μ_3-CO_3^{2-} anions through their three O atoms to generate a 2D network structure (Figure 1b). Thus, each metal center is pentacoordinated with a distorted trigonal-bipyramidal geometry. To the best of our knowledge, this is the first example of a polymeric carbonate complex with supramolecular use of a polyamine ligand containing an imidazole group, although di-, tri-, and tetranuclear zinc(II) carbonate complexes are known.[8] The cationic layers of **1a** and **1b** are packed in an ABAB fashion along the *c* axis to form trigonal channels filled with acetonitrile molecules. The perchlorate anions are located between the cationic layers.

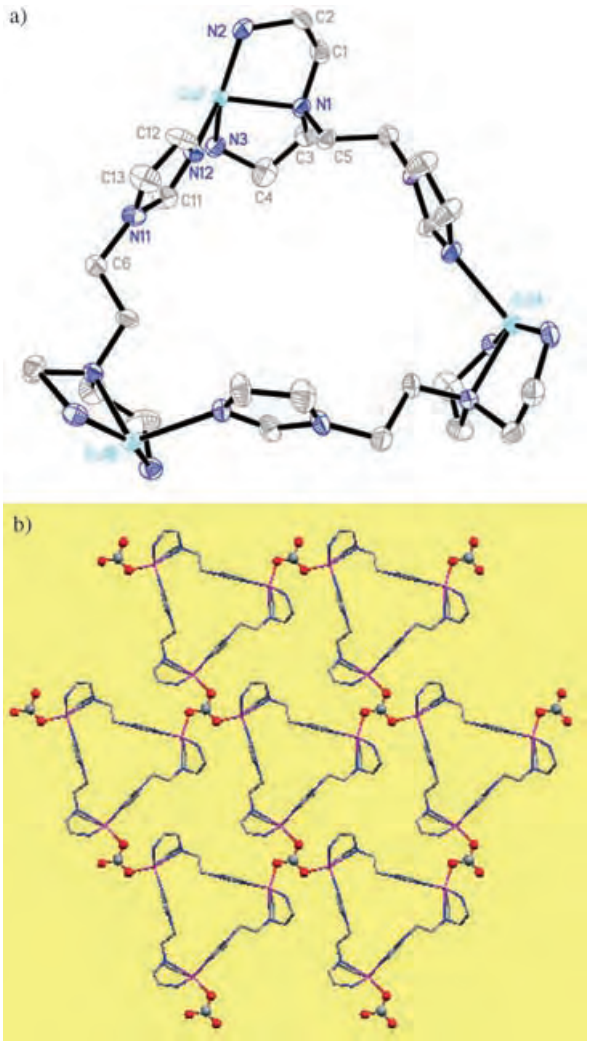

Figure 1. ORTEP drawing of a) the trigonal M_3L_3 structure of **1a**, with thermal ellipsoids at the 50% probability level, and b) the 2D network linked by carbonate anions.

To determine the origin of the carbonate ligands in **1a** and **1b**, the same reactions of L and imidazole with metal perchlorate salts were carried out under an inert atmosphere (Ar or N_2); the zinc(II) complex $[Zn_2(L)_2(im)](ClO_4)_3 \cdot 2CH_3CN \cdot 0.5H_2O$ (**2**; im = imidazolate anion) was successfully isolated and characterized. A single-crystal X-ray analysis[9] revealed that complex **2** features an infinite 1D ladder structure in which the imidazolate units act as the rungs (Figure 2). Each zinc(II) center has a slightly distorted

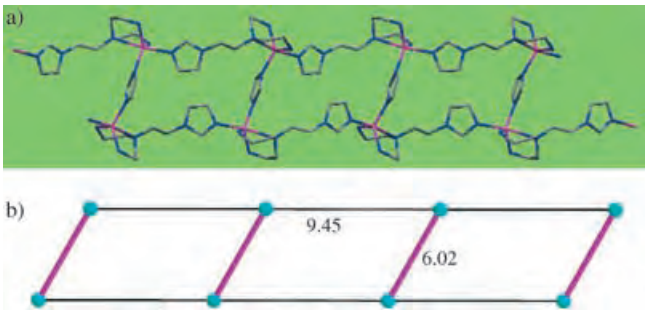

Figure 2. a) 1D ladder structure of **2**. b) The simplified ladder of **2**, where the ligands L and the imidazole units are presented by thin (black) and thick (violet) lines, respectively, and the solid balls denote zinc(II) centers.

trigonal-bipyramidal geometry which is the same as that in **1b**, except that the N atoms of the imidazolate ligands in **2** replace the O atoms of the carbonate ligands in **1b**. Similar to **1b**, each ligand L bridges two zinc(II) centers and each metal atom links two ligands L, although in this case to give an infinite 1D chain structure (Figure 2a) rather than an M_3L_3 ring (see Figure 1a). The imidazolate groups link zinc(II) centers from two 1D chains to form a noninterpenetrating 1D ladder structure (Figure 2a). The Zn···Zn distances in the ladder are 6.02 Å along the rungs and 9.45 Å along the side-rails (Figure 2b). The 1D ladders are linked together by hydrogen bonds with the perchlorate anions, and the voids between the ladders are filled with CH_3CN molecules.

The existence of the carbonate ligands in **1a** and **1b**, and the reaction of **2** with CO_2, were further investigated by IR and NMR spectroscopy. The IR spectra of **1a**, **1b**, and **2** were measured in the solid state. Strong carbonate-related vibra-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tions are observed at 1440 cm^{-1} in **1a** and at 1457 cm^{-1} in **1b**.[10,11] The presence of carbonate ligands in **1b** was further confirmed by the solid-state ^{13}C NMR spectrum. As shown in Figure 3, a peak at $\delta = 167.9$ ppm is observed in the ^{13}C NMR spectrum of **1b**, which can be assigned to the coordinated

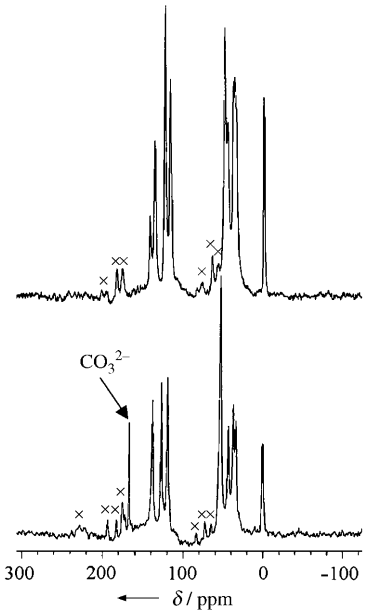

Figure 3. Solid-state ^{13}C NMR spectra of **1b** (bottom) and **2** (top). Peaks labeled with × are spinning sidebands.

carbonate ligand. Complex **2** was found to be stable in the solid state since no IR spectral changes were observed after three weeks of exposure of powdered **2** to the air.[11] However, in solution, the ^1H NMR spectra in CD_3CN/D_2O (2:1) show that **2** reacts with CO_2 quickly.[11] The reaction product of **2** with CO_2 in solution is **1b**, as confirmed by recrystallization of **2** from an aqueous acetonitrile solution in air by slow evaporation.[12]

These results clearly show that the carbonate anion in **1a** and **1b** comes from the hydration of atmospheric carbon dioxide, therefore the copper(II) and zinc(II) complexes of L can fix carbon dioxide. It should be noted that the introduction of the imidazole group into the ligand L plays a crucial role in fixing the CO_2, since the polyamine ligand L0 (see Scheme 1), which contains a hydroxy group, reacts with zinc(II) perchlorate hexahydrate in air to give mono- and dinuclear zinc(II) complexes without absorption of carbon dioxide.[13] In addition, the anion was found to strongly influence the formation of the infinite framework.[14]

Experimental Section

Synthesis of L: The amino groups of L0 were protected by reaction of L0 with phthalic anhydride. The amine-protected L0 (35 g, 0.086 mol) was brominated by slow addition of freshly distilled PBr_3 (7.5 mL) under N_2 in the temperature range 95–100 °C. The pure brominated product (10 g, 0.021 mol), well-ground K_2CO_3 (7.1 g, 0.051 mol), and imidazole (2.9 g, 0.042 mol) in dry dimethylformamide (50 mL) were stirred for 8 h at 100 °C. After cooling to room temperature, the solution was poured into saturated brine (100 mL) and extracted with ethyl acetate to give *N*-(2-imidazolylethyl)-*N*-bis(2-phthalimidoethyl)amine. Deprotection of the amino groups was carried out by treatment with hydrazine to give ligand L·4 HCl. Total yield from L0: ca. 20%, m.p. 192 °C.

Synthesis of **1a**: The reaction was carried out in an open vessel equipped with a magnetic stirrer at room temperature. A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (42.0 mg, 0.11 mmol) in water (2 mL) was added to an aqueous solution (2 mL) of L·4 HCl (38.9 mg, 0.11 mmol) at pH 8 (adjusted by addition of 0.5 M NaOH), and the pH value of the solution was then adjusted to 9 by further addition of 0.5 M NaOH. An aqueous solution (1.5 mL) of imidazole (7.7 mg, 0.11 mmol) was then added and the mixture stirred. The resulting colorless precipitate was dissolved by addition of acetonitrile (ca. 5 mL) to the mixture. Colorless crystals of **1a** were obtained, in about 50% yield, by slow evaporation of the filtrate over two or three days. $C_{34}H_{66}N_{18}O_{19}Cl_4Cu_3$: calcd. C 29.95, H 4.88, N 18.49; found C 29.72, H 4.84, N 18.43.

Synthesis of **1b**: This compound was obtained by the same procedure as described for **1a** but with $Zn(ClO_4)_2 \cdot 6H_2O$ (42.2 mg, 0.11 mmol) instead of $Cu(ClO_4)_2 \cdot 6H_2O$. Yield: ca. 60%. $C_{30}H_{60}N_{16}O_{19}Cl_4Zn_3$: calcd. C 28.00, H 4.70, N 17.42; found C 28.10, H 4.80, N 17.48.

Synthesis of **2**: This complex was synthesized following the same procedure as that for **1b** except that the reaction was carried out under an argon atmosphere at room temperature. The yield was ca. 50%. $C_{21}H_{42}N_{12}O_{12.5}Cl_3Zn_2$ (noncoordinated CH_3CN was lost upon drying) calcd. C 28.03, H 4.70, N 18.68; found C 27.77, H 4.63, N 18.65.

Crystallographic analyses: Crystallographic data for complex **1a** were collected with a Rigaku RAXIS-RAPID Imaging Plate diffractometer at 200 K, using graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.7107$ Å). The structure was solved by direct methods with SIR92 and expanded using Fourier techniques. The collection of crystallographic data for complexes **1b** and **2** was carried out on a Rigaku Mercury or a Saturn CCD area detector at 173 and 123 K, respectively, using graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.7107$ Å). The structure of **1b** was solved by Patterson methods with DIRDIF99 PATTY and that of **2** was solved by direct methods with SIR97 and expanded using Fourier techniques. All non-hydrogen atoms were refined anisotropically by the full-matrix least-squares method. The hydrogen atoms, except those of the water molecules, were generated geometrically. CCDC-263621 (**1a**), -263622 (**1b**), and -263623 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Molecular Devices

A DNAzyme That Walks Processively and Autonomously along a One-Dimensional Track**

*Ye Tian, Yu He, Yi Chen, Peng Yin, and Chengde Mao**

Herein, we report a DNA nanodevice that autonomously and processively moves along a DNA track. The motion mechanism of this DNA device is reminiscent of that of single-headed myosins I, a family of cellular protein motors.[1] The DNA device contains a DNA enzyme (DNAzyme) that constantly extracts chemical energy from its substrate molecules (RNA) and uses this energy to fuel the motion of the DNA device.

Nanomachines have potential applications in smart materials, sensors, and optoelectronic devices.[2] Many approaches have been explored to develop such nanomachines. By taking advantage of a rich body of knowledge of DNA biophysics, various DNA nanomachines have been rationally designed and built based on conformational changes.[3] The motions include opening/closure, extension/contraction, and rotation. More complex nanomechanical devices, such as walkers and gears, have also been demonstrated.[3l,m,o] However, such devices need human intervention for each step of their motions. The DNA structures change only once when the conditions of the solution are changed or a DNA strand is added. These DNA devices are in sharp contrast with cellular protein motors and manmade machines at the macroscale, both of which can continuously work without human interference.

An autonomous DNA motor has recently been reported[3k,n]—here we refer to "autonomous" as being self-contained and not requiring human interference or other external active components such as protein enzymes. The motor performs an extremely simple motion: open and close. In a related, autonomous system, a DNA fragment could be continuously translocated along one direction by natural proteins (a combination of a DNA ligase and two restriction endonucleases).[3o] Logically, we wondered if it is possible to construct a more sophisticated, self-contained autonomous motor that could constantly walk or rotate. Herein, we demonstrate that such a machine is feasible.

The walking mechanism of the new system integrates DNAzyme activity and a strand-displacement strategy (Figure 1). The system consists of a walker and a track: The walker is a 10–23 DNAzyme, **E**,[4] which is a DNA molecule that can cleave RNA with sequence specificity (Figure 1A).

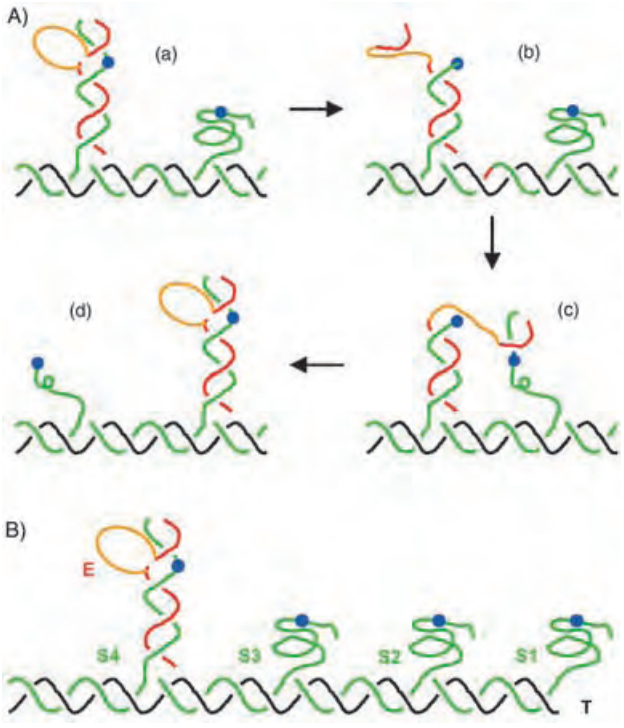

Figure 1. Scheme of a walking DNAzyme and its track. A) The walking principle. B) A construction where the walking DNAzyme is at one end of its track. Black lines: template (**T**); green lines: substrate (**S**); red/yellow lines: a 10–23 DNAzyme (red), with the catalytic core highlighted (yellow); blue dots indicate the bonds to be cleaved by the DNAzyme.

The 10–23 DNAzyme is the 23rd clone after the 10th round of selection in an experiment performed in vitro.[4] The track is a regular, linear array of RNA substrate, **S**. The 10–23 DNAzyme contains a catalytic core and two recognition arms that can bind to a RNA substrate through Watson–Crick base-pairing (Figure 1 A (a)). The two arms are asymmetrical by design: one arm is 7 bases long and the other is 15 bases long. When the RNA substrate is cleaved, the short fragment (7-base) dissociates from the DNAzyme and the long fragment (16-base), in contrast, remains stably associated with the DNAzyme under the experimental condition (b). After the short RNA fragment dissociates, the short arm of the DNAzyme becomes unpaired and can search for other complementary single strands. The RNA substrate next to the enzyme base-pairs with the short recognition arm of the DNAzyme (c). The resulting short duplex is stable as a result of intracomplex hybridization. Following this hybridization, a strand replacement occurs through branch migration, whereby the intact RNA substrate replaces the cleaved RNA fragment to result in a more stable, longer, pseudocontinuous DNA duplex (d). In this process, the DNAzyme moves from one RNA substrate to the next RNA substrate. The process can be repeated such that the DNAzyme moves continuously. Thus, the DNAzyme autonomously and processively moves along the track.

Herein, DNA–RNA chimeras were used as the substrate **S**. In the chimeras, only the two residues that flanked the bond to be cleaved were RNA residues, while all other residues were DNA. Such chimeras could be cleaved efficiently by the DNAzyme, but were more stable than RNA. Each **S** strand contained two segments: one for enzyme recognition and the other as a positional tag. A single template strand, **T**, could base-pair with the positional tags and organize four substrates (**S1**, **S2**, **S3**, and **S4**) into a regular, one-dimensional substrate array to constitute the track (Figure 1 B). The spacings between any two neighboring substrates was two helical turns (7 nm).

The overall DNA construct was stable. We assembled the DNA structure in a stepwise fashion and then analyzed all complexes by native polyacrylamide gel electrophoresis (PAGE, Figure 2). Each complex appeared as a single band with expected mobility which suggests that each combination of DNA strands led to the formation of a stable complex.

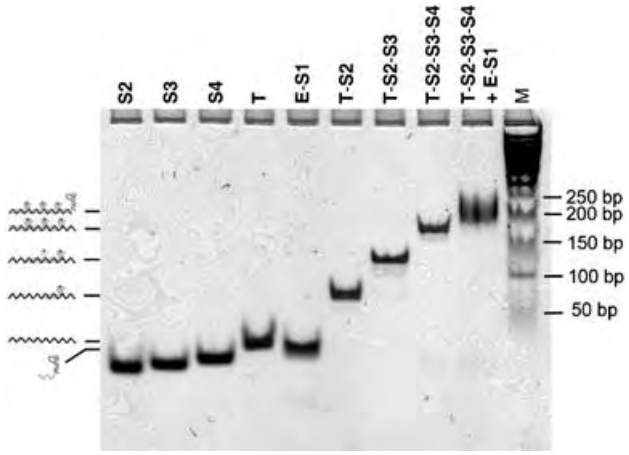

Figure 2. Native PAGE analysis of the DNA complexes. Lane M contains a series of DNA size markers (M = marker; bp = base pair).

The DNAzyme can walk in either direction, **S1**→**S4** or **S4**→**S1** (Figure 1 B). The movement of the DNAzyme was demonstrated by monitoring the differential behaviors of substrate cleavage (Figure 3). When the DNAzyme walks from **S1** to **S4**, the cleavage of the substrate would be in the time order of **S1**–**S2**–**S3**–**S4**, with **S1** cleaved initially and **S4** cleaved last of all. We performed an experiment to confirm this, with separate preparation of complexes **T**-**S2**-**S3**-**S4** and **E**-**S1** and then mixed the two complexes at 22 °C to form an intact track with the DNAzyme at **S1** (Figure 3). Upon mixing, the movement started. The DNAzyme moved from **S1** to **S2** to **S3** and finally to **S4**. This movement was accompanied by sequential cleavage of the substrate. Thus, the order of the substrate cleavage reflects the movement of the DNAzyme. Figure 3 A clearly shows that the digestion order is **S1**, **S2**, **S3**, and **S4**, which is consistent with the design. Note that a substantial population of **S1** was likely to be cleaved before or during association of complex **E**-**S1** with complex **T**-**S2**-**S3**-**S4**.

To further confirm this observation, we performed a similar experiment at 22 °C, but changed the movement to the opposite direction, **S4**→**S1**. Clearly, the order of cleavage reversed (Figure 3 B). When the walking process was performed at 37 °C in both directions, similar orders of substrate

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

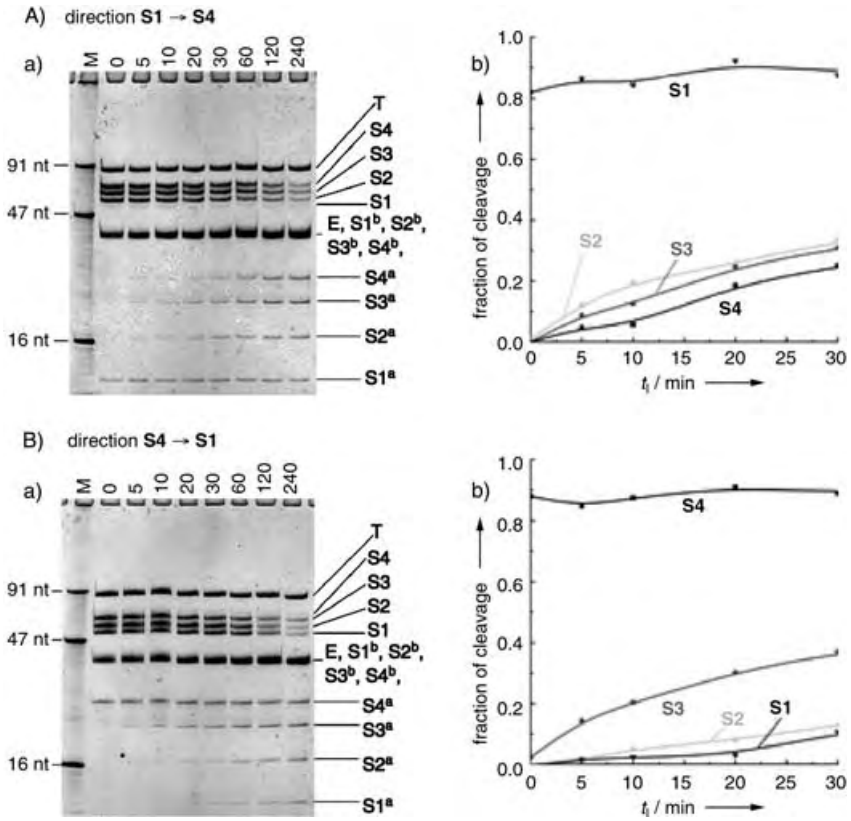

Figure 3. Denaturing PAGE monitoring the movement of the DNAzyme at 22 °C in the directions **S1**→**S4** (A) and **S4**→**S1** (B): a) gel images as a function of incubation time, t_i (lanes M contain three single-stranded DNA size markers; nt = nucleotide (bases); superscripts a and b denote short and long cleaved substrate fragments, respectively); b) quantification of the differential substrate cleavage.

cleavage were observed to those seen at 22 °C, but the process occurred faster at the higher temperature (see Supporting Information). When these walking experiments were repeated (at both temperatures and in both directions), exactly the same orders of substrate cleavage were observed (see Supporting Information).

To exclude the possibility that DNAzyme dissociates from the track after cleaving each substrate, we performed a control experiment (Figure 4). The DNAzyme and substrate

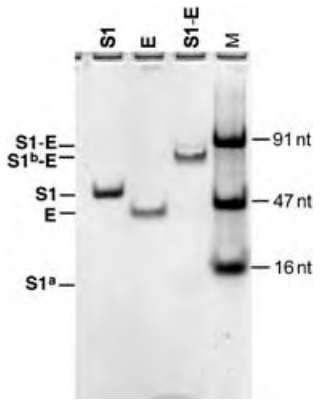

Figure 4. Native PAGE shows that complex **E-S**^{b} is stable, and no dissociation can be observed. Lane M contains three single-stranded DNA size markers.

(or the long cleaved substrate fragment) formed stable complexes under a native condition. The complexes migrated much slower than either the DNAzyme or the substrate alone by native PAGE, and no dissociation was observed. Thus, we confirmed that the DNAzyme did not dissociate from the track and that the movement was processive. In another control experiment, one substrate (**S4**) was incubated with the DNAzyme for two hours, and then another substrate (**S1**) was added to the solution. Upon addition of **S1**, aliquots of the mixture were withdrawn at various time intervals and the enzyme activity was quenched by addition of an excess of EDTA to remove free Mg^{2+}, an essential cofactor of the DNAzyme. The samples were then analyzed by both denaturing and native PAGE, which showed that **S4** was almost completely cleaved, while **S1** underwent almost no cleavage (see Supporting Information). This experiment confirmed that the enzyme could migrate from one substrate to another much more efficiently when both substrates were located along one track than when the substrates were in different complexes.

In conclusion, we have developed a DNA nanodevice that can autonomously move along an engineered track. In similar fashion to a cellular protein motor, it consumes chemical energy for autonomous motion. However, the current DNA device destroys its track when it walks, so the track is not reuseable. Relative to protein motors, the current DNA device moves extremely slowly. On the other hand, cellular protein motors move along straight protein tracks, whereas our engineered DNA system is much more versatile. It is conceivable to engineer tracks to allow a DNA device to move in a more complicated geometry—for example, smooth curves and sharp turns. Other questions that remain include: Can we develop a system with a reuseable track? Can we directly visualize the movement? Can the DNA device transport any cargo? Our next objective is to address these challenges.

Experimental Section

Oligonucleotides: All oligonucleotides were designed with a computer program SEQUIN[5] and purchased from Integrated DNA Technologies (IDT), Inc. CGA ATC AGC ACT TTC GCT TCC ATG CGT TAG ATA CT-3′; Strand **S4**: 5′-TTT TTT TTT TTT TTT TTT TTG TCA CTC rArUG TCC GAA TCA GCA CTT TCG CTG CTA TGC CAC AGA TGG T-3′.

Formation of the Walking System: 1) For the system in which the DNAzyme moved from **S1** to **S4**, the two parts (strands **E** and **S1** (part A); strands **T**, **S2**, **S3**, and **S4** (part B)) were prepared separately. For each part, 1.0 μM DNA strands were combined in an equimolar ratio in TAE/Mg^{2+} (TAE = Tris–acetate–EDTA; EDTA = ethylenediamine tetraacetic acid) buffer, which contained Tris buffer (40 mM, pH 8.0), acetic acid (20 mM), EDTA (2 mM), and $Mg(OAc)_2$ (12.5 mM). Parts A and B were formed by quickly cooling the DNA solution from 95 °C to 22 °C over 10 min. 2) For the system in which the DNAzyme moved from **S4** to **S1**, part A consisted of strands **E** and **S4** while part B consisted of strands **T**, **S1**, **S2**, and **S3**.

DNAzyme Walking: An equimolar ratio of parts A and B was mixed and then incubated at 22 °C or 37 °C to start the movement. At various time intervals during the experiment, a 10-μL aliquot was taken out and the reaction was quenched by the addition of a solution of EDTA (2 μL, 0.1 M) and formamide (6 μL), then the mixture was left on dry ice. All samples were then analyzed by denaturing PAGE.

Denaturing PAGE: Gels contained 20% polyacrylamide (acrylamide/bisacrylamide, 19:1) and urea (8.3 M) and were run at 55 °C. Tris–borate–EDTA (TBE) buffer, which comprised Tris (89 mm, pH 8.0), boric acid (89 mm), and EDTA (2 mm), was used as the separation buffer. Gels were run on a Hoefer SE 600 electrophoresis unit at 600 V (constant voltage).

Native PAGE: Gels contained 6–12% acrylamide (19:1, acrylamide:bisacrylamide) and TAE/Mg^{2+} buffer. 1 μL of a solution of tracking dye, which contained TAE/Mg^{2+}, 50% glycerol, and 0.2% each of Bromophenol Blue and Xylene Cyanol FF, was added to each sample (0.3 μg DNA in 10 μL of TAE/Mg^{-2+}). Gels were run on an FB VE-10–1 vertical electrophoresis system at 120 V (constant voltage) at 4 °C. Gels were stained with Stains-All (0.01% Stains-All from Sigma, 45% formamide) and then scanned.

Quantification of Reaction: Upon completion of electrophoresis, the gels were stained with Stains-All dye (Sigma) and the images were scanned into a computer as jpeg files. With the image files, each band was estimated using OptiQuant (Packard), an image analysis and processing software.

A Free-Running DNA Motor Powered by a Nicking Enzyme**

Jonathan Bath, Simon J. Green, and Andrew J. Turberfield*

Herein, we present a simple linear motor, built from DNA and a restriction enzyme, which moves a DNA cargo in discrete steps along a DNA track. Movement is powered by a nicking enzyme that cuts the track. Damage to the track in the wake of the cargo imposes directionality.

The specificity of base-pairing, the rigidity of short segments of the double helix, and the flexibility of single-stranded segments make DNA an ideal material for construction of nanometer-sized mechanical devices.[1–7] Such devices can generate forces of the order of picoNewtons,[2] in the same range as the forces developed by single-molecule

protein motors.[8,9] A typical device relies on the binding of a fuel strand of DNA to trigger a conformational change. The device can be restored to its initial conformation by subsequent addition of a reset strand that strips the fuel strand from the device. The operation of these devices can be coupled to stepwise movement along a track.[10,11] There is interest in designing free-running devices that operate continuously while the supply of fuel lasts. One approach is to design a secondary structure to slow the conversion of DNA fuel into waste unless catalyzed, and to couple the catalysis of fuel to the operation of a device.[12] Another approach is to use the hydrolysis of the phosphodiester backbone of DNA[6] or a combination of DNA and ATP hydrolysis.[7] We have used the hydrolysis of DNA, catalyzed by a restriction enzyme, as the energy source for our motor. Autonomous, directional motion is achieved by making DNA cleavage conditional on the state of our device. The device moves a cargo stepwise along a one-dimensional track; damage caused to the track by the restriction enzyme prevents the cargo from stepping backwards and therefore imposes directionality—a "burnt bridges" mechanism.[13]

A suitable track is a rigid self-assembled structure with many identical single-stranded stators attached periodically along its length. Motion is driven by cleavage of the stators by the restriction endonuclease N.BbvC IB (New England Biolabs). N.BbvC IB binds to double-stranded DNA at a specific 7-bp (bp = base pair) recognition sequence and catalyzes cleavage of the DNA backbone of one strand only to introduce a nick at a precisely determined position. This nicking property has been specifically engineered by modification of the naturally occurring heterodimeric enzyme BbvC I.[14] The cargo is an oligonucleotide that can hybridize to any one of the stators. It is only when the cargo is hybridized to a stator that N.BbvC IB can cut the stator to release a short fragment of the stator and promote movement of the cargo onto the next stator along the track.

Figure 1 shows one step of the motor. In our experiments, the stators are 24-nt (nt = nucleotide) sequences attached to a double-stranded track every 21 bp (7 nm) by a 3-nt flexible linker. Stators are attached at the 3′ end and, when hybridized with the cargo, can be cut by N.BbvC IB at 8 nt from the 5′ end. The melting temperature of the 8-nt stator fragment generated by cutting is calculated to be between 13 °C and 20 °C, well below the operating temperature of the motor (37 °C). Figure 1 a shows the cargo bound to stator S_i. Cutting by N.BbvC IB releases an 8-nt fragment of the stator and promotes movement of the cargo onto an adjacent stator. Release of the short stator fragment leaves the cargo with an 8-nt single-stranded overhang that can bind to the intact stator S_{i+1}, initiating an energetically favorable step to S_{i+1} (Figure 1 b). The backwards step to S_{i-1} is strongly inhibited because S_{i-1}, which was cut in the previous step, lacks the 8-nt section that is complementary to the exposed overhang of the cargo. The step from S_{i+1} to S_i is a simple branch-migration reaction. The initial part of this reaction involves a random walk of the branch point that marks the junction between sections of the cargo bound to the competing stators S_i and S_{i+1}. For each base pair broken between cargo and S_i, a base pair can be formed between cargo and S_{i+1}. However, the lengths of the tethers that hold the stators to the rigid track limit this process, and stepping to S_{i+1} requires thermally activated, spontaneous dissociation of the last 3–6 nucleotides of the cargo from S_i. After spontaneous dissociation of the last few nucleotides, the cargo arrives at S_{i+1} (Figure 1 c) and the operational cycle is complete.

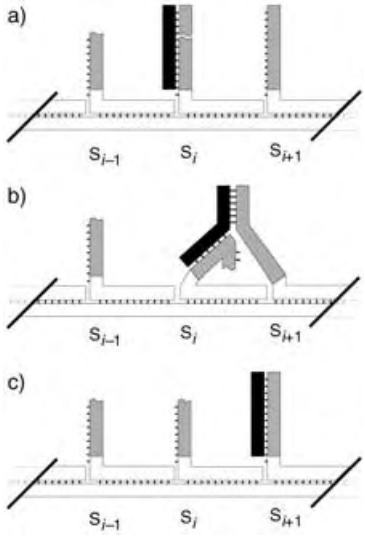

Figure 1. Design of a linear motor powered by a nicking enzyme. DNA strands are represented as black and gray ribbons, with black lines indicating base pairs. The track is an array of periodically spaced single-stranded stators. The cargo (black ribbon) is an oligonucleotide that can bind to any one of the stators. a) The cargo is bound to stator S_i which enables enzyme N.BbvC IB to cut the stator and release a short stator fragment and to leave the cargo with a single-stranded overhang free to bind to the adjacent stator S_{i+1}. The cargo cannot bind to S_{i-1} which was cut in the previous step. b) The cargo then steps onto S_{i+1} by a simple branch-migration reaction. For each base pair broken between cargo and S_i, a base pair can be formed between cargo and S_{i+1}. The tethers that hold the stators to the rigid track limit this process, and stepping to S_{i+1} requires spontaneous dissociation of the last few nucleotides of the cargo from S_i. c) Upon dissociation, the cargo is bound to S_{i+1} and the operational cycle is complete.

Our test track is composed of three stators, S_{1-3} (Figure 2 a, Table 1). The cargo is labeled at the 5′ end with the nonfluorescent quencher, Iowa Black. The track is labeled with Cy3 and Cy5 cyanine dyes, which are arranged such that when the cargo is bound to S_2 the signal from Cy3 is quenched and when the cargo is bound to S_3 the signal from Cy5 is quenched. The test track incorporates modifications to stators S_1 and S_3. The interaction between the cargo and S_1 spans 2 nt more than the interaction between the cargo and either S_2 or S_3 which ensures that the cargo binds more stably to S_1 than to either of the other stators: ΔG°_{37} is calculated to be -30.4, -27.1, and $-23.6\ \mathrm{kcal\,mol^{-1}}$ for binding to S_1, S_2, and S_3 respectively.[15] At equilibrium, under our experimental conditions, we calculate that the cargo is distributed between the stators S_1, S_2, and S_3 in a ratio of 94:6:$\ll$1. This distribution allows us to prepare the track with the cargo bound predominantly to S_1. The complex that forms between S_3 and the cargo contains a single mismatch within the N.BbvC IB recognition site that renders S_3 resistant to cutting.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

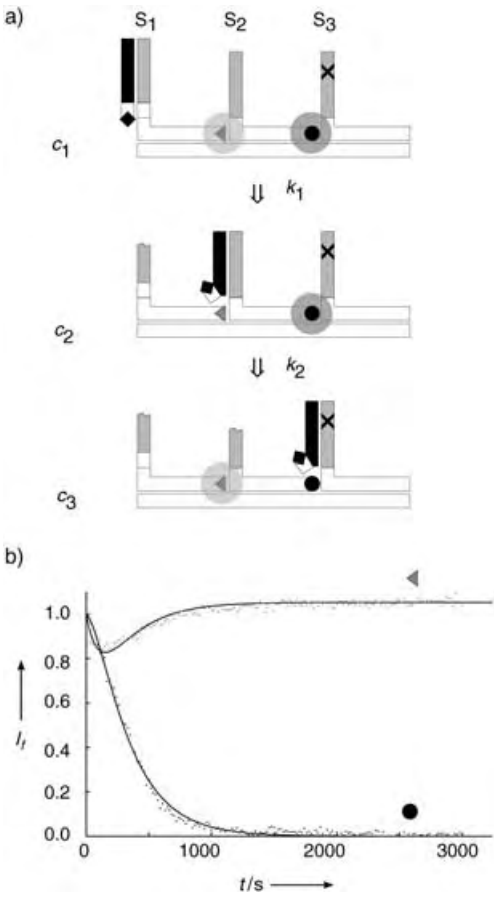

Figure 2. Operation of a linear motor powered by a nicking enzyme. a) The five strands of DNA used to assemble the test track are represented as ribbons. The black square represents the quencher Iowa Black carried by the cargo; as the cargo steps along the track, its position can be determined from the fluorescence signal of the two reporter fluorophores, Cy3 (gray triangle) and Cy5 (black circle). b) Normalized fluorescence intensities (I_f) from Cy3 (gray triangle) and Cy5 (black circle) showing the movement of the cargo when the motor was incubated with N.BbvC IB at 37 °C. The solid lines show the fit to a simple model described in the text. Fluorescence from Cy3 is transiently quenched when the cargo resides on S_2; fluorescence from Cy5 is permanently quenched when the cargo arrives at S_3.

This ensures that when the cargo reaches the "mismatch" stator S_3 it is trapped and the motor stops.

The test track was prepared by self-assembly followed by purification by polyacrylamide gel electrophoresis (PAGE) as described in the Supporting Information. To test the operation of the motor, a purified track with cargo on S_1 at a concentration of approximately 8 nM was incubated at 37 °C. Movement of the cargo from S_1 was triggered by the addition of N.BbvC IB in approximately eightfold excess relative to the concentration of the track. The position of the cargo on the track was measured by recording the fluorescence signals from Cy3 and Cy5 (Figure 2b). Quenching of the signal from Cy3 indicates that the cargo is bound to S_2; quenching of the signal from Cy5 indicates that the cargo is bound to S_3. As the cargo moves from S_1 to S_2 and then to S_3 there is a transient reduction in the signal from Cy3 corresponding to the state in which the cargo is bound to S_2. The signal from Cy5 is permanently quenched when the cargo arrives at S_3.

The movement of cargo along the test track can be modeled with two first-order rate constants—k_1, for stepping between S_1 and S_2; and k_2, for stepping between S_2 and S_3—according to Equation (1), where $c_i(t)$ is the fraction of stator i occupied by the cargo at time t.

$$\begin{aligned}\frac{dc_1(t)}{dt} &= -k_1\, c_1(t)\\ \frac{dc_2(t)}{dt} &= k_1\, c_1(t) - k_2\, c_2(t)\\ \frac{dc_3(t)}{dt} &= k_2\, c_2(t)\end{aligned} \qquad (1)$$

We have assumed that the cargo moves along a track (rather than between tracks), that it cannot hop directly from S_1 to S_3, and that the probability of a backward step is negligible. The relationships between the fluorescence intensities of Cy3 and Cy5 and the fractions c_2 and c_3 are described in the Supporting Information. The data can be fitted very well by this simple model (solid lines in Figure 2b) by using values of 0.003 s^{-1} and 0.009 s^{-1} for k_1 and k_2, respectively, to give a cargo speed of the order of 0.1 nm s^{-1}.

We performed a control experiment in which an excess of free stator is able to compete with track-bound stators for hybridization to the cargo. At a 100-fold excess of competitor, we could still see changes in the fluorescence of Cy3 and Cy5 that are characteristic of stepping of the cargo along the track. We conclude that movement of the cargo between tracks is not significant at the concentration of track used during normal operation of the motor (see Supporting Information).

Direct stepping from S_1 to S_3 is unlikely. For S_1 to approach closer to S_3 than to S_2 would require a bend of the track at S_2 of more than 120°. The fit to the data is not improved by the addition of a third rate constant corresponding to stepping of the cargo directly from S_1 to S_3 which suggests that the cargo does step sequentially along the track.

The probability of a backwards step from an intact stator to a cut stator is negligible as the free energy change is extremely large: $\Delta G^{\circ}_{37} = 10.3\ \text{kcal mol}^{-1} \approx 17\,RT$. We expect the probability of a backwards step between cut stators to be similar to that of a forwards step from an uncut stator: both processes involve blunt-strand exchange—that is, exchange without a toehold[16]—whose rates depend weakly on the length of the strand.[17] The system has been designed to ensure that both of these processes are much less probable than a forwards step from a cut to an intact stator: the cargo has an 8-nt single-stranded toehold that can bind only to an intact stator to initiate strand displacement. Such toeholds greatly increase the rate of strand displacement.[16]

Stepping requires spontaneous dissociation of the last 3–6 nucleotides of the cargo (Figure 1b). S_1 has two extra nucleotides that hybridize to the proximal end of the cargo, so stepping from S_1 to S_2 requires the spontaneous dissociation of approximately one nucleotide more than stepping from S_2 to S_3. The difference in activation energy between the two steps may account for the threefold difference in the rate constants, k_1 and k_2.

The rate at which N.BbvC IB cuts its substrate has been measured as $0.17\ \text{s}^{-1}$,[18] which is much faster than the rate at which the cargo moves along the track: motion of the cargo along the track without first cutting it can therefore be neglected. Dissociation of the 8-nt stator fragment once this has been released by the enzyme is also fast: the melting temperature of this fragment is well below the operating temperature of the device, and the dissociation rate, once the fragment has been released by the enzyme, is estimated to be $> 0.01\ \text{s}^{-1}$.[19] The rate-limiting step is either the release of product by N.BbvC IB or stepping from the cut stator to the intact stator. In a control experiment in which there was competition between free (not track-bound) stators for binding to the cargo, we have shown that in the presence of an excess of N.BbvC IB the stepping rate between stators is proportional to the concentration of competing stators (see Supporting Information). Extrapolation to the effective stator concentration on the track (see Supporting Information) gives an estimate of the order of magnitude of the stepping rate of $0.01\ \text{s}^{-1}$, which is of the same order as that measured. In contrast, the rate constant for stepping from a truncated (precut) stator is four orders of magnitude higher (see Supporting Information). We tentatively conclude that the release of product by N.BbvC IB is the rate-limiting step,[18] although the fact that k_1 and k_2 are different suggests that the spontaneous dissociation of the last few nucleotides of the cargo may also play a role.

The results presented here demonstrate the design, construction, and operation of a directional linear DNA motor driven by an enzyme that nicks DNA. The motor can be halted at a desired location by a simple modification to the track. This nanometer-scale motor moves at a speed of order $0.1\ \text{nm s}^{-1}$ along a self-assembled track.

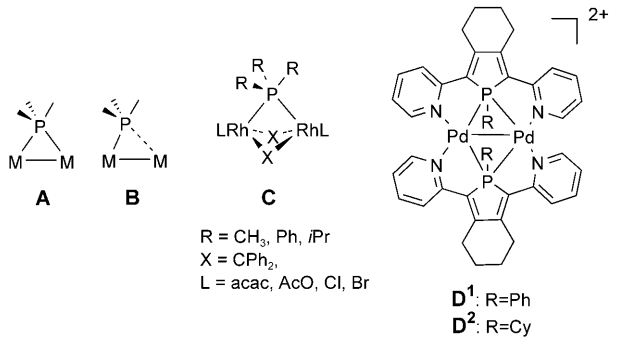
Coordination Modes

Bridging Phosphanes: Exotic or Versatile Binucleating Ligands?**

*François Leca, Christophe Lescop, Elena Rodriguez-Sanz, Karine Costuas, Jean-François Halet, and Régis Réau**

The recent discovery that tertiary phosphanes PR_3 can act as bridging ligands[1] (**A**, Figure 1) was a breakthrough in coordination chemistry,[2] since binucleating ligands potentially allow the synthesis of di- and polynuclear complexes that are of great interest in many fields, such as catalysis, bioinorganic chemistry, and materials sciences.[3] Up to now, only two types of binuclear compounds bearing symmetrically bridging phosphanes are known (Rh^{I}[1] (**C**) and Pd^{I}[4] homodimers (**D**), Figure 1). In order to establish phosphanes as versatile binucleating ligands, it is necessary to show that they can effectively stabilize other dinuclear fragments, and that they possess properties typical of well-established bridging ligands.[3] In this paper we describe the synthesis and characterization in the solid state of the first heterobimetallic complex and the first copper(I) homodimers bearing bridging phosphane ligands. Furthermore, we show that there is a continuum between symmetrically bridging (**A**) and semi-bridging (**B**)[5] coordination modes (Figure 1), a key structural feature analogous to that observed for CO,[6] which is the archetypal bridging ligand.



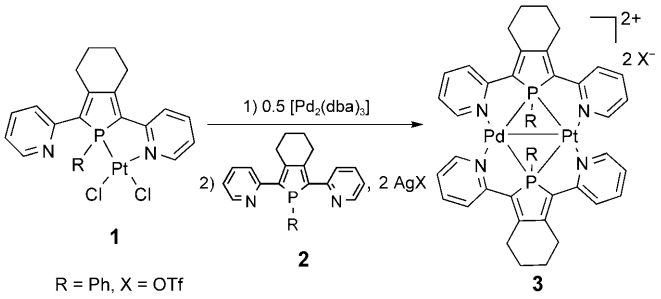


Figure 1. Bridging (**A**) and semi-bridging (**B**) coordination modes for phosphanes, and complexes **C** and **D** bearing bridging phosphanes. acac = acetylacetonate; Cy = cyclohexyl.

We have synthesized a heteronuclear Pd–Pt analog of complex $\mathbf{D^1}$ (Figure 1) by a stepwise method, which allows the sequential introduction of the metal centers.[4b] Treatment of Pt^{II} complex **1** with Pd^0, 2,5-bis(2-pyridyl)phosphole (**2**),[7] and two equivalents of AgOTf gave derivative **3**, which was isolated as an air-stable red powder (69% yield, Scheme 1).

Scheme 1. Synthesis of Pd^{I}–Pt^{I} heterodimer **3**.

High-resolution mass spectrometry data and elemental analyses are consistent with the proposed formula. Between room temperature and 173 K, the $^{31}P\{^1H\}$ NMR spectrum of **3** consists of a sharp singlet at $\delta = 49.9$ ppm ($^1J_{PPt} = 2113.5$ Hz). As expected, two sets of signals are present for the pyridyl groups in the $^{13}C\{^1H\}$ NMR spectrum.[8] It is noteworthy that heterobimetallic **3** is stable in CH_2Cl_2 solution for days; no signals corresponding to the Pd^{I} dimer $\mathbf{D^1}$ ($^{31}P\{^1H\}$ NMR: $\delta =$ 69.9 ppm) or to the corresponding, hitherto-unknown Pt^{I} dimer are observed.

The proposed structure of **3** was confirmed by an X-ray diffraction study (Figure 2).[8] The dication of **3** contains two square-planar metal centers capped by two 2,5-bis(2-pyridyl)phosphole ligands acting as six-electron μ-1κN:1,2κP:2κN donors. The geometric parameters of the 2,5-bis(2-pyridyl)-phosphole ligands are almost identical for **3** and the corresponding homometallic Pd^{I} dimer $\mathbf{D^1}$.[4] The metal–metal distance in **3** (2.7851(9) Å) is fairly long compared to typical Pd^{I}–Pt^{I} single bond lengths,[9] but is similar to that measured for the dipalladium complexes **D** (2.767(1)–2.787(1) Å).[4] The dication of **3** has a crystallographic center of symmetry at the midpoint of the metal–metal bond, which induces an equal occupancy of the Pd and Pt atoms at the two metal positions.[10] The metal–nitrogen bond lengths in **3** and $\mathbf{D^1}$ are essentially equal, although the geometry of the M_2P_2 core differs: for the homobimetallic complex $\mathbf{D^1}$ the P atoms bridge the two Pd^{I} centers symmetrically (Δ(μ-P–Pd) = 0.009(4) Å),[4] and the M_2P_2 core forms a diamond shape (**E** in Figure 2; $M^1 = M^2 = Pd$), whereas in the heterodimer **3** each μ-P atom binds the two metal centers nonsymmetrically (Δ(μ-P–M) = 0.083(3) Å) and the M_2P_2 core adopts a dis-

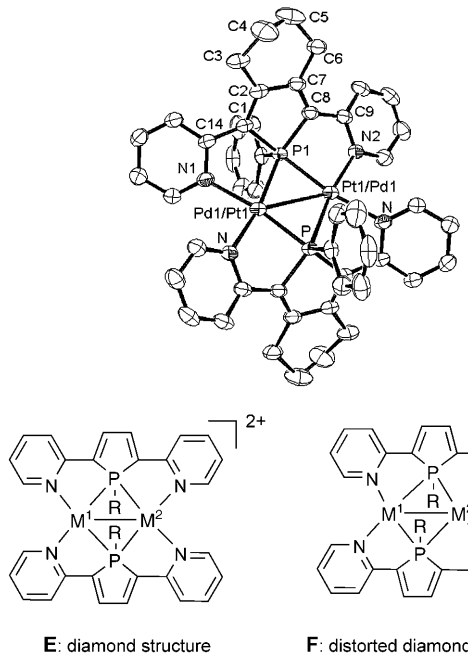

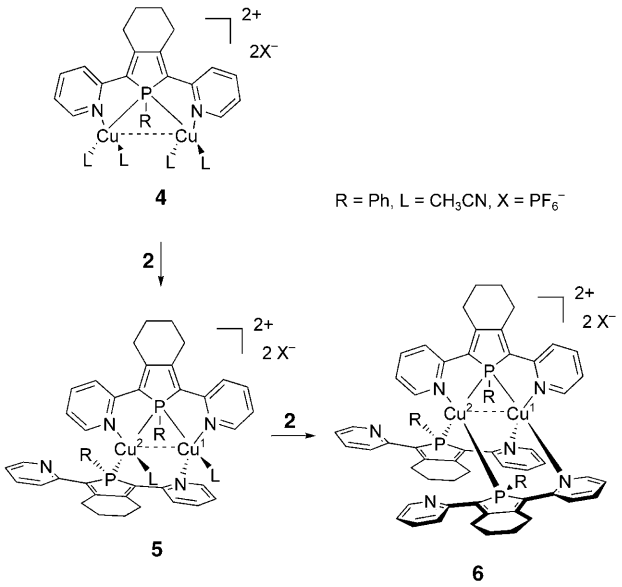

Figure 2. Molecular structure of the cation of complex **3** in the solid state (hydrogen atoms have been omitted for clarity; thermal ellipsoids at 50% probability). Selected bond lengths [Å]: P1–M1 2.3923(14), P1–M2 2.3091(15), N1–M1 2.160(5), N2–M2 2.142(4).

torted diamond shape (**F** in Figure 2; $M^1 = Pd$, $M^2 = Pt$). Hence, in spite of the tridentate coordination mode of the N,P,N-ligand **2**, the P atom can adopt a nonsymmetrical coordination mode. In fact, the μ-P centers of heterobimetallic **3** adopt a geometry that is intermediate between a symmetrically bridging (**A**) and a semi-bridging (**B**) coordination mode (Figure 1). This result suggests that there is no substantial discontinuity between these two coordination modes for μ-PR_3 ligands. In order to verify such a hypothesis, density functional theory calculations were carried out.[8]

The structure of heterobimetallic **3** was first optimized without symmetry constraints. The resulting structural arrangement matches the experimental structure with good accuracy.[8] The two phosphorus atoms are bound asymmetrically to the metal centers ($\Delta(\mu\text{-P}-\text{M}) \approx 0.09$ Å), which gives rise to the experimentally observed distorted diamond structure **F**. Geometry optimization of **3** by imposing a C_2 symmetry axis containing the metal atoms leads to the diamond structure **E.** Interestingly, the energy of **E** is very close to that of **F** ($\Delta E = 0.5$ kcal mol^{-1}).[11] Analogous results were obtained for the homometallic compound $\mathbf{D}^1$: for example, the energies of structures **E** and **F** are almost the same ($\Delta E = 1.1$ kcal mol^{-1}). Obviously, there is a shallow and broad energy minimum around the symmetrical bridging position of the phosphorus atoms in this kind of complex. In other words, there is little energy cost for a bridging P center to move from a symmetrical to a substantially nonsymmetrical bridging position. Tiny changes such as the metal's electronic requirements, the environment about the metal, and/or the crystal packing can be invoked as the cause of the differences in structure between conformers **E** and **F**.

This conclusion was nicely confirmed by synthesis of a novel series of homobimetallic complexes in which two Cu^I atoms are tethered by a bridging phosphole. The reaction of di(2-pyridyl)phosphole (**2**) with $[Cu(CH_3CN)_4]PF_6$ (1:2 ratio) in CH_2Cl_2 at room temperature gives the dimetalated complex **4** (Scheme 2), which was isolated as an air-stable powder

Scheme 2. Synthesis of Cu^I dimers **4**–**6**.

in 95% yield. In its ^{31}P NMR spectrum, besides the PF_6 signal ($\delta = -143.2$ ppm, $J_{P,F} = 704.1$ Hz), a singlet is observed at $\delta = -0.1$ ppm. Integration of the ^1H NMR spectrum suggests that **4** contains one di(2-pyridyl)phosphole and four acetonitrile ligands; the simple $^{13}C\{^1H\}$ NMR spectrum is in favor of a symmetric structure.[8] An X-ray diffraction study[8] revealed that compound **4** has the structure $[Cu_2(\mathbf{2})(CH_3CN)_4](PF_6)_2$ (Figure 3), in which two Cu^I atoms are capped by a 2,5-bis(2-pyridyl)phosphole ligand acting, again, as a six-electron μ-1κN:1,2κP:2κN donor. The Cu^I atoms have a distorted tetrahedral geometry due to the bite angle of the P,N-chelate

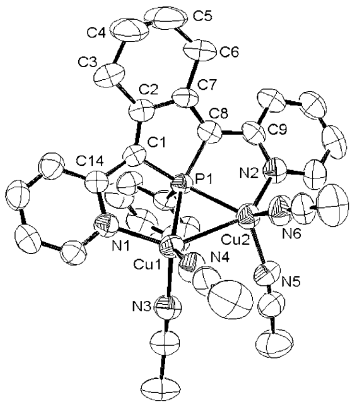

Figure 3. Molecular structure of the cation of complex **4** in the solid state (hydrogen atoms have been omitted for clarity; thermal ellipsoids at 50% probability).

(N1-Cu1-P1 = 85.29(12)°; N2-Cu2-P1 = 85.55(14)°), with a short intermetallic distance (2.568(10) Å).[12] The two Cu–N(pyridine) bond lengths are equal and the P atom adopts an almost symmetrical coordination mode ($\Delta(\mu\text{-P–Cu}) = 0.010(2)$ Å; Table 1). Derivative **4** is the first complex in which two d^{10}-metal centers are bridged by a phosphane donor, and where two metals are held together by one bridging phosphane and no other supporting ligands (**C** is triply bridged and **D** is doubly bridged, Figure 1). These results suggest that bridging phosphane ligands are able to stabilize a large variety of bimetallic complexes and confirm that "*there is no inherent thermodynamic instability associated with this bonding situation*".[2a]

Table 1: Selected bond lengths [Å] for complexes **4**–**6**.

	4	**5**	**6**
Cu1–P1[a]	2.324(1)	2.293(1)	2.265(1)
Cu2–P1[a]	2.314(1)	2.387(1)	2.560(1)
Cu1–N1[a]	2.040(4)	2.047(4)	2.147(5)
Cu2–N2[a]	2.041(5)	2.043(4)	2.052(5)
Cu2–P2[b]	–	2.250(1)	2.299(1)
Cu2–P3[b]	–	–	2.296(1)
Cu1···Cu2	2.568(1)	2.5552(8)	2.6204(9)

[a] P1, N1, and N2 belong to the μ-1κN:1,2κP:2κN ligand; [b] P2 and P3 are the nonbridging P atoms.

The acetonitrile ligands of **4** can be displaced in CH_2Cl_2 solution by one or two equivalents of phosphole **2** to give complexes **5** (85% yield) and **6** (81% yield), respectively, which can be isolated as air-stable powders (Scheme 2).[8] An X-ray diffraction study[8] revealed that these dicationic Cu^I dimers still feature one 2,5-bis(2-pyridyl)phosphole ligand acting as a μ-1κN:1,2κP:2κN donor. The fact that the bridging coordination mode of the P center is retained upon addition of **2** to complex **4** highlights the robustness of bridging phosphanes as binucleating ligands. The tetrahedral geometry of the Cu^I atoms in **5** prevents the formation of a doubly bridged structure of type **D** (Figure 1), which requires square-planar metal centers. The dinuclear fragment of complexes **5** and **6** is bridged by one or two additional 1κP:2κN-chelates **2** (Scheme 2), respectively, the $Cu^I\cdots Cu^I$ separation being hardly perturbed with respect to that of complex **4** (Table 1). Note that the arrangement of the P,N-ligands in **6** (Scheme 2), which leads to two Cu atoms with either a "high-P" or "high-N" environment, is probably due to steric factors.

The series **4**–**6** gives the unique opportunity to study the evolution of the bridging coordination mode of a phosphane upon decreasing the local symmetry of the bimetallic core. It is striking to observe that the difference between the two μ-P–Cu distances increases continuously on going from **4** to **6** ($\Delta(\mu\text{-P–Cu})$: **4**, 0.010(2) Å; **5**, 0.094(2) Å ; **6**, 0.295(2) Å). The value of $\Delta(\mu\text{-P–M})$ found in complex **6** is typical for semi-bridged phosphanes,[5] with the longest P–Cu bond length always being observed for Cu2 (Scheme 2), which has a "high-P" environment (Table 1). Once again, the P atom of the N,P,N-pincer **2** can adopt a nonsymmetric bridging geometry. Moreover, these structural data confirm experimentally that there is no substantial discontinuity between symmetrical bridging (**A**) and semi-bridging (**B**) coordination modes for μ-PR_3 ligands (Figure 1). It is thus likely that these two coordination modes are shallow and broad minima on a flat potential energy surface. This situation is reminiscent of that of CO, the prototypical bridging ligand, and is a clue to understanding many of their key properties (e.g. fluxional behavior, bonding modes).[2a,3d,6]

These results show that chelates featuring bridging phosphanes are versatile binucleating ligands and that phosphanes have now to be considered as standard bridging ligands. The development of the robust Cu^I dimers **4** and **5** as building blocks for supramolecular architectures is under active investigation.

Asymmetric Mannich Reaction

Direct Catalytic Asymmetric Mannich-Type Reactions of *N*-(2-Hydroxyacetyl)pyrrole as an Ester-Equivalent Donor**

Shinji Harada, Shinya Handa, Shigeki Matsunaga, and Masakatsu Shibasaki**

The catalytic in situ generation of metal enolates and enamines from donor substrates in asymmetric carbon–carbon bond-forming reactions has recently received much attention.[1] Although tremendous progress has been made in this area in the last five years with various metal catalysts and organocatalysts,[2] room for improvement remains. For example, in metal catalysis, the donor substrates are mostly limited to ketones.[3,4] The use of donor substrates with the oxidation state of carboxylic acid is still a formidable task since the pK_a value of the α proton in carboxylic acid derivatives is much higher than that in ketones. A few landmark studies addressing this issue were recently reported.[5] In particular, Evans et al. achieved a highly enantioselective aldol reaction utilizing *N*-acyl thiazolidinethione donors and a chiral Ni catalyst.[5a] The reaction proceeded with excellent yield and selectivity; however, stoichiometric amounts of the silylating reagent and amine base were required to facilitate catalyst turnover. The development of a suitable ester-equivalent donor and/or a new asymmetric catalyst to achieve both high enantioselectivity and conversion without additional stoichiometric reagents is desirable. Herein, we report that an *N*-acylpyrrole moiety is an effective achiral template for the in situ generation of metal enolates. New complexes composed of In(O*i*Pr)$_3$ and (*S*,*S*)-linked-binol **1** were used to catalyze the

X=H: (*S*,*S*)-linked-binol **1a**
X=$(CH_3)_3$Si: (*S*,*S*)-6,6',6'',6'''-TMS-linked-binol **1b**

asymmetric Mannich-type reaction of *N*-(2-hydroxyacetyl)-pyrrole and *ortho*-tosylimines, which proceeded through simple proton transfer to give β-amino-α-hydroxy carboxylic acid derivatives in high enantioselectivity (91–98% *ee*, major diastereomer) and good yield (65–98%).

We selected *N*-acylpyrrole as a donor substrate for investigation and as an achiral template for the following reasons. Evans et al. reported the unique properties of *N*-acylpyrrole.[6] We subsequently demonstrated the utility of the *N*-acylpyrrole moiety as an ester surrogate in catalytic asymmetric conjugate additions, in which an α,β-unsaturated *N*-acylpyrrole substrate was used as an activated, monodentate electrophile.[7] Because the lone pair on the nitrogen atom in the pyrrole ring is delocalized in an aromatic system, the properties of the carbonyl group are similar to those of a phenyl ketone. We supposed that *N*-acylpyrrole would also be useful as an ester-equivalent donor because the aromaticity would assist enolate formation. Since the coordination mode of the *N*-acylpyrrole donor is similar to that of an aromatic ketone, the chiral environment optimized for ketone donors would be applicable for *N*-acylpyrrole. Based on our previous report that the complex Et_2Zn/linked-binol **1a** is suitable for the formation of an enolate from an aromatic hydroxyketone,[2c] we used *N*-(2-hydroxyacetyl)pyrrole **2** (Figure 1) and complexes composed of a metal and linked-binol **1a** in the preliminary evaluations of the potential of the *N*-acylpyrrole moiety for the catalytic in situ generation of metal enolates.

The results of the initial screening in the Mannich-type reaction with **2** are shown in Table 1. When the Et_2Zn/**1a**

complex was used for *para*-tosylimine **3a**, a Mannich adduct was obtained in only low yield (Table 1, entry 1, 11%), probably due to the low Brønsted basicity of the Zn catalyst in the formation of the zinc enolate from **2**. Screening of other metal sources revealed that $In(OiPr)_3$ was the most effective.[16] When a 2:1 complex of $In(OiPr)_3$ and **1a** was used, the reaction of **2** and **3a** in THF proceeded at room temperature to give the Mannich adduct in 61% yield and 93% *ee* (Table 1, entry 2). The reaction of *ortho*-tosylimine **4a** under the same conditions gave **6a** with improved yield (94%), diastereoselectivity (*syn*/*anti* = 91:9), and enantioselectivity (96% *ee* (*syn*); Table 1, entry 3).[8,9] In this reaction, we assumed that either an indium alkoxide or an indium phenoxide functions as a Brønsted base and deprotonates **2** at the α position to form the indium enolate in situ. Although there are many reports on Lewis acidic indium catalysts ($In(OTf)_3$, $InCl_3$, $InBr_3$, etc.),[10] the Brønsted basic property of indium chiral catalysis was utilized for the first time in organic synthesis. Furthermore, the present reaction using an α-hydroxy-substituted donor complements the reports by Evans and Shair,[5] in which α-alkyl-substituted donors were used.[11]

The substrate scope of the present reaction is summarized in Tables 2 and 3. The diastereomeric ratio depended on the imines used. As shown in Table 2, alkenyl imines **4a–d** afforded *syn* adducts in good diastereoselectivity (88:12–91:9) and high enantioselectivity (93–97% *ee* (*syn*) Table 2, entries 1–4). The *syn* selectivity of the reactions of imines **4e** and **4f**, which have an unsubstituted and *para*-substituted aromatic ring, respectively, was only modest (Table 2, entries 5 and 6).[12] At present, this reaction with the In-$(OiPr)_3$/(*S*,*S*)-linked-binol complex is limited to sp^2-hybridized imines; however, subsequent functionalization of the C–C double bond in the Mannich adducts obtained from alkenyl imines **4a–d** can afford β-alkyl-substituted β-amino-α-hydroxy carboxylic acid derivatives (see below). Further trials to expand the substrate scope of the reaction to aliphatic imines are ongoing. On the other hand, imines **4g–k**, which contain *ortho*-substituted aromatic rings, and cyclopropyl imine **4l** gave products with *anti* selectivity[8] in high *ee* (92–98% *ee*, *anti*; Table 3). Both electron-withdrawing (Cl, Br) and electron-donating substituents (Me, MeO) on the aromatic ring were applicable. For less reactive substrates, an increased amount of the chiral ligand (15 mol%) was required to obtain products in good yield (Table 3, entries 1, 2, and 5–7). Use of a modified linked-binol ligand **1b** resulted

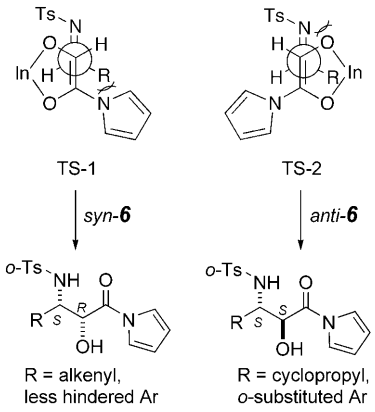
in slightly better stereoselectivity in some cases (Table 3, entries 1, 6, and 8 vs. 2, 7, and 9).

In all entries in Tables 2 and 3, the *syn* and the *anti* adducts were obtained with the same absolute configuration at the β position (*S*), implying that selection of the imine enantioface is identical.[8] Proposed models of the acyclic *anti*-periplanar transition state are shown in Figure 2. Imines **4a–f**



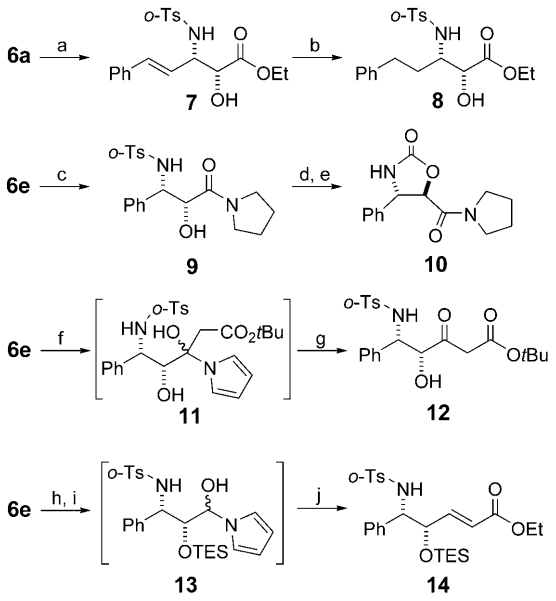


Figure 2. Postulated transition-state model of Mannich-type reactions.

with a planar configuration would favor the TS-1 to minimize *gauche* interactions. On the other hand, imines **4g–l** have a twisted configuration due to steric (**4g–k**) and stereoelectronic (**4l**) effects. Thus, steric repulsion between imine substituents R and the pyrrole ring of the indium enolate would become more predominant, and the *anti*-periplanar TS-2 would be more favorable than TS-1. For a more precise understanding of the diastereoselectivity evidenced in Table 2 and Table 3 and the effects of the modified ligand **1b**, further mechanistic studies including clarification of the structure of the complex of $In(OiPr)_3$ and (*S*,*S*)-linked-binol **1** are required.

Finally, the utility of the *N*-acylpyrrole unit as an ester surrogate was demonstrated through several transformations of Mannich adducts (Scheme 1).[13] The *N*-acylpyrrole unit of **6a** was readily transformed into an ethyl ester unit by treatment with NaOEt at room temperature for 5 min, affording **7** in quantitative yield. Hydrogenation of the C–C double bond in **7** gave **8** in 92% yield, which corresponds to the β-amino-α-hydroxy ester accessible from an aliphatic imine. Substitution with amine also proceeded smoothly. Amide **9** was obtained in quantitative yield by the treatment of Mannich adduct **6e** with pyrrolidine and DBU at 40 °C for 1 h. Neither epimerization nor racemization was observed during substitution. After conversion of **9** into the cyclic carbamate (94% yield), the *o*-Ts group was removed under mild reduction conditions (Mg powder, room temperature, 20 min)[14] to give **10** in 81% yield. In addition to substitution reactions with alcohols and amines, reaction of **6e** with a lithium enolate followed by treatment with DBU provided keto ester **12** in 62% yield. Protection with a triethylsilyl (TES) group followed by reduction with $LiBH_4$ afforded the pyrrole carbinol **13** as a stable intermediate. Under Masamune–Roush conditions,[15] the aldehyde moiety was generated in situ from the crude pyrrole carbinol **13**, and the α,β-unsaturated ester **14** was obtained in 67% yield (in two steps from the TES-protected Mannich adduct).

Scheme 1. Transformations of Mannich adducts. Reaction conditions: a) NaOEt, EtOH, 0 °C→RT, 5 min, quant. yield; b) Pd/C, H_2, MeOH, RT, 30 min, 92%; c) pyrrolidine, DBU, THF, 40 °C, 1 h, quant. yield; d) triphosgene, py, CH_2Cl_2, −78 °C→RT, 1 h, 94%; e) Mg powder, MeOH, RT, 20 min, 81%; f) LDA, *t*Bu acetate, THF, −78 °C, 10 min; g) DBU, CH_2Cl_2, RT, 5 min, 62% (2 steps); h) TESCl, imidazole, DMF, 0 °C, 30 min, 87%; i) $LiBH_4$, THF, RT, 30 min; j) $(EtO)_2P(O)CH_2CO_2Et$, LiCl, DBU, CH_3CN, RT, 7 h, 67% (2 steps). DBU = 1,8-diazabicyclo-[5.4.0]undec-7-ene, py = pyridine.

In summary, we have demonstrated the utility of *N*-acylpyrrole **2** as an ester-equivalent donor in a direct Mannich-type reaction. A catalytic amount of a chiral complex composed of $In(OiPr)_3$ and the (*S*,*S*)-linked-binol **1** was effective in generating the indium enolate in situ from **2**. The reaction is formally a simple proton transfer, and high enantioselectivity (up to 98% *ee*) was achieved at ambient temperature. Mechanistic studies of indium catalysis, trials to improve the unsatisfactory reaction rate and diastereoselectivity, and further application of the *N*-acylpyrrole moiety as an ester-equivalent donor in other reactions are ongoing.

Light-Harvesting Polymers

Star-Shaped Light-Harvesting Polymers Incorporating an Energy Cascade**

Ming Chen, Kenneth P. Ghiggino, San H. Thang, and Gerard J. Wilson*

The photosynthetic apparatus of both photosynthetic bacteria and higher plants involves a reaction center surrounded by intricate arrays of pigments that form an energy gradient for efficient light collection.[1] Artificial systems that can mimic this remarkable natural process have attracted great interest. Among them, polymers used to simulate the process are known as "light-harvesting" or "antenna" polymers.[2] Owing

to their structural features, multiarmed star-shaped polymers are particularly attractive as artificial light-harvesting systems.[3] Compared with linear light-harvesting polymers, the condensed packing of chromophores around a central energy-trap core will lower the average donor–acceptor distance, thus leading to a faster rate and higher efficiency of energy transfer.[4] Star-shaped polymers with an encapsulated lumophore core may also have potential uses in molecular-scale optoelectronics, photonics, security devices, luminescence-based sensors, and other emerging areas of technology.[5] A tetrahedral starlike arrangement of chromophores has previously been shown to exhibit advantages for collection of diffuse light through exciton interactions.[6] Dendritic light-harvesting systems that exhibit cascade-energy-transfer behavior have also been reported recently.[7] However, the multistep syntheses required for such systems have so far limited their widespread application and there remains a need for simpler synthetic strategies to create light-harvesting arrays.

During the last two decades, controlled/living radical polymerization has emerged as one of the most effective synthetic routes to well-defined polymers.[8] Among them, reversible addition–fragmentation chain-transfer (RAFT) polymerization appears to be one of the most efficient and could potentially be applied to any classical radical system.[9] The RAFT process involves performing a conventional radical polymerization in the presence of certain thiocarbonylthio compounds (S=C(Z)-SR), so-called RAFT agents. Light-harvesting polymers with defined properties can be synthesized by RAFT polymerization with specially functionalized RAFT agents.[3,10] We report herein the synthesis by RAFT methods of well-defined star-shaped light-harvesting block copolymers that contain an energy cascade of chromophores from the periphery to the core.

Hexa(dithiobenzoate)-functionalized Ru^{II} tris(bipyridine) (Ru-hexa-RAFT) was synthesized as previously reported.[3] It was used to control the polymerization of a styrene-functionalized coumarin monomer (st-coumarin).[11] The resulting star-shaped polymer **1** has an average length of two st-coumarin repeat units in each arm. Polymer **1** was subsequently used as a macro-RAFT agent to control the polymerization of acenaphthylene to obtain the star-shaped diblock copolymer **2** with a narrow polydispersity and an average length of 36 acenaphthenyl repeat units in each arm. The ratio of the acenaphthenyl to coumarin chromophores in each arm of polymer **2** was designed to provide selective excitation of acenaphthenyl units of this polymer at 295 nm. To avoid the competing quenching effect of the dithiobenzoyl groups on excited chromophores observed previously,[3,10] a triblock copolymer, **3**, with an average length of 44 *N*-isopropylacrylamide (NIPAM) repeat units in each arm was similarly synthesized by using polymer **2** as the macro-RAFT agent and NIPAM monomer.

The numbers of st-coumarin, acenaphthenyl, and NIPAM repeating units in the polymers are calculated based on gravimetric determinations. These values agreed with compositions determined spectrophotometrically by comparing the absorption spectra of the polymers with the corresponding model compounds. The agreement obtained indicates that

incorporating the chromophores in the polymer does not perturb their absorption spectra, that is, there is no evidence for ground-state electronic interactions between chromophores. This observation has also been reported in previous work on related polymers.[3,10] The composition of polymer **1** was also characterized by NMR spectroscopy. The block copolymers **2** and **3** displayed narrow molecular-weight distributions by gel permeation chromatography (GPC).

To investigate the energy-transfer process between acenaphthenyl and coumarin units in the star-shaped polymers, a linear block copolymer, **4**, was synthesized through hydrolysis of the star-shaped diblock copolymer **2** with an amine.[12]

Acenaphthene, a 4-isopropylbenzyl-functionalized coumarin compound (IPB-coumarin), tris(bipyridine) Ru^{II} dichloride, and 4-cyano-4-((thiobenzoyl)sulfanyl)pentanoic acid[3] were selected as model compounds to characterize the electronic interaction between the photoexcited donor chromophore with the ground-state acceptor. Energy transfer between an electronically excited donor and ground-state acceptor is commonly described by the induced dipole–dipole (Förster) mechanism.[13] The strength of the electronic interaction is characterized by the Förster critical transfer distance determined from the spectroscopic and photophys-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ical properties of the donor and acceptor and defined as the distance at which the rate of energy transfer equals the rate of other excited-state relaxation processes of the donor. Assuming an orientation factor (κ^2) equal to 2/3 (corresponding to a random distribution of transition dipole orientations), we calculated the Förster critical distances between these chromophores in degassed dichloromethane solutions as shown in Table 1.

Table 1: The Förster critical transfer distances (R_0 [Å]) between relevant chromophores in degassed dichloromethane solution.

	Acenaphthenyl	Coumarin	Ru^{II} complex	Dithiobenzoyl
acenaphthenyl	13.7	29.2	23.2	24.6
coumarin	29.2	13.0	39.7	16.0
Ru^{II} complex	23.2	39.7	NA	NA
dithiobenzoyl	24.6	16.0	NA	NA

The Förster critical transfer distance between acenaphthenyl and coumarin chromophores (29.2 Å) exceeds that for the acenaphthenyl and Ru^{II} complex moieties (23.2 Å). Owing to the polymer structure, the interchromophoric distance between acenaphthenyl and coumarin units can be expected to be smaller than that between the acenaphthenyl units and the Ru^{II} complex core in the star-shaped block copolymers. Thus, the rate of energy transfer from excited acenaphthenyl molecules to the coumarin units should be faster than that between the excited acenaphthenyl molecules and Ru^{II} complex cores, thus leading to a sequential energy-transfer process.

A comparison of the absorption and emission spectra from degassed dichloromethane solutions of the polymers is shown in Figure 1. Photoexcitation of acenaphthenyl units in the linear polymer **4** at 295 nm, in which absorption is almost exclusively (> 95 %) due to the acenaphthenyl donor, results in fluorescence being predominantly emitted from the coumarin acceptor at 440 nm. After the Ru^{II} core has been introduced into the star-shaped polymers, the coumarin emission is dramatically quenched, whereas significant emission from the Ru^{II} complex core is observed at 615 nm in polymers **2** and **3**. It should be noted that emission from the star-shaped polymers at 415 nm arises largely from acenaphthenyl excimers.[14] Figure 1 also shows that removal of the competing quenching effect of the dithiobenzoyl end groups in the triblock copolymer **3** increases the efficiency of the energy transfer from acenaphthenyl units to the Ru^{II} moieties.

The excitation spectrum of **4**, monitored at 435 nm, contains a major contribution attributable to acenaphthenyl chromophore absorption at 295 nm, which confirms that energy transfer occurs. By comparing the excitation spectrum with the normalized absorption spectrum,[15] the efficiency of energy transfer from the acenaphthenyl to coumarin units in this linear polymer was determined to be 67 %.

When the Ru^{II} complex emission is monitored at 615 nm, the excitation spectra of **2** and **3** exhibit major contributions due to the absorption of coumarin chromophores at 345 nm and acenaphthenyl chromophores at 295 nm. The efficiencies of energy transfer from coumarin units to the Ru^{II} complex

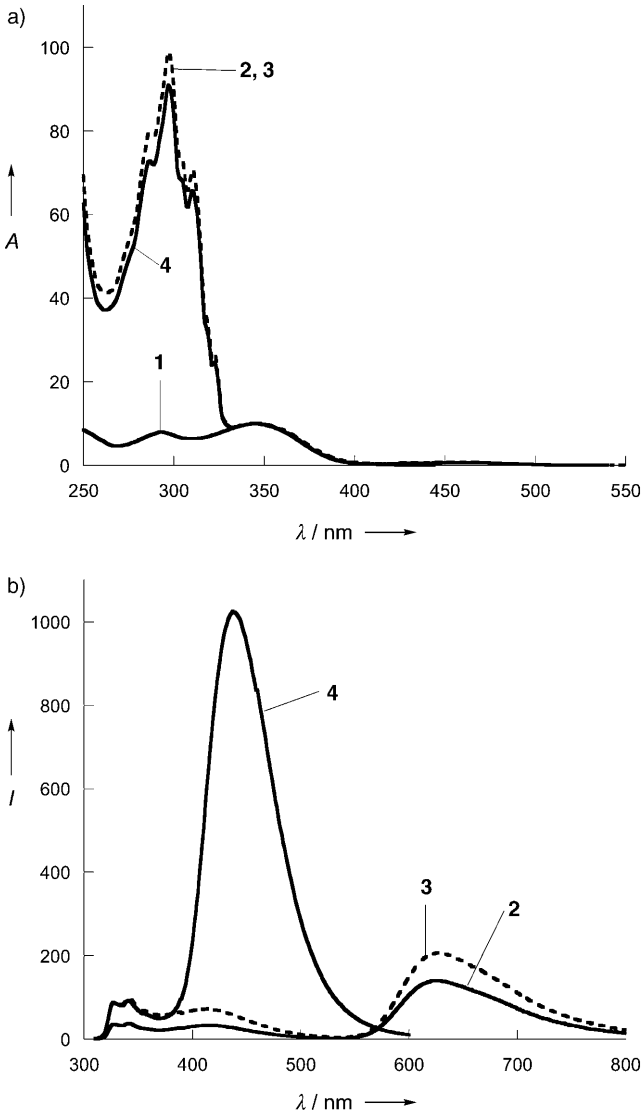

Figure 1. a) Absorption (normalized at $\lambda = 350$ nm) and b) luminescence spectra of polymers **1**–**4** in dichloromethane. For luminescence measurements, all degassed solutions have the same absorbance at the excitation wavelength of 295 nm. Fluorescence in **1** is totally quenched by the adjacent dithiobenzoyl end group.

core, determined as described above, in both star-shaped polymers are 90 %. This is a consequence of the relatively large R_0 (39.7 Å) and short donor-to-acceptor separations. The efficiencies from acenaphthenyl to the Ru^{II} complex core in polymers **2** and **3** are 47 % and 62 %, respectively. The higher efficiency in **3** relative to **2** is the result of a decrease in the competing dithiobenzoyl quenching effect that results from insertion of the photo-inactive NIPAM spacers in the triblock copolymer.

The excited acenaphthenyl units can conceivably pass their excitation energy to the Ru^{II} complex core either in a stepwise cascade fashion through coumarin sequences or by a direct one-step energy-transfer process. In the present case, we believe that the former path is favored for the following reason: Energy transfer between excited acenaphthenyl and coumarin units is kinetically favored as a result of the larger

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Förster critical distance and shorter interchromophoric distance in comparison with those of excited acenaphthenyl units and the Ru^{II} core. This conclusion is also supported by the measured energy-transfer efficiencies. The efficiency of energy transfer from the acenaphthenyl to coumarin units is 67% in the linear model polymer, **4**. The transfer efficiency from coumarin units to the Ru^{II} core is 90%. Hence, the theoretical efficiency for the overall energy-transfer process from acenaphthenyl to the Ru^{II} complex through a cascade route in **3** can be expected to be 60% (i.e., $67 \times 90\%$), which agrees well with the measured value, 62%. The sequence of the energy-transfer processes is depicted schematically in Figure 2.

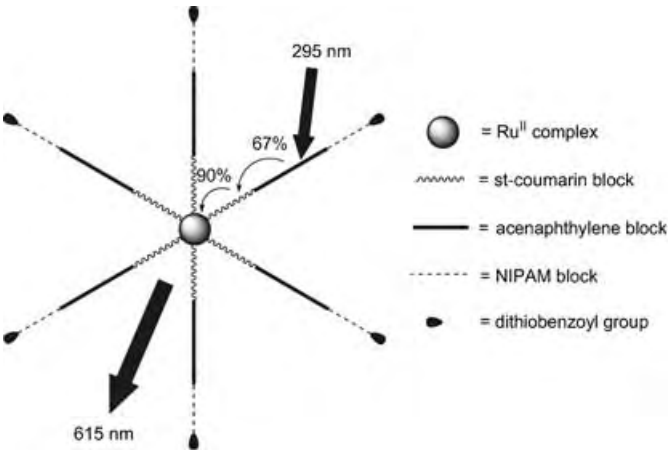

Figure 2. Schematic representation of the energy-transfer processes within the star-shaped block copolymer **3**.

In conclusion, star-shaped block copolymers have been synthesized to obtain light-harvesting systems with an energy gradient from the periphery to the core. Photophysical data suggest that the transfer of excitation energy in the block copolymers occurs mainly through a stepwise energy cascade from the initially excited acenaphthenyl units to the coumarin chromophores and hence to the Ru^{II} complex core.

Experimental Section

Solutions for luminescence measurements were degassed by multiple freeze–pump–thaw cycles at $\approx 10^{-6}$ torr. Emission and excitation spectra were recorded on a Varian Cary Eclipse fluorometer and were corrected for the wavelength dependence of the sensitivity of the detector and the output of the excitation light source by using a calibrated standard lamp source. Molecular-weight determinations were performed in THF at 25 °C with a Waters GPC instrument with a refractive-index detector. Molecular weights are reported as linear polystyrene equivalents.

IPB-coumarin: A mixture of coumarin-2 (0.20 g, 0.92 mmol; Exciton, laser grade), 4-ispropyl benzyl chloride (0.17 g, 1.01 mmol), K_2CO_3 (0.38 g, 2.67 mmol), KI (0.05 g, 0.28 mmol) in CH_3CN (10 mL) was stirred under nitrogen at 85 °C for 24 h. Purification was performed with column chromatography on silica gel (Kieselgel-60, 70–230 mesh) with a mixture of ethyl acetate and *n*-hexane in a ratio of 1:4 as eluent. Yield: 0.25 g, 78%. ^{1}H NMR (200 MHz, $CDCl_3$): $\delta =$ 1.03 (t, 3H, $J = 6.94$ Hz), 1.21 (s, 3H), 1.24 (s, 3H), 2.37 (b, 3H), 2.41 (b, 3H), 2.87 (m, 1H), 3.05 (q, 2H, $J = 6.94$, 14.25 Hz), 4.16 (s, 2H), 6.11 (b, 1H), 6.92(s, 1H), 7.10–7.26(m, 4H), 7.35 ppm (s, 1H). UV/Vis (DCM): λ_{max} ($\log \varepsilon$): 347 (4.16).

1: A mixture of Ru-hexa-RAFT[3] (30 mg, 11.9 μmol), 2,2′-azobis(isobutyronitrile) (AIBN; 0.5 mg, 3.7 μmol), st-coumarin (477 mg, 1.43 mmol) and solvent (1 mL, acetonitrile/chlorobenzene = 1:2, *v*/*v*) was degassed through three freeze–pump–thaw cycles, sealed under vacuum, and heated at 70 °C for 8 h. The polymer was purified by precipitation into MeOH (20 mL). Yield: 78 mg (10%). $\bar{M}_n$ (by calculation) = 6500; $\bar{M}_n$ (by ^{1}H NMR spectroscopy) = 6200; $\bar{M}_n$ (by UV/Vis spectroscopy) = 6500; $\bar{M}_n$ is the number-average molecular weight.

2: Polymer **2** was prepared from polymer **1** (17 mg, 2.6 μmol equivalent Ru-hexa-RAFT), AIBN (0.5 mg, 3.7 μmol), acenaphthylene (474 mg, 3.12 mmol) and chlorobenzene (1 mL) at 70 °C for 16 h. Yield: 120 mg (18%). $\bar{M}_n$ (by calculation) = 39300; $\bar{M}_n$ (by UV/Vis) = 43000; $\bar{M}_n$ (by GPC) = 5300, $\bar{M}_w/\bar{M}_n$ (by GPC) = 1.13; $\bar{M}_w$ is the weight-average molecular weight.

3: Polymer **3** was prepared from polymer **2** (40 mg, 0.9 μmol equivalent Ru-hexa-RAFT), AIBN (0.5 mg, 3.7 μmol), NIPAM (49 mg, 432 mmol) and solvent (1 mL, acetonitrile/chlorobenzene = 1:1, *v*/*v*) at 70 °C for 16 h. Yield: 67 mg (55%). $\bar{M}_n$ (by calculation) = 69100; $\bar{M}_n$ (by GPC) = 3700, $\bar{M}_w/\bar{M}_n$ (by GPC) = 1.16.[16]

4: Polymer **4** was prepared from the hydrolysis of polymer **2** (40 mg) by using *N*,*N*-dimethylethylenediamine (0.5 mL) in chlorobenzene (1 mL) under nitrogen. Yield: 30 mg (75%). $\bar{M}_n$ (by calculation) = 6100; $\bar{M}_n$ (by GPC) = 7100, $\bar{M}_w/\bar{M}_n$ (by GPC) = 1.21.

Total Synthesis of Glycocinnasperimicin D**

*Taihei Nishiyama, Minoru Isobe, and Yoshiyasu Ichikawa**

Glycocinnasperimicin D (**1**) was isolated from the fermentation broth of the producing strain (*Nocardia*), and its structure was elucidated by spectroscopic studies by Umezawa and his co-workers.[1] This molecule belongs to a family of glycocinnamoylspermidine antibiotics which also includes LL-BM123β (**2**), LL-BM123γ_1 (**3**), and LL-BM123γ_2 (**4**); these members contain three different types of unusual amino sugars.[2,3] Glycocinnasperimicin D contains the two highly functionalized amino sugars: 2-ureidopentose (left) and 2-guanidino-4-ureido-6-deoxy-α-D-glucopyranose (right) with the *p*-cinnamoylspermidine aglycone. Moreover, these two unusual amino sugars are joined through a unique glycosyl urea linkage.

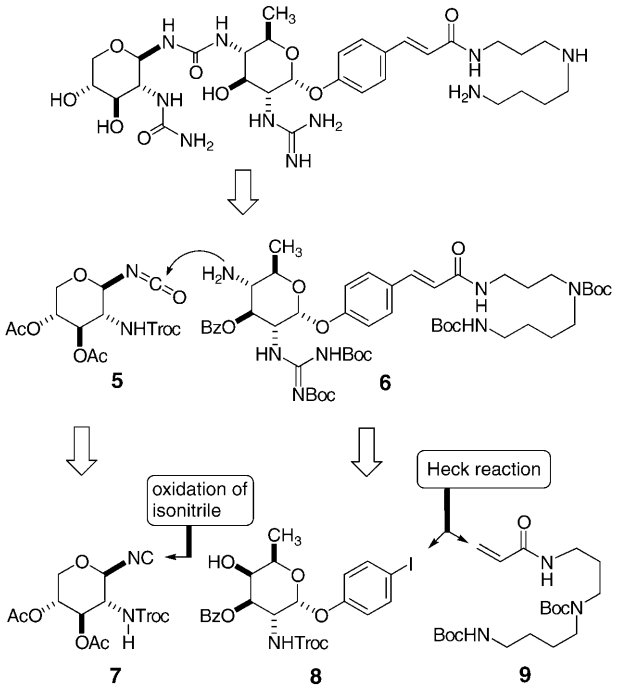
LL-BM123β (**2**) LL-BM123γ_1 (**3**) LL-BM123γ_2 (**4**)

The amino sugar antibiotic **1** is of special interest because of its broad-spectrum activity against Gram-negative organisms; however, the natural product was no longer available as a result of mutation of the *Nocardia* strain.[4] Its intriguing structural features, coupled with its unique biological activity and the lack of availability from natural sources, encouraged us to explore the synthesis of this molecule. We report herein the first total synthesis of glycocinnasperimicin D (**1**).

It is evident that the construction of the urea glycoside in the presence of a variety of nitrogen-containing functional groups constitutes the major challenge in the total synthesis of **1**. Recently, we developed a new approach to the synthesis of urea glycosides which involves the reaction of a highly reactive glycosyl isocyanate with amines.[5] It was envisaged that our protocol could be applied to the synthesis of **1** as represented in the retrosynthetic analysis shown in Scheme 1. Oxidation of the glycosyl isonitrile **7** could generate the glycosyl isocyanate **5**, which would react with the amino sugar **6** at the position indicated. The amino sugar **6** could be obtained by the Heck reaction of the iodophenyl glycoside **8** with the acrylamide **9**, which contains the spermidine moiety. We anticipated that this convergent tactic for the synthesis of the cinnamoyl glycoside would avoid the problems associated with the glycosidation of a poorly nucleophilic phenol bearing an electron-withdrawing substituent.[6]



The synthesis of the left-hand amino sugar in the form of **7** began with the stereoselective synthesis of an allyl amine on the basis of a protocol developed recently by our research group[7] (Scheme 2). Thus, the enantioselective addition of diethylzinc to the α,β-unsaturated aldehyde **10** in the presence of the Soai catalyst **11**[8] proceeded smoothly to afford the allylic alcohol **12** in 79% yield and with high diastereoselec-

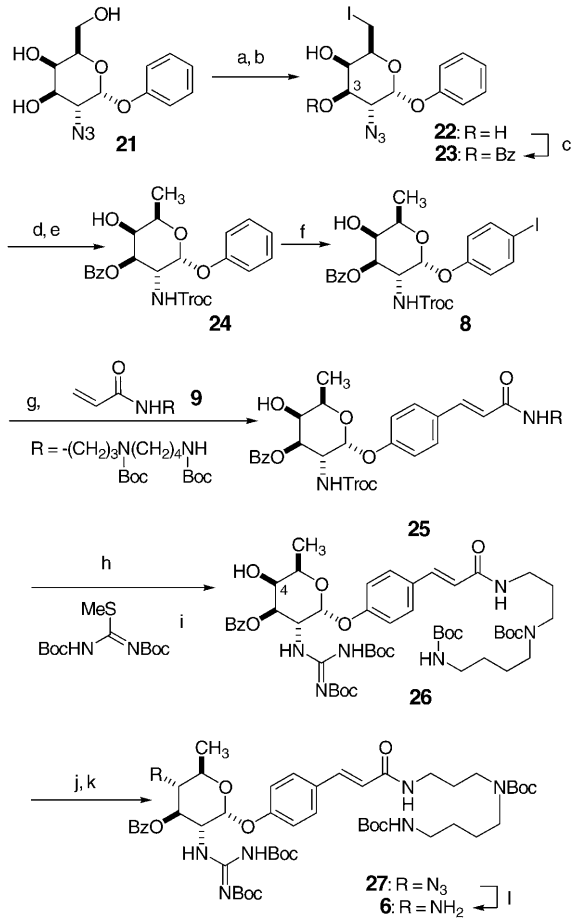
Scheme 1. Retrosynthetic analysis of glycocinnasperimicin D.

Scheme 2. Synthesis of the left-hand amino sugar moiety: a) Et_2Zn, cyclohexane, 0 °C→RT (79%); b) CCl_3CONCO, CH_2Cl_2; c) aqueous K_2CO_3, MeOH (93% over two steps); d) PPh_3, CBr_4, Et_3N, CH_2Cl_2, −40 °C; e) CCl_3CH_2OH, room temperature, overnight (82% over two steps); f) $FeCl_3{\cdot}6H_2O$, $CHCl_3$; g) Ac_2O, pyridine (80%); h) HF·pyridine, THF; i) O_3, CH_2Cl_2, Me_2S; j) Ac_2O, DMAP, pyridine (71% over three steps); k) $TMSN_3$, $SnCl_4$, CH_2Cl_2, (86%); l) PPh_3, THF, H_2O; m) AcOCHO (72% over two steps); n) PPh_3, CBr_4, Et_3N, CH_2Cl_2, (85%). DMAP = 4-dimethylaminopyridine, TMS = trimethylsilyl, Troc = 2,2,2-trichloroethoxycarbonyl.



tivity (15:1, checked by ^1H NMR spectroscopic analysis of the corresponding acetates). The allylic alcohol **12** was then transformed into the allyl carbamate **13** by treatment with trichloroacetyl isocyanate followed by hydrolysis with potassium carbonate in aqueous methanol. Upon dehydration of the carbamate **13** with triphenylphosphane, carbon tetrabromide, and triethylamine at −40 °C, the resulting allyl cyanate **14** underwent a spontaneous [3,3] sigmatropic rearrangement to afford the allyl isocyanate **15** with a high degree of 1,3-chirality.[9] Subsequent trapping of **15** with 2,2,2-trichloroethanol gave the Troc carbamate **16** in 82% yield from **13**.[10]

Hydrolysis of the isopropylidene ketal in **16** was more problematic than we had initially anticipated; the acetonide **16** was subjected to a number of deprotection protocols without success, possibly as a result of silyl-group migration to the adjacent hydroxy groups. Fortunately, Lewis acid catalyzed deprotection with ferric chloride hexahydrate ($FeCl_3{\cdot}6H_2O$) was found to be successful.[11] After treatment of **16** with $FeCl_3{\cdot}6H_2O$ in chloroform followed by workup, the resulting mixture was treated immediately with acetic anhydride and pyridine to prevent silyl-group migration. The required acetate **17** was obtained in acceptable yield (80% based on the consumed starting material) along with recovered **16** (23%). Careful cleavage of the *tert*-butyldiphenylsilyl ether **17** (HF·pyridine, THF)[12] followed by oxidative cleavage of the alkene (O_3, CH_2Cl_2, −78 °C) gave the corresponding lactol, which was subsequently treated with acetic anhydride and pyridine to furnish predominantly the α-*O*-acetyl glycoside **18** in 71% yield over three steps. Treatment of **18** with trimethylsilyl azide in the presence of tin(VI) chloride furnished the β-glycosyl azide **19** exclusively (86%).[13] The isonitrile group at the anomeric position was constructed in a three-step sequence by 1) Staudinger reaction of the glycosyl azide **19**, 2) formylation of the resulting iminophosphorane with acetic formic anhydride (72% yield over two steps), and 3) dehydration of the formamide **20** by the modified Appel procedure[14] to afford the isonitrile glycoside **7** (85% yield).

The synthesis of the right-hand amino sugar in the form of **6** commenced with the α-phenyl 2-azido-D-galactoside **21**,[15] which was prepared from D-galactal in a four-step sequence (Scheme 3). Tosylation of the primary alcohol in **21** followed by displacement with iodide anion gave the iodide **22** in 73% yield over two steps. After selective protection of the equatorial hydroxy group at C3 in **22** as a benzoate group (93% yield), reductive hydrogenolysis of the iodide **23** was carried out with concomitant reduction of the azide group. Subsequent protection of the resulting amine as its Troc carbamate gave the 6-deoxypyranose **24** in 81% yield.[16]

The cinnamic spermidine amide attached to the amino sugar was constructed from the phenyl glycoside **24** by a two-step protocol. Thus, treatment of **24** with ceric ammonium nitrate (CAN) and an iodine salt (nBu_4NI) in acetonitrile at 70 °C furnished the iodophenyl galactoside **8** in 86% yield.[17] The Heck reaction of **8** with acrylamide **9** proceeded smoothly to furnish the cinnamoyl galactoside **25** in 73% yield. Cleavage of the Troc carbamate in **25** (Zn, AcOH, THF) followed by treatment of the resulting amine with *N*,*N*-di-(*tert*-butoxycarbonyl)-*S*-methylisothiourea and mercuric

Scheme 3. Synthesis of the right-hand amino sugar unit: a) TsCl, pyridine (81%); b) NaI, nBu_4NI, DME (91%); c) BzCl, pyridine (93%); d) H_2, Pd-C (5%), Et_3N, EtOH; e) TrocCl, pyridine (81% over two steps); f) nBu_4NI, CAN, CH_3CN (86%); g) $Pd(OAc)_2$, P(*o*-Tol)$_3$, Et_3N, CH_3CN, 70°C (73%); h) Zn, AcOH, THF; i) $HgCl_2$, Et_3N, DMF (72% over two steps); j) Tf_2O, pyridine, CH_2Cl_2; k) NaN_3, DMF (73% over two steps); l) $HS(CH_2)_3SH$, Et_3N, MeOH (73%). Boc = *tert*-butoxycarbonyl, Bz = benzoyl, DME = dimethoxyethane, DMF = *N*,*N*-dimethylformamide, Tf = trifluoromethanesulfonyl, Tol = tolyl.

chloride in DMF afforded the bis(Boc)-protected guanidine **26** in 72% yield for the two steps.[18] The amino group at C4 was introduced by S_N2 displacement of a triflate with azide anion; thus the hydroxyl group in **26** was transformed into the corresponding triflate, and the rather unstable product was subjected immediately to treatment with sodium azide in DMF to furnish **27** in 73% yield over two steps. Whereas reduction of the azide group in **27** with PPh_3, $SnCl_2$,[19] nBu_3SnH,[20] or H_2/Pd-C[21] was unsuccessful, careful treatment with propanedithiol and triethylamine in MeOH[22] furnished the amino sugar **6** in 73% yield to set the stage for the coupling reaction.

With both key amino sugars **6** and **7** in hand, we next investigated their coupling to construct the urea glycosyl linkage (Scheme 4). In the event, oxidation of the isonitrile **7** with pyridine *N*-oxide in the presence of 3-Å molecular sieves and a catalytic amount of iodine in acetonitrile generated the isocyanate **5**,[5] which was treated directly with the amino

Scheme 4. Final coupling and completion of the synthesis of glycocinnasperimicin D (**1**): a) pyridine *N*-oxide, I_2 (cat.), 3-Å molecular sieves, CH_3CN (85% for **28**); b) Zn, AcOH, THF; c) CCl_3CONCO, CH_2Cl_2; d) Et_3N, MeOH (77% over two steps); e) TFA, CH_2Cl_2; f) 28% aqueous NH_3, CH_3OH; g) HPLC purification, lyophilization (23%). TFA = trifluoroacetic acid.

sugar **6**. Gratifyingly, this procedure gave the desired coupling product **28** in good yield (85%). Removal of the Troc group in **28** and subsequent treatment of the resulting amine with trichloroacetyl isocyanate, followed by methanolysis, gave the fully protected glycocinnasperimicin D **29** in 77% yield. Finally, removal of the Boc group in **29** with trifluoroacetic acid and subsequent cleavage of the benzoyl and two acetyl groups in a mixture of aqueous ammonia and methanol yielded glycocinnasperimicin D (**1**). To our delight, careful and laborious purification by HPLC provided pure synthetic material **1** (23% yield, isolated as the hydrochloride), the spectral data (^1H NMR, ^{13}C NMR, HRMS), TLC behavior, and antimicrobial activity of which were in good agreement with those of the natural glycocinnasperimicin D.

In conclusion, the first total synthesis of glycocinnasperimicin D (**1**) has been carried out by a convergent route on the basis of a three-fragment coupling strategy. Our synthesis features a Heck reaction to form the cinnamoyl glycoside, the stereoselective formation of an allyl amine by the [3,3] sigmatropic rearrangement of an allyl cyanate, and the construction of the urea glycoside by the coupling of a glycosyl isocyanate with an amino sugar. In particular, the oxidation of an isonitrile glycoside afforded a highly reactive isocyanate glycoside, which was key to the crucial coupling step.

Nanostructures

Aligning Au Nanorods by Using Carbon Nanotubes as Templates**

*Miguel A. Correa-Duarte, Jorge Pérez-Juste, Ana Sánchez-Iglesias, Michael Giersig, and Luis M. Liz-Marzán**

One of the most exciting challenges in modern chemistry and materials science is the manipulation and assembly at the nanoscale.[1] This is particularly interesting since the properties of the nanomaterials are dependent on their aggregation state, and thus collective properties are in general different from the properties of single nanoparticles.[2] A clear example of such sensitivity to aggregation and interparticle distance is found in metal nanoparticles, which display peculiar optical properties as a result of surface plasmon resonance phenomena.[3] The resonance conditions depend on a number of parameters, such as particle size and shape, surface charge, and the nature of the dielectric environment, but also on interparticle coupling when the separation is small.[4] Furthermore, the formation of anisotropic nanoparticles and assemblies provides a new way to control the optical response through the selective excitation of longitudinal or transverse plasmon modes by polarized light.[5]

The formation of strings of metal nanoparticles in general,[6–8] and metal nanorods in particular,[9,10] has recently attracted a great deal of attention, since such assemblies have

potential uses as waveguides that would allow the miniaturization of devices below the diffraction limit[11] and as catalytic motors.[12]

Herein we present the formation of strings of Au nanorods by using multiwall carbon nanotubes (MWNTs) as templates. The use of MWNTs to template the assembly of aligned nanoparticles is not new,[8] but this is the first example in which the nanorods are assembled with a preferential stringlike alignment. The resulting nanocomposites show broadened absorption bands, as a result of end-to-end plasmon coupling between neighboring nanorods. Additionally, the nanorods can serve as a label to monitor the alignment of carbon nanotubes within polymer films, as demonstrated through optical absorption measurements on stretched poly(vinyl alcohol) (PVA) films loaded with the nanocomposite arrays.

The formation of the aligned composites is based in the polyelectrolyte layer-by-layer (LBL) approach,[13,14] which has been recently applied to assemble silica-coated gold nanoparticles on MWNTs.[8] Gold nanorods were synthesized by the seed-mediated procedure recently published by Nikoobakht and El-Sayed,[15] and the surfactant (cetyl trimethylammonium bromide, CTAB) was exchanged with poly(vinylpyrrolidone) (PVP) to clean the colloid (remove excess surfactant) and reverse the surface charge.[16] Prior to the assembly of nanorods, the MWNTs were wrapped with a negatively charged polyelectrolyte (polystyrene sulfonate, PSS), followed by electrostatic assembly of a positively charged polyelectrolyte (poly(diallyldimethyl) ammonium chloride, PDDA). PSS has been shown to adsorb on MWNTs as a result of suppression of the hydrophobic surface.[17] Once this first (charged) monolayer had been deposited, the standard LBL procedure could be applied.

Figure 1 shows TEM images of Au nanorods assembled on MWNTs at various magnifications. The low-magnification image (Figure 1 a) shows that the assembly is extremely uniform over long distances in the whole sample, while the higher magnification images (Figure 1 b,c) show the high degree of alignment of the nanorods, which in general form stripes, though defects (rods with different orientation) are also observed. It is interesting to note that there is a clear tendency for the particles to align in stripes on opposite sides of the MWNTs, rather than uniformly covering the surface (even though a large excess of nanorods was used) and aiming to achieve maximum coverage. Similar images were obtained for the assembly of nanorods with different aspect ratios of the same carbon nanotubes. The reason for not achieving a full coverage of the MWNTs is related to the anisotropic surface potential of the nanorods. It has been recently shown[18] that the potential decays more rapidly in areas with larger curvature (near the tips) so that the approach of a like-charged object (in this case another nanorod) is more favorable towards the tip than the side, thus favoring a stringlike conformation. It could be argued that such a chainlike structure is derived from the drying process on the TEM grid, which would imply some sort of rearrangement of the nanorods on the MWNTs. This is, however, rather unlikely since the electrostatic interactions involved are relatively strong and thus diffusion of the rods on the MWNT surface is restricted. Additionally, the optical properties in solution (see below) point toward uniaxial plasmon coupling, which would not be expected for a random distribution of nanorods on the nanotubes.

This aligned structure is reminescent of that recently reported by Kamat and co-workers[10] in which mercaptopropionic acid was used as a linker molecule. The optical effect derived from such an alignment is described[10] as uniaxial plasmon coupling, and is reflected in the disappearance of the longitudinal plasmon band and the appearance of a new, broader band centered at longer wavelengths. The same effect is observed during the formation of the anisotropic nanocomposite colloids reported here, as shown in Figure 2, where UV/Vis spectra of the precursor nanorods and the final nanorod–MWNT assemblies are displayed for nanorods with various aspect ratios. The variation in the aspect ratio allows precise tuning of the position of the longitudinal plasmon band of the nanorods, and in all three cases the spectra measured after assembly show broader and red-shifted bands, which reflect the uniaxial plasmon coupling between neighboring nanorods.

Since the longitudinal and transverse surface plasmon modes can be selectively excited by using light polarized with the electric field parallel or perpendicular, respectively, to the long axis of the rods, the oriented assembly of nanorods on the surface of the carbon nanotubes can in principle be used as a sensor of the alignment of the nanotubes themselves; this property is of high relevance for reinforcement applications.[19] We have tested this possibility through the preparation of thin films of the gold nanorod–MWNT composites dispersed in poly(vinyl alcohol) (PVA) thin films. The process

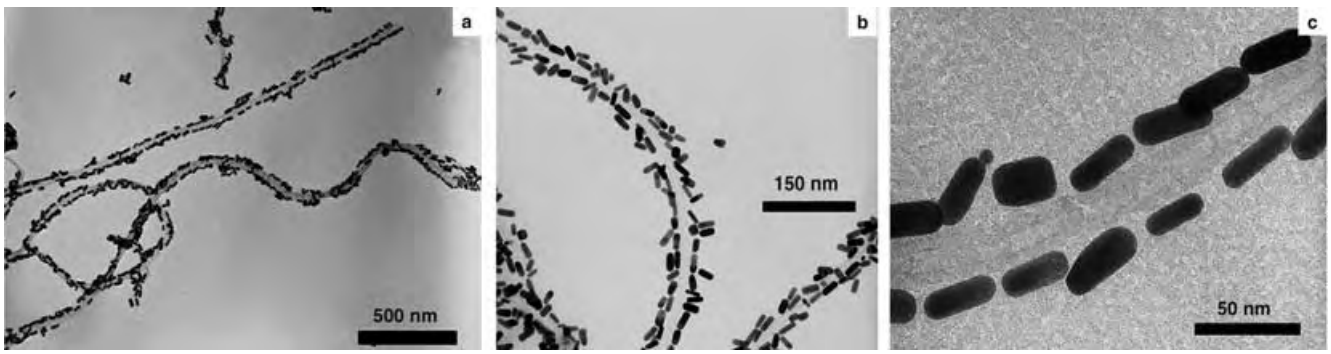

Figure 1. TEM images of Au nanorods (average aspect ratio 2.94), assembled on MWNTs (average diameter 30 nm) at various magnifications.

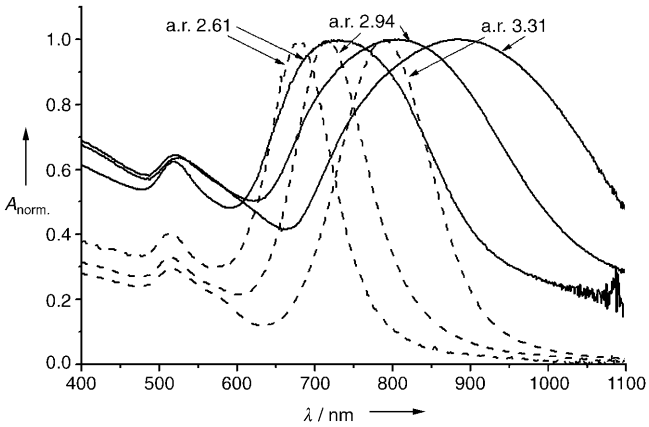

Figure 2. UV/Vis spectra of aqueous dispersions of individual Au nanorods (dashed lines) and nanorods attached on MWNTs (solid lines). The average aspect ratios (a.r.) of the nanorods are indicated.

consisted simply of drying a colloid in the presence of dissolved PVA; this approach has been successfully used by other research groups with silver spheres[20] as well as gold and silver nanorods.[5,21,22] Once the film has been completely dried, alignment is obtained through gently heating and stretching the nanocomposite polymer film. In the case of Au and Ag nanorods, the elongation of the polymer molecules[23] drives the alignment of the small particles toward a preferential direction. We wondered whether the much longer and flexible carbon nanotubes would also get aligned as a result of the stretching of the polymer; this is a very interesting feature for applications in plastic reinforcement. This question was answered by examination of the UV/Vis spectra (Figure 3). The solid black line corresponds to the freshly dried polymer film. Since the nanotubes are randomly oriented, the shape of the spectrum basically coincides with that of the aqueous dispersion, with both plasmon bands clearly visible. Both bands are still visible after stretching the sample (——) since unpolarized light can excite both resonances, irrespective of the nanoparticle orientation. The only difference here is that the longitudinal band is narrower, thus indicating a lower degree of interaction when the nanorod–nanotube composites are pulled and separated from each other. However, the most interesting aspect and definitive indication that a high degree of orientation has been achieved within the film is provided by the spectra of the stretched film obtained using polarized light. The transverse resonance band is fully suppressed and only the longitudinal one is observed when the polarization is parallel to the long axis (•••••, 0°). Conversely, the longitudinal band is suppressed and only the transverse mode is excited when the film is illuminated with light polarized perpendicular to the long axis (–•–•, 90°). Such a result can only be obtained if the nanorods (and in turn the nanotubes) display a well-defined preferential orientation within the film. TEM experiments on this sort of system involve ultramicrotoming of the film and are thus extremely laborious and time consuming, especially when the loading of the CNTs is low, since various experiments are required to actually find the particles. It is however possible (see inset of Figure 3), and this confirms the spectroscopic indication that the nanorods are preferentially oriented within the film.

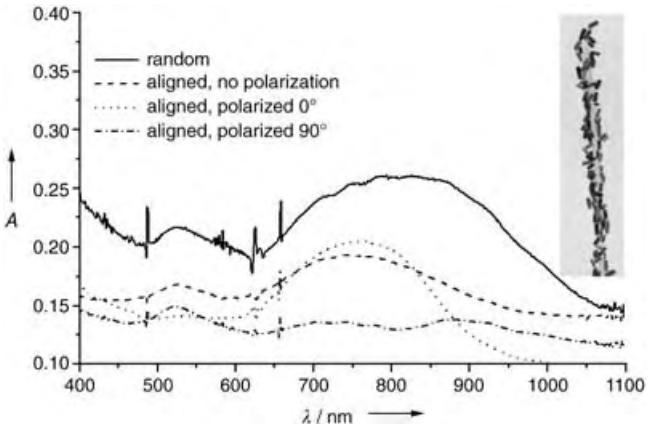

Figure 3. UV/Vis spectra of Au nanorod/MWNT nanocomposites dispersed in a PVA film before (-----) and after (——) stretching. Spectra of the stretched film using polarized light (•••••: 0°; –•–•: 90°) are also shown. The aspect ratio of the rods is 2.94. The inset shows a TEM image of a stretched Au/CNT composite in PVA.

In summary, we have demonstrated the uniform electrostatic assembly of gold nanorods on multiwall carbon nanotubes in such a way that the rods form strings with end-to-end contacts. Such a morphology results in uniaxial plasmon coupling, but can be used to monitor the degree of alignment of carbon nanotubes within polymer films or other nanostructured systems.

Prodrug Activation

Prodrug Activation Gated by a Molecular "OR" Logic Trigger**

*Roey J. Amir, Mikhail Popkov, Richard A. Lerner, Carlos F. Barbas III, and Doron Shabat**

Molecular logic gates are increasingly important in attributing chemical reactivity to molecular devices.[1–5] Specific input signals of basic logic gates can be programmed into single molecules that generate readable output signals, such as fluorescence[6] or UV/Vis light.[7] Here we show that the release of an active drug molecule through a prodrug activation process is a viable output signal. The term "prodrug" is used to indicate that a chemical derivatization has been applied to alter the physicochemical properties of a drug.[8,9] The prodrug is converted into the active drug in vivo by metabolic processes or environmental conditions. Masking of a functional group in a targeted drug with a simple linker which contains two moieties that can be cleaved by different mechanisms can generate a molecular "OR" logic gate trigger. The gate is activated upon a cleavage signal from either of the two input ports. The signal will be translated into a bond cleavage that releases the active drug molecule.

Several anticancer prodrugs have been designed for selective activation in malignant tissues by a specific enzyme secreted within the proximity of the tumor.[10] A prodrug with a molecular "OR" logic gate triggering device could potentially target two different cancerous tissues with different enzyme-expression patterns. There are several examples for enzymes that are present in elevated levels in malignant tissues.[11] The substrates of two of these enzymes could be introduced in the molecular "OR" logic trigger to generate an agent for dual-prodrug monotherapy. Prodrug strategies are sometimes based on the assumption that a particular enzyme is elevated in the tumor tissues and that activation of a prodrug in the tumor tissue will result in a significantly improved therapeutic index. While there is much evidence for overexpression of particular enzymes in tumors, consistent patterns of expression are elusive. Consequently, attempts to develop drugs activated by tumor-specific enzymes in general have not been very successful. Prodrugs with two modes of activation could offer an advantage over single-triggered prodrugs, particularly in circumstances where two different enzymes are present in elevated levels in various regions of the tumor. Herein, we report the design, synthesis, and bioactivation of a molecular "OR" logic trigger which is used to activate a prodrug with dual susceptibility to enzymatic activity.

Classical "OR" logic gates have two input ports and one output port.[12] An activating signal, which operates on either one of the input ports, activates the output signal of the gate (Figure 1). Obviously, positive input signals from both input ports should also activate the gate.

Diethylenetriamine has previously been introduced in a multitriggering mechanism[13] and is used as a linker in the construction of the molecular "OR" logic trigger. The central secondary amine is attached to a drug molecule while the two primary amines are linked to different enzymatic substrates (triggers 1 and 2). The enzymatic cleavage of either one of the substrates generates a free-amine intermediate (intermediate 1 or 2) that initiates an intracyclization reaction to release the free drug unit (Figure 2).

To provide a proof of concept for the "OR" triggering release mechanism suggested in Figure 2, we prepared **1**, which contains two different enzymatic substrates and 4-nitrophenol, as a model compound that represents a potential drug. The two substrates were a phenylacetamide moiety, which is the substrate for penicillin G amidase[14] (PGA), and a retro-aldol retro-Michael substrate that is cleaved by catalytic antibody (Ab) 38C2.[15–17] According to the proposed pathway presented in Figure 3, cleavage by antibody 38C2 or by PGA should catalyze the formation of intermediates **2** or **3**, respectively, and subsequent intracyclization will release 4-nitrophenol.

The "OR" logic trigger substrate **1** was incubated with either antibody 38C2 or PGA in phosphate-buffered saline (PBS) solution (pH 7.4) at 37 °C. The formation of 4-nitro-

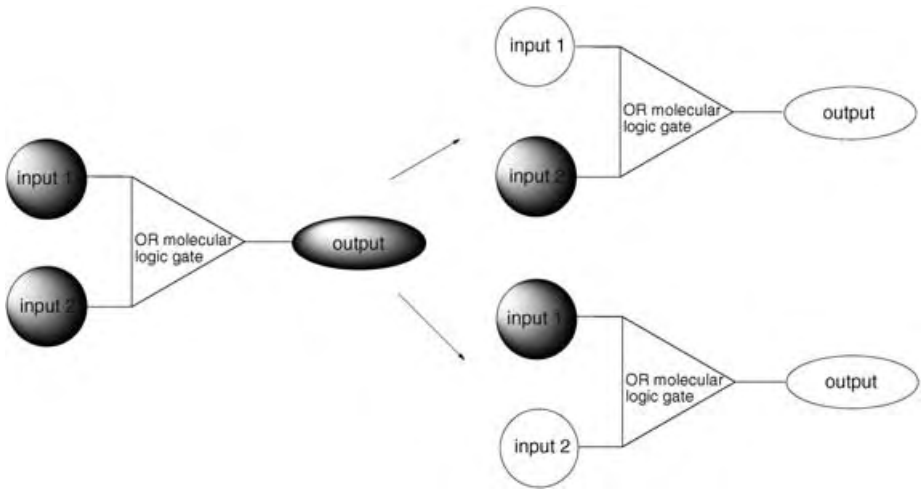

Figure 1. Schematic illustration of an "OR" molecular logic gate. Activation of the gate is indicated by a color change from black to white.

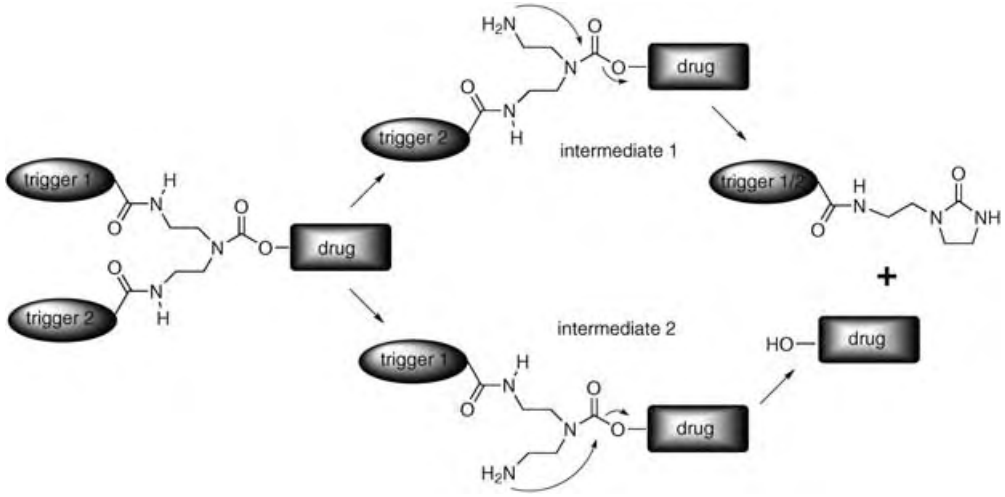

Figure 2. Diethylenetriamine as an "OR" molecular logic trigger.

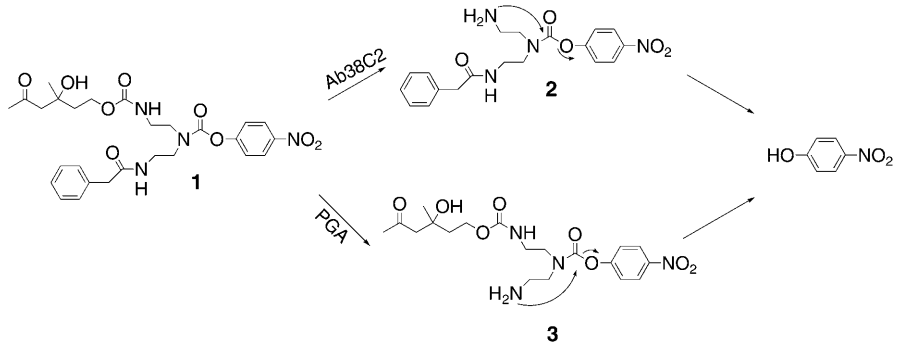

Figure 3. Activation of a molecular "OR" logic trigger by a dual-triggering mechanism with PGA or catalytic antibody (Ab) 38C2.

phenol was monitored by UV/Vis spectroscopy at a wavelength of 405 nm. Figure 4 clearly shows that either the enzyme or the catalytic antibody initiates the activation of compound **1** to release 4-nitrophenol. The reaction was faster with PGA than with antibody 38C2. No release was observed when the substrate was incubated in buffer alone.

Next, we prepared an actual prodrug (pro-Dox) by equipping the "OR" molecular logic trigger with the anticancer drug doxorubicin (Dox). 4-Hydroxybenzyl alcohol was used as a linker between the amino group of Dox and diethylenetriamine (Figure 5). As with the model compound, the two substrates were a phenylacetamide and a retro-aldol retro-Michael substrate. Cleavage by either antibody 38C2 or PGA should result in removal of the 4-hydroxybenzyl alcohol and release of free Dox (through 1,6-elimination).

The prodrug was incubated with either PGA or catalytic antibody 38C2, and the release of free Dox was monitored by reverse-phase HPLC. The HPLC chromatograms in Figure 6 show that upon incubation of PGA (Figure 6a) or antibody 38C2 (Figure 6b) with pro-Dox, intermediates 1 and 2 (shown in Figure 2) were generated and intracyclization liberated the active drug Dox. No release of the drug was observed in the absence of PGA or the antibody.

The "OR" logic gate prodrug was assessed in cell growth inhibition assays. We evaluated the ability of the prodrugs to inhibit cell proliferation in the presence of PGA or catalytic antibody 38C2 using two different cell lines: the human T-lineage acute lymphoblastic leukemia (ALL) cell line MOLT-3 and the human erythroleukemia cell line HEL. The data are shown graphically in Figure 7, and the results are summarized in Table 1. Both PGA and antibody 38C2 could activate the prodrug pro-Dox, and cell growth was inhibited with IC_{50} values close to that of the parent drug.

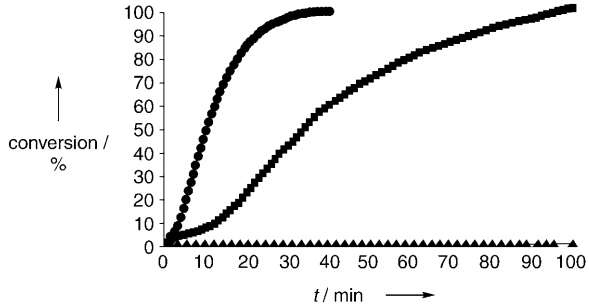

Figure 4. UV/Vis Absorbance at $\lambda = 405$ nm as a function of time in the activation of "OR" molecular logic trigger **1**. ● = **1** + PGA, ■ = **1** + Ab38C2, ▲ = **1** in PBS (pH 7.4). Concentration of substrate is 500 μM; concentrations of PGA or Ab38C2 are 50 μM each.

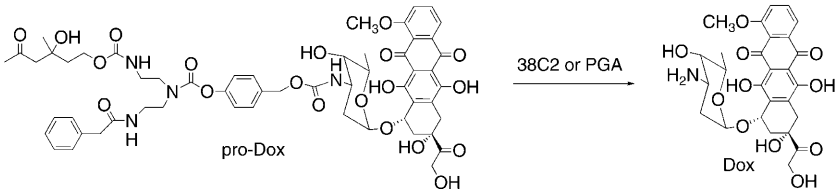

Figure 5. Activation of doxorubicin prodrug by a molecular "OR" logic trigger with antibody 38C2 or PGA.

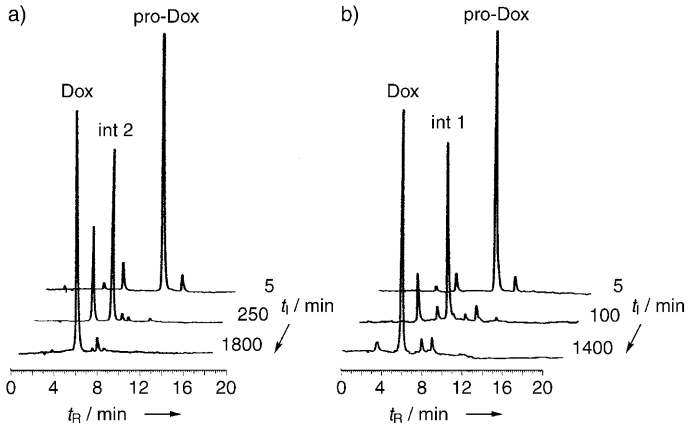

Figure 6. Reverse-phase HPLC chromatograms of a) pro-Dox (70 μM) with PGA (4 μM) in PBS (pH 7.4) and b) pro-Dox (70 μM) with catalytic antibody 38C2 (20 μM) in PBS (pH 7.4). t_R = retention time; t_I = incubation time.

Table 1: IC_{50} values from cell growth inhibition assays.

Drug/Prodrug	IC_{50} [nM]	
	MOLT-3 cells	HEL cells
Dox	3.0	20
pro-Dox	80	200
pro-Dox/38C2	6.5	24
pro-Dox/PGA	7.0	28

A prodrug with a molecular "OR" logic trigger substrate could be used as an efficient tool to evaluate the catalytic activity of the triggering enzymes. In fact, the system allows a direct comparison to be performed between the activities of PGA and antibody 38C2 by using the same prodrug molecule. We used a fixed concentration of the pro-Dox compound (50 nM) and varying concentrations of antibody 38C2 or PGA. The results in Figure 8 show that PGA was about 50-fold more

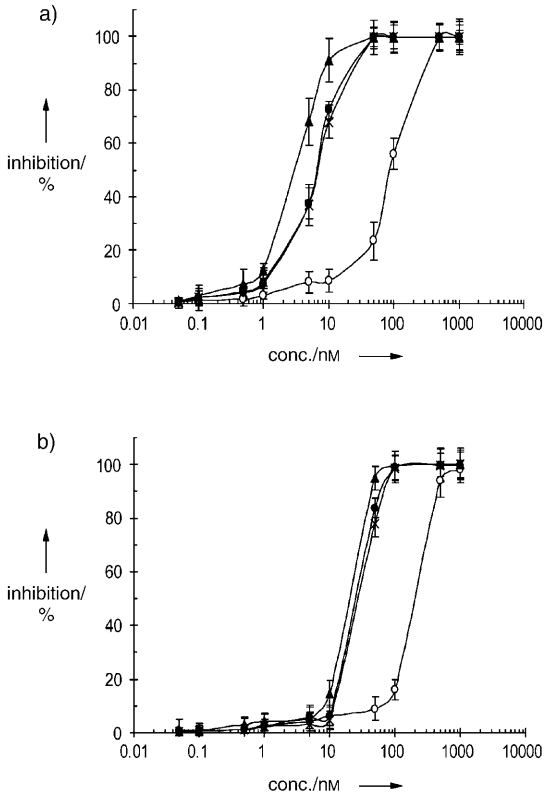

Figure 7. Growth inhibition activity of pro-Dox in the presence and absence of antibody 38C2 and PGA. The growth response of leukemia cell lines MOLT-3 (a) and HEL (b) cells to incubation (72 h) with increasing concentrations of the prodrug in the presence and absence of 38C2 catalytic antibody (1 μM; ●) or PGA (1 μM; ×) was analyzed by using a standard ^3H thymidine proliferation assay. Dox (▲) and pro-Dox (○) were also evaluated. Data points and error bars represent mean values ± standard deviation, respectively.

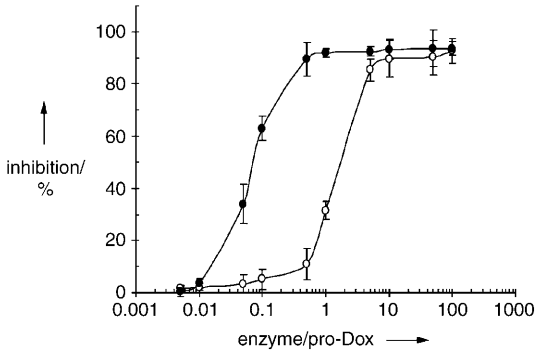

Figure 8. Growth inhibition of HEL cells in the presence of pro-Dox (50 nM) and increasing concentrations of antibody 38C2 (○) or PGA (●), shown as the ratio of enzyme to pro-Dox. Data points and error bars represent mean values ± standard deviation, respectively.

active in growth inhibition of HEL cells than antibody 38C2. Similar results were obtained with MOLT-3 cells (data not shown).

In summary, we have designed and synthesized a molecular "OR" logic trigger operated by two different enzymes. The "smart" linker that is used to mask the doxorubicin amine functionality acts as a dual-input "OR" logic trigger. The input signals are enzymatic cleavages by antibody 38C2 or penicillin G amidase, and the output is the release of the active drug. Our current efforts are focused on the design and synthesis of prodrugs that are activated with a molecular "AND" logic trigger.

Hydrocarbon Chemistry

Simultaneous Conversion of Methane and Methanol into Gasoline over Bifunctional Ga-, Zn-, In-, and/or Mo-Modified ZSM-5 Zeolites**

Vasant R. Choudhary, Kartick C. Mondal, and Shafeek A. R. Mulla*

In response to increased energy demands, worldwide efforts have been made over the past 2–3 decades to develop alternative methods for the conversion of methane (a main constituent of natural gas, coal-bed gas, and biogas) into value-added products. These include ethylene (by oxidative coupling of methane),[1–3] syngas (by partial oxidation with or without simultaneous steam- and/or CO_2-mediated methane reformation),[4–8] and gasoline/liquid hydrocarbon fuels[9–14] that involve either oxidative[1–10] or nonoxidative[11–15] methane activation. As methane and carbon dioxide are key greenhouse gases responsible for global warming, the current industrial practice of emission and/or flaring of produced methane will be banned in the near future. The methane produced in remote places must therefore be converted into easily transportable energy sources like liquid hydrocarbon fuels at the sites of methane production. The most important approach for the transformation of methane into liquid hydrocarbons is the well-established and already commercially proven route:[16] methane→syngas→methanol→gasoline, based on the methanol-to-gasoline (MTG) process developed by Mobil.[16–18] In 1985, Mobil successfully operated a commercial plant in New Zealand for MTG conversions. However, its operation had to be discontinued as a result of unfavorable process economics.[18–20] The cost of the syngas production step (by steam reforming) is about twice the cost of the MTG production step.

The MTG process could become economically viable if it were possible to convert a significant portion of the methane into gasoline without the intermediate steps of conversion into syngas and methanol. Herein, we show that this very difficult goal can be met through the nonoxidative activation of methane and its simultaneous conversion with methanol into gasoline-range hydrocarbons over bifunctional Ga-, In-, Zn-, and/or Mo-modified ZSM-5 type zeolites that have both dehydrogenation and acid functions. We also show that the amount of methane converted can be equimolar to the amount of methanol converted in this novel process, depend-

ing on the specific conditions. The conversion of methane to higher hydrocarbons was confirmed by using ^{13}C-labeled methanol and analysis of the reaction products by GC–MS. This work has the potential to revolutionize the methane-to-liquid hydrocarbons (MTL) conversion technology through the modified MTG process of Mobil.

The results in Figure 1, Figure 2, and Table 1 clearly indicate that methane is nonoxidatively activated and converted at low temperature (< 600 °C) during methanol conversion over the bifunctional zeolite catalysts. However, methane is not activated/converted over H-ZSM-5; instead, it is produced in appreciable quantity (Figure 2). The simultaneous conversion of methane results in a significant change in the hydrocarbon product distribution relative to that of the conventional MTG process. Furthermore, the formation of individual $C_{\geq 2}$ hydrocarbons is increased markedly, as shown in Figure 1 and Table 1. The liquid hydrocarbons formed are mainly C_{7-12} aromatic compounds. The formation of benzene (the presence of which is undesirable because of its toxicity) was very small. In the absence of methane, an appreciable amount of methane is produced in the aromatization of methanol. Therefore, the presence of methane as a co-reactant in our process is beneficial, as the aromatization of methanol results in no net formation of methane. It is of great practical interest that the amount of methane converted per mole of methanol in the feed could meet or exceed 1 mol, depending on the process temperature and methane/methanol ratio in the feed (Figure 2). The required methanol itself can be produced from methane through a well-established technology ($CH_4 \rightarrow$syngas$\rightarrow$methanol). Similarly, methane can also be activated and converted over bifunctional zeolite catalysts during the aromatization of other organic oxygenates, such as ethanol (which can be produced from renewable sources) and dimethyl ether (produced directly from syngas). Notably, Figure 1 illustrates that the hydrocarbon product distribution in the aromatization process presented herein is strongly influenced by the bifunctional zeolite, the oxygenate (methanol, ethanol, or dimethyl ether) used in the process, and the presence of methane in the feed. However, such strong influences are not observed in the aromatization of oxygenates over the monofunctional (acidic) zeolite (H-ZSM-5).

The H-GaAl-ZSM-5 (which is highly acidic and contains finely dispersed gallium oxide species) performs much better than the catalyst prepared through external impregnation of either the gallium, zinc, indium, or molybdenum oxide species on H-ZSM-5. However, the performance of the molybdenum, gallium, and indium oxide-impregnated H-ZSM-5 was

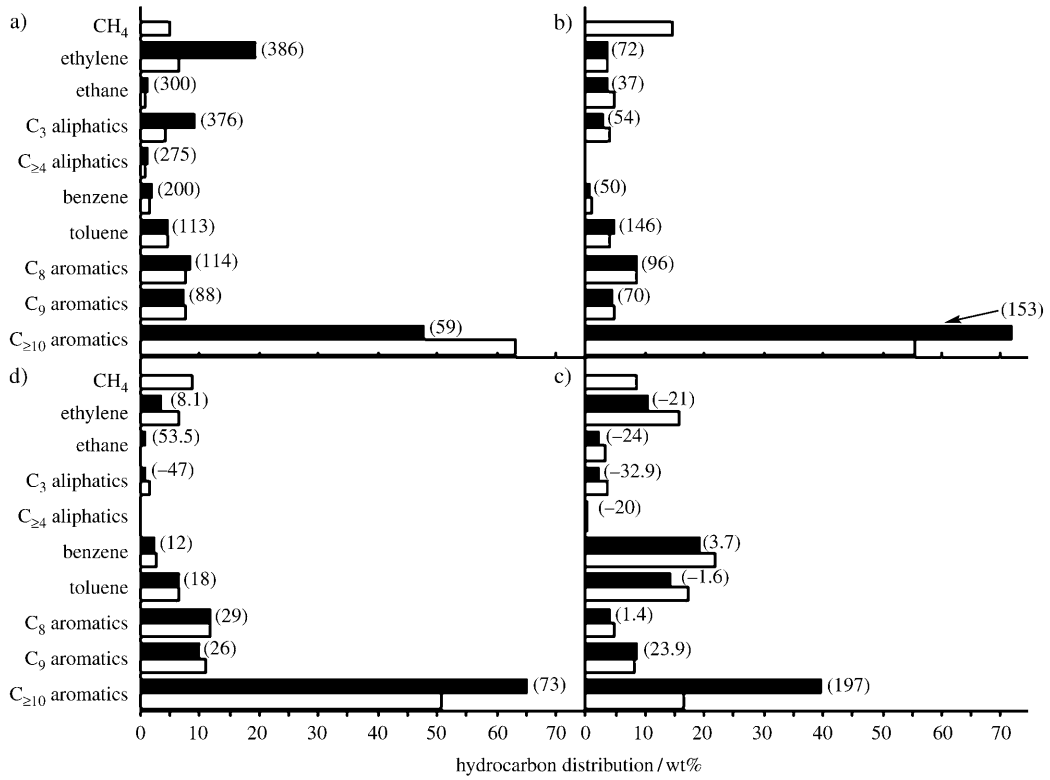

Figure 1. Distribution of hydrocarbons formed in the aromatization of a) methanol over H-GaAl-ZSM-5 at 550 °C, b) methanol over Mo-Zn/H-ZSM-5 at 500 °C, c) ethanol over H-GaAl-ZSM-5 at 625 °C, and d) dimethyl ether (DME) over H-GaAl-ZSM-5 at 550 °C in the presence (solid bars) and absence (open bars) of methane. $CH_4/(CH_3OH$ or DME$) = 15.0{:}1$, $CH_4/C_2H_5OH = 10{:}1$, $CH_4/N_2 = 8.5{:}1$, and gas hourly space velocity (GHSV), measured at 0 °C and 1 atm $= 1050\ cm^3\,g^{-1}\,h^{-1}$. Values in round brackets correspond to the percentage increase in the formation of a particular hydrocarbon as a result of the presence of methane. The conversion of methanol, ethanol, or DME was 100%. In the presence of oxygenate, the amount of methane converted was 0.96 and 1.19 mol/mol CH_3OH for H-GaAl-ZSM-5 and Mo-Zn/H-ZSM-5, respectively, and 0.8 and 0.94 mol/mol CH_3CH_2OH and DME, respectively. In continuous operation for 7 h, both catalysts showed no significant change in catalytic activity for methane conversion.

[a] Moles methane converted per mole methanol. [b] Increase due to the presence of methane.

improved appreciably after the addition of zinc oxide to the catalyst. The catalytically active Mo-containing species may be Mo_2C and/or MoO_xC_y.[21]

Low-temperature (≤ 600 °C) conversion of methane to aromatic hydrocarbons is not thermodynamically feasible, as $\Delta G > 33.4\ kJ\,mol^{-1}_{carbon}$. However, if this conversion is carried out in the presence of methanol over the bifunctional zeolite catalysts, which have strong protic acid and dehydrogenation sites, it becomes thermodynamically favorable as a result of the simultaneous conversion of methane and methanol. (For example, $\Delta G = -8.8$, -15.5, and $-22.2\ kJ\,mol^{-1}$ at 400, 500, and 600 °C, respectively, for one mole of methane converted per mole of methanol.)

In the absence of methanol and/or the absence of bifunctional sites on the zeolite catalyst, there was no conversion of methane. The negative values observed for the ratio of (methane converted)/(methanol converted) with the H-ZSM-5 zeolite (Figure 2a) and in the absence of methane (Figure 2b) indicates the net formation of methane to a significant extent. An temperature optimum is observed for obtaining the highest ratio of (methane converted)/(methanol converted), which depends on the bifunctional zeolite used (Figure 2a). This can be explained by the expected competition between the formation of methane from methanol by cracking reactions (which have a higher rate at higher temperature) and the activation/conversion of methane, which has a lower rate at lower temperature. The ratio of (methane converted)/(methanol converted) is, however, increased markedly with an increase in the methane/methanol ratio in the feed (Figure 2b).

The activation and conversion of methane in the process was confirmed by using ^{13}C-labeled methanol and analysis of the aromatic hydrocarbons formed by GC–MS. The MS data of toluene and xylene produced in the presence and absence of methane in the feed are compared in Figure 3. The mass spectra clearly reveal the formation of unlabeled toluene (formed from methane alone) and partially labeled aromatic compounds (formed from both methane and methanol) in the aromatization of $^{13}CH_3OH$ over the H-GaAl-ZSM-5 and Zn-In/H-ZSM-5 catalysts in the presence of methane. Methane appears to act as an alkylating agent in the formation of methylbenzenes and methylnaphthalenes. Indeed, upon passing a mixture of methane and benzene ($CH_4/C_6H_6 = 12.5:1$) over the H-GaAl-ZSM-5 zeolite at 550 °C, the alkylation of benzene was observed in the formation of toluene and xylenes in significant quantity (with 1.0 % conversion of benzene).

We propose the following mechanism for the activation and conversion of methane during the aromatization of methanol over the bifunctional zeolite catalysts Z, which have strong Brønsted acid sites and nonframework gallium, zinc, and/or indium oxide species, with or without Mo_2C or MoO_xC_y species as dehydrogenation sites in the zeolite channels.

Methanol aromatization [Eq. (1)]:

$$Z^-H^+ + CH_3OH \rightleftharpoons Z^-[CH_3OH_2]^+ \mathbf{I} \rightarrow Z^-H^+ + H_2O + C_{1-12}\,\text{hydrocarbons} \quad (1)$$

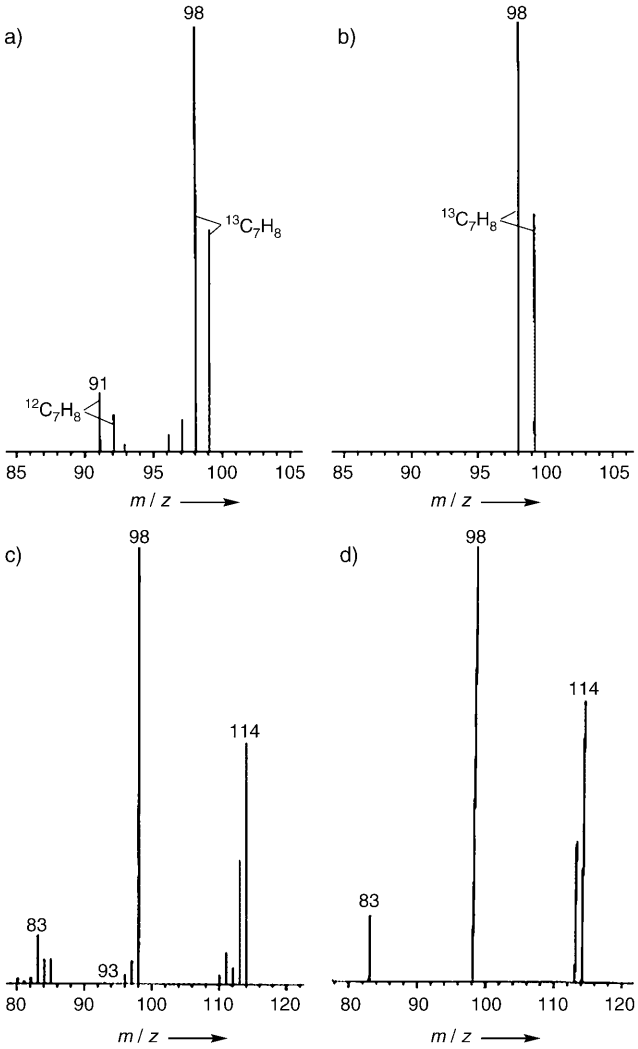

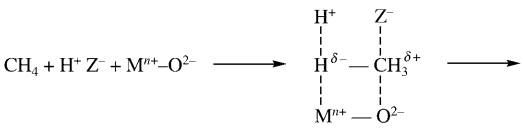

Figure 3. GC–MS spectra of toluene and xylene formed in the aromatization of ^{13}C-labeled methanol ($^{13}CH_3OH$) over the H-GaAl-ZSM-5 zeolite in the presence and absence of methane under identical conditions (at 550 °C and GHSV = 1050 $cm^3 g^{-1} h^{-1}$). Reaction conditions: a) $CH_4/^{13}CH_3OH = 14.7:1$, $CH_4/N_2 = 7.3:1$, toluene, $t_{ret} = 4.56$ min; b) $CH_4/^{13}CH_3OH = 0:1$, $N_2/^{13}CH_3OH = 16.7:1$ toluene, $t_{ret} = 4.56$ min; c) $CH_4/^{13}CH_3OH = 14.7:1$, $CH_4/N_2 = 7.3:1$, xylene, $t_{ret} = 7.68$ min; d) $CH_4/^{13}CH_3OH = 0:1$, $N_2/^{13}CH_3OH = 16.7:1$ xylene, $t_{ret} = 7.68$ min. t_{ret} = retention time.

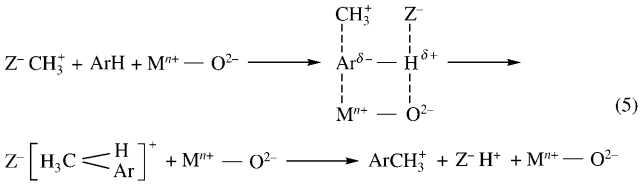
Methane activation and conversion (M = Ga, Zn, or In; X = Mo_2C or MoO_xC_y species) [Eq. (2)–(7)]:



(2)

$$Z^- CH_3^+ \rightarrow Z^- H^+ + CH_2 \quad (3)$$

$$2\,CH_2 \rightarrow C_2H_4 \quad (4)$$

(Z⁻H⁺+Mn−O₂⁻; oligomerization, aromatization; aliphatics, aromatics and H₂)

(5)

$$X + Z^- CH_3^+ \rightarrow XCH_2 + Z^- H^+ \quad (6)$$

$$2\,XCH_2 \rightarrow 2\,X + C_2H_4 \quad (7)$$

Methane is activated mostly as a result of the combined action of the metal oxide species and zeolitic protons, both present at the channel intersections in close proximity to each other. Our earlier studies on the alkane and alkene aromatization over Ga-modified ZSM-5 zeolites also revealed that the zeolitic protons and nonframework gallium oxide species work in cooperation with each other.[22] Methyl cations are likely to be produced through the formation of pentacoordinated carbocations **II**, similar to that proposed earlier by Olah.[23] As no methane conversion is observed in the absence of methanol and/or the bifunctional sites, activation of the H–CH_3 bond and formation of the pentacoordinated carbocations **II** are expected to be facilitated by the nonframework metal oxide species in the presence of oxonium cations **I** and/or carbenium ions formed from the olefins produced from methanol.

The highly unstable methyl cations are expected to be stabilized by the zeolitic framework negative charge (Z^-) as $Z^-CH_3^+$. The role of the metal oxide/carbide species (gallium, indium, and zinc oxides, MoC_2 or MoO_xC_y species) present at the zeolite channel intersections in close proximity to the zeolite protons is not only to facilitate the methane activation but also to facilitate recombination of hydrogen adatoms[24] formed during the C–H bond activation [Eq. (2)]. One mole of H_2 (which appears in the products) is produced per mole of methane activated. The mechanism explains the observed direct conversion of methane into toluene and incorporation of ^{12}C from methane into the aromatics produced from $^{13}CH_3OH$. A very high concentration of methane relative to that of higher hydrocarbons (and consequently relative to methanol) is essential for the formation of a significant amount of methyl cations [by Eq. (2)] and/or pentacoordinated carbocations **II**. This is consistent with the observations; the methane converted per mole of methanol converted is increased markedly with an increase in the methane/methanol ratio in the feed (Table 1, Figure 2b).

Methanol aromatization is highly exothermic ($\Delta H_r \approx -264$ kJ mol^{-1} (*m*-xylene)), and this is one of the major concerns about the MTG process of Mobil. However, in our process, the simultaneous endothermic conversion of methane and exothermic aromatization of methanol over the same catalyst are coupled, which renders the process highly energy efficient. It also eliminates the possibility of process runaway. The other important advantages of this process are: 1) the oxygenate additive (methanol or dimethyl ether) in the methane feed can be produced from methane itself through a well-established technology (methane→syngas→methanol or dimethyl ether); 2) the conversion of the additive is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complete (100%); 3) methane converted per mole of additive can be close to 1.0, hence the requirement of the additive is much smaller than that of the previous process involving higher hydrocarbons as the additive.[11–14] The process of high-temperature (>700°C) methane aromatization over Mo/H-ZSM-5 catalysts[21] is not technically feasible, as the catalyst is deactivated very rapidly. Because of the above highly attractive features, the process presented herein is expected to be much more feasible commercially. Further development of the bifunctional zeolite catalysts and optimization of the process conditions should lead to an economically feasible MTL technology which would not only eliminate the flaring of methane and associated natural gases but which would also satisfy increasing energy demands.

Experimental Section

A mixture of methanol (or ^{13}C-labeled methanol) vapors and premixed methane–N_2 (molar ratio $CH_4/N_2 = 8.5$) gas from a cylinder was passed over bifunctional Ga-, In-, Zn- and/or Mo-modified ZSM-5 (H-GaAl-ZSM-5 (Si/Al = 49.6, Si/Ga = 15.3, nonframework Ga = 0.65 mmol g^{-1}), Mo (2%)–Zn (2%)/H-ZSM-5, Zn (2%)–In (2%)/H-ZSM-5, Mo (2%)–Ga (2%)/H-ZSM-5, and Zn (2.3%)–Ga (2.4%)/H-ZSM-5) zeolite catalysts[25,26] in a tubular quartz reactor[11,26] at different reaction conditions. Before reaction, the Mo-containing catalyst was pretreated by passing a mixture of CH_4–H_2 (6% H_2) over it at 550°C for 4 h, whereas the other catalysts were pretreated in the presence of N_2 under similar conditions. The reaction products were analyzed by GC with thermal conductivity and flame ionization detectors connected in series, or by GC–MS. Methane conversion was determined by using nitrogen as an internal standard: (% CH_4 converted) = $\{[(CH_4/N_2)_{feed} - (CH_4/N_2)_{products}]/(CH_4/N_2)_{feed}\} \times 100$. In all runs, 100% conversion of methanol to hydrocarbons and water was observed. The formation of carbon monoxide in the methanol conversion in the presence or absence of methane was negligible. Furthermore, no formation of carbon monoxide was detected upon passing a mixture of methane and steam over the bifunctional zeolite catalyst at 550°C.

last few years many publications have appeared concerning its implication to ligand-promoted methanol carbonylation.[1] It is commonly accepted that the rate-limiting step of this reaction is precisely the oxidative addition of MeI to a square planar d^8 complex. This reaction is thought to proceed by an S_N2 mechanism. Accordingly, many groups have been working on the acceleration of the overall catalytic reaction by using ligands that increase the electronic density on the metal center as well as stabilizing the ligand through chelation to make it resistant to the harsh conditions of the process.[2] Recent breakthroughs on this topic concern the use of benzoic acid-based flexible *trans*-chelating diphosphines and the use of bis(imino)carbazolide ligands recently reported by Haynes and co-workers, which, to our knowledge, led to the fastest systems published until now.[3,4]

Herein we report on SPANphos mononuclear rhodium complexes, which, even though they resemble the commonly accepted catalyst precursor for methanol carbonylation with phosphine ligands, do not undergo oxidative addition with methyl iodide. As an alternative, we present unprecedented reactivity of SPANphos dinuclear complexes and its implication to the reaction mechanism of the carbonylation of methanol.

Recently, our group reported a *trans*-spanning diphosphine ligand (SPANphos, Scheme 1)[5] for which crystal structures of its mono- and dinuclear rhodium chloro carbonyl

Scheme 1. The SPAN-diphosphine family. Cy = cyclohexyl

complexes have been characterized by X-ray diffraction (Figure 1).[6] These systems are closely related to the those published by Süss-Fink and co-workers and the dinuclear SPANphos rhodium compound resembles the bis-acyl complexes isolated at the end of the reaction by that group.[3] These binuclear complexes, which are formed by the elimination of phosphine, were considered to be inactive but act as a reservoir to the mononuclear, putative catalyst.[3]

Inspired by these results, we considered using complexes of SPANphos ligands, which is a truly *trans*-chelating diphosphine family that cannot *cis* coordinate, as a catalyst for methanol carbonylation. The results obtained showed that SPAN-diphosphines are very active catalyst for this reaction (Table 1). The TOF obtained compare well with those reported by Süss-Fink and co-workers for other *trans*-chelating diphosphine ligands under the same catalytic conditions.[3] In their report, the catalytic cycle is proposed to proceed through a mononuclear species that contains diphosphine ligands in a *trans* disposition.[3]

When a MeOH/rhodium ratio of about 10000:1 was used (Table 1 entries 6–11), high activities were still observed. These results can be considered as an indication that the

observed activity cannot be just attributed to a medium effect caused by phosphine quaternization taking place during the reaction.

Surprisingly, the study of the rate of the oxidative addition of MeI to the mononuclear [ClRh(SPAN-PPh_2)(CO)] (**1**) rendered no rhodium(III) methyl or acetyl compounds, not even after 24 h in pure MeI. Only [RhI(SPAN-PPh_2)(CO)], which arises from halide metathesis, was isolated at the end of the reaction (Scheme 2, reaction a). A previously reported

Scheme 2. a) Reaction of **1** with MeI. b) Reaction of **2** with MeI and the proposed structure for the resulting acyl compound; configuration at the Rh center is unclear.

example of halide exchange instead of oxidative addition was found for a *cis* coordinated mixed P,S-bidentate ferrocenyl ligand.[7] A crystal structure examination of the corresponding [RhCl(CO)(L)] complex showed that one face of the square planar complex is blocked by the ferrocenyl moiety of the ligand backbone, thus inhibiting MeI addition.[7] Both of these cases can be considered as an extreme situation of the extensively studied steric effects on the rate of MeI oxidative addition.[1c,8]

When dimeric [Rh_2(μ-Cl)$_2$(SPAN-POP)$(CO)_2$] was tested as a catalyst for methanol carbonylation (Table 1, entry 11) the results obtained showed that this catalyst is nearly four times more active than the corresponding mononuclear compound (entry 10). These results, together with the fact that when using other *trans*-spanning diphosphines dinuclear structures were isolated at the end of the reaction,[3] brought us to consider a different approach: the activity observed in the case of *trans*-spanning diphosphine ligands should perhaps be attributed to a dinuclear species rather than to the mononuclear species, [RhX(*trans*-P-P)(CO)] (X = Cl, I). To prove this hypothesis, we studied the rate of MeI oxidative addition to the dinuclear compound **2** (Scheme 2, reaction b). The results obtained showed that the oxidative addition to this dimetal species is only ten times slower compared to the most active catalyst reported until now (Figure 2),[4] but it constitutes the most active phosphine-based catalyst. In the IR spectrum of the reaction, the fact that the band at 1981 cm^{-1} decays but does not disappear at the end of the reaction suggests that the migration, and probably also the oxidative addition, occurs only at one of the two rhodium centers. The addition of MeI at only one of the two metallic centers of a rhodium dimer to render a Rh^{I}–Rh^{III} monoacyl species is not unprecedented. Similar reactivity, at much lower reaction rates, has already been reported by Oro and

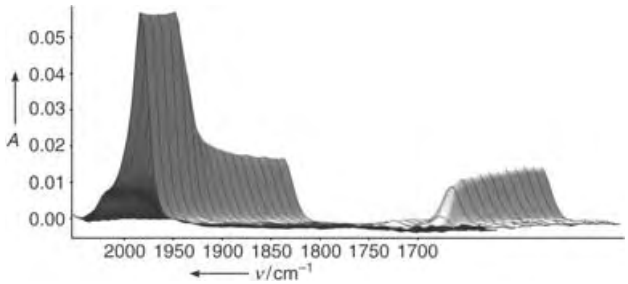

Figure 2. IR decay curves/surface for oxidative addition of MeI to **2** at 283 K. [MeI] = 1.6 M (1 spectrum per minute).

co-workers for dinuclear Rh complexes with diamido bridging ligands.[9] Simultaneous NMR spectroscopy experiments performed on reaction mixtures and GC–MS analysis of reaction products are consistent with this hypothesis.

Kinetic studies by using in situ FTIR have been performed on the reaction of MeI with the dinuclear compound **2**, which showed that the reaction is first order with respect to both MeI and **2**. From the pseudo first-order constants obtained over a range of MeI concentrations and temperatures, the activation parameters ($\Delta H^{\neq} = 32.15\ kJ\,mol^{-1}$, $\Delta S^{\neq} = -163.73\ J\,mol^{-1}\,K^{-1}$) were calculated. These values are in concordance with those previously reported for this reaction with mononuclear complexes.[1c,4,8a,8b]

We conclude that *trans*-spanning diphosphine ligands form mononuclear rhodium compounds that are inactive for the oxidative addition of methyl iodide. The lack of reactivity as established for SPAN-diphosphines should be attributed to one face of the square-planar compound being completely blocked by the backbone of the ligand. Consequently, the activity observed with mononuclear systems as precursors for MeOH carbonylation is most likely to arise from dinuclear species formed by partial dissociation of the ligand. A complete catalytic cycle that involves dinuclear species should be considered. These dimetal compounds showed an unprecedented activity for MeI oxidative addition, and also for MeOH carbonylation, and constitute one of the fastest systems reported until now.

Experimental Section

SPAN-diphosphines were synthesized according to a modified reported procedure published for the diphenyl phosphine derivative.[5]

Compounds **1** and **2** were synthesized in Schlenk tubes by mixing the appropriate quantities of SPAN-PPh_2 and [Rh_2(μ-Cl)$_2$$(CO)_4$], dissolving the mixtures in degassed CH_2Cl_2, passing the resulting solutions through celite, and removing the solvent by evaporation. Yields were quantitative. Suitable crystals for X-ray diffraction were grown by slow diffusion of pentane into CH_2Cl_2 solutions of the rhodium complexes.

(100 MHz, 298 K, TMS): $\delta = 21.4$ (CH_3), 21.5 (CH_3), 29.3 (CH_3), 29.5 (CH_3), 30.6 (CH_3), 30.8 (CH_3), 47.9 (CH_2), 48.1 (CH_2), 86.3 (C), 86.5 (C), 117.2 (C), 127–138 ppm (C_{arom}); ^{31}P NMR (162 MHz, 298 K): $\delta =$ 22.29 (dd, $J = 365.4$, $J = 132.0$ Hz), 26.50 ppm (dd, $J = 365.4$, $J =$ 132.0 Hz); MS [M−Cl].

2: ^{1}H NMR(400 MHz, 298 K, CD_2Cl_2, TMS): $\delta = 0.73$ (s, 3H, CH_3), 1.18 (s, 3H, CH_3), 1.70 (d, $J = 14.4$ Hz, 1H, CH_2), 2.00 (s, 3H, CH_3), 2.10 (d, $J = 14.4$ Hz, 1H, CH_2), 6.28 (dd, $J = 12.0$, $J = 1.6$ Hz, 1H, CH_{arom}), 7.05 (d, $J = 1.5$ Hz, 1H, CH_{arom}), 7.15–7.35 (m, 8H, CH_{arom}), 7.73 ppm (dd, $J = 11.6$, $J = 7.6$ Hz, 1H, CH_{arom}); ^{13}C NMR (100 MHz, 298 K, TMS): $\delta = 21.1$ (CH_3), 29.5 (CH_3), 31.0 (d, CH_3, $J =$ 20.6 Hz), 50.462 (CH_2), 102.5 (C), 117.2 (C), 128–137 ppm (C_{arom}); ^{31}P NMR (162 MHz, 298 K): $\delta = 45.88$ ppm (d, $J = 178.16$ Hz); MS [M−Cl], [M−2Cl].

Catalytic experiments: In a typical experiment 29.3 mL of a mixture MeOH/H_2O was placed in a 100-mL Hastelloy autoclave. The autoclave was then pressurized to 10 bar of carbon monoxide and heated to 150 °C with vigorous stirring (700 rpm). When the reaction temperature was reached and had stabilized, a solution of [$Rh_2Cl_2(CO)_4$] and the appropriate quantity of the corresponding ligand in MeI were added through a liquid injection port and the autoclave was pressurized to the desired reaction pressure. Pressure was maintained constant during the reaction by feeding gas from a 1-L autoclave pressurized with over 60 bar of carbon monoxide. After the required reaction time, the autoclave was cooled to room temperature. The solution was analyzed by NMR spectroscopy to determine the selectivity. The conversion was calculated from gas consumption of the reservoir autoclave.

Kinetic experiments: Kinetic measurements for the reaction of **1** or **2** with MeI in CH_2Cl_2 were performed in situ by using a React IR 4000 from Mettler Toledo equipped with a diamond probe. A solution that contained the corresponding rhodium compound in distilled CH_2Cl_2 was placed in the sample vessel under an argon atmosphere. The temperature was fixed by using a thermostat jacket. When the desired temperature was achieved and remained constant, freshly distilled MeI was added by using a syringe. The IR spectra were scanned in the region 400–2200 cm^{-1} and saved at regular time intervals (usually 10 s) under computer control.

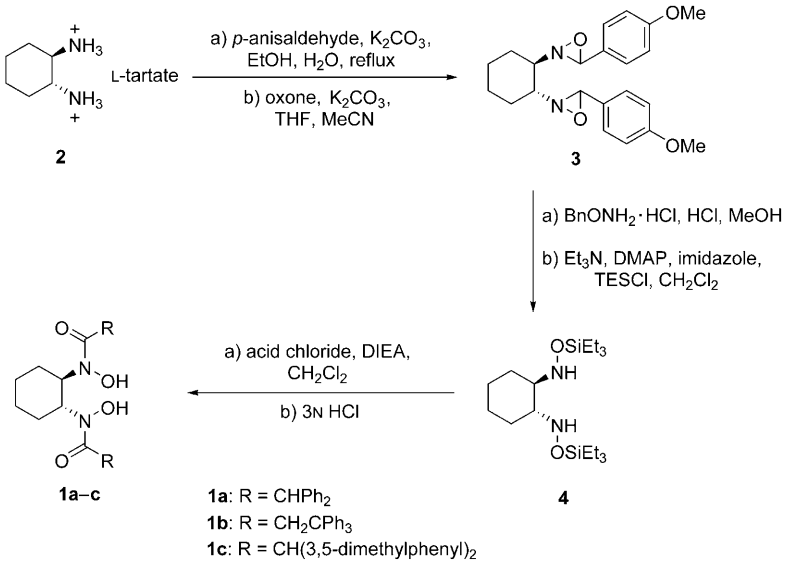
Asymmetric Catalysis



Enantioselective Epoxidation of Allylic Alcohols by a Chiral Complex of Vanadium: An Effective Controller System and a Rational Mechanistic Model**

*Wei Zhang, Arindrajit Basak, Yuji Kosugi, Yujiro Hoshino, and Hisashi Yamamoto**

The asymmetric epoxidation of allylic alcohols by metal catalysts,[1] though a widely used synthetic method, could gain even more practical applications if the following were realized: 1) employment of a ligand designed to achieve high enantioselectivity for *Z* olefins, 2) catalyst loading of less than 1 mol%, 3) reaction temperatures of 0°C to room temperature over a shorter time, 4) use of aqueous *tert*-butyl hydroperoxide (TBHP) as an achiral oxidant instead of anhydrous TBHP, and 5) simple workup procedures for small epoxy alcohols. Many important improvements have been made to the methodology developed by Sharpless and co-workers for the titanium tartarate catalyzed asymmetric epoxidation.[2–4] Nonetheless, each of these approaches fails to fulfil the above criteria.[1–5] Herein, we report our recent progress on all five fronts.

Recently, we developed a series of hydroxamic acid ligands and demonstrated that they were effective for the vanadium-catalyzed asymmetric epoxidation of allylic alcohols.[6,7] These results suggested that several structural features of the hydroxamic acid significantly enhanced the rate and enantioselectivity of the reaction. However, the ligand deceleration effect was still observed in these cases.[6–8] To exclude this effect, we planned to design a new C_2-symmetric bishydroxamic acid **1** that incorporated the following features: 1) an additional binding site with which **1** can chelate as a bidentate ligand to the metal center to complete the generation of a chiral vanadium/ligand complex more efficiently than the monohydroxamic acid and 2) an R group of the amide in **1** that is sufficiently large so the oxygen atom of the carbonyl group is directed towards the cyclohexane ring to minimize steric interaction and restrict its coordination with the metal center. Furthermore, the attachment of additional ligands to the vanadium center will also be restricted because of steric reasons. Thus, doubly or triply coordinated species, which are believed to be inactive, should not be generated from the bishydroxamic acid ligand, and consequently a ligand deceleration effect within the vanadium/**1** catalytic system should not be problematic.[8]

We devised a synthetic protocol for **1** from a readily available diamine tartrate salt (Scheme 1) so that the veracity of our hypothesis could be proved.[9] These reaction sequences can be carried out with satisfactory yields and without any purification to provide **4**, from which we have prepared an array of diverse ligands **1a–c**.

Scheme 1. Preparation of bishydroxamic acid. DIEA = *N*,*N*-diisopropylethylamine, Bn = benzyl, DMAP = 4-dimethylaminopyridine, TESCl = triethylsilyl chloride.

As expected, the use of a complex of vanadium with ligand **1** provided epoxy alcohols both in good yields with high enantioselectivities (Table 1).[9] The catalyst **5a**, derived from vanadium and **1a**, invariably induced excellent enantioselectivities during the epoxidation of *trans*-disubstituted and -trisubstituted allylic alcohols. The most gratifying aspect of this catalytic system was the excellent enantioselectivity observed during the epoxidation of *cis*-substituted allylic alcohols with catalyst **5b**, which was derived from vanadium and **1b.** It is of note that 1) the slow reactivity of some substrates were surmounted by performing the epoxidation at 0°C or room temperature without significant loss of enantioselectivity, 2) the catalyst loading could be as low as 0.2 mol%, 3) all the reactions were performed in air and in the presence of aqueous TBHP; the use of anhydrous TBHP increased neither the yield nor the enantioselectivity.[9] Also as expected, the negative effect of a dynamic ligand exchange was not observed in the vanadium/bishydroxamic acid catalytic system. The high reactivity of the vanadium/ligand complex was maintained, even if the ratio of ligand/vanadium was increased to more than 3:1.[9]

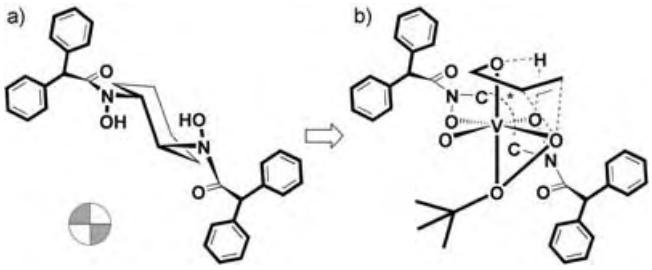
To explain the reaction enantioselectivity, we have proposed a possible intermediate during the epoxidation[10] (Figure 1). If **1a** is divided into four sections, as indicated by the circle in Figure 1, it is seen that the second and fourth quadrants of **1a** (corresponding to the shaded sections) are more crowded than the first and third quadrants (corresponding to the unshaded quarters) because of the structural features of the chiral cyclohexyl bishydroxamic acid (Figure 1a), especially when the vanadium center is introduced. $[VO(OiPr)_3]$ coordinates with **1a** by displacement of two *i*PrOH units with two hydroxy groups from the bishydroxamic acid (Figure 1b). Another *i*PrOH unit of $[VO(OiPr)_3]$ is then displaced by TBHP, which occupies the less-crowded third quadrant. Finally, when the allylic alcohol forms, it will coordinate with the vanadium center through its oxygen atom from the top. During the reaction, the oxygen atom of TBHP is spiro overlapped with the olefin and attacks it from the bottom. Steric bulk at the α position of the carboxylate group, which is greater in the case of **1a**, plays an important role and is suitable for *trans*-substituted allylic alcohols as the sub-



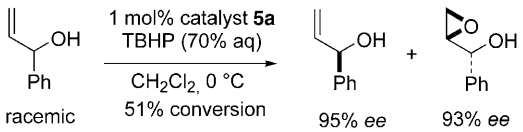


Figure 1. Postulated model of the epoxidation of allylic alcohols catalyzed by the vanadium/**1a** complex. a) Chiral cyclohexyl bishydroxamic acid **1a** and b) the proposed reaction intermediate. The circle represents the division of the bishydroxamic acid into quarters to explain its stereochemistry. The shaded sections of the circle represent the parts of the bishydroxamic acid in bold.

This method was applied to the asymmetric synthesis of small epoxy alcohols, which is a long-standing problem in asymmetric oxidation. Thus, after the reaction, the product was extracted with water to give the enantiopure epoxy alcohols (Table 2).[2,9]

Finally, the method was also applied to the kinetic resolution of a secondary allylic alcohol. As expected, both the epoxy alcohol and the allylic alcohol were isolated with high enantioselectivities [Eq. (1)].[9]

strate. On the other hand, the additional flexibility of **1b** allows the *cis*-substituted allylic alcohols enough space to fit into the chiral pocket, thus resulting in high selectivity.

In conclusion, we have developed a new catalytic system for the asymmetric epoxidation of allylic alcohols. Investigations into the mechanism and further applications of bishydroxamic acid ligands in asymmetric catalysis is in progress.

Experimental Section

Representative experimental procedure: $[VO(OiPr)_3]$ (0.0025 mL, 0.0104 mmol) was added to a solution of **1a** (11.2 mg, 0.0210 mmol) in CH_2Cl_2 or toluene (1 mL), and the reaction mixture was stirred for 1 h at RT. The resulting solution was cooled to 0 °C, and 70 % aqueous TBHP (0.22 mL, 1.59 mmol) and α-phenylcinnamyl alcohol (220 mg, 1.05 mmol) were added. The mixture was stirred at the same temperature for 12 h. The process of epoxidation was monitored by TLC. Saturated aqueous Na_2SO_3 was added, and the reaction mixture was stirred for 1 h at 0 °C. The reaction mixture was then allowed to warm to RT, extracted with Et_2O, dried over Na_2SO_4, and concentrated under reduced pressure. The remaining residue was purified by flash column chromatography on silica gel to provide the epoxy alcohol (93 %, 94 % *ee*). Determination of the *ee* values of the epoxy alcohols is provided in the Supporting Information.

Battery Materials

Self-Assembled Vanadium Pentoxide (V_2O_5) Hollow Microspheres from Nanorods and Their Application in Lithium-Ion Batteries**

*An-Min Cao, Jin-Song Hu, Han-Pu Liang, and Li-Jun Wan**

Self-assembled structures with highly specific morphology and novel properties are of great interest to chemists and materials scientists. As a result of rapid advancements in synthetic strategies, highly organized building blocks of metals,[1] semiconductors,[2] copolymers,[3] organic–inorganic hybrid materials,[4] and biominerals[5] have been synthesized by using various methods. However, controlled organization into curved structures from rodlike building blocks remains a challenge. Such a capability is attractive to scientists not only because of its importance in understanding the concept of self-assembly with artifial building blocks but also for its great application potential.[6–9] Vanadium pentoxide (V_2O_5) has been extensively studied as a well-known transition-metal oxide. Various nanostructures of V_2O_5,[10] such as nanotubes, nanowires, nanofibers, nanobelts, nanorods, and mesoporous structures have already been synthesized by a variety of methods, including reverse-micelle transition, sol–gel process, hydrothermal treatment, and electrochemical deposition. Nanostructured V_2O_5 has potential application in the fields of lithium-ion batteries,[10c,d,11] actuators,[10f] catalysis,[12] and sensors.[13] To our knowledge, hollow microspherical V_2O_5 has not been reported until now although such a structure has long been a focus of research.[14]

Herein, we describe a facile method to self-assemble V_2O_5 nanorods into microspheres. A mediated polyol process was adopted to prepare hollow microspherical V_2O_5, in which ethylene glycol (EG) is treated with a metal salt in the presence of poly(vinylpyrrolidone) (PVP). Such a method was previously used to obtain metal nanoparticles, nanowires (EG as a reductant),[15] and oxide nanowires (EG as a ligand).[16] We now present its use, for the first time, to synthesize hollow microspheres of V_2O_5. Using vanadium(III) acetylacetonate (acac) as the metal-ion source, we have synthesized hollow microspheres with nanorods on their surface; moreover, the morphologies of such nanorods are

readily tunable. The as-prepared vanadium hollow microspheres can be calcined into crystalline V_2O_5 without changing their morphologies. These V_2O_5 products exhibit improved electrochemical properties when they are used as cathode material in lithium-ion batteries and show good application potential.

Briefly, PVP was mixed with $[V(acac)_3]$ in a solution of EG at room temperature and normal pressure then heated at 140 °C for about 100 min, which led to the eventual formation of vanadium precursors with different structures. It is worth noting that PVP had a great influence on the morphologies of the synthesized vanadium precursors. In the absence of PVP, nanorods mainly form, the aspect ratios and diameters of which are tunable. Figure 1a shows such nanorods with

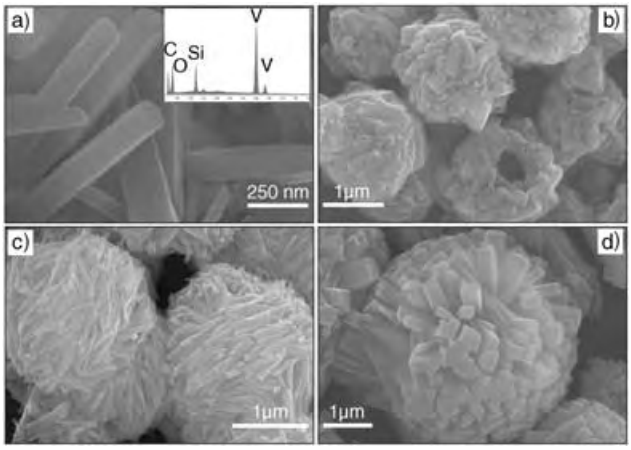

Figure 1. a) SEM image of the vanadium precursor prepared with 6 mM $[V(acac)_3]$ and no PVP. The inset shows the EDX pattern of the rod. b–d) SEM images of the microspheres synthesized with different concentrations of $[V(acac)_3]$ at 6 mM (b), 18 mM (c), and 42 mM (d), while the concentration of PVP was constant at 0.14 mM.

diameters of about 200 nm and lengths up to 2 μm at a concentration of 6 mM $[V(acac)_3]$. The energy-disperse X-ray (EDX) spectroscopic analysis (inset in Figure 1a) of the nanorods shows their chemical composition correlating well to that of the vanadium precursor. Upon the introduction of 0.14 mM of PVP, uniform hollow microspheres formed in large quantity, the morphology of which could be readily regulated by changing the concentration of $[V(acac)_3]$. At a concentration of 6 mM $[V(acac)_3]$, the rods are relatively short and circle around to form the spherical shell just taking the shape of a nest (Figure 1b). A broken sphere in the lower part of Figure 1b clearly shows the hollow feature of the sphere. At a concentration of 18 mM $[V(acac)_3]$, these nanorods become longer and have a higher packing density as shown in Figure 1c. At a concentration of 42 mM $[V(acac)_3]$, these nanorods eventually self-align perpendicular to the spherical surface and emanate from the center rather like the spines of a hedgehog (Figure 1d).

After the preparation of the precursors, we investigated the effect of calcination on the crystallization and morphology of the hollow microspheres. Subsequent calcination at 500 °C over 2 h did not change the individual morphologies of these vanadium precursors. Figure 2a shows a representative SEM image of a calcined V_2O_5 sample, which shows that the structure of the hollow microspheres was preserved. The sample was prepared under the same conditions as those

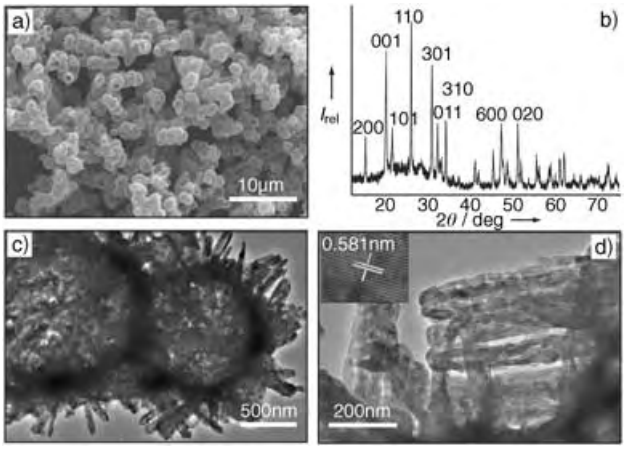

Figure 2. a) SEM image, b) XRD pattern, and c) low and d) high magnification TEM images of the calcinated V_2O_5 hollow microspheres. The inset in Figure 2d is a high-resolution TEM (HRTEM) picture taken from the edge of a nanorod surface.

applied to generate the samples shown in Figure 1c. The following characterizations are all based on this sample unless otherwise noted. Figure 2b shows a wide-angle XRD pattern of this calcined sample, which can be indexed as the orthogonal symmetry of V_2O_5 (space group: *Pmmn* (59), $a = 11.516$, $b = 3.566$, $c = 3.777$ Å; JCPDS card no. 41–1426), thus demonstrating the presence of crystalline V_2O_5. The TEM image in Figure 2c further affirms that the calcined V_2O_5 superstructures are indeed hollow microspheres with nanorods pointing out from the surface. The presence of nanorods can be clearly seen in Figure 2d. In a high-resolution TEM (HRTEM) image taken from the edge of a nanorod (inset of Figure 2d), the lattice fringes are clearly visible with a spacing of 0.581 nm, which is in good agreement with the spacing of the (200) planes of V_2O_5 (JCPDS card no. 41–1426).

Time-dependent experiments were performed to gain insight into the formation process of such vanadium precursors. Products were collected at different stages from the reaction mixture once the precipitate had began to appear in solution, and their morphologies were subjected to SEM investigation. As shown in Figure 3, when a sample was taken immediately after the formation of precipitate ($t = 0$ min), the collected product comprised microspheres with smooth surfaces (Figure 3a); after ten minutes, the surfaces of the samples were found to be rougher (Figure 3b). Nanorods formed over the following 20 minutes (Figure 3c), which were evidently very stable in solution as such their highly ordered superstructure remained unchanged with subsequent heating for over an hour (Figure 3d).

Ethylene glycol has been established as a cross-linking reagent.[16,17] Xia and co-workers proposed that two key steps are involved in producing nanowires: 1) coordination of EG

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

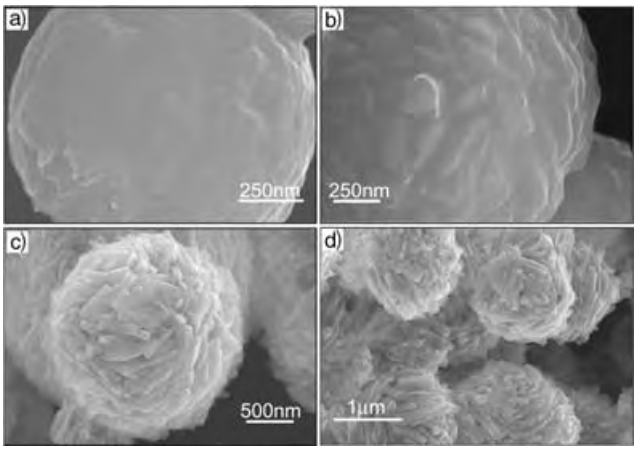

Figure 3. SEM images of the samples collected at different stages after the precipitate appeared in the clear solution: a) 0, b) 10, c) 30, and d) 90 min.

to the central metal ion to form a metal glycolate and 2) subsequent oligomerization.[16] Such a mechanism may be adapted to explain the formation of rodlike vanadium precursors. The XRD pattern (see the Supporting Information) of the vanadium precursor shows its crystalline nature with characteristically strong peaks around 10°, which is a feature of the coordination and oligomerization processes in EG.[16] FTIR spectra (see the Supporting Information) show the gradual displacement of the acac ligands with EG. The C–OH vibration at 1056 cm^{-1} together with the CH_2 band at 2939 and 2877 cm^{-1} in the final product increases at the expense of the characteristically strong bands of C=O in $[V(acac)_3]$ at 1566 and 1527 cm^{-1}. This result indicates that EG has completely replaced acac in a similar way to that proposed by Xia and co-workers.[16]It is evident that PVP plays a completely different role to that reported in the polyol process.[15,16] The introduction of PVP is crucial in obtaining uniform hollow microspheres because of the template effect of the polymer. As the vinyl group is hydrophobic and carbonyl group is hydrophilic, PVP also functions as a surfactant in an EG solution. Indeed, hollow structures have already been synthesized with PVP as the template.[18] A probable mechanism for the evolution of such structures is presented in Figure 4. PVP forms spherical micelles in EG with the carbonyl groups on the outside. The acac ligand of $[V(acac)_3]$ is gradually replaced by EG to form vanadium glycolates, which are easily adsorbed onto the micelle surface through their

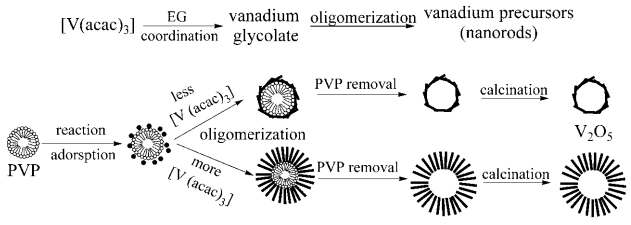

Figure 4. Schematic illustration of the evolution of V_2O_5 hollow microspheres.

abundant hydroxy groups. Nanorods form and grow as the oligomerization of vanadium glycolates proceeds. These rods are flat on the surface at relatively low abundance but gradually turn and pack more tightly as the concentration of $[V(acac)_3]$ increases. Finally, they are perpendicular to the surface because of a spherical hindrance effect. Hollow spheres retain their geometry even after PVP is removed. Considering the abundant carbonyl and hydroxy groups in the system and because PVP is known to be a hydrogen-bonding acceptor,[3a,19] we believe the key factors affecting this self-assembly process are hydrogen bonding and the requirement that the "grafted" nanorods pack effectively. The exact role of PVP in the polyol process has long been an issue of debate,[16,18] and extensive work is underway towards its further clarification.

Cyclic voltammetry was used to investigate the electrochemical behavior of the highly ordered superstructures. Figure 5a shows the cyclic voltammograms (CVs) of V_2O_5

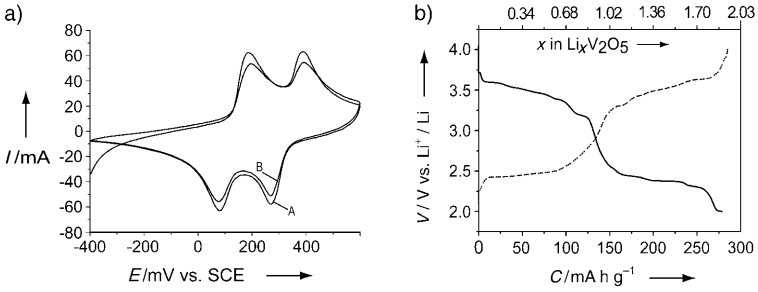

Figure 5. a) Cyclic voltammograms of V_2O_5 microspheres obtained at a scan rate of 10 $mV s^{-1}$. The first scan is indicated by curve A and after 15 cycles by curve B. b) The third charge(dash–dot line)–discharge(solid line) profile with a current rate of *C*/5.

hollow microspheres. Curve A (Figure 5a) is the first scan and B is the scan after 15 cycles. In the potential region from −400 to 600 mV, two sets of peaks can be seen at 80 and 270 mV. These peaks have been attributed to two successive electrochemical processes [Eq. (1) and (2)]:[11a–c]

$$V_2O_5 + {}^1/_2\,Li^+ + {}^1/_2\,e^- \rightleftharpoons Li_{0.5}V_2O_5 \quad (1)$$

$$Li_{0.5}V_2O_5 + {}^1/_2\,Li^+ + {}^1/_2\,e^- \rightleftharpoons LiV_2O_5 \quad (2)$$

In the first reduction peak at 270 mV, only a fraction of the V^{5+} ions is reduced to V^{4+} ions. The remaining V^{5+} ions are reduced to V^{4+} ions in the second peak at 80 mV.[11b] The reverse reactions take place as indicated by the two corresponding oxidation peaks. With the electrochemical reaction, different phases of $Li_xV_2O_5$ are formed. From the binary phase diagram of V_2O_5–$Li_xV_2O_5$, we determined that the cathodic peaks at 80 and 270 mV correspond to the phase transformations from α-V_2O_5 to ε-V_2O_5, and ε-V_2O_5 to δ-V_2O_5, respectively.[11d,e]

The charge–discharge capability of the microspheres was investigated by using V_2O_5 as the cathode in a lithium-ion battery. Figure 5b is the profile of a third charge–discharge cycle. The capacity was as high as 286.4 $mA h g^{-1}$ while the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

charge–discharge efficiency was up to 97.2% in the potential range from 2.0 to 4.0 V. These results show that V_2O_5 might be very good cathode material.[10c,d,11] The V_2O_5 samples with different morphologies (from nest-shaped to hedgehog-shaped) were tested for their electrochemical performances; they exhibited similar CV characteristics and had a variation of capacity in the Li-ion battery of less than 7 mA h g^{-1} (≈2%).

After the electrochemical investigation had been performed, the morphologies of the V_2O_5 samples were reinvestigated by TEM. The results showed that the structure of the hollow microspheres and nanorods remained unchanged.

The correlations among structure, composition, morphology of V_2O_5, and its electrochemical properties in the lithium-ion battery have been well studied by other researchers.[10c,d] In our system, the hollow microspheres together with the porous and rugged nanorods that have interconnected nanoparticles are favorable in reducing the diffusion distance of the solid-state lithium ion. Thus, the intercalation and extraction processes are of much higher efficiency, the kinetic performance of the lithium-ion battery is better, and therefore a higher capacity can be achieved.

In summary, we have developed a mediated polyol process to synthesize V_2O_5 with highly ordered superstructures, in which nanoparticles interconnect to form nanorods, and these rods circle around to form hollow microspheres. The protocol represents a substantial simplification over more conventional methods such as electrostatic spray or thermal evaporation. The physical state of the nanorods on the surface can be varied by changing the concentration of $[V(acac)_3]$ and the formed microspheres can adopt different shapes that range from nest-like to hedgehog-like. The prepared V_2O_5 exhibits desirable electrochemical properties such as high capacity and remarkable reversibility when it is used as cathode material in a lithium-ion battery.

Experimental Section

Preparation of V_2O_5 hollow microspheres: In a typical synthesis, $[V(acac)_3]$ (0.3 g, 18 mM; Aldrich) and PVP (0.4 g, 0.14 mM; $\bar{M}_w$ = 58000; ACROS Organics) were added to ethylene glycol (48 mL; Beijing Chemical Reagent Ltd.) to give a cloudy solution. The mixture was stirred with a magnetic stirrer bar and heated to 140°C. The cloudy mixture turned clear after 20 min and became opaque again after 70 min, indicating the formation of vanadium precursor. The solution was heated for another 30 min to ensure the formation of the composite structure before being allowed to cool to room temperature. The products were washed and separated by centrifugation–redispersion cycles with alcohol. These vanadium precursor was calcined at 500°C for 2 h to obtain crystalline orthogonal V_2O_5.

Characterization: Products were characterized by XRD, (Rigaku Dmax/rb diffractometer with $Cu_{K\alpha}$ radiation, $\lambda = 0.1542$ nm, 40 kV, 100 mA), TEM (Philips TECNAI-20), SEM (Hitachi S-4300F), and by FTIR (Bruker Tensor 27).

CV measurements were conducted by using an electrochemical cell with a three-electrode configuration. The working electrode was a glassy carbon disk of 3 mm in diameter, polished with Al_2O_3 paste, and washed ultrasonically in Millipore water. The experiment was carried out in an $LiClO_4$–propylene carbonate (Li–PC, 1M) solution with a standard calomel electrode (SCE) as the reference electrode and a Pt counter electrode with an EG&G instrument (model 273, Princeton Applied Research). Electrochemical discharge–charge behavior was investigated directly in coin cells assembled in an argon-filled glove box. The cell was made from a lithium anode and a cathode that was a mixture of V_2O_5 (80%), graphite/carbon black (12%), and teflon (8%). The cathode was separated from the anode by an insulator sheet. The electrolyte reservoir was made from $LiPF_6$ (1M) in a mixture of ethylene carbonate/dimethyl carbonate/dimethoxy ethane 1:1:1 (w/w).

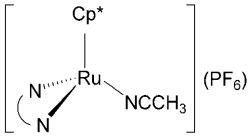
Homogeneous Catalysis

Ruthenium-Catalyzed Allylic Alkylation Reactions: Carbonate-Based Catalysts and Intermediates**

René Hermatschweiler, Ignacio Fernández, Frank Breher, Paul S. Pregosin, Luis F. Veiros, and Maria José Calhorda*

Transition-metal-catalyzed allylic alkylation reactions continue to attract attention. This chemistry can be accomplished using a variety of (primarily) late-transition-metal complexes[1–3] and affords high yields of product. In contrast to palladium(II)-catalyzed allylic alkylation reactions,[1] which often afford the linear (less substituted) product, the use of ruthenium-based catalysts affords primarily branched organic products; that is, the nucleophile prefers to attack at the more substituted carbon,[4] immediately adjacent to the phenyl group [Eq. (1) $Cp^* = C_5Me_5$; X = halide or carbonate].



$$PhCH{=}CHCH_2X + Nu^- \xrightarrow[\text{DMF or acetone}]{[Ru(Cp^*)(CH_3CN)_3]PF_6} PhCH(Nu)CH{=}CH_2 + X^- \quad (1)$$

Trost et al.[4] have shown that the cationic tris(nitrile) complex $[Ru(Cp^*)(CH_3CN)_3]PF_6$ (**1**), is an excellent catalyst for the chemistry shown in Equation (1) and that carbonate is the preferred leaving group, X, in terms of the observed regioselectivity.[4] Bruneau et al.[5] have recently reported that the bipyridine derivatives, **2**, are also efficient catalysts. Further, we note that conventional wisdom suggests that an oxidative addition mechanism is operating in this allylation chemistry,[4,6,7] although no explanation for the role of the anion (chloride or carbonate) has been forthcoming.

2 (N,N = bipyridine or phenanthroline)

We have recently reported[8] that the source of the observed high branched-to-linear regioselectivity (when X = Cl), has an electronic origin. These findings are based on X-ray crystallography and NMR spectroscopy data, together with DFT calculations. In an extension of this study we show herein that a) the carbonate anion can remain in the coordination sphere of the ruthenium and b) an isolated, well characterized Ru^{IV} allyl carbonate complex is a better catalyst than **1**.

Reaction of the branched *tert*-butyl carbonates **4a** and **4b** (Scheme 1) with **1** in DMF at ambient temperature affords the Ru^{IV} cationic complexes **3a** and **3b**, respectively, in excellent yield.[9]

Scheme 1. Synthesis of the new carbonate complexes, **3a** (R = H) and **3b** (R = OMe).

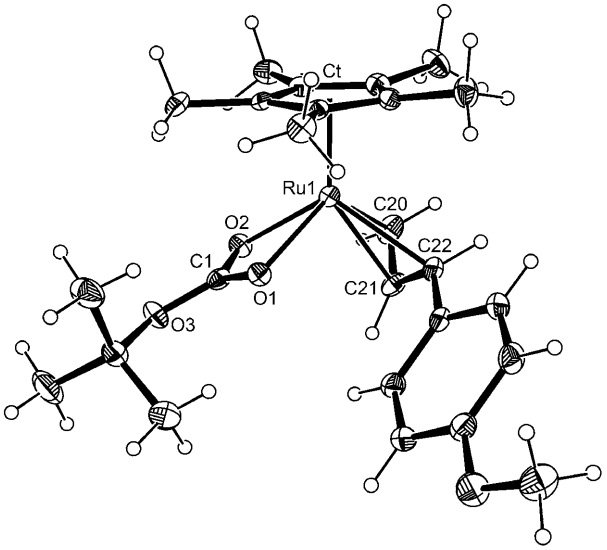
The solid-state structure[10] of **3b** (Figure 1) reveals the expected distorted piano-stool arrangement of the various ligands in this coordinatively saturated complex. The *tert*-butyl carbonate ligand clearly coordinates in a bidentate fashion through two oxygen atoms, and the allyl ligand shows an *endo* configuration such that the phenyl substituent is remote to the bulky Cp* ligand. Thus the oxidative addition affords the monocationic carbonate and not the bis(acetonitrile) dicationic complex.

The characteristic chemical shifts in the ^1H and ^{13}C NMR spectra[9] of pure **3a** have been recorded and compared to the analogous data from the in situ measurement involving stoichiometric amounts of **1** and the branched *tert*-butyl carbonate. These results show that **3a** is formed immediately on mixing, which indicates that a) the oxidative addition is not likely to be the rate-determining step in the catalysis and b) the isolated carbonate complex is not formed during the work-up procedure.

The reaction between a DMF solution of **3a** and one equivalent of the dimethyl malonate anion (DMM) leads to the formation of a mixture of branched and linear organic products [Eq. (2)]. This reaction shows **3a** to be reactive towards nucleophiles.

$$\mathbf{3a} \xrightarrow[\text{DMF}]{\text{DMM anion (1 equiv)}} \text{organic products, branched-to linear ratio = 70:30} \quad (2)$$

 DOI: 10.1002/anie.200500967 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



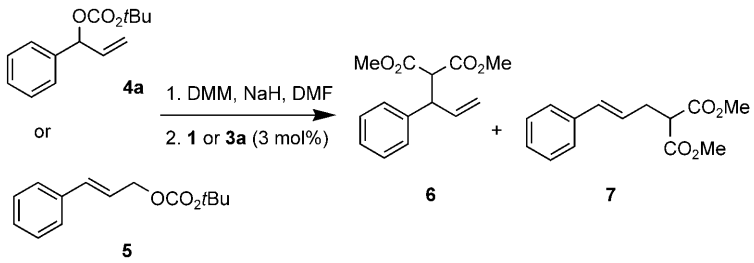


Figure 1. Molecular structure for the cation of **3b**. Thermal ellipsoids are set at 30% probability. The PF_6^- ion has been omitted for clarity. Selected bond lengths [pm] and angles [°]: Ru1-O1 214.8(3), Ru1-O2 211.6(3), Ru1-C20 216.2(5), Ru1-C21 213.7(5), Ru1-C22 230.3(5), Ru1-Ct 183.8(5), C1-O1 126.0(6), C1-O2 127.1(6), C1-O3 131.1(6); O1-C1-O2 117.9(4), O1-C1-O3 125.9(5), O2-C1-O3 116.2(4), C20-C21-C22 116.5(5); $\phi = 32.4°$; Ct = centroid of the Cp* ligand; ϕ is the intersection of the planes described by Ru1, O1, C1, O2 and the atoms of the five-membered Cp* ring.

We have used complex **3a** as a catalyst for the allylic alkylation reaction with dimethyl malonate (Scheme 2, Table 1). With the branched carbonate, **4a**, the reaction was

Scheme 2. Alkylation of branched and linear carbonates by dimethyl malonate/NaH with **1** or **3a** as the catalyst (see Table 1).

25-times faster with complex **3a** than with **1**. Using the linear substrate **5**, the reaction with complex **3a** is only a factor of two faster than **1**.

Table 1: Yields and regioselectivities of the alkylation of **4a** and **5** by dimethyl malonate (see Scheme 2).

Catalyst	Substrate	*t* [min]	Yield [%]	**6**/**7**[a]
1	**5**	40	98	90:10
3a	**5**	20	96	90:10
1	**4a**	25	98	90:10
3a	**4a**	1	97	90:10

[a] The ratio **6**/**7** (branched/linear) was determined by ^{1}H NMR spectroscopy.

We believe the difference between the reactivity of **4a** and **5** is related to the differing stabilities of the η^6-arene complexes formed by these substrates under the reaction conditions.[11] These results suggest that, not only is **3a** a relevant structure in the catalytic cycle, but that the presence of the nitrile ligands in solution, when using catalyst **1**, slows the reaction in Equation (1), presumably as these ligands compete with the olefin for a position on the ruthenium center. We note that for the complexes **2**, Bruneau reports reaction times of around 16 h at ambient temperature whereas with **3a** the reactions are complete within a few minutes.

DFT calculations[12] were carried out on model complexes, where the Cp* ligand was replaced by Cp ($Cp = C_5H_5$), and the *tert*-butyl substituent by a methyl group. Three isomers were considered, namely, an analogue of allyl/carbonates **3a** and **3b**, $[Ru(Cp)\{OC(OMe)O\}(\eta^3\text{-}PhCHCHCH_2)]^+$ (**3′**), and the two ruthenium η^6-arene complexes, **8** (derived from coordination of the linear carbonate, **5**) and **9** (derived from coordination of the branched carbonate **4**). The three optimized structures are represented in Figure 2. The calculated geometry of the carbonate complex **3′** compares well with the experimentally determined structure of **3b** (Figure 1)

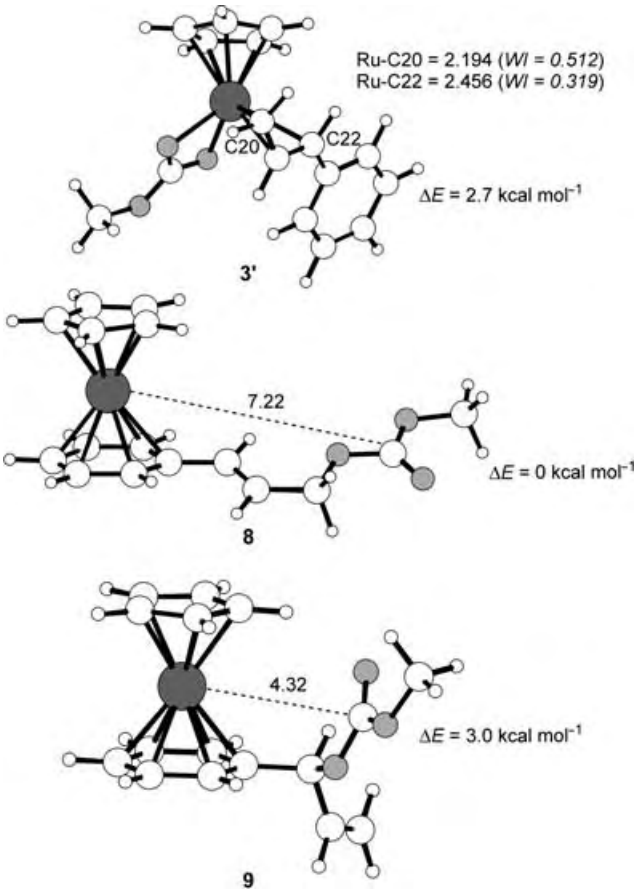

Figure 2. Optimized geometries (B3LYP) of the allyl/carbonate, **3′** and the η^6-arene complexes, **8** (linear carbonate) and **9** (branched carbonate. The Ru and the O atoms are gray and relevant distances [Å], Wiberg indices (italics), and the relative energies of the three isomers are indicated.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with maximum and mean absolute deviations of 0.15 and 0.07 Å, respectively, for the interatomic distances of the metal coordination sphere.

The coordination of the allyl ligand in **3′** is distorted, and is similar to what was observed for $[Ru(Cp^*)Cl(CH_3CN)(\eta^3\text{-}PhCHCHCH_2)]^+$.[8] The bond length from the metal center to the allyl carbon atom C22 adjacent to the phenyl group is 0.26 Å longer than the corresponding distance to the methylene allyl carbon atom C20. This Ru–C22 distance reflects a weaker bond, as shown by the Wiberg indices (Figure 2), and supported by natural population analysis (NPA) charges[12] (−0.32 for C20 and −0.08 for C22) indicative of a less efficient back-donation from the metal to C22.

Interestingly, both the charges calculated for the allylic carbon atoms and the nature of the LUMO of **3′**, with a larger contribution from C22 than from C20 (Figure 3), are in agreement with the observed preference of nucleophilic attack on C22 and the experimentally observed regioselectivity of the reaction.

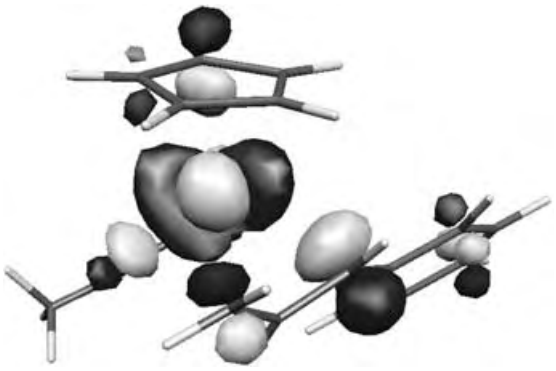

Figure 3. LUMO of **3′**, showing a large contribution from C22 of the allyl ligand.

The calculated relative energies of the isomeric η^6-arene complexes **8** and **9** (Figure 2) indicate that the linear carbonate, **8**, forms a complex which is 3.0 kcal mol^{-1} more stable than the branched analogue, **9**, corroborating the observed differences in reactivity for the corresponding substrates **4a** and **5**. In addition, the geometrical features of the two species might also play a role in the course of the reaction. For the isomer with the branched substrate, **9**, the carbonate group is considerably closer to the metal than in the linear carbonate analogue, **8**. The formation of the allyl/carbonate complex **3′** should hence be considerably easier for **9** than **8**, in agreement with the differences in observed reaction rates. An η^6-arene complex with the branched carbonate could not be detected experimentally.[11]

In conclusion, we have shown that the carbonate anion coordinates to the ruthenium atom, yielding a previously unknown reaction intermediate in the allylic alkylation catalytic sequence. Moreover, when isolated, this ruthenium carbonate species serves as a new, even more efficient catalyst than the reported nitrile complexes, presumably because its use does not lead to the presence of competing ligands in the reaction mixture.

46.51, H 5.46; found: C 46.31, H 5.40. ESI MS: 501.1 [M^+], 457.2 [M^+-CO_2], 401.1, 383.1 [$M^+-C_5H_9O_3$), 353.3 [$M^+-C_{10}H_{11}O$]. Catalysis: Dimethyl malonate (76 μL, 0.65 mmol) and NaH (26 mg, 0.64 mmol, 60 % dispersion in mineral oil) were stirred in DMF (1.5 mL) for 30 min at room temperature, after which time the carbonate **4a** or **5** (0.21 mmol) and the catalyst **1** or **3a** (0.02 mmol, 3 mol %) were added. The resulting solution was stirred at room temperature (see Table 1 for reaction times) and then diluted with diethyl ether and water (ca. 10 mL). After three extractions with diethyl ether, the combined organic extracts were washed with water and brine, dried over $MgSO_4$,and concentrated. The crude product was purified by chromatography on silica gel (hexane/ethyl acetate 6/1). The branched/linear ratio was determined by ^{1}H NMR spectroscopy.

[10] Crystal structure of **3b**: Orange single crystals were obtained from a CH_2Cl_2 solution of **3b** which was layered with *n*-pentane; $C_{25}H_{35}F_6O_4PRu$, orthorhombic, space group *Pbca*; $a = 11.030(1)$, $b = 21.378(2)$, $c = 23.626(2)$ Å; $V = 5570.9(7)$ Å^3; $Z = 8$; $\rho_{calcd} = 1.539$ Mg m^{-3}; crystal dimensions $0.58 \times 0.23 \times 0.13$ mm; diffractometer Bruker SMART Apex; $Mo_{K\alpha}$ radiation, 200 K, $2\Theta_{max} = 49.42°$; 41 497 reflections, 4749 independent ($R_{int} = 0.0451$), direct methods; empirical absorption correction SADABS (v. 2.03); refinement against full matrix (versus F^2) with SHELXTL (v. 6.12) and SHELXL-97, 343 parameters, $R1 = 0.0596$ and w$R2$ (all data) = 0.1231, max./min. residual electron density 0.877/ −1.067 e Å^{-3}. The hydrogen atoms were placed in idealized positions and included as riding atoms. CCDC-265478 (**3b**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[11] Starting from substrate **5**, several 18-electron η^6-arene Ru^{II} complexes of the type, [Ru(Cp*)(η^6-$RC_6H_4CH{=}CHCH_2OC$(O-*t*Bu)O)]PF_6 where R is a *para* substituent can be isolated. This type of arene complex is well known, see *Organometallics* (Eds.: C. Elschenbroich, A. Salzer), 2nd ed., VCH, Weinheim, **1992**, pp. 356–357. However, for the analogous reactions using branched carbonate **4**, the oxidative addition reaction is too rapid for us to isolate the η^6-arene complex.

[12] DFT calculations were performed with the Gaussian 98 software package using the B3LYP hybrid functional. The basis set used for the geometry optimizations (VDZP) included a standard LanL2DZ augmented with a polarization function for Ru and 4-31G(d) for the other atoms. Single point energies were calculated for the optimized complexes using the same functional and a VTZP basis set: SDD with a polarization function for Ru and 6-311G(d,p) for the remaining elements. The atomic charges and Wiberg indices resulted from a Natural Population Analysis (NPA). Computational details and the corresponding list of references are given in the Supporting Information.

Molecular Recognition

Quantification of Cation–π Interactions in Protein–Ligand Complexes: Crystal-Structure Analysis of Factor Xa Bound to a Quaternary Ammonium Ion Ligand**

Kaspar Schärer, Martin Morgenthaler, Ralph Paulini, Ulrike Obst-Sander, David W. Banner, Daniel Schlatter, Jörg Benz, Martine Stihle, and François Diederich**

In our molecular recognition studies, aimed at quantifying the energetics of individual protein–ligand interactions,[1] we became interested in exploring cation–π interactions[2,3] in the D-pocket of thrombin, a central serine protease in the blood coagulation cascade. The bottom of this hydrophobic pocket is lined by the indole residue of Trp215 (Figure 1), an aromatic amino acid side chain frequently involved in cation–π interactions in biological systems.[4] To probe this interaction, we prepared the tricyclic inhibitors[5] (±)-**1** and (±)-**2**, predicted by computer modeling[6] to position a quaternary ammonium ion and an uncharged *tert*-butyl group above the indole ring of Trp215.

(±)-**1** R = NMe_3^+ Br^-
(±)-**2** R = CMe_3

The synthesis of (±)-**1** started with the 1,3-dipolar cycloaddition between maleimide **3**, aldehyde **4**, and L-proline (**5**) to give (±)-**6**, which was transformed into amidinium salt (±)-**7** using a Pinner-reaction (Scheme 1, for full experimen-

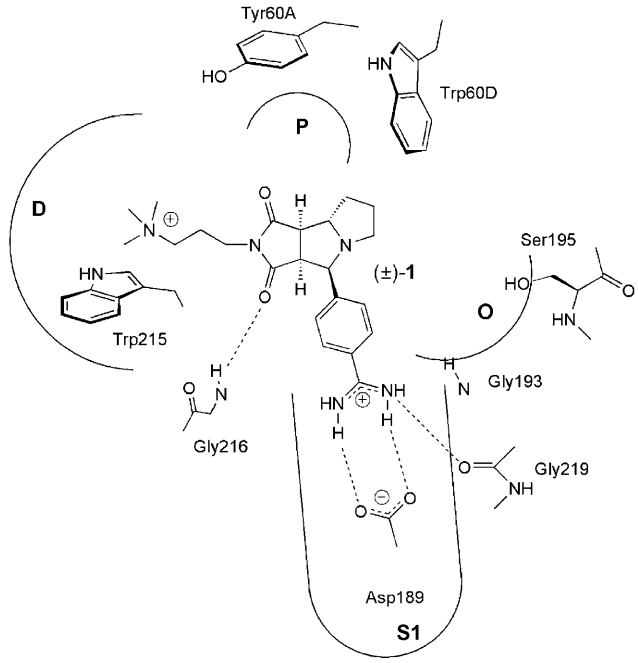

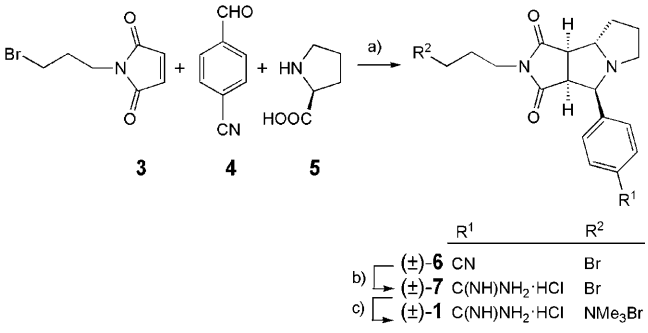

Figure 1. Schematic representation of the binding mode of the designed inhibitor (±)-**1** in the active site of thrombin. Only the 3a*S*,4*R*,8a*S*,8b*R* configured enantiomer is predicted to bind.[5] Reference inhibitor (±)-**2** is predicted by computer modeling to adopt a similar binding mode.

Scheme 1. Synthesis of inhibitor (±)-**1**. a) MeCN, 80 °C, 32%; b) 1. HCl, MeOH, $CHCl_3$, 4 °C; 2. NH_4Cl, MeOH, H_2O, 65 °C, 60%; c) Me_3N, MeOH, RT, 90%.

tal details, see Supporting Information). Nucleophilic substitution with Me_3N subsequently afforded (±)-**1**. The synthesis of reference compound (±)-**2** followed a similar route (see Supporting Information).

The activities of inhibitors (±)-**1** and (±)-**2** were tested, as previously described,[7] towards thrombin, the digestive enzyme trypsin, and two other serine proteases from the blood coagulation cascade, Factor VIIa and Factor Xa (Table 1), representing targets in the treatment of thrombotic diseases.[8] No inhibition of Factor VIIa was observed within the limits of the assay, and the binding of both ligands to trypsin was of similar, moderate strength. In contrast, their affinities against thrombin and Factor Xa differ greatly.

The onium ion inhibitor (±)-**1** showed a much lower activity ($K_i = 7.76$ μM) towards thrombin than the reference

Table 1: Activities (inhibition constants K_i [μM]) of inhibitors (±)-**1** and (±)-**2**.

Inhibitor	K_i [μM]			
	thrombin	trypsin	Factor VIIa	Factor Xa
(±)-**1**	7.76	10.5	> 69[a]	0.28
(±)-**2**	0.13	7.1	> 69[a]	29

[a] Upper limit of the assay.

compound (±)-**2** ($K_i = 0.13$ μM). According to molecular modeling,[6] the large difference in activity (K_i(**1**)/K_i(**2**) = 60 and $\Delta\Delta G = 2.5$ kcal mol^{-1} in favor of the *tert*-butyl inhibitor) cannot be explained by different binding geometries of the two imide-N substituents in the hydrophobic D-pocket.[5] Rather, the data suggest that cation–π interactions between the onium ion of (±)-**1** and a single indole residue (of Trp215) are not very effective and cannot compensate the costs of desolvation of the ionic residue upon incorporation into the D-pocket. Such desolvation costs do not occur in the complexation of a *tert*-butyl residue, and (±)-**2** binds with an affinity similar to that of other inhibitors of this class, which direct large aliphatic residues into the D-pocket.[9a]

In contrast, inhibitor (±)-**1** shows good activity towards Factor Xa ($K_i = 0.28$ μM) while the activity of reference compound (±)-**2** is very low ($K_i = 29$ μM). Thus, towards Factor Xa, the difference in activities (K_i(**2**)/K_i(**1**) = 100, $\Delta\Delta G = 2.8$ kcal mol^{-1}) is even more distinctive than in thrombine but in the opposite sense, favoring onium ion recognition.[10] Again, modeling suggested nearly identical binding modes for both inhibitors. To elucidate the origin of the strong complexation of the onium ion, the X-ray crystal structure of (±)-**1**, co-crystallized with Factor Xa, was measured at a resolution of 1.64 Å (Figure 2).[11]

In the structure, the 3a*S*,4*R*,8a*S*,8b*R* configured enantiomer of (±)-**1** (*ent*-**1**) adopts a binding geometry at the active site of Factor Xa similar to that predicted for the related serine protease thrombin.[9b] The phenylamidinium residue is incorporated in the S1 pocket, and interacts with the carboxylate side chain of Asp189 (*d*(N···O) 3.2 and 3.3 Å), and the "lower" imide-C=O unit undergoes hydrogen bonding to the backbone-NH group of Gly216 (*d*(O···N 3.1 Å). The tricyclic scaffold of *ent*-**1** occupies the central cavity of Factor Xa (Figure 2b).

As expected from computer modeling, the quaternary ammonium ion of *ent*-**1** binds in the S4-pocket of Factor Xa, which is lined by Trp215, Tyr99, and Phe174. The three side chains form an "aromatic box", with the onium ion located in its center. The shortest distances between the N^+ center and closest C atoms of the surrounding aromatic rings are nearly ideal (4.6 to 5.0 Å, Figure 2a) for strong cation–π interactions (see below).

A survey of the literature shows that the S4-pocket of Factor Xa has indeed been filled many times by basic residues. Examples are 4-amino-substituted pyridines, piperazines, pyrrolidines, amidines and phenylamidines, imidazoles and imidazolines, and benzylamines.[12] We presume that the positively charged residues occupy the cation binding site in the aromatic box in their protonated form. The occupation of

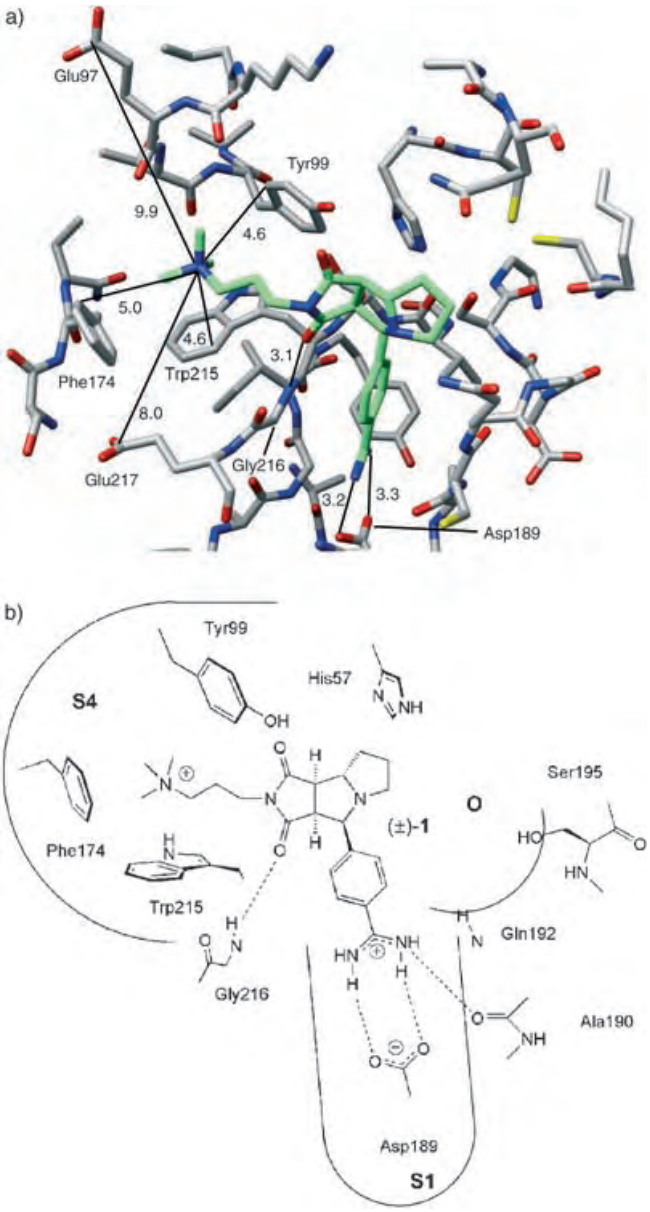

Figure 2. a) Binding mode of inhibitor (3a*S*,4*R*,8a*S*,8b*R*)-**1** in the active site of Factor Xa according to X-ray crystal-structure analysis. Interatomic distances are in Å. Shortest distances between onium ion methyl carbon atoms and carbon atoms of the aromatic box are 3.9 Å (to Tyr 99), 3.9 Å (to Phe 174), and 3.6 Å (to Trp 215); red O, blue N, yellow S, green C_{ligand}, gray $C_{protein}$, b) Schematic representation of the complex between Factor Xa and the active enantiomer of (±)-**1**.

the S4-pocket by an *N*,*N*,*N*-trimethylanilinium residue has also been reported.[13]

In some complexes, the side chains of Glu 97 or Glu 217 in Factor Xa undergo weak ion pairing with phenylamidinium ions occupying the S4-pocket.[12a,13] However, in the large majority of cases, the two carboxylate groups are located at positions remote from the cationic site and are oriented towards the solvent, as seen in the complex of Factor Xa with *ent*-**1** ($d(N\cdots CO_2^-)_{Glu\,97}$ 9.9 Å, $d(N\cdots CO_2^-)_{Glu217}$ 8.0 Å). Thus, Coulombic interactions with the two carboxylate groups are not at the origin of the preference of the S4-pocket for cationic residues.

From these results a new interpretation arises concerning the special feature of this pocket to accept basic residues: in their protonated form, these residues undergo efficient cation–π interactions with the aromatic box formed by Tyr 99, Trp 215, and Phe 174. The difference in binding free enthalpy of $\Delta\Delta G = 2.8$ kcal mol^{-1} favoring (±)-**1** over (±)-**2** corresponds to an averaged value of about 0.9 kcal mol^{-1} per aromatic ring. This value is in accordance with those reported for cation–π interactions with individual aromatic rings.[14] Despite the large free enthalpy increment for the interaction with a single aromatic ring, the results obtained in this work for the D-pocket of thrombin suggest that efficient cation–π interactions require the "solvation" of the cation by several aromatic rings.

Inspired by these results, we performed Protein Data Bank (PDB) searches[15] to identify similar aromatic boxes for the complexation of ammonium ions. Figure 3 shows examples for quaternary ammonium ions bound to different proteins. Figure 3a depicts the already mentioned trimethylanilinium residue in the S4-pocket of Factor Xa (PDB-code: 1LPK).[13] The distances of the N^+ center to the three aromatic rings are very close to those found in our study. Figure 3b features histone H3 permethylated at Lys 27 in the polycomb chromodomain of *Drosophila* (1PFB),[16] while Figure 3c shows an N,N-dimethylated proline in the periplasmic ligand binding protein ProX from *E. Coli* (1R9Q).[17] At least one of the three side chains forming the aromatic boxes shown in Figure 3a–c is a Trp residue. The orientation of the cationic center is always close to the normals passing through the centroids of the aromatic planes which provides for optimal interactions with the π systems. Figure 3d shows a box of four aromatic side-chains from human phosphatidylcholine transfer protein complexed with the choline moiety of its substrate

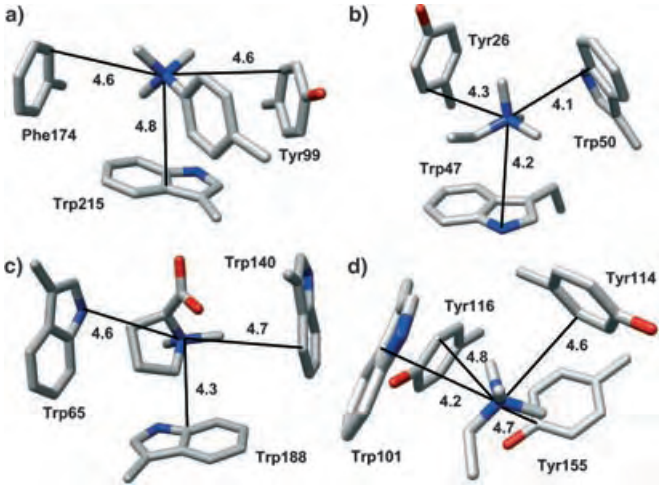

Figure 3. Examples from PDB searches showing quaternary ammonium ions bound in the S4-pocket of Factor Xa (a) and in similar aromatic boxes of other proteins (b–d). The shortest ligand–protein distances are indicated in Å; red O, blue N, gray C. PDB-codes: a) 1LPK, b) 1PFB, c) 1R9Q, d) 1LN3. See text for details.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(1LN3).[18] Similar to the previous structures, the cationic center is located near the centroid normals of the π systems of Trp 101 and Tyr 155. In contrast, the ring planes of Tyr 114 and Tyr 116 are slightly twisted. Their normals are not oriented perfectly towards the cation. Apparently, in this example, the loss of interactions caused by the twisted orientation of these side-chains is compensated by the presence of a fourth aromatic residue. In all the structures shown in Figure 3 the shortest distances between the N^+ center and the aromatic side chains are between 4–5 Å ($d(N^+\cdots C_{arom})$), which seems to be the optimal separation for quaternary ammonium ion–π interactions. For further examples of quaternary ammonium ions in aromatic boxes, see Figures 5–9 in the Supporting Information.

The PDB search was extended to protonated tertiary ammonium ions complexed in aromatic boxes within proteins (Figure 4). Again, the cations are close to the centroid normals of the aromatic rings. An additional interesting feature is the presence of a hydrogen bond formed on the open side of the aromatic box between R_3NH^+ and an acceptor residue of the protein, which results in additional stabilization. This hydrogen bonding is sometimes mediated by a water molecule. Examples are the structure of a (protonated) tertiary amine inhibitor bound to oxidosqualene cyclase (Figure 4a; 1H37),[19] the complex of a protonated N,N-dimethylated lysine residue of a histone in the HP1 chromodomain of *Drosophila* (Figure 4b; 1KNA),[20] the complex of morphine in the antibody 9B1 (Figure 4c; 1Q0Y),[21] and the complex of nicotine in a nicotinic ACh receptor (Figure 4d; 1UW6).[22] Similarly, some of the protonated onium ions in the S4-pocket of Factor Xa not only interact with the aromatic box but also form hydrogen bonds to neighboring polar residues or H_2O molecules.[12a,f] Interestingly, protonated secondary ammonium ions are not found in such arrangements, presumably because of high desolvation costs.

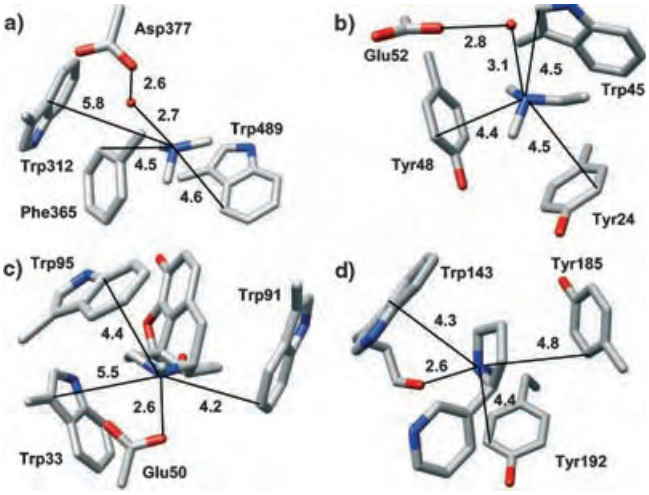

Figure 4. Examples from PDB searches showing protonated tertiary ammonium ions bound in aromatic boxes. The shortest ligand–protein distances are indicated in Å; red O, blue N, gray C. PDB-codes: a) 1H37, b) 1KNA, c) 1Q0Y, d) 1UW6.

Cation–π interactions are also seen in crystal packings of small molecules, although steric factors and the requirements of a dense crystal packing in these cases prevent the formation of aromatic boxes. A search of the Cambridge Structural Database (CSD) for close contacts between tetraalkylammonium ions and arene units furnished 22 examples, seven of which displayed a second close contact to another aromatic residue.[23] As in the case of the protein examples, cations were located close to the centroid normals of the arene systems. A selection of examples is included in Figure 10 in the Supporting Information.

In conclusion, we have shown by biological assays and protein crystallography that the aromatic box formed by the side chains of Phe 174, Tyr 99, and Trp 215 in the S4-pocket of Factor Xa is a very effective onium binding site. By comparing the affinity of the quaternary ammonium ion receptor (±)-**1** to that of the *tert*-butyl derivative (±)-**2**, the free enthalpy increment for cation–π interactions in this box was determined as $\Delta\Delta G = 2.8\ kcal\,mol^{-1}$. PDB searches revealed the more general occurrence of similar cation binding sites in biological systems; hence the observations made in this investigation should provide useful guidance in lead design and optimization.

[11] For protein expression and purification, see the Supporting Information. Crystallization and structure determination: A solution of short-form Factor Xa (15 mg mL^{-1}) was incubated overnight with ligand (3.8 mM) prior to crystallization. The protein–ligand complex was mixed with an equal volume of crystallization buffer (0.2 M NH_4OAc, 0.1 M 2-[2,2′-bis(hydroxylethyl)amino]-2-hydroxymethyl-1,3-propanediol(Bis-Tris) pH 5.5, and 25% PEG 3350) in microbatch mode. Crystals appeared after a week and grew to full size within two weeks. Before data collection, crystals were transferred to crystallization buffer supplemented with 20% glycerol and flash-frozen in liquid N_2. Diffraction data were measured on a Bruker FR591 X-ray generator, with 0.2 mm focus, run at 50 kV/60 mA and equipped with an Osmic focusing monochromator and an Oxford Cryostream cooler run at 100 K. The Marresearch345 (dtb) image plate detector was placed 110 mm from the crystal and scanned with 0.15 mm pixel size. Exposure times were 600 s for 0.5° frames. Data from 262 frames were processed to 1.62 Å resolution using XDS (W. Kabsch, *J. Appl. Crystallogr.* **1993**, *26*, 795 – 800). Space group $P2_12_12_1$; unit cell dimensions $a=48.84$, $b=71.67$, and $c=72.75$ Å. For 163433 measured reflections 32725 were independent, R factor 6.1% (37.4% in the outermost shell, 1.62–1.71 Å), with completeness 98.7% (97.1%) and I/σ 15.5 (4.3). Data reduction used the CCP4 package ("The CCP4 Suite: Programs for Protein Crystallography" *Acta Crystallogr. Sect. D* **1994**, *50*, 760–763). The structure was solved by molecular replacement using 1c5m.pdb as model. Model building with Moloc[6] and refinement with Refmac5 (G. N. Murshudov, A. A. Vagin, E. J. Dodson, *Acta Crystallogr. Sect. D* **1997**, *53*, 240 – 255) to 1.64 Å resolution gave final overall crystallographic R factors of 20.4% (observed) and 23.7% (total), with values in the outer shell (1.64–1.68 Å) of 28.6% and 29.7%, respectively, for 2421 atoms, including one Na^+ ion and 276 H_2O molecules. The inhibitor density is very clear. Coordinates have been deposited with the Protein Data Bank, PDB-code: 2bok.

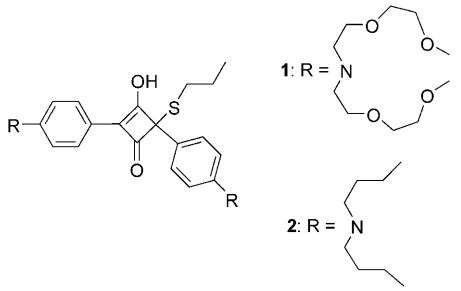
The CSD search was performed using a distance constraint for the distance d between ammonium N atom and the centroid of the aromatic ring of $3.5\text{ Å} < d < 5.5\text{ Å}$. Hits were limited to structures containing no errors or partial disorders, excluding polymeric, powder, or organometallic compounds.

Analytical Chemistry

A Regenerative Chemodosimeter Based on Metal-Induced Dye Formation for the Highly Selective and Sensitive Optical Determination of Hg^{2+} Ions**



José V. Ros-Lis, M. Dolores Marcos, Ramón Mártinez-Máñez, Knut Rurack,* and Juan Soto*

The Hg^{2+} ion is one of the environmentally most important metal ions whose toxicity, even at very low concentrations, has long been recognized and is a problem of primary concern.[1] Moreover, despite a reduction of its industrial use as a result of stricter regulations, high concentrations of mercury are still present in many environmental compartments and it can still be found in many products of daily life such as paints, electronic equipment, and batteries.[2] Accordingly, the need for analytical methods for the sensitive and selective determination of mercury is of topical interest, especially in situations where conventional techniques are not appropriate, for instance in many on-site or in situ analyses and for rapid screening applications. In these fields, optical and electrochemical sensing devices play a leading role, in particular utilizing molecular probes that generate and transduce an analytical signal as a response to the binding event.[3] Although several examples of redox-active,[4] fluorogenic,[5] and chromogenic[6] chemosensors for Hg^{2+} ions have been reported recently, the combined "binding site and signaling subunit" approach that is commonly used with such probes often harbors disadvantages for analysis in realistic media. Many signaling units suffer through the strong hydrogen-bonding ability of water, fluoroionophores often undergo unspecific fluorescence quenching upon binding to heavy-metal ions, and the number of Hg^{2+}-ion-selective receptors is limited.

A particularly attractive alternative presented herein are chemodosimeters that indicate an analyte through a specific chemical reaction between dosimeter molecule and target species, leading to the formation of a fluorescent or colored product.[7,8] A disadvantage of dosimeters, however, is that the reactions are mostly irreversible and thus provide only single-use assays.

To take advantage of the favorable features of chemodosimeters and also reuse them, it is necessary to install a procedure that allows the molecular reporter to be regenerated. We thus designed a method where the indicator dye is passivated first in a chemical addition reaction with a small organic compound, the "spectroscopic inhibitor" that "switches off" the color and fluorescence of the indicator. This addition product is the chemodosimeter. The target ion then reacts with the inhibitor, liberating the dye, that is, signaling is accomplished by "metal-induced dye release" methods. With the proper choice of dye scaffold and passivation reaction, it should thus be possible to generate drastic chromo- and fluorogenic changes that result in a true "switching-on" behavior rather than a modulation of already existing signals or minor shifts of absorption or emission bands.

We have applied this newly designed procedure to the selective analysis of Hg^{2+} ions. The method is based on the thiophilic affinity of the Hg^{2+} ion and its reactivity with 2,4-bis(4-dialkylaminophenyl)-3-hydroxy-4-alkylsulfanylcyclobut-2-enone (APC) derivatives. As we have recently shown, APC derivatives can be elegantly obtained by a simple reaction of squaraines—the indicator dye—with thiols, the inhibitor.[9] A representative compound (**1**) is shown in Scheme 1. Compound **1** contains two independent subchromophores that are electronically separated and chemically bound through an sp^3-hybridized carbon atom. Accordingly, **1** shows two overlapping bands in the UV spectral region; one at approximately 265 nm which is characteristic for the dialkylanilino moiety and a second, 1.3-fold more intensive band centered at around 305 nm (Figure 1). The latter band can be ascribed to the dialkylaminophenylhydroxycyclobut-2-enone (PC) group. Quantum chemical calculations at the semiempirical level are in agreement with the experimental results and reveal the existence of two independent transitions of moderate oscillator strength, the HOMO–LUMO transition that is located on the PC fragment and the energetically higher-lying HOMO-1–LUMO + 1 transition localized on the anilino group.

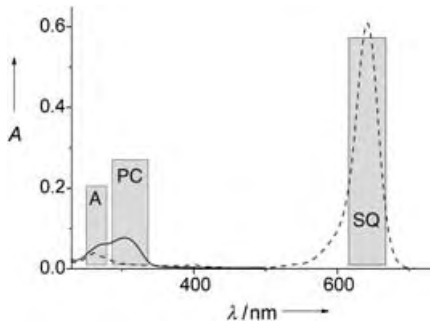

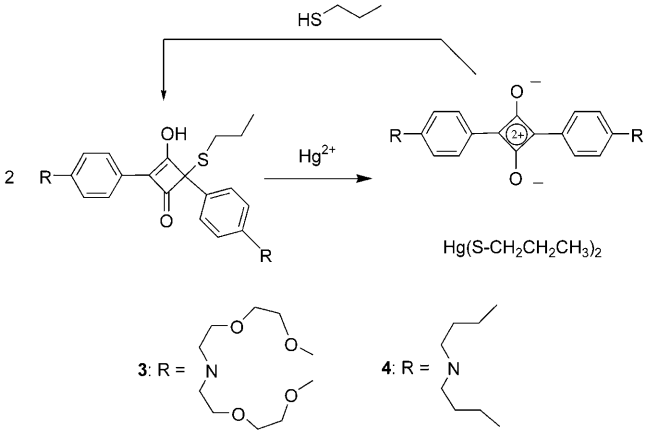

Figure 1. Absorption spectra of **1** (——) and **3** (-----) in water/acetonitrile (4:1 v/v), before and after the reaction of **1** with Hg^{2+} ions. The gray bars denote the region of absorption of the single chromophores: A = anilino moiety (this band is also present as a higher transition in **3**), PC = aminophenylhydroxycyclobut-2-enone group and SQ = squaraine.

and intense absorption band at 642 nm that is typical for a squaraine dye (Figure 1).[9,10] This Hg^{2+}-ion triggered formation of squaraines is shown in Scheme 2. The reaction product

Scheme 2. The analytical cycle: Hg^{2+}-ion-induced formation of **3** and **4** and regeneration of **1** and **2** by reaction with propanethiol.

3 has a comparatively large molar absorptivity ($\lg\varepsilon = 5.05$) and a moderately high fluorescence quantum yield ($\Phi_f = 0.023$) in water/acetonitrile (4:1). This dual chromo- and fluorogenic sensing of Hg^{2+} ions is remarkable as both absorption and emission are found at the red end of the visible spectral window where usually the interference arising from matrix absorption or autofluorescence is negligible. Moreover, this dramatic hyper- and bathochromic shift upon mercury-induced transformation of **1** into **3** allows for straightforward "naked-eye" monitoring of the Hg^{2+}-ion-detection process.[11]

To optimize the method, different pH ranges were tested and a basic pH (9.6, buffered with 2-(cyclohexylamino)ethanesulfonic acid (CHES) 0.01M) was found to yield the best performance of the chromofluorogenic dosimeter. Furthermore, these studies revealed that a maximum signal can be observed at a molar ratio of **1**/Hg^{2+} = 2:1, suggesting the formation of $Hg(SR)_2$ species (see Scheme 2).

As the coordination with thiols is not an exclusive feature of mercury, the reactivity of **1** in the presence of other metal ions was studied. In a typical experiment, up to 10 equivalents of Hg^{2+}, Cu^{2+}, Fe^{3+}, Pb^{2+}, Ni^{2+}, Cd^{2+}, Zn^{2+}, Al^{3+}, and Tl^{+} were added to a solution of **1** in water/acetonitrile (4:1, $c_1 = 6\times10^{-6}$ M, pH 9.6, CHES 0.01M). The results are shown in Figure 2. There is a remarkably selective development of

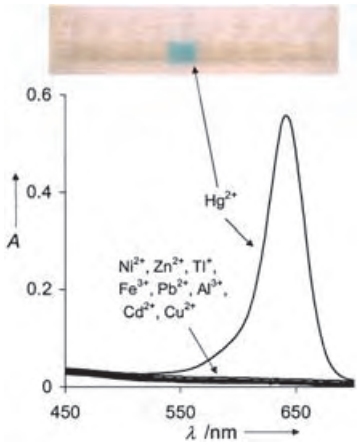

Figure 2. Absorption spectra of **1** (6×10^{-6} M) in water/acetonitrile (4:1 v/v, pH 9.6, CHES 0.01 M) upon addition of 0.5 equivalents of various metal ions. In the photograph, from left to right: Ni^{2+}, Zn^{2+}, Tl^{+}, Fe^{3+}, Hg^{2+}, Pb^{2+}, Al^{3+}, Cd^{2+}, Cu^{2+}, and no metal ion.

the blue color only in the presence of Hg^{2+}, while the other potential competitors remain entirely silent. This chromogenic indication reaction allows Hg^{2+} ions to be detected down to 20 ppb by using a conventional spectrophotometer and standard conditions (such as 10-mm cells).

Despite the inherent interest of the colorimetric response, fluorometric methods can reach much lower detection limits with very low-cost and widely used instrumentation. Considering the high brightness (the product of ε and Φ_f) of squaraine dyes, the present system should be ideal for use in conjunction with fluorescence detection. Thus, similar studies to those described above were performed with $c_1 = 1\times10^{-7}$ M on a conventional fluorometer. Figure 3 shows the fluorescence titration spectra of **1** with Hg^{2+} ions, revealing that the

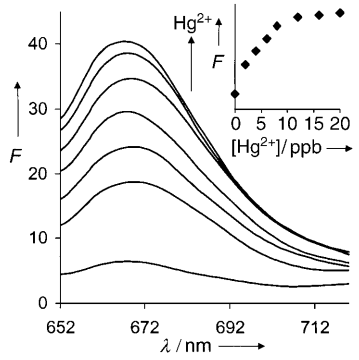

Figure 3. Fluorescence titration spectra of **1** (10^{-7} M) with Hg^{2+} ions in water/acetonitrile (4:1 v/v, pH 9.6, CHES 0.01 M, $\lambda_{exc} = 642$ nm). The inset shows the titration curve obtained from the emission intensities at 670 nm.

detection of less than 2 ppb of Hg^{2+}, which is the U.S. Environmental Protection Agency's limit for drinking water, is clearly possible by the Hg^{2+}-ion-induced release of the highly fluorescent squaraine **3**.

Motivated by these favorable features of the solution-based chemistry, we took a step towards the use of metal-triggered reactions for in situ sensing and rapid screening applications. For this purpose, the APC derivative **2** (Scheme 1) containing hydrophobic *n*-butyl chains was prepared and adsorbed on powdered silica. The butyl chains offer the required hydrophobicity to prevent the leaching of the dye in aqueous samples. This rather simple method allowed an accurate control of the amount of dye that is physisorbed onto the solid. The loading is a key parameter for fluorometric applications as too high loadings can easily lead to self-quenching for dyes with narrow, intense, and weakly Stokes-shifted absorption and fluorescence spectra.

In a series of experiments we found that a suitably sensitive solid able to show dual chromofluorogenic signaling should typically contain **2** in a concentration of 10^{-6} mmol g^{-1}. The powder was then fixed on a polyethyleneterephthalate film for a first prototype of a dip-stick assay that was tested by simply dipping the films into aqueous samples containing Hg^{2+} ions. Once the sticks come into contact with the sample solutions, the solid turns blue ($\lambda_{abs} = 642$ nm) and begins to fluoresce ($\lambda_{em} = 670$ nm). The response time is on the order of a few seconds and the behavior is consistent with the reaction shown in Scheme 2. Compound **2** reacts with the mercuric ion to give the corresponding squaraine derivative **4** that remains adsorbed on the solid, resulting in a chromo- and fluorogenic "switching-on" process indicative of the presence of Hg^{2+} ions. Finally, having accomplished the reaction, the chemical reaction described above[9] can be used to regenerate the chemodosimetrical solid quantitatively with propanethiol (Scheme 2). Upon addition of the "spectroscopic inhibitor", the conjugation in the squaraine is interrupted and the color immediately turns from blue back to colorless; the device is ready for the next cycle (see the Supporting Information).

In summary, we have designed a highly selective and sensitive dual chromofluorogenic chemodosimeter system for the determination of Hg^{2+} ions in aqueous environments using a very simple and specific reaction, that is, Hg^{2+}-triggered formation of a squaraine dye. The method allows the selective detection of Hg^{2+} ions below 2 ppb in aqueous solutions, shows a fluorescence enhancement, and displays a very large shift in absorption with the development of a blue color from colorless solutions. The possibility to adsorb or anchor the probe on suitable supports allowed prototypes of reusable dip-stick assays to be designed for rapid screening for the target analyte. Additionally, we believe that this procedure, based on guest-induced dye release methods using suitable dye scaffoldings and passivation reactions, might be of interest as a new route for the design of new and improved regenerative sensor molecules for the rapid colorimetric screening of a number of other target guests.

A powerful combination of two synthetic methods has advanced the art of organic synthesis like few other reactions. In their Reviews on page 4442 ff. and 4490 ff. K. C. Nicolaou and co-workers illustrate how palladium-catalyzed cross-couplings and metathesis-based reactions, respectively, have blossomed into powerful tools for carbon–carbon bond formation in the total synthesis of natural products.

Sensors
Selective discrimination between closely related amines can be achieved by a molecular recognition process that generates a colorimetric "signature" for each compound. This method is described by K. S. Suslick and co-workers in their Communication on page 4528 ff.

Coordination Chemistry
Dinuclear complexes with bridging {*cyclo*-EP_2}-units are formed from a niobium phosphide anion and divalent Group 14 salts. C. C. Cummins and J. S. Figueroa describe the structures of these compounds in their Communication on page 4592 ff.

Asymmetric Catalysis
In their Communication on page. 4611 ff. T. Hayashi et al. describe rhodium complexes with bidentate chiral phosphine–olefin ligands that are highly efficient catalysts for the enantioselective 1,4-addition of aryl boronic acids to maleimides.

Metathesis Reactions in Total Synthesis

Communications

Seeing smells: Highly selective discrimination between closely related amines has been demonstrated by using an array of chemoresponsive dyes (see picture). Hierarchical classification of amines based on their colorimetric response is successful and matches that expected from qualitative structural and electronic considerations. High sensitivity (ca. 100 ppbv) has been shown for the detection and discrimination of amines.

Complete removal of interstitial water molecules from various foam films of amphiphilic compounds results in self-standing bilayer membranes. The dried foam films (DFFs) in the micrometer to submicrometer range (see picture) are stable even under ultrahigh-vacuum conditions and at temperatures higher than 100 °C.

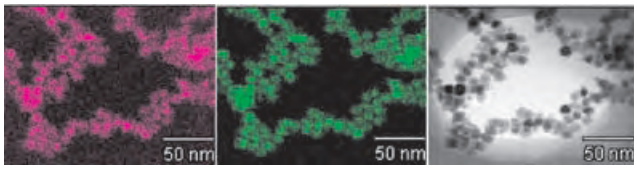
Dried Foam Films: Self-Standing, Water-Free, Reversed Bilayers of Amphiphilic Compounds



A new concept for catalytic reactions in aqueous media is demonstrated by using a temperature-responsive polymer support, poly(*N*-alkylacrylamide), which is converted into a catalyst by assembly with phosphotungstic acid. At high temperature, the catalyst is highly active in the oxidation of alcohols with H_2O_2 owing to the formation of emulsions, whereas the product and catalyst are easily separated at low temperature (see scheme).

Medicinal Chemistry

A Timely Reassessment of Early Prediction in the Bioavailability of Orally Administered Drugs

*Tim Larsen and Andreas Link**

Keywords:
hydrogen bonds · lipophilicity · medicinal chemistry · metabolism · structure–activity relationships

The rapid and efficient biopharmaceutical classification of compounds under investigation is a major focus of the pharmaceutical industry.[1] The reasons for failure during and after the discovery and development of novel chemical entities (NCEs) are multifactorial. Whereas a lack of efficacy associated with improper validation of biological targets or delays at the product portfolio level are not directly linked to the drug candidate itself, many of the reasons for the failure of a candidate can be traced back to the structure of the molecule. For instance, pharmacokinetics, animal toxicity, and the observation of adverse effects in humans are all inextricably linked to the chemical structure of the drug. Therefore, the selection of the right compound to enter clinical development is critical. Medicinal chemists have responded to this turn toward higher quality through the implementation of studies in absorption, distribution, metabolism, elimination, and safety into the discovery process.

In this context, the seminal retrospective analysis of drug properties associated with oral bioavailability performed by Lipinski and co-workers at Pfizer in 1997 fell on fertile ground.[2] The derived rule of thumb ("Rule of Five") rapidly became an important factor in the decrease of failures in early drug development projects.

Despite the practical value of this study on the prediction of good oral absorptivity for a drug candidate based on a number of simple properties, the opportunities and needs for predictive ADMET (adsorption, distribution, metabolism, excretion, toxicology) have never been greater.[1] Over the seven years in which Lipinski's Rule of Five has been applied, its descriptive power has also revealed some shortcomings. The overly rigorous selection of drug candidates to fit the rule may be analogous to the evil deeds of Damastes, also known as Procrustes, the legendary robber of ancient Attica who lived in the area of Eleusis. Nicknamed "the stretcher", he captured passing travelers to fit them in one of his two beds. Short travelers were placed on a long bed, and their limbs were stretched until they fit properly. Tall people were placed on a small bed; extremities that hung over the edge were amputated. This bloody amusement was put to a stop by the hero Theseus, who finally killed Procrustes (Figure 1).[3] In a manner perhaps a little less heroic than that of Theseus, several research groups have tried to counteract the overly rigorous or even erroneous application of the practical "Rule of Five". Many useful refinements have

Figure 1. Procrustes (Damastes), who captured travelers and brutally altered their body size to fit the bed in which they lay (upper right), was killed by Theseus. been proposed as a result, including the suggestion of additional parameters such as percent polar surface area (PSA), cyclicity, and the number of rotatable bonds present.[4–6]

In an examination of the physicochemical properties of 1100 drug candidates in the data records of former SmithKline Beecham Pharmaceuticals, Veber et al. showed that the molecular weight cut-off at $M_r = 500$ alone does not significantly distinguish compounds with poor oral bioavailability from those with acceptable values.[6] Whereas this result is in full accordance with Lipinski's "Rule of Five", it was found that for this special case only two new criteria for a high probability of good oral bioavailability were sufficient instead of the established four. First, there must be 10 or fewer rotatable bonds and second, the polar surface area must be equal to or less than 140 Å^2 (or alternatively, 12 or fewer H-bond donors and acceptors).

This helpful suggestion to decrease the number of selection parameters which was derived from a biased proprietary data set was misinterpreted as the invention of two additional and broadly applicable selection criteria. The expansion of a rule of thumb usually waters down the basic concept and leads to a loss of practical value. Hence, it was argued that increasing the number of progression criteria on discovery projects could aid in the identification of quality compounds, but at the same time, it would also increase the complexity of the discovery process and thus slow it down. As a result, patent lifetimes would decrease, costs would increase, and there would be a drop in competitiveness in an aggressively competitive field.[1]

Therefore, instead of amendments, Leeson and Davis suggest a re-evaluation of the individual share of the parameters clog P (calculated logarithm of the partition coefficient in 1-octanol/water as a measurement of lipophilicity), molecular size expressed as M_r, and the number of H-bond acceptors and donors over time.[7] The resulting question is: Are there any time-related differences in the physical properties of orally available drugs? Vieth et al. observed no meaningful correlation between the year of launch (in the U.S. between 1982 and 2002) and target class, M_r, or lipophilicity for oral drugs.[8]

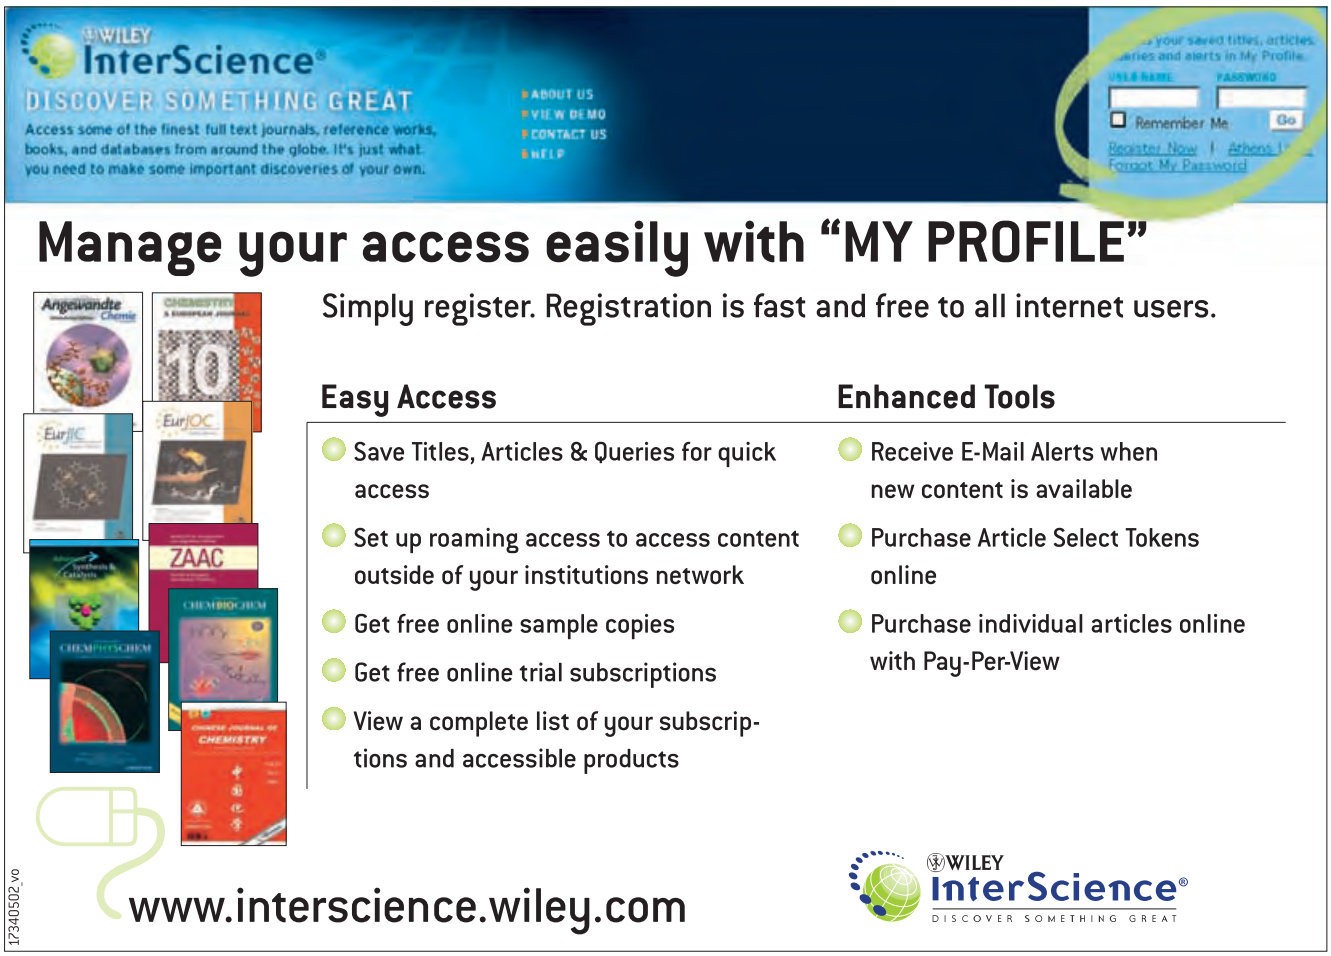
The study by Leeson and Davis revealed that drugs developed and marketed prior to 1983 have characteristics that differ significantly from newer NCEs. In a related study by Wenlock et al., drugs in various phases of clinical development were analyzed. The results showed that the mean molecular weight of compounds in the earlier phases of development was significantly higher than that of candidates in later phases of development and marketed drugs. Similar trends were observed for the characteristics of the number of H-bond acceptors and rotatable bonds present. Furthermore, it was shown that the more lipophilic compounds tended to be discontinued prior to phase III trials. These results highlight the well-known phenomenon that during lead optimization, molecules tend to get larger, more complex, more lipophilic, and so on. This issue has already been clarified by Teague et al. through the highly original concept of "lead-likeness".[9] Subsequently, Wenlock et al. demonstrated that the recognized resorption-limiting factors are not historical artifacts but are under physiological control.[10]

The investigation of Leeson and Davis sought to identify the physical properties that showed a historical shift between drugs developed before 1983 and newer drugs. Therefore, two sets were chosen: the first group contained drugs launched prior to 1983 (864 compounds) and the other collection contained drugs launched between 1983 and 2002 (329 compounds). The mean values of lipophilicity, percent polar surface area, and numbers of H-bond donors did not change over the years. Hence, these are probably the most important physical properties for oral bioavailability, which is related to an underlying requirement for effective membrane permeability.

Hydrogen-bond donors may therefore be more important than acceptors in this respect. This interpretation deserves comment in current models of membrane permeability and should be taken into account in real and virtual data bases, genetic algorithms, and fuzzy logic approaches.

On the one hand, it is necessary for the associated hydrogen-bonded water molecules to dissociate for sufficient membrane permeability; on the other hand, the drug candidate requires adequate solubility in lipids. Cell penetration and absorption are highly dependent on the ability to form hydrogen bonds as well as on drug size and lipophilicity. As medicinal chemists realize intuitively, there is an important and unchanging need to adjust the balance of polar versus nonpolar properties to allow sufficient gastrointestinal absorption.[7] Abraham et al. cast doubt on the assertion that the moderately hydrophilic solvent 1-octanol is an ideal model of the hydrophobic core of the membrane phospholipid bilayer.[11]

The first experimental detection of a low-polarity alkane-like region at the 1-octanol/water interface was reported recently.[12] The implications of this phenomenon that has been termed "grease wall" for the partitioning of drugs in 1-octanol/water mixtures await further investigation. Concentrations of lipophilic compounds at this interface might resemble accumulation in cell membranes. However, the estimation of the balance of polar versus nonpolar properties with the established 1-octanol/water partition coefficients (and the derived values of log P) is far from trivial. The reason that log P values nevertheless add a substantial share to predictive power lies in their considerable redundancy with respect to the other criteria discussed.



To date, in silico ADMET modeling is both a hot topic and difficult prospect.[13] Taking this insight into account, Lipinski's Rule of Five will maintain its value as a simple but highly practicable rule of thumb for years. With the results of Leeson and Davis taken into consideration, medicinal chemists may be rewarded with a robustness and prediction power higher than those derived from present methods.

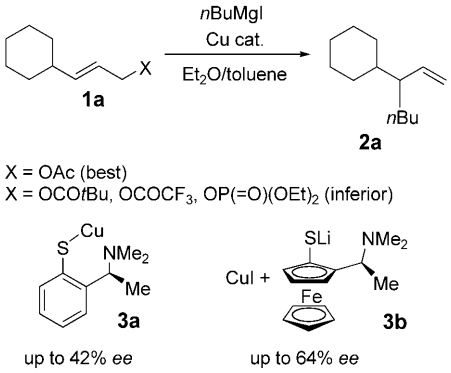
Asymmetric Synthesis

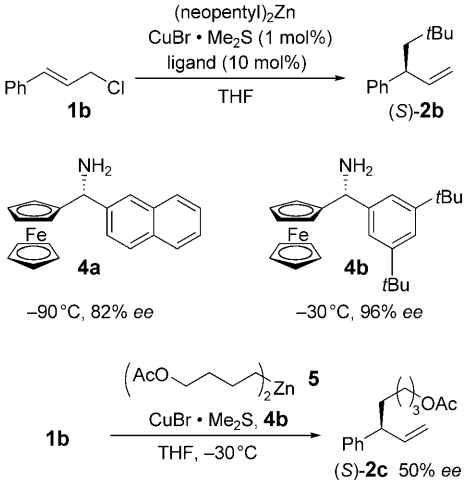


Recent Progress in Asymmetric Allylic Substitutions Catalyzed by Chiral Copper Complexes

Hideki Yorimitsu and Koichiro Oshima**

Keywords:
allylic substitution · asymmetric synthesis · copper · Grignard reagents · organozinc reagents

Allylic substitutions (also known as allylic alkylations) are among the most important carbon–carbon bond-forming reactions in organic synthesis. Palladium-catalyzed allylic substitutions and their asymmetric version have been extensively studied and widely used in a variety of total syntheses.[1] Palladium catalysis mostly requires soft nucleophiles such as malonate carbanions for high stereo- and regioselectivity. On the other hand, copper catalysis allows the use of hard nucleophiles including Grignard and organozinc reagents, thus being complementary to palladium catalysis. Moreover, copper-catalyzed substitution reactions usually proceed with high S_N2' regioselectivity, which guarantees the creation of stereogenic centers. Despite its promising potential, copper-catalyzed allylic substitution reactions had fallen behind, especially with regards to the development of asymmetric reactions.[2] However, since the first report on asymmetric allylic substitutions catalyzed by a chiral copper complex appeared in 1995,[3] remarkable progress in the development of copper-catalyzed asymmetric reactions has been made.



Bäckvall, van Koten, and co-workers reported that chiral arenethiolatocopper(I) **3a** catalyzed the asymmetric allylic substitution of allylic acetate with

Scheme 1.

butylmagnesium reagent (Scheme 1).[3] Their contribution is quite important not only because it reported the first copper-catalyzed asymmetric allylic substitution but also as the inherent difficulty of this asymmetric transformation was pointed out. The enantiomeric excess of the product heavily depended on many factors including the coordinating ability of the leaving group in the allylic substrates, the temperature, and the method of addition of the substrate and the Grignard reagent. The reactions of butylmagnesium iodide with **1a** (X = OAc) catalyzed by **3a** at 0 °C and at 20 °C showed similar enantioselectivities (29 % *ee* and 31 % *ee*, respectively). A lower temperature of −20 °C adversely affected the enantioselectivity (7 % *ee*). Simultaneous addition of the substrate and the Grignard reagent to a solution of **3a** provided the product with 42 % *ee*. Their observations underscored the difficulty in generating a unique transition state that leads to high enantioselectivity; there appeared to be several species present in the reaction mixture. Bäckvall and co-workers recently obtained the highest *ee* value (64 % *ee*) for the reaction of **1a** with butylmagnesium iodide in the presence of ferrocenethiolatocopper(I) **3b**.[4] Even with this latest ligand **3b**, fine tuning of the solvent, temperature, and method of addition was required.

A breakthrough in copper-catalyzed asymmetric allylic substitutions came in 1999,[5] when Dübner and Knochel focused on dialkylzinc as an alkyl source (Scheme 2). To attain a high enantioselectivity, the system required a high ratio of ligand to copper, very low temperatures, and the presence of bulky alkyl groups on zinc. For instance, the reaction of cinnamyl chloride with dineopentylzinc under catalysis by CuBr·Me_2S/**4a** (1:10) at −90 °C afforded (*S*)-**2b** with 82 % *ee*. Note, no enantioselectivity was observed when alkylzinc chloride, RZnCl, was used instead of

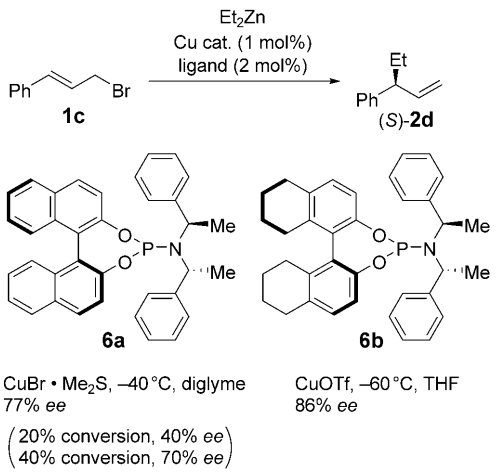
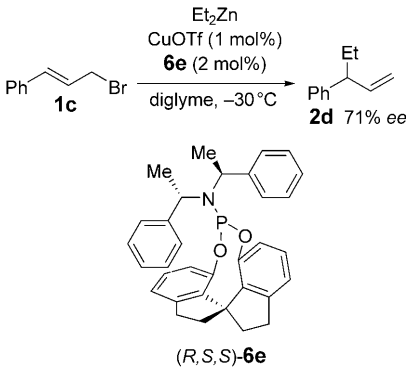
dialkylzinc, R_2Zn (see Woodward's work[6]). Later, ligand **4b** proved to be more effective in this reaction to provide **2b** with 96% *ee*. However, dineopentylzinc still gave the best results. The use of linear dialkylzincs such as dipentylzinc and functionalized dialkylzinc **5** afforded the corresponding products with approximately 44–65% *ee*. Despite the necessity of bulky alkyl groups, the work of Dübner and Knochel contributed to the accelerated development of copper-catalyzed asymmetric allylic substitution reactions.

Highly enantioselective allylic substitutions with linear alkylzinc reagents remained a major challenge, but then Feringa and co-workers proposed chiral phosphoramidite ligands as the solution (Scheme 3).[7] Treatment of cinnamyl bromide with diethylzinc in the presence of $CuBr{\cdot}Me_2S$ coupled with phosphoramidite **6a** in diglyme at −40 °C afforded **2d** with 77% *ee*. Importantly, the enantiomeric excess increased as the reaction proceeded, and it was rationalized that different catalytic species are present at the early stage of the reaction. Further extensive screening of chiral phosphoramidites revealed that **6b** led to improved enantioselectivities.



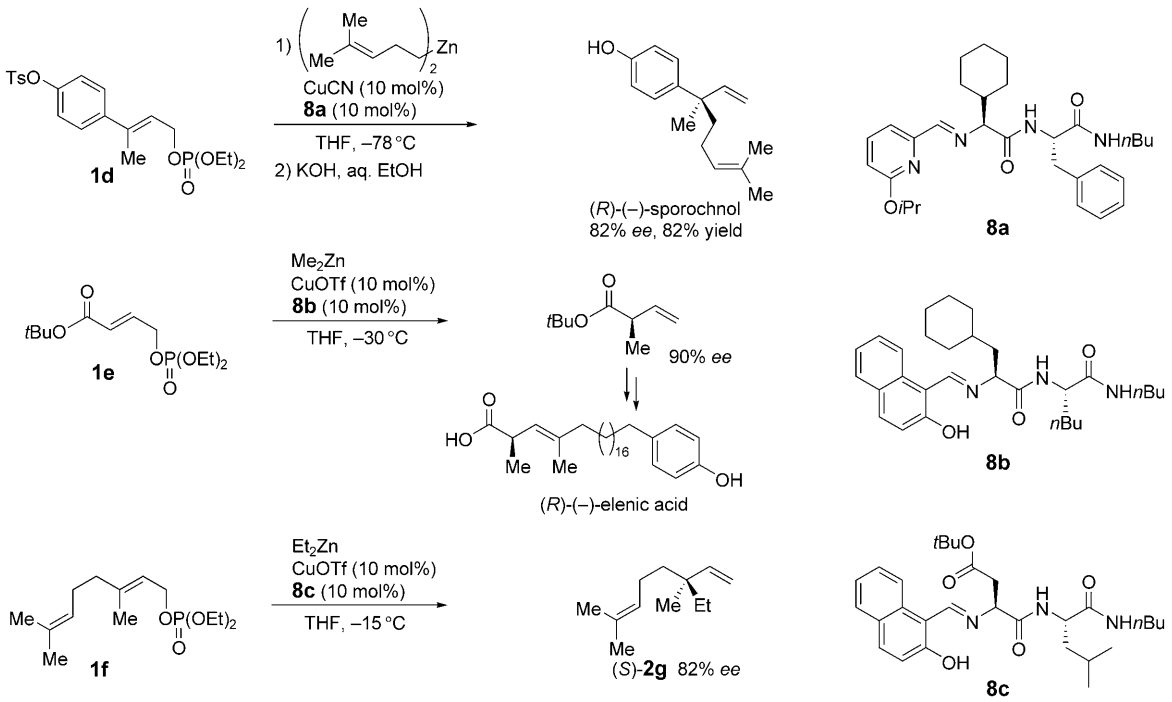
Independently, Alexakis and co-workers developed a system similar to that reported by Feringa for the reaction of Grignard reagents (Scheme 4).[8] As Bäckvall and van Koten also noted, enantioselectivity as well as regioselectivity were functions of many variables, even with the aid of chiral phosphite ligand **6c**. Very recently, a highly effective phosphoramidite ligand **6d** was developed that provided (*R*)-**2d** with high enantioselectivity. This ligand was also suitable for asymmetric allylic substitutions with diethylzinc (91% *ee*, starting from cinnamyl bromide, −40 °C) and with methylmagnesium bromide (96% *ee*). The highly enantioselective methylation was applied to the formal synthesis of (+)-naproxen. Asymmetric substitution with 3-butenyl Grignard reagent followed by ring-closing metathesis in one pot yielded chiral cyclopentene **7**, a new chiral synthon (Scheme 4). At present, this is the most efficient asymmetric allylic substitution reported with a Grignard reagent.



Scheme 4. Cy = cyclohexyl.

Zhou and co-workers devised original chiral spiro phosphoramidite and phosphite ligands and applied them to asymmetric allylic substitution reactions (Scheme 5).[9] Enantiomeric excess of the products was generally moderate. They successfully obtained a single crystal of a copper complex from $CuBr{\cdot}Me_2S$ and a spiro phosphoramidite ligand, L, which was similar to **6e**. X-ray crystallographic analysis disclosed the dimeric structure of $[\{CuBrL_2\}_2]$. Furthermore, the optimal Cu/ligand ratio for the reaction was shown to be 1:2. Although the actual shapes of the active species and the transition state are still not clear, these observations are nonetheless quite informative.

Hoveyda and co-workers developed various peptide-based chiral ligands for asymmetric allylic substitution reactions under copper catalysis (Scheme 6).[10] Through the synthesis and analysis of a library of ligands, the modularity of these ligands could be utilized for the improvement of the efficiency, regioselectivity, and stereoselectivity of the reaction. Dipeptide ligands **8** permitted access to the asymmetric syntheses of quaternary carbon atoms and α-alkyl-β,γ-unsaturated esters starting from allylic phosphates such as **1d**–**1f** (Scheme 6). The reactions were applied to the syntheses of a natural product, (*R*)-(−)-sporochnol, and the topoisomerase II inhibitor, (*R*)-(−)-elenic acid. With the state-of-the-art ligand **8c**, efficient addition of the alkyl reagent to trisubstituted aliphatic, not aromatic, substrates to deliver quaternary carbon centers (from **1f** to **2g**, for instance; see Scheme 6) was



Scheme 3. Diglyme = diethyleneglycol dimethyl ether, Tf = trifluoromethanesulfonyl.

Scheme 5.

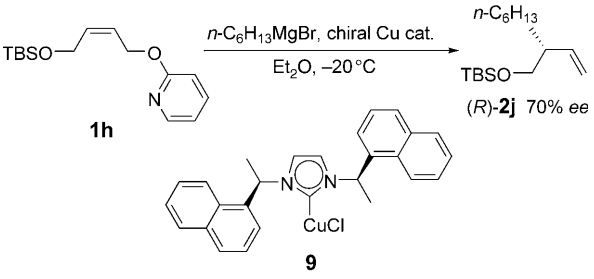
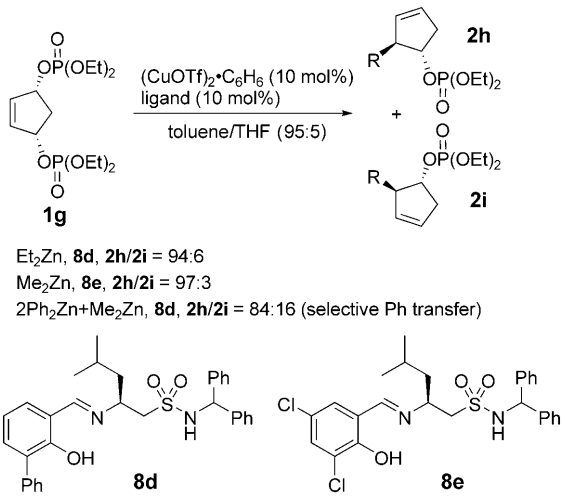


Scheme 6. Ts = *p*-toluenesulfonyl.

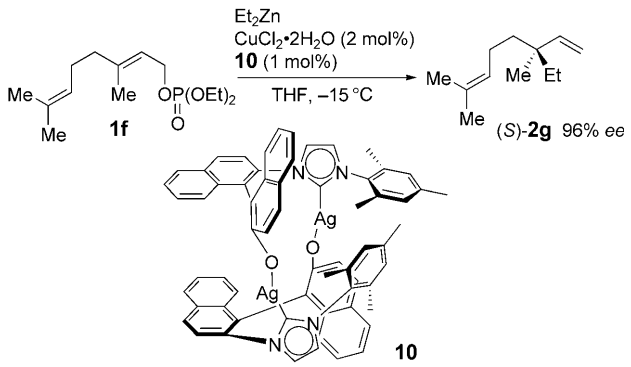
observed. Furthermore, the authors proposed a plausible working model through extensive screening of peptide ligands.

Piarulli, Gennari, and co-workers applied their own library of Schiff bases to the asymmetric desymmetrization of *meso* cyclic allylic bis(diethylphosphates) with organozinc reagents (Scheme 7).[11] Although only the reactions of a 4-cyclopentene-1,3-diol derivative gave satisfactory results, ligands **8d** and **8e** exhibited high efficiencies. Interestingly, in the case of asymmetric phenylation, selective transfer of the phenyl group from a mixed organozinc reagent ($2\,Ph_2Zn + Me_2Zn$) furnished the phenylated product with good enantioselectivity.



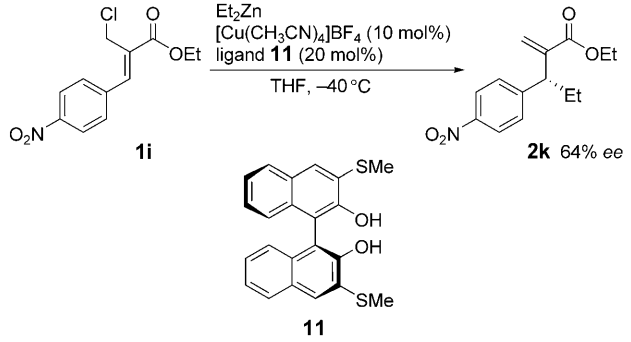
Okamoto and co-workers used C_2-symmetric carbene–copper complexes for asymmetric allylic substitution reactions (Scheme 8).[12] Sterically demanding **9** gave the highest *ee* values. The 2-pyridyloxy group of **1h** as well as the acetoxy group were good leaving groups. Although a moderate level of *ee* was obtained in preliminary results, the use of readily modifiable carbene ligands merits further investigation.

Scheme 8. TBS = *tert*-butyldimethylsilyl.



Hoveyda and co-workers have developed new bidentate carbene-based chiral ligands for efficient copper-catalyzed asymmetric allylic substitutions (Scheme 9).[13] Dinuclear silver complex **10** underwent facile ligand exchange with copper salts to generate highly effective chiral copper complexes. The catalyst loading was significantly lower than required with Schiff base ligands such as **8c**, and a higher extent of asymmetric induction in the alkylation of trisubstituted olefins than that obtained in Scheme 6 was noted. An advantage of the system is that air- and moisture-insensitive $CuCl_2 \cdot 2\,H_2O$ can catalyze the asymmetric reactions.

Woodward and co-workers examined the asymmetric allylic substitution of 2-halomethylcinnamate derivatives (Scheme 10),[14] which are attractive substrates as they are readily prepared on a large scale in two steps through Morita–Baylis–Hillman chemistry. The first generation BINOL (BINOL = 2,2′-binaphthol) catalyst **11** delivered the



Scheme 7. Ph = phenyl.

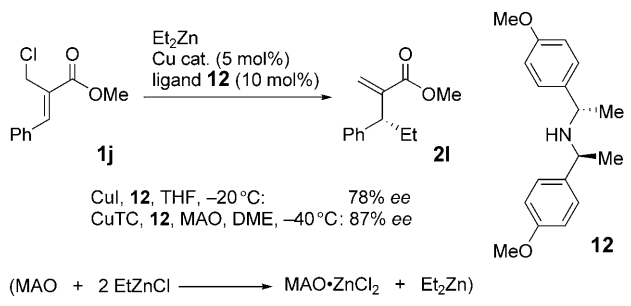

Scheme 9.

Scheme 10.

corresponding products with up to 64% *ee*. Other BINOL-type ligands exhibited lower enantioselectivities, and the system resisted further optimization. Very recently, Woodward and co-workers identified chiral secondary amines as alternative ligands for the asymmetric conversion of 2-halomethylcinnamates (Scheme 11).[6] The C_2-symmetric di(1-arylethyl)amine skeleton was indispensable for efficient stereoselection. By means of high-throughput screening, 4-methoxy-substituted ligand **12** appeared to be the optimal ligand.

During the high-throughput screening of ligands, Woodward and co-workers noticed that free amines such as **12** were always superior to their corresponding hydrochloride salts (Scheme 11). Moreover, kinetic studies revealed that the enantioselectivity of the reaction decreased as the reaction proceeded. Also, as observed by Dübner and Knochel,[5] the deliberate use of ethylzinc chloride instead of diethylzinc also led to poorer enantioselectivity. It was hence expected that removal of EtZnCl, which was gradually formed during the reaction, would enhance the enantioselectivity. To this end, they decided to exploit the zinc Schlenk equilibrium with the aid of methylaluminoxane (MAO). Indeed, the addition of MAO resulted in the anticipated increase in enantioselectivity. After further optimization, they attained up to 87% *ee* (CuTC (copper(I) thiophene-2-carboxylate), **12**, MAO, DME; Scheme 11). Although the difference in the enantiomeric excess in the absence and presence of MAO was not so large, the use of the zinc Schlenk equilibrium is attractive and applicable to other reactions.[15] The report by Woodward and co-workers lacks detailed investigation on the zinc Schlenk equilibrium that featured in their reaction. Thus, further mechanistic studies and more-efficient systems are awaited.

Scheme 11. DME = 1,2-dimethoxyethane.

Copper salts are generally cheaper than those of palladium. More significant advantages are that copper-catalyzed allylic substitutions normally proceed with high S_N2' regioselectivity and that copper catalysis allows the use of hard nucleophiles. Further extension of the scope of organometallic reagents may lead to considerably complex chiral organic molecules: for instance, the use of arylmetal reagents has not been well exploited. Although an increasing number of copper-catalyzed asymmetric allylic substitutions have emerged, little attention has been paid to their mechanistic aspects. Identification of the active species in such reactions is also still in its infancy. On the basis of experimental and theoretical studies on simpler systems,[16] profound mechanistic understanding of the enantioselection should open the door to more diverse copper-catalyzed asymmetric allylic substitutions.

In studying the evolution of organic chemistry and grasping its essence, one comes quickly to the conclusion that no other type of reaction plays as large a role in shaping this domain of science than carbon–carbon bond-forming reactions. The Grignard, Diels–Alder, and Wittig reactions are but three prominent examples of such processes, and are among those which have undeniably exercised decisive roles in the last century in the emergence of chemical synthesis as we know it today. In the last quarter of the 20th century, a new family of carbon–carbon bond-forming reactions based on transition-metal catalysts evolved as powerful tools in synthesis. Among them, the palladium-catalyzed cross-coupling reactions are the most prominent. In this Review, highlights of a number of selected syntheses are discussed. The examples chosen demonstrate the enormous power of these processes in the art of total synthesis and underscore their future potential in chemical synthesis.

1. Introduction

Ever since the first laboratory construction of a carbon–carbon bond by Kolbe in his historic synthesis of acetic acid in 1845, carbon–carbon bond-forming reactions have played an enormously decisive and important role in shaping chemical synthesis. Aldol- and Grignard-type reactions, the Diels–Alder and related pericyclic processes, and the Wittig and related reactions are but a few examples of such processes that have advanced our ability to construct increasingly complex carbon frameworks and, thus, enabled the syntheses of a myriad of organic compounds. In the last quarter of the 20th century, a new paradigm for carbon–carbon bond formation has emerged that has enhanced considerably the prowess of synthetic organic chemists to assemble complex molecular frameworks and has changed the way we think about synthesis. Based on transition-metal catalysis, this newly acquired ability to forge carbon–carbon bonds between or within functionalized and sensitive substrates provided new opportunities, particularly in total synthesis but also in medicinal and process chemistry as well as in chemical biology and nanotechnology.

Prominent among these processes are the palladium-catalyzed carbon–carbon bond-forming reactions. Because the historical, mechanistic, theoretical, and practical aspects of these processes have been amply discussed,[1] in this Review we focus only on selected applications of the most commonly applied palladium-catalyzed carbon–carbon bond-forming reactions in total synthesis, namely, the Heck, Stille, Suzuki, Sonogashira, Tsuji–Trost, and the Negishi reactions, with particular emphasis on the pioneering as well as some of the most recent and exciting examples. In doing so, we hope to illustrate the tremendous enabling ability of these modern synthetic tools.

The Heck reaction can be broadly defined as the palladium-catalyzed coupling of alkenyl or aryl (sp^2) halides or triflates with alkenes (Scheme 1) to yield products which formally result from the substitution of a hydrogen atom in the alkene coupling partner. The first examples of this reaction as we would recognize it today were reported independently by Mizoroki (1971)[2] and, in an improved form, by Heck (1972).[3] However, it would prove to be more than a decade before the broader applicability of this transformation began to be investigated by the wider synthetic organic community. The development of catalytic asymmetric Heck reactions in the late 1980s led to a further resurgence of interest in this field.[4] The Heck reaction now stands as a remarkably robust and efficient method for carbon–carbon bond formation, particularly in the generation of tertiary and quaternary stereocenters and intramolecular ring formation, and remains a flourishing area of research. Significantly, it inspired important variations that, with time, have assumed their own names, identities, and place in total synthesis.

The palladium-catalyzed cross-coupling of organic electrophiles with vinyl organotin compounds is today known as the Stille reaction (Scheme 1),[5] after the late Professor J. K. Stille who pioneered (1978)[6] and subsequently developed[7] this reaction, although the seeds of discovery were sown earlier by Kosugi and his group, who published the first reports of transition-metal-catalyzed carbon-carbon bond-forming reactions with organotin compounds a year earlier.[8,9] Nearly 30 years later the Stille reaction remains one of

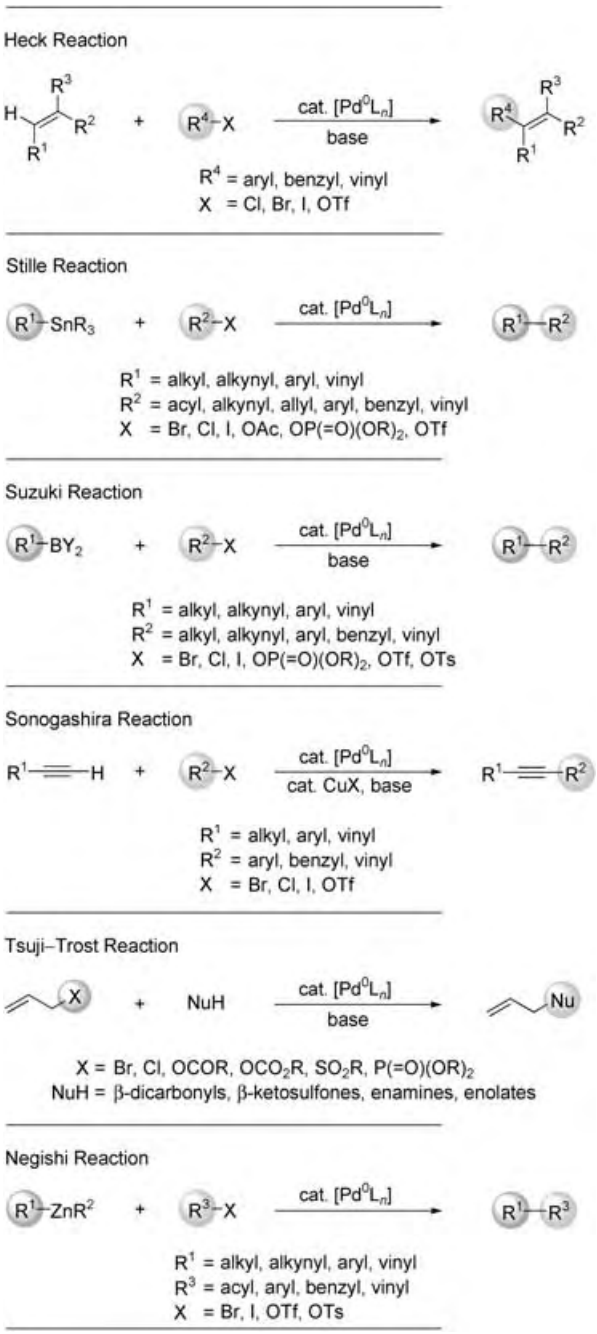
the most widely applied palladium-catalyzed carbon–carbon bond-forming reactions, in large part due to typically mild reaction conditions, the ease of preparation of a wide range of coupling partners, and the tolerance of a wide variety of sensitive functionalities in this transformation. In particular, the number of ingenious and daring applications of Stille couplings in the challenging proving ground of total synthesis bears testament to the faith placed in the robustness and versatility of this reaction by practitioners of this art. Notably, the Stille reaction can be viewed as a variation of the Heck reaction in which a hydrogen atom is replaced by a tin-bearing substituent.[10]

Another extraordinarily useful palladium-catalyzed carbon–carbon bond-forming reaction involves the palladium-mediated coupling of organic electrophiles, such as aryl or alkenyl halides and triflates, with organoboron compounds in the presence of a base (Scheme 1),[11] a process known today as the Suzuki reaction. The first examples of this protocol were reported by the Suzuki group in 1979[12]



K. C. Nicolaou was born in Cyprus and educated in the UK and USA. He is Chairman of the Department of Chemistry at The Scripps Research Institute where he holds the Darlene Shiley Chair in Chemistry and the Aline W. and L. S. Skaggs Professorship in Chemical Biology. He is also Professor of Chemistry at the University of California, San Diego. His impact on chemistry, biology and medicine flows from contributions to chemical synthesis, which are described in numerous publications and patents.

Paul G. Bulger was born in London (UK) in 1978. He received his M.Chem in 2000 from the University of Oxford, where he completed his Part II project under Dr. Mark G. Moloney. He obtained his D.Phil in chemistry in 2003 for research conducted under Professor Sir Jack E. Baldwin. In the fall of 2003, he joined Professor K. C. Nicolaou's group as a postdoctoral researcher. His research interests encompass reaction mechanism and design and their application to complex natural product synthesis and chemical biology.

David Sarlah was born in Celje, Slovenia in 1983. He is currently student in the Faculty of Chemistry and Chemical Technology, University of Ljubljana (Slovenia). Since 2001, he has been a research assistant at the Laboratory of Organic and Medicinal Chemistry at the National Institute of Chemistry (Slovenia) where he carried out research on asymmetric catalysis under the direction of Dr. B. Mohar. During the summer of 2004, he was engaged in total synthesis endeavors as a member of the azaspiracid team under Professor K. C. Nicolaou.

Scheme 1. The most commonly utilized palladium-catalyzed cross-coupling reactions.

although, again, the inspiration or the seeds of this development can be found in earlier work by others, in this case the groups of Heck (1973)[13] and Negishi (1977).[14] The ensuing quarter of a century saw remarkable developments in the field. Amongst its manifold applications, the Suzuki reaction is particularly useful as a method for the construction of conjugated dienes and higher polyene systems of high stereoisomeric purity, as well as of biaryl and related systems. Furthermore, tremendous progress has been made in the development of Suzuki coupling reactions of unactivated

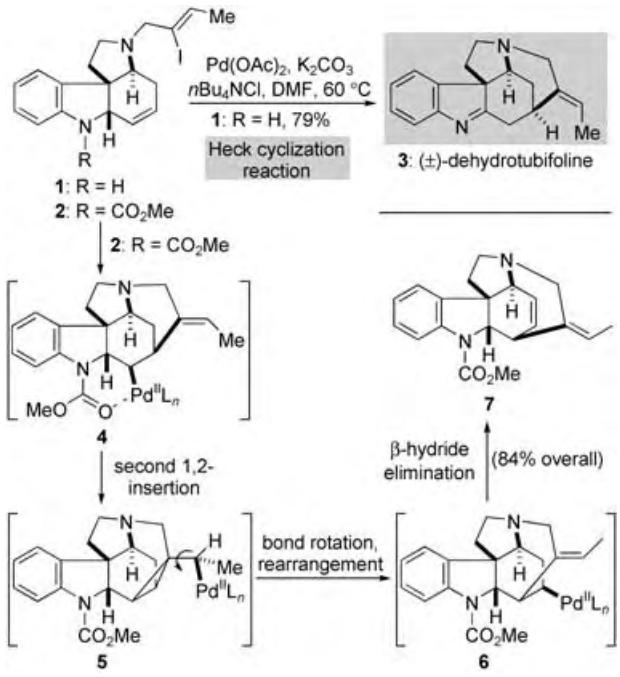
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

alkyl halides, enabling $C(sp^2)$–$C(sp^3)$ and even $C(sp^3)$–$C(sp^3)$ bond-forming processes.[15,16] The ease of preparation of organoboron compounds (e.g. aryl, vinyl, alkyl) and their relative stability to air and water, combined with the relatively mild conditions for the reaction as well as the formation of nontoxic by-products, makes the Suzuki reaction a valuable addition to the armory of the synthetic organic chemist. Indeed, it has become one of the most reliable and widely applied palladium-catalyzed cross-coupling reactions in total synthesis, where it has found a prominent role.[17] It is, again, worth mentioning that the Suzuki reaction may be considered as a variation of the Heck reaction, in which a boron-containing group replaces a hydrogen atom in the olefinic partner of the cross-coupling.

The palladium-catalyzed coupling of terminal alkynes with vinyl or aryl halides was first reported independently and simultaneously by the groups of Cassar[18] and Heck[19] in 1975. A few months later, Sonogashira and co-workers demonstrated that, in many cases, this cross-coupling reaction could be accelerated by the addition of cocatalytic Cu^I salts to the reaction mixture.[20,21] This protocol, which has become known as the Sonogashira reaction, can be viewed as both an alkyne version of the Heck reaction and an application of palladium catalysis to the venerable Stephens–Castro reaction (the coupling of vinyl or aryl halides with stoichiometric amounts of copper(I) acetylides).[22] The Sonogashira reaction provides a valuable method for the synthesis of conjugated acetylenic systems, which are used in a diverse array of important applications from natural products and pharmaceuticals to designed molecules of interest in biotechnology and nanotechnology. Interestingly, the utility of the "copper-free" Sonogashira protocol (i.e. the original Cassar–Heck version of this reaction) has subsequently been "rediscovered" independently by a number of other researchers in recent years.[23]

The palladium-catalyzed nucleophilic substitution of allylic compounds, known as the Tsuji–Trost reaction (Scheme 1), is arguably one of the most synthetically useful carbon–carbon bond-forming reactions to emerge in the last quarter of the previous century.[24] Allyl acetates are by far the most commonly employed electrophiles, and soft anions such as those derived from β-dicarbonyl compounds are most routinely used as the nucleophilic coupling partner. However, a wide variety of substrate combinations is possible, which gives the reaction an exceptionally broad scope. The development of the palladium-catalyzed asymmetric allylic alkylation reaction over the last decade has considerably increased the enabling nature of this transformation.[25] A notable feature of the allylic alkylation reaction is its net reaction at sp^3-hybridized carbon atom centers, a feature common among the palladium-catalyzed coupling reactions only to the Fu modification of the Suzuki reaction. The asymmetric allylic alkylation reaction now provides a powerful method for ring formation, 1,3-chirality transfer, desymmetrization of *meso* substrates, the resolution of racemic compounds, and a plethora of other applications.

Historically, the use of organozinc reagents as the nucleophilic component in palladium-catalyzed cross-coupling reactions, known as the Negishi coupling (Scheme 1), actually predates the development of both the organostannane- (Stille, 1978)[6] and organoborane-based (Suzuki, 1979)[12] procedures, with the first such examples being reported in 1977.[26] Nevertheless, the rapid and widespread embracement of the latter two protocols by synthetic chemists during the 1980s led to the potential of organozinc reagents in cross-coupling processes being relatively underappreciated and underutilized during this time, particularly in total synthesis. However, recent years have witnessed a resurgent interest in the development and application of organozinc-mediated cross-couplings, largely fueled by the recognition that these reagents offer complementary modes of reactivity to those of the less electropositive metals species (e.g. B and Sn). Organozinc reagents exhibit a very high intrinsic reactivity in palladium-catalyzed cross-coupling reactions, which combined with the availability of a number of procedures for their preparation and their relatively low toxicity, makes the Negishi coupling an exceedingly useful alternative to other cross-coupling procedures, as well as constituting an important method for carbon–carbon bond formation in its own right.[27]



In the following sections, we discuss the contributions of these palladium-catalyzed carbon–carbon bond-forming reactions to the art and science of total synthesis and the new thinking that they have precipitated in the field.

2. The Heck Reaction

Total synthesis has benefited enormously from the Heck reaction, which has been widely applied in both its intermolecular and intramolecular variants.[28–30] The enabling attributes of this remarkable reaction manifest themselves in a plethora of ways, including appendage attachments, polyene construction, fragment couplings, and ring-closure reactions. In this section, we highlight a few examples that demonstrate the elegance and effectiveness of strategies based on the Heck reaction as the key step.

Among alkaloid total syntheses employing the Heck reaction, that of dehydrotubifoline (**3**) by Rawal and co-workers stands out (Scheme 2).[31] In this instance the palladium-catalyzed process was used to forge the final carbon–carbon bond and cast the final ring of the polycyclic structure of the target in 79% yield (**1**→**3**, Scheme 2). This effective operation, involving a 6-*exo*-palladation followed by β-hydride elimination and tautomerization of the resulting enamine species, would seem simple enough and certainly predictable, until one considers the different outcome observed with the corresponding *N*-carbomethoxy cyclization substrate **2**. In that initial attempt, the researchers noticed the exclusive formation of the unexpected compound **7**, the apparent product of a 7-*endo*-cyclopalladation reaction, in 84% yield. Moreover, close scrutiny of the spectroscopic data of pentacyclic compound **7** revealed that inversion of geometry of the exocyclic double bond had occurred, an outcome inconsistent with a direct 7-*endo* mode of ring closure. The proposed mechanistic explanation for the formation of **7** is both intriguing and illuminating. Thus, under the Jeffery modification[32] of the Heck conditions

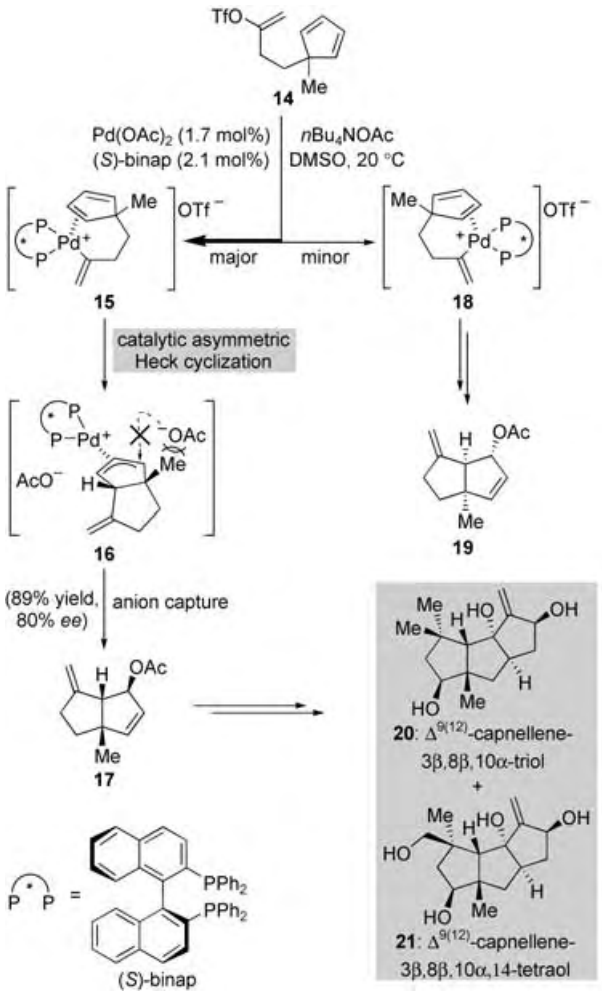
Scheme 2. Intramolecular Heck reactions in the total synthesis of (±)-dehydrotubifoline (**3**) (Rawal et al., 1993).[31]

($Pd(OAc)_2$ cat., K_2CO_3, nBu_4NCl, DMF, 60 °C), the expected 6-*endo* cyclization occurs to yield initially σ-alkyl–palladium species **4** which, due to stabilization by intramolecular carbamate complexation, is prevented from undergoing a normally facile *syn*-β-hydride elimination, despite the presence of a β-hydrogen atom.[33] Instead, this intermediate is sufficiently long-lived to undergo a second cyclopalladation to form the cyclopropylmethyl palladium complex **5**, which is forced by steric congestion to undergo a 120° rotation about the σ bond. This then allows the proper alignment required for fragmentation of the other cyclopropane bond to give palladium complex **6**, which is no longer stabilized by carbamate complexation and undergoes the anticipated β-hydride elimination to provide the observed product **7**. Based on these mechanistic considerations, the Rawal group subjected the "carbamate-free" substrate **1** to the same reaction conditions realizing, much to their delight, the formation of the natural product dehydrotubifoline (**3**). This case serves to illustrate the fact that the "normal" mechanistic pathways of metal-catalyzed processes may be diverted, in certain cases, by the judicious placement of coordinating groups within the employed substrates.[34]

Palladium-catalyzed reactions abound in the spectacular synthesis of quadrigemine C (**13**, Scheme 3), a tetrameric member of the polypyrrolidinoindoline alkaloid family, by Overman and co-workers.[35] Noting that the quaternary C3 and C3‴ stereocenters within the target molecule **13** have the same absolute configuration, these researchers applied catalytic asymmetric Heck reactions[4] to effect the desymmetrization of an advanced *meso* intermediate **10**, formation of the two peripheral indoline residues, and installation of the final two quaternary stereocenters in a single step. This remarkable double cyclization (**10**→**11**→**12**) was preceded by another highly effective palladium-catalyzed carbon–carbon bond-forming reaction, namely a Stille coupling, which was used to assemble the required precursor **10** from its constituent



Scheme 3. Sequential tandem Stille couplings and asymmetric intramolecular Heck reactions in the enantioselective synthesis of (−)-quadrigemine C (**13**) (Overman et al., 2002).[35]

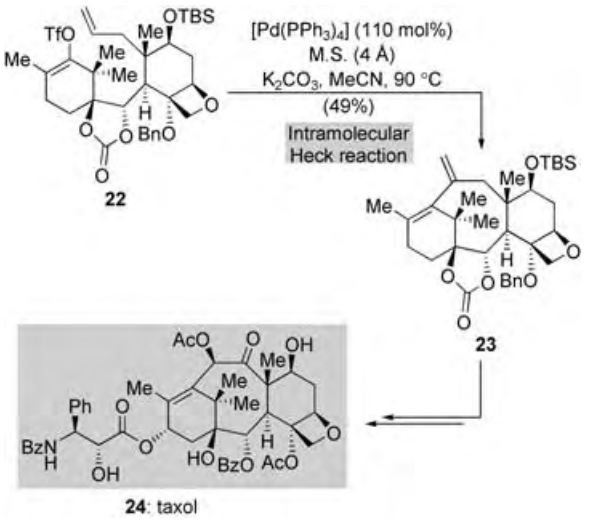
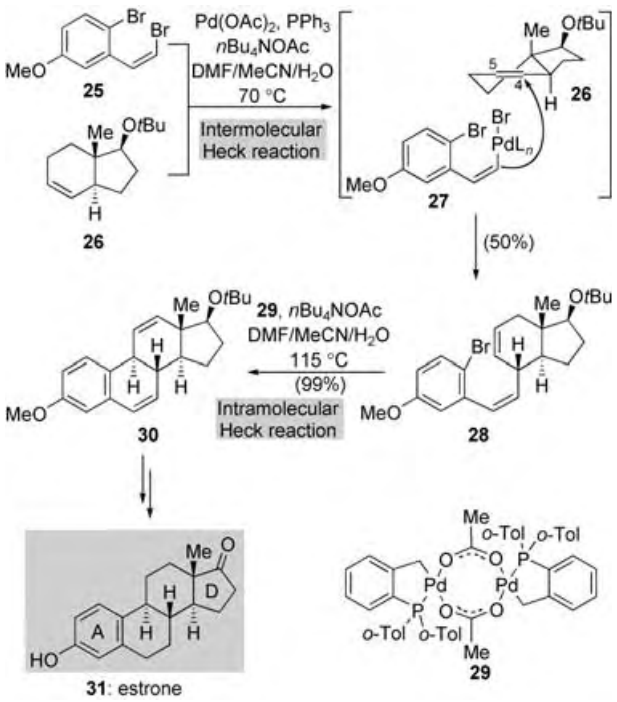
fragments, bisaromatic iodide **8** and stannane **9**. Thus, following assembly of **10** from **8** and **9** under Farina conditions[36] (note the selectivity of the cross-coupling of the vinyl stannane moiety with the aryl iodide groups in the presence of the aryl triflate groups, owing to the higher reactivity of aryl iodides relative to the corresponding triflates towards oxidative addition to Pd^0 species),[37] the crucial asymmetric Heck reaction was induced by treatment with $Pd(OAc)_2$ (100 mol%, precatalyst), (*R*)-Tol-binap (200 mol%, ligand), and 1,2,2,6,6-pentamethylpiperidine (base) in acetonitrile at 80°C to yield decacyclic system **12** in 62% yield with 90% *ee*, together with another two undesired stereoisomeric products in a combined yield of 21%. A few more steps then converted the advanced intermediate **12** into the targeted natural product **13** in good overall yield. This accomplishment stands as a powerful testament to the power of modern synthetic methods, most notably the catalytic asymmetric Heck reaction, to construct quaternary stereocenters[38,39] and crowded bonds.



These workers were not alone in developing the asymmetric Heck reaction. Shibasaki and his group also made pioneering contributions to the field at about the same time. Indeed, it was the Overman and the Shibasaki groups that independently reported the first examples of asymmetric Heck reactions in 1989.[40,41] The Shibasaki group applied their chemistry to the catalytic asymmetric synthesis of vernolepin and, subsequently, compound **17**, a key intermediate in the total synthesis of the complex triquinane sesquiterpenes $\Delta^{9(12)}$-capnellene-3β,8β,10α-triol (**20**) and $\Delta^{9(12)}$-capnellene-3β,8β,10α,14-tetraol (**21**), by making use of an asymmetric Heck reaction/anion-capture cascade sequence (Scheme 4).[42] Thus, starting with the prochiral vinyl triflate **14**, the team was able to prepare the diquinane derivative **17** in 89% yield with 80% *ee* by treatment with catalytic amounts of $Pd(OAc)_2$ (1.7 mol%) in the presence of (*S*)-binap (2.1 mol%) and nBu_4NOAc in DMSO at 20°C. The reaction presumably proceeds through a mechanism involving oxidative addition of the vinyl triflate to the initially formed Pd^0–binap complex, followed by coordination of the resulting vinyl–Pd^{II} species to, potentially, either enantiotopic double bond of the cyclopentadienyl system to give intermediates **15** or **18**. Intermediate **15** enjoys much less steric congestion as a result of the chiral environment created around the Pd^{II} ion than does intermediate **18** and is, therefore, energetically favored; rearrangement of **15** through 1,2-insertion of the coordinated alkene into the Pd–C(vinyl) σ bond is then followed by a rapid σ→π shift to generate the π-allylpalladium species **16**. Trapping of the latter intermediate with an acetate ion derived from nBu_4NOAc, whose presence proved to be essential for the reaction to occur, proceeded in both a regio- (attack at the least-hindered terminus of the π-allyl system) and stereocontrolled (attack from the face opposite to palladium) manner, leading to the key building block, diquinane **17**. Elaboration of this intermediate, and others like it, allowed the formal total syntheses of both natural products **20** and **21**. In addition to these pioneering examples, asymmetric Heck reactions have been successfully employed in several other total syntheses of a structurally diverse range of natural products, including alkaloids, terpenoids, and polyketides. For a fuller coverage of this topic, the reader is referred to a recently published review.[4a]



Scheme 4. Use of a catalytic asymmetric intramolecular Heck reaction to generate a key intermediate (**17**) in the total synthesis of $\Delta^{9(12)}$-capnellene-3β,8β,10α-triol (**20**) and $\Delta^{9(12)}$-capnellene-3β,8β,10α,14-tetraol (**21**) (Shibasaki et al., 1989).[42]

It can be seen from the previous two examples that, besides the customary halide species, the corresponding aryl and vinyl triflates also make excellent electrophilic coupling partners in the Heck reaction. One of the most breathtaking applications of vinyl triflates in the intramolecular Heck reaction was in the construction of the core tricyclic ABC ring system of taxol (**24**) by Danishefsky and co-workers, en route to their total synthesis of this famous natural product (Scheme 5).[43] The intramolecular cyclization of the cyclohexene moiety of triflate **22** onto the pendant terminal alkene was brought about by treatment with $[Pd(PPh_3)_4]$ and K_2CO_3 in refluxing MeCN, thus effecting the closure of the central eight-membered ring to generate the tetracyclic product **23** in 49% yield. It was found to be necessary to add a stoichiometric amount of the palladium "catalyst" in several portions over the course of the reaction to ensure its completion. Nonetheless, this transformation is astonishing for several reasons, not the least of which are the remarkable steric

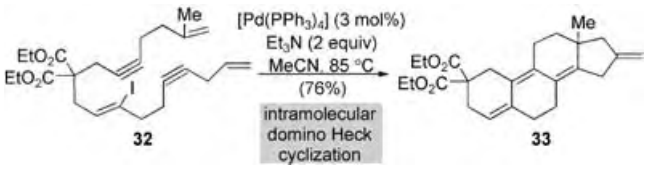
Scheme 5. The intramolecular Heck cyclization of an enol triflate in the total synthesis of Taxol (**24**) (Danishefsky et al., 1995).[43]

Scheme 6. Sequential inter- and intramolecular Heck reactions in the enantioselective total synthesis of estrone (**31**) (Tietze et al., 1998).[50]

hindrance at the junction of ring closure that had to be overcome and the strained nature of the product thus formed, which contains a tetrasubstituted bridgehead double bond. Furthermore, the delicate oxetane ring was retained intact, together with the rest of the sensitive functionality, illustrating the mildness of this ring-closure method. The success of this reaction must be, in no small part, due to the presence of the cyclic carbonate 1,2-diol-protecting group. This protecting group restricts the rotational degrees of freedom available to the precursor **22**, thus making the ring closure less entropically unfavorable.[44]

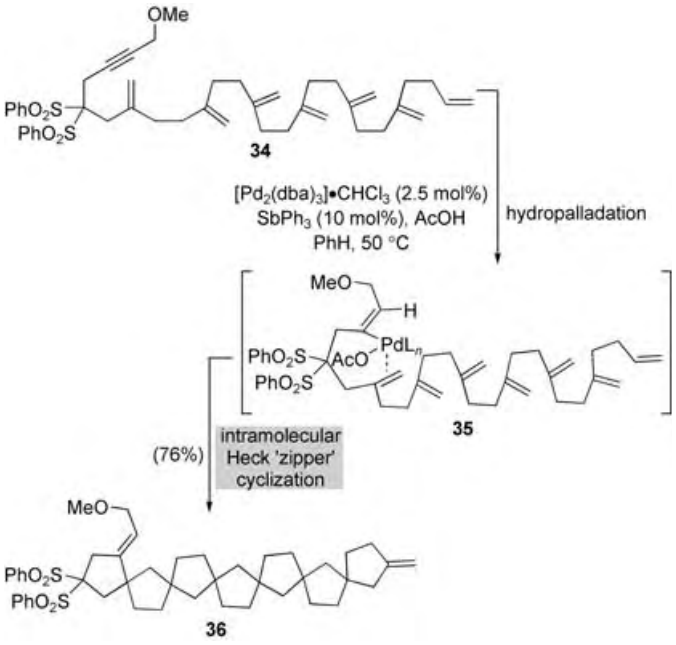
Steroid research can be regarded as one of the triumphs of 20th century science, from the story of their structure elucidation to their manifold pharmaceutical applications. No less significant is the impact this field has had on organic synthesis by providing inspiration for the development and application of a rich collection of novel synthetic methods.[45] Classic examples include the development of Robinson-type annulations,[46] the biomimetic olefin-cation cyclizations, as suggested by the Eschenmoser–Stork hypothesis[47] and pioneered by Johnson and his group,[48] and the cobalt-mediated alkyne cyclotrimerization/*ortho*-quinodimethane strategies introduced by Vollhardt and co-workers.[49]



An alternative approach to the steroid skeleton, based on palladium-catalyzed Heck reactions, has more recently been introduced by Tietze and his group and is exemplified by an elegant, enantioselective total synthesis of the female sex hormone estrone (**31**, Scheme 6).[50] The cornerstone of this strategy relies on the generation of the steroid ring B by the fusion of the functionalized aromatic compound **25** onto the enantiopure hydrindene derivative **26**[51] through consecutive inter- and intramolecular Heck reactions. Specifically, these researchers discovered that treatment of a mixture of **25** and **26** with catalytic amounts of $Pd(OAc)_2$ and PPh_3 in the presence of nBu_4NOAc in a mixed $DMF/MeCN/H_2O$ solvent system at 70 °C led to the selective formation of the intermolecular Heck reaction product **28**; when the latter was treated with a catalytic amount of the novel palladacycle **29**[52] in the same solvent system, but at a slightly higher temperature (115 °C), the desired intramolecular ring closure was effected, generating the estrone core structure **30** in quantitative yield. A few more steps then completed what amounted to a concise total synthesis of the natural product.

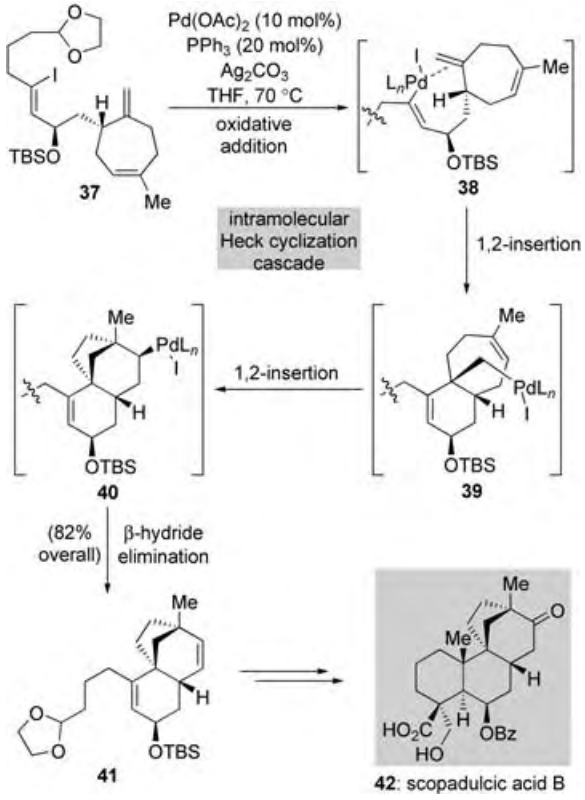
The overall conversion of **25** and **26** into tetracyclic structure **30** is indeed a remarkable transformation, several aspects of which warrant further discussion. First, it will be noted that the initial union of **25** and **26** involves selective reaction at the vinyl bromide moiety of compound **25**. The researchers expected this selectivity based on earlier investigative work which uncovered subtle reactivity differences between the two halogen atoms in dihalides such as **25**: the vinyl–bromine bond was found to be more susceptible to oxidative addition to Pd^0 complexes than the corresponding aryl–bromine bond. Second, whereas the diastereoselectivity of the 1,2-insertion of Pd^{II} complex **27** into the double bond of hydrindene **26** could be confidently predicted on the basis of approach of the complex to the less sterically hindered face of the double bond, the regioselectivity of the insertion would, at first glance, appear to be questionable at best. Fortuitously, the sole regioisomeric product of the reaction was, indeed, the desired one, and in a case of a rationalization after the event, it was proposed that the selectivity was due to stereoelectronic effects in the transition state for 1,2-insertion. Finally, palladacycle **29** was found to be uniquely effective in catalyzing the intramolecular Heck reaction, with more-conventional catalyst systems proving to be much less efficient. Even more impressively, it was subsequently found that the direct conversion of **25** and **26** into tetracyclic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



compound **30**, in a domino reaction without the need for isolation of intermediate **28**, could be effected by treatment of a mixture of the two starting materials with catalyst **29**, although the overall yield (35%) was slightly lower than that of the two-step process.

A famous and equally stunning application of the domino intramolecular Heck reaction can be found in the formation of the steroidal ring framework in compound **33** in a single operation from the polyunsaturated acyclic precursor molecule **32** (Scheme 7).[53] It was Negishi and co-workers who

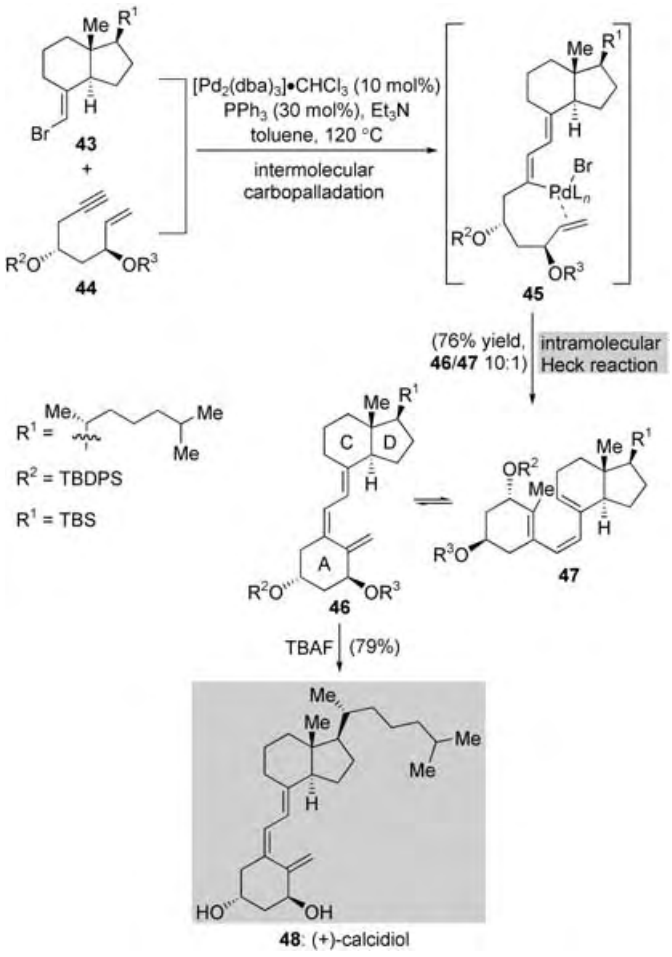


Scheme 7. A palladium-catalyzed "zipper" tetracyclization approach to steroidal skeletons (Negishi et al., 1990).[53]

demonstrated this transformation by treatment of iodide **32** with $[Pd(PPh_3)_4]$ catalyst (3 mol%) in the presence of triethylamine in refluxing acetonitrile. This reaction involves a series of consecutive carbopalladations that lead to the regiocontrolled formation of four new carbon–carbon bonds and four carbocyclic rings, ultimately generating polycycle **33** in an impressive 76% overall yield. Not to be outdone, the Trost group subsequently reported even more spectacular examples of intramolecular Heck-type polycyclization processes. These studies are exemplified by the hydridopalladium acetate catalyzed formation of the intriguing heptacyclic structure **36** in a single operation from the open-chain precursor **34** (Scheme 8).[54] Such cascade cyclization processes, colorfully termed "zipper reactions", provide efficient and economical means of generating polycyclic molecular complexity from simple acyclic materials in a manner that would have been impossible before the advent of palladium-catalyzed carbon–carbon bond-forming reactions, and are illustrative of the enabling power of this methodology.[55,56]

Scheme 8. A hydridopalladium acetate-catalyzed "zipper" polycyclization (Trost and Shi, 1991).[54]

An application of a palladium-catalyzed polyene cyclization reaction in the context of total synthesis can be found in the pioneering approach of the Overman group towards the synthesis of the scopadulcic acid family of diterpenes.[57] In this highly inventive strategy, it was reasoned by the group that the three of the four rings of the formidable tetracyclic structure of the target products, including the sterically congested bridged bicyclic system and two of the three quaternary stereocenters, could be fashioned from a simple monocyclic precursor and in a single step through a palladium-catalyzed intramolecular Heck cyclization cascade process. The realization of this hypothesis in practice is illustrated by the total synthesis of scopadulcic acid B (**42**), as shown in Scheme 9, in which the substituted cycloheptene **37** was converted into tricyclic compound **41** in one step. This cascade was triggered by the addition of $Pd(OAc)_2$ (10 mol%), PPh_3 (20 mol%), and Ag_2CO_3 to a refluxing solution of iodide **37** in THF. The initial oxidative addition into the carbon-iodine bond generated intermediate **38** with retention of configuration. This was followed by the first intramolecular cyclization to generate alkylpalladium(II) intermediate **39**, which was unable to exit the catalytic cycle



Scheme 9. A sequential intramolecular Heck cyclization approach to the total synthesis of scopadulcic acid B (**42**) (Overman et al., 1993).[57]

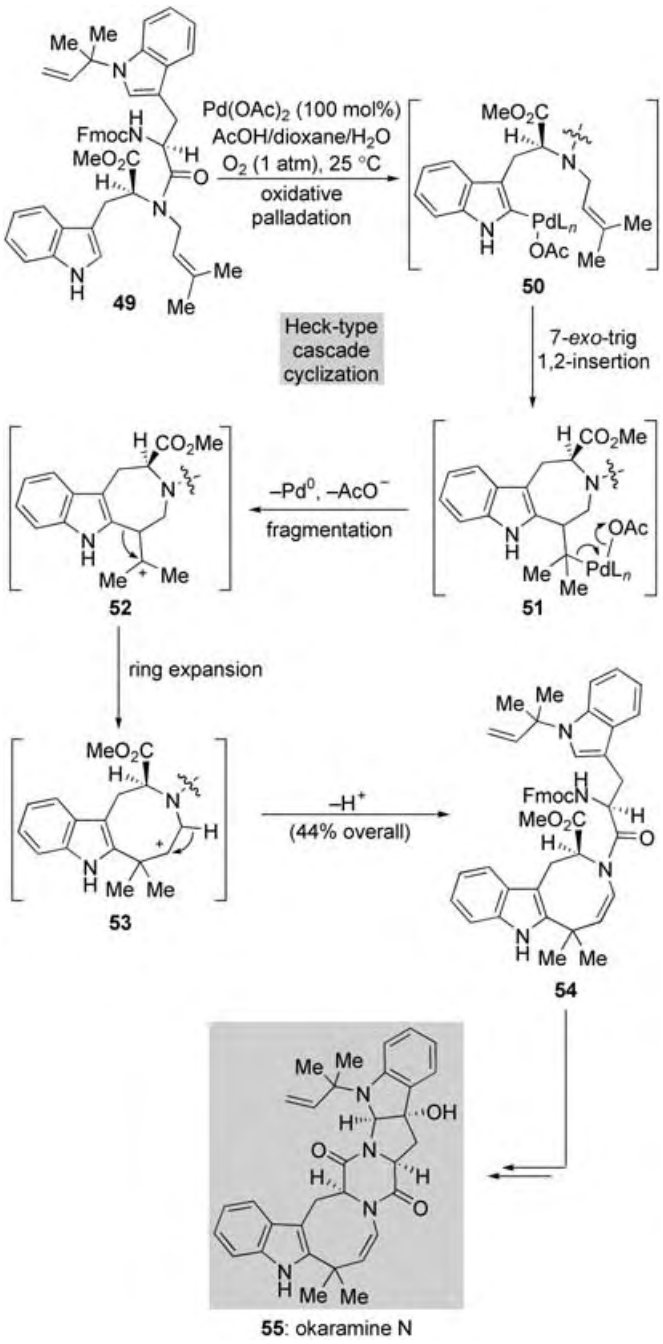
by β-hydride elimination owing to the absence of any suitably disposed hydrogen atoms and thus underwent the second 1,2-insertion reaction into the trisubstituted alkene conveniently located within bonding distance. The resulting species **40**, having exhausted its possibilities for intramolecular carbon–carbon bond formation, finally succumbed to β-hydride elimination to afford the isolated product **41**. Each of these steps proceeded with remarkable efficiency and selectivity: tricyclic compound **41** was isolated in 82% yield as a single stereoisomer! This intermediate could then be elaborated in a number of steps, which included the fusion of the final carbocyclic ring onto the tricyclic system, to complete the total synthesis of scopadulcic acid B (**42**). This synthesis provides further evidence for the utility of the Heck reaction in the construction of sterically crowded systems and quaternary stereocenters through cascade processes.

The Trost group has reported an interesting addition to the menagerie of methods documented for the preparation of the clinically important 1α-hydroxyvitamin D (calcidiol) and its analogues,[58] in a convergent strategy based on a palladium-catalyzed cascade reaction (Scheme 10).[59,60] Thus, the addition of a mixture of bromide **43** and enyne **44** to a heated solution of $[Pd_2(dba)_3]\cdot CHCl_3$ (10 mol%) and PPh_3 (30 mol%) in toluene/Et_3N (1:1 v/v) initiated a sequence involving the oxidative addition of the carbon–bromine bond of vinyl halide **43** to Pd^0 followed by chemoselective intermolecular carbopalladation of the alkyne moiety of compound **44** to yield intermediate **45**. The latter was suitably arranged to undergo a subsequent regioselective intramolecular Heck reaction to form the final carbon–carbon bond of the product. The net result of this reaction sequence was the attachment of the CD-ring fragment, formation of ring A, and creation of the requisite triene system in a single operation! The desired product **46** was in fact isolated as a 10:1 mixture with the isomeric triene **47**. It was shown that this triene mixture derives from a thermal equilibration, by means of a 1,7-sigmatropic hydrogen shift, of the initially formed product **46** under the reaction conditions. Separation of the minor product component **47** and subsequent thermal reequilibration increased the overall yield of the desired triene **46** to 76%. Removal of the two silyl protecting groups then completed the total synthesis of (+)-calcidiol (**48**).[61]



Scheme 10. A tandem intermolecular carbopalladation/intramolecular Heck cyclization approach to the synthesis of (+)-calcidiol (**48**) (Trost et al., 1992).[59]

The versatility of the Heck reaction is such that it is continually finding applications in novel carbon–carbon bond-forming processes, seemingly limited only by the ingenuity of the practitioner. As one recent example, we highlight the masterful synthesis of okaramine N (**55**, Scheme 11) by the Corey group.[62] In this instance, one of the key issues facing the researchers was the formation of the eight-membered medium ring, a motif often notoriously difficult to construct by traditional cyclization methods owing to a combination of enthalpic and entropic factors.[63,64] Nevertheless, the team surmised that it would, in fact, be possible to generate this ring system in a single step from an appropriately substituted acyclic precursor by employing palladium chemistry. Indeed, as shown in Scheme 11, it was found that treatment of indole **49** with $Pd(OAc)_2$ (100 mol%) in an AcOH/dioxane/H_2O solvent system under O_2 (1 atm) at ambient temperature led to the direct formation of pentacyclic compound **54** in reasonable yield (44%).

The visual relationship between the starting material **49** and the product **54** obscures the fact that the proposed mechanism of the reaction linking the two is, in reality, comprised of five distinct transformations, none of which is the apparent 8-*endo* mode of ring closure. Indeed, it may not be readily apparent how the reaction is initiated since, unlike all the other examples discussed so far, there is no carbon–halogen (or triflate) bond within the starting material **49** into which a Pd^0 species can insert. In fact, the first step in the mechanism proposed for this remarkable transformation is the selective and direct palladation of the unprotected indole unit, in the presence of the other *N*-prenylated indole motif, at C2 to generate indolyl–palladium(II) intermediate **50**.[65] Once formed, this palladated species can then undergo the expected 7-*exo*-trig 1,2-insertion to generate the next intermediate in the sequence, namely η^1-alkyl–palladium(II) species **51**. At this point the course of the reaction diverges from that which would, at first inspection, appear to be the most likely outcome. Despite the presence of no fewer than seven appropriately located hydrogen atoms, compound **51** does not undergo β-hydride elimination, but instead suffers a heterolytic fragmentation to generate tertiary carbocation **52**.

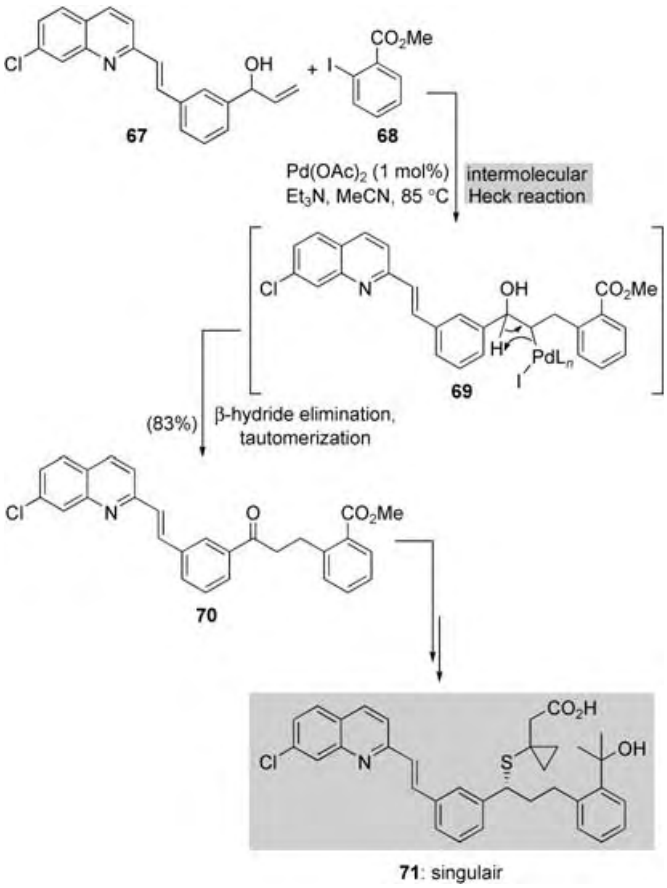
Scheme 11. Use of a novel Heck-type cascade cyclization to furnish an 8-membered ring in the synthesis of okaramine N (**55**) (Corey et al., 2003).[62]

Selective migration of the most-electron-rich group (i.e. the β-(2-indolyl) group) then results in ring expansion to furnish the eight-membered ring system **53**, rapidly followed by loss of a proton to yield the observed product **54**. The researchers' faith in the viability of this whole process was won by earlier model studies that demonstrated its aptitude for the formation of similar systems;[66] nonetheless, its application in the complex setting described here was certainly not without risk, a risk which ultimately paid off handsomely. Critical to the success of this venture was the employment of an $AcOH/H_2O$ solvent system; in the absence of acetic acid, no cyclization occurred, whilst omission of water resulted in the near exclusive formation of seven-membered-ring cyclization products. The direct, selective C–H bond functionalization of the indole nucleus represents a particularly exciting aspect of this methodology.[67] However, such procedures have generally required stoichiometric amounts of palladium(II) salts, which from a practical and economic standpoint, limits their use somewhat, particularly on a large scale. Recently though, the Stoltz group reported protocols for the aerobic oxidative annulation of indoles through C–H bond functionalization that are truly catalytic in palladium and which would thus appear to hold great potential for future development.[68]

The Tietze group recently reported a novel palladium-catalyzed domino reaction for the synthesis of the vitamin E family of tocopherols and tocotrienols (Scheme 12a). This process combines sequential intramolecular enantioselective oxypalladation and intermolecular Heck reactions to rapidly assemble the chiral chroman framework of these biologically and commercially important antioxidant molecules.[69] Treat-



Scheme 12. a) A palladium-catalyzed enantioselective domino reaction in the synthesis of α-tocopherol (**66**); b) regeneration of the catalytically active Pd^{II} species from a Pd^0 complex (Tietze et al., 2005).[69]

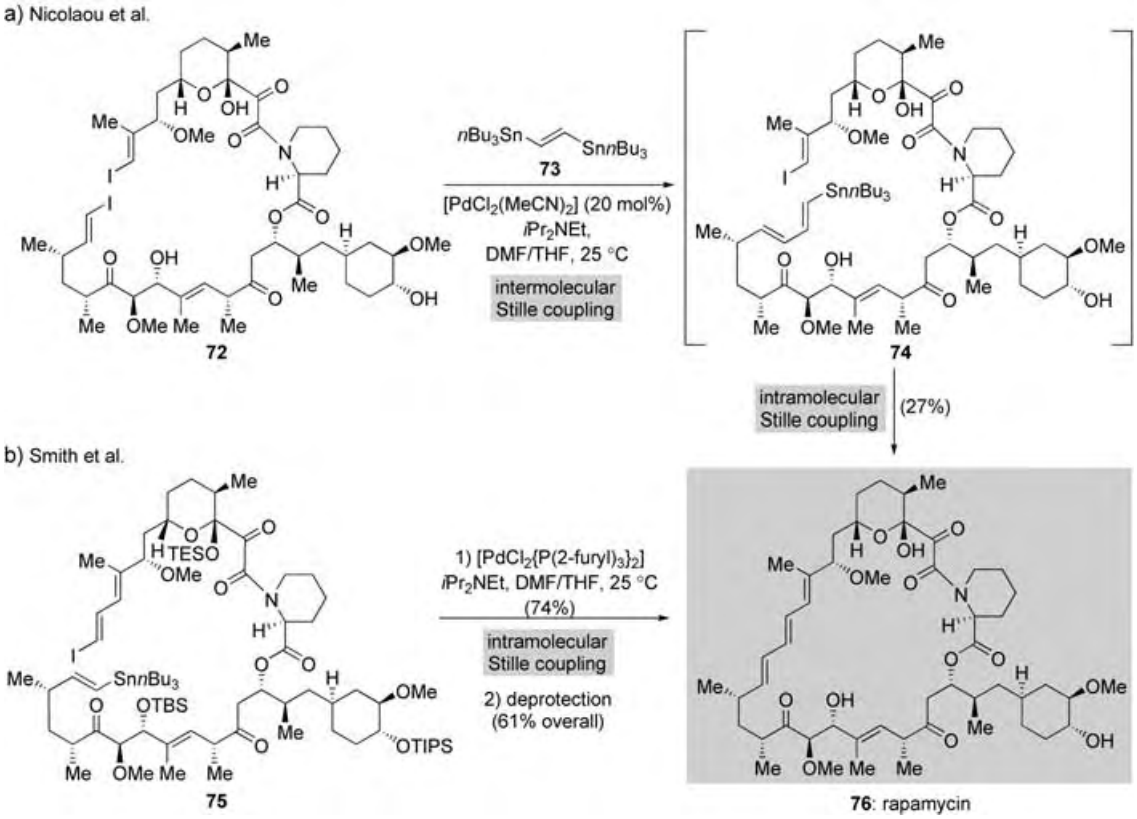
ment of readily available alkene **56** with $Pd(O_2CCF_3)_2$ (10 mol%), ligand **59** (40 mol%), *p*-benzoquinone (4.0 equiv), and either methyl vinyl ketone (**57**) or methyl acrylate (**58**), in CH_2Cl_2 at ambient temperature triggers a series of events that lead to the corresponding products **64** (R = Me) or **65** (R = OMe) in good to excellent yield and with excellent enantioselectivity. The sequence presumably begins with the enantiofacial coordination of the chiral ligated Pd^{II} complex, generated from $Pd(O_2CCF_3)_2$ and the enantiomerically pure ligand **59**, to the 1,1-disubstituted alkene, yielding intermediate **60**. This coordination of Pd^{II} to the π system renders the alkene moiety susceptible to nucleophilic attack, thus enabling the intramolecular cyclization of the free phenolic hydroxy group to generate σ-alkyl–palladium(II) species **61**. Unable to undergo the customary β-hydride elimination, intermediate **61** is sufficiently long-lived to be intercepted by either **57** or **58** in an intermolecular Heck reaction process to afford the observed products **64** or **65**, respectively. Notably, the final β-hydride elimination from intermediates **62** and **63** concomitantly generates a Pd^0 species, whereas it is a Pd^{II} complex that is required, in this case, to initiate the domino reaction. Thus, to avoid the use of stoichiometric amounts of $Pd(O_2CCF_3)_2$, a method needed to be found for the reoxidation of Pd^0 to Pd^{II} in situ, and indeed this was the role played by *p*-benzoquinone (Scheme 12b). The functionalized side chains introduced in the intermolecular Heck reaction provided a sufficient handle for the elaboration of either **64** or **65** into α-tocopherol (**66**), the member of the vitamin E family with the most pronounced biological activity.

The impact of palladium-catalyzed coupling reactions has been felt in a number of fields outside academic research laboratories, particularly in the pharmaceutical industry. Palladium-catalyzed carbon–carbon bond-forming reactions have provided chemists with new avenues for the design, synthesis, optimization, and manufacture of therapeutic agents, and, as such, have dramatically benefited humanity.[70,71] One such example is found in the synthesis of singulair (**71**, Scheme 13), a selective leukotriene receptor antagonist marketed by Merck for the prophylaxis and chronic treatment of asthma. An intermolecular Heck reaction was utilized to couple the two key fragments;[72] treatment of a mixture of allylic alcohol **67** and aromatic iodide **68** with triethylamine and a low catalyst loading (1 mol% of $Pd(OAc)_2$) in refluxing acetonitrile, notably in the absence of any additional ligands for palladium, led to the formation of ketone **70** in 83% yield.[72] Isolation of ketone **70** on a large scale by direct crystallization of the product from the reaction mixture proved to be remarkably facile. The selective formation of ketone **70** in this reaction is the result of β-hydride elimination from the initially formed alkyl–palladium(II) intermediate **69** occurring regioselectively towards the hydroxy substituent as shown, to give an enol species that subsequently tautomerizes to the observed ketone **70**. The formation of carbonyl compounds in such a manner is the usual fate of allylic alcohols when subjected to the Heck reaction[73] and, therefore, this process constitutes a useful alternative to the traditional 1,4-conjugate addition reactions for the construction of such systems.



Scheme 13. The use of an intermolecular Heck reaction in the commercial synthesis of Singulair (**71**) (Merck, 1993).[72]

3. The Stille Reaction

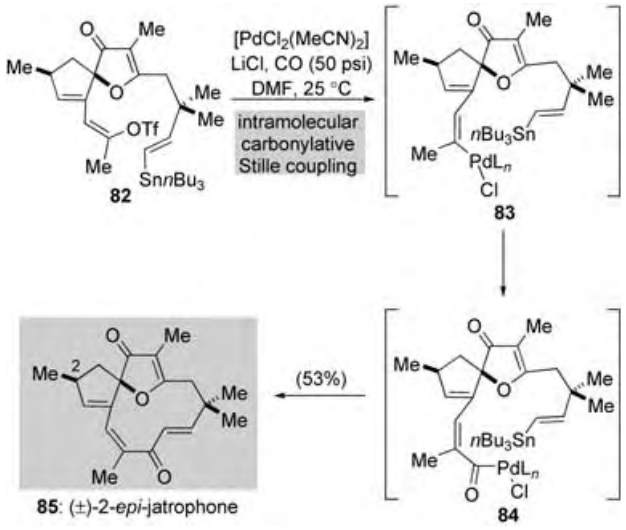
In addition to being a powerful intermolecular carbon–carbon bond-forming process, the Stille reaction has found widespread use in the generation of cyclic structures. The first examples of the intramolecular Stille reaction, reported by Piers and co-workers in 1985,[74] were concerned with the generation of five- and six-membered rings. However, it was not long before the utility of this process for the generation of a wider variety of ring sizes, macrocyclic systems in particular, was demonstrated.[75] Today, the Stille reaction constitutes a reliable and often-used method for the construction of carbocyclic and heterocyclic rings, be they common, medium or large.[76] A striking example of this type of reaction is the pioneering stitching-cyclization reaction applied by the Nicolaou group to construct rapamycin (**76**) from the bis(vinyl iodide) precursor **72** and *trans*-1,2-distannyl ethylene **73** (Scheme 14a).[77] The final step of the total synthesis of rapamycin involved a double Stille coupling process and proceeded from the naked (no protecting groups) precursor **72**, under the influence of $[PdCl_2(MeCN)_2]$ (20 mol%) and iPr_2NEt as a dilute solution in DMF/THF at ambient temperature, presumably through the intermediacy of iodostannane **74**. Thus, in one fell swoop, the 29-membered macrocyclic ring of rapamycin, with its *all-trans* triene system,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 14. Approaches to the total synthesis of rapamycin (**76**). a) A "stitching cyclization" to complete the total synthesis (Nicolaou and co-workers, 1993);[77] b) an intramolecular Stille macrocyclization approach (Smith et al., 1995).[78]

was installed from an acyclic precursor and without the need for any protection/deprotection operations. The success of this macrocyclization reaction undoubtedly relies, to no small measure, on the templating effect of the palladium center, which brings the two ends of the chain into the requisite close proximity for bond formation. A variation of this strategy was subsequently employed by Smith and co-workers in their elegant total synthesis of rapamycin,[78] in this case involving acyclic precursor **75** (Scheme 14b).[79,80]

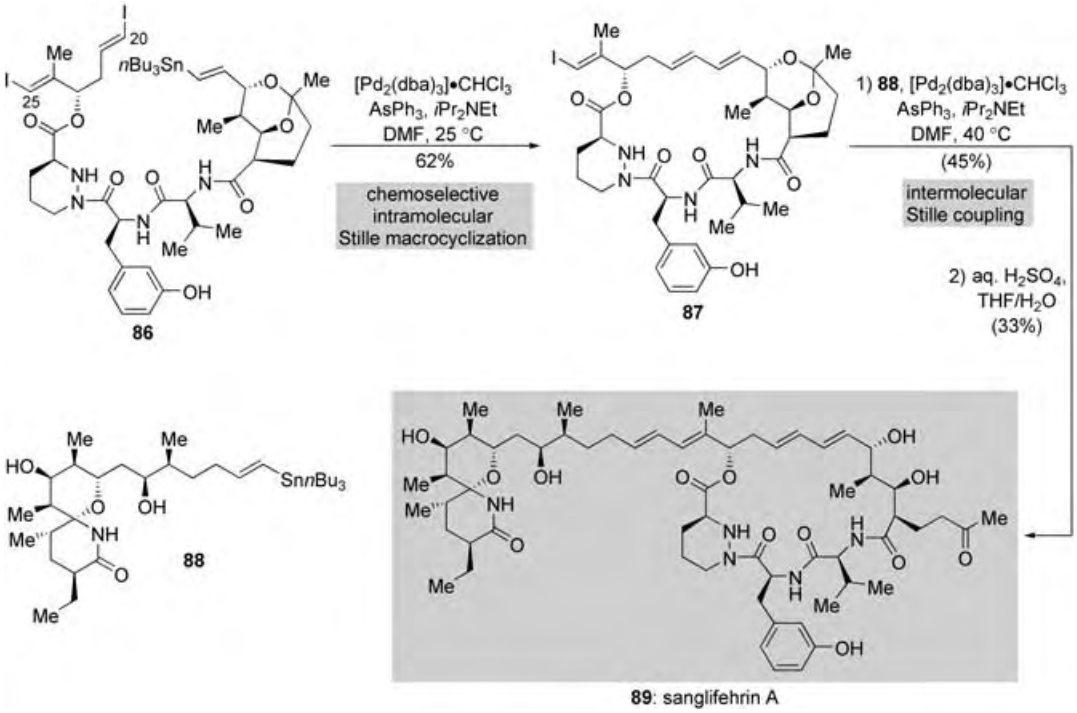
Another spectacular "stitching-cyclization" reaction involving a double Stille reaction was subsequently employed in the total synthesis of the enediyne anticancer antibiotic dynemicin (**81**) by Danishefsky and co-workers (Scheme 15).[81] The bis(iodoalkyne) substrate **77** reacted smoothly with *cis*-1,2-distannyl ethylene (**78**) in the presence of catalytic amounts of $[Pd(PPh_3)_4]$ in a dilute solution in DMF at 75 °C to afford the highly strained 10-membered-ring enediyne intermediate **79** in a remarkable 81% yield, with this pivotal intermediate thence being converted through a multistep sequence into the target molecule. Interestingly, when the structurally related olefin **80** (with a C3–C8 double bond instead of an epoxide moiety) was subjected to the same reaction conditions, none of the corresponding cyclized enediyne product was obtained. This observation highlights the importance of seemingly subtle conformational effects on the outcome of the process, with these factors often proving crucial to the success or failure of a given cross-coupling reaction.[82]



Scheme 15. A "stitching cyclization" route to the enediyne core in the total synthesis of dynemicin (**81**) (Danishefsky et al., 1996).[81]

In a beautiful example of the application of a carbonylative Stille coupling, the Stille–Hegedus group formed the 11-membered ring of 2-*epi*-jatrophone (**85**) by exposing vinyl triflate **82** to a catalytic amount of $[PdCl_2(MeCN)_2]$ and LiCl

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

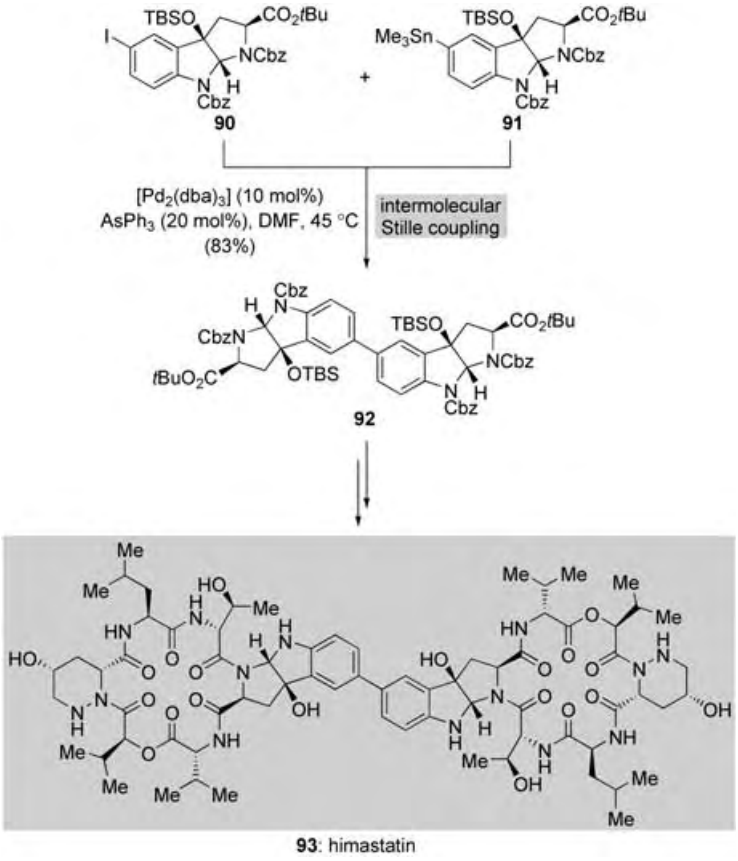


in DMF under a carbon monoxide atmosphere (50 psi) as shown in Scheme 16.[83,84] The mechanism of this impressive reaction, the final step in the total synthesis, presumably involves oxidative addition of a palladium(0) species into the

Scheme 16. The use of an intramolecular carbonylative Stille coupling to complete the synthesis of (±)-2-*epi*-jatrophone (**85**) (Stille et al., 1990).[83]

vinyl triflate C–O bond (**82**→**83**) followed by CO insertion to generate acylpalladium(II) intermediate **84**, and, finally, an intramolecular coupling to yield the observed product **85**. This transformation accomplishes the formation of two carbon–carbon bonds, the incorporation of the final carbon atom of the molecular framework, and the generation of the macrocyclic ring in a single operation—impressive indeed! It is worth recalling here that the carbonylative Stille coupling serves well as an alternative to Stille couplings of acid chlorides, especially when the latter intermediates are either not available or too labile to be used.

The remarkable level of control, in both a chemoselective and stereoselective sense, that is possible in executing Stille reactions is nicely illustrated by our total synthesis of the novel immunosuppressant agent sanglifehrin A (**89**, Scheme 17) by the Nicolaou group.[85] The cornerstone of the devised synthetic strategy was the proposed late-stage chemoselective Stille macrocyclization of bis(vinyl iodide) precursor **86** to generate the 22-membered ring intermediate **87** (Scheme 17), to which the complex spirolactam side chain would be appended through a second Stille coupling process. It was anticipated that participation of the less-hindered vinyl iodide group at C20 in the crucial macrocyclization reaction would be more favored over that involving the other vinyl iodide at C25, thus leading to the desired 22-membered ring, in preference to the alternative 21-membered macrocycle. In the event, this rather daring maneuver paid dividends, as it was found that treatment of a dilute solution of **86** in DMF with $[Pd_2(dba)_3]\cdot CHCl_3$ (15 mol%), $AsPh_3$ (60 mol%), and iPr_2NEt at ambient temperature led to the exclusive formation of the desired sanglifehrin cyclic intermediate **87** in 62% yield. A subsequent intermolecular Stille reaction between vinyl iodide **87** and alkenyl stannane **88** completed the carbon framework of the targeted natural product, which was finally unveiled by rupture of the acetal protecting group under aqueous acidic conditions. A second total synthesis of sanglifehrin A (**89**) was subsequently reported by the Paquette group, who also employed a Stille coupling reaction

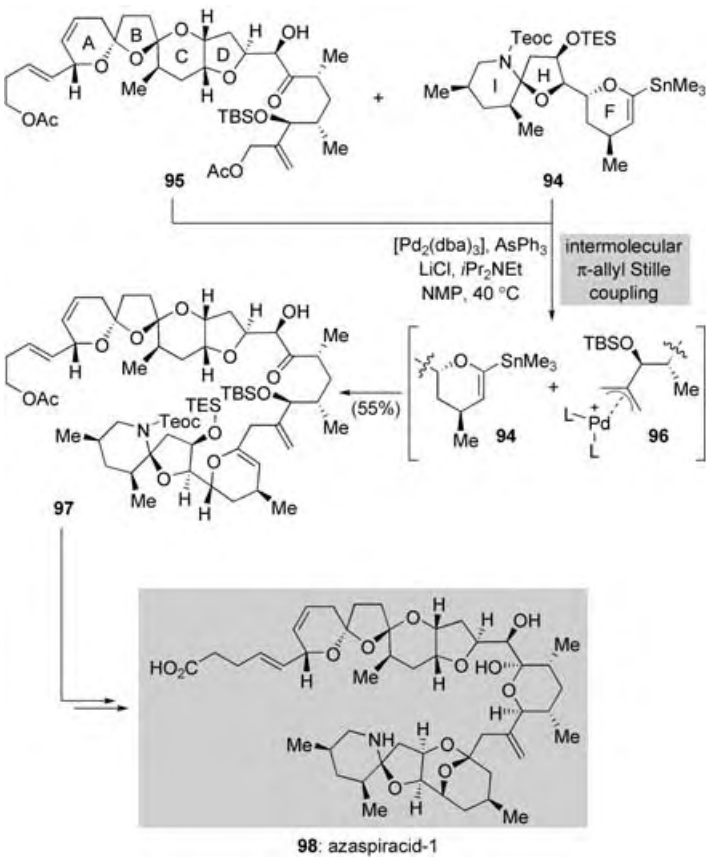


Scheme 17. Chemoselective intra- and intermolecular Stille couplings in the total synthesis of sanglifehrin A (**89**) (Nicolaou et al., 1999).[85]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

between the same two fully elaborated fragments **87** and **88** followed by cleavage of the acetal protecting group as the final synthetic steps.[86] In this case, however, the key macrocyclization step en route to vinyl iodide **87** involved the lactonization of an appropriately substituted seco-acid. Notably, once again the presence of unprotected functionalities such as amino, hydroxy, and secondary amide was tolerated under these palladium-catalyzed reaction conditions, thus underscoring the mildness of such protocols.

The use of transition metals in the formation of aryl–aryl bonds dates back to the beginning of the last century, with the discovery of the copper-promoted reductive coupling of aromatic halides (Ullmann reaction).[87] Whilst vast improvements in such copper-based protocols have been and continue to be made,[88] it was not until the advent of, at first, nickel-promoted and, subsequently, palladium-catalyzed carbon–carbon bond-formation methods that aryl–aryl coupling processes would assume the broad scope and generality that they enjoy today. The Stille reaction ranks among the most synthetically useful of the palladium-catalyzed processes for aryl–aryl bond formation, although arguably to a lesser extent than does the Suzuki reaction (see Section 4), and has found widespread use in this task.[89] An illustrative example of the utility of this transformation can be found in the total synthesis of himastatin (**93**, Scheme 18), a structurally intricate actinomycete metabolite with potent antibacterial and antitumor properties, by Danishefsky and Kamenecka.[90]



Scheme 18. Formation of an aryl-aryl linkage through a Stille coupling in the total synthesis of himastatin (**93**) (Danishefsky and Kamenecka, 1998).[90]

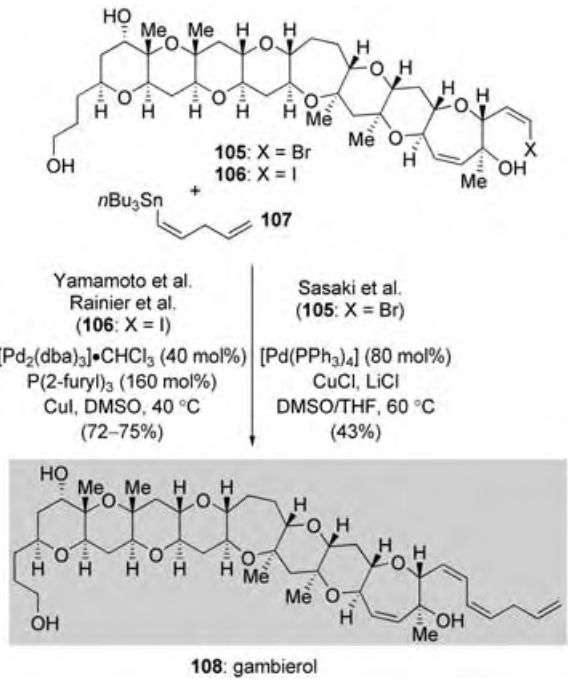
Smooth coupling between aryl iodide **90** and aryl stannane **91** was induced by treatment with catalytic amounts of $[Pd_2(dba)_3]$ (10 mol%) and $AsPh_3$ (20 mol%) in warm DMF to forge the key carbon–carbon bond between the two central indolyl moieties in an impressive 83% yield. Importantly, these reaction conditions were found to be compatible with the sensitive pyrroloindoline core present within both coupling partners **90** and **91**, which allowed the advancement of intermediate **92** through a number of steps to the targeted natural product. It is important to note that, although aryl iodides, bromides, and triflates are by far the most commonly used electrophilic coupling partners in this context with aryl stannanes, there have been extensive efforts at developing viable coupling conditions with the corresponding cheaper and often more readily available (but also far less reactive) aryl chlorides.[91,92]

The examples of Stille reactions discussed so far have focused on $C(sp^2)$–$C(sp^2)$ couplings, that is, between vinyl or aryl halides or triflates and vinyl or aryl organostannanes, which necessarily result in the formation of diene (or higher polyene) systems. However, the use of allylic halides allows formal $C(sp^2)$–$C(sp^3)$ couplings and broadens considerably both the scope of the Stille reaction and the structural diversity of the products that can be formed. This so-called π-allyl Stille coupling reaction provides a reliable and general method for the synthesis of "skipped" 1,4-diene systems. An important development in Stille reaction methodology was the discovery by the Stille–Hegedus group that the more readily available corresponding allylic acetates could be coaxed, under appropriate reaction conditions, into functioning as viable electrophiles for palladium-catalyzed coupling reactions with organostannanes.[93] An example of this type of reaction in the construction of complex natural products can be found in the recent total synthesis and structure elucidation of the marine toxin azaspiracid-1 by the Nicolaou group.[94] As shown in Scheme 19, addition of the vinyl stannane FHI-ring intermediate **94** to a mixture of the allylic acetate ABCD-ring intermediate **95**, LiCl, iPr_2NEt, and catalytic amounts of $[Pd_2(dba)_3]$ and $AsPh_3$ in NMP at 40 °C led to smooth coupling of the two fragments, presumably through the intermediacy of π-allyl–palladium complex **96**, to generate compound **97**. The latter advanced intermediate was elaborated into **98**, the spectroscopic data of which were shown to be identical to those of the natural product, thus solving the mystery and intrigue surrounding the structural identity of one of Nature's most remarkable natural products.

An intramolecular variant of the π-allyl Stille coupling was employed in the elegant total synthesis of the originally proposed structure of amphidinolide A by Pattenden and Lam (Scheme 20).[95,96] In this tour de force of Stille chemistry, an intermolecular coupling reaction between bis(stannane) **99** and vinyl iodide **100** was used to assemble the cyclization precursor **101**. Removal of the silyl protecting groups gave tetraol **102**, which was

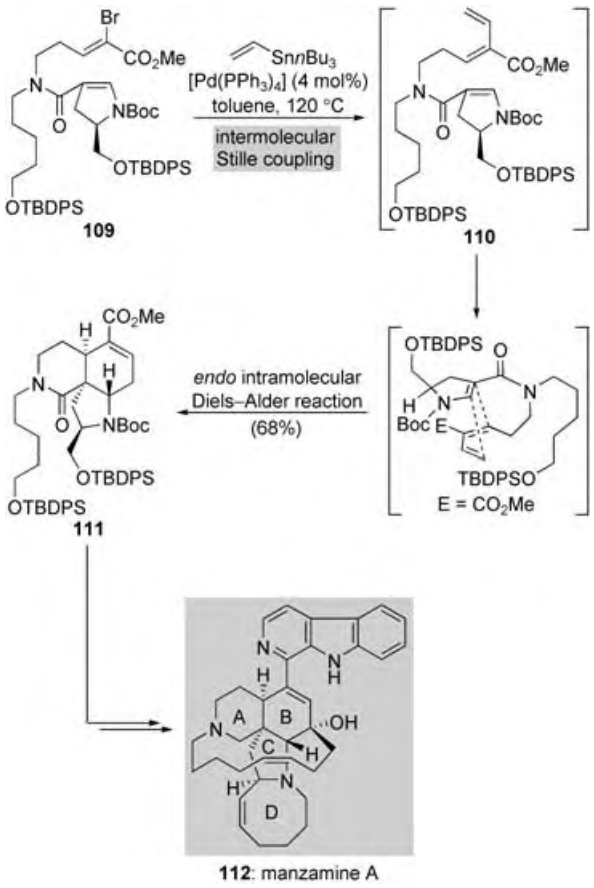
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 19. The use of a fragment-coupling π-allyl Stille coupling in the synthesis of azaspiracid-1 (**98**) (Nicolaou et al., 2004).[94]



treated with catalytic amounts of $[Pd_2(dba)_3]$ and $AsPh_3$ to effect the desired π-allyl–palladium-mediated macrocyclization. The selectivity of the initial coupling between **99** and **100** is particularly noteworthy in view of the number of products that could potentially be formed in this step. Thus, the exclusive formation of the single desired product **101** is the result of discrimination not only between the two stannane units in **99**, but also between the vinyl iodide and allylic acetate moieties embedded within the coupling partner **100**. Thus, remarkably, under the particular conditions employed, coupling is only observed between the less-hindered stannane group in **99** and the more-reactive vinyl iodide group in **100**. Much to the researchers' chagrin, however, the spectroscopic data of the final compound **103** did not match those of the natural product, thus suggesting that the proposed configuration at one or more stereogenic centers was incorrect. Two more years would elapse before the ambiguity surrounding the structure of amphidinolide A was finally resolved, through further chemical synthesis studies by the Trost group (see structure **104**, Scheme 20).[97,98]

In addition to intramolecular cyclization reactions and fragment-coupling processes, the Stille reaction is also a powerful method for effecting appendage attachments. The utility of this protocol is dramatically manifested in the total syntheses of gambierol (**108**, Scheme 21) by the Sasaki[99] and Yamamoto groups.[100] Both groups employed a Stille reaction in the final step of their respective syntheses to append the delicate triene-containing side chain onto a fully elaborated, protecting-group-free polycyclic ether precursor. The Sasaki group coupled stannane **107** with vinyl bromide **105**, while Yamamoto and co-workers utilized the corresponding vinyl iodide **106**. Although there were significant differences in the reaction conditions employed by the two groups, in both cases the presence of cocatalytic Cu^I salts was necessary to facilitate the transmetalation event and, hence, allow the reactions to proceed at acceptable rates. In both cases, the coupling product was formed with the expected retention of the geometry of the alkene, and the overall efficiency of these processes is quite remarkable, given both the steric encumbrance around the coupling site and the sheer size and complexity of the vinyl halides **105** and **106**. Interestingly, this appendage attachment was postponed by both teams until the last step out of necessity rather than choice. While similar couplings could be effected by both groups without undue difficulty at earlier stages in their syntheses (on compounds related to **105** or **106**, but in which the hydroxy functional groups were protected), the sensitivity of the resulting triene systems thwarted all attempts at the successful liberation of



Scheme 20. a) Sequential $C(sp^2)$–$C(sp^2)$ and $C(sp^2)$–$C(sp^3)$ Stille couplings in the synthesis of the structure originally proposed for amphidinolide A (**103**) (Pattenden and Lam, 2002);[95] b) revised structure of amphidinolide A (**104**) (Trost and Harrington, 2004).[97]

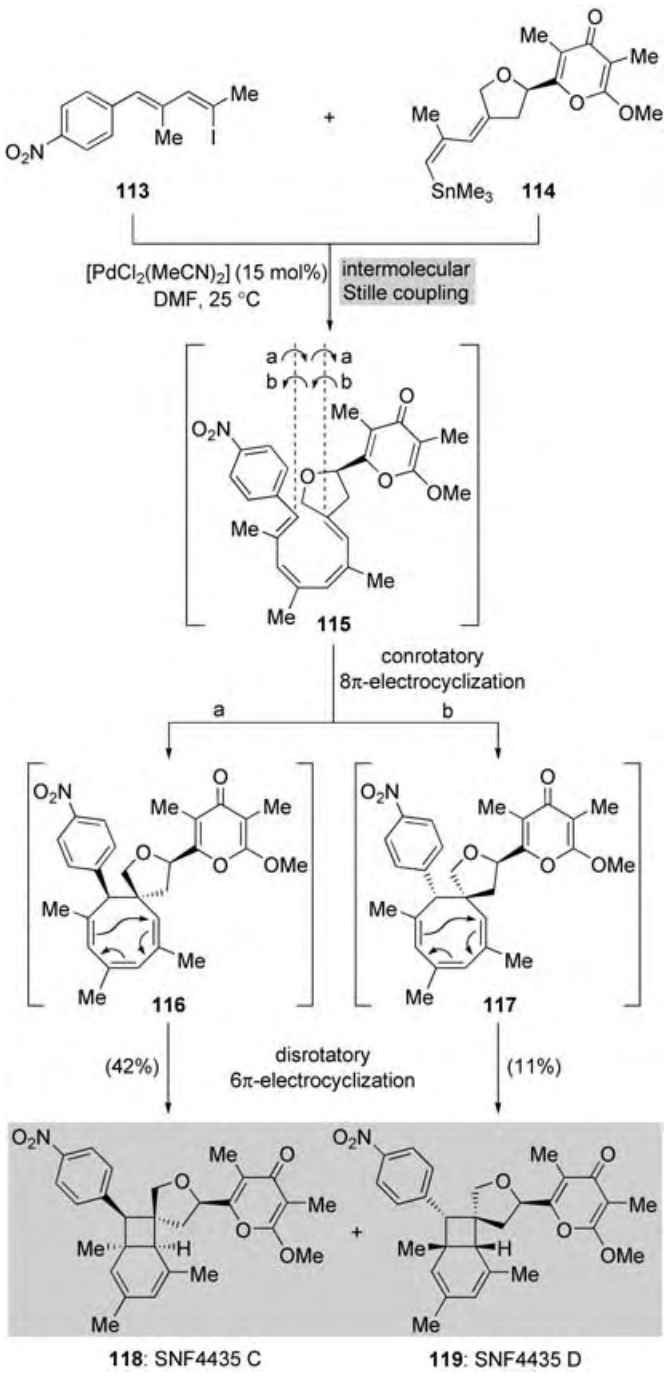
Scheme 21. Appendage of the triene-containing side chain to complete the total synthesis of gambierol (**108**) (Sasaki et al., 2002; Yamamoto and et al.; 2003, Rainier et al., 2004).[99–101]



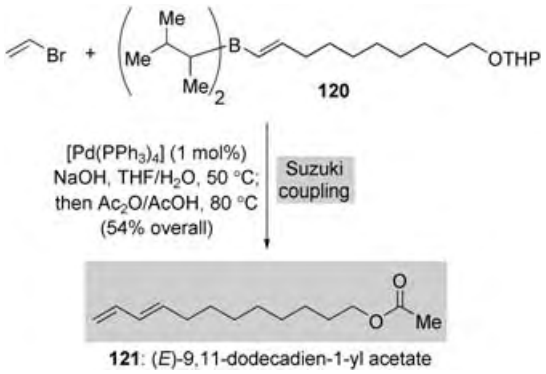
Scheme 22. A tandem intermolecular Stille coupling/intramolecular Diels–Alder approach to the tricyclic core structure of manzamine A (**112**) (Martin et al., 1999).[102]

the said functionality, which, incidentally, highlights once again the sometimes fickle nature of protecting groups in total synthesis. Most recently, Rainier and co-workers have also reported a novel total synthesis of gambierol (**108**).[101] These researchers made use of the conditions employed by the Yamamoto group to install the unsaturated side chain through a Stille reaction, a transformation that was again left until the very end of the synthetic sequence and which, in this case, proceeded in 75% yield.

An extremely useful application of the Stille reaction involves the generation of transient intermediates that can react further, typically in an intramolecular fashion, to produce often dramatic increases in structural complexity in a single operation. Owing to the usually mild conditions of the Stille reaction, intermediates that would otherwise be too fleeting or unstable to be isolated can be produced cleanly and rapidly for subsequent transformations, thus giving rise to powerful cascade sequences. An elegant example of this strategy can be found in the total synthesis of the marine-sponge-derived alkaloid manzamine A (**112**, Scheme 22), by Martin and co-workers, whereby a novel Stille coupling/intramolecular Diels–Alder cascade sequence was employed to furnish the tricyclic core structure of the target molecule.[102,103] Thus, as shown in Scheme 22, treatment of vinyl bromide **109** with vinyl(tri-*n*-butyltin) and a catalytic amount of $[Pd(PPh_3)_4]$ in refluxing toluene initially effected an intermolecular Stille reaction to afford diene **110**, which was suitably disposed to then undergo an *endo*-selective intramolecular Diels–Alder cycloaddition to afford tricyclic compound **111** in 68% yield as a single stereoisomer. In this remarkable transformation, the first notable example of the application of such a cascade process in total synthesis,[104] three new carbon–carbon bonds and three new stereocenters are formed in a single operation, with the relative and absolute stereochemistry of the product **111** being defined by the lone stereocenter in the vinyl bromide starting material **109**.

A number of alternative reaction pathways, besides [4+2] cycloadditions, can be envisaged for the polyene systems generated through Stille fragment-coupling reactions. One such approach that has received considerable attention recently is the development of Stille coupling/electrocyclization cascade processes that provide a rapid entry into polycyclic compounds with high stereospecificity from simple precursor coupling partners. As an astounding example of this principle, we highlight here the recent total syntheses by Parker and Lim[105] of SNF4435 C (**118**) and SNF4435 D (**119**, Scheme 23), two immunosuppressant agents isolated from a culture broth of *Streptomyces spectabilis*.[106] The bicyclo[4.2.0]octadiene core structure of these intriguing natural products bears a striking resemblance to that of the endiandric acids,[107] for which a biosynthetic pathway involving an electrocyclization reaction cascade had been proposed by Black and co-workers[108] and subsequently demonstrated experimentally by the Nicolaou group more than 20 years ago.[109] Therefore, by analogy, it was postulated that the SNF compounds arise through sequential conrotatory

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



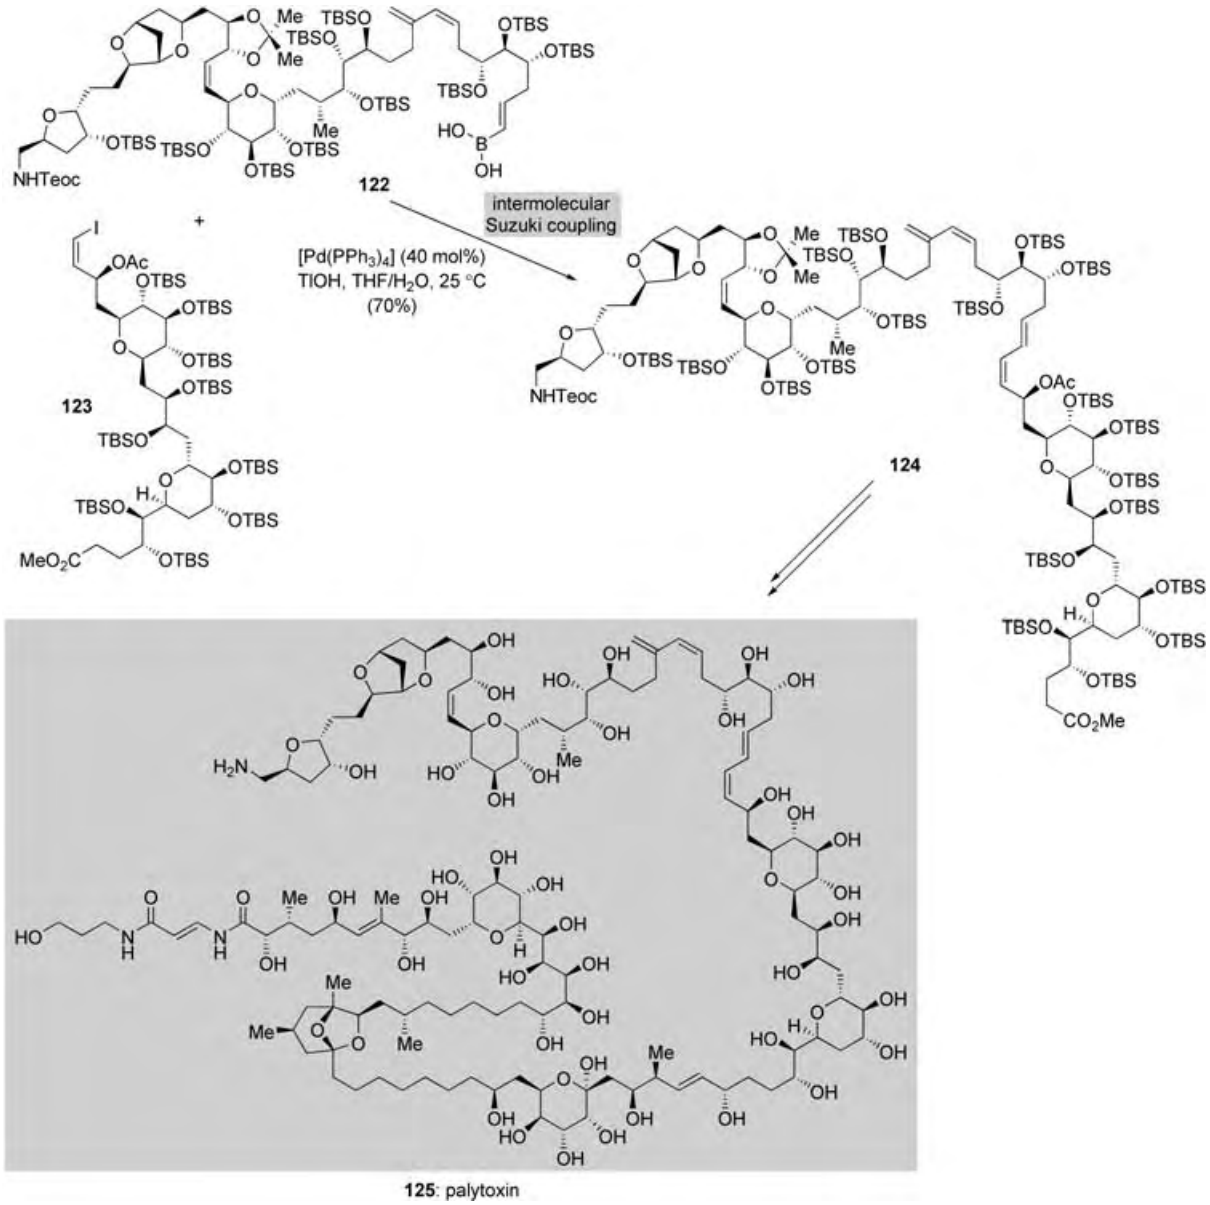
Scheme 23. A tandem Stille fragment coupling/electrocyclization cascade sequence in the total synthesis of SNF4435 C (**118**) and SNF4435 D (**119**) (Parker and Lim, 2004).[105]

8π- and disrotatory 6π-electrocyclizations of the fully elaborated *Z*,*Z*,*Z*,*E*-tetraene **115**, as shown in Scheme 23.[110] The total synthesis of the natural products by Parker and Lim, following this biomimetic strategy, involved as the pivotal step the union of vinyl iodide **113** and vinyl stannane **114** in DMF at room temperature, under the influence of catalytic amounts of $[PdCl_2(MeCN)_2]$, to generate stereoselectively the putative tetraene intermediate **115**. The latter intermediate spontaneously underwent the desired electrocyclization cascade to afford directly a mixture of the target molecules SNF4435 C (**118**) and SNF4435 D (**119**) in 42 and 11 % yields, respectively.[111,112] Interestingly, the ratio of synthetic **118**/**119** produced in this manner (4:1) is not too different from that of the natural products found in Nature (2.3:1). Coupled with the observation that the electrocyclization cascade occurs under ambient laboratory conditions, this result lends credence to the suggestion that this step in the biosynthesis of these compounds is not enzyme-catalyzed.

As we conclude this discussion of the Stille reaction in total synthesis, it is worth mentioning an interesting development in the evolution of metal-mediated cross-coupling reactions of organostannanes with organic electrophiles. Many researchers have reaped the rewards from the beneficial effect of cocatalytic Cu^I salts in accelerating the rate of stubborn Stille coupling reactions, a phenomenon first reported in 1990.[36b] More recently, however, the Liebeskind group pioneered a "palladium-free" Stille reaction protocol in which the coupling of the organostannane and organohalide components is mediated by stoichiometric amounts of Cu^I thiophene carboxylate (CuTC) and proceeds rapidly at or below room temperature.[113] This methodology offers the synthetic chemist a complementary and useful alternative to the traditional palladium-catalyzed Stille coupling processes.[114,115]

4. The Suzuki Reaction

The first application of this cross-coupling reaction in natural products synthesis was reported by Rossi and coworkers in 1981, less than two years after the seminal publications by the Suzuki group,[12] detailing an expedient synthesis of (*E*)-9,11-dodecadien-1-yl acetate (**121**), an insect sex pheromone isolated from *Diparopsis castanea*.[116] Thus, as illustrated in Scheme 24, the targeted compound was prepared by means of the palladium-catalyzed coupling reaction between vinyl borane (*E*)-**120** and vinyl bromide, followed by treatment of the resulting crude product mixture with acetic anhydride in acetic acid to effect the direct conversion of the tetrahydropyranyl protecting group into the corresponding acetate. Although certainly modest by today's standards, this, and other similar early applications demonstrated, for the first

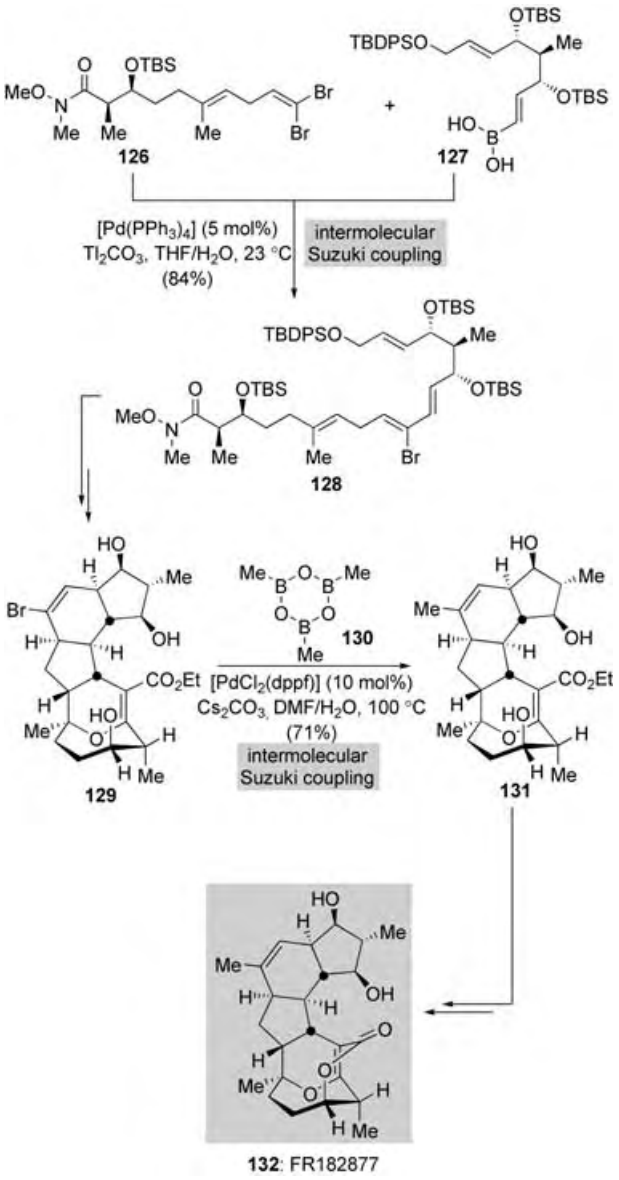


Scheme 24. The first application of a Suzuki reaction in a total synthesis, that of the insect pheromone **121** (Rossi et al., 1981).[116]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

time, the potential of such palladium-catalyzed cross-coupling reactions for the synthesis of diene systems under mild conditions, in good yield, and with a high stereospecificity—often lacking in the traditional olefination methods available at the time. Indeed, it was ground-breaking work such as this that paved the way for the remarkable developments in the field that would be forthcoming over the next quarter of a century. It is certainly instructive to compare this early example with the more-recent applications of the Suzuki reaction highlighted in order to more fully appreciate the degree to which the field has flourished in the intervening years.

One of the most remarkable applications of the Suzuki reaction in natural products synthesis is found in the synthesis of palytoxin (**125**, Scheme 25) by Kishi and co-workers.[117] This Herculean feat holds a special place in the history of total synthesis in that palytoxin is the largest secondary metabolite synthesized to date, in terms of both molecular weight and number of stereocenters.[118] Of no less significance is the fact that, as is often the case with total synthesis, this mammoth endeavor led to the discovery and development of a number of synthetically useful reactions and protocols, among which was a refinement of the conditions of the Suzuki coupling. The researchers' initial efforts at effecting the union of advanced intermediates **122** and **123** (Scheme 25) under conventional Suzuki coupling conditions were met with frustrating failure; thus, forced by necessity, the team proceeded to investigate methods for increasing the rate of the reaction. Eventually, a synthetic roadblock was turned into an avenue of discovery, as it was found that the use of TlOH as the base had a pronounced effect,[119] to the extent that the desired coupling between **122** and **123** occurred rapidly at ambient temperature upon treatment with a substoichiometric amount of $[Pd(PPh_3)_4]$ (40 mol%) in



Scheme 25. Use of a thallium base in a fragment-coupling Suzuki reaction towards the total synthesis of palytoxin (**125**) (Kishi et al., 1994).[117]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

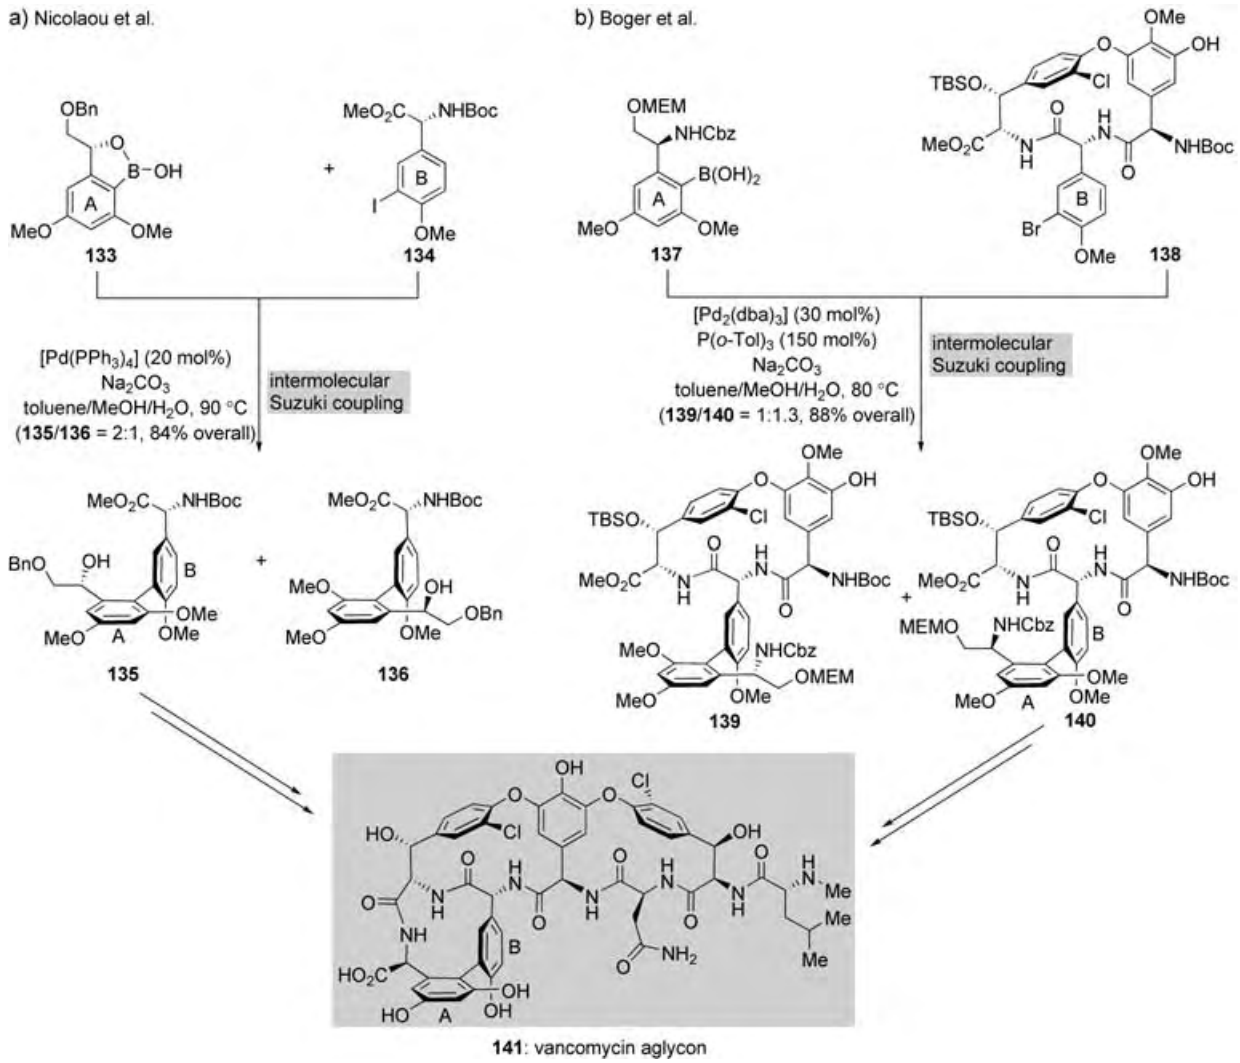
aqueous THF. The product **124** was then elaborated in a series of operations to complete the total synthesis of palytoxin.

The use of thallium bases in Suzuki coupling reactions has since often proved to be superior to many other procedures, particularly with sensitive substrates that would otherwise be labile under prolonged exposure to basic conditions.[120] Evans and Starr made use of this protocol in their recent total synthesis of (−)-FR182877 (**132**, Scheme 26),[121] a structurally and biologically remarkable hexacyclic natural product isolated from a *Streptomyces* species.[122] It was anticipated that the advanced acyclic intermediate **128** could be assembled through the selective Suzuki coupling of boronic acid **127** with the *E* vinyl bromide moiety in 1,1-dibromoolefin **126**. In practice, this coupling was first attempted by following a TlOEt-mediated procedure described by Roush and co-workers.[120] Although the desired product **128** was indeed obtained in 40% yield under these conditions, the reaction

Scheme 26. Suzuki reactions in the total synthesis of FR182877 (**132**) (Evans and Starr, 2002).[121]

was complicated by the unexpected formation of significant amounts (≈20%) of a by-product arising from the reaction of boronic acid **127** with both bromine moieties in dibromide **126**. A number of other bases were then screened, but these reactions were plagued by the formation of a myriad of by-products from competitive decomposition of the starting materials **126** and **127**. To the researchers' delight, however, they ultimately found that the use of Tl_2CO_3 translated to an improved selectivity for the desired coupling product **128** whilst maintaining a reasonable rate of reaction at room temperature and under the optimum coupling conditions ($[Pd(PPh_3)_4]$ (5 mol%), Tl_2CO_3, THF/H_2O 3:1, 23 °C). Compound **128** could be reliably produced in an excellent yield of 84%.

These tribulations serve as an important caveat not only for the Suzuki reaction but, indeed, for most transition-metal-catalyzed carbon–carbon bond-forming processes: a great deal of skill and persistence is often required to unearth the best experimental conditions for a given reaction and these conditions are often very substrate-dependent. Procedures for all types of bond-forming processes that are equally applicable and effective to all substrate types remain an elusive "Holy Grail" in transition-metal-based organic synthesis research. Notably, the selectivity of the formation of compound **128** in this case is due to the faster rate of oxidative addition of the *E* vinyl bromide moiety within the 1,1-dibromoolefin **126** to the Pd^0 species than that of the more sterically hindered *Z* vinyl bromide unit; this general phenomenon which has been employed extensively in natural product synthesis since the pioneering studies of Roush and Riva.[123] Having subsequently converted intermediate **128** into pentacyclic compound **129** through a beautifully orchestrated cascade sequence of transannular Diels–Alder reactions,[124,125] as first suggested by the insightful biosynthetic proposal of Sorensen and co-workers,[126] Evans and Starr were then faced with the task of replacing the remaining bromine atom in intermediate **129** with a methyl group. Again, it proved to be the Suzuki reaction that rose to the challenge. Thus, inspired by the earlier work of Gray and co-workers,[127] the required transformation was effected by treatment of bromide **129** with trimethylboroxine **130**, [$PdCl_2$-(dppf)] (10 mol%), and Cs_2CO_3 in aqueous DMF at 100 °C, yielding compound **131** in 71% yield. Crucially, not only was the presence of the vinylogous ester and the three unprotected hydroxy groups tolerated in this step, but also the delicate and highly strained "anti-Bredt" bridgehead olefin[128] emerged unscathed from the coupling reaction, underlining again the mildness of these protocols.



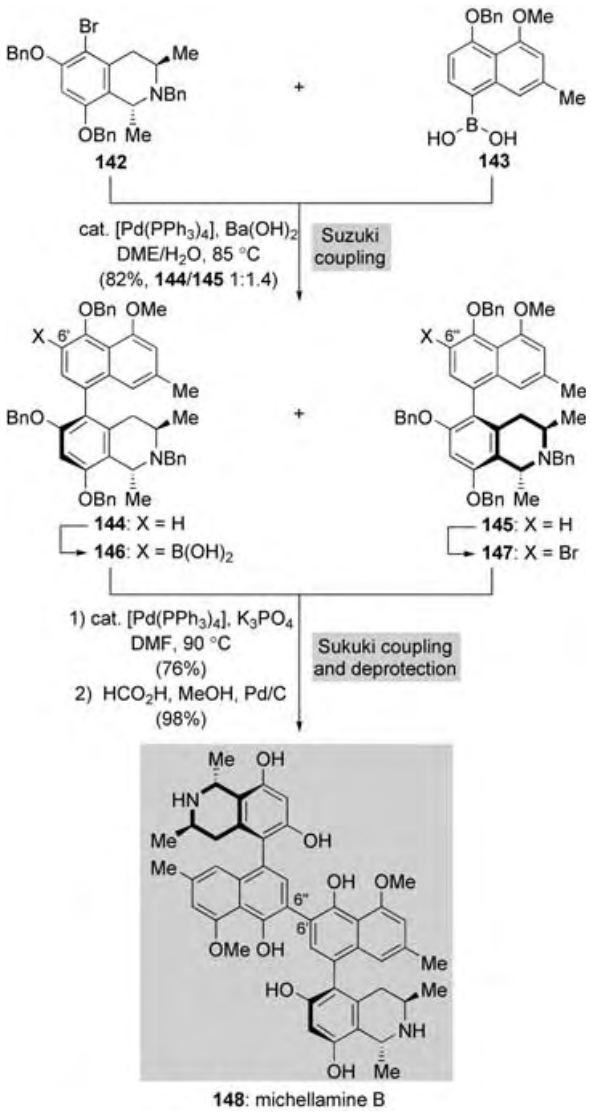
As touched upon in the previous section, the Suzuki reaction represents one of the, if not the most, widely used methods for aryl–aryl bond formation in modern organic synthesis. Given the ubiquitous occurrence of biaryl systems in a host of scientifically and economically important fields, from natural products to ligands for asymmetric catalysis, pharmaceutical compounds, and nanomaterials, extensive research efforts have recently been expended to develop further the utility and efficiency of the Suzuki reaction within this context. For the purposes of this Review, it is instructive to divide, somewhat arbitrarily, Suzuki aryl–aryl couplings

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

into two categories: 1) those resulting in biphenyl-type systems, including binaphthyls, and 2) those leading to heteroatom-containing biaryls. Below we highlight selected examples of both categories in total synthesis.

Our first examples of the former category are found in the approaches to the total synthesis of the vancomycin aglycon (**141**, Scheme 27) described first by the Nicolaou group,[129] and subsequently by Boger and his group.[130] The carbon–carbon bond linking the aryl rings A and B would appear to be a prime candidate for formation through Suzuki coupling, and indeed this was the method adopted by both groups.[131] However, an additional degree of complexity which needed to be taken into consideration in planning such a procedure arises from the atropisomerism of the AB ring-coupled product which is enforced by the restricted rotation around the biaryl axis.[132] For instance, the protocol adopted by the Nicolaou group, involving the coupling of boronic acid **133** with iodide **134**, could potentially produce either or both atropisomeric products **135** and **136** (Scheme 27a), and it is not easy to gauge through cursory inspection which of the two compounds would predominate in such a reaction. As events transpired, under the optimum coupling conditions (Na_2CO_3 and $[Pd(PPh_3)_4]$ (20 mol%) in toluene/MeOH/H_2O (20:2:1) at 90 °C) the two stereoisomers **135** and **136** were formed in a 2:1 ratio and in 84% total yield. Gratifyingly, the major reaction product **135** was shown to have the configuration corresponding to that in the target aglycon and, following chromatographic separation from the undesired minor isomer **136**, was subsequently elaborated to complete the total synthesis.

In the strategy adopted by the Boger team, a Suzuki coupling between an A-ring boronic acid unit and a B-ring aromatic halide was also used to forge the crucial biaryl linkage; however, their approach differed conceptually in two respects from that employed by the Nicolaou group. First, a more elaborate B-ring halide **138** (Scheme 27b) was utilized in which the CD-ring bisaryl ether containing macrocycle was already incorporated. Second, it was anticipated that although the inherent axial stereoselectivity of the Suzuki coupling would not initially be controllable, a subsequent thermal equilibration of the atropisomeric products would, perhaps, yield the desired atropisomer preferentially. Indeed, the

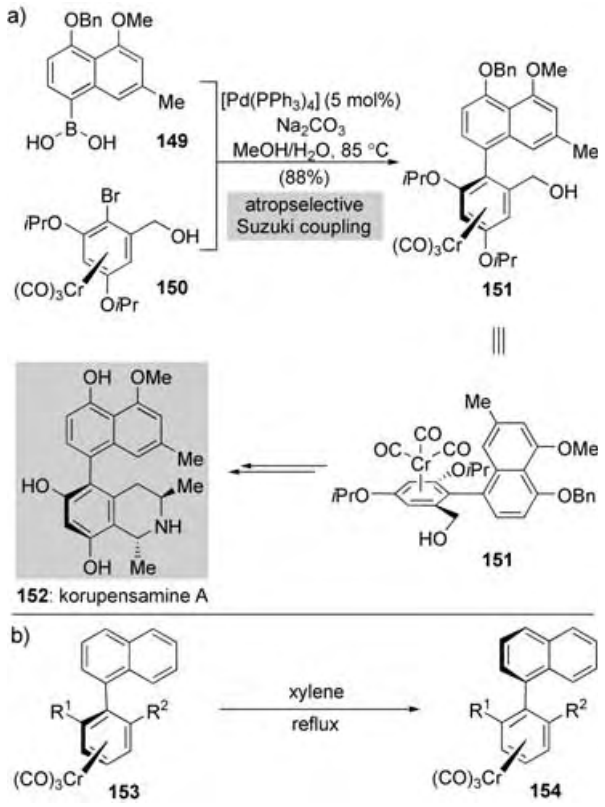


Scheme 27. Atropselective approaches to the AB-ring biaryl domain of vancomycin aglycon (**141**). a) Nicolaou et al. 1998;[129] b) Boger et al., 1999.[130]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coupling of boronic acid **137** with bromide **138** yielded a nearly stereorandom mixture of the desired product **140** and the unwanted atropisomer **139** (**139**/**140** ≈ 1:1.3), although the overall yield for the process was again excellent (88%). Given the steric congestion and electron-rich nature of the coupling partners **137** and **138**, the overall efficiency of this Suzuki reaction is all the more remarkable. Key to its success was the use of the catalyst system derived from $[Pd_2(dba)_3]$ (30 mol%) and P(*o*-tolyl)$_3$ (150 mol%). At elevated reaction temperatures P(*o*-tolyl)$_3$ has often been found to be a superior ligand to the more traditional PPh_3 in such couplings. This is true particularly with organic electrophiles that prove recalcitrant towards oxidative addition to Pd^0, since the more bulky phosphine minimizes undesired quaternization of the phosphorus atom by the halide and also results in the formation of the more thermally stable 14-electron [Pd{P(*o*-tolyl)$_3$}$_2$] complexes.[133] After separation of the two products, it was found that the undesired component **139** could be thermally equilibrated upon heating to 120°C in chlorobenzene to provide a mixture of the two atropisomers that was now significantly enriched in the desired stereoisomer **140** (**139**/**140** ≈ 1:3). In this way, the axial selectivity of the Suzuki coupling could be controlled indirectly, with the majority of the material being channeled down the desired pathway. Note that the preexisting C-O-D bisaryl stereogenic axis was not affected by the conditions employed for the thermal equilibration of the AB-ring system in compound **139** owing to the significantly higher activation energy barrier to isomerization of the former unit (30.4 versus 25.1 kcal mol^{-1}).

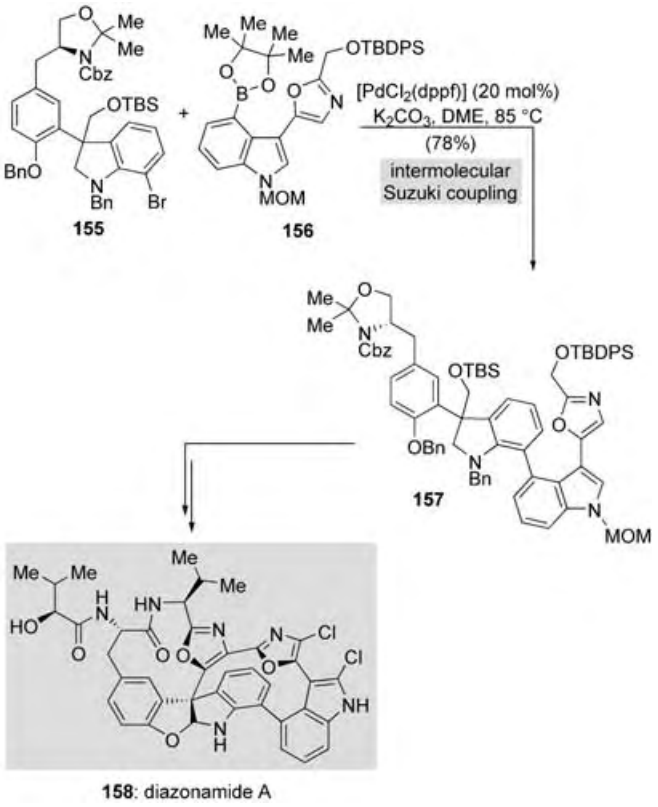
As another example of the use of the Suzuki coupling to fashion atropisomeric systems, we consider the total synthesis of michellamine B (**148**, Scheme 28), a representative member of a class of homo- and heterodimeric alkaloid natural products that exhibit potent anti-HIV activity,[134] by Dawson and co-workers.[135] The coupling of enantiomerically pure bromotetrahydroisoquinoline **142** with naphthyl boronic acid **143** under the influence of $Ba(OH)_2$ and a catalytic amount of $[Pd(PPh_3)_4]$ in aqueous DME at 85°C yielded a nearly equimolar mixture of the two atropisomeric products **144** and **145** in a combined yield of 82%. The team's choice of the Suzuki reaction to effect this coupling was influenced to no small degree by the previously reported model studies of Hoye and Chen, who had demonstrated the clear superiority of this process over both the Stille reaction and the palladium-catalyzed cross-coupling of zinc derivatives for the union of similarly hindered and electron-rich aryl derivatives.[136] Although this step lacked atropselectivity, the researchers were able to turn this to their advantage on the basis of the configuration of the two coupling products **144** and **145** which corresponds exactly to that found in the "bottom" and "top" halves, respectively, of the targeted natural product. Thus, if a method could be found for joining intermediates **144** and **145** through their respective C6′ and C6″ positions (michellamine B numbering), an expeditious and stereospecific route to the complete michellamine B framework could be at hand. To the researchers' delight, compounds **144** and **145** could indeed be regioselectively converted into the corresponding boronic acid and bromo derivatives **146** and **147**, respectively, and another Suzuki coupling was then employed to effect their



Scheme 28. Sequential Suzuki aryl-aryl couplings in the total synthesis of michellamine B (**148**) (Dawson et al., 1996).[135]

union. Removal of all eight benzyl protecting groups from the coupling product through standard procedures then yielded the targeted compound **148**.[137] The coupling of **146** and **147** was initially attempted under the conditions employed earlier in the synthesis, giving the product in 61% yield. However, it was subsequently discovered that the yield for this second merger could be increased to 76% under non-aqueous conditions (cat. $[Pd(PPh_3)_4]$, K_3PO_4, DMF, 90°C), which is somewhat surprising given not only the generally recognized tolerance of water, but also its often beneficial effect in the Suzuki reaction. Note that atropisomerism about the newly formed C6′–C6″ bond is not observed, as rotation about this bond is evidently not sufficiently hindered by the steric environment.

An interesting approach to this issue of atropisomerism in biaryl synthesis, championed in particular by the Uemura group, involves the use of planar chiral tricarbonyl-(arene)chromium complexes[138] in palladium-catalyzed cross-coupling reactions.[139] An illustrative example of this



strategy is found in the synthesis of the alkaloid korupensamine A (**152**, Scheme 29),[140] a molecule that can be formally considered as the monomeric unit of the michellamine alkaloids alluded to above. Thus, as shown in Scheme 29a, the Suzuki coupling of naphthyl boronic acid **149** with enantiopure tricarbonylchromium-complexed aryl bromide **150** led to the smooth formation of biaryl system **151** in 88% yield and as a single stereoisomer. The sense of stereochemical induction in the formation of the atropisomeric biaryl axis in the product **151** is dictated by the preexisting chirality inherent in the starting tricarbonylchromium complex **150**, with the product shown in Scheme 29a having the same configuration as that found in korupensamine A (**152**). This result had, in fact, been anticipated by the research team on the basis of previous studies on similarly highly stereoselective cross-couplings, although the sense of stereochemical induction was found to be remarkably dependent on the nature of the *ortho*-substituent(s) on the tricarbonyl(arene)chromium complex.[141] Intermediate **151** was then elaborated to give the target molecule **152** in a series of steps that maintained the stereochemical integrity of the biaryl axis. Intriguingly, the coupling reaction (**149** + **150** → **151**) yields the less thermodynamically stable isomeric product, in which the axial configuration is such that the naphthyl ring is oriented in the same direction (*syn*) as the tricarbonylchromium unit, and hence suffers from severe steric interactions (as in **151**). To rationalize this counter-

Scheme 29. Atropselective Suzuki coupling of a planar chiral tricarbonyl(arene)chromium complex in the enantioselective synthesis of korupensamine A (**152**) (Uemura et al., 2000).[140]

intuitive phenomenon, it was proposed that isomer **151** represents the kinetic reaction product, which is not subsequently equilibrated to the thermodynamic isomer under the reaction conditions. It was also shown that a number of such kinetic coupling products could indeed be subsequently isomerized to generate the thermodynamically more stable *anti* atropisomers (i.e. **153** → **154**, Scheme 29b), thus enabling the selective formation of either biaryl atropisomer from a single chiral chromium complex. While these results are indeed impressive, the utility of this methodology is mitigated somewhat by the fact that the synthesis of the enantiopure (or enantioenriched) chiral chromium complexes is often far from trivial. Indeed, for all the enabling power of transition-metal-catalyzed reactions discussed herein, synthetic chemists are still singularly lacking truly general methods for the selective synthesis of biaryl atropisomers.

Nevertheless, despite these current limitations, the Suzuki reaction remains an extraordinarily effective and powerful method for aryl–aryl bond formation, particularly with sensitive, densely functionalized substrates and for the construction of sterically congested systems. A case in point is the second-generation synthesis of the revised structure[142] of diazonamide A, reported by the Nicolaou group in 2003.[143] As shown in Scheme 30, indoline bromide **155** and indole boronate ester **156** were successfully merged by employing a catalytic amount (20 mol%) of [$PdCl_2$(dppf)] in the presence of K_2CO_3 in anhydrous degassed DME at 85 °C. The advanced intermediate **157** contains all but one of the aromatic systems destined to be incorporated in the final target structure **158**,

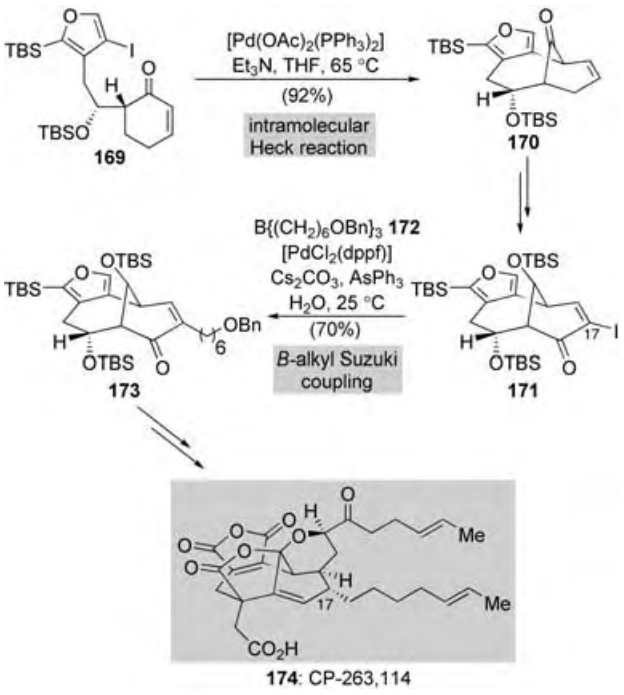
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thus illustrating both the degree of synthetic convergence (and hence efficiency) and the rapid increase in molecular complexity that are possible through the application of the Suzuki reaction and related processes.[144,145]

Palladium-catalyzed reactions have also revolutionized the synthesis of heteroatom-containing biaryl systems, with the Suzuki reaction being at the forefront of this new technology.[146] Over the last 25 years there has been a fundamental shift away from the generation of such motifs through iterative (and often cumbersome) heterocyclic ring syntheses by classical cyclization and dehydration reactions, towards the direct palladium-catalyzed union of preformed, and often fully functionalized, heterocycles.[147] As an illustrative example, such coupling reactions were used not once, but twice in the recent elegant synthesis of dragmacidin F (**168**, Scheme 31) by the Stoltz group.[148] In an exquisitely marshaled sequence of Suzuki coupling events, pyrazine derivative **160** was first coupled with indolyl boronic acid **159** to afford dibromide **161**, which was subsequently coupled with the advanced pyrrole boronate ester fragment **166** to complete a rapid synthesis of the core heptacyclic framework of the targeted natural product. The selectivity of these transformations is outstanding, with the required indolyl bromide unit surviving both transformations intact. This selectivity is the combined result of 1) the faster rate of oxidative addition of pyrazine carbon–halogen bonds to Pd^0 species than that of the corresponding benzenoid carbon–halogen bonds, and 2) the greater susceptibility of carbon–iodine bonds over the corresponding carbon–bromine bonds to oxidative addition. An important finding on the part of the researchers was that precise control of the temperature at which these couplings were conducted was essential to maintain the desired selectivity. Interestingly, the reason for the adoption of this Suzuki coupling strategy was that the team had been thwarted in their earlier attempts to generate similar polycyclic structures through the construction of the central pyrazine ring by classic cyclocondensation chemistry of advanced intermediates, owing to the recalcitrance of the reacting partners to undergo the required cyclization processes.[149] Palladium-mediated chemistry was also instrumental in permitting the synthesis of the pyrrole coupling partner **166**, in which a key carbon–carbon bond-forming step was the oxidative Heck cyclization of monosubstituted pyrrole precursor **162** to produce the congested pyrrole-fused bicyclic structure **165** in good yield and as a single regio- and stereoisomer. Although this transformation, of which we saw a related example in the synthesis of okaramine N (**55**; see Section 2, Scheme 11) described earlier, could not be made catalytic in palladium, it is nevertheless particularly remarkable in that it effects the C–H functionalization of the deactivated C3 position of the acyl pyrrole unit. Furthermore, this direct cyclization of compound **162** (R = H) was found to be superior in terms of both regioselectivity and overall yield to the intramolecular Heck reaction of the corresponding bromide **163** (R = Br).

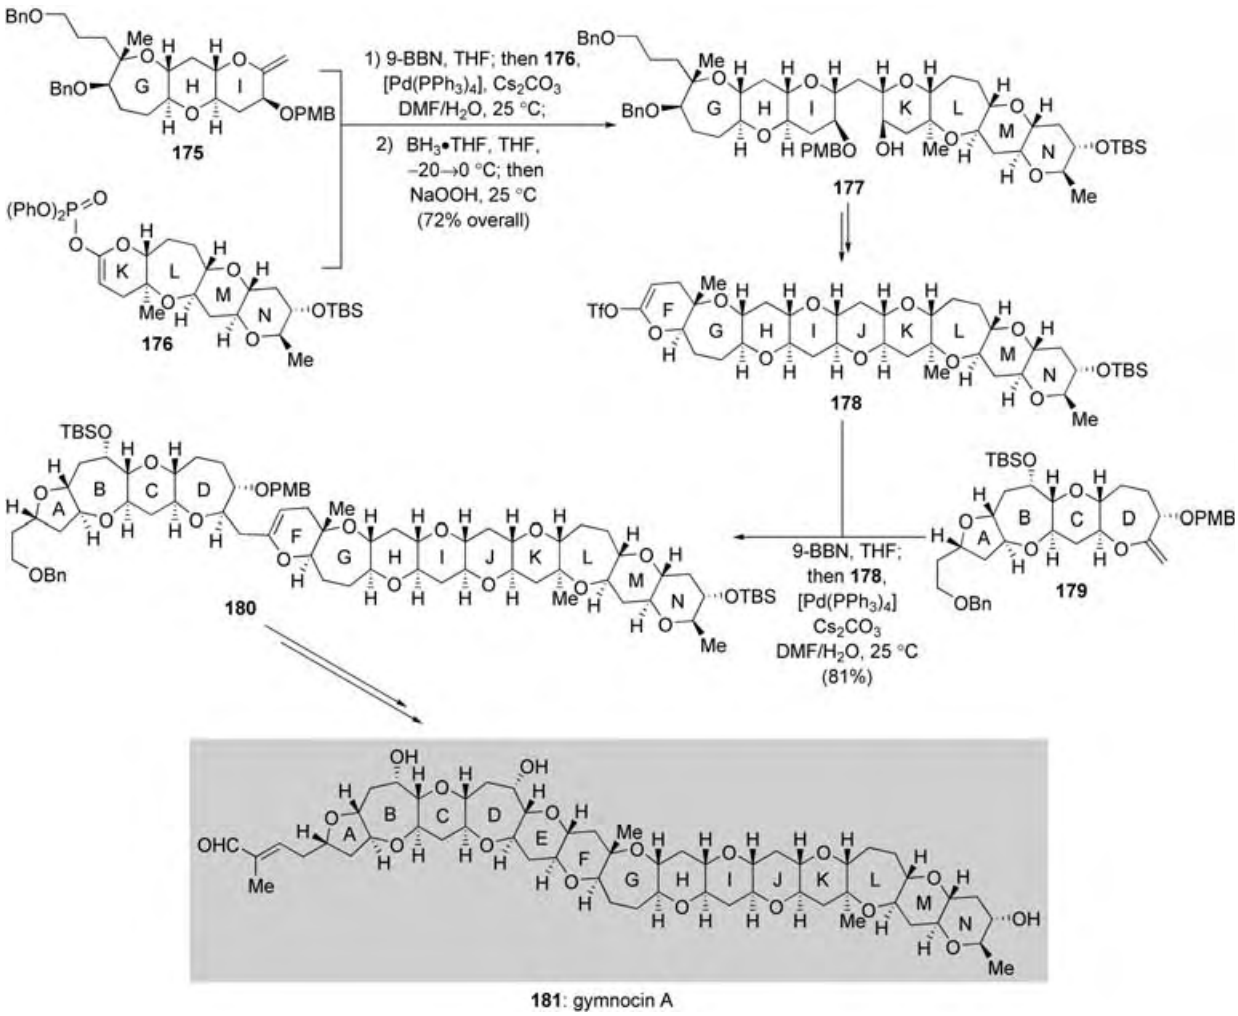


An important trend in the Suzuki reaction over the last 15 years has been the development and application of what have become known as *B*-alkyl Suzuki–Miyaura coupling reactions. In this process an alkyl group (i.e. sp^3-hybridized C atom), as opposed to the more traditionally used vinyl or aryl groups, is transferred from the organoborane component during the palladium-catalyzed coupling process with vinyl or aryl halides or triflates. Compared to the aforementioned $C(sp^3)$–$C(sp^2)$ Stille reactions,[150] *B*-alkyl Suzuki–Miyaura couplings have a much broader scope in that a potentially vast range of alkyl boranes (typically prepared through the regio- and chemoselective hydroboration of readily available alkene precursors and used in situ) can be employed in the reaction.[151] While the Suzuki coupling reactions illustrated so far in this section have been concerned with the assembly of diene systems and biaryl structural motifs, the *B*-alkyl Suzuki–Miyaura reaction is typically, though by no means always,

Scheme 31. Multiple use of palladium-catalyzed carbon–carbon bond-forming reactions in the total synthesis of dragmacidin F (**168**) (Stoltz et al., 2004).[148]

used for the stereoselective generation of isolated alkene units. The first examples of this process were reported by Miyaura and Suzuki in 1986;[152] since its pioneering application in the total synthesis of (+)-quadrilure in 1990 by the Mori group,[153] the *B*-alkyl Suzuki–Miyaura coupling has developed into a versatile and powerful tool in total synthesis.[154] In particular, and as we shall see below, this reaction has recently emerged as a viable alternative to the ring-closing-metathesis of olefins as a method for ring formation. In conjunction with this process, it is worth recalling here, that in an interesting reversal of reactivity, great progress has been made even more recently in the development of practical methods for the coupling of alkyl (i.e. sp^3) halides with vinyl and aryl (i.e. sp^2) organoboron species, which involve the reversal of reactivity of the two reactive ends of the coupling partners.[16]

During the course of their epic,[155] and ultimately successful[156] approach to the total synthesis of the architecturally unique nonadride natural products CP-225,917 and CP-263,114,[157] Danishefsky and co-workers employed a *B*-alkyl Suzuki–Miyaura coupling reaction to append a side chain at C17 of the functionalized tricyclic α-iodoenone **171** (Scheme 32). Thus, the treatment of **171** with trialkylborane **172** in the presence of Cs_2CO_3 and catalytic amounts of [$PdCl_2$(dppf)] and $AsPh_3$ in aqueous DMF led to smooth coupling, generating the alkylated product **173** in 70% yield. First introduced by Johnson and co-workers in 1993,[158] these particular coupling conditions have been found by many researchers to be quite mild and effective for the *B*-alkyl Suzuki–Miyaura reaction, and have subsequently found widespread use in its application. [$PdCl_2$(dppf)] is often shown to be the catalyst of choice for these couplings, as it has



Scheme 32. Sequential intramolecular Heck and intermolecular *B*-alkyl Suzuki reactions in the total synthesis of CP-263,114 (**174**) (Danishefsky et al., 2000).[156]

been suggested that the rate of undesired β-hydride elimination from the transmetalated [Pd(dppf)(alkyl)(vinyl)] complex is slowed down by the presence of the large bidentate ligand,[159] whilst the rate of the product-forming reductive elimination is concurrently enhanced owing to the large bite angle of the ligand.[160] The α-iodo enone coupling partner **171** was prepared through a short sequence of reactions from tricyclic compound **170**, which was itself synthesized by another palladium-catalyzed bond-forming reaction, namely the intramolecular Heck cyclization of the *anti* aldol precursor **169** (Scheme 32). Exposure of compound **169** to a catalytic amount of [$Pd(OAc)_2(PPh_3)_2$] in THF in the presence of Et_3N at 65 °C led to clean, if somewhat slow (4 days were required for the completion of the reaction), cyclization to generate the desired tricyclic compound **170** in 92% yield. The remarkable regioselectivity of this reaction is noteworthy in view of the fact that coupling was observed exclusively between the furan ring and the α-carbon atom of the α,β-unsaturated system, with no trace of the alternative ring closure mode, that is, between the furan ring and the β-carbon atom. This selectivity is presumably a consequence of subtle, yet pivotal, differences between the molecular arrangements (and hence relative energies) required for the two different modes of 1,2-insertion, with the former (α-carbon attack) proving much more facile.

The power and utility of the *B*-alkyl Suzuki–Miyaura reaction in fragment-coupling processes is dramatically manifested in the recent total synthesis of gymnocin A,[161] a member of the polycyclic ether class of marine natural products associated with the notorious "red-tide" phenomena,[162,163] by Sasaki and Tsukano.[164,165] The salient features of the highly convergent synthetic strategy adopted by the Sasaki team are highlighted in Scheme 33. Thus, exocyclic enol ether **175** was subjected to a regio- and diastereoselective hydroboration with 9-BBN and, without purification, the resulting alkyl borane adduct was treated with cyclic ketene acetal phosphate **176** under Johnson conditions to afford, following the regio- and steroselective hydroboration/oxidation of the resulting trisubstituted enol ether, coupled product **177** in good overall yield (72%). Elaboration of the coupling product **177** then gave cyclic ketene acetal triflate **178**, which entered into the second key *B*-alkyl Suzuki–Miyaura fragment coupling reaction, this time with the alkyl borane species derived from hydroboration of the ABCD-ring exocyclic enol ether unit **179**, to give compound **180** in 81% yield. Intermediate **180** was then advanced further to complete the total synthesis of gymnocin A (**181**) in short order. Given the structural complexity and sheer size of the individual fragments, the remarkable efficiency of this second cross-coupling bears testament to the power and reliability of this process in total synthesis. The Sasaki group has developed this efficient approach to polyether construction, and through its application have accomplished the total synthesis of a number of other members of this class of marine natural products.[166]

The use of cyclic ketene acetal phosphates in palladium-catalyzed cross-coupling reactions was pioneered by the Nicolaou group,[167] who was subsequently the first to apply this methodology in the total synthesis of the polyether

marine neurotoxin brevetoxin A (**184**, Scheme 34).[168] They later expanded the scope of this technology to encompass the corresponding cyclic aminal phosphates.[169] Cyclic ketene acetal (or aminal) phosphates, readily prepared from the corresponding lactones (or lactams) by treatment with a strong, non-nucleophilic base followed by quenching with diphenylphosphoryl chloride, smoothly enter into a variety of palladium-catalyzed carbon–carbon bond-forming reactions, including the Stille, Suzuki, and Sonogashira reactions, as well as into carbonylative processes. Furthermore, cyclic ketene acetal phosphates often prove to be superior substrates for these palladium-catalyzed reactions than the corresponding cyclic ketene acetal triflates, owing to the lower cost of the reagents involved in their preparation and their higher stability.[168,169]

Shibasaki and co-workers made use of a number of novel palladium-catalyzed transformations in their elegant synthetic approach to halenaquinone (**194**, Scheme 35) and related pentacyclic marine natural products.[170] The team had previously secured a somewhat arduous synthetic route from the symmetrical catechol derivative **185** to the advanced tricyclic compound **189** in which an intermolecular *B*-alkyl Suzuki–Miyaura coupling reaction and an intramolecular Heck cyclization were used as the carbon–carbon bond-forming steps between a number of protection/deprotection operations. They subsequently realized a significant upgrade in elegance and efficiency in their route to tricyclic system **189** through the application of an unprecedented intermolecular *B*-alkyl Suzuki–Miyaura coupling/intramolecular asymmetric Heck cyclization cascade sequence to fuse the six-membered ring to a symmetrical bis(triflate) precursor **186**, whilst concomitantly installing the benzylic quaternary stereocenter. The desired product **189** could indeed be formed in a single operation from bis(triflate) **186** by treatment with borane **187**,[171] K_2CO_3, and catalytic amounts of $Pd(OAc)_2$ (20 mol%) and (*S*)-binap (40 mol%) in THF at 60 °C. Tricyclic compound **189** was formed with good enantioselectivity (85% *ee*); however, the overall yield for this process was rather low (20%) and, despite the researchers' best efforts, could not be increased further. Major by-products in this reaction were identified as the reduced compound **196** and the double Suzuki coupling product **195**, with the propensity for formation of the latter likely being due to the generally lower rates of Heck reactions than those of Suzuki couplings. Intriguingly, it was found that the use of achiral ligands resulted in much better conversion into (racemic)

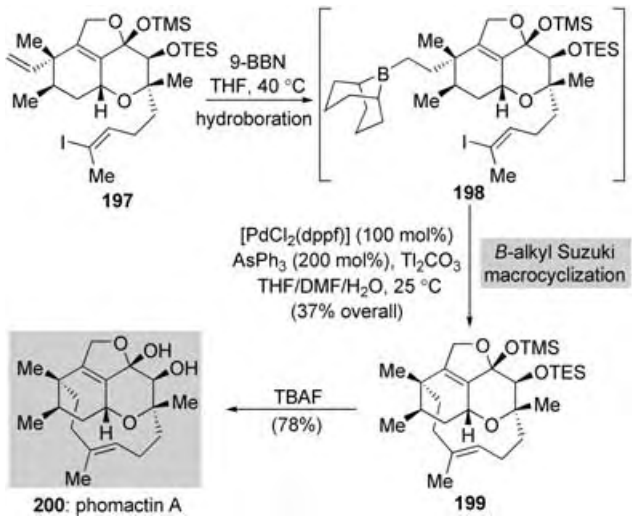
Scheme 34. Pioneering use of cyclic ketene acetal phosphates as organic electrophiles in a palladium-catalyzed cross-coupling reaction, in the total synthesis of brevetoxin A (**184**) (Nicolaou et al., 1998).[168]



Scheme 35. Novel palladium-catalyzed cascade processes in the total synthesis of halenaquinone (**194**) (Shibasaki et al., 1996).[170]

tricyclic compound **189**. Thus, replacing the (*S*)-binap with $AsPh_3$ more than doubled the yield of this cascade process from 20 to 46%. After the elaboration of cyclization product **189** to give acetylenic ketone **190**, another novel palladium-catalyzed cyclization cascade reaction was employed to append the final two rings of the pentacyclic structure, including the highly substituted furan ring, in a single step to give diketone **193**.[172] A few more steps then completed the total synthesis of halenaquinone (**194**). Hence, two palladium-catalyzed reactions resulted in the creation of four new bonds (3 × C–C), three new rings, and, enantioselectively, a quaternary stereocenter.[173]

The intramolecular variant of the *B*-alkyl Suzuki–Miyaura reaction also proves to be a valuable, if still relatively uncharted and underutilized, addition to the repertoire of methods available to the synthetic chemist for ring construction. In particular, this intramolecular cross-coupling protocol allows for the highly regio- and stereocontrolled formation of endo- and exocyclic alkene systems of defined double-bond geometry, especially in the fusion of new rings to preexisting cyclic systems. Although the first such applications reported in 1989 were directed toward the construction of five- and six-membered ring systems,[174] more recently the potential of this reaction in the formation of a wider range of ring sizes, in synthetically useful yields, has begun to be tapped.

One of the most sophisticated applications in total synthesis of the intramolecular *B*-alkyl Suzuki–Miyaura coupling reaction to date was reported by Halcomb and his group, who employed it to forge the 12-membered macrocyclic ring of the terpenoid natural product phomactin A (**200**, Scheme 36).[175] Once the fully elaborated tricyclic precursor **197** had been prepared, the major remaining synthetic hurdle facing the team was the construction of the macrocycle in the presence of the other sensitive functionalities within the molecule, particularly the protected dihydroxyfuran motif. To their delight, they were able to effect the selective regiocontrolled (anti-Markovnikov addition) hydroboration of the terminal alkene in the presence of both the tri- and tetrasubstituted alkene systems upon treatment of compound **197** with 9-BBN in THF at 40 °C to afford the primary trialkyl borane intermediate **198**. Without purification, this intermediate was then slowly added to a mixture of $[PdCl_2(dppf)]$ (100 mol%), $AsPh_3$ (200 mol%), and Tl_2CO_3 in a THF/DMF/H_2O solvent system to afford the desired transannular macrocyclization product **199** in 37% yield. The

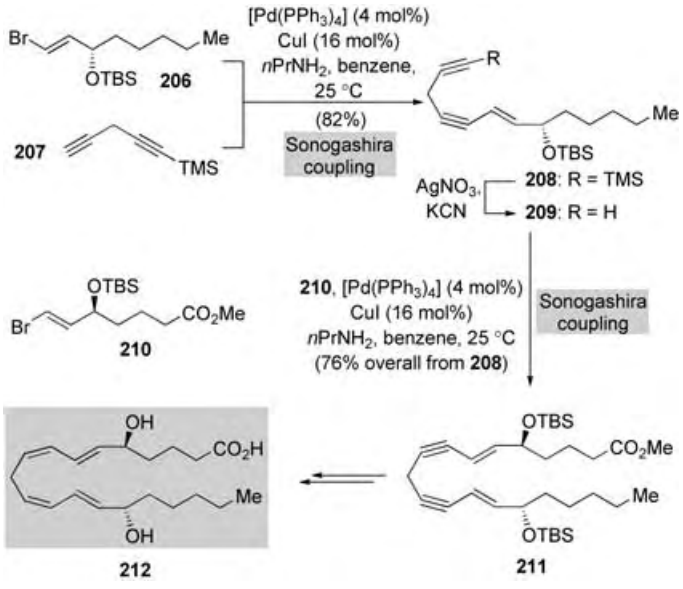
Scheme 36. Use of the *B*-alkyl Suzuki–Miyarua coupling to effect a macrocyclization in the synthesis of phomactin A (**200**) (Halcomb and Mohr, 2003).[175]

subsequent unmasking of the two protected hydroxy groups then completed the total synthesis. Although the yield of this key cyclization is moderate at best, and a high "catalyst" loading is required, it nevertheless sets a new standard for such processes. Note that only the (desired) primary alkyl group is transferred from the boron atom (as its corresponding "ate" complex) during the transmetalation event in the catalytic cycle, owing to the much faster rate of transmetalation relative to that with the secondary alkyl groups on boron. Indeed, reports of synthetically useful *B*-alkyl Suzuki–Miyaura coupling reactions involving secondary alkyl borane species are scarce.[176] The researchers found that the choice of base was crucial to the efficiency of the reaction, and that the use of Tl_2CO_3 (rather than Cs_2CO_3 as in the original Johnson conditions) gave the best results. Presumably, the use of the thallium base increases the rate of the desired macrocyclization to a greater degree than it does the rates of competitive, undesired, intermolecular oligomerization pathways, a factor also influenced by the use of high dilution conditions.[177] The macrocyclization event was postponed until a late stage in the synthesis because of the anticipation that the rigid structure of the tricyclic core would bias the system towards the desired intramolecular process. As expected, the cyclized product **199** was formed exclusively as a single stereoisomer and with retention of configuration of the trisubstituted alkene moiety. This potential for control over olefin geometry in macrocyclization reactions compares favorably with that encountered in the corresponding ring-closing olefin-metathesis processes in which mixtures of isomers are often obtained and the stereochemical course of ring closure is generally not predictable. Thus, the intramolecular *B*-alkyl Suzuki–Miyaura coupling reaction offers a complementary approach to metathesis-based protocols.

In a similar manner to the carbonylative Stille reactions described earlier, the palladium-catalyzed, three-component cross-coupling of organic electrophiles, carbon monoxide, and organoborane compounds also provides an efficient means for the synthesis of unsymmetrical ketones from simpler precursor building blocks.[178] This procedure was applied as one of the key steps in an expedient synthesis of the bisindole alkaloid yuehchukene (**205**) by Ishikura and co-workers,[179] in which a carbonylative Suzuki reaction was used to assemble the 2-indolyl ketone intermediate **204** rapidly (Scheme 37).

Scheme 37. Three-component, carbonylative Suzuki coupling in the total synthesis of yuehchukene (**205**) (Ishikura et al., 1996).[179]

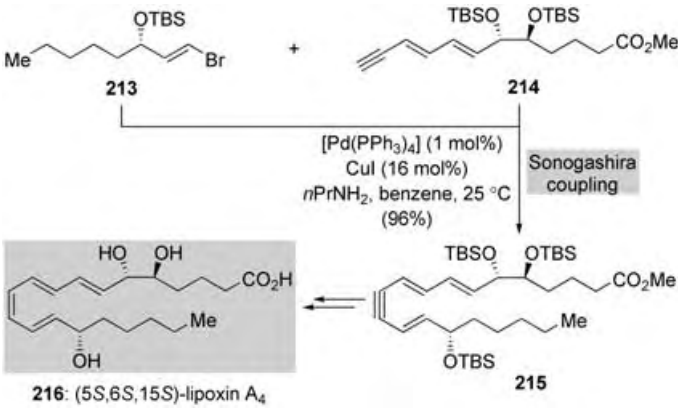
Directed *ortho*-metalation[180] of *N*-Boc-indole (**201**) followed by treatment with triethylborane led to the formation of lithiated "ate" complex **202**, which was not isolated but, instead, added directly to a solution of vinyl triflate **203** and a catalytic amount of $[PdCl_2(PPh_3)_2]$ in THF at 60 °C under a pressurized (10 atm) carbon monoxide atmosphere to effect the desired coupling in good overall yield. It will be noticed that, unlike the other examples of the Suzuki reaction highlighted so far, no additional base is required in the cross-coupling step, since the negatively charged, four-coordinate boron "ate" complex that is required to undergo the transmetalation step in the catalytic cycle is already present. The use of carbon monoxide under high (or at least greater than atmospheric) pressure has often been found to be a convenient method for suppressing a major side reaction sometimes encountered in carbonylative palladium-catalyzed reactions, namely the direct coupling of an organic electrophile and an organometallic component without carbon monoxide insertion.[181] A number of vinyl and aryl halides and triflates were shown to be viable coupling partners in this carbonylation process, enabling the synthesis of a variety of 2-indolyl ketone derivatives.[182] This method for the regioselective acylation at C2 of indoles is complementary to more traditional Friedel–Crafts-type acylations, which result in the preferential functionalization at C3.[183]



5. The Sonogashira Reaction

The Sonogashira reaction has emerged in recent years as one of the most general, reliable, and effective methods for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



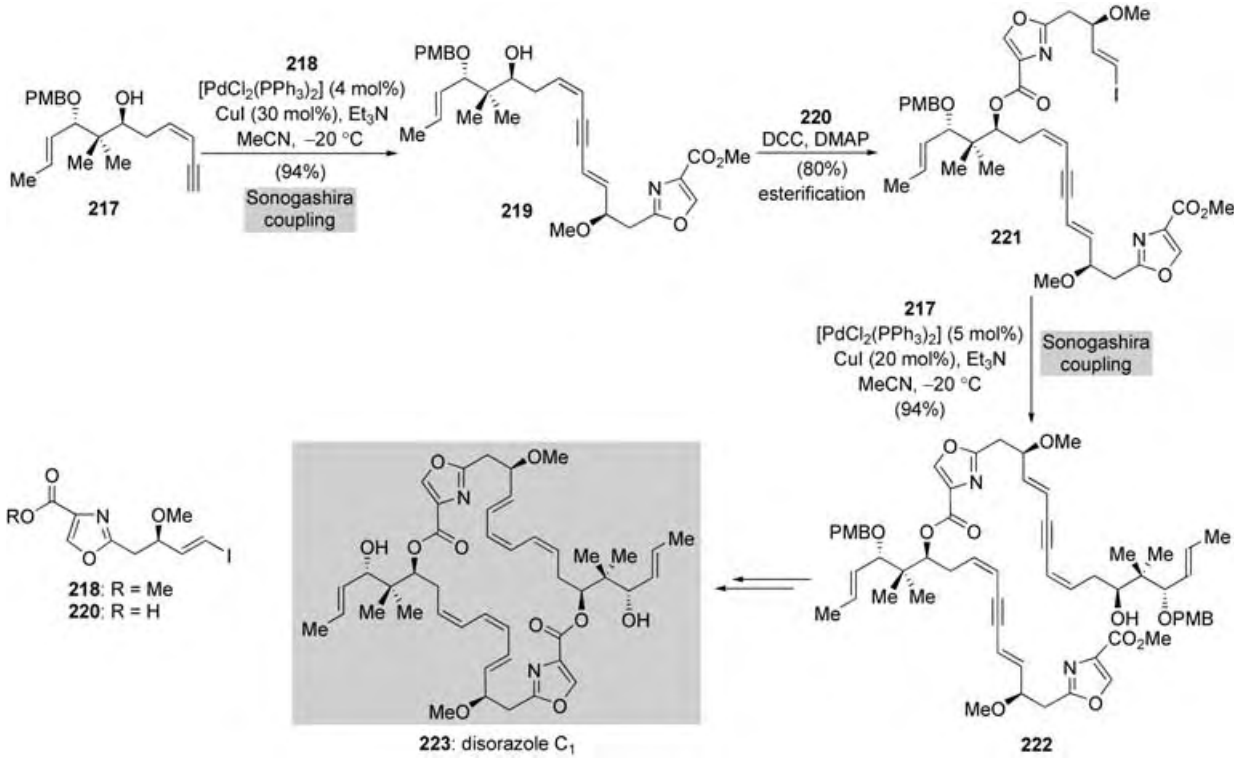
the synthesis of substituted alkynes.[184] The palladium-catalyzed coupling of a number of preformed metal acetylides (e.g. Zn,[185] Mg,[186] B,[187] Al,[188] and Sn[189] derivatives) with organic electrophiles also provides a useful access to substituted alkynes. Nevertheless, the Sonogashira protocol (employing cocatalytic Cu^I salts) is the most widely used of the palladium-catalyzed alkynylation methods, particularly in the context of total synthesis, largely owing to its broad applicability and convenience.

An early application of the Sonogashira reaction in total synthesis can be found in the generalized synthetic route to the biologically significant lipoxins and related eicosanoids pioneered by the Nicolaou group in the early 1980s. As an illustrative example, we highlight the stereospecific synthesis of (5*S*,15*S*)-dihydroxy-6,13-*trans*-8,11-*cis*-eicosatetraenoic acid (**212**),[190] an important metabolite of arachidonic acid. Besides securing the stereochemistry of the remote hydroxy-bearing stereogenic centers, the central problem in the synthesis of this and similar polyunsaturated compounds resides in the construction of an aliphatic chain that have double bonds of defined geometry in specified positions within the molecule. The solution devised by the Nicolaou group involved the stereospecific formation of the conjugated unsaturated systems through Sonogashira coupling reactions in which the acetylene components function as masked *Z*-alkene motifs. Thus, as illustrated in Scheme 38, the coupling of vinyl bromide (*E*)-**206** with the terminal alkyne **207** upon exposure to $[Pd(PPh_3)_4]$ (4 mol%), CuI (16 mol%), and nPrNH$_2$ (1.2 equiv) in benzene proceeded smoothly at room temperature to afford enediyne **208** in good yield. As expected, compound **208** was formed as a single geometric isomer, with the anticipated retention of configuration about the *E* double bond. After the liberation of the terminal acetylene to give compound **209**, a second Sonogashira reaction, this time with vinyl bromide **210** under the same coupling conditions gave bis(enyne) **211** as a single isomer and again in good yield. With the entire molecular framework of the target natural product thus rapidly assembled through this convergent and flexible approach, the few remaining synthetic steps required only selective hydrogenation of the two alkyne units, under Lindlar conditions, and removal of protecting groups.

Scheme 38. Sequential Sonogashira couplings in the total synthesis of **212** (Nicolaou and Webber, 1984).[190]

Variations on this general Sonogashira coupling theme allowed the synthesis of a number of other structurally and biosynthetically related eicosanoid natural products, including the lipoxin family of secondary metabolites. For example, (5*S*,6*S*,15*S*)-lipoxin A$_4$ (**216**) was readily obtained through the smooth union of the enantiomerically pure building blocks **213** and **214**, followed by standard Lindlar reduction and protecting-group cleavage procedures (Scheme 39).[191] A large number of isomeric lipoxin A[192] and lipoxin B[193] derivatives were produced by analogous routes, which enabled not only the identification and structure elucidation of a number of naturally occurring isomers of this series, but also provided meaningful quantities of materials for further biological investigations.[194]

Scheme 39. Application of a fragment-coupling Sonogashira reaction in the total synthesis of (5*S*,6*S*,15*S*)-lipoxin A$_4$ (**216**) (Nicolaou et al., 1985).[191]



These instructive examples serve to highlight the fact that the Sonogashira reaction provides an important alternative to the Stille and Suzuki reactions for the stereoselective synthesis of polyene systems, by means of this two-step protocol of alkyne–alkene coupling followed by selective reduction of the triple bond. Such methodology proves to be of particular use when the organostannane or organoboron components, required for the Stille or Suzuki coupling reactions, respectively, are either unavailable or too unstable to be synthetically useful. It is important to note that both the corresponding *E*- and *Z*-alkene isomers can be readily prepared in a stereoselective fashion from the parent alkyne. Thus, whereas the *Z* alkenes are typically prepared by catalytic hydrogenation procedures, a number of routes are available for the synthesis of the corresponding *E* isomers;[195] the hydrosilylation protocols recently developed by the Fürstner[196] and Trost groups[197] are potentially convenient and chemoselective methods.

The power of the Sonogashira reaction in fragment-coupling processes is nicely illustrated in the synthesis of disorazole C_1 (**223**) by Wipf and Graham (Scheme 40).[198] Noting the symmetry elements inherent within the natural product, the team reasoned that the formidable molecular framework of their target could be broken down into just three relatively simple fragments that could be appropriately unified through the judicious employment of esterification, Sonogashira, and macrolactonization reactions. As shown in Scheme 40, the coupling of alkyne **217**, containing an unprotected secondary hydroxy group, with vinyl iodide **218** occurred rapidly in the presence of $[PdCl_2(PPh_3)_2]$ (4 mol%), CuI (30 mol%), and Et_3N in MeCN to yield the desired coupling product **219** in nearly quantitative yield. The secondary hydroxy group in compound **219** was then esterified with carboxylic acid **220** to give vinyl iodide **221**, onto which was appended another molecule of alkyne **217** through another high-yielding Sonogashira coupling. Hence, in only three operations, the entire carbon framework of the final target structure had been assembled under mild conditions and in a stereospecific manner from the simple starting materials **217**, **218**, and **220**, with no protecting-group manipulation required. A few more steps then completed the total synthesis, with the two sensitive *E*,*Z*,*Z*-triene systems being unveiled in the last step through the selective hydrogenation of the alkyne moieties facilitated by the Lindlar catalyst. Thus, as was the case in the synthesis of **212**, the alkyne unit serves a dual function in the synthesis: as a coupling handle for carbon–carbon bond formation and as a surrogate for a *Z* alkene, enabling the postponement of the unveiling of the latter, rather delicate structural motif until a late stage in the synthesis.

In a similar vein to the other palladium-catalyzed processes discussed so far, the finding that vinyl triflates (also known as enol triflates) are effective electrophiles in cross-couplings with terminal alkynes has significantly expanded the scope and utility of the Sonogashira reaction.[199] One of the first such applications in total synthesis, which indeed remains a prime example of this methodology in natural products synthesis, can be found in the masterful synthesis of ginkgolide B (**227**) by E. J. Corey and co-workers, reported in 1988.[200] In this true classic in total synthesis,[118] one of the key early steps was the formation of enyne **226** through the coupling of enol triflate **224** (derived from the corresponding ketone) with the orthoester-substituted terminal alkyne **225** (Scheme 41). The required transformation was induced by treatment of a mixture of the coupling partners **224** and **225** with a catalytic amount of $[Pd(PPh_3)_4]$ (6 mol%), a substoichiometric amount of CuI (50 mol%), and nPrNH$_2$ (excess) in toluene, providing the desired product **226** in yields between 76 and 84%.

One of the most common applications of the Sonogashira reaction in total synthesis is the incorporation of two-carbon alkyne motifs into synthetic intermediates, either as ring appendages or as a means of acyclic-chain elongation. (Trimethylsilyl)acetylene serves as a conveniently handled acetylene equivalent, with the added benefit that, because one terminus of the alkyne unit is blocked as the corresponding trimethylsilane, monocoupling products are observed exclusively. Such a reaction was applied by Isobe and co-workers at an early juncture in the course of their asymmetric total synthesis of tetrodotoxin,[201] the notorious puffer fish poison that has been called "one of Nature's great marvels".[202] Thus, (trimethylsilyl)acetylene was smoothly cou-

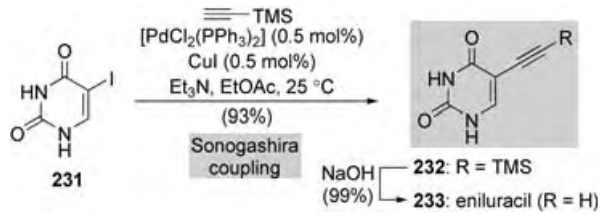
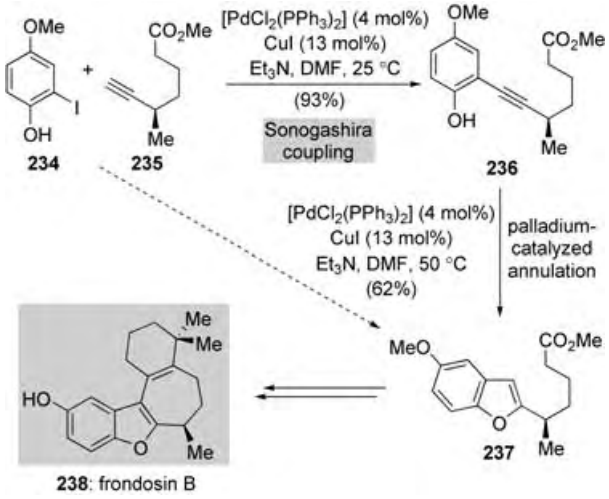


Scheme 41. Application of an enol triflate in a Sonogashira coupling in the total synthesis of ginkgolide B (**227**) (Corey et al., 1988).[200]

pled with vinyl iodide **228** upon exposure to catalytic amounts of $Pd(OAc)_2$ (5 mol%), PPh_3 (10 mol%), and CuI (10 mol%) in the presence of Et_3N in benzene at ambient temperature to afford enyne **229** in near-quantitative yield (Scheme 42). This product was then advanced through a number of steps to complete the total synthesis.

Scheme 42. Use of the Sonogashira reaction to introduce an ethynyl group in the enantioselective synthesis of (−)-tetrodotoxin (**230**) (Isobe et al., 2003).[201]

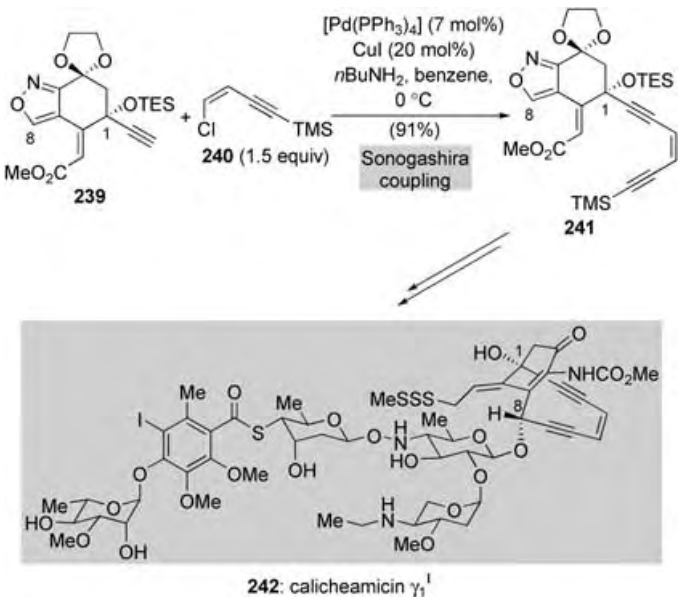


This protocol has also found industrial application, for example, in the concise synthesis of eniluracil (**233**, Scheme 43), a chemotoxic agent enhancer developed by GlaxoSmithKline and used for the treatment of breast and colorectal cancers.[203] In this synthesis, the coupling of 5-iodouracil (**231**) with (trimethylsilyl)acetylene proceeded in excellent yield and, on a large scale, in the presence of catalytic amounts of $[PdCl_2(PPh_3)_2]$ and CuI in EtOAc at ambient temperature. It was found that the catalyst loading of both the palladium complex and the copper salt could be lowered to a mere 0.5 mol% each while maintaining an acceptable reaction rate, with the resultant benefits of lower

Scheme 43. Use of the Sonogashira reaction to introduce an ethynyl group in the synthesis of eniluracil (**233**) (Glaxo SmithKline, 2001).[203]

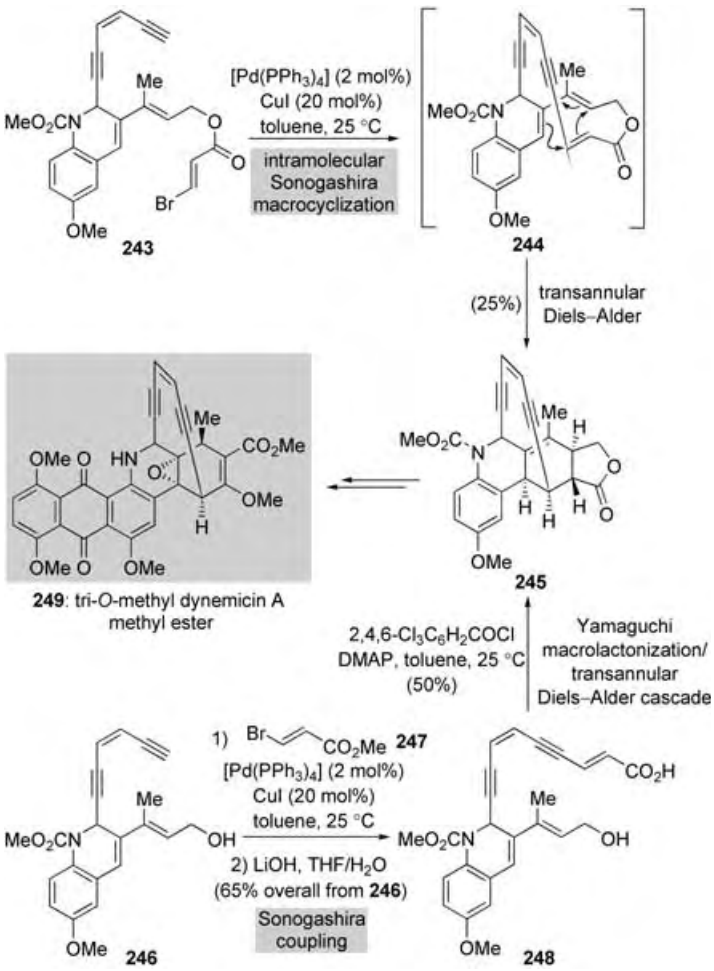
reagent costs and minimal heavy-metal contamination in the process. The subsequent basic hydrolytic cleavage of the silyl protecting group to afford the target compound also proceeded smoothly and in nearly quantitative yield. Thus, this protocol provides a mild, safe, and high-yielding method for the introduction of an unsubstituted ethynyl fragment, thus offering a versatile alternative to the synthesis of such motifs through the standard homologation of aldehyde precursors.[204]

An interesting approach to the total synthesis of the interleukin-8 receptor antagonist frondosin B by employing palladium-catalyzed chemistry was reported by Danishefsky and co-workers.[205] The researchers proposed that a concise and convergent synthetic route to the pivotal benzofuran intermediate **237** could be secured through a heteroannulation reaction between *ortho*-iodophenol derivative **234** and terminal alkyne **235** (Scheme 44). This cascade process would involve the initial Sonogashira coupling between **234** and **235** to generate intermediate **236**, which would then undergo the required intramolecular cyclization in a process that was already known to be catalyzed by palladium salts.[206,207] While it was, indeed, found that this one-pot process could be effected to yield benzopyran **237** directly from **234** and **235**, such procedures were invariably plagued by numerous competing side reactions and decomposition pathways, to the detriment of the formation of the desired product **237**, which, even under optimum conditions, could be isolated only



Scheme 44. Use of the Sonogashira reaction in a heteroannulation protocol in the total synthesis of frondosin B (**238**) (Danishefsky et al., 2001).[205]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

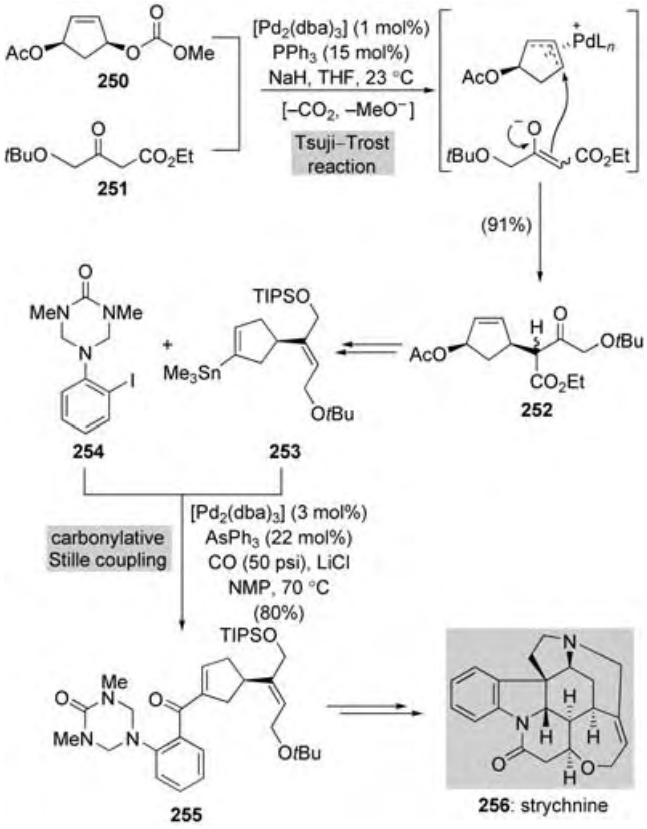


in modest yields (20–40%). To circumvent this dilemma, the researchers investigated the possibility of carrying out the Sonogashira coupling and heteroannulation reactions as separate, subsequent steps. Much to their delight, the coupling of **234** and **235** to give alkyne **236** proceeded in an excellent yield of 93% at room temperature under the influence of $[PdCl_2(PPh_3)_2]$ (4 mol%), CuI (13 mol%), and Et_3N (2.0 equiv) in DMF. The choice of base was found to influence the efficacy of this step dramatically; for example, replacement of Et_3N with piperidine lowered the yield of alkyne **236** to 74%. The isolated, purified alkyne **236** was resubjected to the same reaction conditions, except for the elevated temperature of 50 °C, to effect the smooth cyclization to give the sought-after benzofuran **237** in 62% yield. Both the initial coupling and the subsequent cyclization were found to occur without any erosion of stereochemical integrity of the resulting benzylic tertiary stereocenter.

Some of the most spectacular applications of the Sonogashira reaction can be found in synthetic approaches to various members of the enediyne class of antibiotics, as reported by numerous different groups.[208] The characteristic (*Z*)-1,5-diyne-3-ene motif contained within this family of natural products would appear to lend itself readily to assembly through palladium-catalyzed carbon–carbon bond-forming processes, and indeed has proven to be a significant testing ground for the Sonogashira coupling in total synthesis. We highlight but two of the many such elegant applications. The first of these is in the pioneering total synthesis of calicheamicin γ_1^I (**242**) by the Nicolaou group in 1992.[209] As illustrated in Scheme 45, the coupling of the densely functionalized cyclohexyl-substituted alkyne **239** with vinyl chloride **240** (itself prepared through the Sonogashira reaction of *cis*-1,2-dichloroethylene with trimethylsilyl acetylene) proceeded smoothly to afford the corresponding product **241** in 91% yield. Crucially, and as anticipated, this union occurred with retention of the *Z* geometry of the alkene coupling partner.

In contrast, Schreiber and co-workers made use of both inter- and intramolecular Sonogashira reactions in their captivating and highly inventive approach to the core molecular framework of dynemicin A.[210] The cornerstone of their synthetic strategy was the anticipation that macrocyclic lactone **244** (Scheme 46) could be coaxed into undergoing a transannular Diels–Alder reaction as shown to furnish the advanced pentacyclic intermediate **245**. Such an approach would differ fundamentally from previous approaches to the dynemicin skeleton in which the enediyne motif was appended onto a previously established tricyclic system (for an example see the approach by Danishefsky and co-workers, Section 3, Scheme 15).[211] The Schreiber group investigated the potential viability of two different strategies to the putative macrocyclic transannular Diels–Alder precursor **244**.

Scheme 45. Application of a Sonogashira coupling to generate the enediyne system in the total synthesis of calicheamicin γ_1^I (**242**) (Nicolaou et al., 1992).[209]



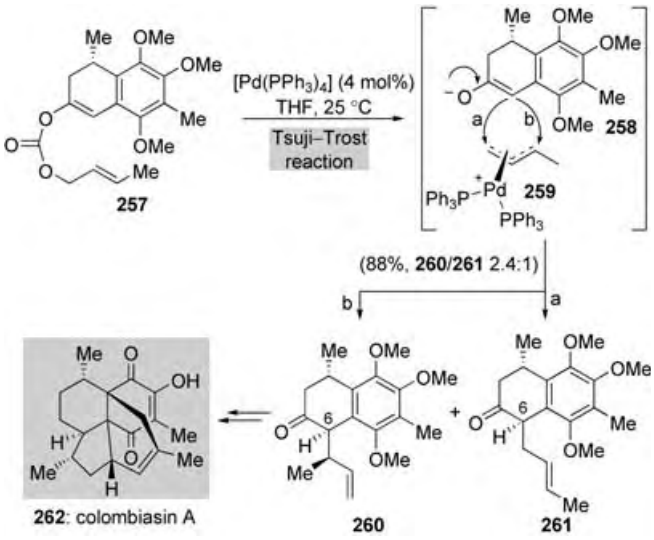
Scheme 46. Different uses of the Sonogashira coupling in cascade reactions en route to tri-*O*-methyl dynemicin A methyl ester (**249**) (Schreiber et al., 1993).[210]

In the first of these, it was proposed that the macrocyclic ring could be generated by the coupling of the terminal alkyne and the bromide-bearing vinyl carbon atom in ester **243** through a Sonogashira coupling reaction. However, to both their surprise and delight, when ester **243** was treated with [Pd(PPh_3)$_4$] (2 mol%) and CuI (20 mol%) in toluene, the sole isolable product was in fact found to be the Diels–Alder cycloadduct **245**, which had been formed as a single stereoisomer in 25% yield. In this amazing and unprecedented tandem Sonogashira/Diels–Alder reaction, three rings and four contiguous stereocenters were formed in a single operation and within 2 h at room temperature, presumably through the transient intermediacy of the expected macrocycle **244**. The second approach made use of an intermolecular Sonogashira coupling between enediyne **246** and bromoacrylate **247**, followed by basic hydrolysis of the resulting ester group, to generate the corresponding polyunsaturated carboxylic acid with complete retention of alkene geometry. When acid **248** was subjected to the Yamaguchi macrocyclization protocol,[212] cyclization to give lactone **244** was again spontaneously followed by the transannular Diels–Alder reaction at room temperature to generate the same pentacyclic intermediate **245**. Such cascade processes serve to highlight the utility and potential of the Sonogashira reaction in generating molecular complexity from much simpler precursor molecules.

6. The Tsuji–Trost Reaction

The alkylation of allylic substrates by stabilized nucleophiles is one of the most synthetically useful reactions catalyzed by palladium(0) complexes. From an historical perspective, this reaction reflects the first demonstration of a metalated species acting as an electrophile, providing a counterpoint to decades of research that had indicated that such entities only behaved as nucleophiles. On a more practical level, the Tsuji–Trost reaction, as this general process is known, typically proceeds under mild conditions, with (generally) high and predictable levels of chemo-, regio-, and stereoselectivity. The stoichiometric allylation of enolates with π-allyl–palladium complexes was first reported by the Tsuji group 40 years ago,[213] and subsequently developed into a catalytic reaction by Trost and co-workers.[25a] A wide range of allylic substrates undergo this reaction with a correspondingly wide range of carbanions, making this a versatile and important process for the formation of carbon–carbon bonds. Whilst the most commonly employed substrates for palladium-catalyzed allylic alkylation are allylic acetates, a variety of leaving groups also function effectively—these include halides, sulfonates, carbonates, carbamates, epoxides, and phosphates. As such, the Tsuji–Trost reaction has been widely embraced by synthetic chemists, and we can highlight but a few of the many elegant applications of this process here. It is important to recall that a wide variety of heteroatom nucleophiles (e.g. N, O, and S nucleophiles) also make excellent coupling partners in the Tsuji–Trost reaction; however, the utility of these processes are beyond the scope of this Review.

A classic and instructive example of the intermolecular Tsuji–Trost reaction can be found in the total synthesis of the naturally occurring enantiomer of strychnine (**256**, Scheme 47) by Overman and co-workers in 1993.[214] Com-

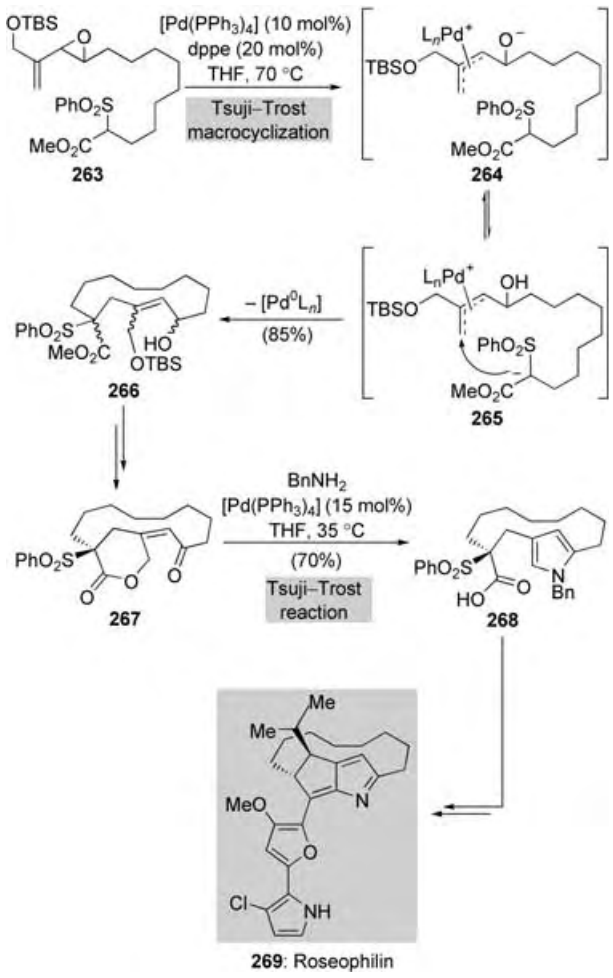


Scheme 47. Tsuji–Trost and carbonylative Stille coupling reactions in the total synthesis of strychnine (**256**) (Overman et al., 1993).[214]

prising only 24 skeletal atoms woven into a bewitching polycyclic structure, strychnine holds a special place in the annals of structure determination and natural product synthesis. However, following the landmark total synthesis of racemic strychnine by Woodward and co-workers in 1954,[215] enantioselective syntheses of this remarkable alkaloid would not be forthcoming for nearly 50 years, with the success of the Overman approach being, in a large part, due to the application of palladium-catalyzed reactions.[216] The first key step in the synthesis involved the allylation of acetoacetate derivative **251** (Scheme 47) with enantiopure allylic carbonate **250**, under the influence of [Pd_2(dba)$_3$] (1 mol%), PPh_3 (15 mol%), and NaH in THF at ambient temperature to furnish the *cis*-alkylated adduct **252** in 91% yield. Several features of this reaction merit further comment. First, the net stereochemical outcome of this reaction is the overall retention of the configuration at the leaving-group-bearing carbon atom, thus complementing normal S_N2 reactions, which proceed with inversion of configuration. As illustrated in Scheme 47, this is the consequence of two successive inversions at this center, and is a general feature of the Tsuji–Trost reactions of soft nucleophiles. Second, the regiochem-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

istry of the alkylation is such that compound **252** is formed exclusively. In general, the regiochemical course of the alkylation of unsymmetrical allylic substrates is such that attack is favored at the less-substituted terminus; however, and as we shall see, this is somewhat dependent on the specific nature of the nucleophile, the electrophile, and the catalyst system. Although cyclopentene derivative **250** contains two potential leaving groups, namely the acetate and the carbonate units, the exclusive displacement of the latter was observed. This outcome had been anticipated on the basis of relevant precedent, which had demonstrated the higher reactivity of allylic carbonates in these processes than that of the corresponding acetates.[217] Finally, compound **252** was formed as a 1:1 mixture of epimers at the stereocenter adjacent to the ketone group, but this proved to be inconsequential as this mixture could be advanced to give stannane **253** as a single stereoisomer. A carbonylative Stille reaction was then employed to effect the linking of stannane **253** with aryl iodide **254** through a carbonyl bridge, affording tricyclic compound **255** in 80% yield. This intermediate was subsequently elaborated to complete the asymmetric total synthesis of (−)-strychnine.

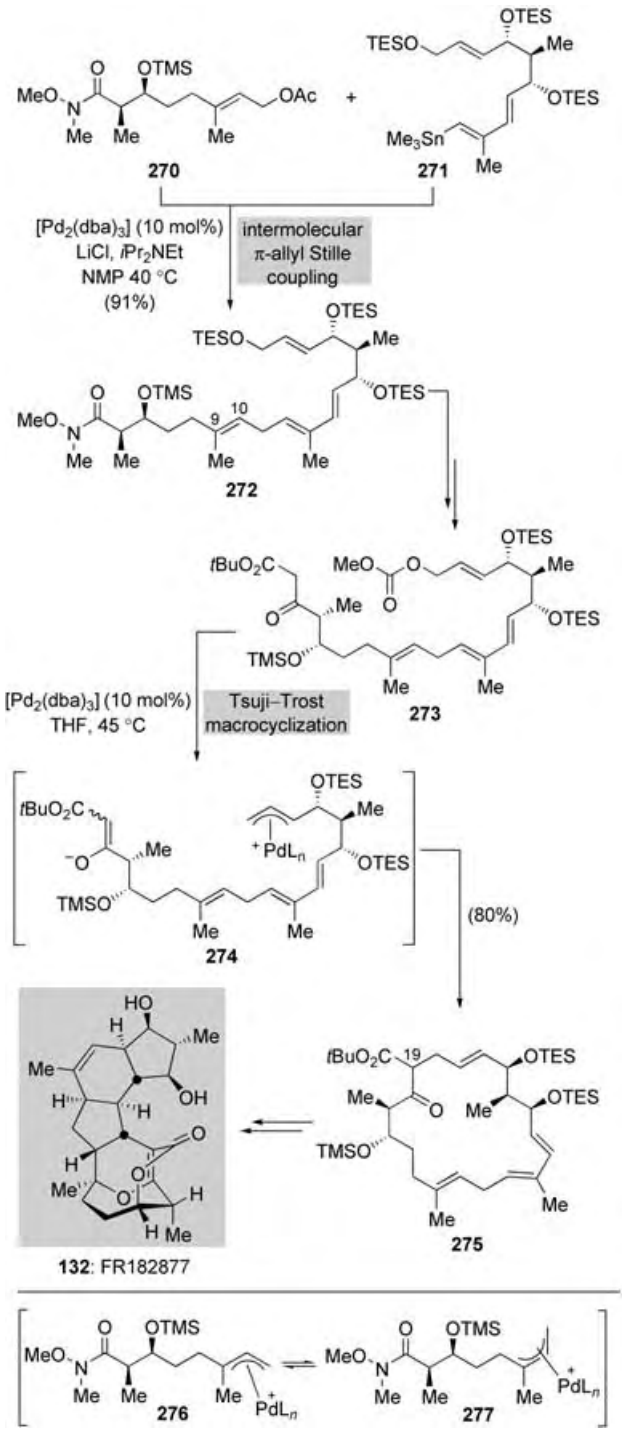


The pioneering total synthesis of the marine diterpenoid colombiasin A (**262**, Scheme 48) by the Nicolaou group in

Scheme 48. Regioselective Tsuji–Trost reaction of a crotyl enol carbonate precursor in the total synthesis of colombiasin A (**262**) (Nicolaou et al., 2001).[218]

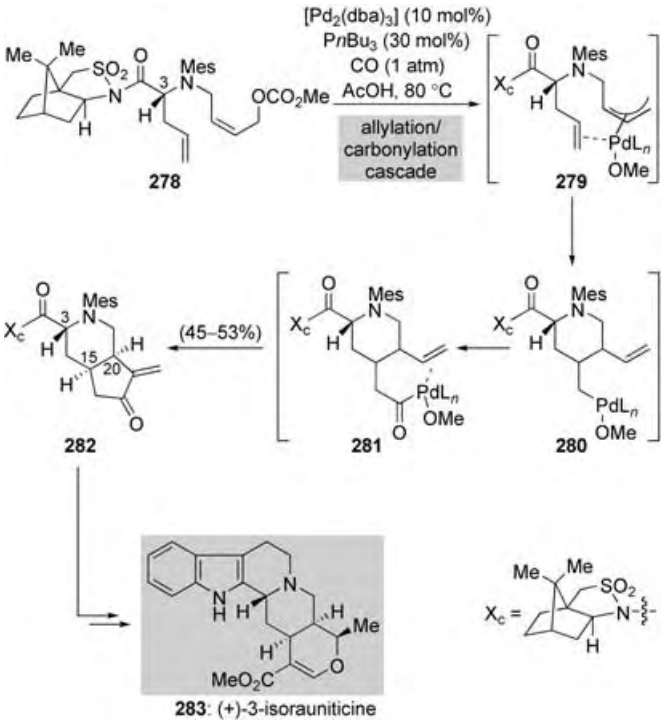
2001[218] was the end result of the development of a number of synthetically useful techniques, foremost amongst them being the extension of the Tsuji–Trost allylation reaction to a new class of substrates as well as interesting observations regarding the regioselectivity of the addition of enolate nucleophiles to η^3-crotyl–palladium electrophilic complexes. The adopted synthetic plan called for the installation of the C6 side chain through a Tsuji–Trost reaction of an appropriately substituted crotyl enol carbonate precursor (i.e. **257**→**260**).[219] However, it was appreciated from the outset that there were a number of potential pitfalls associated with this novel transformation, not the least of which was the issue of the regioselectivity of the addition of enolate intermediate **258** to palladium complex **259**. Indeed, a substantial body of literature precedent suggested that addition would occur predominantly at the less-hindered terminus of the complex (path a) to generate the undesired regioisomeric product **261**. However, it was proposed that if the reaction conditions could be tailored such that electronic factors, rather than the customary steric effects, became the dominant factor in determining the regioselectivity of addition, then the reaction could indeed be coaxed into following the desired pathway (i.e. path b), as the site of greatest partial positive charge in the allylic domain of complex **259** resides at the secondary carbon atom terminus. Gratifyingly, it was found that exposure of enol carbonate **257** to $[Pd(PPh_3)_4]$ (4 mol%) in THF at ambient temperature led to the rapid formation of a mixture of the two regioisomeric products **260** and **261**, in a combined yield of 88%, in which the desired isomer predominated (**260**/**261** 2.4:1). The employment of PPh_3 as a ligand for palladium proved to be crucial in dictating this regiochemical outcome, as it presumably enabled the sufficient accumulation of partial positive charge character on the crotyl ligand in complex **259** to favor attack at the more-substituted carbon terminus. Indeed, it was observed that better σ-donor ligands (e.g. dppe or $P(OiPr)_3$), which would be expected to lower the cationic character of complex **259**, restored the "normal" regioselectivity, with the undesired product **261** predominating in these reactions. These groundbreaking results showed, for the first time in the context of complex molecule construction, that the regioselectivity of nucleophilic addition in the Tsuji–Trost reaction can, under appropriate conditions, be manipulated beyond mere steric control. Certainly, in this instance, it went against established doctrine. The regiochemistry issues notwithstanding, this allylation reaction was, in fact, extremely stereoselective, with both the undesired product **261** and, even more remarkably, the desired compound **260** being formed as single stereoisomers. This outcome presumably reflects the inherent influence of the remote methyl-group-bearing stereocenter in the starting material **257** on the allylation step.[220]

The intramolecular Tsuji–Trost reaction represents a powerful method for the formation of a broad spectrum of ring systems, be they carbocyclic or heterocyclic, small or large. An elegant example of the scope of this process is the total synthesis of the architecturally unique alkaloid roseophilin (**269**, Scheme 49) by Fürstner and Weintritt.[221,222] The central synthetic challenges confronting these researchers were the formation of both the azafulvene-type chromophore and the rather strained *ansa* 12-membered carbocyclic ring; the Tsuji–Trost reaction proved to be instrumental in addressing both these issues. Thus the initial formation of the macrocyclic ring was effected by the addition of a dilute solution of allylic epoxide **263** to catalytic amounts of $[Pd(PPh_3)_4]$ and dppe in refluxing THF to generate compound **266** in an impressive 85% yield (Scheme 49). As with the strychnine example described above, the reaction sequence was initiated by the selective oxidative addition of the more reactive unit of a bifunctional substrate to a palladium(0) species through the judicious modulation of leaving-group



Scheme 49. Sequential use of Tsuji–Trost reactions in the total synthesis of roseophilin (**269**) (Fürstner and Weintritt, 1998).[221]

reactivity. Thus, in this case, the allylic epoxide moiety in compound **263** was opened selectively in the presence of the allylic silyl ether group, driven by the attendant release of ring strain, to generate the presumed alkoxide intermediate **264**. Following equilibration to generate the stabilized carbanion species **265**, macrocyclization can then occur at the less-hindered terminus of the π-allyl system to generate the observed product **266**. There was no inherent diastereoselectivity in this reaction, with the product **266** being formed as a mixture of all possible stereoisomers. This did not prove to be a hindrance as no tedious separation of the individual components was required, and all the isomers eventually converged into the one final target product. Note that the reaction proceeded under neutral conditions, with no external base needed in the reaction cocktail, which, in this case, is due to the generated alkoxide intermediate **264** being of sufficient basicity to deprotonate the β-sulfone ester group. High-dilution conditions were employed for this transformation to favor the desired macrocyclization over competing detrimental oligomerization processes. Following the elaboration of compound **266** to give lactone **267**, another Tsuji–Trost reaction was employed to generate the corresponding *meta*-pyrrolocyclophane **268**. This interesting palladium-catalyzed transformation, which again proceeds under mild neutral conditions, would appear to offer an appealing alternative to traditional acid-catalyzed condensation protocols for the formation of pyrrole ring systems from acyclic 1,4-diketones or their synthetic equivalents.[223]



Brilliant use of π-allyl–palladium(II)-mediated bond-forming reactions was made by Sorensen and co-workers in their enantioselective total synthesis of the naturally occurring enantiomer of FR182877 (**132**).[224] The first of these couplings was the π-allyl Stille reaction between allylic acetate **270** and dienylstannane **271** to afford intermediate **272** as a single stereoisomer in 91% yield (Scheme 50). That this reaction proceeded as superbly as it did was only the result of extensive prior investigative work on the part of the researchers to optimize the coupling conditions. In particular, it was found that the dienylstannane component **271** was exquisitely sensitive to traces of acid,[225] with the consequent protodestannylation of this partner competing with its coupling to allylic acetate **270**. Fortunately, the simple addition of a mild amine base (iPr$_2$NEt) to the reaction medium was found to be sufficient to suppress the undesired protodestannylative destruction of **271** almost completely. Of equal benefit was the discovery that only at reaction temperatures at or below 40 °C could coupling product **272** be obtained as the desired stereoisomer. At higher temperatures, significant amounts of the corresponding C9–C10 *Z* isomer of coupling product **272** were obtained. The formation of the latter was likely due to the erosion of stereochemical integrity of the presumed initially formed reactive π-allyl–palladium intermediate **276**, through competing thermal equilibration, to give a mixture of isomeric complexes **276** and **277** prior to coupling with stannane **271**. Nevertheless, with a practical and highly convergent route to coupled intermediate **272** thus secured, this compound was rapidly advanced to generate allylic carbonate **273**, the precursor for the second pivotal palladium-catalyzed reaction in the sequence, namely a Tsuji–Trost macrocyclization. To the researchers' delight, cyclization of precursor **273** to give the sought-after macrocycle **275** proved to be both remarkably facile and efficient and could be effected by simply treating a moderately dilute solution (0.05 M) of the starting material (**273**) in THF with [Pd$_2$(dba)$_3$] (10 mol%) at 45 °C. In this manner, the cyclized product **275** could be cleanly obtained in 60–85% yield and, interestingly, as a single diastereoisomer (i.e. only one stereoisomer at the newly formed C19 stereogenic center was produced in the cyclization event). The success of this reaction is undoubtedly due to the shrewd employment of a methyl carbonate as the allylic activating group. Carbonate groups enable irreversible palladium oxidative addition under mild conditions, promoted by the expulsion of a molecule of CO_2 and an alkoxide anion (in this case methoxide). This alkoxide anion serves a dual purpose in that, as with the analogous case in the synthesis of roseophilin discussed above, it also functions to deprotonate the activated β-ketoester methylene moiety, thus enabling the required ring closure. These spectacular examples clearly illustrate the practical utility of palladium-catalyzed carbon–carbon bond-formation processes via electrophilic π-allyl intermediates in the construction of complex molecules.

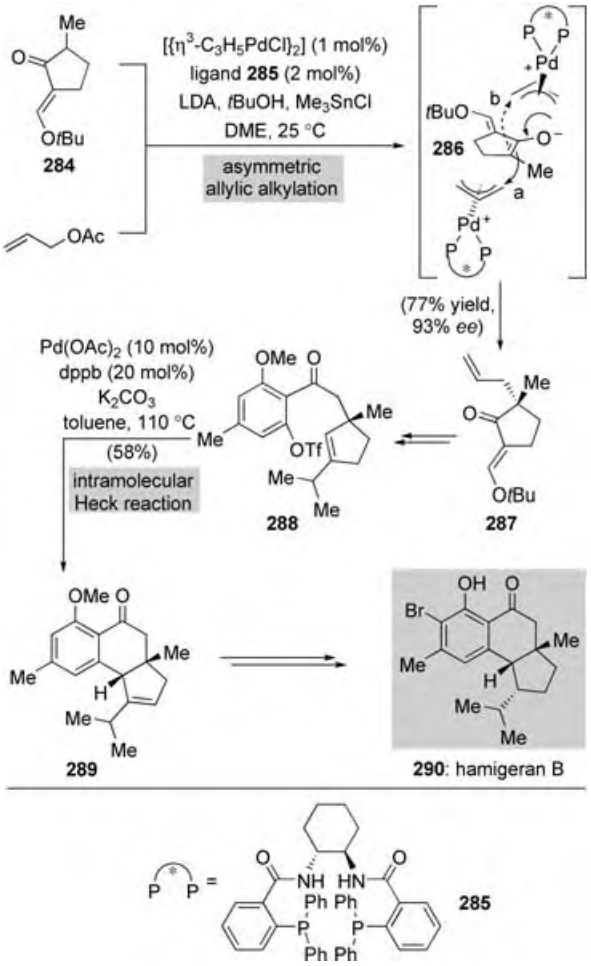
Scheme 50. Application of π-allyl Stille fragment-coupling and Tsuji–Trost macrocyclization reactions in the enantioselective synthesis of FR182877 (**132**) (Sorensen et al., 2003).[224]

The insertion of alkenes into π-allyl–palladium species is a key step in the carbocyclization of allylic electrophiles with alkenes, a process that represents a powerful method for the formation of five- and six-membered carbocyclic and heterocyclic ring systems.[226,227] The combination of palladium-catalyzed allylation and carbonylation reactions is especially attractive as it permits the (potentially stereoselective) formation of three carbon–carbon bonds plus the insertion of a ketone carbonyl group in a single step. The Oppolzer group has been one of the key pioneers and exponents of this methodology, the utility of which is magnificently demonstrated in their synthesis of the heteroyohimbine alkaloid 3-isorauniticine (**283**, Scheme 51).[228,229] Thus, the treatment of

Scheme 51. Application of an allylation/carbonylation cascade reaction in the enantioselective synthesis of 3-isorauniticine (**283**) (Oppolzer et al., 1991).[228]



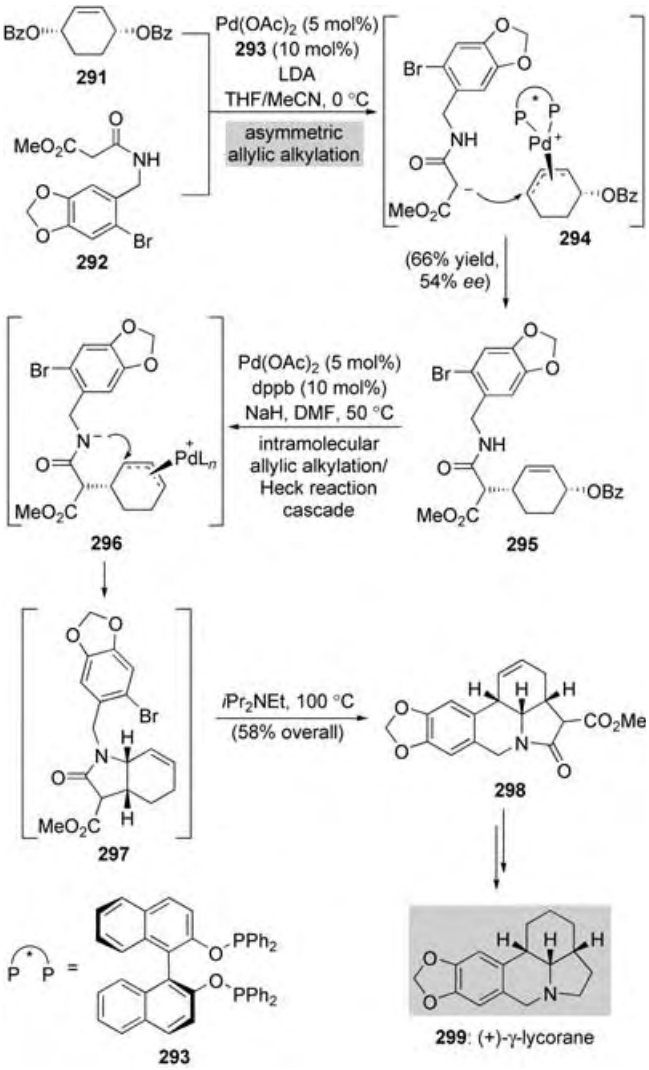
a solution of allylic carbonate **278** in AcOH with catalytic amounts of [Pd$_2$(dba)$_3$] (10 mol %) and P(nBu)$_3$ (30 mol %) at 80 °C under carbon monoxide (1 atm) initiated a highly orchestrated sequence of carbon–carbon bond-forming steps, which culminated in the diastereoselective construction of bicyclic enone **282** in reproducible yields of roughly 50 %. The first step in this sequence is the selective ionization of the allylic moiety within the starting material **278** by a Pd^0 complex, to generate π-allyl–palladium intermediate **279**. This species then undergoes a regioselective insertion into the pendant terminal alkene system (which in effect acts as the nucleophile to capture the electrophilic π-allyl–palladium complex) to form η^1-alkyl–palladium(II) intermediate **280**. This process can be formally considered as a suprafacial palladium-ene cyclization. The insertion of carbon monoxide into η^1-alkyl–palladium(II) intermediate **280** to generate the next intermediate **281** is evidently much faster than the undesired β-hydride elimination. Finally, acyl palladium(II) intermediate **281** undergoes a regioselective intramolecular Heck reaction to afford the observed product **282**. The overall yield for this process was, in fact, more impressive than the illustrated yield of 45–53 % would appear to indicate, as two minor stereoisomeric products, diastereoisomeric with

respect to **282** at the newly formed ring junction, were also formed in a combined yield of 25%. Thus, the preexisting C3 stereogenic center exerted a moderate influence on the diastereoselectivity of the cyclization cascade in generating the C15 and C20 stereocenters.

The development of procedures to induce asymmetry during palladium-catalyzed allylic alkylation reactions has dramatically enhanced the synthetic utility of this process.[230] Any discussion of the asymmetric allylic alkylation reaction is complicated somewhat by the fact that there are a number of different possible mechanisms of enantiodiscrimination, depending on the nature of the nucleophile and/or electrophile and at which point in the catalytic cycle the chiral elements are set. We can but highlight a few of the more commonly applied types of processes here. Nevertheless, the ability to generate stereochemical complexity from simpler (often achiral) starting materials by using only catalytic quantities of chiral ligands, and equally significantly, in a reliable, predictable, and selective fashion, has propelled the asymmetric allylic alkylation reaction to the forefront of modern synthetic methodology.[231]

While stabilized carbanions (e.g. those derived from β-ketoesters or malonate-type compounds) have traditionally been, and indeed continue to be, the most widely used carbon nucleophiles in the asymmetric allylic alkylation reaction,[232] there has been considerable interest in expanding the scope of this process to include a broader range of nucleophiles. The Trost group has been instrumental in pioneering the recent development of viable protocols for the asymmetric alkylation of ketone enolates,[233] arguably the most synthetically useful class of potential nucleophiles, and has applied this to an elegant synthesis of hamigeran B (**290**),[234] an antiviral metabolite isolated from the marine sponge *Hamigera tarangaensis*.[235] As shown in Scheme 52, the synthetic route adopted called for the early installation of the methyl-group-bearing quaternary stereocenter, and this was fashioned by the asymmetric alkylation of cyclic ketone **284**. Under the optimum conditions shown, the desired alkylated product was readily obtained in excellent yield (77%) and with remarkable enantiopurity (93% *ee*) at ambient temperature. The basis of the enantioselectivity of this alkylation resides in the differentiation between the prochiral faces of the nucleophile by the π-allyl complex. Evidently, the chiral environment created around the π-allyl–palladium complex by the bidentate ligand **285** is sufficient to direct the alkylation almost exclusively towards the "bottom" face of enolate intermediate **286**,[236] that is, path a is significantly favored over path b.

Following the elaboration of ketone **287** to give triflate **288**, it was envisaged that the final carbon–carbon bond could be forged by means of an intramolecular Heck reaction. Indeed, it was found that treatment of triflate **288** with $Pd(OAc)_2$ (10 mol%), dppb (20 mol%), and K_2CO_3 in refluxing toluene led to cyclization furnishing, stereoselectively, the desired *cis*-fused tricyclic compound **289** in 58% yield. Critical to the success of this venture was the employment of carbonate rather than tertiary amine bases, since the use of the latter led to simple hydrogenolysis of the triflate moiety without cyclization occurring. A few more steps then completed the total synthesis.[237] In the sense that the



Scheme 52. Use of asymmetric allylic alkylation and intramolecular Heck reactions in the total synthesis of hamigeran B (**290**) (Trost et al., 2004).[234]

stereoselectivity of formation of the remaining two stereogenic centers in the final target molecule **290** was directed by the initially installed quaternary center, all the chiral elements in the final product were thus installed through the asymmetric allylic alkylation reaction.[238] Very recently, the Stoltz[239] and Trost groups[240] independently reported the extension of the palladium-catalyzed enantioselective allylation reaction to produce a broader range of ketone derivatives bearing quaternary stereocenters, through the asymmetric decarboxylative alkylation of the corresponding allyl enol carbonate precursors.

One of the most useful and widely applied classes of asymmetric π-allyl–palladium reactions is the catalytic desymmetrization of *meso* substrates. Readily available *meso*-2-alkene-1,4-diol derivatives, typically contained within cyclic structures, are the most commonly employed electrophilic substrates. As an example of such an application in total synthesis, we highlight the concise enantioselective construction of the alkaloid γ-lycorane (**299**) by Mori and coworkers in 1995 (Scheme 53).[241] The key fragment-coupling step in this synthesis was the desymmetrization of *meso* dibenzoate **291** with the carbanion derived from amide **292** (generated with LDA), induced by catalytic amounts of

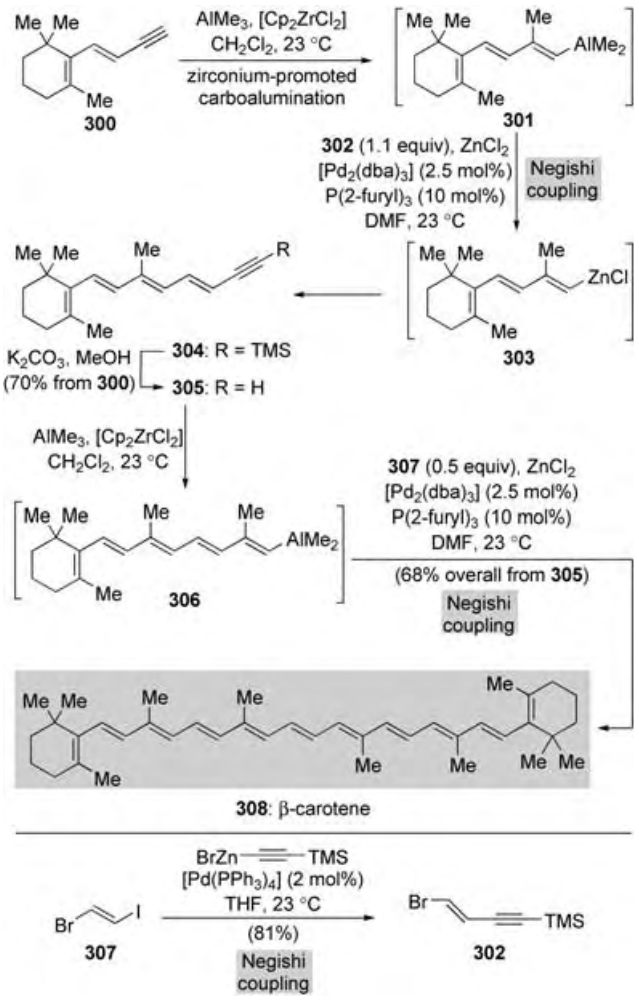
Scheme 53. Use of an asymmetric allylic alkylation reaction in the enantioselective total synthesis of (+)-γ-lycorane (**299**) (Mori et al., 1995).[241]

$Pd(OAc)_2$ (5 mol%) and chiral bis(phosphine) **293** (10 mol%). In this event, selective ionization of one of the two enantiotopic benzoate leaving groups, to generate π-allyl intermediate **294** preferentially, is induced by the chirality of the palladium–ligand complex and forms the basis of the asymmetric induction. Intermediate **294** is superficially similar to the π-allyl–palladium species we saw earlier in the course of the synthesis of strychnine (Scheme 47), and indeed the relative stereochemical outcome of both reactions is the same (i.e. net retention of configuration as the result of two subsequent inversions, nucleophilic attack at the less-hindered terminus of the π-allyl system). However, the two reactions differ fundamentally in how the absolute stereochemistry of the respective products **252** and **295** is introduced. In the present case, an achiral starting material **291** is converted into an enantioenriched product **295** through the action of a chiral, enantiomerically pure catalyst system, whilst in the synthesis of strychnine a chiral starting material **250** is converted into a chiral product **252** under the influence of an achiral catalyst system. It should be mentioned that the enantioselectivity of the alkylation to generate γ-lycorane intermediate **295** is, by modern standards, only moderate (54% *ee*). Indeed, asymmetric alkylations of similar substrates with newer generations of chiral ligands (e.g. **285**, Scheme 52) routinely proceed with greater than 95% *ee*.[242]

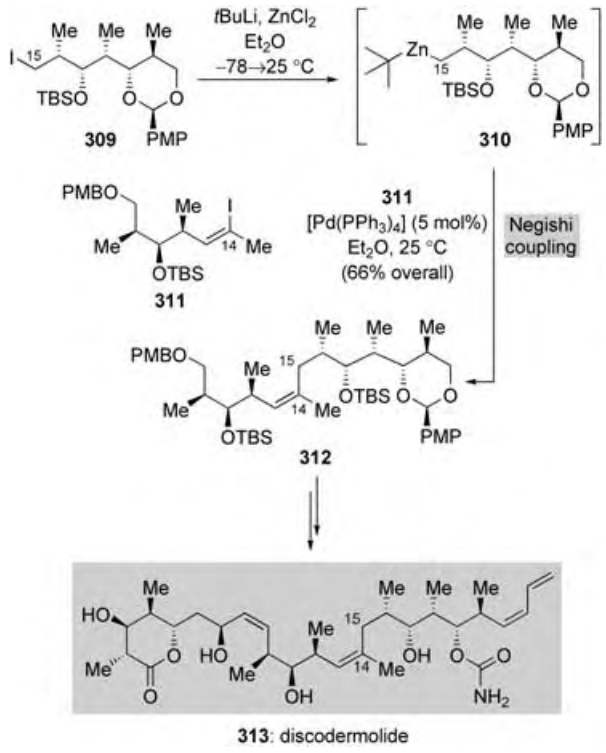
With the alkylated product **295** in hand, the remaining major obstacle separating the researchers' position from the final product was the task of fusing the remaining two rings of the natural product to the cyclohexene scaffold. In a masterful piece of synthetic planning, based on the recognition that intermediate **295** still retains an allylic ester moiety itself capable of undergoing a palladium-catalyzed nucleophilic displacement, the researchers reasoned that this task could be accomplished in a single operation directly from **295**, through the application of an unprecedented, intramolecular allylic alkylation/Heck reaction cascade sequence. Thus, treatment of amide **295** with $Pd(OAc)_2$ (5 mol%), dppb (10 mol%), and NaH in DMF at 50 °C triggered the initial intramolecular allylic alkylation to generate the presumed intermediate **297**, which upon the addition of iPr_2NEt followed by further heating to 100 °C, obligingly underwent the anticipated intramolecular Heck cyclization to afford pentacyclic compound **298** in 58% yield as a single diastereoisomer. Note that the regio- and stereochemical outcome of both the Heck and the (formal) S_N2' displacement steps were dictated solely by steric effects and constraints of the starting material **295**, hence the need for chiral ligands in this transformation was obviated. From this and the other examples discussed above, it is clear that the Tsuji–Trost reaction represents an extraordinarily useful method for carbon–carbon bond formation, yet it can be argued that the true potential of this process, in particular its asymmetric version, has only begun to be tapped.

7. The Negishi Reaction



In the context of total synthesis, the Negishi coupling would appear to have been relatively underutilized, in particular having been overshadowed to a large extent by the developments in the Stille and Suzuki reactions. Nevertheless, recent years have seen renewed interest in the Negishi coupling which, in appropriate cases, is often the cross-coupling method of choice for a given synthetic task. The two classes of organozinc reagents that find most use in Negishi couplings are diorganozinc species (R_2Zn) and organozinc halides (RZnX). The latter, typically prepared either by the direct insertion of zinc (zinc dust) into organic halides or by transmetalation from other organometallic species, are particularly useful when functionalized zinc reagents are required.[243] Despite their only moderate reactivity towards many organic electrophiles, organozinc reagents are among the most reactive of nucleophilic species in palladium-catalyzed cross-coupling reactions, owing to their ability to undergo rapid transmetalation with transition-metal salts, most notably those of palladium. The Negishi reaction is particularly powerful when applied in an intermolecular context in fragment-coupling processes, often succeeding in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

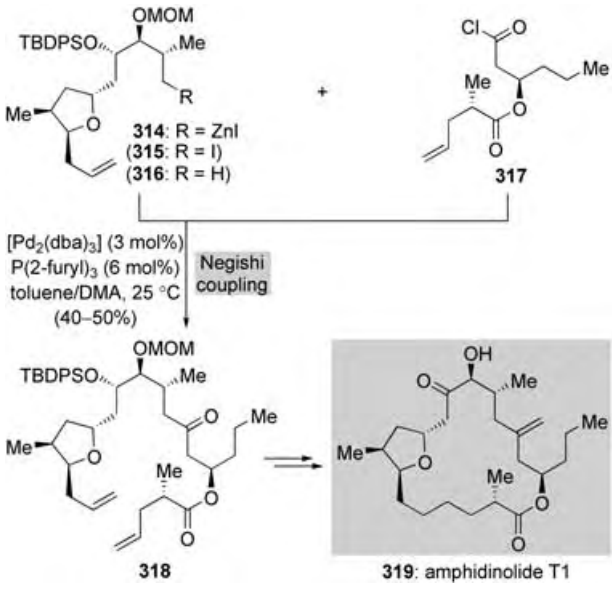


cases in which the corresponding Stille or Suzuki reactions founder. Alkyl–zinc reagents readily enter into the cross-coupling process, expanding the scope of the Negishi reaction beyond standard $C(sp^2)$–$C(sp^2)$ couplings. The major drawback of the Negishi coupling, at least by comparison with the Stille and Suzuki reactions, is the incompatibility of organozinc reagents with many common functional groups, together with their relative sensitivity towards oxygen and water.[244]

An elegant and instructive example of the utility of this coupling reaction to assemble conjugated polyene systems rapidly in high yield and with excellent stereoselectivity is the novel, general synthetic route to the carotenoids reported by the Negishi group.[245] As shown in Scheme 54 for the synthesis of β-carotene (**308**), the key feature of the researchers' approach was the regio- and stereoselective zirconium-catalyzed methylalumination of terminal alkyne precursors, followed by cross-coupling of the resulting vinyl alane intermediates with the appropriate vinyl halide electrophiles. These remarkable carbon–carbon bond-forming processes, each involving four different organometallic intermediates and three transmetalation processes (Zr→Al→Zn→Pd) proceed with remarkable overall efficiency and stereoselectivity, allowing the synthesis of the target molecule **308** in greater than 99% stereoisomeric purity and in only three operations from the starting alkyne **300**! This synthetic route would appear to compare favorably to traditional syntheses of carotenoids proceeding through the venerable Wittig or Horner–Wadsworth–Emmons reaction protocols, which are often plagued by low yields and the formation of stereoisomeric mixtures. Carbometalation (and, by extension, hydrometalation)/cross-coupling tandem processes of the type illustrated here are only made viable by the fast rate of the key transmetalation events to and from the zinc salt, as in its absence such coupling processes are often agonizingly lethargic. This principle of "double metal catalysis",[246] first introduced more than 25 years ago, offers considerable potential for the streamlining of synthetic processes.[247]

As a prime exemplar of both the utility of the Negishi reaction in fragment coupling reactions and the employment of alkyl zinc reagents in these processes to form $C(sp^2)$–$C(sp^3)$ bonds, we highlight here the gram-scale synthesis of the clinically relevant microtubule-stabilizing agent discodermolide (**313**, Scheme 55) by the Smith group.[248,249] In this approach, the two fragments **309** and **311** were coupled to forge the C14–C15 bond of the target product. Significantly, it was found that optimum results in this coupling reaction were obtained only when 3 equivalents of *t*BuLi were employed in the initial lithium–halogen exchange process; when the customary 2 equivalents were used, a 1:1 mixture of the iodide starting material **309** and the expected product **312** was obtained. This led to the proposal that, in this case, the mixed *tert*-butyl alkyl zinc intermediate **310** was in fact the reactive

Scheme 54. Negishi coupling reactions in the total synthesis of β-carotene (**308**) (Negishi and Xeng, 2001).[245]



Scheme 55. Application of a Negishi fragment-coupling reaction in the enantioselective synthesis of discodermolide (**313**) (Smith et al., 2000).[248]

alkyl donor in the cross-coupling step (note then the selective transfer of the primary alkyl group from intermediate **310**), rather than the expected organozinc halide species (RZnI). The researchers also demonstrated the clear superiority of the Negishi protocol over both the palladium-catalyzed Grignard and *B*-alkyl Suzuki coupling, together with cuprate-based procedures, for the union of fragments **309** and **311**. Of no less significance, particularly from a material throughput point of view, was that the reaction proceeded efficiently when using a nearly equimolar ratio of the two coupling partners (**309**/**311** 1.1:1). In contrast, many cross-coupling reactions require a larger excess of one or the other coupling partner in order to proceed to completion, which can be particularly wasteful if it is a valuable, hard-won intermediate that has to be sacrificed in this manner.[250]

The palladium-catalyzed acylation of organozinc reagents with acid chlorides provides a convenient route to unsymmetrically substituted ketones.[251] Given the attenuated reactivity of organozinc compounds, overaddition of the reagent to the ketone product is not usually a troublesome issue in these reactions, which allows the production of a wide variety of alkyl, alkenyl, and aryl ketone systems in good yield and under mild conditions. One of the most elaborate examples of an acyl-Negishi coupling reported to date is that leading to the formation of ketone **318** (Scheme 56), an advanced intermediate in the synthesis of the marine-derived macrolide amphidinolide T1 (**319**) by Fürstner and co-workers.[252] Thus, after a considerable amount of experimentation, it was found that exposure of alkyl zinc iodide species **314** (R = ZnI), derived from the corresponding primary alkyl iodide (**315**, R = I) by treatment with a zinc/copper couple, to the enantiomerically pure acid chloride **317** in the presence of $[Pd_2(dba)_3]$ (3 mol%) and P(2-furyl)$_3$ (6 mol%) in a toluene/DMA mixed solvent system at ambient temperature led to coupling to give the desired ketone **318** in yields between 40 and 50%. Despite the researchers' best efforts, a significant amount (typically 20–30%) of the reduced compound **316** (R = H) was always also formed in this reaction. Nevertheless, sufficient quantities of the pivotal intermediate **318** could be secured by this route to enable the execution of the remaining few steps required to complete the total synthesis.

Scheme 56. Use of an acid chloride as the electrophile in the Negishi coupling in the total synthesis of amphidinolide T1 (**319**) (Fürstner et al., 2003).[252]

A selection of other architecturally intriguing natural products that have been the target of total syntheses involving Negishi couplings as key carbon–carbon bond-forming steps are highlighted in Scheme 57: reveromycin B (**320**) (Theodorakis and Drouet, 1999),[253] papulacandin D (**321**) (Barrett and co-workers, 1996),[254] longithorone A (**322**) (Shair and co-workers, 2002),[255] and xerulin (**323**) (Negishi and co-workers, 2000).[256] The carbon–carbon bond(s) formed in each case is(are) shown, and while such a cursory overview of the state of the art can neither be comprehensive nor do full justice to the remarkable developments in the field and the efforts of the many researchers involved who could not be acknowledged, it can hopefully serve to emphasize how the Negishi

Scheme 57. Selected examples of natural products syntheses employing Negishi reactions (the C–C bonds formed by this cross-coupling process are highlighted with circles): reveromycin B (**320**) (Theodorakis and Drouet, 1999),[253] papulacandin D (**321**) (Barrett et al., 1996),[254] longithorone A (**322**) (Shair et al., 2002),[255] and xerulin (**323**) (Negishi et al., 2000).[256]

coupling reaction offers the synthetic chemist a plethora of opportunities for carbon–carbon bond-forming operations.

8. Summary and Outlook

As amply demonstrated above, total synthesis has benefited enormously from the palladium-catalyzed cross-coupling reactions that have emerged in the last few decades. These marvelous tools allow the artisans of this flagship discipline of chemical synthesis to flourish and produce some of the most stunning masterpieces in the history of total synthesis. To be sure, the ever-growing expansion of these carbon–carbon bond-forming reactions into new vistas will undoubtedly enable even more impressive accomplishments in the future.

Just as the Grignard, Diels–Alder, Wittig, and hydroboration reactions as well as asymmetric oxidation and hydrogenation of double bonds enabled quantum leaps in our ability to construct complex molecules in the laboratory, so do the carbon–carbon cross-coupling reactions. In particular, these processes do not require the preparation of reactive intermediates prior to the carbon–carbon bond-forming event. Rather, they proceed by activation of stable and readily available starting materials in situ and, therefore, are both more practical and often more efficient in terms of overall yield. And beyond these processes, and fortunately for synthetic chemists, who have been empowered so much by them, a new group of reactions catalyzed by transition metals have appeared on the horizon. These powerful processes are known collectively as metathesis reactions, and their impact in total synthesis is discussed in the following Review article.[257]

Abbreviations

9-BBN	9-borabicyclo[3.3.1]nonane
binap	2,2′-bis(diphenylphosphino)-1,1′-binaphthyl
Bn	benzyl
Boc	*tert*-butoxycarbonyl
Bz	benzoyl
Cbz	benzyloxycarbonyl
Cp	cyclopentadienyl
dba	dibenzylideneacetone
DCC	1,3-dicyclohexylcarbodiimide
DMA	*N*,*N*-dimethylacetamide
DMAP	4-dimethylaminopyridine
DME	ethylene glycol dimethyl ether
DMF	*N*,*N*-dimethylformamide
DMSO	dimethyl sulfoxide
dppb	1,4-bis(diphenylphosphino)butane
dppe	1,2-bis(diphenylphosphino)ethane
dppf	1,1′-bis(diphenylphosphino)ferrocene
Fmoc	9-fluorenylmethoxycarbonyl
LDA	lithium diisopropylamide
MOM	methoxymethyl
M.S.	molecular sieves
NMP	1-methyl-2-pyrrolidinone
Piv	pivaloyl
PMB	4-methoxybenzyl
PMP	4-methoxyphenyl
SEM	2-(trimethylsilyl)ethoxymethyl
TBAF	tetra-*n*-butylammonium fluoride
TBDPS	*tert*-butyldiphenylsilyl
TBS	*tert*-butyldimethylsilyl
Teoc	2-(trimethylsilyl)ethoxycarbonyl
TES	triethylsilyl
Tf	trifluoromethanesulfonyl
THP	2-tetrahydropyranyl
TIPS	triisopropylsilyl
TMS	trimethylsilyl
Ts	4-toluenesulfonyl

It is with enormous pride and great pleasure that we thank our collaborators whose names appear in the references cited and whose contributions made the described work so rewarding and enjoyable. We also acknowledge helpful discussions with Professor Phil S. Baran. We gratefully acknowledge the National Institutes of Health (USA), the Skaggs Institute for Chemical Biology, the George E. Hewitt Foundation, Amgen, Merck, Novartis, and Pfizer for supporting our research programs.

[171] The reasoning behind the use of the *Z*-configured trisubstituted alkene motif in borane **187** was the recognition that *Z* alkenes consistently provide higher levels of enantioselectivity in asymmetric Heck reactions than do their *E*-disposed counterparts; for a similar example, see: T. Takemoto, M. Sodeoka, H. Sasai, M. Shibasaki, *J. Am. Chem. Soc.* **1993**, *115*, 8477 – 8478.
[172] Similar reactions for the preparation of indole and furan systems have been reported by Larock and co-workers, see: a) R. C. Larock, E. K. Yum, M. J. Doty, K. K. C. Sham, *J. Org. Chem.* **1995**, *60*, 3270 – 3271; b) R. C. Larock, E. K. Yum, M. D. Refvik, *J. Org. Chem.* **1998**, *63*, 7652 – 7662.
[173] A palladium-catalyzed domino reaction has also been employed in the total synthesis of the structurally related natural product (+)-xestoquinone, in this case an elegant tandem catalytic asymmetric Heck cyclization cascade: S. P.

Maddaford, N. G. Andersen, W. A. Cristofoli, B. A. Keay, *J. Am. Chem. Soc.* **1996**, *118*, 10766 – 10773.

With the exception of palladium-catalyzed cross-couplings, no other group of reactions has had such a profound impact on the formation of carbon–carbon bonds and the art of total synthesis in the last quarter of a century than the metathesis reactions of olefins, enynes, and alkynes. Herein, we highlight a number of selected examples of total syntheses in which such processes played a crucial role and which imparted to these endeavors certain elements of novelty, elegance, and efficiency. Judging from their short but impressive history, the influence of these reactions in chemical synthesis is destined to increase.

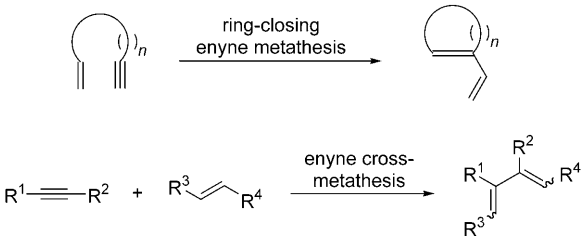
1. Introduction

Ever since the birth of the art of organic synthesis, as marked by Wöhler's synthesis of urea in 1828, progress in this field has, to a large degree, been dependent on our ability to construct carbon frameworks through carbon–carbon bond-forming reactions. The Grignard,[1] Diels–Alder,[2] and Wittig reactions[3] are three of the most prominent such processes that played decisive roles in shaping the science of chemical synthesis as we know it today. During the last quarter of the previous century, two more such reactions emerged as rivals to the aforementioned carbon–carbon bond-forming processes: the palladium-catalyzed cross-coupling reactions and those collectively known as metathesis reactions. As a most stringent test, total synthesis often serves as a measure of the power of a given reaction. Surveys of relevant applications of enabling reactions are, therefore, of importance in that they not only help to underscore the scope and generality of such processes in chemical synthesis, but they also serve to place into perspective that particular reaction within the field, and to inspire future improvements and new applications. In the preceding Review in this issue ("Palladium-Catalyzed Cross-Coupling Reactions in Total Synthesis"),[4] such a critical analysis was provided. The purpose of this Review is to do the same for the alkene, enyne, and alkyne metathesis reactions.[5]

Alkene metathesis, in all its various guises (Scheme 1), has arguably influenced and shaped the landscape of synthetic organic chemistry more than any other single process over the last 15 years.[6] The wealth of synthetic transformations that can be accomplished when this reaction is applied to appropriate substrates is astonishing, since the same catalyst (initiator) systems can promote several different types of reactions, depending on the substrates and reaction conditions employed. The history of alkene metathesis is a fascinating one, beginning with its serendipitous discovery nearly 50 years ago through to the design and application of the latest initiators available today.[7] The elucidation of the mechanistic pathway was, itself, the culmination of nearly two decades of extensive, if not collaborative or competitive, research by numerous groups, and the subject of lively debate in the literature during that period. The generally accepted mechanism of alkene metathesis was originally proposed by



Scheme 1. The most commonly employed alkene-metathesis reactions in organic synthesis.

Hérisson and Chauvin in 1971,[8] with key experimental evidence for its validity subsequently being provided by the Casey,[9] Katz,[10] and Grubbs groups,[11] and invokes metal carbene intermediates as key propagating species in the catalytic cycle. From a practical viewpoint, a key milestone in the evolution of alkene metathesis was the demonstration by Katz and co-workers in 1976 that single-component, well-defined tungsten carbenes, for example $Ph_2C{=}W(CO)_5$, could initiate alkene metathesis without added coactivators.[12,13] This discovery ushered in the modern era of rational catalyst design, and after further development, the alkene-metathesis reaction has developed into one of the most powerful carbon–carbon bond-forming reactions currently available to the synthetic chemist.

Although alkene metathesis constitutes, by far, the most widely utilized type of metathesis reaction, recent years have witnessed the discovery and development of a number of related processes employing a broader range of substrates. Prominent amongst these is the enyne-metathesis reaction, which involves the union of an alkene with an alkyne to form a 1,3-diene system (Scheme 2).[14] Unlike the corresponding

Scheme 2. Enyne-metathesis reactions in organic synthesis.

alkene-metathesis reactions, enyne metatheses are wholly atom economical (that is, no olefin-containing by-product is released during the process)[15] and are therefore driven by enthalpic rather than entropic factors, principally the stability of the conjugated diene system thus produced. Another distinction is that enyne metathesis can occur by any one of several independent mechanistic pathways, with the course of the reaction being dictated by whether metal carbene species or low-valent transition-metal complexes mediate the process, although the net outcome is (usually) the same. The enyne-metathesis reaction was discovered by Katz and his group, who reported the first examples of this process in 1985 in the presence of catalytic amounts of tungsten Fischer carbene complexes.[16] At the same time, these workers proposed the currently accepted mechanism for this type of process, invoking a sequence of [2+2] cycloaddition and cycloreversion steps involving metal carbene species, which closely parallels the mechanism of alkene metathesis. Subsequently, the Trost group documented the cycloisomerization of 1,*n*-enyne systems in the presence of palladium(II) complexes to generate 1,3-diene systems, which formally arise as the result of enyne ring-closing metathesis, yet proceed through non-carbenoid mechanistic pathways.[17] This type of transformation forms an important subset of a larger class of transition-metal-mediated reactions.[18–20] This transformation can also be effected by complexes of a number of other late transition metals, including ruthenium,[21] iridium,[22] and platinum.[23] Nevertheless, in terms of both scope and frequency of use, the metal carbene mediated reactions are the most widely employed among the enyne-metathesis processes.

Most recently, it has proven to be the turn of alkyne metathesis to emerge from the shadow of alkene metathesis and become a valuable addition to the armory of the synthetic chemist in its own right.[24] Unlike enyne metathesis, alkyne metathesis is a direct analogue of the alkene-metathesis reaction and involves the mutual exchange of alkylidyne units between two acetylene moieties (Scheme 3). Alkyne meta-

Scheme 3. Alkyne-metathesis reactions in organic synthesis.

thesis can be applied in both inter- and intramolecular contexts, although the application and development of these processes in the field of total synthesis is still very much in its infancy. The first examples of homogeneously catalyzed alkyne-metathesis reactions were reported by Mortreux and Blanchard in 1974,[25,26] with a mechanistic rationale (involving a Chauvin-type series of metal carbyne and metallacyclobutadiene intermediates as the propagating species) being put forward by Katz and McGinnis less than a year later.[10] As was the case with alkene metathesis, however, the acknowledgment that alkyne metathesis could serve as a synthetically useful tool in the construction of complex molecules would be postponed until the development of newer generations of more practical catalyst systems that could operate efficiently under mild conditions and in the presence of sensitive functionality. Breakthroughs in alkyne-metathesis chemistry within the last decade, largely spearheaded by the pioneering work of the Bunz and Fürstner groups, include the development of practical, selective ring-closing and intermolecular (cross) alkyne-metathesis versions. These processes are often complementary to the corresponding alkene-metathesis reactions and have propelled this field to the forefront of the emerging metathesis technology.

The impact of K. C. Nicolaou's career on chemistry, biology, and medicine flows from his contributions to chemical synthesis, which have been described in numerous publications and patents. His dedication to chemical education is reflected in his training of hundreds of graduate students and postdoctoral fellows. His Classics in Total Synthesis series, which he has co-authored with his students Erik J. Sorensen and Scott A. Snyder, are used around the world as a teaching tool and source of inspiration for students and practitioners of the art of chemical synthesis.

Paul G. Bulger was born in London (UK) in 1978. He received his M.Chem in 2000 from the University of Oxford, where he completed his Part II project under Dr. Mark G. Moloney. He obtained his D.Phil in chemistry in 2003 for research conducted under Professor Sir Jack E. Baldwin. In the fall of 2003, he joined Professor K. C. Nicolaou's group as a postdoctoral researcher. His research interests encompass reaction mechanism and design and their application to complex natural product synthesis and chemical biology.

In this Review, we highlight a number of total syntheses that feature one or more of these transition-metal-catalyzed carbon–carbon bond-forming reactions, and we hope to underscore their power in chemical synthesis.[27]

2. The Alkene-Metathesis Reaction

The alkene-metathesis reaction is the most commonly employed of the metathesis-based carbon–carbon bond-forming reactions. In the context of total synthesis, it has been primarily the alkene ring-closing metathesis reaction and, more recently, the alkene cross-metathesis reaction that have found the most widespread and gainful use. The success of the alkene-metathesis reaction and the many stunning and ingenious situations in which it has been applied are largely due to the advent of today's readily available catalyst systems that display high activity and excellent functional-group tolerance. The three such catalysts most routinely used by organic chemists (all of which are commercially available) are shown in Figure 1. The molybdenum-based catalyst **1** was

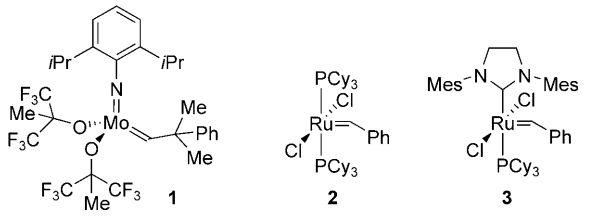

Figure 1. Commonly used alkene metathesis initiators (catalysts).

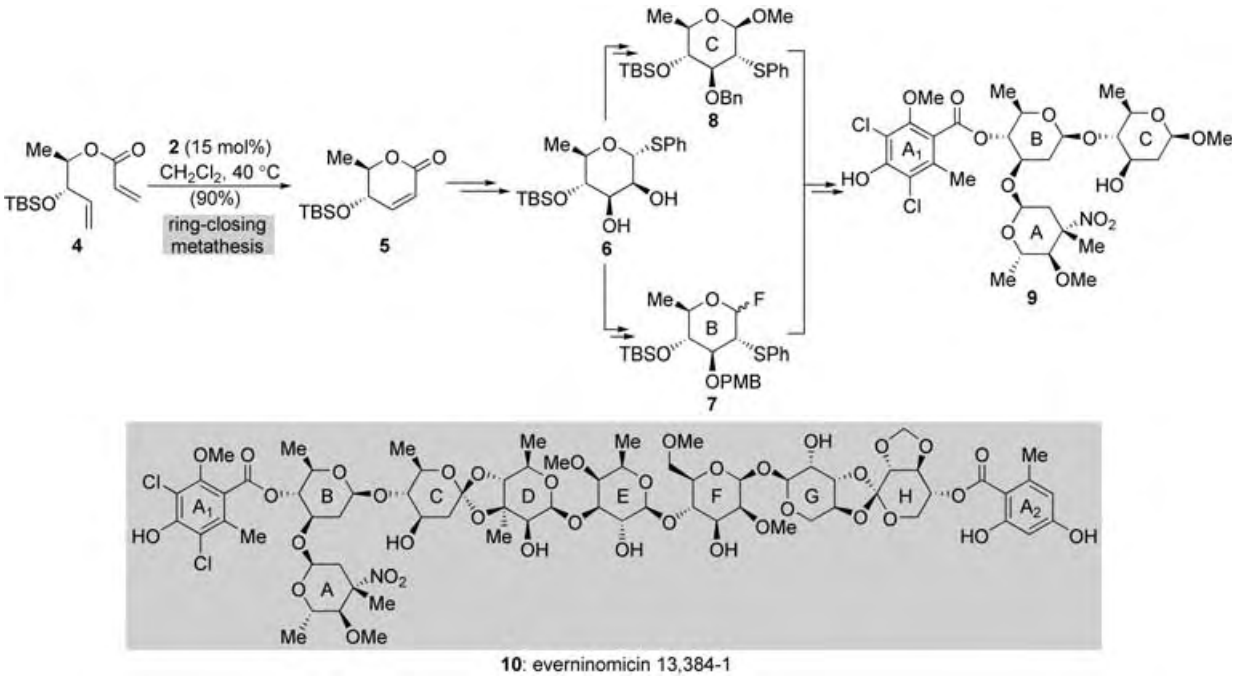
introduced by the Schrock group in 1990,[28] and represented the first real groundbreaking advance in catalyst design since the tungsten carbenes initially used by Katz and co-workers.[12] Catalyst **1** displays superb metathesis activity with a wide variety of alkene substrates, and is particularly useful for the formation of sterically crowded systems.[29] The singular drawback of catalyst **1** is its pronounced sensitivity to oxygen, moisture, and certain polar or protic functional groups owing to the electrophilicity of the high-oxidation-state transition-metal center.[30] Grubbs and co-workers subsequently introduced ruthenium-based carbene complexes,[31] initially optimized to **2**,[32] as general and practical metathesis catalysts.



David Sarlah was born in Celje, Slovenia in 1983. He is currently student in the Faculty of Chemistry and Chemical Technology, University of Ljubljana (Slovenia). Since 2001, he has been a research assistant at the Laboratory of Organic and Medicinal Chemistry at the National Institute of Chemistry (Slovenia) where he carried out research on asymmetric catalysis under the direction of Dr. B. Mohar. During the summer of 2004, he was engaged in total synthesis endeavors as a member of the azaspiracid team under Professor K. C. Nicolaou.

Although less active than the Schrock molybdenum-based systems **1**, the "first-generation" Grubbs initiator **2** exhibits much greater functional-group tolerance and has opened up new vistas in synthetic applications, most notably in the total synthesis of complex products, both natural and designed. Recent developments in catalyst (re)design have focused largely on the specific tailoring of catalyst reactivity through modifications of the ancillary ligands bound to the ruthenium center. In particular, the replacement of one of the phosphine ligands in **2** with an N-heterocyclic carbene ligand,[33] as reported independently by several groups,[34,35] increases the catalytic activity, thermal stability, and functional-group tolerance of the complex. The "second-generation" catalyst **3** engenders metathesis reactions with particularly high levels of activity, in certain cases approaching that of the Schrock system **1**, and with a unique reactivity profile that nicely complements both earlier catalysts **1** and **2**.[36] Despite these advances, the search for increasingly efficient and selective metathesis catalysts continues unabated.[37] It should be mentioned that the complexes used in metathesis reactions are more accurately described as "initiators" rather than "catalysts", since they are generally not recovered unchanged at the end of the process. Nevertheless, the use of the term "catalyst" is so entrenched in the metathesis literature that, in this Review, we use both descriptors interchangeably, being mindful of the somewhat lax use of terminology that results.

2.1. Alkene Ring-Closing Metathesis

Alkene ring-closing metathesis has developed into one of the most powerful and reliable methods for ring formation. A seemingly limitless array of ring systems, be they common, medium or large, carbocyclic or heterocyclic,[38] can be fashioned by this tool, with the limits of its feasibility continually being probed and expanded. Alkene ring-closing metathesis reactions are now so routinely embedded within multistep target-oriented synthesis that the complexity of the target molecule can obscure possible connections to the metathesis event. A case in point is the early studies toward the synthesis of the ornate oligosaccharide antibiotic everninomicin 13,384-1 (**10**, Scheme 4) reported by the Nicolaou group.[39] In an effort to increase the degree of synthetic convergence, a strategy was sought that would enable the preparation of both the B- and C-ring carbohydrate building blocks from a common intermediate. Whilst the array of functionality present in these units in their final format (i.e. **10**) does not reveal any obvious metathesis disconnection, retrosynthetic analysis suggested that both **7** (B-ring) and **8** (C-ring) could likely be constructed from **6**, which in turn could be derived from α,β-unsaturated intermediate **5**. With simplification to this initial goal structure, the connection of these ring systems to metathesis becomes readily apparent. Indeed, the use of this metathesis-based strategy ultimately proved fruitful, as the complete tetracyclic $A_1B(A)C$-ring assembly (i.e. compound **9**) of the target compound **10** was synthesized following the alkene ring-closing metathesis of α,ω-diene **4** in the presence of the first-generation Grubbs ruthenium catalyst **2** (15 mol%, CH_2Cl_2, reflux, 90%

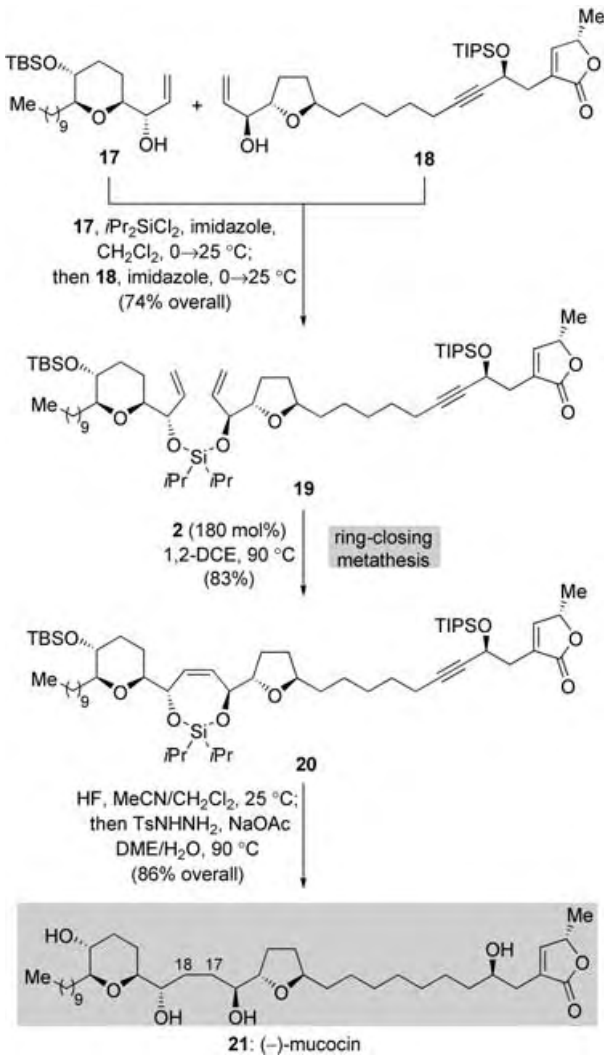
Scheme 4. Ring-closing metathesis in the fashioning of the B- and C-ring carbohydrates of everninomicin $A_1B(A)C$-ring model system (**9**) (Nicolaou and co-workers, 1998).[39]

yield).[40] Although this ring-closing reaction would appear far from groundbreaking today, the use of metathesis in this situation engendered a particularly concise feature to this complex natural product that would have otherwise been challenging to achieve with equal efficiency.[41]

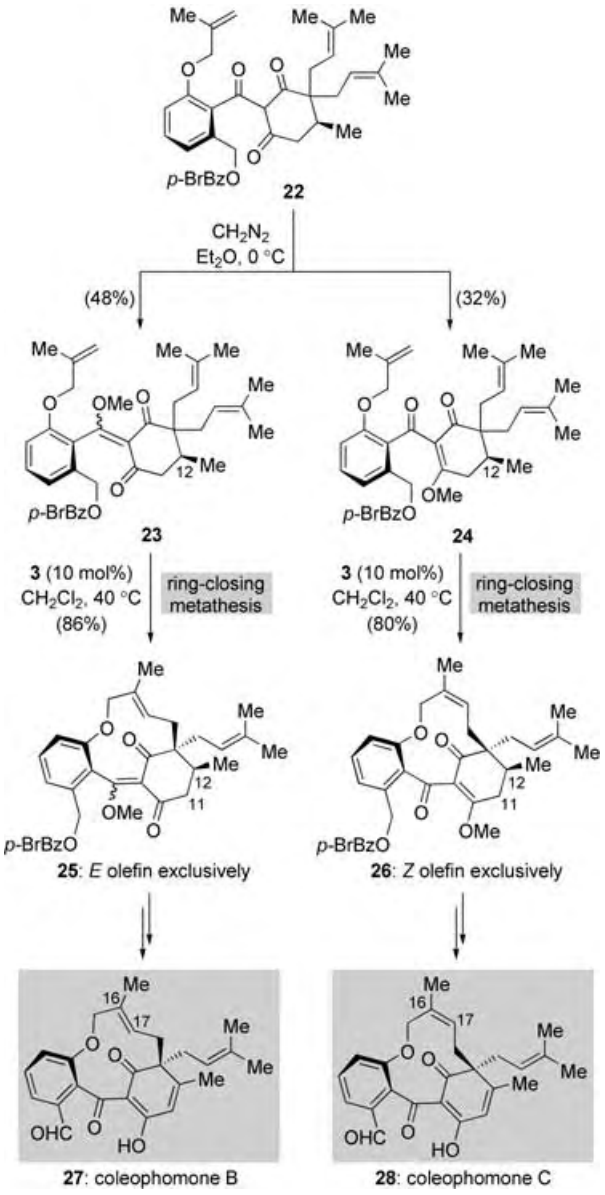


Brilliant use of olefin metathesis reactions in a complex setting was made by Wood and co-workers in their recent total synthesis of ingenol (**16**, Scheme 5).[42] The parent member of a large class of ingenane diterpenes, ingenol (**16**) has captivated the attention of synthetic chemists for more than 20 years.[43] The irresistible lure of this natural product is due partly to its promising biological activity,[44] but also to its rather remarkable polycyclic, highly oxygenated molecular architecture, the most distinctive feature of which is the strained "inside–outside" (*trans*) intrabridgehead stereochemistry of the bicyclic BC-ring system.[45] Indeed, the stereoselective synthesis of this motif has inspired several ingenious approaches, whilst at the same time proving to be the undoing of many more.[46,47] The Wood team proposed that it would be prudent to establish the stereochemical relationship between C8 and C10 before the formation of the BC-ring system, and that the latter task could be accomplished through a ring-closing-metathesis reaction (i.e. **13**→**15**). In an insightful piece of retrosynthetic analysis, they further proposed that **13** could, in turn, arise from diene **12**, the product of a ring-opening cross-metathesis reaction of the norbornene derivative **11**. Indeed, they found that the readily available, enantiomerically pure precursor **11** underwent smooth ring opening upon exposure to initiator **2** (2 mol%) under an ethylene atmosphere (1 atm) in CH_2Cl_2 at ambient temperature to afford diene **12** in nearly quantitative yield. Note that the alternative metathesis pathway available to precursor **11**, namely ring-opening-metathesis polymerization, was efficiently suppressed due to both the relatively high dilution conditions (initially 0.007 M in **11**) and the vast excess of (gaseous) ethylene employed.[48] Following the

Scheme 5. Ring-opening/cross-metathesis and ring-closing-metathesis reactions in the total synthesis of ingenol (**16**) (Wood and co-workers, 2004).[42]

uneventful advancement of diene **12** to give intermediate **13**, the stage was set for the pivotal ring-closing-metathesis reaction. While the team could take heart from previous model studies which had demonstrated the viability of related reactions,[49,50] its successful execution in the present case, and in such an elaborate setting, was by no means a foregone conclusion. To their delight, they found that the desired ring closure could, indeed, be effected in good yield (76%), provided that the novel "phosphine-free" catalyst **14** was employed. Introduced concomitantly and independently by the Hoveyda[51] and Blechert groups[52] in 2000, the cleverly designed complex **14** has proven itself to be a valuable alternative to the second-generation Grubbs catalyst **3** in ring-closing-metathesis processes, particularly in the formation of trisubstituted alkene systems. The incorporation of the cyclopentane A-ring into the cyclization precursor **13** was found to be essential for the formation of the strained BC-ring system by ring-closing metathesis to occur; it is presumed that the presence of this ring biases the conformation of the precursor such that the olefinic termini are in closer proximity and, thus, more amenable to undergo ring closure.[49] Whilst the "southern" portion of cyclized compound **15** looks relatively barren when compared with the targeted structure **16**, the trisubstituted allylic alcohol functionality concomitantly introduced into compound **15** during the metathesis event provided a sufficient handle for its ultimately victorious elaboration, over a number of steps, to the coveted final product **16**.[53]

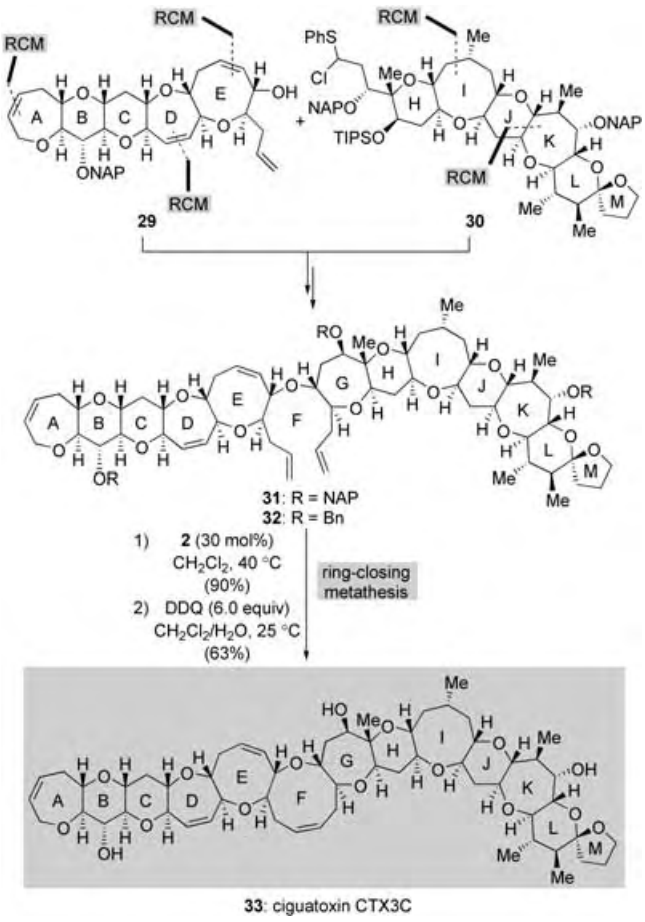
An interesting development in the alkene-metathesis field has been the employment of temporary silicon-based tethers in ring-closing-metathesis reactions, the utility of which has been elegantly exemplified in the total synthesis of the antitumor agent (−)-mucocin (**21**, Scheme 6) by Evans and co-workers.[54] Although the target compound **21** contains three rings that would appear to be prime candidates for construction through ring-closing metathesis, it was, in fact, only the C17–C18 carbon–carbon bond that was forged by this methodology. While this linkage could conceivably be formed through a selective cross-metathesis reaction (see below) between precursors **17** and **18**, it may not, at first glance, be readily apparent how it could be derived from a ring-closing-metathesis event. A clue lies in the two secondary hydroxy groups flanking the two sides of the C17–C18 bond in the target compound. Thus, if precursors **17** and **18** were to be linked together through these hydroxy groups, formation of the C17–C18 bond would then entail an intramolecular as opposed to an intermolecular process. This could endow the reaction with not only entropic advantages, but also higher levels of chemo-, regio-, and stereoselectivity. Temporary silicon tethers have proven to be versatile disposable linkers in a myriad of applications,[55] and the present case represents an instructive addition to this repertoire.[56,57] Thus, as shown in Scheme 6, the mixed bis(alkoxy)silane was readily formed by treatment of allylic alcohol **17** with excess diisopropyldichlorosilane to afford the corresponding monoalkoxychlorosilane, followed by the removal of the excess silylating agent and addition of the second allylic alcohol **18**. The cyclization of the silicon-tethered diene **19**, which can also be viewed as a fragment-coupling reaction, then proceeded as planned upon exposure to ruthenium carbene **2** in refluxing 1,2-dichloroethane. Referring to complex **2** as a "catalyst" would in this case be something of a misnomer, since an excess (180 mol% with respect to **19**, added slowly as a solution in 1,2-dichloroethane over 34 h) was required to drive the reaction to completion. This requirement did not come as a complete surprise to the team, as they had previously shown that the construction of *trans*-1,4-silaketals through ring-closing metathesis was often quite a challenging event.[58] Nevertheless, the cyclized (or coupled) product **20** was obtained in good yield (83%) without any competing and undesired participation of either the alkyne or the butenolide groups. Having fulfilled their various purposes in an exemplary manner, the three silicon groups in compound **20** were then cleaved upon exposure to hydrofluoric acid, with a subsequent chemoselective reduction of both the alkyne and the C17–C18 alkene groups with diimide then unveiling the final product **21**.[59,60]



Scheme 6. Use of a temporary silicon tether to facilitate a ring-closing-metathesis reaction in the enantioselective total synthesis of (−)-mucocin (**21**) (Evans and co-workers, 2003).[54]

There also has been a burgeoning interest in recent years in the formation of medium-sized rings through ring-closing metathesis.[61] An unfortunate complicating factor in this

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



application is that, in addition to the difficulties inherent in the construction of medium-sized rings by any cyclization method, the ring strain present in medium-sized cycloalkenes renders them rather prone to the reverse metathesis processes, namely ring-opening metathesis or ring-opening-metathesis polymerization. A commonly employed tactic to circumvent this problem is the incorporation of some form of conformational constraint (be it cyclic or acyclic) into the cyclization precursor, in order to force (or at least encourage) it to adopt a conformation suitable for ring closure, as was applied in the synthesis of ingenol described above. Another such application is in the total synthesis of coleophomones B (**27**) and C (**28**, Scheme 7) by the Nicolaou group.[62] These two compounds differ only in the geometry of the C16–C17 alkene located within the *ansa* bridge, and while a metathesis-based strategy to fashion this motif would seem particularly appealing, its viability in practice would rest on the answers to two key questions: 1) Would the formation of a trisubstituted alkene system in such a rigid, strained setting by ring-closing metathesis, in fact, be feasible? 2) If so, what would be the stereoselectivity of the process? The latter factor, which could hardly be anticipated a priori, clearly stood as a critical element in reaching both **27** and **28**. As events transpired, it was found that both isomers **27** and **28** could be obtained in their pure geometrical forms in separate metathesis reactions simply through the subtle modification of a common advanced intermediate. The final strategy towards these natural products is illustrated in Scheme 7. Thus, having reached the advanced staging area represented by intermediate **22** (itself a poor metathesis substrate), the rather labile tricarbonyl moiety was "protected" by treatment with CH_2N_2. This step was nonselective and led to the formation of both **23** and **24**, which differ only in the site at which methylation occurred; however, this result proved critical to the success of the overall approach. Separate exposure of **23** and **24** to catalyst **3** (10 mol%) in CH_2Cl_2 at reflux effected the desired metathesis to form the corresponding 11-membered cycloalkene ring systems in good yield, but as singular (and different) geometrical isomers. Remarkably, whereas the cyclization of **23** furnished the *E*-alkene-containing product **25** as the sole isomer, ring-closure of **24** afforded the corresponding *Z*-geometric isomer **26** exclusively. Furthermore, these metathesis reactions were also superbly diastereoselective, in that only the prenyl group *cis* to the vicinal C12 methyl group participated in each ring-closure. In hindsight, this outcome is plausible in light of the fact that such a reactive conformation would place the remaining prenyl group *trans* to the C12 methyl group, an arrangement that would correspond to a more favorable equatorial conformation for both groups on the cyclohexane ring. A few cursory modifications involving the introduction of the final C11–C12 alkene and global deprotection then provided the natural products **27** and **28** from these advanced intermediates **25** and **26**, respectively.[63]

Scheme 7. Stereoselective ring-closing-metathesis reactions in the total synthesis of coleophomones B (**27**) and C (**28**) (Nicolaou and co-workers, 2002).[62]

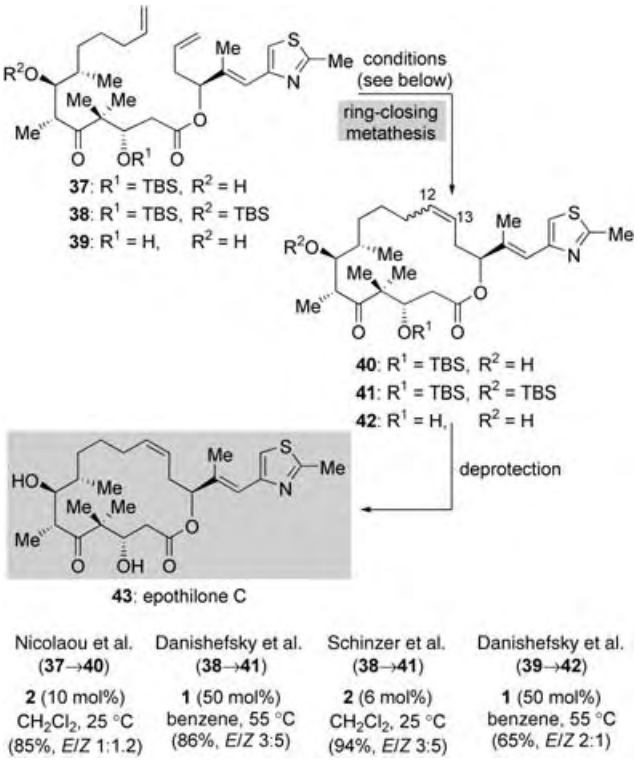
No fewer than six alkene ring-closing-metathesis reactions were used by Hirama and co-workers in their epic total synthesis of ciguatoxin CTX3C (**33**, Scheme 8).[64] Their convergent approach to the daunting polycyclic framework of this remarkable marine metabolite called for the synthesis of two separate fragments **29** and **30**, which correspond to the ABCDE- and HIJKLM-ring domains, respectively, followed by their late-stage union and subsequent formation of the final two ether rings. In the event, alkene ring-closing metathesis was employed in a diverse variety of settings, not only to construct rings A, D, and E in fragment **29**, but also, and perhaps rather less obviously, to forge rings I and J in the complementary hexacyclic fragment **30**. The successful union of the two domains **29** and **30** was then followed by a short sequence of steps to arrive at the advanced intermediate **31**. At this juncture the team was tantalizingly close to the target molecule and needed only to form the final (and thirteenth!) ether ring and then to liberate the three protected secondary hydroxy groups. That the formation of this nine-membered ring was left until the very end of the synthesis bears

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 8. Multiple use of ring-closing-metathesis (RCM) reactions in the total synthesis of ciguatoxin CTX3C (**33**) (Hirama and co-workers, 2002).[64]

testament to the confidence placed by the team in the reliability of the ring-closing-metathesis reaction, trust which had no doubt been garnered in part by its successful implementation at many earlier points in the route. Indeed, it was found that the treatment of diene **31** with initiator **2** (30 mol %) in CH_2Cl_2 at reflux effected the desired cyclization in an astonishing yield of 90 %. Ironically, whereas the potentially troublesome formation of the nine-membered ring proceeded perfectly, it was, in fact, the final deprotection step that caused the team the most consternation. Originally, they had labored heroically to produce the corresponding tris(benzyl ether) **32**, which also underwent efficient ring-closing metathesis to form the corresponding nine-membered ring, only to witness the destruction of most of this precious material during its deprotection to afford the target product **33**, as this step could be achieved in a maximum yield of only 7 %. Thus, in their "second-generation" synthesis, the corresponding 2-naphthylmethyl ether protecting groups were employed, with it being anticipated (and, much to their relief, experimentally demonstrated) that the final deprotection event would proceed much more efficiently.[64b] Indeed, by changing the nature of the protecting groups, the efficiency of this final step was increased by nearly an order of magnitude, occurring in 63 % yield.

It could be argued that some of the most spectacular applications of alkene ring-closing metathesis have been in effecting macrocyclizations. Indeed, one of the first reported uses of a ring-closing-metathesis reaction in total synthesis was the remarkably efficient macrocyclization of diene **34** (Scheme 9), catalyzed by the Schrock molybdenum carbene **1**,



Scheme 9. Ring-closing metathesis in the total synthesis of Sch 38516 (**36**) (Hoveyda and co-workers, 1996).[65]

in the synthesis of the antifungal agent Sch 38516 (**36**) by the Hoveyda group.[65] Early applications such as this, which were admirably daring at the time and which are still noteworthy today, paved the way for more ambitious and challenging ring-closing-metathesis macrocyclizations, while at the same time providing insight into the essential parameters for successful macrocyclization.[66]

In particular, the first approaches to the total synthesis of epothilone C (**43**, Scheme 10) provided an early testing ground for ring-closing-metathesis macrocyclizations, and these studies served to highlight both the advantages and limitations of this methodology.[67] The first olefin-metathesis-based total synthesis of epothilone C (**43**) was reported by the Nicolaou group who, seeking to form the 16-membered macrocyclic ring by a route other than macrolactonization, anticipated that the power of ring-closing metathesis could potentially be employed to fashion the C12–C13 alkene in **40** from a precursor such as **37**. In those early days of the development of olefin metathesis in complex situations, however, several variables in the proposed transformation constituted unexplored territory in the metathesis landscape. Not only was the compatibility of the functionality in precursor **37**, in particular the unprotected hydroxy group and the thiazole unit, with the (then recently developed) ruthenium-based catalysts, such as **2**, questionable, but there were concerns over the stereochemical outcome of the

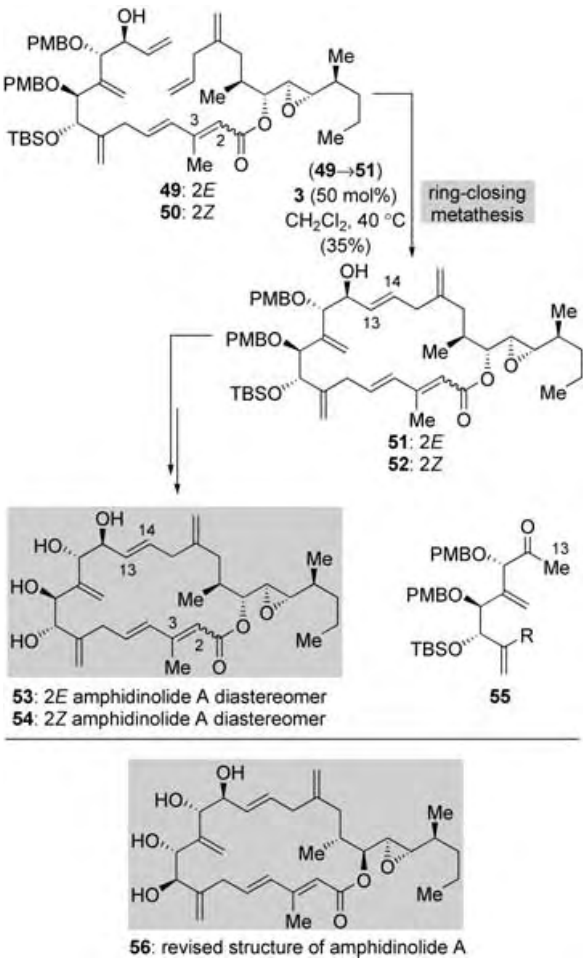
Scheme 10. Ring-closing-metathesis reactions in the total synthesis of epothilone C (**43**) (Nicolaou and co-workers, 1997; Danishefsky and co-workers; 1997, Schinzer and co-workers, 1999).[68,69,71]

cyclization. Fortunately, these worries proved to be relatively unfounded, as exposure of **37** to the Grubbs catalyst **2** (10 mol%) in CH_2Cl_2 at ambient temperature for 20 h effected macrocyclization to **40**, which was obtained as a 1:1.2 mixture of *E*/*Z* isomers in 85% combined yield.[68] Standard cleavage of the lone silyl protecting group in **40** then afforded the targeted product **43**. While the team was amply satisfied with the overall conversion of **37** into **40**, they were nonetheless surprised to find the degree to which seemingly subtle modifications of the array of functionality situated on the backbone of the eventual macrocyclic system dictated the *E*/*Z* ratio of the resultant cycloalkene products. Parallel studies by both the Danishefsky[69,70] and the Schinzer groups,[71] in their explorations of the same type of ring-closing reaction, provided further evidence for this phenomenon. For example, the Danishefsky team showed that the stereoselectivity of the macrocyclization could be dramatically reversed, from being marginally *Z* selective (**38**→**41**) to displaying good *E* selectivity (**39**→**42**), simply by liberating the protected hydroxy groups prior to cyclization. In contrast, the comparable results obtained by the Schinzer group in their conversion of **38** into **41** and the Danishefsky group in their ring-closing metathesis of the same substrate indicates that, at least in this case, changing reaction parameters such as solvent, temperature, or even metathesis catalyst leads to the cycloalkene products in only a slightly altered ratio. In other situations this is often not the case, and changing these latter parameters can exert a drastic influence on *E*/*Z* selectivity.[72] Even though subsequent experimentation in numerous contexts has revealed that most metathesis-based macrocyclizations provide predominantly *E* alkenes,[73] the variability of these results should serve as a reminder that we still lack the ability to reliably predict (or achieve) product geometry for certain ring-closing-metathesis reactions in complex situations. Indeed, this sometimes unpredictable formation of stereoisomeric mixtures represents one of the few significant blots on the landscape of ring-closing-metathesis macrocyclization.

The Nicolaou group subsequently investigated solid-phase synthetic approaches to epothilone C (**43**), with the aim of applying metathesis technology in the context of combinatorial chemistry, in order to generate novel natural product analogues with which the molecular basis for the promising anticancer activity of the epothilones could be probed. To facilitate such screening of diverse epothilone-like structural congeners, these researchers sought to extend their original metathesis approach to generate libraries of analogues by utilizing the power of split-and-pool combinatorial synthesis.[74] In this regard, it was anticipated to fashion an intermediate such as **44** (Scheme 11), poised for a ring-closing-metathesis reaction, in which the tether between the epothilone scaffold and the solid support was appended to the



Scheme 11. Solid-phase synthesis of epothilone C and analogues through a ring-closing-metathesis cyclorelease strategy (Nicolaou and co-workers, 1997).[76]

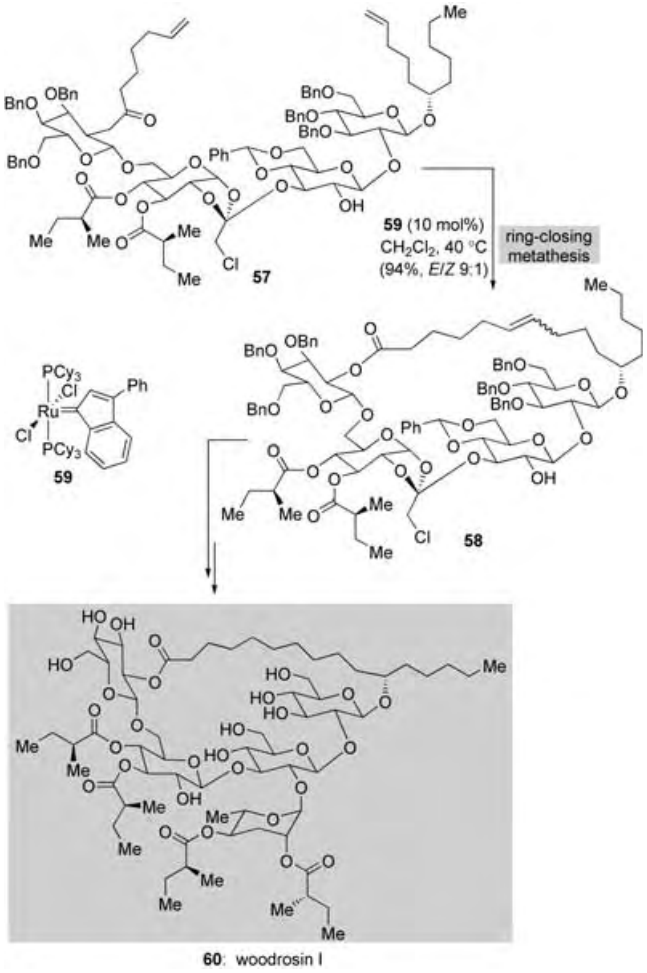
terminal position of one of the olefins that would ultimately participate in the key macrocycle-forming metathesis event. Although the increased steric hindrance imposed by incorporating the alkyl tether at this site could, conceivably, make metathesis more challenging to achieve, the benefits of linking in this manner would far outweigh any potential risk, as ring closure would be attended by traceless cleavage of the desired product from the resin, meaning that no remnants of the original tether that joined the epothilone scaffold to the polystyrene support would remain.[75] This result would be in contrast to most conventional solid-phase approaches, where some signature of the original tether (whether as a hydroxy group or other functional handle) usually remains following cleavage. Perhaps more significantly, appending the solid support in this mode would impart a safety feature to this cyclorelease strategy in that only material capable of undergoing metathesis would ultimately be freed from the resin. As such, any precursor that had not reacted properly during a step leading to **44** would remain attached, thereby ensuring that the products obtained from the metathesis reaction would not be contaminated with undesired by-products.

This strategy proved relatively easy to explore, with **44** being synthesized in short order. Following exposure of this intermediate to carbene initiator **2** in CH_2Cl_2 at ambient temperature, the desired metathesis-based cyclorelease was indeed effected in 52% overall yield over the course of 2 days.[76] However, the ruthenium complex is concomitantly "captured" by the resin during each cyclorelease event, hence the need for the high "catalyst" loading. At the end of this process, a mixture of four products, **40**, **46**, **47**, and **48**, was isolated. Their formation resulted from the anticipated lack of *Z*/*E* selectivity in the metathesis step combined with a 1:1 mixture of C6/C7 *syn* diastereomers within the starting material **44** from an earlier aldol addition. Fortunately, the polarity differences between these four compounds were sufficient to allow their separation by TLC or HPLC. Repetition of this sequence with novel building blocks then led to several hundred distinct analogues, whose biological screening established a clear structure–activity profile for the epothilones, ultimately paving the way for the rational design of novel epothilone-like structures with comparable or even higher antitumor activities than the parent natural product.

In the appropriate situations, however, ring-closing-metathesis macrocyclizations can proceed with excellent selectivity. One such example is found in the synthesis of the originally proposed structure of amphidinolide A (**53**, Scheme 12) by the Maleczka group in 2002.[77] Having arrived at the late-stage intermediate **49**, the team proposed to generate the macrocyclic ring and concomitantly install the C13–C14 1,2-disubstituted alkene through an alkene ring-closing-metathesis reaction. Given the array of alkene functionality contained within intermediate **49**, such a daring, late-stage metathesis step was not without obvious risks. The main question marks centered on the likelihood of actually being able to direct the reaction down the desired pathway, from amongst the plethora of metathesis opportunities available to the polyolefinic substrate, together with the degree of control of alkene geometry should the desired

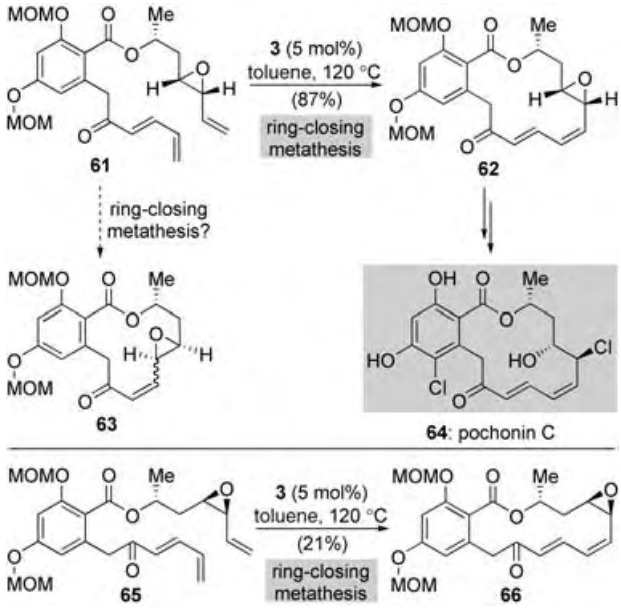
Scheme 12. Ring-closing-metathesis reactions in the total synthesis of amphidinolide A stereoisomers (Maleczka and co-workers, 2002).[77]



reaction indeed prove to be feasible. Much to their delight, the desired macrocyclization of **49** was effected by treatment of the substrate with the second-generation Grubbs ruthenium catalyst **3** in refluxing CH_2Cl_2. Although the ring closure occurred in only moderate yield (35%) and required a relatively high catalyst loading (50 mol%), no other metathesis products were observed. Furthermore, only the desired C13–C14 *E* isomer was formed. This ring closure had, in fact, first been attempted with the less reactive first-generation Grubbs ruthenium carbene **2** in the seemingly logical expectation that a less reactive metathesis catalyst would induce greater selectivity for the less hindered monosubstituted alkenes, and thus the desired C13–C14 metathesis. Surprisingly, exposure of substrate **49** to catalyst **2** merely truncated the allylic alcohol motif to generate the corresponding methyl ketone **55**.[78]

Unfortunately, the team's joy at effecting this macrocyclization was soon to be tempered by the realization that, following the straightforward deprotection of the cyclized product **51** to give the targeted compound **53**, their final product was not the same as natural amphidinolide A. In an effort to uncover the true identity of amphidinolide A, the team subsequently prepared a number of alternative stereoisomers of this structure. One of these compounds was the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

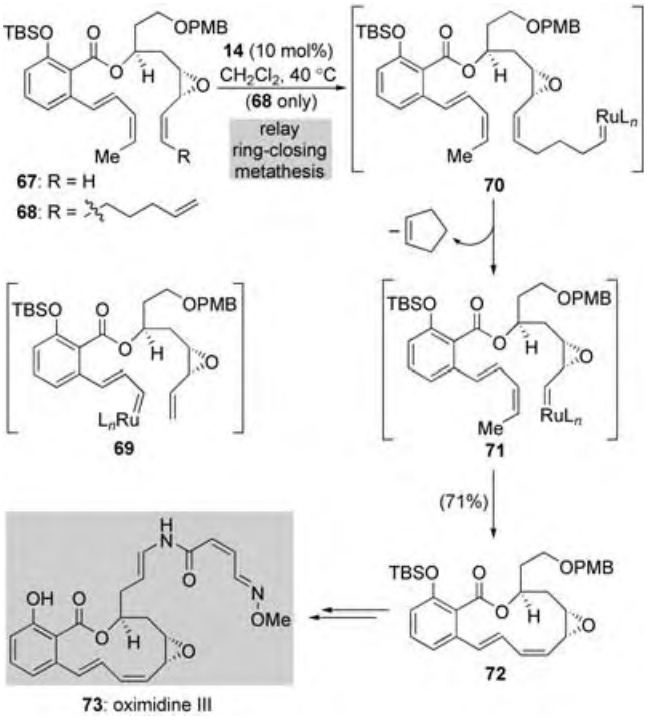


corresponding 2*Z* isomer **54**, which was synthesized through an analogous ring-closing-metathesis macrocyclization strategy. Interestingly, the ring closure of **50** to give **52** proved to be much more efficient proceeding in 88% yield (again with complete *E* selectivity) and requiring only 20 mol% of catalyst **3** to go to completion. This further illustrates the importance of substrate preorganization prior to ring closure. Despite the team's best efforts, however, the mystery surrounding the true structure of amphidinolide A would not be resolved for a further 2 years[79] when the Trost group would provide convincing evidence for its formulation being as compound **56**.[80,81]

In cases in which the stereochemical outcome of ring-closing metathesis is irrelevant (for example, when the resulting alkene system is hydrogenated to give the corresponding alkane), this methodology offers a particularly efficient and practical protocol for the formation of macrocyclic systems, and one which compares favorably with more-traditional methods of macrocyclization. A stunning example of the power of ring-closing metathesis to effect macrocyclization is the total synthesis of woodrosin I (**60**, Scheme 13) by the Fürstner group.[82,83] Having overcome a number of synthetic hurdles during the assembly of the oligosaccharide backbone present in precursor **57**, the team was gratified to find that the anticipated ring-closing-metathesis reaction proceeded smoothly upon exposure of this substrate to a 10 mol% loading of the novel phenylindenylidene complex **59** (championed by the Fürstner group as a useful alternative to the "first-generation" Grubbs catalyst **2**)[37d] in refluxing CH_2Cl_2. Macrocyclic product **58** was obtained in an astonishing yield of 94% (and as an inconsequential 9:1 mixture of *E*/*Z* isomers), with a short sequence of operations involving the hydrogenation of the newly formed alkene, attachment of the rhamnose moiety, and global deprotection, then completing this remarkable total synthesis.

Scheme 13. Ring-closing-metathesis macrocyclization in the total synthesis of woodrosin I (**60**) (Fürstner and co-workers, 2002).[82]

The applicability of ring-closing-metathesis reactions to form higher polyene systems (e.g. conjugated dienes and trienes) in macrocyclic rings has also come under close scrutiny in recent years. An instructive example of this is demonstrated in the total synthesis of pochonin C (**64**, Scheme 14), the most potent member of a small family of



Scheme 14. Ring-closing metathesis to form a diene system in the total synthesis of pochonin C (**60**) (Winssinger and co-workers, 2004).[84]

novel antiviral natural products, reported by Winssinger and co-workers in 2004.[84] While a macrolactonization approach to the 14-membered ring present in the targeted compound **64** would certainly appear to be a viable strategy, these researchers were keen to investigate more modular approaches to the macrocyclic framework, and surmised that the characteristic *E*,*Z*-conjugated diene system could be formed through a ring-closing-metathesis reaction of triene **61**.[85] In addition to the customary questions regarding the stereochemical outcome (i.e. *E* vs. *Z*) of the macrocyclization event, in cases such as these there are also potential regioselectivity issues in that, depending on which double bond of the diene system is engaged in the metathesis event, either the desired diene product (e.g. **62**), or the truncated

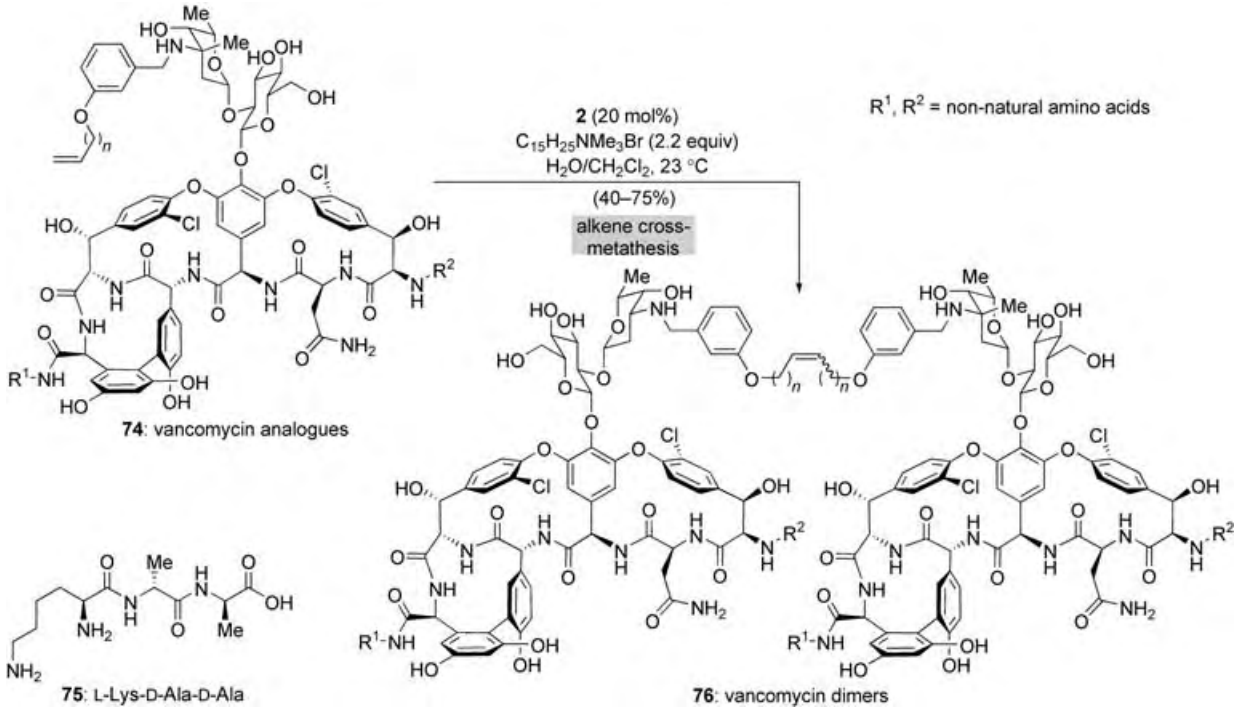
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

monoalkene product (e.g. **63**) could be formed.[86] Again, the outcome can be highly dependent on the reaction parameters, although the former regioselectivity pathway typically predominates. The Winssinger team found that exposure of triene **61** to the second-generation Grubbs catalyst **3** (5 mol%) in toluene at 120°C for 10 minutes (conditions previously developed by the Danishefsky group and shown to be particularly effective in related applications)[87] led to the formation of the required 14-membered ring product **62** as a single regio- and stereoisomer in 87% yield. From intermediate **62**, a few more steps were all that was required to complete the total synthesis of pochonin C (**64**). The influence of the epoxide configuration over the conformational organization of the open-chain metathesis precursor was made evident by the finding that the corresponding *cis*-epoxide **65** underwent metathesis-based ring closure in poor yield (21%), albeit again with excellent regio- and stereoselectivity.

The Porco group has applied the recently developed principle of "relay ring-closing metathesis"[88] to form the conjugated diene system contained within the macrolactone ring of oximidine III (**73**, Scheme 15).[89] Pioneered by the

Scheme 15. Relay ring-closing metathesis in the total synthesis of oximidine III (**73**) (Porco and co-workers, 2004).[89]

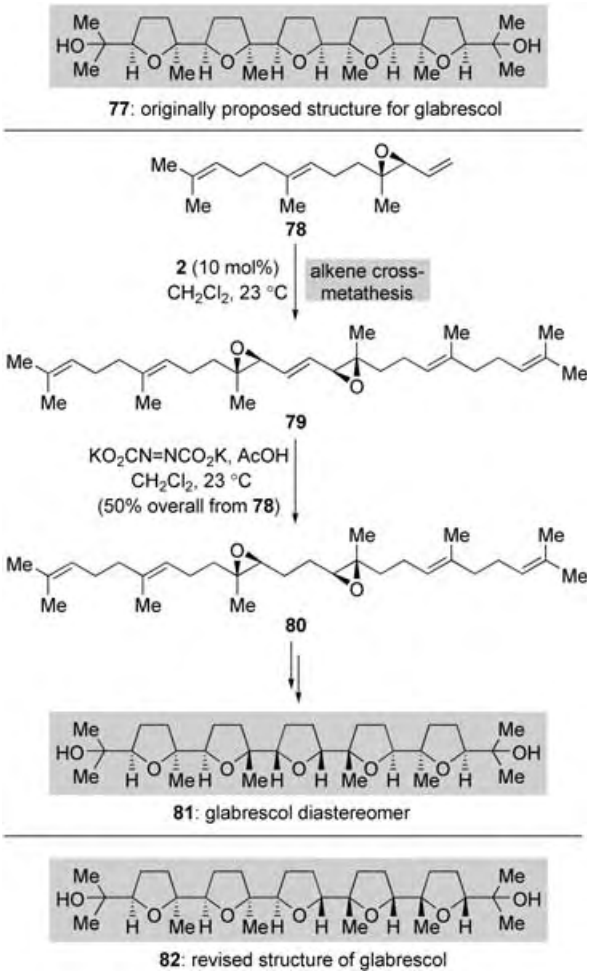
Hoye group,[90] relay ring-closing metathesis has been introduced as a means to enable otherwise sluggish (or entirely unsuccessful) ring-closing-metathesis reactions by moving the site of catalytic initiation away from points of steric hindrance and/or electronic deactivation within a precursor substrate. Thus, as is illustrated in Scheme 15, the addition of precursor **68** to a solution of the Hoveyda–Blechert catalyst **14** (10 mol%) in refluxing CH_2Cl_2 led to the formation of the desired macrocyclic product **72** in good yield (71%). The proposed mechanism of this transformation involves the initial reaction of the ruthenium carbene catalyst with the least hindered terminal double bond to generate carbene complex **70**. This intermediate can then undergo kinetically favorable ring-closing metathesis to extrude cyclopentene and generate the next intermediate **71**, which still contains a metal carbene species and which then undergoes macrocyclization to yield the observed product **72**. The clear superiority, in this instance, of the relay protocol over a conventional ring-closing-metathesis macrocyclization was demonstrated by the observation that when alkene **67** was subjected to the same metathesis conditions, the product **72** was formed in a meager yield of only 15%. In this case, the researchers proposed that the formation of carbene intermediate **69** from alkene **67** competed with the formation of intermediate **71**, with the former species **69** being a stabilized, unreactive ruthenium carbene which shuts down the catalytic cycle, resulting in the low yield. The conversion of precursor **68** into macrocyclic compound **72** was also found to be remarkably stereoselective, with the *E,Z*-diene system being formed exclusively. Having obtained the macrocyclic core of oximidine III (**73**) in this efficient manner, the team was able to manipulate the periphery to complete the total synthesis in a few more steps.[91]



2.2. Alkene Cross-Metathesis

Alkene cross-metathesis has long been of great commercial importance to the industrial sector, but its transition to synthetically viable methodology in total synthesis has been a much more recent affair.[92] Alkene cross-metathesis represents a particularly appealing alternative to other transition-metal-mediated cross-coupling processes (e.g. the Stille or Suzuki reaction) in that readily available alkenes are employed, and no synthetic investment in the preparation of elaborated coupling partners (e.g. vinyl stannanes, vinyl halides, etc.) is required. Furthermore, the mild reaction conditions and functional-group tolerance of modern cross-metathesis often complements the more traditional olefination methods (e.g. the Wittig reaction). Despite its enormous potential for carbon–carbon bond formation, the widespread uptake of alkene cross-metathesis by synthetic chemists has lagged far behind that of the corresponding ring-closing processes. Indeed, until recently, many chemists' experience of cross-metathesis merely involved the unwanted formation of dimeric products arising from a disappointing ring-closing-metathesis event. The biggest challenge in cross-metathesis is the chemo- and stereoselective formation of the desired compound from amongst the myriad of potential reaction products. In this regard, it has been the recent advances in catalyst design, coupled with the development of empirical models for predicting the outcome of cross-metathesis reactions (largely due to the pioneering work of the Grubbs group),[93] that have emboldened chemists with the courage to commit their valuable intermediates to these processes. In return, they have been rewarded with new synthetic avenues and opportunities that were unthinkable even just a few years ago.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



In the context of total synthesis, the applications of the olefin cross-metathesis reaction can be divided, somewhat arbitrarily, into two main classes: 1) chain-elongation processes, and 2) fragment-coupling reactions (including dimerization processes). As one example of the latter, we highlight the efforts of the Nicolaou group towards overcoming emerging bacterial resistance to vancomycin, the antibiotic currently considered to be the last line of defense against methicillin-resistant *Staphylococcus aureus* (MRSA).[94] The strategy entailed the use of alkene cross-metathesis reactions to effect the dimerization of vancomycin-type monomers such as **74** (Scheme 16) to give compounds of type **76**.[95,96] Indeed, during the past decade, several other clinically employed compounds have been dimerized, based on the notion that their biological activity would be enhanced.[97] Among several of the particularly noteworthy features of the developed cross-metathesis protocol to reach these agents (e.g. **76**), as shown in Scheme 16, was the employment of a phase-transfer agent ($C_{15}H_{25}NMe_3Br$) to encapsulate the ruthenium catalyst, and hence enable it to carry out its function in aqueous media at 23 °C. Because these reaction parameters are essentially ambient conditions, it was then decided to extend this initial homodimerization approach to include the selective formation of heterodimers by adding combinations of different substrates of type **74** in the presence of vancomycin's biological target, a terminal L-Lys-D-Ala-D-Ala peptide subunit **75**. Since it had already been established that two monomers of vancomycin could bind simultaneously (and reversibly) to this target through separate hydrogen-bonding networks,[98] this design assumed that those monomers within the collection of examined substrates that bound most tightly to this peptide chain would be captured by cross-metathesis as the corresponding dimer. As such, this approach should lead to the formation of highly active antibacterial agents. Upon execution of this target-accelerated combinatorial strategy, also referred to as dynamic combinatorial screening,[99] non-statistical distributions of dimers were formed. In each case, the compound with the greatest potency (based on synthesizing and testing all potential dimers separately) was the predominant product in each round of compound formation. Significantly, several of the agents prepared in this fashion by cross-metathesis demonstrated not only enhanced activity against MRSA relative to vancomycin, but also potency against several vancomycin-resistant bacterial strains.

Another dimerization-based cross-metathesis approach was employed by the Corey group in their quest to determine the correct structure of the polycyclic oxasqualenoid glabrescol.[100] The team had originally prepared compound **77** (Scheme 17), corresponding to the structure first proposed for the natural product, through a beautifully orchestrated biomimetic polyepoxide-cyclization strategy to fashion all five tetrahydrofuran rings in a single step and in a stereospecific fashion.[101,102] However, much to their dismay, the spectroscopic data of their synthetic material did not match that reported for the natural product.[103] The team was, therefore, faced with the task of having to synthesize a number of other possible stereoisomers, which could correspond to either the C_s- or C_2-symmetric nature of the natural product, before they could clear the ambiguity regarding the actual structure of glabrescol. One of the targeted stereoisomers was compound **81**, which, following their general polycyclization strategy, they hypothesized could be derived from bisepoxide **79**, the symmetrical nature of which lends itself to its preparation through a dimerization protocol.

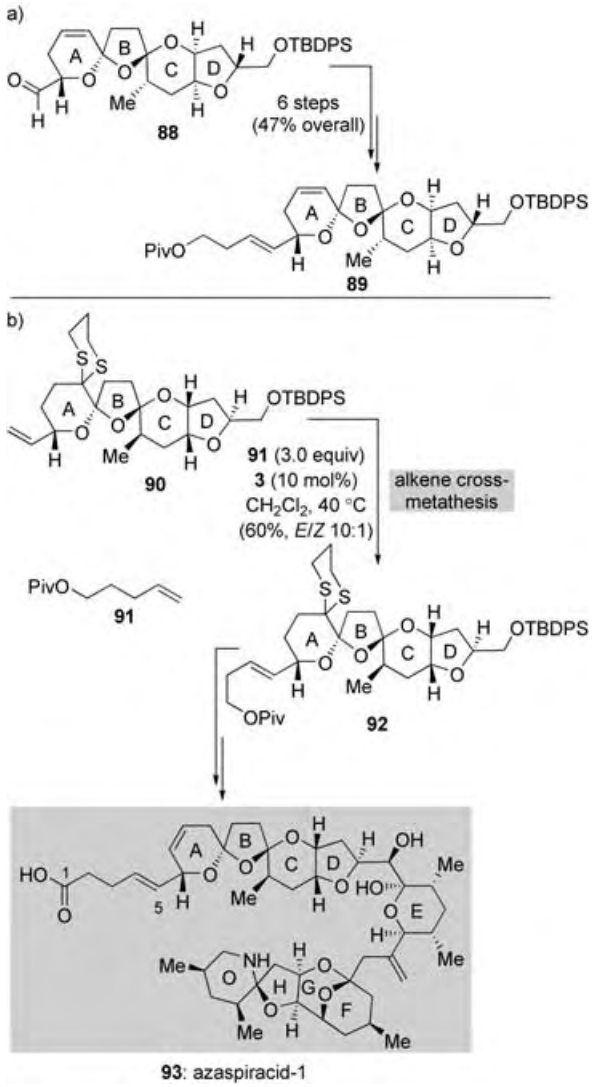
Scheme 16. Dynamic combinatorial synthesis: the use of cross-metathesis to effect selective formation of vancomycin dimers (**76**) under ambient-like conditions in the presence of its biological target, L-Lys-D-Ala-D-Ala (Nicolaou and co-workers, 2001).[95]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 17. Dimerization through cross-metathesis in the total synthesis of a glabrescol diastereomer (**81**) (Corey and Xiong, 2000).[100]

Indeed, the team found that readily available epoxide **78** underwent selective cross-metathesis upon treatment with initiator **2** (10 mol%) in CH_2Cl_2 at ambient temperature to afford the coupled product **79**. Pleasingly, only the terminal alkene units participated in the metathesis event, with no interference from the more sterically hindered trisubstituted olefins. Furthermore, the reaction was also superbly stereoselective, with the *E*-isomeric product being formed exclusively, although in this context the stereoselectivity was irrelevant as the newly formed double bond was immediately reduced in the next step. The resulting product **79** was then elaborated to give the desired pentacyclic diol **81**. Unfortunately, the new synthetic material the team now had in their hands still did not correspond to natural glabrescol, and it would be only after a great deal of further synthetic effort that the true structure of the natural product would be revealed as **82**.[104–106]

An elegant example of the coupling of two different fragments by means of alkene cross-metathesis can be found in the total synthesis and structure revision of amphidinolide W (**86**, Scheme 18) by the Ghosh group.[81a] The strategy adopted by the researchers for the formation of the macrocyclic ring system involved the coupling of the two advanced

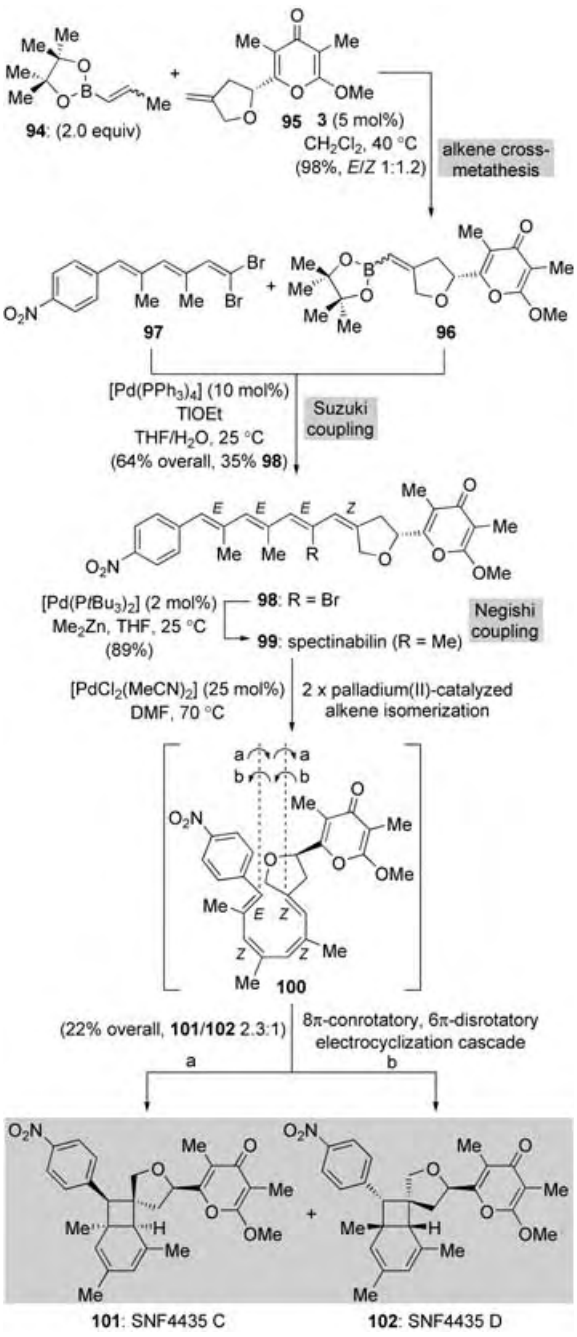


Scheme 18. Fragment coupling through cross-metathesis in the total synthesis of the revised structure of amphidinolide W (**86**) (Ghosh and co-workers, 2004).[81a]

intermediates **83** and **84** through alkene cross-metathesis (with the concomitant installation of the C10–C11 olefin), followed by a late-stage macrolactonization. To their delight, the cross-metathesis between **83** and **84** proceeded smoothly over the course of 15 h upon the addition of catalyst **3** (6 mol%) to a refluxing solution of the two components in CH_2Cl_2, affording the desired product **85** in excellent yield (85%) and with good *E* selectivity (*E*/*Z* 11:1). An excess of alkene **84** was required, as this substrate underwent competitive homodimerization to give compound **87** (which was itself inert to secondary metathesis reactions). Furthermore, it was found that the specific employment of an acetate protecting group for the allylic secondary hydroxy group in coupling partner **83** was required for optimum results. With an efficient, modular approach to compound **85** now at their disposal, the researchers were able to advance this key intermediate over a number of steps to complete the total synthesis of the revised structure **86** of the targeted natural product.[107]

Alkene cross-metathesis was efficiently used as a means of chain elongation in the recent enantioselective synthesis of the revised structure of azaspiracid-1 (**93**, Scheme 19) by the Nicolaou group.[108] Previously, in the course of their synthesis of the originally proposed structure of this remarkable marine neurotoxin (which was subsequently shown to be incorrect), the team employed a six-step sequence to append the C1–C5 unsaturated side chain onto the ABCD-ring intermediate **88** (Scheme 19a).[109] While each individual step proceeded smoothly and in high yield, the somewhat laborious nature of this sequence prompted the team to consider other, more direct methods for the incorporation of this motif. The presence of the 1,2-disubstituted double bond in this side

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

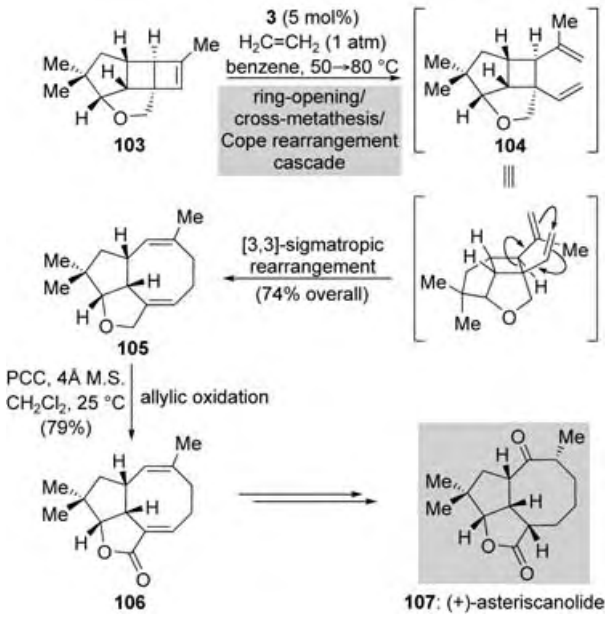


Scheme 19. Introduction of the C1–C5 side-chain in the total synthesis of azaspiracid-1: a) six-step route in the synthesis of the originally proposed structure; b) single-step alkene cross-metathesis approach in the synthesis of the revised structure **93** (Nicolaou and co-workers, 2004).[108]

chain invites the possibility of its construction in a single step through alkene cross-metathesis, and indeed this was the method adopted in the final drive towards the revised structure of the natural product. Thus, exposure of a mixture of tetracyclic compound **90** and the readily available alkene **91** (used in excess) in refluxing CH_2Cl_2 to the second-generation catalyst **3** (10 mol%) resulted in the formation of the desired product **92** in 60% yield and with good stereoselectivity (*E*/*Z* 10:1, isomers readily separable by column chromatography; Scheme 19b). Most of the mass balance of this reaction consisted of unconverted starting material **90**, which could be recovered and resubjected to the reaction conditions. After three cycles, the total yield of **92** was 95%, which represented a considerable increase in both efficiency and elegance over the original six-step route.[110] Notably, the dithiane functionality did not interfere with the cross-metathesis by sequestering the catalyst **3**, further illustrating the remarkable functional-group tolerance of this ruthenium complex.

An exceedingly useful characteristic of the cross-metathesis protocol for chain elongation is that it can be employed for the concomitant generation of functionalized reagents that can be engaged in subsequent reactions to produce further molecular complexity. This is particularly beneficial when it provides access to reagents that could not be readily obtained by other methods. A stunning example of this concept, which furthermore demonstrates both brilliance in synthetic planning and the phenomenal enabling ability of modern transition-metal-mediated cross-coupling reactions, is the biomimetic synthesis of the immunosuppressant agents SNF4435 C (**101**) and SNF4435 D (**102**, Scheme 20) by Baldwin and co-workers.[111] The bicyclo[4.2.0]octadiene core structure of these architecturally unique natural products has been proposed to arise through a sequential 8π-conrotatory/6π-disrotatory electrocyclization cascade of the *Z*,*Z*,*Z*,*E* tetraene precursor **100**.[112] The viability of this hypothesis was experimentally verified by Parker and Lim who, in the preparation of tetraene **100** through a fragment-coupling Stille reaction, observed its rapid and spontaneous rearrangement to generate a mixture of **101** and **102** in a ratio closely matching that of the compounds found in Nature.[113] Furthermore, related electrocyclization cascades had been proposed as key steps in the biosynthesis of the endiandric acids by Black and co-workers[114] and subsequently demonstrated experimentally by the Nicolaou group[115] more than two decades earlier. However, Baldwin and co-workers noted the striking similarity between tetraene **100** and spectinabilin (**99**), the latter being a known natural product isolated from the same producing species (*Streptomyces spectabilis*) more than 25 years earlier by Rinehart and co-workers.[116] Indeed, the two compounds differ only in the geometry of the two central double bonds in their respective tetraene systems, thus leading the Baldwin group to the intriguing proposal that a key intermediate in the biogenesis of SNF4435 C (**101**) and SNF4435 D (**102**) is, in fact, spectinabilin (**99**), which undergoes an initial double alkene isomerization to give *Z*,*Z*,*Z*,*E* tetraene **100**, followed by the electrocyclization cascade.[117] From a synthetic point of view, this proposal is appealing because it should, in principle, be easier to construct a *Z*,*E*,*E*,*E* tetraene system (as in **99**) than the corresponding *Z*,*Z*,*Z*,*E* motif (as in **100**). The issue would then become whether the double isomerization of spectinabilin (**99**) could be effected selectively. Much to their delight, the team found that this biosynthetic proposal could, indeed, be reduced to practice, and the key steps in the synthesis are illustrated in Scheme 20. Thus, following a protocol developed by Grubbs and Morrill,[118] the cross-metathesis of vinyl boronate **94** with disubstituted alkene **95** generated the corresponding product **96** in excellent yield, albeit with moderate stereoselectivity ($E/Z \approx 1{:}1.2$). This methodology offers a convenient approach for the preparation of synthetically useful vinyl boronate species, such as **96**, which would be inaccessible by more conventional means (e.g. hydroboration of alkynes).[119] The selective Suzuki coupling of boronate **96** (as a mixture of *E*/*Z* isomers) with the *E* vinyl bromide moiety in dibromide **97** occurred with retention of stereochemistry with respect to

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

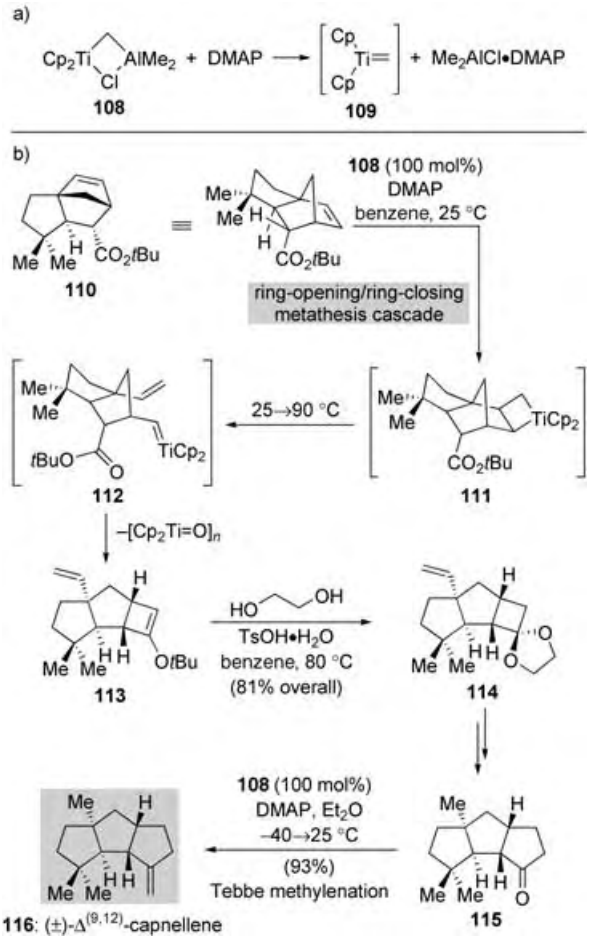


Scheme 20. Multiple use of transition-metal-catalyzed carbon–carbon bond-forming reactions in the total synthesis of SNF4435 C (**101**) and SNF4435 D (**102**) (Baldwin and co-workers, 2004).[111]

both coupling partners,[120] and was followed by separation of the resulting 1:1.2 mixture of stereoisomers to give the desired bromide **98** in 35% overall yield from **96**. A stereospecific Negishi coupling of bromide **98** with Me_2Zn, catalyzed by the commercially available 14-electron complex $[Pd(PtBu_3)_2]$,[121] then afforded spectinabilin (**99**). Finally, exposure of synthetic **99** to $[PdCl_2(MeCN)_2]$ (25 mol%) in DMF at 70°C initiated the novel isomerization/electrocyclization cascade, ultimately producing the target compounds **101** and **102** in a 2.3:1 ratio.[122] Although the overall yield for this cascade process was modest (22%), it nevertheless represents an important proof of principle. While the promotion of the initial double isomerization by a palladium(II) species can hardly be considered to be "biomimetic" in its own right, it is not unreasonable to speculate that Nature has her own complementary methods for effecting such a transformation. This remarkable total synthesis, in which all the key carbon–carbon bond-forming reactions employed transition-metal catalysis, stands as a powerful testament to the current state of the art of metathesis and cross-coupling reactions in contemporary organic synthesis.

2.3. Alkene Metathesis in Cascade Processes

The utility of alkene metathesis extends far beyond merely effecting individual ring-closing or cross-metathesis events, which necessarily generate only one new productive carbon–carbon linkage. The incorporation of metathesis steps into cascade processes has received a burgeoning level of attention in recent years, a trend that is likely to expand in the future, particularly in terms of combining metathesis with other reactions in the current synthetic repertoire. One such application is seen in the recent total synthesis of (+)-asteriscanolide (**107**, Scheme 21) by Limanto and Snapper,

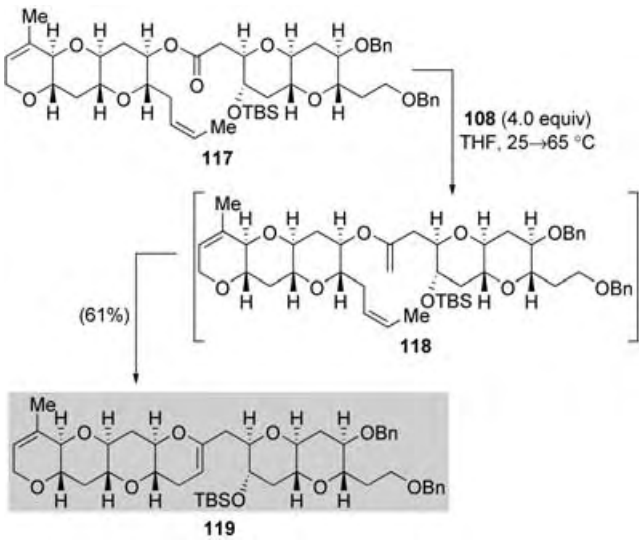


Scheme 21. A ring-opening/cross-metathesis/Cope rearrangement cascade in the enantioselective total synthesis of (+)-asteriscanolide (**107**) (Snapper and Limanto, 2000).[123]

which features the use of a novel ring-opening cross-metathesis/Cope rearrangement strategy to fashion the characteristic tricyclic core structure of the natural product.[123] The primary synthetic target was tricyclic lactone **106**, as this compound had previously been elaborated to the natural product by Wender and co-workers in their pioneering total synthesis of **107**.[124] Limanto and Snapper found that treatment of the highly strained cyclobutene **103** with catalyst **3** (5 mol%) in benzene under an ethylene atmosphere initially

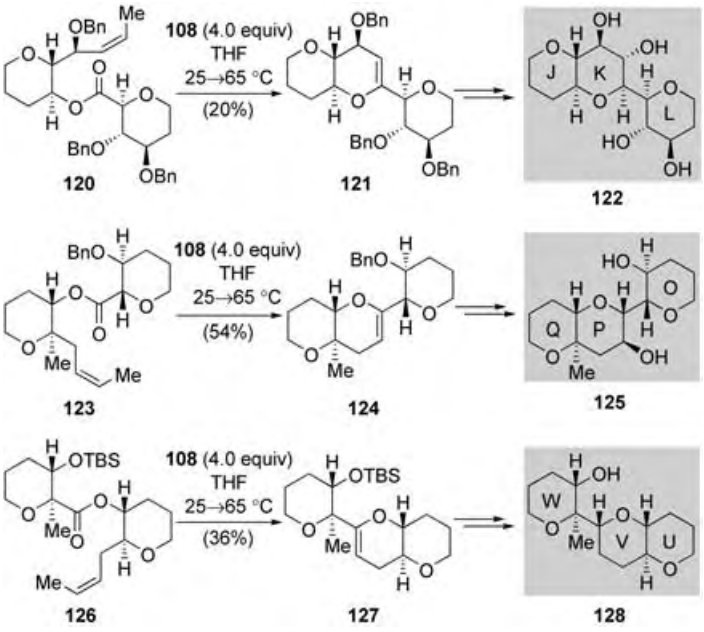
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

effected the selective ring-opening cross-metathesis to afford the presumed intermediate **104**, which under the reaction conditions underwent a [3,3]-sigmatropic rearrangement to yield tricyclic compound **105** in 74% overall yield. In this cleverly designed process, both the metathesis and Cope rearrangement steps enjoy the thermodynamic driving force provided by the relief of ring strain upon fragmentation of different four-membered rings. The uneventful allylic oxidation of product **105** then completed the concise synthesis of the desired lactone **106**, which was then converted into the natural product following the protocol of Wender and co-workers.[125] Cascade reactions that involve a metathesis step in combination with a number of other different transformations, including cycloadditions and Heck reactions,[126] have also been reported.



Alternative strategies involve the design of substrates that can undergo consecutive metathesis reactions in a single step. A beautiful early example of this type of protocol can be found in the expeditious synthesis of (±)-$\Delta^{(9,12)}$-capnellene (**116**, Scheme 22) by the Grubbs group,[127] also highlighting one of the rare applications of the Tebbe reagent (**108**) in a metathesis-based context in total synthesis. First introduced by Tebbe and co-workers in 1978,[128] titanocene complex **108** undergoes reversible elimination of Me_2AlCl (the latter can then be sequestered by a mild base, in this case DMAP) to generate the reactive titanium methylene intermediate **109** (Scheme 22a). For preparative purposes, intermediate **109** can undergo two main types of reaction: 1) olefination of organic carbonyl-containing compounds (including esters and amides) to give Wittig-type methylenated products[129] and 2) reaction with alkenes to form metallacycles that can be used as catalysts in alkene metathesis.[130] From an historical perspective, the reported metathesis activity of carbene **109** predates the development of both the molybdenum- and ruthenium-based catalysts such as **1**, **2**, and **3**.[131] However, the reactivity profile of carbene **109** is such that it reacts with almost all other functional groups in preference to alkenes, accounting for why it is currently widely employed to methylenate carbonyl compounds, but is not a popular catalyst to initiate the metathesis of complex molecules. In the present case, however, the combination of steric hindrance around the *tert*-butyl ester carbonyl group and the increased reactivity of the strained norbornene-type alkene inverts the usual reactivity pattern such that titanium carbene **109** reacts preferentially with the latter motif present in bridged bicyclic compound **110**, at ambient temperature, to afford metallacyclobutane **111** (Scheme 22b). The remarkable regioselectivity of this step had been anticipated by the workers on the basis of model studies and is likely the result of steric effects. Upon heating the solution of this newly formed intermediate to 90 °C, a productive cycloreversion ensued to form the new titanium carbene species **112**, which in a display of its alternate mode of reactivity, reacted with the proximal carbonyl group to afford the observed product **113**. Owing to the sensitivity of the cyclobutene enol ether, this product was immediately protected and isolated as the corresponding ketal **114**, in 81% overall yield from **110**. Although necessarily stoichiometric in the titanium complex **108**, this reaction nevertheless effected the high-yielding conversion of a readily available starting material into an advanced intermediate, which required only a few more steps to reach the targeted compound **116**. Interestingly, the last of these steps called for the methylenation of ketone **115** to give the corresponding exocyclic olefin; again, the use of the Tebbe reagent resulted in an excellent yield.[132,133]

Scheme 22. Titanium methylidene reagents: a) generation from the Tebbe reagent (**108**), b) use in a ring-opening-/ring-closing-metathesis cascade in the total synthesis of (±)-$\Delta^{(9,12)}$-capnellene (**116**) (Grubbs and Stille, 1986).[127]



The Nicolaou group has developed a number of novel approaches to the synthesis of complex polyether frameworks through tandem metathesis reactions. One such protocol makes efficient use of the multifunctional reactivity of titanium carbene complexes as described above to effect tandem methylenation/alkene ring-closing metathesis, a representative example of which is illustrated in Scheme 23.[134] In this case, the sequence is believed to commence with the initial methylenation of the ester carbonyl group (i.e. **117**→**118**), based on the established general preference of this reagent to engage carbonyl functionalities before alkenes. With excess Tebbe reagent in solution, however, subsequent alkene metathesis between the newly generated alkene and its neighboring partner can ensue at elevated temperature (i.e. **118**→**119**). Since the initial disclosure of this transformation, the developed technology has been applied to several of the ring systems embedded within the structure of

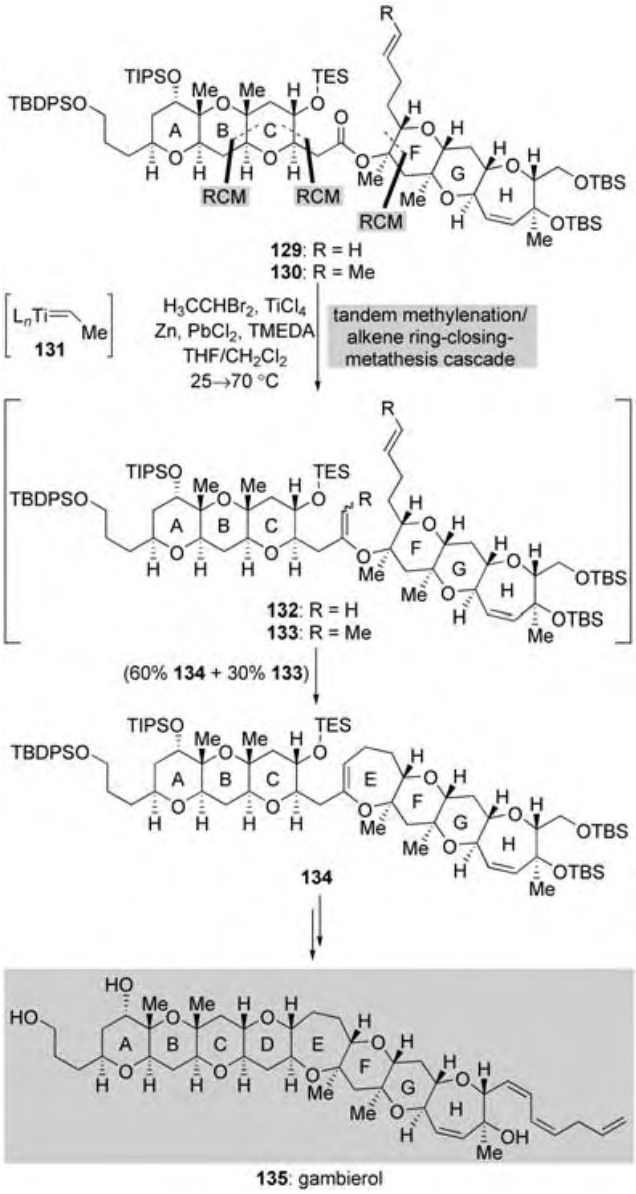

Scheme 23. The synthesis of complex polyether frameworks through tandem methylenation/ring-closing metathesis: proof-of-principle (Nicolaou and co-workers, 1996).[134]

the complex marine natural product maitotoxin (Scheme 24).[135] Rainier and co-workers subsequently made use of this type of tandem methylenation/ring-closing metathesis cascade sequence in their recent total synthesis of the polyether toxin gambierol (**135**, Scheme 25).[136] The convergent strategy adopted by these researchers initially called for the syntheses of separate ABC- and FGH-ring-containing fragments, followed by their union through an intermolecular esterification reaction. Ring-closing-metathesis reactions of enol ethers were instrumental in forging these subunits, used

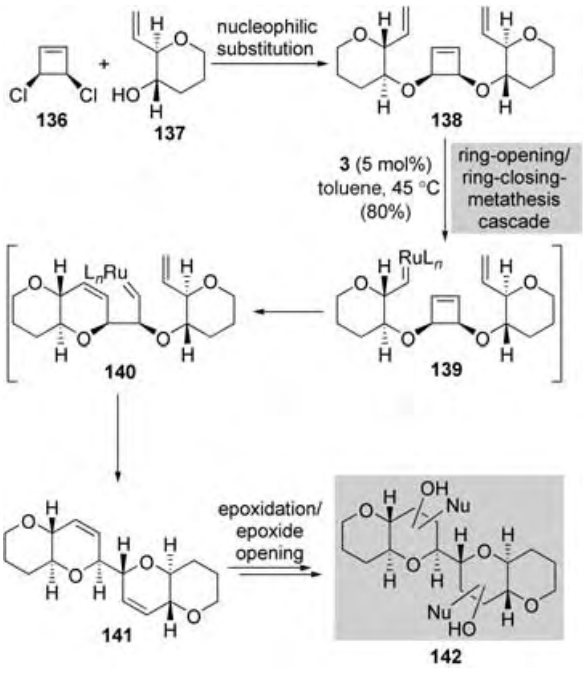


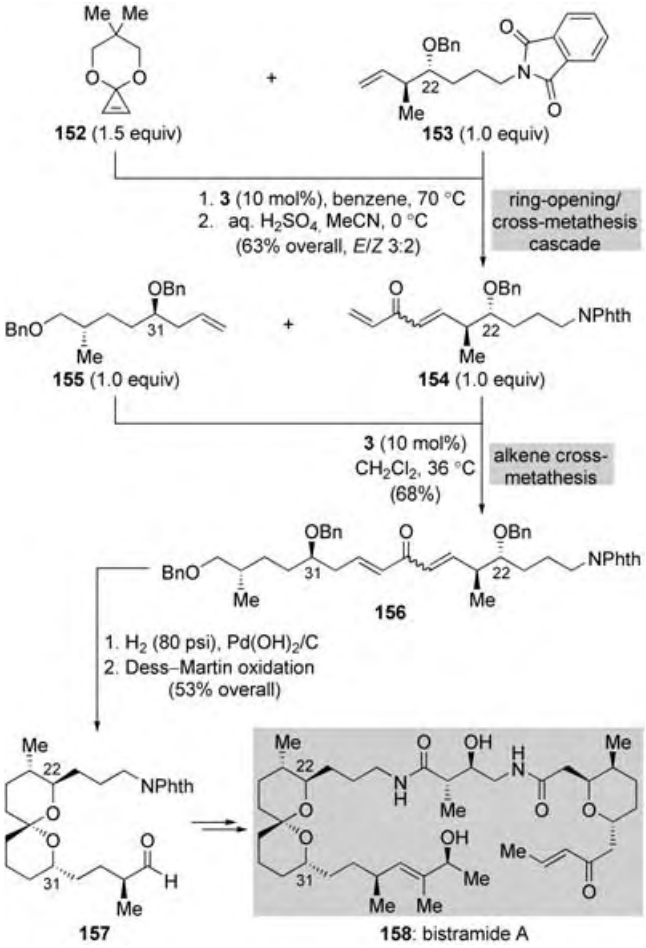
Scheme 25. The synthesis of complex polyether frameworks through tandem methylenation/ring-closing metathesis: application to the total synthesis of gambierol (**135**) (Rainier and co-workers, 2005).[136]

as they were to construct the B-, C-, and F-rings.[137] The fashioning of the F-ring by ring-closing metathesis was particularly noteworthy in light of the fact that it entailed the formation of a crowded tetrasubstituted alkene. Having arrived at the key hexacyclic intermediate **129**, the team had originally planned on closing the seven-membered E-ring to give compound **134** through a two-step process involving a Tebbe-type methylenation, which would generate enol ether **132**, followed by a separate ring-closing-metathesis event. Unfortunately, and to their dismay, they were unsuccessful in all their efforts at converting ester **129** into acyclic enol ether metathesis precursor **132** using the Takai–Utimoto titanium methylidene protocol.[138] Far from heralding the dismantlement of the synthetic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

route, this misfortune inspired the team to investigate other methods for effecting the olefination of this ester carbonyl group. Eventually, and after much experimentation, they made the serendipitous and joyful discovery that subjecting ester **130**, which bore a different alkene-containing side-chain, to the modified Takai–Utimoto conditions shown (ostensibly to generate the corresponding substituted enol ether **133** through the intermediacy of the titanium alkylidene **131**) led to the formation of cyclic enol ether **134** in 60% yield! Furthermore, the expected product **133** was also isolated as a side product in 30% yield, and independently subjected to a ring-closing-metathesis reaction in the presence of the second-generation Grubbs catalyst **3**, also to afford cyclic product **134** in a yield of 60%. Having bypassed this synthetic roadblock in an unexpected manner, these researchers were then able to complete the total synthesis in only a few more steps.[139]

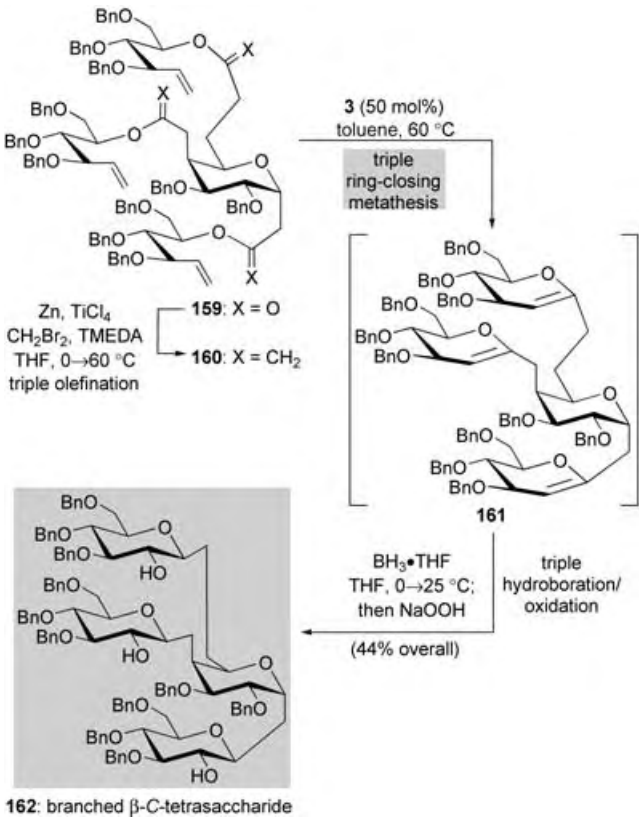
Another protocol developed by the Nicolaou group makes use of a cyclobutene scaffold as a template for tandem metathesis reactions. Thus, as is shown in Scheme 26, treatment of readily available cyclobutene-1,2-diol derivative **138** with the second-generation ruthenium catalyst **3** (5 mol%) in toluene at 45°C effected its smooth conversion into the corresponding tetracyclic compound **141**, with complete transfer of chirality from the original cyclobutene ring to the newly formed pyran systems.[140] Interestingly, and despite close precedent for analogous metathesis reactions with less-hindered substrates,[141] the first-generation catalyst **2** failed to induce the desired reaction in the present case. An alternative mechanism involving initiation at the cyclobutene alkene unit cannot be excluded. It should be recalled that all the steps in the catalytic cycle (and thus, in principle, the overall transformation) are reversible. However, there is a powerful thermodynamic driving force in this type of process that benefits from both entropic (release of ethylene) and enthalpic (release of ring strain) factors. The utility of this cascade process was extended beyond ring formation by the fact that the diolefinic product **141** could be subjected to epoxidation and subsequent stereospecific epoxide-opening reactions with a variety of nucleophiles. Such a route constitutes rapid and flexible access to complex molecular frameworks, which could easily be modified to produce tailor-made intermediates for total synthesis, or compound libraries for biological screening. These types of cascade processes, which involve sequential ring-opening and ring-closing metathesis reactions, have been termed "ring-rearrangement metatheses". Their use in target-oriented synthesis has been championed in particular by the Blechert group, who has applied them to the elegant syntheses of a variety of structurally diverse alkaloid natural products, including tetraponerine T4 (**145**, Scheme 27),[142] (+)-astrophylline (**148**),[143] and (+)-dihydrocuscohygrine (**151**).[144]



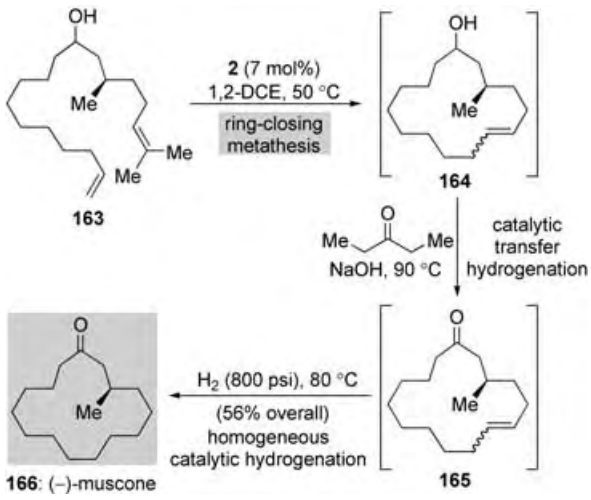
Scheme 26. A ring-opening-/ring-closing-metathesis cascade in the stereocontrolled synthesis of polyether frameworks (**142**) (Nicolaou and co-workers, 2001).[140]

Scheme 27. Ring-rearrangement metathesis reactions in the total syntheses of tetraponerine T4 (**145**), (+)-astrophylline (**148**), and (+)-dihydrocuscohygrine (**151**) (Blechert and co-workers, 2000, 2003, 2002).[142–144]

In a variation on this theme, a ring-opening/cross-metathesis cascade reaction featured prominently in the recent synthesis of the protein kinase C activator bistramide A (**158**,



Scheme 28. Multiple use of alkene cross-metathesis reactions in the enantioselective total synthesis of bistramide A (**158**) (Kozmin and co-workers, 2004).[145]



Scheme 28) by Kozmin and co-workers.[145] The first key carbon–carbon bond-forming reaction in their inventive approach to the spiroketal domain of the targeted product involved the treatment of a mixture of terminal alkene **153** and a slight excess (1.5 equiv) of cyclopropene acetal **152** with second-generation ruthenium catalyst **3** (10 mol%) in benzene at 60 °C to afford, after acidic hydrolysis of the crude product mixture to effect the cleavage of the acetal protecting group, divinyl ketone **154**. The stereoselectivity of this reaction was poor, with the product being formed as a 3:2 mixture of *E*/*Z* isomers, but fortunately this was irrelevant in the context of this synthesis (see below). This ring-opening/cross-metathesis cascade follows the same principles as illustrated earlier in the synthesis of (+)-asteriscanolide **107** (see Scheme 21), except that in this case a substituted alkene is employed as the coupling partner instead of ethylene. As with the corresponding cyclobutenes, cyclopropenes make excellent participants in ring-opening-metathesis processes owing to the enormous relief of ring strain. It should be noted that, unlike the ring-opening/ring-closing metathesis cascade described in Scheme 26, this particular type of tandem process is atom economical (i.e. no ethylene is released), and thus largely driven by enthalpic factors, which must overcome the negative entropic factors (i.e. two molecules being combined into one). The α,β-unsaturated system generated within product **154** readily lends itself to further manipulation, and indeed the very next step involved an intermolecular fragment-coupling/cross-metathesis reaction between **154** and alkene **155**, again catalyzed by ruthenium complex **3**, to afford the expected product **156** in 68% yield. Interestingly, the corresponding acetal obtained before the acidic hydrolysis step proved to be inert towards subsequent metathesis, which may also go some way towards explaining the exclusive formation of the mono-cross-coupled product in the first metathesis step. Although the stereoselectivity of this process was again irrelevant, only a single geometrical isomer (*E*) was generated at the new linkage. Significantly, this cross-metathesis proceeded efficiently, employing only 1 equivalent of each coupling partner, whereas many cross-metatheses require one of the components to be used in an (often large) excess. High-pressure hydrogenation of the stereoisomeric mixture of **156** effected the cleavage of the three benzyl protecting groups, saturation of the two disubstituted alkenes and concomitant stereoselective spiroketalization in one pot. Subsequent Dess–Martin oxidation of the resulting primary alcohol afforded aldehyde **157**. The team thus had a remarkably concise and efficient route to the key spiroketal fragment **157** from which they were able to complete the total synthesis of (+)-bistramide (**158**) in due course.

An area of alkene-metathesis chemistry that has been investigated by a number of researchers involves the use of double, triple, or even quadruple ring-closing-metathesis reactions to generate a variety of bicyclic, tricyclic, and tetracyclic ring systems in a single step from an appropriately substituted acyclic precursor.[146] A highlight of this methodology is the novel approach to branched β-*C*-tetrasaccharides developed by the Postema group, an example of which is illustrated in Scheme 29.[147] Thus, triester **159** was, following the methylenation protocol developed by Takai and co-workers,[138] converted into the corresponding hexaene **160**, which was then exposed to catalyst **3** (50 mol%, added in five portions over 2.5 h) in toluene at 60 °C to effect the desired triple ring-closing metathesis to form tris-glycal **161**. This latter intermediate was not isolated, but directly subjected to a regio- and stereoselective triple hydroboration/oxidation procedure to afford tetrasaccharide **162** in 44% overall yield from triester **159**. Although the catalyst loading may seem relatively high in this case, this reflects the fact that not only do three metathesis reactions have to be catalyzed, but also that ring-closing metathesis of electron-rich enol ethers is known to be more difficult than that of simple alkyl-substituted diene systems.[148,149] Notably, no competing macrocyclization or oligomerization processes were observed during the metathesis step. Strictly speaking, the actual metathesis events cannot be classified as a cascade process, since the individual ring-closures occur independently of each other. Nevertheless, the overall conversion of **159** into **162** represents a highly efficient gain in molecular complexity, involving nine independent transformations (each occurring with an average yield of 91%) and the formation of three new rings and six new stereogenic centers without the need for the purification of any of the intermediates. Through the judi-

cious positioning of alkene units within a precursor molecule, a diverse array of annulated, spirocyclic, and polycyclic ring systems can be fashioned by employing multiple ring-closing metathesis reactions.

Our final example in this section highlights the multifarious uses of ruthenium carbene systems such as **2** and **3**. In addition to being versatile catalysts for metathesis reactions, complexes **2** and **3** have been shown to function also as effective precatalysts for a variety of unrelated transformations, including hydrogenation, radical addition, and the vinylation of terminal alkynes.[150,151] This broad spectrum of activity has been employed by Grubbs and co-workers in a remarkable synthesis of the fragrant natural product (−)-muscone (**166**, Scheme 30), whereby sequential alkene ring-closing metathesis, hydrogen transfer, and hydrogenation reactions were mediated in a one-pot process by complexes derived from a single ruthenium carbene species, namely complex **2**.[152] As illustrated in Scheme 30, this sequence began with the treatment of diene **163**, bearing an unprotected secondary hydroxy group, with initiator **2** (7 mol%) in 1,2-dichloroethane at 50 °C, which effected the desired ring-closing-metathesis reaction to initially afford macrocyclic alkene **164** as a mixture of geometrical isomers. Subsequent addition of 3-pentanone and NaOH to this solution followed by heating to reflux then initiated the ruthenium-catalyzed transfer dehydrogenation of alcohol **164**, formally transferring "H_2" from this intermediate to the 3-pentanone (which is used in excess to drive this reversible reaction in the desired direction) to afford macrocyclic ketone **165**. At this point the reaction mixture was transferred to a Parr hydrogenation apparatus, pressurized with H_2 gas (800 psi), and heated to 80 °C. Under these conditions, the ruthenium complex(es) present is converted into ruthenium hydride species, which function effectively to hydrogenate the 1,2-disubstituted alkene chemoselectively in the presence of the ketone carbonyl group. Only once this stage was complete was the reaction mixture worked up and purified to give the targeted product **166** in an overall yield of 56% for the three steps.[153] This approach to "tandem catalysis"[152] offers great potential for the streamlining of synthetic processes and will undoubtedly find many more exciting applications in target-oriented synthesis once its fuller scope is convincingly demonstrated.[154]

2.4. Diastereoselective and Enantioselective Alkene Metathesis

One of the frontiers of the alkene-metathesis reaction is its use in the generation of stereogenic centers within molecules. The two main methods that have been employed to achieve this process are: 1) diastereoselective ring-closing-metathesis reactions, with achiral metathesis catalysts, of systems containing pre-existing stereogenic centers and 2) enantioselective metathesis reactions of achiral substrates with chiral catalysts. An example of the former protocol is in the novel approach to the synthesis of selective NK-1 receptor antagonists (e.g. **174**, Scheme 31) developed by workers at Merck.[155,156] The spirocyclic core structure characteristic of this class of therapeutic agents had been previously synthesized in a stepwise manner, involving the fusion of the tetrahydrofuran ring onto a preexisting enantiomerically pure piperidine scaffold.[157] The Merck team was keen to investigate more direct and conceptually novel methods for the construction of this bicyclic template and found that this ring system could be formed in a single step from an acyclic precursor by using a diastereoselective double ring-closing-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 31. Diastereoselective double ring-closing metathesis and reductive Heck reactions in the synthesis of an NK-1 receptor antagonist **174** (Merck, 2001).[155]

metathesis reaction. Thus, as is shown in Scheme 31, treatment of the (*S*)-phenylglycine-derived tetraene **167** with the first-generation Grubbs catalyst **2** (4 mol%) in $CHCl_3$ at ambient temperature led to the formation of the two diastereoisomeric products **170** and **171** in a combined yield of 86% yield and with 70% diastereoselectivity. The major pathway for this reaction was believed to involve the initial formation of the five-membered ring to generate dihydrofuran intermediates **168** and **169**, which then undergo the second, slower ring closure. The diastereoselectivity of the overall process thus arises during the first stage, with the preferential cyclization of the *O*-allyl group onto one of the two diastereotopic C5 vinyl groups, dictated by the adjacent tertiary stereocenter. Following the separation of the major isomeric product **170** from the undesired component **171**, a remarkably chemo-, regio-, and stereoselective reductive Heck reaction was then employed to append the aromatic ring onto C3 of the dihydrofuran ring to give tricyclic compound **173**, which was converted, in two steps, into the final target structure **174**.

While undeniably elegant, there are a number of limitations associated with this type of diastereoselective metathesis process. Firstly, one or more stereogenic centers have to be incorporated into the precursor molecule at sites where they can influence the course of the reaction. More importantly, since the stereochemical course of the reaction is under substrate control, it is generally not possible to obtain selectively both possible diastereoisomeric products through modification of the reaction conditions. A more appealing approach in this regard would be to induce asymmetry in achiral molecules through the use of chiral metathesis catalysts since, in principle, one could obtain selectively either product stereoisomer through the use of the appropriate catalyst antipode. Collaborative efforts between the Schrock and Hoveyda groups have led to the development of such chiral molybdenum-based catalysts for catalytic asymmetric alkene metathesis. More recently, chiral ruthenium-based systems have been introduced by the Grubbs group;[158] however, to date, it is the corresponding molybdenum complexes that have been the most widely studied. Applications of this emerging methodology in total synthesis are still rare, and since catalytic asymmetric metathesis has recently been authoritatively reviewed,[159] the most recent example of this process in target-oriented synthesis may suffice to demonstrate its enormous potential. Thus, as illustrated in Scheme 32, Schrock, Hoveyda, and co-workers employed a

Scheme 32. An asymmetric ring-opening/ring-closing-metathesis cascade in the enantioselective synthesis of (+)-africanol (**181**) (Schrock, Hoveyda, and co-workers, 2004).[160]

novel asymmetric ring-opening-/ring-closing-metathesis cascade reaction to furnish the bicyclic core structure and prove the stereochemical identity of the sesquiterpenoid (+)-africanol (**181**).[160] Treatment of readily available diene **175** with the chiral molybdenum carbene initiator **176** in pentane at ambient temperature effected its conversion, over the course of 6 h, into the rearranged bicyclic structure **180**, which was formed in nearly quantitative yield (97%) and with good enantioselectivity (87% *ee*). Notably, this reaction could be carried out under highly concentrated conditions, with sufficient pentane being added just to dissolve the chiral catalyst, yet homodimeric products were not observed. This metathesis cascade effects the enantioselective desymmetrization of a *meso* precursor substrate **175**, the most commonly employed mode of asymmetric alkene metathesis. This cascade sequence gave the team an extremely rapid and enantioselective access to an advanced intermediate **180**, which contained most of the key structural features present in the natural product **181**. Thus, with intermediate **180** in hand, these researchers were able to complete their elegant total synthesis in only a few more steps.

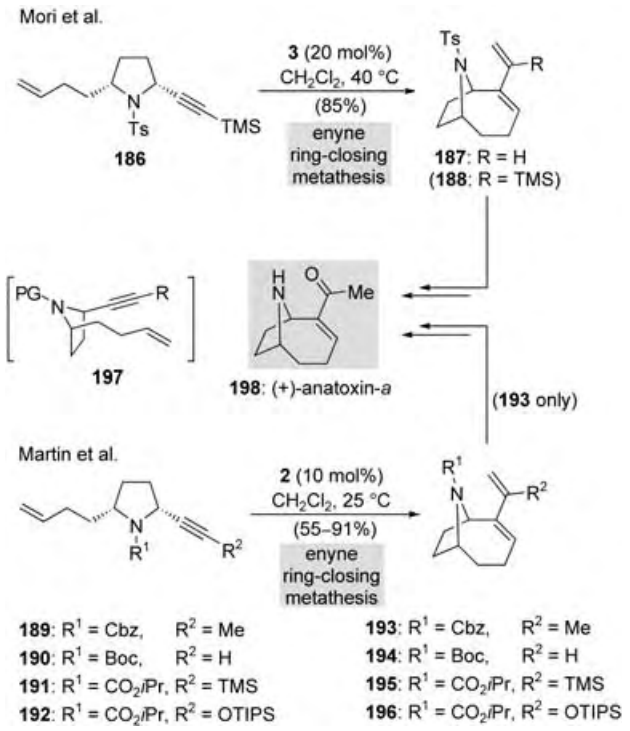
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3. The Enyne-Metathesis Reaction

The enyne-metathesis reaction is an extremely useful method for the construction of 1,3-diene systems, often in a stereoselective manner, from simpler precursor molecules under mild conditions. The synthetic value of this reaction is enhanced by the fact that, in addition to being a means to an end in itself, the 1,3-diene systems thus formed are themselves versatile synthetic intermediates that can undergo further selective transformations (e.g. cycloaddition reactions). The intramolecular (ring-closing) enyne-metathesis reaction is a particularly powerful method for the construction of ring systems, both carbocyclic and heterocyclic and, indeed, it is in this context that the reaction has found the most use. Intermolecular (cross-metathesis) reactions have been employed much less frequently owing to the perceived difficulties in achieving at least reasonable levels of selectivity; however, even in this case there have been tremendous advances in recent years. The most widely used initiators for enyne metathesis are the ruthenium carbene based catalyst precursors, which have been "borrowed" from the alkene-metathesis realm, but which serve equally admirably in this context and exhibit the by now familiar levels of high activity and functional-group tolerance in these processes as well.[161] Here we highlight some of the most elegant and instructive applications of the enyne-metathesis reaction in total synthesis.

3.1. Enyne Ring-Closing Metathesis

It was the Mori group who pioneered the use of ruthenium carbene complexes in enyne-metathesis chemistry, first demonstrating its applicability to the formation of five-, six-, and seven-membered nitrogen-containing heterocyclic rings in 1994.[162] Inspired by this achievement, it was not long before the same group also reported the first application of an enyne-metathesis reaction in a total synthesis, namely that of the tricyclic alkaloid (−)-stemoamide (**185**, Scheme 33) in 1996.[163] The team reasoned that, once a stereoselective route to bicyclic compound **183** had been secured, the resulting diene system would provide a convenient handle for the fusion of the third and final ring onto the structure,



Scheme 33. Enyne ring-closing metathesis in the enantioselective synthesis of (−)-stemoamide (**185**) (Mori and Kinoshita, 1996).[163]

thus completing the total synthesis. The immediate issue then became the construction of bicyclic intermediate **183**, and it was proposed that this compound could, in turn, arise from the enyne ring-closing metathesis of precursor **182**. To their delight, the researchers found that this transformation could be effected by treatment of a solution of precursor **182** in CH_2Cl_2 with the first-generation Grubbs catalyst **2** (4 mol%) at ambient temperature, to furnish bicyclic product **183** in 87% yield and without any erosion of stereochemical integrity at the sensitive propargylic position. This reaction is all the more noteworthy in light of the researchers' previous experience of enyne ring-closing-metathesis reactions of alkyne systems bearing carboalkoxy substituents, namely that, while the cyclization itself is accelerated by the presence of the ester substituent, the resulting sensitive cross-conjugated product typically undergoes extensive decomposition during purification and is only isolated in low yields.[162] To rationalize the apparent discrepancy in the excellent yield of compound **183**, it was proposed that the diene system is forced, by steric effects, to adopt a nonplanar conformation in which conjugation between the two alkene π systems is minimal, thus protecting the system from the destruction that otherwise might have been expected to occur. With intermediate **183** then in hand, only a few more steps were required to arrive at the targeted product **185**.[164] Interestingly, the formation of a trisubstituted alkene system such as **184** (Scheme 33) through simple alkene metathesis in the presence of the ruthenium carbene catalysts available at the time (e.g. **2**) would have been exceedingly difficult, if not impossible, yet this was readily accomplished by means of enyne metathesis.

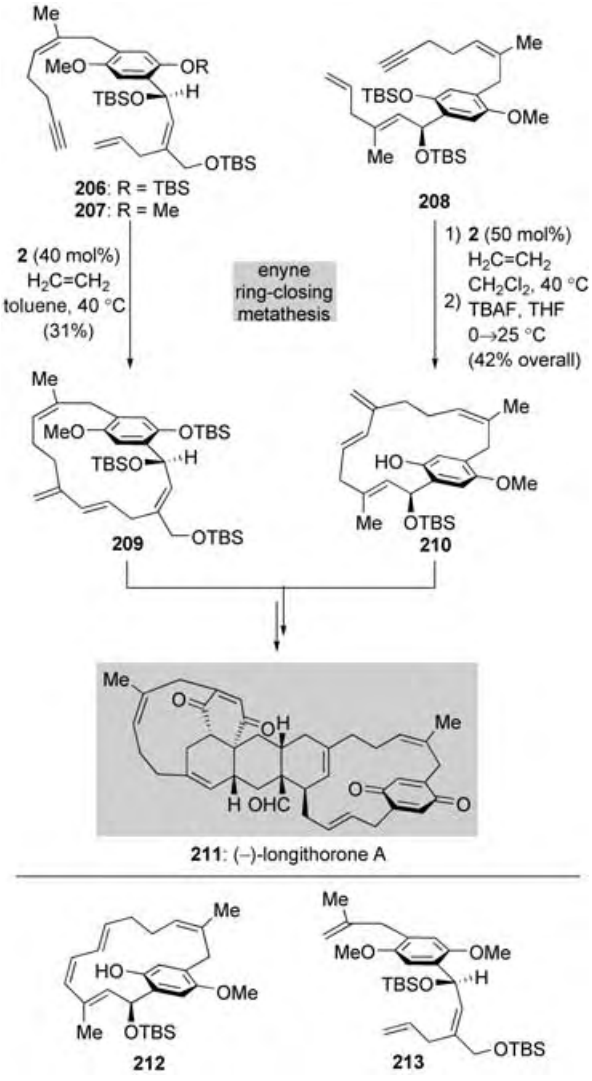
More recent applications of enyne metathesis in alkaloid total synthesis can be found in the concise routes to (+)-anatoxin-*a* (**198**, Scheme 34) developed independently and almost simultaneously by the groups of Martin[165] and Mori.[166] Despite its modest molecular weight, anatoxin-*a* has proven to be a particularly tempting target for synthetic chemists, due not only to its biological profile[167] but also to its unusual aza-bridged bicyclic structure, and has accordingly inspired a legion of elegant synthetic approaches.[168,169] The cornerstone of both groups' strategies was the employment of enyne ring-closing-metathesis reactions of readily available *cis*-2,5-disubstituted pyrrolidine precursors to assemble rapidly the bicyclic core framework, followed by the appropriate side-chain manipulation and amine-deprotection maneuvers required to complete the total synthesis. While the use of ring-closing olefin-metathesis reactions in the construction of bridged aza-bicyclic structures had been documented,[170] the formation of such systems through the corresponding enyne-metathesis processes represented uncharted terrain, which served to heighten the novelty associated with these proposed steps. In the event, both groups found that with the appropriate substrates the desired cyclizations could be effected with remarkable ease and efficiency. Martin and co-workers induced the cyclization of precursor **189** (R^1 = Cbz, R^2 = Me) by treatment with the second-generation Grubbs catalyst **3** (10 mol%) in CH_2Cl_2 at ambient temperature to afford bicyclic compound **193** in 87% yield. Selective oxidative cleavage of the less substituted double bond

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 34. Enyne ring-closing-metathesis approaches to the total synthesis of (+)-anatoxin-*a* (**198**) (Martin and co-workers, 2004; Mori and co-workers, 2004).[165,166]

followed by removal of the Cbz group then yielded the target compound. The group had in fact previously shown that a variety of substituted alkynes, for example, **190**, **191**, and **192**, could undergo enyne ring-closing metathesis to generate the corresponding bicyclic systems **194**, **195**, and **196** in good yields. However, with the finishing line within tantalizing reach, the researchers were thwarted in their valiant efforts at converting any one of **194**, **195,** or **196** into the target compound **198**, and it was with only their fourth substrate **193** that the final synthetic hurdles could be surmounted. If nothing else, these tribulations illustrate the fact that synthetic routes almost invariably contain unexpected pitfalls, and that fortune favors the persistent! Mori and co-workers found that while the enyne metathesis of alkyne **186**, carried out in refluxing CH_2Cl_2 in the presence of catalyst **3** (20 mol%), did indeed yield the desired bicyclic skeleton, unexpected desilylation occurred during the reaction to generate diene **187** as the observed product. Much to the team's relief diene **187** could be elaborated also to give the coveted target compound, this time through a selective oxymercuration/alcohol oxidation sequence. The facile nature of these cyclization reactions in generating rather strained bicyclic systems provides further evidence for the beneficial effects of biasing substrates to adopt a conformation favorable to cyclization. In the present case, the potential $A^{1,3}$-strain between the N-protecting group and the *cis*-2,5-pyrrolidine ring substituents favors the diaxial conformer **197**.[171] Finally, it should be mentioned that the Aggarwal group has also utilized an analogous approach in their elegant synthesis of the related alkaloid (−)-ferruginine, employing an enyne ring-closing metathesis to construct the more constrained azabicyclo[3.2.1]octane core structure present in the natural product.[172]

The intramolecular enyne-metathesis reaction also offers a useful method for the synthesis of macrocyclic ring systems, albeit one much less utilized than the corresponding alkene ring-closing macrocyclizations. However, when applying enyne ring-closing metathesis reactions to the synthesis of large rings, a number of selectivity issues, absent in other metathesis processes, arise and need to be taken into careful consideration. These issues relate to the orientation of ring closure, and have been elegantly summarized by Lee and Hansen.[173] Thus, as shown in Scheme 35, the ruthenium

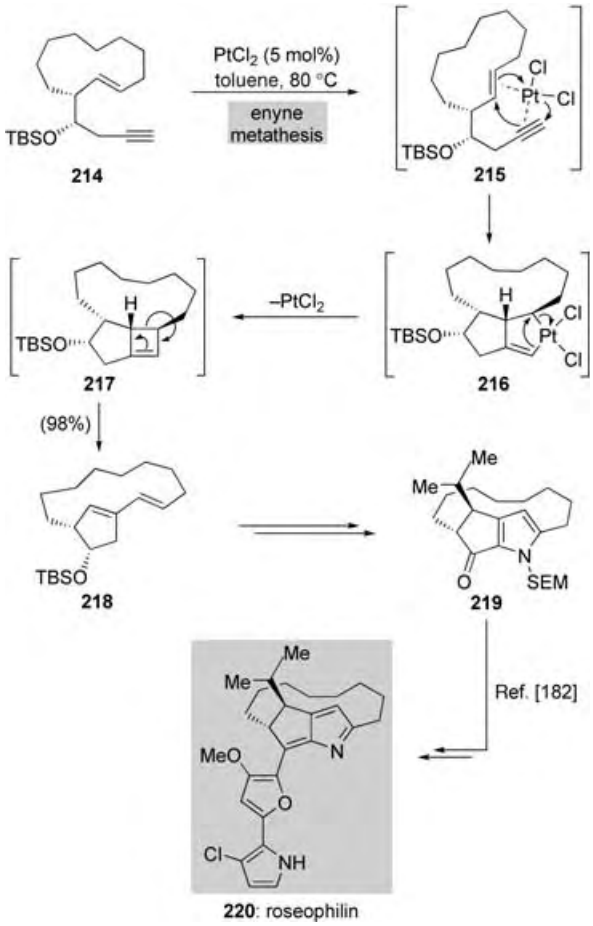


Scheme 35. Models for macrocyclization by enyne ring-closing metathesis: a) direct pathway; b) two-step enyne-cross-metathesis/alkene ring-closing-metathesis pathway (Lee and Hansen, 2003).[173]

carbene intermediate **200** generated from the starting enyne **199** can undergo two possible modes of ring closure, termed *exo* and *endo*, to generate the two different metallacyclobutene intermediates **201** and **202**, which subsequently yield the 1,2-disubstituted product **203** and 1,3-disubstituted product **204**, respectively. Furthermore, the *endo* mode of ring closure leads to products with an additional carbon atom within the ring relative to those derived from the *exo* mode. The mode of ring closure followed in any given case depends largely on the geometric constraints imposed by the tether linking the alkene and alkyne moieties. Thus, the formation of common- and medium-sized rings by enyne ring-closing metathesis is typically constrained to follow the *exo* path (as in the examples discussed above), whereas macrocyclizations generally follow the *endo* mode of ring closure owing to the increased flexibility of the tether. Another important factor to consider is that, following a seminal report by the Mori group,[174] enyne-metathesis macrocyclizations are generally conducted under an atmosphere of ethylene.[175] In these particular cases, the course of the macrocyclization is believed to be diverted away from that of a direct intramolecular

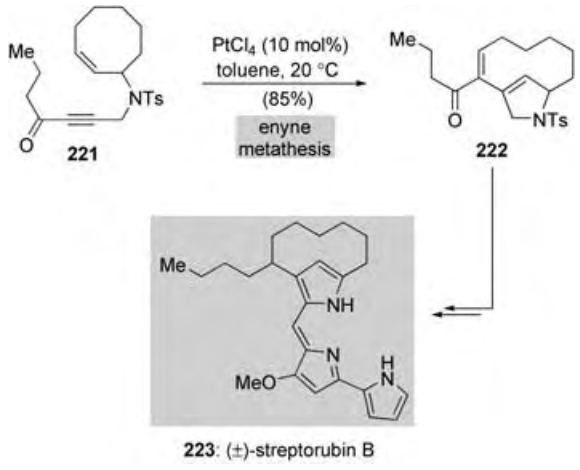
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

enyne-metathesis reaction, which would be expected to be inherently slow owing to the low effective concentration of the reacting termini. Instead, a two-step process has been proposed involving an initial rapid intermolecular enyne cross-metathesis of the terminal alkyne unit with ethylene (a known process, see below) to generate a 2-substituted butadiene **205**, which subsequently undergoes a conventional intramolecular alkene ring-closing-metathesis reaction. Given the sensitivity of the ruthenium metathesis catalysts to steric effects, the less hindered terminal double bond of the butadiene moiety would be expected to be engaged selectively in the macrocyclization event to yield the formal *endo* enyne-metathesis product **204**, and indeed this is observed experimentally.[176]



The regiochemical outcome of enyne-metathesis macrocyclizations certainly weighed heavily on the minds of Shair and co-workers as they embarked on their journey to complete the total synthesis of the marine natural product (−)-longithorone A (**211**, Scheme 36).[177] Inspired by the insightful biogenetic hypothesis of the Schmitz group,[178] the Shair team proposed to employ a beautifully choreographed sequence of inter- and intramolecular Diels–Alder reactions to assemble much of the imposing polycyclic architecture of this remarkable natural product. This then led them to conceive of macrocyclic compounds **209** and **210** as key synthetic intermediates, corresponding to the "left" and "right" halves of the natural product, respectively. On first inspection, the stereocontrolled synthesis of these "simpler" intermediates would still appear to be far from trivial. However, recognizing the characteristic 1,3-disubstituted butadiene system embedded within both compounds **209** and **210**, the team began to contemplate the exciting possibility of constructing both intermediates through enyne ring-closing-metathesis reactions of the respective precursors **206** and **208**. From the discussion above (see Scheme 35), one would be forgiven for thinking that this was a fairly routine assumption, but at the time enyne metathesis had never been applied to the synthesis of macrocycles, only to smaller rings, which had always resulted in the formation of the corresponding 1,2-disubstituted cyclic products. Eager to answer the question of 1,2- versus 1,3-disubstitution selectivity in enyne-metathesis macrocyclizations, the group performed some simple model studies, which showed for the first time that the desired 1,3-disubstituted diene systems could be obtained preferentially, if not exclusively, in the formation of larger rings. Emboldened by this breakthrough, the group set to work on the real system and arrived at intermediates **206** and **208** in short order. At this point, it will be noted that both **206** and **208** bear seemingly extraneous functionality, in the shape of benzylic hydroxy group derivatives, which is not present in the target product **211**. These substituents were, in fact, key to the planning of the macrocyclization reactions, as it was anticipated that these groups would gear the ring closures to produce selectively only the desired atropisomers of the cyclized products. Specifically, the potential steric interactions between the benzylic TBS ether groups and the phenolic hydroxy derivatives would, ideally, dictate that macrocyclization of compounds **206** and **208** occur selectively through the lower-energy conformers shown, thus generating the desired atropisomeric products.[179] In practice, the cyclization of enyne **208**, induced by treatment with catalyst **2** (50 mol%) in refluxing CH_2Cl_2 under ethylene atmosphere, proceeded with both excellent atropselectivity and *E*/*Z* selectivity to afford, after treatment of the crude product mixture with TBAF to effect the selective desilylation of the phenolic hydroxy group, the desired paracyclophane **210** in 42% overall yield. A significant by-product formed in this reaction was the unusual paracyclophane **212** in which a methylene group was lost during the macrocyclization.[180] In contrast, the macrocyclization of enyne **206** was both less atropselective (3:1) and less selective in the control of the endocyclic olefin geometry (*E*/*Z* 4.5:1); nevertheless, the desired product **209** could be produced reliably in yields averaging 31%. In the absence of an ethylene atmosphere, macrocyclization did not occur with either **206** or **208**; thus, it seems likely that both reactions proceed through the two-step process alluded to earlier. Interestingly, when the cyclization of precursor **207** was attempted in the presence of the more

Scheme 36. Enyne ring-closing-metathesis macrocyclizations in the enantioselective total synthesis of (−)-longithorone A (**211**) (Shair and co-workers, 2002).[177]

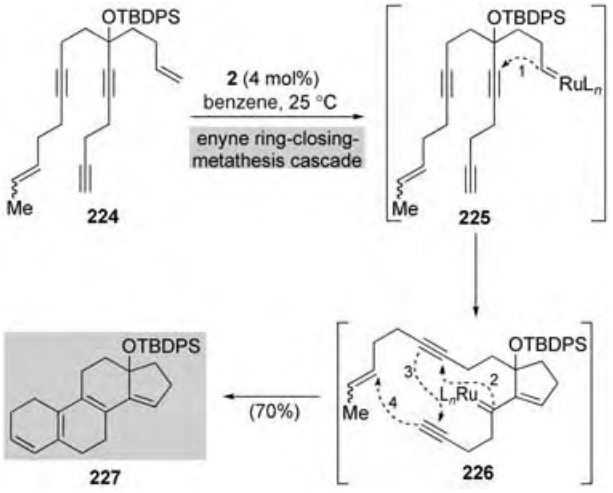


reactive ruthenium initiator **3**, the unexpected product **213** was obtained in which the alkyne-bearing side chain had been truncated, presumably resulting from the increased activity of this catalyst towards trisubstituted olefins. Having secured both the key intermediates **209** and **210**, the Shair group was then able to complete the total synthesis in only a few more steps. Significantly, the 1,3-diene systems formed in both intermediates **209** and **210** ultimately participated in the crucial biomimetic Diels–Alder reactions. This meritorious total synthesis is noteworthy not only for its pioneering applications of enyne metathesis in macrocyclizations, but also in that it sets a new "gold standard" for enyne-metathesis chemistry in general.

An important feature of the enyne-metathesis reaction is that, unlike the other metathesis processes we have discussed so far, the overall process can be mediated by catalysts other than metal carbene containing species, and in these cases the reaction can proceed by (one or more) entirely different mechanisms. An illustrative example can be found in the formal total synthesis of roseophilin (**220**, Scheme 37) by Trost and Doherty.[181,182] The treatment of enantiomerically pure enyne **214** with $PtCl_2$ (5 mol%) in toluene at 80°C initiated a sequence of events involving the formal cleavage of one and the formation of two carbon–carbon double bonds, expansion of a macrocyclic ring by two carbon atoms, and the

Scheme 37. $PtCl_2$-catalyzed enyne metathesis in the formal synthesis of roseophilin (**220**) (Trost and Doherty, 2000).[181]

installation of a bridgehead alkene moiety, ultimately leading to the formation of the bicyclic product **218** as a single stereoisomer in a remarkable yield of 98%! The 1,3-diene system in compound **218** then provided a handle for its elaboration into tricyclic compound **219**, an intermediate in the Fürstner group's pioneering total synthesis of roseophilin (**220**),[183] and thus the completion of the formal synthesis of the natural product. The mechanism proposed for this transformation invokes a platinum(II)⇄platinum(IV) manifold, involving the initial formation of the metallacyclopentene intermediate **216**, followed by reductive elimination to generate cyclobutene **217**, which under the conditions of the reaction undergoes conrotatory electrocyclic ring-opening (driven by the release of ring strain) to yield the observed product **218**. It has been shown that a wide range of electrophilic species, ranging from other transition-metal complexes (e.g. $[\{RuCl_2(CO)_3\}_2]$, $[IrCl(CO)_3]_n$, and various palladacycles) to simple Lewis and Brønsted acids that cannot undergo redox equilibria (e.g. $BF_3{\cdot}OEt_2$, $AlCl_3$, and HBF_4) are also effective catalysts for this type of transformation. In these cases, alternative mechanistic pathways have been proposed involving formal cationic intermediates.[184] These types of transformations have been termed "skeletal reorganizations" to differentiate them from the metal carbene mediated processes; however, they all fall under the banner of enyne metathesis since the net outcome is the same.[185] Semantics aside, these reactions offer a remarkably simple, atom-economical, and user-friendly method for generating molecular complexity by employing the most basic of catalyst systems. Another example of this type of enyne metathesis is in the synthesis of streptorubin B (**223**, Scheme 38) by the



Scheme 38. $PtCl_4$-catalyzed enyne metathesis in the total synthesis of (±)-streptorubin B (**223**) (Fürstner and co-workers, 1998).[183a]

Fürstner group, in which the metathesis of enyne **221**, mediated by a catalytic amount of $PtCl_4$ (10 mol%), generated bicyclic pyrrolophane **222** in 85% yield.[183a] The same transformation could also be effected with $BF_3{\cdot}OEt_2$ or HBF_4 as catalysts, although the yield of the product was somewhat lower in these cases (64% and 57%, respectively).

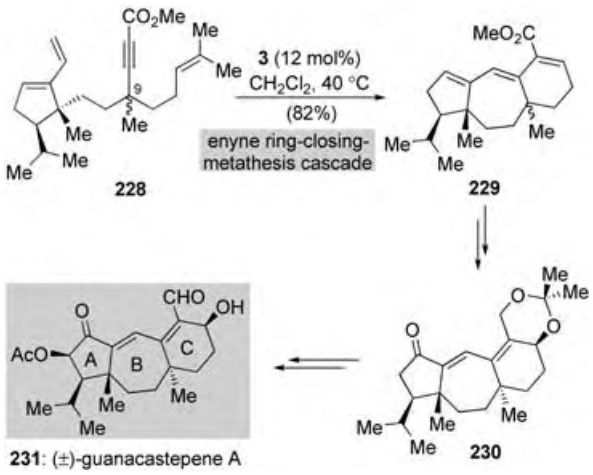
3.2. Enyne Metathesis in Cascade Processes



One of the most exciting and powerful applications of the enyne-metathesis reaction is its use in cascade processes to generate complex polycyclic structures from simpler precursor substrates. An enyne ring-closing-metathesis reaction initially generates a new metal carbene that can potentially be intercepted by another appropriately located olefin within the same molecule, resulting in a second intramolecular metathesis event to form another ring and a new metal carbene species, and so on. The first examples of tandem enyne metathesis were reported by Grubbs and co-workers,[186] with the same group subsequently reporting the instructive example highlighted in Scheme 39.[187] Thus, exposure of acyclic

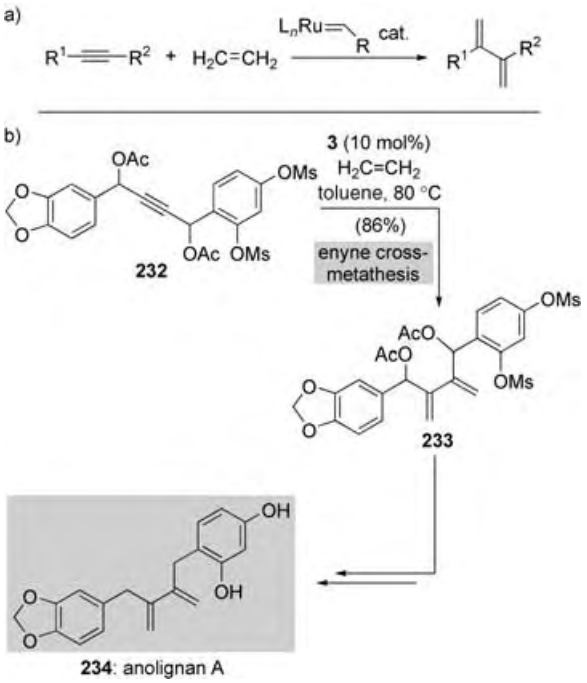
Scheme 39. Use of a domino enyne ring-closing-metathesis sequence for the construction of a steroid-type polycycle **227** (Grubbs and co-workers, 1996).[187]

compound **224** to ruthenium catalyst **2** (4 mol%) in benzene at ambient temperature triggered a cascade sequence resulting in the regiocontrolled formation of four new carbon–carbon bonds and four new rings to afford the steroid-type compound **227** in 70% yield. The initiation of this highly orchestrated process presumably occurred with the insertion of the ruthenium alkylidene into the most (kinetically) reactive terminal alkene of the starting material **224** to generate **225**. The latter carbene species underwent enyne ring-closing metathesis with the proximal triple bond to generate the subsequent intermediate **226**, a substrate poised to react, in order, with the next three sites of unsaturation. Hence, each alkyne unit serves as a metathesis relay point, thus allowing the propagation of the polycyclization cascade until the terminating alkene ring-closing-metathesis event. Through the judicious positioning of unsaturation within an acyclic precursor molecule, one can envisage any possible number of multiple ring-forming processes.

The Hanna group made gainful use of this type of tandem ring-closing process in their recent formal synthesis of guanacastepene A (**231**, Scheme 40).[188] The first total synthesis of this novel tricyclic diterpene had been reported in 2002 by the Danishefsky group,[189] with a subsequent formal

Scheme 40. An enyne ring-closing-metathesis cascade in the formal synthesis of (±)-guanacastepene (**231**) (Hanna and co-workers, 2004).[188]

synthesis being reported by Snider and co-workers a year later.[190] Both of these two elegant syntheses adopted a stepwise approach to the construction of the tricyclic core structure, first fusing the seven-membered ring onto a pre-existing cyclopentane derivative, then at a later point installing the final six-membered ring (i.e. A→AB→ABC). In an unprecedented approach to this terpene skeleton, Hanna and co-workers surmised that it would be possible to generate the characteristic tricyclic ring system of guanacastepene A (**231**) in a single step from an appropriate monocyclic A-ring precursor through a tandem enyne ring-closing-metathesis reaction (i.e. A→ABC). Indeed, it was found that readily available ester **228** (as a 1:1 mixture of epimers at the C9 stereocenter) underwent the desired cyclization cascade upon treatment with the second-generation Grubbs catalyst (12 mol%) in refluxing CH_2Cl_2 to afford exclusively tricyclic compound **229** in 82% yield. The particular use of catalyst **3** was essential to the success of this transformation, as previous studies by the group had indicated that the less active ruthenium-based catalyst **2** was ineffective at promoting similar reactions.[191] The selectivity of this cascade process is quite remarkable, and is again due to the fact that the reaction had been "programmed" to initiate at a specific point in the precursor molecule **228**, namely the least hindered (and hence most kinetically reactive) terminal alkene, thus ensuring the correct regiochemical outcome. Equally important is the fact that the triene functionality concomitantly installed in the formation of intermediate **229** proved to be amenable enough to allow its elaboration to give ketone **230**, a late-stage intermediate in the Danishefsky team's original total synthesis of guanacastepene A (**231**), thus completing the formal synthesis of the natural product.[192]



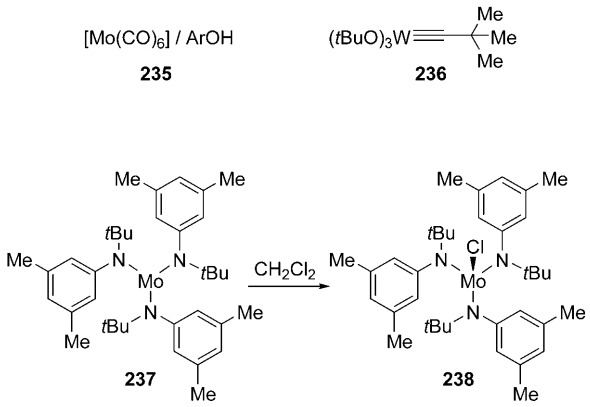
3.3. Enyne Cross-Metathesis

In comparison to the generally reliable, high-yielding, and selective intramolecular processes, intermolecular enyne metathesis (enyne cross-metathesis) has seen little use in

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the synthesis of complex molecules, despite its appealing potential for the formation of synthetically useful acyclic 1,3-diene systems in fragment-coupling processes.[193] The biggest problem in effecting intermolecular metathesis between an alkene and an alkyne is selectivity. Not only can three different types of intermolecular metatheses (alkene, alkyne, and enyne) potentially occur in these reactions, but the formation of stereoisomeric *E*/*Z* mixtures in the desired cross-metathesis diene product can also be a major problem. Currently, the success or failure of any given intermolecular enyne-metathesis reaction appears to be very substrate-dependent, and there is as yet no "working model" that can be used to predict the outcome of these reactions reliably.

The most common application of intermolecular enyne metathesis employs ethylene as the alkene component, and this provides a particularly convenient method for the production of 2,3-disubstituted butadiene systems (or 2-substituted butadienes in the case of terminal alkynes), an important and synthetically useful structural motif (Scheme 41 a). This protocol was introduced by the Mori group,



Scheme 41. Enyne cross-metathesis: a) generalized scheme; b) application to the total synthesis of anolignan A (**234**) (Mori and co-workers, 2002).[194a]

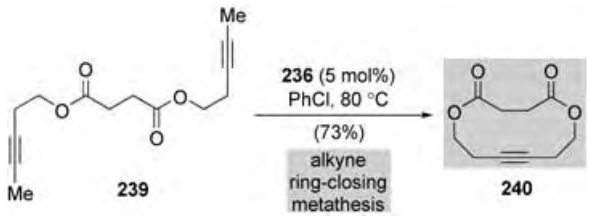
who subsequently applied it to an expedient synthesis of anolignan A (**234**, Scheme 41 b).[194] Thus, the cross-metathesis of internal alkyne **232** was induced by treatment with initiator **3** (10 mol%) in toluene at 80 °C under ethylene at atmospheric pressure to furnish butadiene **233** with the required regiochemistry and in 86% yield. A few more routine steps then completed the total synthesis. These cross-metathesis conditions were found to be more effective than those in the presence of the first-generation ruthenium catalyst **2** (10 mol%, CH_2Cl_2, 25 °C), which gave **233** in lower yield (65%). Indeed, heteroatom substitution at the propargylic position(s) of the alkyne coupling partner is(are) generally required to attain at least satisfactory yields when using catalyst **2** in this type of cross-metathesis, whereas the more active catalyst **3** is effective with a much wider range of terminal and internal alkynes.[195] Atmospheric pressure of ethylene is usually sufficient for these reactions, although the Diver group reported that certain sluggish cases can be accelerated by employing ethylene at elevated pressures.[196]

The first enyne-cross-metathesis reactions of substituted alkenes to afford acyclic 1,3-disubstituted butadiene systems were reported by the Blechert group in 1997.[197] The potential utility of these processes has since caught the attention of many researchers, who have developed their own improvements and applications,[198] including elegant cascade reactions.[199] Nevertheless, the first application of an enyne-cross-metathesis reaction with an alkene other than ethylene in a total synthesis remains an unfulfilled, yet eagerly anticipated, event[200] representing as it does one of the frontiers of enyne-metathesis chemistry.

4. The Alkyne-Metathesis Reaction

Despite the mechanistic parallels between alkyne metathesis and its more ubiquitous alkene-based sibling, the familiar carbene-type catalysts used most routinely in alkene metathesis (e.g. **1**, **2**, and **3**) do not catalyze the corresponding alkyne-metathesis reactions. Instead, this field has its own selected assortment of transition-metal-based catalyst systems, of which the most commonly employed three are illustrated in Scheme 42. The first of these is the classic

Scheme 42. Commonly used alkyne-metathesis initiators.

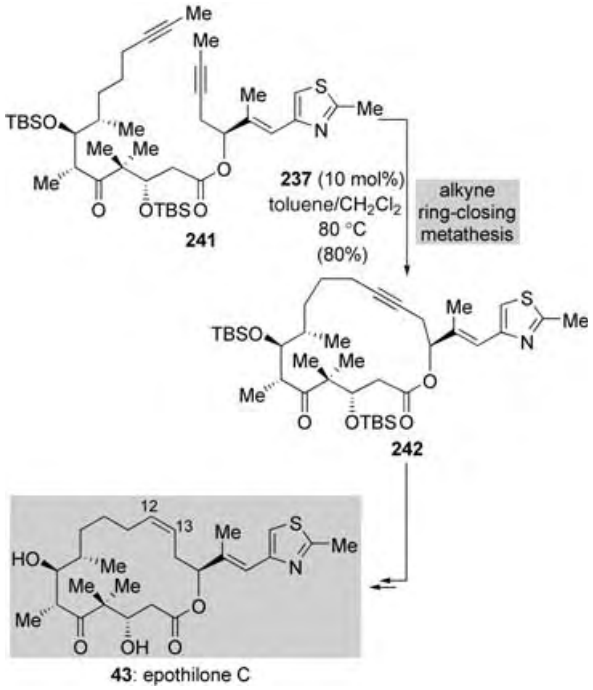


Mortreux system **235**[25] (later refined by Bunz and co-workers)[201] based on a mixture of $Mo(CO)_6$ and any one of a number of phenolic additives (e.g. 4-chlorophenol), which generates one or more not as yet well-defined catalytically active species in situ. The simplicity and user-friendly nature of this catalyst system is offset somewhat by its rather limited tolerance of polar functional groups and the elevated temperatures (ca. 140–150 °C) required to initiate and maintain

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

catalytic activity. A major breakthrough in rational catalyst design for alkyne metathesis came with the development of well-defined tungsten alkylidyne complexes by the Schrock group, of which catalyst **236** is the most widely used.[202] Recently, the Fürstner group introduced the monochloro molybdenum complex **238** as a powerful precatalyst for alkyne metathesis; **238** is conveniently formed in situ by the activation of the corresponding trisamido complex **237** with CH_2Cl_2 as a chlorine source.[203–205] The tungsten and molybdenum complexes **236** and **238** complement each other nicely in terms of scope, activity, and functional-group tolerance, and typically perform more efficiently in advanced settings than do the Mortreux catalysts **235**.

4.1. Alkyne Ring-Closing Metathesis

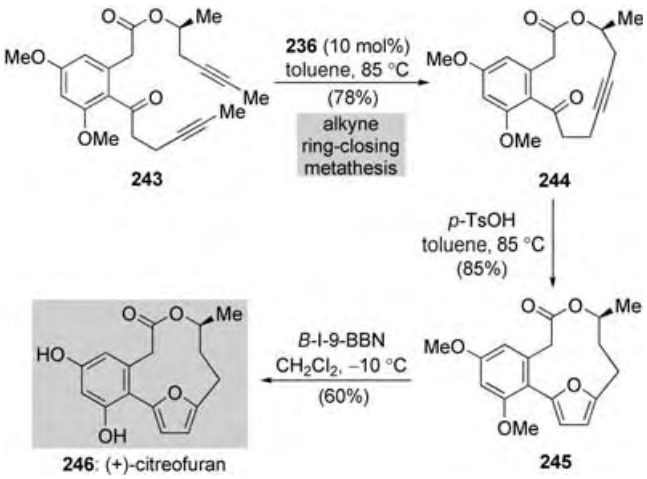


In the 20 or so years following its discovery, alkyne metathesis had found only sporadic and limited application in organic synthesis.[206] However, a groundbreaking report by the Fürstner group in 1998 detailing the first examples of alkyne ring-closing metathesis,[207,208] of which one is illustrated in Scheme 43, heralded a new era for this process. It is

Scheme 43. One of the first applications of alkyne ring-closing metathesis (Fürstner and Seidel, 1998).[207]

an indication of the rapid blossoming of the field that, even only a few years later, these first examples now appear extremely modest; nonetheless they remain highly instructive. Thus, the treatment of diyne **239** with a catalytic amount of the Schrock tungsten initiator **236** (5 mol%) in chlorobenzene at 80 °C led to smooth cyclization to generate the corresponding 12-membered cycloalkyne **240** in 73% yield. Several features of this reaction deserve further comment. First, terminal alkynes make poor substrates for alkyne-metathesis reactions as they deactivate the catalysts and are prone to polymerization. Thus, methyl-substituted alkynes are routinely employed, since not only are they sufficiently reactive, but the by-product (2-butyne), which has to be sacrificed, is volatile and easily removed. Secondly, systems smaller than 12-membered rings have not yet been formed in synthetically useful yields by alkyne ring-closing metathesis,[209] as a result of the geometric constraints of the alkyne unit and the resulting product strain; thus this process is restricted to macrocyclization reactions. Finally, an interesting and useful empirical observation is that alkyne ring-closing-metathesis reactions generally proceed even faster than those of the corresponding alkene ring-closing-metathesis macrocyclizations.

However, the real utility of alkyne ring-closing metathesis stems from the subsequent selective manipulations that are possible with the alkyne system thus formed. In particular, the combination of alkyne ring-closing metathesis followed by stereoselective partial reduction of the triple bond offers an efficient, though indirect, method for the preparation of macrocyclic alkenes of well-defined *E* or *Z* stereochemistry. As we have seen, alkene ring-closing-metathesis macrocyclization reactions are often plagued by the formation of geometrical isomers, with the product distribution often not being predictable and varying dramatically with seemingly subtle changes in precursor structure. This can often have disastrous consequences in terms of product isolation and yield, particularly if it occurs at a late stage in a multistep synthetic route. A case in point is the various approaches to the total synthesis of epothilone C **43** (see Scheme 10). Indeed, it is interesting to note that while three of the earliest total syntheses (those of the Nicolaou,[68] Danishefsky,[69] and Schinzer groups[71]) all employed successful, yet relatively nonstereoselective, alkene ring-closing-metathesis reactions to fashion the C12–C13 double bond; subsequent approaches have largely shied away from this protocol, employing instead more conventional olefination methods, which in this context allowed greater control of alkene stereochemistry.[210] Upon revisiting this problem, the Fürstner group postulated that the stereoselective formation of the coveted natural C12–C13 *Z* isomer of epothilone C could indeed be achieved by metathesis technology through the alkyne ring-closing metathesis of diyne **241** followed by hydrogenation in the presence of the Lindlar catalyst (Scheme 44). This system thus proved to be a significant testing ground for their nascent method. The team found that the desired macrocyclization could be effected in a pleasing 80% yield by treatment of substrate **241** with the

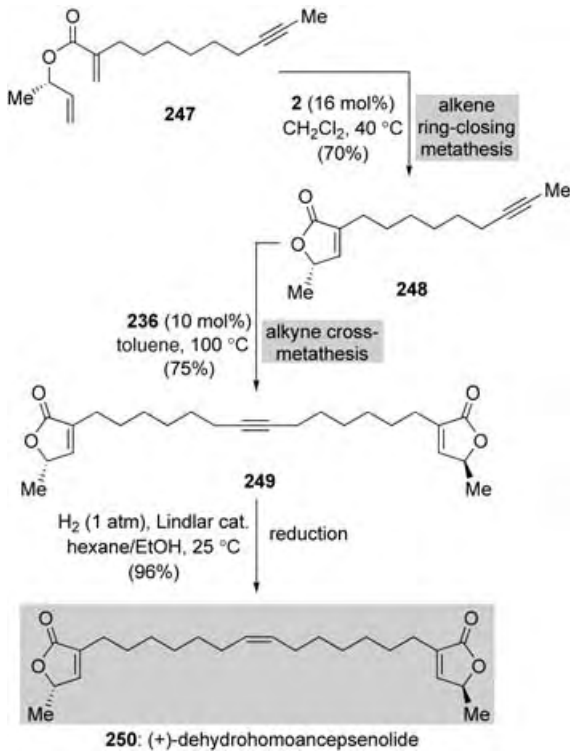


Scheme 44. Alkyne ring-closing metathesis in the total synthesis of epothilone C (**43**) (Fürstner and co-workers, 2001).[211]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

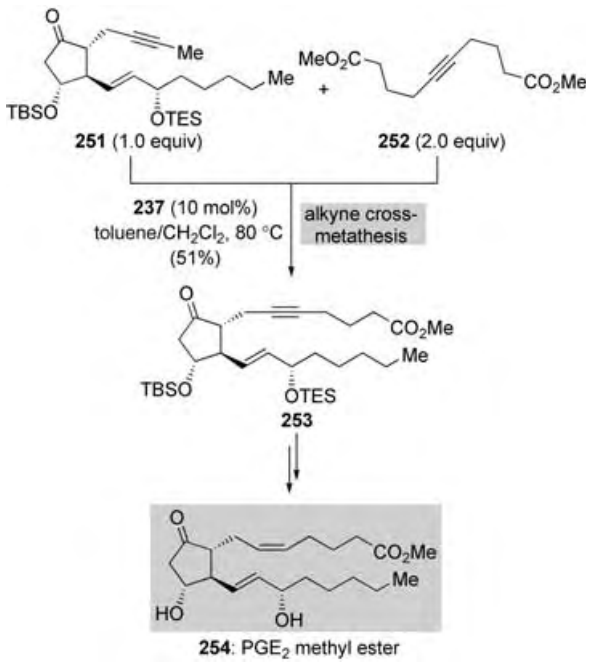
trisamido molybdenum catalyst precursor **237** (10 mol%) in a toluene/CH_2Cl_2 solvent mixture at 80 °C for 8 h.[211] Only two more steps, one of which involved the chemo- and stereoselective semi-hydrogenation of the triple bond under Lindlar conditions, were then required to unveil the target compound **43**.[203b] Notably, the catalyst system rigorously distinguishes between the (reactive) alkyne moieties and the preexisting double bond present in the precursor **241**; indeed, a useful feature of alkyne metathesis is that alkene systems are generally inert toward the catalysts. The particular choice of catalyst system in this case was important, owing to its tolerance of both the sulfur and basic nitrogen atoms of the thiazole ring, the presence of which would have been deleterious to the use of the Schrock catalyst **236**.

The Fürstner group has applied this alkyne ring-closing metathesis/Lindlar reduction protocol in the stereocontrolled synthesis of a number of other macrocyclic natural products,[212] thus demonstrating the versatility, broad applicability, and mildness of this method. It is important to also recall the recent development of novel mild procedures for the conversion of alkynes into the corresponding *E*-alkene systems.[213,214] However, given the synthetic versatility of the alkyne group, it is only appropriate that other ways to elaborate the cycloalkynes formed by alkyne ring-closing metathesis besides simple hydrogenation procedures have begun to be investigated. The first foray into this territory was recently documented in the enantioselective synthesis of (+)-citreofuran (**246**, Scheme 45). Although not readily apparent



Scheme 45. Alkyne ring-closing metathesis in the enantioselective synthesis of (+)-citreofuran (**246**) (Fürstner and co-workers, 2003).[215]

from a cursory inspection of the molecular structure of **246**, an alkyne-metathesis reaction was used to forge the macrocyclic ring system and to provide a handle for the construction of the furan ring.[215] Thus, as shown in Scheme 45, the readily prepared diyne **243** underwent smooth macrocyclization within 1 hour upon the addition of tungsten alkylidyne catalyst **236** (10 mol%) to a solution of the substrate in toluene at 85 °C to afford the 12-membered bicyclic product **244** in 78% yield. The relative ease of this cyclization is likely to be due, in part, to the presence of the preexisting aromatic ring, which restricts the conformational degrees of freedom available to the starting material **243**. Concomitantly, all the elements required for the formation of the furan ring had been installed during the cyclization. Hence, exposure of cycloalkyne **244** to acidic conditions rendered the somewhat strained triple bond susceptible to nucleophilic attack by the neighboring ketone group, thus initiating a transannular cycloaromatization event that led to the formation of tricyclic compound **245**.[216] With the complete skeleton of the target compound thus formed, the uneventful liberation of the phenolic hydroxy groups was all that was required to complete this concise total synthesis.[217] Notably, there is a particular strategic advantage associated with this order of ring construction (i.e. macrocycle then furan), namely that while the tricyclic framework of the natural product is in fact somewhat strained, the bulk of this strain energy is introduced during the kinetically favorable formation of a five-membered ring. In the alternative scenario (i.e. furan then macrocycle), the extra enthalpic energy barrier would have to be overcome during the macrocyclization event, which is inherently less favorable owing to entropic factors.[218]



4.2. Alkyne Cross-Metathesis

Alkyne cross-metathesis also holds great potential for selective and efficient carbon–carbon bond formation. To date, the major use of alkyne cross-metathesis has been in acyclic diyne metathesis (ADIMET) polymerization reactions, particularly in the preparation of poly(*p*-phenyleneethynylene) (PPE) type conjugated organic polymers which have a number of potentially useful applications.[219] Recently, however, the first applications in natural products synthesis have emerged. As with the corresponding alkene cross-metathesis reactions, for the purposes of categorization it is convenient to divide alkyne cross-metathesis into two broad classes: dimerization reactions and chain elongation processes. An example of the former process, which also nicely illustrates the current state of the art of metathesis catalyst design, is found in the concise approach to (+)-dehydrohomoancepsenolide (**250**, Scheme 46) reported by Fürstner and Dierkes.[220] Given the C_2 symmetry of the deceptively simple looking structure of the target compound, a reasonable retrosynthetic scission would appear to involve the breaking of the central *Z*-configured alkene, which would be fashioned in a stereoselective manner through the alkyne cross-metathesis of butenolide **248** followed by hydrogenation in the presence of the Lindlar catalyst. The key step in the formation of butenolide **248** was itself proposed to involve a metathesis event, namely the alkene ring-closing-metathesis reaction of enoate **247**. Indeed, it was found that this initial transformation could be effected by treatment of enoate **247** with the first-generation Grubbs catalyst **2** (16 mol%) in CH_2Cl_2 at reflux for 24 h. This reaction was superbly chemoselective and no competing enyne-metathesis side reactions were observed, which was due only to the modulated reactivity of the catalyst employed as the more active second-generation catalyst **3** failed to distinguish rigorously between the alkyne and alkene moieties of the precursor **247**. Furthermore, no co-catalytic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 46. Sequential alkene ring-closing-metathesis and alkyne-cross-metathesis reactions in the total synthesis of (+)-dehydrohomoancepsenolide (**250**) (Fürstner and Dierkes, 2000).[220]

Scheme 47. Alkyne cross-metathesis in the enantioselective synthesis of PGE_2 methyl ester (**254**) (Fürstner and co-workers, 2000).[222]

$Ti(OiPr)_4$ was required in this reaction, which is often not the case in ring-closing-metathesis reactions of similar substrates with the first-generation catalyst **2**.[221] Treatment of butenolide **248** with the Schrock catalyst **236** (10 mol%) in toluene at 100 °C effected its successful dimerization to give alkyne **249** in 75% yield, and a subsequent Lindlar hydrogenation completed the expedient total synthesis. The chemoselectivity was inverted in the second metathesis step; the catalyst employed this time selectively activated the triple bond at the expense of the alkene group. The lasting impact of this synthesis is its demonstration of the selectivity for different types of unsaturation within the same molecule that is now possible with the metathesis catalysts currently available.

The first examples of alkyne metathesis to effect chain elongation were also documented by the Fürstner group in their recent incursion into the field of prostaglandin synthesis.[222] As shown in Scheme 47, these researchers found that the selective cross-metathesis of cyclopentanone **251** (prepared through a three-component coupling reaction)[223] with an excess of symmetrical alkyne **252** could be achieved in the presence of complex **237** and CH_2Cl_2 (which serves as the activating agent) in toluene at 80 °C to provide the desired product **253** in 51% yield. No unwelcome side products derived through homodimerization of the starting material **251** were observed in this reaction, possibly as a result of steric effects. This transformation attests to both the excellent reactivity profile of the catalyst system, which again selectively engaged the alkyne units in the presence of both the alkene and the polar, coordinating ketone and ester groups, and the overall mildness of the method, leaving as it did the rather fragile β-hydroxyketone motif on the cyclopentane ring unscathed. While the synthetic potential of alkyne metathesis is undeniable, it will only be through its application in a wider variety of settings that a clearer picture of the generality and predictability of this process will emerge.[224]

5. Summary and Outlook

The emergence of metathesis reactions in chemical synthesis over the last few years has been rather dramatic. It has been delightful to review the field and highlight some of its most exciting applications in total synthesis. Indeed, the speed and imagination with which synthetic chemists have adopted the olefin-metathesis reaction and its siblings, the enyne- and alkyne-metathesis reactions, have been both remarkable and highly productive. Despite this progress, however, limitations do remain with these reactions. These shortcomings include the rather poor ability to predict and control the *E*/*Z* ratio of olefin products (except for small and common rings) and the rather large catalyst loading often necessary for reaction completion. Furthermore, more-efficient and practical chiral catalysts are needed to enable asymmetric processes.

Unquestionably, the early and stunning successes of these reactions will be followed by improvements in catalyst design that will overcome at least some of the above-mentioned problems and lead to even more spectacular applications. Furthermore, although the novelty of these reactions may wear off as time goes by, their power as tools in the minds and hands of creative synthetic chemists will always remain sharp as they attempt to solve more complex puzzles, whether posed by natural or designed molecules. It is also evident that

metathesis reactions are beginning to rival the venerable and more-established palladium-catalyzed cross-coupling reactions[4] as means to construct carbon–carbon bonds and as enablers of total synthesis. Equally crystal clear is the fact that together these discoveries have revolutionized the way synthetic chemists go about their business these days.

Abbreviations

Ac	acetyl
B-I-9-BBN	9-iodo-9-borabicyclo[3.3.1]nonane
Bn	benzyl
Boc	*tert*-butoxycarbonyl
Cbz	benzyloxycarbonyl
Cp	cyclopentadienyl
Cy	cyclohexyl
1,2-DCE	1,2-dichloroethane
DDQ	2,3-dichloro-5,6-dicyano-1,4-benzoquinone
DMAP	4-dimethylaminopyridine
DME	ethylene glycol dimethyl ether
DMF	*N*,*N*-dimethylformamide
HPLC	high-pressure liquid chromatography
Mes	2,4,6-trimethylphenyl
MOM	methoxymethyl
Ms	methanesulfonyl
M.S.	molecular sieves
NAP	2-naphthylmethyl
Ns	4-nitrobenzenesulfonyl
*p*BrBz	4-bromobenzoyl
PCC	pyridinium chlorochromate
Phth	phthalimido
Piv	pivaloyl
PMB	4-methoxybenzyl
SEM	2-(trimethylsilyl)ethoxycarbonyl
TBAF	tetra-*n*-butylammonium fluoride
TBDPS	*tert*-butyldiphenylsilyl
TBS	*tert*-butyldimethylsilyl
TES	triethylsilyl
TIPS	triisopropylsilyl
TLC	thin-layer chromatography
TMEDA	*N*,*N*,*N*′,*N*′-tetramethylethylenediamine
TMS	trimethylsilyl
Ts	4-toluenesulfonyl

It is with enormous pride and great pleasure that we thank our collaborators whose names appear in the references cited and whose contributions made the described work so rewarding and enjoyable. We also acknowledge helpful discussions with Professor Phil S. Baran. We gratefully acknowledge the National Institutes of Health (USA), the Skaggs Institute for Chemical Biology, the George E. Hewitt Foundation, Amgen, Merck, Novartis, and Pfizer for supporting our research programs.

Received: January 31, 2005

[52] S. Gessler, S. Randl, S. Blechert, *Tetrahedron Lett.* **2000**, *41*, 9973 – 9976.

[53] For a very recent approach to the "inside–outside" tetracyclic core structure of ingenol employing ring-closing metathesis, see: O. L. Epstein, J. K. Cha, *Angew. Chem.* **2005**, *117*, 123 – 125; *Angew. Chem. Int. Ed.* **2005**, *44*, 121 – 123.

[54] P. A. Evans, J. Cui, S. J. Gharpure, A. Polosukhin, H.-R. Zhang, *J. Am. Chem. Soc.* **2003**, *125*, 14702 – 14703.

[55] For reviews of the utility of temporary silicon tethers in organic synthesis, see: a) L. Fensterbank, M. Malacria, S. M. Sieburth, *Synthesis* **1997**, 813 – 854; b) M. Bols, T. Skrydstrup, *Chem. Rev.* **1995**, *95*, 1253 – 1277.

[56] The first application of a silicon-tethered ring-closing-metathesis reaction in a total synthesis had been disclosed the previous year by the Eustache group, in their elegant synthesis of attenol A: P. Van de Weghe, D. Aoun, J.-G. Boiteau, J. Eustache, *Org. Lett.* **2002**, *4*, 4105 – 4108.

[57] For other examples of silicon-tethered ring-closing-metathesis reactions, see: a) B. A. Harrison, G. L. Verdine, *Org. Lett.* **2001**, *3*, 2157 – 2159; b) S. E. Denmark, S.-M. Yang, *Org. Lett.* **2001**, *3*, 1749 – 1752; c) T. M. Gerash, M. Chytil, M. T. Didiuk, J. Y. Park, J. J. Urban, S. P. Nolan, G. L. Verdine, *Org. Lett.* **2000**, *2*, 3999 – 4000; d) A. Briot, M. Bujard, V. Gouverneur, S. P. Nolan, C. Mioskowski, *Org. Lett.* **2000**, *2*, 1517 – 1519; e) T. R. Hoye, M. A. Promo, *Tetrahedron Lett.* **1999**, *40*, 1429 – 1432; f) P. A. Evans, V. S. Murthy, *J. Org. Chem.* **1998**, *63*, 6768 – 6769; g) G. C. Fu, R. H. Grubbs, *J. Am. Chem. Soc.* **1992**, *114*, 7324 – 7325.

[58] P. A. Evans, J. Cui, G. P. Buffone, *Angew. Chem.* **2003**, *115*, 1776 – 1779; *Angew. Chem. Int. Ed.* **2003**, *42*, 1734 – 1737.

[59] For other total syntheses of mucocin, see: a) S. Takahashi, A. Kubota, T. Nakata, *Angew. Chem.* **2002**, *114*, 4945 – 4948; *Angew. Chem. Int. Ed.* **2002**, *41*, 4751 – 4754; b) S. Takahashi, T. Nakata, *J. Org. Chem.* **2002**, *67*, 5739 – 5752; c) S. Bäurle, S. Hoppen, U. Koert, *Angew. Chem.* **1999**, *111*, 1341 – 1344; *Angew. Chem. Int. Ed.* **1999**, *38*, 1263 – 1266; d) P. Neogi, T. Doundoulakis, A. Yazbak, S. C. Sinha, S. C. Sinha, E. Keinan, *J. Am. Chem. Soc.* **1998**, *120*, 11279 – 11284.

[60] Another temporary tether that has found use in ring-closing-metathesis applications is the ester linkage; for an example, see: G. L. Nattrass, E. Diez, M. M. McLachlan, D. J. Dixon, S. V. Ley, *Angew. Chem.* **2005**, *117*, 586 – 590; *Angew. Chem. Int. Ed.* **2005**, *44*, 580 – 584.

[61] For a Review of the synthesis of medium-sized rings by the ring-closing-metathesis reaction, see: M. E. Maier, *Angew. Chem.* **2000**, *112*, 2153 – 2157; *Angew. Chem. Int. Ed.* **2000**, *39*, 2073 – 2076.

[62] a) K. C. Nicolaou, G. Vassilikogiannakis, T. Montagnon, *Angew. Chem.* **2002**, *114*, 3410 – 3415; *Angew. Chem. Int. Ed.* **2002**, *41*, 3276 – 3281; b) G. Vassilikogiannakis, I. Margaros, M. Tofi, *Org. Lett.* **2004**, *6*, 205 – 208; c) K. C. Nicolaou, T. Montagnon, G. Vassilikogiannakis, C. J. N. Mathison, *J. Am. Chem. Soc.* **2005**, *127*, 8872 – 8888.

[63] A number of other ingenious concepts for controlling the stereochemical course of ring-closing-metathesis reactions to generate medium-sized ring systems have been developed; for selected examples, see: a) A. Fürstner, K. Radkowski, C. Wirtz, R. Goddard, C. W. Lehmann, R. Mynott, *J. Am. Chem. Soc.* **2002**, *124*, 7061 – 7069 (selective formation of either the *E* or *Z* isomer by exerting either kinetic or thermodynamic control, respectively, in the ring-closing-metathesis event); b) A. Ivkovic, R. Matovic, R. N. Saicic, *Org. Lett.* **2004**, *6*, 1221 – 1224 (a ring-closing-metathesis/Grob fragmentation strategy to afford *Z*-configured medium-sized cycloalkenes); c) E. A. Couladouros, A. P. Mihou, E. A. Bouzas, *Org. Lett.* **2004**, *6*, 977 – 980 (control of metathesis precursor conformation through the presence or absence of intramolecular hydrogen bonding, leading to *Z*- or *E*-configured cycloalkenes, respectively).

[64] a) M. Inoue, K. Miyazaki, H. Uehara, M. Maruyama, M. Hirama, *Proc. Natl. Acad. Sci. USA* **2004**, *101*, 12013 – 12018; b) M. Inoue, H. Uehara, M. Maruyama, M. Hirama, *Org. Lett.* **2002**, *4*, 4551 – 4554; c) M. Hirama, T. Oishi, H. Uehara, M. Inoue, M. Maruyama, H. Oguri, M. Satake, *Science* **2001**, *294*, 1904 – 1907.

[65] Z. Xu, C. W. Johnson, S. S. Salman, A. H. Hoveyda, *J. Am. Chem. Soc.* **1996**, *118*, 10926 – 10927.

[66] For a discussion of the parameters required for successful macrocyclization, see: A. Fürstner, G. Siedel, N. Kindler, *Tetrahedron* **1999**, *55*, 8215 – 8230.

[67] For a discussion of the chemistry, biology, and medicine of the epothilones, see: K. C. Nicolaou, A. Ritzén, K. Namoto, *Chem. Commun.* **2001**, 1523 – 1535, and references therein.

[68] a) Z. Yang, Y. He, D. Vourloumis, H. Vallberg, K. C. Nicolaou, *Angew. Chem.* **1997**, *109*, 170 – 173; *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 166 – 168; b) K. C. Nicolaou, Y. He, D. Vourloumis, H. Vallberg, F. Roschangar, F. Sarabia, S. Ninkovic, Z. Yang, J. I. Trujillo, *J. Am. Chem. Soc.* **1997**, *119*, 7960 – 7973.

[69] D. Meng, P. Bertinato, A. Balog, D.-S. Su, T. Kamenecka, E. J. Sorensen, S. J. Danishefsky, *J. Am. Chem. Soc.* **1997**, *119*, 10073 – 11092.

[70] The Danishefsky group had previously reported the first total synthesis of epothilone C, in which they employed a non-metathesis-based approach: A. Balog, D. Meng, T. Kamenecka, P. Bertinato, D.-S. Su, E. J. Sorensen, S. J. Danishefsky, *Angew. Chem.* **1996**, *108*, 2976 – 2978; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 2801 – 2803.

[101] For selected recent reviews of approaches in biomimetic synthesis, see: a) M. C. de la Torre, M. A. Sierra, *Angew. Chem.* **2003**, *115*, 162 – 184; *Angew. Chem. Int. Ed.* **2003**, *42*, 160 – 181; b) K. C. Nicolaou, T. Montagnon, S. A. Snyder, *Chem. Commun.* **2003**, 551 – 564; c) U. Scholz, E. Winterfeldt, *Nat. Prod. Rep.* **2000**, *17*, 349 – 366.
[102] For selected recent examples of biomimetic syntheses, see: a) B. Gerard, G. Jones II, J. A. Porco, Jr., *J. Am. Chem. Soc.* **2004**, *126*, 13620 – 13621; b) S. K. Bagal, R. M. Adlington, J. E. Baldwin, R. Marquez, *J. Org. Chem.* **2004**, *69*, 9100 – 9108; c) G. Vassilikogiannakis, M. Stratakis, *Angew. Chem.* **2003**, *115*, 5623 – 5626; *Angew. Chem. Int. Ed.* **2003**, *42*, 5465 – 5468; d) B. M. Trost, H. C. Shen, J.-P. Surivet, *Angew. Chem.* **2003**, *115*, 4073 – 4077; *Angew. Chem. Int. Ed.* **2003**, *42*, 3943 – 3947.
[103] The synthesis of compound **77** was reported by the Kodama group, who confirmed that it did not correspond to the natural product, soon after the initial disclosure by the Corey group: H. Hioki, C. Kanehara, Y. Ohnishi, Y. Umemori, H. Sakai, S. Yoshio, M. Matsushita, M. Kodama, *Angew. Chem.* **2000**, *112*, 2652 – 2654; *Angew. Chem. Int. Ed.* **2000**, *39*, 2552 – 2554.
[104] The total synthesis and structure revision of glabrescol was first reported by the Morimoto group, who had to prepare a similarly large number of incorrect stereoisomers, a few weeks prior to the corresponding disclosure by the Corey group: Y. Morimoto, T. Iwai, T. Kinoshita, *J. Am. Chem. Soc.* **2000**, *122*, 7124 – 7125.
[105] Molecular-modeling studies subsequently indicated that the originally proposed structure does not correspond to the most thermodynamically favorable form: B. R. Bellenie, J. M. Goodman, *Tetrahedron Lett.* **2001**, *42*, 7477 – 7479.
[106] The Smith group has reported an elegant total synthesis of (−)-cylindrocyclophanes A and F by employing a novel tandem alkene cross-metathesis dimerization/ring-closing-metathesis

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

strategy: A. B. Smith, C. M. Adams, S. A. Kozmin, D. V. Paone, *J. Am. Chem. Soc.* **2001**, *123*, 5925 – 5937; for a discussion of this and other cross-metathesis strategies, see reference [7b], pp. 178–184.

[107] The structure originally proposed for amphidinolide W (**86**) was the 6*S* diastereoisomer, which was also synthesized by the Ghosh group and shown to be different from the natural product.

[108] a) K. C. Nicolaou, S. Vyskocil, T. V. Koftis, Y. M. A. Yamada, T. Ling, D. Y.-K. Chen, W. Tang, G. Petrovic, M. O. Frederick, Y. Li, M. Satake, *Angew. Chem.* **2004**, *116*, 4412 – 4418; *Angew. Chem. Int. Ed.* **2004**, *43*, 4312 – 4318; b) K. C. Nicolaou, T. V. Koftis, S. Vyskocil, G. Petrovic, T. Ling, Y. M. A. Yamada, W. Tang, M. O. Communications

A simple colorimetric sensing array based on four different types of molecular recognition allows the discrimination of functionalized organic vapors. Sensitivities well below 1 ppmv have been observed for amines and the technique even allows the discrimination of isomers. More about this approach can be found in the Communication by K. S. Suslick and co-workers on the following pages.

Sensors

Molecular Recognition and Discrimination of Amines with a Colorimetric Array**

*Neal A. Rakow, Avijit Sen, Michael C. Janzen, Jennifer B. Ponder, and Kenneth S. Suslick**

Electronic nose technology for the generalized detection of volatile organic compounds (VOCs) has generally employed arrays of sensors based either on adsorption into a set of polymers or on oxidations at a set of heated metal oxides.[1,2] While such systems generally allow for distinction between analytes of different chemical functionality, the discrimination of compounds within a given chemical class remains a challenging goal. We have previously reported the colorimetric array detection of a wide range of odorants using a family of metalloporphyrins immobilized on reverse-phase silica[3] and on hydrophobic membranes.[4] Here we report the use of an expanded colorimetric array detector[4] that is capable of the highly sensitive and highly selective discrimination of amines.

Volatile amines are common by-products of rapidly growing cells. As a consequence, the human nose is well-adapted for the detection of amines, with sensitivities approximately 10^4 higher for these compounds than for most alkanes, alcohols, or ketones.[5] For example, cadaverine and putrescene are bacterial metabolic products relevant to food freshness,[6] isobutylamine is diagnostic of bacterial vaginosis,[7] and aniline and *o*-toluidine are biomarkers in lung cancer.[8] While sensitive detection of individual amine compounds has been previously reported,[9] the selective discrimination within a larger family of amines is not easily achieved. Previous approaches to selectively discriminate between amines include sensors based on molecular imprinting,[10,11] functionalized mesoporous silica,[12] and chromogenic reagents.[13] Amines span a wide range of molecular shapes, sizes, and electronic properties; molecular recognition of these compounds poses a unique scientific challenge with important technological consequences.

Molecular recognition relies on the ability to differentiate on the basis of the chemical properties of analytes. Four families of chemically responsive dyes were incorporated into a colorimetric sensor array (Figure 1 and see the Supporting Information) to probe a wide region of "chemical properties space": 1) a series of various metalated tetraphenylporphyrins was used to differentiate analytes on the basis of Lewis acid/base interactions (namely, metal-selective coordination); 2) bis-pocketed Zn porphyrins[14] were used to differentiate on the basis of the size and shape of the analyte; 3) pH acid/base indicators (for example, methyl red and Nile red) were used to differentiate on the basis of Brønsted basicity; and finally 4) highly solvatochromic dyes (for example, Reichardt's ET_{30} betaine dye) were used to indicate the polarity of the analyte. Both the dyes and substrate were chosen to be hydrophobic; as a consequence, changes in humidity over a wide range (10 to >95% relative humidity) do not affect either the initial color of the dyes or the response of the array to analyte vapors.

Responses to a set of very closely related analytes were recorded to provide a stringent test of the molecular recognition by this sensor array: specifically, 12 amines comprising linear, branched, and cyclic structures of similar molecular weight were chosen to provide subtle distinctions in electronic structure and molecular shape (Figure 2). As seen, each amine gives a unique color-difference map. The closest analyte pairs were, not surprisingly, *n*-butylamine and *n*-hexylamine. Even here, however, the array responses are distinct even by eye, and statistical comparisons shows that the variance (that is, the sum of the squares of the differences between the changes in red, green, and blue (RGB) values) among multiple runs of hexylamine is 4.5-fold less than the variance between *n*-hexylamine and *n*-butylamine.

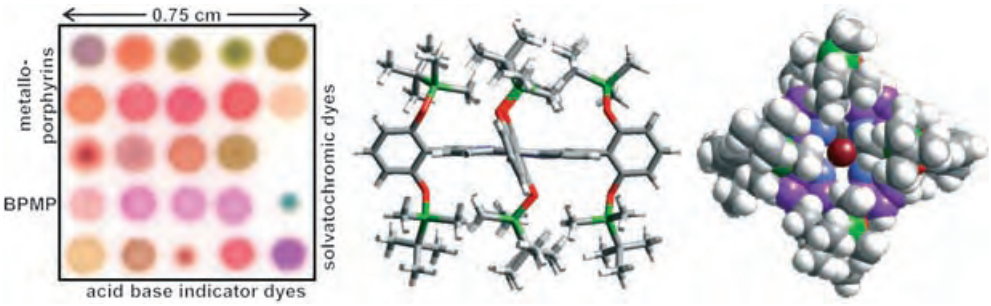

Figure 1. Colorimetric sensor array and the structure of the bis-pocket Zn porphyrin[9a] 5,10,15,20-tetrakis(2′,6′-bis(*tert*-butyldimethylsilyloxyl)phenyl)porphyrinatozinc(II), shown in framework side view (center) and space-filled top view (right). BPMP = bis-pocket metalloporphyrins.

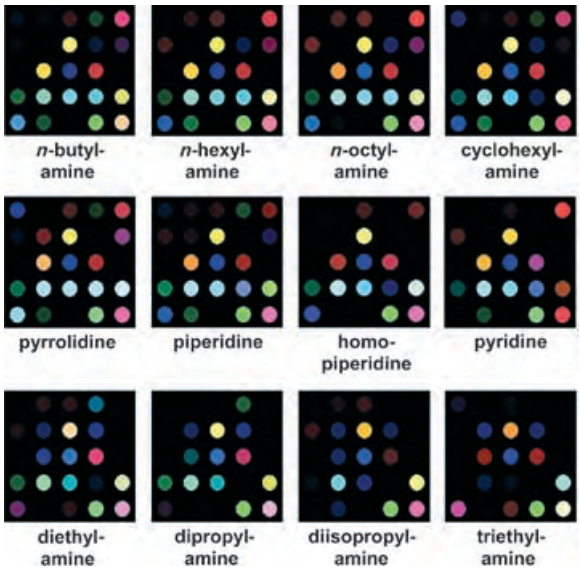

Figure 2. Color-difference maps for a family of 12 amines. Maps are generated from the absolute values of the differences of the red, green, and blue values of each dye spot before and after equilibration with the analytes; saturated analyte vapor at 20 °C. The images shown are in eight bit color expanded from five bit.

The images are digitally obtained and thus detailed statistical analysis of the difference maps is straightforward (all digital data and statistical analyses are provided as Supporting Information): each analyte is represented as a 72-dimensional vector (namely, the red, green, and blue difference values of 24 dyes). Principal component analysis (PCA) provides a quantitative evaluation of the analytical dispersion (that is, selectivity) of a technique based on its number of independent dimensions of discrimination.[11] Other techniques for electronic nose technology generally have very few independent dimensions (typically only two or three for 99% of the total discrimination, with a single dimension highly predominant (>90%)), and consequently only have very limited ability to discriminate between similar analytes.[2] In contrast, because the colorimetric dye array probes a wide range of intermolecular interactions, we observe a very high level of dispersion with the colorimetric dye array. When PCA is applied even to this family of closely related analytes, there are six dimensions necessary for 90% discrimination, eight for 95%, and ten for 99% (Figure 3).

A hierarchical cluster analysis[15] (HCA) was performed and a response dendrogram generated to examine the multivariate distances between the analyte responses in this 72-dimensional RGB color space (Figure 4). Remarkably, the dendrogram is consistent with the qualitative structural and electronic properties of the amines: the branched amines produce one cluster, linear amines another, the cyclic structures are tightly associated, and the lone aromatic amine (pyridine) separate from any of the other clusters. In contrast to prior electronic nose technologies, the colorimetric array is able to easily resolve very similar compounds and even structural isomers. For example, the C_6 amines (*n*-hexylamine, homopiperidine, dipropylamine, diisopropylamine, and triethylamine) have clearly distinct color patterns.

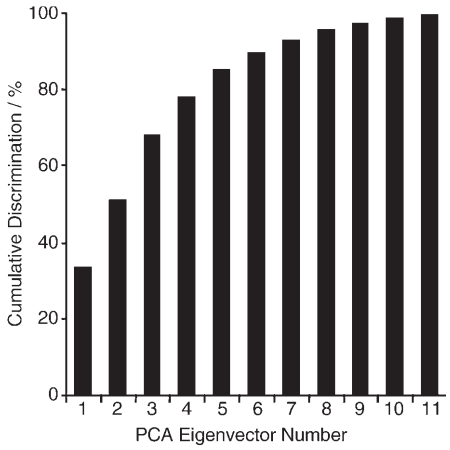

Figure 3. Principal component analysis from 12 very closely related amines shows that the 24-dye sensor array has a very high level of dispersion.

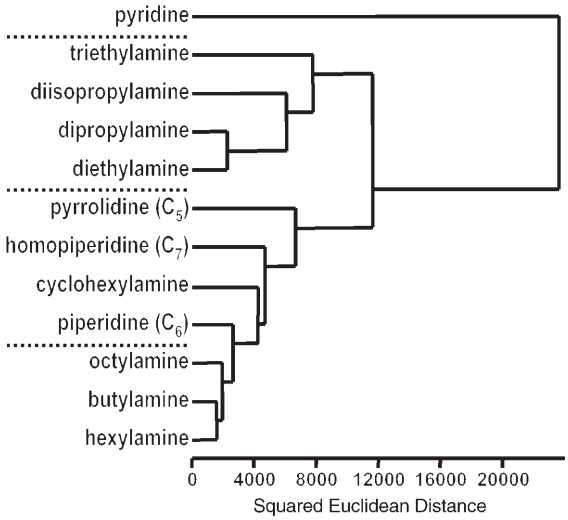

Figure 4. Dendrogram representation of the hierarchical cluster analysis of amines at their saturation vapor pressure from HCA (minimum variance).

The origin of this high level of discrimination lies in the broad range of chemical properties space being probed by the colorimetric array.

In addition to excellent analyte discrimination, high sensitivity to odorants is essential for practical applications. these amine analytes can be readily distinguished at concentrations well below 1 ppmv by using the array. Color-difference maps for a series of amines as a function of concentration are shown in Figure 5, where vivid and easily distinguishable responses are even seen at 600 ppbv. It is important to recognize that the same analyte at different concentrations gives different color change patterns: some dyes change color at low concentrations and then saturate, others do not begin to change until high concentrations. Quantitative analysis is therefore most easily accomplished by quantitative comparison to a library of analyte patterns at various concentrations (see the Supporting Information). Given the magnitude of the color changes observed at

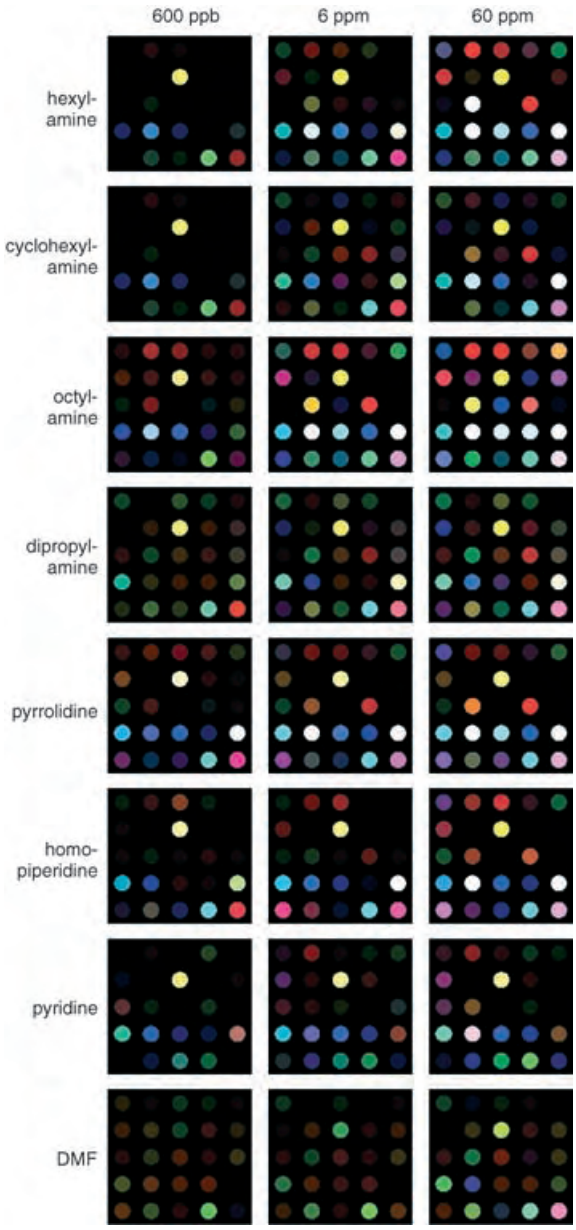

Figure 5. Color difference maps for a family of amines at 600 ppbv, 6 ppmv, and 60 ppmv at 20 °C. The images shown are in eight-bit color expanded from four bit.

600 ppbv, it is clear that detection at even lower concentrations is possible. Indeed, the limits of detection ($3 \times$ signal/noise) for several amines are well under 100 ppbv. Even GC-MS techniques typically achieve only 100 to 1000 ppbv sensitivities for such compounds in the absence of preconcentration. In many cases, these colorimetric arrays are in fact more sensitive than the human nose.[4,5] The origin of this high sensitivity to amines is based on strong and relatively specific interactions (for example, metal ligation): this is in marked contrast to previous electronic nose technologies that rely on weak, nonspecific interactions (for example, physical adsorption onto metal oxides or into polymers). Interestingly, it has been argued recently that the active site of many mammalian olfactory receptors are metalloproteins.[16]

A second 36-dye sensor array was designed without any bis-pocketed metalloporphyrins to test the role of bis-pocketed Zn porphyrins in selective differentiation between closely related amines. The new 36-dye sensor array contained various nonpocketed metalated tetraphenylporphyrins, pH acid/base indicators, and solvatochromic dyes. HCA of the response of 29 amines reveals a clustering of the aromatic and aliphatic amines into distinct branches. Class differentiation between primary, secondary, tertiary, and cyclic amines is reduced (see the Supporting Information), although there remains no possibility of confusion among individual amines. PCA shows our 36-dye array has an extraordinarily high level of dispersion: 11, 14, and 21 dimensions are required to define 90, 95, and 99% of the total variance, respectively.

In summary, we have demonstrated the facile discrimination of a range of functionalized organic vapors by using a simple colorimetric sensing array. Sensitivities well below 1 ppmv have been observed for amines, and in other work, thiols, phosphines, and carboxylic acids. Even distinction between isomeric amines is readily feasible by incorporating dyes that allow for distinction based on metal coordination, molecular size/shape, analyte acidity/basicity, and polarity.

Experimental Section

Methods: A 24-dye colorimetric array[3] composed of metalloporphyrins, free-base porphyrins, pH indicators, and solvatochromic dyes were spotted onto reverse-phase silica gel (Whatman KC2, 200 μm thickness, 350 $m^2 g^{-1}$ surface area) using 0.1 μL microcapillary tubes and employed for the analyses described herein (Figure 1 and see the Supporting Information). The 36-dye arrays used for data given in the Supporting Information were spotted on hydrophobic membranes and are commercially available from ChemSensing, Inc. (www.chemsensing.com, Array no. 031). Images were obtained at 1200 dots per inch in RGB color mode using an ordinary flatbed scanner (Epson Perfection 1200S). Color-difference maps were obtained from the scanned RGB images by digitally subtracting the image before exposure to analytes from the image after exposure, using a 314-pixel average from the center of each dye spot (thus avoiding subtraction artifacts at the periphery of the spots). Statistical analysis was performed with MVSP 3.1 (Kovach Co.). Gas streams containing the vapor of interest at known vapor pressure[17] were generated by flowing nitrogen through the neat liquid analyte in a thermostated, glass-fritted bubbler. To vary analyte concentrations, serial dilution in nitrogen using MKS digital mass-flow controllers was utilized. In all cases, full equilibration of the array by the analyte vapor was confirmed by monitoring images versus time. All liquid analytes were obtained from Aldrich or Fisher Scientific and used as received.

Dried Foam Films

Dried Foam Films: Self-Standing, Water-Free, Reversed Bilayers of Amphiphilic Compounds**

*Jian Jin, Jianguo Huang, and Izumi Ichinose**

Foam films and lipid membranes are typical two-dimensional assemblies of amphiphiles with an inverse molecular arrangement.[1–3] In contrast to lipid membranes, which are spontaneously formed in water, foam films are formed in the air. Thin foam films are composed of a water layer sandwiched between two layers of amphiphiles that direct their hydrophobic moieties outwards.[4,5]

The first historical observation of thin foam films was probably made by Hooke as early as 1672. He reported the films as "holes in soap bubbles", as some parts of the colored bubbles turned black upon draining the water.[6] When interstitial water drains away, the foam film becomes much thinner than the wavelength of visible light and thus appears black as a result of the diminished reflection intensity.[7–9] Such films are named Black Films, and it is possible for the thickness of the water layer to be less than a few nanometers. Bélorgey and Benattar have reported that the thinnest film of ionic surfactant has only three hydration water molecules per counterion.[10] Thin foam films are usually formed in open frames placed in a sealed cell that is filled with saturated vapor, and the films are stable as long as water exists in the interstitial space.[11–14] However, they are so transient in ambient air that the interstitial water molecules have long been deemed to be indispensable to maintain the structure.[15] Herein, we report for the first time that some kinds of foam films exist even after being dried in ambient air. As illustrated in Figure 1, the dried foam films are formed by slowly evaporating the solution of amphiphilic compounds in the holes of substrates. The amphiphilic compounds spontaneously organize into a head-to-head arrangement with their hydrocarbon chains directed towards the air, and give self-standing reversed bilayers. The films form on porous substrates with micron to submicron pores and are stable under ultrahigh vacuum and at temperatures greater than 100 °C.

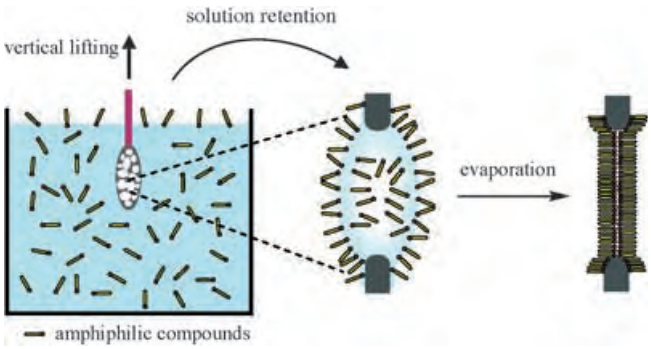

Figure 1. The formation of dried foam films; amphiphilic compounds in solution are illustrated in the monomeric dispersion in conditions below the critical micelle concentration (CMC).

A small amount of an 8.2 mM aqueous solution of dodecyltrimethylammonium bromide (DTAB, Figure 2A) was retained in the holes of the porous substrate by the vertical lifting method. Initially, a perforated polymer membrane on a 150-mesh microgrid (Figure 2B) was used as the substrate. The holes of a few micrometers in the polymer membrane are slightly hydrophobic and are therefore suitable for capturing small droplets of DTAB solution. The substrate was then allowed to stand for one hour in air at a humidity of between 40 and 50 %. The dried foam films obtained were too

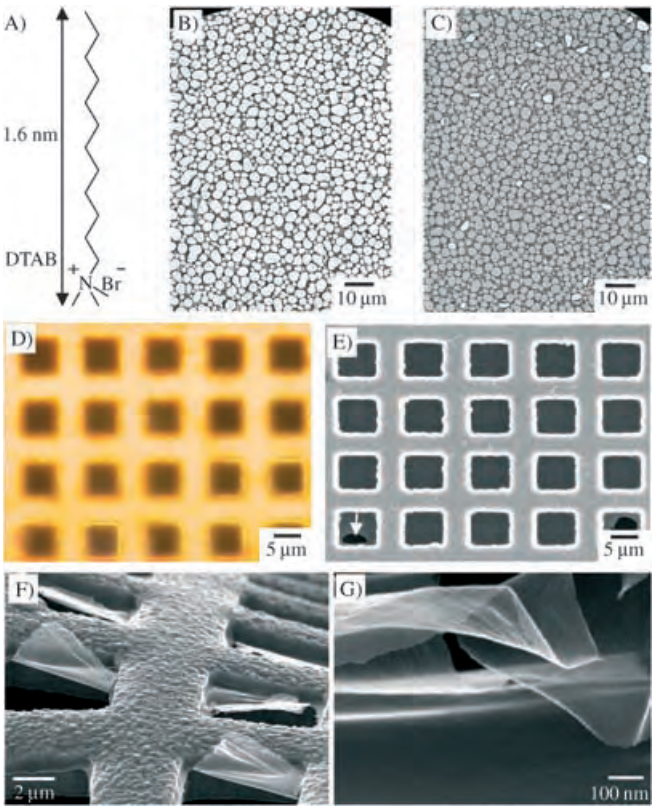

Figure 2. A) Molecular structure of DTAB; B) TEM image of a perforated polymer membrane on a 150-mesh microgrid; C) TEM image of DTAB films formed on the holes of the polymer membrane; D) confocal micrograph of DTAB films formed on a 2000-mesh copper grid; E) FE-SEM image of DTAB films formed on a 2000-mesh copper grid; F) cross-sectional FE-SEM image of DTAB films formed on a 2000-mesh copper grid; G) high-magnification of image in part F).

weak for the focused electron beam of a transmission electron microscope (TEM). However, this problem was successfully solved by coating the specimens with a thin layer of Pt nanoparticles by using a mild ion-sputter. As shown in Figure 2C, DTAB films uniformly cover the holes of the polymer membrane except for a few broken parts; the covered areas are dark because of the presence of the thin Pt layer. The films are extremely smooth and flat without any cracks. We then examined a 2000-mesh copper grid with 7-μm cells. Confocal microscopy, which has a detection limit close to 10 nm, is not useful for the observation of DTAB films owing to their thickness (Figure 2D). However, field-emission scanning electron microscopy (FE-SEM) gave a clear image of the films covering the holes of the copper grid (Figure 2E). Fully covered cells are easily distinguished from the cell; a black broken part is marked with an arrow. This sample was carefully torn and used for cross-sectional observation. As shown in Figure 2F, the film is flexible and prone to be warped by the electron beam when isolated from the wall of the copper grid. The film is transparent, which indicates that the film is thinner than the mean free-path of secondary electrons ($\approx$5 nm) in the SEM observation. By scrutinizing the edge of the film, the thickness was estimated to be 6.5 ± 1.0 nm. The total thickness of Pt layers on both sides of the film was calculated to be about 4.0 nm from the deposition parameters. Therefore, the net thickness of the DTAB film is 2.5 nm, which means that the film probably has a bilayer structure, as the molecular length of DTAB is 1.6 nm.

Many different types of amphiphilic compounds were employed for the preparation of dried foam films. For example, double-chain-type didodecyldimethylammonium bromide (DDAB), zwitterionic dodecylphosphocholine (D-PC), nonionic polyoxyethylene dodecyl ether (Brij-35), natural egg lecithin, and two alkylsilane compounds—octadecyltrimethoxysilane (C18-Si) and octadecyldimethyl(3-trimethoxysilylpropyl) ammonium chloride (C18-N-Si)—were examined. Their dried foam films are shown in Figure 3. DDAB, D-PC, C18-Si, and C18-N-Si gave uniform films on 2000-mesh copper grids. The C18-Si film was prepared from ethanol solution (8.2 mM) because of its low solubility in water. This means that water is not indispensable for the formation of dried foam films. Interestingly, the C18-N-Si film was stable enough to withstand a focused electron beam without Pt coating. This stabilization is probably caused by the hydrolysis of methoxysilane groups and the subsequent formation of a siloxane network.

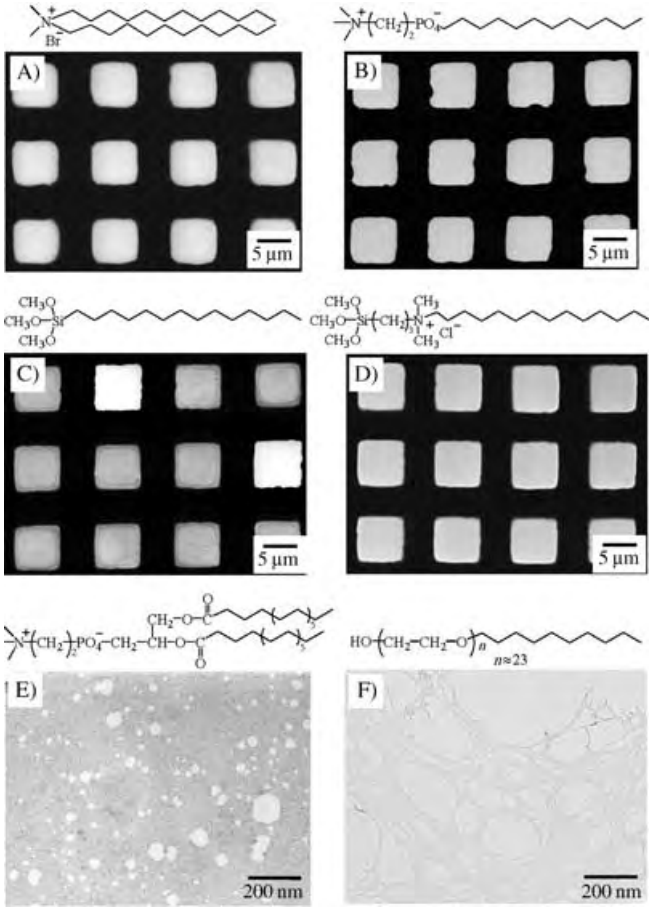

Figure 3. TEM images of the dried foam films of A) DDAB, B) D-PC, C) C18-Si, and D) C18-N-Si prepared on 2000-mesh copper grids; E) lecithin and F) Brij-35 films prepared on the holes of perforated polymer membranes. All films except C18-Si were prepared from aqueous solutions (8.2 mM) of the corresponding amphiphilic compounds.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The lecithin and Brij-35 films are very different from the others. As shown in Figure 3E, many circular pores are observed for the lecithin film. It is known that this compound spontaneously forms vesicular assemblies known as liposomes, and such a structure might be reflected in the circular pores of the dried foam film. The film made of Brij-35 appears to be a torn plastic film (Figure 3F). Natural lipids and nonionic surfactants have been extensively studied by many researchers,[16–19] who have reported that stable and densely packed foam films are readily formed because of the weak electrostatic repulsion between the two monolayers.[17,18] However, these liquid foam films are subject to serious morphology changes after evaporation of the water layer.

In previous studies, the amount of interstitial water has been estimated by transmission FTIR spectroscopy[20,21] as the water layer gives a strong absorption peak in the range from 3200 to 3600 cm^{-1}. The sensitivity of FTIR measurements is very high, and it is possible to detect a water layer not less than 0.2 nm thick.[18] To confirm the disappearance of water from the dried foam films, we recorded FTIR measurements. As shown in Figure 4, the characteristic peaks of water are not

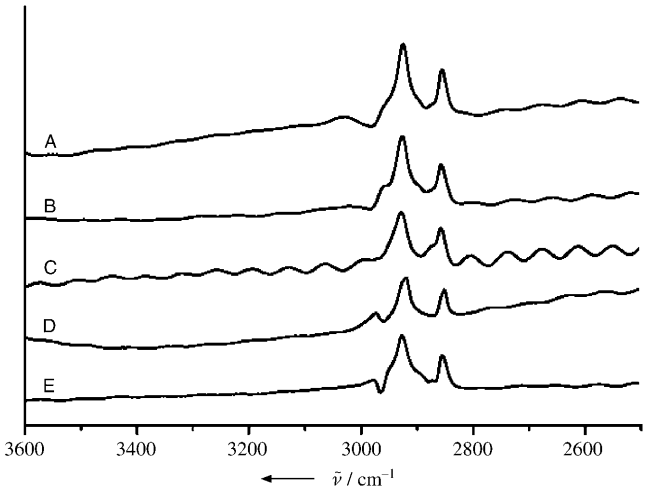

Figure 4. Transmission FTIR spectra of the dried foam films of A) DTAB, B) DDAB, C) D-PC, D) C18-Si, and E) C18-N-Si on porous alumina membranes.

detected at all. It is clear that all the dried foam films have no liquid water and, moreover, no fluidic properties of liquids. Being skeptics, we assumed that a trace amount of water of crystallization should remain in the films. However, we could not find any evidence for the existence of this water. For example, DTAB, which has a trimethylammonium group and a bromide ion in its hydrophilic moiety, cannot strongly bind water molecules by hydrogen bonding, coordination bonding etc. Furthermore, TEM and FE-SEM observations were conducted under high vacuum conditions (lower than 1×10^{-6} torr). In these cases, all the interstitial water should have completely evaporated. What is to be emphasized is the structural stability of the dried foam films. The existence of water or a hydration layer is not necessarily essential to maintain the self-standing reversed bilayer structure.

What is the role of alkyl chains in the structural stabilization of the reversed bilayer structure? In the crystalline state DTAB has an interdigitated bilayer structure. As the cross-section of the alkyl chain is smaller than that of the trimethylammonium group, this amphiphilic compound acquires stable molecular packing by inserting its alkyl chains from both sides of the bilayer. However, the reversed bilayer structure does not allow such interdigitation. If the alkyl chains in an all-*trans* conformation are closely packed in the reversed bilayer, they need to be highly tilted. However, such a molecular arrangement necessarily leads to many defects. We estimated the degree of conformational disorder of the alkyl chains from the FTIR spectra. Alkyl chains that have an all-*trans* conformation in the crystalline state give CH_2 stretching vibration bands near 2918 (ν_{as}) and 2848 cm^{-1} (ν_s). These bands are known to shift up to near 2927 (ν_{as}) and 2856 cm^{-1} (ν_s), respectively, when conformational disorder is induced in the alkyl chains.[22] The dried foam films of DTAB give absorption peaks at 2924.7 (ν_{as}) and 2855.3 cm^{-1} (ν_s). These peaks are significantly shifted to higher wavenumbers from the bands of ordered alkyl chains, thereby indicating that the alkyl chains in the DTAB film are very disordered at room temperature. Similar large shifts to higher wavenumbers were observed for all the dried foam films derived from charged amphiphilic compounds (see the Supporting Information), meaning that the alkyl chains in the films are never closely packed. We have shown that dried foam films are self-standing and that if the alkyl chains are disordered, the hydrophilic moieties have to contribute to the structural stabilization. As observed in the crystallographic analysis of CTAB, the trimethylammonium groups and bromide ions form into two-dimensional ionic sheets.[23] Such a structure might be what makes it possible to keep the film in suspension. The importance of hydrophilic moieties was supported by the following phenomenological facts: C18-N-Si gives films that are very stable against a focused electron beam, and zwitterionic D-PC forms uniform dried foam films. In contrast, nonionic Brij-35 and related surfactants give highly tattered films.

The thermal stability of dried foam films was analyzed statistically by monitoring the change of the surface coverage on a 150-mesh microgrid with increasing temperature. As shown in Figure 5, the coverage of DTAB films lies in a range from 93 to 98% from room temperature to 150°C. However, the coverage drastically decreases to 10% when the grid is heated at 160°C. That this change occurs at a temperature well above the boiling point of water strongly indicates that no water is present in the dried foam films. A bulk crystal of DTAB, in which the alkyl chains have an interdigitated structure, has a melting point of 246°C. The dried foam films that have loosely packed alkyl chains show a transition temperature about 90°C lower than this melting point. These temperatures are considerably higher than the phase transition temperatures of biolipids as the head-groups of biolipids are fully hydrated and their phase transition is generally caused by the disordering of the alkyl chains. What is important is that the coverage in Figure 5 declines sharply. This means that the dried foam films have high molecular cooperativity: if the alkyl chains are disordered, the hydrophilic moieties have to be in the crystalline state. This is probably the reason why the films have high thermal stability.

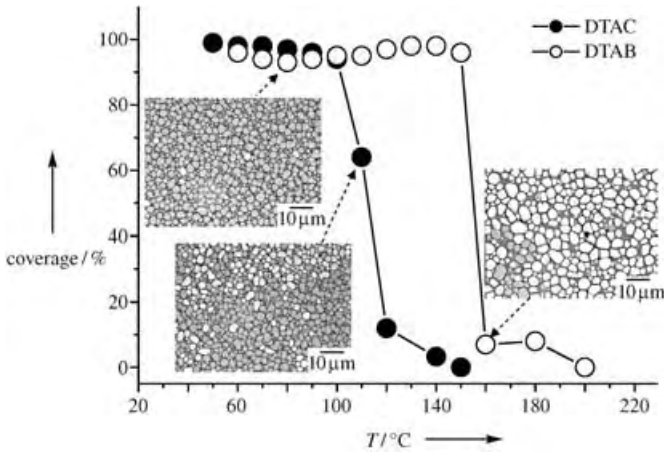

Figure 5. Temperature dependence of the coverage of DTAB and DTAC films.

The coverage of DTAC, which has a chloride ion as the counteranion of a trimethylammonium group, decreases greatly at a temperature about 40 °C lower than that of DTAB, thus showing that the thermal stability is very sensitive to the size of the counterion.[24]

Foam films have been known for more than three centuries and water has always been thought to be an essential component. However, we have found that water is not always indispensable on the micrometer scale as dried foam films are quite stable in the air, under vacuum, and even at high temperature.[25] These findings have immense potential for the design of nanoscale architectures. In fact, we have made it possible to combine a wet process for film formation and a dry process for metal coating. It is also possible to form free-standing films composed of metal oxides and polymers. These artificially organized thin films will contribute widely to various fields of chemistry.

Experimental Section

Materials. The 150-mesh microgrid and 2000-mesh copper grid were purchased from Oken, Japan. The former grid has a perforated polymer membrane, with the surface of the polymer membrane coated with thin glassy carbon to reinforce the pores of a few micrometers. The latter grid is made of pure copper and has regularly arranged square holes of 7 μm at an interval of 2000 per inch. The porous alumina membrane (Anodisc-25) with a pore size of 0.2 μm was purchased from Whatman and used as the substrate for FTIR measurements.

Pt Coating. TEM and FE-SEM specimens were often coated with a 2-nm-thick platinum layer by using a Hitachi E-1030 ion sputter. The coating was performed with a current density of 10 mA at room temperature under an argon pressure of 10 Pa or lower. The thickness was calibrated by using the quartz crystal microbalance technique. Under our experimental conditions, platinum nanoparticles of about 0.8 nm were uniformly deposited on the surfaces of any kind of dried foam film. The deposition did not have any effect on the film morphology. However, deposition of more than 10 nm of platinum was prone to disrupt the films, probably resulting from the high surface tension of the platinum layer.

Characterizations. TEM observations were made with a JEM-1010 (JEOL) instrument at an acceleration voltage of 100 kV. FE-SEM images were obtained with a Hitachi S-4800. The cross-sectional specimen was prepared by carefully tearing a 2000-mesh copper grid covered with dried foam films, followed by Pt coating in a vertical sample holder. FTIR spectra were obtained with a Bio-Rad Win-IR spectrometer. The sample was set in a chamber filled with dried nitrogen gas. Confocal laser microscopy images were obtained with an instrument from Lasertec (VL2000D). The coverage of dried foam films was calculated by counting the films remaining after heating for 15 min at a given temperature. The number of holes examined was higher than 600.

[24] The thermal stability of dried foam films is sensitive to the molecular structure of amphiphilic compounds, too. The dried foam films of D-PC and C18-N-Si disappeared near 160 and 180 °C, respectively. The higher thermal stability of the latter film must be because of the covalent bonding between the hydrophilic groups.
[25] We also found that C18-Si gave very stable films from the ethanol solution. Formation of dried foam films may not, therefore, be restricted to a dehydration mechanism. The molecular design of amphiphilic compounds will provide new types of self-standing films.

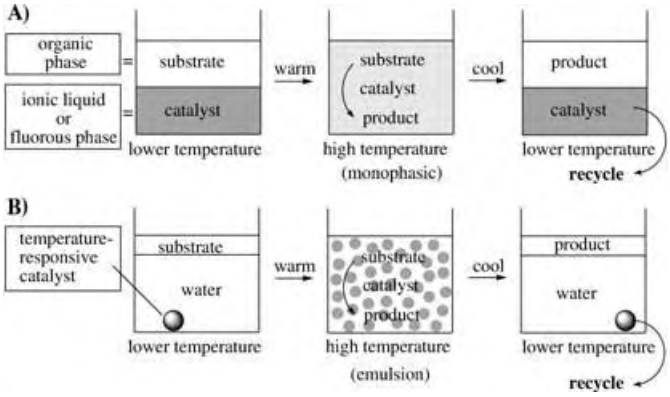
A Recyclable Catalytic System Based on a Temperature-Responsive Catalyst**

*Hiromi Hamamoto, Yachiyo Suzuki, Yoichi M. A. Yamada, Hidetsugu Tabata, Hideyo Takahashi, and Shiro Ikegami**

In modern synthetic organic chemistry, the development of an efficient reagent or catalyst recycling system is regarded as one of the most important topics.[1] A great deal of effort has been invested in devising methodologies for this purpose. Although various types of recyclable catalytic systems have been explored by using solid reagents and catalysts, it is difficult to retain or raise their activities relative to those of their homogeneous counterparts. Recently, much attention has been focused on the creation of catalytic systems that exploit stimuli-responsive materials. The use of a biphasic system comprising ionic liquids or fluorous solvents and an organic solvent and that can be mixed by changing the temperature is a potential strategy (Figure 1 A).[2–4]



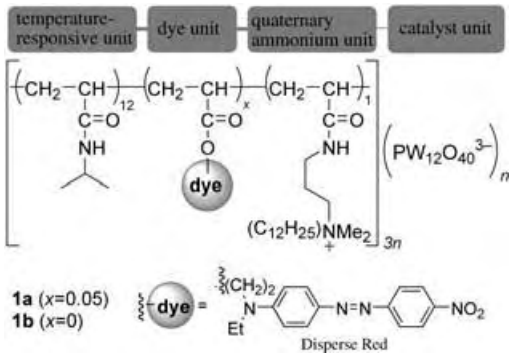


Figure 1. Simplified representation of thermomorphic catalysis. A) Use of a biphasic system comprising ionic liquids or fluorous solvents and an organic solvent. B) Use of a recyclable micellar-type reaction system.

Previously, we investigated the self-assembly of poly(*N*-isopropylacrylamide)-based (PNIPAAm-based) polymer ligands and an inorganic species.[5] This process afforded a networked supramolecular complex in which the polymers are cross-linked by the inorganic species. The complex thus obtained is insoluble in water and functions as an efficient triphase catalyst. In contrast, PNIPAAm polymers intrinsically have temperature-responsive behavior and have been applied to various fields such as drug-delivery systems, column-packing materials, and cell-culture substrates by changing the temperature.[6–8] PNIPAAm polymers undergo thermally reversible changes between water soluble and insoluble states across a lower critical solution temperature (LCST) from 30 to 40 °C. Thus, the polymer chains of NIPAAm are hydrated below the LCST and dehydrated with aggregation above the LCST.[7] The efficient application of soluble PNIPAAm-supported catalysts to biphasic systems has already been reported by Bergbreiter et al.[9]

Colloidal aggregation, such as emulsions formed by amphiphilic molecules in water, has been regarded as an attractive reaction media.[10] This work focuses much attention on the use of the specific hydrophobic species formed by PNIPAAm as a novel organic reaction media in water and provides a recyclable micellar-type reaction system based on PNIPAAm (Figure 1 B). In many cases, the use of a recyclable polymeric catalyst would be advantageous when isolating the product from solution and when removing surfactants that cause environmental pollution.

To design a new recyclable catalytic system from micellar-type aggregates, a dye-labeled catalyst comprising a phosphotungstic acid ($H_3PW_{12}O_{40}$), a PNIPAAm polymer, and a Disperse Red moiety was synthesized (Scheme 1).[5d] Using

Scheme 1. Design of thermomorphic polymer-supported $PW_{12}O_{40}^{3-}$ complex **1**.

this model catalyst **1a**, we investigated the effect of temperature on phase transformation in the presence of an organic substrate and solvent. Although **1a** was insoluble in most solvents at room temperature, the formation of a stable emulsion was observed in water at high temperature (Figure 2 A). Furthermore, an optical micrograph of the mixture at 80 °C showed the presence of hydrophobic beads in water, while such species could not be observed at room temperature (Figure 3). In contrast, **1a** was insoluble in nonpolar solvents such as toluene or octane and soluble in polar organic solvent such as MeCN or *tert*-butyl alcohol at high temperature (Figures 2 B and C).

The results mentioned above prompted us to develop a new reaction system based on the thermomorphic catalyst **1b** for the oxidation of primary and secondary alcohols with hydrogen peroxide.[11] In the oxidation of 1-phenyl-1-propanol in water, the thermoregulated formation of a stable

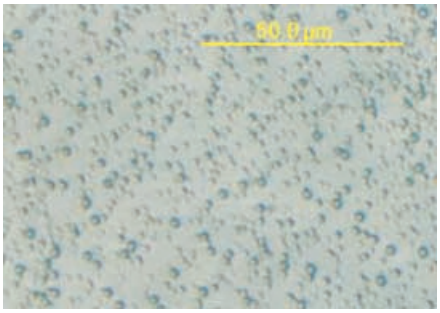

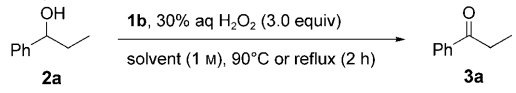

Figure 3. Optical micrograph of a mixture of **1a** and 1-phenyl-1-propanol in water at 80°C.

emulsion was detected at 90°C and higher activity was observed. In contrast, the oxidation hardly proceeded in the absence of catalyst (Table 1, entries 1 and 2). Furthermore, the oxidation proceeded smoothly even when only 0.1 mol% of **1b** was present (entry 3). Recovery of catalyst was very easy; **1b** precipitated on cooling and cleanly separated from the reaction mixture after the addition of diethyl ether (Figure 4). The ^{31}P NMR spectrum of recovered **1b** was unchanged relative to that of **1b** before the reaction and no other species was evident.[11,12] Moreover, recovered **1b** could also be used for consecutive reactions without any significant loss of catalytic efficacy (Scheme 2). The reaction was also carried out in various organic solvents (Table 1, entries 4–7). However, no significant activity was observed in each case. It is noteworthy that this catalytic system based on micellar-type aggregates in water is more effective than homogeneous systems.[13]

Having obtained these results, we extended our catalytic system to the oxidation of other alcohols. Oxidation of the secondary alcohols **2b–e** afforded the corresponding ketones **3b–e** in good yields (Table 2). However, the oxidation of the primary alcohols, **2f** and **2g**, with 3.0 equivalents of hydrogen peroxide afforded selectively the corresponding carboxylic acids **4a** and **4b**.

In summary, we have designed a unique and facile recyclable reaction system based

on a thermomorphic catalyst comprising PNIPAAm. Formation of a stable emulsion, derived from hydrophobic PNIPAAm at high temperature, raises the catalytic activity in the oxidation of alcohols with hydrogen peroxide. Moreover, the catalyst is easily recovered and reused. The results described herein highlight the potential use of PNIPAAm in the field of organic synthesis. Further investigation into the catalytic properties of temperature-responsive catalysts are currently in progress.

Experimental Section

General procedure for the catalytic reaction: A mixture of **1b** (80 mg, 0.01 mmol) and **2** (10 mmol) in 10% aq H_2O_2 (4.5 mL, 15 mmol) was heated to 90°C and stirred for 6 h. After the reaction mixture had been allowed to cool to room temperature, Et_2O (2.5–5 mL) was added and this mixture stirred for 5–10 min. The organic and aqueous phases were removed, and recovered **1b** was washed with ether and distilled water, which were then added to the aqueous phase. The aqueous phase was extracted three times with Et_2O and the combined organic extracts were washed with brine. The organic phase was then dried over $MgSO_4$ and concentrated under reduced pressure. The residual crude reaction mixture was purified by silica-gel column chromatography to give the pure products of **3**. Recovered **1b** was dried under vacuum for 12 h and reused for subsequent catalytic experiments.

[12] The absence of the dye-labeled polymer unit of **1a** in both organic and aqueous phases after oxidation catalyzed by **1a** indicates that tungsten leaching is negligible. Furthermore, the recovered aqueous phase did not show any catalytic activities for the oxidation of alcohols in the presence of surfactant and hydrogen peroxide.

[13] The oxidation of alcohol in water was not accelerated by the presence of $(Bu_4N)_3[PW_{12}O_{40}]$: Yields = 9% (in H_2O), < 5% (in toluene), 55% (in *t*BuOH); conditions: catalyst 0.5 mol%, solvent 1M, H_2O_2 1.5 equiv, 90°C, 2 h.

Heterogeneous Catalysis

Pt–Cu Core–Shell and Alloy Nanoparticles for Heterogeneous NO_x Reduction: Anomalous Stability and Reactivity of a Core–Shell Nanostructure**

Shenghu Zhou, Bindhu Varughese, Bryan Eichhorn, Greg Jackson, and Kevin McIlwrath*

Metallic nanoparticles of the noble metals find wide applications in heterogeneous gas-phase and solution-phase catalytic processes.[1–4] Small particle sizes optimize the dispersion of precious metals, such as platinum and palladium, and can also show anomalous reactivities not observed for the bulk metals. Bimetallic nanoparticles have been studied because of modified (enhanced) activities of noble metals and their abilities to catalyze multistep processes in which each metal participates in a different elementary step.[5–7] Toshima and Wang[8] first reported the synthesis of colloidal PtCu particles and showed their utility in the catalytic hydrogenation in solution. Recent studies[9,10] have suggested that supported PtCu bimetallic catalysts may be effective in NO_x reduction, but coprecipitation/impregnation methods typically used in these studies make it difficult to identify and evaluate the actual catalytic species. While some catalysts have been reported to have high activity for NO_x reduction,[11,12] the best activity and selectivity for N_2 formation (a desirable feature) is typically found with monometallic platinum catalysts.[13–15] To fully understand the catalytic activity of PtCu bimetallic catalysts and compare the activities with the monometallic materials, a detailed understanding of the composition, phase behavior, activation processes, and stabilities of the catalytic components is essential. To this end, we have embarked on a systematic investigation of the synthesis and study of bimetallic PtCu nanoparticles to evaluate their heterogeneous catalytic activities for reduction of gas phase NO with H_2 as the reducing agent.

In addition to monometallic and alloy particles, various core–shell architectures have recently been reported, such as the gold nucleated seeded growth structures.[16–20] These nanoparticles are of interest for catalytic, optical, and magnetic applications, but their synthesis and characterization are often difficult and less studied. In particular, the synthetic routes to many target structures are challenging and the exact composition and/or phase of the resulting core and shell components are often not well understood. Systematic, detailed investigations of core–shell structures are also needed to gain a full understanding of bimetallic systems.

We report herein the synthesis and characterization of the new reciprocal core–shell structures, Pt@Cu and Cu@Pt, as well as their compositional makeup and unusual thermal stabilities. In addition, we describe a modified synthesis of PtCu alloy nanoparticles from a polyol co-reduction process and compare the thermal stability and catalytic properties with those of the core–shell structures and pure metal particles. Preliminary evaluation of γ-Al_2O_3 supported nanoparticles for catalytic NO reduction shows that the Cu@Pt nanoparticles have high activity equal to that of pure platinum nanoparticles but with significantly greater selectivity for N_2 formation.

Platinum and copper monometallic nanoparticles, PtCu alloy nanoparticles, and the Pt@Cu and Cu@Pt core–shell structures were all prepared by polyol reductions with either PVP_{55000} polymer (polyvinylpyrrolidone $M_w = 55000$) or oleylamine/oleic acid stabilizers to control particle sizes. While the individual synthetic methods are quite reproducible in producing particles of a specific size, each type of particle has a different mean particle size. Monometallic platinum and copper nanoparticles were prepared by polyol reduction of $[Pt(acac)_2]$ and $[Cu(acac)_2]$ (acac = acetylacetonate), respectively, in glycol at reflux in the presence of PVP. The mean diameters of the platinum and copper monometallic nanoparticles thus formed are 15 nm and 4 nm, respectively. An alternative method using oleylamine/oleic acid stabilizers gave much smaller platinum particles (3–7-nm particles; mean diameter 4.5 nm). Transmission electron microscopy (TEM) and X-ray diffraction (XRD) data for these materials can be found in the Supporting Information. The PtCu alloy nanoparticles were prepared by a modified version of that of Toshima and Wang[8] in which $[Pt(acac)_2]$ and $Cu(SO_4)\cdot 5H_2O$ (1:1 mole ratio) were heated at reflux in glycol with PVP to give 2–5-nm spherical particles (mean diameter 3.3 nm). Monometallic nanoparticle impurities or sulfur contamination were not detected in the PtCu samples according to TEM, XRD, EDX (energy-dispersive X-ray spectroscopy) and UV/Vis analysis. The TEM image of a representative sample is shown in Figure 1 a. The Cu@Pt nanoparticles were prepared by sequential deposition involving the reduction of $[Cu(acac)_2]$ with glycol at reflux in the presence of PVP and subsequent addition and reduction of $[Pt(acac)_2]$. TEM images showed predominately 9–10-nm hexagonal particles (mean diameter 8.8 nm) with some smaller particles of 5 nm diameter. Field emission scanning TEM (FE-STEM) phase maps qualitatively show that all particles contain platinum and copper in approximately equal quantities (Figure 1 b–d). The Pt@Cu nanoparticles were prepared in a similar fashion

 DOI: 10.1002/anie.200500919 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

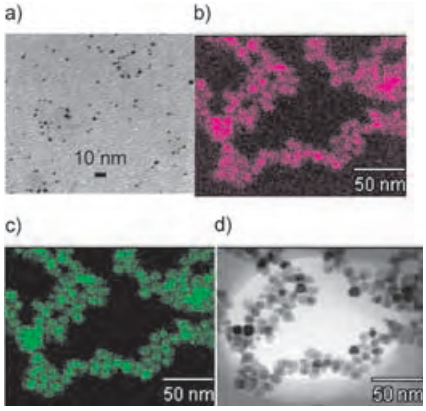

Figure 1. a) Bright-field TEM image (100 kV) of PtCu alloy nanoparticles. b–d) FE-STEM images (200 kV) of Cu@Pt nanoparticles showing b) Cu spectral map, c) Pt spectral map, and d) bright-field image.

with the initial glycol reduction of $[Pt(acac)_2]$ in the presence of PVP followed by a deposition of copper from $Cu(SO_4)\cdot 5H_2O$. FE-STEM analysis showed a broad distribution of particle sizes in the 8–20-nm size range with a mean diameter of 18.3 nm. However, all the particles again had approximately equal quantities of platinum and copper (FE-STEM phase map). A single particle EDX line scan for Cu@Pt is given in the Supporting Information. The presence of both platinum and copper in the core–shell structures is consistent with either PtCu alloys or the formation of the proposed core–shell particles. However, XRD and activity studies (see below) clearly show that the particles are not alloys. As expected, the mean diameters of each core–shell structure is larger than the diameters of the monometallic core particles.

No single analytical technique is sufficient to characterize the complex nanostructure of the core–shell particles. Comparison of several techniques is required to determine the general nature of the structure. The proposed structural models for the nanoparticle architectures described above are based on the evaluation of the combined TEM, EDX, XPS (X-ray photoelectron spectroscopy), XRD, and UV/Vis analyses. The XRD patterns of "as-prepared" PtCu alloy show the expected face-centered cubic (FCC) structure type with broad diffraction peak widths owing to the small particle sizes (mean diameter 3.3 nm, see above). After annealing the sample at 300 °C for 2 h, the peaks sharpen slightly and show 2θ peak positions[21] consistent with the target 1:1 (Pt/Cu) stoichiometry of the reaction mixture. This annealing process seems to have a dramatic effect on the catalytic activity of the particles as discussed below.

To evaluate the importance of the alloy structure in catalytic NO_x reductions, we prepared the core–shell nanoparticles Pt@Cu and Cu@Pt for comparison. The XRD data of the Pt@Cu and Cu@Pt particles are consistent with both the proposed core–shell structures and phase-separated monometallic particles. However, the FE-STEM studies described above and the activity studies (see below) are inconsistent with monometallic particles and allow us to exclude the phase-separated species from consideration. The XRD study (see Figure 2a) shows that the as-prepared Pt@Cu nanoparticles have a Pt FCC core with a $Pt_{1-x}Cu_x$ alloy shell ($x \approx 0.8$). Annealing the sample at 370 °C for 5 h converts the sample into PtCu (Figure 2b) as expected on the basis of the Pt–Cu phase diagram. In contrast, the as-prepared Cu@Pt nanoparticles have an FCC Cu core with an FCC Pt shell (Figure 2c). Surprisingly, annealing the samples at 370 °C for 5 h does not give the PtCu alloy but instead gives a Cu-rich $Pt_{1-x}Cu_x$ core and essentially a pure Pt shell (Figure 2d).

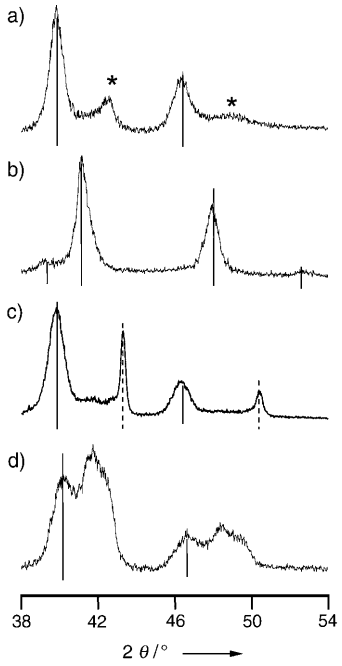

Figure 2. XRD profiles and JCPDS data (compound and file number)[21] for a) Pt@Cu (Pt, 04-0802; the asterisks indicate reflections from the $Pt_{0.2}Cu_{0.8}$ alloy), b) Pt@Cu after annealing (PtCu, 42-1326), c) Cu@Pt (Pt, 04-0802 solid vertical line; Cu, 04–0836 dashed vertical line) d) Cu@Pt after annealing (Pt, 01-1194).

We attribute this anomalous stability to Kirkendall mass-transport phenomena[22] in which the relative rates of migration of one metal into the other kinetically stabilize the Cu@Pt nanoparticles. Because the diffusion of Pt into Cu is fast (approximately $6\times10^{-7}\,cm^2h^{-1}$ at 960 °C) relative to Cu diffusion into Pt (approximately $8\times10^{-8}\,cm^2h^{-1}$ at 1041 °C),[23] the net migration at a Pt–Cu interface strongly favors Pt diffusion into the vacancies of the Cu bulk (i.e. the Kirkendall effect). In the Cu@Pt core–shell structure, the confined Cu core has a small, finite number of vacancies, which impedes net diffusion and thereby retards the alloying process. In contrast, the Cu-rich shell in the Pt@Cu nanoparticle system can maintain a high vacancy population and unhindered Pt-to-Cu diffusion. Therefore, alloying in the Pt@Cu is unimpeded but should result in a hollow PtCu alloy structure. While we know that the PtCu alloy is formed (Figure 2b), we do not yet know if the particles are hollow.

We are confident that the Pt@Cu and Cu@Pt nanoparticles are core–shell particles and not physical mixtures of monometallic components on the basis of the following experiments. 1) Annealing intimately mixed physical mixtures of Cu and Pt nanoparticles under the conditions described above does not result in alloy formation. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

XRD profiles of the annealed physical mixture show clean peaks for FCC Cu and Pt after 5 h at 370 °C, which is in contrast to annealing behavior of both types of core–shell particles. 2) XPS spectra of the core–shell particles (Figure 3)

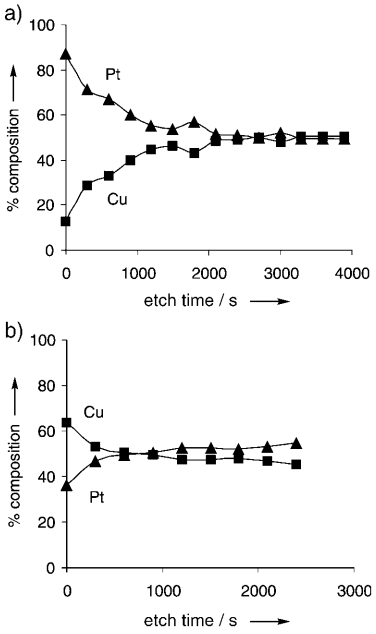

Figure 3. XPS data for a) Cu@Pt and b) Pt@Cu nanoparticles showing Pt (▲) and Cu (■) atomic percentages. Sequential Ar plasma etch sequences are shown as a function of etch time.

show atomic compositions that are highly enriched in the respective shell elements. For example, the Cu@Pt sample shows a Pt/Cu ratio of 88:12 that is indicative of a Pt-rich surface (Figure 3a). A series of 5-minute Ar plasma etches show that the composition becomes more Cu-rich as more of the particle core is exposed (or alloying takes place). After nine etches, the particles reach a 50:50 atomic ratio, which is the stoichiometric composition of the particles. The reciprocal particle, Pt@Cu, does not show the same initial large difference in surface elemental composition but achieves approximately 50:50 ratio after etching in a similar manner (Figure 3b). This behavior is consistent with the formation of the $Pt_{\approx 0.2}Cu_{\approx 0.8}$ alloy shell in contrast to a pure Cu shell and is consistent with the XRD experiments. 3) The STEM images show compositional maps that qualitatively indicate equal concentrations of each element and no monometallic particles (see Figure 1). 4) UV/Vis data show that Cu nanoparticles are not present in the colloid (no surface plasmon resonance band at around 590 nm).[1] 5) The catalytic activities of the core–shell particles are quite different to those of the monometallic particles, their alloys, and physical mixtures.

As an initial screening of the catalytic activity for NO reduction, we prepared samples of the different PtCu nanoparticles on γ-Al_2O_3 (1.06% total Pt loading) by direct deposition from colloidal suspensions. The NO conversions were evaluated by monitoring the formation of N_2, NH_3, NO_2, N_2O, and H_2O from an NO feed and H_2 reductant (0.75% NO, 3% H_2 diluted in Ar). The feed gas was passed across the catalyst (total loading, 105 mg of supported catalyst, pre-reduced in H_2) in a fixed bed reactor with a constant residence time. The reactants and products were measured (mass spectrometry) as a function of temperature. Figure 4 shows

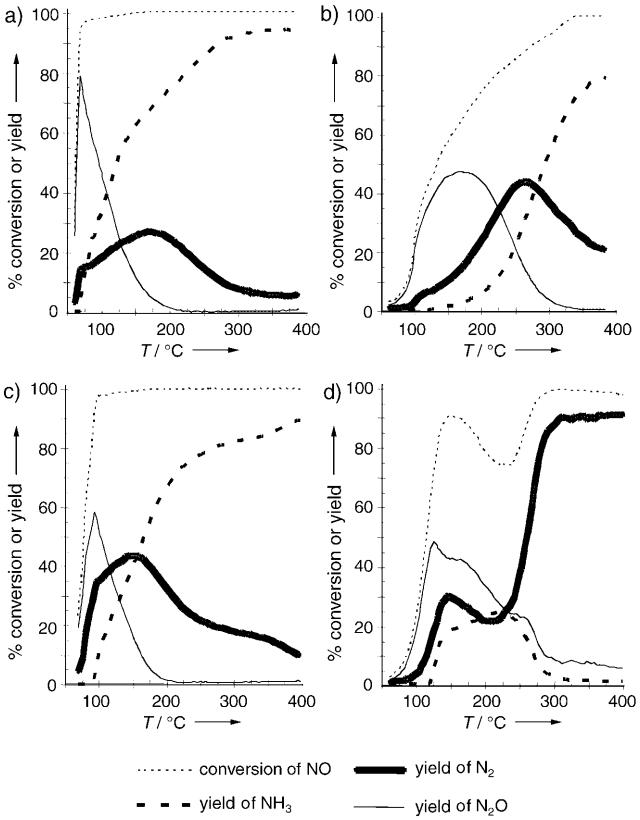

Figure 4. Temperature-programmed reactor studies of Pt–Cu bimetallic nanoparticle structures on NO reduction by H_2: a) pure Pt nanoparticles, b) PtCu alloy nanoparticles, c) Cu@Pt core–shell particles with a 4:1 ratio of H_2/NO, and d) Cu@Pt core–shell particles with a 1:1 ratio of H_2/NO. N_2 selectivity is calculated by dividing the yield of N_2 by the percentage conversion of NO.

the reactivities of a) 4.5-nm Pt, b) PtCu alloy, and c) Cu@Pt catalysts with a 4:1 ratio of H_2 to NO. The net Pt loading is the same in each. The Pt nanoparticles show a very high activity (low light off) with essentially complete NO conversion at 78 °C. However, the optimal selectivity for N_2 formation (vs. NH_3, N_2O, and NO_2) is quite low (26% at 160 °C, Figure 4a). In contrast, the PtCu alloy shows significantly better N_2 selectivity ($\approx$50% at 270 °C) but has significantly poorer activity (Figure 4b). Interestingly, the Cu@Pt core–shell nanoparticles show the high reactivity of the Pt nanoparticles and the high selectivity of the PtCu alloy (Figure 4c). For comparison, a physical mixture of Pt and PtCu alloy nanoparticles shows decreased activity and selectivity relative to the Cu@Pt core–shell system. Moreover, Pt@Cu nanoparticles show very little NO conversion under the same conditions, which is consistent with the Cu-rich shell structure (see Supporting Information).

Varying the H_2-to-NO ratio shows that the Cu@Pt core–shell catalyst can provide N_2 selectivities as high as 93% (at

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

0.75% NO/0.75% H_2/98.5% Ar) over temperatures ranging from 275°C to 400°C as shown in Figure 4d. These remarkably high selectivities coincide with high NO conversion and are significantly better than the monometallic Pt systems. For example, we find 80% selectivity for the 15-nm Pt/Al_2O_3 catalyst at 400°C under identical conditions and Pt loading (see Supporting Information). These results are in good agreement with those of Burch and Coleman who reported approximately 80% selectivity for a Pt/SiO_2 catalyst (5% Pt loading) under similar conditions.[24] The 4.5-nm Pt particles show even better performance (88% selectivity at 400°C; data not shown) but are still not as selective as the Cu@Pt particles under 1:1 or 4:1 H_2/NO reaction conditions.

Further evidence of the kinetic stabilization of the Cu@Pt particles can be found in the stability tests shown in Figure 5.

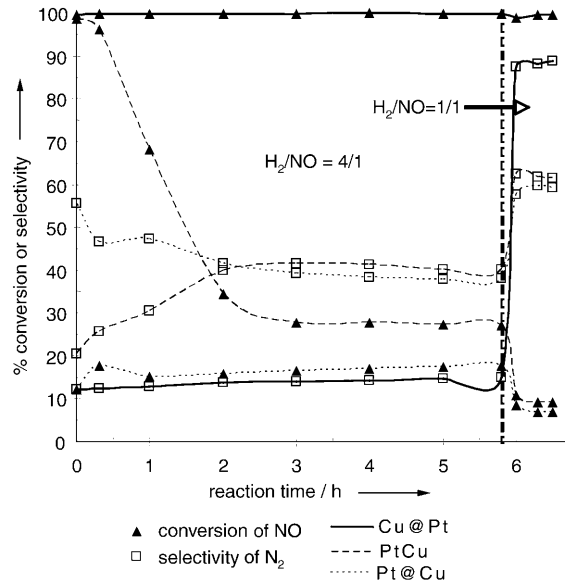

Figure 5. Stability tests for PtCu, Pt@Cu, and Cu@Pt nanocatalysts in the reduction of NO with H_2. The profiles for a 4:1 H_2/NO mixture (reaction time up to 5.8 h) are shown on the left. The subsequent reaction profiles for a 1:1 H_2/NO mixture are shown on the right.

In these experiments, NO conversion was monitored for 5.8 h at 360°C with the three different bimetallic catalysts (Cu@Pt, Pt@Cu, and PtCu) using a 4:1 H_2/NO feed. To highlight the differences in the three systems and test the thermal stability of the Cu@Pt particles under the most severe conditions, we conducted the experiments at 360°C even though the selectivity for N_2 is not optimal at these temperatures in the hydrogen-rich feed. After the 5.8-h runs, the catalysts were evaluated for NO conversion using 1:1 H_2/NO feeds for an additional 0.7 h at 360°C (Figure 5, right). For Cu@Pt, the conversion and selectivity in each feed are stable and the conversion is significantly higher than the other bimetallic systems. Post-reaction XRD analysis shows no sign of PtCu alloy formation (see Supporting Information) indicating that the particles are stable under these conditions. In contrast, the PtCu alloy catalyst rapidly loses activity (% NO conversion) but increases in N_2 selectivity during the first three hours of reaction. This change in performance is accompanied by an increase in crystallinity of the particles that may signify changes in surface structure. Interestingly, the selectivity of the Pt@Cu catalyst decreases during the first three hours and becomes equivalent to that of the PtCu alloy. This finding is consistent with the post-reaction XRD analysis that shows complete alloying of the Pt@Cu particles (see Supporting Information). The final % NO conversion of the alloyed Pt@Cu particle (17%) is lower than that of the PtCu alloy (27%), which is consistent with the significantly larger mean particle size of the Pt@Cu catalysts. Importantly, the stability and activity of the Cu@Pt nanocatalysts are markedly better than the other two bimetallic systems.

The origin of the enhanced performance of the Cu@Pt and related core–shell systems is not completely clear at present but may be related to near surface alloy (NSA) effects described by Greeley and Mavrikakis.[25] In their models, subsurface metal and alloy layers affect the binding of adsorbates (e.g. NO and H) to the particle surface. Changes in binding enthalpies can, in theory, enhance rates and selectivities in catalytic processes. Further studies designed to test these theories are in progress.

Experimental Section

The PtCu nanoparticles were prepared from $[Pt(acac)_2]$ (0.109 mmol), $Cu(SO_4)\cdot 5H_2O$ (0.109 mmol) in glycol (5 mL) with PVP_{55000} (3 mg). The solution was heated under reflux for 2 h to give a stable black colloidal suspension of PtCu nanoparticles. The Cu@Pt nanoparticles were prepared by sequential deposition involving the reduction of $[Cu(acac)_2]$ (0.156 mmol) with glycol (32 mL) and PVP_{55000} (116 mg) at reflux (20 min) to give a reddish colloidal solution. After cooling to 80°C, $[Pt(acac)_2]$ (0.156 mmol) was added and the mixture was slowly heated back to reflux (1 h) to give a black colloidal solution. The Pt@Cu nanoparticles were prepared in a similar fashion with the initial reduction of $[Pt(acac)_2]$ (0.315 mmol) in glycol (7.7 mL) at reflux for 2 h in the presence of PVP_{55000} (18.8 mg) followed by a deposition of Cu from $Cu(SO_4)\cdot 5H_2O$ (0.315 mmol) at reflux for 2 h. The 15-nm Pt particles and 4-nm Cu particles were prepared as described above but without the addition of the second metal. Smaller Pt particles (mean diameter 4.5 nm) were prepared as follows: A solution of $[Pt(acac)_2]$ (41 mg), oleic acid (133 μL; >99%), and oleylamine (133 μL; 70%, technical grade) in decahydronaphthalene (4.2 mL) was injected into decahydronaphthalene (8.3 mL) containing 1,2-hexadecanediol (83 mg; 90%, technical grade) at reflux. After 3 h under reflux, the solution was cooled to room temperature to give a black colloidal suspension of Pt nanoparticles.

Compositional phase maps were acquired using the Hitachi HD-2300 200 kV dedicated FE-STEM with an EDX detector with high sensitivity. Owing to the unique large solid angle, 2-nm spatial resolution is attainable in a relatively short time. NO reduction activity was measured by placing the supported catalyst in a packed bed arrangement in a 6.4-mm internal diameter (ID) quartz tube centered in a vertical programmable tube furnace. The catalyst charge was 5.5 mm in height. The packed bed consisted of 105 mg of catalyst (including support) intermixed with 135 mg of 1-μm quartz particles to provide adequate flow through the bed. The bed was held in place by quartz wool above and beneath, which assisted in preheating the gases to the prescribed furnace temperature. Computer-controlled electronic mass-flow controllers were used to vary flow rates and to fix reactor residence times and the reactor gas velocity (0.16 $m\,s^{-1}$). Product gases were measured continuously with a carefully calibrated magnetic sector mass spectrometer (VG Prima δB). Product compo-

sitions were determined from the calibrated sensitivities and ion-cracking patterns for the analyzed gases.

Host–Guest Chemistry

Host–Guest Interactions: Design Strategy and Structure of an Unusual Cobalt Cage That Encapsulates a Tetrafluoroborate Anion**

Hani Amouri, Lamia Mimassi, Marie Noelle Rager, Brian E. Mann, Carine Guyard-Duhayon, and Laurence Raehm*

The rational design of inorganic artificial receptors for host–guest chemistry is one of the most attractive areas in contemporary supramolecular chemistry.[1] Self-assembly is emerging as an elegant "bottom-up" method for fabricating elaborate architectures[2] such as helicates,[3] cages,[4] metallocryptands,[5] metallomacrocyles,[6] and coordination polymers.[7] This approach is particularly powerful when the ease of control offered by the self-assembly of organic components is combined with electronic, ion-sensing, catalytic, magnetic, or photonic properties of inorganic components.

Over the last decade there has been intensive research into the preparation of inorganic macrocycles, which have shown particular promise in host–guest chemistry.[8]Although the coordination chemistry of cations is well developed, the chemistry of anion encapsulation is still in its infancy despite the fact that anion-coordination chemistry is of interest from environmental, industrial, and health-related perspectives.[9]

We recently reported the self-assembly of iridocryptates that encapsulate BF_4^- anions through hydrogen bonding,[5a] but the present work differs completely to that reported previously in terms of coordination and binding. Herein, we report a rational high-yield strategy (> 90 %) for the preparation of unusual inorganic cages **1a**–**c** (Scheme 1) based on the coordination chemistry of cobalt and demonstrate their properties as hosts for anions. Prior to this work, only a few examples of supramolecular, inorganic-anion receptors had been reported: a metallohelicate that encapsulates a PF_6^- ion[10] and a supramolecular tetrahedral complex that encapsulates a BF_4^- ion[11] are two examples.

Scheme 1. Schematic drawings of ligand L^1 (with atom numbering scheme for ^{1}H NMR assignments) and the related $[Co_2(L^1)_4]$ cages **1a–c**.

The novelty of our work is the use of $Co^{II}(BF_4)_2{\cdot}6H_2O$ as a precursor and a coordinatively unsaturated connector to promote a dative interaction between the metal cation and the weakly coordinating anions in the final supramolecular structure. Rational design of these materials is complicated by uncertain factors such as the counteranion, the solvent, and the ligand geometry. Support for this complication is manifested in the only known Co^{II}-based cage anion $[Co_4L_6]$ (L = di(pyrazolylpyridine)-1,2-phenylene),[12] in which the geometry about each cobalt center is octahedral with the three bidentate ligands, and the encapsulated BF_4^- anion is bound by Coulombic attraction and a symmetry match between the host and the guest. Here, our system behaves completely different. To the best of our knowledge, we describe the first coordinatively unsaturated cobalt-based $[M_2(L^1)_4]$ cage (see Scheme 1) and demonstrate its encapsulation of BF_4^- anions through direct coordination of the unsaturated metal center and the guest anion.

Treatment of two equivalents of ligand L^1 with $Co(BF_4)_2{\cdot}6H_2O$ in a solution of methanol/chloroform for several hours yielded a blue precipitate, which was characterized as $[(CH_3OH)_2Co_2(L^1)_4](BF_4)_4$. The precipitate was recrystallized from CH_3CN/Et_2O to quantitatively afford bright pink crystals, which were characterized as $[(CH_3CN)_2Co_2(L^1)_4](BF_4)_4$ (**1a**). In a similar way, the two other supramolecular cages $[(C_2H_5CN)_2Co_2(L^1)_4](BF_4)_4$ (**1b**) and $[(C_6H_5CN)_2Co_2(L^1)_4](BF_4)_4$ (**1c**) were obtained as light pink and salmon-colored crystals, respectively, through recrystallization from a mixture of the related nitrile solvent RCN ($R = C_2H_5$-; C_6H_5-) in Et_2O. The NMR spectra (^{1}H,^{11}B) of **1a–c** recorded in CD_3CN were all very similar, however, **1b** and **1c** showed displacement of the nitrile solvent RCN ($R = C_2H_5$-; C_6H_5-) by the more strongly coordinating NMR solvent CD_3CN.

The ^{1}H NMR spectrum (400 MHz) of **1a** was recorded in CD_3CN at 292 K, and owing to the presence of Co^{II} atoms the spectrum spanned a broad range from $\delta = 45.70$ to -6.06 ppm, a range that is consistent with the presence of paramagnetic compounds. The spectrum of **1a** shows the presence of 10 signals, which were all assigned by means of peak integration ratios, COSY experiments performed at 352.5 K, and T_1 measurements at 292 K using the Solomon equation[13] (Figure 1). As T_1^{-1} is proportional to $\Sigma(r_{ij}^{-6})$, where r_{ij} is the distance between the hydrogen atoms and the cobalt

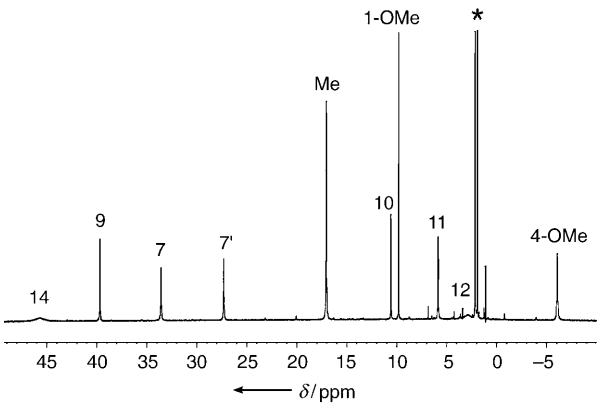

Figure 1. ^{1}H NMR spectrum of **1a** recorded in CD_3CN at 292 K. The symbol * denotes the residual solvent peak (CH_3CN/CD_2HCN).

ions, the relative values of T_1 were estimated and normalized to obtain the best fit with experimental measurements (see Supporting Information). The COSY spectrum showed connectivity between H^{10} and both H^9 and H^{11}, and between H^7 and $H^{7'}$ (see Supporting Information).

Significantly the methylene protons -CH_2^7- are inequivalent and show two signals at $\delta = 33.59$ and 27.30 ppm. The inequivalency results from the formation of a rigid cage, with the arene rings lying along the equator of the approximate sphere of the complexed ion. This result suggests that the presence of a guest anion inside the cavity of the cage increases the rigidity. Remarkably the ^{11}B NMR spectrum of **1a** recorded in CD_3CN showed not only the presence of a sharp singlet at $\delta = -0.82$ ppm that we attribute to the free BF_4^- anion but also another broad signal at $\delta = -105.1$ ppm that was assigned to an encapsulated BF_4^- ion (see Supporting Information). We attribute this large difference in chemical shift values to the paramagnetic nature of the Co ions.

The electrospray mass spectrum of **1a** clearly indicated the formation of the $[Co_2(L^1)_4]$ species in association with varying numbers of BF_4^- anions (see Supporting Information). To ascertain unambiguously the structure of **1a**, an analysis of the crystal structure was undertaken. Crystals of **1a** were grown by vapor diffusion of diethyl ether into a solution of the complex in CH_3CN/CH_3NO_2.[14] The compound crystallized in the monoclinic space group $P2_1/n$. The structure shows the formation of a $[Co_2(L^1)_4]$ tetragonal cage (Figure 2), in which each cobalt ion adopts a square-pyramidal geometry. The equatorial positions are filled by four benzimidazole arms of the bridging ligands L^1, and the axial position is coordinated by a solvent molecule, CH_3CN. The two methoxy groups are arranged in a *trans* fashion with one pointing towards the encapsulated BF_4^- anion while the other is directed in the opposite sense away from the cage cavity. The coordinatively unsaturated cobalt center binds to a BF_4^- anion located inside the cavity through a metal–anion coordination bond with a

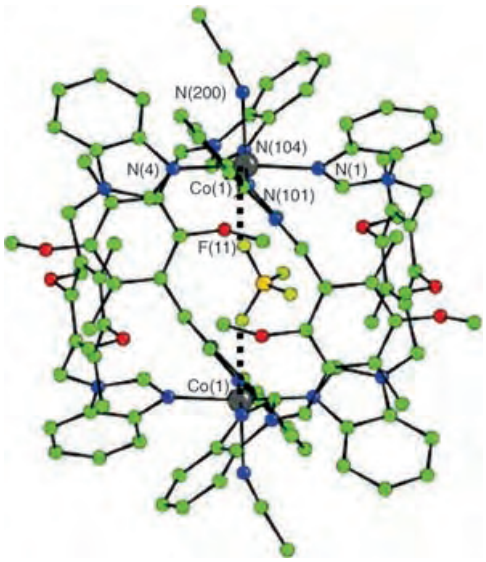

Figure 2. X-ray crystal structure of $[BF_4{\subset}(CH_3CN)_2Co_2(L^1)_4]^{3+}$ (C green, O red, N blue, B yellow, F pale green, Co gray; H atoms omitted for clarity). Selected bond lengths (Å) and angles (°): Co(1)–N(1) = 2.082(8), Co(1)–N(101) = 2.094(9), Co(1)–N(4) = 2.088(8) Co(1)–N(104) = 2.110(9), Co(1)–F(11) = 2.405(8); N(1)-Co(1)-N(4) = 175.5(3), N(101)-Co(1)-N(104) = 174.5(3), Co(1)-N(1)-C(1) = 123.6(7).

bond length of 2.405 Å (Co···F). The two nonbridging fluorine atoms (-FB*F*$_2$F-) occupy four sites (each fluorine atom was refined with half-occupancy). The other three BF_4^- anions are located outside the cavity. The Co···N bond lengths lie in the range of 2.08–2.11 Å, typical for complexes of high-spin Co^{II}.[12] The Co–Co distance is 7.1 Å, and the average distance between two facing phenyl rings is 11 Å.

The present example describes the first structure of a coordinatively unsaturated cobalt cage, which encapsulates a fluorinated anion through an unusual direct Co···F coordination bond. Anions such as BF_4^- are generally considered to be highly noncoordinating and only weakly interacting. The only previous example of a direct host metal/guest anion interaction was reported for a PF_6^- ion encapsulated through interaction with two Pd centers of a quadruply stranded helicate.[10]

We then examined the behavior of the cage **1a** in solution by recording the ^{1}H and ^{11}B NMR spectra at variable temperatures in the range of 292–352.5 K. The observation of separate signals for the -CH_2- protons shows that the structure is rigid. No exchange of the protons H[7] was detected by EXSY (exchange spectroscopy) at the higher temperature which gave a lower limit for the exchange process of $\Delta G^{\neq} = 80\ kJ\,mol^{-1}$. The ^{11}B NMR spectrum at room temperature showed two signals, as discussed earlier. Neither magnetization-transfer measurements nor EXSY showed any evidence of exchange at 60 °C. This result permits a lower limit of $\Delta G^{\neq} = 75\ kJ\,mol^{-1}$ to be set for the release of the encapsulated BF_4^- ion from the cavity. Therefore, the anion is trapped in the cavity with no or slow exchange with the free anions on the NMR timescale.

Ward and co-workers have prepared several cages of the general formula $\{BF_4{\subset}[Co_4(L^2)_6](BF_4)_7\}$, where L^2 is a tetradentate ligand that comprises two pyrazolylpyridine units attached to a 1,2-phenylene or to a 1,2-naphthylene spacer.[15] They found that the ease of exchange of the encapsulated anion depends on the size of the spacer, with facile exchange ($\Delta G^{\neq} = 50\ kJ\,mol^{-1}$) for the complex with a 1,2-naphthylene spacer, while for the rigid bridging 1,2-phenylene spacer the exchange was very slow on the NMR timescale.

In our system the encapsulated BF_4^- anion is an essential part of the structure. In **1a–c** the encapsulated BF_4^- anion plays a pivotal role as a template, around which the two Co^{II} metal ions and the four ligands self-assemble. Furthermore, the rigid nature of the bridging ligand L^1 in which a 1,4-phenylene spacer holds two benzimidazole arms to provide a rigid cage (Scheme 1) means that the encapsulated BF_4^- anion is locked in the cavity and is not released. Future objectives are directed towards the preparation of other bidentate ligands that comprise larger spacers so as to develop flexible cages, destined to encapsulate a variety of anions of different sizes and geometries.

Experimental Section

All experimental manipulations were carried out under argon using Schlenk techniques. ^{1}H and ^{11}B NMR spectra were recorded in CD_3CN using a Bruker AMX-2 400 NMR spectrometer at 400.13 and 128.38 MHz, respectively, and also a Bruker Avance 400 NMR instrument. The temperature of the sample was determined by means of a thermocouple and measured using a Comark N9009 thermometer.

1a: Ligand L^1 (403 mg, 1 mmol; see Scheme 1) in $CHCl_3$ (15 mL) was added to a pink solution of $Co(BF_4)_2{\cdot}6H_2O$ (120 mg, 0.352 mmol) in CH_3OH (15 mL). The solution was stirred at room temperature for 12 h, during which time a deep blue precipitate formed. The solids were collected by filtration, washed with $CHCl_3$, and dried under vacuum. This material was characterized as $[(CH_3OH)_2Co_2(L^1)_4](BF_4)_4$; elemental analysis (%): calcd for $C_{106}H_{112}N_{16}O_{10}Co_2B_4F_{16}$ (2235.24 g mol^{-1}): C 56.96, H 5.05, N 10.03; found: C 56.83, H 5.20, N, 10.13.

The precipitate was then dissolved in CH_3CN and recrystallized from CH_3CN/Et_2O to provide bright pink crystals of $\{[BF_4{\subset}(CH_3CN)_2Co_2(L^1)_4](BF_4)_3\}$ (**1a**); elemental analysis (%): calcd for $C_{108}H_{110}N_{18}O_8Co_2B_4F_{16}$ (2253.28 g mol^{-1}): C 57.57, H 4.92, N 11.19; found: C 55.49, H 5.05, N 10.09; ^{1}H NMR (see Supporting Information); ^{11}B NMR (128 MHz, CD_3CN): $\delta = -0.82$ (sh, free BF_4), -105.1 ppm (br, encapsulated BF_4); IR (KBr disk): $\tilde{\nu}$(B-F) = 1071 cm^{-1}; ES-MS (*m*/*z*): calcd for $C_{104}H_{104}O_8N_{16}Co_2B_4F_{16}$ $[M^{4+} + 3BF_4^-]^+$: 2083.5; found: 2084.54; calcd for $[M^{4+} + 2BF_4^-]^{2+}$: 998.35; found: 998.35; calcd for $[M^{4+} + BF_4^-]^{3+}$: 636.63; found: 636.82; calcd for $[M^{4+}]$: 455.77; found: 456.05.

1b: This supramolecular cage was prepared in a similar way as described for **1a**, but was recrystallized from C_2H_5CN/Et_2O to afford the title compound quantitatively as light pink crystals of $\{[BF_4{\subset}(C_2H_5CN)_2Co_2(L^1)_4](BF_4)_3\}$ (**1b**); elemental analysis (%): calcd for $C_{110}H_{114}N_{18}O_8Co_2B_4F_{16}$ (2281.31 g mol^{-1}): C 57.91, H 5.04, N 11.05; found: C 56.18, H 5.11, N 10.03; the NMR data recorded in CD_3CN were similar to those observed for **1a**, but we note the presence of free displaced C_2H_5CN in the ^{1}H NMR spectrum at δ = 2.38 (q, 4H, CH_2) and 1.23 ppm (t, 6H, CH_3); ^{11}B NMR (128 MHz, CD_3CN) $\delta = -0.74$ (sh, free BF_4), -105.2 ppm (br, encapsulated

Combinatorial Chemistry

Molecular-Weight-Tagged Glycopeptide Library: Efficient Construction and Applications**

*Hiromi Ito, Akihiko Kameyama, Takashi Sato, Katsue Kiyohara, Yoshiaki Nakahara, and Hisashi Narimatsu**

Combinatorial chemistry has become indispensable for drug discovery and biotechnological research with high-throughput screening. Recently, glycoproteomics or glycomics has become a major academic and clinical research priority. Oligosaccharides on glycoconjugates, including glycoproteins and glycolipids, play vital roles in biological processes by influencing the stability of proteins, protein conformation, intra- and intercell signaling, and binding specificity for other biomolecules.[1] However, the functions of glycoconjugates are little understood at the molecular level, mostly because of a lack of sensitive and high-throughput methods for analyzing the structure and interaction of oligosaccharides. To overcome these problems, technologies such as an observational multistage tandem mass-spectral (MS^n) library[2] and arrays for carbohydrate and lectin[3] have been developed. However, a large variety of structurally defined oligosaccharides, that is, an oligosaccharide library,[4] is prerequisite for these technologies. A convenient and effective method for the construction of an oligosaccharide library is desired. Herein, we describe a method for the efficient construction of a glycopeptide library which can be easily converted to an oligosaccharide library by using human recombinant glycosyltransferases.[5] Furthermore, applications for the screening of ligand specificity for lectins by mass spectrometry are demonstrated.

We have developed a method for the construction of molecular-weight-tagged libraries, in which the structure and molecular weight of the components were designed to correspond one-to-one by using glycosyltransferases. Our general strategy for the construction of the libraries is shown in Figure 1. To achieve a diversity of oligosaccharides, the starting peptide or glycopeptide **X**, enzyme **I**, and the donor substrate **A** were added to a reaction mixture, and the reaction was stopped at around a 50% yield of the product

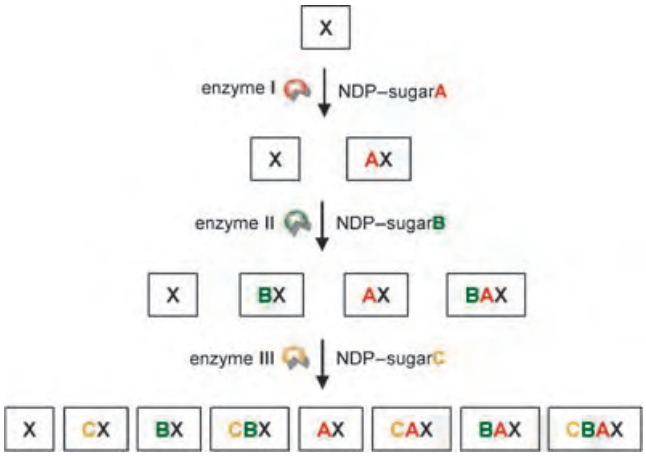

Figure 1. Basic strategy for the construction of oligosaccharide and glycopeptide libraries.

AX by monitoring the time course of the reaction using mass spectrometry. The reaction mixture was kept at 0°C during monitoring to stop the enzymatic reaction from proceeding. After enzyme **I** had been irreversibly denatured and inactivated by heat, enzyme **II** and the donor substrate **B** were added to the mixture of **X** and **AX**, and the mixture was again incubated. Then the transfer reaction of **B** was stopped at around a 50% yield, and enzyme **II** was inactivated. Sequentially, enzyme **III** and substrate **C** were added to the above solution containing **X**, **BX**, **AX**, and **BAX**, and the reaction was stopped at around a 50% yield. Finally, the glycopeptides were easily purified using a solid-phase extraction device, such as a reversed-phase microcolumn. After the three reactions, a mixed library, which theoretically contains eight different compounds (**X**, **CX**, **BX**, **CBX**, **AX**, **CAX**, **BAX**, and **CBAX**), should be generated.

The major advantages of our method are as follows: First, the formation of glycosidic linkages can be strictly controlled because of the excellent regio- and stereoselectivity of glycosyltransferases, which exhibit a clear specificity for substrates.[5] Second, by terminating each enzyme reaction halfway, it is possible to construct a library that has theoretically 2^n (n is the number of reaction steps) structures of oligosaccharides in a single tube. Third, the structure of each component in the library can be identified immediately by mass spectrometry alone, because these libraries are designed as molecular-weight-tagged libraries, that is, each product has a different molecular weight.

Our strategy has the limitation of not allowing the repetitive use of the same glycosyl donor or of diastereomeric donors (e.g., mannose and galactose donors) to achieve variation. Therefore, it is important for the systematic construction of the libraries to design reaction protocols that include the selection of enzymes, the reaction sequence, and the structure of the starting materials.

To demonstrate this strategy, we attempted to construct a library of O-linked glycopeptides, most of which are not commercially available. Extensions of the carbohydrate chain of glycopeptide **1** (β3Gal-Core 3-Muc1a) were achieved by sequential addition of each enzyme (ST6GalNAcI, fucosyl-

transferase 2 (FUT2), and α3GalNAcT (A enzyme)) and its donor substrate (cytidine 5′-monophospho-*N*-acetylneuraminic acid (CMP-Neu5Ac), guanosine 5′-diphospho-β-L-fucose (GDP-Fuc), and uridine 5′-diphospho-*N*-acetylgalactosamine (UDP-GalNAc), respectively) in a single tube (Figure 2a). The time course of each reaction was monitored with a MALDI-TOF MS instrument (ReflexIV, Bruker-Daltonik) by directly applying the reaction solution to the target plate, and the reaction was stopped at around a 50% yield by inactivating the enzyme at 100°C for five minutes. Figure 2b shows the mass spectrum of the final reaction mixture. As α3GalNAcT transfers a GalNAc residue in the α1–3 linkage to the terminal Fucα1–2Gal structure, this library has six (over eight possible) compounds in this case. To each peak, the structure could be instantly assigned from the *m*/*z* value. In the same way, we synthesized a glycopeptide library having various *O*-linked oligosaccharides, that is, B antigen, Lewis^X and sialyl Lewis^X epitope, or Lewis^A and sialyl Lewis^A epitope elongated on the Core 2 and Core 3 structures, respectively (data not shown).

Reductive β elimination[6] by incubating the library at 50°C overnight in 20 μL of NaOH (50 mM) and $NaBH_4$ (500 mM) afforded the corresponding oligosaccharide library (Figure 3). Collision-induced dissociation (CID) spectra were acquired with a MALDI-QIT-TOF MS instrument (AXIMA-QIT, Shimadzu), and deposited in a CabosML database.[7]

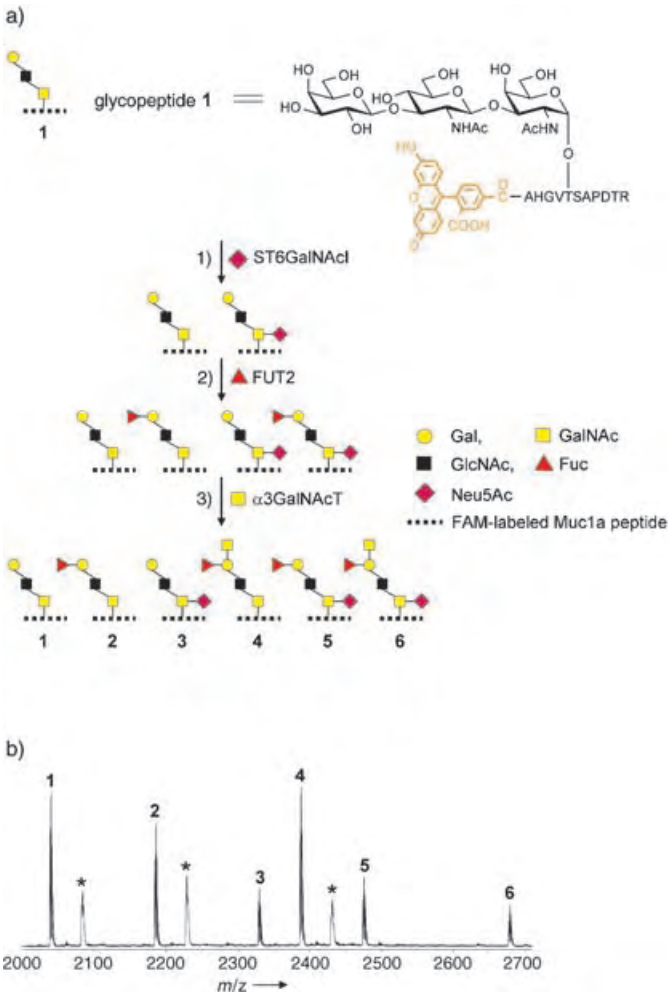

Figure 2. Demonstration of our construction strategy. a) Synthesis of an *O*-linked glycopeptide library including A antigen structures. b) MALDI-TOF mass spectrum of the prepared library. The asterisks indicate metastable ions from the sialylated compounds. Conditions for the enzymatic reactions: 1) ST6GalNAcI (5 μL), *N*-(2-hydroxylethyl)-piperazine-*N*′-2-ethanesulfonic acid (HEPES buffer) (25 mM, pH 7.0), $MnCl_2$ (10 mM), CMP-Neu5Ac (25 nmol), glycopeptide **1** (1 nmol), 37°C, 12 h; 2) FUT2 (2 μL), GDP-Fuc (5 nmol), 37°C, 2 h; 3) α3GalNAcT (2 μL), UDP-GalNAc (2 nmol), 37°C, 3 h. The recombinant glycosyltransferases are bound to anti-Flag M1 affinity gel (Sigma).

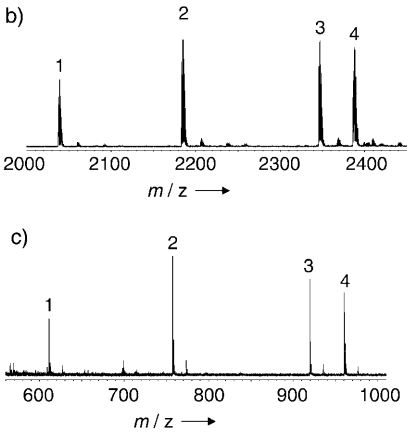

Figure 3. Conversion of a glycopeptide library to an oligosaccharide library. a) Structures and observed signals before and after β-elimination. b) MALDI-TOF mass spectrum of a glycopeptide library. c) MALDI-TOF mass spectrum of the released glycan from this glycopeptide library. The glycopeptides were observed as $[M+H]^+$ ions, the alditols as $[M+Na]^+$ ions.

The libraries described above have many uses. Herein, we demonstrate the screening of ligand specificity for lectins by using mass spectrometry. Ligand specificity for jacalin was determined quite easily by using the prepared library (Figure 4a). Jacalin covalently linked to agarose beads (0, 1, 2.5, and 5 μL) was added to library solutions. Bovine serum albumin (BSA)-conjugated agarose beads were used as the negative control. The solutions were incubated and centrifuged, and the glycopeptides remaining in the supernatants were identified by directly applying the supernatants with the matrix solution to the MS target plate. In this screening system, if the immobilized lectin has binding affinity for a

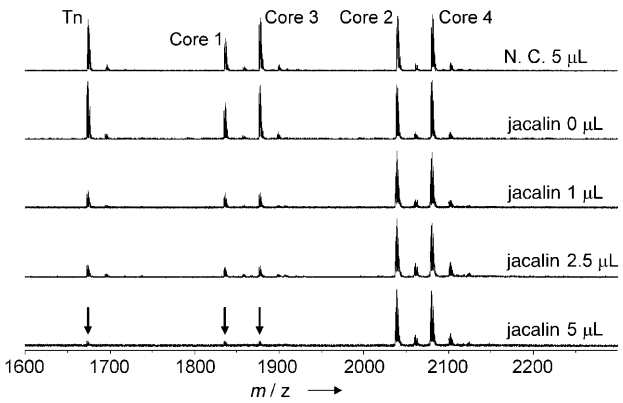

Figure 4. Screening of ligand specificity for jacalin by mass spectrometry. a) Components of the library used for screening. b) MALDI-TOF mass spectra of the library solution at various concentrations of jacalin. BSA covalently linked to agarose beads (5 μL) was used as the negative control (N.C.).

component of the library solution, the corresponding peak of this component becomes small or disappears on the mass spectrum. The intensities of three peaks corresponding to Tn, Core 1, and Core 3 structures in the mass spectra gradually decreased as the amount of added jacalin increased, whereas the intensity of two peaks, Core 2 and Core 4, did not decrease (Figure 4b). These results are consistent with the report that jacalin recognizes Tn and Core 1 residues,[8] and also include some additional findings: 1) jacalin binds to O-linked oligosaccharides, which are linearly elongated on the Gal residue of Core 1 and the GlcNAc residue of Core 3; 2) jacalin does not bind to *O*-glycans in which the O6 position of the GalNAc residue is occupied, that is, Core 2 and Core 4 structures.

In conclusion, we developed molecular-weight-tagged libraries thar were rapidly and readily prepared as mixtures, and the structure of each component in the libraries could be identified immediately by mass spectrometry alone. The libraries were useful for rapid and easy screening for ligand specificity of carbohydrate-binding proteins, such as lectins and antibodies. In the past few years, we have developed more than 160 human glycosyltransferases as recombinant enzymes.[5] It is possible to prepare libraries containing a large variety of natural oligosaccharide structures with these glycosyltransferases. We are increasing the variety of libraries as much as possible, based on different combinations of many enzymes and acceptor substrates, by carefully designing the reaction protocols, thus avoiding the complication attributable to components with the same molecular weight. In addition, this method will be applied to an automated system as a synthesizer for glycan and glycopeptide libraries. The libraries can also be used as carbohydrate microarrays in various fields of research, such as functional glycomics and drug discovery.

Imaging Agents

Water-Soluble Photoluminescent Silicon Quantum Dots**

*Jamie H. Warner, Akiyoshi Hoshino, Kenji Yamamoto, and Richard. D. Tilley**

The quantum confinement of excitons in semiconductor quantum dots leads to interesting optical properties that can be exploited in a range of photonic applications including biological fluorescence imaging[1–6] and optoelectronic devices.[7–13] Quantum dots are becoming popular as replacements for fluorescent dyes in biological fluorescence imaging because of their superior stability against photobleaching. To date, considerable emphasis has been placed on using CdSe quantum dots with a ZnS shell as biological chromophores since they emit light that can be tuned throughout the visible spectrum.[14] However, concerns have been raised about the toxicological issue of using cadmium in biological systems.[15] In particular, Derfus et al. showed that CdSe quantum dots without a ZnS shell were toxic to liver cells after exposure to UV light.[15] The potential biocompatibility of silicon makes photoluminescent silicon quantum dots an ideal candidate for biological fluorescence imaging and should eliminate any potential toxicology problems that might arise from having a CdSe core.[16,17]

Strong quantum confinement in silicon increases the probability of radiative recombination through the direct band gap transitions and reduces phonon-assisted indirect band gap transitions.[18] In silicon, this requires the physical dimensions of the quantum dots to be on the order of or less than the bulk exciton Bohr radius of 4 nm.[19,20] Quantum dot sizes of less than 8 nm are easily achieved using wet chemistry techniques.[19–22] The remarkably successful advances in the synthesis of the semiconductor groups II/VI and III/V have not been applied to silicon as a consequence of the relatively high temperatures required to degrade the precursor and to produce highly crystalline quantum dots. The greatest success in producing silicon quantum dots with strong quantum confinement to date has been by the solution-phase reduction of silicon salts.[19,21,22]

The solution-phase synthesis of silicon quantum dots has previously been reported by Kauzlarich and co-workers[21,22] through the use of a variety of reducing agents, by Korgel and co-workers[19,23] through the use of high temperatures and pressures, and by Wilcoxon et al. by using micelles.[20,24] The current problem associated with the simpler room-temperature syntheses [20–22] is the large size distribution produced. The large size distribution prevents a simple interpretation of the optical spectra. Post-synthesis treatments for narrowing the size distribution of the silicon quantum dots, such as high-pressure gas chromatography (HPGC), have revealed sharp features in the absorption spectra and narrow photoluminescence spectra attributed to direct band gap transitions.[20] We have recently reported the synthesis of 1–2-nm silicon quantum dots that were surface-passivated by 1-heptene. These dots had a narrower size distribution than previously reported and gave a strong blue photoluminescence.[25]

For silicon quantum dots to be used in biomedical applications it is essential that they have a substantial photoluminescence quantum yield in the visible region, have a fast radiative recombination rate, and are water soluble and hydrophilic to prevent aggregation and precipitation in a biological environment. The chemical process used to terminate the surfaces of the silicon quantum dots changes the internal electronic structure and thus plays an important role in the resultant emission wavelength and radiative lifetime, and ultimately determines the solubility.[18] Silicon quantum dots with an oxide surface passivation typically display a dipole-forbidden yellow-red emission with radiative lifetimes of 10^{-3}–10^{-6} s.[18,26] This slow rate of recombination limits the use of oxide-passivated silicon quantum dots in biological imaging. However, silicon quantum dots with a hydrogen or carbon surface passivation have electric-dipole-allowed direct band gap transitions that lead to blue photoluminescence with fast recombination rates of 10^{-8}–10^{-9} s.[18,20]

In this study we describe a simple room-temperature synthesis for producing water-soluble silicon quantum dots that exhibit strong blue photoluminescence with a rapid rate of recombination. The use of hydride reducing agents in these experiments produce hydrogen-terminated particle surfaces.[20,24,25] The Si–H surface bond can then be treated with both a compound containing a C=C bond and a platinum catalyst to produce a variety of surface types through formation of a Si–C surface bond. The surface of the silicon quantum dots are modified with allylamine to form hydrophilic silicon quantum dots (Figure 1). Previous reports of changing the surface-capping molecules of silicon particles have involved treating chloride-terminated particle surfaces with Grignard reagents to produce particles capped with organic molecules[27] or utilized a Si–OR bond.[22] Silicon quantum dots with a chlorine-terminated surface are restricted to a small range of available Grignard reagents, whilst Si–OR bonds have been shown to greatly affect the electronic charge distribution in the silicon quantum dots and consequently reduce the energy of indirect transitions.[18,26]

Figure 2 shows a high-resolution transmission electron microscope (HRTEM) image of a number of allylamine-capped silicon quantum dots on a carbon-coated copper grid.

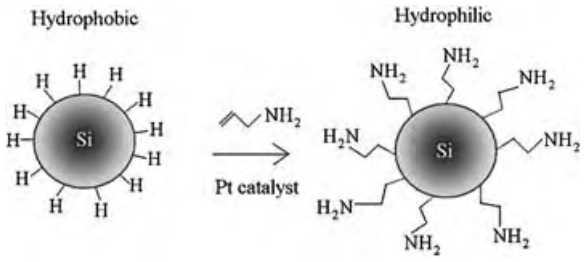

Figure 1. Schematic diagram of the procedure used to change the surface chemistry of the silicon quantum dots from hydrogen to allylamine.

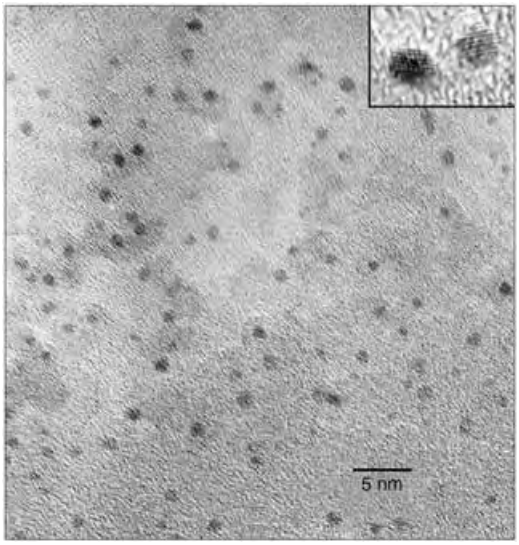

Figure 2. High-resolution transmission electron microscopy (HRTEM) image of a large number of allylamine-capped silicon quantum dots. Inset: HRTEM image of two silicon quantum dots showing the crystal lattice planes.

The water-soluble silicon quantum dots were highly crystalline and the atomic lattice planes of two separate silicon quantum dots can be clearly seen in the inset of Figure 2. Fast Fourier transform (FFT) analysis of the crystal structure shown in the inset of Figure 2 could be matched with the (2,1,−1) and (2,−1,1) planes of diamond silicon when viewed down the [011] direction. The low atomic weight of silicon relative to other metallic and semiconductor quantum dots combined with their extremely small dimensions resulted in low contrast in the HRTEM images. Only by removing almost all of the surfactant (TOAB) could such small (1–2 nm) silicon quantum dots be imaged by HRTEM. Figure 2 shows a relatively high contrast HRTEM image of the 1–2-nm silicon quantum dots along with minimal surfactant, thus indicating that a high level of purification had been achieved. The high purity of the silicon quantum dots enables the photoluminescence to be assigned to the quantum dots and not to other by-products of the reaction, such as silicon-based organosilane polymer/oligomers.

The small dimensions of the silicon quantum dots limits the selected-area electron-diffraction and X-ray diffraction measurements, and no conclusive results have as yet been obtained by using these techniques. The silicon quantum dots were also faceted, which reflects the controlled growth environment.[19] A mean size and size distribution of 1.4 ± 0.3 nm of the allylamine-capped silicon quantum dots was obtained by analyzing 648 quantum dots from different regions on the TEM grid. This small size distribution is a significant improvement on previous reports of 1–2-nm silicon quantum dots synthesized in inverse micelles.[20–22] Energy-dispersive X-ray spectroscopy (EDS) performed on the quantum dots showed a strong peak associated with silicon and no peaks for platinum. This observation confirmed that the platinum catalyst had successfully been removed during purification.

The bonding of allylamine to the surface of the silicon quantum dots was confirmed by FTIR spectroscopy (Figure 3). Peaks were observed at 1460 and 1260 cm^{-1} and

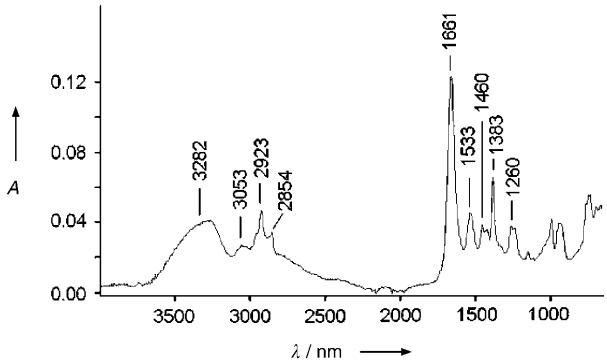

Figure 3. FTIR spectrum of allylamine-capped silicon quantum dots.

attributed to the vibrational scissoring and symmetric bending of Si−CH_2.[27] The absorbance between 2500 and 3500 cm^{-1} is attributed to symmetric and asymmetric vibrations of the C−CH_2 and C−NH_3 molecular components of the allylamine, while the dominant peak at 1661 cm^{-1} is attributed to the allylamine and clearly indicates its attachment to the silicon quantum dots. The peaks between 1000 and 1100 cm^{-1} are attributed to the vibrational stretching of Si−OR.[21] Despite the fact that the silicon quantum dots were heated in atmospheric conditions to remove the solvent for FTIR measurements, the magnitude of the Si−OR vibration is very small when compared to the FTIR reports of siloxane-coated silicon quantum dots, which have a total Si−OR surface coverage.[21] This difference highlights the strength and stability of the Si−C bond formed between the silicon quantum dots and the allylamine as well as the minimal number of Si−OR surface bonds present.

The absorption spectrum of the allylamine-capped silicon quantum dots in water (Figure 4a, curve I) displays a feature at 320 nm which is attributed to the Γ-Γ direct band gap transition.[19,20] This direct band gap transition has blue-shifted because of the effect of quantum confinement in the quantum dots—from the bulk value of 3.4 to 3.8 eV in these silicon quantum dots—and is in good agreement with other reports.[19,20]

The photoluminescence (PL) spectra recorded at 300 and 400 nm (Figures 4a, curves II and III) show a peak at 480 nm

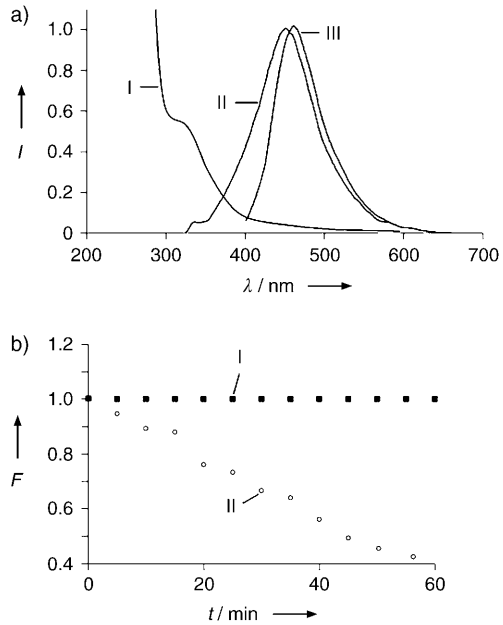

Figure 4. a) Curve I: Absorption spectrum of allylamine-capped silicon quantum dots in water; curve II: photoluminescence spectrum of allylamine-capped silicon quantum dots in water with excitation at 300 nm; curve III: photoluminescence spectrum of allylamine-capped silicon quantum dots in water with excitation at 400 nm. b) Integrated photoluminescence as a function of time of allylamine-capped silicon quantum dots in water (curve I) and rhodamine 6G in water (curve II). An excitation wavelength of 400 nm was used in both cases.

with a full-width at half maximum height (FWHM) of 70–80 nm. All the spectra in Figure 4 have been scaled for clarity of presentation.

Photoluminescence quantum yields of the allylamine-capped silicon quantum dots in water were obtained by using the comparative method of Williams et al.[28] PL quantum yields of up to 10% were obtained relative to the standard, 9,10-diphenylanthracene, in cyclohexane.[29] The optical properties of the colloidal solutions of the allylamine-capped silicon quantum dots were stable for several months. The silicon quantum dots showed better photobleaching stability than the fluorescent dye, rhodamine 6G in water, on excitation with UV light (Figure 4b). The silicon quantum dots showed no signs of any measurable photobleaching (Figure 4b, curve I) under the same illumination conditions during which the photoluminescence from rhodamine 6G dropped by 60% (Figure 4b, curve II).

The origin of the photoluminescence observed in Figure 4 is complicated by the combination of both indirect and direct band gap transitions present in silicon quantum dots and is actively debated.[19] However, there is strong theoretical evidence suggesting that 1–2-nm silicon quantum dots with a hydrogen or carbon surface termination have direct band gap optical transitions that lead to photoluminescence in the UV/blue region of the electronic spectrum.[18] The emission observed in Figure 4a is consistent with the theoretical predictions of direct band gap recombination in silicon quantum dots with carbon surface termination rather than from trap states or surface states, or of silicon quantum dots with oxygen surface termination. Emission from a Si–OR-terminated silicon quantum dot is typified by an emission centered at 600 nm.[20,30]

Further insights into the nature of the photoluminescence can be obtained by analyzing the time-resolved photoluminescence spectra from the allylamine-capped silicon quantum dots in water. Figure 5 shows the time-resolved photoluminescence decays from an aqueous solution of allylamine-capped silicon quantum dots at two different emission wavelengths. The PL decay measured at 420 nm (Figure 5, curve a) is noticeably shorter than the PL decay measured at 500 nm in curve b. Both PL decays required a three exponential fit with an overall average decay of 4 ns.

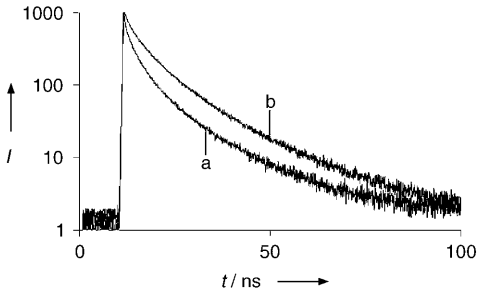

Figure 5. Time-resolved photoluminescence decays of allylamine-capped silicon quantum dots in water measured at emission wavelengths a) 420 nm and b) 500 nm. An excitation wavelength of 380 nm was used.

Indirect band gap materials, such as silicon, generally have slow recombination with PL lifetimes on the order of tens of microseconds to milliseconds, whereas direct band gap materials, such as GaAs and CdSe, have fast recombination with PL lifetimes on the order of 1–10 ns.[31] The PL lifetime measurements obtained here are in good agreement with the experimental findings of the research groups of Korgel [23] and Wilcoxon[20] as well as the theoretical predictions of Zhou et al.[18] The rapid rates of recombination measured here provide strong evidence that the observed emission results from dipole-allowed recombination across the direct band gap transition in silicon quantum dots with a carbon surface termination.

The suitability of allylamine-capped silicon quantum dots as a chromophore for biological imaging is demonstrated in Figure 6, for which an excitation wavelength of 365 nm was used and the emission at 480 nm was monitored. The control image (Figure 6a) shows minimal fluorescence from the HeLa cells relative to the HeLa cells with the incorporated silicon quantum dots (Figure 6b). Thus, the fluorescence observed in the HeLa cells in Figure 6b arises from the emission from silicon quantum dots and not autofluorescence from the cells. The inset in the top left corner of Figure 6b shows the bright blue fluorescence from a vial of allylamine-capped silicon quantum dots in water when excited with UV light. The bright blue fluorescence from the silicon quantum dots is distributed uniformly inside the cytosol of the HeLa cells and this shows the possibility of using these hydrophilic silicon quantum dots as chromophores in biological fluorescence imaging. This result has major implications towards

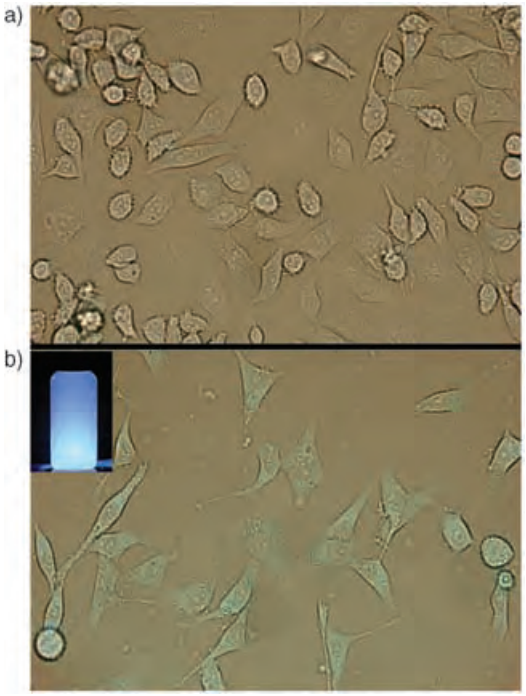

Figure 6. Overlay of the transmission and fluorescence microscope images of a) HeLa cells in the absence of any quantum dots and b) HeLa cells with silicon quantum dots incorporated inside the cytosol. Inset: fluorescence from a vial of allylamine-capped silicon quantum dots in water when excited with a UV lamp.

using colloidal silicon quantum dots effectively in biological fluorescence imaging.

In summary, silicon quantum dots with a narrow size distribution were synthesized using reverse micelles and powerful hydride reducing agents at room temperature and pressure. The surface of the silicon quantum dots was made hydrophilic by modification with allylamine. The silicon quantum dots dispersed in an aqueous environment displayed strong photoluminescence in the blue region of the visible spectrum, with a 10% quantum yield for the photoluminescence. The optical properties of the silicon quantum dots displayed features in both the absorption and emission spectra attributed to the direct band gap transitions in silicon quantum dots with a carbon surface termination. Time-resolved photoluminescence spectroscopy revealed a rapid recombination normally associated with direct band gap materials. The ease of synthesis and optical properties make the silicon quantum dots reported here excellent candidates for biomedical applications, as demonstrated by the imaging of allylamine-capped silicon quantum dots in HeLa cells.

Experimental Section

Synthesis of allylamine-capped silicon quantum dots: Silicon quantum dots were synthesized in reverse micelles by the solution-phase reduction of $SiCl_4$ with 1M $LiAlH_4$ in THF (Aldrich). The surfactant and solvent combination used to form the micelles were tetraoctylammonium bromide (TOAB, Merck) in toluene. Surface modification of the silicon quantum dots was achieved by treating the surface of the particles with allylamine (Aldrich). All experiments were carried out in an argon atmosphere in a glove box to prevent oxidation of the silicon. Oxygen levels were below 10 ppm at all times.

In a typical experiment, $SiCl_4$ (92 μL, 0.0008 mol) was dissolved in TOAB (1.5 g) and anhydrous toluene (100 mL) by using a homogenizer. Silicon quantum dots were then formed by adding a twofold excess of reducing agent. The mixture was left to react for 3 h and then anhydrous methanol (20 mL) was slowly added to quench any excess reducing agent. At this point it is expected that the surface of the particles were terminated with hydrogen.[20,25] Hydrophilic particles were formed by modifying the surface silicon–hydrogen bonds by reaction with 0.05M H_2PtCl_6 (40 μL) in isopropanol as the catalyst and allylamine (2 mL). After modification of the surface, the sample was removed from the glove box and purified by removing the surfactant.[32] The solvent was then removed using a rotary evaporator to produce a white powder consisting of mainly TOAB and silicon quantum dots. Distilled water (50 mL) was then added to the flask and resulted in the hydrophilic silicon quantum dots dissolving, but not the TOAB. The TOAB was then removed by successive filtration through a 0.22-μm membrane filter.

Incorporation of silicon quantum dots into HeLa cells: The HeLa cells were cultured in DMEM/F12 supplemented with 10% heat-inactivated fetal bovine serum at 37°C. The cells were plated at a volume of 1×10^6 cells/well on a 6-well culture plate (Iwaki technoglass, Japan) and were stimulated with a solution of 0.2 nM Si quantum dots. After incubation of the mixtures for 12 h, the cells were washed with a phosphate-buffered saline (PBS) twice to remove the nonspecific binding quantum dots. The cells were then fixed with 1% paraformaldehyde in PBS for 5 min.[33] Fluorescence images of the HeLa cells were acquired with a digital camera D1X (Nikon) on a fluorescent microscope IX-81 (Olympus) using a mirror unit to adjust the excitation wavelength to 365 nm and an oil immersion objective lens. The blue fluorescent light was detected in the cytosol of each cell.

Electrochemistry

Electrochemical Control of the Photocurrent Direction in Intercalated DNA/CdS Nanoparticle Systems**

*Ron Gill, Fernando Patolsky, Eugenii Katz, and Itamar Willner**

In memory of Chava Lifshitz

The use of molecular[1–4] and biomolecular[5–7] assemblies that perform logic gate functions has attracted substantial interest directed toward information storage and processing. In these efforts, nanoparticles have been employed to switch the conductivity properties across interfaces.[8,9] The integration of biomaterials with nanoparticles as active hybrid components in bioelectronic systems is interesting, as the unique recognition properties of biomolecules are combined with the optoelectronic functions of nanoparticles.[10,11] Double-stranded DNA (dsDNA) could act as a matrix to assemble signal-triggered functional nanoparticle structures by binding molecular units to the dsDNA. The conductivity of DNA has been a subject of extensive controversy,[12] and it is accepted that DNA exhibits poor conductivity.[13] However, the conductivity of DNA could be controlled by appropriate ordering of the base sequence[14] or by the incorporation of redox-active intercalators into dsDNA.[15] Herein, we report the design of CdS nanoparticle/DNA conjugates on gold surfaces and describe the effects of intercalators and the applied potential on the photoelectrochemical features of the system. We demonstrate that the resulting photocurrent can be reversibly switched between cathodic and anodic directions by controlling the redox state of the intercalated species.

In a previous study,[16] CdS nanoparticles were linked to gold surfaces and low-value anodic photocurrents in the presence of a sacrificial electron donor were recorded. This photocurrent was explained to originate from CdS nanoparticles that were in intimate contact with the electrode, owing to a low surface coverage of the nanoparticles, and thus the DNA matrix acted only as a linker in this system. In the present study, a dithiol-tethered single-stranded DNA (ssDNA) molecule **1** was self-assembled on the surface of a gold electrode and then hybridized with a complementary dithiolated ssDNA **2** to yield a double-stranded DNA (Figure 1). The resulting surface was treated with CdS nanoparticles to yield a semiconductor nanoparticle interface linked to the surface of the electrode by the dsDNA (Figure 1a). The surface coverage of the different components on the electrode support was determined by quartz-crystal-microbalance (QCM) measurements on Au/quartz crystals and by complementary electrochemical experiments. The surface coverages of the ssDNA **1** and the dsDNA complex were determined by chronocoulometry using $[Ru(NH_3)_6]^{3+}$ as a redox label.[17] The surface coverage of **1** and the dsDNA were found to be 1.8×10^{12} molecules cm^{-2} and 1.46×10^{12} molecules cm^{-2}, respectively. From the frequency changes of the Au/quartz crystal upon the assembly of the CdS nanoparticles, their surface coverage was estimated to be 4.9×10^{11} particles cm^{-2}. Thus, approximately three units of dsDNA link a single CdS nanoparticle to the electrode surface.

Figure 2a, curve 1, shows the photocurrent action spectrum of the CdS nanoparticle/dsDNA system in the presence of triethanolamine, TEOA, as a sacrificial electron donor. A very low anodic photocurrent is observed. The intercalation of doxorubicin (**3**) into dsDNA is well-established.[18] The intercalation of **3** into the dsDNA here results in a fivefold higher photocurrent (Figure 2a, curve 2). The electrolyte solution in the photoelectrochemical experiment is free of **3**, and the enhancement in the resulting photocurrent originates only from intercalated **3**. The coverage of the dsDNA with the intercalator **3** could not be assessed quantitatively, but differential pulse voltammetry experiments clearly indicated

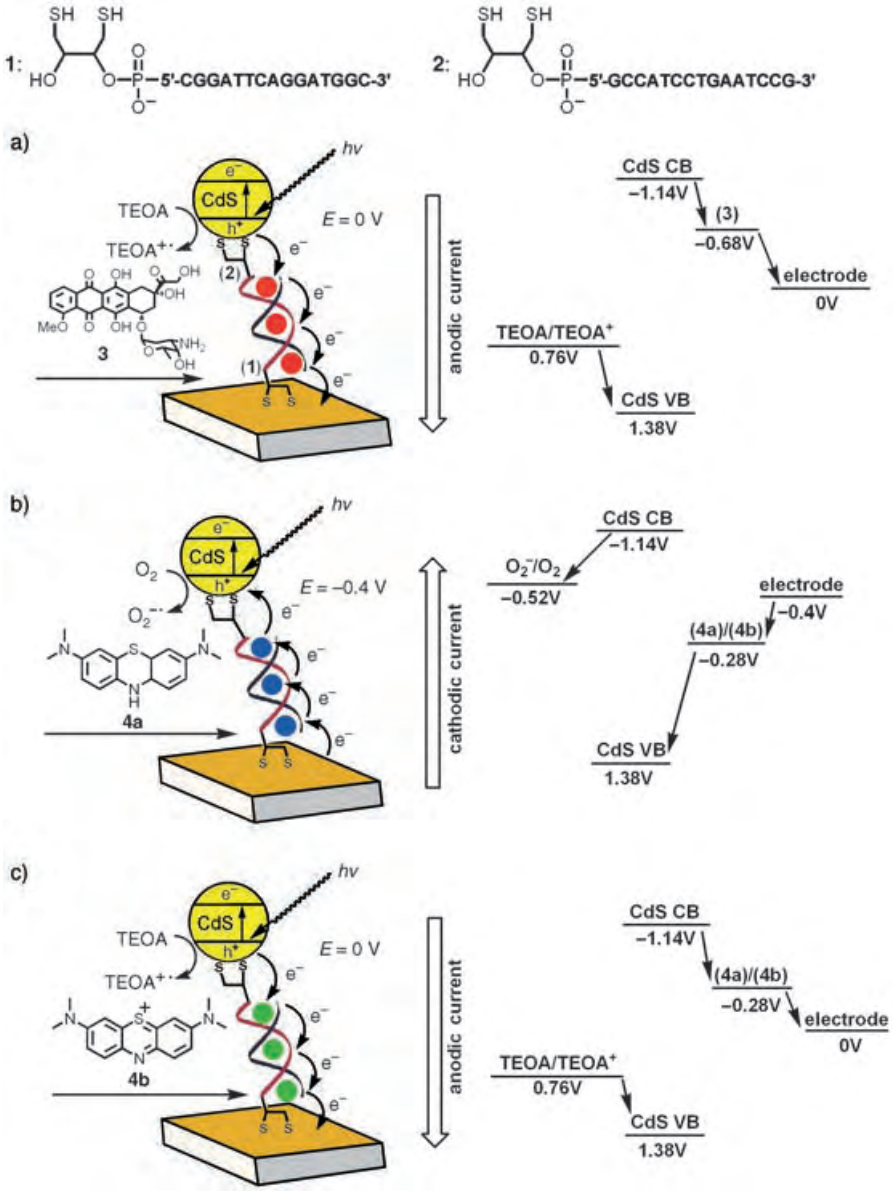

Figure 1. Directional electroswitchable photocurrents in the CdS nanoparticle/dsDNA/intercalator system. a) Enhanced generation of an anodic photocurrent in the presence of the doxorubicin intercalator (**3**; applied potential $E = 0$ V). b) Enhanced generation of a cathodic photocurrent in the presence of the reduced methylene blue intercalator (**4a**; applied potential $E = -0.4$ V). c) Enhanced generation of an anodic photocurrent in the presence of the oxidized methylene blue intercalator (**4b**; applied potential $E = 0$ V). The redox levels of the components that participate in the different photocurrent-generating systems are presented on the right side of the scheme. TEOA = triethanolamine; CB = conduction band; VB = valence band.

the binding of **3** to the dsDNA ($E° = -0.68$ V at pH 7.0). The photocurrent action spectra (Figure 2a) follow the absorbance features of the CdS nanoparticles (Figure 2b) which implies that the photocurrents originate from the photoexcitation of the semiconductor nanoparticles. Control experiments indicate that in the absence of TEOA, or without the association of the CdS nanoparticles, no photocurrents are generated in the systems. The fact that no photocurrent is generated in the presence of doxorubicin ($\lambda_{max} = 480$ nm) when the CdS nanoparticles are excluded from the dsDNA assembly prohibits the possibility that the **3**/TEOA pair contributes to the observed photocurrents. Thus, the enhanced photocurrent in the system that consists of the dsDNA with intercalated **3** is attributed to charge transport of conduction-band electrons to the bulk electrode by the intercalated quinone **3** (Figure 1a). Photoexcitation of the semiconductor nanoparticles yields an electron–hole pair. The transfer of the conduction-band electrons to intercalated **3** facilitates charge separation and the transport of electrons to the electrode to yield enhanced photocurrents. The redox levels of the components that participate in the generation of the photocurrent are presented in Figure 1.[19]

In a second configuration of the CdS nanoparticle/dsDNA system we employed methylene blue (**4**) as intercalator[15,18] (Figure 1b and c). A cyclic voltammogram of the system demonstrated a reversible redox process of intercalated **4** ($E° = -0.28$ V at pH 7.0) that can exist in the reduced state (**4a**; $\lambda_{max} = 400$ nm) or oxidized state (**4b**; $\lambda_{max} < 665$ nm), depending on the applied potential. Coulometric analysis of the reduction wave indicates that the surface coverage of **4** is 3.8×10^{12} molecules cm^{-2}. This value translates to the association of about two to three units of **4** with each dsDNA linked to the electrode. Figure 2c depicts the resulting photocurrents in the CdS nanoparticle/dsDNA system under an applied potential of $E = -0.4$ V and in the presence of O_2 as a sacrificial electron acceptor, in the absence of the intercalator (curve 1) and in the presence of the intercalator (curve 2). At this potential, the intercalator **4** exists in its reduced leuko form, **4a**. Whereas in the absence of **4a** a very low photocurrent is detected, in the presence of the reduced intercalator **4a**, the photocurrent is approximately fourfold higher. Control experiments reveal that upon the elimination of oxygen or the CdS nanoparticles from the assembly, no photocurrent is generated in the system. The photocurrent observed in the system is in the opposite direction to that observed in the presence of **3**. Thus, the enhanced cathodic photocurrent observed in the presence of **4a** originates from facilitated electron transport by the reduced intercalator **4a** (Figure 1b). Photoexcitation of the

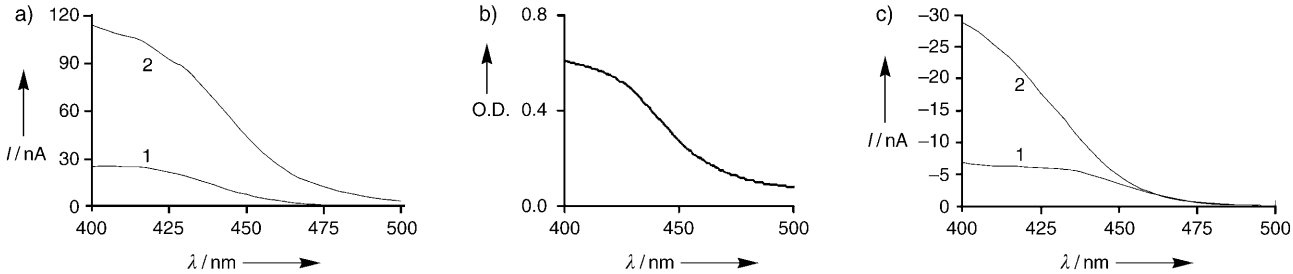

Figure 2. Photocurrent action spectra generated in the CdS nanoparticle/dsDNA systems: a) Anodic photocurrents generated in the absence (1) and in the presence (2) of the doxorubicin intercalator (**3**). The data were obtained at the applied potential $E = 0$ V and in the presence of TEOA (20 mM). b) Absorption spectrum of the CdS nanoparticles (OD = optical density). c) Cathodic photocurrents generated in the absence (1) and in the presence (2) of reduced methylene blue intercalator (**4a**). The data were obtained at the applied potential $E = -0.4$ V and in the presence of O_2 (under equilibrium with air).

semiconductor nanoparticles generates the electron–hole pair. Filling the valence-band holes with electrons that originate from the reduced intercalator **4a** facilitates charge separation and enables the enhanced reduction of O_2 by conduction-band electrons and the continuous generation of the photocurrent in the cathodic direction. The intercalation of the reduced methylene blue (**4a**) in the dsDNA allows charge transport from the electrode to the semiconductor nanoparticles, a process that leads to the effective generation of the cathodic photocurrent. Thus, the nature of the intercalator and its redox state control the direction of the photocurrent in the CdS nanoparticle/dsDNA/intercalator systems. The redox levels of the components that participate in the generation of the cathodic or anodic photocurrents are given in Figure 1.[19]

Inspection of the quasi-reversible cyclic voltammogram of the intercalated methylene blue (**4**) suggests, however, that one might use the same dsDNA intercalator for controlling the direction of the photocurrent by the application of an appropriate potential. That is, at an applied potential of 0 V, the intercalated **4** exists in its oxidized state **4b**, which behaves as electron acceptor. Thus, in the presence of the TEOA electron donor, an anodic photocurrent will be generated in the system (Figure 1c). Switching the potential on the electrode to −0.4 V yields the reduced state of the intercalator, **4a**, and in the presence of O_2 as electron acceptor the photocurrent will be switched to the cathodic direction (Figure 1b). Thus, in the presence of TEOA and O_2, one anticipates the possibility to switch the direction of the photocurrent by the applied potential. Switchable vectorial photocurrent generation was recently demonstrated by Yasutomi et al.[20] who employed helical peptides tethered to two different chromophores that acted as acceptor or donor units, respectively, upon photoexcitation. In contrast to their system, which requires the use of different wavelengths to switch the direction of the photocurrent, our system uses a dsDNA template and an intercalator to switch the direction of the photocurrent by alteration of the applied potential. Figure 3 shows the potential-induced switching of the direction of the photocurrent using the CdS nanoparticle/dsDNA system and either **4a** or **4b** as the intercalator. Photoexcitation of the system at $\lambda = 405$ nm results in an anodic current that is switched "on" and "off" by light at an applied potential

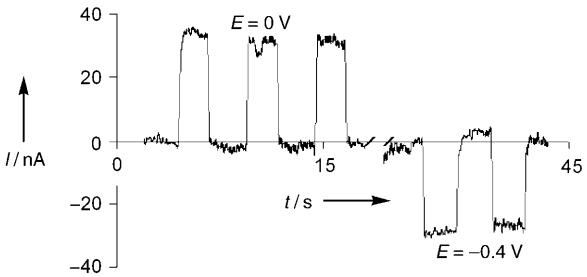

Figure 3. Electrochemically switched anodic and cathodic photocurrents generated in the CdS nanoparticle/dsDNA/**4b** (or **4a**) systems at 0 V and −0.4 V, respectively, in the presence of TEOA (20 mM) and O_2 (under equilibrium with air). Photocurrents were generated upon irradiation at $\lambda = 405$ nm.

of 0 V. Turning the applied potential to −0.4 V switches the photocurrent to the cathodic direction. The electroswitchable directional generation of the photocurrent is reversible and controlled by the applied potential.

The photocurrent generated by the CdS nanoparticle/dsDNA with the use of the intercalators corresponds to an AND logic gate, in which the photocurrent is generated only if the optical signal and the intercalator are introduced as activation stimuli to the system. The potential-controlled generation of the photocurrent in the **4a**/**4b**-intercalated CdS nanoparticle/dsDNA system not only allows the direction of the output current to be controlled but also allows regulation of the extent of opening of the gate and the resulting magnitude of the photocurrent.

To conclude, the present study has demonstrated the use of CdS nanoparticle/dsDNA assemblies on an electrode for the potential-induced switching of the directions of the photocurrents. The dsDNA acts as the template for the accommodation of the intercalators and its electrical contacting with the electrode.

Experimental Section

Dithiolated ssDNA (**1** and **2**) were prepared in situ during oligonucleotide synthesis using dithiophosphoamidite (Glen Research Inc.) by Sigma-Genosys Inc. DNA strands **1** and **2** were then reduced with dithiothreitol (DTT) and purified on a Sephadex G-25 column prior

to the modification of the surfaces. CdS nanoparticles (5.5 nm) were prepared in water using polyphosphate as a capping agent.[21] Glass slides (AF-45) coated with a 250-nm thick layer of gold (Evaporated Coatings Inc) were used as working electrodes. The Au electrode was modified using reduced **1** (10 μM) for 2 h in phosphate buffer (50 mM, pH 7.4) containing NaCl (0.5 M). The electrode was then washed three times with phosphate buffer (0.1M, pH 7.4) and modified with mercaptohexanol (1 mM) in water for 10 min to prevent nonspecific absorption of DNA on the surface. For the hybridization step, the **1**-functionalized electrode was treated with reduced **2** (10 μM) for 2 h in phosphate buffer (50 mM, pH 7.4) containing NaCl (0.5 M). The dsDNA- (**1**·**2**)-functionalized gold electrode was washed three times with phosphate buffer (0.1M, pH 7.4) and incubated in a solution of CdS (50 nM) for 12 h. Doxorubicin (**3**) or methylene blue (**4**) intercalators were incorporated into the dsDNA/CdS nanoparticle assembly by the interaction of the modified electrodes with a 50 μM solution of **3** or **4**, respectively, for 30 min, followed by rinsing of the electrode with phosphate buffer (0.1M, pH 7.4). Electrochemical and photoelectrochemical measurements were performed as described previously.[22] The photocurrents were measured in phosphate buffer (0.1M, pH 7.0) in the presence of either TEOA (20 mM) or oxygen (under equilibrium with air) or both. The working electrode area was 2.1 cm^2. All reported photocurrents represent the difference between the currents observed under light and dark conditions. The electrical potentials are reported relative to the saturated calomel electrode (SCE).

Supramolecular Chemistry

Rare and Diverse Binding Modes Introduced through Mechanical Bonding**

David A. Leigh, Paul J. Lusby, Alexandra M. Z. Slawin, and D. Barney Walker*

Interest in catenanes and rotaxanes has largely focused on the stimuli-induced change in the position of their components for possible exploitation in molecular devices,[1] but other properties and features of these architectures are becoming apparent.[2] Here, we report a previously unrecognized consequence of kinetic stabilization of an otherwise unfavorable association of molecular fragments through mechanical bonding (Figure 1). The raised energy of the interlocked components—brought about by the enforced high local concentration of convergent functional groups, the limitation in the number of conformations and co-conformations that each component can adopt, and the poor solvation of their inner surfaces—facilitates (kinetically and thermodynamically) the formation of internal and external binding motifs that are either not observed or much weaker when the same groups are not confined in this way. The effect is illustrated through a remarkable series of binding modes (including orthogonal bifurcated pyridine–pyridine hydrogen bonding,

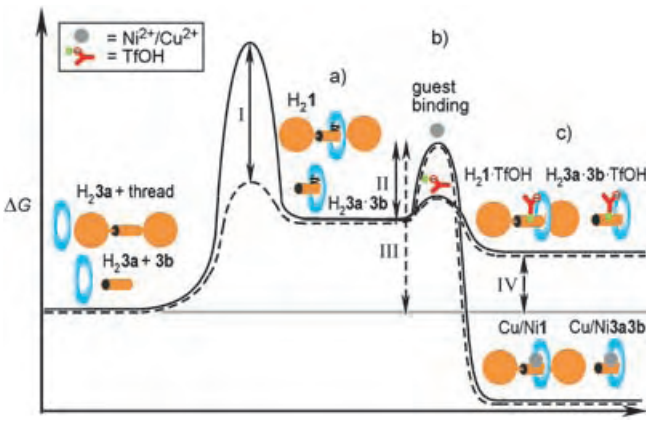

Figure 1. Effects of kinetic stabilization of an otherwise unfavorable association of molecular fragments through mechanical bonding. a) The kinetic stabilization (I) of a mechanically interlocked architecture that features only weakly attractive interactions between the macrocycle and thread permits noncovalent interactions to be observed (as in H_2**1**) which are too weak to stabilize the corresponding host–guest complex (H_2**3a**·**3b**). b) For a rotaxane that is not thermodynamically stable with respect to its free components, the activation energy for tertiary component complex formation is lower than for the analogous noninterlocked system (barrier II is less than III). This arises because the entropic cost of bringing the two components of the rotaxane together has already been paid, some degrees of freedom of the components are already restricted in the mechanically interlocked architecture, and the desolvation of the internal rotaxane surfaces is less energetically demanding than those of the free components. c) The higher energy of such a rotaxane means that a host–guest complex which involves the rotaxane can be favorable (e.g. H_2**1**·TfOH) even when the equivalent trimolecular complex (H_2**3a**·**3b**·TfOH) is not (IV). It also ensures that metal complexes derived from such rotaxanes, such as Cu**1** and Ni**1**, are inherently thermodynamically more stable than the analogous complexes derived from noninterlocked fragments and, in principle, kinetically easier to form. The association/dissociation pathways are shown by black solid (interlocked components) and dashed (noninterlocked components) lines; the horizontal gray line corresponds to the free energy of the nonassociated individual components.

cooperative binding to a sulfonic acid guest through deprotonation by one component and anion–amide hydrogen bonding by the other, enforced square-pyramidal coordination of Cu^{II} and Ni^{II}, and second-sphere coordination in a square-planar $Pd^{II}Cl$ complex) exhibited in solution and the solid state by a [2]rotaxane and an analogous [2]catenane, but not seen with either threadable (but nonmechanically interlocked) versions of the components or flexible covalently bonded systems (Figure 2).

Most catenanes and rotaxanes are synthesized by utilizing templates to thermodynamically favor interlocking,[1a] but subsequent removal of the template can leave a molecule that is energetically unstable with respect to the noninterlocked components and is only held intact by virtue of the mechanical bond. We recently described[3] the assembly of a mechanically interlocked architecture about a Pd^{II} template to give a square-planar [2]rotaxane–metal coordination complex, Pd**1**.[4] We were intrigued to find that upon protic demetalation of the complex to give H_2**1**, the ^{1}H NMR spectrum in $CDCl_3$ indicated significant intercomponent hydrogen bonding between the amide groups of the macrocycle and the pyridine nitrogen atom of the rotaxane thread (the protons of the amide groups in the macrocycle appear 1.7 ppm downfield relative to the corresponding protons in the free macrocycle). Such a binding motif, which requires essentially orthogonal pyridine rings with the nitrogen atoms bridged by bifurcated hydrogen bonds, is extremely rare (a search of the Cambridge Crystallographic Database reveals only one other example[5]) but is somewhat reminiscent of the hydrogen bonding that occurs at 90° to the plane of the lone pairs of amide groups in threads seen extensively in other hydrogen-bonded rotaxanes.[6] Slow cooling of a hot, saturated solution of H_2**1** in acetonitrile/chloroform (10:1) yielded single crystals that were of sufficient quality to confirm the interaction in the solid state by X-ray crystallography (Figure 3a, b) but were inadequate to confidently characterize the interaction in detail.[7] However, when we prepared a [2]catenane that incorporated the same functional groups, H_2**2**, a similar noncovalent interaction was observed in solution in $CDCl_3$ and, in this case, single crystals of excellent quality were obtained by slow cooling of a hot, saturated solution of H_2**2** in acetonitrile. The solid-state structure of H_2**2** (Figure 3c) closely mirrors the hydrogen-bonding motif seen in the crystal structure of H_2**1**, with unsymmetrical intercomponent hydrogen-bond distances (2.28 and 3.10 Å in H_2**2**; 2.3 and 2.8 Å in H_2**1**) and the angle between the planes of the

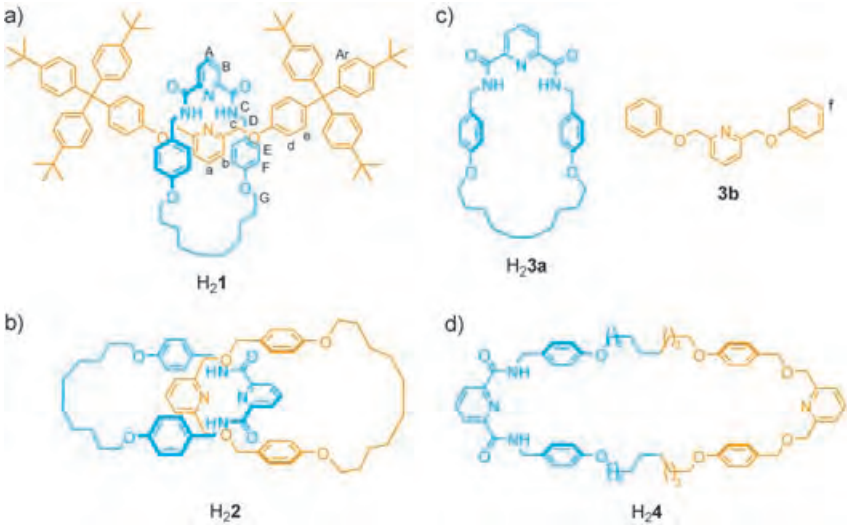

Figure 2. Different ways of linking a 2,6-dialkylpyridine unit with a 2,6-dicarboxamidepyridine unit which lead to significantly different noncovalent binding properties: a) on different components within a [2]rotaxane architecture, H_2**1**; b) on different components within a [2]catenane architecture, H_2**2**; c) on separate threadable, but not mechanically interlocked, molecular components H_2**3a** and **3b**; and d) on a flexible but wholly covalently bonded system, H_2**4**. For ^{1}H NMR spectroscopic assignments (see Figure 4), hydrogen atoms have been labeled A–G and a–f/Ar for the macrocycle and thread, respectively.

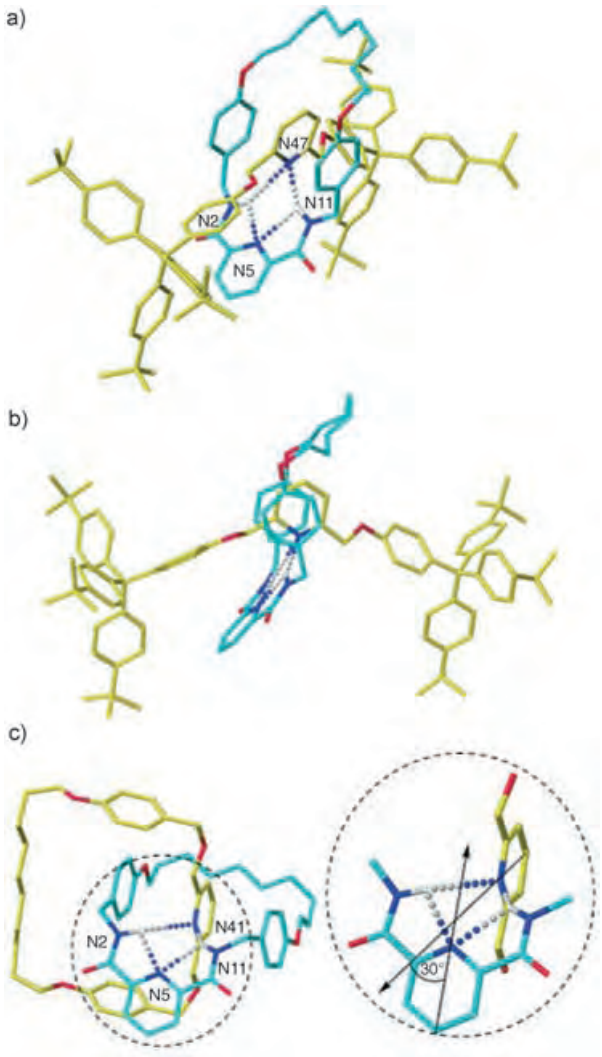

Figure 3. X-ray crystal structures[7] of [2]rotaxane H_2**1** and [2]catenane H_2**2**: a) H_2**1** (twisted view); b) H_2**1** (side view which shows the macrocycle circumscribing the pyridine residue of the thread; disorder in the alkyl chain region and solvent molecules, not the central hydrogen-bonding region, results in a high overall *R* factor of 33%); c) H_2**2** (*R* factor <5%; the intercomponent hydrogen-bond motif mirrors that shown in (a) and (b)). Inset: the lone pairs of the pyridine nitrogen atoms do not point directly at each other, but are tilted 30.0° apart. C (macrocycle) turquoise; C (thread) yellow; O red; N dark blue; H white. For clarity only nitrogen-bound hydrogen atoms are shown. Selected bond lengths [Å] for H_2**1**: N2H–N5 2.4; N11H–N5 2.6; N2H–N47 2.8; N11H–N47 2.3. Selected bond angles [°] for H_2**1**: N2H-N5 151; N11H-N5 153; N2H-N47 96; N11H-N47 108. Selected bond lengths [Å] for H_2**2**: N2H–N5 2.18; N11H–N5 2.33; N2H–N41 2.28; N11H–N41 3.10. Selected bond angles [°] for H_2**2**: N2H-N5 107.1; N11H-N5 102.2; N2H-N41 146.5; N11H-N41 129.0.

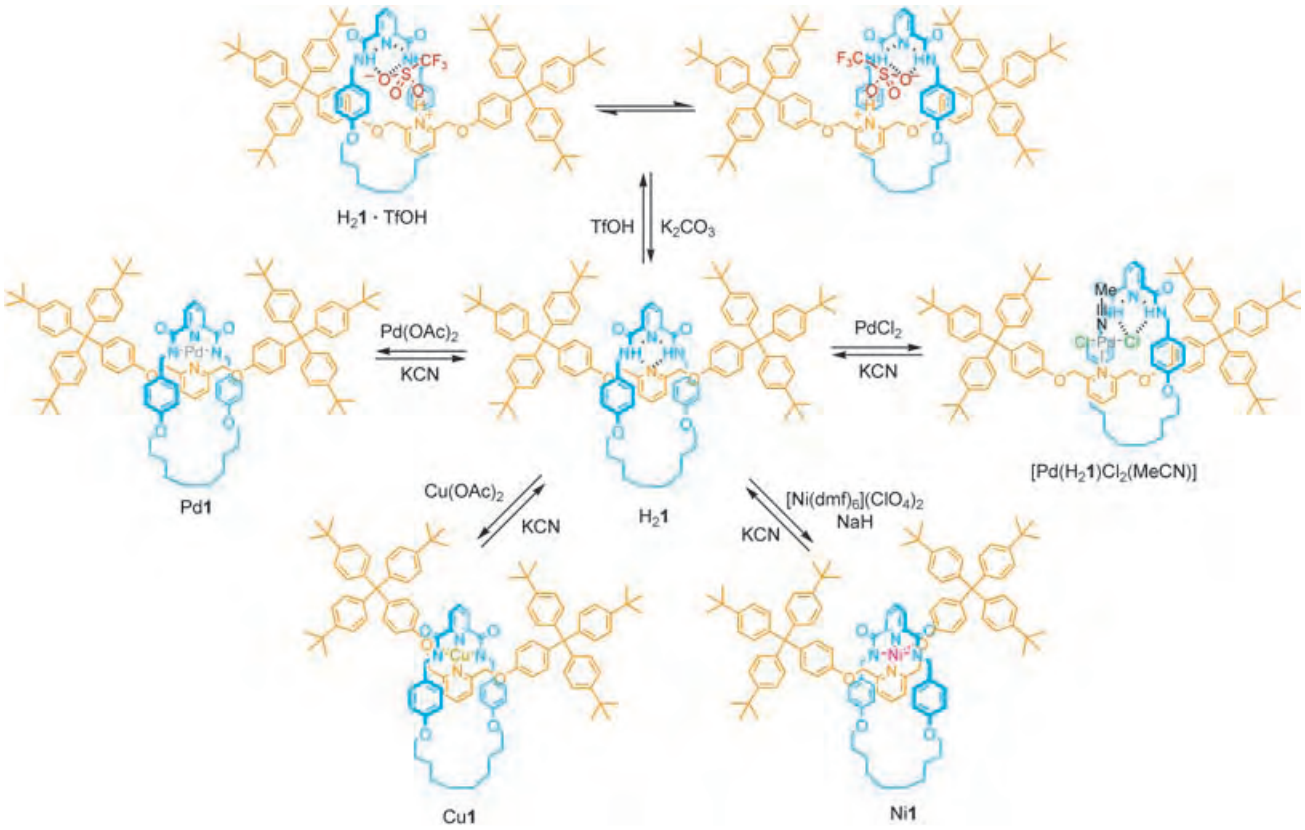

pyridine rings nearly orthogonal (90.7° in H_2**2**; 82° in H_2**1**) but tilted (30.0° in H_2**2** (Figure 3c, inset); 34° in H_2**1**) away from linearity to avoid too close an interaction between the lone pairs on the pyridine nitrogen atoms.

To investigate this atypical binding motif further, we titrated an unstoppered analogue of the thread, **3b**, with the free macrocycle, H_2**3a**, and monitored the titration by ^{1}H NMR spectroscopy ($CDCl_3$) to determine the energetics of the interaction in the absence of the kinetic barrier to dissociation provided by the mechanical bond. However, there was virtually no shift in the amide protons of H_2**3a** in the presence of up to 20 equivalents of **3b** (4–80 mM) which indicates that the bimolecular association constant must be less than $5\,M^{-1}$—the approximate limit of this detection method with the large shifts typically observed through hydrogen-bonding amide groups. Interestingly, the ^{1}H NMR spectrum of the wholly covalently linked analogue H_2**4** in $CDCl_3$ also gave no indication of hydrogen-bonding interactions between the pyridine-2,6-carboxamide protons and the second pyridine residue, even though this very large macrocycle is certainly flexible enough to adopt such a geometry without steric hindrance.

Rare hydrogen-bond motifs have previously been observed within rotaxane architectures (e.g. amide NH to ester acyl oxygen atoms,[8,9] and amide NH to ester alkyl oxygen atoms[9]). The propensity for such unusual interactions in mechanically bonded structures presumably arises for a number of reasons: 1) the enforced high local concentration of functional groups for which there is a low steric cost to relative movement within the vector of the thread; 2) the limited number of conformations and co-conformations that each component can adopt that do not put functional groups into convergent orientations; 3) the imposed orthogonalization of components which can preclude normally preferred noncovalent bonding geometries; 4) freezing out of a single co-conformation for an intercomponent binding event only costs a reduction of two degrees of freedom (translation and rotation of the macrocycle about the thread) in contrast to the multiple degrees of rotational freedom of the alkyl chains that would be lost by internal hydrogen bonding in H_2**4**; 5) the inefficient solvation of internal or congested surfaces of an interpenetrated architecture means that desolvation of binding sites is likely to occur at a lower energetic cost than for conventional structures. All of these factors effectively do the same thing, that is, raise the energy of the rotaxane with respect to the free components. However, the kinetic stabilization of the architecture provided by the stoppers prevents dethreading (the rotaxane is not in equilibrium with the free components). This increase in free energy is actually a form of host preorganization, which serves to enhance binding properties as outlined by Cram over 30 years ago.[10] The result is that interactions which are not strong enough to stabilize a host–guest complex can become thermodynamically favorable if the components are held together by a mechanical bond (Figure 1).

We reasoned that it should be possible to disrupt the intercomponent hydrogen-bonding interaction in H_2**1** by protonation of the more basic 2,6-dioxymethylenepyridine nitrogen atom (Scheme 1). Although treatment of H_2**1** with one equivalent of trifluoromethanesulfonic acid (TfOH) resulted in protonation of the desired site (Figure 4d), the downfield shift of the H_C amide protons indicated that strong hydrogen bonding was still present. The shielding and broadening of particular thread signals at 298 K (Figure 4d) suggests that instead of residing over the pyridine residue as in H_2**1**, the macrocycle is displaced to the side and shuttles between the two halves of the thread relatively slowly on the

Scheme 1. Binding modes observed for [2]rotaxane H_2**1**. All of the complexation reactions are fully reversible. A similar range of complexes are exhibited by [2]catenane H_2**2** (for an X-ray crystal structure of Pd**2**, see ref. [12]). The hydrogen bonding in [Pd(H_2**1**)Cl_2(MeCN)] is observed only in the solid state. Tf = trifluoromethanesulfonyl, DMF = *N*,*N*-dimethylformamide.

NMR timescale. This was confirmed by the ^{1}H NMR spectrum recorded at 238 K (Figure 4e) in which many of the thread resonances were split into two inequivalent sets (H_b/$H_{b'}$, H_c/$H_{c'}$, H_d/$H_{d'}$, H_e/$H_{e'}$) that correspond to solvent-exposed and encapsulated (and thus magnetically shielded by the macrocycle) protons, respectively. The rationale for this behavior was provided by the crystal structure of single crystals grown from acetonitrile (Figure 5a). The [2]rotaxane acts as a host for an entire molecule of TfOH; one component (the thread) deprotonates the acid, and both components hydrogen bond to the resulting anion to generate a neutral complex, H_2**1**·HOTf. The X-ray crystal structure is consistent with the specific shielding effects seen in the ^{1}H NMR spectra, including the upfield shift of the signal for the pyridinium proton (see Figure 4c) as a consequence of other hydrogen-bond donors binding to the triflate anion, and with the noncovalent binding of the sulfonic acid acting as a transient steric barrier to shuttling of the macrocycle between the two halves of the thread.[12] In contrast (Scheme 2), a 1:1 mixture of H_2**3a** and **3b**H^+TfO^- in $CDCl_3$ shows neither upfield shift of resonances H_c, H_d, and H_e (compare Figure 4b with the spectrum of the protonated thread in Figure 4c) nor downfield shifts of the protons from the amide groups in H_2**3a**. Similarly, the absence of shifts in the amide resonances of the protonated covalently linked structure H_2**4**·H^+TfO^- suggests that it does not internally associate through hydrogen bonding.

The mechanically interlocked assemblies also differ from their noninterlocked counterparts in their ability to adopt a range of overall neutral binding modes with metals. Treatment of H_2**1** or H_2**2** with $Cu(OAc)_2$ in MeOH/CH_2Cl_2 with heating at reflux resulted in double deprotonation of the ligand and the generation of the corresponding 1:1 neutral metal-interlocked ligand complex. Recrystallization of the copper [2]rotaxane complex, Cu**1**, from acetonitrile gave single crystals that were suitable for X-ray crystallographic studies (Figure 5b). The solid-state structure shows a square-based pyramidal coordination motif that involves one of the thread oxygen atoms as well as the four nitrogen atoms of the rotaxane which form the near-planar base of the pyramid (N47 lies approximately 10° above the plane defined by N2-N11-N5-Cu). Treatment of H_2**3a**/**3b** or H_2**4** with $Cu(OAc)_2$ under the same conditions gave no indication of formation of a complex nor deprotonation of the amide groups of the macrocycle.

The synthesis of complexes of the mechanically interlocked ligands with nickel required more vigorous conditions ($[Ni(dmf)_6](ClO_4)_2$, NaH, DMF, 60 °C, 1 h) but nonetheless resulted in Ni**1** and Ni**2**, both isolated as orange crystalline compounds. In this case, a similarly colored complex could also be generated with H_2**3a**/**3b**, but unlike Ni**1** or Ni**2** the isolated compound rapidly decomposed and we were unable to isolate or characterize it. The X-ray crystal structure of single crystals of Ni**1** grown from slow cooling of a saturated

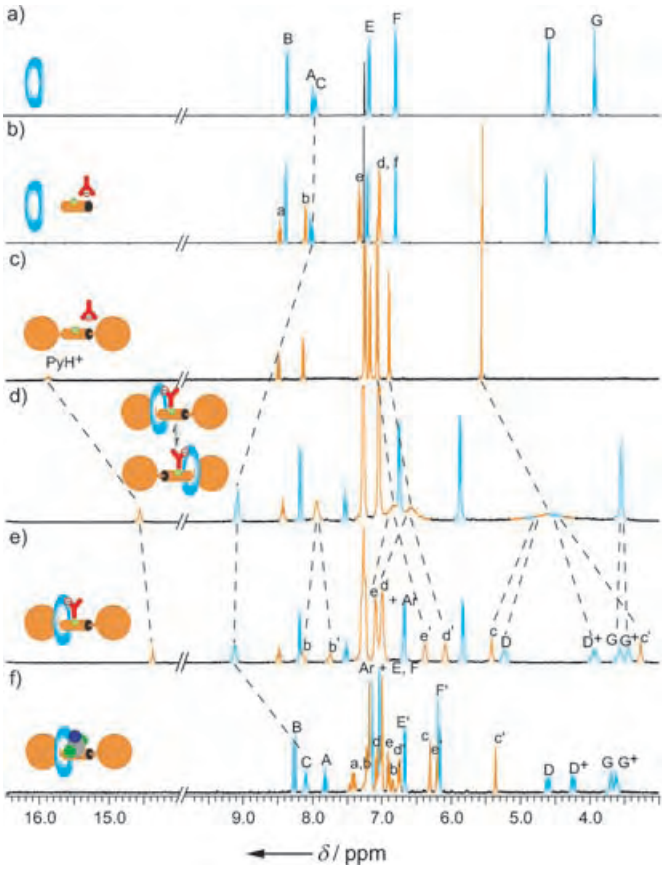

Figure 4. ^{1}H NMR spectra ($CDCl_3$, 400 MHz, 298 K unless otherwise stated): a) macrocycle H_2**3a**; b) H_2**3a** and unstoppered thread **3b** and HOTf; c) thread and HOTf (Py = pyridine); d) [2]rotaxane complex H_2**1**·HOTf showing fast exchange (shuttling) of the macrocycle between equivalent sites on both halves of the thread; e) [2]rotaxane complex H_2**1**·HOTf at 238 K showing slow exchange (reversible noncovalent bonding of the triflate anion provides a transient steric barrier to shuttling); f) [Pd(H_2**1**)Cl_2(MeCN)] showing slow exchange (coordination of [$PdCl_2$(MeCN)] provides a fixed steric barrier to shuttling up to at least 325 K). See Figure 2 for atom labeling scheme.

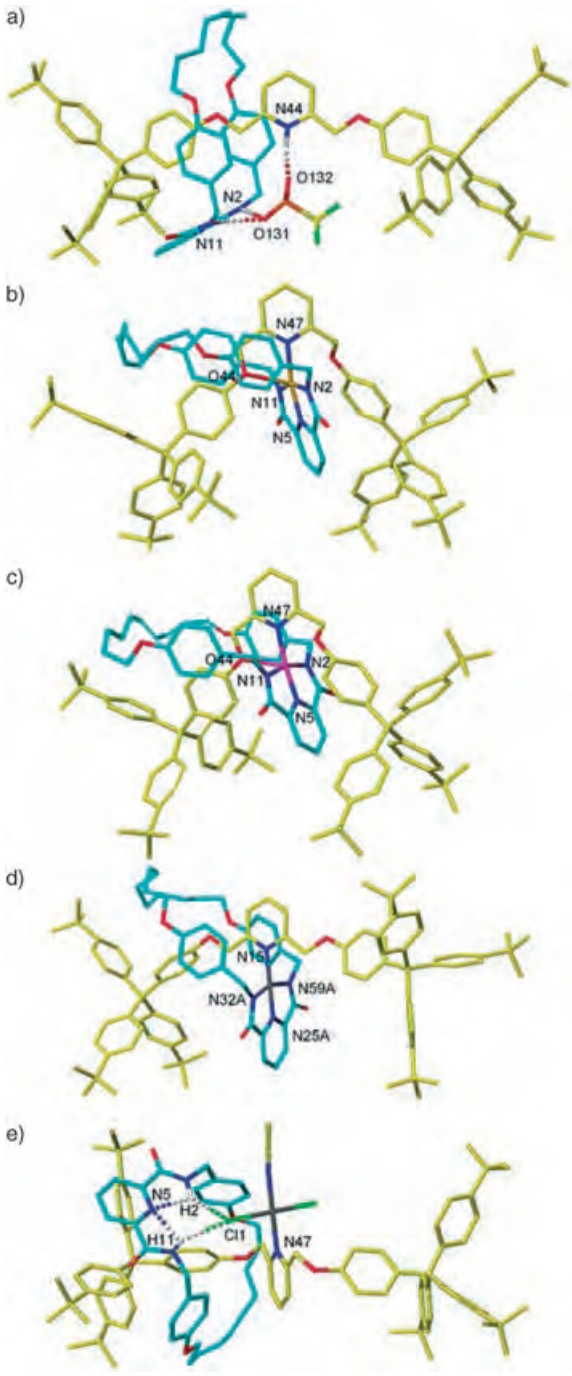
solution in acetonitrile is shown in Figure 5c and is closely related to the structure obtained for Cu**1**. Treatment of any of the rotaxane or catenane metal complexes with KCN in CH_2Cl_2/MeOH regenerated the original interlocked molecule, H_2**1** or H_2**2**. The differences in both the ease of formation and the stability of the metal complexes with the catenane and rotaxane relative to the noninterlocked ligands is, again,



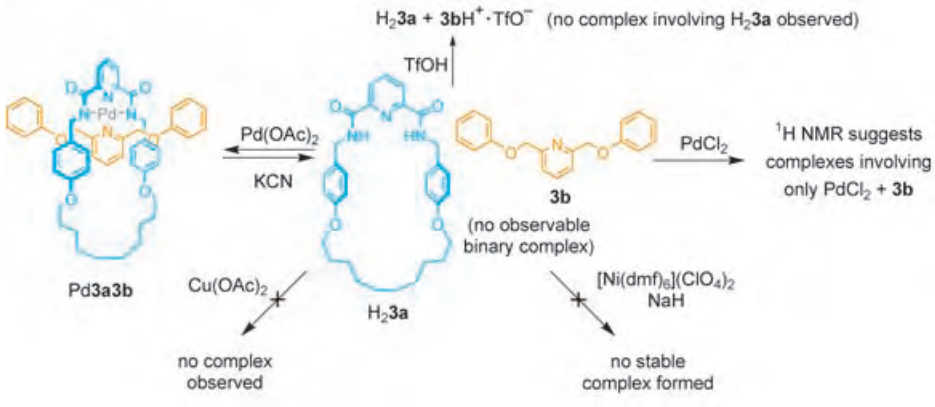


Figure 5. X-ray crystal structures[7] of various complexes of **1**: a) neutral [2]rotaxane–triflic acid complex, H_2**1**·HOTf. Scheme 2. Attempted complexation experiments involving H_2**3a**/**3b**. Similar results were obtained with macrocycle H_2**4** (for an X-ray crystal structure of Pd**4**, see ref. [12]).

consistent with the intrinsic effect of kinetic stabilization of a mechanically interlocked architecture (Figure 1c).

Each of the four ligand sets reacts with $Pd(OAc)_2$ (H_2**1**, H_2**2**, and H_2**4** directly in $MeCN/CH_2Cl_2$; H_2**3a**/**3b** requires preliminary reaction of $Pd(OAc)_2$ with H_2**3a** in MeCN followed by treatment of the resulting complex with **3b** in CH_2Cl_2) to give the corresponding square-planar coordination complexes (Schemes 1 and 2 and Figure 5d). However, the rotaxane and catenane also formed a different type of neutral square-planar coordination complex when treated with $PdCl_2$, an initial palladium salt that features significantly stronger coordinating ligands (chloride is also less basic than acetate). Slow cooling of saturated solutions of either complex in acetonitrile afforded crystals that were suitable for X-ray crystallography, and the structure of the rotaxane complex, $[Pd(H_2$**1**$)Cl_2(MeCN)]$, is shown in Figure 5e (the solid-state structure of the [2]catenane complex is similar but features intermolecular rather than intramolecular NH···Cl–Pd hydrogen bonding). From the crystal structures it can be seen that although Pd coordinates to the thread as in Pd**1**, the original metal chloride ligands remain intact and the macrocycle amides are not deprotonated. In solution the coordination of the $[PdCl_2(MeCN)]$ unit to the pyridine ring of the thread acts as a steric barrier to shuttling (Figure 4f). This is similar to the effect seen with H_2**1**·TfOH, but unlike the complex held together by hydrogen bonds the coordination to the metal is not kinetically labile and persists as a barrier to shuttling up to at least 325 K (close to the boiling point of the solvent $CDCl_3$).[11]

The solid-state structure of $[Pd(H_2$**1**$)Cl_2(MeCN)]$ features hydrogen bonding between the amide groups of the macrocycle and the chloride ligands of the metal (Figure 5e). However, the ^{1}H NMR spectrum shows that this interaction is not present to any significant extent in $CDCl_3$ (the chemical shift of H_C is virtually unchanged compared to H_2**3a**; Figure 4f). Wisner and co-workers recently used a similar interaction to direct an elegant synthesis of a pseudorotaxane.[13] During the course of that work, a macrocycle binding constant that largely results from two sets of isophthalamide groups hydrogen bonding to the chloride ligands of a Pd^{II} complex was determined to be $5\times10^3\,M^{-1}$ in $CDCl_3$.[13] In contrast, Crabtree and co-workers determined the association constant for a single isophthalamide group with Cl^- to be $6\times10^4\,M^{-1}$ in CD_2Cl_2.[14] Accordingly, a C(O)NH···Cl–Pd interaction must be somewhat less than half the strength of a C(O)NH···Cl^- hydrogen bond. This is consistent with the observation that the interaction is too weak to significantly bind the macrocycle in $[Pd(H_2$**1**$)Cl_2(MeCN)]$ in $CDCl_3$, despite the high effective molarity introduced by the mechanical bond, and is in marked contrast to the effective bifurcated pyridine–pyridine hydrogen bonding in H_2**1**. This suggests that the intercomponent binding mode in H_2**1** is not particularly weak and its scarcity as an observed interaction may arise because the geometry of the interlocked architecture precludes otherwise preferred noncovalent bonding geometries.

In conclusion, the kinetically enforced association of molecular fragments within an interlocked architecture facilitates the formation of diverse, and sometimes rare and unusual, binding motifs both in solution and the solid state. These interactions can produce interesting effects in their own right; the cooperative hydrogen bonding of an organic guest by both components of a [2]rotaxane can present an effective barrier to shuttling at low temperatures, whereas a stronger metal–ligand coordination mode can be used to restrict the same motion even at higher temperatures. The fact that many of the observed modes of binding are weaker or not seen at all when the components are not mechanically interlocked makes this consequence of the mechanical bond particularly noteworthy.[15]

[7] Structural data for H_2**1**, Cu**1**, and Ni**1** were collected at 93 K using a Rigaku Saturn diffractometer (MM007 high-flux RA/$Mo_{K\alpha}$ radiation, confocal optic); for H_2**2** and $[Pd(H_2\mathbf{1})Cl_2$-(MeCN)] at 93 K using a Rigaku Mercury diffractometer (MM007 high-flux RA/$Mo_{K\alpha}$ radiation, confocal optic); and for H_2**1**·TfOH at 125 K using a Bruker SMART diffractometer (sealed tube $Mo_{K\alpha}$ radiation, graphite monochromator, $\lambda = 0.71073$ Å). All data collections employed narrow frames (0.3–1.0°) to obtain at least a full hemisphere of data. Intensities were corrected for Lorentz polarization and absorption effects (multiple equivalent reflections). Structures were solved by direct methods, non-hydrogen atoms were refined anisotropically with CH protons being refined in riding geometries (SHELXTL) against F^2. In most cases, amide protons were refined isotropically subject to a distant constraint. Any other restraints or additional features of the refinement are detailed for each structure below. The structure determination for H_2**1** proved particularly problematic; we collected full datasets using a variety of collection routines on more than 15 different crystals from several different crystallization experiments. The data were always poor, principally because of disorder arising from the alkyl chain and solvated molecules. The structure was refined isotropically with no protons included in the refinement. H_2**1**: $C_{112}H_{130}N_4O_6$, $M_r = 1628$, crystal size $= 0.2 \times 0.1 \times 0.03$ mm^3, orthorhombic, *Pbca*, $a = 18.338(4)$, $b = 23.545(5)$, $c = 44.922(9)$ Å, $V = 19396(7)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.115$ Mg m^{-3}; $\mu = 0.068$ mm^{-1}, 18573 data (17303 unique), $R = 0.3339$ for F values of reflections with $F_o > 4\sigma F_o$), $S = 4.90$ for 463 parameters. Phase-Transfer Catalysis

Enantio- and Diastereoselective Catalytic Mannich-Type Reaction of a Glycine Schiff Base Using a Chiral Two-Center Phase-Transfer Catalyst**

Akihiro Okada, Tomoyuki Shibuguchi, Takashi Ohshima, Hyuma Masu, Kentaro Yamaguchi, and Masakatsu Shibasaki**

α,β-Diamino acids are key structural components in molecules such as peptides and β-lactam antibiotics and in medicinally relevant compounds;[1,2] for example, 2,3-diamino-3-phenylpropanoic acid is used as an advanced alternative to the side chain of taxol to improve its water solubility.[3] Various methods for the preparation of optically active α,β-diamino acid derivatives have been reported. Almost all of them, however, require the use of stoichiometric amounts of chiral sources. One common method involves the displacement of the hydroxy group of serine derivatives with an azide moiety followed by reduction of the azide group,[1,4] and another is the addition of glycine ester derivatives to chiral *N*-sulfinyl imines.[5,6] Jørgensen and co-workers reported an efficient catalytic method that relies on the aza-Henry reaction of silyl nitronates with imines.[7] The catalytic asymmetric synthesis of chiral serine derivatives by the Sharpless asymmetric aminohydroxylation reaction is another useful method.[8] Recently, more direct and atom-economically favorable methods using a Mannich-type reaction of a glycine Schiff base with imines were reported by Jørgensen and co-workers[9] and Maruoka and co-workers.[10] Although these methods are highly enantioselective, there is still much room for improvement. For example, the removal of *para*-toluenesulfonate (tosyl) groups is difficult in the method of Jørgensen and co-workers, and low substrate generality is a problem in the method of Maruoka and co-workers. Both methods are also only moderately diastereoselective. Herein, we report a new direct method to access a variety of optically active *syn*-α,β-diamino acid derivatives by a Mannich-type reaction of a glycine Schiff base that uses a new chiral two-center phase-transfer catalyst. The selection of the imine-protecting group was pivotal to achieving high diastereoselectivity (up to 99:1). Moreover, the usefulness of the obtained products was successfully demonstrated by their transformation into a tripeptide and the key intermediate of CP-99,994 through chemoselective deprotection of the *N*-diphenylmethylene and *N*-*tert*-butoxycarbonyl (Boc) protecting groups.

To develop efficient methods for the synthesis of α,β-diamino acid derivatives, we used Mannich protocols under asymmetric phase-transfer reaction conditions because of the preparative advantages of the phase-transfer process, such as simple procedures and mild conditions.[11] Recently, we developed the tartrate-derived diammonium salt (TaDiAS) **1**, which efficiently catalyzes asymmetric phase-transfer alkylations and Michael reactions of a glycine Schiff base **2**.[12]

(*S*,*S*)-TaDiAS **1a**: R^1 = Pr
1b: R^1 = Bu

We initially examined a Mannich-type reaction of **2** using *N*-diphenylphosphinoyl (dpp) imine **3a** as an electrophile because the dpp group can be readily removed under mild conditions.[13] Under phase-transfer conditions using TaDiAS **1b**, which is a suitable catalyst for asymmetric phase-transfer Michael reactions,[12] and fluorobenzene and cesium carbonate were determined to be the best solvent and base, respectively; this reaction afforded the desired Mannich

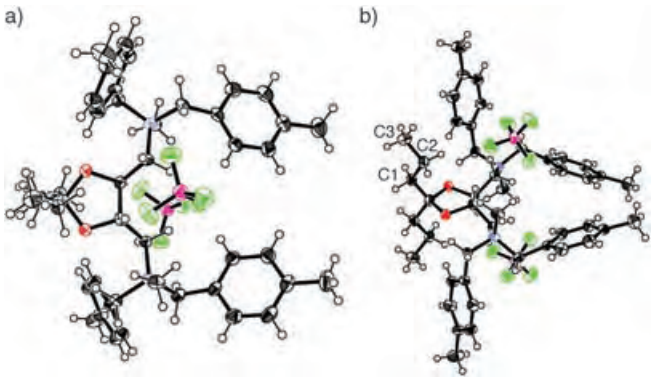
when diphenylmethyl imine **3b** (Table 1, entry 2) and benzyl imine **3c** (Table 1, entry 3) were used, *N*-Boc imine **3d** (Table 1, entry 4) gave the product **4d** in quantitative yield with high diastereoselectivity (*syn*/*anti* = >95:5) and moderate enantioselectivity (53% *ee*). These results suggested that the electron-withdrawing imine-protecting group plays an important role in the reactivity. On the other hand, the *N*-tosyl imine was less reactive and produced a low enantioselectivity (Table 1, entry 5). Thus, we chose the *N*-Boc imine **3d** as a substrate for further investigation because of these results and the fact that a Boc protecting group can be readily removed.

We next examined the structure of the catalyst to improve enantioselectivity. We had previously synthesized a variety of TaDiAS salts **1**, and they had been examined in catalytic asymmetric phase-transfer alkylations and Michael reactions. However, rational design of the catalyst was still difficult because of the lack of conformational information about **1**, except for preliminary computational analysis that suggested the formation of a tight ion complex between the two cation centers in **1** and the enolate of **2**. Thus, on the basis of the above analysis, we performed a conformational investigation of **1**. Although no useful information was obtained by NMR spectroscopy, the structure of **1a** was determined by X-ray crystallographic analysis. A tetrafluoroborate anion is situated very close to each of the ammonium units, thus creating an attractive C_2-symmetrical chiral environment (Figure 1). Another interesting fact is that the alkyl chains of the acetal moiety snake up in a direction perpendicular to the dioxolane ring. A previous examination of substituent effects in asymmetric phase-transfer catalysis revealed that both aromatic and acetal moieties strongly affected enantioselectivity. This unexpected substituent effect by the acetal moiety can be understood from the proximity of the counteranions to the



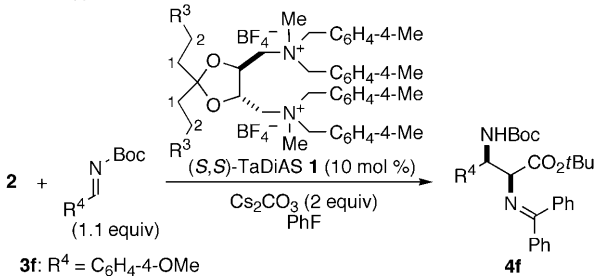


Figure 1. Crystal structure of (*S*,*S*)-TaDiAS (**1a**). a) Top view and b) side view.

acetal side chains, especially to the C2 and C3 positions (Figure 1b).

In the reaction, the enolate of **2** was expected to be replaced with the BF_4^- ion and form a tight complex with the cationic centers of **1**. Therefore, we assumed that longer or more sterically congested acetal substituents would prevent an unfavorable approach by the imines to the enolate of **2**. On the basis of this hypothesis, the substituent effects of the acetal moiety were examined (Table 2).[15] As expected, the

introduction of an aromatic ring at the C2 positions of the acetal side chains improved the enantioselectivity (Table 2, entry 3). On the other hand, the introduction of a benzyl group at C2, which results in an aromatic ring at the C3 position (Table 2, entry 4), and a bulky substituent at C2 (Table 2, entry 6) gave only moderate enantioselectivity. Finally, the best results were obtained from the use of the 4-fluorophenyl-substituted catalyst **1g** (Table 2, entry 7), which

suggests the possibility of π–π interactions.[16] Performing the latter reaction at lower temperature (−45 °C) further improved the enantioselectivity to 82 % *ee* (Table 2, entry 8).

We examined the scope and limitations of the reaction under the optimized conditions using various *N*-Boc imines. As summarized in Table 3, all the asymmetric Mannich-type reactions proceeded in high yield with high diastereoselectivity (*syn*/*anti* = 95:5–99:1) when 10 mol % of TaDiAS **1g** was used with Cs_2CO_3 in fluorobenzene. In terms of enantioselectivity, *C*-phenyl imine derivatives with an electron-donating group at the 4-position were suitable substrates (Table 3, entries 2 and 3). On the other hand, 4-chlorophenyl and 2-naphthyl substituents (Table 3, entries 7 and 8) were only moderately enantioselective.

[a] Determined by HPLC analysis. [b] The *ee* value of the *syn* product was determined by HPLC analysis. [c] Solvent was PhF/pentane (4:1). [d] The *ee* value after a single recrystallization.

Although *N*-Boc C-aliphatic imines could not be applied because of the difficulties in synthesizing them, the use of α,β-unsaturated imines for the Mannich-type reaction followed by hydrogenation is an alternative method (Table 3, entry 10). Another beneficial feature of this process is that most of the products were obtained as crystalline solids, and in fact a single recrystallization of **4f** (82 % *ee*) provided an optically pure compound in 74 % yield. Although the enantioselectivity of the reaction was not very satisfactory, to the best of our knowledge, this diastereoselectivity is the highest reported for a catalytic Mannich-type reaction of a glycine Schiff base **2** with imines.

The synthetic utility of the resulting optically active α,β-diamino acid derivatives was demonstrated by straightforward transformations into tripeptide **6** and key intermediate **8** for the synthesis of the selective and potent neurokinin substance P antagonist (+)-CP-99,994[17–19] through deprotection of the *N*-diphenylmethylene and *N*-Boc groups (Scheme 1, top). Highly chemoselective deprotection of the *N*-diphenylmethylene group of **4f** by aqueous citric acid, followed by a subsequent peptide-coupling reaction gave dipeptide **5**. Next, the *N*-Boc group was readily deprotected with a 2 N solution of HCl in methanol to afford, after another peptide-coupling reaction, the optically pure tripeptide **6** in good yield. Moreover, the protected α,β-diamino ester **4d**, which was synthesized by using (*R*,*R*)-TaDiAS **1g**, was successfully converted into the key intermediate **8**[19] in an optically pure form (Scheme 1, bottom).

Information about the reaction mechanism is essential to improve the efficiency of the catalyst, TaDiAS **1**. Despite the value of mechanistic investigations in catalyst development, however, only limited mechanistic studies on asymmetric phase-transfer catalysis have been reported.[20] To gain insight into the mechanism of this asymmetric phase-transfer catalytic reaction, we performed initial rate kinetic studies.[21] First-order dependency was observed for the glycine Schiff base **2** and Cs_2CO_3, whereas the reaction rate had zero-order dependency for the imine **3** and the catalyst **1**. These results indicated that the rate-determining step of the Mannich-type reaction is deprotonation of **2** by Cs_2CO_3; unexpectedly, **1** was not involved in this step. On the basis of these results, we propose a catalytic cycle for the asymmetric Mannich-type reaction (Scheme 2). Deprotonation of **2** by Cs_2CO_3 at the interface between the liquid and solid phase followed by counteranion exchange with the catalyst **1** gives complex **10**.[22] An asymmetric C–C bond-forming reaction of **10** with the imine **3** gives the Mannich product **11**. Finally, counteranion exchange between **11** and the resulting $CsBF_4$ provides **12** and generates **1**. The very low reaction efficiency that results from the use of a catalytic amount of Cs_2CO_3 indicates that the formation of **10** through direct deprotonation of **2** in

Scheme 2. Proposed catalytic cycle of the asymmetric Mannich-type reaction. rds = rate-determining step.

the liquid phase with **11** or a hydroxide complex of the chiral ammonium cation is slow, thus making the interfacial deprotonation (**2**→**9**) the rate-determining step.

In summary, we have developed a highly efficient (up to quantitative yield) and *syn*-selective (up to 99:1) enantio- and diastereoselective catalytic Mannich-type reaction of a glycine Schiff base **2** with *N*-Boc imines **3** using the newly designed phase-transfer catalyst **1g**. Moreover, we have demonstrated the synthetic utility of the α,β-diamino acid products. Further mechanistic studies and investigations to improve the enantioselectivity are in progress.

Structure Elucidation

An Anomalous Endohedral Structure of Eu@C_{82} Metallofullerenes**

*Bao-Yun Sun, Toshiki Sugai, Eiji Nishibori, Kenichi Iwata, Makoto Sakata, Masaki Takata, and Hisanori Shinohara**

Trivalent metallofullerenes such as La@C_{82} and Ce@C_{82}, in which the metal ions prefer to take a trivalent charge state, have been extensively investigated.[1] However, studies on metallofullerenes encapsulating divalent Sm, Eu, Tm, and Yb metal ions have been limited because of the known low yields in the production of these metallofullerenes despite the development of some improved production and extraction methods during the past several years.[2] This situation has resulted in the structures of such metallofullerenes not having been studied in detail. The variety of encaged metal ions and charge transfer as well as the movement of entrapped metal ions are expected to provide different physical properties. Therefore, it is necessary to study the structure and electronic properties of metallofullerenes in this divalent group.

The Eu ion in Eu@C_{82} was shown by experiment to transfer two electrons to the fullerene cage.[2c] There are no unpaired electrons on the Eu@C_{82} cage and charge transfer results in the $4f^7 5d^0 6s^0$ electronic configuration, which gives rise to the fullerene having paramagnetic character. It is thus difficult to determine the structure of the cage and the symmetry of the complex by NMR spectroscopy. XRD measurements have become the only way to access the detailed structure of Eu@C_{82} fullerenes.

X-ray analysis performed using a combination of the maximum entropy method (MEM) and Rietveld refinement (the MEM/Rietveld method[3]) has proven to be a powerful method for the accurate determination of the structures of metallofullerenes. The endohedral nature of a series of metallofullerenes, such as La, Y, Sc, and Gd@C_{82},[4] Sc_3@C_{82}, La_2@C_{80}, Sc_2@C_{84}, Sc_2@C_{66}, and Sc_2C_2@C_{84}[5] has been determined successfully by this method.

In the present study the structures of the two isomers of Eu@C_{82}(I, III) were successfully determined by the MEM/Rietveld method using synchrotron X-ray powder diffraction data. The endohedral structure of Eu@C_{82}(III) is exceptional in view of the fact that the Eu ion is adjacent to the C–C double bond on the C_2 axis of the C_{2v} carbon cage, whereas the metal ions (such as La, Y, Sc, Er, Lu) in the normal monometallofullerenes are adjacent to a hexagon of the C_{82} cage, except for Gd@C_{82}.[4d,6]

Similar to previous studies of La-, Y-, Sc-, and Gd@C_{82},[4] Sc_3@C_{82},[5a] La_2@C_{80},[5b] as well as Sc_2@C_{84},[5c] the Eu@C_{82}(I, III) crystals are assigned to monoclinic $P2_1$ (no. 4) space groups from the peak positions of the Bragg reflections. The lattice parameters for both isomers are slightly different from each other, namely, $a = 18.2870(4)$, $b = 11.2381(2)$, $c = 11.2371(2)$ Å, $\beta = 107.769(3)°$ for isomer I of Eu@C_{82} and $a = 18.3143(5)$, $b = 11.2478(2)$, $c = 11.2308(3)$ Å, and $\beta = 107.706(3)°$ for isomer III.

The experimental data were analyzed by the MEM/Rietveld method.[3] The reliability factors of the final Rietveld refinement for Eu@C_{82}(I and III) are $R_I = 4.58\,\%$ and $R_{wp} = 2.64\,\%$ and $R_I = 4.57\,\%$ and $R_{wp} = 1.79\,\%$, respectively. The fitting results of the final Rietveld refinement for the two isomers are shown in Figure 1a,b. The number of observed structure factors derived in this analysis was 623 and 602 for isomers I and III, respectively. The MEM analysis was carried out by dividing the unit cell into $90 \times 60 \times 60$ pixels using a MEM program called ENIGMA.[7]

The obtained MEM charge-density distribution (from 0.0 to 2.0 e Å^{-3} with 0.2 e Å^{-3} intervals) and the equicontour density map of the MEM charge density of the half section of Eu@C_{82}(I) (drawn at 1.67 e Å^{-3}) are shown in Figure 2. Both the mirror plane and the double bond at the mirror plane are parallel to the Figure plane and vertical to the Figure plane in Figure 2a and b, respectively.

The MEM charge-density distribution in Figure 2a and b shows clearly that there is a charge-density maximum inside the C_{82} cage which can be assigned to the entrapped metal ion. The density maximum is not at the center but close to the carbon cage, as in other metallofullerenes such as La-, Y-, Sc-, and Gd@C_{82}.[4] The charge densities at the middle points between the Eu ion and the neighboring carbon atoms in positions A, B, and C of Eu@C_{82}(I) are 0.218, 0.207, and 0.224 e Å^{-3}, respectively, which are much less than the corresponding density for Gd@C_{82}.[4d]

The equicontour density map of the MEM charge density of the half section in Figure 2c visualizes the three-dimen-

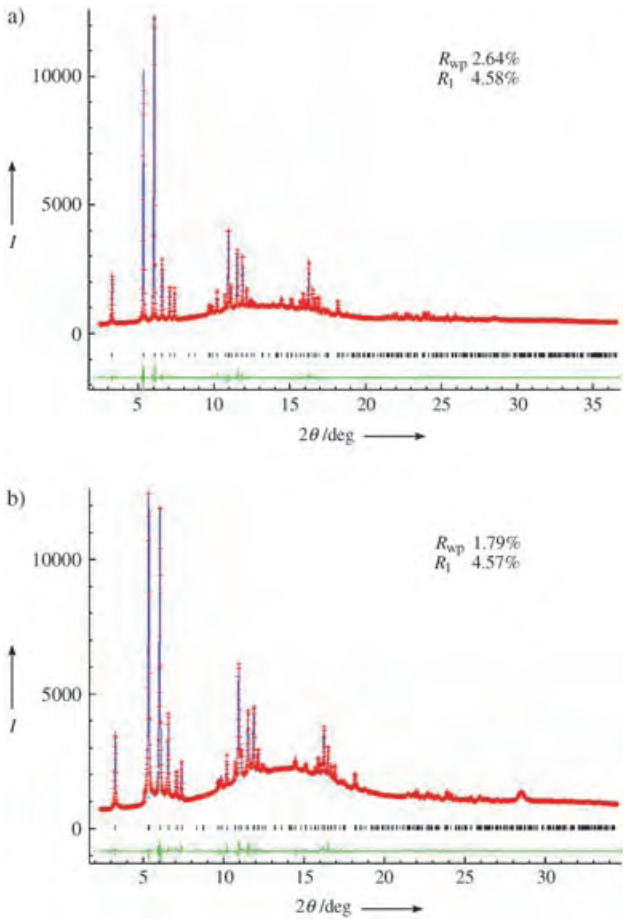

Figure 1. The Rietveld fitting results of Eu@C_{82}: a) isomer I with C_s (no. 6) symmetry and b) isomer III with C_{2v} symmetry.

sional structure of the cage and the entrapped metal ion. The obtained endohedral cage structure has a network of six- and five-membered rings corresponding to C_s (no. 6) symmetry.[8] The charge density of the Eu ion can clearly be seen inside the cage. The total number of electrons inside the region described by the red circle was estimated to be 61.0(8) e, which is very close to that of the divalent Eu ion (61 e). This result indicates that the Eu ion is encaged within C_{82} and the formal electronic structure should be expressed as $Eu^{2+}@C_{82}^{2-}$, which is consistent with the previous result based on EELS analysis.[2c] This finding confirms that the Eu ion prefers to take a +2 charge state in the C_{82} fullerene cage and to form the $4f^7 5d^0 6s^0$ half-filled configuration.

Figure 3 shows the side and top views of the corresponding schematic molecular structure of Eu@C_{82}(I) based on the

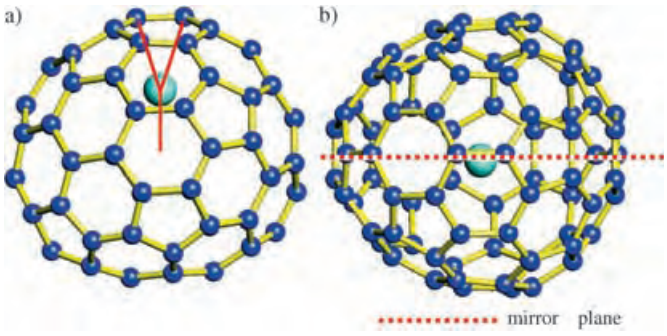

Figure 3. The side view (a) and the top view (b) of Eu@C_{82}(I) with C_s (no. 6) symmetry.

X-ray analysis. The obtained structural model indicates that the metallofullerene has C_s (no. 6) symmetry.[8] The mirror plane is on the Figure plane in the side view (Figure 3a) and is vertical to the Figure plane in the top view (Figure 3b). The Eu ion (colored turquoise) is located near the top of the carbon cage in Figure 3a, adjacent to the C–C double bond on the mirror plane but not to the six-membered ring at the other end of the cage. A similar endohedral structure was reported from a theoretical calculation for Ca@C_{82} with C_s(c), namely, C_s (no. 6) symmetry.[9] The distance between the Eu ion and the cage center is 1.59(4) Å and that between the Eu ion and the nearest (two) carbon atoms is 2.51(3) Å, which is much less than the calculated Ca···C distance in C_s-Ca@C_{82} (2.639(2) Å).[9]

There are nine distinct isomers for the C_{82} cage which satisfy the so-called isolated pentagon rule (IPR).[8] Three of them have C_s symmetry, which are designated as C_s (no. 2), C_s (no. 4), and C_s (no. 6) according to Fowler and Manolopoulos.[8] It is known that the minor isomer of La@C_{82} and one isomer of Tm@C_{82}, normally designated as La@C_{82}(I) and Tm@C_{82}(I), respectively, have been determined to have C_s symmetry by ^{13}NMR spectroscopic studies.[2a,10] However, one-dimensional ^{13}NMR measurements can not determine

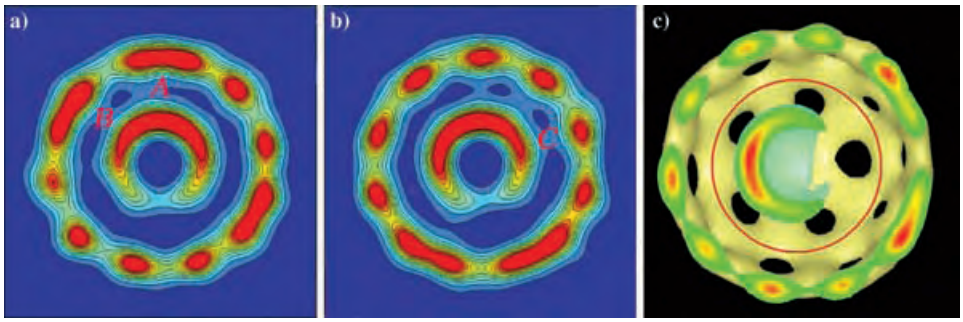

Figure 2. The MEM charge-density distribution (a, b; contour lines are drawn from 0.0 to 2.0 e Å^{-3} with 0.2 e Å^{-3} intervals) and the equicontour density map of the MEM charge density of the half section (c; drawn at 1.67 e Å^{-3}) of Eu@C_{82}(I) with C_s (no. 6) symmetry. Positions *A*–*C* are discussed in the text.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

definitively the final C_s symmetry, that is, whether it is no. 2, 4, or 6. The present XRD experiment enables us, for the first time, to identify that Eu@C_{82}(I) possesses C_s (no. 6) symmetry.

Only one of the nine IPR isomers of C_{82} has C_{2v} symmetry.[8] Most of the C_{82}-caged metallofullerenes, such as La-, Y-, Sc-, and Gd@C_{82}, have been determined to have C_{2v} symmetry by synchrotron X-ray diffraction studies.[4] The present X-ray measurement shows that Eu@C_{82}(III) also possesses C_{2v} symmetry.

The MEM charge-density distribution (from 0.0 to 2.0 e Å^{-3} with 0.2 e Å^{-3} steps, as for isomer I) and the contour line surface of Eu@C_{82}(III) (drawn at 1.67 e Å^{-3}, as for isomer I) are shown in Figure 4. The direction of the C_2 axis is vertical to the double bond at the C_2 axis and parallel to the Figure plane in both Figure 4a and b, but the direction of the double bond at the C_2 axis is parallel to the Figure plane in Figure 4a and vertical to the Figure plane in Figure 4b. The MEM charge density clearly shows that the cage structure of Eu@C_{82}(III) has C_{2v} symmetry (Figure 4a and b). Similar to isomer I, a charge-density maximum is located at an off-center position, which should be the encaged Eu ion. The overlapped charge densities between the Eu ion and the neighboring carbon atoms in Eu@C_{82}(III) are 0.186, 0.215, and 0.189 e Å^{-3} for positions A, B, and C, respectively, which are similar to those in isomer I. The number of electrons contained within the red circle is 61.2(7) e (see Figure 4c). This value is also close to that of an Eu^{2+} ion with 61 e, thus indicating that the Eu center also takes a divalent charge state in this isomer. The six- and five-membered rings can clearly be seen, and the structure has C_{2v} symmetry.

The corresponding schematic molecular structure based on the analysis of Eu@C_{82}(III) is shown in Figure 5. The side and the top views show that the Eu ion (colored turquoise) is located in the C_{2v}-symmetric cage and is adjacent to the C–C double bond along the C_2 axis in Eu@C_{82}(III). These endohedral structures of Eu@C_{82}(I and III) can be contrasted to those of the conventional C_{82}-based mono-metallofullerenes such as La-, Y-, and Sc@C_{82}.[4a–c] Only the mono-metallofullerene Gd@C_{82}[4d] is similar to the present Eu@C_{82} case, in which the Gd ion located close to the C–C double bond on the C_2 axis of C_{2v}-C_{82}. The distance between the Eu ion and the cage center is 1.70(5) Å, which is less than that between the La ion and the cage center in C_{2v}-La@C_{82} (1.96(9) Å).[4a]

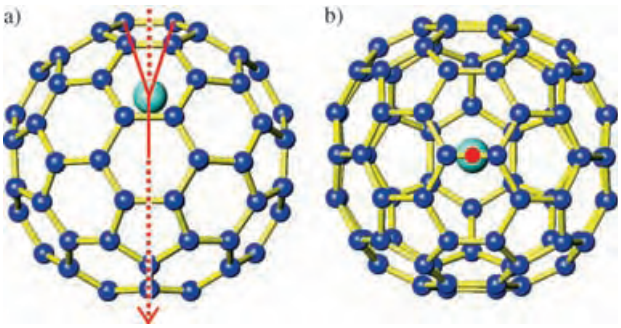

Figure 5. The side view (a) and the top view (b) of Eu@C_{82}(III) with C_{2v} symmetry.

The nearest Eu···C distance (between the Eu ion and two C atoms of the double bond) is 2.50(1) Å in the C_{2v} cage, which is close to those in La-, Y-, and Sc@C_{82} (ca. 2.5 Å).[4a–c]

A recent theoretical calculation[6] on Gd@C_{82} showed that the position of the metal near the C–C double bond is preferred to the position adjacent to a hexagon if relaxation of the cage is considered. The strong overlap in the charge density between the Gd ion and the cage and the back donation of electrons from the C–C double bond stabilize the Gd ion at the position adjacent to the double bond.[6] The calculated total energy is 2.83 eV lower than that at the position adjacent to the six-membered ring. It should be noted that both Gd^{3+} and Eu^{2+} ions have a half-filled configuration $[Xe]^{54}4f^7$.

The overlap in the charge density between the Eu ion and the cage is different from that in Gd@C_{82}. The charge density at the middle point between the Eu ion and the nearest carbon atoms in C_{2v}-Eu@C_{82}(III) (position A in Figure 4) is 0.186 e Å^{-3}, which is only about one-fifth of that found in C_{2v}-Gd@C_{82} (0.996 e Å^{-3}).[4d] Similarly, the charge density at the middle point between the Eu ion and the nearest carbon atoms in the C_s-Eu@C_{82}(I) case (position A in Figure 2) is only 0.218 e Å^{-3}, which is similar to that found in C_{2v}-Eu@C_{82}(III). The results strongly suggest that the interaction between the entrapped Eu ion and the carbon cage is much weaker than that exerted in Gd@C_{82}. This weaker interaction has also been suggested by a downfield shift of the Raman vibration frequency of the metal cage[2e,11] in Tm@C_{82} and Eu@C_{74}. Such low-energy modes in Tm@C_{82} and Eu@C_{74} are

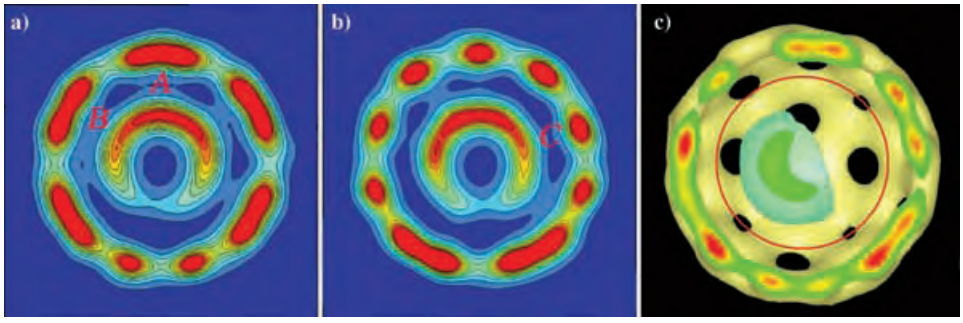

Figure 4. The MEM charge density distribution (a, b; contour lines are drawn from 0.0 to 2.0 e Å^{-3} with 0.2 e Å^{-3} intervals) and the equicontour density map of the MEM charge density of the half section (c; drawn at 1.67 e Å^{-3}) of Eu@C_{82}(III) with C_{2v} symmetry. Positions *A*–*C* are discussed in the text.

lower in frequency than those in trivalent metallofullerenes. The present MEM charge density reveals that the nature of the chemical bonding between the Eu ion and the cage should be highly ionic.

The overlapped charge densities in positions B and C in Eu@C_{82}(III) in Figure 4 are 0.215 and 0.189 e Å^{-3}, respectively, which is similar to that between the Eu ion and the nearest carbon atoms (0.186 e Å^{-3}). The charge densities in Eu@C_{82}(I) in Figure 2 are 0.207 and 0.224 e Å^{-3} for positions B and C, respectively, which are similar to 0.218 e Å^{-3} at position A as in Eu@C_{82}(III). Figures 2 and 4 show that the Eu ion moves over a spatially confined domain both in the C_s (no. 6) and C_{2v} cages. The obtained charge density of the Eu ion exhibits a hemispherical shape at room temperature, which is much wider than those observed in Sc@C_{82} and Gd@C_{82}.[4c,d]

As previously mentioned, the endohedral structure of C_{2v}-Eu@C_{82} is significantly different from that of C_{2v}-Sc@C_{82}[4c] although both of them are divalent metallofullerenes. Firstly, the Eu metal ion is located at the opposite position of that of the Sc ion along the C_2 symmetry axis. Secondly, the Sc ion does not move inside the C_{82} cage even at room temperature and shows a spherical charge-density distribution, whereas the Eu ion floats inside the cage as is clearly seen in Figure 4. The different interaction in Eu@C_{82} and Sc@C_{82} evidently induces the different endohedral structure of the metal ions in the C_{82} cage.

In the present study, a weak intramolecular interaction between the Eu ion and the carbon cage should be one of the important reasons why the yield of Eu–metallofullerenes has been the lowest of the metallofullerenes so far studied. Undoubtedly, if the interaction between the cage and the metal is weak, such as in Eu–metallofullerenes, the probability of losing the metal ion before the closure (that is, completion) of the fullerene cage should increase. The fact that the relative yield of Eu@C_{82} is only about 3% of that of Er@C_{82} or La@C_{82} is consistent with this growth process.

The cage structures of Eu@C_{82} (isomers I and III) have been determined to have C_s (no. 6) and C_{2v} symmetry, respectively, by XRD measurements combined with the MEM/Rietveld analysis. Unlike other M@C_{82} (M = Sc, Y, La, and other lanthanide elements) mono-metallofullerenes (except Gd@C_{82}), the Eu ion is adjacent to the C–C double bond on the mirror plane of the C_s (no. 6) symmetric structure in Eu@C_{82}(I) and adjacent to the C–C double bond (not to a hexagon) on the C_2 axis of a C_{2v} structure of Eu@C_{82}(III). The obtained charge-density mappings for Eu@C_{82}(I, III) show that the charge densities of the Eu ions form a nearly hemispherical shape at room temperature, thus indicating that the Eu ion is floating in the C_{82} cage.[12]

Reaction Mechanisms

Elucidation of the Reaction Mechanism for the Palladium-Catalyzed Synthesis of Vinyl Acetate**

*Dario Stacchiola, Florencia Calaza, Luke Burkholder, Alan W. Schwabacher, Matthew Neurock, and Wilfred T. Tysoe**

Two basic mechanisms have been proposed for the palladium-catalyzed synthesis of the vinyl acetate monomer (VAM) from acetic acid, ethylene, and oxygen [Eq. (1)]:[1]

$$CH_3COOH + C_2H_4 + {}^1/_2O_2 \rightarrow CH_3COOC_2H_3 + H_2O \quad (1)$$

The first, suggested by Samanos et al., involves the coupling of ethylene directly with chemisorbed acetate.[2] The resulting acetoxyethyl–palladium intermediate then undergoes β-hydride elimination to form vinyl acetate. Alternatively, ethylene could first dehydrogenate to form a vinyl–palladium intermediate, which then couples with an acetate species adsorbed on the surface to form the VAM directly. This latter mechanism was proposed by Moiseev et al.[3,4] as well as by Nakamura and Yasui.[5] We have recently shown that ethylene in the gas phase reacts with a model-catalyst surface of η^2-acetate moieties adsorbed on a Pd(111) surface precovered with a (2×2) oxygen overlayer to form the VAM,[6] thus implying that the acetate species is the precursor to formation of the VAM.

The structures of the adsorbed η^2-acetate[7] and ethylene[8] species were determined separately on a Pd(111) surface by using low-energy electron diffraction (LEED) and reflection-absorption IR spectroscopy (RAIRS),[6–9] which showed that both species adsorb on the bridge site. Herein, we discuss the investigation into the nature of the reaction pathway by using isotopically labeled reactants, which allowed the mechanism for the formation of the VAM to be unequivocally identified. The RAIRS experiments were performed in an ultrahigh vacuum apparatus; the experimental procedure has been described in detail elsewhere.[10] Kinetic measurements were typically carried out by the collection of spectra over 100 scans, which is a relatively short procedure that took 25 seconds because of the large intensity of the asymmetric vibrational mode of the acetate moiety (O-C-O) at 1414 cm^{-1}.[6] Some experiments were carried out with a larger number of scans to yield spectra with better signal-to-noise ratios and, therefore, allow additional surface species to be identified. A flux of ethylene impinged onto the sample from a collimated dosing source to obtain an enhanced flux at the Pd(111) single-crystal surface while the background pressure was minimized.[6] C_2H_4 (Matheson, Research Grade), acetic acid (Aldrich, 99.99+%), C_2D_4 (CIL, 98% D), CD_2CH_2 (CDN, 99% D), CHDCHD (CDN, *cis*/*trans* mixture, 99% D), and $^{18}O_2$ (CIL, 95% $^{18}O_2$) were transferred into glass bottles, which were attached to the gas-handling line for introduction into the vacuum chamber.

It has been shown previously that acetate species adsorbed on a Pd(111)–O(2×2) surface undergoes reaction with ethylene in the gas phase to yield the VAM.[6] The experimental titration curves obtained with acetate species can be explained by using a procedure described previously,[6] in which it was assumed that adsorbed ethylene underwent reaction with the acetate species and that ethylene adsorption was blocked by the acetate species. Acetate species adsorbed on clean Pd(111) surfaces (namely, in the absence of the (2×2) oxygen overlayer) are also removed by reaction with ethylene and also can be analyzed by using the same procedure used to reproduce the kinetic data for the oxygen-covered Pd(111) surface; furthermore, these acetate species yield similar rate constants to those found for reactions on the oxygen-covered surface, and therefore the presence of coadsorbed oxygen does not substantially affect the reaction kinetics.

A series of IR spectra for the reaction of the acetate species on a clean Pd(111) surface was collected just after the acetate moieties had been completely removed using C_2H_4, C_2H_4 (on an ^{18}O-covered surface), and C_2D_4 (Figure 1). The spectrum of CO on the Pd(111) surface is shown for comparison (Figure 1a). The CO exposure was selected to

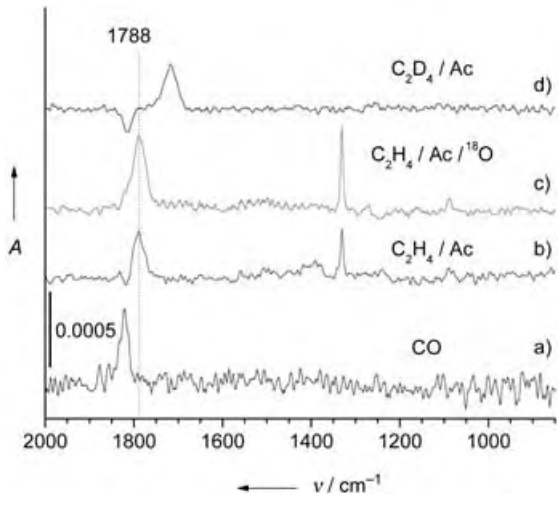

Figure 1. IR spectra of the reaction of acetate species with ethylene at 327 K after the acetate species had been removed. Spectra are given for the reactions of: b) C_2H_4 on an acetate-covered Pd(111) surface, c) C_2H_4 on an acetate-covered Pd(111)–^{18}O(2×2) surface, and d) C_2D_4 with a acetate-covered Pd(111) surface. a) IR spectrum of CO on a Pd(111) surface is shown for comparison. Ac = acetate.

yield a similar intensity of signals to those produced by the reaction between ethylene and the adsorbed acetate species, thus indicating that none of the signals result from CO adsorbed from the background. The signals at 1330 and 1090 cm^{-1} in the spectra in Figure 1b and c arise from the ethylidyne species.[6] Deuterated ethylidyne has very weak IR features and is not detected in the spectrum in Figure 1d. The spectrum in Figure 1b demonstrates that surface oxygen does not participate in the formation of surface species. A signal is evident at 1788 cm^{-1} following the reaction with C_2H_4, whereas another is present at 1718 cm^{-1} following the reaction with C_2D_4. A deuterium isotope effect is measured which indicates that C_2D_4 undergoes reaction with the acetate species approximately six times more slowly than with C_2H_4 (see below). To establish whether the signal at 1718 cm^{-1} results from an isotopic shift of the absorption at 1788 cm^{-1} or a different species and to help establish the nature of the species that gives rise to the signal at 1788 cm^{-1}, both perdeuterated and undeuterated vinyl acetate were adsorbed on an ethylidyne-saturated Pd(111) surface at 300 K (data not shown). The RAIRS spectra revealed that the VAM exhibits a single signal at approximately 1780 cm^{-1} for both the perdeuterated and undeuterated vinyl acetate. The signal at 1718 cm^{-1} evidently does not result from either the vinyl acetate or the monodentate acetate species,[11,12] as the latter would have also been observed during reaction with C_2H_4. The presence of this signal does, however, provide a clue to the reaction pathway. The only species expected to be present on the surface in the pathway proposed by Moiseev et al.[3] are ethylene, the vinyl and acetate moieties, and vinyl acetate. Once the characteristic frequencies of these species are considered, however, it is clear that the signal at 1718 cm^{-1} does not arise from any of these.[6–9] The species present in the pathway proposed by Samanos et al. are ethylene, acetate, vinyl acetate, and the acetoxyethyl–palladium intermediate that results from insertion of ethylene into the acetate–Pd bond. Again bearing in mind their characteristic frequencies, the signal at 1718 cm^{-1} does not arise from ethylene,[9] acetate,[6,11,12] or vinyl acetate.

Density functional theory (DFT) calculations demonstrate that an acetoxyethyl–palladium intermediate has a C=O stretching frequency approximately 80 cm^{-1} lower than that of vinyl acetate. The calculations were carried out by using periodic plane-wave DFT calculations with the DMOL^3 code[13] and the Perdew–Wang91[14] form of the generalized gradient approximation. Pure ethyl acetate has a C=O stretching frequency substantially lower than that of vinyl acetate,[15] and a proposed acetoxyethyl–palladium species on a Pd–Al_2O_3 surface has a characteristic frequency of well below 1788 cm^{-1}.[16] The signal at 1718 cm^{-1} is, therefore, assigned to an acetoxyethyl–palladium intermediate, the presence of which can only be rationalized on the basis of the pathway proposed by Samanos et al.,[2] where this intermediate decomposes to form the VAM by β-hydride elimination. The decomposition rate of the acetoxyethyl–palladium intermediate will be slowed substantially by deuteration at the β position, thus accounting for the appearance of this intermediate when C_2D_4 reacts with the surface acetate species. Reaction with C_2H_4 results in a faster decomposition rate of the intermediate such that insufficient quantities accumulate to allow detection by IR spectroscopy.

In view of this isotope effect, the acetate species on the Pd(111) surface was treated with C_2D_4, CH_2CD_2, and CHDCHD, and the resulting plots of the acetate coverage versus time are displayed, along with the data for C_2H_4, in Figure 2. There are substantial differences in the reaction

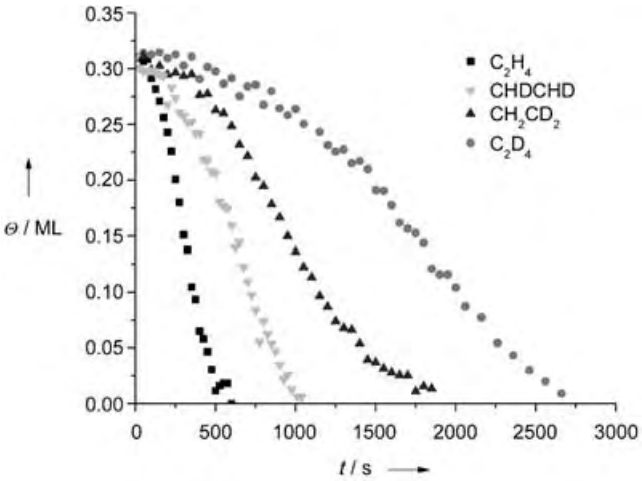

Figure 2. Plot of time versus coverage Θ, as measured from the intensity of the signal at 1414 cm^{-1} of the acetate species, for the reaction of C_2H_4 (■), CH_2CD_2 (▲), CHDCHD (▼), and C_2D_4 (●) carried out with the acetate species adsorbed on a Pd(111) surface, with an ethylene pressure of 2×10^{-7} Torr, and at a reaction temperature of 327 K.

rates between C_2H_4 and C_2D_4 which indicate, as noted above, that hydrogen is involved in the rate-limiting step. Interestingly, the reaction rates for [D_2]ethylene depend on the position of the deuterium isotope: the reaction is slower for the 1,1-dideuterated reactant than for 1,2-dideuteroethylene. This observation allows us to exclude the model proposed by Moiseev et al. immediately as, in this case, the rate-limiting step, which involves hydrogen, must be hydrogen abstraction from ethylene to form the vinyl species. An analysis of the experimental data[6] (Figure 2) yields $k_H/k_D \approx 6$, which is a reasonable value for a primary isotope effect. In the case of the reaction with [D_2]ethylene, and according to the pathway of Moiseev et al., the rate constant should be $(k_H + k_D)/2$ irrespective of the location of the deuterium atom, thus yielding an isotope effect of $2/(1+(k_D/k_H)) \approx 1.7$.

At first sight, a similar effect should occur with the model proposed by Samanos et al. In the case of the reaction with CH_2CD_2, there is an equal probability of CH_2 or CD_2 units being in the β position in the acetoxyethyl–palladium intermediate, thus yielding an isotope effect of approximately 1.7; whereas there will always be a CHD unit at the β position in CHDCHD, thus yielding a similar isotope effect of approximately 1.7. If it is assumed that the acetoxyethyl–palladium intermediate blocks the adsorption of ethylene, however, any intermediates formed from CH_2D_2, which has two deuterium atoms at the β position, will decompose more slowly than those with hydrogen atoms at the β position, thus blocking ethylene adsorption and lowering the reaction rate. For the reaction with CHDCHD, hydrogen atoms will always be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

present at the β position, so the intermediate decomposes more rapidly, which results in decreased blocking of ethylene adsorption by the intermediate. These observations suggest that reaction with CH_2CD_2 should be slower than with CHDCHD, as was found experimentally (Figure 2). This proposal is in accord with the identification of the acetoxyethyl–palladium intermediate in the reaction between the acetate species and C_2D_4 (Figure 1). In this case, there is always a deuterium atom at the β position which results in slower decomposition of the acetoxyethyl–palladium intermediate, thus allowing it to be detected by IR spectroscopic analysis. The detection of this species confirms that sufficient quantities can accumulate on the surface to affect the relative reaction rates of the 1,1- and 1,2-dideuteroethylenes, as found by the data shown in Figure 2.

Thus, the experimental results provide clear evidence that the reaction of ethylene with the acetate species proceeds through the pathway proposed by Samanos et al.,[2] that is, by insertion of ethylene into an adsorbed acetate species and subsequent β-hydride elimination to form vinyl acetate. First, when a reaction is carried out using C_2D_4, a vibrational mode at 1718 cm^{-1} is identified, which is assigned to the acetoxyethyl–palladium intermediate (Figure 1). Second, the differences in the reaction rates for CHDCHD and CH_2CD_2 can only be rationalized by the route of Samanos et al.; therefore, the reasonable assumption can be made that the acetoxyethyl–palladium intermediate blocks the adsorption of ethylene (Figure 2). Our mechanism is essentially the same as that observed for the stoichiometric oxidation of ethylene to the VAM by soluble palladium acetate.[17] Although it was a reasonable proposal that the surface-mediated reaction would be parallel to that of the related solution-phase process, the distinctly different reactivity of ethylene towards the two palladium species made disparate mechanisms plausible. Now that the intermediacy of an acetoxyethyl–palladium species in the surface-mediated process has been established, questions still remain that concern the geometry of each step. Whether the insertion of ethylene proceeds in an *anti* mode, as observed in the solution phase,[17] or by a *syn* process, which is apparently more appropriate for a surface, will be investigated in future studies.

ery). As a result of their nanoscopic size and fractal structure, dendrimers resemble biocomponents such as viruses, enzymes, and proteins.[2] Dendrimers that contain redox-active units are currently attracting much attention.[3] When a large number of redox-active units are placed in the periphery and/or along the branches, dendrimers can undergo multiple electron-transfer processes and perform, for example, as molecular batteries, sensors, and catalysts.[4] Dendrimers with a single redox site as a core are the simplest examples of systems with an encapsulated redox center,[5] and their redox properties are usually modulated by the size and nature of the dendritic branches.[6]

Despite their large structures, which usually render dendrimers attractive as host molecules, suitably designed dendrimers can be equally involved as guests in molecular-recognition phenomena.[7] In such cases, the host species does not interact with the whole dendritric structure, but only with specific component units. Usually, the guest behavior of the dendrimer is connected with the threading of dendritic branches by ring-shaped molecules such as crown ethers,[8] cyclodextrins,[9] and cucurbiturils.[10]. More recently, Kaifer and co-workers[7,11] prepared several dendrimers that contain a single-site, potential guest unit and have investigated their adducts with cucurbit[7]uril, β-cyclodextrin, and bis-*para*-phenylene[34]crown-10.

When the potential guest unit constitutes the core of a dendrimer, the formation of a host–guest complex through threading of ring-shaped hosts cannot take place. It occurred to us that in such a case, tweezer-shaped molecules could be used to enclose the dendritic core into a host structure. Herein, we show that this strategy works in solution when suitably designed host and guest units are used.[12]

Several molecular tweezers and clips that exhibit electron-donating properties have been prepared recently in one of our laboratories.[13] Molecular tweezer **T**, which comprises one naphthalene and four benzene components bridged by four methylene units, was prepared and purified as previously reported (Figure 1).[14] NMR spectroscopy (see Supporting Information for details) showed that tweezer **T** forms a stable 1:1 complex with 4,4′-*N*,*N*-bis(3,5-di-*tert*-butylbenzyl)-bipyridinium $[\mathbf{D0}]^{2+}$. Solvent-dependent binding constants ($K_a = 730\,\text{M}^{-1}$ in [D$_6$]acetone/$CDCl_3$ (2:1) and $K_a = 8400\,\text{M}^{-1}$ in CD_2Cl_2), and complexation-induced upfield shifts of the chemical shifts for the protons of the guest ($\Delta\delta_{max} = 1.01$ or 0.91 ppm (H^o), and 4.12 or 3.22 ppm (H^m)) were determined by ^{1}H NMR titration experiments (500 MHz, Bruker DRX 500) at 25 °C, and the 1:1 stoichiometry of the complex was determined through Job plot analysis. The observed large $\Delta\delta_{max}$ values and the specific broadening of the ^{1}H NMR signals assigned to the bridgehead protons of the complexed tweezer at low temperature are evidence that one of the pyridinium rings of $[\mathbf{D0}]^{2+}$ is positioned inside the cavity of the tweezer and that tweezer **T** shuttles from one pyridinium ring of $[\mathbf{D0}]^{2+}$ to the other. At room temperature the shuttling process is fast and leads to an averaging of the ^{1}H NMR signals of the guest molecule lying inside/outside of the tweezer cavity, while at −75 °C the process is slow with respect to the NMR timescale ($\Delta G^{\ddagger}(\text{shuttle}) = 10\,\text{kcal mol}^{-1}$, estimated from the line broadening). As the 3,5-di-*tert*-butylben-

zyl stopper groups in $[\mathbf{D0}]^{2+}$ are already too bulky to form a complex with tweezer **T** by threading and as the complexation has to proceed by clipping of the guest molecule through the tips of the tweezer, we thought that **T** should also be able to interact with the bipyridinium core (bpy^{2+}) of the first-, second-, and third-generation dendrimers $[\mathbf{D}n]^{2+}$ ($n = 1, 2$ and 3; see Figure 1). NMR spectroscopy, however, could not provide information on the formation of a complex in the case of the dendrimers because of solubility problems and line broadening. Therefore we carried out a photophysical and electrochemical investigation of the interactions.

The hexafluorophosphate salts of the $[\mathbf{D}n]^{2+}$ dendrimers had been prepared during the course of previous work.[15] The equipment used for the photophysical and electrochemical measurements has been described elsewhere.[16] All the experiments were performed at room temperature (293 K) in air-equilibrated solution. Quantum yields of fluorescence were measured following the methods of Demas and Crosby[17], using terphenyl in cyclohexane ($\Phi = 0.82$) as the standard.[18] Dichloromethane was used as the solvent for the photophysical experiments, and mixtures of dichloromethane/acetonitrile (3:1 or 9:1 v/v) were used for the electrochemical experiments. The association constants were obtained from fluorescence titration experiments.

The absorption and emission spectra of tweezer **T** in dichloromethane are shown in Figure 2. The strong fluorescence emission band at $\lambda_{max} = 344$ nm ($\tau = 9.5$ ns, $\Phi = 0.53$)

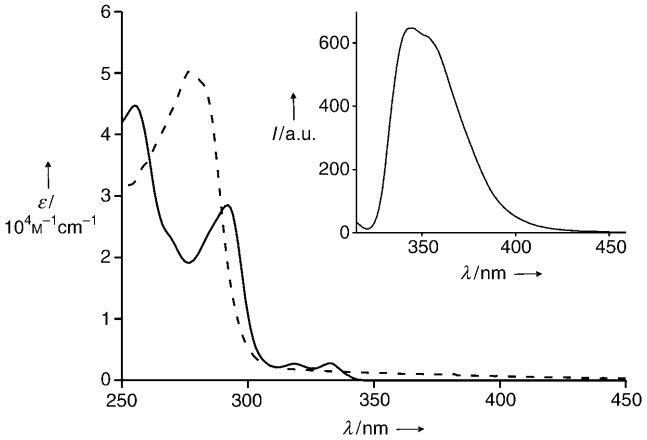

Figure 2. Absorption spectra of tweezer **T** (——) and dendrimer $[\mathbf{D3}]^{2+}$ (as PF_6^- salt; -----) in dichloromethane at room temperature. Inset: Emission spectrum of tweezer **T** in dichloromethane at 293 K ($\lambda_{ex} = 334$ nm).

can be assigned to the naphthalene unit. The absorption spectra of dendrimers $[\mathbf{D}n]^{2+}$ (see Figure 2 for an example) display a strong absorption band around $\lambda = 260$ nm from the bipyridinium unit, while the 1,3-dimethyleneoxybenzene units of the dendrons show an absorption around $\lambda =$ 280 nm. The fluorescence of the 1,3-dimethyleneoxybenzene units is completely quenched in the dendrimers.[15]

In a solution of 9:1 dichloromethane/acetonitrile, tweezer **T** shows an irreversible oxidative process at $+1.6$ V, whereas no reduction process could be observed in the potential window of the solvent used (up to -2.0 V vs. SCE). The $[\mathbf{D}n]^{2+}$ dendrimers[15,19] show two one-electron-transfer processes that correspond to the successive reductions of the 4,4′-bipyridinium core: $bpy^{2+} \rightarrow bpy^{+}$ and $bpy^{+} \rightarrow bpy$. The values of the potentials are gathered in Table 1, and the cyclic voltammetric curve for $[\mathbf{D2}]^{2+}$ is shown in Figure 3.

Table 1: Half-wave potentials versus SCE (saturated calomel electrode)[a] and association constants.[b]

	$bpy^{2+} \rightarrow bpy^{+}$ [V]	$bpy^{+} \rightarrow bpy$ [V]	$K_a \times 10^{-3}$ [M^{-1}]
$[\mathbf{D1}]^{2+}$[c]	−0.25	−0.73

[a] Solvent: dichloromethane/acetonitrile (9:1), unless otherwise noted; $(NBu_4)PF_6$ (0.1 M); under these conditions more than 95% of the electroactive species are in the complexed form. [b] Solvent: dichloromethane; from fluorescence titration experiments. [c] Solvent: dichloromethane/acetonitrile (3:1).

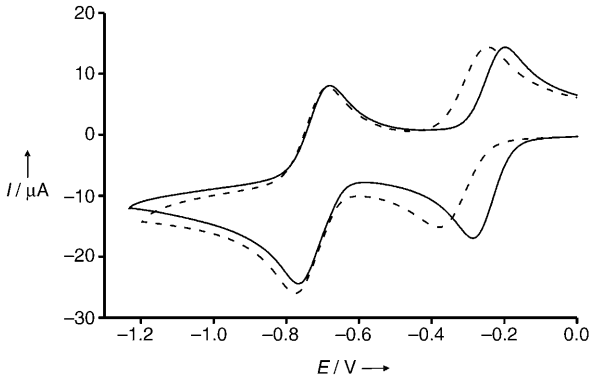

Figure 3. Cyclic voltammetry (CV) curves for a solution of $[\mathbf{D2}]^{2+}$ at 1.0×10^{-3} M in dichloromethane/acetonitrile (9:1) in the absence (——) and presence (-----) of tweezer **T** (3.2×10^{-3} M). Scan rate: 0.2 V s^{-1}; $(NBu_4)PF_6$ (0.1 M).Under such conditions, the association constant (Table 1) shows that about 98% of the species are associated.

Titrations of solutions of tweezer **T** at approximately 10^{-5} M in dichloromethane with the dendrimers did not cause any changes in the absorption spectra relative to the spectra expected from the absorptions of the two components. The fluorescence band of **T** ($\lambda_{max} = 344$ nm), however, was quenched, as shown in Figure 4 for the case of $[\mathbf{D3}]^{2+}$. As dynamic quenching can be ruled out because of the short excited-state lifetime of **T** ($\tau = 9.5$ ns), these results indicate that the tweezer and dendrimers give rise to adducts. We also verified that the fluorescence of **T** is not quenched upon addition to the solution of the dendrons used to construct the dendrimers. Therefore we conclude that adduct formation must involve an interaction between the tweezer and the bipyridinium dendritic cores.

To elucidate the stoichiometry and the strength of adduct formation, fluorescence titration experiments were performed by taking into account[20] the fraction of light absorbed

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

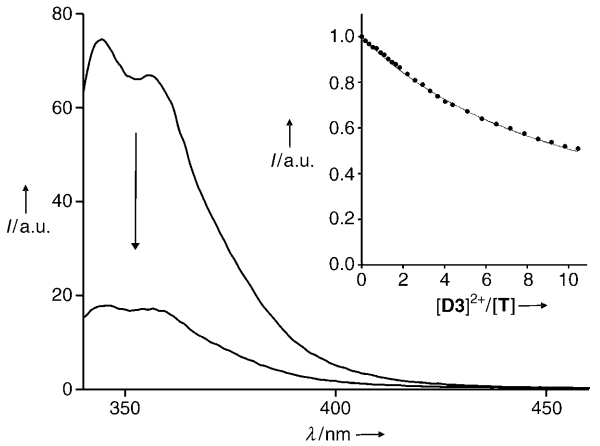

Figure 4. Changes in the fluorescence spectrum of a solution of **T** at 1.6×10^{-5} M in dichloromethane at room temperature upon addition of 10 equivalents of $[\mathbf{D3}]^{2+}$ ($\lambda_{ex}=334$ nm). Inset: The titration curve obtained by plotting the emission intensity at $\lambda=356$ nm as a function of the equivalents of $[\mathbf{D3}]^{2+}$ added, after correction for the fraction of light absorbed by **T**. The solid line shows the fit based on formation of a 1:1 complex. a.u. = arbitrary units.

by the dendrimer. The titration plot obtained for a solution of **T** at 1.6×10^{-5} M in dichloromethane upon addition of $[\mathbf{D3}]^{2+}$ is shown in the inset of Figure 4. As the fluorescence lifetime ($\tau=9.5$ ns) is not affected upon addition of the dendrimer and as there is no evidence of a double-exponential decay, we conclude that even after addition of an excess of dendrimer a significant fraction of tweezer remains uncomplexed in such a dilute solution and that the adducts do not show any appreciable fluorescence.

The results obtained from the titration plots show that 1:1 $[\mathbf{D}\boldsymbol{n}]^{2+}\cdot\mathbf{T}$ adducts are formed, with values for the association constants of the order of $10^4\,\text{M}^{-1}$ which decrease with increasing dendrimer generation (Table 1). A similar dependence of the stability of the complex on the size of the dendrimer was observed in the gas phase by mass spectroscopy.[12] Apparently, even in solution the bipyridinium core is stabilized by "intramolecular solvation", which results from the back-folding of the electron-donor branches, an effect that increases with increasing dendrimer generation.

The CV patterns for reduction of the dendritic cores are affected by the presence of tweezer **T** (Table 1 and Figure 3) which shows that the formation of the adduct involves an interaction between the tweezer and the bipyridinium dendritic cores. In particular, both the cathodic and anodic peaks which correspond to the first one-electron-reduction process of the dendritic core move to more negative values upon addition of the tweezer, whereas the peaks that correspond to the second reduction process are almost unaffected. Such a behavior shows that 1) formation of the adduct is caused by a charge-transfer interaction and 2) the adduct dissociates upon one-electron reduction of the dendritic core.

In conclusion, we have shown that the 4,4′-bipyridinium core of first-, second-, and third-generation $[\mathbf{D}\boldsymbol{n}]^{2+}$ dendrimers that bear Fréchet-type dendrons can be hosted by the molecular tweezer **T**, which comprises a naphthalene moiety and four benzene components bridged by four methylene units. The assembly/disassembly process can be monitored by fluorescence and electrochemical measurements. The tweezering process between **T** and $[\mathbf{D}\boldsymbol{n}]^{2+}$ is quite similar to the threading/dethreading processes observed with bipyridinium-based wire-type units and ring-shaped molecules,[21] with the advantage that tweezering can occur also when the wire-type unit terminates with bulky groups.

Locking and Unlocking of Polyelectrolyte Brushes: Toward the Fabrication of Chemically Controlled Nanoactuators**

*Sergio Moya, Omar Azzaroni, Tamer Farhan, Vicky L. Osborne, and Wilhelm T. S. Huck**

Polymers are ideal building blocks for nanofabrication and the engineering of surfaces because of their response in shape and size to environmental changes in polymer concentration, ionic strength, pH, temperature, and solvent. Furthermore, since they are easy to synthesize, as well as chemically and mechanically robust, polymers are ideal materials to bridge the gap between biological nanomachines and silicon-based devices. Of particular interest herein is the exploration of the use of polymer brushes as nanoactuators.[1]

Polyelectrolytes, that is, polymers containing charged monomers, change from an extended conformation in a solution of low ionic strength to a coiled conformation in solutions of high ionic strength.[2] When polyelectrolytes are covalently attached to a surface to form a brush, the polymer chains show a strongly extended (stretched) conformation in pure water, as a result of both the repulsion between neighboring chains and the repulsion between the monomers.[3–6] In contrast, when polymer brushes are placed in electrolyte solutions, the charges of the pendant groups in the polymer chains are screened, and the minimization of the electrostatic repulsions leads to entropically more favorable collapsed conformations.[4–8] This collapse is comparable to transitions from extended to coil-like conformations commonly observed for polyelectrolytes in solution.[3,4] In the case of polymer brushes, there are constraints on the degrees of freedom related to conformational changes, and as a result the height and the amount of water on the inner brush environment are reduced.[5,8]

Our aim is to use the ionic-strength-sensitive behavior of polyelectrolyte brushes[9–11] in combination with specific binding interactions and ion-size-exclusion effects to design smart polymer surfaces that can be switched between a permanently collapsed and an extended state, where both states have different surface properties. In addition, we aim to find a route toward a "fast switch" that reversibly alternates between different polymer brush conformations, and as a consequence gain control over surface properties[12,13] such as wettability, hydration, and stiffness. Reversibly manipulating the polymer-brush conformation in a chemically selective way (not only by changing the ionic strength) will be a crucial step toward the use of surface-confined polyelectrolytes as nanoactuators.

Cationic brushes of [2-(methacryloyloxy)ethyl]trimethylammonium chloride (METAC)[14] were grown from gold surfaces, patterned into regions containing either initiator or methyl-terminated monolayers (Figure 1a,b), by atom-transfer radical polymerization (ATRP) in an oxygen-free methanol/water (4:1) mixture.[15,16] The responsive behavior of the METAC brushes in different electrolyte environments (NaCl and $MgSO_4$) was studied under liquids using atomic force microscopy (AFM) and a quartz crystal microbalance with dissipation (QCM-D).[17]

The conformational changes in the METAC brush in the presence of 1M NaCl electrolyte solution can be followed with QCM-D,[18,19] where additional information about the water content and the rigidity of the polymer brush can be obtained. Furthermore, QCM-D is well-suited to study the kinetics of the collapse process, which is not possible with AFM, since it takes approximately 15 min before stable images can be acquired after the addition of salt. QCM-D measurements on 50-nm-thick METAC brushes (thickness measured in the dry state with ellipsometry) clearly show an immediate increase in the frequency (Figure 2a) and a decrease in the dissipation (Figure 2b) of the METAC brush/quartz crystal system upon addition of 1M NaCl. The timescales involved in this collapse

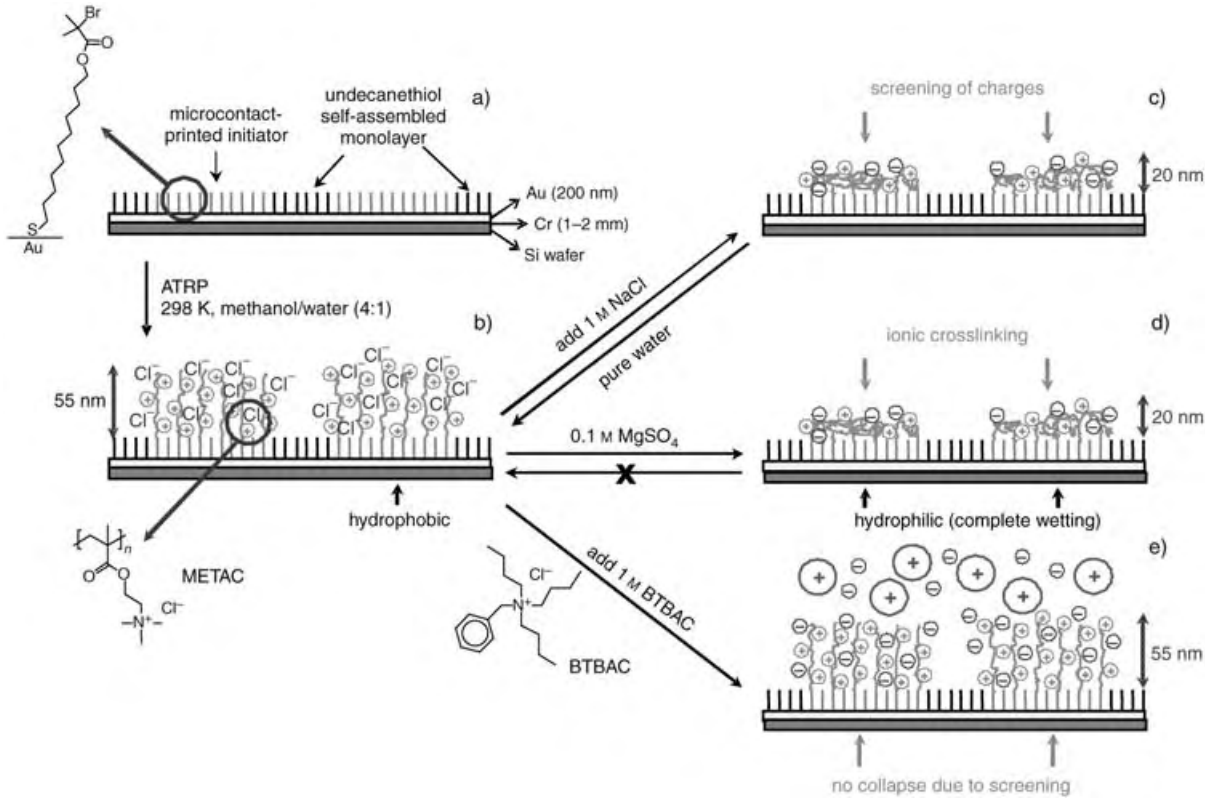

Figure 1. The synthesis (a, b) of polyelectrolyte brushes and their different possible behaviors in response to changes in ionic strength: c) reversible collapse by pure changes in ionic strength, d) irreversible collapse by increases in ionic strength combined with ion pairing, and e) no responsive behavior with the ionic strength because of steric effects.

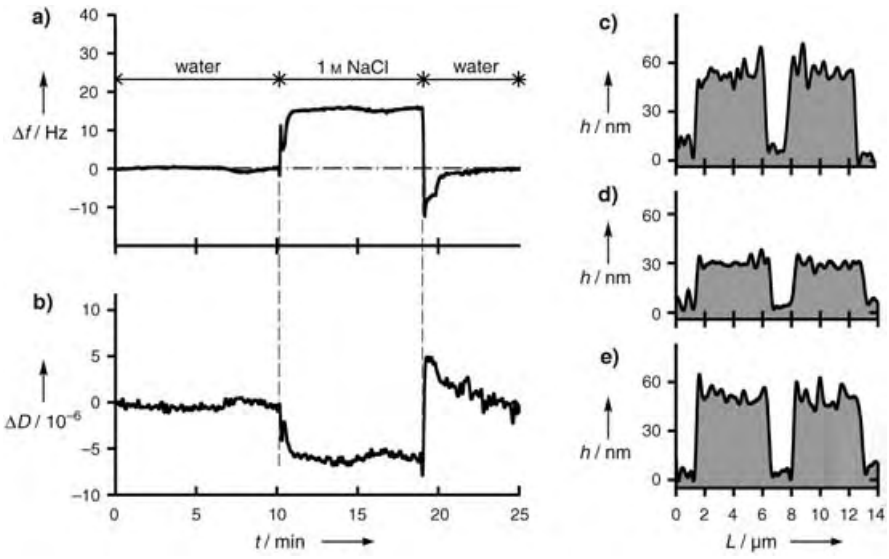

Figure 2. QCM response on a) frequency and b) dissipation when METAC brushes are in the presence of 1 M NaCl. c) Cross-sectional analysis derived from AFM imaging of METAC brushes in water. d) Cross-sectional analysis of patterned METAC brushes imaged in 1 M NaCl. e) Cross-sectional analysis of METAC brushes in water after treatment with 1 M NaCl.

process are less than 3 s. The increase in frequency is related to the loss of water molecules from the polyelectrolyte brush during the collapse process. The decrease in the dissipation (Figure 2b) can be understood as a change from a rather soft polymer film (viscoelastically coupled to the solution) to a more rigid collapsed structure. As shown in Figure 2, when the NaCl solution is replaced with pure water, the frequency and dissipation return to their original values, which indicates that the METAC brush resumes the "extended conformation". To estimate the magnitude of the collapse (brush height, h) under different liquid environments we performed in situ AFM measurements on patterned METAC brushes grown as depicted in Figure 1a and b. By combining AFM imaging (at low loads) under liquids with patterned responsive brushes (Figure 1b) it is possible to obtain reliable information about the actual h value of the polymer brush in the liquid environment. When imaged under pure water (Figure 2c), METAC brushes show $h \approx 55$ nm (extended conformation). In the presence of 1M NaCl electrolyte solutions the polyelectrolyte brushes are completely collapsed, which results in a change in h from ≈ 55 to ≈ 26 nm (Figure 2d). Notably, for NaCl solutions with concentrations lower than 0.1M the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

collapse takes place to a lesser degree. As previously indicated by QCM-D measurements, AFM shows that this collapsed state of the METAC brush in the presence of 1 M NaCl can be easily and completely reversed by simply washing the surface-confined polyelectrolyte with pure water (Figure 2e).

A different effect is observed when $MgSO_4$ is used as the electrolyte instead of NaCl. Addition of 0.5 M $MgSO_4$ electrolyte solution promotes a frequency decrease, while the dissipation is strongly increased (Figure 3a, b). These effects are predominantly a result of the strong changes in viscosity and ionic strength of the liquid environment. AFM imaging (not shown) confirmed, however, that METAC brushes are completely collapsed for $MgSO_4$ concentrations above 10 mM. Surprisingly, the replacement of the 0.5 M $MgSO_4$ electrolyte solution by pure water resulted in an increase of the frequency and simultaneous decrease of the dissipation over the values previously obtained in pure water before flushing with 0.5 M $MgSO_4$. This result can be interpreted as the METAC brushes remaining in a collapsed state while immersed in pure water. When the samples were stored in the QCM cell in pure water overnight, no changes in frequency or dissipation were detected. This finding implies an irreversible collapse of METAC brushes in the presence of SO_4^{2-} anions. However, these collapsed brushes can be "unlocked" by passing a concentrated NaCl solution (1 M) through the QCM chamber and then flushing with water. Figure 3 shows that after this unlocking procedure, both the frequency and dissipation signals return to the original values for fully stretched brushes in water. AFM cross-sectional analysis of METAC brushes ($h \approx 55$ nm in the extended conformation) clearly shows that the surface-confined polyelectrolytes remain collapsed ($h \approx 28$ nm) in pure water after treatment with 0.5 M $MgSO_4$ (Figure 3c).

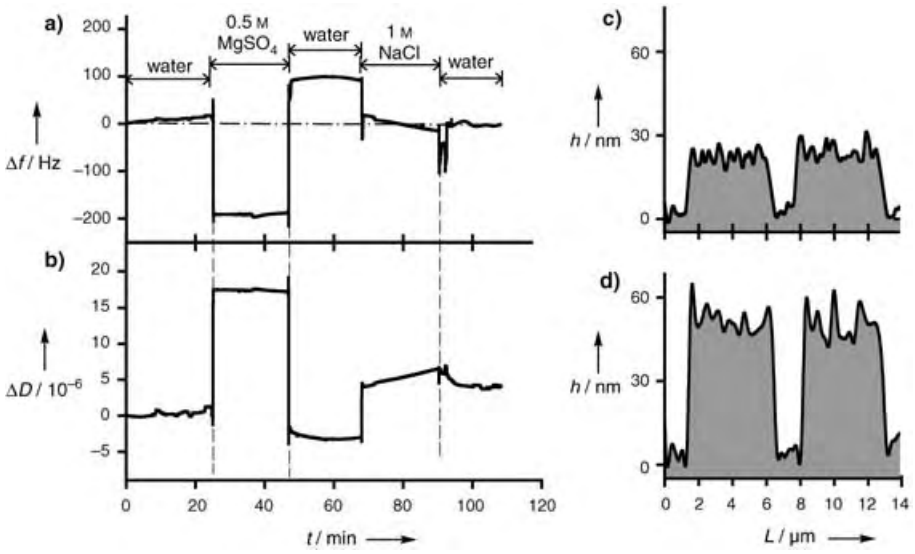

Figure 3. QCM response on a) frequency and b) dissipation when METAC brushes are placed in different electrolyte environments (0.5 M $MgSO_4$ and 1 M NaCl). Cross-sectional analysis, derived from AFM imaging performed under pure water, corresponding to c) patterned METAC brushes placed in 0.5 M $MgSO_4$ for 20 min and d) patterned METAC brushes placed in 0.5 M $MgSO_4$ for 20 min, rinsed with water, and then placed for 30 min in 1 M NaCl.

Figure 3d shows that after treatment of the SO_4^{2-}-collapsed METAC brushes with 1 M NaCl and subsequently storage in pure water, the extended conformation of the brushes is clearly restored ($h \approx 53$ nm). The excess of NaCl can be used to displace the equilibrium SO_4^{2-}/quaternary ammonium ion in such a way that the original chemical/ionic (Cl^--coordinated METAC) composition inside the brush is restored. In addition, washing with water depletes the NaCl excess and leads to the fully extended conformation.

The next step was to measure the contact angle to further characterize the surface properties of collapsed and extended brushes. Surfaces modified with METAC brushes ($h \approx 39$ nm) have a static contact angle of approximately 58° (Figure 4a). Treatment of brushes with 0.5 M $MgSO_4$ and washing with water results in a completely hydrophilic surface (Figure 4b), and the brush is in a collapsed state. The wettability of the surface is not affected by extensive rinsing with water, which demonstrates the robustness of the switch to the wetting behavior (Figure 4c).

The wetting properties are quite surprising, as we expected that the collapsed state (which involves a significant loss of water) would be more hydrophobic than the fully hydrated extended brushes. We hypothesize that during the collapse a considerable quantity of electrolyte (Mg^{2+} and SO_4^{2-} ions) is retained within the polyelectrolyte brush. This excess of strongly hydrated ions results in a highly hydrophilic behavior of the polymer film. QCM measurements confirmed that the collapsed brushes did not exchange salts with a pure water phase for at least 12 hours. "Unlocking" the brushes with NaCl and subsequent rinsing with water restores the original wetting properties (static contact angle: 58°).

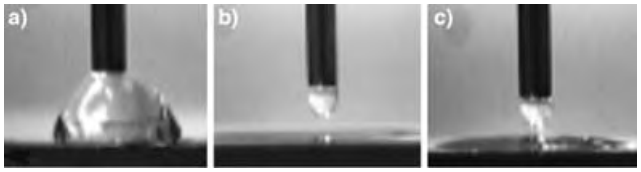

Figure 4. Contact-angle measurements of different METAC-modified gold substrates corresponding to a) Cl^--coordinated METAC brushes, b) SO_4^{2-}-treated METAC brushes, and c) SO_4^{2-}-treated METAC brushes after the substrate was stored for 8 min in pure water.

As a further extension of the combination of ionic strength effects and the chemical switching of the brush, we characterized the responsive behavior of METAC brushes with salts of different cation sizes. We treated METAC brushes with NaCl and benzyltributylammonium chloride

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(BTBAC, see Figure 1e). Both electrolytes have the same anion but a very different cation size. The AFM cross-sectional analysis in Figure 5 clearly shows that in the presence of 10 mM BTBAC the brushes remain fully extended, whereas the same brushes collapse to $h \approx 31$ nm in 10 mM NaCl. Chloride anion transport into the brush cannot be separated from the transport of their cationic counterions. When a bulky cation such as BTBA is chosen, whose permeability into the brush is hindered by steric effects, the ionic strength within the brush environment remains low, despite a high concentration of electrolyte outside the brush. As a result, the brushes do not collapse, thus opening up the possibility to decouple the conformational response of the brush from the external solution.

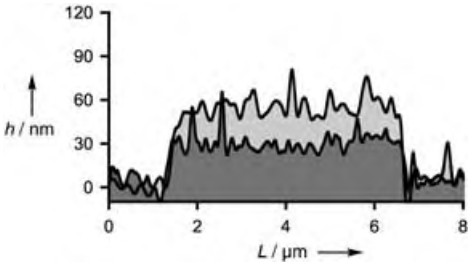

Figure 5. Cross-sectional analysis, derived from AFM imaging performed in 10 mM benzyltributylammonium chloride (light gray) and in 10 mM NaCl (dark gray).

In conclusion, the characterization of polyelectrolyte brushes by using the powerful combination of QCM-D and AFM techniques[20] has enabled us to demonstrate three different cases of brush behavior in the presence of salts: a) their response to the ionic strength, b) strong ion-pairing effects in the case of SO_4^{2-} ions, and c) the exclusion of the ions introducing steric effects. This rich responsiveness can be exploited to create surfaces where the brush is collapsed or extended in either low- or high-ionic-strength conditions (Figure 1). These states not only correspond to changes in thickness, but also to changes in hydration state and wettability. We think that this responsive behavior makes polymer brushes excellent candidates to be used as nano-actuators. By using strong binding interactions between the SO_4^{2-} anions and the quaternary ammonium pendant groups on the METAC brush, we have been able to "lock" the polyelectrolyte conformation in a completely hydrophilic collapsed state. To achieve the actuating character of the polyelectrolyte brush and to "unlock" it we exchanged the "locking" SO_4^{2-} counterions coordinated to the quaternary ammonium pendant groups for Cl^- anions, which restored the original extended state and surface properties.

The extended state could also be "locked" by introducing chloride salts with very bulky cations, decoupling the brush response from the ionic strength in solution, and introducing selectivity. The "lock" and "unlock" METAC brush conformation is also a simple and reversible way to change surface properties, thickness, and wettability, which could control the permeability of brushes if used as a barrier on a coating, and could stop or change the speed of a fluid in a liquid-cell device.

Protein Engineering

An *S*-Selective Lipase Was Created by Rational Redesign and the Enantioselectivity Increased with Temperature**

*Anders O. Magnusson, Mohamad Takwa, Anders Hamberg, and Karl Hult**

Lipases have characteristics that make them attractive tools for the synthesis of fine chemicals. They catalyze acyl-transfer reactions and are stable in organic solvents and at high temperatures. The possibility of modifying the performance of enzymes by biomolecular methods gives the opportunity to create tailor-made catalysts for each desired application. The high enantioselectivity of lipases toward secondary alcohols is a property often used in organic synthesis.[1] The enantioselectivity follows the Kazlauskas rule which normally predicts an *R* selectivity.[2] Structural explanations now exist for the strong chiral preference of many lipases.[3] Efforts to modify their properties have resulted in large improvements of the catalyst, such as increased stability and activity, but few articles report large effects on the enantioselectivity.[4,5] The largest changes in enantioselectivity of lipases concern substrates with a chiral center on the acyl chain of the substrate.[6] We redesigned the active site of *Candida antarctica* lipase B (CALB) to modify its specificity toward secondary alcohols. The enantioselectivity was greatly changed and an *S*-selective enzyme was created, mainly as a result of the increased activity toward the slow-reacting enantiomer. The mutant had very unusual behavior: the enantioselectivity increased strongly with temperature, and thermodynamic analysis showed that the altered enantioselectivity was dominated by entropy. In dynamic kinetic resolution, lipases can be used to produce close to 100% of the *R* enantiomer.[7] The creation of an *S*-selective lipase affords the possibility of achieving high yields of the *S* enantiomer.

CALB is a very robust and efficient catalyst that shows a high regio- and enantioselectivity.[8] The active site contains the catalytic triad Ser-His-Asp, an oxyanion hole that stabilizes the transition states, and a cavity called the stereospecificity pocket.[9] The strong *R* selectivity of CALB toward secondary alcohols is explained by the different binding modes of the enantiomers in the stereospecificity pocket.[10,11] The fast-reacting enantiomer positions its medium-sized substituent in the stereospecificity pocket and its large substituent toward the active-site entrance. For the slow-reacting enantiomer, the medium-sized substituent points toward the active-site entrance and the large substituent is placed in the stereospecificity pocket. Although the large substituent is not easily fitted in the stereospecificity pocket, this is the catalytically active binding mode for the slow-reacting enantiomer. The largest substituent that is well accommodated in the stereospecificity pocket is an ethyl group. This steric limitation makes CALB very selective toward secondary alcohols with a medium-sized substituent not larger than an ethyl group and a large substituent bigger than an ethyl group. When both substituents are larger than an ethyl group, the selectivity is low and the catalytic activity drops drastically.[11] To overcome this limitation in size and to increase the number of secondary alcohols that are good substrates for CALB, we earlier redesigned the volume of the stereospecificity pocket. Trp 104, which forms the bottom of the stereospecificity pocket, was replaced by smaller amino acids. The redesigned stereospecificity pockets were shown to readily accommodate much larger substituents than the stereospecificity pocket of the wild-type lipase. The mutant with the largest stereospecificity pocket, Trp 104 Ala, had a specificity constant (k_{cat}/K_M) of 830 $s^{-1}M^{-1}$ toward 5-nonanol, 5500 times greater than that of the wild-type enzyme.[12]

A larger stereospecificity pocket should affect the enantioselectivity of the lipase. Chiral secondary alcohols might easily position their large substituent in the redesigned stereospecificity pocket of the Trp 104 Ala mutant, which would lead to a low enantioselectivity. Computer modeling was used to compare the binding of secondary alcohols in the active site of the Trp 104 Ala mutant and wild-type CALB. Energy minimizations were performed on the tetrahedral intermediate of both lipase variants with the butanoate ester of (*R*)- and (*S*)-1-phenylethanol covalently bound to the catalytic serine (Figure 1). The *R* enantiomer was similarly positioned in both wild-type CALB and the Trp 104 Ala mutant; the large substituent (phenyl group) was oriented toward the active-site entrance and the medium-sized substituent (methyl group) was positioned in the stereospecificity pocket. The *S* enantiomer had different orientations in the two enzyme variants. In the wild-type lipase the slow-reacting enantiomer could not be accommodated in a catalytically active tetrahedral intermediate, as the phenyl group was too large to fit in the stereospecificity pocket. This finding is in accordance with a low reaction rate for the *S* enantiomer and a high enantioselectivity favoring the *R* enantiomer. However, the redesigned stereospecificity pocket of the Trp 104 Ala mutant comfortably accommodated the phenyl group.

We tested the low enantioselectivity expected for the Trp 104 Ala mutant by performing acyl-transfer reactions from vinyl butanoate to four secondary alcohols in cyclohexane. With 3-methyl-2-butanol, the selectivity for the *R* enantiomer dropped by a factor of 160 as a result of the mutation (Table 1, entries 6 and 7). With 2-hexanol, the *R* selectivity of several hundred for the wild-type enzyme changed into a low *S* selectivity for the mutant (Table 1, entry 5). Thus methyl, isopropyl, and butyl groups are almost equally well-accommodated in the stereospecificity pocket of the Trp 104 Ala

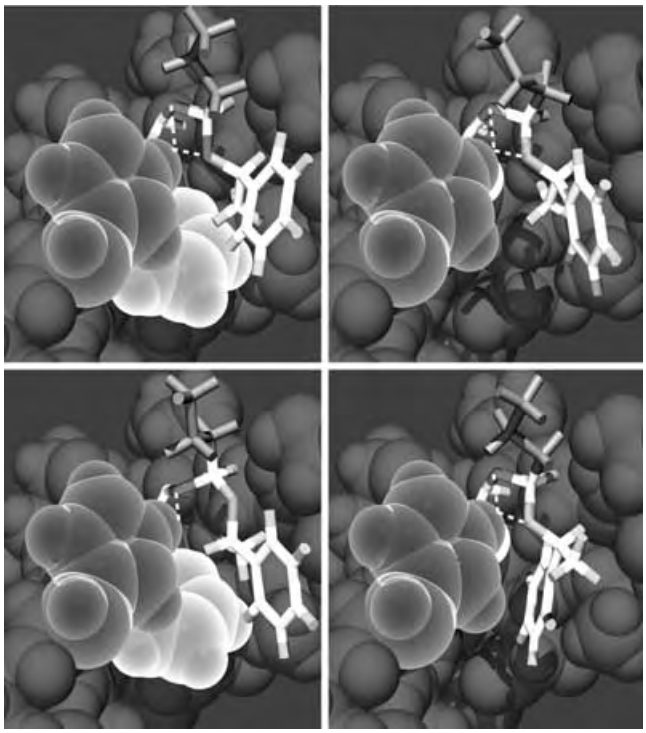

Figure 1. The active site of wild-type CALB (left) and Trp104Ala mutant (right) with the butanoate ester of (*R*)-1-phenylethanol (top) and (*S*)-1-phenylethanol (bottom) covalently bound to the catalytic serine in the tetrahedral reaction intermediate. The substrate is presented with a stick model and amino acid 104 with a space-filling model in white. The *R* enantiomer has a similar configuration in the wild-type CALB and Trp104Ala mutant: the large substituent (phenyl) points toward the active-site entrance and the medium-sized substituent (methyl) is positioned in the stereospecificity pocket. In the wild-type CALB, the *S* enantiomer cannot position its phenyl group in the stereospecificity pocket, and not all the hydrogen bonds required for catalysis can be formed. In the Trp104Ala mutant, the phenyl group is comfortably accommodated in the space liberated by the mutation in the stereospecificity pocket.

mutant. Interestingly, while wild-type CALB has a very high *R* selectivity, the mutant has a moderate *S* selectivity toward the two secondary alcohols with the bulky phenyl group as the large substituent (Table 1, entries 3 and 4). The phenyl group can probably fit well in the space liberated by the Trp104Ala mutation.

The enantioselectivity of wild-type CALB is very sensitive to the solvent used in the incubation.[13] The effects of the solvent and temperature on the enantioselectivity of the Trp104Ala mutant were investigated. We resolved 1-phenylethanol in three solvents and at temperatures between 10 and 70°C (Figure 2). Both the solvent and the temperature had

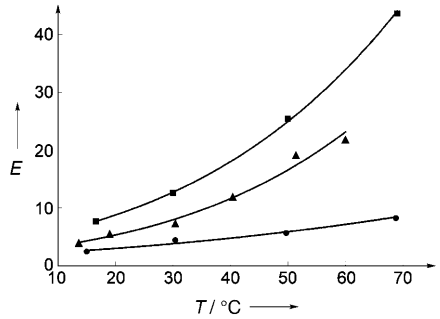

Figure 2. The *S* selectivity increased with temperature in the resolution of 1-phenylethanol catalyzed by the Trp104Ala mutant of CALB in acetonitrile (●), cyclohexane (▲), and *cis*-decalin (■). Trend lines are plotted according to Equation (1) using the values of the entropy and enthalpy terms in Table 1.

large effects on the enantioselectivity. The *S* selectivity increased to a large extent with the molecular size of the solvent. An increase in the temperature also favored the *S* enantiomer, which resulted in the unusual behavior of an increasing enantioselectivity with temperature. These effects gave an *S* selectivity of 44 for the Trp104Ala mutant toward 1-phenylethanol at 69°C in *cis*-decalin. Wild-type CALB is

Table 1: Thermodynamic components for acyl-transfer reactions from vinyl butanoate to secondary alcohols in various solvents catalyzed by wild-type CALB and the Trp104Ala mutant. Differential entropy ($\Delta_{S-R}\Delta S^{\neq}$) and enthalpy ($\Delta_{S-R}\Delta H^{\neq}$) and their standard errors were determined from the linear regression of $R\times\ln E$ versus T^{-1}. The entropic contribution ($T\Delta_{S-R}\Delta S^{\neq}$), Gibbs free energy ($\Delta_{S-R}\Delta G^{\neq}$), and the enantioselectivity (E) were calculated for 303 K. The preferred enantiomer (Pe) and the racemic temperature (T_R) are also presented.

used in dynamic kinetic resolution to achieve the *R* enantiomer,[14] and by using the Trp104Ala mutant in the same processes a high yield and enantiomeric excess could be achieved for the *S* enantiomer. The CALB mutant also has a higher activity (Table 2) and stability compared to those of subtilisin, which has been used in dynamic kinetic resolution to achieve the *S* enantiomer.[15]

Table 2: Apparent kinetic constants, specificity constants, preferred enantiomer (Pe), and *E* value of the wild-type CALB and Trp104Ala mutant for the acylation of the pure enantiomers of 1-phenylethanol in cyclohexane at 30°C with 500 mM vinyl butanoate.

		S	0.00053	71	0.0075		
Trp104Ala		*R*	4.4	29	150	*S*	6.6
		S	34	34	1000		

[a] Calculated from k_{cat}^{app} and K_M^{app}.

The Trp104Ala variant showed the very unusual behavior of increasing enantioselectivity with temperature for all the substrates tested, except for 3-methyl-2-butanol where the selectivity changed from the *R* to the *S* enantiomer. The selectivity between the two enantiomers depends on the difference in activation free energy ($\Delta_{S-R}\Delta G^{\ddagger}$), which can be divided into its enthalpic ($\Delta_{S-R}\Delta H^{\ddagger}$) and entropic components ($\Delta_{S-R}\Delta S^{\ddagger}$) according to Equation (1), where *R* is the gas constant and *T* is the temperature in Kelvin.

$$E = e^{-\Delta_{S-R}\Delta G^{\ddagger}/RT} = e^{(-\Delta_{S-R}\Delta H^{\ddagger} + T\Delta_{S-R}\Delta S^{\ddagger})/RT} \quad (1)$$

The value of the thermodynamic components can be calculated by determining the enantioselectivity (*E*) at several temperatures. This was done for the Trp104Ala mutant with 1-phenylethanol in three solvents (see Figure 2) and with three other secondary alcohols in cyclohexane. The enantioselectivity of the wild-type enzyme was determined for only one of the substrates at several temperatures; with the other substrates the *R* selectivity was too large to be accurately determined by resolution. Equation (1) was rearranged into Equation (2) and, if one assumes that the thermodynamic components are constant within the experimental temperature range, there is a linear correlation between $R\ln E$ and T^{-1}.[16] A good linearity was also seen, which justified this assumption. The differential entropy and enthalpy terms and their standard errors were calculated (Table 1) by linear regression to Equation (2).

$$R\ln E = -\frac{\Delta_{S-R}\Delta G^{\ddagger}}{T} = -\frac{\Delta_{S-R}\Delta H^{\ddagger}}{T} + \Delta_{S-R}\Delta S^{\ddagger} \quad (2)$$

In all the resolutions tested, the *R* enantiomer was favored by the enthalpy ($\Delta_{S-R}\Delta H^{\ddagger} > 0$) and the *S* enantiomer by the entropy ($\Delta_{S-R}\Delta S^{\ddagger} > 0$). The resolution of 3-methyl-2-butanol catalyzed by wild-type CALB afforded the *R* enantiomer, as the enthalpic contribution was larger than the entropic one (Table 1, entry 7). The magnitudes of the thermodynamic components agree well with the values obtained for the resolution of other secondary alcohols catalyzed by the same enzyme.[17] For the resolutions catalyzed by the Trp104Ala mutant, the enthalpic contribution was not significantly different from that of the wild-type enzyme. However, the entropic contribution increased so much that the enantioselectivity was eliminated or reversed. An enantioselectivity dominated by the entropy afforded a very unusual temperature dependence that has rarely been seen before.[18] The enantioselectivity of CALB Trp104Ala increased strongly with temperature: in the resolution of 1-phenylethanol in *cis*-decalin an *E*-value of 44 in favor of the *S* enantiomer was reached at 69°C (Figure 2). The racemic temperature ($T_R = \Delta_{S-R}\Delta H/\Delta_{S-R}\Delta S$),[19] at which the enantioselectivity is 1, was 330 K for this mutant toward 3-methyl-2-butanol; below this temperature the mutant was *R*-selective and above it, *S*-selective. A racemic temperature outside the experimental range should only be used to compare enthalphic and entropic contributions. Resolutions catalyzed by the Trp104Ala mutant have a much lower racemic temperature (Table 1) than those catalyzed by the wild-type lipase. This corresponds to the three to four times higher entropy contribution of the mutant.

The enantioselectivity toward 1-phenylethanol changed from a strong *R* selectivity with wild-type CALB to an *S* selectivity with the Trp104Ala mutant. The Trp104Ala mutation increases the size of the stereospecificity pocket, which should facilitate the binding of the *S* enantiomer in an orientation conducive to catalysis. This would lead to a higher ratio of productive binding of the *S* enantiomer in the Trp104Ala mutant compared to that in the wild-type CALB, and accordingly to a higher reaction rate. The apparent kinetic constants (k_{cat}^{app} and k_M^{app}) were determined for wild-type CALB and Trp104Ala mutant for the acylation of (*R*)- and (*S*)-1-phenylethanol with vinyl butanoate (500 mM) in cyclohexane at 30°C (Table 2). The specificity constant (k_{cat}/K_M) and the enantioselectivity (*E*) were calculated using the kinetic constants determined for both enzyme variants (Table 2).

The enantioselectivity was changed by a factor of 8300000 by the carefully selected point mutation in the stereospecificity pocket of CALB, which is more than any other example found in the literature. Rational design has been used to create variants of a phosphotriesterase with 6900000-fold difference in enantioselectivity, but the largest difference compared to the wild-type enzyme was 18000-fold.[5] The huge change in enantioselectivity by the Trp104Ala mutation of CALB was mainly achieved by increasing the apparent catalytic constant (k_{cat}^{app}) toward the slow-reacting enantiomer. The apparent catalytic constant toward (*S*)-1-phenylethanol was 64000 times larger for the mutant than for the wild-type CALB, while the same constant decreased by a factor of 130 toward the *R* enantiomer. However, the mutation did not affect the apparent Michaelis constant (k_M^{app}) to a large extent. The apparent Michaelis constants for the Trp104Ala mutant

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

were almost equal toward the *R* and *S* enantiomers, and they both decreased by a factor of two compared to those of the wild-type enzyme.

In summary, the redesigned stereospecificity pocket of *Candida antarctica* lipase B (CALB) was able to accommodate much larger groups than that of the wild-type lipase. This change transformed the strongly *R*-selective wild-type CALB into an *S*-selective mutant. The *S* selectivity increased with temperature and it was dominated by entropy. For 1-phenylethanol the enantioselectivity changed by a factor of 8300000 as a result of the mutation. This was mainly achieved by an increased reaction rate toward the *S* enantiomer, which resulted in a very effective catalyst with a high specificity constant of $1000\ s^{-1}M^{-1}$. The *S* selectivity of the Trp104Ala mutant could be increased to a respectable value of $E = 44$ when the reaction was conducted in *cis*-decalin at 69 °C. The altered enantioselectivity of CALB is a demonstration of the possibilities offered by protein redesign and shows the importance of the entropy contribution in enzyme catalysis.

Photocatalyis with Visible Light

Photocatalytic Nanodiodes for Visible-Light Photocatalysis**

*Hyun G. Kim, Pramod H. Borse, Wonyong Choi, and Jae S. Lee**

Photocatalysts that respond to visible light ($\lambda < 400$ nm) are needed to utilize the main part of the solar spectrum for production of hydrogen energy by splitting water,[1,2] purification of water and air,[3] and other applications.[4] Traditional visible-light photocatalysts are either unstable upon illumination with light (e.g., CdS, CdSe)[5] or have low activity (e.g., WO_3, Fe_2O_3).[6] Recently, some UV-active oxides functioned as visible-light photocatalysts by substitutional doping of metals (as in $MTiO_2$ (M = Fe, V, Mn)[7] and $Ni_xIn_{1-x}TaO_4$[8]), reduction of TiO_2 (as in TiO_x ($x < 2$)),[9] and anion doping with N, C, and S (as in $TiO_{2-x}N_x$,[10] $TiO_{2-x}C_x$,[11] TaON,[12] and $Sm_2Ti_2O_5S_2$[13]). However, these doped materials, in general, show a small absorption in the visible-light region, leading to low activities.[14] New and more efficient visible-light photocatalysts are needed to meet the requirements of future environmental and energy technologies driven by solar energy.

Herein we describe a novel configuration of composite solids designated as photocatalytic nanodiodes (PCD). These contain nano-islands of p-type $CaFe_2O_4$ interfaced over a highly crystalline layered perovskite base lattice (n-type $PbBi_2Nb_{1.9}W_{0.1}O_9$), yielding nanodimensional p–n junctions.

This nanodiode material shows greatly enhanced and stable photocatalytic activity for degradation of toxic organic pollutants (acetaldehyde, isopropyl alcohol), oxidation of water to gaseous oxygen, and photocurrent generation, all under visible light ($\lambda > 420$ nm).

In the rational design of this composite material, we employed a combination of concepts that optimize the photocatalytic activity. It has been demonstrated in photovoltaic cells and photoelectrochemical (PEC) cells that diode structures made of n- and p-type semiconductors show greatly enhanced activities compared to devices consisting of a single semiconductor. For example, the fundamental unit of current silicon solar cells consists of p–n junctions with p-type and n-type silicon. Multijunction solar cells and PEC cells with remarkable energy conversion efficiencies have been reported.[15] Nojik constructed an n-TiO_2/p-GaP diode electrode for a PEC cell that was much more active than either n-TiO_2 or p-GaP single-component electrodes for the decomposition of water.[16] He designated his monolithic device a p–n type photochemical diode. We attempted to create a particulate version of the p–n junction on a nanometer scale for photocatalytic applications; this junction should be stable under typical photocatalytic reaction conditions and highly active under visible light. Owing to the employment of the p–n junction concept, the nanoscale size, and the particulate form of our device material, we designated it a p–n type photocatalytic nanodiode (PCD).

The first step in fabricating the PCD was to select proper p- and n-type semiconductors that could absorb visible light. We identified $PbBi_2Nb_2O_9$ as a suitable n-type semiconductor. This material is an Aurivillius-phase layered perovskite, and is an efficient photocatalyst for the oxidation of water to O_2 and the degradation of isopropyl alcohol to CO_2 under visible light.[17] For $PbBi_2Nb_2O_9$ to show n-type semiconductivity, it was doped with tungsten(VI) to provide n-$PbBi_2Nb_{1.9}W_{0.1}O_9$. In addition to the valency, the similarity in size between W^{VI} (0.74 nm) and Nb^{V} (0.78 nm) was a further consideration in our choice. For the p-type semiconductor we chose $CaFe_2O_4$, a metal oxide with a bulk band gap of 1.9 eV.[18] The material by itself shows very low photocatalytic activity under visible light. Yet, we selected it because of its p-type semiconductivity and expected stability in water under illumination.

The next challenge was to combine these two semiconductor particles to form a p–n junction. For the efficient use of such a diode structure, the interfacing area should be maximized. However, in preliminary experiments, we learned that $PbBi_2Nb_{1.9}W_{0.1}O_9$ must be in a highly crystalline state to obtain high activity; this requires a high-temperature synthesis that inevitably produces large particles of 0.1–1 μm in diameter. We therefore devised the configuration of the diode particles as follows: 1) Nanocrystals of p-type $CaFe_2O_4$ and 2) a perovskite lattice of n-type $PbBi_2Nb_{1.9}W_{0.1}O_9$ as a submicron-sized base material. The $CaFe_2O_4$ nanoparticles and $PbBi_2Nb_{1.9}W_{0.1}O_9$ submicron particles were synthesized individually by sol–gel methods and a solid-state reaction, respectively. The individual components were then combined by placing them in a hydrothermal reactor (150 °C for 7 d) to form $CaFe_2O_4$ nano-islands over larger particles of $PbBi_2Nb_{1.9}W_{0.1}O_9$.

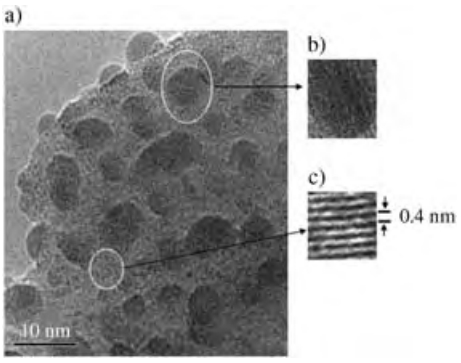

Figure 1. a) HRTEM image of the p–n type photocatalytic nanodiode (PCD). The magnified views show the nanocrystalline p-type $CaFe_2O_4$ (b) interfaced on layers of the n-type $PbBi_2Nb_{1.9}W_{0.1}O_9$ base (c).

Figure 1a shows a HRTEM image of a typical PCD particle. It clearly exhibits the existence of nano-islands dispersed over a single particle of perovskite base material. The micrograph shows many nanocrystalline islands of 5–10 nm, and the magnified view of a nano-island reveals the nanocrystallinity of $CaFe_2O_4$ (Figure 1b). The magnified view of the fringes also demonstrates the existence of a highly crystalline, layered base material corresponding to $PbBi_2Nb_{1.9}W_{0.1}O_9$ (layer thickness 0.4 nm, Figure 1c). The phase identification was also confirmed by elemental analysis with in situ energy-dispersive X-ray microanalysis carried out during the microscopic study.

Based on these experimental observations we propose a model for the PCD as illustrated in Figure 2a. Each island forms a nanoscale p–n junction at the interface, which plays a crucial role in the photocatalytic process. The working principle of PND is shown as an energy band model for one p–n junction (Figure 2b). At thermal equilibrium, the Fermi levels of two semiconductors align. When the device is immersed in an electrolyte, the band edges of the conduction and valence bands bend as indicated. The operation of the PCD is initiated by the absorption of the band-gap photons in both the n- and p-type semiconductors. Photogenerated holes and electrons separate under the influence of the electric field, corresponding to the energy diagram in Figure 2b. Thus,

holes move to the p-$CaFe_2O_4$ side, and electrons to the n-$PbBi_2Nb_{1.9}W_{0.1}O_9$ side. The net effect of the p–n diode formation is the efficient separation of electron–hole pairs to minimize the energy-wasteful electron–hole recombination. This effect leads to the higher photocatalytic activity.

The optical properties of these compounds were probed by UV/Vis diffuse reflectance spectroscopy (Figure 3a). Then a comparison was made with the base material, $PbBi_2Nb_2O_9$, and nitrogen-doped TiO_2, that is, $TiO_{2-x}N_x$. The latter material is considered to be the standard example of a visible-light photocatalyst; the band structure of TiO_2 is modified by nitrogen doping to induce absorption of visible light.[10] From these spectra, we estimated the band gap energies of these materials (Table 1). The PCD powders showed a steep onset of absorption around $\lambda = 530$ nm, corresponding to green light; the band corresponding to this onset covers a major part of the visible region, compared to the other two standards considered here. The $TiO_{2-x}N_x$ sample showed two absorption edges typical of doped materials, the main edge due to the oxide at 390 nm and a shoulder due to the nitride at 451 nm. $PbBi_2Nb_2O_9$ and the PCD showed single sharp edges. Thus, the PCD would absorb more visible-light photons than $TiO_{2-x}N_x$, although their absorption edges were almost the same around 450 nm. Both $PbBi_2Nb_2O_9$ and $TiO_{2-x}N_x$ are yellow, and the PCD is orange, indicating that all these materials absorb visible light.

We then examined the photocatalytic properties of these materials. To investigate the generation of a photocurrent, aqueous suspensions of the materials containing acetate (donor) and Fe^{3+} (acceptor) were illuminated with visible light ($\lambda > 420$ nm).[19] Figure 3b indicates that the PCD generates a photocurrent approximately three and five times faster than $PbBi_2Nb_2O_9$ and $TiO_{2-x}N_x$, respectively. The higher activities of PCD and $PbBi_2Nb_2O_9$ for photocurrent generation result from the beneficial effect of forming photocatalytic p–n nanodiodes. Unmodified TiO_2, with a wide band gap, as well as all catalysts in the dark did not generate a photocurrent, as expected. The generation of photoelectrons is the critical initial step of photocatalytic reactions upon absorption of light, and the rate should directly correlate with the photocatalytic activity of the material.

The materials were then tested for the photooxidation of acetaldehyde, a hazardous air pollutant as well as a common model compound to test the photodegradation capability of photocatalysts. Figure 3c shows the time curves of CO_2 evolution from the reaction $CH_3CHO + 5/2\,O_2 \rightarrow 2\,CO_2 + 2\,H_2O$. The concentration of CO_2 increased steadily with irradiation time at a decomposition rate of about 0.02 μmol h^{-1} under irradiation with light. The CO_2 production stopped when the light was turned off and resumed at the same rate when the light was turned on again. No intermediate reaction products were detected. The superiority of the PCD over $PbBi_2Nb_2O_9$ and $TiO_{2-x}N_x$, as expected from the photocurrent generation behavior, was confirmed. Similar results were obtained for the photodecomposition of isopropyl alcohol, another common organic pollutant of air (not shown).

As the final test reaction, we studied the photodecomposition of water in the presence of sacrificial agents. These

experiments give individual hydrogen- and oxygen-producing activities from each half-reaction of water splitting. In these reactions, two reference catalysts were loaded with 0.1 wt% Pt as a co-catalyst to collect photoelectrons away from holes by forming a Schottky-type junction structure.[16] The rates of oxygen evolution from water in the presence of $AgNO_3$ as the electron scavenger ($2\,H_2O + 4\,Ag^+ \rightarrow O_2 + 4\,H^+$) are listed in Table 1. Again, the PCD demonstrated the best performance

Table 1: Photocatalytic activities for oxygen evolution from an aqueous $AgNO_3$ solution as tested for the various catalysts.[a]

Catalyst	Band gap energy		Oxygen evolution	
	E_g [eV]	λ_{ab} [nm][b]	[μmol][c]	QY [%][d]
$CaFe_2O_4/PbBi_2Nb_{1.9}W_{0.1}O_9$	2.75	450	675	38
$PbBi_2Nb_2O_9$	2.88	431	520	29
$TiO_{2-x}N_x$	2.73[e]	451	221	14

[a] Catalyst 0.3 g; light source 450-W Xe-arc lamp (Oriel) with UV cut-off filter ($\lambda \geq 420$ nm). The reaction was performed in an aqueous $AgNO_3$ solution (0.05 mol L^{-1}, 200 mL). [b] The wavelength at the absorption edge was determined as the intercept on the wavelength axis for a tangent drawn on absorption spectra. [c] Per gram of catalyst and hour. [d] QY = quantum yield (see the Experimental Section). [e] The minimum energy of photoabsorption was estimated from the intercept of the shoulder peak onset.

even without a co-catalyst. The quantum yield of O_2 evolution over the PCD was estimated to be about 38%. To the best of our knowledge, this is the highest value ever reported for the reaction over semiconductor photocatalysts under visible light. The hydrogen evolution with methanol as a hole scavenger was also studied ($H_2O + CH_3OH \rightarrow 3H_2 + CO_2$). The relative activity trend among the three photocatalysts was the same, but the rates were lower than those for oxygen evolution by factors of at least 10, and thus are not reported herein.

It has been demonstrated that PCD is a highly active novel photocatalyst. Application of the p–n diode concept commonly employed in the synthesis of monolithic energy conversion devices and the employment of techniques for nanomaterial synthesis have allowed the production of a nanocomposite between the high-order oxides with a unique configuration. It appears that the p–n diode formation results in the efficient separation of electron–hole pairs to minimize the energy-wasteful electron–hole recombination, which leads to the high photocatalytic activity. The materials involved are all stable oxides, which means less stability problems under irradiation with light. Indeed, the crystal structure did not change during the reaction, and the post-reaction analysis showed no indication of dissolved catalyst components, even after more than 100 h of water decomposition.

The PCD catalyst appears to be particularly active for photooxidation reactions. The activity could be directly exploited for the degradation of toxic organic pollutants, as demonstrated for acetaldehyde and isopropyl alcohol. Cheap and abundant sunlight or weak indoor lighting could be employed as the light source. The high activity for the oxidation of water and the generation of a photocurrent could be of advantage for producing a photoelectrochemical cell that converts optical energy into chemical energy by decomposing water.[2] The overall performance of such a device is determined by the ability of the semiconductor anode[2] to oxidize water, and our PCD photocatalyst with the remarkable oxygen-producing capability could be used for this purpose. Furthermore, since the concept of PCD fabrication could be applied for other visible-light absorbing semiconductors, further improvement in performance may be possible by a materials screening of a wider scope.

Experimental Section

To synthesize the PCD, $PbBi_2Nb_{1.9}W_{0.1}O_9$ was first prepared by the conventional solid-state method. A stoichiometric mixture of PbO (Aldrich 99.999%), Bi_2O_3 (Aldrich 99.99%), Nb_2O_5 (Aldrich 99.999%), and WO_3 (Aldrich 99.999%) was ground in a mortar. The pelletized powders were calcined at 1123 K for 24 h in static air and sintered at 1323 K for 24 h. Next, the sol–gel route was adopted to synthesize the $CaFe_2O_4$ nanoparticles: A stoichiometric ratio of $Ca(NO_3)_2{\cdot}4H_2O$ (Aldrich 99.999%) and $Fe(NO_3)_3{\cdot}9H_2O$ (Aldrich 99.999%) was mixed in 30% aqueous NH_3 solution, and the mixture was stirred at room temperature for 24 h. The PCD composite of $CaFe_2O_4/PbBi_2Nb_{2-x}W_xO_9$ was made by hydrothermal treatment of preformed $PbBi_2Nb_{1.9}W_{0.1}O_9$ and $CaFe_2O_4$ sol at 150°C for 7 d to obtain 2 wt% $CaFe_2O_4$ loading on $PbBi_2Nb_{2-x}W_xO_9$. The $CaFe_2O_4/PbBi_2Nb_{1.9}W_{0.1}O_9$ thus obtained was characterized by high-resolution transmission electron microscopy (HRTEM, Phillips Model CM 200) and UV/Vis diffuse reflectance spectroscopy (Shimadzu, UV 2401).

Prior to the water-splitting reactions, all the catalysts (except the PCD) were loaded with 0.1 wt% Pt by impregnation with $PtCl_2$. The photocatalytic reactions in aqueous solution were carried out at room temperature in a closed system using a 450-W Xe-arc lamp (Oriel) with UV cut-off filter ($\lambda \geq 420$ nm) placed in an inner irradiation-type 200-mL Pyrex reaction cell. The H_2 evolution was examined in an aqueous solution (distilled H_2O (170 mL) + CH_3OH (30 mL)), and the O_2 evolution in an aqueous $AgNO_3$ solution (0.05 mol L^{-1}, 200 mL), both containing 0.3 g of the catalyst. The quantum yield (QY) was calculated as twice the number of generated H_2 molecules or four times the number of generated O_2 molecules divided by the number of photons absorbed by the photocatalyst. The number of absorbed photons was determined with a light flux meter (1815-C, Newport) with the light sensor attached to the photocatalytic reactor.

About 200 ppm of gaseous CH_3CHO or isopropyl alcohol was injected into a 500-mL Pyrex reaction cell filled with air and containing 0.3 g of a catalyst. The concentration of the reaction products (H_2, O_2, CO_2) was determined by a gas chromatograph equipped with a thermal conductivity detector and a molecular sieve 5-Å column. For photocurrent measurements, 25 mg of photocatalyst was suspended in distilled H_2O (75 mL) containing acetate (0.1 M) and Fe^{3+} (0.1 mM) as an electron donor and acceptor, respectively, and the pH value of the suspension was adjusted to 1.4 with $HClO_4$. A Pt plate (1×1 cm^2, 0.125 mm thick, both sides exposed to solution), a saturated calomel electrode (SCE), and a Pt gauze were immersed in the reactor as working (collector), reference, and counter electrodes, respectively. With continuous N_2 purging of the suspension, photocurrents were measured by applying a potential (+0.6 V vs. SCE) to the Pt electrode using a potentiostat (EG&G).

Mesoporous Films

Thermally Stable Nanocrystalline γ-Alumina Layers with Highly Ordered 3D Mesoporosity**

*Monika Kuemmel, David Grosso, Cédric Boissière, Bernd Smarsly, Torsten Brezesinski, Pierre A. Albouy, Heinz Amenitsch, and Clement Sanchez**

Mesostructured materials can be obtained by combining ionic surfactants[1] or block copolymers[2] with the synthesis of metallic oxides through soft chemistry. Amongst the non-silicate mesoporous materials, alumina is very attractive since the Al_2O_3 has perfectly controlled mesoporosity associated with hardness, hydrolytic stability, amphoteric character, and thermal stability of the γ-transition-oxide phases. Indeed, alumina offers a range of possibilities for applications in ultrafiltration of salts,[3] as an adsorbent in environmental cleanup,[4] as an automobile exhaust catalyst,[5] as a heterogeneous catalyst support for hydrodechlorination,[6] and in petroleum refinement.[7] In state-of-the-art syntheses, ordered mesoporosity has been reported for boehmite,[8] gibbsite,[9] and alumina[2,5,10] through the template approach, and also by porogen bead inclusion,[11] by ordered mesoporous carbon (CMK) nanocasting,[12] and by anodization.[8a] However, none of these materials combines pure crystalline γ-Al_2O_3 of high thermal stability with a well-ordered porosity that has a narrow distribution and is adjusted on the mesoscopic scale.

Herein, we describe the preparation and characterization of nanocrystalline γ-Al_2O_3 layers with contracted face-centered cubic (fcc) mesoporosity that are stable up to 900 °C. These coatings were prepared by combining the block copolymer structuring approach[13] and the evaporation-induced self-assembly (EISA) method associated with layer deposition,[14] which has already led to mesoporous silica,[11] transition-metal oxide,[15] and even perovskite[16] layers. Here we show that such fcc-mesostructured alumina layers can be prepared reproducibly by a simple method by which one may

- adjust the mesopore dimension with a relatively narrow size distribution,
- tune the nature of the oxide framework between amorphous alumina to fully nanocrystalline γ-Al_2O_3,
- create up to 55 % volume of open porosity at 900 °C,
- adjust the layer thickness up to 1000 nm, and
- tune the refractive index from 1.19 to that of pure alumina (measured at 700 nm in a dry atmosphere).

These layers can thus find potential applications as low-refractive-index optical thin films or in the various domains mentioned above if used as coatings. In addition, we present the first fcc mesostructure ever reported for a non-silica system. The complete study of such a layer is assessed by 2D small-angle X-ray scattering (SAXS), transmission electron microscopy (TEM), electronic diffraction, atomic force microscopy (AFM), and ellipsometric porosimetry (EP). Finally, explanations for the high-temperature stability are given.

Layers (300-nm thick) of nanocrystalline γ- Al_2O_3 with optical quality were prepared as reported in the Experimental Section. Figure 1 shows the evolution of in situ 2D SAXS patterns obtained during thermal treatment. Indexation of the diffraction spots (Figure 1 b) reveals that the initial structure at 25 °C is a perfect fcc structure with lattice parameters of 36 and 60 nm when the KLE22 (Figure 1 a) and KLE23 block copolymer templates (Figure 1 d) are used, respectively (for KLE composition, see the Experimental Section). The diffraction rings (Figure 1 c, inset) are characteristic of the preferential monoorientation with the [111] direction normal to the surface (direction of shrinkage). Figure 1 c shows the diffraction pattern of a KLE22-templated alumina film calcined for 20 min at 900 °C. For clarity, diffraction points

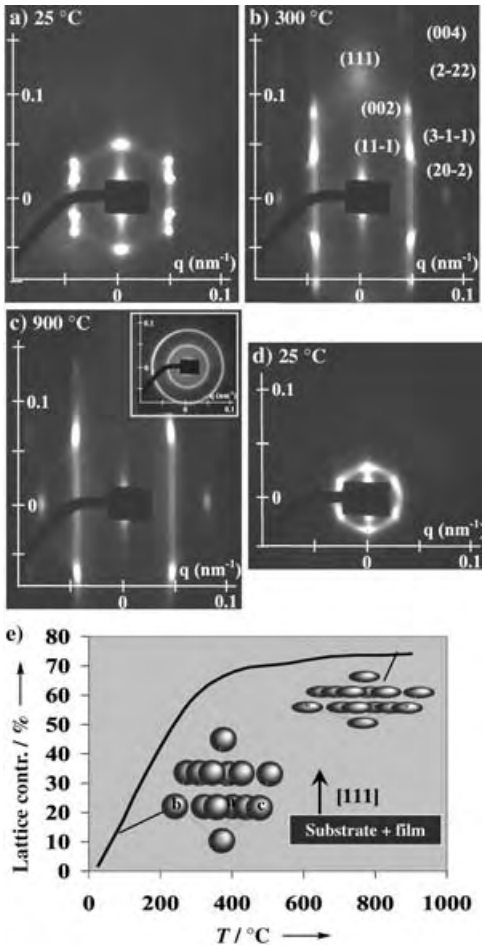

Figure 1. a)–c) 2D SAXS patterns of KLE22-templated alumina layers treated at various temperatures. c) Inset: diffraction rings. d) 2D SAXS patterns of KLE23-templated alumina layer at room temperature. e) Evolution of the fcc lattice contraction in the direction normal to the layer surface ([111] direction of the fcc domains) versus temperature.

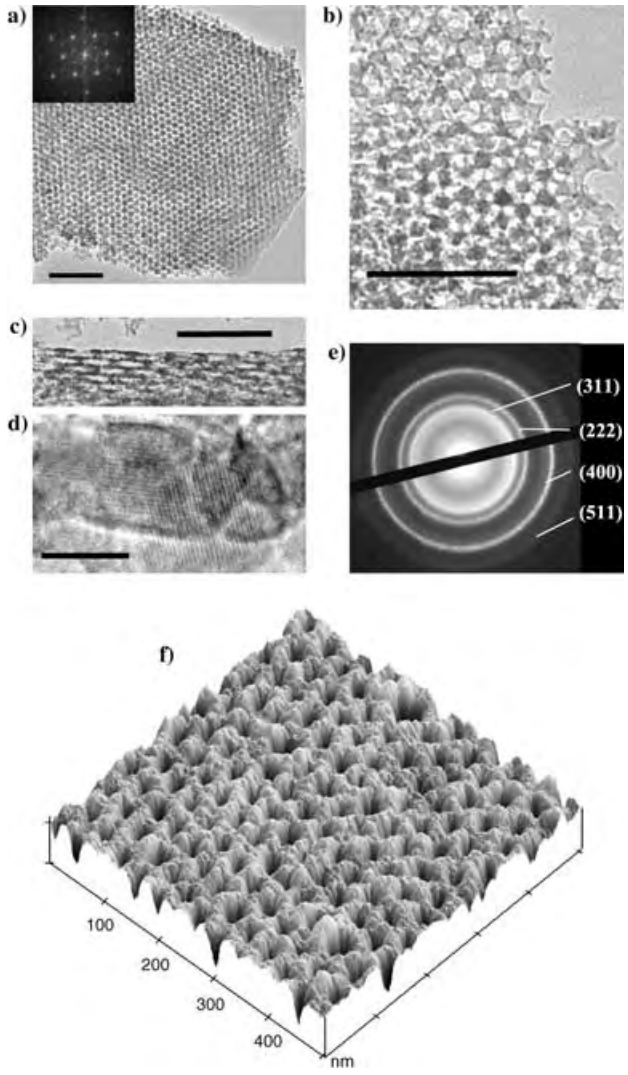

Figure 2. Electronic microscopy and diffraction investigations of KLE22-templated alumina layers treated at 400 °C (a) and at 900 °C (b–e). AFM topography of KLE23-templated layer treated at 900 °C (f). Images of the contracted fcc domains are given in the [111] zone axis for (b) and (c) and in the [1-10] zone axis for (c). Scale bars: 50 nm for (a) and (b), 25 nm for (c), and 5 nm for (d).

corresponding to these contracted systems are indexed with the original fcc structure.

Despite the significant lattice contraction found in Figure 1, the diffraction peaks are still very intense and well-resolved. The initial contraction of 68 % took place between room temperature and 400 °C, while the remaining 6 % occurred between 400 and 900 °C. The cubic structure is clearly confirmed by TEM analysis (see Figure 2), where the [111] view plane of the contracted fcc arrangement of pores exhibits the expected hexagonal arrays (Figure 2 a and b). The side view of the film in Figure 2 c confirms the fcc-based structure. It also reveals that pores are highly anisotropic as a result of the high degree of contraction induced by the thermal treatment. Energy-dispersive X-ray analysis confirmed that the whole mesostructure contains only Al and O elements. The surfaces of the thin films were probed by AFM, and the image obtained for the corresponding KLE23-templated film treated at 900 °C is shown in Figure 2 f.

AFM observations indicated that the porosity is open to the atmosphere through a hexagonal array of well-calibrated circular pores of average diameter 23 nm (see the Supporting Information). This topography is characteristic of the [111] plane from the contracted fcc arrangement of spherical pores with dimension similar to the size of templating micelles. The average pore depth was probed at 6 ± 1 nm. The HRTEM image (Figure 2 d) shows crystalline nanoparticles of around 5 nm in diameter with reticular distances corresponding to the (311) and (222) d spacing of the γ-Al_2O_3 phase. The corresponding diffraction pattern of the latter very stable alumina phase was also observed by electronic diffraction (Figure 2 e). Films treated for 20 min at 400 °C show no crystallinity, which suggests that the alumina framework is amorphous and crystallizes into γ-Al_2O_3 progressively from 400 to 900 °C. Electronic diffraction (see the Supporting Information) revealed that upon treatment above 900 °C, the d spacing slightly decreased, and diffraction spots clearly appeared on the diffraction rings. This finding is attributed to the γ-Al_2O_3 particles coalescing into larger crystalline particles of δ-Al_2O_3

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

through the combined effect of γ-to-δ phase transformation and diffusive sintering of nanoparticles. This transformation is accompanied by a degradation of the mesostructure. δ-Al_2O_3 is the transition alumina phase lying between γ- and α-Al_2O_3 (corundum). Before thermal treatment the inorganic network is probably composed of Al^{3+}-based polymeric species from the initial slightly acidic aqueous solution (hydrated gibbsite or boehmite phases).[9a] Starting at 400 °C, progressive crystallization into transition alumina phases occurs. At 900 °C the structure is that of γ-Al_2O_3 (*Fd3m* lacunar spinel) with the lattice parameter $a = 7.9$ Å. Above 900 °C, the original lattice distorts into δ-Al_2O_3 as a result of the increase in Al atoms located in octahedral sites. Such a particular sequence of transformation is usually observed during thermal decomposition of the boehmite precursor.[17]

It is well known that pore morphology is difficult to assess in thin films as a result of the very low quantity of material. The actual KLE22 and KLE23 block copolymer templates form spherical organic domains that have a given diameter of around 10 and 20 nm, respectively.[18] It is evident from the lattice contraction (Figure 1) that, after thermal treatment, pores adopt an ellipsoidal disk morphology with a large axis (d_w) close to the initial dimension of the porogen template, while the small axis depends on the contraction. For instance, an aspect ratio of 4 can be roughly measured in Figure 2c. Such pore dimensions, their interconnection, and therefore the diffusion through the layer were investigated by EP (see the Supporting Information).[19] Isotherms of water adsorption–desorption of KLE22- and KLE23-templated layers thermally treated at 900 °C are given in Figure 3. A volume of water up to 55 % is adsorbed inside the matrix at high relative humidity, which corresponds to the volume of accessible porosity. The main capillary condensation takes place at narrow relative pressure domains above 0.6, which suggests that mesopores of both layers are relatively well-calibrated. Very little water is adsorbed at low relative pressure, therefore only a tiny fraction of the porosity is expected to consist of micropores. Capillary condensation takes place at higher relative pressures when KLE23 is used because of the wider pores obtained with such a template. The pore-size distributions presented in Figure 3 are evaluated using Kelvin's equation modified for ellipsoidal pores (see the Supporting Information). The characteristics of the porosity are given in Table 1.

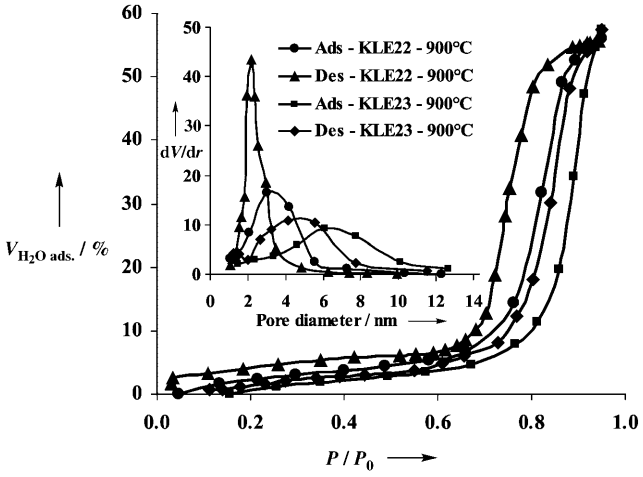

Figure 3. Water adsorption–desorption isotherms obtained from EP measurements performed on KLE22- and KLE23-templated alumina layers thermally treated at 900 °C. Inset: corresponding pore-size distributions deduced from the adsorption and desorption branches.

Table 1: Crystalline phase, pore volume *P*, pore small axis D_s deduced from adsorption, pore wide diameter D_w deduced from pore anisotropic factor, and interconnection diameter D_i deduced from desorption of KLE22- and KLE23-templated alumina layers depending on treatment temperature *T*.

Film	*T* [°C]	Phase	*P* [%]	D_s [nm]	D_w [nm]	D_i [nm]
AlKLE22	900	γ-Al_2O_3	55	3.3 ± 1	13 ± 4	2 ± 0.5
AlKLE22	940	δ-Al_2O_3	55	5 ± 2	–	–
AlKLE23	900	γ-Al_2O_3	55	6 ± 2	24 ± 5	5 ± 2

After crystallization into γ-Al_2O_3, the pore dimensions deduced from the isotherm adsorption branches are 3.3 and 6 nm for KLE22-and KLE23-templated structures, respectively. Both dimensions correspond to the smaller axes of the ellipsoidal pores, whereas their corresponding large axes (13 and 24 nm, respectively) are deduced from the pore aspect ratio. These results are in agreement with the TEM and AFM investigations and confirm the ellipsoidal-disk morphology of the pore, as expected when spherical shapes are unidirectionally contracted. The slightly greater value of the larger pore diameter is related to the matrix densification (crystallization and sintering) at high temperatures. The pore-size distributions become wider after transformation into δ-Al_2O_3 at 940 °C, as a result of the slight degradation of the mesoporous order already observed by TEM and electronic diffraction. No clear pore-size distribution could be deduced from the desorption branches. The dimensions deduced from the desorption branches are characteristic of the pore interconnection (bottleneck) that limits the diffusion of species within the porosity and delays the desorption. Both γ-Al_2O_3 mesostructures present pore-size distributions from desorption branches that are smaller than the dimension of their primary disk-shaped pores (that is, 2 and 5 nm for KLE22 and KLE23, respectively, deduced from the ellipsoidal geometry model). According to the fcc initial structure, every ellipsoidal-disk pore has six first neighbors since they are in an octahedral environment. The pores hold three interconnecting windows on each face of the disk as a result of contraction. A scheme of such an open, contracted-fcc mesostructure is represented in Figure 4.

In summary, the ability to stabilize γ-Al_2O_3 nanoparticles into a well-ordered three-dimensional mesostructured network is first attributed to the stability of the KLE22 template above the dehydration temperature of the inorganic phase. When the treatment reaches the KLE decomposition temperature at 350 °C, the amorphous inorganic dehydrated framework is rigid enough to prevent the mesostructure from collapsing. Above 400 °C, progressive crystallization by nucleation and growth slowly takes place, as expected for transition alumina phases, but the diffusive sintering usually responsible for the collapse of the transition-metal-oxide

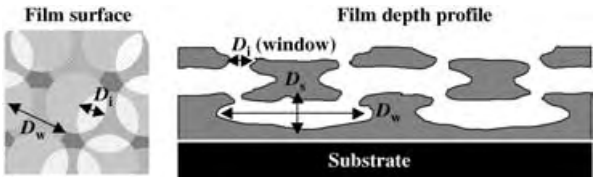

Figure 4. Scheme of the contracted-fcc nanocrystalline mesoporous film structure showing the corresponding surface ([111] zone axis) and depth-profile views ([1-10] zone axis). Pores of small and large diameter (D_s and D_w) with their interconnection dimension (D_i) are represented with respect to the arrangement of the disk-shaped pores.

mesostructure[20] is limited here by the spatial separation of the inorganic walls associated with the ordered mesostructure. The final nanocrystalline mesostructure is composed of ellipsoidal disk-shaped pores, which result from the unidirectional contraction associated with organic decomposition and the densification of the inorganic walls. The porosity (50% volume) is composed of well-calibrated mesopores and is accessible through interconnecting windows 2 or 5 nm in diameter, which is fixed by the template size.

Experimental Section

Isotropic solutions were prepared by dissolving $AlCl_3{\cdot}6\,H_2O$ precursor (0.3 g) and block copolymer KLE22 (BH_{79}-*b*-EO_{89}) or KLE23 (BH_{320}-*b*-EO_{568}) (BH = hydrogenated poly-*b*-butadiene-coethylene; EO = polyoxyethylene) template (0.06 g) in ethanol (5 mL) and H_2O (0.2 mL; 0.1 M NH_4OH). The solutions were aged for 7 days at room temperature before deposition. Films were prepared by dip-coating at a constant relative humidity of 30%. Amorphous ordered mesoporous layers were obtained at 400 °C (10 °C min^{-1} under air) whereas γ- and δ-Al_2O_3 nanocrystalline mesoporous networks were formed at 900 and 940 °C, respectively.

Bridging Ligands

Triatomic EP_2 Triangles (E = Ge, Sn, Pb) as μ_2:η^3,η^3-Bridging Ligands**

*Joshua S. Figueroa and Christopher C. Cummins**

Three-membered, 2π-electron rings comprised of main-group elements are of interest as compact manifestations of $4n+2$ Hückel aromaticity in which $n=0$.[1] The cyclopropenium ion $[cyclo\text{-}C_3H_3]^+$ serves as the prototypical organic representative of this class,[2] while the prospect of substituting one or more CH units of the cyclopropenium ring by an isolobal heteroatom has spurred investigations seeking to extend the concept of π delocalization throughout the p block of the

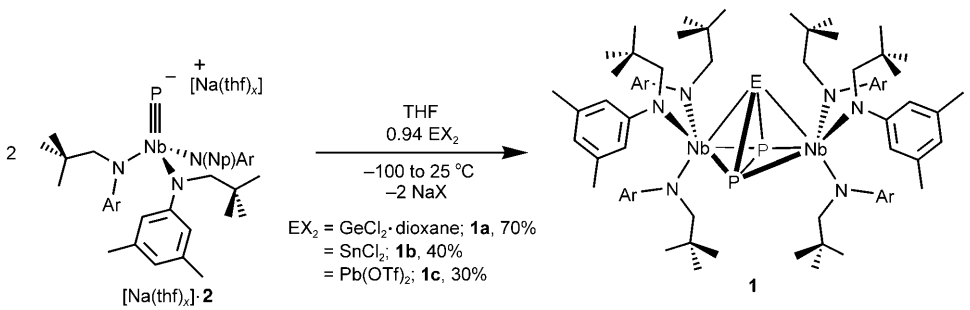
periodic table.[3,4] Reactive unsaturated rings, such as cyclobutadiene, may be stabilized through complexation with a metal center. With this idea in mind, we present herein a study on the synthesis of triatomic {*cyclo*-EP_2} triangles (E = Ge, Sn, and Pb) stabilized within the coordination sphere of a sterically protected diniobium unit. This particular family of {*cyclo*-EP_2} triangles has not been considered previously in either its free or complexed form. Furthermore, divalent atoms from Group 14 have received relatively little attention as components in three-membered, 2π-electron rings. In fact, only the neutral cyclopropene carbene *cyclo*-:$C(C_2H_2)$, diazacyclopropene carbene *cyclo*-:CN_2, and silacyclopropenylidene *cyclo*-:$Si(C_2H_2)$ molecules have been considered theoretically,[5,6] with three-membered rings containing the heavier atoms from Group 14 having been completely neglected to date.



The title complexes [(μ_2:η^3,η^3-*cyclo*-EP_2){Nb[N(Np)Ar]$_3$}$_2$] (**1a–c**; E = Ge, Sn, and Pb, respectively; Np = neopentyl, Ar = 3,5-$Me_2C_6H_3$) were formed as a consequence of the propensity of the niobium phosphide anion [P≡Nb{N(Np)Ar}$_3$]$^-$ (**2**)[7] to undergo electronic rearrangement when functionalized at the phosphorus atom.[7,8] This tendency has already afforded both a new synthesis of phosphaalkynes[8] and of diorganophosphanylphosphinidene complexes.[7] The current manifestation of this phenomenon, which is characterized by the exchange of a niobium/phosphorus multiple-bond interaction for a main-group element/phosphorus bonding interaction, is simply derived from salt elimination reactions of divalent Group 14 halides with the [Na(thf)$_x$]$^+$ derivative of anion **2**.[7]

$^{31}P\{^1H\}$ NMR spectroscopic analysis on a room-temperature solution containing equimolar quantities of [Na(thf)$_x$]·**2** and $SnCl_2$ after mixing in cold THF revealed a single new resonance centered at $\delta = 47.8$ ppm, which is well upfield of the range expected for a niobium phosphinidene complex.[7,9] X-ray structural analysis of a crystal harvested from the reaction mixture established the identity of complex **1b** as containing a central {SnP_2} ring and as the product of a double addition of [Na(thf)$_x$]·**2** to $SnCl_2$ with elimination of NaCl. A purposeful synthesis was then devised and extended to the Ge- and Pb-containing derivatives. Accordingly, the slow addition of 0.47 equivalents of the respective divalent Group 14 source ($GeCl_2$·dioxane, $SnCl_2$, or $Pb(OTf)_2$[10]) to [Na(thf)$_x$]·**2** in cold THF provided dark-red **1a** and forest-green **1b** and **1c**, respectively, in moderate yields of isolated product (**1a**: 65%, **1b**: 40%, **1c**: 30%) after removal of the salt by-product and crystallization from Et_2O (Scheme 1).

Diamagnetic complexes **1a–c** are obtained as crystalline solids, which are soluble in ethereal and aromatic solvents. Complexes **1a** and **1b** retain their integrity in solution at elevated temperatures ([D_6]benzene, 80–100 °C, 2 days), whereas complex **1c** decomposed in solution at room temperature to Pb^0 and the known bridging diphosphide ligand complex [(μ_2:η^2,η^2-P_2){Nb[N(Np)Ar]$_3$}$_2$] (**3**),[11] over several hours; furthermore, the absence of light did not retard the decomposition of **1c**. Therefore, considering the fragile nature of **1c**, the mild conditions of the present synthesis,[12] condition which permitted it to be isolated in pure form, can be further appreciated.

The solid-state structures for complexes **1a–c** are depicted in Figure 1. The μ_2:η^3,η^3 disposition of the {*cyclo*-EP_2} ring between the two niobium centers is evident in each structure. The {*cyclo*-EP_2} units in **1b** and **1c** are near-perfect isosceles triangles, in which the ∢P-E-P angle in **1c** (48.85(5)°) is slightly more acute than that in **1b** (51.23(7)°) as a result of the larger covalent radius of the lead center. Indeed, the average E–P bond lengths in **1b** and **1c** (Sn–P: 2.571 Å, Pb–P: 2.677 Å) follow the trend of the covalent radii going from Sn to Pb and reflect values typical of Sn–P and Pb–P single bonds.[13] Additionally, the P–P distances of 2.223(2) and 2.213(3) Å for **1b** and **1c**, respectively, are in the range typical of P–P single bonds,[14] thus indicating a saturated electronic framework for these {*cyclo*-EP_2} rings when sandwiched between two reducing d^2 niobium centers.[11] Complex **1a**, however, was found to crystallize in the cubic space group $P2_13$ with its Nb–Nb vector coincident with a crystallographic C_3 axis. Unfortunately, this morphology resulted in a crystallographically imposed threefold compositional disorder of the ring atoms in the {*cyclo*-GeP_2} unit. Consequently, chemically suspect metrical parameters were obtained for the complexed {GeP_2} ring, in which the edge distance of 2.460 Å clearly exceeds the value for a P–P single bond and reflects structural dominance by the larger Ge component.[15]

To garner further insight into the geometrical structure of **1a**, the model construct [(μ_2:η^3,η^3-*cyclo*-GeP_2){Nb(NH_2)$_3$}$_2$] (**4a**) was subjected to full geometric optimization at the density functional level (ADF 2004.01, ZORA-TZ2P/BP86). Using the experimental metrical parameters of **1a** as the basis for the initial computational model structure, **4a** converged to a geometry with P–P (2.242 Å) and P–Ge (2.4465 Å av)

Scheme 1. Formation of complexes [(μ_2:η^3,η^3-*cyclo*-EP_2){Nb[N(Np)Ar]$_3$}$_2$] (**1a–c**). E = Ge, Sn, or Pb, respectively; Np = neopentyl, Ar = 3,5-$Me_2C_6H_3$, OTf = O_3SCF_3.

separations consistent with both P–P and P–Ge single bonds.[13,14] All other overall structural features for **4a** were similarly consistent with those found experimentally for **1b** and **1c**. Furthermore, the calculated structural parameters for models **4b** and **4c** were in excellent agreement with their experimental counterparts (**1b** and **1c**, respectively). Therefore, we contend that **4a** represents the molecular geometry for complex **1a** in the absence of crystallographic disorder.

Of particular interest are the electronic-structure attributes attendant with {*cyclo*-EP_2} complexation in **1a–c**. The highest occupied molecular orbitals (HOMOs) calculated for **4b** are shown in Figure 2.[16] The HOMO-1 is part of the σ framework of the {*cyclo*-SnP_2} unit, whereas complexation of the Nb centers consists of a pair of mutually orthogonal two-electron π backbonds. The HOMO involves the out-of-plane valence p orbital of the Sn center as the acceptor component in one of these bonds, whereas the HOMO-2 utilizes a P–P π* orbital as the acceptor component in the other bond. Accordingly, a pair of d^2 niobium trisamide fragments is seen to be electronically complementary to a formally neutral {*cyclo*-EP_2} ring. However, summation of the

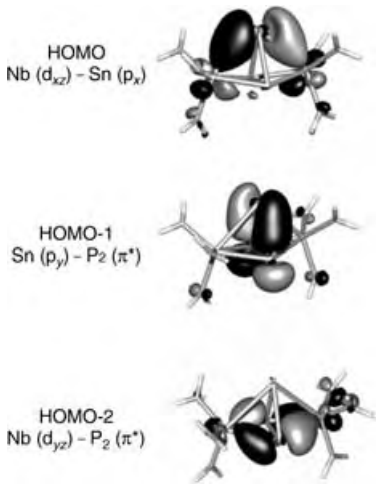

Figure 2. Selected frontier molecular orbitals calculated for **4b**.

calculated multipole-derived charges (MDC-q)[17] on the ring atoms in **4a–c** indicate that each complexed {*cyclo*-EP_2} unit bears a net charge of approximately −1.0 ($\Sigma_{MDC\text{-}q} = -1.186$, −0.917, and −0.837 a.u. for **4a–c**, respectively). Thus, although formally neutral as free entities, complexation by two electropositive d^2 Nb centers renders these {*cyclo*-EP_2} rings moderately anionic. The latter interpretation is consistent with the saturated nature of the {*cyclo*-EP_2} framework, as determined crystallographically for **1b** and **1c**.

It is noteworthy that the net negative charge calculated for the {*cyclo*-EP_2} rings in models **4a–c** decreases in the order Ge > Sn > Pb according to the decreasing electronegativity of the Group 14 atom.[18] Indeed, the negative charge at the phosphorus center is calculated to remain relatively constant between models **4a–c** (−0.384 ± 0.016 a.u.), and the variation in the net charge between each {*cyclo*-EP_2} ring is dictated by the charge at the E center (MDC-q = −0.390, −0.185, and −0.057 a.u. for **4a–c**, respectively). A similar dependence on the identity of the Group 14 atom is observed experimentally in the $^{31}P\{^1H\}$ NMR spectra of complexes **1a–c** in solution ($\delta^{31}P = -15.7$, 47.8, and 115.2 ppm for **1a–c**, respectively). The downfield progression in the resonances is attributed qualitatively to the increase in the paramagnetic component σ_{para} of the total ^{31}P nuclei shielding tensor σ_{total} as the Group 14 atom becomes less electronegative.[19] NMR calculations performed on models **4a–c** are consistent with this suggestion, thus revealing that variation in σ_{para} dominates σ_{total} and increases in the order Pb > Sn > Ge.[20] Mapping the principal components of σ_{para} onto the molecular frame of **4a–c** (Figure 3) reveals that $R(\sigma_{11})$ mediates an occupied–virtual coupling between the Nb_2–P_2 π* backbond (occupied) and the σ* framework (virtual) of the {EP_2} ring in the presence of an applied magnetic field. Thus, a molecular-orbital description of ^{31}P nuclei deshielding as influenced[21] by the identity of the Group 14 atom[22] within the {*cyclo*-EP_2} ring is afforded.

In conclusion, new triatomic molecules are of interest both as synthetic targets and theoretical constructs.[3,4] We have identified that complexed forms of {*cyclo*-EP_2} triangles

containing germanium, tin, and lead can be synthesized as a direct consequence of the remarkable chemistry of the niobium–phosphorus triple bond in phosphide anion **2**.[7,8] Future prospects in this area include chemical liberation of the {*cyclo*-EP_2} triangles, with an aim of establishing their reactivity patterns.

Experimental Section

$[(\mu_2{:}\eta^3,\eta^3\text{-}cyclo\text{-}EP_2)\{Nb[N(Np)Ar]_3\}_2]$ (**1a–c**):[10] Solutions of $[Na(thf)_x]\cdot$**2** (0.300 g, 0.380 mmol) in THF (5 mL) and the corresponding divalent Group 14 salt (0.47 equiv; $GeCl_2$·dioxane, $SnCl_2$, or $Pb(OTf)_2$ for **1a–c**, respectively) in THF (2 mL) were frozen separately in a glove-box cold well. On removal of the solutions from the cold well, the thawing solution containing the salt was added dropwise (approximately 0.6 mL) over 1 min to the thawing solution of $[Na(thf)_x]\cdot$**2**. The reaction mixture was stirred for an additional 3 min, whereupon both solutions were placed back into the cold well. This procedure was repeated twice more until complete addition of the divalent Group 14 salt was achieved. The reaction mixture was then allowed to warm to room temperature and stirred for an additional 30 min before being evaporated to dryness in vacuo. The residue was extracted with *n*-pentane (3 mL), the extract filtered through celite, and the filtrate evaporated to dryness in vacuo. Crystallization of each complex was effected by storing a saturated solution of Et_2O at −35 °C for 1–3 days.

Glycopeptide Synthesis

A General Strategy toward S-Linked Glycopeptides**

*Desiree A. Thayer, Henry N. Yu, M. Carmen Galan, and Chi-Huey Wong**

Glycosylation, the most complex posttranslational modification of proteins, is involved in a number of biological processes. Such highly complex glycan structures have challenged present methods used in the functional study of glycoproteins.[1–4] Therefore, the development of new methods for the syntheses of natural and unnatural homogeneously glycosylated proteins[5–7] is needed for a systematic understanding of glycan function. In this context, the syntheses of natural and modified glycopeptides represent a means for additional glycoprotein studies and therapeutic developments.[8–11]

Naturally occurring glycopeptides most commonly incorporate an O- or N-glycosidic linkage between the saccharide moiety and the side chain of an appropriate amino acid residue. Replacement of the anomeric oxygen or nitrogen atom by sulfur results in the corresponding S-linked glycopeptide, which is known to be more stable chemically,[12] more resistant to the action of glycosidases, and tolerated by most biological systems. Furthermore, members of the closely related S-linked oligosaccharides have been used as enzyme inhibitors[13,14] and are suggested to be better immunogens than their natural O-linked analogues.[15–18] An alternate modification is the C-glycosyl linkage, for which several synthetic methods exist.[19]

The common synthetic approach for S-linked glycosyl amino acids uses an anomeric thiolate nucleophile in reaction with an alanine derivative equipped with a leaving group (Figure 1). The major side reaction is β-elimination, and the subsequent Michael addition results in a diastereomeric mixture at the α-carbon of the amino acid product. Several procedures have since emerged to overcome this problem.[20–24] The most advanced among these is a method reported by Schmidt and co-workers,[24–27] in which the reaction of the thiosugar **1** with β-bromoalanine was performed in an ethyl acetate/water two-phase system containing tetra-*n*-butylammonium hydrogen sulfate (TBAHS) and $NaHCO_3$ (Figure 2). We have used this protocol for the

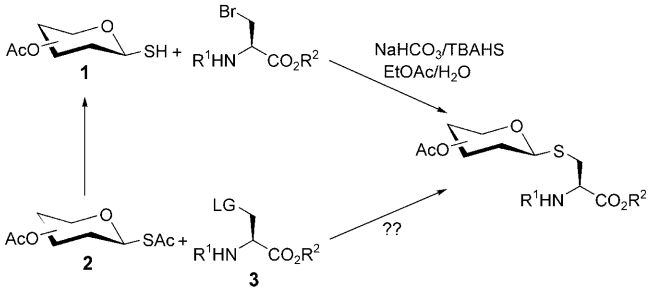

Figure 2. Reported procedure for the two-step synthesis of S-linked glycosyl amino acids and an alternative one-pot approach.

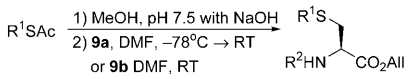
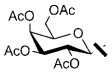
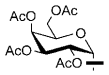
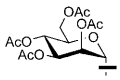
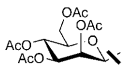


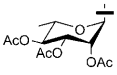
preparation of several different S-linked Boc- and Fmoc-modified glycosyl amino acids (Boc = *tert*-butoxycarbonyl, Fmoc = 9-fluorenylmethyloxycarbonyl). The Fmoc-protected compounds, however, can only be obtained indirectly from the S-linked Boc-modified glycosyl amino acids owing to the basicity of the reaction. The step for the generation of 1-thiosugars requires a special precaution, as it may give low yields due to the facile formation of disulfides during deacetylation of the sulfur atom and subsequent silica gel chromatography.

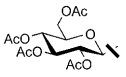


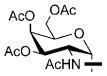


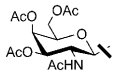


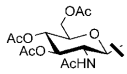


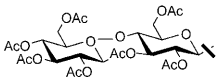




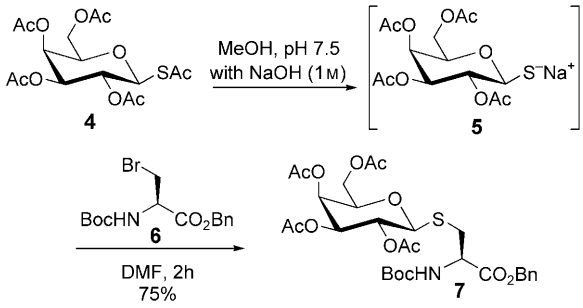








We therefore explored alternate reaction conditions in which thioacetate **2** and the alanine derivative **3** can be subjected to a one-pot reaction to generate the desired thio-linked glycosyl amino acid product (Figure 2). Such reaction conditions should meet several important criteria: first, deacetylation of the thioacetate group should be selective to generate the desired thiolate anion in situ, and to avoid β-elimination of the alanine derivative; second, dimethyl formamide (DMF) should be the solvent of choice, as solubility of large peptides in other solvents can be problematic;[24] furthermore, a set of optimal amino acid protecting groups should be employed to facilitate large-scale solid-phase peptide synthesis (SPPS).



With these goals in mind, we first screened numerous one-pot reaction conditions (Table 1, Supporting Information). A simple "two-step one-pot" reaction emerged as the method of choice (Scheme 1). Therein, with 2,3,4,6-tetra-*O*-acetyl-1-*S*-acetyl-1-thio-β-D-galactopyranose (**4**)[28] as a starting material, the anomeric thioacetate was selectively deprotected in situ with NaOH in anhydrous methanol (pH ≈7.5). After removing the methanol solvent, the resulting thiolate sodium salt **5** was subjected to nucleophilic substitution with β-bromoalanine **6** in dry DMF to give the desired S-linked galactosyl amino acid **7**. This reaction is simple yet very effective. It selectively deacetylates the sulfur atom, preserves the anomeric configuration,[29] and carries out the S_N2 displacement reaction effectively without disrupting the integrity of the α-carbon center. It is necessary to remove the methanol before the nucleophilic substitution reaction, as electrophile **6** would otherwise undergo β-elimination with sodium methoxide generated in situ.

As the Fmoc protecting group is labile in basic conditions, most of the procedures reported in the literature use Boc as

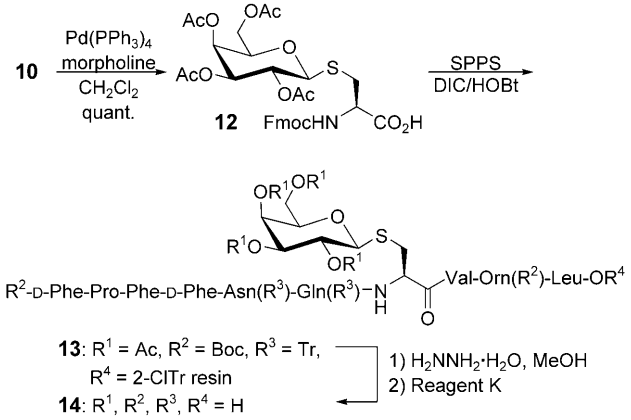
the temporary protecting group to sustain the alkaline conditions in the nucleophilic substitution reaction.[20,24] However, the Boc group must then be replaced with the Fmoc protecting group for the preferred Fmoc SPPS of glycopeptides.[30,31] After the reaction shown in Scheme 1 was carried out following this traditional method, we hypothesized that the basicity of intermediate **5** in DMF would be sufficiently mild to permit the S_N2 reaction with the Fmoc-protected β-bromoalanine species without affecting the Fmoc group itself. Thus, compound **8a** was prepared as reported in the literature (Scheme 2).[32] The allyl ester protecting group

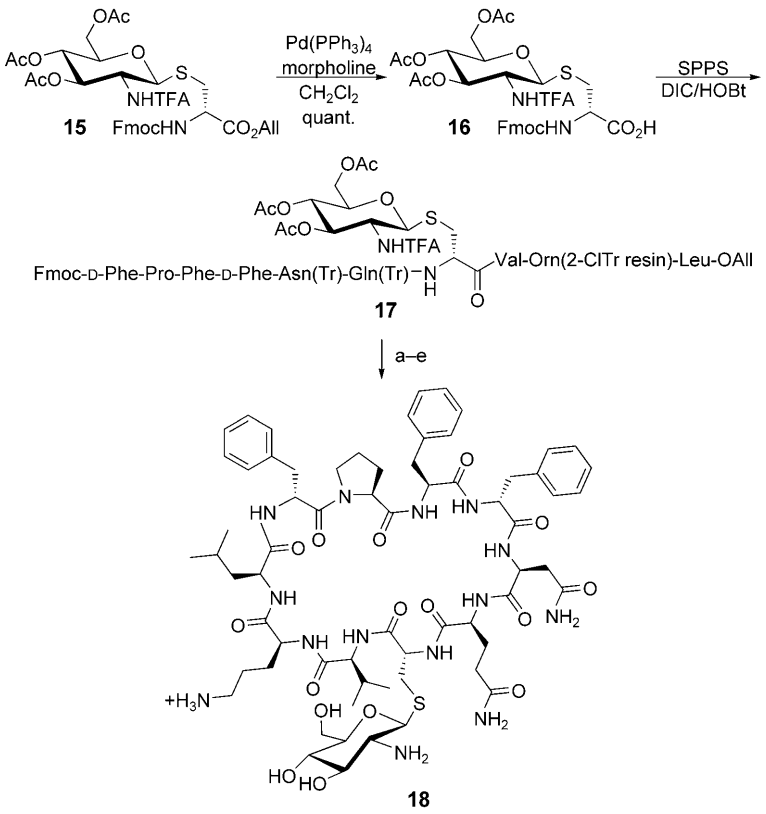


Scheme 2. A direct two-step one-pot synthesis of the S-linked Fmoc-modified glycosyl amino acid **10** with suppression of side product **11**.

was favored over the benzyl ester group, as it is easier to remove in high yield. Bromination of **8a** went smoothly with the solid-support Ph_3P resin and CBr_4 in dichloromethane to give **9a** (100%, TLC),[33] which was pure enough to carry out the next step without purification.[34] Upon performing the S_N2 reaction at ambient temperature, the desired amino acid **10** was obtained (54%), along with side-product **11** (27%). Thiolate **5** presumably attacks Fmoc-CH_2 to give **11**. To suppress the formation of this side-product, the reaction was performed at −78 °C to room temperature. We were gratified to observe that only compound **10** (79%) was formed without any trace of side product **11**.

S-linked glycosyl amino acid **10** was treated with tetrakis(triphenylphosphine)palladium(0) catalyst and morpholine in dichloromethane to give the Fmoc-modified building block **12** swiftly (100%, TLC), which was used without purification to afford the protected S-linked glycodecapeptide **13** (Scheme 3). Deacetylation of the sugar moiety was carried out on-resin by transesterification with hydrazine hydrate in methanol. Removal of the acid-labile amino acid protecting groups concomitant with cleavage from the 2-chlorotrityl resin by Reagent K afforded free S-linked glycopeptide **14** in pure form after HPLC. The whole process, starting from the readily available peracetylated 1-thio galactose to the final glycopeptide **14**, involved only two purifications (silica gel chromatography for **10** and HPLC for **14**). In fact, it is also possible to start with thiolate salt **5**, which can be stored under argon for up to a month without degradation.

Glycopeptide **14** is a linear analogue of tyrocidine A, which is a cyclic cationic decapeptide antibiotic produced in *Bacillus brevis* with an antiparallel amphipathic β-sheet



Scheme 3. Solid-phase peptide synthesis of glycopeptide **14** with Fmoc-modified glycosyl amino acid **12**. The yield from **12** to **14** is 60% (DIC = 1,3-diisopropylcarbodiimide, HOBt = 1-hydroxybenzotriazole, Tr = trityl).

conformation in solution.[35–38] A recent report has shown that several cyclic glycopeptide analogues of tyrocidine A retain biological activity as antibiotics.[39] To further test the method reported herein for the synthesis of S-linked glycopeptides, glycosyl amino acid **15** was synthesized and converted into **16**. After the removal of palladium by scavenger resin, the tyrocidine analogue precursor **17** was produced (Scheme 4). Conversion of **17** to cyclic glycopeptide **18** (an analogue of tyrocidine A in which the wild-type Tyr group at position 7 is replaced by a D-Ser(β-*S*-GlcNH$_2$) residue) was carried out in four steps on solid support followed by cleavage and amino acid side chain deprotection (29% overall yield from **16** to **18**). The biological activity of this glycosylated tyrocidine analogue was evaluated with the minimal inhibitory concentration (MIC) against *B. subtilis* as a measure of the antibiotic activity and the minimal hemolytic concentration (MHC) against human erythrocytes as an evaluation of eukaryotic membrane toxicity. The S-linked glycopeptide analogue **18** was shown to have a better antibiotic profile than tyrocidine A, with MIC values of 12.5 μM for both and MHC values of 100 and 50 μM, respectively.

Although Fmoc SPPS is preferred for glycopeptides, the synthetic approach reported herein should also be applicable for the synthesis of Boc-modified amino acid building blocks. Therefore, Boc-protected S-linked glycosyl amino acid building block **19** (Table 1) was synthesized from **4** and **9b** (Scheme 2) in a similar fashion.

To demonstrate that our approach is also applicable to other thiosugars, we synthesized several different peracetylated 1-thiosugars (Supporting Information). These represent all four possible classes of products: 1,2-*trans*-α (**21** and **23**[15]); 1,2-*trans*-β (**4**,[28] **24**,[40] **26**,[41] **27**,[42] and **28**[43]); 1,2-*cis*-α (**20** and **25**[23]); and 1,2-*cis*-β (**22**[29]). They are conveniently grouped based on the stereochemistry at C1 and its relationship to the functional group at C2 of the sugar ring. All compounds were subjected to the "two-step one-pot" conditions mentioned above to give the corresponding Fmoc- or Boc-protected S-linked glycosyl amino acid building blocks, in yields ranging from 66 to 81%.

Scheme 4. Solid-phase glycopeptide synthesis of the tyrocidine analogue **18**. Reagents and conditions: a) $[Pd(PPh_3)_4]$/4-methylmorpholine, $CHCl_3$; b) piperidine/DMF (20%); c) PyBOP/HOBt, DMF; d) $H_2NNH_2{\cdot}H_2O$, MeOH; e) TFA/CH_2Cl_2/triisopropylsilane (80:15:5); 29% overall yield from **16**. PyBOP = 1-benzotriazolyloxy-tris-(pyrollidino)phosphonium; TFA = trifluoroacetate.

In summary, we have developed a general strategy for S-linked glycopeptide synthesis. With a simple "two-step one-pot" reaction, peracetylated thiosugars are quickly converted into masked S-linked amino acid building blocks. Under such reaction conditions, deacetylation at the sulfur atom is selective, anomeric integrity is retained, and S_N2 substitution is stereoselective. Unmasking the building blocks by deallylation affords Fmoc- or Boc-protected amino acids, which are ready for SPPS. This strategy is applicable for large-scale S-linked glycopeptide synthesis and could also be used for other S-linked glycoconjugates.

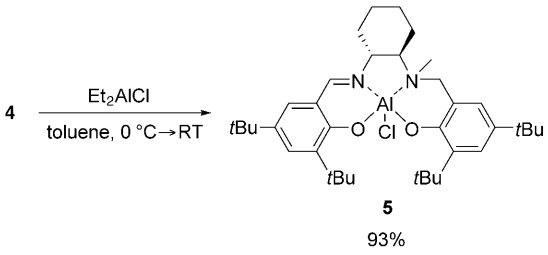
Asymmetric Catalysis

Synthesis of an Optically Active C_1-Symmetric Al(salalen) Complex and Its Application to the Catalytic Hydrophosphonylation of Aldehydes**



*Bunnai Saito and Tsutomu Katsuki**

For the last few decades asymmetric catalysis of optically active complexes has been a major topic in synthetic chemistry, and various types of chiral ligands have been introduced.[1] Among these, tetradentate ligands have been widely used because of their good ability to form complexes. In particular, chiral salen ligands have received a great deal of attention owing to their high asymmetry-inducing ability and ready availability. Chiral metallosalen complexes show potent and diverse asymmetric catalytic activities and have been used as catalysts for a wide range of enantioselective reactions, including epoxidation, aziridination, sulfoxidation, Michael reaction, epoxide opening, etc.[2] Salen complexes adopt mostly an octahedral configuration in which two ancillary ligands are *trans*-oriented. However, recent studies have disclosed that *cis*-β isomers show unique catalytic behavior.[2c] For example, a di-μ-oxo Ti(salen) complex that bears chiral *cis*-β-salen ligands catalyzes asymmetric cyanation with high enantioselectivity.[3] Furthermore, a di-μ-oxo Ti(salen) complex has been found to be an excellent pre-catalyst for asymmetric sulfoxidation, in which a monomeric *cis*-β-peroxo complex has been proven to be the active species.[4] Kol and co-workers reported quite recently that treatment of an achiral hybrid salan/salen tetradentate [ONN(Me)O]-type ligand (hereafter referred to as salalen) with titanium and zirconium tetraethoxides yielded the corresponding octahedral Ti- and Zr(salalen)$(OEt)_2$ complexes, in which the two diastereotopic ethoxy groups are *cis*-oriented and the coordinated amino nitrogen atom that is closer to the metal ion by one C–C bond than the ethylene carbon is chiral.[5] Thus, we expected that the chiral salalen ligand would establish a unique asymmetric reaction site that induces a high extent of asymmetry. Herein, we describe the synthesis of a chiral aluminum salalen complex and its application to the asymmetric hydrophosphonylation of aldehydes to give optically active α-hydroxy phosphonates.

We initially attempted the synthesis of an optically active salalen ligand according to Kol's procedure, but the attempt ended in failure because the key Mannich condensation of 2,4-di(*tert*-butyl)phenol and chiral secondary amines derived from cyclohexane-1,2-diamine and 1,2-diphenylethylenediamine did not proceed. Thus, the salalen ligand **4** was synthesized in a stepwise manner (Scheme 1). Reductive amination of aldehyde **2** with monoammonium salts of diamine **1**[6] in the presence of sodium borohydride, followed by *N*-protection with the *tert*-butoxycarbonyl (Boc) group, gave the corresponding amine **3** in 67% yield. The *N*-methylation of amine **3**, deprotection of the Boc group with aqueous HCl, and condensation of the resulting primary amine with aldehyde **2** afforded the desired ligand **4** in 76% yield. The salalen ligand **4** was then treated with Et_2AlCl to give the corresponding Al(salalen) complex **5** in high yield (Scheme 2). Recrystallization of **5** from heptane and dichloromethane gave single crystals, one of which was submitted for X-ray diffraction analysis (Figure 1).[7] This analysis demonstrated that complex **5** has a unique structure that is different from that of Al(salen) complexes:[8] it adopts a distorted trigonal-bipyramidal configuration, and the absolute configuration of the coordinated tertiary amine is *S*. As the chiral ligand adopts a unique *cis*-β-like structure and as the methyl group on the nitrogen atom is located in the middle of the chiral ligand and close to the chloro ligand that should be replaceable by a substrate such as an aldehyde, we expected that the orientation of the substrate ligated to the

aluminum ion should be efficiently regulated by the ligand. Thus, we considered that **5** should be a highly efficient chiral Lewis acid catalyst. To explore the catalytic behavior of **5**, we first examined the asymmetric hydrophosphonylation of aldehydes.

Optically active α-hydroxy phosphonates and phosphonic acids are biologically active compounds that are widely used in pharmaceutical applications, and much effort has been directed toward the development of asymmetric hydrophosphonylation of carbonyl compounds (the Pudovik reaction).[9,10] To the best of our knowledge, LLB ($LaLi_3$tris(binaphthoxide)) and ALB (AlLibis(binaphthoxide)) reported by Shibasaki and co-workers are the most efficient catalysts for this reaction and have been complementarily used as catalysts for the reaction of various aldehydes.[10d,f] Recently, Kee and co-workers reported that chiral Al(salen) complexes serve as catalysts for asymmetric hydrophosphonylation; however, the enantioselectivities obtained were modest (up to 49% *ee*).[11] The introduction of a novel catalyst that can show wide applicability for various aldehydes, especially aliphatic ones, is therefore still required to achieve a highly efficient Pudovik reaction.

With the Al(salalen) complex **5** in hand, we first examined the asymmetric hydrophosphonylation of benzaldehyde with dimethyl phosphite at room temperature under various conditions (Table 1, entries 1–5). All the reactions proceeded smoothly to give the desired product in acceptable yields and the best enantioselectivity was observed in the reaction with diisopropyl ether as solvent. The reactions with dialkyl phosphites, especially dimethyl phosphite, showed better enantioselectivities than those with diphenyl phosphite (see entries 1–3). Lowering the temperature of the reaction in diisopropyl ether to 0°C improved the enantioselectivity to 89% *ee* (entry 7), whereas a further reduction of the temperature affected the reproducibility of the enantioselectivity (entry 9).[12] The enantioselectivity of the reaction in THF was inferior to that in diisopropyl ether at room temperature, but the reaction at −15°C showed the best and most reproducible enantioselectivity of 90% *ee*, albeit with some reduction of the chemical yield (entry 8).

Thus, we examined the asymmetric hydrophosphonylation of various aldehydes with complex **5** as catalyst at −15°C in THF (Table 2). The electronic effect on enantioselectivity was investigated with *para*-substituted benzaldehyde derivatives, and we found that an electron-withdrawing group increases the enantioselectivity (entries 1–3); the highest enantioselectivity of 94% *ee* was observed in the reaction with *p*-nitrobenzaldehyde (entry 1), although the reaction of *o*-chlorobenzaldehyde also proceeded with high enantioselectivity (entry 4). The reaction of an α,β-unsaturated aldehyde (cinnamaldehyde) was a little slow and showed a slightly reduced enantioselectivity of 83% *ee* (entry 5). To our delight, high enantioselectivity was also observed in the reactions of aliphatic aldehydes. Both nonbranched (entries 6 and 8) and branched (entry 7) aliphatic aldehydes gave the corresponding α-hydroxy phosphonates with high enantioselectivities and in good yields. To the best of our knowledge, this is the first example where a molecular catalyst can be

applied to the reactions of both aromatic and aliphatic aldehydes with enantioselectivities greater than 80% *ee*.

In conclusion, we have synthesized a chiral, trigonal-bipyramidal aluminum(salalen) complex **5** that provides a unique asymmetric reaction site in which an asymmetric nitrogen atom is bound to the metal ion and the *N*-methyl group is *cis* to the chloro ligand. Moreover, complex **5** is an efficient catalyst for the enantioselective hydrophosphonylation of various aldehydes with dimethyl phosphite. Further application of this novel aluminum complex to other asymmetric reactions is under investigation.

Experimental Section

Complex **5** (12.5 mg, 0.02 mol) and dimethyl phosphite (10.1 μL, 0.21 mmol) were dissolved in THF (1.0 mL) under nitrogen, and the solution was stirred for 10 min at room temperature. After cooling to −15 °C, aldehyde (0.20 mmol) was added to the solution and the solution was stirred for 48 h. The reaction was quenched with 1 M HCl and extracted with AcOEt (3 × ca. 1 mL), and the combined organic phase was passed through a pad of Celite and Na_2SO_4. After removal of the solvent under reduced pressure, the residue was chromatographed on silica gel (hexane/acetone, 7:3–3:7) to give the corresponding α-hydroxy phosphonate. The *ee* values were determined by HPLC on a chiral stationary phase under the conditions described in the footnotes to Table 1 and Table 2.

[12] Complex **5** and the product, dimethyl α-hydroxyphenylmethylphosphonate, are weakly soluble in diisopropyl ether. A suspension of **5** in diisopropyl ether became homogeneous upon addition of dimethyl phosphite, but the solution became heterogeneous again as the reaction proceeded. This turbidity might reduce the reproducibility of the enantioselectivity of the reaction at −15 °C.

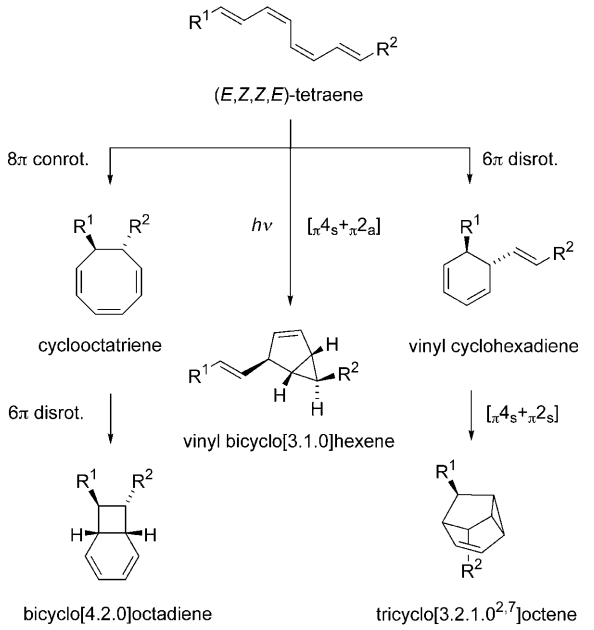
Natural Products Synthesis

Mining the Tetraene Manifold: Total Synthesis of Complex Pyrones from *Placobranchus ocellatus***

*Aubry K. Miller and Dirk Trauner**



Conjugated tetraenes featuring *Z*-configured double bonds can undergo various cyclizations to rapidly generate molecular complexity. Different modes of thermal or photochemical electrocyclizations and cycloadditions afford structurally diverse scaffolds from a relatively simple (*E*,*Z*,*Z*,*E*)-tetraene precursor (Scheme 1).[1] If the tetraene is unsymmetrical ($R^1 \neq R^2$), additional pathways exist that lead to regioisomers and diastereomers. Isomerizations of the polyene geometry further increase the number of potential cyclization products, thus rendering this reaction manifold dauntingly complex.

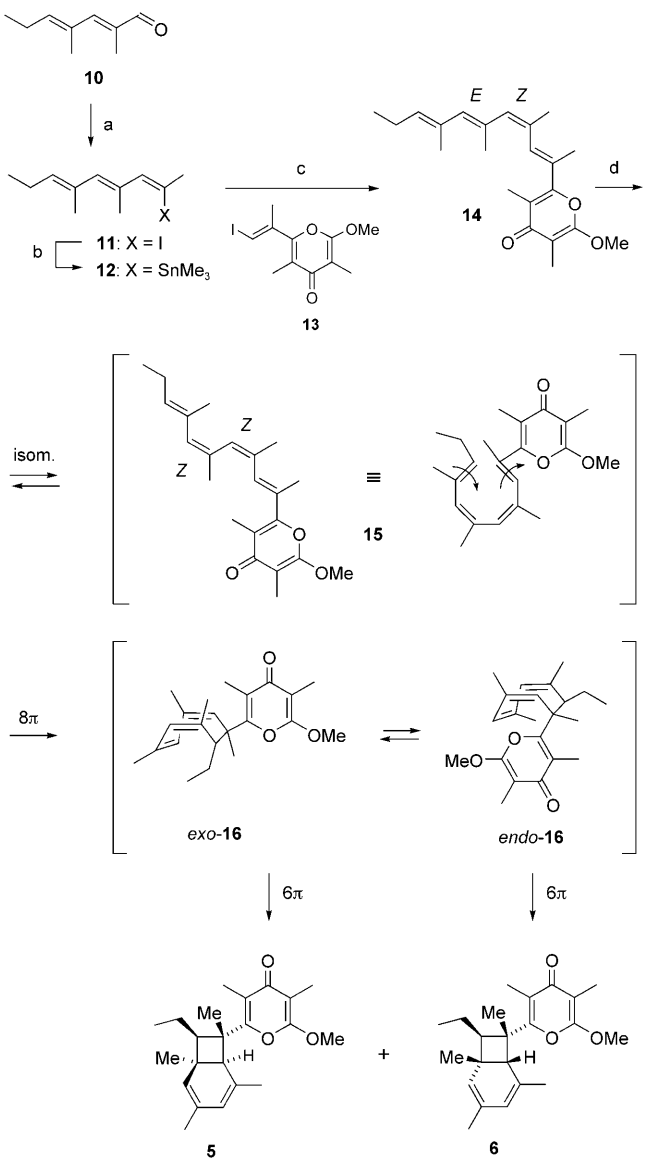
Scheme 1. The tetraene manifold. conrot. = conrotatory, disrot. = disrotatory.

Scheme 2. Polypropionate pyrones isolated from saccoglossan mollusks.

Many of the molecular scaffolds shown in Scheme 1 have been found among natural products isolated from saccoglossan mollusks (Scheme 2). The cyclohexadienes 9,10-deoxytridachione (**1**) and tridachiapyrone A (**2**) were isolated from sea slugs of the genus *Elysia*, which also yielded the bicyclo[3.1.0]hexenes photodeoxytridachione (**3**) and crispatene (**4**).[2]



Recently, several new α-methoxy-γ-pyrones that feature a bicyclo[4.2.0]octane, -octene, or -octadiene skeleton were also found in saccoglossan mollusks. Two unnamed natural products, bicyclo[4.2.0]octadiene **5** and endoperoxide **7**, were found in *Placobranchus ocellatus* which we propose to call ocellapyrones A and B, respectively.[3] Although structure **6** was originally proposed for the bicylco[4.2.0]octadiene natural product (ocellapyrone A), our results (see below) and a recent report by Baldwin and co-workers[4] lead to the reassignment of its structure as **5**. Furthermore, two pyrones with a bicyclo[4.2.0]octane skeleton, elysiapyrones A (**8**) and B (**9**), were isolated from *Elysia diomedea*.[5] Their unusual bisepoxide moiety was proposed to arise biosynthetically from rearrangement of an *endo* peroxide analogous to **7**, which in turn would stem from the corresponding bicyclo[4.2.0]hexadiene through a Diels–Alder reaction that involved singlet oxygen. Note that the elysiapyrones contain one carbon atom less than the ocellapyrones, presumably because of the incorporation of an acetate moiety rather than a propionate unit into their biosynthetic precursor.

Biosynthetically, bicyclo[4.2.0]octadienes **5** and **6** and their oxidized analogues **7**–**9** probably stem from 8π–6π electrocyclization cascades.[6] Similar cascades have been proposed in the biosynthesis of the endiandric acids,[7] as well as the immunosuppressants SNF4435 C/D,[8] and verified by total synthesis.[9]

Herein, we report a synthesis of the racemic ocellapyrones A (**5**) and B (**7**), which originated from a serendipitous discovery. In our previous reports on the total synthesis of photodeoxytridachione (**3**) and crispatene (**4**), we speculated on the possibility of a unified synthetic approach toward both the bicyclo[3.1.0]hexene and cyclohexadiene natural products that would start from an α-methoxy-γ-pyronyl tetraene of type **14** (Scheme 3).[10] To test this hypothesis, vinyl stannane **12** was prepared from the known aldehyde **10** in two steps[11] and then subjected to the Stille coupling procedure[12] with the previously described pyrone building block **13**.[10c,13] The resultant pyronyl tetraene **14**, however, turned out to be quite unstable, as judged by TLC and NMR spectroscopic analysis.

When **14** was heated to 45 °C in $CHCl_3$, a very complex mixture of isomers was formed initially, which over five days gradually converged into bicylo[4.2.0]octadiene **6** accompanied by smaller amounts of ocellapyrone A (**5**). Presumably, *E/Z* isomerization of **14** took place under these conditions to yield (*E*,*Z*,*Z*,*E*)-tetraene **15**. This intermediate then underwent conrotatory 8π electrocyclization to afford cyclooctatriene **16**, which exists as a mixture of *exo* and *endo* conformers. Subsequent 6π electrocyclization of *exo*-**16** gave (±)-ocellapyrone A (**5**), whereas cyclization of *endo*-**16** afforded **6**. Since purified ocellapyrone A (**5**) could not be converted into **6** under the same reaction conditions, this product ratio presumably reflects kinetic control.[14]

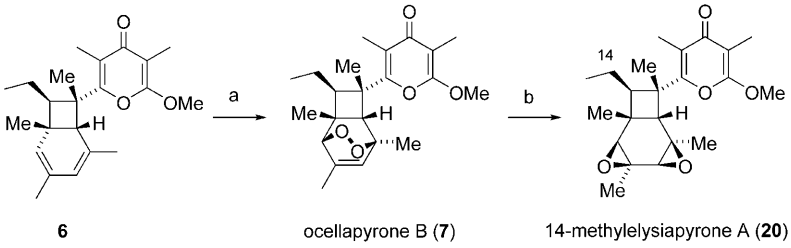
Scheme 3. Synthesis of γ-pyronyl tetraene **14** and cyclization to **5** and **6**. Reagents and conditions: a) $Ph_3P{=}CHCH_3$, I_2, NaHMDS, −78 °C, THF (59%); b) *n*BuLi, $SnMe_3Cl$, −78 °C, THF (69%); c) **13**, 5 mol% $[Pd(PPh_3)_4]$, 350 mol% CsF, 10 mol% CuI, DMF, 1.5 h, 45 °C (89%); d) $CDCl_3$, 45 °C, 5 days (13% **5**; 66% **6**). HMDS = hexamethyldisilazide, DMF = *N*,*N*-dimethylformamide, isom. = isomerization.

The ^1H and ^{13}C NMR spectra of synthetic ocellapyrone A (**5**) match the reported spectra of the previously unnamed bicylo[4.2.0]octadiene natural product isolated from *Placobranchus ocellatus*, whereas the spectra of **6**, which represents the originally proposed structure, show marked differences.[15] The detailed structures of **5** and **6** were elucidated by extensive NOE interaction studies and the conversion of **6** into ocellapyrone B (**7**), whose relative configuration has been unequivocally assigned.[3,16]



A more rational synthesis of **5** and **6** is shown in Scheme 4. Olefination of the known aldehyde **17**[17] followed by iodine–tin exchange, as before, gave vinyl stannane **18**. This material was then coupled to the known vinyl iodide **19**[4,18] under Stille conditions. The resultant tetraene **15** underwent 8π–6π electrocyclization in situ to give a 1:9 mixture of **5** and **6**. Note that the *endo* isomer **6** again prevailed. The much faster formation of the bicyclo[4.2.0]octadienes under these conditions presumably reflects the fact that **15** does not need to undergo *E*/*Z* isomerization to trigger the electrocyclization cascade, which is apparently the rate-determining step in the conversion of **14** into **5** and **6**.

Scheme 4. Rational synthesis of ocellapyrones A and B. Reagents and conditions: a) $Ph_3PCHICH_3$, NaHMDS, −78 °C, THF (12%); b) *n*BuLi, $SnMe_3Cl$, −78 °C, THF (86%); c) **13**, 6 mol% $[Pd(PPh_3)_4]$, 180 mol% CsF, 17 mol% CuI, DMF, 1 h, 45 °C (8% **5**; 78% **6**).

Racemic ocellapyrone B (**7**) was obtained in high yield from cyclohexadiene **6** by a [4+2] cycloaddition of singlet oxygen (Scheme 5). The synthetic material was identical in all respects (^1H and ^{13}C NMR, IR, MS) to the natural product.[3] Finally, ruthenium-catalyzed isomerization[19] of ocellapyrone B (**7**) gave bisepoxide **20**, which is a homologue of elysiapyrone A. Although this compound has not been isolated from natural sources so far, it seems entirely possible that it could be found, as endoperoxides can be readily converted into bisepoxides both under thermal and photochemical conditions.[20] The X-ray crystal structure of **20**, with its appealing "crouched" shape, is shown in Figure 1.[21]

In summary, we have demonstrated that complex pyrones isolated from saccoglossan molluscs can be synthesized by isomerization of stereochemically labile tetraenes followed by pericyclic reaction cascades. In combination with our previous

Scheme 5. Synthesis of ocellapyrone B and 14-methylelysiapyrone A. Reagents and conditions: a) O_2, methylene blue, $CHCl_3$, *hν*, reflux, 30 min (89%); b) 10 mol% $[RuCl_2(PPh_3)_3]$, CH_2Cl_2, 2 h (86%).

total syntheses of photodeoxytridachione[10a,b] and crispatene,[10c] these results demonstrate the remarkable versatility of conjugated polyenes as precursors for complex polycyclic molecular skeleta. On the basis of our experience with these compounds,[22] we predict that further bicylo[4.2.0]octadiene natural products and oxidized versions thereof, in particular isomers of crispatene and tridachiapyrone A, will be found. Studies toward asymmetric electrocyclization cascades and the total synthesis of the elysiapyrones are well underway and will be reported in due course.

[14] The outcome of this isomerization was found to be strongly dependent on the conditions employed; for example, tetraene **14** underwent isomerization under microwave irradiation (PhMe, 150 °C, 20 min) to afford 9,10-deoxytridachione (**1**) and ocellapyrone A (**5**) in approximately equal amounts.

[15] In the reported isolation of bicyclo[4.2.0]octadiene **5** and endoperoxide **7** (Ref. [3]), the relative structure of ocellapyrone A was "… mainly determined on the basis of NOE difference and NOESY experiments recorded on the peroxide derivative [= ocellapyrone B]".

[16] Independent confirmation of the structure of **5** was obtained by conversion into the corresponding *endo* peroxide, whose structure was determined by X-ray crystallographic analysis. [22] In our previous reports on photodeoxytridachione (Ref. [10a,b]), we erroneously reported the 6π electrocyclization

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of tetraenoic ester **21** to afford cyclohexadiene **22**. The "upfield shift" of a vinyl proton ($\delta = 2.93$ ppm) was rationalized with an anisotropic effect exerted by the nearby ester carbonyl group. In fact, double-bond isomerization followed by a stereoselective 8π–6π electrocyclization cascade had taken place. Therefore, the product of this very high-yielding and stereoselective reaction is reassigned as **23**. The structure of **23** was confirmed by reduction of the ester function to a primary alcohol followed by acid-catalyzed ring closure to the caged tricyclic compound **24**. (DIBAH = diisobutylaluminum hydride.)

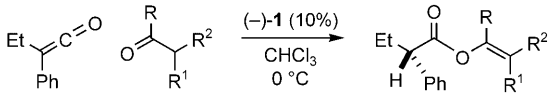
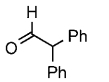
Asymmetric Catalysis

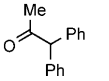
Catalytic Asymmetric Couplings of Ketenes with Aldehydes To Generate Enol Esters**

*Carsten Schaefer and Gregory C. Fu**



The synthesis of enantiopure α-arylalkanoic acids is an objective of significant interest, due in part to the bioactivity and commercial importance of this family of compounds.[1] One approach that has been pursued in industry is the asymmetric addition of alcohols to aryl alkyl ketenes to generate chiral esters (which can then be hydrolyzed to α-arylalkanoic acids).[2–5] Herein, we report a new method for the enantioselective synthesis of esters: the catalytic asymmetric coupling of a ketene with an aldehyde [Eq. (1)].





(1)

In the presence of planar-chiral dimethylaminopyridine (DMAP) derivative **1**,[6] we observed no reaction between phenyl ethyl ketene and *n*-decanal (Table 1, entry 1). In contrast, phenylacetaldehyde coupled with the ketene to furnish an enol ester in modest yield and with very good enantioselectivity (entry 2). Diphenylacetaldehyde was an excellent reaction partner (entry 3: 91% *ee*, 84% yield), whereas a related ketone was not (entry 4).[7,8]

Table 1: Survey of carbonyl compounds: Catalytic asymmetric couplings with ketenes.[a]

Entry	Carbonyl compound	*ee* [%]	Yield [%][b]
1		–	0
2		92	55
3		91	84
4		–	0

[a] All data are the average of two experiments. [b] Isolated product.

As illustrated in Table 2, we achieved the catalytic asymmetric synthesis of a wide array of enol esters of α-arylalkanoic acids through couplings of ketenes with diphenylacetaldehyde.[9–11] Thus, reactions of phenyl alkyl ketenes, in which the alkyl group ranges in size from methyl to *tert*-butyl, proceeded with moderate to excellent enantioselectivity (Table 2, entries 1–6). Furthermore, the addition occurred with very good stereoselectivity regardless of whether the aromatic group of the ketene was bulky (Table 2, entries 7 and 8), electron-rich (entries 8 and 9), or electron-poor (entry 10).

Enol esters are attractive targets in synthetic organic chemistry, in part as a result of the ease with which they can be

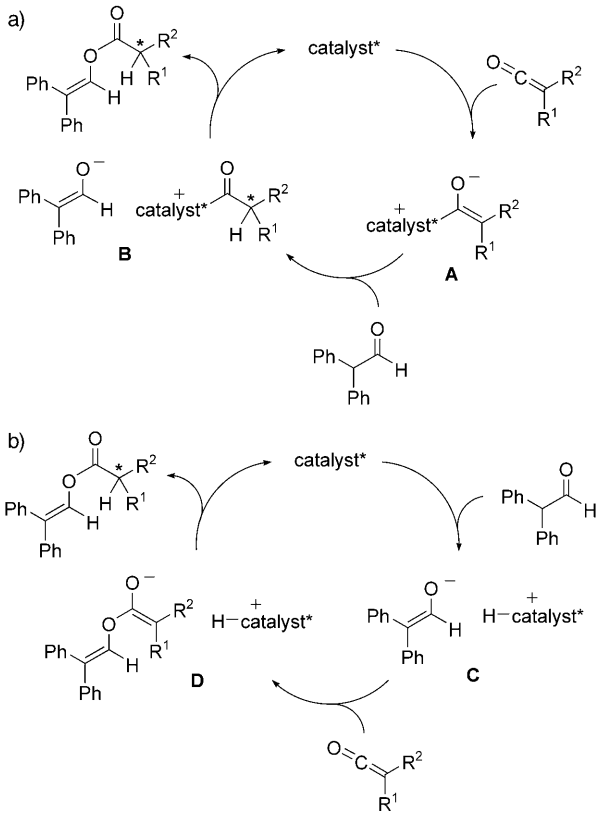
converted into other useful families of compounds. We have established that our diphenyl-substituted enol esters can be hydrolyzed and reduced under mild conditions without racemization [Eqs. (2) and (3)].[12]

(2)



(3)

A number of mechanisms, two of which are illustrated in Scheme 1, can be envisioned for this new catalytic asymmetric coupling of ketenes with aldehydes to generate enol esters. In one possible pathway (Scheme 1a), catalyst **1** serves as a nucleophile and adds to the ketene to afford chiral enolate **A**,[13] which undergoes diastereoselective protonation by the aldehyde to furnish the ion pair **B**. Acylation of the enolate by the acylpyridinium ion then produces the enantioenriched enol ester and regenerates the catalyst.

Alternatively, the role of catalyst **1** may be to serve as a Brønsted base/acid (Scheme 1b). According to this hypothesis, the catalyst deprotonates the aldehyde to furnish an achiral enolate **C**. This nucleophilic enolate then adds to the electrophilic ketene to produce a new achiral enolate **D**,[14] which undergoes enantioselective protonation by its counterion (protonated **1**, a chiral Brønsted acid) to thereby generate the enol ester.[15]

To date, we have made the following observations with respect to the reaction pathway:

- The *ee* value of the product correlates linearly with that of the catalyst;[16]
- When catalyst **1** is mixed with one equivalent of diphenylacetaldehyde, there is no evidence for deprotonation of the aldehyde to form an ion pair;[17]

Scheme 1. Two of the possible mechanisms for the coupling of ketenes with aldehydes to form enol esters: a) nucleophilic catalysis and b) Brønsted acid/base catalysis.

- In the presence of catalyst **1**, the α proton of diphenylacetaldehyde exchanges rapidly with D_2O at 0 °C (in the absence of **1**, there is essentially no exchange after 3 days at room temperature);
- A small primary kinetic isotope effect is observed ($k_H/k_D \approx 2$ for the reaction of diphenylacetaldehyde relative to α-*d*-diphenylacetaldehyde).[18]

These data can be accommodated by either of the pathways illustrated in Scheme 1, as well as by others. A detailed mechanistic investigation will be required in order to gain improved insight into this interesting process.

In summary, we have developed a new method for the synthesis of enantioenriched esters: the catalytic asymmetric coupling of ketenes with aldehydes. We have established that this approach provides access to a wide array of α-arylalkanoic acid derivatives. Future studies will build upon our preliminary mechanistic observations to elucidate the reaction pathway for this intriguing transformation.

[6] For leading references, see: G. C. Fu, *Acc. Chem. Res.* **2004**, *37*, 542–547.

[7] For a report of the O-acylation of β-ketoesters upon treatment with excess ketene ($O{=}C{=}CH_2$) and pyridine, see: K. W. Rosenmund, G. Kositzke, H. Bach, *Chem. Ber.* **1959**, *92*, 494–501.

[8] In contrast, treatment of a ketene with catalyst **1** and a non-enolizable aldehyde (e.g., PhCHO) leads to [2+2] cycloaddition to generate a β-lactone with good stereoselectivity: J. E. Wilson, G. C. Fu, *Angew. Chem.* **2004**, *116*, 6518–6520; *Angew. Chem. Int. Ed.* **2004**, *43*, 6358–6360.

[9] Interestingly, under these conditions, catalyst **1** does not rearrange the enol ester to a 1,3-dicarbonyl compound. For example, see: I. D. Hills, G. C. Fu, *Angew. Chem.* **2003**, *115*, 4051–4054; *Angew. Chem. Int. Ed.* **2003**, *42*, 3921–3924.

[10] General procedure: Under argon, a solution of the ketene (1.0 equiv) in $CHCl_3$ was added by syringe over 7 min to a solution of the catalyst (10%) and diphenylacetaldehyde (1.1 equiv) in $CHCl_3$ at 0 °C. The resulting solution was stirred at 0 °C, and then the reaction was quenched by the addition of MeOH (1 mL). The solvent was removed by rotary evaporation, and the residue was purified by column chromatography.

[11] Notes: a) The reaction of phenyl ethyl ketene with diphenylacetaldehyde proceeds in moderate to excellent enantioselectivity in a variety of solvents (e.g., toluene, Et_2O, EtOAc, 1,2-dimethoxyethane, THF, and CH_2Cl_2; however, not *N*-methylpyrrolidone); b) Slightly lower *ee* values were observed at room temperature; c) Typically, ca. 85% of catalyst **1** can be recovered at the end of the reaction.

[12] These enol esters are more reactive than the aryl esters produced by the addition of 2-*tert*-butylphenol to ketenes (see ref. [4b]).

[13] For other processes catalyzed by **1** that are believed to proceed through chiral enolate **A**, see: a) B. L. Hodous, G. C. Fu, *J. Am. Chem. Soc.* **2002**, *124*, 1578–1579; b) Ref. [8].

[14] For a pioneering study of the O-acylation of enolates by ketenes, see: K. Yoshida, Y. Yamashita, *Tetrahedron Lett.* **1966**, *7*, 693–696.

[15] For a process catalyzed by **1** that is believed to proceed through an analogous chiral Brønsted base/acid pathway, see ref. [4b].

[16] For a review of nonlinear effects in asymmetric catalysis, see: H. B. Kagan, T. O. Luukas in *Comprehensive Asymmetric Catalysis* (Eds.: E. N. Jacobsen, A. Pfaltz, H. Yamamoto), Springer, New York, **1999**, chapt. 4.1.

[17] This behavior contrasts with enantioselective additions of 2-*tert*-butylphenol to ketenes catalyzed by **1** in which the catalyst deprotonates the phenol; the mechanism is likely a chiral Brønsted acid catalyzed pathway (see ref. [4b]).

[18] Owing to the rapidness of the reaction at 0 °C, this experiment was conducted at −90 °C ($t_{1/2} \approx 1$ h).

Organic Synthesis

Synthesis of Seven-Membered-Ring Ketones by Arylative Ring Expansion of Alkyne-Substituted Cyclobutanones**

*Takanori Matsuda, Masaomi Makino, and Masahiro Murakami**

Medium-sized carbocyclic ring systems are often present as the structural core in natural products of interesting biological activities. Thus, the development of new synthetic methods for medium-sized carbocyclic rings has been one of the prime targets in organic synthesis.[1] Fragmentation of an easily accessible bicyclic system circumvents unfavorable enthalpic and entropic factors associated with direct formation of the medium-sized ring by annulation or cyclization.[2] A number

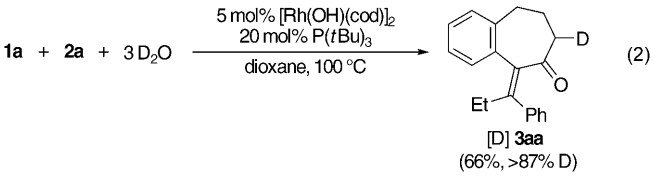
of ring-expansion reactions, which are promoted by acids, radicals, and transition metals, as well as heat, have been developed. Most of them are aided by the release of ring strain as the driving force.

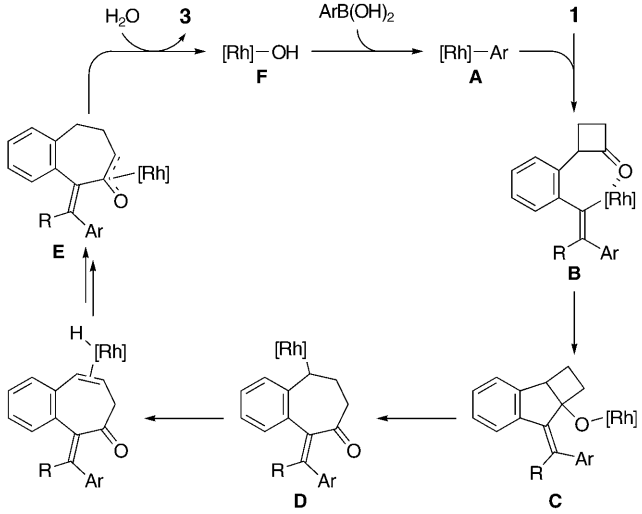
Recently, we found that an arylrhodium adds to a cyclobutanone intermolecularly to afford a ring-opened ketone through β-carbon elimination from the resulting rhodium cyclobutanolate.[3] We then envisaged that intramolecular addition of an organorhodium group to cyclobutanone[4] followed by β-carbon elimination would provide a ring-expansion process [Eq. (1)]. Herein, we describe a new method for construction of seven-membered ring skeletons.

(1)

To establish a route to an organorhodium species necessary for such intramolecular additions, cyclobutanones **1** that bear an alkyne moiety were designed (Scheme 1). 2-(2-But-1-ynylphenyl)cyclobutanone (**1a**) was synthesized in three steps



Scheme 1. Rhodium-catalyzed reaction of alkyne-substituted cyclobutanone **1a** with triphenylboroxin (**2a**). [a] Estimated from ^{1}H NMR spectroscopy of the crude reaction mixture.

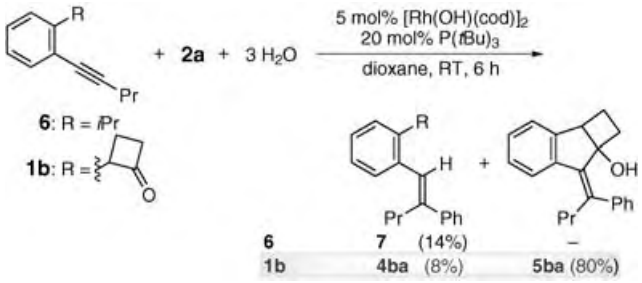


starting from commercially available 2-bromobenzaldehyde.[5] As a rhodium catalyst, we initially employed hydroxo(diolefin)rhodium(I) complexes, which have recently been used successfully in the rhodium-catalyzed reactions of arylboronic acids.[4b,d] Thus, a mixture of **1a**, triphenylboroxin (**2a**, 1.0 equiv), and water (3.0 equiv)[6] was heated in the presence of $[Rh(OH)(cod)]_2$ (10 mol% Rh; cod = cyclo-1,5-octadiene) in 1,4-dioxane at 100 °C. After heating for 6 h, seven-membered-ring ketone **3aa** was isolated in 54% yield along with small amounts of 1,2-adduct **4aa** and cyclobutanol **5aa**. The use of $P(tBu)_3$ as the additional ligand improved the yield of **3aa** to 73% without the formation of **4aa** and **5aa**.

The reaction in the presence of D_2O gave [D]**3aa** with deuterium incorporated exclusively at the α position of the carbonyl group, suggesting the formation of η^3-oxaallylrhodium prior to protonolysis, as previously reported [Eq. (2)].[3]

We propose the following mechanism for the transformation, which consists of a consecutive array of two C–C bond-forming and one C–C bond-cleaving steps (Scheme 2).

(2)



Scheme 2. Proposed mechanism for the formation of **3** from **1**.

Arylrhodium species **A**, generated from hydroxorhodium **F** and arylboronic acid, adds regioselectively across the carbon–carbon triple bond[4b–d,6b,7] of **1** in preference to the carbonyl group to afford vinylrhodium species **B**. Then, 1,2-addition to the adjacent carbonyl group of the cyclobutanone[4] forms rhodium cyclobutanolate **C**. β-Carbon elimination occurs regioselectively with the benzylic carbon atom,[8] and thus the bicyclic [3.2.0] skeleton of **C** is expanded with release of the ring strain to give alkylrhodium **D**. Successive β-hydride elimination/readdition processes take place, leading to the formation of η^3-oxaallylrhodium **E**.[9] Finally, protonolysis of **E** yields **3** and regenerates **F**.

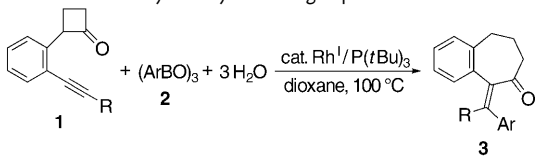
Compound **4aa** is produced when the vinylrhodium species **B** is protonated through a 1,4-shift of rhodium. Protonolysis of the cyclobutanolate **C** affords **5aa**.

To examine the effect of coordination of the carbonyl group of **1**, a control experiment was carried out using 2-isopropyl-1-(pent-1-ynyl)benzene (**6**), whose alkyne structure is sterically similar to that of **1**, which comprises a cyclobutanone moiety (Scheme 3). The reaction of **6** with **2a** was sluggish at room temperature to give 1,2-adduct **7** in 14% yield after 6 h. In contrast, the analogous alkyne **1b** with a cyclobutanone substituent furnished 80% of cyclobutanol **5ba** as well as 8% of **4ba**. These contrasting results obtained with **6** and **1b** clearly indicate that the carbonyl group of **1b** facilitates the initial arylrhodation of the carbon–carbon triple bond by coordination. It also proved that the arylrhodation of **1b** and the following intramolecular carbonyl addition take place at room temperature and that the only ring-opening step by β-carbon elimination requires an

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 3. Effect of coordination of the carbonyl group of **1**.

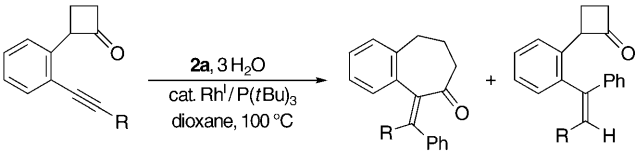
elevated temperature. It is conceivable that the coordination of the carbonyl group retards the 1,4-shift of rhodium[4c,6b,10] which possibly occurs with the intermediate **B** to produce **4**.



Arylboroxins **2b**–**2d** were subjected to the arylative ring-expansion reaction with cyclobutanone **1a** to give **3ab**–**3ad** in 63–71% yields (Table 1, entries 1–3).[11] Next, substituents at the alkyne termini of **1** were examined. Cyclobutanones **1b**–**1d**, which have other alkyl substituents (R), reacted with **2a** to afford the corresponding seven-membered-ring ketones **3ba**–**3da** (Table 1, entries 4–6).

In the reaction of **1e**, which contains a methyl ether linkage, 1,2-adduct **8ea** arising from arylrhodation with the opposite regiochemistry was formed as a byproduct (Scheme 4). Coordination of the ether oxygen center at the propargylic position might cause the regioisomeric 1,2-addition to produce **8ea**. With phenyl-substituted substrate **1f**, a mixture of **3** and **8** in a ratio of almost 1:1 was formed as a result of the barely biased alkyne structure.

Further studies on the scope and limitation of the arylative ring-expansion reaction (Table 2) were carried out. Both fluoro and methoxy substituents at the aryl ring of **1** were tolerated (Table 2, entries 1 and 2). Even a thiophene-derived substrate afforded the corresponding ketone **3ia** in 72% yield (Table 2, entry 3). We failed to obtain the seven-membered-ring ketones from cyclobutanone **1j**, which has an additional methyl substituent at the 2-position; instead, the corresponding cyclobutanol **5ja** was isolated (Table 2, entry 4). It is likely that migration of the rhodium from the oxygen atom to the tertiary carbon atom is difficult for steric reasons.[12] The reaction of **1k**, which contains a tether that is longer by one carbon atom, worked far less efficiently to result in the formation of the eight-membered-ring ketone **3ka** in only 17% yield (Table 2, entry 5).



In summary, a new rhodium-catalyzed ring-expansion reaction was developed in which seven-membered-ring ketones **3** were produced from alkyne-substituted cyclobutanones **1** and arylboroxins **2** through ring opening by β-carbon elimination.

Chiral Phosphine–Olefin Bidentate Ligands in Asymmetric Catalysis: Rhodium-Catalyzed Asymmetric 1,4-Addition of Aryl Boronic Acids to Maleimides**

*Ryo Shintani, Wei-Liang Duan, Takashi Nagano, Atsushi Okada, and Tamio Hayashi**

Transition-metal-catalyzed asymmetric transformations in the presence of chiral ligands have proved to be one of the most efficient methods for the construction of enantioenriched chiral compounds from achiral precursors.[1] The design and synthesis of novel chiral ligands have therefore been a topic of great interest in organic and organometallic chemistry in the past few decades. In late-transition-metal catalysis, the development of phosphorus- and/or nitrogen-based chiral ligands has been most extensively investigated. As conceptually novel chiral ligands, a series of chiral dienes were recently introduced, which opened up a new dimension in the field of asymmetric catalysis.[2,3] Herein we describe the development of chiral phosphine–olefin ligands **1** and their use in the rhodium-catalyzed asymmetric 1,4-addition of aryl boronic acids to maleimides with the highest enantioselectivity reported to date in this class of substrates.

Chiral diene ligands that we developed have been shown to be highly effective in various rhodium-catalyzed asymmetric processes[2] and are superior to conventional chiral bisphosphine ligands in some cases. There are, however, some drawbacks in the use of these chiral dienes: for example, diene ligands are generally weaker than phosphorus-based ligands in their coordination ability to transition metals.[4] To overcome this problem while still maintaining the advantages of chiral dienes, we decided to develop chiral phosphine–olefin ligands as a hybrid of bisphosphines and dienes which would incorporate positive features of both frameworks, namely, the high coordination ability of phosphines and the good chiral environment created around the olefins (Figure 1).

To realize the desired features of these phosphine–olefins, we chose compound **1** as the target. During the course of our study directed toward this goal, Grützmacher described the preparation of chiral phosphine–olefin **2** and utilized it as a

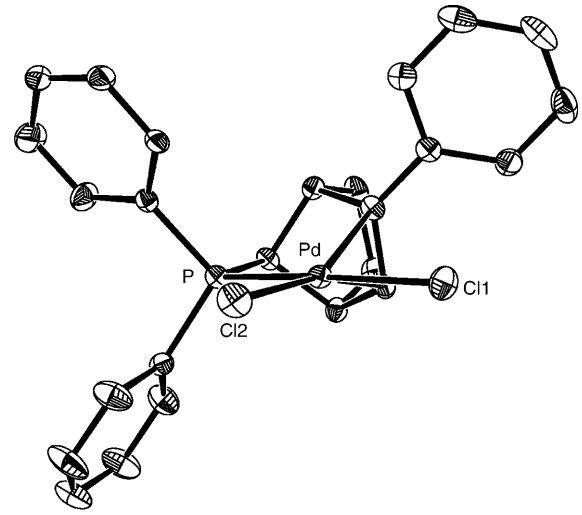
ligand for the iridium-catalyzed asymmetric hydrogenation of an imine with 86% *ee*.[5]

The synthesis of **1** began with known compound (±)-**3**[6] (Scheme 1). Swern oxidation of alcohol (±)-**3** followed by ketalization with ethylene glycol provided (±)-**4**, which was further converted into (±)-**5** by lithiation, phosphination, and then oxidation. Phosphine oxide (±)-**5** was resolved by chiral HPLC on a Chiralcel OD-H column to give each enantiomer

Scheme 1. a) oxalyl chloride, DMSO, Et_3N, CH_2Cl_2, 96%; b) cat. TsOH, ethylene glycol, C_6H_6, 94%; c) 1) *t*BuLi, THF; then $ClPPh_2$; 2) aqueous H_2O_2, acetone, 63% (over two steps); d) chiral HPLC resolution (OD-H column); e) aqueous HCl (1 N), THF, 99%; f) LDA, THF; then $PyNTf_2$, 89%; g) cat. [$NiCl_2$(dppp)], BnMgBr, Et_2O, 86% (for R = Bn); or cat. [$PdCl_2$(dppf)], PhMgBr, Et_2O, 86% (for R = Ph); h) $HSiCl_3$, Et_3N, C_6H_6, 90% for (+)-**1a** and 84% for (+)-**1b**. DMSO = dimethylsulfoxide; Ts = *p*-toluenesulfonyl; LDA = lithium diisopropylamide; Tf = trifluoromethanesulfonyl; dppp = propane-1,3-diylbis(diphenylphosphane); dppf = 1,1′-bis(diphenylphosphino)ferrocene.

of **5**, and then the ketal was cleaved to afford enantiopure ketone (+)-**6**. Conversion of (+)-**6** into its enol triflate, followed by Grignard cross-coupling and reduction with silane, completed the synthesis of (+)-**1a** (R = Bn, 39% overall yield) and (+)-**1b** (R = Ph, 36% overall yield).

We then carried out some complexation experiments with several transition metals to observe their mode of coordination. Thus, treatment of ligand (+)-**1b** (^{31}P NMR: $\delta = -17.1$ ppm; ^{1}H NMR: $\delta = 6.31$ ppm for the olefinic H atom) with 1 equivalent of [Rh(acac)$(C_2H_4)_2$] (acac = acetylacetonate) in dichloromethane at room temperature generated a new species, which showed a doublet at $\delta = 65.0$ ppm (J = 185 Hz) in the ^{31}P NMR spectrum and the signal for the olefinic H atom of (+)-**1b** was shifted upfield to $\delta = 3.82$ ppm in the ^{1}H NMR spectrum, thus indicating that both the phosphorus atom and the olefin were directly bound to rhodium. Similarly, a 1:1 mixture of (+)-**1b** and [$PdCl_2$-$(MeCN)_2$] in benzene led to the clean formation of [$PdCl_2$((+)-**1b**)]. Recrystallization of this complex from dichloromethane/benzene afforded single crystals suitable for X-ray crystallographic analysis.[7] As shown in Figure 2, (+)-**1b** does act as a phosphine–olefin bidentate ligand with



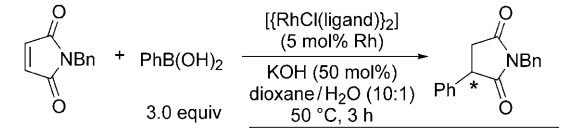


Figure 2. ORTEP illustration of [$PdCl_2$((+)-**1b**)] with thermal ellipsoids drawn at the 50% probability level (hydrogen atoms are omitted for clarity).

palladium, in accordance with the initial design of this novel hybrid ligand. The X-ray crystal structure also establishes the absolute configuration of (+)-**1b** as 1*R*,4*S*,7*R*.[8] Furthermore, it shows that the local structure around the phosphorus center is achiral and that the chirality mostly originates from the steric difference between the two substituents (Ph and H) on the olefin.

To investigate the potential of these ligands **1** in asymmetric catalysis, we chose to explore the rhodium-catalyzed 1,4-addition of aryl boronic acids to maleimides. As shown in Equation (1), the reaction of *N*-

(1)

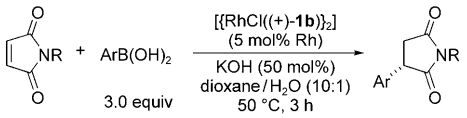
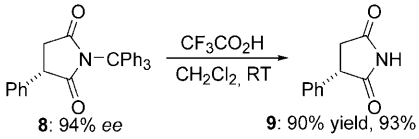
(+)-**1b**	98% yield, 93% *ee* (*S*)



benzylmaleimide with $PhB(OH)_2$ in the presence of (*R*)-binap, a typical chiral bisphosphine ligand for rhodium-catalyzed asymmetric 1,4-additions,[9] gave the 1,4-adduct with only 58% *ee*. The use of chiral norbornadiene (*R*,*R*)-**7**, which was reported by us as the benchmark ligand in the 1,4-addition to maleimides,[2b] led to the desired product with 69% *ee*. The use of benzyl-substituted phosphine–olefin (+)-**1a** significantly improved the enantioselectivity to 91% *ee*. By changing the substituent on the olefin from benzyl to phenyl ((+)-**1b**), the selectivity was improved further (93% *ee*).

Under these conditions with (+)-**1b** as the ligand, various *N*-substituted maleimides can be employed in the reaction

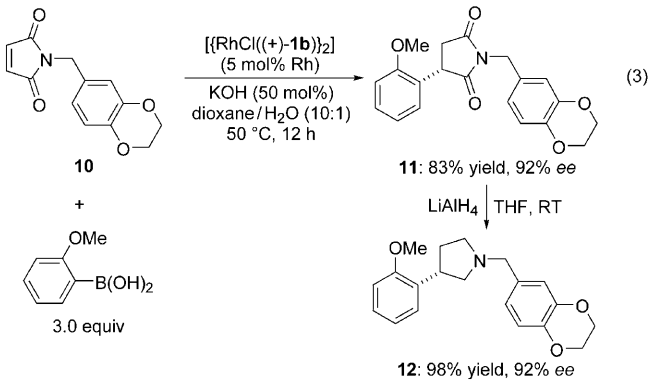
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



with $PhB(OH)_2$ to furnish the 1,4-adducts in uniformly high yield and enantioselectivity (Table 1, entries 1–5). With respect to the nucleophilic component, a variety of aryl boronic acids can be coupled with *N*-benzylmaleimide with high stereoselectivity as well (Table 1, entries 6–10).

Table 1: Rh–(+)-**1b**-catalyzed asymmetric 1,4-addition of aryl boronic acids to maleimides.

Entry	R	Ar	Yield [%]	*ee* [%]
1	Me	Ph	91	88
2	Cy	Ph	96	94
3	$CHPh_2$	Ph	95	94
4	CPh_3	Ph	95	94
5	Ph	Ph	88	90
6	Bn	Ph	98	93
7	Bn	4-$MeOC_6H_4$	98	93
8	Bn	4-FC_6H_4	90	89
9	Bn	3,5-$MeO_2C_6H_3$	90	92
10	Bn	2-MeC_6H_4	98	95



To show the utility of this highly enantioselective 1,4-addition to maleimides catalyzed by Rh–(+)-**1b**, we conducted a deprotection reaction of *N*-trityl 1,4-adduct **8** with 94% *ee* [Eq. (2)]. Thus, treatment of **8** with trifluoroacetic

(2)

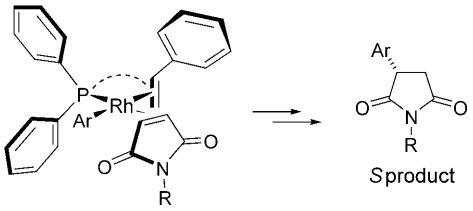
acid in dichloromethane at room temperature furnished the desired product **9** in 90% yield with minimal erosion of the *ee* value.

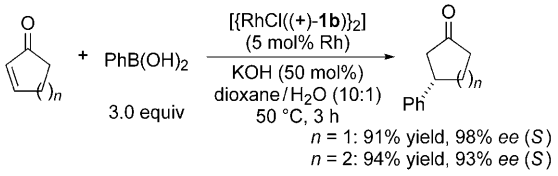
The present asymmetric catalysis can also be applied to an enantioselective synthesis of biologically active compounds. Thus, addition of 2-$MeOC_6H_4B(OH)_2$ to maleimide **10** under Rh–(+)-**1b** catalysis led to 1,4-adduct **11** in 83% yield with 92% *ee* [Eq. (3)]. Reduction of the two carbonyl groups of **11**

(3)

with $LiAlH_4$ furnished pyrrolidine **12** in 98% yield, which is an enantiomer of the potent α-2-adrenoceptor antagonist developed by Novartis.[10]

The stereochemical outcome of these Rh–(+)-**1b**-catalyzed 1,4-additions can be rationalized as depicted in Figure 3,





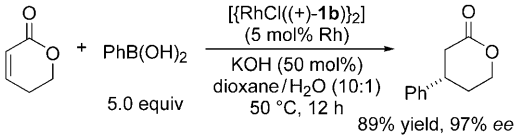


Figure 3. Proposed stereochemical pathway for the asymmetric 1,4-addition to a maleimide catalyzed by Rh–(+)-**1b**.

assuming that the maleimide approaches the aryl rhodium species bearing ligand (+)-**1b** *cis* to the olefin portion of the ligand. To avoid the steric repulsion between the imide moiety of maleimide and the phenyl group on the olefin, the product thus obtained should be an *S* isomer, which is consistent with the observed stereochemistry.

The Rh–(+)-**1b** catalyst is highly effective for asymmetric 1,4-addition to other α,β-unsaturated carbonyl compounds as well. For example, both cyclic enones and enoates[11] furnish the corresponding 1,4-adducts in high yield and enantioselectivity [Eq. (4) and Eq. (5)].

(4)

(5)

In summary, we have designed and synthesized novel chiral phosphine–olefin ligands. These ligands act as bidentate with some transition metals and have proved to be highly effective in the rhodium-catalyzed asymmetric 1,4-addition of aryl boronic acids to maleimides. Future studies will involve the exploration of further applications of these ligands to various transition-metal-catalyzed asymmetric processes.

Experimental Section

Procedure for Table 1: KOH (0.10 mL, 0.10 mmol; 1.0 M aqueous) was added to a solution of $[\{RhCl((+)\text{-}\mathbf{1b})\}_2]$ (4.9 mg, 10 μmol Rh) in 1,4-dioxane (0.50 mL), and the resulting solution was stirred for 5 min at room temperature. After addition of $ArB(OH)_2$ (0.60 mmol) and stirring for 5 min, this mixture was transferred to a vessel containing maleimide (0.20 mmol) with additional 1,4-dioxane (0.50 mL). The

resulting mixture was stirred for 3 h at 50 °C and was then passed through a pad of silica gel with EtOAc. The solvent was removed under vacuum, and the residue was purified by chromatography on silica gel with EtOAc/hexane to afford the 1,4-adduct.

Host–Guest Systems

An Unstable Ligand-Unsupported Cu^{I} Dimer Stabilized in a Supramolecular Framework**

Shao-Liang Zheng, Marc Messerschmidt, and Philip Coppens**

The attractive interactions that exist between d^{10} "closed-shell" elements of Group 11 have received extensive attention.[1,2] The term "aurophilicity" has been coined to describe the Au^{I}–Au^{I} bonding interactions that are evident in many molecular and solid-state structures and have been attributed to correlation and relativistic effects.[3] However, relativistic effects cannot be invoked for $Cu^{I}\cdots Cu^{I}$ interactions, which are generally referred to as "cuprophilicity". These interactions are found in inorganic lattices, polynuclear compounds with bridging ligands[2] or stabilized by electrostatic interactions,[4] and polymeric systems, such as infinite ···Cu-ligand-Cu··· chains with short sideways $Cu^{I}\cdots Cu^{I}$ interactions.[5] The existence of ligand-bridged $Cu^{I}\cdots Cu^{I}$ interactions is supported by spectral evidence[6] and has been examined by a series of theoretical calculations, which have sometimes reached different conclusions.[7] However, a recent comprehensive analysis[8] has shown that only a small part of the intermolecular interaction energy is often gained in the ground state from the $Cu^{I}\cdots Cu^{I}$ interaction, whereas a large component results from $Cu^{I}\cdots$ligand interactions, even in the case of ligand-unsupported $Cu^{I}\cdots Cu^{I}$ species.

Only a few examples of ligand-unsupported Cu^{I} aggregates have been described, most of which have been reported quite recently. These examples include the dimer of trimers based on a substituted pyrazolate;[9] the dimer of dimers with a substituted phenanthroline/bipyridyl ligand;[10] the infinite arrays of $[Cu(t\mathrm{Bu})(CN)Li(OEt_2)_2]$, in which neighboring Cu^{I} dimers are connected through Li^{+} ions;[11] the one- and three-dimensional infinite arrays of Cu^{I} ions in $[Cu(NH_3)_2]Br$ and $[Cu(NH_3)Cl]$, respectively;[12] the one-dimensional chains of Cu^{I} atoms in $[Cu(C_6F_6)(py)]$ (py = pyridine);[13] and the $[(CuCl_2)_2]^{2-}$ dimer cocrystallized with the monomeric $[CuCl_3]^{-}$ ion and with amidinium cations.[14] Except for the $[(CuCl_2)_2]^{2-}$ dimer, all the ligand-unsupported Cu^{I} dimers ("dimer" refers to two Cu^{I} fragments with a short $Cu^{I}\cdots Cu^{I}$ distance) form one-dimensional infinite $Cu^{I}\cdots Cu^{I}$ or π–π-stacked chains.

Much stronger d^{10} metal–metal bonding with a possible formal metal–metal single bond has been predicted to exist in the electronically excited state of $[\{Ag(CN)\}_2^-]_n$.[15] The recently developed method of time-resolved (TR) diffraction allows experimental confirmation of such predictions.[16] A recent TR diffraction experiment on trimeric [{Cu[3,5-$(CF_3)_2$pyrazolate]}$_3$] at 17 K indeed shows a strong contraction of one of the intermolecular $Cu^I\cdots Cu^I$ distances in the one-dimensional infinite chains, thus leading to the formation of an excimer with a lifetime of 52 μs.[17] The systematic luminescence investigations of a series of substituted Cu/pyrazolate trimers showed that the lifetime and wavelength of the luminescence emission were strongly dependent on the temperature and the wavelength of the excitation,[18] thus suggesting the possible population of different excited states at different temperatures.

Supramolecular host matrices provide a well-defined environment in which the encapsulated luminescent guest molecules may occur in different states of aggregation and orientation relative to their environment, thus offering an attractive possibility for isolating photoactive molecular species in a dilute yet crystalline environment.[19] For example, we have shown recently that the xanthone molecule occurs as a monomer and as a dimer in two crystalline resorcinarene-based inclusion complexes and results in significant variation of its spectral properties.[20] On excitation, the xanthone dimer forms a phosphorescing excimer.[21] Its geometry has been determined by TR diffraction methods.[22]

The ligand-unsupported $[\{Ag(NH_3)_2\}_2]^{2+}$ ion has been trapped in a polymeric silver(I) hexamethylenetetramine coordination framework,[23] thus suggesting that a favorable supramolecular system may give rise to a discrete ligand-unsupported Cu^I dimer with the monodentate ammonia ligand. As part of our investigations of well-defined excimers in supramolecular environments,[24] we isolated the analogous Cu^I species in a supramolecular framework composed of tris(hydroxyphenyl)ethane anions (H_2THPE; see the Supporting Information). This structure led to a solid with the composition $[\{Cu(NH_3)_2\}_2][H_2THPE]_2\cdot 3.25\,H_2O$ (**1**), in which no photoactive molecules other than the Cu^I dimer were present, thus simplifying a future TR diffraction analysis.

X-ray diffraction studies[25] show that crystals of **1** contain two crystallographically independent H_2THPE anions connected by hydrogen-bonding interactions (Figure 1; see also the Supporting Information). The dimeric unit is further linked by hydrogen bonds to its center-of-symmetry related equivalent (symmetry code: $-x+2,\ -y,\ -z+1$) which extends into a two-dimensional wavy hydrogen-bonded layer (O···O: 2.435(3)–2.593(4) Å; see the Supporting Information) parallel to the (011) plane. The wavy layer contains square-shaped channels (effective dimension: 2.1×2.1 Å), which constitute 4.8% of the crystal volume and run along the *a* axis.[26] Adjacent hydrogen-bonded layers are juxtaposed along the *b* axis, so as to leave larger channels with an effective cross-section of 5.90 Å (again parallel to the *a* axis), and account for 17.6% of the crystal volume.

Each of the larger channels contains two crystallographically independent Cu^I centers in proximity in each unit cell. Each Cu^I center is ligated by two nitrogen atoms from ammonia (Cu–N: 1.886(3)–1.892(3) Å, N-Cu-N: 176.3(1) and 177.3(2)°; see the Supporting Information). The Cu^I-centers are separated by only 3.0248 Å with N-Cu···Cu-N torsion angles of 73.2(2) and 77.6(2)° for the two cations, respectively (see the Supporting Information). As the $Cu^I\cdots Cu^I$ distance is within the range reported for ligand-

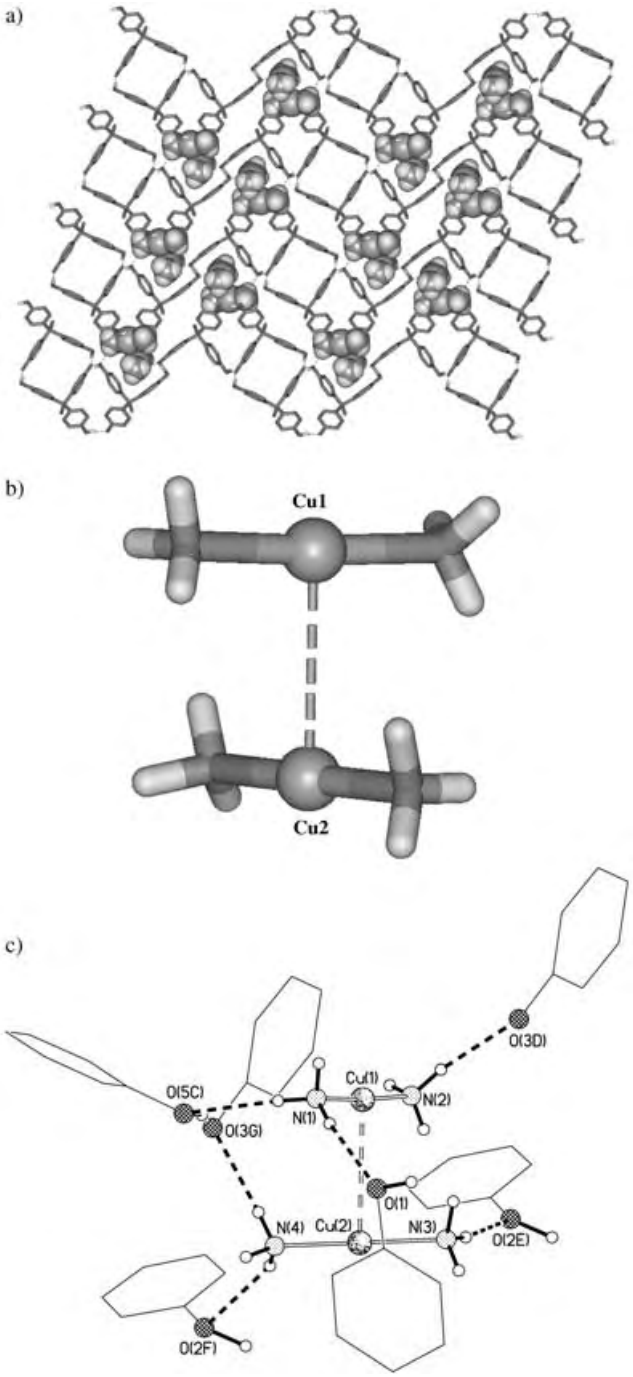

Figure 1. a) Three-dimensional supramolecular architecture of **1** viewed along the *a* axis, b) discrete dimeric $[\{Cu(NH_3)_2\}_2]^{2+}$ species in **1**, and c) the $[\{Cu(NH_3)_2\}_2]^{2+}$ species trapped in the supramolecular framework (selected distances [Å]: N(1)···O(5C) 2.968(4), N(1)···O(1) 3.185(4), N(2)···O(3D) 2.850(3), N(3)···O(2E) 2.996(4), N(4)···O(2F) 3.258(4), N(4)···O(3G) 2.889(4); see the Supporting Information. The water molecules included in the lattice are omitted for clarity.)

unsupported $Cu^{I}\cdots Cu^{I}$ separations (2.71–3.60 Å),[9–14] the complex can be described as a novel dimeric $[\{Cu(NH_3)_2\}_2]^{2+}$ species. The ammonia ligands act as donors in hydrogen-bonding interactions with the oxygen atoms of the hydroxy groups in the adjacent H_2THPE anions (N···O: 2.850(3)–3.258(4) Å; Figure 1c), so that the supramolecular framework provides support and allows the dimeric $[\{Cu(NH_3)_2\}_2]^{2+}$ species to exist. One fully ordered water molecule is clathrated in each larger channel to fill the gap left between the Cu^{I} dimers. The water molecules form hydrogen-bonding interactions with the oxygen atom of the hydroxy group (O(1W)-H···O: 2.772(1) Å) of the host network. The smaller square-shaped channels are occupied by disordered water molecules.

The molecular dilution of the $[\{Cu(NH_3)_2\}_2]^{2+}$ species trapped in the supramolecular framework is pronounced: its concentration is 1.75 mol L^{-1} for **1**, relative to 7.35 mol L^{-1} for two $[Cu(NH_3)_2]^{+}$ ions in $[Cu(NH_3)_2]Br$ crystals.[12] The $Cu^{I}\cdots Cu^{I}$ distance is slightly longer than that found in the one-dimensional infinite $[Cu(NH_3)_2]^{+}$ chains (2.93 Å) in $[Cu(NH_3)_2]Br$.[12]

Molecular-orbital calculations were performed with the X-ray geometry of the $[\{Cu(NH_3)_2\}_2]^{2+}$ dimer to gain insight into the $Cu^{I}\cdots Cu^{I}$ interactions in the dimer. An intermolecular perturbation theory (IMPT)[27] calculation indicates that the Cu^{I} dimer with the geometry found in crystals of **1** is less stable by 309.1 kJ mol^{-1} than the isolated monomers.[28] Variation of the $Cu^{I}\cdots Cu^{I}$ distance shows no local minimum with the observed configuration (see the Supporting Information), thus suggesting that such a dimer is unlikely to occur in solution. Nevertheless, it can be stabilized in the supramolecular environment, as is evident from the crystal structure of **1**. Bimolecular $Cu^{I}\cdots Cu^{I}$ aggregates that have like charges have been calculated to be repulsive.[8] In the ground state, often only a small part of the intermolecular interaction energy gained results from the direct $Cu^{I}\cdots Cu^{I}$ interaction, whereas a large component of this energy results from $Cu^{I}\cdots$ligand interactions. In accordance with the calculations reported by Carvajal et al., the IMPT calculations show that the electrostatic repulsion, which is purely Coulombic in origin, is dominant in the current case (311.8 kJ mol^{-1}; see the Supporting Information). Nevertheless, the orbital interactions, including induction, charge transfer, and dispersion, are stabilized by -27.2 kJ mol^{-1} and so fall into the range of cuprophilic interactions estimated from spectroscopic or theoretical studies.[6–8] The results of the DFT calculations indicate that the HOMO-1 (HOMO = highest occupied molecular orbital) is a $Cu^{I}\cdots Cu^{I}$ σ bonding molecular orbital, the HOMO is a $Cu^{I}\cdots Cu^{I}$ σ antibonding molecular orbital, and the lowest unoccupied molecular orbital (LUMO) has $Cu^{I}\cdots Cu^{I}$ bonding character with 4d, 5s, and 5p contributions from the Cu^{I} center (Figure 2). The Mayer bond order[17,29] of the $Cu^{I}\cdots Cu^{I}$ interaction is calculated to be 0.187 (see the Supporting Information), which is in agreement with the IMPT analysis and shows the orbital interactions to be weakly attractive.

Optimization of the excited triplet state results in a shorter $Cu^{I}\cdots Cu^{I}$ distance of 2.6 Å (see the Supporting Information), which indicates a much stronger metal–metal bonding interaction on population of the $Cu^{I}\cdots Cu^{I}$ bonding LUMO (Figure 2). Emission measurements show an intense photoluminescence at 17 K with emission at 495 nm and a lifetime of approximately 4.2 μs, thus indicating that crystals of **1** may be suitable for TR diffraction studies.[19]

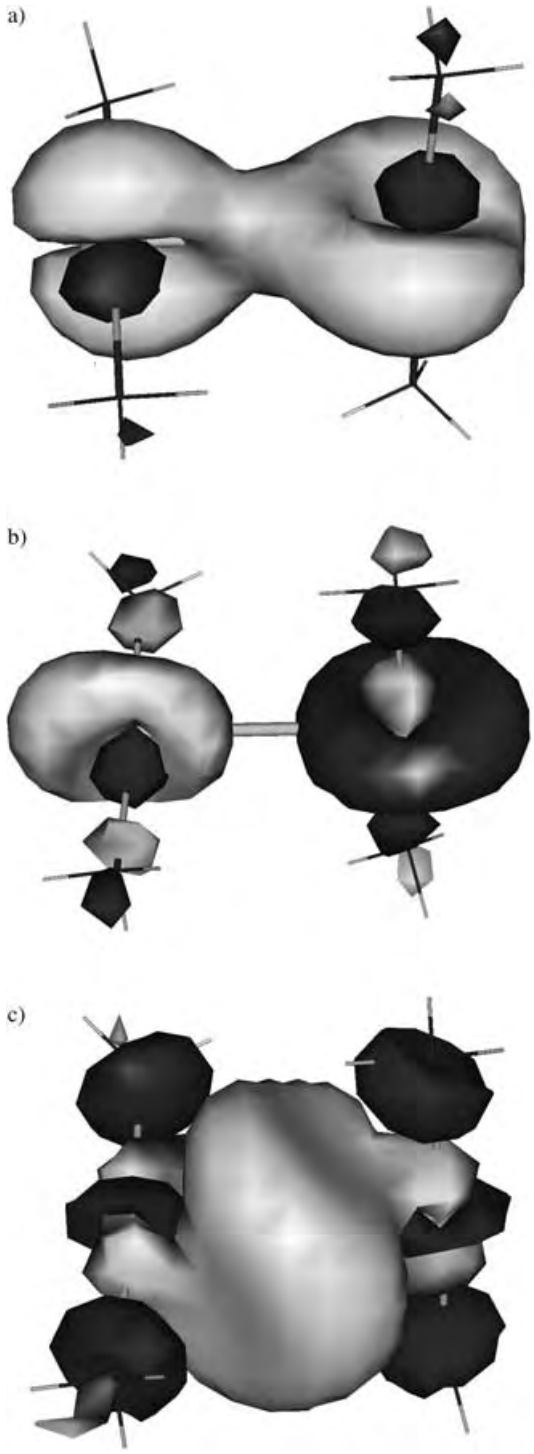

Figure 2. Contour plots (isosurfaces at ±0.04 au) of the frontier molecular orbitals of the $[\{Cu(NH_3)_2\}_2]^{2+}$ species: a) HOMO-1, b) HOMO, and c) LUMO.

In summary, a ligand-unsupported Cu^{I} dimer that is unstable by itself is stabilized in the cavities of a supramolec-

ular framework to give **1**, thus offering the opportunity for systematic studies of the ground state of a Cu^{I} dimer with weak cuprophilicity and of its excited state by the use of TR diffraction methods. Analysis of the isolated dimeric species eliminates effects that occur in infinite chains of species linked through $Cu^{I}\cdots Cu^{I}$ interactions and provides the background needed for analysis of more complicated systems.

Experimental Section

1: Freshly prepared $Cu(OH)_2$ (0.5 mmol), H_3THPE (0.5 mmol), aqueous ammonia (25%, 2.0 mL), and toluene (2 mL) were sealed in a 6-mL pyrex glass tube. The tube was maintained at 160 °C for 40 h and then cooled to room temperature over 2 days. Pale-yellow needle-shaped crystals appeared during the cooling period.

CCDC-267412 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or deposit@ccdc.cam.ac.uk).

Zn– and Cd–Metallothionein Recombinant Species from the Most Diverse Phyla May Contain Sulfide (S^{2-}) Ligands**

Mercè Capdevila, Jordi Domènech, Ayelén Pagani, Laura Tío, Laura Villarreal, and Sílvia Atrian*

After much multidisciplinary research into metallothioneins (MTs), the ubiquitous metal-binding proteins first described by Vallee and Margoshes[1] in 1957, there is still little information on the structures and functions[2,3] of the biological metal–MT complexes. There are two main obstacles to studying the physiological features of MTs. First, although MTs are present in all living organisms except Eubacteria, most of the existing data refers to mammalian MTs, which precludes any homology-driven structural, functional, or evolutionary inference because of the extreme sequence heterogeneity of this family of metalloproteins (see http://www.biochem.unizh.ch/mtpage/MT.html). Second, the difficulties encountered when trying to obtain homogeneous native preparations have led to the common utilization of in vitro reconstituted metal–MT complexes, based on the assumption that they represent genuine structural and functional native MT species. Thus, most of the data available to date, especially referring to MT structure, comes from nonbiological characterization of metal–MT complexes.[4] Following the MT discovery, another class of eukaryote metal-coordinating molecules was reported in plants and fungi: the enzymatically synthesized γ-glutamyl (γ-EC) peptides, also called phytochelatins and cadystins, which have always been considered as providing a very different mechanism of metal detoxification compared to the gene-encoded MTs, sharing few, if any, structural and functional features with them. From the chemical point of view, MTs bind a variety of metal ions giving rise to individual polynuclear clusters that are linked exclusively to cysteine residues through thiolate bonds. In contrast, γ-EC peptides create oligomeric clusters with a variable number of units that, most significantly, include acid-labile sulfide (S^{2-}) ions as additional ligands which induce the clusters to evolve to peptide-coated particles, so-called crystallites.[5]

Herein, we report the first definite evidence that sulfide ions are also present in nearly all the recovered Zn^{II}–MT and Cd^{II}–MT complexes, but never in the Cu^{I}–MT species of a wide range of recombinant metal–MT aggregates, thus sulfide ions are found in species formed in vivo, that is, in a physiological, although heterologous, environment. We have determined the presence of the acid-labile S^{2-} ligands both qualitatively and quantitatively by analytical, spectroscopic, and spectrometric techniques, and it is clear that the features of the recovered Zn^{II}–MT and Cd^{II}–MT complexes correlate well with those reported for plant and yeast Zn– or Cd–γ-glutamyl peptides,[5] therefore bridging the behavior gap between both types of metal-binding molecules.

Recombinant expression in *E. coli* has permitted the routine synthesis of a large number of proteins that are difficult or even impossible to obtain in their native forms. MTs stand out among them because of their extreme complexity and heterogeneity. Nearly ten years ago we developed an *E. coli* expression system that allows the biosynthesis of intact Zn^{II}–, Cd^{II}–, and Cu^{I}–MT complexes, isolated domains, and mutant variants, in sufficient quantity and purity for analytical, spectrometric, and spectroscopic characterization. As a first characterization on the mouse Zn–MT1 system[6,7] fully validated the correspondence between native and recombinant complexes, research was expanded to mammalian MT isoforms (MT1[8–10] and MT4[11]), the crustacean MTH,[12] *Drosophila* MTs (MTN[13] and MTO[14]), and the plant *Quercus suber* QsMT.[15]

We are now focused on studying MT species from the most diverse taxa (Table 1) and in the course of this work we found that many experimental results from analyzing Zn–MT, and particularly Cd–MT complexes, made little sense, as shown in Table 1. First, the stoichiometry of the Cd–MT complexes determined by inductively coupled plasma atomic emission spectroscopy (ICP-AES) was unusually low in comparison with the values expected from the corresponding Zn–MT complexes and the number of cysteine residues available for metal coordination. The metal-binding stoichiometries are assessed directly from the total sulfur and metal content of the sample provided by ICP-AES,[16] assuming that the total sulfur in the preparation arises from the summation of cysteine and methionine residues within the polypeptide. The unusually low stoichiometries calculated first suggested a partial oxidation of thiol groups and consequent loss of MT metal-binding capacity, but the Ellman reaction[17] quantification of the thiol groups in the samples did not support this prediction. Furthermore, ESI-MS analyses of most of the Cd–MT isolates revealed, besides the expected species, the presence of complexes whose mass did not match any

Equivalent analyses with *T. pyriformis* MT1, *C. elegans* MT2, and *M. edulis* MT10IV yielded comparable results with regard to the presence of sulfide in their metal–MT complexes (data not shown). [b] Protein concentration calculated from conventional ICP-AES results. [c] Protein concentration calculated from acid ICP-AES results. Amino acid analysis led to identical values ±0.01. [d] Metal/MT ratio deduced from the metal content measured by conventional ICP-AES and results in (b). [e] Metal/MT ratio deduced from the metal content measured by ICP-AES and the acid ICP-AES and the results in (c). [f] n.d. = not detectable. [g] In this case, the metal/MT ratio represents the mean metal content per MT of preparations which had heterometallic composition (Zn and Cu or Zn and Cd). [h] This work. The corresponding manuscripts including the full MT characterization are in preparation.

possible Cd^{II} metallated complexes. These unknown mass peaks did not arise from the presence of other metal ions in putative heterometallic MT species, as Cd was the only metal detected by ICP-AES. Finally, circular dichroism (CD) spectroscopy of the Cd–MT samples showed features in the 260–280 nm range that clearly were not attributable to the known tetrahedral $Cd(SCys)_4$ chromophores that absorb at approximately 250 nm, which were also present in the spectra (Figure 1).

At this stage, the most likely explanation for our observations was the presence of an additional ligand in the purified Zn–MT and Cd–MT species, but none of the reported possibilities (chloride participation,[18] phosphate-driven dimerization[19]) were consistent with the analytical and spectral features of the samples. However, transitions between 260 and 300 nm have been reported in the CD spectra of Cd-phytochelatins containing sulfide anions[5,20] and we have already suggested that these ligands could be present in *Drosophila* Cd–MTN species.[13] The presence of extra sulfur in our samples as sulfide ligands would provide a sound explanation for all the bizarre results mentioned above as well as the negative oxidation degrees measured by reactions with the 3,3′-dithiobis(6-nitrobenzoic acid) (DTNB).[21] Therefore, we performed a quick test[22] to assess the presence of S^{2-} ions in our panel of recombinant metal–MTs by determining hydrogen sulfide gas generation after acidification of the samples with HCl. Blackening of a filter paper moistened with a solution of $AgNO_3$ which was capping the sample tube, as a consequence of silver sulfide precipitation, unequivocally identified the presence of sulfide in all the Cd–MT and some Zn–MT samples, but not from the control (sample without MT) or any Cu–MT preparations.

Zn–, Cd–, and Cu–MT species from different taxa were analyzed more thoroughly to determine whether sulfide ion binding was common in the diverse metal–MT complexes. If sulfide ions were present, then the ICP-AES approach for global metal–MT ratio calculation was not valid, as the sulfur quantization would not report exclusively on Cys and Met

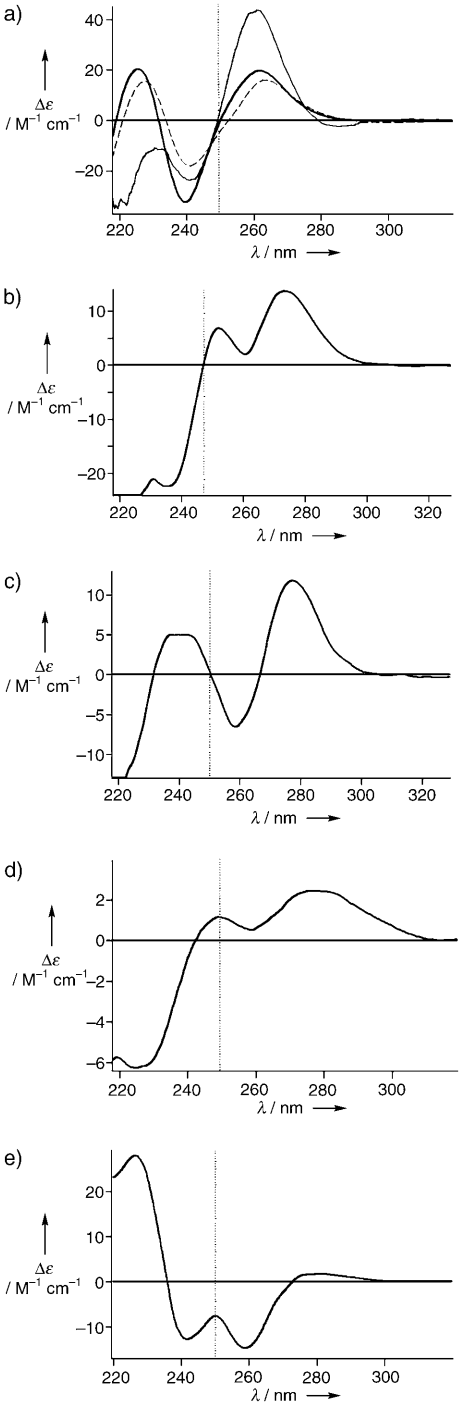

Figure 1. Representative CD spectra of several Cd–MT species from the most diverse taxa. Spectra have been grouped as a) type A (conventional spectra expected for Cd–MT species): Cd–MT1 (solid black line), Cd–SpMTA (solid gray line), and Cd–ckMT (dashed black line); b) type B: Cd–QsMT; c) type C: Cd–MTN; d) type D: Cd-CRS5; e) type E: Cd–MTO. All spectra show the characteristic absorption features of the $Cd(SCys)_4$ chromophores at approximately 250 nm (vertical dotted line) either as derivative shaped signals of different signs (A and B versus C), Gaussian bands (D) or more complex absorptions mixed with chloride participation[18] in Cd binding (E). The most (B, C, D and E) and least (A) intense absorptions at approximately 280 nm could be attributed to the presence of $Cd–S^{2-}$ bonds.

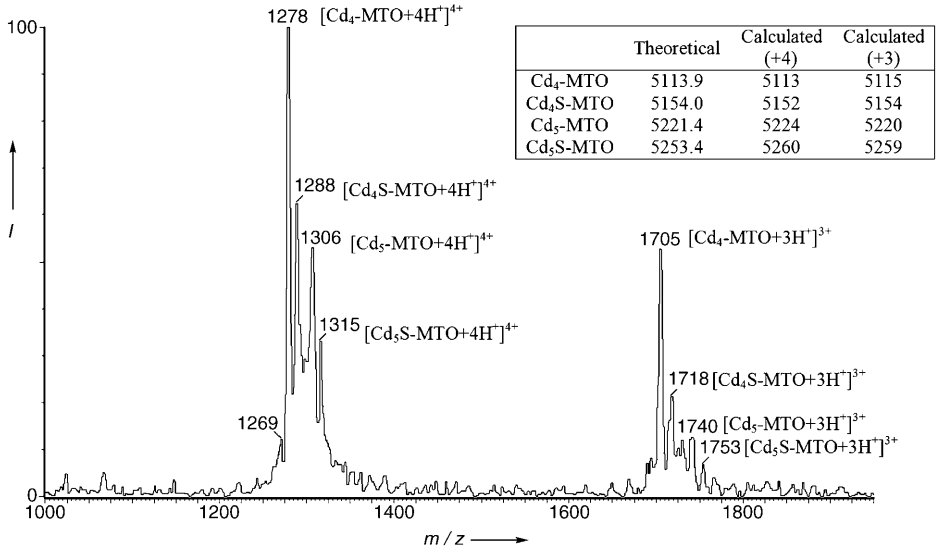

concentrations. Protein concentrations were then redetermined simultaneously by two methods: acid ICP-AES and amino acid analysis. Acid ICP-AES involves acidification of the sample with 1M HCl prior to the conventional method[16] to favor the loss of the acid-labile ligands such as H_2S and thus ensure that all the sulfur remaining in the sample corresponded to Cys and Met. Acid ICP-AES results gave new metal–MT ratios that were now highly consistent with the expected stoichiometries (Table 1). The amino acid analysis was used to quantify protein levels, and these data nicely matched those obtained by acid ICP-AES. Finally, considering single or multiple 32 Dalton (sulfur atomic weight) additions to the value of the mass of the canonical metal–MT species yielded values that were coincident with the unassigned ESI-MS peaks of the sample.

We attempted quantification of the sulfide content in all the samples, initially using a methylene blue method[23] similar to that applied for Cd–phytochelatin analyses.[20] However, this method has serious drawbacks, as some degree of interference with cadmium ions has been reported[24] and it is not suitable for samples containing copper owing to the insolubility of copper sulfide. As a consequence, we adapted a GC-FPD (flame photometric detector) approach initially reported for solid samples.[25] Both methods gave consistent results and permitted the mean S^{2-} ion content per MT to be determined (Table 1). These data demonstrated that acid-labile sulfide was present in all the recombinant Cd–MT samples and in many Zn–MT isolates, although always at lower ratios than in the corresponding Cd–MT samples. Furthermore, ESI-MS analyses of the Zn– and Cd–MT preparations not only accounted for the presence of S^{2-} ions as additional ligands but also showed coexistence of S^{2-}-containing and S^{2-}-devoid metal–MT species (Figure 2), indicating an equilibrium between the two forms in the original preparations. None of the MT proteins synthesized in Cu-supplemented media gave any evidence of sulfide ligands in their complexes. All of these findings are consistent with the features reported for the presence/absence of sulfide in Zn– or Cd–, and Cu–phytochelatins, respectively.[5,26] As for the spectroscopic analyses, evidence that sulfide in the Cd–MT complexes is associated with absorptions in the 260–280 nm range came from acidification/reneutralization experiments(see Supporting Information).

The data presented herein support the hypothesis that recombinant synthesis in *E. coli* of diverse MTs results in the recovery of sulfide-containing complexes in addition to the expected non-sulfide-containing canonical species. This is the first demonstration that Zn–MT and Cd–MT species have the capacity to form Zn- and Cd-thiolate complexes in which labile sulfide ligands contribute to the Zn^{II} and Cd^{II} binding.

This situation has major practical and theoretical implications. From a practical point of view, it is important that the ever-growing community of MT researchers using recombinant strategies to produce metal–MT complexes evaluates the presence of S^{2-} in their preparations to attain a true interpretation of their analytical, spectroscopic, and spectrometric data. From a theoretical angle, the presence of S^{2-} ions in metal–MT aggregates raises significant questions. Because of the observed metal and protein dependency and the

The table gives the corresponding molecular weights of the species as calculated from the MS data and predicted.

equilibrium between S^{2-}-containing and S^{2-}-devoid forms, it is unlikely that S^{2-} binding is a mere artifact, thus it is pertinent to ask if sulfide incorporation also occurs in endogenous metal–MT complexes, that is, in native forms. Should this be the case, it is intriguing why it has not been previously detected. A likely explanation is that for nearly half a century most of the MT research has been carried out using in vitro reconstituted metal–MT species, which are prepared by adding the corresponding metal ions to apo-MT (metal-devoid MT) polypeptides. These species are obtained after heavy acidification of the purified metal–MT forms and thus, any sulfide ions involved in the initial Zn^{II} or Cd^{II} complexation would be lost. Furthermore, the native isolates of MT complexes from many species contain significant heterogeneity of isoforms and metal compositions.[27,28] Therefore a lot of effort has been devoted to obtaining pure chromatographic fractions, which may involve discarding other minor metal–MT species originally present in the sample and that are assumed to be impurities, mixed-metal species, or simply, non-MT metal-containing aggregates.

The S^{2-} ion is a species not restricted to *E. coli*, but rather a universal cell component. At present, evidence is being gathered that relates the presence of S^{2-} ions with physiological events, which have also been proposed for MT function candidates (redox equilibrium,[29] neurotransmission, and neuromodulation[30]). Consequently, evaluation of the sulfide-binding MT capability in endogenous MT forms is worth considering in further studies of native MT forms, especially Zn–MT, as new data could shed light into the physiological significance of this poorly understood protein in view of the recently revised relationship between the biological and inorganic zinc clusters in nature.[31] But, in any case, knowledge of the capability of divalent metal–MTs to include S^{2-} ions in their aggregates, or in other words, to build metal-MT aggregates that include S^{2-} ions would be highly significant for structural, nanobiological, biotechnological, and biomedical applications in which MTs are involved. In conclusion, a new attribute must be added to the already long list of peculiar features of these versatile proteins.

Experimental Section

Zn–, Cd–, and Cu–MT complexes were synthesized according to a recombinant fusion-protein strategy (GST-MT) fully reported in references [6,7]. This method is based on cultures of *E. coli* cells transformed with the corresponding expression constructs in LB (Luria Bertini) medium supplemented with Zn^{II}, Cd^{II}, or Cu^{II} (300 μM, 300 μM, and 500 μM, respective final concentrations). After cell sonication, all the steps were performed under argon atmosphere. The total protein extract was only submitted to Glutathione-Sepharose affinity chromatography, thrombin digestion, and FPLC (fast performance liquid chromatography) in 50 mM Tris-HCl (Tris = 2-amino-2-(hydroxymethyl)-1,3-propanediol), pH 7.5 buffer. All MT complexes were synthesized and purified under identical conditions.

The molecular mass of the metal–MT species was determined by electrospray ionization mass spectrometry (ESI-MS) on a Fisons Platform II Instrument, equipped with MassLynx software and calibrated with horse-heart myoglobin (0.1 mg mL^{-1}). The assay conditions for the Zn- and Cd-containing species were as follows: 20 μL of protein solution injected at 40 μL min^{-1}; the use of an HPLC Uptisphere C_4 33 mm × 2 mm × 5 μm column to separate analytes; capillary counterelectrode voltage, 4.5 kV; lens counterelectrode voltage, 1.0 kV; cone potential, 60 V; source temperature, 120 °C; *m*/*z* range, 850–1950; scanning rate, 3 s scan^{-1}; interscan delay, 0.3 s. The assay conditions for the Cu-containing species were: 20 μL of protein solution injected at 30 μL min^{-1}; capillary counterelectrode voltage, 3.5 kV; lens counterelectrode voltage, 1.0 kV; cone potential, 35 V; source temperature, 160 °C; *m*/*z* range, 850–1950; scanning rate, 3 s scan^{-1}; interscan delay, 0.3 s. In all cases, the running buffer was an appropriate mixture of acetonitrile and 5 mM ammonium acetate/ammonia, pH 7.5.

Electronic absorption measurements were performed on an HP-8453 Diode array UV/Vis spectrophotometer. A Jasco spectropolarimeter (J-715) interfaced to a computer (GRAMS 32 Software)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

was used for CD determinations. The temperature for all measurements was kept at 25 °C by means of a Peltier PTC-351S apparatus.

ICP-AES, using a Polyscan 61E (Thermo Jarrell Ash) spectropolarimeter, allowed determination of S (182.040 nm), Zn (213.856 nm), Cd (228.802 nm), and Cu (324.803 nm) sample contents. Two alternative methods were used: conventional ICP implied no previous sample treatment,[16] while acid ICP included acid incubation of the sample (1 M HCl, 65 °C, 5 min) prior to ICP measurements. In both cases, protein concentration was calculated from the S content, assuming it was only contributed to by the Cys and Met residues of the peptides. In addition, protein concentration was assessed by amino acid analysis (hydrolysis in 6 M HCl at 110 °C for 22 h) on an Alpha Plus Amino Acid Autoanalyzer (Pharmacia LKB). Ser, Lys, and Gly contents were used to extrapolate MT concentrations.

GC-FPD[32] was used as the most suitable methodology for direct (i.e. without sample derivatization) S^{2-} detection at low concentrations, since it presents a quadratic response to compounds including one unique S atom.[25] H_2S was generated by strong acidification (H_2SO_4, pH 0.0) of the sample to ensure disruption of the metal–MT complex and to avoid precipitation of insoluble ZnS and CdS. The calibration curve was determined with dilute standards of S^{2-} at 0, 0.25, 0.5, 1, 1.5, 2.5, and 3 ppm prepared from a stock solution of S^{2-} at 1000 ppm which was obtained by dissolving a single crystal of $Na_2S{\cdot}9H_2O$ in oxygen-free water and standardized by iodine titration using $NaIO_3$.[22] Sample aliquots, as well as the standard solutions, were transferred to airtight 2-mL vials, acidified to a final volume of 0.5 mL, and immediately sealed. Vials were then incubated at 40 °C for 2 h with agitation (250 rpm) to accelerate the evolution of H_2S from the aqueous phase and equilibration of gas phase in the head-space. 500 μL of the head-space gas were subjected to gas chromatography (HP 5890 Serie II coupled to a FPD80 CE Instruments (Thermo Finnigan) detector). The gaseous mixture was carried by a 6.6 mL min^{-1} flux of He through the GC glass column (SPB 608 30 m × 0.25 mm i.d. with 0.5 μm particle size). Both the injection and the detection port were kept at 110 °C while the column was operated at a constant temperature of 35 °C. The H_2S peak generated from MT samples was readily identified by a retention time coincident with that of the standard solutions. All determinations were performed in duplicate with independent samples.

Ambident Anions

Ambident Reactivity of the Nitrite Ion Revisited**

*Alexander A. Tishkov, Uli Schmidhammer, Stefan Roth, Eberhard Riedle, and Herbert Mayr**

Dedicated to Professor Horst Kessler on the occasion of his 65th birthday

Extensive investigations on the reactions of the nitrite ion with alkylating agents[1] led Kornblum to the conclusion "*The greater the carbonium contribution to the transition state the greater is the yield of nitrite ester and the smaller is the yield of nitroparaffin.*"[1a] However, Pearson's specification of this rule, "*tC_4H_9Cl reacts with the hard oxygen atom of NO_2^-, while the softer CH_3I reacts with the softer nitrogen atom,*"[2a] which was expressed by Equation (1) in later theoretical treatments of ambident reactivity,[2b–d] is not in line with experimental findings, because CH_3I and other primary haloalkanes yield mixtures of alkyl nitrites and nitroalkanes with either $NaNO_2$ or $AgNO_2$.[1,2e]

(1)

Fleming's statement "*Although silver nitrite does react with alkyl halides to give nitrites, sodium nitrite gives more nitroalkane than alkyl nitrite*" [Eqs. (2) and (3)][3a] is contradicted by Streitwieser, Heathcock, and Kosower, who compare the reactions of iodoalkanes with $NaNO_2$ and $AgNO_2$ and conclude "*Yields of nitroalkane are higher when silver nitrite is used, but this added economy is tempered by the cost of silver salt*" [Eq. (4)].[3b]

$$AgNO_2 + RBr \rightarrow RONO \quad (2)$$

$$NaNO_2 + RBr \rightarrow RNO_2 \quad (3)$$

$$CH_3(CH_2)_6CH_2I + AgNO_2 \rightarrow CH_3(CH_2)_6CH_2NO_2\ (83\,\%) + CH_3(CH_2)_6CH_2ONO\ (11\,\%) \quad (4)$$

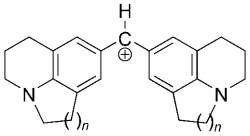
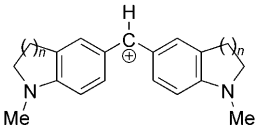
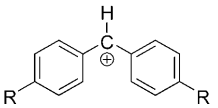
This confusion prompted us to reinvestigate the ambident reactivity of the nitrite ion with emphasis on absolute rate constants.

We have recently reported that the knowledge of absolute rate constants and of the diffusion control limit is a key to understanding the ambident reactivity of the thiocyanate[4a] and cyanide ions[4b] in alkylation reactions. These ambident anions are preferentially attacked at the soft S or C termini by hard and soft alkylating agents. Only when diffusion control is reached, can the attack of carbocations at the hard nitrogen compete with attack at sulfur (SCN^-) or carbon (CN^-), respectively. We now report on the kinetics and selectivities of alkylations of the nitrite ion.

Reactions of the blue benzhydrylium salts (**1a–d**)-BF_4 (see Table 1) with $n Bu_4N^+NO_2^-$ in anhydrous acetonitrile [Eq. (5)], which gave colorless adducts, were followed photo-







(5)

metrically using the stopped-flow technique described previously.[5] For $[\mathbf{1a–d}]_0 = (1–10) \times 10^{-6}$ M and $[NO_2^-]_0 = (1–100) \times 10^{-5}$ M, pseudo-first-order conditions were employed resulting in exponential decays of the benzhydrylium absorptions, from which the pseudo-first-order rate constants $k_{1\psi}$ (s^{-1}) were derived. The second-order rate constants k_2 ($M^{-1}s^{-1}$) listed in Table 1 were obtained as the slopes of the plots of $k_{1\psi}$ vs. $[NO_2^-]$.[6] From the linearity of these correlations one can infer that ion pairing does not play a role under these conditions.

The reactions with the highly electrophilic benzhydrylium ions **1e–k** (see Table 1) were too fast to be followed by stopped-flow techniques. Therefore, these carbocations were generated photolytically in the presence of the nitrite ion. For this purpose, solutions of (**1e–h**)-NO_2 (obtained according to

Table 1: Rate constants of the reactions of nitrite ions with the benzhydrylium cations **1a–k** (20 °C, MeCN).

Benzhydrylium ion			E[a]	k_2 [$M^{-1}s^{-1}$]
	$n=1$	**1a**	−10.04	1.58×10^5
	$n=2$	**1b**	−9.45	3.30×10^5

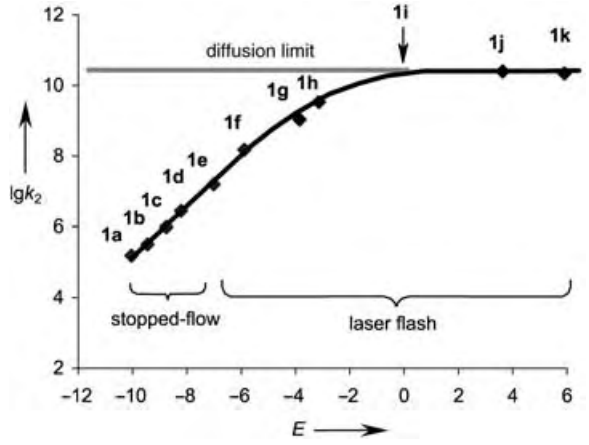
 DOI: 10.1002/anie.200501274 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Eq. (5)) or **1j**-Cl and nBu$_4$N$^+$NO$_2^-$ in acetonitrile were irradiated by laser pulses (< 1 ps, ca. 1.5 μJ, center wavelengths between 250 and 300 nm) to yield the benzhydrylium ions **1e–j** in less than 2 ps. The behavior of these transients (λ_{max} = 460–612 nm) was monitored on different timescales, and we detected reactions with 10 ms > $\tau_{1/2}$ > 10 ns.[7] As in the stopped-flow experiments, these reactions were also performed under pseudo-first-order conditions [Ar$_2$CH$^+$] ≪ [NO$_2^-$], and the second-order rate constants listed in Table 1 were again derived from plots of $k_{1\psi}$ vs. [NO$_2^-$].

In previous work we have shown that the reactions of carbocations with nucleophiles can be described by Equation (6), where k is the second-order rate constant, E is a

$$\log k_{20^\circ C} = s(E + N) \quad (6)$$

nucleophile-independent electrophilicity parameter, and N and s are electrophile-independent nucleophilicity parameters.[5,8] Figure 1 correlates the second-order rate constants listed in Table 1 with the previously determined electrophilicity parameters of benzhydrylium ions[5] and shows that the reactions of carbocations **1a–f** with NO$_2^-$ follow Equation (6).



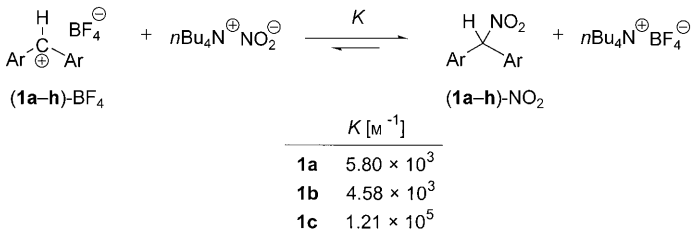


Figure 1. Plot of lg k_2 for the reactions of the nitrite ion with the benzhydrylium ions **1a–k** versus their electrophilicity parameters E (20 °C, MeCN).[5a]

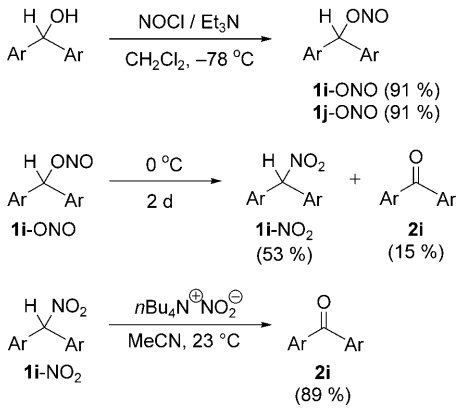
From the linear part of this correlation (**1a–f**) one can derive N = 17.2 and s = 0.72 for the nitrite ion in acetonitrile. For the more electrophilic benzhydrylium ions **1g–k**, a flattening of the curve can be seen, and the observed diffusion limit is in accord with the previously reported value of (2.2–2.7) × 10^{10} M^{-1} s^{-1} for reactions of carbocations with anions in acetonitrile.[6]

Which reactions are responsible for the decay of the benzhydrylium absorbances? Addition of an excess of nBu$_4$N$^+$NO$_2^-$ to solutions of benzhydrylium tetrafluoroborates (**1a–h**)-BF$_4$ in CD$_3$CN gives rise to the exclusive formation of the nitromethanes (**1a–h**)-NO$_2$[9] (Scheme 1), as revealed by the characteristic ^{1}H NMR chemical shifts of the benzhydryl protons (δ = 6.5–6.8 ppm) and the ^{15}N NMR



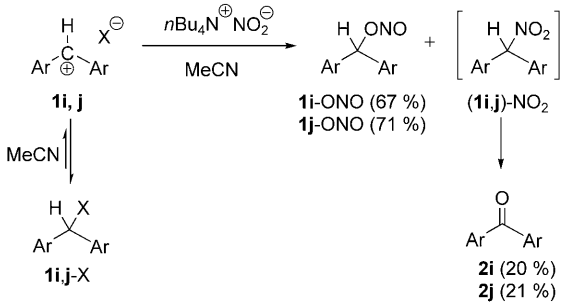
Scheme 1. Reactions of benzhydrylium tetrafluoroborates with nBu$_4$N$^+$NO$_2^-$ (equilibrium constants K in CH$_3$CN at 20 °C).

chemical shift of the nitro group (δ = 3.8 ppm) in **1e**-NO$_2$.[10] For the least reactive carbocations **1a–c** an excess of nBu$_4$N$^+$NO$_2^-$ is needed to drive the reactions toward completion. The equilibrium constants, which were determined by UV/Vis spectroscopy (see the Supporting Information), are listed in Scheme 1.[11]

These observations clearly indicate that the photometrically monitored process for the reactions of **1a–c** with NO$_2^-$ is N attack: Since alkyl nitrites are thermodynamically less stable than the corresponding nitro compounds,[12] the equilibrium constants for the formation of (**1a–c**)-ONO must be much smaller, and one can exclude that the observed rates of carbocation decay are due to the formation of (**1a–c**)-ONO, which rearrange to the observed nitro compounds (**1a–c**)-NO$_2$ in consecutive reactions.[13]

For the more electrophilic benzhydrylium ions **1d–h** one cannot a priori exclude the possibility that the UV/Vis spectroscopically monitored process is the formation of (**1d–h**)-ONO, which successively rearrange to the observed nitro compounds (**1d–h**)-NO$_2$. However, since the obtained rate constants for the reactions of **1d–h** with NO$_2^-$ are on the same correlation line as the rate constants for N attack at **1a–c** (Figure 1), the observed rate constants are compatible only with exclusive N attack or with simultaneous N and O attacks that occur with similar rates. In none of these cases could a biexponential decay be observed as in the reactions of some benzhydrylium ions with SCN$^-$, where the faster reversible S attack was followed by the slower irreversible N attack.[4a]

Pure benzhydrylium nitrites **1i**-ONO and **1j**-ONO were obtained by treatment of the corresponding benzhydrols with NOCl/Et$_3$N (Scheme 2), while analogous attempts to synthe-



Scheme 2. **i**: Ar = 4-MeOC$_6$H$_4$; **j**: Ar = 4-MeC$_6$H$_4$.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

size (**1a**–**h**)-ONO failed.[14] Whereas pure **1j**-ONO remained unchanged when stored at room temperature for several days, **1i**-ONO rearranged within two days at 0 °C into **1i**-NO_2, which decomposed to **2i** either spontaneously or upon treatment with nBu$_4$N$^+$NO$_2^-$ in MeCN (Scheme 2).[15]

Both benzhydrylium nitrites **1i**-ONO and **1j**-ONO were recovered unchanged when kept in a solution of nBu$_4$N$^+$NO$_2^-$ in acetonitrile for 3 h. These experiments show that benzhydryl nitrites **1i**-ONO and **1j**-ONO are kinetically stable under the conditions of the experiment described in Scheme 3. Treatment of the benzhydrylium halides **1i**-Cl and **1j**-Br with

Scheme 3. X = Cl, Br.

nBu$_4$N$^+$NO$_2^-$ in MeCN gave 7:2 mixtures of **1i**-ONO and benzophenone **2i**, and **1j**-ONO and benzophenone **2j**, respectively, which were analyzed by comparison of the NMR spectra of the product mixtures with those of authentic compounds. Since **1i**-ONO and **1j**-ONO are stable under the conditions of the experiment, and the benzophenones **2i** and **2j** are consecutive products of the corresponding diarylnitromethanes **1i**-NO_2 and **1j**-NO_2, the product ratios described in Scheme 3 imply a k_O/k_N ratio of 3.4 for the diffusion-controlled reactions of NO_2^- with the benzhydrylium ions **1i** and **1j**.

We thus conclude that diffusion-controlled reactions of benzhydrylium ions with NO_2^- occur preferentially at the O terminus.[16] Since Figure 1 shows that carbocations with $E > 0$ (i.e., carbocations less stabilized than **1i**) generally undergo diffusion-controlled reactions with NO_2^-, it is evident that the reactions of NO_2^- with most carbocations typically generated in S_N1 processes (e.g., *tert*-alkyl, allyl, and benzyl cations) proceed without an activation barrier. Explanations of the ambident reactivity of NO_2^- based on transition-state models, therefore, cannot apply. On the other hand, those benzhydryl nitrites, which are formed by activation-controlled reactions of benzhydrylium ions with NO_2^-, are thermodynamically unstable and rapidly isomerize to the corresponding nitro compounds.

Let us now turn to S_N2 reactions with the nitrite ion. Silver ion was proven to assist the cleavage of the C–Hal bond during the reactions of $AgNO_2$ with alkyl halides.[1a] However, in contrast to statements in the secondary literature (e.g., see ref. [3a]) silver ions were reported not to exert a significant influence on the O/N selectivity (Table 2, entries 1–4).[2e] On the other hand, the methyl nitrite/nitromethane ratio is changed significantly by variation of the solvent (Table 2, entries 5–8).[17]

We have now studied the reactions of nBu$_4$N$^+$NO$_2^-$ with soft (MeI) and hard ($MeOSO_2Me$, $MeOSO_2CF_3$, and $Me_3O^+BF_4^-$) methylating agents in $CDCl_3$. The yields were determined by integration of the ^{1}H NMR spectra with MeOAc as the internal standard. Overall yields were close to quantitative in all cases, and the methyl nitrite/nitromethane ratios (Table 2, entries 9–12) clearly indicate that the effect of the leaving groups on the O/N selectivities is small. Changing from the soft methylating agent MeI to the hard Me_3O^+ changes the O/N selectivities by only a factor of 2.4, while a larger difference is found among the hard methylating agents $MeOSO_2Me$ and $MeOSO_2CF_3$.

In conclusion, neither S_N1 nor S_N2 alkylations of the nitrite ion are satisfactorily described in the framework of perturbation molecular orbital theory (PMO). The reactions of carbocations with NO_2^- only yield kinetically controlled product mixtures when $k > 1 \times 10^9\,M^{-1}s^{-1}$, that is, when they proceed without an activation barrier. Therefore PMO approaches, such as the Klopman–Salem model, which aim at comparing relative activation energies cannot be applied. Furthermore, O/N selectivities of the methylations of the nitrite ion (Table 2) also do not correlate well with the hardness of the methylating agents. Thus, NO_2^- is the third prototype of the ambident anions (after SCN^- and CN^-)[4] for which the previously accepted rationalization by frontier orbital theory has to be withdrawn.

Table 2: O/N selectivities for methylations of nitrite ions.[a]

Entry	Nitrite	Methylation agent	Solvent	Me-ONO/Me-NO_2
1	$AgNO_2$	MeI	DMSO	46:54[b]
2	$NaNO_2$	MeI	DMSO	54:46[b]
3	$AgNO_2$	MeI	DMF	54:46[b]
4	$NaNO_2$	MeI	DMF	54:46[b]
5	KNO_2/[18]crown-6	$MeOSO_2Me$	EtOH	30:70[c]
6	KNO_2/[18]crown-6	$MeOSO_2Me$	MeCN	50:50[c]
7	KNO_2/[18]crown-6	$MeOSO_2Me$	THF	92:8[c]
8	KNO_2/[18]crown-6	$MeOSO_2Me$	C_6H_6	85:15[c]
9	nBu$_4$N$^+$NO$_2^-$	MeI	$CDCl_3$	30:70[d]
10	nBu$_4$N$^+$NO$_2^-$	$MeOSO_2Me$	$CDCl_3$	32:67[d]
11	nBu$_4$N$^+$NO$_2^-$	$MeOMe_2^+BF_4^-$	$CDCl_3$	50:50[d]
12	nBu$_4$N$^+$NO$_2^-$	$MeOSO_2CF_3$	$CDCl_3$	59:41[d]

[a] At room temperature. [b] Determined by LC with radioactivity detection for reactions of $^{11}CH_3I$ (see ref. [2e]). [c] Determined by GC (see ref. [17]). [d] Determined by integration of ^{1}H NMR spectra (this work, see the Supporting Information).

Asymmetric Synthesis

Highly Enantioselective Preparation of Tertiary Alcohols and Amines by Copper-Mediated Diastereoselective Allylic S_N2' Substitutions**

*Helena Leuser, Sylvie Perrone, Frédéric Liron, Florian F. Kneisel, and Paul Knochel**

The asymmetric preparation of tertiary alcohols and amines is an important synthetic problem that has been the subject of numerous studies.[1,2] Copper-catalyzed S_N2' substitutions are an excellent method for setting up chiral centers in cyclic and acyclic systems.[3–5] Only a few of these reactions can be applied to the construction of quaternary carbon centers.[6] We have recently reported an efficient *anti*-S_N2' allylic substitution reaction with pentafluorobenzoates of trisubstituted allylic alcohols that produces quaternary centers with almost complete transfer of the chiral information.[7] Herein, we report applications of this method for preparing chiral tertiary alcohols **1** and amines and isocyanates such as **2** and **3**, which bear a tertiary chiral center, with high enantioselectivity starting from the chiral allylic substitution products **4**, which were obtained from the allylic pentafluorobenzoates **5** (Scheme 1).

Scheme 1. Enantioselective preparation of tertiary alcohols **1**, amines **2**, and isocyanates **3** bearing a tertiary chiral carbon center.

In a typical procedure the *E* pentafluorobenzoate **5a** (97% *ee*, entry 1 of Table 1) was treated with $Pent_2Zn$ (2 equiv) and CuCN·2 LiCl (1 equiv) in THF at −30 to −10 °C for 14 h to afford the expected *anti*-S_N2' substitution product **4a** (70%, 96% *ee*) with an almost perfect transfer of chiral information. Functionalized diorganozinc reagents such as $(EtO_2C(CH_2)_3)_2Zn$[8] reacted in a similar way providing the corresponding chiral esters **4b** (68%, 96% *ee*) and **4c** (58%, 96% *ee*) with the same level of enantioselectivity. In all these substitutions, allylic pentafluorobenzoates were used as substrates. Other allylic alcohol derivatives such as 2,6-difluorobenzoate **5c** (99% *ee*) underwent the allylic substitution with optimum enantioselectivity leading to the *E* alkene **4d** in 85% yield and 98% *ee* (entry 4). These substrates also gave excellent results with purely alkyl-substituted allylic reagents such as **5d** (99% *ee*, entry 5). In this case, the substitution with Et_2Zn provided the *E* alkene **4e** (80%, 96% *ee*) bearing a quaternary center with three different alkyl substituents. Although allylic acetates react only sluggishly with diorganozinc reagents, in the case of the allylic acetate **5e** (97% *ee*), which bears small substituents (Me and Et) at the double bond, an efficient substitution with $Pent_2Zn$ took place providing the *E* alkene **4f** in 60% yield and 95% *ee*.

This substitution reaction proceeded with a reliable transfer of chirality (entries 7 and 8) and was also performed with secondary diorganozinc reagents like iPr_2Zn to furnish the sterically hindered alkene **4i** (73%, 95% *ee*; entry 9). Interestingly, functionalized allylic pentafluorobenzoates such as **5i** (99% *ee*) and **5j** (99% *ee*) provided useful chiral building blocks like **4j** (69%), **4k** (90%), and **4l** (80%) in enantiomerically pure form (99% *ee*; entries 10–12).

With the chiral alkenes of type **4** in hand, we then developed a straightforward oxidation sequence for the conversion of chiral alkenes **4** to either the corresponding aldehydes **12** or carboxylic acids **13** (Scheme 2). The former intermediate undergoes stereoselective Baeyer–Villiger rearrangement[9] to afford the chiral tertiary alcohol **1**, and the latter undergoes stereoselective Curtius rearrangement[10] leading to the isocyanates **3**, which can be converted to the corresponding amines **2**. In this way the ozonolysis of the alkene **4d** followed by a reductive workup (PPh_3, −78 to 25 °C, 2 h) provided the aldehyde **12a** in 85% overall yield and 98% *ee*. Treatment of **12a** with MCPBA (3 equiv, Na_2HPO_4, CH_2Cl_2, RT, 2 h) furnished, after saponification of the intermediate formyl ester, the tertiary alcohol **1a** (70%, 97% *ee*) with perfect retention of configuration (entry 1 of Table 2). Alternatively, the conversion of **4d** to the corresponding carboxylic acid **13a** (entry 2) was achieved when the ozonolysis was followed by a Jones oxidation. Heating **13a** with $(PhO)_2P(O)N_3$ in toluene for 1 h in the presence of Et_3N afforded an intermediate isocyanate, which was converted to the corresponding chiral amine **2a** (20% HCl, reflux, 18 h, 65%, 98% *ee*) with very high retention of the configuration for the chiral tertiary center.

These reaction sequences proved to be general, and the alkenes **4e** (96% *ee*) and **4g** (98% *ee*) afforded the alcohols **1b** (76%, 92% *ee*; entry 3) and **1c** (68%, 93% *ee*; entry 4), respectively, and the isocyanate **3a** (68%, 98% *ee*). Polyfunc-

[a] The enantiomeric excess was determined by HPLC or GC analysis. In each case the racemic product was also prepared for HPLC or GC calibration. [b] Yield of analytically pure product. [c] In this case the reaction was performed in a 2:1 THF/*N*-methylpyrrolidinone.

Scheme 2. Oxidation–rearrangement sequence for the preparation of chiral tertiary alcohols.

tional products such as selectively protected 1,2-diols bearing a tertiary hydroxyl group can be readily prepared starting from the chiral homoallylic benzyl ethers **4j** (99% *ee*), **4k** (99% *ee*) and **4l** (99% *ee*). After ozonolysis, the intermediate aldehydes **12d** (62%, 99% *ee*; entry 6), **12e** (66%, 99% *ee*; entry 8), and **12f** (71%, 99% *ee*; entry 10) were submitted to the Baeyer–Villiger reaction to provide the mono-protected diols **1d** (70%, 99% *ee*), **1e** (77%, 98% *ee*), and **1f** (93%, 96% *ee*), respectively. By performing the Curtius rearrangement on the corresponding carboxylic acids **13c** (65%, 99% *ee*; entry 7), **13d** (60%, 99% *ee*; entry 9), and **13e** (85%, 99% *ee*; entry 11), we obtained the amino alcohols **2b** (60%, 99% *ee*), and **2c** (88%, 99% *ee*), respectively, as well as the isocyanate **3b** (79%, 99% *ee*).

As an application of this methodology, we prepared the chiral 1,2-diol **14**, which is a key intermediate in the synthesis of the combined NK_1 and NK_2 tachykinin receptor antagonist (Scheme 3).[11] Thus, the S_N2' substitution of **5i** with $(PivO(CH_2)_3)_2Zn$ in the presence of CuCN·2 LiCl provided the chiral alkene **15** in 60% yield and 98% *ee*. The ozonolysis of **15** followed by reductive workup afforded the chiral aldehyde in 76% yield and 98% *ee*. Baeyer–Villiger oxidation of **16** in the presence of NaH_2PO_4 in CH_2Cl_2 followed by the saponification of the two ester functions gave the diol **17** in 70% yield. Quantitative protection of the remote primary hydroxy function as a TBDMS-silyl ether provided an intermediate alcohol, which underwent hydrogenolysis over Pd/C in 2-propanol (H_2 (1 atm), 25°C, 1 h) to furnish the

expected product **14**, an intermediate in the synthesis of a tachykinin receptor antagonist.

In summary, we have developed a straightforward sequence for the synthesis of tertiary alcohols with high enantioselectivity. We have shown that a Curtius rearrangement on the corresponding chiral carboxylic acids provides a stereoselective approach to amines bearing a tertiary center and to amino alcohol derivatives. Further applications of this method to the preparation of polyfunctional chiral building blocks are currently underway in our laboratories.

Experimental Section

Typical procedure for the copper(I)-mediated allylic substitution of fluorobenzoates with dialkylzinc reagents: **4d**:[7a]: $Pent_2Zn$ (2.35 mL, 11.3 mmol, 2.4 equiv) was added at −30 °C to a solution of CuCN·2-LiCl (5.6 mL, 5.6 mmol, 1.2 equiv, 1 M in THF) stirred under argon. The resulting mixture was stirred for 0.5 h at −30 °C, then **5c** (4.7 mmol in THF (2 mL), 1.0 equiv) was added dropwise. The reaction mixture was allowed to warm to −10 °C within 1.5 h and was stirred at −10 °C for 14 h. The reaction mixture was quenched by addition of aq. sat. NH_4Cl (5 mL) and was then poured into 25% aq. ammonia (2 mL), aq. sat. NH_4Cl (100 mL), and Et_2O (100 mL). After extraction with Et_2O (3 × 100 mL), the combined extracts were washed with brine (100 mL) and dried ($MgSO_4$). The solvents were

Scheme 3. Preparation of the diol **14**, an intermediate in the synthesis of the tachykinin receptor antagonist. a) $(PivO(CH_2)_3)_2Zn$, CuCN·2 LiCl, THF, −30→−10 °C, 16 h; b) O_3, CH_2Cl_2, −78 °C; c) PPh_3, RT, 2 h; d) MCPBA, NaH_2PO_4, CH_2Cl_2, RT, 2 h; e) LiOH, MeOH, RT, 5 h; f) TBDMSCl, imidazole, DMF, RT, 5 h; g) 1 atm H_2, Pd/C, *i*PrOH, RT, 1 h. MCPBA = *meta*-chloroperbenzoic acid, TBDMS = *tert*-butyldimethylsilyl.

removed by evaporation and the residue purified by column chromatography to yield alkene **4d** (855 mg, 3.96 mmol, 85 %) as a colorless liquid.

Typical procedure for the oxidation[12] and Baeyer–Villiger rearrangement[9] sequence: **1a**: Ozone was passed through a solution of alkene **4d** (260 mg, 1.20 mmol, 1.0 equiv) in CH_2Cl_2 (30 mL) at −78 °C under N_2 until the solution turned blue (3–10 min); excess O_3 was removed with a stream of N_2. PPh_3 (408 mg, 1.5 mmol, 1.3 equiv) was added in one portion, and the mixture was warmed to 20 °C within 2 h. The reaction mixture was then diluted with Et_2O (10 mL) and washed with water and brine, and then dried ($MgSO_4$). The solvents were removed by evaporation in vacuo, and the residue was purified by column chromatography to give **12a** (194 mg, 0.95 mmol, 85 %, 98 % *ee*) as a colorless liquid. The enantiomeric excess was determined by GC analysis (column: Chiraldex B-PH; 100 °C (30 min), 0.5° min^{-1} until 120 °C: t_R = 78.3 (*R*), 79.7 min^{-1} (*S*)). To a solution of aldehyde **12a** (163 mg, 0.80 mmol, 1.0 equiv) in CH_2Cl_2 (2 mL) was added anhydrous MCPBA (260 mg, 1.2 mmol, 1.5 equiv). The reaction was stirred at room temperature for 24 h before it was quenched with water and extracted with Et_2O (3 × 50 mL). The combined organic layers were dried ($MgSO_4$), concentrated in vacuo, and purified by flash chromatography (pentane/Et_2O = 98:2). (2*S*)-2-phenylheptan-2-yl formate (123 mg, 70 %) was obtained as a colorless liquid. To a solution of (2*S*)-2-phenylheptan-2-yl formate (123 mg, 0.56 mmol, 1.0 equiv) in MeOH (2 mL) was added KOH (62 mg, 1.12 mmol, 2.0 equiv). The reaction mixture was stirred at 20 °C for 1 h, then diluted with Et_2O (10 mL), washed with brine, dried ($MgSO_4$), and concentrated in vacuo. Purification by flash chromatography (pentane/Et_2O = 9:1) yielded **1a** (75 mg, 0.39 mmol, 70 %, 97 % *ee*) as a colorless oil. The enantiomeric excess was determined by GC analysis (column: chiraldex B-PH; 100 °C (30 min), 0.5° min^{-1}, 120 °C (60 min)): t_R = 78.3 (*S*), 79.7 min^{-1} (*R*)). Na_2HPO_4 (1 equiv) can be used as a buffer in order to enhance the rate of the reaction (reaction time reduced to 2 h at 20 °C) and to improve the *ee* value. See the Supporting Information for the preparation of compounds **1b** and **1c**.

Typical procedure for the oxidation[12] and Curtius rearrangement:[10] **2a**: Ozone was passed through a solution of alkene **4d** (432 mg, 2.00 mmol, 1.0 equiv) in acetone (10 mL) at −78 °C under N_2 until the solution turned blue (3–10 min); excess O_3 was removed by a stream of nitrogen. The reaction mixture was cooled to 0 °C, and Jones reagent (2.0 mL, 2.67 M, 5.4 mmol, 2.7 equiv) was added dropwise until the orange color persisted. The mixture was stirred for 1 h at 20 °C, then *i*PrOH (8 mL) was added until the mixture turned green. The solvents were removed by evaporation, and the residue was dissolved in water/ (100 mL, 1:4). After acid–base workup[12c] the desired carboxylic acid **13a** (348 mg, 1.58 mmol, 79 %) was obtained as a colorless liquid. A mixture of **13a** (124 mg, 0.56 mmol, 1.0 equiv), $(PhO)_2P(O)N_3$ (231 mg, 0.84 mmol, 1.5 equiv) and NEt_3 (85 mg, 0.84 mmol, 1.5 equiv) in toluene (5 mL) was heated at reflux for 2 h. After removal of the solvent by evaporation in vacuo, the residue was taken up in ether (50 mL) and washed with water (3 × 50 mL). The organic layer was dried ($MgSO_4$), concentrated in vacuo, and purified by flash chromatography (pentane/Et_2O = 98:2). 1-((2*S*)-2-Isocyanatoheptan-2-yl)benzene (120 mg, quant., 98 % *ee*) was obtained as a colorless liquid. The enantiomeric excess was determined by GC analysis (column: Chiraldex B-PH; 100 °C const.: t_R = 57.8 (*S*), 61.9 min^{-1} (*R*)). 1-((2*S*)-2-isocyanatoheptan-2-yl)benzene (50 mg, 0.23 mmol) was heated at reflux in 20 % aq. HCl (5 mL) for 24 h. The reaction mixture was partitioned in Et_2O and water (4:1), and the layers were separated. The aqueous layer was treated with NaOH (20 %) and extracted with Et_2O (3 × 80 mL). The organic layer was dried ($MgSO_4$) and the solvent evaporated in vacuo to give **2a** (30 mg, 0.16 mmol, 65 %, 98 % *ee*) as a colorless oil.

Protein Folding

^{13}C-Labeled Tyrosine Residues as Local IR Probes for Monitoring Conformational Changes in Peptides and Proteins**

Sandra Tremmel, Michael Beyermann, Hartmut Oschkinat, Michael Bienert, Dieter Naumann, and Heinz Fabian**

Fourier transform infrared (FTIR) spectroscopy has become a valuable tool for studying the secondary structure of proteins and for monitoring conformational changes associated with protein unfolding, folding, and misfolding.[1–3] Most studies in the past have focused on components of the intense amide I band (primarily the C=O stretch of the secondary amide group) in the IR spectra between 1610 and 1700 cm^{-1} as established indicators of protein secondary structure. Besides the amide I band of the peptide backbone, several amino acid side-chain absorption bands may serve as intrinsic local monitors of conformational changes. Very useful is the relatively strong absorption band of the tyrosine side chain (C–C stretching vibration of the aromatic ring) at $\approx$1515 cm^{-1}, which can be distinguished particularly well in the infrared spectra of proteins.[4] The frequency of this band may change in a characteristic manner upon unfolding, folding, and aggregation of proteins. For proteins whose unfolding is reversible, a discontinuous high-frequency shift of the tyrosine vibration around the corresponding denaturation temperatures was observed.[5–7] In a structureless peptide, the tyrosine band displayed only a minor gradual shift to lower wavenumbers upon increasing temperature, reflecting a general effect of temperature.[5] A relatively large downshift of the tyrosine vibration was observed for proteins upon aggregation, which has been suggested as indicative of stronger hydrogen bonds of the tyrosine OH group with acceptors in the protein aggregates.[6,8] However, if the corresponding peptide or protein contains more than one tyrosine residue, the site-specific information is limited. Removal of all but one of the tyrosine residues by site-directed mutagenesis is one possible solution to this problem. However, if the corresponding residues are, for example, part

of the hydrophobic core of the protein, mutating them may destabilize the protein and/or affect its function. Herein we demonstrate that an ideal alternative to site-directed mutagenesis is site-directed isotope labeling, such as the introduction of individual tyrosine residues labeled with ^{13}C at the C4 position of the phenol ring. Consequently site-specific structural specificity is added to the spectrum since the vibration of the labeled residue is shifted by $\approx 10\ cm^{-1}$,[9] thus providing a well separated unique spectroscopic signature. While isotopic labeling of tyrosines to probe proteins by IR spectroscopy is not new, the current application to obtain information on the microenvironment of distinct tyrosine side chains and to monitor simultaneously local conformational changes in different regions of proteins is novel.

To explore the potential of site-directed isotope labeling, we studied changes in the infrared-spectroscopic behavior of distinct tyrosine residues caused by the thermal unfolding of the formin-binding protein 28 (FBP28) WW domain. This protein contains four tyrosine residues, one located in strand 1 (position 11), whereas the remaining three (at positions 19, 20, and 21) are located in strand 2 (Scheme 1, peptide **1** in Table 1). WW domains are the smallest naturally occurring three-stranded β sheets identified so far. They are named after the two conserved tryptophan residues and function as noncatalytic domains of signaling proteins by recognizing proline-containing ligands.[10] Recently, several WW domains served as model systems for studies of β-sheet stability and folding.[11–19] Among them, the FBP28WW domain was reported to be monomeric and stable, although under certain conditions aggregation and even fibril formation have been observed.[18]

Scheme 1. Structural features of the FBP28WW domain. The sequence 6–33 (gray) forms a defined three-dimensional structure, including three strands and two loops.[11] The locations for the application of pseudo-proline building blocks to enable the successful synthesis and the positions for $^{13}C_1$(4)-tyrosine labeling are indicated (Oxa = Ser/Thr-derived oxazolidine-4-carboxylic acid).

[a] Amidated at the C terminus.

The preparation of WW analogues, including the incorporation of labeled amino acids, should be feasible by solid-phase peptide synthesis (SPPS).[20] However, initial attempts to synthesize wild-type FBP28WW (peptide **1**) by SPPS failed, which is not unexpected for the assembly of β-sheet-forming sequences.[21] Fortunately, the synthesis could be improved considerably by insertion of two X-Ser and X-Thr dipeptides (X = pseudo-proline) in the form of the corresponding pseudo-proline derivatives.[22] In addition, aspartate in position 15 was replaced by asparagine (peptide **2**) in order to minimize the high propensity for aspartimide formation[23] of the Asp15-Gly16 unit (Scheme 1; see the Supporting Information).

The low-temperature IR spectra (Figure 1a, blue traces) of the [Asn^{15}]-FBP28WW variant (peptide **2**) recorded between 10 and 90 °C during the course of a thermal denaturation experiment (see the Supporting Information) are characterized by a major amide I band centered at $1636\ cm^{-1}$ and a weaker band component at $1679\ cm^{-1}$, indicating the presence of antiparallel β-sheet structures.[1–3] The infrared bands between 1500 and $1612\ cm^{-1}$ are due to absorptions of amino acid side chains: tyrosine (1515 and $1612\ cm^{-1}$), glutamate ($1565\ cm^{-1}$), and arginine ($1587\ cm^{-1}$).[4] The amide I region of the spectrum recorded at 90 °C is dominated by bands at 1616 and $1685\ cm^{-1}$ (Figure 1a, black trace). These bands are characteristic of intermolecular β-sheet structures,[1–3] indicating that thermal denaturation of the [Asn^{15}]-FBP28WW variant involves aggregation.

During our search for FBP28WW analogues with a reduced tendency toward aggregation, we surprisingly found that insertion of Gln residues in certain positions was very successful (peptide **3**, Table 1). Peptide **3** displayed the typical fold of the FBP28WW domains when it was characterized by NMR spectroscopy[27] and did not form intermolecular β-sheet structures at high temperatures, which is indicated by the lack of the characteristic IR "aggregate" bands at 1616 and $1685\ cm^{-1}$. Instead, the high-temperature spectra of peptide **3** are dominated by a broad and featureless amide I band centered at $1648\ cm^{-1}$ (Figure 1b), indicative of structureless proteins.[1–3] This is also valid for peptide **4** (spectra not shown), in which additionally two Tyr residues have been replaced by Phe in order to permit the assignment of tyrosine-mediated spectroscopic changes to a single Tyr residue. The temperature-induced decrease in intensity of the low-frequency component of the amide band at $1636\ cm^{-1}$ (Figure 2a) and the frequency shift of the stretching vibration of tyrosine's aromatic ring at $\approx 1515\ cm^{-1}$ (Figure 2b) revealed sigmoidal unfolding transitions between 10 and 90 °C for the two peptides.

The Tyr→Phe substitution, however, decreased the denaturation temperature

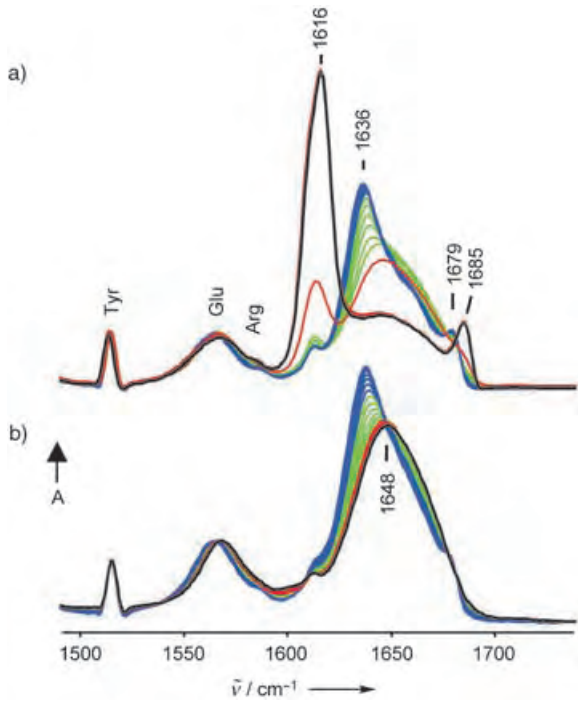

Figure 1. Deconvolved infrared spectra of a) peptide **2** and b) peptide **3** in D_2O buffer (50 mM phosphate, 50 mM sodium chloride, pD 7.6) as a function of temperature. Blue traces, 10–40 °C; green traces, 45–70 °C; red traces, 75–85 °C; black traces, 90 °C.

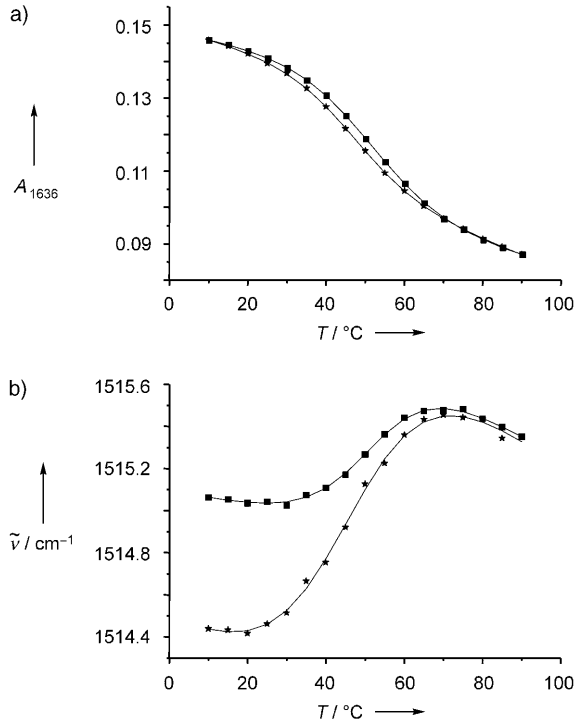

Figure 2. a) Temperature dependence of the peak intensity of the amide I band at 1636 cm^{-1} and b) temperature dependence of the position of the tyrosine band for peptide **3** (■) and peptide **4** (⋆). The peak intensities at 1636 cm^{-1} were normalized relative to the signal obtained at 90 °C. The solid lines represent the best fit used to estimate the denaturation temperatures (T_m).

by ≈5 K,[24] which demonstrates a drawback of the mutation approach. Therefore, we labeled peptide **3** with $^{13}C_1$(4)-Tyr residues site-specifically. In order to probe simultaneously temperature-induced changes in the local environment of Tyr11 located in strand 1 of the WW domain (see Scheme 1), and of Tyr19, a highly conserved residue of the second strand of WW proteins,[11] we synthesized the labeled peptides **5** and **6**. As expected, selective $^{13}C_1$(4)-labeling of Tyr11 (Figure 3, middle trace) or of Tyr19 (Figure 3, upper trace) led to a drop of intensity at 1515 cm^{-1} and the appearance of a new band at 1505 cm^{-1}.

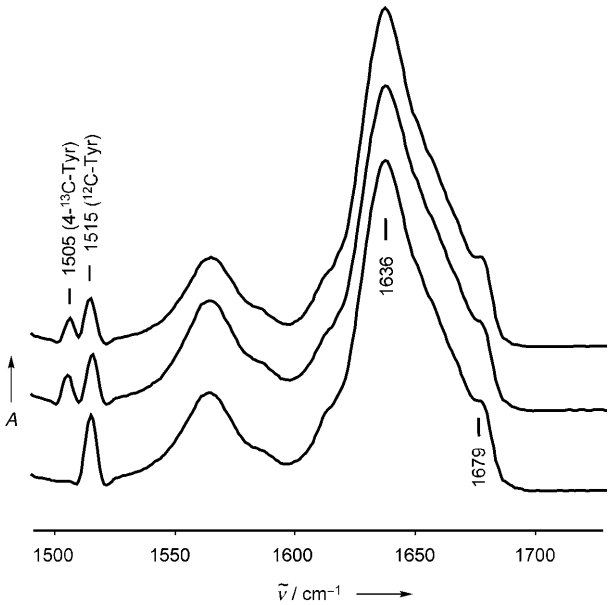

Figure 3. Deconvolved infrared absorbance spectra of unlabeled (peptide **3**, lower trace), site-specifically $^{13}C_1$(4)-Tyr11-labeled (peptide **5**, middle trace), and site-specifically $^{13}C_1$(4)-Tyr19-labeled (peptide **6**, upper trace) FBP28WW peptides in D_2O buffer (50 mM phosphate, 50 mM sodium chloride, pD 7.6) at 10 °C.

The temperatures of thermal denaturation, derived from the IR bands of Tyr11 in strand 1 and of Tyr19 in strand 2, were found to be practically identical,[25] suggesting no major differences in the thermal response of the conformational changes in both strands of the FBP28WW peptide **3**. An inspection of the transition profiles, however, revealed striking differences between the bands of the labeled Tyr11 and Tyr19 residues (Figure 4b). While the band due to Tyr11 displayed only minor frequency changes, a relatively large shift to higher frequencies by ≈0.6 cm^{-1} was observed for Tyr19. At high temperatures, the peak positions were practically identical, as expected for an unfolded peptide. Moreover, the frequency changes of less than 0.2 cm^{-1} due to labeled Tyr11 observed around the thermal denaturation temperature of peptide **5** (Figure 4b) were comparable to the minor mean spectroscopic changes due to unlabeled Tyr11 and Tyr20 in peptide **6** (Figure 4a), suggesting a very similar temperature response of Tyr11 and Tyr20. Altogether, this indicates that in the folded state of the peptides the local

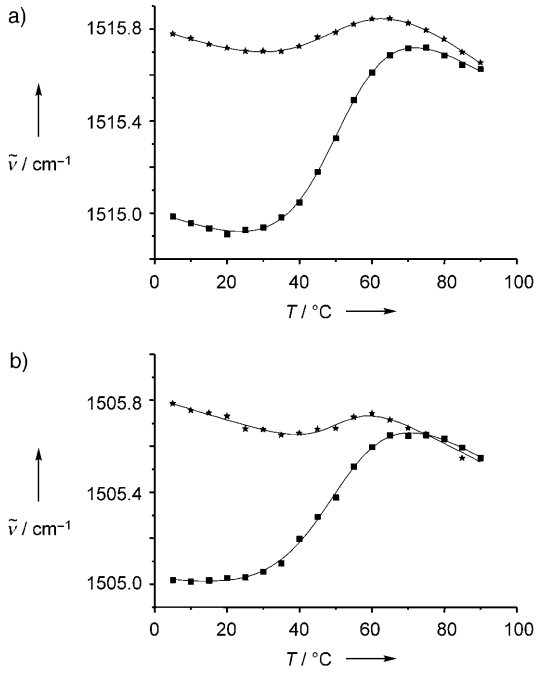

Figure 4. Temperature dependence of the position of the tyrosine bands of site-specifically $^{13}C_1(4)$-Tyr11- and $^{13}C_1(4)$-Tyr19-labeled [Gln^{9,21,23,26,28},Asn^{15}]-FBP28WW. a) Positions of the unlabeled tyrosines of peptide **5** (■) and of peptide **6** (⋆). b) Positions of the labeled tyrosine of peptide **5** (⋆) and of peptide **6** (■).

environments of Tyr19, on one side, and of Tyr11/Tyr20, on the other side, must differ considerably.

A plausible explanation for a strong shift of the tyrosine band to higher frequencies upon protein unfolding would be a strengthening of tyrosine O–H bonds, caused by loosening of hydrogen bonds between the tyrosine OH group and neighboring acceptors.[5,6] The available information on the FBP28WW structure, however, provides no hints for tyrosine OH groups being involved in hydrogen bonding. This suggests that effects other than hydrogen bonding may also affect the spectroscopic features of the corresponding ring vibration. A possible explanation may be altered π–π interactions between tyrosine rings and conjugated systems of other residues.[6,26] In the FBP28WW domain Trp30 is close to Tyr19.[11] Thus, the temperature-dependent shift of the Tyr19 side-chain band observed herein might reflect a disruption of π–π interactions between Tyr19 and the indole ring of Trp30. If so, than the infrared band of Tyr19 provides a local probe of specific interactions between residues located in strands 2 and 3 of the WW domain.

In summary, we have demonstrated that FTIR spectroscopy along with site-directed $^{13}C_1(4)$-labeling of tyrosine residues is a promising new approach to obtain information on the microenvironment of distinct tyrosine side chains and to monitor simultaneously temperature-induced local conformational changes in different regions of a given protein. In combination with time-resolved IR-spectroscopic techniques, this strategy offers novel possibilities for studying protein unfolding and folding events at the level of individual groups in a peptide or protein. We are currently conducting both peptide synthesis and spectroscopic studies in order to improve our insights into the role of the tyrosine residues in the stabilization and unfolding of the β-sheet structure of FBP28WW and other WW domains.

Molecular Devices

Geometrically Precisely Defined Multinanometer Expansion/Contraction Motions in a Resorcin[4]arene Cavitand Based Molecular Switch**

*Vladimir A. Azov, Anna Schlegel, and François Diederich**

The invention of molecular devices that undergo reversible controlled mechanical movements on the nanometer scale and thereby mimic natural phenomena such as muscle expansion/contraction is a hot target in contemporary chemistry.[1] Elegant examples of molecular and supramolecular switches with bistable conformations of profoundly different geometry have been described in recent years.[2–7] On the other hand, the conformational space available in the contracted and expanded states of the reported systems often is rather large and the geometric differences not always well defined. We became interested in developing a rigid molecular system in which both states adopt a precisely defined geometry and report here a first example based on a bridged resorcin[4]arene scaffold. These cavitands, first introduced by Cram and co-workers,[8] can be reversibly switched between a contracted (vase) and an expanded (kite) conformation upon variation of temperature[8–10] or pH,[11] or upon metal-ion addition.[12]

Recent advances in the synthesis of partially or differently bridged resorcin[4]arene cavitands[13,14] enabled the preparation of **1**, in which two opposite cavity walls are greatly extended by attachment of rigid oligo(phenylene ethynylene) arms. A donor–acceptor BODIPY (dipyrromethene boron difluoride) dye pair[15] is attached to the oligomeric termini to allow observation of the switching process by fluorescence resonance energy transfer (FRET).[16] BODIPY dyes were chosen for the targeted pH-induced switching, since their emission behavior features low sensitivity to pH and environmental polarity, as we could confirm in model studies. Computer model building,[17] based on X-ray crystal structures of bridged resorcin[4]arene cavitands in both vase and kite conformations,[12,13b] suggested a ≈1000% difference in the distance between the dye pair in the contracted (≈7 Å) and expanded (≈7 nm) states (Figure 1), which should allow convenient detection of different FRET behavior in the two states.[16a]

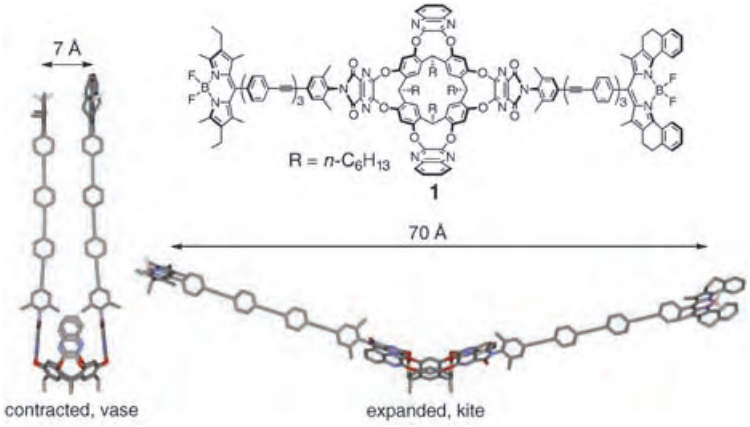

Figure 1. Donor–acceptor dye-labeled cavitand **1** and its extensions in the contracted (vase) and expanded (kite) states. In the models, the alkyl chains ("legs") of the cavitand are omitted.

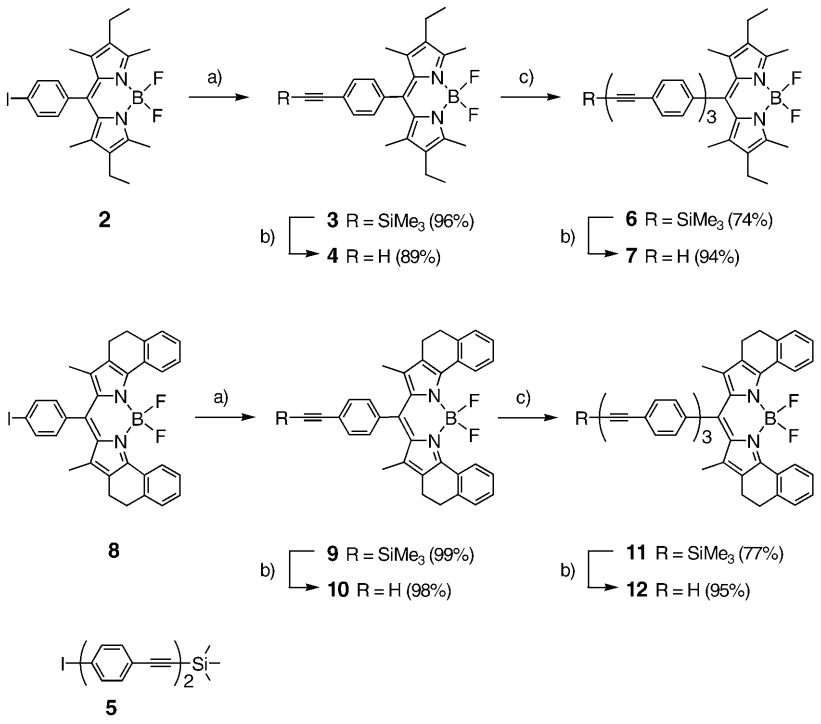
The synthesis of **1** proceeded in a highly convergent manner. Sonogashira cross-coupling[18] of **2**[15b] with Me_3Si-C≡CH afforded **3**, which was deprotected to give **4**. A second cross-coupling with aryl iodide **5**[19] provided **6**, which was deprotected to yield the donor dye-appended **7**. A similar route led from **8**[15a] (via **9**→**10**→**11**) to the acceptor building block **12** (Scheme 1).



The cavitand core **13** was prepared by bridging **14**[13,14] with imide **15** (Scheme 2). ^{1}H NMR investigations revealed reversible vase–kite switching of **13** induced either by changes in temperature or pH. Upon addition of trifluoroacetic acid (TFA) to a solution of **13** in CH_2Cl_2 or when the temperature was lowered from 60 °C to −60 °C, the signals of the methine

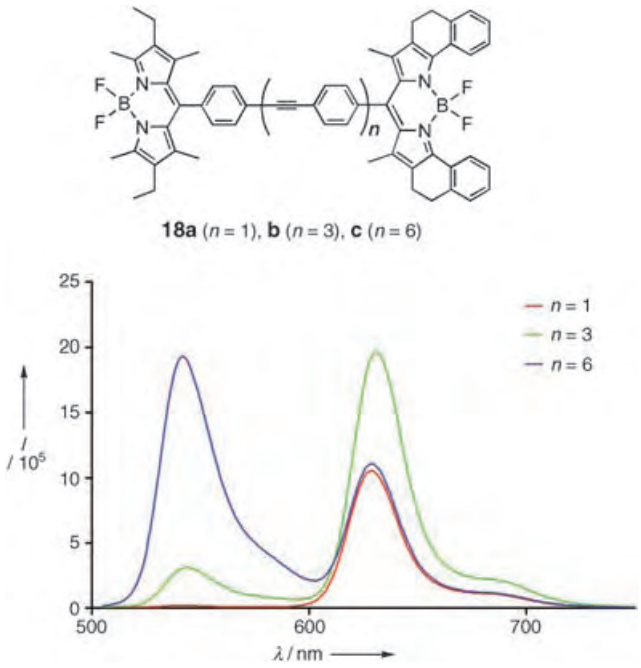
Scheme 1. Synthesis of the donor dye (**7**) and acceptor dye (**12**) building blocks. a) Me_3Si-C≡CH, $[Pd(PPh_3)_4]$, CuI, $Et(iPr)_2N$, tetrahydrofuran (THF), 20 °C, 1–3 d; b) Bu_4NF, THF, −78 °C, 30 min; c) **5**, $[Pd(PPh_3)_4]$, CuI, $Et(iPr)_2N$, THF, 20 °C, 1–3 d.

protons in the resorcin[4]arene core shifted upfield from ≈5.6 ppm to ≈3.6 ppm, which is characteristic for the expansion process (see the Supporting Information). Sonogashira cross-coupling of **13** with **7** afforded a mixture of the three cavitands **13**, **16**, and **17**, which was separated by gel permeation chromatography (GPC, Biorad-BioBeads SX-1, CH_2Cl_2; see the Supporting Information). A second cross-coupling of **16** with **12** provided the target structure **1** as a stable, high-melting dark-violet solid after GPC purification. The reversed sequence of dye addition to **13** (first **12** followed by **7**) was much less fruitful due to the poor solubility of the singly labeled intermediate. The spectroscopic data fully support the structural assignment for **1**. The base peak in the high-resolution matrix-assisted laser-desorption-ionization mass spectrum (HR-MALDI-MS, matrix: 3-hydroxypicolinic acid (3-HPA)) corresponds to the molecular ion after loss of one F atom at *m/z* 2880.2161 ($[M-F]^+$, $C_{188}H_{156}B_2F_3N_{14}O_{12}^+$; calcd 2880.2160).

To test distance-dependent FRET between the chosen donor and acceptor BODIPY dye pair, we also prepared the three oligo(phenylene ethynylene)s **18a–c** of different lengths (Figure 2). Fluorescence spectroscopy in very dilute $CHCl_3$ solution ($c = 0.5 \times 10^{-7}$ M) showed that the FRET efficiency strongly decreases with increasing length of the rigid spacer from about 98% for **18a** (distance $r = 19$ Å between the B atoms of the dyes), to ≈85% for **18b** ($r = 32$ Å), and to ≈35% for **18c** ($r = 53$ Å). Importantly, addition of TFA (up to $c = 0.3$ M) does not affect the emission behavior.

The two bis(BODIPY dye)-appended cavitands **1** and **17** were shown by ^{1}H NMR spectroscopy to adopt the contracted (vase) conformation in CD_2Cl_2 or $CHCl_3$ above 25 °C (see the Supporting Information). Upon lowering the temperature to −60 °C or upon addition of TFA (up to 0.27 M), they both undergo expansion to the kite forms as clearly evidenced by the characteristic large upfield shift (≈5.6 → ≈3.6 ppm) of the resorcinarene methine protons.[20]

Whereas the fluorescence spectrum of bis(donor dye)-appended **17** is nearly identical in the contracted and expanded forms (see the Supporting Information), the emission behavior of target compound **1** differs dramatically in the two states. The UV/Vis spectrum of **1** (Figure 3a) in $CHCl_3$ ($c = 1.0 \times 10^{-5}$ M) displays three strong absorption bands assigned to the oligo(phenylene ethynylene) spacers (λ_{max} 332 nm), the donor dye (529 nm), and the acceptor dye (619 nm); these bands are not affected by the addition of TFA. The emission spectrum in $CHCl_3$ ($c = 0.5 \times 10^{-7}$ M, $\lambda_{exc} = 490$ nm, 20 °C) features two strong peaks at 542 nm (donor dye) and 630 nm (acceptor dye) with an integral ratio of the donor/acceptor fluorescence intensity of 45:55. In view of the prevalence of the contracted vase conformation under these conditions, as demonstrated by ^{1}H NMR spectroscopy, this relatively low FRET efficiency is rather surprising. We tentatively explain it by either a) the dynamic behavior of the cavitand,[20] with constant wagging vibrations separating the two dyes one from another for a statistically important amount of time, or b) unfavorable orientations of the transition dipole moments of the dyes.



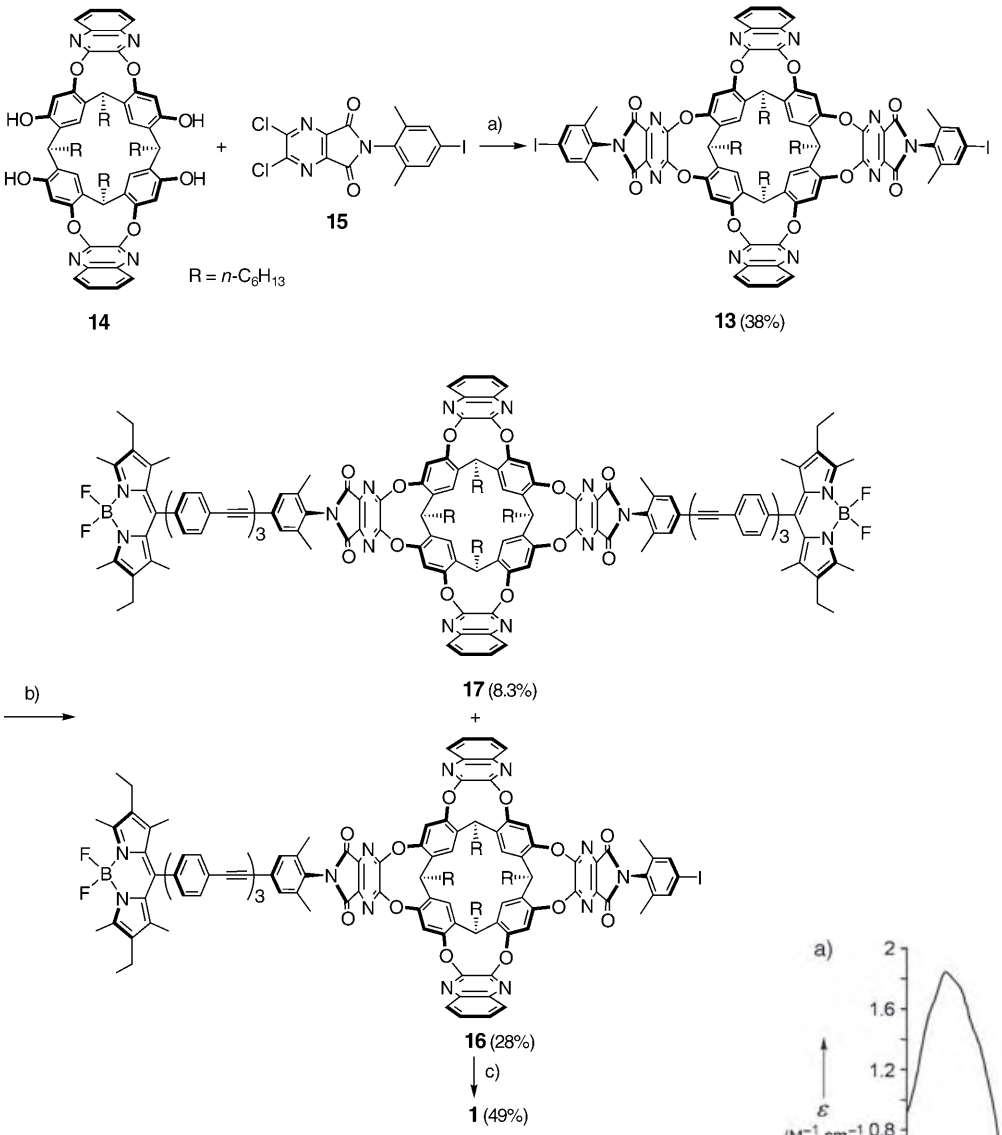


Figure 2. FRET intensities of **18a–c** in $CHCl_3$ ($c = 0.5 \times 10^{-7}$ M). The higher energy band is the donor emission and the lower energy band the acceptor emission.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 2. Synthesis of target compound **1**. a) K_2CO_3, Me_2SO, 35 °C, 2 d; b) **7** (0.75 equiv), [Pd(PPh_3)$_4$], CuI, Et(*i*Pr)$_2$N, THF, 35 °C, 2 d; c) **12** (2.25 equiv), [Pd(PPh_3)$_4$], CuI, Et(*i*Pr)$_2$N, THF, 35 °C, 2 d.

Upon addition of TFA, (Figure 3b) the acceptor fluorescence vanishes nearly completely, whereas the donor fluorescence doubles in intensity. In the expanded state, with a separation of donor and acceptor of ≈ 7 nm, the FRET efficiency is dramatically reduced. This result could only be obtained since the expanded conformation of **1** is very rigid, strongly limiting the available conformational space. Intermolecular FRET is clearly not effective at the low concentration range of the experiment ($c = 0.5 \times 10^{-7}$ M). The spectral changes are reversed upon reneutralization with base (Et(*i*Pr)$_2$N).

Thus, the large-scale expansion/contraction movement of **1** (Figure 1) is clearly proven by both ^{1}H NMR spectroscopy and FRET measurements. We are now further investigating the dynamics of the switching motion in single-molecule studies using confocal fluorescence microscopy.[21]

Experimental Section

Compound **1**: Cavitand **16** (13.2 mg, 5.73 μmol), **12** (9.3 mg, 13 μmol, 2.25 equiv), [Pd(PPh_3)$_4$] (1.3 mg, 0.11 μmol), and CuI (0.22 mg, 0.11 μmol) were mixed together in a Schlenk apparatus filled with Ar. $CHCl_3$ (0.3 mL) and THF (0.3 mL) were added, and the mixture was degassed by freeze-pump-thaw cycles. Et(*i*Pr)$_2$N (0.02 mL, 120 mmol) was added and the mixture degassed again, then stirred at 35 °C for 2 d. The mixture was concentrated to dryness, and flash chromatography (SiO_2; CH_2Cl_2/EtOAc gradient 0→0.5 %) yielded crude **1**. Further purification by repeated GPC (Biorad BioBeads SX-1, CH_2Cl_2), afforded **1** (8.2 mg, 49 %) as a dark-violet solid. M.p. > 300 °C (decomp.); $R_f = 0.32$ (SiO_2; CH_2Cl_2/EtOAc 99.4:0.6); ^{1}H NMR (300 MHz, $CDCl_3$): $\delta =$ 0.91–1.02 (m, 18H), 1.26–1.54 (m, 50H), 2.23 (s, 6H), 2.22–2.36 (m, 12H), 2.49–2.54 (m, 10H), 2.86 (br t, $J = 7$, 4H), 5.62 (t, $J = 8.1$, 2H), 5.71 (t, $J = 8.1$, 2H), 7.24–7.62 (m, 38H), 7.66–7.74 (m, 4H), 7.86–7.91 (m, 4H), 8.25 (s, 4H), 8.80 ppm (br d, $J = 7.8$, 2H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 12.10$, 12.55, 12.75,

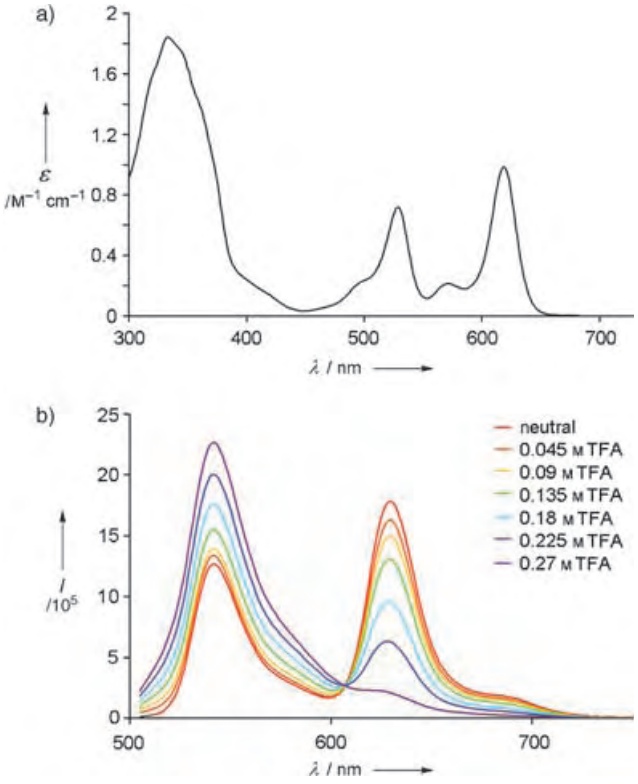

Figure 3. a) UV/Vis spectrum of **1** in $CHCl_3$ at 20 °C ($c = 1.0 \times 10^{-5}$ M). b) Fluorescence spectra of **1** in $CHCl_3$ at 20 °C ($c = 0.5 \times 10^{-7}$ M) recorded at different concentrations of TFA.

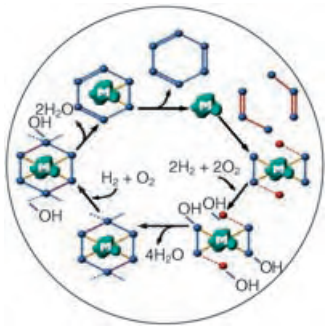
Cover Picture

Jesse L. C. Rowsell and Omar M. Yaghi*



Hydrogen storage strategies for metal–organic frameworks have been developed recently to enhance their applicability in this role, as shown in the cover picture. In their Minireview on page 4670 ff., O. M. Yaghi and J. L. C. Rowsell discuss the various approaches used to reach the required compromise between high porosity and smaller pore size for stronger binding of H_2 under ambient conditions. In their Communication on page 4745, B. Chen, O. M. Yaghi, and co-workers report a promising hydrogen-storage material with open metal sites.

Aldol Reactions
In their Review on page 4682 ff., S. E. Denmark et al. explore the scope and limitations of the catalytic, enantioselective, vinylogous aldol reaction, in which dienolates derived from γ-enolizable α,β-unsaturated carbonyl compounds are added to aldehydes.

Pharmaceutically Active "Prils"
Chiral building blocks for the synthesis of these angiotensin-converting-enzyme inhibitors can be produced on a large scale. Their application in the structure-guided redesign of the active site of almond (*R*)-*Pa*HNL5 is discussed by K. Gruber, A. Glieder, and co-workers in their Communication on page 4700 ff.

No Pressure
The coupling of propylene to generate benzene at 70 °C and atmospheric pressure is discussed by E. W. McFarland and co-workers in the Communication on page 4735 ff. The selectivity of the benzene formation depends on the size of the Pd^0 cluster and on the presence of hydrogen and oxygen.

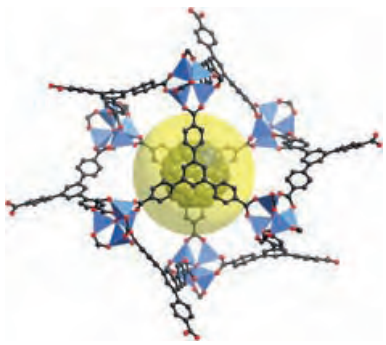
Residual Dipolar Couplings—A Valuable NMR Parameter for Small Organic Molecules



The partial alignment of small organic molecules is now also possible in organic solvents by mechanically constrained polymer gels or modified liquid-crystalline phases. This paves the way to apply residual dipolar couplings to small molecules and thus to use an additional NMR parameter to determine the structure and configuration of small organic molecules (e.g. spiroindene (**1**), see picture).

Strategies for Hydrogen Storage in Metal–Organic Frameworks

Reaching a compromise: Metal–organic frameworks such as MOF-177 (see picture) are potential hydrogen-storage materials, but the pores (yellow sphere) are much larger than the molecular diameter of H_2, thus limiting their effectiveness. Their hydrogen uptake may be improved by impregnation with other moieties (such as C_{60}, gray) to provide additional adsorptive sites and stronger H_2 binding at the expense of high porosity.

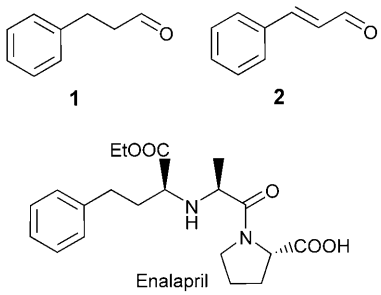
Reviews

The power of the aldol reaction is extended through the use of γ-enolizable α,β-unsaturated carbonyl substrates as "extended dienolates" in the addition to aldehydes. This process gives δ-hydroxy carbonyl compounds **1** or **2** with up to two new stereocenters (see scheme). New methods for the catalytic, enantioselective, vinylogous aldol reaction are summarized, and the scope and limitations of these systems are discussed.



Asymmetric Catalysis

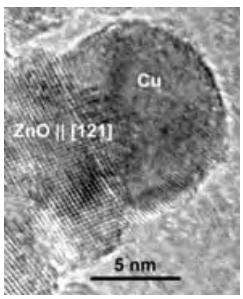
Catalytic, Enantioselective, Vinylogous Aldol Reactions

Communications



Structure-guided redesign of the active site of almond (*R*)-*Pa*HNL5 for increased enantioselectivity resulted in four improved muteins. In particular, mutation V360I gave enhanced conversion rates and enantioselectivities higher than 96% *ee* for two structurally related substrates **1** and **2**. Chiral building blocks for the synthesis of pharmaceutically active "prils" (example shown) can thus be produced on a large scale.

Carving the Active Site of Almond *R*-HNL for Increased Enantioselectivity

Approaching reality: Copper zinc oxide catalysts that were prepared similarly to industrial catalysts were studied by high-resolution electron microscopy. The microstructure of the Cu/ZnO catalysts (see picture) deviates considerably from that of idealized copper model systems. Future model systems for copper catalysts in methanol chemistry must take into account the "real" structure of active copper catalysts.

Monolayer lithography: The concept of orthogonal cleavage of photolabile protecting groups was demonstrated with self-assembled silane layers on solid surfaces. Nitroveratryloxycarbonyl and benzoin derivatives can be addressed independently by light of different wavelengths to selectively liberate amino and carboxylic acid groups, respectively, in mixed silane layers. Specific colloid adsorption on such photopatterned surfaces was investigated.

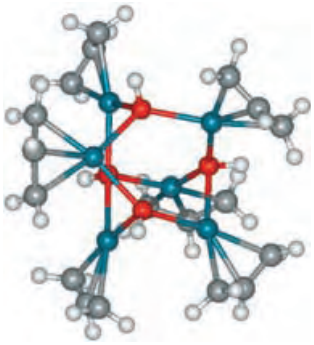
Solid-Phase Synthesis

A. Porzelle, W.-D. Fessner* **4724 – 4728**

Reversible Substrate Anchoring: NC-SPOS as a Sustainable Approach to Solid-Supported Organic Synthesis



An on–off relationship: The main problems of conventional solid-phase organic synthesis (SPOS) are overcome by a freely reversible attachment strategy. Hydrophobic labeling of organic substrates allows noncovalent (NC) binding to hydrophobic carriers in water for solid-phase-assisted reactions ("NC-SPOS"; see scheme). NC-SPOS reactions are free of the diffusion limitations typical for polymer supports and highly environmentally benign.

Cluster Compounds

A. Gogoll,* L. Toom, H. Grennberg **4729 – 4731**

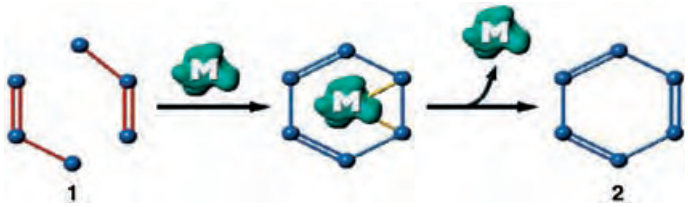
Ligand-Induced Formation of an Adamantanoid Hexanuclear (π-Allyl)Pd^{II}(μ_3-Hydroxo) Cluster Stacked as Hydrogen-Bonded Double Strands

Stranded clusters: The treatment of (η^3-propenyl)palladium chloride with a bulky, basic dinitrogen ligand in the presence of traces of water results in the formation of an unusual adamantanoid [{(η^3-propenyl)Pd}$_6$(μ_3-OH)$_4$] cluster (see picture). The clusters are linked into double strands through hydrogen bonds and bridging counterions.

Self-Assembly

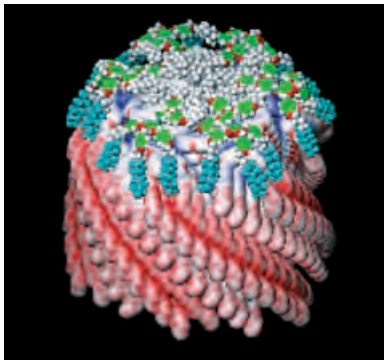
B. Song, Z. Wang, S. Chen, X. Zhang,* Y. Fu, M. Smet, W. Dehaen **4731 – 4735**

The Introduction of π–π Stacking Moieties for Fabricating Stable Micellar Structure: Formation and Dynamics of Disklike Micelles



Enhancing the intermolecular interactions between micelles by introducing a strong π–π stacking moiety and flexible spacers of appropriate length results in the formation of disklike micelles that can maintain their monomolecule-layered structures even when being transferred to hydrophilic substrates (see AFM image, 3 μm × 3 μm).

Nanocluster Catalysts



J. Chou, S. Zhang, S. Sun, E. W. McFarland* **4735 – 4739**

Benzene Formation at 70 °C by Coupling of Propylene on Supported Pd Nanoclusters

The pressure's off: The coupling of propylene (**1**) to generate benzene (**2**) at 70 °C and atmospheric pressure was observed together with propylene hydrogenation and oxygenation on titania-supported Pd nanoclusters (in green). The catalysts consist predominately of metallic Pd^0. The selectivity of benzene formation is dependent on cluster size ($\varnothing$ = 3–12 nm) and the presence of both hydrogen and oxygen.

M. Quack to give Jost Lectures

Martin Quack (ETH Zürich, Switzerland) is to deliver the Wilhelm Jost Memorial Lecture Series of the Academy of Sciences in Göttingen (Germany) and the German Bunsen Society of Physical Chemistry. Quack studied chemistry in Darmstadt (Germany), Grenoble (France), and Göttingen. He obtained a doctorate from the Ecole Polytechnique Fédérale de Lausanne (Switzerland) for work on unimolecular reactions in the group of J. Troe. In 1976/77, he worked as a postdoc in the group of W. H. Miller (UC Berkeley). In 1978, he obtained a habilitation in physical chemistry from the University of Göttingen, where he subsequently worked as a professor until 1982. He then moved to the University of Bonn (Germany) and on to Zurich a year later. Quack has been a member of the editorial board of *Angewandte Chemie* since 2001.

M. Quack

Quack's research is focused on molecular kinetics and spectroscopy and the understanding of the fundamental physical and chemical processes. He successfully combines theoretical and experimental techniques, in particular high-resolution and time-resolved IR spectroscopy. Theoretical aspects of his work include approximations in quantum dynamics and time-resolved quantum dynamics of intramolecular energy flow and vibrational redistribution. His group also studies fundamental symmetry principles in molecular processes as well as molecular chirality and parity violation. He discussed progress in this area in a review in 2002 and in a recent communication in *Angewandte Chemie*.[1]

M. Chisholm Elected to US Academy

Last year, Malcolm H. Chisholm (Ohio State University, Columbus, USA) was recognized with the Fred Basolo Medal for Inorganic Chemistry of the American Chemical Society. He was also elected to the Akademie der Naturforscher Leopoldina in Halle (Germany). This year the trend continues: He was recently elected to the US National Academy of Sciences. The Chisholm group has developed a new generation of polymers by using alkoxide catalysts. They also investigate complexes with metal–metal multiple bonds, π-donor ligands in organometallic chemistry, and the synthesis of polyesters from cyclic esters which are obtained from biomass. A communication on polythiophenes with metal–metal bonds will appear in *Angewandte Chemie* soon.

M. Chisholm

Chisholm earned a PhD under the guidance of D. C. Bradley from London University (UK) in 1969, and subsequently moved to the University of Western Ontario (Canada) as a postdoc and lecturer in H. C. Clark's group. He moved to Princeton University in 1972 and to Indiana University in 1978. In 2000, he accepted his current professorship at the Ohio State University. From 1995 to 2001, he was a member of the editorial board of *Chemistry—A European Journal*.

DuPont Awards for P. Baran, T. Odom, and D. Zhao

The following researchers are among the recipients of the DuPont Young Professor Award 2005:

- Phil S. Baran, Scripps Research Institute in La Jolla, CA (USA), for his work on the total syntheses of complex natural products, such as Avrainvillamide and Stephacidin B;[2]
- Teri W. Odom, Northwestern University in Evanston, IL (USA), for her work on the synthesis and characterization of nanoscale materials, for example the directed growth of small-diameter ZnO nanowires in ordered arrays,[3] the development of new methods for this purpose, and the design of functional assemblies from nano- and mesostructures;
- Dongyuan Zhao, Fudan University in Shanghai (China), for his research on nanophase materials for embedded passive applications. His communication on mesoporous bioactive glasses was published in *Angewandte Chemie* recently.[4]

NMR Spectroscopy

Residual Dipolar Couplings—A Valuable NMR Parameter for Small Organic Molecules

*Ruth M. Gschwind**

Keywords:
gels · liquid crystals · NMR spectroscopy · polymers · structure elucidation

In the last ten years the structure determination of biomacromolecules by NMR spectroscopy has made vast progress owing to the development of new and valuable structural parameters. In addition to classical structural parameters (NOE/ROE data and scalar coupling constants), distance and/or angular information can now be gained from cross-correlated relaxation interferences, chemical shift anisotropies, or residual dipolar couplings (RDCs).[1] Especially RDCs, which require partially aligned molecules in the sample, have come to occupy a very important place in the structure determination of biomacromolecules, since they are quite easy to detect experimentally and the structural information gained from them is very valuable.[2a,b]

To recognize the tremendous potential of RDCs, it is essential to understand their physical basis. In principle, dipolar couplings are quite large interactions and well known from solid-state NMR spectroscopy. Through space the magnetic flux lines of one NMR-active nucleus affect the magnetic field at the site of another nucleus and vice versa, changing the effective fields at both nuclei. The size of the resultant coupling depends on the distance between the two nuclei as well as the direction of their internuclear vector relative to the external magnetic field (B_0). In isotropic solutions the angle-dependent dipolar interactions typically average to zero, owing to the uniform distribution of all orientations (rotational Brownian diffusion). As a result of this isotropic tumbling, the high-resolution NMR spectra show narrow linewidths in solution, which enable the assignment of large or complicated molecules. However, the valuable structural information on the orientations of the internuclear vectors is lost.

The challenge is now to preserve the small linewidths and to additionally gain the vectorial information about the structure from dipolar couplings. This is possible in partially anisotropic media, in which the dissolved molecules are still mobile but show some slightly preferred orientations. The slightly anisotropic tumbling of the molecules, that is, the alignment, is described by an alignment tensor, which is used to analyze the RDCs. At best, the dipolar couplings are reduced by about three orders of magnitude from many kHz in the static case to a few Hz in the partially aligned sample. In the resulting NMR spectra, the RDCs add to the corresponding scalar couplings and cause a splitting $J + D$ (Figure 1).

Although RDCs were originally discovered and theoretically explained for small molecules by A. Saupe in 1968,[2c] RDCs have only rarely been used for the structure determination of small organic molecules up to now. This lack of applications compared to their widespread use in biomacromolecular NMR spectroscopy is attributed to the design of the known alignment media for aqueous solutions. Now recent research results considerably extended the applications of RDCs to small molecules by developing and applying two kinds of alignment media for organic solvents: liquid-crystalline phases[3,4] and mechanically constrained polymer gels.[5] A disadvantage of liquid-crystalline phases is basically that a minimum concentration and thus a minimum alignment exists, which sometimes leads to problems in the analysis of standard spectra.[4b] This problem was solved

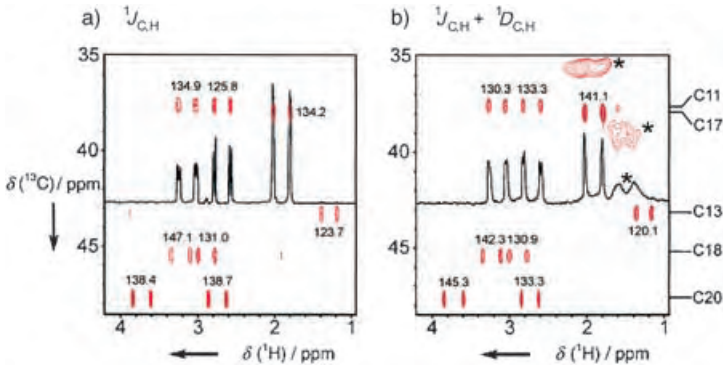

Figure 1. Sections of ^{1}H,^{13}C-HSQC spectra and traces through the HSQC spectra recorded on a strychnine sample without decoupling during acquisition in $CDCl_3$ without (a) and with anisotropic polystyrene gel (b).[5a]

elegantly by scaling the RDCs by variable angle spinning in a solid-state NMR spectrometer.[7] At present the most flexible approach that can be applied to several organic solvents and can include scalable alignment, without the employment of a solid-state NMR spectrometer, is the use of polymeric gels. This method is called "strain-induced alignment in a gel" (SAG) and was already applied successfully to biomacromolecules in aqueous solution. Initially, cross-linked polymers (e.g. polystyrene,[5a] poly(dimethylsiloxane),[5b] poly(vinyl acetate)[5c] or poly(acryl amide)[5d]) are synthesized. A cylindrical stick of the polymer is put into a standard NMR tube and after addition of an organic solvent the polymer swells to a gel. Owing to the shape of the NMR tube the gel does not swell isotropically but anisotropically along the glass wall of the tube (Figure 2). The resulting alignment of the dissolved molecules inside these gels can be easily adjusted by different amounts of cross-linking in the polymer as well as by varying the diameters of the unswollen polymer stick.

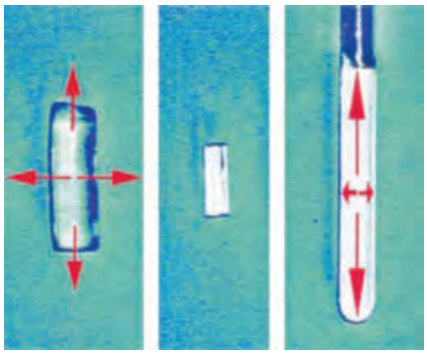

Figure 2. Isotropic (left) and anisotropic (right) swelling of a polystyrene stick (center: unswollen polymer stick).[5a]

The availability of anisotropic gels raises the question about the potential, the limitation, and the application of RDCs as structural parameters for small organic molecules. In principle the potential is tremendous: The distance dependence of RDCs is r^{-3} (versus r^{-6} for NOEs), which therefore allows longer-range internuclear interactions to be monitored. Provided that the distance is known (e.g. in CH moieties), valuable angular information about internuclear vectors relative to the static magnetic field can be obtained. This means that an absolute reference system can be used for the structure determination in solution. This fact is particularly important for molecules with a dearth of protons for which the elucidation of the configuration is not possible as long as only NOEs and scalar couplings are used.

The actual requirements and limitations of the method become apparent when describing the conventional way in which the calculations are performed. Initially, the alignment tensor, that is, the level and direction of order introduced by the partial alignment in the gel or liquid crystal, is calculated on the basis of the experimentally determined RDCs. For this purpose, a reliable structural model is necessary as well as at least five RDCs per fixed moiety that are independent of each other, as nonparallel C–H vectors. Taking into account the structural model used and the determined alignment tensor, the theoretical RDCs are calculated and compared with the experimental data. This cycle is repeated for all proposed structures and the actual structure is identified through significant differences in the correlation between theoretical and experimental RDCs (Figure 3). It is nontrivial to fulfil the described requirements especially for small molecules. First, reliable structural models have to be available from crystal structures or calculations. Second, molecular flexibilities lead to an averaging of the orientation-dependent RDCs, and third, single RDC values are not one-to-one but can originate from several vectorial orientations. This means that only in molecules with a fixed conformation or by a combination of different types of RDCs (e.g., $^{1}D_{C,H}$, $^{2}D_{C,H}$, $^{1}D_{C,C}$) from several spectra is it possible to reach the required high amount of RDCs per fixed molecular moiety. However, once systems meet these conditions, previously undreamt-of possibilities open up for determining the configuration of small organic molecules, which, on the basis of classical structural parameters, have not been possible up to now.

Present applications of RDCs in achiral alignment media are: assigning diastereotopic protons, determining the relative orientation of protons far away from each other, and elucidating the absolute configuration of diastereomers. In chiral gels or liquid crystals it is additionally possible to discriminate enantiomers.[6] Owing to the described requirements, up to now only molecules with rigid units have been used such as sugars,[8,9b] polycyclic molecules,[3,4b,5a–5c,9a] or molecules with fixed conformations in their cyclic moieties.[4a,c,5d]

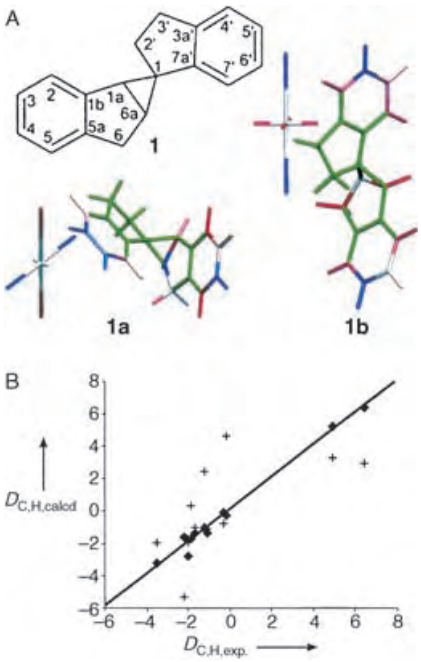

Figure 3. A) Differentiation of the diastereomers (**1a** and **1b**) of spiroindene (**1**) by RDCs (red: negative RDCs, blue: positive RDCs, green: no RDCs or RDCs not used in the analysis). B) A comparison of the experimental and the calculated RDCs, which shows a clear preference for **1b** in a poly(dimethylsiloxane) gel (PDMS gel); + **1a**, ◆ **1b**.[5b]

At first glance, the applicability of RDCs to small molecules seems to be limited by the calculation of the alignment tensor, the required rigidity of the investigated molecules, and the possibly stronger intermolecular interactions of small molecules with the alignment medium. However, the methodical development of RDCs for small organic molecules is still in its infancy.[10] Thus, first approaches exist to analyze RDCs without alignment tensors,[9b] the ambiguity of RDCs can be reduced by using several independent alignment media and the averaging of the RDCs due to internal motion is already used in bio-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

macromolecules to study dynamic processes on a time scale range between femtoseconds and milliseconds.[11] If the methodology of RDCs for organic molecules increases only half as much as it did for biomacromolecules, the structure determination of small organic molecules will be revolutionized during the next few years.

Microporous Materials

Strategies for Hydrogen Storage in Metal–Organic Frameworks

*Jesse L. C. Rowsell and Omar M. Yaghi**

Keywords:
adsorption · hydrogen · metal–organic frameworks · microporous materials · organic–inorganic hybrid composites

Increased attention is being focused on metal–organic frameworks as candidates for hydrogen storage materials. This is a result of their many favorable attributes, such as high porosity, reproducible and facile syntheses, amenability to scale-up, and chemical modification for targeting desired properties. A discussion of several strategies aimed at improving hydrogen uptake in these materials is presented. These strategies include the optimization of pore size and adsorption energy by linker modification, impregnation, catenation, and the inclusion of open metal sites and lighter metals.

1. Introduction

The scope of the United States Hydrogen Initiative[1] has captured the attention of industrial and academic researchers around the world.[2] A measure of success has already been achieved by the initiative; specifically, the uncovering of the extent by which current technology must advance to bring about the use of hydrogen as an energy carrier.[3] Among the challenges facing hydrogen production, distribution, storage, and usage, the improvements required for the safe and efficient storage of the volatile fuel have been cited as the most formidable. As a corollary, it has been claimed that if a breakthrough in hydrogen storage were realized, a favorable impetus would be applied to resolving the other issues. Several reviews have appeared on the use of hydrogen as a fuel and its storage in various media, many of which are cited below. Herein, a brief discussion is presented on hydrogen storage requirements and the current state-of-the-art of established systems. This Review is focused on the use of metal–organic frameworks (MOFs) as new hydrogen storage materials.

2. Hydrogen Storage Requirements

The most compelling goals for hydrogen storage involve transportation (on-board) applications. There are two reasons for this: first, the transportation sector represents the largest consumer of oil, thus making it one of the largest sources of airborne pollutants such as carbon and nitrogen oxides. Secondly, the efficiency and economic demands to make hydrogen competitive with fossil-fuel technology are more challenging than for stationary storage. The current targets set by the U.S. Department of Energy (DOE) have been made with the concept that today's vehicles will be powered by tomorrow's higher efficiency fuel-cell power sources. The vehicles should have a similar range (480 km or 300 miles), operate at close to ambient conditions, and be quickly and safely refueled. As hydrogen has approximately three times the gravimetric energy density of petrol, and fuel cells are expected to perform at least twice as efficiently as internal combustion engines, only 5–10 kg of hydrogen must be stored (although 4 kg or less would be required by smaller, more practical passenger cars[4]). The 2010 energy density targets for the hydrogen storage system (including container and necessary components) are 7.2 MJ kg^{-1} and 5.4 MJ L^{-1}, which translates as 6.0 wt % and 45 kg H_2 per m^3.[3] The goals for 2015 are even more demanding: 9.0 wt % and 81 kg H_2 per m^3, which approach the expectations of the automotive industry.[5] This daunting task is easily put into perspective by noting that the mass density of elemental hydrogen is only 70.8 kg m^{-3} in its liquid state at 20 K (1 atm), and that 5 kg of hydrogen gas

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim DOI: 10.1002/anie.200462786

fills a volume of 56 m^3 under ambient conditions. Furthermore, both of these insights ignore the contribution of the mass of the necessary container.

3. Current Storage Technologies

Compressed hydrogen gas and cryogenically stored liquid hydrogen are the most developed technologies, and are currently utilized in the demonstration vehicles of several automotive manufacturers. While a systems analysis shows that they meet the technical aspects of the DOE 2010 targets, they are unlikely to comply with future ones.[6] In all cases, the containment vessel contributes at least 90% of the system mass, but there is still room for improvement with respect to the maximum pressure that can be maintained (operation at 825 bar is now being demonstrated[7]) or the minimization of liquid boil-off in cryogenic systems.[8] A significant drawback of cryogenic storage is the large amount of energy input necessary for condensation, approximately 40–50% of the fuel's lower heating value.

Understandably, the possibility of breakthroughs in storage efficiency has been sought by chemical means.[9] Solid metal hydrides[10] have been studied for many years, particularly for understanding the process of metal embrittlement upon absorption of hydrogen at interstitial sites. After surface adsorption, molecular hydrogen may dissociate into atoms that form a solid solution of a hydride phase in the metal or alloy or generate an intermetallic region. The uptake of hydrogen continues at nearly constant pressure until the pure hydride phase is formed, which may have volumetric densities of 150 kg H_2 per m^3 (Mg_2NiH_4).[4] In favorable cases this process is reversible and cycling can occur at desirable pressures (1–10 bar). For materials with a significant capacity for hydrogen, however, desorption usually occurs at a higher temperature than the targeted conditions. Improving the uptake/release kinetics and retention of cycling capacity are currently the major areas of materials research. The disadvantages of these compounds include high cost, susceptibility to impurities, and low reversible gravimetric capacity (typically less than 3 wt%).

To circumvent some of these issues chemical hydrides (also called complex or covalent hydrides) such as $NaAlH_4$ have been studied and shown to reversibly cycle hydrogen on doping with a catalyst.[11] Indeed, the DOE has deemed this material worthy of extensive study, as a result of its reversible release of 4.5 wt% hydrogen.[3] Other alanates and borohydrides of Groups 1, 2, and 13 elements have large gravimetric capacities (> 7 wt%), but the extent to which their hydrogen sorption is reversible requires continued investigation. Hydrolysis of alkali metals and their hydrides is also a convenient route for hydrogen release, but requires off-board recycling of the decomposition products.[3,12] Most of these chemical methods still require demonstration of both physical and economic viability.

The fastest way to charge and discharge a storage vessel with hydrogen is to maintain its molecular identity. To reduce the mechanical requirements of pressurized vessels highly porous materials have been investigated for their ability to physisorb molecular hydrogen. This arrangement could potentially allow the confinement of greater masses of fuel within a smaller volume. Carbon materials have received the most attention in this area, because of their low density, high surface area, good chemical stability, and amenability to a wide range of processing conditions. It is precisely this last aspect that has led to controversy with respect to the maximum volume they can adsorb. Since the first account of hydrogen adsorption by carbon nanotubes,[13] a wide range of uptake values have been reported, from negligible to fantastically large. Recently, more consistent results have been achieved by research groups examining many varieties of sample preparations, morphologies, and activations in a single study. Unfortunately, these have revealed adsorption of approximately 5% at 77 K and < 1% at room temperature under high pressure.[14] Theoretical modeling studies of the interaction of hydrogen with carbon in systems of many geometries and scales has been performed to provide a rationale for the larger uptake values. The general conclusion reached is that uptake of only a few wt% is achievable with this class of materials.[15] However, reports of improved uptake on changing the morphology have appeared recently.[16]

Research surrounding hydrogen uptake in carbon materials has highlighted several key points, including the importance of sample and measurement reproducibility by independent investigators, the necessity of establishing standard samples for instrumental calibration (especially for gravimetric methods where adsorbate contamination is a significant

Omar M. Yaghi was born in Amman, Jordan (1965). He received his BS in chemistry from the State University of New York--Albany (1985) and his PhD from the University of Illinois-Urbana (1990) with Prof. Walter Klemperer. After postdoctoral research at Harvard University with Prof. Richard Holm (1990 to 1992) he joined the faculty at Arizona State University. In 1999, he moved to the University of Michigan as a Professor of Chemistry and was later awarded the Robert W. Parry Collegiate Chair. His research concerns the reticular synthesis of discrete polyhedra and extended frameworks from organic–inorganic building blocks.

Jesse Rowsell was born in Black River-Matheson, Ontario, and began his studies of chemistry at the University of Waterloo in Canada. While obtaining his BSc, he performed research on diverse projects including reversible lithium-ion batteries, aluminum hydrolysis, and atmospheric aerosols. With fellowships from the NSERC and the Link Foundation, he is continuing to explore his research interests of the structure and physical properties of solids at the University of Michigan. His efforts there have earned graduate awards for both teaching and research.

issue), and the utility of theoretical studies to gain insight into the details of the uptake mechanism. These lessons can (and should) be applied to the future studies of novel adsorbents. The other point that has been gleaned from this period of research is that hydrogen storage is still awaiting its breakthrough material.

4. Crystalline MOFs as New Materials for Hydrogen Storage

Metal–organic frameworks (MOFs) are crystalline solids that are assembled by the connection of metal ions or clusters through molecular bridges.[17] As such, they have the potential to exhibit properties inherent to the building blocks, such as geometric rigidity, chemical functionality, or chirality. Their simple preparations are generally high yielding and scalable, and by careful use of the building blocks a certain degree of design can be wielded to produce targeted products from the vast number of MOFs that are potentially accessible. One simple outcome of the use of molecular, rather than monatomic, bridges is the extension of the length between the metal centers, which can lead to the definition of large void regions (Figure 1). Considerations of the geometric requirements for a target framework and implementation of the design and synthesis of such a framework have been termed reticular synthesis. This process requires both an understanding of the local coordination patterns of the metal and organic units and foreknowledge of what net topologies they will adopt.[18] The accumulation of knowledge that has given rise to such precepts has primarily resulted from their crystalline nature, which allows a high degree of structural characterization to be achieved through X-ray diffraction methods.

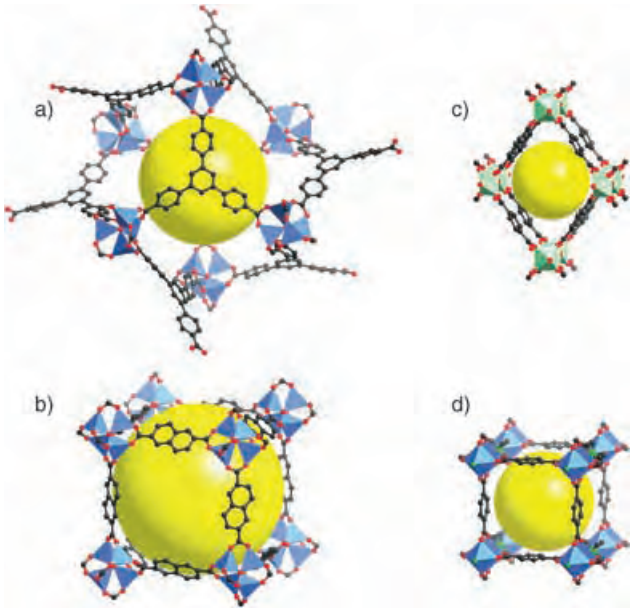

Figure 1. Examples of metal–organic frameworks (MOFs) studied for hydrogen adsorption include a) MOF-177, $Zn_4O(btb)_2$ (btb = benzene-1,3,5-tribenzoate), b) IRMOF-8, $Zn_4O(ndc)_3$ (ndc = naphthalene-2,6-dicarboxylate), c) MIL-53, M(OH)(bdc) (M = Al^{3+} or Cr^{3+}), and d) $Zn_2(bdc)_2(dabco)$ (dabco = 1,4-diazabicyclo[2.2.2]octane). The properties of these compounds are listed in Table 1. Pores in the evacuated crystalline frameworks are illustrated by yellow spheres that contact the van der Waals radii of the framework atoms (C: black, N: green, O: red, Zn: blue polyhedra, M: green octahedra).

Highly crystalline MOFs are also inherently pure in form. The materials are generally prepared in "one-pot" solvothermal syntheses under mild conditions. Powder X-ray diffraction is a simple and effective technique to establish the purity of the crystalline fraction, which often approaches 100% of the sample. Synthetic reproducibility with high purity is essential for the establishment of structure–property relationships, and this issue has been reiterated many times in the studies of hydrogen storage materials.

The cavities within MOFs are filled with solvent molecules in their as-synthesized forms. Successful establishment of permanent porosity has been accomplished in many cases, with the material stable upon removal of the guest species. This is most conveniently demonstrated by the measurement of gas adsorption isotherms, typically using dinitrogen at its normal boiling point. All porous MOFs to date are microporous by IUPAC definition, having cavities less than 2 nm in size and displaying type I isotherms.[19] Two values are typically calculated from these measurements to allow the porosity to be compared: surface area and pore volume. Type I isotherms can often be described by the Langmuir model, which assumes that a homogenous monolayer of the adsorbate is formed on the walls of the adsorbent. An extension to this model to describe multilayer adsorption has given rise to the commonly used Brunauer, Emmett, and Teller (BET) equation, which is primarily used to determine the point at which monolayer coverage is obtained. In either case, the apparent surface area is calculated as the product of the estimated value of monolayer uptake and an accepted value for the area occupied by an adsorbate molecule. While these models do allow simple comparisons of microporous materials, their assumptions are not always appropriate, especially since pore-filling is the predominant mode of uptake. When multilayer adsorption is possible (such as when the width of the pore is greater than three times the adsorbate diameter) or the assumed molecular area is too large (as can occur if the N_2 molecules are oriented as a consequence of strong quadrupolar interactions with surface sites), then an overestimation of the "true" surface area is possible. Sensibly, all equations and parameters used to calculate surface areas should be reported to facilitate adequate comparisons. The micropore volume, usually calculated by the Dubinin–Radushkevich method, is a complementary and perhaps better descriptor of the porosity of a material.[20]

An outstanding property of MOFs that has prompted their study as hydrogen storage candidates is their large apparent surface areas. Many MOFs are now reported in the literature with surface areas greater than 1000 $m^2 g^{-1}$, which is higher than that demonstrated for zeolites. In particular, the dinitrogen isotherm measured for MOF-177 (Figure 1a) at 77 K exhibits the highest uptake of N_2 for any material to date, and gives rise to a monolayer-equivalent surface area of 4500 $m^2 g^{-1}$.[21] The micropore volume is calculated to be 0.69 $cm^3 cm^{-3}$, and single-crystal X-ray diffraction studies

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reveal the framework has cavities of 10.9–11.8 Å diameter connected in all directions by channels. The initial study of the hydrogen uptake by this material at 77 K revealed that while it did not reach saturation at 1 atm, it adsorbed comparatively less than other related materials displaying smaller surface areas.[22] Supercritical hydrogen, as expected, adsorbs more weakly than dinitrogen at 77 K, and pore-filling is not possible at reasonable pressures. Thus, both pore geometry and surface structure must be optimized to increase the uptake in these materials. This study was particularly instructive in demonstrating the diversity in MOFs over nanostructured carbon materials, which show a positive trend in hydrogen uptake with surface area.[14c,15a] As MOFs are composed of a great assortment of chemical moieties that are characterized to a higher degree (by crystallography), they hold more promise for establishing which structural factors are most effective in adsorbing hydrogen.

5. Strategies for Hydrogen Adsorption in MOFs

In the initial report of hydrogen uptake by MOFs alteration of the linking moiety in isoreticular frameworks was shown to improve the uptake to a level of 2.0 wt% in IRMOF-8 (Figure 1b) at 293 K and 10 bar.[23] Saturation uptake is not reached under these conditions and increased pressure results in greater adsorption. For experimental convenience, most reports since then have studied the uptake at 77 K up to 1 atm. The gravimetric uptakes measured under these conditions on a larger subset of Zn_4O-based MOFs also did not exhibit saturation.[22] Calculation of the fraction of the void volume occupied by hydrogen in each material revealed it to be quite low, that is, only a small amount of the surface—let alone the pore volume—is occupied by the guests. This study and others[15a,24] have highlighted the need to optimize pore size to reduce the fraction of under-utilized void space, thereby increasing the volumetric capacity and attractive adsorbate–adsorbent interactions.

5.1. High Porosity with Appropriate Pore Size

The ideal pore size for maximal attraction of an adsorbate is the same as its diameter. This situation results in optimal interaction with all the surrounding adsorbent walls, regardless of geometry, thus maximizing the total van der Waals force on the adsorbate. For adsorbents with thick or dense walls, however, this situation leads to impractically low hydrogen uptake values, as demonstrated for slit and cylindrical pores in nanostructured carbon materials.[15a] Instead, a simple geometric structure resembling a scaffold is preferable. In terms of general considerations, the walls of an adsorbent should be composed of light elements, be as thin as possible (that is, one atomic layer thick, as in graphite), and be highly segmented. A simple calculation demonstrating the advantage of segmenting graphene sheets has recently been reported.[21] The incision process that isolates groups of aromatic rings from each other results in an increased surface area as more edges become exposed. The challenge is to separate these isolated units, and this has already been addressed in MOFs by reticular synthesis. Organic units that represent isolated graphene segments include phenylene, terphenylene, and benzene-1,3,5-triphenylene. These moieties can be reticulated into frameworks where they are isolated from each other by functionalizing their termini with coordinating groups and linking them with metal ions or clusters, as illustrated in Figure 1. This is an alternative perspective of the approach first used to engender porosity in these solids, as described above.

Many MOFs reported, however, have spacings between their walls (or links) that are too large for the effective adsorption of hydrogen. For example, the distance between phenylene faces in MOF-5 describe an approximately spherical pore that is 15 Å in diameter, which is much larger than the 2.89 Å kinetic diameter of H_2 (Figure 2).[25] There would be an unused void volume at the center of these pores that would detract from the volumetric packing density, even at monolayer coverage. To approach the targeted guidelines for H_2 storage it is ultimately required that the density of the adsorbed hydrogen surpasses that of its liquid state. To improve this situation in MOFs, smaller pores are necessary. This arrangement can be afforded by the use of shorter links and the investigation of new topologies. A rigid linear dicarboxylate such as acetylenedicarboxylate is required to stabilize a smaller pore analogue of MOF-5. This is an attractive target for future syntheses, but it is not necessary to only consider simple cubic topologies of this type. By simply distorting the primitive cubic net—for example, by shearing along the face or body diagonals—the pores become elliptical and their shortest dimension is reduced. There are a vast number of smaller pore structures with various topologies that have been published, and their H_2 adsorption requires investigation. While MOFs with constricted pores may exhibit smaller gravimetric capacities, gains may be made in volu-

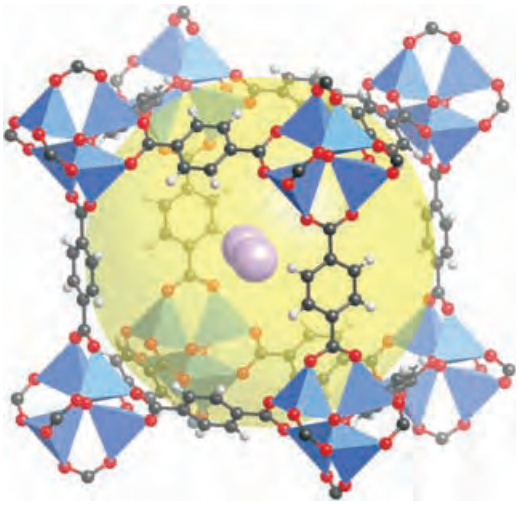

Figure 2. The large pore (yellow sphere) in MOF-5 is 15.2 Å in diameter, much larger than the size of a hydrogen molecule (lilac, shown with atomic van der Waals radii of 1.2 Å) which has a kinetic diameter of 2.89 Å. Framework atoms C: black, H: white, O: red, Zn: blue tetrahedra.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

metric capacity.[24] In addition, MOFs with very short linkers that may at first not appear to be porous from dinitrogen adsorption studies, may be composed of apertures that are too small to admit N_2, but are large enough to allow the passage of H_2.[26] From a design perspective, however, it must always be borne in mind that as the framework density increases, the gravimetric H_2 capacity decreases and therefore a compromise must be found.

5.2. Impregnation

Another approach for pore-size and hydrogen volumetric density optimization is to insert another adsorbate surface within large-pore MOFs. This can be achieved by either impregnation with a nonvolatile guest or catenation by another identical framework. It has been shown that large molecules such as C_{60} and Reichardt's dye can be included into MOF-177 from the solution phase.[21] In addition to reducing the free diameter of the pores, such guests may provide additional adsorptive sites (Figure 3). Impregnation with reactive species could provide the more attractive sites that are ultimately necessary to improve hydrogen uptake at room temperature. As expected, there is a doping level that is reached where the additional mass added by the guest is not compensated by additional hydrogen uptake. The guest should also not block the existing adsorptive sites on the framework, instead straddling the pore with minimal framework contacts. Conversely, the guest must be well-anchored or have very low vapor pressure to prevent its desorption along with the hydrogen. These considerations imply that lightweight and reactive, but large and spindly molecules or complexes are required. Structure–property relationships of impregnated MOFs are essentially unexamined to date.

5.3. Catenation

Framework catenation has long been a topic of interest in MOF research. The intergrowth of two or more frameworks is allowed for many high-symmetry, default topologies and is often observed when long linkers are used. Catenation can take the form of interpenetration, where the frameworks are maximally displaced from each other, or interweaving, where they are minimally displaced and exhibit many close contacts.[27] The most immediate consequence of catenation is a reduction of the free diameter of the pores (shown schematically in Figure 4a–c), therefore, it is a viable strategy for improving hydrogen uptake. There is already some evidence supporting this: in a series of Zn_4O carboxylates studied, the interwoven IRMOF-11 material showed the greatest hydrogen uptake at 77 K.[22] Fourfold catenated IRMOFs have been reported recently to adsorb approximately 1 wt% hydrogen at room temperature and 48 bar.[28]

Interpenetration rather than interweaving is desirable to maximize the exposed surfaces of catenated frameworks. Although interweaving can lead to reinforcement of the individual frameworks, by improving the rigidity and favoring stability in the absence of guests, this is a result of an effective

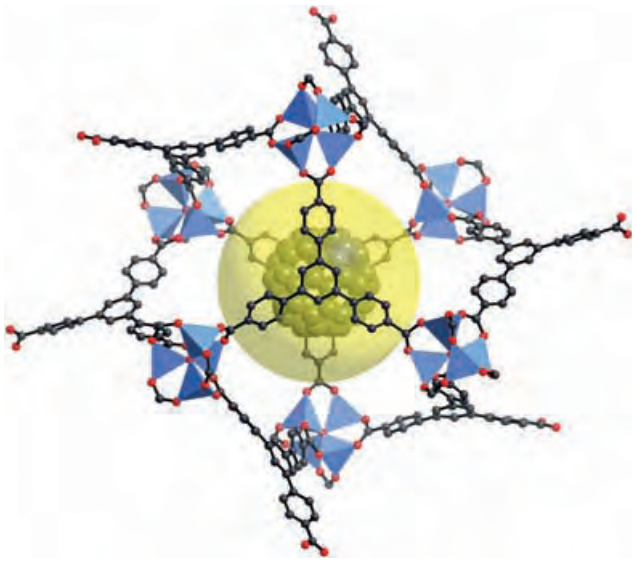

Figure 3. The large pore (yellow sphere) in MOF-177 is 11.8 Å in diameter, large enough to include C_{60} molecules that may provide additional surface sites for the physisorption of H_2.

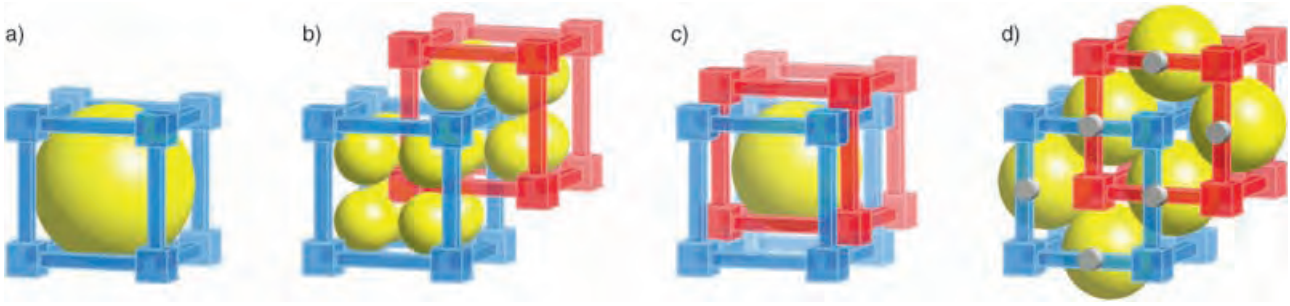

Figure 4. a) Schematic representation of the repeat unit of a crystalline, single-framework MOF with secondary building units (SBUs) shown as cubes and linkers depicted as rods. The yellow sphere represents the large pore defined within the framework. Catenation of two identical frameworks can be used to restrict the dimensions of the pore considerably by interpenetration (b) or to a lesser extent by interweaving (c). Interweaving can improve the material's rigidity by mutual reinforcement; however, this is a result of thicker walls and results in the blockage of potential adsorptive sites. An alternative catenation mode (d) can be achieved by reducing the close contacts between the frameworks to only the midpoints of a proportion of the linkers, as represented by gray discs. The pore dimensions are considerably reduced while a large proportion of the framework atoms, including the SBUs, are still exposed.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

thickening of the walls. Thus, the number of framework atoms and their associated adsorptive sites that are exposed to the pore volume is reduced. Conversely, interpenetration decreases the pore size without blocking any adsorptive sites and in most cases also leads to a more convoluted void region. This is not expected to have an appreciable impact on the diffusion rate of supercritical hydrogen through the solid unless the apertures constrict to the size of the H_2 kinetic diameter.

Although conceptually it seems that interpenetrated frameworks should be targeted over interwoven ones, this mode of catenation is unlikely to be sustained in the evacuated state. Most catenated frameworks to date in fact exhibit interweaving, while those that are truly interpenetrated have free solvent molecules separating the individual frameworks where void regions do exist. Examples of the latter include MOF-9[29] and IRMOF-15.[30] It is inevitable that during the evacuation process attractive interactions between catenated frameworks will result in their interweaving. The extent to which this occurs, that is, the proportion of framework atoms that are involved in close contacts, could be minimized by incorporating specified chemical features that would locally attract each other. For example, the inclusion of a hydrogen bond donor–acceptor group at the midpoint of a linker could lead to localized interframework contacts only at the linker midpoints, thus leaving ample distance between the secondary building units (SBUs, Figure 4d). This arrangement would be optimal in the situation where the primary adsorptive sites are on the SBUs and blocking of them results from full interweaving.

5.4. Open Metal Sites

Perhaps the most attractive structural element of secondary building units in some MOFs is coordinative unsaturation, which can be achieved for metal clusters that have additional terminal ligands bound to them. Quite often these are solvent molecules coordinated to the metal by a Lewis acid/base interaction, and may be liberated with heating as neutral guest species. In the most favorable cases, the terminal ligand is removed without detriment to the framework and an open metal site is exposed to the void region. This has typically been achieved for axial ligands bound to metals displaying a Jahn–Teller distortion, most prominently Cu^{2+} ions.[31] Ligand field effects result in the binding of the axial ligand being sufficiently weak to allow its release. In addition, the resulting geometry (square planar for the example of the dimeric Cu^{2+} "paddlewheel", Figure 5a) is stable and consistent with the symmetry requirements of topologies such as those adopted by MOF-11 and HKUST-1 (Figure 5b and c, respectively). MOFs composed of metal clusters with lesser rigidity or constructed of metal ions that lack the electronic requirements to sustain an open metal site commonly collapse after loss of the terminal ligands, but may rearrange to a new form displaying permanent porosity.[32] Another strategy for constructing MOFs with open metal sites is to embed these within the linker. This has been achieved using the equatorially chelating ligand *N*,*N*′-phenylenebis(salicylideneimine)dicarboxylate, that can be used to construct a framework isoreticular with MOF-69[33] after binding a metal ion at its center.[34] The solvent molecules axially coordinated to the linker-bound metal should be removable after framework construction, since the metal is not a key component of the framework. The prospects of exposing open metal sites in a porous material are exciting indeed. To date, these have been divalent cations that are too electron deficient to be expected to form metal hydrides or hydrogen σ complexes. Their coordinative unsaturation, however, may lead to stronger physisorption and is concurrent with a decrease in the density of the framework as a result of the loss of the terminal ligands. Evidence for stronger binding of H_2 to open Ni^{2+} sites has been presented recently for an open-framework phosphate.[35] The possibility of incorporating other metals with coordinative unsaturation that will reversibly chemisorb hydrogen is plausible and this is an admirable target for future syntheses.

5.5. MOFs of Light Metals

One consideration that should not be overlooked while exploring MOFs composed of other metals is the need to reduce the framework density to enhance gravimetric hydro-

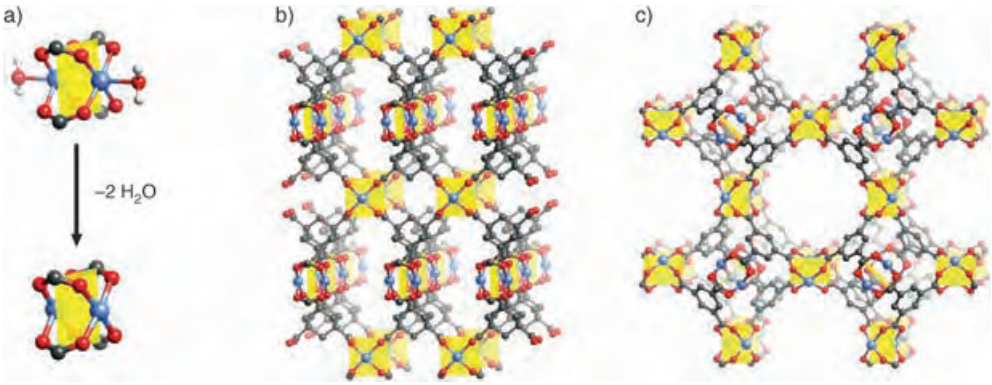

Figure 5. a) The Cu^{II} carboxylate "paddlewheel" cluster is an important square SBU used in some reticulated MOFs. Axial ligands, such as water (shown), may be removed without rearrangement of the cluster and consequent collapse of frameworks such as in MOF-11 (b) and HKUST-1 (c) to yield materials with permanent porosity and a periodic array of open metal sites. Atoms shown as spheres, C: black, H: white, O: red, Cu: blue.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gen capacity. This approach requires investigating the MOFs formed by light main group metal cations such as Li^+, Na^+, Mg^{2+}, and Al^{3+}. While the monovalent cations will most likely produce frameworks that are susceptible to hydrolysis, the large polarizing power of Mg^{2+} and Al^{3+} should give rise to relatively strong coordination bonds. Oxophilicity and predominantly octahedral coordination are well-known characteristics of the two cations, and novel solvent systems will probably need to be employed to avoid formation of dense oxide/hydroxide phases. The only aluminum MOF to date was prepared hydrothermally by using fluoride ions as a mineralizer. The aluminum hydroxide terephthalate MIL-53 (Figure 1c) displays an uptake of 3.8 wt% at 77 K and 16 bar, but an unusual amount of hysteresis upon desorption.[36] Magnesium MOFs are also very rare, in fact few systematic studies of Group 2 MOFs have been reported, as has been recently discussed.[37] None have displayed permanent porosity.

5.6. Functionalized Linkers, SBU Adsorptive Sites, and the Energetics of Physisorption

The impetus for constructing MOFs with constricted pores stems from the need to increase the heat of adsorption of hydrogen in host materials. Ideally, the adsorbent should have both large gravimetric and volumetric capacities at ambient temperature, with the additional criterion of facilitating quick uptake and release of the gas. Since the van der Waals forces that underlie physisorption are weak, the hydrogen capacity of even materials with a very high surface area becomes small at room temperature. An energy of interaction of about 20 kJ mol^{-1} has been suggested for porous materials to maintain high capacity at ambient temperatures. A great deal of work, both theoretical and experimental, has gone into estimating the interaction energy of hydrogen with nanostructured carbon materials. There is now reasonable agreement that this value is approximately 5 kJ mol^{-1}, both from high-level calculations of the gas-phase interaction of H_2 with substituted and expanded aromatic compounds[38] as well as variable-temperature adsorption studies on various carbon materials.[14a,d] Most experimental evidence regarding desorption of hydrogen from activated carbon materials at elevated temperatures have attributed this to chemisorbed hydrogen at dangling bonds.[39] Importantly, it appears that the influence of chemical substitution or nanostructuring of carbon materials on the physisorptive interaction energy is rather small.

Organic linkers with aromatic backbones such as phenylene, naphthalene, bipyridine, and biphenylene have been employed in MOF structures to increase the rigidity of the frameworks. These molecular units mimic the nanostructure of activated carbon materials and nanotubes which are primarily composed of sp^2-hybridized carbon atoms, and hence it is believed that adsorption energetics should be similar for both classes of materials. This situation would be especially true for MOFs where only a small proportion of the framework is composed of metal, such as those with small nuclearity secondary building units. Ab initio calculations indicate that the energy of interaction of hydrogen with substituted benzene is marginally enhanced by the addition of electron-donating groups.[38] The effects of these modifications remain untested in MOFs. Chemical modification with the retention of topology has been demonstrated for a large series of Zn_4O-based MOFs,[30] and initial studies reveal that the linker length and width appear to have an influence on the hydrogen uptake at 77 K[22] and room temperature.[23] As the metrics of the linker have a profound impact on the framework pore size, it is not clear at present whether gains in uptake are more easily achieved by the surface energetics of the linker or the resulting geometric changes in the pore. Further alteration of the linker energetics, such as inclusion of heteroatoms in the aromatic backbone also requires investigation.

With respect to adsorption energetics, MOFs have the additional advantage of a heterogeneous surface structure with local dipoles that may enhance the attraction of hydrogen. These are mainly associated with the SBUs where ionic and dative bonding occur. MOFs composed of $Zn_4O(CO_2)_6$ SBUs such as MOF-5 and MOF-177 can be considered as an assembly of six-membered rings (Figure 6). Here one notes that each benzene ring is attached to two six-membered Zn-O-Zn-O-C-O rings which we believe alter the polarizability of

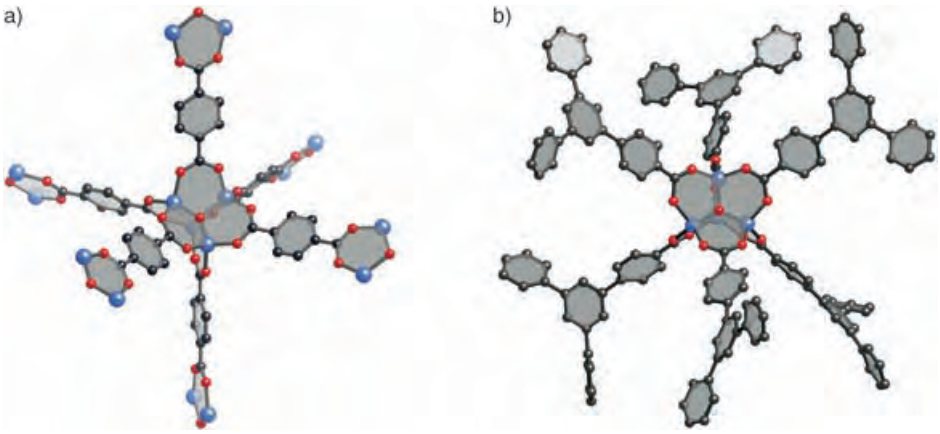

Figure 6. Six-membered rings exist throughout the organic and inorganic backbones of Zn_4O MOFs such as MOF-5 (a) and MOF-177 (b). Atoms shown as spheres, C: black, O: red, Zn: blue.

the π electrons of the link and lead to a higher binding energy for H_2 relative to that of the six-membered rings in graphite and carbon nanotubes. Evidence for stronger binding of H_2 in MOFs was obtained by inelastic neutron scattering experiments.[23] Thus, the composition of such metal-containing ring systems which are incorporated in the SBUs is critical to hydrogen binding. Understanding the details of the hydrogen interaction at the SBUs is particularly important for larger clusters as they begin to resemble an array of metal oxide nanoparticles in a porous organic matrix. As it is clear that the use of alternative metals generates new SBUs and possibly new framework topologies, the search for new MOFs with enhanced uptake is limitless.

6. Characterization of Hydrogen Uptake in MOFs

Metal–organic frameworks have only recently been proposed as candidates for hydrogen storage, but already several reports of uptake in these materials have entered the literature. The uptake is typically characterized by adsorption isotherms measured at 77 K up to 1 atm (the operating range of a typical commercial adsorption apparatus), but data collected at room temperature and high pressure have also been reported. These data have been summarized in Table 1. The high-pressure conditions are more relevant for practical applications, especially as the pressure limits in commercial hydrogen tanks increase. As the low-temperature hydrogen isotherms can be measured using essentially the same apparatus as that used to determine the MOF surface area, these data are also very useful at this early stage of exploration. As always, care must be taken to ensure the accuracy of the results, especially when gravimetric methods are used. As H_2 gas has the lowest molecular weight and physisorbs weakly, ultrahigh-purity gas must be used and the adsorption apparatus adequately tested for leaks. Ideally, the results should be confirmed by a complementary method, such as volumetric adsorption.[22] More extensive measurements are required to quantify the heat of adsorption in the most promising compounds.

Spectroscopic investigation of the hydrogen–framework interaction has been performed using inelastic neutron scattering studies. This technique provides a sensitive probe of the adsorptive sites for molecular hydrogen as it monitors the hindered rotational transitions of bound molecules. Promising observations were made for MOF-5 loaded with varying amounts of hydrogen.[23] These spectra revealed that at least two distinct adsorptive sites exist on the framework,

Table 1: Summary of hydrogen adsorption in MOFs.

Material[a]	Free/fixed diameters[b,c] [Å]	Accessible volume fraction[b,d]	Apparent surface area[e] [$m^2 g^{-1}$]	Pore volume[i] [$cm^3 g^{-1}$]	H_2 uptake [wt%]	Conditions	Reference

which were assigned to the inorganic and organic components. MOFs have a further advantage over nanostructured carbon materials and amorphous adsorbents in that they have a high degree of long-range order. If such adsorptive sites are indeed localized, they are additionally periodically arranged. It therefore may be possible to detect the adsorbed hydrogen molecules at very low temperatures by a diffraction experiment. A report has recently appeared describing the modeling of electron density, measured by synchrotron powder X-ray diffraction, of adsorbed H_2 in the small channels of CPL-1.[40] Neutrons are again the ideal scattering probes for such experiments as X-rays are insensitive to the low electron density of hydrogen atoms.

Computational modeling studies of the hydrogen interaction with metal–organic frameworks and their chemical components will also be important for our understanding of physisorption in these materials. The simplicity and high symmetry of some of the structures should make them ideal candidates for study, to the level that has been achieved for zeolites such as Na-A.[41] Grand Canonical Monte Carlo simulations of argon and methane in MOFs have been reported, and these display good agreement with measured isotherms.[42] The physisorption of hydrogen in MOF-5 has also been examined recently, in addition to more detailed calculations for H_2 with models of its inorganic and organic moieties, by using second-order Møller–Plesset perturbation theory.[38,43,44] The Monte Carlo study indicates that binding at the $Zn_4O(CO_2)_6$ clusters is perhaps 1.5 kJ mol^{-1} higher in energy than at the phenylene groups, but a broad range of interaction energies was determined for their system at 300 K corresponding to occupation of a broad distribution of sites.[44] Further computations of the hydrogen dynamics in MOFs will be indispensable in providing future directions for materials optimization.

7. Concluding Remarks

The series of considerations proposed above are multifaceted and we expect that significant exploration will be required to satisfy many of them simultaneously. A material with high gravimetric and volumetric hydrogen capacity at practical conditions should have a high surface area with pores of appropriate dimension for hydrogen and a large heat of adsorption. The strategies of impregnation, catenation, and the inclusion of open metal sites are just a few possibilities to be tested. To date, nearly 5000 2D and 3D MOF structures have been reported in the literature, but only a fraction of these have been examined for their porosity and far fewer of them have been tested for their hydrogen storage capacity. This fact, combined with the advantages of MOFs such as ease of synthesis and functionalization of their organic linkers and inorganic SBUs are favorable circumstances for achieving the DOE target for on-board hydrogen storage.

In 1935, R. C. Fuson formulated the principle of vinylogy to explain how the influence of a functional group may be felt at a distant point in the molecule when this position is connected by conjugated double-bond linkages to the group. In polar reactions, this concept allows the extension of the electrophilic or nucleophilic character of a functional group through the π system of a carbon–carbon double bond. This vinylogous extension has been applied to the aldol reaction by employing "extended" dienol ethers derived from γ-enolizable α,β-unsaturated carbonyl compounds. Since 1994, several methods for the catalytic, enantioselective, vinylogous aldol reaction have appeared, with which varying degrees of regio- (site), enantio-, and diastereoselectivity can be attained. In this Review, the current scope and limitations of this transformation, as well as its application in natural product synthesis, are discussed.

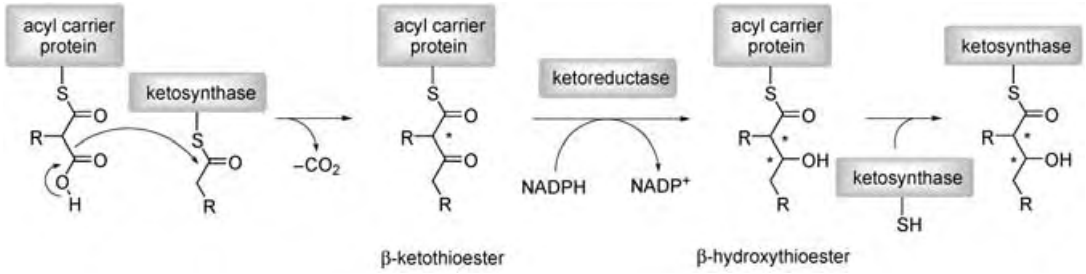
1. Introduction

The potent biological activity and structural diversity of the polyketide class of natural products has provided inspiration and impetus for research in many subfields of the chemical sciences. A main characteristic of these natural products is presence of complex polyol subunits with repeating 1,3-diol relationships within their core structure. Through elegant biosynthetic studies it is now well established that these polyol chains are synthesized in nature by multifunctional enzymes termed polyketide synthetases.[1] By using small carboxylic acid building blocks (primarily acetate, propionate, and butyrate), which are activated as thioesters bound to a ketosynthase protein and through carboxylation (e.g. with malonyl-CoA and 2-methylmalonyl-CoA), the carbon backbone of the polyketide is assembled two carbon atoms at a time as the result of enzymatic, decarboxylative Claisen condensations (Scheme 1). Reduction of the β-keto thioester intermediate by NADPH generates a β-hydroxy thioester, which can undergo acyl-group transfer to a subsequent ketosynthase protein. This sequence is repeated until the appropriate polyol chain length is reached. Each stereogenic center is created with high selectivity owing to the ability of the enzyme to rigidly fix the orientation of the reactive components relative to each other and relative to the enzyme.



A challenge for the modern synthetic chemist is the development of non-enzymatic asymmetric reactions for the construction of polyol subunits with equally high selectivity and efficiency as achieved in nature. With regard to many criteria, the asymmetric aldol addition reaction, which provides β-hydroxy carbonyl compounds with up to two new stereocenters from readily available starting materials, has met this challenge.[2] Indeed, the selectivity, scope, and predictability associated with current aldol-addition methods have allowed this reaction to emerge as a strategy-level reaction in natural product synthesis. Although the aldol addition reaction has found widespread application in the synthesis of linear acyclic polyol structures, it is certainly not the only method available. Other transformations, such as allylations,[3] alkylations of 4-cyano-1,3-dioxanes,[4] and nucleophilic epoxide-opening reactions of epoxyalkynols,[5] have also been developed as viable alternatives to the aldol reaction.

Nevertheless, despite some limitations, the aldol addition is ideally suited for efficient access to the targeted polyol structures. Moreover, the polar nature of the enolate precursor in the addition makes a vinylogous extension of this reaction possible. Defined as the transmission of electronic effects through a conjugated π system, the principle of vinylogy allows the extension of the nucleophilic or electrophilic character of a functional group through the π system of a carbon–carbon double bond.[6] Accordingly, a γ-enolizable α,β-unsaturated carbonyl substrate can be employed as an "extended dienolate" in a vinylogous aldol addition to an aldehyde to give δ-hydroxy-β-ketoesters **2** (Scheme 2) or α,β-unsaturated δ-hydroxy carbonyl compounds **4** (Scheme 3) in which up to two stereocenters and one double bond can be created. These functional arrays are common structural motifs that have found application in synthesis. The newly created hydroxy-substituted stereocenter is adjacent to a double bond or carbonyl group, and these versatile intermediates can therefore be further elaborated by using various highly selective substrate-directable reactions (see Schemes 2 and 3).[7] Among the most useful of these reactions are

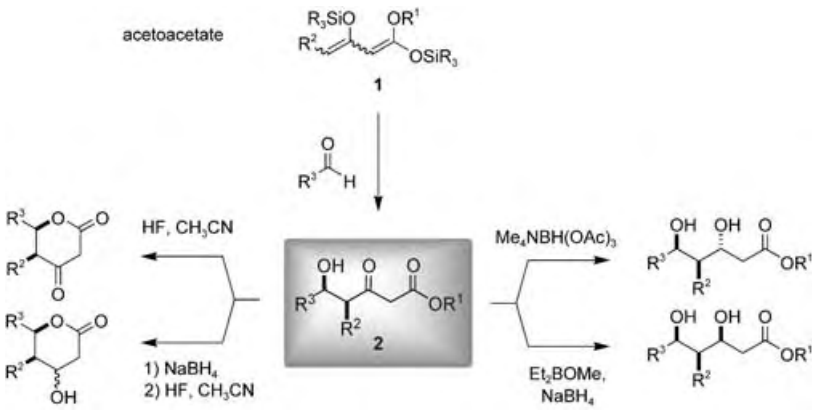
Scheme 1. The biosynthesis of polyol compounds by polyketide synthetases.[1]

conjugate additions to the double bond, oxidations or reductions of the double bond, or in the case of the β-keto carbonyl compounds, directed reductions or cyclizations.

For all its advantages, the vinylogous aldol reaction is still a challenging transformation because the additional problem of site selectivity overlays the issues of diastereo- and enantioselectivity already present in simple aldol reactions. Reactions of dienol ethers or ketene acetals can occur at either the α or the γ carbon atom of the extended conjugated system (Scheme 4). In comparison to the progress of the classic aldol addition reaction, the development of methods that combine high levels of regio- (site), diastereo-, and enantioselectivity in vinylogous aldol reactions has lagged significantly behind. Since 1994, a number of creative and practical solutions have been developed for highly selective catalytic, enantioselective, vinylogous aldol reactions. Their direct application in the total synthesis of natural products, as well as their use in the rapid assembly of complex synthetic intermediates, attests to the utility of these methods. This Review summarizes the scope and limitations of the catalytic, enantioselective, vinylogous aldol reaction and highlights its potential as a powerful and perhaps underutilized method for the synthesis of a number of useful structural motifs when used in conjunction with substrate-directable reactions.

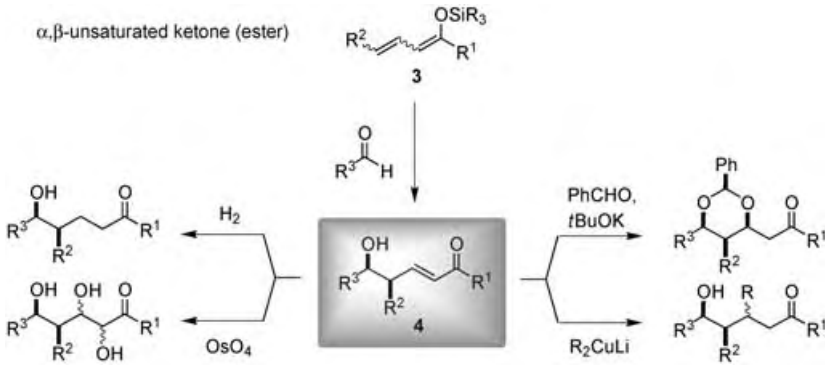
Scott E. Denmark completed his SB degree with Richard H. Holm and Daniel S. Kemp (MIT, 1975), and his DScTech with Albert Eschenmoser (ETH Zürich, 1980). He then moved to the University of Illinois and became full professor in 1987. Since 1991 he has been Reynold C. Fuson Professor of Chemistry. His research interests include new synthetic reactions, exploratory organoelement chemistry, and stereocontrol in C–C bond-forming processes. He is on the Board of Editors of Organic Reactions and Organic Syntheses, was a founding Associate Editor of Organic Letters, and is Co-Editor of Topics in Stereochemistry.

John R. Heemstra, Jr. was born in Oak Lawn, IL in 1978. He graduated from North Central College (Naperville, IL) in 2000 with a BA degree in chemistry. He is currently a graduate student at the University of Illinois in the research group of Scott E. Denmark. His PhD thesis work concerns the development of catalytic, enantioselective vinylogous aldol additions of ketone- and amide-derived silyl dienol ethers.



Gregory L. Beutner was born in Malden, MA in 1976. He graduated in 1998 with a BS in chemistry from Tufts University, where he carried out research with Arthur Utz and Marc d'Alarcao. He completed his PhD in 2004 at the University of Illinois, Urbana-Champaign under the guidance of Scott E. Denmark. He is currently an NIH postdoctoral research associate at the California Institute of Technology in the research group of Robert Grubbs.

2. Early Developments in the Vinylogous Aldol Reaction



Historically, the development of a successful catalytic asymmetric vinylogous aldol reaction had to provide solutions to two major problems: 1) viable access to the requisite dienolates and dienol ethers, and 2) methods to control the site selectivity of the addition. As the formation of the acetoacetate-derived dienol ether **1** has recently been reviewed,[8] this discussion will focus on the formation of dienolates and dienol ethers derived from α,β-unsaturated carbonyl compounds. Early studies on the use of metallodienolates showed that direct deprotonation of unsaturated ester **5** with strong amide bases such as lithium diisopropylamide (LDA) was not possible owing to competitive conjugate addition of the base [Scheme 5, Eq. (1)].[9] In 1972, Rathke and Sullivan reported the first successful enolization of an α,β-unsaturated ester, **5**, by the combination of a bulky amide base (lithium *N*-isopropylcyclohexylamide (LiICA)) and HMPA [Scheme 5, Eq. (2)].[10] Trapping of the enolate intermediate with MeI led to the deconjugated α-alkylation product **7** in good yield and selectivity. Subsequently, Schlessinger and co-workers discovered that a 1:1 mixture of LDA and HMPA generated a non-nucleophilic base that could readily enolize a variety of unsaturated esters. These reactions gave the products of α alkylation in high yields [Scheme 5, Eq. (3)].[9]

The high α-site selectivity observed in these alkylations illustrates an important feature of dienolate chemistry: The vinylogous transmission of electronic effects does not guarantee that reaction at the remote position will be favored or

even observed. However, high γ selectivity is possible through the use of latent dienolate equivalents in Mukaiyama-type aldol reactions[2] promoted by Lewis acids. First reported by Mukaiyama and Ishida, a vinylogous alkylation of the crotonaldehyde-derived silyl dienol ether **8** with dimethyl acetal **9** takes place under activation by $TiCl_4$ (Scheme 6).[11] Since this initial report, the vinylogous aldol addition of silyl dienol ethers to aldehydes has also been demonstrated and high regioselectivities for γ addition have been observed for a variety of dienolate structures.[12]

The reason for the different regioselectivities of the metallodienolate and the silyl dienol ether can be understood by considering the electronic structure of the two reagents. Metallodienolates and their silyl congeners are highly electron rich species, and their reactions are therefore governed by electrostatic interactions, that is, by the total electron density at each carbon atom.[13] Whereas HOMO coefficients and partial charges on the constituent atoms have historically been cited to predict site selectivity,[13] a more meaningful and computationally more accurate measure is the frontier-orbital density recommended by Fukui et al.[14] The frontier-orbital density

Scheme 6. The first reported vinylogous alkylation of a silyl dienol ether.[11]

can be calculated for attack both by electrophiles (electrophilic susceptibility) and nucleophiles (nucleophilic susceptibility). The diagrams in Figure 1 show the HOMO orbital coefficients (O.C.) and electrophilic susceptibility (E.S.) of the lithium enolate (*E*)-**11** of methyl crotonate, the corresponding trimethylsilyl ketene acetal (*E*)-**12**, and the trimethylsilyl enol ether (*E*)-**13** of methyl 2-propenyl ketone.[15] In the lithium enolate (*E*)-**11**, both the HOMO coefficient and the electrophilic susceptibility are greater at C2 than at C4; a preference for the α-addition product is therefore predicted. On the other hand, both silyl ketene acetal (*E*)-**12** and silyl enol ether (*E*)-**13** display larger HOMO coefficients and electrophilic susceptibilities at C4 than at C2, so that selectivity for the formation of the γ-addition products is predicted. The smaller difference between the values at C2 and C4 in (*E*)-**13** relative to that in (*E*)-**12** suggests that the

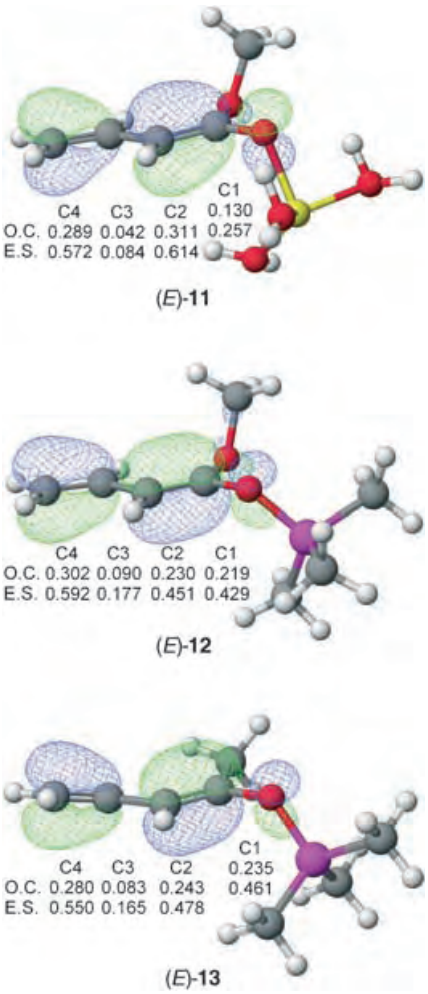

Figure 1. The electronic structures of the lithium dienolate (*E*)-**11**, silyl ketene acetal (*E*)-**12**, and silyl enol ether (*E*)-**13**.

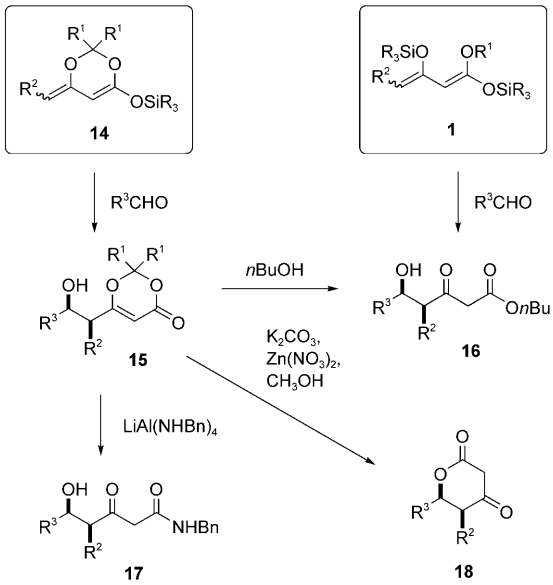


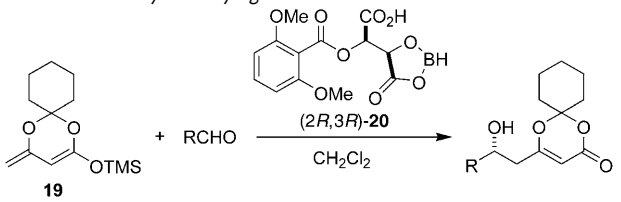
selectivity in ketone dienol ethers may be attenuated compared to silyl ketene acetals.

In rationalizing site selectivity, steric effects cannot be underestimated. In (*E*)-**12** and (*E*)-**13**, C2 is the more sterically hindered site owing to its proximity to the silyl group and the alkyl group of the ester; therefore, the approach of the electrophile to the less sterically encumbered C4 position is favored when C4 is not similarly substituted. For this reason, consideration of both the electrophilic susceptibilities and the steric environment around C2 and C4 is necessary to rationalize the high selectivity for the γ-addition products.

The inherent γ selectivity of silyl dienol ethers in Lewis acid promoted vinylogous Mukaiyama aldol additions has provided an ideal platform for the development of several catalytic enantioselective variants. Furthermore, various dienol ether structures derived from acetoacetates, lactones, esters, and ketones have been used successfully in additions to aldehydes. The following discussion is organized around the individual dienol ether structural types in catalytic, enantioselective, vinylogous aldol additions.

3. Synthetic Equivalents of Acetoacetate Ester Dianions

The frequent occurrence of δ-hydroxy-β-ketoesters **2** and their *syn*- and *anti*-β,δ-diol ester derivatives as structural subunits in biologically active natural products has suggested the use of acetoacetate-derived dienolates **14** and **1** in catalytic, asymmetric, vinylogous aldol reactions (Scheme 7).[8] Whereas the addition of dienolate **1** to aldehydes affords δ-hydroxy-β-ketoesters **16** directly, the addition of the 1,3-dioxin-4-one-derived dienolate **14** affords the protected acetoacetate aldol adduct **15**. To demonstrate the synthetic versatility of this adduct **15**, Singer and Carreira showed that compounds with the dioxinone functionality can be converted not only into a δ-hydroxy-β-ketoesters, but also into amides **17** or lactones **18**.[16] Furthermore, highly diastereoselective reductions of **16** afford both *anti*- and *syn*-dihydroxy esters, which are synthetically useful polyacetate building blocks (Scheme 2). The lactones formed through the cyclization of these adducts are also valuable synthetic subunits, and have been used for the synthesis of several pyran derivatives found in natural products.[8,12a]



Scheme 7. The vinylogous aldol addition of acetoacetate-derived dienol ethers **14** and **1**;[8,16] Bn = benzyl.

The first asymmetric vinylogous aldol reactions of the dioxinone-derived dienol ether **19** were reported by Sato et al. They employed a boron catalyst that had already proven highly selective for Mukaiyama aldol reactions of simple silyl ketene acetals.[17] Under the catalysis of the chiral acyloxyborane (CAB) complex (2*R*,3*R*)-**20**, the vinylogous aldol reaction of dienol ether **19** with a number of aldehydes proceeds in moderate yields and enantioselectivities (Table 1).[18]

Similar problems are encountered in this reaction to those observed in the reactions of silyl ketene acetals catalyzed by **20**, such as a competitive achiral-silyl-cation-catalyzed path-

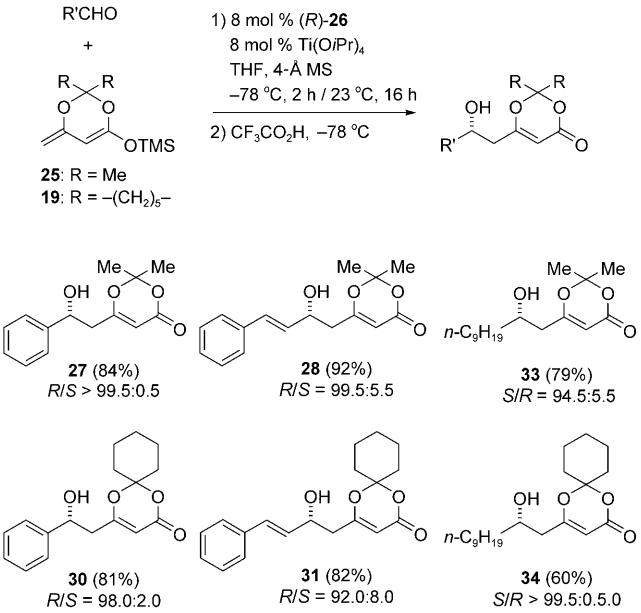
way.[17]. Therefore, slow addition of the silyl dienol ether, low temperatures, and high catalyst loadings (50–100 mol%) are required to attain high selectivities. 1,3,2-Oxazaborolidine catalysts, although not commonly used because of their low selectivity, were employed by Kiyooka and co-workers in the synthesis of a key fragment of the polyol portion of filipin III[19] and in a partial synthesis of the macrolide acutiphycin.[20] In the synthesis of filipin III, the direct product of the vinylogous aldol addition of dienolate **21** to aldehyde **22** catalyzed by oxazaborolidine complex **23** was further elaborated through a substrate-controlled *syn* reduction with Et_2BOMe and $NaBH_4$ to afford polyol **24** (Scheme 8).

Scheme 8. Oxazaborolidinone-promoted vinylogous aldol addition in the total synthesis of filipin III;[19] TBS = *tert*-butyldimethylsilyl; TMS = trimethylsilyl; Ts = toluenesulfonyl.

As part of their ongoing program on the synthesis of dioxanone-containing compounds, Sato et al. sought an improved protocol for these vinylogous aldol reactions. By adopting another well-known Lewis acid catalyst for aldol additions,[21] they found that a titanium(IV)–1,1′-binaphthol (binol) complex generated in situ could be employed (Scheme 9).[22] This complex is also a highly efficient and



Scheme 9. The $Ti(OiPr)_4$/(*R*)-binol-catalyzed vinylogous aldol reaction of dienolates **25** and **19** developed by Sato et al.[22]

selective catalyst for aldol additions of simple silyl ketene acetals. However, in this case, the high selectivities observed with acetate- and propanoate-derived silyl ketene acetals translate well to the reactions of dioxinone-derived silyl dienol ethers. High, although not exceptional, selectivities are observed for a variety of aldehyde substrates. Interestingly, the structure of the dioxinone-derived silyl dienol ether has a dramatic effect on both the yield and the selectivity. Whereas dienolate **25** is superior for reactions with aliphatic aldehydes, the use of the spirodioxinone-derived silyl dienol ether **19** leads to higher yields and selectivities with aromatic and olefinic aldehydes.

The titanium(IV)–binol catalyst has become popular for the vinylogous aldol reaction, and several recent reports from Scettri and co-workers expand the scope of this catalytic method as well as improve upon its selectivity (Scheme 10).[23] During their investigation of the catalyst structure, Scettri and co-workers observed that these reactions exhibit a strong, positive nonlinear effect. The magnitude of the effect is not

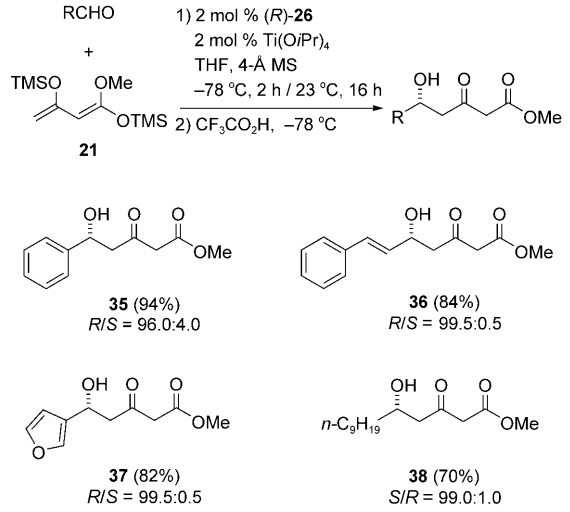
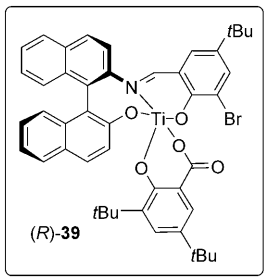
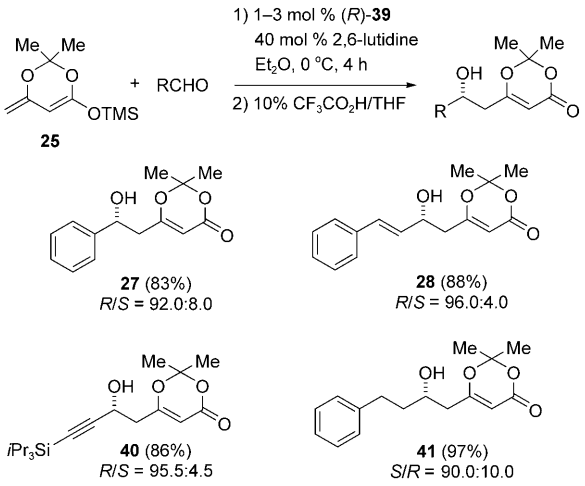


Scheme 10. The Ti(O*i*Pr)$_4$/(*R*)-binol-catalyzed vinylogous aldol reaction of dienolates **25** and **19** developed by Scettri and coworkers.[23]

concentration dependent. This behavior is indicative of an ML_2 catalyst system and suggests that two binol units are incorporated in the active catalytic species.[24] Furthermore, the addition of dienolate **25** to benzaldehyde proceeds through an autoinductive process with an amplification of the enantioselectivity when the reaction is performed in the presence of the enantiomerically enriched aldol product as an additive. These observations led to further refinements in the protocol for the in situ generation of the catalyst, so that reproducibly high enantioselectivities could be attained in the addition of dioxinone-derived dienolates **19** and **25** to a wide range of aldehydes. In a reversal of the trend observed when Sato et al. employed the titanium(IV)–binol catalyst system, dienolate **19** is now more effective in reactions with aliphatic aldehydes, whereas dienolate **25** is superior for aromatic and olefinic aldehydes.



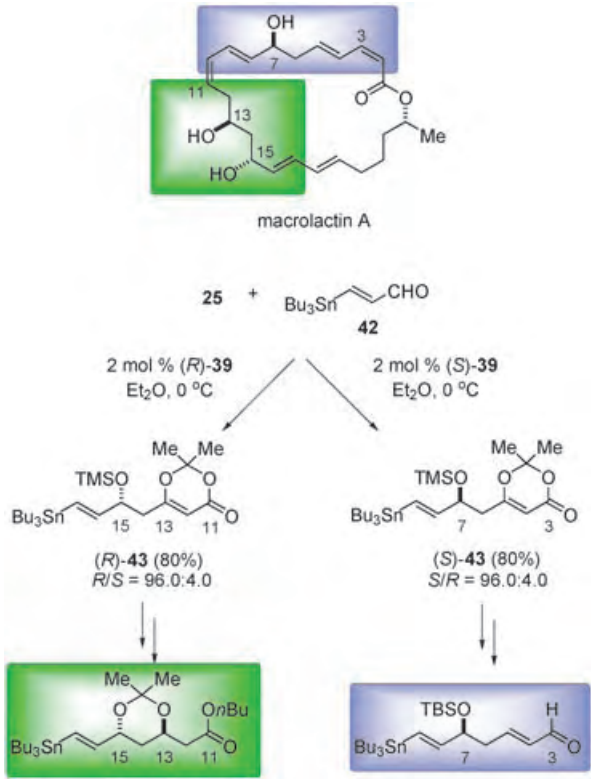
Scettri and co-workers reported that the protocol developed in their laboratories for the in situ generation of the titanium(IV)–binol catalyst system is also suitable for the addition of the Chan diene (**21**) to a wide variety of aldehydes (Scheme 11).[25] Dienolates of this type are extremely reactive and require catalyst loadings of only 2 mol% to afford aldol products in high yields and excellent selectivities. To isolate the aldol product in high selectivity, the use of the procedure developed by Carreira and co-workers for cleaving the silyl protecting group in the aldolate intermediate is essential, as racemization of the newly created stereocenter occurs when other methods are employed.



Although this titanium-based system provides high levels of enantioselectivity for a wide variety of substrates, it is less than ideal for synthetic planning because of its poorly defined catalyst structure and the fact that the autoamplification observed in the case of some substrates may not be general. In 1995, Singer and Carreira reported a well-defined catalyst system with which consistently high enantioselectivities and

Scheme 11. The vinylogous aldol reaction of dienolate **21** catalyzed by the Ti(O*i*Pr)$_4$/(*R*)-binol complex;[25] MS = molecular sieves.

yields can be attained (Scheme 12).[16] The titanium(IV)–Schiff base complex (*R*)-**39**, which had also proven successful for aldol reactions of simple silyl ketene acetals, presents several practical and advantages for synthesis over the catalysts described above. This catalyst system, unlike most catalysts for aldol reactions, provides high yields and enantioselectivities with alkynyl aldehydes as well as aromatic, olefinic, and aliphatic aldehydes.



Scheme 12. The Ti^{IV}/Schiff base catalyzed vinylogous aldol reaction of dienolate **25**.[16]

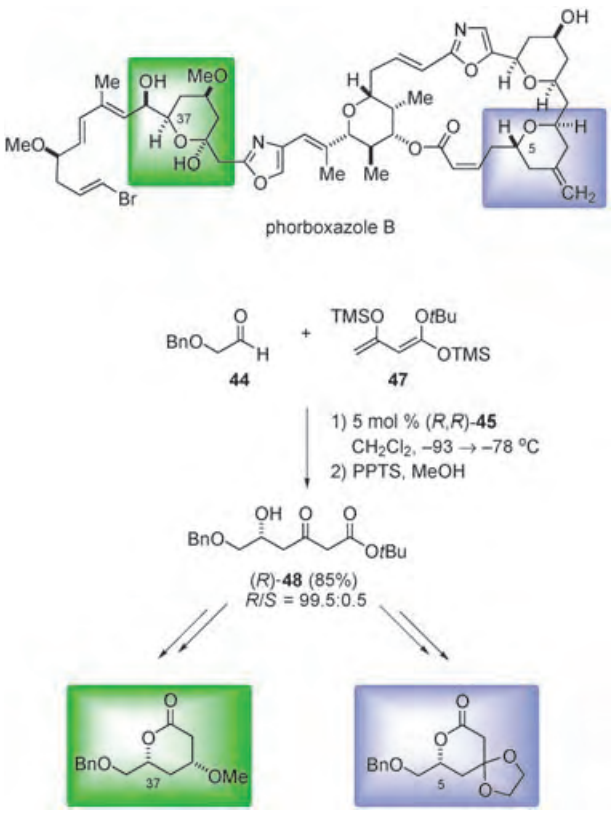
The high selectivity and wide substrate scope of this method makes it useful in complex-molecule total synthesis, as illustrated by the synthesis of macrolactin A[26] and dihydroxy vitamin D_3.[27] In the synthesis of macrolactin A, both enantiomeric forms of the titanium(IV)–Schiff base complex are employed to construct hydroxy-bearing stereocenters present in two key subunits of the molecule (Scheme 13). The protected acetoacetate adducts (*R*)-**43**



Scheme 13. Application of the Ti(IV)/Schiff base catalyzed vinylogous aldol reaction in the total synthesis of macrolactin A.[26]

and (*S*)-**43** were then further elaborated into the C11–C17 and C3–C9 fragments, respectively. The 1,3-*anti*-diol relationship between the C13 and C15 stereocenters is created through a highly selective, substrate-controlled reduction.

Evans and co-workers have applied the well-defined and versatile copper–bisoxazoline catalyst (*S*,*S*)-**45** for vinylogous aldol reactions of the dioxinone- and acetoacetate-derived silyl dienol ethers **25** and **47** with the α-heteroatom-substituted aldehyde **44** (Scheme 14).[28] Because this catalyst requires a potentially chelating substrate for high selectivity, the reaction remains somewhat limited in terms of aldehyde scope. Nevertheless, this method affords the products in high yields and selectivities and has been applied in successful syntheses of phorboxazole B[29] and bryostatin 2.[30] To demonstrate the versatility of the acetoacetate aldol adduct **48**, Evans and co-workers constructed two different pyran rings in phorboxazole B from this product of a vinylogous aldol addition (Scheme 15).

Scheme 14. The Cu^{II}/pybox-catalyzed vinylogous aldol addition of dienolates **25** and **47** to aldehyde **44**;[28] PPTS = pyridinium *p*-toluenesulfonate.

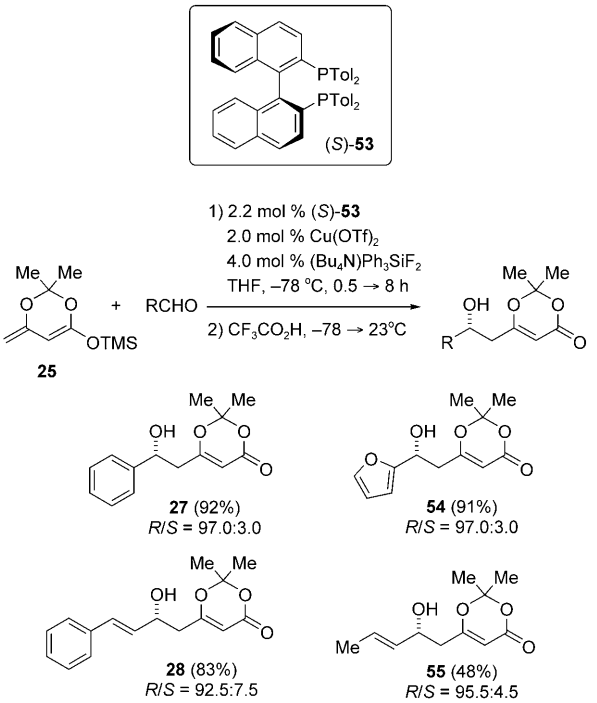
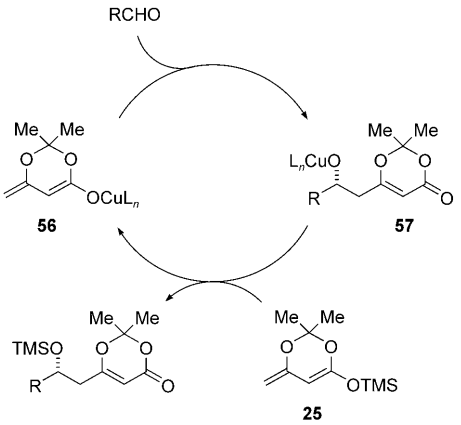
dienol ether **25** (Scheme 16).[31] The enantioselectivity of these reactions is highly sensitive to both the rate of addition of the silyl dienol ether and the solvent used. The low enantioselectivities can be attributed to a competitive silyl-

Scheme 16. The vinylogous aldol reaction of dienolate **25** catalyzed by the cationic chromium–salen complex (*R*,*R*)-**49**.[31]

cation-catalyzed pathway. Slow addition of dienolate **25** with a syringe pump and the presence of protic cosolvents greatly increase the rate of catalyst turnover from the chromium aldolate relative to the release of the silyl cation and lead to an increase in enantioselectivity. Although a protic cosolvent, such as an alcohol, is essential for excellent enantioselectivities to be attained, it also has the detrimental effect of decreasing the yield of the aldol adduct. However, reactions performed in the presence of both an alcohol and an amine base provide the products in improved yields while high enantioselectivities are maintained. The authors propose that coordination of the alcohol to the chromium ion generates a Brønsted acid, which, if not neutralized by the amine base, can effect protodesilylation of dienolate **25**. Under optimized conditions that include 2-propanol as a cosolvent and the addition of Et_3N, a catalyst loading of only 2.5 mol% is adequate to attain moderate to good yields and excellent enantioselectivities with a variety of aldehydes.



As is clear from the preceding examples of enantioselective Lewis acid catalysis, developments in the aldol reactions of simple silyl enol ethers are typically echoed in the vinylogous aldol reaction. The application of "Lewis base activation of Lewis acid" catalysis to the aldol reaction of silyl ketene acetals has also been extended to the vinylogous aldol reaction.[32] In this case, the use of the chiral bisphosphoramide catalyst (*R*,*R*)-**52** in conjunction with $SiCl_4$ leads to the in situ formation of a putative chiral siliconium ion that promotes the addition of the dioxinone-derived dienol ether **51** to a variety of aldehydes in high yields (Scheme 17). Although the aromatic and olefinic aldehydes studied reacted with only moderate enantioselectivity, the addition to the aliphatic aldehyde leads to the aldol adduct with high enantioselectivity.



Scheme 17. The vinylogous aldol reaction of dienolate **51** catalyzed by $SiCl_4$ and bisphosphoramide (*R*,*R*)-**52**.[32]

The catalyst systems discussed thus far represent extensions of asymmetric methods for simple aldol reactions to vinylogous aldol reactions. The active catalyst is a chiral Lewis acid, which binds to the aldehyde and participates in the catalytic cycle by providing electrophilic activation. The first catalyst system that was specifically designed for use in the vinylogous aldol reaction is a copper(II) fluoride/Tol-binap catalyst reported by Carreira and co-workers in 1998 (Scheme 18).[33] Reactions with this catalyst proceed by a different mechanism to that of the reactions discussed previously (Scheme 19). Initial studies suggested that the copper(II) fluoride catalyst reacts with the silyl dienol ether to generate a chiral copper dienolate **56**, which is the active species in the subsequent carbon–carbon bond-forming step. This hypothesis was confirmed by ReactIR studies, in which both the copper dienolate **56** and the copper aldolate **57** were observed. This reaction system leads to high yields and

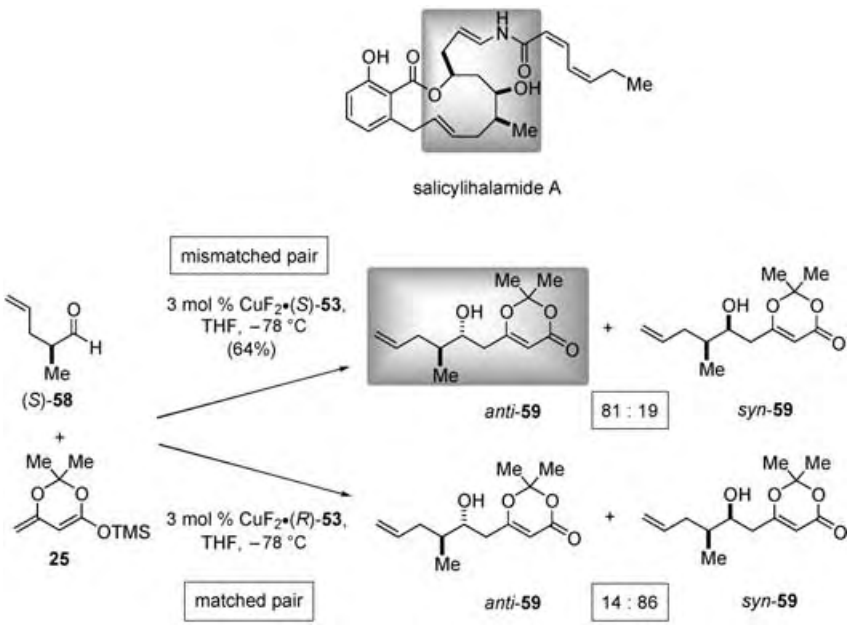
Scheme 18. The vinylogous aldol reaction of dienolate **25** catalyzed by the (*S*)-Tol-binap·CuF_2 complex.[33]

Scheme 19. Catalytic cycle for the vinylogous aldol reaction catalyzed by the Tol-binap·CuF_2 complex.

enantioselectivities for aromatic, heteroaromatic, and olefinic aldehydes in the addition to the dioxinone-derived dienol ether **25**; diminished yields are observed with aliphatic aldehydes, while high selectivity is maintained. This reaction is featured as a key step in the syntheses of leucascandrolide A,[34] salicylihalamide A,[35] a subunit of the group-A streptogramin antibiotics,[36] and the amphotericin B polyol subunit.[37]

In a total synthesis of salicylihalamide A, the ability to override the inherent Cram selectivity of chiral aldehyde (*S*)-**58** in a catalytic, asymmetric vinylogous aldol addition is illustrated.[35] Although Felkin–Heathcock analysis predicts that attack at the *Si* face of the carbonyl group in (*S*)-**58** is preferred, coupling of aldehyde (*S*)-**58** to dienolate **25** in the presence of $Cu(OTf)_2$, (*S*)-Tol-binap, and $(Bu_4N)Ph_3SiF_2$ affords an 81:19 mixture of diastereomers in favor of the aldol adduct *anti*-**59** formed from *Re*-face addition (Scheme 20). In contrast, use of the (*R*)-Tol-binap ligand in an overall matched case of double diastereoselection, produces an 86:14 mixture of diastereomers in favor of the adduct *syn*-**59**. Although the catalyst with the (*S*)-Tol-binap ligand can override the intrinsic facial selectivity of the aldehyde in the mismatched case to afford moderate *anti* selectivity, the inherent Cram selectivity, which favors the *syn* aldol adduct, is low for aldehyde (*S*)-**58**.



Although several highly selective catalyst systems have been developed for enantioselective, vinylogous aldol additions of the 6-methyldioxinone-derived dienolate **25**, a general, highly selective catalyst for the 6-ethyldioxinone-derived analogue **60** has not been reported.[38] In 1995, Sato et al. disclosed the only examples of catalytic, enantioselective, vinylogous aldol additions with dienolate **60** (Scheme 21).[22] Under catalysis with the titanium(IV)–binol complex, the addition of dienolate **60** to benzaldehyde proceeds in modest yield and with *syn* diastereoselectivity. Remarkably, the *syn* diastereomer is produced in enantiomerically pure form. When the CAB complex **20** is employed for the addition of the same substrates, poor *anti* diastereoselectivity is observed along with moderate to good enantioselectivity for both diastereomers.

4. Simple Ester-Derived Silyl Dienol Ethers

Dienol ethers **1** and **14** are synthetic equivalents of ketoester dianions that react with exclusive γ-site selectivity owing to the high nucleophilicity at C4. However, as exemplified in Figure 1, silyl dienol ethers (*E*)-**12** derived from α,β-unsaturated esters are not as electronically biased, and steric effects also need to be considered. Indeed, both α- and γ-addition products have been observed in vinylogous aldol reactions with ester-derived dienol ethers. Although achieving high site selectivity with these dienol ethers is more challenging than with the acetoacetate-derived dienol ethers, it is well worth the effort, as the α,β-unsaturated δ-hydroxy carbonyl adducts **4** are chiral homoallylic alcohols, which can be further functionalized through conjugate addition to, or oxidation or reduction of, the double bond (Scheme 3).

In 1999, Bluet and Campagne expanded the scope of the catalytic, enantioselective, vinylogous aldol reaction to simple ester-derived silyl dienol ethers **3** by employing the titanium(IV)–binol catalyst system (Scheme 22).[39] In this initial study, only the ethyl tiglate derived silyl dienol ether **62** was investigated. Although γ-aldol adducts were obtained exclusively, these less nucleophilic species were found to lead to lower yields and enantioselectivities than more highly oxygenated silyl dienol ethers, such as **25**. Nevertheless, the vinylogous aldol addition of simple ester-derived silyl dienol ethers has found application in the synthesis of complex natural products, such as callipeltoside A (Scheme 23).[40] The C13 stereocenter and the *E*-configured trisubstituted C10–

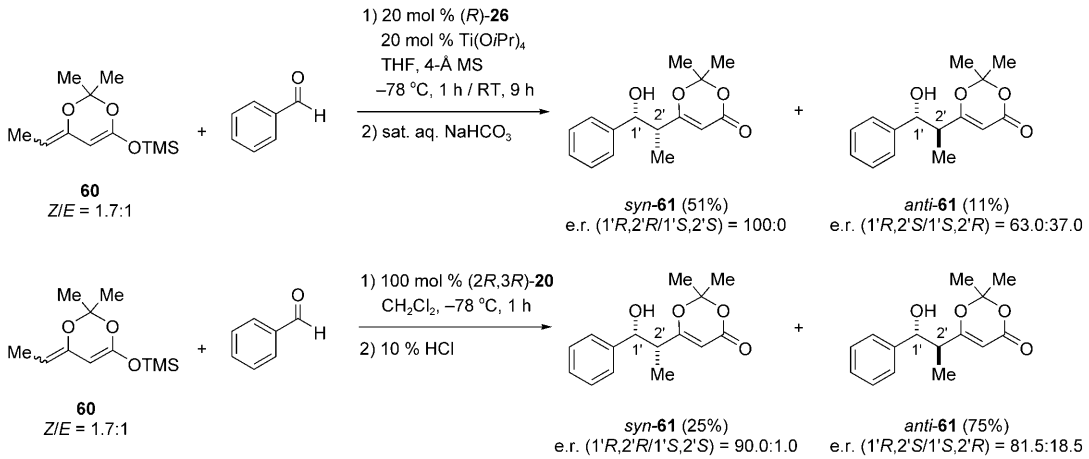
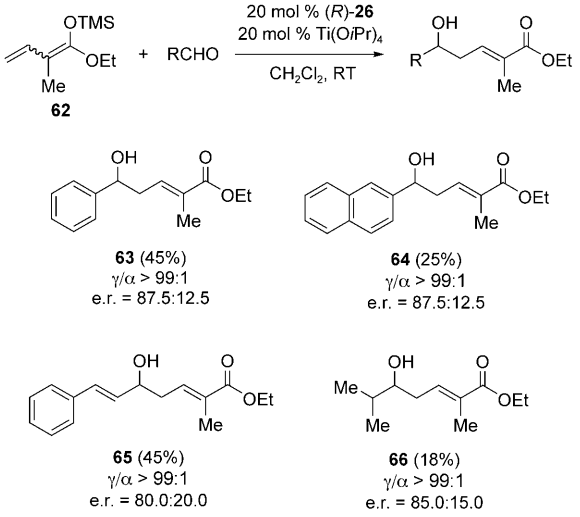


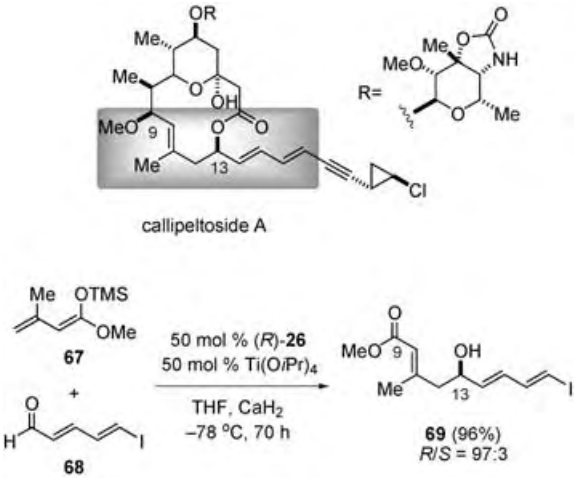
Scheme 20. Addition of dienolate **25** to chiral aldehyde (*S*)-**58** catalyzed by the Tol-binap·CuF_2 complex.[35]

C11 double bond were installed with excellent selectivity by an asymmetric, vinylogous aldol reaction of the methyl senecioate derived silyl dienol ether **67** with dienal **68**. However, high catalyst loadings and long reaction times are required to obtain a high yield because of the low reactivity of the dienolate.



In an earlier approach to callipeltoside A, Evans et al. developed a catalytic, asymmetric, vinylogous aldol reaction with ethyl senecioate derived silyl dienol ether **70** to construct the same hydroxy-substituted stereocenter and trisubstituted *E* double bond (Scheme 24).[41] The addition of dienolate **70** to 2-(4-methoxybenzyloxy)acetaldehyde (**71**) afforded the vinylogous aldol adduct **73** in high yield with complete *E* selectivity and excellent enantioselectivity under catalysis with the air-stable complex (*R*,*R*)-**72**.

Whereas in the preceding system a Lewis acidic copper catalyst was employed to activate the aldehyde prior to the addition, Bluet and Campagne have explored the use of copper as an activator of ester-derived silyl dienol ethers through generation of chiral copper metallodienolates. The use of the Carreira catalyst (*S*)-Tol-binap·CuF_2 produces a metallodienolate that provides exclusive γ-site selectivity along with high yields and moderate enantioselectivities for the vinylogous aldol addition of dienol ether **62** to aromatic and aliphatic aldehydes (Scheme 25).[42] However, in the addition to cinnamaldehyde a 1:1 mixture of the vinylogous aldol adduct and the 1,4-addition product was obtained. Chemical degradation of **63** to a previously described enantiomerically pure compound and comparison of the optical rotation showed that the major enantiomer is the aldol adduct derived from *Si*-face attack on the aldehyde. Remarkably, the sense of asymmetric induction observed in this reaction with the (*S*)-Tol-binap ligand is opposite to that observed by Carreira and co-workers in the addition of the dioxinone-derived silyl dienol ether **25** to aldehydes under catalysis by (*S*)-Tol-binap·CuF_2.[33]



Campagne and co-workers also studied the effect of γ substitution on the dienolate in the addition to aldehydes in the presence of the (*S*)-Tol-binap·CuF_2 catalyst (Scheme 26).[43] The addition of the methyl pentenoate derived silyl dienol ether **74** to various aldehydes yielded mixtures of lactones **75** and vinylogous aldol products **76**. Whereas lactones **75** were formed with excellent *anti* selectivity (>98:2) along with high enantioselectivity in all cases, the linear products **76** were isolated as a 1:1 mixture of racemic *syn* and *anti* diastereomers. The lactones are obtained with high diastereo- and enantioselectivity from the reaction with aromatic, heteroaromatic, olefinic, and aliphatic aldehydes. However, the ratio of the lactone to the linear product, a measure of the *E*/*Z* selectivity in the formation of the double bond, is highly substrate dependent. Whereas aro-

matic aldehydes afford the highest proportion of the lactone product, aliphatic and olefinic aldehydes are less selective, and 2-furaldehyde affords both the linear product and the lactone in a 1:1 ratio.

In an extension of this method, the addition of dienol ether **74** to the chiral aldehyde (*S*)-**77** was investigated (Scheme 27).[43] Felkin–Heathcock analysis of the *S*-config-

Scheme 27. The vinylogous aldol addition of ester-derived dienolate **74** to chiral aldehyde (*S*)-**77** catalyzed by the Tol-binap·CuF_2 complex;[43] TBDPS = *tert*-butyldiphenylsilyl.

ured aldehyde (*S*)-**77** predicts that approach to the *Si* face of the carbonyl group should be preferred, thus leading to the *syn* diastereomer. Additionally, the (*S*)-Tol-binap ligand has the same facial bias for attack at the *Si* face of the aldehyde, as shown above. When the (*S*)-Tol-binap·CuF_2 catalyst system is used, *syn*/*anti*-**78** is formed as the only lactone diastereomer, with the linear product reported to account for less than 10% of the crude reaction mixture. However, when the (*R*)-Tol-binap ligand is employed, an 88:12 mixture of lactones is formed, with a switch in diastereoselectivity now favoring the *anti*/*anti* lactone **78**. Again, the amount of linear product formed is reported to be less than 10% of the crude reaction mixture. Although the selectivity in both the matched and the mismatched case is high, the yields of the isolated product are low for both addition reactions (60 and 55%, respectively).

A systematic study of the effect on the addition to aldehydes of various substitution patterns on the dienol ether further expanded the scope of the vinylogous aldol reaction of ester-derived dienol ethers (Scheme 28).[32] The $SiCl_4$–phosphoramide catalyst system used for the addition of the acetoacetate-derived dienol ether **51** also effectively promotes the addition of the unsubstituted ethyl crotonate derived dienol ether as well as α-, β-, and γ-substituted dienol ethers. Remarkably, excellent γ-site selectivity and *E*-double-bond selectivity are maintained for all substitution patterns on the dienolate in the addition to aromatic, olefinic, and aliphatic aldehydes. Furthermore, this catalyst system maintains the high level of *anti* diastereoselectivity (> 99:1) that is observed in the additions of propanoate-derived silyl ketene acetals.[44] With aromatic and olefinic aldehydes, catalyst loadings of 1 mol% are sufficient to provide vinylogous aldol adducts in high yields and selectivities with all four dienolates surveyed. However, aliphatic aldehydes require higher catalyst loadings and longer reaction times for acceptable yields to be attained in the additions of the unsubstituted crotonate-derived and β-substituted senecioate-derived dienol ethers. Dienol ethers with methyl groups in the γ and α positions were found to be unreactive with aliphatic aldehydes. The aldol adducts are produced with excellent *E* selectivity regardless of the substitution on the dienol ether, including γ substitution. This result stands in contrast to catalysis with Tol-binap·CuF_2. Whereas the addition of the α-substituted methyl tiglate derived dienol ether occurs with exclusive *E* selectivity in the presence of this catalyst, the γ-substituted methyl pentenoate derived dienol ether affords the aldol adduct with modest *Z* selectivity.

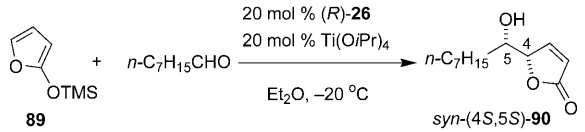
5. Lactone-Derived Dienol Ethers



The Lewis acid catalyzed vinylogous aldol addition of lactone-derived dienol ether **87** to aldehydes leads to the formation of a γ-substituted butenolide **88**, a structural motif that is found in several biologically active natural products (Scheme 29). Furthermore, these adducts are useful chiral building blocks for the preparation of functionalized γ-lactones through manipulation of the double bond. Butenolide **88** has also been used for the preparation of compounds containing 1,2-diol functionality, and for the construction of optically active pyrans.[12a]

Scheme 29. The vinylogous aldol addition of lactone-derived dienol ether **87** and elaboration of the butenolide product.

Figadère and co-workers disclosed the first catalytic, enantioselective addition involving a lactone-derived dienolate in 1998.[45] The titanium-based chiral catalyst system developed by Sato et al. and improved upon by Scettri and co-workers for acetoacetate-derived dienol ethers can also promote highly site-selective additions of the lactone-derived silyl dienol ether **89** to aldehydes. Interestingly, reactions performed in the presence of a 1:1:1 mixture of $Ti(OiPr)_4$, binol, and a second chiral alcohol afforded the aldol addition product in higher yields and enantioselectivities than those carried out in the presence of only $Ti(OiPr)_4$ and binol. The authors suspected that the aldol product becomes incorporated into the catalytic species to generate a new catalyst structure and therefore explored the possibility of an autoinductive aldol reaction (Table 2). The first experiment established that the aldol addition product was produced with higher enantioselectivity in the presence of 5 mol% of the enantiomerically enriched aldolate *syn*-(4*S*,5*S*)-**90** than in the reaction performed in the absence of additives (Table 2, entries 1 and 2). Furthermore, the inclusion of the minor enantiomer *syn*-(4*R*,5*R*)-**90** under the same reaction conditions causes a decrease in enantioselectivity (Table 2, entry 3). To allow amplification of the enantioselectivity through the incorporation of the major *syn* butenolide formed during the reaction into the catalyst structure, a general procedure

Table 2: Modification of the $Ti(OiPr)_4$/binol-catalyzed vinylogous aldol reaction.[45]

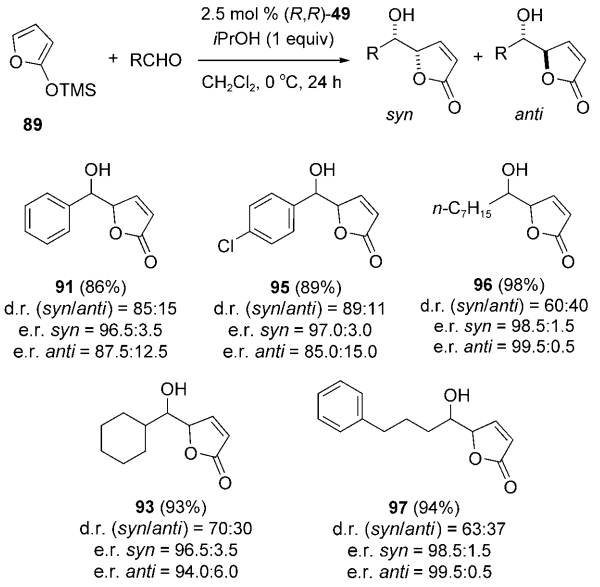
1[a]	none	99	70:30	85:15
2	5% (4*S*,5*S*)-**90**	99	70:30	>98:2
3	5% (4*R*,5*R*)-**90**	99	70:30	70:30
4[b]	none	90	60:40	>98:2

[a] Dienolate **89** was added in one portion. [b] Dienolate **89** was added stepwise in four portions. e.r. = enantiomeric ratio.



involving stepwise addition of dienolate **89** was developed (Table 2, entry 4). This method has been applied to vinylogous aldol reactions of silyl dienol ether **89** and affords adducts with modest to excellent enantioselectivities and modest diastereoselectivities (Scheme 30). Interestingly, the substrate determines which product is formed as the major diastereomer in the addition reaction; whereas aliphatic aldehydes lead to the formation of the *syn* isomer, olefinic and aromatic aldehydes produce the *anti* isomer.

The chromium–salen catalyst (*R*,*R*)-**49** used by Katsuki and co-workers for the addition of dioxinone-derived dienol ether **25** to aldehydes also catalyzes the addition of **89** to aldehydes with high enantioselectivity (Scheme 31).[46] As is the case for the reaction with dienol ether **25**, the addition of a protic cosolvent to the reaction mixture is essential for high and reproducible selectivities to

Scheme 30. The $Ti(OiPr)_4$/(*R*)-binol-catalyzed vinylogous aldol reaction of lactone-derived dienolate **89**.[45]

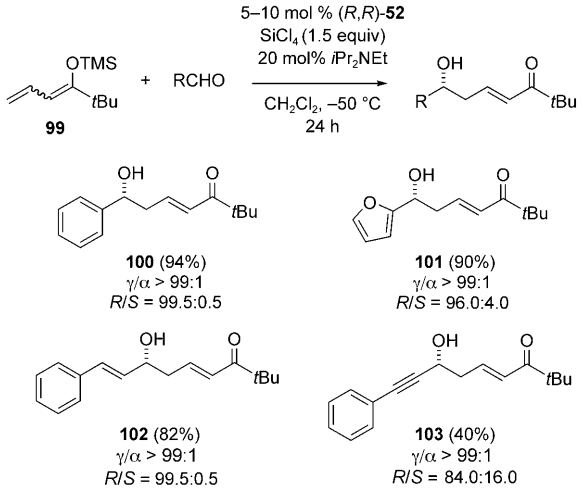
Scheme 31. The vinylogous aldol reaction of lactone-derived dienolate **89** catalyzed by the cationic chromium–salen complex (*R*,*R*)-**49** (absolute configurations were not established by the authors).[46]

be attained. The authors propose that the protic cosolvent is needed to suppress the undesired retroaddition reaction by rapidly converting the aldolate into the hydroxyl lactone product, thereby enabling the isolation of the adduct formed under conditions of kinetic control. Although only modest to good *syn* diastereoselectivities are observed with aromatic and aliphatic aldehydes, both the *syn* and *anti* isomers are formed with good to excellent enantioselectivities.

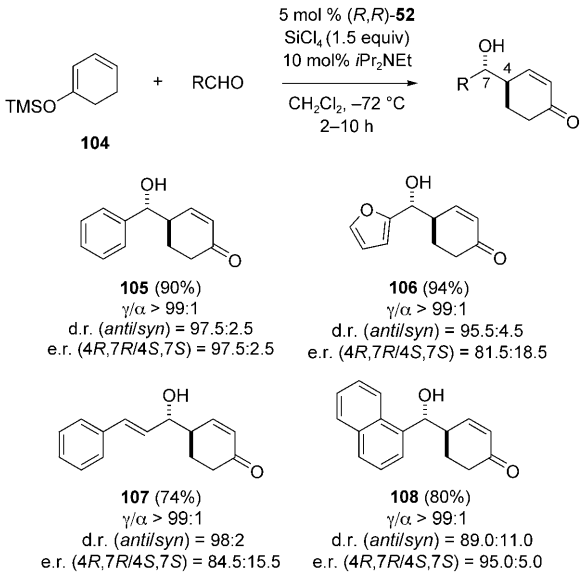


Whereas the two previously described catalyst systems afford only modest diastereoselectivities, the copper–bisoxazoline catalyst (*S*,*S*)-**45** developed by Evans and co-workers affords the *anti* product with high diastereo- and enantioselectivity from the vinylogous aldol reaction of **89** with (benzyloxy)acetaldehyde (**44**; Scheme 32).[28] However, the addition only to aldehyde **44** was demonstrated.

Scheme 32. The vinylogous aldol reaction of lactone-derived dienolate **89** to aldehyde **44** in the presence of the Cu(II)/pybox complex (*S*,*S*)-**45**.[28]

6. Ketone-Derived Dienol Ethers

Although the catalytic, enantioselective, vinylogous aldol addition of dienol ethers derived from α,β-unsaturated esters has been successfully demonstrated, extension of the nucleophile scope to other acyclic α,β-unsaturated carbonyl compounds has remained virtually unexplored. The first use of ketone-derived dienol ethers in catalytic, asymmetric, vinylogous aldol reactions was recently reported from these laboratories.[47] The combination of catalytic amounts of the chiral bisphosphoramide (*R*,*R*)-**52** and $SiCl_4$ promotes the addition of silyl dienol ethers derived from simple acyclic α,β-unsaturated ketones to aldehydes. In this initial report, dienol ether **99** reacts with aromatic, heteroaromatic, olefinic, and propargylic aldehydes with exclusive γ-site selectivity and high enantioselectivity (Scheme 33). However, the failure of aliphatic aldehydes to undergo this reaction remains a limitation of this method.



Scheme 33. The vinylogous aldol reaction of acyclic-ketone-derived dienolate **99** catalyzed by $SiCl_4$ and bisphosphoramide (*R*,*R*)-**52**.[47]

The reactivity of the cyclic-ketone-derived dienol ether **104** was examined to evaluate the diastereoselectivity in the addition to form γ-substituted ketones (Scheme 34).[47] Aldol adducts formed from aromatic, olefinic, and heteroaromatic aldehydes could be obtained with exclusive γ-site selectivity and good to excellent *anti* diastereoselectivity. However, as in the case of acyclic-ketone-derived dienol ethers, **104** did not react with aliphatic aldehydes.

7. Conclusions and Outlook

Excellent progress has been made in the development of the catalytic, enantioselective, vinylogous aldol reaction since the initial report in 1994. Through the extension of existing catalyst systems and the invention of novel ones, several general and highly selective methods now exist for the addition of acetoacetate-derived silyl dienol ethers **1** and **14** to a wide variety of aldehydes (see **111**, Figure 2). Moreover, recent studies with dienolates derived from esters have shown that crotonate-derived silyl dienol ethers, as well as dienolates with α and β substituents, react with a wide range of aldehydes with high selectivity (**120**). This method also allows for high selectivity in the addition of dienolates derived from γ-substituted esters to aromatic and olefinic aldehydes to give compounds **123**. Furthermore, high enan-

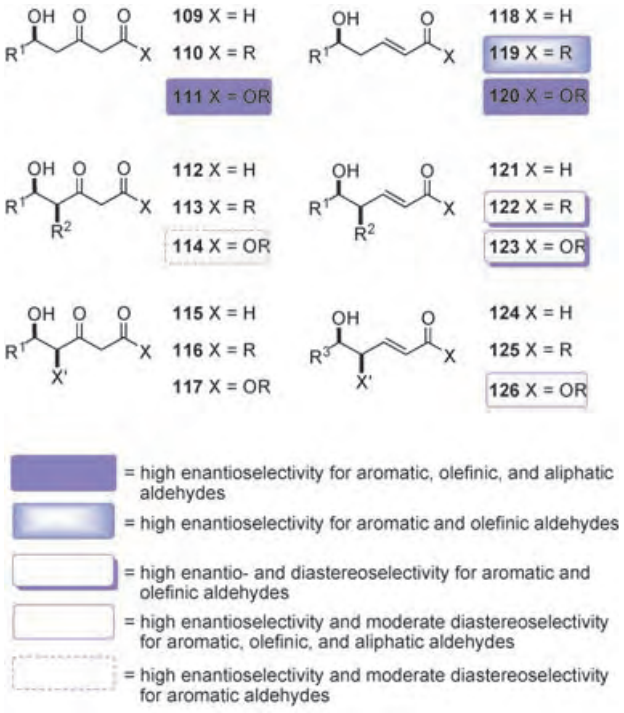

Figure 2. Vinylogous aldol adducts created from simple aldehydes and dienol derivatives derived from β-dicarbonyl compounds or α,β-unsaturated carbonyl compounds.

tioselectivity can be attained in the vinylogous aldol addition of lactone-derived dienol ethers to different aldehyde structures, although a general method that affords high diastereoselectivity is still lacking (**126**).

When one considers the wide range of structural motifs that can be created by employing the vinylogous aldol reaction, the limited number of dienol ethers thus far examined becomes apparent. Figure 2 provides an overview of the aldol adducts that can be created by using catalytic, asymmetric methods through the combination of dienol derivatives derived either from β-dicarbonyl compounds or α,β-unsaturated carbonyl compounds with simple aldehydes. A number of important conclusions are readily apparent. First, the range of nucleophiles is limited primarily to ester-derived reagents. With only a single report of dienol ethers derived from α,β-unsaturated ketones (see **119** and **122**) and no examples of dienol ethers derived from α,β-keto aldehydes (**109**, **112**, and **115**), β-diketones (**110**, **113**, and **116**), or α,β-unsaturated aldehydes (**118**, **121**, and **124**), this is clearly an area for future development. Another serious omission is the lack of methods for the addition of any nucleophile to a wide range of aldehydes with excellent diastereoselectivity. Although progress has been made in the addition of dienol ethers derived from γ-substituted esters, ketones, and lactones, the analogous reactions of dienolates derived from γ-substituted acetoacetates or 1,3-diketones represent opportunities for future investigation.

The presence of the vinylogous aldol motif in many natural products, and the easily manipulated functionalities contained in the resulting α,β-unsaturated δ-hydroxy carbonyl or δ-hydroxy-β-ketoester vinylogous aldol adducts, render this reaction an interesting alternative for the synthesis of many natural products. Although the use of complex enzymes for the synthesis of polyketides is highly successful, the unique strengths and weaknesses of small-molecule asymmetric catalysis inspire the synthetic chemist to find different and innovative solutions to this challenge. The combination of well-established, substrate-controlled asymmetric transformations with these highly selective, catalytic, enantioselective vinylogous aldol reactions is destined to generate new strategies for synthesis in the years to come.

We are grateful to the National Science Foundation (NSF CHE-0105205 and NSF CHE-0414440) for generous financial support. We also thank Dr. Martin Eastgate for performing the DFT calculations.

Communications

The active site of almond hydroxynitrile lyase was redesigned to give highly enantioselective enzyme variants for the synthesis of (*R*)-2-hydroxy-4-phenylbutyronitrile. K. Gruber, A. Glieder et al. describe their rationalization and realization of these biocatalysts in their communication on the following pages.

Protein Engineering

Carving the Active Site of Almond *R*-HNL for Increased Enantioselectivity**

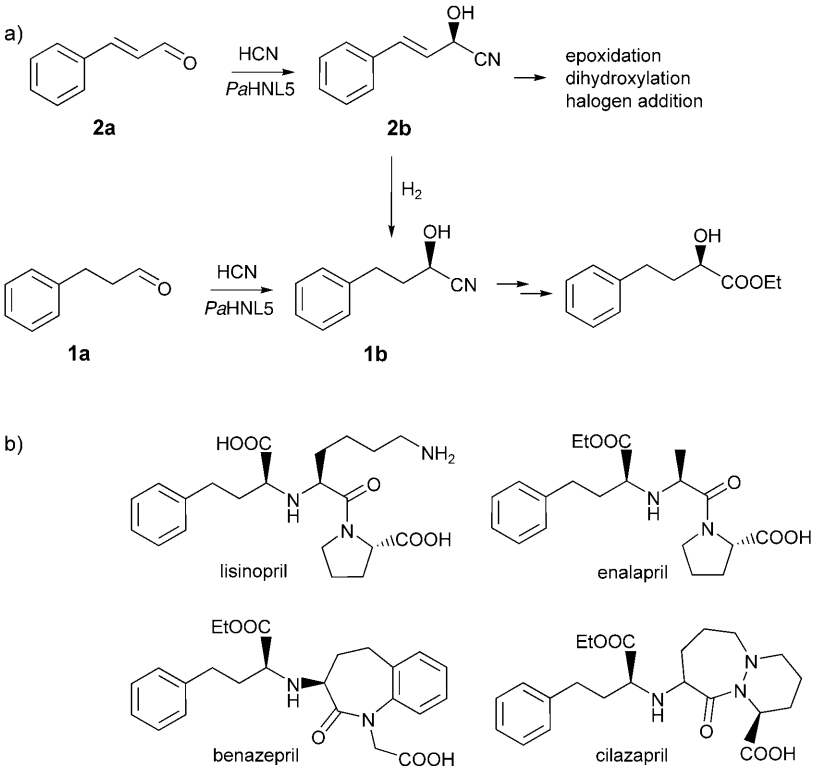
Roland Weis, Richard Gaisberger, Wolfgang Skranc, Karl Gruber, and Anton Glieder**

Hydroxynitrile lyases (HNLs) catalyze quantitative, stereoselective carbon–carbon bond formation in the addition of HCN to aldehydes or ketones yielding enantiopure cyanohydrins, which are key intermediates for numerous synthetic routes.[1] Both *R*- and *S*-selective HNLs are widely present in nature, and several genes have been cloned and expressed.[1] Recombinant almond (*Prunus amygdalus*) (*R*)-HNL isoenzyme 5 (*Pa*HNL5) is secreted to the culture supernatant of *Pichia pastoris*, which can be directly used for biocatalytic conversions in water or biphasic systems without prior enzyme purification or immobilization. Further prerequisites for an industrial application of this enzyme are its stability at acidic pH (suppression of the unselective non-enzymatic background reaction) and its enantioselectivity. Although the high stability of recombinant *Pa*HNL5 already enabled stereoselective enzymatic syntheses in water or biphasic systems even with slow-reacting substrates,[1,2] the enantioselectivity of *Pa*HNL5 is in some cases still too low for biocatalysis on a large scale.

Among the broad substrate range accepted by *Pa*HNL5[3] those with the aldehyde functionality separated from an aromatic moiety by an aliphatic linker represent an especially interesting group. The aromatic ring, which plays an important role in the correct recognition and binding of the natural substrate mandelonitrile (benzaldehyde cyanohydrin),[4] still has to fit into the closer region around the active site. On the other hand its distance from the functional group and the conformational flexibility of the alkyl linker reduce its influence on the stereoselectivity of the reaction. Among such aromatic substrates, 3-phenylpropionaldehyde (**1a**) and 3-phenylpropenal (**2a**, *trans*-cinnamaldehyde), and their corresponding cyanohydrins (*R*)-2-hydroxy-4-phenylbutyronitrile (**1b**) and (*R*)-2-hydroxy-4-phenyl-3-butene nitrile (**2b**) emerged as the most interesting representatives in terms of commercial use. Enantiopure α-hydroxycarboxylic acids, which are important intermediates for the synthesis of a class of angiotensin-converting enzyme inhibitors (ACEi) known as "prils",[5] can be derived from these cyanohydrins by acid hydrolysis. Compound **2a** was described as a notoriously recalcitrant substrate, but palladium-catalyzed hydrogenation of **2b** also yields (*R*)-2-hydroxy-4-phenylbutyric acid.[6] In addition **2b** can be used as a versatile intermediate for asymmetric epoxidation, dihydroxylation, and halogen addition.[7] Only *R* enantiomer **2b** is a building block of pharmacologically active "prils", and commercial production calls for high enantiomeric excesses (> 95 % *ee*), high yields (> 95 %), an environmentally benign process, and economic reaction times with a low enzyme/substrate ratio. Enantiomer separation is feasible by preferential crystallization of diastereomers, although with limited yields (68 %).[8] Other synthetic routes, for example, enantioselective reduction of keto or diketo esters, suffer from complicated procedures or require expensive starting compounds.[5,9]

Considering implementation of these chiral building blocks on a large scale, we investigated a biocatalytic route using very low amounts (i.e. 17 μg enzyme per mmol **1a**) of recombinant *Pa*HNL5 (Scheme 1). This route starts with cheap substrates, minimizes the number of unit operations, and offers optional crystallization after cyanohydrin hydrolysis to recover pure product. Conversion of **1a** to **1b** using recombinant *Pa*HNL5 was almost complete (93 %) after 4 h with 89.4 % *ee* (Table 1, entry 1). However, to avoid enantioselective crystallization as an additional step in the synthetic route, we needed a more selective mutein.

Directed evolution of enzymes has proved to be an efficient tool to influence the enantioselectivity of many (mostly bacterial) enzymes.[10] However, although expression of *Pa*HNL isoenzymes by *E. coli* is feasible, highly active *Pa*HNL5 could only be expressed in *Pichia pastoris*,[1,11] which is not a reliable host system for laboratory evolution. Furthermore a codon dilemma[12] impedes access to all possible amino acid exchanges by point mutations, especially when only a few thousand mutants can be screened. Because of our recent success in designing a more active mutein for sterically demanding mandelonitrile derivatives,[1a] we started a structure-guided approach to increase the enantioselectivity of this lyase. To our knowledge this is the first report on a successful structure-guided design of lyases to improve enantioselectivity, although rational approaches to *Manihot esculenta* HNL variants with reduced substrate transport limitations resulted in improved enantioselectivity for a variety of substrates as well.[13]



We modeled the complexes of *Pa*HNL5 with (*R*)-**1b** and (*S*)-**1b.** For both substrates equivalent binding modes were observed with respect to the position of the phenyl group as well as the mechanistically important polar interactions of the hydroxy and cyano groups with His 498 and His 460 (Figure 1).[4] Differences were observed only for the interactions of *Pa*HNL5 with the alkyl linker chain of **1b**, which was oriented towards Ala 111 in the *S* enantiomer and towards Val 360 in the *R* enantiomer (Figure 1, see also

11	A111GV360I	92	87.6
12	L331A	94	88
13	V360I	98	95.3

[a] Reaction conditions: 30 mmol of **1a** and 0.5 mg of enzyme (17 μg mmol^{-1} substrate), 4 h, 10 °C, pH 3.4.

video material in the Supporting Information). We took advantage of this pseudo mirror symmetry and redesigned the substrate binding site of *Pa*HNL5 to tailor the accessible volume for one or the other enantiomer, similarly to other successful examples of laboratory-evolved enzymes.[14] Amino acids in the binding site were exchanged with residues of different sizes while preserving hydrophobicity. Ala111 and Val360 interact with the alkyl chain of the substrate from opposite sides and therefore are promising sites for mutations. The same is true for Leu331 and Leu343, which mainly interact with the phenyl group and form part of the access tunnel leading to the active site. In total, we studied 24 mutants in silico, and 12 of those—with the largest predicted changes in enantioselectivity—were prepared and analyzed experimentally. In a first test of the hydrocyanation of **1a** with only low amounts of each mutein, V360I yielded the most selective enzyme (Table 1, entry 13). As expected, A111G was less stereoselective. In a more detailed examination, 1 mg each of the best four muteins (entries 10–13) were analyzed for conversion of 2 g (15 mmol) of **1a** (i.e. 67 μg enzyme per mmol substrate). L331A, V360M, and V360I (Table 2, entries 3–5) resulted in almost complete substrate conversion within 4 h with significantly improved enantioselectivity. At the end of the conversion **1b** produced with mutein A111GV360I also showed slightly higher enantiopurity (91.8% *ee*), although the conversion was a little slower.

To explore turnover rates, the amount of the enzyme was adjusted such that with each individual mutein the conversion of 2 g (15 mM) of **1a** was in a roughly linear range during the first 20 min. Specific activities under these conditions (Table 2) served for comparison of the individual muteins for cyanohydrin synthesis, although due to the nonlinear kinetics of *Pa*HNL5-catalyzed reactions in biphasic systems, such numbers cannot be translated to k_{cat} values for higher enzyme concentrations. The introduction of isoleucine at position 360 raised the *ee* to more than 96% and accelerated the transformation of **1a** almost sixfold. Thus the conversion

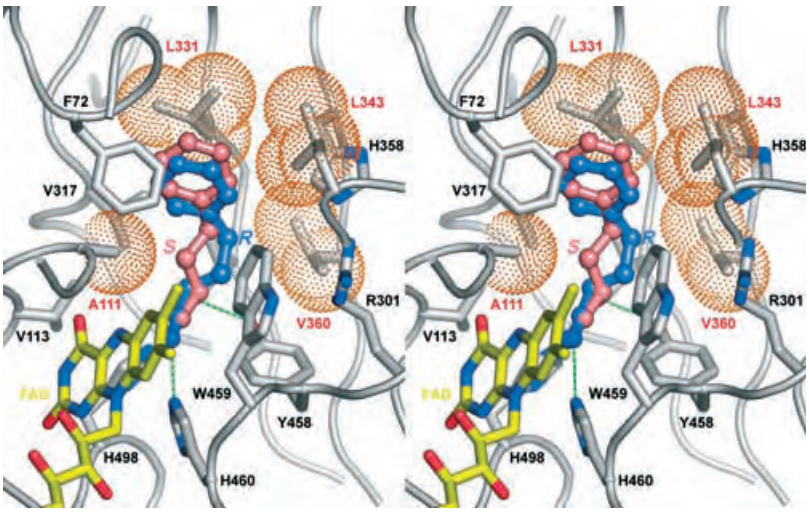

Figure 1. Stereoimage of the superposition of modeled complexes of (*R*)-**1b** (blue) and (*S*)-**1b** (pink) bound to the active site of *Pa*HNL5. Amino acid side chains are shown in light gray, the FAD cofactor in yellow. N and O atoms are shown in blue and red, respectively. Residues selected for mutagenesis are labeled in red, and their van der Waals volumes are represented by small spheres. The image was prepared with the software PyMol (http://www.pymol.org).

was complete within a couple of hours despite a low enzyme/substrate ratio. In contrast, in a recent report at least 30 times more enzyme[6] was employed. Mutations L331A and, surprisingly, A111GV360I also resulted in a moderately increased catalytic rate. Compared to other muteins, however, the turnover rate of A111GV360I decreased during the course of the reaction.

All muteins with increased enantioselectivity for the synthesis of **1b** were also tested in the conversion of 15 mmol of the more rigid **2a** to **2b** (Table 3). Two muteins were also more selective with **2a**, reaching ≈98% *ee* with mutation V360I. In addition all mutations except V360M caused a faster conversion of **2a** than with the original enzyme *Pa*HNL5. The higher rigidity of **2a** compared to **1a** and the larger volume of the methionine residue are likely reasons for the weaker activity of the V360M variant. With only 27 μg of *Pa*HNL5-V360I per mmol **2a**, conversion to **2b** was almost complete after 3 h with an excellent enantiomeric excess of ≈98%. In contrast, Gerrits and co-workers reported a reaction time of 168 h for 97% yield and 98% *ee*.[15] Recently also the Sheldon lab reported highly enantioselective and fast reactions by employing cross-linked enzyme aggregates of native almond HNL.[16]

Structure-guided design was employed to generate recombinant *Pa*HNL5 variants suitable for large-scale stereoselective synthesis of aromatic cyanohydrins in water-based systems. From 24 desigend enzyme variants, 12 of which were prepared, four well-expressed, sit-specific mutants of the *Pa*hnl5 gene with significantly increased stereoselectivity were obtained. All muteins were stable at low pH. As a highlight, the variant *Pa*HNL5-V360I exhibited extraordinary catalytic properties. The enantiomeric excess for the conversion of **1a** was improved to >96% despite a very low enzyme/substrate ratio. This particular mutein reduced the required amount of biocatalyst 10- to 30-fold to produce enantiopure (*R*)-2-hydroxy-4-phenylbutyric acid and derivatives thereof. From *trans*-cinnamaldehyde (**2a**) very low amounts of catalyst with mutation V360I were needed to produce cyanohydrin **2b** with an optical purity of ≈98% *ee* within 3 h. The conversion time for this recalcitrant substrate was reduced from 168 h to 3 h. Interestingly our designed and more selective muteins were also more active. This is in contrast to reports on the design of more selective hydrolases, where just the reactivity with the wrong enantiomer was reduced.[17] *Pa*HNL5-V360I is currently the most efficient catalyst for syntheses of enantiomerically pure building blocks for pharmaceutically active "prils", therefore suggesting itself for industrial application on a large scale.

Heterogeneous Catalysis

The Microstructure of Copper Zinc Oxide Catalysts: Bridging the Materials Gap**

Thorsten Ressler, Benjamin L. Kniep, Igor Kasatkin, and Robert Schlögl*

The progressing shift in resources used in the petrochemical industry from crude oil to natural gas increases the importance of methanol as a basic chemical for the production of synthetic fuels and polymers. In modern MegaMethanol plants that produce more than 5000 tons of methanol per day, supported copper nanoparticles are employed as highly active heterogeneous catalysts. For the efficient use of natural resources the design of more active and selective catalysts is required. However, structure–activity relationships are often deduced from model systems exhibiting structural characteristics very different from those of industrial catalysts. Here we describe the microstructure[1] of copper nanoparticles on zinc oxide prepared similar to industrially used copper catalysts and exhibiting comparable catalytic activities.

Supported copper nanoparticles are active catalysts for methanol synthesis, methanol oxidation, and methanol steam reforming. Structure–activity relationships for copper catalysts have been studied extensively with a variety of materials ranging from single-crystal model systems to multiple-component industrial catalysts with copper concentrations of more than 50%.[2] Several suggestions were made as to the nature of the "real" structure[3] of the copper phase under reaction conditions, including the simplifying assumption that the activity increases linearly with the copper surface area.[4] Conversely, copper nanoparticles were prepared recently with surfaces displaying different catalytic activities. In addition to the surface area, bulk structural parameters like microstrain in the copper particles were identified to correlate with the catalytic activity of these catalysts.[5–7]

Only few microscopic studies of the "real" structure of active copper catalysts have been reported.[8–10] High-resolution transmission electron microscopy (TEM) and in situ TEM studies have been performed on copper particles supported on ZnO with a copper concentration of less than 10%.[11,12] These studies showed faceted well-ordered Cu particles on a large and well-defined ZnO support. Changes in the morphology of the Cu particles, the ratio of the copper facets, and the surface area upon varying the reduction potential of the gas phase were impressively illustrated by in situ TEM. However, these copper model systems were prepared by impregnation of ZnO crystals with a solution of copper acetate. This preparation procedure deviates considerably from the preparation of industrial copper catalysts,[13] and hence, the well-defined model systems studied probably exhibit a microstructure different from that of a catalyst prepared for industrial application. Industrial $Cu/ZnO/Al_2O_3$ catalysts are commonly prepared by precipitating copper zinc hydroxycarbonates from metal nitrate solutions. In addition to the precipitation method, each step in the subsequent treatment of the precipitate and the resulting oxide precursor (i.e. ageing, washing, drying, calcination, and reduction) affects the microstructure of the active copper phase (chemical memory).

Precipitate ageing strongly influences the activity of the resulting Cu/ZnO catalysts.[14–17] The superior activity of Cu/ZnO catalysts obtained from precipitates aged for more than 30 min was shown to correlate with the increasing microstrain in the copper nanoparticles.[18] Apparently, structure–activity relationships revealed for idealized copper model systems should not be extrapolated to the microstructure and catalytic properties of industrial catalysts.

Here we report HRTEM investigations of the microstructure of reduced Cu/ZnO catalysts obtained from differ-

ently aged hydroxycarbonate precipitates. Electron micrographs of Cu/ZnO catalysts obtained from a nonaged (0 min) and an aged (120 min) precipitate are depicted in Figure 1 together with a plot of the the corresponding catalytic

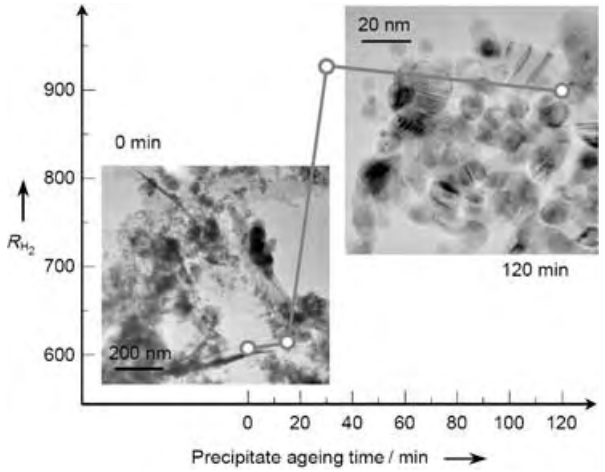

Figure 1. TEM images of Cu/ZnO catalysts obtained from hydroxycarbonate precipitates aged for 0 min and 120 min together with the H_2 production rate R_{H_2} [μmol g^{-1} s^{-1}] of four catalysts as a function of precipitate ageing time (methanol-synthesis activity and ageing time exhibited a similar correlation).

activities in the steam reforming of methanol. Electron diffraction and electron energy-loss spectroscopy identified only Cu metal and ZnO in the samples studied. Various morphologies of Cu and ZnO particles were detected in the Cu/ZnO catalyst obtained from nonaged precipitates, such as large isolated Cu particles, large ZnO plates and needles, and to a lesser degree nanostructured Cu and ZnO particles (Figure 1).

When the precipitate was aged for more than 30 min, a transition to a homogeneous microstructure was observed. In these Cu/ZnO catalysts mostly nanostructured Cu/ZnO particles were found with only minute amounts of isolated Cu particles and ZnO particles detectable (Figure 1). The increase in catalytic activity observed for Cu/ZnO catalysts obtained from precursors aged for more than 30 min (Figure 1) clearly correlates with the distinct change in the microstructure of the catalysts. While the less active Cu/ZnO catalysts comprise a heterogeneous mixture of large and isolated Cu and ZnO particles, the more active catalysts show small and intimately mixed Cu and ZnO particles. The homogeneous microstructure of the more active Cu/ZnO catalysts may constitute a potential lead for future preparations of improved catalysts for methanol chemistry.

The HRTEM images of the Cu/ZnO catalysts show a marked interface between the Cu and ZnO particles (Figure 2a,b). Well-defined copper clusters on large ZnO particles, like the ones observed in the model systems described above,[11] are clearly absent in Cu/ZnO catalysts prepared similarly to industrial copper catalysts. The Cu and ZnO particles in the Cu/ZnO catalysts obtained from more aged precipitates are round-shaped (Figure 2) or oval-shaped independent of their size. The HRTEM images reveal a

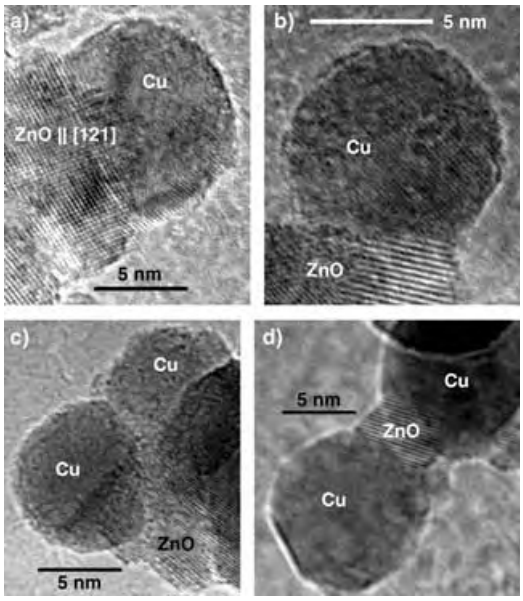

Figure 2. HRTEM images of a Cu/ZnO catalyst obtained from a copper zinc hydroxycarbonate precipitate aged for 120 min.

variety of epitaxial relations between Cu and ZnO (e.g. Cu[110]||ZnO[100], Cu[111]||ZnO[100], Figures 2 and 3) with an average contact angle between the Cu and ZnO

Figure 3. particles of about 61°. Zinc oxide exhibits a higher degree of structural order than the copper nanoparticles in the reduced Cu/ZnO catalyst (Figure 2), and the distinct defects in the ZnO structure may be indicative of the oxygen-deficient nature of the ZnO particles in the catalysts. Moreover, ZnO particles are often located between Cu particles, thus efficiently preventing the Cu particles from sintering (Figure 2c,d).

The nonlinearity frequently observed in correlations of copper surface area and catalytic activity in methanol chemistry is strong evidence for the existence of additional bulk or surface structural parameters that govern the activity of copper nanoparticles.[5–7] The distinct interface between the Cu particles and the ZnO support in the homogeneous microstructure of the more active Cu/ZnO catalysts can be correlated to the previously reported increased degree of strain in the Cu particles in the highly active Cu/ZnO catalysts as determined by averaging bulk structural techniques (XRD, NMR).[18] Thus, the higher degree of disorder in the Cu nanoparticles, which corresponds to an increased deviation from the "ideal" structure of bulk copper metal, results from the increased interface area between Cu and ZnO and is indicative of a more active copper catalyst.

The Cu/ZnO catalysts described are less complex than the most active industrial $Cu/ZnO/Al_2O_3$ catalysts and are thus suitable model systems for investigating the microstructure of copper nanoparticles in methanol-synthesis catalysts (Figure 3). In studies of industrial catalysts the microscopic processes on the surface of heterogeneous catalysts are difficult to unravel because of their huge complexity and the multiple-parameter dependence of catalytic properties. Hence, a detailed understanding of heterogeneous catalysis on an atomistic level will most likely arise from investigations of simplified model systems from which one can elucidate the influence of individual structural parameters on catalytic properties.

The results described here indicate that new and more suitable model systems should be designed according to established structure–activity relationships of copper catalysts that are prepared similarly to industrial catalysts (Figure 3). These second-generation model systems must take into account the deviation from the ideal copper structure to provide a meaningful representation of microscopic processes in catalysis. On the one hand, model systems that closely resemble ideal bulk copper metal may be of limited value in advancing our understanding of the "real" structure of methanol catalysts under reaction conditions and designing suitable preparation routes to improved copper catalysts (Figure 3). On the other hand, copper catalysts obtained by a wet-chemical preparation appear to be less suited mostly because of the inherent difficulty to vary the "real" structure of the resulting materials without changing other relevant structural and chemical parameters (e.g. chemical composition and copper crystallite size). Thin copper films on substrates such as silicon and polyimide, for instance, are currently considered as suitable model systems (Figure 3). With these systems the microstrain in the copper can be adjusted dynamically by thermal treatment or mechanical forceto elucidate the corresponding effect on the electronic structure and the catalytic properties of the copper surface.[19–21]

The "real" structure of the copper catalysts described here deviates considerably from that of ideal bulk copper metal and emphasizes that structural complexity is a prerequisite for an active heterogeneous catalyst. Hence, for an atomistic understanding of catalytic reactions, second-generation model systems are required that reduce complexity yet take the characteristic "real" structure of active copper catalysts into account. Eventually, this will bridge the materials gap and provide the basis for the knowledge-driven improvement of heterogeneous catalysts.

Experimental Section

Preparation of Cu/ZnO catalysts: Copper zinc hydroxycarbonate precursors of Cu/ZnO catalysts with a Co/Zn molar ratio of 70:30 were prepared according to a conventional coprecipitation route.[16] The coprecipitation was performed in a flask filled with 400 mL of doubly distilled water (353 K) by simultaneously addition of 600 mL of an aqueous solution of metal nitrates ($Cu(NO_3)_2{\cdot}3H_2O$ (0.7 M) and $Zn(NO_3)_2{\cdot}6H_2O$ (0.3 M)) and an aqueous solution of sodium carbonate (1.2 M) at constant pH 7. The resulting precipitates were aged under continuous stirring in the mother liquor at 353 K for 0 min, 15 min, 30 min, and 120 min. After filtering, the precipitates were washed six times with deionized water (80 mL) under continuous stirring at 333 K. Finally, the samples were dried at 393 K for 10 h in static air followed by calcination at 603 K in static air for 3 h (heating rate 6 K min^{-1}). The resulting CuO/ZnO materials were reduced in 2.0 vol % H_2 at 523 K for 30 min (heating rate 6 K min^{-1}) to obtain the Cu/ZnO catalysts.

TEM studies were performed on a Phillips CM 200 FEG TEM. The reduced Cu/ZnO catalysts were deposited on holey-carbon films supported on gold grids. The samples were prepated in a glove box to prevent exposure of the reduced Cu/ZnO catalysts to air.

Chemical Photolithography

Surface Modification with Orthogonal Photosensitive Silanes for Sequential Chemical Lithography and Site-Selective Particle Deposition**

*Aránzazu del Campo, Diana Boos, Hans Wolfgang Spiess, and Ulrich Jonas**

The site-selective adsorption of molecules and mesoscopic objects at predefined positions on solid surfaces is a key fabrication step and a major challenge in many applications, such as multifunctional biosensors and novel electronic, mechanical, and photonic devices. The adsorption process is strongly influenced by the functional groups on the surfaces, which can be introduced by different strategies for depositing molecular layers (e.g. self-assembled monolayers, SAMs). In order to direct the adsorption process to predefined regions of the substrate, chemical patterning of these surface layers with discrete micro- to nanometer features is required; this is a critical stage in device fabrication and usually involves iterative combinations of several patterning and surface activation steps.

For this purpose various patterning techniques have been developed, like photolithography and electron beam lithography,[1] microcontact printing,[2] micromachining, and several techniques based on scanning probe microscopy.[3] Light is a particularly convenient medium to introduce lateral patterns, as multiple methods for its generation, handling, and control are available that exploit different mechanisms of how light interacts with molecular surface layers.

In the following, a very brief overview of the fundamental photopatterning strategies is provided with some representative references:

1) Irradiation at very short wavelengths (< 250 nm, high-energy UV) in the presence of oxygen can lead to the chemical degradation of a whole molecular layer; this was shown for aryl- and alkylsilanes at 193 nm.[4]
2) For certain materials under similar irradiation conditions, but often longer wavelengths, specific photoconversion of only the anchor group might take place (rather than degradation of the whole layer). This method has been employed for the photooxidation of thiol monolayers on gold to sulfonates, which bind more weakly to the substrate and can displaced by a second thiol.[5]
3) Instead of photocleavage from the surface, the opposite process of light-induced attachment of a molecular layer onto the substrate was demonstrated with aldehydes and 1-alkenes onto hydrogenated silicon surfaces,[6a] and the photografting polymer layers onto benzophenone-modified silane layers.[6b]
4) Photopolymerization and cross-linking of physisorbed monomers can lead to permanent layer immobilization in the exposed areas due to substantially increased mechanical stability and reduced solubility of the polymerized species. This patterning technique was applied to polydiacetylene lipid layers with subsequent dissolution of the monomeric lipids in the nonirradiated regions.[7]
5) Finally, photoactivation of a surface layer can be achieved if the monolayer-forming molecules are functionalized with a photosensitive group. This is a particularly interesting approach, since a large variety of photosensitive and -reactive species are known that can be combined with many different functional groups.[8] The typical procedure for preparing monolayers with such photosensitive moieties usually involves two steps. First, the surface-active molecules with unprotected functional groups are deposited onto the substrate. These functional groups determine the properties of the newly formed surface, like reactivity, polarity, and charge. In the second step, the photosensitive moieties are introduced into the monolayer by reaction with the functional surface groups.[9] Restrictions of this method are the limited control over the protection step (the coexistence of free and protected functional groups depends on the surface

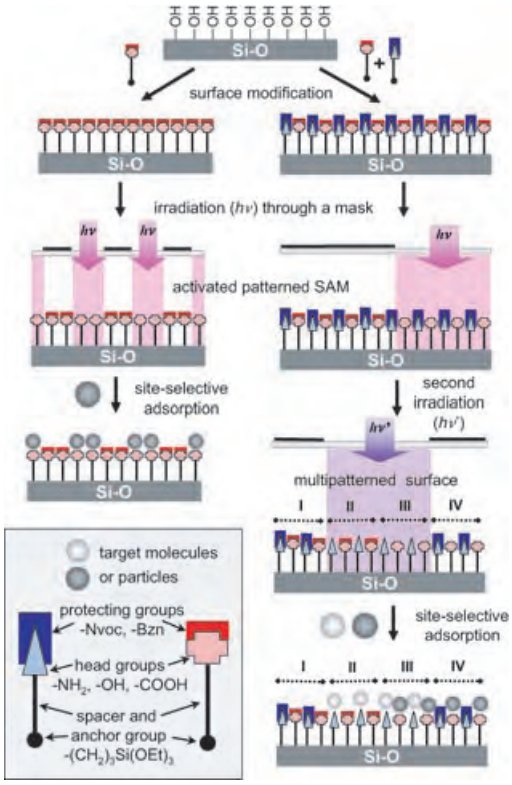
reaction yield) and the limited choice over the layer composition, since mixing of incompatible functional groups in their free form is nontrivial.

A consequential improvement is based on the synthesis of surface-active molecules (like thiols and silanes) with the photosensitive moieties directly attached to the functional groups prior to monolayer preparation.[10] The surface layers are thus intrinsically protected, as we demonstrate here with novel triethoxysilanes bearing light-sensitive nitroveratryl and benzoin protecting groups on terminal amino, hydroxy, and carboxylic acid functionalities.

This advanced silane chemistry opens attractive possibilities for simplying the preparation of chemically patterned surfaces. A major advantage of this method lies in the highly defined, quantitative reactions of the protected surface functionalities (achieved during synthesis and purification prior to layer fabrication) and full control over the layer preparation process. Lateral patterning can be achieved easily by direct irradiation and deprotection of the silane layer through a mask, as performed in standard photolithography. Thus, no additional investment is required for its implementation in current industrial processes, and further processing steps (like developing and removing photoresists) can be minimized. In addition, mixed surface layers can be prepared in one step with different types of functional groups (which may be incompatible in their free form and cause reactions, segregation, or salt formation) and different protecting groups that can be independently addressed by their specific deprotection wavelengths (in line with the orthogonality concept, see Figure 1).[11] The surface density of the free functional groups can be tuned conveniently by irradiation time and intensity during the photolysis reaction, which cleaves the protecting group and restores the initial activity of the functional groups.[9b] Further chemical modification or specific adsorption of targets is possible at the deprotected functionalities in the irradiated regions. A schematic representation of the process is provided in Figure 1.

The principle of orthogonality is defined as the possibility to selectively remove one type of protecting group in the presence of others in any chronological sequence. It represents a mayor challenge but is also the primary virtue of protecting group chemistry. In the case of photosensitive protecting groups, individual addressing requires specific differences in sensitivity to selected wavelengths and intensities, as has been recently demonstrated by C. G. Bochet et al. for nitroveratryl and benzoin derivatives in solution.[11] Amongst the reported photoprotecting groups, 3,5-dimethoxybenzoin esters are known to be effectively cleaved by low-intensity irradiation at wavelengths below 300 nm,[12] while nitroveratryl (Nvoc) derivatives, being less reactive, are cleaved at much longer wavelengths (up to 420 nm).[13]

Based on our previous experience with the Nvoc-protected aminosilane **1**, and to transfer and extend the orthogonality concept from solution to solid surfaces (Scheme 1) we synthesized photoprotected triethoxysilanes with terminal amino- (**1**), hydroxy- (**2**), and carboxylic acid groups (**3**, **4**) with nitroveratryloxycarbonyl (NH-Nvoc for **1**/-NH_2; O-Nvoc **2**/-OH; and CO-Nvoc **3**/-COOH[14]) and 3,5-dimethoxybenzoin substituents (CO-Bzn for **4**/-COOH). The synthesis was achieved by first linking the protecting groups to the corresponding functional 1-alkenes by reported coupling procedures, followed by hydrosilylation to introduce the triethoxysilyl anchor group.[15] The triethoxysilyl anchor group was chosen since it favors the formation of a dense monolayer through the three alkoxy valences and at the same time it is less reactive than chlorosilanes), which facilitates handling of the compounds under laboratory conditions (no inert-gas atmosphere required). Furthermore, the silane anchor group is particularly attractive for the modification of a large variety of technologically relevant materials like silica (SiOH groups on glass, quartz, and oxidized Si wafers) and other oxide surfaces (e.g. ITO, TiO_2, Fe_3O_4, ZrO_2, and oxidized polymer surfaces).



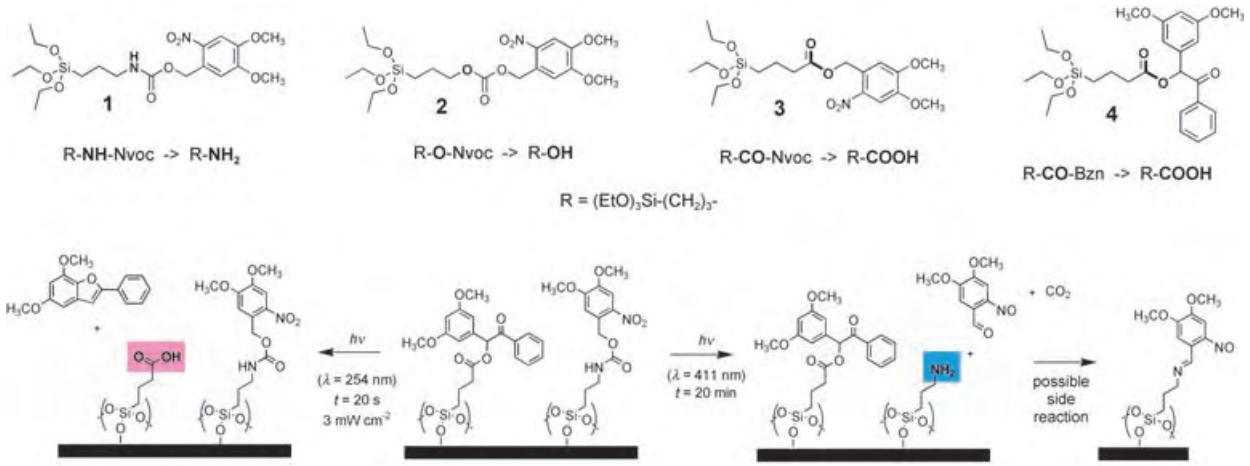


Figure 1. Surface modification and direct monolayer patterning with photosensitive silanes. Left: Formation of a homogenous monolayer by chemisorption of a photosensitive silane. Selected regions of the monolayer are activated by irradiation through a photomask to liberate functional groups. Right: Simultaneous coadsorption of two different silanes (with different functionalities and orthogonal protecting groups) leads to mixed monolayers. Each type of protecting group can be addressed individually in two deprotection steps by irradiation with their corresponding wavelength ($h\nu$ and $h\nu'$), leading to four chemically distinct surface types: I) nonirradiated, fully protected region, II) one in which only one functional group (A) is activated, III) one in which both functional groups are deprotected, and IV) one in which only the second group (B) is liberated. In the deprotected regions adsorption and chemical modification may be achieved for each individual functionality. Nvoc = nitroveratryl, Bzn = benzoin.

During the surface modification process two types of reactions take place simultaneously. First, the trialkoxysilyl groups hydrolyze to give the highly reactive silanol species,

Scheme 1. Chemical structures of the photoprotected triethoxysilanes synthesized and used in this study. Selective deprotection of the amino (blue, from NH-Nvoc **1**) and the carboxylic acid function (red, from CO-Bzn **4**) is shown for a mixed monolayer. A possible side reaction between the liberated amino group and the benzaldehyde fragment might lead to an imine.

which condense in a second step with each other and with free OH groups of the surface to form stable Si-O-Si bonds. In this reaction sequence oligomerization to 1D, 2D, and 3D structures competes with covalent binding to the surface and requires particular consideration. Extensive oligomerization may lead to larger 3D aggregates that would ultimately result in substantial surface roughness.[18b] The progression of these reactions and consequently the characteristics of the final surface layer critically depend on experimental variables such as type of solvent, temperature, and reaction time, as well as on the catalyst and the concentration of the organosilane. Post-silanization curing of the modified substrates at elevated temperature has been shown to improve the stability of the silane films by covalent cross-linking of free silanol groups.

The synthesized silanes were chemisorbed from solution onto quartz substrates and Si wafers at individually optimized prehydrolysis and surface reaction conditions in order to obtain homogeneous and smooth surface layers.[10a,15] The flat layer topography was confirmed by AFM measurements (average roughness of the silane layers was similar to that of the bare substrate, rms ca. 0.4 nm over several 10^4 nm^2). The layer thickness from ellipsometric measurements was in the range of 1–2 nm (±0.5 nm), and advancing water contact angles were around 65–70° (±2)° for the Nvoc surfaces (**1**, **2**, and **3**) and 56 (±2)° for the CO-Bzn **4** layer (bare silica surface ≈0°). After irradiation and deprotection the water contact angles dropped by 10–20° (±5)°, indicating the liberation of the more polar functional groups. The ellipsometric thickness was slightly reduced after irradiation by about 0.2–0.5 nm (within the error range).

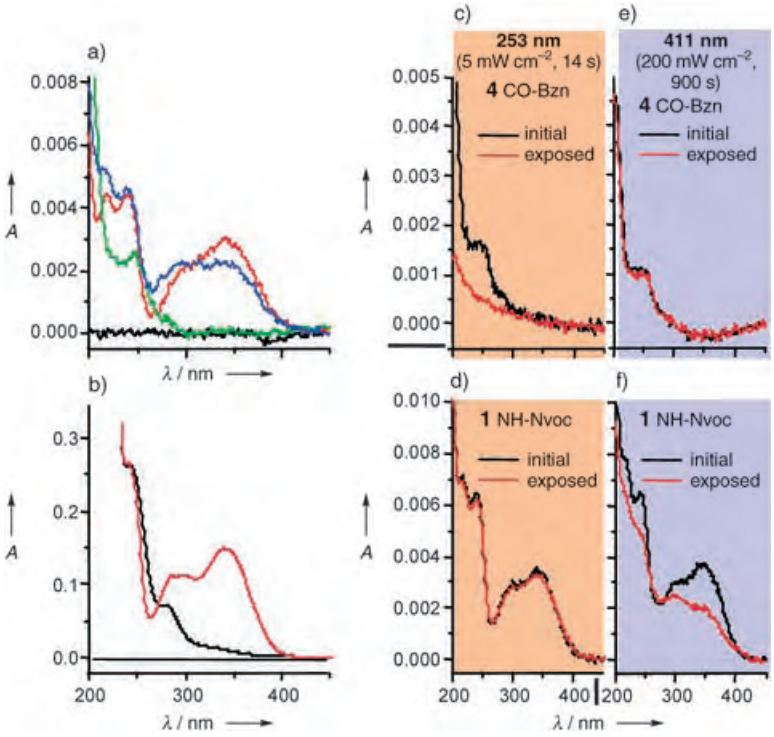

Figure 2. a) UV/Vis spectra of quartz substrates modified with the individual silanes **1** (Nvoc-protected; red), **4** (Bzn-protected; green), a binary mixture of both silanes (blue), and the bare substrate (black). b) UV/Vis spectra of the silanes **1** and **4** in THF; for **4** the absorption band tails far into the visible range. c, d) The absorption for the layer of CO-Bzn **4** decays upon irradiation at 253 nm (c), while that for the layer of NH-Nvoc **1** remains stable at this wavelength (d). During irradiation at 411 nm the layer of CO-Bzn **4** (e) remains stable, while NH-Nvoc **1** (f) is cleaved.

The presence of the photoprotecting groups in the surface layers was also confirmed by their characteristic chromophore absorption in the UV/Vis spectroscopic analysis of silanized quartz substrates. This is demonstrated in Figure 2a for substrates modified with silane **1** (characteristic absorption of the NH-Nvoc group, red curve), with **4** (CO-Bzn group, green curve), and with an equimolar mixture of both (blue curve). These spectroscopic profiles are identical for the corresponding silanes in solution (Figure 2b). The coexistence of both chromophores (Nvoc and Bzn) in the mixed layer corroborates that combinations of different functionalities and protecting groups can be obtained in a single chemisorption

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

step, as also shown for the NH-Nvoc silane and a quaternary ammonium silane.[10a]

A possible problem with the coadsorption of different silanes from a mixture in solution might result from a deviation of the relative ratio of silanes in the adsorbed state and the ratio in solution. Based on the relative UV absorption intensities of the individual components **1**, **4**, and the mixed layer (Figure 2a) and the assumption of random chromophore orientation in the disordered silane layers, one can infer an equimolar coadsorption. The different absorbance maxima of the Nvoc (λ_{max} above 300 nm, tailing beyond 400 nm) and Bzn (λ_{max} below 300 nm, tailing up to 380 nm) protecting groups explain the specific wavelength sensitivity of the deprotection process. In fact, irradiation at 254 nm (5 mW cm^{-2}) for 14 s results in almost quantitative cleavage of the Bzn group of **4** (see Figure 2c), while the NH-Nvoc layer **1** remains fully stable under identical conditions (Figure 2d).[16] The Nvoc group can be effectively photolyzed at its absorbance maximum around 365 nm, but also the Bzn derivative **4** fragments at this wavelength (for a more detailed kinetic analysis see Figure S1 in the Supporting Information). This instability of the Bzn group at 365 nm may be a consequence of the weak absorbance band up to 380 nm evident in the solution spectrum (Figure 2b). In contrast, irradiation at 411 nm leads to a strong decrease of the Nvoc chromophore in layer **1** (Figure 2f), while the CO-Bzn layer **4** remains stable (Figure 2e, see also Figure S1 in the Supporting Information). These results clearly illustrate the possibility of orthogonal deprotection at the substrate surface.

Closer analysis of the photolysis reactions reveals that the relative chromophore intensity in the Nvoc-protected amine **1** never drops below 40–50% even in the presence of a carbonyl scavenger.[17] In contrast, the Nvoc-protected alcohol **2** and carboxylic acid **3** can be cleaved almost quantitatively under identical conditions. This particular behavior might be explained by imine formation between the benzaldehyde fragment and the primary amino group at the surface as a side reaction after photolysis (Scheme 1); this is not possible for **2** and **3**. This result is indicative of a diffusion-controlled process at the substrate surface, in which the separation of the photofragments is slow (compared to the imine formation) due to the 2D confinement imposed by the solid surface.

When the substrates are irradiated through a mask, a pattern of activated and nonactivated areas with the shape of the mask is generated. The resulting chemical contrast between exposed and nonirradiated regions can be used to direct the assembly process of specific targets onto the activated areas (like colloidal particles[10a,18] and fluorescence dyes, see Figure S2 in the Supporting Information). Figure 3 shows the site-selective assembly structures from carboxylated poly(butylmethacrylate) (PBMA) colloids[18a] after photolytic patterning of the surface groups for substrates modified with **1** (a: NH-Nvoc/NH_2), **2** (b: O-Nvoc/-OH), **3** (c: CO-Nvoc/-COOH), and **4** (d: CO-Bzn/-COOH).[15] The contrast in the optical-microscope images (dark-field mode) results from differences in the density of adsorbed particles, which is higher in the brighter areas. On the free amino surface of the irradiated layer **1** a relatively high particle density of 3.5(±0.5) particles per μm^2 is found, while essentially no particles adsorbed onto the nonirradiated regions. This is similar to results obtained by direct functionalization with an aminopropylsilane.[10a] Strong electrostatic attraction between the partially protonated and positively charged amino groups at the substrate and the partially deprotonated and negatively charged carboxyl functions on the latex particles may drive the assembly process. The individual particles at the NH_2 surface are isolated due to a strong repulsion between the like-charged colloids, as seen at higher magnification in the SEM image (inset Figure 3a). On the hydroxy-modified surface of the irradiated layer **2** the

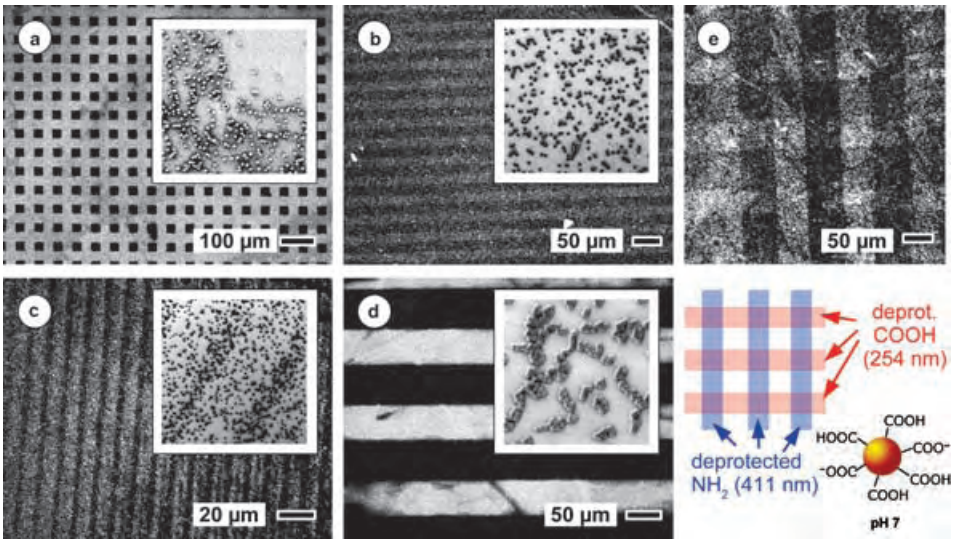

Figure 3. Optical-micrographic images (dark field) of assembly patterns from carboxylated PBMA particles (diameter 183 nm) adsorbed from aqueous suspension at pH 7 onto silane layers of a) **1** (NH-Nvoc/NH_2), b) **2** (O-Nvoc/-OH), c) **3** (CO-Nvoc/-COOH), and d) **4** (CO-Bzn/-COOH) irradiated through a mask. The insets show SEM images of individual particles at higher magnification (width ≈5 μm). Image (e) shows the colloid assembly pattern on a mixed layer of **1** and **4**, which has been irradiated at two different wavelengths (254 and 411 nm) a 90°-rotated line masks (according to the color scheme).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

particle affinity is apparently weaker and a low density of individually dispersed colloids is observed (1.7 particles per μm^2) with unspecific adsorption in the nonirradiated areas (1.3 particles per μm^2). In this case the adsorption process might be driven primarily by polar and hydrogen-bonding interactions between the OH and COOH groups.

Surprisingly, on COO surfaces from exposed layers **3** and **4** a relatively strong colloid adsorption (4.1/1.4 particles per μm^2 for irradiated/nonirradiated **3**; 8.5/1.2 particles per μm^2 for **4**) and substantial particle clustering is found (seen at higher magnification in the SEM image, Figure 3d). This is in contrast to initial expectations, since the carboxy functions on the particles and at the substrate surface should show electrostatic repulsion. Indeed, no particle adsorption is achieved when pure water is used instead of buffer solution as the suspending medium; this indicates the important role of charge screening by the salt. Colloidal adsorption onto a mixed layer of **1** and **4** after successive irradiation through a striped mask, first at 254 nm (CO-Bzn deprotection) and secondly with the mask rotated by 90° at 411 nm (NH-Nvoc deprotection), leads to the checkered pattern shown in Figure 3e, in which the particle density depends on the activated functional groups and the irradiation dose (highest particle density in cross regions).

Other methods for particle assembly have been reported,[19] and one prominent example of orthogonal particle deposition is based on DNA-assisted specific recognition between DNA-modified spots on a substrate and DNA-labeled particles.[20] This method was demonstrated successfully for two different kinds of particles,[20b] but it requires specific DNA labeling of both the substrate and the particles. The advantage of the method presented here is the the fact that a simple silanization process introduces the mixed protected functionalities and patterning is achieved by means of standard photolithographic irradiation; the particles need not be specifically modified with complementary recognition elements (besides the functional surface groups introduced during particle synthesis).

In conclusion, the new photosensitive silanes presented here can be used for direct monolayer lithography and the introduction of functional surface groups, which is not possible directly by silanization (OH and COOH functions are incompatible with the triethoxysilane anchor group). Complex combinations of different functional and protecting groups can thus be achieved by simultaneous coadsorption of the corresponding silane mixtures and orthogonal activation, as demonstrated here for NH-Nvoc **1** and CO-Bzn **4**. Specific colloid assembly onto the photoactivated regions is possible and mediated by the free surface functionalities. Further experiments are currently directed to the selective immobilization of DNA fragments onto the photopatterned mixed layers (relevant for biochip applications) and the extension of the Bzn group to other functionalities.

[14] For molecule **3** the nitroveratryl group is directly linked to the carboxylic acid function through an ester linkage (without a oxycarbonyl moiety), but for simplicity it is referred to as CO-Nvoc.
[15] See the Supporting Information for details.
[16] In analogy to the irradiated silane layers, nonirradiated reference substrates were also washed to identify and account for any intensity loss due to simple removal of the silane layer by washing. All absorbances remained constant after this procedure, corroborating the high stability of these silane layers.
[17] During irradiation a thin film of methanol was sandwiched between the substrate and a covering quartz plate to allow dissolution of the generated protecting-group fragments. In the case of the Nvoc-protected amine **1**, semicarbazide hydrochloride (55 mM solution in methanol) was added as a carbonyl scavenger to capture the photogenerated benzaldehyde and prevent potential imine formation with the free amino surface (Scheme 1).

DNA Polymerase

Enhanced Fidelity in Mismatch Extension by DNA Polymerase through Directed Combinatorial Enzyme Design**

*Daniel Summerer, Nicolas Z. Rudinger, Ilka Detmer, and Andreas Marx**

Dedicated to Professor Bernd Giese on the occasion of his 65th birthday

The fidelity of DNA polymerase activity is of central importance for numerous biotechnological applications.[1,2] The imperfect fidelity of DNA polymerases under the unnatural conditions of several techniques such as those of the polymerase chain reaction (PCR) either restricts the application of these enzymes or demands their tedious optimization. Thus, a prime target for the design of DNA polymerases with altered functions is high fidelity in the formation of Watson–Crick base pairs during DNA synthesis. Progress in this area generates valuable tools for many biological applications like PCR, sequencing protocols, mutagenesis techniques, and genotyping. Through the engineering of DNA and RNA polymerases, it has been possible to design enzymes that accept dideoxynucleoside triphosphates,[3] exhibit an altered substrate spectrum and lower fidelity, higher thermostability, decreased activity at low temperatures, and enhanced resistance to inhibitors.[4]

Herein, we describe an efficient automated high-throughput setup for the rapid parallel screening of DNA polymerase mutant libraries. The readout is based exclusively on enzyme activity through detection of the reaction product by fluorescence. By the randomization of a gene cassette of the Klenow fragment of *E. coli* DNA polymerase I (3′→5′-exonuclease deficient, KF$^-$) and subsequent comparative automated screening, several active variants with significantly higher extension fidelity than the wild-type enzyme were identified. The new properties of mutated KF$^-$ forms were transferred to the thermostable *Thermus aquaticus* (*Taq*) DNA polymerase to provide tools that supersede the wild-type enzyme in highly accurate PCR-based genotyping techniques.

Motif C was recently suggested to be involved in a reaction mechanism shared by members of the A and B families of DNA polymerases, in which mismatches in the primer–template substrate are recognized through indirect H-bonding between the minor groove and a histidine side chain (Figure 1).[5] This β-strand–turn–β-strand structure harbors acidic side chains that bind catalytically essential magnesium ions, reflected in the high conservation among family A DNA polymerases like KF$^-$, and also among sequence families B, RT, X, single subunit RNA polymerases, and the lesion bypass DNA polymerases of family Y.[6] Therefore, motif C seemed a promising target for directed polymerase engineering through focused randomization and subsequent screening.

To modify motif C, we constructed a library of 1316 KF$^-$ mutants randomized at the consensus residues 879–881 (Q879, V880, and H881).[7] This QVH consensus sequence is directly adjacent to the essential catalytic carboxylate group of D882 and forms the main part of a loop that connects the two β strands of motif C. It closely interacts with the deoxyribose moiety of the 3′-terminal primer nucleotide (Figure 1b).

Protein expression was conducted in 96-well plates. Enzymes were screened directly after lysis and dilution, and further purification steps were not required. DNA polymerase activity was monitored after reaction termination by quantitation of synthesized double stranded DNA through staining with Sybr green I (Figure 1c). This setup links enzyme activity to a signal without the need for artificial substrates, which could interfere with the enzymatic reaction. To determine if DNA binding and modifying agents or bacterial DNA in the crude lysate perturbs signal generation, we assayed lysates of *E. coli* expression cultures containing the KF$^-$ wild-type coding vector against those without the KF$^-$ coding vector. Fluorescence measurements revealed low background activity of the negative control with a considerable signal-to-noise ratio of ≈5:1. This enabled the assessment of a large dynamic range in enzyme activity.

We assayed single clones in 384-well plates for the ability to extend primer–template complexes with either a T_{primer}/$A_{template}$ match or a T/G mismatch at the 3′ end of the primer (Figure 1). An automated pipetting device and the fluorescent readout allowed the screening and evaluation of 384

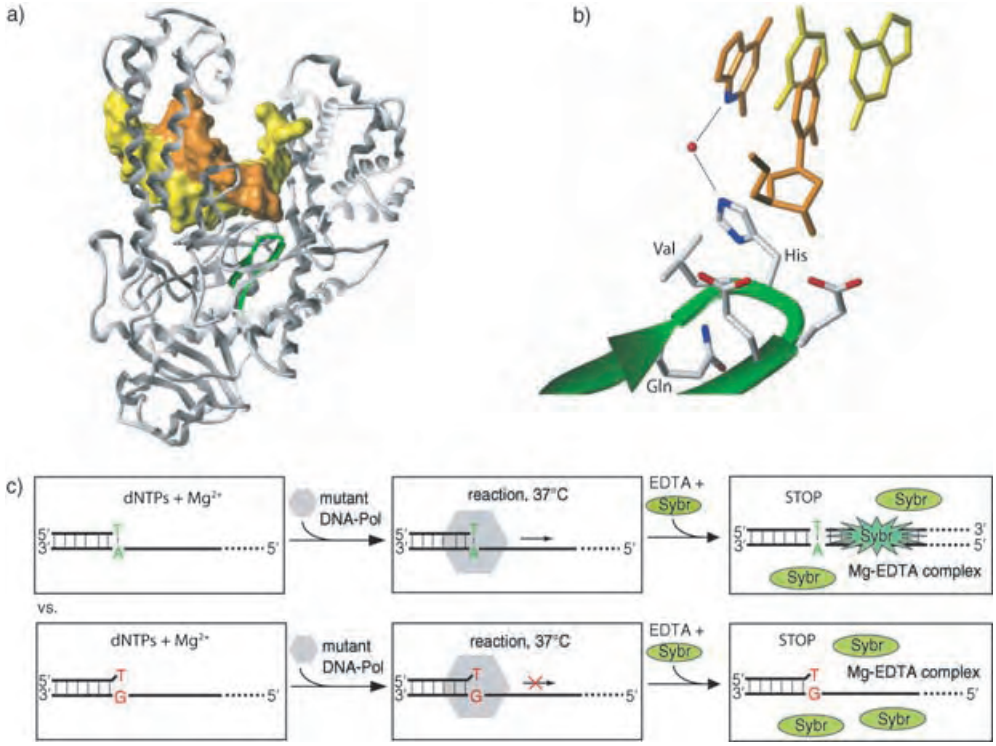

Figure 1. Structural properties of motif C and screening for DNA polymerase variants with increased selectivity. a) Overall view of *Bst* DNA polymerase I (PDB entry 2BDP), which shares high homology with KF^-.[16] The enzyme is shown in gray, motif C in green. The substrate DNA is depicted as a Connolly surface with primer in orange, and template strand in yellow. b) Detailed view of the turn of motif C and the two nucleotide pairs at the 3′ terminus of the primer. For clarity, the sugar–phosphate groups are not depicted for each nucleotide. Primer nucleotides are in orange, template nucleotides in yellow. The indirect hydrogen bond between N3 of histidine (blue) and the 3′-penultimate primer nucleotide is shown in black and is mediated by a water molecule (red sphere). c) General scheme of the screening approach for DNA polymerases with increased extension fidelity. Enzyme variants that extend the canonical primer–template duplex but fail to extend the noncanonical duplex are identified with the DNA duplex-specific dye Sybr green I in a subsequent fluorescence read-out.

reactions in approximately 40 minutes. Extension fidelity was measured by determining the ratios of fluorescence of primer extensions from matched versus mismatched substrates. The template sequences were derived from the human single nucleotide polymorphism (SNP) G1691A of the Factor V Leiden (FVL) gene.[8] The screen revealed considerable mutability of the targeted QVH sequence. Despite the fact that this motif is highly conserved among several DNA and RNA polymerase families,[6] 47% of the mutants exhibited measurable primer extension activity.

The three most selective mutants, PLQ, LVG, and LVL, were chosen for further characterization. First, we assayed the purified enzymes in radiometric primer extensions (Figure 2). All possible base-pair combinations at the primer 3′ terminus were tested under conditions that promote mismatch extension: excess enzyme over primer–template complex and high dNTP concentrations.[7] Measurements revealed that wild-type KF^- is capable of extending almost all mismatches under the chosen conditions, albeit to varying extents consistent with previous studies (Figure 2b).[9] In contrast, all three selected mutants show a marked decrease in the efficiency of mismatch extension. Particularly, mutant LVL fails to fully extend mismatched primer termini in most cases. Steady-state kinetics measurements of single-nucleotide extensions show that in all cases of processing a properly matched primer–template complex, mutants display similar steady-state k_{cat} values as the wild-type enzyme.[7] K_M values of the mutants were generally higher than those for wild-type KF^-, reflected by a slight decrease in DNA synthesis efficiency by the mutant forms. Remarkably, no significant elongation of mismatched primer termini by the mutants was detected under steady-state and single-turnover conditions, whereas the results obtained for wild-type KF^- are consistent with previous reports.[9] This indicates that the k_{cat} values for all base-pair combinations assayed were drastically lower for the KF^- variants than for the wild-type polymerase. Binding studies were performed to determine whether the effects on mismatch extension fidelity are caused by a decrease in substrate-binding affinity in the mutants.[7] Interestingly, only mutant PLQ exhibits a significant decrease in binding affinity to a mismatched primer terminus. For this reason, altered binding affinity does not generally appear to be mandatory for an increase in mismatch extension fidelity.

We next investigated whether the observed effects could be transferred to wild-type *Taq* DNA polymerase (*Taq* wt). Though *Taq* wt and KF^- are both members of the DNA polymerase family A, they differ in several properties such as thermostability and fidelity.[10] The *Taq* QVH consensus sequence was mutated into LVL and the extension fidelity of the resulting mutant polymerase was investigated. We

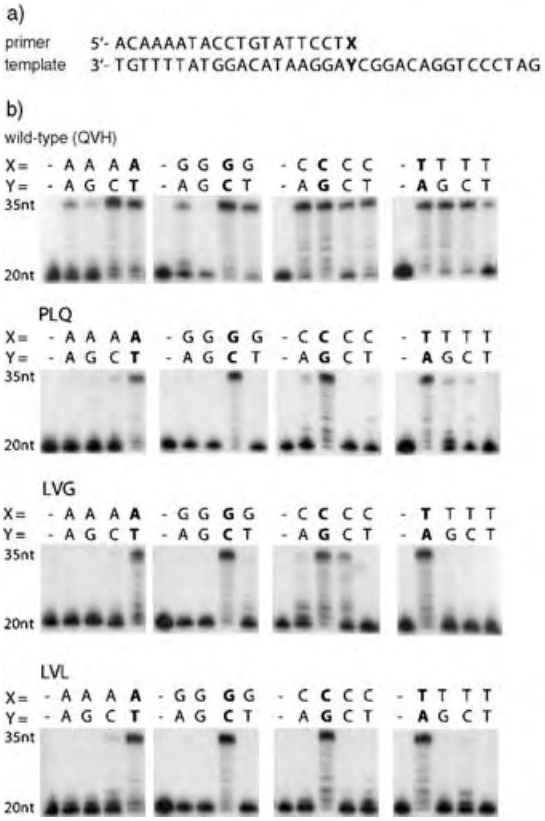

Figure 2. Increased primer extension fidelity of the KF$^-$ mutants PLQ, LVL, and LVG (positions 879–881) in comparison with the wild-type enzyme in different sequence contexts. The conditions were chosen to promote mismatch extension. All reactions contained equal amounts of primer–template complex, enzyme, and dNTPs.[7] a) The sequence of the primer–template duplex employed is derived from the human FVL SNP G1691A.[7] b) Primer extensions catalyzed by the depicted enzyme variants. The first lane of each gel represents a control reaction without enzyme. Nucleotide sequences at the 3′ end of the primer are shown on top of each gel image. Unextended primer (20 nt) and full-length product (35 nt) are indicated at the left side of each image. X = 3′-terminal primer nucleotide, Y = template nucleotide pairing with X leading to matched (bold) or mismatched primer termini.[7]

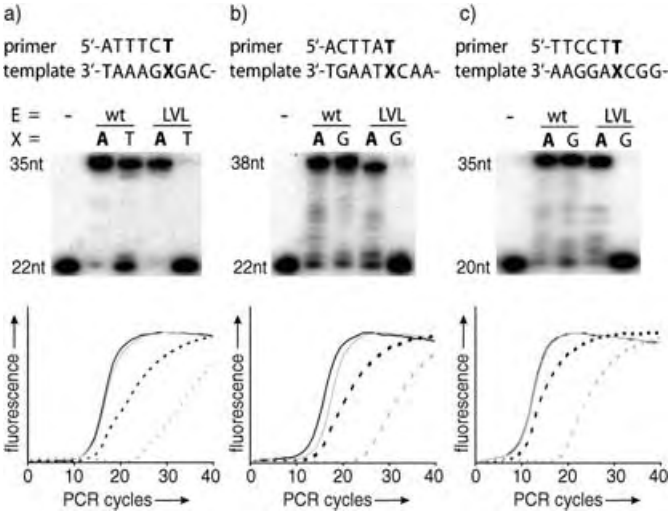

Figure 3. The impact of LVL mutations on the fidelity of *Taq* DNA polymerase within three sequence contexts. Top panel: partial nucleotide sequences of primer–template complexes used for primer extensions. The first lane of each gel represents a control reaction without enzyme. The lengths (nt) of primer and full-length product are shown on the left side of each gel; E = enzyme, X = template nucleotide. Lower panel: real-time allele-specific PCR experiments with either wild-type or mutant LVL *Taq* DNA polymerase in three sequence contexts.[7] Solid lines: wild-type *Taq* DNA polymerase; dashed lines: LVL *Taq* DNA polymerase; black: matched primer–template substrates; gray: mismatched primer–template substrates. Experiments conducted in a) the human BRAF somatic SNP T1796A, b) in the human DPYD SNP G735A, and c) in the FVL SNP G1691A sequence context.[7]

conducted primer extension reactions in three sequence contexts that contain prominent SNPs.[11,12] These experiments show that there are only subtle differences between the extension of matches and mismatches with *Taq* wt under the chosen conditions (Figure 3).

In contrast, the mutant *Taq* DNA polymerase (*Taq* LVL) is clearly capable of discriminating transversion and transition SNPs (Figure 3). *Taq* LVL might greatly expand the technical scope and allow an improvement of PCR-based techniques like allele-specific PCR (asPCR).[13] To test the applicability of *Taq* LVL for asPCR, we performed real-time PCR reactions with the substrate sequence contexts described above. We measured the difference in the threshold-crossing cycle number (ΔC_t) between a matched and a mismatched primer–template complex (Figure 3). *Taq* wt displays weak or no discrimination, whereas *Taq* LVL leads to ΔC_t values of 10 for all sequence contexts. Therefore, the mutant *Taq* LVL shows greater discrimination than *Taq* wt in asPCR, regardless of the sequence context applied or enzyme and template concentrations tested, as shown in additional experiments (Supporting Information).[7]

In summary, the identification of several active DNA polymerase variants that display increased primer extension fidelity shows that none of the chosen amino acid positions is essential for catalysis, and that all positions tolerated substitutions. However, the nature of the side chain of V880 seems to be most conserved, as all identified active and more selective mutants bear a nonpolar amino acid side chain at this position. Furthermore, the absence of any charged residues within the selected active mutants indicates that the introduction of ionic residues in this region might inactivate the enzyme by interference with D882, the magnesium ions, or the incoming dNTP substrate.

The fact that the apparent increased fidelity is not limited to the sequence context employed during screening, is suggestive of a common mechanism for error sensing. It was recently proposed that the histidine group of QVH might be involved in DNA polymerase extension fidelity mechanisms by editing H-bonding patterns in the minor groove of the primer–template duplex (Figure 1b).[5] One of the mutants that exhibits increased extension fidelity has three amino acid substitutions at the targeted site (QVH to PLQ), in which a glutamine side chain replaces histidine at position 881. As mentioned above, glutamine can often replace the H-bond donating ability of the imidazole ring of histidine.[14] Thus, improved editing of H-bond patterns by Q881 in the context of the PLQ sequence might be the cause for the increased fidelity in this variant. However, we identified mutants LVG

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and LVL, both of which lack hydrogen bonding capability within the wild-type QVH region, yet have significantly higher extension fidelity. Thus, abolishing hydrogen bonding to the minor groove results in enhanced polymerase fidelity. Similar results for another KF^- variant (H881A) were recently reported.[15] The origins of the observed selectivity currently remain elusive. It could be that a loss of hydrogen bonding in a complex that is already destabilized (upon mismatch extension catalysis) actually facilitates the editing capacity over that of the wild-type polymerase, in which hydrogen bonding is present.

The approach of rapid DNA polymerase screening discussed herein, which has led to highly valuable enzyme variants, can be used to further tailor DNA polymerase activities for obtaining insight into biological processes and new tools for biotechnological applications.

Reaction Mechanisms

Elucidation of the Mechanism of the 1,6-Cuprate Addition to Acceptor-Substituted Enynes through ^{13}C Kinetic Isotope Effects: Experimental and Theoretical Studies**

Seiji Mori, Marc Uerdingen, Norbert Krause,* and Keiji Morokuma**

The use of organocopper compounds (in particular organocuprates) has opened new avenues in organic and organometallic chemistry.[1] Among many different reaction principles, Michael additions to extended acceptors that bear a triple bond are particularly interesting as they provide efficient access to functionalized allenes.[2] The prototype of these

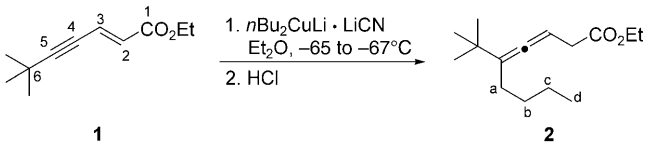
transformations is the 1,6-cuprate addition to 2-en-4-ynoates **A** and similar acceptor-substituted enynes which has found numerous applications in allene chemistry (Scheme 1).[2,3] Moreover, 1,6-addition has provided deep insight into the



Scheme 1. 1,6-Cuprate addition to 2-en-4-ynoates **A** via π complexes **B** provides allenyl enolates **C**, which are protonated to give β-allenic esters **D**.

mechanistic details of copper-promoted reactions.[4] Early NMR spectroscopic investigations have proven the presence of π complexes **B**, which were characterized by their unique chemical shifts and $^{13}C,^{13}C$ coupling constants.[5] In contrast, less is known about further intermediates on the way to the allenyl enolates **C**, whose protonation furnishes β-allenic esters **D** and derivatives thereof.

Kinetic measurements have provided an activation energy value of 70 kJ mol^{-1} for the 1,6-addition of $Me_2CuLi{\cdot}LiI$ to ethyl 6,6-dimethylhept-2-en-4-ynoate;[6] however, the rate-determining step along the reaction pathway has not yet been identified unambiguously. The aim of the study described herein is to close this gap and to provide, with experimental and theoretical tools, a comprehensive mechanistic picture of the 1,6-cuprate addition to acceptor-substituted enynes.

The most powerful and straightforward experimental tool for identifying the rate-limiting step of a transformation is the determination of primary kinetic isotope effects (KIEs), that is, the rate change due to isotopic substitution at the site of bond breaking or bond making in the rate-determining step of a reaction. Instead of actually measuring the reaction rates of different isotopomers of a given substrate, small KIEs are normally determined by competition experiments of isotopically labeled and unlabeled compounds. Singleton and co-workers introduced a powerful NMR spectroscopic technique for measuring ^{2}H and ^{13}C KIEs at natural isotopic abundance which has found widespread application in diverse transformations such as pericyclic reactions,[7] palladium-catalyzed couplings,[8] and copper-promoted reactions.[9–11] The method involves the NMR spectroscopic determination of the relative proportion of the isotope in question for the product (from a reaction with very low conversion) and the substrate (for a reaction with very high conversion) under carefully controlled conditions.

The application of the Singleton technique to the 1,6-cuprate addition to acceptor-substituted enynes required a choice of reactants that allowed the starting material to be isolated readily from a mixture that contained large amounts of the product, and vice versa. We selected the reaction of ethyl 6,6-dimethylhept-2-en-4-ynoate (**1**) with lithium di-*n*-butylcyanocuprate ($nBu_2CuLi{\cdot}LiCN$) in diethyl ether at temperatures between −65 and −67 °C (Scheme 2). A set of three reactions on the 20-mmol scale went to 85, 94, or 92 %

Scheme 2. Reaction used for the determination of experimental ^{13}C KIEs.

completion after a reaction time of 15–16 min, and the unconverted enynoate **1** (200–320 mg) was recovered by repeated vacuum distillation. Conversely, allene **2** (280–550 mg) was isolated by distillation from three reactions that went to 13, 11, or 7 % completion.

The relative amounts of ^{13}C at different positions of the starting enyne **1** and of the product **2** were determined by ^{13}C NMR spectroscopy[25] in relation to the original starting material from the same lot and to an authentic sample of the allene **2** prepared by S_N2' substitution of a propargylic mesylate.[12] The quaternary carbon atom C6 was selected as the internal standard for both the substrate **1** and the product **2** under the assumption that the isotopic ratio remains unchanged in this position during the reaction. The ^{13}C KIEs were calculated by using the standard equations from the work of Singleton and Thomas,[7] and the error analysis was carried out accordingly. The results are summarized in Table 1.

Table 1: Experimental ^{13}C KIEs for the 1,6-addition of $nBu_2CuLi{\cdot}LiCN$ to enynoate **1**.

	KIE from substrate **1**		
	Experiment 1	Experiment 2	Experiment 3
C1	1.001(1)	1.003(2)	1.002(1)
C2	1.001(2)	1.003(2)	1.003(3)
C3	1.002(1)	1.001(3)	1.003(3)
C4	1.005(1)	1.009(3)	1.006(2)
C5	1.011(1)	1.013(3)	1.011(3)
C6		1.000 (internal standard)	
	KIE from product **2**		
	Experiment 1	Experiment 2	Experiment 3
C_a	1.005(1)	1.002(2)	1.009(3)
C_b	1.002(2)	1.001(2)	1.004(1)
C_c	1.001(3)	1.000(3)	1.002(4)
C_d	1.000(3)	1.000(4)	1.000(3)
C6		1.000 (internal standard)	

The ^{13}C kinetic isotope effects for the starting enyne **1** are appreciable at C4 and even more so at C5, thus indicating that bond formation takes place from the triple bond of the substrate in the rate-limiting step of the reaction. This is in accordance with the KIEs determined for the butyl group in product **2**, as the small but distinct isotope effect for C_a suggests a bonding change at this position. To corroborate

these experimental results, the B3LYP density-functional theory was employed with an Ahlrichs SVP basis set for the Cu atom and 6-31G(d) basis sets for others (denoted as 631A)[13,14] for geometry optimization of stationary points of the 1,6-addition of a model system, that is, the reaction of the methyl cuprate $Me_2CuLi{\cdot}LiCl$ with methyl 6,6-dimethylhept-2-en-4-ynoate (Figure 1).[15] To describe the energy profile more accurately, the Stuttgart–Dresden quasirelativistic effective core potential with a (311111/22111/411) contracted basis set[16] and an additional *f* polarization function (exponent $\alpha = 3.72$ optimized according to the procedure by Ehlers et al.[17]) with 6-311G(d) basis sets for the other atoms (denoted as 6311S) were employed. Thermal corrections for enthalpy and Gibbs energy were performed for all stationary points by normal coordinate analyses at the B3LYP/631A level. The reactants (**RT**), a complex with a closed cuprate aggregate (**CPcl**), an open complex (**CPop1**) in which Cu is coordinated to π system of the C=C double bond, another open complex (**CPop2**) in which Cu is coordinated to the π system of the C–C triple bond, the transition state for the C–C bond formation in the 1,6-addition (**TScc**), and the 1,6-adduct (**PD**) were found (Figure 1). The transition state (**TSiso1**) between **CPcl** and **CPop1** is not very high in energy, according to previous theoretical studies for addition reactions of acrolein[18] and cyclohex-2-enone.[19] The transition state **TSiso2** of the isomerization between **CPop1** and **CPop2** was also found. The energy profile is shown in Figure 2:

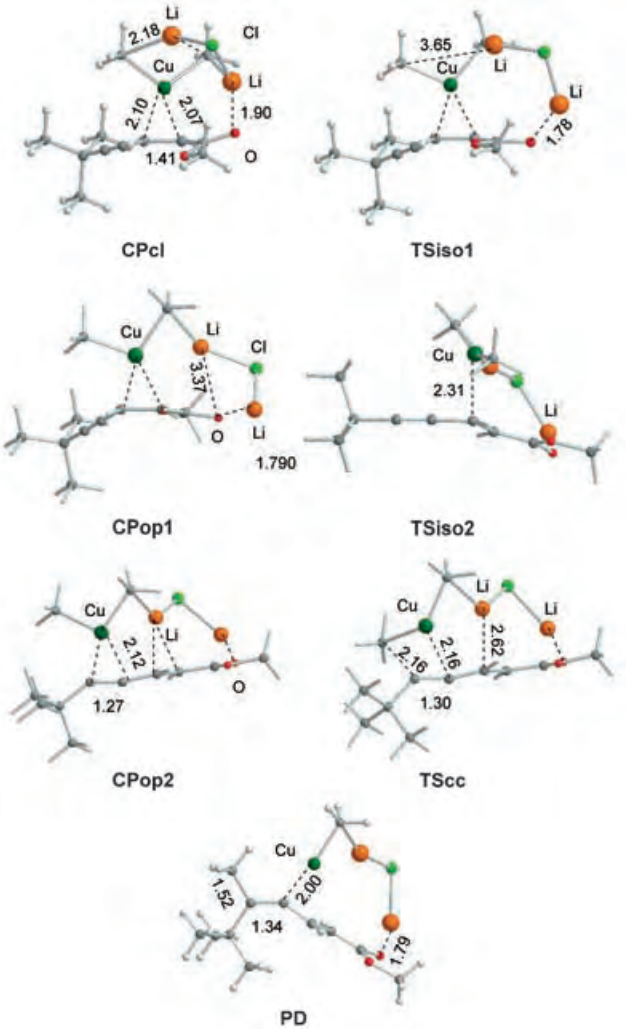

Figure 1. Intermediates, transition states, and the product in the 1,6-addition of $Me_2CuLi{\cdot}LiCl$ to (*E*)-*t*BuC≡CCH=$CHCO_2Me$ calculated at the B3LYP/631A level (bond lengths in Å).

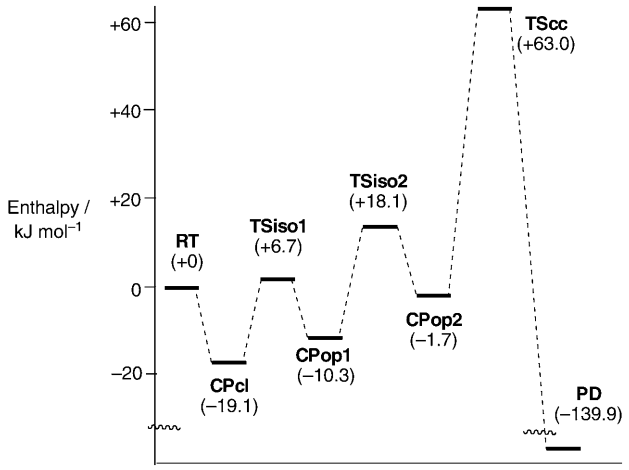

Figure 2. Enthalpy changes in the 1,6-addition of $Me_2CuLi{\cdot}LiCl$ to (*E*)-*t*BuC≡CCH=$CHCO_2Me$ at 208.15 K (B3LYP/6311S//B3LYP/631A). Values below the name of the stationary structures are enthalpies relative to the reactants (**RT**) in kJ mol^{-1}.

CPop2 is higher in enthalpy than **CPop1**, and **CPcl** is lower than **CPop1. TScc** is higher in enthalpy (208.15 K) than **TSiso2** by 44.9 kJ mol^{-1} which suggests that the rate-determining step of the 1,6-addition is the C–C bond formation (in line with the experimental ^{13}C KIEs). The theoretical activation energy ($RT + \Delta H^{\neq}$) was calculated as 66.4 kJ mol^{-1} (gas phase) and 67.5 kJ mol^{-1} (PCM method in solution in Et_2O ($\varepsilon_0 = 4.335$) with the UAKS cavities)[20] at 208.15 K and is also in good agreement with the experimental value of 70 kJ mol^{-1} determined for the reaction of Me_2Cu-Li·LiI with enynoate **1**,[6] in particular if one considers that explicit solvent effects are not included in the present calculation.[21]

The ^{13}C kinetic isotope effects (KIEs)[22] for the formation of the 1,6-addition product in a similar model system, that is, for the reaction of EtMeCuLi·LiCl with (*E*)-*t*BuC≡CCH=$CHCO_2Me$ were calculated at the B3LYP/631A level on the basis of the Bigeleisen equation with Wigner tunnel correction.[23] The theoretical KIE values of **TScce** (the most stable transition state for the rotation about the C_aH_2–C_bH_3 bond; "**e**" denotes the ethyl residue of the EtMeCuLi·LiCl moiety) based on the precursor open Cu π complex **CPop2e** with a C4≡C5 bond (Figure 3) are in good agreement with experimental values (Table 2).[24] The KIE values (1.024 for C_a at the incoming ethyl group and 1.016 for C5) are much larger than those for the other positions of the substrate and the product (0.996–1.002). On the other hand, the theoretical KIE values of **TScce** based on **CPop1e** (the open Cu π complex at the C2=C3 bond) deviate from the experimental values, in

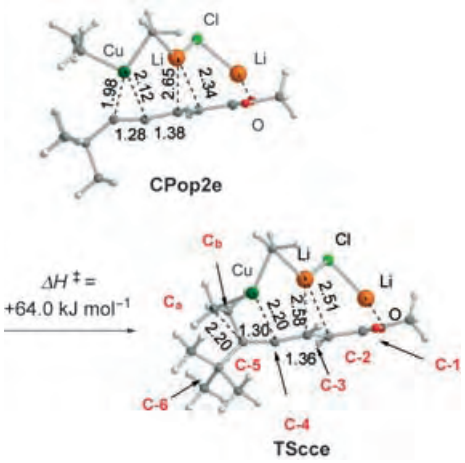

Figure 3. π Complex **CPop2e** and transition state **TScce** for the C–C bond formation in the reaction of EtMeCuLi·LiCl with (*E*)-*t*BuC≡CCH=CHCO$_2$Me (B3LYP/6311S//B3LYP/631A).

Table 2: Theoretical KIE values at −65 °C (C1 to C5) and −67 °C (C_a and C_b) at the B3LYP/631 A level for the reaction of EtMeCuLi·LiCl with (*E*)-*t*BuC≡CCH=CHCO$_2$Me (based on **CPop2e**, **CPop1e, CPcle**).

	CPop2e	CPop1e	CPcle
C1	1.002	1.000	1.002
C2	1.000	0.992	1.000
C3	0.998	0.993	0.995
C4	1.002	1.007	1.007
C5	1.016	1.021	1.022
C6		1.000 (internal standard)	
C_a	1.024	1.023	1.015
C_b	0.996	0.995	0.995

particular for C2 (Table 2). These results show that **CPcle** or **CPop2e** is the "starting material" for the rate-limiting step of the 1,6-addition.

In conclusion, our combined experimental and theoretical studies with ^{13}C kinetic isotope effects have revealed that the C–C bond formation is the rate-determining step of the 1,6-cuprate additions to 2-en-4-ynoates. The reaction proceeds via intermediates **CPop1** and **CPop2**, and the calculated activation barrier for transition state **TScc** is in good agreement with the experimental value. Thus, the mechanism of the 1,6-cuprate additions can be considered as solved, which to date can only be said for very few transition-metal catalyzed transformations.[26]

Reaction Mechanisms

Mechanism of Remote Conjugate Addition of a Lithium Organocuprate to a Polyconjugated Carbonyl Compound**

*Naohiko Yoshikai, Tatsuya Yamashita, and Eiichi Nakamura**

Conjugate addition[1] of a nucleophile to a polyconjugated carbonyl compound is an intriguing reaction as it can potentially result in C–C bond formation at one of the remote carbon atoms. In many cases, however, the regioselectivity may be poor, unpredictable, or condition-dependent, and the origin of the regioselectivity often difficult to determine with certainty.[2,3] The particular combination of a polyenynyl carbonyl compound **A** and a lithium organocuprate is unique in all respects in that the C–C bond formation takes place always at the remote acetylenic carbon atom to give an adduct **D** (Scheme 1).[4,5] Although important

Scheme 1. Regioselective conjugate addition of a lithium organocuprate to a polyenynyl carbonyl compound.

pieces of information—NMR spectroscopic identification of the reaction intermediate and the activation energy of the reaction—have been reported,[4b,c] they do not give an answer to the fundamental question as to why the cuprate addition takes place at the acetylene terminal. We report herein a density-functional study on the reaction pathway and the origin of the regioselectivity of this reaction.[6]

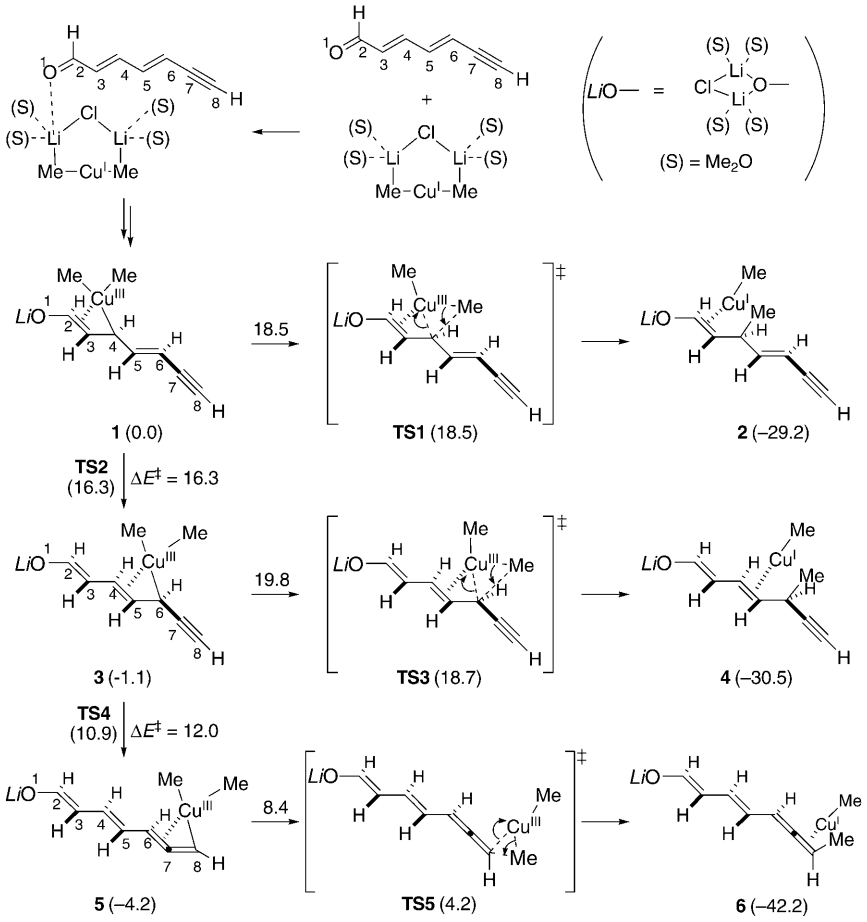
What is intriguing is that the low-temperature NMR spectroscopic analysis of the reaction showed the formation of only one species that can be ascribed to a copper/olefin complex structurally best represented by a σ/π-allyl structure such as **B**, but none of what might be more relevant to the formation of the remote addition product (i.e., **C**).[4b,7] This underscores the importance of the copper/lithium aggregate structure of the organocuprate reagent: Thus, initial formation of the complex **B** can be understood as the result of a sequence of coordination of the Lewis acidic lithium atom to the carbonyl group and the copper atom to the nearest C–C unsaturated bond.[7] On the basis of this background information, we examined the reaction of Me_2CuLi and hepta-2,4-dien-6-ynal (and its shorter homologues; see Supporting Information) as a model reaction, starting from a complex **1**. The pathways for the formation of 1,4-, 1,6-, and 1,8-adducts, and the energy diagram are summarized in Scheme 2 and Figure 1, respectively.[8]

The energy diagram immediately suggests that the kinetically and thermodynamically most favorable pathway is the 1,8-addition pathway that involves three organocopper(III) intermediates **1**, **3**, and **5**. Double migration of the copper atom (**1**→**3**→**5**) and reductive elimination of the final intermediate **5** via **TS5** gives the 1,8-adduct; the first copper migration is the rate-determining step. Reductive elimination of **1** and **3** (via **TS1** and **TS3**) can produce the 1,4- and 1,6-adducts **2** and **4**, respectively, but these routes are kinetically unfavorable relative to the copper migration pathways.[9] Remarkably, the reductive elimination of **5** requires a much lower activation energy than that of **1** and **3**. The reaction pathway is discussed in detail below.



The first intermediate **1** has a structure essentially the same as that of the intermediate generally found in a 1,4-conjugate addition of Me_2CuLi to an α,β-unsaturated carbonyl compound,[7] and can undergo reductive elimination via **TS1** to give the 1,4-addition product **2**. The activation energy (18.5 kcal mol^{-1}) is higher than that of simple 1,4-addition to an acrolein or a cyclohexenone ($\approx$12–15 kcal mol^{-1}),[7] since the C–C bond formation disturbs the polyenyne conjugation system present in **1**.[10]

Alternatively, the Me_2Cu moiety in **1** can migrate to the C5–C6 double bond (via **TS2**) to form a new σ/π-allyl–copper(III) intermediate **3**. The migration ($\Delta E^{\ddagger} = 16.3$ kcal mol^{-1}) is kinetically preferred by 2.2 kcal mol^{-1} over C–C bond formation. **TS2** contains an intrinsically unstable T-shaped triorganocopper(III) geometry (see Supporting Information),[11] but is partially stabilized by the neighboring C5–C6 double bond.

The second intermediate **3** is a σ/π-allyl–copper(III) complex that can either form a C–C bond via **TS3** or undergo further Cu migration to the C7–C8 triple bond via **TS4** to give another copper(III) intermediate **5**. The former process again disturbs the conjugation system, and the latter pathway is overwhelmingly favored by 7.8 kcal mol^{-1}.

The low activation energy of the Cu migration is due to coordination of the terminal acetylene moiety in **TS4** (Figure 2). Intermediate **5** has a distorted square-planar geometry in which the copper atom is much more strongly bonded to the terminal C8 atom (Cu–C8: 2.02 Å) than to the

Scheme 2. Reaction pathways and potential energy changes for 1,4-, 1,6-, and 1,8-addition of Me_2CuLi to hepta-2,4-dien-6-ynal. Potential energies (kcal mol^{-1}, calculated at the B3LYP/631SDD//B3LYP/321SDD level) relative to **1** are shown in parentheses. Energy changes are shown together with arrows.

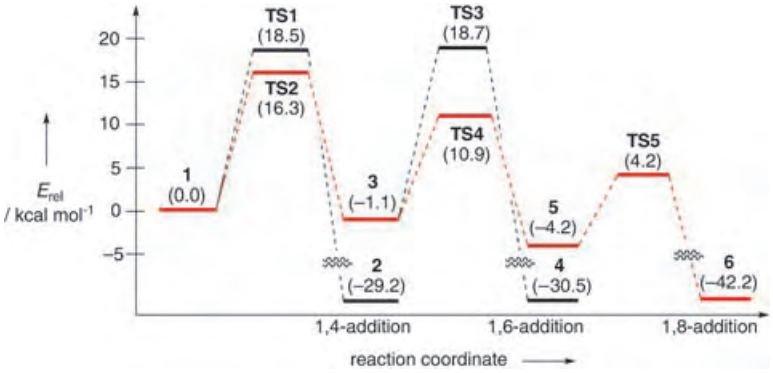

Figure 1. Potential energy profiles for 1,4-, 1,6-, and 1,8-addition pathways (B3LYP/631SDD//B3LYP/321SDD). The energetically most favored 1,8-pathway is shown in red.

C6 atom (Cu–C6: 2.47 Å). This structural feature indicates that the copper atom is σ-bonded to C8 and π-coordinated by the C6–C7 bond, and hence in this case **5** may be called a σ/π-allenyl–copper(III) complex.[10,12] The dissymmetric bonding would be the result of the intrinsic stability of a C(sp^2)–metal bond (relative to a C(sp^3)–metal bond) and the electron-rich dienolate substituent at C6.[10]

The complex **5** undergoes reductive elimination at C8 (via **TS5**) with very low activation energy (8.4 kcal mol^{-1}) owing to the intrinsic linear geometry of the allene: The C6-C7-C8 bond strain (153.9°) is released, and the C6–C7 double bond of **5** is easily detached from the copper(III) center to give a kinetically unstable triorganocopper(III) species,[11] which undergoes rapid reductive elimination (see inset of Figure 2). Furthermore, participation of the allenyl C7–C8 π orbital orthogonal to the Cu–C8 σ bond in C–C bond formation may also contribute to the low activation barrier.[13]

We also studied in some detail the 1,6-addition reaction to the less conjugated analogues pent-2-en-4-ynal and penta-2,4-dienal (see Supporting Information). The former reaction proceeds in essentially the same manner as the 1,8-reaction described above: The 1,6-adduct is formed through a rate-determining Cu migration ($\Delta E^{\ddagger} = 12.2$ kcal mol^{-1}) and quick reductive elimination of the σ/π-allenyl copper(III) intermediate ($\Delta E^{\ddagger} = 8.4$ kcal mol^{-1}). In the latter case, Cu migration takes place with an activation energy of 15.8 kcal mol^{-1} to give a σ/π-allyl–copper(III) intermediate, the reductive elimination of which requires a much higher activation energy (13.3 kcal mol^{-1}) than that of σ/π-allenyl–copper(III) intermediates. Furthermore, theoretical ^{13}C NMR spectroscopic data calculated for the initially formed olefin complex, employing ethyl 6,6-dimethyl-hept-2-en-4-ynoate as a substrate, showed reasonable agreement with experimental findings (see Supporting Information).[4b]

In summary, we proposed a general mechanistic framework for remote conjugate addition of an organocuprate to a polyconjugated Michael acceptor. Interaction between the two reactants initially generates a β-cuprioenolate intermediate, which undergoes sequential copper migration via σ/π-allyl–copper(III) intermediates. The final migration to the acetylene terminal gives a key σ/π-allenyl–copper(III) intermediate, the kinetic instability of which results in rapid C–C bond formation at the terminal carbon atom. C–C bond formation at the internal carbon atoms is disfavored as it disturbs the conjugation system. This mechanism for polyenyne substrates also explains why conjugate addition to polyenyl carbonyl compounds tends to be unpredictable: The copper intermediates formed from a polyene substrate lack such a decisive structural feature as that in **5** and may undergo C–C bond formation at any possible carbon atom, depending on structure and reaction conditions.[2] The present mechanistic framework should apply to remote substitution reactions,[14] and we consider also that rapid 1,3 copper migration similar to that reported herein is responsible for the remarkably high regioselectivity of the multi-

Solid-Phase Synthesis

Reversible Substrate Anchoring: NC-SPOS as a Sustainable Approach to Solid-Supported Organic Synthesis**

*Achim Porzelle and Wolf-Dieter Fessner**

Dedicated to Professor George M. Whitesides

The goal of solid-phase organic synthesis (SPOS) is to accelerate and standardize synthetic operations to be compatible with parallel and automated approaches. In conventional SPOS, substrates are covalently attached to an insoluble matrix and time-consuming workup procedures are simplified to physical separation steps. Products are released after multiple reaction cycles by the chemoselective cleavage of a linker moiety.[1] A major problem with this technology is the difficulty in analytical characterization of synthetic intermediates and impossibility of purification from covalently bound side-products. Moderate loading capacities, limited mechanical stability, and unsatisfactory reagent penetration are further disadvantages of the polymeric supports common to this approach. Matrix material is usually discarded after use because regeneration of the matrix–linker construct is inconvenient and uneconomical. In the search for superior options, alternative concepts[2] have recently been investigated that attempt to amalgamate the advantages of a high-molecular-weight carrier with solution-phase chemistry, such as in soluble-polymer-supported[3] and dendrimer-supported organic synthesis.[4] In other studies distinct techniques for product isolation have been introduced, for example, special product-precipitation methods[5] and liquid/liquid phase separation, including the use of ionic liquids and fluorous phases.[2,6] Inverse approaches consist of the application of immobilized reagents, catalysts, and scavengers.[7] In contrast to reactions with solid-phase resins, reactions with soluble supports can be performed (and analyzed) under homogeneous conditions. Method validation is thus facilitated, but often the practical simplicity and efficiency gained by the use of insoluble supports are lost.[2]

Our interest in the efficacious generation of molecular diversity within biocatalytic synthesis[8] has led us to develop a novel approach to SPOS by using the *noncovalent attachment of substrates* to a solid matrix through hydrophobic interactions (noncovalent SPOS, NC-SPOS).[9] When tagged with a hydrophobic anchor unit, substrates in a highly polar, hydrophilic solvent, such as water, become immobilized on a hydrophobic matrix (Figure 1). Thus, standard SPOS operations, including washing and filtration steps, may be performed on immobilized substrates. As the anchoring affinity depends on the partition coefficient ($\lg P$) of the anchor unit between the matrix and the solution phase,[10] anchored products are released into the solution phase when switched to a nonpolar organic solvent. A typical NC-SPOS reaction procedure would thus consist of three steps: 1) adsorption of the anchor–substrate unit onto the matrix, 2) single or multiple reactions under aqueous conditions, each followed by washing, and 3) final desorption and/or cleavage of the anchor–product unit.

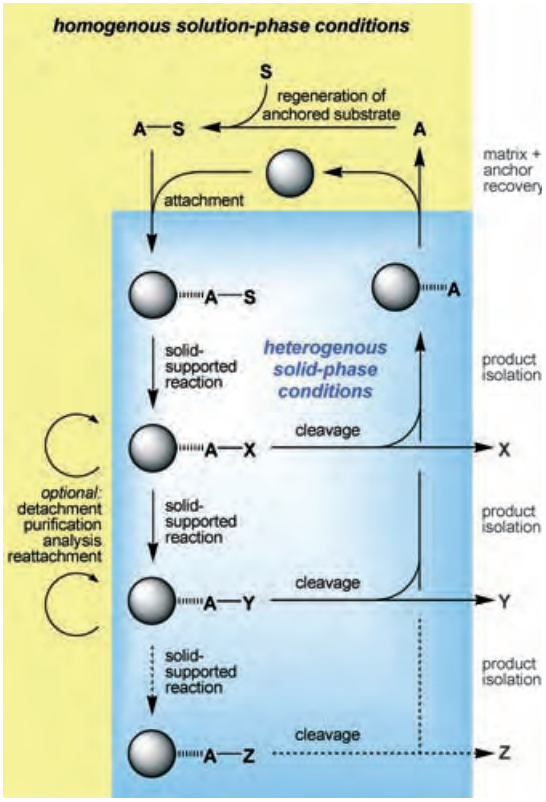

Figure 1. Basic concept of NC-SPOS. A = hydrophobic anchor unit; S = substrate; X, Y, and Z = products. Bead symbols indicate a hydrophobic solid-phase support. Dashed bonds represent noncovalent attachment. The yellow area denotes the nonpolar organic phase, while the blue box indicates the polar hydrophilic phase.

As the attachment is reversible, phase switching may be performed, in principle, at any stage of a given reaction sequence; in this way the NC-SPOS technique displays the same advantages as common solution-phase chemistry. Thus, the reaction can be monitored conveniently by conventional TLC, and reaction intermediates are amenable to spectroscopic analysis (or even optional chromatographic purification) by application of an organic solvent under homogenous conditions. As phase switching is freely reversible, compounds released into solution for analysis may be readsorbed onto the solid matrix by subsequent change to the polar

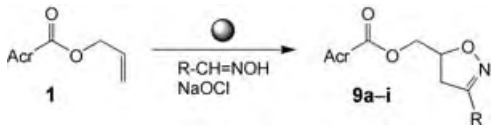
solvent. Likewise, it is immediately obvious that in a multistep synthetic sequence, for example, individual steps may also be performed under nonaqueous conditions if the type of reaction or the choice of reagent is incompatible with SPOS operations or requires a moisture-free organic solvent; thereafter, the NC-SPOS process can be continued after reattachment of the intermediates to the matrix under aqueous conditions.

The final product is released from the hydrophobic anchor unit by conventional linker cleavage and isolated from the solid matrix by washing (Figure 1). Both the collected solid phase and the hydrophobic anchor unit can be recycled. Loading capacity is broadly adjustable and limited only by the accessible hydrophobic surface area of the solid matrix. A broad variety of suitable solid-phase supports with designed properties is commercially available, because the NC-SPOS concept relies on the same phenomenon as conventional solid-phase extraction (SPE) and reversed-phase (RP) chromatography.[11] Although it is very simplistic in design, this approach of reversible substrate binding as a fully integrated strategy of SPOS has, to the best of our knowledge, not been pursued previously.[12] However, polycyclic-arene-based protecting groups with high adsorptive affinity to charcoal or graphite have been reported to facilitate the recovery of tagged products from organic solvent media[13] or for chromatographic purification.[14]

For a first realization of the NC-SPOS concept, we chose standard C_{18}-modified RP silica gel as the hydrophobic matrix and *N*-alkylated acridone derivatives as the hydrophobic anchor moieties (usually 0.5 g of RP matrix per mmol of substrate). The choice of an acridone tag, aside from its low polarity and high (photo)chemical stability, was based on its extremely efficient, bright blue fluorescence, which facilitates the effective establishment of ultrasensitive reaction screening by TLC or HPLC analysis.[15] Indeed, initial experiments with an anchored allyl ether moiety demonstrated that basic alkene functionalization (epoxidation by peracids, dihydroxylation by $KMnO_4$ or by acid epoxide hydrolysis, cleavage by O_3) and carbonyl reactions (aldehyde reduction/oxidation by $NaBH_4/H_2O_2$, hydrazone condensation) could be achieved selectively by typical SPOS procedures.[9]

To test the suitability of the NC-SPOS concept as a rapid reactivity-screening system (Scheme 1), the allyl ester **1** was initially chosen as a generic example of an anchor–substrate unit from which products could be released by simple adjustment of the pH value without further addition of contaminating reagents. The ester functionality has been applied successfully in many SPOS operations because it is easy to generate and can be cleaved selectively under mild conditions that are tolerated by a very broad variety of further functional groups. At an experimental lg *P* value of ≈ 2.5, no remaining **1** could be detected in the solution phase of a RP-matrix/water mixture by UV measurement at $\lambda = 399$ nm, and less than 2% of **1** became desorbed in the presence of 10% methanol as an organic cosolvent. However, when small aliquots of the NC-SPOS slurry were transferred to a TLC plate that was then dried and developed with an organic solvent, a sharp homogenous spot of **1**, indistinguishable from an unbound reference sample, was observed.

Scheme 1. Screening for NC-SPOS reactions. Reagents and conditions: a) O_3, MeOH, −78 °C, then DMS, RT, 24 h, quantitative; b) $SnCl_2$/KI, allyl bromide (6 equiv), H_2O, RT, 90%; c) $SnCl_2$/KI, ethyl 2-bromomethylacrylate (6 equiv), H_2O, RT, 85%; d) $SnCl_2$/KI, propargyl bromide (6 equiv), H_2O, RT, 70%; e) $CH_3CH{=}NOH$ (3 equiv), NaOCl, 0 °C→RT, 8 h, 79%; f) 5 mol% $Pd(OAc)_2$/TPPTS, PhI (1.1 equiv), NEt_3 (2.5 equiv), RT, 20 h, 90%; g) 5 mol% $Pd(OAc)_2$/TPPTS, PhI (1.1 equiv), NEt_3 (2.5 equiv), RT, 20 h, 40%. Bead symbols indicate reactions performed by hydrophobic attachment of the substrates to a reversed-phase silica support. DMS = dimethyl sulfide; TPPTS = tris-(*m*-sulfonatophenyl)phosphane, trisodium salt.



Subsequent to early findings of Breslow, Grieco, and their respective co-workers[16] that water can increase the rate and selectivity of Diels–Alder reactions, a large variety of reactions have been adapted to aqueous conditions.[17] As an entry to the multistep construction of larger entities, we tested metal-mediated Barbier-type allyl additions[18] as one of the best developed reactions in aqueous media by using aldehyde **2** under NC-SPOS conditions. As to be expected, in situ formation of the organometallic allyl reagents from elemental Zn or Sn was largely unsuccessful since the metal surface must be activated by acid treatment or sonication, which also led to partial cleavage of the linker cleavage and unsatisfactory yields. In contrast, in the case of In-mediated reactions good yields were obtained, but inorganic precipitates hampered filtration and matrix purification for reuse. However, the homogenous reagents generated from $SnCl_2$/KI[19] with allyl

bromide, ethyl 2-bromomethylacrylate,[20] and even propargyl bromide consistently gave high yields of isolated adducts **3**–**5**.

Further reactivity screening included 1,3-dipolar cycloaddition of nitrile oxides[21] and Pd-catalyzed C–C cross-coupling reactions[22] to carrier-adsorbed alkenes as consecutive synthesis steps. Generation of the nitrile oxide reagent could be performed advantageously in situ from the corresponding oxime by using 11% aqueous NaOCl at 0°C to furnish Δ^2-isoxazoline **6** in good yield. Also, Pd-catalyzed C–C cross-coupling reactions such as Heck and Sonogashira reactions, which have emerged as valuable tools in organic synthesis to build new C–C bonds, were performed successfully in water by using water-soluble phosphine ligands. In the latter case, air sensitivity of the catalytic Pd complex proved challenging because of the difficulty of degassing the RP-silica solid phase in a practical manner. The Heck reaction, performed without added organic cosolvent, was compromised by competing partial cleavage of the ester linker under the slightly alkaline conditions, because an equivalent of base is needed to scavenge the acid by-product. The reported yield for isolated product thus accounts only for the anchor-conjugated adduct (40%, nonoptimized; *E*/*Z* ratio 16:1) that remained adsorbed to the solid phase, an adduct that, interestingly, proved to be lactone **8** formed by an intramolecular transesterification (>95% purity). In addition, a considerable quantity of further unlabeled Heck product was detected in the aqueous phase. Therefore, the unsatisfactory yield is due to the insufficient stability of the anchoring ester under the reaction conditions, but it should be pointed out that this is not a limitation inherent to the NC-SPOS approach. The ester conjugate was chosen as a simple, uniform linker moiety in this demonstration of reaction screening, but it could be readily replaced by more appropriate functionalities for more focused studies on Heck-type conversions.[1]

In a first attempt to address the potential of the NC-SPOS technique for diversity generation in parallel syntheses, we focused on isoxazoline formation by [3+2] cycloaddition because these reactions are highly atom economical and usually give high yields, and, for comparison, they are well documented under various reaction conditions.[21] Also, isoxazolines are medicinally important pharmacophores and provide versatile building blocks for the synthesis of complex natural products.[23] A series of oximes (Scheme 2, Table 1) was subjected to NaOCl oxidation as before in the presence of RP-silica-bound allyl ester **1**, and product formation was conveniently determined by TLC monitoring. After the usual aqueous washing, all the resulting isoxazolines **9a**–**h** were obtained as single regioisomers by methanol desorption from the solid phase. The crude products from aromatic oximes

were pure by NMR spectroscopic analysis, with only minor impurities from excess reagent and some anchor carboxylic acid arising from undesired cleavage of the anchoring ester linkage. Owing to the lower stability of alkyl oximes (**6** and **9g**–**i**) more reagent was required (up to 3 equiv), and extended exposition to strongly alkaline medium (pH ≈ 11) resulted in diminished yields. For full characterization, products were purified by conventional column chromatography. Yields were within the usual range observed for conventional solution-phase and solid-phase synthesis protocols.[21]

The effectiveness of the protocols for cleavage and matrix/anchor regeneration is illustrated in an exemplary manner by the NC-SPOS synthesis of a small stereocombinatorial[24] library of dideoxyglycosides (Scheme 3). By diverging from

Scheme 3. Examples of cleavage reactions for NC-SPOS products. Reagents and conditions: a) O_3, MeOH, −78°C, then DMS, RT, quantitative; b) $SnCl_2$/KI, allyl bromide (6 equiv), H_2O, RT, 90%; c) aqueous HCl/EtOH, reflux, 2 h, 85%; d) HCl/MeOH, reflux, 30 min, 89%.

the racemic alkene intermediate **3**, ozonolytic generation of the corresponding aldehyde electrophile followed by a second Barbier-type allyl addition gave a mixture of diastereomeric *syn*/*anti* adducts **10** in a 1:1 ratio. Ozonolysis and reductive workup furnished an anchored mixture of 2,4-dideoxysugars, consisting of four distinct α,β anomers (all pairs of enantiomers, eight different stereoisomers altogether) as evident by NMR analysis of a desorbed aliquot (later readsorbed by slurrying with fresh RP silica in water). For cleavage, the solid-phase material was treated with HCl in methanol at room temperature. Solvent exchange to water followed by

filtration provided a fraction of solid matrix containing the free anchor moiety and an aqueous solution of free methyl dideoxyglycosides **12.** The latter were isolated in 89% yield by evaporation of the water and characterized by NMR spectroscopic analysis; the expected diastereomers were obtained in a 3:3:1:1 ratio. Finally, the solids were leached with methanol to furnish the regenerated RP matrix (98% total recovery) and the detached hydrophobic anchor unit as the methyl ester ready for reuse (86% total recovery; >95% purity). Similarly, diol **11** was isolated by acidic cleavage (HCl/EtOH) in 96% total yield together with the ethyl ester of the anchor unit. Cleavage from the anchor could also be performed under aqueous alkaline conditions; this, however, required an additional ion-exchange treatment for neutralization.

In conclusion, we have proposed NC-SPOS as a novel concept for facilitated organic processes and have demonstrated that many modern synthetic reactions can be carried out under such conditions. For all the reactions screened, aided by highly sensitive fluorescent labeling, we have been able to replace an organic-substrate-solubilizing phase with a hydrophobic surface-modified solid matrix and use reagents in water as an environmentally friendly solvent. A general NC-SPOS reaction procedure often takes less time than the equivalent common SPOS process, because there are none of the diffusion limitations that are typical for polymer supports and tedious washing cycles are thus unnecessary. We have generally been able to avoid the use of a vast excess of reagent, which is otherwise typical for SPOS conditions, and thereby minimize potential product contamination from hydrophobic reagents. Clearly, limitations can arise for aqueous NC-SPOS reactions with building blocks or reagents that are poorly soluble in water because these components may stick to the support and lower the reaction rates. However, for those individual reactions investigated, but not optimized, yields so far are comparable to conventional solution-phase conversions and may be improved with further experimentation.

The main problems of conventional SPOS, that is, analysis and purification of intermediates, particularly during multistep syntheses, are overcome by our new freely reversible attachment strategy. The recovery of the RP-silica solid phase and anchor units is facile and efficient, so the technique is highly environmentally benign, in keeping with the philosophy of green chemistry.[25] The NC-SPOS strategy offers practical simplicity that is readily applicable to both automation and scaleup. The study of more sophisticated aspects, such as multiparallel and combinatorial synthesis, asymmetric catalysis, use of anchored scavengers and/or other anchor–linker combinations, further reaction types, and application to multistep syntheses, is currently underway.

Experimental Section

Example synthesis of **3**: A solution of **1** (335 mg, 1 mmol) in MeOH (10 mL) at −78 °C was treated with ozone until a blue color persisted. After the mixture had been purged with O_2 for a further 5 min, dimethyl sulfide (0.5 mL) was added, and the mixture was then allowed to warm to room temperature for 2 h. RP silica 100 (C_{18}, endcapped, 230–400 mesh; 500 mg) was added, and the solvent was removed in vacuo. Further portions of MeOH (3 × 10 mL) were added and evaporated to remove all volatile compounds. In a separate flask, an aqueous solution (10 mL) containing KI (510 mg, 3.0 mmol) and $SnCl_2$ (342 mg, 1.8 mmol) was stirred with allyl bromide (0.14 mL, 6.4 mmol) to give an orange-red reagent solution. This mixture was added to the adsorbed RP silica, and the resulting slurry was stirred at room temperature overnight, during which time the color faded away. After filtration through a thin RP-silica layer (prewashed with MeOH), the solid residue was washed with water (50 mL) and dried. For product release, the solid was washed with methanol, and the filtrates were evaporated to give **3** as a yellow oil (350 mg, 90%); $R_f = 0.4$ (40% EtOAc/cyclohexane); ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 8.52$ (dd, 2H, $J = 8.0$, 1.7 Hz, H_{ar}), 7.68 (ddd, 2H, $J = 8.0$, 7.0, 1.7 Hz, H_{ar}), 7.41 (br d, 2H, $J = 8.7$ Hz, H_{ar}), 7.22 (ddd, 2H, $J = 8.0$, 7.0, 0.7 Hz, H_{ar}), 5.72 (m, 1H, H-4′), 5.08 (m, 2H, H-5′), 4.30 (t, 2H, $J = 7.5$ Hz, H-5), 4.11 (dd, 1H, $J = 11.4$, 3.2 Hz, H-1′a), 3.97 (dd, 1H, $J = 11.4$, 7.0 Hz, H-1′b), 3.85 (m, 1H, H-2′), 2.44 (t, 2H, $J = 6.9$ Hz, H-2), 2.23 (m, 2H, H-3′), 1.95–1.80 ppm (m, 4H, H-3, H-4); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 177.94$ (C=O), 173.09 (C-1), 141.76 (C_{ar}), 134.01 (C_{ar}), 133.41 (C-4′), 128.11 (C_{ar}), 122.54 (C_{ar}), 121.35 (C_{ar}), 118.65 (C-5′), 114.46 (C_{ar}), 69.41 (C-2′), 68.42 (C-1′), 45.77 (C-5), 38.18 (C-3′), 33.93 (C-2), 26.68 (C-4), 22.20 ppm (C-3); MS (70 eV): *m*/*z* (%): 379 (49) [M^+], 208 (100).

Cleavage of **3**: A sample of **3** (100 mg, 0.26 mmol) adsorbed to RP silica (500 mg) was heated at reflux in a mixture of EtOH (30 mL) and concentrated HCl (1 mL) for 2 h. After complete conversion (according to TLC), the solvent was removed by evaporation, and then water (15 mL) and further RP silica (1 g) were added. The resulting slurry was filtered, the solids washed with water (15 mL), and the combined filtrates were evaporated to yield **11** (26 mg, 96%) as a colorless liquid; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 5.82$ (m, 1H, H-4), 5.14 (m, 2H, H-5), 3.80 (m, 1H, H-2), 3.67 (dd, 1H, $J = 11.2$, 3.1 Hz, H-1a), 3.48 (dd, 1H, $J = 11.2$, 7.2 Hz, H-1b), 2.25 ppm (m, 2H, H-3); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 132.77$ (C-4), 119.84 (C-5), 71.75 (C-2), 66.54 (C-1), 37.81 ppm (C-3); MS (70 eV): 124.1 [M+Na]$^+$. The filtered solids were washed with acetone, and the filtrates were evaporated to give the ethyl ester of the anchor unit as a yellow solid (80 mg, 94%).

Synthesis of **12**: A sample of **1** (335 mg, 1 mmol) was processed as above to give adduct **3**, still anchored to the RP silica. The dried solid was taken up in MeOH (10 mL), and the mixture was treated with ozone. This was then followed by reductive workup and solvent removal as above. The resulting RP silica containing the anchored aldehyde was treated again with the aqueous allylation reagent to give the corresponding 1,3-diol adduct **10** (1:1 diastereomeric ratio verified by NMR spectroscopic analysis on a small aliquot); ^{1}H NMR ($CDCl_3$, 300 MHz): $\delta = 8.50$ (dd, 2H, $J = 8.0$, 1.7 Hz, H_{ar}), 7.65 (ddd, 2H, $J =$ 8.0, 7.0, 1.7 Hz, H_{ar}), 7.41 (br d, 2H, $J = 8.7$ Hz, H_{ar}), 7.23 (ddd, 2H, $J = 8.0$, 7.0, 0.7 Hz, H_{ar}), 5.85–5.70 (m, 1H, H-6′), 5.15–5.05 (m, 2H, H-7′), 4.27 (t, 2H, $J = 7.5$ Hz, H-5), 4.16–4.04 (m, 4H, H-1′, H-2′, H-4′), 2.44 (t, 2H, $J = 6.9$ Hz, H-2), 2.27 (m, 2H, H-3′), 1.94–1.87 (m, 4H, H-3, H-4), 1.64–1.60 ppm (m, 2H, H-5′); ^{13}C NMR ($CDCl_3$, 75 MHz): $\delta = 178.03$ (C=O), 173.26 (C-1), 141.61 (C_{ar}), 134.62 (C-6′), 134.21 (C_{ar}), 127.91 (C_{ar}), 122.19 (C_{ar}), 121.46 (C_{ar}), 118.45 (C-7′), 114.62 (C_{ar}), 71.31, 70.41 (C-2′), 68.80, 68.62 (C-1′), 67.74, 67.07 (C-4′), 45.87 (C-5), 42.58, 42.13 (C-3′), 38.85, 38.57 (C-5′), 33.66 (C-2), 26.61 (C-4), 22.15 ppm (C-3); MS (70 eV) *m*/*z* (%): 423 (9) [M^+], 296 (100).

Ozonolysis of **10** under standard conditions resulted in the anchored 2,4-dideoxysugars (NMR spectroscopic analysis). For cleavage, the RP silica containing the adsorbed product was heated under reflux in HCl-saturated MeOH (30 mL) for 2 h. After complete conversion (according to TLC), the solvent was removed, and then water (15 mL) and further RP silica (500 mg) were added. After filtration, the remaining solids were washed with water (15 mL), and the solution was evaporated to yield the stereoisomeric mixture of **12** (116 mg, 79% overall) as a colorless syrup; ^{1}H NMR ($CDCl_3$,

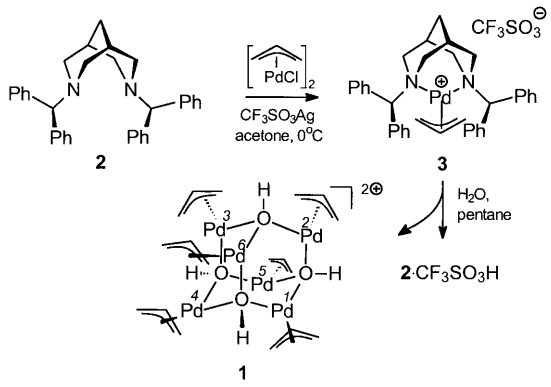
Cluster Compounds

Ligand-Induced Formation of an Adamantanoid Hexanuclear (π-Allyl)Pd^{II}(μ_3-Hydroxo) Cluster Stacked as Hydrogen-Bonded Double Strands



Adolf Gogoll, Lauri Toom, and Helena Grennberg*

Hydroxo complexes of transition metals are of interest in materials science as precursors for intricate metal oxides,[1] and as intermediates in metal-mediated or -catalyzed processes. Hydroxopalladium intermediates have been postulated in some palladium-catalyzed reactions,[2] and they may explain the unexpected stability of some palladium catalysts in the presence of water.[3] In most of its hydroxo complexes, palladium is coordinated to further heteroatom ligands containing P and/or N atoms. Notable exceptions are (μ_2-hydroxo)bis(η^2,η^2-cyclooctadiene)dimethyldipalladium(II) hexafluoroantimonate[4a] and bis(tetrabutylammonium)-bis[(μ_2-hydroxo)bis(pentafluorophenyl)palladium],[4b] which contain palladium coordinated to η^2-alkene or σ-C ligands, respectively.

Isolated hydroxopalladium complexes usually display polynuclearity.[5] The formation of a trinuclear palladium complex was attributed to the presence of traces of water during purification.[6] Trinuclear, mixed-metal complexes were obtained by reaction between hydroxopalladium and metal hydride complexes.[7] Larger clusters of Pd atoms with predominantly carbon monoxide ligands are known, and non-hydroxopalladium clusters of catalytic interest have been studied.[8] A mixed-metal cluster (Pd/Cu) with an adamantanoid Pd–oxygen substructure (hexanuclear in Pd) but without organic ligands on the Pd atoms has been described.[9]

Herein, we report an organometallic, homonuclear hydroxo(π-allyl)Pd cluster **1**, [{(1,3-η^3-propenyl)Pd}$_6$(μ_3-OH)$_4$](CF$_3$SO$_3$)$_2$, without further heteroatom (P or N) ligands. The cluster has a distorted adamantanoid geometry, and the crystal lattice consists of clusters linked into double strands by hydrogen bonds via bridging counterions.

Cluster **1** was obtained during the attempted complexation of the sterically hindered bispidine ligand *N*,*N*′-bis(diphenylmethyl)-3,7-diazabicyclo[3.3.1]nonane (**2**) with a (π-allyl)palladium species, from which we expected to obtain complex **3** (Scheme 1). The formation of **3** was proven by ^{1}H NMR spectroscopy.[10] However, when trying to isolate solid **3** from the acetone solution, we observed the initial formation of colorless, needle-shaped crystals of the protonated ligand salt, **2**·CF$_3$SO$_3$H. Upon further undisturbed standing, the precipitation of yellow, rhomboid crystals was observed in experiments using technical-grade solvent. Under dry conditions, Pd black precipitated. The yellow crystals

Scheme 1. Ligand-induced formation of cluster **1** via complex **3**. The Pd$_6$(OH)$_4$ subunit is emphasized. The trifluorosulfonate ions are omitted for clarity.

were stable for several days at refrigerator temperature (below 4 °C) while covered by the crystallization solvent. Isolated crystals were reasonably stable in air at ambient temperature for several hours. To our surprise, the yellow crystals were not of the expected complex **3**, but of the adamantanoid (π-allyl)Pd^{II} cluster **1** with bridging hydroxo ligands. To the best of our knowledge, this is the first example of an organometallic cluster of palladium of this type.[11,14]

The Pd···C distances in cluster **1** (Figure 1) vary between 2.048 and 2.082 Å (propenyl C-2) and between 2.093 and 2.115 Å (propenyl C-1 and C-3). These distances are shorter

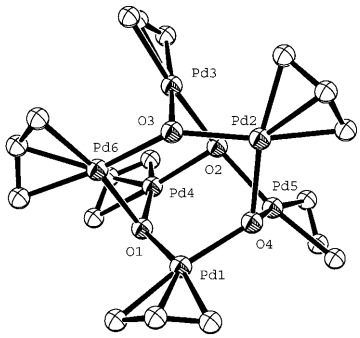


Figure 1. Molecular structure of cluster **1** (counterions omitted for clarity).

than those in the chloro dimer bis[(1,3-η^3-propenyl)palladium chloride] (2.121 Å for C-2, 2.108–2.123 Å for C-1 and C-3),[12] and in (*N*,*N*′-diphenyl-1,5-dimethyl-3,7-diazabicyclo[3.3.1]-nonane-9-one)(1,3-η^3-propenyl)palladium trifluoromethanesulfonate (2.128 Å for C-2 and 2.125–2.126 Å for C-1 and C-3),[15] most likely because of the small *trans* influence of μ_3-hydroxo ligands on the Pd–C bond compared to that of Cl or N ligands.

The Pd···O distances in cluster **1**, which range from 2.133 to 2.179 Å, are shorter than those in the only other reported Pd–(μ_3-OH) cluster, [{Pd(8-methylquinoline)}$_3$(μ_3-Ph$_2$PCH-COOC$_2$H$_5$)(μ_3-OH)]PF$_6$, which are between 2.144 and 2.281 Å.[4] In comparison with a series of μ_2-OH complexes, the Pd···(μ_3-OH) distances in **1** are similar to[16a] or signifi-

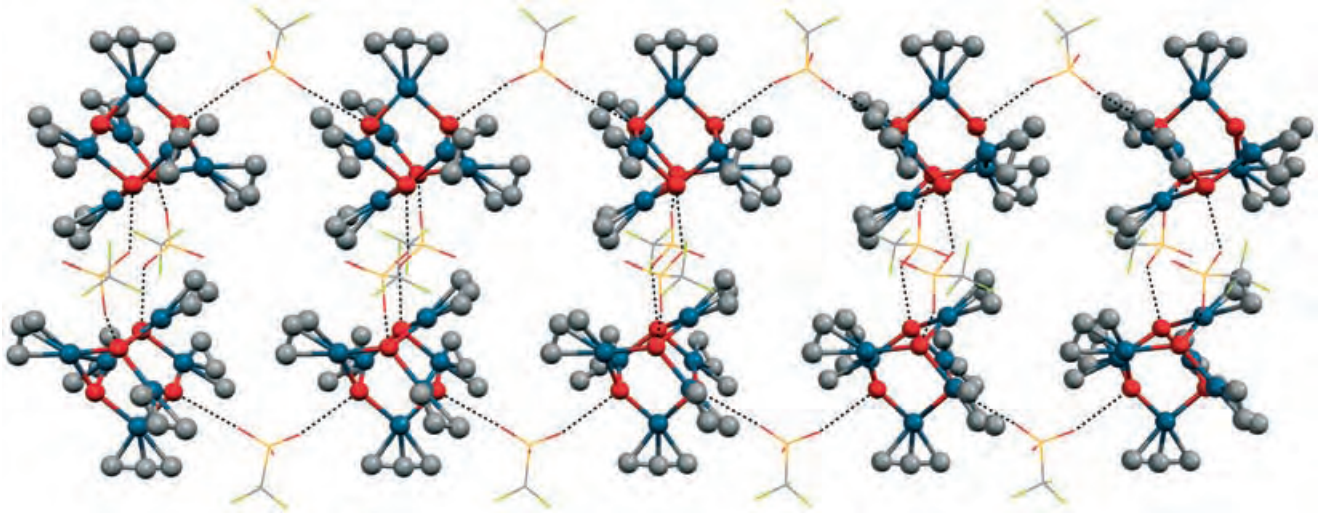

Figure 2. Double strands of clusters of **1**. Cluster pairs bonded via two $CF_3SO_3^-$ ions are linked into strands via two other $CF_3SO_3^-$ ions. Hydrogen bonds are indicated (••••, hydrogen atoms omitted for clarity). The lattice contains one acetone molecule per cluster (not shown).

cantly longer than[4,16b–e] those in the μ_2-OH complexes, where a common feature is that the Pd–(μ_2-O) bond experiences significantly less *trans* influence from other ligands than that exerted by the η^3-propenyl ligands in **1**.

The dicationic clusters of complex **1** are grouped into pairs, linked by two $CF_3SO_3^-$ ions hydrogen-bonded to the hydroxy ligands (connecting O3···O4′ and O4···O3′). These pairs are then linked into double strands of clusters by two more $CF_3SO_3^-$ ions connecting O1···O2′ and O2···O1′, respectively (Figure 2). Hydrogen-bond lengths are shorter between pairs than in the chains of clusters, with CF_3SO_3···(μ_3-H*O*) distances at 2.839 and 2.872–2.921 Å, respectively. Thus, each cluster is surrounded by four shared anions, which leads to a regular crystal lattice composed of double strands.

Hydroxo complexes of transition metals are usually formed by ligand exchange with water.[5b,17] We propose that this is also the case in the formation of cluster **1**. The sequence of steps leading to **1** is coupled to the dynamic process of apparent π-allyl rotation observed in (π-allyl)Pd complexes with chelating dinitrogen ligands.[18] Most likely, steric interactions between the organic ligands in complex **3** favor dissociation of one of its nitrogen atoms. Next, protonation of the basic nitrogen prevents reattachment to the palladium. Instead, the resulting coordinatively unsaturated complex is stabilized by coordination of hydroxy ions, generated by deprotonation of water by the strongly basic ligand **2**.[19] Involvement of η^3–η^1 isomerism of the π-allyl ligand is unlikely, since no exchange between *syn* and *anti* protons of complex **3** was detected by ^{1}H NMR spectroscopy.[10] Furthermore, the cluster **1** is not formed when bispidine ligands other than **2** are used.[15,18b,c]

In conclusion, ligand **2**, although itself not part of the cluster **1**, appears to be responsible for the formation of this new type of palladium complex.

[10] Full characterization of **3** will be presented in a separate paper.
[11] Formation of **1** and **2**·CF_3SO_3H: Ligand **2**[12] (7.6 mg, 16.6 μmol) was dissolved in a mixture of acetone (0.3 mL) and $CHCl_3$ (0.2 mL) in a small test tube. After cooling to 0 °C a solution of bis[(1,3-η^3-propenyl)palladium chloride][13] (3.1 mg, 8.5 μmol) in acetone (0.2 mL) was added, followed by a solution of CF_3SO_3Ag (4.3 mg, 16.7 μmol) in acetone (0.2 mL). After stirring (30 s), the precipitated AgCl was separated by centrifugation. The clear, slightly yellow solution was transferred with a Pasteur pipette into a screw-cap vial, and carefully layered with the same volume of cold hexane, which became slightly cloudy. The closed vial was stored at 4 °C. After one day, colorless needles of **2**·CF_3SO_3H had formed. After two days, yellow rhomboid crystals of **1** appeared (yield ca. 0.1 mg, 4 %).

Self-Assembly

The Introduction of π–π Stacking Moieties for Fabricating Stable Micellar Structure: Formation and Dynamics of Disklike Micelles**

Bo Song, Zhiqiang Wang, Senlin Chen, Xi Zhang, Yu Fu, Mario Smet, and Wim Dehaen*

Amphiphiles can self-organize into micellar structures with defined sizes and shapes[1,2] that may be used in applications such as templates for making nanostructured materials and mimicking biomineralization processes. Engineering robustness is required to make these applications practical, as the micellar structures are inherently dynamic and fluid. Enhancing the intermolecular interactions among the aggregates is one possible method for stabilizing the micellar structures. This approach may rely on generating a strong association among its assembling units through a combination of different interactions, including van der Waals interactions and hydrogen bonding.[3–5] Herein, we report the introduction of a strong π–π stacking moiety into bolaamphiphiles[6] so as to increase the robustness of the self-organized entities, thus providing a new approach to fabricating organic nanostructured materials.

The diaryldiketopyrrolopyrrole (DPP) dye is a recently developed technical pigment with remarkable properties such as a high fade-proof nature, extraordinary thermal stability, and very low solubility as a consequence of strong intermolecular interactions.[7] We attempted to introduce a DPP dye as a strong π–π stacking moiety into bolaamphiphiles, and hoped that such a bolaamphiphile might give rise to a stable micellar nanostructure with light-emitting properties. For this

purpose, a series of bolaamphiphiles bearing diaryldiketopyrrolopyrrole units with different spacer lengths were synthesized, namely, 2,5-bis(*n*-(1-pyridinium)alkyl)-3,6-bis-(2-thienyl)-1,4-dioxopyrrolo[3,4-*c*]pyrrole ditosylate salts, abbreviated as DPP-*n*, where *n* ($n = 7$, 11, 15) corresponds to the number of methylene units in the alkyl chain spacer.

For DPP-11, for example, there exists a critical micelle concentration (cmc) at 5.5×10^{-5} M, as indicated by the plot of the conductivity as a function of the concentration (Figure 1).

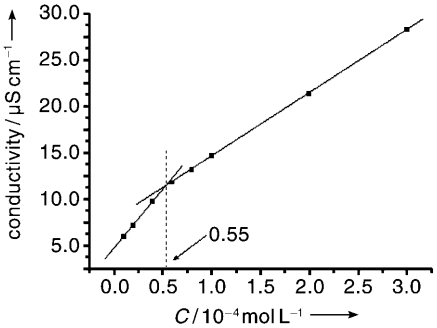

Figure 1. Dependence of the solution conductivity of DPP-11 on concentration; the cmc is around 5.5×10^{-5} M.

When the concentration is above this critical value the bolaamphiphiles self-organize into micelles in aqueous solution. The formation of a micellar structure is also supported by ^{1}H NMR spectroscopic analysis. As seen in Figure 2, the

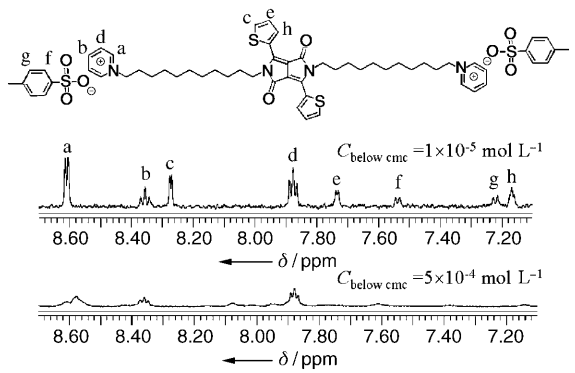

Figure 2. ^{1}H NMR spectra of DPP-11 in D_2O with concentrations lower and higher than its cmc.

^{1}H NMR signals of the aromatic rings from the two terminal pyridinium groups as well as from the rigid unit are well resolved below its cmc. However, all the ^{1}H NMR signals become broad and weak when the concentration is above its cmc. The change in the ^{1}H NMR signals of the thienyl residues in the rigid moiety is even greater than that of the two terminal pyridinium groups. This change can be rationalized by the restricted motion of the amphiphilic molecule in the associated state.[3,8] The segregation of the hydrophobic and hydrophilic parts of the molecule during the self-assembly in water results in the thienyl groups residing in the inner part of the micelles and the terminal pyridinium groups at the outer part of the micelles. Therefore, interaction between the water and the pyridinium groups is stronger than that with the thienyl residues, thus leading to increased local mobility and less line broadening of the NMR signals.

We found that if the concentration of the DPP-11 solution was above the cmc the solution turned from bright red to dark purple. We anticipated that the color change was indicative of the formation of micelles, which was further supported by spectroscopic studies: We first identified the UV/Vis spectral absorption bands of the DPP-11 monomer and aggregate. As shown in Figure 3, there are two absorption bands around 514

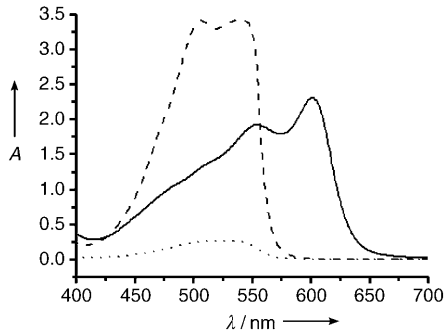

Figure 3. Concentration-dependent UV/Vis spectra of DPP-11: in methanol at 1.0×10^{-4} M (dashed line); in aqueous solution at 1.0×10^{-4} M, above the cmc (solid line); in aqueous solution at 1.0×10^{-5} M, below the cmc (dotted line).

and 540 nm in dilute aqueous solution (below the cmc, dotted curve) or in the good solvent, methanol (dashed curve). These bands are assigned to the monomer of DPP-11. In concentrated solution (above the cmc), a new absorption band appears around 601 nm (solid curve), which is attributed to the aggregate state of DPP-11. The bathochromic shift of the absorption bands is caused by the strong π–π stacking of the diketopyrrolopyrrole units in the amphiphiles upon self-assembly into micellar structures. Interestingly, in contrast with the normal formation of micelles that reaches equilibrium in a very short time, we found that DPP-11 requires a relatively long period to self-assemble, thus allowing the dynamic process to be monitored (Figure 4). Only absorption bands at around 514 and 540 nm corresponding to the monomer absorption exist at the beginning. The monomer absorption becomes weaker and weaker over time and concomitantly the absorption band of the aggregate around 601 nm appears and then becomes greater and greater, thus indicating the formation of micelles and the increase in their numbers. There is an isosbestic point around 560 nm. Figure 4b shows that the absorption change of DPP-11 almost reaches a plateau after about 10 minutes, thus suggesting an equilibrium situation.

To determine whether the aggregation is temperature-dependent in solution we carried out systematic experiments of the variation of the UV/Vis spectrum with temperature. As shown in Figure 5, the UV/Vis absorption experiment indeed shows that the aggregate can disassemble as the temperature increases and reassemble as the temperature decreases. The increase and decrease of the characteristic absorption bands of the aggregates (601 nm) and monomers of the DPP-11

molecules (514 nm) show aggregation is a reversible process. At the same time, the reversible phenomena also indicate the DPP-11 molecules experience self-assembly through supramolecular interactions.

The micelles formed in aqueous solution could be adsorbed on freshly cleaved mica sheets and visualized by ex situ atomic force microscopy (AFM). As exhibited in Figure 6, DPP-11 forms disklike micelles with diameters

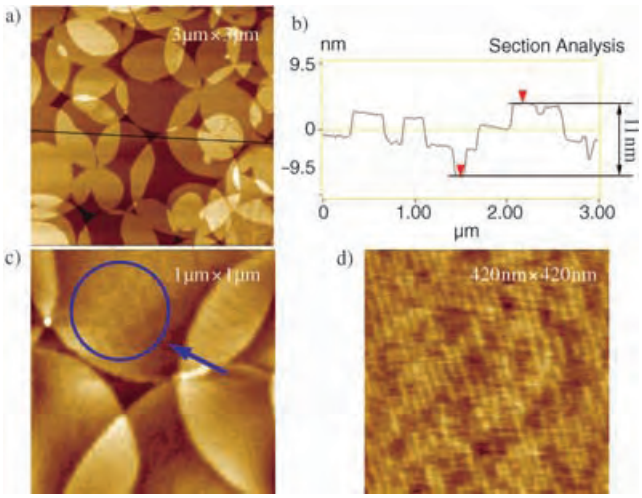

Figure 6. Ex situ AFM images of DPP-11 micellar structures adsorbed on a mica sheet: a) large area image; b) section analysis of (a); c) and d) magnified images.

ranging from several hundreds of nanometers to one micrometer. Adjacent disklike micelles partially overlap, and the overlapping parts stack together to form double layers, triple layers, or even multilayers. The section analysis (Figure 6b) shows that the disk has an average thickness of about 3.7 nm. This value agrees well with the length of a single DPP-11 molecule, thus suggesting that the disks form a monolayer structure with the thickness of a single molecule. Although the self-assembly of the amphiphiles is mainly driven by the hydrophobic effect, once the disklike micelle forms, the π–π stacking interaction becomes another dominating factor that enhances the stability of the disks. This is the reason why we can readily observe the micellar structure by ex situ AFM: the micellar structure formed in this way is stable enough toward the drying process. When looking more closely at the disks we found that there were uniform stripes with a width of about 10 nm (Figure 6c, d). These stripes have a preferred orientation within one disk, although the orientation can be different in different disks. Thus, the surface disklike micelle is a combination of micro- and nanostructures, which can be explained in terms of a compromise between the different intermolecular interactions. The intermolecular π–π stacking in the middle part of the aggregate forces the molecules to pack closely, while the repulsive interaction of the positively charged head groups has the reverse effect. We believe that the repulsion between the charged head groups may be enhanced as a consequence of water evaporation during the drying process. A compromise between these two types of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

interaction could lead to crystallization of the amphiphiles, which is responsible for the formation of the observed stripelike structure.

The disklike micellar structure in the dry state as revealed by ex situ AFM should also reflect its associated structure in solution. This speculation is supported by the following experimental facts. First, in situ AFM studies demonstrate the presence of similar disks as those observed by ex situ AFM, thus excluding the possibility that the disks are formed during the air-drying process. Second, the disks can also be observed when adsorbed onto hydrophilic quartz slides. This fact indicates that formation of the disks is not induced by the mica substrate, and that the disklike micelles formed in the aqueous solution are robust enough to resist the effect of the substrate. Third, the UV/Vis absorption bands for the adsorbates on both a mica sheet and quartz slide are almost the same as that for the micellar suspension, which indicates the micelles are resistant to the transferring and drying processes. Fourth, the enhanced stability is also supported by AFM studies at elevated temperature. The disks undergo no apparent changes until the substrate is heated to 80 °C, after which they gradually melt as the temperature is further increased.

In addition, an appropriate length of the flexible spacers is also necessary for such bolaamphiphile to self-organize into the disklike micellar structure. We performed similar studies on DPP-7 and DPP-15, but failed to obtain self-assembled structures for these two bolaamphiphiles where the spacers are shorter and longer than DPP-11, respectively. Neither the concentration/conductivity plot nor the UV/Vis spectra for DPP-7 show any distinct phase transition, thus indicating that this compound can not form micellar structures in aqueous solution. Analysis of the adsorbate on a hydrophilic substrate by AFM showed no regular structures were formed. The self-assembly of DPP-15 is inhibited by its poor solubility, since the increase in the spacer length decreases its solubility in water significantly.

In summary, interesting disklike micelles have been obtained by self-assembly of a novel bolaamphiphile, and the dynamics of disk formation have been investigated. The disklike micelles can maintain their monomolecule-layered structures even when being transferred to hydrophilic substrates, thus showing their high stability as a result of the introduction of a strong π–π stacking moiety into the amphiphile. Although micelles are inherently dynamic and fluid, they can be stabilized by enhancing the intermolecular interactions, thus providing a new approach for the fabrication of organic nanostructured materials.

Experimental Section

A commercial multimode Nanoscope IV AFM was used to characterize the surface structure. In situ AFM: The substrate was mounted under a liquid cell and the solution injected into the cell. After leaving the solution to stand for at least 30 minutes to reach equilibrium, it was scanned in the tapping mode. Ex situ AFM: The substrate was incubated in the solution for at least 30 minutes, before a sample was removed from the solution and air-dried. The sample was then scanned in the tapping mode. UV/Vis spectra were measured with a HITACHI U-3010 spectrophotometer. A weighed amount of DPP-11 was dissolved in a minimum quantity of methanol (a good solvent for DPP-11) and then the solution injected into a certain volume of water. The UV/Vis spectrum was then recorded immediately by capturing one spectrum every 44 s. ^{1}H NMR spectroscopic analysis (600 MHz) was performed in deuterium oxide. The substrates used in the AFM studies were commercial mica and quartz slides. Before each use, the mica was freshly cleaved, and the quartz slides treated with piranha solution (concentrated sulfuric acid and 30% H_2O_2 (7:3)) to obtain a hydrophilic surface.

The three bolaamphiphiles DPP-7, DPP-11, and DPP-15 were synthesized in an analogous way. The synthesis of DPP-11 is presented as an example. 3,6-Bis-(2-thienyl)-1,4-dioxopyrrolo[3,4-*c*]pyrrole (DPP) was synthesized as reported before.[9] 7-Bromo-1-heptanol was obtained by monobromination of 1,7-heptanediol with HBr, and 15-bromo-1-pentadecanol was prepared by cleaving ω-pentadecalactone with H_2SO_4/HBr, followed by reduction with borane·methyl sulfide complex (2 M solution in THF).

2,5-Bis-(11-hydroxyundecyl)-3,6-bis-(2-thienyl)-1,4-dioxopyrrolo-[3,4-*c*]pyrrole (**1**): 11-Bromo-1-undecanol (1.7 g, 6.8 mmol), K_2CO_3 (1 g, 7.2 mmol), and NaI (1 g, 6.7 mmol) were added to a solution of DPP (1 g, 3.3 mmol) in dry DMF (40 mL). The mixture was stirred at 60 °C for 18 h. After cooling the mixture to room temperature, it was poured into water and extracted with ethyl acetate. The organic phase was dried over $MgSO_4$ and the solvent was evaporated in vacuo. The product (0.6 g, 28%) was obtained by column chromatography (SiO_2, CH_2Cl_2). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, tetramethylsilane (TMS)): $\delta = 8.92$ (d, ^3J(H,H) = 4.2 Hz, 2H,), 7.64 (d, ^3J(H,H) = 4.2 Hz, 2H), 7.28 (t, ^3J(H,H) = 4.2 Hz, 2H), 4.07 (t, ^3J(H,H) = 7.2 Hz, 4H), 3.64 (t, ^3J(H,H) = 3.6 Hz, 4H), 1.29–1.74 ppm (m, 36H).

2,5-Bis-(11-tosyloxyundecyl)-3,6-bis-(2-thienyl)-1,4-dioxopyrrolo-[3,4-*c*]pyrrole (**2**): Tosyl chloride (TosCl; 0.6 g, 3 mmol) and 4-dimethylaminopyridine (0.6 g, 4.9 mmol) were added to a solution of **1** (0.6 g, 0.9 mmol) in dichloromethane (140 mL). The mixture was stirred at room temperature for 24 h, and then the solvent evaporated in vacuo. The product (0.16 g, 19%) was obtained by column chromatography (SiO_2, CH_2Cl_2). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.92$ (d, ^3J(H,H) = 4.2 Hz, 2H), 7.80 (d, ^3J(H,H) = 8.7 Hz, 4H), 7.64 (d, ^3J(H,H) = 4.2 Hz, 2H), 7.34 (d, ^3J(H,H) = 8.7 Hz, 4H), 7.28 (t, ^3J(H,H) = 4.2 Hz, 2H), 3.99–4.09 (m, ^3J(H,H) = 7.2 Hz, 8H), 2.44 (s, 6H), 1.29–1.74 ppm (m, 36H).

DPP-11: Dry pyridine (4 mL) was added to a solution of **2** (0.165 g, 0.17 mmol) in dry chloroform (10 mL). The solution was refluxed under nitrogen for 20 h. After cooling the mixture to room temperature, it was added dropwise to toluene (150 mL). The resulting red precipitate (0.18 g, 93%) was purified by two precipitations by adding a solution of the product in methanol to diethyl ether. ^{1}H NMR (300 MHz, DMSO, 25 °C, TMS): $\delta = 9.07$ (d, ^3J(H,H) = 6.0 Hz, 4H; 2-H, 6-H Py), 8.80 (d, ^3J(H,H) = 4.2 Hz, 2H; 3-H Th), 8.58 (t, ^3J(H,H) = 7.2 Hz, 2H; 4-H Py), 8.14 (t, ^3J(H,H) = 7.2 Hz, 4H; 3-H 5-H Py), 8.10 (d, ^3J(H,H) = 4.2 Hz, 2H; 5-H Th), 7.47 (d, ^3J(H,H) = 8.1 Hz, 4H; 2-H, 6-H Tos), 7.40 (t, ^3J(H,H) = 4.2 Hz, 2H; 4-H Th), 7.10 (d, ^3J(H,H) = 8.1 Hz, 4H; 3-H, 5-H Tos), 4.57 (t, ^3J(H,H) = 7.2 Hz, 4H; CH_2Py), 3.99 (t, ^3J(H,H) = 7.2 Hz, 4H; CH_2DPP), 2.50 (t, ^3J(H,H) = 1.7 Hz, 6H; CH_3 Tos), 1.88 (m, 4H; CH_2CH$_2$Py), 1.62 (m, 4H; CH_2CH$_2$DPP), 1.20 ppm (m, 28H; CH$_2$CH$_2$(CH_2)$_7$CH$_2$CH$_2$).

DPP-7: ^{1}H NMR (300 MHz, DMSO, 25 °C, TMS): $\delta = 9.07$ (d, ^3J(H,H) = 6.0 Hz, 4H; 2-H 6-H Py), 8.80 (d, ^3J(H,H) = 4.2 Hz, 2H; 3-H Th), 8.58 (t, ^3J(H,H) = 7.2 Hz, 2H; 4-H Py), 8.14 (t, ^3J(H,H) = 7.2 Hz, 4H; 3-H 5-H Py), 8.10 (d, ^3J(H,H) = 4.2 Hz, 2H; 5-H Th), 7.47 (d, ^3J(H,H) = 8.1 Hz, 4H; 2-H, 6-H Tos), 7.40 (t, ^3J(H,H) = 4.2 Hz, 2H; 4-H Th), 7.10 (d, ^3J(H,H) = 8.1 Hz, 4H; 3-H; 5-H Tos), 4.57 (t, ^3J(H,H) = 7.2 Hz, 4H; CH_2Py), 3.99 (t, ^3J(H,H) = 7.2 Hz, 4H; CH_2DPP), 2.50 (t, ^3J(H,H) = 1.7 Hz, 6H; CH_3 Tos), 1.90 (m, 4H; CH_2CH$_2$Py), 1.62 (m, 4H; CH_2CH$_2$DPP), 1.37 ppm (m, 12H; CH$_2$CH$_2$(CH_2)$_7$CH$_2$CH$_2$).

Nanocluster Catalysts

Benzene Formation at 70 °C by Coupling of Propylene on Supported Pd Nanoclusters**

*Ju Chou, Siyan Zhang, Shouli Sun, and Eric W. McFarland**

Reactions on supported transition metal clusters have important applications and often display unexpected reactivity when the cluster size is on the nanometer scale.[1] As reliable methods of preparing size-selected supported clusters have been developed, relationships between the preparation method, size, and/or support have become apparent, albeit poorly understood. Metal clusters can be synthesized by using micelle encapsulation, and this method has been further developed to make nanocluster powders supported on metal oxides.[2–4] The metal ions are initially dissolved homogeneously within the hydrophilic block copolymer cores of the micelle solutions, and the length and structure of the copolymers can be used to control the sizes of the clusters.[3,5] A uniform distribution of metal nanoclusters is created throughout the polymer matrix[5] and in the resulting powder catalyst.

Supported Pd clusters on metal oxides are widely used as industrial heterogeneous catalysts.[6] They are known catalysts for the hydrogenation of olefins,[7] propylene epoxidation,[8–9] and the production of hydrogen peroxide.[10] Coupling or cyclization of the alkynes acetylene[11–14] and propyne[15–16] has also been observed. The cyclotrimerization of acetylene on Pd deposited on MgO thin films or W surfaces was observed to occur at 330 K and higher, and was found to be dependent on the size and coverage of Pd nanoclusters. This coupling reaction leads to the formation of benzene through C activation on the Pd surface and end-to-end C–C coupling. Propyne has also been observed to couple to benzene on a Cu surface at 260 K in an ultra high vacuum (UHV) system.

Head-to-tail interaction of two propyne molecules takes place to produce benzene with the elimination of hydrogen.[16] Though observations of propylene coupling to form aromatic compounds on acid or bifunctional catalysts has been previously observed, these have all been attributed to radical processes that require high temperatures (> 300 °C).[17] To our knowledge, there are as yet no reports of propylene coupling to benzene on supported metal catalysts at low temperature.

In our previous investigations of propylene partial oxidation (epoxidation) on supported Au in the presence of hydrogen and oxygen, we observed traces of benzene while using Au–Pd alloys. With an increased Pd/Au ratio we observed an increase in the rate of benzene production. Herein, we describe our subsequent follow-up to the preliminary observations in which we addressed the following questions: what are the conditions under which Pd clusters supported on TiO_2 can catalyze propylene coupling to produce benzene? Is the propylene coupling reaction size-dependent? What is the mechanism involved in the formation of benzene from propylene coupling?

Three Pd nanocluster sizes were prepared in micelles of three different block copolymers respectively and supported on TiO_2 by impregnation. The powders were dried and calcined at 300 °C. The calcination procedure removed the polymer surrounding the metal cluster (observed by MS, $M_r = 44$) and partially reduced Pd^{II} to metallic Pd^0. The calcination was followed by treatment with hydrogen at 250 °C to complete the reduction of Pd^{II} to Pd^0. The final powder catalysts, Pd/TiO_2, were characterized by HRTEM (Figure 1).

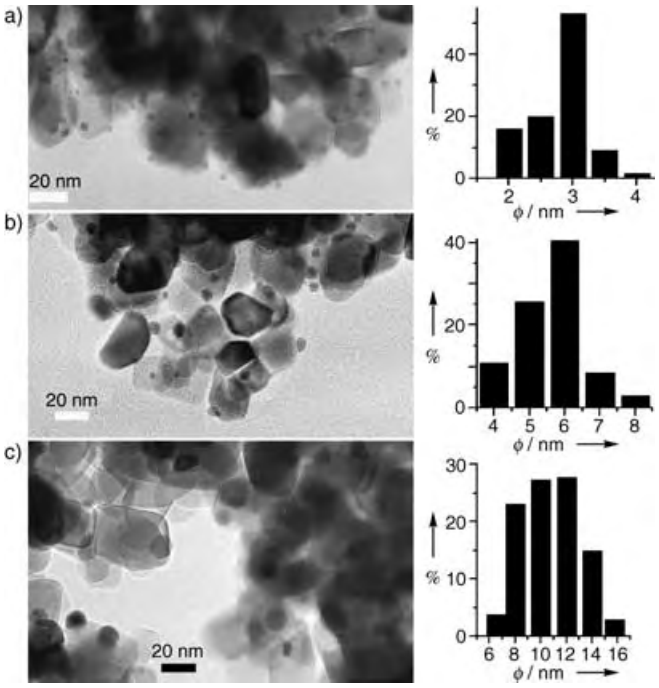

Figure 1. TEM images (left) of Pd nanoparticles prepared on titania supports from polymers with three different head sizes after calcination and reduction. Histograms (right) show the corresponding Pd size distributions obtained for: a) PS(54300)-P2VP(8800), $\varnothing = 3 \pm 1$ nm; b) PS(81000)-P2VP(14200), $\varnothing = 6 \pm 2$ nm; c) PS(53000)-P2VP(43800), $\varnothing = 12 \pm 3$ nm.

The micrographs and corresponding histograms show Pd nanoclusters uniformly dispersed on TiO_2 with a narrow size distribution. The diameters of the nanoclusters from the three different polymers were determined by HRTEM to be 3 ± 1, 6 ± 2, and 12 ± 3 nm.

X-ray photoelectron spectra (XPS) were collected with the Pd/TiO_2 catalyst to determine the Pd oxidation states before and after calcination, after reduction in hydrogen, and after the reaction. Figure 2 shows the measured Pd 3d core-level spectra of the Pd/TiO_2 ($\varnothing = 6$ nm). While still surrounded by the polymer micelle before calcination, the binding energy (E_b) of the Pd catalyst is observed as two broad peaks which are thought to be the superposition of two pairs of peaks at $E_b = 336.3$ and 341.6 eV, and at $E_b = 338.1$ and 343.3 eV. The former pair is assigned to PdO[10] and the latter ($E_b = 338.1$ and 343.3 eV) we believe corresponds to Pd^{II} bound to the CH_3COO^- groups of the micelle. Both peaks are consistent with Pd^{II}.

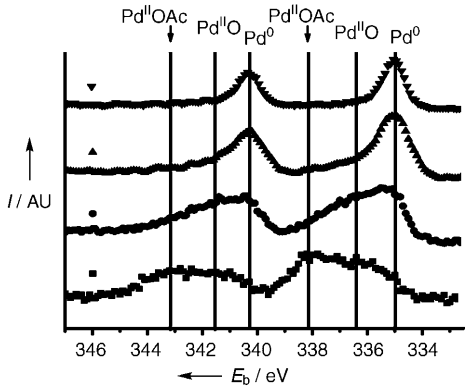

Figure 2. XPS of the Pd 3d region of the Pd/TiO_2 catalyst before calcinations (■), after calcinations (●), after reduction in hydrogen (▲), and after propylene reaction (▼).

After calcination the binding energy decreases, and two chemical states of Pd are observed. Peaks at 336.3 and 341.6 eV are still assigned to $Pd^{II}O$; however, the peaks at 335.0 and 340.3 eV are attributed to Pd^0.[18] Therefore, calcination partially reduces palladium(II) and removes the measurable polymer surrounding Pd. After reduction in hydrogen, the major peaks are at 335.0 and 340.3 eV which arise from Pd^0; a small tail of $Pd^{II}O$ remains, however.

The activity of Pd/TiO_2 in a mixture of propylene, hydrogen, and oxygen was measured in a packed bed reactor with argon as a carrier and calibration standard. The mixture was controlled by a mass flow controller at 2 mL min^{-1} for each gas with a total flow rate of 8 mL min^{-1}. The reaction products were analyzed by MS, GC, and ^{1}H NMR spectroscopy.[4,19]

Figure 3 shows the products of the reaction of propylene, hydrogen, and oxygen on Pd/TiO_2 as measured by on-line MS during a temperature increase at a rate of 2.5 °C min^{-1}. At approximately 70 °C, a rapid increase in benzene production ($M_r = 78$) was observed as well as increases in the production of species with $M_r = 44$ (CO_2 and C_3H_8), $M_r = 43$ (C_3H_8), and $M_r = 58$ (C_3H_6O). The masses of both CO_2 and C_3H_8 are 44;

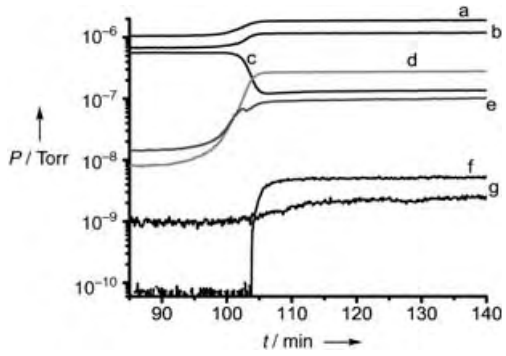

Figure 3. On-line MS data from the reaction of propylene, hydrogen, and oxygen on Pd/TiO_2 ($\varnothing = 3$ nm) as the catalyst temperature is increased from room temperature to 70 °C. Species shown and their corresponding M_r values are: a) Ar, 40; b) C_3H_6, 42; c) O_2, 32; d) ($CO_2 + C_3H_8$), 44; e) C_3H_8, 43; f) C_6H_6, 78; g) C_3H_6O, 58.

however, C_3H_8 has a unique fragment at $M_r = 43$. Therefore, the change in $M_r = 44$ results from the presence of both CO_2 and C_3H_8, whereas the signal at $M_r = 43$ is solely that of C_3H_8. The signal at $M_r = 58$ is also ambiguous and could be from the isomers acetone, propanal, or propylene oxide.

Further identification of each product was confirmed by both GC and NMR spectroscopy. On-line GC analysis shows that the products include CO_2, acetone, propane, and benzene. Finally, the reaction products were collected by a cold trap of $CDCl_3$. Figure 4 shows the ^1H NMR spectrum of

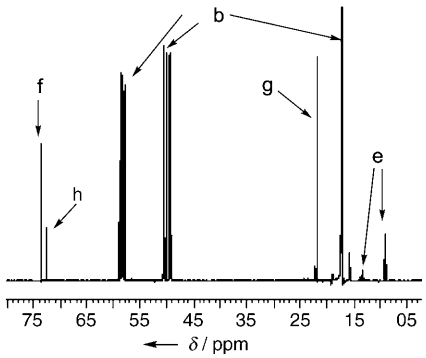

Figure 4. ^1H NMR spectrum of the products of the catalytic reaction at 25 °C on Pd/TiO_2 ($\varnothing = 3$ nm). The peaks are assigned to b) C_3H_6; e) C_3H_8; f) C_6H_6; g) C_3H_6O (acetone); h) $CDCl_3$.

collected products. The chemical shift at $\delta = 7.4$ ppm is that of benzene. Propane and acetone were also observed in the NMR spectrum (Figure 4), which is in good agreement with our analysis of the GC and MS results. For all cases in which benzene was formed, we observed that it is preceded by oxidation and hydrogenation, and is accompanied by the condensation of water at the reactor outlet.

The activities of the different Pd nanocluster sizes on TiO_2 were determined, and Table 1 shows product conversion and selectivity as a function of nanocluster size at 70 °C. Under the same experimental conditions, the 3-nm diameter Pd clusters were the most active. The selectivity for deep oxidation to carbon dioxide is inhibited on the smallest clusters, which

Table 1: Performance of TiO_2-supported Pd nanoclusters (≈1% by weight) of different sizes for the reaction of a mixture of propylene, hydrogen and oxygen.

Pd Size [nm]	T [°C]	Selectivity [%]				Conversion C_3H_6 [%]
		Benzene	Acetone	Propane	CO_2	
3	70[a]	4.9	1.7	69.5	23.9	20.3
6	70[a]	4.2	0.7	36.5	58.6	12.0
6	70[b]	4.3	0.9	19.8	75.0	33.5
12	70[a]	2.5	0.4	31.1	66.0	11.4

Reactant gas molar ratios: [a] $Ar/O_2/H_2/C_3H_6 = 2:2:2:2$. [b] $Ar/O_2/H_2/C_3H_6 = 1:3:2:2$.

favor hydrogenation, coupling, and partial oxidation. As a control, large (bulk) Pd clusters were prepared by sintering the powder catalyst to 1000 °C. The large cluster sizes were confirmed by SEM and were inactive for propylene coupling to form benzene at 70 °C; the only observed products in this case were propane and acetone.

After reaction, XPS analysis of the catalyst shows the presence of only Pd^0. To test the hypothesis that Pd^0 is required for the formation of benzene, the reaction was carried out with a Pd catalyst lacking prior reduction, leaving $Pd^{II}O$ on the surface. Under the same reaction conditions as above, benzene formation was not observed, which suggests that metallic Pd^0 is necessary for the formation of benzene.

The production of benzene requires the co-reactants oxygen and hydrogen; on Pd/TiO_2 ($\varnothing = 3$ nm) in the presence of both oxygen and hydrogen ($O_2/H_2/C_3H_6 = 2:2:2$ mL min^{-1}), benzene formation was observed. Upon replacement of hydrogen with Ar to maintain the total flow rate at 6 mL min^{-1} ($Ar/O_2/C_3H_6 = 2:2:2$ mL min^{-1}), the production of benzene and all other products (CO_2, propane, and acetone) stopped. No activity was observed at 70 °C without hydrogen.

When oxygen was absent, not surprisingly, oxidation of propylene to CO_2 and acetone stopped; however, hydrogenation to propane was observed by both MS and NMR spectroscopy. Upon returning to the original flow rates of propylene, oxygen, and hydrogen (2:2:2 mL min^{-1}) on the same catalyst, the formation of benzene was again observed.

These observations indicate that both oxygen and hydrogen are required for the production of benzene at low temperatures on the Pd clusters. The product reactions are summarized in Equations (1)–(4):

$$H_3C{-}CH{=}CH_2 + H_2 \rightarrow H_3C{-}CH_2{-}CH_3 \quad (1)$$

$$H_3C{-}CH{=}CH_2 + O_2 + H_2 \rightarrow (H_3C)_2{-}C{=}O + H_2O \quad (2)$$

$$H_3C{-}CH{=}CH_2 + 5\,O_2 + H_2 \rightarrow 3\,CO_2 + 4\,H_2O \quad (3)$$

$$H_3C{-}CH{=}CH_2 + O_2 + \frac{1}{2}\,H_2 \rightarrow \frac{1}{2}\,C_6H_6 + 2\,H_2O \quad (4)$$

For the reaction of propylene to produce benzene we tentatively propose a mechanism on the Pd cluster surface that involves H-atom abstraction that initially couples two propylene molecules. This is energetically driven by the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formation of water with C–H bond activation through an activated intermediate of the hydrogen/oxygen reaction. Figure 5 illustrates the proposed reaction cycle. The observation that benzene formation from propylene is preceded by

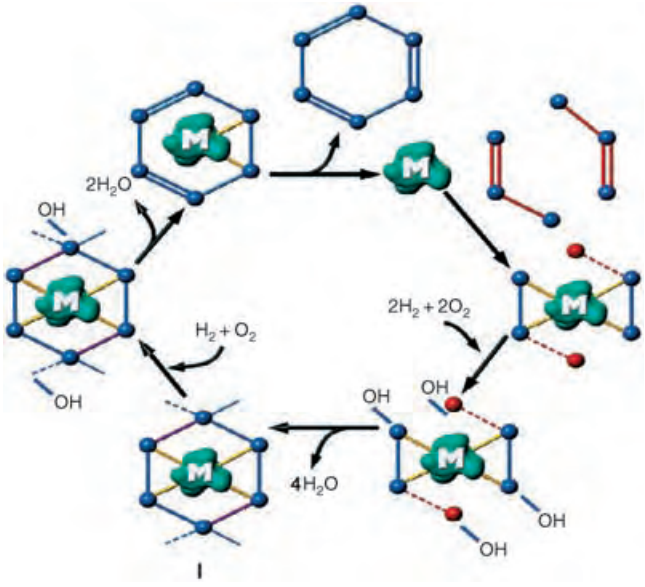

Figure 5. Mechanism of propylene coupling, leading to the formation of benzene. M represents one or more metal sites.

hydrogenation and oxidation suggests that the Pd surface is populated by hydroxy and/or peroxide species that result from the dissociative chemisorption of hydrogen and oxygen.[10,20] These species abstract a hydrogen atom from the terminal methyl group of a π-bound propylene molecule on the surface. This initial hydrogen abstraction produces a symmetric allyl intermediate[21] which then cyclizes with an adjacent allyl group to form the cyclic intermediate **I** and water. Although it is known that on a bifunctional catalyst, two allyl groups can couple to form 1,5-hexadiene as a by-product and benzene by dehydrogenation, 1,5-hexadiene products were not observed by MS. Thus, in the low-temperature Pd-catalyzed propylene coupling reaction, the cyclization apparently does not follow the conventional mechanism via 1,5-hexadiene; instead, it may proceed to form intermediate **I** (Figure 5). The mechanism of propyne coupling to form benzene via cyclohexadiene intermediates has been proposed.[16] The formation of water provides the energetic drive necessary for the removal of hydrogen. The fact that Pd nanoclusters are required for efficient low-temperature coupling suggests that either the very low coordination (giving rise to the suggested structures analogous to bis-(allyl)palladium complexes) and/or surface intermediates that are sufficiently different from the pure metal (or metal–ligand complexes previously studied) are responsible for this unusual reactivity.

Experimental Section

Block copolymers of poly(styrene)–block–poly(2-vinylpyridine) (PS-b-P2VP) of three molecular weights were used to make Pd micelle solutions.[3,17] Pd/TiO_2 catalysts were prepared by using Pd acetate with the following procedure: 50 mg block copolymer PS(x)-b-P2VP(y) (54300/8800, 81000/14200, 54000/43800, Polymer Source, Inc., Canada) was dissolved in toluene (10 mL) and stirred for 5 h. This was followed by the addition of 20 mg Pd acetate (or 16 mg for 3-nm diameter Pd) into the solution and continuous stirring for 48 h. The different Pd nanocluster sizes were obtained by changing the length of the polymer head (PS). The Pd micelle precursors were then deposited onto anatase TiO_2 (1 g, donated by Siant-Gobain) which was ground into powder and filtered by a sieve (mesh size 60). The surface area of the support was 34.8 $m^2 g^{-1}$. The solvent was slowly evaporated in air until the sample was completely dry. The dry sample (200 mg) was calcined in the mixture of oxygen and argon (20:80 *v*/*v*) at 300 °C after increasing the temperature 5 °C min^{-1} for 1 hour, after which the temperature was decreased to 50 °C. The sample was reduced at 250 °C for 30 min in the hydrogen/argon mixture (10:80 *v*/*v*). The sample was cooled to room temperature before starting the reaction studies. Bulk Pd catalyst was prepared by mixing Pd (2 mg) with TiO_2 (198 mg). The sample was calcined at 1000 °C for 4 h to form large Pd and was also reduced with hydrogen at 250 °C before the catalytic reaction.

A continuous-flow packed-bed reactor (0.6 × 30 cm) was used for the activity studies. In a typical run, the volumetric flow ratios of argon, propylene, hydrogen, and oxygen were 1:1:1:1, controlled by mass flow controllers. The total flow rate was 480 mL h^{-1}. The products were analyzed by GC (SRI 8010 A), MS (SRI), and NMR spectroscopy (Varian UNITY INOVA 400 MHz). A Porapack column was used for the separation of products. Both a thermal conductivity detector and flame ionization detector were used. For NMR spectroscopic analysis, the products were collected in a $CDCl_3$ solvent cold trap.

The Pd/TiO_2 catalysts were imaged by HRTEM (JEOL 2010FX) to determine the morphology and size of the Pd nanoclusters. The binding energies of Pd in the Pd/TiO_2 catalyst were monitored by XPS (Kratos, Axis Ultra) with a monochromated $Al_{K\alpha}$ source.

Liquid Crystal Dendrimers

Self-Assembly of Semifluorinated Janus-Dendritic Benzamides into Bilayered Pyramidal Columns**

Virgil Percec, Mohammad R. Imam, Tushar K. Bera, Venkatachalapathy S. K. Balagurusamy, Mihai Peterca, and Paul A. Heiney*

Amphiphilic dendrons that adopt the shape of a disk or disk fragment can self-assemble into supramolecular columns which self-organize into *p6mm* hexagonal or *p2mm* and *c2mm* rectangular 2D periodic assemblies.[1,2] The apex of such dendrons generates the hollow[1l] or occupied[1a–k] functional core of the supramolecular column (Figure 1 a). Twin-tapered dendritic benzamides self-assemble into supramolecular columns generated by an orthogonal hydrogen-bonded stack of dendritic benzamide units (Figure 1 b).[3] These supramolecular columns self-organize into periodically ordered *p6mm* hexagonal assemblies or co-assemble into more complex hexagonal superlattices.[3] Amphiphilic dendrons that adopt the shape of a sphere fragment can self-assemble into spherical supramolecular dendrimers, which self-organize into periodic $Pm\bar{3}n$,[1d,h,4a–4c] $Im\bar{3}m$[4d–f] 3D cubic and $P4_2/mnm$ 3D tetragonal,[4g] and quasiperiodic 3D 12-fold symmetry-forbidden liquid quasicrystals.[4h] It was recently reported that semifluorination of the conical dendron $(3,4,5)^2$12G2-CO_2CH_3 yields the crownlike dendron $(3,4,5)^2$12F8G2-CO_2CH_3 as one of the two products.[5] This

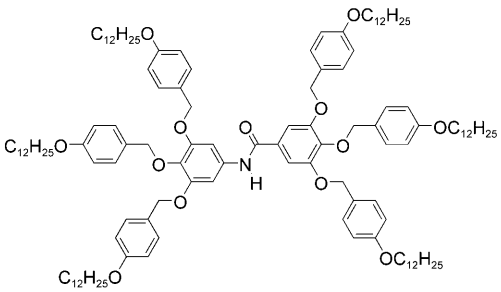
process changes the mode of self-assembly from a supramolecular sphere (for $(3,4,5)^2$12G2-CO_2CH_3) to a supramolecular pyramidal column for $(3,4,5)^2$12F8G2-CO_2CH_3 (Figure 1c). Herein, we report that semifluorination of one of the two dendrons of the twin-dendritic benzamides (that is, a benzamide containing two identical dendrons)[3b,c] changes the mode of self-assembly from a single-layer supramolecular column to an unprecedented bilayered pyramidal supramolecular column. The supramolecular pyramidal columns generated from these semifluorinated Janus-dendritic benzamides (that is, a benzamide containing two different dendrons) exhibit diameters more than twice as large as their nonfluorinated or semifluorinated twin-dendritic benzamide counterparts. Nonfluorinated Janus-dendritic benzamides continue to self-assemble like twin-dendritic benzamides.



Our study involved two nonfluorinated benzamides (3,4,5)12G1-(3,4,5)12G1-BzA **1** and (4-3,4,5)12G1-(4-3,4,5)12G1-BzA **3**, one fluorinated twin-dendritic benzamide (3,4,5)12F8G1-(3,4,5)12F8G1-BzA **2**, and a nonfluorinated Janus-dendritic benzamide (3,4,5)12G1-(4-3,4,5)12G1-BzA **4**. The synthesis, structural analysis, and mechanism of self-assembly of the two nonfluorinated twin-dendritic benzamides **1** and **3** were reported previously.[3b,c] Both **1** and **3** self-assemble into supramolecular columns by the orthogonal hydrogen-bonded stack mechanism outlined in Figure 1b. The fluorinated twin-dendritic benzamide **2** was synthesized with the procedure used for the corresponding nonfluorinated twin-dendritic benzamides[3b] (see Supporting Information). The semifluorinated twin-dendritic benzamides self-assemble into supramolecular columns by a mechanism similar to that of the nonfluorinated twin-dendritic benzamides (Figure 1b). The phase transitions for these three twin-dendritic benzamides, identified by a combination of

differential scanning calorimetry (DSC) and X-ray diffraction (XRD) experiments, are reported in Table 1. Their structural and retrostructural analysis by a combination of XRD, thermal optical polarized microscopy (TOPM), and molecular modeling experiments is reported in Table 2. Surprisingly, the nonfluorinated Janus-dendritic benzamide **4** also self-assembles into a supramolecular column by a mechanism similar to that of the twin-dendritic benzamides (Figure 1b).

The semifluorinated Janus-dendritic benzamides (3,4,5)12G1-(3,4,5)12F8G1-BzA **5** and (4-3,4,5)12G1-(4-3,4,5)12F8G1-BzA **7** were synthesized from dendrons with identical structures, except one is semifluorinated and the other has hydrogenated alkyl groups on the periphery. Both dendritic benzamides self-assemble into supramolecular columns that self-organize in a *p6mm* columnar hexagonal (Φ_h) liquid crystal (LC) lattice (Table 1 and Table 2). However, the diameter of the supramolecular column self-assembled from **5** is twice that of the column self-assembled from the twin-dendritic benzamides **1** and **2**. A similar result was observed for the diameter of the supramolecular column self-assembled from **7**. The benzamide (3,4)12G1-(3,4,5)12F8G1-BzA **6** self-assembles into a less perfect supramolecular column with a diameter approximately twice as large as that of the column generated from **2** (Table 1 and Table 2). The less perfect supramolecular column produced by **6** self-organizes in a columnar nematic mesophase.

The XRD and TOPM textures of the columnar hexagonal lattices generated from nonfluorinated twin-dendritic benzamides are compared with those of semifluorinated Janus-dendritic benzamides in Figure 2 and Figure 3. Electron density calculations were performed to elucidate the origin of the difference between the diameters of the supramolecular columns self-organized from twin- and Janus-dendritic benzamides.

The Janus-dendritic benzamide **4**, which contains hydrogenated aliphatic chains, shows a strong and a very weak reflection in the XRD pattern recorded at 70 °C. The *d* spacings of these reflections are 27.4 Å and 15.9 Å, respectively (Table 2). The ratio of these *d* spacings is 1.72:1, which is very close to $\sqrt{3}$. This ratio demonstrates a Φ_h phase that exhibits only (10) and (11) reflections. Furthermore, these reflections give a column diameter of 31.7 Å. This is

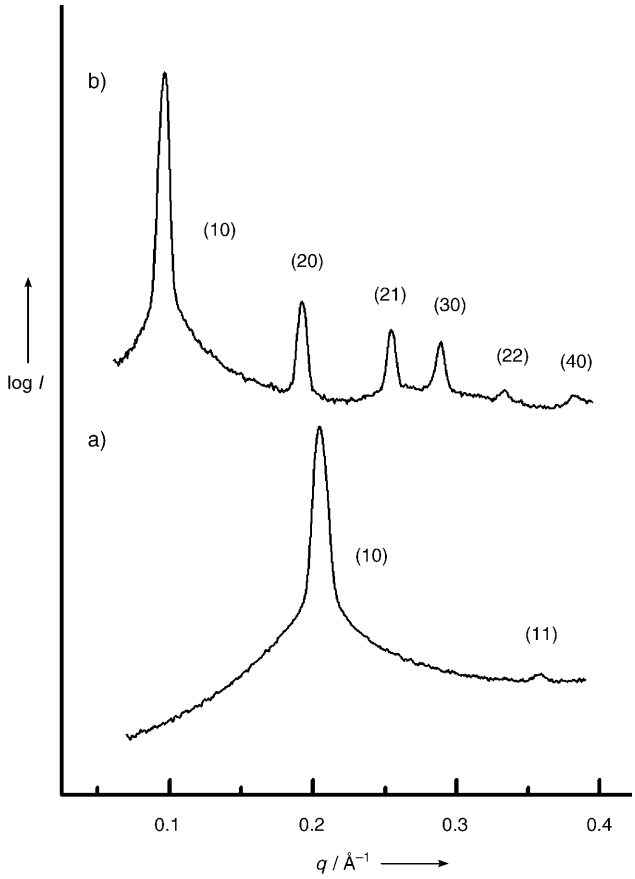

Figure 2. XRD pattern in the Φ_h phase of a) **3** and b) **7**. In b), the observed peaks shift to larger *d* spacings, which leads to a greater than twofold increase in column diameter.

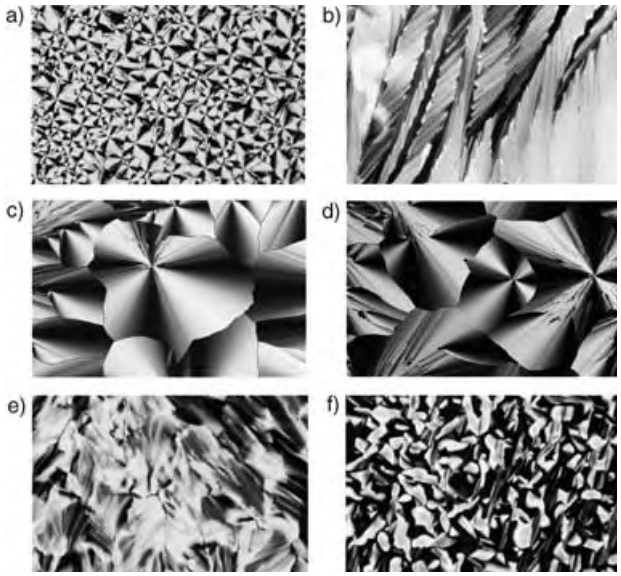

Figure 3. Representative TOPM textures of the hexagonal columnar (Φ_h) mesophase, obtained by cooling at a rate of 1 °C min^{-1} from isotropic phase of a) **1**; b) **2**; c) **3**; d) **4**; e) **5**; and f) **7**.

smaller than that of the twin-dendritic benzamide **3** (a = 34.1 Å, Figure 2a and Table 2), which forms an orthogonal stack of dendrons in its supramolecular column.[3c] However, the column diameter of the Janus benzamide **4** (a = 31.7 Å) is larger than that of the supramolecular column generated from the twin benzamide **1** (a = 25.3 Å).[3b] This indicates that the nonfluorinated Janus-dendritic benzamide **4** forms an orthogonal stack of dendrons in the column of its Φ_h phase that is similar to those of the columns self-assembled from nonfluorinated twin-dendritic benzamides **3** and **1**.

The twin-dendritic benzamide **2**, which contains only semifluorinated aliphatic chains, shows four reflections in the XRD pattern at 78 °C. They are indexed to the (10), (11), (20), and (21) peaks of a 2D Φ_h phase generated from columns with a diameter of 33.2 Å (Table 2). This diameter is substantially larger than that of the nonfluorinated twin-dendritic benzamide **1**. However, the column diameter is close to that of the supramolecular column of the nonfluorinated Janus-dendritic benzamide **4**, evidence that its corresponding supramolecular column is constructed from an orthogonal stack of building blocks.

The semifluorinated Janus-dendritic benzamide **7**, which contains hydrogenated aliphatic chains in one dendron and semifluorinated aliphatic chains in the other, forms a Φ_h phase above 137.3 °C. The X-ray diffraction pattern at 150 °C shows the reflections (10), (20), (21), (30), (22), and (40) that index to a 2D Φ_h lattice with a column diameter of 75.0 Å (Figure 2b). This column diameter is about 2.2-fold larger than that of the twin-based column of **3** (a = 34.1 Å), suggesting that in the semifluorinated Janus column, the fluorinated aliphatic regions do not mix with the hydrogenated aliphatic regions as a result of a fluorophobic effect.[6] If they mixed, they would generate only an orthogonal stack with a column diameter expected to be very close to that of the nonfluorinated Janus-dendritic benzamide **4**. Similarly, the semifluorinated Janus-dendritic benzamide **5** self-assembles into a supramolecular column with a column diameter of 59 Å (Table 2), which is 2.3-fold larger than that of the corresponding nonfluorinated twin-dendritic benzamide, **1** (a = 25.3 Å). These results suggest that the semifluorinated Janus-dendritic benzamides **5** and **7** self-assemble into a bilayered disc or crown in which the semifluorinated regions are segregated from hydrogenated aliphatic regions, with the aromatic part of the molecules occupying the intermediate region between the core and the periphery. The disc or crownlike aggregate generates the supramolecular column. This arrangement contrasts with the orthogonal stack formed by nonfluorinated or semifluorinated twin-dendritic benzamides and by nonfluorinated Janus-dendritic benzamides.

Electron density profiles were computed with the aid of the integrated intensity data calculated from the X-ray diffraction peaks obtained in the Φ_h phase to visualize the molecular organization of the dendrons in various supramolecular columns (Figure 4).[4a] The XRD of the nonfluorinated Janus benzamide **4** in the Φ_h phase shows a very strong (10) peak and a very weak (11) peak that are expected from the orthogonal stacks formed by these molecules.[3c] The electron density profile computed with the phase choice "+ −" for these two reflections exhibits a maximum in the core. The maximum electron density of the core decreases towards the periphery of the column, becoming almost constant on the periphery (Figure 4a). This variation of the electron density

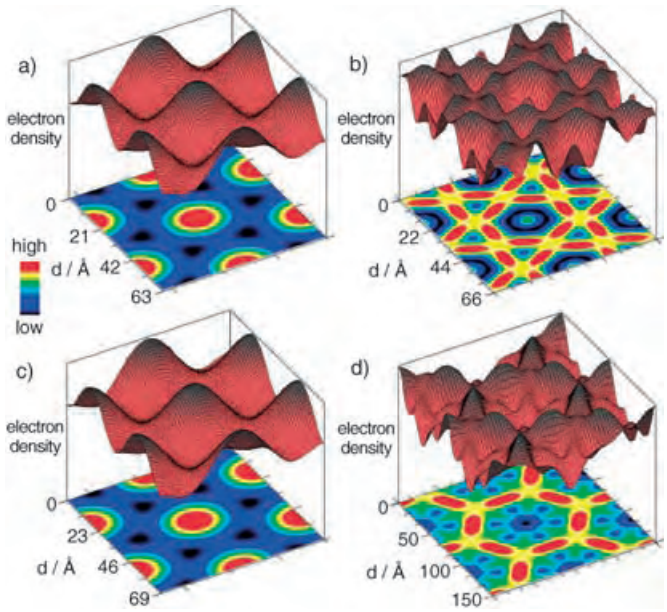

Figure 4. Electron density profiles and contour plots of the twin- and Janus-dendritic benzamides a) **4** showing the center of the supramolecular columns with high electron density (red) due to the aromatic parts; b) **2** with high electron density (red) in the periphery of the columns which corresponds to the semifluorinated aliphatic chains, and the low electron density (black), which corresponds to the hydrogenated aliphatic chains; c) **3** showing the center of the supramolecular columns with high electron density (red), which corresponds to the aromatic parts; and d) **7** with high electron density (red) in the periphery of the columns which corresponds to the semifluorinated aliphatic chains.

profiles is consistent with the nanophase segregation expected in these systems.[1c,d,4a] The maximum and the surrounding high electron density regions correspond to the aromatic portion of the molecules, and the near-constant peripheral regions represent the aliphatic part of the molecules from the orthogonal stack of the twin-dendritic benzamides. Similar electron density profiles were observed for the supramolecular columns self-assembled from the twin-dendritic benzamide **1**.

The semifluorinated twin-dendritic benzamide **2** shows additional reflections in the Φ_h phase that correspond to a strong (10) peak, a moderately strong (21) peak, a very weak (20) peak, and a weak (11) peak. The observation of a moderately strong (21) peak rather than a sequence of higher order peaks with decreasing intensity suggests that the semifluorinated aliphatic chains of the molecules occupy the peripheral regions of the columns. The electron density profiles computed with the phases "$- - + +$" for the peaks (10), (11), (20), and (21), respectively, show high and nearly constant electron density regions on the periphery of the columns (Figure 4b). They also show an intermediate electron density region near the core of the columns that corresponds to the aromatic portions. As one moves toward the periphery from the aromatic regions of the column, the electron density reaches a minimum and then rises toward the semifluorinated regions on the periphery. The regions surrounding the minima in the electron density correspond to the hydrogenated aliphatic part of the molecule. Notably, the electron density profile is similar to that observed in the Φ_h phase of a pyramidal columnar supramolecular dendrimer with semifluorinated aliphatic chains that was reported previously.[5a]

The electron density profiles of the twin-dendritic benzamide **3** is shown in Figure 4c. These profiles show maximum electron density in the center of the columns corresponding to the aromatic regions and low electron density corresponding to the aliphatic region in the periphery. The semifluorinated Janus-dendritic benzamide **7** shows the reflections (10), (20), (21), (30), (22), and (40). Whereas the peak with the strongest intensity is (10), the intensities of (20) and (30) peaks are higher than that of the (21) peak (Figure 2b). This is consistent with the semifluorinated aliphatic chains occupying the peripheral region of the column. Accordingly, the electron density profiles for the phases "$- + - - + -$" has high electron density in the peripheral region of the column and low electron density in the central region of the column (Figure 4d). Starting from the center of the column, the electron density increases from the lowest value to a small local maximum that corresponds to the aromatic part of the molecules. As one moves closer to the periphery from the aromatic region, the electron density decreases slightly owing to the hydrogenated part of the semifluorinated aliphatic chains. Therefore, the electron density profiles are consistent with the bilayered columnar structure containing the hydrogenated aliphatic chains in the core and the semifluorinated aliphatic chains in the periphery with the aromatic part occupying the intermediate region. Molecular models of the bilayered supramolecular columns obtained from small- and wide-angle XRD of oriented fibers are shown in Figure 5,

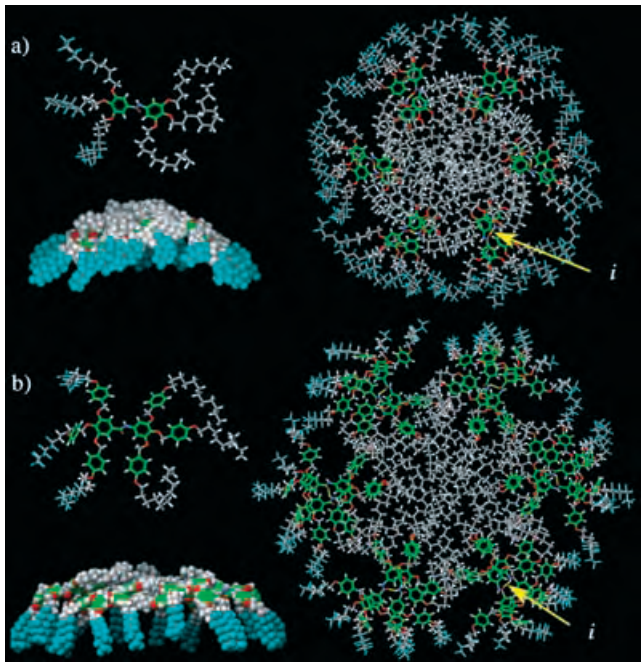

Figure 5. Structures of a) **5** and b) **7**. Top left: single dendron with the semifluorinated tails in blue; bottom left: space-filling side view of one crownlike layer; right: top view of two consecutive crownlike layers (*i* indicates the hydrogen bonding between layers).

Figure 6, and Figure 7. These models illustrate the location of the nonfluorinated alkyl chains in the central region of the column and the perfluorinated regions in the periphery of the column. Nonorthogonal hydrogen bonding is available in the crownlike stratum of the pyramidal column (Figure 5 and Figure 6). *N*-methylation of the –NH– groups of the Janus-dendritic benzamides almost destroys the pyramidal columnar assembly. The *N*-methylated Janus-benzamide derivative **5** displays a monotropic crystalline *p2mm* simple rectangular phase before melting at 67 °C (see Supporting Information). The crystals of its precursor benzamide **5** melt into a Φ_h phase at 106 °C, followed by isotropization at 157 °C (Table 1). The behavior of the latter demonstrates that hydrogen bonding is responsible for the formation of the LC phases of the Janus-dendritic benzamides.

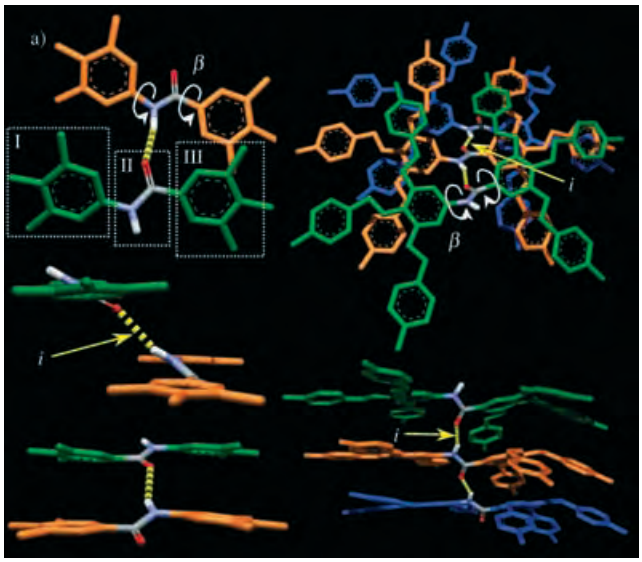

Figure 6. Hydrogen-bonding details for Janus benzamides a) **5** and b) **7**; only the aromatic regions are shown, with each dendron molecule colored differently. The formation of hydrogen bonds (*i*) requires a benzamide torsion angle (β) of about 30°, as the layer spacing is approximately 4.5–5.0 Å. Top left: dihedral angles between planes I and II, approximately 30°; between planes II and III, approximately 30° (Ref. [7]); and between planes I and III, 0°. The dihedral angle between planes I and III was chosen to be 0° instead of 62.6°, as reported in Ref. [7], to decrease the steric constrains and to facilitate better packing.

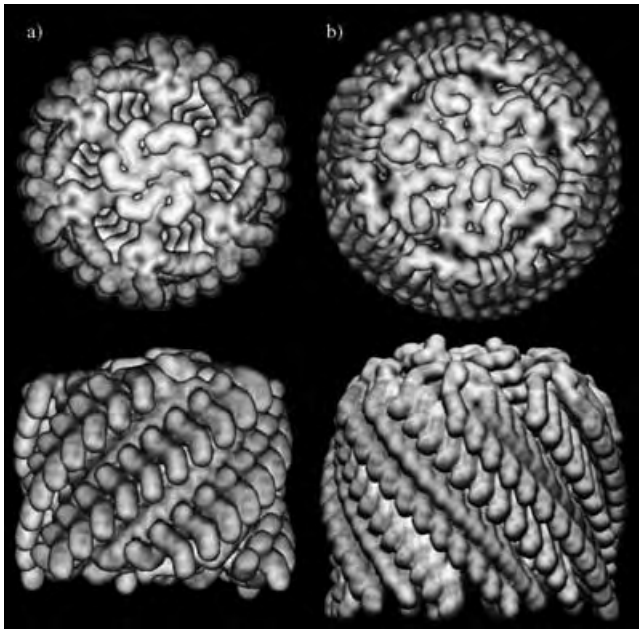

Figure 7. Supramolecular assembly models of a) **5** and b) **7**, indicating the higher electron density on the semifluorinated periphery and the short-range helical order of the supramolecular assembly.

In conclusion, the selective attachment of nonfluorinated aliphatic chains on one dendron and semifluorinated aliphatic chains on the other dendron of the twin-tapered dendritic benzamides generates semifluorinated Janus-dendritic benzamides. These, in turn, self-assemble into supramolecular pyramidal columns that exhibit diameters more than double those of the columns generated from nonfluorinated or semifluorinated twin-dendritic benzamides. This new mode of self-assembly of the semifluorinated Janus-dendritic benzamides results from the tendency of the semifluorinated aliphatic chains to segregate from the hydrogenated aliphatic chains. Aside from providing an unusual example of the fluorophobic effect in self-assembly[8,9] and the second example of supramolecular pyramidal dendrimers[5a,b] self-assembled from supramolecular crowns, this novel bilayered supramolecular pyramidal columnar structure opens numerous new strategies for the construction of complex supramolecular nanosystems.[2m,n,10] This initiates a new direction in the area of Janus-derived supramolecular liquid crystals,[2h,i] complements pyramidal mesophases generated from covalent crownlike molecules,[11] and raises the question about the generality of this concept.

Microporous Materials

High H_2 Adsorption in a Microporous Metal–Organic Framework with Open Metal Sites**

Banglin Chen, Nathan W. Ockwig, Andrew R. Millward, Damacio S. Contreras, and Omar M. Yaghi**

Metal–organic frameworks (MOFs) are a rapidly growing class of porous materials that are studied for their amenability to design[1] and extraordinary permanent porosity.[2] The recent discovery that MOFs take up significant amounts of

hydrogen has further intensified research in this area.[3] In particular, the focus remains on identifying strategies for designing MOFs with high hydrogen-storage capacities. We have already found that both the metal-oxide units and the organic links are important features for hydrogen binding,[3a,d] and that interpenetrating MOFs take up more hydrogen than their noninterpenetrating counterparts.[3d] In this report, we highlight the synthesis and structure of a MOF (named MOF-505) based on the NbO topology which has two kinds of pores, open metal sites, permanent porosity, and a high capacity for hydrogen adsorption.

We have previously synthesized MOFs with $Cu_2(CO_2)_4$ "paddle-wheel" units, and illustrated their use in the design of 0-periodic discrete[4] and 3-periodic extended structures.[5,10] MOF-505 was synthesized under analogous conditions: the solvothermal reaction of 3,3′,5,5′-biphenyltetracarboxylic acid (H_4bptc; 25 mg, 0.076 mmol)[6] and $Cu(NO_3)_2{\cdot}(H_2O)_{2.5}$ (52 mg, 0.22 mmol) in *N*,*N*-dimethylformamide (DMF)/ethanol/H_2O (3:3:2 *v*/*v*/*v*) at 65 °C for 24 h gave green, block-shaped crystals (47 mg, 86 % yield based on H_4bptc). The compound was formulated as $[Cu_2(bptc)(H_2O)_2(dmf)_3(H_2O)]$ by elemental microanalysis[7] and single-crystal X-ray diffraction studies.[8]

The $Cu_2(CO_2)_4$ unit is a square secondary building unit (SBU; Figure 1 A) that is defined by the carboxylate carbon atoms, and the $bptc^{4-}$ unit is a rectangular SBU that is defined by the 3, 3′, 5, and 5′ carbon atoms (Figure 1 B). The carboxylate functionalities of the $bptc^{4-}$ ligand are nearly coplanar with the biphenyl rings (the dihedral angle between the carboxylate group and the phenyl ring is 7.4°).[2] Thus, when the square SBUs are linked to the biphenyl rings, they must be mutually orthogonal (Figure 1 C), an aspect that is the hallmark of the NbO topology.[9,10] The crystal structure of MOF-505 (Figures 1 D and E) clearly shows that the link has predisposed the inorganic square SBUs at nearly 90° angles (94.4°) to the organic rectangular SBUs. This arrangement yields an overall 3-periodic network which has two kinds of pores. The first of these pores is defined by six inorganic SBUs (representing the faces of a cubic NbO subunit) with a spherical volume of 290 Å^3 and a pore diameter of 8.30 Å (Figures 1 D and F), while the second, and larger, pore is defined by six organic SBUs (again representing the faces of a cubic NbO subunit) and has a solvent-accessible void of 540 Å^3 with a pore diameter of 10.10 Å (Figures 1 E and G).[11] These roughly spherical pores are arranged in a rhombohedrally distorted CsCl-type fashion with the small pores surrounded by eight large pores, each of which is also surrounded by eight small pores. There are a total of six pores (three large and three small) per unit cell, which are coupled through an interconnected porous network of 6.70 Å diameter apertures. This provides a total accessible free volume of 2713 Å^3 (37.1 %).[11,12]

Thermal gravimetric analysis (TGA) and powder X-ray diffraction (PXRD) patterns were used to evaluate the framework stability under solvent-exchange conditions. PXRD reveals the same pattern of intense diffraction lines in each of the simulated, as-synthesized, and acetone-exchanged materials (see Supporting Information). However, upon desolvation of the exchanged material, decreased

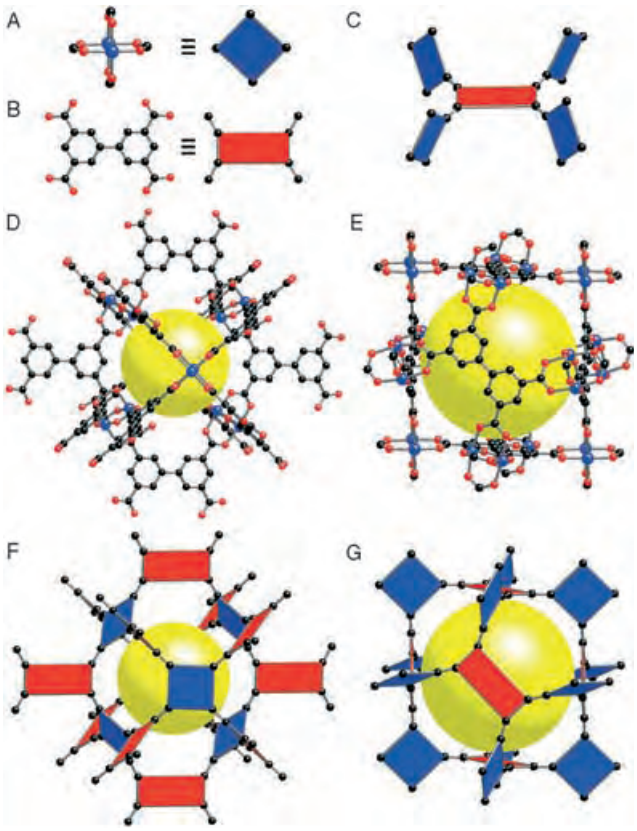

Figure 1. The single-crystal X-ray structure of MOF-505 showing A) $Cu_2(CO_2)_4$ units (blue, square SBUs) and B) $bptc^{4-}$ units (red, rectangular SBUs) that are C) orthogonally joined. The overall 3-periodic crystal structure (D, E; Cu blue, C black, O red, and the yellow sphere represents the largest sphere that would occupy the cavity without contacting the interior van der Waals surface) has two different types of pores and an underlying NbO-type net (F, G). Hydrogen atoms, guest molecules, and terminal solvent molecules have been omitted for clarity.

diffraction intensities and broadened reflections were observed in the PXRD pattern. This indicates some loss of long-range order but not necessarily loss of porosity, as detailed below. To examine the thermal stability of MOF-505 and estimate the temperature of desolvation we conducted a TGA study: the weight loss of 30.83 % below 250 °C corresponds to the liberation of 2.5 acetone molecules and three water molecules per Cu_2bptc formula unit (calcd: 30.53 %).

To evaluate whether the framework structure is maintained upon evacuation of the pores, we obtained the gas sorption isotherms using a Cahn C-1000 microgravimetric balance to measure the change in mass of samples suspended within a glass enclosure under a chosen gas atmosphere. The as-synthesized MOF-505 crystalline sample was activated by immersion in acetone for 72 h (3 × 50 mL for 24 h each) to exchange the dmf guests. The resulting damp, blue-green solid (617 mg) was loaded into the apparatus and evacuated ($<10^{-3}$ Torr) in three stages (I–III), with both weight loss and color changes being recorded (stage I: 15 h at room temperature (weight decreased to 358 mg, 42.0 % weight loss, light blue); stage II: heating at 70 °C for 15 h (weight

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

decreased to 325 mg, 5.3% weight loss, dark blue); and stage III: a final dehydration at 120°C for 12 h (weight decreased to 296 mg, 4.7% weight loss, purple)), to leave the evacuated sample. Nitrogen and hydrogen isotherms were obtained at each of these activation stages (I–III) as elaborated below. To ensure complete removal of all volatile contaminants from the system, the gas manifold was evacuated overnight and heated to 100°C prior to the introduction of gas. The system was purged three times at room temperature with the gas to be studied (ultra-high-purity grade, 99.999%) before cooling to 77 K with liquid nitrogen. The sample temperature was monitored by a thermocouple suspended in close proximity to the sample. Pressures were measured with two MKS Baratron 622 A pressure transducers (10 and 1000 Torr, accuracy $\pm 0.25\%$ of range). The gas was introduced incrementally and data points were recorded when no further change in mass was observed (< 0.02 mg per 10 min). An empirical buoyancy correction was applied to all data points based on the buoyancy experienced by standard aluminum foil weights within the pressure range of the gas at 77 K.

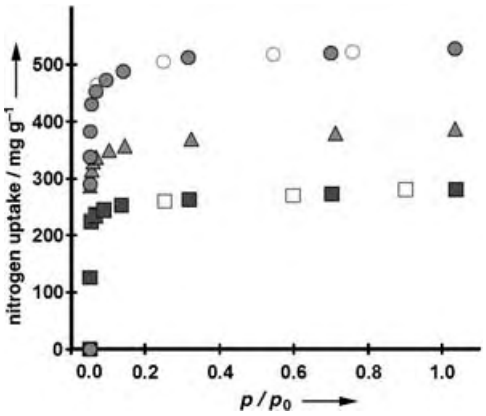

Figure 2. N_2 isotherms for MOF-505 (77 K) after three different activation stages: stage I (25°C, squares), stage II (70°C, triangles), and stage III (120°C, circles); filled shapes indicate adsorption and open shapes indicate desorption data points.

Nitrogen sorption by this material clearly shows reversible type-I isotherms at each of the activation stages (Figure 2), indicative of permanent porosity. At stage I (25°C), an uptake of 278 mg g^{-1} is achieved, with an equivalent Langmuir surface area (A_s) of 967 m^2 g^{-1}, and $K_{N_2} = 0.193$ for a 16.2 Å^2 molecular cross-section. Assuming liquid-nitrogen density (0.808 g cm^{-3}) in the pores, extrapolation of the Dubinin–Radushkevich equation[13] from the low-pressure data points yields an available micropore volume (V_p) of 0.33 cm^3 g^{-1}. Further evacuation of the pores (stage II) removes an additional 5.3% of guests, providing a 36% greater uptake (386 mg g^{-1}, $A_s = 1343$ m^2 g^{-1}, $K_{N_2} = 0.327$, and $V_p = 0.45$ cm^3 g^{-1}) than that observed in the first stage. The fully activated material obtained after stage III shows a substantial increase in the sorption to give a final N_2 uptake of 526 mg g^{-1} ($A_s = 1830$ m^2 g^{-1}, $K_{N_2} = 0.362$, and $V_p = 0.63$ cm^3 g^{-1}). These data are summarized in Table 1.

Table 1: Sorption data for MOF-505.

Activation Stage	T [°C]	Uptake [mg g^{-1}] N_2	H_2	A_s [m^2 g^{-1}][a]	K_{N_2} [Torr^{-1}][a,c]	K_{H_2} [Torr^{-1}][a,d]	V_p [cm^3 g^{-1}][b]
I	25	278	14.1	967	0.193	0.0071	0.33
II	70	386	19.7	1343	0.327	0.0070	0.45
III	120	526	24.7	1830	0.362	0.0086	0.63

[a] Calculated from a Langmuir fit of the data. [b] Calculated by extrapolation of the Dubinin–Radushkevich equation. [c] Calculated from N_2 data. [d] Calculated from H_2 data.

The hydrogen isotherms of MOF-505 measured at 77 K at the same stages of activation are shown in Figure 3. This temperature is well above the critical temperature (33 K) for hydrogen,[14] which suggests that condensation in the pores would be unlikely and complete saturation would not be achieved without much higher pressures. The isotherms measured (0 to 750 Torr) did not show saturation; however, the maximum uptake at 750 Torr for each of the three hydrogen isotherms demonstrates similar increases in capacity to those observed in the nitrogen isotherms, with the fully activated MOF-505 adsorbing an exceptional 2.47 wt% hydrogen at 750 Torr and 77 K. This extraordinary hydrogen sorption capacity is unprecedented in previously reported MOF materials under these conditions.[3h]

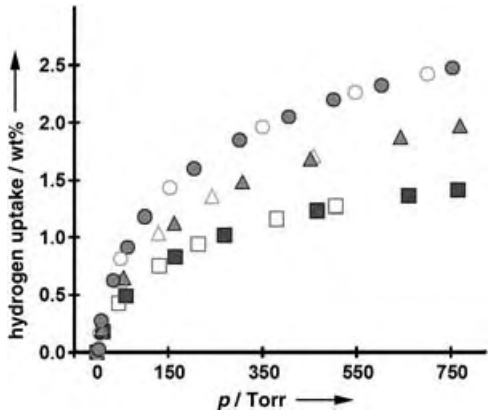

Figure 3. H_2 isotherms for MOF-505 (77 K) after three different activation stages: stage I (25°C, squares), stage II (70°C, triangles), and stage III (120°C, circles); filled shapes indicate adsorption and open shapes indicate desorption data points.

Removal of noncoordinated guests during activation has at least two positive effects on the adsorption capacity: a decrease of sample mass and an increase of available micropore volume and specific surface area. However, removal of the water ligands (bound axially to the copper centers) has the same benefits and also introduces open metal sites that we think enhance the hydrogen–framework interaction. The existence of such open metal sites in MOFs has been confirmed previously by single-crystal X-ray diffraction of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

MOF-11.[5b] Room temperature evacuation overnight (stage I) yields an initial hydrogen uptake of 14.1 mg g^{-1} (1.41 wt% H_2; Table 1). The second activation step (stage II) removes an additional 5.3 wt% (partial dehydration) and increases the hydrogen uptake by 5.6 mg g^{-1} (19.7 mg g^{-1}, 1.97 wt% H_2). Further removal of 4.7 wt% (stage III, complete dehydration) increases the hydrogen uptake capacity by an additional 5.0 mg g^{-1} to 24.7 mg g^{-1} or 2.47 wt% H_2. Upon comparison, the initial activation step (stage I, evacuation of bulk guests) shows an increase in hydrogen sorption of 0.34 mg g^{-1} per percent mass loss whereas the last two activation steps (stages II and III, dehydration with loss of six water molecules per Cu_2bptc formula unit) show a corresponding increase of 1.06 mg g^{-1} per percent mass loss during activation. Indeed, at stage I the H_2 uptake (77 K) is 14.1 mg g^{-1}, while the fully activated material (stage III) containing open metal sites displays an uptake nearly twice as high (24.7 mg g^{-1}) despite only a 10% mass loss. The lack of any hysteresis in the isotherm illustrates that this physisorption process is completely reversible, and that the presence of these open metal sites does not hamper the desorption process, nor do the pore apertures of 6.70 Å significantly hinder small-molecule diffusion through the host framework. Although there are slight curvatures in the Langmuir plots (leading to some degree of uncertainty) some insight pertinent to this specific system can still be gleaned. Increasing K_{H_2} values reveal a trend toward increasing hydrogen affinity of the fully dehydrated framework relative to the partially evacuated material (Table 1).

Although we speculate that the open metal sites have a favorable impact on the hydrogen sorption capacity of MOF-505, further experimentation is required to verify this. Another plausible explanation for the high hydrogen uptake capacity of MOF-505 is a simple correlation between specific surface area (A_s) and uptake. Similar correlations have been made for activated carbons and zeolites[15] but have yet to be established for MOF materials. In fact, we would like to specifically point out that, so far, MOF materials with very high surface areas (1000–4500 m^2 g^{-1}) do not cleanly follow this correlation.[3d] Nevertheless, we do observe that each stage of activation is accompanied by distinct changes in sample color, which is consistent with a change in the coordination environment of the metal sites as a result of the removal of terminal ligands. As-synthesized MOF-505 is blue-green and the first-stage activation changes this to light blue; further activation deepens the blue color, while the final activation step yields a deep-purple material. An activated sample exposed to ambient air for 36 h shows a dramatic color change from purple back to blue-green, with the subsequent TGA showing a loss of 18.7 wt% below 250 °C, corresponding to the loss of six water molecules per Cu_2bptc formula unit (calcd: 19.3%). Undoubtedly, two of these water molecules are axially coordinated to the paddle wheels, while the remaining four may be located in the equatorial quadrants defined by adjacent carboxylate groups of every paddle wheel.

At present, we are targeting the application of MOFs to gas sorption and selective separations in order to establish their optimal performance and to establish principles for improved inert-gas storage capacities. The unprecedented 2.47 wt% H_2 uptake of MOF-505 is an important milestone toward achieving these objectives.

Chemical Vapor Deposition

The Mechanism of Chemical Vapor Deposition of Cubic Boron Nitride Films from Fluorine-Containing Species**

W. J. Zhang, C. Y. Chan, X. M. Meng, M. K. Fung, I. Bello, Y. Lifshitz, S. T. Lee, and X. Jiang*

The unique properties of cubic boron nitride (cBN) make it an excellent material for mechanical and electronic applications. Powders of cBN were synthesized by using a high-pressure, high-temperature method[1] and films of cBN were deposited by energetic ion-assisted physical vapor deposition (PVD).[2–5] The latter technique involves two distinct stages: nucleation and growth. The nucleation of cBN is preceded by a soft incubation interlayer of, first, amorphous BN (aBN) and, second, turbostratic BN (tBN). cBN nucleates on the edges of the basal planes of tBN. Energetic particle bombardment is crucial to cBN nucleation but results in highly stressed, nanocrystalline cBN films with poor adhesion and a limited thickness, thus hindering both mechanical and electronic applications. Deposition through energetic particle bombardment is a shallow implantation ("subplantation") process,[6] that is, nucleation and growth occur at several atomic layers below the surface.[7] This process is the origin of the sp^2-bonded aBN/tBN top surface layer that covers the cBN crystallites in PVD cBN films.

Chemical vapor deposition (CVD) of diamond employs hydrogen chemistry to selectively etch sp^2-bonded carbon atoms to grow high-quality, thick films. Hydrogen does not selectively etch sp^2-bonded BN, thus attempts to grow cBN by hydrogen-based CVD methods failed.[8] However, the deposition of films of up to around 20-μm thick of cBN by fluorine-based bias-assisted CVD methods was recently reported.[9–11] Similar to the CVD of diamond, the nucleation stage of cBN requires an ion-assisted physical mechanism that involves a tBN incubation interlayer as described previously.[10] The application of fluorine-containing species for the growth stage that follows this nucleation enables a drastic decrease in the required bombarding ion energy (< 20 eV),[11] especially for the direct deposition of cBN on diamond, upon which no interlayer (no nucleation stage) forms.[12]

Herein, we show the successful development of a surface CVD growth process of cBN and outline a new mechanism initiated by the introduction of fluorine-containing species. Our study involves a combination of high-resolution transmission electron microscopy (HR-TEM) characterization of the topmost layers of cBN films, X-ray photoelectron spectroscopy (XPS) analysis of the composition of the surface of the film, and optical emission spectroscopy (OES) of the composition of the plasma. The possibility of growing cBN by a true surface CVD process and the understanding of the growth mechanism paves the way to the growth of single-crystal, electronic-grade wafers of cBN for electronic applications.

Deposition of the cBN film was performed in an electron cyclotron resonance (ECR)-enhanced microwave (MW) plasma of a $He(Ar)/N_2/BF_3/H_2$ gas mixture generated by an ASTeX 1.5 kW MW source with a magnetic field of approximately 875 G.[13] The deposition conditions were as follows: MW power, 1.4 kW; pressure, 2×10^{-3} Torr; Ar and He (plasma-processing gases) flow, 10 and 140 std $cm^3 min^{-1}$, respectively; N_2, BF_3, and H_2 (reactant gases) flow, 50, 1.5, and 3 std $cm^3 min^{-1}$, respectively. During deposition, a bias voltage of -20 to -40 V was applied to the substrate, which was maintained at about 950 °C as measured by an optical pyrometer.

We first discuss a comparative HR-TEM study of the structure of the topmost layers of two samples, A (deposited by CVD) and B (deposited by bias-enhanced radio-frequency magnetron sputtering PVD[14]). Both samples were coated with a protecting layer of gold (10-nm thick) directly after deposition of cBN. Specimens for cross-sectional TEM were prepared by the standard procedure, that is, grinding, dimpling, and final ion milling. A 200 kV field-emission TEM apparatus (Philips CM200) was used.

Figure 1 displays cross-sectional overviews of samples A (Figure 1a) and B (Figure 1b). Figure 1a (CVD sample) shows a clear interface between the cBN film and the gold layer and that the cBN and gold lattices are in direct contact; there is no amorphous interlayer. Figure 1b (PVD sample) shows a much more defective, nanocrystalline cBN structure with aBN and tBN impurities and a thin aBN top layer (indicated) that clearly covers the surface of the cBN film with a thickness of about three atomic layers.

A layer of aBN is absent from the top of the CVD cBN film, yet it is present on the film obtained by PVD. This

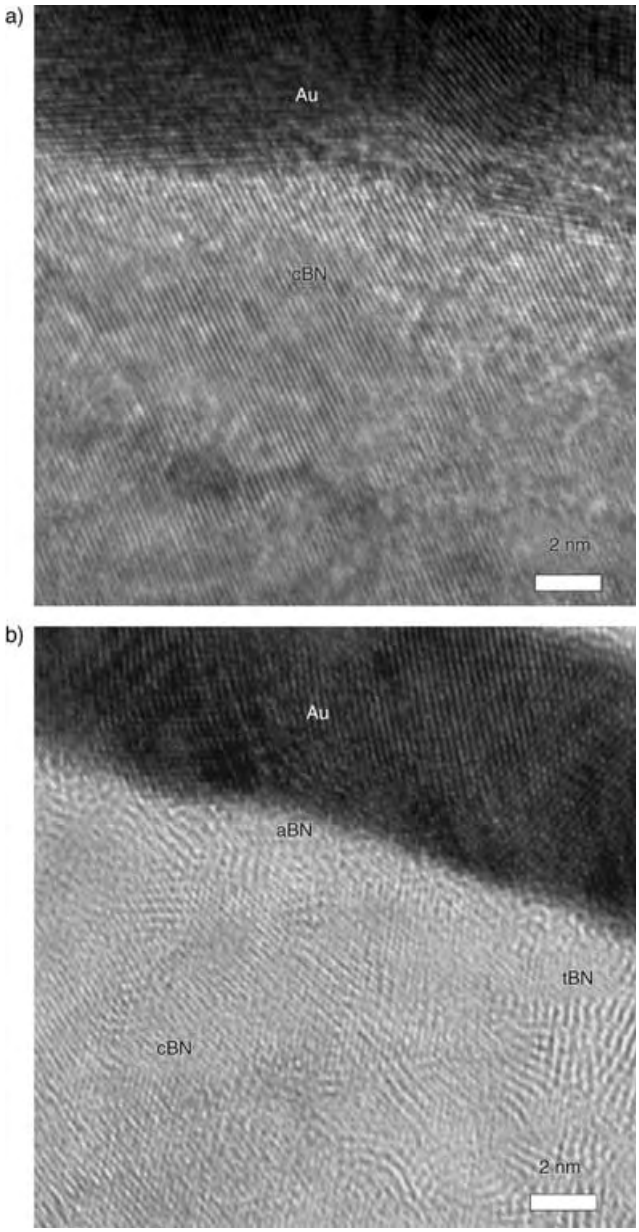

Figure 1. Cross-sectional HR-TEM image of the surface region of the film deposited by a) ECR MW CVD and b) magnetron sputtering. A gold coating on the cBN surface protects and marks the surface region.

indicates the difference between the growth mechanisms in the two deposition schemes: CVD involves a surface-growth process associated with surface etching, whereas PVD involves a subsurface growth that leads to a typical aBN skin. In accord with the TEM data, SEM images (not shown) indeed show the faceted nature of the CVD films[15] which is not observed for the PVD films. The HR-TEM data thus substantiate the conclusion that cBN growth by chemical pathways was obtained by the introduction of fluorine-containing species.

Optical emission spectroscopy of the plasma used for cBN growth reveals the reactive gas species and provides insight into the growth mechanism. The small quantity of BF_3 and H_2

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

used relative to the much larger amounts of Ar, He, and N_2 present inhibit the observation of most reactant species in the actual plasma used for cBN growth. Hence, we chose to study the composition of the $BF_3 + H_2$ plasma with different H_2/BF_3 ratios (0:1 to 5:1) instead. The study was performed by using a substrate holder made of hBN to enable the observation of hBN etching by $BF_3 + H_2$ plasma. OES of pure BF_3 plasma (Figure 2a) indicates the formation of atomic F, BF, H, and N_2

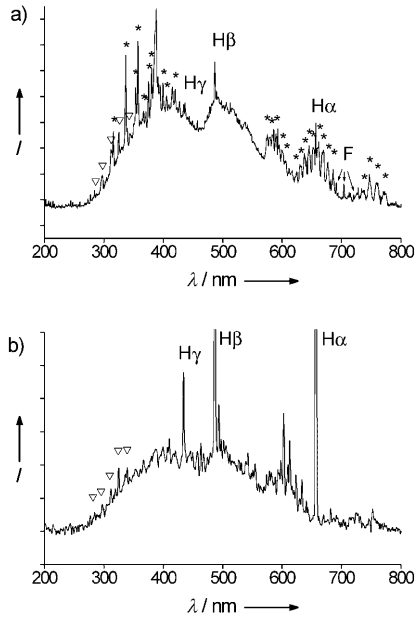

Figure 2. OES data of the plasma (impinging an hBN holder) with a gas flow of a) 5 std $cm^3 min^{-1}$ BF_3 and b) 5 std $cm^3 min^{-1}$ BF_3 and 10 std $cm^3 min^{-1}$ H_2. Emissions from N_2 (*) and BF (▽) are indicated.

clusters; F and BF clusters are expected in the BF_3 plasma. The small quantity of atomic hydrogen evident, which decreased with time, is likely to have arisen from residual H_2 released from the surfaces of the chamber. The signal corresponding to N_2 was constant with time and no N_2 was introduced into the system. The emission intensity of both N_2 and F decreased with the introduction of H_2 and finally disappeared (Figure 2b) for a gas flow rate of 5 std $cm^3 min^{-1}$ for BF_3 and 10 std $cm^3 min^{-1}$ for H_2. The signal corresponding to N_2 that followed a periodic decrease and increase of the H_2 flow rate was studied and observed only for low flow rates of H_2. This observation rules out residual N_2 in the system as the N_2 source. Therefore, the etching of the hBN substrate holder by F atoms, which are formed in pure BF_3 plasma or BF_3 plasma with low H_2 concentrations, is the only plausible source of N_2. The concentration of F atoms decreases with the introduction of H_2 as a result of the formation of HF, which seems not to react with hBN. Hence, the hBN etching (revealed by the N_2 signal) stops at a sufficiently high concentration of H_2. The etching of hBN at only low H_2/BF_3 ratios is in accord with the optimal window of the H_2/BF_3 ratio for successful cBN deposition, whereas at higher H_2/BF_3 ratios only hBN films evolve.[16] The flow rate of H_2 controls the production rate of solid BN from the gas phase, and the ratio of H to F atoms controls the equilibrium between film formation and etching.

The last observation from this OES study is the nearly constant emission intensity of the BF_x cluster with increasing hydrogen flow rates, whereas no signal pertaining to BH_x clusters could be detected. This result suggests that the growth species are clusters of BF_x rather than of BH_x. This finding from OES is consistent with the higher bond energy of the B–F bond (757 kJ mol^{-1}) relative to that of the B–H bond (340 kJ mol^{-1}). Quantum mechanical calculations indicate that B–F termination stabilizes the boron surface of cBN.[17,18] The F-terminated boron surface, however, was found by quantum mechanical calculations to be resistant to abstraction and adsorption of N-containing growth species for further cBN growth.[17,18] B–F bond breaking followed by surface abstraction and adsorption of N-containing species may be facilitated by low-energy ion bombardment, which is still needed for cBN growth from F-containing species.[9,11]

Angle-resolved XPS (VG, EscaLab 220i-XL, $Al_{K\alpha}$ radiation) of cBN films grown by the ECR system was used to gain further insight into the cBN growth process. Spectra were collected at emission angles of 10° and 90° to evaluate the elemental depth distributions, as the probing depth at 90° ($\approx$5 nm) is much larger than that at 10° ($\approx$1 nm).[19] Table 1

Table 1: Elemental concentration calculated from XPS data.

	Elemental Concentration [%]	
Emission angle	90°	10°
B	43.7	39.4
N	47.6	47.7
C	5.7	8.7
O	2.3	3.2
F	0.7	1.0

summarizes the elemental concentration of the film, which includes mainly boron and nitrogen and small amounts of fluorine, carbon, and oxygen. The B/N ratio is less than 1 and decreases from 0.92 to 0.83 with decreasing emission angle (90°→10°) thus indicating boron-deficient surfaces. The low concentration of fluorine (0.7% and 1.0% for 90° and 10°, respectively) indicates that only a small portion of the surface is terminated by F atoms. These results are in accord with the feeding gas composition of the plasma ($BF_3/N_2 = 1.5{:}50$). The high concentration of N_2 in the gas phase leads to a high probability of termination with N atoms. This point was further verified by exposing the film to a $BF_3 + Ar + He$ plasma, which lead to a significant increase of both the B/N ratio (to greater than 1:1) and the concentration of F atoms (to approximately 6%). Further exposure to $N_2 + H_2$ plasma decreased the B/N ratio and the concentration of fluorine to their initial values. Finally, the O and C atoms are mostly surface contaminants from the atmosphere as revealed by the angle-dependent XPS analysis.

We note that N_2 molecules fed to the plasma decompose to N atoms and then combine with H or F atoms. The bonding energies of N–H ($\approx$340 kJ mol^{-1}) and N–F (343 kJ mol^{-1}) are similar,[17,18] so both NH_x and NF_x clusters may exist.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

However, the low concentration of F atoms in our present XPS data ($\approx 1\,\%$) rules out the possibility of N–F termination of the cBN surface, and the results of secondary ion mass spectrometry (SIMS) of a cBN film suggest that N atoms are partly bonded to H atoms.[20] It is therefore most likely that only NH_x clusters contribute to the surface processes that lead to cBN growth. Furthermore, we note that the adsorption energy of NH_x clusters ($416\,kJ\,mol^{-1}$) is larger than that of NF_x clusters ($17\,kJ\,mol^{-1}$) on F-terminated boron surfaces.[17,18] N–H bonds are also found to be much more effective than N–F bonds in incorporating B-containing species after H abstraction, and in stabilizing and maintaining sp^3-hybridized surface atoms.[17,18]

Our experimental findings lead to the following conclusions regarding the growth of cBN through the introduction of fluorine-containing species: 1) the growth of cBN is a surface process (HR-TEM data); 2) hBN constituents are etched by F atoms in the plasma (OES data); 3) BF_x and NH_x species are responsible for the growth of cBN (OES and XPS data); 4) the cBN film surface is boron-deficient and the termination of dangling bonds by F atoms is minor (XPS data). On the basis of these conclusions, we now offer the following sequence of cBN growth from fluorine-containing species, as shown in Figure 3:

1) The excited plasma contains reactive species, namely, H, F, BF_x, NH_x, which are responsible for the etching of hBN (mainly F atoms) and cBN crystal growth (BF_x and NH_x) (Figure 3a). The cBN surface at any stage contains a large number of N atoms terminated by H atoms but a very small number of B atoms terminated by F atoms.

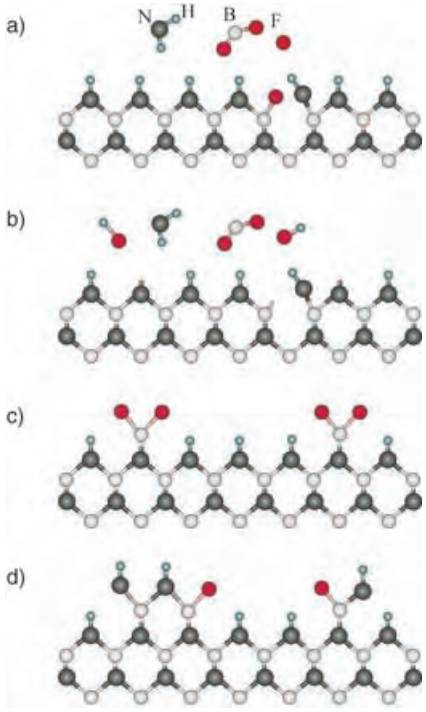

Figure 3. A proposed cBN growth sequence in fluorine-based ECR-assisted MW CVD. The growth is illustrated on a (001) surface (see text for details).

2) The cBN crystal surface is activated by surface abstraction by the impingement of plasma species, thus providing free unsaturated sites for further growth (Figure 3b). B–F bond breaking is most likely assisted by energetic particle bombardment (bias of about 20 V) while N–H bond breaking is easier.
3) B atoms are added to N-activated sites by incorporation of BF_x species, whereas N atoms are added to B-activated sites by incorporation of NH_x species (Figure 3c).
4) Each B surface site is subject to deposition by an NH_x molecule at a much higher rate than the deposition of BF_x on N surface sites (the BF_3/N_2 flow rate feeding the plasma is 1.5:50), thus leading to a B-deficient surface at any stage (Figure 3d).

Layer-by-layer growth of a cBN crystal requires the alternate deposition of B atoms on the nitrogen surface and the deposition of N atoms on the boron surface, which means (on a macroscopic scale) equal surface concentrations of B and N atoms. The surface of our ECR films is B-deficient owing to the plasma composition needed for cBN growth (BF_3/N_2 flow rate = 1.5:50). As stated above, our experimental findings support that N surface atoms are terminated by H atoms, whereas B surface atoms are terminated by F atoms. The N–H bonds of N–H terminated surface sites were found to be energetically effective in abstraction and adsorption of incoming B-containing species.[17,18] The H atom that terminates an N surface atom is abstracted by plasma F atoms to form HF and leave room for BF_x adsorption. The chemical bond strength of B–F is large, which makes it resistant to abstraction and adsorption of NH_x molecules. In our work, the breaking of B–F bonds and formation of a dangling bond needed for NH_x adsorption and further cBN growth are most likely to be facilitated by the low-energy ion bombardment of the growing surface (Figure 3b).

The high abundance of N-containing clusters in the plasma (relative to B-containing clusters) dictates that the coverage rate of each B surface atom (F terminated) by N atoms will be much larger than the coverage rate of N surface atoms (H terminated) by B atoms. This rules out the possibility of a layer-by-layer growth and leaves island formation of cBN with a major surface coverage of H-terminated N atoms as the dominant growth mechanism (Figure 3d). The hydrogen concentration in the plasma determines 1) the concentration of NH_x species (needed for growth) which increases with the concentration of H atoms; 2) the concentration of F atoms (needed for activation of H-terminated N surface atoms and for etching of noncubic BN constituents) which decreases with H concentration. This is how the hydrogen/fluorine ratio controls the deposition rate and phase purity resulting in an optimal window of the H_2/BF_3 ratio for cBN growth.[16]

In conclusion, a combination of HR-TEM, OES, and XPS studies has revealed that ECR fed by a gas mixture of $He(Ar)/N_2/BF_3/H_2$ leads to the surface CVD growth of cBN, which is fundamentally different from PVD growth by ion-assisted methods. The new data collectively support a cBN surface-growth sequence, which includes 1) formation of H, F, BF_x, and NH_x species in the plasma in which the amount of F

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

and NH_x species is balanced by the concentration of hydrogen atoms, 2) abstraction of H atoms and activation of N sites by F atoms, 3) abstraction of F atoms and activation of B sites by energetic particle bombardment, 4) growth by adsorption of BF_x (boron source) on N surfaces and NH_x (N source) on B surfaces, and 5) etching of noncubic BN phases by F atoms. The possibility to grow cBN through surface reactions with little damage from ion bombardment suggests that the growth of electronic grade, single-crystal cBN wafers is feasible (similar to electronic grade, single-crystal diamond wafers grown by CVD).

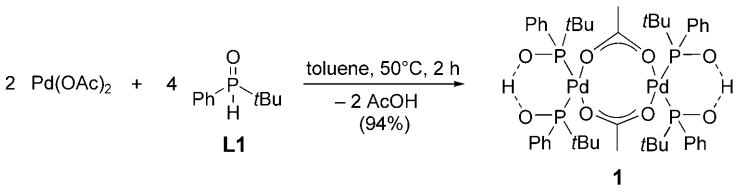
Palladium-Catalyzed Chemistry

[2+1] Cycloadditions of Terminal Alkynes to Norbornene Derivatives Catalyzed by Palladium Complexes with Phosphinous Acid Ligands**

*Julie Bigeault, Laurent Giordano, and Gérard Buono**

Secondary phosphine oxides (SPOs) have been widely used for the synthesis of tertiary phosphine oxides and have found applications as Wittig–Horner reagents[1–2] and, later, as effective ligands for transition-metal complexes.[3] Recently, Li et al. showed that SPOs form air-stable palladium complexes, such as POPd1, when they are mixed with $PdCl_2(MeCN)_2$ and then treated with Et_3N.[4] These complexes proved efficient as catalysts in several cross-coupling reactions[4–5] as well as in asymmetric allylic alkylations.[6] Recent reports showed also that these new ligands are suitable for other types of catalyzed reactions such as the hydrolysis of nitriles[7] and the asymmetric hydrogenation of imines[8] and alkenes.[9] Our continued interest in the metal-catalyzed cycloaddition reactions between alkynes and norbornadiene[10] prompted us to investigate the catalytic behavior of palladium(II) complexes coordinated by SPOs.

POPd1



First, we developed an easier way to synthesize the palladium catalyst **1**. Upon treatment of $Pd(OAc)_2$ with *tert*-butyl(phenyl)phosphane oxide (**L1**), dihydrogen di-μ-acetatotetrakis(*tert*-butylphenylphosphinito-κ-*P*)dipalladate (**1**) was quantitatively obtained without further treatment (Scheme 1).[11] Second, as a model we examined the reaction of phenylethyne (**3a**) with norbornadiene (**2**) in the presence of 2.5 mol% of **1** in toluene at 50°C for 24 h. Unexpectedly, the palladium(II) complex **1** coordinated by **L1** favored the formation of benzylidenecyclopropane (**4a**) as a single diastereomer in 17% yield (Scheme 2) and contaminated by an unidentified byproduct (5%). Surprisingly, a similar reaction using the known chloro-bridged analogue **5**[6a–12] as catalyst did not work. Furthermore, in the reaction catalyzed by **5**, the addition of 10 mol% of AgOAc (4 equiv relative to

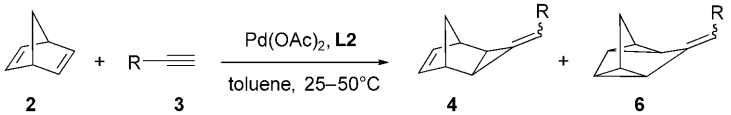
4	**L2**	25	80
5	**L3**	25	21
6	**L3**	50	58



[a] All reactions were carried out with **2**/**3a**/$Pd(OAc)_2$/**L** in a ratio of 2:1:0.05:0.1 for 24 h. [b] Yield of isolated product. Cy = cyclohexyl.

Having established the feasibility of the cycloaddition reaction, we tested various terminal alkynes **3a**–**k** to extend its applicability. Under optimized conditions, all reactions proceeded cleanly and various functional groups such as ethers, esters, alcohols, sulfones, or tertiary amines present in the alkyne were tolerated (Table 2). Propargylic alcohols **3f** and **3g**, sulfone **3i**, and tertiary amine **3j** also reacted with **2** to afford **4f**, **4g**, **4i**, and **4j**, respectively, in 57–75% yields

catalyst **5**) led to the formation of **4a** in 15% yield.[13] Even if few examples of ruthenium-[14] or palladium-catalyzed[15] cyclopropanations of norbornene derivatives with alkynes are known, a catalytic process that is able to favor the direct formation of alkylidenecyclopropanes as illustrated in Scheme 2 has, to our knowledge, not been reported. Herein, we show that palladium(II) complexes stabilized by secondary phosphine oxides are active catalysts for an unusual [2+1] cycloaddition of norbornene derivatives with terminal alkynes to produce various alkylidenecyclopropanes.

In a preliminary study, we found that the addition of 5 mol% of acetic acid was beneficial to the reaction and led to the formation of **4a** as the exclusive product in 26% yield. This finding revealed that acetate plays an important role in the reaction. Indeed, AcOH was released in the reaction medium during the formation of catalyst **1**. This observation prompted us to test the formation of catalysts in situ. Two other SPOs, **L2** and **L3**, were tested under similar conditions by generating the catalyst in situ (Table 1). The best result was observed when $Pd(OAc)_2$ was associated with **L2** (1:2 molar ratio), affording **4a** in satisfactory yield at room temperature (entry 4).[16–17] Similarly, palladium catalyst systems generated with **L1**[18] or **L3** proved active but less efficient (entries 2 and 6).

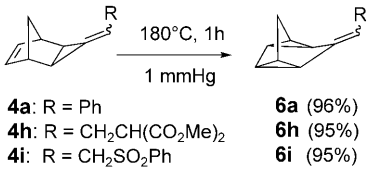
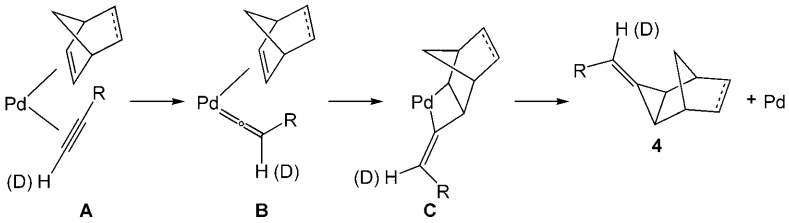
[a] Experiments were performed on a 1-mmol scale using 5 mol% of $Pd(OAc)_2$ and 10 mol% of **L2** (**2**/**3**/Pd/**L2** = 2:1:0.05:0.1). [b] Yield of isolated product. TMS = trimethylsilyl; Bn = benzyl; Mp = morpholinyl (C_4H_8NO).



(Table 2, entries 7, 8, 10, and 12). For an unknown reason, no product was obtained with propargylsilane **3c** (entry 3).[19] Likewise, with an unfunctionalized alkyne such as **3b**, the reaction was slow and conversion was very low (Table 2, entry 2). Surprisingly, an acetate group in a propargylic position such as in **3e** afforded the desired cyloadduct **4e** without formation of byproducts (entry 5).[20] A notable difference in reactivity was observed for tertiary acetates such as **3l** and **3m**. In this case, known allenylidenecyclopropanes[21] **7l** and **7m** were obtained in 27% and 64% yield, respectively (Scheme 3).

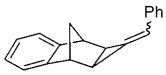
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

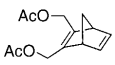
Scheme 3. Synthesis of allenylidenecyclopropanes **7l** and **7m** from tertiary acetates. Conditions: **2**/**3**/Pd/**L2** = 2:1:0.05:0.1.

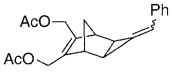


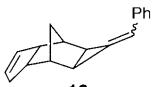
With the electron-deficient alkyne **3k** (Table 2, entry 13), the expected cycloadduct **4k** and the rearranged (valence isomerization) product **6k** were observed in 1:1 ratio in the crude reaction mixture. After purification by chromatography on silica gel, only **6k** was isolated in 56% yield. Valence isomerization proved to be effective on cycloadducts **4a**, **4h**, and **4i** under thermal conditions in the absence of solvent: heating these cycloadducts to 180 °C at 1 mm Hg resulted in clean and complete conversion after 1 h (Scheme 4).[22–23]

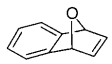
Scheme 4. Thermal rearrangements (valence isomerization) of **4**.

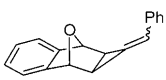












The cycloaddition reaction was extended to other norbornene derivatives by using phenylethyne (**3a**) as a partner (Table 3).[24] The cyclopropanation of alkenes **8**–**12** afforded expected benzylidenecyclopropanes **13**–**17** in moderate to good yields. The best yields were observed for norbornene (**8**) or benzonorbornene (**9**; entries 2 and 3). The cycloaddition with functionalized norbornenes gave the products in fair yields (entries 4 and 6). For cyclopentadiene dimer **11**, the cyclopropanation occurred exclusively at the most strained double bond to yield the cycloadduct **16** in 51% as a 1:1 mixture of diastereomers (Table 3, entry 5). Note the exclusive formation of cyclopropane **15** from **10** (entry 4). Indeed, diacetate **10** has been previously used in palladium(0)-catalyzed elimination[25] and alkylation[26] reactions and proceeds via an intermediate π-allyl complex.

Although the mechanism of this unusual cyclopropanation remains unclear at the moment, we assume that the reaction may involve palladium vinylidene species as key intermediates in a catalytic process that favors the formation of [2+1] cycloadducts over dimerization[27] products of alkynes (Scheme 5). Palladium vinylidene complex **B** may be generated from 1-alkyne **3**,[28,29] and **B** could allow a [2+2] cycloaddition with the double bond of the norbornene. The resulting 2-alkylidene palladacyclobutane (**C**) would release cycloadduct **4** after reductive elimination. The formation of this unprecedented Pd vinylidene complex is supported by results from deuterium-labeling experiments. Starting from monodeuterophenylacetylene [D$_1$]**3a** and **2**,

Scheme 5. A possible pathway for the palladium-catalyzed [2+1] cycloaddition of norbornadienes and alkynes. (D) denotes the proton exchanged for deuterium in labeling experiments.

under similar conditions the reaction led to compound [D$_1$]**4a** in 88% yield with 80% incorporation of deuterium on the external double bond (Scheme 5).[30] For the formation of allenylidenecyclopropanes **7l** and **7m**, the reaction is thought to proceed through a similar mechanism via a palladium allenylidene intermediate (Pd=C=C=CR$_2$).[31]

Finally, we briefly examined the interesting asymmetric version of this cycloaddition by using chiral secondary phosphine oxides (−)-**L1** and (−)-**L2** obtained by separation with chiral HPLC.[32] Indeed, alkylidenecyclopropanes synthesized from symetrical **2** showed geometrical enantiomorphic isomerism.[33–34] Preliminary results obtained are encouraging: an asymmetric induction of 59% *ee* was achieved with (−)-**L1** without optimization of the reaction conditions (Table 4, entry 1).

In conclusion, we have shown that palladium(II) complexes stabilized by secondary phosphine oxide ligands catalyze a very unique [2+1] cycloaddition of norbornene derivatives with various terminal alkynes to afford functionalized alkylidenecyclopropanes.[35–36] Moreover, our results suggest a Pd vinylidene complex as a key intermediate. A detailed investigation of the mechanism and the development

[11] With enantiopure **L1**, the complex **1** was clearly identified by NMR spectroscopy. The acetato-bridged structure was supported by the ESI mass spectrum of the palladium complex **1** (see Supporting Information).

[12] Complex **5** was prepared according to Li's procedure[4] from **L1**. As shown by ^{31}P NMR spectra and X-ray crystallography, only one diastereomeric complex was obtained which exhibits C_2 symmetry and retention of configuration at phosphorus (see Supporting Information). During the course of our work, Leung and co-workers reported chiral bisphosphinite metalloligands derived from a P-chiral secondary phosphine oxide: E. Y. Y. Chan, Q. F. Zhang, Y.-K. Sau, S. M. F. Lo, H. H. Y. Sung, I. D. Williams, R. K. Haynes, W.-H. Leung, *Inorg. Chem.* **2004**, *43*, 4921–4926.

[13] Cycloadduct **3a** was also contaminated with 5% of an unidentified byproduct.

[16] Other catalysts associated with two PPh_3 ligands such as $[PdCl\{\eta^3\text{-}(C_3H_5)\}_2]$, $Pd(OAc)_2$, and $[Pd_2(dba)_3]\cdot CHCl_3$ (dba = dibenzylideneacetone) did not promote the reaction at all.

[17] Toluene gave the best results. The [2+1] cycloaddition proceeded well in heterogeneous media in solvents such as Et_2O (74% yield), THF (59% yield), or CH_2Cl_2 (49% yield). The lowest yields were obtained with more polar solvents such as *N*,*N*-dimethylformamide (10% yield) or CH_3CN (6% yield).

[18] The catalytic system was stable under the experimental conditions described and could be recovered after the reaction by column chromatography.

[19] A difference in reactivity was observed by using trimethylsilylacetylene in place of propargylsilane **3c**: Only an adduct of hydroalkynylation was obtained as a single diastereomer in 68% yield.

[20] The reaction is probably catalyzed by a Pd^{II} catalyst. Indeed, Pd^0-catalyzed reactions of various propargylic compounds proceed by the formation of either σ-allenyl or σ-prop-2-ynylpalladium species; see: J. Tsuji, *Palladium Reagents and Catalysts: New Perspectives for the 21st Century*, Wiley, Chichester, **2004**, chap. 6, pp. 543–563; for the Pd^0- and Pd^{II}-catalyzed reactions of alkynes, see: J. Tsuji, *Palladium Reagents and Catalysts: New Perspectives for the 21st Century*, Wiley, Chichester, **2004**, chap. 7, pp. 565–599.

Biosynthesis

Mutasynthesis of Rapamycin Analogues through the Manipulation of a Gene Governing Starter Unit Biosynthesis**

*Matthew A. Gregory, Hrvoje Petkovic, Rachel E. Lill, Steven J. Moss, Barrie Wilkinson, Sabine Gaisser, Peter F. Leadlay, and Rose M. Sheridan**

Rapamycin **1**, FK506 **2**, and FK520 **3** are biogenetically related natural products which are synthesized by mixed polyketide synthase (PKS)/nonribosomal peptide synthetase (NRPS) systems and which possess potent antifungal and immunosuppressive activities. Compounds **1**–**3** possess a

1: Rapamycin

2: FK506, R =

3: FK520, R = Et

common structural motif which is responsible for their specific binding to FK506-binding proteins (FKBPs). This binding triggers the subsequent binding of the binary complex to a downstream protein target, either mTOR (mammalian target of rapamycin) or calcineurin (FK506, FK520) which mediate their biological effects.[1] Inhibition of mTOR by

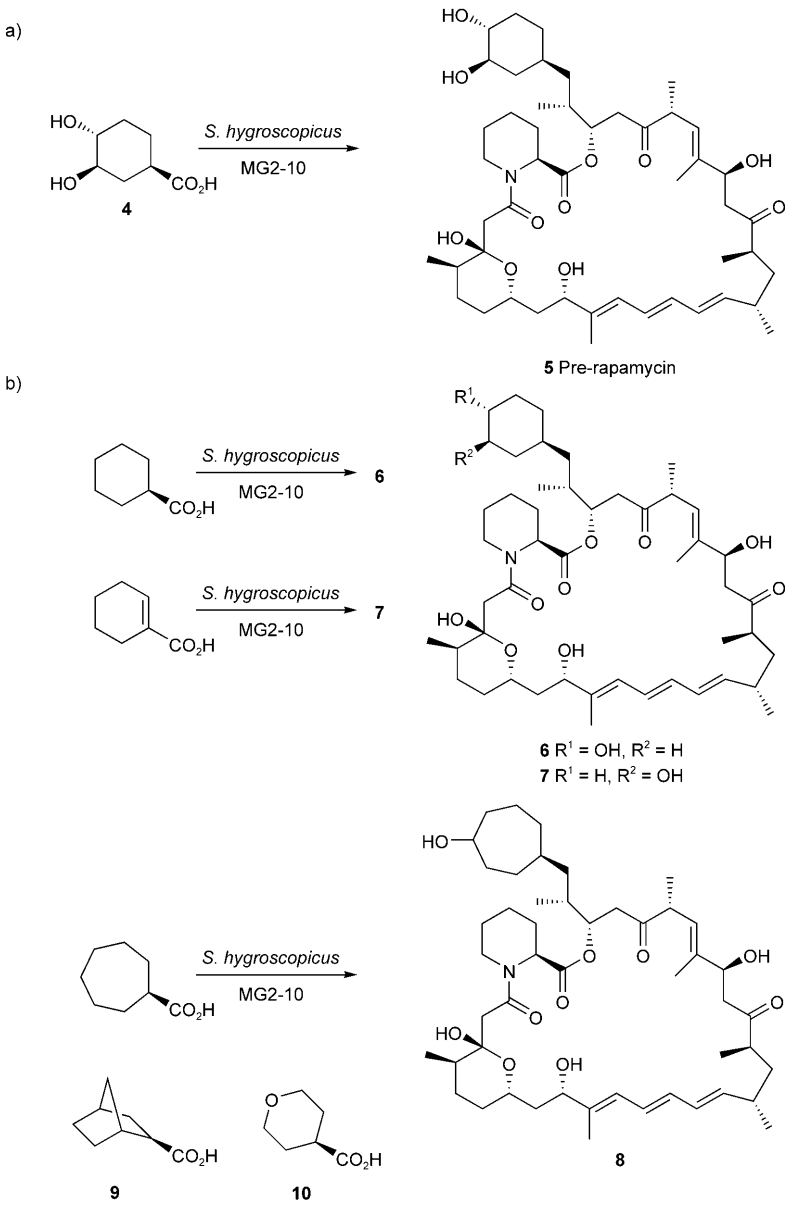
rapamycin is also the basis for current interest in such compounds as anticancer drugs.

The dihydroxycyclohexane moiety of rapamycin arises through the incorporation of a 4,5-dihydroxycyclohex-1-enecarboxylic acid (DHCHC) starter unit derived from shikimic acid in an analogous manner to that of FK520.[2] Cyclohexanecarboxylic acid (CHC), the starter unit for asukamycin[3] and phoslactomycin,[4] also arises from shikimic acid. These biosynthetic pathways share a common first step, the 1,4-conjugate elimination of water from shikimic acid.

Selection and activation of the carboxylic acid group of the rapamycin PKS starter unit is carried out by a carboxylic acid ligase (CL) like domain, in a manner analogous to that of adenylation domains of NRPS systems (Scheme 1a). Following covalent tethering to the ACP domain, the double bond of

Scheme 1. a) Proposed pathway for CL-catalyzed activation and subsequent attachment of the natural starter unit to the rapamycin PKS. b) Translocation of ACP-bound starter unit involves reduction of the Δ^1 bond by the ER domain of the loading module of RAPS1, the N-terminus of which is shown with a linear arrangement of the predicted catalytically active domains. AMP = adenosine monophosphate, PPi = inorganic phosphate, CL = carboxylic acid ligase like domain, KS = β-ketoacyl synthase, ACP = acylcarrier protein, AT = acyltransferase, DH = dehydratase.



DHCHC is reduced by the action of the enoyl reductase (ER) domain of the rapamycin PKS loading module (Scheme 1b). Efficient incorporation of the pseudostarter acid 1,2-dihydro-DHCHC was also observed during feeding experiments with stable isotopes, thus leading to speculation that the domains of the PKS involved in selection of the starter unit might have broad substrate tolerance.[2,5] Indeed, a recent report has shown that novel analogues of rapamycin are biosynthesized in addition to rapamycin when simple analogues of the natural starter unit are fed to the rapamycin-producing organism.[6]

The immediate product of the rapamycin PKS is pre-rapamycin **5**, which is then modified by a series of two cytochrome P450 monooxygenases (RapJ and RapN) and three O-methyltransferases (RapI, RapM, and RapQ). When a region of DNA including the genes thought to encode these enzymes was excised (*rapKIJMNOQL*) from the rapamycin biosynthetic gene cluster, no production of rapamycins was observed from the resulting strain, *Streptomyces hygroscopicus* MG2–10. The mutant strain MG2–10 was then independently complemented with full-length copies of each of the genes which had been removed. Surprisingly, the production of **5** was only observed when *rapK* was reintroduced and expressed in the strain.[7] The gene *rapK* has previously been proposed as a candidate gene to encode a pteridine-dependent dioxygenase,[8] which (like its homologue in the FK506 cluster, *fkbO*) might catalyze the oxidation of the C9 hydroxy group after initial hydroxylation at C9 catalyzed by the cytochrome P450 RapJ.[9] However, we now have clear evidence that RapJ alone is capable of both oxygen insertion and further oxidation to give a C9 keto group.[10]

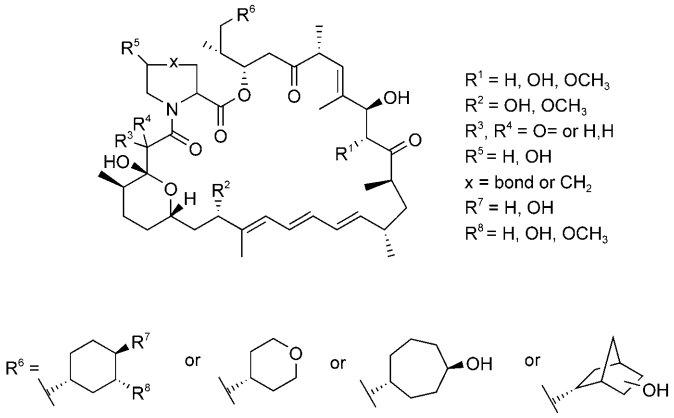
Furthermore, comparison of the sequences between RapK[11] and its homologues from the FK520 (FkbO),[12] FK506 (FkbO),[13] and hyg (ORF5)[14] biosynthetic gene clusters have revealed that the proposed binding motif for a pteridine derivative present in RapK[8] is not present in any of the other three proteins. These findings. together with the surprising effect of *rapK* on pre-rapamycin production in strain MG2–10,[7] have led us to reexamine the role of this gene, and of its product, in rapamycin biosynthesis.

We first carried out a series of experiments in an attempt to explain the lack of production of the rapamycin macrocycle by *S. hygroscopicus* MG2-10. These included feeding experiments in which exogenous pseudostarter carboxylic acid **4** was added to the fermentation medium to verify that the supply of this component was not a limiting factor. To our surprise, the addition of **4** to the fermentation led to the efficient production of **5** (Scheme 2a), which was fully characterized by mass spectrometry and NMR spectroscopy and shown to be identical to authentic pre-rapamycin.[7] Furthermore, the addition of other carboxylic acids in place of **4**, as reported for the wild-type organism,[6,15] was found to lead to the specific production of pre-rapamycin analogues in which these non-natural starter acids had been incorporated, in most cases after prior hydroxylation (Scheme 2b). CHC, cyclohex-1-enecarboxylic acid, and cycloheptanecarboxylic acid were all fed separately to *S. hygroscopicus* MG2–10, which led to the production of analogues **6**–**8**, respectively. Compounds **7** (22 mg) and **8** (77 mg) were isolated from the fermentation broth[16] by preparative chromatography[7] and their structures were confirmed by using high-resolution FT-ICR-MS^n.[17] Compound **6** (100 mg) was isolated and its structure confirmed by a combination of high-resolution FT-ICR-MS^n and multidimensional NMR spectroscopy experiments.[18] The MS and NMR data were in complete harmony with the results of previous work on the fully processed variants of these compounds.[6] Other compounds were fed, including norbornane carboxylic acid **9**, which had previously been unsuccessfully fed to the wild-type strain.[15] LC-MS analysis showed the production of low levels of a pre-rapamycin analogue arising

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 2. a) Reestablishment of pre-rapamycin **5** production in *S. hygroscopicus* MG2–10 by feeding the pseudostarter unit **4**. b) Exclusive production of the analogues **6**–**8** of pre-rapamycin by feeding, respectively, cyclohexanecarboxylic acid, cyclohex-1-enecarboxylic acid, and cycloheptanecarboxylic acid to *S. hygroscopicus* MG2–10.

from incorporation (after hydroxylation) of **9**, thus demonstrating that removal of competition from the natural starter acid allows a more efficient mutasynthesis of pre-rapamycin analogues.



The hydroxylation of the incorporated starter acids appears to occur before synthesis of the polyketide chain.[6] Consistent with this idea, the hydroxylation seen in strain MG2–10 shows that none of the *rapKIJMNOQL* genes are involved. The enzyme or enzymes responsible remain to be identified. Interestingly, when the heterocycle tetrahydro-2*H*-pyran-4-carboxylic acid (**10**)[19] was fed to MG2-10, LC-MS studies revealed low levels of incorporation without hydroxylation. This observation reveals that hydroxylation is not essential for incorporation.

To test whether *fkbO*, the *rapK* homologue found in the FK520 cluster, has a similar function to *rapK*, *fkbO* was amplified by the polymerase chain reaction (PCR) from *S. hygroscopicus* var. *ascomyceticus* genomic DNA and ligated into the expression plasmid pSGSet1, which contains the P_{act} promoter.[10] This unit was introduced into *S. hygroscopicus* MG2–10 and the strain was analyzed for production of **5**. Levels of **5** were observed similar to those produced by *S. hygroscopicus* MG2–10 when complemented by *rapK*. This result indicates that FkbO has a similar function to RapK and opens the way to analogous mutasynthesis of FK506 and FK520 analogues.

The surprising observation that feeding exogenous starter unit carboxylic acids to *S. hygroscopicus* MG2-10 complements the absence of *rapK* provides strong evidence that the product of this gene is involved directly in the biosynthesis of DHCHC or in its regulation. Further sequence comparisons (data not shown) have revealed that *rapK* and its three homologues so far identified share a C-terminal domain which is present in a broadly distributed family of over 200 proteins—members of the YjgF/YER057c/UK114 family.[20] These proteins have been tentatively implicated in a range of regulatory functions. We propose that RapK is involved in the regulation of DHCHC production from shikimate.

Rapamycin and its analogues are the only established inhibitors of mTOR and the most selective inhibitors of kinase activity known to date, and therefore represent exciting candidates for the development of anticancer therapeutics.[21] All of the rapamycin analogues presently in clinical trials (for example, CCI-779, SDZ-RAD, and ABT-578) contain semisynthetic alterations at positions derived from the starter unit.[22] We have shown here that novel starter units can be efficiently and exclusively incorporated into the rapamycin molecule by feeding them to a *rapK*-deleted mutant of *S. hygroscopicus* MG2–10. The advantages of such mutasynthesis in a strain background not capable of producing natural rapamycins are clear (compare with the production of the modified avermectin analogue doramectin).[23] By combining alternative starter units, with controlled late-stage processing, by the selective expression of the methyltransferases RapI, RapM, and RapQ as well as monooxygenases RapJ and RapN (along with the ferridoxin RapO),[10] and with potential incorporation of alternative amino acid analogues in place of the natural pipecolic acid,[24] combinatorial biosynthesis of a wide range of rapamycin analogues is now possible (Scheme 3) even before engineered alterations of the macrocycle by PKS/NRPS engineering are considered. Such analogues offer great potential as chemical genetic probes of the molecular path-

Electrochemistry

An Electrolytic System That Uses Solid-Supported Bases for In Situ Generation of a Supporting Electrolyte from Acetic Acid Solvent**

*Toshiki Tajima and Toshio Fuchigami**

Electroorganic synthesis is one of the most useful methods in organic synthesis and is even applied in large-scale industrial processes.[1] It has recently attracted much interest as an environmentally friendly method because electrodes are inherently environmentally friendlier reagents than conventional oxidizing and reducing reagents. However, large

amounts of supporting electrolytes are necessary to provide sufficient electrical conductivity to the solvents for electrolyses. Therefore, after the electrolyses, separation of the supporting electrolytes is required, and these separated supporting electrolytes generally become industrial waste because they are mostly unrecyclable, except for some industrialized cases.[2] Furthermore, the inefficient separation of supporting electrolytes from solvents requires a huge consumption of energy and produces large amounts of additional industrial waste.

To solve such separation and industrial-waste problems, a capillary-gap cell,[3] distillation of supporting electrolytes,[2] solid polymer electrolytes,[4] electrochemical microreactors,[5] and a thin-layer flow cell[6] have been developed. To the best of our knowledge, an ideal electroorganic synthetic system from the viewpoint of green sustainable chemistry should be one that does not require the addition of any supporting electrolytes. Although solid polymer electrolytes, electrochemical microreactors, and the thin-layer flow cell provide such an ideal electroorganic synthetic system, they require special equipment.

It is well known that electron transfer between one solid and another is very difficult.[7] Therefore, it can be expected that solid-supported bases should act as bases in bulk solutions and at the same time be electrochemically inactive reagents at an electrode surface. In the presence of solid-supported bases such as amines, protic organic solvents such as acetic acid should dissociate into anions and protons to some extent [Eqs. (1) and (2)]. This system would be suitable

for electroorganic synthesis because the protons derived from the protic organic solvent would play the role of the main carrier of an electronic charge via ammonium ions [Eq. (2)].[8] In this system, protic organic solvents would therefore serve both as a solvent and a supporting electrolyte generated in situ. We report herein a novel electrolytic system using solid-supported bases for the generation of a supporting electrolyte in situ from acetic acid as the solvent.

The cyclic voltammograms of *N*-methylmorpholine (**1**) and polystyrene-supported morpholine (**2**) were first measured in nBu$_4$NBF$_4$/anhydrous acetonitrile. As shown in Figure 1a, **1** is easily oxidized at around 1.2 V vs. SCE, while **2** is not oxidized at all, even when stirring. This means that solid-supported bases are not oxidized at the electrode surface. Next, the cyclic voltammogram of **2**/AcOH (0.1 M based on the concentration of morpholine) was measured; however, and rather unexpectedly, neither an oxidation current nor a reduction current was observed. Acetonitrile was then added as a co-solvent and the cyclic voltammogram of 0.1 M **2**/AcOH/MeCN was measured. As shown in Figure 1b, both an oxidation wave for AcO^- at about 2.1 V vs. SCE and a reduction current for H^+ were observed.[9] Therefore, it is clear that solid-supported bases cause acetic acid to dissociate into acetate anions and protons, and the resulting protons seem to act as the main carrier of the electronic charge.

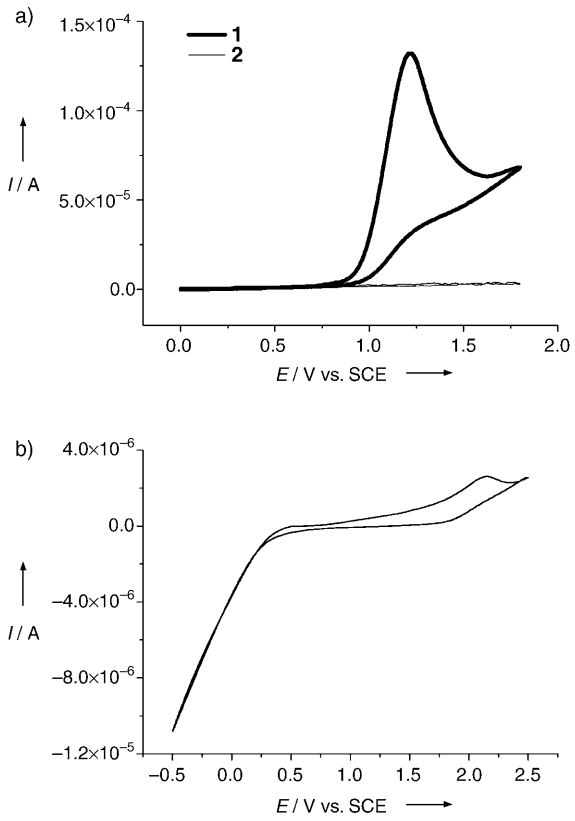

Figure 1. Cyclic voltammograms of a) *N*-methylmorpholine (**1**, 0.1 M) and polystyrene-supported morpholine (**2**, 0.1 M) in 0.1 M nBu$_4$NBF$_4$/MeCN, and b) AcOH/MeCN (50/50 v/v) in the presence of **2** (0.1 M) recorded at a Pt disk anode (ϕ = 0.8 mm). The scan rate was 100 mV s^{-1}.

We then investigated anodic α-acetoxylation using solid-supported bases with phenyl 2,2,2-trifluoroethylsulfide (**3**)[10] as the model compound as anodic acetoxylation is one of the most useful reactions in electroorganic synthesis.[11] The overall experimental procedure is illustrated in Figure 2.

The results with various solid-supported bases are shown in Table 1; polystyrene-supported morpholine gave the α-acetoxylated product **4** in low yield (entry 1), while similar

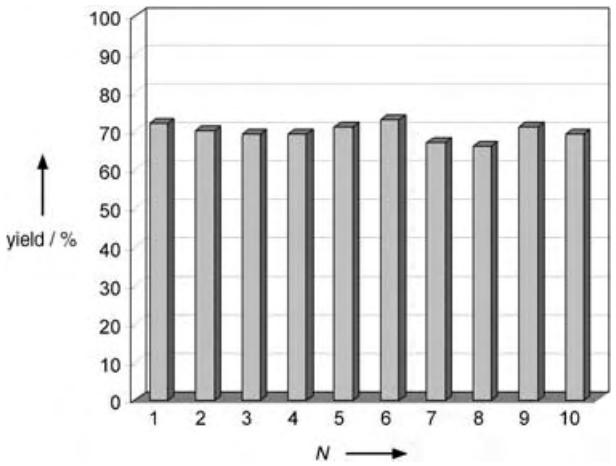
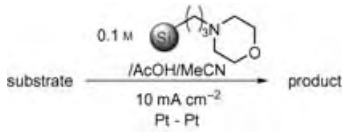
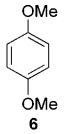
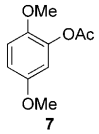
reactions with porous polystyrene-supported and silica gel supported morpholine proceeded efficiently to provide **4** in good to high yields (entries 2 and 3). These results indicate that the solvent compatibility of the solids is highly significant. The acetoxylated product **4** was obtained in only 24% yield with silica gel supported pyridine, whose basicity is lower than that of morpholine (Table 1, entry 4), which means it does not dissociate acetic acid into acetate anions and protons efficiently. On the other hand, the acetoxylated product **4** was formed in 56% yield with silica gel supported imidazole (Table 1, entry 5). Unexpectedly, anodic acetoxylation of **3** resulted in a low yield (25%; Table 1, entry 6) when silica gel supported **5** was used, even though its basicity is much higher than that of morpholine. This can be explained as follows. Silica gel supported **5** can dissociate acetic acid into acetate anions and protons efficiently; however, **5** is protonated by the resulting protons because it is strongly basic. Therefore, the equilibrium of Equation (2) shifts to the left, and the resulting proton mobility is much lower than those of the other bases.[12]

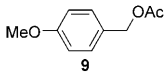
Anodic acetoxylation of **3** was successfully carried out 10 times after recycling of the silica gel supported morpholine. In this recycling process, silica gel supported morpholine is easily separated and recovered by simple filtration (Figure 2). As shown in Figure 3, the yield of **4** was always more than 65%

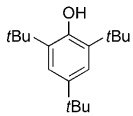












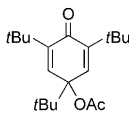


Figure 3. Yield of acetoxylated product **4** depending on the number *N* of reuses of the silica gel supported morpholine.

and did not decrease at all upon reuse of the silica gel supported morpholine. This clearly shows that solid-supported bases are not subject to oxidative decomposition at the electrode surface and therefore recyclable many times.

The generality of the new electrolytic system is shown in Table 2. Anodic acetoxylation of **6** was carried out to provide

Table 2: Anodic acetoxylation of various compounds with silica gel supported morpholine.

Entry	Substrate	Electricity [×96480 C mol^{-1}]	Product	Yield[a] [%]
1	 **6**	6	 **7**	91
2	 **8**	6	 **9**	72[b]
3	 **10**	5	 **11**	95

[a] Yield of isolated product. [b] The benzylic diacetoxylated product was also formed.

the corresponding acetoxylated product **7** in excellent yield. Anodic benzylic acetoxylation of **8** also proceeded to provide the acetoxylated product **9** in good yield. Furthermore, anodic acetoxylation of **10**, a phenol derivative, took place to provide the acetoxylated product **11** in excellent yield.

In conclusion, we have developed a novel electrolytic system for anodic acetoxylation that uses solid-supported bases. This system has many practical advantages and characteristics. For instance, it does not require addition of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

supporting electrolytes as the supporting electrolyte is generated in situ from acetic acid as the solvent. Furthermore, it allows a simple separation of the acetoxylated products and solid-supported bases by filtration, and the solid-supported bases are electrochemically stable and recyclable. The limitations of this new methodology and its further application for electroorganic synthesis are now under investigation. In addition, we plan to apply this system to a capillary-gap cell to reduce the high internal resistance compared with conventional methods.

Metallophthalocyanines

Highly Fluorescent Self-Coordinated Phthalocyanine Dimers**

*Kazuya Kameyama, Mitsuhiko Morisue, Akiharu Satake, and Yoshiaki Kobuke**

Phthalocyanines have been studied for many possible applications because of their excellent optical and electronic properties as well as their chemical, thermal, and light stability.[1] Their expanded π orbitals create the large oscillator strength in the Q band (S_1) region and result in high quantum yields of fluorescence. Pigments, dyes, nonlinear optics,[2] and optical data storage devices are important applications for phthalocyanines. Phthalocyanines are also ideal for applications in electronic conduction[3] as a result of the extra stabilization of electrons/holes in their large π-electronic frameworks.

In the related field of porphyrin chemistry, Kobuke et al. previously reported a methodology for supramolecular organization. For imidazolyl-substituted porphyrins, complementary coordination of the imidazolyl group from one porphyrin molecule to the central Zn^{II} ion in a second porphyrin molecule causes a "slipped cofacial dimer", with an extremely large stability constant of $10^{11}\,M^{-1}$. This organization has served as a basic building block of linear and macrocyclic porphyrin arrays, which have increased the utilities of porphyrins for photosynthesis and functional dyes.[4]

The organization of phthalocyanines into controlled structures has been the target of extensive investigations. Besides π–π interactions in solution,[5] in thin films,[6] and in the solid state,[7] metal–ligand,[8] hydrogen-bonding,[9] and donor–acceptor interactions[10] have been reported for the phthalocyanines. It is well-known that J-aggregates of organic dyes are fluorescent[11] whereas H-aggregates are not.[12] Therefore, head-to-tail dimers and J-aggregates are highly desirable to maximize their optical properties. However, except for a few fluorescent phthalocyanines[13,14] only face-to-face dimers and H-aggregates have been observed. Herein, we report highly fluorescent phthalocyanine dimers that result from complementary coordination of imidazolyl groups to zinc and magnesium ions.

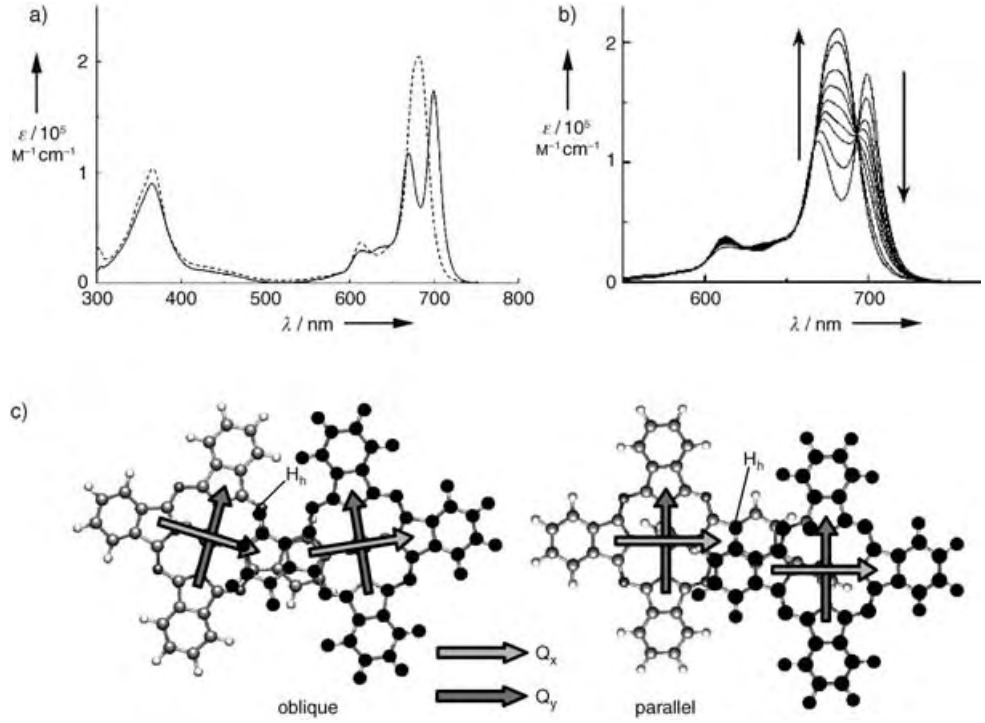
Zinc(II) hexa-*n*-butoxyimidazolylphthalocyanine (**1**) was prepared from the condensation of 6-cyanodiiminoisoindoline with 5 equivalents of 6,7-dibutoxydiiminoisoindoline in the presence of $Zn(OAc)_2$, followed by treatment with *N*-methylethylenediamine to convert the cyano groups into imidazolinyl substituents (29% yield based on 6-cyanodiiminoisoindoline). Oxidation of the imidazolinyl derivative with 5% Pt/C in boiling diphenyl ether afforded **1** in 95% yield (see Supporting Information). The MALDI-TOF mass spectrum of purified **1** revealed a peak for the molecular ion at $m/z = 1091.6$ $[M+H]^+$ as well as a peak for the dimer $[\mathbf{1}]_2$ at $m/z = 2182.0$ $[M+H]^+$ in a ratio of 6:5. Similarly, zinc(II) and magnesium(II) tri-*tert*-butylimidazolylphthalocyanines **2** and **3** were synthesized from zinc(II) and magnesium(II) tri-*tert*-butylcyanophthalocyanines, respectively.

The self-association behavior of **1**–**3** was first examined with UV/Vis spectroscopy by performing titrations in toluene. Phthalocyanine **1** (1.07×10^{-6} M) showed split Q bands at 670 and 700 nm (Figure 1a, solid line). If we assume that dimer $[\mathbf{1}]_2$ forms (Scheme 1),[15] the split Q bands are best interpreted in terms of exciton interactions of Q_x and Q_y transition dipoles to give red-shifted Q_x and blue-shifted Q_y bands (Figure 1c).[16] These Q bands converged into a single peak through isosbestic points at 624, 650, and 693 nm upon addition of *N*-methylimidazole (Im; Figure 1b), and the spectra reached a stationary state after adding 1.44×10^{-2} M Im. The final converged spectrum (Figure 1a, dashed line) resembles that of zinc(II) octa-*n*-butoxyphthalocyanine (**4**) in toluene with axial coordination of Im.

On the basis of the association constants determined for **4** with Im ($K_{\mathbf{4}\text{-Im}} = 2.8 \times 10^5\ M^{-1}$) from another titration experiment (data not shown), the constant for self-association of **1** in toluene was evaluated as $K_{\mathbf{1}\text{-}\mathbf{1}} = 1.1 \times 10^{12}\ M^{-1}$. The extremely large association constant is thought to originate from the



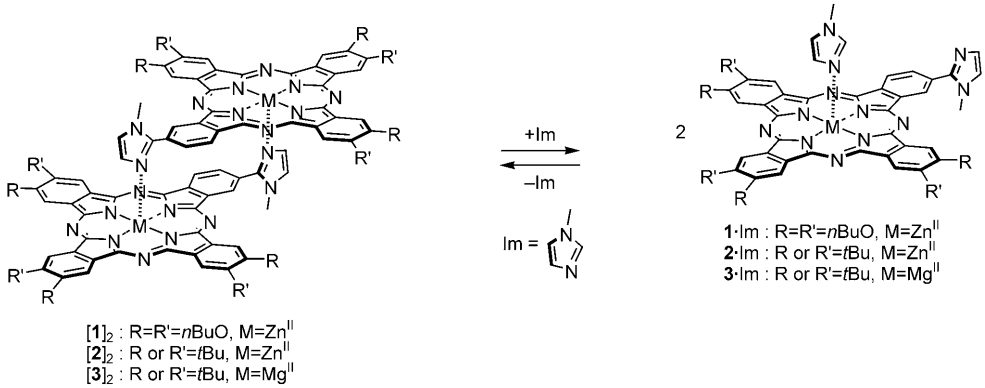


Figure 1. a) UV/Vis spectra of dimer $[\mathbf{1}]_2$ (——) and dissociated monomer **1**·Im (-----) in toluene. b) Changes in the spectra of $[\mathbf{1}]_2$ upon addition of Im (0.00, 0.32×10^{-3}, 0.73×10^{-3}, 1.04×10^{-3}, 1.44×10^{-3}, 2.01×10^{-3}, 2.93×10^{-3}, 4.45×10^{-3}, and 1.44×10^{-2} M). c) Oblique and parallel geometric isomers of $[\mathbf{1}]_2$, and the directions of the transition dipoles. Hydrogen atom H_h is highlighted (see Figure 2).

Scheme 1. Dimer⇌monomer equilibrium of metalloimidazolylphthalocyanines **1**–**3**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

complementary nature of the coordination. Dilution of $[\mathbf{1}]_2$ down to 1.03×10^{-9} M did not lead to any spectral changes, which is in accord with the high association constant. As the UV/Vis spectra followed Beer's law, at least, up to 2×10^{-4} M,[17] further aggregation of $[\mathbf{1}]_2$ caused by commonly observable π–π stacking is considerably suppressed relative to zinc tetra-*tert*-butylphthalocyanine (dimerization constant in toluene, $K=2.5\times10^{4}\,\mathrm{M}^{-1}$).[18]

The formation of stable dimers was also observed in other noncoordinating solvents such as $CHCl_3$ and CH_2Cl_2. Furthermore, **2** and **3** also showed similar split Q bands at 671 and 700 nm for **2** and at 672 and 701 nm for **3**, and their self-association constants in toluene were $K_{\mathbf{2}\text{-}\mathbf{2}}=1.7\times10^{11}$ and $K_{\mathbf{3}\text{-}\mathbf{3}}=1.4\times10^{11}\,\mathrm{M}^{-1}$. These results indicate that the Zn and Mg imidazolylphthalocyanine motifs lead to stable dimeric complexes of defined structure, regardless of the nature of the peripheral substituents.

A detailed structural analysis was carried out by NMR spectroscopy using various techniques. As the imidazolyl substituent does not lie along the symmetry axis defined by the pyrrolic N···N atoms, two isomeric dimers should emerge upon coordination: one parallel, with the two metallophthalocyanine units aligned but slip-stacked; and the other oblique, with the imidazolyl group of one unit aligned with the pyrrolic symmetry axis of the other (see Figure 1c). The presence of two dimeric structures was clearly displayed in the ^{1}H NMR (Figure 2) and heteronuclear multiple quantum coherence (HMQC) spectra. The hydrogen atom H_k, which lies closest to the plane of the second phthalocyanine unit upon coordination, appeared characteristically as two highly shielded peaks at $\delta=2.91$ and 2.83 ppm. The second closest hydrogen atom H_j and imidazolyl-*N*-methyl H_i atoms were observed as moderately shielded pairs of peaks at $\delta=5.57$ and 5.47 ppm and at $\delta=2.55$ and 2.39 ppm, respectively. When trifluoroacetic acid (TFA) was gradually added to the dimer, the two peaks for H_k at $\delta=2.91$ and 2.83 ppm shifted downfield and converged at $\delta=7.71$ ppm. Similarly, the peaks for the other imidazolyl protons, H_i and H_j, also shifted downfield and converged as indicated by arrows in Figure 2b. These results reveal that the coordinated dimers dissociates into the corresponding monomer upon addition of TFA and that the twin peaks originate from two isomeric dimers upon coordination.

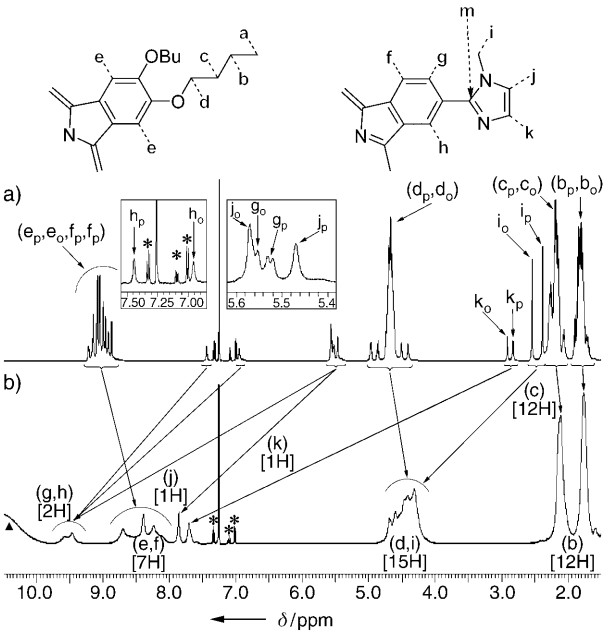

Figure 2. ^{1}H NMR spectra of a) dimer $[\mathbf{1}]_2$ (20 mM) in $CDCl_3$ at room temperature and b) monomer **1**·TFA, from the dissociation of the dimer by the addition of 10% TFA. The subscripts o and p denote oblique and parallel, respectively, and refer to the isomers shown in Figure 1. Symbols ⋆ and ▲ indicate the residual peaks of the solvent (diphenyl ether) and TFA, respectively. Relative integration intensities are provided in square parentheses in (b).

Two sets of signals for all the protons were assigned by total correlation and heteronuclear multiple bond coherence NMR spectroscopy (TOCSY and HMBC). Proton H_h was the most sensitive to the isomeric structures and appeared at $\delta=$ 6.96 and 7.44 ppm. The proton H_h in the oblique configuration is located closer to the center of the molecule, and the signal for H_h at $\delta=6.96$ ppm was assigned to the oblique isomer whereas that at $\delta=7.44$ ppm was assigned to the parallel isomer. The ratio of parallel to oblique dimers for $[\mathbf{1}]_2$ was approximately 1:1 from the integration of the areas for various well-separated peaks. All the NMR signals were consistent with the expected J-type phthalocyanine dimers. ^{1}H NMR spectra of dimers **2** and **3** were assigned to similar isomeric dimers.

All of the J-type dimers emit strong fluorescence in toluene. The quantum yield of $[\mathbf{1}]_2$ ($\Phi_F=0.45$) is identical to that of the dissociated monomer **1**·Im ($\Phi_F=0.45$), and the same pattern is observed for the other dimers, with $\Phi_F=0.26$ for $[\mathbf{2}]_2$ ($\Phi_F=0.27$ for **2**·Im) and $\Phi_F=0.76$ for $[\mathbf{3}]_2$ ($\Phi_F=0.76$ for **3**·Im). These results indicate that both the oblique and parallel conformational isomers emit in the same way as the monomeric metallophthalocyanines. In the case of a previously reported noncomplementary coordination dimer,[13b] the fluorescence quantum yield was decreased by a half as a result of its flexible structure. Other supramolecular motifs reported so far have weaker interactions, such that J-type dimerization only occurred under specific conditions of concentration, composition of solvent mixture, and temperature.[13] The orientation and spatial position of the two phthalocyanines units were not reported in those cases, but the imidazolylphthalocyanine motif developed here constitutes a unique basis set for supramolecular expression.

Analysis by differential pulse voltammetry of $[\mathbf{1}]_2$ showed split oxidation waves at 510 and 619 mV (versus Ag/AgCl)[19] for oxidation of the phthalocyanine ring that correspond to one- and two-electron oxidations from the dimer, respectively. The first oxidation potential was almost identical to that of the dissociated monomer **1**·Im, and the second wave appeared at a higher potential. This pattern suggests delocalization of the cation radical over the two π–π interacting phthalocyanine units. Such so-called charge–resonance interaction[20] is effective in lowering the charge density of the cation generated on the phthalocyanine rings and decreases the solvent reorganization energy and is therefore beneficial for efficient charge separation.[4b]

In conclusion, we have demonstrated a complementary phthalocyanine dimer. This report is the first example of a noncovalent J-type dimer of fluorescent phthalocyanines with well-defined structural analysis. This supramolecular dimer unit will be useful in applications that require efficient excitation-energy transfer, charge separation, and hole-transfer reactions, as was shown previously with a porphyrin dimer.[4] The present methodology which employs a slipped-cofacial dimer of imidazolyl-appended phthalocyanine is expected to produce advanced materials with excellent fluorescence properties combined with stabilities toward various external sources.

Asymmetric Catalysis

Oxidative Cyclization of Diols Derived from 1,5-Dienes: Formation of Enantiopure *cis*-Tetrahydrofurans by Using Catalytic Osmium Tetroxide; Formal Synthesis of (+)-*cis*-Solamin**

Timothy J. Donohoe and Sam Butterworth*

In 1965, Klein and Rojahn discovered that treatment of 1,5-hexadiene with $KMnO_4$ afforded *cis*-2,5-bis(hydroxymethyl)-tetrahydrofuran.[1] The mechanism of the reaction was a matter of some debate but eventually was considered to be a concerted cyclization of a metal–glycolate complex across a distal alkene.[2] This mechanism is consistent with the fact that the addition across both alkenes is stereospecific (*syn*) and also that stereoselective formation of *cis*-tetrahydrofurans is observed. Since the original reports using $KMnO_4$, several

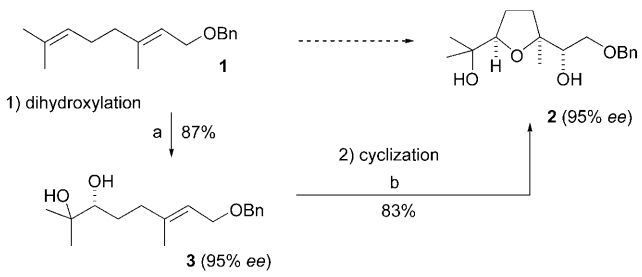
other metals have been shown to mediate this type of cyclization, including ruthenium[3] and, more recently, osmium.[4]



We recently described the development of the oxidative cyclization of 1,5-dienes using catalytic amounts of OsO_4 (5 mol%) under acidic conditions (see **1**→**2**, Scheme 1).[5] This sequence is remarkable for its high yields, especially during the oxidation of mono- and disubstituted alkenes, which tend to give overoxidation products with manganese and ruthenium oxidants.

Scheme 1. Oxidative cyclization of 1,5-dienes. Reagents and conditions: a) OsO_4 (5 mol%), Me_3NO (4 equiv), camphor sulfonic acid (6 equiv), CH_2Cl_2. Bn = benzyl.

A major obstacle to the application of this sequence in synthesis is the fact that racemic mixtures are produced. Attempts to introduce asymmetric induction into this reaction by the addition of chiral amine ligands failed, presumably because the pH values of the solutions were too low to enable efficient coordination of the amines to the osmium center. However, we now report a reaction sequence that overcomes this hurdle, allows the formation of tetrahydrofuran (THF) systems with complete control over both the relative and absolute stereochemistries, and uses catalytic amounts of a transition metal. We have discovered that vicinal diols derived from 1,5-dienes will cyclize to form the THF ring system when they are subjected to oxidative cyclization conditions (see **3**→**2**, Scheme 2). This cyclization reaction becomes a powerful methodology because the starting diols can be obtained from 1,5-dienes in a regio- and stereoselective manner by using, for example, the Sharpless asymmetric dihydroxylation (AD) reaction.[6] We have proven unambiguously by HPLC analysis that there is no loss of stereochemical integrity during the cyclization process.

The cyclization of diol **3** gave **2**, which was identical to the product obtained from the corresponding diene. This result

Scheme 2. Two-step procedure for the formation of enantiopure *cis*-THF rings. Reagents and conditions: a) AD-mix-β; b) OsO_4 (5 mol%), Me_3NO (4 equiv), trifluoroacetic acid (TFA; 6 equiv), acetone/H_2O, RT.

suggests that the 1,2-diol forms a chelated osmate ester in situ (see intermediate **A**, Scheme 1) that then cyclizes as before.

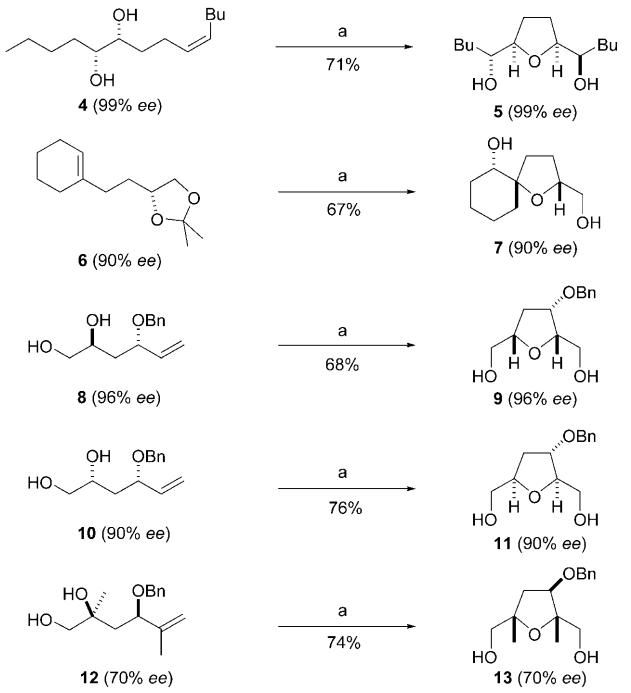
Naturally, we were intrigued by the oxidation state of the osmium center in **A**, because the diene cyclization protocol provides Os^{VI} directly and the diol cyclization route commences with Os^{VIII}.[7] Therefore, we examined the role of additives in the cyclization of **3** (Table 1) and found that a range of

Table 1: Oxidation of (+)-**3**→(−)-**2**.

Entry	Sacrificial alkene[a]	*t* [h]	Conversion [%][b]
1	none	6	30
2	none	30	85 (55)
3	cyclohexene (5)	6	40
4	cyclohexene (5)	30	100 (83)
5	isoprene (5)	6	45

[a] Equivalents given in brackets. [b] Yield of isolated product given in brackets.

sacrificial alkenes improved the yield (5 equiv were best). It is possible that this second alkene is able to generate Os^{VI} in situ (from Os^{VIII}) by a dihydroxylation reaction and thus acts to increase the amount of active Os^{VI} catalyst in the reaction mixture.



Although we could find no advantage to using cyclohexene rather than isoprene, the choice of sacrificial alkene becomes important in the purification as the product occasionally coelutes with the diol derived from this second alkene.

This investigation is related to the oxidative cyclization of bishomoallylic alcohols using Re^{VII} reagents (to give *trans*-tetrahydrofurans)[8] and diols using Cr^{VI} reagents[9] (the yields for this process are low), which have both been used successfully in synthesis.[10] However, both sets of conditions use stoichiometric amounts of the metal reagent to accomplish these transformations, and the advantages of catalytic metal oxidants are clear.

Next, we examined the oxidative cyclization of a range of diols derived from 1,5-dienes (Scheme 3). The diol starting materials were made by a regio- and stereoselective dihydroxylation of a diene by using the Sharpless AD reaction—although there are other viable routes to the diol precursors. The cyclization was shown to be tolerant of a variety of different substitution patterns on the alkene, diol unit, and even the backbone (Scheme 3). The yields were good and the products from the diol cyclizations were identical, as shown by NMR spectroscopic analysis, to a (racemic) compound formed by the cyclization of the corresponding 1,5-diene under the conditions shown in Scheme 1. As expected, the sequence is highly selective in each case for the formation of *cis*-tetrahydrofurans. Moreover, the enantiomeric purity of the diol was transferred completely to the THF product.

We then sought to exemplify this new cyclization reaction in synthesis. Our target was *cis*-solamin, which is an annonaceous acetogenin with potent biological activity (e.g., *cis*-solamin displays cytotoxicity and hemolytic activity).[11,12] Brown and co-workers[12] recently reported a clever synthesis of this molecule, whereby $KMnO_4$ was used to oxidatively cyclize a 1,5-diene precursor that was loaded with a chiral

Scheme 3. Oxidative cyclization of various diols. Reagents and conditions: a) OsO_4 (5 mol%), Me_3NO (4 equiv), TFA (6 equiv), acetone/H_2O, RT. Isoprene (5 equiv) was used as an additive in each entry, except for **4** in which cyclohexene was used.

auxiliary to control the absolute stereochemistry of the product.

This literature route was used to prepare compound **15** in four steps (Scheme 4). The ester group was then reduced and a regioselective AD reaction was performed on hydroxy-substituted diene **16** to yield **17** in 86% yield from **15** and with >90% *ee*. The key oxidative cyclization reaction of **17** worked well and gave THF product **18** in 81% yield. This product was subsequently transformed into tosylate **19** (>90% *ee* as determined by HPLC), which was spectroscopically identical to the product reported by Brown and co-workers. This investigation constitutes a formal synthesis of the target as **19** can be converted into (+)-*cis*-solamin in four steps and 56% yield by using a literature precedent.[12] This osmium-catalyzed oxidation methodology compares well with the permanganate-based alternative (e.g., **15**→**18**: obtained in five steps and 46% overall yield from the method of Brown and co-workers[12] compared with three steps and 70% overall yield from our new approach).

Scheme 4. The synthesis of *cis*-solamin. Reagents and conditions: a) diisobutylaluminum hydride; b) AD-mix-α,$(DHQ)_2PHAL$; c) OsO_4 (5 mol%), Me_3NO (4 equiv), TFA (6 equiv), isoprene (5 equiv), acetone/H_2O, RT; d) Bu_2SnO, *p*-toluenesulfonyl chloride (TsCl), benzene. $(DHQ)_2PHAL$ = hydroquinine 1,4-phthalazinediyl diether.

To conclude, we present herein a new catalytic oxidation reaction that promotes the cyclization of vicinal diols onto a proximal alkene with a high level of stereocontrol. The diol precursors are readily prepared as single enantiomers, which means that the oxidation products (tetrahydrofurans) can also be accessed in enantiopure form. This method is simple to perform, high yielding, and tolerant of substitution on the THF backbone. The usefulness of this method has been proved in a short and extremely efficient (formal) synthesis of (+)-*cis*-solamin.

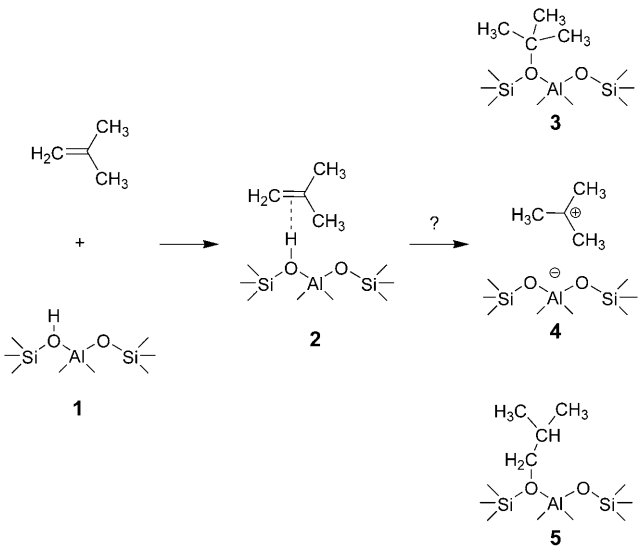
Isobutene in Zeolites



Protonated Isobutene in Zeolites: *tert*-Butyl Cation or Alkoxide?**

*Christian Tuma and Joachim Sauer**

Acid zeolite catalysts are industrially used for a variety of hydrocarbon transformation processes. Initially it was assumed that these reactions follow mechanisms known from chemistry in superacidic media, and involve carbocations as intermediates formed upon protonation of hydrocarbons by Brønsted acid sites.[1] However, NMR spectroscopic studies failed to find simple carbenium ions as intermediates, and instead produced evidence for surface alkoxides.[2,3] Around the same time, quantum chemical calculations employing small cluster models showed that alkoxides are minima on the potential energy surface (PES) and, hence, intermediates, while carbenium ions represent saddle points on the PES and are only present as extremely short-lived transition states.[4] So far, evidence for persistent carbenium ions has only been produced for cyclic alkenyl or aromatic carbenium ions by NMR,[5] UV/Vis,[6] and IR spectroscopy[7] or computational techniques.[8]

Among the carbenium ions derived from small alkenes, the *tert*-butyl cation has attracted much interest because it is more stable than primary or secondary carbenium ions; the competing formation of *tert*-butoxide may be sterically hindered. Previous computational studies have shown that, depending on the framework and the position at the zeolite wall to which they are bound, *tert*-butoxides may be as unstable as the *tert*-butyl cation.[9–12] Only the embedded cluster study by Boronat et al.[12] reports a local minimum on the PES for the *tert*-butyl cation in mordenite. It is, however, about 26 kJ mol^{-1} less stable than the adsorption π complex of isobutene with the Brønsted site. Nevertheless, all experimental attempts[13,14] to produce evidence for either the *tert*-butyl cation or an alkoxide have been unsuccessful so far, and the existence of *tert*-butyl cations in zeolites remains controversial.

Herein we report density functional theory (DFT) calculations for the reaction of isobutene with H-ferrierite (H-FER, **1**) with formation of the π complex **2** (Scheme 1). We applied periodic boundary conditions to a large simulation cell of dimensions $1870 \times 1417 \times 1496$ pm^3.[15] We show that the complex with the *tert*-butyl cation (**4**)—one possible structure formed upon proton transfer to isobutene in **2**—is a local minimum on the potential energy surface. For the first time we have evaluated entropy contributions to assess the stability of **4** relative to the adsorption π complex **2** and other possible proton transfer products, that is, surface alkoxides (**3**, **5**), at finite temperatures.

Scheme 1. Reactions considered for the protonation of isobutene in H-FER (**1**).

Our simulation cell of H-FER (**1**) has the composition $HAlSi_{71}O_{144}$. After aluminum substitution at the crystallographic position T2,[16] the proton is most stable at O7.[15] We used the Perdew–Burke–Ernzerhof (PBE) density functional[17] with a plane wave basis set.[18] Stationary points obtained by relaxation of the positions of all atoms in the cell are characterized by harmonic frequencies, from which zero-point vibrational energies, finite temperature energy, and entropy contributions are obtained.[19] All calculations employed the CPMD code.[20]

The calculated structures and the corresponding reaction energies are shown in Figure 1 and Table 1. Formation of the π complex of isobutene with the Brønsted acidic site is exothermic (**2**, $\Delta E_0 = -6.6$ kJ mol^{-1}). In contrast, chemisorption of isobutene is an endothermic process. Of the two different alkoxides, the isobutoxide (**5**) is more stable than the *tert*-butoxide (**3**). The longer C–O bond in *tert*-butoxide (161 pm) compared to isobutoxide (151 pm) indicates increased steric constraints due to the three methyl groups at the C–O carbon atom. Both the adsorbed isobutene and the *tert*-butyl cation are connected by hydrogen bonds to the zeolite framework. The corresponding bond lengths are 190.2 and 242.5 pm for r(AlOH···C^1) and r(AlOH···C^2) in the π complex and 174.0 pm for r(AlO···HC) in the carbenium ion structure. The carbenium ion complex **4** is electronically least favored. It is 46 kJ mol^{-1} less stable than the adsorption π complex, while isobutoxide is 14 kJ mol^{-1} and *tert*-butoxide is 27 kJ mol^{-1} less stable.

Similar relative energies have been found in a previous DFT (PW91) study for chabasite, ZSM-22, and mordenite[11]

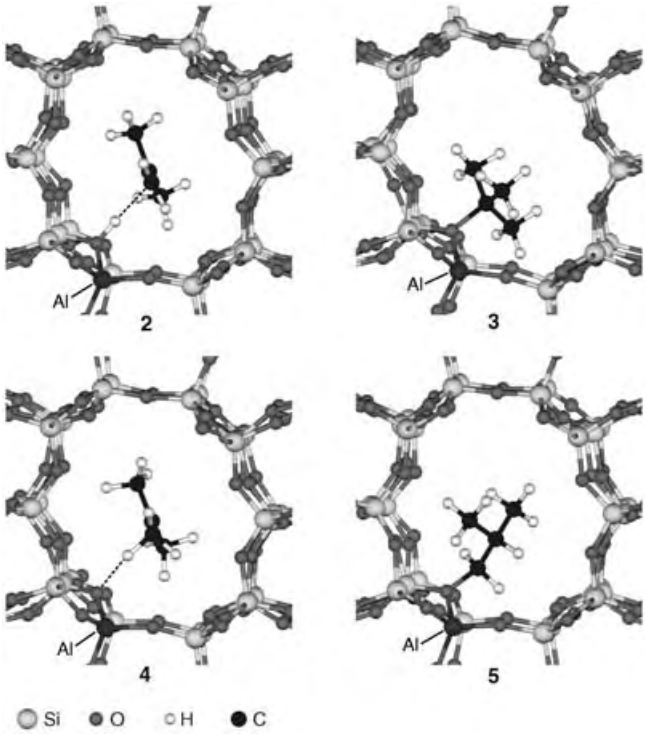

Figure 1. Portions of the structures calculated for the π complex of isobutene in ferrierite (**2**), for the *tert*-butyl cation in ferrierite (**4**), and for the *tert*-butoxide (**3**) and isobutoxide (**5**) of ferrierite.

Table 1: Electronic (ΔE) and ZPVE-corrected (ΔE_0) reaction energies, enthalpies (ΔH_{298}), and Gibbs energies (ΔG_{298}; pressure 1 atm) in kJ mol^{-1} for the formation of structures **2**–**5** from isobutene and H-FER (**1**).

Compound	ΔE	ΔE_0	ΔH_{298}	ΔG_{298}
2	−9.4	−6.6[a]	−4.9	40.4
3	17.2	35.0	27.5	119.0
4	36.2	32.2	34.9	76.0
5	4.8	24.4	18.8	96.8

[a] For comparison, ΔE_0 for isobutene in mordenite is −6.4 kJ mol^{-1} (B3PW91).[12]

as well as in a B3PW91 study on mordenite.[12] The density functionals that are currently used do not properly account for dispersion interactions (see, e.g., references [21,22]). This results in too low energies of adsorption, but may also change the relative energies of chemisorbed species compared to adsorption π complexes and carbenium ions.[15] Future refinements of the present results by explicit inclusion of dispersion interactions may be obtained by an MP2/DFT hybrid technique[23] or by adding a damped dispersion term.[22] The results obtained with the PBE/PW91 family of functionals require less correction than those with functionals including Becke exchange.[21,22,24]

Inclusion of zero-point vibrations and finite temperature effects stabilizes the *tert*-butyl carbenium ion relative to the chemisorbed species (see ΔE_0 and ΔH_{298} in Table 1). An important new finding of the present study is the effect of entropy on the Gibbs energy: At temperatures higher than about 120 K, the *tert*-butyl cation complex **4** becomes favored over the alkoxides (**3**, **5**, Figure 2). The different slopes for the change in Gibbs energy for the alkoxides compared to the π complex and the carbenium ion reflect different entropy contributions. The existence of an additional covalent bond in the alkoxides (C–O) limits the mobility of the hydrocarbon species, and suggests a lower entropy compared to the other two structures.

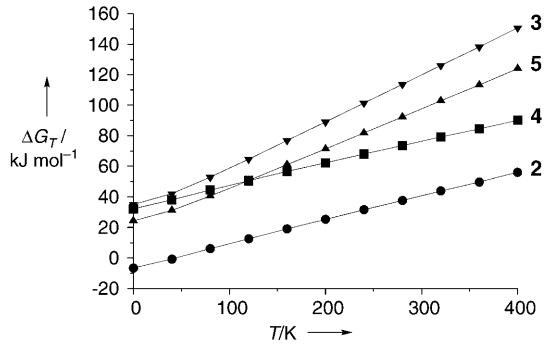

Figure 2. Plot of the Gibbs energy ΔG_T as a function of temperature T (at 1 atm) for the formation of **2**–**5** from isobutene and H-FER (**1**).

The vibrational states obtained from our frequency calculations are shown in Figure 3 (the vibrational frequencies can be found in the Supporting Information). A nearly continuous vibrational region from 1250 cm^{-1} down to far infrared with a window between about 1000 and 800 cm^{-1} is seen for unloaded H-FER (**1**) as well as for the hydrocarbon-containing structures. This is characteristic of zeolite lattice vibrations. The calculated frequencies for the zeolitic O–H and O–D stretching modes in unloaded H-FER (3643 and 2652 cm^{-1}, respectively) compare well with experimental data (3609 and 2663 cm^{-1}, respectively).[25] Quantitative agreement is not expected because of the limited accuracy of DFT and neglected anharmonicities. The vibrational spectra of structures **2**–**5** approximately resemble superpositions of those of the unloaded zeolite and the gas-phase species. In the isobutene π complex **2**, hydrogen bond formation shifts the zeolitic O–H and O–D stretching mode by −819 and

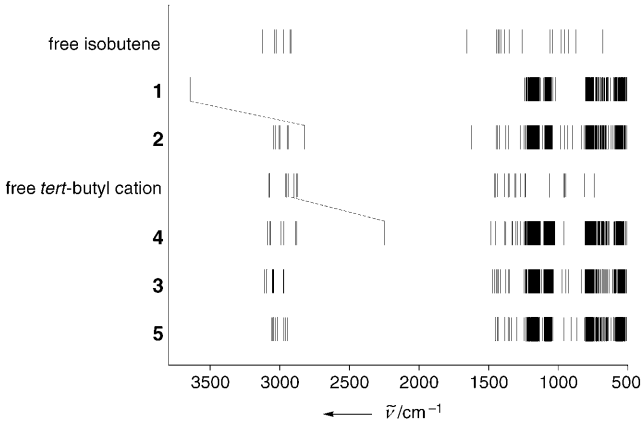

Figure 3. Vibrational spectra calculated for isobutene and the *tert*-butyl cation (both in the gas phase) as well as for structures **1**–**5**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

−585 cm^{-1}, respectively. Corresponding measurements on deuterated forms of different zeolites yield somewhat smaller O−D shifts: −416 cm^{-1} (mordenite)[14] and −388 cm^{-1} (faujasite).[26] It is known[27] that the PBE functional overestimates O−H frequency shifts upon hydrogen bond formation.

A significant change is predicted for the IR spectrum of the carbenium ion complex **4**: Only 8 instead of 9 vibrational modes are seen in the C−H stretching region around 3000 cm^{-1}; the remaining mode corresponding to the O···HC hydrogen bond is found at 2245 cm^{-1}, that is, well separated from the others. This is a new prediction which may help to identify the *tert*-butyl cation as a transient species in future laser-spectroscopic experiments.[28]

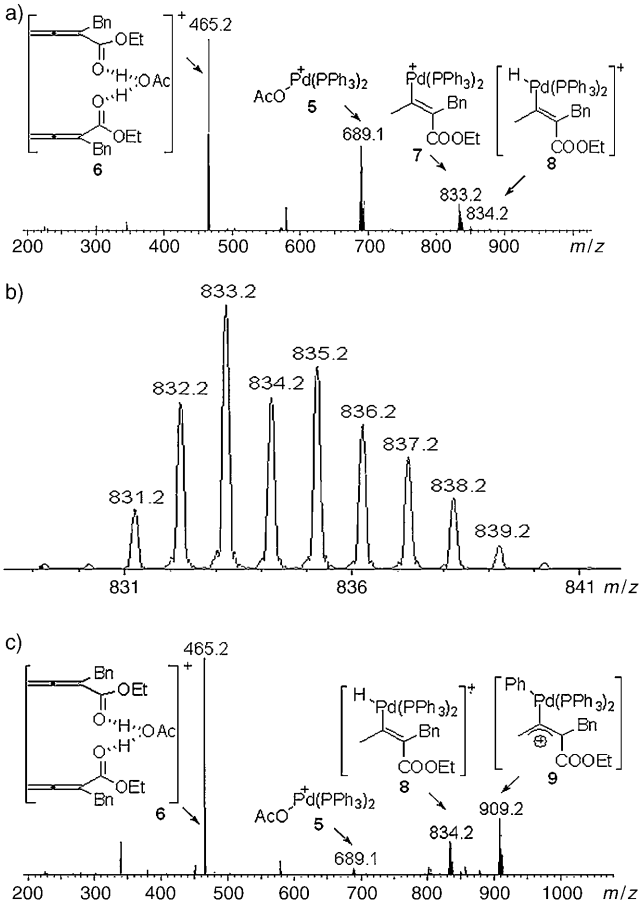
usually requires the isolation and characterization of organometallic species, which is usually not easy and is often time-consuming.[2] Thus, the interception and detection of reaction intermediates by instrumental analysis is a facile and reliable alternative method.[3–5] Molecular analysis by mass spectrometry (MS) has greatly benefited from the development of electrospray ionization (ESI) techniques,[6,7] since molecules and supramolecules of high polarity and molecular complexity can be easily ionized by ESI for investigation by MS.[4,5] ESI-MS is a technique that allows the ions present in solution to be transferred into the gas phase, where they can be analyzed and eventually characterized, with minimal fragmentation. Thus, straightforward analytical applications of ESI-MS to the characterization of organometallic intermediates have started to catch the attention of chemists.[8] Here we report our recent observation of the high resolution and high-mass-accuracy MS characterization of several organometallic species, which leads to a better understanding of the reaction mechanism of the palladium-catalyzed highly regio- and stereoselective addition of organoboronic acids to allenes in the presence of AcOH.

Although allenes have been considered as highly unstable,[9] recent studies show that they demonstrate useful reactivities and selectivities.[9–11] During our systematic study on the chemistry of allenes,[12] we have developed a palladium-catalyzed highly regio- and stereoselective hydroarylation or hydroalkenylation of allenes with organic boronic acids that gives tri- or tetrasubstituted alkenes (Scheme 1).[13] Despite the importance of its synthetic utility this reaction still has a number of unaccountable features, including the mechanistic details.

Scheme 1. The Pd-catalyzed addition reaction of allenes with organoboronic acids in the presence of an acid.

After some preliminary studies, we successfully found that the ESI-FTMS monitoring of the $[Pd(PPh_3)_4]$-catalyzed reaction of 2,3-allenoate with two organoboronic acids (**2a** and **2b**, Scheme 2) in the presence of AcOH in THF yielded some interesting information about the reaction intermediates. A solution of allenoate **1**[14] (0.05 mmol), organoboronic acid (0.1 mmol), $[Pd(PPh_3)_4]$ (0.005 mmol), and AcOH (0.05 mmol) in THF (6 mL) was stirred at room temperature under N_2 atmosphere for the time indicated in Figure 1.[13] Then, 20 μL of this solution was diluted with 80 μL of methanol and transferred into the ESI source at a flow rate of 10 μL min^{-1} for the MS detection.

The palladium intermediates involved in the catalytic cycle were intercepted, detected, and characterized by high resolution accurate mass measurements of their corresponding ions with the ESI-FTMS instrument in the positive-ion mode. After three minutes of the reaction with organoboronic acid **2a**, ions assigned to intermediate **5** (principal ion of *m*/*z* 689.1004; calcd. for $C_{38}H_{33}O_2P_2{}^{106}Pd^+$: *m*/*z* 689.1003; Figure 1a) and the by-product **6** (principal ion of *m*/*z* 465.2276; calcd. for $C_{28}H_{33}O_6^+$: *m*/*z* 465.2277; Figure 1a) were detected.



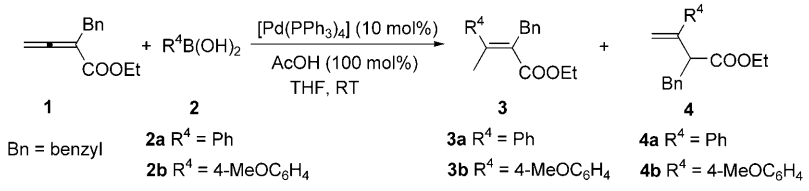


Figure 1. ESI-(+)-MS of the sample taken at a) 3 min and c) 2 h after mixing allenoate **1** and organoboronic acid **2a**. b) Experimental isotopic distribution of the mixture of **7** and **8**.

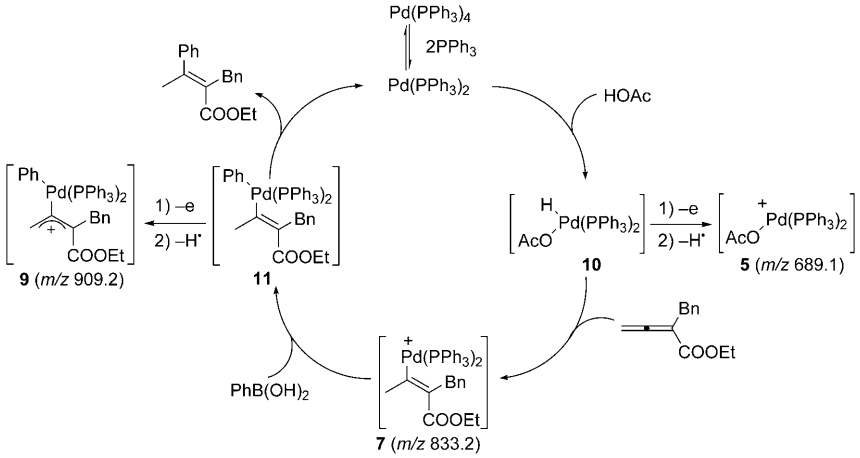
The composition of the major cationic intermediates changes dramatically with time. Continuous monitoring of these intermediates by ESI-FTMS also allowed us to detect three other ions: the palladium cation **7** (principal ion of *m*/*z* 833.1993; calcd. for $C_{49}H_{45}O_2P_2{}^{106}Pd^+$: *m*/*z* 833.1945; Figure 1a), which usually disappeared five minutes after initiation of the reaction, the palladium cation **8** (principal ion of *m*/*z* 834.2025; calcd. for $C_{49}H_{46}O_2P_2{}^{106}Pd^{\bullet+}$: *m*/*z* 834.2023; Figure 1a and Figure 1c), which might result from the oxidation of the neutral intermediate $HPd(PPh_3)_2$–vinyl species during the ESI process,[15,16] and the



Scheme 2. The reaction of a 2,3-allenoate with two organoboronic acids, as monitored by ESI-FTMS.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cationic π-allyl intermediate **9** (principal ion of *m/z* 909.2265; calcd. for $C_{55}H_{49}O_2P_2{}^{106}Pd^+$: *m/z* 909.2259; Figure 1c), which may be formed by sequential oxidation during the ESI process and elimination of H· from the (η^3-allyl)palladium complex in the gas phase.[8,17,18] Similar results were observed for organoboronic acid **2b** (see the Supporting Information). All the experimental isotopic distributions of the palladium-containing species matched the theoretical isotopic distributions, as simulated with the Bruker Xmass 6.1.2 program.

For further structural characterization of the intermediates of this reaction, all isotopolog ions forming the isotopic clusters of **7**, **8**, and **9** were isolated for a SORI-CAD (sustained off-resonance irradiation collision-activated dissociation) experiment with argon in a tandem mass spectrometric analysis.[19] Figure 2a–c show that intermediates **7** (principal ion of *m/z* 833.1993), **8** (principal ion of *m/z* 834.2025), and **9** (principal ion of *m/z* 909.2265) yield palladium cations **7A** (principal ion of *m/z* 571.1046; calcd. for $C_{31}H_{30}O_2P^{106}Pd^+$: *m/z* 571.1029; Figure 2a), **8A** (principal ion of *m/z* 572.1105; calcd. for $C_{31}H_{31}O_2P^{106}Pd^{\cdot+}$: *m/z* 572.1107; Figure 2b), and **9A** (principal ion of *m/z* 647.1342; calcd. for $C_{37}H_{34}O_2P^{106}Pd^+$: *m/z* 647.1344; Figure 2c) by loss of one PPh_3 ligand. The above results allow us to propose a mechanism for the reaction, which is shown in Scheme 3 with organoboronic acid **2a** as an example. Firstly, the oxidative addition reaction between AcOH and Pd^0 affords the palladium hydride species **10**, which may undergo hydropalladation with the less-sterically hindered terminal C=C bond in the allene moiety, with elimination of OAc^-, to afford alkenylpalladium intermediate **7**.[20] Transfer of the aryl group from the arylboronic acid to **7** gives **11**, which affords the final product by reductive elimination.[21]

Scheme 3. Proposed catalytic cycle for the palladium-catalyzed addition of an organoboronic acid to an allene in the presence of AcOH based on the MS study.

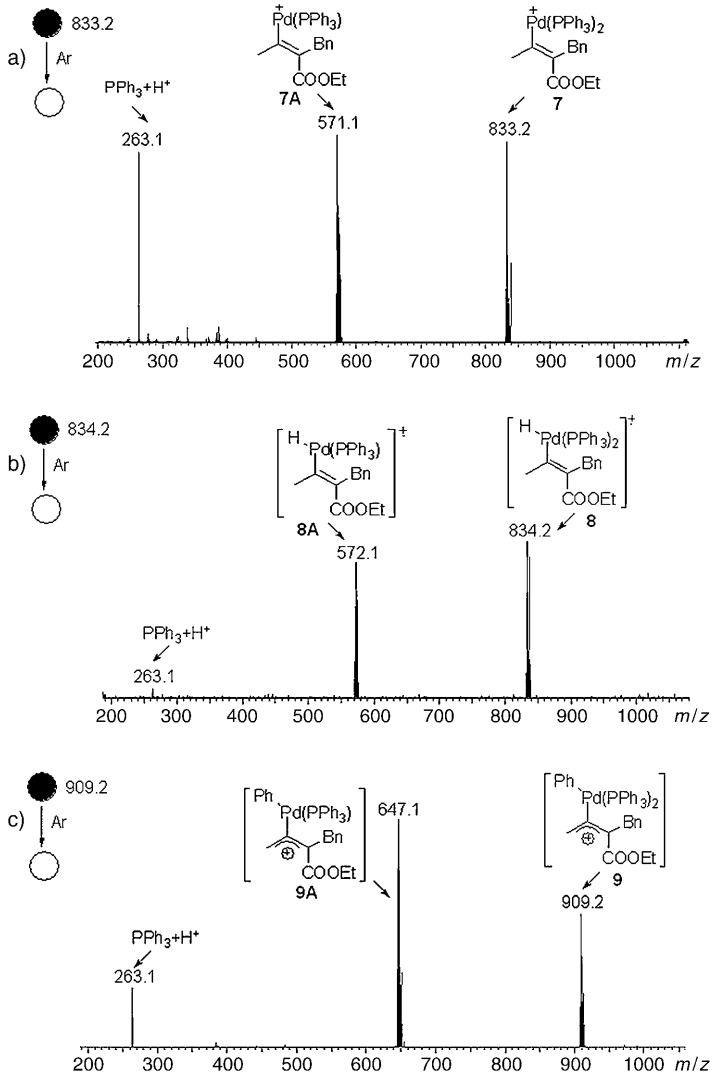


Figure 2. ESI-(+)-MS/MS of a) intermediate **7** (principal ion of *m/z* 833.1993), b) intermediate **8** (principal ion of *m/z* 834.2025), and c) intermediate **9** (principal ion of *m/z* 909.2265).

In conclusion, we have successfully characterized some key intermediates in the Pd^0-catalyzed addition reaction of allenes with boronic acids in the presence of AcOH by ESI-FTMS, and this has led to the mechanism shown in Scheme 3. Further studies in this area are being carried out in our laboratory.

Dimethyl Carbonate in the Supercages of NaY Zeolite: The Role of Local Fields in Promoting Methylation and Carboxymethylation Activity**

*Francesca Bonino, Alessandro Damin, Silvia Bordiga, Maurizio Selva, Pietro Tundo, and Adriano Zecchina**

In the last two decades the need for safer processes has focused a great deal of attention on the use of small organic carbonates, especially dimethyl carbonate ($MeOCO_2Me$: DMC). DMC is a nontoxic compound that can profitably

replace very harmful methyl halides (or dimethyl sulfate) and phosgene in both methylation and carboxymethylation processes.[1] In recent times it has been observed that methylation of primary aromatic amines with DMC is efficiently catalyzed by alkali-metal-exchanged faujasites (e.g. NaY). The peculiarity of the process is that DMC-mediated methylation of amines proceeds with unprecedented monomethyl selectivity (up to 99%) and complete chemoselectivity at the amino group in the case of ambident nucleophiles. Another peculiarity of NaY is that it also catalyzes carboxymethylation reactions. These findings suggest that under the appropriate conditions the DMC/NaY interaction leads to weakening (activation) of both $O-CH_3$ and $C-OCH_3$ bonds. The discovery of highly selective catalysts for reactions involving DMC is of special interest from both environmental and synthetic standpoints because it offers important and innovative protocols for the synthesis of high-value-added pharmaceutical intermediates and dyestuffs.[2]

It has been reasonably hypothesized that activation of DMC in the restricted spaces of the internal cavities (supercages) of NaY occurs by an electric-field-induced polarization of the molecule, which is accompanied by elongation and weakening of the $O-CH_3$ and/or $C-OCH_3$ bonds. To clarify this fundamental point, the aim of this investigation is to shed light on the structural perturbation induced in DMC upon interaction with the positively charged counterions present in the supercages. For this purpose a study of the modification of the IR properties of DMC, induced by the interaction with NaY, has been performed; the experimental results obtained are compared with ab initio simulations. It will be shown that the interaction of DMC with Na^+ ions fully explains why NaY is so effective in promoting the methylation and carboxymethylation activity of DMC.

This spectroscopic investigation takes advantage of the fact that, as DMC is a liquid, it can be easily dosed from the gas phase onto activated NaY and that, upon diffusion inside the pores, the IR spectrum of DMC can easily be recorded in situ.[3]

The available frequency range for the IR study on NaY ($\tilde{\nu} > 1300\ cm^{-1}$) only allows the observation of the $\nu(CO)$ mode of the $C-O_1$ bond (see Figure 1a), the $\nu_{asymm.}(CO_2)$ mode of the O_2-C-O_3 moiety (see Figure 1b), and the $\delta(CH_3)$ modes of the methyl groups. The bands associated with $\nu_{symm.}(CO_2)$, $\nu_{symm.}(O-CH_3)$, and $\nu_{asymm.}(O-CH_3)$, which would be of high diagnostic utility, cannot be observed because they fall within the zeolite framework region.

The dashed line in Figure 2a represents the background-subtracted spectrum of DMC completely filling the supercages (DMC/$Na^+ > 1$) (obtained by equilibration at the vapor pressure of DMC). Under these conditions the spectrum is characterized by broad and complex absorptions in both the $\nu(CO)$ (1805–1710 cm^{-1}) and $\nu_{asymm.}(CO_2)$ (1340–1235 cm^{-1}) ranges due to the superposition of the contributions from DMC interacting directly with the cations of the walls and liquid-like DMC filling the residual spaces of the supercages. Because of this multiple contribution, this spectrum is of little utility.

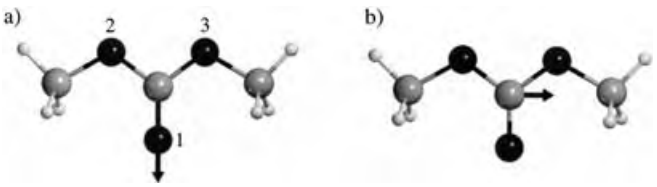

Figure 1. Pictorial representation of the normal modes of DMC1: a) $\nu(CO)$; b) $\nu_{asymm.}(CO_2)$. White spheres: H atoms; gray spheres C atoms; black spheres: O atoms.

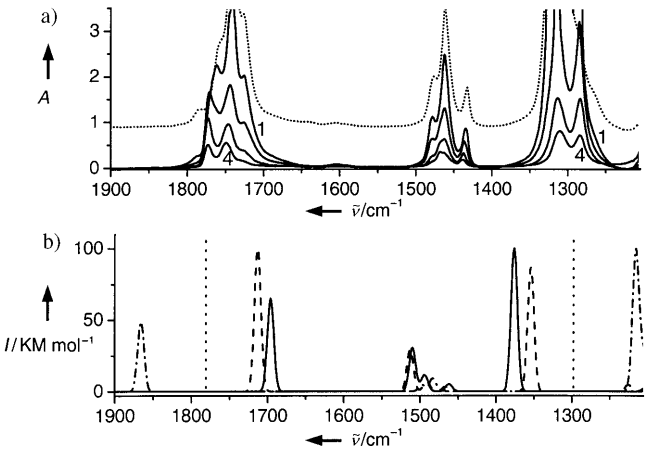

Figure 2. a) Dashed line: background-subtracted spectrum of vapor pressure of DMC on NaY zeolite outgassed at 673 K. Curves 1–4: effect of progressive outgassing at 353, 393, 423, and 453 K respectively. b) Computed IR spectra of structures **b**, **c**, and **d** reported in Figure 4. Dotted lines correspond to the computed spectrum of the DMC1 isomer.

To reveal the contribution of DMC in direct contact with the Na^+ ions present on the walls, we removed the liquid-like fraction by controlled desorption and collected a series of spectra corresponding to decreasing DMC/Na^+ ratios (curves 1–4, solid lines in Figure 2a). It can be seen that, after removal of liquid-like DMC, the $\nu(CO)$ and $\nu_{asymm.}(CO_2)$ modes clearly split into two major components at 1772–1747 and 1311–1284 cm^{-1}, respectively, while the bending frequencies of the methyl groups are essentially unaffected. The half-width of the components of the 1747–1311 cm^{-1} pair is larger than that of the 1772–1284 cm^{-1} pair, which suggests that they are caused by a family of similar species, instead of a single one. A shoulder is also observable at 1728 cm^{-1}. The relative intensity of the doublets' components changes with coverage, which allows us to conclude that the 1772–1284 and the 1747–1311 doublets belong to two different species (I and II, respectively). For the reasons described above, species II has a composite structure. A relevant observation concerning the species I and species II pairs is that the frequency difference $\Delta\nu$ between the $\nu(CO)$ and $\nu_{asymm.}(CO_2)$ modes is such that $\Delta\nu_I > \Delta\nu_{gas} > \Delta\nu_{II}$. This observation will be of great utility for comparison with the theoretical results (see below). In conclusion, from the IR spectroscopic data we can infer that the interaction of DMC with the Na^+ ions present in the supercages induces a relevant perturbation of the molecule, which influences the vibrational properties, and hence the force constants, of bonds with C–O character. On the basis of these results, it was not possible to advance an unambiguous

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structural interpretation of the observed vibrational perturbations. Consequently, B3-LYP calculations of the structural, energetic, and vibrational features of model Na^+/DMC adducts were performed. To this end both *cis–cis* and *cis–trans* DMC structures (hereafter DMC1 and DMC2, respectively; see stick-and-ball representations in Figure 3) were

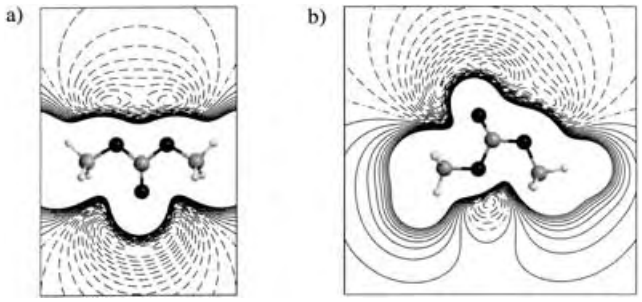

Figure 3. Pictorial representation of the computed electrostatic potential (ESP) of a) DMC1 and b) DMC2. Solid line: ESP > 0. Dashed line: ESP < 0. White spheres: H atoms; gray spheres: C atoms; black spheres: O atoms.

considered because they are very similar from the stability point of view (DMC2 being less stable by only about 12.9 kJ mol^{-1}), and hence they could be both present in the supercages as the result of an isomerization process. The computational scheme adopted (see Experimental Section for further details) is fully appropriate for this type of computation because the geometry and vibrational frequencies obtained for the DMC1 conformer are in agreement with the experimental observations.[4,5] The analysis of the molecular electrostatic potential (ESP) of DMC1 and DMC2 is shown in Figure 3, and reveals that: 1) DMC1 possesses two distinct nucleophilic sites (ESP < 0) on the oxygen of the C–O_1 bond and on the oxygen atoms of the O_2–C–O_3 moiety, and 2) DMC2 has only one nucleophilic site on the C–O_1 bond. On this basis three different DMC adducts with the complete series of naked alkali-metal cations were considered (Figure 4, structures **b**, **c**, and **d**). Such an approach has been demonstrated to be able to describe the electrostatic origin of

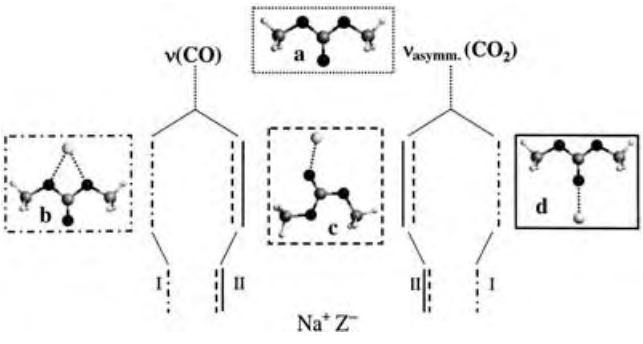

Figure 4. Vertical lines represent schematically ν(CO) and $\nu_{asymm.}(CO_2)$ of DMC under different conditions. Gas phase: isomer **a** top part; adducts **b**, **c**, and **d** middle part; experimental values obtained for NaY bottom part. The models are represented as sticks and balls with the same color code used in Figure 3. Na^+ ions in clusters **b**–**d** are represented as white spheres.

the interaction between the CO molecule and counterions in exchanged zeolites.[6] A subsequent article[7] has shown that the presence of the $AlH(OH)_3^-$ counteranion does not substantially change the conclusions reached in reference [6]. The stabilities of the adducts, as evaluated by binding energy calculations (DMC1 taken as reference reactant, BSSE accounted for),[8] are in the order **c** > **d** > **b**. As shown in Figure 5a, there is a linear correlation (positive slope)

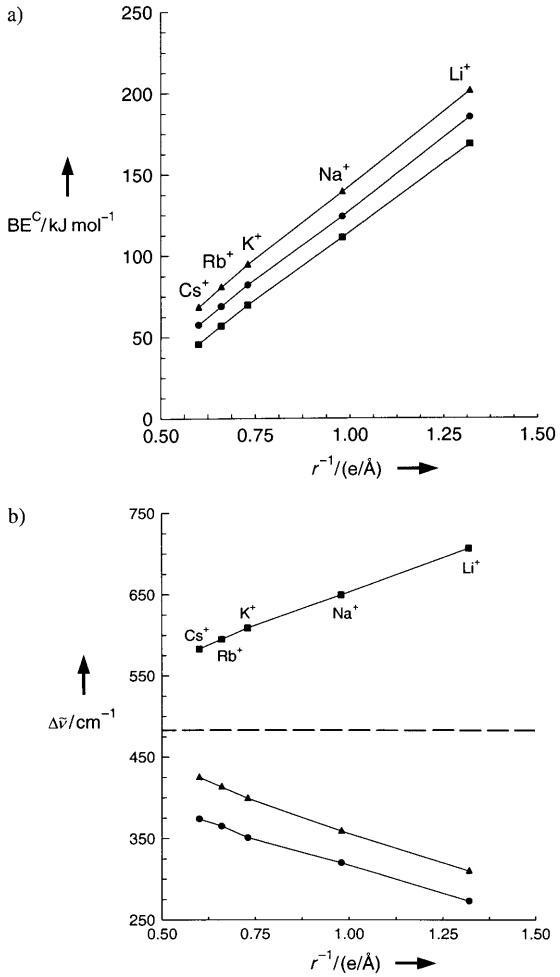

Figure 5. a) Computed BE^c (binding energy corrected for the BSSE) versus the charge density of the interacting alkali-metal cations. (■), (▲), and (●) refer to adducts **b**, **c**, and **d**, respectively. b) Computed $\Delta\nu$ ($\nu(CO) - \nu_{asymm.}(CO_2)$) versus the charge density of the interacting alkali-metal cations. (■), (▲), and (●) refer to adducts **b**, **c**, and **d**, respectively.

between the computed binding energy for the three adducts and the charge density (i.e. the reciprocal of the ionic radius for monovalent cations), thus confirming the pure electrostatic origin of the interaction. When the interaction occurs through the oxygen of the C–O_1 moiety (structures c and d in Figure 4), the calculations predict an elongation (weakening) of the C–O_1 and the $O_{2/3}$–CH_3 bonds, the remaining two C–$O_{2/3}$ bonds being shortened (strengthened). When the interaction occurs through the latter two oxygen atoms (structure **b** in Figure 4), the C–O_1 moiety undergoes a shortening

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(strengthening), while the $C{-}O_{2/3}$ and the $O_{2/3}{-}CH_3$ bonds undergo a lengthening (weakening). Further interesting results come from the computed frequencies of the adducts: in structures **c** and **d** of Figure 4 the ν(CO) and $\nu_{asymm.}(CO_2)$ are red- and blue-shifted, respectively, with respect to isolated DMC1, whereas in structure **b** of Figure 4 the opposite behavior is observed. The computed spectra obtained in the case of Na^+ are shown in Figure 2b and in Figure 4 as dotted (**a**), dot-dashed (**b**), dashed (**c**), and full (**d**) lines, and show that $\Delta\nu_{\mathbf{b}} > \Delta\nu_{gas} > \Delta\nu_{\mathbf{c}} \approx \Delta\nu_{\mathbf{d}}$. A similar trend is observed for the other alkali-metal cations, as shown in Figure 5b, from which it is clear that this observation also correlates with the charge density of the interacting cations.

These values are clearly in qualitative agreement with the experimental observations (reported in Figure 2a and schematized in Figure 4). Another interesting result is that structures **c** and **d** have very similar spectroscopic features and hence they behave as a family of similar species, in agreement with the observed half-width of the components of species II. Of course, the computed Δν values are higher than the experimental ones, because the model adducts involve bare Na^+ ions; in fact their polarizing power is higher than that of the Na^+ counterions in the supercage, whose positive charge is partially counterbalanced by the negative charge of the framework.

In conclusion, on the basis of a comparison of the experimental and computed data we have been able to conclude that both *cis–cis* and *cis–trans* species are present in the NaY supercages and to identify the properties of the adducts formed by these species with the Na^+ ions. In particular, the electrostatic perturbation in adducts **c** and **d** induces an elongation (weakening) of the $O{-}CH_3$ bonds, a fact which can explain the catalytic activity of NaY in methylation reactions. In adduct **b** an elongation of the $C{-}OCH_3$ occurs, which justifies the catalytic activity of NaY in carboxymethylation reactions. Finally, the observation that the IR components associated with structure **b** are the preferred ones at lowest coverage (higher evacuation temperature) could explain a different selectivity of the DMC/NaY system towards carboxymethylation reactions.

Taken together, these results afford, in a simple and direct manner, a reasonable explanation why NaY is a useful catalyst for methylation and carboxymethylation reactions with DMC. The role of polarization forces associated with the Na^+ counterions that are present in the restricted spaces of the supercages in DMC activation is also clearly demonstrated.[2c]

Experimental Section

An NaY sample (Aldrich, Si/Al ≈ 3), in the form of a thin, self-supported wafer, was activated at 673 K in vacuo (up to 10^{-5} mbar) before contact with DMC. Liquid DMC (ACROS Organics, 99% in purity) was dosed in the gas phase in a vacuum manifold directly connected to the measurement cell. IR spectra were recorded with a Bruker IFS 66 FTIR spectrometer equipped with an HgCdTe cryodetector (4000–700 cm^{-1} range) with a resolution of 2 cm^{-1}.

All calculations were performed by density functional theory procedures[9] with the B3-LYP[10] Hamiltonian, as implemented in Gaussian 98.[11] Li, Na, K, Rb, and Cs atoms were described with basis-set adopted by Ferrari et al.[6]. For C and O atoms, the fully optimized triple-ζ valence basis-set (TZV) of Ahlrichs et al.[12] was emplyed. A double set of diffuse p functions on the cations was added ($\zeta_p(Na) = 0.131$ and 0.0196 $Bohr^{-2}$). Moreover, the TZV basis sets for C and O atoms (hereafter TZV2d) were also supplemented by a double set of polarization d functions: ζ_d values were derived from the standard ones[13] following an even-tempered recipe ($\zeta_d(C) = 1.6$ and 0.4 $Bohr^{-2}$; $\zeta_d(O) = 2.4$ and 0.6 $Bohr^{-2}$). Hydrogen atoms in the DMC molecule were described by means of a standard Pople 6-311 + G(d,p) basis set.

Heterogeneous Catalysis

CO Oxidation Catalyzed by Supported Gold: Cooperation between Gold and Nanocrystalline Rare-Earth Supports Forms Reactive Surface Superoxide and Peroxide Species**

*Javier Guzman, Silvio Carrettin, Juan C. Fierro-Gonzalez, Yalin Hao, Bruce C. Gates, and Avelino Corma**

Novel catalysts for environmental and energy-related conversions are increasingly emerging from rational design based on the understanding of relationships between structure at the molecular level and catalyst performance. Gold that is highly dispersed on metal oxides has surprisingly been found to be an active and selective catalyst for numerous reactions,[1,2] including CO oxidation.[3] Contradictory hypotheses have been advanced to account for the CO oxidation activity,[4–13] and the nature of the active sites and reactive oxygen intermediates remains elusive.[14,15] Herein we show by time-resolved spectroscopy of working catalysts consisting of gold nanoclusters on nanocrystalline CeO_{2-x} that η^1-superoxide and peroxide intermediates are formed at one-electron defect sites at the metal–support interface and oxidize adsorbed CO to CO_2. The reactive oxygen species are not formed on conventionally prepared CeO_2, and their formation on nanocrystalline CeO_{2-x} is enhanced by the presence of the gold. This report is the first that unambiguously identifies and quantifies reactive oxygen species in low-temperature CO oxidation catalysis. The new concept advanced here is the representation of the catalytically active species as a composite that uniquely facilitates the formation of reactive oxygen species at the metal–support interface. The generality of the concept is exemplified by results showing that the nanocrystalline oxide can be either CeO_{2-x} or Y_2O_3.[16] This concept opens new avenues to the design of novel materials with improved activities and selectivities for catalytic oxidation.

We prepared high-surface-area ($S_{BET} = 180\ m^2 g^{-1}$; BET refers to Brunauer, Emmett, and Teller) and thermally stable nanocrystalline CeO_{2-x} with the fluorite structure by self-assembly in a liquid-crystal phase of individual CeO_2 nanoparticles with an average diameter of 5 nm.[17] Calcination of the nanocrystalline CeO_{2-x} at 873 K either in the absence or in the presence of 20 wt% H_2O produced minor changes in the BET surface area ($S_{BET} = 160\ m^2 g^{-1}$). CeO_2 was also prepared by a conventional precipitation–calcination method to facilitate a comparison with the nanocrystalline material and to allow investigation of the influence of the surface structure.[12] Deposition–precipitation of gold on the two supports yielded samples with gold loadings in the range of 0.9–4.6 wt%. These samples were characterized by the following spectroscopic methods as they functioned as catalysts for CO oxidation at steady state in flow reactors: X-ray absorption near edge structure (XANES); extended X-ray absorption fine structure (EXAFS); Raman; IR. Each of the samples catalyzed CO oxidation but gold supported on conventional CeO_2 was much less active than that on the nanocrystalline support. The spectra provide information that characterizes the oxidation state(s) and structure of the gold atoms as well as reactive oxygen species derived from the support and reactants.

Highly active gold supported on nanocrystalline CeO_{2-x} was characterized during treatment in He and during catalytic CO oxidation at room temperature; in each case, the EXAFS first-shell Au–Au coordination number $N_{Au\text{-}Au}$ was close to 4 (Table 1), thus indicating the presence of small gold nanoclusters. The absence of higher-shell Au–Au contributions confirms that the nanoclusters did not aggregate during catalysis. Time-resolved XANES spectra (see Supporting Information) indicate cationic gold clusters in the catalyst, which were stable during CO oxidation and this result is consistent with those that show cationic gold clusters in other supported catalysts.[4,5,12]) EXAFS contributions from Au–O at a distance of approximately 2.1 Å demonstrate covalent bonding between gold atoms in the supported clusters and oxygen atoms of the support,[18] and Au–O contributions for longer distances (3.5 Å) indicate nonbonding interactions of gold clusters with oxygen of the support surface (Table 1).

The data that represent the family of samples show a striking correlation: the catalytic activity of nanocrystalline CeO_{2-x}-supported gold clusters increases approximately in proportion to the EXAFS coordination number that represents the Au–O contribution for longer distances (Figure 1). This result indicates the participation of oxygen species at the support surface in CO oxidation. Bolstering this inference, IR spectra recorded for the sample treated with CO in the absence of O_2 indicate formation of CO_2 (see Supporting Information). Thus, the results indicate that nanocrystalline CeO_{2-x} supplies reactive oxygen to the active gold species in CO oxidation, which is consistent with the idea of CeO_2 acting as an oxygen reservoir by releasing and taking up oxygen through redox processes that involve the Ce^{4+}/Ce^{3+} couple.[6] The correlation between catalytic activity and the number of oxygen atoms surrounding—but not bonded to—the gold

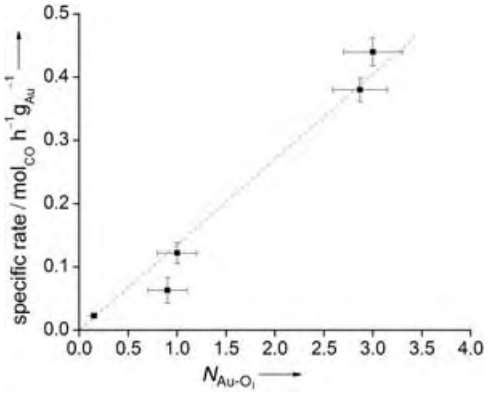

Figure 1. Catalytic activity as a function of the EXAFS coordination number of Au–O_i during CO oxidation catalyzed by gold supported on nanoparticulated CeO_2.

clusters implies that these species are involved in the catalysis, possibly as reactive intermediates that are continuously regenerated by reaction of the surface with O_2.

In contrast, the EXAFS data that characterize gold clusters supported on conventional CeO_2 (which was barely active as a catalyst under the same conditions) do not indicate any Au–O contributions distinguishable above the noise.[19,20] We attribute the near absence of catalytic activity of gold species on the conventional support to the lack of oxygen atoms at the cluster–support interface that can interact fruitfully with the gold atoms. Consistent with this interpretation, we did not detect CO_2 during IR experiments when CO alone was brought in contact with the sample. Furthermore, the differences in catalytic activity between the gold catalysts prepared with conventional and nanocrystalline supports cannot be associated with effects from the different size of the gold particles because the two catalysts have similar distributions of particle size (with an average diameter of about 3–4 nm; see TEM images in the Supporting Information).

To elucidate the nature of the reactive oxygen species on the nanocrystalline support that interact with the gold clusters, we recorded Raman spectra during the room-temperature adsorption of O_2 on CeO_{2-x} alone and on the sample consisting of gold on nanocrystalline CeO_{2-x}; the samples were subsequently exposed to 10% CO in He (Figure 2).

The precise identity of the reactive oxygen species on supported metal catalysts remains to be clarified, although various types of oxygen species have been characterized on cerium oxide.[21] Our results contribute to the understanding of these species and give evidence of a correlation that connects the concentration of reactive oxygen species, their rate of consumption, and the catalytic rate of formation of CO_2 on our catalyst. The spectrum that characterizes the products of O_2 adsorption on nanocrystalline CeO_{2-x} presents bands at 1123, 964, 871, and 831 cm^{-1}, which, on the basis of published data,[22–24] are assigned to η^1-superoxide, peroxide at one-electron defect sites, nonplanar bridging peroxide, and η^2-peroxide species, respectively (see Supporting Information). When CO came into contact with this sample, the intensities of the bands of the oxygen species remained constant and no CO oxidation was detected. In contrast, when O_2 was adsorbed on the gold supported on nanocrystalline CeO_{2-x}

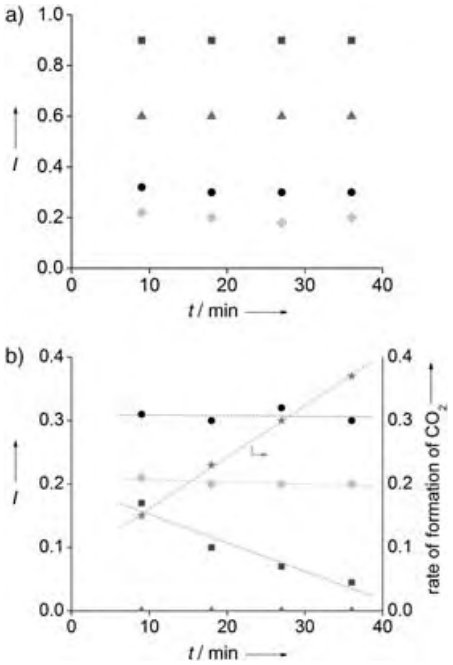

Figure 2. Raman spectra characterizing the formation and reactivity of oxygen species on Au supported on nanostructured CeO_2. Operating conditions were 298 K and 760 Torr: a) adsorption of O_2; b) subsequent exposure to 10% CO in He. The Raman intensities I corresponding to various oxygen species were obtained from the following bands: η^1 superoxide: 1123 cm^{-1} (squares); peroxide at one-electron defect site: 966 cm^{-1} (triangles); nonplanar bridging peroxide: 871 cm^{-1} (circles); and η^2 peroxide: 831 cm^{-1} (diamonds). The rate of formation of CO_2 (stars in (b)) was determined from analysis of the evolved gas phase.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

(Figure 2a), the intensities of the bands representing η^1-superoxide and peroxide species at one-electron defect sites were greater than those characterizing the support alone, whereas the intensities of the bands representing nonplanar bridging peroxide and η^2-peroxide species were almost the same. These results indicate a promoting effect of the gold species on the formation of η^1-superoxide and peroxide at one-electron defect sites on the support.

It has been suggested that the presence of gold clusters weakens the bonding of the oxygen species on CeO_2 and facilitates the formation of more reactive species.[6,25] Consistent with this suggestion, we observed that the peroxide species at one-electron defect sites were completely depleted when CO interacted with the sample to form CO_2 (observed in the gas phase); η^1-superoxide species were consumed simultaneously (Figure 2b). There is a correlation between the concentration of each of these species and its rate of consumption and also with the catalytic rate of formation of CO_2 (Figure 2b). In contrast, the concentrations of nonplanar bridging peroxide and η^2-peroxide species remained unchanged (Figure 2b), which indicates that these species do not participate directly in the CO oxidation. Thus, η^1-superoxide and peroxide at one-electron defect sites are identified as reaction intermediates under our conditions, whereas nonplanar bridging peroxide, η^2-peroxide, and molecular oxygen species are either spectators or involved in virtually equilibrated elementary steps in the catalytic cycle.

Consistent with this interpretation, when we performed the same experiments but with a barely active catalyst consisting of gold supported on conventional CeO_2, the only oxygen species observed were nonplanar bridging peroxide adspecies, η^2-peroxide, $O_2^{\delta-}$ $(0<\delta<1)$, and molecular oxygen; no CO_2 formation was detected with this sample under our conditions.

Results of temperature-programmed reduction (TPR) with CO characterizing the catalytically active gold on nanocrystalline CeO_{2-x} confirm the participation of the separate surface oxygen species, which are reactive under various conditions (see Supporting Information). The species reduced at high temperature (820 K) are associated with lattice oxygen, which does not participate in CO oxidation at low temperatures. The oxygen species with maximum CO uptakes at 385 and at 473 K may be attributed to superoxide and peroxide adspecies, respectively. Cyclic TPR experiments (see Supporting Information) demonstrate the regeneration of the active gold sites during reduction and oxidation of the catalyst.

Our results imply a cooperation between gold and the nanocrystalline CeO_{2-x} which promotes the formation of reactive oxygen species (Figure 3). An explanation for the enhanced activity of the catalysts prepared with nanocrystalline CeO_{2-x} is based on the stabilization of cationic gold (indicated by previous reports and supported by our own XANES data)[5,12] and reactive intermediate oxygen species, all at the cluster–support interface; the stabilization is inferred to be caused in part by oxygen vacancies on the nanocrystalline support and facilitated by a synergistic effect associated with the smallness (nanoscale) of both the gold and the support. Consistent with this interpretation, the high surface/grain–boundary area that is characteristic of the CeO_{2-x} nanocrystals is associated with the presence of defects that enhance the electron-transport properties of sintered nanostructured CeO_{2-x} relative to that of bulk CeO_2.[17]

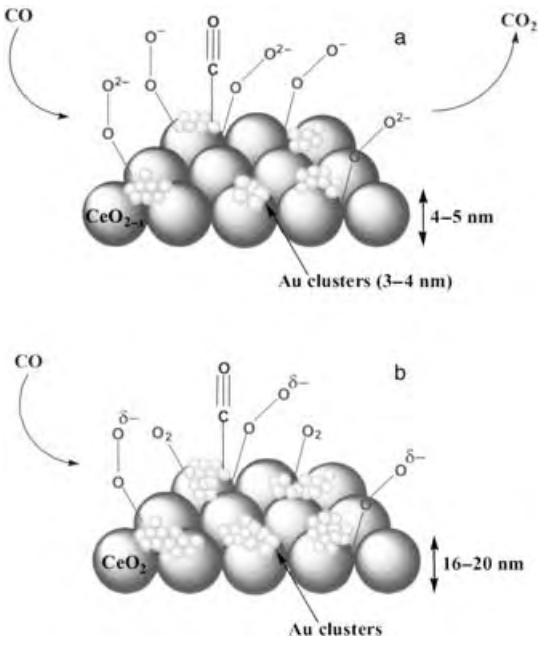

Figure 3. Schematic representation of CO oxidation catalyzed by gold on nanocrystalline (a) and regular (b) CeO_2. a) CO is adsorbed on the gold, whereas the oxygen is supplied through the nanocrystalline CeO_2 support as η^1-superoxide and peroxide adspecies at one-electron defect sites to give CO_2. b) CO is adsorbed on the gold atoms and the oxygen is adsorbed as molecular O_2 and $O_2^{\delta-}$. The size of the atoms is not scaled.

As described in reference [16], a catalyst consisting of gold on Y_2O_3, both nanocrystalline and conventionally prepared, showed similar differences in the catalytic activity as the one studied here; the activity of the catalyst prepared from nanocrystalline Y_2O_3 was shown to be comparable to the activities of the most active supported gold catalysts under similar conditions,[3,13] and the reactive intermediate oxygen species identified by Raman spectroscopy during catalysis were peroxide and superoxide species (see Supporting Information). These results bolster those observed for the CeO_{2-x}-supported samples and demonstrate a general synergistic effect associated with the interfaces between gold and nanocrystalline redox-active supports in promoting the formation of reactive oxygen species that participate in catalytic CO oxidation.

In summary, we have shown a correlation between the catalytic activity of gold supported on nanocrystalline CeO_{2-x} and reactive η^1-superoxide and peroxide species at one-electron defect sites on the support. The formation of reactive oxygen species on the nanocrystalline support is enhanced by the gold. The pattern extends to Y_2O_3 supports, and we infer that the existence of reactive peroxides at gold nanocluster–support interfaces is general and will be useful in the design of novel materials with enhanced catalytic activity and selectivity for oxidation reactions.

Experimental Section

Nanocrystalline CeO_2 and Y_2O_3 were prepared from colloidal dispersions of CeO_2 and Y_2O_3 nanoparticles with average diameters of 5 nm. The conventional CeO_2 support was prepared by precipitation of $Ce(NO_3)_4$; conventional Y_2O_3 was supplied by Nyacol, Inc. Gold was deposited on each support by deposition–precipitation of $HAuCl_4$ with NaOH, as described elsewhere.[12,16] The catalysts were not calcined. The total Au content of each final catalyst was determined by chemical analysis.

Raman spectra, with a resolution of 2 cm^{-1}, were collected with a Renishaw inVia Raman spectrometer equipped with a Leica DMLM microscope and a 514-nm Ar^+ ion laser as an excitation source and with a laser power at the sample of 2.0 mW. Each reported spectrum is the average of 20 scans with an exposure time each of 10 s. O_2 adsorption and CO oxidation experiments were conducted with an in situ cell (Linkam Scientific, THMS 600). The catalysts were pretreated at 323 K under vacuum (10^{-2} Pa) for 1 h before adsorption experiments.

The X-ray absorption spectroscopy experiments were performed at beamline X-18B at the National Synchrotron Light Source, Brookhaven National Laboratory, Upton, NY, USA. The storage ring electron energy was 2.8 GeV and the ring current varied within the range of 110 to 250 mA. Spectra were collected in the fluorescence mode. Higher harmonics in the X-ray beam were minimized by detuning the Si(111) double-crystal monochromator by 20 to 25 % at the Au L_{III} edge (11919 eV). A PIPS detector was used, and each reported spectrum is the average of six scans. Data were recorded during CO oxidation catalysis at 298 K and also with the catalysts in flowing He at atmospheric pressure and 298 K. Catalyst powder (0.3 g) was loaded into a cell/reactor and installed in the flow system at the beamline.

CO oxidation catalysis was carried out at atmospheric pressure in a standard once-through, nearly isothermal tubular packed-bed flow reactor (9 mm in diameter). Total feed flow rate to the reactor was 100 mL (normal temperature and pressure) per minute with a molar ratio of CO/air/He of 0.2:19.8:80.0, with an inverse space velocity of 18.6–94.0 $g_{cat}\,h\,mol_{CO}^{-1}$. The conversions were determined by gas chromatographic analysis of the product stream with an accuracy of about $\pm 5\,\%$. An on-line gas chromatograph (Varian, Star 3400 CX) equipped for column switching (Porapak and molecular sieves) in combination with two-channel detection (with a thermal conductivity detector and a flame-ionization detector) was used to analyze the gas stream.

Gene Technology

Polyethylenimine-Grafted Multiwalled Carbon Nanotubes for Secure Noncovalent Immobilization and Efficient Delivery of DNA

Ye Liu, De-Cheng Wu, Wei-De Zhang, Xuan Jiang, Chao-Bin He, Tai Shung Chung, Suat Hong Goh, and Kam W. Leong*

The functionalization of carbon nanotubes (CNTs) has been carried out in various ways for numerous applications in biotechnology,[1–15] including for the preparation of sensors,[2,3] as scaffolds for cell growth,[4] imaging reagents,[5] and transporters for drug delivery.[6–8,13,15] One way is to immobilize DNA onto the surface of CNTs through noncovalent interactions[8–13] or covalent bonds.[3,12–15] Covalent-bond approaches might compromise and even spoil the functions of DNA owing to chemical reactions and the difficulty in releasing DNA.[13,14b,15] Nevertheless, noncovalent approaches developed to date may only provide metastable immobilization of DNA onto the surface of CNTs. It was reported that the migration of DNA linked covalently to CNTs was retarded in gel electrophoresis but noncovalent interactions between DNA and CNTs did not completely prevent migration.[14b] Polyethylenimine (PEI) is a type of polymer with a high density of amines, thus DNA may be immobilized securely onto the surface of multiwalled carbon nanotubes (MWNTs) that have been functionalized with PEI through strong electrostatic interactions arising from these amines. Hence, we have adopted a grafting-from approach to prepare polyethylenimine-graft multiwalled carbon nanotubes (PEI-g-MWNTs). DNA has been immobilized securely onto the surface of PEI-g-MWNTs as demonstrated by the total inhibition of the migration of DNA in gel electrophoresis, and PEI-g-MWNTs showed transfection efficiency for delivery of DNA that was similar to or even several times higher than that of PEI (25 K) and several orders of magnitude higher than that of naked DNA.

PEI was grafted onto the surface of MWNTs by performing a cationic polymerization of aziridine in the presence of amine-functionalized MWNTs (NH_2–MWNTs). NH_2–MWNTs were obtained by introducing carboxylic acid groups onto the surface of MWNTs by heating at reflux in 3.0 M nitric acid. The carboxylic acid groups were transformed into acyl chloride groups by treatment with thionyl chloride[16] followed by treatment with ethylenediamine.[14] The grafting of PEI was realized through two mechanisms, the activated monomer mechanism (AMM) or the activated chain mechanism (ACM), by which protonated aziridine monomers or the terminal iminium ion groups of propagation chains, respectively, are transferred to amines on the surface of MWNTs.[17] (see Supporting Information.)

The relative amount of PEI grafted onto the surface of MWNTs was investigated by thermogravimetric analysis (TGA) performed under nitrogen. MWNTs were thermally stable up to 600 °C (Figure 1 A, curve a) whereas pure PEI degraded completely at about 500 °C (Figure 1 A, curve d). At 500 °C, pristine MWNTs, NH_2–MWNTs, and PEI-g-MWNTs showed negligible, about 2.3 %, and 10.5 % weight losses, respectively, thus PEI-g-MWNTs contained about 8.2 % PEI. Grafting with PEI made PEI-g-MWNTs easy to disperse in water, and the resulting suspension was still stable after six months. However, NH_2–MWNTs dispersed poorly in water and precipitation occurred within several hours (see Supporting Information). Transmission electron microscopy (TEM) provides direct evidence of grafting of PEI onto the surface of MWNTs. Figure 1 B shows TEM images of PEI-g-MWNTs on a holey carbon film: individually dispersed MWNTs are separated from others. High-resolution TEM (Figure 1 B, inset) indicates that PEI was grafted onto the surface of MWNTs as lumps with different sizes instead of as a uniform coating. This clumping results from the carboxylic acid groups, the ethylenediamine, and the PEI adhering preferably to the defects, which are the most active locations for chemical or physical functionalization;[18] these defects tend to cluster at the bends along the surface of MWNTs grown by chemical vapor deposition (CVD).[19] In Figure 1 C, the ^{1}H NMR spectrum of PEI-g-MWNTs in D_2O is compared with that of PEI in D_2O (pH 7.0). The signal at about $\delta =$ 3.1 ppm for PEI-g-MWNTs is attributed to grafted PEI, but the significantly decreased mobility of the PEI chains in PEI-g-MWNTs leads to broadening of the resonances. Some of the amine groups of PEI were protonated (pK_a of PEI is greater than 8.0); we found that protonation or partial protonation of PEI was necessary for the formation of a stable aqueous suspension of PEI-g-MWNTs and neutralizing PEI by adjusting the pH value to 9 or higher led to precipitation of dispersed PEI-graft-MWNTs within several hours.

PEI obtained by cationic polymerization of aziridine has a dendritic structure that contains primary, secondary, and tertiary amines with a molar ratio of about 1:2:1.[20] Grafting PEI onto the surface of MWNTs should have a negligible effect on the chemistry. The migration of DNA was totally inhibited in gel electrophoresis when the weight ratio of PEI-

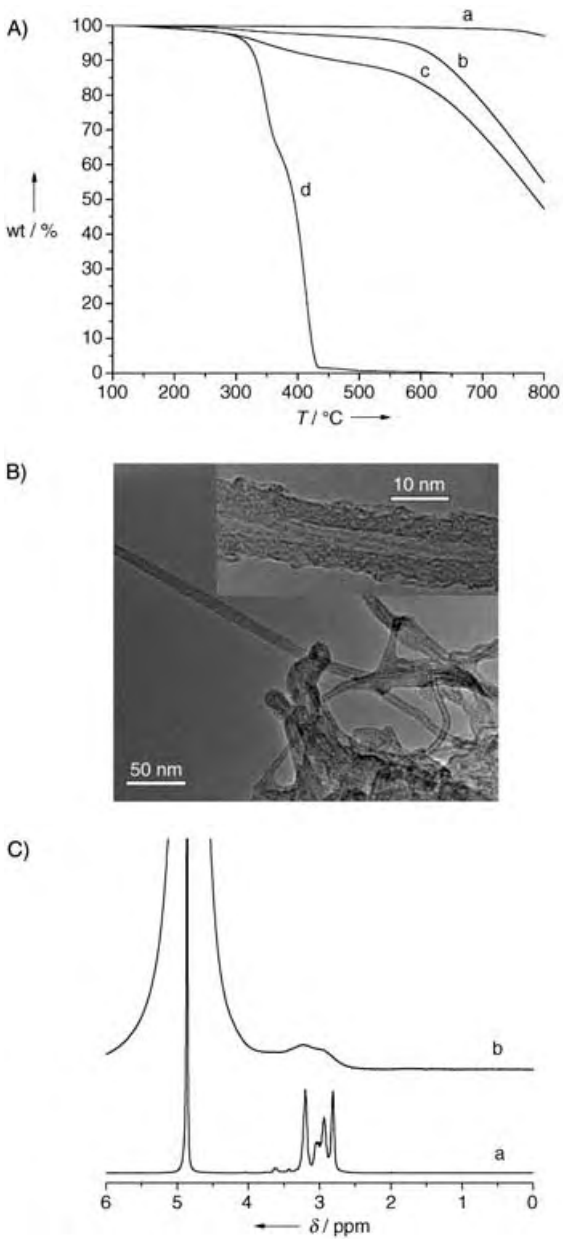

Figure 1. A) TGA curves of a) pristine MWNTs, b) NH_2–MWNTs, c) PEI-g-MWNTs, and d) PEI. B) TEM images of PEI-g-MWNTs; inset, high-resolution TEM image of PEI-g-MWNTs . C) ^1H NMR spectra of a) PEI in D_2O (pH 7) and b) PEI-g-MWNTs in D_2O.

g-MWNTs to DNA was about 4:1 (see Supporting Information). This result indicated that the dendritic grafted PEI with a high content of primary, secondary, and tertiary amines could function as anchor points for the secure immobilization of DNA onto the surface of MWNTs. In contrast, the presence of pristine MWNTs and NH_2–MWNTs showed little effect on the migration of DNA, even at a high weight ratio of 100:1 (see Supporting Information). Furthermore, a monolayer of PEI (25 K) was adsorbed onto the surface of CNTs directly after thorough rinsing,[21] but this monolayer of PEI did not prevent the migration of DNA (see Supporting Information). Thus, DNA could not be securely immobilized onto the surface of pristine MWNTs, NH_2–MWNTs, and MWNTs that were covered by a physically absorbed monolayer of PEI (25 K) because the interaction was too weak.

Recently it was demonstrated that amine-terminal oligoethylene glycol functionalized MWNTs (*f*-MWNTs) are promising for the delivery of DNA into cells, but the in vitro transfection efficiency of *f*-MWNTs was much less effective than that of lipids and only ten times higher than that of naked DNA.[8] In comparison, PEI-g-MWNTs that we have developed showed good transfection efficiency for DNA delivery. Figure 2 compares the transfection efficiency of PEI-g-MWNTs for DNA delivery in 293 cells with that of naked DNA and PEI (25 K), one of the most efficient polymers for the delivery of DNA.[22] The optimal weight ratio for PEI-g-MWNTs to DNA was about 45:1, with a N/P ratio of about 28.5:1 (10:1 for PEI at 25 K).[22] Under these conditions, the transfection efficiency of PEI-g-MWNTs was more than three times higher than that of PEI (25 K), and four orders of magnitude higher than that of naked DNA. PEI-g-MWNTs showed good transfection efficiency of DNA in other cells as well. The transfection efficiencies of PEI-g-MWNTs in COS7 and HepG2 cells were around twice and half, respectively, of those of PEI (25 K) and much higher than those of naked DNA under an optimal N/P ratio of between 10 to 16:1 (see Supporting Information).

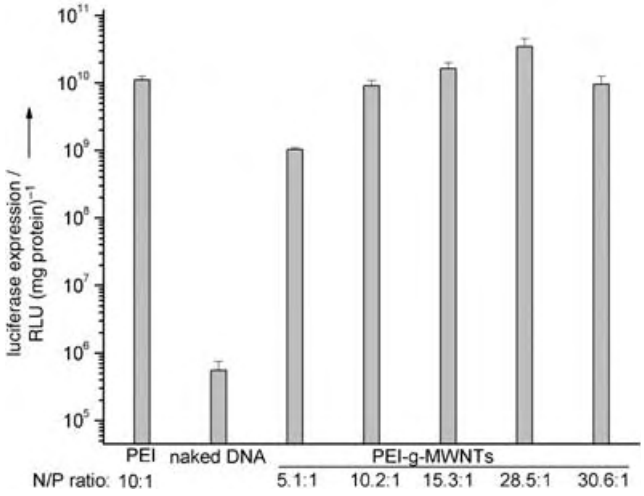

Figure 2. Transfection efficiency of PEI-g-MWNTs for DNA delivery relative to that of PEI (25 K) and naked DNA in 293 cells. The level of gene (pCMV-Luc) expression is given in relative light units (RLU) per mg of protein for quadruplicate runs (mean ± standard deviation ($n = 4$)).

The uptake of CNTs or their conjugates by the cells was suggested to occur by phagocytosis[5] or endocytosis,[6] which is in contrast to an insertion and diffusion mechanism in which MWNTs function as nanoneedles that inject DNA through the cell membranes.[7,8] We labeled PEI-g-MWNTs with fluorescein isothiocyanate (FITC); confocal microscope imaging demonstrated that the complexes of DNA with fluorescently labeled PEI-g-MWNTs entered cells after incubation for 1 h at 37 °C, but only very weak green fluorescence could be detected after incubation for 1 h at 4 °C (see Supporting Information). Therefore, the uptake of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the complexes of PEI-g-MWNTs and DNA should occur by endocytosis as reported.[5,6] The high transfection efficiency of PEI-g-MWNTs is attributed to several factors. The first factor is the secure immobilization of DNA onto the surface of MWNTs which leads to the formation of stable complexes that protect DNA well from degradation. The second factor is that the proton-sponge effect of the grafted PEI would allow the PEI-g-MWNTs/DNA complexes to escape easily from endosomes or other vesicles in cells, as has been well documented.[22] Furthermore, the larger complexes of PEI-g-MWNTs and DNA would improve the proton-sponge effects of PEI and facilitate a more effective sedimentation onto the cells.[23]

Pristine and some functionalized carbon nanotubes have been demonstrated to be of low cytotoxicity.[5–8] In 293 cells, the complexes of PEI-g-MWNTs/DNA with a weight ratio of 10:1 showed no significant effects on cellular metabolism but higher ratios led to a decreased cell number. Pure PEI-g-MWNTs showed a higher cytotoxicity. Figure 3A shows that

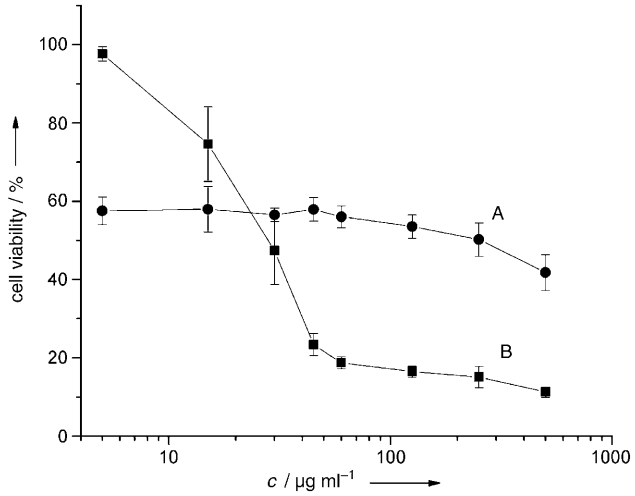

Figure 3. Cytotoxicity of A) PEI-g-MWNTs and B) PEI (25 K) in 293 cells.

about 60% of the cells were viable when the concentration of PEI-g-MWNTs was about 5 $\mu g\,mL^{-1}$, but the increased concentration of PEI-g-MWNTs showed less effect on the cell viability as compared with PEI (25 K; Figure 3B). Similar results were observed in COS7 and HepG2 cells (see Supporting Information). The cytotoxicity of PEI is related to the molecular weight: a higher molecular weight results in a higher cytotoxicity.[23] One PEI-g-MWNT may behave as high-molecular-weight PEI and thus it would have a certain degree of cytotoxicity.

In conclusion, we have prepared PEI-g-MWNTs. The grafted PEI chains function as efficient anchors to securely immobilize DNA onto the surface of MWNTs. This approach might be exploited to prepare highly sensitive CNT-based DNA sensors or probes and novel safe and efficient gene-delivery systems by fine-tailoring the PEI or by adopting other low toxic and biocompatible substitutes.

Experimental Section

PEI-graft-MWNTs: MWNTs were prepared by catalytic CVD of methane on Co–Mo/MgO catalysts. NH_2–MWNTs[14] and aziridine[25] were prepared by procedures similar to those reported. In a typical process for preparing PEI-g-MWNTs, NH_2–MWNTs (0.1 g) were dispersed in 1,2-dichloroethylene (20 mL) by ultrasonication over 20 min; aziridine (0.45 mL) was then added into the mixture under stirring followed by HCl (10 M; 10 μL). The reaction mixture was left at 80 °C for 24 h, after which time PEI-g-MWNTs were collected by filtration through a 0.2-μm pore polycarbonate membrane then washed with dichloromethylene ten times. PEI-g-MWNTs were purified by dispersing in deionized water, filtering through a 0.2-μm pore PVDF membrane, and washing with deionized water followed by drying under vacuum at 60 °C.

TGA was performed by scanning from 100 to 820 °C under nitrogen at a heating rate of 20 °C min^{-1} by using a Perkin Elmer TGA7. TEM was performed on a Philips CM300 FEGTEM instrument at 300 kV, and the samples were prepared by dropping one droplet of an aqueous suspension of PEI-g-MWNTs onto a holey copper mesh covered with carbon. NMR spectra were obtained on a Bruker DRX-400 spectrometer. The procedures for gel electrophoresis, evaluation of transfection efficiency for delivery of DNA, and cytotoxicity, were similar to those reported previously,[26] and these procedures are described in the Supporting Information together with the preparation of FTIC-labeled PEI-g-MWNTs, their incubation with cells, and confocal microscopy experiments.

Macrocycle Synthesis

Diversity Oriented One-Pot Synthesis of Complex Macrocycles: Very Large Steroid–Peptoid Hybrids from Multiple Multicomponent Reactions Including Bifunctional Building Blocks**

Ludger A. Wessjohann, Brunhilde Voigt, and Daniel G. Rivera*

Dedicated to Professor Armin de Meijere on the occasion of his 65th birthday

One of the most fascinating challenges in modern organic chemistry is the design of strategies capable of providing structurally diverse and complex molecules, which are useful either for the study of important biological processes[1] or for the development of supra- and nanomolecular systems.[2] The chemical genomics approach especially has focused efforts towards the rapid generation of molecules able to modulate protein functions, with the hope of thereby achieving a better understanding of the role of these molecules in many cellular pathways as well as providing new targets for drug development.[3] Frank in his recent review on chemical genomics concludes:[1e] "A general concept for the construction of protease-resistant (protein-like) synthetics for the interference of such (protein–protein) interactions is not yet available." Also, in contrast to small classic enzyme inhibitors, molecules to study protein–protein interactions are believed to require much larger interaction surfaces with an interplay of lipophilic and polar interaction areas. A promising solution could be the one-pot construction of extended, highly complex structures in which spatially separated recognition motifs combine to achieve overall binding. For this purpose, macrocyclic skeletons are considered to be an especially remarkable class of target scaffolds, as they can combine conformational preorganization with flexibility and biological stability.[4]

A useful prospect has been the development of diverse routes towards synthetic and natural-product-like macrocycles.[5,6] However, most (large) macrocycles utilized by the chemical community so far are either of the repetitive type (for example, the homooligomeric cyclodextrins and calixarenes) or have to be made by multistep, complex synthetic routes, which allow the generation of a single specimen but do not easily provide the diverse libraries required for holistic or evolutionary approaches and activity/property screenings.

Naturally occurring macrocycles are usually endowed with unique structural complexity[4] which, for example, enables the disruption of protein–protein interactions or binding to specific protein domains. Whilst diversity-oriented approaches have been devised to create the crucial complexity and diversity,[7] improvements are still required for macrocyclization strategies to rapidly and readily access diversity and to simultaneously introduce, for example, protein binding motifs in a unified task in the macrocyclization step itself.

We have recently addressed this quest and devised a new strategy for developing macrocycle diversity, in which the proper application of multiple multicomponent macrocyclizations including bifunctional building blocks (MiBs) allows rapid access to libraries of constitutionally defined peptoid-containing macrocycles.[6] Herein we describe the first applications of this concept for the straightforward synthesis of very large macrocycles (up to 60-membered rings), in which up to 4 multicomponent reactions (including the macrocyclization step) incorporate 12 components in 1 pot.

The Ugi four-component reaction (Ugi-4CR) has evolved as one of the most useful reactions in diversity-oriented approaches toward drug discovery.[8] The only by-product of this (atom) economic process is water. Moreover, bifunctional building blocks have been appropriately utilized to access a variety of structurally diverse cyclic scaffolds.[9] However, the multicomponent reaction itself has previously not been exploited for recognition-motif generation or, with some exceptions,[6,10] as a ring-closing reaction in macrocyclization strategies.

A simple survey of the skeletal (peptoid-core) diversity achieved by employing different symmetrically bifunctionalized (Ugi) components in a bidirectional macrocyclization is presented in Scheme 1. The ring size of the final macrocycle depends on the chosen combination of bifunctional building blocks. As either endo- or exocyclic amide bonds can be formed, higher or lower flexibility can be generated for both the ring and the differently tethered residues. However, it is important to note that even in the simplest double Ugi-4CR based approach, the two Ugi-4CRs do not occur simultaneously because a linear macrocycle precursor is formed initially. To understand the proper design of macrocycles, the final cyclization step is crucial to assess the ring size (multiplicity) and efficiency (yield), and thereby the result of the overall process.[5a,g] In the case of Ugi-type reactions, the analysis should not only be directed to the strain of the final macrocycle but also to the cyclic precursor α-adduct, as well as the possibly strained 1,3-*ansa*-like intermediate of the Mumm rearrangement, both resulting from the various

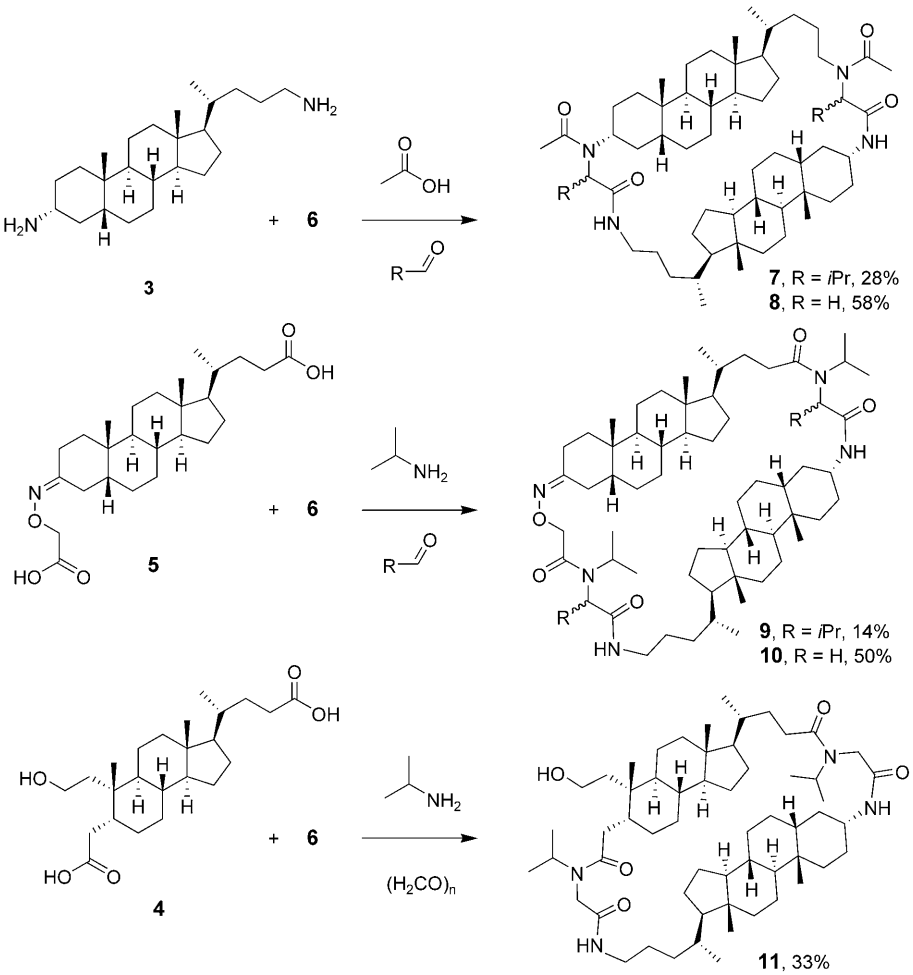
bifunctional building block combinations (Scheme 1; for example, aldehyde/acid building blocks bridging R^1 and R^4).[6]



With a view to applying this concept in the work described herein, we concentrated on a straightforward strategy towards steroid–peptoid hybrid macrocycles through a one-pot multiple Ugi-4CR of steroidal bifunctional building blocks. Steroids combine several structural features that render them suitable architectural components in macrocycle synthesis. They present one of the few extended, readily available, chiral units that can be additionally functionalized by a large set of established procedures. The natural stereochemical diversity and rigid array of concave-directed differentiable functionalities in the steroidal nucleus have been previously used in the (target-oriented) design of macrocyclic frameworks for biomimetic and molecular recognition applications.[11]

Scheme 2 summarizes the synthesis of the steroidal bifunctional building blocks from lithocholic acid (**2**). Synthesis of diamine **3** and diisonitrile **6** proceeded by a double Mitsunobu reaction to the corresponding reduced acid, followed by azide displacement,[12a] reduction, and subsequent isonitrile formation.[12b] Steroidal dicarboxylic acids are a source of additional skeletal diversity. They are most rapidly obtained from the 3-oxo derivative through lactone formation by a Baeyer–Villiger reaction[13] and consecutive ring-opening saponification or alternatively by condensation with *O*-(carboxymethyl)hydroxylamine; these reactions afforded the dicarboxylic acids **4** and **5**, respectively.

All multiple macrocyclizations by the Ugi-4CR presented here were carried out under pseudodilution conditions by adding the diisonitrile building block at a rate of $0.1\ mL\,h^{-1}$ ($c = 0.05\ mmol\,mL^{-1}$) to a mixture of the other components. Competing oligomerization was successfully minimized and an almost equal mixture of head-to-head (H-H) and head-to-tail (H-T) isomers resulted in all cases with at least two bifunctional asymmetric building blocks.[6,14] Three examples, highlighted in Scheme 3, illustrate the initial attempt to explore our strategy. By using the diamine **3** and the diacids **4** and **5** as counterparts of the common diisonitrile **6** in the Ugi-4CR, two different types of peptoid backbones are produced, according to the considerations summarized in Scheme 1. The diamine/diisonitrile combination is characterized by an

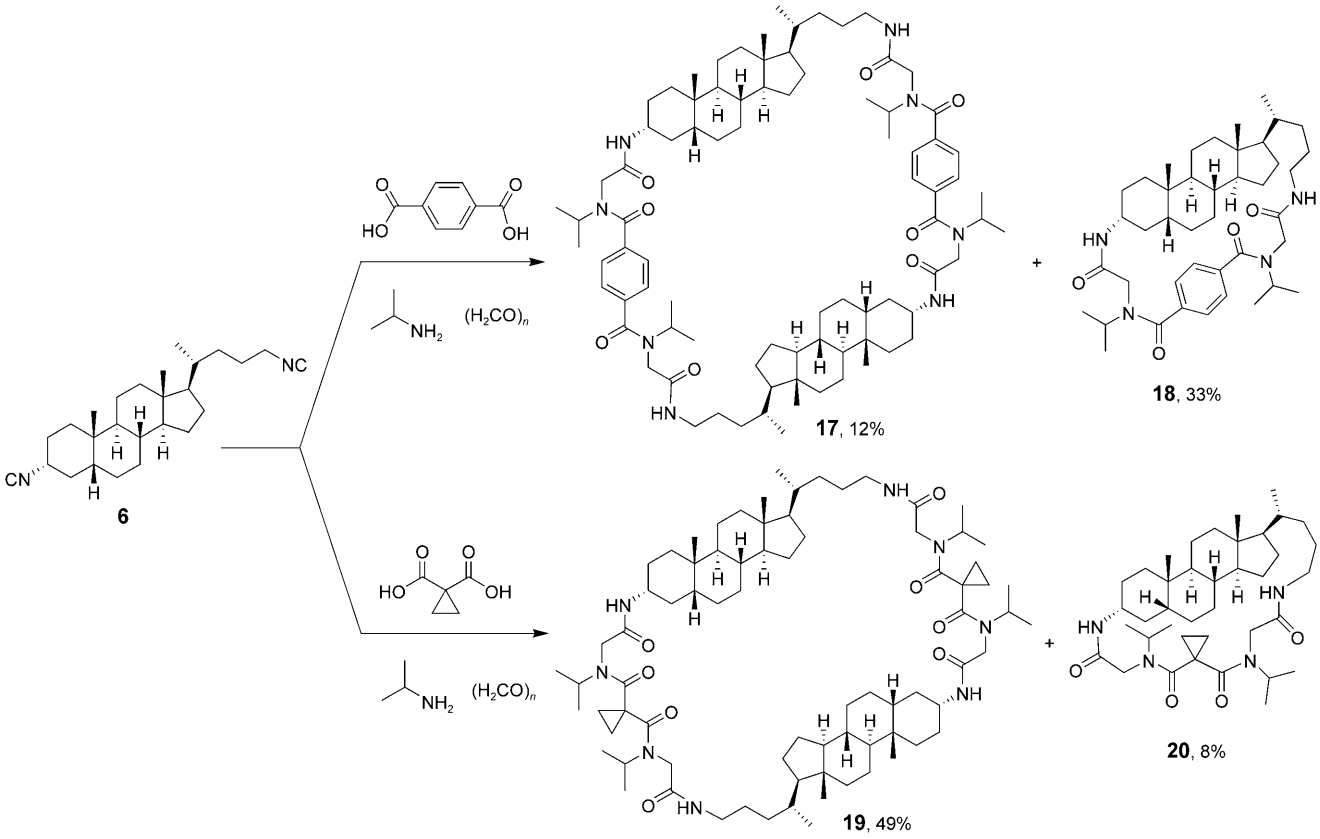
exocyclic amide bond which shortens the tether chain but increases the flexibility of the peptoid portion.

Of the various components that can be varied, the oxo component exhibits special influence on ring formation and stereochemical complexity. Thus, macrocycles **7**–**10** were isolated as almost equally distributed mixtures of diastereomers.[15] The Ugi approach facilitates the rapid generation of stereochemical diversity that is much more difficult to access in a multistep synthetic strategy, although it could also be considered a drawback owing to the required (but often easy) separation and difficult characterization work. Furthermore, when isobutyraldehyde was replaced by paraformaldehyde there was a marked increase in the macrocyclization yields, which is probably the result of lower steric hindrance or a significantly modified prefolding bias.

To improve the size as well as recognition-motif diversity of the peptoid core of the macrocyclic skeleton, we set out to design a fourfold Ugi-4CR macrocyclization by using two equivalents of the steroidal diisonitrile **6** and another (at this stage simpler) bifunctional building block. This complementary and direct approach, which allows manipulation of the nature and length of the steroid bridging tethers, succeeded for the synthesis of the fourfold macrocycles **12**–**16** (Scheme 4) with ethylenediamine or succinic acid as the simpler bifunctional building blocks. Interestingly, in the case with succinic acid and with paraformaldehyde as the oxo component the smaller macrocycle **14** was also formed, although in lower yield, a result confirming that the succinate-bridged double dipeptoid chain is just long enough to span the distance between the two functional groups of the steroidal skeleton. An alternative third pathway, isonitrile (imidate) induced condensation to succinic anhydride leading to the Ugi three-component product, was not observed, but it was also not specifically looked for, as the desired macrocycles were formed in typical combined yield.

The different outcomes in these macrocyclizations by using different aldehydes pinpoint the importance of understanding the effect of a bulky aldehyde side chain on the success and result of the overall process. In addition to pure steric effects, the favoring (or disfavoring) of double[16] or fourfold Ugi-4CR based macrocyclizations is dependent on the length, flexibility, and prefolding characteristics of the acyclic precursor. The strain and strain change of the cyclic α-adduct are also crucial aspects which determine the formation and further ability to rearrange to the final macrocycle. Thus, the sterically demanding isopropyl groups might cause significant steric strain or incorrect prefolding in the formation of the cyclic α-adduct, thereby prohibiting the formation of the smaller macrocycle. Larger (for example, sixfold Ugi-4CR based) macrocycles, in contrast, could not be identified to any significant amount by ESI-FT-ICR mass spectrometry.

After reliable fourfold Ugi-4CR macrocyclizations were established and because of the intriguing result obtained with a diacid as the bridging building block, we extended our plan to cover other types of peptoid tethers for the steroids. This could be achieved with diacids that have a significant influence either on the molecular recognition behavior or on the internal folding of the obtained macrocycle. Terephthalic and cyclopropane-1,1-dicarboxylic acids were chosen as the counterparts, and consequently macrocycles **17**–**20** were



Scheme 4. Fourfold Ugi-4CR based macrocyclization of bifunctional building blocks (MiBs of diacid/diisonitrile and diamine/diisonitrile type). A mixture of H-H and H-T isomers is observed for fourfold reactions, (i.e., not for **14**).[14,16]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

synthesized in a similar fashion, with paraformaldehyde as the best oxo component for analytical purposes. Scheme 5 highlights the convincing results of our design. It also shows the effect of a more strained chain on the success of the fourfold Ugi-4CR macrocyclization versus the double reaction. With the long and straight terephthalic acid, the double Ugi-4CR based small macrocycle **18** was the main product, whereas the short, kinked 1,1-cyclopropane diacid led to the formation of the fourfold Ugi-4CR based large macrocycle **19** as the major product; this result shows that the formation of the cyclopropane-bridged double dipeptoid chain is disfavored owing to its significantly lower flexibility and shorter length to span the steroidal moiety. At this point it should be mentioned that, for example, a yield of 49% for isolated **19** corresponds to an approximately 96% calculated yield for each individual reaction/bond formed, *including* the macrocyclization.

Apart from the vast array of functionalities that could be placed inside the macrocyclic cavity by altering one of the differentiable faces of the steroidal moiety, the proven degree of complexity and diversity accessible through this one-pot synthetic process can be highlighted by considering four distinct issues: 1) additional binding elements or biologically or catalytically interesting motifs can be appended as side chains to some of the Ugi components, 2) the macrocyclization can be performed in a template-based manner to control the size of the cavity, 3) further skeletal diversity can be achieved by varying the nature of the building blocks, and 4) conformational diversity of the cavity can be designed either a) from geometrically varied building blocks (for example, straight or kinked, as shown above) or b) by generating new stereogenic centers. While the first issues are being developed in connection with ongoing projects, an efficient access to diastereoselective Ugi reactions (4b) is the last problem that remains unsolved—with a few exceptions.[17] Supported by the possible automation of the Ugi-4CR,[5,6,8] the current strategy may be extended to independently modify the different access points of diversity generation in a parallel (or mixed) combinatorial fashion. Moreover, the whole system is suitable for evolutionary-based or holistic approaches, for the generation of sets of biologically relevant molecules or biomimetic supramolecular systems, or for any application that requires large, constitutionally defined complex molecules of a nonrepetitive or only partly repetitive nature.

In conclusion, we have presented a very straightforward strategy to generate a collection of chimeric peptoid macrocycles—here specifically with steroid moieties—of a size and structural complexity that bears no resemblance to any known natural product but that is potentially useful in chemical genomics approaches, as well as for artificial receptors for molecular recognition studies or as bottom-up building units for nanotechnology. To our knowledge, multicomponent reactions have not so far been used to directly form macrocycles of this size and complexity that can easily incorporate and display chemical motifs previously identified as suitable, for example, for anion and carbohydrate recognition.[18] We believe that no other macrocycle synthesis is known that better combines ease, versatility, functionality,

Scheme 5. Fourfold versus double Ugi-4CR based macrocyclizations of geometrically different bifunctional building blocks. A mixture of H-H and H-T isomers is observed for **17** and **19**.[14]

size control, and speed in one pot than the process presented here. Finally, the principal concept of MiBs[6] should not be limited to Ugi type multicomponent reactions only.

Experimental Section

General procedure for the Ugi-4CR based macrocyclizations: A solution of the oxo component (2 mmol) and the amino component (2 mmol) in MeOH (250 mL) was stirred for 1 h at room temperature. The diacid building block (0.5 mmol) was then added and the stirring was continued for another 30 min. A solution of diisocyanide **6** (0.5 mmol) in MeOH (10 mL) was added slowly to the reaction mixture by using a syringe pump (flow rate of 0.1 $mL\,h^{-1}$). After addition was complete, the reaction mixture was concentrated under decreased pressure and the crude material was purified by flash column chromatography or preparative HPLC to afford the corresponding macrocycles, usually as amorphous solids.

[14] For bidirectional MiBs with at least two bifunctional asymmetric building blocks, see ref. [6]. For simplicity reasons only the head-to-tail (H-T) isomers are shown in all schemes. The yields refer to the mixture of both isomers, which often cannot be distinguished by the available structural determination techniques (HRMS, NMR) prior to chromatographic separation. This separation, however, is usually not problematic.

[15] HPLC and LC-MS spectra showed the presence of all diastereomers in the mixture in close to equal amounts.

[16] The double MiBs of Schemes 4 and 5 are different from those in Scheme 3 in that only one bifunctional building block is steroidal. This results in a different multiplicity bias (disfavoring the double MiBs) and the absence of regioisomers (H-H/H-T isomers).

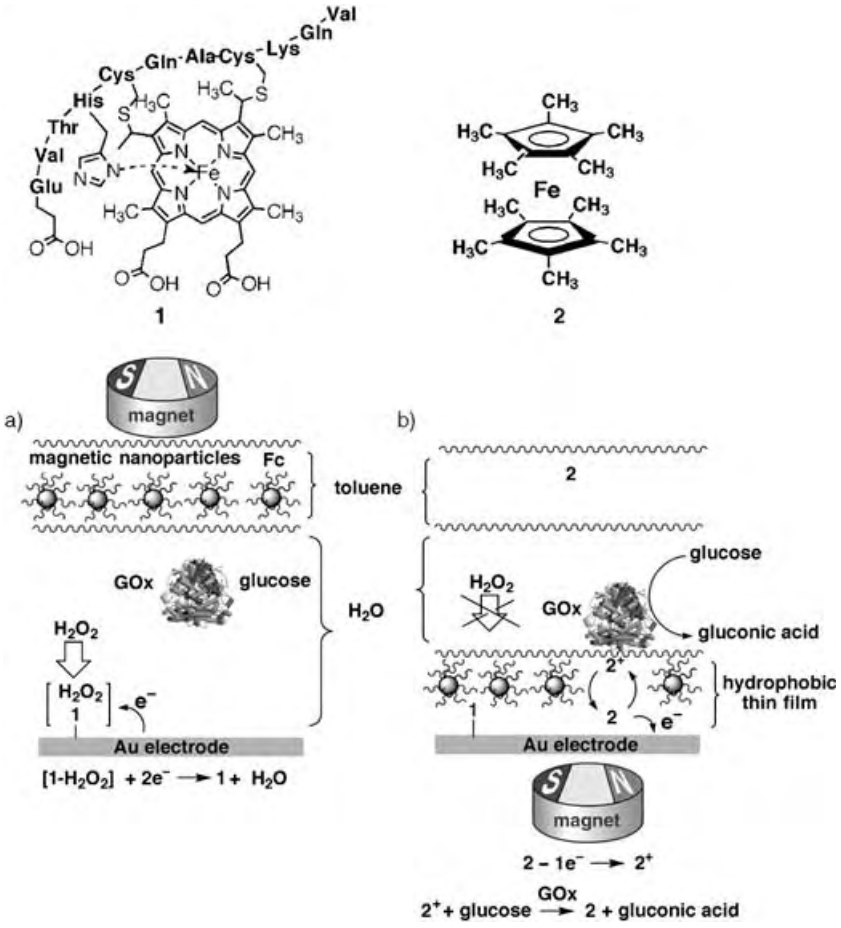
Electrochemistry



Switching of Directions of Bioelectrocatalytic Currents and Photocurrents at Electrode Surfaces by Using Hydrophobic Magnetic Nanoparticles**

*Eugenii Katz and Itamar Willner**

Magnetic particles—microspheres, nanospheres, and ferrofluids—are widely studied and applied in various fields of biology and medicine, such as magnetic targeting (drugs, genes, radiopharmaceuticals), magnetic resonance imaging, diagnostics, immunoassays, RNA and DNA purification, gene cloning, and cell separation and purification.[1] Extensive research efforts were recently directed towards the application of functionalized magnetic particles for controlling electrochemical transformations at electrode interfaces or chemical reactivity at solid supports.[2] The magnetic attraction or retraction of magnetic particles that are functionalized with redox units to and from electrode surfaces was used to switch "on" and "off" redox processes and subsequently activate/deactivate bioelectrocatalytic transformations.[3] Similarly, catalytic magnetic particles such as nickel nanoparticles were used to switch on and off electrocatalytic processes at electrode supports by using an external magnet.[4] The rotation of magnetic particles on electrode supports was reported to enhance electrocatalytic and bioelectrocatalytic processes by the hydrodynamic transport of the reacting substrates to the electrode.[5] Enhanced electrochemically generated chemiluminescence was reported in the presence of rotating magnetic particles,[6] and the system was employed for the amplified detection of DNA,[6,7] antigen–antibody complexes,[6] and cancer cells.[8] Recently, magnetic nanoparticles with a hydrophobic capping layer were employed to reversibly separate surface-confined and diffusional redox processes at electrodes.[9,10] By dissolving the hydrophobic magnetic nanoparticles in an organic phase, the magnetic nanoparticles were transported to the electrode surface with a colayer of hydrophobic solvent. This layer enabled a change of electrochemical processes of the electrode-confined species from aqueous type to organic-phase type, and the co-transport of hydrophobic substrates to the electrode surfaces allowed switchable electrocatalysis.[10]

Herein, we demonstrate the use of hydrophobic magnetic nanoparticles in a water/toluene biphasic system to switch reversibly at a fixed potential the bioelectrocatalytically and photoelectrochemically generated currents from cathodic to anodic directions.

Magnetite nanoparticles (diameter ca. 5 nm, saturation magnetization ca. 36.4 emu g^{-1}) functionalized with a monolayer of undecanoic acid[9] were dissolved in toluene (1 mg mL^{-1}), and the solution was added to the electrochemical cell to yield a system in which the upper organic layer was immiscible with the aqueous electrolyte solution. In the first system (Scheme 1), a gold surface placed at the bottom of the electrochemical cell was modified with the hemo-undecapeptide microperoxidase-11 (MP-11; **1**) by covalent linkage of MP-11 to a monolayer of cystamine.[11] Glucose oxidase (GOx, 1 mg mL^{-1}), glucose (50 mM), and H_2O_2 (50 mM) were added to the aqueous electrolyte solution. The upper toluene phase contained the hydrophobic magnetic nanoparticles and decamethylferrocene (**2**; 2 mM). When the external magnet was positioned above the electochemical cell, the magnetic nanoparticles were confined to the organic phase and the system adopted the configuration shown in

Scheme 1. Magnetoswitchable anodic/cathodic currents generated at the electrode functionalized with microperoxidase-11 (**1**) by using hydrophobic magnetic nanoparticles to gate the bioelectrocatalytic processes.

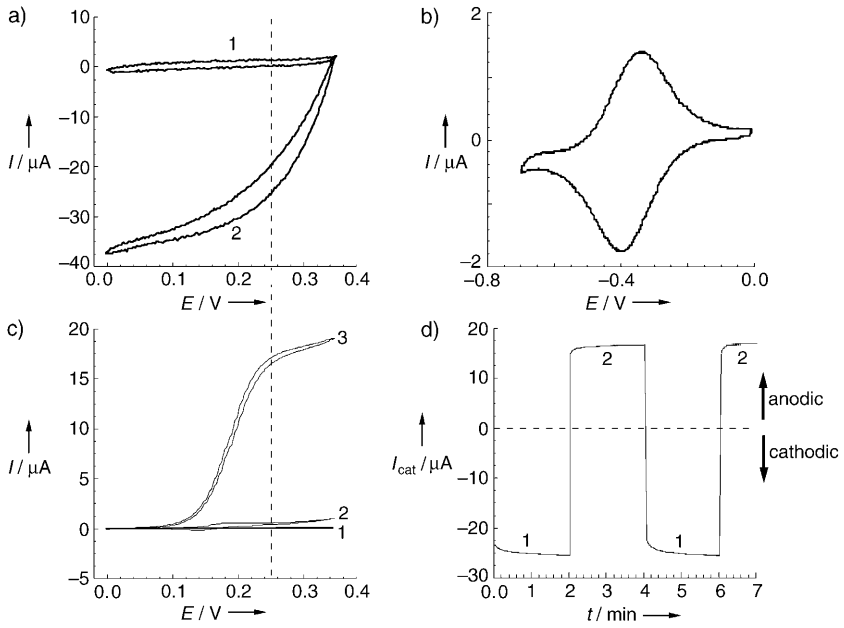
Scheme 1a. The cyclic voltammogram of the system is depicted in Figure 1a, curve 2. The electrocatalytic cathodic wave that starts at approximately 0.35 V is attributed to the electrocatalyzed reduction of H_2O_2 by **1**, as previously shown.[11a] In the absence of H_2O_2 in the aqueous phase, the cyclic voltammogram recorded at positive potentials shows a background current (Figure 1a, curve 1) while the quasi-reversible redox wave of the surface-confined MP-11 (**1**) is observed at negative potentials ($E^\circ = -0.4$ V; $\approx 1.4 \times 10^{-10}$ mole cm^{-2} surface coverage of **1**; Figure 1b). The shift in the reduction potential of H_2O_2 relative to the quasi-reversible wave of **1** observed in the absence of H_2O_2 was attributed to the formation of a complex between H_2O_2 and the heme center of MP-11 (**1**) that stimulated the reduction of H_2O_2 at the positive potentials.[11a]

Positioning of an external magnet below the electrode attracted the hydrophobic magnetic nanoparticles to the electrode. The magnetic attraction of the hydrophobic magnetic nanoparticles, which were associated with a layer of toluene that also includes **2**, to the electrode surface resulted in the cyclic voltammogram shown in Figure 1c, curve 3. In the absence of glucose in the aqueous phase, the quasi-reversible cyclic voltammogram of **2** associated with the hydrophobic magnetic nanoparticles was detected (Figure 1c, curve 2; the low voltammetric response is due to the slow scan rate). The electrocatalytic anodic current shown in Figure 1c, curve 3, is attributed to the bioelectrocatalytic oxidation of glucose by GOx mediated by **2**; that is, the oxidation of **2** in the toluene film yields the respective ferrocenyl cation that mediates the oxidation of glucose by GOx (Scheme 1b). Note, however, that upon attraction of the magnetic nanoparticles to the electrode surface, the electrocatalyzed reduction of H_2O_2 by **1** is totally blocked as a result of the formation of the hydrophobic thin film on the electrode which impedes contact between H_2O_2 dissolved in the aqueous phase and the **1**-functionalized electrode. Indeed, in the absence of **2** in the toluene phase and upon magnetic attraction of the nanoparticles from the organic phase to the electrode surface, the system shows complete blocking of the currents as a result of the isolation of the electrode surface by the hydrophobic thin film (Figure 1c, curve 1).



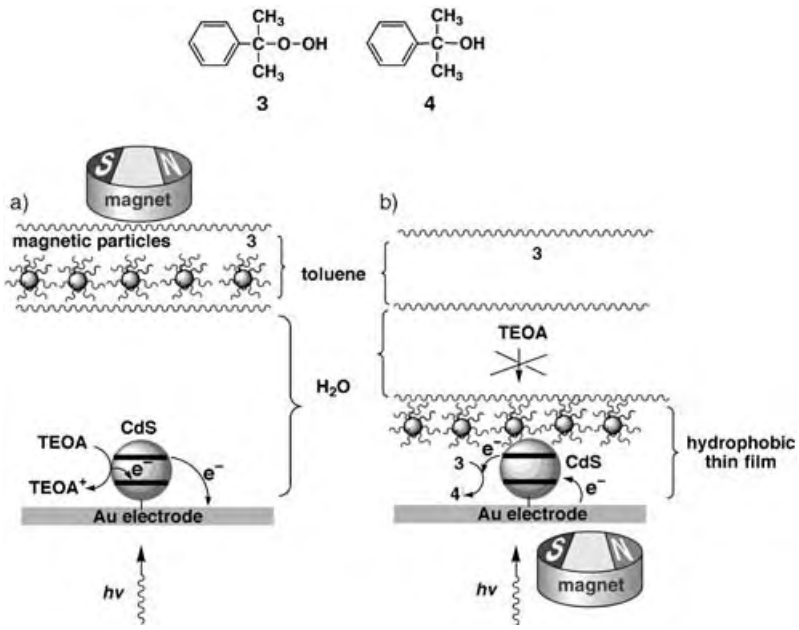


Figure 1. a) Cyclic voltammograms (potential scan rate: 5 mV s^{-1}) recorded in the presence of the **1**-functionalized electrode when the magnetic nanoparticles are retracted from the surface: 1) in the absence of H_2O_2 and 2) in the presence of H_2O_2 (50 mM). b) Cyclic voltammogram of the **1**-functionalized electrode recorded in the absence of H_2O_2 at a potential scan rate of 100 mV s^{-1}. c) Cyclic voltammograms (potential scan rate: 5 mV s^{-1}) recorded in the presence of the **1**-functionalized electrode when the magnetic nanoparticles are attracted to the surface: 1) in the absence of decamethylferrocene (**2**) in the toluene phase, 2) in the presence of **2** (2 mM) in the toluene phase and the absence of glucose in the aqueous phase, and 3) in the presence of **2** (2 mM) in the toluene phase and of glucose (50 mM) in the aqueous phase. d) Switchable bioelectrocatalytic currents generated in the system upon application of a fixed potential at 0.25 V, in the presence of H_2O_2 (50 mM) and glucose (50 mM) in the aqueous phase and **2** (2 mM) in the toluene phase, when the magnetic nanoparticles are retracted from the surface (1) or attracted to the surface (2). The data were recorded in a solution of phosphate buffer (0.1 M, pH 7.0) containing GOx (1 mg mL^{-1}).

The selective activation of the bioelectrocatalyzed reduction of H_2O_2 (by **1**) or the bioelectrocatalyzed oxidation of glucose (by **2** and GOx) enables the selection of a fixed potential value (e.g. 0.25 V vs. SCE) at which the direction of the current at the electrode surface can be reversibly switched by the hydrophobic magnetic nanoparticles (Figure 1d). When the nanoparticles are retracted from the electrode surface (Figure 1d, domains 1), the bioelectrocatalyzed reduction of H_2O_2 by **1** proceeds and a cathodic current of approximately -25 μA is observed at the applied potential of 0.25 V. Attraction of the magnetic nanoparticles to the electrode surface blocks the electrocatalytic reduction of H_2O_2, but the ferrocene-mediated bioelectrocatalyzed oxidation of glucose by GOx proceeds (Figure 1d, domains 2). A bioelectrocatalytic anodic current of about 15 μA is observed in the system at the applied potential of 0.25 V. By the cyclic retraction and attraction of the magnetic nanoparticles from or to the electrode surface, the current is switched between cathodic and anodic values, respectively.

By using a similar concept, the photoelectrochemical currents generated upon the illumination of a layer of CdS nanoparticles associated with an electrode could be switched between cathodic and anodic photocurrents by means of the hydrophobic magnetic particles (Scheme 2). A monolayer of CdS nanoparticles (diameter 5 nm) functionalized with a layer of 3-mercaptopropionic acid/3-mercaptoethanesulfonic acid was covalently linked to a cystamine-functionalized gold electrode.[12] Parallel microgravimetric quartz-crystal microbalance measurements indicated a surface coverage of approximately 3×10^{12} particles cm^{-2}. The system comprised the electrode functionalized with CdS nanoparticles and a biphasic system composed of an aqueous solution of triethanolamine (TEOA; 20 mM) as electron donor in phosphate

Scheme 2. Magnetoswitchable anodic/cathodic photocurrents generated at the electrode functionalized with CdS nanoparticles by using hydrophobic magnetic nanoparticles to gate the photoelectrochemical processes.

buffer (0.1 M, pH 7.0) and a solution in toluene of cumene hydroperoxide (**3**; 2 mM) and the hydrophobic magnetic nanoparticles (Scheme 2a).

Irradiation of the CdS nanoparticles through a semitransparent gold-coated glass electrode, while confining the magnetic nanoparticles to the toluene phase, resulted in an anodic photocurrent (Figure 2a, curve 1). This photocurrent is generated only if TEOA is dissolved in the aqueous medium. The photocurrent action spectrum follows the absorbance spectrum of the CdS nanoparticles, which implies that it originates from the photoexcitation of the nanoparticles; that is, upon irradiation of the CdS nanoparticles an electron–hole pair is generated. The oxidation of TEOA by the holes and the transport of the conduction-band electrons to the electrode result in the formation of the anodic photocurrent (Scheme 2a).

The magnetic attraction of the hydrophobic magnetic nanoparticles from the toluene phase containing **3** to the electrode resulted in a cathodic photocurrent (Scheme 2b and Figure 2a, curve 3). In the absence of **3** in the toluene phase, no photocurrent was generated (Figure 2a, curve 2). Thus, the cathodic photocurrent originates from the transfer of the photoexcited conduction-band electrons in CdS nanoparticles to cumene hydroperoxide (**3**) to yield the respective reduction product cumene alcohol **4** and the concomitant transfer of electrons from the electrode to the semiconductor valence-band holes (Scheme 2b). Thus, the magnetic attraction of the hydrophobic magnetic nanoparticles to the surface functionalized with CdS nanoparticles results in the blocking of the electrode surface towards the aqueous solution of TEOA, while allowing the contact of the electrode surface with the electron acceptor **3** associated with the generated hydrophobic thin film. By the cyclic attraction and retraction of the magnetic nanoparticles to and from the electrode surface, the photocurrents generated by the semiconductor nanoparticles are switched between cathodic and anodic directions, respectively (Figure 2b). The quantum yields for the generation of photocurrents (taking into account the light flux, its reduction by the semitransparent electrode, and the absorbance of the CdS monolayer) were estimated to be approximately 5% and 3% for the anodic and cathodic photocurrents, respectively.

Note that in a previous study,[13] the direction of photocurrents at an electrode was switched between cathodic and anodic values by tethering two different chromophores (an electron acceptor or electron donor) to helical peptides associated with the electrode, and the photocurrents in this system were generated by irradiation of the system at two different wavelengths. In the present study, the switchable photocurrents originate from irradiation of the system in the same spectral region and through the control of the composition of the system at the electrode surface.

In conclusion, we have demonstrated switchable systems that can be gated between anodic and cathodic currents or photocurrents at a defined potential region or upon irradiation. To the best of our knowledge, these systems represent the first examples of inherent switchable amperometric responses that originate from the tailored local composition at the electrode interface. We believe that the results present a new concept for electron transfer at electrode surfaces and for the future design of bioelectronic and optobioelectronic systems.

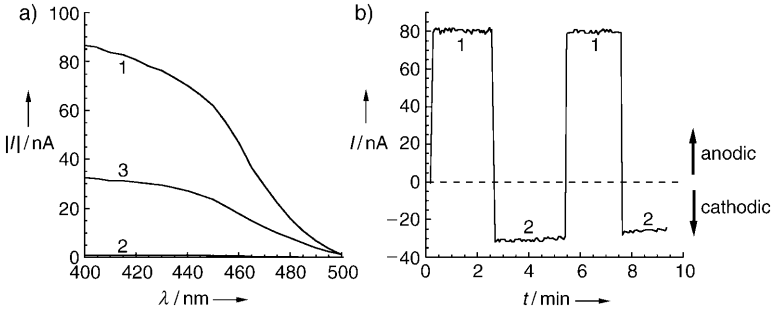

Figure 2. a) Photocurrent action spectra recorded on the electrode functionalized with CdS nanoparticles: 1) Anodic photocurrents generated when the magnetic nanoparticles are retracted from the surface; 2) cathodic photocurrents generated when the magnetic nanoparticles are attracted to the surface from the toluene phase containing cumene hydroperoxide (**3**; 2 mM); 3) no photocurrent is observed when the magnetic nanoparticles are attracted to the surface in the absence of associated **3**. b) Switchable photocurrents generated in the system upon 1) retraction from the electrode and 2) attraction to the electrode of the magnetic nanoparticles associated with **3**. The data were recorded in solutions of phosphate buffer (0.1 M, pH 7.0) containing TEOA (20 mM) and upon application of a potential of 0 V (vs. SCE).

Experimental Section

Microperoxidase-11 (**1**), glucose oxidase (GOx, EC 1.1.3.4; type X-S from *Aspergillus niger*), β-D-glucose, decamethylferrocene (**2**), cumene hydroperoxide (**3**), cystamine (2,2′-diaminodiethyldisulfide), undecanoic acid, triethanolamine (TEOA), 4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid sodium salt (HEPES), 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC), and all other chemicals were purchased from Sigma or Aldrich and used without further purification. CdS nanoparticles coated with a shell composed of 3-mercaptopropionic acid and 3-mercaptoethanesulfonic acid were prepared according to a published procedure.[12] Magnetic nanoparticles of Fe_3O_4 coated with a shell of undecanoic acid were prepared according to a published procedure except that only a single capping layer was generated on the surface of the nanoparticles.[14] Ultrapure water from NANOpure Diamond (Barnstead) was used throughout all the experiments.

A gold-coated (50-nm thick layer) glass plate (Analytical μ-Systems, Germany) was used as a working electrode. Cystamine was self-assembled on the electrode, and the resulting amine-functionalized gold electrode was treated with microperoxidase-11 (**1**; 10 mM) in HEPES buffer (0.1M, pH 7.2) in the presence of EDC (1 mM) for 2 h to yield the **1**-functionalized gold electrode.[11] Alternatively, the amine-functionalized gold electrode was treated with carboxylated CdS nanoparticles (1 mg mL^{-1}) in HEPES buffer (0.1M, pH 7.2) in the presence of EDC (1 mM) for 2 h to yield the nanoparticle-functionalized electrode.[12]

Cyclic voltammetry measurements were performed using an electrochemical analyzer (model 6310, EG&G) connected to a personal computer with EG&G 270/250 software). The photoelectrochemical measurements were performed using a homemade system that allows recording of action spectra of photocurrents.[12] The measurements were carried out at ambient temperature (25 ± 2 °C) in a conventional electrochemical cell consisting of a modified Au working electrode (0.3 cm^2 area exposed to the solution) assembled at the bottom of the electrochemical cell, a glassy carbon auxiliary electrode, and a saturated calomel electrode (SCE) connected to the working volume with a Luggin capillary. All potentials are reported with respect to this SCE reference electrode. Phosphate buffer (0.1M, pH 7.0) was used as an aqueous background electrolyte. The magnetic nanoparticles functionalized with undecanoic acid were added to the cell as a solution in toluene (0.5 mL, 1 mg mL^{-1}) to yield an immiscible system of an organic layer (upper) and the aqueous electrolyte solution (lower). Cumene hydroperoxide (**3**; 2×10^{-3} M) or decamethylferrocene (**2**; 2×10^{-3} M) was added to the toluene phase. The functionalized magnetic nanoparticles were attracted to the surface of the Au electrode from the upper organic layer by positioning a 12-mm-diameter magnet (NdFeB/Zn-coated magnet with a remnant magnetization of 10.8 kG) below the bottom electrode. The magnetic nanoparticles were removed from the electrode surface and retransported to the organic phase by positioning the external magnet above the electrochemical cell. A flow of argon through the solution was used to remove oxygen from the electrochemical cell. The cell was placed in a grounded Faraday cage.

Nanoparticles

Temperature-Induced Inversion of Nanoparticle-Stabilized Emulsions**

Bernard P. Binks, Ryo Murakami, Steven P. Armes, and Syuji Fujii*

Emulsions are mixtures of immiscible liquids where one liquid is dispersed as micrometer-sized drops in the continuous phase of the other. They occur as end products in a wide range of areas including the food, cosmetic, and pharmaceutical industries. To prevent phase separation, surfactants or proteins are usually added to cover the liquid–liquid interfaces.[1] It has been shown recently that certain solid nanoparticles act as excellent emulsifiers alone[2–5] and novel materials can be made from them.[6,7] Inversion of such emulsions from oil-in-water (o/w) to water-in-oil (w/o) or vice versa can be effected by changes in the oil:water ratio,[8] pH value,[9] or oil type.[10] Herein we describe for the first time temperature-modulated emulsion inversion using sterically stabilized polystyrene latex particles as the sole emulsifier. The steric stabilizer is a diblock copolymer in which one block is thermo-responsive, exhibiting inverse temperature solubility behavior. Thus the particle surface becomes less hydrophilic at higher temperature, causing inversion from o/w to w/o to occur in batch emulsions.

Emulsions stabilized by ionic surfactant invert from w/o to o/w with increasing temperature as a result of the increased dissociation of counterions bound to surfactant head groups, making the surfactant more hydrophilic.[11] In contrast, nonionic surfactant-stabilized emulsions invert the other way around; increasing temperature causes dehydration of head groups, making them more hydrophobic.[11] Inversion with respect to temperature is important industrially and is exploited to prepare fine emulsions of increased stability.[12] Small solid particles act in many ways like surfactant molecules in that they adsorb at fluid–fluid interfaces, allowing stabilization of droplets in emulsions and bubbles in foams.[3] However, it is only recently that their precise role has begun to be elucidated in surfactant-free systems. The wettability of the particles at the oil–water interface is crucial in determining which type of emulsion is formed, with hydrophilic particles preferentially forming o/w emulsions and hydrophobic particles forming w/o emulsions. Although the influence of temperature on the stability of either w/o[13] or o/w[14] emulsions stabilized solely by nanoparticles has been reported, the ability to phase invert such emulsions with temperature has not been demonstrated.

The particulate emulsifier employed in this study was a sterically stabilized polystyrene (PS) latex of 152 nm diameter. The steric stabilizer was a near-monodisperse diblock copolymer, poly[2-(dimethylamino)ethyl methacrylate-*block*-methyl methacrylate], PDMA-*b*-PMMA.[15] The hydrophobic PMMA block is designed to adsorb onto the latex surface and the solvated PDMA block acts as the hydrophilic steric stabilizer. As reported earlier,[16] the cationic charge density of the PDMA block can be adjusted by controlling the solution pH value and this dictates the emulsification performance of these PS latex particles. At 25 °C, batch emulsions containing equal volumes of *n*-hexadecane and 2 wt % aqueous PS latex are o/w at all pH values above 3, and the stability of these emulsions towards coalescence increases progressively on increasing the pH from 3 to 8. It was argued that this effect was due to progressive deprotonation of the PDMA-based stabilizer chains with increasing pH, causing the sterically stabilized PS latex particles to become less hydrophilic and hence better emulsifiers.[16]

In this work, we investigate the effect of temperature on emulsions stabilized by the same particles as above, prepared at pH 8.1, which are completely stable to coalescence at 25 °C. In one series of experiments, an *n*-hexadecane/water (1:1) emulsion stabilized by 2 wt % particles was prepared at room temperature and heated progressively up to 70 °C with gentle shaking. Although the emulsion remained o/w at all temperatures, substantial coalescence occurred at and above 60 °C. In a second series, an emulsion was prepared at each temperature after pre-equilibration of the two phases at that temperature. The difference between the two is that particles are already adsorbed at oil–water interfaces in the first series, whereas they are free to become adsorbed at different temperatures in the second series. Importantly in the second series, phase inversion of the emulsions occurs from o/w at low temperatures to w/o at higher temperatures. This result is shown in Figure 1, which summarizes the emulsion conductivities (κ) and the drop test findings obtained at various temperatures. At temperatures below 52 °C, the conductivities are relatively high ($\kappa_{aq} = 25$, $\kappa_{oil} = 0.1\ \mu S\,cm^{-1}$), the emulsions disperse in water and not in oil and are therefore water continuous. At and above 65 °C, the emulsions exhibit low conductivities, disperse in oil rather than in water, and are therefore oil continuous. At intermediate temperatures indicated by the dotted lines (53–64 °C), emulsions can be either of the two types, which may co-exist.

Optical micrographs of the emulsions of the second series are shown in Figure 2. At 25 °C (Figure 2a) oil drops in an o/w emulsion are discrete and some appear non-spherical. At 55 °C (Figure 2b) in addition to simple emulsions, there is some evidence for multiple emulsions, in this case of water-in-oil-in-water (w/o/w), in which water drops are present within oil globules themselves dispersed in water. The appearance of

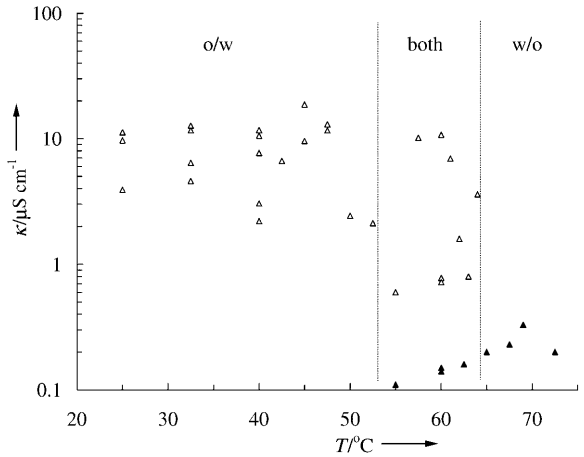

Figure 1. Conductivity κ of batch emulsions (second series, see text for details) comprising equal volumes of *n*-hexadecane and 2 wt% aqueous PDMA-*b*-PMMA-stabilized PS latex (152 nm diameter, pH 8.1) as a function of temperature. Emulsions are only o/w (△) to the left of the first dotted line and only w/o (▲) to the right of the second dotted line, but can be either type or multiple at intermediate temperatures. The labels for emulsion type are based on drop test results.

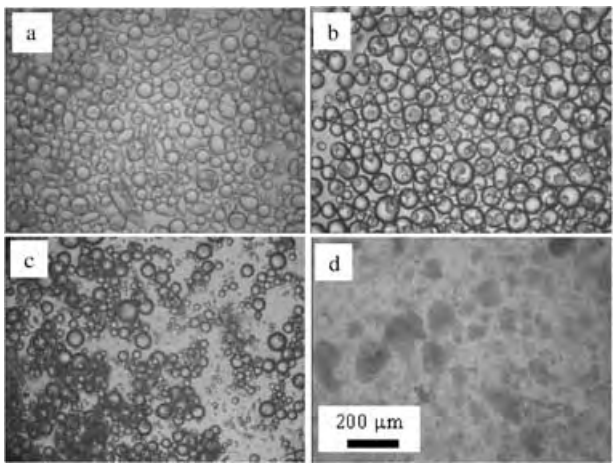

Figure 2. Optical micrographs of emulsions prepared as in Figure 1 at a) 25 (o/w), b) 55 (w/o/w), and c) 65 °C (w/o). Also shown is micrograph of the 2 wt% aqueous PS latex (pH 8.1) held at 70 °C for 30 min on a glass slide (d). The scale bar refers to all images.

multiple emulsions around conditions of phase inversion in surfactant-stabilized systems is common; the balanced surfactant satisfies the preference for both types of emulsion simultaneously.[12] Such emulsions are notoriously unstable to coalescence (of both drops and globules), whereas these solid-particle-stabilized emulsions are stable. The stabilization of multiple emulsions by only one type of particle has been reported for silica.[17] At 65 °C, water drops in a w/o emulsion are characteristically flocculated (Figure 2c), since any repulsion between particle surfaces on neighboring drops is mediated through the oil phase, which has a low dielectric constant, and little steric stabilization is provided by the PDMA chains in this oil.

A measure of the average diameter of drops in both types of emulsion is plotted against temperature in Figure 3. For

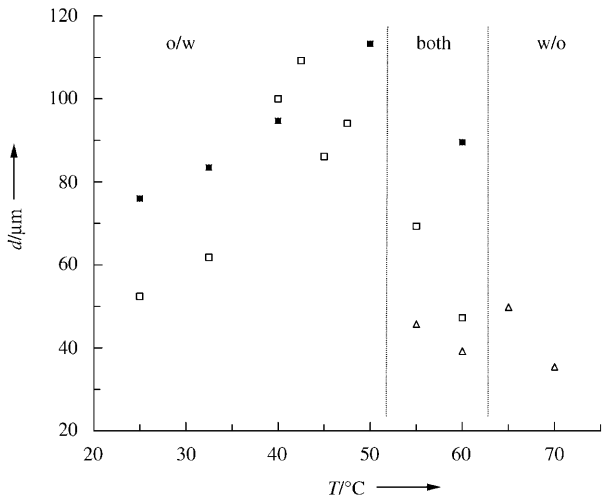

Figure 3. Average drop diameter *d* versus temperature for batch emulsions prepared as in Figure 1 immediately after preparation. Sizes determined by optical microscopy (□ o/w, △ w/o) and using light diffraction (■ o/w) are shown.

o/w emulsions, the number-average mean determined by optical microscopy (40 drops) is shown, as is the median diameter measured using light diffraction. For w/o emulsions, only the mean by microscopy has been determined. The average oil-drop size increases with temperature on approaching inversion and the size of water drops is less than that of oil drops. Assuming that particles form a hexagonally close-packed monolayer around oil drops, we calculate that at 25 °C approximately 35 % of the particles originally in water become adsorbed around drops of average diameter 76 μm. This number falls to 24 % for the larger drops of 113 μm at 50 °C. On this basis, there is thus a distribution of particles between interface and bulk, although no exchange is likely because of the high energies of particle attachment to interfaces.[3]

The stabilities of these latex-stabilized emulsions six months after preparation are summarized in Figure 4. The parameters *f*(oil) (and *f*(water)) are defined as the volumes of oil (or water) resolved relative to the initial volumes of oil (or water). At temperatures prior to inversion, the oil drops in o/w emulsions cream within 1–2 h at all temperatures with no further change subsequently. The oil volume fraction in the cream is now increased beyond 0.5 and, apart from the stable emulsion at 25 °C, a low degree of coalescence occurs in emulsions approaching 50 °C. At intermediate temperatures (between the dotted lines), the creaming of o/w emulsions is reduced and w/o emulsions sediment but are stable to coalescence. At temperatures above inversion, sedimentation of water drops occurs gradually in the first 24 h followed by their coalescence. Eventually, virtually complete phase separation ensues as indicated by near unity values of both *f*(oil) and *f*(water).

We seek to understand the origin of emulsion phase inversion with temperature, which occurs in the same sense as that for non-ionic surfactants. Some clues to this can be found in the behavior of the aqueous PS latex particle dispersions in the absence of oil. Dynamic light-scattering studies indicate

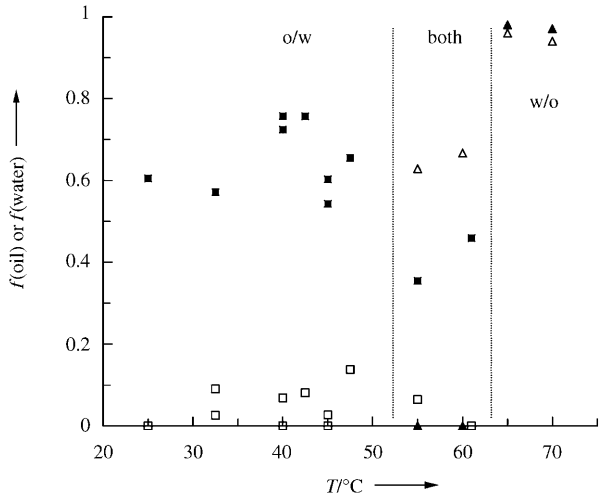

Figure 4. Stability of batch emulsions after six months at different temperatures. For o/w, f(water) (■) relates to creaming and f(oil) (□) relates to coalescence. For w/o, f(oil) (△) relates to sedimentation and f(water) (▲) relates to coalescence.

that the mean hydrodynamic diameter remains constant at 152 nm between 20 and 50 °C and increases to 173 nm at 53 °C, above which significant flocculation is apparent. Optical microscopy investigations of a drop of dispersion on a glass slide shows no features above 1 μm up to 50 °C but particle aggregates of increasing size above this critical temperature (Figure 2d). Since PDMA homopolymer in water at pH 8.1 exhibits a lower consolute solution temperature between 32 and 46 °C (depending on its mean degree of polymerization),[18] it is likely that the temperature-induced flocculation of the latex particles reflects the thermo-responsive character of the PDMA block in the stabilizer chains. This hypothesis was verified by performing contact-angle measurements of water drops under *n*-hexadecane on spin-coated films of PDMA homopolymer at different temperatures. As shown in Table 1, the contact-angle measured through water increases with temperature from near-wetting (hydrophilic) at 25 °C to values that are characteristic of hydrophobic surfaces above 60 °C. They are also in line with the predicted change in the wettability of the particles in emulsions, from predominantly hydrophilic at low temperatures (o/w) to more hydrophobic at high temperatures (w/o).

Table 1: Effect of temperature on the contact angle θ of a water drop.[a]

T [°C]	θ (w/o) [°]	θ (o/w) [°]
25	4	3
35	6	6
45	11	12
55	28	28
60	34	32
65	33	30
75	58 ± 10	65 ± 10

[a] At pH 8.1 under *n*-hexadecane, measured through water, on a glass slide coated with a film of PDMA homopolymer. Data given for water (w/o) or oil (o/w) contacting the substrate first.

Two competing effects caused by increasing temperature may cause this change. The first is the disruption of hydrogen bonds surrounding the PDMA chains, leading to an increase in their hydrophobicity. The second is an increase in the degree of protonation of tertiary amine groups resulting in increased particle hydrophilicity. For trimethylamine in water, this has been measured as an increase in K_b (equilibrium constant) with temperature, taking into account the increase in the dissociation constant of pure water.[19] It is therefore clear that for these sterically stabilized PS latex particles, the dominant influence of temperature is in reducing the degree of hydration of the PDMA chains to such an extent that these particles become preferentially wetted by oil.

Nanoparticles are effective emulsifiers of oil and water. Appropriate design of the latex surface allows the particle wettability to be controlled by adjusting the temperature, which in turn allows the preparation of either o/w or w/o emulsions. The emulsions described herein are temperature-dependent but not temperature-responsive. Manipulating the behavior of particles adsorbed at fluid interfaces in this way augurs well for the development of a novel range of simple and multiple emulsions for use in cosmetic, food, and drug and formulations.

Experimental Section

The synthesis and characterization of the PDMA-*b*-PMMA-stabilized PS particles (diameter = 152 nm, M_n = 38400 g mol^{-1}, M_w/M_n = 1.14) was described earlier.[15,16b] Dynamic light scattering of 2 wt% aqueous PS latex at pH 8.1 was measured using a Malvern Nano ZS ZEN3600 instrument under a N_2 atmosphere at a scattering angle of 173°. Three measurements were made at each temperature, with 30 min being allowed for equilibration. Batch emulsions of equal volumes (2 mL) of *n*-hexadecane and aqueous PS latex (pH 8.1), equilibrated at the appropriate temperature, were prepared at that temperature using an Ultra Turrax T25 homogenizer (1 cm head) operating at 11000 rpm for 2 min. Emulsion type was determined by conductivity measurements and the drop test. Their stabilities at different temperatures were measured by monitoring the movement of the oil–emulsion and water–emulsion interfaces. Drop size distributions of o/w emulsions were measured using a Malvern MasterSizer 2000 instrument using either cold or hot water as diluting phase. For microscopy, a dilute sample of emulsion/dispersion was placed in a haemocytometer cell (Weber Scientific) and viewed with a Nikon Labophot microscope fitted with a DIC-U camera (World Precision Instruments). Images were processed using Adobe Photoshop 5.0 software. The contact angles of water drops (10 μL, pH 8.1) under *n*-hexadecane on films of PDMA homopolymer (M_n = 21300 g mol^{-1}) spin-coated onto glass slides from a 5 wt% solution in methanol (Speciality Coating Systems model P6700, 2000 rpm for 1 min) were determined using a Krüss DSA10 apparatus with a thermostatted cell. At least five separate drops were used at each temperature.

Prussian blue derivatives

The Co Ligand Field: A Key Parameter in Photomagnetic CoFe Prussian Blue Derivatives**

*Virginie Escax, Guillaume Champion, Marie-Anne Arrio, Michele Zacchigna, Christophe Cartier dit Moulin, and Anne Bleuzen**

Various interesting electrochemical,[1] magnetic,[2] or photomagnetic[3] properties have been revealed in Prussian blue and its analogues. In the face-centered-cubic structure of the CoFe Prussian blue analogues of chemical formula $C_xCo_4[Fe(CN)_6]_{(8+x)/3}\square_{(4-x)/3}\cdot n H_2O$, where C^+ is an alkali-metal cation and $\square$ represents the intrinsic $[Fe(CN)_6]$ vacancies, both of which are randomly distributed throughout the solid,[4] the Wyckoff positions 4a (0,0,0) are occupied by Fe ions or $\square$ and the 4b positions (1/2,1/2,1/2) are occupied by Co ions.[5] The alkali-metal cations are distributed over the tetrahedral sites.[5] Such compounds may display unusual photomagnetic effects due to a light-induced Co^{III}(low spin, $S=0$)–Fe^{II}(S=0)→(Co^{II}(high spin, $S=3/2$)–Fe^{III}(S=1/2))* electron transfer accompanied by a spin change of Co and a lengthening of the Co–ligand bonds from 1.91 Å for Co^{III}(LS) to 2.08 Å for Co^{II}(HS).[3,6,7]

It has been proposed that the stabilization of the Co^{III}(LS)–Fe^{II} switchable pairs is correlated with the average number of cyanide ligands in the Co coordination sphere. The average chemical composition of the Co coordination polyhedron is given by $Co(NC)_{(8+x)/2}(OH_2)_{(4-x)/2}$. When x increases,

weak-field H_2O ligands are replaced by stronger ones (CN^-) in the Co coordination sphere. An increase of the number of cyanide ligands in the Co coordination sphere should then lead to an increase of the Co ligand field and of the reducing power of Co, and therefore stabilize the Co^{III}(LS)–Fe^{II} photoactive diamagnetic pairs.[4,8,9] As the $[Fe(CN)_6]$ entity is stable and rigid,[10–12] the Co ligand field appears to be a key parameter for understanding the switchable properties of CoFe Prussian blue analogues.

Since a quantitative UV-vis spectroscopic investigation is impossible due to the existence of large charge-transfer bands in the visible range (the compounds are all dark violet or dark brown),[9] we used X-ray absorption spectroscopy (XAS) to determine the Co crystal-field parameter ($10\,Dq$) in two well-crystallized compounds for which the Co coordination sphere is expected to be different. For $Co^{II}_4[Fe^{III}(CN)_6]_{2.7}\square_{1.3}\cdot 18\,H_2O$[6] (**1**) and for $Rb_{1.8}Co^{III}_{3.3}Co^{II}_{0.7}[Fe^{II}(CN)_6]_{3.3}\square_{0.7}\cdot 13\,H_2O$[6] (**2**), which has photomagnetic properties, the average Co coordination spheres and cell parameters are $Co(NC)_4(OH_2)_2$ ((10.32 ± 0.05) Å) and $Co(NC)_5(OH_2)$ ((9.96 ± 0.05) Å), respectively.[12] This study allowed us to measure unexpected $10\,Dq$ values and to propose a structural model that explains the Co crystal-field parameter and the oxidation- and spin-states of Co in these compounds.

The L_3 edge can be used to directly probe the 3d levels of the metallic ion ($2p^63d^n \rightarrow 2p^53d^{n+1}$ transitions) as it is sensitive to the crystal-field parameter. X-ray absorption spectra of **1** and **2** were therefore recorded at the Co L_3 edge and compared to the spectrum of $[Co^{II}(OH_2)_6](NO_3)_2$ (Figure 1).

Peaks A to D are the signature of Co^{II}(HS) in an octahedrally symmetric environment,[7,13] and peaks E to G, at higher energy, the signature of Co^{III}(LS) also for octahedral symmetry.[7] Given the spectral shapes of compounds **1** and **2**, any Co coordination number other than six can be excluded.[14]

Simulation of the spectra using the ligand-field multiplet model[13,15] reproduces very well the experimental data

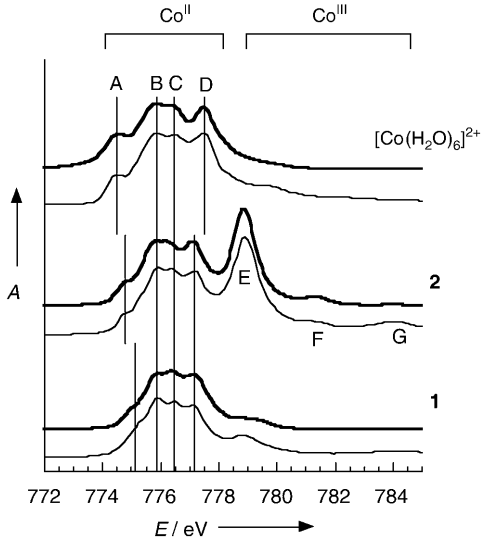

Figure 1. Experimental Co L_3-edge spectra (——) and best simulations (——) obtained from the ligand-field multiplet model for $[Co^{II}(OH_2)_6](NO_3)_2$, **1**, and **2**.

(Figure 1). The Co^{II} signature is different from one spectrum to the other. These differences in the energy positions of the multiplet features are significant. Multiplet calculations show that an increase of the energy gap between the peaks A and D of Co^{II} species corresponds to an increase of $10\,Dq(Co^{II})$.[14] Attempts to reproduce any of the Co^{II} experimental contributions with more than one $10\,Dq(Co^{II})$ value, that is, different Co environments, failed. This surprisingly shows that $10\,Dq$(Co) is the same (within the experimental error) for all Co^{II} atoms in a single compound. In the same way, $10\,Dq(Co^{III})$ is, within the experimental error, the same for all Co^{III} atoms in **2**.

To characterize the influence of the ligands on $10\,Dq$, the model developed by Jorgensen[16] to formulate the spectrochemical series for octahedral complexes was used. In this model, the crystal-field parameter is treated as the product of two independent factors f and g ($10\,Dq = fg$), where f describes the strength of a ligand relative to water, which is assigned a value of 1, and g is characteristic of the metal ion. The $10\,Dq$ values given by multiplet calculations, and the corresponding f values, are gathered in Table 1.

Table 1: $10\,Dq$ parameters, obtained by multiplet calculations, and the corresponding f values.

	$10\,Dq$ [eV]	f
Co^{II} in $[Co(OH_2)_6]^{2+}$	1	1
Co^{II} in **1**	0.55	0.55
Co^{II} in **2**	0.7	0.7
Co^{III} in **2**	2.4	1.2[a]

[a] This value was calculated from the ratio $g(Co^{III})/g(Co^{II}) = (18\,600/9300) = 2$.[17]

The $10\,Dq$ values of Co^{II} in $[Co(OH_2)_6](NO_3)_2$ and of Co^{III} in **2** are in the expected spectral range for Co^{II}(HS) and Co^{III}(LS) molecular species, respectively.[18] The f factor corresponding to the environment of Co^{III} in **2** is the expected one for a metal ion surrounded by an average of five CN^- and one H_2O ligands, in the range of the f factors of most N-ligating ligands (NH_3 ($f = 1.25$), $NH_2CH_2CH_2NH_2$ (1.28), CH_3CN (1.22)).[17]

Surprisingly, the f factors corresponding to the environment of Co^{II} in **1** and **2** are, to the best of our knowledge, much weaker than any f value reported for octahedral Co^{II}(HS) molecular coordination compounds ($f = 0.7$ for the weak-field bromide ion and almost always > 1 for N-ligating ligands[17]). Such weak crystal fields, which have never been found in molecular compounds, are probably associated with three-dimensional network strains. The replacement of H_2O in the Co^{II} coordination sphere by CN^- does not strengthen the Co crystal field and does not explain the stabilization of the Co^{III}–Fe^{II} photoactive pairs in CoFe Prussian blue analogues. The stabilization of the Co^{II}(HS)–Fe^{III} or of the Co^{III}(LS)–Fe^{II} state is not simply due to a local chemical effect but to a cooperative structural one associated with the three-dimensional character of the compounds.

To explain these values, we have proposed a hypothesis based on structural considerations. In a molecular compound without steric hindrance, linear most-stable Co^{II}–NC bonds

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

are expected with an f value close to 1.2.[17] In **1**, we propose that the geometry of the Co^{II}–NC–Fe entities deviates from the linear one: as a consequence of 3D network strains they are bent,[10] as shown for the (100) plane of one unit cell of **1** in Figure 2a. This bending leads to a weaker orbital interaction

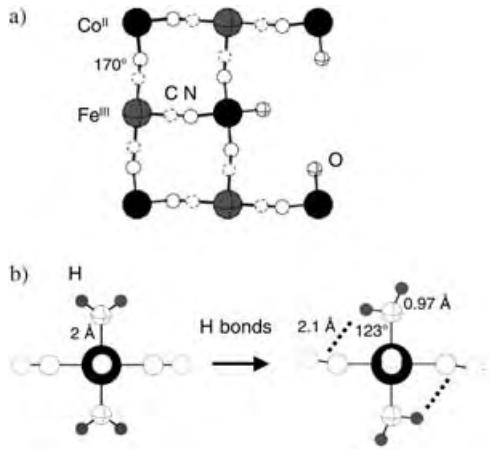

Figure 2. Proposed scheme for the (100) plane of one unit cell (a) and the Co^{II} coordination polyhedron with sensible structural parameters (b) for compound **1**.

between Co and CN^- and a weaker ligand field than for a linear geometry. The geometry of the Co–OH_2 entities also deviates from the most stable one,[19] leading again to a decrease of the ligand field exerted by H_2O. These deviations can be explained by the formation of hydrogen bonds between H_2O bonded to Co and the electronic density on the CN^- ligand, as shown, with sensible structural parameters,[20] in Figure 2b. As a consequence of these interactions, the H_2O ligands rotate around the O position so that the orbital interaction between Co and H_2O is also weakened. Such interactions may also explain the bending of the Co–NC–Fe entities in **1**. A bent Co-N-C geometry, probably stabilized by an H bond, stabilizes the Co^{II}(HS) state in **1**.

Complex **2** contains a majority of Co^{III}(LS), with an $f(Co^{III})$ value corresponding to linear Co^{III}–NC–Fe entities.[10] These globally impose the short cell parameters and the structure of the compound. The relatively high X-ray crystallinity of a sample containing a mixture of Co^{III}(LS) and Co^{II}(HS), which have very different Co-to-ligand bond lengths,[6] implies that the remaining 20% of the Co^{II}(HS) ions are situated in particular positions and fit into the structure as proposed in Figure 3. They are close to the $[Fe(CN)_6]$ vacancies (□), and are displaced slightly from the crystallographic site toward the vacancy. Along the Co^{II}–□ fourfold axis, the Co–NC entity prefers the most stable geometry due to the presence of the vacancy on the opposite site of this Co–NC bond. In the equatorial plane, the four Co–NC entities are bent (due to network strains), with an angle fixed by the Co^{II}–N bond lengths along the fourfold axis. The $f(Co^{II})$ value in **2** (0.73), which is close to the experimental value (0.7), can be estimated by assuming an average f value for bent Co–NC entities deduced from **1** (0.55), an approximate f value for linear Co–NC entities deduced from **2** (1.2),

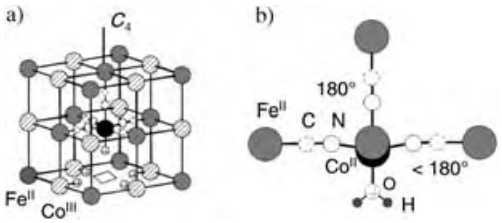

Figure 3. Co^{II} coordination polyhedron in a) a conventional unit cell, in which the alkali-metal cations have been omitted for clarity, and b) extracted from the unit cell of compound **2**.

and the f value for the Co–OH_2 entity in the most stable geometry (1).[21]

In **2**, 80% of the Co ions are low-spin with an oxidation state of +3. These oxidation- and spin-states of Co are probably due to the linearity of the Co–NC–Fe entities associated with a stronger orbital interaction between Co and CN^- and a stronger Co ligand field. We can propose three ways to explain this linear geometry: 1) the stoichiometry (x) implies a reduced amount of H_2O in the Co coordination sphere, which means that it is no longer able to form enough hydrogen bonds to impose the bent Co–NC geometry; 2) Rb in the tetrahedral sites interacts with the CN bridges,[10] and this interaction imposes the linear geometry; 3) the interactions between Rb and the CN bridges reduce the number of CN bridges available to form hydrogen bonds with Co-linked water molecules.

This is the first experimental determination of Co crystal-field parameters in photomagnetic CoFe Prussian blue analogues by XAS. We have shown that, contrary to expectation, the Co^{II} crystal-field parameter is, to the best of our knowledge, smaller than for any other octahedral Co^{II}(HS) molecular entities.[18] The $10Dq$ value is essentially determined by the geometry of the Co coordination polyhedron, which is imposed by weak and strong cooperative interactions within the three-dimensional structure rather than by the chemical nature of the ligands.

It is noticeable that the Co crystal-field parameter values are all far from HS–LS frontier values. In the switch from one state to the other, the Co spin-state change is therefore probably not the driving effect. Work is in progress to determine $10Dq$(Co) in the photo-induced metastable state of **2**.

Experimental Section

The syntheses of compounds **1** and **2** have been described elsewhere.[6]

The Co L_3-edge spectra were collected at the Beamline for Advanced diCHroism (BACH)[22] at the ELETTRA Synchrotron Radiation Source in Trieste, Italy.

XAS data parameters of the calculated spectra, a brief description of the simulation method, and determination of the f parameters are available as Supporting Information.

[19] If only the geometry of the Co–NC entities were responsible for the small $10Dq(Co^{II})$ values in **1** and **2**, with the Co–OH_2 bonds being similar to those in $[Co^{II}(OH_2)_6]^{2+}$, one would expect a smaller $10Dq(Co^{II})$ for **2** than for **1**, firstly because the number of CN^- ligands involved in bent Co–NC entities in the Co coordination sphere would be higher in **2** than in **1** (due to the stoichiometry), and secondly because the cell parameters, which are smaller in **2** than in **1**, imply a shorter Co^{II}–Fe distance (fixed by the Co^{III}–Fe distance) in **2** and therefore a narrower Co-N-C angle and weaker orbital interaction between Co and NC. However, the reverse is observed experimentally. The geometry of the Co–NC entities is therefore probably not the only effect responsible for the small $10Dq(Co^{II})$ values.

Protein Folding

Circular Dichroism Spectroscopy of Folding in a Protein Monolayer**

*Neil Keegan, Nicholas G. Wright, and Jeremy H. Lakey**

DNA arrays on surfaces have caused a revolution in nucleic acid analysis, and a similar revolution is required for proteins if high-throughput screening of their functions is to be realized.[1,2] In addition, proteins can also form the basis of self-assembling nanostructures.[3,4] One important obstacle is the assembly of functional protein monolayers on useful surfaces. Unlike DNA, proteins must retain an intricate three-dimensional structure to function, and measurement of these conformations under changing solution conditions is difficult in monomolecular films. However, our increasing awareness of natively unfolded proteins, which adopt defined conformations only upon interaction with ligands or receptors, means that structural change is also an important readout for protein–protein and protein–DNA interactions.[5] Finally, measurement of changes in protein secondary structure that lead to insoluble protein aggregates is crucial to the study and identification of conditions such as Alzheimer's disease and Creutzfeldt–Jacob disease (CJD).[6]

Fourier-transform infrared spectroscopy in either attenuated total internal reflection or grazing incidence modes is very useful for measuring protein structure in monolayers,[3,7] but its use is limited by its sensitivity to bulk water. Fluorescence spectroscopy is a sensitive but not a generic assay for protein folding, as it relies upon the presence of aromatic amino acids in suitable positions. Circular dichroism (CD) spectroscopy in the ultraviolet range ($\lambda = 180$–250 nm) measures the conformation of the core peptide backbone and is insensitive to the presence of bulk water.[8] The characteristic spectra for helix, sheet, or random structures, which arise from the π–π^* and n–π transitions, make this the spectroscopic method of choice for protein scientists who wish to monitor folding, stability, and conformational change.[9] Small sample size, accessible concentrations, and relatively inexpensive instrumentation mean that CD spectroscopy is the

most commonly used noncrystallographic method for protein structure characterization. It is also the only method that can measure the changing structure of proteins exposed to different aqueous bulk solutions. In the past, sensitivity has been a problem, but modern spectrometers easily resolve signals as small as $10^{-5}\,\Delta A$ (0.3 mdeg), and synchrotron sources now allow us to access data at wavelengths shorter than 180 nm.[10] Recently, CD spectra have been collected for proteins on gold films using extended acquisition times (10^3 scans).[11] With this in mind we investigated the practical limits for CD spectroscopy on a single protein monolayer, and we found that high-quality data can be collected with reasonable acquisition times on an unmodified commercial spectrometer.

The C-terminal, pore-forming (P) domains of colicins have been extensively studied by CD spectroscopy,[12,13] and we chose the 22.4-kDa colicin N P-domain (ColN-P) to test the sensitivity of CD to a protein monolayer. It is helix rich with a globin fold found in many protein families.[14] The exposed alanine residue at position 351 was replaced by a single cysteine (A351C) moiety by site-directed mutagenesis (Figure 1). The mutant protein ColN-P-Cys and the cysteine-free wild-type ColN-P were purified as described[15] and gave the expected helix-rich CD spectrum.

Figure 1. Structure of the pore-forming domain of colicin N (PDB:1A84) showing the position of alanine replacement by cysteine. The shape of the observed CD spectrum (Figure 3A) results from the 60% α-helix content.

If one treates ColN-P as a sphere of 3-nm diameter, a 1-mm^2 area of a *perfectly packed* protein monolayer should contain 1.1×10^{11} protein molecules (2.7 $ng\,mm^{-2}$). In a normal solution experiment using a 0.2-mm-pathlength CD cuvette and a protein concentration of 0.5 $mg\,mL^{-1}$ (2.2×10^{-5} M), an equivalent 1-mm^2 light beam will traverse a volume of 0.2 mm^3 or 0.2 μL containing 4.4×10^{-12} mol of protein or 2.6×10^{12} protein molecules. Thus the densest monolayer will provide a signal about 20-fold smaller than normal.

We created a reproducible protein monolayer by sulfur–gold chemisorption. All experiments were performed in buffer A, which comprised sodium phosphate (50 mM, pH 7.0) and NaCl (300 mM), with additions as specified. The ColN-P-Cys mutant was reduced with β-mercaptoethanol (2-sulfanylethanol, 10 mM), which was subsequently removed by gel filtration (Pharmacia PD-10 column or equivalent). Surface plasmon resonance (SPR; Biacore model X, Biacore Ltd., St. Albans, UK) was used to measure monolayer formation. Bare gold surfaces (Biacore AU-Chip) bound > 2200 resonance units (RU; 2.2 $ng\,mm^{-2}$ [16]) of both ColN-P and ColN-P-Cys proteins (Figure 2A). A wash step with sodium dodecyl sulfate (Buffer A + 0.5% w/v SDS) removed only some of the nonspecifically bound ColN-P from the surface, thus leaving 1200 RU. Under the same conditions 1900 RU of ColN-P-Cys protein remained, of which much is likely to be nonspecifically bound. Pretreatment of the gold

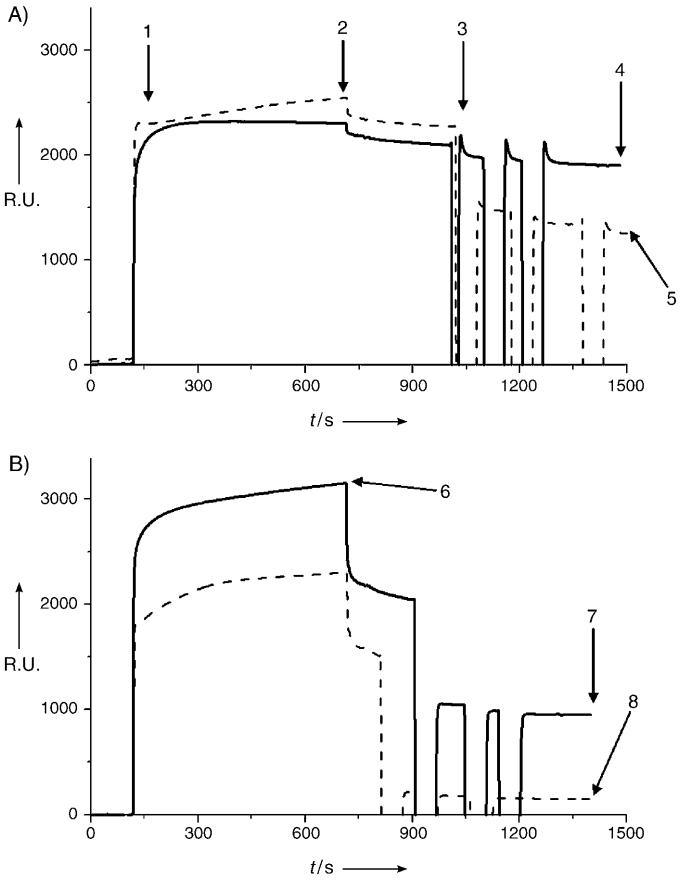

Figure 2. Surface plasmon resonance. A) Injection of ColN-P (2.5 $mg\,mL^{-1}$; -----) and ColN-P-Cys (——) in buffer A over a bare gold surface starting at point 1 (5 μL min^{-1}). Both proteins bind strongly to the surface and do not desorb upon washing with buffer (point 2). After washes with 0.5% SDS, indicated by regions with a negative baseline (point 3), the cysteine-free wild-type protein shows significant nonspecific binding (1200 RU (point 5)). ColN-P-Cys shows additional binding (1900 RU (point 4)). B) Pretreatment of the gold surface with β-mercaptoethanol (5 mM) increases the specificity of binding during identical injections both before, and especially after, the SDS washes. The upward slope on the ColN-P-Cys trace during injection indicates that the protein monolayer has not saturated during this short assembly period (point 6). ColN-P-Cys shows 1000 RU (point 7) final binding whereas ColN-P only binds 150 RU (point 8). All solutions contain phosphate (50 mM)/NaCl (300 mM) as buffer (pH 7.0).

with short-chain thiols inhibits nonspecific protein interactions with gold,[3] and therefore the surface was pretreated with β-mercaptoethanol (5 mM) in buffer A. When ColN-P was applied to this thiol-functionalized surface, which was then washed with 0.5% SDS, only 150 RU remained bound compared to 1000 RU (equivalent to 1 $ng\,mm^{-2}$) of ColN-P-Cys[16] (Figure 2B). Thus, 85% is likely to be bound through the cysteine residue, and the continuing upward slope of the SPR signal during the injection phase (Figure 2B) indicates that higher densities would result from longer incubation times.[3]

CD spectroscopy was performed in a standard demountable 0.2-mm-pathlength quartz-glass cuvette (106-QS, Hellma) and, as calculated above, a far-UV spectrum of a 20-fold diluted ColN-P solution (0.025 $mg\,mL^{-1}$ or $1.1\times$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

10^{-6} M) provided a clearly resolvable signal (Figure 3A). For monolayer measurements the flat cover was coated by evaporation on one side with 2 nm of chromium followed by 10 nm of gold. This layer gave a characteristic absorption spectrum (not shown[11]), a CD spectrum (accumulated mean of 50 scans) which deviated by less than ± 1 mdeg from air baseline values (Figure 3A), and a photomultiplier voltage that only exceeded the empirical limit of >600 V at wavelengths below 196 nm (Figure 3B). The gold-layer baselines differed slightly between samples, possibly as a result of small variations in gold thickness, so the corresponding baseline for the cuvette containing the relevant buffer was subtracted from each set of data. Correct repositioning of the cuvette each time was also important. After baseline acquisition the gold was incubated with ColN-P-Cys (0.7 mg mL^{-1}, buffer A) for 3 h. Without pretreatment with β-mercaptoethanol, the protein bound strongly to the surface, and after a buffer wash it gave a signal larger (2 mdeg at 208 nm; Figure 3A) than the theoretical maximum, which indicated that, as in the SPR experiment, large amounts of nonspecific binding had occurred. A subsequent wash with 0.5% SDS reduced the value to the theoretical maximum seen in the diluted standard (1.5 mdeg at 208 nm). However, the SPR data indicate that this is still likely to contain nonspecifically bound protein.

To overcome this problem and ensure that data from a single monolayer of thiol-immobilized protein was collected, the gold surface was pretreated with β-mercaptoethanol (5 mM) in ethanol for 1 h. Incubation of this surface with ColN-P-Cys followed by washing steps with 0.5% SDS resulted in a lower intensity of 0.6 mdeg at 208 nm (Figure 3C). This value, which resulted from a longer assembly period than in the SPR experiment, equates to a protein density of 1.6 ng mm^{-2} (60% higher than that recorded by SPR). The signal corresponds to 62% of the maximum calculated packing and compares well with the 50% of maximum packing observed for OmpF (*Escherichia coli* outer membrane protein F) on gold surfaces.[3] Thus, the CD arises from a less than fully packed monolayer and could be further improved.

The utility of immobilized proteins was demonstrated by an unfolding–refolding cycle commonly used in protein stability measurements. This cycle would normally require a series of protein samples pre-equilibrated at a range of increasing denaturant concentrations.[17] A spectrum of the ColN-P-Cys monolayer was measured in phosphate buffer. This buffer was replaced by 2 M urea, which partially unfolded the secondary structure. Then the same sample was equilibrated in 8 M urea causing a complete loss of secondary

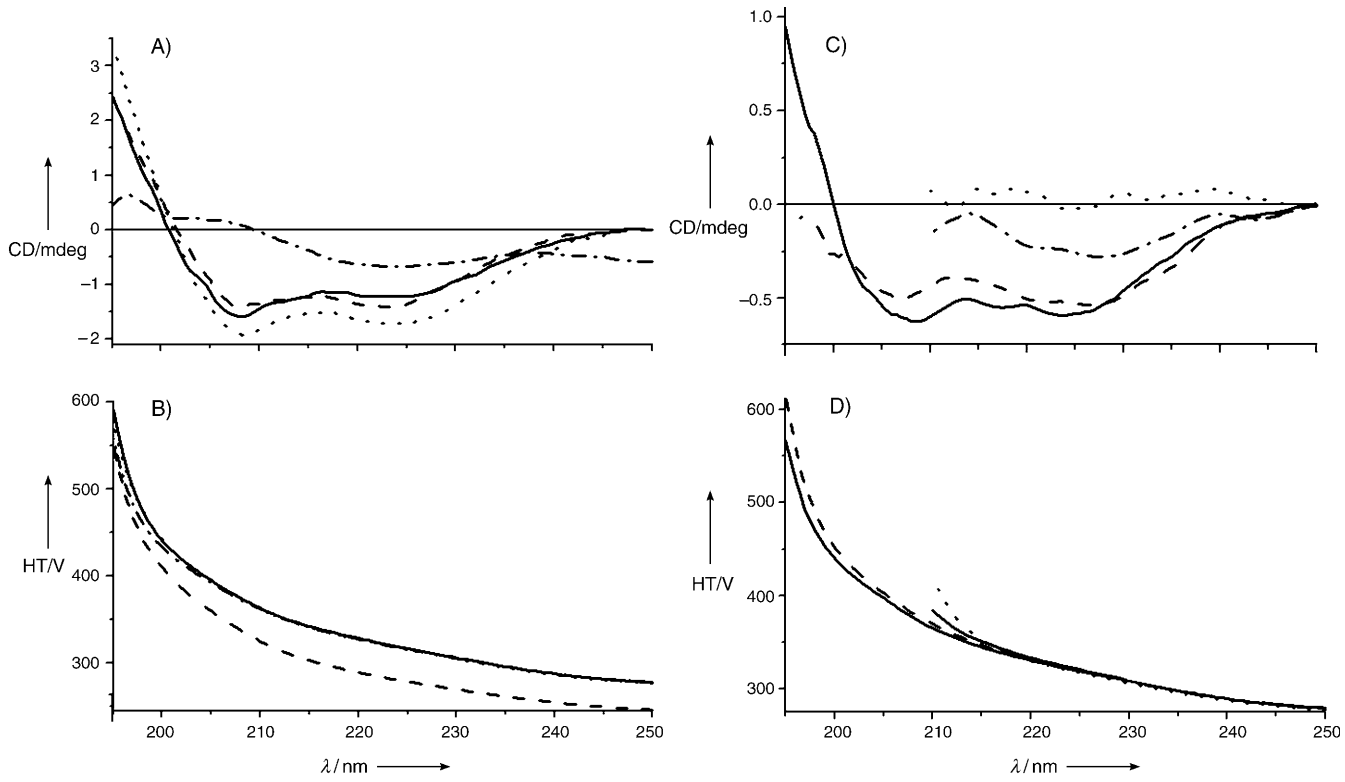

Figure 3. Circular dichroism. A) Solution measurement of ColN-P (0.025 mg mL^{-1}) in a 0.2-mm-pathlength cuvette (10 scans; ——). The gold baseline spectrum (–•–•) in the appropriate buffer was subtracted from all the following spectra. ColN-P-Cys bound to untreated gold (••••) and after SDS wash (-----; see Figure 2A). B) Photomultiplier voltage for the spectra in (A). C) Specific binding of ColN-P-Cys on β-mercaptoethanol-functionalized gold (see Figure 2B). Immobilized ColN-P-Cys in phosphate buffer (——) was then treated with 2 M urea (–•–•; absorption of urea limits data to >210 nm), 8 M urea (••••), and again in urea-free phosphate buffer (-----). D) Photomultiplier voltage for the spectra in (C); data from voltages >600 V were removed. Conditions: displayed data are means of 50 spectra collected at 20 nm min^{-1}, 4 s response time, 0.5 nm data pitch, bandwidth 2 nm, 25 °C, smoothed with a seven-point Savitzky–Golay[20] method (Jasco Spectra Analysis Software 1.53) on a Jasco J-810 spectrometer. All solutions contain phosphate (50 mM)/NaCl (300 mM) as buffer (pH 7.0). Further data showing untreated spectra, examples of data treatment, and Figure 3A, C with error bars added are to be found in the Supporting Information. HT is the photomultiplier voltage and is inversely related to light intensity passing through the sample.

structure. This finding repeats published solution data,[13] and refolding was achieved by simply incubating the sample again in buffer A.

The results demonstrate that even a crude system in which the protein is directly coupled to gold can be used to study the unfolding and refolding of the same protein sample rather than a series of different samples. The method could be improved by binding the proteins through a linker group to further reduce interaction with the gold surface.[2] Solutions can now flow over the immobilized proteins, so it is possible to add or remove ligands and denaturants easily, and the longer data collection times could be compensated for by designing overnight unfolding–refolding experiments where buffers are exchanged automatically on one fixed protein sample. Combined with the ability to assemble membrane proteins on gold and perform parallel SPR on these surfaces,[3,18] the use of immobilized protein monolayers in CD spectroscopy offers a way to extend the applications of this technique. Methods that increase the surface roughness of the gold[19] could further increase the sensitivity of the procedure.

Chiral Polymerization

Transfer of Chirality from (−)-Sparteine Zinc(II) (Meth)acrylate Complexes to the Main Chains of Their (Meth)acrylate Polymer Derivatives**

*Satyasankar Jana and David C. Sherrington**

Optically active polymers represent a class of materials of importance because of their unique properties and potential application as chiral chromatographic stationary phases, as supports for or ligands in asymmetric catalysts, and as components in nonlinear optical and liquid-crystalline materials. However, vinyl and related polymers that are optically active as a result of the configuration of their main chains, rather than chiral side-chain substituents, are very rare as this requires very special stereoregular symmetries of consecutive repeat units.

In general, symmetry operations are more difficult to recognize in a long polymer chain made up of uniformly repeating units than in low-molecular-weight compounds. Wulff, however, recognized that only one specific sequence of eight possible hexad sequences of a homopolymer of a monosubstituted vinyl monomer is chiral.[1] Not surprisingly it is extremely difficult to control a vinyl polymerization to introduce such a chiral hexad sequence in a polymer backbone. One of the methods proposed by Wulff to reduce this difficulty was to introduce a second repeat unit in the polymer backbone to help break down the overall symmetry. For such copolymers, triad sequences (Figure 1) in which a syndiotactic

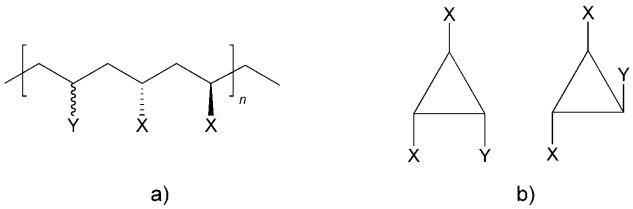

Figure 1. Chiral triad in a linear chain (a) and in a ring structure (b) (see Reference [1]).

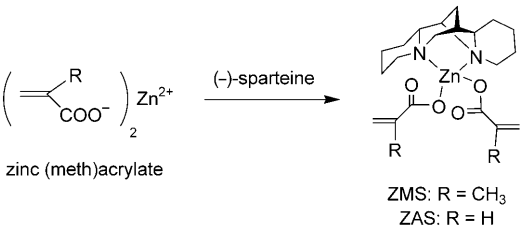

(or racemic) diad sequence of one comonomer is spaced apart by a repeat unit of another comonomer would be chiral.[1] Indeed Wulff et al. went on to complete some extremely elegant syntheses that involved the use of covalently bound chiral templates to confirm that his rationalizations were correct.[1,2]

Kakuchi and Obata,[3] Sivaram and co-workers,[4] and Sherrington and co-workers[5] have subsequently used essentially the same synthetic strategy with different templates to confirm the generality of Wulff's approach. In all of these cases, multifunctional vinyl monomers have been covalently bonded to a chiral moiety and then polymerized, followed by cleavage and washing away of the template, to produce main-chain chiral polymers.

Although this strategy has been valuable, the use of covalently bound chiral templates is not particularly convenient nor is it versatile, as, in effect, specifically functionalized monomers need to be synthesized. A more attractive methodology in this context would be one that exploited a noncovalently or more weakly bound chiral template that could be readily synthesized and later easily removed from the polymer product once asymmetry is induced. If in addition such a template could be employed with a routinely available monomer, then the potential for application would be far greater. Preliminary work on this alternative noncovalent approach was carried out by Sherrington and co-workers,[6] who showed that hydrogen bonding and metal coordination also can be exploited in synthesizing carbon–carbon main-chain optically active polymers. However, to date, these approaches have been useful only for a very limited number of monomers and the levels of specific optical rotation that have been reported is limited. Herein, we report the use of metal coordination as the source of weaker interaction between the chiral template and the monomer, with the latter being simply a methacrylate or acrylate anion.

In our search for a new noncovalent or more weakly bound template–monomer system, two chiral (−)-sparteine zinc (meth)acrylate complexes ZMS and ZAS (Scheme 1) were prepared by mixing a solution of (−)-sparteine in methanol with commercially available zinc(II) methacrylate or zinc(II) acrylate (Aldrich), respectively, in chloroform. Addition of cold diethyl ether to the mixtures led to crystallization of the products. The structures of the white crystalline products (yields: 82% ZMS and 92% ZAS) were deduced by elemental microanalysis, FTIR and ^{1}H and ^{13}C NMR spectroscopy, single-crystal X-ray crystallography (Figure 2), and polarimetry (Table 1). The specific rotations of ZAS proved to be 6–8-times higher than those of ZMS (Table 1).

The solution copolymerization of each complex with styrene (St; Scheme 2) using AIBN as initiator (2 wt% relative to total C=C content) in methanol at 70 °C (oil-bath temperature) under a nitrogen atmosphere for 20 h resulted in the spontaneous precipitation of the polymer products **1a**, **3a**, **5a**, and **7a** (Table 2), which were collected by simple filtration and washed repeatedly with methanol. These copolymers were insoluble in all organic solvents tested, which is perhaps not surprising as both ZMS and ZAS are in effect difunctional monomers and so are likely to yield cross-linked products on (co)polymerization. Surprisingly, however, when dichloroethane (DCE) was used as the polymerization solvent (Table 2), even after 20 h of reaction the reaction mixtures remained homogeneous and the products **2a**, **4a**, **6a**, and **8a** had to be recovered by precipitation in excess methanol. These copolymers were readily resoluble in DCE and chloroform which, together with the absence of any signals from pendent vinyl groups in the ^{1}H NMR and FTIR spectra, is most easily explained in terms of the ZMS and ZAS comonomers undergoing selective cyclopolymerization of

[a] Copolymer compositions: ZMS = sparteine zinc methacrylate; ZAS = sparteine zinc acrylate; St = styrene; MAA = methacrylic acid; MMA = methyl methacrylate; AA = acrylic acid; MA = methyl acrylate; 2VN = 2-vinylnaphthalene. [b] 0.5–1.5 g/100 mL. [c] 2.0 g/100 mL. [d] 0.25 g/100 mL.

Scheme 2. Ideal cyclopolymerization of chiral zinc (meth)acrylates ZMS (R = Me) and ZAS (R = H) with vinyl arene monomers (Ar) to yield main-chain chiral Ar-MAA and Ar-AA copolymers, followed by methylation of the latter to yield main-chain chiral Ar-MMA and Ar-MA copolymers. AIBN = azobis(isobutyronitrile); TMSDM = (trimethylsilyl)-diazomethane.

their two vinyl groups, as elegantly demonstrated by Wulff with his covalently templated bis-styrylboronate comonomer.[1] Whether or not some ZMS- or ZAS-derived segments are incorporated with insertion of one or more styrene segments between the (meth)acrylate segments is impossible for us to say. However homopolymerization of ZMS in DCE and copolymerization of ZMS with methyl methacrylate in DCE both result in gelation, which suggests that in these two polymerization processes the reaction of the various methacrylate functions is statistical and results in cross-linked products. In contrast, in copolymerizations of ZMS or ZAS with the electron-rich monomer styrene in DCE, the latter plays an important role in generating linear soluble copolymers.

We believe therefore that copolymerization of styrene with ZMS or ZAS in DCE results in the formation of at least some Wulff-type chiral triads (Figure 1; Y = St, X,X = ZMS or ZAS) in the backbone of the resultant copolymers and most likely with some of these triads also present in the copolymers prepared in methanol as well. The workup of **1a**–**8a** (see Table 2 and Supporting Information) destroys the template Zn complex and removes the Zn and (−)-sparteine components to yield the corresponding styrene–(meth)acrylic acid copolymers St-MAA and St-AA (**1b**–**8b**; Scheme 2 and Table 2). This was confirmed by the appearance of the signal for CO_2H and disappearance of the resonances for (−)-sparteine in the ^{1}H NMR spectrum, by the appearance of a peak for the C=O group of the carboxylic acid in the FTIR spectrum, and by the absence of nitrogen upon elemental analysis of the products. Copolymers **1b**–**8b** were readily soluble in THF, consistent with the loss of any cross-links arising from removal of bridging Zn centers in ZMS- or ZAS-derived segments. Polarimetric measurements of solutions of copolymers **1b**–**8b** showed small but definite dextrorotatory specific optical rotation (Table 1), in contrast to the levorotatory rotations of (−)-sparteine, ZMS, ZAS, and the unpurified template-containing copolymers **2a** and **6a** (Table 1). Furthermore compounds **2b**, **4b**, **6b**, and **8b**, which were derived respectively from **2a**, **4a**, **6a**, and **8a**, with the latter group prepared as a soluble species in DCE, consistently show a greater specific rotation than **1b**, **3b**, **5b**, and **7b**, which were each derived respectively from **1a**, **3a**, **5a**, and **7a**, with the latter group formed as precipitates in MeOH (Table 2).

Methylation of copolymers **1b**–**8b** using (trimethylsilyl)-diazomethane (TMSDM) in a 1:3 mixture of methanol/THF under nitrogen at room temperature yielded quantitatively the corresponding styrene–methyl (meth)acrylate copolymers St-MMA and St-MA (**1c**–**8c**; Scheme 2). These were isolated by precipitation into hexane and were characterized by microanalyses and also FTIR and ^{1}H NMR spectroscopy. The specific rotation values of **1c**–**8c** are also dextrorotatory (Table 1). As a control, copolymers were synthesized with styrene using achiral zinc methacrylate or zinc acrylate in methanol. The polymers precipitated from solution as they formed and were decomplexed by stirring with dilute HCl to

[a] Conditions: AIBN = 2 wt% of total C=C content, 24 h, 70°C (oil-bath temp), concentration of C=C in solution = 1 M. [b] See Supporting Information. [c] From elemental analysis. [d] 20 h, concentration of C=C in solution = 0.75 M. [e] Partially soluble.

yield St-MAA and St-AA copolymers, both of which exhibited no optical rotation.

The effect of varying the polymerization feed ratio of ZAS/St is also shown in Tables 1 and 2. As the proportion of ZAS in the monomer feed decreases, the optical activity of the resulting St-AA copolymers also decreases. The effect is most obvious in the copolymers prepared in DCE, that is, **4b**, **6b**, and **8b**. Reassuringly, this observation tends to confirm that the degree of induction of chirality into the carbon–carbon main chain of the copolymer is indeed controlled by the chiral ZAS or ZMS complex. Furthermore, analysis of the St-MMA and St-MA copolymers by double-detection (refractive index/light scattering) size-exclusion chromatography (SEC) confirms that the copolymers are indeed macromolecular species with number-average molecular weights, M_n, in the range 15000–50000.

Copolymerization of ZMS and ZAS, respectively, with other monomers were also evaluated, and some remarkable results were attained. Most interestingly, 2-vinylnaphthalene (2VN) was used to prepare copolymers **9a**–**13a**. Removal of the template afforded the corresponding 2VN–(meth)acrylic acid copolymers **9b**–**13b**, and methylation of selected examples of these produced the 2VN–methyl (meth)acrylate copolymers 2VN-MMA and 2VN-MA (**10c** and **12c**; Table 2). These show significantly enhanced values of specific optical rotation (Table 1) which we believe is associated, at least in part, with the increased bulk of the naphthyl group relative to the phenyl group in the analogous styrene copolymers. Also, the rotations of the methacrylate copolymers are lower than those of the corresponding acrylate species, as found with the styrene copolymers. SEC data confirmed the molecular weights of the 2VN-MMA and 2VN-MA copolymers **10c** and **12c** to be indeed in the polymeric range ($M_n \approx 15000$).

Finally, the circular dichroism spectra of some selected chiral carboxylic acid copolymers, namely **2b, 4b, 9b**, and **11b**, all showed the Cotton effect around their maximum absorption in their UV spectra (Figure 3). The styrene-based

species **2b** and **4b** showed small but positive Cotton effects around 218 nm, whereas the 2-vinylnaphthalene-based species **9b** and **11b** showed larger, both positive and negative Cotton effects around 230 and 218 nm, respectively. A similar type of behavior was observed earlier by Wulff and Dhal[7] and Kakuchi et al.[8] for their carbon–carbon main-chain copolymers synthesized using covalently linked chiral templates.

In conclusion, a novel methodology has been developed for the synthesis of chiral vinyl polymers in which the chirality is associated only with the configuration of the backbone stereogenic centers. The methodology is somewhat more convenient than those previously reported, as a chiral (−)-sparteine Zn complex is used as an easily cleavable template and the source of asymmetry control, with chirality being transferred to the polymer main chain. If required, the complex can be prepared in situ just prior to polymerization. The method also allows the direct use of methacrylic acid and acrylic acid monomers as their respective anions, with no covalent chemical modification of these required. The liberation of the chiral copolymers from the template therefore involves only decomplexation, and the resulting macromolecules are readily available for further chemical derivatization if required as they are simple methacrylic and acrylic acid copolymers. Overall we believe the facile and core nature of the methodology will provide a convenient and cost-effective source of main-chain optically active vinyl polymers perhaps even in large quantities. The new methodology does, of course, still require a stoichiometric relationship between the chiral ligand and the (meth)acrylate monomers, and the major challenge that remains is to develop a similar templating methodology that is substoichiometric or catalytic in this respect—we are currently considering how this might be achieved.
